Pentafluorophenyl silver(I) (AgC_6F_5) (614 mg, 2.23 mmol) and **1** (1.183 g, 2.23 mmol) were placed into a 100 mL bomb to which was added 50 mL of toluene. The vessel was sealed and warmed to 100°C in an oil bath for 23.5 h. The flask was cooled to room temperature and the green solution was cannula-transferred to a two-neck round-bottom flask with a frit assembly under an argon flow. The toluene was removed under vacuum and CH_2Cl_2 was condensed in at –78°C. The green solution was extracted from the silver powder by filtration and washed until the extracts were colourless. The solvent was removed in vacuo to afford a dark green solid. Yield: 1.397 g (2.00 mmol, 90%). Crystals of **3-C_6F_5** were grown at 25°C when dissolved into a minimum amount of dry CH_2Cl_2 layered with hexane. UV (TFT) λ_{max} (nm) (ε): 258 (1.33×10^4). ^{1}H NMR (d_8-toluene): 43.8 (bs, WHM = 1150 Hz), 30.2 (bs, WHM = 1400 Hz), 24.2 (bs, WHM = 780 Hz). ^{13}C NMR: 142.7 (d, 4C, $^1J_{CF}$ = 225 Hz), 139.3 (d, 2C, $^1J_{CF}$ = 246 Hz, C_p), 133.6 (d, 4C, $^1J_{CF}$ = 246 Hz). ^{11}B NMR: –23.7 (bs, 55 Hz). ^{19}F NMR: –139.6 (bs, 6F, F_o), –161.0 (s, 3F, F_p), –167.8 (d, 6F, F_m). Anal. calcd. for $C_{28}H_9BF_{15}Fe$: C 48.24, H 1.30; found: C 48.25, H 1.30.

Preparation of [FcB(C_6F_5)$_3$][Cp_2Co] (4)

3-C_6F_5 (420 mg, 0.619 mmol) and cobaltocene (117 mg, 0.619 mmol) were dissolved in dry CH_2Cl_2 (12 mL). The solution was stirred at room temperature for 2 h. The solution was run through a frit and the solvent removed to afford a brown crystalline solid. Yield: 490 mg (0.564 mmol, 91%). ^{1}H NMR: 5.60 (s, 10H, Co(C_5H_5)), 4.00 (t, 2H, J = 1.68 Hz, H_β), 3.94 (bs, 2H, H_α), 3.67 (s, 5H, Fe(C_5H_5)). ^{13}C NMR: 149.3 (d, $^1J_{CF}$ = 246 Hz), 138.4 (d, $^1J_{CF}$ = 245 Hz, C_p), 137.0 (d, $^1J_{CF}$ = 258 Hz), 85.2 (s, Co(C_5H_5)), 75.9 (s, C_α), 68.3 (s, Fe(C_5H_5)), 67.0 (s, C_β). ^{11}B NMR: –13.2 (bs, WHM = 39 Hz). ^{19}F NMR: –128.3 (d, 6F, F_o), –164.5 (dt, 3F, F_p), –168.0 (t, 6F, F_m). Anal. calcd. for $C_{38}H_{19}BCoF_{15}Fe$: C 51.51, H 2.16; found: C 51.30, H 2.34.

Preparation $[FcAc]^+[B(C_6F_5)_4]^-$

Acetylferrocenium tetrafluoroborate (298 mg, 0.946 mmol) and lithium tetrakis(pentafluorophenyl)borate etherate (843 mg, 0.947 mmol) were dissolved in CH_2Cl_2 and stirred for 12 h. The mixture was filtered and the solid washed with CH_2Cl_2 three times. The solvent was removed from the filtrate to afford a fluffy blue solid. Yield: 794 mg (0.875 mmol, 92%). ^{1}H NMR: 35.8 (bs, WHM = 750 Hz), 30.4 (bs, WHM = 1800 Hz), 0.90 (s, 3H, COOCH_3), –12.1 (bs, WHM = 120 Hz). ^{13}C NMR: 147.5 (d, $^1J_{CF}$ = 242 Hz), 138.2 (d, $^1J_{CF}$ = 232 Hz), 135.9 (d, $^1J_{CF}$ = 232 Hz), 126.3 (bs, C_{ipso}(C_6F_5)). ^{11}B NMR: –16.9 (s, WHM = 28 Hz). ^{19}F NMR: –135.6 (s, 8F, F_o), –164.4 (s, 4F, F_p), –169.4 (s, 8H, F_m). Anal. calcd. for $C_{36}H_{12}BF_{20}FeO$: C 47.66, H 1.33; found: C 46.88, H 1.53.

Preparation of 3-FcAc

Borane **1** (262 mg, 0.494 mmol) and $[FcAc]^+[B(C_6F_5)_4]^-$ (440 mg, 0.485 mmol) were loaded into flask fitted with a frit assembly. CH_2Cl_2 (15 mL) was condensed onto the solids under vacuum transfer conditions. The solution was warmed to room temperature and stirred for 80 min. The solvent was removed in vacuo to afford a violet solid which was triturated with dry hexanes and filtered to collect the

© 2001 NRC Canada

solid, which was washed with hexanes three times. Yield: 683 mg (0.475 mmol, 98%). IR (cm^{-1}): 3123, 1644 (C=O), 1516, 1464, 1277, 1089, 979. ^{1}H NMR: 45.2 (bs, 2H, WHM = 1630 Hz, $H_{\alpha/\beta}$); 31.9 (bs, 5H, WHM = 900 Hz, BCpFe(C_5H_5)), 22.3 (bs, 2H, WHM = 1900 Hz, $H_{\alpha/\beta}$), 7.21 (s, 2H), 6.85 (s, 5H, AcCpFe(C_5H_5)), 2.15 (s, 3H, CH_3). ^{11}B NMR: –17.0 (s, WHM = 17.4 Hz, $B(C_6F_5)_4$). ^{19}F NMR: –149.8 (s, 1F), –151.2 (s, 2F), –153.4 (s, 1F), –158.9 (s, 1F), 164.8 (s, 1F), –133.2 (s, F_o, 8F), –162.4 (s, F_p, 4F), –167.2 (s, F_m, 8F).

Relative Lewis acidity

In the dry box a known amount of Lewis acid was placed into an NMR tube, dissolved in a measured volume of CD_2Cl_2 and capped with a rubber septum. The sample was cooled to –78°C to which dry crotonaldehyde was added via microsyringe to the NMR tube. The tube was quickly shaken to ensure mixing. The ^{1}H NMR spectrum was collected at –20°C.

Cyclic voltammetry

Cyclic volammetric measurements were made on α,α,α-trifluorotolune (TFT) solutions under argon at 25°C, using a three-electrode cell attached to a Hitek Instruments of England Potentiostat (Type DT2101) and a Waveform Generator PPRI system. The electrolyte employed was $[n\text{-}Bu_4N]^+[B(C_6F_5)_4]^-$ with electrolyte:substrate concentrations of approximately 100:1. The air tight electrochemical cell consisted of a thick-walled glass bulb, Kontes Teflon tap, a set of platinum wire electrodes (working and secondary), and a silver wire quasireference electrode. Each experiment involved collecting the data for the substrate alone, which was then referenced to the Fc/Fc^+ couple in this medium. Samples were prepared in the dry box as follows: a known amount of electrolyte $[nBu_4N]^+[B(C_6F_5)_4]^-$ was dissolved into a minimum amount of dry TFT and added quantitatively to a volumetric flask. This solution was diluted to a known volume with additional TFT. The solution was mixed thoroughly and transferred to the electrochemical cell which contained the substrate and a small stir bar under argon. The Teflon tap was closed and a small amount of ferrocene was placed in a side arm. Outside the dry box, the electrochemical cell was attached to the potentiostat and the data were collected with a scan rate of 0.1 V s^{-1} without stirring. After the data for the substrate were collected the Teflon tap was opened to allow the ferrocene in the side arm to be added and dissolved. The stirring was halted and the CV data for the internal reference were collected along with the substrate. The half-wave potential of the substrate was referenced to that of the Fc/Fc^+ redox couple.

X-Ray crystallography

Suitable crystals were mounted on glass fibers using paraffin oil and cooled to the data collection temperature; details of crystal data, data collection, and structure refinement have been provided in Table 3.

*Structural determination of **1** and **3-Otf***

Data were collected on a Bruker AX SMART 1k CCD diffractometer using 0.3° ω-scans at 0, 90, and 180° in ϕ. Unit-cell parameters were determined from 60 data frames collected at different sections of the Ewald sphere. Semiempirical absorption corrections based on equivalent reflections were applied (32) to **1**. Attempts to correct the data set of **3-OTf** for absorption yielded T_{min}/T_{max} of unity and no correction was applied. Systematic absences in the diffraction data and unit-cell parameters were uniquely consistent with the reported space groups. The structures were solved by direct methods, completed with difference Fourier syntheses, and refined with full-matrix least-squares procedures based on F^2. Refinement of the Flack parameter for **1** yielded 0.39(1) indicating that the true hand of the data set could not be determined. All non-hydrogen atoms were refined with anisotropic displacement parameters. The triflate ion in **3-OTf** was located disordered in two positions with refined site occupancy of roughly 50/50. All hydrogen atoms were treated as idealized contributions. All scattering factors and anomalous dispersion factors are contained in the SHEXTL 5.1 program library (Sheldrick, 1997, WI.).

*Structural determination of **2** and **3-F***

Measurements were made on a Rigaku AFC6S diffractometer with graphite monochromated Mo Kα radiation for **2** and on an Enraf–Nonius CAD-4 diffractometer with graphite monochromated Cu Kα radiation for **3-F**. Cell constants and an orientation matrix for data collection were obtained from 25 reflections. The data were collected at a temperature of 170(2) K (**2**) and 295(2) K (**3-F**) using the ω-2θ scan technique. The intensities of three standard reflections were measured after every 200 reflections and decreased by 1.1% (**2**) and 0.69% (**3-F**). The data were corrected for decay, absorption (33), and for Lorentz and polarization effects. The structure of **2** was solved by direct methods (34) and expanded using Fourier techniques (35). The non-hydrogen atoms were refined anisotropically. The Cp and phenyl rings were constrained as regular pentagons and hexagons, respectively. H-atoms were included at geometrically idealized positions. The structure of **3-F** was solved by direct methods and expanded using Fourier techniques. There were two independent molecules in an asymmetric unit. The non-hydrogen atoms were refined anisotropically. H-atoms were included at geometrically idealized positions. For both structures, the weighting scheme was based on counting statistics and the final difference Fourier map was essentially featureless. Neutral atom scattering factors were taken from Cromer and Waber (36). Anomalous dispersion effects were included in *F*calc (37); the values for $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley (38). The values for the mass attenuation coefficients are those of Creagh and Hubbel (39). All calculations were performed using the teXsan (40) crystallographic software package of Molecular Structure Corporation.

*Structural determination of **3-C_6F_5***

Measurements were made on a Rigaku/ADSC CCD area detector with graphite monochromated Mo Kα radiation. The data were collected at a temperature of –93(1)°C to a max 2θ value of 61.1° in 0.50° oscillations with 14.0 s exposures. A sweep of data was done using ϕ oscillations from 0.0 to 190.0° at χ = –90° and a second sweep was performed

using ω oscillations between –23.0 and 18.0° at χ = –90°. The crystal-to-detector distance was 38.851(6) mm and the detector swing angle was –10.0°. The data were corrected for decay, absorption (33), and for Lorentz and polarization effects. The structure was solved by direct methods (34) and expanded using Fourier techniques.(35) The non-hydrogen atoms were refined anisotropically and hydrogen atoms were fixed in calculated positions with C-H = 0.98 Å. The final cycle of full-matrix least-squares refinement was based on all 6493 unique reflections and 406 variable parameters. Neutral atom scattering factors were taken from Cromer and Waber (36). Anomalous dispersion effects were included in *F*calc (37); the values for $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley (38). The values for the mass attenuation coefficients are those of Creagh and Hubbel (39). All calculations were performed using the teXsan (40) crystallographic software package of Molecular Structure Corporation.

Acknowledgments

Funding for this work from Nova Chemicals of Calgary, Alberta and the Natural Sciences and Engineering Research Council of Canada (NSERC) are gratefully acknowledged. BEC and WEP thank Professor Scott Hinman (Calgary) for use of his electrochemical equipment and helpful discussions. Also, we thank Professor Bill Gieger (Vermont) for details on the synthesis and use of $[Bu_4N][B(C_6F_5)_4]$ prior to publication.

Tetraacetatodirhodium(II) complexes with tris(methoxyphenyl)phosphines, their reactivity, structure, and antitumor activity

Florian P. Pruchnik, Radosław Starosta, Zbigniew Ciunik, Adam Opolski, Joanna Wietrzyk, Elżbieta Wojdat, and Danuta Duś

Abstract: Reactions of $[Rh_2(\mu\text{-}OAc)_4(H_2O)_2]$ ($[\mathbf{1}\cdot(H_2O)_2]$) with tris(3-methoxyphenyl)phosphine at 1:1 and 1:2 molar ratios yield, first, the appropriate adducts: $[\mathbf{1}\cdot(H_2O)\{P(C_6H_4\text{-}3\text{-}OMe)_3\}]$ and $[\mathbf{1}\cdot\{P(C_6H_4\text{-}3\text{-}OMe)_3\}_2]$, and then $[Rh_2(\mu\text{-}OAc)_3\{\mu\text{-}(C_6H_3\text{-}3\text{-}OMe)P(C_6H_4\text{-}3\text{-}OMe)_2\}(HOAc)_2]$ ($[\mathbf{2}\cdot(HOAc)_2]$), and $[Rh_2(\mu\text{-}OAc)_2\{\mu\text{-}(C_6H_3\text{-}3\text{-}OMe)P(C_6H_4\text{-}3\text{-}OMe)_2\}_2(HOAc)_2]$ ($[\mathbf{3}\cdot(HOAc)_2]$) complexes, respectively. They have been characterized by spectroscopic methods. The molecular structure of $[\mathbf{3}\cdot(HOAc)(H_2O)]$ has been determined crystallographically. The complexes $[\mathbf{3}\cdot(HOAc)_2]$, $[Rh_2(\mu\text{-}OAc)_3\{\mu\text{-}(C_6H_3\text{-}4\text{-}OMe)P(C_6H_4\text{-}4\text{-}OMe)_2\}(HOAc)_2]$ ($[\mathbf{4}\cdot(HOAc)_2]$), and $[Rh_2(\mu\text{-}OAc)_2\{\mu\text{-}(C_6H_3\text{-}4\text{-}OMe)P(C_6H_4\text{-}4\text{-}OMe)_2\}_2(HOAc)_2]$ ($[\mathbf{5}\cdot(HOAc)_2]$) reversibly react with CO giving mono- and biadducts. Antitumor activity of binuclear rhodium(II) compounds $[\mathbf{3}\cdot(HOAc)_2]$, $[Rh_2(\mu\text{-}OAc)_3\{\mu\text{-}(C_6H_3\text{-}2\text{-}O)P(C_6H_3\text{-}2\text{-}OMe)_2\}(HOAc)]$ ($[\mathbf{6}\cdot($HOAc)]), and $[Rh_2(\mu\text{-}OAc)_3\{\mu\text{-}(C_6H_3\text{-}6\text{-}OMe\text{-}2\text{-}O)P[(C_6H_3\text{-}2,6\text{-}(OMe)_2]_2\}(HOAc)]$ ($[\mathbf{7}\cdot(HOAc)]$) have been investigated in vitro. The most active agent for investigated tumor lines is complex $[\mathbf{6}\cdot(HOAc)]$. It shows higher activity than cisplatin (*cis*-$[PtCl_2(NH_3)_2]$). Antitumor activity decreases in the series: $[\mathbf{6}\cdot(HOAc)] > [\mathbf{7}\cdot(HOAc)] > [\mathbf{3}\cdot(HOAc)_2]$. Activity of all investigated rhodium(II) complexes is higher than that of $[\mathbf{1}\cdot(H_2O)_2]$.

Key words: dirhodium(II) complexes, functionalized phosphines, aryl phosphines, ferrocenylmethylphosphines, adducts with CO, antitumor activity, orthometallation reactions.

Résumé : Les réactions du $[Rh_2(OAc)_4(H_2O)_2]$ ($[\mathbf{1}\cdot(H_2O)_2]$) avec la (3-méthoxyphényl)phosphine, à des rapports molaires de 1:1 et 1:2, conduisent à la formation d'adduits appropriés soit premièrement à $[\mathbf{1}\cdot(H_2O)\{P(C_6H_4\text{-}3\text{-}OMe)_3\}]$ et $[\mathbf{1}\cdot\{P(C_6H_4\text{-}3\text{-}OMe)_3\}_2]$ et ensuite à $[Rh_2(OAc)_3\{(C_6H_3\text{-}3\text{-}OMe)P(C_6H_4\text{-}3\text{-}OMe)_2\}(HOAc)_2]$ ($[\mathbf{2}\cdot(HOAc)_2]$) et $[Rh_2(OAc)_2\{(C_6H_3\text{-}3\text{-}OMe)P(C_6H_4\text{-}3\text{-}OMe)_2\}_2(HOAc)_2]$ ($[\mathbf{3}\cdot(HOAc)_2]$). Ces complexes ont été caractérisés par des méthodes spectroscopiques. La structure moléculaire du complexe $[\mathbf{3}\cdot(HOAc)(H_2O)]$ a été déterminée par cristallographie. Les complexes $[\mathbf{3}\cdot(HOAc)_2]$, $[Rh_2(OAc)_3\{(C_6H_3\text{-}4\text{-}OMe)P(C_6H_4\text{-}4\text{-}OMe)_2\}(HOAc)_2]$ ($[\mathbf{4}\cdot(HOAc)_2]$) et $[Rh_2(OAc)_2\{(C_6H_3\text{-}4\text{-}OMe)P(C_6H_4\text{-}4\text{-}OMe)_2\}_2(HOAc)_2]$ ($[\mathbf{5}\cdot(HOAc)_2]$) réagissent de façon réversible avec le CO pour donner des mono- et des bisadduits. On a évalué l'activité antitumorale in vitro des composés binucléaires de rhodium $[\mathbf{3}\cdot(HOAc)_2]$, $[Rh_2(OAc)_3\{(C_6H_3\text{-}2\text{-}O)P(C_6H_3\text{-}2\text{-}OMe)_2\}(HOAc)]$ ($[\mathbf{6}\cdot(HOAc)]$) et $[Rh_2(OAc)_3\{\mu\text{-}(C_6H_3\text{-}6\text{-}OMe\text{-}2\text{-}O)P[(C_6H_3\text{-}2,6\text{-}(OMe)_2]_2\}(HOAc)]$ ($[\mathbf{7}\cdot(HOAc)]$). Le complexe $[\mathbf{6}\cdot(HOAc)]$ est l'agent le plus actif pour les familles de tumeur étudiées. Il présente une activité supérieure à celle du cisplatine, *cis*-$[PtCl_2(NH_3)_2]$. L'activité antitumorale diminue dans la série $[\mathbf{6}\cdot(HOAc)] > [\mathbf{7}\cdot(HOAc)] > [\mathbf{3}\cdot(HOAc)_2]$. L'activité de chacun des complexes de rhodium(II) est supérieure à celle du $[\mathbf{1}\cdot(H_2O)_2]$.

Mots clés : complexes dirhodium(II), phosphines fonctionnalisées, arylphosphines, ferrocénylméthylphosphines, adduits avec le CO, activité antitumorale, réactions d'organométallation.

Introduction

The product of reaction of rhodium tetraacetate with triphenylphosphine, first reported by Cotton and co-workers (1) was one of the first examples of bimetallic *ortho*-metallated compounds. Since that time, attention has been paid to different *ortho*-metallated dirhodium(II) compounds with triaryl and alkyl–aryl phosphines because of the growing interest in the problem of activation of the C—H bond (2–14). However, reactions of tetraacetatodirhodium(II) with

functionalized phosphines were not intensively studied. Water-soluble *ortho*-metallated complexes with tris(3-sodium sulfonatophenyl)phosphine (TPPTS), $[Rh_2(\mu\text{-}OAc)_3\{\mu\text{-}(C_6H_3\text{-}3\text{-}SO_3Na)P(C_6H_4\text{-}3\text{-}SO_3Na)_2\}]$, and $[Rh_2(\mu\text{-}OAc)_2\{\mu\text{-}(C_6H_3\text{-}3\text{-}SO_3Na)P(C_6H_4\text{-}3\text{-}SO_3Na)_2\}_2]$ have been investigated (15). It has been found that in reaction of tris(2,4,6-trimethoxyphenyl)phosphine (TMPP) (16–18), tris(2-methoxyphenyl)phosphine (OMP) (19, 20), and tris(2,6-dimethoxyphenyl)phosphine (DOMP) (20) with [**1**·$(H_2O)_2$], the O—CH_3 bond is split off and complexes with Rh-$P(C_6H_3(R)OMe)_2C_6H_2(R)(R')O$-Rh (where R, R′ = H or OMe) bridges are formed. In this paper we report on synthesis of $[Rh_2(\mu\text{-}OAc)_3\{\mu\text{-}(C_6H_3\text{-}3\text{-}OMe)P(C_6H_4\text{-}3\text{-}OMe)_2\}(HOAc)_2]$ ([**2**·$(HOAc)_2$]) and $[Rh_2(\mu\text{-}OAc)_2\{\mu\text{-}(C_6H_3\text{-}3\text{-}OMe)P(C_6H_4\text{-}3\text{-}OMe)_2\}_2(HOAc)_2]$ ([**3**·$(HOAc)_2$]) as well as properties and reactivity of binuclear rhodium(II) complexes containing other *ortho-C*- and *ortho-O*-metallated tris(methoxyphenyl)phosphines.

It has been known for many years, that rhodium(II) carboxylato complexes $[Rh_2(\mu\text{-}O_2CR)_4]$ and their derivatives (21–25), complexes $[Rh_2(\mu\text{-}O_2CR)_2(\mu\text{-}N\text{-}N)_2(H_2O)_2]^{2+}$ (N-N = bpy, phen) (25–31) are promising antitumor agents. However, antitumor properties of rhodium(II) complexes with phosphine bridges were not examined. Here we describe antitumor activity in vitro of some binuclear rhodium(II) compounds with methoxyphenylphosphines, namely complexes [**3**·$(HOAc)_2$], $[Rh_2(\mu\text{-}OAc)_3\{\mu\text{-}(C_6H_4\text{-}2\text{-}O)P(C_6H_4\text{-}2\text{-}OMe)_2\}(HOAc)]$ ([**6**·(HOAc)]) and $[Rh_2(\mu\text{-}OAc)_3\{\mu\text{-}(C_6H_3\text{-}6\text{-}OMe\text{-}2\text{-}O)P[(C_6H_3\text{-}2,6\text{-}(OMe)_2]_2\}(HOAc)]$ ([**7**·(HOAc)]), dhfmp as well as, for comparison, activity of *cis*-diaminadichloroplatinum(II).

Results and discussion

Syntheses of Rh(II) complexes with methoxyphenylphosphines

In reactions of [**1**·$(L)_2$] (L = Lewis base) and other dirhodium(II) carboxylates with phosphines, PR_3 ligands are first coordinated along the Rh-Rh axis forming reactive adducts [**1**·(PR_3)L] or [**1**·$(PR_3)_2$].

Formation of mono- and biadducts of [**1**·$(H_2O)_2$] with MMP ([**1**·(H$_2$O)(MMP)] and [**1**·$(MMP)_2$]) was followed with ^{31}P NMR spectroscopy. For the monoadduct in $CDCl_3$, a doublet of doublets at –30.2 ppm (^1J (P-Rh) = 97.7 Hz, ^2J (P-Rh) = 31.7 Hz) and for the biadduct, a broad singlet at –11.0 ppm have been observed (see Table 1). This indicates that axial phosphine ligands in the biadduct are labile. Coordination chemical shifts ($\Delta\delta$ (^{31}P) = δ (P_{adduct}) – δ (P_{ligand})) are –27.25 and –8.05 ppm for monoadduct and biadduct, respectively. $\Delta\delta$ (^{31}P) values are similar to those found in analogous dirhodium(II) compounds with other phosphines: ca. –30 and –10 ppm for monoadducts and biadducts, respectively, (2–4, 6–10, 12, 15, 18, 20, 32). Analogous adducts [**1**·(PR_3)] and [**1**·$(PR_3)_2$] were obtained with TPPTS (15) and PMP (21).

In the next step, phosphine ligands migrate to equatorial coordination sites and then the C—H bond of the PR_3 ligand can be activated giving the binuclear product of *ortho*-metallation.

In the reaction of [**1**·$(H_2O)_2$] with MMP complexes, $[Rh_2(\mu\text{-}OAc)_3\{\mu\text{-}(C_6H_3\text{-}3\text{-}OMe)P(C_6H_4\text{-}3\text{-}OMe)_2\}(HOAc)_2]$ ([**2**·$(HOAc)_2$]) and mainly [**3**·$(HOAc)_2$] were obtained.

In the contrast to the selective reactions of tris(4-methoxyphenyl)phosphine (PMP) with rhodium(II) acetate, which give $[Rh_2(\mu\text{-}OAc)_3\{\mu\text{-}(C_6H_3\text{-}4\text{-}OMe)P(C_6H_4\text{-}4\text{-}OMe)_2\}(HOAc)_2]$ ([**4**·$(HOAc)_2$]) and $[Rh_2(\mu\text{-}OAc)_2\{\mu\text{-}(C_6H_3\text{-}4\text{-}OMe)P(C_6H_4\text{-}4\text{-}OMe)_2\}_2(HOAc)_2]$ ([**5**·$(HOAc)_2$]) complexes at [**1**·$(H_2O)_2$]:PMP ratios equal to 1:1 and 1:2, respectively, (32), in the reactions of MMP with [**1**·$(H_2O)_2$] we obtained mainly [**3**·$(HOAc)_2$]. A mixture of compounds [**3**·$(HOAc)_2$], [**2**·$(HOAc)_2$], and [**1**·$(H_2O)_2$] was obtained even in the presence of excess of rhodium(II) acetate, at ratios of [**1**·$(H_2O)_2$]:MMP > 1. Thus complex [**2**·$(HOAc)_2$] is very reactive and can be easily transformed into compound [**3**·$(HOAc)_2$].

In the case of reactions of [**1**·$(H_2O)_2$] with methoxyphenylphosphines containing methoxy groups in *ortho* posi-

[**3**·(HOAc)(hfmp)]	1.14 (s, 3H) (OAc bridge); 1.12 (s, 3H) (OAc bridge); 2.07 (s, 6H) (molecule of HOAc); 4.13 (s, 10H^A) (cyclopentadienyl ring); 2.6–5.5 (OMe groups and protons of hfmp); 5.8–7.5 (aromatic protons)
[**3**·$(hfmp)_2$]	1.00 (s, 6H) (OAc bridges); 2.07 (s, 6H) (molecule of HOAc); 4.15 (s, 10H^A) (cyclopentadienyl ring); 2.6–5.5 (OMe groups and protons of hfmp); 5.8–7.5 (aromatic protons)

tions, the O—Me bond of the methoxy group is activated and a Rh-PC_6H_2RR'–2-O-Rh bridge is formed. Thus, tris(2-methoxyphenyl)phosphine (OMP) and tris(2,6-dimethoxyphenyl)phosphine (DOMP), at molar ratio [P]:[Rh_2] of 2:1, give complexes [**6**·(HOAc)] (19, 20) and [**7**·(HOAc)] (20) with only one bridging phosphine ligand. In these reactions, a methyl cation of one of the methoxy groups is split off and a $\{(CH_3)PAr_3\}^+$ cation is formed.

Complexes [**2**·$(HOAc)_2$] and [**3**·$(HOAc)_2$] have been characterized by a combination of ^{1}H, ^{13}C, and ^{31}P NMR spectroscopies (Table 2). The Chemical shift of OAc groups in *cis* positions is much lower (1.30 ppm, 6H) than that for the OAc bridge (2.32 ppm, 3H) in the *trans* position relative to the phosphine bridging ligand coordinated via P and C (*ortho*) atoms. Both coordination chemical shift and Rh-P coupling constants (^1J (P-Rh) = 151.4 Hz, ^2J (P-Rh) = 4.9 Hz) for complex [**2**·$(HOAc)_2$] (Table 2) are typical of *ortho*-metallated complexes [$Rh_2(\mu\text{-}OAc)_3\{\mu\text{-}(C_6H_3R)P(C_6H_4R)_2\}$]. In the case of complex [**4**·$(HOAc)_2$], ^1J (P-Rh) = 147.4 Hz and ^2J (P-Rh) = 6.1 Hz (22). The ^{1}H, ^{13}C, and ^{31}P NMR data indicate that complex [**3**·$(HOAc)_2$] has a head-to-tail structure. The ^1J (P-Rh) = 166.8 Hz for compound [**3**·$(HOAc)_2$] and is similar to that found for complex [**5**·$(HOAc)_2$] (168.9 Hz).

Molecular structure of [3·(H_2O)(HOAc)]

The molecular structure of [**3**·(H_2O)(HOAc)] shown in Fig. 1 confirms the structure of [**3**·$(HOAc)_2$] established with spectroscopic methods. Details of X-ray data collected are summarized in Table 3. Table 4 contains selected bond lengths and angles. The structure consists of a binuclear rhodium core bridged by two acetate groups and two MMP ligands in which *ortho*-metallation has occurred at one of the phenyl rings. The bridging phenyl rings are coordinated via C-6 atoms: C(46) and C(16). Phosphine ligands are in *cis* position to each other with H-T (head-to-tail) structure. One of the axial sites is occupied by a molecule of water and the second one by a molecule of acetic acid.

The molecular structure shows distorted octahedral coordination around the central atoms. The complex has an almost eclipsed conformation, torsion angles O(1)-Rh(1)-Rh(2)-O(2) and O(3)-Rh(1)-Rh(2)-O(4) are 19.4° and 17.6°, respectively. The torsion angles of the bridging *ortho*-metallated ligand are slightly smaller: P(1)-Rh(1)-Rh(2)-C(16) = 14.2° and P(2)-Rh(2)-Rh(1)-C(46) = 13.8°. The Rh(1)—Rh(2) distance is 2.4913(18) Å, indicating a rather strong single bond between two metal atoms. Rh(1)—P(1) and Rh(2)—P(2) bond lengths are 2.193 Å and Rh(1)—C(46) and Rh(2)—C(16) distances are 1.993(14) and 1.995(14) Å, respectively. Lengths of Rh—O^{equatorial} bonds change in the range 2.12–2.17 Å. The bond lengths between the phosphorus atom and carbon atom of the metallated ring are shorter than those between the phosphorus and carbon atoms of the nonmetallated rings. Methoxy substituents in the phosphine ligands lie approximately in the planes of the phenyl rings.

Lengths of rhodium – axial ligand bonds (Rh(1)—O(1w) = 2.313(9) Å, Rh(1)—O(5) = 2.363(12) Å) indicate rather weak bonding of these ligands. HOAc molecule is coordinating via oxygen atom of carbonyl group; the -OH group is involved in the formation of a strong hydrogen bond with the oxygen atom of the bridging acetato ligand (O(6)-H(6)···O(2), d_{O-O} = 2.565(18) Å).

A rather strong intermolecular hydrogen bond is formed between the axial molecule of water and the oxygen atom of the acetate bridge of another molecule of the compound (O(1w)-H(2w)···O(3) (1 –*x*, 2 – *y*, –*z*), d_{O-O} = 2.695(13) Å).

possessing only σ-donor properties. Adducts [**3**·(L)] and [**3**·$(L)_2$] are the products of these reactions.

Reactions of complex [**3**·$(HOAc)_2$] with {(η^5-C_5H_5)Fe(η^5-C_5H_4)CH_2}$_2$$PCH_2OH$ (hfmp) (Table 2) give stable complexes. Pure adducts [**3**·(hfmp)(HOAc)] and [**3**·$(hfmp)_2$] can be obtained in chloroform at a [**3**·$(HOAc)_2$]:hfmp ratio equal to 1:1 and 1:2, respectively. However, $\Delta\delta$ (^{31}P) = δ (P_{adduct}) – δ (P_{ligand}) for axial hfmp ligands in this case are lower than those for adducts with arylphosphines: –19.1 and –2.6 ppm for [**3**·(hfmp)(HOAc)] and [**3**·$(hfmp)_2$], respectively, (Table 2). Coordination of the ferrocenylmethylphosphine ligand causes large changes in chemical shifts of the bridging MMP ligand; binding hfmp as axial ligand moves the signals of MMP to lower fields and raises the coupling constants between MMP and rhodium atom. In [**3**·(hfmp)(HOAc)], there are two signals of *ortho*-metallated MMP ligand: a doublet of doublets at 27.6 ppm (^1J (P-Rh) = 183.1 Hz, ^2J (P-P) = 15.2 Hz) and a doublet at 20.85 ppm (^1J (P-Rh) = 155.1 Hz); in biadduct [**3**·$(hfmp)_2$] there is only one doublet of MMP at 24.2 ppm (^1J (P-Rh) = 170.4 Hz).

For monoadducts [**1**·(hfmp)(H_2O)], [**1**(dhfmp)$(H_2O)_2$] (dhfmp = (η^5-C_5H_5)Fe(η^5-C_5H_4)$CH_2P(CH_2OH)_2$), and [**7**·(hfmp)], almost the same $\Delta\delta$ (^{31}P) were observed as for [**3**·(HOAc)(hfmp)].

Complex [**3**·$(HOAc)_2$] in methanol, acetone, and chloroform under a CO atmosphere very easily forms biadduct [**3**·$(CO)_2$] that is considerably more stable than adducts [**6**·(CO)], [**6**·$(CO)_2$], and [**7**·(CO)] (20). Complex [**3**·$(CO)_2$] is stable in these solvents in an air, nitrogen, or argon atmosphere at room temperature for several hours. The first band observed in the electronic spectrum of complex [**3**·$(HOAc)_2$] in acetone at 559 nm is shifted to 399 nm in biadduct [**3**·$(CO)_2$]. The spectrum of the starting compound can be observed after prolonged bubbling of nitrogen through solution, which proves reversibility of the binding of CO. The

presence of [**3**·$(CO)_2$] was also demonstrated by the ^{1}H and ^{13}C NMR spectra of complex [**3**·$(HOAc)_2$] in $CDCl_3$ in an atmosphere of ^{13}CO (Tables 5 and 6). The AA′XX′ type spectrum of the ^{13}CO ligand has been observed at 243 K (d = 174.4 ppm, ^1J (C-Rh) = 46.5 Hz, ^2J (C-Rh) = 4.0 Hz, $^3J_{C-C}$ = 31.7 Hz, and ^1J (Rh-Rh) = 3.5 Hz) (Table 6, Fig. 2).

Relatively high stability of the Rh—CO bond in [**3**·$(CO)_2$] was confirmed by IR spectra. Stretching frequency ν (CO) for this adduct is low (2036 cm^{-1}) and similar to ν (CO) observed for [**5**·$(CO)_2$] (2032 cm^{-1}). This band is shifted to 1991 cm^{-1} for complex [**3**·$(^{13}CO)_2$], which agrees very well with the calculated value. For other adducts, the ν (CO) frequencies are higher, e.g., [**1**·$(CO)_2$] (2105 cm^{-1}), [**7**·(CO)] (2084 cm^{-1}), [**6**$(CO)_n$] (2085 and 2105 cm^{-1}).

Adducts [**4**·(CO)(HOAc)] and [**4**·$(CO)_2$] are less stable than [**3**·$(CO)_2$]. They are relatively stable in chloroform solutions and less stable in more polar solvents, methanol and acetone. At room temperature, in chloroform, the mixture of labile monoadduct [**4**·(CO)(HOAc)] and biadduct [**4**·$(CO)_2$] is formed. This was confirmed by ^{31}P and ^{13}C NMR spectra of these complexes in chloroform under CO atmosphere (Table 6). In the ^{31}P NMR spectrum only one doublet was observed at 11.7 ppm (^1J (P-Rh) = 140.2 Hz). This signal is shifted for 3 ppm to higher fields in comparison with complex [**4**·$(HOAc)_2$]. In the ^{13}C NMR spectrum at room temperature, ligand ^{13}CO gave a broad singlet at 165 ppm. However, the ^{31}P and ^{13}C spectra at 243 K indicate that monoadduct [**4**·(CO)(HOAc)] and biadduct [**4**·$(CO)_2$] are rigid. In the ^{31}P NMR spectrum, two doublets of the ratio of intensities 4.5:5.5 are observed. In the ^{13}C NMR spectrum of [**4**·$(^{13}CO)_2$] and [**4**·(^{13}CO)] at 243 K one can observe two broad singlets at 171.6 and 168.8 ppm which can be assigned to [**4**·$(CO)_2$] and a broad doublet at 156.1 ppm (^1J (C-Rh) = 45.8 Hz). Two signals of ^{13}CO in the biadduct are observed due to unequivalent axial positions in complex **4**. The doublet at 156.1 ppm should be assigned to [**4**·(CO)]. Similar chemical shift and ^1J (C-Rh) were found for monoadduct [**7**·(^{13}CO)] (δ (^{13}C) = 153 ppm, ^1J (P-Rh) = 42.0 Hz) (20). The approximate [**4**·(CO)(HOAc)]:[**4**·$(CO)_2$] ratio calculated from ^{13}C NMR is 3:7 and is similar to that determined from the ^{31}P NMR spectrum.

Antitumor activities of investigated complexes

We have investigated antitumor activity in vitro of some complexes against a few cell lines (KB (oral carcinoma), Hu1703 (bladder cancer), SW707 (colon adenocarcinoma), and T47D (breast cancer). Activities of investigated compounds [**3**·$(HOAc)_2$], [**6**·(HOAc)], [**7**(HOAc)], and dhfmp were compared to the activity of *cis*-diaminadichloroplatinum(II) (Table 7).

The most active agent against all investigated tumor lines is complex [**6**·(HOAc)]. It shows higher activity than cisplatin. Antitumor activity decreases in the series: [**6**·(HOAc)] > [**7**·(HOAc)] > [**3**·$(HOAc)_2$] > dhfmp. Activity of all investigated rhodium(II) complexes is higher than that of [**1**·$(H_2O)_2$].

To explain possible mechanisms of antitumor activity of these complexes we have investigated interactions in situ of complexes [**3**·$(HOAc)_2$] and [**6**·(HOAc)] with adenine, adenosine, AMP, ATP, guanine, guanosine, cytosine, cytidine, glutathione (GSH), oxidized glutathione (GSSG), and cysteine using UV–vis spectroscopy. Complex [**6**·(HOAc)] reacts immediately with adenine, adenosine, AMP, and ATP giving adducts most probably coordinated with the Rh atom via the N7 atom. This follows from the blue shift of the first band in the visible region from 618 nm for compound **5** to 564 nm for the adduct with adenine and 566 nm for the one with adenosine. The lowest shift, to 596 nm, was observed in the case of the adduct with ATP (Fig. 3). This observation is supported by literature data indicating that adenine and adenosine, when coordinated as axial ligands to dirhodium(II) complexes, usually interact via the N7 atom (33–35). Spectra of a solution containing [**6**·(HOAc)] and 10-fold excess of guanine, guanosine, cytidine, or cytosine are very similar to the spectrum of the pure complex. Thus, these nucleotide bases do not interact with complex [**6**·(HOAc)] or are coordinated through the O atom and therefore can be easily substituted by other oxygen-containing ligands present in cells (H_2O, $RCOO^-$, etc.). Interaction of adenine with complex [**3**·$(HOAc)_2$] is much weaker than with compound [**6**·(HOAc)]. The first band observed at 547 nm was shifted only to 545 nm after addition of 10 mol of adenine.

Complex [**6**·(HOAc)] easily reacts with compounds containing sulfhydryl groups, GSH, and cysteine. Even at a molar ratio [**6**·(HOAc)]:HSR of 1:1, the complex immediately is reduced to the diamagnetic mixed valence Rh(I)–Rh(II) complexes, most likely containing a Rh_4^{6+} core, showing a very intensive band at 552 nm (Fig. 4). It was found that complexes $[Rh_2(\mu\text{-}OAc)_2(\mu\text{-}N\text{-}N)_2(H_2O)_2]^{2+}$ can also be readily reduced with sulfhydryl compounds (GSH, cysteine,

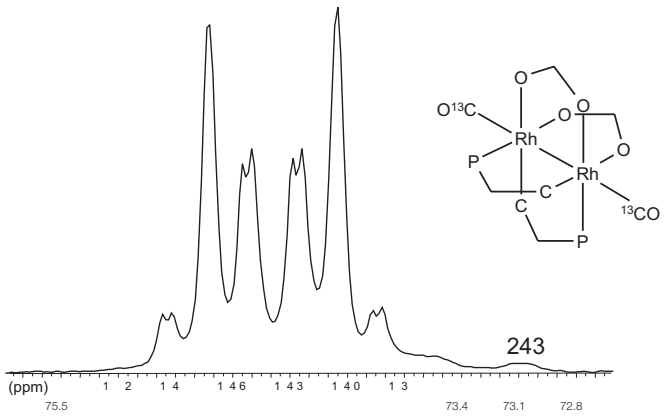
[**3**·(HOAc)$_2$] + CO (MeOH-d_4, room temperature)	15.1 (d), ^{1}J (P-Rh) = 152.6	
[**3**·(HOAc)$_2$] + CO ($CDCl_3$, room temp.)	13.2 (d), ^{1}J (P-Rh) = 151.5	
[**3**·(HOAc)$_2$] + ^{13}CO ($CDCl_3$, 243 K)	14.2 (d), ^{1}J (P-Rh) = 149.0	^{13}CO: (AA′ part of AA′XX′): 174.38 ppm, ^{3}J (^{13}C–^{13}C) = 31.7, ^{1}J (Rh-Rh) = 3.5, ^{1}J (^{13}C-Rh) = 46.5, ^{2}J (^{13}C-Rh) = 4.0



and coenzyme A) giving polynuclear rhodium compounds (36) intensively absorbing in the same region, at ca. 590 nm. Similar spectra were also observed for tetranuclear and polynuclear complexes with isocyanides $[Rh_4(\mu\text{-}CNRNC)_8]^{6+}$ (37–40), $[Rh_4(OAc)_4(N\text{-}N)_4](OAc)_2$ (41), and $\{[Rh_2(OAc)_2(N\text{-}N)_2]^{+}\}_nX_n^{-}$ (42), where N-N = bpy, phen and $X^{-} = BF_4^{-}$, PF_6^{-}. Interaction of complex [**6**·(HOAc)] with GSSG is very weak and the electronic spectrum of [**6**·(HOAc)] after addition of GSSG almost does not change. That proves that complex [**6**·(HOAc)] is easily reduced with GSH.

Absorbance of the reaction product of complex [**3**·(HOAc)$_2$] with GSH is considerably greater than the starting compound, however in the 750–400 nm region, only a shoulder at ca. 550 nm is present (Fig. 5). This suggests that reduction of compound [**3**·(HOAc)$_2$] with GSH proceeds less effectively than reduction of complex [**6**·(HOAc)].

Antitumor activity of complex [**6**·(HOAc)], reacting effectively with adenine and its derivatives and with sulfhydryl compounds, is much higher than the activity of complex [**3**·(HOAc)$_2$] that reacts with the same compounds much less intensely.

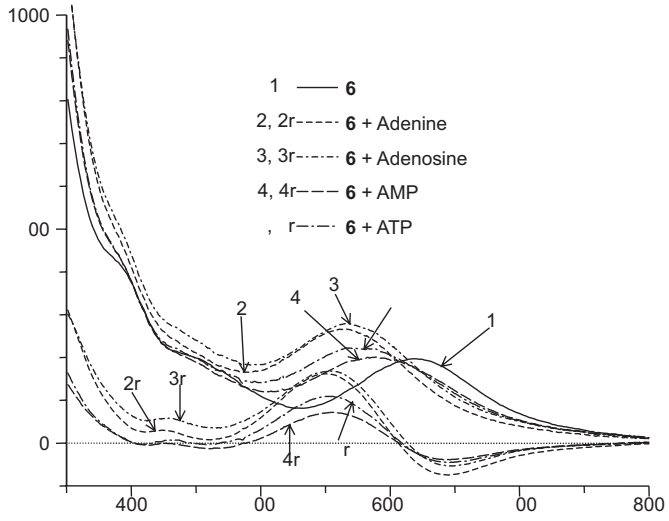
Fig. 2. Fragment of the ^{13}C NMR spectrum of [**3**·($^{13}CO)_2$] spectrum in $CDCl_3$ (temperature 243 K) (^{13}CO groups signal (AA′XX′ type)).

Experimental

Procedures and materials

Tris(4-methoxyphenyl)phosphine (PMP), tris(3-methoxyphenyl)phosphine (MMP), tris(2-methoxyphenyl)phosphine (OMP), and tris(2,6-dimethoxyphenyl)phosphine (DOMP) were purchased from Strem or Avocado and used without further purification. Adenine, adenosine, adenosine 5′-monophosphate (AMP), adenosine 5′-triphosphate (ATP), guanine, guanosine, cytosine, cytidine, glutathione (GSH), oxidized glutathione (GSSG), and cysteine were purchased from Reanal (Hungary) and also used as purchased. All solvents were deoxidized prior to use. Infrared spectrum (KBr pellet) was measured on a Bruker IFS 113v and UV–vis spectra on a Beckman DU 7500 spectrometer. ^1H NMR and ^{31}P NMR spectra were measured in $CDCl_3$ on a Bruker AMX 300 spectrometer with traces of $CHCl_3$ as an internal reference for ^1H (δ = 7.23 ppm) and 85% H_3PO_4 in H_2O as an external standard for ^{31}P. Mass spectra were measured on Finnigan Mat TSQ 700 ESI.



Syntheses

All operations were performed in dinitrogen or argon atmosphere using standard Schlenk technique. Complexes $[Rh_2(\mu\text{-}OAc)_4(H_2O)_2]$ ([**1**·$(H_2O)_2$]) (43), $[Rh_2(\mu\text{-}OAc)_3\{\mu\text{-}(C_6H_3\text{-}4\text{-}OMe)P(C_6H_4O\text{-}4\text{-}OMe)_2\}(HOAc)_2]$ ([**4**·$(HOAc)_2$]) (21), $[Rh_2(\mu\text{-}OAc)_2\{\mu\text{-}(C_6H_3\text{-}4\text{-}OMe)P(C_6H_4\text{-}4\text{-}OMe)_2\}_2(HOAc)_2]$ ([**5**·$(HOAc)_2$]) (21), $[Rh_2(\mu\text{-}OAc)_3\{\mu\text{-}(C_6H_4\text{-}2\text{-}O)P(C_6H_4\text{-}2\text{-}OMe)_2\}(HOAc)]$ ([**6**·(HOAc)]) (19), and $[Rh_2(\mu\text{-}OAc)_3\{\mu\text{-}(C_6H_3\text{-}6\text{-}OMe\text{-}2\text{-}O)P[(C_6H_3\text{-}2,6\text{-}(OMe)_2]_2\}(HOAc)]$ ([**7**·(HOAc)]) (20) were synthesized according to literature methods.

[Rh_2(μ-OAc)$_2${μ-(C_6H_3-3-OMe)P(C_6H_4-3-OMe)$_2$}$_2$(HOAc)$_2$] ([3·(HOAc)$_2$])

A suspension of [**1**·$(H_2O)_2$] (0.144 g, 0.3 mmol) and MMP (0.226 g, 0.6 mmol) in a mixture of 5 cm^3 of ethanol and 5 cm^3 of acetic acid was refluxed with stirring for 3 h. The initial orange color of the reaction mixture was replaced by brown-gray and then by deep violet solution. The solution was evaporated to dryness and the product was crystallized from mixture of chloroform (5 cm^3) and acetic acid (3 cm^3). Yield: 0.316 g, 69%. Mass spectrum (M = $Rh_2(\mu\text{-}OAc)_2\{\mu\text{-}(C_6H_3\text{-}3\text{-}OMe)P(C_6H_4\text{-}3\text{-}OMe)_2\}_2$) (signals of intensity higher than 16%): 367 (100%) ($MMP^+ + CH_3$), 926 (18%), 967 (30%) ($M^+ - OAc$), 1335 (20%) ($M^+ - OAc + MMP + CH_3$), 1993 (20%) ($M_2^+ - OAc$). Anal. calcd. for $C_{50}H_{54}O_{14}P_2Rh_2$: C 52.37, H 4.75; found: C 52.42, H 4.71.

Fig. 3. UV–vis spectra of the mixtures of [**6**·(HOAc)] with adenine, adenosine, AMP, and ATP (in molar ratios 1:10) in the mixture of H_2O and AcMe (1:1 by volume). *X* axis: λ (nm), *Y* axis: $e = Ac_0^{-1}\ L^{-1}$.

[(η^5-C_5H_5)Fe(η^5-C_5H_4)$CH_2P(CH_2OH)_2$ (dhfmp) and {(η^5-C_5H_5)Fe(η^5-C_5H_4)CH_2}$_2$$PCH_2OH$ (hfmp)

Both phosphines were synthesized according to literature methods (44, 45) describing the synthesis of dhfmp as a single product.

19.27 g of an 80% solution of $P(CH_2OH)_4Cl$ in H_2O was diluted with MeOH (20 cm^3), deoxidized, and placed under an Ar atmosphere; KOH (4.26 g, 0.076 mol) was added to the solution. The resulting mixture was stirred for 2 h at room temperature. Then $[C_5H_5FeC_5H_4CH_2N(CH_3)_3]I$ (10.0 g, 0.026 mol) suspension in methanol (20 cm^3) was slowly added and the reaction mixture was refluxed with stirring for 20 h. After that time two-thirds of the solvent was evaporated and H_2O (15 cm^3), diethyl ether (45 cm^3), and triethylamine (15 cm^3) were added. After 1 h of stirring, the water layer was removed and reextracted with diethyl ether (15 cm^3). The combined extracts were washed a few times with small portions (5 cm^3) of water (to dispel the characteristic smell of amine). After removing ether under reduced pressure, the products were recrystallized from the mixture of CH_2Cl_2 (5 cm^3), MeOH (5 cm^3), and light petroleum ether (35 cm^3). In all experiments, we have always obtained two products, which were isolated using the difference of their solubility in the mixture of water and methanol. In methanol–water (50:50 by mass) practically only dhfmp is dissolved. The purity of products was controlled using TLC (5 × 20 cm plates with reversed phase silicagel (C_{18}) from Alltech). Eluent: 90% solution of methanol in water. Intense yellow color of products facilitated the

observations. Yield: 47% for dhfmp and 21% for hfmp. Mass spectrum of dhfmp (M = $(C_5H_5)Fe(C_5H_4)CH_2P(CH_2OH)_2$) (signals of intensity higher than 16%): 199 (100%) $\{FcCH_2^+\}$, 292 (20%) $\{M^+\}$, 322 (42%) $\{M^+ + CH_2OH\}$, 460 (18%) $\{(FcCH_2)_2P(CH_2OH)^+\}$, 490 (20%) $\{(FcCH_2)_2PH(CH_2OH)_2\}$. Mass spectrum of hfmp (M = $\{(C_5H_5)Fe(C_5H_4)CH_2\}_2PCH_2OH$) (signals of intensity higher than 16%): 199 (72%) $\{FcCH_2^+\}$, 461 (100%) $\{M^+ + H\}$, 491 (68%) $\{M^+ + CH_2OH\}$. Anal. calcd. for $C_{13}H_{17}FeO_2P$ (dhfmp): C 53.46, H 5.87, P 10.60; found: C 53.4, H 5.6, P 9.8. Anal. calcd. for $C_{23}H_{25}Fe_2OP$ (hfmp): C 60.04, H 5.48, P 6.73; found: C 59.8, H 5.3, P 6.4.

X-ray structure determination

All measurements were made at 170(2) K on a Kuma KM4CCD κ-axis diffractometer with graphite monochromated Mo Kα radiation (λ = 0.71073 Å, 3.30 = θ = 27.00). The crystallographic data together with data collection and structure refinement details are given in Table 2. All the data were corrected for Lorentz and polarization effects but absorption and extinction were not applied. The crystal was positioned at 65 mm from the KM4CCD camera. Frames (612) were measured at 0.75° intervals with a counting time of 20 s. The data were corrected for Lorentz and polarization effects. Data reduction and analysis were carried out with the Kuma Diffraction programs (46, 47). The structure was solved by direct methods and refined by the full-matrix least-squares method on F^2 (48). The refinement was performed using the SHELXL program (49). Non-hydrogen atoms were refined with anisotropic thermal parameters; hydrogen atoms were included from the geometry of molecules and Δρ maps but were not refined.

Crystals of [**3**·(HOAc)(H_2O)] suitable for X-ray analysis were obtained from recrystallization of [**3**·$(HOAc)_2$] from the mixture of $CHCl_3$ and 96% EtOH in H_2O.

Cytotoxic activity in vitro

Compounds

Test solutions of the compounds tested (1 mg mL^{-1}) were prepared ex tempore by dissolving the substance in 100 μL of solvent completed with 900 μL of tissue culture medium. Afterwards, the tested compounds were diluted in culture medium (described below) to reach the final concentrations of 100, 10, 1, 0.1, and 0.01 μg mL^{-1}. The solvents (in dilu-

© 2001 NRC Canada

tion corresponding to its highest concentration applied to the tested compounds), did not exert any inhibitory effect on cell proliferation.

Cells

The below listed, established in vitro, human cancer cell lines were applied: SW707 (colon adenocarcinoma), Hu1703 (bladder cancer), T47D (breast cancer), KB (oral carcinoma). All lines were obtained from the American Type Culture Collection (Rockville, Maryland, U.S.A.) and are maintained in the Cell Culture Collection of the Institute of Immunology and Experimental Therapy, Wroclaw, Poland.

The cells were plated in 96-well plates (Sarstedt, U.S.A.) at a density of 1×10^4 cells per well, 24 h before addition of the tested agents. The cells were cultured in the opti-MEM medium supplemented with 2mM glutamine (Gibco, Warsaw, Poland), streptomycin (50 μg mL^{-1}), penicillin (50 U mL^{-1}) (both antibiotics from Polfa, Tarchomin, Poland), and 5% fetal calf serum (Gibco, Grand Island, New York). The cell cultures were maintained at 37°C in a humid atmosphere saturated with 5% CO_2.

Antiproliferative assay in vitro

SRB. The details of this technique were described by Skehan et al. (50). The cytotoxicity assay was performed after 72-h exposure of the cultured cells to varying concentrations (from 0.01 to 100 μg mL^{-1}) of the tested agents. The cells attached to the plastic were fixed by gently layering cold 50% TCA (trichloroacetic acid, Aldrich-Chemie, Germany) on the top of the culture medium in each well. The plates were incubated at 4°C for 1 h and then washed five times with tap water. The background optical density was measured in the wells filled with culture medium, without the cells. The cellular material fixed with TCA was stained with 0.4% sulforhodamine B (SRB, Sigma, Germany) dissolved in 1% acetic acid (POCh, Gliwice, Poland) for 30 min. Unbound dye was removed by rinsing (4×) with 1% acetic acid. The protein-bound dye was extracted with 10 mM unbuffered Tris base (tris (hydroksymethyl) aminomethane, POCh, Gliwice, Poland) for determination of optical density (at 540 nm) in a computer-interfaced, 96-well microtiter plate reader Multiskan RC photometer (Labsystems). Each compound in given concentration was tested in triplicates in each experiment, which was repeated 3–5 times.

The results of cytotoxic activity in vitro were expressed as ID_{50} — the dose of compound that inhibits proliferation rate of the tumor cells by 50% as compared to control untreated cells.

Supplementary material

Supplementary material may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada (for information on ordering electronically http://www.nrc.ca/cisti/irm/unpub_e.shtml). Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre. Copies of the data can be obtained, free of charge, on application to the Director, CCDC, 12 Union Road, Cambridge CB2, 1EZ, U.K. (Fax: (+44)1223-336-033 or e-mail: deposit@ccdc.cam.ac.uk).

Octaarylethynyl and octaarylbutadiynyl phthalocyanines

Clifford C. Leznoff and Bohdan Suchozak

Abstract: 4,5-Diphenylethynylphthalonitrile, 4,5-di(*p*-*tert*-butylphenylethynyl)phthalonitrile, 4,5-di(*p*-neopentoxyphenylethynyl)phthalonitrile, and 4,5-di(*p*-neopentoxyphenyl-1,3-butadiynyl)phthalonitrile were prepared via 4,5-diiodophthalonitrile and the appropriate alkyne in palladium-catalyzed coupling reactions. Condensation of the above alkynylphthalonitriles with lithium 1-octanolate in 1-octanol afforded the desired polyalkynylphthalocyanines, but only 2,3,9,10,16,17,22,23-octa (*p*-neopentoxyphenylethynyl)phthalocyanine and 2,3,9,10,16,17, 22,23-octa (*p*-neopentoxyphenylbutadnyl)phthalocyanine were soluble enough to be suitably characterized.

Key words: phthalocyanines, phenylacetylenes, 1-phenyl-1,3-butadiynes.

Résumé : On a préparé le 4,5-diphényléthynylphtalonitrile, le 4,5-di(*p*-*tert*-butylphényléthynyl)phtalonitrile, le 4,5-di-(*p*-néopentoxyphényléthynyl)phtalonitrile, le 4,5-di-(*p*-néopentoxyphénylbuta-1,3-diynyl)phtalonitrile en procédant au couplage catalysé par le palladium du 4,5-diiodophtalonitrile avec l'alcyne approprié. La condensation des alcynylphtalonitriles mentionnés plus haut avec de l'octan-1-olate de lithium dans l'octan-1-ol permet d'obtenir les polyalcynylphtalocyanines recherchées; toutefois seules la 2,3,9,10,16,17,22,23-octa(*p*-néopentoxyphényléthynyl)phtalocyanine et la 2,3,9,10,16,17,22,23-octa-(*p*-néopentoxyphénylbutadiynyl)phtalocyanine sont suffisamment solubles pour être caractérisées de façon adéquate.

Mots clés : phtalocyanines, phénylacétylènes, 1-phénylbuta-1,3-diynes.

[Traduit par la Rédaction]

Introduction

2,3,9,10,16,17,23,24-Octa-substituted phthalocyanines are well-known (1), and have been studied for applications in a wide variety of areas, including dyes (2), chemical sensors (3), nonlinear optics (4), and photodynamic therapy of cancer (5, 6). Recently, poly(phenylalkynyl) benzenes (7) and alkynylporphyrins (8) have been described as possible compounds for use in nonlinear optics and arrays (8, 9). With this in mind, a series of 2,3,9,10,16,17,23,24-octaalkynylphthalocyanines were prepared (10) and their ^{1}H NMR spectra studied with respect to their variation in chemical shifts with concentration and temperature. Alkynyl-substituted phthalocyanines (Pcs) have been found to be particularly interesting in that each alkynyl group causes a red shift of 4–6 nm in the Q-band region of the spectrum, and can hence be applied in "fine-tuning" a Pcs absorption spectrum.

Not investigated in our original series of octaalkynylphthalocyanines were those substituted with phenylethynyl groups, which would be expected to give a greater red shift due to more extensive π-electron delocalization. Reports of enhanced nonlinear effects in molecules with extreme bond-length alternations (11), including conjugated diynyl systems (12) have also prompted our interest in butadiynyl substituted phthalocyanines. In this paper, the synthesis of some 2,3,9,10,16,17,23,24-octa(phenylethynyl)phthalocyanines will be described. The synthesis of a 4,5-di(butadiynyl)-substituted phthalonitrile is also outlined and its condensation reaction with lithium 1-octanolate will be discussed.

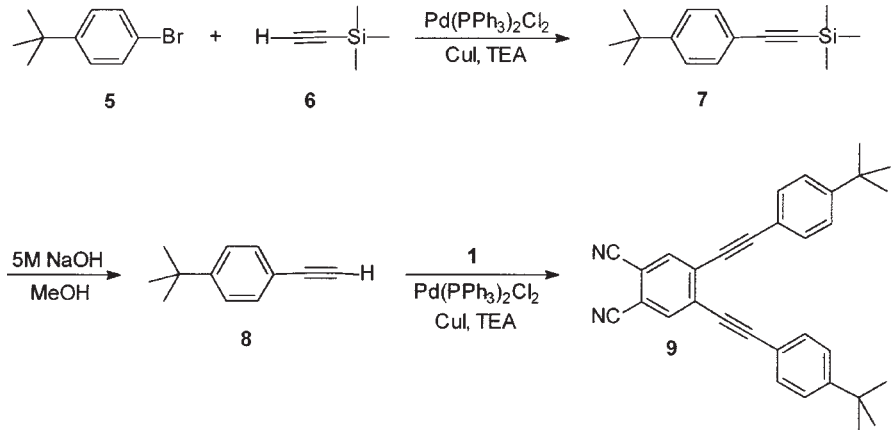
Results and discussion

Using catalytic quantities of $Pd(PPh_3)_2Cl_2$ and CuI in triethylamine (TEA), 4,5-diiodo-phthalonitrile (**1**) was coupled with 2 molar equiv of phenylacetylene (**2**), to afford 4,5-di(phenylethynyl)phthalonitrile (**3**) in 70% yield (Scheme 1). Subsequent condensation of **3** with lithium 1-octanolate in 1-octanol gave, after work-up, a dark green solid which was extremely insoluble in most organic solvents (see Scheme 3 below). Purification of this product, which is believed to be 2,3,9,10,16,17,23,24-octa(phenylethynyl)phthalocyanine (**4**), was made extremely difficult due to its insolubility, and consequently failed to afford satisfactory proton NMR or FAB mass spectra. A recently acquired MALDI-TOF mass spectrometer has allowed us to record the parent ion cluster at (1314) of **4**. However, a UV–vis spectrum of a probe from the reaction mixture at 20 h seems to suggest the formation of an MPc. This is indicated by a strong absorption maximum at 720 nm, which would correspond to the expected Q-Band absorption of the dilithium Pc.



The high degree of insolubility displayed by the product of this reaction, assuming that it is indeed **4**, was believed to

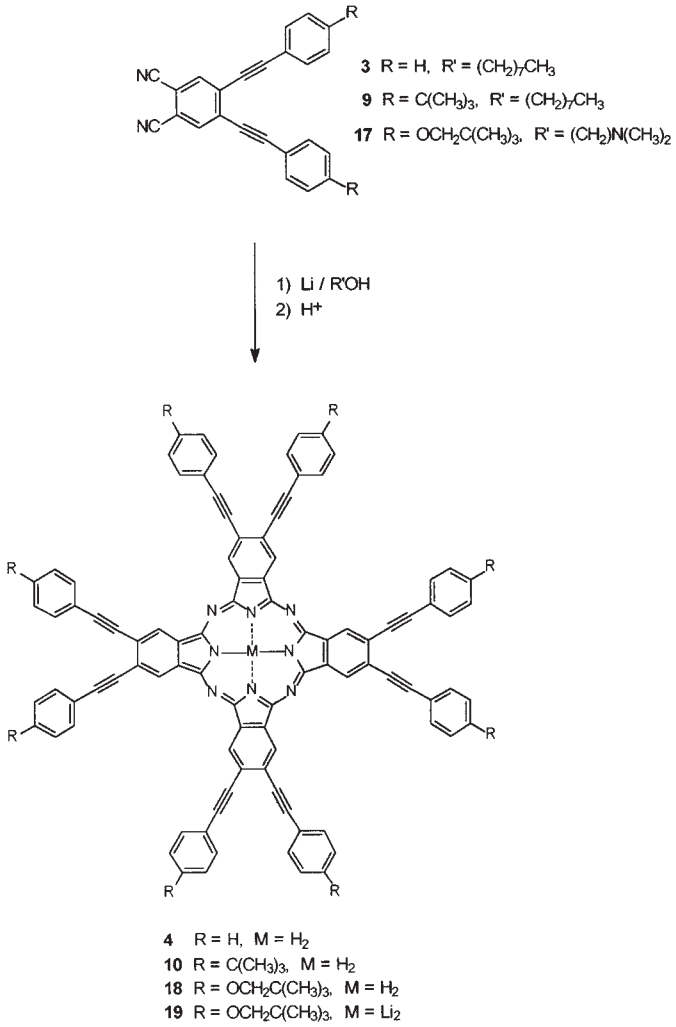
Scheme 1.

Scheme 2.

be due to aggregation. In an attempt to minimize these intramolecular aggregative effects, the phenylacetylene moiety was functionalized with the bulky *tert*-butyl group. Thus, 1-bromo-4-*tert*-butylbenzene (**5**) was coupled with trimethylsilylacetylene (**6**) using $Pd(PPh_3)_2Cl_2$ and CuI in TEA in a pressure bottle at 95°C, to give 1-trimethylsilyl-2-(*p*-*tert*-butylphenyl)acetylene (**7**) in 75% yield. This compound was then deprotected by treatment with aqueous 5 M NaOH in methanol to give *p*-*tert*-butylphenylacetylene (**8**) in 98% yield. This was subsequently coupled with 4,5-diiodophthalonitrile (**1**), again using $Pd(PPh_3)_2Cl_2$ and CuI, to afford 4,5-di(*p*-*tert*-butylphenylethynyl)phthalonitrile (**9**) in 88% yield (Scheme 2).



Condensation of **9** to the corresponding Pc (**10**) was performed using lithium 1-octanolate in 1-octanol at 100°C (see Scheme 3 below). A UV–vis probe of this reaction after 22 h revealed an absorption at 722 nm, believed to be the Q-band absorption of the intermediate dilithium Pc. An acid work-up of the reaction was performed to obtain the metal free Pc **10**, but the dark-green product isolated from this reaction was found to be just as insoluble in organic solvents as Pc **4**. Similar difficulties were also encountered in trying to obtain satisfactory NMR and mass spectra, although a MALDI-TOF mass spectrum of **10** exhibited a parent ion cluster at 1762 amu. If phthalocyanine **10** had indeed formed in this reaction, as suggested by the UV–vis spectrum, then it seemed evident that the *tert*-butyl groups did little to enhance the solubility of these Pcs in their metal-free state.

Previous work in our laboratory has shown that neopentoxy groups are highly effective at increasing the solubility of Pcs (13). It was therefore hoped that by replacing the *tert*-butyl groups with neopentoxy groups, a more soluble octaphenylethynyl Pc could be synthesized and full characterization might be facilitated. The synthesis was initiated with the tosylation of neopentyl alcohol (**11**) in pyridine to give neopentyl tosylate (**12**), which was obtained in 85% yield. Tosylate **12** then reacted with *p*-iodophenol (**13**) to give *p*-iodoneopentoxybenzene (**14**) in 82% yield. This was subsequently coupled with trimethylsilylacetylene (**6**) using $Pd(PPh_3)_2Cl_2$ to give 1-trimethylsilyl-2-(*p*-neopentoxyphenyl)acetylene (**15**) in 88% yield. The trimethylsilyl group was then cleaved from **15** using 5 M aq NaOH in methanol to give, in 97% yield, *p*-neopentoxyphenylacetylene (**16**). Terminal alkyne **16** was then coupled with 4,5-diiodophthalonitrile (**1**), again using $Pd(PPh_3)_2Cl_2$ as a catalyst, to give 4,5-di(*p*-neopentoxyphenylethynyl)phthalonitrile (**17**) in 70% yield (Scheme 4). Subsequent condensation of **17** in Li–DMAE at 100°C (Scheme 3) yielded 2,3,9,10,16,17,23,24-octa(*p*-neopentoxyphenylethynyl)phthalocyanine (**18**) as a dark green solid, after work-up. Although not exceedingly soluble, Pc **18** was found to dissolve appreciably well in benzene, toluene, $CHCl_3$, CH_2Cl_2, and THF. Purification of this compound was accomplished by column chromatography using flash silica gel and CH_2Cl_2 as eluent, followed by gel permeation chromatography using SX-2 Biobeads® and THF as eluent. This was followed by reprecipitation from benzene–ethanol and then further chromatography, again using flash silica gel and CH_2Cl_2. After exhaustive purification, **18** was obtained in an overall yield of 8%.

The UV–vis absorption spectrum of phthalocyanine **18** in THF is shown in Fig. 1. A broad absorption band was observed in the 600–800 nm region with an absorption max at 678 nm and a shoulder at 720 nm. Neither dilution of the so-

Scheme 3.

lution, nor heating to 60°C caused any observable changes in its spectral patterns. Although the known metal-free octa(*alkyl*)ethynyl phthalocyanines show a pair of sharp Q-band absorptions in the same region (10), this is not the case for **18**. The corresponding dilithium Pc (**19**) was formed by treating **18** with lithium metal in THF at 50°C. The UV–vis spectrum of this compound in THF, shown in Fig. 2, displays the same sharp Q-band absorption at 720 nm as observed in the spectral probes for the condensation reactions of **3** and **9**. This result lends evidence supporting the formation of Pcs **4** and **10** in the aforementioned reactions.

A comparison of the electronic spectrum of **19** with unsubstituted dilithium phthalocyanine, which displays a Q-band absorption at 688 nm (14), suggests that the eight peripheral *p*-neopentoxyphenylethynyl groups impart a red-shift of approximately 32 nm. Further comparison with the electronic spectrum of a representative octa*alkyl*ethynyl Pc, dilithium-2,3,9,10,16,17,23,24-octapentynylphthalocyanine, which displays a Q-band absorption at 700 nm (15), suggests that the eight peripheral phenyl groups on **19** have the effect of increasing the red-shift in dilithio-octaalkynylphthalocyanines by an additional 20 nm.

Phthalocyanines **18** and **19** were also characterized by ^{1}H NMR spectroscopy in toluene-d_8 at 300 K, at a concentration of 1.0×10^{-3} M. The spectrum of **18** exhibited three broad signals in the aromatic region, one corresponding to the protons on phthalocyanine itself, and the other two corresponding to the protons on the peripheral neopentoxyphenyl rings. The outer neopentoxy groups were observed as a pair of broad singlets, one at 3.48 ppm, corresponding to the OCH_2 hydrogens and the other at 1.16 ppm, corresponding to the hydrogens on the terminal $C(CH_3)_3$ groups. The two protons on the inner nitrogens however were not observed, and a series of high-temperature ^{1}H NMR experiments were subsequently conducted to determine whether aggregation may have any effect in obscuring this signal. The same sample was rerun at incrementally higher temperatures, ranging from 300 to 363 K, but the signal still remained absent. Only after extreme vertical expansion of the spectra was a very broad singlet detected at –4.8 ppm. Additionally, the previously broad aromatic singlets at 300 K began to sharpen, and eventually appeared as a pair of doublets (Fig. 3). FAB-MS analysis of **18** exhibited the parent ion (M + 1, m/z = 2004), but the elemental analysis exhibited somewhat low carbon values, typical of some Pc compounds. The MALDI-TOF mass spectrum also exhibited a parent ion at 2002 amu. The FAB-MS spectrum for **19** did not show a molecular ion peak, but exhibited rather, two ion clusters that are consistent with the loss of one and two lithium atoms; (M – Li) centred around m/z = 2010 and (M – 2 Li) centred around m/z = 2004.

The synthesis of a 4,5-di(butadiynyl)-substituted phthalonitrile was achieved via a palladium-catalyzed cross-coupling between a monosubstituted butadiyne and 4,5-diiodophthalonitrile (**1**). This was accomplished first, by treatment of **16** with an ethyl Grignard and iodine to give 1-iodo-2-(*p*-neopentoxyphenyl)acetylene (**20**) in 26% yield, along with an undesired by-product, 1,4-di(*p*-neopentoxyphenyl)-1,3-butadiyne (**21**). This was followed by a palladium-catalyzed coupling with trimethylsilylacetylene (**6**) to give 1-(trimethylsilyl)-4-(*p*-neopentoxyphenyl)-1,3-butadiyne (**22**) in 29% yield. Subsequent desilylation using 5 M aq NaOH in MeOH at room temperature afforded 1-(*p*-neopentoxyphenyl)-1,3-butadiyne (**23**) in 95% yield. This was followed immediately by a palladium-catalyzed cross-coupling with **1** to give 4,5-di[4-(*p*-neopentoxyphenyl)-1,3-butadiynyl]phthalonitrile (**24**) in 75% yield (Scheme 5). Slow heating of this compound on a melting point apparatus showed no melting point below 300°C, but the addition of a crystal on a hot Kofler block exhibited a sharp decomposition point at 223°C.

Condensation of **24** to 2,3,9,10,16,17,23,24-octa[4-(*p*-neopentoxyphenyl)-1,3-butadiynyl]phthalocyanine (**25**) was attempted using lithium 1-octanolate in 1-octanol at 80°C (Scheme 6). After 18 h, a UV–vis probe of the dark-green reaction mixture in THF revealed a sharp absorption at 738 nm, which was believed to correspond to the Q-band absorption of the dilithium derivative of **25**. A standard workup procedure was attempted whereby the reaction mixture was treated with dilute aqueous acid, followed by several dissolution–reprecipitation cycles from EtOH–H_2O. Unexpectedly, upon contact with aqueous acid or water, the previously dark-green reaction mixture turned brown and

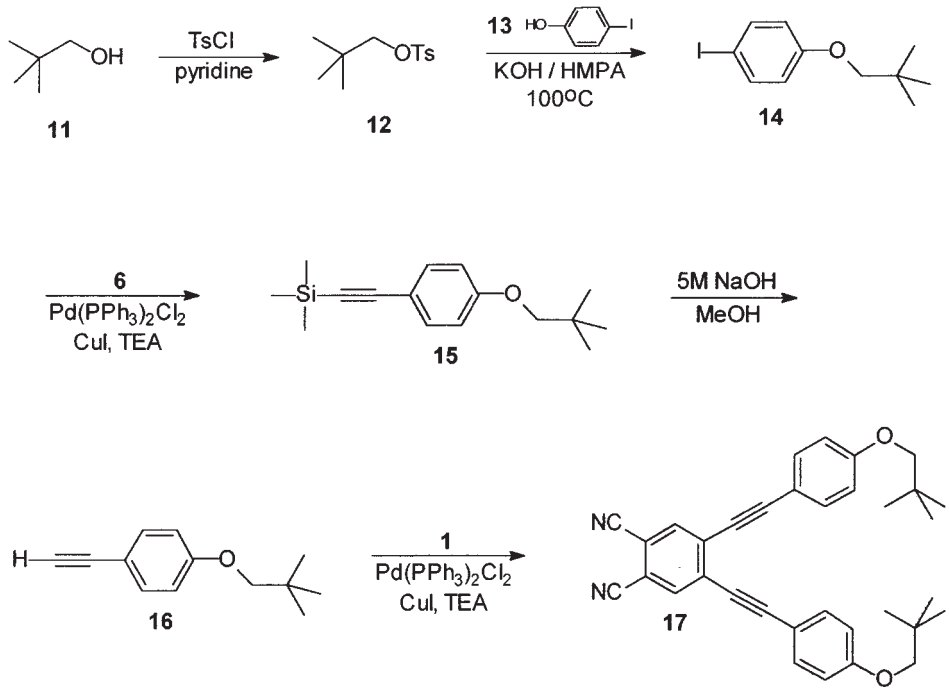

Fig. 1. The UV–vis absorption spectrum of Pc **18**.

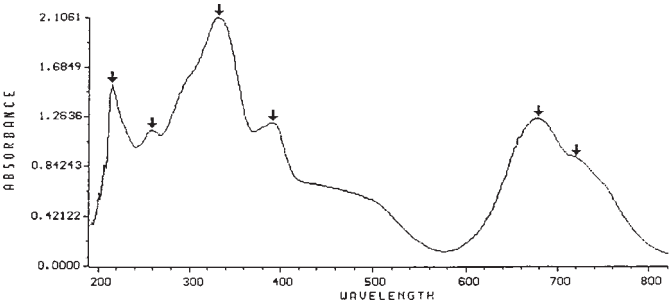

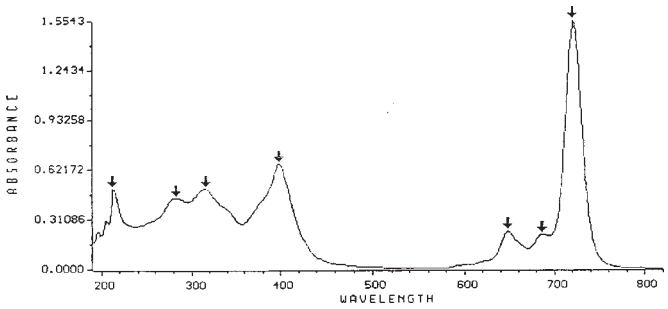

Fig. 2. The UV–vis absorption spectrum of Pc **19**.

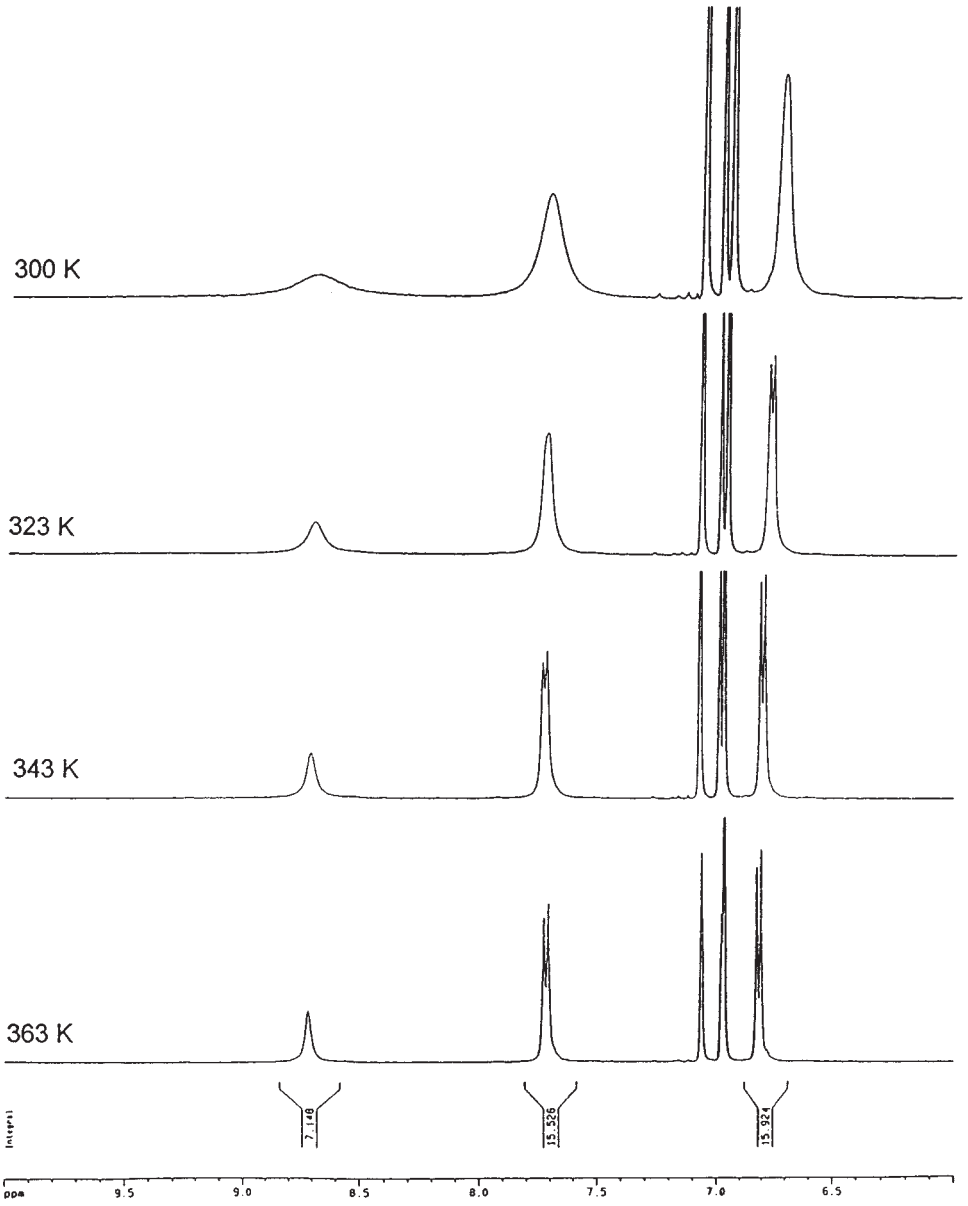

formed a highly insoluble precipitate. A UV–vis spectrum of this material showed almost no absorption in the Q-band region, a result which suggested to us that the Pc had decomposed or polymerized. Attempts were, therefore, made at isolating the intermediate dilithium Pc (**26**) under anhydrous conditions by precipitating the reaction mixture into hexane, followed by gel permeation chromatography of the crude product using dry THF and SX-2 Biobeads®. A dark-green solid was isolated from the column after evaporation of the solvent. An electronic spectrum of this material in THF is shown in Fig. 4. Proton NMR analysis of this material in pyridine-d_5 at 300 K showed a spectrum which was consistent with the structure of **26**. Two singlets were observed at 1.08 and 3.61 ppm, which would correspond to resonances arising from the protons of the eight neopentoxy groups. The aromatic signals arising from the outer neopentoxyphenyl groups corresponded to two doublets centered around 6.92 and 7.67 ppm, and the eight benzo protons on the Pc macrocycle corresponded to a singlet observed at 9.98 ppm. Although, this compound proved to be too unstable to give either a satisfactory elemental analysis or FAB mass spectrum, MALDI-TOF mass spectrometry of **26** did provide a parent ion minus one lithium ion at 2200 amu.

Experimental

Unless otherwise noted, all reaction processes were performed using magnetic stirring methods under an inert atmosphere of Matheson high-purity argon. All organic solvents were dried by appropriate methods and distilled before use. Ultrasound activation was carried out using a Branson 1200 sonicator. Thin layer chromatography (TLC) was performed using Merck silica gel 60 F_{254} polyester-backed plates and column chromatography was performed using Caledon flash grade silica gel 60 of particle size 40–63 μm. Gel permeation chromatography was performed with Bio-Rad SX-2 Biobeads®, using THF as the eluting solvent. Infrared (IR) spectra were recorded on a Unicam Mattson 3000 FT IR spectrometer using samples prepared as KBr discs, unless otherwise noted. Ultraviolet-visible (UV–vis) spectra were recorded on a Hewlett–Packard HP8451A diode array spectrophotometer using THF as the solvent. Melting points (mp) were determined using a Kofler hot stage melting point apparatus and are reported uncorrected. Nuclear magnetic resonance (NMR) spectra for proton and carbon were recorded on a Bruker ARX 400 high field Fourier transform

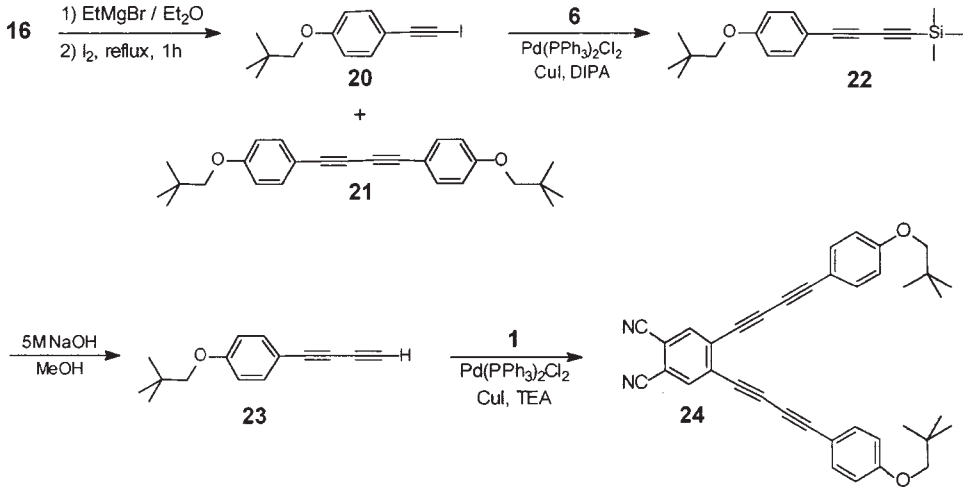
Fig. 3. The temperature dependent ^{1}H NMR spectra of Pc **18**.

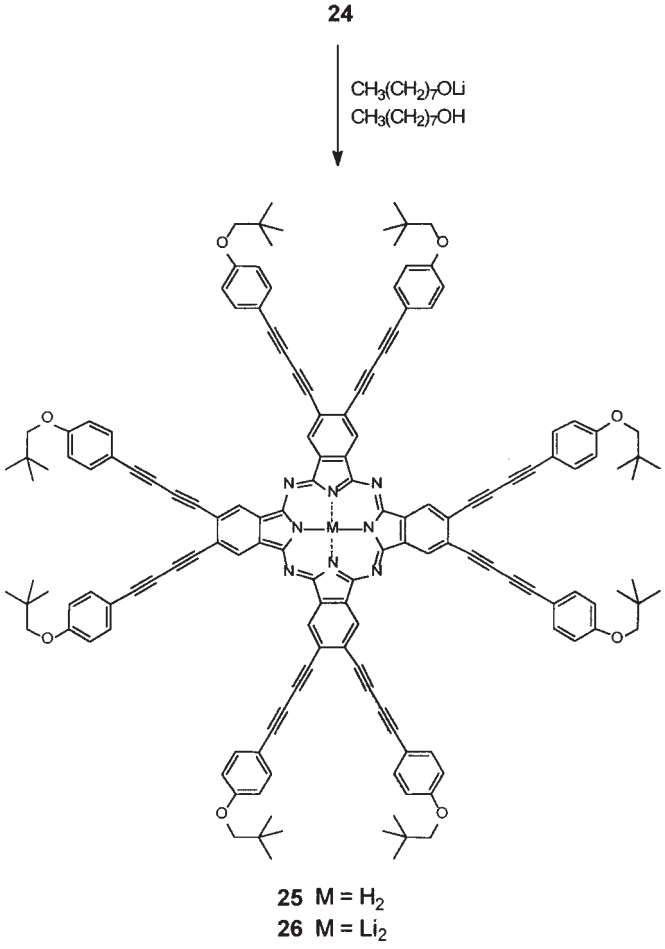
instrument at room temperature unless otherwise stated. Chemical shifts are reported in ppm relative to a tetramethylsilane (TMS) internal standard. Splitting patterns of proton resonances are described as singlets (s), doublets (d), triplets (t), quartets (q), doublet of doublets (dd), multiplets (m), or as broad signals (br). Coupling constants for signals other than singlets and multiplets are reported in Hz. Resonances are reported as the proton decoupled chemical shifts for ^{13}C NMR spectra. Electron-impact mass spectral analyses (EI-MS) were performed by Dr. B. Khouw (York University, Toronto, Ontario, Canada) and Ms. Lisa Nelson (York University, Toronto, Ontario, Canada). MALDI-TOF mass spectra were performed neat using a Voyager Str instrument. Fast atom bombardment (FAB) and high resolution mass spectrometric analyses (HR-MS) were performed by Dr. R. L. Cerny (Nebraska Center for Mass Spectrometry, University of Nebraska-Lincoln, Lincoln, Nebraska, U.S.A.). Microanalyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ontario, Canada.

4,5-Diiodophthalonitrile (1)



This compound was prepared in three steps according to a published procedure (10) (overall yield 50% from phthalimide); mp 216–217°C (lit. value (10), 216 to 217°C).

4,5-Di(phenylethynyl)phthalonitrile (3) general procedure



To a solution of 200 mg (0.53 mmol) of 4,5-diiodophthalonitrile (**1**) dissolved in 30 mL of triethylamine (TEA) was added 36 mg (0.051 mmol) of $Pd(PPh_3)_2Cl_2$, 10 mg (0.051 mmol) of CuI, and then 0.13 mL (0.11 g, 1.2 mmol) of phenylacetylene (**2**). The reaction was heated to 60°C for 2 h under argon and then allowed to cool to room temperature overnight. The reaction was analyzed by

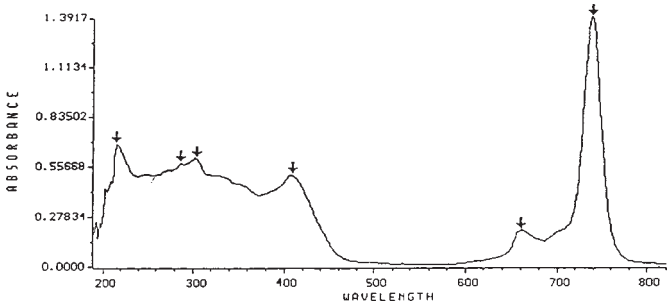
Scheme 6.

TLC using benzene as eluent, and judged complete by the disappearance of the starting material. The solvent was removed by rotary evaporation at 40°C, the residue was suspended in ethyl acetate, suction filtered through celite, and then the solvent was removed from the filtrate in vacuo at 40°C. This brown residue was chromatographed with flash grade silica gel using 98:2 hexane:ethyl acetate to afford **3** as a yellow solid (121 mg, 70% yield), mp 190–192°C. EI-MS *m*/*z* (%): 328 (M^+, 100). UV–vis (THF) λ_{max} (nm): 222, 276, 301, 345. IR (KBr) (cm^{-1}): 2217 (C≡N). ^1H NMR ($CDCl_3$) δ: 7.93 (s, 2H), 7.59 (d, *J* = 7.1 Hz, 4H), 7.43 (m, 6H). ^{13}C NMR ($CDCl_3$) δ: 136.34, 132.22, 131.09, 130.21, 128.92, 121.72, 114.90, 114.27, 100.70, 85.74. Anal. calcd. for $C_{24}H_{12}N_2$: C 87.79, H 3.68, N 8.53; found: C 87.72, H 3.66, N 8.42.

2,3,9,10,16,17,23,24-Octa(phenylethynyl)phthalocyanine (4)



Lithium metal (20 mg, 2.9 mmol) was added to 2 mL of 1-octanol at 60°C and allowed to dissolve over 20 h under argon. After all of the lithium had dissolved, the mixture was cooled to room temperature and then 50 mg (0.15 mmol) of **3** was added. The reaction was heated to 80°C and allowed to stir at this temperature for 6 h. The reaction was monitored by TLC using benzene as the eluent. After all of the starting material had disappeared, the reaction was stopped by the addition of 20% ethanol–water and several drops of 1 M HCl. The reaction mixture was centrifuged, the precipitate was collected, and then washed several times with methanol until the filtrate was colourless. The remaining dark green solid was dried in vacuo to give 10 mg of **4** in a crude yield of 20%. Due to its extreme insolubility in most solvents, this material could not be further purified. MALDI-MS *m*/*z*: 1321.5 (M^+ + Li), 1315.5 (M^+). UV–vis (pyridine) λ_{max} (nm): 726, 650, 396, 306.

1-(*p*-*tert*-Butylphenyl)-2-trimethylsilylacetylene (7)

Into a 100 mL pressure bottle was placed 0.87 mL (1.1 g, 5.0 mmol) of 1-bromo-4-*tert*-butylbenzene (**5**), 0.23 g (0.32 mmol) of $Pd(PPh_3)_2Cl_2$, 19 mg (0.10 mmol) of CuI, and 50 mL of TEA. This yellow suspension was degassed with argon for approximately 5 min, and then 1.5 mL (1.0 g, 10 mmol) of (trimethylsilyl)acetylene (**6**) was added. The bottle was sealed and heated in an oil bath at 95°C overnight. The reaction mixture was allowed to cool to room temperature and was then filtered through celite. The solids were washed with ethyl ether until the washings were colourless and the filtrate was evaporated to dryness under reduced pressure. The residue was chromatographed with

Fig. 4. The UV–vis absorption spectrum of Pc **26**.

flash grade silica gel using hexane as the eluent to give **7** as a pale yellow oil (898 mg, 78% yield). EI-MS *m*/*z* (%): 230 (M^+, 58), 215 (100). ^{1}H NMR ($CDCl_3$) δ: 7.40 (d, *J* = 8.6 Hz, 2H), 7.31 (d, *J* = 8.5 Hz, 2H), 1.31 (s, 9H), 0.25 (s, 9H). The ^{1}H-NMR spectrum matched that of the previously reported compound (16).

p-*tert*-Butylphenylacetylene (8)

To a stirred solution of 200 mg (0.87 mmol) of 1-(*p*-*tert*-butylphenyl)-2-trimethylsilylacetylene (**7**) dissolved in 10 mL of MeOH was added 0.5 mL (2.5 mmol) of 5 M NaOH. After 15 min, the reaction mixture was acidified with 1 M HCl, extracted twice with hexane, and the extracts were dried over $MgSO_4$. Filtration, followed by evaporation of the filtrate in vacuo gave **8** as a pale yellow liquid (134 mg, 98%). IR (neat) (cm^{-1}): 2109 (C≡C). ^{1}HNMR ($CDCl_3$) δ: 7.44 (d, *J* = 8.6 Hz, 2H), 7.35 (d, *J* = 8.1 Hz, 2H), 3.03 (s, 1H), 1.32 (s, 9H). The ^{1}H NMR spectrum matched that of the previously reported compound (16).

4,5-Di(*p*-*tert*-butylphenylethynyl)phthalonitrile (9)

The same procedure was used as for the synthesis of **3**, using 1.0 g (2.6 mmol) of **1**, 1.0 g (6.3 mmol) of **8**, 222 mg (0.32 mmol) of $Pd(PPh_3)_2Cl_2$, 30 mg (0.16 mmol) of CuI, and 30 mL of TEA to give 1.0 g of **9** in 88% yield, mp 168 to 169°C. EI-MS *m*/*z* (%): 440 (M^+, 60), 426 (100). UV–vis (THF) λ_{max} (nm): 214, 279, 309, 354. IR (KBr) (cm^{-1}): 2213 (C≡N). ^{1}H NMR ($CDCl_3$) δ: 7.91 (s, 2H), 7.53 (d, *J* = 8.4 Hz, 4H), 7.43 (d, *J* = 8.6 Hz, 4H), 1.36 (s, 18H). ^{13}C NMR ($CDCl_3$) δ: 153.81, 136.36, 132.09, 131.23, 125.96, 118.79, 115.04, 113.99, 101.09, 85.45, 35.27, 31.34. Anal. calcd. for $C_{32}H_{28}N_2$: C 87.24, H 6.41, N 6.36; found: C 87.25, H 6.42, N 6.12.

2,3,9,10,16,17,23,24-Octa(*p*-*tert*-butylphenylethynyl)phthalocyanine (10)

Lithium metal (16 mg, 2.3 mmol) was added to 3 mL of 1-octanol at 80°C and allowed to dissolve over 20 h under argon. After all of the lithium had dissolved, the mixture was cooled to room temperature and then 200 mg (0.45 mmol) of **9** was added. The reaction was heated to 110°C and allowed to stir at this temperature for 15 h. The reaction was monitored by TLC using benzene as the eluent. After all of the starting material had disappeared, the reaction was stopped by the addition of 20% ethanol–water and several drops of 1 M HCl. The reaction mixture was centrifuged, the precipitate was collected, and then washed several times with methanol until the filtrate was colourless. The remaining dark-green solid was dried in vacuo to give 30 mg of **10** in a crude yield of 15%. Due to its extreme insolubility in most solvents, this material could not be further purified. MALDI-MS *m*/*z*: 1770.8 (M^+ + Li), 1764.8 (M^+). UV–vis (pyridine) λ_{max} (nm): 726, 656, 398, 316.

Neopentyl tosylate (12)

To a stirred, ice water cooled solution of 50 g (0.57 mol) of neopentyl alcohol (**11**) in 350 mL of pyridine was slowly added a solution of 162 g (0.85 mol) of *p*-toluenesulfonyl chloride in 200 mL pyridine. The resulting cloudy brown mixture was allowed to stir overnight at room temperature, after which time the pyridine was removed by rotary evaporation at 45°C. To the remaining residue was added 300 mL of ice-cold water, and the mixture was stirred for 1 h. The mixture was extracted three times with 200 mL portions of ethyl ether, and the combined organic layers were washed with successive 200 mL portions of 1 M HCl, sat. $NaHCO_3$, H_2O, and then brine. The extract was dried over $MgSO_4$, filtered, and the solvent was removed in vacuo to leave **12** as an amber oil. This crude product was crystallized from MeOH–H_2O to afford a white crystalline solid (116 g, 85% yield), mp 48 to 49°C (lit. value (17), 47 to 48°C). ^{1}H NMR ($CDCl_3$) δ: 7.76 (d, *J* = 8.4 Hz, 2H), 7.32 (d, *J* = 8.1 Hz, 2H), 3.63 (s, 2H), 2.42 (s, 3H), 0.87 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 144.75, 133.20, 129.91, 127.97, 79.59, 31.71, 26.10, 21.69.

p-Iodoneopentoxybenzene (14)

A mixture of 10 g (45 mmol) of 4-iodophenol (**13**), 12.1 g (50 mmol) of neopentyl tosylate (**12**), and 2.8 g (50 mmol) of potassium hydroxide in 30 mL of hexamethylphosphoramide (HMPA) (Caution: Carcinogen) was vigorously stirred at 100°C for 3 days. This mixture was then poured into 300 mL of H_2O and extracted three times with 100 mL portions of ethyl ether. The combined ether extracts were successively washed with 100 mL portions of H_2O, 1 M HCl, H_2O, and then brine, followed by drying over $MgSO_4$, filtration and removal of the solvent by rotary evaporation. The remaining amber oil was chromatographed using silica gel and hexane as eluent to afford **14** as a clear, colourless liquid (10.8 g, 82% yield). EI-MS *m*/*z* (%): 290 (M^+, 60), 220 (100). UV–vis (THF) λ_{max} (nm): 234, 282. ^{1}H NMR ($CDCl_3$) δ: 7.54 (d, *J* = 8.8 Hz, 2H), 6.68 (d, *J* = 8.8 Hz, 2H), 3.55 (s, 2H), 1.03 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 159.65, 138.27, 117.17, 82.50, 78.16, 32.05, 26.78. Anal. calcd. for $C_{11}H_{15}IO$: C 45.54, H 5.21; found: C 45.47, H 5.36.

1-Trimethylsilyl-2-(*p*-neopentoxyphenyl)acetylene (15)

The same procedure was used as for the synthesis of **3**, using 8.0 g (28 mmol) of **14**, 4.7 mL (3.3 g, 33 mmol) of trimethylsilylacetylene (**6**), 968 mg (1.4 mmol) of $Pd(PPh_3)_2Cl_2$, 263 mg (1.4 mmol) of CuI, and 300 mL of TEA, except that the entire reaction was carried out at room temperature. The crude product was chromatographed using silica gel and hexane as eluent to afford **15** as a white solid (6.3 g, 88% yield), mp 78 to 79°C. EI-MS *m*/*z* (%): 260 (M^+, 40), 245 (20), 190 (50), 175 (100). UV–vis (THF) λ_{max} (nm): 214, 261. IR (KBr) (cm^{-1}): 2157 (C≡C). ^{1}H NMR ($CDCl_3$) δ: 7.39 (d, *J* = 8.4 Hz, 2H), 6.81 (d, *J* = 8.6 Hz, 2H), 3.59 (s, 2H), 1.04 (s, 9H), 0.25 (s, 9H). ^{13}C NMR

© 2001 NRC Canada

($CDCl_3$) δ: 160.02, 133.62, 115.17, 114.60, 105.63, 92.39, 78.08, 32.08, 26.80, 0.32. Anal. calcd. for $C_{16}H_{24}OSi$: C 73.79, H 9.29; found: C 73.40, H 9.23.

p-Neopentoxyphenylacetylene (16)

The same procedure was used as for the synthesis of **8**, using 10 g (38 mmol) of **15**, 23 mL (115 mmol) of 5 M NaOH, and 600 mL of MeOH to afford **16**. The crude product was chromatographed using silica gel and hexane as eluent giving the title compound as a clear, colourless oil (6.5 g, 95% yield). EI-MS *m*/*z* (%): 188 (M^+, 10), 118 (100). UV–vis (THF) λ_{max} (nm): 213, 252, 293, 318, 343. IR (neat) (cm^{-1}): 2107 (C≡C). ^1H NMR ($CDCl_3$) δ: 7.42 (d, *J* = 8.7 Hz, 2H), 6.84 (d, *J* = 8.6 Hz, 2H), 3.60 (s, 2H), 2.99 (s, 1H), 1.04 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 160.21, 133.73, 114.71, 114.03, 84.05, 78.11, 75.81, 32.08, 26.78. 2,3,9,10,16,17,23,24-Octa(*p*-neopentoxyphenylethynyl)phthalocyanine (18)

To 2.5 mL of dimethylaminoethanol (DMAE) was added 30 mg (4.3 mmol) of lithium metal. After the metal had completely dissolved, 200 mg (0.4 mmol) of **17** was added to the well-stirred alkoxide solution, and the reaction mixture was heated to 100°C for 15 h. After this time, the reaction mixture was cooled to room temperature and diluted with 10 mL of 20% MeOH–H_2O. After being allowed to stand for 90 min, the reaction mixture was centrifuged and the crude Pc was collected, dissolved in THF and precipitated from hexane. This crude pigment was chromatographed using silica gel and CH_2Cl_2 as eluent, followed by gel permeation chromatography using SX-2 Biobeads® and THF as eluent. This material was further purified by reprecipitation from benzene–ethanol and then by chromatography using silica gel and CH_2Cl_2 as eluent to give **18** as a dark green solid (64 mg, 8% yield). FAB-MS: 2004. MALDI-MS *m*/*z*: 2003.9 (M^+). UV–vis (THF) λ_{max} (nm) (log ϵ): 716 (6.08), 678 (6.19), 390 (6.18), 330 (6.41), 258 (6.14), 216 (6.23). ^1H NMR (toluene-d_8, 1.0×10^{-3} M, 363 K) δ: 8.71 (br, 8H), 7.71 (d, *J* = 7.8 Hz), 6.81 (d, *J* = 8.1 Hz), 3.58 (s, 16H), 1.14 (s, 72H), –4.81 (br, 2H). Anal. calcd. for $C_{136}H_{130}N_8O_8$: C 81.49, H 6.54, N 5.59; found: C 80.06, H 5.80, N 5.27.

[2,3,9,10,16,17,23,24-Octa(*p*-neopentoxyphenylethynyl)phthalocyaninyl]dilithium (19)

To a suspension of 10 mg (0.72 mmol) of lithium metal in 2 mL of dry THF was added 2 mg (1.0×10^{-3} mmol) of Pc **18**. The mixture was stirred at 50°C for 5 days, after which time the excess lithium was removed by filtration and the solvent was removed in vacuo at 40°C to give **19** (2 mg, 100% yield). FAB-MS: 2010 (M – Li), 2004 (M – 2Li). UV–vis (THF) λ_{max} (nm) (log ϵ): 720 (6.89), 686 (6.04), 648 (6.07), 398 (6.52), 316 (6.40), 282 (6.35), 212 (6.40). ^1H NMR (pyridine-d_5, 4.0×10^{-4} M, 333 K) δ: 8.86 (br, 8H), 7.75 (br, 16H), 6.79 (d, *J* = 7.4 Hz), 3.53 (s, 16H), 1.12 (s, 72H).

1-Iodo-2-(*p*-neopentoxyphenyl)acetylene (20)

To 11.5 mL (35 mmol) of ethylmagnesium bromide (3.0 M solution in ether) was slowly added a solution of 5.0 g (27 mmol) of *p*-neopentoxyphenylacetylene (**16**) in 15 mL of anhydrous ether. The reaction mixture was then heated to reflux as 6.7 g (23 mmol) of powdered iodine was slowly added through the top of the condenser. The solution was refluxed for another hour, allowed to cool to room temperature and then poured into 150 mL of H_2O. The mixture was acidified with glacial acetic acid, the ether layer was separated, and the aqueous layer was extracted twice with 50 mL portions of ether. The combined organic extracts were washed with sat. $Na_2S_2O_3$, sat. $NaHCO_3$, H_2O, and brine, then dried over $MgSO_4$, filtered and evaporated under reduced pressure. The title compound (**20**) was obtained as a white solid after recrystallization from MeOH–H_2O (2.2 g, 26% yield), mp 54 to 55°C. EI-MS *m*/*z* (%): 314 (M^+, 35), 244 (100), 118 (65). UV–vis (THF) λ_{max} (nm): 214, 262. IR (KBr) (cm^{-1}): 2166 (C≡C). ^1H NMR ($CDCl_3$) δ: 7.36 (d, *J* = 8.7 Hz, 2H), 6.83 (d, *J* = 8.7 Hz, 2H), 3.59 (s, 2H), 1.03 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 160.26, 133.94, 115.45, 114.62, 94.38, 78.13, 32.08, 26.79, 3.56. Anal. calcd. for $C_{13}H_{15}IO$: C 49.70, H 4.81; found: C 50.06, H 4.78.

The by-product, 1,4-di-(*p*-neopentoxyphenyl)-1,3-butadiyne (**21**), was obtained in 59% yield (2.9 g) as a white solid, mp 189–191°C. UV–vis (THF) λ_{max} (nm): 214, 269, 282, 300, 320, 343. IR (KBr) (cm^{-1}): 2388, 2139, 1601, 1503, 1291, 1247, 1166, 1016, 831. ^1H NMR ($CDCl_3$) δ: 7.44 (d, *J* = 8.7 Hz, 2H), 6.85 (d, *J* = 8.7 Hz, 2H), 3.60 (s, 2H), 1.04 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 160.50, 134.19, 114.89, 113.85, 81.59, 78.16, 73.10, 32.09, 26.78. EI-MS *m*/*z* (%): 374 (M^+, 50), 234 (100). Anal. calcd. for $C_{26}H_{30}O_2$: C 83.38, H 8.07; found: C 82.90, H 8.40.

1-(Trimethylsilyl)-4-(*p*-neopentoxyphenyl)-1,3-butadiyne (22)

To a solution containing 200 mg (0.64 mmol) of **20** dissolved in 5 mL of THF were added 22 mg (0.032 mmol) of $Pd(PPh_3)_3Cl_2$, 3.0 mg (0.016 mmol) of CuI, 0.16 mL (116 mg, 1.15 mmol) of diisopropylamine (DIPA), and then 0.36 mL (250 mg, 2.55 mmol) of trimethylsilylacetylene (**6**). The reaction mixture was allowed to stir overnight at room temperature, after which time the solvent was evaporated in vacuo, the residue was suspended in hexane and then filtered through a bed of celite. The filtrate was concentrated under reduced pressure, chromatographed using silica gel and hexane as eluent, and then recrystallized from EtOH–H_2O to

© 2001 NRC Canada

give **22** as a white, crystalline solid (53 mg, 29% yield). EI-MS *m*/*z* (%): 284 (M^+, 65), 214 (65), 199 (100). UV–vis (THF) λ_{max} (nm): 214, 240, 275, 291, 309. IR (KBr) (cm^{-1}): 2203, 2103, 1603, 1509, 1299, 1249, 1172, 1108, 1048, 1014, 847, 760, 694. ^1H NMR ($CDCl_3$) δ: 7.41 (d, *J* = 8.7 Hz, 2H), 6.83 (d, *J* = 8.7 Hz, 2H), 3.59 (s, 2H), 1.03 (s, 9H), 0.23 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 160.72, 134.49, 114.89, 113.06, 90.03, 88.41, 78.13, 77.48, 73.13, 32.08, 26.77, –0.10. Anal. calcd. for $C_{18}H_{24}OSi$: C 76.00, H 8.50; found: C 76.07, H 8.20.

1-(*p*-Neopentoxyphenyl)-1,3-butadiyne (23)

To a stirred solution of 1.0 g (3.5 mmol) of (**22**) dissolved in 50 mL of MeOH was added 2.1 mL (11 mmol) of 5 M NaOH. After 15 min, the reaction mixture was acidified with 1 M HCl, extracted twice with hexane, and the extracts were dried over $MgSO_4$. Filtration, followed by evaporation of the filtrate in vacuo gave a grey solid, which after chromatography through a plug of silica gel using hexane, afforded 709 mg of **23** as a white solid, which rapidly darkened on exposure to light and air (95% yield). (This material was used immediately in the synthesis of **24**). EI-MS *m*/*z* (%): 212 (M^+, 20), 142 (100). UV–vis (THF) λ_{max} (nm): 214, 281, 298. IR (KBr) (cm^{-1}): 2204, 1896, 1602, 1562, 1509, 1473, 1400, 1364, 1295, 1255, 1170, 1109, 1048, 1017, 921, 834, 624. ^1H NMR ($CDCl_3$) δ: 7.45 (d, *J* = 8.6 Hz, 2H), 6.85 (d, *J* = 8.7 Hz, 2H), 3.61 (s, 2H), 2.46 (s, 1H), 1.04 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 160.86, 134.59, 114.93, 112.74, 78.18, 75.99, 72.50, 70.87, 68.69, 32.09, 26.76.

4,5-Di[4-(*p*-neopentoxyphenyl)-1,3-butadiynyl]phthalonitrile (24)

The same procedure was used as for the synthesis of **3**, using 631 mg (1.66 mmol) of **1**, 740 mg (3.49 mmol) of **23**, 122 mg (0.174 mmol) of $Pd(PPh_3)_2Cl_2$, 33.2 mg (0.174 mmol) of CuI, and 40 mL of TEA, except that the entire reaction was carried out at room temperature. After 18 h, the solvent was removed in vacuo and then the residue was dissolved in CH_2Cl_2, washed with H_2O and brine, dried over $MgSO_4$ and filtered. The solvent was removed from the filtrate under reduced pressure and the brown residue was triturated twice with ethyl ether to leave **24** as a golden-yellow solid (683 mg, 75% yield), mp 233°C (decomp.). HR-MS (*m*/*z*) calcd. for $C_{38}H_{32}N_2O_2$: 548.2464; found: 548.2464. UV–vis (THF) λ_{max} (nm): 218, 262, 280, 294, 308, 386. IR (KBr) (cm^{-1}): 2203 (C≡N). ^1H NMR ($CDCl_3$) δ: 7.86 (s, 2H), 7.52 (d, *J* = 8.7 Hz, 4H), 6.89 (d, *J* = 8.7 Hz, 4H), 3.63 (s, 4H), 1.05 (s, 18H). ^{13}C-NMR (acetone-d_6) δ: 162.76, 138.72, 135.69, 131.19, 116.38, 116.24, 115.64, 113.14, 88.62, 85.03, 79.13, 77.41, 72.81, 32.67, 26.96. Anal. calcd. for $C_{38}H_{32}N_2O_2$: C 83.18, H 5.88, N 5.11; found: C 81.14, H 5.64, N 4.76.

Dilithium-2,3,9,10,16,17,23,24-octa[4-(*p*-neopentoxyphenyl)-1,3-butadiynyl]phthalocyanine (26)

To a vigorously stirred suspension containing 25 mg (0.046 mmol) of **24** in 0.4 mL of 1-octanol, was added 4 mg (0.58 mmol) of lithium metal (rolled to a foil in an argon purged plastic bag). The reaction mixture was heated to 80°C overnight, after which time the colour turned from bright yellow to dark green. The reaction mixture was diluted with 10 mL of hexane and then centrifuged. The supernatant liquid was discarded, the crude pigment was dissolved in anhydrous THF, reprecipitated into 5 mL of hexane and centrifuged again. This cycle was repeated four times until the octanol was removed and the supernatant liquid was colourless. The remaining crude Pc was dissolved in 2-mL of anhyd THF and loaded onto a gel permeation column consisting of SX-2 Biobeads® and anhyd THF as the eluting solvent. A single green band was collected in five, 2 mL fractions, each of which were analyzed by UV–vis spectroscopy. The fractions containing the least intense absorptions in the 200–500 nm region of the spectrum were combined and the solvent removed in vacuo to give what is believed to be **26** as a dark green solid (7 mg, 28% yield). MALDI-MS *m*/*z*: 2202 (M^+ – Li). UV–vis (THF) λ_{max} (nm): 214, 304, 408, 660, 738. ^1H NMR (pyridine-d_5, 4.53×10^{-4} M, 300 K) δ: 9.98 (br, 8H), 7.67 (d, *J* = 8.4 Hz, 16H), 6.92 (d, *J* = 8.4 Hz, 16H), 3.60 (s, 16H), 1.08 (s, 72H).

Conclusion

We have demonstrated that it is possible to prepare octaarylethynyl and octaarylbutadiynyl phthalocyanines, but that solubility and stability problems may make their use in nonlinear optics and other applications difficult. Solubilizing groups on the aryl groups *ortho* to the alkyne groups may provide the dual goal of solubilization and stabilization.

Note added in Proof

One different octaarylethynylphthalocyanine has recently been reported (see R. Faust and F. Mitzel. J. Chem. Soc. Perkin Trans. 1, 3746 (2000)).

Fluorous biphasic catalysis. 2. Synthesis of fluoroponytailed amine ligands along with fluoroponytailed carboxylate synthons, $[M(C_8F_{17}(CH_2)_2CO_2)_2]$ (M = Mn^{2+} or Co^{2+}): Demonstration of a perfluoroheptane soluble precatalyst for alkane and alkene functionalization in the presence of *tert*-butyl hydroperoxide and oxygen gas

Jean-Marc Vincent, Alain Rabion, Vittal K. Yachandra, and Richard H. Fish

Abstract: Fluorous biphasic catalysis (FBC) is a relatively new concept for homogeneous catalysis where the fluorocarbon soluble catalyst resides in a separate phase from the substrate and products. Therefore, separation of the catalyst and the products occurs by a facile decantation process. In this contribution, we present the synthesis of new R_f-fluoroponytailed synthons, 2-iodo-1-perfluorooctyl-3-propanol (**1**), 3-perfluorooctyl-1-propanol (**2**), and 3-perfluorooctyl-1-iodopropane (**3**), a variety of new R_f-fluoroponytailed ligands (**4**–**8**), with starting amines, 1,4,7-triazacyclononane, bis-picolylamine, and bis-picolylaminoethylenediamine, as well as new R_fMn^{2+} and R_fCo^{2+} fluoroponytailed carboxylate synthons, $[Mn(O_2C(CH_2)_2C_8F_{17})_2]$ (**9**), and $[Co(O_2C(CH_2)_2C_8F_{17})_2]$ (**10**), where R_f is C_8F_{17}. The only totally perfluoralkane soluble ligand we found was 1,4,7-tris-*N*-(4,4,5,5,6,6,7,7,8,8,9,9,10,10,11,11,11-heptadecafluoroundecyl)-1,4,7-triazacyclononane (R_fTACN, **4**), and it was utilized, along with synthons **9** and **10**, to generate in situ R_fMn^{2+}–R_fTACN and R_fCo^{2+}–R_fTACN complexes as precatalysts for functionalization of alkanes and alkenes. We will demonstrate that indeed this novel FBC approach for the separation of the precatalyst from the substrates and (or) products is viable for oxidation of alkanes and alkenes in the presence of the necessary oxidants, *tert*-butyl hydroperoxide (TBHP), and O_2 gas. We will also show that these oxidation reactions occur via an autoxidation mechanism under our FBC conditions, while using electron spin resonance (ESR) techniques to ascertain the redox chemistry occurring with the starting mononuclear R_fMn^{2+}–R_fTACN complex.

Key words: fluorous solvents, biphasic catalysis, alkane/alkene oxidation.

Résumé : La catalyse biphasique en milieu fluoré est un concept récent de catalyse homogène nécessitant l'emploi de catalyseurs solubles dans les perfluorocarbures. Le catalyseur se trouvant dans une phase différente du substrat et des produits de réaction, il peut être recyclé par une simple décantation. Nous présentons la synthèse de nouveaux synthons (**1**–**3**), et ligands (**4**–**8**), à chaîne perfluorée, ainsi que de nouveaux complexes métalliques à ligands carboxylates fluorés, $[Mn(O_2C(CH_2)_2C_8F_{17})_2]$ (**9**) et $[Co(O_2C(CH_2)_2C_8F_{17})_2]$ (**10**). Le ligand 1,4,7-tris-*N*-(4,4,5,5,6,6,7,7,8,8,9,9,10,10,11,11,11-heptadecafluoroundecyl)-1,4,7-triazacyclononane (R_fTACN, **4**) est le seul ligand à être soluble dans les perfluorocarbures. A partir des composé **9** et **10** et du ligand **4**, les complexes R_fMn^{2+}–TACN et Co^{2+}–TACN générés in situ servent de précatalyseurs pour les oxydations d'alcanes et alcènes. Les réactions sont réalisées en milieu biphasique en présence des oxydants TBHP et O_2 et les produits sont facilement séparés du catalyseur par simple décantation. Dans les

Introduction

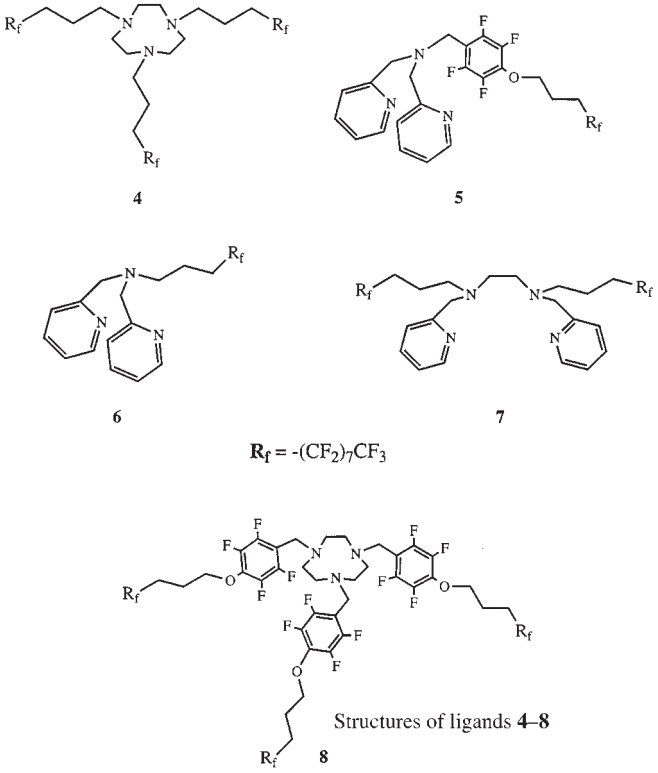
Recently, Horváth and Rábai (1) published an important paper on a new homogeneous catalysis concept, *fluorous biphasic catalysis* (FBC), that entailed the use of a fluorocarbon as one phase containing a modified fluoroponytailed catalyst, while the substrate and the product were soluble in a second hydrocarbon phase; this FBC concept was also reported in a Ph.D thesis that was not readily accessible by the catalysis community (2). More importantly, the Horváth and Rábai paper has been a virtual catalyst for chemists interested in new biphasic concepts, while this novel FBC approach has led to many contributions in a very short time frame (3). The process of developing a new paradigm for the separation of the homogeneous catalyst from the substrate and the product must start with the solvent system. Therefore, it is well-known that perfluorohydrocarbons have unusual properties that entail being extremely hydrophobic and lacking hydrogen bonding capabilities, which renders them to be relatively insoluble in their hydrocarbon analogs, and they are also able to dissolve various gases such as oxygen, hydrogen, and carbon dioxide, as examples (4). Thus, it is surprising that it took so long for this FBC approach to be discovered, since the above mentioned parameters would allow a number of critical catalytic reactions to be demonstrated using perfluorohydrocarbons as one phase in a biphasic solvent mode (1–3).

We have been interested in homogeneous oxidation catalysis for many years with the focus on functionalizing alkanes and alkenes at ambient temperatures (5). Our fascination with the FBC process provided an opportunity to also demonstrate this novel concept for the functionalization of alkanes and alkenes, and in a preliminary account (6), we did indeed verify this new biphasic approach for alkane and alkene functionalization, and in fact, a similar approach was also published by Pozzi et al. (7) very soon after. Therefore, in this full account, we present the synthesis of R_f-fluoroponytailed synthons (**1**–**3**), a variety of new R_f-fluoroponytailed ligands (**4**–**8**), with starting amines, 1,4,7-triazacyclononane (TACN), bis-picolylamine (BPA), and bis-picolylaminoethylenediamine (BisPICEN), as well as new R_fMn^{2+} and R_fCo^{2+} fluoroponytailed carboxylate synthons, $[Mn(O_2C(CH_2)_2C_8F_{17})_2]$ (**9**), and $[Co(O_2C(CH_2)_2C_8F_{17})_2]$ (**10**), where R_f is C_8F_{17}, and clearly demonstrate the critical need to pay close attention to the structures of the ponytailed ligands as it pertains to their solubility in perfluorocarbons.

To reiterate, we will further demonstrate the utilization of the FBC paradigm with the functionalization of alkanes and (or) alkenes, using in situ generated R_fMn^{2+}–R_fTACN and R_fCo^{2+}–R_fTACN as precatalysts that are totally soluble in the fluorous phase, and in the presence of the necessary oxidants, *tert*-butyl hydroperoxide (TBHP) and O_2 gas (6). In comparison to the new FBC concept presented in this paper, it is important to note that the oxidation of alkanes with TBHP in acetonitrile, and epoxidation of alkenes with hydrogen peroxide (H_2O_2) in acetone, were previously achieved in one homogeneous phase by the in situ preparation of Mn^{2+} catalysts, using 2,2′-bipyridine and tris-*N*-methyl-TACN ligands, respectively, and further state that separation of the Mn^{2+} catalyst from the product will be relatively difficult or impossible (8).

Results and discussion

Synthesis of fluoroponytailed ligands 4–8



One of the key components of the FBC approach includes the synthesis of fluoroponytailed ligands that are totally soluble in fluorocarbon solvents at ambient temperature. Therefore, we set out initially to create a fluoroponytail synthon that we could append to our target ligands, which were aliphatic and aromatic substituted aliphatic amines. We chose aliphatic amines as ligands for several reasons that included their ease in appending fluoropontytails via alkylation reactions, and their metal complexes have been widely used in previous homogeneous oxidation chemistry of hydrocarbons (8). In our initial experiments to find a suitable fluoroponytailed synthon, we evaluated a compound that had a two-carbon spacer ($C_8F_{17}CH_2CH_2I$) but quickly found that in the presence of the aliphatic amine ligand that loss of HI prevailed rather than alkylation. Therefore, it is important to recognize that the three-methylene-carbon spacer in compound **3** was necessary, not only to insulate the amine from the powerful e-withdrawing effect of the perfluoroalkyl group, but also to avoid the above mentioned facile elimination reaction of HI that predominately occurs when a two-carbon spacer was used during the formation of ligands **4**–**8**.

The first step to the three-carbon spacer synthon, perfluoroalkyl iodide (**3**) proceeded by a free radical addition of a perfluoroalkyl iodide ($C_8F_{17}I$) to allyl alcohol that was initiated with AIBN to provide the perfluoroalkylated iodohydrin **1** (this procedure was slightly different than the one described by Kotora et al., who synthesized 3-perfluorohexyl-1-propanol ($C_6F_{13}(CH_2)_3OH$) using copper powder as a free radical initiator in neat solution followed by tin hydride reduction. See ref. 9). Compound **1** was then reduced to the perfluoroalkyl alcohol **2**, by using tributyltin hydride in dry benzotrifluoride. Iodination of **2** to form **3** was achieved using 85% phosphoric acid in the presence of phosphorous pentoxide and potassium iodide in 85% yield (Scheme 1).

The first alkylation approach we utilized to introduce the fluoroponytail, **2**, was the aromatic nucleophilic substitution with the *N*-pentafluorophenyl derivatives of the TACN and BPA ligands, leading to ligands **5** and **8** (Scheme 1). We introduced **2**, via a nucleophilic substitution of the *p*-fluoro substituent of the *N*-pentafluorophenyl group by using phase transfer catalysis in a mixture of 50% NaOH–trifluorotoluene, and in the presence of the phase transfer agent, Aliquat 336. The other alkylation approach, which directly alkylates

© 2001 NRC Canada

amine ligands (TACN), (BPA), and (BisPICEN) to provide **4**, **6**, and **7** with **3**, was conducted using K_2CO_3 in DMSO.

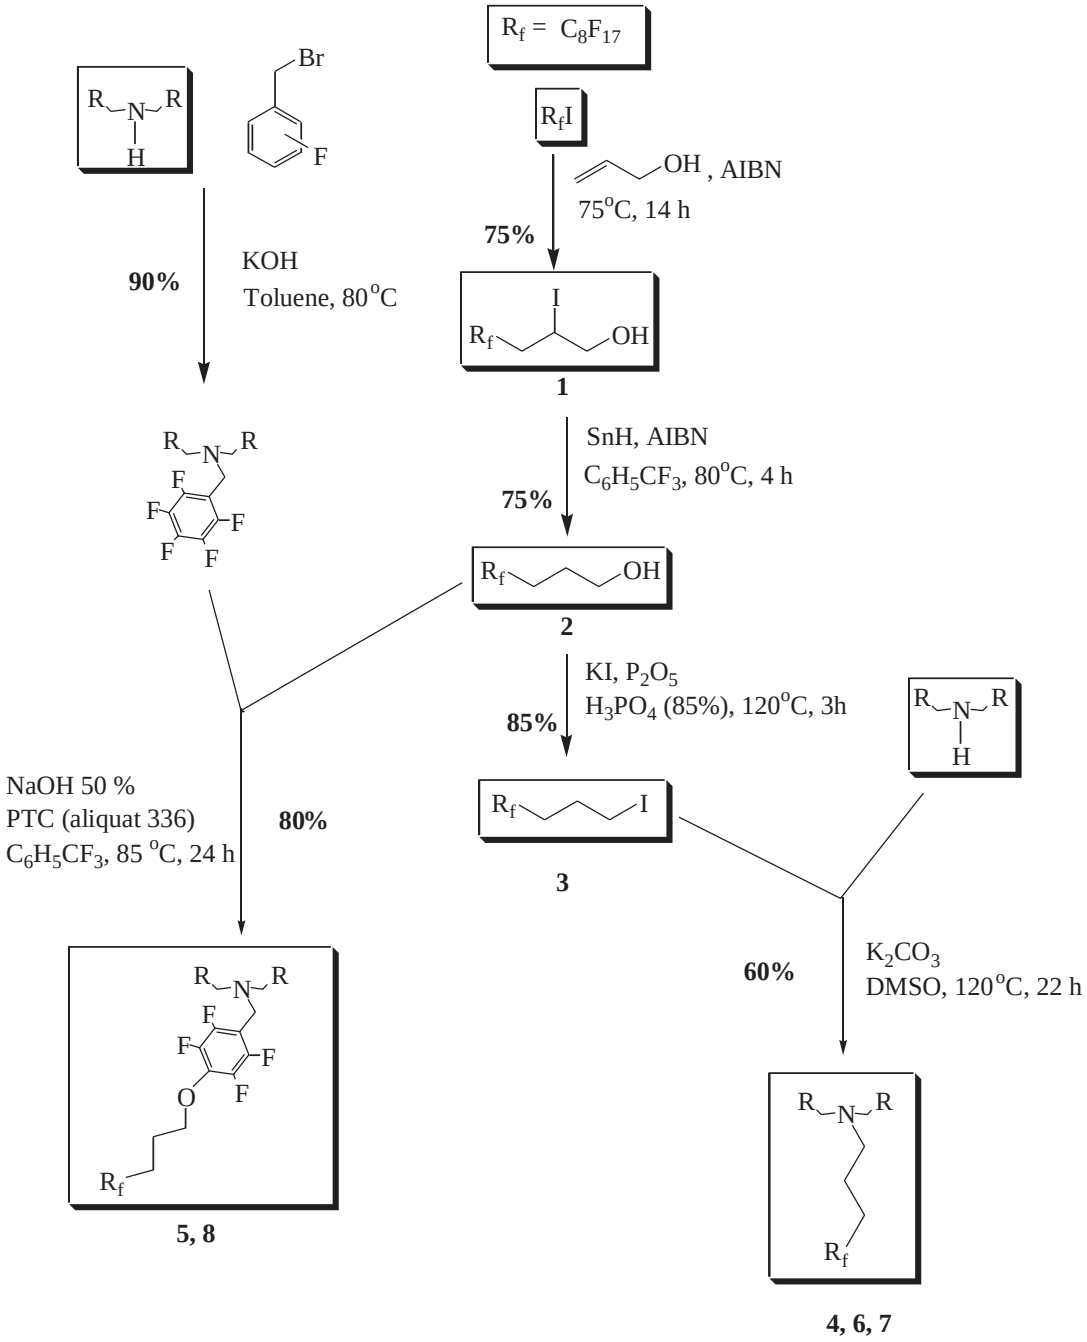
We were totally amazed to find that **4**, tris-*N*-(4,4,5,5,6,6,7,7,8,8,9,9,10,10,11,11,11-heptadecafluoroundecyl)-1,4,7-triazacyclononane (R_fTACN), *was the only fluoroponytailed ligand found to be soluble in perfluorocarbons, such as perfluoroheptane (PFH) or perfluoromethylcyclohexane (PFMC), at room temperature.* Fluoroponytailed ligands **5**–**8**, with a fluorine content for **5**–**8** of <60% were only soluble in hot perfluorocarbons (~50°C), while **4** had a fluorine content of 64.2%. These results vividly demonstrate that polar groups such as a pentafluorophenyl group or a nonfluorinated pyridine have to be avoided to obtain good solublity in perfluorocarbons; these are extremely nonpolar solvents. It also shows that the solubilzation of ligands, and moreover, the subsequent metal complexes, could represent an important limiting step in the FBC approach for oxidation chemistry. Moreover, it is of interest to also note that **4** represented at that time, to our knowledge, the first example of an R_f–amine ligand (6) to be found to be soluble in a perfluorocarbon solvent, subsequently also verified by Pozzi et al. (7) with their tetra-azamacrocycle systems.

Synthesis of Mn^{2+} and Co^{2+} fluoroponytailed carboxylate complexes 9 and 10

To insure fluorcarbon solvent solubility of the metal complexes of ligand **4**, the only amine ligand we found to have total fluorocarbon solubility at ambient temperature, we thought that appending fluoroponytailed groups to the metal complexes we were going to utilize as synthons would help in this important aspect, since metal complexes with multiple charges and counter anions, such as ClO_4^-, NO_3^-, PF_6^-, would be very difficult to solubilze in perfluorocarbons. Therefore, the new R_fMn^{2+} and R_fCo^{2+} complexes $[Mn(C_8F_{17}(CH_2)_2CO_2)_2]$ (**9**) and $[Co(C_8F_{17}(CH_2)_2CO_2)_2]$ (**10**) were synthesized by reaction of $Mn(ClO_4)_2\cdot 6H_2O$ or $Co(ClO_4)_2\cdot 6H_2O$ in acetone with 2 equiv of the triethylammonium salt of the 3-R_f-alkylpropionic acid $C_8F_{17}(CH_2)_2CO_2H$; elemental analysis of **9** and **10** provided a metal:carboxylate ligand ratio of 1:2, while **9** was found to be slightly soluble in perfluorocarbons, exhibited an intense and broad ESR signal at $g = 2$ (9 K), and displayed the broad six-line hyperfine structure ($J = 90$ G). This could be attributed either to an oligomeric Mn^{2+} structure, consistent with a $Mn(OAc)_2$ trimeric structure, or a mononuclear Mn^{2+} complex of low solubility in perfluorocarbons at 9K (10). In addition, it appears that the carboxylate group is chelating, rather than being in a monodentate coordination mode, in agreement with the small difference ($\Delta\nu = 132$ cm^{-1}) observed in the IR spectrum of **9** between the asymmetric and symmetric C—O stretch ($\nu = 1578$ and 1446 cm^{-1}), respectively. Complex **10** had a similar IR spectrum as **9** and we suggest that the Co^{2+} analog has a similar structure as the Mn^{2+} complex.

Interestingly, when 1 equiv of **4** was added to a solution of **9** in perfluoroheptane, the complete solubilization of **9** occurred concomitantly with the appearance of a new UV absorption band at 320 nm tentatively suggesting that a new $[R_fMn(R_fTACN)]^{2+}$ complex (**11**) was formed in situ. A similar result was also achieved when ligand **4** and complex **10** were added together to provide $[R_fCo(R_fTACN)]^{2+}$ (complex **12**).

Functionalization of alkanes and alkenes utilizing in situ generated $[R_fMn(R_fTACN)]^{2+}$ and $[R_fCo(R_fTACN)]^{2+}$ (complexes 11 and 12) as precatalysts



The FBC oxidation results for several substrates are presented in Table 1. All the experiments were carried out under biphasic conditions, generating complexes **11** or **12**, in situ in perfluoroheptane (Scheme 2), while the upper phase was the substrate itself. Importantly, the oxidation products were detected only in the colorless upper phase after decantation (GC), while the colored perfluoroheptane lower phase contains only traces (<5%) of product. Clearly, a facile and rapid separation of the products from the catalyst was achieved using this FBC approach.

Table 1 demonstrates that the olefin with allylic hydrogens, cyclohexene, provides the highest % yield of oxidation products (650%/TBHP in 3 h) with TBHP–O_2, while alkane oxidation was much lower as noted with cyclohexane to cyclohexanol–cyclohexanone (CyOH–CyONE, 12%/TBHP in 24 h) and toluene to benzyl alcohol–benzaldehyde ($PhCH_2OH$–PhCHO, 65%/TBHP in 24 h). In the presence of **11**, TBHP, and O_2 (1 atm (1 atm = 101.325 kPa)), and under vigorous stirring, cyclohexene was converted to a product ratio of 2-cyclohexen-1-one (CyenONE, ~65%), 2-cyclohexen-1-ol (CyenOH, ~35%), and a small amount of cyclohexene oxide (<2%), while with complex **12** similar oxidation results were obtained.

It is also important to note that styrene, with no allylic hydrogens, was not converted to styrene epoxide under these biphasic conditions. *In the absence of O_2 or TBHP, only negligible amounts of CyenOH and CyenONE were detected,*

Scheme 1. Preparation of fluoroponytailed synthon **3** and alkylation to provide ligands **4**–**8**.

indicative of an autoxidation reaction, i.e., both were necessary for oxidation to proceed. At the end of the reaction, the upper phase was removed and new aliquots of cyclohexene and TBHP were added to provide a 400% yield after 5 h, showing that the catalyst, after decantation, was only present in the lower fluorocarbon phase.

Autoxidation mechanism and fate of the Mn^{2+} precatalyst

The presented results are in agreement with an autoxidation mechanism involving alkoxy (RO·) or alkylperoxy (ROO·) radicals (11), where the reaction was initiated by *t*-BuO· or *t*-BuO_2· radicals produced from redox reactions (Haber–Weiss process with Mn^{2+}/Mn^{3+}). In the case of the substrate cyclohexene, the allylic radical that formed was then trapped by O_2 ($k > 1 \times 10^9$ M^{-1} s^{-1}) to provide cyclohexenylperoxy radicals, which were able (ROO-H = 90 kcal mol^{-1}) to homolytically remove a hydrogen from benzylic or allylic C—H bonds (85 kcal mol^{-1}), and hence, propagate the radical reactions. The secondary cyclohexenyl hydroperoxide that was formed then decomposes catalytically in the presence of the $R_fMn(R_fTACN)$ catalyst to give the alcohol and the ketone products (12). Scheme 3 defines the initiation, propagation, termination, and product-forming steps for the sequence of reactions (eqs. [1]–[8]).

Moreover, the lower yields observed in the case of cyclohexane are consistent with the stronger C—H bond strength

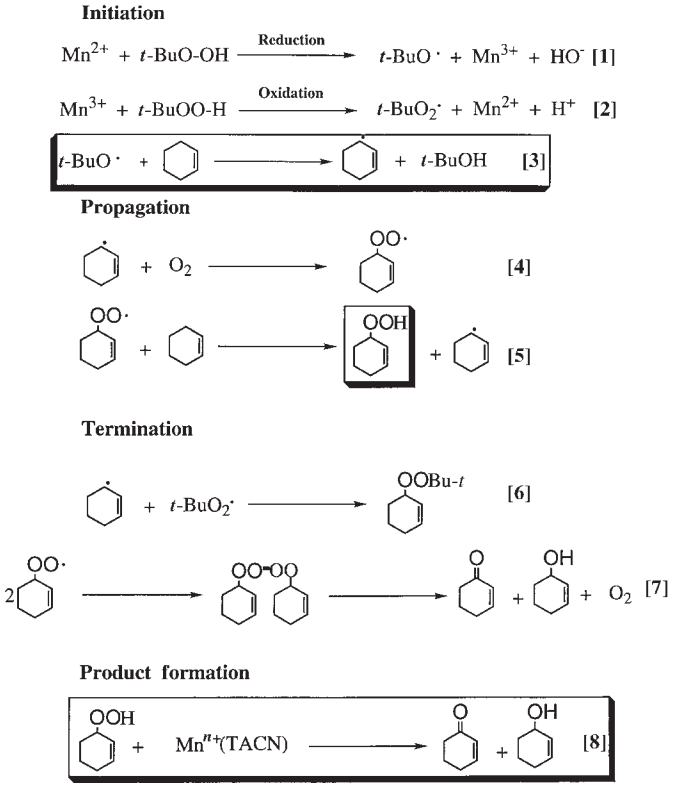
Table 1. Alkene and alkane functionalization under fluorous biphasic catalysis conditions.[a]

Precatalyst	Substrate	Oxidant	Products (μmol)	Yield (%)[b]	*t* (h)
11	Cyclohexene	TBHP–O_2	CyenOH (160) CyenONE (300)	650	3
11	Cyclohexene	TBHP	CyenOH (<2) CyenONE (<2)		7
11	Cyclohexene	O_2	CyenOH (<1) CyenONE (<1)		24
9	Cyclohexene	TBHP–O_2	CyenOH (130) CyenONE (160)	360	12
11	Styrene	TBHP–O_2	no epoxide		24
11	Toluene	TBHP–O_2	PhCHO (15) PhCH2OH (30)	65	24
11	Cyclohexane	TBHP–O_2	CyOH (5) CyONE (3.5)	12	24
12	Cyclohexene	TBHP–O_2	CyenOH (185) CyenONE (360)	750	20
12	Cyclohexane	TBHP–O_2	CyOH (7) CyONE (5.5)	17	24

[a]Conditions: [$M(R_f(CH_2)_2CO_2)_2$] (3.5 μmol), Mn or Co, and the R_fTACN ligand (3.5 μmol) were dissolved in hot perfluoroheptane (3 mL) and then the substrate (2 mL) was added. The reaction starts after the addition of TBHP (90%, 72 μmol) under an O_2 atmosphere at ambient termperature.
[b]Total yield was based on TBHP added.

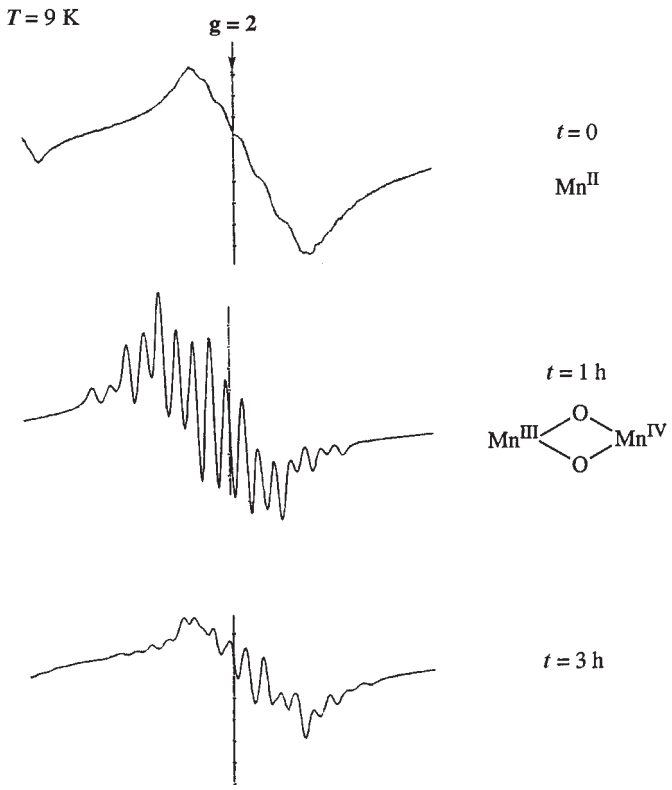


Scheme 2. Fluorous biphasic oxidation catalysis with cyclohexene as the substrate and complex **11** formed in situ from **4** and **9**.

(95 kcal mol^{-1}) (11), which implicates the cyclohexylperoxy radical, and thus causes a lowering of the rate of the propagation step. The chain termination step presumably comes mainly from the coupling of two cyclohexenylperoxy radicals to give alcohol, ketone, and O_2 (Russell-type mechanism (Scheme 3, eq. [7])) (11).

We found that the [R_fMn(R_fTACN)] complex, formed during the oxidation of **11**, was plausibly a $R_fMn^{3+}Mn^{4+}$ dimer. Therefore, when TBHP was added to the reaction mixture, the solution turns brown, and exhibits intense UV–vis absorptions (ε per atom is ~9000 and 1130 M^{-1} cm^{-1} at 300 and 500 nm, respectively, after 1 h) characteristic of dinuclear $Mn^{3+}Mn^{3+}$, $Mn^{3+}Mn^{4+}$, or $Mn^{4+}Mn^{4+}$ complexes (13). The occurrence of such a putative $R_fMn^{3+}Mn^{4+}$ dimer from starting complex **11** (Fig. 1, top spectrum), under oxidation conditions, was unambiguously confirmed by ESR studies at 9 K. Thus, a strong, distinctive 16-line signal of an antiferromagnetically coupled $R_fMn^{3+}Mn^{4+}$ dimer complex at $g = 2$ was observed in the perfluoroheptane phase, after 1 h of reaction in the presence of TBHP–O_2 and cyclohexene (Fig. 1, middle spectrum). Indeed, it has recently been shown that the decomposition of TBHP in the presence of a dinuclear

Scheme 3. Initiation, propagation, termination, and product forming steps with cyclohexene as substrate.



Mn_2^{3+}(2-OHsalpn)$_2$ complex resulted in the formation of *t*-BuO· radicals and a dinuclear $Mn^{3+}(\mu\text{-}O)_2Mn^{4+}$ complex (14).

Furthermore, rxn. [1] (Scheme 3) was favored over rxn. [2] with complex **11** for two important reasons: (*i*) it has been previously shown that in nonpolar solvents, eq. [2] was found to be very slow (15); and (*ii*) the $R_fMn^{3+}Mn^{4+}$ dimeric species formed upon the addtition of TBHP to complex **11** was not very efficient in the oxidation of TBHP. Interestingly, after 3 h (Fig. 1, lower spectrum), the 16-line ESR signal had almost disappeared, suggesting that this $R_fMn^{3+}Mn^{4+}$ dinuclear mixed valent species might be involved in the catalytic decomposition of the cyclohexenyl hydroperoxide intermediate to provide the alcohol and ketone products.

Fig. 1. ESR experiments at 20 K and 9 K (see *Experimental* for details). Top spectrum: $[R_fMn(R_fTACN)]^{2+}$ complex (**11**) at 20 K in benzotrifluoride; middle: after addition of TBHP–O_2 and cyclohexene (9 K); lower: after 3 h of reaction (9 K).

Conclusions

Finally, as we have clearly shown in this contribution, as well as being pointed out recently by Pozzi et al. (16), despite the apparent simplicity of the FBC concept, the concrete demonstration of this strategy is still a difficult challenge, since the solubilization of the fluoroponytailed metal complexes used in perfluorocarbons is one limiting step along with catalyst stability and the favorable recycling of the catalyst system. Thus, we were able to successfully solubilize complexes **11** and **12** in perfluoroheptane, using both the new R_fTACN ligand **4**, and the new R_fMn^{2+} and R_fCo^{2+} complexes **9** and **10**, with fluoroponytailed carboxylate ligands. Moreover, we have been able to perform alkane and alkene oxidations under FBC conditions in the presence of TBHP and O_2 as oxidants, and hence, separate the products from the catalyst by a simple decantation process. The oxidation process occurs via an autoxidation mechanism, with formation of alkenyl or alkyl hydroperoxides as the key intermediates, which then are catalytically decomposed by the R_fMn– or R_fCo–R_fTACN catalyst, probably at the solvent interface, to provide the alcohol and ketone products. Future studies will attempt to further the scope of the FBC approach to oxidation chemistry.

Experimental

Materials and instrumentation

The fluorocarbon solvents and some starting perfluoro derivatives were purchased from Pierce Chemical Co., while the alkenes and alkanes were from Aldrich Chemical Co. The oxidant, *tert*-butyl hydroperoxide (70% TBHP) was a commercial product from Aldrich Chemical Co., and all were used without further purification. The ^{1}H NMR spectra were obtained on a 500 MHz Brucker NMR spectrometer, while GC and GC–MS analysis were performed on Hewlett–Packard (HP) instruments. The UV–vis spectra were recorded on an HP diode array instrument with accompanying software. The ESR experiments were performed at the Calvin Laboratory at LBNL and the following describes the equipment used. EPR spectra were collected on a Varian E-109 spectrometer with an E-102 microwave bridge. The EPR spectra were collected using a home built signal averager and stored for further analysis on a VAX 4000-300. Samples were maintained at cryogenic temperatures using an Air Products Heli-tran liquid helium cryostat. For detecting the Mn^{2+} complex the conditions were as follows: 3300 ± 1000 G scan range, 10 mW microwave power, 20 K temperature, 32 G modulation amplitude, 100 kHz modulation frequency, 2 min/scan, 0.25 s time constant. Spectrometer conditions were as follows for detecting the 16 line spectrum from the coupled binuclear Mn^{3+}/Mn^{4+} complex: 2800 ± 500 G scan range, 30 mW microwave power, 9 K temperature, 32 G modulation amplitude, 100 kHz modulation frequency, 0.25 s time constant, 9.26 GHz microwave frequency. The amplitudes were calculated from the low-field and high-field peak-to-trough amplitudes for each designated peak.

2-Iodo-1-perfluorooctyl-3-propanol (1)

The R_fI ($R_f = C_8F_{17}$, 7 g, 12.8 mmol), allyl alcohol (1 mL, 14.7 mmol), and AIBN (84 mg, 0.51 mmol) were heated at 70–75°C under an inert atmosphere for 14 h. Every 2 h, a new portion of AIBN was added to the reaction mixture. The pale yellow solid obtained was recrystallized in refluxing hexane (40 mL). Compound **1** was obtained in 75% yield, mp 93–94°C. EI-MS: [M+] 604. ^{1}H NMR (400 MHz, $CDCl_3$, 25°C) δ: 4.45 (m, 1H, -C*H*I-), 3.79 (m, 2H, -C*H*$_2$-OH), 2.9 (2m, 2H, R_f-C*H*$_2$), 2.04 (t, -O*H*). Elemental anal. calcd. for $C_{11}H_6F_{17}IO$: C 21.87, H 1.00; found: C 22.06, H 0.97.

3-Perfluorooctyl-1-propanol (2)

Compound **1**, $R_fCH_2CHICH_2OH$ (8 g, 13.2 mmol), and AIBN (52 mg, 0.31 mmol) were partially dissolved in dry trifluorotoluene (40 mL). The tributyltin hydride (4.2 mL, 15.8 mmol) was then added dropwise and the reaction mixture was heated at 80°C under an inert atmosphere for 4 h (reaction followed by GC). After removing the solvent under vacuum, the resulting residue was dissolved in a perfluoroheptane–toluene mixture. After decantation, the lower phase was separated from the upper one, which mainly contains $(Bu)_3SnI$. By removing the perfluoroheptane, compound **2** was isolated as a white powder in 75% yield. Compound **2** can be recrystallized from hexane. EI-MS: [M+] 477. ^{1}H NMR (400 MHz, $CDCl_3$, 25°C) δ: 3.75 (m, 2H, -CH_2-OH), 2.20 (m, 2H, Rf-CH_2-), 1.88 (m, 2H, -CH_2-

© 2001 NRC Canada

CH_2-CH_2-), 1.57 (s, -OH). Elemental anal. calcd. for $C_{11}H_7F_{17}O$: C 27.63, H 1.46; found: C 27.72, H 1.63.

3-Perfluorooctyl-1-iodopropane (3)

The phosphorous pentaoxide (3.4 g) was added to phosphoric acid (85%, 7.1 mL) in a 50 mL round-bottom flask and then the mixture was cooled to 0°C. The KI (1.39 g, 8.2 mmol) was first added, followed immediately by $R_fCH_2CH_2CH_2OH$ (1.5 g, 3.1 mmol). The mixture was heated at 120°C for 3.5 h. At ambient temperature, 10 mL of water was added, and the resulting brown solution was extracted four times with 25 mL of diethyl ether. The organic layer was washed twice with 25 mL thiosulfate (0.1 M), then dried over Na_2SO_4. After removing the solvent, the iodo derivative was obtained as an oil, which solidified at 4°C. Compound **3** was used without further purification (yield 85%); however, **3** can be recrystallized from methanol. EI-MS: [M+] 588. ^{1}H NMR (400 MHz, $CDCl_3$, 25°C) δ: 3.26 (t, 2H, I-C*H*$_2$-), 2.16 (2m, 4H, -C*H*$_2$-C*H*$_2$-R_f). Elemental anal. calcd. for $C_{11}F_{17}H_6I$: C 22.47, H 1.02; found: C. 22.80, H 1.26.

Tris-*N*-(4,4,5,5,6,6,7,7,8,8,9,9,10,10,11,11,11-heptadecafluoroundecyl)-1,4,7-triazacyclononane (4)

The TACN (88.4 mg, 0.73 mmol), K_2CO_3 (423 mg, 3.1 mmol), and $R_fCH_2CH_2CH_2I$ (1.41 g, 2.41 mmol) were dissolved in DMSO (10 mL, distilled over CaH_2) and heated at 90°C for 24 h. Then perfluoroheptane (20 mL) was added to the reaction mixture and the brown fluorous lower phase was separated and then filtered. After removing the solvent, compound **4** was obtained as a brown oil. After crystallization from hot hexane, compound **4** was isolated as a yellowish powder in 50% yield. FAB-MS: [M + H$^+$] 1510. ^{1}H NMR (400 MHz, $CDCl_3$, 25°C) δ: 2.71 (s, 12H, -N-C*H*$_2$-C*H*$_2$-N), 2.55 (t, 6H, -N-C*H*$_2$-C*H*$_2$-), 2.17 (m, 6H, -CH_2-C*H*$_2$-CH_2), 1.58 (m, 6H, -CH_2-C*H*$_2$-Rf). Elemental anal. calcd. for $C_{39}H_{30}F_{51}N_3$: C 31.03, F 64.20, H 1.98, N 2.78; found: C 30.74, F 64.31, H 2.02, N 2.70.

Synthesis of the *N*-(pentafluorotoluene)-bis-picolylamine and ligand 5

This procedure for the preparation of **5** was similar to that used to prepare ligand **8**. At the end of the reaction, the toluene was removed under vacuum, and a brownish solid was obtained. This solid was triturated with pentane affording a beige powder. Ligand **5** was obtained in 85% yield and provided a satisfactory ^{1}H NMR spectrum. ^{1}H NMR (400 MHz, $CDCl_3$, 25°C) δ: 8.52 (d, 2H, aromatic H), 7.65 (t, 2H, aromatic H), 7.51 (d, 2H, aromatic H), 7.15 (m, 2H, aromatic H), 3.90 (s, 2H, -CH_2-C_6F_5), 3.85 (s, 4H, -C*H*$_2$-C_5H_4N).

Synthesis of ligand 6

BPA (59 mg, 0.296 mmol), K_2CO_3 (57 mg,), $R_fCH_2CH_2CH_2I$ (191 mg, 0.325 mmol) in DMSO (0.5 mL, distilled over CaH_2) were heated at 90°C for 16 h. The reaction mixture was filtered and the solvent removed in vacuo. Ligand **6** was purified by alumina column chromatography (CH_2Cl_2–MeOH) and was recovered as a beige oil, which solidifies at 4°C providing a yield of 60%. Ligand **6** was found to be soluble in hot, but not in cold perfluoroheptane. ^{1}H NMR (400 MHz, $CDCl_3$, 25°C) δ: 8.54 (d, 2H, pyr), 7.66 (t, 2H, pyr), 7.46 (d, 2H, pyr), 7.16 (m, 2H, pyr), 3.83 (s, 4H, -N-CH_2-pyr), 2.63 (t, 2H, -N-C*H*$_2$-CH_2-), 2.03 (m, 2H, -CH_2-C*H*$_2$-CH_2), 1.76 (m, 2H, -CH_2-C*H*$_2$-Rf). FAB-MS : [M + H$^+$] 660.

Synthesis of ligand 7

The BisPicen (50 mg, 0.206 mmol), K_2CO_3 (80 mg, 0.580 mmol), and $R_fCH_2CH_2CH_2I$ (266 mg, 0.450 mmol) were dissolved in DMSO (2.5 mL, distilled over CaH_2) and then heated at 90°C for 24 h. The solvent, benzotrifluoride, was added at room temperature to dissolve a brown oil, and then the solvent was removed under vaccum. To the sticky residue was added dichloromethane and then the solution was filtered, and the solvent removed under vaccum. The ligand (**7**) was purified first by alumina column chromatography (CH_2Cl_2–MeOH) and then by recrystallization from hexane to obtain a yellowish powder in 40% yield. ^{1}H NMR (400 MHz, $CDCl_3$, 25°C) δ: 8.54 (d, 2H, pyr), 7.66 (t, 2H, pyr), 7.46 (d, 2H, pyr), 7.16 (m, 2H, pyr), 3.83 (s, 4H, -N-CH_2-pyr), 2.63 (t, 2H, -N-C*H*$_2$-CH_2-), 2.03 (m, 2H, -CH_2-C*H*$_2$-CH_2), 1.76 (m, 2H, -CH_2-C*H*$_2$-R_f). FAB-MS: [M + H$^+$] 1163. Anal. calcd. for C_{36} H_{28} N_4 F_{34}: C 37.2, H 2.40, N 4.82; found: C 36.51, H 2.33, N 4.38.

Synthesis of tris-*N*-pentafluorophenyl-1,4,7-triazacyclononane and ligand 8

To a stirring solution of TACN (3.7 mmol) in anhydrous toluene (10 mL) in a glovebox was added powdered KOH (11 mmol) slowly, and then the resulting suspension was treated with $C_6F_5CH_2Br$ (11 mmol) dropwise. The reaction mixture was heated to 80°C and stirred at this temperature for 8 h. After being cooled to room temperature, it was then treated with an additional portion of powdered KOH and then $C_6F_5CH_2Br$. The mixture was stirred and heated to 80°C for another 8 h. After filtration, the toluene is removed under vacuum leading to a yellow solid, which gave a satisfactory NMR spectrum. Tris-*N*-pentafluorophenyl-1,4,7-triazacyclononane can be further purified by recrystallization from MeOH; mp 75°C. EI-MS: [M+] 669. ^{1}H NMR (400 MHz, $CDCl_3$, 25%C) δ: 2.70 (s, 12H, -CH_2-TACN), 3.71 (s, 6H, -CH_2-Ph). ^{13}C NMR (MHz, $CDCl_3$, 25°C) δ: 48.31, 54.69, 135.99, 138.50, 144.63, 146.62. ^{19}F NMR (MHz, $CDCl_3$–$CFCl_3$, 25°C) δ: –142.82 (2F), –156.11 (1F), –162.91 (2F). Elemental anal. calcd. for $C_{28}H_{18}F_{15}N_3$: C 48.4, F 42.5, H 2.7, N 6.3; found: C 48.3, F 42.4, H 2.8, N 6.2.

The PTC catalyst, Aliquat 336 (49 μmol), trifluorotoluene (5 mL), tris-*N*-pentafluorophenyl-1,4,7-triazacyclononane (1.49 mmol), $R_fCH_2CH_2CH_2OH$ (4.92 mmol), and NaOH 50% (5 mL) were stirred at 85°C for 22 h. After removing the solvent in vacuo, the solid was taken off with a mixture of trifluorotoluene, dichloromethane, and water. After stirring, the cloudy organic phase was isolated and the solvent stripped in vacuo. After washing the resulting orange solid with dichloromethane, compound **8** was obtained, after filtration, as a white powder (80%). Compound **8** can be further purified by alumina gel chromatography (CH_2Cl_2–MeOH, 0–2%). m p 98°C. FAB-MS: [M+H$^+$] 2044. ^{1}H NMR (400 MHz, $CDCl_3$, 25°C) δ: 4.27 (t, 6H, -O-CH_2-), 3.68 (s, 6H, N-CH_2-C_6F_4), 2.71 (s, 12H, CH_2-TACN), 3.37 (m, 6H, O-CH_2-C*H*$_2$), 2.10 (m, 6H, -CH_2-C*H*$_2$-Rf). ^{13}C NMR (MHz,

$CDCl_3$, 25°C) δ: 48.31, 54.69, 135.99, 138.50, 144.63, 146.62. ^{19}F NMR (MHz, $CDCl_3$–$CFCl_3$, 25°C) δ: –81.29 (3F), –114.92 (2F), –122.23 (2F), –122.43 (4F), –123.23 (2F), –124.00 (2F), –126.63 (2F), –144.16 (2F), –158.19 (2F). Anal. calcd. for $C_{60}H_{36}N_3F_{63}O_3$: C 35.3, H 1.8, N 2.1, F 58.6; found: C 35.6, H 1.9, N 2.1, F 59.6.

$[Mn(C_8F_{17}(CH_2)_2CO_2)_2(H_2O)_2]$ (9)

The $CF_3(CF_2)_7CH_2CH_2CO_2H$ (1.35 g, 2.80 mmol) was dissolved in acetone (15 mL) and to this solution was added triethylamine (380 mL, 2.80 mmol). This resulting solution was added dropwise to $Mn(ClO_4)_2 \cdot 6H_2O$ (500 mg, 1.37 mmol) dissolved in acetone (30 mL). The sticky precipitate which formed was vigorously stirred for 2 h. After filtration, **9** was obtained as a white powder in 75% yield. Elemental anal. calcd. for $C_{22}F_{34}H_{12}O_6Mn$: C 24.61, F 60.19, H 1.12, Mn 5.12; found: C 25.37, F 59.77, H 0.94, Mn 5.50.

$[Co(C_8F_{17}(CH_2)_2CO_2)_2(H_2O)_2]$ (10)

The same procedure, as conducted with complex **9**, was used for the synthesis of **10**, except with $Co(ClO_4)_2 \cdot 6H_2O$. A pink precipitate formed immediately, and after filtration, a pink powder was obtained in 100% yield. Elemental anal. calcd. for $C_{22}H_{12}F_{34}CoO_6$: C 24.53, H 1.11, F 59.98, Co 5.46; found: C 25.05, H 1.27, F 60.15, Co 5.35.

ESR–FBC experiment

The ESR spectrum for in situ generated **11** was conducted at 20 K in benzotrifluoride (top spectrum, Fig. 1). Using standard oxidation conditions for cyclohexene as outlined in Table 1, aliquots of the perfluoroheptane layer were removed and immediately frozen at 100 K in an ESR tube (middle and lower spectra, Fig. 1). ESR spectra were recorded at 9 K using microwave power at 10 mW, modulation amplitude 32 G, a time constant of 0.5 s, at a frequency of 9.18 GHz, and gain of 3.2×10^{-3}.

Acknowledgment

The studies at LBNL were generously supported by a gift grant (R.H.F.) and a postdoctoral fellowship to J.-M. V. from Elf Aquitaine Inc., and the Department of Energy under Contract no. DE-AC03–76SF00098. We thank Dr. István T. Horváth and Dr. Jozsef Rábai for many helpful discussions concerning our FBC program.

Dithiophosphinates of gold (I); oxidative addition of Cl_2 to a neutral, dinuclear gold(I) dithiophosphinate complex, and X-ray crystal structures of $[AuS_2P(C_2H_5)_2]_2$, $[AuS_2PPh_2]_2$, $Au_2(CH_2)_2PMe_2(S_2PPh_2)$, and $Au_2Cl_2[(CH_2)_2PMe_2][S_2PPh_2]$

Werner E. van Zyl, José M. López-de-Luzuriaga, John P. Fackler, Jr., and Richard J. Staples

Abstract: The formation and characterization of dinuclear gold(I) dialkyl- and diaryl-dithiophosphinate complexes of the type $[AuS_2PR_2]_2$ are described. The complexes are readily prepared from the reaction between a chloro–gold(I) starting material and the corresponding dithiophosphinate salt. The structures of the complexes show both the absence (R = Et, **1**) and presence (R = Ph, **2a**) of intermolecular Au···Au interactions as confirmed by X-ray crystallographic study in the solid state. Reaction between $[AuS_2PPh_2]_2$ and $[Au(CH_2)_2PMe_2]_2$ in CH_2Cl_2 solution leads to a ligand transfer reaction to form the hetero-bridged complex $[Au_2\{(CH_2)_2PMe_2\}\{S_2PPh_2\}]$ (**3a**) in high yield. Additionally, the latter complex reacts with Cl_2 to form the oxidative addition product $[Au_2Cl_2\{(CH_2)_2PMe_2\}\{S_2PPh_2\}]$ (**4**), the first gold(II) complex with a S-P-S bridging moiety. The X-ray crystal structure of both **3a** and **4** exhibit rare boat conformations in the solid state, and **4** has a formal Au(II)—Au(II) single bond of 2.5611(5) Å. Reaction between $[AuS_2PPh_2]_2$ and dppm (dppm = $Ph_2PCH_2PPh_2$) leads to a sparsely soluble three-coordinate dinuclear gold(I) complex with the molecular formula $[Au_2\{dppm\}\{S_2PR_2\}_2]_n$ (n = 1 or ∞) (**5**).

Key words: dithiophosphinates, ylide, dithiols, gold–gold bond.

Résumé : On décrit la préparation et la caractérisation de complexes dinucléaires de dialkyl- et diaryldithiophosphinates d'or(I), du type $[AuS_2PR_2]_2$. Les complexes se forment facilement par réaction d'un produit de départ contenant du chloro-or(I) avec le sel de dithiophosphinate correspondant. Les structures des complexes montrent dans un cas l'absence (R = Et, **1**) et dans l'autre la présence (R = Ph, **2a**) d'interactions Au···Au intermoléculaires qui ont été confirmées par une étude cristallographique par diffraction des rayons X à l'état solide. La réaction entre le $[AuS_2PPh_2]_2$ et le $[Au(CH_2)_2PMe_2]_2$, en solution dans le CH_2Cl_2, donne lieu à une réaction de transfert de ligand qui conduit à la formation, avec un rendement élevé, du complexe hétéroponté $[Au_2\{(CH_2)_2PMe_2\}\{S_2PPh_2\}]$, **3a**. De plus, ce dernier complexe réagit avec le Cl_2 pour former le produit d'addition oxydante $[Au_2Cl_2\{(CH_2)_2PMe_2\}\{S_2PPh_2\}]$, **4**, le premier complexe d'or(II) comportant un pont S-P-S. Les structures de diffraction des rayons X des produits **3a** et **4** montrent toutes les deux la présence de conformations bateaux, rares à l'état solide; de plus, le produit **4** comporte aussi une liaison simple Au(II)—Au(II) de 2,5611(5)Å. La réaction du $[AuS_2PPh_2]_2$ avec le dppm (dppm = $Ph_2PCH_2PPh_2$) conduit à la formation d'un complexe d'or(I) dinucléaire, tricoordiné et à peine soluble de formule moléculaire $[Au_2\{dppm\}\{S_2PR_2\}_2]_n$ (n = 1 ou ∞), **5**.

Mots clés : dithiophosphinates, ylure, dithiols, liaison or–or.

Scheme 1.

Introduction

The chemistry of gold–sulfur compounds finds significant application ranging from surface science (1) to medicine (2). The use of gold(I) dithiophosphates as sensitizers in photographic films is well established (3). Recently the luminescent properties of gold(I) dithiocarbamates and related materials has been suggested for possible use as photosensors (4). The organophosphor-1,1-dithiolato class of compounds (which includes the dithiophosphinates) have found widespread use as anti-oxidant additives in the oil and petroleum industry (5), insecticide derivatives (6), and metal ore extraction reagents (7). Although the dithiophosphinic acids, $R_2P(S)SH$, have been known for more than a century (8), gold(I) complexes of these ligands have not been studied extensively. In 1968, Kuchen et al. (9) reported the first examples of gold(I) dithiophosphinate complexes. The complexes were obtained by reduction of gold(III) and required the separation of several by-products. Dinuclearity was suggested for the majority of these compounds based on osmometric molecular weight determinations in chloroform. Further research remained dormant until 1995 when Siasios and Tiekink (10) reported the structure of $[AuS_2PPh_2]_2$ as the first diaryldithiophosphinate complex of gold. The complex was obtained as a decomposition product, a non-reproducible synthesis, and the structure was determined in the wrong space group, *I*4.

The first systematic study of gold(I) dithiophosphinate complexes was reported by Schmidbaur and co-workers (11). The main focus of their study was to use dithiophosphinic acid anions $[R_2PS_2]^-$ as potential bidentate ligands to form efficient clustering centers for gold(I) cations, as exemplified by complexes such as $[Ph_2P\{SAu(PR_3)\}_2]^+$ and $Me_2P(S)SAuPR_3$.

As part of our ongoing studies of sulfur compounds of the Group 11 elements, the chemistry of the complexes of dithio-phosphorus ligands, $[AuS_2PR_2]_2$, sulfur analogs of the bis(ylide) complexes (for reviews of this chemistry see, ref. 12), is reported in this study. These materials show both the absence (R = Et) and the presence (R = Ph) of weak intermolecular Au···Au interactions in the solid state. The compound $[AuS_2PEt_2]_2$ was readily prepared from the sodium salt of the ligand, $Na[S_2PEt_2]$, and shows a solution ^1H NMR with $^3J_{P,H}$ larger than $^2J_{P,H}$. The analog $[AuS_2PPh_2]_2$ was obtained by a direct synthesis and its structure redetermined. A ligand transfer reaction with an ylide has led to a new, mixed ligand ylide–dithiophosphinate product, which like the previously studied bis(ylide), methylene-thiophosphinate and mixed ligand dithiocarbamate–bis(ylide) products (12), form stable Au(II) derivatives upon oxidation with halogens.

Results and discussion

Preparative methods

The reaction between [Au(tht)Cl] (tht= tetrahydrothiophene) and $Na[S_2PEt_2]\cdot 2H_2O$ in THF (molar ratio 1:1) leads to the cyclic dinuclear complex $[AuS_2PEt_2]_2$ (**1**). Following extraction of the product into CH_2Cl_2 solution and filtration through anhydrous $MgSO_4$ to remove water and NH_4Cl, complex **1** was isolated in >70% yield.

Different synthetic methodologies were investigated for the complex $[AuS_2PPh_2]_2$ (**2a**). Although **2a** and its analog $[AuS_2P(C_6H_4\text{-}p\text{-}Me)_2]_2$ (**2b**) were isolated in a manner similar to **1**, the yield for **2a** was only ~50% because of the product's sparse solubility in organic solvents, which hampered an efficient separation from by-products. Significantly improved yields (>75%) were obtained by extraction with water (in which **2a** remained stable) to remove NH_4Cl (from the ammonium salt of the ligand and the [Au(tht)Cl] and to obtain the product as a yellow paste, which was dried by consecutively washing with methanol and ether. A third method to prepare **2a** was discovered by accident in a reaction shown in Scheme 1. In hot benzene the disulfide $Ph_2P(S)S\text{-}SP(S)Ph_2$ was reduced by cleavage of the S–S bond, in the presence of [(tht)Au(I)Cl], to form the dinuclear complex **2a** in ~30% isolable yield. Organic by-products were not identified. Unlike the low thermal stability of the acid $Ph_2P(S)SH$, which decomposes through rapid elimination of hydrogen sulfide (11), the gold complex **2a** appears to have remarkable thermal stability. It was recovered nearly quantitatively from a boiling benzene solution exposed to air for 3 days.

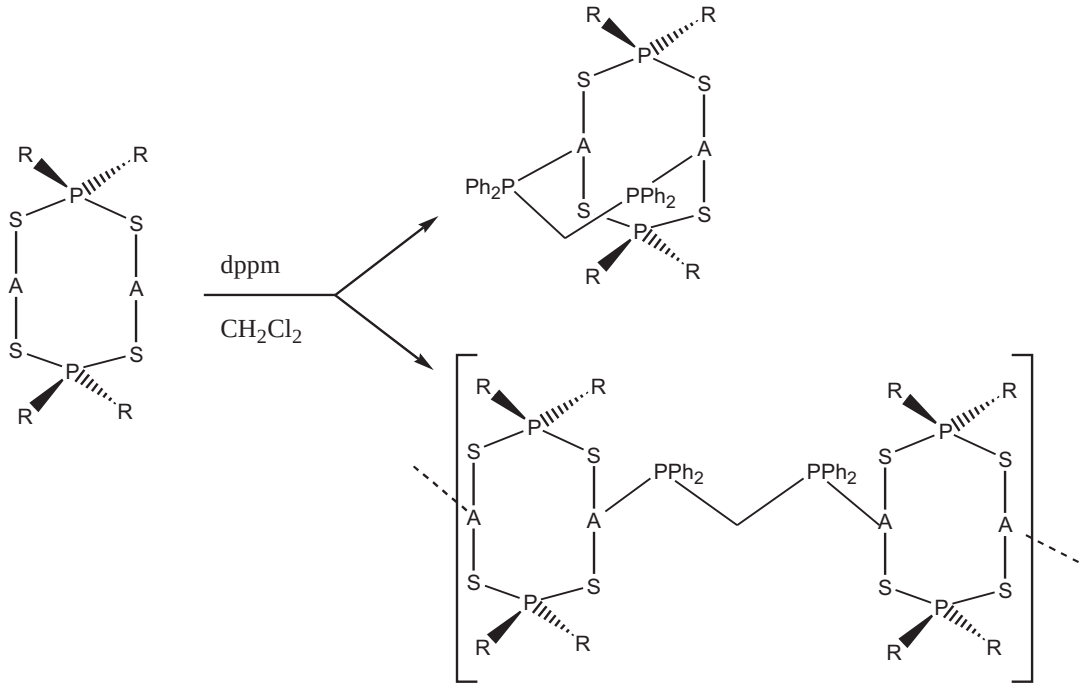
Fig. 1. Drawings of two reasonable structures for the complex $[Au_2\{dppm\}\{S_2PPh_2\}_2]_n$ where $n = 1$ (top) or $n = \infty$ (bottom) following the reaction between **2a** and dppm.



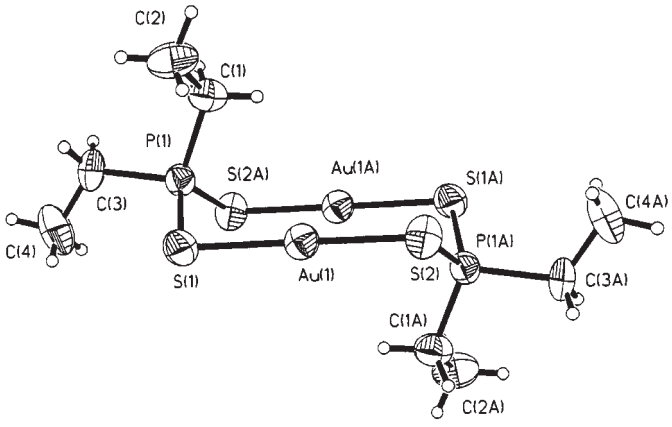


Fig. 2. View of the molecular structure (50% thermal ellipsoids) of complex **1** showing the atomic labeling scheme. Selected bond lengths (Å) and angles (°): Au(1)···Au(1A) 3.1822(13), Au(1)—S(1) 2.309(4), Au(1)—S(2) 2.310(4), S(1)—P(1) 2.035(5), P(1)—C(1) 1.780(14) Å; S(1)-Au(1)-S(2) 173.87(13), S(2)-Au(1)-Au(1A) 93.19(10), P(1)-S(1)-Au(1) 100.4(2), S(2A)-P(1)-S(1) 115.0(2)°.

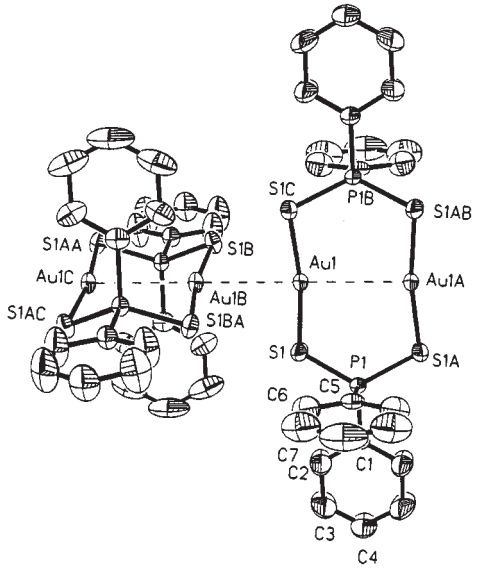
Complexes **3a** and **3b** were formed in good yield (~80%) from the reaction between $[AuS_2PPh_2]$ (**2a**) and $[AuS_2PEt_2]$ (**1**), respectively, with $[Au(CH_2)_2PMe_2]_2$ (molar ratio 1:1) in a CH_2Cl_2 solution. The reaction was complete after 20 min. Complexes **3a** and **3b** are the first reported dinuclear gold(I) complexes with heterobridged phosphor-1,1-dithiolato moieties and bis(ylide) bridging ligands and show some unique structural features (vide infra). Laguna and co-workers (13) previously reported heterobridged complexes with dithiocarbamate $S_2CN(CH_2Ph)_2^-$, and xanthate S_2COR^-, along with bis(ylide) ligands bridging the two gold(I) centers.

Formation of the oxidative addition product $[Au_2Cl_2\{(CH_2)_2PMe_2\}\{S_2PPh_2\}]$ (**4**) was accomplished with Cl_2 in a CH_2Cl_2 solution. Upon Cl_2 addition the solution immediately turns from colorless to orange. Interestingly, following work-up and isolation of **4**, this solid product slowly releases chlorine gas at 140–160°C. The material gradually changes color from orange to colorless without additional decomposition. The compound melts at ~205°C, which is in the same range as the expected reductive elimination product **3a**. The elimination of chlorine gas was determined in a separate experiment wherein a saturated starch – NaI solution on filter paper was placed above ~100 mg of **4** that was heated. The chlorine released caused the filter paper to turn purple as expected for iodine formation. This apparently reversible reductive elimination appears related to the reversible CH_3Br addition–elimination observed with $[Au(CH_2)_2PPh_2]_2$ (12), but has not been observed previously with halogens.



The gold(I) complex $[Au_2\{dppm\}\{S_2PPh_2\}_2]_n$ ($n = 1$ or ∞) (**5**) is formed from the reaction between **2a** and dppm (dppm = $Ph_2PCH_2PPh_2$) in CH_2Cl_2 in good yield. The complex is sparingly soluble in organic solvents, a result which hinders detailed spectroscopic investigation. However, based on limited ^1H NMR data and elemental analysis, two three-coordinate gold(I) structures are consistent with the available data. They are sketched in Fig. 1. Of these compounds, precedence exists for the molecular adduct with cationic complexes of dinuclear gold(I) dithiocarbamates, $[Au_2(\mu\text{-}S_2CNEt_2)\{\mu\text{-}PPh_2)_2C{=}CH_2\}_2]^+$, prepared and structurally established by X-ray crystallography (14). The limited solubility of **5** precluded $^{31}P\{^1H\}$ NMR studies.

Solution ^1H and ^{31}P NMR studies

All the complexes reported were studied in solution by ^1H and $^{31}P\{^1H\}$ NMR spectroscopy, except **5**. In several cases

Fig. 3. View of the molecular structure (50% thermal ellipsoids) of two adjacent units of the chain of complex **2a** showing the atom labeling scheme (determination 1). Atoms are shown as thermal ellipsoid plots at the 50% probability level. Selected bond lengths (Å) and angles (°): Au(1)—Au(1B) 2.9610(3), Au(1)—Au(1A) 3.0859(3), Au(1)—S(1) 2.3112(10), S(1)—P(1) 2.0265(11), P(1)—C(5) 1.817(6) Å; S(1C)-Au(1)-S(1) 171.29(4), P(1)-S(1)-Au(1) 100.84(5), C(1)-P(1)-C(5) 105.1(2), S(1)-P(1)-S(1A) 116.00(8)°.

interesting and somewhat unexpected NMR results were obtained. Due to the symmetry of **1**, the solution NMR spectrum is simple and consistent with the X-ray structure. Both CH_2 and CH_3 protons couple to the ^{31}P nuclei (I = 1/2) giving a doublet of quartets and a doublet of triplets, respectively. The $^3J_{P,H}$ coupling constant (21.78 Hz) is *larger* than the $^2J_{P,H}$ coupling constant (10.98 Hz). This phenomenon is not uncommon in ethyl derivatives of four-coordinate P(V) compounds, which often show a similar behavior (15) with the extent of the three bond coupling depending primarily on the P-C-C-H dihedral angle (16). The same observation was made for the heterobridged complex **3b**. The ethyl groups show coupling constants of $^3J_{P,H}$ = 21.3 Hz and $^2J_{P,H}$ = 7.8 Hz for the CH_3 and CH_2 groups, respectively.

The homoleptic complexes **1**, **2a**, and **2b** each show only a singlet in the $^{31}P\{^1H\}$ NMR resonating at δ 82.5, 67.4, and 66.6 ppm respectively. The heterobridged complexes **3a** and **3b** show a doublet, a $^4J_{P,P}$ coupling (8–11 Hz at 300 MHz) for each ^{31}P nuclei. This coupling was not observed for the oxidative addition product **4** wherein each ^{31}P appears as a single resonance. In complex **4** the chemical shift is down field with respect to the unoxidized precursor complex **3a**.

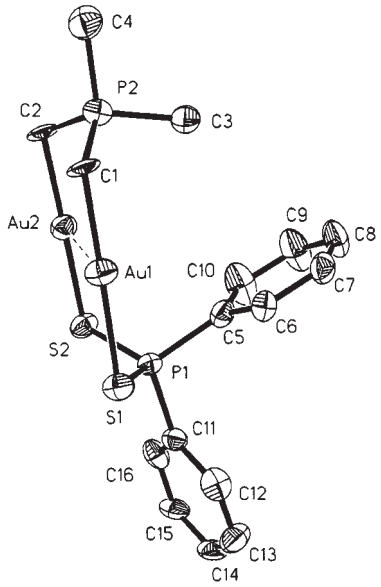
Structural studies

The dinuclear gold(I) structures reported in the present study are all neutral eight-membered ring metallocycles in an elongated chair or boat conformation with short transannular Au···Au interactions. Complex **1** does not contain intermolecular Au···Au interactions, which is as observed for the previously reported methyl derivative (10). The molecule crystallizes in the monoclinic space group $P2_1/n$ with an inversion center between the two gold atoms. The structure is shown in Fig. 2.

The structure of **2a** was previously reported (10), but several details raised suspicion causing us to further investigate the material. A significant concern was the absence of an inversion center (space group $I\bar{4}$) for this molecularly symmetrical molecule. Other troublesome indicators were the unequally sized thermal ellipsoids reported for gold atoms (Z = 79) and large variations in the presumably equal Au—S bond lengths which range from 2.23(2) to 2.38(2) Å. Following a rational synthesis (vide supra), high quality single crystals of **2a** were obtained, which allowed for successful structure refinement in the tetragonal space group $I4/m$. Unlike the methyl and ethyl derivatives which shows no intermolecular Au···Au interactions, the phenyl derivative shows short intermolecular Au···Au contacts of 2.9610(3) Å. This structure was determined at room temperature also for spectroscopic purposes. The results are statistically insignificant for the general structure but the intramolecular Au—Au distance is about 1% longer, and the intramolecular Au—Au distance about 1% shorter at room temperature than at –77°C. The structure of **2a** is shown in Fig. 3.

The complex **3a** crystallizes in the space group $P2_1/c$ with no intermolecular Au···Au interactions. An unusual feature of this structure is that the complex crystallizes in a boat conformation. Few examples of this form apparently exist for dimetallocycle Au(I) compounds (see Lin and co-workers (17)) when compared with the common chair conformation. The carbon atoms C(1) and C(2) were refined with some difficulty since the structure is close to that of a C-centered lattice, suggesting that the symmetry of the molecule is higher than the symmetry of the generated lattice. There also could be some ligand disorder, which would influence C(1) and C(2). The structure of **3a**, for which data was collected three times, is shown in Fig. 4.

Interestingly, the oxidative addition product of chlorine to **3a**, namely **4**, also crystallizes in a boat conformation. The single bond formed between the two Au(II) centers in **4** is clearly demonstrated by the crystallographic study. The intramolecular Au—Au distance decreases from 3.0966(7) Å (standard aurophilic bond) in **3a** to 2.5611(5) Å (single bond) in **4**. The structure is shown in Fig. 5. There is a significant twist of the two 5-membered rings in the molecule about the very short Au(II)–Au(II) bond which presumably arises from the constraints of the two different bridging ligands.



Experimental

General

All reactions and manipulations were carried out under an inert atmosphere with a positive nitrogen gas flow (pre-dried by two columns of Drierite) using standard Schlenk techniques. Solvents were distilled and kept under dinitrogen. The following chemicals were purchased from Aldrich: tetrahydrothiophene, aluminum trichloride, sodium sulfide nonahydrate, thiophosphoryl chloride, bis(diphenylphosphino)methane, ethylbromide. Elemental sulfur was obtained from J.T. Baker. The following compounds were prepared using literature procedures: $Et_2P(S)P(S)Et_2$ (18), $Na[S_2PEt_2]\cdot 2H_2O$ (19), $[NH_4][S_2PPh_2]$ (20),

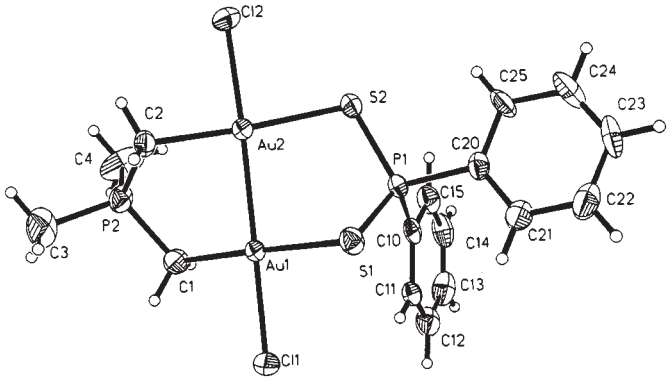
Atoms are represented by thermal ellipsoids at the 50% probability level. Selected bond lengths (Å) and angles (°): Au(1)—Au(2) 3.0966(7), Au(1)—S(1) 2.339(3), Au(2)—S(2) 2.317(3), Au(1)—C(1) 2.052(12), Au(2)—C(2) 2.080(12), C(1)—P(2) 1.756(14), P(1)—S(1) 2.031(4) Å; C(1)-Au(1)-S(1) 178.4(4), C(2)-Au(2)-Au(1) 87.9(4), C(5)-P(1)-S(2) 110.2(4),



$Ph_2P(S)$-S-S-$P(S)Ph_2$ (21), $H[AuCl_4]\cdot 3H_2O$ (22), [Au(tht)Cl] (23), $[Au_2\{dppm\}_2]Cl_2$ (24), $[Au_2\{dppm\}Cl_2]$ (25), $[Au\{(CH_2)_2PMe_2\}]_2$ (26), and $PhI\cdot Cl_2$ (27). All chemicals were used as received.

Instrumentation

Melting points were measured on a Unimelt (A.H. Thomas Co, Philadelphia, PA) capillary melting point apparatus and are uncorrected. Elemental analyses were performed at Desert Analytics Inc., Tucson AZ. ^{1}H NMR spectra were obtained on a Varian XL-200 spectrometer operating at 200 MHz, or a Varian UnityPlus-300 spectrometer operating at 299.9 MHz. ^{1}H NMR data are expressed in parts per million (ppm) downfield referenced internally to the residual proton impurity in the deuterated solvent, and are reported as: chemical shift position (^{1}H NMR (δ)), multiplicity (s = singlet, d = doublet, t = triplet, q = quartet, m = multiplet, br = broad), coupling constant (*J* (Hz)), relative integral, and assignment. All $^{31}P\{^1H\}$ NMR spectra were obtained on either a Varian XL 200 MHz broadband spectrometer operating at 81 MHz, or a Varian UnityPlus-300 spectrometer operating at 121.4 MHz with chemical shifts reported relative to a 85% H_3PO_4 in D_2O external standard solution. Positive fast atom bombardment (+FAB–DIP) (DIP = direct insertion probe) mass spectra were acquired on a VG Analytical (Manchester, U.K.) 70S high resolution, double focusing mass spectrometer. Samples for analyses were prepared by dissolving the solid compound in appropriate solvent with a nitrobenzylalcohol (NBA) matrix added.

Fig. 5. Molecular structure of the Au(II)–Au(II) complex **4** showing the atom labeling scheme. Atoms are represented as thermal ellipsoids at the 50% probability level. There is a significant twist to the two chelate rings about the nearly linear Cl-Au-Au-Cl axis with the C(2)-Au(2)-S(2) axis offset by about 20° from the C(1)-Au(1)-S(1) axis. Selected bond lengths (Å) and angles (°): Au(1)—Au(2) 2.5611(5), Au(1)—C(1) 2.075(8), Au(2)—C(2) 2.063(8), Au(1)—Cl(1) 2.392(2), Au(1)—S(1) 2.401(2), Au(2)—S(2) 2.376(2) Å; C(1)-Au(1)-S(1) 177.8(3), Cl(1)-Au(1)-S(1) 91.05(7), S(1)-P(1)-S(2) 113.00(13)°.

X-ray crystallography

Crystals that were used in diffraction intensity measurements at room temperature were mounted on the tip of a quartz fiber with fast-adhesive glue. Single crystal diffraction analysis was carried out on complex **1** at Texas A&M using an automated Nicolet R3 four-circle diffractometer utilizing the Wyckoff scanning technique with graphite monochromated Mo Kα (λ = 0.71073 Å) radiation. Refined cell parameters were determined from setting angles of 25 reflections with 20° < 2θ < 30°. The unit cell was determined using search, center, index, and least-squares refinement routine. The Laue class and lattice dimensions were verified by axial oscillation photography. The intensity data were corrected for absorption, Lorentz, and polarization effects. An empirical absorption correction was performed based on ψ scans of five strong reflections spanning a range of 2θ values. All data processing were performed on a Data General Eclipse S140 minicomputer using the SHELXTL crystallographic package (version 5.1) and Siemens SHELXTL PLUS (Micro Vax II) (28). The systematic absences were consistent with the space group assigned. The structure was solved using direct-methods to determine the gold atom positions, while all other atoms were located with difference Fourier maps. Structure refinement was carried out using SHELX 93. The position of the hydrogen atoms were calculated by assuming idealized geometries, C—H = 0.93 Å.

X-ray data for complexes **2a**, **3a**, and **4** were collected at Harvard University on a Siemens (Bruker) SMART CCD (charge coupled device) based diffractometer equipped with a LT-2 low temperature apparatus operating at 213 K. Data for **2a** was collected three times including once at room temperature. A suitable crystal was chosen in each case and mounted on a glass fiber using grease. Data were measured

using omega scans of 0.3° per frame for 30 s, such that a hemisphere was collected. A total of 1271 frames were collected. The first 50 frames were collected again at the end of the data collection to monitor for decay. Cell parameters were retrieved using SMART software (29) and refined using SAINT on all observed reflections. Data reduction were performed using SAINT software (30) which corrects for Lp and decay. Absorption corrections were applied (semi-empirical from psi-scans) using SADABS (31) supplied by G. Sheldrick. The structures were solved by direct methods using the SHELXS 97 (32) program and refined by least-squares method on F^2, SHELXL 97 (33). The structures were solved in space groups consistent with analysis of systematic absences. All non-hydrogen atoms were refined anisotropically. The crystals used for diffraction showed no decomposition during data collection. Crystallographic data and structure refinement results are listed in Table 1. Bond lengths and angles are reported in the appropriate figure captions.

Preparation of compounds

*$[AuS_2PEt_2]_2$ (**1**) (9)*

A 50-mL Schlenk tube was charged with a solution of $Na[S_2PEt_2]\cdot 2H_2O$ (0.16 g, 0.72 mmol) and [Au(tht)Cl] (0.22 g, 0.70 mmol) in THF (35 mL) and stirred for 1 h at room temperature. The solvent was subsequently evaporated under reduced pressure, the crude mixture was extracted with CH_2Cl_2 (30 mL), active charcoal was added, and the mixture filtered through anhydrous $MgSO_4$ to remove water and NaCl. The volume of the filtrate was reduced in vacuo to 5 mL, and the clear solution transferred to a 10 mL test-tube, which was transferred to a larger vial that contained hexane. The larger vial was corked and after three days in the closed system the CH_2Cl_2 solvent diffused into the hexane yielding crystals and trace amounts of dark brown decomposition product (Au_2S?). Crystals of **1** suitable for X-ray crystallographic studies were obtained as colorless plates, yield 0.36 g (73%), mp 153°C. +FAB-MS (NBA/CH_2Cl_2) m/z: 701 ($[M + 1]^+$). ^{1}H NMR (200 MHz, $CDCl_3$, 19°C) δ: 1.36 (dt, $J_{P,H}$ = 21.78 Hz, 12H, $4CH_3$), 2.33 (dq, $J_{P,H}$ = 10.98 Hz, 8H, $4CH_2$). ^{31}P NMR (CH_2Cl_2 with 85% H_3PO_4 insert in 85% D_2O, 200 MHz, 20°C) δ: 82.59 (s). Anal. calcd. for $C_8H_{20}P_2S_4Au_2$: C 13.72, H 2.88; found: C 13.62, H 2.81.

*$[AuS_2PPh_2]_2$ (**2a**) (9)*

Method A: A 50-mL Schlenk tube was charged with a solution of $[NH_4][S_2PPh_2]$ (0.11 g, 0.415 mmol) in THF (40 mL) at room temperature. Upon dissolution, [Au(tht)Cl] (0.131 g, 0.408 mmol) was added in one portion. The solution immediately afforded a white precipitate (NH_4Cl). The mixture was stirred for 1 hour at room temperature. The solvent was removed in vacuo, and CH_2Cl_2 (40 mL) was added to extract the product. The mixture was filtered through anhydrous $MgSO_4$ (3 mm). The solvent was evaporated under reduced pressure, washed with dry ether, and vacuum dried for 1 hour.

Method B: Similar to Method A, but after THF was removed in vacuo, water (40 mL) was added to dissolve the NH_4Cl. The product (a wet yellow paste, stable in water) was filtered and washed consecutively with methanol and ether. The yellow product was dried in the air.

Method C: To a 100-mL beaker was added a solution of $Ph_2P(S)S\text{-}SP(S)Ph_2$ (0.2 g, 0.40 mmol) and [Au(tht)Cl] (0.26 g, 0.80 mmol) in benzene (40 mL) at room tempera-

ture. The mixture was heated to boiling for 20 min, which yielded a clear solution. Upon cooling, a yellow microcrystalline powder was obtained, which was filtered on a frit and washed with ether. Yields: Method A: 55% (some loss occurs due to the limited solubility of the product in CH_2Cl_2.); Method B: 78% (this was our best method); Method C: 28% (as crystallized product), mp 295°C (dec.). +FAB-MS (insolubility of product prevented satisfactory spectrum to be obtained). The complex is partially soluble in chlorinated solvents and THF, and insoluble in ether and hexane. ^{1}H NMR (300 MHz, $CDCl_3$, 20°C) δ: 8.06–7.92 (m, 8H, Ph), 7.58–7.38 (m, 12H, Ph). ^{31}P NMR (200 MHz, $CDCl_3$, 19°C) δ: 67.43 (s). Anal. calcd. for $C_{24}H_{20}P_2S_4Au_2$: C 32.32, H 2.24, S 14.33; found: C 32.92, H 2.13, S 13.86.

*$[AuS_2P(C_6H_4$-p-$Me)_2]_2$ (**2b**)*

Starting from $[NH_4][S_2P(C_6H_4$-*p*-$Me)_2]$ the toluene derivative was obtained in the same manner as described in Method A for **2a**, yield 77%, mp 275°C. ^{1}H NMR (200 MHz, $CDCl_3$, 20°C) δ: 7.90–7.78 (m, 8H, Ph), 7.22–7.12 (m, 8H, Ph), 2.37 (br s, 12H, 4Me). ^{31}P NMR (200 MHz, $CDCl_3$, 20°C) δ: 66.62 (s). Anal. calcd. for $C_{28}H_{28}P_2S_4Au_2$: C 35.45, H 2.97; found: C 35.62, H 3.08.

*$Au_2[(CH_2)_2PMe_2](S_2PPh_2)$ (**3a**)*

A 50-mL Schlenk tube was charged with a solution of **2a** (75.8 mg, 0.085 mmol) and $[Au(CH_2)_2PMe_2]_2$ (48 mg, 0.085 mmol) in CH_2Cl_2 (10 mL) at room temperature. An orange–yellow colored suspension was initially obtained since both starting materials are sparingly soluble in CH_2Cl_2. After the reaction mixture had been stirred for 10 min, a clear orange solution was obtained, and stirring was continued for an additional 20 min, followed by filtration through anhydrous $MgSO_4$. The filtrate solution was concentrated by evaporation of the solvent under reduced pressure, and ether was added to precipitate the product, which was filtered on a frit and air dried. Colorless blocky crystals suitable for X-ray studies were obtained from a concentrated CH_2Cl_2 solution layered with either ether or hexane, yield 52.3 mg (84%), mp 208°C (dec.). +FAB-MS (NBA/$CHCl_3$) *m*/*z*: 733 ($[M + 1]^+$). ^{1}H NMR (300 MHz, $CDCl_3$, 20°C) δ: 8.22–8.08 (m, 4H, Ph), 7.48–7.35 (m, 6H, Ph), 1.24 (d, $J_{P,H}$ = 13.2 Hz, 4H, $2CH_2$), 1.10 (d, $J_{P,H}$ = 12.6 Hz, 6H, $2CH_3$). ^{31}P NMR (300 MHz, $CDCl_3$, 20°C) δ: 68.52 (d, $J_{P,P}$ = 11.9 Hz, PPh_2), 34.78 (d, $J_{P,P}$ = 11.9 Hz, PMe_2). Anal. calcd. for $C_{16}H_{20}P_2S_2Au_2$: C 26.24, H 2.75; found: C 26.32, H 2.81.

*$[Au_2\{(CH_2)_2PMe_2\}\{S_2PEt_2\}]$ (**3b**)*

Prepared in the same fashion as **3a**, but **1** was used as a starting material instead of **2a**, yield 78%. ^{1}H NMR (300 MHz, $CDCl_3$, 20°C) δ: 2.30 (dq, $J_{P,H}$ = 7.8 Hz, 4H, $2CH_2CH_3$), 1.60 (d, $J_{P,H}$ = 12.3 Hz, 6H, 2P-CH_3), 1.38 (dt, $J_{P,H}$ = 21.3 Hz, 6H, $2CH_2CH_3$), 1.23 (d, $J_{P,H}$ = 12.3 Hz, 4H, 2P-CH_2-Au). ^{31}P NMR (300 MHz, $CDCl_3$, 20°C) δ: 81.93 (d, $J_{P,P}$ = 7.9 Hz, PEt_2), 34.20 (d, $J_{P,P}$ = 7.9 Hz, PMe_2).

*$Au_2Cl_2[(CH_2)_2PMe_2][S_2PPh_2]$ (**4**)*

A 50-mL Schlenk tube was charged with a solution of **3a** (60 mg, 0.082 mmol) in CH_2Cl_2 (8 mL) at room temperature. The solution was cooled to 0°C and PhI·Cl_2 (26 mg, 0.095 mmol) was added in one portion. The solution immediately turned deep orange. The reaction mixture was stirred for 30 min with a gradual increase of temperature until room temperature was reached. The solvent was partially removed under reduced pressure, and subsequently ether was added when the solution became sufficiently concentrated to induce precipitation of the product. The product was filtered, dried under vacuum for 2 h, and stored in a refrigerator, yield 78%, mp at ~ 205°C. +FAB-MS (NBA/$CHCl_3$) *m*/*z*: is similar to **3a**, ($[M - Cl_2]^+$). ^{1}H NMR ($CDCl_3$, 300 MHz, 20°C) δ: 8.05–7.90 (m, 4H, Ph), 7.60–7.40 (m, 6H, Ph), 2.05 (d, $J_{P,H}$ = 7.79 Hz, 4H, $2CH_2$), 1.81 (d, $J_{P,H}$ = 8.19 Hz, 6H, $2CH_3$). ^{31}P NMR (300 MHz, $CDCl_3$, 20°C) δ: 70.06 (s, no $^4J_{P,P}$ coupling detected, PPh_2), 42.02 (s, no $^4J_{P,P}$ coupling detected, PMe_2). Anal. calcd. for $C_{16}H_{20}Cl_2P_2S_2Au_2$: C 23.92, H 2.51; found: C 22.84, H 2.49 (some loss of Cl_2 is expected). Orange needles suitable for X-ray crystallographic studies were obtained from a concentrated CH_2Cl_2 solution layered with hexane.

*$[Au_2\{dppm\}\{S_2PPh_2\}_2]_n$ (**5**)*

A 50-mL Schlenk tube was charged with a solution of **2a** (0.1 g, 0.11 mmol) in CH_2Cl_2 (10 mL) at room temperature. To the yellow suspension was added dppm (0.043 g, 0.11 mmol) in one portion. The initial suspension became a clear solution after a few minutes, followed by formation of a white precipitate that emerged after 30–40 min. The solvent was subsequently removed under reduced pressure until a concentrated solution was obtained. Ether was added in excess to precipitate and consolidate the solid. The product was filtered on a frit and washed with ether. The product is a white solid and is sparingly soluble in polar and non-polar solvents, yield 72%, mp 227°C. ^{1}H NMR (300 MHz, $CDCl_3$, 20°C) δ: 8.28–8.12 (m, 8H, Ph), 7.80–7.62 (m, 12H, Ph), 7.50–7.35 (m, 8H, Ph), 7.26–7.10 (m, 12H, Ph), 4.26 (br s, 2H, PCH_2P). Anal. calcd. for $C_{49}H_{42}P_4S_4Au_2$: C 46.09, H 3.32, S 10.04; found: C 45.07, H 3.42, S 8.83.

Making a 16-electron bromo (or iodo) complex of ruthenium(II) and a C—F bond in one pot

Peter Barthazy, Diego Broggini, and Antonio Mezzetti

Abstract: The 16e$^-$ bromo or iodo complexes $[RuX(dppp)_2]^+$ (dppp = 1,3-bis(diphenylphosphino)propane, X = Br (**1c**), I (**1d**)) and $[RuX(dppe)_2]^+$ (dppe = 1,2-bis(diphenylphosphino)ethane, X = Br (**2c**), I (**2d**)) have been prepared exploiting the reaction of the fluoro complexes $[RuF(dppp)_2]^+$ (**1a**) and $[Tl(\mu\text{-}F)_2Ru(dppe)_2]^+$ (**3**) with activated alkyl bromides or iodides. The X-ray structures of **1c**, **1d, 2c**, and **2d** suggest that the distortion of the Y-shaped trigonal-bipyramidal structure of $[MX(P^\frown P)_2]^+$ is possibly related to the formation of intramolecular hydrogen bonds between the halide ligand and the *ortho*-hydrogen atoms of the neighbouring phenyl rings. The five-coordinate species **1c**, **1d**, **2c**, and **2d** react with H_2 to form the dihydrogen complexes $[RuX(\eta^2\text{-}H_2)(P^\frown P)_2]^+$. The reaction of the dppp derivatives **1c** and **1d** with H_2 (P = 1 atm, 1 atm = 101.322 kPa) is an equilibrium. Quantitative formation of $[RuBr(\eta^2\text{-}H_2)(dppp)_2]$ (**4c**) is obtained under H_2 pressure (100 bar, 1 bar = 100 kPa), whereas the iodo analogue is not stable under analogous conditions. The less crowded dppe derivatives **2c** and **2d** react quantitatively with H_2 under ambient pressure. The iodo and bromo derivatives $[RuX(\eta^2\text{-}H_2)(P^\frown P)_2]^+$ contain elongated dihydrogen ligands, as indicated by their transverse relaxation times T_1 (min). The present data suggest that Cl, Br, and I have similar donor properties in these dihydrogen complexes, and that the different chemical behaviour in the Cl, Br, I series is mainly a result of steric effects.

Key words: 16e$^-$ complexes, ruthenium, fluoro complexes, bromo complexes, iodo complexes, dihydrogen complexes.

Résumé : On a préparé les complexes bromés ou iodés à 16e$^-$ $[RuX(dppp)_2]^+$ (dppp = 1,3-bis(diphénylphosphino)propane, X = Br (**1c**), I (**1d**)) et $[RuX(dppe)_2]^+$ (dppe = 1,2-bis(diphénylphosphino)éthane, X = Br (**2c**), I (**2d**)) en mettant à profit la réaction des complexes fluorés $[RuF(dppp)_2]^+$ (**1a**) et $[Tl(\mu\text{-}F)_2(dppe)_2]^+$ (**3**) avec des bromures ou des iodures d'alkyles activés. Les structures des composés **1c**, **1d**, **2c** et **2d**, déterminées par diffraction des rayons X, suggèrent que la déformation de la structure trigonale-bipyramidale "en forme de Y" du cation $[MX(P^\frown P)_2]^+$ pourrait être reliée à la formation de liaisons hydrogènes intramoléculaires entre le ligand halogénure et les atomes d'hydrogène en *ortho* des noyaux phényles voisins. Les espèces pentacoordinées **1c**, **1d**, **2c** et **2d** réagissent avec H_2 pour former les complexes de dihydrogène $[RuX(\eta^2\text{-}H_2)(P^\frown P)_2]^+$. La réaction des dérivés dppp **1c** et **1d** avec H_2 (P = 1 atm, 1 atm = 101.322 kPa) est un équilibre. On arrive à une formation quantitative du $[RuBr(\eta_2\text{-}H_2)(dppp)_2]$ (**4c**) en opérant sous une pression de 100 bars (1 bar = 100 kPa) de H_2; le dérivé iodé analogue n'est toutefois pas stable dans des conditions analogues. Les dérivés dppe **2c** et **2d**, moins encombrés d'un point de vue stérique, réagissent quantitativement avec H_2, à la pression ambiante. Les dérivés iodés et bromés $[RuX(\eta^2\text{-}H_2)(P^\frown P)_2]^+$ comportent des ligands dihydrogènes "allongés" d'après leurs temps de relaxation transversale, T_1 (min). Les données présentées suggèrent que, dans ces complexes de dihydrogène, les atomes de Cl, Br et I possèdent des propriétés semblables comme donneurs et que le comportement chimique différent des atomes dans la série Cl, Br et I résulte principalement d'effets stériques.

Mots clés : complexes à 16e$^-$, ruthénium, complexes fluorés, complexes bromés, complexes iodés, complexes de dihydrogène.

[Traduit par la Rédaction]

Introduction

Ancillary ligands, such as halides, allow the fine-tuning of the electronic and steric properties of transition-metal complexes. This is particularly important in the case of coordinatively unsaturated complexes with a d^6 electron count such as the ruthenium(II) complexes $[RuX_2P_3]$ (X = halide, P = phosphine donor)[3], $[RuH(X)(CO)P_2]$[4], $[RuX_2NP_2]$ (N = nitrogen donor) (3), [RuX(P)(PCP)] (PCP = pincer ligand with a P_2C donor set) (4), $[RuX(CO)(R)P_2]$ (R = alkyl) (5), $[RuI(H)(\eta^2\text{-}H_2)(PCy_3)_2]$ (6), $[RuClP_2N_2]^+$ (7), or $[RuXP_4]^+$ (8) (P = phosphine donor). We have been studying

Scheme 1.

the 16e⁻ complexes of the type $[MXP_4]^+$ (M = Ru or Os) (8*b*, *c*, g) that exhibit a rich reactivity pattern, including the formation of (η^2-H_2)- (for review articles see ref. 9; for selected examples of H_2-activation by $[RuClP_4]^+$ complexes see ref. 10) and (η^2-O_2)-complexes (11). The halide ligand plays (at least) a twofold role in the stabilization of these five-coordinate complexes. As a bulky ligand, it favours the five-coordinate complexes relative to the corresponding six-coordinate ones as a result of the release of steric crowding in the former. As a π-donor, it stabilizes the 16e⁻ configuration even in the absence of strong σ-donor ligands, such as hydride (12). The resulting formally coordinatively unsaturated complexes adopt a typical distorted (Y-shaped) trigonal-bipyramidal structure to optimize the π-donation from the halide to the 16e⁻ metal center (12).

Recently, the nature of the halide ligand has been shown to play an essential role in a number of catalytic reactions. In particular, the use of fluoride as ligand in transition-metal catalysts, which has been reviewed recently (13). The addition of soluble fluoride sources to catalytic systems based on late transition metals (Pd, Ir) has been found to enhance the enantioselectivity in olefin hydrogenation (14) and hydroamination (15). Five-coordinate 16e⁻ complexes stabilized by π-donor ligands have recently been applied in a number of catalytic reactions that include the transfer hydrogenation of ketones (3*a*, 4*b*), olefin metathesis[5], oligomerization (5*a*, 17), hydrosilylation (3*a*, 18), cyclopropanation (8*g*, 19), and epoxidation (8*g*, 20). Although several types of 16e⁻ complexes are known, the effect of changing the halide ligand has been investigated systematically only for $[RuH(X)(CO)P_2]$ (X = F, Cl, Br, I), showing how their reactivity depends dramatically on the nature of X (21). In the other series, reports of bromo and iodo derivatives are sparse. Thus, besides $[RuCl_2(PPh_3)_3]$, only $[RuBr_2(PPh_3)_3]$ (22) is known in the $[RuX_2P_3]$ series. The five-coordinate vinylidene and vinyl complexes $[RuBr_2(C{=}CH\text{-}t\text{-}Bu)(PPh_3)_2]$ (23) and $[RuBr(CO)(\sigma\text{-}E\text{-}C(H){=}C(H)CH_2PPh_3)(PPh_3)_2]$ (24) have been reported, and the five-coordinate iodo complex $[RuI(PPh_3)(C_6H_3(CH_2NMe_2)_2\text{-}2,6)]$ has been characterized crystallographically (25). Some bromo and iodo five-coordinate complexes of the type $[RuXL_4]^+$ are also known (7*b*, 8*a*, *b*).

We have undertaken a systematic investigation of 16e⁻ complexes that are stabilized by different halides, including fluoride. Thus, we recently reported the fluoro complex $[RuF(dppp)_2]PF_6$ (**1a**), which is prepared by reaction of $[RuCl(dppp)_2]PF_6$ (dppp = 1,3-bis(diphenylphosphino)propane) (**1b**) with TlF (26). Complex **1a** reacts with activated haloalkanes R-X (X = Cl, Br, I) to give the fluoroalkane R-F and the corresponding halo complex $[RuX(dppp)_2]^+$ (X = Cl (**1b**), Br (**1c**), I (**1d**)) (Scheme 1). Reactivity trends for the haloalkanes have been discussed previously (26*b*). The halide-exchange reaction has a potential for both the organic and the inorganic chemist. Indeed, this reaction not only forms a C–F bond (a useful organic synthesis), but also cleanly introduces the desired halide in the five-coordinate complex $[RuX(P^{\frown}P)_2]^+$. This method allows avoidance of the halide metathesis with large excesses of inorganic salts (8*b*), a procedure that can result in mixed-halide complexes (27, 28). In this paper, we show the use of fluoro complexes in the synthesis of the five-coordinate complexes $[RuX(P^{\frown}P)_2]^+$ (X = Br or I, P⌒P = dppp or 1,2-bis(diphenylphosphino)ethane (dppe)) and investigate the reaction of the resulting bromo and iodo complexes with dihydrogen.

Experimental

All operations were carried out under argon using standard Schlenk techniques. All reagents and solvents were Fluka puriss. grade or had comparable purity. $[RuF(dppp)_2]PF_6$ (**1a**) (26), $[RuCl(dppe)_2]PF_6$ (8*d*), and 1,3-diphenylallyl bromide (29) were prepared according to literature methods. ^1H and ^{31}P NMR spectra were recorded on Bruker Avance 250 or 500 MHz spectrometers. Chemical shifts (δ) are in ppm relative to internal $SiMe_4$ (^1H) and to external 85% H_3PO_4 (^{31}P). Relaxation times were measured with a standard inversion–recovery experiment between 303 and 213 K (every 10 K). Equilibrium constants were measured as previously described (10*d*). IR spectra were recorded on a PerkinElmer Paragon 1000 FT-IR spectrophotometer. FAB⁺-MS were measured by the analytical service of Laboratorium für Organische Chemie of the ETH Zürich on a ZAB VSEQ instrument.

$[RuBr(dppp)_2]PF_6$ (1c)

Complex **1a** (22 mg, 20 μmol) and 1,3-diphenylallyl bromide (4.8 mg, 20 μmol) were dissolved in $CDCl_3$ (0.5 mL). Addition of 2-PrOH (1 mL) and evaporation of the $CDCl_3$ yielded a dark-brown crystalline product, which was filtered off and dried under vacuum. Yield: 21 mg (90%). Crystals for X-ray and elemental analyses were obtained by slow evaporation of CH_2Cl_2–2-PrOH solutions of the complex. FAB⁺-MS *m*/*z* (%): 1007 ($[M + H]^+$, 100), 926 ($[M - Br]^+$, 6), 511 ($[Ru(dppp)]^+$, 5). ^1H NMR (250 MHz, $CDCl_3$) δ: 7.80–7.90 (m, 4H, PhH), 7.10–7.60 (m, 24H, PhH), 6.80– 7.00 (m, 12H, PhH), 2.90–3.00 (m, 2H, CH_2), 2.60–2.70 (m, 2H, CH_2), 2.10–2.50 (m, 4H, CH_2), 1.60–1.70 (m, 2H, CH_2), 0.80–0.90 (m, 2H, CH_2). ^{31}P NMR (101 MHz, $CDCl_3$) δ: 43.5 (t, $J_{P,P}$ = 32 Hz), –4.4 (t, $J_{P,P}$ = 32 Hz), –143 (septet, $J_{P,F}$ = 710 Hz, PF_6). Anal. calcd. for $C_{54}H_{52}BrF_6P_5Ru{\cdot}0.25CH_2Cl_2$: C 55.59, H 4.51; found: C 55.63, H 4.63.

[RuI(dppp)$_2$]PF$_6$ (1d)

Complex **1a** (22 mg, 20 μmol) and *t*-BuI (24 μL, 20 μmol) were dissolved in $CDCl_3$ (0.5 mL). After 6 h 2-PrOH (10 mL) was added, and the $CDCl_3$ was evaporated. The resulting dark-green crystalline product was filtered off and dried under vacuum. Yield: 19 mg (81%). Crystals for X-ray and elemental analyses were obtained by slow evaporation of CH_2Cl_2–2-PrOH solutions of the complex. FAB$^+$-MS *m*/*z* (%): 1052 ([M]$^+$, 100), 926 ([M – HI]$^+$, 9). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 8.00–8.05 (m, 4H, PhH), 6.96–7.61 (m, 28H, PhH), 6.85–6.94 (m, 4H, PhH), 6.72–6.82 (m, 4H, PhH), 2.82–3.00 (m, 2H, CH_2), 2.48–2.67 (m, 2H, CH_2), 2.05–2.42 (m, 4H, CH_2), 1.15–1.52 (m, 4H, CH_2). ^{31}P NMR (101 MHz, $CDCl_3$) δ: 31.9 (t, $J_{P,P}$ = 31 Hz), 5.7 (t, $J_{P,P}$ = 31 Hz), –143 (septet, $J_{P,F}$ = 710 Hz, PF_6). Anal. calcd. for $C_{54}H_{52}F_6IP_5Ru\cdot 0.75CH_2Cl_2$: C 52.13, H 4.27; found: C 52.04, H 4.52.

Observation of [RuBr(η^2-H$_2$)(dppp)$_2$]PF$_6$ (4c)

Complex **1c** (20 mg, 17 μmol) was dissolved in $CDCl_3$ (0.5 mL) and treated with H_2 gas (100 bar, 1 bar = 100 kPa). After 1 h of reaction time at room temperature, the pressure was released, and the sample was removed from the autoclave. Its ^{31}P NMR spectrum shows a conversion of 40% to the dihydrogen complex **4c** as well as 60% of unchanged starting material. This sample was used to measure the longitudinal relaxation times (T_1 (min)). ^{1}H NMR (250 MHz, $CDCl_3$) δ: –10.3 (br s, 2H, Ru-(η^2-H$_2$)). ^{31}P NMR (101 MHz, $CDCl_3$) δ: 5.1 (s), –143 (septet, $J_{P,F}$ = 710 Hz, PF_6).

Observation of [RuI(η^2-H$_2$)(dppp)$_2$]PF$_6$ (4d)

Complex **1d** (20 mg, 17 μmol) was dissolved in $CDCl_3$ (0.5 mL) and treated with H_2 gas at 1 atm (1 atm = 101.322 kPa). After 3 h of reaction time, the ^{31}P NMR spectrum of the sample showed the signals of **1d** (93%) and **4d** (7%). ^{1}H NMR (250 MHz, $CDCl_3$) δ: –10.8 (br s, 2H, Ru-(η^2-H$_2$)). ^{31}P NMR (101 MHz, $CDCl_3$) δ: 5.1 (s, 4P, **4d**), –143 (septet, $J_{P,F}$ = 710 Hz, PF_6). After measuring the NMR spectra, the solution was pressurized to 100 bar H_2 for 16 h in an autoclave, the pressure was released, and the ^{1}H and ^{31}P NMR spectra were recorded again.

[RuBr(dppe)$_2$]PF$_6$ (2c)

Complex **3** (24 mg, 20 μmol) and 1,3-diphenylallyl bromide (4.8 mg, 20 μmol) were dissolved in $CDCl_3$ (0.5 mL). After 24 h of reaction time, addition of 2-PrOH (1 mL) and evaporation of the $CDCl_3$ precipitated a dark-brown crystalline product. Yield: 20 mg (86%). Crystals for X-ray and elemental analyses were obtained by slow evaporation of CH_2Cl_2–2-PrOH solutions of the complex. FAB$^+$-MS *m*/*z* (%): 979 ([M(^{81}Br)]$^+$, 100), 977 ([M(^{79}Br)]$^+$, 89), 897 ([M – HBr]$^+$, 16), 497 ([Ru(dppe)]$^+$, 3). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 7.76–7.82 (m, 4H, PhH), 7.53–7.62 (m, 2H, PhH), 7.13–7.39 (m, 18H, PhH), 6.95–7.03 (m, 12H, PhH), 6.74–6.81 (m, 4H, PhH), 2.38–2.65 (m, 6H, CH_2), 1.40–1.62 (m, 2H, CH_2). ^{31}P NMR (101 MHz, $CDCl_3$) δ: 81.1 (t, $J_{P,P}$ = 12 Hz), 58.4 (t, $J_{P,P}$ = 12 Hz), –143 (septet, $J_{P,F}$ = 710 Hz, PF_6). Anal. calcd. for $C_{52}H_{48}BrF_6P_5Ru\cdot CH_2Cl_2$: C 52.71, H 4.17; found: C 52.94, H 4.46.

[RuI(dppe)$_2$]TlI$_4$ (2d)

Complex **3** (128 mg, 0.1 mmol) and *t*-BuI (0.6 mL, 0.5 mmol) were dissolved in CH_2Cl_2 (10 mL). Addition of 2-PrOH (10 mL) and evaporation of the $CDCl_3$ precipitated a dark green-brown crystalline product. Yield: 156 mg (90%). FAB$^+$-MS *m*/*z (%)*: 1153 ([M + I]$^+$, 100), 897 ([M – HI]$^+$, 50). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 7.85–7.93 (m, 4H, PhH), 7.59–7.66 (m, 2H, PhH), 6.88–7.50 (m, 30H, PhH), 6.70–6.89 (m, 4H, PhH), 2.31–2.75 (m, 6H, CH_2), 1.75–1.96 (m, 2H, CH_2). ^{31}P NMR (101 MHz, $CDCl_3$) δ: 75.4 (t, $J_{P,P}$ = 12 Hz), 65.3 (t, $J_{P,P}$ = 12 Hz), –143 (septet, $J_{P,F}$ = 710 Hz,

PF_6). Anal. calcd. for $C_{52}H_{48}I_5P_4RuTl \cdot 0.75CH_2Cl_2$: C 35.19, H 2.77; found: C 35.43, H 2.95.

Observation of $[RuBr(\eta^2\text{-}H_2)(dppe)_2]PF_6$ (5c)

Complex **2c** (24 mg, 21 μmol) was dissolved in $CDCl_3$ (0.5 mL) and treated with gaseous H_2 (1 bar, 4 h). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 7.24–7.37 (m, 24H, PhH), 6.98–7.08 (m, 16H, PhH), 2.78–3.01 (m, 4H, CH_2), 2.21–2.46 (m, 4H, CH_2), –11.4 (br s, 2H, Ru-η^2-H_2). ^{31}P NMR (101 MHz, $CDCl_3$) δ: 50.9 (s), –143 (septet, $J_{P,F}$ = 710 Hz, PF_6).

Observation of $[RuI(\eta^2\text{-}H_2)(dppe)_2]TlI_4$ (5d)

Complex **2d** (24 mg, 20 μmol) was dissolved in $CDCl_3$ (0.5 mL) and treated with H_2 gas (1 bar, 10 min). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 7.41–7.53 (m, 4H, PhH), 7.29–7.36 (m, 12H, PhH), 7.10–7.15 (m, 24H, PhH), 3.07–3.22 (m, 4H, CH_2), 2.40–2.57 (m, 4H, CH_2), –10.6 (br s, 2H, Ru-η^2-H_2). ^{31}P NMR (101 MHz, $CDCl_3$) δ: 47.3 (s), –143 (septet, $J_{P,F}$ = 710 Hz, PF_6).

X-ray structure determinations

Crystals of the complexes were grown by slow evaporation of CH_2Cl_2–*i*-PrOH solutions. Crystallographic data for **1c**, **1d**, **2c**, and **2d** are summarized in Table 1.[6]

1c

Dark-brown platelet. Data were collected on a four-circle Syntex $P2_1$ diffractometer. Unit cell dimensions determination and data reduction were performed by standard procedures. No absorption correction was applied. The structures were solved with SHELXS 96 using direct methods, and refined by full-matrix least-squares on F^2 with anisotropic displacement parameters for all non-H atoms. In addition to the complex cation and $[PF_6]^-$, the unit cell contains one CH_2Cl_2 molecule. Of the 2609 unique reflections with index ranges $0 \le h \le 11$, $0 \le k \le 14$, $14 \le l \le 14$, 2362 with $F > 2.0\sigma(F)$ were used in the refinement (631 parameters). Disordered atoms were refined isotropically. Hydrogen atoms were introduced at calculated positions, and refined with the riding model and individual isotropic thermal parameters for each group. Max and min difference peaks +0.636 and –0.795 e Å^{-3}; largest and mean Δ/σ = –0.003 and 0.000.

1d

Dark-green prism. Data were collected on a Siemens CCD SMART area detector system equipped with a normal focus Mo-target X-ray tube. Unit cell dimensions determination and data reduction were performed by standard procedures. An empirical absorption correction (SADABS) was applied. The structures were solved with SHELXS 96 using direct methods, and refined by full-matrix least-squares on F^2 with anisotropic displacement parameters for all non-H atoms. In addition to the complex cation and $[PF_6]^-$, the unit cell contains one CH_2Cl_2 molecule. Of the 9630 unique reflections with index ranges $-14 \le h \le 4$, $-17 \le k \le 18$, $-18 \le l \le 19$, 5908 with $F > 2.0\sigma(F)$ were used in the refinement (631 parameters). Max and min difference peaks +0.52 and –0.73 e Å^{-3}; largest and mean Δ/σ = 0.574 and 0.038.

2c

Dark-brown prism. Data collection, structure solution, and refinement were as described for **1d**. In addition to the complex cation and $[PF_6]^-$, the unit cell contains one severely disordered CH_2Cl_2 molecule, whose atomic positions were not refined. Of the 7390 unique reflections with index ranges

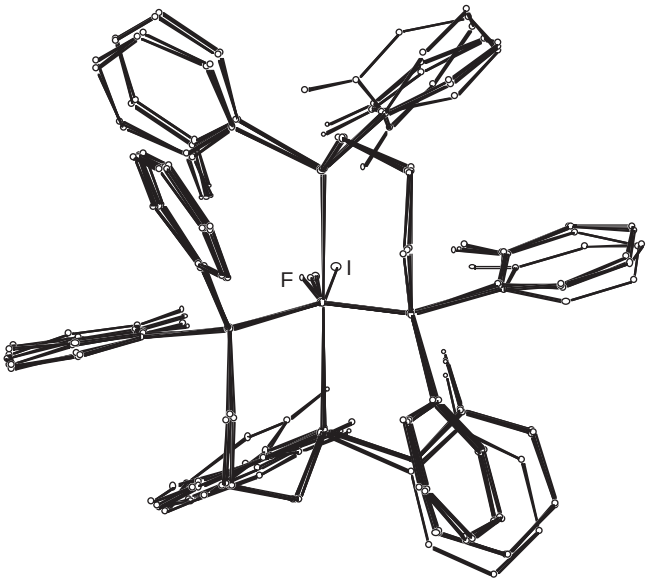
Note: Halogen data from J. E. Huheey, E. A. Keiter and R. L. Keiter. Inorganic chemistry: Principles of structure and reactivity. Harper Collins, New York, N.Y. 1993. p. 991.
[a]Calculated from the values of the van der Waals radius r_{vdW} and the experimental Ru—X distance.
[b]Calculated from atomic coordinates in ref. 30.
[c]$\Delta(d(X\cdots H)_{av})$ is the difference between the sum of the van der Waals radii of C and H ($r_{vdW}(C) + r_{vdW}(H)$) and the average of the four shortest C···H contacts ($d(X\cdots H)_{av}$).

$-13 \le h \le 7$, $-17 \le k \le 17$, $-29 \le l \le 29$, 5711 with $F > 2.0\sigma(F)$ were used in the refinement (586 parameters). Max and min difference peaks +0.64 and –0.80 e Å^{-3}; largest and mean Δ/σ = –0.005 and 0.000.

2d

Dark-green brown prism. Data collection and structure solution and refinement were as described for **1d**. The unit cell contains two crystallographically independent complex cations, two independent $[TlI_4]^-$ anions, one CH_2Cl_2 molecule in general positions, and a second CH_2Cl_2 molecule (0.5 occupancy) whose C atom lies close to a binary axis. Of the 28 299 unique reflections with index ranges $-22 \le h \le 19$, $-24 \le k \le 23$, $-26 \le l \le 23$, 14 820 with $F > 2.0\sigma(F)$ were used in the refinement (1175 parameters). Max and min difference peaks +1.46 and –1.47 e Å^{-3}; largest and mean Δ/σ = –0.298 and 0.003.

Results and discussion



$[RuX(dppp)_2]^+$

The reaction of the fluoro complex $[RuF(dppp)_2]PF_6$ (**1a**) (26*a*) with 1,3-diphenylallyl bromide gives $[RuBr(dppp)_2]PF_6$ (**1c**) as shown in Scheme 1.[7]

[7]Complex **1c** has been previously prepared from $[RuBr_2(PPh_3)_3]$ (8*a*).

© 2001 NRC Canada

Fig. 3. Superposed structure drawings of **1a**–**d**.

The reaction is instantaneous at room temperature and gives the already known bromo complex in essentially quantitative yield. Alternatively to 1,3-diphenylallyl bromide, Ph_2CHBr or $(CH_3)_3CBr$ can be used as source of bromide. The iodo analogue $[RuI(dppp)_2]PF_6$ (**1d**) was prepared by reaction of **1a** with *tert*-butyl iodide (Scheme 1). The substitution reaction occurs within 5 h at room temperature and is favoured with respect to the elimination reaction, as only 9% of isobutene is formed with *t*-BuI. In contrast, *t*-BuBr reacted with **1a** only at 50°C giving isobutene as the major product, but with a quantitative yield of **1c** (26*a*). The identity of the fluoro alkyls and their yield have been ascertained as previously described (26). In the present paper, we focus the attention on the characterization of inorganic counterpart, i.e., the $[RuX(P^{\frown}P)_2]^+$ complexes (X = Br or I).

To study the effect of the diphosphine ligand parallel to that of the halide, we attempted the synthesis of the dppe analogue of **1a**, i.e., $[RuF(dppe)_2]PF_6$ by the same method followed for **1a** (halide exchange with TlF). Instead of the expected five-coordinate fluoro complex, the reaction of $[RuCl(dppe)_2]PF_6$ (**2b**) (8*d*) with TlF gave a doubly F-bridged thallium adduct $[Tl(\mu\text{-}F)_2Ru(dppe)_2]PF_6$ (**3**).[8] However, complex **3** reacts with alkyl bromides or iodides in the same way as **1a**. Thus, $[RuBr(dppe)_2]PF_6$ (**2c**) was obtained by treating **3** with 1,3-diphenylallyl bromide. Also, the reaction of **3** with *tert*-butyl iodide yielded $[RuI(dppe)_2]TlI_4$. However, in this case the Tl(I) ion activates the C–I bond, and $[TlI_4]^-$ is formed. Therefore, the reaction only goes to completion when an excess of *t*-BuI is added (approximately 5 equiv). Under these conditions, we isolated crystals of $[RuI(dppe)_2]TlI_4$ (**2d**), which contained tetraiodothallate(III) as counterion.

As a general comment, it should be noted that the above procedure requires neither the use of bromide- or iodide-containing precursors, nor the halide metathesis carried out with large excesses of halide salts (8*b*, *c*). Moreover, as the fluoride ion is effectively scavenged by the formation of R-F (or, in part, of HF), this method is safe with respect to the formation of mixed-halo complexes, whereas halide metathesis starting from chloro complexes occasionally fails because of the higher affinity of ruthenium(II) for chloride than for bromide or iodide (27, 28). Furthermore, the synthesis via the fluoro complexes **1a** and **2a** can also be applied in the cases where a suitable starting material is not available (e.g., a metal salt), which is the case of the iodo derivatives.

The characterization of **1c**, **1d**, **2c**, and **2d** is based on elemental analyses, FAB^+-MS, and ^{31}P and ^1H NMR spectroscopy. Additionally, their structures were determined crystallographically. As already observed for the fluoro and chloro analogues **1a** and **1b**, the ^{31}P NMR spectra of **1c** and **1d** are static at room temperature, which indicates that the exchange process between the axial and equatorial phosphines is slow on the NMR time-scale at 20°C. The AA′XX′ spin systems are indicative of C_2 symmetry. Also **2c** and **2d** give static AA′XX′ spectra at room temperature. The complexes have dark-brown (**1c**, **2c**), dark-green (**1d**), or intermediate colours (**2d**), and are stable in dichloromethane or chloroform solution for several days under inert gas.

X-ray structures of $[RuX(dppp)_2]^+$ (X = F, Cl, Br, I)

To get some insight into the effect of the halide on the structural features of the whole series $[RuX(dppp)_2]^+$ (X = F (**1a**), Cl (**1b**), Br (**1c**), I (**1d**)), we determined the X-ray structures of the new five-coordinate complexes **1c** and **1d** (Figs. 1 and 2, respectively), which will be discussed jointly and compared with those of the already known **1a** (26) and **1b** (30) (Table 2). The crystals of **1b**, **1c**, and **1d** are isomorphous, whereas **1a** crystallizes in the $P2_1/n$ space group with $Z = 4$ (Table 1).

The most striking aspect is the similarity of the five-coordinate structure throughout the series. The largest difference is obviously the Ru—X distance, which is expected to be indicative of the presence of a π-component of the Ru–X bond. Indeed, all Ru—X distances are in the lower range observed for the corresponding halide. The Ru—Br distance in **1c** (2.491(2) Å) is slightly shorter than the average observed for ruthenium bromo complexes (2.52(4) Å) (31). This value compares with the Ru—Br distances of other $16e^-$ bromo complexes reported, i.e., $[RuBr_2(PPh_3)_2]$ (2.515(1) and 2.526(1) Å) (22), $[RuBr_2(C{=}CH\text{-}t\text{-}Bu)(PPh_3)_2]$ (2.469(2) and 2.460(2) Å) (23), and $[RuBr(CO)(\sigma\text{-}E\text{-}C(H){=}C(H)CH_2PPh_3)(PPh_3)_2]$ (2.541(2) Å) (24). Taken together, however, these data do not show an unambiguous correlation between the Ru—Br bond length and the electron count of the metal.

In the iodo derivative **1d**, the Ru—I distance of 2.705(1) Å is close to the one of 2.710(1) Å observed in the $16e^-$ complex $[RuH(I)(\eta^2\text{-}H_2)(PCy_3)_2]$ (6). These compare with the Ru—I distances in six-coordinate Ru(II)-complexes from the CSD database, whose average and lower quartile are 2.74(3) and 2.716 Å, respectively, (31). The much longer Ru—I distance (2.8025(4) Å) found in the five-coordinate $[RuI(PPh_3)(C_6H_3(CH_2NMe_2)_2\text{-}2,6)]$ (25) is possibly a result of the high *trans* influence of the aryl ligand that occupies the position *trans* to I.

[8] Details of the preparation and characterization of **3** will be published elsewhere.

[a]From ref. 8*d*. Atoms have been renumbered for consistency with **2c** and **d**.

It has been proposed that the π-donation decreases in the series F > Cl > Br > I (32). However, comparison of the data of **1** suggests that the increase of the Ru—X bond length (Δd_{Ru-X}) along the series F, Cl, Br, and I parallels the increase of the covalent radius of the halogens (Δr_{cov}) (Table 3). Thus, the effect if any, is too small to be observed by X-ray crystallography.

Whatever the contribution of the π-donation from the halide ligand may be, all complexes show the typical geometrical features of the Y-shaped coordination that have been observed in a number of five-coordinate complexes of *d* metal ions (12). Thus, the equatorial P-Ru-P angle is reduced to a value close to 90°. This distortion rehybridizes the empty d_{xy} orbital towards the halide ligand and maximizes its overlap with one doubly occupied p_π orbital of the halide (12). In **1c** and **1d**, the two equatorial phosphorus atoms, the halide, and the ruthenium are coplanar within ±0.02 Å.

Interestingly, the average Ru—P distances remain constant throughout the series (2.34 Å for **1a**–**c** and 2.35 Å for **1d**), which is a strong indication that **1a**–**d** are very similar, both electronically and sterically. The bite angles of the chelate (88 and 89°) in the four dppp complexes **1a**–**d** match the usual value found for this ligand (26, 30). In **1a**–**d** the angles formed by an equatorial and axial phosphorus in different ligands is opened up to 95–98°, which is probably due to the sterically demanding Ph_2P groups.

The superimposition of molecular diagrams of the four complexes $[RuX(dppp)_2]^+$ (X = F, Cl, Br, or I) reveals a further structural trend (Fig. 3). The RuP_4 units fit nearly perfectly, as well as the phenyl groups on the equatorial P atoms (P_{eq}). In contrast, the position of the halide ligand changes monotonously on going from F to I. Inspection of the P_{eq}-Ru-H angles indicates that the Y-shape of the equatorial plane becomes more symmetric on going from F to I. In fact, an intriguing feature of many Y-shaped $16e^-$ complexes is the asymmetry of the Y-frame in the equatorial plane, which results in two largely different P_{eq}-M-P_{eq} angles (12*b*). In the case of the iridium-complexes $[IrX(QPh_3)_2(biph)]$ (Q = P or As; biph = biphenyl-2,2′-diyl), a hybrid quantum mechanical – molecular mechanics method predicts a C_2-symmetric structure instead, and it has been suggested that the distortion of the Y-frame is a result of steric effects (33). This distortion of the C_2-symmetric structure has been described in the case of $[IrX(QPh_3)_2(biph)]$ by means of φ, the angle between the M–X vector, and the ideal binary axis bisecting the L_{eq}-M-L_{eq} angle (L_{eq} is C in this case) (33). We have calculated the φ values for the complexes of the series $[RuX(dppp)_2]^+$ (**1a**–**d**) (Table 2). The data show clearly that fluoride gives the largest deviation from the C_2 symmetry, and that φ decreases on going to the heavier halides. The reason for this fact is not evident, and we tentatively suggest an explanation below.

First, it should be considered that although the cone angle remains nearly constant in the series F, Cl, Br, and I, the actual size of the halide does increase along these series as indicated by the van der Waals radii (Table 3). Figure 3 shows that the pocket formed by the four axial and two equatorial phenyl groups can also accommodate the largest halide(iodide) without major distortions. Thus, it is not evident why the smallest halide (fluoride) gives the larger distortion from the electronically favoured structure, and why the deviation from the ideal Y-shaped geometry decreases on going from **1a** to **1d**. The only explanation we can think of is based on the analysis of the nonbonded distances between the halide ligand and the *ortho*-hydrogen atoms of the neighbouring phenyl groups (Table 2). All four complexes exhibit short X···H-C contacts to the *ortho*-H atoms of the neighbouring phenyl rings. In the case of the fluoro analogue **1a**, the average of the four shortest F···H-C contacts between the disordered F atom and the *ortho*-H atoms of the phenyl rings are 0.38 Å shorter than the sum of the van der Waals radii of fluorine and hydrogen (ca. 2.7 Å) (26*b*), but the disorder of the fluoro ligand precludes a closer analysis. The chloro analogue **1b** shows four X—C distances that are shorter than 3.0 Å, the sum of the van der Waals radii of Cl and H. The Cl···H-C angles are in a range compatible with hydrogen bonding (137–169°) (Table 2). Two H atoms H(8) and H(44) lie further away. This pattern remains qualitatively similar in the bromo and iodo derivatives **1c** and **1d**, which exhibit X···H-C contacts ca. 0.4 Å shorter than the sum of the van der Waals radii (Table 3).

The above data suggest that the breakdown of the C_2 symmetry in the complexes of the lighter halides is due to an "attractive interaction" between the halide ligand and the C–H bonds of the neighbouring phenyl rings. A repulsive in-

teraction would not explain why the smallest halide (fluoride) gives the largest distortion ϕ. Furtermore, the smallest P_{eq}-Ru-X angle is the one involved in the shortest X···H-C contacts, i.e., P(2)-Ru-X. Such interactions are apparently the hydrogen bonds X···H-C, whose structural features have been discussed above. Thus, the smaller and more electronegative halides move away from the pseudo-C_2 axis to optimize the contact to one of the equatorial phenyl rings.

The problem of the existence and relevance of C-H···B hydrogen bonds in crystals (B is a hydrogen bond acceptor) has been recently reviewed (34). Short C-H···Cl contacts involving chloride ions, found in a number of neutron-diffraction crystal structures, have been interpreted as hydrogen bonds (35). Moreover, the $16e^-$ complex $[RhCl_2(Ph)(PPh_3)_2]$ exhibits two short contacts (2.72(1) Å) to *ortho*-H atoms from the phenyl groups of PPh_3 that have been interpreted as hydrogen bonds on the basis of DFT calculations (36). A word of caution is required in the case of **1a**–**d**, as the X···H-C distances are based on "calculated" hydrogen positions (C—H = 1.00 Å) from X-ray data, and thus accurate H atom positions are not available. However, we consider these data as fairly significant because the van der Waals radii used are those calculated for Ru—X bonds in organic compounds (i.e., $CHCl_3$), which are considerably less polar than metal–halide bonds (37). Indeed, the ionicity of the metal–chloride bond increases the effective van der Waals radius of chloride to a value larger than 1.75 Å calculated for C—Cl bonds (37). Similar, albeit smaller, effects are expected for Br and I.

As a final comment, it should be noted that weaker Cl···H-C interactions are expected for an alyphatic than for an aromatic C–H bond. Indeed, $[RuCl(dcpe)_2]^+$ (dcpe = 1,2-bis(dicyclohexylphosphino)ethane) (8*b*), which contains cyclohexyl instead of phenyl groups, also features short Cl···H-C contacts to α-carbon atoms of three axial and one equatorial cyclohexyl groups (2.47, 2.69, 2.77, and 2.92 Å). However, as expected, the mean value of these contacts (2.71 Å) is slightly larger than in **1b** (2.66 Å).

X-ray structures of $[RuX(dppe)_2]^+$ (X = Cl, Br, I)

In the dppe series $[RuX(dppe)_2]^+$ (X = Cl (**2b**), Br (**2c**), I (**2d**)), the crystals of **2b** and **2c** are isomorphous, whereas those of **2d** are not, owing to the presence of the $[TlI_4]^-$ anion. The crystal of **2d** contains two crystallographically independent complex cations and two independent $[TlI_4]^-$ anions. All nonbonded Ru···Tl distances are longer than 9 Å, and the closest contacts between $[RuI(dppe)_2]^+$ and $[TlI_4]^-$ occur between the iodine atoms and the phenyl rings of dppe.

In the dppe series, the trend of the Ru—X bond lengths is less regular than in the $[RuX(dppp)_2]^+$ complexes. In particular, the Ru—Br distance in **2c** is somewhat longer than expected (Table 4). In **2c**, the two equatorial phosphorus atoms, the bromine, and the ruthenium lie in a perfect plane. In contrast, in **2d**, the iodo ligand is displaced by 0.11 Å from the Ru-P(1)-P(3) plane towards P(4). In both complexes, a further distortion derives from the bite angle of the dppe ligand (ca. 80°).

Interestingly, the equatorial plane of **2b**–**d** has a much more symmetric Y-shape than the dppp series **1a**–**d** (Figs. 4 and 5), as shown by the values of the ϕ angle (Table 4). We suggest that the C_2 symmetry is imposed by the 1,2-ethanediyl bridge of dppe, which is less flexible than the 1,3-propanediyl framework of dppp. Indeed, the "edge on" axial-phenyl groups C(13)–C(18) and C(38)–CC(43) of the dppp derivatives are pinned back as compared with the dppe complexes owing to the smaller chelate ring. Taking the bromo derivatives as example, one sees that H(26) and H(48) are 5.71 Å apart in $[RuBr(dppe)_2]^+$ (**2c**), whereas the equivalent H atoms of $[RuBr(dppp)_2]^+$ (**1c**), H(18) and H(38), are only 5.35 Å apart. Thus, in the dppp complex **1c**, the "edge on" axial-phenyl groups come closer to the halide than in **2c**, and the corresponding hydrogen bonds are shorter (2.83 and 2.67 Å vs. 2.93 and 2.96 Å). Under such conditions, the bromo ligand in **1c** forms short hydrogen bonds (<2.8 Å) to one equatorial phenyl (H(24)) and two axial ones (H(32) and H(38)). As all these Br··· contacts lie in

X = Br (**4c**)
X = I (**4d**)

the same quadrant, their shortening goes at the expense of the H(44)···Br contact to the other equatorial phenyl, which is stretched to 3.07 Å. In contrast, the axial phenyl rings are essentially out of reach in the dppe complex **2c**, and the shortest contacts of the bromo ligand involve both equatorial phenyl rings. The Br···H—C contacts with the *ortho*-H atoms H(4) and H(30) are 2.86 and 2.81 Å, respectively. Thus, the X···H—C interactions in the dppe complexes **2** are distributed symmetrically and the Y-shape is least distorted.

In conclusion, we suggest that the higher flexibility of dppp as compared to dppe favours the formation of short hydrogen bonds to the axial phenyl groups and allows the formation of three short contacts within one quadrant. The latter feature enhances the asymmetry of the Y-shape in the dppp complexes.

$[RuX(\eta^2\text{-}H_2)(P^{\frown}P)_2]^+$

The 16e$^-$ complexes $[RuX(P^{\frown}P)_2]^+$ (X = H or Cl) are known to react with H_2 to give the corresponding dihydrogen complexes $[RuX(\eta^2\text{-}H_2)(P^{\frown}P)_2]^+$ (**4**) (9, 10). The properties of the complexes of type **4** strongly depend on nature of the ancillary ligand X. Thus, hydrido-complexes of d^6 metals such as $[MH(\eta^2\text{-}H_2)(P^{\frown}P)_2]^+$ generally feature a rapidly spinning (η^2-H_2) ligand with low acidity (9, 38), whereas their chloro analogues $[MCl(\eta^2\text{-}H_2)(P^{\frown}P)_2]^+$ contain elongated dihydrogen ligands (8*d*, 10). Moreover, both calculation and experiment show that the introduction of a halide as ancillary ligand enhances the acidity of the dihydrogen ligand, which makes the complexes of the type $[RuCl(\eta^2\text{-}H_2)(P^{\frown}P)_2]^+$ interesting for the heterolytic activation of dihydrogen (8*d*, 10*d*, 38–40). Thus, we investigated the reactivity of the bromo and iodo derivatives **1c**, **1d**, **2c**, and **2d** toward dihydrogen (Scheme 2). The resulting dihydrogen complexes $[RuX(\eta^2\text{-}H_2)(P^{\frown}P)_2]^+$ where characterized by ^{1}H and ^{31}P NMR and the minimum relaxation times of the (η^2-H_2) ligand (Table 5). Based on the singlet observed in the ^{31}P NMR spectrum, all dihydrogen complexes are formed as the *trans*-isomer.

The bromo derivative **1c** reacts with H_2 to give the dihydrogen complex $[RuBr(\eta^2\text{-}H_2)(dppp)_2]^+$ (**4c**). The formation of **4c** is an equilibrium reaction as already observed for $[RuCl(dppp)_2]^+$ (**1b**) (10*d*). When a 4×10^{-3} mol L^{-1} solution of **1c** is treated with 1 atm H_2 (1 atm = 101.322 kPa) for 24 h of reaction time, the resulting solution contains 90% of **1c** and 10% of the dihydrogen complex **4c**. The resulting equilibrium constant (*K*) of **1c** is 45, which compares with the value of 72 found for the chloro analogue **1b** (10*d*). The equilibrium is driven to completion when **1c** is treated with H_2 under high pressure (100 bar) in an autoclave for 24 h of reaction time.

The iodo analogue **1d** gives $[RuI(\eta^2\text{-}H_2)(dppp)_2]^+$ (**4d**) by reaction with H_2 at 1 atm. In a 1×10^{-3} mol L^{-1} solution of **1d**, 7% of starting **1d** is converted into **4d** after 3 h of reaction time. Complex **4d** is stable only for limited periods of time (ca. 12 h), and slowly reacts to give the already known $[RuH(\eta^2\text{-}H_2)(dppp)_2]$ and additional unidentified products. We estimate a constant *K* of 16 (under 1 atm H_2) for the equilibrium between **1d**, **4d**, and H_2 based on ^{1}H NMR measurements. Under these conditions the decomposition is slow, and **1d** and **4d** are the only complexes observed by ^{31}P NMR spectroscopy. We attempted to prepare the iodo derivative $[RuI(\eta^2\text{-}H_2)(dppp)_2]^+$ by reacting **1d** with H_2 in an autoclave under 100 bar H_2. However, the dihydrogen complex is formed in minor amounts (ca. 6%) together with the already known $[RuH(\eta^2\text{-}H_2)(dppp)_2]^+$ (ca. 13%) and other unidentified products after 16 h of reaction time. The hydride(dihydrogen) complex $[RuH(\eta^2\text{-}H_2)(dppp)_2]^+$ is apparently formed by elimination of HI from **4d**, followed by readdition of H_2, a reaction that has been observed for the reaction of the fluoro derivative $[RuF(dppp)_2]^+$ with H_2 (26*b*).

In contrast to the dppp complexes, the dppe derivatives **2c** and **2d** react quantitatively with H_2 at atmospheric pressure to give $[RuX(\eta^2\text{-}H_2)(dppe)_2]^+$ (X = Br (**5c**), I (**5d**)). The complexes $[RuX(\eta^2\text{-}H_2)(P^{\frown}P)_2]^+$ (X = halide) such as **4** and **5** are typical elongated dihydrogen complexes. Such complexes have attracted the attention both of synthetic chemists (6, 10) and of theoreticians (38, 40[9], 41) due to the enhanced

[9]For a review of theoretical studies of dihydrogen complexes, see ref. 9.

© 2001 NRC Canada

acidity and the puzzling nature of their dihydrogen ligand. The data in Table 5 show that the properties of the (η^2-H_2) ligand mainly depend on the nature of the diphosphine ligand, whereas the choice of the halide primarily affects the reactivity of $[RuX(P^{\frown}P)_2]^+$ with H_2. As for the effect of the halide ligand on the elongation of the dihydrogen ligand, it should be noted that the T_1 (min) data are nearly constant within each series **4b**, **4c**, and **5b**–**d**. Thus, the T_1 (min) values of **5b**–**d** can be considered identical within experimental error, and the *d*(H—H) bond length remains substantially unchanged troughout the halide series. Hence, the H—H distances in the bromo and iodo derivatives **4c**, **4d**, **5c**, and **5d** are close to those of the corresponding chloro derivatives **4b** and **5b** (1.02 and 1.16 Å, respectively), which were estimated from the value of the $J_{D,H}$ coupling constant (10*d*, 8*d*).

The insensitivity of the T_1 (min) values on the nature of X both in the dppp and in the dppe complexes indicates that the donor properties of the chloro, bromo, and iodo ligands are very similar. As there is ongoing debate on the electronic effects of halide ligands (37, 38, 40, 41), this result is in no way obvious. However, if one accepts that the slight differences observed are significant, then the T_1 (min) data suggest a slight increase of the electron density at the metal on going from Cl to I. This is not necessarily an effect of the π-donor capability of X alone, as the σ-donation (which is larger for iodide) also contributes. It is possible that the decrease of π-donor ability on going down the halide group (32) is counterbalanced by the increased σ-donation in the same sequence (39). In any case, it should be noted that an increase of the T_1 (min) values on going from chloride to bromide for the osmium analogues $[OsX(\eta_2\text{-}H_2)(dppe)_2]^+$ (X = Cl, Br) has been reported by Morris and co-workers (10*e*), although no effect on the *d* (H—H) distance was observed. Unfortunately, we do not have reliable *d* (H—H) values, as the $J_{D,H}$ coupling constants of **4b**, **4c**, and **5b**–**d** are not yet available.

The most remarkable effect of changing the halide is observed in the *K* values of the formation of the dppp derivatives **4** (Table 5). In contrast, the less crowded dppe derivatives **5b**–**d** also give stable dihydrogen complexes with iodide. Taken together, the above observations suggest that changing the halide ligand (Cl, Br, or I) affects the steric crowding of the complex rather than the electron density of the metal. Indeed, although the cone angle remains roughly constant from Cl to I, the van der Waals radius of X increases along the series (Table 3). The position of the equilibrium in Scheme 2 depends on the relative stability of the six-coordinate complex **4** relative to the five-coordinate complex **1**. Ceteris paribus, an increase of the coordination number from 5 to 6 increases the crowding of the complex. The X-ray structure of the osmium analogue $[OsCl(\eta^2\text{-}H_2)(dppp)]^+$ shows that the chloride ligand is fully embedded into a pocket formed by four phenyl groups (10*d*). In this kind of arrangement, the crowding around the metal depends on the van der Waals radius of X rather than on the cone angle, which explains why the stability of the dihydrogen complexes decreases along the series Cl > Br > I owing to increasing crowding in the six-coordinate complex. This is also an indication that besides π-donation, steric factors play an important role in the stabilization of the 16e$^-$ complexes of the heavier halogens as they destabilize the corresponding six-coordinate complexes (7*b*, 8*b*).

Finally, it is noteworthy that the hydrogenolysis of the Ru–X bond is the main reaction at both ends of the F, Cl, Br, and I series. Indeed, both $[RuF(dppp)_2]^+$ and $[RuI(dppp)_2]^+$ form (either quantitatively or in part) $[RuH(\eta^2\text{-}H_2)(dppp)_2]^+$ upon reaction with H_2. In the case of **1a**, we speculated that $[RuH(\eta^2\text{-}H_2)(dppp)_2]^+$ is formed by dissociation of the thermodynamically stable HF from the putative $[RuF(\eta^2\text{-}H_2)(dppp)_2]$ followed by addition of H_2. In the case of $[RuI(\eta^2\text{-}H_2)(dppp)_2]^+$, the same reaction may be triggered by the acidity of the dihydrogen ligand, as iodide is a much weaker base than fluoride. Indeed, a recent theoretical study has shown that the pseudo-aqueous pK_a value of $[MX(\eta^2\text{-}H_2)(H_2PCH_2CH_2PH_2)_2]$ (M = Ru, Os) increases on going from X = F to Br (38). Future work will be directed to assessing the acidity of the $[RuX(\eta^2\text{-}H_2)(P^{\frown}P)_2]^+$ complexes.

Conclusions

The reaction of the fluoro complex $[RuF(dppp)_2]^+$ affords easy access to five-coordinate bromo and, in particular, iodo complexes of ruthenium(II). In turn, the latter complexes are interesting for the investigation of steric and electronic effects of the heavier halogens as ancillary ligands in 16e$^-$ complexes. Preliminary results on H_2 activation suggest that Cl, Br, and I are very similar electronically, which is not obvious in view of their different electronegativities. Thus, one can take advantage of their different size to tune the steric properties of five-coordinate complexes (and of their six-coordinate addition products), while keeping the electron density at the metal constant.

Acknowledgement

We thank Dr. Heinz Rüegger (Laboratory of inorganic chemistry, ETH-Zürich) for the ^{1}H NMR spectroscopic measurements (T_1 (min)).

Hydrogen transfer from formic acid to alkynes catalyzed by a diruthenium complex

Yuan Gao, Michael C. Jennings, and Richard J. Puddephatt

Abstract: The diruthenium(0) complex $[Ru_2(\mu\text{-}CO)(CO)_4(\mu\text{-}dppm)_2]$ (**1**) (dppm = $Ph_2PCH_2PPh_2$), is a catalyst for the transfer hydrogenation, using formic acid as hydrogen donor, of the alkynes PhC≡CPh, PhC≡CMe, EtC≡CEt, and PrC≡CPr but not of the terminal alkynes HC≡CH, PhC≡CH, BuC≡CH, or the alkynes containing one or two electron-withdrawing substituents PhC≡CCO_2Me and MeO_2CC≡CCO_2Me. In the successful reactions, the formic acid is first decomposed to carbon dioxide and hydrogen, which then hydrogenates the alkynes in a slower reaction. In the unsuccessful reactions, the decomposition of formic acid is strongly retarded by the alkyne. In the case with the alkyne PhC≡CH, it is shown that the alkyne reacts with protonated **1** to give first $[Ru_2(\mu\text{-}CPh{=}CH_2)(CO)_4(\mu\text{-}dppm)_2][HCO_2]$, which then isomerizes to give the catalytically inactive, stable complex $[Ru_2(\mu\text{-}CH{=}CHPh)(CO)_4(\mu\text{-}dppm)_2][HCO_2]$. This complex has been structurally characterized and both of the μ-styrenyl complexes are shown to be fluxional in solution.

Key words: ruthenium, hydrogenation, catalysis, binuclear.

Résumé : Le complexe de diruthénium(0) $[Ru_2(\mu\text{-}CO)(CO)_4(\mu\text{-}dppm)_2]$ (**1**) (dppm = $Ph_2PCH_2PPh_2$) est un catalyseur pour l'hydrogénation par transfert dans laquelle l'acide formique est utilisé comme source d'hydrogène; cette réaction est efficace pour les alcynes tels que PhC≡CPh, PhC≡CMe, EtC≡CEt et PrC≡CPr, mais elle ne fonctionne pas avec les alcynes terminaux, tels que HC≡CH, PhC≡CH, BuC≡CH, ou avec les alcynes comportant un ou deux substituants électroaffinitaires, tels que PhC≡CCO_2Me et MeO_2CC≡CCO_2Me. Dans les réactions qui donnent les résultats espérés, l'acide formique est initialement décomposé en bioxyde de carbone et en hydrogène qui provoque l'hydrogénation des alcynes dans une réaction plus lente. Dans les réactions qui ne donnent pas les résultats espérés, la décomposition de l'acide formique est fortement ralentie par l'alcyne. Dans le cas de l'alcyne PhC≡CH, on a démontré que l'alcyne réagit avec le complexe **1** protoné pour donner dans une première étape le $[Ru_2(\mu\text{-}CPh{=}CH_2)(CO)_4(\mu\text{-}dppm)_2][HCO_2]$ qui s'isomérise alors pour donner le complexe stable et inactif $[Ru_2(\mu\text{-}CH{=}CHPh)(CO)_4(\mu\text{-}dppm)_2][HCO_2]$. On a caractérisé la structure de ce complexe et on a démontré que, en solution, les deux complexes μ-styrényles sont en état de fluxion.

Mots clés : ruthénium, hydrogénation, catalyseur, binucléaire.

[Traduit par la Rédaction]

Introduction

There has been increasing interest in using formic acid in catalytic transfer hydrogenation of multiple bonds, as an alternative to the traditional hydrogenation using hydrogen gas (1–3). Several active catalysts for this transfer hydrogenation have been identified, and all such catalysts are also active in the decomposition of formic acid to CO_2 and H_2 (1–4). All the catalysts studied so far have been mononuclear, and only a few of these have been studied in terms of reaction mechanisms (3, 4). Since the binuclear complex $[Ru_2(\mu\text{-}CO)(CO)_4(\mu\text{-}dppm)_2]$ (dppm = $Ph_2PCH_2PPh_2$) has been shown to have high activity toward the decomposition of formic acid (5), and also to react easily with terminal alkynes (6), it was considered likely that it might also be active for the catalytic transfer hydrogenation of alkynes using formic acid. This article reports that the desired catalysis is successful and also describes studies of the reaction mechanism.

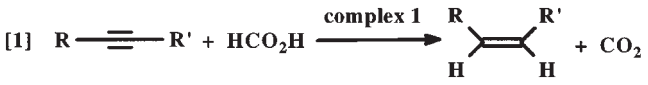
Results

Hydrogen transfer from formic acid to internal alkynes



In the presence of $[Ru_2(\mu\text{-}CO)(CO)_4(\mu\text{-}dppm)_2]$ (**1**) the reaction of HCOOH with internal alkynes, containing either phenyl or alkyl substituents (diphenylacetylene, 1-phenyl-1-propyne, 3-hexyne, or 4-octyne), in acetone at room temperature gave the pure *cis*-alkene as shown in eq. [1]. No trace of *trans*-alkene, and no further hydrogenation of alkene to alkane, was detected when the reactions were monitored by ^{1}H NMR. Using a 20:10:1 ratio of formic acid to diphenylacetylene to complex **1**, the reaction to give *cis*-stilbene was complete in 1 day. Incomplete conversion of about 40% was observed when using equimolar amounts of formic acid and diphenylacetylene under similar conditions. The conversion rate of alkyne to alkene was found to follow

 DOI: 10.1139/cjc-79-5/6-915 © 2001 NRC Canada

Scheme 1. Reagents: (*i*) H^+; (*ii*) HCO_2H, H_2; (*iii*) H_2, H^+; (*iv*) HCO_2^-, CO; (*v*) CO_2; (*vi*) CO, H_2; (*vii*) CO; (*viii*) H^+, CO, H_2.

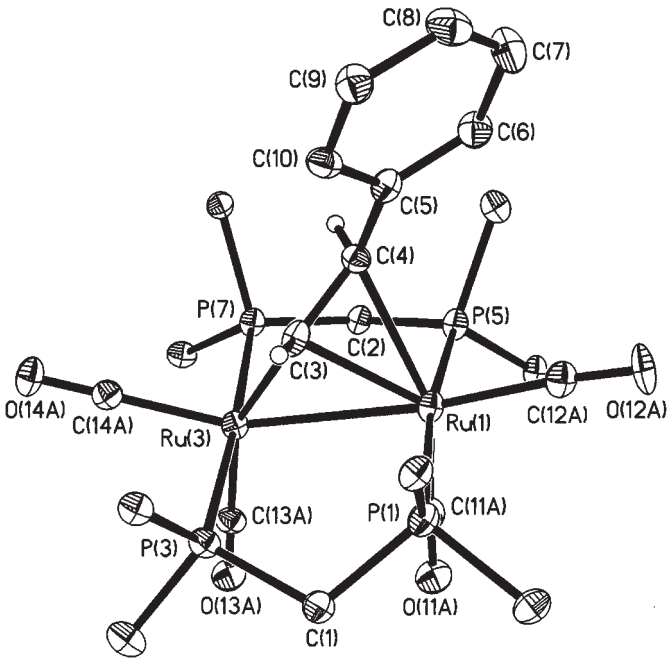
the sequence: diphenylacetylene > > 1-phenyl-1-propyne > 3-hexyne ≈ 4-octyne. For example, using a 10:10:1 molar ratio of HCO_2H:PhCCMe:complex **1**, the conversion was

about 15% after 1 day.

These catalytic hydrogenation reactions were all slower than the catalytic decomposition of formic acid by complex **1** (5). This reaction could be monitored independently by ^1H NMR and it was complete in about 20 min under the above conditions, to give CO_2 and H_2. It is therefore clear that the catalytic transfer hydrogenations occur in two steps. First, the formic acid is decomposed to give hydrogen and then, in a much slower reaction, catalytic hydrogenation of the alkyne occurs. Excess formic acid is required because excess hydrogen is needed for the slow second step. A similar reaction sequence has been proposed for catalytic transfer hydrogenation using formic acid and the mononuclear catalyst $[RuCl_2(PPh_3)_3]$, either alone or in combination with the heterogeneous hydrogenation catalyst Pd/C (7). Complex **1** was shown to be a catalyst for hydrogenation of diphenylacetylene using hydrogen gas at 1 atm (1 atm = 101.325 kPa) pressure, consistent with the above mechanism, and the hydrogenation is not affected by the presence or absence of free carbon dioxide.

The reactions were monitored at low temperature (–5 to –10°C) by NMR using $H^{13}COOH$. The catalytic decomposition of formic acid occurred by way of the intermediates shown in Scheme 1, and occurred at a similar rate as in the absence of alkyne (5). No new intermediates were observed and complex **1** was regenerated once the catalytic decomposition of formic acid was complete (5). No alkene was detected until the formic acid was completely decomposed to CO_2 and H_2. During the subsequent slow hydrogenation step, the only complex present in detectable quantity was complex **1**. This result is not unexpected since these internal alkynes without electronegative substituents (eq. [1]) do not react with complex **1**, but it does show that all reaction intermediates are short-lived (6).

Hydrogen transfer from formic acid to terminal alkynes and to internal alkynes with electron-withdrawing substituents



The terminal alkynes (PhCCH, HCCH, 1-hexyne) or internal alkynes with electron-withdrawing substituents ($PhCCCO_2Me$, MeO_2CCCCO_2Me) strongly inhibited the decomposition of formic acid to carbon dioxide and hydrogen. Thus, using $H^{13}CO_2H$ to allow detection of $^{13}CO_2$ by ^{13}C NMR, no CO_2 was detected at room temperature and only a trace was detected on warming the sample to 50°C. In terms of the ruthenium complexes present, in each case complexes **2** and **3** were formed first, in the same way as in the absence of the alkyne. This is consistent with the faster reaction of **1** with formic acid than with the alkynes (5, 6). However, the other intermediates of Scheme 1, including the important intermediate **4**, were not observed. Instead, products arising from reactions of **2** or **3** with the alkynes were observed. In the cases with the alkynes $PhC{\equiv}CCO_2Me$ or $MeO_2CC{\equiv}CCO_2Me$, the reactions gave complex mixtures that could not be identified but the terminal alkynes reacted more selectively, as described below.

The reaction of $PhC{\equiv}CH$ with complex **2** was relatively slow and thus was chosen for detailed study. At room temperature, the reaction occurred through several steps, as monitored by ^1H and ^{31}P NMR, to finally give a single product after 1 day at room temperature. This compound was characterized crystallographically as $[Ru_2(\mu\text{-}\eta^1{:}\eta^2\text{-}CHCHPh)(CO)_4(\mu\text{-}dppm)_2][HCOO]$ (**7**) and it is logical to suggest that it is formed from **2** by *cis*-insertion of phenylacetylene into the ruthenium hydride bond, with loss of a carbonyl ligand.

The molecular structure of the cation **7** is shown in Fig. 1 and selected interatomic distances and angles are listed in Table 1. The unit cell contains two independent cations **7** as well as formate anions and solvent molecules. Table 1 shows equivalent bond parameters for the two cations **7** in each row, and there are no major differences. The discussion will focus on the cation containing atoms Ru(1) and Ru(3) shown in Fig. 1. Each cation **7** contains a $Ru_2(\mu\text{-dppm})_2$ group in which the $Ru_2P_4C_2$ atoms adopt a slightly twisted, extended boat conformation. In addition each ruthenium is bound to two terminal carbonyl ligands and to the bridging styrenyl group. The α-carbon (C(3)) of the styrenyl group is σ-

Fig. 1. A view of the structure of the cation $[Ru_2(CO)_4(\mu\text{-}\eta^1,\eta^2\text{-}CH{=}CHPh)(\mu\text{-}dppm)_2]^+$. Only the ipso carbon atoms of the phenyl substituents of the dppm ligands are shown for clarity.

bonded to Ru(3) (Ru(3)C(3) = 2.09(1) Å) and the C=C unit is π-bonded to Ru(1) (Ru(1)C(3) = 2.27(1) Å, Ru(1)C(4) = 2.39(1) Å). Both C(3) and C(4) are chiral centers and the unit cell contains equal numbers of the *R,S* and *S,R* enantiomers: Fig. 1 shows the *S,R* enantiomer and the molecule containing Ru(2)Ru(4) is *R,S*. The distance C(3)—C(4) = 1.38(1) Å is slightly longer than a free double bond (1.34 Å) but significantly shorter than a single bond (1.53 Å), indicating relatively weak back-bonding to the C=C π*-orbital. The phenyl substituent of the styrenyl group is positioned between a sheath of phenyl substituents of the dppm ligands. The angles Ru(3)-C(3)-C(4) = 129.4(7) and C(3)-C(4)-C(5) = 123(1)° are each somewhat greater than the ideal angles of 120° for a double bond and, of course, significantly greater than the tetrahedral angle. Again this suggests that the carbon—carbon bond of the μ-styrenyl group is close to a double bond. The distortion of the angle Ru(3)-C(3)-C(4) is probably to maximize the Ru(1)-C(3-)C(4) π-bonding interaction. The distance Ru(1)—Ru(3) = 2.855(1) Å is consistent with a metal—metal single bond. Each ruthenium then has an 18-electron configuration if Ru(1) carries the positive charge. The structural features are consistent with those of other μ-alkenyl complexes (8).

The ^{31}P NMR spectrum of **7** contained only a very broad singlet at δ = 33 at room temperature and so **7** is clearly fluxional. The ^{1}H NMR spectrum at room temperature contained two vinyl resonances, each as a doublet of quintets, at δ = 8.4 and δ = 5.5, assigned to the hydrogen atoms on the α- and β-carbons [C(3) and C(4) in Fig. 1], respectively, (9). The magnitude of the doublet coupling constants ^3J (H-H) = 14 Hz confirm that these protons are *trans* within the vinyl group, and so confirms the stereochemistry shown crystallographically. Both vinyl hydrogen resonances show effectively equal coupling to the four phosphorus atoms, with J $(P\text{-}H)_{obs}$ = 7 and 3 Hz for the α- and β-protons, respectively. The phenyl protons of the bridging styrenyl ligand were observed δ = 6.9 (*para*), δ = 6.5 (*meta*), and at δ = 5.7 (*ortho*). These unusual chemical shifts for aryl protons are probably due to shielding by the surrounding four phenyl groups of the dppm ligands. Two broad, unresolved resonances were observed for the $CH^aH^bP_2$ protons at δ = 4.2 and 3.7 ppm.

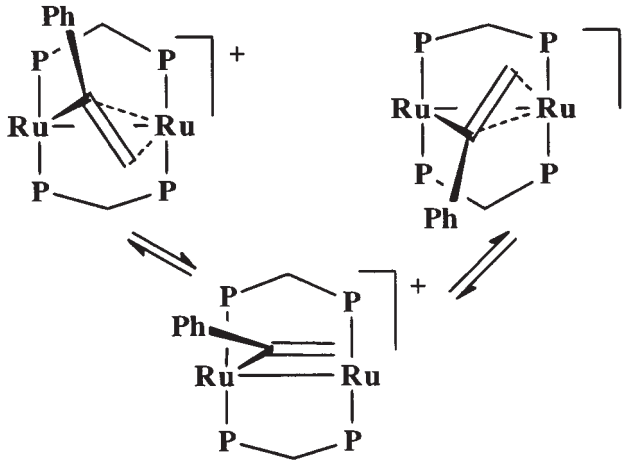
At –50°C, complex **7** exhibits an ABCD pattern of peaks in the ^{31}P NMR spectrum, consistent with the structure established in the solid state by X-ray crystallography. The fluxional process that leads to the equivalence of phosphorus atoms must include not only the process A (Scheme 2), which can be considered to arise from an intermediate in which the plane of the vinyl group is perpendicular to the metal—metal bond (10–12), but also process B (Scheme 2), which requires an intermediate in which the plane of the vinyl group is parallel with the metal—metal bond. Process A is thought to occur through a $\mu\text{-}\eta^1$-vinyl intermediate (10–12), but it is likely that process B occurs by way of an intermediate with a terminal σ-vinyl group. Certainly the conventional ruthenium—alkene π-bond will be lost in the transition state in which the vinyl group and Ru—Ru bond are coplanar. At low temperature, four resonances were observed for the CH_2P_2 protons (one coupled pair at δ = 4.7 and 4.3 and the other at δ = 4.4 and 3.2), indicating that all are inequivalent. The chemical shifts of the vinyl protons did not change significantly but the appearance did. In particu-

© 2001 NRC Canada



Scheme 2.

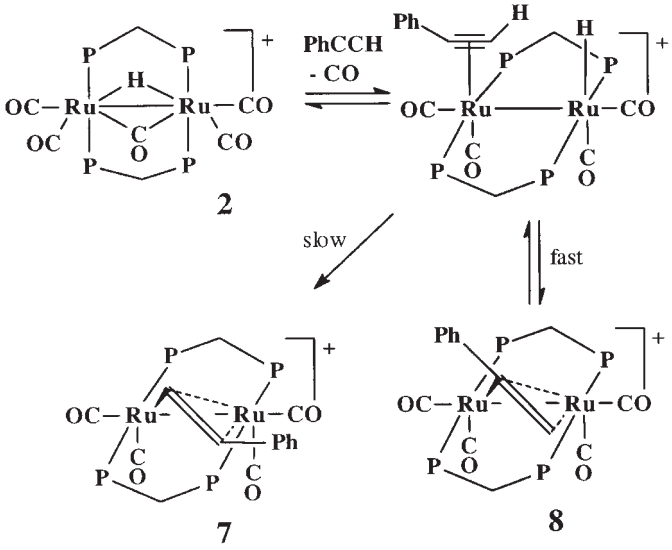
lar, the β-H resonance now appeared as a doublet of doublets with ^3J (H-H) = 14 Hz and J (P-H) = 10 Hz, thus showing coupling to only one phosphorus atom. The α-H resonance gave a complex unresolved multiplet, indicating nonequivalent couplings to several phosphorus atoms. These data are all easily rationalized in terms of the static structure determined crystallographically.

When the reaction of **1** with formic acid and phenylacetylene was monitored by NMR, a reaction intermediate was detected and characterized as $[Ru_2(\mu\text{-}\eta^1\text{:}\eta^2\text{-}CPhCH_2)(CO)_4(\mu\text{-dppm})_2][HCOO]$ (**8**). Complex **8** displays an AA′BB′ pattern of peaks in the ^{31}P NMR spectrum with δ (P) = 25.0 and 26.8 ppm. The vinyl protons appeared as broad singlets in the ^1H NMR spectrum at δ 4.8 and 5.5; the absence of resolved coupling between them indicates that these are geminal protons and this was confirmed by a $^1H^{13}C$ HSQC experiment which showed that both vinyl protons are attached to the same carbon atom at δ (C) = 111.5. The phenyl protons of the styrenyl group appeared at δ = 6.3 (ortho), 6.6 (*meta*), and 6.8 (*para*). The ^{31}P NMR spectrum broadened but did not split further at –90°C. Since the static structure is expected to give an ABCD pattern of peaks in the ^{31}P NMR spectrum, it is clear that the fluxionality differs from that of complex **7**. In particular, the two processes analogous to A and B of Scheme 2 must have different rates, one being fast and the other slow on the NMR time scale; it is likely that B is rapid but that A is slow. The distinction can be made on the basis of the CH_2P_2 resonances in the ^1H NMR spectrum. In each process, the styrenyl group stays on the same side of the $Ru_2(\mu\text{-dppm})_2$ unit, so each CH_2 group will have nonequivalent protons CH^aH^b. However, process A does not lead to equivalent dppm ligands, whereas process B does. Hence, if it is process A that is fast, four resonances (each 1H) are expected whereas, if process B is fast, two resonances (each 2H) are expected for the CH_2P_2 protons. The spectrum contains two resonances for the CH_2P_2 protons at δ = 3.2 (2H) and 3.4 (2H), indicating that it is process B that is fast. It is likely that steric hindrance in complex **8** prevents process A, which requires the phenyl substituent of the styrenyl group to swing by the phenyl substituents of the

Scheme 3.

dppm ligands. A much smaller motion of the α-phenyl substituent is required in process B. Following this line of reasoning, it is likely that process B is also fast for complex **7** (Scheme 2) and that process A is rate-determining. The proposed fluxionality of **8** is shown in Scheme 3.

The complex **8** was formed rapidly and isomerized to **7** slowly over a period of several hours at room temperature. Clearly then, **8** is the kinetic product arising from reaction of PhCCH with **2**, and it isomerizes slowly to the thermodynamic product **7**. The isomerization is suggested to occur by a β-elimination–reinsertion sequence (Scheme 4). The stereochemistry of the intermediate is uncertain, as is the mechanism of insertion and β-elimination, which could occur at one or across both metal centers.



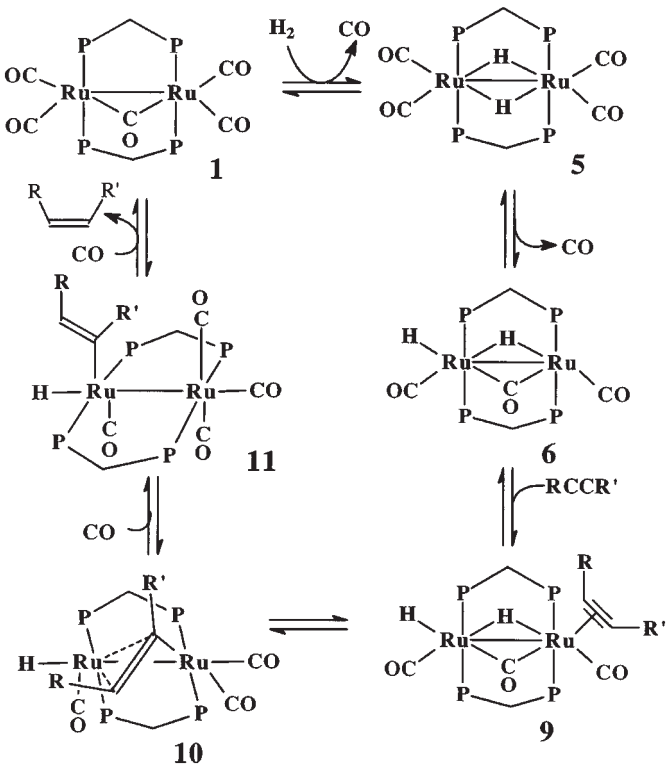
It is noteworthy that complex **7** is stable in solution in the presence of excess PhCCH, hydrogen gas, acids (HBF_4, HCO_2H), or bases (Et_3N, potassium *t*-butoxide). The strong inhibition of the catalytic decomposition of formic acid by phenylacetylene, and absence of catalytic transfer hydrogenation of phenylacetylene, can therefore be attributed to formation of the stable complex **7**, which is not an active catalyst. It has not been possible to characterize the products obtained when using the alkynes HCCH, BuCCH, MeO_2CCCCO_2Me, or $PhCCCO_2Me$, since intractable mixtures were obtained, but it is likely that they also give stable alkenyl or alkyne complexes that are not active catalysts.

Discussion

In catalytic transfer hydrogenation using formic acid, the donor must transfer two hydrogen atoms to the metal center (with loss of CO_2) to give metal hydride bonds, and the substrate must coordinate to the metal and accept the hydrogen atoms, typically by insertion followed by reductive elimination. However, within this framework there are many possible reaction sequences (1–3). One important classification is based on whether the hydrides react rapidly with substrate as they are formed, as is implied by the term transfer hydrogenation, or are first eliminated as free dihydrogen. The second case is then equivalent to hydrogenation with hydrogen gas, but with the hydrogen generated in situ from the formic acid (13). There is evidence for both cases in catalytic transfer hydrogenation using formic acid and mononuclear catalysts

© 2001 NRC Canada

Scheme 4.



(1–3, 7). In the present case, the successful hydrogenations all occur by the mechanism in which formic acid is catalytically decomposed to carbon dioxide and hydrogen, followed by the slower catalytic hydrogenation of the alkyne.

In the successful catalytic reactions, no intermediates were detected in which the alkyne or its hydrogenation products were coordinated to ruthenium. This was the case when using any of HCOOH, HCOOH:Et_3N (5:2), or H_2 as the hydrogen source. It is likely that weak binding of the alkyne to the diruthenium complex is a prerequisite to successful catalysis, since those alkynes known to bind strongly (6) were not hydrogenated. On the other hand, alkenes are not hydrogenated by this catalyst system and they do not coordinate either. It seems there is a balance such that both substrates that bind strongly (terminal alkynes, alkynes with electon-withdrawing substituents) and those that cannot coordinate at all (alkenes) are not hydrogenated, and that substrates that are hydrogenated can probably bind transiently to the diruthenium center (internal alkynes without electron-withdrawing groups).

The mechanism of hydrogenation is necessarily speculative. The only difference in observed intermediates, compared to those observed in the catalytic decomposition of formic acid in the absence of alkynes, was that the hydride derivatives **5** and **6** were not observed. It is easy to understand how the coordinatively unsaturated hydride **6** might react with alkynes, and one possible mechanism based on this observation is shown in Scheme 5. Since none of the possible intermediates **9**–**11** of Scheme 5 is directly observed, the structures are very tentative. However, the overall mechanism involving oxidative addition of hydrogen with CO loss to give **5** and **6**, followed by rapid alkyne coordination (complex **9**), *cis*-insertion to give a vinyl derivative (complexes **10**, **11**), and reductive elimination of alkene with CO addition to regenerate the resting state complex **1**, is consistent with the observations. There are numerous instances of related mechanistic proposals with mononuclear ruthenium complexes, but the extension to binuclear catalysts is new (13, 14).

Scheme 5.

Experimental

All manipulations were operated under a dry nitrogen atmosphere using either standard Schlenk techniques or a glove box. Acetone was dried over 3 Å molecular sieves, toluene was dried by distillation from sodium benzophenone, and CH_2Cl_2 was distilled before use from CaH_2. The HCOOH (96%) and $H^{13}COOH$ (95%, 99 C^{13} atom%) contained 4 to 5% water and were used as purchased. [Ru_2(μ-CO)$(CO)_4$(μ-dppm)$_2$] (**1**) was synthesized according to literature procedure (15). ^1H, ^{13}C, and ^{31}P NMR spectra were recorded using Varian Inova 400 or Gemini 300 spectrometers.

Hydrogen transfer studies from HCOOH to alkynes

To a saturated solution of [Ru_2(μ-CO)$(CO)_4$(μ-dppm)$_2$] (**1**) (1.1×10^{-3} mmol) in acetone-d_6 (0.5 mL, 2.2 mM) in an NMR tube was added PhCCPh (1.98 mg, 1.1×10^{-2} mmol) and the tube was sealed with a septum. HCOOH (1.00 μL, 2.2×10^{-2} mmol) was then injected through the septum by syringe. The decay of formic acid and formation of *cis*-stilbene were monitored as a function of time by comparing the integrals of the formyl and vinyl hydrogen resonances with the integral of the CH_2P_2 resonance of **1** in the ^1H NMR spectrum. The decomposition of HCO_2H to H_2 and CO_2 was complete in 20 min, while the hydrogenation of PhCCPh to *cis*-stilbene was complete in 24 h at 20°C.

Reactions with diphenylacetylene, 1-phenyl-1-propyne, 3-hexyne, and 4-octyne were carried out in a similar way. For comparison of rates, the ratio of alkyne:formic acid:**1** was maintained at 10:10:1. Alkene products were characterized by their ^1H NMR spectra in acetone-d_6 as follows: *cis*-stilbene (16): δ (^1H) = 6.6 (s, =CH); *cis*-1-phenylpropene

© 2001 NRC Canada

(17): δ (^{1}H) = 7.3 (m, 5H, Ph), 6.42 (dq, *J* (H-H) = 13 Hz, *J* (H-H) = 2 Hz, PhCH=), 5.77 (dq, *J* (H-H) = 13 Hz, *J* (H-H) = 7 Hz, MeCH=), 1.85 (dd, *J* (H-H) = 7 Hz, *J* (H-H) = 2 Hz, Me); *cis*-3-hexene (18): δ (^{1}H) = 5.3 (m, =CH0, 2.03 (m, CH_2), 0.9 (t, *J* (H-H) = 6 Hz, Me); *cis*-4-octene (19): δ (^{1}H) = 5.3 (m, =CH), 2.03 (m, CH2)], 1.38 (m, CH_2), 0.9 (t, *J* (H-H) = 6 Hz, Me).

In the similar reaction using PhCCH (3 μL, 0.027 mmol), the complete decomposition of HCOOH (6.5 μL, 0.130 mmol) took 2 weeks to reach completion and no hydrogenation product (styrene) was detected. The only ruthenium complex present at the final stage was complex **7**. The alkynes HCCH, BuCCH, $PhCCCO_2Me$, and MeO_2CCCCO_2Me also retarded the decomposition of formic acid by complex **1** and failed to give the alkenes expected to be formed by catalytic hydrogenation.

Synthesis of $[Ru_2(CO)_4(\mu\text{-}\eta^1,\eta^2\text{-}CH{=}CHPh)(\mu\text{-}dppm)_2][HCOO]$ 7

To a saturated solution of $[Ru_2(\mu\text{-}CO)(CO)_4(\mu\text{-}dppm)_2]$ in acetone-d_6 (0.5 mL, 2.2 mM) in a septum-sealed NMR tube was added PhCCH (3 μL, 0.027 mmol) and HCOOH (6.5 μL, 0.130 mmol) by syringe. The solution was set aside for 18 h at room temperature to give complex **7** as the only product as determined by NMR. The same product was formed by heating to 45°C for 3 h, and using CD_2Cl_2 as solvent. Crystals were obtained from CD_2Cl_2 by slow diffusion of pentane. The crystals were formed with solvent occluded (see structure determination), which was partially lost on drying, thus making it difficult to obtain good analytical data. ^{1}H NMR (acetone-d_6, 20°C) δ: 8.4 (s, 1H, *H*COO], 8.2 (m, 1H, PhCH-C*H*), 5.4 (d quin, 1H, ^3J (H-H) = 14 Hz, *J* (P-H) = 3 Hz, PhC*H*-CH), 5.7 (d, 2H, ^3J (H-H) = 8 Hz, *Ph*CHCH), 6.5 (t, 2H, *J* (H-H) = 8 Hz, *Ph*CHCH), 6.8 (t, 1H, *J* (H-H) = 8 Hz, *Ph*CHCH), 5.05 (br s, 2H, P-C*H*-P), 3.65 (br s, P-C*H*-P). ^{31}P NMR δ: 33 (br s, dppm). ^{1}H NMR (acetone-d_6, –50°C) δ: 8.6 (s, 1H, *H*COO), 8.4 (m, 1H, PhC*H*-CH), 5.4 (dd, 1H, ^3J (H-H) = 14 Hz, ^3J (P-H) = 10 Hz, PhCH-C*H*), 5.6 (d, 2H, *J* (H-H) = 7 Hz, *Ph*CHCH), 6.44 (t, 2H, *J* (H-H) = 7 Hz, *Ph*CHCH), 6.8 (t, 1H, *J* (H-H) = 7 Hz, *Ph*CHCH), 4.7, 4.4, 4.3, 3.2 (m, each 1H, P-C*H*-P). ^{31}P NMR δ: 49.3 (ddd, *J* (P^a-P^b) = 56 Hz, *J* (P^a-P^c) = 237 Hz, *J* (P^a-P^d) = 30 Hz, P^a), 35.1 (ddd, *J* (P^a-P^b) = 56 Hz, *J* (P^b-P^c) = 38 Hz, *J* (P^b-P^d) = 267 Hz, P^b), 32.6 (ddd, *J* (P^a-P^c) = 237 Hz, *J* (P^b-P^c) = 30 Hz, *J* (P^c-P^d) = 73 Hz, P^c), 30.9 (ddd, *J* (P^a-P^d) = 30 Hz, *J* (P^b-P^d) = 267 Hz, *J* (P^c-P^d) = 73 Hz, P^d).

Structure determination

Crystals of $[(CO)_2Ru(\mu\text{-}dppm)_2(\mu\text{-}CHCHPh)Ru(CO)_2]\text{-}[HCOO]\cdot 1.5CH_2Cl_2\cdot 0.5C_5H_{12}\cdot 0.5H_2O$ were grown from CH_2Cl_2–pentane. A yellow block was mounted on a glass fibre at dry ice temperature. Data were collected at 200 K using a Nonius Kappa-CCD diffractometer using COLLECT software (20). The unit cell parameters were calculated and refined from the full data set. Crystal cell refinement and data reduction was carried out using the Nonius DENZO package. The data were scaled using SCALEPACK (21) and no other absorption corrections were applied. The SHELXTL 5.101 (22) program package was used to solve the structure by direct methods and refinement was by successive difference Fouriers. All non-hydrogen atoms were refined with anisotropic thermal parameters. One formate anion was poorly behaved and the C—O bond distances were fixed. The hydrogen atoms were calculated geometrically and were riding on their respective carbon atoms. There were several disordered solvent molecules in the lattice, and these were modeled isotropically and with partial occupancies. The crystal data and refinement parameters are listed in Table 2. The crystal was of poor quality, with disordered anion and solvent molecules, but the structure of the cations was well-defined.

Oxidation of copper(II) hydroxyporphyrin (oxophlorin); oxidative ring opening and formation of an ester-linked, dinuclear copper complex

Shane Phillips, Bruce C. Noll, Marilyn M. Olmstead, and Alan L. Balch

Abstract: Addition of copper(II) acetate to octaethyl(*meso*-hydroxy)porphyrin (H_2OEPOH) in THF under a dinitrogen atmosphere produces Cu^{II}(OEPOH), which has been isolated as red crystals and shown to have a *meso*-hydroxyporphyrin structure by UV–vis and EPR spectroscopy. Cu^{II}(OEPOH) undergoes oxidation by dioxygen to form a novel dinuclear copper complex {Cu^{II}(OEPOC(O)OEB)Cu^{II}}. This dinuclear complex is composed of a copper(II) *meso*-substituted porphyrin portion (with a planar CuN_4 unit), which is attached through an ester linkage to a helical copper(II) tetrapyrrole that has been ring-opened through oxidative cleavage of a second molecule of Cu^{II}(OEPOH). The oxidative ring-opening reaction resembles that of natural heme catabolism but is arrested at a stage where the oxidized *meso*-carbon is still appended to the helical open tetrapyrrole. A mechanism is suggested for this process.

Key words: copper porphyrin, crystal structure, porphyrin oxidation, linear tetrapyrrole, hydroxy-porphyrin, oxophlorin.

Résumé : L'addition d'acétate de cuivre(II) à de l'octaéthyl(*méso*-hydroxy)porphyrine, H_2OEPOH, dans du tétrahydrofurane, sous atmosphère de diazote, conduit à la formation de Cu^{II}(OEPOH) que l'on a isolé sous la forme de cristaux rouges; sur la base des spectroscopies UV–vis et RPE, ces cristaux possèdent une structure *méso*-hydroxyporphyrine. Sous l'influence du dioxygène, le Cu^{II}(OEPOH) subit une oxydation conduisant à la formation d'un nouveau complexe dinucléaire du cuivre, le {Cu^{II}(OEPOC(O)OEB)Cu^{II}}. Ce complexe dinucléaire est formé d'une partie cuivre(II)/porphyrine substituée en *méso* (avec une unité CuN_4 planaire) qui est attachée par le biais d'une liaison ester à un cuivre(II)/tétrapyrrole hélicoïdal avec un cycle qui a été ouvert par un clivage oxydant d'une deuxième molécule de Cu^{II}(OEPOH). Cette réaction d'ouverture oxydante du cycle ressemble à celle du catabolisme naturel de l'hème, mais il s'arrête à un stade dans lequel le carbone *méso* oxydé est toujours attaché au tétrapyrrole hélicoïdal ouvert. On suggère un mécanisme pour ce processus.

Mots clés : cuivre porphyrine, structure cristalline, oxydation d'une porphyrine, tétrapyrrole linéaire, hydroxyporphyrine, oxophlorine.

[Traduit par la Rédaction]

Introduction

Classical studies of the interaction of porphyrins with dioxygen focused on the issue of reversible dioxygen binding and subsequently on the ability of metalloporphyrins and heme enzymes such as cytochrome P-450 to activate dioxygen toward the attack on various substrates (1). Dioxygen, especially in the presence of a reducing agent, can also cause the destruction of the metalloporphyrin itself (2, 3). This process generally occurs through attack on a *meso*-carbon atom of the porphyrin to produce the *meso*-substituted porphyrin shown as **1a** and **1b** in Scheme 1.

This tetrapyrrole macrocycle can exist in two tautomeric forms, the *meso*-hydroxyporphyrin (**1a**) and the oxophlorin (**1b**) as seen in Scheme 1 (4). This relatively modest change to the porphyrin ligand core results in a tetrapyrrole that is more readily oxidized than the corresponding porphyrin and which has a rich coordination chemistry that involves not only the N_4 core but also can involve the exocyclic oxygen atom. Scheme 2 shows the principal structural forms that have been characterized to date for transition metal complexes of the octaethyl-substituted form of **1**. Four basic coordination modes have been identified (4). These modes include: **2** with porphyrin-like coordination mode and a *meso*-hydroxyl group, **3** with bridging coordination through the *meso*-oxygen atom, **4** with oxophlorin coordination and a *meso*-keto group, and **5** with ligand-based free radical coordination. Examples of each type of structure have been isolated and characterized through single crystal X-ray diffraction and by UV–vis, infrared (IR), and ^{1}H NMR spectroscopy. To simplify interpretation of the spectroscopic data this work has utilized the symmetric ligand, H_2OEPOH, **1a** with a–h = C_2H_5.

Metal complexes of **1a** are sensitive to oxidation, which can take several paths. In pyridine solution, air oxidizes the

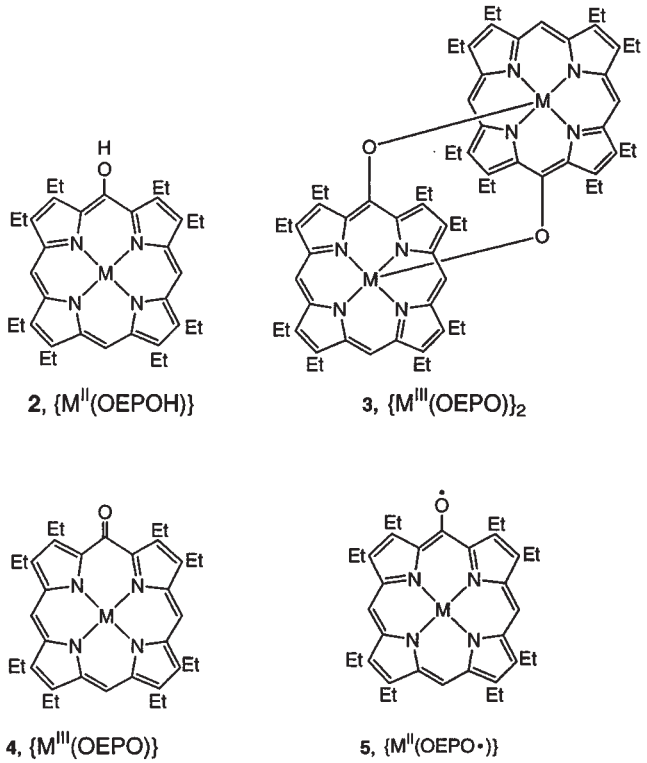
porphyrin-like complexes, Ni^{II}(OEPOH) and Zn^{II}(OEPOH), to produce stable free radical complexes $(py)_2Ni^{II}(OEPO^{\bullet})$ and $(py)Zn^{II}(OEPO^{\bullet})$, which have been isolated (5, 6). However, treatment of {$(py)Co^{II}$(OEPOH··py)} with either dioxygen or diiodine produces {$(py)_2Co^{III}$(OEPO)} in which the metal ion, not the ligand, has been oxidized (7). The behavior of iron complexes of H_2OEPOH is more complex and is summarized in Scheme 3. Note that in this Scheme the oxidation state of the iron in {$(py)_2$Fe(OEPO)} is not specified since the electrons can be apportioned between the ligand and iron in several different resonance structures (4). Not only are several reactions that result in ligand oxidation observed in Scheme 3, but the reactions shown at the lower right side of the Scheme involve ring-opening of the porphyrin to form the biliverdin complex {$(py)_2Fe^{III}$(OEB)}, and the verdoheme complex $[(py)_2Fe^{II}(OEOP)]^+$ (2, 8, 9). These ring-opening reactions are relevant to the operation of the enzyme heme oxygenase, which binds heme as substrate and uses it to activate dioxygen, which then attacks the heme at a *meso* carbon atom to yield the bile pigment biliverdin, carbon monoxide, and free iron ion (10).

Results



Formation and characterization of Cu^{II}(OEPOH) and its trifluoroacetic ester derivative, Cu^{II}(OEPTFA)

The synthetic work described here is summarized in Scheme 4.

Addition of a blue THF solution of copper(II) acetate to a blue THF solution of **1** (*a*–*h* = Et) under a dinitrogen atmosphere produces a red solution that contains Cu^{II}(OEPOH), which has been isolated as red crystals. After removing the solvent under vacuum, the red solids were dissolved in dichloromethane. This solution was washed with water, and the red organic layer was collected and dried to give a 89% yield of Cu^{II}(OEPOH). The trifluoroacetoxy analog, Cu^{II}(OEPTFA), was synthesized in 83% yield in a similar manner from H_2OEPTFA.

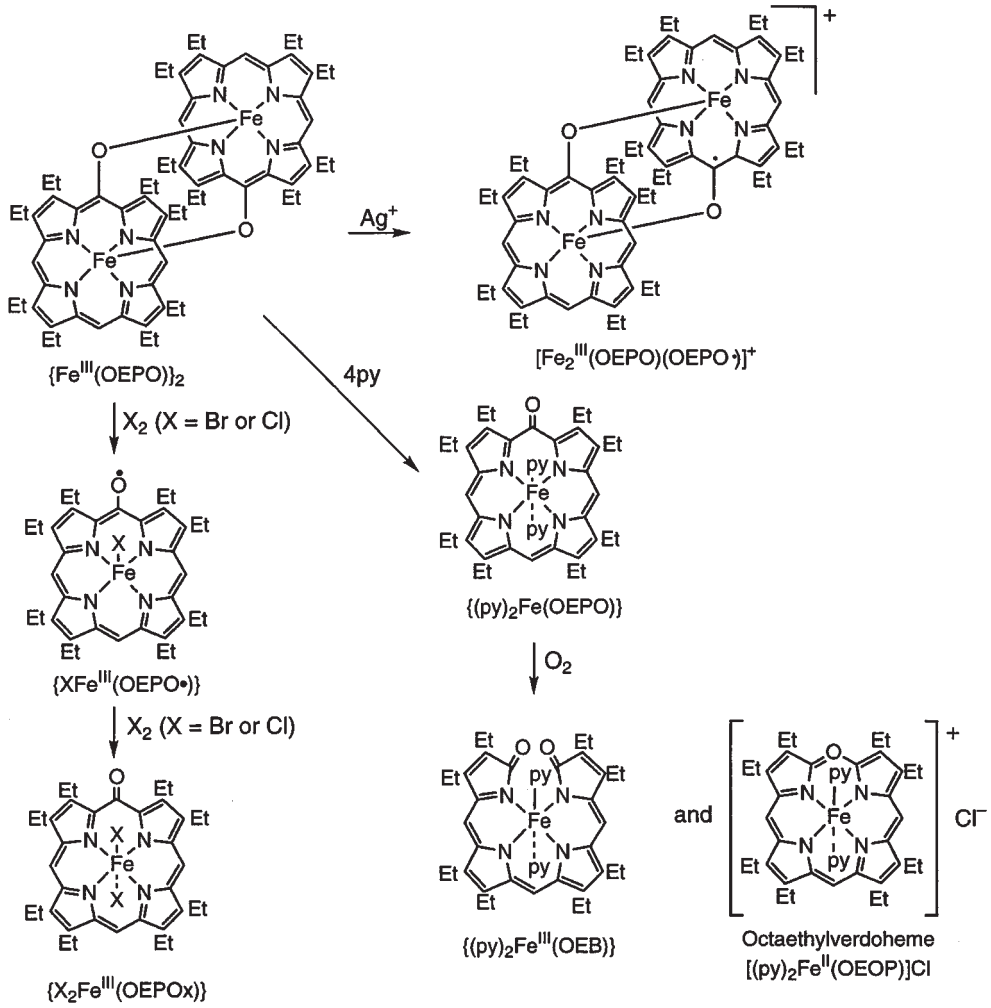
The electronic spectrum of Cu^{II}(OEPOH) in dichloromethane solution (Fig. 1*a*) consists of an intense Soret band at 404 nm and Q-bands at 528 and 560 nm. This spectrum is typical of the spectra of divalent metal complexes of type **2** in Scheme 2, such as Ni^{II}(OEPOH) and Zn^{II}(OEPOH) (5, 6). Cu^{II}(OEPTFA) in dichloromethane solution gives a very similar spectrum, with a Soret band at 400 nm and Q-bands at 526 and 564 nm. This similarity of the spectra of Cu^{II}(OEPOH) and Cu^{II}(OEPTFA) indicates that both have ligands that coordinate in the form **2** rather than **4**. The IR spectrum of Cu^{II}(OEPOH) as a mineral oil mull shows a broad peak at 3508 cm^{-1} corresponding to the hydroxyl functionality and no strong peaks above 1600 cm^{-1} where a carbonyl peak would be expected. Cu^{II}(OEPTFA), however, shows no hydroxyl peak above 3000 cm^{-1}, but does give a strong, sharp absorption at 1792 cm^{-1}, which is due to the C=O portion of the ester. The electron impact mass spectrum (EI-MS) of Cu^{II}(OEPOH) shows a molecular ion peak at 611 amu and *no peaks at higher masses*.

Scheme 2.

2, {M^{II}(OEPOH)} **3**, {M^{III}(OEPO)}$_2$

4, {M^{III}(OEPO)} **5**, {M^{II}(OEPO•)}

The electron spin resonance (ESR) spectra of these complexes are similar to those of other copper(II) d^9 porphyrin compounds (11). Cu^{II}(OEPTFA) produces an asymmetric quartet due to hyperfine coupling to the spin 3/2 copper atom centered at g = 2.10 with A_{Cu} = 96 G. The two high field signals are further split by superhyperfine coupling to the four nitrogen atoms with A_N = 16 G. The room temperature ESR spectrum of Cu^{II}(OEPOH) in dichloromethane solution is similar. The typical four band pattern is less well resolved for Cu^{II}(OEPTFA), but the signals are centered at g = 2.10 with a smaller copper hyperfine coupling constant of A_{Cu} = 86 G and a nitrogen superhyperfine coupling constant of A_N = 16 G.



Cu^{II}(OEPTFA) can be hydrolyzed under basic conditions to form Cu^{II}(OEPOH). Washing a dichloromethane solution of Cu^{II}(OEPTFA) with a 1.0 M aqueous solution of KOH results in a color change from red to green. Subsequent washing with water generates the red complex, Cu^{II}(OEPOH), and this material gives electronic and IR spectra that match those observed previously.

Formation and structure of {Cu^{II}(OEPOC(O)OEB)Cu^{II}}

Cu^{II}(OEPOH) undergoes oxidation to form a novel dinuclear copper complex, {Cu^{II}(OEPOC(O)OEB)Cu^{II}}.

Scheme 3.

Slow diffusion of methanol into a chloroform–pyridine (9:1 v/v) solution of Cu^{II}(OEPOH) in air over a period of several weeks yielded large, single blocks. Fast atom bombardment mass spectrometry (FAB-MS) (1238 amu mass peak) and X-ray crystallography indicated that these red–purple crystals contain the unique binuclear complex, {Cu^{II}(OEPOC(O)OEB)Cu^{II}}. Representative crystals from the batch used in the crystallographic investigation also had an electronic spectrum that is similar to that of Cu^{II}(OEPOH). The electronic spectrum of {Cu^{II}(OEPOC(O)OEB)Cu^{II}}, which is shown in Fig. 1*b*, is dominated by the copper(II) porphyrin part of the dinuclear complex, which has a very large molar extinction coefficient. However, important spectral differences are seen in the broad shoulder at 460 nm and the broad feature seen at 748 nm. For comparison, the spectrum of Cu(OEFB), where OEFB is the dianion of octaethylformylbiliverdin (see Scheme 4), shows absorptions at 432, 752, and 844 nm, which have much lower absorptivities than those of Cu^{II}(OEPOH) (12). Thus, the feature at 748 nm in the spectrum of {Cu^{II}(OEPOC(O)OEB)Cu^{II}} is consistent with the presence of the ring-open tetrapyrrole portion of the molecule.

The structure of {Cu^{II}(OEPOC(O)OEB)Cu^{II}} has been determined by single crystal X-ray diffraction. A perspective view of the complex is given in Fig. 2. Atomic coordinates are given in Table 1. Selected bond distances and angles are given in Tables 2 and 3. The compound crystallizes with a molecule of {Cu^{II}(OEPOC(O)OEB)Cu^{II}} and a molecule of chloroform in the asymmetric unit. The dinuclear complex is composed of a copper(II) porphyrin portion, which is attached through an ester linkage to a second copper(II) tetrapyrrole that has been obtained through oxidative cleavage of a second molecule of Cu^{II}(OEPOH).

The porphyrin portion of the dinuclear complex contains a planar copper(II) ion bound to four pyrrole nitrogen atoms with an average Cu—N bond distance of 2.006 Å. This distance is comparable to the average Cu—N bond distance of 1.998 Å found in Cu^{II}(OEP) (13). Figure 3 shows a formal diagram that illustrates the out-of-plane displacements of the core atoms (in 0.01 Å units) of the porphyrin portion of the molecule from the mean plane defined by the copper atom, the four nitrogen atoms, and the 20 carbon atoms of the porphyrin's core. The core is nearly planar, but it does exhibit some unusual saddle-shaped distortions on its periphery in the vicinity of the *meso*-bound oxygen atom. The copper ion and the four pyrrole nitrogen atoms are distinctly planar.

The cleaved porphyrin portion of {Cu^{II}(OEPOC(O)OEB)Cu^{II}} also contains a copper(II) ion bound to the four pyrrole ni-

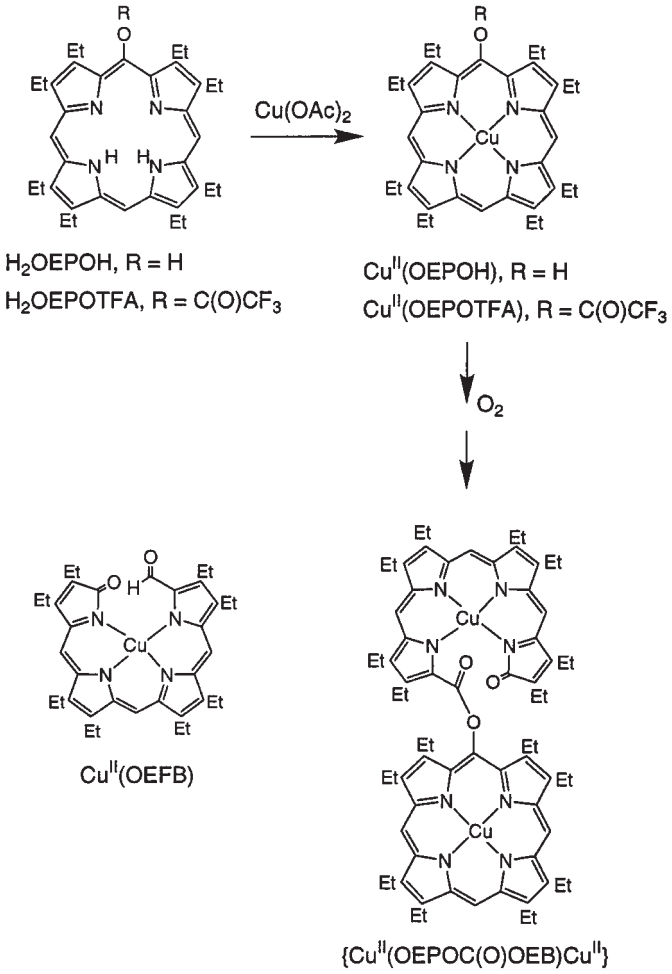

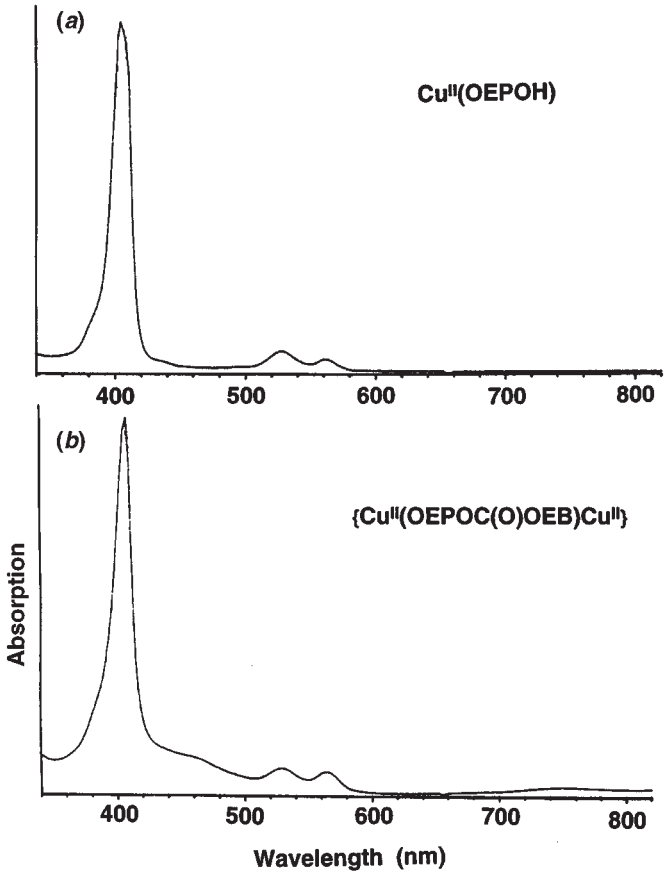

Fig. 1. Electronic absorption spectra of: (*a*) Cu^{II}(OEPOH) in dichloromethane solution; and (*b*) {Cu^{II}(OEPOC(O)OEB)Cu^{II}} in dichloromethane solution.

trogen atoms in an irregular geometry. The overall geometry of this portion is similar to that of Cu^{II}(OEFB), whose structure is diagrammatically shown in Scheme 4 (14). The Cu(2)—N bond distances (average Cu(2)—N distance, 1.953 Å) in {Cu^{II}(OEPOC(O)OEB)Cu^{II}} are slightly shorter than those found in the porphyrin part of the dinuclear complex, where the average Cu(1)—N distance is 2.006 Å, but they are similar to the Cu—N bond distances in the linear tetrapyrrole complex Cu^{II}(OEFB) where the average Cu—N distance in 1.953 Å (14). The Cu(2) atom is constrained to a geometry between planar and tetrahedral. Three of the *cis* N-Cu(2)-N angles (90.76(13), 91.14(13), and 90.28(13)°) are close to 90°, while the forth (N(5)-Cu(2)-N(8), 97.02(13)°) at the open end of the tetrapyrrole is wider. The pseudo-*trans* angles, N(5)-Cu(2)-N(7), 158.74(14)° and N(6)-Cu(2)-N(8), 154.44(14)°, are much narrower than the 180° required for planar coordination but wider than the 109.5° expected for tetrahedral coordination. As seen in Figs. 2 and 4, which shows a side-on view of each portion of the dinuclear complex, the macrocycle forms a helical arrangement around Cu(2). This arrangement allows the open ends of the ligand to avoid each other. The separation between O(3) and C(37) is 3.85 Å which is larger than the corresponding non-bonded O···O separations of 3.17 and 3.22 Å found in biliverdin complexes (15). The C(2)—O(1) and C(37)—O(1) bond lengths (1.419(5) and 1.370(5) Å, respectively) in the ester group are, as expected, longer than the C(37)—O(2) and C(56)—O(3) bond lengths (1.210(5) and 1.214(5) Å, respectively). The carbonyl oxygen of the ester link interacts weakly, if at all, with Cu(2). The Cu(2)—O(2) distance is 2.921(4) Å. This interaction may simply result from constraints of the bridge between the two parts of this dinuclear complex. The other carbonyl oxygen of the open chain tetrapyrrole is further away from Cu(2) with a Cu(2)···O(3) separation of 3.396(4) Å. The non-bonded Cu–Cu separation in {Cu^{II}(OEPOC(O)OEB)Cu^{II}} is 7.748(2) Å.

The formation of the dinuclear complex {Cu^{II}(OEPOC(O)OEB)Cu^{II}} is a complex process in which Cu^{II}(OEPOH) undergoes an oxidative ring opening that is somewhat similar to the behavior of iron porphyrins shown in Scheme 3, and some speculation in regard to the mechanism of this reaction is in order. Scheme 5 shows a proposed mechanism for the formation of the dinuclear complex, {Cu^{II}(OEPOC(O)OEB)Cu^{II}}. In the initial step dioxygen oxidizes a portion of Cu^{II}(OEPOH) to Cu^{II}(OEPO$^{\bullet}$). This step has precedent in the reactivity of both Ni^{II}(OEPOH) and Zn^{II}(OEPOH) with dioxygen in pyridine solution (5, 6). Moreover, solutions of Cu^{II}(OEPOH) in pyridine gradually develop a green color and new absorption bands at 440 (Soret) and 802 nm when exposed to dioxygen. An identical spectrum, which is characteristic of the formation of complexes of type **5**, is obtained rapidly by oxidizing

meso carbon to produce the crucial O–C bond that links the dinuclear complex. Subsequent addition of dioxygen to the resulting radical results in the eventual rupture of one of the *meso* C–C bonds. Finally, the process is terminated through reaction of the ring-open radical with superoxide via a RO_4H species (not shown) that is analogous to the termination of autoxidation though the interaction of two peroxy radicals as established by Russell (19). This mechanism predicts that the oxygen atom of the lactam ring is derived from molecular oxygen, while the other two oxygen atoms in the dinuclear product originate in the initial sample of Cu^{II}(OEPOH). Further studies of this oxidation process are clearly warranted. However, it is also clear from the present work that oxidative ring opening of metalloporphyrins can be stopped at a stage before the *meso*-carbon atom is removed (as carbon monoxide) from the tetrapyrrole. Of course the formation a dinuclear species analogous to $\{Cu^{II}(OEPOC(O)OEB)Cu^{II}\}$ is prohibited in enzymatic degradation of heme by the protein, which isolates the heme and prohibits interaction of one heme with another.

Fig. 3. A formal diagram that illustrates the out-of-plane displacements of the core atoms (in 0.01 Å units) of the porphyrin half of the dinuclear complex $\{Cu^{II}(OEPOC(O)OEB)Cu^{II}\}$ from the mean plane defined by the Cu(I), the four nitrogen atoms, and the 20 carbon atoms of the porphyrin's core.

Experimental

Preparation of compounds

Samples of H_2OEPOH and Cu^{II}(OEPTFA) were obtained by previously published methods (16–18).

Cu^{II}(OEPOH)

A sample of H_2OEPOH (47.5 mg, 0.086 mmol) dissolved in THF (50 mL) was mixed under nitrogen with a 50 mL THF solution containing copper(II) acetate monohydrate (18.0 mg, 0.090 mmol). The aqua blue solution immediately turned red and a precipitate begins to form. The solution was allowed to react for several hours before removing the solvent under vacuum. The solids were redissolved in dichloro-

methane and precipitated with methanol. The red crystalline product was collected by filtration, washed with methanol, and vacuum dried to give an 89% yield of Cu^{II}(OEPOH). UV–vis (in CH_2Cl_2) λ_{max} (nm) (ε (M^{-1} cm^{-1})): 404 (420 000), 528 (24 000), 560 (16 000). IR (mineral oil) (cm^{-1}): 3508 (s), 1592 (s), 1540 (w), 1501 (w), 1466 (m), 1389 (w), 1370 (w), 1275 (s), 1261 (m), 1226 (w), 1186 (m), 1155 (w), 1123 (w), 1099 (w), 1056 (m), 1018 (s), 957 (m), 830 (w), 794 (w), 692 (w).

Cu^{II}(OEPTFA)

The trifluoroacetoxy derivative was prepared in the same manner as Cu^{II}(OEPOH) to give an 83% yield of Cu^{II}(OEPTFA). UV–vis (in CH_2Cl_2) λ_{max} (nm) (ε (M^{-1} cm^{-1})): 400 (160 000), 526 (7 000), 564 (9 000). IR (mineral oil) (cm^{-1}): 1792 (s), 1591 (m), 1526 (w), 1477 (w), 1343 (m), 1275 (m), 1216 (s), 1176 (s), 1153 (m), 1130 (s), 1062 (m), 1019 (m), 957 (m), 845 (m), 753 (w).

X-ray data collection for {Cu^{II}(OEPOC(O)OEB)Cu^{II}}·$CHCl_3$

A homogeneous collection of red–purple blocks of {Cu^{II}(OEPOC(O)OEB)Cu^{II}}·$CHCl_3$ were obtained by slow diffusion of air-saturated methanol into an air-saturated chloroform–pyridine solution of Cu^{II}(OEPOH). The datum crystal was coated with a light hydrocarbon oil and mounted in the 121 K dinitrogen stream of a Siemens P4 rotating anode diffractometer that was equipped with a low-temperature device. Two check reflections showed less than a 2% decay during the data collection. The data were corrected for Lorentz and polarization effects. Crystal data and data collection parameters: $C_{73}H_{87}Cl_3N_8O_3Cu_2$, MW = 1357.94, triclinic, $P\bar{1}$, α = 14.6140(10), β = 14.642(2), γ = 16.690(2) Å, a = 84.18(2), b = 87.57(2), c = 76.55(2)°, V = 3454.8(7) $Å^3$, Z = 2, ρ_c = 1.305 g cm^{-3}, m = 2.233 mm^{-1} (121(2) K; Cu Kα (λ) = 1.54178). A complete set of unique data, 9017 re-

© 2001 NRC Canada

flections, was collected using $2\theta - \omega$ scans in the range $0 < h < 15$, $-15 < k < 15$, $-17 < l < 17$ on a needle cut to dimensions of 0.08 × 0.20 × 0.22 mm.

Solution and refinement

The structure was solved by direct methods using the SHELXS 86 suite of programs. Refinement (on F^2) was performed with the SHELX 93 software. Scattering factors for neutral atoms and corrections for anomalous dispersion were taken from a standard source (20). An absorption correction was applied to the data (21). Hydrogen atoms were placed at calculated positions and allowed to ride on the position of the parent carbon atom. Hydrogen atom thermal parameters were set to 1.2 times the equivalent isotropic thermal parameters of the adjacent carbon atom.

A badly disordered molecule of chloroform was located during refinement. The molecule appears to occupy more than three sites in a void space in the unit cell. No satisfactory model could be found to accommodate all of the observed electron density. The void space was analyzed with the SQUEEZE routine of PLATON (22). A volume of 237 Å^3 containing about 60 electrons was located. With 58 electrons, a single chloroform molecule is a good fit to the electron density. A new data file eliminating contributions from this electron density was created and used in subsequent cycles of refinement. The atoms of this chloroform molecule are thereby removed from the list of atom positional parameters. The density that was removed is incorporated in an output file that has been included in the refinement details of the cif.

Full-matrix least-squares refinement based on F^2 with 782 parameters and 9017 data yielded $R_1 = 0.077$, $wR_2 = 0.140$ for all data and a conventional $R_1 = 0.054$ computed for 6548 observed data ($I > 2\sigma(I)$). $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = \Sigma||F_o| - |F_c||\sqrt{w}/\Sigma|F_o|\sqrt{w}$.

Tables of crystal data, bond lengths and angles, anisotropic displacement parameters, and hydrogen coordinates may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada. For information on obtaining material electronically go to http://www.nrc.ca/cisti/irm/unpub_e.shtml. Crystallographic information has also been deposited with the Cambridge Crystallographic Data Centre. Copies of the data can be obtained, free of charge, on application to the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. (fax: 44-1223-336033 or e-mail: deposit@ccdc.cam.ac.uk).

Instrumentation

Absorption spectra were recorded on a Hewlet–Packard 8452A diode array spectrophotometer. Infrared spectra were acquired on an IBM IR/32 spectrometer. EPR spectra were recorded in the X band on a Bruker spectrometer. EI (70 eV) mass spectrometry was performed on a VG Analytical ZAB-2F-HS mass spectrometer.

Synthesis and characterization of the pentadentate macrobicyclic ligand, 14-thia-1,4,8,11-tetraazabicyclo[9.5.3]nonadecane (L1) and its nickel(II) complexes. X-ray crystal structure of $[Ni(L1)(ClO_4)](ClO_4)\cdot 2[Ni(L1)(OH_2)](ClO_4)_2\cdot 6H_2O$

Kevin R. Coulter, Alexander McAuley, and Steven Rettig

Abstract: The pentadentate macrobicycle,14-thia-1,4,8,11-tetraazabicyclo[9.5.3]nonadecane (L1), has been synthesized by high dilution cyclization of 1-thia-4,8-diazacyclododecane ([10]aneN$_2$S) (**2**) with *N*,*N*′-bis(α-chloro acetamido) propane (**3**) and subsequent reduction of the di-oxo intermediate. The structure of the $[Ni(L1)(ClO_4)](ClO_4)\cdot 2[Ni(L1)(OH_2)](ClO_4)_2\cdot 6H_2O$ complex (monoclinic, $P2_1/c$, a = 13.9261(4) Å, b = 30.279(2) Å, c = 17.1248(3) Å, β = 94.5065(3)°) at R = 0.039 (R_w = 0.034) for 911 parameters using 18 266 reflections with $I > 3\sigma I$ has been determined. The ligand adopts a *trans*-III configuration. The Ni(II) ion is pseudooctahedral with Ni—S = 2.3896(10) Å in $[Ni(L1)(ClO_4)]^+$ and 2.4193(10) Å, 2.4225(10) Å, in the two $[Ni(L1)(H_2O)]^{2+}$ cations. Both nickel(II) and nickel(III) complexes are six-coordinate in solution. Oxidation of the $[Ni(L1)(OH_2)]^{2+}$ complex with $K_2S_2O_8$ in aqueous solution yielded an ESR active Ni(III) species and the frozen solution spectrum displayed axial symmetry with $g_\perp$ = 2.159 and $g_\parallel$ = 2.024. In CH_3CN, the $[Ni(L1)(solv)]^{2+}$ complex showed two reversible redox waves corresponding to the $Ni^{2+/+}$ couple at $E_{1/2}$ = –1.807 V vs. $Fc^{+/0}$ and $Ni^{3+/2+}$ couple at $E_{1/2}$ = 0.715 V vs. $Fc^{+/0}$.

Key words: synthesis, structure, polydentate macrobicycle, nickel(II).

Résumé : On a synthétisé le macrobicycle pentadentate, 14-thia-1,4,8,11-tétrabicyclo[9.5.3]nonadécane (L1), en procédant à la cyclisation à haute dilution du 1-thia-4,8-diazacyclododécane (([10]aneN$_2$S) (**2**) avec le *N*,*N*′-bis(α-chloroacétamido)propane (**3**) et à une réduction subséquente de l'intermédiaire dioxo. On a déterminé la structure du complexe $[Ni(L1)(ClO_4)](ClO_4)\cdot 2[Ni(L1)(OH_2)](ClO_4)_2\cdot 6H_2O$ (monoclinique, $P2_1/c$, a = 13,9261(4) Å, b = 30,279(2) Å et c = 17,1248(3) Å, β = 94,5065(3)°) avec R = 0,039 (R_w = 0,034) pour 911 paramètres utilisant 18 266 réflexions avec $I > 3\sigma(I)$. Le ligand adopte une configuration *trans*-III. L'ion Ni(II) est pseudo-octaédrique avec Ni—S = 2,3896(10) Å dans le cation $[Ni(L1)(H_2O)]^{+2}$ et 2,4193(10) et 2,4225(10) Å dans les deux cations $[Ni(L1)(H_2O)]^{+2}$. En solution les complexes à nickel(II) et à nickel(III) sont tous les deux hexacoordiné. L'oxydation du complexe $[Ni(L1)(OH_2)]^{2+}$ par du $K_2S_2O_8$ en solution aqueuse fournit une espèce Ni(III) active en RPE et le spectre de la solution congelée présente une symétrie axiale avec $g_\perp$ = 2,159 et $g_\parallel$ = 2,024. Dans le CH_3CN, le complexe $[Ni(L1)(solv)]^{2+}$ présente deux vagues redox réversibles qui correspondent au couple $Ni^{2+/+}$ à $E_{1/2}$ = –1,807 V vs. $Fc^{+/0}$ et au couple $Ni^{3+/2+}$ à $E_{1/2}$ = 0,715 V vs. $Fc^{+/0}$.

Mots clés : synthèse, structure, macrobicycle polydentate, nickel(II).

[Traduit par la Rédaction]

Introduction

The coordination chemistry of the 14-membered tetraaza ligand cyclam (cyclam = 1,4,8,11-tetraazacyclotetradecane) has been studied extensively (1–7) owing to the propensity of various conformational isomers (8) to bind a wide range of first row transition-metal ions, forming complexes of considerable thermodynamic and kinetic stability. A detailed analysis has been presented recently of all nickel 14-membered macrocycles in the Cambridge data base (9), where

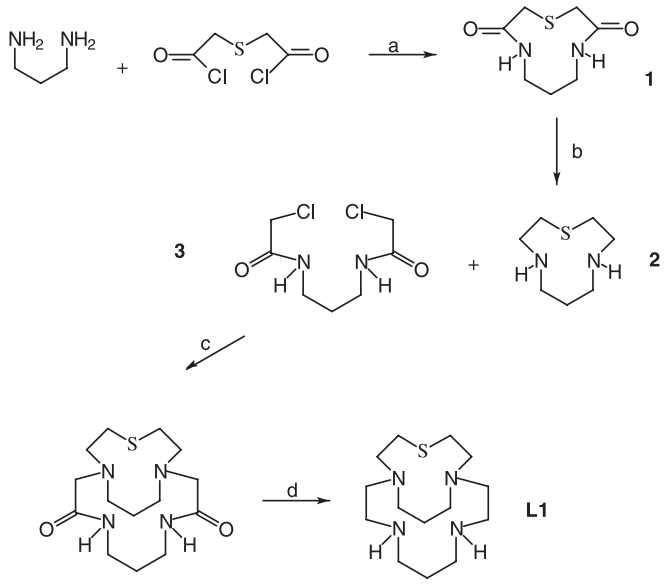
it is seen that the majority of *trans*-I species are square-planar or square-pyramidal, and the *trans*-III conformation is associated with octahedral symmetry. Also, *N*-alkylation appears to confer additional thermodynamic stability to the *trans*-I configuration (10).



Previous studies in this laboratory (11–14)[3] have reported the syntheses of macrobicyclic pentacoordinate ligands 14-X-1,4,8,11-tetraazabicyclo[10.5.2]nonadecane (L2) in which a nine-membered cyclononane ring ([9]aneN_2X where X = NH, O, S) is fused to an ethylene segment of the 14-membered tetraaza cyclam ring. Each of the (L2) cations adopts the *trans*-I conformation in the solid state.

The coordination properties of sulfur donors continue to be of great interest (15–18), particularly those involving thioethers, which tend to be rare and of the weak apical type. Recently (15), the *s*- and *p*-donor properties have been examined in the possible use of macrocyclic thioethers in ^{99}Tc complexes with possible use as pharmaceuticals. Use has also been made (17) of the resistance of thioethers to aerial oxidation and hydrolysis to examine structure–function relationships in complex formation reactions with square-planar metal centers. Several studies have been presented (19–23) in which mixed *N*- and *S*-donor ligands, either open-chain or macrocyclic, form complexes with metal ions. This paper reports the synthesis of the (L1) macrobicycle, a structural isomer of (L2), which unlike the former, can also adopt a *trans*-III geometry. As a result of ligand conformation in these systems, if the sulfur binds, it must do so at the axial site. Also, since the electronic nature of the N_4S donor set is identical in both (L1) and (L2), any differences in the resulting coordination properties might be attributed principally to structural effects.

Experimental section

NMR spectra, both ^{1}H and ^{13}C, were recorded on Bruker AMX360 or Bruker AC300 high-field spectrometers with either D_2O (MeOH as external standard) or $CDCl_3$ (TMS) as the solvent. Mass spectra of the free ligands were recorded on a Finnegan 330 GC–MS instrument by methane chemical ionization and electron impact techniques. Mass spectra of acidified ligand perchlorate salts and metal complexes were recorded on a Kratos Concept spectrometer either by FAB or electrospray ionization techniques. Infrared spectra were recorded on either a Bruker IFS25 (FT IR) spectrometer or a PerkinElmer 1330 spectrometer. A Cary 5 UV–vis–NIR spectrophotometer was used to record spectra. Elemental analyses were performed by Canadian Microanalytical Services Ltd., Delta, BC, Canada. Electrochemistry was performed using a Princeton Applied Research model 273 potentiostat–galvanostat, interfaced with an IBM PC microcomputer. The data were recorded using the corrWare program (Scribner Associates Inc). The electrochemical cell employed the standard three electrode configuration: platinum working and counter electrodes with Ag–$AgNO_3$ or silver wire as the reference electrode and 0.1 M $(Bu)_4NClO_4$ as background electrolyte. The ferrocene–ferrocenium couple ($Fc^{0/+}$) was used as both an external and internal standard.

Scheme 1. (*a*) 2 mol equiv diaminopropane (C_6H_6), rapid stirring, high dilution, RT; (*b*) BH_3·THF; (*c*) 1:1 $CHCl_3$:CH_3CN–CH_3CN, Na_2CO_3, high dilution; (*d*) BH_3·THF.

Molecular mechanics calculations were carried out on a Power Macintosh 7100/80 computer using the CAChe Scientific Worksystem software package, version 3.7. This software uses Allinger's MM2 (24) force field modelling program.

Reagent grade starting materials were used without further purification. Liquid amines were purified by vacuum distillation. Chloroform was twice distilled over CaH_2 to remove the ethanol present as stabilizer. Benzene was dried with sodium metal and freshly distilled before use. Increased yields in cyclisation reactions were observed with rapid stirring, and an apparatus was constructed for this purpose (25) where solutions were stirred mechanically at 1900 rpm.

Syntheses

The [10]aneN_2S precursor ligand was synthesized via the high dilution cyclisation of thiodigylcolic acid chloride with diaminopropane. The synthetic route to ligand L1 from [10]aneN_2S is outlined in Scheme 1.

Thiodiglycolic acid chloride

This material was prepared by reaction of $SOCl_2$ with the corresponding acid (26). To a sample of 15 g (0.1 mol) of thioglycollic acid, was added 150 mL (2.1 mol) of thionyl chloride. The solution was stirred for 20 h at room temperature under a strictly monitored N_2 atmosphere. Unreacted $SOCl_2$ was removed by vacuum distillation leaving a dark oil from which the pure acid chloride was obtained by microdistillation in vacuo. Yield: 14.5 g (0.078 mol), 78%. ^{1}H NMR ($CDCl_3$): 3.86 (CH_2-S). ^{13}C NMR ($CDCl_3$): 44.3 (CH_2-S), 169.5 (*C*=O).

1-Thia-4,8-diazacyclodecane-3,9-dione (1)

Samples of diaminopropane (8.88 g, 0.12 mol) and thiodiglycolic acid chloride (11.22 g, 0.060 mol), each in 50 mL of benzene, were added simultaneously from the sy-

[3] T. Rodopoulos. Unpublished observations.

ringe pump apparatus over a period of 10 h to 2.5 L chloroform stirred under N_2 at room temperature. The resulting white precipitate of diaminopropane dihydrochloride was filtered off and the product recovered by evaporation of the colourless filtrate in vacuo. The major product was the 1:1 condensate (**1**), but some 2:2 adduct ([20]-aneN_4S_2 tetraamide) was also observed. Pure samples of (**1**) were obtained by washing the product with 50 mL of MeOH per gram of solid. Yield: 7.1 g (0.038 mol), 63%; mp > 200°C. CI-MS *m*/*e*: 189 (M+1), 217 (M+29), 229 (M+41). IR (cm^{-1}): C=O stretch, 1640 (s, brd). ^{1}H NMR (D_2O): 1.65 (m, C-C*H*$_2$-C), 3.12 (m, C*H*$_2$-S, C*H*$_2$-N). ^{13}C NMR (D_2O): 24.9 (C-*C*H$_2$-C), 36.4, 39.9 (*C*H$_2$-S, *C*H$_2$-N), 171.8 (*C*=O). Anal. calcd. for $C_7H_{12}N_2O_2S$: C 44.66, H 6.43, N 14.88; found: C 44.66, H 6.42, N 14.66.

1-Thia-4,8-diazacyclodecane (2)

To 2.0 g (11.0 mmol) (**1**) was added 45 mL of 1 M BH_3·THF (0.045 mol) under N_2. The slurry was stirred at room temperature for 20 min and then refluxed for 4 h. After cooling in an ice bath, the excess borane was destroyed by slow dropwise addition of distilled water (2 to 3 mL) and the resulting solution was taken to dryness on a rotary evaporator. The white solid produced was dissolved in 40 mL of 6 M HCl and refluxed for 2 h. After cooling, the solution was taken to dryness on a rotary evaporator and dried further in vacuo. The resulting pale orange solid was dissolved in 25 mL of 2.5 M NaOH and extracted into chloroform (6 × 50 mL). The organic layers were combined, dried over sodium sulfate, and taken to dryness yielding a pale yellow or colourless oil. Yield: 1.55g (9.7 mmol), 88%. CI-MS *m*/*e*: 161 (M+1), 189 (M+29), 201 (M+41). ^{1}H NMR ($CDCl_3$): 1.6 (quintet, C-C*H*$_2$-C), 2.6–2.8 (m, 12H). ^{13}C NMR ($CDCl_3$): 27.9 (C-*C*H$_2$-C), 35.3 (*C*H$_2$-S), 48.1, 49.7 (*C*H$_2$-N).

***N*,*N*′-Bis(α-chloro acetamido)propane (3)**

The procedure was essentially that of Bradshaw et al. (27). Reaction of chloroacetyl chloride (0.37 mol) with diaminopropane (14.8 g, 0.20 mol) in aqueous base and resulting work-up yielded 21.3 g (0.094 mol), 47% of **3**. CI-MS *m*/*e*: 227 (M+1), 255 (M+29). ^{1}H NMR ($CDCl_3$): 1.72 (quintet, C-C*H*$_2$-C), 3.18 (quartet, C*H*$_2$-N), 4.05 (singlet, C*H*$_2$Cl). ^{13}C NMR ($CDCl_3$): 29.4 (C-*C*H$_2$-C), 36.4 (*C*H$_2$-N), 42.6 (*C*H$_2$Cl), 166.8 (*C*=O).

14-Thia-1,4,8,11-tetraazabicyclo[9.5.3]nonadecane-3,9-dione (4)

Samples of ([10]aneN_2S) (**2**) 1.48 g (9.25 mmol) in 200 mL 50:50 $CHCl_3$–CH_3CN and (**3**) 2.1 g (9.25 mmol), in 200 mL CH_3CN, were added drop-wise simultaneously in four batches of 50 mL from the syringe pump apparatus over a period of 8–10 h per 50 mL batch (40 h total) to 2.5 L of refluxing distilled CH_3CN containing 2.5 g (2.5 equiv) of sodium carbonate under N_2. After cooling to room temperature and filtering, evaporation to dryness in vacuo, gave a white powdery solid. Yield: 2.1 g, (6.69 mmol), 71.5%; mp > 200°C. CI-MS *m*/*e*: 315 (M+1), 343 (M+29), 355 (M+41). IR (cm^{-1}): C=O stretch, 1645 (s, brd.). ^{1}H NMR ($CDCl_3$): 1.4–1.9 (m, C-C*H*$_2$-C), 2.4–2.6, 2.8–3.4, 3.6–3.8 (m, 20H, C*H*$_2$-S, C*H*$_2$-N). ^{13}C NMR ($CDCl_3$): 26.8 (C-*C*H$_2$-C), 27.9 (C-*C*H$_2$-C), 36.3, 39.5, 54.5, 55.2, 60.0 (*C*H$_2$-N, *C*H$_2$-S), 170.7 (C=O). Anal. calcd. for $C_{14}H_{26}N_4O_2S$: C 53.48, H 8.33, N 17.82; found: C 53.12, H 8.12, N 16.87. We have no explanation for the low figure for nitrogen analysis.

14-Thia-1,4,8,11-tetraazabicyclo[9.5.3]nonadecane (L1)

To 1.0 g (3.18 mmol) of the diamide (**4**) was added, under nitrogen, 20 mL of 1 M BH_3·THF (20 mmol, 6 equiv). The slurry was stirred for 20 min then refluxed for 4.5 h and processed as described earlier. After reflux in acid, cooling and drying in vacuo, the resulting material was dissolved in strongly basic NaOH and extracted with chloroform (6 × 40 mL). The combined organic layers were dried over anhyd Na_2SO_4 and taken to dryness in vacuo yielding a colourless oil. Yield: 0.72 g (2.52 mmol), 79%. The material was purified by dissolving 0.72 g (2.52 mmol) of crude L1 in 2 mL 1:1 v/v methanol and water, followed by dropwise addition of 70% $HClO_4$ (*CAUTION*) until the mixture was distinctly acidic. A colourless crystalline precipitate of composition $[H_4L1](ClO_4)_4$ formed overnight. The precipitate was filtered, washed successively with methanol, ether and dried in vacuo. Yield: 0.83 g (1.21 mmol). FAB-HR-MS calcd. for $[C_{14}H_{31}N_4S]^+$: 286.2269: found: 286.2255. ^{1}H NMR (D_2O): 1.6–1.8 (m, 4H, C-C*H*$_2$-C), 2.2–3.4 (m, 24H). ^{13}C NMR (D_2O): 18.9 (C-*C*H$_2$-C), 24.4 (C-*C*H$_2$-C), 28.5 (*C*H$_2$-S), 44.1, 49.9, 50.2, 52.7, 53.0 (5 × *C*H$_2$-N). The free ligand, L1, was obtained by dissolving the perchloric acid salt (0.83 g) in 15 mL of 5 M NaOH and extracting with chloroform (4 × 50 mL). The combined extracts were dried over anhyd Na_2SO_4 and taken to dryness in vacuo, leaving a viscous colourless oil. Yield: 0.191 g (0.67 mmol), 55%. CI-MS *m*/*e*: 287 (M+1), 315 (M+29), 327 (M+41). ^{1}H NMR ($CDCl_3$): 1.6–1.8 (m, 4H, C-C*H*$_2$-C), 2.4–2.9 (m, 24H). ^{13}C NMR ($CDCl_3$): 29.0 (C-*C*H$_2$-C), 29.3 (C-*C*H$_2$-C), 36.4 (*C*H$_2$-S), 46.7, 51.9, 55.2, 56.0, 57.9 (5 × *C*H$_2$-N).

CAUTION! Perchlorate salts are explosive and care should be taken when using these compounds. Only small quantities should be prepared. Experiments should be carried out only in designated fume hoods.

$[Ni(L1)(ClO_4)](ClO_4)\cdot 2[Ni(L1)(OH_2)](ClO_4)_2\cdot 6H_2O$

To 150 mg (0.52 mmol) of L1 and 192 mg (0.52 mmol) K_2CO_3 in 20 mL dry acetonitrile was added, with stirring, a solution of 72 mg (0.52 mmol) $[Ni(OH_2)_6](ClO_4)_2$ in 10 mL dry acetonitrile. The mixture was refluxed for 4 h to ensure complete coordination, filtered, and taken to dryness in vacuo. The pale pink residue was dissolved with heating in 8 mL of 5% $HClO_4$. Upon cooling, pale pink needle crystals formed which were removed by filtration and dried. Yield: 122 mg (0.069 mmol), 40%. The presence of the perchlorate cation was confirmed by FAB-HR-MS: calcd. for $[Ni(L1)(ClO_4)]^+$: 443.1029; found: 443.0966.

Crystallography

$[Ni(L1)(ClO_4)](ClO_4)\cdot 2[Ni(L1)(OH_2)](ClO_4)_2\cdot 6H_2O$

Pale pink crystals of dimension 0.35 × 0.25 × 0.20 mm, grown from dilute perchloric acid were used. X-ray measurements were made on a Rigaku/ADSC CCD area detector with graphite monochromated Mo Kα radiation (λ = 0.71069 Å). Data were collected in 0.30° oscillations with 12.5 s exposures. A sweep of data was done using φ oscilla-

[a]Temperature 193(2) K, Mo Kα (λ = 71069 Å) radiation, graphite monochromator, Rigaku/ADSC CCD area detector, $R = \Sigma||Fo| - ||Fc||/\Sigma|Fo|$, $Rw = [(\Sigma w(|Fo| - |Fc|)^2/\Sigma wFo^2)]^{1/2}$.

tions from 0.0 to 190.2° at χ = –90° and a second sweep was performed using ω oscillations between –23.0 and 17.8° at χ = 90°. Corrections were made for Lorentz and polarization effects. The structure was solved by direct methods (28*a*) and expanded using Fourier techniques (28*b*). The asymmetric unit contained two $[Ni(L1)(H_2O)]^{2+}$, and one $[Ni(L1)(ClO_4)]^+$ cations, with five perchlorate anions and six water molecules in the lattice. Three perchlorate moieties were modelled as disordered. Two of these (containing Cl(1) and Cl(6) were mirror disordered with respect to a common O_3 plane and the third (containing Cl(3) was disordered by a rotation about one of the Cl—O bonds. Population parameters were adjusted to yield approximately equal thermal parameters for the corresponding components. All but two of the water hydrogen atoms (those associated with O(28)) were placed in difference map positions but were not refined. The location of the uncoordinated water hydrogen atoms is tentative and some of these hydrogen atoms may be disordered and (or) incorrectly placed. Some low occupancy non-hydrogen atoms were refined isotropically (Cl(1a), Cl(6a), O(4a), O(12a), O(13a), O(14a), and O(23a)) while the rest were refined anisotropically. N-H and C-H hydrogen atoms were fixed in calculated positions with N—H = 0.91 Å, C—H = 0.98 Å. Details of the crystallographic data are presented in Table 1. Neutral atom scattering factors were taken from Cromer and Weber (28*c*). Anomalous dispersion effects were included in *F*calc (28*d*) and the values for $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley (28*e*). The values for the mass attenuation coefficients are those of Creagh and Hubbell (28*f*). All calculations were performed using the teXsan (28*g*) crystallographic software package of Molecular Structure Corporation. Complete lists of atomic coordinates, angles and distances are presented in supplementary Table S1 (see *Supplementary material*).

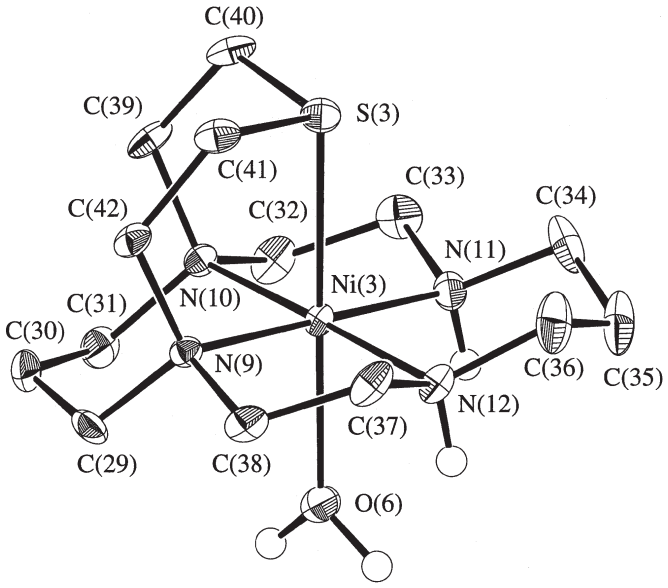
Results and discussion

Synthetic aspects

The precursor (**1**) was synthesized by the high dilution cyclisation of thiodiglycolic acid chloride with diaminopropane (Scheme 1) as an alternative to the Richman–Atkins tosylate method (29, 30). The product yield depended considerably on the stirring conditions. High stirring speeds were employed to reduce any side products in the cyclisation of (**2**) with *N*,*N*′-bis(α-chloro acetamido)propane (**3**). Also, the analogous reaction (14) using 1-oxa-4,8-diazacyclododecane (**(**[10]aneN_2O) proceeded in 100% yield. This adaptation of the reactivity reported by Bradshaw et al. (27) appears to be both general and efficient, presumably due to preorientation of the C—Cl bonds in (**3**) owing to the presence of the adjacent amides. However, the reaction yield is dependent on the solubility of the reagents, which appears to be enhanced by the presence of small amounts of moisture. The borane reduction of (**4**) produced L1 in good yield. However, during extraction, if the aqueous layer was not >4 M NaOH, the chloroform extract consisted exclusively of colourless crystals of the mono-protonated ligand. An attempted crystallographic resolution[4] identified an extremely large unit cell containing the adduct $\{[HL1](ClO_4)\cdot CHCl_3\}_4$, confirming that the ligand acts as a proton sponge. The N_4S ligand structurally closest to those under consideration is the bicyclic species 12,17-dimethyl-5-thia-1,9,12,17-tetraazabicyclo[7.5.5]nonadecane, in which the N_4 donor set is part of a 12-membered cyclen ring (23). It is of interest

[4] S. Rettig. Unpublished results.

© 2001 NRC Canada



that this bicyclic ligand also acts as a very strong proton acceptor, with pK_a values for the *mono*- and *bis*-protonated species being 11.91 and 8.78, respectively.

The ligand L1 did not readily coordinate nickel(II) perchlorate in aqueous solution, presumably owing to the unique proton affinity observed for this isomer. Reaction of nickel(II) perchlorate with L1 in acetonitrile, followed by evaporation to dryness gave a white residue which, upon dissolution in hot 5% $HClO_4$, yielded reproducibly, upon cooling, pale pink needle crystals of $[Ni(L1)(ClO_4)](ClO_4)\cdot 2[Ni(L1)(OH_2)](ClO_4)_2\cdot 6H_2O$. Interestingly, if the pink-colored aqueous or acetonitrile solutions derived from the reaction residue were left to stand at room temperature for an extended period of time (days to weeks), the solution turned brown and yielded a brown solid residue. Recrystallization of the brown residue from 5% $HClO_4$ produced golden brown needle crystals similar in size and shape to the pale pink crystals. (Anal. calcd. for $[Ni(C_{14}H_{32}N_4S)](Cl_2O_9)$: C 29.93, H 5.74, N 9.97, S 5.71; found: C 29.74, H 5.23, N 9.75, S 5.79) of this golden brown form conforms to the formulation $[Ni(L1)](ClO_4)_2\cdot H_2O$. It may be in this case, that the S donor is detached and adopts the exo-configuration to give a square-planar nickel(II) center, since the HR-MS (FAB, calcd. = 443.1029; observed = 443.0970 *m*/*e*) is consistent with the $[Ni(L1)]^+$ cation and the colour of the material.

Molecular structures

In the nickel(II) cations, the four nitrogen donors of the cyclam ring are coordinated in a planar equatorial fashion and the thioether sulfur is coordinated axially. The cyclam ring adopts a *trans*-III conformation (8), in contrast to the isomeric $[Ni(L2)(ClO_4)]^+$ ions which are constrained to be *trans*-I. Extensive H-bonding was seen in the lattice of $[Ni(L1)(ClO_4)](ClO_4)\cdot 2[Ni(L1)(OH_2)](ClO_4)_2\cdot 6H_2O$, (supplementary Fig. 1, see *Supplementary material*). For clarity, only the structure of $[Ni(L1)(OH_2)]^{2+}$ is shown in Fig. 1. The ORTEP of the complex incorporating the perchlorate ion is shown in supplementary Fig. 2 (see *Supplementary material*). Principal values for bond distances and angles are presented in supplementary Table S2 (see *Supplementary material*). The geometry of the cations $[Ni(L1)(X)]^{n+}$ (X = ClO_4 or H_2O) is pseudooctahedral. In $[Ni(L1)(ClO_4)]^+$, the four nitrogen atoms show only minor deviations (0.053–0.071 Å) from coplanarity. In contrast to the 0.111 Å displacement observed (10) in $[Ni(L2)(ClO_4)]^+$, (*trans*-I) cation, the nickel in $[Ni(L1)(ClO_4)]^+$ is displaced from the N_4 plane by only 0.0045 Å towards the sulfur. The Ni—NH bond lengths (2.059 Å and 2.067 Å) are similar to those in $[Ni(L2)(ClO_4)]^+$. For the *trans*-III configuration, the hole size in free cyclam has been calculated (31) as 2.05 Å. However, the observed Ni—N(*tert*) distances (2.105 Å and 2.113 Å) are close to the calculated ideal high-spin Ni(II)—N bond (2.10 Å) (32, 33). In the present system, the implication is that the cyclam ring in L1 has expanded to accommodate the nickel(II) ion consistent with the coplanarity of the metal center and the N_4 framework. The Ni-S vector is tilted 5.7° from the perpendicular to the N_4 plane towards the tertiary nitrogens which is similar to the 6.5° tilt in the $[Ni(L2)(ClO_4)]^+$ cation. In the perchlorate complexes, the Ni—S bond lengths are virtually identical at 2.39 Å. In contrast, each of the two $[Ni(L1)(H_2O)]^{2+}$ cations has a slightly longer Ni—S bond distance at 2.42 Å which implies that a small *trans* effect exists for aquo vs. perchlorato coordination in the remaining sixth axial site. Also, in both $[Ni(L1)(H_2O)]^{2+}$ cations, the Ni—OH_2 bond vectors (2.18 Å and 2.19 Å) are tilted towards the two secondary nitrogens of the unbridged propylenediamine chelate. However, in $[Ni(L1)(ClO_4)]^+$, the Ni—$OClO_3$ bond vector is 2.24 Å and tilted 5.7° from the perpendicular to the N_4 plane, but now towards the N2-N3 ethylenediamine chelate.

Fig. 1. ORTEP diagram of $[Ni(L1)(OH_2)]^{2+}$ with 25% ellipsoids.

The relatively minor differences in the coordination geometries of the nickel(II) ions complexed with L1 and L2 suggests that the ligands are relatively flexible with the constraints of the metal ion dictating the observed geometry. However, there may exist some differences in ligand strain, if only due to the *trans*-III vs. *trans*-I conformations. Molecular mechanics calculations were undertaken to determine such variations. To optimize ligand geometries in their *trans*-I or III configurations, the fractional atomic coordinates of only the ligand atoms from the structures of the complexes were used. An iterative calculation was then conducted to find the minimum energy conformation of the free ligands. The difference in total energies of the coordinated versus free ligand forms is then an assessment of the ligand strain induced by coordination of the metal ion. The results of these calculations are provided in Table 3.

While the ligand isomers L1 and L2 are of comparable total energy (only 4 kJ mol^{-1} difference) in their *trans*-III and *trans*-I states, respectively, both ligands develop considerable strain (>95 kJ mol^{-1}) upon coordination. However, the Ni(II) ions with ligand L1 (*trans*-III) developed about 33 kJ mol^{-1} less strain energy than the L2 isomer which cannot adopt that configuration. In each case, bond stretch and van der Waals factors contributed most to the total strain. Although overall bond angle and torsional strain energies are less in magnitude, they differ significantly between L1 and L2. Owing to a lack of knowledge of the ligand structure in reduced metal complexes, no corresponding analysis was undertaken.

Solution studies

The UV–vis data are listed in Table 4 where data in aqueous and acetonitrile media are presented. Dissolution of the mixed aquo – perchlorato complex was considered to yield a solvento ion owing to the weak ligating properties of the perchlorate. In water, the spectrum of the pink pseudo-octahedral $[Ni(L1)(solv)]^{2+}$ ion is consistent with a water molecule as the sixth axial donor (14). This complex also exhibits exceptional kinetic stability, even in strongly acidic solutions. The $^3A_{2g} \rightarrow {}^3T_{1g}$ transition (498 nm) may be compared to the $[Ni(L2)(OH_2)]^{2+}$ isomer (504 nm) (11) which has a similar pattern of bands and intensities. The solution spectra of $[Ni(L1)(OH_2)]^{2+}$ and $[Ni(L2)(OH_2)]^{2+}$ ions differ slightly, possibly due to *trans*-III vs. *trans*-I configurations. The most significant difference in the spectra was observed in the bands at 989 nm for $[Ni(L1)(OH_2)]^{2+}$ and 1020 nm for $[Ni(L2)(OH_2)]^{2+}$. This may be a reflection of the differences in strain energy described earlier, deriving from the displacement of the nickel(II) from the N_4 plane in $[Ni(L2)(ClO_4)]^{2+}$. The yellow form of the complex is consistent with a square-planar ion.

EPR spectroscopy

Oxidation of the $[Ni(L1)(OH_2)]^{2+}$ cation with $K_2S_2O_8$ in aqueous solution yielded the EPR-active $[Ni(L1)(OH_2)]^{3+}$ ion with $g_\perp = 2.159$ and $g_\parallel = 2.024$ characteristic (34, 35) of a low-spin d^7 ion in a distorted octahedral environment of axial symmetry. There is the possibility of formation of some sulfato complex owing to the oxidant used, but it is unlikely that this would cause a significant change in the spectrum. The values are similar to the $g_\perp = 2.169$ and $g_\parallel = 2.025$ reported (10) for the $[Ni(L2)(solv)]^{3+}$ isomer suggesting that the coordination properties of the Ni(III) complexes

© 2001 NRC Canada

do not differ significantly. However, there is a difference between these values, and those for $[Ni([9]aneN_4O)(solv)]^{3+}$ [3] ($g_\perp$ = 2.200 and $g_\parallel$ = 2.028) and $[Ni(cyclam)(OH_2)_2]^{3+}$ (35) ($g_\perp$ = 2.219 and $g_\parallel$ = 2.033), respectively. Thus, the nature of the axial donor provides a much more dominant effect than the ligand structure probably owing to the presence of the electron in the d_{z2} orbital.

Electrochemistry

Studies of the $[Ni(L1)(solv)]^{2+}$ complex exhibited two waves in CH_3CN (0.1 M $(Bu)_4NClO_4$). The first at $E_{1/2}$ = –1.807 V vs. $Fc^{+/0}$, corresponding to the $[Ni(L1)(solv)]^{2+/+}$ couple was quasireversible ($E_{pc} - E_{pa}$ = 135 mV) and independent of scan rate. This value contrasts with the $[Ni(L2)(solv)]^{2+/+}$ potential of –1.685 V, suggesting that any structural rearrangement upon reduction favours the *trans*-I starting structure in which the nickel is displaced towards the sulfur. The second wave observed at $E_{1/2}$ = 0.715 V vs. $Fc^{+/0}$ for $[Ni(L1)(solv)]^{3+/2+}$ was chemically and electrochemically more reversible ($E_{pc} - E_{pa}$ = 87 mV). The half-wave potential of this couple is virtually identical to that of $[Ni(L2)(solv)]^{3+/2+}$ ($E_{1/2}$ = 0.719 V vs. $Fc^{+/0}$).[5] This result is somewhat surprising, given that the two isomers exhibited slight differences in their UV–vis and ESR spectra. It thus appears that the presence of the *trans*-III vs. *trans*-I configuration in the equatorial cyclam ring has no significant effect upon the stability of the $Ni^{3+/2+}$ redox couple. In contrast, Pierce et al. (36) have reported the isolation and characterization of *trans*-I-$[Ni(cyclam)]^{2+}$ and compared its electrochemical behavior to that of *trans*-III isomer (both complexes are low-spin square-planar perchlorate salts). In that study, it was found that, despite the similarity of the UV–vis spectra, the two configurational isomers showed markedly different electrochemical behaviour. The *trans*-I-$[Ni(cyclam)]^{2+}$ complex exhibited a broad, irreversible oxidation wave at 1.0–1.1 V (vs. 3.5 M NaCl calomel reference electrode) and then subsequently isomerized to the *trans*-III form which exhibits a reversible wave at 0.772 V. At higher sweep rates (>0.5 V s^{-1}), a reversible wave was observed for *trans*-I-$[Ni(cyclam)]^{2+}$ which permitted the formal potential to be estimated at $E_{1/2}$ = 0.92 V, 150 mV higher potential than the *trans*-III isomer. Clearly, further work is required on the present complexes to examine more closely any relationship between ring conformation and redox potentials.

Conclusion

The synthesis of L1 proceeded in high yield. Upon coordination of nickel(II), the ligand adopts the *trans*-III configuration of nitrogen donors which contrasts the *trans*-I configuration observed for the isomeric macrobicyclic ligand (L2). A stable protonated form $HL1^+$ has also been identified. In $[Ni(L1)(OH_2)]^{2+}$, the Ni(II) ion is coplanar with the N_4 donor set in contrast to the corresponding L2 ion where there is a marked displacement towards the S donor. These variations are reflected in slight differences in solution spectra and electrochemical potentials. Molecular mechanics calculations based on the solid-state structures also show an energy difference between the isomers.

N,*N*-dimethylhydroxamidovanadium(V). Interactions with sulfhydryl-containing ligands: V(V) equilibria and the structure of a V(IV) dithiothreitolato complex

Sudeep Bhattacharyya, Anette Martinsson, Raymond J. Batchelor, F.W.B. Einstein, and Alan S. Tracey

Abstract: The major aqueous equilibrium complexation reactions of vanadate in the presence of *N*,*N*-dimethylhydroxylamine (DMHA) and with dithiothreitol (DTT), β-mercaptoethanol, glycine, or cysteine in solution have been studied using ^{51}V NMR spectroscopy. Previously unreported DMHA complexes of 2:1 and 2:3 V:DMHA stoichiometry were observed and characterized. Concentration studies showed that, for the three sulphur-containing ligands, the major product of sulphur coordination has a 1:2:1 stoichiometry of vanadate to dimethylhydroxylamine to heteroligand. These products do not carry a charge in neutral to moderately basic solution. A second product type of 1:1:1, V to DMHA to heteroligand, stoichiometry is also formed. These products carry a single negative charge. A reductive reaction between vanadate and excess DTT to form a V(IV) complex was also observed and a solid product was isolated. This product could also be obtained by direct reaction of vanadyl sulphate with DTT. It was characterized by X-ray diffraction studies. Crystal structure of $[\{VO(SCH_2CHOHCHOCH_2S)\}_2]$ $[AsPh_4]_2$: monoclinic, space group $P2_1/n$, $Z = 2$, $a = 10.1607(18)$ Å, $b = 17.8255(42)$ Å, $c = 15.1520(33)$ Å, $\beta = 104.\ 000(15)°$, $V = 2662.8$ Å^3, $R_F = 0.038$ for 2327 data ($I_o \geq 2.5\sigma(I_o)$) and 325 variables.

Key words: vanadate, vanadyl, dithiothreitol, mercaptoethanol, cysteine, glycine, equilibrium constants, crystal structure, X-ray, vanadium NMR.

Résumé : Faisant appel à la RMN du ^{51}V, on a étudié les principales réactions de complexation en équilibre aqueux du vanadate, en présence de *N*,*N*-diméthylhydroxylamine (DHMA), avec le dithiothréitiol (DTT), le β-mercaptoéthanol, la glycine et la cystéine. On a observé et caractérisé des complexes du DMHA de stoechiométries V:DMHA 2:1 et 2:3. Des études de concentrations montrent que, pour les trois ligands contenant du soufre, le produit principal de la coordination du soufre comporte une stoechiométrie 1:2:1 du vanadate par rapport à la diméthylhydroxylamine et à l'hétéroligand. En solution neutre ou faiblement basique, les produits ne portent pas de charge. Il se forme aussi un deuxième type de produit de stoechiométrie 1:1:1 du V au DMHA à l'hétéroligand. Ces produits portent une charge négative simple. On a observé une réaction réductrice entre le vanadate et l'excès de DTT; elle conduit à la formation du'un complexe V(IV) et on a isolé un produit solide. On peut aussi obtenir ce produit par réaction directe du sulfate de vanadyle avec le DTT. On l'a caractérisé par des études de diffraction des rayons X. Les cristaux de $[\{VO(SCH_2CHOHCHOCH_2S)\}_2][AsPh_4]_2$ sont monocliniques, groupe d'espace $P2_1/n$, $Z = 2$, $a = 10{,}1607(18)$ Å, $b = 17{,}8255(42)$ Å et $c = 15{,}1520(33)$ Å, $\beta = 104\ 000(15)°$, $V = 2662{,}8$ Å^3, $R_F = 0{,}038$ pour 2327 données ($I_0 \geq 2{,}5\sigma(I_o)$) et 325 variables.

Introduction

It is frequently asserted that vanadium(V) oxides (vanadate) are rapidly reduced by thiolates but this is true only for specific conditions. Indeed, although stable V(IV) thiolates are frequently reported, it is not uncommon to have mixed vanadium (IV/V) states and even vanadium(V) thiolates can be quite stable in solution (1, 2). As a part of our ongoing studies on the reactivities of V(V) and thiolates, we have previously carried out a detailed study of the aqueous equilibria established between vanadate and dithiothreitol (DTT) and have proposed structures for the major product formed in that system (2). A crystal structure of the complex of β-mercaptoethanol with vanadate has also been reported and this structure correlated with aspects of the associated aqueous chemistry (1).

Our interest in these thiolate complexes has evolved from our studies of the insulin-mimetic effect of vanadium compounds and of protein tyrosine phosphatases (PTPases) that may be relevant to that effect. The PTPases are group of signal transduction enzymes that regulate a number of key cellular responses that are initiated by certain tyrosine phosphorylated proteins (3, 4). The event of dephosphorylation of the phosphotyrosine group of the substrate proteins by the PTPase regulates the cellular response. The dephosphorylation takes place via a concerted and cooperative mechanism effected by the catalytic active site residues of the enzyme. The chemistry of the process is complex, and involves the critical active site residues, aspartate and cysteine via a thiophosphate intermediate. Vanadate, a transition-metal analog of phosphate, is an excellent inhibitor of this hydrolytic process. Recently, it has been shown that *N*,*N*-dimethylhydroxylamine (DMHA) derivatives of vanadate (here referred to collectively as DMHAV) have a similar effect. Specifically, bis(*N*,*N*-dimethylhydroxamido)hydroxooxovanadate ($(dmha)_2V(O)OH$) is a very good inhibitor of PTPase activity (5). Furthermore, this compound is functional as an insulin-mimetic in some cell cultures where vanadate is inactive (6).

An understanding of the chemistry involved in the inhibition of PTPase function by the small molecules of DMHAV is important since it provides a basis for the design of other metallorganic inhibitors. To an extent, the identity of the actual inhibiting species is still speculative. The details of the specific interactions of DMHAV with the surrounding active site residues are not yet known although the interactions very likely involve direct reaction at the sulphur of the active site cysteine (7). The influence of externally added thiolate redox buffers like dithiothreitol (DTT) and β-mercaptoethanol is also not fully understood. Both of these buffers are known to form complexes with oxovanadium species (1, 8) and these, and various other sulphur-containing ligands are highly reactive with DMHAV (9). An understanding of the chemistry promoted by sulfur-containing reagents is critically important for the development of our understanding of the chemistry of the inhibition itself. Some time ago we reported a preliminary study of the reactions of DMHA complexes of vanadate with DTT (9). We are now able to provide a much more detailed description of the aqueous chemistry and also are able to draw some comparisons with the closely related ligand β-mercaptoethanol and with the amino acids glycine and cysteine. We also report an X-ray crystal structure of a V(IV) complex with DTT which is compared to and contrasted with the structure we propose for its V(V) analog.

Experimental section

Materials

All chemicals used in this work were of reagent or better quality. Divanadium(V) pentoxide, *N*,*N*-dimethylhydroxylamine hydrochloride, dithiothreitol, tetraphenylarsonium chloride, glycine, cysteine and β-mercaptoethanol were obtained from Sigma–Aldrich and used without further purification. Potassium chloride (99.5% analytical reagent) was from BDH Inc.

Solutions

Preparative methods for stock solutions of sodium vanadate, DMHA, KCl, and DTT are described elsewhere (9). The ionic strength of all solutions were maintained at 1.0 M with KCl. In each case, the solutions at different pH were prepared following a two-step addition. Initially, appropriate amounts, for the desired final concentrations, of the stock KCl, DMHA, and DTT solutions were combined. The pH of the solution was then adjusted, using appropriate amounts of HCl or KOH, to a value so that after, the addition of the stock vanadate solution, the pH would be close to, but below the desired value. In the second step the vanadate was added, the pH adjusted upward with KOH, and finally the final desired volume was made up with water previously brought to the particular pH. This procedure avoided the formation of decavanadate which tends to form in solutions below the neutral pH.

Synthesis of $As_2C_{56}H_{54}O_6S_4V_2$

At room temperature, an aqueous solution (2 mL) of DTT (0.15 g, 1 mmol), adjusted to pH 8.5, was added dropwise, with stirring, to a 2.5 mL aqueous solution of $VOSO_4.xH_2O$ (0.2 g, 1 mmol). The resultant solution gradually turned green. It was stirred for an additional 5 min and the desired compound was then precipitated by adding a warm saturated solution of tetraphenylarsonium chloride (0.42 g, 1 mmol), in 5 mL of water. The product, obtained in green microcrystalline form, was recrystallized from warm acetonitrile. Yield: (0.4 g) 67%. FT-IR (KBr) (cm^{-1}): 961, V=O stretching. Anal. calcd. for $As_2C_{56}H_{54}O_6S_4V_2$: C 55.9, H 4.5; found: C 55.78, H 4.52.

^{51}V NMR Spectroscopy

^{51}V NMR spectra were obtained either from a Bruker AMX400 NMR spectrometer operating at 105.2 MHz at ambient temperature or from a Bruker AMX600 operating at 157.7 MHz. Vanadium chemical shifts are reported relative to the chemical shift of the external reference $VOCl_3$ at 0 ppm. The following NMR parameters were used: pulse width 60°; spectral width 62.5 kHz; acquisition time 0.065 s. The data was process using the spectrometer manufacturers software WINNMR. A line-broadening factor of 40 Hz was applied to all spectra and after Fourier transformation, the

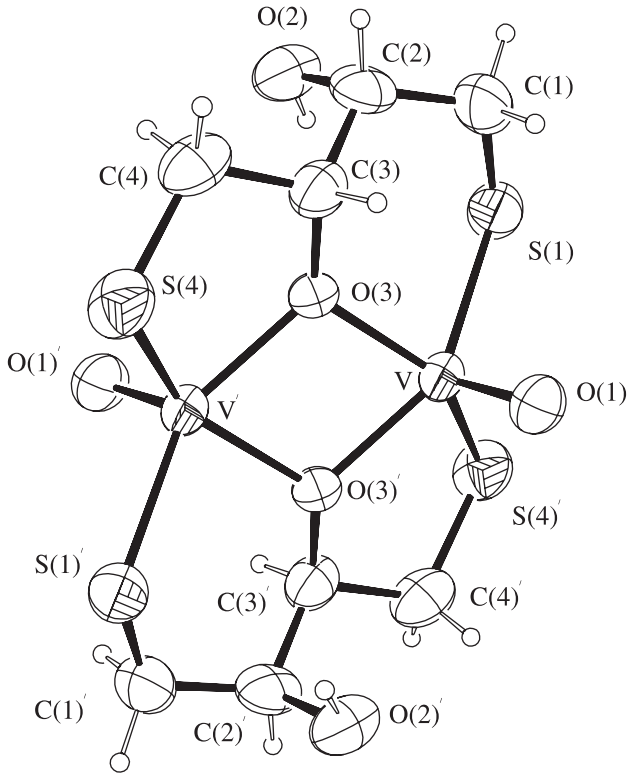
spectra were baseline corrected before integration. Where necessary, signal deconvolution was also carried out using the WINNMR program.

Data analysis

The procedures for analysis of the NMR data are outlined in the text. All errors in parameters are reported at the 95% (3σ) confidence level.

X-ray crystallography



A cleaved segment of a light green, plate-shaped crystal was mounted on a glass fiber using epoxy glue as an adhesive. Data were recorded with an Enraf Nonius CAD4F diffractometer using graphite-monochromatized Mo K_α radiation. Data reduction included corrections for Lorentz and polarization effects.

All non-hydrogen atoms' coordinates and anisotropic displacement parameters as well as the hydroxyl hydrogen atoms' coordinates and isotropic displacement parameter were refined. All other hydrogen atoms were placed in calculated positions and their coordinates were linked with those of their respective carbon atoms during refinement. Isotropic displacement parameters for these latter hydrogen atoms were initially assigned proportionately to the equivalent isotropic displacement parameters of their respective carbon atoms. Subsequently, these hydrogen atom displacement parameters were refined, but were constrained such that those within each phenyl group or those within the vanadium complex had the same shifts.

The data collection was performed using the program DIFRAC (10). The programs used for absorption corrections, data reduction, structure solution, and graphical output were from the NRCVAX Crystal Structure System (11). Full-matrix least-squares refinement was carried out using CRYSTALS (12). Complex scattering factors for neutral atoms (13) were used in the calculation of structure factors. Crystal data and experimental details are given in Table 1. The atomic coordinates, equivalent isotropic thermal parameters, and site occupancies for the non-hydrogen atoms are listed in Table 2.

Fig. 1. Molecular structure of the complex anion formed from dithiothreitol and vanadyl sulphate. 50% probability ellipsoids are shown for all non-hydrogen atoms. Hydrogen atoms are indicated by spheres of arbitrary radius.

Results and discussion

The complexation of the vanadium(V) oxoanion, vanadate, by dithiothreitol (DTT) has been studied for the pH range 7.1–9.7 and reduction of V(V) to V(IV) reported to occur in about a 90 min timescale (2). In the solutions utilized for this study at pH levels above neutral pH, partial reduction of vanadium(V) to V(IV) was observable after about 1–1.5 h. Consequently, the formation of the various V(V) solution products was readily studied by ^{51}V NMR spectroscopy without needing to take into account the redox reactions. However, at pH values below neutrality, and particularly at the higher concentrations of DTT, the reduction rate increases substantially. For example, at pH 6.2, in the reaction of 40 mmol DTT with 3 mmol vanadate, discoloration of the solution as V(IV) is formed becomes clearly evident in about 20 min. In the presence of sufficient *N*,*N*-dimethylhydroxylamine (DMHA) to effectively remove any free vanadate from solution, the reduction of V(V) to V(IV) is greatly slowed.

Efforts to isolate a crystalline V(V)–DTT–DMHA complex was not successful. However, as a result of V(V) reduction to V(IV) in the reaction medium, a V(IV) complex was obtained in crystalline form. The product contained DTT but no DMHA. A successful procedure for preparation of this V(IV)–DTT product from vanadyl sulphate was developed and is reported in the *Experimental section* and summarized below.

Crystal structure

The formation of the V(IV) dithiothreitol complex ($As_2C_{56}H_{54}O_6S_4V_2$) was carried out in water by adding a stoichiometric amount of dithiothreitol to vanadyl sulphate. The product was precipitated from solution as the tetraphenylarsonium salt. The microcrystalline compound appeared to be chemically stable. It was found to have medium solubility in common organic solvents such as chloroform and acetone and, in solution, did not show signs of decomposition even after several days at ambient temperature. An acetonitrile solution of the compound was allowed to slowly evaporate to give green crystals suitable for X-ray crystallographic analysis.

The molecular structure of the $[\{VO(SCH_2CHOHCHOCH_2S)\}_2]^{2-}$ anion is shown in Fig. 1. The anion has crystallographic inversion symmetry and the associated tetraphenylarsonium cation is in a general position. There are no inter-ionic contacts significantly shorter than the appropriate sums of accepted van der Waals radii and there is no water in the cell. Each vanadium atom is coordinated to one thiolate and one bridging alkoxy group from two oppositely directed dithiothreitol molecules. One hydroxyl group of each DTT is not coordinated and there are no close intermolecular contacts of the oxygen of this hydroxyl group to any other group. Consequently, the hydroxyl group does not undergo hydrogen bonding interactions.

The bond distances and bond angles obtained for the anion are listed in Table 3. Each vanadium(IV) is in an irregular five-coordinate environment which is close to a square-pyramidal structure with the V=O (O(1)) in an axial position. The six-membered chelate ring (V-S(1)-C(1)-C(2)-C(3)-O(3)) has a chair conformation with the hydroxyl group (O(2)) in an axial position. The five-membered chelate ring (V′-S(4)-C(4)-C(3)-O(3)) has an envelope conformation with C(4) constituting the flap. The arrangement around O(3) is close to planar (cf. the sum of the three bond angles at O(3) is 356.8°).

Solution studies

In aqueous solution, both dithiothreitol (2) and *N*,*N*-dimethylhydroxylamine (14–16) react spontaneously with vanadate. If DTT is designated as T, then complexes of V_2T stoichiometry are formed with DTT. The chemistry with DMHA is quite complex but under moderate total vanadate concentrations, the predominent product stoichiometries with DMHA (L) are VL and VL_2. Additional mixed products of varying stoichiometry are formed when the two ligands are together in solution. In anticipation of the results summarized below, Fig. 2 identifies the various signals and Table 4 gives their ^{51}V chemical shifts.

These studies of vanadate complexation reactions with *N*,*N*-dimethylhydroxylamine and associated heteroligands have utilized overall vanadium concentrations considerably higher than we have previously used in studies of this type. One consequence of this was the observation of NMR signals that corresponded to multinuclear vanadium–DMHA complexes. The concentrations of these compounds were sufficiently high that it was necessary to identify them so that proper characterization of the mixed ligand complexes of predominant interest could be carried out. Initial studies indicated that the compounds were binuclear complexes of

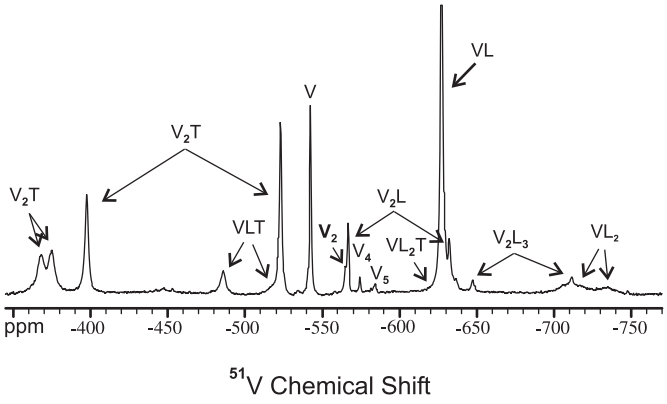
V_2L and V_2L_3 stoichiometries. The stoichiometry of these complexes was most easily established through the use of the known mononuclear complex, VL (15), as a reference compound. Equations [1] –[3] then describe the formation of these products. The

$$[1] \quad V + L \overset{K_{110}}{\rightleftharpoons} VL \qquad [V][L]K_{110} = [VL]$$

$$[2] \quad 2VL \overset{K_{110,210}}{\rightleftharpoons} V_2L + L \qquad [VL]^2 K_{110,210} = [V_2L][L]$$



$$[3] \quad 2VL + L \overset{K_{110,230}}{\rightleftharpoons} V_2L_3 \qquad [VL]^2[L]K_{110,230} = [V_2L_3]$$

formation constant determined for VL ($K_{110} = (1.4 \pm 0.1) \times 10^3$ M^{-1}) agrees well with that previously reported (15).

The characterization of V_2L was complicated by the fact that one NMR signal (–632 ppm) from this compound occurred very close to that from VL while the second (–567 ppm) was partially superimposed on that of divanadate. As near as could be judged, both of these signals had the same intensity and exhibited the same concentration dependencies. They were therefore assigned to the individual vanadiums of the same product. On that basis, the formation constant was $K_{110,210} = (0.12 \pm 0.01)$.

Similarly to those of V_2L, two NMR signals (–648 ppm, –712 ppm) had a concentration dependence corresponding to a V_2L_3 stoichiometry. The second of these signals was superimposed on one of the VL_2 signals but appropriate concentrations of reactants could be obtained that allowed it to be established that these signals were of equal intensity. Consequently, they were assigned to the individual signals of V_2L_3. Fig. 3 shows the equilibrium data plotted according to

Fig. 2. ^{51}V NMR spectrum of vanadate in the presence of dithiothreitol (T) and *N*,*N*-dimethylhydroxylamine (L). The signals of various products discussed in the text are identified. Conditions of the experiment: vanadate (10 mM), dithiothreitol (10 mM), *N*,*N*-dimethylhydroxylamine (5 mM), KCl (1.0 M), pH 8.54.

eq. [3]. The value determined for the formation constant was $K_{110,230} = (4.2 \pm 0.2) \times 10^3$ M^{-2}.

From the relative values of $K_{110,210}$ and $K_{110,230}$ (note different units) it is evident that V_2L and V_3L_2 are found in equal proportions in solution when the free DMHA concentration is about 5 mM. Because of the L stoichiometry, the relative proportion of V_2L_3 increases with higher concentration of L free in solution and decreases with a lower concentration. This is evident in Fig. 2 where, as reflected in the NMR spectrum, the V_2L concentration is significantly higher than that of V_3L_2.

Of critical importance is the observation that VL (–627 ppm) and a mixed ligand product VL_2T (–626 ppm), have overlapping NMR signals. Products that have VLT stoichiometry have been assigned to NMR signals at –485 and –517 ppm. Both of these signals occur with low relative intensities, with the –515 ppm signal being much the smaller of the two. The identity of the –517 ppm product was inferred from that of the –485 ppm signal because the relative intensities of the two signals, as well as could be judged, maintained a constant proportionality throughout the various concentration studies. Because of the ligand and proton stoichiometries, the –485 ppm signal is observable at pH 6.73 only under low DMHA and quite high DTT concentrations. This condition also ensures formation of low amounts of VL_2T so that there is selective suppression of this –626 ppm product. The situation is quite different at pH 8.54 where the –485 ppm signal can be observed even when the concentration of DTT is low (Fig. 2).

Under neutral conditions, preliminary experiments identified the concentrations of vanadate, DMHA, and DTT, that provided a useful distribution of free vanadate and its products. Using appropriate concentrations of reactants, as established above, a pH variation study was carried out. At low pH (below 6.00), vanadate is a reasonably effective oxidant of DTT while at high pH (above 9.5) the vanadate complexes are highly dissociated. A pH range for the study of product formation from pH 6.7 to 8.7 was therefore adopted. Detailed solution studies were then carried out at both pH 6.73 and pH 8.54. In each case the concentrations of V,

The insets show the influences of varying amounts of dithiothreitol (T) with fixed total concentrations of vanadate and *N*,*N*-dimethylhydroxylamine (L). Conditions of the experiments: vanadate (5 mM), *N*,*N*-dimethylhydroxylamine (40 mM), dithiothreitol (60 mM) (main trace), pH 8.54, KCl (1.0 M); total dithiothreitol concentrations: 2, 5, 8, 10, 20, 30, 60, 120 mM bottom to top traces of the insets.

DMHA, and DTT were selectively varied in independent experiments. Figure 4 shows the results of one such concentration study.

There, however, is an analytical problem that arises because some product formation constants are large. Under certain reaction conditions, free DMHA ([L]) and free DTT ([T]) concentrations can be very low and thus difficult to accurately specify from the conservation equations. This arises because the errors in the determination of product concentrations are comparable to the free DMHA or free DTT concentrations. However, these problems were circumvented by a judicious choice of reactant concentrations. Studies were initially carried out under the assumption that the mixed ligand product at –626 ppm was of stoichiometry VLT, as previously assigned (5). It was possible to show that that assignment of stoichiometry was incorrect by studying first the formation of the minor product giving a signal at –485 ppm. The product giving rise to this latter signal could unequivocally be shown to have a VLT stoichiometry and also it could be shown that the stoichiometry of this product was different from the product giving rise to the partially obscured signal at –626 ppm.

The formation of two V_2T complexes (eq. [4]) has previously been reported (2) and, as is evident from Fig. 2, it was necessary to take them into account in this study.

$$[4] \qquad 2V + T \overset{K_{201}}{\rightleftharpoons} V_2T \qquad [V]^2[T]K_{201} = [V_2T]$$

The stoichiometry corresponding to the –485 ppm (and by inference the –517 ppm) signal was established by varying the total concentrations of V, L, and T in separate experiments. Figure 4 provides a graphical display of the influence of varying the concentration of DTT while total vanadate and total DMHA were maintained constant. The constant ratio of signal intensities of the –485 and –517 ppm signals is

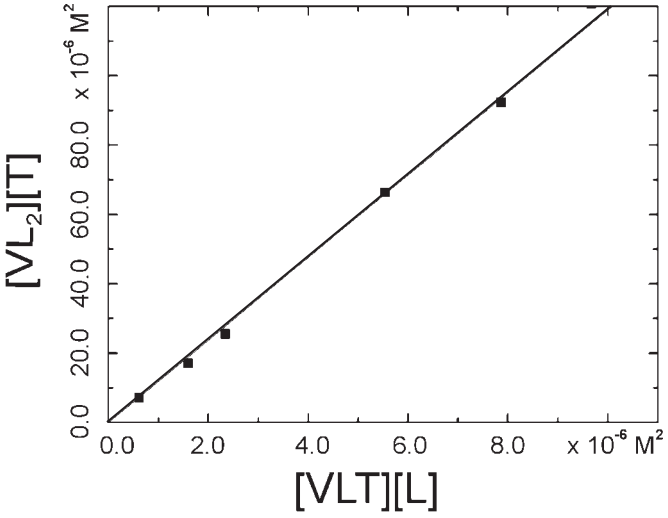
Fig. 5. Correlation indicating the formation of VLT from VL_2 and dithiothreitol (T) with the release of 1 equiv of *N*,*N*-dimethylhydroxylamine (L) as described by eq. [8]. Data for pH 8.54.



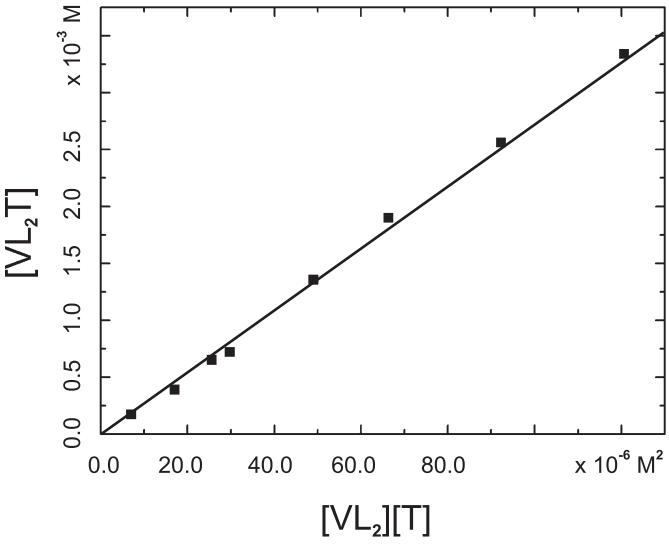


Fig. 6. Linear relationship between the product described as VL_2T and the VL_2 concentration multiplied by the dithiothreitol (T) concentration as required by eq. [9]. Data for pH 8.54.

evident in the inset of Fig. 4. In a similar experiment where DMHA was varied with constant total DTT, the two signals also maintained a constant proportionality with each. This indicates that these products have the same V to DMHA to DTT stoichiometry and therefore probably correspond to isomers, possibly arising from rotational isomerization of the hydroxamido group (15). From the concentration study, it was also evident that the signal corresponding to the product designated VL_2T at –626 ppm gained in magnitude relative to the VL and VLT signals as the L (DMHA) concentration was increased. These concentration studies are consistent with the equilibria expressed in eqs. [5] and [6] for the –485, –517 (eq. [5]), and –626 (eq. [6]) ppm products, respectively.

$$[5] \qquad V + L + T \overset{K_{111}}{\rightleftharpoons} VLT \qquad [V][L][T]K_{111} = [VLT]$$

$$[6] \qquad V + 2L + T \overset{K_{121}}{\rightleftharpoons} VL_2T \qquad [V][L]^2[T]K_{121} = [VL_2T]$$

Since, with a 600 MHz NMR spectrometer, it was possible to obtain a good enough resolution of the overlapped –626 and (or) –627 ppm signals to use lineshape fitting to resolve them into the two component parts it was possible to unambiguously establish the identity of the –485 (–517) and the –626 ppm products. The –627 ppm product is known to correspond to VL (15) and that identity has been confirmed in this study. Addition of 1 equiv of DTT to VL provides VLT (–485 ppm) as described by eq. [7]. Figure 5 shows the results of a concentration study carried out at pH 8.54 with the relevant quantities plotted according to eq. [7]. From this graph,

$$[7] \qquad VL + T \overset{K_{110,111}}{\rightleftharpoons} VLT \qquad [VL][T]K_{110,111} = [VLT]$$

$K_{110,111} = 12.8 \pm 0.9\ M^{-1}$. The corresponding value obtained for pH 6.73 was $13.0 \pm 1.1\ M^{-1}$. VL is singly negatively charged and, throughout the pH range of this study, does not form VL^{2-}. As a consequence of this, the finding that the formation constants are pH independent shows that VLT carries a single negative charge and, like VL^-, does not lose an additional proton.

It is possible to obtain the stoichiometry of the VLT product by an alternative method. Its formation can be written as occurring from VL_2, as described by eq. [8] so that VL_2 is the

$$[8] \qquad VL_2 + T \overset{K_{120,111}}{\rightleftharpoons} VLT + L$$

reference compound rather than VL. The observation of good straight lines when plotting the data according to eq. [8] was in accord with the assignment of VLT stoichiometry to the product providing the –485 ppm signal (and also, for the reasons described above, to the –517 ppm product).

The VL_2 complexes also provide a suitable reference for characterizing the product providing the –626 ppm signal, here assigned to VL_2T. Its formation can be written as in eq. [9], where cVL_2 represents the overall concentration of VL_2 complexes, and the

$$[9] \qquad VL_2 + T \overset{K_{120,121}}{\rightleftharpoons} VL_2T \qquad cVL_2[T]K_{120,121} = [VL_2T]$$

experimental results appropriately plotted. Figure 6 shows the good linear correlation obtained at pH 8.54, $K_{120,121} = (28.5 \pm 1.0)\ M^{-1}$. A similar correlation was obtained for the pH 6.73 study, $K_{120,121} = (35.6 \pm 0.9)\ M^{-1}$. The VL_2 complexes, which do not carry a charge in the slightly acidic to slight basic pH range, have a pK_a in the order of 9.0 (see below). The decrease in formation of VL_2T from VL_2 on going from pH 6.73 to pH 8.54 is fully accounted for by the averaged pK_a of VL_2 and therefore VL_2T does not have a pK_a within the range of pH of this study and is non-ionic.

The reactions of β-mercaptoethanol (M) with dimethylhydroxamidovanadates are quite similar to those of

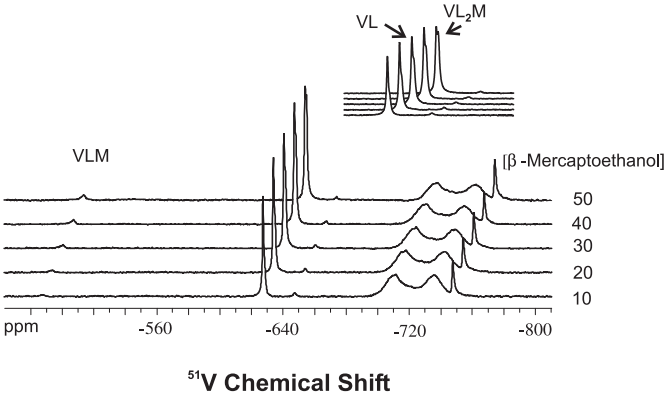
Fig. 7. ^{51}V NMR spectra of vanadate in the presence of varying amounts of β-mercaptoethanol (M) with fixed total concentrations of vanadate and *N*,*N*-dimethylhydroxylamine (L). The chemical shift scale refers to the lower trace only, the remaining spectra are offset from that trace. Conditions of the experiments: vanadate (5 mM), *N*,*N*-dimethylhydroxylamine (40 mM), β-mercaptoethanol (as indicated), pH 8.54, KCl (1.0 M).



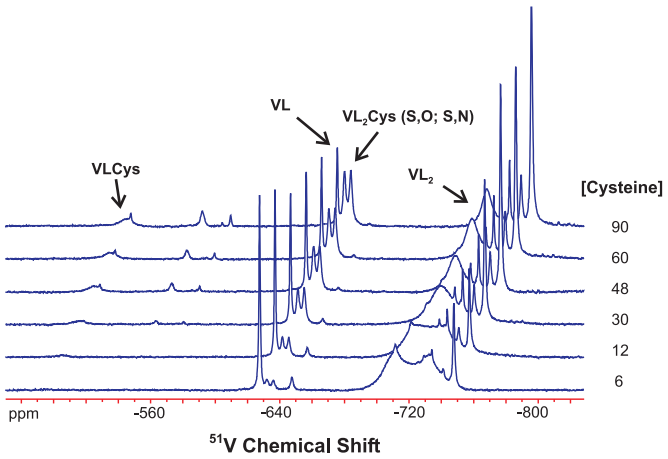


Fig. 8. The influence of varying amounts of cysteine on the ^{51}V NMR spectra of vanadate in the presence of a fixed total concentration of *N*,*N*-dimethylhydroxylamine (L). The chemical shift scale refers to the lower trace only, the remaining spectra are offset from that trace. Conditions of the experiments: vanadate (5.0 mM), *N*,*N*-dimethylhydroxylamine (40 mM), cysteine (as indicated), KCl (1.0 M), pH 8.50.

DTT. Figure 7 displays NMR spectra from a pH 8.54 β-mercaptoethanol concentration study. The VLM product gives a signal at –487 ppm, a 2 ppm shift to higher field of the corresponding VLT derivative at –485 ppm. This behaviour is mirrored in the VL_2M product where there is a small change of chemical shift to –628 ppm from –626 of the DTT complex. The formation of VLM can be described by an equation that is equivalent to eq. [7] and the data plotted appropriately. An excellent linear relationship was obtained. The formation constant for formation of VLM from VL and β-mercaptoethanol was 5.0 ± 0.2 M^{-1}. This value is close to one-half of that observed for formation of VLT and this is consistent with the fact that, structurally, DTT is equivalent to a dimer of β-mercaptoethanol and statistically, this will double the forward rate of complexation. There seems to be little stabilizing influence of the additional potentially ligating groups of the DTT ligand. In contrast to this, formation of VL_2M is less favoured by about a factor of four ($K_{120,121}$ = 6.5 ± 0.6 M^{-1}) compared to the formation of VL_2T ($K_{120,121}$ = 28.0 ± 1.0 M^{-1}).

The reaction of DMHA–vanadate with cysteine is considerably more complex than with DTT or β-mercaptoethanol. Figure 8 shows a cysteine concentration study carried out at pH 8.54. A previous study (9) has shown that bidentate complexation occurs through both *N*,*S* and *O*,*S* linkages and also through the *O*,*N*. However, there are problems arising because of a reaction involving the two VL_2 compounds with NMR signals at –710 and –732 ppm. With increase in cysteine content these signals collapsed into a single signal (–720 ppm, Fig. 8) corresponding to a complex of unknown identity. This behaviour was not observed with either dithiothreitol or β-mercaptoethanol. The reaction offered some complications in characterizing the cysteine system so an initial study of the simpler amino acid, glycine (G) was carried out. The coalescence of the –710 and –732 ppm signals was also observed with glycine, and, as for cysteine, new signals appeared in the –740 ppm region of the spectrum. Signals of the latter type have also been observed when simple peptides have been included in the medium (17) but the coalescence behaviour was not observed. The collapse of the –710 and –732 ppm signals into a single signal suggested the formation of a new product. However, a number of concentration studies, where the concentrations of V, L, or glycine were varied, showed that the single product signal corresponded to a VL_2 stoichiometry. If the formation of VL_2 is written from VL as described in eq. [10], and that of the glycine (N,O) complex as in eq. [11],

$$[10]\quad VL + L \overset{K_{110,120}}{\rightleftharpoons} VL_2 \qquad [VL][L]K_{110,120} = [VL_2]$$

$$[11]\quad VL_2 + G \overset{K_{120,121}}{\rightleftharpoons} VL_2G \qquad [VL_2][G]K_{120,121} = [VL_2G]$$

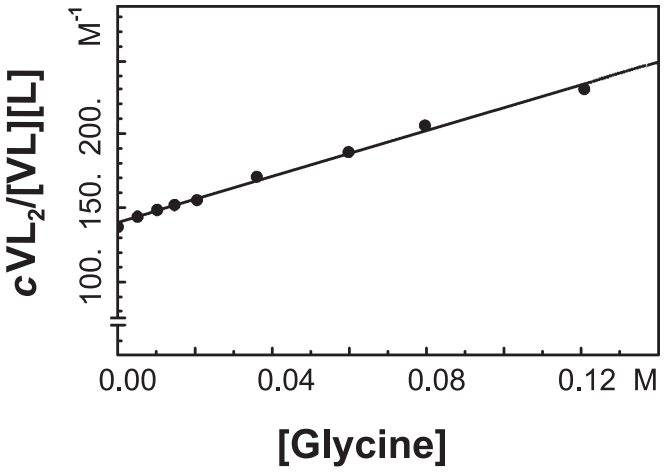
then summation and rearrangement of the two equations gives eq. [12] where cVL_2 refers to

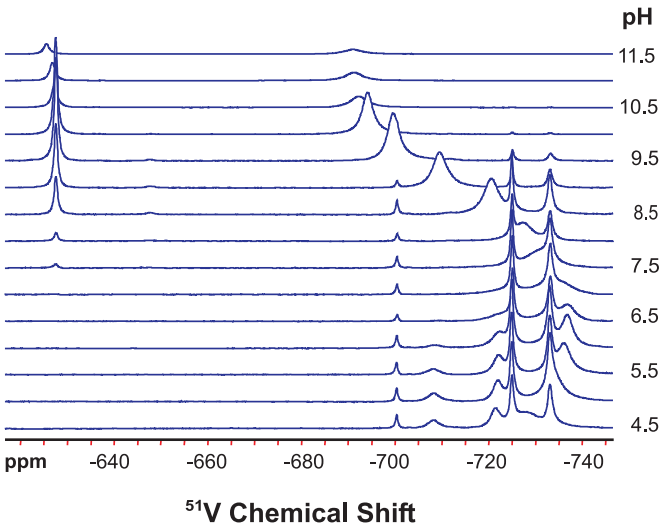
$$[12]\quad cVL / [VL][L] = K_{110,120} + K_{110,120}K_{120,121}[G]$$

the total concentration of VL_2 + VL_2G products. Figure 9 shows the results plotted according to eq. [12]. A good linear correlation is in accord with this description of the equilibria. The intercept of the graph gives a value of 140 ± 3 M^{-1} for $K_{110,120}$ while the value for the slope (770 ± 50 M^{-2}) divided by the value for the intercept gives $K_{120,121}$ = 5.5 ± 0.4 M^{-1} for pH 8.54. This study is fully consistent with a VL_2 stoichiometry for the –720 ppm signal and suggests that the amino acid is catalyzing an exchange process between the VL_2 isomers. This might, for instance, be caused by the formation of a transient outer sphere complex that promotes rotational isomerization of the DMHA ligands. This isomerization already occurs in the timescale of a few milliseconds at room temperature (15).

© 2001 NRC Canada

Fig. 9. Relationship between the quantities, as described in eq. [12], for the formation of VL_2 and VL_2G from VL, L (*N*,*N*-dimethylhydroxylamine) and glycine (G). cVL_2 represents the sum of concentrations of VL_2 and VL_2G products.





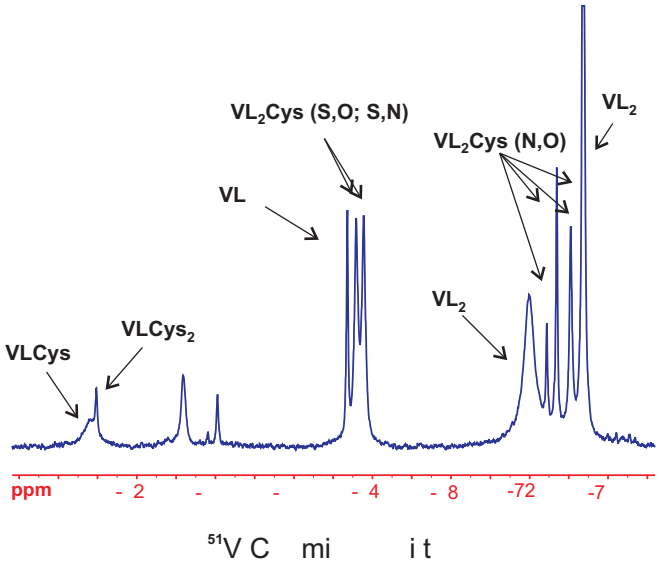


Fig. 10. Influence of pH on the NMR spectra of vanadate in the presence of *N*,*N*-dimethylhydroxylamine (DMHA) and glycine. Conditions of the experiments: vanadate (5 mM), DMHA (40 mM), glycine (120 mM) KCl (1.0 M), variable pH as indicated.

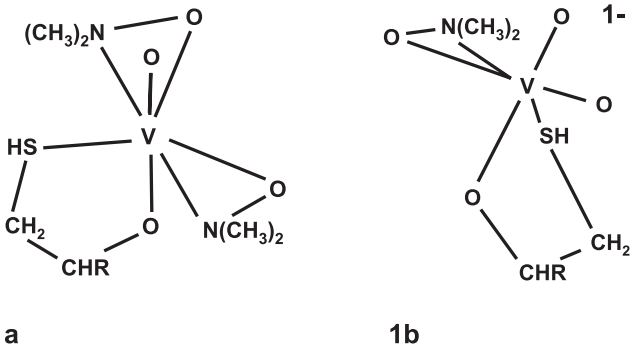
A pH variation study (pH 4.5–11.5) in the presence of 120 mM glycine revealed a systematic change in position of the –720 ppm signal (Fig. 10). Removal of glycine from the solution at pH 10 had no influence on peak position. Furthermore, a more detailed glycine concentration study at pH 10 revealed no reaction between glycine and any DMHA complex in solution. This is expected if the mixed ligand (glycine–DMHA) vanadate complexes do not have a pK_a in the high pH range. An additional pH study in the absence of glycine revealed that an increase in pH leads to generation of a single DMHA product signal above pH 9. Given then, that the –720 ppm signal is a time-averaged signal, the pH titration curve represents an averaged pK_a for the VL_2 products. Because of this, the pK_a from the titration curve (pK_a = 9.0) is not particularly meaningful. The VL_2 complexes can also be protonated at low pH to form cationic species (15) and this accounts for the downfield shifts observed in the spectral in the low pH region of Fig. 10. An interesting point to be made from Fig. 10 is that, near the high pH limit of the study, the signal of VL^- starts to change position. This indicates that VL has a second pK_a under strongly basic conditions.

Fig. 11. ^{51}V NMR spectrum of vanadate (5 mM) in the the presence of *N*,*N*-dimethylhydroxylamine (L, 40 mM) and cysteine (Cys, 120mM) obtained at pH 8.50 with 1.0 M KCl.



With the identification of the –720 ppm product signal as VL_2, characterization of the cysteine–DMHA complexes was reasonably straightforward. Cysteine (Cys) forms product complexes both with vanadate and with DMHA–vanadate. Vanadate, in the presence of only cysteine gives product complexes with ^{51}V NMR signals at –243, –309, –393, and –405 ppm. Under the conditions utilized in this study, oxidative instability precluded detailed characterization of these products. However, a cysteine concentration study suggested that the –243 and –309 ppm products contained at least two cysteine moieties per vanadium while the products giving signals at –393 and –405 contained less cysteine, most likely only one cysteine per vanadium.

In the presence of DMHA, both VLCys and VL_2Cys products were observed. Figure 11 shows a spectrum from a cysteine concentration study. The broad signal at –496 ppm derives from VLCys whiles those at –631 and –635 ppm arise from VL_2Cys products of *S*,*O* and *S*,*N* coordination. As for glycine, the broad VL_2 signals at –710 and –732 ppm collapsed into one signal (–720 ppm) with addition of cysteine. The sharp signal found at –747 ppm also arises from a VL_2 complex but the concentration studies revealed that an additional product signal is superimposed on the –747 ppm signal. The broad and sharp signals from VL_2 have been assigned to 6 ($(dmha)_2V(O)OH$) and 7 ($(dmha)_2V(O)(OH)H_2O$) coordinated products, respectively, (15, 18). Cysteine *N*,*O*-coordinated products give NMR signals at –729, –734, and –741 and, as mentioned, an additional product signal is found at –747 ppm. This latter

© 2001 NRC Canada

Scheme 1.

1a 1b

product was not observed at pH 7.3 (9) and apparently corresponds to a product of reaction with $(dmha)_2V(O)(OH)H_2O$. At pH 8.5, this coordination, relative to that of $(dmha)_2V(O)OH$, is much more highly favoured than it is at pH 7.3. The signals at –544, –556, and –561 apparently correspond to VLCys products. These latter signals are not observed in the absence of DMHA, so it seems likely that DMHA is complexed in an end-on fashion in these complexes. If so, the chemical shifts of these compounds suggest they are not coordinated through sulphur. The remaining NMR signal occurs at –500 ppm and is assigned to $VLCys_2$. Since the influence on chemical shift of this compound is small relative to the chemical shift of sulphur-coordinated VLCys (–496 ppm), it is likely that the second cysteine of $VLCys_2$ is not coordinated through a sulphur.

The formation constant for VLCys from VL and cysteine was 6.7 ± 1.2 M^{-1} while that of VL_2Cys was 8.2 ± 0.5 M^{-1} overall for the *S*,*O* and *S*,*N*-coordinated products from VL_2 and cysteine. As can be judged from Fig. 11, there is little selectivity of reaction of *N*,*S*- vs. *O*,*S*-coordination in these complexes. The magnitude of these formation constants is similar to those with the ligands DTT and β-mercaptoethanol. The overall constant for formation of the *N*,*O*-coordinated cysteine products was 11 ± 2 M^{-1}.

Discussion

^{51}V chemical shifts

The influence of ligating atoms on vanadium(V) chemical shifts has been of interest for a number of years (19–21) and various relationships have been drawn. Sulphur is known to have a large influence on chemical shifts compared to oxygen whereas the influence of nitrogen seems quite small. For instance, the complex formed between vanadate and β-mercaptoethanol (–362 ppm) is 160 ppm to low field of the structurally similar ethylene glycol complex (–522 ppm). The chemical shifts of VLT (–485 ppm) and VLM (–487 ppm) are 140 ppm to low field of the parent complex VL (–626 ppm) while those of VL_2T and VL_2M are about 95 ppm to low field of the precursor VL_2 complexes. Similarly, sulphur in cysteine complexes with VL_2 causes a shift of about +105 ppm compared to the *N*,*O* complexes of cysteine and serine (9). It seems evident then, that inclusion of a single sulphur in the coordination shell of vanadate complexes will cause a shift of about +100 to +150 ppm in the signal position compared to oxygen and changes in signal position of this magnitude should be looked for when studying thiolate complexes.

N,*N*-dimethylhydroxylamine has a large influence on vanadium chemical shifts that is comparable to the influence of hydrogen peroxide. Ligation of *N*,*N*-dimethylhydroxylamine causes a high field shift in resonance positions of about 100 ppm per ligand. This large change was used as a basis for assigning the individual vanadium signals of V_2L and V_2L_3. It is somewhat surprising that no product signals corresponding to the dimers V_2L_2 and V_2L_4, were observed in this study. It may be that the asymmetry in the V_2L and V_2L_3 complexes adds an additional element of stability to the formation of these dimer-like complexes. At higher overall vanadate concentrations, V_2L_2 and V_2L_4 dimers will probably be observable; certainly V_2L_4 ($\{(dmha)_2V(O)\}_2O$) is the crystalline form of the complex (15).

Coordination

The dimeric coordination of V_2L_4, $\{(dmha)_2VO\}_2O$, as observed in the crystal structure, and also assigned to the structure in aqueous solution (15) together with the observation of large differences in chemical shifts between the individual vanadiums (Fig. 2, Table 4), as expected from selective sulphur coordination, provides a firm foundation for assigning the coordination structures of V_2L and V_2L_3. The coordination is assigned here to be similar to that of V_2L_4 except that the compounds are not symmetrical, being $\{dmhaV(O)_2\}O\{V(O)_2OH\}^{2-}$ and $\{(dmha)_2VO\}O\{dmhaV(O)_2\}^{1-}$. No information about the acidity constants of these compounds was obtained in this study.

It seems likely that coordination of a thiolate sulphur does not induce a significant change in coordination geometry compared to oxygen. Certainly this is the case for the β-mercaptoethanol complex. The structure of this vanadate complex is not much different from the glycolate complexes with adenosine (22), with a glycoside (23), or with the proposed ethylene glycol complex (24). All are dimeric structures with the cyclic $[VO]_2$ core that is characteristic of many vanadium complexes.

X-ray structures of a number of VL_2 complexes with oxygen- and (or) nitrogen-coordinated bidentate heteroligands have been reported (14, 16) and their structures are very similar. It seems likely that the DTT and β-mercaptoethanol derivatives are, structurally, not very different from those complexes, all of which are pentagonal bipyramidal.

It is interesting to speculate on the position of the thiolate sulphur in the complex. Does it occupy an equatorial or apical position? A recent crystal structure of a tridentate $O(CH_2CH_2S)_2^{2-}$ complex of vanadium(V) shows both sulphurs in equatorial positions (25). In the β-mercaptoethanol–V(V) complex, the sulphur is also in an equatorial position but, in this case, the formation of the $[VO]_2$ core of the complex forces the equatorial location for the sulphur. It is suggested here that the sulphur will be found in the equatorial position in these complexes as indicated in Scheme 1a. Since VL_2T, like the parent VL_2 does not carry a charge under close to neutral conditions, then the ligand must retain one proton, either on the S or the O of the

© 2001 NRC Canada

ligating group. It seems likely that it is retained on the sulphur since the *S*-substituted cysteine (-SC(O)OBz) forms a product complex (–627 ppm) with VL_2 (9). In a related case where a bidentate ethylene glycol complex is formed under forcing conditions, a proton is retained on one of the oxygens of the ligand. The resultant bond to vanadium is, however, very long (2.321(4) Å) (26) compared to a more typical distance of about 1.9 Å for a V—O bond.

The assignment of a coordination geometry to VLT is complicated by the fact that there are no crystal structures of closely related compounds. However, if the bonding to the hydroxamido ligand is formally considered to be unidentate then the vanadiums in the crystalline dimer $\{(dmha)_2V(O)\}_2O$, can be considered to have a tetrahedral coordination (15). Since vanadate, itself, also has tetrahedral coordination, it seems unlikely that VL will have other than tetrahedral coordination. Bidentate complexation of the thiolate can reasonably be expected to expand the coordination sphere (Scheme 1b). On this basis, and if the DMHA ligand is formally considered unidentate, both VL_2T and VLT may be considered to be trigonal bipyramidal. Since there is no indication from these studies that more than one sulfhydryl or more than one hyroxyl group are involved in the complexation of DTT with VL or with VL_2, the β-mercaptoethanol complexes are unlikely to show significant structural differences from the corresponding DTT complexes.

These proposed coordination modes of Scheme 1 are very different from the coordination found in the V(IV) complex with DTT (V_2T_2, Fig. 1) and indeed from the structure previously proposed for the V(V) complex of DTT (2) where the stoichiometry is V_2T. The structure that was suggested for V_2T is quite similar to that observed here for the V(IV) complex. However, there is a significant difference in that the V(V) complex has only one DTT ligand that binds each vanadium differently while the V(IV) complex has two ligands and identical vanadiums. The proposed structures of Scheme 1 are similar to those observed for some amino acid and dipeptide complexes (16, 17) except that the latter complexes do not have sulphur ligation.

Although these β-mercaptoethanol and dithiothreitol complexes are of interest in their own right, they serve as useful models for the study of other thiolate complexes. In particular, they have aided in unraveling the complex equilibrium pattern of the cysteine ligand and have also provided critical information for the study of DMHAV complexation in the active site of protein tyrosine phosphatases (7). The structures of the VLCys and VL_2Cys complexes are probably not much different from those proposed above for the DTT and β-mercaptoethanol complexes except that, in the one case, a nitrogen takes the place of the oxygen. The fact that the *S,O* and *S,N* VL_2Cys complexes are formed in almost equal amounts suggests there is little to choose between nitrogen and oxygen in terms of binding affinity to vanadium in these types of complexes. Since only a single broad signal is observed for the VLCys products, it is not possible to know whether this observation also applies to this type of complex. Although, in VL_2Cys, *N,O*-coordination is as well favoured as is *S,O*- (*S,N*-) coordination at pH 8.5, this will be a pH-dependent phenomenon that is determined by the pK_a values of the various reactants and products.

Nature of the active silane alcoholysis catalyst in the $Ru_wCl_x(CO)_y(PMe_3)_z$ (*w*, *x*, *y*, *z* = 1 or 2) system; $Ru_2(\mu\text{-}Cl)_2Cl_2(CO)_4(PMe_3)_2$ as a new catalyst for silane alcoholysis in a polar solvent[1]

Mee-Kyung Chung, George Ferguson, Valerie Robertson, and Marcel Schlaf

Abstract: The dimeric complex $Ru_2(\mu\text{-}Cl)_2Cl_2(CO)_4(PMe_3)_2$ (**1**) forms an active silane alcoholysis complex in the polar solvent *N*,*N*-dimethylamino-acetamide (DMA). The dynamic behaviour of **1** in DMF-d_7 solution has been investigated by variable temperature (VT) ^1H NMR. The solid state structures of **1** and *cis,cis,trans*-$RuCl_2(CO)_2(PMe_3)_2$ (**3**) have been determined by single crystal X-ray diffractometry. Using ethylene glycol – triethylsilane as a model system, the catalytic activity of **1** in DMA is compared to that of a series of known silane alcoholysis catalysts, including $RhCl(PPh_3)_3$, PdX_2 (X = Cl^-, OAc^-), and *cis,cis,trans*-$[IrH_2S_2L_2]SbF_6$ (L = PPh_3, S = THF). Complex **3** is not an active silane alcoholysis catalyst in this solvent, but is active in nonpolar solvents. Its structure and spectroscopic signature is, however, different from that of a previously reported catalyst of the same composition.

Key words: silane alcoholysis, polar solvent, ruthenium catalyst.

Résumé : Dans un solvant polaire comme le *N*,*N*-diméthylacétamide (DMA), l'alcoolyse du complexe dimère $Ru_2(\mu\text{-}Cl)_2Cl_2(CO)_4(PMe_3)_2$ (**1**) donne lieu à la formation d'un complexe de silane actif. Faisant appel à la RMN du ^1H à température variable, on a étudié le comportement dynamique de **1** en solution dans le DMF-d_7. On a déterminé les structures de **1** et du *cis,cis,trans*-$RuCl_2(CO)_2(PMe_3)_2$ (**3**) à l'état solide par diffraction des rayons X par un cristal unique. Utilisant le système éthylèneglycol/triéthylsilane comme modèle, on a comparé l'activité catalytique de **1** dans le DMA avec celles d'une série de silanes connus comme catalyseurs de l'alcoolyse, y compris $RhCl(PPh_3)_3$, PdX_2 (X = Cl^-, OAc^-) et *cis,cis,trans*-$[IrH_2S_2L_2]SbF_6$ (L = PPh_3, S = THF). Dans ce solvant, ce composé **3** n'est pas un silane actif comme catalyseur de l'alcoolyse; il est toutefois actif dans les solvants non polaires. Sa structure et ses caractéristiques spectroscopiques sont toutefois différentes de celles rapportées antérieurement pour un catalyseur de même composition.

Mots clés : alcoolyse de silanes, solvant polaire, catalyseur de ruthénium.

[Traduit par la Rédaction]

Introduction

The silane alcoholysis reaction (eq. [1]) constitutes an exceptionally mild and efficient method of protecting hydroxyl functions by trialkyl or aryl-silyl groups.

The high enthalpic driving force of the oxygen–silicon bond formation, together with the entropically favourable generation of 1 equivalent of hydrogen gas, generally results in clean and quantitative conversions. The reaction is catalyzed by a large variety of transition metal complexes (1–7). Specific examples of highly active catalysts are *cis,cis,trans*-$[IrH_2S_2L_2]SbF_6$ (L = PPh_3, S = THF) (8), *all-cis*-$RuCl_2(CO)_2(PMe_3)_2$ (9), $Co_2(CO)_8$ (10), $RhCl(PPh_3)_3$ (11–13), $IrX(CO)L_2$ (L = PR_3) (14), and $[IrCl(C_8H_{14})_2]_2$ (14). Most simply, palladium metal, generated in situ by reduction of PdX_2 (X = OAc^-, Cl^-) (15) also catalyzes the reaction. Another commercially available and metal-free catalyst system is $B(C_6F_5)_3$, recently described by Blackwell et al. (16).

Common to all these catalyst systems is that, to date, they have only been tested in nonpolar, non-coordinating organic solvents such as benzene, toluene, pentane, or methylene chloride. We are interested in applying the silane alcoholysis reaction to highly polar polyol and sugar substrates with multiple hydroxyl functions, which are insoluble in these solvents, but soluble in chemically largely inert amides such as *N*,*N*-dimethylformamide (DMF), *N*-methyl-pyrrolidin-2-one (NMP), and *N*,*N*-dimethylacetamide (DMA). In order to establish which of a selection of the known catalyst systems

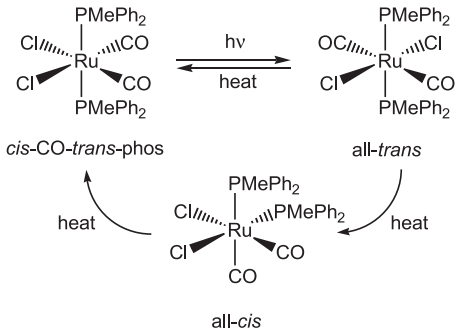
 DOI: 10.1139/cjc-79-5/6-949 © 2001 NRC Canada

would tolerate the anticipated *coordinative inhibition* by the donor atoms (O, N) in these solvents, we conducted an activity evaluation of a series of catalysts in DMA using ethylene glycol and triethylsilane as a model system. In the course of this study we found that the most active homogeneous catalyst system in DMA is derived from the general composition $Ru_wCl_x(CO)_y(PMe_3)_z$ (w, x, y, z = 1 or 2), but that the structures of the active catalyst precursors are in fact $Ru_2(\mu\text{-}Cl)_2Cl_2(CO)_4(PMe_3)_2$ (**1**) or *cis,cis,trans*-$RuCl_2(CO)_2(PMe_3)_2$ (**3**) rather than *all-cis*-$RuCl_2(CO)_2(PMe_3)_2$ (**2**) as previously reported (17). The dynamic solution behaviour of dimer **1** in amide solvents, as well as the solid state structures of the complex **1** and **3** as determined by single crystal X-ray structure analysis, are reported.

Results

The conditions and reagents for the synthesis of the catalyst system $Ru_wCl_x(CO)_y(PMe_2)_z$ as published are shown in eq. [2] (17).

[2] RuC$_3$ + 2 M$_3$ + CO( ) —u→ M = 2-m t o y- t no



2

Following this procedure we obtained materials that gave inconsistent results with respect to catalytic activity and whose NMR and IR spectra in no case matched the previously reported data. Singer et al. (17) assigned the *all-cis* configuration **2** to their reaction product based on ^{1}H NMR and IR data.[3] They reported a single doublet at 1.78 ppm with $J_{H,P}$ = 12 Hz in $CDCl_3$ and two ν(CO) stretching frequencies at 2085 and 2022 cm^{-1} in Nujol. While the IR data and symmetry considerations support a *cis* position of the two CO ligands, the assignment does not match with the position of the phosphine ligands. In an *all-cis* arrangement one of the phosphines must be *trans* to the σ-donor – π-acceptor CO, while the other must be *trans* to the σ-donor – π-donor Cl^-. Two different chemical environments and chemical shifts should, therefore, result for the phosphorus and by extension carbon and proton nuclei on the two phosphine ligands, unless their shifts are fortuitously equivalent. This, however, appears to be unlikely, as the structurally very closely related complex *all-cis*-$RuCl_2(CO)_2(PMePh_2)_2$ shows two separate doublets for the methyl substituents on the phosphine ligands (18). Also the *all-cis* configuration of this complex is thermally unstable against isomerization to *cis,cis,trans*-$RuCl_2(CO)_2(PMePh_2)_2$ and only accessible through a photochemical reaction via the even more unstable *all-trans* form (Fig. 1).

The expected ^{1}H NMR of the *all-trans* form, i.e., a doublet of doublet or pseudo triplet for the methyl signals due to coupling to the two phosphorus nuclei, equally would not match the literature spectral data. These considerations together with wide variations of catalyst activity in the silane alcoholysis reactions using the material isolated by us, prompted us to reinvestigate the $Ru_wCl_x(CO)_y(PMe_3)_z$ system in more detail.

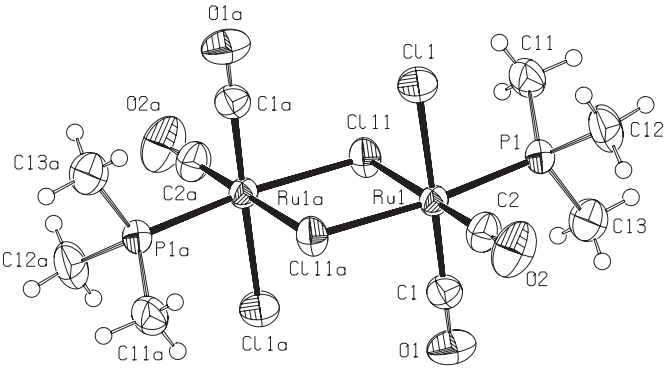
Fig. 1. Photochemically and thermally induced stereochemical rearrangements observed for $RuCl_2(CO)_2(PMePh_2)_2$.

Synthesis and isolation

The reaction of eq. [2] gives an amorphous solid from which two different products of different crystal habit are obtained by fractional crystallization, first from CH_2Cl_2–Et_2O and subsequently from EtOH–H_2O. The latter solvent system is also the one used by Singer et al. (17). Single crystal X-ray diffraction analysis revealed the structure of the first product to be the dimeric complex $Ru_2(\mu\text{-}Cl)_2Cl_2(CO)_4(PMe_3)_2$ (**1**) and that of the second component to be the mononuclear complex *cis,cis,trans*-$RuCl_2(CO)_2(PMe)_2$ (**3**). The yields for both products (**1** and **3**) are between 30 and 40%, with a total yield of about 70% with respect to ruthenium. By ^{1}H and ^{31}P NMR, both compounds are present in about the same ratio in the crude product, i.e., the product identity and distribution is not an artifact of the fractional crystallization.

Structure determinations

ORTEP diagrams (19) of the structures of the dimer $Ru_2(\mu\text{-}Cl)_2Cl_2(CO)_4(PMe_3)_2$ (**1**) and that of the mononuclear complex *cis,cis,trans*-$RuCl_2(CO)_2(PMe)_2$ (**3**) are shown in Figs. 2 and 3, respectively.



Selected bond angles and distances of complexes **1** and **3** are summarized in Tables 1 and 2, respectively. The dimer **1** has a center of inversion in the plane defined by the two ruthenium centers and the bridging chloride ligands. The two Ru—Cl bond distances in this plane are, however, not equivalent, but slightly shorter (2.457 Å) for the bond *trans* to the strong π-acceptor CO and slightly longer (2.496 Å) for the bond *trans* to the phosphine, resulting in a distorted diamond shape with Cl-Ru-Cl and Ru-Cl-Ru bond angles in this plane of 83.95 and 96.04°, respectively. The Ru—Cl bond distance of the terminal chloride ligand is very close to that of an average value of 2.409 Å as reported by Orpen et al. (20) The other bond angles around ruthenium closely approach that of an idealized octahedral environment with bond lengths in the expected ranges.

All ruthenium ligand bond lengths in the mononuclear complex **3** are pairwise equivalent within the 3σ level and

[3] The original formulation in the paper by Singer et al. is: "The dérivé III (i.e., $RuCl_2(CO)_2(PMe_3)_2$) isolé possède tous ses ligands en position *cis*."

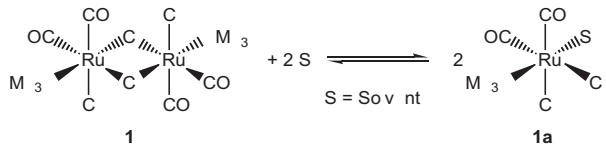
Fig. 2. Molecular structure of the dimer complex $Ru_2(\mu\text{-}Cl)_2Cl_2(CO)_4(PMe_3)_2$ (**1**) as determined by single crystal X-ray diffraction (ORTEP plot at 30% probability level).



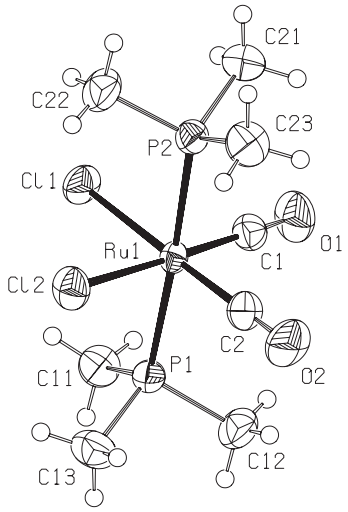
fall within the expected ranges and bond angles approach that of an idealized octahedral environment around the ruthenium center. In the solid state the two PMe_3 ligands are staggered about the P-Ru-P axis by 63.93° breaking the otherwise high symmetry of the ligand arrangement.

Spectroscopy

The spectroscopic data of **1**, **1a**, and **3** are summarized in Table 3.

Dissolving an authentic sample of X-ray grade crystals of **1** in either $CDCl_3$ or DMF-d_7 results in an ^{1}H NMR spectrum that displays two doublets for the PMe_3 ligands at the chemical shifts listed in Table 3 in relative intensities of 0.42:1, with the lower shift component as the more abundant one. Based on the high symmetry of the solid state structure of **1**, whose center of inversion would render the two phosphines chemically and magnetically equivalent, this spectral appearance immediately suggests a breakup of the dimer in solution, most likely through solvent coordination in the manner indicated in eq. [3], which retains the mutual *trans* arrangement of the π-donor chloride and π-acceptor carbonyl.

[3]



1 **1a**

The variable temperature (VT) ^{1}H NMR spectrum of the methyl signals of a sample of **1** in DMF-d_7 is shown in Fig. 4 and reveals the existence of a dynamic process in solution, which supports the above hypothesis.

The two doublets coalesce at ~100°C and reemerge as a time averaged doublet above ~120°C. In order to simplify a more quantitative analysis of this process through simulations, the VT experiment was repeated with phosphorus decoupling, which collapses the doublets into two simple coalescing singlets. Using the MEX program by Bain and Duns (21) a set of spectra were simulated that matched the these decoupled spectra over the temperature range from 65 to 124°C. From an Eyring plot of the rate constants calculated by the program vs. $1/T$ (in Kelvin) the approximate activation parameters of the process were determined to $\Delta H^{\ddagger}$ =

Fig. 3. Molecular structure of complex *cis,cis,trans*-$RuCl_2(CO)_2(PMe_3)_2$ (**3**) as determined by single crystal X-ray diffraction (ORTEP plot at 30% probability level).

18.0 ± 0.4 kcal mol^{-1} and $\Delta S^{\ddagger}$ = –2.7 ± 0.9 cal mol^{-1} K^{-1} for the reaction of the minor to the major component ($k_{reverse}$: **1a** → **1**) and through $K_{eq} = k_f/k_r$ to $\Delta H^{\ddagger}$ = 18.4 ± 0.9 kcal mol^{-1} and $\Delta S^{\ddagger}$ = –3.0 ± 0.9 cal mol^{-1} K^{-1} for the reaction of the major to the minor component ($k_{forward}$: **1** → **1a**). Within the experimentally achievable error ranges the activation parameters are the same for the forward and the reverse reaction, which reflects an equilibrium constant K_{eq} close to unity. K_{eq} ranges from 0.45 to 0.49 in the temperature range used and was determined from the integral ratios of the ^{31}P decoupled signals at low temperatures and extrapolated for the higher temperatures, where beginning coalescence makes a reliable integration impossible.

Further support for the reaction of eq. [3] comes from the ^{13}C and ^{1}H NMR spectra of the same sample at ambient temperature. In addition to the 1:1:1 triplet for the carbonyl carbon of free DMF-d_7 at 162.7 ppm, a second small 1:1:1 triplet ($J_{C,D}$ = 30 Hz) is observed at 169.2 ppm, which we assign to the coordinated DMF-d_7 in complex **1a**. This ^{13}C signal is matched by a very small singlet at 8.45 ppm in ^{1}H NMR, which disappears with the beginning coalescence of the methyl signals and which we assign to the aldehyde proton of coordinated DMF-d_6. The signal reversibly reappears upon cooling to ambient temperature.

An unambiguous assignment of the larger and smaller sets of peaks to **1** and **1a**, respectively follows from the ^{13}C NMR signals of the carbonyl ligands. In the dimer **1** the two carbonyl ligands are chemically and magnetically inequivalent and should give rise to two doublets due to coupling to the phosphorus nucleus. In complex **1a** both carbonyl ligands are chemically and magnetically equivalent and should, thus, result only in a single doublet. Two larger doublets of approximately equal intensity are observed at 198.12 and 192.93 ppm, the latter of which overlaps with a smaller doublet at 193.08 ppm. The larger peaks must, therefore, belong to complex **1**, bearing the two nonequivalent carbonyl ligands. By extension, the larger peaks in the ^{1}H and ^{31}P NMR spectra are assigned to the dimer **1**, which is

therefore the major component in solution at ambient temperature.

The IR spectrum of the same sample of **1** dissolved in $CDCl_3$ displays only two well defined bands at 2068 and 2010 cm^{-1}, i.e., does not show the presence of two components in solution as observed by NMR. This can be rationalized by the fact that in both complexes (**1** and **1a**) both carbonyl ligands are *trans* to the same π-donor chloride and the ν(CO) stretching frequencies are, therefore, presumably very close to or even identical with each other in both complexes.

The NMR spectra of complex **3** show no dynamic phenomena and display the expected coupling patterns for the *cis*,*cis*,*trans*-arrangement. The pseudo triplet observed for the methyl signals of **3**, also establishes that it cannot have been the compound originally isolated by Singer et al. (17), whose identity remains unknown.

Evaluation of the catalysts in DMA

The catalytic activity of the new complexes **1** and **3** was evaluated using the ethylene glycol – triethylsilane system as the model reaction (eq. [4]) and compared to a series of catalyst systems consisting of *cis*,*cis*,*trans*-$[IrH_2S_2L_2]SbF_6$ (L = PPh_3, S = THF) (8), $RhCl(PPh_3)_3$ (11–13), $Co_2(CO)_8$ (10), and PdX_2, (X = Cl^-, OAc^-) (15).

[4] $$HOCH_2CH_2OH + n\ Et_3SiH \xrightarrow[-n\ H_2(\ )]{[c\ t.]} \begin{matrix} HOCH_2CH_2OSiEt_3 \\ + \\ Et_3SiOCH_2CH_2OSiEt_3 \end{matrix}$$

In all reactions ethylene glycol (2.5 mmol) in DMA (6 mL) were reacted with one or two equivalents of triethylsilane at a catalyst concentration of 3 mol% with respect to metal content. Complexes **3** and $Co_2(CO)_8$ are inactive in DMA, however, **3** is an active catalyst in THF, the solvent used by Oehmichen and Singer (9). All other tested catalysts are active in the DMA solvent and quantitative results as determined by direct quantitative GC analysis of the reaction mixtures are summarized in Table 4. The data gives a direct comparison of the relative activity of the catalyst systems in the amide solvent, total yields of silylated products, as well as their selectivity towards mono- and disilylation of the diol substrate in the presence of one or two equiv of silane, respectively. The reaction times given in Table 4 refer to the end point of the reaction as indicated by the end of hydrogen gas evolution and by the complete consumption of triethylsilane as indicated by the GC trace of the reaction mixture.

Of all the catalyst systems tested, by far the most active is the dimer **1**, which even surpasses the activity of the heterogeneous palladium systems. The true catalyst of unknown structure and composition formed from **1** and triethylsilane in DMA, therefore, does not suffer from coordinative inhibition by the solvent. This contrasts with the behaviour of complex **3**, which does suffer inhibition by the solvent to the point of being inactive in the amide solvent, and the iridium system $[IrH_2(PPh_3)(THF)_2]SbF_6$, which shows as many as 130 000 turnovers per hour in methylene chloride solvent at 25°C (8), but requires heating to 45°C to achieve acceptable reaction rates in DMA. Consistent with the latter result, Crabtree et al. (22) had previously shown that the same iridium complex suffers strong inhibition by even trace amounts of coordinating solvents when used as an olefin hydrogenation catalyst. The active catalyst resulting from $RhCl(PPh_3)_3$ also must suffer coordinative inhibition, as it has been reported to give complete conversion to silane alcoholysis products within minutes in benzene solution at 20°C and catalyst concentrations as low as 0.05 mol% (13).

The yields of monosilylated product achieved by the catalysts in DMA solvent are moderate to good, but in no case

reach the near quantitative conversions to silylated products typically observed in this reaction with equimolar amounts of silane and alcohol in nonpolar solvents. Even with rigorous drying of the hygroscopic DMA solvent by distillation from barium oxide[4] under argon and subsequent storage over activated 4 Å molecular sieves, some of the silane is consumed by the reaction with adventitious water forming the silanol and siloxane side products Et_3SiOH and $Et_3SiOSiEt_3$. A control experiment in the absence of ethylene glycol also yielded Et_3SiOH and $Et_3SiOSiEt_3$ confirming the presence of water in the solvent. By GC–MS no disilane $Et_3SiSiEt_3$ could be detected in either the control or any of the actual alcoholysis reactions. Both observed side products were identified and authenticated by GC, ^{1}H NMR, and GC–MS, but not quantified. However, qualitatively the amounts of the side products formed appeared to be insufficient to explain the low yields. Even though we found no direct evidence of the solvent itself reacting with the silane,

[4] This drying agent has been suggested by Andrews (23) to be very effective for amide solvents.

[b]By quantitative GC with respect to ethylene glycol.

i.e., there are no unaccounted peaks in the GC traces of the silylation reactions, we cannot exclude the possibility that the DMA solvent signal observed in the GC contains such reaction products that do not chromatographically separate as a result of hydrogen bond interactions within the solvent.[5] Another possible explanation is that larger amounts of silanol are actually formed in the reactions, but are not detected because of a reaction with the GC injector liner and (or) the column itself.

The selectivity to monosilylation:disilylation with one equivalent of silane ranges from 1:2.4 to 1:7.7. Interestingly, the most active catalyst **1** gives some of the best selectivity at a ratio of 1:6.2 at yields comparable to those of the other catalyst systems. As expected with two equiv of triethylsilane the selectivities increasingly favour disilylation. Good yields of disilylated products are, however, only achieved by $PdCl_2$ and the iridium system.

The temperature range investigated was limited to 0–45°C, as we were only interested in reaction conditions that could ultimately be applied to more complex and very temperature sensitive polyols and sugars. Within this range no clear trend of temperature dependency of yields and selectivities can be extracted from the data. Instead the conditions for the optimization of these two goals are unique to the catalyst used.

Equation [5] shows a possible pathway of an HCl catalyzed silane alcoholysis, which is conceivable for the chloride containing catalysts.

$$[5]\quad \begin{aligned} &L_nM\text{-}Cl + H\text{-}SiR_3 \longrightarrow L_nM\text{-}SiR_3 + HCl \\ &HCl + H\text{-}SiR_3 \longrightarrow Cl\text{-}SiR_3 + H_2(g) \\ &Cl\text{-}SiR_3 + R'OH \longrightarrow R'O\text{-}SiR_3 + HCl \\ &R' = H,\ CH_2CH_2OH \end{aligned}$$

Such a pathway may, in particular, be possible in the DMA solvent, which should be capable of stabilizing highly polar intermediates. The HCl would be generated from the chloride content of the catalysts through the reaction with triethylsilane. In order to exclude this possibility, we carried out a control reaction with concentrated aq HCl added in an amount equimolar to the metal catalysts used, i.e., 3 mol% $H_3O^+Cl^-$ with respect to ethylene glycol. The control reaction asserted that HCl catalyzed processes are irrelevant, as only very small amounts of silane hydrolysis and glycol silylation products were detected even at greatly extended reaction times compared to the metal catalyzed reactions in Table 4.

Discussion

While the selectivities and yields achieved so far are only moderate, the use of DMA as a solvent extends the utility of

[5]GC columns of various polarity did not result in further resolution of the solvent DMA peak. A GC–MS investigation of the solvent peak itself is not practical as it is entirely dominated by the solvent fragmentation pattern.

[a]Definitions of indices: $R_1 = \Sigma(F_o - F_c)/\Sigma(F_o)$; $wR_2 = [\Sigma[w(F_o^2 - F_o^2)^2]/\Sigma[w(F_0^2)^2]]^{1/2}$.

the silane alcoholysis reaction to much more polar substrates than previously accessible. We anticipate that with more complex DMA soluble polyol and carbohydrate substrates bearing multiple hydroxyl of more differentiated reactivity, better overall selectivity towards silylations of a single hydroxyl function can be achieved in future studies. Increased yields of selectively silylated products may also be obtainable through the use of excess silane in order to account for reagent loss due to practically unavoidable traces of water in the hygroscopic solvent.

The similarity between the chemical and physical properties of DMF and DMA suggests that **1** would show very similar behaviour in DMA as observed by NMR results in DMF-d_7. Substitution of the labile solvent ligand in **1a** by either the alcohol or the silane, for the latter possibly in an η^2-fashion analogous to the mechanism proposed for $[IrH_2(PPh_3)(THF)_2]SbF_6$ by Luo and Crabtree (8), could start a sequence of reactions leading to the formation of the true catalyst. The composition and structure of the actual active species, however, remain elusive. An NMR scale reaction of **1** with triethylsilane in DMF-d_7 at ambient temperature resulted in complicated ^{1}H and ^{31}P spectra suggesting the formation of at least five different unidentified complexes in solution. Remarkably no signals were observable in the hydride region of the spectrum at this temperature. Upon subsequent addition of an equimolar amount of ethylene glycol to the NMR tube reaction mixture the normal silylation products were again observed.

Conclusion

The new dimeric complex $Ru_2(\mu\text{-}Cl)_2Cl_2(CO)_4(PMe_3)_2$ (**1**) forms an active silane alcoholysis catalyst in DMA. In contrast to the two other homogeneous catalysts systems investigated, $[IrH_2(PPh_3)(THF)_2]SbF_6$ and $RhCl(PPh_3)_3$, **1** does not suffer from coordinative inhibition in this solvent. The heterogeneous system consisting of Pd(0) generated in situ through reduction of PdX_2 (X = Cl$^-$, OAc$^-$) by the silane also is an active catalyst in DMA. The new complex *cis,cis,trans*-$RuCl_2(CO)_2(PMe)_2$ (**3**) isolated from the same reaction mixture as **1** is an active silane alcoholysis catalyst in nonpolar solvents, but completely inactive in DMA.

Experimental

General

All manipulation were performed under a dry argon atmosphere by standard Schlenk-tube techniques. NMR spectra were recorded on a Bruker Avance 400 MHz instrument and IR spectra on a BOMEM FT-IR. ^{1}H NMR spectra simulations were performed using the MEX program (21). For the VT NMR studies the probe temperatures of the NMR spectrometer were independently calibrated using an internal thermocouple. ^{31}P NMR spectra were recorded using a capillary containing 85% H_3PO_4 as the internal standard. GC analyses were performed on a HP 6850 gas chromatograph equipped with a flame ionization detector and integrator.

© 2001 NRC Canada

Mass spectra were obtained with a HP 5970-IN GC-MS spectrometer at the University of Guelph Laboratory Services Division or on a VARIAN Saturn 2000. GC-MS/MS were obtained in our own laboratory. Elemental analyses were performed by Guelph Chemical Laboratories.

Reagents were purchased from Aldrich, Strem Chemicals, Caledon Laboratories, or Fisher Scientific and used as received. Solvents and ethylene glycol were purified by standard techniques and stored under argon. DMA was dried by vacuum distillation from BaO (23) and subsequently stored over activated 4 Å molecular sieves. $[IrH_2(PPh_3)_2(THF)_2]SbF_6$ was synthesized according to the literature methods (8, 14).

Synthesis of $Ru_2(\mu\text{-}Cl)_2Cl_2(CO)_4(PMe_3)_2$ and *cis,cis,trans*-$RuCl_2(CO)_2(PMe_3)_2$

With the exception of the recrystallization procedure, this method is essentially the same as the previously published procedure; carbon monoxide was passed through a boiling solution of ruthenium trichloride dihydrate (0.87 g) in 2-methoxyethanol (25 mL) for 3.5 h. Trimethylphosphine (0.54 g) was added to the hot solution and carbon monoxide was passed through the boiling solution for a further 19 h. The solution had become brownish yellow. The solvent was evaporated under reduced pressure. The resulting greenish-white solid (yield 73%) was recrystallized from CH_2Cl_2–Et_2O giving dimeric species $Ru_2(\mu\text{-}Cl)_2Cl_2(CO)_4(PMe_3)_2Cl_2$ in 38% yield with respect to ruthenium. Subsequent evaporation of the remaining mother liquor and recrystallization of the remaining solid residue from EtOH–water gives the complex *cis,cis,trans*-$RuCl_2(CO)_2(PMe_3)_2$ in 34% yield. Total yield in ruthenium is 34 + 38 = 72%.

*$Ru_2(\mu\text{-}Cl)_2Cl_2(CO)_4(PMe_3)_2$ (**1**)*

For spectroscopic data, see Table 3. Anal. calcd. for $C_{10}H_{18}Cl_4O_4P_2Ru_2$: C 19.74, H 2.98; found: C 19.93, H 3.03.

*$RuCl_2(CO)_2(PMe_3)(O{=}C(CD_3)N(CD_3)_2)$ (**1a**)*

For spectroscopic data see Table 3.

cis,cis,trans-*$RuCl_2(CO)_2(PMe_3)_2$ (**3**)*

For spectroscopic data see Table 3. Anal. calcd. for $C_8H_{18}Cl_2O_2P_2Ru$: C 25.26, H 4.77; found: C 25.48, H 5.21.

X-ray crystal structure determinations

Colourless X-ray quality crystalline samples of both complexes (**1** and **3**) were obtained by slow crystal growth from saturated solutions of the respective solvent–cosolvent mixture at low temperature. Intensity data were collected on a Nonius CAD4 diffractometer. General data collection parameters are listed in Table 5.[6] Accurate cell dimension and crystal orientation matrices were obtained by a least-squares fit of the setting angles of 25 reflections in the ranges indicated in Table 5. Data were acquired using the $\omega - 2\Theta$ method over the ranges indicated in Table 5 and are corrected for Lorentz-polarization and absorption effects. The intensities of 3 standard reflections were measured every 120 reflections and showed 0.8% decay for **1** and no decay for **3**. For both structures the position of the ruthenium atoms were determined by the Patterson method and other nonhydrogen atoms were located by successive difference Fourier syntheses. The structures were refined anisotropically by full-matrix least-squares on F^2. The weighting scheme was $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$ where $P = (F_o^2 + 2F_c^2)/3$. Hydrogen atoms were clearly visible in difference maps and positioned on geometric grounds (C—H 0.96 Å). All calculations were performed using SHELX 97 (24) and PLATON (25) on a Pentium III computer running the LINUX 2.1 operating system.

O-silylation of ethylene glycol

The *O*-silylation reactions of ethylene glycol were conducted by three methods, each of which was found to be most practical depending on the catalyst system used.

Method 1

For catalyst $[IrH_2(PPh_3)_2(THF)_2]SbF_6$; a DMA (3 mL) solution of the Ir catalyst (0.075 mmol = 3 mol% in metal with respect to ethylene glycol) and ethylene glycol (2.5 mmol, 155 mg, 140 μL) was prepared in a three-neck round-bottomed flask fitted with a pressure-equilibrating addition funnel and an Schlenk stopcock. The apparatus was connected to a gas bubbler. A second DMA (3 mL) solution of Et_3SiH (1 eq. = 2.5 mmol, 291 mg, 399 μL or 2 eq. = 5.0 mmol, 582 mg, 798 μL) was prepared in the addition funnel. The silane solution was quickly added with stirring from the addition funnel to the three-neck round-bottomed flask containing the solution of the catalyst and ethylene glycol. The rate of reaction was qualitatively followed by monitoring the speed of the evolved hydrogen with time until hydrogen evolution had stopped indicating the end point of the reaction.

Method 2

For catalysts $RhCl(PPh_3)_3$, $Ru_2(\mu\text{-}Cl)_2Cl_2(CO)_4(PMe_3)_2$, *cis,cis,trans*-$RuCl_2(CO)_2(PMe_3)_2$, and $Co_2(CO)_8$; a DMA, (6 mL) solution of Et_3SiH (1 eq. = 2.5 mmol, 291 mg, 399 μL or 2 eq. = 5.0 mmol, 582 mg, 798 μL) and ethylene glycol (2.5 mmol, 155 mg, 140 μL) was prepared in the addition funnel. The mixed solution was added quickly from the addition funnel to the Schlenk flask containing catalyst (0.075 mmol or 0.0375 mmol for dimer **1** = 3 mol% of metal with respect to ethylene glycol). The rate of reaction was qualitatively followed by monitoring the speed of the evolved hydrogen with time until hydrogen evolution had stopped indicating the end point of the reaction.

Method 3

For catalysts $PdCl_2$ and $Pd(OAc)_2$; a DMA (6 mL) solution of Et_3SiH (1 eq. = 2.5 mmol, 291 mg, 399 μL or 2 eq. = 5.0 mmol, 582 mg, 798 μL) was prepared in an addition fun-

[6] CIF files containing all relevant data for the crystal structure determinations of **1** and **3**, as well as original kinetic data for Fig. 4, have been deposited with CISTI. The supplementary material may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada. For information on obtaining material electronically go to http://www.nrc.ca/cisti/irm/unpub_e.shtml. Crystallographic information has also been deposited with the Cambridge Crystallographic Data Centre. Copies of the data can be obtained, free of charge, on application to the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. (fax: 44-1223-336033 or e-mail: deposit@ccdc.cam.ac.uk).

nel. The silane solution was added quickly from the addition funnel to a three-neck round-bottomed flask containing the catalyst (0.075 mmol = 3 mol% of metal with respect to ethylene glycol). The system was allowed to equilibrate for 3 min. Ethylene glycol (2.5 mmol, 155 mg, 140 μL) was added via a syringe into the mixture. The rate of reaction was qualitatively followed by monitoring the speed of the evolved hydrogen with time until hydrogen evolution had stopped indicating the end point of the reaction.

Product analysis

The reaction products $Et_3SiOCH_2CH_2OH$, $Et_3SiOCH_2CH_2OSiEt_3$, as well as the side products Et_3SiOH and $Et_3SiOSiEt_3$, were authenticated by ^1H and ^{13}C NMR, and by matching their GC–MS spectra to their known fragmentation patterns available from the NIST compound database supplied with the MS spectrometer software. Quantitative analysis of the reaction mixtures was performed through multi-level calibration of the GC for ethylene glycol, triethylsilane, $Et_3SiOCH_2CH_2OH$, and $Et_3SiOCH_2CH_2OSiEt_3$ over the entire relevant concentration range using authentic compound samples and NMP as an internal standard.

$Et_3SiOCH_2CH_2OH$: ^1H NMR ($CDCl_3$, 298K) δ: 3.65 (m, 4H, $SiOCH_2CH_2OH$), 2.10 (br s, 1H, OH), 0.93 (t, $J_{H,H}$ = 8 Hz, 9H, $Si(CH_2CH_3)_3$), 0.59 (q, $J_{H,H}$ = 8 Hz, 6H, $Si(CH_2CH_3)_3$). ^{13}C NMR ($CDCl_3$, 298K) δ: 63.69, 63.65 (2 s, $SiOCH_2CH_2OH$), 6.67 (s, $Si(CH_2CH_3)_3$), 4.29 (s, $Si(CH_2CH_3)_3$).

$Et_3SiOCH_2CH_2OSiEt_3$: ^1H NMR($CDCl_3$, 298K) δ: 3.64 (s, 4H, $SiOCH_2CH_2OSi$), 0.92 (t, $J_{H,H}$ = 8 Hz, 9H, $Si(CH_2CH_3)_3$), 0.58 (q, $J_{H,H}$ = 8 Hz, 6H, $Si(CH_2CH_3)_3$). ^{13}C NMR ($CDCl_3$, 298K) δ: 64.18 (s, $SiOCH_2CH_2OSi$), 6.37 (s, $Si(CH_2CH_3)_3$), 4.34 (s, $Si(CH_2CH_3)_3$).

The life, death, and ROMP activity of ruthenium complexes containing the basic, chelating diphosphine bis(dicyclohexyl)-1,4-phosphinobutane

Dino Amoroso, Glenn P.A. Yap, and Deryn E. Fogg

Abstract: Reaction of $RuCl_2(PPh_3)_3$ with bis(dicyclohexyl)-1,4-phosphinobutane (dcypb) under N_2 affords access to a formerly elusive family of dcypb complexes based on the $RuCl_2(PP)$ core. Under Ar or vacuum atmosphere, decomposition occurs via Ru-promoted dehydrogenation of the dcypb ligand. While the N_2-stabilized species $[RuCl_2(dcypb)]_2(N_2)$ (**4a**) is easily handled under N_2 in nonchlorinated solvents, reaction with chlorinated solvents rapidly yields paramagnetic $Ru_2Cl_5(dcypb)_2$ (**5**). The N_2 ligand within **4a** is readily displaced under H_2 or CO atmosphere, yielding $Ru_2Cl_4(dcypb)_2(H_2)$ (**6**) or $RuCl_2(dcypb)(CO)_2$, the latter as a mixture of *ccc*-(**7**) and *tcc*-(**8**) isomers. Benzylidene derivative $RuCl_2(dcypb)(CHPh)$ (**1a**), prepared in situ by reaction of **4a** with $PhCHN_2$, proves exceptionally active in ring-opening metathesis polymerization (ROMP) of norbornene. The X-ray crystal structure of **5** is reported: triclinic, a = 13.390(2), b = 15.726(2), c = 19.524(2) Å, α = 77.325(2), β = 70.964(2), γ = 73.478(2)°, with space group $P\bar{1}$ and Z = 2.

Key words: ruthenium, alkylphosphine, dehydrogenation, carbene, metathesis, crystal structure.

Résumé : La réaction du $RuCl_2(PPh_3)_3$ avec le bis(dicyclohexyl)-1,4-phosphinobutane (dcypb), sous atmosphère d'azote, permet d'accéder à la famille antérieurement élusive de complexes de dcypb comportant un noyau $RuCl_2(PP)$. Sous atmosphère d'argon ou sous vide, il se produit une décomposition qui se produit par le biais d'une déshydrogénation du ligand dcypb provoquée par le Ru. Alors que l'on peut facilement manipuler l'espèce stabilisée par le N_2 $[RuCl_2(dcypb)]_2(N_2)$, **4a**, sous atmosphère d'azote, dans des solvants non chlorés, la réaction dans des solvants chlorés conduit à la formation de l'espèce paramagnétique $Ru_2Cl_5(dcypb)_2$, **5**. On peut facilement déplacer le ligand N_2 du composé **4a** sous atmosphère de H_2 ou de CO avec formation de $Ru_2Cl_4(dcypb)_2(H_2)$, **6**, ou de $RuCl_2(dcypb)(CO)_2$ qui existe sous la forme de mélange d'isomères *ccc*-(**7**) et *tcc*-(**8**). Le dérivé benzylidène, $RuCl_2(dcypb)(CHPh)$, **1a**, préparé in situ par réaction du composé **4a** avec $PhCHN_2$, est exceptionnellement actif dans la polymérisation par ouverture de cycle et métathèse du norbornène. On a déterminé la structure cristalline par diffraction des rayons X du composé **5**: triclinique, a = 13,390(2), b = 15,726(2) et c = 19,524(2)Å, α = 77,325(2), β = 70,964(2) et γ = 73,478(2)°, groupe d'espèce $P\bar{1}$ et Z = 2.

Mots clés : ruthénium, alkylphosphine, déshydrogénation, carbène, métathèse, structure cristalline.

[Traduit par la Rédaction]

Introduction

Enhanced catalytic activity is associated with use of electron-rich phosphine ligands in a range of reactions promoted by late transition metal complexes, including metathesis (1, 2) and hydrogenation (3, 4) catalysis. Complexes of chelating alkyldiphosphines remain little explored in such chemistry, relative to the ubiquitous aryldiphosphine derivatives. We recently described the first Ru–diphosphine catalysts to exhibit high activity in ring-opening metathesis polymerization (ROMP) without ligand loss (2). Benzylidene catalysts $RuCl_2(PP)(CHPh)$ (PP = $R_2P(CH_2)_4PR_2$; R = Cy (dcypb, 1,4-bis(dicyclohexylphosphino)butane) (**1a**), R = Ph (dppb, 1,4-bis(diphenylphosphino)butane) (**1b**)) were generated in situ by reaction of mixed-phosphine species $RuCl_2(PP)(PPh_3)$ (**2**) or dimeric $[RuCl_2(dppb)]_2$ with phenyldiazomethane. The inhibiting effect of free PPh_3 was explored within the $RuCl_2(dppb)(PPh_3)$–$[RuCl_2(dppb)]_2$ pair, but no route to the corresponding $[RuCl_2(dcypb)]_2$ precursor existed. Here we report a new route to PPh_3-free Ru complexes containing the chelating, basic diphosphine ligand dcypb, with insights into decomposition pathways that have until now hindered the broader deployment of such systems. The ROMP activity of the PPh_3-free system is described.

Experimental

Unless otherwise stated, all operations were performed under N_2 using standard Schlenk or drybox techniques. Dry, oxygen-free solvents were obtained using an Anhydrous Engineering solvent purification system, and stored over Linde 4 Å molecular sieves. $CDCl_3$ and C_6D_6 were dried over activated sieves (Linde 4 Å) and degassed by consecutive

 DOI: 10.1139/cjc-79-5/6-958 © 2001 NRC Canada

freeze-pump-thaw cycles. Phenyldiazomethane (5), dcypb (6), $RuCl_2(PPh_3)_3$ (**3**) (7), and *t*-$RuCl_2(dppe)_2$ (8) were prepared according to literature procedures. $RuCl_3 \cdot 3H_2O$ was purchased from Strem Chemicals. Norbornene was purchased from Aldrich and distilled from sodium under N_2. Hydrogen (Praxair, UHP grade) was passed through a Deoxo cartridge and Drierite column in series; CO (Praxair) was used as received.

^{31}P and ^{13}C NMR spectra were recorded on a Varian XL-300 spectrometer, ^1H NMR spectra on a Varian Gemini 200 or Bruker AMX-500 spectrometer. Peaks are reported in ppm, relative to 85% aq. H_3PO_4 (^{31}P) or the deuterated solvent (^1H, ^{13}C). Solid state NMR data were recorded on a Bruker ASX-200 MHz spectrometer, infrared spectra on a Bomem MB100 IR spectrometer. Microanalytical data were obtained using a PerkinElmer Series II CHNS/O instrument. Gel permeation chromatography (GPC) data were obtained with CH_2Cl_2 as eluent (flow rate 1.0 mL min^{-1}; samples 1–2 mg mL^{-1}) using a Wyatt DAWN light-scattering instrument equipped with Optilab DSP refractometer, HPLC system with a Waters model 515 pump, Rheodyne model 7725i injector with a 200 μL injection loop, and Waters Styragel HR3 column.

Preparation of $Ru_2Cl_4(dcypb)_2(N_2)$ (4a)

A green solution of **3** (500 mg, 0.52 mmol) and dcypb (259 mg, 0.57 mmol) in C_6H_6 (5 mL) was stirred at 21°C under N_2. Orange **4a** began to precipitate from solution within 1 h. The orange suspension was diluted with hexanes after 18 h and the product was filtered off, washed with hexanes (3 × 10 mL), and dried under a steady flow of N_2 for 24 h. Yield: 0.303 g (91%). FAB-MS (*m*/*z*): 1245 ([M – N_2]$^+$). IR (Nujol) (cm^{-1}): 2124 (N_2) (m). ^1H NMR ($CDCl_3$) δ: 0.7–3.1 (br, C*H*$_2$, Cy of dcypb). $^{31}P\{^1H\}$ NMR ($CDCl_3$) δ: 57.5 (d, $^2J_{P,P}$ = 39 Hz), 45.0 (d, $^2J_{P,P}$ = 27 Hz), 44.6 (d, $^2J_{P,P}$ = 39 Hz), 42.3 (d, $^2J_{P,P}$ = 27 Hz); (C_6D_6) δ: 60.1 (d, $^2J_{P,P}$ = 39 Hz), 49.1 (d, $^2J_{P,P}$ = 26 Hz), 45.3 (d, $^2J_{P,P}$ = 39 Hz), 37.4 (d, $^2J_{P,P}$ = 26 Hz). Solid-state $^{31}P\{^1H\}$ CP-MAS NMR (80.9 MHz) δ: 45–57 (br, unresolved), 43.6 (br), 41.2 (br). Anal. calcd. for $C_{56}H_{104}Cl_4N_2P_4Ru_2$: C 52.81, H 8.25, N 2.20; found: C 52.90, H 8.19, N 1.90.

Preparation of $Ru_2Cl_5(dcypb)_2$ (5)

Complex **4a** (40 mg, 0.04 mmol) was dissolved in $CDCl_3$ (0.5 mL) and the solution was monitored by $^{31}P\{^1H\}$ NMR. Resolution degraded perceptibly over ~30 min, and a broad singlet emerged at 50 ppm. On further reaction, S/N values decreased, and many new peaks could be discerned (46–63, 15–32 ppm). Slow evaporation deposited red crystals of **5**.

Decomposition of 4a under vacuum

(*i*) NMR-scale. A solution of **4a** (3.0 mg, 4.7 μmol Ru) in C_6D_6, with *t*-$RuCl_2(dppe)_2$ (2.3 mg, 2.35 μmol) as an internal standard, was freeze-pump-thaw degassed in a round-bottom Schlenk flask. $^{31}P\{^1H\}$ NMR spectra were measured after every second cycle of degassing. No NMR signals were discerned after six degassing cycles, though gas evolution was sustained over three further cycles. (*ii*) Large-scale. A suspension of **4a** (20 mg, 0.016 mmol Ru_2) in benzene (10 mL) was freeze-pump-thaw degassed until no signals were evident by NMR. Concentration and addition of cold hexanes afforded a dark grey-green solid, which was filtered off, washed with cold hexanes, and dried under a flow of Ar. Yield: 16 mg. IR (Nujol) (cm^{-1}): 1944 (Ru-H) (m-w), 1629 (C=C) (m-w). (*iii*) Prolonged exposure of solid **4a** to vacuum at 50°C resulted in a mixture of diamagnetic products (multiple ^{31}P NMR signals in the region from 75 to –15 ppm).

NMR-scale preparation of $Ru_2Cl_4(dcypb)_2(H_2)$ (6)

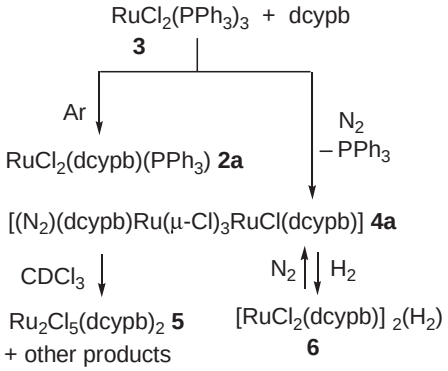
Stirring a suspension of **4a** (4 mg, 3 μmol Ru_2) in C_6D_6 (0.5 mL) under H_2 at room temperature afforded a homogeneous orange solution within 15 min. No starting material was spectroscopically observable after 30 min. ^1H NMR (C_6D_6) δ: 0.6–3.0 (br, C*H*$_2$, Cy of dcypb), –11.8 (br s, *H*$_2$). $^{31}P\{^1H\}$ NMR (C_6D_6) δ: 65.1 (d, $^2J_{P,P}$ = 25 Hz), 59.2 (d, $^2J_{P,P}$ = 40 Hz), 45.9 (d, $^2J_{P,P}$ = 25 Hz), 43.9 (d, $^2J_{P,P}$ = 40 Hz). Hydride T_1 (min) = 26 msec (300 K, 500 MHz).

Preparation of $RuCl_2(dcypb)(CO)_2$ (ccc-(7), tcc-(8))

A suspension of **4a** (27 mg, 39 μmol Ru_2) in THF (5 mL) was stirred under CO for 24 h, affording a clear yellow solution. The solution was concentrated and hexanes added to coprecipitate **7** and **8** as a yellow powder (1:4). Yield: 23 mg (88%). IR (Nujol) (cm^{-1}): 2052 (CO) (s, **7**), 2038 (s, **8**), 1976 (s, **8**), 1962 (s, **7**). ^1H NMR (C_6D_6) δ: 0.8–2.4 (br, C*H*$_2$, Cy of dcypb). $^{13}C\{^1H\}$ NMR (C_6D_6) δ: 198.7 (t, $^2J_{P,P(cis)}$ = 12 Hz, **7**), 193.5 (dd, $^2J_{P,P(trans)}$ = 113 Hz, $^2J_{P,P(cis)}$ = 11 Hz, **7**), 193.8 (dd, $^2J_{P,P(trans)}$ = 109 Hz, $^2J_{P,P(cis)}$ = 23 Hz, **8**). $^{31}P\{^1H\}$ NMR (C_6D_6) δ: 39.4 (d, $^2J_{P,P}$ = 22 Hz, **7**), 17.1 (d, $^2J_{P,P}$ = 22 Hz, **7**), 13.8 (s, **8**). Anal. calcd. for $C_{30}H_{52}Cl_2O_2P_2Ru$: C 53.09, H 7.72; found: C 53.39, H 7.93.

In situ polymerization of norbornene by 1a

Optimization of the procedure has been described (2). Blank polymerization experiments carried out without added Ru catalyst showed no ROMP over 24 h. In a representative catalytic procedure, $PhCHN_2$ (1.1 μL, 10.6 μmol) was added to an orange suspension of **4a** (6.6 mg, 10.6 μmol) in C_6D_6 (2 mL). Vigorous bubbling ensued, and all of the solids dissolved, forming a deep orange solution, which was immediately added to a stirred solution of norbornene (200 mg, 2.1 mmol) in $CDCl_3$ or C_6D_6 (5 mL). The progress of the reaction was monitored by removing aliquots for NMR analysis. (*i*) ROMP via **4a** + 2 $PhCHN_2$ in $CDCl_3$–C_6D_6: M_n 2.4 × 10^6, M_w/M_n = 1.4; (*ii*) via **2a** (prepared in situ by addition of 2 equiv PPh_3 to **4a**) + $PhCHN_2$ in $CDCl_3$–C_6D_6: M_n 2.4 × 10^6, M_w/M_n = 1.2; (*iii*) via **4a** + 2 $PhCHN_2$ in neat benzene: bimodal, M_n 1.9 × 10^6, M_w/M_n = 2.4; M_n 20 000, M_w/M_n = 3.8.



X-ray crystallographic analysis of 5

Crystal and data collection parameters for **5** are provided in Table 1.[2] Suitable crystals were selected, mounted on thin glass fibres using viscous oil, and cooled to the data collection temperature. Data were collected on a Bruker AX SMART 1k CCD diffractometer using 0.3° ω-scans at 0, 90,

[2] Copies of materials on deposit may be purchased from The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, ON K1A OS2, Canada. Tables of hydrogen atom coordinates and bond lengths and angles have also been deposited with the Cambridge Crystallographic Database, and can be obtained on request from the Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge CB2 1EZ, U.K.

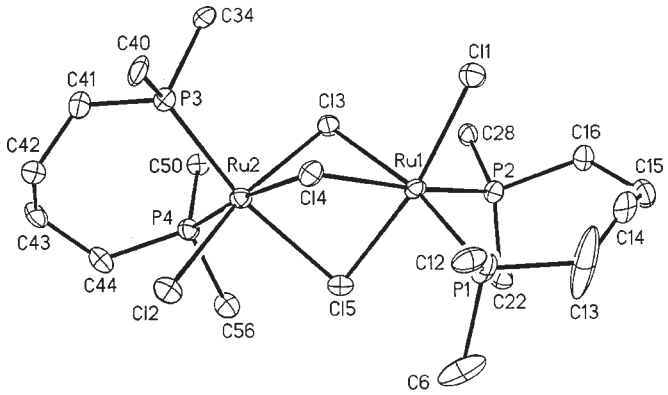
Scheme 1.



and 180° in ϕ. Unit-cell parameters were determined from 60 data frames collected at different sections of the Ewald sphere. Semi-empirical absorption corrections based on equivalent reflections were applied (9). No symmetry higher than triclinic was evident from the diffraction data. Solution in $P\bar{1}$ yielded chemically reasonable and computationally stable results of refinement. The structure was solved by direct methods, completed with difference Fourier syntheses and refined with full-matrix least-squares procedures based on F^2. A carbon atom, C(14), in one of the ligands was located conformationally disordered in two positions with roughly 50/50 site occupation distribution. The large anisotropic displacement parameters on C(13) suggest similar disorder. Attempts to model this disorder were unsuccessful, however, owing to insufficient resolution between the contributing atomic positions. A molecule of benzene and two molecules of chloroform were located in the asymmetric unit. The benzene molecule of crystallization was constrained as flat hexagon. All nonhydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were treated as idealized contributions. All scattering factors and anomalous dispersion factors are contained in the SHEXTL 5.10 program library (10).

Results and discussion

Treatment of **3** with dcypb in benzene under Ar yields the mixed-phosphine complex **2a** (11), which differs from its dppb analogue **2b** in undergoing no dimerization (with loss of PPh_3) in solution. The very high solubility of **2a** has so far prevented its isolation. In strong contrast is the reaction of **3** with dcypb under N_2 atmosphere, which affords a high-yield route to sparingly soluble $[(N_2)Ru(dcypb)(\mu\text{-}Cl)_3RuCl(dcypb)]$ (**4a**) (Scheme 1). This net displacement of triphenylphosphine ligand by N_2 has no precedent in the corresponding aryldiphosphine chemistry. The identity of **4a** is confirmed by NMR and IR spectroscopy and microanalysis. ^{31}P NMR analysis reveals four doublets for the inequivalent phosphine groups within **4a**, in a pattern similar to that earlier reported (12) for dppb analogue **4b**. The ^1H NMR spectrum of **4a** is less informative, consisting only of a series of overlapping multiplets between 0.7–3.1 ppm arising from the cyclohexyl protons and the methylene protons of the dcypb backbone. A strong IR band for ν(N≡N) is evident at 2124 cm^{-1}.

Fig. 1. ORTEP drawing of $Ru_2Cl_5(dcypb)_2$ (**5**). Thermal ellipsoids depicted at 30% probability level; cyclohexyl rings, hydrogen atoms, and solvate molecules omitted for clarity. A detailed structural representation is included in the Supplementary Material.

The solubility of **4a** is slightly improved in halogenated solvents such as CH_2Cl_2 or $CDCl_3$, but decomposition in these solvents yields the mixed-valence dimer $Ru_2Cl_5(dcypb)_2$ **5**.[3] James and co-workers (12, 13) have reported extensively on the synthesis, reactivity, and catalytic chemistry of such species, obtained via reaction of chelating diphosphines with $RuCl_3(PR_3)_2$ (R = Ph, *p*-tolyl). Attempts to prepare clean **5** on large scale by the reaction of **4a** with $CDCl_3$ or ethereal HCl, resulted in product mixtures, as judged by in situ ^{31}P NMR analysis prior to complete loss of the diamagnetic signals. Slow evaporation of $CDCl_3$ solutions under N_2 permitted isolation of crystals suitable for X-ray analysis. The molecular structure of **5** is shown in Fig. 1; crystal data and selected structural parameters appear in Tables 1 and 2, respectively.

Complex **5** adopts a triply chloride-bridged diruthenium structure, in which the coordination geometry at each metal center is distorted octahedral. The structure is unsymmetrical, with one of the octahedra being rotated by 120° about the Ru–Ru vector. A similar structure was earlier reported for $Ru_2Cl_5(P(n\text{-}Bu)_3)_4$ (14), whereas the only previous crystal structure of a chelating diphosphine derivative, $Ru_2Cl_5(chiraphos)_2$, exhibits a symmetrical ligand arrangement (13). Ruthenium—phosphorus and —chloride distances fall within the ranges reported, as do angles within the Ru-P-Cl skeleton. Chloride atoms *trans* to phosphorus display distinctly longer Ru—Cl bond distances (av. 2.49 Å) compared to those *trans* to Cl (av. 2.38 Å), as expected from the stronger *trans* influence of phosphine. The average bridging angle in **5** (83.7°) is nearly 15° larger than the ideal value of 70.5° for two regular face-sharing octahedra (14), indicating that the Ru centers are further apart than expected for a regular cofacial bioctahedron. The Ru—Ru distance of 3.278 Å is considerably longer than the upper limit associated with the presence of a metal–metal bond (2.95 Å) (13). As with the chiraphos and the $P(n\text{-}Bu)_3$ complexes, the crystallographic data do not permit assignment of formal oxidation states to the ruthenium atoms.

[3] Note added in proof: complex **5** was originally prepared via this route, and partially transformed into **6** by treatment with H_2 in DMA or CH_2Cl_2. Private communication from B.R. James, based on data contained in ref. 6.

In aromatic solvents, **4a** is stable for weeks in solution under N_2. In contrast with the dppb systems, which exist in equilibrium with the "naked" dimers $[RuCl_2(PP)]_2$ **9** under N_2 (eq. [1], (12)), no peaks for $[RuCl_2(dcypb)]_2$ are observed.

[1] $$\underset{\mathbf{4}}{Ru_2Cl_4(PP)_2(N_2)} \rightleftharpoons \underset{\mathbf{9}}{Ru_2Cl_4(PP)_2} + N_2$$

The lability of the dinitrogen ligand is indicated, however, by its facile replacement under H_2 or CO atmosphere. Displacement of N_2 by dihydrogen is complete within 10 min at 1 atm H_2, as indicated by a pronounced shift in the location of the ^{31}P NMR doublets associated with the "L-end" of the complex (Table 3). The ^1H NMR spectrum reveals a singlet for bound H_2 at –11.8 ppm. The T_1 (min) value of 26 msec (300 K, 500 MHz) corresponds to an H—H distance of 0.89 Å, assuming rapid rotation of the dihydrogen ligand; this compares well with the value of 0.86 Å reported for **4b** (15). H_2-coordination is readily reversed under N_2 atmosphere. Under CO, mononuclear $RuCl_2(dcypb)(CO)_2$ is formed as a mixture of isomers, **7** and **8** (Scheme 2). The two are readily distinguished by $^{31}P\{^1H\}$ NMR; the phosphine groups of *all-cis*-**7** appear as a pair of doublets, whereas a singlet is found for *tcc*-**8**. Consistent with the proposed structures is the carbonyl region of the $^{13}C\{^1H\}$ NMR spectrum, as well as the IR data. The former shows a triplet and a doublet of doublets for **7**, but only a doublet of doublets for **8**. Two IR ν(CO) bands are seen for each complex.

Surprisingly, in view of the observed lability of the dinitrogen ligand in **4a**, no peaks for a dimer of type **9** were evident even under Ar atmosphere, or following freeze-pump-thaw (FPT) experiments carried out to shift the presumed equilibrium (eq. [1]) to the right. Sustained gas evolution was observed in NMR tubes subjected to successive FPT cycles (>20), but no new peaks were evident by $^{31}P\{^1H\}$ NMR, even at low temperature (183 K). Degassing experiments using *trans*-$RuCl_2(dppe)_2$ as internal standard were carried out in Schlenk vessels, in which the higher surface area permitted more efficient removal of dissolved gas. A steady decrease in concentration of **4a** is measured with increasing number of FPT cycles, signifying conversion of **4a** to a paramagnetic Ru product. Gas evolution is sustained after complete loss of the NMR signals, probably owing to paramagnetic broadening of signals for remaining **4a**. Observation of a large ^1H NMR singlet for dissolved H_2 at 4.2 ppm after each FPT cycle is consistent with Ru-promoted

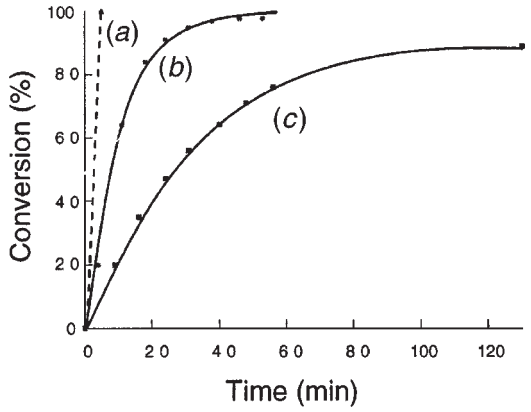

Scheme 2.

dehydrogenation of the cyclohexyl rings and (or) the dcypb backbone (catalytic dehydrogenation of the solvent itself is excluded by observation of this behaviour in benzene solvent). A ν(C=C) stretching band appears at 1629 cm^{-1} in the IR spectrum, as well as a signal at 1944 cm^{-1} assigned to Ru–H. No HCl was detected by GC-MS, and no precipitate formed on forcing the effluent gas through concentrated ammonia or NH_4PF_6 solutions, suggesting that HCl is not evolved in the reaction.

The utility of closely related Ru complexes in catalytic dehydrogenation of sp^3 C–H bonds has been established by Leitner and co-workers (16, 17). While forcing conditions were required for activation of cyclooctane, dehydrogenation of the cyclohexyl rings within complexes containing $Cy_2P(CH_2)_nPCy_2$ (n = 3, 4) was induced at 50°C, resulting in diamagnetic η^3-cyclohexenyl derivatives. Chaudret and co-workers (18–20) have likewise described intramolecular dehydrogenation of cyclohexyl rings within Ru–PCy_3 complexes at room temperature, affording Ru(II) complexes containing η^3- and (or) η^2-cyclohexenyl rings. A related process is almost certainly involved in dehydrogenation of **4a**, in which retention of both chloride ligands may be responsible for formation of a Ru(III) product. We do not exclude the possibility of concomitant attack on the four-carbon backbone; agostic interactions between Ru and bound dppb, culminating in deuterium incorporation into the backbone methylene groups, have been noted (21), while we have observed C–H bond activation within the dcypb backbone in related silylene chemistry (22). Confirmation of the identity of the dehydrogenation product(s) is hampered by paramagnetism and poor crystallinity. Attempts to probe the reaction by thermal gravimetric analysis are complicated by the observation of other diamagnetic products in solid-state degassing experiments. The high activity of these species toward activation of saturated C–H bonds under exceptionally mild conditions is notable; however, facile intramolecular attack may be attributed to the combination of steric bulk and high basicity in the dcypb ligand. The ease of such reactions in the absence of stabilizing donor ligands may account for prior difficulties in gaining access to this chemistry under Ar atmosphere. Use of N_2 as a labile donor to inhibit intramolecular attack opens up a potentially rich catalytic and coordination chemistry.

Fig. 2. ROMP activity of dcypb complexes. (*a*) **4a** + 2 $PhCHN_2$, $CDCl_3$-C_6D_6; (*b*) **2a** + 2 $PhCHN_2$, $CDCl_3$-C_6D_6; and (*c*) **4a** + 2 $PhCHN_2$, C_6D_6.

We recently described polymerization via $RuCl_2(PP)(CHPh)$ systems derived from **2**, in which high ROMP activity in norbornene polymerization was observed despite the presence of the catalyst poison PPh_3 (2). PPh_3-free **1a**, generated in situ by addition of $PhCHN_2$ to **4a** (Scheme 2), functions as a much more avid catalyst (Fig. 2). Thus, while ROMP of norbornene by the **2a**–$PhCHN_2$ system requires nearly an hour at substrate:catalyst ratios of 200:1, polymerization via **4a** is complete before the first NMR measurement can be taken (5 min, lower limit for the turnover frequency = 2400 h^{-1}). Despite the susceptibility of **4a** to decomposition by chlorinated solvent, mixed solvent systems, in which the catalyst was generated in C_6D_6 and subsequently added to a $CDCl_3$ solution of norbornene, showed much higher activity than ROMP in neat C_6D_6. Decreased metathesis activity in nonpolar solvents is characteristic of these Ru systems (1). The slow rate of polymerization in neat benzene permits competing decomposition via extrusion of the carbene as stilbene (a process characteristic of Ru–carbene complexes). Polymer polydispersities for reactions in benzene are consequently *higher* than those observed in the mixed solvent systems (PDI 3.8 vs. 1.2–1.4), and a bimodal molecular weight distribution is observed, indicating the presence of more than one ROMP-active species. The very rapid rate of polymerization in $CDCl_3$–C_6D_6 (Fig. 2*a*) suggests that decomposition of **1a** cannot compete with norbornene metathesis in this solvent system, and this is supported by the low polydispersity obtained.

Conclusions

The foregoing describes the first general route into the chemistry of chlororuthenium–phosphine complexes con-

© 2001 NRC Canada

taining the basic, bulky diphosphine, dcypb. Steric pressure, allied with high electron density, renders these species susceptible to decomposition by attack on solvent or on the dcypb ligands. Where such processes can be restrained, this heightened reactivity can be redirected and exploited in catalysis, as exemplified in the potent ROMP reactivity of the carbene derivative.

Intra- and inter-ion-pair protonic—hydridic bonding in polyhydridobis(phosphine)rhenates

Kamaluddin Abdur-Rashid, Alan J. Lough, and Robert H. Morris

Abstract. The hexahydridobis(phosphine)rhenate anions, $[ReH_6(PR_3)_2]^-$ (PR_3 = PCy_3, P-*i*-Pr_3, PPh_3, PMe_3) were generated by potassium hydride deprotonation of the neutral heptahydride conjugate acids ($ReH_7(PR_3)_2$), isolated as their $[K(18\text{-crown-6})]^+$ and $[K(1,10\text{-diaza-18-crown-6})]^+$ salts, and characterized by NMR and IR spectroscopy and elemental analyses. Structures from single crystal X-ray diffraction were obtained for the $[K(1,10\text{-diaza-18-crown-6})]^+$salts and these indicate the presence of short protonic—hydridic bonds involving the hydrides of the anions and the proton donor NH moieties of the cations. The structure of $[K(1,10\text{-diaza-18-crown-6})][ReH_6(P\text{-}i\text{-}Pr_3)_2]$ adopts a one-dimensional zigzag chain with alternating cations and anions connected and held together by inter-ion N-H$\cdots$H$_x$-Re interactions (x = 1 or 2). Short distances between the NH protons of the cations and hydrides of the anion ranging from 1.6 to 1.9 Å are estimated for this complex. A different kind of chain structure is observed for $[K(1,10\text{-diaza-18-crown-6})][ReH_6(PMe_3)_2]$ in which the combined effects of inter-ion protonic—hydridic bonding (N-H$\cdots$H$_x$-Re) and inter-ion electrostatic interactions (ReH$_x^-\cdots$K$^+\cdots$H$_x^-$Re), result in one-dimensional networks of alternating cations and anions, with the metals and hydrides occupying the interior and the organic moieties of the phosphine ligands and crown ether lining the exterior of cylindrical supramolecular assemblies. A combination of intra- and inter-ion protonic–hydridic and intra-ion-pair electrostatic interactions in $[K(1,10\text{-diaza-18-crown-6})][ReH_6(PPh_3)_2]$ result in the formation of discrete two-dimensional $\{[K(1,10\text{-diaza-18-crown-6})][ReH_6(PPh_3)_2]\}_4$ tetramers. The PCy_3 salt is disordered but appears to consist of isolated 1:1 ion pairs containing strong intra-ion-pair NH$\cdots$HRe bonding. The solid-state IR spectra of the $[K(1,10\text{-diaza-18-crown-6})]^+$ salts show low-frequency shifts for the NH bands relative to $[K(1,10\text{-diaza-18-crown-6})][BPh_4]$, and perturbed Re-H bands relative to those in the $[K(18\text{-crown-6})]^+$ salts. The magnitude of $\Delta\nu$NH is related to the basicity of the anion as indicated by the pK_α^{THF} of the conjugate acid form ($ReH_7(PR_3)_2$), which increases as $PPh_3 < < PMe_3 < P\text{-}i\text{-}Pr_3 < PCy_3$. Solution ^{1}H NMR, NOE, and T_1 relaxation measurements of $[K(1,10\text{-diaza-18-crown-6})][ReH_6(PPh_3)_2]$ indicate that these interactions also persist in toluene solutions of this compound.

Key words: rhenium, hydride, phosphine, hydrogen bonding, self-assembly.

Résumé : On a généré les anions hexahydrobis(phosphine)rhénate, $[ReH_6(PR_3)_2]^-$ (PR_3 = PCy_3, P-*i*-Pr_3, PPh_3, PMe_3) par une déprotonation à l'aide d'hydrure de potassium des acides conjugués, heptahydrure neutre, $ReH_7(PR_3)_2$; on les a isolés sous la forme de sels $[K(18\text{-couronne-6})]^+$ et $[K(1,10\text{-diaza-18-couronne-6})]^+$ et on les a caractérisés par RMN, spectroscopie infrarouge et analyses élémentaires. On a déterminé les structures des sels $[K(1,10\text{-diaza-18-couronne-6})]^+$ par diffraction des rayons X sur des cristaux uniques et celles-ci indiquent la présence de courtes liaisons proton—hydrure impliquant les hydrures des anions et les portions de NH donneur de proton des cations. Le structure $[K(1,10\text{-diaza-18-couronne-6})][ReH_6(P\text{-}i\text{-}Pr_3)_2]$ adopte la forme d'une chaîne monodimensionnelle en zigzag comportant, en alternance, des cations et des anions reliés et retenus ensemble par des interactions N-H$\cdots$H$_X$-Re entre les ions (x = 1 ou 2). On a évalué que les distances entre les protons NH des cations et les hydrures de l'anion sont courtes et qu'elles vont de 1,6 à 1,9 Å. On observe une structure différente pour la chaîne du $[K(1,10\text{-diaza-18-couronne-6})][ReH_6(PMe_3)_2]$ dans laquelle les effets combinés de la liaison interionique proton—hydrure, N-H$\cdots$H$_x$-Re, et des interactions électrostatiques interioniques, ReH$_X^-\cdots$K$^+\cdots$H$_X^-$Re, conduisent à des réseaux unidimensionnels de cations et d'anions en alternance alors que les atomes de métal et les atomes d'hydrure occupent l'intérieur et les portions organiques des ligands phosphines et que l'éther couronne recouvre la partie extérieure des assemblages supramoléculaires cylindriques. Dans le $[K(1,10\text{-diaza-18-couronne-6})][ReH_6(PPh_3)_2]$, une combinaison d'interactions électrostatiques intra- et inter-ion proton–hydrure et intra-paire d'ions conduit à la formation de tétramères individuels $\{[K(1,10\text{-diaza-18-couronne-6})][ReH_6(PPh_3)_2]\}_4$. Le sel de PCy_3 est désordonné, mais il semble être formé de paires d'ions 1:1 isolées qui contiennent de fortes liaisons NH$\cdots$HRe intra-paires d'ions. Les spectres infrarouges à l'état solide des sels de $[K(1,10\text{-diaza-18-couronne-6})]^+$ montrent que les bandes NH se déplacent faiblement vers de plus faibles fréquences par rapport au $[K(1,10\text{-diaza-18-couronne-6})][BPh_4]$ et que les bandes de Re-H sont perturbées par rapport à celles des sels de $[K(18\text{-couronne-6})]^+$. L'amplitude du $\Delta\nu$NH est liée à la basicité de l'anion, telle qu'indiquée par le pK_α^{THF} de la forme

conjuguée de l'acide, $ReH_7(PR_3)_2$, qui augmente de $PPh_3 < < PMe_3 < P\text{-}i\text{-}Pr_3 < PCy_3$. L'EON en RMN du ^1H et les mesures des temps de relaxation T_1 du [K(1,10-diaza-18-couronne-6)][$ReH_6(PPh_3)_2$] indiquent que ces interactions persistent aussi dans les solutions de ce composé dans le toluène.

Mots clés : rhénium, hydrure, phosphine, liaison hydrogène, autoassemblage.

[Traduit par la Rédaction]

Introduction

Since the first reports of M-H···H-X protonic—hydridic or dihydrogen bonds (1–3), there have been numerous studies of this bonding between various hydrogen bond donors, X-H (X = O, N, C), and transition-metal hydride complexes (4–13) or main group hydride compounds (M = B, Ga) (14–19). These interactions have been verified by solution NMR, IR, single crystal X-ray, and neutron diffraction studies and theoretical calculations (20, 21) and have been shown to have similar structural, energetic, electronic, and spectroscopic characteristics to conventional X-H···Y hydrogen bonds, where X and Y are electronegative elements. Classical hydrogen bonds play crucial roles in various chemical, biological, and material systems (22). Similarly, it is becoming increasingly evident that this nonclassical hydrogen bonding represents more than just a unique and fascinating phenomenon; it can influence the chemical and physical characteristics and reactivity profiles of organometallic and main group metallohydride systems. For example, Haack et al. (23) reported an active catalyst for the asymmetric solvent-transfer hydrogenation of ketones that contains a RuH···HN interaction while Gatling and Jackson (19) recently highlighted the role of "dihydrogen bonds" in determining the stereoselective reactivity of aminoboranes.

Various research groups are currently investigating the use of these nonclassical hydrogen bonds for the systematic crystal engineering of organized molecular solids (6, 16, 17, 24–28). These protonic—hydridic bonds facilitate templated covalent bond formation during the pyrolysis of borohydride adducts of amines and aminoalcohols (28). Gladfelter's group (17) reported that these interactions are important in determining the solid-state structure of gallium hydride – amine adducts, such as cyclotrigallazane, and are significant in facilitating the formation of nanocrystalline gallium nitride during their thermal decomposition at elevated temperatures.

Some of our most recent studies involve the utilization of ion-pairing to facilitate and enhance protonic–hydridic interactions between transition-metal polyhydride anions $[MH_x(PR_3)_2]^-$, (M = Os, Ru, Ir) and potassium aza-crown cations to assemble novel and well-defined ionic structural motifs (6, 24, 25). Our choice of such systems was based on the expectation that the high basicity of anionic hydrides would make them better hydrogen bond acceptors compared to their neutral or cationic counterparts. In addition, an electrostatic contribution to the protonic—hydridic bond formation is expected, since the proton donor is a constituent of the cation. This has resulted in the first reports of one-dimensional chains held together by a combination of protonic–hydridic and electrostatic M-CO···K interactions in the solid-state structures of $[K(aza\text{-}18\text{-}crown\text{-}6)]^+$ salts of $[MH_3(XO)(P\text{-}i\text{-}Pr_3)_2]^-$ anions (M = Os, Ru, Re; X = C, N) (24), while one-dimensional chains held together by intermolecular protonic—hydridic bonds are observed in the $[K(1,10\text{-}diaza\text{-}18\text{-}crown\text{-}6)]^+$ salts of $[MH_x(P\text{-}i\text{-}Pr_3)_2]^-$ (M = Ir, × = 4; M = Os, Ru, x = 5) anions (6, 24, 25). The strength of the protonic–hydridic interactions in these salts, as verified by NMR and solution and solid-state IR studies, were shown to be related to the basicity of the anions (6, 24), which compliments previous studies that relates the strength of these interactions with the acidity of the proton donor species (7, 9, 29). An interesting observation was the spectacular increase in the activity of both the M—H (M = Os, Ru) and N—H bonds in solutions of these salts, leading to rapid and efficient deuteration of these two moieties upon exposure to D_2 gas (6). This observation has resulted in our subsequent development of novel ruthenium-based catalyst systems for the hydrogenation of nitriles, ketones, and imines (30, 31).

Our current study seeks to exploit and combine the synergistic effects of ion-pairing and intermolecular protonic—hydridic bonding to assemble and design novel supramolecular structural types. Furthermore, it is expected that reactivity studies involving these systems could help in identifying novel catalysts. Thus, we have extended our study to include salts of rhenium polyhydride anions. In a recently reported compilation of acidities of transition-metal hydrides and dihydrogen complexes in tetrahydrofuran (32), we found that the pK_α^{THF} of various cationic and neutral rhenium polyhydride acids are exceptionally sensitive to the nature of the ligands. The high polarizability of the Re—H bonds in rhenium polyhydride anions is expected to significantly influence the proton-accepting ability of the hydride ligands in the formation of protonic—hydridic bonded species, while steric congestion in the conjugate anions can be selectively controlled by an appropriate choice of phosphine ligands. In addition, the favorable electrostatic interactions that are known to exist between potassium crown-ether cations and the hydrides of rhenium polyhydride anions should also contribute another dimensionality in the formation of organized molecular assemblies (33–35). Here we report the synthesis, spectroscopic properties, and X-ray crystal structures of a series of hexahydridobis(phosphine)rhenate salts. This report demonstrates the subtle and related roles of ligand nucleophilicity and stereochemistry in determining the degree and types of intermolecular interactions and, hence, the molecular packing in the crystal lattice. The salts $K[ReH_6(PPh_3)_2]$, $[K(THF)_2][ReH_6(PPh_3)_2]$ (33), and [K(18-crown-6)][$ReH_6(PR_3)_2$], R = Ph, C_6H_4F, (34) were the only compounds of this type reported before this work.

Experimental section

General

All preparations and manipulations were carried out under H_2, N_2, or Ar atmospheres with the use of standard Schlenk, vacuum line, and glove box techniques in dry, oxygen-free

solvents. Tetrahydrofuran (THF), diethyl ether (Et_2O), and hexanes were dried and distilled from sodium benzophenone ketyl. Deuterated solvents were degassed and dried over activated molecular sieves. Potassium hydride, 18-crown-6, 1-aza-18-crown-6, 1,10-diaza-18-crown-6, trimethylphosphine, and rhenium metal (powder) were supplied by Aldrich Chemical Company. $ReOCl_3(P\text{-}i\text{-}Pr_3)_2$ and $ReOCl_3(PMe_3)_2$ were synthesized using a similar procedure as reported for the preparation of $ReOCl_3(PCy_3)_2$ (36), while the neutral heptahydrides, $ReH_7(PR_3)_2$, R = Cy (32, 36), *i*-Pr (37), Ph (32, 38), Me (39), were prepared using the simplified and modified procedure illustrated below for $ReH_7(PPh_3)_2$. NMR spectra were recorded on a Varian Unity-500 (500 MHz for ^1H) or on a Varian Gemini 300 MHz spectrometer (300 MHz for ^1H and 121.5 for ^{31}P). All ^{31}P spectra were recorded with proton decoupling and ^{31}P chemical shifts were measured relative to 85% H_3PO_4 as an external reference. ^1H chemical shifts were measured relative to partially deuterated solvent peaks but are reported relative to tetramethylsilane. T_1 measurements were made at 500 MHz using the inversion recovery method. The temperature of the probe was calibrated using the temperature dependence of the chemical shifts of MeOH. NOE measurements were also obtained at 500 MHz. Infrared spectra were obtained on a Nicolet 550 Magna-IR spectrometer. Microanalyses were performed by Guelph Chemical Laboratories Ltd. Although the samples were crystalline and spectroscopically pure, the carbon analyses were low in most cases.

Synthesis

$ReH_7(PPh_3)_2$

Diethyl ether (100 mL) was added to a mixture of $ReOCl_3(PPh_3)_2$ (1.0 g, 1.22 mmol) and $LiAlH_4$ (500 mg, 12.5 mmol) under an atmosphere of argon and the mixture was stirred for 1 h and then filtered. Ethanol was added slowly and dropwise to the filtrate, with thorough mixing between each addition until there was no further evolution of hydrogen gas. The resulting mixture was evaporated to dryness under vacuum, and the solids extracted with 4 × 10 mL of THF. The combined THF extract was concentrated to 5 mL and hexanes (20 mL) added, precipitating a white solid, which was filtered, washed with 2 × 3 mL of hexanes, then dried under vacuum. Yield = 602 mg, 70%. The purity of the compound was determined by comparing its ^1H and ^{31}P NMR spectra with those reported in the literature (32, 38).

*$[K(Q)][ReH_6(PR_3)_2]$ (Q = 18-crown-6 (**1**), 1,10-diaza-18-crown-6 (**2**)) (PR_3 = PCy_3 (**a**), P-i-Pr_3 (**b**), PPh_3 (**c**), PMe_3 (**d**))*

These salts were prepared using similar procedures as illustrated for $[K(18\text{-crown-6})][ReH_6(PPh_3)_2]$ (**1c**).

*$[K(18\text{-crown-6})][ReH_6(PPh_3)_2]$ (**1c**)*

THF (5 mL) was added to a mixture of $ReH_7(PPh_3)_2$ (300 mg, 0.42 mmol), KH (50 mg, 1.25 mmol), and 18-crown-6 (112 mg, 0.42 mmol). After stirring for 4 h, the mixture was filtered and the solids washed with 2 × 1.0 mL THF. Hexanes (15 mL) were added to the combined filtrate to precipitate a yellow solid that was filtered off, washed with hexanes and dried in vacuo. Yield = 398 mg, 93%. Note: Definition of R indices: $R_1 = \Sigma(F_o - F_c)/\Sigma(F_o)$; $wR_2 = [\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]]^{1/2}$.

Deuteration studies

A weighed sample of the desired complex was dissolved in the required solvent in a NMR tube under an argon atmosphere. The tube was then fitted with an adapter, by which it was connected to a vacuum line. The sample was cooled to liquid nitrogen temperature, degassed and closed. After warming to room temperature, D_2 gas at 1 atm (1 atm = 101.325 kPa) pressure was allowed into the NMR tube, which was then flame-sealed.

Determination of pK_α^{THF}

The pK_α^{THF} of $ReH_7(P\text{-}i\text{-}Pr_3)_2$ was related to the pK_α^{THF} = 41 of $ReH_7(PCy_3)_2$ (32) by the following procedure: a mixture of $ReH_7(PCy_3)_2$ (20 mg, 0.027 mmol) and [K(18-crown-6)][$ReH_6(P\text{-}i\text{-}Pr_3)_2$] (22 mg, 0.027 mmol) was dissolved in THF-d_8 and allowed to reach acid–base equilibrium over a period of 6 h. The concentrations of the added compounds along with their respective conjugate species were determined by ^{1}H and gated–decoupled ^{31}P NMR (K = 0.16). The derived pK_α^{THF} value of $ReH_7(P\text{-}i\text{-}Pr_3)_2$ was used to determine the pK_α^{THF} of $ReH_7(PMe_3)_2$ using similar procedures.

X-ray structure analysis

Crystals were obtained by the slow diffusion of diethyl ether or hexanes into THF solutions of the complexes under a nitrogen atmosphere. Data were collected on a Nonius Kappa-CCD diffractometer using Mo Kα radiation (λ = 0.71073 Å). The CCD data were integrated and scaled using the DENZO-SMN software package and the structures were solved and refined using SHELXTL Ver.5.0. The crystallographic data for complexes **2b**, **2c**, and **2d** are listed in Table 1. The hydrides in **2c** were located and refined with isotropic thermal parameters.

Results and discussion

Synthesis of the complexes

Several procedures are available for the preparation of the neutral rhenium heptahydrides, $ReH_7(PR_3)_2$ (34, 36, 40); however, the modified method used in this study resulted in spectroscopically pure products and greater than 60% isolated yields. Addition of diethyl ether to a mixture of $ReOCl_3(PR_3)_2$ and $LiAlH_4$ gave a colorless solution after stirring at room temperature for several minutes. Removal of the excess $LiAlH_4$ and quenching the etheral solution with ethanol resulted in the generation of the heptahydrido complexes. $ReH_7(PCy_3)_2$ and $ReH_7(PPh_3)_2$ were isolated as white powders, while $ReH_7(P\text{-}i\text{-}Pr_3)_2$ and $ReH_7(PMe_3)_2$ were isolated as tan-coloured viscous oils. Incomplete removal of triphenylphosphine from $ReOCl_3(PMe_3)_2$ resulted in the formation of a small amount of $ReH_5(PMe_3)_2(PPh_3)$ as an impurity during the preparation of $ReH_7(PMe_3)_2$.

The anionic hydride salts, [K(Q)][$ReH_6(PR_3)_2$], were prepared in 75–98% yields by deprotonation of the neutral heptahydide conjugates using KH in the presence of the desired crown ether (Q) in THF under N_2 or Ar atmospheres. The presence of the crown ether resulted in

$$[1]\quad ReH_7(PR_3)_2 + KH + Q \xrightarrow[-H_2]{THF} [K(Q)][ReH_6(PR_3)_2]$$

a shorter reaction time than that reported for the preparation of $K[ReH_6(PPh_3)_2]$, using KH alone (33), which is quite likely due to an increase in the solubility of the otherwise insoluble KH in the presence of the crown ether. The excess KH was conveniently removed by filtration, and the polyhydride salt precipitated as its $[K(crown\text{-}ether)]^+$ salt by the addition of hexanes or diethyl ether. The contamination of $ReH_7(PMe_3)_2$ with some $ReH_5(PMe_3)_2(PPh_3)$ posed no problem in the reaction with KH since, under the reaction conditions, the heptahydride complex is selectively deprotonated. Another complication was the formation of small amounts of salts of the anionic dimer $[\{ReH_2(PMe_3)_2\}_2(\mu\text{-}H_3)]^-$, which could be avoided by carrying out the deprotonation reaction under a H_2 atmosphere. A full study of a series of these novel anionic dimers is currently underway and will be reported elsewhere in due course (41).

The hexahydrido rhenium salts, **1a**, **2a**, **1b**, **2b**, **1d**, and **2d** were isolated as colourless, air- and moisture-sensitive salts, which are soluble in THF, benzene, and toluene. Complexes **1c** and **2c** are yellow, only moderately air-sensitive as solids and display similar solubility characteristics as the other salts. All of these rhenium hexahydride salts are expected to exist as 1:1 ion-pairs in solution, as evidenced by their solubility in the aromatic solvents. The X-ray structures and solid-state IR spectra establish the presence of NH···HRe interactions in the $[K(1,10\text{-diaza-18-crown-6})]^+$ salts (see below).

Relative pK_α^{THF} values for the complexes

The pK_α^{THF} values for the neutral conjugate acids of the complexes used in this study were determined by neutral acid – anionic base reactions in THF-d_8 by means of quantitative ^{31}P and ^{1}H NMR spectroscopy. These pK_α^{THF} values are approximations to absolute, free ion pK_α^{THF} and are obtained by crudely correcting the observed K for 1:1 ion-pairing effects by use of the Fuoss equation (32). The pK_α^{THF} value of $ReH_7(P\text{-}i\text{-}Pr_3)_2$ was determined to be 40.2 by using eq. [3] and the previously reported value of 41 for the pK_α^{THF} of $ReH_7(PCy_3)_2$ (32). No correction ΔpK_d is required for ion pairing because the inter-ion distances are expected to be very similar.

$$[2]\quad ReH_7(PCy_3)_2 + [K(18\text{-crown-}6)][ReH_6(P\text{-}i\text{-}Pr_3)_2] \underset{}{\overset{K}{\rightleftharpoons}} [K(18\text{-crown-}6][ReH_6(PCy_3)_2] + ReH_7(P\text{-}i\text{-}Pr_3)_2$$

$$[3]\quad pK_\alpha^{THF}\{ReH_7(P\text{-}i\text{-}Pr_3)_2\} = pK_\alpha^{THF}\{ReH_7(PCy_3)_2\} - pK + \Delta pK_d$$

Similarly, from an equilibrium involving $ReH_7(P\text{-}i\text{-}Pr_3)_2$ and **1d** (K = 0.016), the pK_α^{THF} of $ReH_7(PMe_3)_2$ was determined to be 38.4. The pK_α^{THF} of $ReH_7(PPh_3)_2$ in THF was previously reported to be 30 (32). A comparison of the pK_α^{THF} values show that the acidities of the neutral heptahydride complexes are exceptionally susceptible to substituent effects of the phosphine ligands, with an unprecedented 11 pK_α^{THF} unit difference between the acid dissociation constants for $ReH_7(PCy_3)_2$ and $ReH_7(PPh_3)_2$. To date, these complexes represent some of the least acidic polyhydride complexes to have their pK_α^{THF} determined.

of [K(1,10-diaza-18-crown-6)]BPh_4 in THF-d_8 is also included in Table 2, since this salt is totally insoluble in toluene. The triplets in the hydride region of the ^{1}H NMR spectra of the salts are indicative of a fluxional process that makes all six hydrides chemically equivalent in the presumably dodecahedral structure. In general, the salts show increasingly high-field shifts for the hydride resonance with

Fig. 2. Solid-state (Nujol mull) IR spectra of [K(1,10-diaza-18-crown-6)]$^+$ (NH region) with the anions shown.

increasing basicity of the phosphine ligands, except for the PCy_3 complexes, which have chemical shifts at lower fields than the analogous P-*i*-Pr_3 complexes.

The hydride region of the ^{1}H NMR spectra of the PCy_3 and P-*i*-Pr_3 salts shows a slight up-field shift of the hydride resonance in the [K(1,10-diaza-18-crown-6)]$^+$ salts, relative to their [K(18-crown-6)]$^+$ analogues. Such changes were also observed in other protonic—hydridic bonded polyhydride compounds and are believed to be a characteristic feature of this phenomenon. A low-field shift in the resonance of the proton donor moiety is a characteristic feature of protonic—hydridic bonding (2, 6, 9, 25, 29, 42–45). Thus, the results in Table 2 clearly indicate that these interactions are present in the [K(1,10-diaza-18-crown-6)]$^+$ salts, the extent of which is obviously dependent on the nature of the tertiary phosphine ligands. Relative to δ NH of [K(1,10-diaza-18-crown-6)][BPh_4], Δδ NH of the polyhydride salts is in the order PPh_3 < PMe_3 < P-*i*-Pr_3, which is consistent with the trend observed for the change in the hydride chemical shift relative to the [K(18-crown-6)]$^+$ salts. The much smaller change for the PPh_3 complex may be due to shielding caused by the phenyl ring currents. The NH peak of **2a** is obscured by the peaks of the tricyclohexylphosphine protons.

Only **2c** has a resonance for the NH in the ^{1}H NMR spectrum that is free from overlap with those of the phosphine ligands. On this basis **2c** was chosen for a NOE difference experiment. Irradiation of the hydride resonance at –6.90 ppm resulted in a definite, but unquantified, NOE enhancement of the NH resonance at 1.04 ppm. Likewise, irradiation of the NH resonance resulted in enhancement of the hydride resonance. This clearly indicates the existence of dipolar interactions between the hydrides and NH moieties in solutions of this complex.

Spin lattice relaxation (T_1) is very sensitive to dipole–dipole interactions at short distances since the strength of the interaction is proportional to r^{-6}. Thus, T_1 measurements have been used to quantitatively determine the strength of protonic–hydridic interactions in neutral, cationic, and anionic protonic—hydridic bonded systems (2, 6, 9, 12, 24). Table 3 summarizes the ^1H T_1 times of the hydride and NH moieties in **1c** and **2c**, while Fig. 1 shows the plot of ln T_1 against inverse temperature for the hydride in each salt. This shows a lower hydride min T_1 in **2c** (156 ms, 500 MHz) relative to **1c** (172 ms, 500 MHz) indicating that there are small dipolar contributions from the NH moieties to the relaxation rate of the hydride nuclei. The min T_1 values are typical of classical rhenium polyhydride complexes with no short hydride–hydride distances (no dihydrogen ligands) (46). If a typical ReH···HN contact of 1.8 Å were present at all times, then we estimate that the minimum T_1 of **2c** should have been about 100 ms.[2] Therefore these protonic—hydridic-bonded ion pairs appear to be only a fraction of the total number of ion-pair structures in the toluene-d_8. However, the minimum T_1 of the hydride in **2c** occurs at a higher temperature (278 K) than in **1c**, which could be on account of the formation of intermolecular protonic—hydridic bonded aggregates of **2c** in solution. The minimum T_1 of the NH moiety of **2c** is 410 ms at 230 K, 500 MHz, which is significantly lower than the 548 ms at 189 K, 500 MHz reported for the NH in [K(diaza-18-crown-6)][$OsH_5(P\text{-}i\text{-}Pr_3)_2$] (6). This indicates that the average NH···HM distance is shorter for the rhenium compound than the osmium compound in solution. This also depends on differences in the dynamic behavior of the ion pairs.

Infrared spectra of the complexes

Changes in the IR stretching modes of both the proton donor and acceptor are characteristic of hydrogen bonding in general, including protonic—hydridic bonding. This allows the strength of this nonclassical hydrogen bond to be estimated using various empirical relationships (2, 6, 9, 43). The wavenumbers of the NH vibration modes for the series of [K(1,10-diaza-18-crown-6)]$^+$ salts in Nujol are listed in Table 2. Except for **2a**, the [K(1,10-diaza-18-crown-6)]$^+$ salts all show a decrease in the NH stretching mode relative to [K(1,10-diaza-18-crown-6)][BPh_4], in which there is no protonic–hydridic interaction. The IR spectrum of **2a** shows three ν NH bands at 3336, 3276, and 3178 cm^{-1}. This is unlike the trend observed for **2b**, **2c**, and **2d**, and may reflect the disordered structure of the ion pair detected by single crystal X-ray diffraction. The NH vibrational modes in **2b**, **2c**, and **2d** are broad singlets at 3229, 3214, and 3186 cm^{-1}, respectively, which are more intense and shifted to lower frequencies relative to those of [K(1,10-diaza-18-crown-6)][BPh_4] at 3284 and 3279 cm^{-1} (Fig. 2).

The broadening and shifting to lower frequency of the NH mode in these salts are indicative of protonic–hydridic inter-

[2] If we assume that **2c** has a structure with five hydrides with the same max relaxation rates at 500 MHz as **1c** (1/0.173 = 5.78 s^{-1}) and one hydride with an additional relaxation contribution from protonic—hydridic bonding at 1.8 Å (1/0.173 + 77.5/(1.8^2) = 29.7 s^{-1}) (46), then we calculate an averaged max relaxation rate of 5.78 × 5/6 + 29.7 × 1/6 = 9.77 s^{-1} which corresponds to a minimum T_1 of 102 ms.

actions, the strength of which are in the order PPh_3 < PMe_3 < P-*i*-Pr_3. In addition, the intensities of the N-H vibrational modes in the salts differ immensely, and are in the order PPh_3 < PMe_3 < P-*i*-Pr_3; the same order as observed for Δν NH. Interestingly, the NH vibrational mode at 3178 cm^{-1} in **2a** is lower than any of the NH modes observed for **2b**, **2c**, and **2d**, and could possibly be due to a very strong intra-ion-pair protonic–hydridic interaction in this salt. Such a low NH vibrational mode would be consistent with the very low acidity of $ReH_7(PCy_3)_2$. Thus, the basicity and steric bulk of the ancillary phosphine ligands are obviously important factors in controlling and determining the extent of protonic–hydridic interactions in these salts.

The IR spectra of the hexahydride salts have lower ν ReH wavenumbers in the PCy_3 complex (1717 cm^{-1}) than for the PPh_3 complex (1884, 1853 cm^{-1}). A lower metal–hydride stretching frequency might be expected to be indicative of weaker metal—hydride bonding. This suggests that destabilization of the rhenium—hydride bonds in the anions is possibly a strong determinant in the acidity of the neutral conjugate species.

The formation of protonic—hydridic bonding in transition-metal complexes usually results in lower wavenumber and broad M-H vibrational modes. In general, the ν Re-H bands in the [K(1,10-diaza–18-crown-6)]$^+$ salts are much broader and more intense relative to those in the respective [K(18-crown-6)]$^+$ analogues. However, the presence of several Re-H bands and the overlapping of vibrational modes prevent correlation between the strength of the protonic—hydridic bond and Δν Re-H.

Deuteration studies

Complexes **2a**, **2b**, **2c**, and **2d** undergo H–D exchange upon exposure to an atmosphere of D_2 gas in toluene-d_8 and THF-d_8 solutions, with incorporation of deuterium in the NH moieties of the cations and hydride hydrogens of the anions. This is evidenced by a reduction in the intensities of the hydride and NH chemical shifts, and the observation of HD gas in the ^{1}H NMR spectra of the complexes. The reaction was invariably slow for all of complexes, requiring months for significant reduction in the intensities of the NH and hydride chemical shifts at room temperature. This prevented accurate comparisons of rates for the deuterium exchange process. On the other hand, no H–D exchange was observed for the series of [K(18-crown-6)]$^+$ salts over a similar time period. The observation of deuterium exchange in the [K(1,10-diaza-18-crown-6)]$^+$ salts is further evidence of close intermolecular contacts between the NH moieties of the cations and hydrides of the anions in solution of these salts.

Structure of the complexes

The crystal structures of the [K(1,10-diaza-18-crown-6)][$ReH_6(PR_3)_2$] salts were determined in this work. The structure of **2a** was disordered and contained several positional occupancies of the cation that prevented proper refinement. However, the anionic moiety in the unit cell crystallizes with *cis*-PCy_3 ligands, with a P-Re-P bond angle of 146.8°, while the potassium is shifted out of the plane of the cation, and is presumably electrostatically interacting with the undetected hydrides of the anion. The distance between the potassium of the cation and rhenium of the anion is 3.7 Å, which is similar to the 3.81 and 3.77 Å observed for the two units in **2c** (see below). Further discussion of this

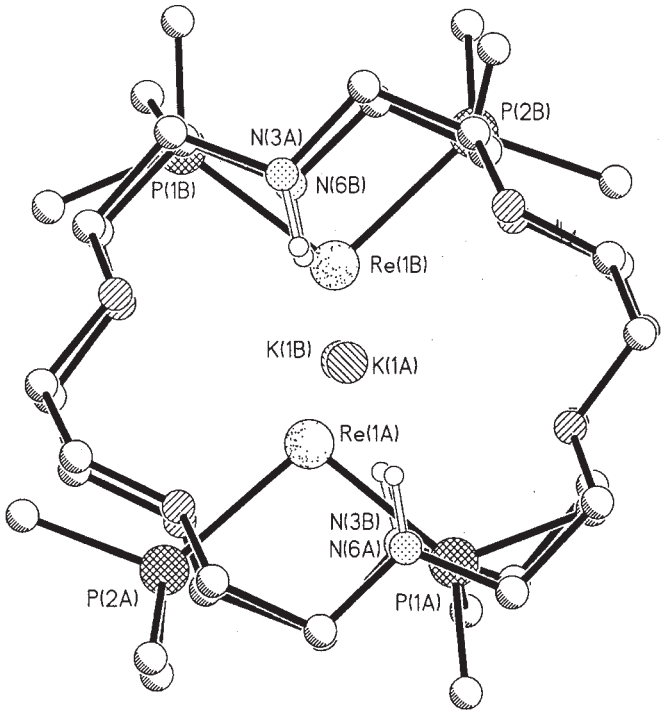
structure is not merited, on account of the extent of the disorder in the crystal structure.



The crystal structure of **2b** is shown in Fig. 3 and includes the atomic numbering of all non-hydrogen atoms. Selected bond angles and bond lengths are listed in Table 4. The salt crystallizes with a THF molecule trapped in the crystal lattice which is not interacting with either the cation or anion. The hydrides of the anion were not located. The potassium is located on an inversion center in the cation. The P-Re-P bond angle is 151.19(4)°. The average Re—P bond distance is 2.362(1) Å which is longer than that observed in the isoelectronic $[MH_x(P\text{-}i\text{-}Pr_3)_2]^-$ anions (M = Ir, 2.261 Å; Os, 2.293 Å) (25). The cations are oriented so that the NH hydrogens are directed towards the rhenium of the anions, and are apparently interacting, through protonic—hydridic bonding, with the undetected hydrides.

Fig. 8. View of the asymmetric unit of [K(1,10-diaza-18-crown-6)][$ReH_6(PMe_3)_2$] showing the cylindrical assembly.

Unlike the linear one-dimensional chain structures observed for [K(1,10-diaza-18-crown-6)][$MH_x(P\text{-}i\text{-}Pr_3)_2$] (M = Ir, Os, Ru) (6, 25), the structure of the rhenium salt consist of zigzag chains of alternating cations and anions, since the NH moieties of the cations are interacting with hydrides on the same side of the anions and opposite to the two isopropylphosphine ligands. This is more clearly illustrated in Fig. 4.

The two NH moieties are approximately directly pointing towards the rhenium atom, with N-H-Re bond angles of 165 and 175°. If a typical N—H bond length of 1.0 Å is used, then the distances of the NH hydrogens of the cations from the rhenium atoms of the anions are 3.2 and 3.5 Å. Likewise, the distances of the nitrogen atoms from the rhenium atoms are 4.19 and 4.48 Å, respectively. These distances are equal or shorter than the corresponding distances of 3.4 Å (NH···Ru) and 4.37 Å (N···Ru) in [K(1,10-diaza-18-crown-6)][$RuH_5(P\text{-}i\text{-}Pr_3)_2$] (6), which is calculated to have a proton–hydride NH···HRu distance of 1.8 Å. These results indicate that short proton–hydride distances in the range of 1.6–1.9 Å are present in complex **2b**.

The molecular structure of **2c** consists of two similar structural units, each of which is comprised of two [K(1,10-diaza-18-crown-6)][$ReH_6(PPh_3)_2$] subunits, one of which is shown in Fig. 5. Selected bond lengths and angles are listed in Table 5. The two P-Re-P bond angles in each unit are 103.2° and 106.6°. The potassium is shifted 0.6 Å out of the best plane through the O_4N_2 ring towards the anion and is electrostatically bonded to three of the hydride ligands, with K—H bond lengths ranging from 2.81 to 3.01 Å. These distances are similar to the 2.63–2.92 Å reported in the crystal structure of [$K(THF)_2$][$ReH_6(PPh_3)_2$] (33).

The NH units of the cations are directed towards the hydrides of the anions to foster the formation of nonclassical hydrogen bonds. There are two types of NH···HRe interactions in the crystal structure (Fig. 6). One of these involves an intra-ion-pair protonic—hydridic bond between one of the NH moieties of the $[K(1,10\text{-diaza-18-crown-6})]^+$ cation and a hydride of its associated anion, with an NH···HRe bond distance of 2.3 Å. The other involves an inter-ion interaction between the other NH unit of the same cation and a hydride of the adjacent anion, with a similar NH···HRe bond distance of 2.3 Å. The N-H groups of the NH···HRe bonds are directed to a point beyond the Re—H bond in a similar fashion to the NH···HIr bonds in (pyridinethione)hydridoiridium(III) complexes (4–13). The two $[K(1,10\text{-diaza-18-crown-6})]^+$ cations interacting with each anion are oriented so that the N-Re-N bond angle subtended between the two NH moieties and the rhenium is 112.1°, while the angle between the best planes of the two cations is approximately 80°. The bonding arrangements and the relative orientation of the anions and cations result in the two structural units forming a two-dimensional tetrameric {[K(1,10-diaza-18-crown-6)][$ReH_6(PPh_3)_2$]}$_4$ assembly.

The structure of **2d** consists of two similar units, shown in Fig. 7 with appropriate atomic numbering. The metrical parameters are listed in Table 6. The two trimethylphosphine ligands in the anion are *cis* to each other with a P-Re-P bond angle of 99.91°. The crystal lattice consists of extended infinite one-dimensional chains of alternating and interpenetrating anions and cations, which are held together by a

Table 7. Comparison of selected solid-state properties of the complexes [K(1,10-diaza-18-crown-6)][$ReH_6(PR_3)_2$].

Phosphine	PMe_3	PPh_3	P-*i*-Pr_3	PCy_3
Tolman's cone angle (θ)	118	145	160	170
Re-P (Å)	2.34	2.36, 2.37	2.36	2.36
P-Re-P (°)	100	106.6, 103.2	151	147
N···Re (Å)	4.02	4.19	4.19	—
N′···Re′ (Å)[a]	4.12	4.20	4.48	—
K···Re (Å)	3.86	3.81	5.33	3.7
K···Re′ (Å)[b]	3.88	6.23	5.85	8.4
IR Δν NH (cm^{-1})[c]	67	52	95	103, 5

[a]N′ refers to the other nitrogen in the diazacrown while Re′ is the closest Re to this N′.
[b]Re′ is the next closest Re to this potassium ion.
[c]Shift to lower wavenumber from the ν NH of [K(1,10-diaza-18-crown-6)]BPh_4 (3281 cm^{-1}) that is not involved in H-bonding.

combination of inter-ion protonic–hydridic, N-H···H-Re, and Re-H_x···K^+···H_xRe, interactions.

The anion is oriented so that the two phosphine ligands are directed away from the cations, with the P-Re-P plane almost perpendicular to the plane containing the two NH moieties of neighboring cations and the rhenium of the anion. The N-Re-N angle between the NH moieties of the neighboring cations and the rhenium of the anion is 74.8°. This arrangement facilitates the most unhindered approach of the NH moieties and potassium of the two neighboring cations to the undetected hydrides of the anion. The potassium atom is only slightly out of the plane of the crown ether, with a N-K-N bond angle of 177.3°. The NH hydrogens of the cation are not directly pointed at the hydrides of the anion. This may be due to a steric imposition on the structure so as to accommodate both types of interactions. There is also the possibility of the formation of bifurcated bonding modes between the proton and two or more hydrides of the anion. The distances of the NH protons of the cations from the rhenium of the anion are 3.32 and 3.34 Å, while the distances of the respective nitrogen atoms from the rhenium are 4.02 and 4.12 Å. These distances indicate much closer approaches of the NH moieties to the anion than in any other [K(1,10-diaza-18-crown-6)]$^+$ polyhydride salt. The electrostatic interaction between the potassium atom and hydrides of the anions is obviously a very significant synergistic contributor to the extended molecular chain assembly. The Re-K distances of adjoining cations are 3.87 and 4.44 Å. If typical Re-H distances of 1.65 Å are assumed, then the estimated H^-···K^+ distances are 2.22 and 2.79 Å, which are much shorter than those observed in complexes **2b** and **2c**.

An interesting feature of the molecular structure of **2d** is the observation of an extended one-dimensional cylindrical supramolecular assembly when the molecular chain assembly is viewed along its axis. This is illustrated in Fig. 8. The cylindrical stacking is such that all the potassium atoms of the [K(1,10-diaza-18-crown)]$^+$ cations are superimposed, while the rhenium atoms of the anions are arranged in an alternating fashion on either side of the potassium atoms and are superimposed. The constituent atoms of the 1,10-diaza-18-crown-6 (C, N, O) are superimposed. The two sets of trimethylphosphine ligands on either side of the cations are also superimposed. The overall structure is such that the metal atoms and hydride ligands (undetected) occupy the interior, while the organic moieties of the crown-ether and phosphine ligands line the periphery of the supramolecular cylindrical structure.

Comparison of the solid-state properties

Table 7 lists selected properties of the complexes in the order of increasing size of the ligands according to the Tolman's cone angle θ (47). The usual increase in metal—phosphorus bond length with increase in θ is observed. The small P-Re-P angles for the PMe_3 and PPh_3 complexes may result from the strong interaction of the potassium with the hydrides; in each case there are short K···Re distances. The PCy_3 complex also appears to have a short K···Re distance but it maintains a larger angle between the bulky phosphine ligands apparently by a distortion of the crown, that is not well-defined because of the disorder in the structure. The structures (the first three, at least) have the common property of containing short Re···N distances (4.0–4.5 Å) to all of the nitrogens in the crowns. Clearly ReH···HN bonding is important in all cases when judged by these distances and the reduction in ν NH from the non-hydrogen-bonded value of approximately 3281 cm^{-1}. The P-*i*-Pr_3 structure is unique in that NH···HRe bonding is more important than K···HRe bonding. This is seen in the long, uniform 5.3 and 5.85 Å spacing between the K^+ and $ReH_6(P\text{-}i\text{-}Pr_3)_2^-$ centres.

Conclusions

Reaction of $ReH_7(PR_3)_2$ with KH in the presence of 18-crown-6 and 1,10-diaza-18-crown-6 resulted in the formation of [K(crown-ether)][$ReH_6(PR_3)_2$] salts. The solid-state structures of the [K(1,10-diaza-18-crown-6)]$^+$ salts vary with the size of the ligands. The disordered salt with large PCy_3 groups appears to consist of isolated 1:1 ion pairs with a strong intra-ion-pair NH···HRe bond. In contrast the P-*i*-Pr_3 salt has evenly spaced anions and cations in a chain held together by protonic—hydridic bonds. The salt with the smaller PPh_3 groups consists of 1:1 ion pairs with K···HRe and intra-ion-pair NH···HRe bonding with additional weaker, inter-ion-pair NH···HRe bonds that result in a unique ring structure of four ion pairs. The small $ReH_6(PMe_3)_2^-$ units allow close approach of the potassium and NH groups to form

© 2001 NRC Canada

chains held together by Re-$H_x^-\cdots K^+\cdots H_x^-$-Re and NH···HRe interactions.

Intermolecular protonic—hydridic bonding is also present in solutions of these salts, as illustrated by the ^{1}H NMR variable temperature T_1 and NOE measurements of [K(1,10-diaza-18-crown-6)][$ReH_6(PPh_3)_2$]. The strength of the protonic—hydridic bonds was qualitatively examined by the change in the NH stretching frequency of the cation as a function of the ancillary phosphine ligands of the anions, and was found to be in the order $PPh_3 < PMe_3 <$ P-*i*-Pr_3. The pK_α^{THF} of the neutral conjugate acids $ReH_7(PR_3)_2$, is in the order $PPh_3 << PMe_3 <$ P-*i*-$Pr_3 < PCy_3$. Thus the strength of the protonic–hydridic interactions is clearly dependent on the basicity of the anions. Even though $[ReH_6(PCy_3)_2]^-$ represents the most basic anion, there appear to be both strong and weak protonic—hydridic bonds on the basis of ν NH in the disordered solid-state structure of its [K(1,10-diaza-18-crown-6)]$^+$ salt.

A computational approach to seeking methylmercury(II) thiolate calix[4]arene hosts for both octasulfur and organosulfur compounds as guests

Stephan Knoblauch, H. Fred Koch, Catherine Polydore, and D. Max Roundhill

Abstract: Calculations have been carried out on the conformational preferences of calix[4]arene thiols and their methylmercury(II) derivatives. Calculations have also been carried out on host–guest combinations of methylmercury(II) ethanethiolate calix[4]arenes and 1,4-dithiacyclohexane, octasulfur, thiacyclopropane, and thiophene. For the 1,4-dithiacyclohexane, thiacyclopropane, and thiophene guests, calculations have been carried out for both 1:1 and 1:4 ratios of the methylmercury(II) ethanethiolate calix[4]arene to the sulfur containing guests. For octasulfur only the 1:1 host–guest ratio has been considered because it has four sulfurs that are conformationally arranged to bind to the four mercury(II) centers. The computational results generally show that host–guest formation is enthalpically favored over the separated molecules in cases where adducts with mercury-sulfur donor atom interactions are allowed to reach energy minima.

Key words: calixarene, methylmercury, octasulfur, organosulfur compounds.

Résumé : On a effectué des calculs théoriques sur les préférences conformationnelles des calix[4]arènethiols et de leurs dérivés méthylmercure(II). On a aussi effectué des calculs sur des combinaisons hôte–invité entre les dérivés méthylmercure(II) de calix[4]arèneéthanethiolates et le 1,4-dithiacyclohexane, l'octasoufre, le thiacyclopropane et le thiophène. Dans les cas où l'invité est le 1,4-dithiacyclohexane, l'octasoufre et le thiophène, on a effectué des calculs pour des rapports 1:1 et 1:4 de dérivés méthylmercure(II) de calix[4]arèneéthanethiolates et de molécules invitées contenant du soufre. Dans le cas de l'octasoufre, on n'a considéré que les résultats du rapport 1:1 en raison du fait que cette molécule comporte quatre atomes de soufre qui sont conformationnellement arrangés pour se lier aux quatre centres mercure(II). Pour les cas où les adduits comportant des interactions entre le mercure et l'atome donneur de soufre peuvent atteindre les énergies minimales, les résultats des calculs montrent que d'une façon générale, la formation d'une paire hôte–invité est enthalpiquement favorisée par rapport aux molécules séparées.

Mots clés : calixarène, méthylmercure, octasoufre, composés organosulfurés.

[Traduit par la Rédaction]

Introduction

Calixarenes are cyclic oligomers that have cavities that can occlude guest molecules. These calixarene molecules have a wide rim with *tert*-butyl substituents, and a narrow rim with phenol groups (1). The guest molecules can be uncharged organic compounds, anions, or metal cations that bind to selective functional groups. An alternate target is to prepare metallocalixarenes that can act as selective hosts for different classes of organic molecules, especially those that can interact with the metal centers (2). Although there are examples of metallacages that can act as hosts, there are few examples of such hosts being constructed from calixarenes (3–11).

One approach is to target metallocalixarenes with metals on either rim as selective hosts for elemental sulfur, organosulfur, or organonitrogen compounds. The discovery of hosts for these compounds is important because environmental concerns place ever more stringent requirements on removing sulfur, organosulfur compounds, and organonitrogen compounds from hydrocarbon mixtures. To remove trace quantities of these compounds from pure hydrocarbons, one approach is to use a host that will selectively bind them. One strategy therefore is to use size and shape selectivity to achieve this goal, but another is to use the coordination properties of the metals in the metallocages to bind the sulfur atoms in the targeted guest molecules. Since mercury(II) forms stable complexes with sulfur donor ligands, we have computationally targeted methylmercuric thiolate calix[4]arenes as hosts for sulfur and organosulfur compounds.

Results

Calculations were carried out on a DEC α computer system (433 MHz) using the SPARTAN Version 5.0.2 software

package. This package was chosen because it has the algorithms available for metals such as mercury. All calculations were carried out using PM3 geometry optimization. All reasonable conformations were computationally searched before the one with the minimum energy was chosen. The enthalpies for the systems that we have investigated are collected in Tables 1–7. These chosen systems are the conformational preferences for the 2-ethanethiol narrow rim substituted calix[4]arene (10) and its methylmercury(II) de-

rivative. Other systems on which calculations have been carried out combine this methylmercury(II) calix[4]arene with 1,4-dithiahexane, octasulfur, thiacyclopropane, and thiophene. Pairwise calculations have been made for both the bound and unbound combinations among these compounds, and calculations have been carried out with both one and four organosulfur compounds associated with the methylmercury(II)-substituted calix[4]arene through mercury(II)–sulfur donor atom interactions. Conformational calculations have also been carried out on the simple calix[4]arene thiol (12) and its hypothetical methylmercury(II) derivative, along with the octasulfur adduct of the methylmercury(II) derivative. For comparison, calculations have also been carried out on the hypothetical derivatives having the thiol or methylmercury functionalities on the wide rim, and also on a host–guest octasulfur compound with this wide rim functionalized methylmercury(II)-

substituted calix[4]arene. In each calculation the energy min is sought for each compound investigated. Nevertheless, we recognize that in molecules of this size and complexity with heavy metals present there are many conformational types possible, so we only consider large differences in energy as being significant, and we have made no attempt to rationalize small energy differences as we have sought the lowest energy conformation.

The results in Table 1 summarize the computational energies found for the cone (*u*, *u*, *u*, *u*), partial cone (*u*, *u*, *u*, *d*), 1,3-alternate (*u*, *d*, *u*, *d*), and 1,2-alternate (*u*, *u*, *d*, *d*) of the 2-ethanethiol-substituted calix[4]arenes. The computations on this particular molecule in some respects have been carried out as an evaluation of our method. As expected the calculations show that there are only small energy differences between the four different conformers. The highest energy is found for the partial cone conformation (–104 kcal mol^{-1}), with the other three conformers being very closely spaced in energy (–129 to –138 kcal mol^{-1}). This is not an unreasonable finding. The results in Table 2 are again conformational energies, but this time for the methylmercury(II) ethanethiolate-substituted calix[4]arene. Again computational energy differences are observed, but now the difference in energies between the conformers are considerably larger, ranging from –30 to –159 kcal mol^{-1}. These larger conformational energy values likely result from the steric interactions being greater

for compounds with methylmercury groups than for hydrogens on sulfur, and also because there are many more electrons in the methylmercury(II) groups than hydrogen that will be affected by these interactions. These computational results suggest that the cone conformation (–159 kcal mol^{-1}) will be the most favored conformation, and that the 1,3-alternate will be the least favored. Because we find the cone conformation to be the most computationally favored, it is this conformer that we have used to compute the energies of the adducts with sulfur and organosulfur guests.

In computing the energies of the different host–guest combinations we have in each case made two sets of calculations. In the first case we calculate the energy of the system when the host and guest(s) are placed sufficiently far apart that there are no interactions between the two molecules. In the second case the host–guest molecules are initially placed sufficiently close that intermolecular attractions between mercury(II) and sulfur donor atoms can occur. During minimization the host–guest combination remain within their van der Waals radii. In each case we have carried out a sufficient number of iterations (usually of the order of 200–300) that minimization occurs. This strategy of carrying out pairwise calculations is employed because each computational pair involves systems that are isoelectronic with each other, and therefore direct comparisons can be made between the two systems. In Table 3 the computational data for the separated host–guest pairs are collected for the methylmercury(II) ethanethiolate calix[4]arene and a single 1,4-dithiacyclohexane, octasulfur, thiacyclopropane, or thiophene molecule, and in Table 4 the data are the results for the systems where these host–guest combinations interact. Since we anticipate that the largest interactions within these pairs will be between the mercury centers on the host and the electron pairs on sulfur on the guest, these are the configurations that we have allowed to minimize. For the energy differences between the separated and combined host–guest configurations we obtain the following values in kcal mol^{-1}, where a negative value corresponds to a lowering in energy upon host–guest adduct formation: 1,4-dithiacyclohexane (–49), octasulfur (–125), thiacyclopropane (–66), and thiophene (+3). The large decrease in energy resulting from interaction of the sulfur atoms of octasulfur with the four mercury(II) centers in the methylmercury(II) ethanethiolate calix[4]arene indicates that there is a very favorable host–guest interaction between the two. This favorability is a consequence of their being four mercury(II)–octasulfur interactions in the molecule, and that the octasulfur can maintain its preferred chair conformation in the bound host–guest system. The energy lowering upon forming a host–guest complex with either 1,4-dithiacyclohexane or thiocyclopropane is significantly smaller. In each case there are fewer mercury(II)–sulfur interactions than there are with octasulfur. The greater lowering in enthalpy for thiacyclopropane (–66) than for 1,4-dithiacyclohexane (–49) is interesting, especially since the latter has two mercury(II)–sulfur interactions. A possible explanation for this result is that the advantage of the additional mercury–sulfur interaction is counteracted by the raising of the conformational energy of the guest, since in the host–guest complex the 1,4-dithiacyclohexane is present in the boat conformer rather than in the energetically favored chair.

The simple calix[4]arene thiol with SH rather than OH groups on the narrow rim has been reported in the literature (13), and a series of host–guest molecules are also potentially available from this precursor. We have therefore computationally investigated the methylmercury(II) derivative of this precursor, along with its host–guest complex with octasulfur. The results of these calculations are collected in Table 5. Again we find that the host–guest complex has a lower energy than does the separated pair, with the energy lowering being 88 kcal mol^{-1}. This change is smaller than is observed with the previous system, which has an oxygen and the two additional methylene groups of the ethanethiolate moiety on the narrow rim. This reduced lowering of enthalpy upon host–guest formation with the shorter chain

© 2001 NRC Canada

system may be a consequence of this system having the mercury(II) centers closer to the calix[4]arene template, and therefore having less conformational flexibility to adapt to the steric requirements of the octasulfur guest molecule.

A further set of calculations have been carried out for thiacyclopropane and thiophene as a guest. In these calculations each methylmercury(II) host is associated with a single sulfur atom, which leads to a host:guest ratio of 1:4. Again, computational comparisons are made between the separated and complexed analogs (Table 6). For thiacyclopropane, the enthalpy decrease upon complexation of four molecules is 35 kcal mol^{-1}, and for four thiophene molecules the corresponding enthalpy decrease is 102 kcal mol^{-1}. Interestingly, the binding of four thiophenes results in a decrease in the enthalpy of the system, whereas the binding of a single thiophene results in a small enthalpy increase. Inspection of the two enthalpy minimized structures indicates that in the one with four bound thiophenes, the thiophene molecules are somewhat oriented in toward the calix[4]arene structure, possibly indicative of weak π-interactions between them. There is no indication of any π,π-interactions between the thiophene molecules themselves. A final set of calculations have been carried out on another hypothetical methylmercury(II) host. This host is similar to that shown in Tables 2–4, except that now these functionalities are present on the wide rim rather than on the narrow rim. These data are collected in Table 7. The host–guest combination with octasulfur show a decrease in enthalpy of 279 kcal mol^{-1} from the separated pair. Since this decrease is larger than is observed upon host–guest formation with the narrow rim substituted derivative (125 kcal mol^{-1}), it is suggestive that the wide-rim-substituted methylmercury(II) host may be a better one for an octasulfur guest than the narrow rim analog.

We suggest that this computational approach may have some validity in seeking hosts for octasulfur and organosulfur guests. We recognize that this approach has many limitations, and that the unfavorable entropic contribution will reduce the favorability of these host–guest adduct associations, and may even be sufficient to cause the free energies of host–guest formation to be positive. Clearly, experimental data will be required before approaches such as this one can be fully judged and evaluated.

Synthesis, spectroscopic characterization, and structural studies of new Cu(I) and Cu(II) complexes containing organophosphorus ligands, and crystal structures of $(Ph_3P)_2Cu[S_2PMe_2]$, $(Ph_3P)_2Cu[(OPPh_2)_2N]$, $Cu[(OPPh_2)_2N]_2$, and $Cu[(OPPh_2)(SPPh_2)N]_2$

Anca Silvestru, Adina Rotar, John E. Drake, Michael B. Hursthouse, Mark E. Light, Sorin I. Farcas, Roland Rösler, and Cristian Silvestru

Abstract: The Cu(I) complexes, $(Ph_3P)_2CuL$ (L = $[S_2PMe_2]^-$, $[OSPR_2]^-$ (R = Me, Ph), $[(XPR_2)(YPR'_2)N]^-$ (X, Y, R, R′ = O, O, Ph, Ph; O, S, Ph, Ph; O, S, OEt, Ph; S, S, Me, Me)) and Cu(II) complexes, CuL_2 (L = $[(XPR_2)(YPR'_2)N]^-$ (X, Y, R, R′ = O, O, Ph, Ph; O, S, Ph, Ph)), have been prepared. The Cu(I) derivatives were characterized by multinuclear NMR spectroscopy and in two cases by X-ray crystallography. $(Ph_3P)_2Cu[S_2PMe_2]$ (**1**) crystallizes in the orthorhombic space group $P2_12_12_1$ (No. 19) with cell parameters a = 9.782(2), b = 17.808(4), c = 20.216(4) Å, V = 3521(6) Å^3 and Z = 4, and $(Ph_3P)_2Cu[(OPPh_2)_2N]$ (**4**) in the triclinic space group $P\bar{1}$ (No. 2) with cell parameters a = 9.8079(2), b = 12.9141(3), c = 22.5666(5) Å, α = 75.714(2), β = 79.465(2), γ = 68.2770(8)°, V = 2559.9(1) Å^3 and Z = 2. In both cases the phosphorus ligands are bidentate, thus resulting in monomeric molecules that contain tetrahedral CuP_2S_2 and CuP_2O_2 cores. The molecular structures of two of the Cu(II) derivatives were also determined. $Cu[(OPPh_2)_2N]_2$ (**8**) and $Cu[(OPPh_2)(SPPh_2)N]_2$ (**9**) crystallize in the triclinic space group $P\bar{1}$ (No. 2) with cell parameters a = 8.887(2), b = 10.739(2), c = 12.477(3) Å, α = 77.61(3), β = 76.15(5), γ = 79.46(3)°, V = 1118.3(4) Å^3 and Z = 1 for **8**, and a = 9.626(2), b = 14.151(3), c = 24.752(5) Å, α = 88.23(3), β = 79.93(3), γ = 89.77(3)°, V = 3181(1) Å^3 and Z = 3 for **9**. The molecule of $Cu[(OPPh_2)_2N]_2$ (**8**) has a planar CuO_4 core, while in $Cu[(OPPh_2)(SPPh_2)N]_2$ (**9**) both planar and tetrahedral copper cores are observed in a ratio of 1:2.

Key words: structure, copper, thiophosphinates, oxo- and thio-imidodiphosphinates.

Résumé : On a préparé les complexes suivants du Cu(I), $(Ph_3P)_2CuL$ (L = $[S_2PMe_2]^-$, $[OSPR_2]^-$ (R = Me, Ph), $[(XPR_2)(YPR'_2)N]^-$ (X, Y, R, R′ = O, O, Ph, Ph; O, S, Ph, Ph; O, S, OEt, Ph; S, S, Me, Me)) et du Cu(II), CuL_2 (L = $[(XPR_2)(YPR'_2)N]^-$ (X, Y, R, R′ = O, O, Ph, Ph; O, S, Ph, Ph)). On a caractérisé les dérivés du Cu(I) par spectroscopie RMN multinucléaire et, dans deux cas, par diffraction des rayons X. Les cristaux de $(Ph_3P)_2Cu[S_2PMe_2]$ (**1**) sont orthorhombiques, groupe d'espace $P2_12_12_1$ (No. 19) avec a = 9,782(2), b = 17,808(4) et c = 20,216(4) Å, V = 3521(6) Å^3 et Z = 4; ceux du $(Ph_3P)_3Cu[OPPh_2)_2N]$ (**4**) sont tricliniques, groupe d'espace $P\bar{1}$ (No. 2) avec a = 9,08079(2), b = 12,9141(3) et c = 22,5666(5) Å, α = 75,714(2), β = 79,465(2) et γ = 68,2770(8)°, V = 2559,9(1) Å^3 et Z = 2. Dans les deux cas, les ligands phosphorés sont bidentates ce qui conduit à des molécules monomères qui comportent des unités centrales CP_2S_2 et CP_2O_2 tétraédriques. On a aussi déterminé les structures moléculaires de deux des dérivés du Cu(II). Les cristaux de $Cu[(OPPh_2)_2N]_2$ (**8**) et de $Cu[(OPPh_2)(SPPh_2)N]_2$ (**9**) sont tous les deux tricliniques, groupe d'espace $P\bar{1}$ (No. 2) avec a = 8,887(2), b = 10,739(3) et c = 12,477(3) Å, α = 77,61(3), β = 76,15(5) et γ = 79,46(3)°, V = 1118,3(1) Å^3 et Z = 1, pour le composé **8**, et avec a = 9,626(2), b = 14,151(3) et c = 24,752(5) Å, α = 88,23(3), β = 79,93(3) et γ = 89,77(3)°, V = 3181(1) Å^3 et Z = 3, pour le composé **9**. La molécule de $Cu[(OPPh_2)_2N]_2$ (**8**) comporte une unité centrale de CuO_4 qui est plane alors que dans la molécule de $Cu[(OPPh_2)(SPPh_2)N]_2$ (**9**), on observe la

[Traduit par la Rédaction]

Introduction

Relatively few copper complexes containing both neutral donors and *O*,*O*′-diorganodithiophosphato ligands have been structurally characterized (1, 2). For Cu(I) derivatives, the presence of the P-neutral ligand affords tetrahedral mononuclear $(Ph_3P)_2Cu[S_2P(OR)_2]$ (R = Et (3), $(OR)_2$ = $(OCH_2)_2CMe_2$ (4)) or dinuclear $[(Ph_3P)Cu\{S_2P(OEt)_2\}]_2$ (5) complexes. Polynuclear phosphine adducts of Cu(I) thiolates have also been reported (6, 7). Recent studies on neutral Cu(I) thiocarboxylates with triphenylphosphine demonstrate that complexes of different stoichiometry and structure can be obtained with small changes in the thio ligand. Thus, for example, using 1:1:1 stoichiometric ratios of CuCl:Na[S(O)CR]:PPh_3, the thioacetate anion gave the tetramer $[Cu\{S(O)CMe\}(PPh_3)]_4$, while for R = Ph a 4:4:3 complex $[Cu_4\{S(O)CPh\}_4(PPh_3)_3]$ was isolated. Attempts to prepare a 4:4:3 derivative for R = Me failed; only the tetrameric complex being isolated. Thioacetate and thiobenzoate ligands both gave products of 1:1:2 stoichiometry, but for R = Me the complex was a dimer $[Cu\{S(O)CMe\}(PPh_3)_2]_2$, whereas for R = Ph it was a monomer (8). In the absence of a neutral ligand, a polynuclear Cu(I) cluster complex, $[Cu\{S_2P(O\text{-}i\text{-}Pr)_2\}]_4$, has been isolated (9). On the other hand, the use of $[(XPR_2)_2N]^-$ (X = S, Se) ligands, which are characterized by flexible XPNPX skeletons and a larger X···X bite, resulted in the displacement of a coordinated triphenylphosphine, leading to trigonal, mononuclear Cu(I) complexes, $(Ph_3P)Cu[(XPR_2)_2N]$ (R = Ph, X = S (10), Se (11)). Reaction of Cu(II) salts with dithio ligands of the type $(SPR_2)(SPR'_2)NH$ resulted in polynuclear Cu(I) complexes such as trinuclear $[Cu\{(XPR_2)(YPR'_2)N\}]_3$ (R, R′ = *i*-Pr, *i*-Pr; *i*-Pr, Ph; *i*-Pr, OPh; OEt, OPh (12)) or tetranuclear $[Cu^I_4\{(SPPh_2)_2N\}_3][Cu^ICl_2]$ (R, R′ = Ph, Ph (13, 14)). By contrast, with *O*,*S*- and *O*,*O*-phosphorus ligands of the type $[OSPR_2]^-$ and $[(OPR_2)(YPR'_2)N]^-$, no Cu(I) complexes have been reported to date, and only one Cu(II) complex $Cu[\{OP(OPh)_2\}_2N]_2$ (15) has been reported. Therefore, we decided to examine the differences that result in copper complexes using related ligands when the organic groups and (or) the chalcogens attached to the phosphorus atoms are changed.

We report on the synthesis and spectroscopic characterization of new $(Ph_3P)_2CuL$ and CuL_2 complexes of anionic phosphorus ligands, as well as the crystal and molecular structures of two Cu(I) derivatives, $(Ph_3P)_2Cu[S_2PMe_2]$ and $(Ph_3P)_2Cu[(OPPh_2)_2N]$, along with two Cu(II) derivatives, $Cu[(OPPh_2)_2N]_2$ and $Cu[(OPPh_2)(SPPh_2)N]_2$.

Experimental

Materials

Starting materials were prepared according to published methods: $NaS_2PMe_2\cdot 2H_2O$ (16), $NaOSPMe_2\cdot 1.5H_2O$ (17), NH_4OSPPh_2 (18, 19), $Na[(OPPh_2)_2N]$ (20), $K[(OPPh_2)(SPPh_2)N]$ (21), $K[\{OP(OEt)_2\}(SPPh_2)N]$ (22), and $K[(SPMe_2)_2N]$ (23). All solvents were dried and distilled prior to use.

Physical measurements

The ^1H, ^{13}C, and ^{31}P NMR spectra were recorded on a Varian Gemini 300S instrument operating at 299.5, 75.4, and 121.4 MHz, respectively, using solutions in dried $CDCl_3$. The ^1H and ^{13}C and ^{31}P chemical shifts are reported in ppm relative to TMS and external H_3PO_4 85%, respectively. Electron spin resonance (ESR) measurements were performed at room temperature on a Radiopan SE/X-2543 9GHz ESR spectrometer, using a 100 kHz field modulation.

Preparation of $(Ph_3P)_2CuL$ compounds (1–7)

Typically, stoichiometric amounts of $(PPh_3)_2CuNO_3$ (0.54 g, 0.83 mmol) and $NaS_2PMe_2\cdot 2H_2O$ (0.15 g, 0.81 mmol) were placed in a round-bottom flask and solvent (CH_2Cl_2, ca. 20 mL) was added. The reaction mixture was stirred for 2 h at room temperature, followed by filtration to remove $NaNO_3$. Concentration under vacuum gave $(Ph_3P)_2Cu[S_2PMe_2]$ (**1**), as a colorless solid. Recrystallization from a CH_2Cl_2–*n*-hexane mixture gave crystals suitable for X-ray diffraction studies, yield 70% (0.35 g), mp 185–187°C. ^1H NMR δ: 1.77 (d, $^2J_{P,H}$ = 12.8 Hz, 6H, P-CH_3), 7.24 (t, $^3J_{H,H}$ = 7.2 Hz, 12H, P(C_6H_5)$_3$-*meta*), 7.34 (t, $^3J_{H,H}$ = 7.1 Hz, 6H, P(C_6H_5)$_3$-*para*), 7.45 (dd, $^3J_{H,H}$ = 8.5, $^3J_{P,H}$ = 9.2 Hz, 12H, P(C_6H_5)$_3$-*ortho*). ^{13}C NMR δ: 31.84 (d, $^1J_{P,C}$ = 48.2 Hz, P-*C*H_3), 128.40 (d, $^2J_{P,C}$ = 8.7 Hz, P(C_6H_5)$_3$-*ortho*), 129.44 (P(C_6H_5)$_3$-*para*), 134.11 (d, $^3J_{P,C}$ = 14.6 Hz P(C_6H_5)$_3$-*meta*). ^{31}P NMR δ: –4.1 (2P, *P*Ph_3), 60.7 (1P, *P*Me_2).

In the same fashion the following compounds were prepared:

$(Ph_3P)_2Cu[OSPMe_2]$ (**2**)*:* from $(PPh_3)_2CuNO_3$ (0.46 g, 0.70 mmol) and $NaOSPMe_2\cdot 1.5H_2O$ (0.11 g, 0.69 mmol) Recrystallization gave colorless crystals, yield 88% (0.44 g), mp 143–145°C. ^1H NMR δ: 1.54 (d, $^2J_{P,H}$ = 12.7 Hz, 6H, P-CH_3); 7.32 (m, 30H, P(C_6H_5)$_3$). ^{31}P NMR δ: –2.7 (2P, *P*Ph_3), 64.1 (1P, *P*Me_2).

$(Ph_3P)_2Cu[OSPPh_2]$ (**3**)*:* from $(PPh_3)_2CuNO_3$ (0.47 g, 0.72 mmol) and NH_4OSPPh_2 (0.18 g, 0.71 mmol). Recrystallization gave colorless crystals, yield 98% (0.49 g), mp 148–151°C. ^1H NMR δ: 7.22 (m, 36H, P(C_6H_5)$_3$, P-C_6H_5-*meta* + *para*), 7.75 (dd, $^3J_{H,H}$ = 6.9, $^3J_{P,H}$ = 12.6 Hz, 4H, P-C_6H_5-*ortho*). ^{13}C NMR δ: 127.60 (d, $^3J_{P,C}$ = 12.8 Hz, P-C_6H_5-meta), 128.45 (d, $^2J_{P,C}$ = 8.5 Hz, P(C_6H_5)$_3$-*ortho*), 129.60 (P(C_6H_5)$_3$-*para*, P-C_6H_5-*para*), 130.80 (d, $^2J_{P,C}$ = 9.9 Hz, P-C_6H_5-*ortho*), 134.00 (d, $^3J_{P,C}$ = 13.8 Hz, P(C_6H_5)$_3$-*meta*). ^{31}P NMR δ: –3.8 (2P, *P*Ph_3), 55.3 (1P, *P*Ph_2).

$(Ph_3P)_2Cu[(OPPh_2)_2N]$ (**4**)*:* from $(PPh_3)_2CuNO_3$ (0.38 g, 0.58 mmol) and $Na[(OPPh_2)_2N]$ (0.26 g, 0.59 mmol). Recrystallization gave colorless crystals, yield 84% (0.42 g), mp 168–170°C. ^1H NMR δ: 7.15 (m, 42H,

P(C_6H_5)$_3$, P-C_6H_5-meta + *para*), 7.68 (dd, $^3J_{H,H}$ = 7.4, $^3J_{P,H}$ = 11.1 Hz, 8H, P-C_6H_5-*ortho*). ^{13}C NMR δ: 127.43 (d, $^3J_{P,C}$ = 12.8 Hz, P-C_6H_5-meta), 128.17 (P(C_6H_5)$_3$-*ortho*), 129.10 (P(C_6H_5)$_3$-*para*), 129.28 (P-C_6H_5-*para*), 131.36 (d, $^2J_{P,C}$ = 9.2 Hz, P-C_6H_5-*ortho*), 134.13 (d, $^3J_{P,C}$ = 7.8 Hz, P(C_6H_5)$_3$-meta). ^{31}P NMR δ: –6.5 (2P, *P*Ph$_3$), 18.9 (2P, *P*Ph$_2$).

*(Ph$_3$P)$_2$Cu[(OPPh$_2$)(SPPh$_2$)N] (***5***):* from (PPh$_3$)$_2$CuNO$_3$ (0.34 g, 0.52 mmol) and K[(OPPh$_2$)(SPPh$_2$)N] (0.24 g, 0.50 mmol). Recrystallization gave colorless crystals, yield 94% (0.47 g), mp 170°C. ^{1}H NMR δ: 7.22 (m, 42H, P(C_6H_5)$_3$, P-C_6H_5-*meta* + *para*), 7.59 (ddd, $^3J_{H,H}$ = 7.0, $^4J_{H,H}$ = 1.1, $^3J_{P,H}$ = 12.1 Hz, 4H, P(O)-C_6H_5-*ortho*), 7.85 (ddd, $^3J_{H,H}$ = 7.5, $^4J_{H,H}$ = 1.4, $^3J_{P,H}$ = 13.5 Hz, 4H, P(S)-C_6H_5-*ortho*). ^{13}C NMR δ: 127.46 (d, $^3J_{P,C}$ = 11.4 Hz, P-C_6H_5-*meta*), 127.61 (d, $^3J_{P,C}$ = 10.9 Hz, P-C_6H_5-*meta*), 128.21 (d, $^2J_{P,C}$ = 8.0 Hz, P(C_6H_5)$_3$-*ortho*), 129.04 (P(C_6H_5)$_3$-*para*), 129.43 (P-C_6H_5-*para*), 129.54 (P-C_6H_5-*para*), 130.93 (d, $^2J_{P,C}$ = 10.3 Hz, P(O)-C_6H_5-*ortho*), 131.26 (d, $^2J_{P,C}$ = 9.1 Hz, P(S)-C_6H_5-*ortho*), 134.12 (d, $^3J_{P,C}$ = 15.2 Hz, P(C_6H_5)$_3$-*meta*). ^{31}P NMR δ: –5.7 (2P, *P*Ph$_3$), 18.1 (1P, *P*(O)Ph$_2$), 30.0 (1P, *P*(S)Ph$_2$).

*(Ph$_3$P)$_2$Cu-[{OP(OEt)$_2$}(SPPh$_2$)N] (***6***):* from (PPh$_3$)$_2$CuNO$_3$ (0.46 g, 0.71 mmol) and K[{OP(OEt)$_2$}(SPPh$_2$)N] (0.29 g, 0.71 mmol). Recrystallization gave colorless crystals, yield 92% (0.46 g), mp 160°C. ^{1}H NMR δ: 1.01 (t, $^3J_{H,H}$ = 6.9 Hz, 6H, P-O-CH$_2$C*H*$_3$), 3.67 (dq, $^3J_{H,H}$ = 6.9, $^3J_{P,H}$ = 7.1 Hz, 4H, P-O-C*H*$_2$CH$_3$), 7.24 (m, 36H, P(C_6H_5)$_3$, P-C_6H_5-*meta* + *para*), 7.90 (dd, $^3J_{H,H}$ = 7.4, $^3J_{P,H}$ = 13.4 Hz, 4H, P-C_6H_5-*ortho*). ^{31}P NMR δ: –5.2 (2P, *P*Ph$_3$), 4.4 (1P, *P*(OEt)$_2$), 34.2 (1P, *P*Ph$_2$).

*(Ph$_3$P)$_2$Cu[(SPMe$_2$)$_2$N] (***7***):* from (PPh$_3$)$_2$CuNO$_3$ (0.41 g, 0.63 mmol) and K[(SPMe$_2$)$_2$N] (0.15 g, 0.62 mmol). Recrystallization gave colorless crystals, yield 80% (0.40 g), mp 149–152°C. ^{1}H NMR δ: 1.81 (d, $^2J_{P,H}$ = 12.0 Hz, 12H, P-C*H*$_3$), 7.35 (m, 30H, P(C_6H_5)$_3$). ^{31}P NMR δ: –2.9 (2P, *P*Ph$_3$), 40.0 (2P, *P*Me$_2$).

Preparation of Cu[(OPPh$_2$)$_2$N]$_2$ (8)

Stoichiometric amounts of $CuCl_2 \cdot 2H_2O$ (0.095 g, 0.56 mmol) and K[(OPPh$_2$)$_2$N] (0.51 g, 1.12 mmol) were placed in a round-bottom flask and solvent (MeOH, ca. 20 mL) was added. The reaction mixture was stirred for 12 h at room temperature and the solvent was removed to dryness under vacuum. The blue-greenish residual solid was extracted twice with CH_2Cl_2 (ca. 20 mL) to remove KCl and unreacted starting materials. Concentration of the blue solution under vacuum then gave Cu[(OPPh$_2$)$_2$N]$_2$ (**8**) as a blue solid. Recrystallization from a CH_2Cl_2–*n*-hexane mixture gave crystals suitable for X-ray diffraction studies, yield 72% (0.36 g), mp 273 to 274°C. ESR (X band): $g_\perp$ = 2.017 ± 0.004, $g_\parallel$ = 2.086 ± 0.004, A = 140 ± 10 Gs, B = 30 ± 10 Gs.

Preparation of Cu[(OPPh$_2$)(SPPh$_2$)N]$_2$ (9)

Stoichiometric amounts of $CuCl_2 \cdot 2H_2O$ (0.092 g, 0.54 mmol) and K[(OPPh$_2$)(SPPh$_2$)N] (0.5 g, 1.06 mmol) were placed in a round-bottom flask and CH_2Cl_2 (20 mL) was added. The reaction mixture, which immediately turned brown, was stirred for 6 h at room temperature before KCl was filtered off to leave a brown solution. Concentration under vacuum gave Cu[(OPPh$_2$)(SPPh$_2$)N]$_2$ (**9**) as a dark brown solid. Recrystallization from a CH_2Cl_2–*n*-hexane mixture gave crystals suitable for X-ray diffraction studies, yield 66% (0.33 g), mp 90–91°C. ^{31}P NMR δ: 21.5 (1P), 23.5 (1P, *P*(O)Ph$_2$, *P*(S)Ph$_2$).

X-ray crystallographic analysis

Colourless, block crystals of (Ph$_3$P)$_2$Cu[S$_2$PMe$_2$] (**1**) and (Ph$_3$P)$_2$Cu[(OPPh$_2$)$_2$N] (**4**), a blue block crystal of Cu[(OPPh$_2$)$_2$N]$_2$ (**8**), and a dark brown block crystal of Cu[(OPPh$_2$)(SPPh$_2$)N]$_2$ (**9**) were mounted on glass fibres. Data for **1**, **4**, and **8** were collected on an Enraf Nonius KappaCCD area detector (ϕ scans and ω scans to fill Ewald sphere) at the University of Southampton EPSRC National Crystallography Service. For **9**, data collection and processing was carried out by G. Yapp, then at the University of Windsor, using a Siemens SMART/CCD system. Cell refinement (24) gave cell constants corresponding to orthorhombic (for **1**) and triclinic (for **4**, **8**, and **9**) cells whose dimensions are given in Table 1, along with other experimental parameters. An absorption correction was applied (25), which resulted in transmission factors ranging from 0.870 to 0.825 for **1**, 0.943 to 0.842 for **4**, 0.937 to 0.773 for **8**, and 0.927 to 0.861 for **9**.

The structures were solved by direct methods (26). All of the nonhydrogen atoms were treated anisotropically. Hydrogen atoms were included in idealized positions with isotropic thermal parameters set at 1.2 times that of the carbon atom to which they were attached. The data for **1** and **4** were of much better quality than that for **8**, and the positions of the higher residual peaks in the latter made no chemical sense. The final cycle of full-matrix least-squares refinement (27) was based on 8027 (**1**), 10601 (**4**), 3925 (**8**), and 9164 (**9**) observed reflections (4949 (**1**), 6343 (**4**), 3289 (**8**), and 7548 (**9**) for $F^2 > 4\sigma(F^2)$) and 399 (**1**), 613 (**4**), 269 (**8**), and 799 (**9**) variable parameters and converged (largest parameter shift was 0.001 times its esd). The absolute configuration parameter for **1** was –0.017(12). Selected distances and bond angles are given in Tables 2–5 and the molecules are displayed in the ORTEP diagrams in Figs. 1–4.[2]

Results and discussion

The preparation of the Cu(I) complexes ((Ph$_3$P)$_2$CuL) is achieved by the reaction of stoichiometric amounts of

[2] Supplementary material including the final atomic coordinates and equivalent isotropic thermal parameters for the nonhydrogen atoms, anisotropic thermal parameters for the nonhydrogen atoms, final fractional coordinates and thermal parameters for hydrogen atoms, and all bond distances and angles, have been deposited and may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, ON, Canada, K1A 0S2 (http://www.nrc.ca/cisti/irm/unpub_e.shtml). Tables of atomic coordinates for the structures reported in this paper have also been deposited with the Cambridge Crystallographic Data Centre. Copies of the data can be obtained, free of charge, on application to the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, U.K. (fax: 44-1223-336033 or e-mail:deposit@ccdc.cam.ac.uk). Structure factor amplitudes are no longer being deposited and may be obtained directly from the author.

$(Ph_3P)_2CuNO_3$ with the ammonium or alkali salt of the appropriate organophosphorus acid in CH_2Cl_2 as solvent, in accord with rxn. [1]

$$[1] \quad (Ph_3P)_2CuNO_3 + ML \rightarrow (Ph_3P)_2CuL + MNO_3$$

where L = (S_2PMe_2) (**1**), $(OSPR_2)$ (R = Me (**2**), Ph (**3**)), $[(XPR_2)(YPR'_2)N]$ (X, Y, R, R′ = O, O, Ph, Ph (**4**), O, S, Ph, Ph (**5**), O, S, OEt, Ph (**6**), S, S, Me, Me (**7**)).

All of the compounds are isolated in good yields as crystalline colorless solids and X-ray quality crystals are obtained for **1** and **4**. In previous reports, the use of $[(XPR_2)_2N]^-$ (X = S, Se) ligands was found to result in displacement of a coordinated triphenylphosphine and isolation of trigonal $(Ph_3P)Cu[(XPR_2)_2N]$ (R = Ph, X = S (10), Se (11)). By contrast, for all reactions (eq. [1]) investigated in this work, the isolated products are found to preserve two neutral phosphine ligands coordinated to the metal atom, even though similar reaction conditions were used. This suggests that changes in the organic groups and (or) chalcogens on phosphorus can influence the stoichiometry of the isolated Cu(I) adducts.

The $(Ph_3P)_2CuL$ derivatives are readily dissolved in chloroform, which is therefore used as the preferred solvent for recording NMR spectra. In all cases, both ^1H and ^{31}P NMR data are consistent with a 2:1 molar ratio between the neutral and anionic ligands. For $(Ph_3P)_2Cu[OSPR_2]$ (R = Me, Ph) derivatives, the magnitude of the ^{31}P chemical shifts is indicative of an *O*,*S*-bidentate coordination of the monothio ligand moieties δ: R = Me, 64.1 (PMe_2) (cf. $Me_2P(S)OMe$ 94.3 (28), $Me_2P(O)SMe$ 45.9 (29)), R = Ph 55.3 (PPh_2) (cf. $Ph_2P(S)OMe$ 83.5 (29), $Ph_2P(O)SMe$ 42.8 (29)). The ^{31}P chemical shifts assigned for the phosphorus atoms of the anionic ligand in the spectra of the Cu(I) imidodiphosphinato complexes $(Ph_3P)_2Cu[(XPR_2)(YPR'_2)N]$, are also consistent with a chelated ligand. This behavior suggests that tetrahe-

Note: Symmetry equivalent position (*–x, –y, –z)* given by a prime.

dral structures similar to that established in the solid state for $(Ph_3P)_2Cu[S_2PMe_2]$ (**1**) and $(Ph_3P)_2Cu[(OPPh_2)_2N]$ (**4**) (see below), are preserved in solution. However, a recent report (8) demonstrates that the nature of the anionic ligand may result in significant structural modifications so that, in the solid state, $(Ph_3P)_2Cu[S(O)CPh]$ is mononuclear with only a weak intramolecular Cu···O interaction (2.439(2) Å), while $[(Ph_3P)_2Cu(OSCMe)]_2$ is dinuclear with different coordination modes for the monothiocarboxylato moieties (*S*-bridging and *O*,*S*-bridging).

The Cu(II) complexes, $Cu[(OPPh_2)(YPPh_2)N]_2$ (Y = O (**8**), S (**9**)), are obtained by reacting stoichiometric amounts of $CuCl_2 \cdot 2H_2O$ with the potassium salt of the imidodiphosphinato acid in organic solvent at room temperature, in accord with rxn. [2].

$$[2] \quad CuCl_2 \cdot 2H_2O + K[(OPPh_2)(YPPh_2)N] \rightarrow Cu[(OPPh_2)(YPPh_2)N]_2 + 2KCl + 2H_2O$$

Blue crystals of the dioxo derivative **8** are also formed directly in an NMR tube during evaporation in open atmosphere of a $CDCl_3$ solution of $(Ph_3P)_2Cu[(OPPh_2)_2N]$ (**4**) (*m*/*z* 896 (molecular ion), and identical spectroscopic properties as a pure sample of the same compound). In the EPR spectrum of **8**, the characteristic hyperfine structure for Cu(II) ions is observed. The hyperfine tensor exhibits axial symmetry with the strongest interaction for the case when the magnetic field is parallel to the deformation axis of the paramagnetic center. For the perpendicular orientation the splitting is too small and the four lines cannot be separated. The analysis of the spectrum was carried out with the axially symmetric spin Hamiltonian, the nuclear quadrupole interaction being neglected. The values of the hyperfine tensor *A* and *B* (parallel and perpendicular components to the tetragonal axis) and of the *g*-factors were calculated. The *g*-factors are consistent with a $|x^2 - y^2>$ ground state of the paramagnetic ion, while the magnitude of the *A* value suggests a relatively large electronic density at the Cu nucleus.

The brown crystals of the monothio derivative **9** are readily soluble in organic solvents, and the ^{31}P NMR spectrum of its $CDCl_3$ solution exhibited two broad resonance signals. A more detailed examination of its spectroscopic properties, both in solution and the solid state, is being undertaken.

Crystal structure of $(Ph_3P)_2Cu[S_2PMe_2]$ (1)

The dithiophosphinato derivative $(Ph_3P)_2Cu[S_2PMe_2]$ (**1**), is monomeric. Its molecular structure is displayed as an ORTEP diagram (Fig. 1), and important bond distances and bond angles are given in Table 2. The dithio ligand is essentially isobidentate (Cu(1)—S(1) 2.4343(12), Cu(1)—S(2) 2.4797(12) Å), resulting in approximately tetrahedral

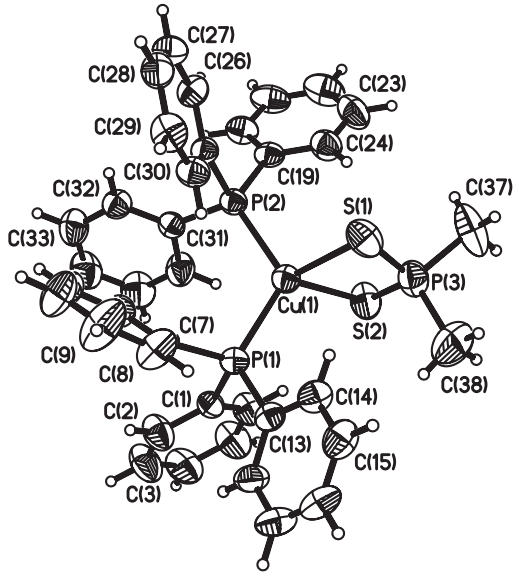

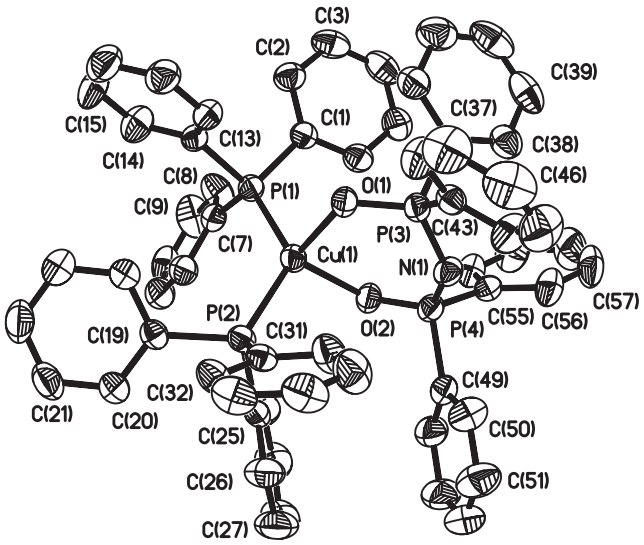

Fig. 2. ORTEP plot of the molecule $(Ph_3P)_2Cu[(OPPh_2)_2N]$ (**4**). The atoms are drawn with 50% probability ellipsoids. Hydrogen atoms are omitted for clarity.

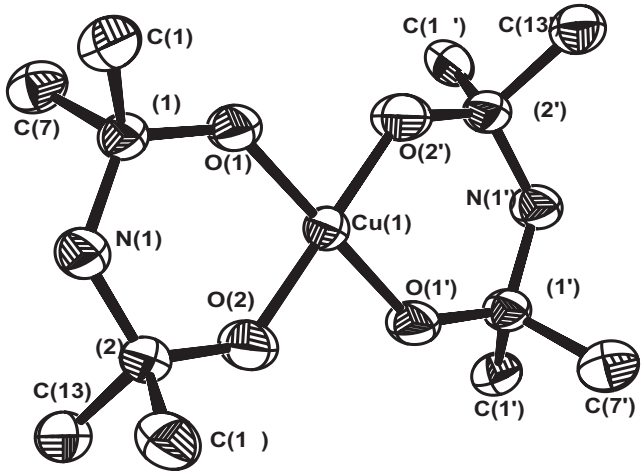
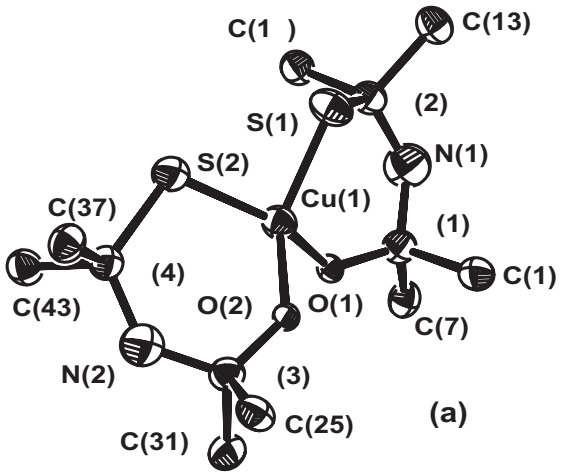
CuP_2S_2 coordination (dihedral angle Cu(1)-P(1)-P(2) – Cu(1)-S(1)-S(2) 86.9°). The four-membered CuS_2P chelate ring is nonplanar but folded about the S(1)–S(2) axis (17.3°). The overall molecular structure is very similar to that of the related dithiophosphato derivative, $(Ph_3P)_2Cu[S_2P(OEt)_2]$ (3). The main difference is in the relative magnitudes of the phosphorus sulfur bond lengths (1.997(2), 2.000(2) Å in **1** vs. 1.967(2), 1.973(2) Å), reflecting the nature of the phosphorus ligands, which contain P–C or P–OC bonds.

Crystal structure of $(Ph_3P)_2Cu[(OPPh_2)_2N]$ (4)

The molecular structure of the Cu(I) imidodiphosphinate, $(Ph_3P)_2Cu[(OPPh_2)_2N]$ (**4**), is displayed as an ORTEP diagram (Fig. 2), and important bond distances and bond angles

Fig. 3. ORTEP plot of the molecule $Cu[(OPPh_2)_2N]_2$ (**8**). The atoms are drawn with 50% probability ellipsoids. Carbon atoms of the phenyl rings other than the ipso atoms and hydrogen atoms are omitted for clarity. Copper located at –1 symmetry center.





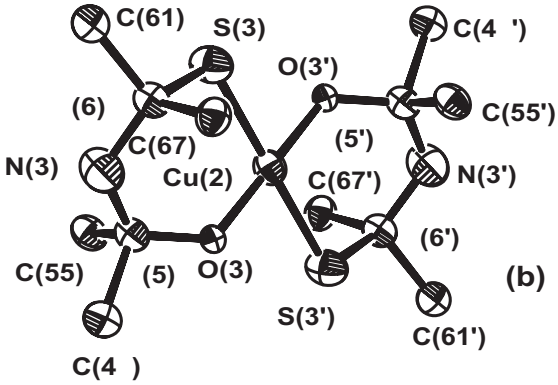


Fig. 4. ORTEP plot of the molecule $Cu[(OPPh_2)(SPPh_2)N]_2$ (**9**) showing the two copper environments: (*a*) tetrahedral, with Cu located at a general position; and (*b*) square planar, with Cu located at –1 symmetry center. The atoms are drawn with 50% probability ellipsoids. Carbon atoms of the phenyl rings other than the ipso atoms and hydrogen atoms are omitted for clarity.

are given in Table 3. This mononuclear compound contains a chelating dioxo ligand (Cu(1)—O(1) 2.122(2), Cu(1)—O(2) 2.165(2) Å), and the resulting tetrahedral CuP_2O_2 core is characterized by a dihedral angle Cu(1)-P(1)-P(2) – Cu(1)-O(1)-O(2) 88.1° close to that observed in **1**. The six-membered CuO_2P_2N chelate ring displays a twisted boat conformation being folded about the P(3)–O(2) axis (dihedral angle O(2)-Cu(1)-O(1)-P(3) – O(2)-P(4)-N(1)-P(3) 29.0°). Similar tetrahedral, mononuclear structures have also been reported for related β-diketonato derivatives, such as $(R_3P)_2Cu[(OCCF_3)_2C]$ (R = Ph (30), Cy (31)).

Crystal structure of $Cu[(OPPh_2)_2N]_2$ (8)

The crystal of the Cu(II) complex **8** contains discrete molecules of $Cu[(OPPh_2)_2N]_2$ displayed as an ORTEP diagram in Fig. 3. Both imidodiphosphinato ligands act as chelating units, leading to a distorted square planar CuO_4 core, with *trans*-O-Cu-O angles of 180° and *endocyclic*-O-Cu-O angles (94.67(13)°) larger than *exocyclic* (85.33 (13)°). Not only is the CuO_4 core planar (dihedral angle Cu(1)-O(1)-O(2) – Cu(1)-O(1′)-O(2′) 0°), but the whole spiro-bicyclic system is almost planar (deviations from the CuO_4 plane: P(1) –0.136, P(2) 0.076, N(1) –0.002 Å). The quasi-planarity of the six-membered CuO_2P_2N ring in **8** is in strong contrast to the twisted boat conformation observed in **4**, pointing out the high flexibility of the OPNPO skeleton. The Cu—O bond distances are considerably shorter in **8** (1.917(3), 1.918(3) Å) than in **4** (2.122(2), 2.165(2) Å), while the P—O and P—N distances are similar as are the O-P-N angles. However, the P-N-P and Cu-O-P angles are larger in **8** than in **4** (ca. 4 and 13°, respectively, (Table 3)), which is presumably required to achieve the planarity of the chelate ring. The overall structure is similar to that of the related derivative, $Cu[\{OP(OPh)_2\}_2N]_2$ (15), indicating that at least in this case, replacement of phenoxy by phenyl groups on phosphorus atoms does not result in significant structural changes.

Crystal structure of $Cu[(OPPh_2)(SPPh_2)N]_2$ (9)

The most interesting feature of the solid state structure of the monothio derivative, $Cu[(OPPh2)(SPPh_2)N]_2$ (**9**), is the presence of both tetrahedral (*a*) and square-planar (*b*) copper environments in a 2:1 ratio, as displayed as an ORTEP diagram in Fig. 4. Important bond distances and bond angles are given in Table 4.

The copper atom is in a special position in the square-planar molecule (Fig. 9*b*) to give the *trans*-CuO_2S_2 core (O(3)-Cu(2)-O(3′) and S(3)-Cu(2)-S(3′) of 180°) with the *endocyclic* O(3)-Cu(2)-S(3) angle (97.47(8)°) again larger than the *exocyclic* O(3)-Cu(2)-S(3′) (82.53(8)°). A similar coordination geometry is found in one of the two independent molecules of $Cu[(OCPh)(SCNEt_2)CH]_2$ (32) in which the crystals contain one molecule with a *trans*-arrangement of the square-planar CuO_2S_2 core and a second molecule with a *cis*-arrangement of the chalcogen atoms around the metal center. In contrast to the dioxo derivative **8**, the six-membered $CuOSP_2N$ ring in **9b** exhibits a twisted boat conformation which is folded about the P(6)–O(3) axis (dihedral angle O(3)-Cu(2)-S(3)-P(6) – O(3)-P(5)-N(3)-P(6) 44.3°).

The other molecule (Fig. 9a) exhibits tetrahedral distortion, with a dihedral angle Cu(1)-O(1)-S(1) – Cu(1)-O(2)-S(2) of 46.51°. The two $CuOSP_2N$ rings, which are not related by symmetry, also exhibit distorted boat conformations, but one ring is folded about the P(1)–S(1) axis (dihedral angle S(1)-Cu(1)-O(1)-P(1) – S(1)-P(2)-N(1)-P(1) 145.2°), while the other is folded about the Cu(1)–N(2) axis (dihedral angle Cu(1)-O(2)-P(3)-N(2) – Cu(1)-S(2)-P(4)-N(2) 26.5°). The P-N-P angles within the two chelate rings in **9a** are significantly different (125.53(19) and 132.57(19)°); both being larger than in **9b** (120.93(19)°).

The Cu—O, P—O, P—S, and P—N bond distances in the two independent molecules are similar (Table 4), but the Cu—S bond distances in the square-planar core of **9b** (2.3398(13) Å) are significantly longer than in the tetrahedral core of **9a** (2.2837(11), 2.2931(1) Å) or in the *trans*-$Cu[(OCPh)(SCNEt_2)CH]_2$ complex (*trans*-isomer 2.254(1) Å, *cis*-isomer 2.236(2), 2.244(2) Å).

Concluding comments

Previous reports have indicated that ligands such as $[(XPPh_2)_2N]^-$ (X = S, Se) tend to displace coordinated triphenylphosphine resulting in the isolation of trigonal $(Ph_3P)Cu[(XPR_2)_2N]$ species. By contrast, monomeric, tetrahedral Cu(I) complexes of the type $(Ph_3P)_2CuL$ (L = $[(XPR_2)(YPR'_2)N]^-$ (X, Y, R, R′ = O, O, Ph, Ph; O, S, Ph, Ph; O, S, OEt, Ph, S, S, Me, Me)), $[S_2PMe_2]^-$, $[OSPR_2]^-$ (R = Me, Ph) are formed by treatment of $(Ph_3P)_2CuNO_3$ with salts of the appropriate organophosphorus acid, regardless of the nature of the organophosphorus ligands. The presence of a tetrahedral Cu^IX_4 core is confirmed by the X-ray structures of $(Ph_3P)_2Cu[S_2PMe_2]$ (**1**) and $(Ph_3P)_2Cu[(OPPh_2)_2N]$ (**4**), and NMR studies indicate that the tetrahedral coordination environment at the Cu(I) atom is also preserved in solution.

For related Cu(II) complexes, $Cu[(OPPh_2)_2N]_2$ (**8**) has the expected planar CuO_4 core but, remarkably, the whole spiro-bicyclic system is almost planar. Even more surprising is the existence of copper in both planar and tetrahedral environments in the case of the monothio derivative $Cu[(OPPh_2)(SPPh_2)N]_2$ (**9**), with the planar and tetrahedral molecules being in a ratio of 1:2.

The conformations of the six-membered $CuOXP_2N$ (X = O, S) rings differ considerably in **1**, **4**, and **8**, providing further evidence of the high flexibility of the OPNPX skeleton.

The reduction of oxygen and hydrogen peroxide on dinuclear ruthenium phthalocyanine electrocatalytic surfaces

Mehrdad Ebadi, Christos Alexiou, and A.B.P. Lever

Abstract: The electrochemical properties of both mononuclear $L_2Ru^{II}Pc$ and dinuclear $[(THF)Rupc]_2$ species are described. The former is dominated by ring oxidation and reduction processes while the latter displays a series of metal localized processes. A Pourbaix diagram describes the various surfaces which can be generated by exposing a graphite electrode modified with $[(THF)Rupc]_2$ to aqueous buffer at different polarization over a wide range of pH. The behavior of these various surfaces towards the electrocatalytic reduction of both oxygen and hydrogen peroxide is described. Most importantly, three different regimes of hydrogen peroxide reduction are observed dependent on the nature of the modified electrode surface. At high pH the four electron reduction of oxygen to water is observed via a 2 + 2 mechanism.

Key words: phthalocyanine, ruthenium, ruthenium phthalocyanine, cyclic voltammetry, suface modified electrode, Pourbaix diagram, electrocatalysis, oxygen reduction, hydrogen peroxide reduction.

Résumé : On décrit les propriétés électrochimiques des espèces mononucléaires $L_2Ru^{II}Pc$ et dinucléaires $[(THF)Rupc]_2$. Les propriétés du premier sont dominées par des processus d'oxydation et de réduction du cycle alors que celles du deuxième présentent une série de processus métalliques localisés. Un diagramme de Pourbaix permet de décrire les diverses surfaces qui peuvent être générées lorsqu'on expose une électrode de graphite modifiée avec du $[(THF)Rupc]_2$ à divers tampons, à diverses polarisations et sur une grande plage de pH. On décrit le comportement de ces diverses surfaces vis-à-vis la réduction électrocatalytique de l'oxygène ainsi que du peroxyde d'hydrogène. Et, de façon plus importante, on observe trois régimes différents de réduction du peroxyde d'hydrogène suivant la nature de la surface de l'électrode modifiée. À des valeurs élevées de pH, on peut observer que la réduction de l'oxygène par quatre électrons pour donner de l'eau se fait par un mécanisme 2 + 2.

Mots clés : phtalocyanine, ruthénium, phtalocyanine de ruthénium, voltampérométrie cyclique, électrode à surface modifiée, diagramme de Pourbaix, électrocatalyse, réduction de l'oxygène, réduction du peroxyde d'hydrogène.

[Traduit par la Rédaction]

Introduction

There is intense interest in the use of metallophthalocyanine species in the design of chemical sensors (1). Metallophthalocyanines are especially important in this respect because of their rich redox behavior, the ability to use almost any metallic and some nonmetallic elements in the central cavity, their easy modification by substituting the ring, their intense color, and general medical inertness (2). An especially simple approach is to lay down a monolayer (or a few layers) of a metallophthalocyanine on a graphite surface thereby creating a metallophthalocyanine electrode and to measure the response of this electrode to perturbation by a redox active target (for examples using this approach, see refs. 3–18).

It is general practice to place these modified metallophthalocyanine (or metalloporphyrin) electrodes into an aqueous phase (in which the metallophthalocyanine surface is usually totally insoluble) and observe an electrocatalytic response to the target, often as a function of the pH of the aqueous phase (8, 15–17, 19–28). The nature of the surface of a metallophthalocyanine modified electrode will change as the polarization of the electrode changes or as the pH of the solution, in which it is immersed, changes. Clearly the catalytic activity must also change with the surface. If we observe an $M^{II/I}$ redox wave and suppose that M^I reduces molecular oxygen but M^{II} does not, then there is the rather obvious fact that polarized positive of the $M^{II/I}$ wave, there is no oxygen reduction, i.e., the surface is inactive, and close to, or negative of this $M^{II/I}$ wave, oxygen reduction proceeds, i.e., the surface is active. One might suppose that as one proceeds further negative of the $M^{II/I}$ wave, perhaps to a putative $M^{I/0}$ wave, activity would continue, however the surface will have changed, in this example, from predominantly M^I to predominantly M^0. The catalytic activity of the M^0 surface can be expected to be different from that of an M^I sur-

face and it does not follow that any catalytic activity will necessarily be retained as demonstrated here and elsewhere (16, 29, 30).

In this report we analyze the surface electrochemistry (31, 32) of dinuclear ruthenium phthalocyanine as a function of the polarization of the electrode and the pH of the aqueous phase in which it is immersed. The reactivity of oxygen and of hydrogen peroxide on the various surfaces is probed.

Dinuclear ruthenium phthalocyanine is of especial interest for study in this context because of the prior rather limited experience of oxygen activation by ruthenium porphyrins (33–35) coupled to the interest in generating a four electron oxygen reduction catalyst using cofacial dinuclear porphyrin species (19, 21, 27, 36–44). Although less directly relevant, there has also been interest recently in tetra-ruthenated metalloporphyrins (45) and in various carbido and nitrido bridged phthalocyanines and porphyrin–phthalocyanines (46–53).

Experimental

The buffer solutions were prepared by using 0.1 M $NaCH_3COO$, 0.1 M KH_2PO_4, and 0.15 M $KHCO_3$. The desired pH was obtained by addition of conjugate acids or 0.1 M NaOH solution and monitored with a pH meter. Nitrogen gas was used to remove dissolved oxygen in the solutions prior to the cyclic voltammetric (CV) experiment. Tetrahydrofuran (THF, Caledon) was distilled over sodium wire before use. Tetrabutylammonium hexafluorophosphate ($TBAPF_6$, Aldrich) was used without further purification. Oxygen and nitrogen gas (Praxair) were used as supplied.

Bis(dimethylsulfoxide)phthalocyaninatoruthenium(II) was prepared following a literature procedure (54). $RuCl_3$ (0.5 g) was added to phthalonitrile (5 g) and naphthalene (2 g). The solids were transferred into a test tube and heated to 275°C. After 1 h, the test tube was left to cool to room temperature and the crude product was Soxhlet extracted with MeOH (2 h) and hexane (24 h). The crude Rupc was then transferred into degassed DMSO (60 mL) and refluxed under nitrogen at 130°C. After three hours of heating the solution was left to cool to room temperature and violet $(DMSO)_2$Rupc was collected and washed with DMSO, followed by MeOH, and dried under vacuum at 70°C. Dissolving in the minimum amount of chloroform and reprecipitating the product by addition of DMSO leads to further purification of the $(DMSO)_2$Rupc. Yield 60%. The NMR and UV–vis spectra were consistent with the literature (54).

Bis(phthalocyaninato)diruthenium(II) $[Rupc]_2$ was prepared by the thermal decomposition of $(DMSO)_2$Rupc at 330°C under vacuo (ca. 1×10^{-5} torr) (54). The UV–vis spectrum (in THF, bands at 296 (s), 422 (w), 598 (vs), and 698 (m) nm.) is consistent with the previous literature (55).

Electrochemical measurements were performed with an RDE3 Pine potentiostat and an X-Y recorder. A basal plane pyrolytic graphite (bpg, Union Carbide) disc, sealed to a copper shaft with polyolefin heat shrinkable tubing was used as a working electrode in the surface CV experiments. The electrode was mounted on the shaft with the basal plane of the graphite exposed. The surface of the electrode was polished with 0.05 μm alumina powder, sonicated in doubly distilled water, and rinsed with acetone and water before each experiment. Exposing the polished bpg electrode to an oxygen-free THF solution of $[(THF)Rupc]_2$ (0.1 mM) modified the graphite electrode with a surface of $[(THF)Rupc]_2$. After 1 min of soaking, the electrode would be removed, rinsed with MeOH and doubly distilled water, and transferred to the cell. A saturated calomel electrode was used as a reference electrode in the surface experiments in water. Surface experiments using dichloromethane employed an AgCl/Ag electrode with ferrocene added as an internal standard. Due to the irreversibility of the ferrocenium/ferrocene couple, there was no additional check on the validity of the AgCl/Ag electrode.

In the solution CV experiments, a platinum disc sealed in glass was used as the working electrode and AgCl/Ag as the reference. The ferrocenium/ferrocene couple was used to reference the data to SCE (56). The platinum disc was polished with 0.3 μm alumina powder, rinsed, and sonicated in doubly distilled water before each experiment. A platinum wire was used as the counter electrode in both surface and solution CV experiments.

In O_2 reduction experiments, solutions were bubbled with pure gas for 20–30 min. The following parameters were used in our calculations: $D_{O_2} = 1.67 \times 10^{-5}$ ($cm^2\ s^{-1}$) (57), saturated $[O_2] = 1.1$ mM (58), and 0.01 $cm^2\ s^{-1}$ for the kinematic viscosity of water (59). A 2% solution of H_2O_2 was prepared in distilled water for hydrogen peroxide studies.

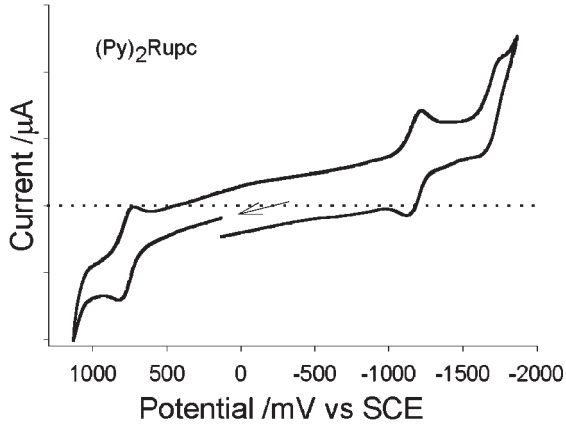
Results and discussion

Ruthenium phthalocyanine forms a series of octahedral mononuclear species of general formula $L_2Ru^{II}pc$ (13, 60–80). In addition, the dimeric $[Rupc]_2$ has been described. This is formed most readily by the thermal decomposition of $(DMSO)_2Ru^{II}pc$ (54, 55, 62, 81, 82) and contains a Ru—Ru bond of length 240 pm. The dinuclear species dissolves in coordinating solvents (sol) to generate the mononuclear $(sol)_2Ru^{II}pc$. It is also reactive towards oxygen generating, in solution, oligomeric pcRu-O-Rupc species (82, 83). $L_2Ru^{II}pc$ species may also be prepared by dissolving $[(THF)Rupc]_2$ in oxygen-free THF and adding a coordinating ligand, L. However the species in THF in the absence of oxygen and any coordinating ligands (L) is evidently the dimeric $[(THF)Rupc]_2$ complex. Under such conditions, its electronic spectrum and electrochemical properties differ significantly from those of an $L_2Ru^{II}pc$ species (84) dissolved in THF, e.g., as would be expected for $(THF)_2Ru^{II}pc$.

Electronic spectra and electrochemistry of the mononuclear $L_2Ru^{II}pc$ species

Thus, $L_2Ru^{II}pc$[2] species usually give rise to an electronic spectrum typical of a fourfold symmetric metallophthalocyanine species, having a single and intense Q band with vibrational satellites (85), albeit in some cases rather broader than usually observed (60, 61, 69, 73, 74, 86,

[2] The normal oxidation state of a phthalocyaninato anion is –2. For simplicity this is written as pc. However, the first ring oxidized species is written pc^{1-} while pc^{3-}…pc^{6-} refer to the successively one-electron reduced species, respectively.



© 2001 NRC Canada

87). In THF, on the other hand, a solution of $[(THF)Rupc]_2$ gives an atypical spectrum exhibiting a Q band with a well-defined additional but weaker peak at lower energy (55).

Mononuclear $L_2Ru^{II}pc$ (L = coordinating neutral ligand such as DMSO, pyridine, carbon monoxide, imidazole, acetonitrile) are oxidized initially at the ring, at ca. 0.5–0.8 V vs. SCE, to generate $L_2Ru^{II}pc^{1-}$ species (Fig. 1, Table 1) (61, 74, 88–90). When L is a halide or nitrite anion (X) oxidation to $X_2Ru^{III}pc$ apparently occurs, near 0 V vs. SCE (69, 86, 87), but ring oxidized products are again obtained if L_2 is CO or X (X is a halide anion) (74).

Ring reduction to $L_2Ru^{II}pc^{3-}$ species for coordinating neutral ligands (L) is observed near –1.0 to –1.3 V vs. SCE. (74, 88, 90) such that the difference in ring oxidation and reduction potentials is in the range of ca. 1.8–2.0 V. The second reduction step to $L_2Ru^{II}pc^{4-}$ species occurs about 0.5 V to a more negative potential than the first (56, 88).

Fig. 1. The cyclic voltammogram of $(Py)_2Ru^{II}pc$. This solution was obtained by dissolving dimeric $[(THF)Rupc]_2$ into dichloromethane and adding 2% pyridine. Scan rate 100 mV s^{-1}, 0.1 M $TBAPF_6$.

Solution electrochemistry of the dinuclear $[(THF)Rupc]_2$

Dinuclear $[Rupc]_2$ dissolved in THF exhibits an electronic spectrum (Fig. 6, spectrum 1 of ref. 55) inconsistent with that for an $L_2Ru^{II}Pc$ species. Moreover, its previously unpublished electrochemical profile shown here (Fig. 2, Table 1) is completely different from that of a typical metallophthalocyanine species (56). Figure 2 displays the cyclic voltammogram of $[(THF)Rupc]_2$ in THF at –15°C. Four redox waves at 0.98 (wave I), 0.48 (wave II), –0.13 (wave III), and –0.55 (wave IV) vs. SCE are observed. By scanning the potential more negative than wave IV, an irreversible wave at –1.38 (wave V) is also observed. The peak currents of waves I–IV are linearly proportional to the square root of scan rate, characteristic of diffusion controlled redox processes. A weak wave observed around 0.8 V, absent from a freshly prepared solution, grows when oxygen is allowed into the electrochemical cell and evidently arises from an oxygenated impurity (55). These optical and electrochemical data clearly identify the solution species in THF as the dimeric species probably axially coordinated by solvent, i.e., $[(THF)Rupc]_2$.

To determine the number of electrons involved at each wave, a series of chronoamperometry experiments (91) were conducted (Fig. 3). In these experiments, an initial potential equal to the open circuit potential (open circuit potential lies between waves II and III) is applied to the working electrode. The potential is then stepped to a diffusion-controlled region of waves I–V and the current is recorded as a function of electrolysis time. Figure 3 shows the current functions ($i.t^{1/2}$) obtained from these chronoamperometry experiments. The magnitude of $i.t^{1/2}$ is used to determine the relative number of electrons involved in each redox wave, and is defined as:

$$[1] \qquad i.t^{1/2} = nFAC_oD_o{}^{1/2}\,\pi^{-1/2}$$

where A is the area of the electrode (cm^2), C_o is the concentration (mol cm^{-3}), and D_o is the diffusion coefficient ($cm\ s^{-1}$).

In Fig. 3, the current functions obtained for the reduction of $[(THF)Rupc]_2$ at a potential negative of wave III and positive of wave IV, are equal in magnitude (but opposite in sign) to those obtained for $[(THF)Rupc]_2$ oxidation at a potential positive of wave II and negative of wave I, suggesting an equal number of electrons are involved in these two waves. Using the data in Fig. 3, the relative number of electrons involved at each wave was determined to be one electron for each of waves II, III, and IV, and two electrons for waves I and V. The chronoamperometry results were reproducible for all the waves, with the exception of wave I where values between 2–3 were observed. Wave I lies close to the solvent limiting potential, which can result in overestimation of the number of electrons involved at this wave. The relative CV peak currents of waves I–IV are essentially the same suggesting that one electron is also involved at wave I. Attempts to obtain further information through spectroelectrochemical studies failed, as a result of the instability of the oxidation and reduction products on this longer time scale.

The first two reduction processes occurring between 0 and –0.5 V vs. SCE lie significantly positive of the ring reduction process noted above for monomeric $L_2Ru^{II}pc$ species. Due to the large ligand field strength of low spin octahedral d^6 Ru^{II} species, reduction to the Ru(I) species will occur at a significantly negative potential and this process has not been identified in six coordinate Ru^{II} phthalocyanine species.

However in four coordinate dinuclear species, lower lying empty orbitals will arise. Thus a molecular orbital description of the frontier orbitals in $[(THF)Rupc]_2$ has been presented (55). Coupling of the d orbitals of two d^6 ruthenium(II) moieties leads to a frontier description (81) $\sigma^2\pi^4\delta^2\delta^{*2}\pi^{*2}$ yielding a Ru=Ru double bond. The two reduction couples then reasonably are assigned to addition of electrons to the $d(\pi^*)$ level forming first the mixed valence Ru^I–Ru^{II} species and then subsequently the Ru^I–Ru^I species, possessing a single Ru–Ru bond. Correspondingly the two oxidation couples may refer to sequential loss of electrons from $d(\pi^{*2})$ yielding mixed valence Ru^{II}–Ru^{III} and finally Ru^{III}–Ru^{III}, which we note in passing, will have a triple bond. However, the magnitude of the potentials does not allow us to exclude the alternate possibility that phthalocyanine ring oxidation, commonly observed with mononuclear ruthenium phthalocyanines (60, 61, 69, 74,

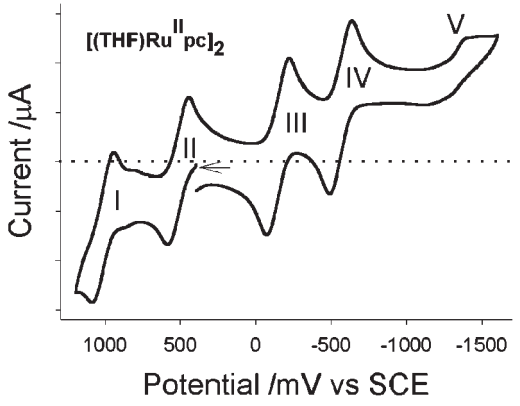
Table 1. Summary of selected redox potentials ($E_{1/2}$, V) vs. SCE.

Complex	Conditions	Oxidation	Reduction[a]
$(DMSO)_2Rupc$	CH_2Cl_2–DMSO	0.78	–1.07, –1.57
$(Py)_2Rupc$	CH_2Cl_2–Py	0.77	–1.18, –1.70
$[(THF)Rupc]_2$	THF	0.98 (I), 0.48 (II)	–0.13 (III), –0.55 (IV), –1.38 (V)
$[(THF)Rupc]_2$	Surface pH = 1.97[b]		–0.005, –0.58
$[(THF)Rupc]_2$	Surface pH = 11.6[b]	–0.30	–0.63, –1.22
$[(THF)Rupc]_2$	Surface, CH_2Cl_2	0.84 (A), 0.30 (B)	–0.45 (C), –0.94 (D)

[a]Reduction processes for $L_2Ru^{II}Pc$ species are ring reduction processes. The first two reduction processes for $[(THF)Rupc]_2$ are metal localized, the third reduction is probably ring localized.
[b]Aqueous solution; the axial THF molecule may be replaced by water, or by hydroxyl ion in the basic medium.

Fig. 2. The cyclic voltammogram of $[(THF)Rupc]_2$ in THF. Scan rate 100 mV s^{-1}, 0.1 M $TBAPF_6$.



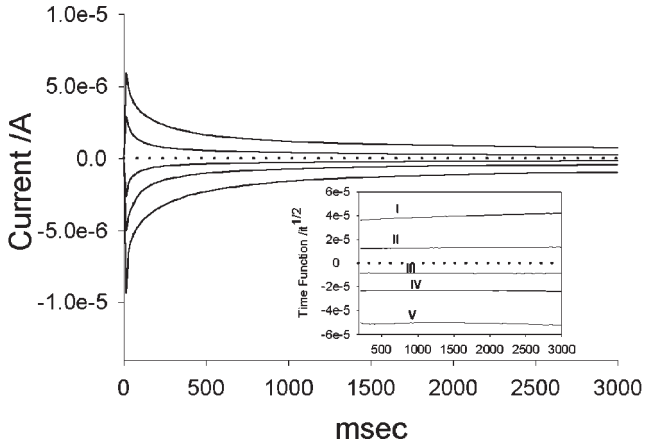


Fig. 3. Chronoamperometric current as a function of time following the potential step for $[(THF)Rupc]_2$ in THF, 0.1 M $TBAPF_6$. E(initial) = 200 mV vs. SCE. Potential was stepped to 1200, 650, –450, –950, and –1600 mV vs. SCE from the top curve down to the bottom, respectively. The top two represent oxidation processes and the bottom three reduction processes. Insert: the $i.t^{1/2}$ function plotted against time for the data in the main part of the figure.

92), is occurring here. Wave V is likely the ring reduction process, pc^{2-}/pc^{3-}. The electrochemical behaviour in THF, characteristically different from that of a mononuclear metallophthalocyanine species, is unequivocal proof of the existence therein of the dimeric $[(THF)Rupc]_2$.

In addition we note that in the solution chemistry of the monomer, the difference between the first oxidation process and the first reduction process is 1.8–2.0 V, while for the dimer in solution, the difference between first oxidation and *second* reduction is only about 1 V. This arises because in the former case, oxidation and reduction involve ring processes, while in the latter, they involve metal localized processes.

Surface electrochemistry of the dinuclear $[(THF)Rupc]_2$

When a basal plane pyrolytic graphite electrode is dipped into a THF solution of $[(THF)Rupc]_2$, a deposit is laid down to generate a modified ruthenium phthalocyanine electrode. The surface electrochemistry of this modified electrode is very reminiscent of the $[(THF)Rupc]_2$ solution electrochemistry discussed above. Thus if this electrode is exposed to dichloromethane, four waves are observed (Fig. 4, Table 1) with approximately the same potentials as observed for the solution species (Fig. 1, Table 1). There can be little doubt that waves A, B, C, and D correspond in assignment to those described above as I, II, III, and IV, respectively.

When this modified electrode is exposed to aqueous solution,[3] waves B, C, and D can be observed, depending on solution pH (Fig. 5). They are true surface processes whose current has a linear dependence on scan rate (91). The open circuit potential of this surface is just positive of wave B confirming that waves C and D are both reduction processes. These surface waves are dependent on the pH of the solution in which the electrode is immersed as shown in Figs. 5 and 6 shifting to more negative potentials with increasing pH and with a slope corresponding with a *n*-proton – *n*-electron system (91).

Further confirmation of the dimeric nature of the surface, and its inherent stability, is obtained by laying down the phthalocyanine layer on glass instead of bpg. If this layer is then dried and re-dissolved in THF, the majority species recovered, based on electronic spectroscopy, is again $[(THF)Rupc]_2$ contaminated with some incidental oxidation product.

Further, we also briefly explored the surface electrochemistry of $(DMSO)_2Rupc$. The first scan of such a surface (not shown) shows a single wave at –0.50 V at pH 1.8. This can be readily ascribed to the $Ru^{II}pc^{2-}/Ru^{II}pc^{3-}$ wave (seen in Fig. 1 at –1.2 V) shifted to –0.50 V under these acidic conditions. This is fully consistent with the previous literature concerning the pH dependence of the Mpc^{2-}/Mpc^{3-} wave (7,

[3]In the aqueous environment, the axial THF is probably replaced by water or hydroxide ion.

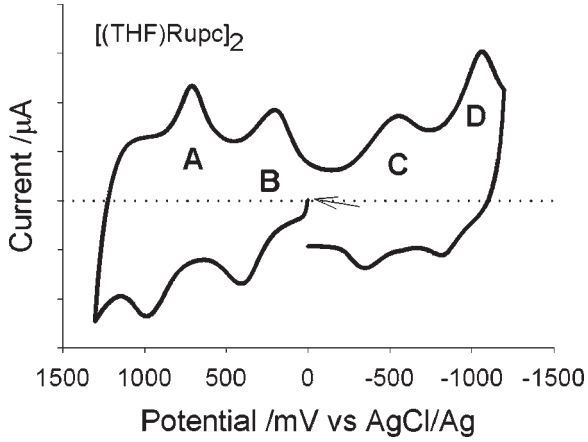
Fig. 4. Cyclic voltammogram of a surface modified $[(THF)Rupc]_2$/bpg electrode immersed in dichloromethane. Scan rate 100 mV s^{-1}, 0.1 M $TBAPF_6$.



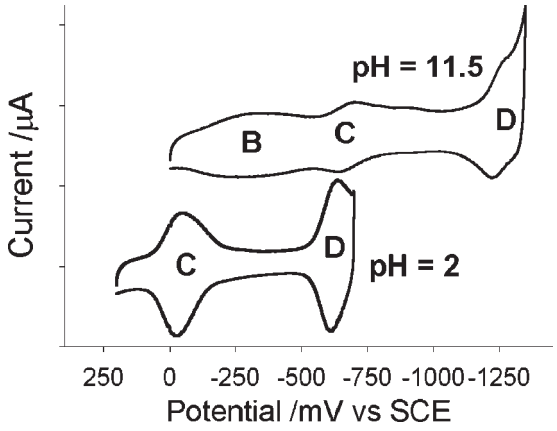


Fig. 5. Cyclic voltammograms for surface modified $[(THF)Rupc]_2$/bpg electrodes immersed in aqueous phosphate buffer at pH = 2.0 and 11.5 as indicated. Waves A and B are net reduction, while wave C is oxidation of the surface. Scan rate 100 mV s^{-1}.

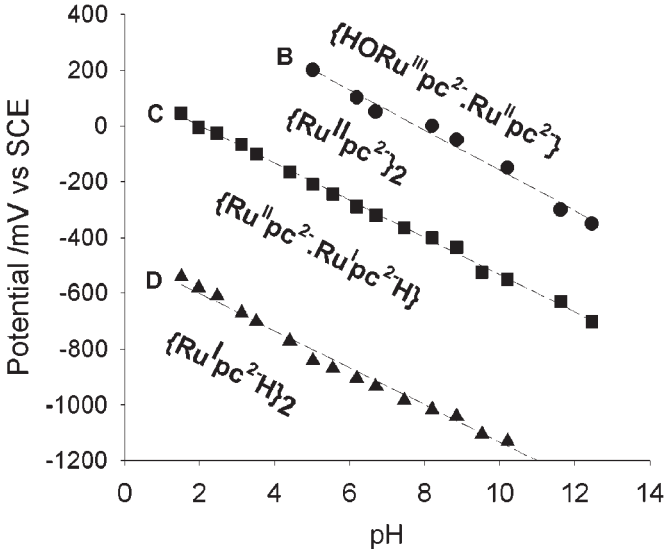


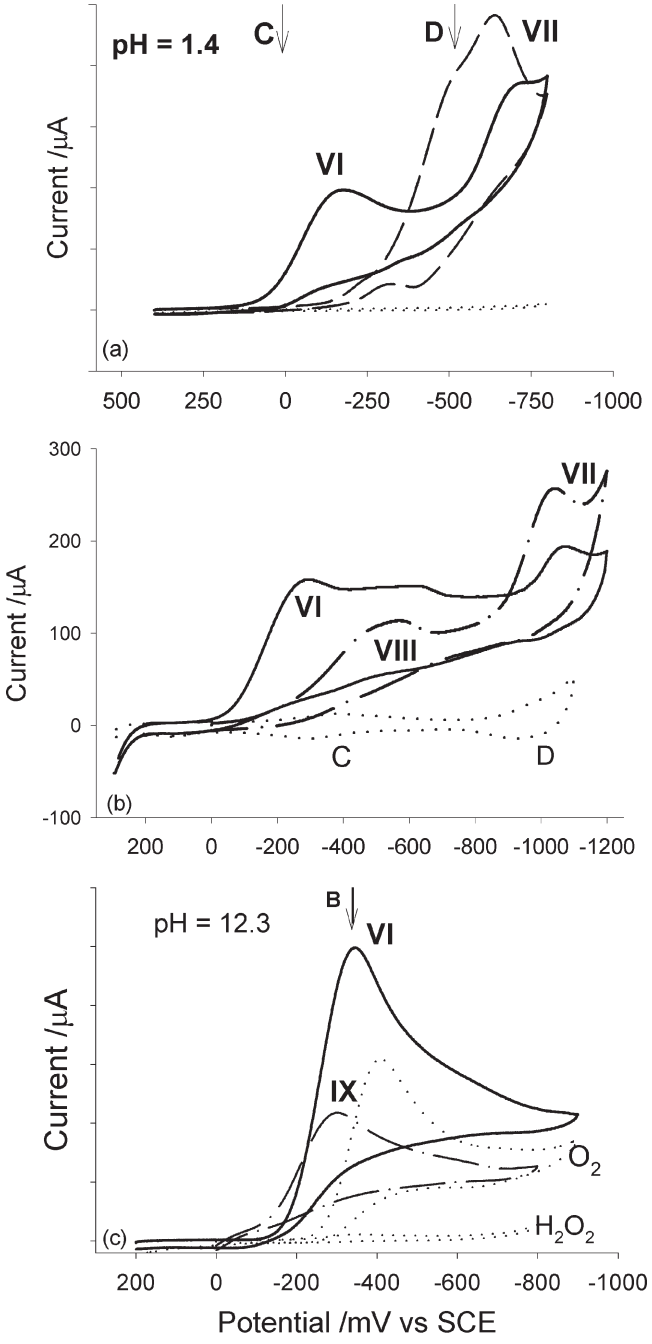
16, 93). The key conclusion is that a surface bound monomeric $L_2Ru^{II}pc$ species only displays a single reduction wave under conditions where $[(THF)Rupc]_2$ displays two waves.

A Pourbaix diagram for dimeric ruthenium phthalocyanine

By varying the pH at which cyclic voltammetric data are collected, a Pourbaix diagram (pH vs. potential) can be constructed (94). This diagram (Fig. 6) demonstrates an approximately –60 mV pH^{-1} dependence for all three waves. Previously the $Fe^{III/II}$ couple in Fepc and related species has been shown to be pH dependent because of the $HOFe^{III}pc/Fe^{II}pc$ couple (16, 28, 95). Wave B likely results from the similar process $[HORu^{III}pc{\cdot}Ru^{II}pc]/[Ru^{II}pc{\cdot}Ru^{II}pc]$. In the case of Fepc, there is usually a break in the *E* vs. pH line indicative of the pK_b of the $HOFe^{III}pc$ species. This is not evident here (nor with Cl_{16}Fepc (95)) indicating the very high Lewis acidity of the Ru^{III} centre. Waves C and D probably involve successive protonation at the aza bridge sites (96). Aside from displaying the potential at which waves B,

Fig. 6. A Pourbaix diagram indicating the pH dependence of waves B, C, and D, and indicating the nature of the surface modified regions (phosphate buffer).

C, and D can be observed as a function of pH, this diagram serves an especially useful purpose for surface electrochemistry. Assuming that just positive of wave B, the species on the electrode is $[HORu^{III}pc{\cdot}Ru^{II}pc]$ one can infer the nature of the surface formed upon subsequent 1-electron – 1-proton reduction, defined by the ca. –59 mV pH^{-1} slopes. Thus, in the range shown (Fig. 6), four different surface modified electrodes are effectively generated. We can then proceed to investigate the oxygen and hydrogen peroxide reduction chemistry on these various surfaces.



Oxygen and hydrogen peroxide electrocatalytic reduction

There is a long history of studies of the electrocatalytic reduction of oxygen and of hydrogen peroxide at phthalocyanine modified electrodes (3, 5, 7, 9, 11, 14, 15, 26, 28, 30, 93, 95, 97–126). Most research has been carried out with iron and cobalt phthalocyanines. Usually, oxygen is reduced in a two electron process to hydrogen peroxide, and with appropriately active phthalocyanines, this is often followed at more negative potentials by a further two electron reduction of hydrogen peroxide to water. The four electron reduction of water, which is more desirable from the viewpoint of fuel cell applications, has been observed in a number of cases involving iron, cobalt, rhodium, iridium, or platinum phthalocyanines (7, 17, 22, 98, 109, 112–115, 117, 118, 121, 122, 127–131). However, it is still a sought after process whose mechanistic details are yet poorly understood.

Dimeric ruthenium phthalocyanine exhibits new, hitherto unobserved, facets of oxygen and hydrogen peroxide reduction electrocatalysis due specifically to the variation in the active surface caused by the choice of polarization potential and the pH in which the electrode is immersed. Oxygen reduction (wave VI) occurs in a fairly narrow and flat potential range throughout the pH regime from 1–14 (Figs. 5 and 6). This is very similar to earlier studies (7, 11, 95, 126), except that in some of these studies there is a pronounced shift for the oxygen reduction wave to less negative potentials at very

© 2001 NRC Canada

Fig. 7. Comparison of oxygen and hydrogen peroxide reduction at a $[(THF)Rupc]_2$/bpg surface modified electrode. Phosphate buffer, scan rate 100 mV s^{-1}. Because of variation in concentration, the relative current between oxygen and hydrogen peroxide reduction is not meaningful. In all three graphs, the solid line is for oxygen reduction, peak labeled VI, and the hatched line is for hydrogen peroxide reduction, peaks VII, VIII, and IX. The blank bpg response is shown as a dotted line. Labels C and D define the positions of the $[(THF)Rupc]_2$/bpg reduction processes and B, the first oxidation process at the relevant pH locations shown as short vertical arrows: (*a*) pH 1.4; (*b*) H_2O_2 pH 6.2, O_2 pH 7.0; and (*c*) pH 12.3. The two dotted line curves refer to blank uncoated bpg responding to oxygen or hydrogen peroxide as labeled.

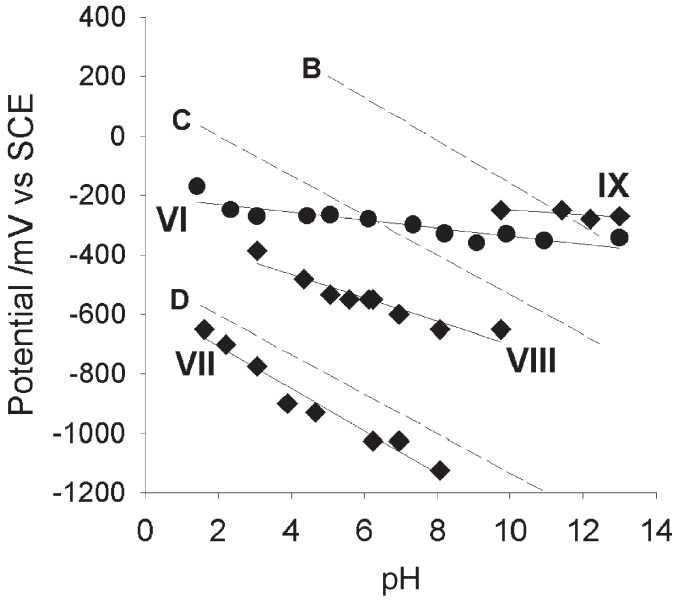
low pH, i.e., the process becomes pH dependent. This is absent in the current study at least down to pH 2. The oxygen reduction wave is followed at more negative potentials, up to pH 10, by one or two additional waves, which correspond with the subsequent reduction of hydrogen peroxide formed at the electrode from the initial two-electron reduction of dioxygen.

The identity of these additional waves due to hydrogen peroxide reduction is confirmed by independent studies of the $[(THF)Rupc]_2$/bpg electrode immersed in oxygen-free hydrogen peroxide. The same waves are generated (Fig. 7). Most unfortunately, the $[(THF)Rupc]_2$ surface is rather unstable in bulk hydrogen peroxide, with the second and subsequent scans revealing some decomposition. The very small amounts of hydrogen peroxide formed upon oxygen reduction, are reduced to water or diffuse away, such that the surface under an oxygen environment is quite stable and subsequent scans are very similar to the first scan. Above pH 10, there is no concomitant hydrogen peroxide reduction wave and we demonstrate below that water is then the primary product of a net four electron reduction of oxygen. Note that if a $[(THF)Rupc]_2$/bpg electrode is used to study oxygen reduction, and is subsequently placed into a deaerated aqueous solution, the original B, C, and D waves are recovered, indicating that the surface is stable to oxygen exposure (unlike the solution) (83).

In oxygen reduction studies at a surface modified electrode, the appearance of an additional wave due to subsequent hydrogen peroxide reduction is, of course, well known (3, 7, 17, 18, 26, 28, 102, 110, 120, 122, 124–126, 132). The striking observation with the $[(THF)Rupc]_2$ surface is the presence of three different potential regions for hydrogen peroxide reduction (waves VII–IX), depending on the active surface, which is correspondingly dependent on pH. We discuss first the reduction chemistry of hydrogen peroxide on these surfaces, since the oxygen reduction chemistry is related thereto. Because of the aforementioned decomposition in the presence of bulk hydrogen peroxide, the potentials of the waves noted below were derived from the oxygen reduction experiments except for pH > 10.

Hydrogen peroxide reduction at the $[(THF)Rupc]_2$/bpg modified electrode

Wave VII – low pH



In the pH range 1–7, hydrogen peroxide is reduced at relatively negative potentials (wave VII), shifting to more negative potential with increasing pH (Fig. 8). This is a typical region observed in previous studies of hydrogen peroxide reduction at a metallophthalocyanine/graphite modified electrode (7, 8, 11, 126). Indeed the potential vs. pH correlation is almost coincident for $[(THF)Rupc]_2$ and for the cobalt crown phthalocyanine previously described (7). However, while in the cobalt crown phthalocyanine case, the linearity extends unbroken to higher pH, on the $[(THF)Rupc]_2$ surface, this more negative wave disappears from about pH 6 to be replaced by a second hydrogen peroxide reduction wave at less negative potential.

Wave VIII – near pH 7

In the pH range ca. 3–10 a hydrogen peroxide reduction wave (VIII) appears at ca. −400 to −650 mV, which is very

© 2001 NRC Canada

Fig. 8. A Pourbaix diagram indicating the pH dependence of waves B, C, and D, as well as oxygen reduction and the three regions of hydrogen peroxide reduction (phosphate buffer). The labels VI,VII, VIII, and IX correspond with the waves shown in Figs. 7*a–c*.

similar to the data observed for cobalt polytetraaminophthalocyanine (3). This wave VIII shifts slightly to more negative potentials with increasing pH (Fig. 8). In the range from about pH 3–8, both waves VII and VIII can be observed in the same voltammogram. Below pH 5 this wave is very weak appearing, if at all, only as an indistinct shoulder on the oxygen reduction wave. With bulk hydrogen peroxide at pH 1.4 there is a shoulder on the wave VII reduction process, near –500 mV, which may be associated with the wave VIII process, but the instability and lack of reproducibility of the surface in the presence of bulk hydrogen peroxide, makes this conjecture hard to confirm.

Wave IX – above pH 10.

Above about pH 10 a new, almost pH independent, hydrogen peroxide reduction wave (IX) appears near –300 mV (Fig. 6*c*). This wave was explored using bulk hydrogen peroxide in the cell, recording only the first voltammogram. The existence of this wave IX at a potential close to and indeed slightly positive of the oxygen reduction wave explains the absence of any additional hydrogen peroxide reduction wave appearing in the oxygen reduction experiment at pH 10 and above. Any hydrogen peroxide formed upon reduction of oxygen in this pH range would rapidly be reduced to water.

Oxygen reduction

The electrochemical reduction of oxygen has been explored in great detail for many years (133–135) and is, therefore, not presented in detail here. On a $[(THF)Rupc]_2$/bpg surface modified electrode, oxygen reduction occurs at a potential (wave VI) only slightly less positive than that observed on a bare bpg surface (Fig. 6). The process is essentially pH independent, consistent with many studies of oxygen reduction at a platinum electrode (133, 135). In the pH range where hydrogen peroxide reduction occurs at a significantly more negative potential than oxygen reduction, the well-documented two-electron reduction of oxygen to hydrogen peroxide is observed. Above pH 10, in the regime where oxygen reduction occurs at a similar potential or indeed negative of hydrogen peroxide reduction, the 2 + 2 electron reduction of oxygen directly to water is observed (Fig. 6). Thus, the formation of water above pH 10 is clearly associated with the ability of the surface to reduce hydrogen peroxide at a potential positive of that of oxygen reduction. Note that bare bpg does not reduce hydrogen peroxide within the limits noted in Fig. 6.

These observations are confirmed by conventional Koutecky–Levich plots (136, 137) for oxygen reduction generating straight lines (not shown) whose slopes in the mass transfer region at pH = 12.3 (slope = 2.18×10^4 $As^{-1/2}$) and pH = 2.3 (slope = 1.16×10^4 $As^{-1/2}$) correspond well with the theoretical values for $n = 4$ (slope = 2.43×10^4 $As^{-1/2}$) and $n = 2$ (slope = 1.13×10^4 $As^{-1/2}$), respectively. The linearity of the plot also indicates that oxygen reduction is first order with respect to dissolved O_2. More detailed analysis of the mechanism of oxygen reduction on $[(THF)Rupc]_2$/bpg is presented elsewhere (138).

Summary and conclusions

While oxygen reduction at the $[(THF)Rupc]_2$/bpg electrode has similar features to many other metallophthalocyanine modified electrodes, the hydrogen peroxide reduction is unique in displaying three independent regions of activity depending on pH. The simultaneous appearance within a narrow pH range of both waves VII and VIII is most noteworthy. The significance of this is as yet undetermined. It is possible that we are observing two sequential one-electron reductions of hydrogen peroxide to water, an observation which would be extremely unusual but may occur as consequence of the formation of stable hydroperoxyruthenium species on the surface. Certainly iron forms such electrochemically active species, of considerable importance in the biological field (139–144) and hydroperoxoiron species show complex electrochemical activity leading to cleavage of the peroxo bond and formation of oxo species (145). Thus similar and complex reactivity towards ruthenium centers can be anticipated. It is obvious from Fig. 5 that the three processes are electrocatalyzed by three different $[(THF)Rupc]_2$/bpg surfaces; in effect there are three different electrodes which respond necessarily in different ways to the bulk hydrogen peroxide. It is also highly probable that the various intermediate "H_2O_2" ruthenium species involve a varying number of bound protons.

It is unfortunate that the surface is unstable in the presence of bulk hydrogen peroxide, since this precludes a detailed electrochemical analysis to obtain information on reaction rates, order of reactant species, influence of film thickness, etc. A future study of perhalogenated $[(THF)Rupc]_2$ is planned in the expectation that such a surface should be much more stable. More detailed studies of the oxygen reduction process on the $[(THF)Rupc]_2$ electrode are available (138), but in view of the previous extensive lit-

erature on metallophthalocyanine electrocatalyzed oxygen reduction, such data are not presented here.

The intent of this paper was to demonstrate that through polarizing a modified electrode immersed in buffers of various pH, a range of different surface modified electrodes can be obtained and that the properties of these electrodes can vary dramatically. We have demonstrated here that the reactivities of variously reduced surfaces towards hydrogen peroxide are quite different. Elsewhere (29, 32) we shall demonstrate examples of where a surface, active towards reduction becomes totally inactive when polarized at more negative potentials even though the thermodynamic driving force must have increased, and then becomes active again at a further negative potential. The longer term application of this concept is to explore systems where the products of reduction of a target such as carbon dioxide will vary with polarization and pH as the surface chemistry is modified.

The role of a hydroxycyclopentadienyl ruthenium dicarbonyl formate in formic acid reductions of carbonyl compounds catalyzed by Shvo's diruthenium catalyst

Charles P. Casey, Steven W. Singer, and Douglas R. Powell

Abstract: Addition of excess HCO_2H to $\{2,5\text{-}Ph_2\text{-}3,4\text{-}Tol_2(\eta^5\text{-}C_4CO)]Ru(CO)_2\}_2$ (**6**) at –20°C led to the formation of $[2,5\text{-}Ph_2\text{-}3,4\text{-}Tol_2(\eta^5\text{-}C_4COH)]Ru(CO)_2(\eta^1\text{-}OCHO)$ (**5**), a proposed intermediate in catalytic transfer hydrogenations developed by Shvo. Hydroxycyclopentadienyl formate **5** undergoes rapid reversible dissociation of HCO_2H at –20°C, and undergoes decarboxylation at 1°C to form a 1:10 mixture of $\{[2,5\text{-}Ph_2\text{-}3,4\text{-}Tol_2(\eta^5\text{-}C_4CO)]_2H\}Ru_2(CO)_4(\mu\text{-}H)$ (**3**):$[2,5\text{-}Ph_2\text{-}3,4\text{-}Tol_2(\eta^5\text{-}C_4COH)Ru(CO)_2H]$ (**4**). **5** does not reduce PhCHO below the temperature at which **5** is converted to hydride **4**. The catalytic production of benzyl alcohol from **5** and PhCHO in the presence of excess HCO_2H is not accelerated by higher concentrations of PhCHO, indicating that **5** does not directly reduce PhCHO. Formate complex **5** is the precursor of hydride **4** which transfers hydrogen to PhCHO. A crucial role for the CpOH proton in the decarboxylation of **5** was indicated by the much slower decarboxylation of the methoxycyclopentadienyl analog $[2,5\text{-}Ph_2\text{-}3,4\text{-}Tol_2(\eta^5\text{-}C_4COCH_3)]Ru(CO)_2(\eta^1\text{-}OCHO)$ (**7**). A mechanism for decarboxylation of **5** is proposed which involves reversible dissociation of formic acid to form the unsaturated dienone dicarbonyl ruthenium intermediate **C**, followed by simultaneous transfer of hydride to ruthenium from the formic acid carbon and of proton to the carbonyl of **C** from the formic acid OH group.

Key words: Shvo catalyst, ruthenium formate, decarboxylation.

Résumé : L'addition d'un excès de HCO_2H au complexe $\{2,5\text{-}Ph_2\text{-}3,4\text{-}Tol_2(\eta^5\text{-}C_4CO)][Ru(CO_2\}_2$ (**6**), à –20°C, conduit à la formation de $[2,5\text{-}Ph_2\text{-}3,4\text{-}Tol_2(\eta^5\text{-}C_4COH)]Ru(CO)_2(\eta^1\text{-}OCHO)$ (**5**), un intermédiaire présumé dans les hydrogénations par transfert catalytique développées par Shvo. Le formate d'hydrocyclopentadiényle, **5**, subit une dissociation réversible rapide en HCO_2H à –20°C et il subit une décarboxylation à 1°C conduisant à la formation d'un mélange 1:10 de $\{[2,5\text{-}Ph_2\text{-}3,4\text{-}Tol_2(\eta^5\text{-}C_4CO)]_2H\}Ru_2(CO)_4(\mu\text{-}H)$ (**3**) : $[2,5\text{-}Ph_2\text{-}3,4\text{-}Tol_2(\eta^5\text{-}C_4COH)Ru(CO)_2H]$ (**4**). Le composé **5** ne réduit pas le PhCHO en dessous de la température à laquelle ce composé est transformé en hydrure **4**. La vitesse de la production catalytique d'alcool benzylique à partir de **5** et de PhCHO, en présence d'un excès de HCO_2H n'est pas accélérée par des concentrations plus élevées de PhCHO; ce résultat indique que **5** ne réduit pas le PhCHO directement. Le complexe **5** à base de formate est le précurseur de l'hydrure **4** qui transfère de l'hydrogène au PhCHO. Un rôle crucial pour le proton du CpOH dans la décarboxylation du composé **5** est mis en évidence par la décarboxylation beaucoup plus lente de l'analogue méthyoxycyclopentadiényle, $[2,5\text{-}Ph_2\text{-}3,4\text{-}Tol_2(\eta^5\text{-}C_4COCH_3)]Ru(CO)_2(\eta^1\text{-}OCHO)$ (**7**). On propose un mécanisme de décarboxylation du composé **5**; il implique une dissociation réversible de l'acide formique conduisant à la formation de l'intermédiaire insaturé **C**, ruthénium dicarbonyle diénone, suivi par un transfert simultané d'hydrure du carbone de l'acide formique vers le ruthénium et du proton du groupe OH de l'acide formique vers le carbonyle de l'intermédiaire **C**.

Mots clés : catalyseur de Shvo, formate de ruthénium, décarboxylation.

[Traduit par la Rédaction]

Introduction

Recently, we began investigating Shvo's fascinating hydrogenation catalyst, $\{[2,3,4,5\text{-}Ph_4(\eta^5\text{-}C_4CO)]_2H\}Ru_2(CO)_4(\mu\text{-}H)$ (**1**), which catalyzes the reduction of a wide variety of unsaturated organic substrates (1). Shvo has proposed that $[2,3,4,5\text{-}Ph_4(\eta^5\text{-}C_4COH)Ru(CO)_2H]$ (**2**), a unique organometallic complex containing both acidic OH and hydridic

Scheme 1.

RuH functions, is the active species in the reductions. Our long term interest in complexes containing acidic and hydridic hydrogens and their growing importance in homogeneous catalysis prompted us to initiate a detailed mechanistic study of Shvo's catalytic system (2, 3). Our studies of the tolyl-substituted analogs {[2,5-Ph_2-3,4-Tol_2(η^5-C_4CO)]$_2$H}$Ru_2(CO)_4$(μ-H) (**3**) and [2,5-Ph_2-3,4-Tol_2(η^5-C_4COH)$Ru(CO)_2H$] (**4**) (Scheme 1) provided persuasive evidence that **4** reduced carbonyls and imines by a concerted hydrogen transfer mechanism (4). Alkenes appear to be reduced by a very different mechanism, probably involving CO dissociation from **4** to form a reactive 16e species.

One puzzling aspect of the chemoselectivity of catalysis by **1** was that carbonyls were efficiently reduced by either H_2 or HCO_2H, but alkenes were reduced only by H_2 (5). Shvo's proposal that hydroxycyclopentadienyl hydride **2** was the common active species in all the catalytic reactions appeared to be at odds with the observation that chemoselectivity could be affected by the choice of the reducing agent used to generate **2**. We considered the possibility that the hydroxycyclopentadienyl ruthenium formate **B** might play a direct role in reductions catalyzed by **1** that use HCO_2H as the reducing agent. Shvo had proposed the intermediacy of formate **B** but had never observed it (Scheme 2). Formate complexes have also been proposed as important intermediates in transfer hydrogenation reactions where HCO_2H is the hydrogen source and in the transition-metal-catalyzed reductions of CO_2 (6).

We initiated studies of the interaction of HCO_2H with the Shvo catalytic system to answer three questions: (*i*) Are formate complexes formed? (*ii*) Do they reduce carbonyls and (or) alkenes? (*iii*) Are they converted to hydrides, and if so, how? Here, we report the low-temperature observation of a tolyl-substituted analog of hydroxycyclopentadienyl formate **B**, its failure to reduce benzaldehyde, and mechanistic studies of its decarboxylation. These studies afford insight into the decarboxylation of formate complexes and clarify the role of HCO_2H in Shvo's catalytic system.

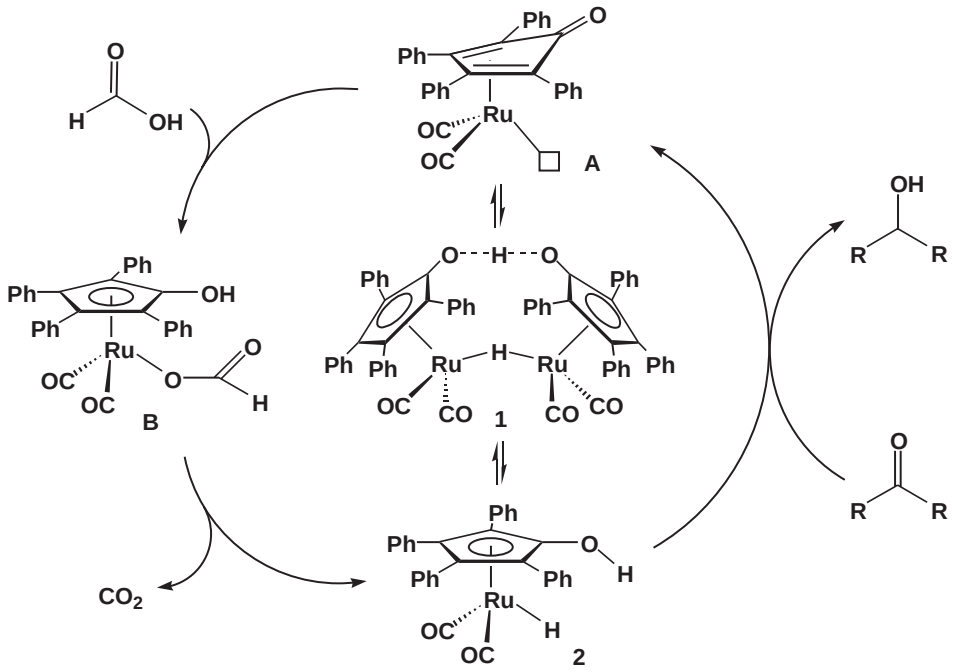
Results

Observation of a hydroxycyclopentadienyl ruthenium formate

We previously reported that heating diruthenium hydride **3** with excess HCO_2H at 80°C in THF-d_8 for 10 min led to the formation of a solution of hydroxycyclopentadienyl ruthenium hydride **4** (4). A possible intermediate in this reaction is the hydroxycyclopentadienyl formate **5**. In an effort to observe this species directly, we monitored the reaction of excess HCO_2H with a suspension of the more reactive diruthenium complex {2,5-Ph_2-3,4-Tol_2(η^5-C_4CO)$Ru(CO)_2$}$_2$ (**6**) in THF-d_8 by ^{1}H NMR spectroscopy at room temperature (Scheme 3). After 5 min, two new tolyl resonances were observed at δ 2.16 and 2.18 in 1:2 ratio in addition to the tolyl resonance of **6** at δ 2.11. The resonance at δ 2.16 and a hydride resonance at δ –9.76 were assigned to hydroxycyclopentadienyl hydride **4**. The resonance at δ 2.18 and a characteristic (7) formate resonance at δ 7.76 were assigned to the hydroxycyclopentadienyl formate complex [2,5-Ph_2-3,4-Tol_2(η^5-C_4COH)]$Ru(CO)_2$(η^1-OCHO) (**5**). After 10 min, a 1:1 ratio of **4**:**5** was observed and a small hydride resonance at δ –18.25 indicated the formation of some diruthenium hydride **3**. After 30 min, the only species seen were a 1:1 ratio of **3**:**4**; all of diruthenium complex **6** was consumed and there was no evidence for remaining intermediate formate complex **5**. The ratio of **3**:**4** remained constant for 10 h at room temperature. The mixture was converted to a solution of **4** by heating for 10 min at 80°C.

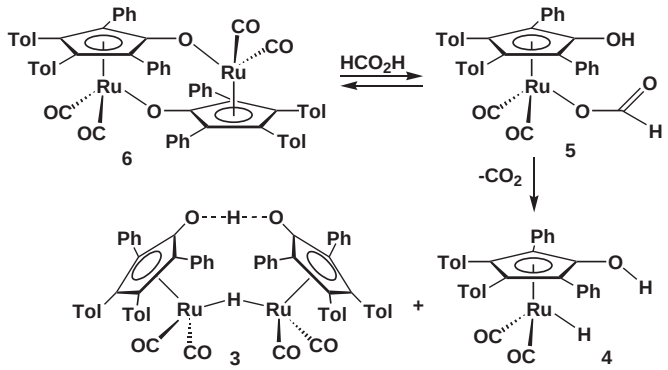
The reaction was complicated by the low solubility of dimer **6** in THF-d_8; all solid material was not dissolved until after 30 min of reaction. To circumvent these solubility problems, the reaction was also studied in CD_2Cl_2, in which **6** is more soluble. HCO_2H (0.4 M) was injected into a CD_2Cl_2 solution of **6** (0.02 M) at room temperature and the reaction was immediately monitored by ^{1}H NMR spectroscopy. After 2 min, >95% of **6** was consumed, and the major product was formate **5**, identified by a formate resonance at δ 7.87 and a tolyl resonance at δ 2.23. Hydroxycyclopentadienyl hydride **4** and diruthenium hydride **3** were present in a 4:5 ratio. The tolyl methyl resonance of **3** overlaps the resonance of **5**, so the relative amounts of **3**, **4**, and **5** were estimated by comparison of the intensity of the formate resonance to that of the hydride resonances of **3** (δ –18.63) and **4** (δ –9.81). After 5 min, dimer **6** was completely consumed, there was no evidence for remaining formate intermediate **5**, and the major products were a 2.5:1 mixture of **3**:**4**. After 20 min, the ratio of products was steady at 2.5:1. The ratio of **3**:**4** slowly changed over time; after 10 h, the ratio of **3**:**4** was 4:1.

Clean conversion of ruthenium dimer 6 to hydroxycyclopentadienyl ruthenium formate 5 at –20°C



Since evidence for the transient formation of hydroxycyclopentadienyl ruthenium formate **5** from **6** and excess HCO_2H was obtained at room temperature, low-temperature studies were initiated in an effort to observe high concentrations of **5**. HCO_2H (0.2 M) was injected into an NMR tube containing a CD_2Cl_2 solution of **6** (0.03 M) at –78°C. The tube was inserted into an NMR probe precooled to –20°C and the reaction was followed by ^{1}H NMR spectroscopy. After 30 min, 5% **6** (tolyl methyl δ 2.06) remained and 95% of the material had been converted to **5** (tolyl methyl δ 2.20, formate hydrogen δ 7.47). No further change in the equilibrium ratio (K_{eq} = [**5**]^2/[**6**][HCO_2H]^2 $\approx$ 55) was seen over the next 30 min. In the ^{13}C NMR spectrum, the formate resonance of **5** was observed at δ 172. At concentrations $\geq$0.4 M HCO_2H, no resonances for dimer **6** were observed, consistent with the estimated equilibrium constant.

Isotope labeling evidence for reversible dissociation of HCO_2H from 5



The observation of a steady ratio of **5**:**6** in the presence of excess HCO_2H requires an equilibrium process. Equilibration is readily explained by invoking dienone carbonyl inter-

Scheme 3.

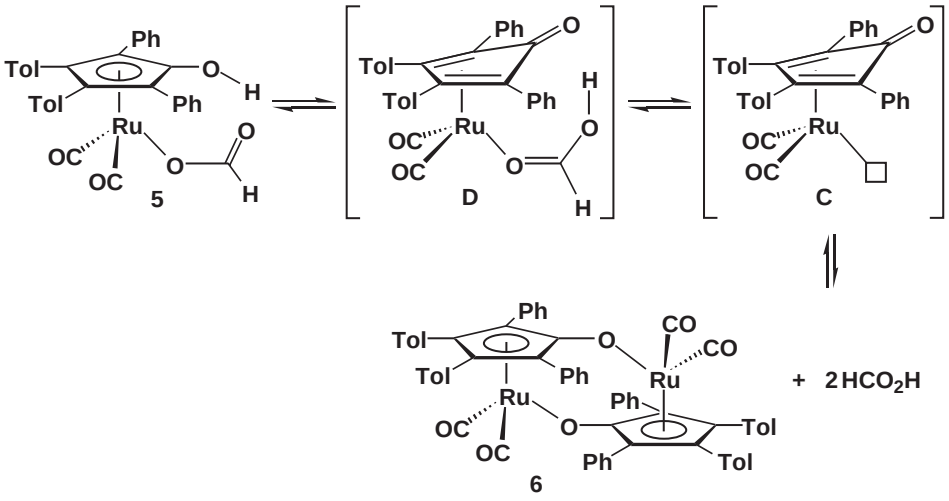
mediate **C** which can either dimerize to form **6** or react with HCO_2H to give **5**, possibly via an intermediate formic acid complex **D** (Scheme 4).

Exchange of DCO_2H with **5** occurred rapidly at –20°C and is consistent with the intervention of intermediate **C**. A solution of deuterated formate complex was prepared by addition of DCO_2H (0.3 M) to a CD_2Cl_2 solution of **6** (0.03 M) at –20°C. After 30 min, the ^{1}H NMR spectrum showed >98% conversion to [2,5-Ph_2-3,4-Tol_2(η^5-C_4COH)]Ru(CO)$_2$(η^1-OCDO) (**5-d**); no formate ^{1}H NMR resonance was observed. The tube was cooled to –78°C and an equal amount of HCO_2H (0.3 M) was added. When the tube was replaced in the NMR spectrometer at –20°C, a formate resonance was seen at δ 7.75. The integrated intensity of this resonance relative to the tolyl methyl resonance of **5** at δ 2.20 was 0.5:6, indicating a 1:1 equilibrium mixture of **5**:**5-d**. Equilibration is rapid at –20°C.

Kinetics of decarboxylation of hydroxycyclopentadienyl ruthenium formate 5

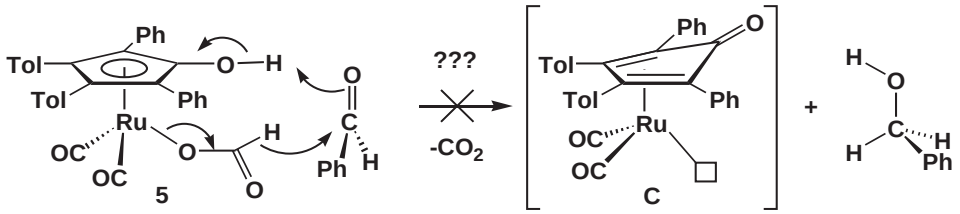
The rate of decarboxylation of **5** generated from **6** and excess HCO_2H in CD_2Cl_2 at –20°C was measured by ^{1}H NMR spectroscopy at 1°C. The major product of the decarboxylation was diruthenium hydride **3** and hydroxycyclopentadienyl hydride **4** was the minor product (10:1 ratio). Duplicate kinetic runs on 0.06 M solutions of **5**, formed from **6** and 0.2 M HCO_2H, gave k_{obs} = 5.9 and 5.8 × 10^{-4} s^{-1}. Rates were slower in the presence of higher concentrations of HCO_2H. Duplicate runs on solutions of **5** prepared from **6** and 0.4 M HCO_2H gave k_{obs} = 3.2 and 4.2 × 10^{-4} s^{-1}. Duplicate runs on solutions of **5** prepared from **6** and 1.0 M HCO_2H gave k_{obs} = 2.0 and 1.7 × 10^{-4} s^{-1}.

Isotope effects on decarboxylation were investigated using 0.06 M solutions of **5-d** prepared by adding 0.2 M DCO_2H to CD_2Cl_2 solutions of **6** at –20°C. Duplicate kinetic runs on solutions of **5-d** at 1°C gave k_{obs} = 5.6 and 5.2 × 10^{-4} s^{-1}. The isotope effect on decarboxylation, $k_5/k_{5\text{-}d}$ = 1.1 ± 0.1, was negligible.



Previous studies on decarboxylation of CpFe(CO)$_2$(η^1-OCHO) had shown that reversible CO dissociation was the first step in the decarboxylation (8). To test whether CO dissociation was involved in the decarboxylation of **5**, the rate of decarboxylation of **5** under 1.4 atm (1 atm = 101.325 kPa) of ^{13}CO was measured in the presence of 0.2 M HCO_2H at 1°C. No inhibition of decarboxylation (k_{obs} = 5.7 × 10^{-4} s^{-1}) was observed and there was no incorporation of ^{13}CO into diruthenium hydride **3** or hydroxycylopentadienyl hydride **4** (10:1 ratio of products). The formation of [2,5-Ph_2-3,4-Tol_2(η^4-C_4CO)]Ru(CO)$_2$(^{13}CO) as a byproduct (<5%) of the decarboxylation was indicated by a characteristic tolyl methyl resonance at δ 2.25 in ^{1}H NMR.

Hydroxycyclopentadienyl ruthenium formate 5 does not reduce benzaldehyde



Shvo proposed that hydroxycyclopentadienyl hydride **4** is the active hydrogen transfer agent in all the reductions catalyzed by diruthenium hydride **3**. For reductions with HCO_2H, we wished to explore the possibility that the

Scheme 4.

Scheme 5.

hydroxycyclopentadienyl formate **5** might be the active reducing agent (Scheme 5) (Formic acid and formate salts are well-known reducing agents, see ref. 9).

We devised a method for producing **5** in the presence of benzaldehyde at low temperature patterned after our earlier observation that reaction of **4** with PhCHO in the presence of CF_3CO_2H leads to the formation of benzyl alcohol and [2,5-Ph_2-3,4-Tol_2(η^5-C_4COH)]Ru$(CO)_2$(η^1-O_2CCF_3). We have proposed that the hydroxycyclopentadienyl trifluoroacetate complex is formed by addition of CF_3CO_2H to the coordinatively unsaturated intermediate **C** generated by hydrogen transfer from **4** to PhCHO.

PhCHO (0.8 M) was added to a CD_2Cl_2 solution of **4** (0.03 M) containing HCO_2H (0.5 M) at –78°C and the solution was monitored by ^{1}H NMR spectroscopy at –29°C. Rapid disappearance ($t_{0.5} \approx 1$ min) of the δ –9.74 hydride resonance of **4** and rapid appearance of resonances for $PhCH_2OH$ and **5** were observed. No further reduction of PhCHO by **5** was observed even after the temperature was raised to –15°C. These observations indicate that **4** is a much more reactive reducing agent than **5**; indeed, no observation requires that **5** act as a hydride donor.

When the above solution was warmed to 0°C, the onset temperature for decarboxylation of **5**, the resonance for $PhCH_2OH$ began growing slowly. Upon further warming to 20°C, rapid catalytic reduction of PhCHO was observed, along with the appearance of characteristic NMR resonances for diruthenium hydride **3**. After 20 min, the ratio of **5** to **3** was 1:6, unreacted HCO_2H (0.06 mmol) and PhCHO (0.10 mmol) remained, and 10 equiv of benzyl alcohol had been produced.

The above experiment does not exclude the possibility that **5** may transfer hydrogen to substrates at a rate similar to that of decarboxylation. To test for this possibility, decarboxylation of **5** was carried out at 10°C in the presence of varying amounts of PhCHO. If the rate of hydrogen transfer from **5** to PhCHO is competitive with decarboxylation, the rate of $PhCH_2OH$ formation should increase at higher PhCHO concentration. The rate of formation of $PhCH_2OH$ (δ 4.68 in ^{1}H NMR) was monitored in solutions containing 0.4 M and 0.8 M PhCHO. Plots of the concentration of $PhCH_2OH$ vs. time were linear. (The constant rate of alcohol formation is due to the nearly constant concentrations of **5,** which is continually regenerated, and of benzaldehyde, which is present in excess.) The rate of formation of benzyl alcohol did not depend on the concentration of benzaldehyde ($k = 1.20 \times 10^{-1}$ s^{-1} for 0.4 M PhCHO, and $k = 1.16 \times 10^{-1}$ s^{-1} for 0.8 M PhCHO). Therefore, the hydroxycyclopentadienyl ruthenium formate **5** does not directly reduce benzaldehyde.

Synthesis of a methoxycyclopentadienyl ruthenium formate

Our studies of the reduction of carbonyls and imines by hydroxycyclopentadienyl ruthenium hydride **4** highlighted the crucial importance of the CpOH proton in promoting hydrogen transfer. The triethylsiloxy derivative of **4**, [2,5-Ph_2-3,4-Tol_2(η^5-$C_4COSiEt_3$)]Ru$(CO)_2$H, was unreactive towards carbonyls and imines under the same conditions that **4** was highly reactive (4). The possible role of the CpOH proton of **5** in decarboxylation and hydrogen transfer reactions prompted us to investigate the reactivity of its methoxy-substituted analog.

[2,5-Ph_2-3,4-Tol_2(η^5-C_4COCH_3)]Ru$(CO)_2$(η^1-OCHO) (**7**) was synthesized in a two-step procedure from dimer **6** (Scheme 6). Reaction of excess CH_3I with **6** in CH_2Cl_2 led to the isolation of the methyoxycyclopentadienyl ruthenium

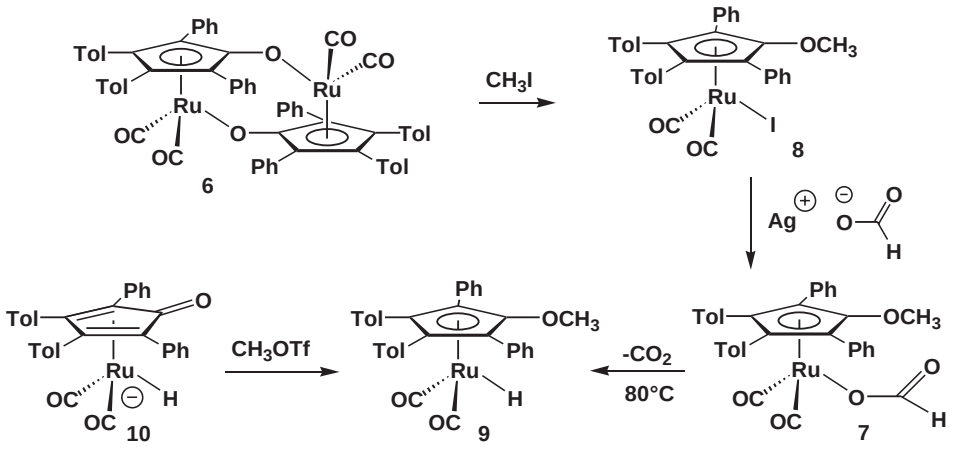
Scheme 6.



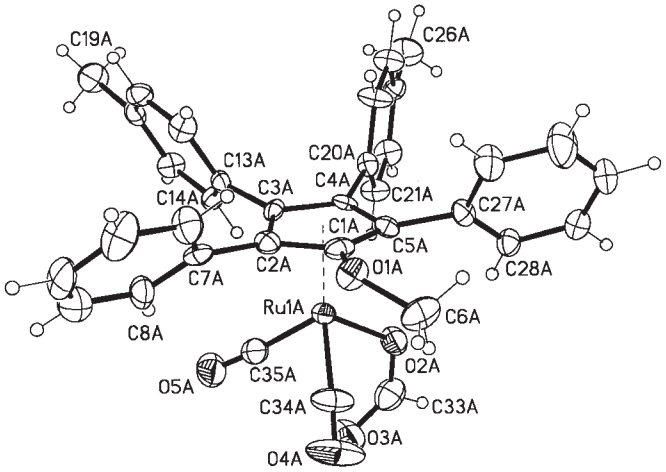


Fig. 1. X-Ray crystal structure of [2,5-Ph_2-3,4-Tol_2(η^5-C_4COCH_3)]Ru$(CO)_2$(η^1-OCHO) (**7**). Thermal ellipsoids are drawn at 50% probability.

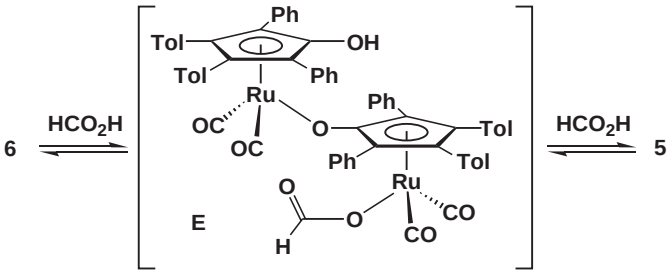
iodide [2,5-Ph_2-3,4-Tol_2(η^5-C_4COCH_3)]Ru$(CO)_2$I (**8**) as a red powder in 67% yield. Following a procedure similar to that used for the synthesis of Pd(II) formates (10), reaction of **8** with a suspension of AgOCHO in CH_2Cl_2 gave the desired methoxycyclopentadienyl ruthenium formate **7** as an off-white powder in 56% yield. **7** was thermally stable in the solid state and solution at room temperature. Addition of excess DCO_2H to a CD_2Cl_2 solution of **7** resulted in no diminution of its formate ^{1}H NMR resonance (δ 7.81) after 24 h.

Complex **7** has spectroscopic features characteristic of a metal formate complex: an IR band at 1618 cm^{-1} assigned to the ν_{asym} (CO_2) absorption (11), a formate ^{1}H NMR resonance at δ 7.81, and a formate ^{13}C NMR resonance at δ 168.3. The X-ray crystal structure of **7** confirmed its structural assignment as an O-bound η^1-formate complex (Fig. 1). The unit cell contained three molecules per asymmetric unit and two of the molecules were disordered with respect to the position of the formate and the carbon monoxide ligands. In the ordered molecule, the O(2A)—C(33A) distance (1.27 Å) and C(33A)—O(4A) distance (1.23 Å) are similar to structurally characterized η^1-formate complexes (12). The Ru(1A)—O(1A) distance (2.30 Å) and C(1A)—O(1A) distance (1.35 Å) are characteristic of η^5 coordination of the CpOMe ligand.[2]

Very slow decarboxylation of methoxycyclopentadienyl ruthenium formate 7

The high thermal stability of **7** is remarkable in comparison to the rapid decarboxylation of **5** at room temperature. Decarboxylation of **7** required heating at 80°C in THF-d_8 (k_{obs} = 1.7 × 10^{-4} s^{-1}; $t_{0.5}$ = 67 min) (Scheme 6). The major product formed in 75% yield was the methoxycyclopentadienyl ruthenium hydride [2,5-Ph_2-3,4-Tol_2(η^5-C_4COCH_3)]Ru$(CO)_2$H (**9**), which was characterized by spectroscopy (RuH at δ –9.78 in ^{1}H NMR) and by independent synthesis from NEt_4[2,5-Ph_2-3,4-Tol_2(η^4-C_4CO)Ru$(CO)_2$H] (**10**) and excess CH_3OTf. The decarboxylation of **7** was not clean and produced small amounts of four unidentified side products. In an independent control experiment, **9** was stable for 1 h at 80°C in THF-d_8. When the decarboxylation was attempted under 1.7 atm (1 atm = 101.325 kPa) of ^{13}CO at 80°C and the formate ^{1}H NMR resonance of **7** was monitored, <5% decarboxylation was observed. Over the same time, the ^{13}C NMR resonance at δ 201 for the CO ligands of **7** grew relative to the aromatic resonances, indicating ^{13}CO incorporation into **7**.

Discussion



Direct observation of hydroxycyclopentadienyl ruthenium formate 5

Shvo had proposed the intermediacy of hydroxycyclopentadienyl ruthenium formate **B** in reductions catalyzed by **1** that use HCO_2H as the reducing agent (5*b*),

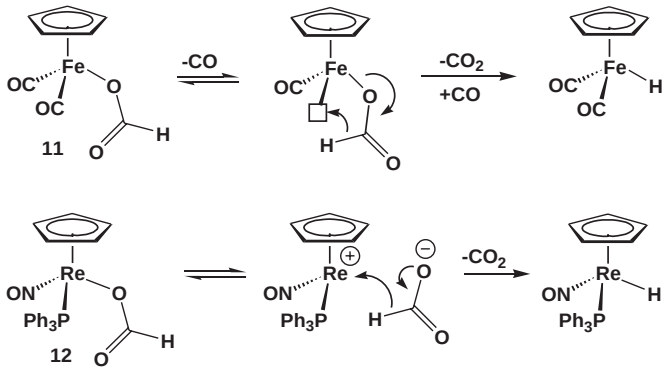
Scheme 7.

but had never observed it. We have found that the hydroxycyclopentadienyl ruthenium formate **5** is readily formed by addition of excess HCO_2H to Ru dimer **6** at low temperature. The hydroxycyclopentadienyl formate is unstable and loses CO_2 at 0°C to form hydroxycyclopentadienyl ruthenium hydride **4**. In addition, **5** undergoes rapid exchange with DCO_2H at –20°C, presumably by reversible dissociation of formic acid and formation of the unsaturated dienone dicarbonyl intermediate **C**. The rapid decarboxylation of **5** is consistent with the failure to observe it under catalytic conditions.

Mays et al. (13) reported that scrambling of two symmetric Ru dimers analogous to **6** required heating at 52°C for 55 min. The rate of dissociation of dimer **6** at –20°C should be very slow while the reaction between **6** and HCO_2H has a half-life of about 15 min at this temperature. Since the rate of addition of HCO_2H to dimer **6** is much faster than dissociation of the dimer, the mechanism of formation of **5** must involve direct addition of HCO_2H to dimer **6**, instead of dissociation of **6** to dienone intermediate **C** followed by oxidative addition of HCO_2H. A possible mechanism proceeding through the diruthenium HCO_2H adduct **E** is outlined in Scheme 7.



Hydroxycyclopentadienyl ruthenium formate 5 does not reduce benzaldehyde

At the beginning of this work, we hypothesized that the hydroxycyclopentadienyl formate **5** might be the active reducing agent in reductions of carbonyls by formic acid using the Shvo catalyst. This hypothesis seemed plausible since the formate anion has been demonstrated to act as a hydride donor in a number of organic reactions and has been shown to donate hydride directly to NAD^+ in reactions catalyzed by formate dehydrogenase (9, 14). However, we have obtained no evidence that **5** directly transfers hydrogen to carbonyls. The hydroxycyclopentadienyl formate **5** does not reduce benzaldehyde below the temperature at which it decarboxylates to give the hydroxycyclopentadienyl hydride **4**, which we have previously shown to reduce benzaldehyde very rapidly. Moreover, higher concentrations of PhCHO do not cause more rapid formation of benzyl alcohol from **5**. Therefore, the role of hydroxycyclopentadienyl formate **5** is to decarboxylate to **4** which is the active hydrogen transfer agent.

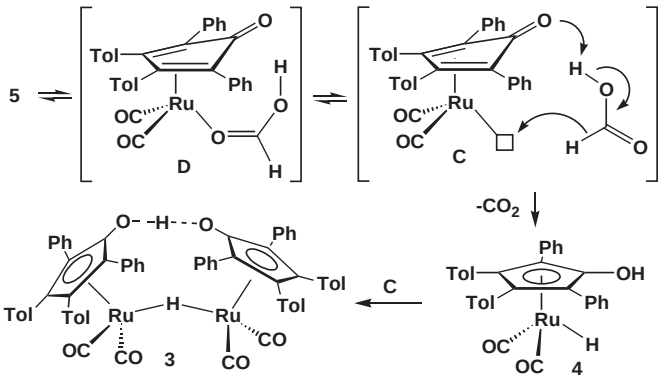
Mechanism of decarboxylation of hydroxycyclopentadienyl ruthenium formate 5

Two types of mechanism have been proposed for metal formate decarboxylations and both involve initial generation

Scheme 8.

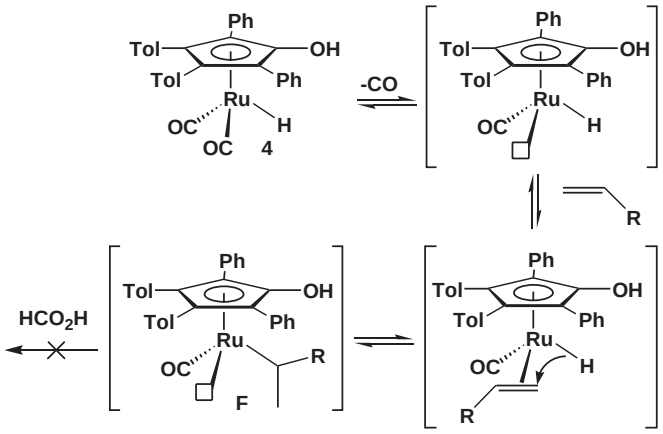
of a vacant coordination site. Darensbourg et al. (8) showed that $CpFe(CO)_2(\eta^1\text{-OCHO})$ (**11**) exchanges ^{13}CO faster than it undergoes decarboxylation, and proposed a mechanism involving CO dissociation to give an unsaturated species, followed by β-hydride elimination concurrent with CO_2 formation (Scheme 8). Based upon kinetic studies and deuterium isotope effects, Merrifield and Gladysz (15) proposed that decarboxylation of $CpRe(NO)(PPh_3)(\eta^1\text{-OCHO})$ (**12**) proceeds by dissociation of formate ion to form a tight ion pair, followed by hydride transfer from the formate ion to the unsaturated rhenium cation. Our evidence suggests that the decarboxylation of **5** does not proceed by either type of mechanism.

The hydroxy group on the cyclopentadienyl ring of **5** plays a crucial role in the decarboxylation since **5** decomposes at temperatures 79° lower ($t_{0.5}$ = 19 min at 1°C) than the corresponding methoxycyclopentadienyl formate complex **7** ($t_{0.5}$ = 67 min at 80°C). CO inhibition of the decarboxylation of **7** and ^{13}CO exchange into **7** at 80°C provides persuasive evidence that CO dissociation is the initial step in the decarboxylation of **7**, just as it is in the case of iron formate **11**. However, since CO does not inhibit decarboxylation of **5** and since ^{13}CO does not exchange into **5** and is not incorporated into its decarboxylation products, it is clear that decarboxylation of **5** does not involve CO dissociation.



The huge difference in the rates of decarboxylation between **5** and **7** is also inconsistent with a simple ion pair mechanism as proposed by Merrifield and Gladysz (15) for rhenium formate **12**. If **5** decomposed by an ion-pair mechanism, then the same pathway should have been available to **7** and the compounds should have undergone decarboxylation at similar rates.

Any viable mechanism for the decarboxylation of **5** must account for: (*i*) the much faster decarboxylation of **5** compared to its CpOMe derivative **7**; (*ii*) the lack of CO inhibition of the rate of decarboxylation of **5**; (*iii*) the lack of ^{13}CO incorporation into **5** or its decarboxylation products; (*iv*) the rapid exchange of DCO_2H with **5**; (*v*) a negligible deuterium isotope effect on decarboxylation of $k_5/k_{5\text{-}d}$ = 1.1 ± 0.1; (*vi*) and slower decarboxylation at higher HCO_2H concentration.



The mechanism shown in Scheme 9 provides an attractive explanation for these observations. The CpOH proton plays a special role in the formation of unsaturated dienone intermediate **C** and formic acid via a formic acid complex **D**. The

© 2001 NRC Canada

Scheme 9.

Scheme 10.

very rapid and reversible dissociation of formic acid from **D** explains DCO_2H exchange with **5**. The key step in the decarboxylation is a slower concerted transfer of hydride from the carbon of formic acid to ruthenium of **C** and of proton from the oxygen of formic acid to the dienone carbonyl of **C** that produces hydroxycyclopentadienyl hydride **4** and CO_2. The slower decarboxylation at higher formic acid concentration can be explained by stabilization of **5** by hydrogen bonding between formic acid and the formate ligand of **5** that must be broken up in the formation of **C** (16).[3]

A primary deuterium isotope effect would be expected for this mechanism. In other formate decarboxylations, k_H/k_D was 1.55 for the decarboxylation of rhenium formate **12** (15), 3.1 for the Rh-catalyzed transfer hydrogenation of itaconic acid with HCO_2H (17), and 2.2 for hydride transfer from HCO_2^- to NAD^+ catalyzed by formate dehydrogenase (13b). While the small to negligible isotope effect observed in the decarboxylation of **5** is troublesome, we have not been able to devise a satisfactory alternative mechanism.

Relevance to Shvo catalytic system

Our studies show how HCO_2H reduces carbonyl compounds in the Shvo catalytic system. Formic acid first reacts with ruthenium species to generate the transient hydroxycyclopentadienyl formate complex **5**. This formate complex is not itself a hydride transfer agent but it undergoes rapid decarboxylation to generate the hydroxycyclopentadienyl hydride **4**. This hydride then rapidly reduces carbonyl compounds. The unsaturated dienone dicarbonyl intermediate **C** generated in this process rapidly reacts with formic acid to regenerate **5** and continue the catalytic cycle or reacts with **4** to generate the diruthenium hydride complex **3**, which can slowly reenter the catalytic cycle by reaction with HCO_2H.

Our results also help explain why the Shvo system does not catalyze the reduction of alkenes by HCO_2H. We have shown that while hydroxycyclopentadienyl hydride **4** rapidly reduces aldehydes, it reduces alkenes only under a hydrogen atmosphere. We suggest that alkene reduction proceeds via CO dissociation from **4**, coordination of an alkene, and reversible hydride migration to give unsaturated alkyl intermediate **F**. H_2 addition to **F** leads to alkene reduction but HCO_2H interaction with intermediate **F** does not lead to alkane formation (Scheme 10). However, further experiments are needed to more fully understand the catalytic reactions of **4** with alkenes.

The much more rapid decarboxylation of hydroxycyclopentadienyl formate **5** than methoxycyclopentadienyl formate **7** highlights the crucial importance of an acidic proton in promoting decarboxylation. In related work on the hydrogenation of CO_2 to formic acid catalyzed by $[Rh(norbornadiene)(PMe_2Ph)_3]BF_4$ and by $Ru(PMe_3)_4H_2$, Tsai and Nicholas (18*a*) and Noyori and co-workers (18*b*) have independently proposed that the acidic proton of a coordinated water interacts with CO_2 to promote hydride addition to generate formate intermediates. Earlier we reported that the acidic CpOH proton of **4** is required for concerted hydride addition to carbonyl compounds (4). A deeper understanding of the role of acidic protons in mediating the formation and consumption of CO_2 by transition metal complexes should lead to more efficient catalysts for both transfer hydrogenation and CO_2 reduction.

Experimental

General methods

Manipulations of air and moisture sensitive compounds were performed in a nitrogen atmosphere glovebox or using standard high-vacuum line techniques. THF-d_8, toluene, and hexane were distilled from sodium–benzophenone. CH_2Cl_2 and CD_2Cl_2 were distilled from CaH_2. PhCHO (Amend) was distilled immediately before use. 96% HCO_2H (Aldrich) and 95% DCO_2H (Aldrich) were stored under nitrogen. Syntheses of $\{[2,5\text{-}Ph_2\text{-}3,4\text{-}Tol_2(\eta^5\text{-}C_4CO)]_2H\}Ru_2(CO)_4(\mu\text{-}H)$ (**3**), $[2,5\text{-}Ph_2\text{-}3,4\text{-}Tol_2(\eta^5\text{-}C_4COH)Ru(CO)_2H]$ (**4**), $\{2,5\text{-}Ph_2\text{-}3,4\text{-}Tol_2(\eta^5\text{-}C_4CO)]Ru(CO)_2\}_2$ (**6**), and $NEt_4[2,5\text{-}Ph_2\text{-}3,4\text{-}Tol_2(\eta^4\text{-}C_4CO)Ru(CO)_2H]$ (**10**) were previously described (4). AgOCHO was synthesized by the method of Yamamoto and co-workers (19). All other reagents were used as received.

[3] Puddephatt and co-workers observed slower $[Ru_2(\mu\text{-}CO)(CO)_4(\mu\text{-}dppm)_2]$ catalyzed decarboxylation of formic acid at higher HCO_2H concentrations. His proposed mechanism involved HCO_2^- in the rate determining step; higher concentration of formic acid was suggested to shift the equilibrium to a less reactive hydrogen bonded adduct $[(HCO_2)_2H]^-$.

© 2001 NRC Canada

^{1}H NMR were obtained on a Bruker AC 250, Bruker AC 300, or Varian Unity 500 spectrometer. ^{13}C NMR spectra were obtained on a Varian Unity 500 spectrometer operating at 125 MHz. IR spectra were measured on a Mattson Polaris FT-IR spectrometer. Mass spectra were determined on a VG AutoSpec M mass spectrometer. Elemental analysis was performed by Desert Analytics of Tucson, Arizona.

Addition of HCO_2H to 6 in THF-d_8

HCO_2H (6.8 μL, 0.18 mmol, 0.4 M) was added to a THF-d_8 solution of **6** (11 mg, 0.01 mmol, 0.02 M) at –78°C. The reaction was monitored by ^{1}H NMR spectroscopy at room temperature. Spectra were obtained at 5 min intervals for 35 min, until the solution was homogeneous and **6** had been completely consumed. After 10 h, the relative amounts of **3** and **4** were measured. During the reaction, the tube was periodically shaken to dissolve the remaining solid material.

Addition of HCO_2H to 6 in CD_2Cl_2

HCO_2H (6.3 μL, 0.17 mmol, 0.4 M) was added to a CD_2Cl_2 solution of **6** (12 mg, 0.01 mmol, 0.02 M) at –78°C. The homogeneous solution was monitored by ^{1}H NMR spectroscopy at room temperature. Spectra were obtained at 5 min intervals for 30 min, until **6** had been completely consumed. After 10 h, the relative amounts of **3** and **4** were measured.

[2,5-Ph_2-3,4-Tol_2(η^5-C_4COH)]Ru(CO)$_2$(η^1-OCHO) (5)

HCO_2H (3.2 μL, 0.08 mmol, 0.2 M) was added to a CD_2Cl_2 solution of **6** (13 mg, 0.01 mmol, 0.03 M) and the tube inserted into an NMR probe precooled to –20°C. After 30 min, the area ratio of the tolyl methyl resonances at δ 2.20 (**5**):δ 2.06 (**6**) was 20:1. For **5**, ^{1}H NMR (CD_2Cl_2, 500 MHz) δ: 2.20 (s, 6H, tolyl CH_3), 6.84 (AA′BB′, 8H, tolyl), 7.32 (m, 6H, phenyl), 7.42 (m, 4H, phenyl), 7.47 (s, OCHO). ^{13}C NMR (CD_2Cl_2,125 MHz) δ: 21.8 (tolyl CH_3), 87.9 (C 3,4 of Cp), 99.1 (C 2,5 of Cp), 126.7–138.7 (8 resonances aromatic), 147.0 (C1 of Cp), 172.0 (OCHO), 199.2 (CO). Four aliquots of 3.2 μL of HCO_2H were added at –78°C to the solution of **5** in CD_2Cl_2 containing 0.2 M HCO_2H. After the addition of each aliquot, the NMR tube was reinserted into the probe cooled to –20°C and a ^{1}H NMR spectrum was obtained. The ^{1}H NMR chemical shifts of the formate hydrogen of **5** changed by 0.36 ppm with concentration: [HCO_2H], δ **5**; 0.2 M, 7.47; 0.4 M, 7.67; 0.6 M, 7.76; 0.8 M, 7.80; 1.0 M, 7.83. Over the same concentration range, the formate hydrogen of free formic acid changed by 0.18 ppm from δ 7.92 to 8.10.

Exchange of [2,5-Ph_2-3,4-Tol_2(η^5-C_4COH)]Ru(CO)$_2$(η^1-OCDO) (5-d) with HCO_2H

DCO_2H (5.2 μL, 0.13 mmol, 0.3 M) was added to a CD_2Cl_2 solution of **6** (15 mg, 0.01 mmol, 0.03 M) at –78°C. The tube was placed in an NMR probe precooled to –20°C and the reaction monitored by ^{1}H NMR. After 30 min, >98% conversion to **5-d** was observed. No formate hydrogen resonance in the region between δ 7.50 and δ 8.00 was visible. The tube was removed and cooled to –78°C. HCO_2H (5μL, 0.12 mmol, 0.3 M) was added via syringe and the tube replaced in the spectrometer at –20°C. A formate resonance at δ 7.75 was observed in the ^{1}H NMR spectrum.

Kinetics of decarboxylation of 5

HCO_2H (3 μL, 0.1 mmol, 0.2 M) was added to a CD_2Cl_2 solution of **6** (15 mg, 0.01 mmol, 0.03 M) at –78°C. The tube was placed in an NMR probe precooled to –20°C and the reaction monitored by ^{1}H NMR as described above. The NMR tube was removed from the probe and cooled to –78°C. The NMR probe was warmed to 1 ± 0.5°C and the tube reinserted. Decarboxylation was monitored by the disappearance of the resonance for phenyl protons at δ 7.45 in the ^{1}H NMR spectrum. The reaction followed first order kinetics to >80% conversion. See *Results*.

Decarboxylation of 5 under ^{13}CO

HCO_2H (2.9 μL, 0.08 mmol, 0.2 M) was added to a CD_2Cl_2 solution of **6** (14 mg, 0.01 mmol, 0.03 M) at –78°C. The tube was placed in an NMR probe precooled to –20°C and the reaction monitored by ^{1}H NMR spectroscopy until **5** and **6** had reached equilibrium. The tube was removed from the probe, cooled to –78°C, degassed, and ^{13}CO (1 atm) (1 atm = 101.325 kPa) was added. The tube was placed in an NMR probe precooled to 1 ± 0.5°C and the rate of decarboxylation of **5** was measured as described above (k_{obs} = 5.7×10^{-4} s^{-1}, $t_{0.5}$ = 20 min).

Competition between 4 and 5 in PhCHO reduction

Diruthenium hydride **3** (12 mg, 0.01 mmol) in THF was degassed and placed under 1 atm (1 atm = 101.325 kPa) of H_2 at –78°C. The tube was sealed at –78°C and heated to 80°C for 8 h. THF was evaporated and CD_2Cl_2 was condensed in to dissolve the yellow, oily solid. The solution was cooled to –78°C and HCO_2H (10 μL, 0.26 mmol, 0.5 M) and PhCHO (30 μL, 0.29 mmol, 0.8 M) were added successively via syringe. The tube was placed in an NMR probe precooled to –29°C. The reaction was monitored at –29°C for 25 min, at –15°C for 10 min, at 0°C for 10 min, and at 21°C for 20 min. See *Results*.

Effect of PhCHO concentration on rate of benzyl alcohol formation

Two identical solutions of **5** were prepared by addition of HCO_2H (7.8 μL, 0.2 mmol, 0.5 M) to CD_2Cl_2 solutions of Ru dimer **6** (15 mg, 0.01 mmol, 0.025 M) at –78°C. Tubes containing the solutions were placed into an NMR probe precooled to –20°C and the reaction monitored by ^{1}H NMR until no **6** was observable in the ^{1}H NMR spectrum. The tubes were cooled to –78°C and 17 μL PhCHO (0.16 mmol, 0.4 M) was syringed into one tube and 34 μL PhCHO (0.32 mmol, 0.8 M) was syringed into the second tube. The tubes were placed in an NMR probe precooled to 10 ± 0.5°C and the rate of appearance of the ^{1}H NMR resonance for $PhCH_2OH$ (δ 4.68) was monitored for 40 min. Plots of the concentration of $PhCH_2OH$ were linear. For 0.4 M PhCHO, $k = 1.20 \times 10^{-1}$ s^{-1}; for 0.8 M PhCHO, $k = 1.16 \times 10^{-1}$ s^{-1}.

[2,5-Ph_2-3,4-Tol_2(η^5-C_4COCH_3)]Ru(CO)$_2$I (8)

Reaction of **6** (200 mg, 0.17 mmol) with CH_3I (400 μL, 6.40 mmol) in CH_2Cl_2 (10 mL) for 40 h at room temperature followed by evaporation of solvent under vacuum gave a red, oily solid. Chromatography on silica gel using 1:1 CH_2Cl_2:hexane afforded **8** as a red powder (167 mg, 67%), mp 195–202°C (dec). IR (CH_2Cl_2) (cm^{-1}): 2033 (s), 1988

(s). ^{1}H NMR (CD_2Cl_2, 300 MHz) δ: 2.21 (s, 6H, tolyl CH_3), 3.45 (s, OCH_3), 6.87 (AA′BB′, 8H, tolyl), 7.32 (m, 6H, phenyl), 7.53 (m, 4H, phenyl). ^{13}C NMR (CD_2Cl_2, 125 MHz) δ: 21.2 (tolyl CH_3), 62.9 (OCH_3), 88.0 (C3,4 of Cp), 102.4 (C2,5 of Cp), 126.8–138.8 (8 resonances, aromatic), 147.0 (C1 of Cp), 198.2 (CO). Anal. calcd. for $C_{34}H_{27}O_3RuI$: C 57.39, H 3.82; found: C 57.56, H 3.77.

[2,5-Ph_2-3,4-Tol_2(η^5-C_4COCH_3)]Ru(CO)$_2$(η^1-OCHO) (7)

A suspension of AgOCHO (150 mg, 0.87 mmol) in a solution of **8** (130 mg, 0.18 mmol) in CH_2Cl_2 (10 mL) was stirred for 18 h at room temperature until IR monitoring indicated complete consumption of **8**. The mixture was filtered to give a light green solution. Evaporation of solvent and chromatography of the resulting green solid on silica gel using 3:1 CH_2Cl_2:acetone gave **7**, as an off-white powder (75 mg, 56%), mp 130–135°C (dec). IR (CH_2Cl_2) (cm^{-1}): 2043 (s), 1993 (s), 1618 (m). ^{1}H NMR (CD_2Cl_2, 300 MHz) δ: 2.20 (s, 6H, tolyl CH_3), 3.46 (s, OCH_3), 6.84 (AA′BB′, 8H, tolyl), 7.32 (m, 6H, phenyl), 7.48 (m, 4H, phenyl), 7.81 (s, OCHO). ^{13}C NMR (CD_2Cl_2, 125 MHz) δ 21.2 (tolyl CH_3), 62.0 (OCH_3), 88.4 (C 3,4 of Cp), 102.5 (C 2,5 of Cp), 126.7–138.7 (8 resonances, aromatic), 143.7 (C1 of Cp), 168.3 (OCHO), 198.8 (CO). Anal. calcd. for $C_{35}H_{28}O_5Ru$: C 66.76, H 4.48; found: C 66.56, H 4.38.

Decarboxylation of 7

A THF-d_8 solution of **7** (0.03 M) containing ferrocene as an internal standard was heated at 80 ± 0.2°C. The disappearance of the ^{1}H NMR resonance for -OCHO (δ 7.68) was monitored at 20, 66, 119, and 194 min; $k_{obs} = 1.7 \times 10^{-4}$ s^{-1}, $t_{0.5}$ = 67 min. The major product was [2,5-Ph-3,4-Tol(η^5-C_4COCH_3)]Ru(CO)$_2$H (75%); four unidentified minor products were also observed.

Decarboxylation of 7 in the presence of ^{13}CO

A THF-d_8 solution of **7** (0.03 M) containing ferrocene as an internal standard was heated to 80 ± 0.2°C under ^{13}CO (1 atm added at –78°C (1 atm = 101.325 kPa)). The disappearance of the ^{1}H NMR resonance for -OCHO (δ 7.68) was monitored at 30, 60, and 120 min. ^{1}H NMR showed that <5% of **7** had reacted after 2 h. ^{13}C NMR showed dramatic growth of the CO resonance of **7** (δ 201) relative to aromatic resonances of **7**.

[2,5-Ph_2-3,4-Tol_2(η^5-C_4COCH_3)]Ru(CO)$_2$H (9)

Addition of CH_3OTf (250 μL, 2.2 mmol) to a suspension of NEt_4[2,5-Ph_2-3,4-Tol_2(η^4-C_4CO)Ru(CO)$_2$H] (**10**) (225 mg, 0.31 mmol) in toluene (10 mL) gave a green solution with a white precipitate. The solution was filtered and solvent evaporated under vacuum. The residue was dissolved in hexane (5 mL), filtered through a glass wool, and cooled to –30°C for 18 h to give **9** (40 mg, 22%) as a yellow precipitate. IR (CH_2Cl_2) (cm^{-1}): 2018 (s), 1958 (s). ^{1}H NMR (CD_2Cl_2, 300 MHz) δ: –9.80 (s, RuH), 2.21 (s, 6H, tolyl CH_3), 3.42 (s, 3H, OCH_3), 6.86 (d, ^3J = 8.4 Hz, 4H, tolyl), 6.96 (d, ^3J = 8.4 Hz, 4H, tolyl), 7.25 (m, 6H, phenyl), 7.37 (m, 4H, phenyl). ^{13}C NMR (CD_2Cl_2, 125 MHz) δ: 21.2 (tolyl CH_3), 66.9 (OCH_3), 94.9 (C 3,4 of Cp), 104.6 (C 2,5 of Cp), 127.9–137.5 (8 resonances, aromatic), 138.9 (C1 of Cp), 202.1 (CO). HR-MS (EI) calcd. for $C_{34}H_{28}O_3Ru$: 586.1075; found: 586.1029.

X-ray crystal structure determination of [2,5-Ph_2-3,4-Tol_2(η^5-C_4COCH_3)]Ru(CO)$_2$(η^1-OCHO) (7)

X-ray quality crystals were grown by slow evaporation of a CH_2Cl_2–hexane solution of **7**. A yellow plate-shaped crystal of dimensions 0.38 × 0.25 × 0.21 mm was selected for structural analysis. Intensity data for this compound were collected using a Bruker SMART ccd area detector mounted on a Bruker P4 goniometer using graphite-monochromated Mo Kα radiation (λ = 0.71073 Å). The sample was cooled to 133(2) K. The intensity data, which nominally covered 1.5 hemispheres of reciprocal space, were measured as a series of *f* oscillation frames each of 0.4° for 60 s per frame. The detector was operated in 512 × 512 mode and was positioned 5.00 cm from the sample. Coverage of unique data was 98.8% complete to 25.00 deg in θ. Cell parameters were determined from a nonlinear least-squares fit of 5158 peaks in the range $3.30 < \theta < 25.32°$. The first 50 frames were repeated at the end of data collection and yielded 459 peaks showing a variation of –0.15% during the data collection. A total of 30 480 data were measured in the range $3.28 < \theta < 25.00°$. The data were corrected for absorption by the empirical method (20) giving min and max transmission factors of 0.8084 and 0.8871. The data were merged to form a set of 15 000 independent data with R(int) = 0.0586.

The orthorhombic space group $P2(1)2(1)2(1)$ was determined by systematic absences and statistical tests and verified by subsequent refinement. The structure was solved by direct methods and refined by full-matrix least-squares methods on F^2 (21). Hydrogen atom positions were initially determined by geometry and were refined using a riding model. Non-hydrogen atoms were refined with anisotropic displacement parameters. A total of 1210 parameters were refined against 216 restraints and 15 000 data to give $wR(F^2) = 0.1067$ and $S = 1.010$ for weights of $w = 1/[\sigma^2 (F^2) + (0.0300P)^2 + 2.2000P]$, where $P = [F_o^2 + 2F_c^2]/3$. The final $R(F)$ was 0.0483 for the 11 005 observed, $[F > 4\sigma(F)]$, data. The largest shift/s.u. was 0.003 in the final refinement cycle. The final difference map had maxima and minima of 0.581 and –0.505 e $Å^{-3}$, respectively. The absolute structure was determined by refinement of the Flack parameter (22).

Polymerization of 1-hexene catalyzed by Cp^*TiMe_3-$B(C_6F_5)_3$; a mechanistic and structural study

Michael C. Murray and Michael C. Baird

Abstract: Solutions of the Ziegler–Natta system Cp^*TiMe_3 – $B(C_6F_5)_3$ in toluene catalyze the polymerization of 1-hexene to mixtures of atactic poly-1-hexenes and complex oligomeric materials, which were characterized by ^1H and $^{13}C\{^1H\}$ NMR spectroscopy and gel permeation chromatography (GPC). The polymer molecular weights and the relative proportions of polymers and oligomers vary with temperature, monomer:catalyst ratios, and degree of dilution and may generally be rationalized in terms of a conventional Ziegler–Natta mechanism. The $^{13}C\{^1H\}$ NMR spectra of the polymers exhibit resonances suggesting significant degrees of 2,1-insertions during propagation, while experiments utilizing $Cp^*Ti(^{13}CH_3)_3$ verify that initiation in toluene involves predominantly via 1,2-insertion of the first monomer unit but that 2,1-insertions occur up to 15–20% of the time in CH_2Cl_2. NMR experiments involving $Cp^*Ti(^{13}CH_3)_3$ demonstrate that both methyl groups in the presumed active species $Cp^*TiMe_2^+$ are incorporated into polymer

Key words: titanium, polymers, polymerization, Ziegler–Natta.

Résumé : Des solutions dans le toluène du système de Ziegler–Natta Cp^*TiMe_3 – $B(C_6F_5)_3$ catalysent la polymérisation du hex-1-ène en mélanges de polyhex-1-ènes atactiques et à des matériaux oligomères que l'on a caractérisés par spectroscopie RMN du ^1H et du $^{13}C\{^1H\}$ et par chromatographie par perméation de gel (CPG). Les poids moléculaires et les proportions relatives des polymères et des oligomères varient avec la température, les rapports monomère/catalyseur et le degré de dilution et on peut généralement les rationaliser en fonction d'un mécanisme de Ziegler–Natta conventionnel. Les spectres RMN du $^{13}C\{^1H\}$ des polymères comportent des résonances qui suggèrent des degrés significatifs d'insertions 2,1 au cours de la propagation alors que des expériences à l'aide de $Cp^*Ti(^{13}CH_3)_3$ permettent de confirmer que l'initiation dans le toluène implique principalement une insertion 1,2 de la première unité de monomère mais que des insertions 2,1 se produisent dans 15 à 20 % des cas dans le CH_2Cl_2. Des expériences de RMN impliquant $Cp^*Ti(^{13}CH_3)_3$ démontrent les polymères incorporent les deux groupes méthyles présumément actifs des espèces $Cp^*TiMe_2^+$.

Mots clés : titane, polymères, polymérisation, Ziegler–Natta.

[Traduit par la Rédaction]

Introduction

The utilization of metallocenes of the type Cp'_2MR_2 (M = Ti, Zr, Hf; R = alkyl; Cp′ = substituted cyclopentadienyl) as homogeneous olefin polymerization catalyst precursors has received considerable attention in recent years, in large part because of the high degrees of stereoregularity and the narrow molecular weight distributions that are often possible (1). Activation is readily achieved by alkyl abstraction reactions involving, e.g., Lewis acid cocatalysts such as the borane $B(C_6F_5)_3$ (eq. [1]), which give the formally $14e^-$ cationic species $[Cp'_2MR]^+$; these are believed to be the actual catalysts.

[1] $$Cp'_2MR_2 + B(C_6F_5)_3 \rightarrow [Cp'_2MR]^+ + [BR(C_6F_5)_3]^-$$

Similar species are apparently formed on treating, for example, metallocene dihalides with the oligomeric methylalumoxane (MAO), and commercially viable processes are based on use of this cocatalyst. Of increasing importance is the utilization of such catalyst systems to prepare homo- and copolymers of α-olefins such as 1-hexene (2), of interest both from the perspective of understanding mechanisms of α-olefin polymerization and because of the high commercial importance of materials such as polyethylene-co-1-hexene (linear low-density polyethylene, LLDPE).

We (3) and others (4) have reported the analogous utilization of monocyclopentadienyl–titanium olefin polymerization systems, often based on activation of Cp^*TiMe_3 by $B(C_6F_5)_3$ (eq. [2]).

[2] $$Cp^*TiMe_3 + B(C_6F_5)_3 \rightarrow Cp^*TiMe_2(\mu\text{-}Me)B(C_6F_5)_3 \ (\mathbf{I})$$

[a]Value in parentheses represents volume of toluene (mL).
[b]M_{W_P} = most probable molecular weight (peak maximum), PD = polydispersity.

The active species $Cp^*TiMe_2(\mu\text{-}Me)B(C_6F_5)_3$ (**I**) behaves as a source of the $10e^-$ cationic complex $[Cp^*TiMe_2]^+$, which is an extremely active initiator for both Ziegler–Natta and carbocationic polymerization reactions (3, 4). Increasing attention has also recently been devoted to polymerization of α-olefins such as 1-hexene by mono- and non-cyclopentadienyl metal compounds (5). We have previously shown that **I** is an active initiator for the polymerization of 1-hexene (3*h*), and we provide here further details of this investigation. We also provide insight into the mechanisms by which this process occurs, and the unusual microstructures of the resulting polymers. The effects of temperature, catalyst, and monomer concentration on the yields, molecular weights, molecular weight distributions, and stereo- and regio-regularities of the materials produced are used to extract mechanistic insight into the polymerization processes.

Experimental

All operations were performed under purified argon using normal Schlenk techniques or a Vacuum Atmospheres Dry Lab. Solvents were purified by standard methods, and distilled and degassed before use. All 1D ^1H, ^{13}C, and $^{13}C\{^1H\}$ NMR spectra and 2D COSY and HMQC spectra were recorded using Bruker Avance 400 or 500 spectrometers in CD_2Cl_2 or $CDCl_3$ (polymers), chemical shifts being determined by reference to residual ^1H and ^{13}C solvent peaks. Calculations of ^{13}C chemical shifts were carried out utilizing commercial software (6). Gel permeation chromatography (GPC) experiments with the polymers were carried out at room temperature using a Waters Model 440 liquid chromatograph or a Waters Model 2690 with THF as eluent and polystyrene standards. The compounds Cp^*TiMe_3 (7*a*), $Cp^*Ti(^{13}CH_3)_3$ (3*c*), and $B(C_6F_5)_3$ (7*b*) were prepared as reported previously.

Purification of 1-hexene was effected by stirring over CaH_2 followed by vacuum distillation. In a typical polymerization run, a toluene solution of $B(C_6F_5)_3$ (31 mg, 0.06 mmol) was added to a stirred toluene solution of Cp^*TiMe_3 (14 mg, 0.06 mmol) and 1-hexene (3 mL, 24 mmol). The reaction was quenched after 30 min by the addition of MeOH, all of the volatile materials were removed under reduced pressure, and the resulting polymer residue was dissolved in hexanes (40 mL) and passed through 10 g of silica gel to remove the purple catalyst residue. The reaction flask and column were washed with hexanes (3 × 40 mL), the fractions were combined, and the solvent was removed under reduced pressure. The resulting polymer mixtures were analyzed by ^1H and $^{13}C\{^1H\}$ NMR spectroscopy and GPC. Fractionation of several samples was effected by reduced pressure trap-to-trap distillation of a low boiling oligomeric fraction. The high molecular weight polymer fractions were then analyzed by ^1H and $^{13}C\{^1H\}$ NMR spectroscopy and GPC; the low molecular weight fraction by ^1H and $^{13}C\{^1H\}$ NMR spectroscopy. Experimental conditions and results are outlined in greater detail in Table 1, where data are given for the polymeric materials obtained. The data given are, in most cases, averages of the results of two or more experiments, with the experimental errors as indicated. Conversions are given as percentages of the 1-hexene polymerized.

Results and discussion

Polymer syntheses and properties

Abstraction of a methyl ligand from Cp^*TiMe_3 by 1 equiv of the Lewis acid $B(C_6F_5)_3$ produces the polymerization initiator $Cp^*TiMe_2(\mu\text{-}Me)B(C_6F_5)_3$ (**I**, eq. [2]). In a typical polymerization run, a toluene solution of $B(C_6F_5)_3$ was added to a solution of Cp^*TiMe_3 in 1-hexene or in toluene–1-hexene; polymerization runs were carried out at various monomer:catalyst ratios, degrees of dilution, and temperatures, although it should be noted that those conducted at room temperature and above were not thermostatted effectively and generally became quite warm. In most of the polymerization runs, the viscosity of the solutions increased noticeably within minutes, indicating that extensive polymerization had occurred.

A summary of experimental data, conversions, and molecular weights for representative polymerization runs is pre-

sented in Table 1. As we wished to acquire catalyst activity data, most of the polymerization runs were terminated after 0.5 h, although higher conversions were shown to be possible by allowing the reactions, in some cases, to proceed for longer periods of time. Experiment 1, for instance, was begun at –30°C but allowed to warm to +6°C over 12 h, and as can be seen, the conversion is relatively high although we cannot in fact reliably estimate the activity in this case. The catalyst system is very sensitive to trace impurities, especially Lewis bases and proton sources, and many of the runs were carried out several times to check for reproducibility.

As may be noted in Table 1, most experiments involved a monomer:catalyst ratio of 400:1 in 5 mL toluene. In most of these cases, bimodal distributions of polymers were obtained with a very high molecular weight fraction (M_w varying from $>10^5$ at low temperatures to 4.5×10^4 at room temperature) and a low molecular weight fraction ($M_w \leq 10^4$). In addition to these two polymer fractions, most reactions also produced small amounts of very low molecular weight liquid oligomers (0–25% of the total); these could be removed by trap-to-trap distillation, as described in the *Experimental* section. Although in some cases oligomers were the major product, they were little studied; however, consideration of the relative intensities of the olefinic resonances in the ^{1}H NMR spectra of several suggested that M_n ~250.

As is clear from Table 1 (expt. 2, 4, 5), there is a general inverse relationship between temperature and molecular weights of the high molecular weight fractions. This trend is consistent with earlier results on, e.g., the polymerization of propylene by **I** (3*k*) and of 1-hexene by metallocenes (2*f*), and presumably is to be attributed to an increased rates of propagation relative to rates of chain termination – transfer. Complementing these results, it was also found that decreasing the monomer:catalyst ratios to 130:1 and 44:1, i.e., by

Fig. 3. $^{13}C\{^{1}H\}$ NMR spectrum of crude poly–oligo-1-hexene.

factors of ~3 and ~9, respectively, resulted in drastically decreased molecular weights in the more monomer starved systems; similar behaviour has been reported for other systems (5*d*). Maintaining the monomer:catalyst ratio at 400:1 while diluting the reaction mixtures (15 mL toluene) also resulted in decreases in molecular weights; presumably the rate of (bimolecular) coordination of monomer to active site decreased relative to the rate of (unimolecular) chain termination via β-H elimination. Conversions of 1-hexene were lower at the lowest temperatures, presumably for kinetic reasons, and also at higher temperatures, presumably because of catalyst decomposition.

Following our preliminary communication (3*h*), similar catalyst activities and polymer molecular weights were reported for catalyst systems involving Cp^*TiCl_2(*O*-aryl) activated by MAO (4*o*). We note also that the highest catalytic activities of **I** for the polymerization of 1-hexene are comparable with those of some metallocene systems (2*g*, *m*, *o*, *r–t*, *v*), although lower than others (2*k*, *u*). We note that neither the bimodality of the poly-1-hexene distribution nor the proclivity under certain conditions to produce predominantly oligomers has been noted previously with other catalyst systems.

Polymer microstructures; modes of chain propagation

Although only very low conversions were obtained at temperatures below –30°C, the high molecular weight polymers thus formed appeared to be highly regioregular. The numbering system for regioregular poly-1-hexene is shown in Fig. 1, the $^{13}C\{^{1}H\}$ NMR spectrum of such a polymer in Fig. 2. As can be seen, the spectrum exhibits only the anticipated six resonances, centered at δ 14.1 (sharp s, C6), 23.3 (br s, C5), 28.5 (m, C4), 34 (m, C3), 32.2 (br s, C2), and 40.5 (m, C1). In contrast to the $^{13}C\{^{1}H\}$ NMR spectra of highly stereoregular isotactic (2*k*) and syndiotactic (2*u*) poly-1-hexenes, which exhibit uniformly narrow resonances, the C(1)–C(4) resonances of the polymers discussed here consisted of broad multiplets indicative of the presence of comparable amounts of most of the possible pentads. Thus the materials are atactic (8*b*).

The $^{13}C\{^{1}H\}$ NMR spectra of the poly-1-hexenes formed at –10°C and above exhibit not only the six primary resonances mentioned above, but also many additional resonances (Fig. 3), many narrow, some broad. In particular, we

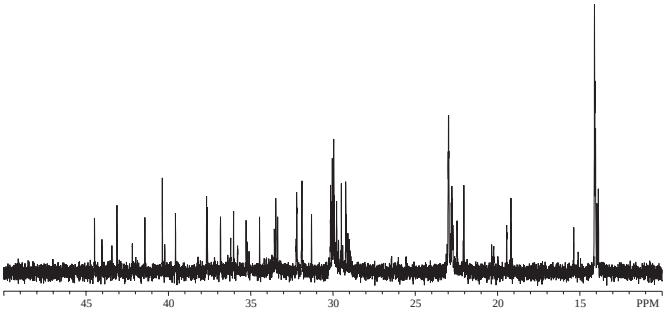
Fig. 4. $^{13}C\{^1H\}$ NMR spectrum of purified oligo-1-hexene.



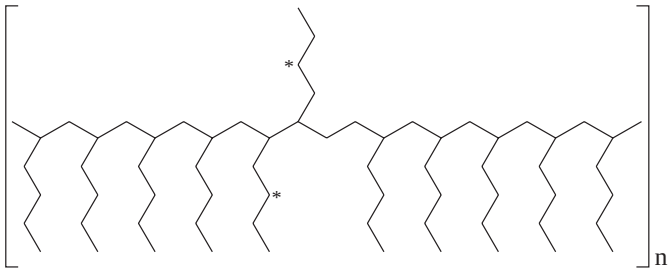


Fig. 5. Microstructure of regioirregular poly-1-hexene, showing tail-to-tail moiety.

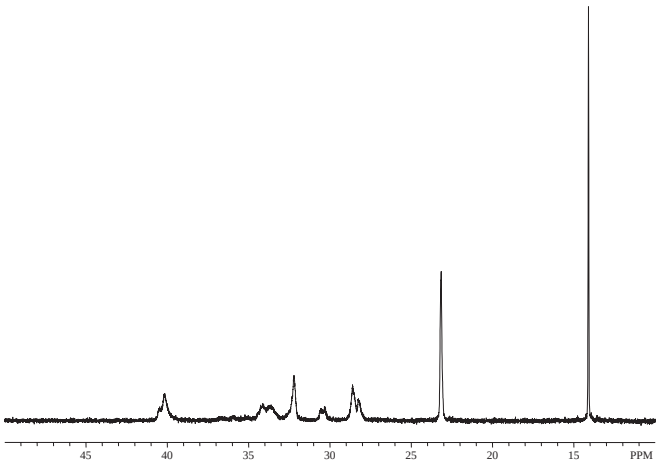
note a rather intense, broad (1 ppm in width) resonance centered at δ ~30.5 and attributable to CH_2 groups on the basis of J-mod experiments, in addition to weaker broad resonances in the region δ 35–38, and many sharp, weaker resonances in the regions δ 19–24 and 28–45. Although we originally interpreted the sharp resonances in terms of regioirregularities in the polymer chain arising from 2,1-insertions (3*k*), in fact they are substantially removed on separation of oligomer from polymer and are present in the NMR spectra of oligomers (Fig. 4).

In contrast, the broad anomaly in the $^{13}C\{^1H\}$ NMR spectra of poly-1-hexene at δ ~30.5 remains in the polymer spectra after the low molecular weight oligomers have been removed, and must be interpreted in terms of unusual polymer microstructures since it has rarely been reported in the $^{13}C\{^1H\}$ NMR spectra of poly-1-hexenes reported elsewhere (2*o*, 8*a*). We can also rule out, on the basis of relative intensities, the possibility that it is to be attributed to end groups of some kind (2*o*, 8*a*), and we are left with the alternative that it is to be attributed to significant amounts of a main chain carbon microstructure that is not normally found in poly-1-hexene formed in a Ziegler–Natta process.

One such possibility is that the anomalous resonance involved 2,1-insertion of 1-hexene molecules followed by chain straightening via a series of reversible β-elimination and reinsertion processes, akin to the "chain walking" nickel(II) and palladium(II) catalyzed polymerizations of α-olefins (10). However, net 5,1-enchainments can be readily ruled out because a comparable number of methyl branches would result and the $^{13}C\{^1H\}$ NMR spectra are essentially devoid of the requisite methyl resonances at δ ~20 (6, 9), while similar 6,1-insertions may also be ruled out as HMBC and HSQC-TOCSY experiments indicate that one or more components of the resonance at δ ~30.5 exhibit spin–spin coupling to methyl group protons, at least a six bond coupling if the resonance is to be attributed to a "chain straightened" backbone methylene carbon atom (of course we cannot rule out the possibility that some of the resonances in the δ ~30.5 manifold are a result of 6,1-insertions.)

The other possibility is that the anomalous resonance at δ ~30.5 is indicative of a microstructure resulting from a 2,1-followed by a 1,2-insertion of 1-hexenes, i.e., involving tail-to-tail incorporation of two monomers (Fig. 5). There would result a poly-1-hexene chain that would contain -CH(Bu)CH_2CH_2CH(Bu)- units, and we find indeed that ^{13}C NMR chemical shift calculations predict (6), for the carbon atoms indicated by asterisks, a downfield shift of 1.3 ppm relative to "regular" C(4) carbon atom chemical shifts (δ ~28.5) (see also ref. 10*b*). Interestingly, 2,1-insertions are normally found to result in significant retardation of metallocene catalyzed polymerization of propylene (1*d*), the accepted rationale being that rates of propagation following a 2,1-insertion are low because of increased steric hindrance near the metal. However, the active sites of monocyclopentadienyl catalysts are much less sterically congested than are those of metallocenes, and it has been shown that rates of propagation with such systems are not severely lowered by 2,1-insertions during the polymerization of propylene by **I** (3*k*). For instance, up to 15% of the monomer incorporated involves 2,1-insertions during propylene polymerizations catalyzed by **I** (3*k*), much higher than the ~1% observed in metallocene systems (1*f*). Interestingly, 2,1-insertions have rarely been reported for metallocene catalyzed polymerizations of α-olefins larger than propylene.



As will be shown below, experiments involving 1-hexene polymerization by Cp*Ti($^{13}CH_3$)$_2$(μ-Me)B(C_6F_5)$_3$ in CH_2Cl_2 confirm that a significant proportion of 2,1-insertions occurs during the initiation step. In addition, 2,1-insertions followed by β-H elimination are found to give the most predominant olefinic end group, identified by ^1H NMR spectroscopy, and thus, it is very reasonable that 2,1-insertions occur during the propagation step of 1-hexene polymerization by **I** in toluene. Other resonances are to be anticipated for the tail-to-tail structure shown in Fig. 6, and chemical shift calculations (6) suggest that some are obscured by the stronger "regular" resonances, but that others are to be seen as rather weak resonances in the region δ 35–38 of purified polymer (Fig. 6).

Oligomer microstructures

The $^{13}C\{^1H\}$ NMR spectra of the oligo-1-hexenes (Fig. 4) exhibit only very sharp resonances, consistent with assignments to low molecular weight materials. In addition, there are many as yet unassigned resonances that are not normally present in spectra of poly-1-hexene, a result in part of the low molecular weights of the materials since end group resonances would clearly be more evident. In addition, many isomers are possible, resulting from multiple β-H elimination reactions. However, unusual resonances such as those at δ ~20 and 12 may be indicative of methyl and ethyl branches arising from 5,1- and 4,1-insertions, respectively, (incomplete chain walking), while intense resonances at δ ~30 are consistent both with 6,1-enchainments (see above for discussion of mechanism) and with resonances of dimers and (or) trimers of 1-hexene (2*h*, *p*). Under those conditions which produce predominantly oligo-1-hexene, the observed conversions and product distributions require formation of up to 20

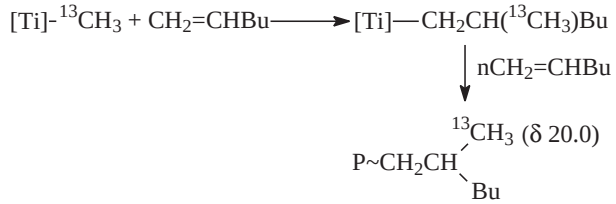
Fig. 6. $^{13}C\{^1H\}$ NMR spectrum of purified poly-1-hexene (partially) regioirregular.



molecules of oligomer per catalyst site. Thus the resulting methyl branches do not arise solely via insertions of 1-hexene into the original Ti–Me bonds of the catalyst, but rather via the olefin incorporation–isomerization processes discussed above. In these cases, the rates of propagation must be low relative to the rates of isomerization, and we note that oligomer formation is indeed favoured when the monomer:catalyst ratio is low, i.e., under conditions where the system is starved of monomer. Also consistent with this hypothesis, we note that lower molecular weights are obtained under conditions of greater dilution even when the monomer:catalyst ratio is the normal (400:1). In these cases, the rates of the presumed bimolecular propagation process become less competitive than the rates of isomerization, an internal reorganization of the coordinated polymer chain.

Mechanisms of initiation by I

As is generally true for polymerization of α-olefins (1, 2, 5), the preferred mode of initiation in toluene is via 1,2-insertions into the Ti–Me bonds. Evidence for this is obtained from labelling experiments which were carried out using $Cp^*Ti(^{13}CH_3)_3$. In a typical experiment, a solution of $Cp^*Ti(^{13}CH_3)_3$ in toluene at 0°C was treated with a solution of 1.1 equiv of $B(C_6F_5)_3$ in 5 mL toluene, as above, and the $^{13}C\{^1H\}$ NMR spectrum was found to be identical to that shown in Fig. 3, except that it also exhibited a relatively strong resonance at δ ~20, consistent with terminal methyl branching formed as in eq. [3] (5*c*, *f*).

[3]

The crude poly-1-hexene was then fractionated, and the $^{13}C\{^1H\}$ NMR spectra of both fractions were found to exhibit relatively strong resonances at δ ~20, thus in both cases, it would seem that 1,2-insertion processes are involved in the initiation steps.

In a complementary NMR experiment carried out in CD_2Cl_2 at –50°C, a solution of $Cp^*Ti(^{13}CH_3)_3$ was treated with a solution of 1.1 equiv of $B(C_6F_5)_3$ in CD_2Cl_2, also at –50°C. ^1H and $^{13}C\{^1H\}$ NMR spectra of $Cp^*Ti(^{13}CH_3)_2(\mu\text{-}^{13}CH_3)B(C_6F_5)_3$ (3*c*) were observed; in addition, a small amount of free $[^{13}CH_3B(C_6F_5)_3]^-$ was also invariably formed, as evidenced by a broad resonance at δ ~10. This observation is consistent with an equilibrium between contact and solvent separated ion pairs (eq. [4]).

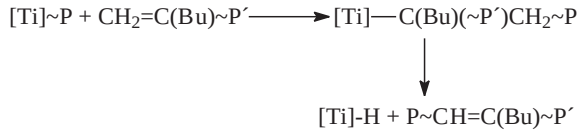
[4] $$Cp^*Ti(^{13}CH_3)_2(\mu\text{-}^{13}CH_3)B(C_6F_5)_3 \rightarrow [Cp^*Ti(^{13}CH_3)_2]^+ + [^{13}CH_3B(C_6F_5)_3]^-$$

On the addition of 0.1 mL of 1-hexene (1-hexene:Ti ratio = 13) in CD_2Cl_2 at –50°C, the $[^{13}CH_3B(C_6F_5)_3]^-$ resonance at δ ~10 increased in intensity and the resonance of **I** disappeared immediately as the 1-hexene coordinated to the titanium centre and displaced the borate ligand. Interestingly, there were observable no resonances of significant intensity attributable to Ti–$^{13}CH_3$ groups, implying that both of the original Ti–$^{13}CH_3$ groups were very quickly incorporated into polymer. As the sample warmed to room temperature, a weak methane resonance appeared at δ ~–4.2. The ^1H and $^{13}C\{^1H\}$ NMR spectra of polymer (containing only trace amounts of oligomers) exhibited, in addition to all of the expected polymer resonances, prominent resonances at δ ~20 and 10.5 in the $^{13}C\{^1H\}$ NMR spectrum. The former corresponds to type of ^{13}C labelled methyl end group discussed above, while the latter could be attributed to an ethyl end group, resulting from a 2,1-insertion process. These assignments were consistent with chemical shift comparisons with calculated ^{13}C chemical shifts (6, 9), the possibility that the resonance at δ ~10.5 were to be attributed to residual $[^{13}CH_3B(C_6F_5)_3]^-$ being ruled out because of an absence of the corresponding methyl resonance at δ ~0.44 in the ^1H NMR spectrum (3*m*).

An unambiguous demonstration of 2,1-insertion during initiation of 1-hexene polymerization has not, apparently, been previously reported. In addition, the catalyst system under consideration here seems to induce 2,1-insertions to a much greater extent than is the case for α-olefin polymerization by metallocenes (29). Comparisons of the relative integrations of the resonances at δ ~20 and 10.5 in an NOE suppressed $^{13}C\{^1H\}$ NMR spectrum showed that 2,1-insertions occur 15–20% of the time, quite consistent with the comparable number of 2,1-insertions during propylene polymerization catalyzed by **I** (3*k*).

As mentioned above, the $^{13}CH_3$ resonance of the Ti–$^{13}CH_3$ groups of **I** disappears immediately on interaction with 1-hexene in CD_2Cl_2, and no new resonances attributable to Ti–$^{13}CH_3$ groups are observed. This observation suggests that both methyl groups are very quickly involved in polymerization and that two polymer chains are probably growing simultaneously from the titanium, a process which seems not to have been demonstrated previously for other catalyst systems.

Mechanisms of chain termination – transfer



The ^1H NMR spectra of most samples of poly–oligo-1-hexenes exhibit resonances at δ ~4.66 and 4.72, ~5.3–5.5, and ~5.1, attributable, respectively, to vinylidene groups

© 2001 NRC Canada

RR′(C=CH_2), dialkyl-substituted alkenes (RCH=CHR′), and trialkyl-substituted alkenes (RCH=CHR′R″) (9). The vinylidene groups are formed via β-H elimination following a 1,2-insertion, a common but not the predominant mode of chain transfer during the polymerization of α-olefins by metallocene catalysts (2*f*).

Disubstituted alkenes may be formed via β-H elimination after a 2,1-insertion, a very important mode of chain transfer during the 1-hexene polymerization by metallocenes (2*f*). Presumably dialkyl-substituted alkenes RCH=CHR′ do not leave the inner coordination sphere of the titanium during the reversible β-H elimination steps, as **I** has been shown to be incapable of polymerizing cyclohexene (3*e*), and we find that **I** does not copolymerize ethylene with *cis*- or *trans*-2-butene although it does homopolymerize 1-hexene in the presence of a mixture of *cis*- and *trans*-2-butene.

Trialkyl-substituted olefins are presumably a result of the types of vinylidene insertion – β-H elimination processes shown in eq. [5], and have been postulated previously (2*n*, 11).

[5]

The ^{1}H NMR spectra also exhibit much weaker resonances at δ ~5.65, ~5.8 (total intensity 1), and ~4.95 (total intensity 2), suggestive of vinyl end groups (P~CH_2CH=CH_2) (9*a*), which would arise from the above mentioned "chain walking" after a 2,1-insertion followed by β-H elimination (10).

Upon separation of the crude poly–oligo-1-hexene mixture into oligo-1-hexene and poly-1-hexene fractions, there were noticeable differences between the NMR spectra of the two fractions. The olefinic region of the ^{1}H NMR spectrum of the poly-1-hexene exhibited only a strong resonance at δ ~5.45, attributed to disubstituted olefinic groups, and much weak resonances at δ 5.1 and 4.7, attributed to lesser amounts of trialkyl substituted internal alkenes and vinylidene groups, respectively. The relative amounts of the three different types of olefinic groups, and therefore, the relative importance of the chain transfer mechanisms leading to them are similar to findings during the polymerization of 1-hexene by metallocene catalysts (2*f*). The ^{1}H NMR spectra of purified oligo-1-hexene fractions exhibit the remainder of the olefinic peaks mentioned above.

Nature of the initiator(s)

As mentioned above, **I** functions as a precursor to the cationic, 10e$^-$ species $[Cp^*TiMe_2]^+$, which is believed to the true Ziegler–Natta catalyst in this system. Although $[Cp^*TiMe_2]^+$ has been long known to behave as a very effective catalyst for the polymerization of, e.g., ethylene and propylene (3*g*, *k*, *n*), this study is to our knowledge the first to demonstrate that both Ti–methyl groups are quickly transferred to growing polymer chains. In contrast, during the carbocationic polymerization of styrene initiated by the same cationic complex, the Ti–methyl bonds largely remain intact once chain growth begins (3*g*).

The fact that polymerization occurs at two sites on the titanium distinguishes **I** fundamentally from both metallocene-based Ziegler–Natta (1) and constrained geometry catalyst (1*g*) systems, which can contain only one active alkyl ligand *cis* to a vacant site. While it is not at all clear at this point why **I** can simultaneously form high and low molecular weight polymers in addition to oligomers, with each component often exhibiting relatively narrow molecular weight distributions ($M_w/M_n \approx 1.5$–3.0), clearly there is more than one initiator responsible for the polymerization of 1-hexene and other α-olefins by Cp^*TiMe_3 and $B(C_6F_5)_3$ (3*l*, 9*f*) and the bifunctionality of the system may be a factor. For instance, it is possible that chain propagation processes at the two sites do not proceed independently, but that the presence of one long chain or branching near the titanium changes drastically the relative rates of propagation and chain transfer at the other. It is also possible that β-H elimination to give a titanium hydride could be followed by association of two cationic titanium centres via a hydride bridge, again altering the relative rates of propagation and chain transfer of the system.

Stereochemistry at carbon upon protonolysis of a late transition metal-alkyl bond: a reaction of relevance to catalytic enantioselective hydrogenation of olefins

Jason A. Wiles, Steven H. Bergens, and Victor G. Young, Jr.

Abstract: Reaction of [Ru((*R*)-BINAP)(H)(MeCN)$_n$(acetone)$_{3-n}$](BF$_4$) (where n = 0–3) (**2**) with 1 equiv of the olefin substrate methyl α-acetamidoacrylate (MAA) in acetone at room temperature immediately generated a mixture (72:28) of two diastereomers of the complex [Ru((*R*)-BINAP)(MeCN)(MAA(H))](BF$_4$) (**3**). The olefin–hydride insertion reaction between **2** and MAA to generate **3** was regioselective, with transfer of the hydride to the β-olefinic carbon and transfer of ruthenium to the α-carbon in both diastereomers of **3**. The two diastereomers of **3** differ by the absolute configuration at the α-carbon of MAA(H) (($S_{C\alpha}$)-**3** and ($R_{C\alpha}$)-**3**). The absolute configuration of the major (($S_{C\alpha}$)-**3**) diastereomer was determined by X-ray diffraction in conjunction with NMR spectroscopic data. Protonolysis of the ruthenium–carbon bond in **3** and in the methyl α-acetamidocinnamate (MAC) analog ([Ru((*R*)-BINAP)(MeCN)((*S*)-MAC(H))](BF$_4$) (($S_{C\alpha}$)-**4**)) by addition of 2 equiv HBF$_4$·Et$_2$O in CH$_2$Cl$_2$ at room temperature was not stereospecific and did not occur with β-hydride elimination from the methyl or benzyl groups.

Key words: ruthenium, BINAP, enantioselective, hydrogenation, catalysis.

Résumé : La réaction du [Ru((*R*)-BINAP(H)(MeCN)$_n$(acétone)$_{3-n}$](BF$_4$) (dans lequel n = 0–3) (**2**) avec un équivalent du substrat oléfinique α-acétamidoacétate de méthyle ("MAA"), dans l'acétone, à la température ambiante, conduit immédiatement à la formation d'un mélange (72:28) de deux diastéréomères du complexe [Ru((*R*)-BINAP(MeCN)("MAA"(H))](BF$_4$) (**3**). La réaction d'insertion oléfine–hydrure entre **2** et "MAA" pour générer **3** est régiosélective; dans les deux diastéréomères de **3**, le transfert de l'hydrure se portant sur le carbone oléfinique β et le transfert de ruthénium sur le carbone α. Les deux diastéréomères de **3** diffèrent par la configuration absolue au niveau du carbone en α du "MAA"(H) (($S_{C\alpha}$)-**3**) et (($R_{C\alpha}$)-**3**). On a déterminé la configuration absolue du produit principal, le diastéréomère (($S_{C\alpha}$)-**3**), par diffraction des rayons X alliée aux données de spectroscopie RMN. La protonolyse de la liaison ruthénium–carbone présente dans le composé **3** et dans son analogue α-acétamidocinnamate de méthyle ("MAC"), le [Ru((*R*)-BINAP(MeCN)((*S*)-"MAC"(H))](BF$_4$) (($S_{C\alpha}$)-**4**), a été réalisée par addition de deux équivalents de HBF$_4$·Et$_2$O, dans du CH$_2$Cl$_2$, à la température ambiante; cette réaction n'est pas stéréospécifique et elle ne se produit pas par le biais d'une élimination β à partir des groupes méthyle ou benzyle.

Mots clés : ruthénium, BINAP, énantiosélective, hydrogénation, catalyseur.

[Traduit par la Rédaction]

Introduction

The first reported use of ruthenium complexes as homogeneous catalysts for hydrogenation of olefins was a landmark paper published by James and co-workers (1) nearly 40 years ago. This paper, in part, laid the groundwork for James' further development of the first enantioselective catalytic hydrogenation using a ruthenium catalyst containing a chiral bis(phosphine) ligand (2). These papers helped found and inspire the development of ruthenium – chiral bis(phosphine) catalysts, the most versatile and widely used catalyst systems for the enantioselective hydrogenation of olefins and ketones.

The mechanisms for hydrogenations catalyzed by ruthenium–bis(phosphine)-halide complexes, as well as the chemistry of such compounds, have been extensively studied by James et al. (3). Mechanistic studies by James, Noyori, and others showed that hydrogenation of α,β-unsaturated acids (e.g., tiglic acid ((*E*)-CH$_3$CH=C(CH$_3$)CO$_2$H)) using Ru((*R*)-BINAP)(O$_2$CCH$_3$)$_2$ (**1**) as catalyst in MeOH proceeds by heterolytic cleavage of H$_2$ and subsequent protonolysis of a ruthenium(II)–alkyl bond (4). As the putative ruthenium(II)–alkyl intermediate occurred after the turnover-limiting step in the catalytic cycle, it was impossible to detect in solution, and the stereochemistry of this key enantio-determining step

Received September 1, 2000. Published on the NRC Research Press Web at http://canjchem.nrc.ca site on July 11, 2001.

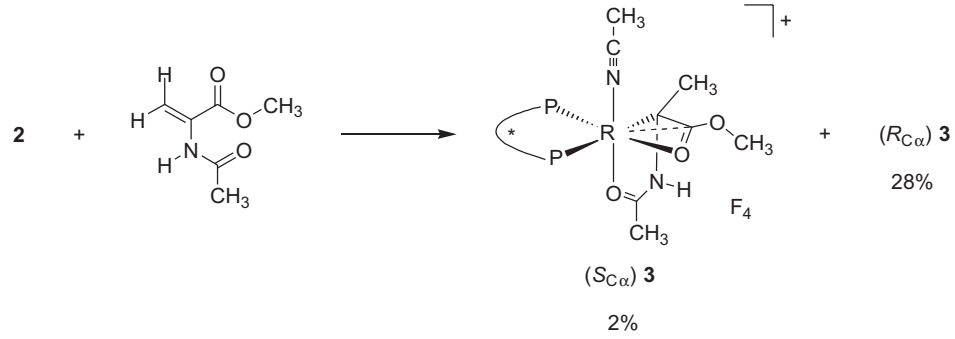
could not be directly observed. A comparison of NMR data for the isotopomers of $CH_3CHDCD(CH_3)CO_2H$ obtained from deuterations of tiglic acid in MeOD using **1** and using $RhCl(PPh_3)_3$ as a catalyst lead to the conclusion that protonolysis proceeded via retention of configuration at carbon (*4b*). Most catalytic hydrogenations of olefins that involve protonolysis (solvolysis) of a metal–carbon bond are believed to, or have been shown to, proceed via a net *syn*-addition of H_2 across the olefin; the presumed consequence of retention at carbon during the protonolysis. There are reported examples, however, for which direct protonolysis of Pt–C σ bonds through back-side attack was postulated to account for catalytic net *anti*-addition of deuterium to certain olefins using platinum–tin complexes as catalysts (5). We now report the first direct observations of protonolysis of the catalyst–alkyl bond in two putative diastereomeric intermediates for catalytic hydrogenation of olefins.

Results and discussion

Reaction of [Ru((*R*)-BINAP)(H)$(MeCN)_n(acetone)_{3-n}$](BF$_4$) (where n = 0–3) (**2**) (6) with 1 equiv of methyl α-acetamidoacrylate (MAA) in acetone at room temperature generated upon mixing (>99% by NMR analysis) a mixture of two species in a ratio of 72:28 (eq. [1]).

NMR spectroscopy, electrospray-ionization mass spectrometry (EI-MS), and microanalysis indicated that these species were two diastereomeric forms of the complex [Ru((*R*)-BINAP)(MeCN)(MAA(H))](BF$_4$) (**3**). Complex **3** resulted from olefin–hydride insertion between MAA and **2**. We previously reported the preparation, solid-state structure, and reactivity of a related complex formed by reaction between **2** and methyl α-acetamidocinnamate (MAC) in >99% diastereomeric excess (de), viz., [Ru((*R*)-BINAP)(MeCN)((*S*)-MAC(H))](BF$_4$) (($S_{C\alpha}$)-**4**) (6). In accord with ($S_{C\alpha}$)-**4**, the olefin–hydride insertion reaction between **2** and MAA was regioselective, with transfer of the hydride to the β-olefinic carbon in MAA and transfer of ruthenium to the α-carbon in both diastereomers of **3** (for similar regioselective insertion of MAA into Ru–H bonds of chiral clusters, see ref. 7). NMR

Fig. 1. Structure of ($S_{C\alpha}$)-**3** as determined by X-ray diffraction.[2,3]



chemical shifts and coupling constants for both diastereomers of **3** parallel those previously found for ($S_{C\alpha}$)-**4**. For example, $^{13}C\{^1H\}$ NMR signals from the coordinated amido and the ester carbonyls, as well as from the α-carbon of **3** (that σ-bonded to ruthenium) are comparable to those of ($S_{C\alpha}$)-**4**. From these similarities, we conclude that the two diastereomers of **3** differ by the absolute configuration at the α-carbon of MAA(H) (($S_{C\alpha}$)-**3** and ($R_{C\alpha}$)-**3**). The absolute configuration of the major (72%) diastereomer was determined as follows.

Slow liquid–liquid diffusion of di-*n*-butyl ether into a 1,2-dimethoxyethane solution of **3** (72:28) at room temperature produced X-ray quality crystals.[2] Diffraction data was collected from two separate samples. In both cases, the molecular structure of the isolated species was of ($S_{C\alpha}$)-**3**, as shown in Fig. 1. The molecular structures of ($S_{C\alpha}$)-**3** and ($S_{C\alpha}$)-**4** are quite similar.

Both are best described as the enolates of MAA(H)$^-$ and MAC(H)$^-$ bonded to ruthenium through Cα (C3) and through

[1]

[2] Crystal data for ($S_{C\alpha}$)-**3**: $C_{52}H_{45}BF_4N_2O_3P_2Ru$, FW = 995.72, yellow plate, crystal size 0.40 × 0.25 × 0.13 mm, orthorhombic, $C222_1$, a = 21.4849(2), b = 29.7175(2), c = 18.8513(2) Å, V = 12036.1(2) Å^3, Z = 8, $\rho_{calcd.}$ = 1.099 g cm^{-3}, μ (Mo Kα) = 0.361 mm^{-1}, T = 173(2) K, λ (Mo Kα) = 0.71073 Å. Data were collected using a Siemens SMART Platform CCD diffractometer (θ range for data collection of 1.17 to 25.04°); 10589 independent reflections (8758 with $F_o^2 > 2\sigma(F_o^2)$) were measured. The structure was solved via direct methods (SHELXTL-V5.0). Full-matrix least-squares refinement on F^2 (SHELXTL-V5.0) yielded R_1 = 0.0480 ($F_o^2 > 2\sigma(F_o^2)$) and wR_2 = 0.1261 (all data). GoF on F^2 = 1.041.

the amido and ester carbonyl groups.[3] To determine if ($S_{C\alpha}$)-**3** was the major or minor diastereomer, the crystal used for one of the two structure determinations was dissolved at –78°C in CD_2Cl_2. The ^1H NMR spectrum revealed a 95:5 (major:minor) mixture of the diastereomers of **3** within the crystal.[4] These X-ray and NMR data show that the major diastereomer of **3** formed by reaction of MAA and **2** is ($S_{C\alpha}$)-**3**. As stated above, use of MAC results in almost exclusive formation of this diastereomer (($S_{C\alpha}$)-**4**).[5]

Crystals of the minor diastereomer suitable for X-ray diffraction could not be obtained. In an attempt to confirm that it was ($R_{C\alpha}$)-**3**, we effected the protolytic cleavage of the Ru–Cα bond with $HBF_4{\cdot}Et_2O$ in CH_2Cl_2 solution. Addition of 2 equiv $HBF_4{\cdot}Et_2O$ to a solution of **3** (72:28) in CH_2Cl_2 at room temperature followed by addition of excess MeCN (9.5 equiv) generates *N*-acetylalanine methyl ester ($MAA(H)_2$) and the known dicationic compound [Ru((*R*)-BINAP)$(MeCN)_4$]$(BF_4)_2$ (8). Protonolysis with retention of configuration at Cα of the mixture of ($S_{C\alpha}$)-**3** and ($R_{C\alpha}$)-**3** (72:28) will generate $MAA(H)_2$ in 44% (*R*) enantiomeric excess (ee) (72% (*R*)-$MAA(H)_2$ and 28% (*S*)-$MAA(H)_2$). The ee of the $MAA(H)_2$ isolated from the protonolysis was 44% (*S*); the protonolysis of the Ru–C bond in **3** occurred with apparent inversion of configuration at carbon.[6] This experiment was repeated twice.

Two control experiments showed that ($S_{C\alpha}$)-**3** and ($R_{C\alpha}$)-**3** do not interconvert in the absence of acid under these conditions. First, the compositions of 72:28 and 95:5 mixtures of these diastereomers did not change over several days in CH_2Cl_2 at room temperature. Second, exposure of **3** to D_2 (1 atm, 1 atm = 101.325 kPa) at room temperature does not result in H–D exchange at Cβ (Ru-Cα-C*H*$_3$). We previously showed that formation of the MAC analogue (($S_{C\alpha}$)-**4**) is reversible under these conditions using a similar experiment (6*b*). Specifically, exposure of ($S_{C\alpha}$)-**4** to D_2 (1 atm) resulted in H–D exchange at Cβ of MAC(H) (Ru-Cα-C*H*$_2$Ph) via β-hydride elimination and subsequent H–D exchange at the ruthenium-hydride. Thus, conversion between ($S_{C\alpha}$)-**3** and ($R_{C\alpha}$)-**3** did not occur to an appreciable extent prior to reaction with acid.

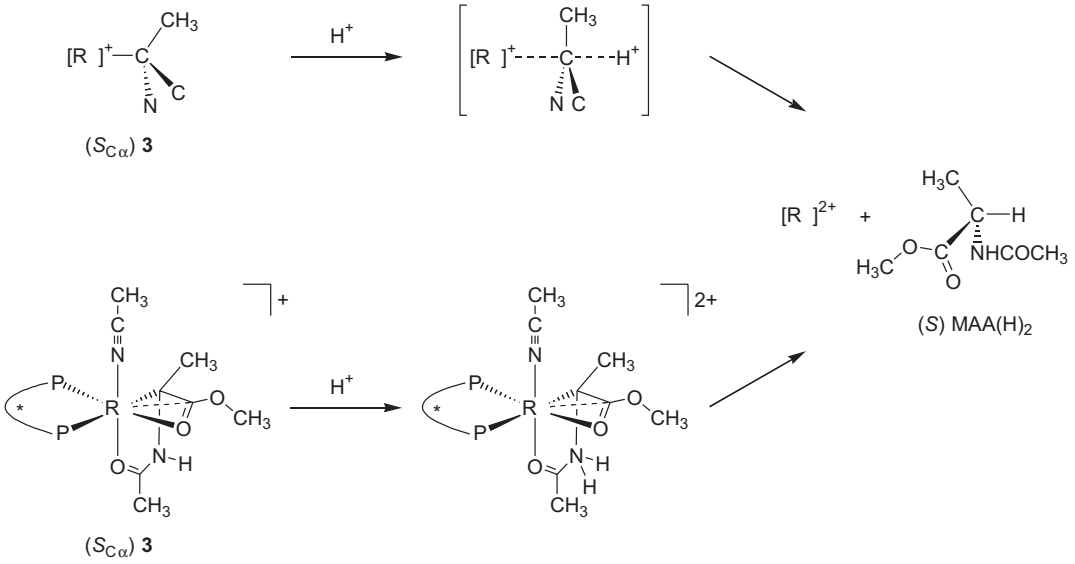
There is the possibility that reaction of **3** with $HBF_4{\cdot}Et_2O$ generated dicationic diastereomeric ruthenium(IV)–hydrido-alkyl complexes ($S_{C\alpha}$)-**3′** and ($R_{C\alpha}$)-**3′** by protonation at the ruthenium centre. These dicationic diastereomers could in principle interconvert via β-H elimination from the methyl group before elimination of $MAA(H)_2$. To investigate this possibility, we prepared **3**-d_1 (in which one β-H of Ru-Cα-C*H*$_3$ was replaced by deuterium, prepared by reaction of **2**-d_1 with MAA) and reacted it with 2 equiv $HBF_4{\cdot}Et_2O$. After treatment with MeCN and purification, the recovered $MAA(H)_2$ consisted of $MAA(H)_2$-β-d_1 as the sole isotopomer. β-H elimination at the methyl group of **3′**, face flip of the coordinated olefin, and olefin–hydride insertion is expected to cause some scrambling of deuterium between the α- and β-positions of $MAA(H)_2$. The absence of any such scrambling shows that if the dicationic diastereomers ($S_{C\alpha}$)-**3′** and ($R_{C\alpha}$)-**3′** do form, they do not interconvert via β-H elimination from the methyl group.

Although these experiments indicated that protonolysis of the ruthenium–carbon bonds in ($S_{C\alpha}$)-**3** and ($R_{C\alpha}$)-**3** proceeded by inversion, protonation of a sample enriched in ($S_{C\alpha}$)-**3** (95:5) using 2 equiv $HBF_4{\cdot}Et_2O$ yielded, after treatment with MeCN and purification, $MAA(H)_2$ in 44% ee (*S*). This is the same ee as that obtained from the 72:28 mixture of ($S_{C\alpha}$)-**3** and ($R_{C\alpha}$)-**3**, respectively, and it shows that the protonolysis is not stereospecific. This result is confirmed by protonolysis of ($S_{C\alpha}$)-**4**-d_1, the MAC derivative of ($S_{C\alpha}$)-**3**-d_1 (where one β-H of Ru-Cα-C*H*$_2$Ph was replaced by deuterium), prepared by reaction of **2**-d_1 with MAC (6*a*). Reaction of ($S_{C\alpha}$)-**4**-d_1 with 2 equiv $HBF_4{\cdot}Et_2O$ yielded, after treatment with MeCN and purification, $MAC(H)_2$-β-d_1 as the sole isotopomer in 12% ee (*R*). Thus, protonolysis of the ruthenium–carbon bond in ($S_{C\alpha}$)-**4**-d_1 is also not stereospecific, and it too does not involve β-H elimination from the benzyl group.

Conclusions

Our previous report of the MAC compound ($S_{C\alpha}$)-**4** was the first solid-state structure of a diastereomeric catalyst–substrate complex of the same absolute configuration as the major product enantiomer of an olefin hydrogenation. This report of the MAA compound ($S_{C\alpha}$)-**3** is the second; as such, it adds to the sparse knowledge base of the structures of these diastereomeric putative catalytic intermediates. Reaction of MAC with **2** favours almost exclusive formation of

[3] Selected bond lengths (Å) and angles (°) with estimated standard deviations for ($S_{C\alpha}$)-**3** are as follows: Ru(1)—N(2) 1.995(4), Ru(1)—P(1) 2.3525(13), Ru(1)—P(2) 2.2640(11), Ru(1)—O(1) 2.072(3), Ru(1)—O(2) 2.278(3), Ru(1)—C(3) 2.230(5), Ru(1)—C(5) 2.345(5), C(3)—C(4) 1.515(7) Å; C(5)-C(3)-C(4) 119.1(4), N(1)-C(3)-C(5) 112.1(4), N(1)-C(3)-C(4) 111.4(4), Ru(1)-C(3)-N(1) 101.4(4), Ru(1)-C(3)-C(4) 132.0(3), Ru(1)-C(3)-C(5) 76.1(3)°.



[4] We both dissolved the crystal and analyzed the resulting solution at low temperature to prevent any diastereomeric interconversion that may occur. This precaution was not necessary as ^{31}P NMR spectroscopic analysis of **3** (72:28 and 95:5 (major:minor) diastereomeric ratios) in acetone-d_6 over a range of temperatures from –80 to +25°C showed the ratios of diastereomers did not vary under these conditions. The 95:5 ratio observed in the crystal analyzed by X-ray diffraction was the same ratio found for the entire crop of crystals (bulk sample).

[5] As we reported previously, only ($S_{C\alpha}$)-**4** is observed in NMR spectra recorded at room temperature. Subsequent spectra recorded at low temperature show the presence (8%) of the other fluctional diastereomer, ($R_{C\alpha}$)-**4**. Selected NMR data (CD_2Cl_2, –40°C) for ($S_{C\alpha}$)-**4** and ($R_{C\alpha}$)-**4** (the asterisks denote resonances attributed to the minor diastereomer (($R_{C\alpha}$)-**4**): $^{13}C\{H\}$ NMR (100.6 MHz) δ: 36.1 (s, Ph*C*H$_2$CRu*), 37.8 (s, Ph*C*H$_2$CRu), 66.9 (dd, $^2J_{P(B),C}$ = 42.0 Hz, $^2J_{P(A),C}$ = 3.5 Hz, Ru*C*), 70.0 (dd, $^2J_{P(B'),C}$ = 42.0 Hz, $^2J_{P(A'),C}$ = 3.5 Hz, Ru*C**), 157.9 (br s, *C*O$_2$CH$_3$*), 159.7 (d, $J_{P(B),C}$ = 3.0 Hz, *C*O$_2$CH$_3$), 179.6 (d, $J_{P(B),C}$ = 7.0 Hz, NH*C*OCH$_3$), 179.9 (d, $J_{P(B'),C}$ = 7.0 Hz, NH*C*OCH$_3$*). $^{15}N\{H\}$ NMR INEPT (40.5 MHz) δ: 184.4 (dd, $^2J_{P(A),N}$ = 4.5 Hz, $^2J_{P(B),N}$ = 3.0 Hz, CH$_3$C*N*-Ru). The corresponding ^{15}N resonance for ($R_{C\alpha}$)-**4** was not observed; however, the $^{31}P\{^1H\}$ NMR spectrum of ($R_{C\alpha}$)-**4** prepared using $CH_3C^{15}N$ displayed $^2J_{P(A'),N}$ = 4.5 Hz and $^2J_{P(B'),N}$ = 3.0 Hz. $^{31}P\{H\}$ NMR (161.9 MHz) δ: 32.9 (d, $^2J_{P,P}$ = 23.5 Hz, 1P, P(B)), 40.1 (d, $^2J_{P,P}$ = 24.0 Hz, 1P, P(B′)*), 55.2 (d, $^2J_{P,P}$ = 24.0 Hz, 1P, P(A′)*), 59.4 (d, $^2J_{P,P}$ = 23.5 Hz, 1P, P(A)).

[6] The ee of $MAA(H)_2$ was spectroscopically (^1H NMR) determined using a chiral shift reagent ((+)-Eu(tfc)$_3$) after separation from [Ru((*R*)-BINAP)$(MeCN)_4$]$(BF_4)_2$ by colum chromatography (Florisil–EtOAc). The absolute configuration of the major enantiomer was determined by comparison to authentic (*S*)-$MAA(H)_2$.

Scheme 1.

($S_{C\alpha}$)-**4** as major diastereomer (6). The methyl analogue generated using MAA favours the same absolute configuration as major diastereomer (($S_{C\alpha}$)-**3**), but with a weaker bias (72:28). The protonolysis of these compounds under the described conditions is not stereospecific, and it does not proceed via β-H elimination from the benzyl or methyl groups. Although the lack of observable β-H elimination from the benzyl or methyl groups implies that equilibration of the diastereomers does not occur during the protonolysis, such equilibration may still occur via protonation at the amido nitrogen followed by β-H elimination to form an iminium. These experiments and labeling studies are moot on this point because of rapid proton exchange between the amido group and $HBF_4{\cdot}Et_2O$.

Another explanation for this lack of stereospecificity is that two pathways operate in parallel for the protonolysis. One pathway, resulting in retention at carbon, is protonation at ruthenium followed by elimination of alkane. We note that although there are few examples, all reported electrophilic abstractions of alkyl or vinyl ligands from early or late transition-metal centres by protonolysis occur with retention of configuration at carbon (9). The other pathway, resulting in inversion at carbon, is electrophilic attack at the back side of the Ru–C σ-bond (Scheme 1). Such a possibility has been suggested to account for inversion of configuration at carbon for alkyl abstraction from zirconium complexes by boranes (10), and as discussed in the introduction, for the observed net *anti*-addition of H_2 in certain hydrogenations of olefins (5).

Another explanation for this lack of stereospecificity is prior protonation of a substrate lone pair followed by intramolecular proton transfer. Similar processes have been reported in the literature (cleavage of a Fe–C σ-bond via protonation at nitrogen has been observed, see ref. 11). Scheme 1 shows such a pathway involving protonation of the amido group of MAA(H), followed by a suprafacial intramolecular proton delivery to C(3) with inversion of stereochemistry (intramolecular proton delivery and its role in the reversal of stereochemistry has appeared in the literature, see ref. 12).

Further experimentation (such as low-temperature NMR studies) is required to investigate the stereochemical course of these protonation reactions and their relevance to catalytic hydrogenation of olefins. These results do show, however, that protonolysis of a catalyst–carbon bond is a complicated process, one that should not be assumed a priori to proceed with strict retention.

Experimental

General considerations

All reactions were conducted under an atmosphere of dry Ar (Praxair, 99.998%) using standard Schlenk and glovebox techniques. NMR spectra were recorded using a Bruker AM-400 (^1H at 400.1 MHz, ^2H at 61.4 MHz, ^{13}C at 100.6 MHz, ^{15}N at 40.5 MHz, and ^{31}P at 161.9 MHz) spectrometer. The chemical shifts for ^1H, ^2H, and ^{13}C are reported in parts per million (δ) relative to external TMS and were referenced to residual solvent signals. The chemical shifts for ^{15}N and ^{31}P are reported in parts per million (δ) relative to external liquid NH_3 and external 85% H_3PO_4, respectively. NMR abbreviations used: broad (br), singlet (s), doublet (d), doublet of doublets (dd), doublet of doublet of doublets (ddd), triplet (t), quartet (q), doublet of quartets (dq), doublet of triplets (dt), and multiplet (m). Electron-impact high-resolution mass spectrometry (EI-HRMS) of *N*-acetylalanine methyl ester ($MAA(H)_2$) was performed on a Kratos MS50 spectrometer. Mass spectrometric analysis of **3** (MeCN solution) was performed on a Micromass ZabSpec Hybrid Sector-TOF spectrometer using positive-mode electrospray ionization (ESI-MS (pos)). Calculated *m*/*z* values refer to the isotopes ^{12}C, ^1H, ^{14}N, ^{16}O, ^{31}P, and ^{102}Ru. Microanalyses were performed at the University of Alberta Microanalysis Laboratory.

Materials

Argon gas (Praxair, 99.998%) was dried by passage through a column containing 3 Å molecular sieves and phosphorus pentoxide before use. Dihydrogen gas (Praxair, 99.99%) was passed through an Alltech Oxy-Trap to remove trace amounts of oxygen before use. Dideuterium gas (Aldrich, 99.8%; Praxair, 99.7%) was used as received. All protiated solvents (Anachemia, Caledon, and Fisher Scientific) and deuterated solvents (99.5–99.9% D, Cambridge Isotope Laboratories) were distilled from appropriate drying agents (13) under an atmosphere of argon gas before use except absolute ethanol (200 proof), which was used as received. Unless stated otherwise, all reagents were used as received from Aldrich. [Ru((*R*)-BINAP)(H)(MeCN)$_n$(acetone)$_{3-n}$](BF$_4$) (where n = 0–3) (**2**), **2**-d_1, methyl α-acetamidoacrylate (MAC), [Ru((*R*)-BINAP)(MeCN)((*S*)-MAC(H))](BF$_4$) (($S_{C\alpha}$)-**4** and ($S_{C\alpha}$)-**4**-d_1) were prepared as described previously (6). The ee and absolute configuration of the MAC(H)$_2$-β-d_1 generated from protonolysis of ($S_{C\alpha}$)-**4**-d_1 was determined as described previously (6). Methyl α-acetamidoacrylate (MAA) was purified by column chromatography on neutral alumina (acetone) before use. (*rac*)-MAA(H)$_2$ and (*S*)-MAA(H)$_2$ were prepared by the esterification of (*rac*)-*N*-acetylalanine and (*S*)-*N*-acetylalanine, respectively, using diazomethane (14).

Syntheses

All glassware and syringes were successively treated with ethanolic ammonium hydroxide solution, acetone, and oven-dried before use. Organometallic products were isolated in a glovebox filled with dinitrogen gas and were stored at –30°C for prolonged periods.

3 *and* **3**-d_1

[Ru((*R*)-BINAP)(1–3;5,6-η-C$_8$H$_{11}$)(MeCN)](BF$_4$) (6) (323.9 mg, 0.338 mmol) was partially dissolved in acetone (15.0 mL) under an atmosphere of Ar and subjected to 3 freeze-pump-thaw cycles. The reactor was backfilled with H$_2$ (20 psig, 1 psig = 6.894 kPa) at room temperature and vigorously shaken for 10 min. The resulting orange solution was subjected to 3 freeze-pump-thaw cycles and backfilled with Ar. To this solution at room temperature was added an acetone solution (5.0 mL) of MAA (48.3 mg, 0.338 mmol). The resulting amber solution was shaken for 1 min and the solvent was removed under reduced pressure to give a yellow solid. Dropwise addition of Et$_2$O (80 mL) to a CH$_2$Cl$_2$ (2.0 mL) solution of the product afforded a yellow powder. The product was collected by filtration and washed with Et$_2$O (3 × 10 mL) to yield 310.7 mg (92%) of **3**. NMR spectroscopic analysis showed that the product contained a diastereomeric mixture of ($S_{C\alpha}$)-**3** and ($R_{C\alpha}$)-**3** (72:28). An in situ reaction monitored by NMR spectroscopy displayed the same ratio of diastereomers. The method used for the preparation of **3**-d_1 was the same as that for **3** with substitution of D$_2$ for H$_2$. ESI-MS (pos) *m*/*z*: 909.2 ([M – BF$_4$]$^+$) (exact mass calcd. for C$_{52}$H$_{45}$N$_2$O$_3$P$_2$Ru, 909.2). NMR spectroscopic data for **3** (the asterisks denote resonances attributed to the minor diastereomer (($R_{C\alpha}$)-**3**): ^{1}H NMR (400.1 MHz, (CD$_3$)$_2$CO, 25°C) δ: 1.17 (d, $^4J_{P,H}$ = 5.0 Hz, 3H, RuC-C*H*$_3$*), 1.61 (d, $^4J_{P,H}$ = 5.0 Hz, 3H, RuC-C*H*$_3$), 1.83 (s, 3H, C*H*$_3$CN), 1.92 (s, 3H, C*H*$_3$CN*), 2.04 (s, 3H, NHCOC*H*$_3$), 2.17 (s, 3H, NHCOC*H*$_3$*), 3.77 (s, 3H, CO$_2$C*H*$_3$*), 3.85 (s, 3H, CO$_2$C*H*$_3$), 6.4–8.1 (aromatic), 8.38 (br s, 1H, N*H*COCH$_3$), 9.02 (br s, 1H, N*H*COCH$_3$*). ^{1}H NMR (400.1 MHz, (CD$_3$)$_2$CO, –40°C) δ: 0.99 (d, $^4J_{P,H}$ = 5.0 Hz, 3H, RuC-C*H*$_3$*), 1.55 (d, $^4J_{P,H}$ = 5.0 Hz, 3H, RuC-C*H*$_3$), 1.84 (s, 3H, C*H*$_3$CN), 1.89 (s, 3H, C*H*$_3$CN*), 2.03 (s, 3H, NHCOC*H*$_3$), 2.17 (s, 3H, NHCOC*H*$_3$*), 3.74 (s, 3H, CO$_2$C*H*$_3$*), 3.82 (s, 3H, CO$_2$C*H*$_3$), 6.4–8.1 (aromatic), 8.69 (br s, 1H, N*H*COCH$_3$), 9.28 (br s, 1H, N*H*COCH$_3$*). ^{13}C{^{1}H} NMR (100.6 MHz, CD$_2$Cl$_2$, 25°C) δ: 4.2 (s, *C*H$_3$CN-Ru*), 4.5 (s, *C*H$_3$CN-Ru), 17.4 (br s, RuC-*C*H$_3$*), 18.8 (s, RuC-*C*H$_3$), 19.7 (s, NHCO*C*H$_3$*), 20.4 (s, NHCO*C*H$_3$), 52.6 (s, CO$_2$*C*H$_3$*), 52.9 (s, CO$_2$*C*H$_3$), 63.3 (dd, $^2J_{P,C(trans)}$ = 44.0 Hz, $^2J_{P,C(cis)}$ = 4.0 Hz, Ru*C*), 66.4 (br d, $^2J_{P,C(trans)}$ = 43.0 Hz, Ru*C**), 126–142 (overlapping aromatic and CH$_3$*C*N), 161.5 (d, $J_{P,C}$ = 3.0 Hz, overlapping ($S_{C\alpha}$)-**3** and ($R_{C\alpha}$)-**3**, *C*O$_2$CH$_3$), 179.3 (d, $J_{P,C}$ = 7.0 Hz, NH*C*OCH$_3$), 179.9 (d, $J_{P,C}$ = 7.0 Hz, NH*C*OCH$_3$*). ^{13}C{^{1}H} NMR (100.6 MHz, CD$_2$Cl$_2$, –40°C) δ: 4.1 (s, *C*H$_3$CN-Ru*), 4.3 (s, *C*H$_3$CN-Ru), 16.9 (s, RuC-*C*H$_3$*), 18.2 (s, RuC-*C*H$_3$), 19.5 (s, NHCO*C*H$_3$*), 20.1 (s, NHCO*C*H$_3$), 52.4 (s, CO$_2$*C*H$_3$*), 52.6 (s, CO$_2$*C*H$_3$), 63.0 (dd, $^2J_{P,C(trans)}$ = 43.5 Hz, $^2J_{P,C(cis)}$ = 4.0 Hz, Ru*C*), 66.8 (dd, $^2J_{P,C(trans)}$ = 44.5 Hz, $^2J_{P,C(cis)}$ = 3.0 Hz Ru*C**), 124–141 (overlapping aromatic and CH$_3$*C*N), 159.1 (s, *C*O$_2$CH$_3$*), 160.1 (s, *C*O$_2$CH$_3$), 178.6 (d, $J_{P,C}$ = 7.0 Hz, NH*C*OCH$_3$), 179.1 (d, $J_{P,C}$ = 6.5 Hz, NH*C*OCH$_3$*). ^{15}N NMR INEPT (40.5 MHz, (CD$_3$)$_2$CO, 25°C) δ: 183.1 (dd, $^2J_{P(A),N}$ = 4.5 Hz, $^2J_{P(B),N}$ = 3.0 Hz, CH$_3$C*N*-Ru), 184.8 (dd, $^2J_{P(A),N}$ = 4.0 Hz, $^2J_{P(B),N}$ = 3.0 Hz, CH$_3$C*N*-Ru*). ^{15}N NMR INEPT (40.5 MHz, (CD$_3$)$_2$CO, –40°C) δ: 181.9 (br apparent t, $^2J_{P(A),N}$ = $^2J_{P(B),N}$ = 3.5 Hz, CH$_3$C*N*-Ru), 183.5 (br, CH$_3$C*N*-Ru*). ^{31}P{^{1}H} NMR (161.9 MHz, (CD$_3$)$_2$CO, 25°C) δ: 33.8 (d, $^2J_{P,P}$ = 22.0 Hz, 1P, P(B)), 38.8 (br d, $^2J_{P,P}$ = 21.0 Hz, 1P, P(B′)*), 58.5 (br d, $^2J_{P,P}$ = 21.0 Hz, 1P, P(A′)*), 59.7 (d, $^2J_{P,P}$ = 22.0 Hz, 1P, P(A)). ^{31}P{^{1}H} NMR (161.9 MHz, (CD$_3$)$_2$CO, –40°C) δ: 33.4 (d, $^2J_{P,P}$ = 23.0 Hz, 1P, P(B)), 38.7 (d, $^2J_{P,P}$ = 22.0 Hz, 1P, P(B′)*), 57.1 (d, $^2J_{P,P}$ = 22.0 Hz, 1P, P(A′)*), 59.4 (d, $^2J_{P,P}$ = 23.0 Hz, 1P, P(A)). Anal. calcd. for C$_{52}$H$_{45}$BF$_4$N$_2$O$_3$P$_2$Ru: C 62.72, H 4.56, N 2.81; found: C 62.35, H 4.88, N 2.64.

Protonations of **3** *and* **3**-d_1

To a stirred solution of ($S_{C\alpha}$)-**3** and ($R_{C\alpha}$)-**3** (72:28) (101.0 mg, 0.101 mmol) in CD$_2$Cl$_2$ (0.50 mL) at room temperature was added a solution of HBF$_4$·Et$_2$O (54% w/w in Et$_2$O, 28.0 μL, 0.203 mmol). The originally orange colored solution immediately turned red in color upon addition of HBF$_4$·Et$_2$O. After stirring for 15 min, CD$_3$CN (50.0 μL, 0.957 mmol) was added to the reaction mixture to generate a yellow colored solution. Analysis of the reaction mixture by ^{1}H and ^{31}P NMR spectroscopy indicated that exclusive formation of MAA(H)$_2$ and [Ru((*R*)-BINAP)(CD$_3$CN)$_4$](BF$_4$)$_2$ occurred. The solution was evaporated to dryness and the residue was thoroughly washed with EtOAc (3 × 5 mL) and the wash was passed through a column of Florisil™ (0.5 cm × 7.0 cm). The clear, colorless eluent was evaporated to dryness to give pure MAA(H)$_2$. Protonation of **3**-d_1 exclusively liberated MAA(H)$_2$-β-d_1, as determined by ^{1}H and ^{2}H NMR spectroscopy (^{1}H NMR (400.1 MHz, CDCl$_3$, 25°C) δ: 1.39 (dt, $^3J_{H,H}$ = 7.0 Hz, $^3J_{H,D}$ = 2.0 Hz, 2H, CHC*H*$_2$D (Hβ)), 2.02 (s, 3H, NHCOC*H*$_3$), 3.76 (s, 3H,

© 2001 NRC Canada

CO_2CH_3), 4.60 (apparent q, $^3J_{H,H}$ = 7.0 Hz, 1H, C*H*CH_2D (Hα)), 6.05 (br s, 1H, N*H*$COCH_3$). $^2H\{^1H\}$ NMR (61.4 MHz, $CHCl_3$, 25°C) δ: 1.39 (s, $CHCH_2D$)). The enantiomeric excess (ee) and absolute configuration (44% (*S*)) of purified $MAA(H)_2$ and $MAA(H)_2$-β-d_1 were determined as follows. The ee was spectroscopically determined (^1H NMR) using a chiral lanthanide shift reagent (europium tris[3-(trifluoromethylhydroxymethylene)-(+)-camphorate] ((+)-Eu(tfc)$_3$)) in $CDCl_3$. Sufficient shift reagent was added (0.2–0.4 equiv) to separate the methoxy signals (ca. 4 ppm) of the two enantiomers of $MAA(H)_2$ (low-field enantiomer (*R*), high-field enantiomer (*S*)). That these were signals of the enantiomers of $MAA(H)_2$ was confirmed by repeating the experiment using (*rac*)-$MAA(H)_2$. The ratio of these methoxy signals was used to quantify the ee. The absolute configuration of the major enantiomer of the product was determined by addition of authentic (*S*)-$MAA(H)_2$ to the samples and subsequently determining the ee via NMR spectroscopy as described above. Addition of (*S*)-$MAA(H)_2$ caused the intensity of the high-field ((*S*)-enantiomer) methoxy signal to increase.

Deuteriolysis of **3**

In a 5-mm NMR tube, ($S_{C\alpha}$)-**3** and ($R_{C\alpha}$)-**3** (72:28) (10.3 mg, 0.0103 mmol) were dissolved in CD_2Cl_2 (0.50 mL) at room temperature under Ar. The headspace of the NMR tube was thoroughly purged with D_2 and the tube was vigorously shaken. Monitoring the reaction over a 30-min period by ^1H NMR spectroscopy showed the generation of $MAA(H)_2$-α-d_1 (10%) and no detectable incorporation of deuterium in the two diastereomers of **3** (($S_{C\alpha}$)-**3** and ($R_{C\alpha}$)-**3**).

Crystal structure determination of ($S_{C\alpha}$)-3

Slow liquid-liquid diffusion of di-*n*-butyl ether into a 1,2-dimethoxyethane solution of **3** (72:28) at room temperature produced X-ray quality crystals. The structure was determined as described in the supplementary material.[7] Crystal data for ($S_{C\alpha}$)-**3**: $C_{52}H_{45}BF_4N_2O_3P_2Ru$, FW = 995.72, yellow plate, crystal size 0.40 × 0.25 × 0.13 mm, orthorhombic, $C222_1$, a = 21.4849(2), b = 29.7175(2), and c = 18.8513(2) Å, V = 12036.1(2) Å^3, Z = 8, $\rho_{calcd.}$ = 1.099 g cm^{-3}, μ (Mo Kα) = 0.361 mm^{-1}, T = 173(2) K, λ (Mo Kα) = 0.71073 Å. Data were collected using a Siemens SMART Platform CCD diffractometer (θ range for data collection of 1.17–25.04°); 10589 independent reflections (8758 with $F_o^2 > 2\sigma(F_o^2)$) were measured. The structure was solved via direct methods (SHELXTL-V5.0). Full-matrix least-squares refinement on F^2 (SHELXTL-V5.0) yielded R_1 = 0.0480 ($F_o^2 > 2\sigma(F_o^2)$) and wR_2 = 0.1261 (all data). GoF on F^2 = 1.041. Selected bond lengths (Å) and angles (°) with estimated standard deviations for ($S_{C\alpha}$)-**3** are as follows: Ru(1)—N(2) 1.995(4), Ru(1)—P(1) 2.3525(13), Ru(1)—P(2) 2.2640(11), Ru(1)—O(1) 2.072(3), Ru(1)—O(2) 2.278(3), Ru(1)—C(3) 2.230(5), Ru(1)—C(5) 2.345(5), C(3)—C(4) 1.515(7) Å; C(5)-C(3)-C(4) 119.1(4), N(1)-C(3)-C(5) 112.1(4), N(1)-C(3)-C(4) 111.4(4), Ru(1)-C(3)-N(1)101.4(3), Ru(1)-C(3)-C(4) 132.0(3), Ru(1)-C(3)-C(5)76.1(3)°.

Acknowledgments

We sincerely appreciate the technical support and helpful discussions provided by Mr. G. Bigam, Mrs. G. Aarts, and Dr. T. Nakashima of the University of Alberta High Field NMR Laboratory. We also thank the Natural Sciences and Engineering Research Council of Canada (NSERC) and the University of Alberta for financial support.

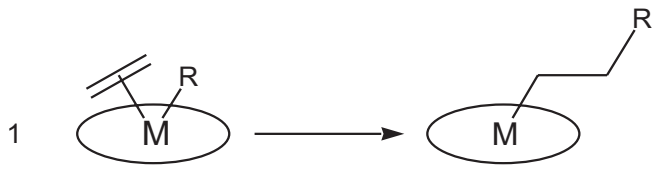
Transition metal phthalocyanine and porphyrin complexes as catalysts for the polymerization of alkenes

Gregory S. Long, Benjamin Snedeker, Kyle Bartosh, Michelle L. Werner, and Ayusman Sen

Abstract: Vanadium phthalocyanine and porphyrin complexes, in conjunction with methylaluminoxane (MAO) or $EtAlCl_2$ cocatalyst, have been found to catalyze the homopolymerization of ethene. In addition, the copolymerization of ethene with propene and 1-decene was achieved with the vanadium phthalocyanine complex and MAO. Nickel phthalocyanine complex was also found to catalyze the polymerization of ethene in the presence of MAO. However, only dimerization was observed when $EtAlCl_2$ was used as the cocatalyst.

Key words: phthalocyanine, porphyrin, polymerization, copolymerization, ethene, propene, 1-decene.



Résumé : On a observé que l'utilisation de complexes de vanadium avec la phtalocyanine et la porphyrine, en association avec du méthylaluminoxane (MAO) ou du $EtAlCl_2$ comme cocatalyseurs, permet de catalyser l'homopolymérisation de l'éthène. De plus, il a été possible de réaliser une copolymérisation de l'éthène avec du propène et du déc-1-éne avec le complexe de vanadium avec la phtalocyanine en présence de MAO. On a aussi observé que, en présence de MAO, le complexe de nickel avec la phtalocyanine catalyse la polymérisation de l'éthène. Toutefois, on n'a observé qu'une dimérisation en présence de $EtAlCl_2$ comme cocatalyseur.

Mots clés : phtalocyanine, porphyrine, polymérisation, copolymérisation, éthène, propène, déc-1-ène.

Introduction

The catalytic insertion polymerization and copolymerization of simple alkenes, such as ethene and 1-alkenes, is of intense academic and industrial interest. Highly active alkene polymerization catalysts based on: (*i*) metallocenes derived from early transition metals; and (*ii*) late transition-metal diimine complexes, have been developed. These and related developments in the area have been reviewed recently (1, 2). To our knowledge, similar alkene polymerization catalysts based on metal complexes with flat phthalocyanine and porphyrin ligands have not been reported. Metal-catalyzed alkene polymerization requires the insertion of a precoordinated alkene into a metal—carbon bond *cis* to it and, a priori, it is not clear that that an alkene and an alkyl group can occupy *cis*-coordination positions in metal phthalocyanine and porphyrin complexes (see eq. [1]).

Herein, we demonstrate that metal phthalocyanine and porphyrin complexes can, indeed, be effective catalysts for alkene polymerizations. The metal complexes employed are shown in Fig. 1.

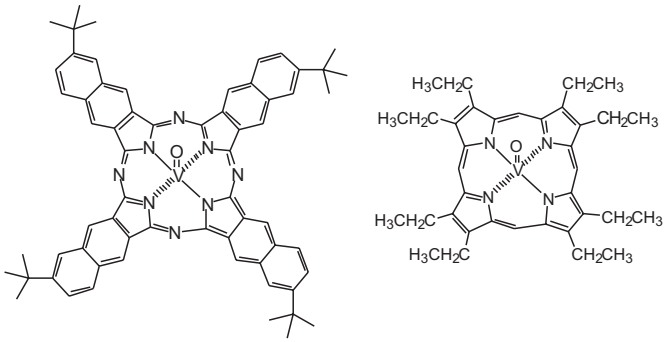
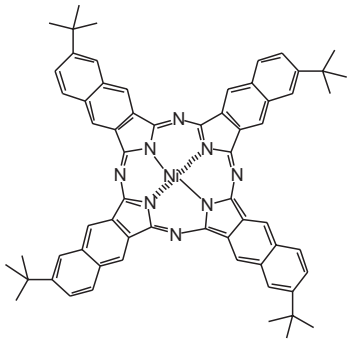
Experimental



General procedures and materials

All reactions were prepared in an inert atmosphere (N_2) drybox. Polymerizations utilizing ethene were performed in a 125 mL Parr stainless steel autoclave equipped with a glass liner unless otherwise noted. Ambient temperature NMR analyses were performed on a Bruker DPX300 or DRX400 NMR, using $CDCl_3$ as the solvent unless otherwise noted. All high-temperature NMR analyses were performed on a Bruker DPX300 NMR at 120°C in 1,2-dichlorobenzene or 1,1,2,2-tetrachloroethane using d_6-DMSO or d_2-1,1,2,2-tetrachloroethane as lock solvents, respectively.



All complexes and reagents were used as supplied from Aldrich Chemical Company. Ethene and propene were used as supplied from MG Industries. Methylaluminoxane (MAO, 30 wt% solution in toluene) was used as supplied from Albemarle Chemicals, Inc. Solvents were dried over CaH_2,

distilled, and freeze–thaw degassed three times prior to use in the inert atmosphere drybox.

GC analysis for butene was performed on a HP5890 series II gas chromatograph with a J & W Scientific DB-5 column, 30 m × 0.530 mm i.d. and 0.50 μm film thickness, run at 30°C for 10 min.

Synthesis of polyethene using vanadium phthalocyanine and porphyrin compounds A and B

To a glass-lined autoclave was added **A** or **B** (10 μmol), 10 mL chlorobenzene, and either 100 equiv MAO (90 mg of 30 wt% solution in toluene, 1 mmol) or 30 equiv $EtAlCl_2$ (218 mg of 1 M solution in hexanes, 0.3 mmol). The vessel was sealed and pressurized to 700 psi with ethene and stirred at 50°C for 4 h. The vessel was cooled and the remaining ethene pressure was released slowly. Methanol (10 mL) was added to the reaction mixture to quench the remaining reactive aluminum species and precipitate any insoluble product. Solid product was collected by vacuum filtration, washed with 10 mL methanol, and dried in vacuo.

Copolymerization of ethene and propene with vanadyl 2,11,20,29-tetra-*tert*-butyl-2,3-naphthalocyanine (A)

To a glass-lined autoclave was added **A** (10.0 mg, 10 μmol), 10 mL chlorobenzene, and 100 equiv MAO (90 mg of 30 wt% solution in toluene, 1 mmol). The vessel was sealed and charged with 5.2 g propene in an acetone – dry ice cooling bath. The autoclave was subsequently pressurized to 700 psi with ethene and stirred at 120°C for 20 h. The vessel was cooled and the unreacted gaseous monomer mixture was released slowly. Methanol (10 mL) was added to the reaction mixture to quench the remaining reactive aluminum species and precipitate any insoluble product. Product was collected by vacuum filtration, washed with 10 mL methanol, and dried in vacuo to yield 0.58 g rubbery solid.

Copolymerization of ethene and 1-decene with vanadyl 2,11,20,29-tetra-*tert*-butyl-2,3-naphthalocyanine (A)

To a glass-lined autoclave was added **A** (10.0 mg, 10 μmol), 10 mL chlorobenzene, 100 equiv MAO (90 mg of 30 wt% solution in toluene, 1 mmol), and 1 g 1-decene. The vessel was sealed and pressurized to 700 psi with ethene and stirred at 120°C for 20 h. The vessel was cooled and the remaining ethene pressure was released slowly. Methanol (10 mL) was added to the reaction mixture to quench the remaining reactive aluminum species and precipitate any insoluble product. Product was collected by vacuum filtration, washed with 10 mL methanol, and dried in vacuo to yield 3.32 g rubbery solid.

Synthesis of butene using nickel(II) chloride

To a glass-lined autoclave was added nickel(II) chloride (6.5 mg, 50 μmol), 10 mL chlorobenzene, and either 30 equiv $EtAlCl_2$ (1.1 g of 1 M solution in hexenes) or 100 equiv MAO (450 mg of 30 wt% solution in toluene, 5 mmol). The vessel was sealed and pressurized to 700 psi with ethene and stirred at 50°C for 1 h. The vessel was cooled and the gas containing ethene and butene was released slowly, with samples taken for GC analysis. Methanol (10 mL) was added to the reaction mixture to quench the remaining reactive aluminum species. Butene was quantified by GC.

Synthesis of butene and polyethene using nickel(II) 2,11,20,29-tetra-*tert*-butyl-2,3-naphthalocyanine (C)

To a glass-lined autoclave was added **C** (49.8 mg, 50 μmol), 10 mL chlorobenzene, and either 30 equiv $EtAlCl_2$ (1.1 g of 1 M solution in hexanes) or 100 equiv MAO (450 mg of 30 wt% solution in toluene, 5 mmol). The vessel was sealed and pressurized to 700 psi with ethene and stirred at 50°C for 1 h. The vessel was cooled and the gas containing ethene and butene was released slowly, with samples taken for GC analysis. Methanol (10 mL) was added to the reaction mixture to quench the remaining reactive aluminum species and (or) to precipitate insoluble polyethene. The solid product was isolated and dried under vacuum.

Results and Discussion

Homopolymerization of ethene by vanadium compounds

Table 1 summarizes our results of ethene homopolymerization by vanadyl naphthalocyanine and porphyrin complexes, **A** and **B**, respectively. Control experiments indicated that neither the vanadium complexes nor the aluminum cocatalysts were by themselves active for ethene polymerization under the reaction conditions. The vanadyl naphthalocyanine complex **A** appears to be more productive than **B**, given the low solubility of **A** in the volume of solvent used in this system. Although alkylation of the solvent

C	$EtAlCl_2$ (30)	None	1.01	20.2
C	MAO (100)	0.32	Trace	6.5

[a]Reaction conditions: 125 mL glass-lined stainless autoclave, 10 mL chlorobenzene, 700 psi ethene, 50°C, 1 h.

occurs when toluene is used in conjunction with $EtAlCl_2$, toluene is an acceptable (if not better) solvent when MAO is used as the cocatalyst, as can be seen in Table 1. The solid product formed is linear polyethene. This is confirmed by the observation of a singlet at 1.2 ppm in the ^{1}H NMR spectrum. The absence of a significant methyl resonance also rules out branching. Differential scanning calorimetry (DSC) also confirmed a linear structure with a T_m above 130°C.

Copolymerization of ethene and 1-alkenes by vanadyl naphthalocyanine (A)

Homopolymerization attempts with alkenes other than ethene were unsuccessful. However, it was possible to copolymerize 1-alkenes with ethene (Table 2). Interestingly, significant incorporation of 1-alkene is only observed at higher reaction temperatures and with MAO as the cocatalyst. Comonomer incorporation was confirmed and quantified by ^{1}H NMR spectroscopy, which showed larger methyl peak integrations compared to linear polyethene and the appearance of methine and nonmain-chain methylene proton resonances. The decrease of product crystallinity compared to linear polyethene also supported copolymer formation, with typical peak T_m values decreasing from greater than 130°C for linear polyethene to approximately 123°C for the ethene–propene copolymer and just below 130°C with ethene–1-decene product; the DSC peak for the latter was significantly broader than the DSC peak of linear polyethene.

Polymerization and oligomerization of ethene by nickel compounds

Perhaps the clearest influence of the macrocyclic ligand can be seen in reactions involving nickel compounds. As shown in Table 3, both the nature of the alkylating agent and the presence of the naphthalocyanine ligand has a strong effect on the reaction with ethene. Thus, with MAO as the alkylating agent, ethene is selectively dimerized by $NiCl_2$ but polymerized by the naphthalocyanine complex, **C**. Interestingly, compound **C** catalyzes the dimerization rather than polymerization of ethene when $EtAlCl_2$ is used as the alkylating agent. Control experiments indicated that neither $NiCl_2$ nor **C** alone was capable of ethene polymerization–dimerization.

Conclusion

It is clear from the above results that metal complexes with flat phthalocyanine and porphyrin ligands are indeed effective catalysts for the polymerization of ethene. The failure of the same catalyst to homopolymerize higher alkenes and the relatively low incorporation of the latter alkenes in copolymerization with ethene can be ascribed to unfavorable steric interactions between the ligand and the alkyl substituent on the monomer.

The observed alkene polymerization by metal phthalocyanine and porphyrin complexes raises a number of

© 2001 NRC Canada

interesting mechanistic questions. First, is the polymerization proceeding in accordance with the mechanism shown in eq. [1]? In principle, this is possible for the vanadium complexes since the ligands are 8-e^- donors leaving the vanadium center with multiple coordination unsaturation. However, the observed activity of the nickel phthalocyanine complex is less easily explained. The Ni(II) complex is a 16-e^- system, with only one coordination position open. Upon alkylation an anionic alkyl species should form and, for polymerization–dimerization to proceed, the ethene has to directly insert into the nickel-alkyl bond *without* prior coordination to the metal center. Such a step has little precedence in alkene polymerization (1, 2). The *complete* decoordination of the phthalocyanine ligand does not appear likely since product formation was not observed when ethene was exposed to a 1:1:30 mixture of $NiCl_2$, aluminum phthalocyanine, and $EtAlCl_2$ (also see Table 3). The combination of aluminum(III) phthalocyanine chloride and MAO was also found to be inactive.

Another interesting issue concerning the reactivity of the nickel phthalocyanine complex is the dramatic change in product selectivity as a function of the alkylating agent (Table 3). In most alkene polymerization systems, MAO is a better cocatalyst than $EtAlCl_2$ because of the ability of the former to function both as an alkylating agent, as well as a strong Lewis acid that is capable of creating a vacant coordination site on the (transition) metal by ligand abstraction (1, 2). In the nickel phthalocyanine complex, following alkylation, there is no ligand present that can be easily removed by a Lewis acid (the decoordination of one of the coordinated nitrogens on the phthalocyanine rings is possible but not very likely).

Studies are currently underway to address the above and related mechanistic questions.

A novel coordination mode for a pyridylphosphine ligand. X-ray structures of $[RuCl_2(NO)L]$ (I) and $[RuCl_2(NO)L]\cdot DMSO$ (II) (L = $[(2\text{-py})_2PC_2H_4POO(2\text{-py})_2]^-$)

Alzir A. Batista, Salete L. Queiroz, Peter C. Healy, Robbie W. Buckley, Sue E. Boyd, Susan J. Berners-Price, Eduardo E. Castellano, and Javier Ellena

Abstract: The ruthenium(II) complex, $[RuCl_2(NO)L]$ (**I**), (L = $[(2\text{-py})_2PC_2H_4PO_2(2\text{-py})]^-$) was obtained from recrystallization of $RuCl_3NO$(d2pype) (d2pype = $(2\text{-py})_2PC_2H_4P(2\text{-py})_2$) in the presence of HNO_3, crystallizing in the monoclinic space group $P2_1$ (no. 4), with a = 8.012(4) Å, b = 14.454(4) Å, c = 9.353(3) Å, β = 105.77(3)°, and Z = 2. Crystals of the DMSO solvate of the complex (**II**) were obtained from $(CD_3)_2SO$ solution, crystallizing in the monoclinic space group $P2_1/c$ (no.14) with a = 9.7080(2) Å, b = 22.2920(5) Å, c = 11.5230(3) Å, β = 92.0450(10)°, and Z = 4. In both complexes, the geometry about the ruthenium atom is a distorted octahedron mainly as a result of the tridentate [*P*,*N*,*O*]-bonding mode of L. The ν (NO) bands at 1875 cm^{-1} in both complexes are consistent with the linear disposition of the NO group and the Ru atom as is observed in the X-ray crystal structure (Ru-N1-O1 angle = 178.5(4)°).

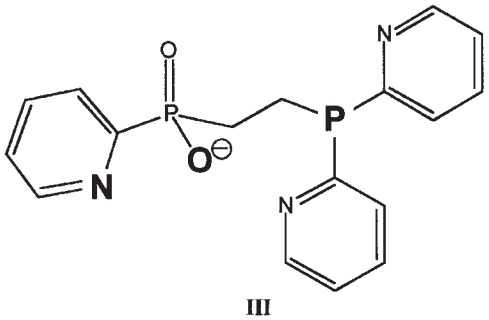
Key words: pyridylphosphine, nitrosyl, ruthenium complex, X-ray structure.

Résumé : La recristallisation du $RuCl_3NO$(d2pype) (d2pype = $(2\text{-(py)}_2PC_2H_4P(2\text{-py})_2$) en présence de HNO_3 conduit à la formation du complexe de ruthénium(II), $[RuCl_2(NO)L]$ (**1**), (L = $[(2\text{-py})_2PC_2H_4P(2\text{py})_2)]^-$) qui cristallise dans le groupe d'espace $P2_1$ (no. 4), avec a = 8,012(4) Å, b = 14,454(4) Å et c = 9,353(3) Å, β = 105,77(3)° et Z = 2. Les cristaux du produit de solvatation du complexe par le DMSO (2) ont été obtenus à partir d'une solution de $(CD_3)_2SO$; ils cristallisent dans le groupe d'espace $P2_1/c$ (no.14) avec a = 9,7080(2) Å, b = 22,2920(5) Å et c = 11,5230(3) Å, β = 92,0450(10)° et Z = 4. Dans les deux complexes, la géométrie autour de l'atome de ruthénium est un octaèdre déformé en raison principalement du mode de liaison tridentate [*P*,*N*,*O*] de L. Les fréquences des bandes NO, à 1875 cm^{-1}, dans les deux complexes sont en accord avec une disposition linéaire du groupe NO et de l'atome de Ru; c'est ce qui est observé dans la structure cristalline obtenue par diffraction des rayons X alors que l'angle Ru-N1-O1 est de 178,5(4)°.

Mots clés : pyridylphosphine, nitrosyle, complexe du ruthénium, structure cristalline par diffraction des rayons X.

[Traduit par la Rédaction]

Introduction



Pyridylphosphines are very attractive ligands for coordination chemistry. Their importance in inorganic medicinal chemistry has been demonstrated (1) and they have been utilized in the development of potential homogeneous catalysts for use in aqueous media (2–7). At a more fundamental level, they are of interest because of the variety of coordination modes which they demonstrate. Indeed, pyridylphosphine metal complexes have been observed (for *P*-coordinated see ref. 8; for *P*,*N*-coordinated see ref. 9; for *N*,*N*′-coordinated see ref. 10; for *N*,*N*′,*N*″-coordinated see ref. 11; for *P*,*N*,*N*′-coordinated see ref. 12; for *P*,*P*,*N*-coordinated see ref. 7) in which the ligand binds via the P atom, via the phosphorus and one pyridyl group (*P*,*N*), via two pyridyl groups (*N*,*N*′; PPh(py) and $P(py)_3$), via three pyridyl groups (*N*,*N*′,*N*″; $P(py)_3$) and via the phosphorus and two pyridyl groups (*P*,*N*,*N*′, $PPh(py)_2$ and $P(py)_3$).

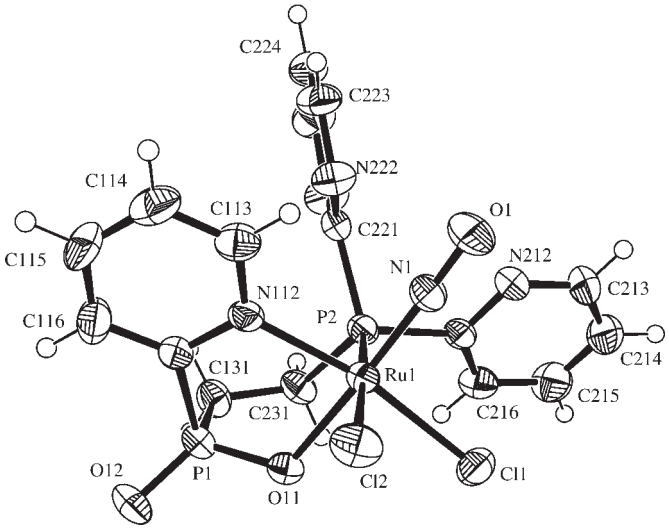
Recently, a new coordination mode was reported for pyridylphosphines. In the complex $RuCl_2((2\text{-py})_2P(CH(CH_2)_3CH)P(2\text{-py})_2)PPh_3$, the ligand has a *P,P,N*-bonding mode, with either a *mer*- or *fac*-arrangement of the three P donor atoms (7). Adding to the increasing coordination possibilities of this intriguing and versatile class of ligands, we report here the X-ray structure determination of the complexes $[RuCl_2(NO)L]$ (**I**) (L = $[(2\text{-py})_2PC_2H_4PO_2(2\text{-py})]^-$), and its DMSO solvate (**II**) in which the ligand, **III**, acts as an unusual tridentate [*P,N,O*] ligand.



Experimental

Infrared spectra were recorded as CsI pellets on a Bomem-Michelson 102 instrument. ^{31}P, ^1H, and $^1H\{^{31}P\}$ NMR spectra (^{31}P 161.9 MHz) were obtained in DMSO-d_6 solutions at room temperature with a Varian Unity 400 spectrometer. ^1H NMR chemical shifts are reported in ppm, relative to residual DMSO (taken as δ 2.49 ppm). ^{31}P NMR chemical shifts are reported relative to external H_3PO_4 (85%) (taken as 0 ppm). Spectral assignments were confirmed by analysis of absolute value, gradient selected, COSY, NOESY (τ_{mix} = 800 ms), and ^{31}P HMBC (J_{PH} = 20 Hz) experiments conducted on the solution. Pulse sequences were as supplied in the Varian VNMR6.1B NMR package. The numbering scheme adopted for the reporting of the ^1H NMR data parallels the numbering scheme used for the attached ^{13}C atoms in the X-ray structure of the complex (Fig. 1). Coupling constants are recorded as absolute values, in Hz. Elemental analyses were performed at the Department of Chemistry, Federal University of São Carlos, São Carlos (SP), Brazil.

Reagent grade solvents were distilled from $Na(Et_2O)$, $CaH_2(CH_2Cl_2)$, $Mg–I_2(MeOH)$ under Ar. $RuCl_3\cdot 3H_2O$ and perdeuterated dimethylsulfoxide were used as supplied (Aldrich). 1,2-Bis(di-2-pyridylphosphino)ethane (d2pype) and $RuCl_3NO$ were prepared according to published procedures (2, 13).

$RuCl_3NO$(d2pype) was obtained from the reaction of $RuCl_3NO$ (100 mg, 0.42 mmol) with d2pype (170 mg, 0.42 mmol) in 5 mL of CH_2Cl_2. The mixture was stirred for 2 h under Ar at room temperature. The volume of the solution was then reduced and the resultant yellow precipitate collected by filtration and washed with methanol and ether and dried under vacuum. Yield: 0.245 g, 91%. Anal. calcd. $C_{22}H_{20}Cl_3N_5OP_2Ru$ (%): C 41.30, H 3.15, N 10.95; found: C 41.00, H 3.22, N 11.00. Crystals of **I** (yield 15%), of reddish color, were obtained by slow evaporation of a CH_2Cl_2 – diethyl ether solution of the crude product $RuCl_3NO$(d2pype) (to increase the solubility of the yellow solid two drops of HNO_3 were added to this solution). ^1H NMR (400 MHz, DMSO-d_6, 298 K) δ: 8.77 (dd, 1H, *J* = 6.3, 1.3, *H*113), 8.71 (ddd, 1H, *J* = 4.8, 1.6, 1.3, *H*213), 8.54 (ddd, 1H, *J* = 4.8, 1.7, 1.1, *H*223), 8.05 (ddd, 1H, *J* = 7.6, 7.6, 1.3, *H*115), 7.96 (m, 1H, *H*215), 7.93 (m, 1H, *H*216), 7.79 (m, 1H, *H*226), 7.76 (m, 1H, *H*225), 7.70 (m, 2H, *H*114, *H*116), 7.52 (ddd, 1H, *J* = 7.2,4.8, 1.7, *H*214), 7.39 (ddd, 1H, *J* = 7.2, 4.8, 1.6, *H*224), 3.3 (m, 2H, CH_2[2]), 2.58 (m, 1H, CH_2), 2.18 (ddd, 1H, *J* = 17, 12, 5, CH_2). ^{31}P NMR (161.9 MHz, DMSO-d_6, 298 K) δ: 33.8 (d, $^3J_{PP}$ = 22.2 Hz, (2-Py)*P*OO), 26.0 (d, (2-Py)$_2$*P*Ru). Anal. calcd. $C_{17}H_{16}Cl_2N_4O_3P_2Ru$: C 36.58, H 2.89, N 10.04; found: C 36.42, H 3.00, N 10.02. Crystals of **II** (of reddish color) were obtained from a perdeuterated DMSO solution of **I** on standing.

Fig. 1. ORTEP view of the asymmetric unit of $[RuCl_2(NO)(2\text{-py})_2PC_2H_4P{=}O,O^-(2\text{-py})]$ (**I**), showing the atom labelling and the 50% probability ellipsoids.

X-ray crystallographic analyses

$[RuCl_2(NO)L]$

All measurements were made on a Rigaku AFC7R rotating anode diffractometer with graphite monochromated Mo Kα (λ = 0.71070 Å) radiation. The final unit cell parameters were based on 25 reflections with $18.4 \le 2\theta \le 19.4$. The data were processed using the teXsan package (14) and corrected for Lorentz and polarization effects. The structure was solved by heavy atom Patterson techniques, expanded by using Fourier techniques and refined by full-matrix least-squares on |*F*|s (14).

$[RuCl_2(NO)L]\cdot DMSO$

All measurements were made on an Enraf–Nonius κCCD diffractometer with graphite monochromated Mo Kα (λ = 0.71070 Å) radiation. The final unit cell parameters were based on all reflections. The structure was solved by direct methods with SHELXS-97 (15). The Fourier map obtained showed all non-hydrogen atoms. The model was refined by full-matrix least-squares procedure on F^2 by means of SHELXL-97 (16). The DMSO solvent molecule presents some degree of disorder, which was modeled with two positions for the sulfur atom with their occupation factors adding to one.

The hydrogen atoms of the aromatics rings and CH_2 groups were set to isotropic, with a thermal parameter 20% greater than the equivalent isotropic displacement parameter of the carbon atom to which each one is bonded; this percentage was set to 50% for the hydrogen atoms of the methyl groups. All the hydrogen atoms were stereochemically positioned and

[2] Resonances coincide with the H_2O resonance.

[a] For non-deuterated DMSO.
[b] Data collection, data processing, structure solution, and structure refinement, respectively.

refined with the riding model. All non-H atoms were refined anisotropically.

Crystal data, data collection procedures, structure determination methods, and refinement results are summarized in Table 1. Complete tables of crystallographic data, hydrogen atom coordinates, anisotropic thermal parameters, bond lengths and angles, torsion angles, intermolecular contacts, and least-squares planes have been deposited as supplementary material.[3]

Results and discussion

The single crystal structure determinations of the two complexes are consistent with the formation of discrete molecular complexes separated by normal van der Waals interactions. In spite of their different crystal symmetry and the presence of a solvent molecule in one the structures, the molecular structures of the complexes in both crystal forms are essentially identical, as can be seen by comparing the bond lengths and angles reported in Table 2. For this reason we shall refer to the unsolvated form to discuss the molecular geometry of the complex. The molecular structure of the complex is both interesting and unexpected. For the reaction of $RuCl_3NO$ with the d2pype ligand, one would expect a complex with formula $RuCl_3NO$(d2pype-*P,P′*), with the phosphorous atoms coordinated *trans* to the chlorine atoms as a bidentate ligand, as obtained for the dppm, dppe, and dppp diphosphine ligands (13, 21), with the further possibility of coordination of pyridyl nitrogen through displacement of one chloride anion (7, 12). In this case however, as can be seen in the X-ray structure (Fig. 1), one of the phosphorus atoms of the d2pype ligand has been oxidized to a phosphinate (R_2POO^-) with loss of one pyridyl group. This affords a rare example of a tridentate [*P,N,O*] ligand (22) that coordinates to the ruthenium atom through the unoxidized phosphorus atom, a nitrogen atom from the pyridyl group attached to the oxidized phosphorus and the deprotonated hydroxyl group on the oxidized phosphorus, the latter displacing one chloride anion from the coordination sphere.

While the mechanism for the formation of this ligand and complex remains speculative at this stage, we (23) have shown previously in studies on compounds of bidentate phosphine ligands with silver(I) salts that coordination of bidentate phosphine ligands can be via a single phosphorous

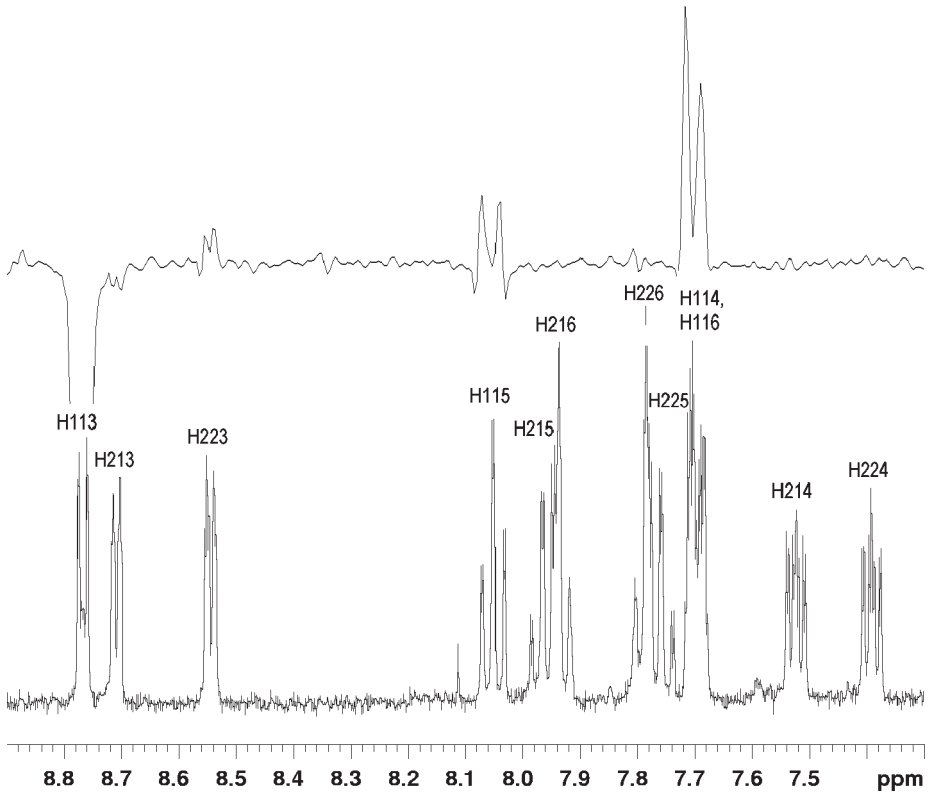
atom and that the noncoordinated phosphine in these complexes can undergo oxidation to the phosphine oxide. It seems reasonable to assume in the present circumstances that at least a small concentration of a $RuCl_3NO$(d2pype) complex exists in solution with the d2pype ligand coordinated to the ruthenium ion via one phosphorus atom only and that the presence of the strong oxidizing acid HNO_3 has oxidized the noncoordinated P atom. It is worth noting that, while the elimination of a pyridyl group and oxidation of the phosphorus to the phosphinate has not been observed previously for pyridyl phosphines, autoxidation of alkyl phosphines to phosphinates and phosphate esters, via a proposed radical chain mechanism, has been observed (24).

The geometry around the ruthenium atom in **I** (Fig. 1) is a distorted octahedron, the distortion mainly due to the tridentate mode of bonding by the ligand L.



Bond lengths (Table 2) are consistent with a *trans* influence of the coordinated phosphorus atom, P2. The Ru—Cl2 bond (2.425(2) Å) *trans* to P2 is significantly longer than the Ru—Cl1 bond (2.369(1) Å) *trans* to N112. In addition, the Ru—NO bond length (1.728(4) Å), for which the nitrogen atom is *trans* to the oxygen (O^-), is shorter than the Ru—NO distance for which the nitrogen is *trans* to phosphorus or chlorine in the $RuCl_3$(dppb)NO and $[RuCl_5(NO)]^{2-}$ complexes (1.748(8) Å and 1.738(2) Å, respectively) (21, 25). This reflects the $P > Cl^- > O^-$ order in the *trans* influence series (26). The Ru—P2 distance (2.345(2) Å) is similar to other monodentate coordinated P atoms (22, 27). The Ru—O bond length in the present complex (2.024(3) Å) also lies within the range of similar bond lengths reported in the literature (22). The short metal—nitrogen bond (Ru—NO, 1.728(4) Å) and the NO bond length of 1.159(6) Å, longer than in the free NO^+ group (1.06 Å) (28) by almost 0.1 Å, consistent with significant π-bonding between the ruthenium and the nitrogen atom of the NO^+ ligand. The P=O bond length (1.467(4) Å) is not significantly different from that found for triphenylphosphine oxide (1.46(1) Å) (29) and dppbO (1.482(2) Å) (30). The other bond lengths in the complex are similar to those found in the literature (8–13, 31). The observed Ru-N-O bond angle for **I** (178.5(4)°) shows that these atoms are almost colinear in the complex. The angles involving the phosphorus atoms (Table 2) show that these atoms are in tetragonal environments, as expected.

It is interesting that the complex adopts a stable "closed" environment because of the favourable, intramolecular, donor–acceptor interactions occurring between the N atoms of the noncoordinated pyridyl rings and the NO^+ group. This is evidenced in the pyridyl—nitrosyl distances O1—N212 (3.360(7) Å) and O1—N222 (3.138(7) Å). The coordination geometry of the coordinated pyridyl function completes the closed structure (N222—N212 = 3.610(7) Å and H113—N222 = 2.870(7) Å).

The IR of a CsI disk of **I** shows a strong, sharp band at 1875 cm^{-1} corresponding to ν (NO^+) (13, 21, 32). The IR data previously observed for *fac*-[$RuCl_3$(NO)(dppm)] and

Fig. 2. Aromatic region of the ^{1}H NMR (400 MHz, DMSO-d_6, 298 K) spectrum of **I**. The upper trace shows the corresponding region of a row extracted from a GNOESY experiment (τ_{mix} = 800 ms) conducted on the same sample. Cross relaxation occuring between nuclei located on different pyridyl residues is evidenced by the cross peak correlating the resonances at δ 8.77 and δ 8.54.

mer-[$RuCl_3(NO)(AsPPh_3)_2$], in which the nitrosyls are *trans* to chlorine atoms, have their ν (NO) bands at 1867 and 1869 cm^{-1}, respectively, (13, 21, 33). Medium bands at 1570, 1447, and 1424 cm^{-1} correspond, respectively, to C=N(py) and C=C stretching vibrations of the aromatic rings (32, 34). A medium band at 1284 cm^{-1} and a strong one at 1231 cm^{-1} belong to the P=O and P-O, respectively, (32). Other bands typical of the aromatic rings are present in the spectrum between 500–1000 cm^{-1}.

^{31}P and ^{1}H NMR data recorded for complex **I** (Fig. 2) suggest that the structure of the complex in solution is not substantially different from that observed in the solid state.

The lack of symmetry in the complex renders all resonances inequivalent. The spin system was therefore readily assigned, either directly by inspection or by analysis of standard two-dimensional experiments. As expected, the ^{1}H NMR spectroscopic properties of the two noncoordinated pyridyl groups were quite similar and distinct from those of the *N*-coordinated pyridyl. The relative arrangement of these two pyridyls, with respect to their relative individual proximities to the *N*-coordinated pyridyl, was evidenced by weak cross peaks in the NOESY matrix between δ 8.77 and 8.54 ppm (Fig. 2), which are indicative of nOe transfer occurring between *H*113 and *H*223. This suggests that on average these protons are separated by a distance <5 Å, consistent with the X-ray data which positions these protons 3.324 Å apart. No other significant inter-pyridyl nOes were present in the spectrum.

Conclusion

Coordinated pyridylphosphine ligand in the presence of a strong oxidizing acid can be oxidated to a phosphinate, with loss of one pyridyl group. Surprisingly, the $RuCl_2(NO)(2\text{-}py)_2PC_2H_4$ $POO(2\text{-}py)_2$ (where the phosphine is a tridentate [*P,N,O*] ligand), is chemically very stable and does not react with strongly coordinating ligands such as DMSO. ^{31}P NMR data recorded for complex **I** in $(CD_3)_2SO$ suggest that the structure of the complex in solution is not substantially different from that observed in the solid state. A $(CD_3)_2SO$ solution of complex **I** produces only the solvated species (complex **II**). The sharp band at 1875 cm^{-1} in the IR spectrum shows that complex **I** is of the {Ru^{II}-NO^+} type.

Reactions of SO_2 with *trans*-Ir(CO)(Cl)(TPPTS)$_2$ in water

Allen A. Bowden and Jim D. Atwood

Abstract: Reaction of SO_2 with *trans*-Ir(CO)(Cl)(TPPTS)$_2$ in water mirrors the nature of SO_2 dissolved in water. At low pH (pH = 1) where SO_2 exists as the hydrated species $SO_2 \cdot H_2O$, only Ir(CO)(Cl)(SO_2)(TPPTS)$_2$ forms. At higher pH (pH = 6) where HSO_3^- dominates, no SO_2 complex is observed and a hydride, Ir(CO)(Cl)(H)(OH)(TPPTS)$_2$, is the primary product. A mixture of SO_2 and O_2 does not lead to an iridium sulfate or show any evidence of the dioxygen adduct upon reaction in water with *trans*-Ir(CO)(Cl)(TPPTS)$_2$, in contrast to the analogous reaction in organic solvents. In water, only the SO_2 complex, Ir(CO)(Cl)(SO_2)(TPPTS)$_2$, is observed prior to decomposition. The contrasts to the PPh_3 analogues in organic solvents provide further insight to water as a solvent for organometallic complexes.

Key words: iridium(I), sulfur dioxide, water soluble, TPPTS.

Résumé : La réaction du SO_2 avec le *trans*-Ir(CO)(Cl)(TPPTS)$_2$ dans l'eau est un miroir de la nature du SO_2 dissous dans l'eau. À faible pH (pH = 1), alors que le SO_2 existe sous la forme d'espèces hydratées $SO_2 \cdot H_2O$, il ne se forme que du Ir(CO)(Cl)(SO_2)(TPPTS)$_2$. À des pH plus élevés (pH = 6), alors que l'anion HSO_3^- prédomine, on n'observe pas de formation de complexe avec le SO_2 et le produit primaire est un hydrure, Ir(CO)(Cl)(H)(OH)(TPPTS)$_2$. Un mélange de SO_2 et de O_2 ne conduit pas à la formation d'un sulfate d'iridium; de plus, on ne détecte aucune indication de formation d'un adduit avec le dioxygène lors de la réaction dans l'eau du *trans*-Ir(CO)(Cl)(TPPTS)$_2$ et ceci est en opposition avec la réaction analogue dans les solvants organiques. Dans l'eau, on n'observe que la formation du complexe avec le SO_2, Ir(CO)(Cl)(SO_2)(TPPTS)$_2$, avant sa décomposition. Le contraste avec les analogues PPh_3 dans les solvants organiques permet de comprendre le mécanisme d'action de l'eau comme solvant pour les complexes organométalliques.

Mots clés : iridium(I), bioxyde de soufre, soluble dans l'eau, TPPTS.

[Traduit par la Rédaction]

Introduction

Addition reactions of small molecules to square-planar iridium(I) complexes have been extensively studied since Vaska's initial investigations began in 1961 with O_2 addition to *trans*-Ir(CO)Cl(PPh_3)$_2$ (1). These complexes have been used as models for intermediates in catalytic cycles (2) with a wide variety of reactants forming stable adducts with Vaska's complex and derivatives (3). One of the main advantages of these complexes is that triphenylphosphine can be easily substituted by a different phosphine ligand and thus the effect of changing the electronic and steric environment around the metal center can be monitored. For example, studies on O_2 binding have increased the understanding of steric and electronic factors in dioxygen coordination (4). In addition the recent development of water-soluble phosphines such as the trisulfonated triphenylphosphine derivative, TPPTS (TPPTS = P(*m*-$C_6H_4SO_3Na)_3$), means that water-soluble square-planar metal complexes can be made and hence the effect of carrying out these reactions in water can be investigated.

This manuscript examines the reactions of *trans*-Ir(CO)Cl(TPPTS)$_2$ (**1**) with sulfur dioxide at various pHs. There have been very few modeling studies in water, thus, investigation of these reactions increases understanding of the various interactions of organometallic complexes in water. SO_2 reactions are of further interest due to environmental problems and the hope that a metal complex may lead to a route for removal of SO_2 from waste streams (5).

Experimental

Materials

$IrCl_3 \cdot 3H_2O$ was purchased from Johnson Matthey. Anhydrous SO_2(g) was purchased from Matheson. Deuterated solvents were purchased from Cambridge Isotope Lab, Aldrich Chemical Co., or MSD labs. Carbon monoxide was purchased from Praxair. All were used without further purification. Compound (**1**) was prepared as previously described (6). The water used was triply distilled and deionized. Solvents were used as received without further purification. Control of pH was effected with Baker DILUT-IT buffers.

Instrumentation

Infrared spectra were recorded on a Mattson Polaris Fourier transform spectrophotometer, in the range 2200–400 cm^{-1}. Solution spectra were recorded using a 0.1 mm CaF_2 solution cell. Solid-state spectra were recorded as KBr discs. All spectra are reported in wavenumbers (cm^{-1}) and summarized in Table 1.

NMR spectra, both ^1H and ^{31}P, were recorded on a Varian VXR-400 spectrometer. For ^1H NMR spectra, residual solvent peaks were used as an internal reference. The aromatic proton signals were not assigned. An external sample of 85% H_3PO_4 in D_2O was used as a reference for the ^{31}P NMR spectra; this was assigned a shift of 0.0 ppm. ^{31}P NMR spectra are proton decoupled. Spectra recorded in H_2O used a sealed capillary containing D_2O for the lock. All chemical shifts (δ) are reported in ppm and all coupling constants (J) in Hz. ^{31}P NMR spectra are summarized in Table 1.

Reactions

NMR scale reactions with O_2 and SO_2 used pressures of 600 mmHg (1mmHg = 133.322 Pa). The reactions with mixtures of O_2 and SO_2 used 300 mmHg (1mmHg = 133.322 Pa) of each gas.

Reaction of *trans*-Ir(CO)(Cl)(TPPTS)$_2$ with SO_2

1 (0.1 g, 0.067 mmol) was dissolved in H_2O (10 mL) and then SO_2 was passed over the solution for 5 min. The solution immediately turned bright green and the IR spectrum indicated a single CO stretch at 2043 cm^{-1} that was assigned to the SO_2 complex, Ir(CO)Cl(SO_2)(TPPTS)$_2$ (**3**). Additionally a ^{31}P NMR spectrum, recorded using an internal D_2O standard, indicated a single product at 10.9 (s) ppm. Isopropanol was added to precipitate this product as a green solid. After the solid was vacuum dried an IR spectrum was recorded in KBr indicating **1** and **3**. This suggests that the addition of SO_2 is reversible. Precipitated solid: (KBr) ν_{CO} = 1980 cm^{-1} (**1**) (59%), ν_{CO} = 2017 cm^{-1} (**3**) (41%).

1 (25 mg, 0.017 mmol) was dissolved in D_2O and placed under an atmosphere of SO_2 (570 mmHg (1 mmHg = 133.322 Pa)). The solution immediately turned bright green. The initial ^{31}P NMR spectrum taken after 10 min revealed a single peak for **3**. The solution was left for several weeks under an SO_2 atmosphere, at which point a new, unassigned peak was observed at 44 ppm. Despite the acidic nature of the solution, the ^1H NMR spectrum showed no hydride signal. After several months, the peak at 44 ppm dominated and the solution was colorless. ^{31}P NMR (D_2O), 10 min: 10.9 (s) (**3**); several weeks: 44.1 (s) (23%), 10.9 (s) (**3**) (77%).

The procedure was repeated using d^6-DMSO. As with the reaction in D_2O a bright green solution formed within 10 min. Analysis by ^{31}P NMR spectroscopy showed the chemical shift for the product was similar to that for the reaction in D_2O. In this solvent there was also a peak observed at around 44 ppm after several weeks but in greatly reduced amounts (2% vs. 23% in D_2O). ^{31}P NMR (d^6-DMSO) 10 min 11.2 (s) (**3**); several weeks: 43.4 (s) (2%), 11.2 (s) (83%).

Results and discussion

Coordination of SO_2 to Ir(I) complexes has been extensively studied for many years (7–9). Coordination is reversible with a pyramidal SO_2 along the z axis. The reaction of SO_2 with *trans*-Ir(CO)(Cl)(TPPTS)$_2$ in water is very similar producing a single complex which, by comparison to previously published data (7, 8), could be identified as the SO_2 complex, Ir(CO)Cl(SO_2)(TPPTS)$_2$. The solid state IR data were very close to those for the analogous PPh_3 complex. The KBr spectrum for the TPPTS complex had a CO stretch at 2017 cm^{-1} compared to 2013 cm^{-1} for the equivalent PPh_3 complex (7). In addition, further support for the formation of this complex comes from the ^{31}P NMR data. The chemical shift for Ir(CO)Cl(SO_2)(P(*p*-tolyl)$_2$)$_2$ in d^8-toluene is reported at 10.3 (s) ppm, compared to 10.9 (s) ppm for the TPPTS complex in D_2O (8). The characterization data provide strong support for formation of Ir(CO)(Cl)(SO_2)(TPPTS)$_2$ although the product could not be isolated pure because of reversible SO_2 loss typical for such complexes (7–9).

The exclusive formation of the SO_2 complex is pH dependent. When SO_2 is added to water (pH $\cong$ 1.0) the composition is essentially hydrated SO_2 (10). In fact $SO_2 \cdot H_2O$ is the dominant species until the pH reaches about 1.5. As pH increases, the concentration of HSO_3^- increases. At pH 4 it is the major species in solution. Finally, above pH 6.5, SO_3^{2-} is the major species.

When the reaction of SO_2 with *trans*-Ir(CO)(Cl)(TPPTS)$_2$ was carried out at pH 2 there were some differences in the ^{31}P NMR spectrum from the solution with no pH control. Although the solution was still the characteristic green color of the SO_2 complex, there were two additional minor prod-

ucts, one of which was shown by ^1H NMR spectrum to contain a hydride. As pH was increased, the amount of SO_2 complex decreased and the hydride-containing product **5** continued to grow as shown by a new resonance in the ^{31}P NMR spectrum at 1.9 (s) ppm together with the hydride signal in the ^1H NMR spectrum. At pH 6 there were more significant changes, the solution was a dark yellow color and the ^{31}P NMR spectrum showed the amount of hydride containing product had greatly increased. There was no signal for the SO_2 complex at this pH. The ^1H NMR spectrum confirmed that the new complex contained an iridium-hydride resonance at –13.3 ppm. These changes with pH are summarized in Table 2.

The identity of complex **5** would most likely be the six-coordinate species, $Ir(CO)Cl(H)(OH)(TPPTS)_2$. The characterization for this complex (^{31}P NMR = 1.9 ppm, ^1H NMR = –13.3 (t)) is similar to those for HCl addition (^{31}P NMR = 2.5 ppm, ^1H NMR = –15.8 (t)) and HBF_4 or H_2SO_4 addition (^{31}P NMR = 7.4, ^1H NMR = –14.8 (t)), but more similar in ^{31}P NMR shift to the neutral HCl addition product. The solution is considerably less acidic for formation of $Ir(CO)(Cl)(H)(OH)(TPPTS)_2$ than for the other hydride complexes.

An alternative could involve HSO_3^- coordination to iridium. There are very few examples of HSO_3^- coordination to metal centers. These can be formed by either insertion of SO_2 into a metal hydroxy bond (9) or hydrolysis of bound -SO_3R (11). One example was prepared from the reaction between *trans*-$Ir(CO)(OH)(P(p\text{-tolyl})_3)_2$ and SO_2. The product formed was assigned to $(HO_2SO)Ir(CO)(SO_2)(P(p\text{-tolyl})_3)_2$ (9).

Oxidation of SO_2 to sulfate has been shown to occur upon reaction of SO_2 with $Ir(CO)(Cl)(O_2)(PPh_3)_2$ (12). In water, the analogous reaction does not occur.

$$[1] \qquad Ir(CO)(Cl)(O_2)(TPPTS)_2{}^2 + SO_2 \rightarrow [\mathbf{A}] \rightarrow Ir(CO)(Cl)(SO_2)(TPPTS)_2$$

Instead a species **A** is formed quickly in high yield (eq. [1]). **A** can be precipitated by addition of isopropanol; **A** has a CO stretch at 2078 cm^{-1} and a ^{31}P NMR at –9.8 (s) ppm. If **A** is left in solution or redissolved in H_2O it rearranges to the SO_2 complex, $Ir(CO)(Cl)(SO_2)(TPPTS)_2$. We cannot unequivocally identify **A**, however the simplest suggestion involves SO_2 coordinated to the Ir(III) complex as a planar molecule. Planar coordination of SO_2 is preferred when the metal is in a higher oxidation state (14). The coordination site could be opened by Cl^- dissociation, expected to occur readily in aqueous solution. When the dioxygen is eliminated (several hours in solution) the SO_2 changes to the pyramidal geometry favored for Ir(I) (9).

The THF reaction between *trans*-$Ir(CO)Cl(PPh_3)_2$ and H_2SO_4 (15) formed a single product, $Ir(CO)Cl(SO_4)(PPh_3)_2$, via an unidentified hydride species. The ^1H NMR spectrum for reaction of H_2SO_4 with *trans*-$Ir(CO)(Cl)(TPPTS)_2$ in H_2O showed two hydrides, one of these (–15.8 (t) ppm) corresponds to the HCl addition product $Ir(CO)(Cl)_2(H)(TPPTS)_2$ (**7**) prepared independently and, in combination with the ^{31}P NMR data, confirms the presence of this complex.[3] The chemical shifts in the ^{31}P NMR (7.5 (s) ppm) and the IR spectra (ν_{CO} = 2060 $cm^{-1)}$ suggest that the other hydride complex (–14.8 (t) ppm, $J_{P\text{-}H}$ = 11 Hz) is the six-coordinate cation, $Ir(CO)(Cl)(H)(OH_2)(TPPTS)_2]^+HSO_4^-$. There was no evidence for formation of a sulfate complex.

A shift of the CO stretching mode to higher frequency in H_2O as compared to solid state (KBr) or DMSO solution was previously attributed to hydrogen bonding of water along the *z* axis of a square-planar complex (16). A similar shift is observed for three complexes reported in this manuscript, $Ir(CO)(Cl)(SO)_2(TPPTS)_2$, $Ir(CO)(Cl)(O_2)(TPPTS)_2$, and $Ir(CO)(Cl)_2(H)(TPPTS)_2$ indicating that the shift to higher frequency (30 cm^{-1}) in water is not limited to a specific geometry for the metal center.

Conclusions

The reaction with SO_2 in strongly acidic solution is the same as with similar square-planar complexes in organic solution. A single product is formed with data consistent for formation of square pyramidal $Ir(CO)Cl(SO_2)(TPPTS)_2$. The SO_2 is bound reversibly. There are significant differences when the pH is altered, as the pH increases a new product forms, $Ir(CO)Cl(H)(OH)(TPPTS)_2$, until at pH 6 it is the only complex present.

Synthesis of sulfated mono- and ditertiary phosphines, complex chemistry and catalysis

H. Gulyás, A. Dobó, and J. Bakos

Abstract: Cyclic and bicyclic sulfates have been prepared from commonly available alcohols. Nucleophilic cleavage of the cyclic sulfates affords a new type of water-soluble mono- and ditertiary phophines bearing -OSO_3Li groups in distinguished positions in the molecular framework. Both phosphines have amphiphilic character. Reactions of the chiral **2** and the dppp analogue **5** with $[Rh(COD)Cl]_2$ and $Pt(PhCN)_2Cl_2$ provide novel zwitterionic complexes. Rhodium complexes of **2** and **5** have been successfully applied in liquid biphasic hydroformylation of styrene and octene-1. When the rhodium complex of **5** was used as catalyst in hydroformylation of styrene, less then 4 ppm rhodium could be detected in the organic phase.

Key words: cyclic sulfates, water soluble phosphines, amphiphilic character, Rh complexes, Pt complexes, hydroformylation.

Résumé : On a préparé des sulfates cycliques et bicycliques à partir d'alcools disponibles facilement. Le clivage nucléophilique des sulfates cycliques conduit à la formation d'un nouveau type de phosphines mono- et ditertiaires, solubles dans l'eau, portant des groupes -OSO_3Li dans des positions définies du squelette moléculaire. Les deux types de phosphines présentent un caractère amphiphilique. Les réactions du $[Rh(COD)Cl]_2$ et du $Ph(PhCN)_2Cl_2$ avec composé chiral **2** et de son analogue à la dppp, **5**, conduisent à la formation de nouveaux complexes zwitterioniques. On a pu appliquer avec succès les complexes **2** et **5** du rhodium à l'hydroformylation biphasique liquide du styrène et de l'oct-1-ène. Quand on a utilisé le complexe de rhodium **5** comme catalyseur dans l'hydroformylation du styrène, on n'a détecté que quatre ppm de rhodium dans la phase organique.

Mots clés : sulfates cycliques, phosphines solubles dans l'eau, caractère amphiphilique, complexes du rhodium, complexes du platine, hydroformylation.

[Traduit par la Rédaction]

Introduction

Much effort has been directed toward the synthesis of new catalytic species with recent focus on water-soluble catalysts (for recent reviews see ref. 1). Transition-metal complexes can easily be rendered water soluble by incorporating polar substituents (2) e.g., -SO_3Na, -CO_2Na, -OH, -PMe_3^+, -NMe_3^+, -$PO(ONa)_2$, and polyethers.

Recently we introduced a novel route to a new class of water-soluble phosphines (3). We have reasoned that this methodology will be of particular interest since: (*i*) a wide range of starting compounds (e.g., diol, triol, tetrol) is available; (*ii*) the synthesis is simple; and (*iii*) provides an easy access to a series of amphiphilic or water-soluble phosphines. Water solubility of these phosphines is provided by the -OSO_3Li group.

Salts of sulfuric acid hemiesters are known to be excellent detergents. For example sodium dodecylsulfate is used in many aqueous organometallic catalytic systems to improve the catalytic activity and (or) selectivity of the reaction (4). In our case the sulfate group is attached to the ligand itself, rendering it not only water-soluble, but also amphiphilic. To our knowledge, only a very few ligands with amphiphilic properties have been reported (5). These ligands are expected to increase the activity of organic–aqueous biphasic catalytic systems by improvement of the miscibility of the two liquid phases (6). Also quite few ligands are known, where the coordinating functional group is not affected by the group providing the water solubility (7). In these molecules the -PPh_2 unit is remote enough from the -OSO_3Li function so that the electronic nature of the -PPh_2 group will be unaffected.

Hemilabile ligands have recently come into focus. Weak coordination of a functional group can stabilize certain conformations of the catalytically active complex and improve the selectivity of a reaction (8). Another advantage of a

weakly coordinating functional group is that it can be easily replaced by the substrate resulting in an increase in the activity of the catalyst. A hard sulfate group is not expected to have strong coordination ability toward soft metal centers, but its labile coordination should not be overlooked.

We report here detailed synthetic route for the preparation of mono- and ditertiary phosphines. Complex formation and catalytic application of the model compounds are presented.

Experimental

General information

Synthesis of the phosphines and their complexes were carried out under a purified argon atmosphere using standard Schlenk-type techniques. Tetrahydrofuran (THF), diethyl ether (Et_2O), toluene, and benzene were distilled from sodium benzophenone ketyl under argon. Methylene chloride (CH_2Cl_2) and pyridine were distilled from CaH_2 and methanol (MeOH) was distilled from $Mg(OMe)_2$ under argon. Water (H_2O) was distilled twice under argon. Deuterated methanol and water (CD_3OD and D_2O) were deoxygenated by bubbling with argon for 10 min. Deuterated chloroform ($CDCl_3$) was deoxygenated by distillation under argon. Pentaerythritol was purchased from Aldrich and used as received. (2*R*,4*R*)-2,4-Pentanediol was prepared by the slightly modified literature method (9). GC analyses were performed using a Hewlett–Packard 5830A gas chromatograph (SPB-1 30 m column, film thickness (0.1 μm), N_2 carrier gas (2 mL min^{-1})). Optical rotations were obtained using a Schmidt Haensch 21245 polarimeter. Nuclear magnetic resonance spectra were recorded on a Varian Unity 300 and Bruker DRX-500 spectrometer using $CDCl_3$, CD_3COCD_3, D_2O, and CD_3OD as solvents. The ^1H and ^{13}C NMR chemical shifts are referenced to internal or external standard $SiMe_4$, and to residual portio-solvent peaks (i.e., $CHCl_3$). The ^{31}P NMR spectra were recorded with 85% H_3PO_4 as an external standard. The ^{195}PtNMR (64 MHz) chemical shift is given in ppm relative to Na_2PtCl_6 as an external standard. Positive chemical shifts are downfield from the standard. Adjustments of pH were performed using an OP-211/1 Laboratory Digital pH Meter. Rhodium content of the organic phase was determined by atom absorption using a PerkinElmer 5100 PC atom absorption spectrometer, electrothermal atomization HGA 600, AS 70 autosampler, and GEM software. Fast atom bombardment (FAB) mass spectrometric measurements were performed using a VG-ZAB-2SEQ reverse geometry instrument operating at an accelerating voltage of 8 kV. A cesium ion gun producing 30 keV ions was utilized for ion bombardment. Glycerol was used as the FAB matrix.

Catalysis

Two-phase hydroformylation reactions of styrene and 1-octene with rhodium complexes of **2** and **5** were carried out in a 20 mL stainless steel autoclave. The catalysts were made in situ. Mixing the water, toluene, alkene, phosphine, and $[Rh(COD)Cl]_2$ resulted in an orange emulsion which was transferred into the autoclave under argon atmosphere. The autoclave was pressurized with CO–H_2 and then placed in a heating mantle preheated to the desired reaction temperature. The autoclave was shaken at a frequency of 180 min^{-1}, 75 deg from the upright position, with a horizontal amplitude of 3 cm. The reaction was monitored by the change in pressure.

Leaching of rhodium was determined as follows: The toluene phase was separated. 0.5 mL of cH_2SO_4 and 1 mL of cH_2O_2 were added. Further 5x1mL of cH_2O_2 was added during one week. All volatiles were evaporated from the homogenous solution. 10 mL of deionised water and 0.1 g of Na_2SO_4 were added. Analysis was undertaken on a Perkin Elmer 5100 PC atom absorption spectrometer in conjunction with a series of rhodium standards.

Cyclic sulfates

Cyclic sulfate **1** was prepared using the general literature method described by Gao and Sharpless (10).

Synthesis of (4*R*,6*R*)-4,6-dimethyl-2,2-dioxide-1,3,2-dioxathiane (1)

Thionyl chloride (4.6 mL, 0.064 mol) was added, via a dropping funnel, to (2*R*,4*R*)-2,4-pentanediol (5.5 g, 0.053 mol) in 50 mL CCl_4. The resulting light brown solution was refluxed for 1 h to complete the sulfite formation. HCl was removed under reduced pressure (the water aspirator was adjusted to a quite gentle flow). CH_3CN (50 mL), $NaIO_4$ (16 g, 0.075 mol), and $RuCl_3$ hydrate (0.008 g, 0.032 mmol, 40% ruthenium) were added to the solution. The resulting brown mixture was cooled to 0°C and 75 mL of water was added slowly. The mixture turned orange within 5 min. The reaction was allowed to stir at ambient temperature for 1 h. The mixture was then diluted with Et_2O (400 mL). The organic phase was separated, washed with water (20 mL), saturated $NaHCO_3$ solution (2 × 20 mL), and brine (20 mL). After being dried over $MgSO_4$ the solution was filtered through a pad of SiO_2 to remove the ruthenium. The solvent was removed in vacuum. Recrystallization of the product from Et_2O–hexane yielded a white crystalline solid (8.85 g, 82%), mp 34 to 35°C. $[\alpha]_D^{24}$ = 37.5° (c 5.02, $CHCl_3$). ^1H NMR (300.15 MHz, $CDCl_3$) δ: 1.64 (d, J_{HCCH} = 6.6 Hz, 6H, CH_3), 2.03 (t, J_{HCCH} = 5.6 Hz, 2H, CH_2), 5.03 ppm (pseudo-sext due to signal overlap, 2H, CH). ^{13}C NMR (75.42 MHz, $CDCl_3$) δ (ppm): 20.0 (s, CH_3), 35.5 (s, CH_2), 80.3 (s, CH).

Synthesis of 2,4,8,10-tetraoxa-3,9-dithiaspiro[5.5]undecane 3,9-dioxide (3)

A solution of $SOCl_2$ (17.5 mL, 0.24 mol) in pyridine (20 mL) was added dropwise to a solution of pentaerythritol (13.6 g, 0.1 mol) in pyridine (250 mL). The reaction mixture was stirred for 3 h. The solvent, remaining $SOCl_2$, and most of the pyridine–hydrochloride were removed under reduced pressure. The brownish-white solid residue was washed with water, $NaHCO_3$ solution, water again, and with diethyl ether. After drying, the product was obtained as a white, microcrystalline solid (19.3 g, 85%), mp 152°C. ^1H NMR (500.13 MHz, CD_3COCD_3) δ: 3.929 (d, J_{HCH} = 12.0 Hz, 1H, CH_2), 3.934 (d, J_{HCH} = 12.0 Hz, 1H, CH_2), 4.406 (d, J_{HCH} = 12.1 Hz, 1H, CH_2), 4.411 (d, J_{HCH} = 12.1 Hz, 1H, CH_2, 4.61 (d, J_{HCH} = 12.1 Hz, 2H, CH_2), 4.94 ppm (d, J_{HCH} = 12.3 Hz, 2H, CH_2). ^{13}C NMR (75.42 MHz, CD_3COCD_3) δ (ppm): 35.68 (s, C), 59.95 (s, CH_2), 59.99 (s, CH_2).

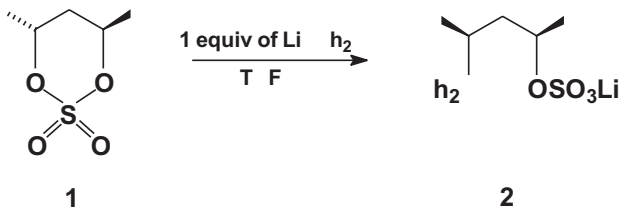
Synthesis of 2,4,8,10-tetraoxa-3,9-dithiaspiro[5.5]undecane 3,3,9,9-tetraoxide (4)

$NaIO_4$ (54.3 g, 0.25 mol) and $RuCl_3$ hydrate (27.2 mg, 0.107 mmol, 40% ruthenium) were added to the bicyclic sulfite **3** (19.3 g, 0.085 mol) in 400 mL of CH_3CN. Water (240 mL) was added slowly to the brown suspension. The mixture turned orange and a considerable amount of white solid precipitated. The reaction was stirred further for 1.5 h. The white solid was filtered and washed exhaustively with water. The white residue was dried at ambient temperature and extracted with hot acetone. Removal of the solvent under reduced pressure yielded a white, microcrystalline solid (17.6 g, 68% calculated for pentaerythritol), mp 280–282°C. ^{1}H NMR (300.15 MHz, CD_3COCD_3) δ (ppm): 5.01 (s, 8H, CH_2). ^{13}C NMR (75.42 MHz, CD_3COCD_3) δ (ppm): 34.30 (s, C), 74.4 (s, CH_2).



Synthesis of (2*R*,4*S*)-4-(diphenylphosphino)-pent-2-yl sulfate lithium salt (2)-butyl sulfate lithium salt

(4*R*,6*R*)-4,6-Dimethyl-2,2-dioxide-1,3,2-dioxathiane (**1**) (2.0 g, 0.012 mol) in THF (15 mL) was added to $LiPPh_2$·dioxane adduct (4.4 g, 0.016 mol) in THF (50 mL) at 0°C, meanwhile the bright red color turned light brown. The mixture was stirred at ambient temperature for 1 h. The THF was removed under reduced pressure, then deoxygenated water (40 mL) and Et_2O (20 mL) were added. The aqueous phase was separated and washed with Et_2O (20 mL) again. The pH of the solution was adjusted to 7.0 using diluted H_2SO_4 solution. The water was removed under reduced pressure, then CH_2Cl_2 (20 mL) was added. Li_2SO_4 was removed by filtration. Evaporation of the solvent under vacuum yielded a white, solid foam (3.1 g, 72%). FAB-MS$^-$: 351 (M – Li$^+$). ^{1}H NMR (300.15 MHz, $CDCl_3$) δ (ppm): 0.84 (dd, J_{PCCH} = 15.1 Hz, J_{HCCH} = 6.6 Hz, 3H, CH_3), 1.01 (d, J_{HCCH} = 6.0 Hz, 3H, CH_3), 1.02 (overlapped by the signal of CH_3, 1H, diastereotopic CH_2), 1.57 (br m, 1H, diastereotopic CH_2), 2.55 (br s, 1H, C*H*-PPh_2), 4.49 (br m, 1H, C*H*-OSO_3Li), 6.91 (br m, 6H, Ar), 7.23 (br m, 4H, Ar). ^{31}P NMR (121.42 MHz, $CDCl_3$) δ (ppm): 1.13. ^{13}C NMR (125.77 MHz, D_2O) δ: 17.99 (d, J_{PCC} = 14.7 Hz, *C*H_3-CH-PPh_2), 23.40 (s, *C*H_3-CH-OSO_3Li), 27.37 (d, J_{PC} = 6.9 Hz, CH_3-*C*H-PPh_2), 42.63 (d, J_{PCC} = 15.8 Hz, *C*H_3-CH-OSO_3Li), 77.71 (d, J_{PCCC} = 12.3 Hz, CH_3-*C*H-OSO_3Li), 131.03 (s, Ar), 131.50 (d, J_{PCC} = 6.3 Hz, Ar), 135.99 (d, J_{PCC} = 17.6 Hz, Ar), 138.41 (d, J_{PCC} = 32.7 Hz, Ar).

Preparation of 1,3-bis(diphenylphosphino)-2,2-bis(lithiumsulfatemethyl)-propane (5)

2,4,8,10-Tetraoxa-3,9-dithiaspiro[5.5]undecane 3,3,9,9-tetraoxide (**4**) (3.0 g, 0.012 mol) in THF (20 mL) was added to $LiPPh_2$·dioxane adduct (8.4 g, 0.035 mol) in THF (60 mL) at 0°C, meanwhile the red color of the reaction mixture faded. The mixture was stirred at ambient temperature for 1 h. The THF was removed under reduced pressure, then deoxygenated water (40 mL) and Et_2O (20 mL) were added. After separation of the phases, the aqueous phase was washed with Et_2O (20 mL) again. The pH of the solution was adjusted to 7.0 using a diluted H_2SO_4 solution. The water was removed under reduced pressure, then CH_2Cl_2 (20 mL) and CH_3OH (6 mL) were added. Li_2SO_4 was removed by filtration. The solvent was evaporated in vacuum

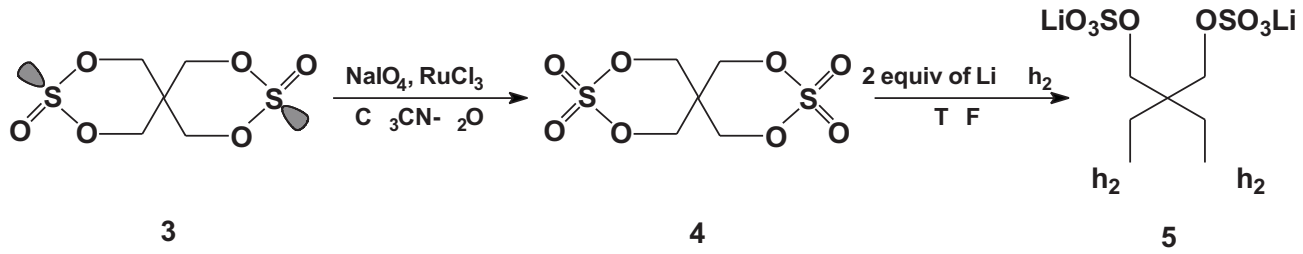
to give a white solid foam (5.42 g, 73%). FAB-MS$^-$: 637 (M – Li$^+$). ^{1}H NMR (500.13 MHz, D_2O) δ (ppm): 2.28 (s, 4H, CH_2), 3.89 (s, 4H, CH_2), 6.89 (m, 8H, Ar), 6.95 (t, J_{HCCH} = 7.1 Hz, 4H, Ar), 7.09 (m, 8H, Ar). ^{31}P NMR (202.45 MHz, D_2O) δ (ppm): –28.9. ^{13}C NMR (125.77 MHz, D_2O) δ (ppm): 33.05 (m, CH_2), 42.20 (t, J_{PCC} = 12.1 Hz, C), 71.62 (m, CH_2), 128.98 (d, J_{PCCC} = 3.8 Hz, Ar), 129.29 (s, Ar), 133.15 (d, J_{PCC} = 21.4 Hz, Ar), 138.35 (d, J_{PC} = 7.5 Hz, Ar).

Results and discussion

Preparation of cyclic sulfates



Cyclic sulfate of (2*R*,4*R*)-2,4-pentanediol (**1**) (Scheme 1) was obtained by a simple one pot reaction following the procedure developed for 1,2-cyclic sulfates by Gao and Sharpless (10). The synthesis involves the treatment of diols with thionyl chloride followed by ruthenium-catalyzed oxidation. Sulfate **1** could be obtained in this way with high yield (82%).

The bicyclic sulfate of pentaerythritol (**4**) could not be prepared by the general literature method. Pentaerythritol and $SOCl_2$ react with negligible reaction rate in CCl_4, which is the recommended solvent for the sulfite formation. Obviously, this fact is due to the poor solubility of the tetrol in CCl_4. Although, upon addition of dioxane to the CCl_4, the bicyclic sulfate could be isolated after the oxidation step, the yield was still very poor (17%).

To gain the product in a satisfying yield, a different procedure has been developed for the synthesis of **4** (Scheme 2). (*i*) The formation of sulfite and the oxidation were carried out in consecutive manner by the isolation of the intermediate sulfite **3**. Reaction of pentaerythritol and $SOCl_2$ in pyridine provided the corresponding bicyclic sulfite **3** with good yield (85%). Even though this spiro-compound is a known molecule of great practical importance (11), its stereochemistry has not been discussed in the literature in details. In a double chair conformation this molecule should have a C_2 axis as the only symmetry element, but its ^{1}H NMR spectrum exhibits a more complex picture. Details of the stereochemical investigation of the bicyclic sulfite will be presented in a subsequent publication. (*ii*) Racemic bicyclic sulfite was dissolved in CH_3CN. $NaIO_4$ and a catalytic amount of $RuCl_3 \cdot 3H_2O$ were added. Slow addition of water to this mixture initiated the oxidation. The crude product was precipitated from the reaction mixture spontaneously. The modified procedure afforded the bicyclic sulfate ester **4** in a 68% overall yield after purification.

Preparation, stability, and characterization of the novel phosphines

The monotertiary phosphine **2** has been prepared by the nucleophile cleavage of the cyclic sulfate of (2*R*,4*R*)-2,4-pentanediol **1** with $LiPPh_2$ in THF (Scheme 1). Nucleophilic attack occurred with complete inversion at the stereogenic center.

The bicyclic sulfate ester **4** reacts smoothly with 2 equivalents of $LiPPh_2$ to give the new water-soluble "sulfated" phosphine **5**, which has two hydrophilic tails attached to the bridgehead carbon atom (Scheme 2). It is interesting to note that the ditertiary phosphine **5** is a structural analogue of the well-known ligands dppp (1,3-(diphenylphosphino)propane) and dpppts (tetrasulfonated dppp). Both dppp and dpppts have important catalytic applications (12).

Although it is known that an ionic sulfate group can act as a leaving group (13), it was clear that its anionic nature renders it kinetically much less reactive than a $ROSO_2OR'$. The negative charge decreases the polarity of C—O bond, and the electrostatic repulsion between the "leaving group" and an anionic attacking group also increases the activation energy of the substitution. Accordingly, no replacement of the $-OSO_3Li$ was experienced in THF at ambient temperature, even when an excess of $LiPPh_2$ was used. The sulfated phosphines proved to be stable in hot, neutral, or slightly basic aqueous solution also. For example, when the aqueous solution of **5** was heated at 80°C for 1 h, or the aqueous solution of **2** was heated at 90°C, pH = 10 for several hours no appreciable amount of decomposition or hydrolysis could be detected.

NMR and FAB-MS data are in agreement with the formula in the case of both phosphines. Both phosphines feature amphiphilic character. For example, at ambient temperature solubility of **2** is 490 g L^{-1} in H_2O and 290 g L^{-1} in CH_2Cl_2. For a comparison, the water solubility of TPPMS (monosulfonated triphenylphosphine) having about the same size and one sulfonate group is 12 g L^{-1} (14). Ditertiary phosphine **5** with two sulfated tails attached to the bridgehead carbon atom has a great water solubility and is also soluble in a number of organic solvents (alcohols, THF).

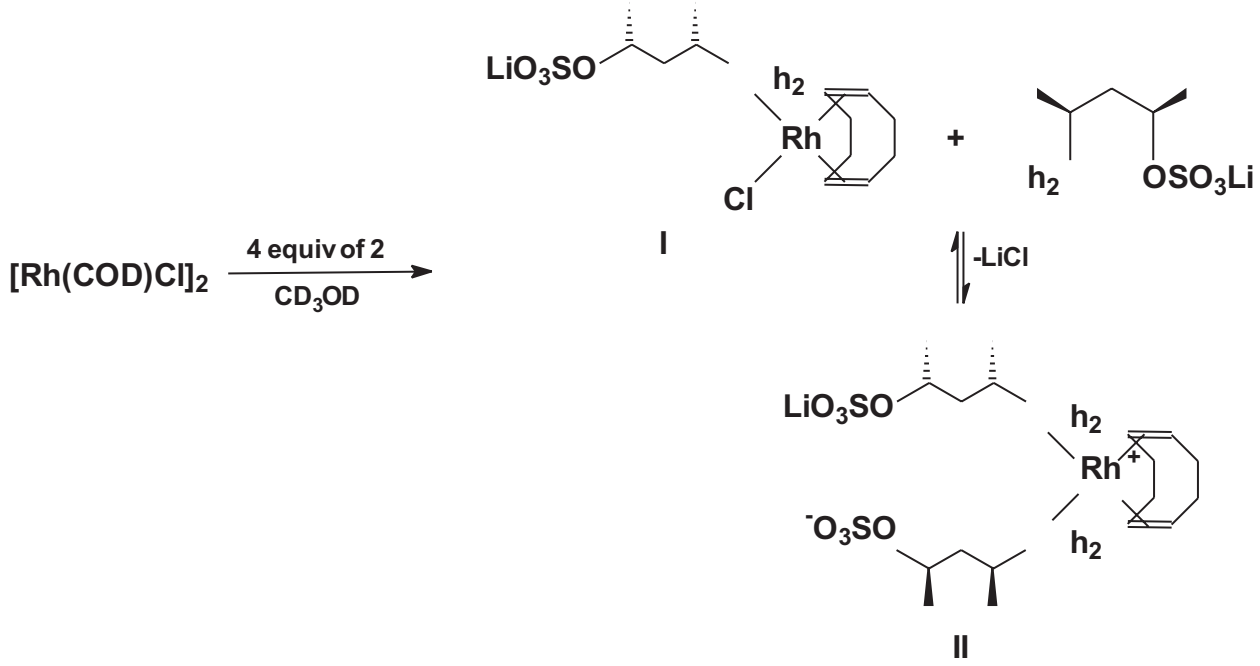
Characterization of Rh(I) and Pt(II) complexes

Rh(I) and Pt(II) complexes are often applied catalysts in homogenous catalysis (15). To study the coordination features of the new phosphines, reactions of **2** and **5** with $[Rh(COD)Cl]_2$ (COD = 1,5-cyclooctadiene) and $Pt(PhCN)_2Cl_2$ were carried out. Reactions were monitored by ^{31}PNMR spectroscopy since the coordination shifts and metal–phosphorus coupling constants are diagnostic features for the identification of the products.

Coordination chemistry of the ligands with rhodium

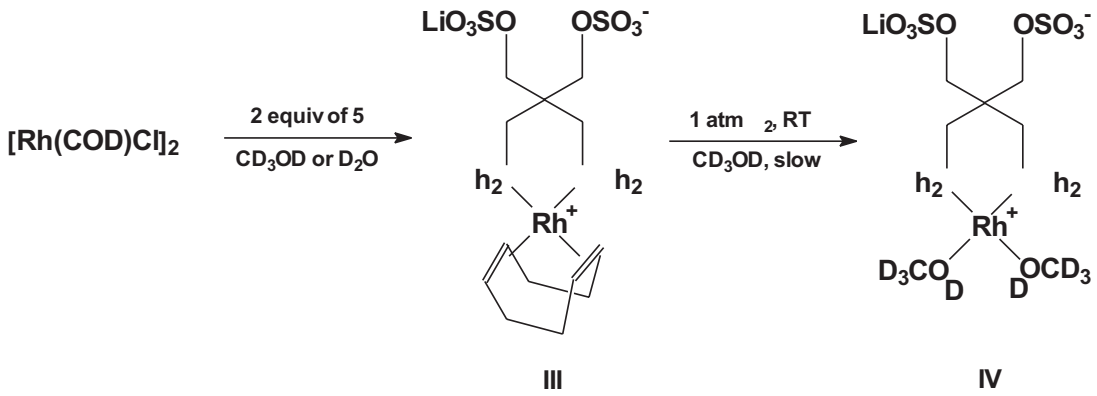
The monotertiary phosphine **2** was reacted with $[Rh(COD)Cl]_2$ at a 2:1 phosphorus:Rh ratio in CD_3OD and D_2O (Scheme 3). In both solvents two complexes were formed and some of the ligand remained uncoordinated. The ^{31}P NMR spectrum (CD_3OD) exhibited resonances at 36.8 ppm (d, $J_{Rh\text{-}P}$ = 147 Hz) and 30.4 ppm (d, $J_{Rh\text{-}P}$ = 147 Hz). The coordination shifts ($\Delta\delta = \delta_{complex} - \delta_{free\ ligand}$) are 29.5 and 35.9 ppm, respectively. Relative intensity of the two doublets (signal at 30.4 ppm compared to the signal at 36.8 ppm) was 0.3. The broad signals were indicative of a dynamic equilibrium between the complexes and the free ligand, which was more significant in D_2O than in CD_3OD. For example doublet character of the signal at 30.4 ppm was not perceptible in D_2O.

We presumed that $[Rh(COD)Cl]_2$ was cleaved by 2 equiv of the phosphine to give complex **I**, but the substitution of chloride leading to complex **II** did not take place completely. To prove our hypothesis, the experiment was repeated in CD_3OD saturated with KCl. Under these conditions, chloride substitution didn't take place at all, which resulted in the disappearance of the doublet at 30.4 ppm and an increase in the intensity of the signal of the free ligand.



When ligand **2** was reacted with $[Rh(COD)Cl]_2$ at a 1:1 or lower phosphorus:Rh ratio in CD_3OD the doublet at 30.4 ppm was absent from the spectrum again. When phosphorus:Rh ratio was increased to 4, the relative intensity of the two signals (30.4 vs. 36.8 ppm) was found to increase to 0.66, and a new species appeared at about 50 ppm. All signals were broad probably as a result of an exchange between the free and coordinated phosphine. Doublet character of the signal at 36.8 ppm and multiplicity of the new resonance were not observable. Finally, $[Rh(COD)Cl]_2$ was treated with $AgNO_3$ in CD_3OD to obtain $[Rh(COD)(CD_3OD)_2]NO_3$. This complex, with two weakly coordinating ligands, was reacted with 2 equiv of the phosphine. Now the spectrum displayed only a doublet at 30.4 ppm.

These results clearly indicate that the doublet at 36.8 ppm belongs to the complex **I**, and the other doublet at 30.4 ppm can be assigned to the complex **II**. Chemical shifts are consistent with the proposed structures. Since chloride is expected to be a weaker σ-donor and a stronger π-acceptor ligand than phosphine **2**, electron density of the central atom should be larger in **II** than in **I** resulting a more downfield resonance for complex **I**.



When chelating phosphine **5** was reacted in a 2:1 ratio with $[Rh(COD)Cl]_2$ in CD_3OD or D_2O–EtOAc, complex **III** formed as the only species (Scheme 4). ^{31}P NMR data of **III** (δ 13.9 ppm (d, J_{RhP} = 141 Hz), in CD_3OD or D_2O) do not significantly differ from that of the analogue complex of

© 2001 NRC Canada

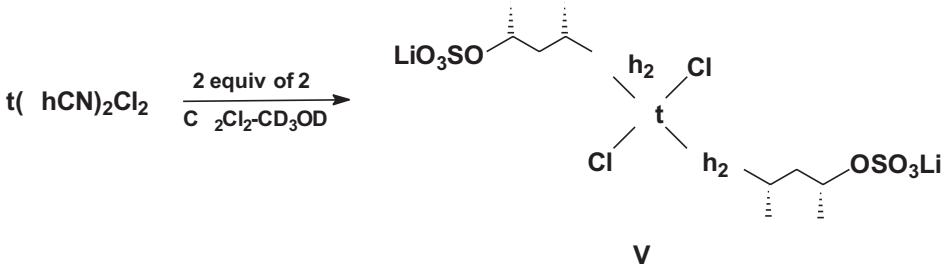
Scheme 3.

Scheme 4.

dppp (16). MS-FAB$^+$ and MS-FAB$^-$ spectra of the complex showed parent ions [M + Li^+] (*m*/*z* = 855) and [M – Li^+] (*m*/*z* = 848). A zwitterionic structure for the complex is suggested in which one of the -OSO_3^- groups of the ligand acts as a counterion for the rhodium.

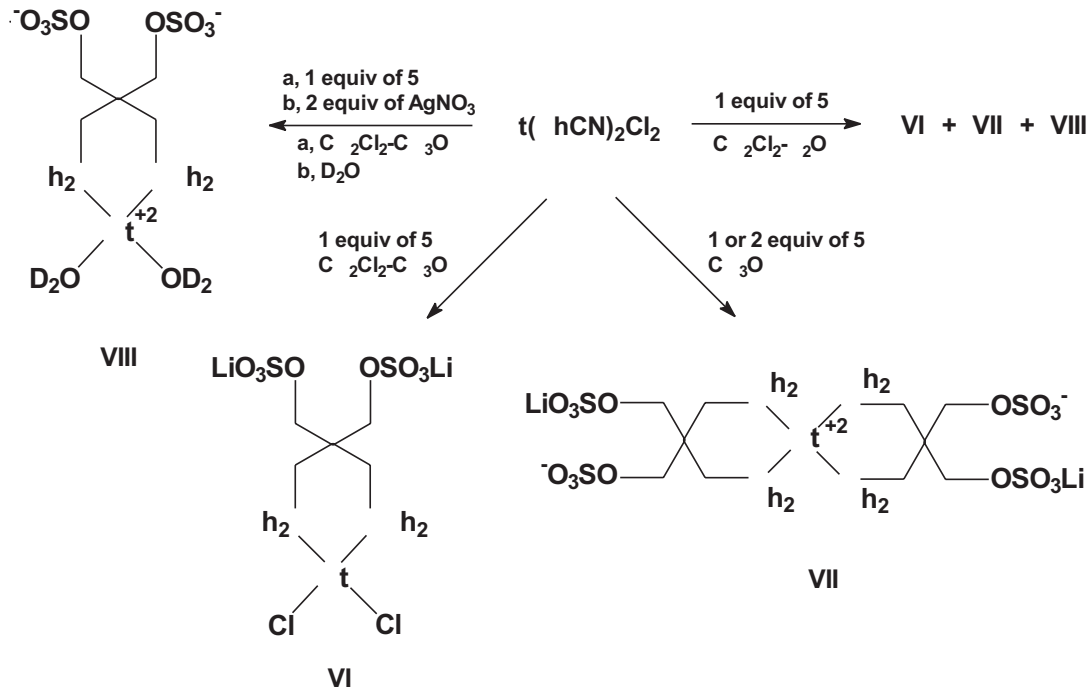
When H_2 was bubbled into the solution of **III**, a minor amount (13% based on ^{31}P NMR) of complex **IV** arose (δ 37.5 ppm (d, J_{RhP} = 187 Hz) in CD_3OD). The relative resistance of **III** against oxidative addition of H_2 is not surprising. Analogous complexes behave in a similar way as described in the literature (16). Complexes containing NBD (NBD = 2,5-bicyclo[2.2.1]heptadiene) instead of COD tends to react with hydrogen without difficulty, since NBD is easily saturated under a hydrogen atmosphere (17).

Coordination chemistry of the ligands with Pt(II)



When amphiphilic phosphine **2** was reacted in a 2:1 ratio with $Pt(PhCN)_2Cl_2$ in CH_2Cl_2 or in a mixture of CH_2Cl_2 and MeOH, complex **V** formed exclusively. ^{31}P NMR spectrum of the complex is characteristic of a square-planar, *dsp*^{2} hybrid PtP_2X_2 species (δ 27.7 (s, $J_{Pt\text{-}P}$ = 2544 Hz) in CD_3OD). The value of $J_{Pt\text{-}P}$ clearly indicates the presence of two phosphine ligands *trans* to each other (Scheme 5).

Compound **5** forms three complexes when reacted in a 1:1 ratio with $Pt(PhCN)_2Cl_2$ in a mixture of CH_2Cl_2–D_2O. Complex **VI** (δ –1.8 ppm (s, $J_{Pt\text{-}P}$ = 3467 Hz), in D_2O), **VII** (δ –3.0 ppm (s, $J_{Pt\text{-}P}$ = 2215 Hz), in D_2O), and **VIII** (δ –6.8 ppm (s, $J_{Pt\text{-}P}$ = 3438 Hz), in D_2O) are generated in a 1:0.81:0.73 ratio (Scheme 6). ^{31}P NMR data clearly indicated that both of the phosphorus on the chelating ligand are coordinated and that they are equivalent (i.e., the other two coordination sites should be occupied by the same species in each complex). The coupling values of $J_{Pt\text{-}P}$ of **VI** and **VIII** suggested chloride or solvent coordination *trans* to the phosphorus, whereas $J_{Pt\text{-}P}$ of **VII** is characteristic of Pt(II) phosphine complexes with phosphorus atoms *trans* to each other.



Complex **VII** could be obtained as the only product from the reaction mixture when the experiment was carried out in

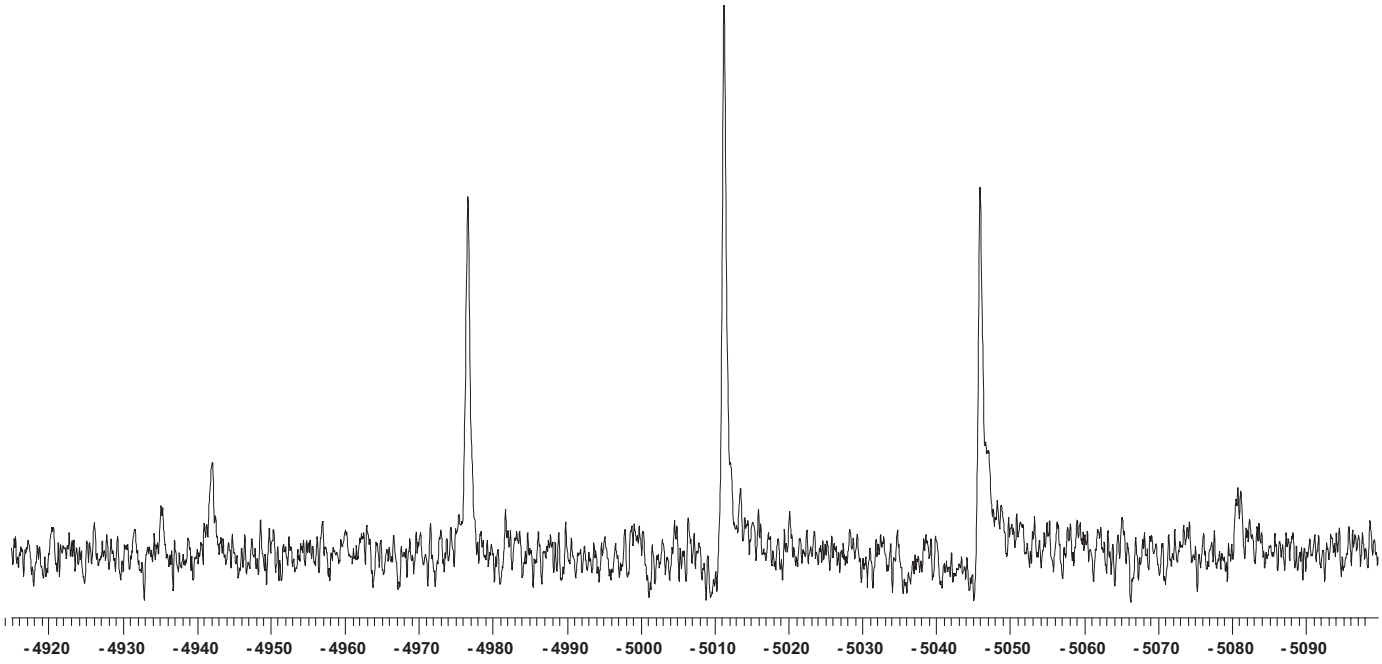
Scheme 5.

Scheme 6.

CD_3OD at a 1:1 or 1:2 ligand:metal ratio. Some of the starting complex remained unreacted when a 1:1 ligand to platinum ratio was used. Based on the ^{31}P NMR data and the experimental evidence, either a dimeric or a monomeric square-planar PtP_4 structure could be imagined for complex **VII**. The $^{195}Pt\{^1H\}$-NMR spectrum clearly showed the presence of four equivalent phosphorus atoms coordinating to the platinum (δ –5011 ppm (q, $J_{Pt\text{-}P}$ = 2215 Hz), in D_2O) (Fig. 1). This fact confirms the square-planar, zwitterionic PtP_4 structure, in which two OSO_3^- groups act as counter ions for the central atom. Further evidence of the structure was obtained by FAB-MS spectroscopy. The parent ion [M – Li^+] was detected and the measured isotopic distribution showed nice agreement with the simulated one (Fig. 2). Note that the formation of **VII** as a single product even at a 1:1 ligand-to-metal ratio under the conditions above is probably due to the poor solubility of the precursor in MeOH and as a consequence an excess of the ligand was present in the solution.

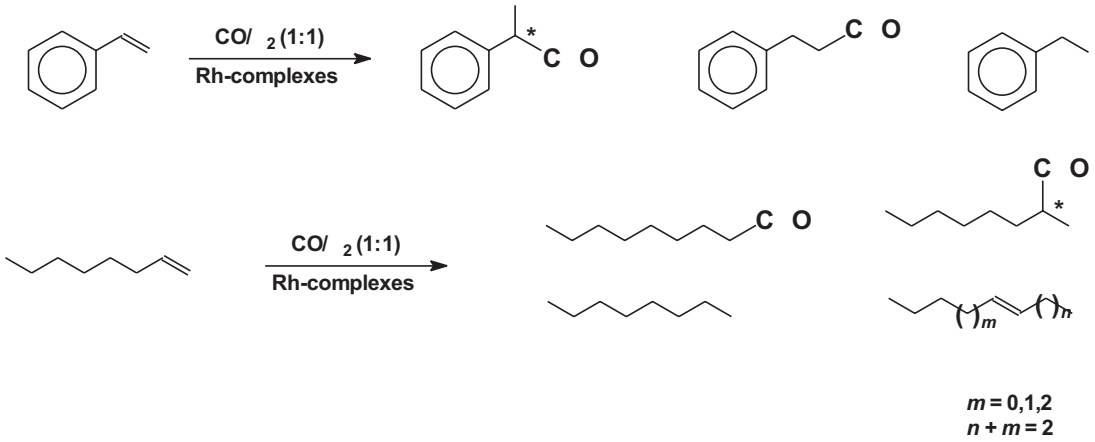
To inhibit the substitution of chlorides either by a second phosphine ligand or solvent, the ligand was dissolved in MeOH and was added to a CH_2Cl_2 solution of the precursor [$Pt(PhCN)_2Cl_2$] in a 1:1 ratio (Scheme 6). In this case only one complex was formed which was assumed to be complex **VI** based on ^{31}P NMR data (CD_3OD, δ –1.5 ppm (s, $J_{Pt\text{-}P}$ = 3445 Hz), in CD_3OD). The slight difference in the spectroscopic data is probably due to the different nature of the solvent.

Dichloro-complex **VI** could be transformed into the aqua complex **VIII** by treatment with $AgNO_3$ in H_2O (D_2O) or with CF_3SO_3Ag in a THF–H_2O (D_2O) solvent mixture. A negligible amount of **VII** was also formed in both cases. Since the NMR data of the complex **VIII** are independent of the applied silver salt, strong coordination of NO_3^- or $CF_3SO_3^-$ can be excluded. The broad resonances of complex **VIII** were indicative of an exchange of H_2O molecules in the coordination sphere.



Hydroformylation of styrene and octene-1

Rhodium complexes of **2** and **5** were used for hydroformylation of styrene and octene-1 (Scheme 7). Both systems proved to be suitable catalysts for hydroformylation (Table 1).



Ligands **2** and **5** gave complete chemoselectivity toward hydroformylation of styrene: no hydrogenation of the substrate was observed.

© 2001 NRC Canada

Fig. 1. ^{195}Pt NMR spectrum of the complex **VII**.

Scheme 7.

Up to 90% regioselectivity towards the more valuable branched aldehyde was observed when **2** was used as the ligand. At the same time, though, no optical induction was detected. It is not surprising, since optically active monodentate ligands usually provide very poor enantioselectivity even in relatively apolar medium. Additionally, the enantiomeric excess of the chiral products obtained in aqueous media is generally much lower than in organic solvents (17). An explanation for the lower enantiomeric excess could be the partial racemization via an enol intermediate, which is known to proceed swiftly in protic media (18). The evaluation of the suitability of the chiral ligand **2** for other asymmetric catalysis is in progress.

The rhodium complex of **5** gives a lower regioselectivity (81%) in a toluene–H_2O two-phase system. An important finding was that after separation of the phases, less than 4 ppm of the rhodium with respect to the amount of the rhodium catalyst employed was detected in the colorless organic phase. The aqueous phase could be recycled. The decrease in activity is probably due to the partial oxidation of the phosphine and a small loss of the catalyst during phase separation. In the absence of organic solvent, the regioselectivity toward the branched aldehyde increased to 86%.

No hydrogenation side product was observed in the hydroformylation of octene-1 either, although both ligands allow a moderate isomerization of the substrate (Table 2). Both ligands provide rather low selectivity under the applied conditions toward the more valuable normal aldehyde. Increasing the ligand **2**:rhodium ratio from 2 to 4 led to a slight increase in selectivity to *n*-aldehyde, but the activity

decreased. The complex modified with **5** provided the highest normal:branched ratio in a substrate–water two-phase system, but a considerable amount of isomerized octenes was formed.

Conclusions

We have discovered a versatile route for the synthesis of water-soluble mono- and ditertiary phosphines. The starting materials are readily available, and the transformations highly selective. The synthetic route is sufficiently flexibile to allow fine tuning of the structure of water-soluble ligands. Reaction of **2** with $[Rh(COD)Cl]_2$ resulted in an equilibrium of Rh(COD)Cl(**2**) and zwitterionic $Rh(COD)(\mathbf{2})_2$ complexes, meanwhile **5** gave the zwitterionic Rh(COD)(**5**) complex as the only product. Treatment of **2** with $Pt(PhCN)_2Cl_2$ gave the square-planar *trans*-$PtCl_2(\mathbf{2})_2$ complex. Reaction of **5** with $Pt(PhCN)_2Cl_2$ in a D_2O–CH_2Cl_2 two-phase system provided three complexes, which could be identified as $PtCl_2(\mathbf{5})$, and zwitterionic complexes $Pt(\mathbf{5})_2$ and $Pt(D_2O)_2(\mathbf{5})$.

Rhodium complexes of **2** and **5** could be successfully applied as catalysts for hydroformylation of styrene and octene-1. The use of **2** in the hydroformylation of styrene resulted in high regioselectivity toward the branched aldehyde (up to 90%), however, no optical induction was observed. When the rhodium complex of **5** was applied as a catalyst in the biphasic hydroformylation of styrene, only 4 ppm of rhodium could be detected in the organic phase.

The application of these sulfated phosphines in other biphasic and aqueous transition-metal catalyzed reactions is being studied.

Scope and limitations of ruthenium-catalyzed metathesis of simple polymer-bound alkenes

Peter G. Breed, James A. Ramsden, and John M. Brown

Abstract: Synthetic procedures for the preparation of two types of functional resin are described, both based on 2% cross-linked polystyrene with a high density (>60%) of side-chains and terminated by a primary alcohol. In the first case the C_{11} side-chain is linked to the polymer through a sulfide, and in the second an ether linkage is employed to incorporate a $(CH_2CH_2O)_4$ unit. In both cases the resins have ^{13}C NMR spectra that are informative in the chain terminus region without special operating conditions. Model intermolecular metathesis reactions were carried out on allylcarbamic acid *tert*-butyl ester and various alkenes with Grubbs' catalyst. On the basis of these experiments, gel-phase metathesis was successfully demonstrated between a polymer-bound allyl ether and simple symmetrical disubstituted alkenes, monitoring the extent of reaction by ^{13}C NMR. These reactions did not go to completion even with recycling and some evidence for competing interchain metathesis is presented, based on the increased broadening and reduced mobility of the ensuing polymer.

Key words: alkene metathesis, ruthenium, gel-phase, ^{13}C NMR.

Résumé : On décrit des méthodes de synthèse de deux types de résines fonctionnelles qui comportent toutes les deux du polystyrène réticulé à 2%, une densité élevée (>60%) de chaînes latérales et qui se terminent par un alcool primaire. Dans le premier cas, la chaîne latérale en C_{11} est liée au polymère par un sulfure et, dans le deuxième cas, on utilise une liaison éther pour incorporer une unité $(CH_2CH_2O)_4$. Dans les deux cas, les spectres RMN du ^{13}C des résines fournissent de l'information sur la région terminale de la chaîne sans nécessiter de conditions spéciales. Utilisant le catalyseur de Grubb, on a effectué des réactions modèles de métathèse intermoléculaire avec l'ester *tert*-butylique de l'acide allylcarbamique et divers alcènes. Sur la base des résultats de ces expériences et faisant appel à la RMN du ^{13}C pour suivre le déroulement de la réaction, on a pu mettre en évidence la métathèse en phase gel entre un oxyde d'allyle lié au polymère et des alcènes simples disubstitués de façon symétrique. Ces réactions ne sont pas complètes, même si on fait du recyclage; de plus, en se basant sur une augmentation de l'élargissement des signaux et sur la mobilité réduite du polymère qui en résulte, on présente des données qui mettent en évidence l'existence de réactions compétitives de métathèse interchaînes.

Mots clés : métathèse d'alcène, ruthénium, phase gel, RMN du ^{13}C.

Introduction

With the rapid development of solid-phase organic synthesis in response to the demands of combinatorial chemistry and high-throughput screening (1), suitable reaction types have been appraised. Desirable qualities include the ability to separate the polymer-bound product from reagents, solvents, and other reaction components, appropriate reactivity for the required functional transformation, and above all quantitative conversion so that the product is a coherent species. On this basis homogeneous catalysis seems ideal where applicable, since the solution phase catalyst may be separated from the medium by a simple filtration, and the reaction rate controlled by catalyst concentration. In addition, all the efforts that have been channeled into catalyst specificity applied to chemo-, regio-, and stereo-control may be brought to bear in solid-phase reactions. In some cases, the application of catalysis to solid-phase reactions has been routinely successful (e.g., in Suzuki coupling) (2) but in others it has proved more difficult to reproduce the stereoselectivity of solution-phase results across the board (e.g., in Sharpless dihydroxylation) (3).

As in any other area of synthesis, progress in solid-phase synthesis depends on methods for the analysis of product purity. Although considerable strides have been made in direct on-bead assay by IR (4), NMR (5), and other techniques (6), it remains a challenge for the discipline. This is especially the case when reactions are conducted on resin phases where the loading of reacting sites is low, as in the case of the popular Wang resin (typically 0.5 mmol g^{-1}) (7), Argogel (typically 0.43 mmol g^{-1}) (8), and Tentagel (typically 0.2 mmol g^{-1}) (9). This provided a basis for the synthesis of polystyrene resins with a high level of functionality, based on a readily accessible precursor. The use of 2% cross-linked 63% chloromethylated polystyrene (Fluka) provided

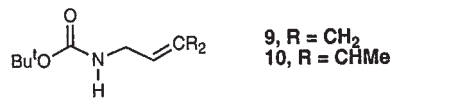
polymers that were suitable for our purpose based on the criteria of mechanical stability and solvent-swelling properties, where the loading is in the 2 to 3 mmol g^{-1} region (for an alternative dendrimer-based approach to high–loading polystyrene, see ref. 10). Methods for the incorporation of side-chains, and the ease of obtention of good quality ^{13}C NMR spectra that reveal signals from the terminal region of the side-chain have already been reported (11).

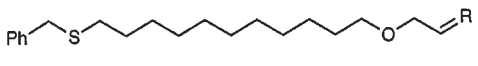
In the present paper the application of alkene metathesis to solid-phase chemistry is described, using high-loading resins. In prior work, Bletcher and co-workers (12) demonstrated that Tentagel or polystyrene bound dialkenes could be subjected to efficient Ru-complex catalyzed intramolecular metathesis leading from 70 to >90% of the ring-closed product based on isolation by cleavage from the resin. In addition intermolecular metathesis between polymer-bound terminal alkenes and disubstituted alkenes was similarly shown to occur in 46 to >95% yield. A contemporary study employed solid-phase metathesis for the simultaneous cyclization and release of the product from the polymer (13). The high reactivity of norbornene in ring-opening metathesis has been exploited with styrene as the solution coreactant (14); the reverse strategy with vinylpolystyrene and norbornene leads to ring opening methathesis polymerization (ROMP) in the solid state and results in a support with a far higher density of functional sites than the original (15). The significance of solid-phase reactions has been recognized in recent reviews on alkene metathesis by Grubbs and others (16).

Results and discussion



Polymer synthesis

For the preparation of sulfide-linked polymers, the synthetic route of Scheme 1 was adopted. Commercially available 11-bromoundecanol (**1**) was converted into its allyl ether **2**, which was in turn converted into the *S*-thioester **3a** by S_N2 displacement. Hydrolysis then produced the thiol **3b**. Two strategies were adapted for the polymer linkage step; either the thiolate anion was generated in situ from **3a**, or directly from the thiol. In both cases the reaction with 63% chloromethylated polystyrene (2% crosslinked) gave polymer **4** quantitatively within experimental error. Although most use was made of standard ^{13}C NMR spectra in the characterization of polymers, magic angle spinning (MAS) was occasionally also used, and Fig. 1 records the spectrum of **4** swollen in C_6D_6. For initial studies of metathesis, a related synthesis was conducted. 11-Acetylthioundecanoic acid (**5a**) (17) was converted into the corresponding diallylamide **5b** via the corresponding acid chloride, and then attached to polymer in the manner described for **3a**, again the reaction to form polymer **6** was quantitative as judged by weight gain and ^{13}C NMR results.



The related synthesis of O-linked polymers is shown in Scheme 2. The allyl ether **7b** of tetraethylene glycol **7a** was prepared, and its Na salt was reacted with PS for 18 h at 60°C in THF. These conditions, the result of some optimization efforts, produced polymer **8** in 90% yield, with characteristic ^{13}C NMR fingerprint.

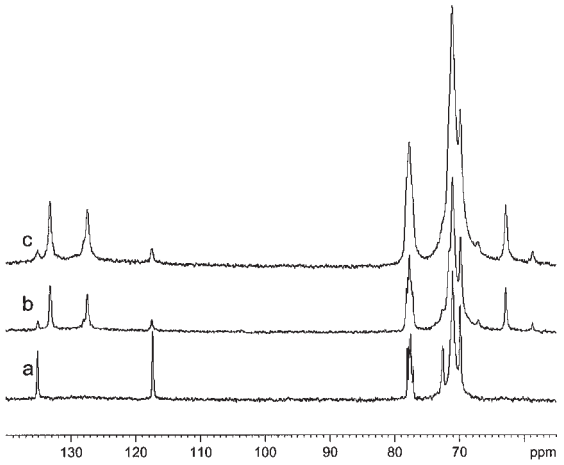
Metathesis experiments

Conditions suitable for cross-metathesis of a terminal alkene **9** with *Z*-but-2-ene were established first. In these and subsequent reactions the "standard" Grubb's catalyst (bis(tricyclohexylphosphine)benzylidineruthenium(IV) dichloride) was utilized. It was found that employing a 100-fold excess of *Z*-but-2-ene in CH_2Cl_2 at ambient temperature with 2 mol% catalyst gave complete reaction to form a *Z*:*E* mixture (1:3) of the disubstituted alkene **10**. Applying these exact conditions to the metathesis of polymer **4** did not result in observable metathesis or significant change in weight. At first the thiolate residue was suspected, and hence, monomer **11** was synthesized. This was shown to be reactive under the conditions of metathesis, giving **12** as an *E*/*Z* mixture in 85% yield. Furthermore, the intramolecular metathesis of polymer **6** to give the corresponding pyrroline **13** occurred smoothly, although 10% Ru catalyst and a reaction time of 48 h were required. It was noted that although the product polymer gave a good ^{13}C NMR spectrum corresponding to complete loss of starting material and the formation of cyclopentene, it appeared dark green-black under a microscope, despite intensive washings with a variety of solvents.

9, R = CH_2
10, R = CHMe

11, R = CH_2
12, R = CHMe

15



16a R = TBDMSi
16b R = H
16c R = Me
16d R = $CH_2OCH_2CH_2OMe$

This appeared to indicate some catalyst decomposition and irreversible reaction with the polymer.

On the basis of this set of experiments there appeared to be two further explanations for the failure of polymer cross-metathesis; firstly that the concentration of reagent and (or) catalyst in the polymer interstices was intrinsically low, and

Fig. 2. (*a*) Polymer **8** swollen in $CDCl_3$, 125 MHz; (*b*) after one cycle of metathesis with *Z*-but-2-en-1,4-diol to give predominantly **17**; (*c*) after two cycles of metathesis. Note the broadening of both resin and solvent (78 ppm) resonances.

secondly that the polymer environment led to a lowered reactivity. The first of these possibilities was tested in part by changing the reaction conditions, conducting metathesis of polymer **4** in CH_2Cl_2:*Z*-but-2-ene (1:1) in a sealed tube with 3 mol% catalyst. After 3.5 days at ambient temperature, workup gave a polymer whose ^{13}C NMR spectrum indicated complete reaction to form an *E*:*Z* isomeric mixture of the butenyl ether **14** (Scheme 3). This success could not, however, be duplicated with other alkenes and cross-metathesis of polymer **4** with either *E*-hex-2-ene (**15**) or the bis-TBDMS ether of *Z*-but-2-en-1,4-diol **16a** failed.

Appraisal of the results at this stage suggested that the reactivity of polymer **4** in metathesis was substantially lower than expected from the model experiments. One possibility was that the polarity of the polymer medium was lower than that of the solution because of the high density of hydrocarbon chains. This could lead to both unfavourable partition and lower reactivity of the catalyst in the polymer phase. For these reasons further metathesis experiments were carried out with the polymeric allyl ether **8**. Since the initial experiments failed completely for alkenes other than *Z*-but-2-ene, the polyether polymer **8** was reacted first with *Z*-but-2-en-1,4-diol **16b**. Under a variety of conditions slow metathesis was observed, but the ^{13}C NMR of the product **17** always showed some unreacted starting material. A single run with the corresponding ether **16c** went to completion, however. For the diol, best results were obtained when the solvent was diglyme (83%, 3 mol% catalyst, 168 h) Less successful experiments were conducted in CH_2Cl_2 (63%, 18 h) and THF (30%, 18 h). The presence of 10% of MeOH appeared to slow the turnover rate in CH_2Cl_2 even though it makes the partly immiscible diol fully soluble. In DMSO, DMF, or MeCN turnover was not observed, although there is some swelling of the polymer in these solvents. No discernable reaction took place in water (18).

Since only 83% yield was observed under the most favourable conditions, the polymer **17**, thus formed, was resubjected to the same reaction conditions. This, however, led to a rather small enhancement of the overall yield (83–87%). At the same time it was noted that the ^{13}C NMR resonances of the polymer became broader after each cycle (Fig. 2). This indicates that a change in the morphology of the polymer takes place during metathesis. The simplest interpretation is that crosslinking takes place within the bead by interchain metathetical reactions. Indeed an additional 1 to 2% of linkages would be expected to make a profound difference to the mobility of polymer-bound chains and thus affect the ^{13}C NMR line-widths. At this level there should be detectable additional signals in the NMR spectrum and there was an unassigned shoulder at 127.5 ppm in the spectra of samples of polymer **17**. This was close to, but not coincident with, the alkene carbon resonance of model compound **16d** at 129 ppm, taken in the presence of polymer **8** to best simulate the signal environment of the trace impurity in **17**.

In summary these experiments demonstrate the feasibility of metathesis reactions on the pendant side-chains of high-loading polystyrene resins, and the feasibility of monitoring the product directly by ^{13}C NMR. Under the conditions described, the utility is limited because of the low on-polymer reactivity and the lack of quantitative reaction (a prerequisite for successful solid-state combinatorial chemistry) with any but the most simple alkene reactants.

Experimental

General

Reactions involving air-sensitive reagents were performed under a dry argon atmosphere, using standard vacuum line techniques in Schlenk glassware. Solvents were deoxygenated where necessary by repeated freeze-thaw-freeze cycles, in which the solvent was frozen using liquid nitrogen, and allowed to warm until fully molten in vacuo or by pump-fill degassing, in which case the solvent was cooled to near freezing, usually using a dry ice – acetone bath, evacuated, and refilled with argon while swirling using a Whirlimixer™ to facilitate complete gas exchange. Transfers were carried out using stainless steel cannula wire or by syringe. For reactions using resin bound substates, "Swirler" refers to a Büchi Rotavapor M and "Bubbler" refers to a designed piece of glassware where the resin was supported on a glass sinter in solvent and agitated by argon passage.

Solvents were purchased from Rathburns, Fisons, Ultrafine, Aldrich, or Prolabo and dried immediately before use by distillation from standard drying agents (19). Merrifield resin was purchased from Fluka, and was 2% crosslinked with divinylbenzene (~4.3 mmol Cl per g resin) 200–400 mesh. Flash chromatography was performed using Fluorochem Silca gel 60, 40–63 μm, 550 $m^2\ g^{-1}$, or with commercial Biotage apparatus; KP-Sil™ 90 g cartridges (32–63 μm, 60 Å, 500–550 $m^2\ g^{-1}$ silica). Melting points were recorded by the author on a Reichert–Koffler block apparatus and are uncorrected. Infrared spectra were recorded on PerkinElmer 1750 or PerkinElmer Paragon 1000 FT spectrometers. ^1H and ^{13}C NMR spectra were recorded on Varian Gemini 200 (200 MHz), Bruker AM 200 (200 MHz), Bruker WH 300 (300 MHz), Bruker DPX 400 (400 MHz), Bruker AMX 500 (500 MHz), or Bruker AM 500 (500 MHz) spectrometers. MAS spectra were recorded on a Bruker MSL 200 (50.3 MHz) spectrometer. Polymer samples to be analyzed were prepared by placing an appropriate amount of polymer (usually ~120–130 mg) in a 5 mm

© 2001 NRC Canada

NMR tube and small amounts of solvent until the polymer was fully swollen and 2–4 mm of excess solvent remained. The tube was then vibrated either using a sonicator, whirlimixer, or by gently tapping the tube on a wooden surface until no air bubbles were visible and the suspension appeared homogeneous. The samples were then allowed to settle for a minimum of 10 min before being place in the spectrometer. For MAS samples by swelling the polymer in the solvent and transferring to a sinter. The excess solvent was removed by brief suction (~30 s) the sample was then transferred to the rotor. Unless otherwise stated operations were performed at room temperature.

Synthesis of polymers and their precursors

*Preparation of 3-(11-bromo-undecyloxy)propene (**2**)*

Sodium hydride (2.24 g, 60% in paraffin, 56 mmol) was washed with pentane (3 × 10 mL) and then suspended in THF (80 mL) and allyl bromide (10.4 mL, 120 mmol). 11-Bromoundecanol (10 g, 40 mmol) in THF (50 mL) was added dropwise. The solution was heated under reflux for 18 h. The solvent was removed in vacuo, the residue was dissolved in water (100 mL) and extracted with dichloromethane (1 × 125 mL, 1 × 100 mL). The combined organic extracts were washed with water (100 mL), dried over magnesium sulfate, and the solvent was removed in vacuo. The product was further purified by column chromatography (SiO_2, pentane–toluene, 2:1) and Kugelrohr distilled (150°C, 4 mbar) to give a colourless oil (8.86 g, 76%). IR (thin film) (cm^{-1}): 3080 (m, C=C-H_2, str), 2928 (s, C-H_2, str), 2856 (s, C-H_2, str), 1728 (m), 1647 (w, C=C, str), 1464 (s, C-H, def), 1346 (s, CH_3, def), 1254 (m), 1106 (s, C-O, str), 996 (m, -CH=CH_2, def), 922 (s, -CH=CH_2, def), 722 (w, CH_2, rocking), 645 (m, C-Br). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 5.92 (ddt, J = 17.2, 10.6, 5.2 Hz, 1H, $H_{2'}$), 5.27 (dq, J = 17.2, 1.6 Hz, 1H, $H_{3'a}$), 5.17 (dq, J = 10.4, 1.3 Hz, 1H, $H_{3'b}$), 3.96 (dt, J = 6.8, 1.3 Hz, 2H, $H_{1'}$), 3.42 (t, J = 7.0 Hz, 2H, H_1 or H_{11}), 3.41 (t, J = 7.1 Hz, 2H, H_{11} or H_1), 1.85 (tt, J = 7.5, 7.0 Hz, 2H, H_{10}), 1.58 (tt, J = 7.0, 7.0 Hz, 2H, H_2), 1.43–1.26 (m, 14H, H_{3-9}). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 135.1 ($C_{2'}$), 116.6 ($C_{3'}$), 71.7 ($C_{1'}$), 70.5 (C_1), 34.0 (C_{11}), 32.8 (C_{10}), 29.7, 29.5, 29.4, 29.4, 28.7, 28.1 ($C_{2,4-9}$), 26.1 (C_3).

Preparation of thioacetic acid S*-(11-allyloxy-undecyl) ester (**3a**)*

To a solution of potassium thioacetate (5.71 g, 50 mmol) in dimethylformamide (50 mL) was added 3-(11-bromo-undecyloxy)propene (27.28 g, 25 mmol). The solution was stirred for 18 h, then added to water (350 mL). This solution was then extracted with ether (3 × 100 mL, 2 × 50 mL). The combined ether extracts were washed with potassium carbonate solution (100 mL, 10%) and saturated potassium carbonate (2 × 100 mL), dried over sodium carbonate, and the solvent was removed in vacuo. The product was further purified by column chromatography (SiO_2, pentane–dichloromethane, 1:1) to give the product as a colourless oil (5.29 g, 74%). CI-MS (NH_4) *m/z* (%): 287 ($[M + H]^+$, 38), 245 ($[M + H - CH3CO]^+$, 39), 227 ($[M + H - CH_2CHCH_2OH]^+$, 27), 187 ($[M - CH_3CO - OCH_2CH{=}CH_2]^+$, 100). HRMS calcd.: 287.2045; found: 287.2047. *Preparation of poly[1-(11-allyloxy-undecylsulfanylmethyl)-4-vinyl benzene-co-vinyl-benzene-co-divinyl-benzene] (**4**)*

From thioacetic acid S*-(11-allyloxy-undecyl)ester:* To a suspension of sodium methoxide (730 mg, 13.5 mmol) in THF (5 mL) was added dropwise, via cannula, a solution of thioacetic acid *S*-(11-allyloxy-undecyl)ester (3.22 g, 11.25 mmol) in THF (5 mL). After 1 h, THF (10 mL) was added, followed by dimethylformamide (30 mL). This solution was added via cannula to a flask containing Merrifield resin (1.74 g, 4.3 mmol g^{-1}) and this suspension was swirled at 50°C for 60 h The suspension was then transferred to a sinter and washed with dichloromethane (3 × 50 mL), dimethylformamide (3 × 50 mL), dichloromethane (3 × 50 mL), water (50 mL), methanol (50 mL), dichloromethane (3 × 50 mL), dimethylformamide (3 × 50 mL), dichloromethane (3 × 50 mL), and pentane (3 × 50 mL). Drying in vacuo gave the product as a colourless opaque tacky polymer (3.28 g, 98%). IR (KBr disk) (cm^{-1}): 3082 (vw, C=C-H_2, str) 3058 (vw, C=C-H_2, str), 3024 (w, Ar-H, str), 2924 (s, C-H_2, str), 2852 (m, C-H_2, str), 1723 (w) 1702 (w), 1647 (w, C=C, str), 1604 (w, ar), 1510 (m, ar), 1494 (w), 1452 (m, C-H, def), 1421 (w, C-H, def), 1347 (m), 1271 (w), 1239 (w), 1137 (vw), 1104 (s, C-O, str), 1018 (vw), 997 (w, -CH=CH_2, def), 920 (s, -CH=CH_2, def), 827 (m, para Ar, C-H bnd), 760 (m, Ph), 700 (s, Ph). ^{13}C MAS NMR (50.3 MHz, C_6D_6) δ: 135.9 ($C_{2'}$), 115.8 ($C_{3'}$), 71.8 ($C_{1'}$), 70.5 (C_1), 30.3, 30.0, 29.7, 29.3, 26.7 (C_{2-11}).

*Through isolation of the intermediate 11-allyloxy-undecane-1-thiol (**3b**):* Thioacetic acid *S*-(11-allyloxy-undecyl) ester (4.29 g, 15 mmol) in methanol (50 mL) was placed in round-bottom flask, and a solution of sodium hydroxide (2.40 g, 60 mmol) in water (3.8 mL) – methanol (10 mL) was added via cannula. The solution was heated at reflux for 25 min, then poured into phosphate buffer (pH 5.5, 100 mL). The solution was extracted with dichloromethane (2 × 100 mL, 1 × 25 mL). The combined extracts were washed with water (1 × 100 mL), and solvent was removed in vacuo. The product was further purified by column chromatography (SiO_2, pentane–toluene, 1:1) to give 11-allyloxy-undecane-1-thiol as a colourless oil (1.784 g, 49%). CI-MS (NH_4) *m/z* (%): 262 ($[M + NH_4]^+$, 22). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 5.91 (ddt, J = 17.3, 10.6, 5.5 Hz, 1H, $H_{2'}$), 5.26 (dq, J = 17.3, 1.6 Hz, 1H, $H_{3'a}$), 5.16 (dq, J = 10.3, 1.5 Hz, 1H, $H_{3'b}$), 3.95 (dt, J = 5.5, 1.5 Hz, 2H, $H_{1'}$), 3.41 (t, J = 6.6 Hz, 2H, H_1), 2.51 (q, J = 7.3 Hz, 2H, H_{11}), 1.75 (br s, 1H, SH), 1.63–1.54 (m, 4H, H_2, H_{10}), 1.40–1.22 (m, 14H, H_{3-9}). ^{13}C NMR

(125 MHz, $CDCl_3$) δ: 135.0 ($C_{2'}$), 116.6 ($C_{3'}$), 71.7 ($C_{1'}$), 70.5 (C_1), 34.0 (C_{10}), 29.7, 29.5, 29.4, 29.0, 28.3 ($C_{2,4-9}$), 26.1 (C_3), 24.6 (C_{11}). Sodium hydride (288 mg, 60% in paraffin, 7.2 mmol) was washed with pentane (3 × 10 mL) and suspended in THF (10 mL). Merrifield resin (1.047 g, 4.5 mmol) was added washing into flask with THF (20 mL), followed by 11-allyloxy-undecane-1-thiol (1.650 g, 6.75 mmol), rinsing the syringe with THF (15 mL). Upon addition of the thiol, effervescence was observed. The suspension was swirled at 60°C overnight. Water (10 mL) was added, and the suspension was swirled for 10 min. The suspension was transferred to a sinter and washed with dichloromethane (25 mL), water (25 mL), dichloromethane (3 × 25 mL), and ethanol (25 mL), and then dried in vacuo to give the product as a colourless tacky polymer (1.993 g, quant.).

*Preparation of (11-allyloxy-undecylsulfanylmethyl)benzene (**11**)*

Sodium hydride (180 mg, 60% in paraffin, 4.5 mmol) was washed with pentane (3 × 5 mL) and suspended in THF (6 mL). *S*-Benzylisothiouronium chloride (405 mg, 2 mmol) was added and the mixture was heated at reflux for 150 min. THF (10 mL) was added and the mixture was heated at reflux for 4 h. 3-(11-Bromo-undecyloxy)propene (583 mg, 2 mmol) was added and the mixture was heated at reflux for 18 h. After cooling, toluene (20 mL) and water (10 mL) were added and the THF was removed in vacuo. Toluene (40 mL) was added and the mixture was washed with water (3 × 30 mL). The combined water washings were extracted with toluene (20 mL), and the combined toluene extracts were dried over sodium sulfate. The product was isolated by column chromatography (SiO_2, dichloromethane–pentane, 1:1) giving the product as a pale yellow oil (466 mg, 69%). CI-MS (NH_4) *m*/*z* (%): 335 ($[M + H]^+$, 100). Preparation of thioacetic acid S*-(10-diallylcarbamoyl decyl) ester (**5b**)*

To a solution of 11-acetylsulfamyl-undecanoic acid (1.820 g, 7 mmol) in toluene (10 mL) was added thionyl chloride (2 mL, 27 mmol), and the mixture was heated at reflux for 2 h. The solvent was removed in vacuo. The acid chloride was dissolved in toluene (10 mL), and diallylamine (5 mL, 40 mmol) was added. The mixture was stirred for 1 h before the addition of saturated sodium hydrogen carbonate (20 mL). Dichloromethane (100 mL) was then added; the solution was washed with saturated sodium hydrogen carbonate (50 mL) and phosphate buffer (pH 5.5, 50 mL), then dried over magnesium sulfate. The product was further purified by column chromatography (SiO_2, pentane – ethyl acetate, 5:1) to give the product as a pale yellow oil (1.569 g, 69%). CI-MS (NH_4) *m*/*z* (%): 340 ($[M + H]^+$, 100), 298 ($[M - C_3H_5]^+$, 14). *Preparation of poly-[*N,N*-diallyl-11-(4-vinyl-benzyl sulfanylundecanoic acid amide)-co-vinyl-benzene-co-divinyl-benzene] (**6**)*

To sodium methoxide (194 mg, 3.6 mmol) was added a solution of thioacetic acid *S*-(10-diallylcarbamoyl decyl) ester (1.018 g, 3 mmol) in THF (2 mL). The solution was stirred for 1 h, then a small aliquot removed and analyzed by ^{1}H NMR, which showed complete deacetylation. The solvent was then removed in vacuo, the solid was redissolved in THF (10 mL), and the solution was added via cannula to a flask containing Merrifield resin (465 mg, 4.3 mmol g^{-1}) swollen in THF (5 mL). The suspension was swirled at 55°C for 18 h, then transferred to a sinter and washed with dichloromethane (2 × 40 mL), water (40 mL), dimethylformamide (4 × 40 mL), and dichloromethane (5 × 40 mL), then dried in vacuo yielding the product as a colourless polymer (1.019 g, quant.). IR (KBr disk) (cm^{-1}): 3081 (w, C=C-H_2, str), 3024 (w, C=C-H or Ar-H, str), 2921 (s, C-H, str), 2852 (m, C-H, str), 1701 (m, C=O, str), 1654 (s, C=C, str), 1636 (s, C=C, str), 1458 (m, C-H, def), 1420 (m, C-H, str), 1213 (br, m), 1113 (w), 1016, 989 (m, -CH=CH_2, def), 912 (m, -CH=CH_2, def), 824 (m), 761 (m, Ph), 698 (m, Ph). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 173.2 (C_1), 133.5, 133.0 ($C_{2'}$), 117.1, 116.5 ($C_{3'}$), 49.2, 47.8 ($C_{1'}$), 33.0 (C_2), 31.7, 29.4 (C_{4-11}), 25.3 (C_3).

*Preparation of 2-(2-(1-(2-allyloxy-ethoxy)-ethoxy)-ethoxy)-ethanol (**7**) (20)*

A 500 mL round-bottom flask was charged with sodium (5.93 g, 0.257 mol) and tetraethylene glycol (200 g). The solution was stirred at 80°C for 18 h. The solution was allowed to cool to room temperature, then 3-bromopropene (23 mL, 0.266 mol) was added dropwise over 15 min. The solution was warmed to 70°C for 90 min and 100°C for 60 min. The solution was allowed to cool to room temperature and added to a mixture of saturated sodium chloride (400 mL) and water (200 mL). The aqueous solution was extracted with dichloromethane (2 × 200 mL, 4 × 50 mL). The combined extracts were extracted with water (2 × 200 mL, 11 × 100 mL), however TLC showed that some product remained in the dichloromethane layer. The solvent was reduced in vacuo to 150 mL and the solution was further extracted with water (2 × 150 mL). The solvent was then totally removed in vacuo, and the oil was redissolved in ether (500 mL) and extracted with water (5 × 100 mL). Sodium chloride was added to the combined water extracts until the solution was saturated. The solution was extracted with dichloromethane (3 × 150 mL, 6 × 100 mL), and the combined extracts were

© 2001 NRC Canada

reduced in vacuo to 500 mL. The solution was dried over sodium sulfate and solvent was removed in vacuo. The oil was then fractional distilled using a 5 inch Vigreux column, and the fraction at 102–112°C at 0.03–0.04 mm Hg (1 mm Hg = 133.32 kPa) was collected. TLC showed this to be a mixture consisting mainly of the desired product, but contained small amounts of tetraethyleneglycol diallyl ether and tetraethylene glycol. The oil was redissolved in saturated sodium chloride (300 mL), and extracted with ether (2 × 200 mL, 5 × 100 mL). The combined extracts were dried over magnesium sulfate, and solvent was removed in vacuo. The oil was triturated with pentane (2 × 50 mL). Solvent was removed in vacuo giving a colourless oil (30.76 g, 50%), which contained a slight trace of the diallyl ether of tetraethyleneglycol, bp 102–112°C, 0.03–0.04 mm Hg ((lit. (21) 99–101°C, 0.2 mm Hg). CI-MS (NH_4) *m/z* (%): 235 ($[M + H]^+$, 100). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 5.87 (ddt, *J* = 17.2, 10.3, 5.7 Hz, 1H, $H_{2'}$), 5.22 (dq, *J* = 17.2, 1.6 Hz, 1H, $H_{3'a}$), 5.13 (dm, *J* = 10.3 Hz, 1H, $H_{3'b}$) 3.98 (dm, *J* = 5.6 Hz, 2H, $H_{1'}$), 3.68–3.54 (m, 8H, $H_{1–8}$), 2.81 (br s, 1H, OH). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 134.7 ($C_{2'}$), 116.8 ($C_{1'}$), 72.5 (C_7), 72.0 ($C_{1'}$), 70.5, 70.5, 70.5, 70.2 ($C_{2–7}$), 69.3 (C_1), 61.6 (C_8).

*Preparation of poly[1-(2-(2-(1-(2-allyloxy-ethoxy)-ethoxy)-ethoxy)-ethoxy methyl)-4-vinyl benzene-co-vinyl-benzene-co-divinyl-benzene] (**8**)*

Merrifield resin (1.164 g, 4.3 mmol g^{-1}), sodium hydride (800 mg, 60% in paraffin, 20 mmol), THF (20 mL), and 2-(2-(1-(2-allyloxy-ethoxy)-ethoxy)-ethoxy)-ethanol (**7**) (4.686 g, 20 mmol) were placed in 50 mL round-bottom flask, and swirled at 60°C for 18 h. The suspension was transferred to a sinter with THF, and washed with DMF (3 × 30 mL), water (3 × 30 mL), methanol (3 × 30 mL), tetraethyleneglycol dimethyl ether (3 × 30 mL), methanol (3 × 30 mL), and dichloromethane (3 × 30 mL) and dried in vacuo giving the product as colourless opaque tacky polymer (2.056 g, 90%). ^{13}C MAS NMR (50.3 MHz, $(CD_3)_2SO$) δ: 134.1 ($C_{2'}$), 115.1 ($C_{3'}$), 71.1 ($C_{1'}$), 70.0 ($C_{2–8}$), 69.1 (C_1).

Experimental for metathesis reactions

Diallylcarbamic acid *tert*-butyl ester (21, 22), 2,5-dihydropyrrole-1-carboxylic acid *tert*-butyl ester (23), and allyl-carbamic acid *tert*-butyl ester (23) were prepared by literature procedures.

Preparation of but-2-enylcarbamic acid-tert-*butyl ester (**10**) (24)*

Bis(tricyclohexylphosphine)benzylidineruthenium(IV) dichloride (27.4 mg, 1 mol%) and allylcarbamic acid-*tert*-butyl ester (**9**) (524 mg, 3.33 mmol) were placed in a Schlenk tube fitted with a dry ice condenser. Dichloromethane (65 mL) was added via cannula. *Z*-2-Butene was condensed into a Schlenk tube cooled in a dry ice – acetone bath, and 3.5 mL was transferred into the tube using a dry ice cooled syringe. The solution was stirred for 6 h, the condenser was then removed, a needle was inserted into the septum, and the solution was left overnight. The solvent was then removed in vacuo and the product was isolated by column chromatography (SiO_2, pentane – ethyl acetate, 2:1) to give the product as brown oil (510 mg, 89%). A small quantity of the two isomers was partially separated by preparative GLC (Peg 20M, 15%, 175°C). ^{1}H NMR (500 MHz, $CDCl_3$) δ (*Z*)-isomer: 5.60 (dqd, *J* = 10.4, 6.7, 1.0 Hz, 1H, H_2), 5.42 (dtd, *J* = 10.4, 7.0, 1.0 Hz, 1H, H_3), 4.48 (br s, 1H, NH), 3.78 (br s, 2H, H_4), 1.67 (dd, *J* = 6.7, 0.9 Hz, 3H, H_1), 1.45 (s, 9H, H_7); (*E*)-isomer: 5.60 (dq, *J* = 14.7, 7.0, 1H, H_2), 5.45 (dt, *J* = 14.7, 6.3 Hz, 1H, H_3), 4.54 (br s, 1H, NH), 3.66 (br s, 2H, H_3), 1.67 (d, *J* = 7.0 Hz, 3H, H_1), 1.45 (s, 9H, H_7). ^{13}C NMR (125 MHz, mixed isomers, $CDCl_3$) δ: 155.8 (C_{5Z}), 155.7 (C_{5E}), 127.6 (C_{3E}), 127.5 (C_{2E}), 127.2 (C_{3Z}), 126.7 (C_{2Z}), 79.1 (C_6), 42.5 (C_{4E}), 37.3 (C_{4Z}), 28.4 (C_7), 17.6 (C_{1E}), 12.9 (C_{1Z}).

General procedure for screening of metathesis of allyl-carbamic acid tert-*butyl ester (**9**)*

Allyl-carbamic acid *tert*-butyl ester (78.6 mg, 0.5 mmol) and bis(tricyclohexylphosphine)benzylidineruthenium(IV) dichloride (8.2 mg, 10 μmol) were placed in a Schlenk tube and degassed. In a separate Schlenk tube dichloromethane (10 mL) and the alkene (5 mmol) were degassed. The liquid was transferred via cannula to the first Schlenk tube. The reactions were followed both by TLC and (or) by removing aliquots (0.5 mL), removing the solvent in vacuo, and analyzing by ^{1}H NMR.

Pent-2-enyl-carbamic acid tert-*butyl ester (25):* Using *E*-2-hexene; ^{1}H NMR (500 MHz, $CDCl_3$) δ: 5.63 (dtt, *J* = 15.3, 6.2, 1.3 Hz, 1H, H_3), 5.43 (dt, *J* = 15.3, 5.9 Hz, 1H, H_4), 4.55 (br s, 1H, NH), 3.68 (br t, 2H, H_5), 2.02 (qddd, *J* = 7.3, 6.2, 1.5, 1.2, 2H, H_2), 1.44 (s, 9H, H_8), 0.97 (td, *J* = 7.4, 1.2, 3H, H_1). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 155.7 (C_6), 134.6 (C_4), 125.3 (C_3), 79.1 (C_7), 42.5 (C_5), 28.4 (C_8), 25.2 (C_2), 13.4 (C_1).

*4-*tert-*Butoxycarbonylamino-but-2-enyl)-carbamic acid* tert-*butyl ester:*

Bis(tricyclohexylphosphine)benzylidineruthenium(IV) dichloride (97 mg, 2 mol%) and allyl-carbamic acid *tert*-butyl ester (1.00 g, 5.92 mmol) were placed in a Schlenk tube. Chloroform (50 mL) was added via cannula and the solution was stirred at 50°C for 3 days. More bis(tricyclohexylphosphine)benzylidineruthenium(IV) dichloride (97 mg, 2 mol%) was added and the solution was stirred for a further 3 days at 50°C. The solvent was removed in vacuo and the stereoisomeric products were separated by chromatography on a Biotage apparatus (ethyl acetate – pentane, 1:4). ^{1}H NMR (500 MHz, $CDCl_3$) *E*-isomer δ: 5.55 (br s, 2H, H_1), 4.88 (br s, 2H, NH), 3.77 (br s, 4H, H_2), 1.44 (s, 18H, H_1). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 155.7 (C_3), 128.4 (C_1), 79.4 (C_4), 41.9 (C_2), 28.4 (C_5). ^{1}H NMR (500 MHz, $CDCl_3$) *Z*-isomer δ: 5.61 (br s, 2H, H_1), 4.63 (br s, 2H, NH), 3.72 (br s, 4H, H_2), 1.44 (s, 18H, H_5). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 155.9 (C_3), 128.9 (C_1), 79.4 (C_4), 37.1 (C_2), 28.4 (C_5).

*Preparation of 11-(but-2-enyloxy-undecyl)-sulfanylmethylbenzene (**12**)*

Bis(tricyclohexylphosphine)benzylidineruthenium(IV) dichloride (8.2 mg, 2 mol%) was placed in a Schlenk tube fitted with a dry ice condenser. *Z*-2-butene was condensed into a Schlenk tube cooled in a dry ice – acetone bath, and 0.5 mL was transferred into the tube using a dry ice cooled syringe.

© 2001 NRC Canada

11-(Allyloxy-undecylsulfanylmethyl)benzene (0.5 mmol, 167 mg) in dichloromethane (10 mL) was added via cannula, and the solution was stirred for 5.5 h. The solvent was removed in vacuo and the product was further purified by column chromatography (SiO_2, dichloromethane–pentane, 1:1) yielding the product as a yellow oil (134 mg, 85%). CI-MS (NH_4) *m*/*z* (%): 349 ($[M + H]^+$, 100), 293 ($[M - C_4H_7]^+$, 2). HRMS calcd.: 349.2565; found: 349.2575. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.31 (s, 2H, H_{14} or H_{15}), 7.30 (s, 2H, H_{15} or H_{14}), 7.27–7.20 (m, 1H, H_{16}), 5.75–5.53 (m, 2H, $H_{2'}$ and $H_{3'}$), 4.02 (ddt, *J* = 6.6, 1.5, 1.0 Hz, 2H, $H_{1'Z}$), 3.88 (dt, 6.2, 1.2 Hz, 2H, $H_{1'E}$), 3.70 (s, 2H, H_{12}), 3.41 (t, *J* = 6.9 Hz, 2H, H_{1Z}), 3.39 (t, *J* = 6.9 Hz, 2H, H_{1E}), 2.40 (t, *J* = 7.6 Hz, 2H, H_{11}), 1.71 (ddt, *J* = 6.5, 1.6, 1.2 Hz, 3H, $H_{4'E}$), 1.66 (ddt, *J* = 6.8, 1.7, 0.9 Hz, 3H, $H_{4'Z}$), 1.61–1.51 (m, 4H, H_2 and H_{10}), 1.40–1.14 (m, 14H, H_{3-9}). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 138.7 (C_{13}), 129.2 ($C_{2'E}$), 128.8 (C_{15}), 128.4 (C_{14}), 127.8 ($C_{3'E}$), 127.5 ($C_{2'Z}$), 127.1 ($C_{3'Z}$), 126.8 (C_{16}), 71.5 (C_{1E}), 70.4 (C_{1Z}), 70.3 ($C_{1'E}$), 66.0 (C_{1Z}), 36.3 (C_{12}), 31.4 (C_{11}), 29.8, 29.5, 29.5, 29.2, 28.9 ($C_{2,4-10}$), 26.2 (C_3), 17.7 ($C_{4'E}$), 13.2 ($C_{4'Z}$).

*Preparation of poly[1-(2,5-dihydro-pyrrol-1-yl)-11-(4-vinyl benzyl sulfanyl)-undec-1-one-co-vinyl-benzene-co-divinyl-benzene] (**6**)*

Bis(tricyclohexylphosphine)benzylidineruthenium(IV) dichloride (26 mg, 31 μmol) and resin **75** (150 mg, 312 μmol) were placed in a round-bottom flask and dichloromethane (6 mL) was added. The suspension was swirled under argon for 48 h, before being transferred to a sinter with dichloromethane, and washed with dichloromethane (3 × 25 mL), dimethylformamide (3 × 25 mL), and various combinations of ethanol, methanol, dimethylformamide, pentane, toluene, acetonitrile, and dimethylsulfoxide. However no washing solvent, or combination successfully removed the dark-green colour from the bead. The polymer was finally washed with dichloromethane (3 × 25 mL), and dried in vacuo, giving the product as a dark green polymer (142 mg, 92%). IR (KBr disc) (cm^{-1}): 3081 (w), 3055 (w), 3024 (m), 2926 (s), 2848 (m), 1944 (br, m), 1719 (s), 1702 (s), 1654 (s), 1648 (s), 1420 (m), 1263 (m), 1198 (m), 1107 (m), 1069 (w), 997 (m), 917 (m), 823 (s), 737 (s), 695 (m, Ph), 669 (s). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 171.8 (C_1), 126.0 ($C_{2'}$), 53.5 ($C_{1'a}$), 52.9 ($C_{1'b}$), 34.5, 33.2, 29.44, 26.3, 25.0 (C_{2-11}).

*Preparation of poly-[11-but-2-enyloxy-undecyl sulfanyl methyl-(4-vinyl benzene)-co-vinyl-benzene-co-divinyl-benzene] (**14**)*

*From metathesis of resin **4** with Z-2-butene:* Resin **4** (200 mg, 2.27 mmol g^{-1}) was placed in a thick walled glass tube (12 mm bore) and washed down with THF. The solvent was removed by blowing argon over the suspension until no solvent was visible outside the polymer. The polymer was then dried in vacuo. The tube was then cooled in a dry ice – acetone bath. *Z*-2-Butene was condensed into a Schlenk tube cooled in a dry ice – acetone bath, and 0.6 mL was transferred into the tube using a dry ice cooled syringe. Bis(tricyclohexylphosphine)benzylidineruthenium(IV) dichloride (11.2 mg, 3 mol%) in dichloromethane (0.6 mL) was then added to the tube. The bottom of the tube was cooled in liquid nitrogen before sealing. The tube was left at room temperature for 84 h. The lower half of the tube was then cooled in liquid nitrogen and the upper part was broken. The polymer was transferred to a sinter with dichloromethane and washed with dimethylformamide (3 × 25 mL), dichloromethane (3 × 25 mL), and pentane (3 × 25 mL), and dried in vacuo yielding the pale orange product polymer (206 mg, 94%). IR (thin film) (cm^{-1}): 3052 (w, C-H, str), 3023 (m, Ar-H or C=C-H, str), 2926 (s, C-H, str), 2850 (m, C-H, str), 1720 (m), 1702 (m), 1603 (m, Ar-H, def), 1509 (m, Ar-H, def), 1492 (m, Ar-H, def), 1440 (m, C-H, def), 1420 (m, C-H, def), 1364 (w, C-H_3, def), 1312 (w), 1260 (m), 1212 (w), 1180 (w, C-O, str), 1144 (w), 1108 (m, C-O, str), 1066 (w), 1018 (w), 965 (m, (E)-H-C=C-H, def), 908 (w), 823 (m, para Ar, C-H bnd), 759 (m, Ph, bnd), 747 (m), 698 (m, Ph, bnd), 672 (w), 661 (m). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 128.9 ($C_{2'}$), 127.6 ($C_{3'}$), 71.2 (C_1), 70.0 ($C_{1'}$), 31.2, 29.3, 25.8 (C_{2-11}), 17.6 ($C_{4'E}$), 13.0 ($C_{4'Z}$).

From Resin-OH and crotyl bromide: Potassium hydride (35% in mineral oil) was placed in a preweighed Schlenk tube and washed with pentane (3 × 10 mL). The residual pentane was removed in vacuo to give (120 mg, 3.0 mmol). The Schlenk tube was cooled in dry ice – acetone bath, and solution of 18-crown-6 (555 mg, 2.1 mmol) in THF (22 mL) was added slowly via cannula. Resin-OH (12) was placed in the swirler, and the potassium hydride solution was added via cannula. As the suspension warmed to room temperature effervescence was observed. The suspension was allowed to warm to room temperature and swirled for 30 min. Crotyl bromide (1.0 mL, 10 mmol) was added and the suspension was swirled overnight, then transferred to a sinter with dichloromethane, and washed with dimethylformamide (3 × 30 mL), dichloromethane (30 mL), and pentane (30 mL), then dried in vacuo to give the product as a colourless tacky polymer (521 mg, 18% (by ^{13}C NMR)).

*General procedure for screening of metathesis of resin **8** and various alkenes*

Resin **8** (150 mg, 0.32 mmol) and bis(tricyclohexylphosphine)benzylidineruthenium(IV) dichloride (7.8 mg, 3 mol%) were loaded into a small Schlenk tube with a small magnetic follower. The contents of the Schlenk tube were degassed. The alkene and solvent were placed in a separate Schlenk tube, degassed, and added via cannula. The suspension was stirred slowly for the stated amount of time, then transferred to a sinter with a solvent (usually dichloromethane) and washed with some of the following solvents: dichloromethane, dimethylformamide, methanol, pentane, tetraglyme, THF, and dried in vacuo For the cross-metathesis product with *Z*-but-2-en-1,4-diol. ^{13}C NMR (125 MHz, $CDCl_3$) δ: 133.2 ($C_{3'}$), 127.4 ($C_{2'}$), 70.9 ($C_{3'}$), 69.8, 67.2 (C_{1-8}), 62.8 ($C_{1'}$), 58.6 ($C_{4'}$).

Proton- and lanthanide-coordinating properties of the tetraaza macrocycle (EDDA–KA)$_2$ in aqueous solution

Bin Song, Glen S. Kurokawa, Shuang Liu, and Chris Orvig

Abstract: The new potentially multidentate ligand (EDDA–KA)$_2$ has been prepared and its acid–base properties determined. Its coordination properties with three lanthanide ions (La^{3+}, Gd^{3+}, and Lu^{3+}) and Fe^{3+} have been studied in aqueous solution (I = 0.16 M NaCl, 25°C) by potentiometric pH, spectrophotometric, and ^{1}H NMR titrations. In total, eight pK_a values could be determined by these diverse methods. From the ^{1}H NMR titrations, all the deprotonation steps could be determined and assigned (in groups). Strong hydrogen bonding among two nitrogen atoms and one oxygen atom on the pyrone ring was observed, and the corresponding pK_a values were estimated to be 13.2 and 14.0. By comparison with similar systems, an equilibrium constant for the formation of the hydrogen bond was estimated, $K_I = 10^{4.4}$. Eight stability constants in total were determined for various protonation states of the La^{3+} and Gd^{3+} complexes, but for Lu^{3+} only the last four constants were obtained. The species distribution diagram showed that [M(EDDA–KA)$_2$-4H]$^{2-}$ predominated in the range $5 \le pH \le 9$ and [M(EDDA–KA)$_2$-6H]$^{4-}$ predominated in the region $9 \le pH \le 11$. In the former complex, two strong hydrogen bonds anchored the macrocycle and Ln^{3+} was coordinated with the four carboxylate groups; in the latter, the two hydrogen bonding protons were absent and the metal ion might also bind to the nitrogens on the macrocycle. The stability of Gd^{3+}–(EDDA–KA)$_2$ is lower than the analogous Gd^{3+} complexes of DOTA, DTPA, and DTPA–BMA.

Key words: acidity constants, stability constants, La^{3+}, Gd^{3+}, Lu^{3+}, Fe^{3+}, amino carboxylate chelator.

Résumé : On a préparé le nouveau ligand (EDDA–KA)$_2$ qui est potentiellement multidentate et on a déterminé ses propriétés acide–base. Faisant appel à des titrages spectrophotométriques, à l'aide de pH potentiométrique ou de la RMN du ^{1}H et opérant en solutions aqueuses (I = 0,16 M NaCl, 25°C) on a étudié ses propriétés de coordination avec trois ions de la série des lanthanides (La^{3+}, Gd^{3+} et Lu^{3+}) ainsi qu'avec le Fe^{3+}. Au total, on a ainsi déterminer huit valeurs de pK_a par ces diverses méthodes. Sur la base des titrages par RMN du ^{1}H, on a pu déterminer toutes les étapes de déprotonation et les attribuer (en groupes). On a observé de fortes liaisons hydrogènes entre deux atomes d'azote et un atome d'oxygène sur la pyrone; on a évalué que les valeurs correspondantes des pK_a sont 13,2 et 14,0. Par comparaison avec d'autres systèmes semblables, on a évalué que la constante d'équilibre pour la formation de la liaison hydrogène est $K_I = 10^{4,4}$. On a déterminé un total de huit constantes de stabilité pour les divers états de protonation des complexes de La^{3+} et Gd^{3+}; toutefois, dans le cas du Lu^{3+}, on n'a déterminer que les quatre dernières constantes. Le diagramme de distribution des espèces montre que [M(EDDA–KA)$_2$-4H]$^{2-}$ est l'espèce prédominante à des pH allant de 5 à 9 et que [M(EDDA–KA)$_2$-6H]$^{4-}$ est l'espèce prédominante à des pH allant de 9 à 11. Dans le premier complexe, deux liaisons hydrogènes fortes permettent d'ancrer le macrocycle et le Ln^{3+} est coordiné aux quatre groupes carboxylates; dans le dernier complexe, les deux protons formant la liaison hydrogène sont absents et l'ion métallique pourrait aussi se lier aux azotes du macrocycle. La stabilité du Gd^{3+}–(EDDA–KA)$_2$ est inférieure à celles des complexes analogues du Ga^{3+} avec DOTA, DTPA et DTPA–BMA.

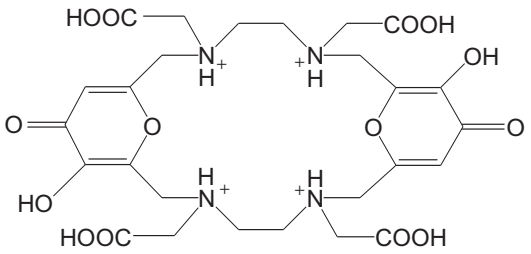
Mots clés : constantes d'acidité, constantes de stabilité, La^{3+}, Gd^{3+}, Lu^{3+}, Fe^{3+}, agent de chélation aminocarboxylate.

[Traduit par la Rédaction]

Introduction

Aminocarboxylate compounds are widely used as chelators for a variety of transition-metal and lanthanide ions; some of these complexes are used in vivo as diagnostic probes, such as magnetic resonance imaging (MRI) contrast agents (1-3).

Received October 2, 2000. Published on the NRC Research Press Web site at http://canjchem.nrc.ca on July 17, 2001.



Dedicated to Professor Brian R. James on the occasion of his 65th birthday.

The solution chemistry of these ligands is of critical importance — the results evince the structures of the complexes in solution and the species distribution as a function of concentration, L:M ratio, and pH, information of direct relevance to the function of these compounds in vivo. The aqueous chemistry of lanthanide ions (Ln^{3+}) is dominated by their oxophilicity (4, 5) with the strongest binding ligands containing carboxylato or phosphonato oxygen donors. Amines alone are poor donors for Ln^{3+} in water; however, incorporated into aminocarboxylates they form quite stable Ln(III) complexes. There are numerous reports of stability constants for Ln(III) complexes of aminocarboxylate derivatives including EDTA analogues (e.g., DTPA (6)) and macrocycles (e.g., DOTA (7)). Replacing the carboxylate group with other functional groups, for example hydroxyl or pyridine (8), has been tried to alter the coordination ability of the aminocarboxylates.

In this study, we have prepared a rather unusual macrocylic amino carboxylate compound $(EDDA–KA)_2$ (see Scheme 1), measured its acidity constants, and studied its aqueous complexation with La^{3+}, Gd^{3+}, and Lu^{3+}. $(EDDA–KA)_2$ is unusual in that the insertion of a pyrone ring between the two EDDA molecules renders the proton and metal ion binding properties of, and hydrogen-binding in, $(EDDA–KA)_2$ very different from its parent ligand EDDA and from the structurally similar compound DOTA.

Experimental section

Materials

EDDA was from Sigma, kojic acid was from Lancaster, and paraformaldehyde was from Fisher Scientific. Atomic absorption standard solutions of La^{3+} and Lu^{3+} were purchased from Sigma, while that of Gd^{3+} was from Aldrich. NaOH (1 M) solution used as titer was from Fisher Scientific, and its concentration was established with potassium biphthalate from Anachemia Canada Inc. Standard buffer solutions (pH = 4.00 and 7.00), NaCl for controlling the ionic strength of the solution, and HCl(aq) were also purchased from Fisher Scientific. Water used in the experiments was deionized (Barnstead D8902 and D8904 cartridges) and distilled (Corning MP-1 Megapure still) and depleted in CO_2 by boiling under Ar for about 30 min. D_2O, NaOD, and DCl were purchased from Cambridge Isotope Laboratories.

Instrumentation

Potentiometric measurements were carried out with an automatic titration system consisting of a Metrohm 713 pH meter equipped with Metrohm 6.0233.100 electrode, a model 665 Metrohm Dosimat autoburet (5 mL burette, absolute error ±0.015 mL, accuracy ±0.005 mL), water-jacketed titration vessels, and a Julabo UC circulating bath. Both pH meter and autoburet were controlled by an IBM compatible PC and the titration was controlled by a locally written QBasic program. UV spectra were recorded with a HP 8453 spectrophotometer and the ^1H NMR spectra were obtained at 200MHz on a Bruker AC-200 instrument.

Preparation of $(EDDA–KA)_2$

To a suspension of EDDA (1.75 g, 10 mmol) in 90% ethanol (180 mL) was added paraformaldehyde (0.8 g, 27 mmol), and kojic acid (3.0 g, 10 mmol). The reaction mixture was heated to reflux for 48 h. The mixture was then cooled to room temperature, and the resulting solid was col-

© 2001 NRC Canada

lected by filtration, washed with ethanol, and dried under vacuum overnight. This crude product was suspended in 20 mL water with stirring, and the resulting solution was slowly titrated with 5 M NaOH to pH ~ 10. After clarification of this solution by filtration, concentrated HCl was then added dropwise to the filtrate until the pH of the mixture was 3.0; after stirring the resulting suspension for 1 h, the solid was collected by filtration, washed with ethanol, and dried under vacuum overnight. The yield was ≥90%. ^{1}H NMR (D_2O) δ: 6.50 (s, 2 H), 4.45 (s, 4 H), 3.92 (s, 4 H), 3.78 (s, 4 H), 3.42 (t, 4 H), 3.32 (s, 4 H), 2.90 (t, 4 H). ^{13}C NMR (D_2O, 150 MHz) δ: 182.9, 176.0, 168.5, 167.5, 153.9, 148.1, 61.8, 56.1, 52.8, 50.9, 48.6, 47.6. MS (EI, 70 eV) *m*/*z* (relative intensity, assignment): 625 (12, $[M + H]^+$), 609 (24, $[M + H\text{-}O]^+$), 313 (100, $[M + 2H]^{2+}$), 297 (27, $[M + 2H\text{-}O]^{2+}$), 177 (20). Elemental anal. calcd. for (EDDA–KA)$_2$·1.5H_2O (%): C 47.93, H 5.41, N 8.60; found: C 47.93, H 5.31, N 8.56.

Potentiometric pH titrations

The acidity constants for (EDDA–KA)$_2$ were determined by titrating 50 mL aq 5.6 mM HCl (I = 0.16 M NaCl, 25°C) in the presence of 0.3 mM to 0.4 mM (EDDA–KA)$_2$ under Ar with 3 mL 0.11 M NaOH. The constants were calculated on an IBM compatible computer containing a Pentium II processor using a curve-fit procedure (a Newton–Gauss nonlinear-least-squares program) and the data within the range $2.3 \le pH \le 10.3$. This corresponded to about 67% neutralization for the equilibrium $[H_2(EDDA–KA)_2]^{2+}$–$[H(EDDA–KA)_2]^+$ and about 99% neutralization for the equilibrium $[(EDDA–KA)_2\text{-}3H]^{3–}$–$[(EDDA–KA)_2\text{-}4H]^{4–}$. The direct pH meter readings were used to calculate the acidity constants (the pH meter was calibrated with standard buffer solutions pH = 4.00 and pH = 7.00 every day before the titrations); i.e., these constants are the so-called practical, mixed, or Brønsted constants (9). Their negative logarithms, given for aqueous solutions at I = 0.16 M (NaCl) and 25°C, may be converted into the corresponding concentration constants by subtracting 0.02 log unit (9). This conversion term contains both the junction potential of the glass electrode and the hydrogen ion activity (9, 10). The final results of the acidity constants were determined from the average of 19 independent titrations.

The stability constants of La^{3+}, Gd^{3+}, and Lu^{3+} with (EDDA–KA)$_2$ were determined under the same conditions as for the acidity constants, except that Na^+ was partly replaced by the respective metal ion (I = 0.16 M, 25°C). The ligand to M^{3+} ratios used in these experiments were slightly greater than 1:1. The calculations were carried out by a similar curve-fitting procedure using a Newton–Gauss nonlinear least-square program in the range $2 < pH < 10$. The final results come from the average of at least eight independent titrations for each metal ion.

UV titrations

A series of 0.04 mM (EDDA–KA)$_2$ solutions were prepared, and the pH of each solution was adjusted at 25°C and the ionic strength was kept at 0.16 with 1.6 M NaCl; the UV spectrum of each solution was then recorded at 25°C. At a given wavelength, the absorption and the corresponding pH could be fitted with a curve-fit procedure using a Newton–Gauss nonlinear-least-squares program; pK_a values could be calculated from this fitting. The lowest pH taken in the experiments was 1.6, corresponding to about 28% neutralization for the equilibrium $[H_2(EDDA–KA)_2]^{2+}$–$[H(EDDA–KA)_2]^+$, and the highest pH was 13.5, about 28% neutralization for the equilibrium $[(EDDA–KA)_2\text{-}5H]^{5–}$–$[(EDDA–KA)_2\text{-}6H]^{6–}$. In addition to the potentiometric pK_a values, pK_a values in the high pH range ($13 \le pH \le 14$) were also obtained. The results obtained by this method came from the avg of five independent experiments.

^{1}H NMR titrations

(EDDA–KA)$_2$ (0.085 g, 0.13 mmol) was dissolved in 16 mL D_2O and 0.05 mL 30% NaOD. The pH meter reading value pH* of this solution was 13.4 and the concentration was about 0.09 M. About 0.5 mL of the solution was taken as an aliquot for ^{1}H NMR measurement and the pH of the remaining solution was adjusted to 13.24 with concentrated DCl solution and another 0.5 mL of solution removed as a second aliquot. The above procedure was continued until a series of solutions with different pH values was obtained and a series of NMR spectra were recorded. The chemical shifts of each signal at each pH were used to evaluate the acidity constants. The calculation was carried out on an IBM-compatible computer with a Pentium II processor by a curve-fit procedure using a Newton–Gauss nonlinear-least-squares program with data over the pD range $1.8 \le pD \le 13.8$, corresponding to about 20% neutralization for the equilibrium $[H_2(EDDA–KA)_2]^{2+}$–$[H(EDDA–KA)_2]^+$ and about 24% neutralization for the equilibrium $[(EDDA–KA)_2\text{-}5H]^{5–}$–$[(EDDA–KA)_2\text{-}6H]^{6–}$. During the calculation, the pH meter reading values pH* were converted to pD by adding 0.4 log unit (11). The pK_a values obtained in D_2O could be converted to the corresponding values in H_2O by eq. [1] (12). The results obtained by NMR were from three independent series of experiments.

$$[1] \qquad pK_a\ (H_2O) = (pK_a\ (D_2O) - 0.45)/1.015$$

Results and discussion

Synthesis of (EDDA–KA)$_2$

It is known that kojic acid undergoes Mannich reactions with primary or secondary amines in the presence of excess paraformaldehyde (13, 14). The aminomethylation occurs at the *ortho* position to the enolic hydroxyl group at room temperature. The hydroxymethyl group at C6 (the *para* position of the enolic hydroxyl group) is relatively unreactive towards amines. In this study, however, we found that kojic acid reacted with ethylenediamine-*N*,*N*′-diacetic acid (EDDA) in the presence of formaldehyde to form a novel macrocyclic chelant (EDDA–KA)$_2$. The reaction was carried out in 90–95% ethanol under reflux for 48 h (Scheme 2).

The Mannich reaction proceeds through two pathways (15) and is usually a result of a complex series of equilibria, related to the nature of the reactants and reaction conditions. EDDA reacts with paraformaldehyde first, to form a substituted five-membered imidazolidine intermediate (Scheme 2), which undergoes rapid electrophilic reaction at the *ortho* position of the enolic hydroxyl group to give the initial EDDA–KA adduct. Because of the *N*-substitution, the amine N atom is more basic and the carboxylate proton is shifted to

the amine N atom to form a zwitterion. The N-H group forms a strong hydrogen bond with the pyrone O atom, rendering the 6-hydroxymethyl group more reactive towards the remaining amine N atom (Scheme 2) of another EDDA–KA adduct thus dimerizing and causing the relative orientation of the two pyrone groups in $(EDDA–KA)_2$.

Acidity constants

These were determined by three different methods — potentiometry, UV spectrophotometry, and ^1H NMR spectroscopy. From the structure of $(H_4(EDDA–KA)_2)^{4+}$ (Scheme 1), one can deduce that ten protons in total may be ionisable from the fully protonated 4+ species, i.e., four protons from the carboxylate groups, four protons from the nitrogen atoms, and two protons from the pyrone OH groups. According to the corresponding acidity constants of EDDA, DOTA, and maltol, listed in Table 1 with structures in Scheme 1, initial guesses of the pK_a values for $[H_4(EDDA–KA)_2]^{4+}$ could be made and these values are listed in the last row of Table 1. This was a necessary process because of the complexity of the protonation problem in $(EDDA–KA)_2$.

It is surprising that only six acidity constants were determined in the range $2 \le pH \le 11$. From low to high, the pK_a values are: 1.95 ± 0.12, 2.60 ± 0.08, 3.19 ± 0.04, 3.80 ± 0.03, 7.42 ± 0.04, 8.24 ± 0.04. As was estimated in Table 1, the first two protons are released mainly from the two carboxylate groups, with pK_a values lower than 2. Therefore, eight more deprotonation steps should have been observed in the range $2 \le pH \le 11$. Another discrepancy between the potentiometrically measured pK_a values and the estimated ones is that, in the range $6 \le pH \le 10$ only two pK_as were determined whereas there should be four pK_as according to the estimation.

To ascertain if there were more deprotonation steps in the range pH > 12, UV spectrophotometric titrations were undertaken; however, with this method only three groups of pK_a values were determined. It was impossible to separate the four pK_as in the range $2 \le pH \le 4$ and the two pK_as in the range $7 \le pH \le 9$ with the absorbance vs. pH fitting; only the avgs of the pK_as were obtained in these two pH ranges.

Since the UV absorption of the compound is associated with the n-π^* transition of the pyrone ring and, in the range $7 \le pH \le 9$, the absorption band has a significant red shift with increasing pH, it is reasonable to assign the deprotonation(s) in this pH range to the OH group(s) of the pyrone ring. The important result obtained by this method is that in the region $12 \le pH \le 14$, there is an absorbance change with pH and a pK_a value can be determined. As discussed above, it is impossible from the fitting to quantify the number of deprotonation steps in this pH range.

The pK_a values of the three groups measured by this UV spectrophotometric method, i.e., $2 \le pH \le 4$, $7 \le pH \le 9$ and pH > 13 are 3.00, 7.93, and 13.64, respectively (Table 2). Whereas the averages of pK_as from potentiometric titration in the first two pH ranges are 2.89 and 7.83. The results from the two different methods agree, and evince their reli-

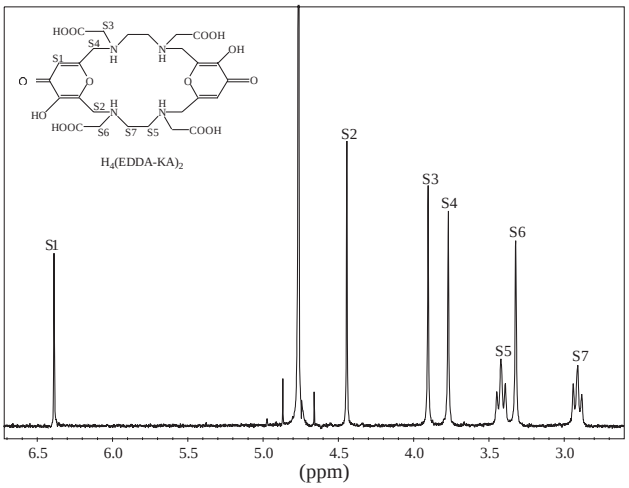

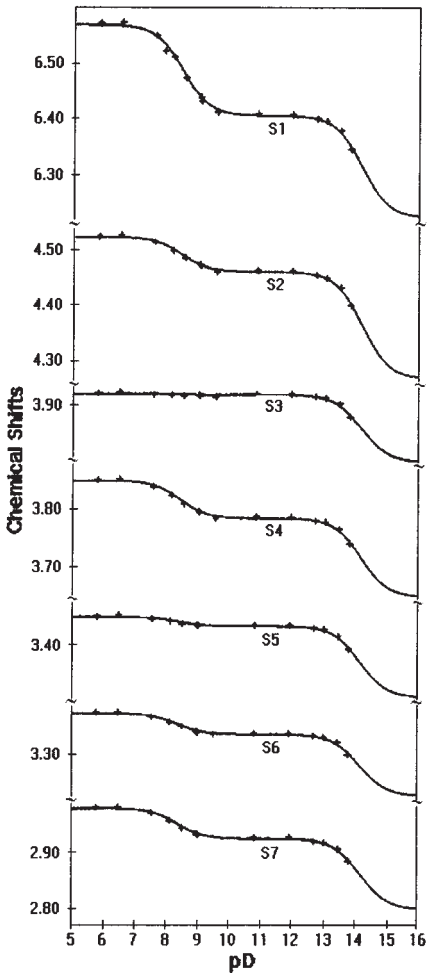

Fig. 2. NMR chemical shifts vs. pD for $(EDDA–KA)_2$; the points represent the experimental results and the lines are the best fit using the determined acidity constants in Table 2.

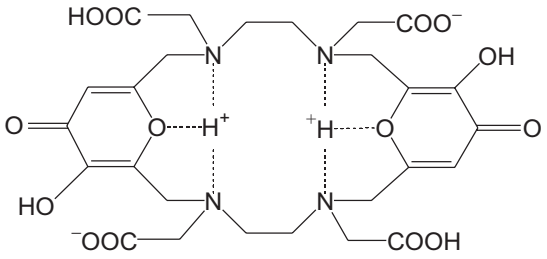
ability. It should be noted, however, that because the highest pH taken in the UV experiment was 13.5, it is difficult to determine an accurate value for the last pK_a by spectrophotometry (hence the large error limit).

The third method used in determining the acidity constants of the complicated system $(H_4(EDDA–KA)_2)^{4+}$ was ^1H NMR spectroscopy, a powerful technique since it provides structural information about sites of deprotonation over a given pH range.



The ^1H NMR spectrum of $(EDDA–KA)_2$ at pD = 12 is shown in Fig. 1. The signal at about 6.4 ppm (S1) clearly belongs to the methine hydrogen atom on the pyrone ring and the 2 triplets (S5 and S7) belong to the methylene hydrogen atoms between the two nitrogen atoms. The other assignments were made according to the chemical shift changes of each signal with pH. Figure 2 shows the chemical shift changes with pH for all seven signals. That S1 has the largest shift in the range $6 \le pD \le 9$ proves that, in this pH range, the two pyrone OH groups deprotonate, in agreement with the UV spectrophotometric study. With this in mind, the other signals could be assigned; for example, S3 was assigned to the CH_2 group farthest from the OH, and S7 to the CH_2 closer to the OH residue than the S5 CH_2. All the assignments are shown in Fig. 1.

From separate experiments, it was determined that in the low pD range, $1 \le pD \le 4$, most of the signals had large chemical shift changes, but the fitting was poor because of precipitation (vide supra). Some deprotonations at the nitrogen atoms occurred in this pD range. From the potentiometric pH titrations it was known that there were four deprotonation steps in this pD range; therefore, two of the protons could be assigned to the ammonium groups and the other two protons to the carboxylate groups.

The fittings in Fig. 2 also reveal the corresponding acidity constants which are listed in the last row of Table 2. Since the highest pD in the NMR experiment was only 13.8, the pK_a result in the range $13 \le pD \le 14$ has correspondingly large error limits. It is clear that the NMR experiment is in good agreement with the results obtained from the other two methods. The result for the final pK_a value in the range $13 \le pH \le 14$ should be the average of the result from the UV and NMR titrations, that is (13.64 + 13.5)/2 = 13.6 ± 0.4. As we know from the structure of the substance, there are always two protons which have the same chemical environment, so

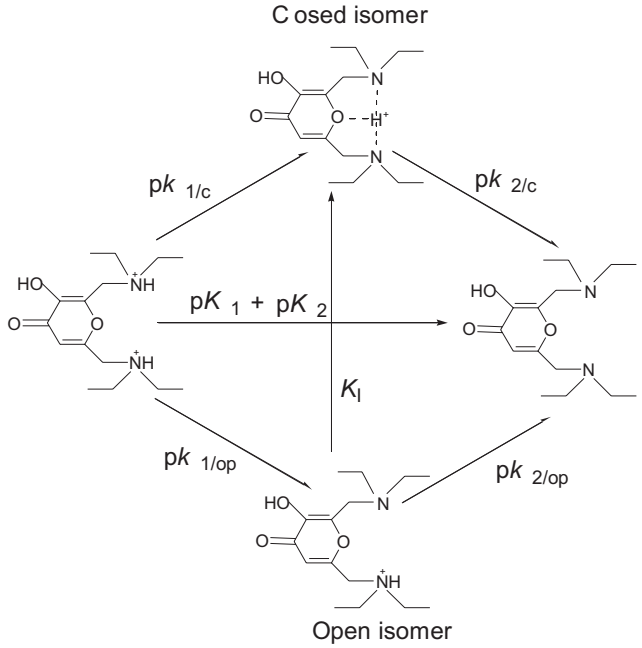
Scheme 3.

there should be two pK_a values in this pH range. It is difficult to estimate how much these two deprotonation steps influence each other and therefore it is difficult to resolve the two acidity constants from the above result. If we suppose that there is no interdependence between the two deprotonation steps, according to statistics, the two pK_a values should lie at least 0.6 log unit apart (20). Comparing with the result for the two OH groups, however, two protons far away from each other have pK_a values separated by about 0.8 log unit — still larger than the statistical estimation. Therefore we use $1 \times 10^{0.8}$ as the lower limit of the difference of the two constants in the range $13 \le pH \le 14$. In this way two pK_a values: $pK^{H}_{(L-4H)} = 13.2 \pm 0.4$ and $pK^{H}_{(L-5H)} = 14.0 \pm 0.4$ were obtained. These values are necessary for the evaluation of the stability constants of $(EDDA–KA)_2$ with metal ions.



Solution structure of $(EDDA–KA)_2$ and its deprotonation steps

From the above results with the three different methods, a clear picture can be elucidated of how $[H_4(EDDA–KA)_2]^{4+}$ is deprotonated step-by-step in aqueous solution under these experimental conditions. Starting in acid solution, the first two protons are released from the two carboxylate groups in $[H_4(EDDA–KA)_2]^{4+}$ with pK_a < 1; these two acidity constants must be lower than the corresponding values in EDDA (vide infra). In the second deprotonation step, two ammonium nitrogen atoms are deprotonated and two strong hydrogen bonds are thus formed with a proton shared among two nitrogen atoms and one oxygen atom (Scheme 3). A neutral species is now formed, with the lowest solubility in aqueous solution of all the species; hence the precipitation in the range $2.8 \le pH \le 3.0$ and the dissolution if either acid or base is added to the solution. The pK_a values for these first two ammonium deprotonations are 1.95 and 2.60. Subsequently, the other two carboxylate groups are deprotonated with pK_a values 3.19 and 3.80. In the range $7 \le pH \le 9$, both UV and NMR spectra have proven that deprotonation occurs at the OH groups on the pyrone ring with pK_a values 7.42 and 8.24.

Lastly, with pK_a values as high as 13.2 and 14.0, the two strong hydrogen bonds are finally deprotonated. These last two $(EDDA–KA)_2$ pK_a values can be understood because the strong four centre hydrogen bonds must be very stable; however, why are the other two protons on the ammonium nitrogen atoms so acidic (pK_a values 1.95 and 2.60)?

In our previous studies, factors affecting the acidity constants in similar systems have been discussed in detail (21). Among the factors, a charge effect (coulombic), a polar effect, a statistical effect, and intramolecular hydrogen bonding are normally important. It is known that intramolecular hydrogen bonding between two nitrogen atoms is very weak because nitrogen is a poor hydrogen bond acceptor (22); however, oxygen is an excellent hydrogen bond acceptor. Thus, in $(EDDA–KA)_2$, the intramolecular hydrogen bond among the two nitrogen atoms and one oxygen atom is so strong, with an average pK_a value 13.6 (Table 2).

Scheme 4.

Scheme 4 illustrates the microscopic deprotonation behaviour of the ammonium N atoms and the formation of the intramolecular hydrogen bonds in $(EDDA–KA)_2$. Because of the high symmetry of the molecule, in each step, two protons (Scheme 3) are involved and the average of the acidity constants are used in this discussion. In Scheme 4, the macro acidity constant pK_{a2} has been determined but pK_{a1} and K_I are unknown. To calculate these two constants, at least two micro acidity constants should be known.

In Table 1, the two acidity constants for EDDA (average of literature values) pK_{a1} = 6.52 and pK_{a2} = 9.53 are listed (16,17). For en (1,2-diaminoethane), the corresponding values are pK_{a1} = 7.19 and pK_{a2} = 9.99 (25°C, 0.16 M KCl) (23). The difference (–1.13) between (pK_{a1} + pK_{a2}) of EDDA and (pK_{a1} + pK_{a2}) of en reflects the effect of the two carboxyl groups in EDDA; we can therefore estimate for each constant an average effect of 0.56 pK unit. Since the micro acidity constants for the open isomer of en are known (p$k_{a1/op}$ = 7.40 and p$k_{a2/op}$ = 9.78) (21), the corresponding values for EDDA can be estimated by deducting 0.56 from the value for en, i.e. p$k_{a1/op}$ = 6.84 and p$k_{a2/op}$ = 9.22. (Here we suppose that the stability of the intramolecular hydrogen bond in each system is identical, a reasonable assumption because the two molecules are structurally similar and it is known that the intramolecular hydrogen bond between two amine N atoms is very weak (21, 22). Another assumption is that p$k_{a1/op}$ and p$k_{a2/op}$ for $(EDDA–KA)_2$ and for EDDA are the same. By comparing the structure of the two compounds,

Table 3. Stability constants of La^{3+}, Gd^{3+}, and Lu^{3+} with $(EDDA–KA)_2$ as measured by potentiometric pH titration (I = 0.16 M NaCl, 25°C).

Stability constant	La^{3+}	Gd^{3+}	Lu^{3+}
$\log K^{M}_{MHL}$	3.0 ± 0.5	3.0 ± 0.5	—
$\log K^{M}_{ML}$	3.4 ± 0.2	3.6 ± 0.2	—
$\log K^{M}_{M(L-H)}$	3.42 ± 0.17	3.7 ± 0.2	—
$\log K^{M}_{M(L-2H)}$	3.83 ± 0.14	3.90 ± 0.10	—
$\log K^{M}_{M(L-3H)}$	6.26 ± 0.08	6.80 ± 0.09	6.1 ± 0.2
$\log K^{M}_{M(L-4H)}$	7.62 ± 0.06	8.81 ± 0.10	8.26 ± 0.14
$pK^{M}_{M(L-4H)}$	9.41 ± 0.15	9.04 ± 0.07	9.4 ± 0.3
$pK^{M}_{M(L-5H)}$	9.6 ± 0.2	9.36 ± 0.10	9.6 ± 0.3
$\log K^{M}_{M(L-5H)}$	11.4 ± 0.3	13.0 ± 0.3	12.1 ± 0.4
$\log K^{M}_{M(L-6H)}$	15.8 ± 0.4	17.6 ± 0.3	16.5 ± 0.4

one can see that this assumption should be no problem. In Scheme 4, $pk_{a1/op}$ = 6.84, $pk_{a2/op}$ = 9.22 and pK_{a2} = 13.6; thus, pK_{a1} can be easily calculated according to eq. [2].

$$[2] \quad pK_{a1} = pk_{a1/op} + pk_{a2/op} - pK_{a2} = 6.84 + 9.22 - 13.6 = 2.46$$

This value is very close to the average of our experimentally measured two values averaging 2.28 at low pH range ((1.95 + 2.60)/2), whereas $k_{a1/cl}$ can be calculated from K_{a1} and $k_{a1/op}$ (24) (eq. [3]).

$$[3] \quad k_{a1/cl} = K_{a1} - k_{a1/op} = 1 \times 10^{-2.46} - 1 \times 10^{-6.84} = 1 \times 10^{-2.46}$$

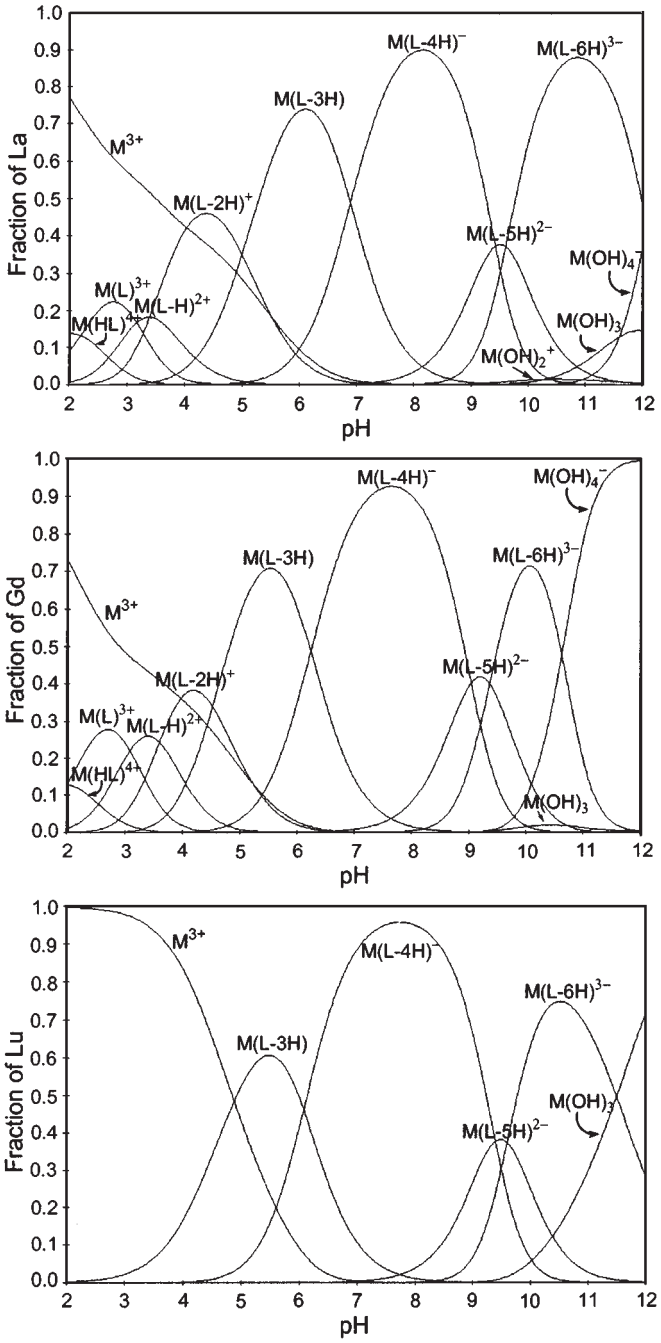
That is, $pk_{a1/cl}$ = 2.46. These calculations suggest that the deprotonations of the first two ammonium residues in $(EDDA–KA)_2$ have low pK_as because of intramolecular hydrogen bonding.

Now the formation constant K_I of the intramolecular hydrogen bond in $(EDDA–KA)_2$ can be evaluated from $pk_{a1/cl}$ and $pk_{a1/op}$ as in eq. [4].

$$[4] \quad \log K_I = pk_{a1/op} - pk_{a1/cl} = 6.84 - 2.46 = 4.38 \approx 4.4$$

As soon as K_I is known, the degree of formation of the intramolecular hydrogen bond can be evaluated according to eq. [5].

$$[5] \quad \text{Closed\%} = [K_I/(K_I + 1)] \times 100\%$$



In the case of $(EDDA–KA)_2$, $\log K_I = 4.4$, $K_I = 2.4 \times 10^4$, closed% ≈ 100%. These values give us some quantitative ideas about how strong is the intramolecular hydrogen bond, and it is!

Stability constants of $(EDDA–KA)_2$ with La^{3+}, Gd^{3+}, and Lu^{3+}

Since there are 11 protonation states in pH-dependent equilibrium in solution for $(EDDA–KA)_2$, it is theoretically possible for a given metal ion to form 10 metal complexes, differing only the number of protons included in the complex. As described above, if $(EDDA–KA)_2$ is used to express the neutral ligand, the 10 possible complexes for M^{3+} are: $[MH_3(EDDA–KA)_2]^{6+}$, $[MH_2(EDDA–KA)_2]^{5+}$, $[MH(EDDA–KA)_2]^{4+}$, $[M(EDDAKA)_2]^{3+}$, $[M(EDDA–KA)_2\text{-}H]^{2+}$, $[M(EDDA–KA)_2\text{-}2H]^{+}$, $[M(EDDA–KA)_2\text{-}3H]$, $[M(EDDA–KA)_2\text{-}4H]^{-}$, $[M(EDDA–KA)_2\text{-}5H]^{2-}$, $[M(EDDA–KA)_2\text{-}6H]^{3-}$. Just as the first two pK_as were too low to be determined, the first three stability constants for species $[MH_3(EDDA–KA)_2]^{6+}$ and $[MH_2(EDDA–KA)_2]^{5+}$, cannot be measured in the range $2 \le pH \le 10$. Therefore, only the last eight species exist and the corresponding stability constants may be determined.

Using potentiometric pH titrations, eight complexes in the range $2 \le pH \le 10$ could be determined and fit to the experimental data with eight log K values for each of the three

Table 4. Hydrolysis constants of La^{3+}, Gd^{3+}, and Lu^{3+} used in the calculation of the stability constants $M(EDDA–KA)_2$ (25). (I = 0.16 M NaCl, 25°C).

Hydrolysis constant	La^{3+}	Gd^{3+}	Lu^{3+}
$pQ_{11}(M^{3+} + H_2O = M(OH)^{2+} + H^+)$	8.5	8.0	8.7
$pQ_{12}(M^{3+} + 2H_2O = M(OH)_2^+ + 2H^+)$	17.2	16.4	17.5[a]
$pQ_{13}(M^{3+} + 3H_2O = M(OH)_3 + 3H^+)$	27.5	25.2	25.8[a]
$pQ_{14}(M^{3+} + 4H_2O = M(OH)_4^- + 4H^+)$	39.1	34.4	—

[a]Because of lack of data for Lu^{3+}, these values are the corresponding values for Yb^{3+}.

metal ions studied. The results are summarized in Table 3; according to the stability constants, species distribution diagrams were calculated and are given in Fig. 3.

The log K^M_{MHL} data in Table 3 have large error limits because these are estimated values. For Lu^{3+}, the first four constants could not be obtained from the fitting, possibly because the corresponding constants were too small to be determined. Hydrolysis is a big problem in determining the stability constants of lanthanide complexes in aqueous solution (25). In the data fitting, the hydrolysis species $M(OH)_y$ (y = 1–4) were included with constants listed in Table 4. It is clear from the fitting that hydrolysis must be included for all three metal ions studied.

The $pK^H_{M(L-4H)}$ and $pK^H_{M(L-5H)}$ values in Table 3 represent the deprotonation of two hydrogen bonded protons from each metal ion complex. These constants can be directly fit and are independent of the pK_a values of the ligand. Because of the presence of the metal ion, the protons were more easily released from the complex than they were from the ligand itself. This acidifying effect can be quantified with ΔpK values, that is the difference between the pK_a values of ligand and the corresponding pK_a values of the complexes. The calculated ΔpK values are: $\Delta pK_{L-4H} = pK^H_{(L-4H)} - pK^H_{M(L-4H)}$ = 3.8 (La^{3+}), 4.2 (Gd^{3+}), 3.8 (Lu^{3+}); $\Delta pK_{L-5H} = pK^H_{(L-5H)} - pK^H_{M(L-5H)}$ = 4.4 (La^{3+}), 4.6 (Gd^{3+}), 4.4 (Lu^{3+}). The error limits of these values are 0.4; for different metal ions, the values are the same within the error limits. In line with similar acidities of these three ions, there are increases in acidity of the complexes by three to five log units.

The stability constants of the coordinated complexes can be evaluated from the acidity constants of the ligand and the $pK^H_{M(L-4H)}$ and $pK^H_{M(L-5H)}$ values according to the following equations:

$$[6] \quad \log K^M_{M(L-5H)} = pK^H_{M(L-4H)} + \log pK^M_{M(L-4H)} - pK^H_{M(L-4H)}$$

$$[7] \quad \log K^M_{M(L-6H)} = pK^H_{(L-5H)} + \log K^M_{M(L-5H)} - K^H_{M(L-5H)}$$

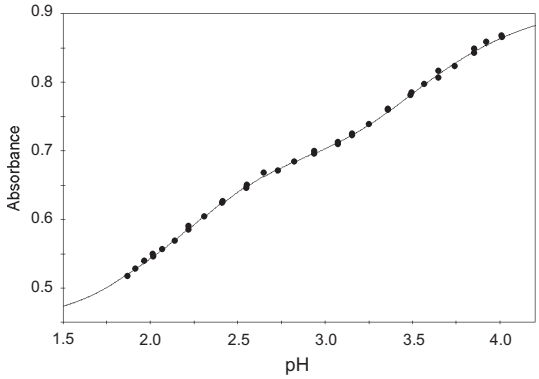
The results are given in the last two rows in Table 3. Because the error limits for $pK^H_{(L-4H)}$ and $pK^H_{(L-5H)}$ are quite large, the results for log $K^M_{M(L-5H)}$ and log $K^M_{M(L-6H)}$ also have larger error limits than the corresponding $pK^H_{M(L-4H)}$ and $pK^H_{M(L-5H)}$ values.

Structure of the metal ion complexes

Before comparing the stability constants of the La^{3+}, Gd^{3+}, and Lu^{3+} complexes, let us first consider the structures of the complexes in solution. We have discussed the stepwise deprotonation of the ligand and the strong four center intramolecular hydrogen bonds which are stable in the range $3 \le pH \le 12$. In the presence of a metal ion, these hydrogen bonds will break, and the proton will be released at a lower pH because any coordination of the metal ion will make the proton on the ligand more acidic (26). Since for each metal complex the corresponding pK_a values ($pK^H_{M(L-4H)}$ and $pK^H_{M(L-5H)}$, e.g. for Gd^{3+}, 9.04 and 9.36) are still larger than are the acidity constants (7.42 and 8.24) of the pyrone OH groups, we can be sure that the deprotonation occurred at the hydrogen bonding amine residue and not at the pyrone OH. This means that, for all other complex species in solution except the fully deprotonated species $[M(L-6H)]^{3-}$, the four center intramolecular hydrogen bonds among the amine residues and the pyrone oxygens are still present. Where is the metal ion located then in these species, in which the amine residues are occupied by the intramolecular hydrogen bonds? In the case of $M(L-H)^{2+}$ and $M(L-2H)^+$, only carboxylate groups are deprotonated; hence, the metal ion can coordinate with these groups. In [M(L-3H)] and $[M(L-4H)]^-$, the OH group(s) on the pyrone ring is (are) deprotonated; therefore it is also possible for the metal ion to coordinate to the pyrone ring to form a five-membered chelate.

To locate the metal ion in the [M(L-3H)] and $[M(L-4H)]^-$ complexes, several UV and NMR experiments with the La^{3+} system were undertaken. The NMR spectra of $La(EDDA–KA)_2$ are very similar to those of the ligand itself, i.e. seven signals were observed although the signals are somewhat broader. This suggests that the symmetry of the compound does not change upon lanthanum coordination. From the potentiometric titrations, no $La_2(EDDA–KA)_2$ is known to form; if the metal ion binds at only one pyrone, the molecular symmetry would be lowered. The NMR studies also showed that signal S1 (related to methine hydrogen atom on the pyrone ring) in the NMR spectra of $La(EDDA–KA)_2$ had almost same chemical shift as in $(EDDA–KA)_2$ at the same given pH (e.g., pH = 8.0 and 10.4). These results suggest that the metal ion coordinates at the carboxylate groups rather than at the pyrone in the species [M(L-3H)] and $[M(L-4H)]^-$. Similar results were obtained by UV spectrophotometric titration. A blue shift of the spectrum was not observed when La^{3+} was added to a $(EDDA–KA)_2$ solution at pH 9.0; if the metal ion coordinated at the pyrone, the positive charge of the metal ion would have caused a blue shift in the spectrum of the ligand, just like hydrogen does.

Comparing the stability of the complexes of La^{3+}, Gd^{3+}, and Lu^{3+}



Comparing the stability constants listed in Table 3, it can be seen that regardless of the protonation state in the complexes, the stabilities for the three complexes are always $La^{3+} \cong Lu^{3+} < Gd^{3+}$. This result is quite at odds with the order of the stabilities of La^{3+}, Gd^{3+}, and Lu^{3+} complexes of other similar ligands. In Table 5, the stability constants of La^{3+}, Gd^{3+}, and Lu^{3+} with five oxygen–nitrogen donor ligands are listed; it is evident that for each ligand there is a stability order $La^{3+} < Gd^{3+} < Lu^{3+}$. Therefore, the discrepancy of the stability constants of $(EDDA–KA)_2$ must be caused by its structure.

Table 5. Stability constants of La^{3+}, Gd^{3+} and Lu^{3+} with EDDA, EDTA, oxalic acid, DO2P, and DOTA.

Stability constant	La^{3+}	Gd^{3+}	Lu^{3+}	Conditions	Ref.
log K_1 (M^{3+} + $EDDA^{2-}$ = $M(EDDA)^+$)	7.04	8.13	9.09	I = 0.1 M KNO_3, 25°C	27
log β_2 (M^{3+} + $2EDDA^{2-}$ = $M(EDDA)_2^-$)	11.77	14.21	17.57	I = 0.1 M KNO_3, 25°C	27
log K (M^{3+} + $EDTA^{4-}$ = $M(EDTA)^-$)	15.19	16.82	19.14	I = 0.1 M KCl, 25°C	28
log β_2 (M^{3+} + $2ox^{2-}$ = $M(ox)_2^-$)	7.9	8.68	9.2	I = 1.0 M $NaClO_4$, 25°C	29, 30
log K (M^{3+} + $DO2P^{4-}$ = $M(DO2P)^-$)	16.0	18.2	19.3	I = 0.1 M KNO_3, 25°C	31
log K (M^{3+} + $DOTA^{4-}$ = $M(DOTA)^-$)	21.7	24.0	29.2	I = 0.1 M KCl, 25°C	32, 33

Fig. 4. Fit of the absorbance vs. pH data for the Fe^{3+}–$(EDDA–KA)_2$ system. The points are from the titration data and the curve is the best fit using the values discussed in the text.

In $(EDDA–KA)_2$, the pyrone rings not only make the macrocycle larger in size, but also inhibit changes of the molecular conformation. A smaller metal ion like Lu^{3+} may not fit the macrocycle so well and only a few of the atoms on the macrocycle might actually coordinate the metal ion; whereas the larger Gd^{3+} and La^{3+} may bind with more atoms on the macrocycle and may also coordinate to the four carboxylate groups with a structure similar to that of $Ln(DOTA)^-$ (34). Hence, the order of the stability of the complexes of these two metal ions with $(EDDA–KA)_2$ would be the same as with other similar ligands (Table 5). The absolute values of log $K^{M}_{M(L-6H)}$ for the complexes of $(EDDA–KA)_2$ (Table 3) are still much smaller than the corresponding values of log $K^{M}_{M(L-4H)}$ for $Ln(DOTA)^-$ (Table 5), even for Gd^{3+} and La^{3+}, meaning that the coordination of the atoms on the macrocycle is weaker in $[Ln(EDDA–KA)_2]^-$ than that in $Ln(DOTA)^-$. That the values for $[Ln(EDDA–KA)_2]^-$ (Ln = Gd^{3+}, log $K^{M}_{M(L-6H)}$ = 17.6; La^{3+}, log $K^{M}_{M(L-6H)}$ = 15.8) are only slightly larger than the corresponding values of $Ln(EDTA)^-$ (Ln = Gd^{3+}, log $K^{M}_{M(EDTA)}$ = 16.82; La^{3+}, log $K^{M}_{M(EDTA)}$ = 15.19) means that the macrocycle, including four nitrogen atoms and two oxygen atoms, has a coordination ability on a par with the two nitrogen atoms in EDTA. This suggests that the metal ion might only coordinate with some of the atoms on the macrocycle in $[Ln(EDDA–KA)_2]^-$.

To avoid toxicity with MRI agents, a most important point is the stability of the complex at physiological pH, i.e., pH = 7.4. The conditional stability constant K^{*}_{ML} (eq. [8]) is often used to compare the relative thermodynamic stabilities of different chelators at pH 7.4 (3).

$$[8] \quad K^{*}_{ML} = K_{ML}/(1 + K_1[H] + K_1K_2[H]^2 + \ldots + K_1K_2 \ldots K_n[H]^n)$$

K_1, K_2, … K_n are the stepwise protonation constants of the ligand. However, for $(EDDA–KA)_2$, this is not a good idea because the stepwise stability constants (K_{MHL}, K_{MH2L}, … $K_{MHn\text{-}1L}$) are not included in eq. [8], whereas at pH 7.4, the predominant species is $[M(EDDA–KA)_2\text{-}4H]^-$ for this system (Fig. 3). This problem can be avoided by comparing pM values of the chelators at pH 7.4 (35). For Gd^{3+}–$(EDDA–KA)_2$, a value 6.82 was obtained (calculated for pH = 7.4 with $[L]_{tot} = [M]_{tot} = 1 \times 10^{-6}$ M). Comparing with other chelators (e.g. DOTA 11.93, DTPA 12.02, DTPA–BMA 10.38) (35),[2] this value is really too small for practical application; the result implies that Gd^{3+}–$(EDDA–KA)_2$ is not stable enough to be a MRI contrast agent.

The selectivity of $(EDDA–KA)_2$ is also not good. Although the ligand coordinates to Ca^{2+} very weakly (the stability constant measured for $[Ca(EDDA–KA)_2\text{-}4H]^{2-}$ is 2.5 and the formation of $[Ca(EDDA–KA)_2\text{-}6H]^{4-}$ was not observed by potentiometric titration), the coordination of $(EDDA–KA)_2$ to Cu^{2+} is quite strong and the corresponding pM value is 7.3. As the selectivity of a chelator to Gd^{3+} and Cu^{2+}, Zn^{2+}, and Ca^{2+} reflects the toxicity of the Gd^{3+} complex (36), this result implies that Gd^{3+}–$(EDDA–KA)_2$ would not be selective enough to be a good MRI contrast agent.

Coordination of Fe^{3+} to $(EDDA–KA)_2$

We also tried to measure the stability constants of the $Fe(III)(EDDA–KA)_2$ complexes under the same conditions as the stability constants of lanthanide complexes were measured. Because of the strong tendency to hydrolyze of Fe^{3+} (25), it was not possible to determine the constants at pH > 4. A strong color change was observed in the range $2 \leq pH \leq 4$ when the ligand and Fe^{3+} were mixed, and the stability constants for the complexes formed in the low pH range could be determined spectrophotometrically.

A series of absorbances measured at different pH values can be fitted in a manner similar to that used to fit the potentiometric data by taking into account the species Fe^{3+}, $[Fe(EDDA–KA)_2\text{-}H]^{2+}$, $[Fe(EDDA–KA)_2\text{-}2H]^+$, and $[H_2(EDDA–KA)_2]^{2+}$, $[H(EDDA–KA)_2]^+$, $(EDDA–KA)_2$, $[(EDDA–KA)_2\text{-}H]^-$, $[(EDDA–KA)_2\text{-}2H]^{2-}$. This does mean that the deprotonation of the pyrone OH group was ignored and that only the coordination of the carboxylate groups was included in the model. This is clearly a reasonable model for pH < 4 and the good fit (Fig. 4) bears this out. The results

[2] The values are calculated by using the stability constants given in refs. 18 and 35 for pH 7.4 with [L] = [M] = 1×10^{-6} M. The results are different from the results given in ref. 35 because of the different conditions.

© 2001 NRC Canada

obtained for the stability constants are log K = 3.43 ± 0.12 and log K = 4.11 ± 0.06, which are quite close to the corresponding results listed in Table 3 for La^{3+} and Gd^{3+}. Further complexation clearly happens, but it cannot prevent the hydrolysis of Fe^{3+}. It is reasonable from this limited study to suppose that the stability constants with Fe^{3+} have values similar to those for $(EDDA–KA)_2$ with La^{3+} and Gd^{3+}.

Conclusions

The acidity constants determined suggest that there are two strong four center intramolecular hydrogen bonds in $(EDDA–KA)_2$ in the range $3 \leq pH \leq 12$. The strong hydrogen bonds make the last two deprotonation steps difficult, with very high pK_a values; the first two protons are released from the fully protonated amine groups easily. For $[M(EDDA–KA)_2\text{-}5H]^{2–}$ and $[M(EDDA–KA)_2\text{-}6H]^{3–}$, the metal ion may also coordinate with the nitrogens or pyrone oxygens, whereas for all other species, the metal ion only coordinated with the four carboxlate groups in aqueous solution. That the stability of the complex $[Lu(EDDA–KA)_2\text{-}6H]^{3–}$ is lower than the corresponding Gd^{3+} complex may be because Lu^{3+} is too small to fit into the macrochelate ring of the ligand. On the stability and selectivity point of view, the Gd–$(EDDA–KA)_2$ complex will not be a good MRI contrast agent.

Aggregation studies of benzoporphyrin derivative

David Delmarre, Noboru Hioka, Ron Boch, Ethan Sternberg, and David Dolphin

Abstract: The photophysical properties of a ring B benzoporphyrin derivative 1,3-diene dimethylester were investigated in solution (water–DMSO mixtures). At low proportions of water in DMSO, the diester obeys Beer's law at all pH values and ionic strengths investigated. For solvent systems containing more than 30% water, the extent of deviation from Beer's law as a function of porphyrin concentration is attributed to formation of porphyrin dimers. Dimerization equilibrium constants (*K*d) have been determined in different percentage of solvent mixtures, using absorption and fluorescence spectroscopies, and were found to exhibit a linear correlation between log (*K*d) and the inverse of the dielectric constant (log (*K*d) = 24.6 – 1060.4 × $1/\varepsilon_{mix}$). This equation permits the calculation of *K*d in mixtures of water–DMSO.

Key words: porphyrins, dimerization, aggregation, fluorescence, benzoporphyrin derivative, photodynamic therapy, photosensitizers.

Résumé : Opérant en solution (mélanges DMSO–eau), on a étudié les propriétés photophysiques d'un diester méthylique 1,3-diénique du cycle B d'une benzoporphyrine. À des concentrations faibles d'eau dans le DMSO, le diester obéit à la loi de Beer, à tous les pH et à toutes les forces ioniques étudiées. Pour les systèmes de solvant contenant plus de 30% d'eau, on observe une déviation par rapport à la loi de Beer qui varie avec la concentration en porphyrine; cette déviation est attribuée à la formation de dimères de la porphyrine. On a déterminé les constantes d'équilibre de la dimérisation (*K*d) à divers pourcentages de mélanges de solvant en faisant appel aux spectroscopies d'absorption et de fluorescence et on a trouvé qu'il existe une corrélation linéaire entre log (*K*d) et l'inverse de la constante diélectrique (log (*K*d) = 25,6 – 1060,04 × $1/\varepsilon_{mél}$). Cette équation permet de calculer la valeur de *K*d dans des mélanges d'eau–DMSO.

Mots clés : porphyrine, dimérisation, agrégation, fluorescence, dérivé de la benzoporphyrine, thérapie photodynamique, photosensibilisateur.

Introduction

Porphyrins are versatile molecules. They possess interesting redox behaviour, affinity towards metals and biological functions. They are also amenable to modifications of their peripheral substituents. An interesting aspect of porphyrin chemistry concerns their use as photosensitizers for photodynamic therapy (PDT) (1–3). Photodynamic therapy involves administration of a photosensitizer that accumulates with some selectivity in the target tissues. Tissue is then irradiated with visible light to initiate the generation of oxidants which then go on to generate damage. This treatment has been tested against cancer, age-related macular degeneration (AMD), psoriasis (4, 5), arthritis, and viral infections (6, 7). The first generation of porphyrins used in PDT, Photofrin®, has been approved in Canada, Europe, Japan, and the U.S.A. for the treatment of several different cancers (8).

We have focussed our attention on benzoporphyrin derivatives (9) since these compounds are structurally related to BPDMA verteporfin (**1**), which is QLT Inc.'s second generation PDT drug (recently approved in North America and Europe, as Visudyne®, for the treatment of age-related macular degeneration), to investigate the aggregation processes in aqueous–organic solvents.

In general, porphyrins have a high tendency to aggregate and it is known that the aggregation state determines their photophysical properties (10–12), as well the binding properties to biological targets (13). This later point may be detrimental to the success of a prospective drug since whereas the large hydrophobicity of dimers or higher aggregates may increase the affinity for target tissues aggregation reduces the production of singlet oxygen and thus the efficiency of the PDT treatment.

nickel was achieved according to Adler et al. (15). Buffers used were potassium phosphate or potassium phthalate. The ionic strength was kept at 0.1 using KCl. The water–dimethylsulfoxide (DMSO) mixtures were prepared by volume. In static fluorescence experiments all samples were excited at 430 nm (Soret band) and emission recorded in the 600–800 nm region.

Apparatus

Visible spectra were obtained using Hewlett–Packard 8452A Diode Array and Cary 50 spectrophotometers with cuvettes of 1.0 cm optical length. Static fluorescence measurements were performed using an Aminco Bowman Series 2 luminescence spectrometer. The excited-state lifetimes were measured at 25°C with a multifrequency (0.1–200 MHz) phase-modulation fluorometer described elsewhere (16). The samples were excited at 442 nm with a liconix He-Cd laser and DCM (4-dicyanomethylene-2-methyl-6-p-dimethylamino-styryl-4H-pyran) in DMSO was used as a reference (τ = 2.130 ns). The emission wavelength was selected by means of a cut-off filter (GG475).

Fig. 1. Absorption spectra of compound **2** in various H_2O–DMSO mixtures ($c = 5 \times 10^{-6}$ mol L^{-1}) for 0% water (+), 20% water (X), 30% water (△), 40% water (□), 50% water (○), 60% water (◇).

Results and discussion

Absorption spectroscopy

The tetraester porphyrin (**2**) in pure DMSO exhibits a major band at 692 nm attributed to the monomeric form. Figure 1 shows changes in the spectra of the diester at different ratios of water–DMSO mixtures. For ratios below 30% water, small changes in the absorption spectra were observed. Increasing the water concentration to 30% (or higher) caused a new band (red shift) to appear at 724 nm while the peak at 692 nm decreased in intensity. For a 60% concentration of water the spectral peak at 692 nm is absent with only one band at 724 nm present. This new band can be attributed to dimers of porphyrins and the presence of an isosbestic point at 700 nm is in agreement with this analysis. Experiments performed at various water:DMSO ratio mixtures and at various diester concentration reveal in the same way, the isosbestic point and dimer peak. The absorbance values at 692 nm against porphyrin concentration for increasing proportion of water:DMSO ratios are shown in Fig. 2. When the solvent ratio is below 30% water, a linear correlation between the absorbance and concentration of porphyrin is obtained. Behaviour according to Beer's law indicates that only monomer is present under these conditions. For ratios above 30% water, deviations from linearity are observed. In these cases the data can be fitted by assuming an equilibrium between monomer and dimer which can be expressed as:

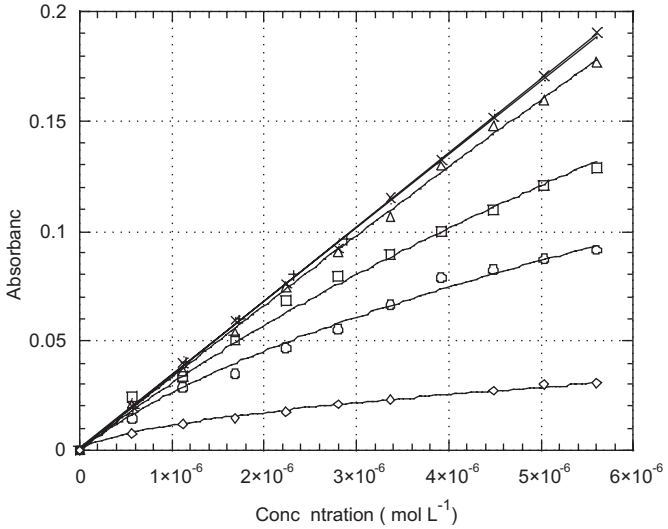
$$M + M \underset{}{\overset{Kd}{\rightleftharpoons}} D$$

where *K*d is the dimerization constant and D and M are respectively the dimer and the monomer forms; *K*d can be expressed as:

[1] $\quad Kd = [D] / [M]^2$

© 2001 NRC Canada

Fig. 2. Absorbance at 692 nm as a function of the concentration of the porphyrin: 0% water (+), 20% water (X), 30% water (△), 40% water (□), 50% water (○), 60% water in DMSO (◇). Lines represent calculated values derived using a linear regression or eq. [3].



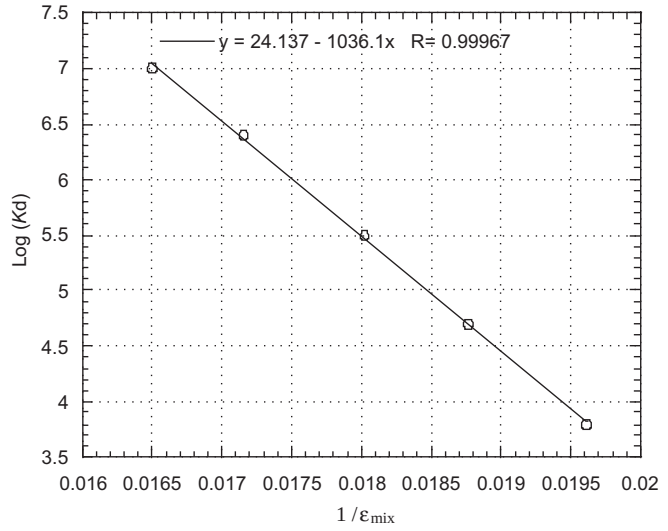


Fig. 3. Log (*K*d) as a function of $1/\varepsilon_{mix}$ at T = 25°C.

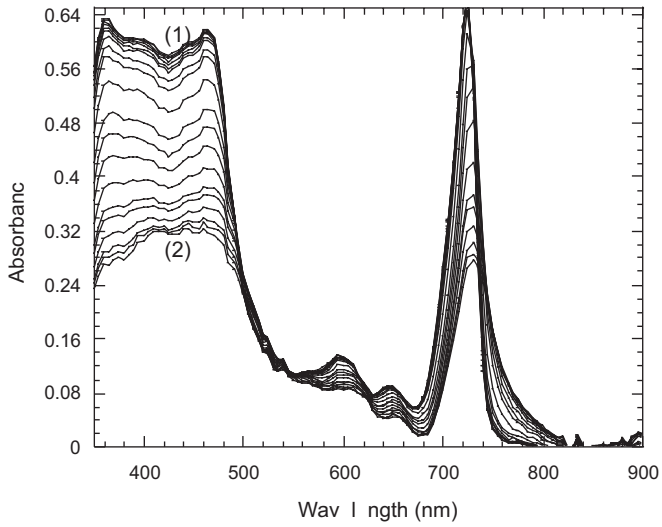
The total concentration of the porphyrins [Po] can be expressed as

[2] $[Po] = [M] + 2[D]$



Absorbance for the monomers may be expressed as

[3] $$A_M = ((1 + 8 \times K\mathrm{d} \times [Po])^{0.5} - 1) \times \varepsilon_M / (4 \times K\mathrm{d})$$

where ε_M is the absortivity of the monomer.

A similar equation can be developed for the dimer band. These equations assume that: (*i*) there is negligible overlap between the absorption bands of the dimer and the monomer which is true for the present case; (*ii*) the ε_M does not change with solvent composition and ε_M = 33 800 mol^{-1} L cm^{-1} obtained from experiments involving 0–20% water was used for all cases.

Fig. 4. Effect of temperature on the absorption spectra of compound **2** in 66% water, 33% DMSO: (*a*) T = 25°C, (*b*) T = 85°C.

As shown in Fig. 2, for solvent mixtures above 30% water, the data were fitted by eq. [3] or by an equation based on the dimer band (not shown), and for each case the *K*d was calculated. The calculated values of the logarithm equilibrium constant, from the data in Fig. 2, are 3.8, 4.7, 5.5, 6.4, and 7 at water mixtures in DMSO of 30, 40, 50, 60, and 66%, respectively, at 25°C.

Although **2** is a hydrophobic molecule, it still has a small dipolar moment, thus dipole–dipole interactions can provide a correlation between *K*d and the dielectric constant of the solvent (ε_{mix}).

The free energy (ΔG) in an equilibrium has two components, the non-electrostatic (ΔG_{nE}) and the electrostatic which is a function of 1/ε. Therefore,

[4] $$\Delta G = \Delta G_{nE} + A/\varepsilon$$

where A contains several terms. ΔG is given by:

[5] $$\Delta G = -RT \ln K$$

Rearranging eqs. [4] and [5], gives

[6] $$\log K = C - (A / (2.3RT)) \times 1/\varepsilon$$

In this case, C and A are set as constants. The dielectric constant of the different mixtures (ε_{mix}) can be approximated by a linear relation as:

[7] $$\varepsilon_{mix} = x_{DMSO} \times \varepsilon_{DMSO} + x_{H_2O} \times \varepsilon_{H_2O}$$

Where x is the molar fraction of each component and ε_{DMSO} = 46.6 and ε_{H_2O} = 78.3 at 25°C (17).

Figure 3 represents the logarithm of the equilibrium constant as a function of the theoretical $1/\varepsilon_{mix}$ (18). A linear relationship can be observed between log (*K*d) and $1/\varepsilon_{mix}$ which indicates that the dimerization process for the diester in water–DMSO solvents obey the dipole–dipole interaction model for the dielectric effect. The equation log (*K*d) = 24.6 – 1060.4 × $1/\varepsilon_{mix}$ can be used to calculate the equilibrium constant as a function of water percentage in DMSO, as shown in Fig. 4.

Fig. 5. Relationship of fluorescence intensity to total porphyrin concentration in a mixture of 66% water – 33% DMSO according to eq. [10] for compound **2**. Symbols show experimental results: the straight line is calculated by using linear regression analysis.

Parameters other than the solvent sometimes can be influential in aggregation. In particular, the pH and the ionic strength. The effects of pH (3–8) and ionic strength (1×10^{-3} to saturating concentration of 1×10^{-1} M) with KCl were investigated and found to have no influence on the aggregation process.

Furthermore, no changes were observed when the temperature was increased from 25°C to 85°C of the diester in pure DMSO. However, in a mixture of 66% water in DMSO, an increase in temperature promotes a red shift from 724 to 736 nm coupled to decreasing intensity and broadening (Fig. 4). The Soret band similarly undergoes a decrease. This shift of the band probably indicates the formation of bigger aggregates or reorganization of the solvent. After addition of detergent a blue shift is observed from 736 to 690 nm which indicates the return to the monomeric form.

Emission spectroscopy

The fluorescence properties of the diester **2** were studied over the concentration range 1×10^{-9} to 1×10^{-7} mol L^{-1} in various mixtures of water–DMSO. In all solvents the emission spectrum of the diester consists of a single band with a maximum centered at 700 nm. No new band or shift were observed by adding water (19–22).

Table 2. Summary of the absorption properties of compound **2** and metallated compound with nickel.

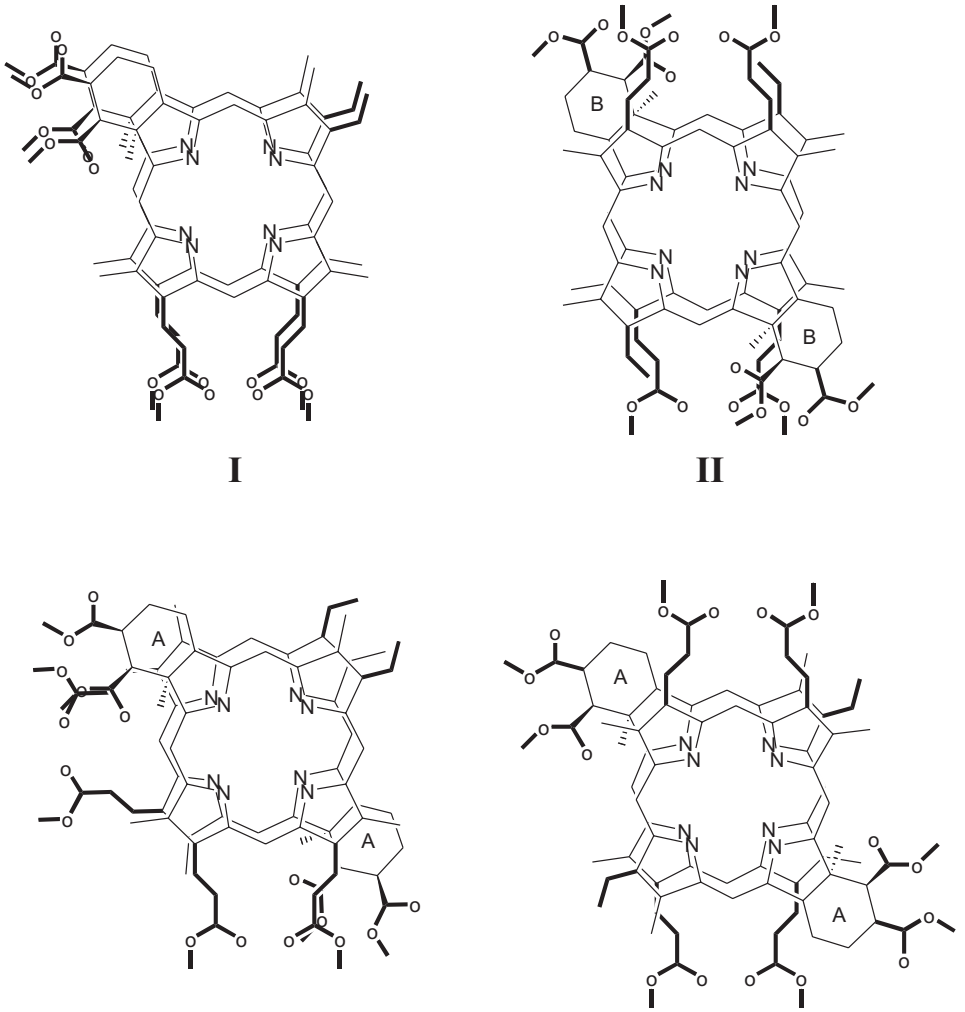
	DMSO (nm)	Water–DMSO (66–33%) (nm)
Compound **1**	692	724
Compound **3**	673	690
Compound **3** + piperidine	665	665

Using time resolved fluorescence in pure DMSO revealed a unique species with a life-time of 6 ± 0.1 ns (χ_r^2 = 1.03) which was determined by the Maximum Entropy Method (MEM) as described by Livesey and Brochon (23) and Brochon (24).

Introducing small quantities of water does not change the life-time, but χ_r^2 is not seen to increase. For 30% water χ_r^2 was found to be 4.7. Introducing a second or a third exponential neither improved or decreased χ_r^2. These high χ_r^2 values mean that new nonfluorescent species are being formed. These results agree with the literature that porphyrin dimers do not fluoresce (3).

The fluorescence quantum yields (*Q*f) were determined using ZnTPP in toluene as reference. The *Q*f values were obtained under air-saturated conditions, listed in Table 1; these were estimated from eq. [3]:

$$[8] \qquad Qf^S = (n^S/n^R)^2(F^S \times A^R)/(A^S \times F^R) \times Qf^R$$



Where Qf^R is the quantum yield of ZnTPP in toluene (*Q*f = 0.033), *A* is the absorbance at the excitation, *F* is the integrated area of the emission spectra, and *n* is the refractive index of the solution. The symbols S and R refer to the sample and reference, respectively. Table 1 shows a decrease of *Q*f as the percentage of water increases. Once again, these results indicate the presence of dimeric forms of the diester in solvent mixtures with high water content.

For solvent mixtures containing less than 20% water, the integrated fluorescence intensity (*F*) data shows that for an increase in diester concentration (1×10^{-9} to 1×10^{-7} mol L^{-1}), a linear correlation between *F* and the concentration of diester is observed (not shown). However, the fluorescence intensity was found to increase in a nonlinear fashion with the concentration of the diester for solvent mixtures above 20% of water.

The plot of the integrated fluorescence intensity over the concentration range can also be used to calculate the dimerization constant *K*d according to Margalit et al. (25).

Fig. 6. Possible conformations for A–A and B–B dimers.

This model assumes that dimerization is the dominant aggregation process and only the monomeric species present in solution fluoresces. This was previously determined by time-resolved fluorescence experiments.

Taking eqs. [1] and [2], the total porphyrin concentration [Po] can be expressed as

$$[9] \qquad [Po] = [M] + 2Kd[M]^2$$

Using the second hypothesis and experimental conditions where absorbance at the excitation wavelength is lower than 0.1, we can assume a direct proportionality between the emitted fluorescence intensity F and concentration of the monomer.

If a is the constant of proportionality, eq. [9] can be written

$$[10] \qquad [Po]/F = a + 2a^2KdF$$

The constant of dimerization can be obtained using the values for the slope and intercept of the plot of [Po]/F vs. F (Fig. 5).

The logarithm of the constant of dimerization for 66% water solution is 6.9 and for 50% water solution is 5.6. Using the previous equation obtained from absorption spectroscopy (log (Kd) = 24.6 – 1060.4 × $1/\varepsilon_{mix}$), the calculated log Kd were 7 and 5.5, respectively, for 66% and 50% water. These values are in good agreement with the absorption results. Table 1 shows a summary of these results.

Structure of the dimer

Usually porphyrin dimers show a blue shift (26) in the Q-band relative to the monomeric form. For diester **2**, a red shift was observed from 692, to give a new sharp, more intense band at 724 nm, probably corresponding to a stacked structure similar to a "deck of cards" (J-aggregate) (27). This type of aggregate was observed for binding of tetracationic porphyrins with DNA (28–34) and for the self aggregation of *meso*-tetra(4-sulfonatophenyl)porphyrin (29–31). To confirm this observation, the metallated (nickel) porphyrin diester (**3**) was prepared. In pure DMSO, this metallated porphyrin shows a maximum Q-band at 673 nm

© 2001 NRC Canada

and no fluorescence. Upon adding water to the solution, a red shift was observed as a result of the porphyrin dimerization.

Adding excess piperidine to the nickelated diester in pure DMSO promoted the complexation of nickel by two piperidine molecules (Ni porphyrins are well known to accept two axial ligands). This compound exhibited a band at 665 nm which was invariant upon addition of water; a dimer peak was not observed. In this case, the piperidine ligand prevent the aggregation process by steric effects. Table 2 summarizes the results.

The same type of experiment was completed with zinc complex and once again no dimer was observed, even in the absence of amine. Presumably this is due to axial complexation of water ligands.

If both hydrophobic and dipolar (electrostatic) interactions account for the formation of this unique dimer, then why is an inverse correlation with dielectric constant seen when no dependence on ionic strength was observed? We suggest below a structure for the dimer in which the dipoles of the monomer cancel each other out. If this occurs, then electrostatic interactions will be smaller. Since we could only work between 1×10^{-3} to 1×10^{-1} M KCl this may have been too low an ionic strength to see an effect.

So far we have seen none of this specific dimerization with any A-ring derivatives of benzoporphyrin derivatives, such as **1**. However, all of the B-ring derivatives of **2** that we have studied show this specific dimerization. Does this difference between A- and B-ring systems suggest the nature of the dimer? If we simply superimpose two molecules of an A-ring derivative directly one on top of each other (as shown in Fig. 6, (I)) we might anticipate that while the net dipoles are aligned the hydrophobic interactions of both the porphyrins and "benzo" rings should be maximized (the same would be true for two B-ring molecules superimposed in this manner). However, this is unlikely since the trans conformation of the benzo ring substituents prevents close approach of these parts of the molecule and consequently the molecules as a whole.

If however, two B-ring molecules are superimposed in a head-to-tail fashion (Fig. 6, (II)) close approach of the two porphyrin rings is possible. Molecular simulation (MM+ force field optimized by Polack-Ribiere, see ref. 32) suggests that the closest approach of the benzo rings in a head-to-head fashion is ~5.4 Å whereas in a head-to-tail arrangement the porphyrin rings can approach to ~2.7 Å to each other. In addition, the dipoles of the two molecules can cancel each other (even the eight ester groups can take up conformations to achieve this). Moreover, even the two vinyl groups can have hydrophobic interactions with the propionate side chains. When, on the other hand two A-ring molecules are superimposed in this fashion (Fig. 6, (III and IV)) the dipoles cannot cancel and there is less opportunity for the esters to align dipoles or for the vinyl groups to have any hydrophobic interactions. Thus, the face-to-face, head-to-tail conformation depicted in Fig. 6 for the B-ring derivatives seems to be the structure which best explains the observation described above and at the same time may explain why B-ring derivatives form these specific dimers while A-ring derivatives do not.

Conclusion

These results demonstrate that the BPD B-ring derivative **2** in water–MSO undergoes self-aggregation. The red shift observed in the absorption spectra is most likely a consequence of dimer formation consisting of two head-to-tail stacked molecules of the diester. This tendency may be partially explained by both favorable hydrophobic interactions between the aromatic moieties of the porphyrin systems, whose contribution would increase as the percentage of water in DMSO increases and to favorable dipolar interactions in this conformation. The special pair at the reaction centers of plants and photosynthetic bacteria (where dimerization is aided by Mg··· side chain interaction) also show similar red-shifted sharp absorption bands (33). In this case, the nature of the dimer has been elucidated by X-ray crystallography (34). The dimerization constants obtained from absorption and fluorescence spectroscopy are in good agreement and follow the equation $\log (K\mathrm{d}) = 24.6 - 1060.4 \times 1/\varepsilon_{mix}$ which permits the calculation of *K*d in water–DMSO at various composition ratios. Metallated porphyrins with ligands in axial positions can prevent the dimerization process and could be used as a drug for PDT.

Titanocene(III) catalyzed homogeneous hydrosilation–hydrogenation of pyridines

John F. Harrod, Ronghua Shu, Hee-Gweon Woo, and Edmond Samuel

Abstract: The homogeneous catalytic hydrosilation–hydrogenation of pyridines is observed in the presence of Cp_2TiMe_2 (Cp = η^5-C_5H_5) and CpCp*$TiMe_2$ (Cp* = η^5-C_5Me_5) as catalysts and using $PhSiH_3$ or $PhMeSiH_2$ as the source of Si-H. Under appropriate conditions, and with appropriate ring-substitution, good yields of the *N*-silyldihydropyridine or *N*-silyltetrahydropyridine products are be obtained. Although complete saturation is not achieved with organosilane alone, carrying out the reaction under moderate H_2 pressures can give excellent yields of *N*-silylpiperidines. Under moderate pressures of H_2, $[Cp_2TiH]_2$ catalyzes rapid H–D exchange between H_2 and the 2- and 6-positions of C_5D_5N. Under the same conditions, only traces of hydrogenation are observed. This, together with the regioselectivity of 3-picoline hydrosilation–hydrogenation, leads to the conclusion that the key step in the reaction is probably addition of Ti-Si to C=N.

Key words: hydrosilation, hydrogenation, pyridines, dimethyltitanocene, catalysis.

Résumé : Lorsqu'on utilise du $PhSiH_3$ ou du $PhMeSiH_2$ comme source de Si-H, en présence de Cp_2TiMe_2 (Cp = η^5-C_5H_5) ou de CpCp*$TiMe_2$ (Cp* = η^5-C_5Me_5) comme catalyseurs, on peut observer une hydrosilation–hydrogénation catalytique homogène des pyridines. Dans des conditions appropriées et en présence de substituants appropriés, il est possible d'obtenir de bons rendements de *N*-silyldihydropyridines ou de *N*-silyltétrahydropyridines. Même si l'on n'arrive pas à obtenir une saturation complète avec l'organosilane seul, les réactions effectuées sous des pressions modérées d'hydrogène peuvent conduire à d'excellents rendements des *N*-silylpipéridines. Sous des pressions modérées d'hydrogène, le $[Cp_2TiH]_2$ catalyse un échange rapide de H–D entre le H_2 et les positions 2 et 6 du C_5H_5N. Dans les mêmes conditions, on n'observe que de traces d'hydrogénation. Ce résultat et la régiosélectivité de l'hydrosilation/hydrogénation de la 3-picoline nous amènent à conclure que l'étape clé de la réaction est probablement l'addition de Ti-Si sur la double liaison C=N.

Mots clés : hydrosilation, hydrogénation, pyridines, diméthyltitanocène, catalyse.

[Traduit par la Rédaction]

Introduction

Many catalytic and stoichiometric reactions of titanocene derivatives with Group 14 hydrides have been reported. These include the dehydropolymerization of silanes (1) and germanes (2), cross-dehydrocoupling of silanes with alcohols (3), amines (4), hydrazines (5), and acetylenes (6), hydrosilation of ketones (7), esters (8), imines (9), and olefins (10), reductive cyclization of eneones (11), and polymerization of acetylenes (12).

Catalytic hydrosilation of a variety of unsaturated substrates has been widely used for functionalization of silicon compounds (13) and polymers (14, 15) and in organic synthesis (7–10, 16–18). A large class of substrates, which have to date resisted attempts at homogeneous catalytic hydrosilation, are the highly resonance stabilized aromatics such as benzene, pyridine, pyrrole, and thiophene. In this paper we report the use of titanocene derivatives as catalysts for the first examples of homogeneously catalyzed hydrosilation–hydrogenation of pyridines.[3]

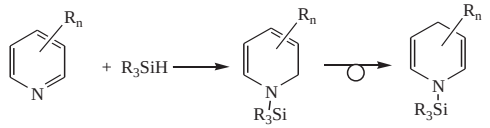
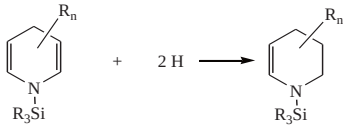
Fig. 1. Reactions of 3-picoline.





Results

Hydrosilation of pyridines in the presence of titanocene-derived catalysts

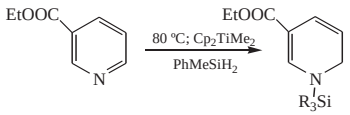
To our knowledge, pyridine is the only example of an aromatic substrate that has been successfully hydrosilated. A number of platinum group metals catalyze the addition of Me_3SiH to pyridine, with palladium being particularly effective (20). However, there is no report in the literature of a homogeneous catalytic hydrosilation of pyridine.

In the present work, both Cp_2TiMe_2 (Cp = η^5-C_5H_5) and CpCp*$TiMe_2$ (Cp* = η^5-C_5Me_5) were found to catalyze the hydrosilation–hydrogenation of pyridine, and a number of its derivatives, with $PhMeSiH_2$. Depending on the conditions, the reaction results in the addition of either Si-H, or Si-H and 2 additional atoms of H to the aromatic nucleus (eqs. [1] and [2]). The addition of more hydrogen to the primary diene product is expected in view of the known high catalytic activity of Cp_2TiMe_2 for hydrogen transfer from Si-H to certain olefinic substrates (21).

[1] 

[2] 

When the reaction is carried out at 80°C in the presence of Cp_2TiMe_2 with pyridine, or 4-picoline, the *N*-silyldihydropyridine intermediate is not observed, presumably because its hydrogenation occurs too rapidly. Under the same conditions 3,5-lutidine gives the *N*-silyl-1,4-dihydropyridine as the principal product, while 3,4-lutidine does not react.

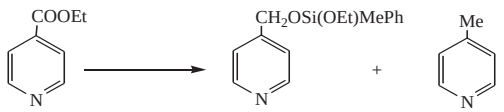


Even in the presence of a large excess of silane, the third double bond is not saturated, but reactions of pyridine, or 4-picoline, under a moderate pressure of H_2 (15–20 atm, 1 atm = 133.322 Pa) do result in complete saturation to give the respective *N*-silylpiperidines as the major products. Reaction of 3,5-lutidine under H_2 pressure gives substantial conversion to the *N*-silyl-1,2,3,4-tetrahydrolutidine, but none of the fully saturated product is produced.

The behavior of 3-picoline varies dramatically, depending on the reaction conditions. The three main reactions are summarized in Fig. 1. At 80°C, in the absence of H_2, the two *N*-silyltetrahydropyridine isomers, **1** and **2**, are the principal products. Under H_2, the **1**-isomer is fully saturated, while the **2**-isomer is unreactive.

Lowering the temperature both slows down the reaction steps and modifies the regioselectivity with respect to **1** and **2**. As the temperature is lowered, the rate of step [2] slows relative to step [1], resulting in ever-increasing amounts of the *N*-silyl-1,4-dihydro-3-picoline (**3**) relative to the tetrahydro-3-picolines, **1** and **2**. At the same time, the ratio of **1** to **2** progressively increases, until at 0°C **1** is no longer detectable. The influences of temperature on the products of the 3-picoline reaction are summarized in Table 1.

In general, the presence of a substituent at the 2- or 6-position shuts down the ring hydrosilation reaction. Thus, no hydrosilation was detected in reactions of $PhMeSiH_2$ with 2-picoline, 2,6-lutidine, 2-cyanopyridine, or 2,2′-bipyridine. An exception to this rule is quinoline, which undergoes reaction in the absence of additional H_2 to give a 3:1 mixture of *N*-phenylmethylsilyl-1,2,3,4-tetrahydroquinoline and *N*-phenylmethylsilyl-1,4-dihydroquinoline. Under moderate H_2 pressure, the only product isolated is *N*-phenylmethylsilyl-1,2,3,4- tetrahydroquinoline.



Hydrosilation of ethyl nicotinate (eq. [3]) gives a near-quantitative yield of *N*-phenylmethylsilyl-1,6-dihydro-3-carboethoxypyridine (**5**). The high selectivity for reduction

[3] 

5

of the pyridine ring rather than the ester group is surprising, given the known high reactivity of esters towards hydrosilation under similar conditions (8). It should also be noted that the apparent regioselectivity in this case (1,6-addition) differs from that seen with 3-picoline and 3,5-lutidine (1,4-addition). However, given the high catalytic activity of the dimethyltitanocene–silane system for double bond migration (10), these products are more likely to be thermodynamically, rather than kinetically, determined.

An interesting reversal of selectivity is observed with ethyl isonicotinate (eq. [4]). In this case, the ester function is preferentially reduced, and no ring-hydrosilated products are observed. The major product (ca. 80%) under our standard conditions is **6**, in which the ester has been reduced to the alkoxide level. A significant amount (20%) of 4-picoline is also produced.

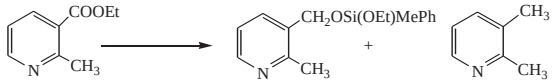
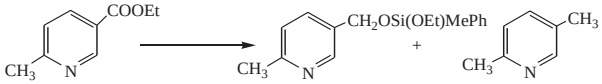


Scheme 1.



Relative rate	50	:	20	:	7	:	3	:	1
pK_a			5.58		5.70		5.99		6.15

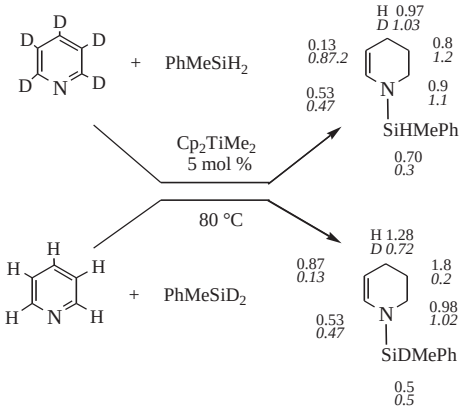
Ring hydrosilation of ethyl nicotinate can be suppressed by substitution at the ring 2-, or 6-position. Thus, both ethyl 2-methyl- and ethyl 6-methyl-nicotinate hydrosilate exclusively at the ester function (eqs. [5] and [6]). Again, in both cases there is significant reduction to the alkoxide level products, **7** and **8**, and the respective lutidines. In the case of ethyl 2-methyl-nicotinate, the lutidine is the major product. No ring reduction products were detected by NMR spectrocopy. In all of the nicotinate and isonicotinate reactions, conversion of the reactant is quantitative by NMR.

[5]

[6]

Cp_2TiMe_2 is ineffective for the hydrosilation–hydrogenation of pyridine with $PhSiH_3$, or Ph_2SiH_2, because of competing Si-H–SiH dehydrocoupling reactions. The resulting oligophenylsilanes then hydrosilate the pyridine to give an intractable mixture of products. Neither *N*-silyldihydropyridine nor *N*-silylpiperidine products were detected by NMR in any of the $PhSiH_3$ reactions. The effectiveness of $PhMeSiH_2$ is due to its slower rate of homodehydrocoupling. With a CpCp*$TiMe_2$ catalyst the rate of dehydrocoupling of $PhSiH_3$ is relatively much slower than hydrosilation as compared to the Cp_2TiMe_2 catalyst, and successful hydrosilation can be achieved with this combination of reactants.

A reaction of CpCp*$TiMe_2$ with pyridine and $PhSiH_3$ (molar ratio of 1:2:4, respectively) at room temperature for four days gave 85% conversion of the pyridine to a mixture of *N*-(phenylsilyl)-1,2,3,4-tetrahydropyridine and *N*-(phenylmethylsilyl)-1,2,3,4-tetrahydropyridine. NMR spectroscopy showed the product also contained CH_4, $PhMeSiH_2$, and $PhMe_2SiH$, the usual products arising from methyl transfer reactions from the catalyst precursor (1*b*). The two *N*-silyl-tetrahydropyridine derivatives were present in a ratio of 4:1 and were the only observable pyridine-derived products. No CpCp*Ti species were detectable by NMR spectroscopy in the product. A similar reaction using $PhMeSiH_2$ instead of $PhSiH_3$ proceeded much more slowly to give the *N*-phenylmethylsilyl- and *N*-phenyldimethylsilyl-tetrahydropyridine products.



Influence of ring substitution on the rate of hydrosilation

The rates of reaction of some of the hydrosilations described above were qualitatively measured from the initial slopes of reactant concentration vs. time plots. The qualitative rate order from the reactants studied is shown in Scheme 1.

This sequence shows that the rate of ring hydrosilation correlates inversely with the basicity of the pyridine. Although no complexity constant data are available for this particular system, the first formation constant with alkyl pyridines for the later transition-metal consistently correlates with the basicity of the pyridine (22). There is no reason to believe that the case would be otherwise with the titanocene(III) system, and it is reasonable to infer that the

Fig. 2. Results of H–D exchange experiments with pyridine.

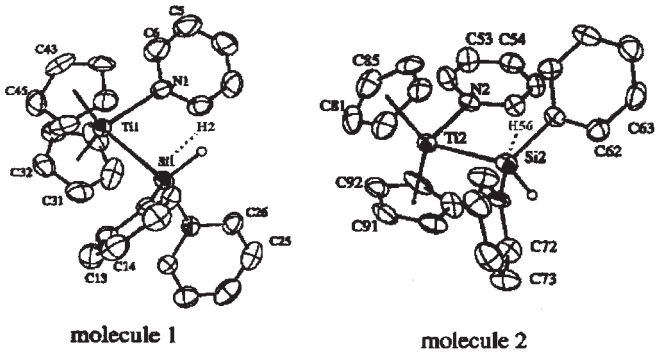
rate is higher the more weakly bound the pyridine is to the Ti center for the examples studied.

Experiments involving H–D exchange

^{1}H NMR spectra of reactions of pyridine-d_5 with $PhMeSiH_2$, and of unlabeled pyridine with $PhMeSiD_2$ in the presence of Cp_2TiMe_2, revealed extensive H–D exchange between unreacted pyridine and unreacted silane. The amount of exchange at the 2- and 6-positions of the recovered pyridine was much greater than at the other positions.

After hydrosilation–hydrogenation in these reactions had gone to completion, the recovered *N*-silyltetrahydropyridines showed minor, irregular H–D exchange at all positions of the reduced pyridine ring, with the 6-position clearly showing a higher extent of exchange than the others. The data for the two complementary exchange experiments are summarized in Fig. 2. It should be noted that the estimated errors in these NMR-determined values are about ±10%. Given the obvious complexity of the reactions leading to these products, and the likelihood of kinetic isotope effects, no real significance can be attributed to the small amounts of scrambling observed.

A reaction of Cp_2TiMe_2, pyridine-d_5, and $PhMeSiD_2$ gave *N*-(phenylmethyldeuterosilyl)-2,3,4-tetradeuteropyridine-d_5. Neither unreacted $PhMeSiD_2$, nor the small amount of $PhMe_2SiD$ produced by Me transfer from Cp_2TiMe_2 to silicon, showed any evidence of H incorporation into the Ph or Me groups. There was also no NMR evidence for migration of D to the Cp rings nor for transfer of D to, or from, toluene solvent.



Reactions of pyridine with H_2

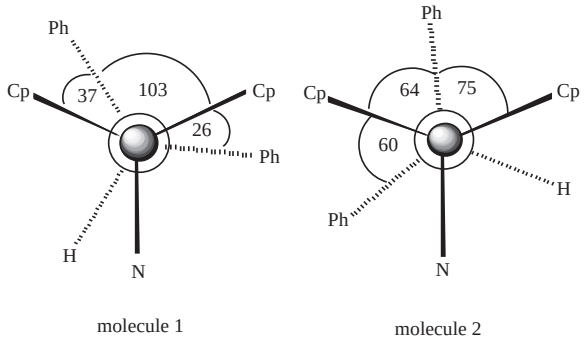
Given the activity of the titanocene system for the hydrosilation of the pyridine ring, its activity for hydrogenation was also studied. A preprepared $[Cp_2TiH]_2$ catalyst (20) proved to be weakly active for hydrogenation of pyridine (~5% conversion to piperidine after 24 h at 80°C under 400 psi H_2, 1 psi = 6.894 kPa). However, under these conditions, pyridine-d_5 underwent essentially complete exchange of H with the D at the 2- and 6-positions of the unreacted pyridine.

Titanocene(III) (silyl)pyridine and pyridyl complexes

Complexes of the general type $Cp_2Ti(SiHRR')(py)$ (**9**) (R = H, alkyl, or aryl; R′ = alkyl or aryl; py = pyridine or substituted pyridine) can be easily prepared by precipitation from mixtures of the appropriate pyridine and $[Cp_2Ti(SiHRR')]_2$ in toluene (1*b*). The same compound precipitates in a one-pot reaction of Cp_2TiMe_2, $RR'SiH_2$, and the appropriate pyridine in toluene (19). The products are generally purple, air-sensitive, microcrystalline solids with low solubility in hydrocarbon solvents.

Fig. 3. The two conformers of **9a** in the solid state. The ORTEP thermal ellipsoids are shown at the 30% probability level (19).

Crystals suitable for structure determination by X-ray diffraction analysis were obtained for the case py = pyridine and R = R′ = Ph, **9a**. The monoclinic crystals contain eight formula units of **9a** and two disordered molecules of pyridine solvent in the unit cell. The eight molecules of **9a** are present as two conformers, molecule 1 and molecule 2, as shown in Fig. 3 (19).



The structure of **9a** can be compared to the analogous Me_3P complex (23). The Ti—Si bond lengths of the two conformers of **9a** are within the range observed for $Cp_2Ti(SiR_3)(PMe_3)$ complexes. However, the Si-Ti-N bond angles of the two conformers of **9a** are quite different from each other and significantly larger (87.2(2)° for molecule 1 and 91.4(2)° for molecule 2) than those in the Me_3P complexes with $SiHPh_2$ (84.8(1)°), SiH_2Ph, and SiHPhMe (both 80.9(1)°) ligands (23). The fact that the angles between the Si-Ti-N planes and the pyridine ring planes of the two conformers are quite different (28.8(4)° for molecule 1 and 14.8(3)° for molecule 2) suggests that steric effects are largely responsible for these differences.

Molecule 2 is close to a gauche configuration (Fig. 4) and, hence, intramolecular contacts are minimized. On the other hand, molecule 1 is constrained, presumably by lattice forces, to a conformation that is much closer to eclipsed. In both conformers there is a close contact between Si and the *ortho*-hydrogen, H(2) (2.83 Å, molecule 1), or H(56) (2.82 Å, molecule 2), which is responsible for the tilting of the pyridine ring. These calculated distances are much shorter than the calculated contact radius sum (3.3 Å) and probably represent a minimum approach that can be tolerated without some distortion of the molecule. In molecule 1, the smaller Si(1)-Ti(1)-N(1) angle increases the encroachment of the Si on H(2), forcing a larger tilting of the pyridine ring plane. There are also important changes in the orientations of the phenyl groups to accommodate the differing steric interactions in the two conformers.

Compounds **9** with R and (or) R′ = alkyl are more soluble, and more prone to decomposition, than those where R and R′ = Ph or H. Thus, reactions of $PhMeSiH_2$, or *n*-$BuMeSiH_2$,

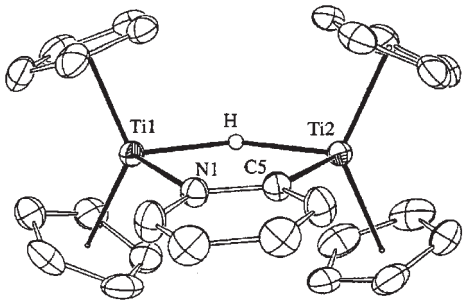
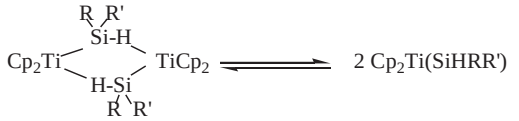
Fig. 4. Projections of molecules 1 and 2 along the Ti–Si bond.

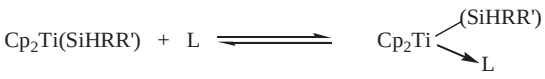


with Cp_2TiMe_2 in the presence of pyridine initially give purple solutions of **9**, but these solutions rapidly darken at room temperature and eventually precipitate dark brown crystals of a new compound, **10**.

The structure of **10** (Fig. 5) closely resembles those of several other hydride-bridged bimetallic titanocene complexes whose structures have been reported. $Cp_2Ti(\mu\text{-}H)(\mu\text{-}HSiHPh)TiCp_2$ (**11**) (1*b*), $Cp_2Ti(\mu\text{-}H)(\mu\text{-}PCy_2)TiCp_2$ (**12**) (24), and $CpTi(\mu\text{-}H)(\mu\text{-}\eta^5,\eta^5\text{-}C_{10}H_8)(\mu\text{-}Cl_2AlEt_2)TiCp$ (25) all have the motif of two titanocene-derived units connected by one hydride bridge and one formally uninegative ligand bridging through a lone pair. The Ti—H bond distances in **10** (1.92(2) and 1.91(2) Å) are not significantly different from those of **11** (1.97(4) Å) and **12** (2.01(5) and 2.00(5) Å). Similarly, the Cp—Ti distances (2.09(1) Å) and Cp-Ti-Cp angles (131.8(2) and 132.7(3)°) in **10** are also close to the corresponding values in **11** (2.053(3) to 2.081(4) Å; 130.6(1) and 131.1(1)°) (R = H, R′ = Ph) and **12**. The Ti(1)—C(5) length (2.205(2) Å) is the same as the Ti(2)—N length, as a result of the C–N disorder. This length is close to the lengths (2.18 to 2.19 Å) found for other sp^2-C ligands bound to titanocene (26), and the same as the Ti—N distance (2.202(2) Å) in a dimeric titanocene(III) pyrazole complex (2.206(4) Å) (27). It is slightly longer than the Ti—N length in titanocene(II)bipyridyl (2.14(2) Å) (28). In the similar monometallic species $Cp^*_2Sc(\eta^2\text{-}N,C\text{-}C_5H_4N)$ (29) and $[Cp_2Zr(\eta^2\text{-}N,C\text{-picolyl})(PMe_3)]^+$ (30) the M—C bonds are slighly longer than the M—N bonds.

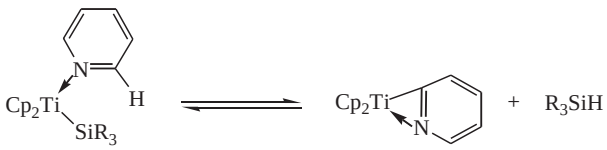


The mechanism of the formation of 9 and 10

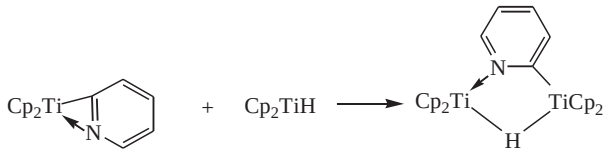


The Cp_2TiMe_2 catalyzed silane dehydrocoupling reaction of $PhMeSiH_2$ is almost completely suppressed in the presence of pyridine, 3- and 4-methylpyridine, or 3,5-lutidine. 2,6-Lutidine has no influence on the dehydrocoupling reaction, behaving essentially as an inert solvent. In the latter case, no complex **9** could be detected (by EPR spectroscopy), or isolated. It is, therefore, likely that the formation of **9** blocks the activity of those titanocene species responsible for the dehydrocoupling reaction. These results provide strong evidence in support of the equilibria shown in eqs. [7] and [8]. In the absence of a donor ligand L, the equilibrium in eq. [7] shifts to the left to give the Si-H bridged bimetallic complex (23a). In the presence of a strong donor ligand, such as a pyridine, or trimethylphosphine, the equilibrium in eq. [8] shifts to the right to produce the ligated, monometallic titanocene(III) silyl complexes. The influence

Fig. 5. The structure of **10**. The ORTEP thermal ellipsoids are shown at the 30% probability level (19)



of the steric bulk of both the silyl and the donor ligands on the equilibria is very evident. As mentioned above, with bulkier donor ligands, such as 2,6-dimethylpyridine or triphenylphosphine, formation of the ligated silyl complex is inhibited and the equilibria shift towards the left. Bulkier silyl groups can also prevent the formation of a ligated complex.

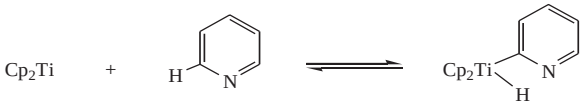


[7] 

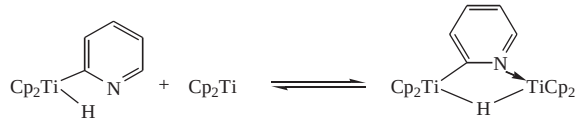
[8] 

The formation of **10** could take place through a number of plausible routes. One would be the prior formation of $Cp_2Ti(\eta^2\text{-}N,C\text{-pyridyl})$ (**13**) by the 1,3-silane elimination reaction shown in eq. [9], followed by reaction with Cp_2TiH (eq. [10]). Reaction [9] is strongly favored by the close approach of the Si to the proximal pyridine C-H hydrogen, revealed in the structure of **10**. In such a mechanism, the activation energy would be relatively low, since the Ti could move from $\eta^1\text{-}N$ coordination to $\eta^2\text{-}N,C$ coordination with relatively little sacrifice in energy. A similar process was previously proposed by Klei and Teuben (30) for the decomposition of $Cp_2Ti(alkyl)(py)$ complexes, and this type of coordination has been demonstrated for a number of metals (31, 32). However, **13** has not been thoroughly structurally characterized. *ortho*-Metallations of pyridine by other early transition metals have also been reported (33–35). The reaction mechanism seems to be similar in all of these systems.

[9] 



13



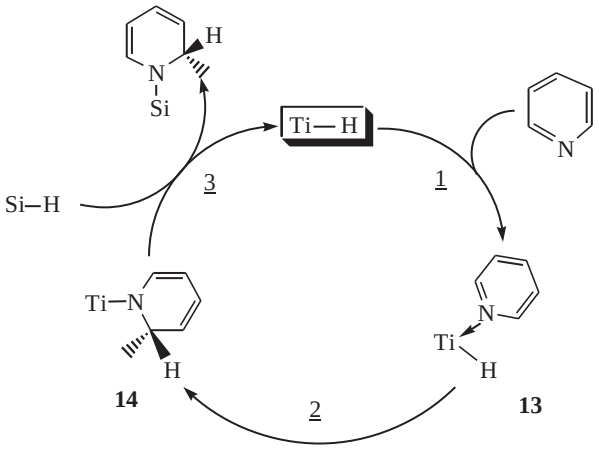
[10] 

© 2001 NRC Canada

Another mechanism analogous to eq. [9], but involving Cp_2TiH(pyridine) (**14**), rather than $Cp_2Ti(SiR_3)$(pyridine), is also plausible. Attempts to detect **14** during hydrosilation reactions, or during the synthesis of **10**, were unsuccessful. This is not surprising since **14**, generated at –20°C by reaction of $[Cp_2TiH]_2$ (21) with pyridine, decomposes rapidly on warming to room temperature. The product of this decomposition exhibits an EPR signal (g = 1.9905), which is very close to that reported for the putative $Cp_2Ti(\eta^2$-*N*,*C*-$MeC_5H_3N)$ (30). It is possible that both of these intramolecular eliminations participate in the production of **10**. Although there is little doubt that the hydride route occurs rapidly in the absence of any silyl ligands, the same cannot be said for the silyl route, since primary and secondary titanocene silyls are known to decompose to produce titanocene hydrides.

A third plausible mechanism for the production of **10** is reaction of a molecule of a Cp_2TiH(pyridyl) complex (**14**) with Cp_2Ti. The former complex could be produced by a concerted oxidative addition of a pyridine C-H bond to Cp_2Ti, as shown in eqs. [11] and [12]. A similar process was proposed earlier to explain the formation of **11** (1*b*). We have also previously suggested that Cp_2Ti could be produced as a transient intermediate in the reactions of Cp_2TiMe_2 with silanes. It is possible that the pyridine competes more effectively for the titanocene intermediate than the less reactive secondary silanes, resulting in the formation of a hydrido(pyridyl), rather than a silyl(pyridine) product. The more reactive silanes (phenylsilane and diphenylsilane) could compete more effectively than the pyridine for titanocene.

[11] 



[12] 

The mechanism of the hydrosilation–hydrogenation of pyridines

The results described above indicate that the reactions proceed first by hydrosilation, followed by hydrogenation. The diene resulting from the initial hydrosilation step is expected to be a good substrate for titanocene-catalyzed hydrogenation by the by-product H_2 from dehydrocoupling reactions, or by direct titanium-mediated transfer of H from Si-H, since such cohydrogenation is commonly used in titanocene catalyzed dehydrocoupling reactions (10, 36).

The isolation of complexes **9** supports the assumption that Cp_2Ti^{III}(silyl)(py) complexes are intermediates, or at least catalytic precursors, in the hydrosilation–hydrogenation reactions. On the other hand, the deuterium–proton exchanges between substrates, or between substrates and H_2, clearly indicate the participation of undetected hydride species as well. Isotope exchange between Si-H and the 2- and 6-positions of pyridine substrates can be accounted for by assuming that eq. [9] is reversible. There are a number of other

Fig. 6. A Ti-H based catalytic cycle.

examples of such *ortho*-metallations of pyridine, involving Ti^{III} and other transition metal ions (27, 34, 35). Exchanges at other positions of the ring are expected to occur by conventional reversible β-hydride addition–elimination cycles as further hydrogenation of the *N*-silyldihydropyridine proceeds. However, the results summarized in Fig. 2 show there is relatively little H–D scrambling in the product other than at the 6-position.

The hydrosilation of pyridines is a special case of imine hydrosilation. Willoughby and Buchwald (9) proposed a plausible mechanism for ketimine hydrosilation involving a classical hydrometallation. The pyridine analogue of this mechanism is illustrated in Fig. 6. In this figure the catalytic cycle is carried by a Ti-H species and silylation occurs by a σ-bond metathesis between Si-H and Ti-N.

Since very little direct hydrogenation of pyridine occurs with these catalysts, it is unlikely that the initial step involves addition of a Ti-H bond to the C=N bond of pyridine. An alternative mechanism involves a cycle in which it is Ti-Si that carries the catalysis, as shown in Fig. 7. This is supported to some degree by the regioselectivities observed with 3-picoline as the substrate. If there is a methyl group at the 3-position of the pyridine, steric hindrance will induce the bulky Cp_2Ti group to move to the 6-position rather than the 2-position, as illustrated in Fig. 8. This is indeed the regioselectivity observed in the lower temperature regime (see Table 1). At higher temperatures, the relative rate of the higher activation energy process of migration of the Cp_2Ti towards the 2-position will increase, as observed. In the case of the Ti-H mechanism, there would be little steric preference for the migration of H to the 2- or the 6-position.

There is ample evidence for both M–H addition and M–Si addition occurring in later transition metal catalyzed olefin hydrosilation (37). M–H addition will normally be faster than M–Si addition. However, β-hydrogen elimination can also be so fast, particularly in the present case where it involves rearomatization, that formation of product is frustrated. In such a situation, the slower M–Si addition can lead to product if the reverse process is also relatively slow.

The minor amounts of H–D scrambling observed in the isotopic labeling experiments show that the hydrogen transfer steps following hydrosilation are essentially irreversible. The larger amount of scrambling at the 6-position in these

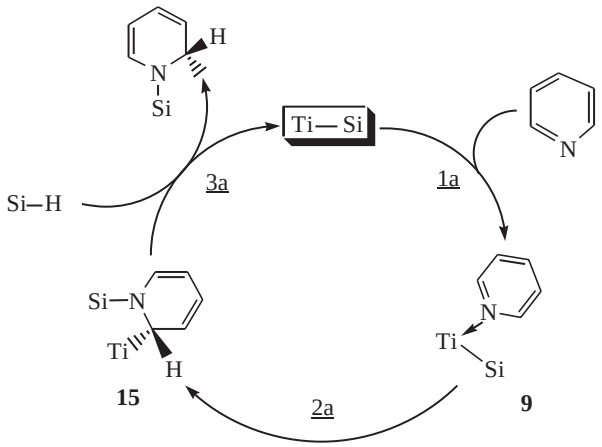
Fig. 7. A Ti-Si based catalytic cycle.



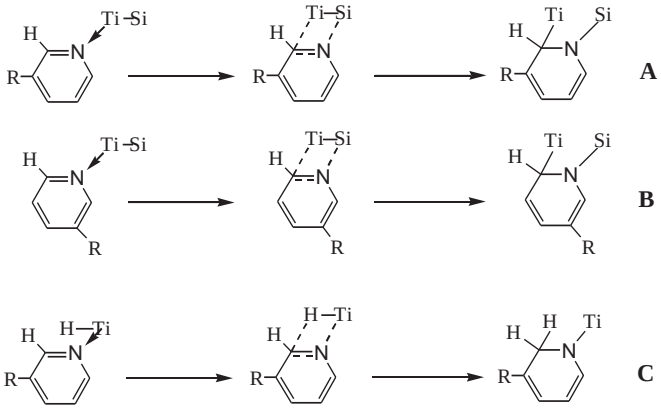


Fig. 8. The two alternative reaction coordinates for C=N insertion into the Ti–Si bond. At 25°C **a**:**b** > 15; at 50°C **a**:**b** = 3.

experiments cannot be attributed to an *ortho*-metalation, such as eq. [9], since this would also cause a similar amount of scrambling at the 2-position. The apparent absence of scrambling at the 2-position requires that the rate of the initial addition of Si-H to N=C be faster than the process that leads to isotope exchange at the 2- and 6-positions of the *unreacted* pyridine. Also, the enhanced exchange at the 6-position of the hydrosilated–hydrogenated product most likely results from an unproductive β-hydride addition–elimination reaction of the eneamine, due to stabilization of the double bond through conjugation to the N.

Once the hydrosilation step has occurred, the nature of the final observed products is determined by the outcome of a complicated set of reactions, including double bond migrations and hydrogenations, effected by reversible β-hydride addition–elimination reactions. The degree to which the products from the alkyl-substituted pyridines are kinetically, or thermodynamically, determined is the subject of continuing study.

The resistance of the enamine products to complete saturation could be due to the stabilization of one of the critical intermediates in the hydrogenation cycle by intramolecular *N*-coordination, or simply because of the unusual stability of the double bond through conjugation to the N lone pair. Blocking of the reaction at the diene level in the case of 3,5-lutidine appears to be the consequence of the much lower reactivity of a trisubstituted double bond towards hydrogenation in this system. In the case of the 3-picoline reaction, a similar lowering of reactivity explains the resistance of **2** to hydrogenation.

The influence of ring substitution on rate.

The reactivity order for the series of substituted pyridines shown above correlates with the basicity of the pyridine. Since the stability of complexes **9** should increase with the basicity of the pyridine, we conclude that tight binding of the pyridine to the Ti has a negative effect on reaction rates, presumable by increasing the activation energy of step 2*a* in Fig. 7. If binding becomes too weak, as in the case of substrates with substituents at the 2- or 6-positions, then reaction is also inhibited.

The dramatic reversal of chemical selectivity between ethyl nicotinate and ethyl isonicotinate may also be due to the fact that the ester group in the 4-position lowers the binding of the N to Ti, relative to binding of the ester function, to the point that ester reduction is the dominant reaction. With the ester group in the 3-position the absence of conjugation between the ester and N leaves the N sufficiently basic, which is the preferred coordination site.

Conclusions

Titanocene derivatives show an exceptional activity for the catalytic hydrosilation of pyridines and, to date, are the only known homogeneous catalysts for this reaction. The reactions show interesting variations in the level of reduction and regioselectivity of the substrate, depending on the ring substitution and the reaction conditions. The ability of the catalyst to effect hydrogenation in the presence of H_2 allows the synthesis of dihydro- and tetrahydro-pyridines, and piperidines in reasonable yields using a single catalyst system. An unusual chemical selectivity is observed with nicotinic and isonicotinic esters. In the former case, only reduction of the ring occurs, while in the latter exclusive reduction of the ester is observed. These results illustrate the extreme sensitivity of the reactions to electronic and steric effects.

The initial step in the reaction appears to be the addition of a Ti–Si species across the C=N bond of the pyridine to give an *N*-silyldihydropyridine. A further two hydrogen atoms can be transferred to give the tetrahydropyridine, but complete reduction only occurs in the presence of H_2.

We are continuing to study the reactions of prochiral pyridines in the presence of chiral titanocene catalysts.

Experimental

All manipulations were performed under an atmosphere of argon, using standard Schlenk techniques. Dry, oxygen-free solvents were employed throughout. Glassware was flame-dried, or oven-dried, before use.

Elemental analyses were performed by Galbraith Laboratories, Inc., and by Oneida Research Services, Whitesboro, New York. $LiAlD_4$, $LiAlH_4$, *n*-BuLi, and Cp_2TiCl_2 (Aldrich) were used as received. Pyridine-d_5 (Aldrich) was dried over

© 2001 NRC Canada

4 Å molecular sieves. Pyridine and alkyl pyridines (Aldrich) were distilled over calcium hydride before use. Quinoline (Aldrich) was distilled under reduced pressure before use. Organosilanes and deuterated organosilanes were prepared from the corresponding chlorosilanes (Hüls America) by reduction with $LiAlH_4$ ($LiAlD_4$) (38). Cp_2TiMe_2 (39) and $CpCp^*TiMe_2$ (40) were prepared according to literature procedures.

Manipulation of air-sensitive crystals was performed either in standard Schlenk apparatus, or in a Braun LabMaster 130 inert-atmosphere glove-box equipped with a catalytic purifier and an Ar atmosphere circulation system. Both H_2O and O_2 were maintained at <2 ppm.

^1H and ^{13}C NMR spectra were recorded on a Varian Unity 500 FT spectrometer operating at 499.9 MHz for ^1H and 125.7 MHz for ^{13}C. ^1H spectra were referenced to C_6H_5D in C_6D_6 (δ 7.15). ^{13}C NMR spectra were referenced to C_6D_6 (δ 128.0). Silicon NMR spectra were recorded in C_6D_6 on a Varian XL-300 spectrometer operating at 59.9 MHz and employing a DEPT pulse sequence (41). The structures of all organic products were confirmed using COSY and HQMC methods. An external standard of tetramethylsilane was used.

Mass spectra were recorded on a KRATOS MS25RFA spectrometer equipped with a KRATOS DS90 data system.

Preparation of $Cp_2Ti(SiHPh_2)(py)$ (9a)

This complex was prepared using a modification of the method for the preparation of titanocene(silyl)trimethylphosphine complexes (22). Typically, Cp_2TiMe_2 (75 mg, 0.36 mmol) was added to a solution of diphenylsilane (0.17 mL, 0.72 mmol) and pyridine (0.5 mL, 6.20 mmol.) in *n*-hexane–toluene (6 mL, 5:1 v/v). In the course of 4 h, the solution turned dark brown and then deep violet. After a further 16 h at room temperature, the solution was stored at –20°C for 2 days to yield small, dark violet needles of **9** (yield: 146 mg, 92%). Anal. calcd. for $C_{28.25}H_{27.25}N_{1.25}SiTi$: C 73.72, H 5.97, N 3.81, Si 6.10, Ti 10.40; found: C 72.83, H 5.99, N 3.22, Si 5.98, Ti 10.26. The instability of this compound in solution precluded recrystalization and X-ray data were obtained on crystals isolated directly from the reaction. The X-ray structure showed the presence of 0.25 molecules of lattice pyridine per molecule of **9** (19).

Preparation of $Cp_2Ti(\mu\text{-}H)(1\kappa N,2\kappa C\text{-pyridyl})TiCp_2$ (10)

Cp_2TiMe_2 (120 mg, 0.58 mmol) was added to a solution of phenylmethylsilane (0.24 mL, 1.73 mmol) and pyridine (1.0 mL, 12.4 mmol) in *n*-hexane–toluene (6:1 v/v, 7.0 mL). After standing for 2 h without stirring, the solution had turned deep violet in color. On standing for a further 24 h at room temperature, the solution slowly turned dark brown. It was then kept at 5°C for 1 day to yield dark brown plates suitable for X-ray analysis (yield: 83 mg, 56%). Anal. calcd. for $C_{27.5}H_{27.5}N_{1.5}Ti_2$: C 69.56, H 5.84, N 4.42, Ti 20.18; anal. calcd. for $C_{26}H_{26}Ti_2N$: C 68.98, H 5.79, N 3.22, Ti 22.01; found: C 66.27, H 5.12, N 3.04, Ti 22.33. The X-ray structure of these crystals showed the presence of 0.5 molecules of lattice pyridine per molecule of **10** (19). The poor elemental analysis resulted in part from loss of lattice pyridine from the crystal during vacuum drying of the sample. EPR: (toluene, 220 K): g_{iso} = 1.984, A_{Ti} = 12 G.

The ^1H NMR spectrum of a saturated solution of **10** in toluene-d_8 at room temperature consisted of two very broad, unresolved, paramagnetically shifted peaks at δ 31.6 (20H, Cp) and 15.6 (4H, pyridyl). No resonance assignable to the bridging hydride was detected.

Catalytic hydrosilation–hydrogenation reactions of pyridines

Synthesis of N-*(phenylmethylsilyl)-2,3,4-tetrahydropyridine*

$PhMeSiH_2$ (3.5 mL, 25.6 mmol) and pyridine (1.0 mL, 12.5 mmol) were added to Cp_2TiMe_2 (0.13 g, 0.7 mmol, 6 mol% catalyst based on pyridine). After a while, the solution color changed to dark blue, then purple accompanied by gas evolution. The mixture was stirred at 80°C. After 12 h an ^1H NMR spectrum of the dark-brown-purple reaction mixture showed that >95% of the pyridine had reacted to give a yield of ca. 80% of *N*-(phenylmethylsilyl)-2,3,4-tetrahydropyridine. The crude product was distilled under vacuum to give 1.29 g (50% isolated yield) *N*-(phenylmethylsilyl)-2,3,4-tetrahydropyridine as a colorless liquid (bp 57°C, 0.12 mm Hg). EI-MS *m/z* (%): 203 (M^+, 100), 188 ([M – $CH_3]^+$ 18.5), 121 ([M – $C_5H_8N]^+$, 76.6). ^1H NMR (300 MHz, benzene-d_6, 22°C) δ: 0.28 (d, *J* = 3.3 Hz, 3H, $SiCH_3$), 1.57 (m, 2H, $NCH_2CH_2CH_2CH$=CH), 2.00 (m, 2H, $NCH_2CH_2CH_2CH$=CH), 2.99 (m, 2H, $NCH_2CH_2CH_2CH$=CH), 4.62 (m, 1H, $NCH_2CH_2CH_2CH$=CH), 5.01 (q, *J* = 3.3 Hz, 1H, SiH), 6.28 (dt, ^3J = 7.8 Hz, ^4J = 3.0 Hz, 1H, $NCH_2CH_2CH_2CH$=CH), 7.2 and 7.5 (2m, 5H, C_6H_5). $^{29}Si\{^1H\}$ NMR (59.9 MHz, benzene-d_6, 22°C) δ: –9.1.

Synthesis of N-*(phenylmethylsilyl)piperidine*

$PhMeSiH_2$ (5.0 mL, 36.5 mmol), pyridine (2.0 mL, 24.7 mmol), and Cp_2TiMe_2 (0.36 g, 1.72 mmol) were thoroughly mixed and sealed in a glass lined, stirred autoclave. The conditions were set at 80°C and 250 psi H_2. After 24 h, *N*-(phenylmethylsilyl)-piperidine (2.0 g, 40% based on pyridine) was isolated by vacuum distillation as a pale yellow liquid (bp 54–56°C, 0.01 mm Hg).^1H NMR (500 MHz, benzene-d_6, 22°C) δ: 0.29 (d, *J* = 3.0 Hz, 3H, $SiCH_3$), 1.27 (m, 4H, $NCH_2CH_2CH_2CH_2CH_2$), 1.40 (q, *J* = 5.5 Hz, 2H, $NCH_2CH_2CH_2CH_2CH_2$), 2.8 (m, 4H, NCH_2CH_2 $CH_2CH_2CH_2$), 5.02 (quart, *J* = 3.0Hz, 1H, SiH), 7.22 and 7.58 (2m, 5H, C_6H_5). $^{29}Si\{^1H\}$ NMR (59.9 MHz, benzene-d_6, 22°C) δ: –10.5. COSY and HMQC NMR experiments were in conformity with the structure assignment.

Reactions of C_5H_5N with $PhMeSiD_2$ and C_5D_5N with $PhMeSiH_2$

$PhMeSiD_2$ (0.44 mL, 3.2 mmol) and pyridine (0.09 mL, 1.0 mmol) were added to Cp_2TiMe_2 (23 mg, 0.11 mmol, 10 mol% catalyst per pyridine). After a while, the solution color changed from orange to dark blue, then to purple accompanied by gas evolution. The mixture was stirred at 80°C. After 12 h an ^1H NMR spectrum indicated that *N*-(phenylmethylsilyl)-2,3,4-tetrahydropyridine(H/D) had been produced in 94% yield, based on pyridine. After exposure to dry air to oxidize the catalyst, the ^1H and ^2H NMR spectra were recorded without further purification.

A reaction between $PhMeSiH_2$ (0.89 mL, 6.5 mmol) and pyridine-d_5 (0.35 mL, 4.32 mmol) was carried out in the

© 2001 NRC Canada

presence of Cp_2TiMe_2 (45 mg, 0.22 mmol, 5 mol%). The mixture was stirred at 80°C for 8 h and then distilled under vacuum to give 0.19 g (20% isolated yield, bp 57°C, 0.12 mm Hg) of *N*-(phenylmethylsilyl)-2,3,4-tetrahydropyridine(H/D) as a colorless liquid

Reaction of Cp_2TiMe_2, pyridine-d_5, and $PhMeSiD_2$ under H_2

$PhMeSiD_2$ (0.30 mL, 2.2 mmol), and pyridine-d_5 (0.12 mL, 1.4 mmol) were added to Cp_2TiMe_2 (0.15 g, 0.36 mmol). The reaction mixture was stirred at room temperature under H_2 (1 atm). After three days, the dark-brown solution was fractionally distilled to give 0.18 g of *N*-(phenylmethylsilyl)-2,3,4-tetrahydropyridine(H/D) as a colorless liquid.

Reaction of 3-picoline, Cp_2TiMe_2, and $PhMeSiH_2$

$PhMeSiH_2$ (3.56 mL, 26 mmol), 3-picoline (1.8 mL, 18.4 mmol), and Cp_2TiMe_2 (0.40 g, 1.8 mmol) were added to a Schlenk tube and stirred at 80°C. After six days, the dark brown–purple reaction mixture was distilled under vacuum (yield 1.3 g, bp 84–86°C, 0.02 mm Hg). NMR showed the product to be a mixture of **1** and **2** (in a ratio of 3:2, respectively). **1**: ^{1}H NMR (500 MHz, benzene-d_6, 22°C) δ: 0.72 (m, 3H, $NCH_2C(H)(CH_3)CH_2CH{=}CH$), 1.64 (m, 1H, $NCH_2C(H)(CH_3)CH_2CH{=}CH$), 2.04, 1.71 (m, 2H, $NCH_2C(H)(CH_3)CH_2CH{=}CH$), 2.98, 2.60 (m, 2H, $NCH_2C(H)(CH_3)CH_2CH{=}CH$), 4.57 (m, 1H, $NCH_2C(H)(CH_3)CH_2CH{=}CH$), 4.99 (quart, J = 3.5 Hz, 1H, SiH), 6.22 (t, J = 8.5 Hz, 1H, $NCH_2C(H)(CH_3)CH_2CH{=}CH$), 7.2, 7.5 (m,$C_6H_5$). EI-MS *m*/*z* (%): 217 ([M^+], 100), 202 ([M – $C_7H_9Si]^+$, 50), 121 ([M – $C_9H_{10}N]^+$, 26). **2**: ^{1}H NMR (500 MHz, benzene-d_6, 22°C) δ: 0.28 (d, J = 3.4 Hz, 3H, $SiCH_3$), 1.54 (m, 2H, $NCH{=}C(CH_3)CH_2CH_2CH_2$), 1.61 (d, J = 1.0 Hz, 3H, $NCH{=}C(CH_3)CH_2CH_2CH_2$), 1.85 (t, J = 6.25 Hz, 2H, $NCH{=}C(CH_3)CH_2CH_2CH_2$), 2.91 (m, 2H, $NCH{=}C(CH_3)CH_2CH_2CH_2$), 5.02 (quart, J = 3.4 Hz, 1H, SiH), 6.08 (m, 1H, $NCH{=}C(CH_3)CH_2CH_2CH_2$), 7.2 and 7.5 (2m, 5H, C_6H_5).

Reaction of 3-picoline, Cp_2TiMe_2, and $PhMeSiH_2$ under H_2

$PhMeSiH_2$ (3.56 mL, 26 mmol), 3-picoline (1.8 mL, 18.4 mmol), and Cp_2TiMe_2 (0.40 g, 1.8 mmol, 10 mol%) were added to a 50 mL stirred pressure bomb and heated at 80°C under hydrogen (200 psi). After four days the product was shown by ^{1}H NMR to be mainly a mixture of **2** and **4**, in a ratio of 3:7. The mixture was fractionally distilled under vacuum to give 1.0 g of pure **2** (bp 84–86°C, 0.02 mm Hg).

Synthesis of N*-(phenylmethylsilyl)-2,3,4-tetrahydro-4-picoline*

A mixture of $PhMeSiH_2$ (3.56 mL, 26 mmol), 4-picoline (1.8 mL, 18.4 mmol), and Cp_2TiMe_2 (0.40 g, 1.8 mmol) was stirred at 80°C for six days and then distilled under vacuum to give *N*-(phenylmethylsilyl)-2,3,4-tetrahydro-4-picoline as a colorless liquid (2.1 g, 53% isolated yield based on 4-picoline, bp 85–87°C, 0.15 mm Hg). EI-MS *m*/*z* (%): 217 (M^+, 37), 202 ([M – $CH_3]^+$, 100), 121 ([M – $C_5H_8N]^+$, 37). ^{1}H NMR (200 MHz, benzene-d_6, 22°C) δ: 0.30 (d, J = 3.3 Hz, 3H, $SiCH_3$), 1.0 (d, J = 6.8 Hz, 3H, $NCH_2CH_2CH(CH_3)CH{=}CH$), 1.6, 1.3 (m, 2H, $NCH_2CH_2CH(CH_3)CH{=}CH$), 2.28 (m, 1H, $NCH_2CH_2CH(CH_3)CH{=}CH$), 3.02 (m, 2H, $NCH_2CH_2CH(CH_3)CH{=}CH$), 4.56 (dd, ^3J = 7.8 Hz, $^3J'$ = 3.0 Hz, 1H $NCH_2CH_2CH(CH_3)CH{=}CH$), 5.04 (quartet, J = 3.3 Hz, 1H, SiH), 6.26 (dd, ^3J = 7.8 Hz, ^4J = 1.8 Hz, 1H, $NCH_2\ CH_2CH(CH_3)CH{=}CH$), 7.2 and 7.5 (2m, 5H, C_6H_5).

Preparation of N*-(phenylmethylsilyl)-2,3,4-tetrahydroquinoline*

$PhMeSiH_2$ (6.0 mL, 43.2 mmol) and quinoline (3.3 mL, 28.8 mmol) were added to Cp_2TiMe_2 (0.60 g, 2.88 mmol, 10 mol%) in a stirred autoclave under 200 psi of H_2 at 80°C. After 48 h, *N*-(phenylmethylsilyl)-2,3,4-tetrahydroquinoline was vacuum distilled as a yellowish liquid (4.0g, 54% isolated yield, bp 160°C, 0.02 mm Hg). EI-MS *m*/*z* (%): 253 ([M^+], 100), 132 ([M – $C_7H_9Si]^+$, 38.3), 121 ([M – $C_9H_{10}N]^+$, 42.1). ^{1}H NMR (200 MHz, benzene-d_6, 22°C) δ: 0.44 (d, J = 3.4 Hz, 3H, $SiCH_3$), 1.55 (m, 2H, $NCH_2CH_2CH_2$), 2.60 (t, J = 6.6 Hz, 2H, $NCH_2CH_2CH_2$), 3.11 (m, 2H, $NCH_2CH_2CH_2$), 5.37 (quart, J = 3.4 Hz, 1H, SiH), 6.7–7.2 and 7.5–7.7 (2m, 4H, CH on the phenylene ring). ^{29}Si NMR (59.9 MHz, benzene-d_6) δ: –12.6 ppm.

Reaction of quinoline, Cp_2TiMe_2, and $PhMeSiH_2$

$PhMeSiH_2$ (2.0 mL, 14.4 mmol) and quinoline (1.1 mL, 9.6 mmol) were added to Cp_2TiMe_2 (0.20 g, 0.96 mmol, 10 mol%) and stirred at 80°C for 36 h. *N*-(Phenylmethyl-silyl)-2,3,4-tetrahydroquinoline and *N*-(phenylmethylsilyl)-2-dihydro-quinoline were formed in a ratio of 3:1, respectively. ^{1}H NMR *(N*-(phenylmethylsilyl)-2-dihydro-quinoline) (200 MHz, benzene-d_6, 22°C) δ: 0.38 (d, J = 3.3 Hz, 3H $SiCH_3$), 3.48 (m, 2H, $NCH_2CH{=}CH$), 4.71 (m, 1H, $NCH_2CH{=}CH$), 6.22 (d, ^2J = 7.7 Hz, 1H, $NCH_2CH{=}CH$). ^{29}Si NMR (59.9 MHz, benzene-d_6): –10.6. A small amount of 1,2,3,4-tetrahydroquinoline was also detected in the mixture: ^{1}H NMR (500 MHz, benzene-d_6, 22°C) δ: 1.57 (m, 2H, $NCH_2CH_2\ CH_2$), 2.51 (t, J = 6.3 Hz, 2H, $NCH_2CH_2CH_2$), 2.76 (t, J = 5.54 Hz, 2H, NCH_2), 3.0 (br s, 1H, NH), 6.22 (d, J = 8.0 Hz, 1H), 6.62 (t, J = 7.0 Hz, 1H), 6.85 (d, J = 7.0 Hz, 1H), 6.95 (t, J = 7.0 Hz, 1H).

Reaction of 3,5-lutidine and $PhMeSiH_2$

$PhMeSiH_2$ (3.56 mL, 26 mmol), 3,5-lutidine (2.1 mL, 18.4 mmol), and Cp_2TiMe_2 (0.31 g, 1.41 mmo, 8 mol%) were mixed a Schlenk tube. After a while the solution turned dark blue, then violet, progressively accompanied by gas evolution. The violet solution was stirred at 80°C for 8 days, and then distilled under vacuum. Analysis of the crude product by ^{1}H NMR showed a complete conversion of the lutidine and a 70% yield of *N*-(phenylmethylsilyl)-4-dihydro-3,5-lutidine. Fractional distillation yielded the pure dihydropyridine (2.5 g, 60% yield, bp 80–90°C, 0.02 mm Hg). FAB-MS (NBA) *m*/*z*: 229 [M^+]. ^{1}H NMR (500 MHz, benzene-d_6, 22°C) δ: 0.25 (d, J = 3.0 Hz, 6H $NCH{=}C(CH_3)CH_2C(CH_3){=}CH$), 2.69 (s, 2H, $NCH{=}C(CH_3)CH_2C(CH_3){=}CH$), 4.99 (quartet, J = 3.0 Hz, 1H, SiH), 5.87 (s, 2H, $NCH{=}C(CH_3)CH_2C(CH_3){=}CH$), 7.2 and 7.5 (2m, 5H, C_6H_5). ^{29}Si NMR (59.9 MHz, benzene-d_6, 22°C) δ: –8.0.

Reaction of ethyl nicotinate and $PhMeSiH_2$ in the presence of Cp_2TiMe_2

$PhMeSiH_2$ (0.45 mL, 3.3 mmol) and ethyl nicotinate (0.3 mL, 2.2 mmol) were added to Cp_2TiMe_2 (40 mg, 0.20 mmol). After a while, the solution color changed from orange to dark blue, then purple, accompanied by gas evolution. The mixture was stirred at 80°C for 3 h, at which point an ^1H NMR spectrum of the product showed that conversion of ethyl nicotinate was complete and ethyl *N*-(phenylmethylsilyl)-1,6-dihydronicotinate was produced in 90% yield. EI-MS *m*/*z* (%): 274 ($[M + 1]^+$, 3.6), 196 ($[M - C_6H_5]^+$, 4.4). ^1H NMR (200 MHz, benzene-d_6, 22°C) δ: 0.06 (d, J = 3.5 Hz, 3H, $SiCH_3$), 0.97 (t, J = 7.2 Hz, 3H, OCH_2CH_3), 3.32 (m, 2H, NCHC(OEt)CHCHCH_2), 4.06 (t, J = 7.2 Hz, 2H, OCH_2CH_3), 4.60 (dt, J = 8.0 Hz, J' = 3.4 Hz, 1H, NCH=C(OEt)CH=CHCH$_2$), 4.72 (q, J = 3.5 Hz, 1H, SiH), 5.58 (dm, J = 8.0 Hz, 1H, NCH=C(OEt)CH=CHCH$_2$), 7.48 (s, 1H, NCH=C(OEt)CH=CHCH$_2$).

Reaction of ethyl isonicotinate with $PhMeSiH_2$ in the presence of Cp_2TiMe_2

$PhMeSiH_2$ (0.26 mL, 1.91 mmol) and ethyl isonicotinate (0.13 mL, 0.95 mmol) were added to Cp_2TiMe_2 (10 mg, 0.05 mmol). The solution color became dark blue then brown over the course of 3 h. It was then stirred at 80°C for a further 36 h. Near-quantitative conversion the ethyl nicotinate to a mixture of 4-picoline and the silylether **6** (ratio 1:5) was observed by ^1H NMR. ^1H NMR (200 MHz, benzene-d_6, 22°C) δ: 0.35 (s, 3H, $SiCH_3$), 1.15 (t, 3H, OCH_2CH_3), 3.7 (q, 2H, OCH_2CH_3), 4.61 (m, 2H, CH_2O), 6.8–8.5 (m, 9H, PhH and the H on the pyridine ring).

Reactions of ethyl 2-methylnicotinate and methyl 6-methylnicotinate with $PhMeSiH_2$ in the presence of Cp_2TiMe_2

Ethyl 2-methylnicotinate and $PhMeSiH_2$ were reacted under the same conditions as ethyl isonicotinate and similar color changes occurred during the raction. The mixture was stirred at room temperature for 24 h. Quantitative conversion to 2,3-lutidine and **7** (ratio 2:3) was observed in 5 h by ^1H NMR. ^1H NMR of **7** (200 MHz, benzene-d_6, 22°C) δ: 0.35 (s, 3H, $SiCH_3$), 1.15 (t, 3H, OCH_2CH_3), 2.40 (s, 3H, Me on the ring), 3.7 (q, 2H, OCH_2CH_3), 4.60 (m, 2H, CH_2O), 6.7–8.6 (m, 8H, PhH and H's on the pyridine ring).

Under similar conditions, methyl 6-methylnicotinate gave a quantitative conversion to 2,6-lutidine and **8** (ratio of 1:4) by ^1H NMR. ^1H NMR for **8** (200 MHz, benzene-d_6, 22°C) δ: 0.37 (s, 3H, $SiCH_3$), 2.50 (s, 3H, Me on the ring), 3.40 (s, 3H, OCH_3), 4.65 (m, 2H, CH_2O), 6.6–8.0 (m, 8H, PhH and H's on the pyridine ring)].

Relative rates of reaction of pyridine, 3-picoline, 4-picoline, 3,5-lutidine, and ethyl nicotinate with Cp_2TiMe_2 and $PhMeSiH_2$

In separate Schlenk reactors, pyridine (0.35 mL, 4.6 mmol), 3-picoline (0.45 mL, 4.6 mmol), 4-picoline (0.45 mL, 4.6 mmol), 3,5-lutidine (0.48 mL, 4.6 mmol), and ethyl nicotinate (0.67 mL, 4.6 mmol) were added to a mixture of Cp_2TiMe_2 (0.09 g, 0.43 mmol) and $PhMeSiH_2$ (0.89 g, 6.5 mmol) together with 50 μL of $SiEt_4$ (in the case of pyridine 0.13 mL of C_6D_6 was also added). The mixtures were stirred at room temperature. NMR samples were extracted periodically by syringe. The conversions were calculated based on the comparison of integrals.

Reaction of pyridine-d_5 with H_2 catalyzed by Cp_2Ti-H

Pyridine-d_5 (0.30 mL, 3.94 mmol) was added to a solution of Cp_2Ti-H (50 mg, 0.28 mmol in 1 mL toluene-d_8, containing a known concentration of Me_4Si as calibrant) in a miniature stirred pressure reactor. The mixture was held at 400 psi H_2 and 80°C for 10 h. Analysis by ^1H NMR showed <10% of the pyridine was hydrogenated, but >90% of the D at the 2- and 6-positions was exchanged with H.

Reaction of $CpCp^*TiMe_2$, pyridine, and $PhSiH_3$

A 5 mm NMR tube was charged with $PhSiH_3$ (30 μL, 0.24 mmol), $CpCp^*TiMe_2$ (20 mg, 0.07 mmol), pyridine (11 μL, 0.14 mmol), and benzene-d_6 (0.4 mL). After thorough mixing, the solution was left to stand at room temperature. It very slowly turned green and after 4 days the ^1H NMR spectrum only showed resonances assignable to the following compounds: *N*-(phenylsilyl)-2,3,4-tetrahydropyridine; ^1H NMR (200 MHz, benzene-d_6, 22°C) δ: 1.52 (m, 2H, $NCH_2CH_2CH_2CH$=CH), 1.92 (m, 2H, $NCH_2CH_2CH_2CH$=CH), 2.96 (m, 2H, $NCH_2CH_2CH_2$ CH=CH), 4.99 (s, 2H, SiH_2), 6.22 (m, 1H, $NCH_2CH_2CH_2CH$=CH), 6.64 (m, 1H, $NCH_2CH_2CH_2CH$=CH), 7.14 (m, 3H, *m*-, *p*-C_6H_5), 7.42 (m, 2H, *o*-C_6H_5). *N*-(phenylmethylsilyl)-2,3,4-tetrahydropyridine, $PhMeSiH_2$, $PhMe_2SiH$, and CH_4. The *N*-(phenylsilyl)-2,3,4-tetrahydropyridine and *N*-(phenylmethylsilyl)-2,3,4-tetrahydropyridine formed in a ratio of 4:1. No CpCp*Ti species were observed in the NMR spectra, probably because of paramagnetism.

REVIEW / SYNTHÉSE

The Heck reaction in the production of fine chemicals

Johannes G. de Vries

Abstract. An overview is given of the use of the Heck reaction for the production of fine chemicals. Five commercial products have been identified that are produced on a scale in excess of 1 ton/year. The herbicide Prosulfuron™ is produced via a Matsuda reaction of 2-sulfonatobenzenediazonium on 3,3,3-trifluoropropene. The sunscreen agent 2-ethylhexyl *p*-methoxy-cinnamate has been produced on pilot scale using Pd/C as catalyst. Naproxen™ is produced via the Heck reaction of 2-bromo-6-methoxy-naphthalene on ethylene, followed by carbonylation of the product. Monomers for coatings are produced via a Heck reaction on 2-bromo-benzocyclobutene. A key step in the production of the antiasthma agent Singulair™ is the use of the Heck reaction of methyl 2-iodo-benzoate on allylic alcohol (**18**) to give ketone (**20**). The high cost of palladium has spurred much research aimed at the development of more active palladium catalysts. Ligandless catalysts are very attractive for production, but work only on reactive substrates. Palladacycles are much more stable than Pd–phosphine complexes and can be used at higher temperatures. The same effect has been reached with pincer ligands. Bulky ligands lead to coordinatively unsaturated Pd-complexes, which are highly active for the Heck reaction. Recycle of palladium catalysts is also very important to reduce cost. Immobilization of catalysts by attaching ligands to solid support is not very useful, because of leaching and reduced activity. In ligandless Heck reactions the catalyst can be precipitated on carriers such as silica, dicalite, or celite. This material can be restored to its original activity by treatment with I_2 or Br_2.

Key words: homogeneous catalysis, palladium, arylation, olefination, ligandless, catalyst recycle.

Résumé : On présente une revue de l'utilisation de la réaction de Heck dans la production de produits chimiques fins. On a identifié cinq produits commerciaux qui sont produits sur une échelle supérieure à une tonne par année. L'herbicide Prosulfuron® est produit par le biais d'une réaction de Matsuda du 2-sulfonatobenzènediazonium sur le 3,3,3-trifluoropropène. L'agent solaire 4-méthoxycinnamate de 2-éthylhexyle a été produit à l'échelle pilote à l'aide d'un catalyseur de Pd/C. Le Naproxen® est produit par le biais d'une réaction de Heck du 2-bormo-6-méthoxynaphtalène sur l'éthylène, suivie d'une carbonylation du produit. Des monomères de couches protectrices sont produits par le biais d'une réaction de Heck sur le 2-bromobenzocyclobutène. Une étape clé dans la production de l'agent antiasthmatique Singulair® est l'utilisation de la réaction de Heck du 2-iodobenzoate de méthyle sur l'alcool allylique **18** pour obtenir la cétone **20**. Le prix élevé du palladium a provoqué beaucoup de recherches dans le but de développer des catalyseurs du palladium qui soient plus actifs. Les catalyseurs sans ligands sont très attrayants pour la production, mais ils ne sont utiles qu'avec des substrats réactifs. Les cycles palladiés sont beaucoup plus stables que les complexes Pd/phosphine et ils peuvent être utilisés à des températures plus élevées. On peut obtenir le même effet avec des ligands en forme de pinces. Les ligands encombrés conduisent à des complexes à coordination insaturée du Pd qui sont très actifs pour la réaction de Heck. Le recyclage des catalyseurs de palladium est important afin de minimiser les coûts. L'immobilisation des catalyseurs en attachant des ligands à un support solide n'est pas très utile en raison du lessivage et de la réduction de l'activité. Dans les réactions de Heck sans ligand, il est possible de précipiter le catalyseur sur des porteurs, comme la silice, la dicalite ou la célite; ce matériel peut être ramené à son activité originale par traitement avec du I_2 ou du Br_2.

Mots clés : catalyse hétérogène, palladium, arylation, oléfination, sans ligand, recyclage du catalyseur.

Introduction

Fine chemicals are produced on a scale of roughly between 1 and 10 000 tons per year. They comprise pharmaceuticals, agrochemicals, polymer additives, flavours and fragrances, food and feed additives, and chemical intermediates to name the most important classes. With relatively few exceptions, fine chemicals are produced via stoichiometric chemistry as this is easily scaled up and does not need specialized equipment. Unfortunately, these production methods also lead to relatively large amounts of waste (1).

Use of homogeneous catalysis has a number of obvious advantages (1–3): (*i*) less waste; (*ii*) lower cost, in particular if shortcuts in total syntheses can be achieved; (*iii*) high chemo- and regioselectivity, easily tuned by the ligands; (*iv*) asymmetric catalysis for the single step production of enantiopure fine chemicals.

If a product grows to a large volume, use of catalysis in a second-generation process becomes attractive because low cost is essential. Prime examples are Ibuprofen™ (carbonylation) (5), Naproxen™ (Heck reaction and carbonylation) (6), malonate esters (carbonylation) (7), and Metolachlor™ (asymmetric hydrogenation) (8).

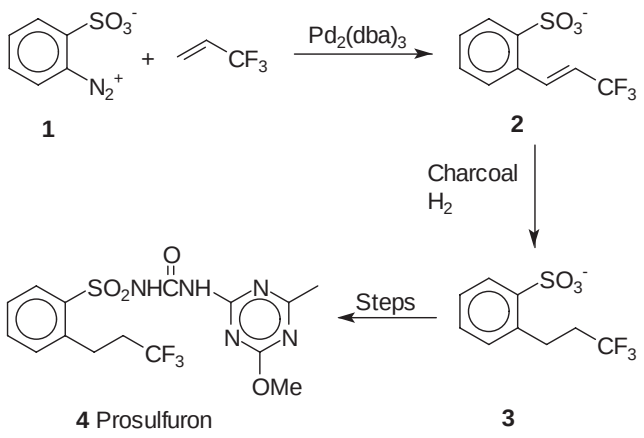
The lack of homogeneous catalysis in first generation processes is very apparent in the production of pharmaceuticals. This is related to the limited duration of patent protection inducing a very strong time-to-market incentive. Because of this it is not possible to drastically change complex synthesis routes. Fortunately, there is an increasing interest in the use of homogeneous catalysis among medicinal chemists.

The history of homogeneous catalysis fine chemicals was initially largely dominated by asymmetric catalysis, particularly enantioselective hydrogenations (9). Recently, palladium catalysed aromatic substitution reactions have been used increasingly for the production of fine chemicals. In the past few years, five new processes based on the use of the Heck reaction have been reported.

The Heck reaction

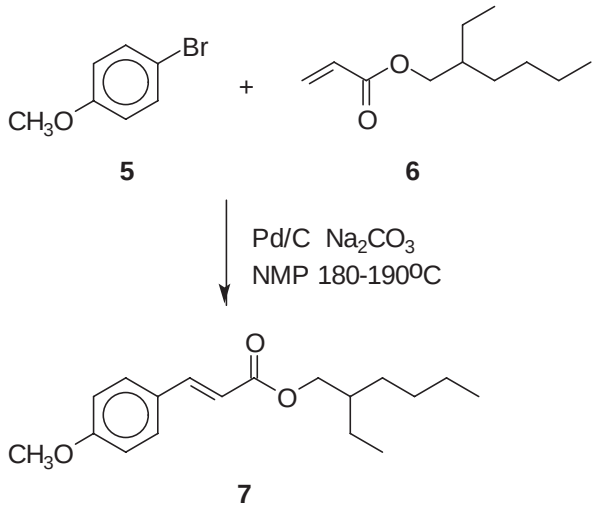
The Heck arylation reaction (Scheme 1), invented independently by Mizoroki and Heck (10) in 1970 establishes a bond between olefins and aromatic rings. Initially, reports only mentioned the use of aryl bromides and iodides as arylating agent. Later, variants were developed using aromatic triflates (11), aroyl chlorides (12), aryl sulfonyl chlorides (13), aromatic diazonium salts (14) (the Matsuda reaction), aroyl anhydrides (15), aryl chlorides (16–20), and arylsilanols (21). Consequently, the number of commercially available aromatic substrates is very high. The diazonium salts work at room temperature or below and thus are suitable for reactions with thermally labile olefins. In situ preparation of the diazonium salt from the aniline during the Heck reaction has also been reported (22). The variant using aromatic anhydrides only produces the aromatic acid as side product, which can be recycled. In addition it does not need phosphine ligands or a base (15). Hence, this reaction is salt free.

Most heteroaromatic halides and pseudohalides can be used in the Heck reaction, though sometimes substrates with halide *ortho*- to the heteroatom cause problems (10).



The Heck reaction works best with alkenes containing electron-withdrawing groups and in most cases gives the β-arylated products exclusively. Olefins with electron-donating groups give rise to mixtures of α- and β-arylated products. If palladium complexes with bidentate ligands are used the regioselectivity can be determined by the choice of leaving groups. Noncoordinating anions like triflate lead mainly to the α-arylated products, whereas halides predominantly give the β-products (10*e*). Simple olefins may suffer from Pd-catalyzed isomerization reactions leading to mixtures. Acetylenes may also be used and are generally more reactive than olefins (10).

Pd-catalysts are used with very few exceptions, usually $PdCl_2$ or $Pd(OAc)_2$ alone or in combination with Ph_3P or *o*-Tol_3P (2 or 3 equiv). Almost all Heck reactions require the presence of a base, which is often triethylamine. The combination $Pd(OAc)_2$, $MHCO_3$ (M = Na, K), KOAc or K_2HPO_4 with a phase transfer salt is also often used (Jeffery conditions) (10*f*). The ligand, the counter ion, the base, the phase transfer salt, and the solvent all have a profound influence on the rate and the selectivity of the reaction; many of these effects are related to the oxidation state and the coordination chemistry of the catalyst (23). It is also possible to use heterogeneous palladium catalysts such as Pd/C (24). Palladium clusters have also shown to be active (25); in fact Pd-clusters seem to form in most phosphine free Heck reactions. There is an ongoing debate whether the clusters themselves are catalytically active or if it is a monomeric soluble form of Pd that is the active catalyst (10*i*, 26). Obviously, to increase activity it is of importance to keep the size of these nanoclusters small. This can be achieved by the addition of tetraalkylammonium salts (Jeffery conditions) (10*f*) or with weakly binding polymers (27) or dendrimers (28). In most cases the active species is based on Pd(0), though it can be anionic (23). Proposals have also been advanced for Pd(II)–Pd(IV) cycles (29–31).



Typical solvents for the Heck reaction are dipolar nonprotic solvents like DMF and NMP. An asymmetric variant

Scheme 3. Sunscreen agent via the Heck reaction.

of the Heck reaction has been developed (32). The scope of this transformation has been limited thus far.

Use of the Heck reaction for the production of fine chemical intermediates

The herbicide Prosulfuron™

The first reported example of industrial use of the Heck reaction was for the production of Prosulfuron™, a new and highly active herbicide, by Ciba–Geigy (now Novartis) (33). In this instance, the Matsuda variant was used to great advantage as the substrate also contains a sulfonate group. The 2-sulfonatobenzenediazonium, which was prepared by diazotization of the aniline, is a neutral compound and relatively stable. The Heck reaction of this betaine on 3,3,3-trifluoropropene was performed at 15°C in HOAc using $Pd_2(dba)_3$ (0.5–1 mol%) as catalyst (Scheme 2). It was not necessary to isolate the Heck product. After addition of some active carbon to deposit the palladium on, the double bond was hydrogenated. Not only was the catalyst used in two consecutive steps, this method also allowed the catalyst to be reclaimed by filtration in 95% yield. The reaction is performed in a single reactor without isolation of the intermediates. The average yield per step is in excess of 90%.

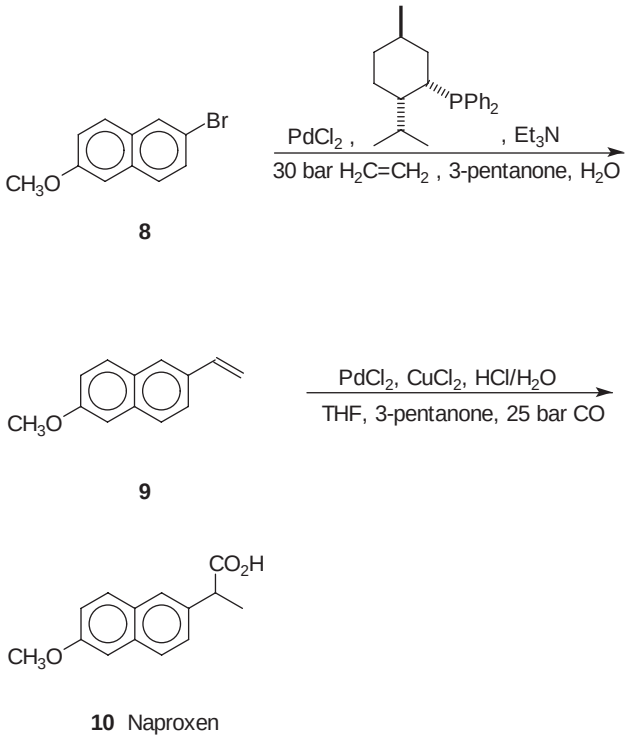
Sunscreen agent via a ligandless Heck reaction

Companies producing bromine and aromatic bromides are of course in an excellent position to apply the Heck reaction. This advantage is not limited to the raw material position, but also involves the ability to recycle the bromide salts that are formed as waste. Because of the presence of large deposits of bromide, Israel has a flourishing organobromide industry. This has lead to the development of a new process for the production of 2-ethylhexyl *p*-methoxy-cinnamate, the most common UV-B sunscreen (34). The process involves the Heck reaction of *p*-bromoanisole with 2-ethylhexyl acrylate (Scheme 3). In this process, palladium on carbon is used as the catalyst without any ligands. This has the disadvantage of relatively low reactivity as compared to most homogeneous catalysts, necessitating a reaction temperature of 190°C. Also, as a result of the high reaction temperature some diarylation is found, mainly the 3,3′-isomer in up to 4%. Presumably, some palladium dissolves during the reaction, but after consumption of the starting materials all palladium precipitates, allowing easy catalyst recovery. The reaction mixture can contain up to 15% of water, which actually has an accelerating effect. This process, which was developed at the IMI institute for R & D in Israel, has been used on pilot scale to produce several tons of sunscreen agent in yields ranging from 75–92%.

Naproxen™ via Heck reaction and hydroxycarbonylation

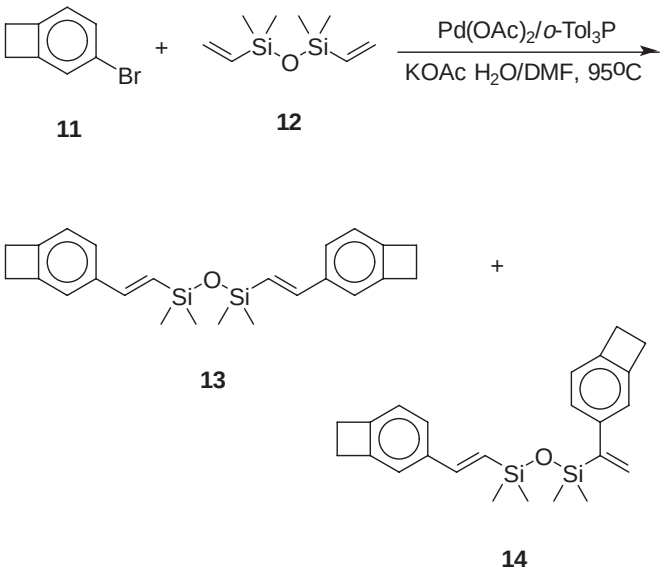
Another producer of organobromine compounds, Albemarle, developed a new process for the production of Naproxen™, based on the Heck reaction of 2-bromo-6-methoxynaphthalene with ethylene, followed by carbonylation to Naproxen™ (Scheme 4) (6, 35, 36). The bromide already was an intermediate for the existing production of Naproxen™ and hence was available at a low price (37).

The key to the commercial success was finding a catalyst for the Heck reaction that was sufficiently active. This was accomplished by screening ligands based on their steric and electronic properties. From these results it was found that a phosphine ligand with steric and electronic properties in the middle of those screened would be optimal. These properties were found in neomenthyldiphenylphosphine. Because of the high activity of the catalyst it was possible to use a substrate:catalyst ratio of between 2000 and 3000 with the reaction going to completion at 95–105°C within a few hours. An ethylene pressure of around 3 kPa was used. This process is run on a scale of 500 tons per year. The bromide is recycled.



The hydroxycarbonylation process is catalyzed by a mixture of $PdCl_2$, $CuCl_2$ and HCl.

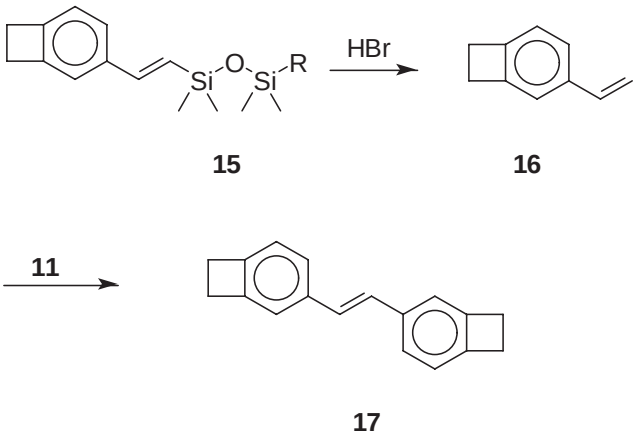
Monomers for coatings of electronic components



The mild conditions of the Heck reaction are also highly suitable for making carbon—carbon bonds with aromatic compounds that are thermally labile. This was the key to success in the production of benzocyclobutene-containing monomers. These are used to form coatings (known as

© 2001 NRC Canada

Scheme 4. Naproxen™ via Heck reaction and hydroxycarbonylation.



Scheme 5. Monomers for coatings via the Heck reaction.

Cyclotene™) for electronic components. The benzocyclobutene groups form *ortho*-quinone-dimethanes upon heating to 180°C, which may react with the double bond introduced by the Heck reaction, thus leading to cross-linking by Diels–Alder reaction.

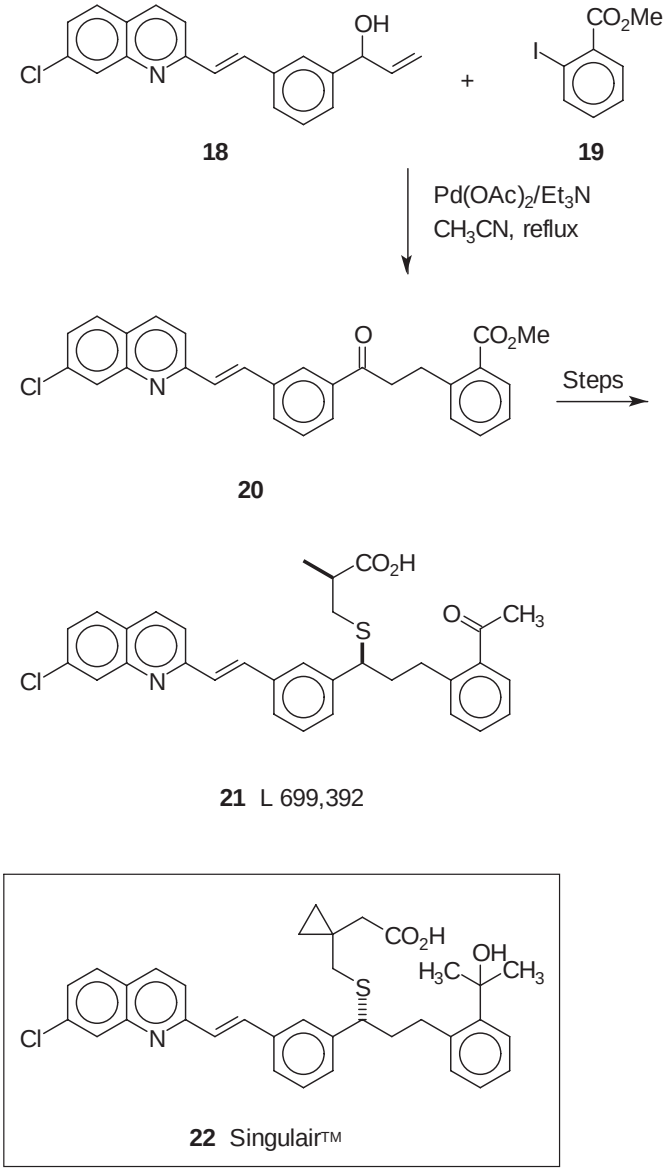
The monomers are formed by Heck reaction of 4-bromobenzocyclobutene with tetramethyldivinyldisiloxane catalyzed by $Pd(OAc)_2$–*o*-Tol_3P in DMF–H_2O using KOAc as base (Scheme 5) (38). The optimal catalyst for this reaction

Scheme 6. Mechanism of formation of the stilbene side product.

was found after screening a range of phosphorus ligands at 95°C. Tri-*ortho*-tolylphosphine gave the best results of the commercially available ligands in terms of product yield (83%). No correlation was found between ligand parameters on one hand, and conversion of bromide, yield of product, or regioselectivity on the other hand. The ligand parameters used were cone angle for bulkiness and pK_a for electronic properties.

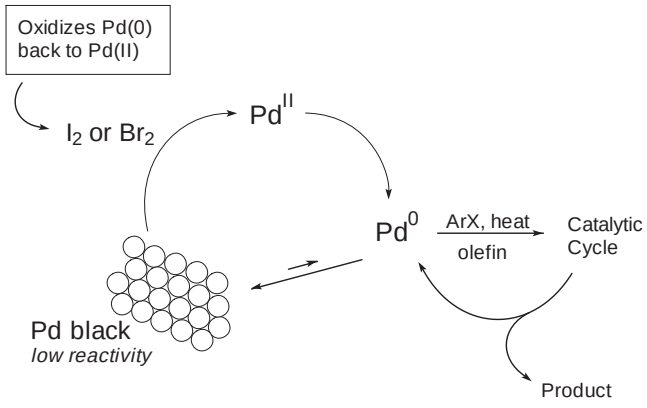
A major side product (3–11%) in these reactions is the stilbene (**17**), which is formed by desilylation of the initially formed monoarylated disiloxane (**15**) followed by Heck reaction on the vinyl group (Scheme 6). Initial results using Et_3N as base gave much higher yields of this side product.

This Heck reaction is performed by Dow on a scale of several tons per year.



The Heck reaction as the key step in the production of an antiasthma agent

An important aspect of the attractiveness of the Heck reaction is the ability to form carbon—carbon bonds without the use of strongly basic reagents such as Grignards and lithiated carbon nucleophiles. Hence, the functional group tolerance of the Heck reaction is very wide allowing its use in the latter stages of a total synthesis. This aspect is very important in the production of Merck's LTD_4 antagonist Singulair™ (**22**) (39) that has been introduced on the market as an antiasthma agent. A synthesis has been published for the closely related L-699 392 (**21**) (Scheme 7) (40). The key step in the synthesis is the Heck reaction of methyl 2-iodobenzoate with allylic alcohol (**18**). Because of the high reactivity of these substrates it was possible to use ligandless $Pd(OAc)_2$ as catalyst with Et_3N as base in CH_3CN as solvent. With 1 mol% of catalyst the reaction is complete in 1 h. A minor by-product was formed via arylation of the 2-position. However, the product could be obtained in pure form by crystallization.



In this variant, reaction on the allylic alcohol leads to the formation of a ketone, because β-hydride elimination of the palladium–alkyl intermediate leads to the preferential formation of the enol.

Scheme 7. The Heck reaction in the production of antiasthma agents.

Scheme 8. A practical catalyst recycle for ligandless Heck reactions.

Development aspects

A major aspect in the development of a homogeneous catalyzed reaction is the cost of the catalyst. This in turn is strongly dependent on two important parameters: (*i*) The activity of the catalyst expressed as turnover frequency (TOF: mol of product/mol of catalyst h); (*ii*) The stability of the catalyst expressed as total turnover number (this might include recycling; TON = mol of product/mol of catalyst).

For this reason, much effort has been put into the development of new, more active, and more stable palladium catalysts. The palladacycle developed by Herrmann et al. (17) is a good example. Because of its increased stability, the catalyst can be used at higher temperatures, thus producing higher reaction rates. In addition, unreactive arylating agents like aryl chlorides can be used. More variations on this theme are the use of bulky phosphite (18, 41) or phosphoramidite ligands (42), carbene ligands (43, 44), and pincer ligands (31, 45). Another interesting, cheap, and very active class of catalysts are the palladacycles based on aromatic compounds with side chains containing N (41, 46), O (47), or S (48, 49). The more active catalysts also have allowed the use of chloroarenes as arylating agents, which is tremendously important because of the much wider commercial availability and the lower costs of these compounds (16–20).

Separation of the product can sometimes be hampered by the presence of a phosphine ligand. Therefore, ligandless Heck reactions are preferred where possible, as shown in three of the above five cases.

Because of the steadily rising cost of palladium, catalyst recovery and recycle has become a major issue. Recovery is easy in the case of the ligandless Heck reactions as the catalyst precipitates completely once all the substrate has been used up. If ligands are used this can be a problem, though sometimes water-soluble ligands can be used to allow for two-phase catalysis (50–53). Ionic liquids have also been reported as an aid in catalyst recycle (54–56). The recovered catalyst is usually returned to the catalyst manufacturer for reclaiming as catalyst activity is greatly diminished. Recycling methods based on the immobilization of ligands are usually flawed, as the instability of the palladium complexes will invariably lead to leaching (10*i*). In addition, reactivity is usually severely compromised. Immobilization of ligandless palladium has some merit (57). Even though leaching occurs extensively, the palladium precipitates on the support at the end of the reaction. However, these catalysts are usually less active.

Recently, a new method for catalyst recycle was reported from our laboratories (58, 59). In this method, $Pd(OAc)_2$ is used as ligandless catalyst. At the end of the reaction, the catalyst precipitates in >99% as Pd(0) on an inexpensive carrier material like silica, dicalite, or celite. This catalyst is about 10 times less active than the $Pd(OAc)_2$ that is used initially. However, full catalytic activity can be restored by the addition of a few equivalents of I_2 or Br_2 (Scheme 8). These halogens oxidize Palladium(0) to Pd(II) which is then reduced again during the next cycle to form highly active catalytic species.

© 2001 NRC Canada

Conclusion

The Heck reaction is finding increasing use for the production of fine chemicals on a scale of 1–500 tons per year. At least five published cases are known of products that have been produced on a scale of more than 1 ton using the Heck reaction. Advantages when compared to more classical methods such as Friedel–Crafts chemistry are superb functional group tolerance, mild conditions, less waste, and sometimes a shorter route than the original stoichiometric route. This has spurred renewed activity in the area of development of new, faster and more stable catalysts. Catalyst recycle is particular easy with ligandless catalysts, where treatment of the precipitated Pd with I_2 leads to full regeneration of activity.

The versatility of azobenzene polymers

Almeria Natansohn and Paul Rochon

Abstract: The well-known *trans–cis–trans* photoisomerization of azobenzenes produces at least three different kinds of motion in the polymer materials to which the azobenzenes are bound. The first is a photoinduced motion of the azobenzene groups only, and they can align in a selected position with respect to the light polarization. The second is a macroscopic motion of huge amounts of polymeric material, producing surface deformation, and the third is a reorganization of smectic domains in liquid crystalline polymers. These motions and their consequences are briefly discussed in relation to the polymer structure and some possible photonic applications are mentioned.

Key words: photoinduced orientation, azobenzene polymers, surface gratings, photonics, thermochromism, photochromism, photorefractivity, photoinduced chirality and switching.

Résumé : La photoisomérisation bien connue *trans-cis-trans* des azobenzènes donne lieu à au moins trois types différents de mouvements dans les matériaux polymères auxquels ils sont liés. Le premier est un mouvement photoinduit impliquant uniquement les groupes azobenzène et ils peuvent s'aligner dans une position choisie par rapport à la polarisation de la lumière. Le deuxième est un mouvement macroscopique de grandes quantités de matériau polymère qui provoque une déformation de la surface et le troisième est une réorganisation dans les domaines smectiques des polymères à l'état de cristal liquide. On discute brièvement de ces mouvements et de leurs conséquences en relation avec la structure du polymère et on fait état de quelques applications photoniques possibles.

Mots clés : orientation photoinduite, polymères azobenzène, réseaux de surface, photonique, thermochromie, photochromie, photoréfractivité, chiralité photoinduite, inversion de chiralité.

[Traduit par la Rédaction]

Introduction

Azobenzenes have been known and studied for a very long time. Their initial use was as dyestuff for a variety of things. Azobenzene photoisomerization is also very well-known and has been reviewed in a reference book (1). When the azobenzene group is incorporated into a polymer, its photoisomerization can have a wide range of unexpected possible consequences. These have also been reviewed (2).

About 15 years ago, Todorov et al. (3) noted yet another unexpected phenomenon related to the photoisomerization of some azobenzene groups when dissolved into a polymer matrix. The azobenzenes photoisomerize under polarized laser illumination and eventually orient perpendicular to the laser polarization, producing dichroism and birefringence in the polymer film. Around 1987, a few papers from Ringsdorf and Wendorff's laboratories in Germany rediscovered the same phenomenon in liquid crystalline polymers containing azobenzene groups. These groups were now the mesogens *and* the photoactive moieties (4). At about the same time, Ichimura et al. (5), in Japan, proposed the "command surfaces" concept, where the azobenzene was the "commander" and liquid crystalline Langmuir–Blodgett films were the "soldiers" which would align with the *trans* or with the *cis* azobenzene, and the switching was initiated by illumination. Although all these papers appeared before the review by Kumar and Neckers (2), they were too recent then to be included there.

By 1991, at the time we got involved in this type of research, the field practically exploded with papers coming from many research groups all over the world. A consistent trait of these reports was that most were unaware of both the pioneering work done in this field and of the work done at the same time by other groups. This was certainly true in our case. The findings were unexpected, exciting, and raised enormous possibilities for reversible optical memory and photonic applications. In the last 10 years, the research activity has grown exponentially, and there still is no review covering all these new implications of azobenzene photoisomerization in polymer structures. Here, we mention some very useful reviews: one by us in 1993 (6) covering most of the literature to date; one reviewing surface gratings research done mainly in Tripathy's group (7), and a more

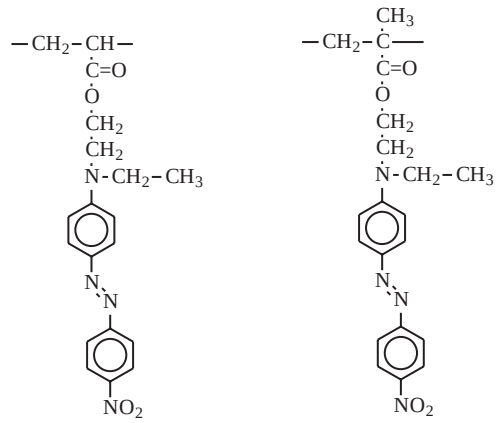
recent one covering photoalignment in liquid crystalline polymers (8). The best review available, covering both photoinduced birefringence and surface relief gratings, belongs to Delaire and Nakatani (9).

This article is not intended to review the state of the art on photoinduced motions in polymers triggered by azobenzene photoisomerization. We are working on a review on this subject, and — as expected — the task is huge and challenging. In this article, we will give a summary of our own involvement in this area of research and we will point out what we believe are our contributions. This is a wonderful area of research, in our experience almost anything we start studying reveals new and exciting findings. It also has helped us, and others, challenge some very basic concepts of polymer science.

Azobenzene photoisomerization

One can think of azobenzene as a photochromic material, because it has two isomers, *cis* and *trans*, that absorb at different wavelengths. The max absorbance depends on the substituents, but for the unsubstituted azobenzene the *trans* isomer has a max absorbance at 313 nm and the *cis* isomer at 436 nm (1). In principle, one could use light to switch between the two isomers and "store" information until switched back. In practice, this is not possible, for two reasons. First, the color change is not noticeable, because of the much lower absorptivity of the *cis* isomer. Second, the *cis* isomer is very unstable and it cannot be conserved ("stored") for more than a few hours. With donor–acceptor substituents, the *trans* and *cis* absorbances become superimposed, thus such azobenzenes are not photochromic anymore. The *cis* lifetime is also much shorter. Thus, donor–acceptor substituted azobenzenes will switch back and forth between the *trans* and *cis* isomers for as long as they are illuminated at the absorbing wavelength. The schematic illustration of azobenzene photoisomerization is shown in Fig. 1.

Motions induced by photoisomerization



While the azobenzene (azo) group is subjected to continuous laser illumination at low intensities (normally a few mW cm^{-2}), photoisomerization occurs at a very high rate. Although the details are not yet well understood, the quantum yields are high (1) and the switching time is believed to be shorter than picoseconds. Even when the azobenzenes are not bound on a polymer chain, but just dispersed in it as a solid solution, this constant *trans–cis–trans* photoisomerization activity results in the azobenzene group moving around and slightly changing its position. This type of motion is expected, especially when the azo group is not bound to the polymer. This was the case for the first report of photoinduced birefringence (3). When the azobenzene group is bound, the presence of a flexible spacer, separating the rather rigid, but mobile azo group, from the rigid and entangled polymer backbone, was believed to be required. This spacer would "decouple" the azo motion from the backbone, allowing it to move around. This was the basis for the liquid crystalline polymer research (4). The longer the spacer between the azo group and the backbone, the more "freedom" the azo groups would have, but this longer spacer and the presence of the mesogenic azo groups would also provide liquid crystalline properties to the resulting polymer. At that time it was believed that liquid crystallinity was a required condition to allow the azo group freedom to move. Working with polymers with shorter spacers (two methylene units, see Fig. 2), we were very surprised to discover (10, 11) that this kind of motion can occur well below the glass transition temperature (*T*g) of the material. In fact, the liquid crystallinity requirement was unnecessary, as we and then many other research groups demonstrated.

Yet another, much more surprising type of movement happens while photoisomerization takes place. If the laser light intensity is modulated and hits the surface of the polymer film at different intensities, a massive movement of the polymer material may accompany the photoisomerization. The motions are thus not limited to the azo rigid group, but involve many polymer chains, because the volumes affected by this kind of movement are of the order of up to cubic microns. This extremely surprising finding was reported almost at the same time by our group (12) and by Tripathy's group (13).

Finally (although other surprises may still await discovery), another novel type of movement in polymer materials

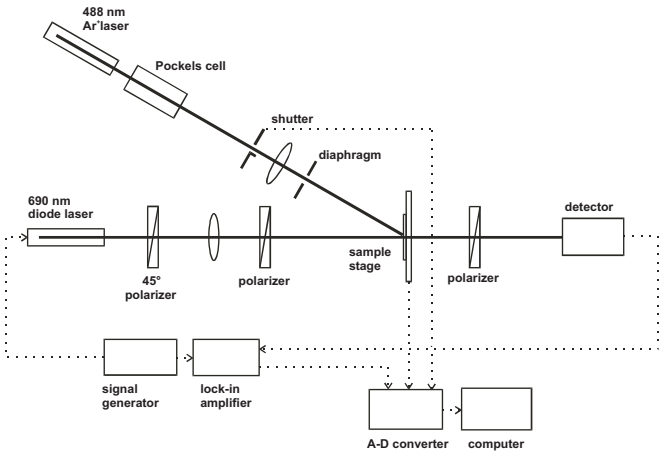
Fig. 3. A random distribution of the azo groups in a hypothetical 6-*mer* chain. The groups with an asterisk are already perpendicular to the light polarization direction (represented by the arrow). The azo group shown at the lower right side of the chain goes through a series of isomerizations until it reaches the inert alignment.



containing azobenzene groups is a reorientation of whole smectic (liquid crystalline) domains in polymers. If subjected to circularly polarized light, for example, the domains will rearrange from a disordered state to a supramolecular helical ordered state of the same handedness as the incoming light. This can be observed by measuring optical rotation or circular dichroism (14, 15). Some more details about these three kinds of unexpected motions will be given in the following subchapters.

Photoinduced birefringence

Regarding the first type of motion, involving solely the azobenzene groups and leaving the main chain almost inert, an interesting consequence occurs when linearly polarized light is being used. In an amorphous, high-*T*g polymer film containing azobenzene groups, these groups tend to be randomly distributed. When the film is prepared by spin coating, which happens in most cases, the rotation of the stage produces a preferred orientation within the plane of the film. This preferred orientation can be destroyed by heating the film above *T*g. Heating randomizes all preorientation and allows any trapped solvent to escape. Illuminating such a film with linearly polarized light activates the photoisomerization of the azo groups having a component of their dipole parallel to the polarization direction of the light. In other words, any azobenzene group that happens to lie perpendicular to the light polarization will not photoisomerize. The azo groups that do isomerize will also move slightly in the process, and if at the end of a photoisomerization cycle they happen to fall perpendicular to the light polarization, they will also become inert to light. This means that the concentration of the azo groups lying perpendicular to the light polarization will steadily increase and eventually reach a saturated value. A possible schematic illustration of the phenomenon is shown in Fig. 3. A portion of an azo polymer chain containing six structural units is shown in four stages of illumination. The polarization of the light is shown in the figure as an arrow. The azo groups already perpendicular to the light polarization, thus inert to the process, are marked with asterisks. The emphasis is on the motion of the "gray" chromophore, that isomerizes and moves slightly between 1 and 4, when it happens to fall in the position perpendicular to the light polarization. Thus, at the end of the schematic process represented here, the number of chromophores aligned perpendicular to the light polarization has increased from three to four. It is possible to measure this alignment of the azo groups either as dichroism or as birefringence. A typical set-up for measuring birefringence is illustrated in Fig. 4.

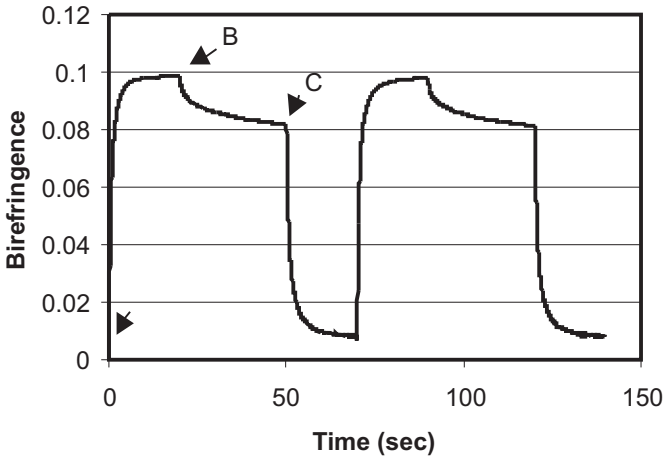


Fig. 4. A typical set-up to measure photoinduced birefringence in azo polymers. The 488 nm laser is used as a pump and the 690 nm laser is used as a probe.

Thus, starting with a sample with no preferred orientation of the azo groups, after illumination one obtains a birefringent sample. Using a laser on a random sample, the illuminated spot is now birefringent. Upon turning the laser off, the photostationary state, containing some *cis* isomers, relaxes to a stable state in which the orientation (and birefringence) is conserved to a significant level (typically between 60 and 95%, depending on the material). The most exciting aspect of the phenomenon, that was pointed out by

© 2001 NRC Canada

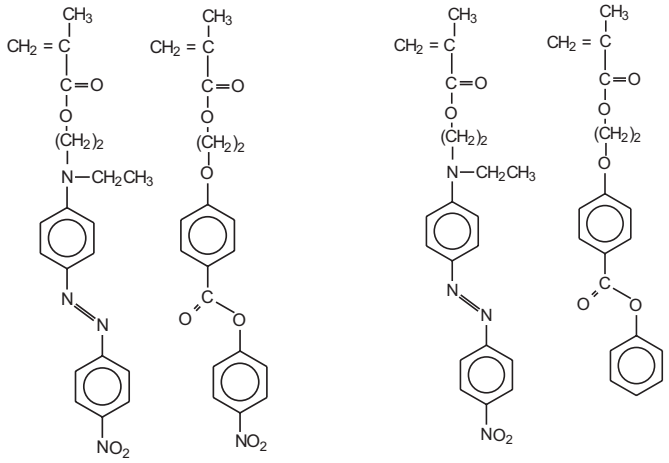

Fig. 5. Typical repeated measurement of photoinduced birefringence on a sample of pDR1M. Linearly polarized light is turned *on* at point A and the photoinduced birefringence starts growing and reaches a saturated level. At point B the light is turned off and some relaxation occurs. At point C, circularly polarized light is turned *on* and the photoinduced birefringence is erased.

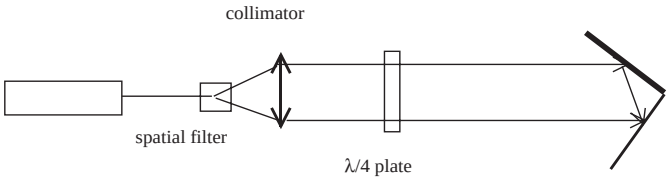
our group for the first time (11), is that illumination with circularly polarized light will restore the preferred random orientation of the azobenzene groups, thus "erasing" the birefringence. A typical birefringence measurement is shown in Fig. 5, where birefringence is induced, allowed to relax, and then erased, twice. This cycle is very reproducible and can be repeated tens of thousands of times on the same spot on the polymer film before photobleaching starts occuring (16).

A lot of research was dedicated in our group to investigating the levels of birefringence, the rates of photoinducing it, the rates of relaxation and — especially — the relation between the polymer structure and the photoinduced birefringence. We have investigated various azobenzene groups as chromophores, and linked them into polymer structures by various means, for example as side groups (with different types and lengths of spacers) or within the main chain. We have varied the concentration of the azobenzene groups in the polymer film, by synthesizing copolymers and preparing blends with various comonomers and polymers, respectively. It is not possible to review or even to summarize this work here, but good overviews can be found in a book chapter (17) and in a "research news" article in *Advanced Materials* (18). We would like to mention here the most significant (and surprising) result in photoinduced birefringence obtained by our group. This was the existence of cooperative motions well below the polymer glass transition temperature. Cooperative motion is well-known and understood in ordered systems. When some of the groups (like azobenzenes) in such a system are subjected to motion (in this case photoinduced motion), the thermodynamic drive to form ordered phases coerces any other group to move in concert. Figure 6 illustrates two pairs of comonomers studied for cooperative motion. For the pair on the left, both comonomers contain rigid-rod structures of comparable polarity, one is an azobenzene and one is an ester. Copolymers with compositions varying between 0 and 100% azobenzene structural units were synthesized and their photoinduced motion ana-

Fig. 6. Two pairs of comonomers to demonstrate cooperative motion in amorphous high-*T*g copolymers.



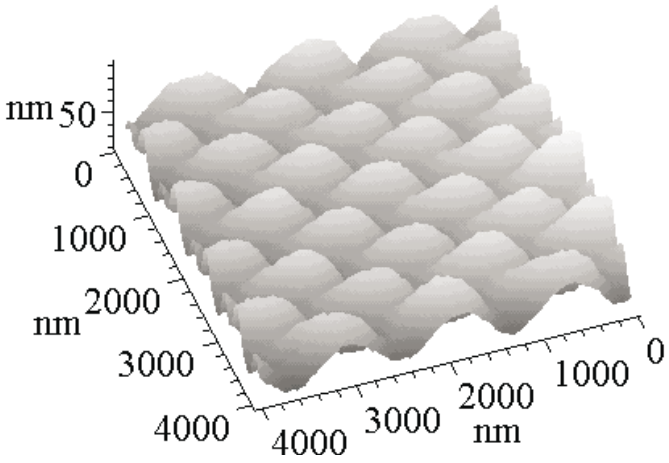
lyzed both by optical (19) and by spectroscopic (20) means. Both methods clearly indicate that the azobenzene group not only changes its own orientation when irradiated with polarized light, but it also moves the ester group in concert. The cooperative motion of the ester group is very powerful, it can be estimated that — of the overall photoinduced birefringence — almost 45% can be due to the ester group. What drives the ester group to move? These copolymers are not semicrystalline or liquid crystalline, thus it is difficult to imagine a steric factor being the determining one. Both the ester and azo groups are polar, and their relative orientation within the copolymer film insures electrical neutrality of the film. If some groups are moved (the azo groups are being moved by the polarized light), then the equilibrium dipolar distribution is altered, and the ester group may be moving to restore this equilibrium. To check this assumption, the pair of comonomers on the right in Fig. 6 was synthesized, and — again — a series of copolymers covering the whole possible range of compositions was prepared. These copolymer films were also subjected to the photoinduced birefringence procedure, and the results were indeed different. Even though there still was some cooperative motion of the nonpolar ester groups, this cooperative motion was minimal. We could then conclude that polarity is the main driving force behind cooperative motion in amorphous azo copolymers well below their *T*g. This conclusion also helped solve some long-standing disagreements in the literature (21).

Surface relief gratings

About 1993, in an effort to compare our azobenzene polymers with the new photorefractive polymers reported in the current literature, we started trying to produce volume holographic gratings, to measure their diffraction efficiency. By using a mirror set-up (Fig. 7) and thus an interference pattern, we expected to produce volume polarization gratings of alternating orientation domains in the polymer films. We expected to be able to measure diffraction efficiencies of about 1%, which was at that time the state-of-the-art level for photorefractive polymers. Much to our surprise, our very first experiment produced a grating with 20% diffraction efficiency. It took us some time to realize that the gratings — now visible with the naked eye — were due to a certain de-

© 2001 NRC Canada

Fig. 7. Set-up for gratings inscription.



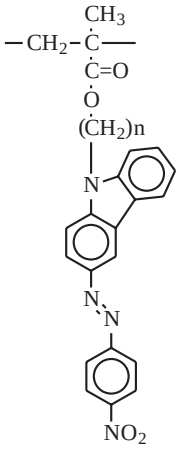
formation of the surface of the film. Also, these gratings were not optically erasable, but it was possible to write on top of them, while keeping the initial ones still there. Atomic force microscopy showed that the corrugation achieved only with light on polymer films of high *T*g was as deep as hundreds of nanometers, even to the micron level (12) (Fig. 8).

The explanation for these phenomena, also reported by groups in the U.S. and Denmark, is the second kind of motion mentioned in the *Photoinduced motions* part of this article. The actual mechanism for the unusual phenomenon is still under investigation; currently four possible mechanisms are proposed (22–26). There is a wide range of possible application of these gratings in photonic devices, some of them mentioned in one of our articles (18).

Photorefractivity

If one thinks in terms of photonic devices, photoinduced birefringence can produce reversible waveguides, while surface relief gratings can act as couplers of the light in and out of these photoinscribed waveguides. Thus, on a simple polymer film, one could inscribe a "photonic printed circuit" using light only. Another necessary function would be switching. If our polymers would also be photorefractive as can be verified by the two-beam coupling procedure (27), then switching can be done electronically. The requirements for photorefractivity in a polymer are: (*i*) the possibility to modulate the refractive index with an electric field; (*ii*) photoconduction; and (*iii*) the presence of charge traps. Our azo-based polymers already fulfill the first condition, since the azo groups we are using have nonlinear optical (NLO) properties based on their delocalized electronic structure. Such azo polymers were amongst the first to be used in NLO materials, mainly for second harmonic generation (28). The presence of charge traps is usually taken for granted in any polymer material, thus the only condition needed for our polymers to exhibit photorefractive properties is photoconduction. This is relatively easy to accomplish if one replaces the amine end of the azobenzene chromophore with a carbazole or a tetramethyldiaminobiphenyl (TPD) moiety, which are very well-known photoconductive groups. Figure 9 shows the structure of a few polymers designed to fulfill all the required properties for photorefractivity. These polymers are either side-chain methacrylates (29, 30), or very stable polyimides with carbazole within the main chain (31), or TPD-based polyesters.[2] None of these polymers have optimal photorefractive properties. Nevertheless, they are the first polymers mentioned in the literature to contain all the required structural attributes for photorefractivity within a single structural unit *and* show the possibility to combine three photonic "functions" (waveguiding, coupling, and switching).

Fig. 8. AFM pictures of two superimposed gratings successively inscribed on the same piece of film.



Photoinduced liquid crystalline phases

Studies of the surface relief gratings are very active worldwide, on the one hand because of the still intriguing mechanism of formation and control, on the other hand because of the wide area of possible applications. In collaboration with Professor Pietsch's group (Potsdam, Germany), we obtained some other unexpected results. Professor Pietsch was using SAXS to monitor the disappearance of the surface relief gratings while subjecting the polymer sample to various temperature programs. Amazingly, it was found that when light is used in situ together with heating, and after the surface grating starts disappearing (as confirmed by atomic force microscopy), a volume density grating is being formed below the surface where the relief grating was present. The density grating has a similar diffraction efficiency, but it is not "visible" by surface analysis. This means that below the surface of the polymer film, a dense phase is formed and alternates with a less dense phase. The periodicity of the buried structure is identical to the initial periodicity of the surface deformation induced by light. Interestingly, such a density grating can be obtained in a polymer film of pDR1M (see Fig. 2), but it does not form in a film of a very similar polymer, without the donor–acceptor substitution at the azobenzene ring. The explanation suggested for this phenomenon (32) is the formation of a liquid crystalline phase (the dense phase) where the peaks of the surface gratings existed before heating. Figure 10 schematically illustrates the formation of the buried density grating. PDR1M is an amorphous polymer, and the presence of a photo- and thermally induced novel liquid crystalline phase has still to be demonstrated. If true, this would be the only instance (to our knowledge) of a photoinduced liquid crystalline phase in an otherwise amorphous polymer. Photoinduced isotropization, at temperatures just below clearing, is very well-known and studied. Photoinduced ordering, to the order level of a liquid crystal, was only known in materials that do have a crystalline or liquid crystalline phase and need the light energy to provide thermodynamic ordering.

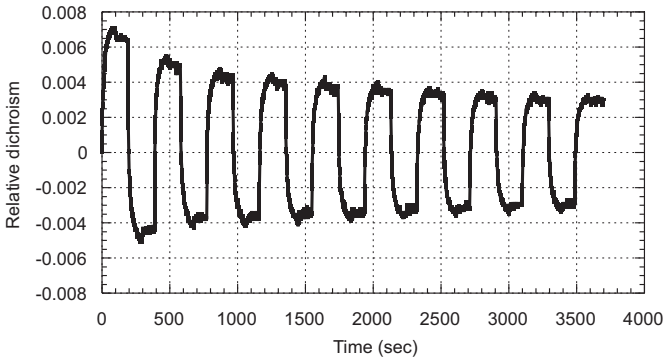
pnMAN



Thermo- and photochromism

This brings us back full circle, into studying liquid crystalline polymers, after having dedicated most of our time to high-*T*g amorphous materials. Photoinduced orientation in liquid crystalline polymers was reported — as we already mentioned — in 1987 (4). Since these materials have an intrinsic tendency to order, the levels of photoinduced birefringence can be much higher than in amorphous polymers (33). Of course, the obvious disadvantage of such materials is that erasing the photoinduced birefringence is not simple, for exactly the same reason it is so easy to obtain high degrees of order. Surface gratings formation in liquid crystalline azo polymers has also been studied (34).

We decided to study, systematically, a series of liquid crystalline polymers consisting of our most investigated mesogen (amino-nitro-substituted azobenzene), a methacrylate backbone and a spacer of variable length (different number of methylene units). The general formula of the series is given in Fig. 11. A subtle difference between p2MAN and pDR1M, for example, is the substituent at the nitrogen atom of the chromophore. While our "workhorse" had an ethyl group, because it was prepared from the dye Disperse Red 1, the liquid crystalline polymer equivalent

© 2001 NRC Canada

Fig. 12. Circular dichroism switching in p4MAN by irradiation with right circularly polarized light and then with left circularly polarized light.

(and the other members of this series) has a methyl. The difference allows better packing of the chromophores, and they become mesogens. P2MAN is liquid crystalline, while pDR1M has no known thermotropic phase. All pnMAN polymers exibit a glassy state, followed by a smectic range. The transition temperatures (glassy–smectic and smectic–isotropic) depend on the spacer length.

As usual, and as we have already became accustomed to, there were plenty of surprises to uncover when we investigated photoinduced motions in this series. First, these polymers show thermochromic and photochromic behavior (35). Both depend on the spacer length, with the polymers being divided into two major types. The first, with the spacer length roughly up to nine methylene groups, forms amorphous reddish films upon spin coating. The color changes *irreversibly* to orange after heating the films above their *T*g. In the smectic phase, however, the film become cloudy and the color is again more red than orange. The second type, polymers with spacers longer than nine methylene groups, form orange films upon spin coating, and their color changes *reversibly* to red upon heating. In both cases, the orange color is more stable, and it has been assigned to an antiparallel pairing of the donor–acceptor substituted azo chromophores. The color change is — of course — accompanied by an absorbance shift in the electronic spectra.

When an orange film of a shorter spacer polymer film is irradiated with linearly polarized light, the color changes again to red. This change is irreversible if the sample is kept in the dark. The explanation for this photochromic effect is as follows. In an orange film, the chromophores are mostly paired in an antiparallel fashion. Linearly polarized light induced isomerization and reorientation of the azobenzene group, thus breaking the pairs. Isolated chromophores, which are a result of illumination, absorb preferentially at higher wavelengths, thus the film color changes from orange to red. The change is very specific and the contrast is good enough to allow the use of masks for "writing" on the polymer films.

The main question that still needs to be answered is how general is the thermo- and photochromism phenomenon. Obviously, this requires a spacer that is long enough to allow independent motion of the mesogen–chromophore and produce the antiparallel pairing. Does this mean that only polymers having a liquid crystalline phase undergo this pairing? We still don't have the answer to this question, but research is in progress.

Photoinduced chirality and switching

The other major surprise offered by the pnMAN series was its behavior when illuminated with circularly polarized light in the smectic phase. This is the third type of motion mentioned in the *Photoinduced motions* part of this article. A polymer film in its smectic phase consists of a multitude of smectic domains of various sizes and arrangements. Since the films were obtained by spin coating, it is reasonable to assume that most of the azobenzene mesogens are in the film plane, because of the centrifugal force of film formation. Thus, the smectic layers should be perpendicular to the film surface and each domain should have a slightly different orientation of these layers. The incoming circularly polarized light will be affected by the first smectic layer on the film surface, which will change its polarization to slightly elliptic. The now slightly elliptic light penetrating through to the second smectic domain will now change the overall orientation of this domain towards becoming perpendicular to the long axis of the ellipse. This, in turn will make the light more elliptical and the next domain will be affected even more than the second, and so on. Thus, circularly polarized light illuminated on the smectic film will move the successive domains on the vertical axis more and more in the direction of the handedness of the light. In other words, right circularly polarized light will photoinduce a right-handed helical organization of the smectic domains as the light penetrates the film. From a polymer with no chiral center in its structure, one can obtain a helical supramolecular arrangement just by illumination (15). This is clearly seen in the circular dichroism spectrum of the material after illumination. Prior to illumination the material shows no circular dichroism.

The fact that chirality can be induced in achiral azo smectic polymer films had been previously reported (14, 36–38). Only recently, the relation between the handedness of the circularly polarized light and the handedness of the photoinduced supramolecular helix has been clarified (15, 37). These findings raise many more questions than they answer. Some obvious ones are: Is the smectic phase a requirement for this phenomenon? Does the polarity of the mesogen play any role? What is the nature of the photoinduced helix? Needless to say, research is in progress in our group and in other groups worldwide.

The most interesting aspect of this phenomenon, though, is the fact that circularly polarized light of the opposite handedness can unwind the photoinduced supramolecular helix, to again produce an achiral material. This means that addressing these materials with circularly polarized light of opposite handedness actually operates like an optical switch, as illustrated in Fig. 12. There is a slight decrease of the circular dichroism value after a few cycles; this is due to the tendency of the circularly polarized light to align the chromophores perpendicular to its polarization, i.e., in the direction of propagation of light. When the chromophores are perpendicular to the film surface, they do not contribute to the circular dichroism spectrum. The initial value for dichroism can be recovered after heating the film above its isotropization temperature, thus the dichroism decrease is not a photobleaching effect.

Possible photonic applications

There are many possible photonic applications of the phenomena reported here. Reversible optical storage, either digital or holographic, is the most obvious one. This application is very attractive, since the writing procedure is relatively fast and extremely easy, the long term stability is excellent, and erasing is again a very simple and efficient procedure. Digital storage can be performed point by point, which allows flexibility for the process, while holographic storage can be envisaged on a three-dimensional scale, because of the possibility to store more than one image on the same polymer film by rotating the film upon exposure.

Even more attractive is the possibility to build a whole photonic device on a simple polymer film. The first type of photoinduced motion allows writing lines, as well as points, and these lines can act as waveguides, confining an optical signal within them. Surface gratings can act as couplers of light in and out of these waveguides, and photorefractivity allows switching of the light signals between two different paths optically written on the polymer film.

Apart from these two major possibilities, photonic filters, polarization separators, shape recognition, liquid crystal orientation and switching, and many, many other possible photonic applications exist. Some of them were reviewed in ref. 18.

Conclusions

The recent discoveries in azobenzene photoisomerization and the motions that it induces in a variety of polymer materials are extremely exciting, both from a fundamental understanding of materials and from a practical point of view, as there is a huge potential for photonic applications. This area of research is only about 15-years-old, and the most interesting discoveries are probably still awaiting us.

A fluorescent host–guest complex of cucurbituril in solution: a molecular Jack O'Lantern

Brian D. Wagner, Shannon J. Fitzpatrick, Monica A. Gill, Andrew I. MacRae, and Natasa Stojanovic

Abstract: Fluorescence enhancement of a probe molecule in solution by the container molecule cucurbituril (CB) is reported for the first time. The fluorescence of the probe 2-anilinonaphthalene-6-sulfonate (2,6-ANS) in aqueous Na_2SO_4 solution is found to increase by a maximum factor of 5.0 upon addition of cucurbituril. This fluorescence enhancement is the result of the formation of a host–guest inclusion complex, in which the guest 2,6-ANS is incorporated inside the cavity of the host, cucurbituril. Measurement of the enhancement as a function of cucurbituril concentration yielded a value of the equilibrium constant (K) of 52 ± 10 M^{-1}. It is proposed that the mode of inclusion involves the phenyl group of the 2,6-ANS, because of the relatively small size of the cucurbituril cavity. It is further proposed that the observed enhancement is a result of loss of rotational mobility of the phenyl ring relative to the naphthyl fluorophore of 2,6-ANS upon inclusion of the phenyl ring. Since the name cucurbituril is derived from the Latin word for "pumpkin," this fluorescent host–guest complex is referred to as a "molecular Jack O'Lantern," with the 2,6-ANS serving as the candle.

Key words: host–guest chemistry, fluorescence, cucurbituril, inclusion compounds.

Résumé : On a provoqué pour la première fois une augmentation de la fluorescence d'une molécule sonde, en solution, à l'aide la molécule de cucurbiturile. On a trouvé que, en solution aqueuse de Na_2SO_4, l'addition de cucurbiturile provoque une augmentation (facteur maximal de 5,0) de la fluorescence de la sonde 2,6-ANS. L'augmentation de la fluorescence résulte de la formation d'un complexe d'inclusion hôte/invité dans lequel le 2,6-ANS invité est incorporé dans la cavité du cucurbiturile qui agit comme hôte. Des mesures de l'augmentation en fonction de la concentration de cucurbiturile ont permis de déterminer que la valeur de la constante d'équilibre, K, est de 52 ± 10 M^{-1}. Il est suggéré que, en raison de la taille relativement faible de la cavité du cucurbiturile, le mode d'inclusion implique le groupe phényle du 2,6-ANS. On suggère de plus que l'augmentation observée résulte d'une perte de mobilité rotationnelle du noyau phényle par rapport au fluorophore naphtyle du 2,6-ANS lors de l'inclusion du noyau phényle. Puisque le nom cucurbiturile est dérivé du mot latin pour "citrouille," on réfère à ce complexe fluorescent hôte/invité comme à une "lanterne moléculaire" dans laquelle le 2,6-ANS sert de chandelle.

Mots clés : chimie hôte/invité, fluorescence, cucurbiturile, composés d'inclusion.

[Traduit par la Rédaction]

Introduction

In this paper we report the first observation of fluorescence enhancement of a guest molecule in solution by the host molecule cucurbituril (CB). Cucurbituril (1–3) is an interesting cage compound consisting of a C,N σ-framework, as shown in Fig. 1. It was first prepared by Behrend et al. (4) in 1905, but was not characterized until the work of Mock and co-workers (5) in 1981. The most interesting feature of this molecule is that it contains a rigid and well-defined internal cavity, which has a diameter of ca. 5.5 Å with two opposing portals of diameter ca. 4.0 Å lined with carbonyl groups. The presence of this internal cavity makes cucurbituril a potential host molecule for the encapsulation of smaller guest molecules. This potential for forming supramolecular host–guest inclusion complexes is the reason for the growing interest in the properties and applications of this molecule. Specific host–guest inclusion complexes of other container molecules (6), such as cyclodextrins (7) and calixarenes (8), have found various useful applications, including improved trace analysis techniques and molecular recognition. Those of cucurbituril also have the potential for practical applications; this potential is as yet completely unexplored.

The host abilities of cucurbituril have now been well-demonstrated. Cucurbituril has been shown to form host–guest inclusion complexes with a wide range of guest molecules, including alkylammonium ions (9), alkali metal cations (10), amino acids and alcohols (11), tetrahydrofuran (12), and aromatic molecules such as organic dyes (13) and toluene (14). It has also shown to be proficient at forming rotaxanes, threading onto various types of molecules containing alkyl chains (15).

All of these previous studies on the host–guest inclusion complexes of cucurbituril have been performed using NMR (9, 12), UV–vis spectroscopy (10, 13), or calorimetry (11, 14). However, there have been no reports of fluorescence

studies of the host–guest inclusion complexes of cucurbituril in solution. In fact, none of the guests previously shown to be encapsulated by cucurbituril have been shown to undergo fluorescence enhancement when incorporated into the cucurbituril cavity. This is in marked contrast to the inclusion complexes of cyclodextrins for example that have been extensively investigated by fluorescence spectroscopy (16). This technique has proven to be an extremely sensitive and informative method for studying such host–guest inclusion phenomena. Furthermore, enhancement of guest fluorescence leads to the potential application of cucurbituril as a molecular sensor for specific guests, since the observation of increased fluorescence provides a simple and sensitive means for detecting the presence of the guest. In the work described in this paper, we report the results for a fluorescent probe, which is not only encapsulated by cucurbituril, but also exhibits significant enhancement of its fluorescence upon encapsulation.

In a previous attempt to observe fluorescence enhancement by cucurbituril in solution using the highly polarity-sensitive fluorescent probe 1-anilinonaphthalene-8-sulfonate (1,8-ANS), a fluorescent precipitate was obtained (17). This interesting solid, also reported by Buschmann and Wolff (18), proved to be a lattice-inclusion compound, rather than the expected host–guest inclusion compound (17). In the present work, the fluorescence enhancement in solution of the related probe 2-anilinonaphthalene-6-sulfonate (2,6-ANS, shown in Fig. 1) is described. This probe was chosen for two reasons. First, its fluorescence is also extremely sensitive to the polarity of its local environment (19, 20), and thus, should show changes to its fluorescence upon inclusion within cucurbituril. Second, it has a more streamlined shape than 1,8-ANS, with less steric crowding between the two groups on the naphthalene; this should allow it to be included more easily into the relatively small cavity of cucurbituril.

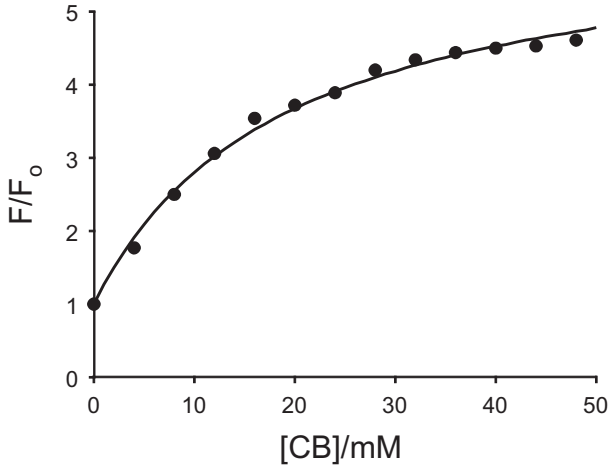
Experimental

Materials

The synthesis and characterization of the cucurbituril (CB) used has been previously described (17). The sample used was found to contain 30.0% H_2O (by drying for 4 h in a vacuum oven at 140°C and 10 torr (1 torr = 133.322 kPa)) and 2.0% H_2SO_4 (by NaOH titration) by mass; these values were taken into account in the preparation of cucurbituril solutions of specific concentrations. Na_2SO_4, K_2SO_4, Na_2HPO_4, and NaH_2PO_4 were obtained from Fisher Scientific and used as received. High purity 2,6-ANS was obtained from Molecular Probes and used as received.

Spectroscopic measurements

All absorption and fluorescence measurements were performed on solutions in 1 cm^2 quartz cuvettes. Absorption spectra were measured on a Cary 50 Bio UV–vis spectrophotometer. Fluorescence spectra were measured on a Photon Technologies International LS-100 luminescence spectrometer.



Solutions were made in 0.20 M aqueous Na_2SO_4 (necessary for significant CB solubility), with [2,6-ANS] = 2.0×10^{-5} M. At the excitation wavelength used (330 nm), there was a small absorption by the host cucurbituril, increasing the absorbance from 0.32 in the absence of CB to 0.41 at the highest [CB]. Blank solutions containing CB only were found to exhibit emission (although at much lower levels than the solutions also containing 2,6-ANS, ranging from 10 to 26%). For this reason, the fluorescence of these blank solutions was measured at the same [CB] as for the 2,6-ANS solutions, and the measured integrated fluorescence subtracted from that of the solutions containing guest. The fluorescence enhancement (F/F_o) was determined quantitatively by taking the ratio of integrated area under the fluorescence spectrum in the presence (F, corrected for CB emission as described above) and absence (F_o) of cucurbituril.

Results and discussion

When cucurbituril (CB) was added to a solution of 2,6-ANS, the fluorescence of the solution was found to increase significantly, i.e., fluorescence enhancement was observed, as shown in Fig. 2 (it should be noted that the spectra in Fig. 2 have not been corrected for the emission of the CB reference solutions). Figure 3 shows a plot of the fluores-

Fig. 3. Observed fluorescence enhancement (F/F_0) of 2,6-ANS (2.0×10^{-5} M) in Na_2SO_4 solution (0.20 M) as a function of cucurbituril concentration.

cence enhancement F/F_0 (corrected for CB emission) as a function of [CB]. This plot clearly shows that the enhancement increases sharply with [CB] at lower concentrations, then levels off at an enhancement of ca. 5.0. This behavior is indicative of the formation of a 1:1 host–guest complex, ANS + CB $\rightleftharpoons$ ANS:CB, for which (21):

$$[1] \qquad F/F_0 = 1 + (F_\infty/F_0 - 1)\frac{[\mathrm{CB}]_0 K}{(1 + [\mathrm{CB}]_0 K)}$$

where F_∞/F_0 is the enhancement when every guest molecule is complexed, and K is the association constant (K = [ANS:CB]/[ANS][CB]). This can be tested by plotting a reciprocal-reciprocal plot of F_0/F vs. 1/[CB]; this plot will be nonlinear if higher-order complexes are formed. In this case, the plot was linear (R = 0.997) confirming simple 1:1 host–guest complexation. Nonlinear least-squares fitting of the data to eq. [1] gave a value of $K = 52 \pm 10$ M^{-1} and $F_\infty/F_0 = 6.1 \pm 0.7$; this fit is shown as the solid line in Fig. 3.

Other salt solutions were also used, and gave similar results for the enhancement and K. In 0.20 M K_2SO_4, $K = 44 \pm 11$ M^{-1} and $F_\infty/F_0 = 6.0 \pm 0.6$. This result is of interest, since it has been proposed that cucurbituril is soluble in aqueous salt solutions as a result of coordination of the cation to the carbonyls along the upper and lower rims of the molecule (12). The lack of a significant effect of changing the counterion from Na^+ to K^+ suggests that the coordinated cation does not interfere with the interaction between the host cucurbituril and the 2,6-ANS guest. In a Na_2HPO_4–NaH_2PO_4 buffer solution (pH = 6.80), $K = 36 \pm 12$ M^{-1} and $F_\infty/F_0 = 6.7 \pm 1.0$. These similar values (within experimental error) in the buffered vs. unbuffered Na salt solutions is also significant, as it indicates that acid content is unimportant in the formation of this inclusion complex. This observation is important because there is a small amount (2%) of sulfuric acid contained in our CB sample as a result of the synthesis procedure.

It is interesting to compare these results to those reported for 2,6-ANS in α-cyclodextrin (α-CD) and its hydroxypropylated derivative (HP-α-CD) (22), which has a slightly larger cavity size (5.7 vs. 5.0 Å), but with a much larger opening (5.7 vs. 4.0 Å). The fit values of F_∞/F_0 were reported to be 22 in α-CD and 58 in HP-α-CD, compared with the value of 6.1 in CB. Thus, the CD's provide significantly higher enhancement for 2,6-ANS than does CB. The values of K were reported to be ≤20 M^{-1} in α-CD and 110 M^{-1} in HP-α-CD, compared with the value of 52 M^{-1} in CB. Thus, 2,6-ANS forms a stronger complex with CB than with α-CD, but weaker than that with HP-α-CD.

These results can also be compared with values of K for similar CB inclusion complexes obtained by other techniques. In particular, inclusion complexes of a number of aromatic dyes, with shapes and sizes similar to 2,6-ANS, have been previously studied. In the case of phenol blue, a value of K = 93 M^{-1} was determined in aqueous HCl solution by measuring dye stabilization by the host (23). This value was much larger than that found for β-CD. In the case of methyl orange, a value of K = 58 M^{-1} was obtained in water:formic acid solution by UV–vis spectroscopy (13), with a slightly higher value of K = 69 M^{-1} found for β-CD. These values of the association constant are very similar to that of 52 M^{-1} obtained by fluorescence in this work.

From a consideration of the size of the cucurbituril cavity and opening, and the size and shape (substitution at each end of the naphthalene ring) of 2,6-ANS, it seems most likely that it is the anilino group that is becoming included within the CB cavity, rather than the naphthalene fluorophore itself. This proposal is supported by three pieces of experimental evidence: (*i*) the values of K for this complex and for those with the organic dyes described above, which only contain phenyl groups, are very similar. (*ii*) Although significant enhancement of the 2,6-ANS fluorescence is observed, there is only a very small accompanying blue shift in the spectrum (≤3 nm). This value would be expected to be much larger if the naphthalene fluorophore was experiencing a less polar environment due to inclusion into the CB cavity, for example, a significant blue shift is clearly seen in both 1,8-ANS (15–55 nm) (24) and 2,6-ANS (28–40 nm) (22) in various cyclodextrins. (*iii*) Although the enhancement observed is significant, it is much lower than that observed in the cyclodextrins, as described above, in which inclusion is more likely to involve the naphthalene moiety rather than the phenyl group. We propose that in the CB inclusion complex, the enhancement is not a result of decreased polarity from inclusion of the naphthalene ring, but instead a result of decreased rotational freedom of the included phenyl ring. It has been established that in aqueous solution, charge transfer followed by energy transfer is the major nonradiative decay pathway for 2,6-ANS (19, 20). However, for this to occur, there is a required twisting of the phenyl ring relative to the naphthalene ring in the S_1 state. If the phenyl group is included in the massive CB cage, this ability to twist would be greatly reduced, resulting in moderately enhanced fluorescence but no spectral shift.

Although this fluorescence data does not provide direct evidence that a true host–guest inclusion complex has formed, the significant enhancement observed, as well as its dependence on cucurbituril concentration, does provide compelling indirect evidence that such an inclusion complex is indeed formed, since interfacial interactions would not be expected to be particularly strong between these two molecules. If a linear analog of CB could be obtained, then it

© 2001 NRC Canada

could be determined conclusively whether the presence of the cavity is required to observe enhancement. It should be noted that glycoluril itself (the building block of cucurbituril) is insoluble in aqueous solution, and thus its effect on 2,6-ANS cannot be investigated. Direct evidence for inclusion, as well as the specific mode of inclusion, could of course be obtained from X-ray crystallography, if single crystals of the CB:2,6-ANS complex could be obtained. We are currently working on this approach to conclusively determine the structure of the CB:2,6-ANS complex.

This observed inclusion of 2,6-ANS in CB in solution, as indicated by the significant 2,6-ANS fluorescence enhancement, is in marked contrast to the previously reported interaction of 1,8-ANS with CB, in which a lattice inclusion solid compound formed, with no inclusion of the 1,8-ANS molecule inside the CB cavity (17). This difference must be attributable to the steric interactions between the nearby sulfonate and phenyl groups in 1,8-ANS. These steric interactions are absent in 2,6-ANS, since the two groups are at opposite ends of the naphthalene ring and point in opposing directions. This significant difference in the guest structure allows for the inclusion of the phenyl group in the case of 2,6-ANS in CB, but prevents its inclusion in the case of 1,8-ANS. The reasons why a lattice inclusion precipitate is formed in the latter case were discussed previously (17).

Since the name cucurbituril is derived from the Latin for pumpkin, we describe this unique fluorescent inclusion complex as a *molecular Jack O'Lantern*, with the fluorescent 2,6-ANS serving as the candle inside the hollow pumpkin of cucurbituril. In our proposed structure, the "candle" is partly hanging outside of the "pumpkin." In future work, we hope to find a fluorescent guest that not only is small enough to fit completely inside the CB cavity but also is sensitive enough to show enhanced fluorescence, and also absorbs at a wavelength well above the absorption band of cucurbituril. In this way, the candle will be completely inside the pumpkin, providing a better example of a molecular Jack O'Lantern. Finding such a probe is expected to be quite challenging, especially since small probes tend to absorb at short wavelengths.

Conclusions

Fluorescence enhancement of the probe 2,6-ANS by cucurbituril has been observed in solution. In comparison to α-CD, the cyclodextrin most similar in cavity size, cucurbituril was found to bind 2,6-ANS more strongly, but resulted in a significantly smaller fluorescence enhancement. This observed enhancement indicates that the formation of a host–guest inclusion complex of 2,6-ANS into the cavity of cucurbituril occurs in solution. This is in contrast to previously reported results for the related probe 1,8-ANS, which formed a lattice inclusion solid with cucurbituril. This work shows that not only is cucurbituril a good receptor for guest molecules, but also, like cyclodextrins, it can enhance guest fluorescence, and thus has the potential to be useful in fluorescent molecular sensor design.

A convenient and selective route to a *trans*-difunctionalized macrocyclic hexadentate N_4O_2 ligand

Hongyan Luo, Robin D. Rogers, and Martin W. Brechbiel

Abstract: The synthesis and characterization of a novel difunctionalized tetraaza macrocycle, 1,8-bis(2-hydroxybenzyl)-1,4,8,11-tetraazacyclotetradecane (abbreviated H_2bcyclamb), is described. The diprotic hexadentate ligand N_4O_2 was conveniently synthesized in two steps by the cyclic condensation reaction of 1,4,8,11-tetraazacyclotetradecane (abbreviated cyclam) and salicylaldehyde, followed by $NaBH_4$ reduction of the cyclic hexahydropyrimidine condensate. The difunctionalization was selective and is the first procedure of *trans*-difunctionalization of a tetraazamacrocycle, without generating mono-, tri-, or tetra-functionalized products, with only 1,8-difunctionalized product being isolated, and with the convenience of the functionalization occurring as a result of deprotection. The *trans*-arrangement of the two functional groups in H_2bcyclamb was verified by X-ray crystallographic studies of the copper(II) complex $[Cu(H_2bcyclamb)](OAc)_2\cdot 2H_2O$. The crystal is monoclinic, $P2_1/c$, with a = 10.0931(2), b = 13.8820(1), c = 10.8752(1) Å, β = 106.332(1)°, V = 1462.26(3) Å^3. The structure of $[Cu(H_2bcyclamb)](OAc)_2\cdot 2H_2O$ also shows the metal ion in an elongated octahedral geometry.

Key words: 1,8-difunctionalized, cyclam, copper(II) complex.

Résumé : On décrit la synthèse et la caractérisation d'un nouveau tétraazamacrocycle bifonctionnel, le 1,8-bis(2-hydroxybenzyl)-1,4,8,11-tétraazacyclotétradécane (abrév.: H_2bcyclamb). On a facilement synthétisé, en deux étapes, le ligand diprotique hexadentate N_4O_2 par le biais d'une réaction de condensation cyclique du 1,4,8,11-tétraazacyclotétradécane (abrév.: cyclam) et du salicylaldéhyde, suivie d'une réduction par le $NaBH_4$ de l'hexahydropyrimidine cyclique provenant de la condensation. La bifonctionnalisation s'est faite de façon sélective et il s'agit de la première réaction de bifonctionnalisation *trans* d'un tétraazamacrocycle, sans génération de produits mono-, tri- et tétrafonctionnalisés; seul le produit résultant de la 1,8-bifonctionnalisation est isolé grâce au fait que la fonctionnalisation se produit à la suite d'une déprotection. L'arrangement *trans* des deux groupes fonctionnels du H_2bcyclamb a été confirmé par des études de diffraction des rayons X du complexe de cuivre(II), $[Cu(H_2bcyclamb)](OAc)_2\cdot 2H_2O$. Les cristaux sont monocliniques, groupe d'espace $P2_1/c$, avec a = 10,0931(2), b = 13,8820(1) et c = 10,8752(1) Å, β = 106,332(1)° et V = 1462,26(3) Å^3. La structure cristalline du $[Cu(H_2bcyclamb)](OAc)_2\cdot 2H_2O$ montre aussi que l'ion métallique se trouve dans une géométrie octaédrique allongée.

Mots clés : 1,8-bifonctionnalisé, cyclame, complexe de cuivre(II).

[Traduit par la Rédaction]

Introduction

Tetraaza macrocycles are widely used as building frameworks for chelates that retain the advantage of the macrocyclic effect inherited from the tetraaza parents (1–3). One of the current efforts involves introducing pendant donating sites to two of the nitrogen atoms on the framework. The goal of this effort has been to expand the coordination sphere from the square-plane provided by the parent tetraazamacrocycle to an octahedral environment, so as to meet the geometric preference of metal centers with six-coordinate tendencies. The coordination chemistry of difunctionalized tetraaza chelates has been summarized recently (4). We have been interested in developing *trans-N,N″*-difunctionalized tetraaza macrocyclic chelates with two 2-hydroxybenzyl groups that provide an N_4O_2 donor-set as an extension of our ongoing studies on the use of bifunctional tetraaza macrocyclic chelates for the sequestration of radioisotopes for medical applications (5–9). While this would provide a six-coordinate environment with two phenolic donors, we have also envisioned this class of compound as a potential intermediate to eight coordinate ligands of mixed donor character. Additionally, the 2-hydroxybenzyl groups could either be retained in such a case, or serve as protecting groups that could serve to permit sequential introduction of two other sets of *trans* arranged sets of metal binding groups

(10). In this communication, we present our progress in this regard.

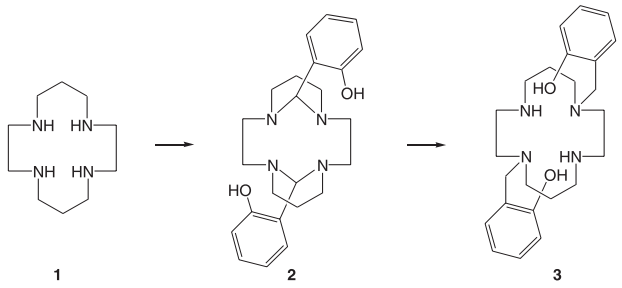
Technically, placing pendant groups on only two of the four equivalent nitrogen atoms on tetraaza frameworks has been more difficult to accomplish than alkylating only one, three, or all four nitrogens. The difficulties result in part from the possible generation of regioisomers and from complications arising from the possible presence of mono-, tri-, and (or) tetra-substituted products that co-occur with the desired disubstituted product (11). Furthermore, unlike for mono- or tetra-functionalization, using a large excess of one of the reactants is not applicable for maximizing production of the desired disubstituted product. Direct *N*,*N*″-difunctionalization of tetraazamacrocycles by haloalkylation has been attempted, but tedious chromatography for isolation of the desired product was necessary and contributed to low yields (15–35%) (12).

N,*N*″-Difunctionalization of tetraazamacrocycles has been accomplished indirectly in several cases via protected *N*,*N*″-diprotected tetraazamacrocycles by tosylation (11, 13, 14), carbamylation (15, 16), or sulfomethylation (17, 18). This was made possible as a result of the achieved isolation of only one predominant regioisomer of *N*,*N*″-diprotected tetraazamacrocycles under carefully chosen conditions, such as reaction solvents, temperature, pH, or slow, careful addition of reagents (11, 14, 16, 18–20). However, in many of the examples, other regioisomers of diprotected (11, 18), triprotected (14), or tetraprotected (16) species were also found to be present (19). A stepwise route to *trans*-dialkylated derivatives of tetrazamacrocycles by haloalkylation under 3- or 4-nitrogen-bridged protection provided by one silicon-, carbon-, or other heteroatom-containing group was reported (21, 22). This route, however, has not found application in preparation of *N*,*N*″-difunctionalized tetraaza macrocyclic chelates, presumably due to inconvenience as compared to the other routes.

Protection via formation of hexahydropyrimidine (aminal) provides another route to produce *N*,*N*″-difunctionalized cyclam-based macrocyclic chelates (cyclam = 1,4,8,11-tetraazacyclotetradecane) (23–26). The intermediates of the protected cyclam, were prepared either by cyclic condensation of the tetraaza and dichloromethane (23, 26) or formaldehyde (27) (Scheme 1). The intermediates were either reacted with a haloalkane followed by hydrolysis (24) or reduction (23), or hydrogenation followed by a reaction with haloalkane (25). *trans*-*N*,*N*″-Difunctionalized tetraazamacrocyclic products have been prepared via this route recently for 2-pyridyl (3 steps) (26), aminoalkyl, and carboxymethyl functional groups (4 steps) (25).

In the previously described hexahydropyrimidine route, the aldehyde was used only as a protecting group, i.e., the corresponding fragment was either removed or reduced to a methyl group that was not an essential part of the donor character of the chelating moiety and the two remaining secondary amines were converted to tertiary amines that are usually less coordinating than the secondary counter-part. Thus, the hexahydropyrimidine route could be further explored, since there are possibilities to provide an efficient introduction of additional donor groups by using aldehydes that bear donating functional groups. Salicylaldehyde and other aldehyde derivatives have been used to provide a convenient and selective functionalization route to unsymmetric acyclic chelates from *N*-monoalkylated or *N*,*N*′-dialkylated diamines (28). We report herein application of this chemistry to the regioselective preparation of a *trans*-*N*,*N*″-macrocyclic hexadentate $N_4O_2^{2-}$ ligand from cyclam (Scheme 2), and the synthesis and characterization of the corresponding Cu(II) complex unequivocally confirming the structure of this ligand.

In the present study, cyclam and two equivalents of salicylaldehyde were reacted, affording a sole, bisaminal or bis(hexahydropyrimidine) analog, 15,16-bis(2-hydroxyphenyl)-1,4,8,11-tetraazatricyclo[9.3.1.1^{4,8}]hexadecane in moderate yields.[3] The hexahydropyrimidine rings were then selectively cleaved upon borohydride reduction to yield the 1,8-disubstituted cyclam-based N_4O_2 ligand, 1,8-bis(2-hydroxybenzyl)-1,4,8,11-tetraazacyclotetradecane (abbreviated H_2bcyclamb or **3**, Scheme 2).[4] Satisfactory analytical data for **2** and **3** were obtained.[5] In this case, salicylaldehyde functions both as a protecting agent and as a source of a functional potential donor via a phenol group. The two 2-hydroxybenzyl groups are available to function as pendant



[3] To cyclam (1.75 g, 8.7 mmol) in MeOH (15 mL) was added salicylaldehyde (3.13 g, 25.6 mmol) in MeOH (15 mL) in a round-bottom flask. The mixture was heated at reflux for 4 h, then concentrated to a yellow solid. The solid was recrystallized from MeCN and an off-white crystalline product was obtained after storage at −4°C for 2 days. The product was filtered off, washed with Et_2O (2 × 15 mL), then dried in vacuo overnight (yield: 2.55 g, 71%). CI-MS *m*/*z*: 409 ([M + 1]$^+$). $^{13}C\{^1H\}$ NMR ($CDCl_3$, 125.708 MHz) δ: 158.2, 128.8, 127.9, 123.7, 118.4, 118.2 (minor, Me*C*N), 117.3, 50.9, 49.5, 45.0, 29.6 (minor, *Me*CN), 19.9 (br). Anal. calcd. for $C_{24}H_{32}N_4O_2 \cdot 0.45MeCN$: C 70.04, H 7.87, N 14.60; found: C 70.03, H 8.31, N 14.81.

[4] To **2** (1.53 g, 3.74 mmol) in MeOH (70 mL) was added $NaBH_4$–Al_2O_3 (wt. 10%, 2.12 g, ~5.7 mmol) in small portions. The mixture was heated at reflux for 6 h, evaporated to near dryness at low pressure, treated with 10% NH_4OAc (100 mL), and then extracted with $CHCl_3$ (2 × 150 mL). The organic phase was dried over Na_2SO_4 and then concentrated to a yellow residue, which was treated with cold acetone. A white powder was isolated from the yellow solution. The powder was filtered out, washed with acetone (5 mL), and air dried. The yield was 0.596 g (39%, based on **2**). CI-MS *m*/*z*: 413 ([M + 1]$^+$). $^{13}C\{^1H\}$ NMR ($CDCl_3$, 127.7 MHz) δ: 158.0, 131.4, 129.3, 125.0, 118.3, 117.4, 54.3, 53.2, 51.2, 49.2, 46.6, 24.6. Anal. calcd. for $C_{24}H_{32}N_4O_2 \cdot 0.45H_2O$: C 66.67, H 8.90, N 12.96; found: C 66.48, H 8.56, N 12.81.

[5] NMR spectra were recorded on Varian Gemini 300 spectrometer, with δ referenced to the internal TMS. CI-MS and FAB-MS were recorded with a Finnigan 3000 and Extrel 4000 with positive ion detection, respectively. Elemental analyses were performed by Galbraith Laboratories Inc. Knoxville, TN 37921-1750.

donating groups as soon as the deprotection is done. Thus, the new route is different from the previous hexahydropyrimidine route, with the overall reaction being shortened significantly and with the product retaining two of the secondary amine N-atoms (24, 25).

The efficiency of the procedure (2 steps) reported herein for *trans*-difunctionalization of tetraaza **1** is an improvement from the currently known conditionally selective procedures for tetraazamaclocycles-based *trans*-N_4O_2 ligands (usually 4 or more steps) (11, 14, 18–20, 25). In contrast to haloalkylation routes, the overall reaction is concise and selective. In fact, it is the first procedure of *trans*-difunctionalization of a tetraaza macrocycle that does not generate mono-, tri-, or tetra-functionalized products, with only 1,8-difunctionlized product being isolated, and it is also coupled with the convenience of the functionalization occurring as a result of the deprotection. This efficiency was ensured by use of a stoichiometric cyclic condensation[6] and subsequent clean cleavage of the cyclic condensate. Formation of the *trans*-difunctionalized product in our case was exclusive, presumably due to the steric control of the reductive ring opening (deprotection) process, which prevented the formation of a *cis*-difunctionalized product. Regioselectivity was not observed in the reduction of an analogous condensate, 1,4,8,11-tetraazatricyclo[9.3.1.$1^{4,8}$]-hexadecane, which lacked the bulky character of the 2-hydroxybenzyl substituent on the bridging carbon atoms (25). The X-ray crystal structure of the Cu(II) complex from **3** confirms unequivocally the assignment of *trans*-difunctionalization for **3**. Thus, synthesis of a *trans*-difunctionalized tetraaza ligand was accomplished both conveniently and regioselectively.

Examples of Cu(II) complexes of cyclic N_4O_2 ligands with two *trans*-arranged difunctional groups have appeared in the past decade (13, 29–33). The known cyclic N_4O_2 com-

Fig. 1. ORTEP drawings of $[Cu(H_2bcyclamb)]^{2+}$; 50% probability thermal ellipsoids are shown. Hydrogen atoms attached to carbon atoms are excluded for clarity. Selected bond distances (Å) and bond angles (°): Cu—N(1) 2.046(2), Cu—N(2) 2.013(2), Cu—O 2.651(2) Å; N(1)-Cu-N(2) 93.01(8), N(1)-Cu-N(1a) 180.0, N(1)-Cu-N(2a) 86.99(8), N(2)-Cu-N(2a) 180.0, O(1)-Cu-N(1) 85.4(1), O(1)-Cu-N(2) 88.8(1), O(1)-Cu-N(1a) 94.6(1), O(1)-Cu-N(2a) 91.2(1), O(1)-Cu-O(1a) 180.0°.

plexes of Cu(II) with solved structures were all functionalized with acetate functional groups. A reaction of **3** with $Cu(OAc)_2 \cdot H_2O$ was carried out. The mixture of the two reactants was dissolved in methanol–chloroform (1:1) upon heating to boiling. The solution was filtered immediately and permitted to evaporate slowly. Pink solids, isolated after several days, were dried in vacuo and identified as $[Cu(H_2bcyclamb)](OAc)_2 \cdot 1/3H_2O$ by microanalysis and mass spectrometry.[7] A crystal from the mother liquor was suitable for crystallographic studies and the structure of $[Cu(H_2bcyclamb)](OAc)_2 \cdot 2H_2O$ was solved.[8] An ORTEP drawing of the molecular structure is shown in Fig. 1.

trans-Difunctionalized N_4O_2 chelates are superior to their *cis* counterparts in formation of six-coordinate copper(II) complexes, because, in the latter case, not all donor sites will be coordinated to the metal due to strain or steric effects (29, 33). Given that a lengthened octahedron is preferred for the coordination geometry of the Cu(II) complex cation owing to the Jahn–Teller effect, the *trans*-difunctionalized N_4O_2 chelate permits expansion of the coordination sphere accordingly with the two pendant donor sites, while the coordination of the Cu-N_4 fragment remains intact. In this specific case, the Cu—N bonds are 2.013(2) and 2.046(2) Å, which are close to the values of 2.005(2) and 2.062(2) Å found in

[6] A slight excess of aldehyde was used to ensure that there was no 1:1 condensation product.

[7] FAB-MS *m/z*: 474 ($[Cu(H_2bcyclamb) - 1]^+$). Anal. calcd for $C_{28}H_{42}N_4O_6Cu \cdot 1/3H_2O$: C 56.03, H 7.17, N 9.33; found: C 56.05, H 7.40, N 9.21.

[8] The crystals are monoclinic, space group $P2_1/c$, with cell parameters and calculated volume of: a = 10.0931(2), b = 13.8820(1), c = 10.8752(1) Å, β = 106.332(1)°, V = 1462.26(3) Å^3. For Z = 2 and FW = 630.23 the calculated density of $[Cu(H_2bcyclamb)](OAc)_2 \cdot 2H_2O$ is 1.431 g cm^{-3}. Preliminary examination and data collection were performed with Mo Kα radiation. A total of 9006 reflections were collected on a Siemens SMART diffractometer, and 3387 were unique (R(int) = 0.036) and 2553 were considered observed ($I > 2\sigma(I)$). Refinement of the structure utilized all 3387 unique reflections. The structure was solved using the program SHELXTL 5 and was refined by full-matrix least-squares methods to 0.0401 and 0.0772 for R and wR, respectively, (calculated on observed reflections only). A complete set of data may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada. For information on obtaining material electronically go to http://www.nrc.ca/cisti/irm/unpub_e.shtml. Crystallographic information has also been deposited with the Cambridge Crystallographic Data Centre (No. 162851). Copies of the data can be obtained, free of charge, on application to the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. (fax: 44-1223-336033 or e-mail: deposit@ccdc.cam.ac.uk).

the carboxylic congener (13) and comparable to the value of 2.02 Å observed in the Cu(II)—cyclam (34). At a distance of 2.651(2) Å, the two phenolic oxygen atoms are coordinated to the metal center without deprotonation, as found in some cases with carboxylic analogs (13, 29). It is known, however, that neutral Cu(II) complexes can be formed when a base is added during complexation with diprotic *trans*-difunctionalized N_4O_2 chelates (13, 30–32). Thus, formation of neutral Cu(II) complexes with this chelate may be possible if increased basic conditions are employed.

Our new N_4O_2 chelate with two phenolic functional groups on cyclam is complementary to the difunctionalized cyclam that is dominated with carboxylic groups. Since this novel chelate is stable in aqueous solution and common organic solvents, in contrast to the known carboxylic counterpart that was found to be lactamized in aqueous solution (13), this chelate has potential in complexing metallic isotopes such as ^{64}Cu and ^{67}Cu in radiopharmaceutical applications. In addition, as demonstrated here and in other reports, one could instead employ aldehyde derivatives to react with the tetraazamacrocycle (27, 35). Hence, this general method appears suitable for generation of numerous structural derivatives that maintain the hexadentate metal coordination sphere based on cyclam.[9,10] Furthermore, the new hexadentate N_4O_2 chelate itself can also be used in synthesis of octadentate chelates based on tetraaza macrocycles, wherein a variety of other donor groups could be introduced at the two remaining secondary nitrogens.

In conclusion, we have developed a convenient route to a new type of diprotic hexadentate N_4O_2 chelate based on cyclam with two 2-hydroxybenzyl pendant groups. The new route to this *trans*-difunctionalized hexadentate (N_4O_2) ligand was not only simple and efficient, as featured by just two convenient steps, but also regioselective. The *trans*-difunctionalized cyclam with two phenolic pendant donor sites are complementary to the current difunctionalized cyclam community. This expected *trans*-difunctionalized structure of the chelate was confirmed by X-ray crystallography. Work remains underway to investigate the coordination chemistry of this chelate, preparation of further derivatives based upon this chelate, and their potential radiopharmaceutical chemistry.

Acknowledgments

We thank Mr. Noel Wittaker and Mr. Wesley White for their service in mass spectrometry and NMR spectroscopy, respectively, on our samples.

[9] Preliminary results affirmed that cyclam reacted with two equivalents of 2-pyridinecarboxaldehyde in a similar fashion and yielded the expected condensate with satisfactory analytical results. Reduction of this intermediate yielded the desired product as verified by FAB-MS. The details of synthesis and coordination chemistry of the potential $N_4N'_2$-chelate will be reported elsewhere.

[10] During the preparation of this manuscript, routes to *cis*-bis(pyridylmethyl) and *trans*-bis(pyridylmethyl) functionalized cyclam were reported starting from cyclam (3 steps), or the corresponding macrocyclic dioxotetraamine (2 steps) (36).

An efficient route to 5-iodo-1-methylimidazole: synthesis of xestomanzamine A

Francis B. Panosyan and Ian W.J. Still

Abstract: An efficient and practical route to C-5 functionalized *N*-methylated imidazoles is reported. 5-Iodo-1-methylimidazole was synthesized in four steps from imidazole, with complete regiospecificity, in 73% overall yield. The synthesis of xestomanzamine A, a marine natural product isolated in 1995 from an Okinawan sponge of *Xestospongia* sp., has been achieved using 5-iodo-1-methylimidazole in a modified Grignard reaction with a β-carboline ester moiety, in an overall yield of 59% based upon imidazole and 53% based upon tryptamine.

Key words: xestomanzamine A, 5-iodo-1-methylimidazole, methyl β-carboline-1-carboxylate.

Résumé : On propose une méthode efficace et pratique de préparer des imidazoles *N*-méthylés et fonctionnalisés en C-5. On a synthétisé le 5-iodo-1-méthylimidazole en quatre étapes à partir de l'imidazole, avec une régiospécificité complète et un rendement global de 73%. Faisant appel à une réaction de Grignard modifiée entre le 5-iodo-1-méthylimidazole et un ester de la β-carboline, on a réalisé la synthèse de la xestomanzamine A, un produit naturel marin isolé en 1995 à partir de l'éponge d'Okinawa *Xestospongia* sp.; le rendement global est de 59% à partir de l'imidazole et de 53% sur la base de la tryptamine.

Mots clés : xestomanzamine A, 5-iodo-1-méthylimidazole, β-carboline-1-carboxylate de méthyle.

[Traduit par la Rédaction]

Introduction

There has recently been intensive interest in the biological activity of naturally occurring marine alkaloids (for a recent review of marine natural products, see ref. 1). The very prolific β-carboline class of alkaloids has been the focus of particular attention (2, 3). Many of these alkaloids are isolated from sponges and two such compounds are xestomanzamine A (**1**) and its 3,4-dihydro analogue xestomanzamine B (**2**). These cytotoxic constituents of an Okinawan sponge (*Xestospongia* sp.) were first isolated in 1995 (4), and one synthesis of xestomanzamine A has been reported (5). This synthesis required at least eight steps from indole-3-carboxaldehyde, as well as a key coupling reaction with a 5-lithiated 1-methylimidazole, itself requiring three steps for its preparation, which proceeds in a yield of less than 50%. We have developed a considerably shorter, more efficient route to xestomanzamine A, which we now describe.

Results and discussion

A likely biosynthetic route to xestomanzamine A would probably involve condensation of tryptophan **3** with the *N*-methylated histidine-derived aldehyde **4** to produce the tetrahydro-β-carboline[2] intermediate **5**. Decarboxylation, and a series of oxidative steps would then lead to **2** and finally to **1**, Scheme 1. We decided to adopt a similar strategy in our approach but with the initial construction of the β-carboline unit in the form of the 1-carboxylate ester **6**. We then planned to carry out a modified Grignard reaction, using a 5-halo-1-methylimidazole **7**, to lead directly to xestomanzamine A, Scheme 2.

Before we began our approach to **7b** and **7c** we attempted, without success, to form the Grignard reagent from the commercially available 5-chloro-1-methylimidazole **7a**. While the analogous 5-bromo- and 5-iodoimidazoles are not, at first sight, difficult synthetic targets, one well documented complication in imidazole chemistry is the rapid equilibration of 4- and 5-imidazolyl anions to their much more stable 2-imidazolyl anion counterpart (6, 7). Thus, lithiation of *N*-methylimidazole, followed by bromination or iodination, was ruled out. Attempts to carry out regioselective bromination of *N*-methylimidazole with a variety of reagents, including NBS, pyridinium tribromide, 2,4,4,6-tetrabromo-2,5-cyclohexadienone, and dibromotriphenylphosphorane were also unsuccessful. Some conversion (20%) of *N*-methylimidazole to **7b** was achieved using 2,3-dibromo-5,5-dimethylhydantoin (DBDMH) in THF at 0°C (8). The low yield obtained, however, combined with a report (9) of the low reactivity of 5- and 4-bromo-1-methylimidazoles towards magnesium, convinced us to turn our attention to the synthesis of the iodo compound **7c**.

The synthesis of 5-iodo-1-methylimidazole was attempted by the strategy used by Balaban and Pyman (10) and, more recently, by Garegg and Samuelsson (11). We planned to carry out iodination of imidazole at all three carbons, selective deiodination and then regiospecific methylation to afford 5-iodo-1-methylimidazole **7c**, Scheme 3.

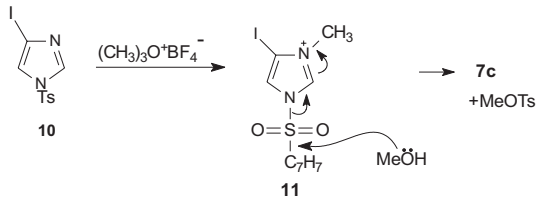
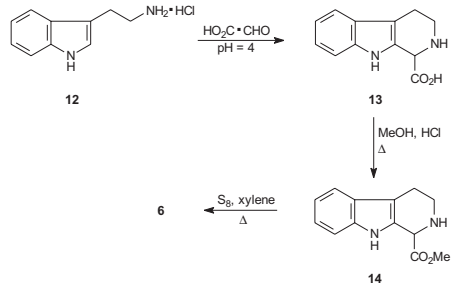
Scheme 3.



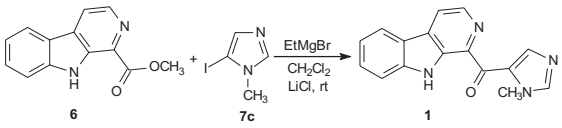
In our hands, the conversion of imidazole to the triiodiomidazole **8** was best achieved with iodine in an aqueous solution of sodium hydroxide, in the presence of potassium iodide (12). 2,4,5-Triiodoimidazole **8** separated from the solution upon neutralization with acetic acid, in 76% yield.

The next step was the selective deiodination of **8** to 4(5)-iodoimidazole **9**. The use of sodium sulfite by Balaban and Pyman (10) for the analogous bromo-series has been extended to the selective deiodination reaction of **8** (13). This reaction, in our hands, afforded **9** in 99% yield, by using 30% ethanol in water as the refluxing solvent, instead of water, to avoid complete deiodination. The ^{1}H NMR spectrum of the reduction product **9** showed the expected signals at δ 7.62 and 7.18, indicative of H(2) and H(4)-(5), respectively.



Numerous attempts to regioselectively methylate **9** to produce the desired **7c** were to no avail, under a variety of pH conditions and using both methyl iodide and dimethyl sulfate as methylating agents. Finally, we were able to take advantage of a highly selective two-step procedure that involves the initial, regioselective tosylation (14) of **9** to produce 4-iodo-1-tosylimidazole **10** in 98% yield. This selectivity may be rationalized on steric grounds, although the formation of **10** as a result of a thermodynamic equilibration of two initially formed regioisomers cannot be ruled out.

The final conversion of **10** into the desired 5-iodo-1-methylimidazole **7c** was achieved using trimethyloxonium



Scheme 4.

Scheme 5.

Scheme 6.

tetrafluoroborate, followed by a methanol quench, in a modification of a recent report by Lindel and Hochgürtel (15). This reaction afforded **7c** in 99% yield. The ^{1}H NMR spectrum had three singlet peaks at δ 3.62, 7.13, and 7.62, for the methyl, H(4), and H(2) protons, respectively. These values were in excellent agreement with the reported literature values (12) for 5-iodo-1-methylimidazole.

This very successful, regioselective methylation at N(3) of **10** using trimethyloxonium tetrafluoroborate presumably proceeds via the 5-iodo-1-methyl-3-tosylimidazolium salt **11**, which is not isolated, Scheme 4.

The sequence of reactions leading to **7c** from imidazole (Scheme 3) does not carry the disadvantages associated with many earlier methods for the synthesis of 5-iodo-1-methylimidazole; namely, low yields, poor reproducibility, and tedious purification methods. The overall yield for the four-step synthesis of **7c** from imidazole was 73%.

The synthesis of the β-carboline ester **6** was much more straightforward, Scheme 5. The initial 1,2,3,4-tetrahydro-β-carboline derivative **13** was obtained through a Pictet–Spengler condensation of tryptamine hydrochloride **12** with glyoxylic acid, forming **13** as a white solid, in 80% yield. The Pictet–Spengler reaction is known to proceed under mildly acidic conditions. This reaction was initiated by the addition of a concentrated solution of potassium hydroxide to solubilize the reagents, and then the pH was adjusted to about 4 with glacial acetic acid. Purification of **13** was readily achieved by simply stirring the product briefly in methanol at 0°C and then filtering. The acid showed the IR bands at ν 3343 (NH) and 1616 (bonded C=O) cm^{-1}, as expected for this compound (16).

© 2001 NRC Canada

Fischer esterification of **13** with methanol gave methyl 1,2,3,4-tetrahydro-β-carboline-1-carboxylate **14**, as its hydrochloride salt (17). The synthesis of **6** was completed by dehydrogenation of **14**, after careful neutralization of the salt with 2,2,6,6-tetramethylpiperidine, using sulfur in refluxing xylene, in 87% yield. The ester showed a carbonyl band in the IR at ν 1678 cm^{-1}, which is attributed to strong intramolecular hydrogen bonding with the indole NH.

Our initial attempt to complete the synthesis of xestomanzamine A was carried out by addition of a solution of EtMgBr and 5-iodo-1-methylimidazole **7c** in THF to a solution of the β-carboline methyl ester **6** in THF, in the presence of excess lithium chloride (17). The indole NH present in **6** was first deprotonated with the addition of one equivalent of EtMgBr, prior to the addition of **7c**. Xestomanzamine A was obtained, but in very low yield. A mild procedure has been reported for metal–halogen exchange with *N*-protected 4-iodoimidazoles (18), using EtMgBr in CH_2Cl_2. Repeating the reaction in CH_2Cl_2 again afforded xestomanzamine A, this time in greatly improved yield. We speculate that the use of dichloromethane may give the Grignard organomagnesium intermediate greater covalent character, thus making the imidazol-5-yl carbanionoid less sensitive to equilibration with its imidazol-2-yl counterpart, Scheme 6.

It was noticed during these initial attempts that the addition of EtMgBr to **7c** produced a white precipitate prior to addition to the β-carboline ester. Grignard reagents are known to exist in equilibrium with the corresponding binary organomagnesium compounds. At low temperatures, and when there is a solvent-induced precipitation of the magnesium salt, there is a shift of the equilibrium towards the organomagnesium species $MgAr_2$. We, thus, decided to direct the equilibrium towards the Grignard reagent ArMgX by warming the solution of EtMgBr and **7c** briefly, prior to addition to the β-carboline methyl ester **6**. In this way the yield of xestomanzamine A was increased finally to 81%.

The physical data (mp, IR, ^1H and ^{13}C NMR), which we obtained for xestomanzamine A, are in excellent agreement with those reported for the natural product (4).

Our four-step preparation of 5-iodo-1-methylimidazole in excellent overall yield provides ready access to a synthetic intermediate with the potential to facilitate the synthesis of other natural products with the *N*-substituted, C-5 functionalized imidazole substructure (19). The efficient total synthesis of xestomanzamine A (**1**) has been achieved through a modified Grignard reaction of **7c** with the β-carboline ester **6**, involving a total of four steps from tryptamine (53% overall yield) and five steps from imidazole (59% overall yield).

Experimental

Methanol was dried over magnesium. Xylenes and dichloromethane were distilled over calcium hydride. Tetrahydrofuran and diethyl ether were dried over sodium benzophenone ketyl. Molecular sieves (3 Å) were activated by heating in a furnace to 500°C for 3 h. All glassware for anhydrous reactions was dried overnight prior to use and these reactions were carried out under argon. TLC were run on Merck silica gel 60 F_{254} plates, with detection by means of a 254 nm UV visualizer. Melting points were recorded on a capillary melting point apparatus and are uncorrected. IR spectra reported were recorded on a Nicolet FT-IR spectrophotometer in the form of KBr disks, unless specified otherwise. The ^1H NMR spectra (200 MHz) and ^{13}C NMR spectra (125 MHz), unless specified otherwise, were obtained in $CDCl_3$ with an internal standard of TMS.

2,4,5 Triiodoimidazole (8)

Modification of a described procedure (11): a solution of iodine (45.0 g, 0.18 mol) in 20% aqueous potassium iodide (300 mL) was added dropwise to a stirred solution of imidazole (7.06 g, 0.1 mol) in 2 M sodium hydroxide (600 mL) at room temperature and the resulting mixture was stirred overnight. Addition of acetic acid until the mixture was neutral gave a white precipitate, which was filtered off, washed with water, and air dried to give a product sufficiently pure to continue in the next step: (35.4 g, 76%): mp 186–190°C, lit. (11) mp 190–192°C.

4(5)-Iodoimidazole (9)

Modification of a described procedure (13): triiodoimidazole (1.0 g, 2.24 mmol) and sodium sulfite (4.2 g, 33.3 mol) were heated at reflux in 30% ethanol in water solution (50 mL) for 24 h. The ethanol was removed under reduced pressure. The remaining solution was filtered and the filtrate extracted with diethyl ether (3 × 15 mL). The organic extracts were combined, dried (Na_2SO_4), and concentrated under reduced pressure to afford the pure product **9** as a white solid (0.43 g, 99%): mp 136 to 137°C, lit. (13) mp 137 to 138°C. ^1H NMR δ 7.18 (s, 1H), 7.62 (s, 1H). ^1H NMR (DMSO-d_6) δ 7.31 (s, 1H), 7.65 (s, 1H).

4-Iodo-1-*p*-toluenesulfonylimidazole (10)

Compound **10** was prepared from **9** based upon the procedure of Cliff and Pyne (14). White solid (98%): mp 146 to 147°C (EtOH), lit. (14) mp 146 to 147°C; ^1H NMR δ 2.46 (s, 3H), 7.37 (s, 1H), 7.40 (d, J = 8.5 Hz, 2H), 7.83 (d, J = 8.5 Hz, 2H), 7.88 (s, 1H).

5-Iodo-1-methylimidazole (7c)

To a solution of **10** (0.94 g, 2.81 mmol) in dry CH_2Cl_2 (30 mL) was added trimethyloxonium tetrafluoroborate (0.46 g, 3.11 mmol). After the mixture was stirred at room temperature for 24 h, methanol (15 mL) was added. The solvent was removed under reduced pressure and the residue was acidified with 1% HCl and extracted with CH_2Cl_2 (2 × 15 mL). The aqueous solution was then basified with 5% $NaHCO_3$ solution and extracted with CH_2Cl_2 (3 × 15 mL). The organic extracts from the basified solution were combined, dried (Na_2SO_4), and the solvent removed under reduced pressure to afford the white product **7c** (0.58 g, 99%): mp 106 to 107°C, lit. (12) mp 102 to 103°C. ^1H NMR δ 3.62 (s, 3H), 7.13 (s, 1H), 7.62 (s, 1H).

1,2,3,4-Tetrahydro-β-carboline-1-carboxylic acid (13)

Tryptamine hydrochloride **12** (1.95 g, 9.91 mmol) was dissolved in water (30 mL) while heating. Glyoxylic acid monohydrate (1.10 g, 11.95 mmol) in water (10 mL) was added to this solution, followed by the dropwise addition of potassium hydroxide (0.65 g, 11.58 mmol) in water (10 mL). The pH was adjusted to 4.0 with HOAc and the mixture al-

© 2001 NRC Canada

lowed to stir at room temperature for 2 h. The solution was then chilled and vacuum filtered, giving an impure yellow solid. The solid was dried under vacuum and suspended in methanol at 0°C, then quickly filtered by suction to afford the pure white product (1.99 g, 80%): mp 210 to 211°C, lit. (20) mp 205–208°C. IR (cm^{-1}): 3343 (NH), 1616 (C=O).

Methyl 1,2,3,4-tetrahydro-β-carboline-1-carboxylate (hydrochloride salt) (14)

The carboxylic acid **13** (4.50 g, 20.80 mmol) was stirred in dry methanol (100 mL), while dry HCl gas was bubbled through the mixture for approximately 2 min. The solid dissolved giving a golden yellow solution. The mixture was then brought to reflux through 3 Å sieves in a Soxhlet apparatus for 3 h under argon. Most of the methanol (70 mL) was removed under reduced pressure. The precipitate formed was collected by suction filtration, washed with cold toluene (30 mL), and dried under vacuum, giving the ester hydrochloride as yellow crystals (5.23 g, 94%): mp 205–208°C, lit. (21) mp 212–214°C. IR (cm^{-1}): 3384 (NH), 1757 (C=O). ^{1}H NMR (DMSO-d_6) δ 3.00 (t, J = 6.0 Hz, 2H), 3.54 (t, J = 6.2 Hz, 2H), 3.88 (s, 3H), 5.70 (s, 1H), 7.05–7.20 (m, 2H), 7.44–7.52 (m, 2H), 10.30 (s, 2H), 11.17 (s, 1H).

Methyl β-carboline-1-carboxylate (6)

The ester hydrochloride **14** (4.00 g, 15.02 mmol), precipitated sulfur (1.13 g, 35.15 mmol), and 2,2,6,6-tetramethylpiperidine (2.40 g, 17.03 mmol) were heated at reflux in dry xylenes (200 mL) for 5 h giving a brown solution. Evolution of H_2S could be detected with lead acetate paper. The solution was allowed to cool slowly overnight, forming brown needles. The xylene was removed under reduced pressure and the residual solids were placed in a Soxhlet thimble and extracted with acetone (100 mL) for 3 h. The acetone extracted the ester **6** from the reaction mixture while leaving the insoluble 2,2,6,6-tetramethylpiperidine hydrochloride in the Soxhlet thimble. The acetone was removed under reduced pressure giving a brown solid. Purification of the solid by column chromatography (ethyl acetate) gave **6** as a pale yellow solid (2.94 g, 87%): mp 165 to 166°C, lit. (22) mp 166°C. IR (cm^{-1}): 3378 (NH), 1678 (C=O). ^{1}H NMR δ 4.14 (s, 3H), 7.35–7.63 (m, 3H), 8.15–8.19 (m, 2H), 8.60 (d, J = 4.8 Hz, 1H), 9.90 (s, 1H).

Xestomanzamine A (1)

Ethylmagnesium bromide (1 M in hexane) (0.5 mL, 0.50 mmol) was added dropwise to a solution of 5-iodo-1-methylimidazole **7c** (0.104 g, 0.50 mmol) in dichloromethane (15 mL) under argon at 0°C. After completing the addition, the mixture was warmed briefly with a heat gun to complete the dissolution and then allowed to stir for 1 h at room temperature. In another flask, to a stirring solution of β-carboline ester **6** (0.104 g, 0.46 mmol) and lithium chloride (0.2 g, 4.7 mmol) in dichloromethane (20 mL) under argon at 0°C, ethylmagnesium bromide (1 M in hexane) (0.5 mL, 0.50 mmol) was added dropwise with a syringe. After completion of stirring (1 h), the solution of **7c** and ethylmagnesium bromide was added by cannula dropwise to the β-carboline ester solution at 0°C. The temperature of the reaction flask was allowed to reach 25°C and the mixture was stirred for 24 h. The mixture was quenched (5% $NaHCO_3$) and extracted with dichloromethane (3 × 25 mL). The organic extracts were combined and dried (Na_2SO_4). The dichloromethane was removed under reduced pressure and the resulting solid was purified by column chromatography (ethyl acetate–methanol, 95:5) to give the final product **1** as a yellow solid (0.103 g, 81%): mp 184 to185°C, lit. (4) mp 185 to 186°C. IR (Nujol) (cm^{-1}): 3419, 1606, 1214, 1127 (lit. (4) IR (KBr pellet) (cm^{-1}): 3427, 1612, 1211, 1128). ^{1}H NMR δ 4.11 (s, 3H), 7.35 (dd, J = 7.9, 6.4 Hz, 1H), 7.55 (dd, J = 7.5, 6.4 Hz, 1H), 7.60 (d, J = 7.5 Hz, 1H), 7.69 (s, 1H), 8.17 (d, J = 4.9 Hz, 1H), 8.20 (d, J = 7.9 Hz, 1H), 8.60 (d, J = 4.9 Hz, 1H), 8.94 (s, 1H) (lit. (4) ^{1}H NMR ($CDCl_3$) δ 4.05 (s, 3H), 7.30 (dd, J = 8.2, 6.2 Hz, 1H), 7.55 (dd, J = 7.3, 6.2 Hz, 1H), 7.57 (d, J = 7.3 Hz, 1H), 7.66 (s, 1H), 8.09 (d, J = 5.0 Hz, 1H), 8.12 (d, J = 8.2 Hz, 1H), 8.55 (d, J = 5.0 Hz, 1H), 8.93 (s, 1H)). ^{13}C NMR δ 184.4, 143.8, 143.4, 141.0, 138.2, 136.7, 136.6, 131.7, 129.8, 129.3, 121.8, 120.9, 120.7, 118.6, 111.9, 35.3 (lit.(4) ^{13}C NMR ($CDCl_3$) δ 184.2, 143.6, 143.3, 140.8, 137.9, 136.5, 136.4, 131.5, 129.7, 129.6, 121.7, 120.6, 120.5, 118.4, 111.8, 35.2.

Note added in proof: After this work had been accepted for publication we became aware of a related report on the synthesis of xestomanzamines A and B: B.E.A. Burm, P. Blokker, E. Jongmans, E. van Kampen, M.J. Wanner, and G.-J. Koomen. Heterocycles, **55**, 495 (2001).

Synthesis and antifungal properties of benzylamines containing boronate esters

Christopher M. Vogels, Liliya G. Nikolcheva, David W. Norman, Heather A. Spinney, Andreas Decken, Mark O. Baerlocher, Felix J. Baerlocher, and Stephen A. Westcott

Abstract: Addition of 3-$H_2NC_6H_4$Bpin (pin = 1,2-$O_2C_2Me_4$) to a series of aldehydes and 4-(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)acetophenone afforded the corresponding benzylideneamines in moderate to high yields. Hydroboration of these imines with catecholborane (HBcat, cat = 1,2-$O_2C_6H_4$) at room temperature gives, upon aqueous workup, the corresponding borylamines. An X-ray diffraction study was carried out on imine **1h** derived from 9-anthraldehyde and 3-$H_2NC_6H_4$Bpin. Crystals of **1h** were triclinic, a = 9.6793(4) Å, b = 10.7397(4) Å, c = 11.5353(4) Å, α = 105.1890(10)°, β = 97.3030(10)°, γ = 102.1480(10)°, Z = 2 with space group $P\bar{1}$ and crystals of *N*-[3-(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)phenyl]-4-methoxybenzylamine **2c** were orthorhombic, a = 8.6612(4) Å, b = 10.3794(4) Å, c = 20.6033(9) Å, Z = 4 with space group $P2_12_12_1$. Amines have been tested for their antifungal properties against *Aspergillus niger* and *Aspergillus flavus*.

Key words: benzylamines, boronate esters, aminoboron, hydroboration, antifungal.

Résumé : L'addition de 3-$H_2NC_6H_4$Bpin (pin = 1,2-$O_2C_2Me_4$) à une série d'aldéhyde et à la 4-(4,4,5,5-tétraméthyl-1,3,2-dioxaborolan-2-yl)acétophénone conduit aux benzylidèneamines correspondantes avec des rendements qui vont de bons à excellents. L'hydroboration de ces imines avec du catécholborane (HBcat, cat = 1,2-$O_2C_6H_4$), à la température ambiante, fournit les borylamines correspondances après extraction. Une étude par diffraction des rayons X a été réalisée sur l'imine **1h** provenant du 9-anthraldéhyde et du 3-$H_2NC_6H_4$Bpin. Les cristaux de **1h** sont tricliniques, groupe d'espace $P\bar{1}$, avec a = 9,6793(4) Å, b = 10,7397(4) Å et c = 11,5353(4) Å, α = 105,1890(10)°, β = 97,3030(10)° et γ = 102,1480(10)° et Z = 2; les cristaux de *N*-[3-(4,4,5,5-tétraméthyl-1,3,2-dioxaboralan-2-yl)phényl]-4-méthoxybenzylamine, **2c**, sont orthorhombiques, groupe d'espace $P2_12_12_1$, avec a = 8,661(4) Å, b = 10,3794(4) Å et c = 20,6033(9) Å et Z = 4. Les amines ont été évaluées pour leur activité antifongique contre *Aspergillus niger* et *Aspergillus flavus*.

Mots clés : benzylamines, esters de l'acide boronique, aminobore, hydroboration, antifongique.

[Traduit par la Rédaction]

Introduction

The bioinorganic chemistry of boron is an area of growing interest (1–10). For example, boron-containing amino acids are among the most potent inhibitors of the serine proteases chymotrypsin and subtilisin (10). Serine proteases are a diverse group of proteolytic enzymes whose numerous physiological functions include digestion, growth, differentiation, cell signalling and migration, immunological defence, and apoptosis. Proteases are also vital in the generation of most disease processes. Much effort has therefore focused on the synthesis of boron-containing amino acid and peptide derivatives for possible applications as enzyme inhibitors. Although aminoboronic acid derivatives have significant biological activity and are useful synthetic intermediates in organic chemistry (11,12), synthetic routes to these compounds are scarce and involve complicated procedures. As a result, relatively few examples of aminoboron compounds have been studied (13–19). As part of our program to develop synthetically attractive routes to aminoboron compounds, we have prepared a series of boronated benzylamines derived from the reaction of 3-$H_2NC_6H_4$Bpin (pin = 1,2-$O_2C_2Me_4$) with various aldehydes and the boron-containing ketone 4-(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)acetophenone and tested these compounds for their antifungal properties. Results are reported herein.

Experimental

Reagents and solvents used were obtained from Aldrich Chemicals. NMR spectra were recorded on a JEOL JNM-

 DOI: 10.1139/cjc-79-7-1115 © 2001 NRC Canada

GSX270 FT NMR spectrometer. ^{1}H NMR chemical shifts are reported in ppm and referenced to residual protons in deuterated solvent at 270.05 MHz. ^{11}B NMR chemical shifts are referenced to external $F_3B{\cdot}OEt_2$ at 86.55 MHz. ^{13}C NMR chemical shifts are referenced to solvent carbon resonances as internal standards at 67.80 MHz. Multiplicities are reported as (s) singlet, (d) doublet, (t) triplet, (q) quartet, (quint) quintet, (m) multiplet, (br) broad, and (ov) overlapping. Infrared spectra were obtained using a Mattson Genesis II FT-IR spectrometer and reported in cm^{-1}. Melting points were measured uncorrected with a Mel-Temp apparatus. Microanalyses for C, H, and N were carried out at Desert Analytics (Tucson, Arizona).

Transesterification

Protection of the starting boronic acids (10.0 mmol) with 1 equiv of pinacol was carried out in methylene chloride in the presence of 10 g of activated molecular sieves (type 4A). The reactions were allowed to proceed for 5 days at which point the sieves were removed by suction filtration and the product isolated upon removal of the solvent under vacuum.

2-(4,4,5,5-Tetramethyl-1,3,2-dioxaborolan-2-yl)benzaldehyde (2-FPBpin)

Yield: 68% of a yellow oil; bp 97°C. IR (Nujol): 2920, 2856, 1699, 1595, 1462, 1379, 1257, 1146, 860, 764, 666. ^{1}H NMR (in $CDCl_3$) δ 10.54 (s, 1H), 7.95 (d, J = 8 Hz, 1H), 7.87 (d, J = 8 Hz, 1H), 7.58 (m, 2H), 1.35 (s, 12H). ^{13}C NMR δ 194.4, 141.1, 135.3, 132.8, 130.6, 130 (br, C-B), 127.7, 84.2, 24.6. ^{11}B NMR δ 31.7 (br).

3-(4,4,5,5-Tetramethyl-1,3,2-dioxaborolan-2-yl)benzaldehyde (3-FPBpin)

Yield: 77% of a white solid; mp 49°C. IR (Nujol): 2970, 2880, 1710, 1605, 1460, 1361, 1194, 1144, 965, 702. ^{1}H NMR (in $CDCl_3$) δ 10.05 (s, 1H), 8.31 (s, 1H), 8.08 (d, J = 8 Hz, 1H), 8.00 (d, J = 8 Hz, 1H), 7.54 (t, J = 8 Hz, 1H), 1.37 (s, 12H). ^{13}C NMR δ 192.6, 140.7, 137.3, 135.8, 131.3, 130 (br, C-B), 128.4, 84.3, 24.9. ^{11}B NMR δ 31.2 (br). Anal. calcd. for $C_{13}H_{17}O_3B$: C 67.28, H 7.38; found: C 67.38, H 7.28.

4-(4,4,5,5-Tetramethyl-1,3,2-dioxaborolan-2-yl)benzaldehyde (4-FPBpin)

Yield: 71% of a pale yellow solid; mp 50°C. IR (Nujol): 2972, 2880, 1711, 1460, 1361, 1144, 858, 651. ^{1}H NMR (in $CDCl_3$) δ 10.05 (s, 1H), 7.98 (d, J = 8 Hz, 2H), 7.88 (d, J = 8 Hz, 2H), 1.37 (s, 12H). ^{13}C NMR δ 192.9, 138.8, 135.5, 135 (br, C-B), 128.8, 84.5, 25.1. ^{11}B NMR δ 31.1 (br). Anal. calcd. for $C_{13}H_{17}O_3B$: C 67.28, H 7.38; found: C 67.56, H 7.25.

4-(4,4,5,5-Tetramethyl-1,3,2-dioxaborolan-2-yl)acetophenone

Yield: 97% of a pale yellow solid; mp 60–62°C. IR (Nujol): 2941, 2858, 1691, 1556, 1508, 1460, 1360, 1265, 1215, 1144, 1093, 1016. ^{1}H NMR (in $CDCl_3$) δ 7.91 (m, 4H), 2.60 (s, 3H), 1.35 (s, 12H). ^{13}C NMR δ 197.9, 138.7, 134.7, 130 (br, C-B), 127.0, 83.9, 26.5, 24.6. ^{11}B NMR δ 31.2 (br). Anal. calcd. for $C_{14}H_{19}O_3B$: C 68.32, H 7.78; found: C 68.28, H 7.86.

Preparation of imines

Imines were prepared by combining the starting aldehyde (or ketone) with 1 equiv of 3-$H_2NC_6H_4$Bpin in methylene chloride and 10 g of activated molecular sieves (type 4A). After 3–5 days the sieves were removed by suction filtration and the imine was obtained following removal of the solvent under vacuum. Imine **1j** was isolated following crystallization from hot hexane.

1a

Yield: 81% of an off-white solid; mp 70°C. IR (Nujol): 2925, 1629, 1573, 1452, 1377, 1353, 1140, 1069, 963, 906, 801, 755. ^{1}H NMR (in $CDCl_3$) δ 8.52 (s, 1H), 7.91 (m, 2H), 7.68 (m, 2H), 7.49 (m, 3H), 7.40 (m, 2H), 1.37 (s, 12H). ^{13}C NMR δ 160.6, 151.7, 136.5, 132.6, 131.5, 129.0, 129 (br, C-B), 128.9, 128.8, 126.2, 125.0, 84.1, 25.1. ^{11}B NMR δ 31.5 (br).

1b

Yield: 79% of a bright yellow solid; mp 111°C. IR (Nujol): 2925, 2856, 1708, 1628, 1602, 1525, 1461, 1360, 1319, 1147, 1075, 967, 908, 852, 705. ^{1}H NMR (in $CDCl_3$) δ 8.61 (s, 1H), 8.35 (d, J = 8 Hz, 2H), 8.09 (d, J = 8 Hz, 2H), 7.76 (d, J = 8 Hz, 1H), 7.67 (s, 1H), 7.48–7.38 (ov m, 2H), 1.37 (s, 12H). ^{13}C NMR δ 157.6, 150.5, 149.5, 141.9, 133.7, 130 (br, C-B), 129.6, 129.0, 126.1, 125.2, 124.2, 84.3, 25.1. ^{11}B NMR δ 31.2 (br).

1c

Yield: 92% of a white solid; mp 92°C. IR (Nujol): 2968, 2893, 1705, 1620, 1605, 1572, 1510, 1456, 1352, 1248, 1140, 1026, 831, 706. ^{1}H NMR (in $CDCl_3$) δ 8.43 (s, 1H), 7.85 (d, J = 8 Hz, 2H), 7.64 (ov m, 2H), 7.39 (ov m, 2H), 6.99 (d, J = 8 Hz, 2H), 3.87 (s, 3H), 1.36 (s, 12H). ^{13}C NMR δ 162.2, 159.7, 151.8, 132.1, 130.6, 130 (br, C-B), 129.4, 128.6, 126.2, 124.9, 114.2, 83.9, 55.4, 25.0. ^{11}B NMR δ 31.6 (br).

1d

Yield: 85% of a pale yellow solid; mp 98°C. IR (Nujol): 2959, 1609, 1561, 1456, 1370, 1314, 1150, 1070, 964, 853, 791, 705. ^{1}H NMR (in $CDCl_3$) δ 8.79 (s, 1H), 7.70 (d, J = 8Hz, 1H), 7.59 (s, 1H), 7.41 (t, J = 8 Hz, 1H), 7.29 (d, J = 8 Hz, 1H), 6.92 (s, 2H), 2.53 (s, 6H), 2.32 (s, 3H), 1.37 (s, 12H). ^{13}C NMR δ 161.1, 152.8, 139.9, 138.8, 132.1, 130.8, 130 (br, C-B), 129.9, 128.7, 126.5, 124.3, 84.1, 25.0, 21.4, 21.3. ^{11}B NMR δ 32.1 (br).

1e

Yield: 82% of an off-white solid; mp 145°C. IR (Nujol): 2935, 2858, 1626, 1591, 1562, 1462, 1414, 1375, 1352, 1267, 1140, 1111, 1070, 962, 916, 856, 818, 706. ^{1}H NMR (in $CDCl_3$) δ 9.21 (s, 1H), 8.16 (d, J = 8 Hz, 1H), 7.85 (d, J = 8 Hz, 1H), 7.76 (s, 1H), 7.69 (m, 1H), 7.55–7.40 (ov m, 4H), 1.38 (s, 12H), 1.33 (s, 12H). ^{13}C NMR δ 162.6, 162.4, 151.5, 135.3, 132.1, 130.8, 130.1, 130 (br, C-B), 128.7, 127.0, 126.4, 125.4, 84.0, 83.8, 24.9, 24.8. ^{11}B NMR δ 31.3 (br).

1f

Yield: 86% of an off-white solid; mp 219°C. IR (Nujol): 2935, 2858, 1630, 1599, 1572, 1462, 1377, 1348, 1140, 964,

Synthesis of amines

Catecholborane (1.2 mmol) in 5 mL of toluene was added dropwise to a stirred solution of the imine (1.0 mmol) in 10 mL of toluene under an atmosphere of dinitrogen. The reaction was allowed to proceed for 24 h at which point water (5 mL) was added. The organic phase was extracted and the corresponding amine was isolated by flash chromatography through alumina followed by removal of solvent. Conversely, formation of the amine could also be achieved by reduction of the imine with 3 equiv of $NaBH_4$ in 10 mL of methanol, followed by an organic extraction with Et_2O and filtration.

2a

Yield: 78% of a white solid; mp 86°C. IR (Nujol): 3416, 2969, 2885, 1602, 1582, 1515, 1447, 1353, 1320, 1274, 1143, 1073, 965, 863, 706. ^{1}H NMR (in $CDCl_3$) δ 7.36–7.31 (ov m, 5H), 7.18–7.15 (ov m, 3H), 6.73 (m, 1H), 4.35 (s, 2H), 1.33 (s, 12H). ^{13}C NMR δ 147.5, 139.3, 130 (br, C-B), 128.6, 128.5, 127.4, 127.1, 123.9, 119.1, 115.3, 83.5, 48.1, 24.7. ^{11}B NMR δ 31.8 (br). Biological testing

New boron compounds were tested for antifungal activity against pure cultures of *Aspergillus niger* and *Aspergillus flavus* supplied by Ward's Natural Science Ltd. (St. Catharines, Ontario, Canada). Cultures were maintained on Sabouraud dextrose agar (20, 21). Eight agar plugs (10 mm diameter) were cut from a 5–8 day-old colony and homogenized in distilled, sterilized water (4 mL). From this suspension, 0.5 mL was transferred aseptically to a Petri plate with Sabouraud dextrose agar (15 mL) and spread evenly over the entire surface. Each plate was provided with four evenly spaced paper disks (7 mm Whatman Number 1 filter paper) containing the boron compound (0, 25, 50, and 100 μg respectively). Each compound was applied to the disks as a solution (50 mg compound per 10 mL of acetone) where control disks were treated with neat acetone (20 μL). Test plates with fungal homogenates were incubated at 20°C for 48 h. Four replicate plates were used for each test. Antifungal activity was taken by the diameter of the clear zone surrounding the disk.

X-ray crystallography

Crystals of **1h** and **2c** were grown from methylene chloride solutions cooled to 5°C. Single crystals were mounted using a glass fibre and Paratone-N oil and frozen in the cold stream of the goniometer. Data were collected on a Bruker AXS P4/SMART 1000 diffractometer using ω and φ scans with a scan width of 0.3° and 30 s exposure times. The detector distance was 4 cm. The data were reduced (SAINT) and corrected for absorption (SADABS). The structures were solved by direct methods and refined by full-matrix least-squares on F^2(SHELXTL). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located in Fourier difference maps and refined isotropically. Crystallographic data are summarized in Table 1 and atomic coordinates, thermal parameters, and bond lengths and angles have been deposited as supporting information.[3]

Results and discussion

We have found that attempts to prepare imines from 3-aminophenylboronic acid (3-$H_2NC_6H_4B(OH)_2$) proved exceedingly difficult owing to the ease with which boronic acids form insoluble anhydrides (6). However, protection of the boronic acid groups can be accomplished by transesterification with pinacol ($HOCMe_2CMe_2OH$) to afford quantitative formation of the organic soluble aminoboronate ester 3-$H_2NC_6H_4$Bpin (pin = 1,2-$O_2C_2Me_4$) (22). Reactions of this amine with aldehydes proceed smoothly to give the corresponding boron-containing aldimines **1a**–**i** in moderate to high yields (Fig. 1). This methodology provides an easy and general route to imines derived from aniline and benzaldehyde derivatives where the boronate ester functionality can be selectively incorporated into either or both of the aryl groups. Imines containing boronate esters are important intermediates in organic chemistry and have been used recently to prepare a number of pharmacologically important compounds (23–27). For instance, Whiting and co-workers (23) have recently used imine intermediates containing boronate esters to make enantio-enriched γ-phenyl-γ-amino alcohols. Incorporation of the boronate ester functionality in these cases is accom-

plished by deprotonation of acetophenone-derived imines followed by alkylation with ICH_2Bpin at low temperatures. Reduction of these imines is subsequently achieved with BH_3 reagents. Likewise, boronated imines have been used in Suzuki–Miyaura cross-coupling reactions in the synthesis of 4-substituted phenylalanine derivatives (24). Carborane imines have also been prepared lately for use in boron neutron capture therapy (28).

In this study, we have found that aldimines **1a**–**i** show a signal for the N=CH methine proton between δ 8.50 and 9.70 ppm in the ^{1}H NMR spectra and a resonance at ca. 160 ppm in the ^{13}C NMR spectra corresponding to this sp^2 carbon. A broad peak at around 30 ppm in the ^{11}B NMR spectra is observed for all aldimines, indicating that the boron atom lies in a three-coordinate C-Bpin environment (29). This result is somewhat surprising for the 2-FPBpin derivative **1e** as it suggests no significant intramolecular interac-

tion exists between the boron atom and the imine nitrogen (30). Yet we have found that imines derived from 2-FPBpin and ethylene diamine show considerable interaction in both solution and in the solid state.[4] An X-ray diffraction study on **1h** was carried out to verify the formation of imines in these reactions. The molecular structure of **1h** is shown in Fig. 2 and crystallographic data given in Table 1. Selected bond distances and angles are shown in Table 2 and atomic coordinates are provided in Table 3. The imine C(17)—N(16) bond distance of 1.277(1) Å is comparable to azomethine compounds derived from salicylaldehyde and phenylboronic acid (25). The B—O bond distances (avg = 1.361(1) Å) are also typical for three-coordinate Bpin groups (22) and significantly shorter than those observed in chelate complexes with diphenylborinic acid (ca. 1.5 Å), where the boron atom is four-coordinate (31). Interestingly, **1h** is distorted from planarity as the anthracene ring is twisted 87.3° away from the N(16)–arene plane.

Diboronated imines will be of special interest as potential enzyme inhibitors as the corresponding amines contain two boron groups that may enhance specific binding to biomolecules. Along with aldimines **1e**–**g** we have prepared the diboronated ketimine derivative **1j** from a condensation reaction of 3-$H_2NC_6H_4$Bpin with 4-(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)acetophenone. Although the methyl group for this compound shows a peak at δ 2.22 ppm in the ^{1}H NMR spectra, two different pinacol resonances are observed at 1.37 and 1.34 ppm, suggesting slightly different environments for the Bpin groups. The ^{11}B NMR spectra for **1j**, however, shows only one peak at δ 30.9 ppm as the two different boron resonances could not be differentiated.

Reduction of imines **1a**–**j** using $NaBH_4$ in methanol gave selective formation of the corresponding benzylamines **2a**–**j** in low to moderate yields. Related benzylaminoboronic acids have been reported previously (32). Indeed, benzazaborole derivatives have been prepared by condensation of 2-

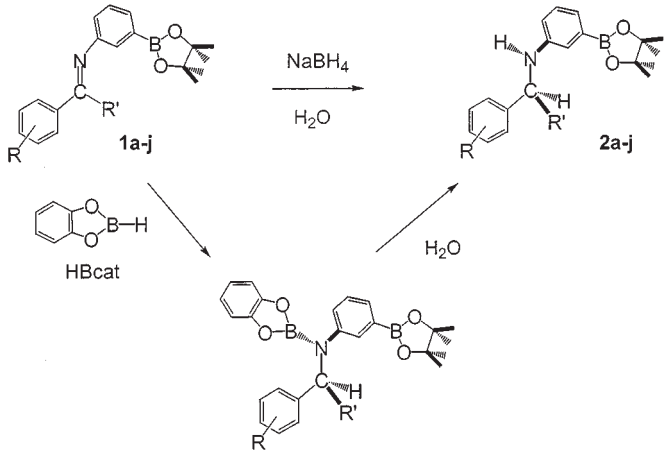
Fig. 3. Molecular structure of **2c** with ellipsoids drawn at the 30% probability level. Hydrogen atoms were omitted for clarity.



(aminomethyl)benzene boronic acids (33–35). Protection of the boronic acid group by transesterification with pinacol, however, inhibits such intramolecular cyclizations from occurring in the case of **2e**. Formation of amines **2a**–**j** in these reactions is monitored by disappearance of the imine N=CH resonance in the ^{1}H NMR spectra with concomitant formation of a peak at around δ 4.3 ppm corresponding to a benzylic CH_2 resonance. Once again, the ^{11}B NMR spectra show broad peaks around δ 30 ppm, suggesting no significant intramolecular or intermolecular N → B interaction is occurring in these complexes. An X-ray diffraction study was carried out on **2c** to confirm this result. The molecular structure of **2c** is shown in Fig. 3 and selected bond distances and angles are given in Table 2. Atomic coordinates are provided in Table 4. As expected, the N(16)—C(17) bond distance of 1.451(2) Å in **2c** is significantly longer than the double bond observed for **1h**. The B—O bond distances are once again typical for three-coordinate Bpin environments at B(1)—O(5) 1.367(1) and B(1)—O(2)

Table 5. Boron compounds tested for antifungal activity.

Entry	Compound	Dose (μg/disk)	Diameter of clear zone (mm)	
			A. niger	*A. flavus*
1	PhC(O)H	100	0	0
2	2-FPBA	25	16.2	13.4
3	2-FPBpin	25	12.0	9.4
4	3-$H_2NC_6H_4B(OH)_2$	100	0	0
5	**2b**	100	3.0	4.5
6	**2c**	100	9.0	6.3
7	**2e**	100	0	0

Note: Each compound was introduced onto a small paper disk which was placed in a culture medium. The diameter of the clear zone (the area where fungus — *A. niger* or *A. flavus* — did not grow) around each disk indicated antifungal activity.

1.368(1) Å. No significant interaction between the boron and nitrogen atoms is observed.

Interestingly, reduction of the imines could also be carried out using the gentle hydroboration reagent, catecholborane (HBcat, cat = 1,2-$O_2C_6H_4$). Reactions proceed to give the corresponding *N*-borylamine products where the hydride has added to the imine carbon and the electron deficient boryl group (BR_2) is bound to the electron rich nitrogen atom (Fig. 4). Interestingly, the ^{11}B NMR spectra for these multiply borated intermediates show broad overlapping peaks around δ 30 and 21 ppm corresponding to the C-Bpin and N-Bcat resonances, respectively. Addition of catecholborane to these bulky imines usually requires reaction times of up to 2 h. Subsequent addition of water to the *N*-borylamine intermediates afforded the benzylamines **2a**–**j** along with boric acid. Unfortunately, we were unable to affect hydroborations of these imines using pinacolborane (HBpin), even when a metal catalyst was employed (36, 37). This result is not surprising as HBpin is a significantly less reactive borane than HBcat (38).

Recent studies have shown that related heterocyclic boron compounds show appreciable antifungal activity (39–41). We therefore decided to examine these new benzylamine derivatives for their antifungal activities (42). Selected results for these compounds are shown in Table 5. Benzaldehyde was tested as a control and, as expected, showed no antifungal behaviour against either *A. niger* or *A. flavus*. Remarkably, both 2-formylphenylboronic acid (2-FPBA, Entry 2) and 2-FPBpin (Entry 3) showed considerable fungitoxicity, with the unprotected boronic acid showing slightly enhanced activity over the pinacolated derivative. These data suggest that the boron groups are responsible for the observed toxicities. Unfortunately, no activity was observed with the analogous 3- and 4-boronated derivatives (3- and 4-FPBpin) or the amine control, 3-$H_2NC_6H_4B(OH)_2$ (Entry 4). Of all the benzylamine derivatives tested, only **2b** (Entry 5) and **2c** (Entry 6) showed any appreciable activity. Higher doses of the amine, as compared with the aldehyde derivatives (100 vs. 25 μg/disk), were required. Somewhat surprising is the observation that the amine derived from 2-FPBpin (**2e**) showed no toxicity even at these higher doses (Entry 7). Further work is therefore being conducted to further our understanding of the role boron plays in fungitoxicity. The results of which will be reported in due course.

Conclusion

We have prepared a number of new imines containing boronate ester groups via condensation reactions with 3-$H_2NC_6H_4$Bpin (pin = 1,2-$O_2C_2Me_4$) and readily available aldehydes. A novel diboronated ketimine derived from 3-$H_2NC_6H_4$Bpin and 4-(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)acetophenone was also prepared. Reduction of these imines with catecholborane generated the corresponding amines, upon aqueous workup. This methodology provides an easy and efficient route to secondary benzylamines containing boronate esters where the boron functionality can be selectively incorporated into either or both of the amine aryl rings. We have also found that several of these boron containing compounds display antifungal behaviour against both *A. niger* and *A. flavus*.

Reduction of hexaammineruthenium(III) ions by a series of tris(polypyridyl)chromium(II) ions — Revisiting the $Cr(NN)_3^{3+/2+}$ self-exchange rate

K. Omar Zahir

Abstract: The kinetics of the outer-sphere oxidation of $Cr(NN)_3^{2+}$ ions (NN = 2,2′-bipyridine, 1,10-phenanthroline, and their substituted analogs) by hexaammineruthenium(III) was studied using laser flash photolysis. The $Cr(NN)_3^{2+}$ ions were generated via the reductive quenching of the $*Cr(NN)_3^{3+}$ excited states by oxalate ions or by H_2edta^{2-}. The second-order rate constants were found to vary with the driving force of the reaction. The rate constants increase from $(7.1 \pm 0.5) \times 10^6$ M^{-1} s^{-1} for $Cr(5\text{-Clphen})_3^{2+}$ to $(2.6 \pm 0.2) \times 10^8$ M^{-1} s^{-1} for $Cr(4,7\text{-Me}_2\text{phen})_3^{2+}$. The self-exchange rate constant for the couple ($Cr(NN)_3^{3+/2+}$) was calculated by applying Marcus cross relation to present and other known reactions of $Cr(NN)_3^{n+}$ ions, where $n = 3$ or 2 with various reactants and is estimated to be $(6 \pm 4) \times 10^7$ M^{-1} s^{-1}.

Key words: tris(polypyridyl)chromium(II)/(III) self-exchange rate, hexaammineruthenium(III), oxidation of $Cr(NN)_3^{2+}$.

Résumé : Faisant appel à la photolyse éclair au laser, on a étudié la cinétique de l'oxydation dans la couche externe d'ions $Cr(NN)_3^{2+}$ (NN = 2,2′-bipyridine, 1,10-phénanthroline et leurs analogues substitués) par l'hexaammineruthénium(III). Les ions $Cr(NN)_3^{2+}$ ont été générés par le biais d'un piégeage réducteur des états excités $*Cr(NN)_3^{3+}$ par des ions oxalate ou par du H_2edta^{2-}. On a trouvé que les constantes de vitesse du deuxième ordre varient avec l'affinité de la réaction. Les constantes de vitesse augmentent de $(7{,}1 \pm 0{,}5) \times 10^6$ M^{-1} s^{-1} pour le $Cr(5\text{-Clphen})_3^{2+}$ à $(2{,}6 \pm 0{,}2) \times 10^8$ M^{-1} s^{-1} pour le $Cr(4,7\text{-Me}_2\text{phen})_3^{2+}$. On a calculé la constante de vitesse d'autoéchange du couple $Cr(NN)_3^{3+}/2+$ en appliquant la relation croisée de Marcus à ces réactions et à d'autres réactions connues d'ions $Cr(NN)_3^{n+}$ ($n = 3$ ou 2) avec divers réactifs et on l'a évaluée à $(6 \pm 4) \times 10^7$ M^{-1} s^{-1}.

Mots clés : vitesse d'autoéchange tris(polypyridyl)chrome(II)/(III), hexaammineruthénium(III), oxydation de $Cr(NN)_3^{2+}$.

[Traduit par la Rédaction]

Introduction

Over the past 20 years, considerable attention has been directed at studying the electron and energy transfer reactions of transition-metal excited states particularly that of polypyridyl complexes of ruthenium(II) and chromium(III) ions ($*M(NN)_3^{n+}$) (1, 2). This interest in these excited states derives in part from their possible use in solar energy conversion (3, 4). An additional reason for this interest is that the rates of electron transfer reactions of these complexes can be used to test the theoretical models of electron transfer reactions (5, 6). Most of such studies, however, have been focused on $Ru(NN)_3^{*2+/3+}$ systems and with the exception of $Cr(bpy)_3^{2+}$ (bpy = 2,2′-bipyridine), few studies involving the electron transfer reactions of $Cr(NN)_3^{2+}$ complexes have been reported.

The difficulty in studying the oxidation of $Cr(NN)_3^{2+}$ has been partly due to the instability of the $Cr(NN)_3^{2+}$ ion. However, such studies have now become possible due to the availability of a laser flash photolysis method which involves irreversible quenching of the ^2E excited states of $Cr(NN)_3^{3+}$ to generate $Cr(NN)_3^{2+}$ ions (7). This method, which consists of using H_2edta^{2-} or oxalate ions as the quencher of the $*Cr(NN)_3^{3+}$ excited states, is an excellent way of producing $Cr(NN)_3^{2+}$ ions with a quantum yield of 2, and has been employed to study electron transfer reactions of $Cr(NN)_3^{2+}$ with dioxygen (7), Co(III) amine complexes (8), and SO_2 (9).

No experimental determination of the rate of $Cr(NN)_3^{3+/2+}$ self-exchange reaction has been made, and in the few cases where Marcus cross relation was used to examine the self-exchange reaction, it led to a wide range of values (5, 10–12). A better estimation of this intrinsic parameter is essential if $Cr(NN)_3^{3+/2+}$ systems are to be applied to test the theoretical models of electron transfer reactions. We have now employed the above mentioned method of generating $Cr(NN)_3^{2+}$ to study the kinetics of the reduction of $Ru(NH_3)_6^{3+}$ by a series of $Cr(NN)_3^{2+}$ ions. Both sets of reaction partners are inert to substitution requiring that the reaction proceeds through an outer-sphere mechanism. The self-exchange rate constant for the $Ru(NH_3)_6^{3+/2+}$ couple has been experimentally determined (13–15), and the standard free energy changes for the reactions between $Ru(NH_3)_6^{3+}$ and $Cr(NN)_3^{2+}$ are well-known. The results from the present study and others available in the literature on the cross-reaction between $Cr(NN)_3^{2+}$ and various oxidants are then subjected to Marcus cross relation to estimate the rate constant for the self-exchange reactions for $Cr(NN)_3^{3+/2+}$.

Experimental

Materials

Tris(polypyridine)chromium(III) complexes were prepared according to the published procedures (5, 16, 17), and their purity was checked by comparison of the UV–vis spectra, emission spectra, and lifetime values. Hexaammineruthenium(III) chloride was prepared and purified according to the published procedures (14). Sodium oxalate (T.J. Baker) and disodium ethylenediaminetetraacetate (Na_2H_2edta) (Fischer) were used as received. Sodium chloride was used to adjust the ionic strength of the solutions at 0.1 M.

Kinetic data

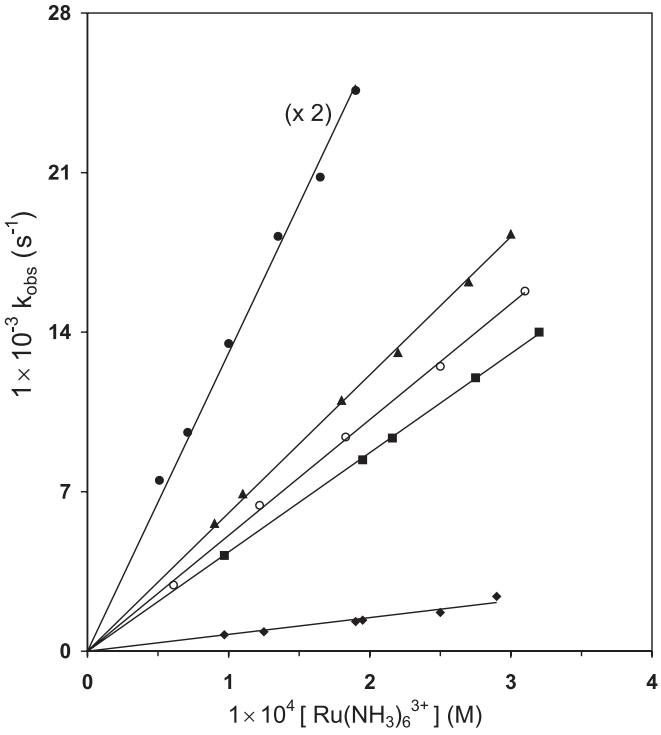
The kinetic data were obtained using a homebuilt laser flash photolysis system that was based on literature design (18). The excitation of the $Cr(NN)_3^{3+}$ complexes was carried out at either 423 or 452 nm by a 300 ns pulse from a modified Model DL-1200 PhaseR dye laser. The quenching of the $*Cr(NN)_3^{3+}$ excited states by oxalate ions or H_2edta^{2-} was monitored at 728 nm. The formation and then subsequent disappearance of $Cr(NN)_3^{2+}$ were monitored at 440 nm for NN (5-Clphen), 430 nm (phen), 480 nm (5-Mephen), 440 nm (4,7-Me_2phen), and 560 nm (bpy) (11). The kinetic studies were carried out under an oxygen-free atmosphere using Argon gas. Pseudo-first-order conditions with more than 10-fold excess of ruthenium(III) complex were maintained. The absorbance–time data for the loss of $Cr(NN)_3^{2+}$ (typically 6–8 μM) collected in each experiment were analyzed by a nonlinear least-squares analysis of exponential absorbance–time curves.

Results and discussion

Kinetics of the Cr(II)–Ru(III) reactions

Under the experimental conditions employed, the formation of $Cr(NN)_3^{2+}$ was very rapid. The details of this quenching process were discussed elsewhere (7). Control experiments were carried out to investigate whether any competitive quenching of $*Cr(NN)_3^{3+}$ by $Ru(NH_3)_6^{3+}$ occurs. Under our experimental conditions, no significant quenching of $*Cr(NN)_3^{3+}$ by $Ru(NH_3)_6^{3+}$ took place and the formation of $Cr(NN)_3^{2+}$ was the only quenching pathway that was operative. The loss of $Cr(NN)_3^{2+}$ due to its reaction with $Ru(NH_3)_6^{3+}$ is rapid, and proceeds as shown in eq. [1].

$$[1] \quad Cr(NN)_3^{2+} + Ru(NH_3)_6^{3+} \rightarrow Cr(NN)_3^{3+} + Ru(NH_3)_6^{2+}$$



For a given complex, the kinetic data were the same regardless of which quencher (H_2edta^{2-} or oxalate ions) were used to generate $Cr(NN)_3^{2+}$. The rate law for the reaction described in eq. [1] can be written as

$$[2] \quad -d[Cr(NN)_3^{2+}]/dt = k_{12}[Cr(NN)_3^{2+}][Ru(NH_3)_6^{3+}]$$

$$[3] \quad k_{obs} = k_{12}[Ru(NH_3)_6^{3+}]$$

Here k_{12} is the second-order rate constant for the oxidation of $Cr(NN)_3^{2+}$ by $Ru(NH_3)_6^{3+}$. The kinetic data for rxn. [1] is plotted in Fig. 1 which shows that k_{obs} increases linearly with an increase in the concentration of $Ru(NH_3)_6^{3+}$ complex. As the plots in Fig. 1 pass through the origin for all the Cr(II) complexes studied, it is suggested that eq. [1] is the sole pathway for the disappearance of $Cr(NN)_3^{2+}$ and eqs. [2] and [3] are applicable. The values of the second-order rate constant (k_{12}) were obtained from the slopes of such plots, and a summary of the cross-reaction rate constants (k_{12}) for rxn. [1] is presented in Table 1. The slowest reaction was observed with $Cr(5\text{-Clphen})_3^{2+}$ which has the smallest $\Delta°E$ value of 0.21 V, and for $Cr(4,7\text{-}Me_2phen)_3^{2+}$ which has the largest $\Delta°E$ value among all the Cr(II) complexes studied, the value of k_{12} obtained was the largest.

Fig. 1. Plot of k_{obs} (the observed rate constant for the reduction of $Ru(NH_3)_6^{3+}$ complex by $Cr(NN)_3^{2+}$ complexes) vs. $[Ru(NH_3)_6^{3+}]$ at ambient temperature. The data are shown for NN = 4,7-Me_2phen (circles), 5-Mephen (triangle), phen (open circles), bpy (squares), and 5-Clphen (diamonds).

Estimation of the self-exchange rate for the $Cr(NN)_3^{2+/3+}$ couple using Marcus cross relation

Considering that both partners in rxn. [1] are substitutionally inert, it is expected that rxn. [1] proceeds via an outer-sphere electron transfer mechanism. Marcus cross relation (eq. [4]) has been successfully utilized to evaluate the self-exchange reaction of many redox couples (13, 19, 20).

$$[4] \quad k_{12} = (k_{11}k_{22}K_{12}f_{12})^{1/2}$$

$$\log f_{12} = (\log K_{12})^{1/2}/[4 \log (k_{11}k_{22}/Z^2)]$$

Here, k_{12} is the rate constant for the cross-reaction, k_{11} and k_{22} are the self-exchange rates for the two partners, and K_{12} is the equilibrium constant for the cross-reaction. The results from the present study and other systems for which kinetic and thermodynamic data are available were subjected to such treatment to estimate the rate constant for the $Cr(NN)_3^{3+/2+}$ self-exchange reaction (eq. [5]) and the results are presented in Table 1.

[5] $$Cr(NN)_3^{2+} + Cr(NN)_3^{3+} \longrightarrow Cr(NN)_3^{3+} + Cr(NN)_3^{2+}$$

The data in Table 1 shows that the calculated values of $Cr(NN)_3^{3+/2+}$ exchange rate span over a large range. However, out of the 18 reactions examined, the majority of the estimated values fell in the range 1×10^7 to 1×10^8 M^{-1} s^{-1}. In an earlier study (12), a value of 4×10^9 M^{-1} s^{-1} was estimated for the cross-reaction of $Cr(bpy)_3^{2+}$ with $Cr(5,6\text{-diMephen})_3^{3+}$ in 0.1 M HCl – 90% methanol. In another study, an exchange rate of 1×10^9 M^{-1} s^{-1} was estimated from the rate constant for the reaction of $Co(sepulcrate)^{2+}$ with $Cr(5\text{-Mephen})_3^{3+}$ (5). On the other hand, a much lower value of 1×10^5 M^{-1} s^{-1} was estimated for the reduction of Fe^{3+} by $Cr(NN)_3^{2+}$ ions under acidic conditions (11).

At this point, it would also be interesting to examine the ground-state self-exchange rate ($Cr(NN)_3^{3+/2+}$) in the light of the excited state self-exchange rate ($Cr(NN)_3^{2+}$) (eq. [6]).

[6] $$*Cr(NN)_3^{3+} + Cr(NN)_3^{2+} \rightarrow Cr(NN)_3^{2+} + *Cr(NN)_3^{3+}$$

Here $*Cr(NN)_3^{3+}$ is the ^2E excited states of $Cr(NN)_3^{3+}$. Considering that the two pairs of reactants in the ground and excited state reactions (eqs. [5] and [6]) are very similar in size and charge type, it is expected that the solvent reorganization barrier and the work terms will be same for the two reactions. Assuming that both the reactions are adiabatic, they would differ only in their inner-sphere barrier. As the inner-sphere barrier for the ground- and the excited-state exchange reactions are the same, the $Cr(NN)_3^{3+/2+}$ and

© 2001 NRC Canada

$Cr(NN)_3^{*3+/2+}$ exchange reactions should be expected to proceed at similar rates. In earlier estimates of the excited-state self-exchange rate ($Cr(NN)_3^{2+}$), values of 1×10^8 M^{-1} s^{-1} (5) and 4×10^7 M^{-1} s^{-1} (10) were reported.[1] These estimated values for the excited-state exchange reaction fall in the middle of the range of values estimated in the present study for the ground-state self-exchange reaction, $Cr(NN)_3^{3+/2+}$. We conclude that the most likely value for the ground state self-exchange reaction ($Cr(NN)_3^{3+/2+}$) is very similar to the values of 1×10^8 M^{-1} s^{-1} or 4×10^7 M^{-1} s^{-1} estimated for the excited-state exchange reaction ($Cr(NN)_3^{2+}$).

For the few cases in Table 1 where significantly different values were obtained for the ground-state exchange reaction, it is suspected that such a discrepancy may be due to the uncertainties in the parameters used for the calculations or due to other contributing factors. For example, the value of 5×10^5 M^{-1} s^{-1} obtained for the $Cr(NN)_3^{2+}$–Fe^{3+} cross-reaction is certainly low, perhaps due to the reported non-adiabaticity of the Fe(II)/(III) couple or because of the large driving force of this reaction which might place it in the Marcus inverted region. For the $Cr(NN)_3^{2+}$–$Co(en)_3^{3+}$ reaction, two values have been reported for the cross-reaction which are almost an order of magnitude different from each other. One of the values (4×10^7 M^{-1} s^{-1}) is within the range for the majority of the values, whereas the other value (1×10^9 M^{-1} s^{-1}) appears to be too large.

The data in Table 1 shows that the majority of the reactions gave values for the ground-state exchange reaction that are relatively closely clustered, and are also in the same range as the excited-state self-exchange rate. Based on these results, we propose an average value of $(6 \pm 4) \times 10^7$ M^{-1} s^{-1} for the $Cr(NN)_3^{3+/2+}$ self-exchange reaction. This value by no means can be considered as the true value for that reaction, however, it is perhaps the best estimate so far as it is based on a relatively larger body of data and the parameters used to calculate the self-exchange reaction of the $Cr(NN)_3^{3+/2+}$ couple using Marcus cross relation are known with higher certainty.

Kinetic study of the proton transfer reaction between 1-nitro-1-(4-nitrophenyl)alkanes and TBD and MTBD bases in acetonitrile solvent

Iwona Grześkowiak, Włodzimierz Gałęzowski, and Arnold Jarczewski

Abstract: The rates of proton transfer reactions between C-acids of the series of nitroalkanes with increasing bulk of R = H, Me, Et, *i*-Pr substituent as: 4-nitrophenylnitromethane (**0**), 1-(4-nitrophenyl)-1-nitroethane (**1**), 1-(4-nitrophenyl)-1-nitropropane (**2**), 2-methyl-1-(4-nitrophenyl)-1-nitropropane (**3**) and 1,5,7-triazabicyclo[4.4.0]dec-5-ene (TBD), 7-methyl-1,5,7-triazabicyclo[4.4.0]dec-5-ene (MTBD) have been measured in acetonitrile at pseudo-first-order conditions. The product of the proton transfer reaction with MTBD in acetonitrile is dissociated into free ions while that of the TBD reaction is composed of a comparable amount of ions and ion pairs. The second-order rate constants (k_{2H}) for these bases of almost equal strength in acetonitrile (pK_a = 24.70, 24.97 for MTBD and TBD) and C-acids **1**, **2**, and **3** are: 317, 86, 7.6 dm^3 mol^{-1} s^{-1}; and 15 200, 5300, 1100 dm^3 mol^{-1} s^{-1}, respectively. The appropriate primary deuterium kinetic isotope effects (k_H/k_D) are 12.5, 10.8, 6.9; and 9.9, 11.2, 12.6. The influence of steric hindrance brought by reacting C-acids and bases is discussed. The different structure of the transition states and the products as mono- and double-hydrogen bonded complexes for these series of C-acids and MTBD and TBD bases is manifested by a distinct reaction mechanism which we attempt to explain.

Key words: proton transfer, kinetic study, C-acids, organic bases, acetonitrile, kinetic isotope effects.

Résumé : Opérant dans l'acétonitrile, dans des conditions de pseudo-premier ordre, on a mesuré les vitesses des réactions de transferts de proton entre le 1,5,7-triazabicyclo[4.4.0]déc-5-ène (TBD) et le 7-méthyl-1,5,7-triazabicyclo[4.4.0]déc-5-ène (MTBD) et les C-acides d'une série de nitroalcanes comportant des substituants R = H, Me, Et, *i*-Pr de plus en plus volumineux, comme les 4-nitrophénylnitrométhane, **0**, 1-(4-nitrophényl)1-nitroéthane, **1**, 1-(4-nitrophényl)-1-nitropropane, **2**, 2-méthyl-1-(4-nitrophényl)-1-nitropropane, **3**. Le produit de la réaction de transfert avec le MTBD dans l'acétonitrile est dissocié en ions libres alors que celui de la réaction avec le TBD est composé de quantités comparables d'ions et de paires d'ions. Les constantes de vitesse du deuxième ordre, k_{2H}, pour ces bases de force pratiquement égales dans l'acétonitrile (pK_a = 24,70 pour le MTBD et 24,97 pour le TBD) avec les C-acides **1**, **2** et **3** sont 317, 86 et 7,6 dm^3 mol^{-1} s^{-1} et de 15 200, 5300 et 1100 dm^3 mol^{-1} s^{-1} respectivement pour le MTBD et le TBD. On discute de l'influence de l'empêchement stérique qui se développe entre les C-acides et les bases. Les différentes structures des états de transition et des produits sous les formes de complexes avec une seule ou deux liaisons hydrogènes pour les C-acides et les bases MTBD et TBD se manifestent par des mécanismes de réactions distincts que l'on essaye d'expliquer.

Mots clés : transfert de proton, étude cinétique, C-acides, bases organiques, acétonitrile, effets isotopiques cinétiques.

[Traduit par la Rédaction]

Introduction

In our previous papers (1–4), we found that the proton transfer reaction from nitroalkanes differing by the bulk of R substituents and also by the types of electron withdrawing group, but having very similar acidity in acetonitrile, showed significant differences in the kinetic behavior particularly in the presence of a common BH^+ cation. Generally, the products of reactions of these systems of C-acids and strong guanidine and amidine bases in acetonitrile are at least 97% dissociated into free ions as indicated by conductometric measurements (4, 5). The reason why this went undetected in earlier spectrophotometric studies, in which the Benesi–Hildebrand formalism was applied, has been already explained in detail (1, 4, 5). Then a general indication for kinetic experiments of the proton transfer reactions, in particular those of not very large equilibrium constants, was to carry out measurements in BH^+–B buffer solutions to maintain reversible pseudo-first-order conditions (5, 6). However, large concentrations of BH^+ cation caused an anion association that was manifested by a blue shift in electronic spectra (6). Also in some cases the unexpected negative salt effect was observed (2). In our previous paper (1), a general equation for the rates of proton transfer reac-

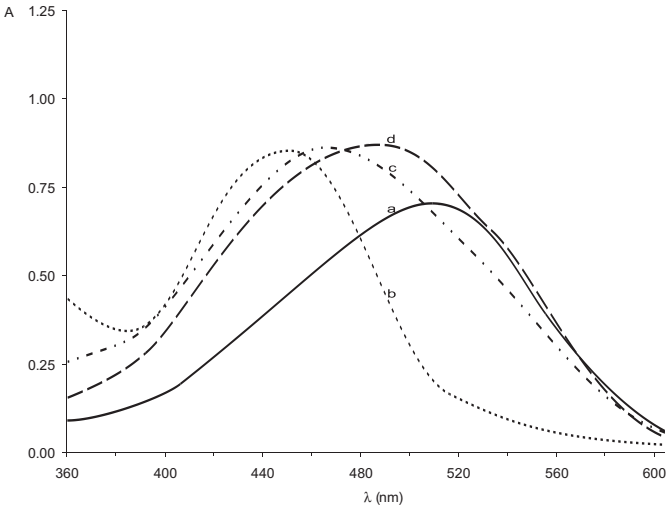
Scheme 1. C-acids and bases used in the experiments.

tions between C-acids and strong organic bases with a product existing in two forms, ions and ion pairs, was derived and its applicability tested for a number of the reaction systems. We found that this equation is fulfilled for most reaction systems, which is visible from the parallel plots of k_{obs} vs. base concentration for different [BH^+] concentrations (1). The reactions between C-acids **1**, **2** (7), and **3** (5) and MTBD base, that has a negligible homoconjugation constant (8) and very large basicity (9), show considerable decrease of second-order rate constants with the concentration of $MTBDH^+$ (1). The extent of this reduction increased with the bulk of alkyl substituent in the C-acid. This negative salt effect is rather unusual, since for reactions with transition state more polar than substrates, normally the increase of the rate constants with ionic strength is observed (10). The most reasonable explanation of this effect was to assume the mechanism including the pyramidal carbanion as an intermediate (11–13).

In this paper the results of kinetic and equilibrium experiments with the systems of reaction of proton transfer between C-acids **0**, **1**, **2**, and **3** and strong cyclic bases (TBD and MTBD in acetonitrile (MeCN)) are reported. It was interesting to study the different reactivity of TBD and MTBD bases and to compare these results with those obtained previously in THF solvent (2).

We also wanted to learn if the same pattern of reactivity with varying steric hindrance in the C-acid would be held in a polar medium as we already found a weak dependence of KIE values on this factor as well as steric hindrance of reactants (1–4). This prompted us to verify if the position of nitro groups (14) of reacting C-acids provided the predominant contribution in formation of the transition state (Scheme 1).

Experimental



Acetonitrile, the spectroscopic grade solvent from Romil, was stored over CaH_2, distilled over P_2O_5 and finally, fractionally distilled over CaH_2. The middle fraction was collected and stored under a nitrogen atmosphere, free from moisture and CO_2.

C-acids

4-Nitrophenylnitromethane (**0**) (4 and refs. cited therein), 1-(4-nitrophenyl)-1-nitroethane (**1**), 1-(4-nitrophenyl)-1-nitropropane (**2**), 2-methyl-1-(4-nitrophenyl)-1-nitropropane (**3**) were prepared according to procedures already published (4). The melting points and spectra after recrystallization from ethanol were in accordance with the literature.

The deuterated analogues of **1**, **2**, and **3** were prepared as previously described (4).

Fig. 1. Spectra for reactions of 1-(4-nitrophenyl)–1-nitropropane (**2**) (2.5×10^{-5} M) with TBD (1×10^{-3} M) and MTBD (1×10^{-3} M) in MeCN and THF solvents. Curves: (a) **2** with MTBD in MeCN, λ_{max} = 514 nm; (*b*) **2** with TBD in THF, λ_{max} = 450 nm; (*c*) **2** with TBD in MeCN, λ_{max} = 460 nm; (d) as c traces of oxygen present, red intermediate, λ_{max} = 488 nm.

Bases

1,5,7-Triazabicyclo[4.4.0]dec-5-ene (TBD) and 7-methyl-1,5,7-triaza-bicyclo[4.4.0]dec-5-ene (MTBD), commercial products from Aldrich, were used without further purification. The purity of the bases was satisfactory as tested by NMR and titration methods (16). The results of titration of base solutions were consistent with gravimetric concentrations within 1%.

The product of reaction of nitroalkanes with TBD in MeCN in an inert atmosphere (argon) was indefinitely stable. However, in the presence of atmospheric oxygen the band at ~460 nm slowly disappeared (Fig. 1*c*), which was accompanied by the appearance of a new band, very similar to nitronate ion (Fig. 1*a*), at $\lambda_{max} \cong 488$ nm (red intermediate) (Fig. 1*d*). This step of the reaction could be turned over to 460 nm, characteristic for the mixture of nitronate ions and ion pairs by saturation of the reaction mixture with argon. Repeated delivery of traces of atmospheric oxygen caused the appearance of the red intermediate until the concentration of the oxygen was not large or the exposure of the reaction to it was not long enough. In other words, the isosbestic point for the reaction of TBD could be observed in between anions – hydrogen bonded ion pairs and the red intermediate λ_{max} = 475 nm, (Fig. 1*c*, *d*) as far as the final product — ketone λ_{max} = 270 nm (not shown in Fig. 1) — is not formed. This caused the loss of the isosbestic point, indicating irreversibility of the reaction step to ketone (Scheme 2).

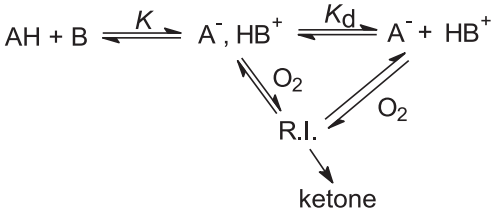
Addition of water to the ion pair, product protected with argon, did not cause visible appearance in the spectrum of the red intermediate. This eliminates the possibility that the atmospheric moisture facilitates dissociation of the ion pair. Then we presume that the red species is an oxidation product of the ion pair, to ketone (Scheme 2). The attempts to isolate or characterize this product, λ_{max} = 488 nm, by NMR spectrometry failed, possibly due to its very low concentration which eventually turns to ketone. We were unable to produce a larger concentration of this even by bubbling the air through concentrated solution of the ion-pair product in MeCN. The red oxidation intermediate absorbing at λ_{max} = 488 nm is not visible for the MTBD reaction where the double hydrogen bonded complex cannot be formed. The control experiments show that the presence of air had no effect on the reaction of MTBD with nitroalkanes when ion association to the mono-hydrogen-bonded complex was forced by a massive amount of BH^+ cation (6). Then, under aerobic conditions, we did not observe a slow increase in absorbtion band at λ_{max} = 488 nm. Moreover, in anaerobic conditions the initial product of the MTBD reaction shows λ_{max} = 514 nm band characteristic for nitronate anion excluding the possible "red intermediate". So we presume that the red species is characteristic only for the reaction of TBD.



The slow follow up oxidation of TBD product had no effect on the results of our proton transfer kinetic measurements, however, further experiments in a longer observation period, towards the careful identification of this red species that could be erroneously considered as free nitronate anion, seem to be necessary. Leffek and Matinopoulos-Scordou (18) already observed similar complicity for the reaction of ethyl bis(4-nitrophenyl)acetate with TMG in THF solvent. They suggested the reaction pathway via three colored species: carbanion (λ_{max} = 513 nm), presumably a radical anion (λ_{max} = 665 nm), and finally dinitrobenzophenone (λ_{max}= 292 nm). A similar type of reaction sequence has been noted for the base-catalyzed autooxidation of substituted esters (19), however there were no further suggestions why this particular carbanion is susceptible to oxidation in the presence of excess base and an electron acceptor as atmospheric oxygen present in the reaction system.

The working solutions of C-acids and bases were prepared freshly before each kinetic or equilibrium experiment and kept under argon, to protect the system against atmospheric CO_2, O_2, and moisture. Kinetic measurements were performed using a stopped flow spectrophotometer made by Applied Photophysics. The values of k_{obs} were measured for typically five concentrations of base in a large excess over C-acid [2.5×10^{-5} M] to ensure pseudo-first-order kinetics (Tables 1 and 2). The second-order rate constants k_f were obtained by the least-squares calculation. The activation parameters were evaluated from these by means of the method of the least-squares fit to the transition-state theory equation.

Electronic absorption spectra were completed on a Hewlett-Packard 8452A diode array spectrophotometer using a thermostated cell holder. All spectra were recorded at 25°C.

The value of spectrophotometric equilibrium constant K of 0.352 for the reaction between **3** and MTBD in acetonitrile was calculated using the following equation: $K = f^2[BH^+][A^-]/[B][AH]$. $[A^-]$ was found from the absorbance at λ = 600 nm, where the absorption of the ion pair is negligible, [AH] was calculated as a difference of an analytical C-acid's concentration and the sum of ($[A^-]$ + [ion pair]). The K_d used for calculation of [ion pair] is 0.0024 (6).

Scheme 2. Equilibrium between nitronate anions and hydrogen-bonded ion pairs for the reaction of TBD and C-acids: **0**, **1**, **2**, **3** in MeCN. (AH (C-acids **0**–**3**), B (TBD base), A^-HB^+ (hydrogen-bonded ion pair), R.I. (red intermediate), ketone).

The proton transfer for these systems of reactions is complete in the concentration ranges shown in Tables 1 and 2.

The conductometric titration of **3** with TBD in MeCN was carried out at 25°C. Initial concentration of **3** was 2×10^{-2} M. The conductometric cell was protected against moisture, CO_2, and O_2 with argon. The measurements were completed using a Tesla BM–484 semiautomatic conductivity bridge operating at 1592 Hz with a conventional, calibrated cell with platinum electrode. The cell constant was 0.8744 cm^{-1} (5).

Results and discussion

The reaction of a series of C-acids with different steric hindrance (Scheme 1) with MTBD in acetonitrile gives colored nitronate anions of λ_{max} = 508, 514, and 515 nm for **1**, **2**, and **3** respectively (Fig.1*a*) while the spectrum of TBD product is a sum of the two spectra for free nitronate anions and ion pairs (Fig. 1*c*) (6). The λ_{max} = 460 nm for ion pairs and nitronate anions (Fig. 1*c*), for reaction of **2** with TBD in MeCN, is close to that of λ_{max} = 450 nm found in THF (Fig. 1*b*), where the dissociation of the ion-pair product is meaningless (2). Generally, the same pattern of the products is observed for C-acids **1**–**3** including 4-nitrophenylnitromethane (**0**), which could be considered as the least hindered compound in this series.

Then the mechanism of reaction could be illustrated by Scheme 2.

This observation is general for C-acids **0**–**3**. Thus, the dissociation constant measured for TBD with **0** was $K_d = 0.81 \times 10^{-4}$ M while with MTBD the corresponding value was 100 times larger ($K_d = 1.15 \times 10^{-2}$ M) (6). The rough conductometric K_d value for the ion-pair product of **3** with TBD was $K_d = 5 \times 10^{-4}$ M, $\Lambda_o = 151.6 \pm 0.1$ ohm^{-1} cm^2 mol^{-1} while with MTBD the corresponding value was $K_d = 2 \times 10^{-3}$ M (6).

The range of the base concentration was chosen to minimize the contribution of the reverse reaction to the observed rate constant k_{obs} so the plots of k_{obs} vs. [B] concentration cross the origin within the standard deviation (Fig. 2). Then the values of the rate constant for the backward reaction (k_b) could be omitted. This enabled us to perform the kinetic measurements of these proton transfer reactions in the absence of BH^+–B buffer (1, 5, 6).

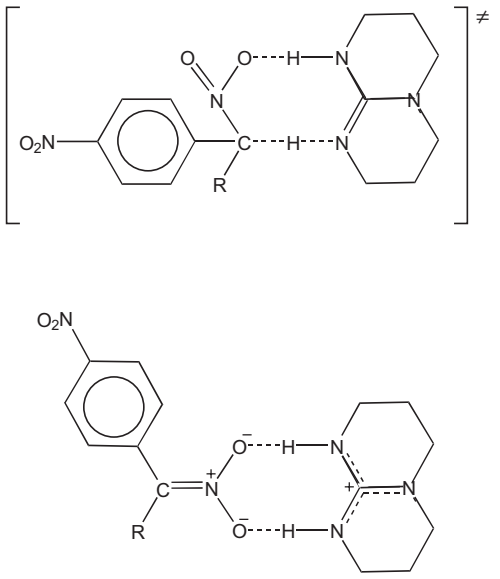
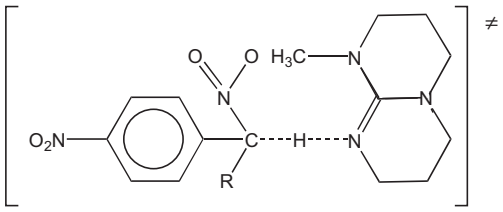
[d]Data from ref. 2.

Then observed values of rate constants were a function of base concentration [B], according to following equation,

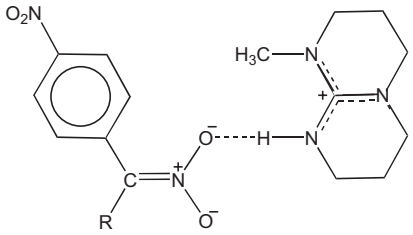


$$[1] \qquad k_{obs} = k_2[B]$$

where k_{obs} (s^{-1}) is the observed rate constant, k_2 (dm^3 mol^{-1} s^{-1}) is the rate constant of the forward reaction, and [B] is the base concentration.



The rate constants k_2 were calculated using k_{obs} values collected in Tables 1 and 2. The errors quoted for proton k_{2H} and deuteron k_{2D} transfer reactions are standard deviations.



Rate constants k_{2H} for the reactions of C-acids **1**–**3** and TBD base (Table 1) decrease by one order of magnitude along with growing bulk of R substituents (15 200, 5300, and 1100 dm^3 mol^{-1} s^{-1}). A similar relation is observed for the reaction of more hindered base MTBD (Table 2), although for much smaller rate constants (317, 86, and 7.6 dm^3 mol^{-1} s^{-1}) due to different structure of the transition state which is not stabilized by two hydrogen bonds as occurred for the TBD reaction (20, 21) (Scheme 3).

Scheme 3. Structures of the transition state and the product for the proton transfer between C-acids: **0**–**3** and TBD and MTBD bases in acetonitrile solvent.

Reaction product

Reaction product

The ratios k_{TBD}/k_{MTBD} varied considerably with the structure of C-acid and were 4–7, 26, and 55 for deprotonation of diarylmethanes (16), ethyl bis(4-nitrophenyl)acetate (22), and dimethyl(4-nitrophenyl)malonate (23), respectively. These ratios evaluated for reactions of **1**–**3** in THF were

Scheme 4. Low-energy conformers of 1-(4-nitrophenyl)-1-nitropropane (**2**) and 2-methyl-1-(4-nitrophenyl)-1-nitropropane (**3**).

much larger (118, 146, and 287, respectively (2)). The influence of position of nitro groups in nitro-substituted diarylmethanes on the k_{TBD}/k_{MTBD} = 4–7 is distinct as was estimated before by kinetic methods (16). This effect is not as large as for the present system of reactions where k_{TBD}/k_{MTBD} = 48–150 depending on the structure of C-acids **1**–**3** (Tables 1 and 2).

Generally, along with the growing bulk of the R substituent, significant reduction of the rate constants is observed which is consistent with earlier observations made by Bordwell and co-workers (24, 25). This indicates that the steric factors play an important role, and is similar with the results reported by other authors for the case of presence of different crowding in the vicinity of the reaction center (26–30). This relation is consistent with increased steric inhibition to planarity in the carbanion and most of all different structure of the complex of the transition state (2).

The KIEs' values are moderately large, but almost invariable ranging from 10–13 for TBD base, with the tendency to be larger for more hindered C-acids: 9.9, 11.2, 12.6 for **1**, **2**, and **3**, respectively (Table 1).

The unusual KIE values are obtained for the reaction with MTBD (Table 2) where they are declining with the increase of bulk of the R substituent: 12.5, 10.8, 6.9. Usually the steric hindrance causes an increase of KIE due to either desolvation of the transition state or a steeper energy barrier (4, 30). However, just the reverse effect was already found that steric hindrance in both the base and C-acid may in fact reduce the KIE (3, 4, 26).

The rate constants and KIE are insensitive to the polarity of the solvent (Table 3). One can expect much faster ionogenic reaction in polar MeCN than nonpolar CB. The fastest reaction in this set of C-acids has been observed for TBD both in MeCN and THF while for MTBD the rates are two orders of magnitude smaller. Then we presume that the charge separation in two different hydrogen-bonded complexes of transition state for TBD and MTBD reactions (Scheme 3) is not advanced. This is manifested by the meaningless influence of polarity of the solvent, also suggesting an uncoupled mechanism (31).

The different mechanism for the reactions of **1**–**3** with TBD and MTBD is reflected in the values of activation parameters collected in Table 4.

The large, negative $\Delta S^{\neq}$ values close to –110 J mol^{-1} K^{-1} for TBD and MTBD are characteristic for ionogenic mechanism of reaction. There is a distinct increase in $\Delta H^{\neq}$ together with the bulk of R in the sequence of C-acids for reaction with DBU. The largest value of enthalpy of activation ($\Delta H^{\neq}$) has been found for the most hindered reaction between **3** and MTBD (Table 4). There is a significant difference between the $\Delta H^{\neq}$ found for TBD and MTBD reactions with **3** ($\Delta H^{\neq}_{TBD}$ = 19.4 and $\Delta H^{\neq}_{MTBD}$ = 33.2 kJ mol^{-1}) indicating a different mechanism for the latter reaction. The simultaneous increase of enthalpy of activation ($\Delta H^{\neq}$) and negative values of entropy of activation ($\Delta S^{\neq}$) along with increasing steric hindrance of reactants cause a rise in free enthalpy of activation ($\Delta G^{\neq}$) of 6.7 and 9.3, for TBD and MTBD, respectively. Hence, the lack of a compensating effect suggests that restriction of free motion within the active complex rather than desolvation of the transition state determine the changes of the entropy of activation.

The reactions with TBD and MTBD show different patterns of the effect of steric hindrance on KIE. The KIE values grow with steric hindrance for the TBD reaction while with DBU and MTBD, the reverse effect was observed (Table 3). In the case of the TBD reaction, the double hydrogen bond determines the structure of the transition state (Scheme 3) (2, 23). By means of PM3 level computation, with the assumption of the T.S. structure (Scheme 3), it was proved that generally for reaction of C-acids **1**–**3** with TBD base, the HCNO dihedral angle in the T.S. complex decreases along with the bulk of R substituent in the C-acid.

The reaction with MTBD proceeds with different structures of T.S. complexes (Scheme 3). The PM3 calculation level applied for the most stable conformer of **3** with

© 2001 NRC Canada

antiperiplanar positions of the hydrogen atoms with MTBD base show three energetically equivalent T.S. complexes with the Me group of the base located in between NO_2 and $PhNO_2$, $PhNO_2$ and *i*-Pr, NO_2 and *i*-Pr (Scheme 4). The same computation applied for C-acid **2** with MTBD indicated the lowest energy conformer for T.S. complex with the Me group of the base located between $PhNO_2$ and Me groups (Scheme 4).

In this case, the HCNO angle is small, i.e. the nitro group is almost coplanar with the proton transfer axis. For the least hindered C-acid **1**, the Me group of the MTBD base is always located between NO_2 and $PhNO_2$. The MTBD transition states are characterized by a larger level of energy, than in the case of TBD, which is in good agreement with a little larger values of enthalpy of activation (Table 4).

Thus, the reaction of MTBD proceeds with different structures of transition state than the TBD reaction (Scheme 3), where along with growing bulk of substituent R in C-acid, a decrease in HCNO angle is found. Hence, the conclusion can be drawn, that the smaller the angle the larger is KIE.

The results of this work indicate two factors influencing KIE values. The additional stabilization of the transition state by a hydrogen bond, such as in TBD reactions, seems to increase KIE. Steric hindrance in C-acid, which affects the HCNO angle in the transition state of the TBD reaction, also increases KIE.

The above conclusions could be summarized in a statement that, for the reactions of nitroalkanes with guanidine bases, the KIE values increase when the structure of the transition state is less product-like.

In conclusion, we claim that the KIE values are greatly influenced by the factor resulting from the structure of the complex of transition state which is formed with hydrogen bonds between a base and oxygen atom of nitro groups of reacting C-acid. The further study of this problem seems to be advisable.

Equilibrium geometry, vibrational frequencies, and heat of formation of HOBr, $HBrO_2$, and $HBrO_3$ isomers

Cristina Maria P. Santos, Roberto B. Faria, Juan O. Machuca-Herrera, and Sérgio de P. Machado

Abstract: The equilibrium geometries, vibrational frequencies, heat capacity, and heat of formation for compounds of general formula $HBrO_x$ were calculated by DFT (BP and pBP methods) with DN* and DN** numerical basis sets. The comparison of our HOBr calculated results with the HOBr experimental values points out that the BP and pBP methods are as good as other ab initio and DFT methods related in the literature employing extended basis sets. The calculated $HBrO_x$ total energy and heat of formation values, at 0 and 298.15 K, present the following order: HOBr < HBrO; HOOBr < HOBrO < $HBrO_2$; HOOOBr < $HOBrO_2$ < HOOBrO < $HBrO_3$. The $HBrO_x$ heat of formation was calculated using isodesmic and homodesmic reactions and the results show that, in general, the use of these reactions gives similar results.

Key words: HOBr, $HBrO_2$, $HBrO_3$, DFT, numerical basis.

Résumé : Utilisant des ensembles de base numériques DN* et DN**, on a déterminé les géométries d'équilibre, les fréquences vibrationnelles, les capacités calorifiques et les chaleurs de formation de composés de formule générale $HBrO_x$ à l'aide de calculs DFT (méthodes BP et pBP). La comparaison des valeurs que nous avons calculées pour HOBr avec les valeurs expérimentales correspondantes suggère que les méthodes BP et pBP sont aussi bonnes que d'autres méthodes ab initio et DFT apparentées de la littérature qui font appel à des ensembles de base élargis. Les valeurs calculées, à 0 K et à 298,15 K, pour l'énergie totale et la chaleur de formation des $HBrO_x$ sont dans l'ordre suivant: HOBr < HBrO < ; HOOBr < HOBrO < $HBrO_2$; HOOOBr < $HOBrO_2$ < HOOBrO < $HBrO_3$. La chaleur de formation des $HBrO_x$ a été calculée à l'aide de réactions isodesmiques et homodesmiques et les résultats montrent que, en général, l'utilisation de ces réactions conduit à des résultats semblables.

Mots clés : HOBr, $HBrO_2$, $HBrO_3$, DFT, ensembles de base numériques.

Introduction

Halogen compounds are involved in the mechanisms of ozone depletion in the stratosphere and underlying troposphere (1, 2). These reactions occur in catalytic cycles including free radicals as well halogen oxides and some of them connect bromine and chlorine chemistry to the destruction of the ozone layer (3). In addition to the very well known effect of chlorine compounds, Barrie et al. (4) have shown that a lower level of ozone can be related to a high concentration of the bromine compounds in the atmosphere. These authors associated the ozone depletion to the photochemistry of bromoform ($CHBr_3 + h\nu \rightarrow Br\cdot + CHBr_2\cdot$) and to catalytic reactions involving BrO_x radicals. Related to a global impact on the ozone layer, the bromine species has been responsible for 40% and 25% of the ozone loss over Arctic and Antarctica regions, respectively, during the winter (5, 6). Other experimental results (7–9) have suggested that the reaction $BrO\cdot + HO_2\cdot \rightarrow HOBr + O_2$ proceeds faster than had been supposed before by Cox and Sheppard (10). Elrod et al. (11) proposed a temperature dependence for this reaction and also determined HBr and O_3 as another possible products. More recently, McElroy et al. (12) associated the enhanced concentrations of bromine species in the atmosphere to catalytic reactions involving bromine monoxide, originated from the sea salt accumulated on the snow pack.

With all this bromine chemistry being proposed, we have decided to use the HOBr to verify the ability of theoretical methods and basis set to calculate the equilibrium geometry, vibrational frequencies, and heat of formation of compounds involving hydrogen, oxygen, and bromine atoms. This choice was made considering that the HOBr contains three elements related with catalytic cycles of ozone depletion, presents several theoretical results in the literature, and has known experimental values.

In this study, we employed the BP and pBP density functional models with numerical basis set using the Spartan 5.0. The comparison of the calculated HOBr results with experimental values have shown that these theories are as good as

other ab initio and DFT methods employing extended basis sets. Based on these HOBr results, we applied BP and pBP models to forecast the equilibrium geometry, vibrational frequencies, and the thermodynamic properties for all HOBr, $HBrO_2$, and $HBrO_3$ isomers.

Several theoretical studies have been done for the HOBr and the HBrO isomers. McGrath and Rowland (13), based on Gaussian-2 theory, determined the ideal gas heat of formation of HOBr. Lee (14) used the CCSD(T) level of theory, with a triple ζ-polarized basis set, for the determination of equilibrium structures, vibrational frequencies, quadratic force fields, dipole moments, and IR intensity of HOBr, HBrO, and other triatomic bromine compounds. Francisco et al. (15), using 962(d)/6-311G(d,p) basis, reported MP2, CISD, CCSD(T), and MRCISD optimized geometries and total energies for the HOBr ground state. These authors also calculated the vibrational frequencies by MP2, CISD, and CCSD(T) methods. Ying and Zhao (16) employed MP2 and B3LYP models with a basis set including polarization functions (6-311G(d,p)) and polarization and diffuse functions (6-311++G(d,p)) to obtain HOBr geometry and vibrational frequencies. Equilibrium geometry and harmonic frequencies for HOBr using CCSD(T) method with pseudo+TZ2P basis were determinated by Füsti-Molnár et al. (17). The HOBr and HBrO equilibrium geometries were determinated by Li and Francisco (18) using the CCSD(T) method with 6-31G, 6-311G (2d,2p), 6-311G (2df,2p), and 6-311G(3df,3pd) basis sets while the vibrational frequencies were calculated only by the 6-31G and 6-311G(3df,3pd) basis sets.

For the $HBrO_2$ isomers, only four theoretical works were found. Lee (19) using CCSD(T) level of theory, with the TZ2P basis set, calculated the equilibrium geometries, dipole moments, harmonic vibrational frequencies, and rotational constants for the HOOBr, HOBrO, and $HBrO_2$ molecules. Based on the isodesmic reaction HOOBr + HOH →HOOH + HOBr, where the same number of bond types is maintained on the reactants' and on the products' side, Lee (19) also determinated the heat of formation of the $HBrO_2$ isomers. Guha and Francisco (20) made the same determinations employing various density functional methods (BLYP, SVW, and B3LYP) with the 6-311++G (3df,3pd) basis set. The energies for the $HBrO_2$ isomers were calculated using the G2 and CCSD(T) methods based on the geometries forecasted by the B3LYP theory with 6-311++G(3df,3pd) basis set. More recently, Guha and Francisco (21, 22) studied the isomerization pathways for the $HBrO_2$ isomers. The geometries, vibrational frequencies, and relative energies were obtained for the $HBrO_2$ isomers and their transition states using the QCISD method with 6-31G(d), 6-311G(d,p), and 6-311G(2d, 2p) basis sets (21). Also using the QCISD method, they determined the equilibrium geometry, vibrational frequencies, and relative energies for the HOOBr → HOBrO isomerization transition state (22).

The $HBrO_3$ isomers were studied by Guha and Francisco (23, 24). In the first work, these authors determined the equilibrium geometries, vibrational frequencies, and relative energies for the HOOOBr, $HOBrO_2$, HOOBrO, and $HBrO_3$ molecules using ab initio (MP2, CISD, and CCSD(T)) and DFT (B3LYP) methods, with TZ2P and 6-311++G(3df,3pd) basis sets. The HOOOBr heat of formation was calculated based on the isodesmic reaction HOOOBr + 2HOH → 2HOOH + HOBr. In the second work, they determinated the geometries, vibrational spectra, and relative energies for the HOOOBr and HOOBrO isomers using the quadratic configuration interaction method (QCISD) with 6-31G(d,p), 6-311G(d,p), and 6-311G(2d,2p) basis sets.

The density functional methods employed in this work present a basic difference to the other methods because it employs numerical basis sets (25) and not the more common Gaussian basis sets. Comparisons of bond distances and dipole moments calculated using numerical and Gaussian basis sets suggest that DN* and DN** numerical basis sets perform similar to 6-31G(d) and to 6-311G(d,p) basis sets, respectively (25). Because of this, numerical basis sets have been employed recently on studies involving rare gas dimers (26), heterocycle compounds (27, 28), and annelated oxirenes (29) and has been claimed as performing as good as some of the most sophisticated Gaussian basis sets (29). In addition, comparisons between numerical and their similar Gaussian basis sets has shown that the relative computational time are greater for the Gaussian basis sets than for the numerical basis sets making the last more attractive (25).

Computational methods

All calculations were done using SPARTAN (Wavefunction Inc., Irvine, California), Version 5.0, on a RISC 6000 workstation, using the density functional method (DFT). In doing this, two different nonlocal DFT models were used. These models are based on nonlocal corrections added to the local density model as proposed by Becke (30) and Perdew (31). In the Becke–Perdew (BP) model, a new potential, comprising a local part and a gradient correction (32), is used in place of the local potential in the self-consistent field (SCF) procedure. This gradient correction needs to be recalculated at every SCF iteraction. In the perturbative Becke–Perdew (pBP) model, an alternative computational approach is used and the gradient correction is introduced only after the convergence based on the local potential alone has been achieved. Both DN* and DN** numerical basis sets employed in DFT calculations describe the inner shell of each atomic orbital by a single function and the valence shell by a pair of functions and include a set of five *d*-type polarization functions for all atoms except hydrogen. The DN** is identical to DN* except for the fact that it includes *p*-type polarization functions for hydrogen atoms.

The zero-point vibrational energy (*ZPVE*) and vibrational thermal energy (E_{vib}) were obtained directly from the program, based on eqs. [1] and [2].

$$[1] \qquad ZPVE = 0.5 N_A h \Sigma \nu_i$$

$$[2] \qquad E_{vib} = RT \Sigma [(h\nu_i/kT)/(e^{h\nu_i/kT} - 1)$$

Where N_A is Avogadro's number, h is the Planck constant, ν_i is the fundamental vibrational frequency, k is the Boltzmann constant, R is the perfect gas constant, and T is the temperature in kelvin scale (33).

Results and discussion

HOBr — geometry, vibrational frequencies, and C_p^0

The calculated equilibrium geometries, total energies, and vibrational frequencies for the HOBr isomer can be found in Table 1. The calculated equilibrium geometry has the expected angular geometry (C_S symmetry). The comparison of BP and pBP geometries with the experimental values shows that the O—Br bond length is more difficult to reproduce than the H—O bond length. Despite the closer proximity of all calculated equilibrium geometry values with the experimental ones, the CCSD(T)/pseudo+TZ2P used by Füsti-Molnár et al. (17) (H—O = 0.965 Å, O-Br = 1.834 Å, HOBr = 102.3°) is slightly better than all other results in the literature.

The comparison of calculated vibrational frequencies related in the literature with the experimental values shows that H—O stretching is the most difficult to reproduce, being generally overestimated, in some cases by more than 200 cm^{-1}. Based on this, our DFT results can be considered in good agreement with the experimental values, mainly for HOBr bend and HO stretch frequencies. From these results, we can say that BP and pBP methods with DN* and DN** numerical basis sets are a good option to forecast vibrational frequencies for bromine compounds.

The HOBr heat capacity (C_p°) was calculated based on the summation, at 298.15 K, of the vibrational ($C_{p\ vib.}^\circ$), translational ($C_{p\ trans.}^\circ$), and rotational ($C_{p\ rot.}^\circ$) contributions, as shown by eqs. [3]–[5], respectively (33). The molecule was considered a rigid rotor and an harmonic oscillator.

$$[3] \qquad C_{p\ vib.}^\circ = R\Sigma\{(h\nu_i/kT)^2[(e^{h\nu_i/kT})/(e^{h\nu_i/kT} - 1)^2]\}$$

$$[4] \qquad C_{p\ trans.}^\circ = 5/2R$$

$$[5] \qquad C_{p\ rot.}^\circ = 3/2R$$

Both HOBr heat capacity values (C_p°) obtained by BP and pBP methods (at 298.15 K) are very close to the 9.2 cal mol^{-1} K^{-1}, in agreement with the McGrath and Rowland (13) result of 9.18 cal mol^{-1} K^{-1}.

HBrO — geometry, vibrational frequencies, and C_p^0

For the HBrO isomer, with angular geometry (C_S symmetry), the results are also listed on Table 1. The DFT results show this isomer at approximately 0.09 hartree higher than HOBr, in agreement with Lee (14) whocalculated this difference as 0.1 hartree. For vibrational frequency, our DFT values are closer to the CCSD results (18).

Considering that CCSD methods has calculated HOBr geometry in good agreement with the experimental values and supposing that the same tendencies will be maintained for the HBrO, the geometries obtained by these methods (14, 18) should be the most probable. Otherwise, based on the fact that DFT methods gave a good set of results for the HOBr vibrational frequencies, we can be confident of the following prevision for the HBrO isomer: $\nu_{Br\text{-}O} \cong 700$ cm^{-1}, $\delta_{HOBr} \cong 780$ cm^{-1}, and $\nu_{H\text{-}Br} \cong 2000$ cm^{-1}.

HOBr and HBrO heat of formation

The HOBr heat of formation was calculated using eq. [7], based on the same isodesmic reaction (rxn. [6]) employed by McGrath and Rowland (13).

$$[6] \qquad HOBr + ClO\cdot \rightarrow HOCl + BrO\cdot$$

$$[7] \qquad \Delta H_f^\circ\ (HOBr) = \Delta H_f^\circ\ (HOCl) + \Delta H_f^\circ\ (BrO\cdot) - \Delta H_f^\circ\ (ClO\cdot) - \Delta H_r$$

The ΔH_r (heat of reaction) was obtained from the calculated values for all species in rxn. [6]. The experimental ΔH_f° values for the species in the right side in eq.[7] were obtained from *NIST–JANAF Thermochemical Tables* (34).

	[12]	–1.039 (–1.155)	–13.3 (–10.7)	42.27 (44.85)
	[13]	0.293 (0.416)	–13.6 (–11.0)	41.91 (44.48)
Experimental (35)		—	–13.59 (–11.09)[b]	—
Experimental (36)		—	–14.3 (–11.8)	—
Benson's value (37)		—	–19[c]	—
Experimental (38)		—	–9[c]	—

[a]Values in parenthesis are at 0 K.
[b]Values corrected considering ΔH_f^0(OH) of 9.175 kcal mol^{-1} (at 0 K) and 9.318 kcal mol^{-1} (at 298.15 K) (34).
[c]Values at 300 K.

At 298.15 K,

$$[8] \quad \Delta H_r = \Delta E + \Delta ZPVE + \Delta E_{vib} + \Delta E_{rot} + \Delta E_{trans} + \Delta nRT$$

where ΔE is the electronic energy calculated by the quantum mechanical program and Δn is the change in the number of mol. In eq. [8], each term was obtained from the difference between the calculated values for products and reactants. Considering that for rxn. [6] Δn is equal to zero and $\Delta E_{rot} = \Delta E_{trans} = \Delta n(3/2)RT$ for angular molecules ($\Delta E_{rot} = \Delta nRT$ and $\Delta E_{trans} = \Delta n(3/2)RT$ for linear molecules), the expression above becomes

$$[9] \quad \Delta H_r = \Delta E + \Delta ZPVE + \Delta E_{vib}$$

At 0 K, the heat of reaction is given by

$$[10] \quad \Delta H_r = \Delta E + \Delta ZPVE$$

Considering only isodesmic rxn. [6], it can be seen in Table 2 that ΔH_f°(HOBr) values, calculated by BP and pBP methods, at 298.15 K, are close to –22 and –14.5 kcal mol^{-1}, respectively. This 7.5 kcal mol^{-1} difference between these two values can be attributed to the 8.0 kcal mol^{-1} difference found between the total energy values obtained for ClO· using the BP and pBP methods. It was a surprise that such a difference was not observed for BrO·. In addition, the pBP values are very close to the McGrath and Rowland (13) result of –14.2 kcal mol^{-1}, that was obtained using Gaussian-2 theory. These pBP and G2 values are in good agreement with the experimental Ruscic and Berkowitz's value (35) (at 298 K) of –13.59 ± 0.42 kcal mol^{-1} and Lock and co-workers's (36) value of –14.3 ± 1 kcal mol^{-1}. The Ruscic and Berkowitz value presented here was corrected for the more recent ΔH_f° (OH) of 9.175 kcal mol^{-1} (at 0 K) and 9.318 kcal mol^{-1} (at 298.15 K) listed in the *NIST–JANAF Thermochemical Tables* (34). Benson's (37) and Monks and co-workers's (38) values are very different to these mentioned results. Based on the proximity of the Ruscic and Berkowitz (35) and Lock et al. (36) experimental values, we consider these two results as the more reliable. Consequently, we can say that the pBP theory results are in good agreement with the most reliable experimental results.

At 0 K, our pBP HOBr heat of formation values, determined using rxn. [6], are very close to the G2 value (13) of –11.7 ± 1.6 kcal mol^{-1} and the experimental values (35, 36) of –11.09 ± 1 kcal mol^{-1} (corrected for the OH heat of formation of 9.175 kcal mol^{-1}) and –11.8 ± 1 kcal mol^{-1}.

From the comparison of our results and the experimental values we conclude that the pBP level of theory, with DN* or DN** numerical basis set, gives good results for calculations of thermodynamic properties of HOBr based on isodesmic rxn. [6]. As can be seen from the small difference of 0.4 kcal mol^{-1} between the results using DN* and DN**, the polarization on hydrogen included in the DN** basis set did not make a significant difference for the description of HOBr and HOCl molecules used in isodesmic rxn. [6]. Otherwise, the BP model was not able to handle the ClO· radical and turned the ΔH_f° (HOBr) calculated value far from the more reliable experimental results.

The HBrO heat of formation presented on Table 2 was obtained based on the calculated relative energy to HOBr. Considering only the pBP theory and isodesmic rxn. [6] we can

ν_{H-Br}	1724	1761	1663	1703

state that the ΔH_f° (HBrO) is close to 40 kcal mol^{-1} (at 298 K).

Isodesmic and homodesmic reactions

As can be noticed in Table 2, the HOBr heat of formation values obtained by the BP model using rxn. [6] are significantly lower than the values obtained using the pBP model. This posed a question to us about the validity of the employment of isodesmic reactions involving open shell molecules. In this way, we have decided to try other reactions to calculate the HOBr heat of formation. In these reactions called homodesmic after Lee (14), the number of bonds of the same type was conserved but not necessarily between the same atoms. In Table 2 we also present the HOBr heat of formation calculated by the homodesmic rxns. [11]–[13].

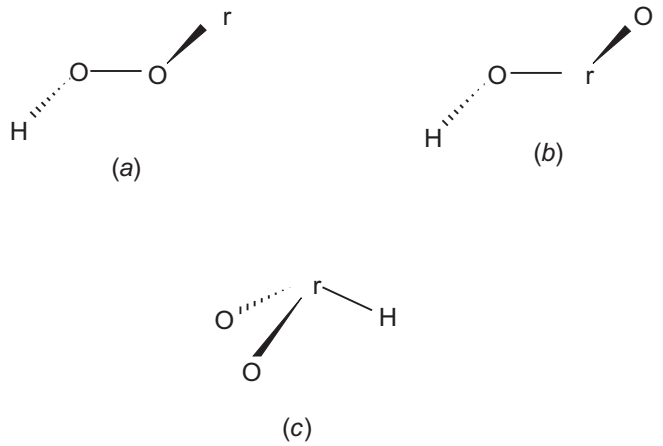
[11] $HOBr + HCl \rightarrow HOCl + HBr$

[12] $HOBr + Cl_2 \rightarrow HOCl + BrCl$

[13] $HOCl + Br_2 \rightarrow HOBr + BrCl$

As can be seen in Table 2, all calculated HOBr heat of formations using homodesmic rxns. [11]–[13] are very close to each other and close to the more reliable experimental values in a range of 2 kcal mol^{-1}.

$HBrO_2$ isomers — relative energies, geometry, vibrational frequencies, and C_p^0



The equilibrium geometry energy values obtained in this work provided the following order: HOOBr < HOBrO < $HBrO_2$. This stability order is the same found by Lee (19) and Guha and Francisco (20). The average energy values for HOOBr, HOBrO, and $HBrO_2$ are equal to –2725.483 hartree, –2725.481 hartree, and –2725.395 hartree, respectively, and agree well with the Guha and Francisco (20) values that used BLYP and B3LYP theories.

The calculated equilibrium geometries, total energies, and vibrational frequencies are presented in Tables 3 and 4 for all $HBrO_2$ isomers. The $HBrO_2$ isomers have their calculated structures presented in Fig. 1.

For the HOOBr, our pBP/DN* O—O value is equal to the value calculated by Guha and Francisco (20, 21) using the B3LYP/6-311++G(3df,3pd) and QCISD/6-311G(d,p), but

© 2001 NRC Canada

Fig. 1. Calculated structures for $HBrO_2$ isomers: (*a*) HOOBr, (*b*) HOBrO, and (*c*) $HBrO_2$. See Table 3 for geometrical parameters.

our H—O and Br—O bond lengths are longer. Angle values are in close agreement with the BLYP and B3LYP methods (20), both with the 6-311++G basis set. In general, our calculated vibrational frequencies are in good agreement with other calculated values (19–21). The calculated HOOBr heat capacity points to a value of 12.8 cal mol^{-1} K^{-1}.

For the HOBrO isomer our average calculated dihedral angle of 81.3° is very close to the other calculated results (19–22). Our H—O, Br—O_t, and Br—O bond length values are in good agreement with those calculated by the BLYP (20) and QCISD (21) methods. The HOBr and $OBrO_t$ angles are in concordance with the values presented on the literature (19–21). For the vibrational frequency our calculated BP and pBP torsion values (τ) are smaller than CCSD(T) and B3LYP methods (19, 20) but agree very well with BLYP and QCISD methods (20, 21). The $\nu_{Br\text{-}O}$ and the $\nu_{Br\text{-}Ot}$ values are in good agreement with the CCSD(T) (19) and BLYP (20) methods, respectively. Our $\nu_{H\text{-}O}$ average value of 3578 cm^{-1} is closer with the BLYP (20) result than the other calculated values. Our OBrO and HOBr bend values are in agreement with the CCSD(T) (19) and BLYP (20) values, respectively. All HOBrO heat capacity determinated in this work point to a value of 13.5 cal mol^{-1} K^{-1}, being independent of the method or basis set employed.

The $HBrO_2$ isomer with C_1 symmetry, presents the H—Br and Br—O bond lengths and the HBrO and OBrO angles in agreement with the values obtained by Guha and Francisco (20, 21). Our calculated vibrational frequencies are very close to the BLYP (20) values. The predicted BP and pBP $HBrO_2$ heat capacity value is 12.5 cal mol^{-1} K^{-1}.

$HBrO_2$ isomers — heat of formation

As $\Delta n = 0$, the eqs. [9] and [10] can be used to obtain all the heat of reaction (ΔH_r) values. Table 5 presents the heat of reaction and the HOOBr, HOBrO, and $HBrO_2$ heats of formation obtained by the use of the rxns. [14] and [16]. The HOBrO and $HBrO_2$ values were obtained from their calculated relative energies to the HOOBr isomer.

For isodesmic rxn. [14], we have

[14] HOOBr + HOH → HOOH + HOBr

[15] ΔH_f° (HOOBr) = ΔH_f° (HOOH) + ΔH_f° (HOBr) − ΔH_f° (HOH) − ΔH_r

In eq. [15], the HOOH and HOH ΔH_f° experimental values were taken from *NIST–JANAF Thermochemical Tables* (34). For the HOBr heat of formation we have used the values of –11.46 kcal mol^{-1}, at 0 K, and –13.97 kcal mol^{-1}, at 298.15 K that was an average of the Ruscic and Berkowitz (35) and Lock et al. (36) values. The Ruscic and Berkowitz value was corrected for the more recent ΔH_f° (OH), as cited above.

For homodesmic rxn. [16], we have

[16] HOOBr + HOH + Cl_2 → HOOH + HOCl + BrCl

[17] ΔH_f° (HOOBr) = ΔH_f° (HOOH) + ΔH_f° (HOCl) + ΔH_f° (BrCl) − ΔH_f° (HOH) − ΔH_f° (Cl_2) − ΔH_r

All the HOOH, HOCl, BrCl, HOH, and Cl_2 ΔH_f° experimental values were taken from *NIST–JANAF Thermochemical Tables* (34).

At 0 K, the HOOBr heat of formation values were determinated for the first time by Guha and Francisco (20) using isodesmic rxn. [14]. Our BP and pBP values using isodesmic rxn. [14] and homodesmic rxn. [16] agree very well with their BLYP/6-311++G (3df,3pd) value (20) of 5.2 kcal mol^{-1}. The CCSD(T)/TZ2P (19), G2/6-311++G(3df,3pd) (20), and B3LYP/6-311++G(3df,3pd) (20) values of 10.5 kcal mol^{-1}, 7.8 kcal mol^{-1}, and 8.1 kcal mol^{-1} are in agreement with each other but are higher than our values.

Based on rxns. [14] and [16], the BP and pBP HOBrO heat of formation values (see Table 5), at 0 K, are very close to the B3LYP/6-311++G(3df,3pd) value (20) of 13.8 kcal mol^{-1} and the CCSD(T)/TZ2P value (19) of 14.7 kcal mol^{-1}. Otherwise, the G2 value (20) of 10.7 kcal mol^{-1} and the BLYP value (20) of 8.6 kcal mol^{-1} are lower than our calculated values.

At 0 K, the $HBrO_2$ isomer heat of formation, using rxns. [14] and [16] and the DN* basis set, show values in good agreement with the CCSD(T)/TZ2P (19) of 64.3 kcal mol^{-1} and B3LYP/6-311++G(3df,3pd) (20) of 65.3 kcal mol^{-1}. The inclusion of polarization on hydrogen by the use of the DN** basis set increases the heat of formation of this isomer by, approximately, 3 kcal mol^{-1}.

$HBrO_3$ isomers — relative energies, geometry, vibrational frequencies, and C_p^0

The equilibrium geometry energy values obtained in this work provided the following order: HOOOBr < $HOBrO_2$ < HOOBrO < $HBrO_3$. The pBP and BP methods indicate that the HOOOBr is more stable (0.014 hartree and 0.016 hartree, respectively), than the $HOBrO_2$. This order is not in agreement with the Guha and Francisco results (23) which gave $HOBrO_2$ more stable than the HOOOBr by 0.001 hartree. The $HBrO_3$ isomers' equilibrium geometry, total energies, and vibrational frequencies are presented on Tables 6 and 7. The Fig. 2 presents the structures of all calculated $HBrO_3$ isomers.

For the HOOOBr, the BP, and pBP H—O_a, O—O_a, and Br—O_b bond lengths are slightly higher than the literature values (23, 24). The O—O_b values are smaller than the B3LYP (23) and QCISD (24) results. The BrOOO dihedral angle that conferred the lower energy is 82.4°, in good agreement with the QCISD/6-311G(d,p) value of 82.2° (24). The BP and pBP HO_aO angles are smaller than other literature values (23, 24) and the O_aOO_b and BrO_bO angles are close to the B3LYP result (23). For vibrational frequencies, the BrOOO torsion is lower than the value of 131 cm^{-1} determinated by Guha and Francisco (23, 24) and the HOOO torsion is lower than the values of 395 cm^{-1} and 437 cm^{-1} obtained using B3LYP (23) and QCISD (24) methods, respectively. The symmetric $\nu_{O\text{-}O}$ values are slightly higher than the B3LYP (23) and QCISD (24) methods. The $\nu_{O\text{-}H}$ values are lower than the Guha and Francisco values of 3713 cm^{-1} and 3726 cm^{-1} (23, 24). The OO_bBr, O_aOO_b, and HO_aO bend values are lower than B3LYP (23) and QCISD (24) results. Based on vibrational frequencies, the HOOOBr heat capacity was estimated as equal to 17.5 cal mol^{-1} K^{-1}.

Fig. 2. Calculated structures for $HBrO_3$ isomers: (*a*) HOOOBr, (*b*) $HOBrO_2$, (*c*) HOOBrO, and (*d*) $HBrO_3$. See Table 6 for geometrical parameters.

For the $HOBrO_2$ isomer there is only the Guha and Francisco results using the B3LYP method (23). Comparing it with our results, we find that our bond length values and $OBrO_t$ angles are slightly higher and the HOBr angle is slightly lower than the B3LYP results (23). Generally, the BP and pBP methods gave vibrational frequency values lower than the calculated by Guha and Francisco (23). The average of the calculated heat capacity has a value of 17.7 cal mol^{-1} K^{-1}.

The HOOBrO isomer bond lengths and angles values are in agreement with the QCISD results (24). For vibrational frequencies, the OOBrO torsion has scattered values considering all mentioned methods. The BP and pBP asymmetric $\nu_{Br\text{-}O}$ are higher than the values of 481 cm^{-1} and 476 cm^{-1} obtained by B3LYP (23) and QCISD (24) methods, respectively; $\nu_{O\text{-}O}$, $\nu_{O\text{-}H}$, and symmetric $\nu_{Br\text{-}O}$ are lower than the values obtained by these same methods. The bend values are slightly lower than those in the literature (23, 24). The HOOBrO heat capacity obtained has an average value of 17.6 cal mol^{-1} K^{-1}.

The $HBrO_3$ isomer presents HBr and BrO bond lengths slightly higher than B3LYP values (23) and BP and pBP HBrO angles in good agreement with the Guha and Francisco result of 103.4° (23). All BP and pBP vibrational frequencies have lower values when compared to the Guha and Francisco results (23). The $HBrO_3$ heat capacity calculated values are close to 16.0 cal mol^{-1} K^{-1}.

$HBrO_3$ isomers — heat of formation

As $\Delta n = 0$, the eqs. [9] and [10] were used to obtain the ΔH_r. The heat of reaction and all $HBrO_3$ heats of formation are presented in Table 8 together with other literature results. The $HOBrO_2$, HOOBrO, and $HBrO_3$ heats of formation were obtained based on relative energies.

The calculation of the HOOOBr heat of formation was made using two reactions. For isodesmic rxn. [18], we have

[18] $\quad HOOOBr + 2HOH \rightarrow 2HOOH + HOBr$

[19] $\quad \Delta H_f^\circ\,(HOOOBr) = 2 \times \Delta H_f^\circ\,(HOOH) + \Delta H_f^\circ\,(HOBr) - 2 \times \Delta H_f^\circ\,(HOH) - \Delta H_r$

[a]Values at 0 K are presented between parenthesis.

For the homodesmic rxn. [20], we have

[20] $HOOOBr + 2HOH + Cl_2 \rightarrow 2HOOH + HOCl + BrCl$

[21] $\Delta H_f^\circ(HOOOBr) = 2 \times \Delta H_f^\circ(HOOH) + \Delta H_f^\circ(HOCl) + \Delta H_f^\circ(BrCl) - 2 \times \Delta H_f^\circ(HOH) - \Delta H_f^\circ(Cl_2) - \Delta H_f^\circ$

The BP and pBP HOOOBr heats of formation were calculated using eq. [19] and eq. [21], with the calculated ΔH_r and the experimental ΔH_f°obtained from the *NIST–JANAF Thermochemical Tables* (34).

As can be seen in Table 8, our results for the heats of formation of the $HBrO_3$ isomers are not sensitive to the method or basis set used. At 0 K, the heats of formation for the isomers HOOOBr, $HOBrO_2$, HOOBrO, and $HBrO_3$ can be considered close to 13 kcal mol^{-1}, 22 kcal mol^{-1}, 29 kcal mol^{-1}, and 93 kcal mol^{-1}, respectively. Otherwise, the results of Guha and Francisco (23), reproduced in this table for comparison purposes, show that the heat of formation values for these isomers are very dependent of the method and basis used as has been noticed for $HClO_3$ isomers (43). This dependence of the method and basis used can be understood as a special difficulty posed by these halogen compounds. For the HOOBrO isomer, our results are in the middle of the Guha and Francisco results calculated by several methods and not too far from the values of 32.7 kcal mol^{-1} and 32.8 kcal mol^{-1} obtained by the highest basis set calculations. For HOOOBr, our results are close to G1 and G2 values. For the $HOBrO_2$ and $HBrO_3$ isomers, our results are significantly higher than the other results.

In this way, we calculated the HOOOBr isomer as the most stable isomer, in disagreement with Guha and Francisco (23) results that indicate $HOBrO_2$ as the most stable isomer. Considering the basis size and the methods used by these authors, the $HOBrO_2$ should be the most stable isomer. It means that the BP and pBP methods using DN* or DN** basis sets have some difficulty in handling the very special kind of chemical bond that is present between the oxygen atoms in the HOOOBr isomer.

Conclusions

Relative energy, equilibrium geometry, vibrational frequencies, heat capacity, and heat of formation of several compounds of general formula $HBrO_x$ were calculated by BP and pBP models, using numerical basis sets.

The comparison of the BP and pBP HOBr results with the HOBr experimental results has shown a good agreement and suggests that these methods and basis sets can be a good option to forecast properties of inorganic bromine compounds. The comparison of our calculated HOBr values with other very reliable calculation methods support this conclusion, too.

The HOBr heat of formation results obtained by the use of homodesmic and isodesmic reactions gave similar results, with the exception for the BP method considering a isodesmic reaction containing ClO· species. In addition, the calculated HOBr heat of formation values support the experimental values of Ruscic and Berkowitz (35) and Lock et al. (36).

The density functional theories when applied for HBrO, $HBrO_2$, and $HBrO_3$, isomers give the total energy orders: HOBr < HBrO; HOOBr < HOBrO < $HBrO_2$; HOOOBr < $HOBrO_2$ < HOOBrO < $HBrO_3$. For the HOOOBr and $HOBrO_2$ isomers, the calculated stability order is exchanged in relation to the order reported by Guha and Francisco (23, 24) suggesting that the BP and pBP methods using the DN* or DN** basis set have some difficulty in handling the O—O—O bond present in HOOOBr. Otherwise, as the $HBrO_2$ isomers' energy order is the same calculated by the most sophisticated methods and basis sets, this suggests that

© 2001 NRC Canada

the methods and basis set used in this work can handle the peroxide bond correctly.

The calculated equilibrium geometry, vibrational frequencies, and heat capacity are in agreement with other methods as has been observed for HOBr.

No clear tendency was observed for the results obtained by BP and pBP models, nor by the use of the DN* or DN** basis sets. In addition, the use of homodesmic and isodesmic reactions gave, in most of the cases, very similar results.

Note

During the submission of this paper a theoretical work by Guha and Francisco on isomerization pathways for $HBrO_3$ isomers has appeared (44). The results presented in this paper show that the $HOBrO_2$ isomer is the most stable based only on the total energy calculated by the QCISD method using several different basis sets and the geometry obtained by QCISD/6-311G(2d,2p). No heat of formation results were presented.

Using secondary alpha deuterium kinetic isotope effects to determine the stereochemistry of an E2 reaction; the stereochemistry of the E2 reaction of 1-chloro-2-phenylethane with potassium *tert*-butoxide in *tert*-butyl alcohol

Peter James Smith, David A.J. Crowe, and Kenneth Charles Westaway

Abstract: Isotopic labelling studies have shown that the E2 reaction of 1-chloro-2-phenylethane with potassium *tert*-butoxide in *tert*-butyl alcohol occurs via an anti-periplanar stereochemistry. This demonstrates that the different secondary alpha deuterium kinetic isotope effects found for the high and low base concentrations and in the presence of 18-crown-6 ether are because of changes in transition state structure that occur when the form of the reacting base changes rather than to a change in the stereochemistry of the reaction.

Key words: E2 reaction, stereochemistry, secondary alpha deuterium kinetic isotope effects, transition state.

Résumé : Des études de marquage isotopique ont permis de démontrer que la réaction E2 du 1-chloro-2-phényléthane avec *tert*-butylate de potassium dans l'alcool *tert*-butylique se produit avec une stéréochimie antipériplanaire. Cette observation démontre que les divers effets isotopiques cinétiques secondaires du deutérium en alpha qui ont été observés à des concentrations élevées et faibles de base et en présence de l'éther 6-couronne-18 sont dus à des changements dans la structure de l'état de transition qui se produisent lorsqu'il se produit un changement dans la forme de la base qui réagit plutôt que la stéréochimie de la réaction.

Mots clés : réaction E2, stéréochimie, effets isotopiques cinétiques secondaires du deutérium en alpha, état de transition.

Introduction

The stereochemistry of E2 elimination reactions has been investigated for some time (1–5). An E2 reaction can occur with an anti-periplanar (the dihedral angle between the abstracted β-hydrogen and the leaving group is 180°, Fig. l*a*) or a syn-periplanar (the dihedral angle between the leaving group and abstracted β-hydrogen is 0°, Fig. l*b*) stereochemistry. Although theoretical calculations (3, 6) indicate that the anti-periplanar stereochemistry is favoured, not all E2 reactions follow the anti-periplanar pathway. For example, syn-periplanar E2 reactions are observed in rigid cyclic systems where a β-hydrogen and the leaving group are coplanar (2, 7). Syn-periplanar E2 eliminations are also observed when the less rigid, but rotationally restricted, 1,2-dihaloacenaphthalenes (8) and 2,3-dihalo-2,3-dihydrobenzofurans (9) react with alkoxide ions.

Changes in the form of the abstracting base can also affect the stereochemistry of an E2 reaction. Bartsch and Zavada (5) state that alkoxide ions exist as dissociated ions, ion pairs, several different complex ions, or ion-pair aggregates connected by a series of equilibria (eq. [1]).

The amount of association increases as (*i*) the cation is made smaller, i.e., going from cesium to lithium; (*ii*) the alkoxide ion is made larger, i.e., the base is changed from methoxide ion to *tert*-butoxide ion; and (*iii*) when a less polar solvent is used and the strength of the base is increased, e.g., the solvent is changed from ethanol to *tert*-butyl alcohol (10–12). Surprisingly, 18-crown-6 ether does not affect the degree of association (13), although a 1:1 K^+–18-crown-6 ether complex does form in potassium *tert*-butoxide – *tert*-butyl alcohol (l4). Zavada et al. (15) found a greater percentage of syn-periplanar dehydrohalogenation of 5-decyl halides with the associated base (potassium *tert*-butoxide in benzene) than when the base was the dissociated ion (potassium *tert*-butoxide in *tert*-butyl alcohol). Bartsch and Lee (2) also found the amount of syn-elimination from *endo*-2-bicyclo[2.2.1]heptyl bromide and 2,4,6-triisopropylbenzenesulfonate was significantly higher with the associated base (potassium *tert*-butoxide in triglyme) than when 18-crown-6 ether was present. The higher proportion of syn-elimination with the associated base may occur because the counter ion in the associated base stabilizes the partial charge on the leaving group in the syn-periplanar E2 transition state (Fig. 2).

 DOI: 10.1139/cjc-79-7-1145 © 2001 NRC Canada

[1] 

Zavada et al. (15) also reported that the amount of syn-elimination increased as the electronegativity of the leaving group increased from bromo to fluoro in the E2 reactions of 5-decyl halides. Several workers (16–18) have suggested that Elcb-like E2 reactions (with poor leaving groups) occur with the syn-periplanar stereochemistry rather than the anti-periplanar stereochemistry that is found for E2 reactions, which have good leaving groups and central transition states.

Smith and Westaway (19) reported that the syn-periplanar E2 elimination from 2-phenylethyldimethylamine oxide had a large secondary alpha deuterium kinetic isotope effect of 1.34, whereas a small secondary alpha deuterium kinetic isotope effect of 1.02 was found for the anti-periplanar E2 reaction of 2-phenylethyltrimethylammonium ion with ethoxide ion in ethanol. Although both reactions had extensive C_β–H and C_α–N bond rupture in their transition states, there is obviously a very different amount of C=C bond formation in the two transition states, i.e., large in the anti-periplanar transition state and small in the syn-periplanar transition state. This led to the suggestion that one might be able to use the magnitude of the secondary alpha deuterium isotope effect to determine the stereochemistry of the E2 elimination reaction. Recently, different secondary alpha deuterium kinetic isotope effects have been found when different concentrations of base (potassium *tert*-butoxide in *tert*-butyl alcohol) were used in the E2 reaction of 1-chloro-2-phenylethane. The different isotope effects could arise because (*i*) the structure of the E2 transition state changes and (or) (*ii*) because the stereochemistry of the reaction changes when different concentrations of base (different bases) are used. This study was undertaken to determine whether the change in the secondary alpha deuterium isotope effect was due to a change in the stereochemistry of the E2 reaction between 1-chloro-2-phenylethane and *tert*-butoxide ion.

Results and discussion

The secondary alpha deuterium kinetic isotope effects observed for the E2 reaction of 1-chloro-2-phenylethane at different base (potassium *tert*-butoxide in *tert*-butyl alcohol) concentrations (eq. [2]) are presented in Table 1. The results show that a smaller secondary alpha deuterium isotope effect of 1.032 ± 0.004 is found for the 1-chloro-2-phenylethane E2 reaction at low base concentrations (between 0.036 and 0.228 M), while a larger isotope effect of 1.050 ± 0.005 is observed at higher concentrations of base (>0.36 M) and at low base concentrations in the presence of 18-crown-6 ether.[2] The 1-chloro-2-phenylethane at low base concentrations were thought to react via the normal anti-periplanar stereochemistry. The larger secondary alpha deuterium kinetic isotope effects found for the E2 reaction of 1-chloro-2-phenylethane at high base concentrations and in the presence of the crown ether could be observed because (*i*) the stereochemistry of the reaction changed to syn-periplanar and (or) (*ii*) the transition state structure changes when the form of the abstracting base changes. At low concentrations of base and in the presence of 18-crown-6 ether, the abstracting base is undoubtedly the free ion. At high concentrations of base, the abstracting base would be one or more of the ion pair, the triple ion, or an ion aggregate. Changing the form of the abstracting base could alter the stereochemistry of the E2 reaction (Fig. 1) and (or) cause a change in the structure of the transition state altering the magnitude of the alpha deuterium kinetic isotope effect. This study was undertaken to determine if the change in the secondary alpha deuterium kinetic isotope effect was due to a change in the stereochemistry of the E2 reaction or due to a change in the structure of the E2 transition state.

The diastereomers of 1-chloro-2-phenyl-1,2-d_2 ethane were synthesized via the scheme shown in Fig. 3. An NMR analysis of the β-bromostyrene showed that the starting material for the synthesis consisted of 75% of the (*E*)-isomer and 25% of the (*Z*)-isomer. A spinning-band distillation of the β-bromostyrene gave samples of isomeric purity ranging from 75 to 88% of the (*E*)-isomer. However, it was not possible to obtain a pure sample of the (*E*)-isomer, so the synthesis was carried out on three different mixtures of β-bromostyrene isomers. These stereospecific syntheses led to the *threo*-(*RS*,*SR*) and *erthyro*-(*SR*,*RS*) 1-chloro-2-phenyl-1,2-d_2 ethanes. The *threo* diastereomers were formed from the (*E*)-isomer of the β-bromostyrene and the *erythro* diastereomers from the (*Z*)-isomer of β-bromostyrene. These mixtures of diastereomers were reacted at both low and high concentrations of base, i.e., where the different secondary al-

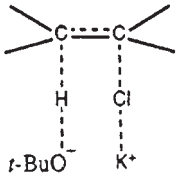
[a]The error in the isotope effects is $1/k_D[(\Delta k_H)^2 + (k_H/k_D)^2 \times (\Delta k_D)^2]^{1/2}$, where Δk_H and Δk_D are the standard deviations for the average rate constants for the reactions of the nondeuterated and deuterated substrates, respectively.

[b]Standard deviation. The student t-test indicated that the secondary alpha deuterium kinetic isotope effects at "high base" concentrations and in the presence of 18-crown-6 are different from those at "low base" concentrations at the 99% confidence level.

Fig. 1. The anti-periplanar (*a*) and syn-perplanar (*b*) stereochemistry for an E2 reaction.

pha deuterium kinetic isotope effects were observed. All the possible E2 products, formed when the different diastereomers of the 1-chloro-2-phenyl-1,2-d_2 ethanes react with *tert*-butoxide ion in *tert*-butyl alcohol, are presented in Fig. 4. The *threo* diastereomers produce compounds I and II when the elimination occurs via the anti-periplanar stereochemistry, whereas compounds III and IV would be formed if the elimination occurred via the syn-periplanar stereochemistry. The *erythro* compounds on the other hand, form products III and IV when the elimination occurs with an anti-periplanar stereochemistry and compounds I and II when it occurs by the syn-periplanar pathway. Thus, if the E2 reaction occurs only via the anti-periplanar pathway, the %(I + II) and the %(III + IV) should be the same as the %(*E*)-isomer and the %(*Z*)-isomer, respectively, in the starting material, i.e., all of

Fig. 2. A syn-periplanar E2 reaction with the counter ion in the ion-pair assisting the removal of the leaving group.



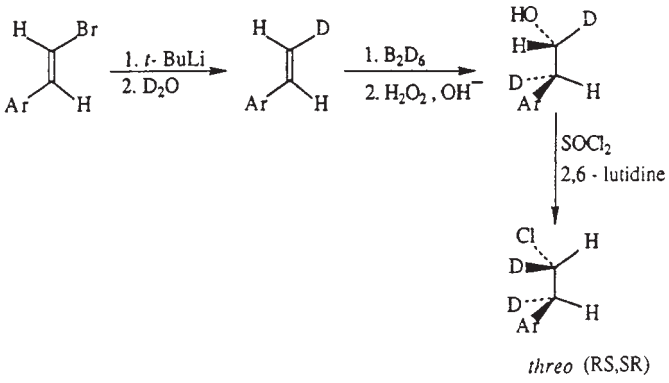


Fig. 3. The stereospecific synthesis of the 1-chloro-2-phenylethane diastereomers.

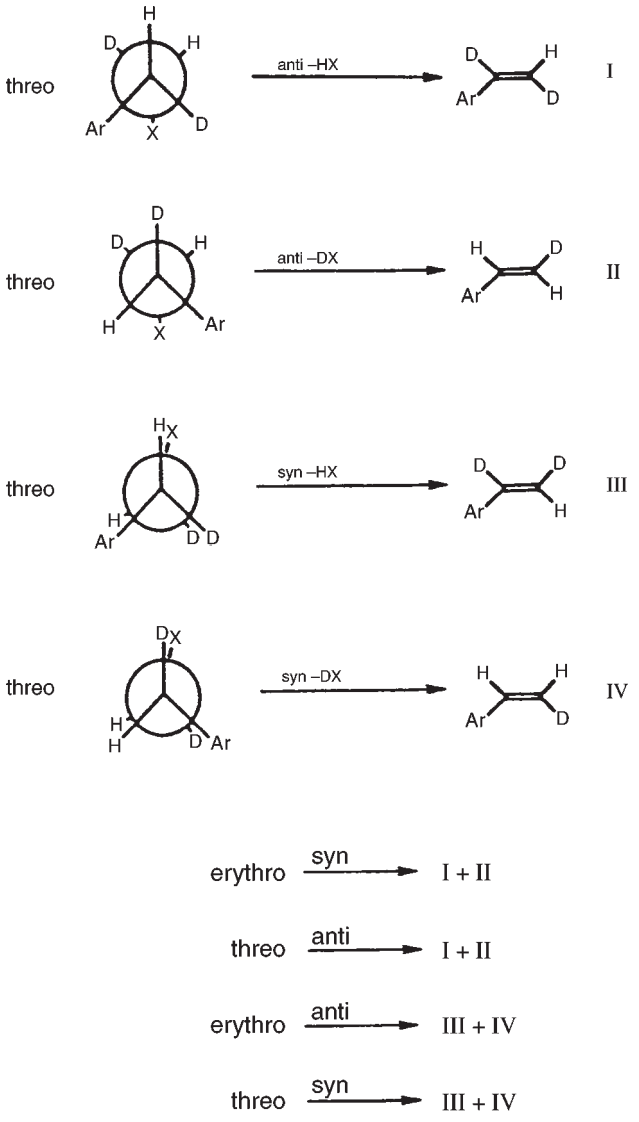

the *threo* isomer (made from the (*E*)-isomer in the synthesis) will form products I and II while the *erthyro* isomers (made from the (*Z*)-isomer in the synthesis) will form products III and IV. If the elimination occurs by the syn-periplanar pathway, the %(I + II) and the %(III + IV) should be opposite the %(*E*)-isomer and the %(*Z*)-isomer, respectively, in the starting material, i.e., the *threo* isomer will only form III and IV while the *erthyro* isomer will produce only I and II. Finally, if the stereochemistry of the elimination reaction is partly syn- and partly anti-, the %(I + II) and the %(III + IV) will be intermediate between the above values.

The stereochemistry of the E2 reactions of the 1-chloro-2-phenyl-1,2-d_2 ethane diastereomers was determined by isolating the products and analyzing them by NMR spectroscopy. The chemical shifts and coupling constants for all of the possible products formed from a syn- and an anti-periplanar elimination are shown in Table 2. The %(I + II) and the %(III + IV) obtained when the 1-chloro-2-phenyl-1,2-d_2 ethane diastereomers were reacted with potassium *tert*-butoxide in *tert*-butyl alcohol concentrations ranging from 0.062–0.23 M (where the secondary alpha deuterium kinetic isotope effect was 1.032) and ranging from 0.36–0.39 M (where the isotope effect was 1.050) are presented in Table 3. The %(I + II) and the %(III + IV) are, within experimental error, identical to the %(*E*)- and %(*Z*)-isomers, respectively, in the starting material in every case. This clearly indicates that (*i*) the E2 reaction of of 1-chloro-2-phenylethane occurs 100% via the anti-periplanar pathway at all concentrations of *tert*-butoxide ion and (*ii*) the change in the secondary alpha deuterium kinetic isotope effect is not due to a change in the stereochemistry of the reaction but must be due to a change in the structure of the E2 transition state.

It is worth noting that the method of determining the stereochemistry of the E2 reactions was tested by reacting

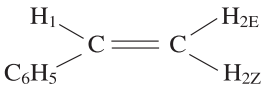
Fig. 4. The E2 products formed from anti- and syn-periplanar elimination of the possible deuterated 1-chloro-2-phenylethane diastereomers.

the 1-chloro-2-phenyl-1,2-d_2 ethane with ethoxide ion in ethanol. These reactions were investigated because they were expected to react via an anti-periplanar stereochemistry. This stereochemistry was expected because (*i*) the substrates are acyclic (3, 6); (*ii*) ion pairing is much less likely in the more polar solvent ethanol than in *tert*-butyl alcohol (10); and (*iii*) because the leaving group in these reactions is at least as good as the trimethylammonium leaving group (16, 18) Bourns and Frosst (20) used to demonstrate that the E2 reaction of 2-phenylethyltrimethylammonium bromide with ethoxide ion in ethanol occurred with an anti-periplanar stereochemistry. The %(I + II) and the %(III + IV) was identical, within experimental error, to the %(*E*)- and the %(*Z*)-isomers, respectively, in the starting material. Thus, the results indicate that this E2 reaction in ethoxide ion and ethanol proceeds with an anti-periplanar stereochemistry and confirm that the stereochemical test is valid.

The results clearly show that the E2 reaction of 1-chloro-2-phenylethane with *tert*-butoxide ion in *tert*-butyl alcohol occurs with an anti-periplanar stereochemistry. Therefore, the different secondary alpha deuterium kinetic isotope effects found at different concentrations of base are not due to a change in stereochemistry, but reflect differences in the structure of the E2 transition state. It is also obvious that the change in the secondary alpha deuterium kinetic isotope effect (transition state structure) must result from changes in the form of the reacting base.



Although the reactive form of the base might be the triple ion or an ion pair aggregate at the highest potassium *tert*-butoxide concentrations (0.3–0.4 M) used in this study, it seems more likely, for two reasons, that the ion pair or a solvated ion pair is the reacting base. Zavada and co-workers (13) reported that the ion pair is the dominant form of the base in 0.1–0.5 M potassium *tert*-butoxide–*tert*-butyl alcohol. This, coupled with the first order dependance of the rate on *tert*-butoxide ion, suggests that the ion pair is the reacting base when the base concentration is 0.3–0.4 M and the larger secondary alpha deuterium kinetic isotope effect is observed.

Conversely, at low base concentrations (<0.23 M) in the absence of 18-crown-6 ether, the reacting base is almost certainly the free ion. However, it seems likely that the reaction does not occur via a simple E2 mechanism under these conditions. Zavada et al. (4) demonstrated that 5-decyl bromide reacts with potassium *tert*-butoxide in *tert*-butyl alcohol by two competing mechanisms; a simple E2 reaction and a reaction where a *free* (dissociated) K^+ ion complexes with the leaving group and provides electrophilic catalysis for its removal (Fig. 5). The reaction was first order in base indicating that the complexing reaction was kinetically indistinguishable from the uncomplexed reaction (21). If the complexing mechanism is operative at low base concentrations, the reaction occurs with a stronger base (the negative charge on the oxygen of the *free tert*-butoxide ion would be greater than that on the oxygen of the ion pair, the reactant at high base concentrations). Also, the low base concentration reaction with the free *tert*-butoxide ion has a better leaving group (the complexed chloride ion leaving group would be a weaker base than the uncomplexed chloride ion). The More O'Ferrall energy surface diagram predicts (*i*) that changing to a better leaving group would not change the amount of C_α–X bond rupture in the transition state but that (*ii*) changing to a stronger base would lead to an E2 transition state with less C_α–X bond rupture. The net effect of these two changes in the reactants should lead to a transition state with less C_α–X bond rupture. This would produce the smaller secondary alpha deuterium kinetic isotope effect that is observed.

Finally, the larger secondary alpha deuterium kinetic isotope effect in the reaction with the crown ether at low base concentrations, suggests that C_α–X bond rupture is more advanced in the transition state when 18-crown-6 ether is used. 18-Crown-6 ether forms a 1:1 complex with potassium ions (13). This means the potassium ion is no longer available to assist in the removal of the leaving group, i.e., that there is a poorer leaving group. Since the More O'Ferrall energy surface diagram suggests that changing to a poorer leaving group leads to a transition state with a longer C_α–X bond, a

larger secondary alpha deuterium kinetic isotope effect would be expected in the 18-crown-6 ether reactions. This is, in fact, what is observed.

Conclusion

Obviously, the magnitude of the secondary alpha deuterium kinetic isotope effects cannot be used to determine the stereochemistry of an E2 reaction. Rather, the changes in the secondary alpha deuterium isotope effect in these E2 reactions are due to changes in the structure of the transition state that occur when the form of the reacting base is altered.

Experimental

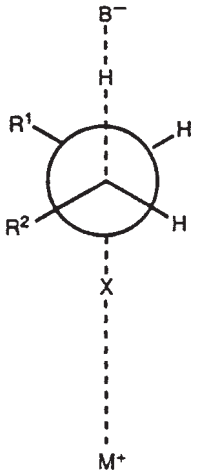
General

NMR spectra were determined in solution in chloroform-*d* on a Bruker AM300 instrument. All the chemical shifts are reported in ppm from tetramethylsilane. The UV spectra were measured on a Hewlett Packard HP8451A diode array spectrophotometer. An NMR analysis showed that both the 1, 1-d_2, and the 1,2-d_2 1-chloro-2-phenylethanes were 99% deuterated at the appropriate positions.

Preparation of reagents

1-Chloro-2-phenylethane

2-Phenylethanol was prepared using the method of Amundsen and Nelson (22). Ethyl phenylacetate (5.9 g, 0.036 mol) in anhyd ether (10 mL) was added slowly to a stirred mixture of lithium aluminum hydride (1.4 g, 0.038 mol) in anhyd ether (60 mL). The mixture was heated at reflux for 7 h and allowed to cool. Sulphuric acid (10%, 50 mL) was added slowly. The organic layer was separated, washed with water, dried over anhyd magnesium sulphate, and the ether removed on a rotary evaporator. The 2-phenylethanol was used in the next step without further purification. ^{1}H NMR δ 7.22–7.38 (m, 5H), 3.86 (t, J = 6.6 Hz, 2H), 2.87 (t, J = 6.6 Hz, 2H), 1.39 (br s, 1H).



The 1-chloro-2-phenylethane was prepared by adding a mixture of 2-phenylethanol (1 g, 0.0082 mol) and 2,6-lutidine (0.9 g, 0.0082 mol) dropwise to a stirred solution of thionyl chloride (1.2 g, 0.010 mol) in toluene (2 mL). Two drops of water were added to break up the solid that formed and the reaction was stirred for 30 min at 40°C. Cold water was added slowly and the toluene separated as an upper layer. The toluene layer was washed successively with water, 10% sodium bicarbonate solution, and water, then dried over anhyd sodium sulphate and the solvent removed on a rotary evaporator. Distillation gave 1.0 g (0.0071 mol, 87%) of 1-chloro-2-phenylethane bp 47–50°C, 1.5 mm Hg (lit. (23) 34°C, 1 mm of Hg). ^{1}H NMR δ 7.20–7.35 (m, 5H), 3.71 (t, J = 7.5 Hz, 2H), 3.06 (t, J = 7.5 Hz, 2H).

1-Chloro-2-phenyl-1,2-d_2 *ethane diastereomers*

*(*E*)-Styrene-*β*-*d*:* (*E*)-Styrene-β-*d* was prepared using the method described by Tao and Saunders (24). (*E*)-β-Bromostyrene (Aldrich) (1.0 g, 5.5 mmol) in dry ether (7 mL) (heated at reflux over and distilled from sodium) was cooled to –78°C and *tert*-butyl lithium in pentane (1.7 M, 4.9 mL) (Aldrich) was added slowly. The mixture was stirred for 30 min at –78°C, then deuterium oxide (>99.9% d_2) (0.22 g, 11 mmol) was added dropwise with stirring. The reaction mixture was warmed to room temperature and water (10 mL) was added. The organic layer was separated and the aqueous layer was extracted once with

Fig. 5. An anti-periplanar E2 elimination from a free *tert*-butoxide ion and a metal-complexed leaving group.

ether. The combined organic layers were dried over anhyd magnesium sulphate and the solvent was removed on a rotary evaporator at room temperature. The crude yield of (*E*)-styrene-β-*d* was 0.56 g (96%). If the product was not used immediately, it was stored as an ether solution to minimize isomerization and (or) polymerization.

NMR spectroscopy showed that the β-bromostyrene consisted of 75% of the (*E*)-isomer, the rest being (Z). Several attempts to separate the isomers were made, spinning-band distillation being the most successful. Several batches of styrene-β-*d* were made, with degrees of isomeric purity ranging from 75 to 88% of the (*E*)-isomer. In each case, the isomeric constitution of the styrene-β-*d* determined by NMR was the same as that of the β-bromostyrene used for the synthesis.

erythro-*2-Phenyl-1,2*-d_2 *ethanol:* The procedure used by Dohner and Saunders (25) was followed. Deuteroborane, generated by the addition of boron trifluoride etherate (4.75 mL, 0.029 mol) to a solution of sodium borodeuteride (>98% d_4) (0.921 g, 0.022 mol) in tetrahydrofuran (200 mL) at 0°C, was added dropwise to (*E*)-styrene-β-*d* (0.56 g, 0.005 mol) in tetrahydrofuran (5 mL) in a 50 mL three-necked round-bottom flask equipped with a nitrogen inlet, a nitrogen outlet, and a dropping funnel. After the reaction mixture had been stirred for 3 h at room temperature, water (0.8 mL), sodium hydroxide (4 mL, 3 M), and hydrogen peroxide (4 mL of a 30% solution) were added. This mixture was stirred for 4 h and then extracted with ether (3 × 30 mL). The combined ether extracts were washed with an aqueous ferrous sulphate solution, then with water, and dried over anhyd magnesium sulphate. Evaporation of the ether and distillation at 49–50°C at 1.5 mm yielded 0.55 g (88%) of the product. ^{1}H NMR δ 7.22–7.38 (m, 5H), 3.84 (d, J = 4.5 Hz, 1H), 2.85 (d, J = 4.5 Hz, 1H), 1.39 (br s, 1H).

threo-*1-Chloro-2-phenyl-1,2*-d_2 *ethane:* This was prepared from *erythro*-2-phenyl-1,2-d_2 ethanol using the method and quantities described for 1-chloro-2-phenylethane.[3] ^{1}H NMR δ 7.20–7.35 (m, 5H), 3.71 (m, 1H), 3.06 (d, 1H). ^{13}C NMR δ 138.0, 128.8, 128.6, 126.9, 44.6 (t, J = 23 Hz), 38.8 (t, J = 20 Hz).

Potassium tert-*butoxide in* tert-*butyl alcohol*

tert-Butyl alcohol was dried over 3 Å molecular sieve beads for at least 24 h, then refluxed over and distilled from powdered 3 Å molecular sieves under a dry nitrogen atmosphere (26). Sufficient potassium (typically, 8 g of potassium in 1 to 2 g chunks) was added to dry *tert*-butyl alcohol (200 mL) through which dry, high purity nitrogen was being bubbled. The mixture was left until all the potassium had reacted. The base solution was stored under dry nitrogen in the refrigerator and aliquots were removed under dry nitrogen and diluted with dry *tert*-butyl alcohol for kinetic studies. When the base had been diluted for kinetic studies, its concentration was determined by titrating it in CO_2-free distilled water with 0.01 N sulphuric acid (BDH Volumetric) to a bromocresol green endpoint. A blank sample containing only CO_2-free distilled water and indicator normally reached the end point with the first drop of sulphuric acid. Although every attempt was made to keep the potassium *tert*-butoxide solution free of air and water, some of the *tert*-butoxide ion was inevitably destroyed by reaction with water or carbon dioxide. Thus, second order rate constants measured with different batches of the base were not reproducible to better than ±10%.

Kinetic measurements

Two different methods were used. For reactions where the base concentration was 0.01 M or less, the reaction was carried out and monitored in a 1 cm cuvette in the spectrophotometer cell. Because of the significant absorption of *tert*-butoxide ion in the 200–250 nm range at base concentrations >0.01 M, the reactions were carried out in a constant temperature bath and aliquots of the reaction mixture were quenched before measurement of the spectrum. All the rate constants were measured under pseudo first-order conditions with the base being at least twenty times more concentrated than the substrate in the reaction mixture. No attempt was made to control the ionic strength.

Water-bath method

The potassium *tert*-butoxide solution was made by pipetting the required volume of the stock (1 M) base solution into a dry 200 mL volumetric flask and making up the volume with dry *tert*-butyl alcohol. Approximately 22 mL of this solution was transferred into each, of up to seven, 25 mL dry, volumetric reaction vessels fitted with serum caps. The solutions were temperature equilibrated in the constant temperature bath for at least 30 min and filled up to the mark with the base solution. To one of the reaction ves-

[3] A referee expressed concern about the formation of a phenonium ion, which would alter the stereochemistry of this step of the synthesis. This reaction was done in toluene and since phenonium ions have only been found in good ionizing solvents such as HOAc or formic acid, (27) it is difficult to envisage it forming it this reaction. More important, the phenonium ion intermediate can be ruled out because there was no evidence of the rearranged product when this reaction was used in the synthesis of the 1-chloro-2-phenyl-1,1-d_2 ethane that was to measure the secondary alpha deuterium KIE. A referee also questioned the stereochemistry of the chlorosulfite ester reaction. However, March (28) reports that this reaction proceeds with inversion of configuration.

© 2001 NRC Canada

sels was added 1 mL of temperature-equilibrated dry *tert*-butyl alcohol and the solution was titrated to determine the base concentration.

The reactions were started by adding 1 mL of a temperature equilibrated solution of the substrate (approximately 5×10^{-5} M, but accurately known) in dry *tert*-butyl alcohol to the reaction vessel with a calibrated syringe. At intervals of several minutes, 1 mL aliquots of the reaction mixture were withdrawn with a syringe and quenched in 20 mL of the appropriate concentration of hydrochloric acid in distilled 95% ethanol. The quenched aliquot was diluted to 25 mL with 95% ethanol and the UV spectrum was recorded. Best results were obtained by measuring against a reference sample of ethanol or quenching solution, subtracting the absorbance at a point on the baseline of the product spectrum from the absorbance at λ_{max} for the product. Ten aliquots were normally taken from each vessel over two half-lives.

After ten or more half-lives, samples were taken and quenched to obtain a value for the product absorbance when the reaction was complete (OD_∞). The pseudo first-order rate constant was obtained from the slope of the plot of ln ($OD_\infty - OD_t$) vs time (t).

Cuvette method

The base solution was prepared by diluting the stock base solution using the method described above. If required, 18-crown-6 was first weighed into a 50 mL volumetric flask and 3 mL of the base solution were pipetted into each of seven oven dried cuvettes with tightly fitting stoppers. The cuvettes were left in the thermostated cell holder in the spectrophotometer for at least 20 min to allow them to reach thermal equilibrium. One cell was used as the reference. The reactions were started by adding between 5–10 μL of substrate solution (typically 5×10^{-3} M in *tert*-butyl alcohol) to the cuvette using a syringe and inverting the cuvette several times to ensure mixing.

The computer-controlled spectrophotometer measured absorbencies for the samples at predetermined intervals over at least two half lives. Rate constants were obtained from between 25–40 data points using either the above OD_∞ method or from Guggenheim plots.

Secondary alpha deuterium kinetic isotope effects

When the water bath method was used to determine the secondary alpha deuterium kinetic isotope effect, the rate constants for six reactions were determined simultaneously in the same constant temperature bath; three reactions used the deuterated substrate and three used the nondeuterated substrate. When the cuvette method was used, the rate was determined for three deuterated and three nondeuterated substrates simultaneously in the thermostated cell holder. The secondary alpha deuterium kinetic isotope effect was obtained by dividing the average rate constants for the nondeuterated and deuterated substrates.

Determination of the elimination stereochemistry

A stock potassium *tert*-butoxide solution was diluted in a volumetric flask with dry *tert*-butyl alcohol, temperature equilibrated in a constant temperature bath, and filled to the mark with dry *tert*-butyl alcohol. This stock solution was at least twenty times more concentrated than the substrate. The required amount (approximately 20 mg) of the 1-choro-2-phenyl-1,2-d_2 ethane diastereomers was weighed into the reaction vessel and temperature equilibrated. The reaction was started by quickly adding the base solution to the reaction vessel. After ten half-lives (>99.9% reaction) the reaction was quenched by adding cold water and the organic products were extracted three times with pentane. After the combined pentane extracts had been washed with water and dried over anhyd magnesium sulphate, the pentane was removed at room temperature in a rotary evaporator. An NMR analysis of the residue in 1 mL of chloroform-*d* gave the composition of the product.

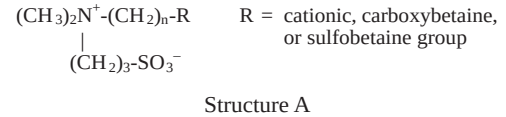
Original disymmetric bolaforms bearing at least one sulfobetaine head; synthesis and surface properties

Souad Souirti and Michel Baboulène

Abstract: We describe a simple and efficient method for the synthesis of disymmetric bolaforms bearing at least one sulfobetaine head. In this process, we could introduce successively on α,ω-bis(dialkylamino) alkane a sulfobetaine head and a cationic, a sulfobetaine, or a carboxybetaine head, in excellent yield. This is the first synthesis of disymmetric sulfobetaine bolaforms. The method is easily generalized to various types of head functional groups. The wide range of bolaforms produced by this method has been exploited to study their surface properties and to determine the respective roles of the polar heads and the lengths of the spacers (*n*) on self-aggregation in aqueous media. A critical micellar concentration (cmc) was observed with the compounds with a spacer of 12 carbon atoms (*n* = 12). Micellization appeared to be consistent with a "wicket-like" conformation, which did not appear to form with the *n* = 8 compounds.



Key words: disymmetric bolaform, sulfobetaine, carboxybetaine, cationic amphiphile, synthesis, surface properties.

Résumé : Nous décrivons une simple et efficace méthode d'accés à des dissymmétriques bolaformes ayant au moins une tête sulfobétaine. Dans ce procédé nous pouvons introduire successivement sur les azotes d'un α,ω-bis(dialkylamino) alkane une tête sulfobétaine et une tête cationique ou sulfobétaine ou carboxybétaine avec d'excellents rendements. C'est la première synthèse de sulfobétaines bolaformes dissymétriques. La méthode décrite est facilement généralisable à diverses têtes polaires. La diversité des bolaformes ainsi obtenus permet d'aborder, à partir d'une étude tensiométrique, leurs propriétés de surface et de discuter du rôle des têtes polaires et de la distance entre les deux têtes (*n*) dans le mode d'aggrégation de ces composés en milieu aqueux. Les composés avec *n* = 12 se prêtent à la détermination d'une concentration micellaire critique (cmc). Leur micellisation semble en accord avec une conformation " en boucle" qui ne se retrouve pas pour les composés avec *n* = 8.

Mots clés : bolaforme disymmétrique, sulfobétaine, carboxybétaine, amphiphile cationique, synthèse, paramètres de surface.

Introduction

There have been a large number of descriptions of the synthesis of amphiphilic molecules, which self-aggregate into vesicles, as these compounds have a variety of application in chemistry and biochemistry (1, 2). Among the numerous families of surfactants, a novel architecture represented by the bolaform structure has been developed (3). Bolaforms are molecules bearing two polar heads separated by a hydrophobic chain of variable length. This structure lends itself to a modular synthesis of derivatives with different chains and polar heads. However, despite numerous reports on bolaforms, to our knowledge there are no descriptions of bolaforms with betaine heads. We have currently been investigating bolaforms derived from betaine (4). The encouraging preliminary results prompted us to examine derivatives with a sulfobetaine head. These compounds find applications as detergents and in cosmetics (5). Recently, Spencer et al. (6) have reported the inhibitory action of *N,N′*-bis[dimethylammonium-1-(4-butylsulfonyl)]dodecane, a sulfobetaine surfactant, on squalene synthetase. Nevertheless, the amphiphilic character of this compound was not conjured up, and we also know the importance of organized molecular systems into biological applications. Consequently, the bolaform structure open new perspectives for the surfactant chemistry. For this purpose, knowledge of the surface properties and comprehension of the process of vesicle formation will also require a number of derivatives for studying the self-aggregation behaviour. The interest of different polar heads at the ends of the hydrophobic chain is an added interest for such investigations.

Structure A

We present here a simple and general method for preparation of original disymmetric bolaforms bearing a sulfobetaine head with the other head being either cationic

or a betaine (structure A). The surface properties of the compounds prepared was then examined.

Synthesis

The sulfobetaine structure is readily produced by condensation of an amine with an alkylsultone (7). We employed this method using α,ω-bis(dialkylamino) alkane **1** according to Scheme 1.

This condensation reaction is quantitative. The sulfobetaines **2** are readily recovered with a high degree of purity by filtration because of the absence of by-products and the crystalline nature of the product. However, if the reaction mixture is heated, the reaction does not stop at the monocondensation product, but we did succeed in obtaining a quantitative yield of the monocondensed product **3** by using a large excess of sultone at a temperature of 15–20°C (Scheme 2). We have envisaged to take advantage of this particular reactivity. The compounds **3**, which are readily isolated in a pure state, can be utilized as intermediates in the synthesis of the disymmetric bolaforms (Scheme 2). The insertion of the second polar head is simple and easily generalized to various types of head.

Table 1 lists typical results that illustrate the possibilities of these novel synthons. This process should not be difficult to carry out on an industrial scale.

The bolaforms prepared were characterized from their IR and NMR spectra. It should be noted that the deshielding

observed on the chemical shifts of the $N\text{-}CH_3$ and $N\text{-}CH_2$ groups are consistent with quaternization of the nitrogen atom. Furthermore, the disymmetry of the polar heads was indicated by the differentiation of the ^{13}C NMR peaks of the $N\text{-}CH_3$ groups, which was further support for the proposed structures.

Surface properties

The surfactant properties of these novel bolaforms were studied by measuring interfacial tension (γ) in water, and calculated using the Gibbs' equation (8). The data are illustrated in Figs. 1 and 2 and listed in Table 2.

All compounds tested led to a marked reduction in interfacial tension at the air–water interface (30–35 mN m^{-1}). However, this action was found to depend on the concentration of the particular compound as a function of polar head and length of spacer. The compounds with $n = 12$ exhibited a break in the interfacial tension vs. concentration plots. This property of micellization occurred at relatively low values of critical micelle concentration (cmc), which shows promise for industrial applications.

We noted that the cmc value was strongly dependent on the nature of the polar head. The carboxy-sulfobetaine bolaform **6b** (cmc = 5.5 mM) was a better surfactant than the symmetrical sulfobetaine **2b** (cmc = 8.2 mM) or the carboxybetaine analogs (cmc = 6.7–8 mM (4)). On the other hand, the passage of carboxy-sulfobetaine **6b** to ammonium-sulfobetaine **5b** led to an increase in cmc (cmc = 18 mM). This can be accounted for by the stronger repulsion of the polar heads enhanced by steric interactions. Our findings are in line with those described for cationic bolaforms (12–18 mM (9)). Furthermore, these results were in accordance with those of the general literature; a spacer with $n = 8$ does not permit micellization. By contrast, we noted that introduction of a long alkyl chain onto the nitrogen atom led to a decrease in the cmc value. This was attributed to an increased hydrophobicity. For example, compound **4c** micellized at low concentration (cmc = 5 mM) despite the short spacer ($n = 8$), which is not generally compatible with micellization (9). The surfactants **4c** and **4d**, thus, represent

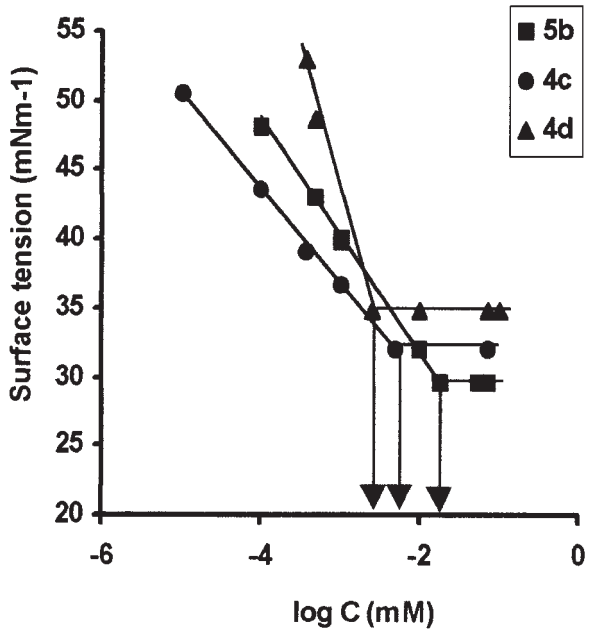
Fig. 1. Plots of interfacial tension (obtained by tensiometry) vs. log [bolaform] at 25°C in water.



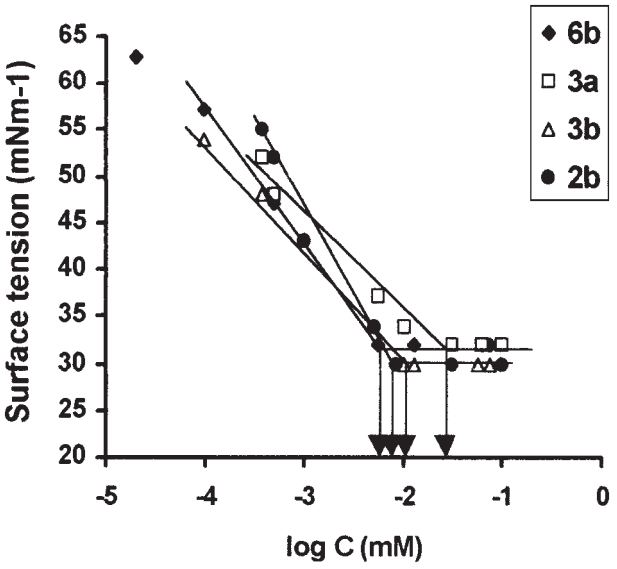


Fig. 2. Plots of interfacial tension (obtained by tensiometry) vs. log [bolaform] at 25°C in water.

a new family of surfactants as a hybrid between bolaforms and gemini surfactants (10). The synthesis proposed here is in keeping with the general pattern of the current research on the access to new potential surfactants. It was noteworthy that the presence of an iodine atom on the cationic head of the bolaforms **4a** and **4b** prevented micellization (at the concentrations studied = 10^{-1} M) even with a -$(CH_2)_{12}$- spacer (comparison **4b** and **4f**).

A number of comments can be made on the surface areas as calculated from the Gibbs' equation (8). The betaine bolaforms **6b** and **2b** occupy a space at the interface that is the arithmetic sum of the surface areas of the two polar heads (11, 12). These results are consistent with the length and flexibility of the spacer, which indicates that these surfactants adopt a " wicket-like" conformation at the air–water interface. By contrast, the calculated surface areas of the head of the disymmetric bolaforms **4d** (A = 188 Å^2) and **4f** (A = 167 Å^2) is slightly superior as the arithmetic sum of the calculated surface areas of the two polar heads (A ~ 130 Å^2) suggests the "wicked-like" conformation undergoes a flattening at the air–water interface. The presence of the methyl acetate group in compound **5b** (A = 252 Å^2) led significantly to flattening out of the molecule at the interface. A same arrangement was proposed for the bolaforms with a spacer n = 8 (see **4c**, A = 275 Å^2). This influence of the length of the hydrophobic chain was also demonstrated by comparison of the molecular areas of compounds **3a** with **3b**. This linear arrangement would be consistent with a more extended occupation of the interface. This type of molecular organization has been described for non-ionic (13) and cationic bolaforms.[2] On the other hand, it can envisage that these structures lead to a vesicular self-association. Further interpretations will have to await the results of light scattering and electron microscopic studies (in progress).

Table 2. Surface parameters of compounds in water at 25°C.

	γ (mN m^{-1})[a]	cmc (mM)	Γ (mol m^{-2})[a]	A (Å^2)[a]

Conclusion

We describe here a convenient route to disymmetric bolaforms bearing at least one sulfobetaine head, which could be scaled up for industrial applications. The method lends itself to a modular synthesis enabling preparation of a variety of derivatives with different polar heads and different spacers. To our knowledge, this is a first synthesis of sulfobetaine disymmetric bolaforms.

Our preliminary results on the surface properties of these bolaforms are encouraging, as they all led to a marked reduction in interfacial tension at the air–water interface at low concentrations. This surfactant action suggests that, by comparison with the well-known activity of other betaine surfactants, these bolaforms have potential applications as

[2] I. Rico-Lattes personal communication.

corrosion inhibitors. The role of the disymmetric head structure and the length of the spacers were demonstrated in micellar self-aggregation behaviour. Self-organization into vesicles is currently under investigation. Comprehension of their physicochemical properties will be facilitated by this convenient route to a wide range of derivatives of original disymmetric bolaform structure.

Experimental

General

Reagents were of commercial quality and were used without purification. IR spectra (ν, cm^{-1}) were recorded on a PerkinElmer 683 spectrophotometer. ^1H and ^{13}C NMR spectra (δ, ppm) were obtained on Bruker AC 80 or Bruker AC 200 instruments. Surface active properties were calculated using Gibbs' equation with the data obtained from measurements carried out Prolabo No. 3 tensima.

Typical procedure for the synthesis of compounds 1

A solution of dimethylamine (33% of ethanol) (3×10^{-2} mol) and dibromoalkane (1×10^{-2} mol) were added to a solution of sodium carbonate (2×10^{-2} mol) in ethanol (60 mL) and water (15 mL). The reaction mixture was heated at reflux and stirred for 24 h. Then the resulting compound was isolated by evaporating of the solvent under reduced pressure. The crude product washed with water (1×10 mL) was extracted with EtO_2.The organic phase was dried on anhyd Na_2SO_4 and evaporated in vacuo. The crude oil was purified by distillation.

*1,8-bis(*N,N- *dimethylamino)octane (**1a**)*

Yield: 98%. Colourless oil, bp 60°C, 0.06 mm Hg. ^1H NMR (200 MHz, $CDCl_3$) δ 1.1 (m, 12H, $(CH_2)_6$), 2.3 (t, 4H, NCH_2), 1.9 (s, 12H, NCH_3). ^{13}C NMR (200 MHz, $CDCl_3$) δ 27.2–28.3 ($(CH_2)_6$), 45.2 (NCH_3), 59.7 (NCH_2). Anal calcd. for $C_{12}H_{28}N_2$ (200.37): C 71.86, H 13.97, N 13.97; found: C 71.66, H 14.15, N 14.13.

*1,12-bis(*N,N-*dimethylamino)dodecane (**1b**)*

Yield: 98%. Colourless oil, bp 80–82°C, 0.05 mm Hg. ^1H NMR (200 MHz, $CDCl_3$) δ 1.1 (m, 20H, $(CH_2)_{10}$), 2.1 (t, 4H, NCH_2), 1.9 (s, 12H, NCH_3). ^{13}C NMR (200 MHz, $CDCl_3$) δ 27.4–28.5 ($(CH_2)_{10}$), 45.4 (NCH_3), 59.9 (NCH_2). Typical procedure for the synthesis of compounds 2

Compounds **2** were prepared by the addition of diamine **1** (1×10^{-2} mol) to 1,3-propane sultone (2.2×10^{-2} mol) in anhyd acetonitrile (100 mL). The solution was stirred at reflux for 4 h, then cooled and filtered. After crystallization from methanol–acetone (1:9), pure compounds **2** were obtained as solid, which decomposed during melting point determination.

*1,8-bis(*N,N- *dimethylammonio*-N-*propyl-1-sulfonate)octane (**2a**)*

Yield: 95%. White powder, mp 210°C. Typical procedure for the synthesis of compounds 3

Sulfobetaine **3** was prepared by the addition of α,ω-bis(*N*,*N*-dimethylamino) alkane (1×10^{-2} mol) to a stirred solution of 1,3-propane sultone (2×10^{-3} mol) in anhyd acetone (50 mL). The reaction mixture was stirred at room temperature for 3 h, cooled, and filtered. The amphiphilic product was purified by recrystallization from methanol–ether (1:9), and dried in vacuo over phosphorus pentoxide.

*1-(*N,N-*dimethylammonio*-N-*propyl-1-sulfonate)-8-(*N′,N′-*dimethylamino)octane (**3a**)*

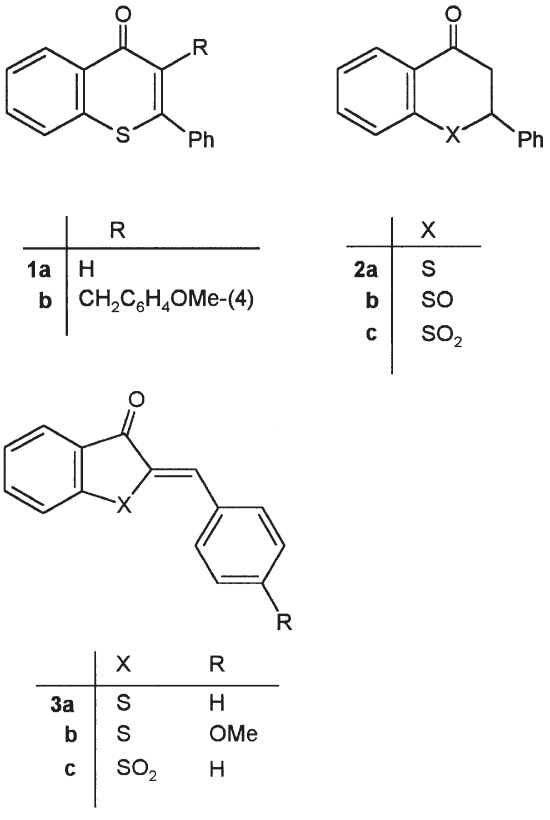
Elimination, ring-contraction, and fragmentation reactions of 1-thioflavanone 1-oxides

László Somogyi

Abstract: Epimeric thioflavanone sulfoxides (**2b**) were selectively transformed into thioflavone (**1a**), thioaurone (**3a**), and di(2-cinnamoylphenyl) disulfide (**4**). Disulfide **4** can be recyclized into thioaurones (**3a**–**c**) and thioflavanones (**2a**, **5**) with heterolysis of the S—S bond. The 3-*p*-anisylidene sulfoxide analog of **2b** (**6**) transforms, with fragmentation, into 4′-methoxythioaurone **3b**.

Key words: chalcone, ring contraction, sulfoxides, thioaurones, thioflavonoids.

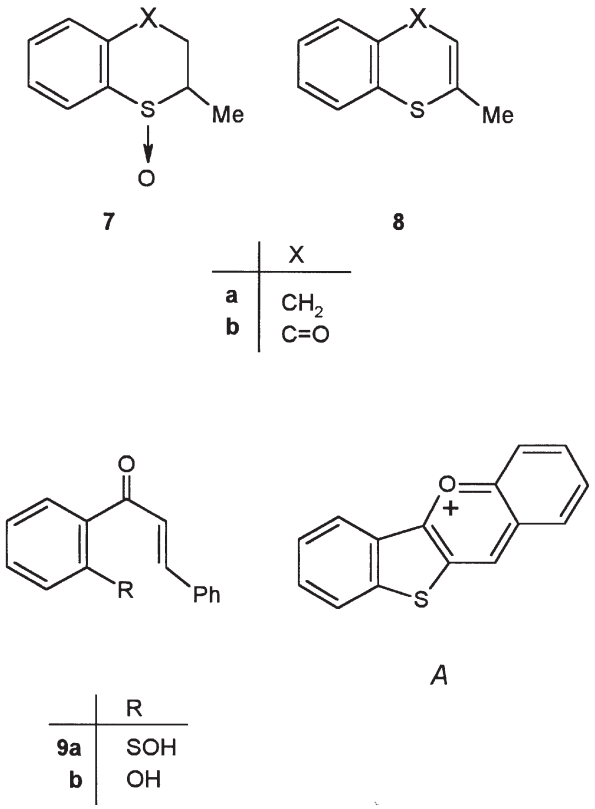


Résumé : On a réalisé la transformation sélective des sulfoxydes épimères de la thioflavanone (**2b**) en thioflavone (**1a**), thioaurone (**3a**) et en disulfure de di(2-cinnamoylphényle) (**4**). Le disulfure **4** peut être recyclisé en thioaurones (**3a**–**b**) et en thioflavanones (**2a**, **5**) avec hétérolyse de la liaison S—S. Le sulfoxyde de 3-*p*-anisylidène analogue de **2b** (**6**) subit une fragmentation et se transforme en 4′-méthoxythioaurone (**3b**).

Mots clés : chalcone, contraction de cycle, sulfoxydes, thioaurones, thioflavonoïdes.

[Traduit par la Rédaction]

Introduction



In the course of our efforts for the synthesis of 1-thioflavone derivatives, dehydrogenation of the dihydrobenzothiopyran (thioflavan) ring became necessary. Several methods useful in flavonoid chemistry have been successfully adopted (1, 3*c*) for thioflavanones, however, in some cases these methods were found either ineffective or, just the opposite; destructively drastic. Due to the greater variability of the electronic states of sulfur as compared to that of oxygen, additional methods, e.g., treatment (2) with PCl_5, or ceric ammonium nitrate (CAN) oxidation (3*a*–*c*) of thioflavanone (**2a**), and also alkali-mediated (2, 3*b*) or Pummerer-type transformation (3*b*) of sulfoxides (e.g., **2b**, in ca. 50% yield) have been successfully applied for the dehydrogenation. The PCl_5, CAN, or alkali-mediated transformations may have severe limitations when sensitive functional groups are present. As to the Pummerer-type transformation, 2-methyl-1-thiochroman 1-oxides (**7a**, **b**) have been transformed (3*d*) into the corresponding thiochromenes (**8a**, **b**) in nearly quantitative yields by treatment with acetic anhydride. However, due to the different electronic properties of the Me and Ph groups, the sulfoxides **2b** and 6-Me-**2b** undergo also ring-contraction reaction photochemically (4*b*, 4*d*), thermally (1), or upon treatment with I_2–DMSO (1) to give thioaurones (**3a**, 5-Me-**3a**) merely in 14–70% yields. Because of the relatively poor yields and the competing formation of **1a** and **3a**, we decided to find a selective conversion of thioflavanone 1-oxide (**2b**) into **1a** or **3a**.

Results and discussion

The conversions of thioflavanone 1-oxide (**2b**) into either thioflavone (**1a**) or thioaurone (**3a**) proceed with loss of the elements of water, which are consumed by Ac_2O. The initial steps of these elimination reactions are, however, different. The Pummerer-type reactions of sulfoxides involve (3*e*, 3*f*) transient formation of sulfur and sulfur-stabilized carbonium cations. Accordingly, reaction conditions favouring the activation of the acyl moiety of the anhydrides may be advantageous for the formation of thioflavone, which starts with an electrophilic attack at the sulfoxide group exerted by the proton of the acid catalyst, or by the acetyl cation generated from Ac_2O by protonolysis or by the electrophilic acetyl moiety of Ac_2O being activated by the strong nucleophile (15) 4-dimethylaminopyridine (DMAP) (see Scheme 1). Thus, treatment of sulfoxide **2b** with Ac_2O–(TsOH), Ac_2O–DMPA, or TFAA–Et_3N afforded **1a** in excellent yields (>80% for the pure product, see Table 1).

The methylene group of 1-(thio)benzopyran-4-ones is activated by the neighboring carbonyl and -XCH(Ph)- groups (X = O, S, SO, SO_2), so this is the reactive site of the molecule when treated with bases. Thus, the deprotonated C-3 creates a bond to the electron-deficient sulfur, and then the transiently generated thiiranium (4) species is stabilized by ring contraction and loss of proton to give 2-benzylidenebenzo[*b*]thiophen-3(2*H*)-one (thioaurone **3a**, see Scheme 1). Accordingly, treatment of sulfoxide **2b** with Ac_2O in the presence of NaOAc, which behaved as a strong base in this medium, afforded thioaurone (**3a**) almost quantitatively (see Table 1).

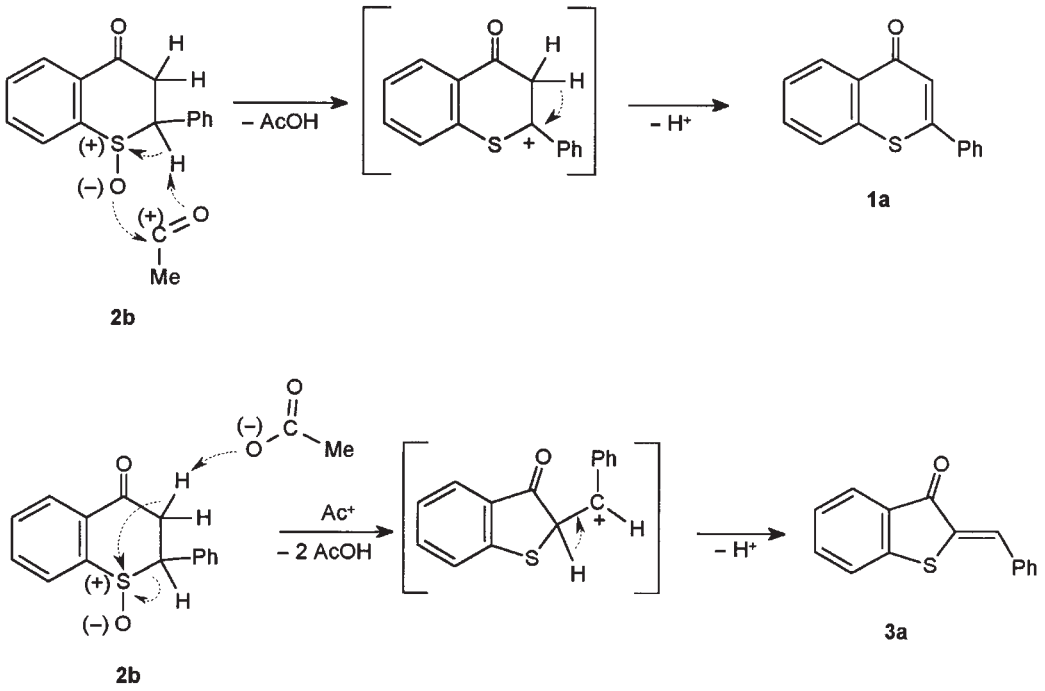

Fig. 1. ORTEP drawing of compound **4** with 50% of the thermal ellipsoids.

On varying the acid or base character of the additives, treatment of sulfoxide **2b** with Ac_2O–Et_3N or $(EtCO)_2O$–Et_3N, and also with 1,3-diisopropylcarbodiimide (DIC, see Table 1), gave a new high-melting yellow product sparingly soluble in most of the common organic solvents. (In the reaction of **2b** with DIC a considerable amount of thioflavanone 1,1-dioxide **2c** was also produced, see Table 1). At room temperature, the Ac_2O–Et_3N-mediated transformation of the *equatorial* (1,2-*trans*) sulfoxide epimer (5) **2b** afforded this product in a yield half times higher than the *axial* (1,2-*cis*) (3*c*, 5) compound (see Table 1). One the basis of C, H, and S analyses (see footnotes of Table 1) and the nonanalyzable 200 MHz ^{1}H NMR spectrum, a $C_{15}H_{11}OS$ (FW = 239.31) elemental composition was first suggested for the new compound with some uncertainty, as the hydrogen content was concerned. The product was, however, quite different in all respects (color, mp, TLC, solubility, IR, ^{1}H NMR and EI-mass spectra, etc.) from **1a** and **3a**, respectively, ($C_{15}H_{10}OS$, FW = 238.3) or **2a** ($C_{15}H_{12}OS$, FW = 240.3). Eventually, the MALDI-TOF spectrometry (see also Table 1, footnotes) indicated a $C_{30}H_{22}O_2S_2$ (FW = 478.61) composition. X-Ray diffraction analysis of this new compound revealed the open-chain disulfide structure **4** (see Fig. 1) with an S—S bond distance of 2.053 Å. (Previously, photolysis of thiochroman-4-one 1-oxides has been reported (4*d*) to give o-hydroxyaralkyl disulfides in 6–8% yields via thiyl radicals). The *trans*-chalcone structure of compound **4** was corroborated by the J = 15.77 Hz coupling of the vinylene hydrogens at δ = 7.90 and 7.77 ppm in the 500 MHz ^{1}H NMR spectrum. Disulfide **4** was presumably produced from sulfoxide **2b** via a 2-cinnamoylbenzenesulfenic acid intermediate (**9a**). This step of the ring-opening of **2b** seems to be similar to the well-known base-mediated formation of 2′-hydroxychalcones (e.g., **9b**) from flavanones, however, sulfenic acids (3*g*) are generally highly unstable. Decomposition of pseudopeptidic sulfoxides via β-elimination to sulfenic acids (followed by bimolecular recombination to thiolsulfinates RS(O)SR) and the corresponding alkene has been reported most recently (16). Upon treatment with trihaloacetic anhydride [$(CX_3CO)_2O$, X = F, Cl] in a Pummerer-like reaction, thiolsulfinates are known (17) to transform into disulfides and sulfinyl carboxylates [$RS(O)OCOCX_3$] which latter gives adducts readily with olefins.

Scheme 1.

Before performing the MALDI-TOF MS and X-ray measurements discussed above to lead to the identification of the disulfide-structure for **4**, EI-MS (see footnotes of Table 1) and HR-MS experiments were carried out with the *m*/*z* = 240 ion (M = 240.0599 Da). However, neither these mass spectral studies nor the 200 and 360 MHz ^{1}H NMR spectra (each containing superimposed signals in the "aromatic" region; δ = 8.16–7.42 ppm) gave convincing evidence for the structure of the new compound. The fragment *m*/*z* = 237 (base peak in the EI-MS) could be attributed to the formation of the benzo[*b*]thieno-[3,2-*b*]pyrylium ion (*A*), whose perchlorate has been previously prepared (7) by the condensation of 1-thia-3-indanone with salicylic aldehyde in AcOH–$HClO_4$. The same fragment was observed in the EI-MS of 1,2-*cis*-**2b** (3*c*, 5) and **3a** as a base peak, but with lesser intensity for the 1,2-*trans*-**2b**, (5) and not at all in the spectrum of thioflavone (**1a**) where *m*/*z* = 238 [$M^{+\cdot}$] was the base peak (5).

Since the reaction of other sulfoxides with active methylene compounds in the presence of dehydrating agents (Ac_2O, P_4O_{10}, DCC) has been reported (6) to furnish sulfonium ylides, a possible formation of 1,2- or 1,3-sulfur ylides similar to the thiiranium intermediate mentioned above was considered. Therefore, the reactivity of the sparingly soluble new compound **4** (at that time with uncertain structure) was also examined (see Table 2). Thus, treatment with Ac_2O–H_2SO_4 afforded thioflavone (**1a**) and thioaurone (**3a**) in poor yields. Similarly, when reacted with the I_2–DMSO couple or (in contrast to the transformation of **2b** in acid medium) with hot AcOH or cold sulfuric acid again **3a** was formed, and the reaction with CAN resulted in thioaurone 1,1-dioxide (**3c**). Interestingly, upon treatment with 4-methoxybenzaldehyde–piperidine (which is known to transform **2a** into **5**), compound **4** underwent transformation into 4′-methoxythioaurone (**3b**) and 3-(4-methoxybenzylidene)thioflavanone (**5**, see Scheme 2). Cleavage of the S—S bond, exhibiting acid–base properties can be effected by both nucleophiles or bases and electrophiles (3*g*).

The aforementioned anisaldehyde–piperidine-mediated recyclization of **4** into the thiaindanone and thiobenzopyranone derivatives **3b** and **5** can be explained by the heterolysis of the S—S bond followed by cyclization into **3a** and **2a** (see Scheme 3), and their subsequent transformation with the aldehyde into **3b** and **5**, respectively. Indeed, treatment of thioaurone **3a** with 4-anisaldehyde in piperidine at 150°C for 1.5 h afforded ca. 65% of **3b**. Compound **3b** was also formed in good yield in a fragmentation reaction upon treatment of 3-(4-methoxybenzylidene)thioflavanone 1-oxide (**6**) with Ac_2O–TsOH (see Table 1). Recently, deprotection–cyclization of 4-methoxybenzyl-protected 2′-mercaptochalcones into thioflavanones has been reported (14).

Experimental

Melting points (uncorrected): Kofler block. Solutions were concentrated under reduced pressure in a rotary evaporator (<50°C, bath). TLC: Kieselgel 60 F_{254} (Merck, Alurolle). IR(KBr discs): PerkinElmer 16 PC-FT spectrometer. ^{1}H NMR: 200 MHz, Bruker WP 200 SY and 500 MHz, Bruker DRX 500 spectrometers. MS: VG-7035 GC–MS–DS (EI, 70 eV, direct insertion technique); high-resolution spectrometry (EI, 70 eV, resolution 10 000, accuracy ±5 ppm, direct insertion), AEI MS-902; MALDI-TOF measurements, Bruker BIFLEX III^{TM} mass spectrometer (19 kV acceleration voltage with pulsed ion extraction (PIE^{TM}); detection of the positive ions, reflection mode (20 kV); laser desorption, nitrogen laser (337 nm, 1 ns pulse width) operating at 4 Hz, 100–120 shots were summed; external linear calibration, with poly(ethylene glycol) (M_n = 1450, MWD = 1.02). tions for preparation of samples: 1,8-dihydroxy-9(10*H*)-anthracenone matrix–THF (20 mg mL^{-1}), AgTFA–THF (5 mg mL^{-1}) to enhance the cationization; 0.5 μL of the mixture of solutions analyte (1 mg **4** mL^{-1} CH_2Cl_2) – matrix – AgTFA in 10:50:1 v/v ratio was deposited onto the sample plate (stainless steel) and allowed to air-dry). X-ray diffraction analysis (for yellow plate crystals (0.48 × 0.39 × 0.1 mm) of $C_{30}H_{22}O_2S_2$, grown from Ac_2O, M = 478.6, orthorhombic, a = 10.387(1) Å, b = 12.298(1) Å, c = 18.471(1) Å, V = 2359.7 $Å^3$, Z = 8, space group: *Pbcn*, ρ_{calc} = 1.347 g cm^{-3}): Enraf–Nonius MACH3 diffractometer; data were collected at 293(1) K, Mo Kα radiation λ = 0.71073 Å, ω-2Θ motion, Θ_{max} = 27.8°, 2222 reflections of which 1612 were unique with $I > 2\sigma(I)$; decay: 4%. The structure was solved using the SIR-92 software (8) and refined on F^2 using SHELX-97 program (9); publication material was prepared with the WINGX-97 suite (10); R(F) = 0.039 and $wR(F^2)$ = 0.094 for 2222 reflections, 154 parameters.

General method for the preparation and work-up of the reaction mixtures

The substrate was added to a mixture of the reagents and allowed to react, if necessary with stirring, as indicated in Tables 1 and 2. The reaction mixtures were processed:

(A) The product was filtered off from the cold reaction mixture; (B) The reaction mixture was concentrated; (C) The residue was triturated with MeOH and (or) water to give a crude product; (D) A $CHCl_3$ solution of the residue was washed with (when DMAP was used at first with aq. $KHSO_4$) aq. $NaHCO_3$ and water, dried ($MgSO_4$), treated with fuller's earth and charcoal and then concentrated; (E) The cold reaction mixture was poured into ice water; (F) The crude product was purified by column chromatography (eluent, $CHCl_3$); (G) The residue was triturated with hexane to give a crude product; (H) The crude product was triturated with $CHCl_3$ and the undissolved material was filtered off; (I) The material dissolved in the filtrate was purified by column chromatography (eluent, $CHCl_3$); (J) The mixture was extracted with $CHCl_3$ and processed as in (D); (K) Crystallization from the solvent indicated in Table 1 or 2; (L) A $CHCl_3$ solution of the residue was washed with a necessary amount of aq. $Na_2S_2O_3$ and water, dried ($MgSO_4$), treated with charcoal and then concentrated.

*3-(4-Methoxybenzyl)thioflavone (**1b**)*

According to the known method (11), a mixture of anisaldehyde (8.753 g, 98%, 63 mmol), thioflavanone (**2a**, 14.418 g, 60 mmol), and piperidine (2.5 mL, 25.28 mmol) was heated at 152°C (bath) for 2.5 h (instead of the 1 h reported), cooled and treated with MeOH to give crude (6.311 g, 29.3%, mp 123–126°C) or recrystallized 3-(4-methoxybenzylidene)thioflavanone (**5**, 5.572 g, 25.9%), mp 133–133.5°C (from 2-PrOH); ref. 11: 132°C (from MeOH), yield 52.2%. The mother liquor of the crude product **5** was concentrated and the residue triturated with EtOAc (10 mL) to give, after successive addition of hexane (30 mL), crude (2.623 g, 12.2%) or recrystallized colorless **1b** (2.245 g, 10.4%), mp 148.5°C (from 2-PrOH). IR (KBr) (cm^{-1}) ν: 1618 (C=O). ^{1}H NMR ($CDCl_3$, 360 MHz) δ 8.57–8.55 (m, 1 H, 5-H), 7.60–7.36 (m, 8 H, 6,7,8-H and Ph), 6.96–6.93 (d-shaped m, 2 H, 2″, 6″-H) 6.73–6.69 (m, 2 H, 3″, 5″-H), 3.94 (s, 2 H, CH_2), 3.73 (s, 3 H, OMe). Anal. calcd. for $C_{23}H_{18}O_2S$ (%): C 77.07, H 5.06; found (%): C 77.26, H 5.08.

Détermination de la stabilité du complexonate peu soluble à partir des données pH-métriques

Igor Povar

Résumé : Nous avons élaboré une méthode de détermination du produit de solubilité du complexonate avec une composition connue à partir seulement des valeurs d'équilibre du pH, étant donnée la composition initiale du mélange hétérogène (le lot *a*). Pour la détermination de la constante de stabilité en solution, ce lot des données est complété par l'information sur la solubilité du précipité. Nous avons montré que, dans l'absence de réactions de formation des complexes dans la solution, on peut évaluer les concentrations d'équilibre, celles-ci résiduaires des composantes du précipité, sur la base du lot *a*. On tire la conclusion sur la possibilité de l'application de la méthode élaborée pour le test et la standartisation des électrodes ion-sélectives. On discute les qualités et les défauts de la méthode élaborée. Par ailleurs, les valeurs des constantes d'équilibre et des concentrations d'équilibre et les concentrations résiduaires pour une série de systèmes réels, que nous avons calculées à partir des données expérimentales connues, s'accordent bien avec celles des tables obtenues dans les mêmes conditions.

Mots clés : méthode potentiométrique, système hétérogène, complexonate peu soluble, complexone, concentration d'équilibre, produit de solubilité, constante de stabilité, réaction d'hydrolyse.

Abstract: A new method has been developed for the determination of the solubility product of complexonate of known composition; because of the initial composition of the heterogeneous mixture (lot *a*), it uses only the equilibrium values of the pH. For the determination of the stability constant in solution, these data have been completed with information on the solubility of the precipitate. We have shown that, on the basis of lot *a* and in the absence of reactions of formation of complexes in solution, it is possible to evaluate the equilibrium constants, since they are residuals of the compositions of the precipitate. We conclude on the possibility of applying this method to the test and standardization of ion-selective electrodes. The qualities and defect of the method are discussed. Otherwise, the values for the equilibrium constants and the equilibrium as well as the residual concentrations that we have calculated for a series of real systems from known experimental data are in good accord with those reported in tables under the same conditions.

Key words: potentiometric method, heterogeneous system, slightly soluble complexonate, complexone, equilibrium concentration, solubility product, stability constant, hydrolysis reaction.

[Journal Translation]

Introduction

Les produits de solubilité (K_S) de même que les constantes de stabilité des complexonates peu solubles dans un système « phase solide – solution saturée » sont utilisés à la résolution de plusieurs importantes tâches de la chimie analytique (1–3).

À présent les caractéristiques quantitatives d'équilibre des systèmes hétérogènes, y compris les produits de solubilité, sont déterminées par les méthodes physico-chimiques, parmi lesquelles la plus efficace est la méthode potentiométrique (4–6). Une des méthodes les plus sévères de la détermination de K_S est la méthode de la mesure de l'activité de tous les ions formant le précipité. Cependant cette méthode est liée à certaines suppositions et admissions, inévitables à la mesure de l'activité des ions du précipité. En plus, la question de la création des électrodes ion-sélectives stables et reproduites est décidée pour un petit nombre des ions.

L'une des méthodes d'étude des équilibres chimiques hétérogènes la plus souvent utilisée reste la méthode classique de solubilité. Dans le cadre de cette méthode lors de l'étude des équilibres chimiques dans le système « complexonate peu soluble (la phase solide) – solution saturée (la phase liquide) », on obtient deux lots de données expérimentales : (*i*) la dépendance de la solubilité (*S*) de concentrations initiales des constituants dans la solution et (*ii*) la mesure de *S*, accompagnée de la détermination d'une ou de quelques fonctions supplémentaires de la composition de la solution, le plus souvent du pH. Dans le second cas une certaine partie d'information sur les concentrations initiales devient fréquemment superflue, et c'est pourquoi une partie des données n'est parfois pas présentée. Du moment où toutes les constantes sont connues, la connaissance des concentrations analytiques (les concentrations résiduelles) des constituants du sédiment dans la solution saturée est largement suffisante pour calculer les concentrations d'équilibre et du produit de solubilité (4).

Suite à l'analyse de la solubilité des complexonates, les auteurs (3) ont constaté la régularité suivante. Pour les ligands comme les anions d'EDTA et ses analogues, la formation des complexonates peu solubles protonés (type I) est plus caractéristique avec la composition générale $M'_1M_xH_yL_{z(S)}$ (7–10) (ici et plus bas, la quantité de l'eau hydratée en précipité n'est pas indiquée), où M'_1 est le cation du métal alcalino-terreux, $x = 0, 1, 2$, en fonction des valeurs de charges de l'ion du métal M et du ligand L. Par ailleurs, les complexones avec la plus petite dentantité forment des complexonates peu solubles $M'_x\ ML_{(S)}$ (type II) (11). Il convient de remarquer que les mesures de la solubilité sont caractérisées par une plus grande durée et un grand volume du travail en comparaison avec d'autres méthodes de la détermination des constantes de l'équilibre (4).

Nous avons élaboré auparavant une méthode potentiométrique de la détermination du produit de solubilité des acides peu solubles (y compris des complexones) de composition connue, qui est basée sur les données de pH de leurs solutions saturées. L'essence de la méthode consiste en un compte sévère de l'influence du pH pour le procès de la formation du complexonate peu soluble. La valeur du pH peut influencer soit directement, dans le cas de la formation du complexonate protonés ou hydroxocomplexes mixtes, soit indirectement, quand les ions de H^+ ou de OH^- figurent dans la réaction de protonation du ligand-complexone, qui sont les bases conjuguées des acides faibles. Cette méthode a été utilisée pour la détermination de K_S des complexones peu solubles, comme le EDTA et les autres.

Le but de ce travail est l'élaboration de la méthode potentiométrique de la détermination du produit de solubilité des complexonates peu solubles des deux types, ainsi que de leurs constantes de stabilité en solution à partir des données sur la solubilité en combinaison avec des mesures du pH.

La méthode peut être utilisée même si la phase solide ne contient pas d'ions de H^+ ou de OH^- (complexonates du type II). Dans ce cas, il est nécessaire qu'au moins l'un des constituants du complexonate neutre participe aux réactions d'hydrolyse ou de protonation (protolyse).

Partie théorique

D'abord, nous examinerons le système hétérogène contenant un complexonate protoné peu soluble ayant la composition $M'_1M_xH_yL_{z(S)}$ (du type I) en qualité de phase solide. Dans la phase liquide, nous considérerons une série d'équilibres coexistants. En fonction de valeurs de pH dans la solution aqueuse, peuvent se former des complexes protonés MH_xL normaux (moyens) ML et même des hydroxocomplexes mixtes $M(OH)_xL$. À l'augmentation du rapport ligand/métal, la formation des complexonates avec la composition ML_2 et ML_3 est possible. Dans le cas général, le lot complet des équilibres indiqués peut être représenté sous forme des équations (pour la simplicité les charges on laisse passer) :

$$[1]\qquad M'_lM_xH_yL_{z(S)} = lM' + xM + yH + zL,$$

$$K_S = [M']^l[M]^x[H]^y[L]^z$$

$$[2]\qquad M + (n-m)H + mH_2O + kL = MH_n(OH)_mL_k,$$

$$\beta_{1n(m)k} = \frac{[MH_n(OH)_mL_k]}{([M][H]^{n-m}[L]^k)}$$

$$[3]\qquad M + iH_2O = M(OH)_i + iH, \quad K_i = [M(OH)_i][H]^i/[M]$$

$$[4]\qquad L + jH = H_jL, \quad K_j = [H_jL]/([H]^j[L])$$

Les équations [3] et [4] incluent les réactions possibles d'hydrolyse de l'ion métallique et celles de protolyse de l'anion du complexonate. On indique aussi les constantes d'équilibre correspondantes. Le système d'équations du bilan des matériaux dans ce système hétérogène peut être écrit sous la forme (12, 13) :

$$\begin{aligned} C^0_M &= C_M + x[M'_lM_xH_yL_z]_{(S)} \\ [5]\qquad C^0_L &= C_L + z[M'_lM_xH_yL_z]_{(S)} \\ C^0_H &= C_H + y[M'_lM_xH_yL_z]_{(S)} \end{aligned}$$

où C^0_M et C^0_L sont les concentrations initiales en ion métallique et en ligand dans le mélange hétérogène; C^0_H (C^0_{OH}) représente la concentration en excès des ions d'hydrogène (d'hydroxyde) ($C^0_H = -C^0_{OH}$). Dans les équations [5] par C_i nous avons noté les concentrations résiduaires des ions et par $[M'_lM_xH_yL_z]_{(S)}$, le nombre de moles du précipité par litre de solution. Il est à signaler, que les équations du type [5] ne se réalisent exactement que pour les solutions diluées, quand le volume du mélange hétérogène est pratiquement égal au volume de la phase liquide (14). Dans le cas du déroulement des réactions [2] à [4], les concentrations résiduaires des ions sont exprimées par les relations :

$$[6]\qquad C_M = \sum_{i=0}[M(OH)_i] + \sum_{n=1}\sum_{m=0}\sum_{k=0}[MH_n(OH)_mL_k]$$

$$[7]\qquad C_L = \sum_{j=0}[H_jL] + \sum_{n=1}\sum_{m=0}\sum_{k=0}k[MH_n(OH)_mL_k]$$

$$[8]\qquad C^0_H = [H] - [OH] + \sum_{j=1}j[H_jL] - \sum_{i=1}i[M(OH)_i] + \sum_{n=1}\sum_{m=0}\sum_{k=0}(n-m)[MH_n(OH)_mL_k]$$

En excluant le terme $[M'_lM_xH_yL_z]_{(S)}$ du système d'équations [5], nous obtenons

$$[9]\qquad zC^0_M - xC^0_L = z\sum_{i=0}[M(OH)_i] - x\sum_{j=0}[H_jL] + \sum_{n=1}\sum_{m=0}\sum_{k=0}(z-ky)[MH_n(OH)_mL_k$$

$$[10]\qquad yC^0_M - xC^0_H = \sum_{i=0}(y+ix)[M(OH)_i] - x\sum_{j=1}j[H_jL] - x[H] + x[OH] + \sum_{n=1}\sum_{m=0}\sum_{k=0}(y-x(n-m))[MH_n(OH)_mL_k]$$

En exprimant les concentrations d'équilibre des espèces dans les équations [6] à [10] par les constantes d'équilibre [2] à [4], nous obtenons (si $i = 0$, alors $K_0 = 1$) :

© 2001 CNRC Canada

$$[11]\quad C_M = [M]\alpha_M + \sum_{n=1}\sum_{m=0}\sum_{k=0}\beta_{1n(m)k}[M][H]^{n-m}[L]^k$$

$$[12]\quad C_L = [L]\alpha_L + \sum_{n=1}\sum_{m=0}\sum_{k=0}k\beta_{1n(m)k}[M][H]^{n-m}[L]^k$$

$$[13]\quad C_H = [H] - K_W[H]^{-i} + [L]\varphi_L - [M]\varphi_M + \sum_{n=1}\sum_{m=0}\sum_{k=0}(n-m)\beta_{1n(m)k}[M][H]^{n-m}[L]^k$$

$$[14]\quad zC_M^0 - xC_L^0 = z[M]\alpha_M - x[L]\alpha_L + \sum_{n=1}\sum_{m=0}\sum_{k=0}(z-ky)\beta_{1n(m)k}[M][H]^{n-m}[L]^k$$

$$[15]\quad yC_M^0 - xC_H^0 = \sum_{i=0}(y+ix)K_i[M][H]^{-i} - x[H] + x[OH] - x\varphi_L + \sum_{n=1}\sum_{m=0}\sum_{k=0}(y-x(n-m))\beta_{1n(m)k}[M][H]^{n-m}[L]^k$$

Dans les équations mentionnées plus haut, la notation (13) a été utilisée :

$$\alpha_M = \sum_{i=o}K_i[H]^{-i} \qquad \alpha_L = \sum_{j=o}K_j[H]^j$$

$$\varphi_M = \sum_{i=o}iK_i[H]^{-i} \qquad \varphi_L = \sum_{j=1}jK_j[H]^j$$

En mesurant la solubilité du complexonate $M'_1M_xH_yL_{z(S)}$ en fonction du pH, donc et de C_H^0 alors $zC_M^0 = xC_L^0 = const$ et $C_L = zS$. Il faut mentionner que $pH = -\log a_{H+} = -\log [H^+]\gamma_{H+}$, où γ_{H+} est le coefficient d'activité du proton. En partant des données S(pH), à condition que les constantes d'équilibre [2] à [4] soient connues, sur la base de la solution du système d'équations [11] et [12] avec deux inconnues [M] et [L], nous pouvons déterminer le produit de solubilité du complexonate peu soluble. Si la solubilité est mesurée en eau, alors pour le calcul il faut utiliser l'équation [13], puisque dans ce cas $C_H = yS$. Alors nous parvenons au système d'équations [11] à [13], grâce auquel nous pouvons, en principe, calculer la constante de stabilité β de l'un des complexonates en solution. Ainsi, on peut être sûr que la quantité obtenue β sur la base d'une seule mesure, S(pH) n'aura qu'un caractère approximatif.

Nous admettons qu'en qualité de données expérimentales nous avons des concentrations initiales des constituants du précipité dans le mélange hétérogène C_i^0 et leurs concentrations résiduaires dans la solution C_i, de même que le pH du mélange. À la variation du rapport des concentrations en C_M^0 et en C_L^0, existe une corrélation évidente entre la solubilité S et les concentrations résiduaires C_i. Si $C_M^0 < C_L^0$, alors $C_M = xS$, $C_L > zS$. Par contre, si $C_M^0 > C_L^0$, alors $C_L = zS$ et $C_M > xS$. Dans le cas d'un lot complet de données C_i^0, C_i et pH, nous pouvons utiliser les équations [11] à [15], les trois desquelles sont indépendantes. À l'analyse des ces équations nous pouvons tirer les conclusions suivantes. Sur la base du système d'équations [14] et [15] et des constantes d'équilibre de table [2] à [4], nous calculons les concentrations d'équilibre de l'ion métallique et du complexone à l'aide de la corrélation [1] — la quantité K_S. Ainsi, le produit de solubilité peut être déterminé seulement sur la base des valeurs du pH de la solution saturée, connaissant la composition initiale du mélange préparé. En résolvant le système de trois équations indépendantes arbitraires, par exemple, {[11], [14], [15]} ou {[11], [12], [15]}, on obtient la constante de stabilité de l'une des espèces solubles du complexonate. Pour atteindre ce but, il faut mesurer encore la concentration de l'un des constituants du précipité ou sa solubilité.

Si dans la solution saturée la formation des complexes est absente, alors les équations [14] et [15] se simplifient, ayant la forme suivante :

$$[16]\quad zC_M^0 - xC_L^0 = z[M]\alpha_M - x[L]\alpha_L + \sum_{n=1}\sum_{m=0}\sum_{k=0}(z-ky)\beta_{1n(m)k}[M][H]^{n-m}[L]^k$$

$$[17]\quad yC_M^0 - xC_H^0 = \sum_{i=0}(y+ix)K_i[M][H]^{-i} - x[H] + x[OH] - x\varphi_L + \sum_{n=1}\sum_{m=0}\sum_{k=0}(y-x(n-m))\beta_{1n(m)k}[M][H]^{n-m}[L]^k$$

La solution du système des équations [16] et [17] donne les résultats suivants :

$$[18]\quad [M] = \frac{\{C_M^0(qx-y) + x([OH]-[H])\}\alpha_L + \varphi_L C_M^0(z-nx)}{z\varphi_L\alpha_M - \alpha_L\sum_{i=0}(y+ix)K_i[H]^{-i}}$$

$$[19]\quad [L] = \frac{C_M^0(nx-z) + z[M]\alpha_M}{x\alpha_L}$$

Ainsi, si les valeurs de C_i^0 et de pH de la solution sont connues, la solution du système d'équations [16] et [17] permet de déterminer les concentrations d'équilibre [M] et [L]. À l'aide de la relation

$$C_i = [i] \times \alpha_i$$

on calcule les concentrations résiduaires des constituants « i » du précipité (ou sa solubilité).

On examine aussi le cas de formation du complexonate moyen peu soluble (du type II) de composition $M'_xML_{(S)}$:

$$[20]\quad M'_xML_{(S)} = xM' + L + M, \qquad K_S = [M']^x[M][L]$$

Nous examinerons le lot des réactions [2] à [4] en solution. Les équations du bilan des matériaux dans la solution [11] à [13] (ici $C_H^0 = C_H$) sont complétées par les relations

$$C_M^0 = C_M + [M'_xML_{(S)}], \qquad C_L^0 = C_L + [M'_xML_{(S)}]$$

La différence entre la deuxième et la première est :

$$[21]\quad C_L^0 - C_M^0 = [L]\alpha_L - [M]\alpha_M + \sum_{n=1}\sum_{m=0}\sum_{k=0}(k-1)\beta_{1n(m)k}[M][H]^{n-m}[L]^k$$

Comme dans le cas précédent, à condition de connaître la composition initiale du mélange (C_i^0) et des valeurs du pH en solution saturée, on peut calculer la quantité K_S [20] sur la base des équations [13] et [20] et des constantes

d'équilibre des réactions [2] à [4]. Si on mesure encore la solubilité du précipité ou la concentration résiduaire de l'ion métallique ou du ligand, alors, sur la base du système de trois équations indépendantes [13], [17], [11] ou [12], on détermine la constante de stabilité de l'espèce chimique fixée du complexonate.

Donc, pour la détermination du produit de solubilité du complexonate dans tous les deux cas il est suffisant de connaître la composition initiale du mélange et la valeur d'équilibre du pH de la solution. Pour la détermination de la constante de stabilité du complexe, ce lot minimum des paramètres doit être complété par des données sur la solubilité de la phase solide. Il faut mentionner que la possibilité de cette minimisation n'a jamais été remarquée.

Résultats du calcul et discussion

Comme illustration de la mise en œuvre du moyen proposé de la détermination des constantes d'équilibre, nous ferons l'analyse de deux types du système « complexonate peu soluble – solution saturée[2]».

Les données expérimentales pour les systèmes examinés ici ont été obtenues par les auteurs (7, 8, 15) par la méthode des concentrations résiduelles (ou de la solubilité) à la concentration initiale constante du sel $Y(NO_3)_3$, $C_Y° = 0{,}01$ mol L^{-1}, en changeant le rapport des concentrations $n = C_L^0/C_Y^0$. Après l'acquisition de l'état de l'équilibre, la phase liquide était séparée de la phase solide par le filtrage. La détermination des concentrations résiduelles de l'yttrium et des ligands était faite selon la méthode spécialement élaborée (7, 8, 15). À la base de la méthode se trouve la détermination spectrophotométrique des ions de l'yttrium en forme de complexe avec l'arsenazo III et la détermination du ligand selon la réduction de l'absorption du complexe de l'yttrium avec un autre indicateur, le bleu de thymol.

La valeur du pH était mesurée avec une électrode en verre, et la concentration d'équilibre des ions de l'hydrogène était trouvée en utilisant le coefficient de l'activité calculée selon l'équation de Davies (16).

Type I. Les complexonates $YH_2L_{(S)}$ (L^{5-}–oxyéthylidènediphosphonate, oedph; le système A) et $YH_2A_{(S)}$ (A^{5-}–glycine–bis-méthylphosphonate, gph; le système B)

Les données expérimentales connues pour ces systèmes (7, 15) sont réunies au tableau 1. Les deux ligands représentent des anions de l'acide penta-basique. Les constantes de protonation des ligands ($I_1 = 0{,}1$) (3, 17) ont été recalculées à force ionique $I_2 = 0{,}03$ à l'aide de l'équation élargie de Davies (16) :

$$[22] \quad \log K_2 = \log K_1 + 0{,}509 \sum_i v_i Z_i^2 \left[\frac{\sqrt{I_2} - \sqrt{I_1}}{(1+\sqrt{I_1})(1+\sqrt{I_2})} \right]$$

La concentration de l'ion d'hydrogène a été calculée par Tereshin et al. (7) en utilisant le coefficient d'activité, à l'aide de l'équation de Devis (16). La composition des deux précipités est exprimée par la formule $MH_2L_{(S)}$. Les expériences ont été effectuées en milieu fortement acide, où l'hydrolyse de l'ion de l'yttrium ($\alpha_y = 1$) n'a pas lieu. Les auteurs (7, 15) ont démontré que la réaction de complexation de l'yttrium avec des complexones en solution dans les conditions examinées n'a pas lieu. D'après les données présentées par les auteurs (7, 15), $nC_M^0 = C_L^0$ et $C_H^0 = 5C_L^0 = 5nC_M^0$. Pour ces systèmes, les équations du bilan [14] et [15] prennent la forme :

$$[23] \quad C_M^0 - C_L^0 = [M] - [L]\alpha_L,$$

$$2C_M^0 - C_H^0 = 2[M] - [H] - \varphi_L[L]$$

où

$$\alpha_L = 1 + \sum_{j=1}^{5} K_j [H]^j, \quad \varphi_L = \sum_{j=0}^{5} j K_j [H]^j$$

En utilisant l'équation [23] on trouve immédiatement que

$$[24] \quad [M] = [L]\alpha_L + C_M^0(1-n)$$

et

$$[25] \quad [L] = \frac{[H] - 3nC_M^0}{2 + K_1[H] - K_3[H]^3 - 2K_4[H]^4 - 3K_5[H]^5}$$

Déterminant [M] et [L] à l'aide des équations [24] et [25], on calcule K_S :

$$MH_2L_{(S)} = M + 2H + L, \; K_S = [M][H]^2[L].$$

Comme on peut voir au tableau 1, nos résultats du calcul de K_S coïncident bien avec les valeurs des produits de solubilité, déterminées par les auteurs (7) sur la base des concen-

[2] Il faut remarquer que le choix des données expérimentales nécessaires n'était pas évident, puisque habituellement les auteurs n'indiquent pas le lot complet de données. Dans la littérature nous n'avons trouvé que trois ouvrages (7, 8, 15), dans lesquels sont indiqués tous les paramètres expérimentaux figurant aux équations de comtes [18] et [19].

trations résiduaires en ion de l'yttrium et en ligand. En même temps, nos calculs ont confirmé la supposition que, dans les conditions examinées, les complexes de la composition YH_iL en solution ne se forment pas.

Ainsi, cette méthode peut être appliquée pour le contrôle de l'authenticité et la justesse du modèle de l'équilibre défini plus tôt (la composition, la stabilité et les constantes de la formation des espèces chimiques).

Complexonate $YHL_{(S)}$ (L^{4-}–aminobenzylidène-diphosphonate, abdph)

Dans le système $Y(NO_3)_3$–H_4L–H_2O le précipité $YHL_{(S)}$ se forme à C_Y^0 = 0,01 mol L^{-1} seulement pour $n = C_L^0/C_Y^0 = 1$ (8). Dans le domaine $1 < n \leq 3,4$ la formation du précipité d'une composition variable a été établie, où le rapport du ligand à l'yttrium augmente jusqu'à la valeur 3,35, et où, en qualité des phases individuelles, se contiennent des précipités de $YHL_{(S)}$ et d'acide. Par example, pour n = 2,5 la composition du précipité s'exprime avec la formule $YH_7L_{2,5}$ = YHL + 1,5H_4L (tableaux 2 et 3). À la température ambiante, la valeur mesurée $[H^+]$ de la solution saturée, contenant le précipité, est à 2,94 × 10^{-2} mol L^{-1}. Pour cette valeur basse de $[H^+]$, la formation des complexes en solution est absente, $\alpha_Y = 1$ et α_L est calculé par la relation :

$$\alpha_L = 1 + \sum_{j=1} K_j [H]^j$$

où les constantes K_j recalculées ici à force ionique I indiquée au tableau 2 selon l'équation [22] ont été empruntées de (20) : log K_1 = 10,29; log K_2 = 18,46; log K_3 = 23,75 et log K_4 = 25,35 (I = 0,1 mol L^{-1}, t = 25 ± 0,1°C).

Pour n = 1, les équations [18] et [19] se réduisent à ($q = 4 \times n = 4$) :

$$[26] \quad [Y] = C_Y = \frac{(3C_Y^0 - [H])\alpha_L}{K_2[H]^2 + 2K_3[H]^3 + 3K_4[H]^4 - 1},$$

$$[L] = \frac{C_L}{\alpha_L} = \frac{[Y]}{\alpha_L}$$

Alors le produit de solubilité pour la réaction

$$YHL_{(S)} = Y^{3+} + H^+ + L^{4-}$$

est égal

$$K_S = [Y][H][L] = \alpha_L [H] \frac{(3C_Y^0 - [H])^2}{K_2[H]^2 + 2K_3[H]^3 + 3K_4[H]^4 - 1} = 5,29 \times 10^{-29}$$

où

$$pK_S = -\log K_S = 28,28$$

La valeur obtenue coïncide pratiquement avec celle de la moyenne géométrique pK_S = 28,3, calculée dans (8) sur la base de C_Y et C_L.

34,93	4,22	1,612	14,26	10,45
21,84	1,81	1,750	14,69	10,92
17,47	1,62	1,853	14,55	10,78
1,97	0,41	2,789	14,36	10,57
Valeur moyenne	$p\overline{K}_s = 14{,}5 \pm 0{,}2$			
	$\log \overline{\beta}_1 = 10{,}7 \pm 0{,}2$			

Les équations [18] et [19] permettent aussi de vérifier la sûreté et la concordance des données expérimentales obtenues avant sur les concentrations de l'équilibre et celles résiduaires (ou la solubilité), seulement sur la base de la valeur d'équilibre du pH de la solution, connaissant la composition initiale du mélange. Les valeurs de la concentration d'équilibre de l'ion de l'yttrium [Y^{3+}] et la concentration résiduelle du ligand [L^{4-}], mesurées par les auteurs (8), ainsi que les résultats de nos comptes sont présentés aux tableaux 2 et 3. La coïncidence satisfaisante reçue entre les données de comptes seulement à la base des données du pH et les données expérimentales confirme la justesse des équations [18], [19] et [26].

Par example, pour n = 1,25, les auteurs (8) ont donné les valeurs suivantes [Y^{3+}] = 0,26 × 10^{-3} mol L^{-1} et C_L = 1,29 × 10^{-3} mol L^{-1}. Le calcul d'après [26] donne le résultat suivant : [Y^{3+}] = 0,26 × 10^{-3} mol L^{-1} et C_L= 1,28 × 10^{-3} mol L^{-1}, qui s'accorde bien avec les valeurs obtenues auparavant (8).

Donc, la méthode proposée ici de la détermination des concentrations d'équilibre des ions du complexe peu soluble peut être utilisée pour le contrôle et la standartisation des nouvelles électrodes ion-selectives. Pour cela, il est nécessaire de choisir un tel système hétérogène, pour qui les constantes de l'équilibre des réactions secondaires [3] et [4] ainsi que la composition de la phase solide formée sont connues exactement.

Type II. Complexonate $LaL_{(S)}$ (L^{L3-}–nitryletriacétate, nta)

Dans le travail (11) la solubilité du sel LaL × $nH_2O_{(S)}$ a été étudiée en fonction de p[H] = –log [H] en deux milieux à I = const : (*i*) en mélange $HClO_4$ et $NaClO_4$ et (*ii*) en milieu $NaClO_4$. Les valeurs K_S et β_1 ont été calculées à l'aide des équations

$$[27] \quad S = (K_S \alpha)^{1/2} + \beta_1 K_S$$

$$K_S = [La][L], \quad \beta_1 = [LaL]/K_S$$

au moyen de la détermination des paramètres de la relation linéaire $S(\alpha_L^{1/2})$ par la méthode des moindres carrés. Toutefois, une telle méthode a des restrictions. Comme la solubilité du sel en milieu acide augmente d'habitude très fortement, la condition I = *const* n'est pas satisfaite et les valeurs sont mesurées avec une précision différente. En plus, l'équation [27] a été déduite sur la base des suppositions :

$$(i) \ \alpha_L \approx \sum_{j=1} K_j [H]^j$$

et

$$(ii) \ S \approx [ML]$$

juste dans le cas de la formation des espèces protonées très stables ([L] ≅ 0) et des complexonates stables ([M] ≅ 0).

Tableau 5. Les données de table et celles calculées des constantes d'équilibre dans le système La^{3+}–nitryletriacétate–H_2O à 25°C et I = 0,1 (H, Na)ClO_4.

$\log \beta_1$	pK_S	Référence
10,7 ± 0,2	14,4 ± 0,2	(11)
10,7 ± 0,2	14,5 ± 0,2	le travail présent

En milieu acide la solubilité du nitryletriacétate de lanthane se fait à 25°C environ 10^{-3} mol L^{-1} (tableau 2). L'anion L^{3-} forme trois espèces protonées (18, 19) :

$$L^{3-} + H^+ = HL^{2-} \quad \log K_{HL} = 9{,}73$$

$$L^{3-} + 2H^+ = H_2L^- \quad \log K_{H_2L} = 12{,}22$$

$$L^{3-} + 3H^+ = H_3L \quad \log K_{H_3L} = 14{,}11$$

Les complexonates protonés de lanthane ne se forment pas (3). L'espèce cationique H_4L^+ prédomine en solutions aqueuses à pH < 0,8.

Pour ce système, les équations [11] à [13] ont la formule ($C_M = C_L = S$) :

$$[28] \quad S = [M] + [ML], \quad S = [L]\sum_{j=0}^{3} K_j [H]^j + [ML]$$

$$C_H^0 = [H] + [L]\sum_{j=1} jK_j [H]^j = [H] + [L]\varphi_L$$

Delà, on obtient

$$[29] \quad [L] = (C_H^0 - [H])/\varphi_L$$

$$[M] = [L]\alpha_L = C_H^0 - [H])\alpha_L/\varphi_L$$

Ensuite, on détermine K_S à l'aide de l'équation [29].

Des équations [28] et [29], on trouve

$$[30] \quad [ML] = S - [M] = S - (C_H^0 - [H])\alpha_L/\varphi_L$$

La résolution des équations [27] à [30] donne l'expression du calcul de la constante de stabilité en phase aqueuse

$$[31] \quad \beta_1 = \frac{S\varphi_L^2 - \alpha_L (C_H^0 - [H])\varphi_L}{\alpha_L (C_H^0 - [H])^2}$$

Au tableau 4, sont réunis les résultats des mesures, exécutées en (11), de même que les valeurs $\log \beta_1$ et $pK_S = -\log K_S$, calculées par les équations [31] et [27] à [29]. Leurs valeurs s'accordent avec les données (11) (tableau 5). Elles confirment la justesse des suppositions du travail (11) pour ce système.

© 2001 CNRC Canada

Conclusion

L'exigence préliminaire nécessaire pour l'utilisation du procédé élaboré est la réalisation des conditions suivantes : (*i*) les coefficients d'activité se maintiennent constants; (*ii*) la composition de la phase solide connue d'avance doit rester constante; (*iii*) les constantes d'équilibre utilisées dans les calculs doivent être exactes et sûres; (*iv*) dans le cas $C_H^0 \cong$ [H], il est impossible d'obtenir des résultats fidèles sur la base des équations, qui contiennent la différence des quantités $C_H^0 -$ [H].

Les avantages de l'approche proposée sur la détermination K_S par comparaison avec la méthode (11) consistent dans le fait qu'on n'exige pas la connaissance de la valeur de *S*, qui est déterminée d'habitude avec une précision plus petite que celle obtenue par la mesure potentiométrique du pH. (À présent on peut mesurer le pH avec la reproductivié de ± 0,005 unités (18), en utilisant les électrodes en verre de haute qualité. En plus, par un choix soigneux et un maintien des conditions de l'expérience la reproductivité peut être augmentée encore par un ordre de grandeur (20)). En même temps l'équation du type [31] donne la solution exacte de la valeur de la constante de stabilité β_1, sans recourir à la méthode itérative du calcul ou au traitement graphique des résultats.

La méthode donnée peut aussi être utilisée, comme on l'a montré ci-dessus, pour la vérification de la justesse des valeurs de table des constantes d'équilibre obtenues auparavant.

La réalisation des expériences doit être adéquate aux équations utilisées. À cet égard, nous prêterons attention à la nécessité de satisfaire à une haute précision et exactitude au cours de la préparation des solutions, puisque dans les formules de calcul figurent les concentrations initiales des constituantes du précipité. Les relations déduites ne sont justes que dans les conditions de la précipitation de l'un des composés considérés. Si deux et plusieurs précipités différents se forment, autrement dit, si nous obtenons un précipité de composition variable à la suite du mélange de quelques substances individuelles dans un rapport différent, les équations perdent leur sens.

Considérant les particularités de la méthode donnée à la présentation des données expérimentales, il faut indiquer non seulement la force ionique, la température et la méthode de la mesure, mais encore les concentrations initiales de tous les composants ajoutés au système. La méthode élaborée peut être utilisée largement, puisque un grand nombre des réactions d'équilibre passant dans les systèmes hétérogènes examinés répondent très sensiblement aux changements du pH de la solution (4). Cette méthode, naturellement, peut aussi être appliquée pour des complexes avec d'autres ions multifonctionels.

Reconnaissance

L'auteur exprime la gratitude au critique (rédacteur) scientifique, dont quelles remarques et les conseils ont permis d'améliorer considérablement la qualité de l'article.

Synthetic dyes: simple and original ways to 4-substituted flavylium salts and their corresponding vitisin derivatives

Christine Roehri-Stoeckel, Emmanuel Gonzalez, André Fougerousse, and Raymond Brouillard

Abstract: Flavylium salts substituted at the 4-position have been prepared according to a Grignard reaction of some flavones with appropriate alkyl- and aryl-magnesium bromides. Among these compounds, 4-methyl flavylium salts were gently reacted with aromatic aldehydes, affording new anthocyanidin pigments, some of which are of the vitisin family. These are the first examples of chemically synthesized vitisidins (aglycones of vitisins). Compared to the more common flavylium salts, they demonstrate a large bathochromic shift (from about 100–200 nm), thus providing blue-violet and green colours, so difficult to obtain with anthocyanidins in general.

Key words: 4-substituted flavylium chlorides, vitisin aglycones, blue-violet and green anthocyanidin pigments.

Résumé : Nous avons développé la synthèse de sels de flavylium substitués en position 4. Ils ont été obtenus par réaction de bromures d'alkyle et d'aryle magnésium avec des flavones. Les chlorures de flavylium substitués en position 4 par un groupement méthyle réagissent, dans des conditions douces, avec des aldéhydes aromatiques conduisant à de nouveaux pigments anthocyanidiques dont certains appartiennent à la famille des vitisines. Il s'agit ici de la première synthèse chimique de vitisidines. La bande d'absorption de ces nouveaux pigments subit un effet bathochrome (de 100 à 200 nm) par rapport aux sels de flavylium les plus connus. Ils produisent des couleurs bleu-violet et vertes, que l'on n'observe quasiment jamais avec les anthocyanidines les plus communes.

Mots clés : chlorures de flavylium substitués en position 4, aglycones de vitisines, pigments anthocyanidiques bleu-violet et verts.

Introduction

Flavylium salts (2-phenyl-benzopyrilium salts) are the aglycones of the large natural family of molecules known as anthocyanins. These pigments are ubiquitous in higher plant flowers and fruits (1, 2). The chemistry of these compounds has been reviewed (3–5). To prepare them, two synthetic approaches have been largely used. One is the condensation reaction of 2-hydroxybenzaldehydes with acetophenones; the other uses reductive or oxidative reagents, which are applied to various kinds of flavonoid compounds.

In the present work, flavones and Grignard reagents are the starting compounds (6, 7). They could be made to react, leading to the formation of 4-substituted flavylium salts (Scheme 1). Flavylium salts bearing a substituent at the 4-position are important compounds since they are known to be less sensitive to nucleophiles, especially water, and they give only minor amounts of the colourless pseudobases (8). Indeed, a detailed investigation of the structures usually appearing in slightly acidic aqueous media, shows that the presence of a substituent at C-4 enlarges the pH domain where the flavylium cationic form exists to approximately pH 5, with at the same time significant amounts of quinonoidal bases being formed. Compared to common 3-deoxyanthocyanidins (aglycones), 4-substituted flavylium salts feature characteristic hypsochromic spectral shifts. A strong absorption also occurs in the near-UV range (370–390 nm).

Moreover, 4-methylflavylium derivatives are also interesting because of the exceptionally high acidity of the methyl group attached to the electrophilic C-4 carbon atom. This unique feature allows them to react with aromatic aldehydes for instance, to give new flavylium dyes, which are characterized by unusually large bathochromic shifts in the visible range (maxima of absorption situated between 500 and 750 nm). By increasing the length of the aldehyde conjugated chain (9, 10), the maximum of absorption evolves towards the near-IR region. For instance, in methanol, going from **8** to **10** results in a 80 nm bathochromic shift. Kanitz et al. (11), have described an analogous type of reactivity for the 2-alkylbenzopyrilium cations with aromatic aldehydes in the preparation of varied polymethine dyes. Within the same frame of research, other 2-(arylalkenyl)-benzopyrilium perchlorates could also be prepared (12, 13).

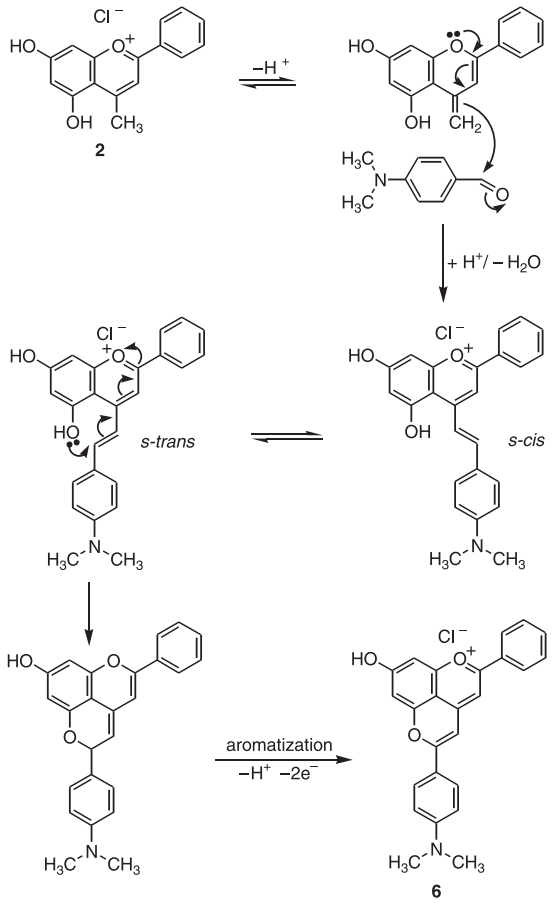
Results and discussion

Reaction of 5,7-dihydroxyflavone or chrysin, with an excess of phenylmagnesium bromide in THF under reflux conditions, followed by hydrochloric acid hydrolysis, afforded **1** (Scheme 1). Compound **2** was obtained in the same way, replacing phenylmagnesium bromide with methylmagnesium bromide. In this case, however, hydrolysis using saturated ammonium chloride, instead of hydrochloric acid, was necessary to have the flavylium salt precipitated. Nevertheless, this is not the most suitable work-up since the remaining magnesium salt also precipitates in that medium. Therefore, to remove the undesirable magnesium salt, several washings were applied to the crude precipitate. Compound **3** was prepared from the 7,3′,4′,5′-tetramethoxyflavone and methylmagnesium bromide. It could not be obtained readily by just pouring the mixture into saturated ammonium chloride. For this compound, the following procedure proved to be useful: the chromenol intermediate was extracted from the saturated ammonium chloride solution using ethylacetate, and then concentrated under reduced pressure. The corresponding residue was then dissolved in acidified methanol (hydrochloric acid 12 M, three drops) and stirred for one more hour. In particular, we observed that for the flavone itself, or for nonhydroxylated flavones, the corresponding flavylium cations were more difficult to obtain. A mixture of the chromenol and its parent flavylium form was obtained, even in fairly acidic solutions. Compound **4** was prepared like **2**, and **5** like **1**.

The condensation reactions of 4-*N*,*N*-dimethylaminobenzaldehyde and 4-*N*,*N*-dimethylaminocinnamaldehyde were performed using **2**, **3**, and 7-hydroxy-4-methylflavylium chloride (previously prepared in our laboratory following known procedures (3)) (Scheme 2). Concerning the stereochemistry of double bonds, in all cases, ^{1}H NMR coupling constants indicated an *E* configuration. With **7** and **10**, rotating Overhauser enhancement (ROE) ^{1}H NMR spectra feature through space interactions between protons H(5) and Hα, H(6″) and Hα (in the case of **7**), and H(6″) and Hγ (in the case of **10**). Another through space interaction relates proton β to H(3). These data (represented by arrows on Scheme 2) pointed out a s-*cis* conformation. Very interestingly, addition of 4-*N*,*N*-dimethylaminobenzaldehyde to **2**



Scheme 2.

led to an adduct rapidly transforming into a more stable cyclic structure showing a lowering of the visible absorption maximum compared to the first formed open structures (Scheme 3). Also in this case, immediately after mixing the reagents under reflux conditions, the solution turned green then slowly evolved towards purple. In all the other cases, with the exception of **9**, the solution remained green. The kinetic course of the transformation of **2** into **6** was monitored by UV–vis absorption spectrometry using a diluted sample made of **2** and 4-*N*,*N*-dimethylaminobenzaldehyde. Spectral features characteristic of three different structures could be registered as a function of time (Fig. 1). Using identical conditions, except for the nature of the aldehyde, the rate of formation of **9** was shown to be lower than that of **6**, probably

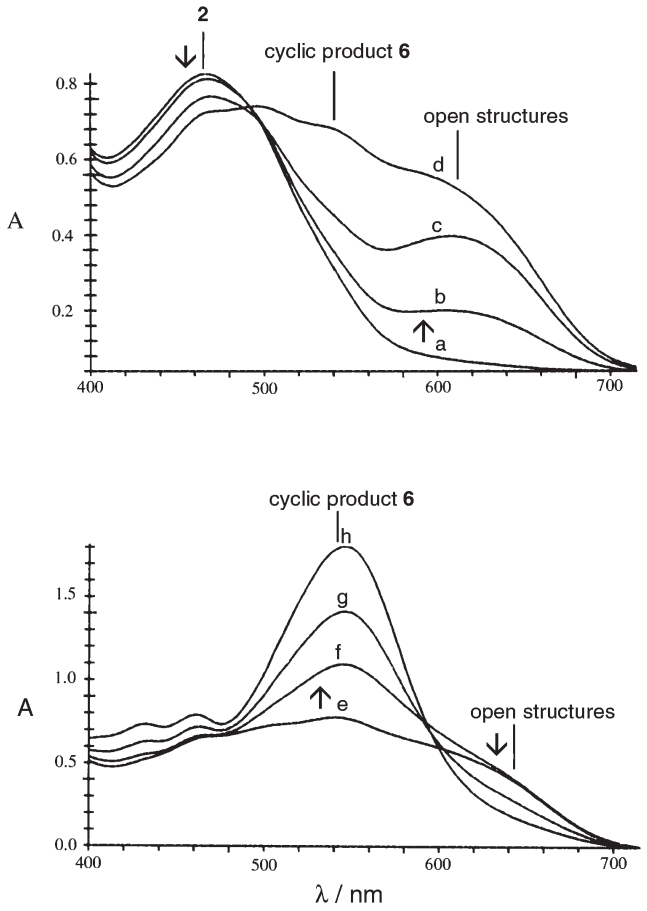
Scheme 3.



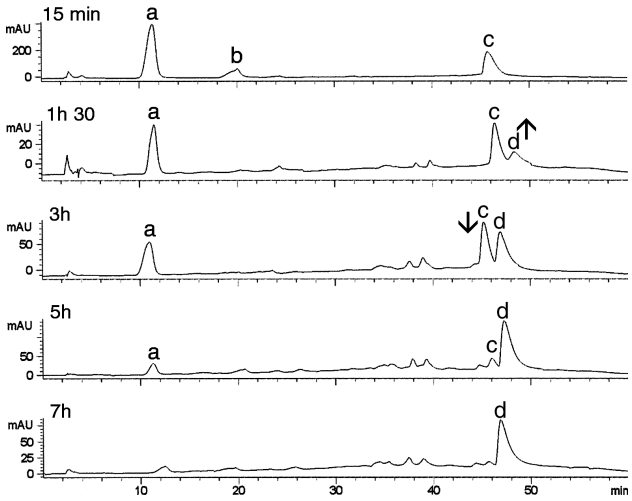
because of the difference in the energy of activation between the s-*cis* and the s-*trans* tautomers. HPLC chromatograms were very helpful to monitor the progress of the reaction until completion (Fig. 2). Compounds **6** and **9** are colourants similar to the vitisins, a new family of pigments recently isolated from red wine (14–17). Vitisins are bisflavylium cations characterized by two mesomeric forms.

Conclusion

New 3-deoxyanthocyanidins were prepared using flavones and alkyl- or aryl-magnesium bromides leading to 4-substituted flavylium salts shown to feature more stable colours than the corresponding nonsubstituted flavylium analogs. Compounds **1**–**5** were obtained in one step in excellent yields. Moreover, 4-methyl-flavylium cations could be made to react with aromatic aldehydes, under mild conditions, furnishing compounds **6**–**10** characterized by an unusual visible absorption range from 500 to 700 nm; common anthocyanins only absorbing light in the 500–550 nm range. Increasing the length of the aldehyde conjugated chain or changing the aldehyde structure could afford flavylium chlorides absorbing in the near-IR region. Now, we know how to produce the basic red, blue, and yellow colours, with a unique family of dyes: the 3-deoxyanthocyanidins. Moreover, among these dyes, the vitisin aglycones of **6** and **9** could be interesting especially in the field of human health, in relation to what is known as the "French Paradox" (18).

Fig. 1. UV–vis absorption evolving bands of the transformation of **2** into **6** (in methanol under reflux conditions). Uppert part: (*a*) *t* = 0; (*b*) *t* = 1 h; (*c*) *t* = 3 h; (*d*) *t* = 6 h. Lower part: (*e*) *t* = 10 h; (*f*) *t* = 14 h; (*g*) *t* = 18 h; (*h*) *t* = 22 h.

Indeed, the "French Paradox" tells us that wine polyphenols are responsible of the surprisingly low rate of cardiovascular diseases in the French population. It should be kept in mind that wine anthocyanins and tanins (polyphenols) evolve during wine ageing giving rise to new wine pigments, among which, vitisins are probably an important class. These type of pigments are not to be found in grapes and this is why pigments **6** and **9**, although not natural, may be useful drugs to combat heart disorders.



Experimental

General

Methyl-, phenyl-, and 4-fluorophenyl-magnesium bromides, as well as chrysin, 4-*N*,*N*-dimethylaminobenzaldehyde, and 4-*N*,*N*-dimethylaminocinnamaldehyde are commercial reagents. 7-Hydroxy-4-methylflavylium chloride and 7,3′,4′,5′-tetramethoxyflavone were synthesized in our laboratory according to previously published procedures (3, 19). Tetrahydrofuran (THF) was dried over sodium and benzophenone. Reactions implying alkyl- and aryl-magnesium bromides were performed under a nitrogen controlled atmosphere. Merck Silica gel (0.063–0.200 mm, 70–230 mesh) was used for column chromatography. HPLC pigment purity was checked by HPLC (Spectra Physics apparatus equipped

with a Hewlett Packard diode-array detector), with a reversed phase Merck C-18 LiChrospher column (5 μm, 125 × 4 mm). Binary elution systems were **A** (47.5 CH_3CN – 47.5 H_2O – 5 HCOOH) and **B**: (95 H_2O – 5 HCOOH). A flow rate of 0.5 mL min^{-1} was used with a linear 30 min gradient from 30 to 90% **A**, reaching 100% **A** at 50 min and going back to 30% **A** at 60 min. Compounds **9** and **10** were eluted with 100% **A**. Detection wavelengths (nm) are as follows: 280, 360, 470, 540, and 598.

UV–vis spectra were recorded from a diode-array spectrometer fitted with a 1 cm quartz cell. Hydrochloric acid (0.1 M) or methanolic solutions were used to measure wavelengths (nm) of maximum of absorption. Mass spectrometry analyses are of three different types: electronic impact (EI), positive electrospray ionization (ES^+), and positive fast atom bombardment (FAB^+). ^1H NMR spectra were recorded either from a 200 or a 500 MHz apparatus. Chemical shifts (δ, ppm) are related to internal standards as follows: TMS (δ_H = 0.00), CD_3OD (δ_H = 3.35). Coupling constants *J* are expressed in Hertz (Hz). Compound **6** ^1H NMR signals were assigned by COSY experiments and **7**, **9**, and **10** ^1H NMR signals by COSY and ROESY experiments.

Syntheses

*5,7-Dihydroxy-4-phenylflavylium chloride or 5,7-dihydroxy-2,4-diphenyl-1-benzopyrilium chloride (**1**)*

A solution of chrysin (400 mg, 1.57 mmol) in dry THF (15 mL) was dropwise added to 9.5 mL (6 eq.) of a 1 M phenylmagnesium bromide solution in THF.

Method A: the mixture was heated at reflux for 2 h and stirred 2 more hours at room temperature. Acidified water (150 mL of 12 M hydrochloric acid, a few drops) were then added to the mixture. After evaporation of THF, a red precipitate appeared. Filtration gave **1** (546 mg, 99%). MW = 350.5. HR-MS [M^+] calcd. for $C_{21}H_{15}O_3$: 315.1021; found: 315.1022. UV–vis (HCl 0.1 M with 1% methanol) λ (nm) (ε, M^{-1} cm^{-1}): 388 (18 600 ± 200), 454 (10 000 ± 100). ^1H NMR (200 MHz, CD_3OD) δ 8.38 (dd, *J* = 1.5, 7.5 Hz, 2H, H2′, H6′), 8.00 (s, 1H, H3), 7.79–7.54 (m, 8H, H3′, H4′, H5′, H2″, H3″, H4″, H5″, H6″), 7.10 (d, *J* = 2 Hz, 1H, H6 or H8), 6.65 (d, *J* = 2 Hz, 1H, H6 or H8).

*5,7-Dihydroxy-4-methylflavylium chloride or 5,7-dihydroxy-4-methyl-2-phenyl-1-benzopyrilium chloride (**2**)*

A solution of chrysin (5,7-dihydroxyflavone) (1.08 g, 4.25 mmol) in dry THF (30 mL) was dropwise added to 9 mL (6 eq.) of a 3 M methylmagnesium bromide solution in THF.

Method B: after heating at reflux for 2 h, the mixture was poured into a saturated ammonium chloride solution (100 mL). A red precipitate was formed, then filtered, and finally washed with tap water (150 mL); 800 mg of **2** was obtained (yield 65%). MW = 288.5. ES^+-MS: 253. UV–vis (HCl 0.1 M with 1% methanol) λ (nm) (ε, M^{-1} cm^{-1}): 378 (12 800 ± 200), 436 (9 000 ± 200). ^1H NMR (200 MHz, CD_3OD) δ 8.40 (dd, *J* = 1.5, 7.5 Hz, 2H, H2′, H6′), 8.16 (s, 1H, H3), 7.83–7.76 (m, 3H, H3′, H4′, H5′), 7.04 (d, *J* = 2 Hz, 1H, H-6 or H8), 6.77 (d, *J* = 2 Hz, 1H, H6 or H8) (the methyl protons exchange with solvent deuterium atoms (20)).

*7,3′,4′,5′-Tetramethoxy-4-methylflavylium chloride or 7-methoxy-4-methyl-2-(3,4,5-trimethoxyphenyl)-1-benzopyrilium chloride (**3**)*

7,3′,4′,5′-Tetramethoxyflavone (400 mg, 1.17 mmol) in anhydrous THF (15 mL) was dropwise added to 1.6 mL (4 eq.) of a 3 M methylmagnesium bromide solution in THF.

Method C: after heating at reflux for 2 h, the mixture was poured into saturated ammonium chloride (50 mL). Extraction with ethyl acetate gave a residue, which was treated with acidified methanol after removal of the ethyl acetate. The solution was then stirred for 1 h and finally concentrated under vacuum to give a red solid **3** (yield 418 mg, 95%). MW = 376.5. HR-MS [M^+] calcd. for $C_{20}H_{21}O_5$: 341.1389; found: 341.1417. UV–vis (HCl 0.1 M with 1% methanol) λ (nm) (ε, M^{-1} cm^{-1}): 444 (28 200 ± 500). ^1H NMR (200 MHz, CD_3OD) δ 8.68 (s, 1H, H3), 8.43 (d, *J* = 9 Hz, 1H, H5), 8.03 (d, *J* = 2 Hz, 1H, H8), 7.84 (s, 2H, H2′, H6′), 7.59 (dd, *J* = 2, 9 Hz, 1H, H6), 4.22 (s, 3H, OCH_3-C(7)), 4.08 (s, 6H, OCH_3-C(3′), OCH_3-C(5′)), 4.00 (s, 3H, OCH_3-C(4′)) (the methyl proton exchange with solvent deuterium atoms).

*5,7-Dihydroxy-4-(4-fluorophenyl)flavylium chloride or 5,7-dihydroxy-4-(4-fluorophenyl)-2-phenyl-1-benzopyrilium chloride (**4**)*

Compound **4** (470 mg, yield: 70%) was obtained by heating at reflux for 5 h, 10 mL (6 eq.) of a 1 M fluorophenylmagnesium bromide solution and chrysin (430 mg, 1.69 mmol) in anhydrous THF. Work-up followed method B. MW = 368.5. HR-MS [M^+] calcd. for $C_{21}H_{14}FO_3$: 333.0927; found: 333.0934. UV–vis (HCl 0.1 M with 1% methanol) λ (nm) (ε, M^{-1} cm^{-1}): 386 (19 100 ± 300), 454 (10 000 ± 300). ^1H NMR (200 MHz, CD_3OD) δ 8.39 (dd, *J* = 1.5, 7.5 Hz, 2H, H2′, H6′), 7.95 (s, 1H, H3), 7.82–7.28 (m, 7H, H3′, H4′, H5′, H2″, H3″, H5″, H6″), 7.03 (d, *J* = 2 Hz, 1H, H6 or H8), 6.61 (d, *J* = 2 Hz, 1H, H6 or H8).

*7,3′,4′,5′-Tetramethoxy-4-phenylflavylium chloride or 7-methoxy-2-(3,4,5-trimethoxyphenyl)-4-phenyl-1-benzopyrilium chloride (**5**)*

Compound **5** (330 mg, yield: 64%) was obtained by heating at reflux for 4 h, 7,3′,4′,5′-tetramethoxyflavone (400 mg, 1.17 mmol) and 4.7 mL (4 eq.) of a 1 M phenylmagnesium bromide solution in dry THF. Work-up followed method A. MW = 438.5. HR-MS [M^+] calcd. for $C_{25}H_{23}O_5$: 403.1545; found: 403.1553. UV–vis (HCl 0.1 M with 1% methanol) λ (nm) (ε, M^{-1} cm^{-1}): 364 (15 100 ± 300), 458 (30 000 ± 800). ^{1}H NMR (400 MHz, CD_3OD) δ 8.67 (s, 1H, H3), 8.21 (d, *J* = 9 Hz, 1H, H5), 8.13 (d, *J* = 2 Hz, 1H, H8), 7.94 (m, 2H, H2″, H6″), 7.92 (s, 2H, H2′, H6′), 7.85–7.77 (m, 3H, H3″, H4″, H5″), 7.59 (dd, *J* = 2, 9 Hz, 1H, H6), 4.25 (s, 3H, OCH_3-C(7)), 4.09 (s, 6H, OCH_3-C(3′), OCH_3-C(5′)), 4.02 (s, 3H, OCH_3-C(4′)).

*8-Hydroxy-5-phenyl-2-(4-(*N,N*)-dimethylamino)phenyl-1,6-dioxaphenalene chloride (**6**)*

A solution of 5,7-dihydroxy-4-methylflavylium chloride (**2**) (576 mg, 2 mmol) and 4-*N*,*N*-dimethylaminobenzaldehyde (328 mg, 1.1 eq.) in methanol (30 mL) was heated at reflux for 3 h. The initially red solution rapidly turned green, then purple. The progress of the reaction was monitored using HPLC. The solvent was removed under vacuum and the precipitate washed with a 50:50 mixture of diethyl ether and ethyl acetate; 470 mg (yield 56%) of **6** was obtained after recrystallization in ethanol. MW: 417.5. HR-MS [M^+] calcd. for $C_{25}H_{20}NO_3$: 382.1443; found: 382.1443. UV–vis (methanol with 5% HCl 0.1 M) λ (nm) (ε, M^{-1} cm^{-1}): 548 (46 500 ± 500). ^{1}H NMR (500 MHz, CD_3OD) δ 7.97 (d, *J* = 7.5 Hz, 2H, H2′, H6′), 7.78 (d, *J* = 9 Hz, 2H, H2″, H6″), 7.61 (m, 1H, H4′), 7.53 (m, 2H, H3′, H5′), 7.25 (s, 1H, H4 or H3), 7.18 (s, 1H, H4 or H 3), 6.89 (d, *J* = 2 Hz, 1H, H9 or H7), 6.83 (d, *J* = 2 Hz, 1H, H9 or H7), 6.62 (d, *J* = 9 Hz, 2H, H3″, H5″), 3.00 (s, 6H, $2CH_3$).

*4-[4-(4-(*N,N*-Dimethylamino)phenyl)ethenyl]-7-hydroxyflavylium chloride or 4-[4-(4-(*N,N*-dimethylamino)phenyl)ethenyl]-7-hydroxy-2-phenyl-1-benzopyrilium chloride (**7**)*

Compound **7** was synthesized from 7-hydroxy-4-methylflavylium chloride (400 mg, 1.47 mmol) and 4-*N*,*N*-dimethylaminobenzaldehyde (240 mg, 1.1 eq.) in the same way as **6**. A green precipitate was obtained (yield, 500 mg, 84%). MW: 403.5. HR-MS [M^+] calcd. for $C_{25}H_{22}NO_2$: 368.1650; found: 368.1654. UV–vis (methanol with 5% HCl 0.1 M) λ (nm) (ε, M^{-1} cm^{-1}): 640 nm (80 000 ± 1000). ^{1}H NMR (500 MHz, CD_3OD) δ 8.42 (d, *J* = 15 Hz, 1H, Hβ), 8.39 (d, *J* = 9 Hz, 1H, H5), 8.25 (d, *J* = 7.5 Hz, 2H, H2′, H6′), 8.14 (s, 1H, H3), 7.87 (d, *J* = 9 Hz, 2H, H2″, H6″), 7.76 (d, *J* = 15 Hz, 1H, Hα), 7.72–7.61 (m, 3H, H3′, H4′, H5′), 7.07 (d, *J* = 9 Hz, 1H, H6), 6.97 (s, 1H, H8), 6.86 (d, *J* = 9 Hz, 2H, H3″, H5″), 3.17 (s, 6H, $2CH_3$).

*4-[4-(4-(*N,N*-Dimethylamino)phenyl)ethenyl]-3′,4′,5′,7-tetramethoxyflavylium chloride or 4-[4-(4-(*N,N*-dimethylamino)phenyl)ethenyl]-7-methoxy-2-(3,4,5-trimethoxyphenyl)-1-benzopyrilium chloride (**8**)*

Compound **8** was prepared from **3** (180 mg, 0.48 mmol) and 4-*N*,*N*-dimethylaminobenzaldehyde (78 mg, 1.1 eq.) in the same manner as **6**. A green precipitate was obtained (yield, 196 mg, 80%). MW: 507.5. HR-MS [M^+] calcd. for $C_{29}H_{30}NO_5$: 472.2124; found: 472.2125. UV–vis (methanol with 5% HCl 0.1 M) λ (nm) (ε, M^{-1} cm^{-1}): 652 (78 600 ± 800). ^{1}H NMR (200 MHz, CD_3OD) δ 8.69 (d, *J* = 15 Hz, 1H, Hβ), 8.47 (d, *J* = 9 Hz, 1H, H5), 8.25 (s, 1H, H3), 7.95 (d, *J* = 9 Hz, 2H, H2″, H6″), 7.72 (d, *J* = 15 Hz, 1H, Hα), 7.58 (s, 2H, H2′, H6′), 7.51 (d, *J* = 2 Hz, 1H, H8), 7.28 (dd, *J* = 2, 9 Hz, 1H, H6), 6.92 (d, *J* = 9 Hz, 2H, H3″, H5″), 4.08 (s, 3H, OCH_3-C(7)), 4.06 (s, 6H, OCH_3-C(3′), OCH_3-C(5′)), 3.95 (s, 3H, OCH_3-C(4′)), 3.29 (s, 6H, $2CH_3$).

*8-Hydroxy-5-phenyl-2-[2-(4-(*N,N*)-dimethylamino)phenyl]-ethenyl-1,6-dioxaphenalene chloride (**9**)*

Compound **9** was obtained by heating at reflux in methanol 5,7-dihydroxy-4-methylflavylium chloride (550 mg, 1.9 mmol) and 4-*N*,*N*-dimethylaminocinnamaldehyde (367 mg, 1.1 eq.). The progress of the reaction was monitored by HPLC. The solution rapidly became green then turned purple. After refluxing the mixture for 7 h, the reaction was stopped. Once the methanol was evaporated, the residue was washed with a 50:50 mixture of diethyl ether and ethyl acetate and with a 50:50 mixture of chloroform and ethyl acetate giving 750 mg of a black purple solid (yield 89%). MW: 443.5. HR-MS [M^+] calcd. for $C_{27}H_{22}NO_3$: 408.1600; found: 408.1600. UV–vis (methanol with 5% HCl 0.1 M) λ (nm) (ε, M^{-1} cm^{-1}): 628 (19 100 ± 300). ^{1}H NMR (500 MHz, CD_3OD) δ 7.99 (d, *J* = 7.5 Hz, 2H, H2′, H6′), 7.67–7.54 (m, 4H, H3′, H4′, H5′, Hβ), 7.36 (d, *J* = 9 Hz, 2H, H2″, H6″), 7.26 (s, 1H, H4), 6.96 (d, *J* = 2 Hz, 1H, H7 or H9), 6.93 (d, *J* = 2 Hz, 2H, H7 or H9), 6.73 (s, 1H, H3), 6.69 (d, *J* = 15 Hz, 1H, Hα), 6.54 (d, *J* = 9 Hz, 2H, H3″, H5″), 2.94 (s, 6H, $2CH_3$).

*4-[4-(4-(*N,N*-Dimethylamino)phenyl)-butadienyl]-3′,4′,5′,7-tetramethoxyflavylium chloride or 4-[4-(4-(*N,N*-dimethylamino)phenyl)-butadienyl]-7-methoxy-2-(3,4,5-trimethoxyphenyl)-1-benzopyrilium chloride) (**10**)*

Compound **10** was obtained by heating at reflux in methanol for 3 h **3** (150 mg, 0.40 mmol) with 4-*N*,*N*-dimethylaminocinnamaldehyde (77 mg, 1.1 eq.). After the methanol was evaporated, the green residue was purified over silica gel (elution: MeOH–CH_2Cl_2, 5:95) and gave 160 mg of **10** (yield, 75%). MW: 533.5. HR-MS [M^+] calcd. for $C_{31}H_{32}NO_5$: 498.2280; found: 498.2291. UV–vis (methanol with 5% HCl 0.1 M) λ (nm) (ε, M^{-1} cm^{-1}): 730 (66 600 ± 900). ^{1}H NMR (500 MHz, CD_3OD with TFA) δ 8.62 (dd, *J* = 12, 15 Hz, 1H, Hβ), 8.39 (d, *J* = 9 Hz, 1H, H5), 8.38 (s, 1H, H3), 7.72 (d, *J* = 9 Hz, 2H, H2″, H6″), 7.65 (s, 2H, H2′, H6′), 7.61 (d, *J* = 15 Hz, 1H, Hδ), 7.59 (d, *J* = 2 Hz, 1H, H8), 7.53 (d, *J* = 15 Hz, 1H, Hα), 7.45 (dd, *J* = 12, 15 Hz, 1H, Hγ), 7.34 (dd, *J* = 2, 9 Hz, 1H, H6), 7.10 (d, *J* = 9 Hz, 2H, H3″, H5″), 4.07 (s, 3H, OCH_3-C(7)), 4.03 (s, 6H, OCH_3-C(3′), OCH_3-C(5′)), 3.92 (s, 3H, OCH_3-C(4′)), 3.21 (s, 6H, $2CH_3$).

Photochemical behaviour of 1,4-dichlorobenzene in aqueous solution

Laurence Meunier, Jean-François Pilichowski, and Pierre Boule

Abstract: Several photoproducts were identified in the direct photolysis of 1,4-dichlorobenzene (1,4-DCB) in air-saturated aqueous solution, namely 4-chlorophenol, hydroquinone, hydroxybenzoquinone, and 2,5-dichlorophenol. In the absence of oxygen the latter is not formed and phenol was detected, but the unexpected formations of 4,4′-dichlorobiphenyl, 2,4′,5-trichlorobiphenyl, and a terphenyl derivative are observed. Mechanisms are proposed to explain the formations of identified photoproducts. The phototransformation of 1,4-DCB may be photoinduced by NO_3^- or Fe^{III} salts. The main primary product is 2,5-dichlorophenol, which results from a hydroxylation without dechlorination. Some other products have been identified in particular 4-chlorophenol and 2,5-dichlorobenzoquinone in the case of Fe^{III} salts.

Key words: 1,4-dichlorobenzene, photolysis, aqueous solution, induced phototransformation.

Résumé : Plusieurs photoproduits ont été identifiés lors la photolyse du 1,4-dichlorobenzène (1,4-DCB) en solution aqueuse aérée : le 4-chlorophénol, l'hydroquinone, la benzoquinone et le 2,5-dichlorophénol. En absence d'oxygène ce dernier ne se forme pas, mais il apparaît du phénol et surtout on observe la formation de 4,4′-dichlorobiphényle, de 2,4′,5-trichlorobiphényle et d'un dérivé de type terphényle. Des mécanismes réactionnels sont proposés pour expliquer la formation des divers produits identifiés. La phototransformation du 1,4-DCB peut aussi être photoinduite par des ions nitrate ou des sels ferriques. Le principal produit initialement formé est le 2,5-dichlorophénol qui résulte d'une hydroxylation sans déchloration. Quelques autres produits ont été identifiés en particulier le 4-chlorophénol et la 2,5-dichlorobenzoquinone dans le cas des sels ferriques.

Mots clés : 1,4-dichlorobenzène, photolyse, solution aqueuse, transformation photoinduite.

Introduction

1,4-Dichlorobenzene (1,4-DCB) is produced in very large amounts and its use is very popular in many homes. Most often it is used without any precaution as an insect repellant or to eliminate bad smells. It is included in the list of Priority Substances to be assessed under the Canadian Environmental Protection Act (1). Its LD_{50} (500 mg kg^{-1} orally in rats) (2) is a little lower than that of chlorophenols (3). Special attention was focussed on the population exposure in Ontario (1), and its physico-chemical and biological properties were the subject of many studies (4).

The photochemical behaviour of chlorobenzenes in water is interesting since photochemical pathways depend on the solvent and very little is known about the transformation of 1,4-DCB in water. To our knowledge, the direct photolysis of 1,4-DCB in water was briefly reported by Boule et al. (5). The main initial photoreaction was assumed to be photohydrolysis leading to 4-chlorophenol, but products (hydroquinone and hydroxybiphenyls) resulting from secondary reactions were also detected by fluorescence even at low conversions. The quantum yield of disappearance was evaluated at 0.010. The yield of formation of the triplet state in methanol was evaluated at 0.95 by Alfassi and Previtali (6). The same authors measured the rate constant of disappearance of the triplet state in methanol ($[3.0 \pm 0.4] \times 10^5$ s^{-1}) that corresponds to a lifetime equal to 3.3 μs.

It may be assumed that the mechanism of this reaction is similar to the mechanism of monochlorobenzene transformation into phenol, which was the subject of some controversies. According to Previtali and Ebbesen (7), the main reaction observed when monochlorobenzene is photolyzed in pure water is the transformation into phenol, but the reduction into benzene is also detected. These reactions are assumed to result from two competitive pathways: a singlet state photosubstitution reaction with the radical cation as an intermediate, and a homolytic C—Cl bond cleavage in both excited singlet and triplet states. On the other hand, Tissot et al. (8) observed a quantitative transformation into phenol, which was attributed to the photohydrolysis of a polarized short-lived triplet state that was not directly observed. The transformation of monochlorobenzene induced by hydroxyl radicals was reported by Merga et al. (9). The major prod-

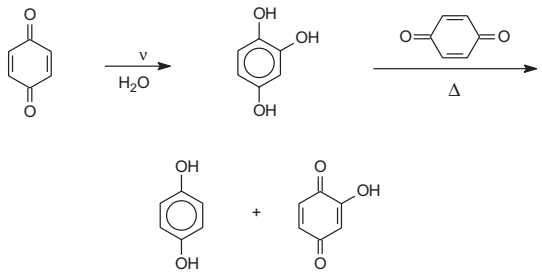
ucts are the three isomeric chlorophenols. This reaction implies the intermediate formation of an $OH^{\bullet}$ adduct. No results were reported about the transformation of monochloro- or dichlorobenzenes induced by excitation of photoinducers such as nitrate ions or ferric salts that produce hydroxyl radicals under irradiation.

The aim of the present work is to study the mechanism of the direct phototransformation of 1,4-DCB in pure water. The reactions induced by excitation of nitrate ions and Fe^{III} salts are also considered.

Experimental

Reactants and analytical standards

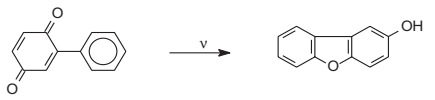


1,4-Dichlorobenzene (99+%) from Aldrich was used without further purification. The following compounds were used as analytical standards: 4-chlorophenol 99+% (Aldrich), 2,5-dichlorophenol >98% (Fluka), hydroquinone >99.5% (Merck), benzoquinone 99% (Merck), 2,5-dichlorohydroquinone (Kodak). Potassium nitrate, used as photochemical inducer, was obtained from Prolabo RP Normapur, while ferric perchlorate nonahydrate (>97%) was purchased from Fluka.

2,5-Dichlorobenzoquinone was obtained by oxidation of 2,5-dichlorohydroquinone by ferric perchlorate in excess. The mixture was heated at 60°C overnight. 2,5-Dichlorohydroquinone was quantitatively transformed and the reaction mixture was directly used for the calibration of HPLC.

4′-Chlorophenyl-*p*-benzoquinone was synthesized from 4-chloroaniline and *p*-benzoquinone. The procedure, which was proposed by Brassard and L'Ecuyer (10) and reported by Carlson and Miller (11), involves the diazotation of 4-chloroaniline. The crude product was recrystallized from an ethanol–acetone mixture. Its structure was supported by mass spectrometry results ((70 eV) *m*/*z*: 218–220, main fragment at 183).

4′-Chloro-2,5-dihydroxybiphenyl-(4′-chlorophenylhydroquinone) (4′-$ClPhQH_2$) was obtained by reduction of previous compound by sodium dithionite ($Na_2S_2O_4$). The crude product was purified by HPLC. Its formula was supported by mass spectrometry results (*m*/*z*: 220–222, main fragment at 185).



Hydroxybenzoquinone was obtained by irradiation of benzoquinone in solution. Actually, irradiation leads to two main products, hydroquinone and hydroxybenzoquinone, in approximately equal amounts (12).

[1]

From the HPLC evaluation of benzoquinone transformed and hydroquinone formed, it is possible to deduce an approximate value of the concentration of hydroxybenzoquinone present.

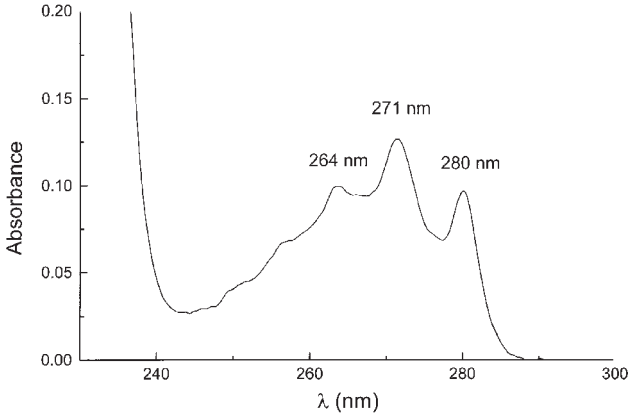
2-Hydroxydibenzofuran was obtained by photocyclization of phenylbenzoquinone in aqueous solution. Phenylbenzoquinone was provided by Eastman. The reaction is quantitative by irradiation at 365 nm (13):

[2]

Solutions were prepared with water purified with Milli-Q device and controlled by its resistivity (>18 MΩ cm).

Irradiations

Direct phototransformation of 1,4-DCB was studied by irradiating aqueous solutions at 254 nm in a quartz reactor with a low pressure mercury lamp (germicidal lamp). Reactor and lamp were located on both focal axes of a cylindrical mirror with an elliptic base. The number of photons received was evaluated at 7.09×10^{15} photons cm^{-3} s^{-1} using uranyl oxalate as a chemical actinometer (14).



This device is appropriate for the analysis of products since incident photon flow is relatively intense. However it is not appropriate for the determination of quantum yields since the optical path is not well defined and it is not possible to calculate the percentage of light absorbed. For determination of quantum yields solutions were irradiated in quasi-parallel beam using one germicidal lamp. The incident photon flow was evaluated at 1.33×10^{14} photons cm^{-3} s^{-1} using potassium ferrioxalate as the chemical actinometer (14), since it is much more sensitive than uranyl oxalate.

To study the photochemical degradation induced by excitation of nitrate ions solutions were irradiated with 6 fluorescent lamps Duke GL20E. These lamps emit light not only between 275 and 350 nm with a maximum near 310 nm but also on the mercury lines located at 365, 405, and 436 nm. Wavelengths shorter than 290 nm were cut off using a Pyrex reaction chamber. The number of photons received in the range 290–350 nm was roughly evaluated at 6×10^{15} photons cm^{-3} s^{-1} by uranyl oxalate. It is difficult to obtain an accurate value since the actinometer absorbs a low percentage of photons emitted on mercury lines.

Reactions photoinduced by excitation of Fe^{III} were studied by irradiating solutions with three Mazda MAW125 lamps. These lamps consist of filtered medium pressure mercury arc. Actually, according to the spectrum given by the manufacturer, they emit about 87% of photons at 365 nm, about 6% at 334 nm, and 3% at 313 nm. Emission at 313 nm is perhaps lower after use, therefore, direct excitation of 1,4-DCB is completely excluded. The reactor in Pyrex was placed along the central axis of the device and the solution maintained at room temperature by a cooling jacket. With this device the photon flow received by the solution was evaluated at 1.2×10^{16} photon cm^{-3} s^{-1} using Aberchrome 540 as the actinometer (15), because uranyl oxalate is not sufficiently absorbing at this wavelegth and potassium ferrioxalate is too sensitive for this device.

Fig. 1. UV spectrum of an aqueous solution of 1,4-dichlorobenzene (1,4-DCB) (4.0×10^{-4} M).

Deoxygenation

To control the influence of oxygen on the formation of photoproducts some solutions were deoxygenated. Argon bubbling cannot be used with diluted solutions because of the high vapor pressure of 1,4-DCB. Water contained in the photochemical reactor in the presence of some crystals of 1,4-DCB was deoxygenated by argon bubbling before dissolution of the reactant. After closing the reactor with a septum, the water was magnetically stirred to dissolve the 1,4-DCB. The concentration was evaluated from HPLC according to a reference solution of known concentration.

Analyses

The UV spectra were recorded on Cary 3 (Varian) spectrophotometer. Irradiated solutions were analysed by HPLC on Waters 996 equipped with a photodiode array detector or on Merck L-6200 equipped with fluorescent detection. In both cases the column was C_{18} 250 mm × 4 mm, and the eluent water–methanol (30:70 or 25:75, v/v).

Several photoproducts were identified by GC–MS on Hewlett-Packard 5989 equipped with a capillary column Machery Nagel Optima 5 (25 m × 0.25 mm i.d.). Products were detected by electronic impact (70 ev) mass spectrometry (EI-MS). Nuclear magnetic resonance (NMR) spectra were obtained on samples dissolved in acetone-d_6 (internal reference) with a Bruker AC400 spectrometer. ^{1}H and H–H COSY (2D) classical sequences were used.

The formation of chloride ions in irradiated solutions was measured with a specific electrode after calibration with standard aqueous solutions of NaCl.

Isolation of photoproducts V and VI

About 100 mL of a deoxygenated solution of 1,4-DCB almost saturated was irradiated for 30 min with 6 low pressure mercury lamps. This process was repeated 20 times. The irradiated solutions were filtered to remove remaining crystals of 1,4-DCB and purged with nitrogen to completely eliminate unreacted 1,4-DCB from the solution. The products were extracted with ether and, after evaporation, isolated by HPLC (Column C_{18}, eluent water–methanol (25:75 v/v)).

Table 1. Formation of H^+ and Cl^- in a solution of 1,4-DCB (4.5×10^{-4} M) irradiated at 254 nm.

1,4-DCB converted	$[H^+]$	$[Cl^-]$
2.7×10^{-4} M (59%)	$(3.6 \pm 0.2) \times 10^{-4}$	$(4.0 \pm 0.2) \times 10^{-4}$

Results

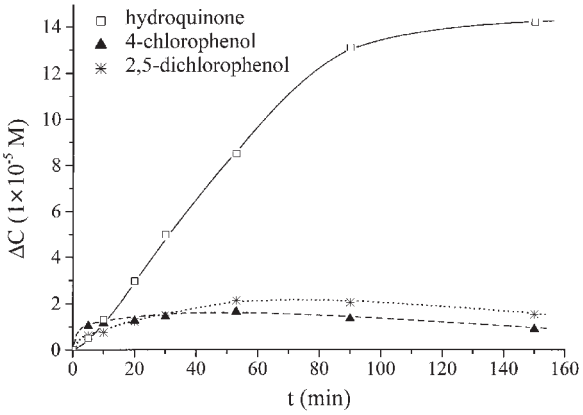
Physico-chemical properties of 1,4-DCB

1,4-DCB is a white crystalline solid. According to the Handbook of Chemistry and Physics, its density at 20°C is 1.2475. It is often classified as insoluble in water. Nevertheless, its solubility is sufficient to record its UV spectrum in aqueous solution. The solubility was evaluated by comparing the UV spectrum of an aqueous saturated solution with the spectrum of a solution of known concentration in a mixture MeOH–H_2O (5:95 v/v), and it was evaluated at $(4.8 \pm 0.3) \times 10^{-3}$ M (i.e., 71 ppm), which is in good agreement with literature data (74–80 ppm (4)). It was checked that the molar absorption coefficient of 1,4-DCB is not influenced by low percentage of MeOH.

The UV spectrum of 1,4-DCB is given in Fig.1. The absorption band has several maxima located at 264, 271, and 280 nm. The corresponding molar absorption coefficients were evaluated at 246, 310, and 236 M^{-1} cm^{-1} respectively. No absorption was detected at $\lambda > 290$ nm.

Direct photolysis at 254 nm

Air-saturated solutions



A solution (4.7×10^{-4} M) was irradiated for a few hours at 254 nm. The quantum yield, calculated by HPLC measurement of the amount of 1,4-DCB transformed, was determined to be $\phi = 0.050 \pm 0.01$. This value is significantly higher than the previous evaluation (0.01) (5). The significant increase of absorbance during the irradiation complicates the evaluation of absorbed light and, consequently, the calculation of the quantum yield.

The disappearance of 1,4-DCB can be compared with the formation of H^+ and Cl^- evaluated from the pH decrease and specific electrode measurements, respectively (Table 1). It was experimentally proved that the relative formation of H^+ and Cl^- increases with increasing conversion, which may be related to the elimination of the second chlorine atom in a secondary reaction.

The main products identified on the HPLC chromatogram are hydroquinone (**II**), 4-chlorophenol (**III**), 2,5-dichlorophenol (**IV**), and hydroxybenzoquinone (**I**). Their formations were quantified using commercial compounds (Fig. 2) except for hydroxybenzoquinone, which was only qualitatively identified. It was noted that the formation of 2,5-dichlorophenol is twice as high in oxygen-saturated solution as compared to the air-saturated solution. The major product initially formed is 4-chlorophenol, but it does not accumulate and its formation reached a stationary concentration after a few minutes. This phenomenon is related with a short delay observed in the formation of hydroquinone, which is due to the high transformation quantum yield of 4-chlorophenol, higher than 0.6 according to Grabner et al. (16). Therefore, it was not possible to establish an accurate

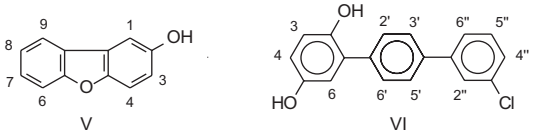
Fig. 2. Quantification of the main photoproducts identified in an air-saturated aqueous solution of 1,4-DCB (3.7×10^{-4} M) irradiated at 254 nm (one germicidal lamp).



initial mass balance. To prove that 4-chlorophenol cannot accumulate in the solution, 4-chlorophenol (1.4×10^{-5} M) was added to a solution of 1,4-DCB (8.9×10^{-5} M), and after 10 min irradiation the concentration of 4-chlorophenol was only 1.2×10^{-6} M.

The phototransformation of 1,4-DCB was also observed in solutions irradiated in the range 275–350 nm, along with the formation both of hydroxybenzoquinone and trace amounts of hydroquinone. 4-Chlorophenol and 2,5-dichlorophenol are formed in a first stage as it appears in Fig. 2, but do not accumulate in these conditions due to the fact they absorb at longer wavelengths than 1,4-DCB.

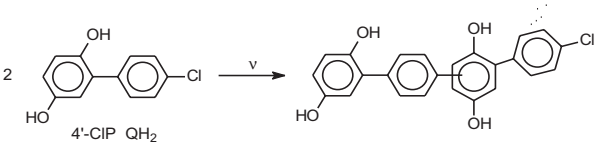
Deoxygenated solutions

Solutions of 1,4-DCB (3.7×10^{-4} M), deoxygenated as reported in *Experimental* section, were irradiated at 254 nm. The formation of 2,5-dichlorophenol was not observed, but two unexpected photoproducts **V** and **VI** appeared on the HPLC chromatogram. These two products were not observed in irradiated diluted solutions (6.7×10^{-5} M). They were isolated as described in the *Experimental* section and identified by MS and ^{1}H NMR spectroscopy, respectively, as 2-hydroxydibenzofuran (2-HDBF) and 3″-chloro-2,5-dihydroxy-*p*-terphenyl (CDTP):

V VI

*Product **V**:* MS *m*/*z* (%): 184 ($M^{\bullet+}$, 100), 128. ^{1}H NMR (CD_3COCD_3) δ 8.37 (s, OH), 8.00 (dd, *J* = 7.0, 1.3 Hz, H6), 7.55 (dd, *J* = 7.9, 0.9 Hz, H9), 7.47 (dt, *J* = 7.9, 1.3 Hz, H8), 7.47 (d, *J* = 2.5 Hz, H1), 7.44 (d, *J* = 8.8 Hz, H4), 7.33 (dt, *J* = 7.5, 0.9 Hz, H7), 7.01 (dd, *J* = 8.8, 2.5 Hz, H3).

The identification of **V** was corroborated by its typical UV spectrum (maxima at 251, 289, 310–320 nm) and by comparison of its HPLC retention time with those of an authentic sample of 2-HDBF obtained by photolysis of phenylbenzoquinone.



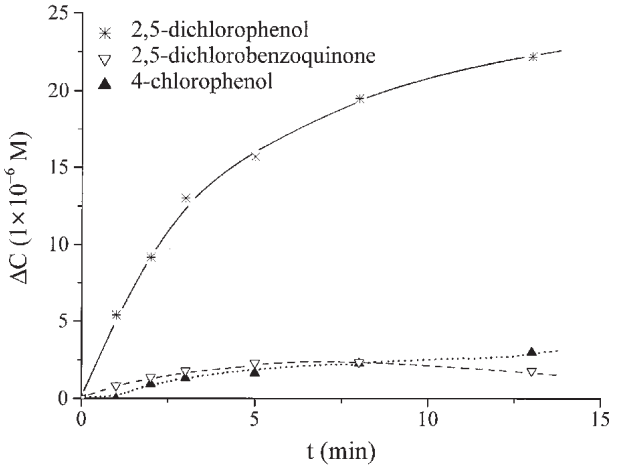
*Product **VI**:* MS *m*/*z* (%): 296 ($M^{\bullet+}$, 100), 298 ($M^{\bullet+}$, 33), consistent with $C_{18}H_{13}ClO_2$. ^{1}H NMR (CD_3COCD_3) δ 7.83 (s, OH), 7.82 (s, OH), 7.72 (t, *J* = 1.9 Hz, H2″), 7.70 (s, 4H, H2′, 3′, 5′, 6′), 7.67 (m, H6″), 7.49 (t, *J* = 7.9 Hz, H5″), 7.39 (m, H4″), 6.86 (d, *J* = 3.0 Hz, H6), 6.84 (d, *J* = 8.75 Hz, H3), 6.69 (dd, *J* = 8.75, 3.0 Hz, H4).

It was deduced from the H–H COSY spectrum that the four protons 2′, 3′, 5′, and 6′ are fortuitously equivalent and generate a single absorption (δ = 7.70 ppm) without any apparent coupling constant.

Three other photoproducts were identified as phenol (*m*/*z* = 94), 4,4′-dichlorobiphenyl (*m*/*z* = 222, 224, 226) and 2,4′,5-trichlorobiphenyl (*m*/*z* = 256, 258, 260) from GC–MS analysis of the crude product of phototransformation after evaporation of water.

The formations of 2-HDBF and terphenyl derivative were also observed in deoxygenated solutions of 1,4-DCB irradiated between 275 and 350 nm. Some complementary experiments were carried out to explain the formation of 2-HDBF in deoxygenated solution. (*i*) A deoxygenated solution of hydroquinone (6.7×10^{-4} M) and 1,4-DCB ($c \approx 4 \times 10^{-3}$ M) was irradiated in the range 290–350 nm. In these conditions the excitation of 1,4-DCB is negligible compared to the excitation of hydroquinone. It was observed that 2-HDBF appears as one of the main photoproducts. (*ii*) 4′-Chloro-2,5-dihydroxybiphenyl (4′-$ClPhQH_2$), synthesized as described in the *Experimental* section, was irradiated in the range 290–350 nm in various conditions. 2-HDBF was the main photoproduct on HPLC chromatogram of a deoxygenated dilute solution ($c \approx 6 \times 10^{-5}$ M) irradiated for a few minutes. This reaction was not observed in the presence of oxygen and it is a minor pathway when the concentration of 4′-$ClPhQH_2$ is as high as 1.4×10^{-3} M. In relatively concentrated solutions irradiation leads to the formation of an insoluble product identified as an adduct resulting from elimination of HCl between two molecules (CI-MS *m*/*z* = 404, 405 [M + 1], and 433 [M + 29]).

[3]



Reactions induced by excitation of nitrate ions or ferric ions

Nitrate ions absorb at wavelengths shorter than 340 nm with a maximum at 302 nm (molar absorption coefficient ε = 7.2 M^{-1} cm^{-1} at 302 nm), hence, when solutions are irradiated in the range 290–350 nm, NO_3^- is excited without excitation of 1,4-DCB.

An air-saturated solution of 1,4-DCB (3.3×10^{-4} M) and KNO_3 (1×10^{-2} M) was irradiated between 290 and 350 nm. The incident photon flow was roughly 6×10^{15} photons cm^{-3} s^{-1} (see *Experimental* section), but the solution absorbs only a fraction of this energy (probably less than 20%). The main photoproduct detected on the HPLC chromatogram of a solution irradiated for 165 min was 2,5-dichlorophenol. The formation of 4-chlorophenol was also observed, but in such minor amounts that it could not be quantified. Nitrate ions

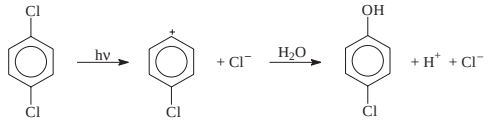
Fig. 3. Quantification of the main photoproducts identified in an air-saturated aqueous solution of 1,4-DCB (3.6×10^{-4} M) irradiated at 365 nm in the presence of ferric salts (1×10^{-3} M).

are converted into nitrite. 2,5-Dichlorophenol presents a kinetics of formation of primary photoproduct.

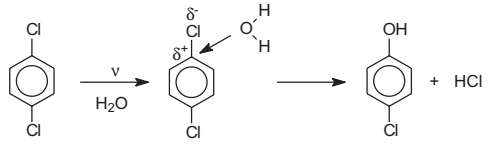
The mass balance was not expected to be very good since irradiations were long and in a range where most of photoproducts, such as 2,5-dichlorophenol, 4-chlorophenol, hydroquinone, benzoquinone (not quantified but necessarily formed from 4-chlorophenol), absorb.

Ferric salts absorb at longer wavelengths than nitrate ions and can be excited at 365 nm without excitation of 1,4-DCB. In our experimental conditions, only quinones are expected to absorb at this wavelength. However, it can be noted that the lamps used for the irradiation have a minor emission at 313 nm (about 3% of photons) and at 334 nm (about 6%). A solution of 1,4-DCB (2.6×10^{-4} M) with added ferric salt (1×10^{-3} M) was irradiated under these conditions. The main photoproducts detected by HPLC are 2,5-dichlorophenol, 2,5-dichlorobenzoquinone, and 4-chlorophenol. These products present a kinetics of primary photoproducts (Fig. 3). A small amount of benzoquinone was also detected at 250 nm.



The absence of hydroquinone and 2,5-dichlorohydroquinone result from their oxidation by Fe^{III}, as it was checked that Fe^{III} easily oxidizes these two compounds into 1,4-benzoquinone and 2,5-dichloro-1,4-benzoquinone, respectively.

Discussion and mechanisms



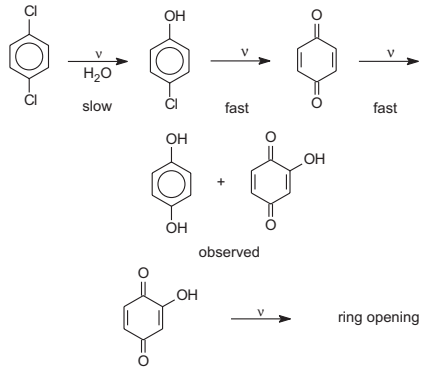
Direct photolysis

Formation of 4-chlorophenol and hydroquinone

In previous work the main initial reaction was assumed to be a photohydrolysis leading to the formation of 4-chlorophenol (5). This mechanism is most likely since it also agree with the phototransformation of monochlorobenzene and several other chloroaromatic derivatives, such as 3-chlorophenol (17), 3-chloroaniline, and one derivative used as a pesticide (18). The intermediate formation of a carbocation may be suggested (eq. [4]),

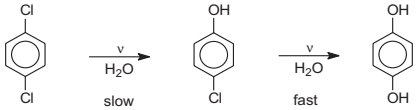
[4] 

but a concerted mechanism is more likely since, in the case of 3-chlorophenol and 3-chloroaniline, no transient was observed in laser flash photolysis (eq. [5]).



[5] 

Photohydrolysis may be assumed to occur either from the excited singlet state or from the triplet state. The triplet state is more likely for the following reasons: (*i*) Alfassi and Previtali (6) experimentally proved that the yield of formation of 1,4-DCB triplet state is about 0.95 in methanol; (*ii*) the photohydrolysis of monochlorobenzene can be sensitized by acetone-d_6 (19); and (*iii*) the photohydrolysis of monohalogenophenols can also be sensitized (20).



4-Chlorophenol does not accumulate much since it absorbs at the irradiation wavelengths and its quantum yield of disappearance is high. It does, however, accumulate a little better when solutions are irradiated at 254 nm as compared to 275–350 nm, because it absorbs more at longer wavelengths when compared to 1,4-DCB. According to the concentration of oxygen, it is transformed into hydroquinone (20–22). The reaction involves the intermediate formation of a carbene (20, 23). *p*-Benzoquinone cannot be observed when solutions are irradiated at 254 nm since it has a strong absorption band at 245 nm and it is easily phototransformed into hydroquinone (12). Thus, the formation of hydroquinone in air-saturated solutions is attributed to the following sequence controlled by the first step (eq. [6]), whereas in the absence of oxygen hydroquinone is formed by photohydrolysis (eq. [7]) (21).

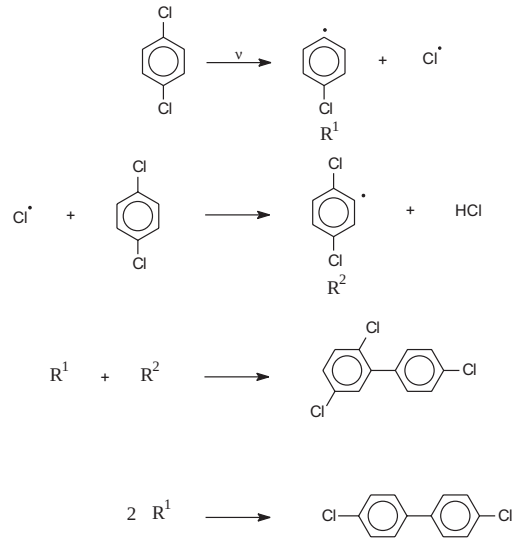
[7]

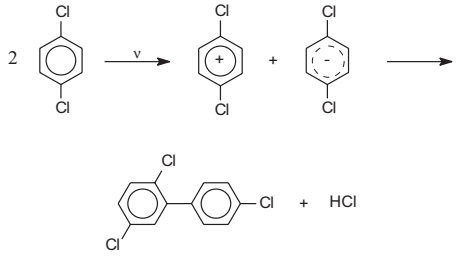
Formation of 2,5-dichlorophenol

The formation of 2,5-dichlorophenol is not negligible when 1,4-DCB is irradiated in pure water. It was not observed in the absence of oxygen, which is not surprising since it implies the oxidation of the ring. It can be explained either by the photoionization of the excited singlet state or by the oxidation of triplet state by oxygen or by the oxidation of the ground state by singlet oxygen resulting from the deactivation of 1,4-DCB. The latter may be ruled out because the rate of deactivation of singlet oxygen in water is 5×10^5 s^{-1} (24) and the rate of reaction of 1,4-DCB is ca. 1.7×10^5 M^{-1} s^{-1} or lower, since it is 1.7×10^5 with 9,10-dichloroanthracene in $CHCl_3$ (24). With a concentration of 1,4-DCB equal to 4.7×10^{-4} M, the rate of reaction of $^1O_2$ is expected to be ca. 6000 times lower than the rate of deactivation. In contrast, both other mechanisms are consistent with experimental results. If the formation of 2,5-dichlorophenol results from the photoionization of the singlet state, the effect of oxygen is explained by a competition between the trapping of ejected electron by oxygen and the recombination electron–cation. On the other hand the oxidation of the triplet state of 1,4-DCB by oxygen is consistent with the lifetime of the triplet state. It can be noted that the lifetime of the triplet state of 1,4-DCB is most likely shorter in water than in methanol (3.3 μs according to ref. 6), since Previtali and Ebbesen (7) reported that the triplet state of monochlorobenzene is about 10 times shorter in water than in methanol.



[8]

In a second stage, 2,5-dichlorophenol may be formed by $OH^\bullet$ radicals resulting from the excitation of H_2O_2.

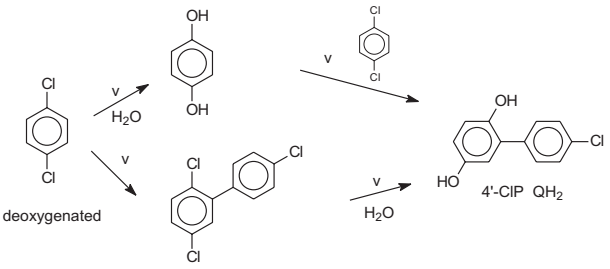


In the absence of oxygen the formation of 4,4′-dichlorobiphenyl and 2,4′,5-trichlorobiphenyl may be explained by the C–Cl bond homolysis in the triplet state:

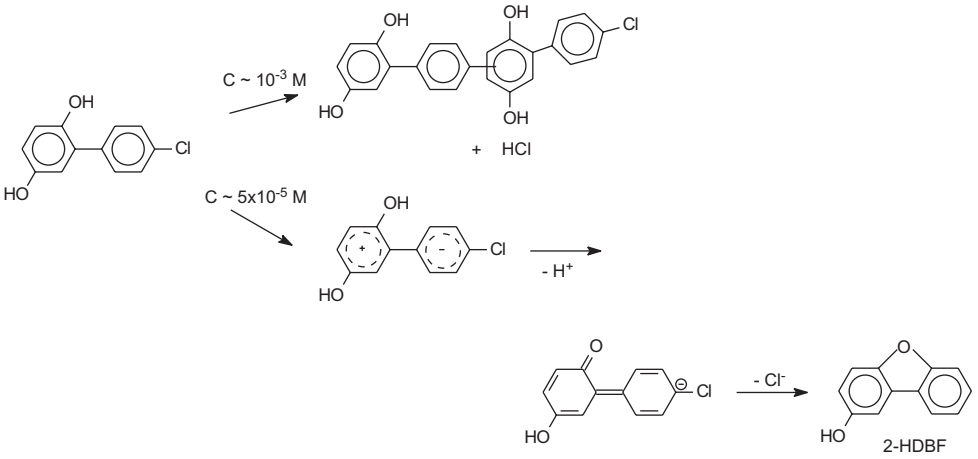
[9]

However, the charge transfer from the triplet state, disregarded in the case of monochlorobenzene (7), cannot be excluded here since the triplet state has a high yield of formation (0.95) and a longer lifetime (6).

[10]



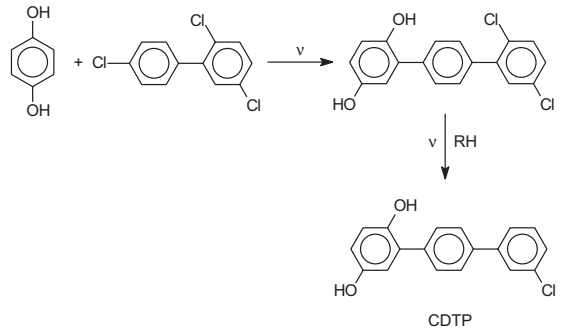
Formation of 2-hydroxydibenzofuran (2-HDBF) and 3″-chloro-2,5-dihydroxy-p-terphenyl (CDTP)



It was previously reported that phenylbenzoquinone photocyclizes with a high yield into 2-HDBF (13). In our experimental conditions it is difficult to explain the intermediate formation of phenylbenzoquinone. In addition, the following features can be noted: (*i*) the formation of 2-HDBF was observed when a deoxygenated solution of hydroquinone is excited in the presence of 1,4-DCB; (*ii*) the excitation of a deoxygenated mixture hydroquinone and 4-chlorophenol leads to the formation of 2,4′,5-trihydroxybiphenyl (20); (*iii*) 2,4′,5-trichlorobiphenyl is expected to be photohydrolyzed into 4′-chloro-2,5-dihydroxybiphenyl (4′-$ClPhQH_2$) (other products are not excluded); and (*iv*) it was observed (present work) that 4′-$ClPhQH_2$ irradiated in diluted deoxygenated solution leads to the formation of 2-HDBF. Therefore, the formation of 2-HDBF may be attributed to an internal charge transfer in excited 4′-$ClPhQH_2$. In relatively concentrated solutions an intermolecular charge transfer leads to the formation of a four-ring adduct (eq. [11*b*]).

© 2001 NRC Canada

[11a]



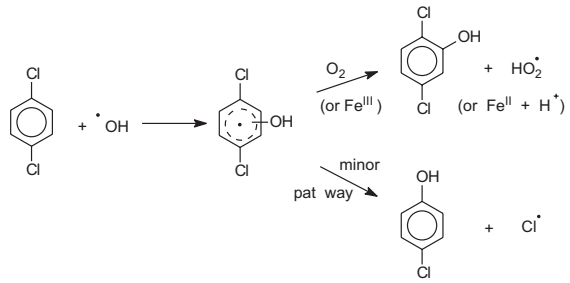
[11b]

The formation of CDTP may be explained similarly by the addition of hydroquinone on 2,4′,5-trichlorobiphenyl followed by a reductive elimination of one chlorine atom.

[12]

Induced phototransformation

The excitation of nitrate ions or ferric salts leads to the formation of hydroxyl radicals:



[13]

$$NO_3^- + H_2O \xrightarrow{v} {}^{\bullet}NO_2 + {}^{\bullet}OH + {}^{-}OH \quad (26)$$

$$Fe^{III}\text{–}OH \xrightarrow{v} Fe^{II} + {}^{\bullet}OH \quad (27)$$

The formation of 4-chlorophenol and 2,5-dichlorophenol result from the hydroxylation of the ring with or without dechlorination:

[14]

Hydroquinone observed in the case of excitation of nitrate ions may result from the further photohydrolysis of 4-chlorophenol or from the substitution of Cl by $OH^{\bullet}$. In the case of the excitation of Fe^{III}, hydroquinone and 2,5-dichlorohydroquinone cannot be observed since they are oxidized by Fe^{III}. The observed formation of benzoquinone and 2,5-dichlorobenzoquinone result from this oxidation.

Dimeric and polymeric [Eu(tta)$_3$L] complexes (tta = thenoyltrifluoroacetonato, L = 4,4′-bipyridine, *trans*-1,2-bis(4-pyridyl)ethylene, 4,4′-bipyridine-*N*,*N*′-dioxide)

Corey Seward and Suning Wang

Abstract: The reaction of Eu(tta)$_3$ (tta = thenoyltrifluoroacetonato) with 4,4′-bipyridine (bipy), *trans*-1,2-bis(4-pyridyl)ethylene (bipyete), and 4,4′-bipyridine-*N*,*N*′- dioxide (bipyo) yielded three distinct complexes [Eu(tta)$_3$(bipy)(H$_2$O)] (**1**), [Eu(tta)$_3$(bipyete)(CH$_3$OH)]·CH$_3$OH·bipyete (**2**), and [Eu(tta)$_3$(bipyo)]·CH$_3$OH (**3**), respectively. Compounds **1** and **2** have a hydrogen-bond linked dimer structure, while **3** has a one-dimensional chain structure linked by coordination bonds, which further forms two-dimensional arrays, resulting in an intercalation lattice that hosts methanol guest molecules. In solution compounds **1** and **2** emit a red color, characteristic of Eu(III), when irradiated by UV light, while compound **3** has no emission either in solution or the solid state.

Key words: europium complexes, luminescence, structure, 4,4′-bipyridine, 1,2-bis(4-pyridyl)ethylene, 4,4′-bipyridine-*N*,*N*′-dioxide.

Résumé : Les réactions de Eu(tta)$_3$ (tta = thénoyltrifluoroacéténato) avec la 4,4′-bipyridine (bipy), le *trans*-1,2-bis(4-pyridyl)éthylène (bipyete) et le *N*,*N*′-dioxyde de la 4,4′-bipyridine (bipyo) conduisent à trois complexes distincts qui sont respectivement [Eu(tta)$_3$(bipy)(H$_2$O)] (**1**), [Eu(tta)$_3$(bipyete)(CH$_3$OH)]·CH$_3$OH·bipyete (**2**) et [Eu(tta)$_3$(bipyo)]·CH$_3$OH (**3**). Les composés **1** et **2** comportent une structure dimère reliée par des liaisons hydrogènes alors que la structure du composé **3** est une chaîne unidimensionnelle avec des liaisons de coordination qui forme ensuite des arrangements bidimensionnels qui conduit à un réseau d'intercalation qui agit comme hôte pour les molécules de méthanol invitées. En solution, lorsqu'ils sont soumis à une irradiation par de la lumière UV, les composés **1** et **2** donnent lieu à l'émission d'une couleur rouge caractéristique de Eu(III) alors que le composé **3** ne donne lieu à aucune émission en solution ou à l'état solide.

Mots clés : complexes d'europium, luminescence, structure, 4,4′-bipyridine, 1,2-bis(4-pyridiyl)éthylène, *N*,*N*′-dioxyde de la 4,4′-bipyridine.

[Traduit par la Rédaction]

Introduction

Thenoyltrifluoroacetonato europium(III) complexes of the general formula Eu(tta)$_3$L (tta = thenoyltrifluoroacetonato and L = a neutral chelate, e.g., 1,10-phenanthroline) have attracted much attention recently because some of them have been demonstrated to be promising red emitters in electroluminescent devices (1). The tta ligand is one of the best ligands known for activating red emission of Eu(III) ions (2). Because of the poor volatility of Eu(tta)$_3$L complexes, the electroluminescent devices that use them as emitters are often fabricated by doping into a polymer matrix (1). Linking the Eu(tta)$_3$ units together by bridging ligands could lead to polynuclear species that may facilitate the direct thin-film formation of Eu(III) compounds by spin-coating without using a polymer matrix. Recently we have demonstrated the utility of the 4,4′-bipyridine ligand and the roles of polynuclear species in promoting luminescent film formation of Tb(III) benzoate compounds by spin-coating processes (3). In addition to 4,4′-bipyridine (bipy), *trans*-1,2-bis(4-pyridyl)ethylene (bipyete) and 4,4′-bipyridine-*N*,*N*′-dioxide are also known to be good bridging ligands for metal ions (4, 5). Therefore, we examined the utility of bipy, bipyete, and bipyo as bridiging ligands for the formation of luminescent polynuclear complexes containing the Eu(tta)$_3$ unit. Three novel Eu(III) complexes have been isolated and characterized, which show distinct structural features and luminescent properties. The detail is described herein.

Experimental

All syntheses were carried out in a fumehood, in air, at room temperature. Chemicals were purchased from Aldrich and used without further purification. Methanol was purchased from Caledon and used without further purification.

 DOI: 10.1139/cjc-79-7-1187 © 2001 NRC Canada

The hydration content of 4,4′-bipyidine-*N*,*N*′-dioxide was determined to be 1.5 by thermogravometric analysis (TGA) using a PerkinElmer TGA7 Thermogravometric Analyzer. Elemental analyses were performed by Canadian Microanalytical Service, Ltd., Delta, British Columbia. Excitation and emission spectra were recorded on a Photon Technologies International QuantaMaster Model C-60 spectrometer.

Synthesis of $[Eu(tta)_3(bipy)(H_2O)]$ (1)

A solution of europium chloride hexahydrate (0.183 g, 0.5 mmol) in a minimum amount of methanol was added to a solution of thenoyltrifluoroacetone (Htta) (0.333 g, 1.5 mmol) dissolved in a minimum amount of methanol in a 20 mL vial. The pale yellow solution was neutralized with a saturated solution of sodium hydroxide in methanol. Methanol (8 mL) was layered carefully upon this solution, and a solution of 4,4′-bipyridine (0.156 g, 1.0 mmol) in a minimum amount of methanol was added dropwise. The reaction vial was allowed to diffuse slowly, and then the solvent was allowed to evaporate slowly at ambient temperatures, yielding yellow block crystals of **1** in 93% yield. Anal. calcd. for $C_{34}H_{22}F_9N_2O_7S_3Eu$: C 41.26, H 2.24, N 2.83; found: C 41.71, H 2.19, N 3.03.

Synthesis of $[Eu(tta)_3(bipyete)(CH_3OH)]\cdot CH_3OH\cdot$bipyete (2)

Europium chloride hexahydrate (0.5 g, 1.365 mmol), Htta (0.910 g, 4.094 mmol), and sodium hydroxide (0.164 g, 4.094 mmol) were dissolved in methanol (10 mL) with stirring. The solution was filtered into a 40 mL vial, and methanol (8 mL) was carefully layered upon it. A solution of *trans*-1,2-bis(4-pyridyl)ethylene (0.497 g, 2.73 mmol) in methanol (10 mL) was then added dropwise. The reaction vial was allowed to diffuse slowly, then to evaporate slowly at ambient temperatures, yielding pale yellow plates of **2** in 31% yield. Anal. calcd. for $C_{50}H_{40}F_9N_4O_8S_3Eu$: C 48.28, H 3.24, N 4.50; found: C 48.24, H 2.84, N 4.43.

Synthesis of $[Eu(tta)_3(bipyo)]\cdot$MeOH (3)

Europium chloride hexahydrate (0.125 g, 0.34 mmol), Htta (0.227 g, 1.02 mmol), and sodium hydroxide (0.040 g, 1.02 mmol) were dissolved in methanol (10 mL). Methanol (10 mL) was carefully layered upon the solution. A solution of 4,4′-bipyridine-*N*,*N*′-dioxide·1.5hydrate (0.128 g, 0.595 mmol) in methanol (10 mL) was added dropwise. The reactants were allowed to diffuse slowly, then the solvent was allowed to evaporate slowly at ambient temperatures, affording pale yellow needles of **3** in 39% yield. Anal. calcd. for $C_{35}H_{24}F_9N_2O_9S_3Eu$: C 40.59, H 2.34, N 2.70; found: C 39.98, H 2.16, N 2.70.

X-ray crystallography analysis

Single crystals of **1**–**3** were obtained from methanol solutions, and mounted on glass fibres. Data were collected on a Bruker SMART CCD 1000 diffractometer with graphite-monochromated Mo Kα radiation, operated at 50 kV and 35 mA at 23°C for **1** and **2**, and at 25°C for **3**. The 2θ ranges were 3.82–50.02, 3.64–45.02, and 2.22–46.60° for **1**, **2**, and **3**, respectively. No significant decay was observed. Data were processed on a Pentium PC using Bruker AXS SHELXTL software package (version 5.1) (6). The structures were solved by direct methods. One of the C_5H_3S rings in each structure displays a small degree of rotational disorder but could not be modeled. Some of the CF_3 groups that display a typical rotational disorder have been modeled and refined successfully. Metal, sulfur, oxygen, fluorine, nitrogen, and most carbon atoms were refined anisotropically. The positions of hydrogen atoms were calculated, and their contributions in structural factor calculations were included. Crystal data are summarized in Table 1.[2]

Results and discussion

Syntheses and structures

Compounds **1**–**3** were obtained from methanol solution by a "one-pot" reaction of $EuCl_3\cdot 6H_2O$ with Htta and the bridging ligand bipy, bipyete, or bipyo in the presence of NaOH. Although similar reaction conditions were employed for the three compounds, compounds **1**–**3** have distinct compositions and structures. Compound **1** $[Eu(tta)_3(bipy)(H_2O)]$ has one bipy ligand and one aqua ligand, compound **2** $[Eu(tta)_3(bipyete)(CH_3OH)]\cdot CH_3OH\cdot$bipyete has one coordinated bipyete ligand, one free bipyete, one coordinated methanol ligand, and one non-coordinate methanol ligand, and compound **3** $[Eu(tta)_3(bipyo)]\cdot CH_3OH$ has one bipyo ligand and one non-coordinate methanol molecule.

Compound **1** was synthesized initially with the intention to produce bipy linked polynuclear Eu(III) compounds. X-ray crystal structural analysis, however, revealed that compound **1** has a dimeric structure in the solid state. As shown in Fig. 1, only one nitrogen donor from each bipy ligand is coordinated to the Eu(III) center. The remaining nitrogen donor forms a hydrogen bond with the aqua ligand as indicated by the N(2A)···O(7) distance of 2.74(1) Å. The two bipy ligands are nearly eclipsed with the shortest atomic separation distance between the two ligands being 3.63(2) Å. The Eu(III) center is eight-coordinated with an approximate square antiprism geometry, commonly observed in lanthanide complexes. The separation distance between the two Eu(III) centers is 13.367 Å and the N(1)-Eu(1)-O(7) angle is 76.5(5)°. All three C_4H_3S rings are oriented away from the bipy ligands (i.e., adopting the pseudo "*fac*" geometry), perhaps to minimize the interactions between bipy and tta ligands. The failure of bipy to link $Eu(tta)_3$ units together by coordination bonds to form polynuclear species is somewhat surprising since bipy is a well-known ligand to act as a bridge between two metal ions. One possible explanation is the geometric (i.e., N-Eu-N bond angle) restriction that

would force the bipy ligand to bend if the bipy ligand were bridging two Eu(III) ions by coordination bonds.

To increase the flexibility of the bridging ligand, we replaced bipy with a longer bridging ligand *trans*-1,2-bis(4-pyridyl)ethylene, resulting in compound **2**, $[Eu(tta)_3(bipyete)(CH_3OH)]\cdot CH_3OH\cdot bipyete$.

The structure of **2**, shown in Fig. 2, resembles that of **1**. The bipyete ligand is bound to the Eu(III) center by one nitrogen atom only. A methanol molecule is coordinated to the Eu(III) center, which forms a hydrogen bond with N(2A) atom, as indicated by N(2A)···O(7) distance of 2.68(1) Å. The N(1)-Eu(1)-O(7) angle of 73.5(3)° is slightly less than the corresponding angle in **1**. The Eu(1)···Eu(1A) separation distance of 15.583 Å is much longer than that in **1**, which is not surprising since the bipyete ligand contains an extra CH=CH unit with respect to 4,4′-bipy. In contrast to the structure of **1**, two of the C_4H_3S rings are oriented away from bipyete, while the third one is oriented toward the bipyete ligands. The two bipyete ligands are planar and are nearly eclipsed with the shortest atomic separation distance between them being 3.483 Å. There is a non-coordinating bipyete molecule in the lattice, which forms a hydrogen bond with a non-coordinating methanol solvent molecule. The non-coordinating bipyete molecule stacks with coordinated bipyete ligands in the crystal lattice as shown by the crystal packing diagrams in Fig. 3. The shortest atomic separation distance between the coordinate and non-coordinate bipyete ligands is 3.405 Å. The planarity of the bipyete ligand, attributable to the conjugation of the pyridyl portion with the ethylene portion, forces the bipyete ligand to coordinate to the Eu(III) center in a similar linear fashion as observed for the 4,4′-bipy in **1**, which is again believed to be responsible for the formation of the hydrogen-bond linked dimer structures of **2**.

The third bridging ligand we investigated was 4,4′-bipyrdine-*N*,*N*′-dioxide (bipyo). Long et al. (5*a*) have shown recently that bipyo is capable of linking lanthanide ions together by coordination bonds. Because of the geometry of the lone pairs of electrons from the oxygen atoms, the bipyo ligand has been found to bind to two metal ions in a nonlinear fashion, with the two metal ions being either *trans* or *cis* with respect to the bipyridyl unit (5). Hence, we anticipated that the bipyo ligand may be able to link two $Eu(tta)_3$ units together by coordination bonds. Indeed, as shown by the structure of compound **3** in Fig. 4, the bipyo ligand functions as a bridging ligand by binding to two Eu(III) centers through the two oxygen atoms, thus resulting in the formation of a one-dimensional coordination polymer. Each Eu(III) center in **3** is eight-coordinate with an approximate square antiprism geometry. The arrangement of the three tta ligands in **3** has a similar pseudo "*fac*" geometry as observed in **2**. The $Eu(tta)_3$ units are all arranged in a *cis*-fashion, relative to the bipyo chains. The O(7)-Eu(1)-O(8A) angle of 67.4(2)° is much less than the corresponding angles observed in **1** and **2**, and the Eu···Eu separation distance within the one-dimensional chain is 12.276 Å. An interesting feature of **3** is that the one-dimensional chains are coupled in an approximate face-to-face fashion to form a two-dimensional layered array. The shortest nonhydrogen atom separation distance between two neighbouring layers is

~5.4 Å. Furthermore, methanol solvents are situated in the channels between the layers as shown in Fig. 5. The methanol molecule (O(9)) forms a hydrogen bond with O(7) atom of the bipyo ligand as evident by the O(7)···O(9) distance of 2.967 Å. The extended structure of **3** can be, therefore, considered as a two-dimensional intercalation (7) host material for methanol guest molecules. TGA experiments indicated the methanol molecules in **3** could be driven out of the host lattice by heating to 65°C, but the readsorption of methanols to the crystal lattice appears to be irreversible.

Luminescence

$Eu(tta)_3$ and $Eu(tta)_3(phen)$ are well-known to have a bright red luminescence, attributed to the efficient activation of the emission from the Eu(III) center by the tta ligand (1, 2, 8). It is, therefore, not surprising to observe red luminescence from compounds **1** and **2** in solution. The emission spectra of both compounds are identical and dominated by an intense and narrow emission band at $\lambda = 613$ nm due to the $5D_0 \rightarrow 7F_2$ transition, as shown in Fig. 6. The UV–vis spectra and excitation bands of **1** and **2** in solution (CH_2Cl_2 or THF) are from the ligands and resemble those of $Eu(tta)_3$ and $Eu(tta)_3(Phen)$ (2, 8). Therefore, we believe that the observed red luminescence from **1** and **2** is due to an *indirect* excitation process or energy transfer process facilitated by the tta ligand. The free ligands, 4,4′-bipy and 4,4′-bipyete, have an emission band at 381 and 386 nm, respectively. Their excitation bands (321 nm and 327 nm, respectively)

overlap with part of the excitation bands of **1** and **2** (at ~ 300–350 nm region). The fact that no emission bands that match those of free 4,4′-bipy or 4,4′-bipyete were observed in the spectra of **1** and **2** indicates that these ligands are also likely involved in the energy transfer process to the Eu(III) center

Fig. 3. A diagram showing the π-stacking between coordinate and non-coordinate bipyete ligands in **2**.

and that they are likely still bound to the Eu(III) center in solution. Because of the insolubility of compound **3**, its' luminescent property in solution was not investigated. In the solid state, only compound **1** shows a bright red luminescence (Fig. 6*b*), while **2** has a very weak emission that is barely above the noise level, and **3** has no emission at all. The excitation band of **1** in the solid state has a maximum similar to that in solution, but is much broader than the solution excitation band. The broad excitation band of **1** is characteristic of ligands, not the Eu(III) ion. Therefore, the red emission of **1** in the solid state can also be attributed to an *indirect* excitation process. It is, however, somewhat surprising that **2** displays only very weak luminescence in the solid state. The crystal structural analysis shows that there is a π-stacking among the coordinated and non-coordinated bipyete

ligands and no π-stacking between the tta ligands in the crystal lattice. It is, therefore, possible that the absence of luminescence of **2** in the solid state is related to the π-stacking of the bipyete ligands, which may interfere with the energy transfer process. Although luminescent quenching via π-stacking has been well-documented previously (9), the relationship between the π-stacking of bipyete ligands in the crystal lattice and the very low emission intensity of Eu(III) emission of **2** in the solid state is yet to be understood.

The absence of luminescence of **3** in the solid state appears to be caused by bipyo ligands. The mixture of $Eu(NO_3)_3$ with bipyo ligands in a methanolic solution shows no luminescence at all, indicating that the bipyo ligand by itself is not capable of activating the emission from Eu(III). Addition of bipyo ligands to a bright red luminescent solution containing $Eu(tta)_3(phen)$ resulted in a complete quenching of red emission from the Eu(III) center, which supports the hypothesis that the absence of emission from **3** is indeed caused by the bipyo ligand. The free bipyo ligand has a weak blue emission band in solution (λ = 400 nm) and the solid state (λ = 484 nm). The excitation band (λ = 416 nm in the solid state) of bipy overlaps with that of the tta ligand in **1**, **2**, and $Eu(tta)_3(phen)$. It is, therefore, likely that the bipyo ligand interferes with the energy transfer process from the tta ligand to the Eu(III) center, thus quenching the Eu(III) emission in **3**.

Because compound **1** is a bright red emitter in solution and the solid state, we attempted to use it as a red emitter in electroluminescent devices. Thin films of compound **1** can be achieved by spin-casting the solution of **1** in toluene and THF to a polymer substrate (PVK). Alternatively, compound **1** can be doped into PVK, and then spin-casted into thin films. The photoluminescent spectra of the films of **1** are similar to that of compound **1** in solution and the solid state. Two-layer devices with the structure of ITO/PVK/**1**/(Mg/Ag) and three-layer devices with the structure of ITO/PVK/**1**/PBD/(Mg/Ag) were fabricated using the same procedure reported previously, where PVK and PBD (2-(4-biphenylyl)-5-(4-*tert*-butylphenyl)-1,3,4-oxadiazole) are used as a hole transport and an electron transport layer, respectively. However, no electroluminescence was observed from any of the devices fabricated. There are many possible causes for the failure of the EL devices. The most likely cause is the mismatch of the host layers, thereby preventing efficient energy transfer to the Eu(III) center. Modification of the hole transport and electron transport materials in the devices may be the key for obtaining electroluminescence from **1**. However, suitable hole transport and electron trans-

Fig. 6. (*a*) UV–vis, excitation and emission spectra of **1** amd **2** in solution (1.0×10^{-4} M in CH_2Cl_2); and (*b*) excitation and emission spectra of **1** and **2** in the solid state.

port materials for Eu(III) films obtained by spin-casting are still rather rare, which limits our current study on electroluminescent properties of **1**.

In summary, we have demonstrated that bipy and bipyete ligands are capable of linking $Eu(tta)_3$ units together to form red luminescent dinuclear complexes by both coordination and hydrogen bonds, and bipyo can link $Eu(tta)_3$ units together by coordination bonds to form a novel one-dimensional chain structure and in turn an intercalation lattice that can host methanol molecules. However, the bipyo ligand is not capable of activating red emission from Eu(III) centers and effectively quenches the red emission from the $Eu(tta)_3$ unit. The application of compound **1** as a red emitter in electroluminescent devices requires further investigation.

Acknowledgments

We thank the Natural Sciences and Engineering Research Council of Canada (NSERC) and the Xerox Research Center of Canada (XRCC) for financial support. We thank Dr. Nanxing Hu at XRCC for assistance in the attempted electroluminescent device fabrication.

Synthesis, structure, and reactivity of diamidophosphine complexes of yttrium and the lanthanides

Michael D. Fryzuk, Peihua Yu, and Brian O. Patrick

Abstract: The reaction of the dilithiodiamidophosphine ligand precursor $PhP(CH_2SiMe_2NPh)_2Li_2(THF)_2$([NPN]$Li_2(THF)_2$) with $LnCl_3(THF)_3$ (Ln = Y, Sm, Ho, Yb, Lu; THF = tetrahydrofuran) in refluxing toluene generates the mononuclear complexes [NPN]LnCl(THF) in good yield. The molecular structures have been shown to be five-coordinate in the solid state and in solution. Attempts to prepare alkyl derivatives have only met with partial success; the reaction of MeMgCl with [NPN]YCl(THF) generates the partially characterized mixed-metal derivative [NPN]YMe_2MgCl. The reaction with $LiAlH_4$ results in complete ligand exchange and the formation of the tetranuclear lithium aluminum hydride derivative {[NPN]$AlH_2Li(THF)$}$_2$. Reduction of the lutetium derivative with KC_8 and naphthalene generated the dinuclear naphthalene-bridged species {[NPN]Lu}$_2$(μ-η^4:η^4-$C_{10}H_8$) wherein each Lu centre engages in η^4-coordination to opposite sides of the arene moiety. X-ray crystallography was used to characterize the four complexes.

Key words: lanthanides, yttrium, mixed-donor ligands, aluminum, lithium, naphthalene.

Résumé : La réaction du précurseur de ligand dilithiodiamidophosphine $PhP(CH_2SiMe_2NPh)_2Li_2(THF)_2$([NPN]$Li_2(THF)_2$) avec du $LnCl_3(THF)_3$ (Ln = Y, Sm, Ho, Yb, Lu; THF = tétrahydrofurane), dans du toluène au reflux, génère des complexes mononucléaires [NPN]LnCl(THF) avec de bons rendements. Il a été démontré que, à l'état solide ainsi qu'en solution, les structures moléculaires sont pentacoordinées. Les essais effectués en vue de préparer des dérivés alkylés n'ont donné que des succès partiels; la réaction du MeMgCl avec le [NPN]YCl(THF) conduit à la formation du dérivé métallique mixte [NPN]YMe_2MgCl, qui a été partiellement caractérisé. La réaction avec le $LiAlH_4$ donne lieu à un échange complet de ligands et à la formation de l'hydrure de lithium et d'aluminium tétranucléaire {[NPN]$AlH_2Li(THF)$}$_2$. La réduction du dérivé du lutécium avec du KC_8 et du naphtalène génère l'espèce dinucléaire ponté par du naphtalène, {[NPN]Lu}$_2$(μ-η^4:η^4-$C_{10}H_8$) dans lequel chaque centre Lu est engagé dans une coordination η^4 avec les côtés opposés de la portion arène. On a fait appel à la diffraction des rayons X pour caractériser quatre des complexes.

Mots clés : lanthanides, yttrium, ligands à donneurs mixtes, aluminium, lithium, naphtalène.

[Traduit par la Rédaction]

Introduction

Early transition metal complexes with formally d^0 electronic configurations have been prominent as catalyst precursors for the polymerization of α-olefins (1). While the cyclopentadienyl ancillary ligand provided the initial surge of activity, recent reports have focused on nonmetallocene systems, and in particular, multidentate amido ligands (2–4). Our strategy for ligand design has centred on the combination of two vastly different donor types in a chelate array in an effort to allow access to a variety of different oxidation states at the metal centre. Several new multidentate ligands based on varying the number of amide and phosphine moieties have been developed in our lab (5–7). Herein we report on the preparation of a series of lanthanide complexes [NPN]LnCl(THF) that incorporate a tridentate ligand containing one phosphine and two amido donors ([NPN] = [$PhP(CH_2SiMe_2NPh)_2$]; Ln = Y (**1**), Sm (**2**), Ho (**3**), Yb (**4**), Lu (**5**)).

Experimental

All experimental manipulations were carried out under an atmosphere of purified dinitrogen rigorously excluding air and moisture using standard Schlenk or glovebox techniques (Vacuum Atmospheres HE-553-2 glovebox equipped with a MO-40-2H purification system and a −40°C freezer). Solvents were purified according to conventional procedures and were freshly distilled prior to use. Unless otherwise stated, ^1H and $^{31}P\{^1H\}$ NMR spectra were recorded on a Bruker AC-200 instrument operating at 200 and 81.0 MHz, respectively.

The compounds $LnCl_3(THF)_3$ (8), [NPN]$Li_2(THF)_2$ (9), and KC_8 (10) were prepared as described in the literature.

 DOI: 10.1139/cjc-79-7-1194 © 2001 NRC Canada

MeMgCl (solution in THF), $LiAlH_4$, and naphthalene were purchased from Aldrich.

Elemental analyses were performed in the microanalysis laboratory of this department by Mr. P. Borda.

Preparation of [NPN]LnCl(THF) (Ln = Y, Sm, Ho, Yb, Lu)

General procedure for **1**–**5**: at room temperature, toluene (100 mL) was added to a mixture of $[NPN]Li_2(THF)_2$ (1.18 g, 2 mmol) and $LnCl_3(THF)_3$ (2 mmol) and the resulting slurry was heated under reflux overnight. After cooling to room temperature, the mixture was filtered through Celite. The solvent was evaporated to dryness and the residue washed with hexane and dried under vacuum, yielding **1** (0.97 g, 70%), **3** (0.96 g, 68%), **5** (1.12 g, 71%) as white powders, **2** (1.15 g, 75%) as a yellow powder, and **4** (1.18 g, 74%) as an orange powder.

Methylation of [NPN]YCl(THF) using MeMgCl

To a suspension of [NPN]YCl(THF) (**1**) (0.63 g, 1 mmol) in toluene (30 mL) was added MeMgCl (0.7 mL, 3.0 M in THF, 2.1 mmol) at room temperature, and the mixture was stirred overnight. After removal of the volatiles, the residue was extracted with hexane–toluene (1:1, 2 × 5 mL), and the mixture was filtered through Celite. Upon cooling to –30°C a white crystalline product formulated as $[NPN]YMe_2MgCl(THF)$ (**6**) could be obtained in 50% yield (0.34 g). ^1H NMR (C_6D_6, 200 MHz, 298 K) δ: 7.68 (m, 2H, PPh *o*-H), 7.50 (m, 6H, NPh *m*-H and PPh *m*-H), 7.12 (m, 1H, PPh *p*-H), 6.97 (m, 4H, NPh *o*-H), 6.85 (m, 2H, NPh *p*-H), 2.61 (m, 4H, THF), 1.18 (m, 2H, PCH_2Si), 1.06 (m, 2H, PCH_2Si), 0.71 (m, 4H, THF), 0.45 and –0.02 (s, 12H total, $SiCH_3$), –0.14 (m, 3H, Me), –0.62 (m, 3H, Me). $^{31}P\{^1H\}$ NMR (C_6D_6, 81 MHz, 298 K) δ: –46.5(s). Anal. calcd. for $C_{30}H_{45}ClN_2OPSi_2MgY$: C 52.55, H 6.68, N 4.08; found: C 52.98, H 6.59, N 4.02.

Reaction of [NPN]YCl(THF) with $LiAlH_4$; synthesis of $\{[NPN]AlH(\alpha\text{-}H)Li(THF)\}_2$ (7)

To a stirred mixture of [NPN]YCl(THF) (**1**) (1.26 g, 2 mmol) and $LiAlH_4$ (0.1 g, 2.6 mmol) was added THF (50 mL) at –78°C. After warming to room temperature, the mixture was stirred overnight. After removal of the precipitate by filtration, the solvent was evaporated to dryness under vacuum, the white residue was extracted with toluene (2 × 15 mL), and the mixture filtered through Celite. Partial removal of the volatiles and cooling to –30°C to yield (0.58 g, 54%) compound **7** as colorless crystals. ^1H NMR (C_6D_6, 200 MHz, 298 K) δ: 7.75 (m, 2H, PPh *o*-H), 7.05 (m, 10H, NPh *o*-H and *m*-H, and PPh *m*-H), 6.81 (m, 2H, NPh *p*-H), 3.61 (m, 4H, THF), 1.68 (m, 2H, PCH_2Si), 1.25 (m, 4H, THF), 0.95 (m, 2H, PCH_2Si), 0.52 and –0.21 (s, 12H total, $SiCH_3$). $^{31}P\{^1H\}$ NMR (C_6D_6, 81 MHz, 298 K) δ: –36.01 (q, $J_{P,Li}$ = 66.4 Hz). Anal. calcd. for $C_{28}H_{41}N_2OPSi_2AlLi$: C 61.97, H 7.61, N 5.16; found: C 61.68, H 7.24, N 5.30.

Reaction of [NPN]LuCl(THF) with KC_8 and naphthalene ($C_{10}H_8$); preparation of $\{[NPN]Lu\}_2(\mu\text{-}\eta^4\text{:}\eta^4\text{-}C_{10}H_8)$ (8)

To a mixture of [NPN]LuCl(THF) (**5**) (1.43 g, 2 mmol), KC_8 (0.27 g, 2 mmol), and naphthalene (0.128 g, 1 mmol) was added toluene at –78°C, leading the immediate development of a purple colour. The mixture was warmed to room temperature and stirred overnight to generate a dark purple colour. After filtration, the volatiles were removed under vacuum, the residue was washed with hexane (3 × 15 mL), and then the remaining solid was recrystallized from toluene. Compound **8** was obtained as dark red crystals by slowly evaporating the solvent at room temperature. Yield 35% (0.47 g). ^1H NMR (C_6D_6, 200 MHz, 298 K) δ: 7.25 (m, 4H, PPh *o*-H), 7.02 (m, 20H, NPh *o*-H and *m*-H, and PPh *m*-H), 6.78 (m, 4H, NPh *p*-H), 4.12 (m, 4H, $C_{10}H_8$), 2.51 (m, 4H, $C_{10}H_8$), 1.24 (m, 4H, PCH_2Si), 0.65 (m, 4H, PCH_2Si), 0.21 and 0.02 (s, 24H total, $SiCH_3$). $^{31}P\{^1H\}$ NMR (C_6D_6, 81 MHz, 298 K) δ: –9.1 (s). ^{13}C NMR (C_6D_6, 75.45 MHz, 298 K) δ: 159.7 (m, ipso-C_6H_5N), 131.6 (m, *o*-C_6H_5N), 129.6 (s, *m*/*p*-C_6H_5N), 122.9 (m, ipso-C_6H_5P), 120.6 (m, *o*-C_6H_5P), 105.8 (m, ipso-$C_{10}H_8$), 104.4 (s, *m*/*p*-C_6H_5P), 89.8

X-ray crystallography

Single crystals of compounds **1**, **4**, **7**, and **8** suitable for X-ray diffraction studies were selected and mounted on a glass fiber using Paratone oil. The crystallographic data appear in Table 1.[3] All measurements were made on a Rigaku/ADSC CCD area detector at 173 K, with graphite monochromated Mo Kα radiation (λ = 0.71069 Å), performing 2θ–ω scans. The structures of **1**, **4**, and **7** were solved by direct methods using SIR97 (11) and **8** by the Patterson method (12) and refined by full-matrix least-squares methods on F^2 for all data. Unless otherwise stated, all nonhydrogen atoms were refined anisotropically. All hydrogen atoms were included in the model at geometrically calculated positions with C—H distances of 0.98 Å and the isotropic thermal parameter for each H atom (B_H) is equal to 1.2 times B_{iso} of the atom to which it is bonded. Unmodified statistical weights ($w = 1/\sigma^2(F_o^2)$) were employed for all structures. The coordinated THF molecules in **1** and **4** were found to be disordered and were subsequently refined isotropically in two separate orientations.

Results and discussion

A series of complexes of the formula [NPN]LnCl(THF) ([NPN] = $[PhP(CH_2SiMe_2NPh)_2]$; Ln = Y (**1**), Sm (**2**), Ho (**3**), Yb (**4**), Lu (**5**)) were prepared in high yield (>70%) by reaction of $[NPN]Li_2(THF)_2$ with $LnCl_3(THF)_3$ in molar ratio of 1:1 in toluene under reflux (eq. [1]).

[1]

Ln = Y **1**
Ln = Sm **2**
Ln = Ho **3**
Ln = Yb **4**
Ln = Lu **5**

Using THF as the solvent led to lower yields of the products. Compounds **1**–**5** are moisture sensitive, moderately soluble in toluene and Et_2O, but very soluble in THF. The

compounds were characterized by elemental analyses, mass spectrometry, and ^{1}H and ^{31}P NMR spectroscopy where possible. The most intense peaks observed in the mass spectra correspond to the fragments [NPN]LnCl ($[M - THF]^+$) and [NPN]Ln ($[M - THF - Cl]^+$). Although the Sm(III), Ho(III), and Yb(III) derivatives (**2**, **3**, and **4**, respectively) are paramagnetic, the samarium derivative [NPN]SmCl(THF) (**2**) exhibited ^{1}H NMR signals (although no ^{31}P NMR resonance could be detected); no diagnostic signals could be detected in both the ^{1}H and ^{31}P NMR spectra for compounds **3** and **4**. For complexes **1** and **5**, the ^{1}H NMR spectra each show two signals due to coordinated THF at ca. 2.9 and 0.7 ppm, respectively. More importantly, both diamagnetic derivatives **1** and **5** show very symmetrical NMR patterns in solution suggestive of at least C_s symmetry; for example, only two environments for the silylmethyl protons ($SiMe_2$) are observed and the phenyl groups attached to nitrogen are equivalent.

The molecular structures of **1** and **4** were determined by X-ray crystallography and are shown in Figs. 1 and 2, respectively; selected bond distances and angles are given in Tables 2 and 3. These two derivatives are isostructural and isomorphous in the solid state. Both compounds display

five-coordinate environments around the central metals with the coordinated THF occupying the position opposite to the phosphorus atom. Overall, the geometries around each central metal are very similar and can be described as distorted square pyramidal by defining the base of the pyramid by P(1), O(1), N(1), and Cl(1), with N(2) in the apical position. This rather unsymmetrical geometry observed in the solid state cannot account for the solution data; in fact, the solution data are more consistent with a trigonal bipyramidal structure wherein the two amide donors and the chloride occupy the equatorial plane with the phosphine and THF moieties are apical resulting is C_s molecular symmetry. Presumably the small structural differences between the solid state and in solution are a result of crystal packing in the former.

The Y—Cl (2.7561(6) Å) bond distance in **1** is longer than that reported for the mononuclear diamido complex [DADMB]YCl(THF)$_2$ (Y—Cl 2.574(2) Å), while Y—N (average 2.250 Å) and Y—O (2.350(2) Å) in compound **1** are comparable to those in compound [DADMB]YCl(THF)$_2$ (DADMB = [6,6′-Me_2-(C_6H_3)$_2$](2,2′-$NSiMe_2$-*t*-Bu)$_2$) (average Y—N 2.250 Å, average Y—O 2.376 Å) (2). The bond distances Yb—Cl (2.710 Å), Yb—N (average 2.212 Å), and

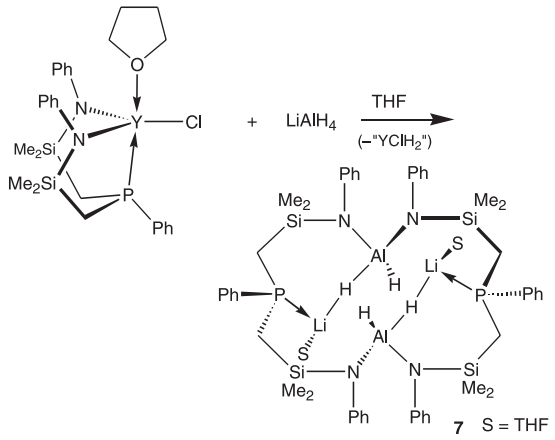
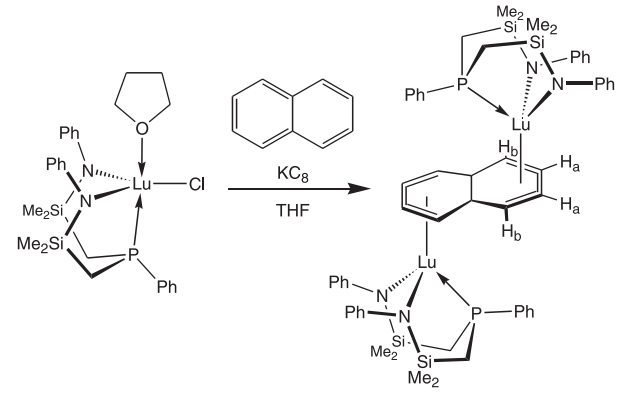
Fig. 3. Molecular structure of $\{[NPN]AlH(\mu\text{-}H)Li(THF)\}_2$ (**7**). For clarity the Ph groups at N and P are omitted.



Yb—P (2.881 Å) in compound **4** can be compared to other Yb(III) phosphine complexes; for example, in $Cp^*_2YbCl(dmpm)$, the Yb—Cl bond distance of 2.532 Å is considerably shorter than that found in **4**, while the Yb—P bond length in **4** is slightly shorter than 2.941 Å found in the aforementioned permethylytterbocene derivative (13). The Yb(II) derivative $[(Me_2Si)_2N]_2Yb(dmpe)$ shows Yb—N and Yb—P bond distances of 2.331 and 3.012 Å, respectively, which are both longer than that found in **4** (14).

Attempts to generate metal–carbon bonds by metathesis of the remaining chloride ligands of [NPN]LnCl(THF) have not met with success. Generally mixtures of products are obtained upon addition of RLi (R = Me, CH_2SiMe_3) to [NPN]YCl(THF) (**1**). However, it was found that the addition of MeMgCl to **1** did result in the formation of an adduct of the empirical formula $[NPN]YMe_2MgCl$ (**6**). This material is clearly not the expected product, [NPN]YMe(THF). The proposed formulation of **6** is from elemental analyses; while ^1H and ^{31}P NMR spectroscopy could be obtained, a definitive structure has so far eluded us, as have suitable crystals for single crystal X-ray diffraction studies. From the solution NMR data, it is clear that phosphorus is not bound to Y (no coupling between yttrium-89 and phosphorus-31) and there are two metal–methyl environments. Further speculation on the structure of **6** must await additional data.

Attempts to prepare a hydride of the general formula $\{[NPN]YH(THF)\}_x$ by the reaction of **1** with $LiAlH_4$ in THF instead resulted in ligand transfer from yttrium to aluminum and the production in reasonable yield of the air-, moisture-, and slightly light-sensitive dinuclear aluminate **7** (eq. [2]).

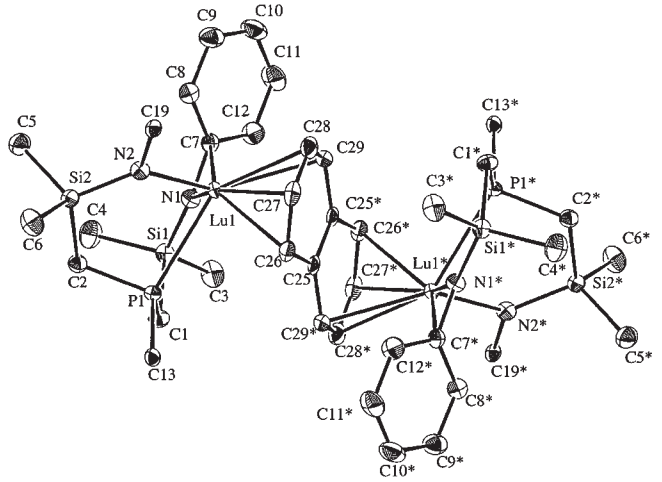


The molecular structure of **7** was determined by X-ray crystallography. As shown in Fig. 3, the Al atoms are each coordinated by two amido donors and two hydrides in a distorted tetrahedral coordination mode. Selected bond distances and angles are given in Table 4. The Li atoms are each coordinated by three atoms (P, O, H) and the angles of P-Li-O (113.7(3)°), P-Li-H (109.5°), and O-Li-H (105.2°) are in agreement with those expected for pseudo-tetrahedral geometries. The average Al—N (1.85 Å), Al—H (1.57 Å), and Li—H (1.84 Å) distances are comparable to those in the related disilylamido aluminate, $[(Me_3Si)_2N]_2Al(\mu\text{-}H)_2Li\cdot 2Et_2O$ (Al—N 1.86, Al—H 1.58, and Li—H 1.93 Å) (15). Stoichiometry requires that $YClH_2(THF)_x$ also be generated; however, the identity of the yttrium side-product was not pursued.

[2]

Recently, we have reported the formation of yttrium and lutetium complexes with polycyclic aromatic compounds that were formulated as $\{[P_2N_2]Ln\}_2(\mu\text{-}\eta^4\text{:}\eta^4\text{-}C_{10}H_8)$ by reducing $\{[P_2N_2]LnCl\}_2$ (Ln = Y, Lu) using KC_8 in the presence of aromatic compounds such as naphthalene and anthracene (16). A similar reaction of [NPN]LuCl(THF) with KC_8 and naphthalene resulted in the generation of $\{[NPN]Lu\}_2(\mu\text{-}\eta^4\text{:}\eta^4\text{-}C_{10}H_8)$ (**8**) in moderate yield (eq. [3]).

[3]



Exactly analogous transformations are also evident for the reaction of the holmium and yttrium analogues, although these reactions were not examined in detail. While the lutetium reaction provides proof of concept for this process for some of the lanthanides, it is interesting to note that this kind of reductive process completely fails to provide any kind of isolable product for the samarium and ytterbium derivatives **2** and **4**, despite the fact that divalent states are known for these particular lanthanide elements; it is not

Fig. 4. Molecular structure of $\{[NPN]Lu\}_2(\mu\text{-}\eta^4\text{:}\eta^4\text{-}C_{10}H_8)$ (**8**). For clarity the Ph groups at N(2) and P(1) are omitted.

clear if reduction to a putative "Ln(II)[NPN]" species complicates these latter reactions. The ^{1}H NMR spectroscopic data of **8** show only two sets of signals for the $C_{10}H_8$ moiety, which indicate that the bridging naphthalene unit is symmetrically bound. In addition, only one signal for its $^{31}P\{^1H\}$ NMR spectrum also demonstrates equivalent phosphine donors on both Lu(III) centers.

The crystal structure of **8** has been determined and is shown in Fig. 4. Selected bond distances and angles are given in Table 5. The conformation of **8** is very similar to that of compound $\{[P_2N_2]Y\}_2(\mu\text{-}\eta^4\text{:}\eta^4\text{-}C_{10}H_8)$. Each [NPN]Lu unit binds in an η^4 fashion on the opposite sides of the different rings of the naphthalene unit. The naphthalene moiety is distorted slightly with elongated bond lengths, and its rings become nonplanar (16). The average Lu—C (2.59 Å) π-bond distances in compound **8** is found similar to the average π-bond distance of Lu—C(Cp) (2.63 Å) in compound $(C_5H_5)_2$Lu-*t*-Bu(THF) (17). It is interesting to note that the short distance between Lu(1) and C(7) (2.75 Å) appears to indicate a η^2-N,C interaction of the amide in solid state. However, the ^{13}C NMR spectrum shows no evidence of any asymmetry and both ipso carbons resonate at 159.7 ppm, a shift typical for uncoordinated NPh linkages (2).

Conclusions

The results of this study indicate that the NPN ligand system can be incorporated onto certain Group 3 and lanthanide derivatives to generate five-coordinate, mononuclear complexes. However, these materials are not especially versatile as starting materials for entry into organometallic chemistry as most of the attempts to generate metal–carbon bonds result in mixtures of complexes. The only successful transformation so far is the incorporation of naphthalene under reducing conditions to give a bridging naphthalene unit. Since incorporation of alkyl species has proven difficult, it is likely that the use of these ligand systems with Group 3 and the lanthanides as catalyst precursors for polymerization of α-olefins will not be optimal.

Tetrazole ethers from lignin model phenols: synthesis, crystal structures, and photostability

Andy Z. Lu, Thomas Q. Hu, David A. Osmond, Brian O. Patrick, and Brian R. James

Abstract: The phenolic OH moiety in lignin is one of the key functional groups responsible for the photo-induced yellowing of mechanical wood pulps and papers. To evaluate new protective groups for the stabilization of lignin phenols, the model compounds, 2-methoxy-4-propylphenol (**1**) and 4-hydroxy-3-methoxyacetophenone (**2**) were reacted with 5-chloro-1-phenyl-1*H*-tetrazole to give the corresponding tetrazole ethers **1′** and **2′**, respectively, that were then studied for their photostability. The synthesis of these ethers was more efficient than that of alkyl ethers because of less hydrolysis of the alkylating agent under the reaction conditions. Compounds **1′** and **2′** were fully characterized, including X-ray crystal structure analyses. Crystals of **1′** and **2′** were monoclinic of space groups $P2_1/c$ and $P2_1/a$, respectively. For **1′**: a = 9.8679(6), b = 16.708(1), c = 10.2841(6) Å, β = 109.732(5)°, Z = 4. For **2′**: a = 7.7212(2), b = 27.350(5), c = 14.569(3) Å, β = 101.30(2)°, Z = 8. The structures were solved by direct methods and refined by full-matrix least-squares procedures to R = 0.039 (R_w = 0.046) for 2029 reflections with $I \geq 3\sigma(I)$ (for **1′**), and to R = 0.055 (R_w = 0.073) for 3634 reflections with $I \geq 3\sigma(I)$ (for **2′**). Compound **2′** was much more photostable than the precursor phenol on exposure to strong fluorescent light, while **1′** was only slightly more stable than the precursor phenol.

Key words: alkylation, ethers, lignin model compounds, methylation, phenols, yellowing inhibition.

Résumé : Le groupe OH de la portion phénolique de la lignine est l'un des groupes fonctionnels clés responsables du jaunissement photoinduit des pâtes et papiers mécaniques dérivés du bois. Dans le but d'évaluer de nouveaux groupes protecteurs pour la stabilisation des phénols des lignines, on a fait réagir des composés modèles, le 2-méthoxy-4-propylphénol (**1**) et la 4-hydroxy-3-méthoxyacétophénone (**2**), avec le 5-chloro-1-phényl-1*H*-tétrazole pour obtenir respectivement les éthers correspondants **1′** et **2′** du tétrazole dont on a alors étudié la photostabilité. La synthèse de ces éthers s'avère plus efficace que celle des oxydes d'alkyles en raison d'une plus faible hydrolyse de l'agent alkylant dans les conditions réactionnelles. On a caractérisé complètement les éthers **1′** et **2′**, y compris par diffraction des rayons X. Les cristaux des composés **1′** et **2′** sont monocliniques, groupes d'espaces $P2_1/c$ et $P2_1/a$, respectivement. Pour **1′**, a = 9,8679(6), b = 16,780(1) et c = 10,2841(6) Å, β = 109,732(5)° et Z = 4. Pour **2′**, a = 7,7212(2), b = 27,350(5) et c = 14,569(3) Å, β = 101,30(2)° et Z = 8. Les structures ont été résolues par des méthodes directes et affinées par des procédures des moindres carrés (matrice complète) jusqu'à des valeurs de R = 0,039 (R_w = 0,046) pour 2029 réflexions avec $I \geq 3\sigma(I)$ (pour **1′**) et de R = 0,055 (R_w = 0,073) pour 3634 réflexions avec $I \geq 3\sigma(I)$ (pour **2′**). Lorsqu'on le soumet à une forte lumière fluorescente, le composé **2′** est beaucoup plus photostable que son précurseur phénolique alors que le composé **1′** n'est que légèrement plus stable que son précurseur phénolique.

Mots clés : alkylation, éthers, composés modèles pour la lignine, méthylation, phénols, inhibition du jaunissement.

[Traduit par la Rédaction]

Introduction

Canada is the world's largest producer of mechanical wood pulps. In 1998, Canada produced about 10 million tonnes of such pulps, accounting for one third of the total world production (1). Mechanical wood pulps, produced in 90–98% yields because of the retention of practically all the cellulose, hemicelluloses, and lignin in wood, have high opacity and are good materials for making printing papers; however, such papers turn yellow and lose brightness rapidly when exposed to light and this limits their main use to the production of short-life paper products such as newsprint and telephone directories (2).

Lignin is a random, three-dimensional biopolymer of substituted phenylpropane units. The light-induced yellowing of mechanical wood pulps and papers is due to the oxidation of lignin phenoxy radicals to yellow *o*-quinones (3, 4). One important source of the phenoxy radicals is lignin phenols that can produce the radicals via direct photolysis (5), or H-atom abstraction from the phenolic-OH by photoexcited lignin carbonyl groups (6) or singlet oxygen (7).

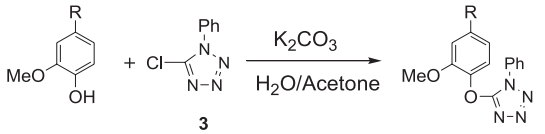
Alkylation of lignin phenols with the extremely toxic dimethylsulfate (8) has been shown to retard the photoreactivity of the lignin phenols in wood, newspapers, and groundwood pulps (5, 9), but a large excess of the reagent (in weight, greater than that of the oven-dried pulp) (9, 10) is required because of its rapid hydrolysis in the aqueous alkaline conditions needed. Other less toxic reagents such as olefin oxides (11) and diazomethane (12) have been studied for the alkylation of lignin phenols. Propylene- and butylene-oxides effect only partial protection of lignin phenols and give lower brightness stabilization (vs. dimethylsulfate) of groundwood mechanical pulps (11). Diazomethane is less effective than propylene-oxide in improving the brightness stability of spruce thermomechanical pulp (12), and its generation and alkylation require an anhydrous environment.

We have tested 5-chloro-1-phenyl-1*H*-tetrazole, a nontoxic and nonvolatile alkylating reagent, for the alkylation and possible stabilization of lignin phenols. This paper describes the reaction of this reagent with the lignin model phenols, 2-methoxy-4-propylphenol (**1**) and 4-hydroxy-3-methoxyacetophenone (**2**), and the structural and photostability studies of the ether products (**1′** and **2′**, respectively).



Results and discussion

Alkylation of lignin model phenols with 5-chloro-1-phenyl-1*H*-tetrazole (3)

5-Chloro-1-phenyl-1*H*-tetrazole (**3**) is a water-insoluble alkylating reagent available commercially and readily synthesized from sodium azide and *N*-phenyldichloroazomethine (13, 14). It has been used to alkylate simple phenols in dry acetone to give tetrazole ethers that can then be hydrogenolyzed to give simple arenes (15, 16). None of the literature examples, however, involved the use of an aqueous reaction medium or substrates resembling the structures of lignin phenols.

Treatment of **1** with 1 equiv. of **3** and 2 equiv. of K_2CO_3 in 1:1 v/v H_2O–acetone (pH 13.3) at 60°C for 18 h gave the purified tetrazole ether **1′** in 62% yield (eq. [1]). The structure of **1′** was established by ^{1}H NMR, MS, elemental analysis, and an X-ray crystal structure (Fig. 1). Similarly **2** gave **2′** in 39% yield, eq. [1] (Fig. 2). Both **1′** and **2′** are new compounds; no attempt was made to optimize the yields. Under the conditions used (pH 13.3), it is expected that other OH groups (aliphatic hydroxyl groups in lignin and those in carbohydrates) would react much slowly with **3** than the lignin phenolic-OH groups, if such a treatment were to be applied to mechanical wood pulps.

[1]

R = ^{n}Pr (**1**); C(O)Me (**2**) R = ^{n}Pr (**1'**); C(O)Me (**2'**)

The structures of **1′** and **2′** reveal expected bond lengths and angles. Within the tetrazole rings the double bonds between N(2)—N(3) and between N(4)—C(11) (or N(4)—C(10)) are characterized by bond lengths of 1.286–1.306 Å, while N(1)—N(2) and N(3)—N(4) have single bond lengths of 1.358–1.376 Å. The N(1)—C(12) lengths are 1.432 and 1.431 Å, and at the newly formed ether O-atom, the O(1)—C(tetrazole) bonds are 1.331 and 1.327 Å in **1′** and **2′**, respectively, which are shorter than the O(1)—C(phenyl) lengths of 1.417 and 1.418 Å. Within the tetrazole ring, the smallest angles are at N(1), N(2), and N(4) (106.9, 106.0, and 104.2° in **1′**, and 106.3, 107.0, and 104.2° in **2′**), while those at N(3) and C(10 or 11) are all in the 111.1–111.8° range. Differences in corresponding torsion angles of **1′** and **2′** likely result from crystal packing effects; for example, the N(2)-N(1)-C(12)-C(13) angle in **1′** is –124.1°, whereas the N(2)-N(1)-C(11)-C(12) angle in **2′** is –155.7°.

Compound **2** was more difficult to alkylate than **1**, and this was shown by monitoring the conversions of the phenols using GC with 3,4-dimethoxy-1-ethylbenzene added as an internal reference to the reaction medium. For example, the conversions of **1** at 60°C were 42 (6 h), 62 (18 h), and 75% (23 h), vs. corresponding values of 12, 39, and 50% for conversions of **2**. The lower reactivity of **2** is attributed to the lower nucleophilicity of its phenolate anion resulting from the delocalization of the anionic charge by the electron-withdrawing α-carbonyl group. A very low reactivity of lignin model phenols possessing α-carbonyl groups toward alkylation by ethylene oxide has been reported previously (17).

We also compared the alkali-induced hydrolysis of **3** (to give the 5-hydroxy derivative) with that of the easily handled α-butylene oxide (to give 1,2-dihydroxybutane) in H_2O–acetone (1:1 v/v) at 60°C with a 2:1 molar ratio of K_2CO_3 to the

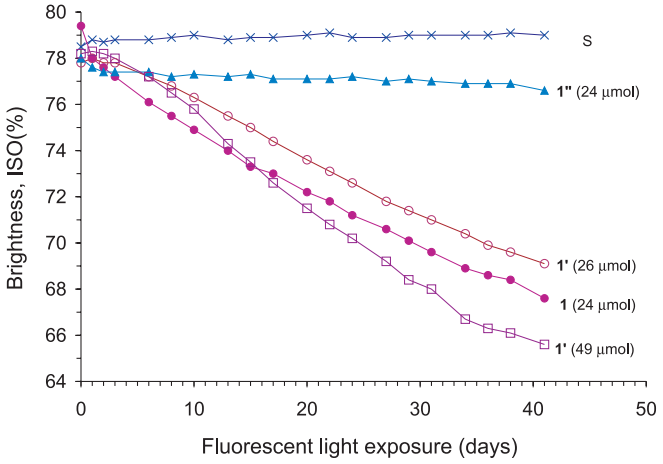

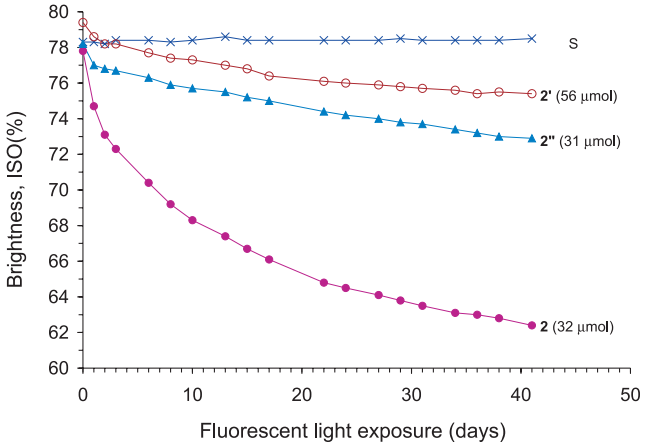

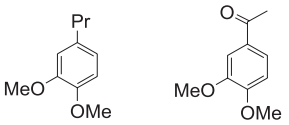

Fig. 4. %ISO brightness vs. fluorescent light exposure time for the paper sheets impregnated with solvent (S) and models **2**, **2′**, and **2″**.

alkylating reagent. We found that **3** was more stable toward alkali-induced hydrolysis than α-butylene oxide (12 and 43% hydrolysis of **3** after 6 and 21 h, respectively, vs. 33 and 77% hydrolysis for the butylene oxide). Data for α-butylene oxide were obtained by GC analyses of samples withdrawn from a single reaction using toluene as an internal reference; those for **3** were obtained from gravimetric determinations of **3** recovered from two reactions. The higher stability towards alkali-induced hydrolysis of **3** is likely responsible for the efficient synthesis of **1′** using just one equivalent of **3**.

Photostability of the tetrazole ethers

To study the photostability of the tetrazole ethers **1′** and **2′**, their corresponding phenols **1** and **2**, as well as the methylated derivatives **1″** and **2″** in a solid-state, cellulosic environment, we first deposited the compounds in filter paper sheets made from pure cellulose. The sheets were soaked with 0.10 M solutions of the compounds in methyl cellosolve, $MeOCH_2CH_2OH$ (one sheet per compound), and a control sheet (soaked with methyl cellosolve only) was also prepared to allow for the estimation of incorporated methyl cellosolve. The tetrazole ethers **1′** and **2′** had about twice the affinity for the filter papers as the precursor phenols or the methylated derivatives: the amounts absorbed were 24, 49, and 24 μmol for **1**, **1′**, and **1″**, and 32, 56, and 31 μmol for **2**, **2′**, and **2″**, respectively. Another sheet was soaked with a 0.06 M solution of **1′** to give a sheet impregnated with 26 mol of **1′**.

1'' 2''

Next, the model compound-impregnated filter sheets were subjected to an accelerated yellowing experiment using "cool white" fluorescent lamps as the light source. The lamps have a similar broadband spectrum to normal office fluorescent lamps with the maximum spectral output at ~570 nm, but have about nine times the intensity. They were used to simulate paper use in an office environment. Figures 3 and 4 show the plots of %ISO brightness vs. fluorescent light exposure time of the sheets impregnated with the solvent (S), **1**, **1′**, and **1″** and with the solvent (S), **2**, **2′**, and **2″**, respectively. At a higher impregnation (49 μmol), tetrazole ether **1′** was slightly more stable than the precursor phenol **1** (24 μmol) at the early stage of light-induced yellowing but less stable at the later stage. At similar impregnation, **1′** (26 μmol) was more stable than **1** throughout the exposure time, but it was less stable than the methylated derivative **1″** (Fig. 3). For example, after 41 days the %ISO brightness for **1′** has dropped from 77.8 to 69.1 (8.7 brightness point loss), while values for **1** and **1″** changed from 79.4 to 67.5 (11.9 brightness point loss) and from 78.2 to 76.6 (1.6 brightness point loss), respectively. These data represent a brightness stabilization (yellowing inhibition) of only 27% when the phenolic group in **1** was protected as the tetrazole ether, but a brightness stabilization of 86% when the phenolic group was protected as the methyl ether. The percent brightness stabilization is defined as [(change in brightness of reference sample – change in brightness of treated sample) / change in brightness of reference sample] × 100% (18).

The tetrazole ether **2′** was much more stable than the precursor phenol **2** and the methylated derivative **2″** on exposure to the fluorescent light (Fig. 4). For example, after 41 days, the %ISO brightness for **2** and **2″** have dropped from 77.8 to 62.4 (15.4 brightness point loss) and from 78.2 to 72.9 (5.3 brightness point loss), respectively. The %ISO brightness for **2′** changed only from 79.4 to 75.4 (4.0 brightness point loss), even though the amount of **2′** in the sheet was close to double that of **2** and **2″** (a lower impregnation value for the same sample will always give a lower brightness loss, see Fig. 3). These data represent a brightness stabilization of 74% when the phenolic group in **2** was protected as the tetrazole ether, compared to a brightness stabilization of 66% when protected as the methyl ether. The tetrazole ethers **1′** and **2′** are both white as powders. The more light-induced yellowing of **1′** than **2′** likely indicates

© 2001 NRC Canada

more cleavage of the tetrazole ether bond in **1′** under light exposure; whether the increased yellowing of **1′** is due to a colour-forming reaction from the cleaved tetrazole group, the cleaved phenol, or both, is unclear.

The above photostability data show that effective photostabilization of lignin phenols by conversion to tetrazole ethers is favored by the presence of an α-carbonyl at the C(1) position of the lignin aromatic ring. In softwood lignins, the number of free phenols is probably <20 per 100 phenylpropane units (19). Among such phenols, only one has been estimated to have a C(1) α-carbonyl group, the majority having an α-hydroxyl group (19). As the α-hydroxyl group and alkyl group (such as the Pr substituent in **1**) have similar electronic properties, e.g., the Hammett σ_{para} values for -CH(OH)CH_3 and *n*-Pr are –0.07 and –0.15, respectively, (20), conversion of the hydroxyl group to an α-carbonyl group may be necessary to obtain significant lignin photostabilization by conversion of the lignin phenols to tetrazole ethers. 2,3-Dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) can oxidize the α-hydroxyl to the α-carbonyl group in lignin model compounds (21) and lignin (22), but a reagent more compatible with wood pulp reactions is needed, and catalytic, oxidative-dehydrogenations are being considered by us. The success of **3** in photostabilizing the acetophenone derivative (**2**), via the formation of **2′**, has also prompted us to introduce a sulfonate group in to the phenyl ring of **3** to give a water-soluble derivative. Future papers will describe our efforts in these areas of research.

Conclusions

The protection of the phenolic hydroxyl groups in lignin model compounds, 2-methoxy-4-propylphenol (**1**) and 4-hydroxy-3-methoxyacetophenone (**2**), as the tetrazole ethers can be achieved in aqueous alkaline media using 5-chloro-1-phenyl-1*H*-tetrazole (**3**) as the alkylating agent; **3** is nontoxic and more stable toward alkali-induced hydrolysis than other alkylating agents such as α-butylene oxide. The tetrazole ether **2′** from **2** is much more photostable than the precursor phenol on exposure to strong fluorescent light, while the tetrazole ether **1′** from **1** is only slightly more stable than the precursor phenol. Photostablization of lignin phenols by conversion to tetrazole ethers seems to require conversion of the α-hydroxyl to α-carbonyl groups, which is unlikely to be commercially viable.

Experimental

General procedures

All chemicals were purchased from Aldrich unless otherwise specified. Reactions were carried out under Ar and monitored by GC and (or) TLC. GC was performed on a Hewlet-Packard model 5890 using a 25 m × 0.2 mm Carbowax column (80°C for 2 min, then an increase to 220°C at a rate of 10°C per min, and a final time of 8 min at 220°C). TLC was performed on Al-backed, precoated silica gel plates (E. Merck, type 5554). ^{1}H NMR spectra were recorded in $CDCl_3$ using $SiMe_4$ as the internal standard on a Bruker AC-200 spectrometer. Mass spectra were determined on a Kratos-AEI model MS 50 spectrometer operating at 70 eV. 2-Methoxy-4-propylphenol (**1**) and 1,2-dimethoxy-4-propylbenzene (**1″**) were prepared from the hydrogenation of eugenol and 4-allyl-1,2-dimethoxybenzene over Pd/C, respectively, (23). The residual light yellow colors in **1**, **1″**, and 4-hydroxy-3-methoxyacetophenone (**2**) (Aldrich) were removed by filtration of their solutions in CH_2Cl_2 through Celite–activated charcoal–Florisil–silica (1:5:5:1).

Synthesis of 2-methoxy-4-propylphenyl-1′-phenyl-5′-tetrazole ether (1′)

To **1** (0.399 g, 2.4 mmol) in distilled water (5 mL) and acetone (5 mL) in a 25 mL flask equipped with a condenser and a magnetic stirring bar was added K_2CO_3 (0.663 g, 4.8 mmol) and 5-chloro-1-phenyl-1*H*-tetrazole (**3**) (0.433 g, 2.4 mmol). The mixture was stirred at 60°C overnight (ca. 18 h), cooled to room temperature (~20°C), acidified with 1 N HCl solution, and then extracted with Et_2O (4 × 30 mL). The combined ether extract was dried over anhydrous $MgSO_4$ for 20 min before being filtered. Removal of the filtrate solvent under reduced pressure gave 0.620 g of crude **1′** as a light-yellow solid (83% crude yield). Purification by column chromatography on silica gel using hexane:ethyl acetate (9:1 and then 1:1) as eluent, followed by recrystallization from MeOH, gave 0.463 g of **1′** as white crystals (62% yield). Crystals suitable for X-ray analysis were obtained at –20°C from a diluted MeOH solution of **1′**. EI-MS *m/z* (%): 310 (M^+, 42), 240 (58), 165 (85), 117 (100). ^{1}H NMR δ: 0.95 (t, 3H, CH_2CH_3), 1.63 (m, 2H, CH_2CH_3), 2.60 (t, 2H, CH_2CH_2), 3.75 (s, 3H, OCH_3), 6.80–7.90 (m, 8H, aromatic). Anal. calcd. for $C_{17}H_{18}N_4O_2$: C 65.79, H 5.85, N 18.05; found: C 66.08, H 5.85, N 18.19.

Synthesis of 3-methoxy-4-(1′-phenyl- 5′-tetrazol)-oxyacetophenone (2′)

Identical to the preparation of **1′**, **2** (0.407 g, 2.4 mmol) was reacted with **3** (0.433 g, 2.4 mmol) and K_2CO_3 (0.663 g, 4.8 mmol) in H_2O–acetone (1:1, 10 mL) to give 0.290 g of **2′** as a light-yellow crystalline solid (39% yield). Filtration of a CH_2Cl_2 solution of this solid through Celite–activated charcoal–Florisil–silica (1:5:5:1) gave **2′** as colorless crystals. EI-MS *m/z* (%): 310 (M^+, 12), 240 (13), 198 (10), 165 (34), 117 (100). ^{1}H NMR δ: 2.62 (s, 3H, OCH_3), 3.86 (s, 3H, C(O)CH_3), 7.40–7.90 (m, 8H, aromatic). Anal. calcd. for $C_{16}H_{14}N_4O_3$: C 61.93, H 4.55, N 18.06; found: C 61.94, H 4.56, N 17.80.

X-ray crystallographic analyses of 1′ and 2′

A needle crystal of **1′** (~ 0.45 × 0.25 × 0.20 mm) and a plate crystal of **2′** (~ 0.40 × 0.10 × 0.50 mm) were each mounted in a glass fibre. Measurements were made on a Rigaku ADSC CCD area detector with graphite monochromated Mo Kα (for **1′**) or Cu Kα (for **2′**) radiation. For **1′**, cell constants and an orientation matrix for data collection, derived from 6295 reflections, corresponded to a monoclinic cell, space group $P2_1/c$ (No. 14), FW = 310.35 with dimensions: a = 9.8679(6), b = 16.708(1), c = 10.2841(6) Å, β = 109.732(5)°, V = 1596.0(2) Å^3, Z = 4, ρ_{calc} = 1.37 g cm^{-3}; absent reflection: $h0l$: ($l \neq 2n$), $0k0$: ($k \neq 2n$). The data were collected at –100 ± 1°C to a max 2θ value of 55.8° in 0.50° oscillations with 15.0 s exposures. A sweep of data was done using Φ oscillations from 0.0 to 190.0° at χ = 0°, and a second sweep was performed using ω oscillations between

© 2001 NRC Canada

–19.0 and 23.0° at $\chi = 90.0°$. The crystal to detector distance was 40.64 mm. The detector swing angle was –5.52°. Of the 13144 reflections which were collected, 3407 were unique (R_{int} = 0.052); equivalent reflections were merged. Data were collected and processed using the d*TREK program (MSC). The linear absorption coefficient (μ) for Mo Kα radiation is 0.9 cm^{-1}, and the data were corrected for Lorentz and polarization effects.

For **2′**, the unit-cell parameters for the monoclinic cell were refined by least-squares on setting angle values for 22 reflections (86.69° < 2θ < 98.43°). Crystal data at 21°C are: space group = $P2_1/a$ (No. 14), FW = 310.31, a = 7.7212(2), b = 27.350(5), c = 14.569(3) Å, β = 101.30(2)°, V = 3017(1) $Å^3$, Z = 8, ρ_{calc} = 1.37 g cm^{-3}; absent reflection: $h0l$: ($h \neq 2n$), $0k0$: ($k \neq 2n$). Data collection and reduction were as described earlier (23) with some modifications: the diameter of the incident beam collimator was 1.0 mm; of the 6933 reflections that were collected, 6448 were unique (R_{int} = 0.056); over the course of data collection, the standards increased by 6.8% and a linear correction factor was applied to the data to account for this phenomenon; for Cu Kα radiation μ is 7.7 cm^{-1}, and a correction for secondary extinction was applied (coefficient = 3.3×10^{-6}).

The structures were solved using the methods cited earlier (23). Compound **2′** crystallizes with two molecules in the asymmetric unit, and these are related by a pseudocentre of inversion, with only the orientation of the MeO substituent breaking any true symmetry. The final cycle of full-matrix least squares refinement for **1′** was based on 3286 observed reflections ($I > 0.00\ \sigma(I)$) and 208 variable parameters, and converged (largest parameter shift was 0.00 times its esd) with unweighted (R) and weighted (R_w) agreement factors of 0.072 and 0.106, respectively. For **2′**, there were correspondingly 6299 observed reflections, 416 variable parameters, and agreement factors of 0.101 and 0.170. R is defined as $\Sigma||F_o| - |F_c||/\Sigma|F_o|$, and R_w as $(\Sigma(F_o^2 - F_c^2)^2/\Sigma_w(F_o^2)^2)^{1/2}$. For **1′**, R = 0.039 (R_w = 0.046) for the 2029 reflections with $I \geq 3\sigma(I)$; for **2′**, the corresponding R and R_w values are 0.055 and 0.073, respectively, for 3634 reflections. The standard deviation of an observation of unit weight was 1.15 (for **1′**) and 2.35 (for **2′**). The max and min peaks on the final difference Fourier map corresponded to 0.34 and –0.32 e $Å^{-3}$, respectively, for **1′**, and 0.33 and –0.35 e $Å^{-3}$ for **2′**.

Final atomic coordinates and equivalent isotropic thermal parameters (B_{eq}), bond lengths, bond angles, anisotropic thermal parameters, torsion angles, intermolecular contacts (out to 3.60 Å), and least-square planes are included as supplementary materials.[3]

Impregnation of a model compound into a filter paper sheet

A 5.0 × 6.3 cm Whatman (No. 1) filter paper (~275 mg) was conditioned at 23°C and 50% humidity for 2 days, weighed, and soaked in a 0.10 or 0.06 M compound solution in methyl cellosolve ($MeOCH_2CH_2OH$) or just methyl cellosolve alone for 10 min. The sheet was removed, air-dried for 10 min, and conditioned at 23°C and 50% humidity for 20 h and weighed again. The amount of impregnated model compound was calculated by subtracting the amount of methyl cellosolve incorporated into the sheet (2.4 ± 0.1 mg) from the weight difference of the conditioned sheet before and after impregnation with the model compound. Using 0.10 M solutions, the amounts of model compounds impregnated were 24, 49, and 24 μmol (i.e., 3.9, 15.2, and 4.3 mg) for **1**, **1′**, and **1″**, respectively, and 32, 56, and 31 μmol (i.e., 5.3, 17.5, and 5.5 mg) for **2**, **2′**, and **2″**, respectively. Using a 0.06 M solution, the amount of **1′** impregnated was 26 μmol (i.e., 8.1 mg).

Accelerated fluorescent light-induced yellowing experiments

The accelerated, fluorescent light-induced yellowing experiments were performed in a light-box (LuzChem Research Inc.) equipped with 8 F8T5CW fluorescent lamps (Albrite Lighting Ltd.) which have a max output at ~570 nm and a light intensity of ~1500 foot-candle. The irradiation was performed in the 23°C temperature and 50% humidity room, and the brightness (%ISO) of the sheets monitored in a Technibrite Micro TB-1C instrument. ISO (International Standardization Organization) brightness of a paper is a measurement of the directional reflectance of light at 457 nm of the paper in an Elrepho instrument, calibrated to be 100% for MgO and 0% for a dark black background (24). The higher the %ISO brightness, the whiter (less yellow) the paper.

Acknowledgments

We thank Alexandra Kwong for her assistance with the yellowing experiments and Dr. Cyril Heitner for discussions. We also thank the Natural Sciences and Engineering Research Council of Canada (NSERC) for partial financial support to A.Z. Lu via the Mechanical and Chemimechanical Pulps Network and a research grant.

Electrical conductivity, speeds of sound, and viscosity of aqueous ammonium nitrate solutions

Abdul Wahab and Sekh Mahiuddin

Abstract: Density, electrical conductivity, speeds of sound, and viscosity of aqueous ammonium nitrate solutions were measured as functions of concentration (m, mol kg^{-1}) ($0.1599 \leq m \leq 20.42$) and temperature (T, K) ($273.15 \leq T \leq 323.15$). Experimental values are consistent with the reported data. Variation of isotherms of electrical conductivity, isentropic compressibility, and structural relaxation time with concentration evoke structural information on the ion solvation in aqueous ammonium nitrate solution at different concentration regions. The primary hydration numbers of ammonium nitrate were estimated at a particular concentration at which the isentropic compressibility isotherms converge. The existence of free hydrated ions, resulting from strong ion solvent interactions in dilute to 9.1 mol kg^{-1}, the solvent-separated ion-pairs resulting from the relative competition between the ion–solvent and the ion–ion interactions in 9.1 to 12.0 mol kg^{-1}, and the solvent-shared ion-pairs beyond 12.0 mol kg^{-1} resulting from a decrease in the number of solvent molecules, govern the transport process.

Key words: electrical conductivity, speeds of sound, viscosity, ammonium nitrate, hydration number.

Résumé : On a mesuré les densités, conductivités électriques, vitesses du son et viscosités de solutions aqueuses de nitrate d'ammonium en fonction de la concentration (m, mol kg^{-1}) ($0{,}1599 \leq m \leq 20{,}42$) et de la température ($T$, K) ($273{,}15 \leq T \leq 323{,}15$). Les valeurs expérimentales sont en accord avec les données rapportées dans la littérature. Les variations dans les isothermes de la conductivité électrique, de la compressibilité isentropique et du temps de relaxation structurale en fonction de la concentration fournit des indications structurales sur la solvatation de l'ion en solution aqueuse de nitrate d'ammonium dans les diverses régions de concentration. On a évalué les nombres d'hydratation primaires du nitrate d'ammonium à une concentration donnée, celle à laquelle les isothermes de compressibilité isentropiques convergent. L'existence d'ions hydratés libres observée dans la région de concentration de diluée à 9,1 mol kg^{-1} résulte de fortes interactions ion solvant, celle des paires d'ions séparés par le solvant observée dans la région de concentration allant de 9,1 mol kg^{-1} à 12,0 mol kg^{-1} résulte de la compétition relative entre d'une part l'ion et le solvant et d'autre part les paires d'ions séparés par le solvant et enfin celle des paires d'ions qui se partagent le solvant observées dans la région de concentration allant au-delà de 12,0 mol kg^{-1} résulte d'un nombre trop faible de molécules de solvant pour gouverner le processus de transport.

Mots clés : conductivité électrique, vitesses du son, viscosité, nitrate d'ammonium, nombre d'hydratation.

[Traduit par la Rédaction]

Introduction

The solvation structure of ions in different concentration regions in water and nonaqueous media have been of immense importance to the technologist and theoretician because of the different interactions and equilibria involved. The existence of ions, solvated ions, ion-pairs (solvent-separated, solvent-shared, and contact ion-pairs), and free solvent depends on the concentration region (1).

The reported hydration number of NH_4^+ is varied from 4 to 11 (2). On the other hand, NH_4^+ with same molar mass, equivalent partial molar volume, and tetrahedral structure as that of water fits in the water cage (3). The hydration number of H_3O^+ is reported as 4 (2). Therefore, the primary hydration number of NH_4^+ should be around 4. X-ray (4) and neutron (5) diffractions of aqueous ammonium nitrate have been reported in the concentration region of ~12–18 mol kg^{-1}. X-ray studies showed that NO_3^- is only hydrated, whereas neutron diffraction studies suggested the formation of ion-pairs within the reported concentration region. Recent ab initio simulation (6) of NH_4^+ in water medium predicted that five molecules of water are coordinated to NH_4^+. The simulation studies (6) also reveal that out of five water molecules, four water molecules are directly attached to NH_4^+ through strong hydrogen bonding interactions resulting in rigid structure, whereas the fifth water molecule is mobile and is exchanged with one of the four water molecules.

Among the many approaches (2), the acoustic method (7–9) seems to be an alternative proposition for studying the solvent structure around ions. Earlier we reported (10–12) that if both cation and anion are hydrated a rigid structure is formed and the isentropic compressibility isotherms converge at a particular concentration, which is characteristic of

an electrolyte. On the other hand, the existence and equilibria of hydrated ions and different ion-pairs (solvent-separated ion-pair, solvent-shared ion-pair, and contact ion-pair) in a wide concentration region have an influence on the viscosity and the electrical conductivity. Therefore, in this paper, we report the electrical conductivity, speeds of sound, and viscosity of aqueous ammonium nitrate solutions as functions of concentration and temperature.

Experimental

Ammonium nitrate (>99.5%, Qualigens Fine Chemicals, India) was recrystallized twice from double-distilled water and then kept under vacuum desiccator over P_2O_5. Double-distilled water was used to prepare solutions. All solutions were prepared by mass with ±0.2% uncertainty.

Densities (ρ, kg m^{-3}) of all solutions were measured accurately to ±0.1 kg m^{-3} by using a single-stem graduated pycnometer. The pycnometer was calibrated by using double-distilled water.

Electrical conductivities (κ, S m^{-1}) were measured by employing precision component analyzer 6425 (Wayne Kerr) with an accuracy of ±0.1%. Uncertainty in conductivity was within ±0.4 S m^{-1}. The conductivity cell was calibrated by using 0.1 mol kg^{-1} KCl solution (13). The cell constant was found to be 173 m^{-1} with negligible temperature coefficient.

Viscosities (η, mPa s) were measured with the help of a Schott-Geräte AVS 310 unit equipped with micro-Ubbelohde viscometer. Two viscometers were used depending on the magnitude of the viscosity of solutions. The viscometers were calibrated by using double-distilled water and were found to be 0.009595 and 0.013103 mm^2 s^{-2}. Average of five efflux times was taken to calculate viscosity. The uncertainty in efflux time was ±0.05 s.

Speeds of sound (u, m s^{-1}) in aqueous ammonium nitrate solutions were measured with an accuracy of ±0.1 m s^{-1} by using a variable path-interferometer (multifrequency ultrasonic interferometer, M-83, Mittal Enterprises, New Delhi) at 2 MHz. Details of measurements are given elsewhere (10–12, 14).

All the measurements were made as functions of concentration (m, mol kg^{-1}) ($0.1599 \le m \le 20.42$) and temperature (T, K) ($273.15 \le T \le 323.15$). Thermostat type CT–1520 (Schott-Geräte), RSL 6D (Lauda), or F32 HP (Julabo) was used to maintain the temperature of the solution to ±0.02 K.

Results and discussion

Densities were found to be a linear function of temperature and are given in Table 1. An isotherm of ρ vs. m at 298.15 K, as an example, is illustrated in Fig. 1 along with the reported values (15–18). Experimental density values at 298.15 K were comparable within ±0.4% with the literature values. Values of speeds of sound, electrical conductivity, and viscosity are given in Tables 1S-3S (*Supplementary materials*), respectively.[2]

Isotherms of η vs. m and κ vs. m at three different temperatures are shown in Figs. 2 and 3, respectively. The present viscosities were compared with the reported values (15, 16, 18) at 298.15 K. It was found that the measured viscosities are comparable within ±1% with the reported values (15, 16, 18) up to 6 mol kg^{-1}. Beyond this concentration the measured viscosities are ~4.3% higher than that of Campbell and Kartzmark (16) and ~2.6% than that of Campbell et al. (18). On the other hand, viscosity values of Campbell et al. (18) are ~2.7% higher than that of Campbell and Kartzmark (16).

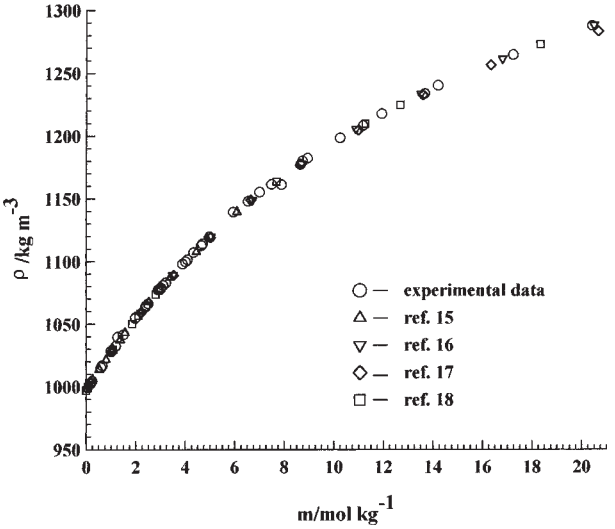
Fig. 1. Variation of density with concentration of aqueous ammonium nitrate solutions at 298.15 K.



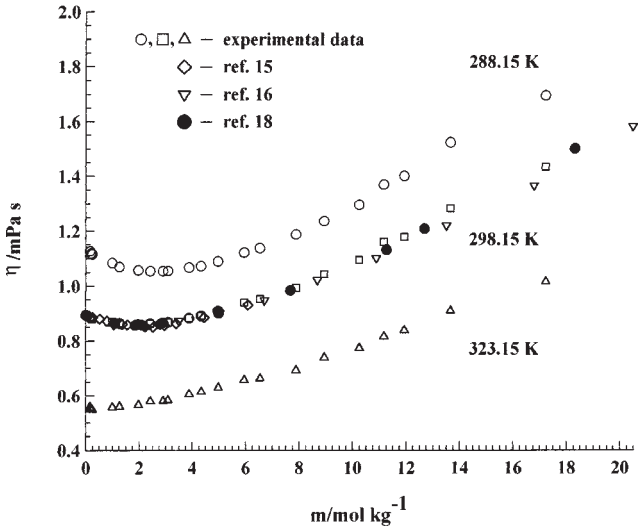


Fig. 2. Plots of viscosity vs. concentration of aqueous ammonium nitrate solutions at three different temperatures.

The deviation in electrical conductivity values between ours and that of Campbell and Kartzmark (16) and Wishaw and Stokes (19) was ~9% in the concentration range of ~2–5 mol kg^{-1} and is gradually reduced to ~1% in the higher concentration range. We could not compare the speeds of sound data because of the lack of reported values.

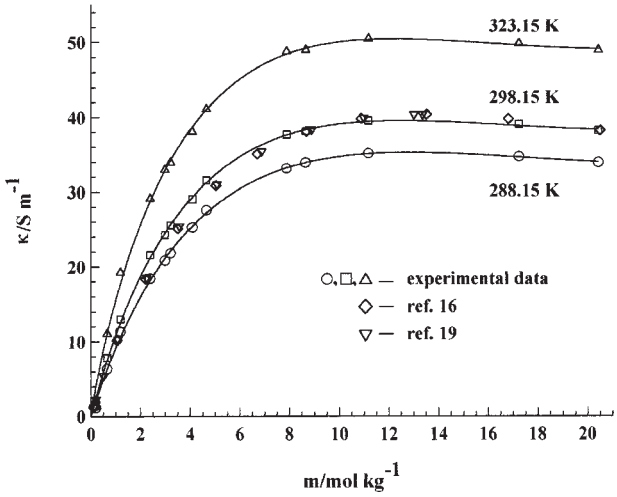
The isentropic compressibilities (κ_s, Pa^{-1}), of aqueous ammonium nitrate solutions were calculated from the following relation:

$$[1] \qquad \kappa_s = 1/u^2\rho$$

where u is the speeds of sound and ρ is the density of the solutions. Isotherms of κ_s vs. m at three temperatures are plotted in Fig. 4. In earlier papers (11, 12), we reported an isothermal equation of the following form:

$$[2] \qquad \kappa_s = a_1 + b_1 m + c_1 m^d$$

Fig. 3. Isotherms of electrical conductivity of aqueous ammonium nitrate solutions at three different temperatures. Symbols are experimental and reported values and solid lines are calculated from eq. [4].



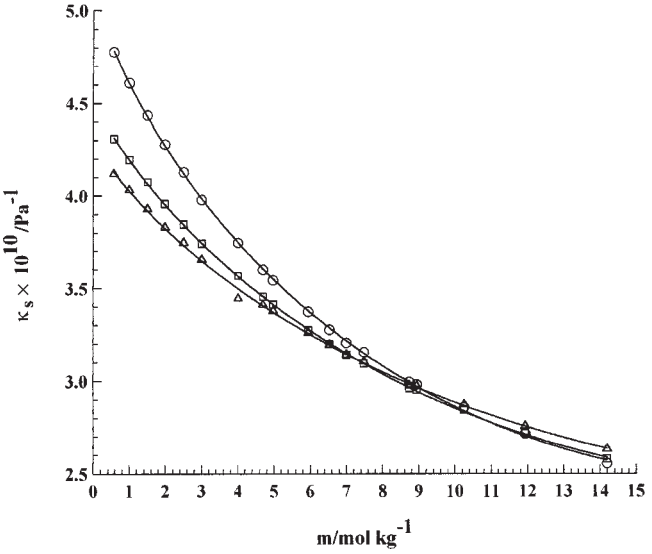


Fig. 4. Plots of isentropic compressibility vs. concentration of aqueous ammonium nitrate solutions at: 273.15 (○), 298.15 (□), and 323.15 (Δ) K.

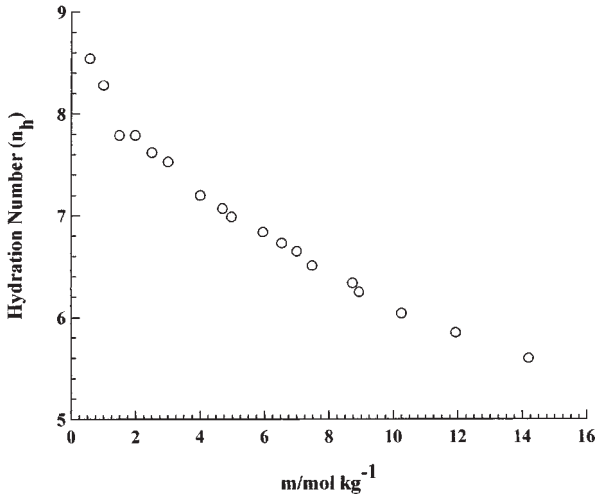
to fit the isentropic compressibilities. In eq. [2], a_1, b_1, and c_1 are the temperature-dependent parameters, d is the adjustable parameter, and m is the concentration in mol kg^{-1}. The best-fit values of the parameters in eq. [2] are collected in Table 2. Surprisingly, as it is apparent from Table 2 and Fig. 4, eq. [2] can reproduce the isentropic compressibilities within ±0.7%, except for 4.009 mol kg^{-1} at 323.15 K, where the reproducibility was ±1.6%.



Considering the temperature range of our study, we consider qualitatively that the isentropic compressibility isotherms converge at 9.1 mol kg^{-1} (Fig. 4). At this concentration all the available water molecules are involved in the primary hydration shell of ammonium nitrate with $\kappa_{s,h}$ = 2.960 × 10^{-10} Pa^{-1}, $\kappa_{s,h}$ is the isentropic compressibility of the primary hydration shell of the solute at 9.1 mol kg^{-1}. Fig. 5. Variation of hydration number of aqueous ammonium nitrate solutions at 298.15 K.

$\kappa_{s,h}$ of ammonium nitrate is lower than that of sodium nitrate ($\kappa_{s,h} = 3.04 \times 10^{-10}$ Pa^{-1}) (20) and lithium nitrate ($\kappa_{s,h} = 3.34 \times 10^{-10}$ Pa^{-1}) (11) and much lower than that of free water ($\kappa_s = 4.477 \times 10^{-10}$ Pa^{-1}). These results indicate stronger ion–solvent interactions in ammonium nitrate solutions at 9.1 mol kg^{-1} than in the above cited nitrate salt solutions.

The hydration numbers (n_h) of ammonium nitrate were calculated from the reported relation (10, 11)

$$[3] \qquad n_h = [\kappa_{s,\phi} - \kappa_{s,h}V_\phi]/[V_1(\kappa_{s,h} - \kappa_{s,1})]$$

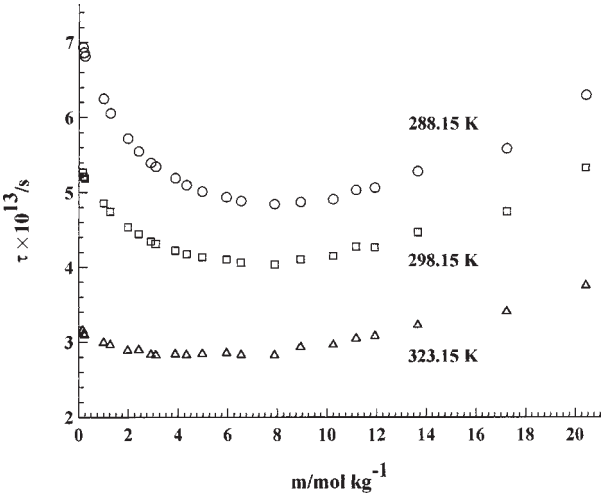
In eq. [3], $\kappa_{s,\phi}$ is the conventional apparent molal isentropic compressibility (21), V_ϕ is the apparent molal volume, V_1 is the molar volume of the solvent, and $\kappa_{s,1}$ is the isentropic compressibility of the solvent. The apparent molal volume at infinite dilution was found to be 4.72×10^{-6} m^3 mol^{-1} and is in good agreement with the reported values (22) at 298.15 K, which suggests the reliability of the experimental density values.

The calculated hydration numbers from eq. [3] are depicted in Fig. 5. The primary hydration number of ammonium nitrate at 9.1 mol kg^{-1} was found to be 6.2 and is in good agreement with the water molecules per mol of solute (6.1) at that concentration. Solubility data (23) suggested a structural transition at around 42% (~9.05 mol kg^{-1}) in aqueous ammonium nitrate solution. On the other hand, the phase diagram constructed based on the available data in the literature (24–26) showed that the eutectic point appears at 0.145 mol fraction (~9.4 mol kg^{-1}). These concentrations (~9.05 and 9.4 mol kg^{-1}) are in good agreement with the concentration (~9.1 mol kg^{-1}) at which the isentropic compressibility isotherms converge (Fig. 4).

To distribute the total primary hydration number (6.2) of ammonium nitrate into its ionic hydration number, we require the primary hydration number of either NH_4^+ or NO_3^- as a reference. For aqueous ammonium nitrate, contradictory primary hydration numbers of NH_4^+ have been reported in the literature (2, 4, 5). It has also been reported that NH_4^+ and H_2O have same molar mass and equivalent molar volumes and both have a tetrahedral structure (3). Therefore, NH_4^+ can fit in the water structure. The primary hydration number for NH_4^+ may be equivalent to 4, which is the same as that for H_3O^+ (2).

X-ray (4) and neutron (5) diffraction have been employed to study the hydration of NH_4^+ and NO_3^- in 8.0 mol L^{-1} (~13.5 mol kg^{-1}) and 12.0 and 15.0 mol kg^{-1} ammonium nitrate solutions, respectively. X-ray diffraction studies revealed the hydration of NO_3^-, whereas neutron diffraction studies showed the ion-pair formation and the water molecules are weakly hydrogen bonded to both NH_4^+ and NO_3^-. From Fig. 4, it may be noted that at 9.1 mol kg^{-1} the primary hydration shell of ammonium nitrate is just saturated and beyond this concentration overlap of cation and anion occurs leading to the formation of ion-pairs due the strong and predominant ion–ion interactions. Recent ab initio simulation (6) of ammonium ion in water showed that there are five water molecules coordinated to NH_4^+, with four of them are directly hydrogen bonded to each proton of NH_4^+ in the tetrahedral cage. The remaining water molecule is mobile and is exchangeable with one of the four water molecules directly attached to NH_4^+.

The variation of electrical conductivity isotherms of aqueous ammonium nitrate solutions as depicted in Fig. 3 show that the conductivity maximum (κ_{max}) occurs at ~12 mol kg^{-1}. To quantify the concentration at which κ_{max} appears, the Casteel–Amis equation (27):



$$[4] \qquad \kappa = \kappa_{max}\ (m/\mu)^a\ \exp\ [b(m - \mu)^2\text{-}a(m - \mu)/\mu]$$

323.15	50.40	0.8751	0.1673	12.12	0.76

Fig. 6. Variation of structural relaxation time with concentration of aqueous ammonium nitrate solutions at three different

has been used to fit the conductivity data, and the least-squares fitted values of the parameters in eq. [4] are collected in Table 3. In eq. [4], μ is the concentration (mol kg^{-1}) at which conductivity becomes maximum (κ_{max}), m is the concentration (mol kg^{-1}), and a and b are the empirical parameters. Equation [4] can reproduce the conductivity data within ±3% except in the low concentration region. From Table 3, it is apparent that the maximum conductivity appears at 12.43 ± 0.34 mol kg^{-1}, beyond this concentration conductivity values decrease by 3.0–3.8% within the temperature range of the present study.

From Figs. 3 and 4 it may be argued that up to 9.1 mol kg^{-1} free hydrated NH_4^+ and NO_3^- exist, and in the concentration range 9.1–12.0 mol kg^{-1} solvent-separated ion-pairs are formed. Beyond 12.0 mol kg^{-1}, transition to the solvent-shared ion-pairs occurs as a result of a decrease in the number of available water molecules in comparison to hydration number (Fig. 5). To support our views we have plotted shear relaxation time ($\tau = 4\eta\kappa_s/3$) vs. m (mol kg^{-1}) at three different temperatures (Fig. 6). It is apparent that τ decreases up to ~7–9 mol kg^{-1} then increases with concentration. The shallow minimum at m_{min} in τ vs. m isotherms is more pronounced at low temperatures, because at low temperatures the hydrogen bond of water is reinforced significantly (28), which is further broken by NH_4^+. The structure breaking effect of NH_4^+ causes the τ values to decrease up to ~7–9 mol kg^{-1}. Beyond ~7–9 mol kg^{-1}, the NH_4^+ and NO_3^- are set for ion association due to a decrease in the number of available water molecules around them resulting in the increase in τ values with concentration. Small deviation in τ vs. m isotherms at ~7–9 mol kg^{-1} at higher temperatures may be attributed to breaking–loosening of hydrogen bonds in bulk water and water in the secondary hydration sphere of ions due to the thermal vibrations.

In the preceding section we obtained 6.2 as the total primary hydration number of ammonium nitrate. Considering the primary hydration number of NH_4^+ as 4.0 (6), the primary hydration number of NO_3^- is estimated to be 2.2. The estimated primary hydration number of NO_3^- in aqueous ammonium nitrate is less than 3–6 water molecules around NO_3^- (2). To fulfil the minimum primary hydration number of NO_3^- in aqueous ammonium nitrate solution, NO_3^- may share water molecules involved in the primary hydration sphere of NH_4^+ leading to the formation of solvent-separated ion-pairs.

Effect of kinetic synergist on transport of copper(II) through a liquid membrane containing P_{507} in kerosene

Dingsheng He, Ming Ma, Hui Wang, and Pandeng Zhou

Abstract: A new kinetic synergism system for copper(II) transport through a bulk liquid membrane containing mono(2-ethyhexyl)-2-ethyhexyl phosphate and Manoxol OT (OT) was examined. The influence of stripping agent, anion, pH in feed phase, and carrier concentration were investigated. The kinetics of Cu(II) transport could be analyzed in the formalism of two consecutive irreversible first-order reactions, considering both extraction and stripping. The pseudo-first-order apparent rate constants of interfacial reactions in membrane transport are determined by altering the temperature. The activation energy values are 38.1 kJ mol^{-1} for extraction and 32.8 kJ mol^{-1} for stripping. The experiments demonstrated that Manoxol OT is a good kinetic synergist for Cu(II) transport through liquid membranes in this study. The kinetic synergism of OT for extraction of Cu^{2+} ions is analyzed.

Key words: copper ions, kinetic synergist, liquid membrane.

Résumé : On a étudié un nouveau système de synergie cinétique pour le transport du cuivre(II) à travers une membrane formée d'une masse liquide contenant du phosphate de mono(2-éthylhexyle)-2-éthylhexyle ainsi que du Manoxol OT (OT). On a examiné l'influence de l'agent de redissolution, le pH de la phase insérée et la concentration du porteur. On peut analyser la cinétique du transport du Cu(II) dans un formalisme de deux réactions irréversibles et consécutives du premier ordre appliquées à l'extraction et à la redissolution. Les constantes apparentes de pseudo-premier ordre des réactions interfaciales dans le transport à travers la membrane ont été déterminées en modifiant la température. Les valeurs de l'énergie d'activation sont de 38,1 kJ mol^{-1} pour l'extraction et de 32,8 kJ mol^{-1} pour la redissolution. Les expériences réalisées au cours de cette étude ont démontré que le Manoxol OT est un bon agent de synergie cinétique pour le transport du Cu(II) à travers des membranes liquides. On a analysé la synergie cinétique du OT pour l'extraction des ions Cu^{2+}.

Mots clés : ions cuivres, synergie cinétique, membrane liquide.

[Traduit par la Rédaction]

Introduction

In metal recovery, liquid membranes play an attractive role in separation science (1, 2). This is shown in references to the broad applications for copper recovery by liquid membranes (3). The separating power of liquid membranes is directly related to the efficiency of the carrier molecules present in the membrane. Mono(2-ethyhexyl)-2-ethyhexyl phosphate (HEH(EHP), P_{507}) is an acidic extractant most in use. Although P_{507} has been used in extraction separation of Co(II) and Ni(II) ions, little work has been reported on its use as a carrier in a liquid membrane for transport of Cu(II). This aspect assumes particular importance because of the problem of separation of Cu(II) from other valuable metal ions such as Co(II), Ni(II), and Mn(II). In extraction of Cu(II) with liquid membrane containing P_{507} as the carrier, the rate of mass transfer is very slow. To promote the rate of mass transfer and to devise an efficient liquid membrane system for the extraction of Cu(II) with P_{507}, a kinetic synergist (Manoxol OT, $C_{20}H_{37}O_7SNa$, abbreviation OT or NaA) is added to the membrane. Manoxol OT is a surfactant and used as a kinetic synergist for the extraction of Cu(II) with oxime (4), but in liquid membranes, where extraction and stripping can take place simultaneously, the kinetic synergism system composed of OT and acidic phosphoric extractor has scarcely been investigated. In this paper, the permeation rate of Cu(II) ions through a liquid membrane containing P_{507} and OT in kerosene has been studied as a function of different transport conditions. The pseudo-first-order apparent rate constants were determined between the membrane and feed solution interface or stripping solution interface. When the temperature was altered, the kinetics of coupled transport of Cu(II) ions through a liquid membrane containing P_{507} and OT is analyzed, considering both extraction and stripping behavior. To date, the effect of the kinetic synergist (OT) on transport of Cu(II) ions through liquid membrane containing an acidic extractor as carrier is little reported in the literature.

Fig. 1. Schematic description of counter-transport.

Theoretical section

Copper(II) sulfate pentahydrate ($CuSO_4 \cdot 5H_2O$) was used in this study. The extraction reaction on feed side-membrane interface is (5):

[1] $$Cu^{2+}_{aq} + 2H_2R_{2org} = CuR_2 \cdot 2HR_{org} + 2H^+_{aq}$$

The stripping reaction on the stripping side membrane interface is:

[2] $$CuR_2 \cdot 2HR_{org} + 2H^+_{aq} = Cu^{2+}_{aq} + 2H_2R_{2org}$$

where H_2R_2 is dimerized from HEH(EHP) (an acidic extractant). According to ref. 6, the mechanism of coupled transport of Cu(II) ions through a liquid membrane is a counter-transport. The schematic description is summarized in Fig. 1.

In the experiments, the variation of Cu(II) concentration with time was directly measured in both the donor (c_d, M) and the acceptor (c_a, M). The corresponding change in the membrane (c_m, M) was established from the material balance. For practical reasons, mol fractions are used

[3] $$R_d = \frac{n_d}{n_{do}} \quad R_m = \frac{n_m}{n_{do}} \quad R_a = \frac{n_a}{n_{do}}$$

where n_{do} is the initial mol of Cu(II) ions in the donor phase at $t = 0$ and n_d, n_m, and n_a are the mol of Cu(II) ions in the donor, membrane, and acceptor phases (at $t = t$), respectively. Obviously, we have $R_d + R_m + R_a = 1$. Our experimental results (as shown in the later sections) reveal that R_d decreases monoexponentially with time, and R_a follows a monotonically increasing sigmoid-type curve, while the time evolution of R_m presents a maximum. These results suggest that the transport of Cu(II) ions obeys the kinetic laws of two consecutive irreversible first-order reactions according to the kinetic scheme (7, 8):

[4] $$d \xrightarrow{k_1} m \xrightarrow{k_2} a$$

where d, m, and a stand for Cu(II) ions in the donor, membrane, and acceptor phases, respectively. It was found that the presence of the important proton gradient drives the whole transport process to completion without any back leakage of Cu(II) ions. Therefore, the above kinetic scheme may be described by the following eqs. (7):

[5] $$\frac{dR_d}{dt} = -k_1 R_d = J_d$$

[6] $$\frac{dR_m}{dt} = k_1 R_d - k_2 R_m$$

[7] $$\frac{dR_a}{dt} = k_2 R_m = J_a$$

where J stands for flux and $k_1$and k_2 are the pseudo-first-order apparent rate constants of the interfacial rxns. [1] and [2].

When $k_1 \neq k_2$, integrating the above differential equations gives

[8] $$R_d = \exp(-k_1 t)$$

[9] $$R_m = \frac{k_1}{k_2 - k_1}[\exp(-k_1 t) - \exp(-k_2 t)]$$

[10] $$R_a = 1 - \frac{1}{k_2 - k_1}[k_2 \exp(-k_1 t) - k_1 \exp(-k_2 t)]$$

It can be seen that R_d vs. t yields a decreasing monoexponential curve, whereas the time variation of both R_m and R_a is biexponential. The actual numerical analysis was carried out by nonlinear curve fitting.

According to eq. [9], R_m increases at first, then decreases with time, i.e., it has a max when $dR_m/dt = 0$.

[11] $$t_{max} = \frac{\ln (k_1/k_2)}{k_1 - k_2}$$

[12] $$R_m^{max} = \left(\frac{k_1}{k_2}\right)^{-k_2/(k_1 - k_2)}$$

Experimental

Materials

All the reagents, including $CuSO_4 \cdot 5H_2O$, H_2SO_4, HCl, $Na_2SO_4 \cdot 10H_2O$, used in the present work were of analytical grade. They were supplied by Hunan Chemical Reagent Corporation. P_{507} is a commercial extractant and is product of Shanghai Organic Chemistry Institute. OT is L.R. grade.

Stock solution of Cu(II) was prepared by dissolving $CuSO_4 \cdot 5H_2O$ in deionized water and was analyzed by $Na_2S_2O_3$ titration using starch as the indicator. The Cu(II) feed solution was prepared by taking a known amount of the Cu(II) stock solution and diluting it with water to a given extent after adding a calculated amount of the desired CH_3COOH and CH_3COONa.

The stripping solution was prepared by taking the required amount of HCl and diluting it with deionized water to a known volume.

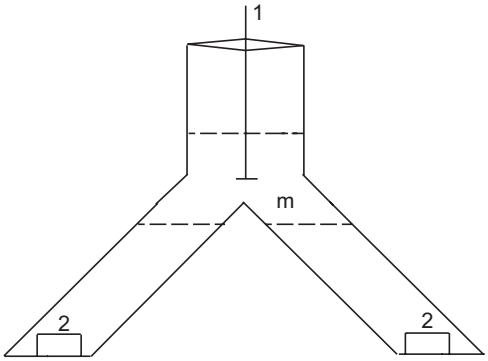

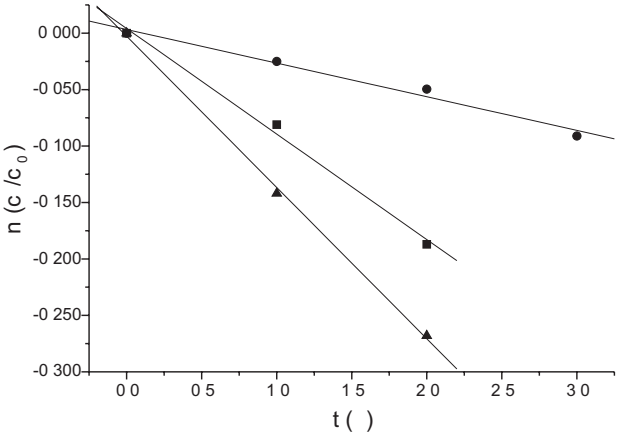

Fig. 3. Plot of ln of Cu(II) ions in feed phase through SLM vs. time. (■) 9.4×10^{-6} M OT; (●) 0.08 M P_{507}; (▲) 0.08 M P_{507} + 9.4×10^{-6} M OT (stripping phase = 2 M HCl).

HEH(EHP) solution was prepared by taking the calculated amount of extractant and diluting it with kerosene. Distilled kerosene (185–225°C) was obtained by washing commercial kerosene with concentrated sulfuric acid and then distilling it.

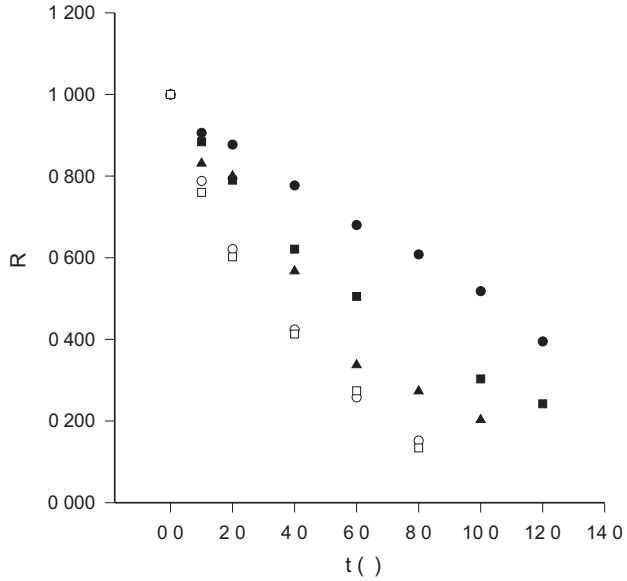
A microporous polypropylene membrane was used as a solid support. The film was obtained from the Hunan Plastic Research Institute. It was a 0.02 mm thick film with a nominal porosity of 51% and an effective pore size of 0.03 μm.

All the experiments were carried out using the deionized water saturated with kerosene.

Transport experiments of bulk liquid membrane (BLM)

The transport experiments were carried out using a thermostat (T = 30 ± 0.1°C) as presented in Fig. 2. The aqueous feed solution (40.00 mL) consisted of 1.57×10^{-3} M Cu^{2+}, pH = 4.35 (CH_3COONa–CH_3COOH), I = 0.5. The feed solution was put in the left side (*b*) of the vessel and stirred at 650 rpm. The stripping solution, which consisted of 2 M HCl (40.00 mL), was located in the right side (*a*) of the vessel and was stirred at 650 rpm. The membrane phase (30.00 mL) containing HEH(EHP) in kerosene was added to the top of the water solution and stirred at 650 rpm. The interface surfaces were as follows: $S_{feed\text{-}membrane} = S_{membrane\text{-}stripping\ phase} = 5.90\ cm^2$.

Fig. 4. Plot of R_d vs. time at different carrier concentrations: (●) 0.04; (■) 0.08; (▲) 0.12; (○) 0.16; (□) 0.20 M. Membrane = 7.5×10^{-4} M OT + different carrier concentration, stripping phase = 2 M HCl, feed phase = 1.57×10^{-3} M Cu^{2+}, pH = 4.35 (CH_3COOH–CH_3COONa), I = 0.5, T = 32 ± 0.1°C.



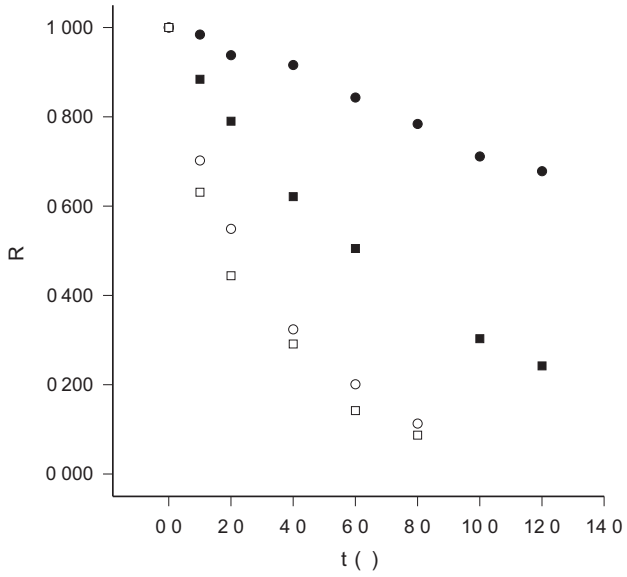


Fig. 5. Plot of R_d vs. time at different pH in feed solution. Membrane = 0.08 M P_{507} + 7.5×10^{-4} M OT, stripping phase = 2 M HCl, feed phase = 1.57×10^{-3} M Cu^{2+}, I = 0.5, T = 32 ± 0.1°C. pH (CH_3COOH–CH_3COONa) in feed phase (●) 3.80; (■) 4.35; (○) 4.81; (□) 5.47.

Transport experiments of supported liquid membrane (SLM)

The experiments were performed at 30 ± 0.1°C with a simple diffusion cell. The diffusion cell consisted of two Perspex half cells. The two half cells were separated by a membrane with an area of 18 cm^2. The membrane was impregnated with the carrier dissolved in kerosene and clamped between the two half cells. The aqueous feed solu-

Table 2. Effect of P_{507} concentration on interfacial tension between feed phase and membrane or stripping phase and membrane

	P_{507} (M)				
	0.04	0.08	0.12	0.16	0.20
$\sigma_{\text{feed-membrane}}$ (mN m^{-1})	15.10	13.10	11.84	11.18	10.57
$\sigma_{\text{stripping-membrane}}$ (mN m^{-1})	17.64	16.63	16.22	15.40	15.70

Note: Membrane at different P_{507} concentration in kerosene, feed phase = 1.57 × 10^{-3} M Cu^{2+}, pH = 4.35 (CH_3COOH–CH_3COONa), I = 0.5, stripping phase = 2 M HCl.

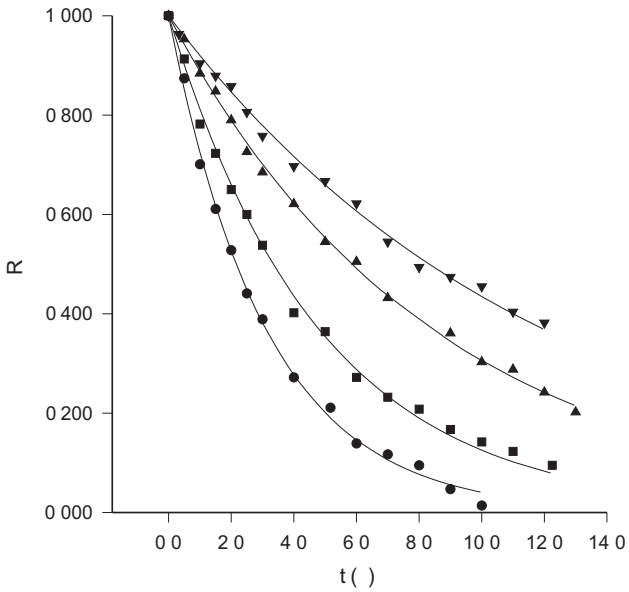

Fig. 6. Time dependence of R_d in feed phase, R_m in membrane phase, and R_a in stripping phase. Membrane = 0.08 M P_{507} + 7.5 × 10^{-4} M OT–kerosene, T = 32°C. Theoretical curves calculated from eqs. [8]–[10]: (●) R_d; (▲) R_m; (■) R_a.

tion (140 mL) consisted of 1.57 × 10^{-3} M Cu^{2+}, pH = 4.35. The stripping solution (140 mL) consisted of 2 M HCl. The stirring rates are 650 rpm in donor and acceptor phases.

In transport experiments, the samples were taken out from the feed solution and stripping solution at scheduled time intervals and analyzed for copper content using spectrophotometry. The experimental results reported are the arithmetic mean of two independent experiments. Some experimental results are given by doing a repeated number of experiments. The reproducibility is very good. The fluxes obtained were reproducible within ca. ±10%.

Fig. 7. Time evolution of R_d during coupled transport. Membrane = 0.08 M P_{507} + 7.5 × 10^{-4} M OT–kerosene. Theoretical curves calculated from eq. [8]: (▼) T = 22; (▲) T = 32; (■) T = 41; (●) T = 50°C.

Determination of interfacial tension

Interfacial tension was measured by the drop volume method (9). All measurements were carried out in a water bath at 30 ± 0.1°C. The instrument for determination of interfacial tension was first corrected using the known interfacial tension of a benzene–water system. A good agreement between experiments and literatures was shown.

Results and discussion

Effect of OT on extraction of Cu(II)

Extraction experiments

To witness kinetic synergism of OT for extraction of Cu(II) ions with P_{507}, solvent extraction experiments were devised. The results are shown in Table 1. The experimental data in Table 1 reveal that the extraction equilibrium time is 1 min when trace OT was added to the organic phase containing P_{507}, while it was 5 min when the organic phase merely contained P_{507}. This indicates that trace OT can accelerate the extraction of Cu(II) ions when it is added to the organic phase only containing P_{507}. Because there is a close fraction extracted in the presence and absence of OT, Table 1 also shows that OT is a kinetic synergist.

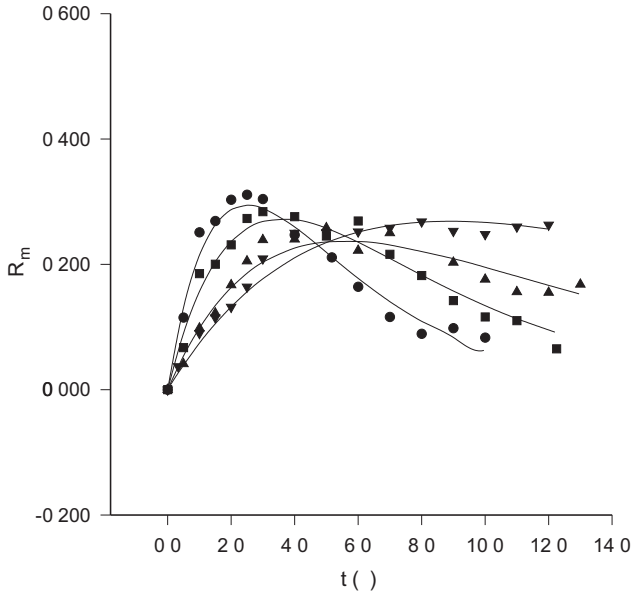
Fig. 8. Time evolution of R_m during coupled transport. Membrane = 0.08 M P_{507} + 7.5×10^{-4} M OT–kerosene. Theoretical curves calculated from eq. [9]: (▼) T = 22; (▲) T = 32; (■) T = 41; (●) T = 50°C.



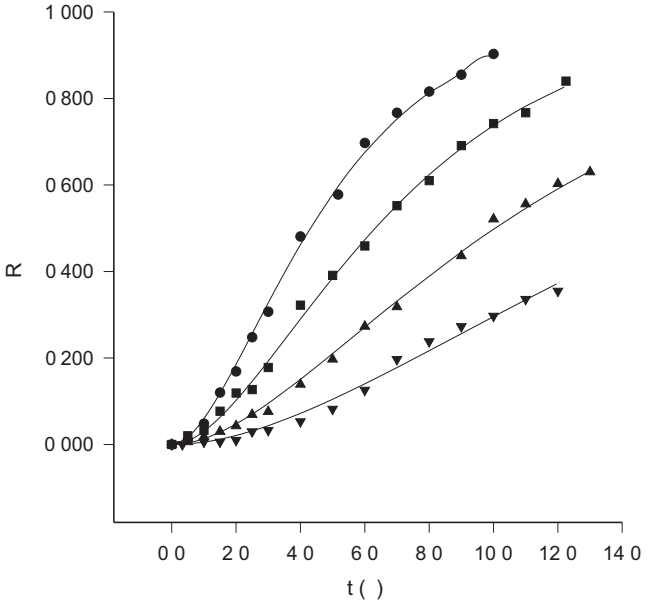


Fig. 9. Time evolution of R_a during coupled transport. Membrane = 0.08 M P_{507} + 7.5×10^{-4} M OT–kerosene. Theoretical curves calculated from eq. [10]: (▼) T = 22; (▲) T = 32; (■) T = 41; (●) T = 50°C.

Experiments of SLM

Figure 3 shows that Manoxol OT can raise the membrane entrance flux. The experiments of SLM and extraction verify that OT is a kinetic synergist for extraction of Cu(II) in the study.

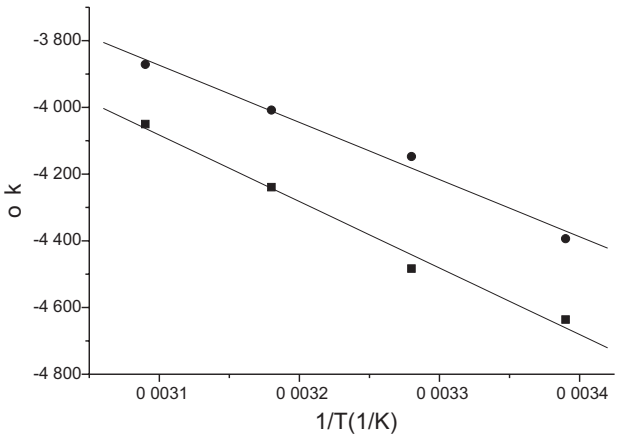
Experiments of bulk liquid membrane

Effect of stripping agent on transport of Cu(II)

When the feed solution and membrane were as above and the stripping phase contained either 2 M HCl, 2 M HNO_3, and 1 M H_2SO_4, the values of R_d are 0.386, 0.512, and 0.434, respectively, after transport of 8 h. Consequently, HCl is used as the stripping agent in later experiments.

Effect of anion in feed on transport of Cu(II)

To compare the relative effectiveness of the various anions in promoting Cu(II) ion transport, experiments on the effect of the anion on transport of Cu(II) ions through liquid membranes were devised. When the composition of the membrane and stripping phase was as above and the feed solution contained either 0.5 M Na_2SO_4 and 0.5 M CH_3COONa, the values of R_d are 0.551 and 0.386, respectively, after transport of 8 h. These experiments indicate that the transport of Cu(II) ions is promoted by CH_3COO^- in the feed solution.



Effect of carrier concentration

The transport experiments were accomplished at five different carrier concentrations: 0.04, 0.08, 0.12, 0.16, and 0.20 M. It is quite clear from Fig. 4 that the flux of Cu(II) increases with an increase in the concentration up to 0.16 M carrier in the membrane, and beyond 0.16 M carrier, the flux has no distinct increase up to 0.2 M carrier in membrane.

In a lower carrier concentration, the interface between the feed phase and membrane is not saturated by the carrier. Therefore, the flux increases with an increase in the carrier concentration. Table 2 indicates the variation of interfacial tension with carrier concentration in the membrane. The experimental result indicates that the carrier molecule has a weak surface activity and that the adsorption of carrier molecules at the interface between the feed solution and the membrane or stripping solution and membrane increases with an increase in carrier concentration. The conclusion explains the fact that the fluxes of the Cu(II) ions increase with an increase in carrier concentration.

Fig. 10. Arrhenius plot of log k (k, s^{-1}) vs. $1/T$ (T, K): (■) log k_1 ~ $1/T$; (●) log k_2 ~ $1/T$.

In addition, a blank experiment was performed in which the membrane contained no carrier. No detectable movement of the Cu(II) ions through the liquid membrane was found in the blank experiment.

Effect of pH in the aqueous feed solution

The effect of pH in the feed solution on the transport of Cu(II) ions was investigated. The experiments were accomplished at four different pH values, 3.80, 4.35, 4.81, and 5.47. It is shown in Fig. 5 that the flux of Cu(II) ions increases with an increase in values of pH of the feed solution. This reveals the importance of protons in the feed phase for coupled transport of Cu(II) ions. According to the principle of shift of chemical equilibrium, if the amounts of protons in the feed phase decrease, rxn. [1] will shift to the right. The variation of fluxes with pH in the feed solution is therefore explained.

Effect of temperature on transport of Cu(II) ions

The effect of temperature on the transport of Cu(II) ions across the bulk liquid membrane was examined at 295, 305, 314, and 323 K. The experimental results are collected in Table 3 and Figs. 6–9. It is quite obvious that k_{1d} and k_{2a} increase with an increase in the temperature. In all cases, $k_{1d} < k_{2a}$ at every temperature. An Arrhenius-type plot is followed perfectly in Fig. 10. The activation energy values are 38.1 kJ mol^{-1} for extraction and 32.8 kJ mol^{-1} for stripping.

Figures 6–9 indicate the time evolution of the concentration of Cu(II) transported in the feed, membrane and stripping phase, respectively.

A good agreement between the theoretical curves and the experimental points is shown in Figs. 6–9. The experimental results in Table 2 indicate that the carrier molecules have weak surface activity and can be adsorbed at the interface. This is beneficial to the extraction reaction at the feed-membrane interface. The results suggest that the Cu(II) ions transport could be described by the kinetic laws of two consecutive irreversible first-order reactions disregarding diffusion processes (as shown in eq. [4]).

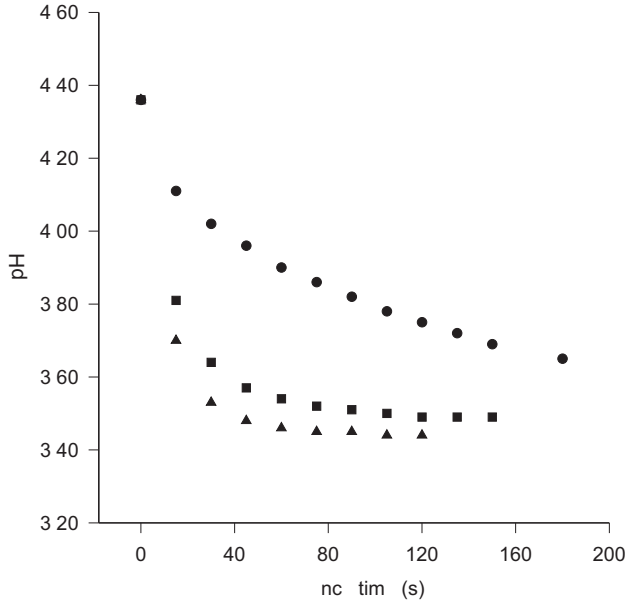
Analysis of kinetic synergic mechanism

OT is an ionic surfactant. It is absorbed at the interface between kerosene and the feed phase when OT is dissolved in kerosene. The ionic reaction between OT and Cu^{2+} in the feed solution is faster than the complex reaction between P_{507} and Cu^{2+} ions. According to ref. 10, Cu^{2+} ions in the feed solution can preferentially react with OT at the interface in the following manner:

[13] $Cu^{2+}_{aq} + 2HA \text{ (or } NaA)_{interface} \rightarrow CuA_{2\ intrface} + 2H^+ \text{ (or } Na^+)_{aq}$

HA is an acid of OT. Because the ionic associated substance, CuA_2, is not as stable as a P_{507}–Cu^{2+}coordination compound, the exchange reaction between CuA_2 and P_{507} can take place at the interface.

Fig. 11. Plot of pH vs. equilibrium time of releasing H^+ in extraction reaction: (●) curve (*a*), 1.6 mL 0.1 M P_{507}–kerosene, feed phase = 35 mL 1.57×10^{-3} M Cu^{2+}, pH = 4.35 (no CH_3COOH–CH_3COONa); (■) curve (*b*), 1.6 mL (0.1 M P_{507} + 2.3×10^{-5} M OT (HA)), feed phase is the same as curve (*a*); (▲) curve (*c*), 1.6 mL (0.1 M P_{507} + 4.6×10^{-5} M CuA_2), feed phase is the same as curve (*a*).



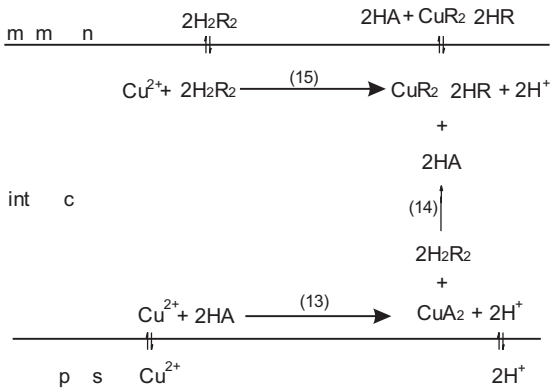


Fig. 12. Schematic description of extraction of Cu^{2+} ions in presence of OT.

© 2001 NRC Canada

[14] $CuA_{2interface} + 2H_2R_{2interface} = CuR_2 \cdot 2HR_{interface} + 2HA_{interface}$

The total reaction for rxns. [13] and [14] is as follows:

[15] $Cu^{2+}_{aq} + 2H_2R_{2org} \rightarrow CuR_2 \cdot 2HR_{org} + 2H^{+}_{aq}$

Reaction [14] is a key reaction for understanding the kinetic synergism of OT for rxn. [15]. To verify that rxn. [14] is faster than rxn. [15], extraction experiments were devised. First, according to eq. [15], a feed solution of Cu(II) ions and 0.1 M P_{507}–kerosene was mixed and shaken. The pH in the feed solution was determined at different times with a pH meter. The time of releasing H^+ ions for eq. [15] was ascertained. If rxn. [15] is in the equilibrium, the pH value in feed phase does not change. Then, the equilibrium time is given. If the equilibrium time of releasing H^+ ions is longer, eq. [15] takes place at a slower rate. Second, the trace copper salt (CuA_2) for OT was added in 0.1 M P_{507}–kerosene. According to eq. [14], the extraction experiment is repeated with the same feed solution of Cu(II) ions. The equilibrium time of releasing H^+ ions for eq. [14] is also determined. By comparison with the equilibrium times of releasing H^+ ions for eqs. [14] and [15], we know which reaction of eqs. [14] and [15] is faster.

Figure 11 indicates that the equilibrium times are 135, 90 and 60 s for curves (*a*), (*b*), and (*c*), respectively. The experimental result verifies that rxn. [14] is faster than rxn. [15] and that OT can accelerate the extraction of Cu^{2+} ions. The kinetic synergism of OT for extraction of Cu^{2+} ions is achieved through rxns. [13] and [14]. The schematic description of the extraction is shown in Fig. 12.

Conclusion

Cu(II) ions can be effectively transported through a liquid membrane containing P_{507} and OT in kerosene. The experiments confirmed that OT is a good kinetic synergist for transport of Cu(II) ions when it is added in liquid membranes containing P_{507} in kerosene. The pseudo-first-order apparent rate constants of the interfacial reactions of extraction and stripping are determined on the basis of a scheme implying two consecutive irreversible first-order reactions.

One-pot sol-gel synthesis of sulfated ZrO_2–SiO_2 catalysts for alcohol dehydration

Quan Zhuang and Jack M. Miller

Abstract: Sulfated ZrO_2–SiO_2 catalysts were synthesized by one-pot sol-gel method using ammonium sulfate, zirconium propoxide, and tetraethyl orthosilicate as precursors. The catalysts were characterized by N_2 adsorption and DRIFTS. On calcining the gel at elevated temperature, the ammonium sulfate decomposed, giving a sulfated zirconia–silica catalyst. By adding ammonium sulfate to the sol-gel synthesis system, the surface area, pore size, and pore volume of the resultant catalyst were increased. The one-pot sol-gel synthesized catalyst with an optimum loading of SO_4^{2-} 14 mol% showed significantly higher catalytic activity, with a selectivity of 100%, for isopropanol dehydration when compared to the impregnated catalyst. The one-pot sol-gel synthesis method is an effective way to prepare sulfated zirconia catalyst.

Key words: sulfated zirconia, sol-gel synthesis, acid catalyst, alcohol dehydration, N_2 adsorption, DRIFT.

Résumé : On a synthétisé des catalyseurs de ZrO_2–SiO_2 sulfatés par une méthode monotope sol-gel utilisant du sulfate d'ammonium, du propylate de zirconium et de l'orthosilicate de tétraéthyle comme précurseurs. On a caractérisé les catalyseurs par adsorption de N_2 et DRIFTS. Par calcination du gel à température élevée, il y a décomposition du sulfate d'ammonium qui conduit au catalyseur de zircone–silice sulfaté. L'addition de sulfate d'ammonium au système de synthèse sol-gel, il y a augmentation de l'aire de la surface, de la taille des pores et du volume des pores du catalyseur qui en résulte. Pour la réaction de déshydratation de l'isopropanol, l'activité catalytique du catalyseur du catalyseur obtenu par synthèse monotope sol-gel, avec un contenu optimal de 14 mol% de SO_4^{2-}, est beaucoup plus élevée que celle du catalyseur imprégné et sa sélectivité est de 100%. La méthode de synthèse monotope sol-gel est une voie efficace pour préparer un catalyseur de zircone sulfatée.

Mots clés : zircone sulfatée, synthèse sol-gel, catalyseur acide, déshydratation d'alcools, adsorption de N_2, DRIFTS.

[Traduit par la Rédaction]

Introduction

Sulfated zirconia is an important catalyst for fuel and energy industry because of its high activity for the isomerization of light hydrocarbons at lower temperature (1). Cosmo Oil of Japan and UOP have jointly commercialized an industrial production process for light naphtha isomerization by use of a proprietary sulfated zirconia catalyst.[1] It has been reported that after sulfation, the zirconia surface becomes strongly acidic (2), or even superacidic (3), because it may show a Hammett function value ($-H_0$) of larger than 12. Usually zirconia is sulfated as follows: in the preparation stage, the zirconium hydroxyl gel is treated with a sulfuric acid or ammonium sulfate solution (4). Also it can be prepared by impregnation with ca. 0.5–1.0 M sulfuric acid or ammonium sulfate on zirconia (5). In either case the catalyst should be calcined at 450–550°C, otherwise no strong- or super-acidity will be observed (6). Tanabe et al. (7) and Yamaguchi (8) have reported that incorporating a small amount of silica into the catalyst may increase the surface area and the thermal stability.

In recent years, there have been extensive studies on sol-gel synthesis of oxides, because it may provide specific properties to the oxide, which cannot be obtained by the conventional coprecipitation preparation method (9). Under appropriate synthesis condition, such as metal alkoxide concentration, pH, the type of complexing agent, the amount of hydrolyzing water, drying techniques, the textural properties of the oxide can be precisely controlled. Since the advent of this method, it has stimulated more and more interests in its application in the field of catalytic materials research. The sol-gel synthesis method can be used to prepare both catalysts and catalyst supports (10). With the sol-gel synthesis method, if the precursor (metal salt or complex) of an active component (a metal or metal oxide) in a supported catalyst is added to the preparation solution, a supported catalyst can be obtained after hydrolysis, gelation, drying, and calcining. This is the so-called one-step or one-pot synthesis of a catalyst (11, 12), which is simple and convenient for preparing catalysts in some cases.

Supported sulfate catalysts are commercially available for alcohol dehydration in laboratories (13). It is also being applied in industry (14).

In this paper, we report our attempt to prepare the sulfated zirconia–silica catalyst by the one-pot sol-gel synthesis method using ammonium sulfate, zirconium(IV) propoxide, and tetraethyl orthosilicate as precursors. Its catalytic perfor-

Fig. 1. N_2 adsorption isotherms of the catalysts with different SO_4^{2-} content (based on synthetic concentrations).

mance was evaluated for isopropanol dehydration, which is known as an acid-catalyzed reaction. N_2 adsorption and DRIFTS were employed to characterize the catalysts.

Experimental

One-pot sol-gel synthesis of the catalysts

n-Butanol was obtained from Caledon Laboratories, all other chemicals were obtained from Aldrich and used as received.

A series of sulfated ZrO_2–SiO_2 (molar ratio, 75:25) with sulfur contents up to 20 mol% were synthesized by the one-pot sol-gel method. Briefly, ammonium sulfate, zirconium propoxide, and tetraethyl orthosilicate were used as the precursors and 2,4-pentanedione (H-acac) as the complexing agent (9).[3] The appropriate amounts of zirconium propoxide and tetraethyl orthosilicate were dissolved in the solvent, *n*-butanol. The solution was heated to 60°C under stirring to thoroughly mix the components, then it was cooled down to room temperature, and H-acac was added. The alkoxides in the solution were hydrolyzed over night by adding an aqueous solution of ammonium sulfate. A yellowish transparent gel was obtained, which was dried at 100°C to remove the solvent and then calcined at 500°C for 3 h in air to remove the organics. The total concentration of the alkoxides in *n*-butanol solution was 0.8 M. The molar ratio of the complexing agent to the alkoxides was 0.5. The molar ratio of hydrolyzing water to alkoxide was 11:1. A reference catalyst was also prepared by impregnating a sol-gel synthesized ZrO_2–SiO_2 (75:25) with 1 M ammonium sulfate solution. The slurry was evaporated to dryness under stirring and then calcined at 500°C for 1 h.[4]

Characterization of the catalysts

N_2 adsorption analysis was measured by using a Coulter SA 3100 instrument at –196°C. Samples were degassed under vacuum at 200°C for 1 h immediately prior to N_2 adsorption analysis. From the isotherm, Brunauer–Emmett–Tellar (BET) surface area, pore volume, and pore size distribution were calculated by using the Barret, Joyner, and Halenda (BJH) method (15).

DRIFTS spectra were acquired using a Spectra Tech DRIFTS accessory (The Collector) in an ATI Mattson Research Series FT-IR spectrometer equipped with a Michelson interferometer, a helium–neon laser, a KBr beam splitter, a DTGS (deuterated triglycerol sulfate) detector with a spectra range of 4000–400 cm^{-1}, and a standard high-intensity source. The diffuse-reflectance FT-IR were recorded under vacuum after evacuating the samples at 100°C for 30 min. The sample chamber was designed to be used in situ on the collector DRIFTS accessory. Five hundred scans were collected.

Isopropanol dehydration evaluation

The catalytic activity evaluation of the catalysts for isopropanol dehydration was performed using a continuous flow fixed-bed micro reactor made of Pyrex glass.[3] The inner diameter of the reactor was 6 mm, its length was 25 cm. With each reaction, 200 mg fresh catalyst was put into the middle of the reactor. A thermocouple was placed just below the catalyst bed to monitor the reaction temperature, which was manipulated by a temperature controller. Before the reaction, the catalyst was heated to the reaction temperature under a flow of N_2. The reactions were performed at temperature range of 100–160°C at 1 atm (1 atm = 103.325 kPa). The reactant, isopropanol, was introduced into the reactor by a N_2 bubbler, which was kept at a constant temperature (16).[3] The flow rate of N_2 was 100 mL min^{-1}, giving a weight hour space velocity (WHSV) of the reactant as 1.8 h^{-1}. The products were analyzed by an on-line PerkinElmer Sigma 3B gas chromatograph, employing a Porapaq R column, 800/100 mesh, 6 ft × 0.125 in, with a thermal conductivity detector (TCD). To analyze all of the products in the exit stream from the reactor, the GC column was heated by programming from 150 to 220°C for 15 min.[3] The main product was propylene, with minimal amounts of diisopropylether as the byproduct. The activities were stablized in ca. 20 min. After that time, two consecutive analyses were carried out, which were within 5%. An average is reported throughout the *Discussion* section.

Results and discussion

Figure 1 shows the N_2 adsorption isotherms of the catalysts. The catalysts showed type IV isotherms, some with H2 hysteresis (15). By adding the $(NH_4)_2SO_4$ into the sol-gel synthesis solutions, the N_2 adsorption of the resultant catalysts increased, especially at the intermediate and high relative pressure range. The pore size distributions of the catalysts are displayed in Fig. 2. It can be seen that the textural structure of the catalysts were mesoporous. As the

amount of $(NH_4)_2SO_4$ was increased in the one-pot synthesis solution, both of the pore size and pore volume of the catalysts increased.

The surface area and pore volume of the catalyst are summarized in Table 1. By adding $(NH_4)_2SO_4$ to the sol-gel synthesis solution, the pore volume of the resultant catalysts significantly increased, and it even could be doubled at SO_4^{2-} 20 mol%. But only at higher $(NH_4)_2SO_4$ contents, did the surface area of the catalyst increase. Usually, from the N_2 adsorption isotherm, the contribution to the surface area comes mainly from the low relative pressure adsorption, while the pore volume contribution comes from the intermediate and high relative pressure adsorption. The addition of $(NH_4)_2SO_4$ to the gel mainly increased the N_2 adsorption at the intermediate and higher relative pressure range, thus showing in the increase of the pore volume.

It has been reported that SO_4^{2-} can form bridge structures between zirconium atoms in a sulfated zirconia catalyst (17). In the synthesis of the catalysts by the one-pot sol-gel method, the $(NH_4)_2SO_4$ is probably incorporated into the gel in a similar way, which may affect the structure of the gel. After drying and calcining, this kind of textural structure might be partly retained in the framework of the catalyst, resulting in large pore size and pore volume.

It can be seen from Table 1, with the impregnated catalyst (SO_4^{2-} 14 mol%), its surface area and pore volume decreased to ca. half of those of the ZrO_2–SiO_2 support. This was caused by the interaction of the acidic solution of $(NH_4)_2SO_4$ with the ZrO_2–SiO_2 gel, causing a shrinkage in the porous structure.

Fig. 3. DRIFTS spectra of the catalysts, SO_4^{2-} 14 mol% (synthesis level), after calcining at different temperatures.

The DRIFT spectra of the catalyst with SO_4^{2-} 14 mol% after calcining at different temperatures are shown in Fig. 3. The absorption peaks at 1050 cm^{-1} can be assigned to the Si-O-Zr vibration (18). The small shoulder peaks at 1224 and 1346 cm^{-1} are from the asymmetric stretching of S=O. The unresolved absorption peaks at 2700–3700 cm^{-1} are due to the hydrogen-bonded OH, and possibly some adsorbed water (with the bending peaks at 1631 cm^{-1}) on the catalyst surface. The peak at ca. 618 cm^{-1} is due to the vibration of zirconia (18). The absorption peaks at 2800–3000 cm^{-1} are assigned to the residual organics in the gel. When calcined at higher temperatures, these peaks were totally eliminated. At ca. 1559 and 1460 cm^{-1}, two peaks were observed and are assigned to the vibration of N—H (19). As the calcining temperature was increased to 200°C, these two peaks increased. This is principally due to the release of the organics and the evolution of the porous structure of the gel, which enabled more N-H groups migrating to the surface to be well distributed or dispersed. When the calcining temperature was further increased, the N—H absorption peaks decreased and finally disappeared. This was possibly caused by the decomposition of $(NH_4)_2SO_4$ and elimination of NH_3.

Figure 4 shows the catalytic activities of the one-pot sol-gel synthesized catalysts with different SO_4^{2-} content. As the SO_4^{2-} content was increased, the activity increased first, then decreased, giving an optimum content of SO_4^{2-} at 14 mol%. This was due to both the loading and the dispersion of SO_4^{2-} in the catalyst. As SO_4^{2-} content in the catalyst was increased, the activity increased. However, when the SO_4^{2-} content was increased over a certain value, its dispersion decreased. Therefore, the activity decreased too.

Figure 5 shows the activities and selectivities of two catalysts with SO_4^{2-} content of 14 and 17 mol%, respectively, under different temperatures. Two perspectives can be ob-

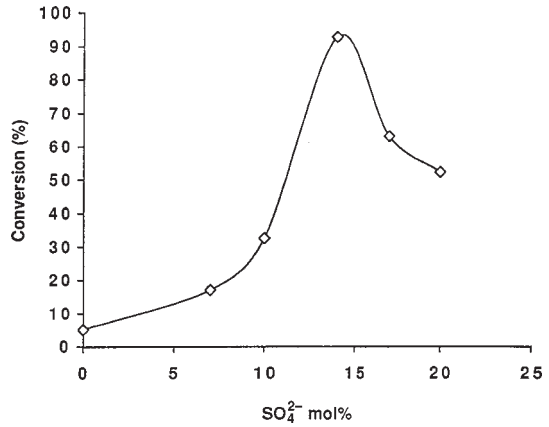
Fig. 4. The catalytic activities of the catalysts with different SO_4^{2-} content for isopropanol dehydration (140°C, 1 atm, WHSV = 1.8 h^{-1}).



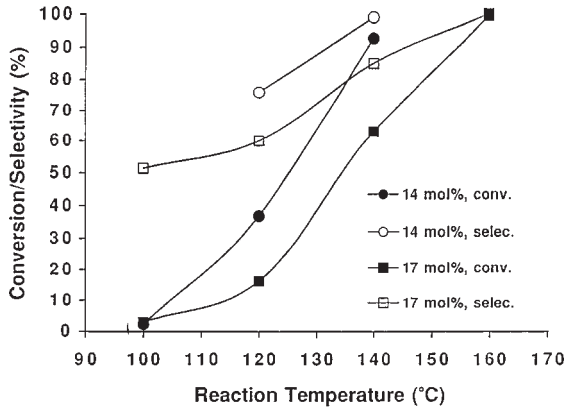


Fig. 5. The activity and selectivity of SO_4^{2-}–ZrO_2–SiO_2, 14 and 17 mol% vs. reaction temperature.

tained from the experimental results. First, at higher temperature, hence higher conversion, the selectivity was higher and could reach 100%. Second, with a catalyst of higher activity, its selectivity was also higher.

The byproduct, diisopropyl ether, seems to be formed by a consecutive reaction between isopropanol and propylene. When the conversion was higher, less isopropanol is available, thus giving a higher selectivity (20).

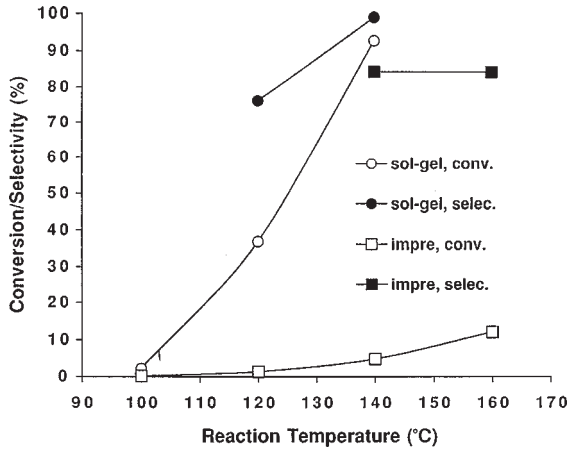

Figure 6 shows the catalytic performance of the one-pot sol-gel synthesized and the impregnated catalysts. The one-pot sol-gel synthesized catalyst was far more active and selective than the impregnated catalyst.

The activity of the present catalyst for isopropanol dehydration was higher than the solid acid catalyst TiO_2–SiO_2 (TiO_2–SiO_2 50 wt%, 3% conversion at 140°C).[3] It can be pointed out that a strong solid acid catalyst can be obtained by the one-pot sol-gel synthesis method using $(NH_4)_2SO_4$ as one of the starting materials.

Conclusions

The one-pot sol-gel synthesis method by using $(NH_4)_2SO_4$ as starting material is effective for preparing sulfated zirconia catalyst. By adding $(NH_4)_2SO_4$ to the sol-gel preparing solution, the surface area, pore size, and pore volume of the

Fig. 6. The activity and selectivity of SO_4^{2-}–ZrO_2–SiO_2, 14 mol%, prepared by one-pot sol-gel method and impregnation vs. reaction temperature.

resultant catalysts were increased. After calcining, the $(NH_4)_2SO_4$ decomposed, giving a sulfated catalyst with relatively higher pore size and pore volume. The optimum loading of SO_4^{2-} with the one-pot sol-gel synthesized catalyst was 14 mol%, showing much higher catalytic activity, with a selectivity of 100%, for isopropanol dehydration than the impregnated catalyst.

Sol-gel synthesis of ternary phosphate–ZrO_2–SiO_2 catalysts for alcohol dehydration

Quan Zhuang and Jack M. Miller

Abstract: Phosphate–ZrO_2–Si_2O catalysts were synthesized by sol-gel method using tributyl phosphite, zirconium propoxide, and tetraethyl orthosilicate as precursors. They were characterized by N_2 adsorption, ^{31}P CP MAS NMR, and DRIFTS. At lower P content, monomeric phosphates were formed on the surface of the catalysts, which were mainly responsible for the isopropanol dehydration activity. At higher P content, polyphosphates were formed, and thus, the dehydration activity decreased. An optimum P content for dehydration activity was found to be at 10 mol%.

Key words: sol-gel synthesis, ternary oxides, phosphate, acid catalyst, alcohol dehydration, ^{31}P CP MAS NMR, N_2 adsorption, DRIFTS.

Résumé : On a synthétisé des catalyseurs phosphate–ZrO_2–SiO_2 par la méthode sol-gel utilisant du phosphite de triéthyle, du propylate de zirconium et de l'orthosilicate de tétraéthyle comme précurseurs. On les a caractérisés par adsorption de N_2, RMN CP MAS du ^{31}P et DRIFTS. À des teneurs faibles en P, il se forme des phosphates monomères à la surface des catalyseurs qui se sont avérés responsables pour activité de déshydratation de l'isopropanol. À des teneurs en P plus élevées, il se forme des polyphosphates et il en résulte une diminution de l'activité de déshydratation. On a déterminé que la teneur optimale en P pour l'activité de déshydratation est de 10 mol%.

Mots clés : synthèse sol-gel, oxydes ternaires, phosphate, catalyseur acide, déshydratation des alcools, RMN CP MAS du ^{31}P, adsorption du N_2, DRIFTS.

[Traduit par la Rédaction]

Introduction

Recently, phosphorus-containing oxides have been synthesized by various methods to obtain inorganic materials with new porous structures and (or) new properties. Among them, SAPO and AIPO types have been reported as having uniform porous structure, showing molecular sieve function, as well as catalytic activity, for some reactions due to the surface acidity (1, 2). Meanwhile, supported phosphoric acid catalysts prepared by impregnation have been widely used as catalysts for catalyzing olefin hydration (3), alkylation (4), dehydration (5–7), and dimerization (4).

On the other hand, there have been extensive studies on sol-gel synthesis of oxides, because it may provide specific properties to the oxide that cannot be obtained by the conventional coprecipitation preparation (8). Under appropriate synthesis conditions, such as metal alkoxide concentration, pH, the type of complexing agent, the amount of hydrolyzing water, drying technique, the textural properties of the oxide can be controlled. Since the advent of this method, it has stimulated more and more interest in its application in the field of catalytic materials research. The sol-gel synthesis method can be used to prepare both catalyst and catalyst support (9).

In this paper, we report our attempt to prepare the ternary phosphate–zirconia–silica catalysts by the sol-gel synthesis method using tributyl phosphite, zirconium(IV) propoxide, and tetraethyl orthosilicate as precursors. Its catalytic performance was evaluated for isopropanol dehydration, and N_2 adsorption, DRIFTS, and ^{31}P CP MAS NMR were employed to characterize the catalysts.

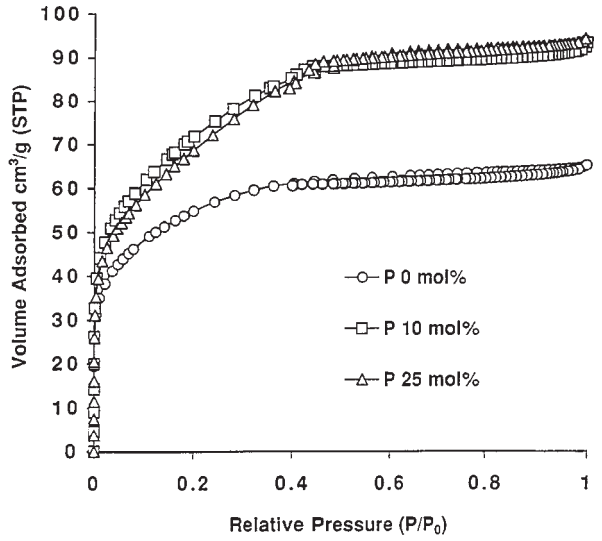
Experimental

Sol-gel synthesis of the catalysts

n-Butanol was obtained from Caledon Laboratories, all other chemicals were obtained from Aldrich and used as received.



A series of P–ZrO_2–SiO_2 (Zr:Si molar ratio was fixed at 75:25) catalysts with P contents of up to 25 mol% were synthesized by the sol-gel method. Briefly, tributyl phosphite (density 0.925 g mL^{-1}), zirconium propoxide (70%, density 1.044 g mL^{-1}), and tetraethyl orthosilicate (98%, density 0.93 g mL^{-1}) were used as the precursors and 2,4-pentanedione (H-acac) as the complexing agent (8).[2] The appropriate amounts of zirconium propoxide and tetraethyl orthosilicate were desolved in the solvent, *n*-butanol (density 0.81 g mL^{-1}). The solution was heated to 60°C under stirring to mix the components thoroughly, then it was cooled down to room temperature. Tributyl phosphite and H-acac were added and the solution was stirred for 30 min. Then the alkoxides in the solution were hydrolyzed over night by adding water. A yellowish transparent gel was obtained, which

was dried at 100°C to remove the solvent and then calcined at 500°C for 3 h to remove the organics. The total concentration of the alkoxides in *n*-butanol solution was 0.8 M. The molar ratio of the complexing agent to the alkoxides was 1:2. The molar ratio of hydrolyzing water to alkoxide was 11:1. Table 1 shows the reagent amounts used in the catalyst preparation.[3]

Characterization of the catalysts

N_2 adsorption analysis was measured by using a Coulter SA 3100 instrument at –196°C. Samples were degassed under vacuum at 200°C for 1 h immediately prior to N_2 adsorption analysis. From the isotherm, the Brunauer–Emmett–Tellar (BET) surface area, pore volume, and pore size distribution were calculated by using the Barret, Joyner, and Halenda (BJH) method (10).

CP MAS NMR experiments were carried out on a Bruker Avance DPX 300 multinuclear FT NMR instrument. A standard bore Bruker MAS/CP MAS probe with 4 mm zirconia rotors was used. ^{31}P NMR spectra were obtained at 121.50 MHz using cross polarization with proton decoupling during acquisition and referenced to $(NH_4)_3PO_4$ (chemical shift = 0 ppm). Samples were spun at 8 kHz. A 1 ms cross-polarization contact time was used with a 4 s recycle delay between the pulses. 124 FIDs were accumulated with a spectral window of 36 kHz. Prior to recording the spectra, the samples were degassed at 100°C for 30 min in a flow of helium and immediately transferred into the zirconia rotors for the NMR measurements.

DRIFTS spectra were acquired using a Spectra Tech DRIFTS accessory (The Collector) in an ATI Mattson RS-1 FT-IR spectrometer equipped with a Michelson interferometer, a helium–neon laser, a KBr beam splitter, a DTGS (deuterated triglycerol sulfate) detector with a spectra range of 4000–400 cm^{-1}, and a standard high-intensity source. The diffuse-reflectance FT-IR were recorded at 100°C under vacuum after evacuating the samples at 100°C for 30 min. The sample chamber was designed to be used in situ on the collector DRIFTS accessory.

Isopropanol dehydration evaluation

The catalytic activity evaluation of the catalysts for isopropanol dehydration was performed using a continuous flow fixed-bed micro reactor made of Pyrex glass.[2] The inner diameter of the reactor was 6 mm, its length was 25 cm. With each reaction, 200 mg of fresh catalyst was put into the middle of the reactor. A thermocouple was placed just below the catalyst bed to monitor the reaction temperature, which was manipulated by a temperature controller. Before each reaction, the catalyst was heated to the reaction temperature under a flow of N_2. The reactions were performed at the temperature range of 150–230°C at 1 atm (1 atm = 101.325 kPa). The reactant, isopropanol, was introduced into the reactor by a N_2 bubbler, which was kept at 23°C (11).[2] The flow rate of N_2 was 100 mL min^{-1}, giving a weight hour space velocity (WHSV) of the reactant as 1.8 h^{-1}. The products were analyzed by an on-line PerkinElmer Sigma 3B gas chromatograph, employing a Porapaq R column, 800/100 mesh, 6 ft × 0.125 in, with a thermal conductivity detector (TCD). To analyze all of the products in the exit stream from the reactor, the GC column was heated by programming from 150 to 220°C for 15 min.[2] The activities were stablized in ca. 20 min. After that time, two consecutive analyses were carried out, which were within 5%. An average is reported throughout the *Discussion* section. The main product was propylene, with trace amounts of diisopropyl ether as by-product, with selectivity close to 100%.

Results and discussion

Figure 1 shows the N_2 adsorption isotherms of the catalysts. The catalysts display type IV isotherms (10). By add-

ing phosphorus in the form of tributyl phosphite into the sol-gel synthesis solutions, the N_2 adsorption of the resultant catalysts increases, especially at the intermediate and high relative pressure range. The pore size distributions of the catalysts are displayed in Fig. 2. It can be seen that the textural structure of the catalysts are mesoporous. As the amount of P is increased in the synthesis solution, the pore size distribution broadens to the larger pore diameter side, and the total pore volume of the catalysts increases. From P 0.0 to 25 mol%, the surface area increases from 180 to 250 $m^2\ g^{-1}$ and the pore volume from 0.10 to 0.14 $cm^3\ g^{-1}$.

To evaluate the evolution process of the ternary P–ZrO_2–SiO_2 catalysts, ^{31}P CP MAS NMR spectra of the catalyst with P 10 mol% calcined at different temperatures were acquired and the results are shown in Table 2 and Fig. 3. As the calcining temperature is increased, the chemical shift of ^{31}P NMR resonance shifts up field, from –4.1 ppm after being heat treated at 100°C to –11.5 ppm with the sample treated at 500°C. The intensities of the ^{31}P NMR peaks decrease when increasing the temperature of heat treatment. The ^{31}P NMR resonance peaks at the above chemical shift ranges are due to the monomeric phosphates (2, 12). It is well-known that P(III) can be easily oxidized to P(V) (13). Thus in our system, after heat treating the gel in air, the P(III) from tributyl phosphites is oxidized to P(V) in the form of phosphates.

Figure 4 and Table 3 show the ^{31}P NMR spectra of the catalysts with different P contents after calcining at 500°C. It can be seen that when the P content in the catalyst is increased, the intensity of the ^{31}P resonance increases, with an

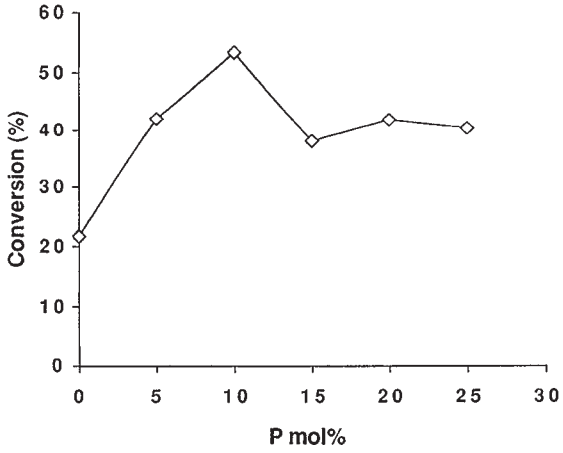
Fig. 5. DRIFTS spectra of the catalyst after calcining at different temperatures (P 10 mol%).

upfield shift (from –10.4 ppm with P 5 mol% to –14.7 ppm with P 25 mol%). These changes are caused by partial formation of polyphosphates when the P contents in the catalysts are increased.

The DRIFT spectra of the catalyst with P 10 mol% after calcining at different temperatures were measured, and the results are shown in Fig. 5 together with the DRIFT spectra of ZrO_2:SiO_2 (75:25) calcined at 233 and 500°C, respectively. The absorption peaks at ~980 cm^{-1} are assigned to Si—OH stretching and Zr-O-Si modes of ZrO_2–SiO_2 (14). Nogami (15) reported that the peaks at 500–600 cm^{-1} are due to the polyhedra ZrOx. It can be seen that in our catalysts these ZrOx polyhedra exist. The absorption at ~3730 cm^{-1} is caused by the vibration of Si—OH. The peaks at ~3500 cm^{-1} are ascribed to the hydrogen-bonded hydroxyl band (16, 17). As shown in the ^{31}P CP MAS NMR results, after calcining, the phosphorus species in the gel gradually change to the phosphate, and hence, the new absorption peaks at ~3650 cm^{-1} could be reasonably assigned to the OH groups affiliated to the phosphates, which are acidic. The peaks at 1540 and 1445 cm^{-1} appear after increasing the calcining temperature to 233°C. On further increasing the calcining temperature, they disappear. Since we could not observe these peaks with pure ZrO_2–SiO_2 system, they must be related with some specific intermediate organic phosphorous species being formed, which then migrate to the surface and decompose during the evolution of the structure of the final catalysts on heat treatment at higher temperature (18). The phosphorus-containing gel is yellow, whereas ZrO_2–SiO_2 is nearly white and tributyl phosphite is colorless, indicating that at the gel stage the two materials have different structures. This can be seen from their DRIFTs spectra after calcining at 233°C. On heat treating at higher temperature (500°C) the frameworks of the two materials are similar, because they show similar DRIFTs spectra. The phosphates

Fig. 6. The catalytic activities of the catalysts with different P content for isopropanol dehydration (210°C, 1 atm, WHSV = 1.8 h^{-1}) (concentration based on synthesis).



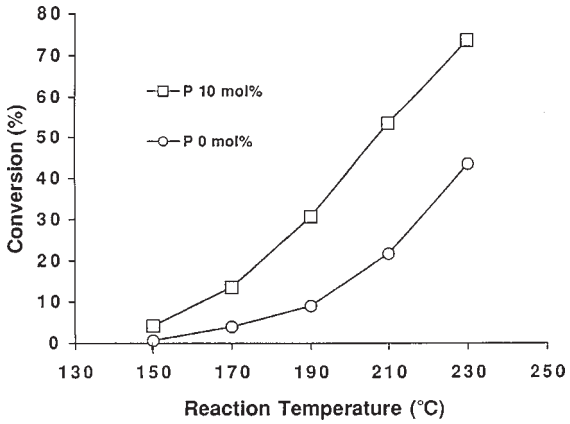


Fig. 7. The activity (as conversion) of P–ZrO_2–SiO_2, P 0.0 and 10 mol% vs. reaction temperature.

may have only weak interaction with the framework of ZrO_2–SiO_2.

Figure 6 shows the catalytic activities of the sol-gel synthesized catalysts with different P content for isopropanol dehydration. As the P content is increased, the activity increases first, then decreases, and then levels off, giving an optimum content of P at 10 mol%. It is clear that the dehydration activity of the catalysts are due to the acidity of the phosphates on the surface (3). As the P content in the catalysts is increased, some of the monomeric phosphates change to polyphosphates as evidenced by the results of ^{31}P NMR characterization. This may explain the decline of the activity of the catalysts with higher P content.

Figure 7 shows the activities of the two catalysts without P and with 10 mol% of P, respectively, under different temperatures. Under the tested reaction temperature range, the activity of the P containing catalyst is higher than the catalyst without P.

Conclusions

By sol-gel method, phosphate–ZrO_2–SiO_2 catalysts were synthesized. The ^{31}P CP MAS NMR spectra revealed that at lower P content, monomeric phosphates were formed on the

© 2001 NRC Canada

surface of the catalysts, which were mainly responsible for the isopropanol dehydration activity. When P content was increased, polyphosphates were formed, causing the decrease of the activity. The optimum P content was 10 mol%.

Stereoselective addition of acetone to the C=N bond of [4.3.0] boron heterobicycles

Victor Barba, Damian Cuahutle, Rosa Santillan, and Norberto Farfán

Abstract: The reaction of *N*-salicylidene-2-aminophenolate (SAP-H_2) derivatives with phenyl boronic acid afforded five new boron bicyclic species in moderate yields, as confirmed by an X-ray study of the boron heterocycle derived from 2-amino-4-chlorophenol. The results also showed that the boron complexes derived from Schiff bases undergo an acetolysis reaction to give the corresponding dioxazaborocines containing all substituents on the same side also in good yields. The structure of one of the addition products was established by X-ray analysis showing that, in the solid state, it exists as a dimeric structure formed by hydrogen bonds.

Key words: borocines, tridentate ligands, imines, boronic acids.

Résumé : La réaction de dérivés du *N*-salicylidène-2-aminophénolates (SAP-H_2) avec l'acide phénylboronique conduit, avec des rendements modérés, à la formation de cinq nouvelles espèces bicycliques du bore dont la structure a été confirmée par diffraction des rayons X sur l'hétérocycle contenant du bore dérivé du 2-amino-4-chlorophénol. Les résultats montrent aussi que les complexes du bore dérivés des bases de Schiff subissent une réaction d'acétolyse conduisant à la formation, avec de bons rendements, des dioxazaborocines correspondantes comportant tous les substituants sur le même côté. La structure de l'un des produits d'addition a été déterminée par une étude par diffraction des rayons qui a montré que, à l'état solide, il existe sous la forme d'une structure dimère formées par des liaisons hydrogènes.

Mots clés : borocines, ligands tridentates, imines, acides boroniques.

[Traduit par la Rédaction]

Introduction

The addition reaction of nucleophiles to the C=N bond of imines or imine derivatives is a well-known procedure that provides reactive iminium salts, nitrones, acylimines, and sulfonimine when the electrophilicity of the carbon atom of the C=N bond is increased by *N*-alkylation (1), *N*-oxidation (2), *N*-acylation (3), or *N*-sulfonation (4). Moreover, the use of organometallic reagents results in a more efficient addition of the nucleophilic species to the imine owing to an increased polarization of the C=N bond (5–7). These reactions are very interesting because the use of chiral imines allows asymmetric synthesis of amines (8) whereby the selectivity and efficiency of a nucleophilic addition of an organometallic reagent to the C=N bonds are assisted by the presence of stoichiometric amounts of an external chiral auxiliary (8, 9).

In contrast, boron reagents are highly electrophilic so that coordination of the nitrogen atom to the boron could polarize the C=N bond and increase the ability of a nucleophilic species to react with the carbon atom in this group. We have prepared several boron compounds derived from tridentate Schiff bases and arylboronic acids (10–17); these complexes form bicyclic or macrocyclic structures showing intramolecular N–B dative bonds where the polarization of the C=N is increased.

Continuing our investigations on boronates, herein we described the formation of five new bicyclic boron complexes (**2a**–**e**) derived from iminodiphenols (**1a**–**e**) and phenylboronic acid. These derivatives contain a C=N bond that is polarized by coordination of the nitrogen atom to the boron atom forming a N–B dative bond. The polarization of this bond was evidenced by acetolysis of the imine group of the boron compounds to produce dioxazaborocines **4a**–**e** showing all substituents on the same side with very high diastereoselectivity.

Results and discussion

Tridentate ligands **1a**–**e** were synthesized by condensation of salicylaldehyde with the corresponding aminophenol derivative. The reaction was carried out under reflux of methanol for 30 min to give the corresponding imines in good yields. The ^{1}H NMR spectra of compounds **1a**–**e** present a single signal between 8.07 and 9.10 ppm, typical of an imine proton.

Treatment of **1a**–**e** with 1 equivalent of phenylboronic acid in the presence of THF gives boronates **2a**–**e** (Scheme 1) via elimination of 2 equivalents of water. From this reaction, boronate **2c** was obtained in crystalline form allowing determination of its X-ray crystal structure, which showed that upon coordination the ligand adopts a geometry

that leads to a highly delocalized system with enhanced stability, as described in previous studies (16, 17). Compounds **2a**–**e** were obtained as pale yellow-orange solids and were characterized by elemental analysis, mass spectrometry, IR, and ^{1}H, ^{13}C, and ^{11}B NMR spectrometry. Formation of similar [4.3.0] heterobicyclic systems using an ONO donor ligand has been described previously for elements, such as phosphorus (18), manganese (19), vanadium (20–22), and molybdenum (23–25). The mass spectra of compounds **2a**–**e**, showing the molecular ion $[M]^+$ and a base peak corresponding to the loss of the phenyl group, is in agreement with previous results (26).

The C=N stretching band in the IR spectra is shifted to higher wavenumbers by $\Delta\bar{\nu}$ = 4–8 cm^{-1} upon complex formation as shown in other boron compounds (10–17). The ^{1}H NMR data show that the signal corresponding to the azomethine group is shifted to lower field in the boron complexes as compared to the free ligands ($\Delta\delta \approx 0.6$ ppm). The same effect is observed in the ^{13}C NMR spectra where the signal for C-7 is observed between 147.9 and 152.0 ppm for compounds **2a**–**c** and **2e**, whereas the same signal in ligands **1a**–**c** and **1e** appears between 161.3 and 165.3 ppm. The only exception was compound **2d**, which shows a similar shift (162.9 ppm) to the free ligand (162.3 ppm). The ^{11}B NMR chemical shifts are indicative of tetra-coordinated species (δ = +8.6, +11.0, +9.0, +7.5, and +8.0 for **2a**–**e**, respectively) (27).

The X-ray analysis for **2c** (Fig. 1) established the [4.3.0] heterobicyclic structure; details of the crystal data and summary of collection parameters are given in Table 1 and selected bond distances and bond angles are compared in Table 2.[2] The value for the intramolecular N—B donor-acceptor bond length for boronate **2c** is 1.591(6) Å, which is shorter than the unsubstituted boronate **2f** (1.613(5) Å) (17) and in accordance with the N—B dative bond distances for boronates, which are in the range from 1.586(2) to 1.681(5) Å (28).

The N(1)—C(7) bond length (Table 2) is significantly longer in **2c** (1.284(5) Å) as compared to **2f** (1.249(4) Å), indicating a weaker N–B dative bond in **2c**. The bond angles around the boron atom in **2c** are in the range of 99.8(4)–113.7(4)°. The lowest value corresponds to the O(2)-B(1)-N(1) bond angle in the five-membered heterocycle, whereas the largest corresponds to the O(1)-B(1)-C(Ph) bond angle; the values are similar to those found in compound **2f**.

The environment of the boron atom can be evaluated by the tetrahedral character (THC) (28) showing a large distortion (74%), due to high strain in the five-membered heterocycle. The ring strain of the two heterocycles is perhaps best expressed by torsion angles of 33.4° for the O(1)-B(1)-N(1)-C(7) in the six-membered ring and –20.2° in the O(2)-B(1)-N(1)-C(8) of the five-membered ring.

When the reaction of **1d** was carried out in ethanol under reflux, the monomeric structure **3** was formed (Scheme 2). In this case the solvent reacts through an intermediate, which results from reaction of the phenolic group of the ligand with a hydroxyl group from phenylboronic acid, as proposed in Scheme 3. The formation of type IV boronates can be explained based on the observation that six-membered boron heterocycles (type II) are more stable than five-membered ones (type III), as indicated by the formation of compound **3** where the hydroxyl group attached to the boron atom is substituted by an OCH_2CH_3 group.

The X-ray crystal structure of **3** (Fig. 2) consists of discrete molecules with strong intramolecular hydrogen bonds between the ethoxy moiety and phenolic fragment as can be inferred from the O(3)···O(2) bond distance (2.615 Å). Selected bond lengths of **3** are summarized in Table 2 and compared with the corresponding data for boronate **2c**. It can be seen that significant differences in the N—B, B—O, N(1)—C(8), and N(1)—C(7) bond lengths are found; the longer distances are found for **3**. For example the N—B bond for **3** is 1.621(2) Å), whereas the N—B bond for **2c** is 1.591(6) Å.

The bond angles around the boron atoms for **3** and **2c** are very similar; however, the THC value is larger for **3** (77%) indicating that the annular tension produced by formation of a five-membered ring distorts the tetrahedral geometry.

Scheme 2.

Evidence for the formation of boronate **3** was also obtained from the NMR spectra. The ^{1}H NMR spectrum shows a single signal at 8.17 ppm, which is shifted to lower field compared with **2a**–**e**. However, the ^{13}C NMR spectrum shows the signal corresponding to C-7 at δ = 163.8, which is at lower field in comparison with boronates **2a**–**e**. The tetracoordination of the boron atom can be seen from the ^{11}B NMR spectrum, where a value of +7.0 ppm has been measured.

The dioxazaborocines **4a**–**e** were obtained in moderate yields (45–89%) by aldol condensation, resulting in the acetolysis of boronates **2a**–**e** after 6 h of heating at reflux (Scheme 4). The lowest yield corresponds to complex **2a** containing a NO_2 group that produces an electron-withdrawing effect.

Exclusive formation of the diastereoisomer containing the CH_3COCH_2 and NH groups in a *cis* configuration supports the proposal of a six-membered transition state. It is impor-

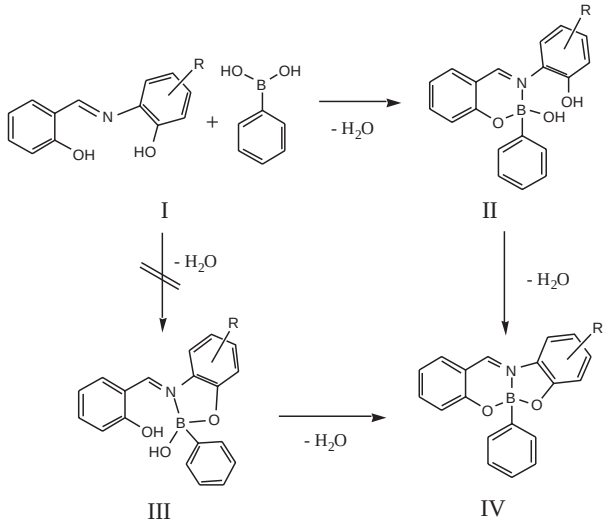
Scheme 3.



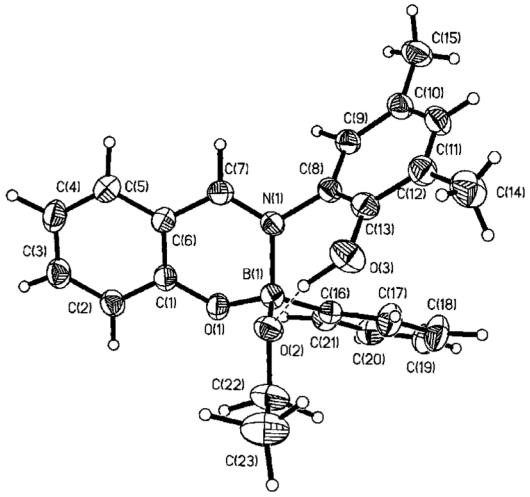


Fig. 2. ORTEP diagram of the molecular structure of compound **3**.

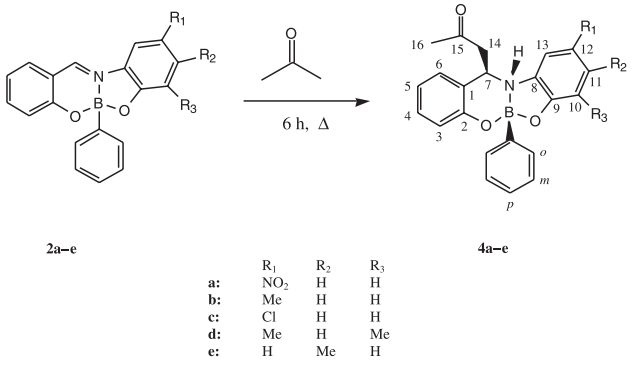
tant to notice that the fusion of the [4.3.0] heterobicyclic system is also *cis*, in contrast to the dioxazaborocines described by Woodgate (29), which provide a *cis–trans* diasteromeric mixture of [4.4.0] heterobicycles, although the major product also has a *cis* fusion. As a matter of fact, our results are in accordance with the results found in [3.3.0] dioxazaborocines that provide a *cis* fusion (30, 31).

The spectroscopic data allowed complete characterization for **4a**–**e**. The IR spectra showed the absence of the C=N group and appearance of a new band between 1702–1706 cm^{-1} corresponding to the C=O group, and the mass spectra showed the molecular ion for the boronates.

The NMR spectra show a singlet corresponding to the NH group between 8.07 and 9.02 ppm. In solution, there is no evidence for hydrogen bonding involving this group although it is present in the solid state (vide infra), as shown for **4d**. The -CH_2-CH- fragment gives rise to an AMX system at δ = 2.83–3.71 due the existence of stereogenic centers. The ^{11}B NMR spectra of **4a**–**e** show a broad signal between 7.6 and 12.0 ppm, characteristic for tetra-

Scheme 4.



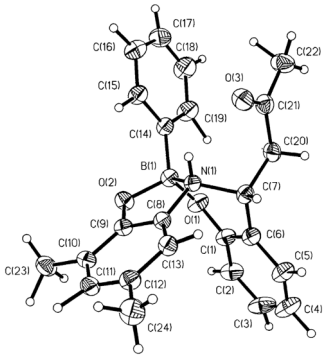


Fig. 3. ORTEP diagram of the molecular structure of compound **4d**.

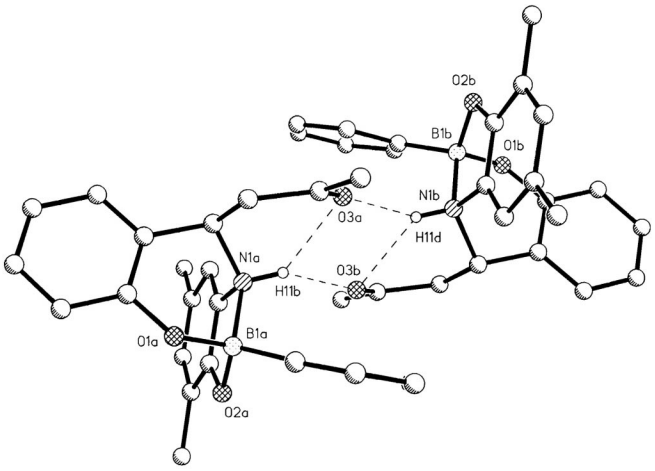

coordinated boron atoms bonded to two oxygen atoms, one nitrogen atom, and one carbon atom.

A crystal suitable for X-ray diffraction was obtained for compound **4d** and the molecular structure is shown in Fig. 3. Details of the crystal data and summary of data collection parameters are given in Table 1 and selected bond distances and angles are listed in Table 2. The N—B bond length (1.677(3) Å) is larger than that of **2c** and **3** and similar boronates described in the literature (10–17, 28). The difference in these values may be partially attributed to an increase in bond distance on going from an sp^2 to sp^3 hybridization on the nitrogen atom. The B—O distance is shorter in the six-membered (1.456(3) Å) than in the five-membered heterocycle (1.484(3) Å) due to higher annular tension in the five-membered ring. The angles around the boron atom are approximately tetrahedral in the range between 100.0(2)° (O(2)-B(1)-N(1)) and 113.0(2)° (O(2)-B(1)-(C_{Ph})) and are similar to the boronates described previously (10–17) showing a THC value of 75%.

Figure 3 shows that the boron–phenyl moiety, the -CH_2COCH_3 fragment, and the hydrogen attached to the nitrogen atom have a *cis* disposition. The molecular packing reveals the interaction present at the oxygen and hydrogen atoms forms a dimeric structure in the solid state. The molecular structure of this compound is evident in Fig. 4 whereby the centrosymmetric structure is formed by relatively strong hydrogen bonds that result in the formation of the four-membered heterocycle ring through inter- and intramolecular interactions. The H(11b)···O(3a) intramolecular distance of 2.20 Å is slightly shorter than the

© 2001 NRC Canada

Fig. 4. ORTEP diagram showing the dimeric form for **4d** by hydrogen bonding.

H(11b)···O(3b) intermolecular distance of 2.28 Å. The H(11b)—N(1a) distance (0.89 Å) is in accordance with this type of bond (32). These results allow the conclusion that the additional stabilization of the molecule is achieved owing to the inter- and intramolecular hydrogen bonding that leads to the dimeric structure.

Conclusions

In conclusion, boron complexes derived from tridentate ligands are readily formed leading in all cases to [4.3.0] heterobicyclic structures containing dative N–B bonds as evidenced by the X-ray analysis of compound **2c**. The use of different solvents leads to other heterocycles, as was shown by formation of compound **3**. Furthermore, it was shown that coordination of the nitrogen atom to boron is responsible for the polarization of the C=N bond and the facile and stereoselective reaction with nucleophiles such as acetone, leading to the products having all substituents in a *cis* configuration. The stereochemistry of the NH, phenyl, and carbonyl groups in **4d** is responsible for the dimeric structure formed in the solid state.

Experimental

Reagents and instrumentation

All starting materials were commercially available. Solvents were used without further purification, but single crystals were grown from spectrophotometric grade solvents.

NMR spectra were recorded in $CDCl_3$ and DMSO-d_6 solutions on Bruker Avance DPX 300 and Jeol GSX-270 spectrometers. Chemical shifts (ppm) are relative to $(CH_3)_4Si$ for ^1H and ^{13}C and $BF_3{\cdot}OEt_2$ for ^{11}B. Coupling constants are quoted in Hz. Infrared spectra were recorded on a PerkinElmer 16F-PC FT-IR spectrophotometer. Mass spectra were recorded on a Hewlett-Packard 5989A spectrometer. Melting points were obtained on a Gallenkamp MFB-595 equipment and are uncorrected. Midwest Microlab, LLC, Indianapolis, IN 46250 performed elemental microanalyses.

General procedure for the preparation of ligands 1a–e

To prepare the tridentate ligands **1a–e**, equimolar quantities of the corresponding aminophenol and salicylaldehyde were heated at reflux in methanol for 30 min. The solvent and the water formed during the reaction were removed by a Dean–Stark trap to yield a solid, which was washed with chloroform and used without further purification. The preparation of **1b** has been published (33).

*[2-(2-Hydroxybenzyliden)amino]-4-nitrophenol (**1a**)*

Compound **1a** was prepared from 2-amino-4-nitrophenol (1.0 g, 6.49 mmol) and salicylaldehyde (0.79 g, 6.49 mmol). The product was obtained as an orange solid (yield: 1.1 g, 4.26 mmol, 66%), mp 228–231°C. MS (70 eV) *m*/*z* (%): 258 (M^+, 100), 241 (19), 211 (53), 165 (23), 128 (8), 119 (9), 77 (20). IR (KBr) (cm^{-1}): 3448, 2918, 2850, 1624, 1522, 1336, 1278, 1140. ^1H NMR (300 MHz, DMSO-d_6) δ: 9.10 (s, 1H, H7), 8.27 (d, *J* = 2.7 Hz, 1H, H13), 8.07 (dd, *J* = 8.9, 2.7 Hz, 1H, H11), 7.69 (d, *J* = 7.7 Hz, 1H, H6), 7.42 (td, *J* = 7.7, 1.3 Hz, 1H, H4), 7.20 (d, *J* = 8.9 Hz, 1H, H10), 6.98 (t, *J* = 7.7 Hz, 1H, H5), 6.96 (d, *J* = 7.7 Hz, 1H, H3). ^{13}C NMR (75 MHz, DMSO-d_6) δ: 165.3 (C7), 161.4 (C2), 158.6 (C12), 140.8 (C9), 136.6 (C8), 134.4 (C4), 133.6 (C6), 124.6 (C11), 120.2 (C1), 119.9 (C5), 117.6 (C3), 117.2 (C10), 116.2 (C13).

*[2-(2-Hydroxybenzyliden)amino]-4-methylphenol (**1b**)*

Compound **1b** was prepared from 2-amino-4-methylphenol (1.01 g, 8.18 mmol) and salicylaldehyde (1.0 g, 8.18 mmol). The product was obtained as dark red crystals (yield: 1.79 g, 7.85 mmol, 95%), mp 162–165°C. MS (70 eV) *m*/*z* (%): 227 (M^+, 60), 227 (100), 197 (19), 134 (70), 106 (12), 77 (40). IR (KBr) (cm^{-1}): 3854, 2914, 1634, 1624, 1598, 1524, 1488, 1466, 1294, 1282, 1230, 1192, 1160, 1144, 764, 590. ^1H NMR (300 MHz, DMSO-d_6) δ: 8.95 (s, 1H, H7), 7.60 (dd, *J* = 7.7, 1.6 Hz, 1H, H6), 7.38 (td, *J* = 7.7, 1.6 Hz, 1H, H4), 7.18 (d, *J* = 1.6 Hz, 1H, H13), 6.97 (dd, *J* = 7.7, 1.6 Hz, 1H, H3), 6.95 (t, *J* = 7.7 Hz, 1H, H5), 6.93 (d, *J* = 8.2 Hz, 1H, H10), 6.86 (d, *J* = 8.2 Hz, 1H, H11), 2.25 (s, 3H, Me). ^{13}C NMR (75 MHz, DMSO-d_6) δ: 161.3 (C7), 160.7 (C2), 148.8 (C9), 134.4 (C8), 132.7 (C4), 132.2 (C6), 128.4 (C12), 128.2 (C11), 119.7 (C1), 119.5 (C13), 118.6 (C5), 116.6 (C3), 116.2 (C10), 20.0 (Me).

*[2-(2-Hydroxybenzyliden)amino]-4-chlorophenol (**1c**)*

Compound **1c** was prepared from 2-amino-4-chlorophenol (0.56 g, 3.95 mmol) and salicylaldehyde (0.48 g, 3.95 mmol). The product was obtained as an orange solid (yield: 0.83 g, 3.35 mmol, 85%), mp 221–223°C. MS (70 eV) *m*/*z* (%): 249 ($[M + 2]^+$, 34), 247 (M^+, 100), 238 (11), 154 (73), 127 (26), 99 (20), 77 (37), 51 (48). General method for the preparation of compounds 2a–e

An equimolecular amount of phenylboronic acid was added to a solution of the tridentate ligand in THF (usually about 10 mL for 2 to 3 mmol). The mixture was heated at reflux for 30 min and the water removed with a Dean–Stark trap. The solid obtained was collected by filtration under vacuum and washed with small amounts of benzene and hexane.

*2-Phenyl-4′-nitrobenzo[*d*]benzo[*h*]-6-aza-1,3-dioxa-2-boracyclonon-6-ene (**2a**)*

Compound **2a** was prepared from **1a** (0.26 g, 1.00 mmol) and phenylboronic acid (0.12 g, 1.00 mmol). The product was obtained as a yellow solid (yield: 0.30 g, 0.87 mmol, 87%), mp 236–238°C. MS (70 eV) *m*/*z* (%): 344 (M^+, 16), 268 (15), 267 (100), 221 (60), 193 (8), 77 (11), 51 (10). IR (KBr) (cm^{-1}): 3420, 2918, 2850, 1646, 1628, 1610, 1550, 1506, 1466, 1456, 1334, 1300, 1182, 1154, 914. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.54 (s, 1H, H7), 8.42 (d, *J* = 2.3 Hz, 1H, H13), 8.32 (dd, *J* = 8.0, 2.3 Hz, 1H, H11), 7.65 (td, *J* = 7.5, 1.4 Hz, 1H, H4), 7.48 (dd, *J* = 7.5, 1.8 Hz, 1H, H6), 7.16 (d, *J* = 7.5 Hz, 1H, H3), 7.13–7.30 (m, 6H, H10, H-*o*, -*m*, -*p*), 7.03 (td, *J* = 7.5, 1.4 Hz, 1H, H5). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 163.8 (C2), 158.3 (C12), 152.0 (C7), 140.2 (C9), 139.9 (C4), 132.5 (C6), 131.2 (C-*o*), 130.9 (C8), 128.7 (C-*p*), 127.9 (C-*m*), 124.6 (C11), 121.3 (C5), 120.8 (C3), 119.1 (C1), 114.8 (C13), 111.9 (C10). ^{11}B NMR (96 MHz, $CDCl_3$) δ: +8.6 ($h_{1/2}$ = 152 Hz). Anal. calcd. for $C_{19}H_{13}BN_2O_4$: C 66.28, H 3.78, N 8.14; found: C 65.98, H 3.91, N 8.54.

*2-Phenyl-4′-methylbenzo[*d*]benzo[*h*]-6-aza-1,3-dioxa-2-boracyclonon-6-ene (**2b**)*

Compound **2b** was prepared from **1b** (0.26 g, 1.00 mmol) and phenylboronic acid (0.12 g, 1.00 mmol). The product was obtained as a yellow solid (yield: 0.27 g, 0.86 mmol, 87%), mp 219 to 220°C. MS (70 eV) *m*/*z* (%): 313 (M^+, 9), 268 (1), 236 (100), 165 (1), 102 (2), 77 (6). Anal. calcd. for $C_{23}H_{22}BNO_3$: C 74.39, H 5.93, N 3.77: found C 74.53, H 6.31, N 3.68.

Instrumentation

The X-ray diffraction studies were determined on an Enraf-Nonius CAD4 diffractometer (λ (Mo Kα) = 0.71073 Å, graphite monochromator, *T* = 293 K, ω-2θ scan) and the crystals were mounted in LINDEMAN tubes. Absorption correction was not necessary, corrections were made for Lorentz and polarization effects. Solution and refinement: direct methods (SHELXS 86) for structure solution and SHELXS 97 (34) software package for refinement and data output. Hydrogen atoms were determined by difference Fourier maps and their positions as well as one overall isotropic thermal parameter were refined.

Synthesis and decarboxylation of Δ^2-cephem-4,4-dicarboxylic acids

Saul Wolfe, Stephen Ro, Chan-Kyung Kim, and Zheng Shi

Abstract: Penicillin V was converted in 14 steps into Δ^2-cephems having hydrogen at C-3, hydrogen or methyl at C-2, and two methoxycarbonyl, two benzyloxycarbonyl, or one methoxycarbonyl and one benzyloxycarbonyl substituent at C-4. Deprotection of these Δ^2-cephem-4,4-dicarboxylic acid esters by alkaline hydrolysis (in the case of methyl esters) or hydrogenolysis (in the case of benzyl esters) led in all cases to rapid decarboxylation of the Δ^2-cephem-4,4-dicarboxylic acid or Δ^2-cephem-4,4-dicarboxylic acid monoester. With hydrogen at C-2, hydrolysis of the dimethyl ester with 1 equiv of base produced a Δ^2-cephem. With 2 equiv of base, and with all compounds having methyl at C-2, hydrolysis or hydrogenolysis afforded 4α-substituted-Δ^2-cephems.

In contrast, simpler benzyl or methyl acetamidomalonates could be deprotected without difficulty to afford stable malonic acids. Reasons for the differences in ease of decarboxylation were examined using semiempirical (AM1) and ab initio (3-21G) molecular orbital calculations. The decarboxylation barriers of unionized cephem or acetamido malonic acids were found to be high (35–40 kcal mol^{-1}). Although the monoanion of acetamidomalonic acid retained a high barrier, the epimeric monoanions of a Δ^2-cephem malonic acid decarboxylated with barriers of only 2 kcal mol^{-1}.

Key words: mercaptoazetidinone, bromomalonate esters, MO calculations, sulfoxides, hydrogenolysis.

Résumé : On a transformé la pénicilline V en quatorze étapes en Δ^2-céphèms portant un hydrogène en C-3, un hydrogène ou un méthyle en C-2 et deux méthoxycarbonyles, deux benzoyloxycarbonyles ou un méthoxycarbonyle et un benzoyloxycarbonyle comme substituants en C-4. Le déprotection de ces esters de Δ^2-céphem-4,4-dicarboxylique par hydrolyse alcaline (dans le cas des esters méthyliques) ou par hydrogénolyse (dans les cas des esters benzyliques) conduit dans tous les cas à une décarboxylation rapide de l'acide Δ^2-céphem-4,4-dicarboxylique ou de son monoester. L'hydrolyse de l'ester diméthylique du produit portant un hydrogène en C-2 à l'aide d'un équivalent de base conduit à un Δ^2-céphem. Avec deux équivalents de base ainsi qu'avec tous les composés portant un groupe méthyle en C-2, l'hydrolyse ou l'hydrogénolyse conduit à des Δ^2-céphems portant un substituant en position 4α.

Par ailleurs, il est possible de déprotéger sans difficulté les acétamidomalonates de benzyle ou de méthyle plus simples pour obtenir des acides maloniques stables. Faisant appel à des calculs d'orbitales moléculaires semi-empiriques (AM1) et ab initio, on a étudié les différences dans la facilité de ces décarboxylations. On a trouvé que les barrières à la décarboxylation des acides céphems dicarboxyliques et des acétamidomaloniques non ionisés sont relativement élevées (35-40 kcal/mol). Même si la barrière est encore élevée pour le monoanion de l'acide acétamidomalonique, les monoanions épimères d'un acide Δ^2-céphem malonique se décarboxylent avec une barrière qui n'est que d'environ 2 kcal mol^{-1}.

Mots clés : mercaptoazétidinone, esters de l'acide bromomalonique, calculs OM, sulxoydes, hydrogénolyse.

Introduction

The antibacterial activity of the Δ^2-cephem-4α-carboxylic acid **1** is 100 times less than that of the Δ^3-cephem **2** (1). Since cephalosporins undergo $\Delta^3 \rightleftarrows \Delta^2$ equilibration in solution to give mixtures in which the 4α-carboxy-Δ^2-isomers (**3a**) usually predominate (2), there is a resultant loss of activity, and the origin of this loss of activity has received considerable attention (3).

The cephalosporin receptor is a serine peptidase whose active site hydroxyl group is acylated by the β-lactam ring (4). Most workers accept that this chemical reaction proceeds by deprotonation of the serine OH, coupled to nucleophilic addition of the resulting anion to the β-lactam carbonyl group (5). In terms of this mechanism, the decrease in antibacterial activity that accompanies the isomerization to **3a** would be a consequence of the decreased susceptibility of the β-lactam carbonyl group of a Δ^2-cephem towards nucleophilic attack. Indeed **1** is most readily obtained by *alkaline hydrolysis* of the methyl ester of **2** (6).

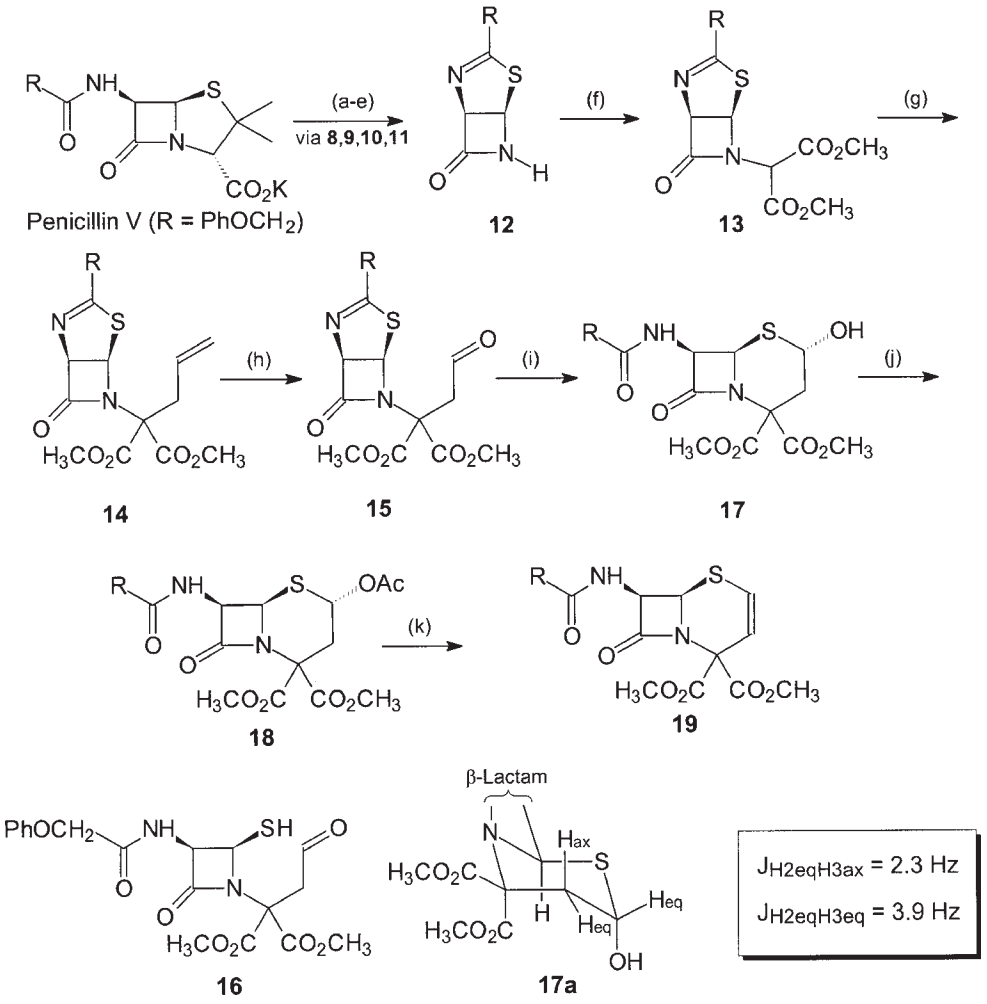
However, in the case of an exocellular peptidase from *Streptomyces* R61, which has been studied in some detail (7), including a crystal structure (8), the catalytic efficiencies towards 6-aminopenicillanic acid, cephaloglycine and penicillin G are 0.2, 22, and 13 000, respectively, but the corresponding second-order rate constants for alkaline hydrolysis of the β-lactam rings of these compounds are 0.15, 0.90, and 0.50 M^{-1} s^{-1} (7). The absence of any correlation between the trends in the enzymatic and nonenzymatic rate constants is not consistent with the claim that the acyl-enzyme is formed by nucleophilic addition to the β-lactam carbonyl group.

In a different approach to the problem, following an examination of the crystal structures of active and inactive β-lactam compounds, Cohen (9) proposed that **3a** are inactive as a consequence of a misfit with the receptor, and suggested that their 4β-carboxy epimers (**3b**) would exhibit a better fit, with restored activity. However, the activity of a Δ^2-cephem-4β-carboxylic acid proved to be less than that of its 4α-epimer (10).

Independently, structure-activity studies and calculations by Wolfe and Hoz (11) led to the proposal that **3a** react more rapidly than Δ^3-cephems with the hydroxyl group of the peptidase receptor, but are less effectively complexed; in addition, in agreement with Cohen, it was suggested that epimerization to **3b** would lead to improved complexation with the receptor, at the expense of an inherent decrease in reactivity with the serine hydroxyl group.

These findings led to the idea that the presence of the 4β-carboxyl group in a Δ^2-cephem-4,4-dicarboxylic acid such as **4** might allow effective complexation to the peptidase, and the concurrent presence of the 4α-carboxyl group might enhance the rate of the acylation step, the two effects together leading to enhanced antibacterial activity in a Δ^2-cephem. The work reported here was undertaken to test this idea. Although it was known that the malonate **5** had yielded only the decarboxylated product **6** following alkaline hydrolysis and acidification (12), that reaction mixture was maintained at pH 2 for 1 h prior to the isolation of the product. It was hoped that decarboxylation could be avoided in the present work by the elimination of an extended acidic treatment following the deprotection of a Δ^2-cephem-4,4-dicarboxylic acid diester.



Syntheses of substrates

Malonyl-substituted thiazoline-azetidinones of type **7** have often been reported in the literature (13), usually as intermediates in syntheses requiring the attachment of an acetate chain to the β-lactam nitrogen. By virtue of its acidic α-proton, **7** also serves as a potential branch point for the construction of a new ring. The conversion of penicillin V into the Δ^2-cephem **19** is summarized in Scheme 1. Scheme 2 summarizes a different sequence leading to the 2-methyl-Δ^2-cephems **24**.

In Scheme 1, dimethyl bromomalonate, prepared by irradiating a solution of bromine and dimethyl malonate, was reacted with the thiazoline azetidinone **12** (14) in the presence of benzyl trimethylammonium hydroxide (Triton B) to give **13** in 50% yield. Coupling with allyl bromide in the presence of Triton B or sodium hydride produced **14** which, upon ozonolysis and treatment with dimethyl sulfide afforded an aldehyde (**15**) in quantitative yield. Exposure of this aldehyde to 3% perchloric acid in a 1:1 solution of dichloromethane–acetone (15), led to hydrolysis to the mercaptoazetidinone **16**, followed by cyclization to the hydroxycepham **17** in 94% from **14**.

Scheme 1. Reagents and conditions: (*a*) CH_3I, DMF; (*b*) AcOH, H_2O_2, CH_2Cl_2; (*c*) $P(OMe)_3$, $MgSO_4$, toluene; (*d*) Et_3N; (*e*) $KMnO_4$, $MgSO_4$, EtOH; (*f*) Triton B, $BrCH(CO_2CH_3)$, DMF, –50 to 20°C; (*g*) Triton B or NaH, allyl bromide; (*h*) O_3, CH_2Cl_2-CH_3OH, –78°C, then Me_2S; (*i*) $HClO_4$, CH_2Cl_2–acetone; (*j*) Ac_2O, H_2SO_4, AcOH; (*k*) pTsOH, toluene, Δ.

The configuration at C-2 and the conformation of the six-membered ring of **17** (see **17a**) were evident from the ^1H NMR spectrum, which showed J_{H2H3} and $J_{H2H3'}$ = 2.3 and 3.9 Hz, respectively. The axial orientation of the hydroxyl group is evidence of an S-C-O Edward–Lemieux effect (16).

The dehydration of **17** was unexpectedly difficult and was best achieved in 52% yield by acetylation to **18**, followed by heating with *p*-toluenesulfonic acid in refluxing toluene.

In Scheme 2, the dimethyl malonate **14** and its dibenzyl ester and mixed methyl benzyl ester analogs, prepared by the reaction of **12** with the appropriate bromomalonate followed by allylation, were treated with iodine in a mixture of methylene chloride and water to give the 2β-substituted iodomethylcephams **20** (13). In each case, the configuration at C-2 and the conformation shown in **20a** could be assigned on the basis of a positive NOE between H_2 and H_6, and from H_2H_3 coupling constants of 1.9 and 12.2 Hz.

At this point, the synthetic plan called for dehydrohalogenation of **20** to **23**, and isomerization to **24**. However, exposure of **20** to sodium hydride or 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) or Triton B produced complex mixtures. To circumvent the possibility that this was the result of participation by sulfur in the elimination of iodide, the iodomethylcephams were first oxidized to the sulfoxides **21** using sodium periodate in aqueous methanol. Dehydrohalogenation with DBU now proceeded smoothly to give the exomethylene sulfoxides **22**, which afforded the exomethylene cephams **23** following reduction with phosphorus tribromide. Isomerization to **24** was achieved using trifluoroacetic acid.

In the case of the epimeric methyl benzyl esters (R_1 = Me, R_2 = CH_2Ph), which were formed in a 1:1 ratio in the coupling with **12**, separation was achieved at the stage of the exomethylene sulfoxide **22**. Since 2D-NOESY experiments were inconclusive in allowing configurations to be assigned to the epimers of **22**–**24**, the technique of aromatic solvent-induced shifts (ASIS) (17) was applied to **24**. Changing the solvent from deuterated chloroform to benzene leads to an upfield chemical shift of atoms or groups on the convex (α) face of the molecule, because the V-shaped bicyclic ring system blocks access of the solvent to the concave (β) face.

As seen in Table 1, except for H_3, the change from chloroform to benzene leads to an upfield shift of the protons. The data suggest that epimer A has the benzyl ester on the α face and that epimer B has the methyl ester on the α face.

To corroborate these conclusions, ASIS measurements were performed on a compound of known stereochemistry, the methyl ester of penicillin V. In deuterated chloroform,

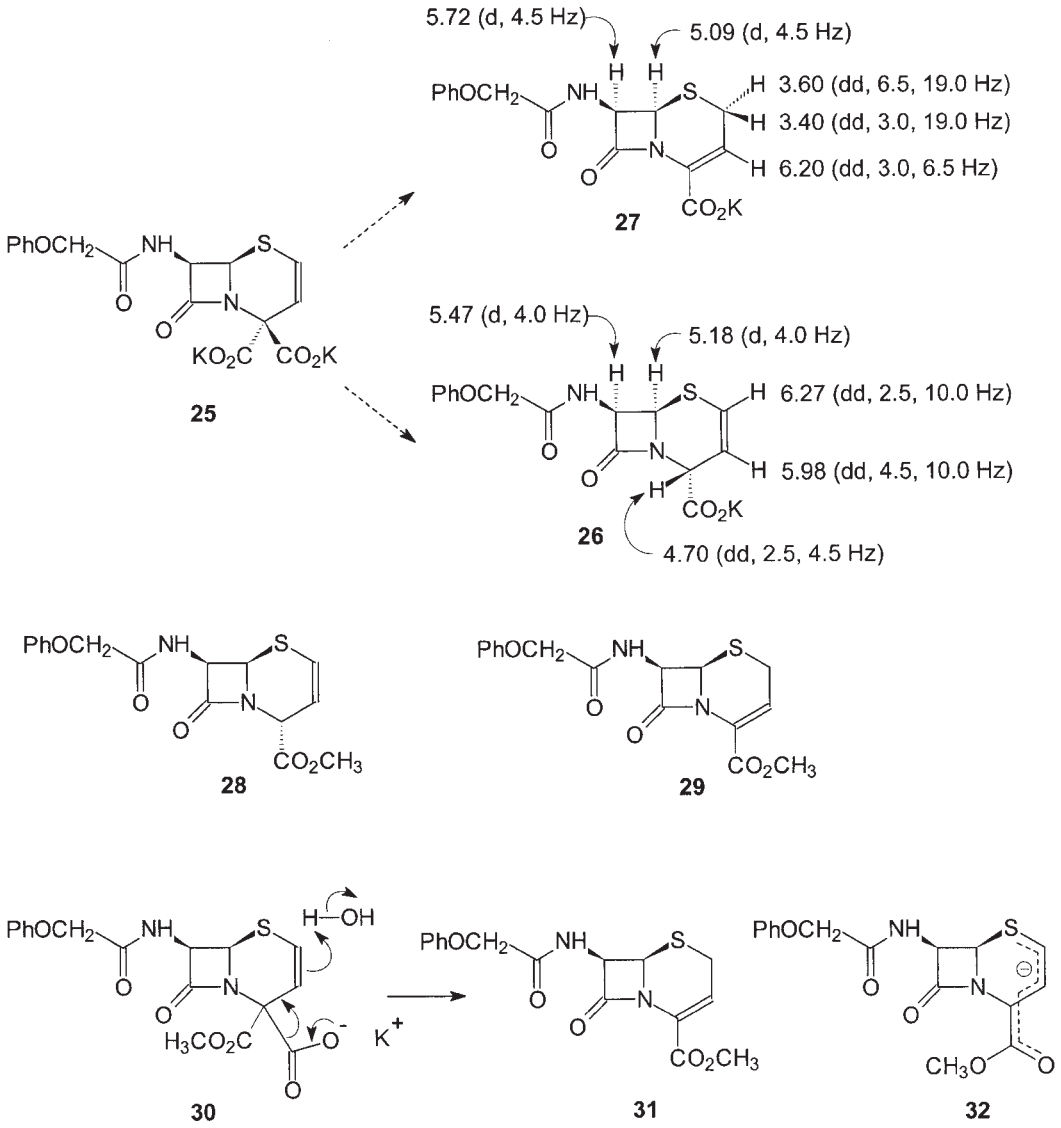
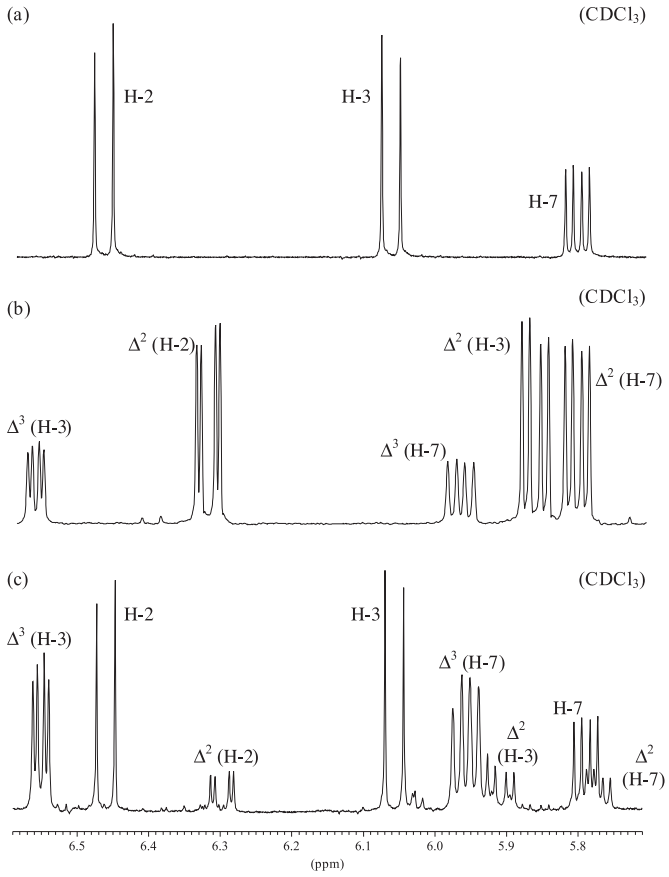
the ester methyl group, which occupies the convex face of the molecule, is found at 3.76 ppm. In deuterated benzene the chemical shift is 3.20 ppm, a difference of 0.56 ppm. The corresponding difference in epimer B is 0.50 ppm.



Deprotection of the Δ^2-cephem-4,4-dicarboxylic acid esters

Alkaline hydrolysis of 19

In an initial set of experiments, **19** was treated at –8°C with 2 equiv of potassium hydroxide in aqueous pyridine, and the solvent was then removed under reduced pressure below 30°C. This afforded a product that exhibited significant antibacterial activity against a penicillin-sensitive strain of *Staphylococcus aureus*. However, the product was not the malonate salt **25**. As seen in **26** and **27**, the ^{1}HMR spectrum (in D_2O) was that of a mixture of *decarboxylated* Δ^2- and Δ^3-cephems. Cephems of type **27**, having hydrogen at C-3, are known to be active, and one of these, ceftizoxime, is a widely used antibiotic (18).



Following these initial experiments, subsequent hydrolyses were performed with a minimum of manipulation: reaction mixtures were acidified, and the products quickly extracted into an appropriate organic solvent and esterified with diazomethane. Using this protocol, the reaction of **19** with *2* equiv of potassium hydroxide produced a 7:1 mixture of decarboxylated Δ^2- and Δ^3-cephem esters (**28** and **29**, respectively). However, *1* equiv of potassium hydroxide reversed the **28**:**29** ratio to 1:4 (see Fig. 1).

These results suggest that a carboxylate anion **30**, formed in the first hydrolysis step, undergoes rapid decarboxylation concerted with a shift of the double bond, as depicted in **30** → **31**. Subsequently, C-2 deprotonation of **31**, leading, via **32**, to the more stable Δ^2-isomer **28**, competes with the hydrolysis of the second ester.

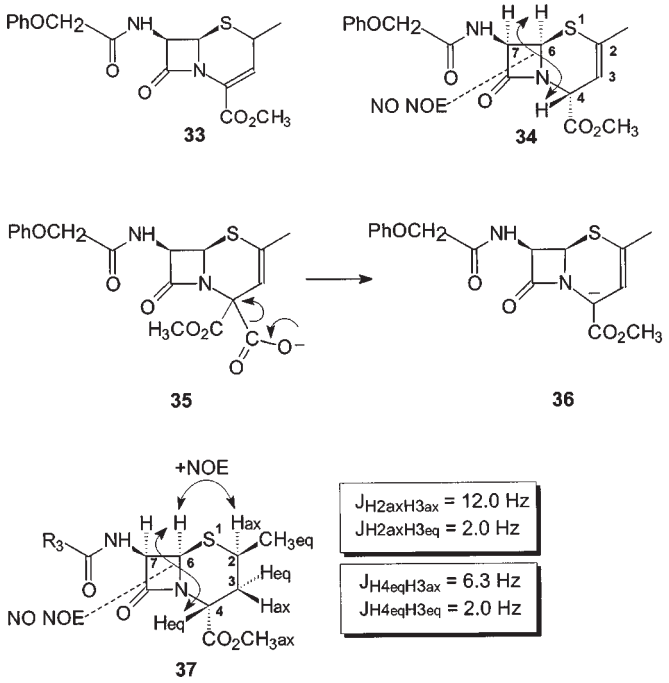
Fig. 1. (*a*) The 5.5–6.6 ppm region in the ^{1}H NMR spectrum of **1**; (*b*) spectrum of a mixture of **28** and **29**; (*c*) after exposure of **19** to 1 equiv of KOH in aqueous pyridine.

Alkaline hydrolysis of 24 ($R_1 = R_2 = Me$)



The foregoing analysis suggested that the introduction of an electron-releasing C-2-methyl group, as in **24**, might affect the results of alkaline hydrolysis in two ways: preferably, the concerted decarboxylation pathway that is presumed to cause the lability of the Δ^2-cephem-4,4-dicarboxylic acid would become disfavoured; alternatively, if this is not the case and the initial product is again a Δ^3-ester (**33**), this ester should resist isomerization of the double bond, because C-2 deprotonation leading to the more stable Δ^2-ester **34** would be disfavoured.

In the event, the hydrolysis of the dimethyl ester (**24**, $R_1 = R_2 = Me$) with either 1 or 2 equiv of potassium hydroxide in aqueous pyridine, followed by the usual work-up, afforded the *same* product in each case, the Δ^2-cephem **34**.

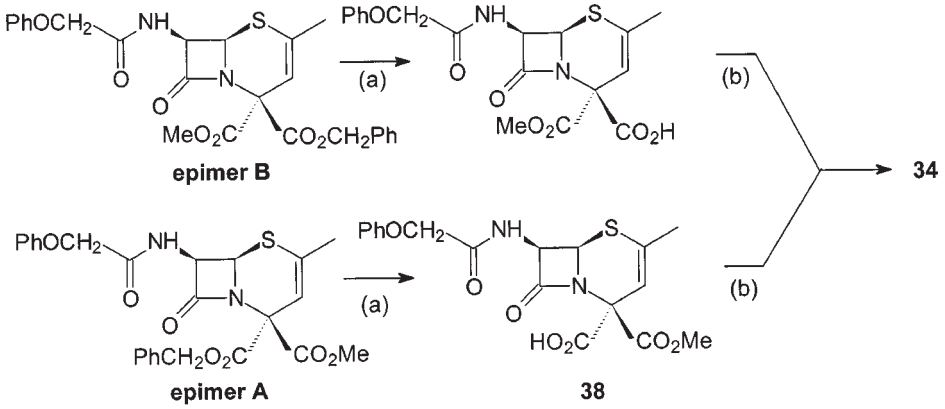
The simplest explanation of these results is that the carboxylate anion **35** decarboxylates rapidly to **36**. Although the concerted decarboxylation pathway leading initially to the Δ^3-isomer is disfavoured, the presence of the C-2-methyl group leads to direct decarboxylation to the Δ^2-isomer as the predominant pathway. An alternative explanation is that, despite our expectations regarding the kinetic acidity of **33**, under alkaline conditions the introduction of the C-2-methyl group somehow *enhances* the $\Delta^3 \rightarrow \Delta^2$ rearrangement. This point was addressed using the dibenzyl ester **24** ($R_1 = R_2 = CH_2Ph$).

Hydrogenolysis of 24 ($R_1 = R_2 = CH_2Ph$)

Experiments were performed using 10% palladium on carbon, in aqueous ethanol containing 2 equiv of sodium bicarbonate (Method A), and in aqueous acetic acid (pH 4 to 5) (Method B). Products were isolated by filtration through Celite, followed by evaporation or lyophilization and conversion to the methyl ester. This led, in ethanol, to the Δ^2-ester **34** as the sole product (>90%). In acetic acid, the products were **34** and the *cepham* **37**, whose stereochemistry was elucidated from the H_2H_3 coupling constants, a positive NOE between H_2 and H_6 and the absence of an NOE between H_4 and H_6.

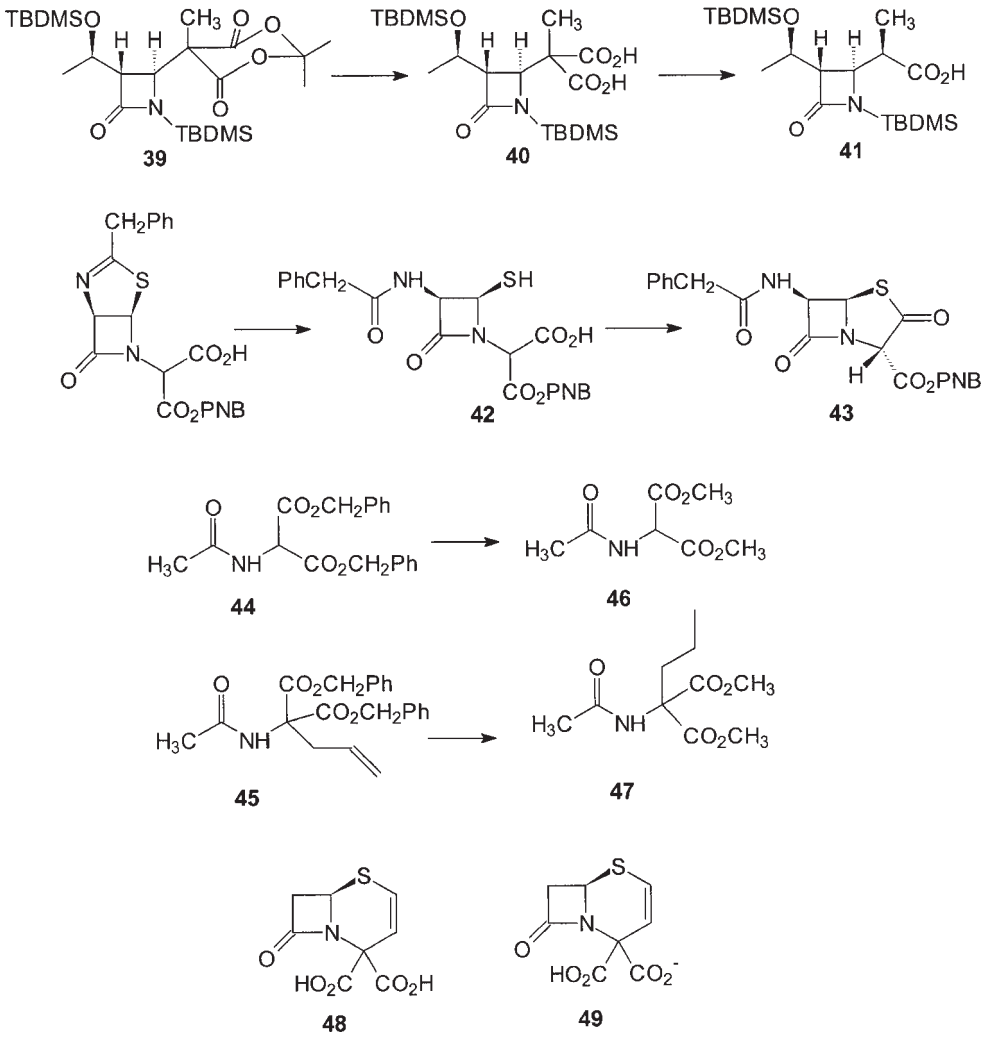
Thus, in contrast to the C-2-unsubstituted diester **19**, which, following the exposure of one carboxyl group, decarboxylates with rearrangement of the double bond, in the case of the C-2-methylated esters there is rapid decarboxylation *without rearrangement of the double bond*.

Hydrogenolysis of the epimeric methyl benzyl esters 24 (R_1, R_2 = Me, CH_2Ph)



As summarized in Scheme 3, hydrogenolysis using Method B resulted in decarboxylation with the formation of **34** in both cases. Carbanion **36** is implicated as an intermediate in these reactions since the decarboxylation of **38** proceeds with inversion of configuration at C-4. The pK_1 of malonic acid is 2.85 at 298 K (19), so that in aqueous acetic acid the Δ^2-cephem-4,4-dicarboxylic acid **38** would be fully ionized.

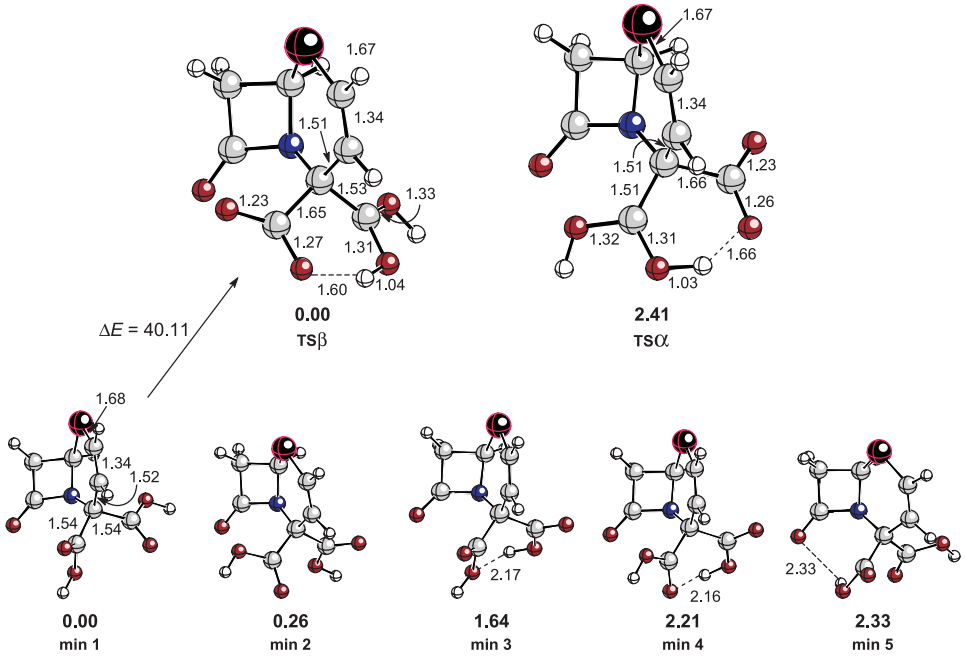
Preparation and deprotection of acetamidomalonate esters



There are numerous examples of stable β-lactam-containing malonic acids (20). The Meldrum acid derivative **39** hydrolyzes under basic conditions to give the malonic acid **40**, whose decarboxylation to **41** requires refluxing ethyl acetate in the presence of formic acid. The malonic

© 2001 NRC Canada

Scheme 3. Reagents and conditions: (*a*) H_2, Pd/C, HOAc–H_2O; (*b*) CH_2N_2, CH_2Cl_2–EtOH, 0°C.



acid **42** can be isolated and converted to the penam **43**. Based on these precedents, the rapid decarboxylation observed in all cases following deprotection of **19** and **24** was unexpected. In an effort to understand this result, the dibenzyl acetamidomalonates **44** and **45** were synthesized (see *Experimental*) and subjected to hydrogenolysis followed by esterification with diazomethane. The products, isolated in 81% and 82% yields, respectively, were the dimethyl malonates **46** and **47**. Subsequent experiments established that the malonic acid precursors of **46** and **47** could be maintained at room temperature for at least 24 h without noticeable decomposition.

Fig. 2. Neutral decarboxylation of **48** (AM1 calculations). **Min 1**–**min 5** are the five lowest energy structures of the diacid; TSα and TSβ are the transition structures for α- and β-decarboxylation. Energies are in kcal mol^{-1}, relative to **min 1** and TSβ.

Theoretical considerations

The reasons for the differences in ease of decarboxylation were examined using semiempirical and ab initio molecular orbital calculations. With AM1 (21), calculations on 4,4-dicarboxy-Δ^2-cephem (**48**) yielded 5 minima corresponding to torsion within the carboxyl groups. The most stable structure (**min 1**) and the least stable structure (**min 5**) differ in energy by 2.3 kcal mol^{-1} (Fig. 2). The two most stable structures (**min 1** and **min 2**) have the *Z*-conformation (22). The next two (**min 3** and **min 4**) have one carboxyl group in the *Z*-conformation and other in the *E*-conformation. The least stable structure (**min 5**) has both carboxyl groups in the *E*-conformation.

The transition structures **TS**α and **TS**β, calculated for the decarboxylation of the α- and β-carboxyl groups of **48** are included in Fig. 2. The β-decarboxylation barrier, corresponding to decarboxylation from the concave face of the molecule, is lower by 2.4 kcal mol^{-1}.

The transition structures are late, as proton transfer is almost complete. The barrier, calculated from **min 1** is 40.1 kcal mol^{-1}. In Bach's high level ab initio calculations (23), malonic acid was found to have a decarboxylation barrier of 33.2 kcal mol^{-1}. The experimental barrier is 30.8 kcal mol^{-1} (23). Since the calculated neutral barriers are high, the facile decarboxylations observed experimentally cannot be attributed to the decarboxylation of a 4,4-dicarboxy-Δ^2-cephem or its monoester.

On the other hand, the α- and β-decarboxylation barriers of the monoanions **49** (Fig. 3) are vanishingly small (2.04 and 2.08 kcal mol^{-1}, respectively).

Figures 4 and 5 show the results of ab initio (3-21G) calculations of the decarboxylation barriers of acetamidomalonic acid (35.2 kcal mol^{-1}) and its monoanion (26.3 kcal mol^{-1}). The barrier decreases in the anion, but does not become vanishingly small. It is noteworthy that the monoanion of phenylmalonic acid decarboxylates 3 to 4 times faster than the undissociated acid (24).

The calculations are consistent with experiment: the undissociated cephem and acetamidomalonic acids have comparable (high) decarboxylation barriers, which disappear in the case of the cephem monoanions. Since these anions would be fully formed at pH > 3 in water solvent, it does not appear possible to test the prediction that 4,4-dicarboxy-Δ^2-cephems will have significant antibacterial activity.

Experimental

General

All reactions were performed under dry nitrogen using oven-dried (140°C, 24 h) glassware. The glassware was allowed to cool in a desiccator under vacuum and assembled cold, capped with rubber septa, and evacuated with dry nitrogen gas. Solvents were distilled prior to use and dried, as necessary, by literature procedures (25). Diazomethane was prepared by treatment of a cold solution of *N*-methyl-*N*-nitrosotoluene-4-sulfonamide (DIAZALD) in 95% ethanol with 1.0 mL portions of 12.5 M sodium hydroxide. Both ^{1}H and ^{13}C nuclear magnetic resonance (NMR) spectra were recorded on a Bruker Model AMX 400 Spectrometer operating at 400.1 MHz and 100.6 MHz, respectively. Chemical shifts (δ) are reported in parts per million (ppm) relative to tetramethylsilane (TMS) in an appropriate deuterated solvent. Infrared (IR) spectra were obtained on a Bomen–Hartmann–Braun spectrometer (1% KBr or 1% solution). High-resolution mass spectra refer to either direct inlet electron impact (EI) measurements or chemical ionization (CI) measurements, using isobutane, and were provided by Dr. G. Eigendorf at the University of British Columbia. Low-

Carlo Erba model 1106 elemental analyzer at Simon Fraser University.

Penicillin V methyl ester (8)

Methyl iodide (14.0 mL, 31.9 g, 225 mmol) was added dropwise, with stirring, to a suspension of penicillin V (77.0 g, 198 mmol) in dimethylformamide (400 mL). Stirring was continued at room temperature for 17 h. The solvent was then removed under reduced pressure, and the residual oil was diluted with dichloromethane (300 mL), washed successively with water (4 × 150 mL), and saturated sodium chloride (300 mL), dried over magnesium sulfate and evaporated to give the product as an orange oil (72.3 g, 94%), which crystallized upon trituration with ether; mp 60 to 61°C. $[\alpha]_D^{20}$ +124.1° (c 0.137, $CHCl_3$). Mass spectrum (CI, *m*/*z*): 365 (M+1). IR (KBr) (cm^{-1}): 3366, 1786, 1744, 1701. ^1H NMR ($CDCl_3$): 7.35 (4H, t, Ar + NH), 7.05 (1H, t, Ar), 6.94 (1H, d, Ar), 5.75 (1H, dd, 4.3, 9.3 Hz, H-6), 5.59 (1H, d, 4.3 Hz, H-5), 4.57 (1H, d, 15.1 Hz, CHH), 4.55 (1H, d, 15.1 Hz, CHH), 4.47 (1H, s, H-3), 3.78 (3H, s, ester CH_3), 1.60 (3H, s, CH_3), 1.49 (3H, s, CH_3). ^{13}C NMR ($CDCl_3$): 172.96 (acetamido C=O), 168.04 (β-lactam C=O), 167.87 (ester C=O), 157.11, 129.86, 122.47, 114.20 (aromatic), 70.57 (C-3), 67.85 (C-5), 67.38 ($PhOCH_2$), 64.79 (C-2), 58.23 (C-6), 52.35 (CO_2CH_3), 31.91 (CH_3), 26.91 (CH_3). Anal. calcd. for $C_{17}H_{20}N_2O_5S$: C 56.03, H 5.53, N 7.69; found: C 55.75, H 5.55, N 7.59.

Penicillin V methyl ester sulfoxide (9)

Hydrogen peroxide (34.0 mL of 50%, 17.0 g, 500 mmol) was added, with stirring during 1 h, to a solution of penicillin V methyl ester (72.3 g, 198 mmol) in dichloromethane (800 mL) and glacial acetic acid (92 mL). Stirring was continued for 17 h, and the yellow solution was then washed successively with saturated sodium bicarbonate (2 × 200 mL), water (2 × 200 mL), and saturated sodium chloride (400 mL), dried over magnesium sulfate and evaporated. The resulting yellow foam crystallized upon treatment with hot methanol (150 mL). The product was collected and washed with cold methanol (40 mL) to give 76.4 g (78%) of the methyl ester of penicillin V sulfoxide; mp 118–120°C (lit. (27) mp 121.5 to 122.5°C). $[\alpha]_D^{20}$ +202.7° (c 0.148, $CHCl_3$). Mass spectrum (CI, *m*/*z*): 381 (M+1). IR (KBr) (cm^{-1}): 3380, 1802, 1757, 1694, 1065. ^1H NMR ($CDCl_3$): 8.26 (1H, d, 10.4 Hz, NH), 7.29 (2H, m, Ar), 7.01 (1H, t, Ar), 6.94 (2H, d, Ar), 6.09 (1H, dd, 4.6, 10.5 Hz, H-6), 5.04 (1H, d, 4.6 Hz, H-5), 4.68 (1H, s, H-3), 4.53 (2H, s, $PhOCH_2$), 3.82 (3H, s, ester CH_3), 1.73 (3H, s, 2-CH_3), 1.22 (3H, s, shows nOe with H-5 at 5.04 ppm, 2-CH_3). ^{13}C NMR ($CDCl_3$): 173.08 (acetamido C=O), 168.30 (β-lactam, ester C=O), 157.20, 129.72, 122.26, 115.02 (aromatic), 76.57 (C5), 75.32 (C2), 67.29 ($PhOCH_2$), 66.55 (C-3), 55.67 (C-6), 52.91 (ester CH_3), 19.44 (CH_3), 18.73 (CH_3). Anal. calcd. for $C_{17}H_{20}N_2O_6S$: C 53.67, H 5.30, N 7.36; found: C 53.30, H 5.30, N 7.36.

Rearrangement of penicillin V sulfoxide

Trimethylphosphite (70.0 mL, 73.6 g, 593 mmol) was added to a mixture of penicillin V methyl ester sulfoxide (53.0 g, 139 mmol) and anhydrous magnesium sulfate (33.0 g, 274 mmol) in benzene (1100 mL). The reaction mixture was refluxed overnight, with stirring, and then cooled and filtered through Celite. The filtrate was concentrated under reduced pressure, using a Javex trap, to afford a yellow oil having a crude weight of 68 g (140%). Purification by column chromatography, using ethyl acetate – hexanes (1:1), afforded **10** as a white solid (43.9 g, 87%), mp 56–58°C. $[\alpha]_D^{20}$ –165.6° (c 0.157, $CHCl_3$). Mass spectrum (CI, *m*/*z*): 347 (M+1). IR (KBr) (cm^{-1}): 1765, 1738. ^1H NMR ($CDCl_3$): 7.28 (2H, t, Ar), 7.00 (1H, t, Ar), 6.93 (2H, d, Ar), 6.01 (1H, dt, 1.2, 4.1 Hz, H-3), 5.93 (1H, d, 4.2 Hz, H-4), 5.10 (1H, q, 1.4 Hz, allylic H), 4.97 (1H, dd, 1.4, 14.6 Hz, C*H*H), 4.92 (1H, br s, =CH*H*), 4.91 (1H, dd, 1.4, 14.6 Hz, C*H*H), 4.84 (1H, br s, =CH*H*), 3.76 (3H, s, ester CH_3), 1.75 (3H, br s, CH_3). ^{13}C NMR ($CDCl_3$): 173.23 (thiazoline N=C), 169.30 (ester C=O), 165.02 (β-lactam C=O), 157.73, 129.64, 121.97, 114.84 (aromatic), 134.67 (*C*H_2=CH), 117.46 (CH_2=*C*CH_3), 92.25 (C-3), 67.78 ($PhOCH_2$), 67.21 (C-4), 58.86 (*C*HCO_2CH_3), 52.52 (CO_2CH_3), 21.52 (CH_2=C*C*H_3). Anal. calcd. for $C_{17}H_{18}N_2O_4S$: C 58.94, H 5.24, N, 8.09; found: C 59.27, H 5.26, N 7.78.

Isomerization of 10

Triethylamine (8.5 mL, 61 mmol) was added dropwise, with stirring, to a solution of **10** (48.3 g, 140 mmol) in dichloromethane (270 mL). The solution was stirred for 3 h, and the solvent was then evaporated under reduced pressure. The residue crystallized from warm methanol to give 30.1 g (62%) of **11**, mp 64–66°C. $[\alpha]_D^{20}$ +24.4° (c 0.205, $CHCl_3$). Mass spectrum (CI, *m*/*z*): 347 (M+1). IR (KBr) (cm^{-1}): 1759, 1723, 1643, 1597. ^1H NMR ($CDCl_3$): 7.26 (2H, m, Ar), 6.99 (1H, t, Ar), 6.94 (2H, d, Ar), 6.06 (1H, dt, 1.2, 4.0 Hz, H-3), 5.87 (1H, d, 4.0 Hz, H-4), 4.99 (1H, dd, 1.2, 14.3 Hz, C*H*H), 4.93 (1H, dd, 1.2, 14.3 Hz, CH*H*), 3.75 (3H, s, ester CH_3), 2.22 (3H, s, =CCH_3), 1.76 (3H, s, =CCH_3). ^{13}C NMR ($CDCl_3$): 172.09 (thiazoline N=C), 163.76 (β-lactam C=O), 163.37 (ester C=O), 157.74, 129.67, 122.03, 114.86 (aromatic), 155.79 (NC=C$(CH_3)_2$), 118.72 (N*C*=C$(CH_3)_2$), 92.70 (C-3), 69.51 (C-4), 67.74 ($PhOCH_2$), 51.90 (CO_2CH_3), 23.77, 21.88 (C=C(*C*$H_3)_2$). Thiazoline azetidinone (12)

A solution of potassium permanganate (12.2 g, 77 mmol) and magnesium sulfate (8.41 g, 70 mmol) in water (480 mL) was added during 80 min to a solution of **11** (30.1 g, 87 mmol) in 95% ethanol (600 mL). Additional potassium permanganate (5 × 3.6 g, 114 mmol) was subsequently added every 10 min. The solvent was then removed under reduced pressure, and the brown residue was shaken with ethyl acetate (720 mL) and water (360 mL), and filtered. The organic layer was separated and the aqueous phase was extracted with ethyl acetate (3 × 100 mL). The combined organic extracts were washed with saturated sodium chloride (1000 mL), dried over magnesium sulfate, and evaporated. The residue was treated with hot ethyl acetate to give **12** as yellowish-white crystals (15.9 g, 78%), mp 157 to 158°C (lit. (27) mp 157 to 158°C). $[\alpha]_D^{20}$ +121.4° (c 0.14, $CHCl_3$). Mass spectrum (CI, *m*/*z*): 235 (M+1). IR (KBr) (cm^{-1}): 3216, 1757, 1719. ^1H NMR ($CDCl_3$): 7.29 (2H, m, Ar), 7.02

Dimethyl bromomalonate (28)

Bromine (1.8 mL, 5.58 g, 35 mmol) was added dropwise with stirring, during 60 min, to a solution of dimethyl malonate (3.46 mL, 4.0 g, 35 mmol) in carbon tetrachloride (15 mL), with irradiation by a 150 W bulb mounted beneath the reaction vessel. When the evolution of gas had ceased, water (50 mL) was added and the phases were separated. The aqueous layer was extracted with chloroform (2 × 40 mL) and the combined organic extracts were washed successively with saturated sodium bicarbonate (2 × 75 mL) and saturated sodium chloride (100 mL), dried over magnesium sulfate, and evaporated. The residue was distilled, and the fraction boiling at 105–108°C and 11 torr (1 torr = 133.322 Pa) was collected as a colourless oil (5.02 g, 62%). ^{1}H NMR ($CDCl_3$): 4.85 (1H, s, CH), 3.83 (6H, s, CH_3).

Dibenzyl malonate

Concentrated sulfuric acid (0.2 mL of 96%, 0.2 g, 1.96 mmol) was slowly added to a suspension of malonic acid (20.1 g, 193 mmol) and benzyl alcohol (47.0 mL, 49.1 g, 454 mmol) in toluene (70 mL). Employing a Dean–Stark trap, the mixture was heated to reflux for 2 h, and approximately 7 mL of water were removed. The solution was cooled, diluted with ethyl acetate (100 mL), and washed successively with saturated sodium bicarbonate (2 × 100 mL), water (2 × 100 mL) and saturated sodium chloride (100 mL), dried over magnesium sulfate, and evaporated. The residue was distilled, and the fraction boiling at 188°C and 0.2 torr (1 torr = 133.322 Pa) was collected as a colourless oil (50.0 g, 91%). Mass spectrum (EI, *m*/*z*): 285 (M). IR (neat) (cm^{-1}): 1745. ^{1}H NMR ($CDCl_3$): 7.35–7.32 (10H, m, Ar), 5.18 (4H, s, benzyl CH_2), 3.48 (2H, s, malonyl CH_2).^{13}C NMR ($CDCl_3$): 166.18 (ester C=O), 135.34, 128.59, 128.41, 128.27 (aromatic), 67.26 ($PhCH_2O$), 41.61 ($COCH_2CO$).

Dibenzyl bromomalonate (20*a*, 29)

With irradiation by a 250 W bulb mounted beside the reaction vessel, bromine (6.5 mL, 20.2 g, 126 mmol) was added dropwise during 2 h, with stirring, to a solution of dibenzyl malonate (19.6 g, 69.0 mmol) in carbon tetrachloride (51 mL). Water (50 mL) was then added and the layers were separated. The aqueous layer was extracted with dichloromethane (2 × 40 mL) and the combined organic extracts were washed successively with saturated sodium bicarbonate (2 × 75 mL) and saturated sodium chloride (100 mL), dried over magnesium sulfate, and evaporated. The oily residue (22.0 g) was purified by column chromatography using ethyl acetate – hexanes (1:8) to yield 6.91 g (28%) of the product as a colourless oil, which solidified in the freezer as white crystals, mp 26 to 27°C. IR (neat) (cm^{-1}): 1744. ^{1}H NMR ($CDCl_3$): 7.36–7.30 (10H, m, Ar), 5.22 (4H, s, benzyl CH_2), 4.92 (1H, s, CH). ^{13}C NMR ($CDCl_3$): 164.28 (ester C=O), 134.58–128.29 (aromatic), 68.72 ($PhCH_2O$), 42.20 ($COCHBrCO$). Anal. calcd. for $C_{17}H_{15}O_4Br$: C 56.22, H 4.16; found: C 55.84, H 4.09.

Benzyl methyl bromomalonate

Dimethyl malonate (10 mL, 11.56 g, 87.5 mmol), in methanol (70 mL), was treated with a solution of potassium hydroxide (4.89 g, 87.2 mmol) in methanol (70 mL). The solution was stirred for 24 h, then refrigerated overnight. The white crystals were filtered, rinsed with cold methanol, and dried to give 9.72 g (65%) of potassium methyl malonate, mp 160–162°C (dec). Mass spectrum (CI, *m*/*z*): 103 (M+1-(K+CH_3)). IR (KBr) (cm^{-1}): 1738, 1728. ^{1}H NMR (D_2O): 3.56 (3H, s, CH_3), 3.15 (2H, s, CH_2). ^{13}C NMR (D_2O): 176.78 (carboxyl C=O), 174.80 (ester C=O), 55.36 (CO_2CH_3). Anal. calcd. for $C_4H_5O_4K$: C 30.76, H 3.23; found: C 30.69, H 3.19.

Benzyl bromide (3.8 mL, 5.46 g, 31.9 mmol) was added to a suspension of potassium methyl malonate (5.63 g, 32.7 mmol) in dimethylformamide (80 mL). The mixture was stirred for 22 h, diluted with ethyl acetate (150 mL), washed with water (3 × 150 mL), dried over magnesium sulfate, and evaporated to give benzyl methyl malonate as a colourless oil (6.47 g, 97%). IR (neat) (cm^{-1}): 1755, 1732. Mass spectrum (CI, *m*/*z*): 209 (M+1). ^{1}H NMR ($CDCl_3$): 7.36 (5H, m, Ar), 5.19 (2H, s, $PhCH_2$), 3.74 (3H, s, CH_3), 3.44 (2H, s, malonyl CH_2). ^{13}C NMR ($CDCl_3$): 166.83 (ester C=O), 166.31 (ester C=O), 135.42, 128.60, 128.42, 128.25 (aromatic), 67.18 (CO_2CH_2Ph), 52.41 (CO_2CH_3), 41.30 (malonyl CH_2). Anal. calcd. for $C_{11}H_{12}O_4$: C 46.01, H 3.86; found: C 46.03, H 3.88.

With irradiation by a 150 W Westinghouse reflector spotlight mounted underneath the reaction vessel, bromine (2.7 mL, 8.38 g, 52.4 mmol) was added dropwise during 60 min, with stirring, to a solution of benzyl methyl malonate (11.0 g, 52.8 mmol) in carbon tetrachloride (40 mL). Once the evolution of gas had ceased, water (40 mL) was added and the phases were separated. The aqueous layer was extracted with chloroform (2 × 40 mL) and the combined organic extracts were washed with saturated sodium bicarbonate (2 × 120 mL) and saturated sodium chloride (120 mL), dried over magnesium sulfate, and evaporated. The residue was purified by column chromatography using ethyl acetate – hexanes (30:70) to give the product as a colourless oil (10.3 g, 68%). Mass spectrum (CI, *m*/*z*): 287, 289 (M+1). IR (neat) (cm^{-1}): 1767, 1746. ^{1}H NMR ($CDCl_3$): 7.36 (5H, m, Ar), 5.25 (2H, s, $PhCH_2$), 4.89 (1H, s, malonyl CH), 3.80 (3H, s, CH_3). ^{13}C NMR ($CDCl_3$): 164.97 (ester C=O), 164.38 (ester C=O), 134.68, 128.89, 128.74, 128.33 (aromatic), (CO_2CH_2Ph), 53.92 (CO_2CH_3), 42.02 (malonyl CH).

Coupling of 12 with dimethyl bromomalonate

A solution of **12** (4.45 g, 19 mmol) in dimethylformamide (40 mL) was cooled to –55°C and Triton B (15.0 mL of a 40% methanolic solution, 6.36 g, 38 mmol) was added dropwise. Stirring was continued for 30 min, and a solution of dimethylbromomalonate (4.85 g, 23 mmol) in dimethylformamide (20 mL) was then added dropwise. Stirring was continued overnight, and the mixture was

© 2001 NRC Canada

warmed to room temperature. Ethyl acetate (450 mL), saturated sodium chloride (110 mL), and 1.0 M hydrochloric acid (50 mL) were added, and the organic phase was separated, washed with water (2 × 120 mL) and saturated sodium chloride (150 mL), dried over magnesium sulfate, and evaporated under reduced pressure. The residue was purified by column chromatography using ethyl acetate – hexanes (2:3) to give **13** (3.33 g, 50%). $[\alpha]_D^{20}$ –88.2° (c 0.17, $CHCl_3$). IR (neat) (cm^{-1}): 1782, 1755, 1748, 1682. Mass spectrum (EI, *m*/*z*): 364 (M). ^{1}H NMR ($CDCl_3$): 7.29 (2H, t, Ar), 7.00 (1H, t, Ar), 6.92 (2H, d, Ar), 6.09 (1H, dt, 1.2, 4.2 Hz, H-3), 6.00 (1H, d, 4.2 Hz, H-4), 5.12 (1H, s, CH), 4.98 (1H, dd, 1.2, 14.3 Hz, PhOC*H*H), 4.89 (1H, dd, 1.2, 14.3 Hz, PhOCH*H*), 3.82 (3H, s, CH_3), 3.72 (3H, s, CH_3). ^{13}C NMR ($CDCl_3$): 172.99 (thiazoline N=C), 165.12 (β-lactam C=O), 164.29 (ester C=O), 157.78, 129.64, 122.02, 114.86 (aromatic), 93.17 (C-3), 68.10 (C-4), 67.90 ($PhOCH_2$), 60.29 (malonyl CH), 55.96 (CO_2CH_3), 53.40 (CO_2CH_3). Allylation of the mixed ester

The azetidinone (4.35 g, 10.2 mmol) was dissolved in dimethylformamide (35 mL), the solution was cooled to 0°C, and 40% methanolic Triton B (6.0 mL, 2.21 g, 13.2 mmol) was added dropwise over 20 min, with stirring. Then allyl bromide (2.6 mL, 3.63 g, 30.0 mmol) was added and stirring was continued for 2 h at 0°C. Ethyl acetate (150 mL) was added and the solution was washed with water (3 × 150 mL) and saturated sodium chloride (150 mL), dried over sodium sulfate, and evaporated to give an orange oil. Chromatography on silica gel using ethyl acetate – hexanes (1:1) gave the product as a yellow oil (3.94 g, 83%). IR (neat) (cm^{-1}): 1778, 1755, 1746. ^1H NMR ($CDCl_3$): isomer A: 7.29 (8H, t, Ar), 6.91 (2H, t, Ar), 5.98 (1H, d, 4.1 Hz, H-4), 5.90 (1H, dt, 1.1, 4.2 Hz, H-3), 5.70 (1H, ddt, 6.5, 10.0, 17.0 Hz, CH_2C*H*=CH_2), 5.21 (2H, s, PhCH_2), 5.15–5.06 (2H, m, $CH_2CH=C$*H*$_2$), 4.93 (1H, dd, 1.1, 14.3 Hz, PhOC*H*H), 4.79 (1H, dd, 1.2, 14.3 Hz, PhOCH*H*), 3.73 (3H, s, CH_3), 3.14–3.01 (2H, m, C*H*$_2$CH=CH_2). Conversion of 14 into the hydroxycepham 17

A solution of **14** (8.14 g, 20.1 mmol) in dichloromethane (100mL) and methanol (50 mL) was cooled to –78°C, and treated with ozone at a rate of 1.5 L min^{-1} until a blue colour persisted. Excess ozone was purged using nitrogen gas, and the reaction was quenched with dimethyl sulfide (12.3 mL, 10.4 g, 167.5 mmol). The cooling bath was then removed and the solution was allowed to warm to room temperature. Evaporation of the solvent afforded a yellow syrup (9.0 g). This was dissolved in a mixture of dichloromethane (150 mL) and acetone (150 mL), and treated with 3% perchloric acid (25 mL, 0.75 g, 7.47 mmol). The mixture was stirred for 90 min and then diluted with ethyl acetate (300 mL), washed with saturated sodium chloride (6 × 100 mL), dried over magnesium sulfate, and evaporated to give a yellow oil. Purification by column chromatography using ethyl acetate – hexanes (1:1) yielded **17** (8.0 g, 94%). $[\alpha]_D^{20}$ +217.7° (c 0.40, $CHCl_3$). Mass spectrum (CI, *m*/*z*): 407 ((M+1)-H_2O). IR (KBr) (cm^{-1}): 3480, 3341, 1778, 1753, 1680. ^1H NMR ($CDCl_3$): 7.38 (1H, d, 9.3 Hz, NH), 7.31 (2H, t, Ar), 7.01 (1H, t, Ar), 6.92 (2H, d, Ar), 5.77 (1H, dd, 4.6, 9.3 Hz, H-7), 5.55 (1H, d, 4.6 Hz, H-6), 5.35 (1H, 2.3, 3.9, H2), 4.52 (2H, s, PhOCH_2), 3.85 (3H, s, CH_3), 3.81 (3H, s, CH_3), 2.78 (1H, dd, 3.9, 14.4 Hz, H-3), 2.53 (1H, dd, 2.3, 14.4 Hz, H-3). ^{13}C NMR ($CDCl_3$): 168.91 (acetamido C=O), 167.83 (β-lactam C=O), 165.04 (ester C=O), 163.76 (ester C=O), 156.94, 129.76, 122.36, 114.84 (aromatic), 70.71 (C-2), 67.11 (PhOCH_2), 61.70 (C-7), 59.01 (C-6), 54.63 (C-4), 53.94 (CO_2CH_3), 53.47 (CO_2CH_3), 35.62 (C-3). Anal. calcd. for $C_{18}H_{20}N_2O_8S$: C 50.94, H 4.75, N 6.60; found: C 50.58, H 4.89, N 6.16.

Dehydration of 17

A solution of **17** (200 mg, 0.47 mmol) in acetic anhydride (1.4 mL, 1.5 g, 14.8 mmol) was treated, with stirring, with a 1% w/v solution of sulfuric acid in acetic acid (0.3 mL, 3 mg, 0.03 mmol). After 2.5 h, sodium acetate hexahydrate (750 mg, 3.9 mmol) was added and stirring was continued overnight. Ethyl acetate (50 mL) was added and the organic layer was washed successively with water (2 × 50 mL) and saturated sodium bicarbonate (50 mL), dried over magnesium sulfate, and evaporated to give a pale yellow oil. A solution of this oil in toluene (150 mL) was treated with *p*-toluenesulfonic acid monohydrate (70 mg, 0.37 mmol), and the mixture, protected from moisture by a calcium chloride drying tube, was refluxed overnight. The solvent was then evaporated under reduced pressure. The residue was purified by column chromatography using ethyl acetate – hexanes (3:2) to give the 4,4-dimethoxycarbonyl-Δ^2-cephem **19** as a yellow foam (489 mg, 52%). $[\alpha]_D^{20}$ +400.0° (c 0.26, $CHCl_3$). Mass spectrum (CI, *m*/*z*): 407 (M+1). IR (KBr) (cm^{-1}): 3310, 1786, 1748, 1690. ^1H NMR ($CDCl_3$): 7.39 (1H, d, 9.0 Hz, NH), 7.33 (2H, t, Ar), 7.04 (1H, t, Ar), 6.94 (2H, d, Ar), 6.47 (1H, d, 10.4 Hz, H-2), 6.07 (1H, d, 10.4 Hz, H-3), 5.81 (1H, dd, 4.2, 9.0 Hz, H-7), 5.31 (1H, d, 4.2 Hz, H-6), 4.56 (2H, s, PhOCH_2), 3.87 (3H, s, CH_3), 3.84 (3H, s, CH_3).

Diazotization of dibenzyl malonate (30)

Anhydrous potassium carbonate (6.58 g, 47.6 mmol) was added to a solution of dibenzyl malonate (4.50 g, 15.8 mmol) in acetone (45 mL). The mixture was stirred for 15 min, cooled to 0°C, and a solution of benzenediazonium chloride, prepared by addition of a solution of sodium nitrite (1.10 g, 16 mmol) in water (13.2 mL) to a solution of aniline hydrochloride (2.07 g, 16.0 mmol) in 1.0 M hydrochloric acid (16.2 mL), was added dropwise. The ice bath was removed and stirring was continued at room temperature for 10 min. The reaction mixture was then poured onto crushed

ice and extracted with ethyl acetate (3 × 100 mL), dried over magnesium sulfate, and evaporated to afford a red oil which slowly solidified in the freezer. Trituration with anhydrous methanol produced yellow needles (5.21 g, 85%), mp 47–49°C. Mass spectrum (CI, *m/z*): 389 (M+1). IR (KBr) (cm^{-1}): 1726, 1530. ^1H NMR ($CDCl_3$): 7.42–7.13 (15H, m, Ar), 5.34 (2H, s, benzyl CH_2), 5.33 (2H, s, benzyl CH_2), 3.48 (1H, s, NH). ^{13}C NMR ($CDCl_3$): 163.17 (ester C=O), 163.04 (ester C=O), 141.80–115.73 (aromatic), 66.74 (CO_2CH_2Ph). Anal. calcd. for $C_{23}H_{20}N_2O_4$: C 71.12, H 5.19, N 7.21; found: C 71.17, H 4.97, N 7.10.

Dibenzyl acetamidomalonate

Zinc dust (7.23 g, 110.6 mg-atoms) was added to a solution of the diazo compound (6.50 g, 16.7 mmol) in acetic anhydride (29.0 mL, 31.4 g, 307.4 mmol) and glacial acetic acid (116 mL). The mixture was stirred at room temperature for 1 h, at 40°C for 20 min, and then filtered. The insoluble material was rinsed with glacial acetic acid (10 mL) and the combined filtrates were treated with water to the cloud point. The product was allowed to crystallize, collected, and recrystallized from absolute ethanol to give dibenzyl acetamidomalonate (1.97 g, 35%) as white needles, mp 107–109°C. Mass spectrum (CI, *m/z*): 342 (M+1). IR (KBr) (cm^{-1}): 3299, 1753, 1657. ^1H NMR ($CDCl_3$): 7.32 (6H, m, Ar), 7.25 (4H, m, Ar), 6.54 (1H, s, 7.0 Hz, NH), 5.29 (1H, d, 7.0 Hz, CH), 5.20, 5.16 (4H, ABq, 18.7 Hz, benzyl CH_2), 2.07 (3H, s, CH_3). ^{13}C NMR ($CDCl_3$): 169.66 (acetyl C=O), 166.17 (ester C=O), 134.72–128.19 (aromatic), 68.18 (CO_2CH_2Ph), 56.55 ($CH_3CONHCH$), 22.71 (CH_3CO). Anal. calcd. for $C_{19}H_{19}NO_5$: C 66.85, H 5.61, N 4.10; found: C 66.65, H 5.59, N 4.25.

Dibenzyl allyl acetamidomalonate

A solution of dibenzyl acetamidomalonate (38.1 mg, 0.112 mmol) in acetone (4.0 mL) was treated with anhydrous potassium carbonate (40.5 mg, 0.293 mmol) and sodium iodide (23.9 mg, 0.159 mmol). The mixture was stirred for 10 min, and allyl bromide (0.02 mL, 28.0 g, 0.231 mmol) was added. The mixture was then refluxed, with stirring, for 19 h, cooled, and ethyl acetate (10 mL) and water (2 mL) were added. The organic layer was separated, washed successively with 5% hydrochloric acid (10 mL), water (10 mL) and saturated sodium chloride (10 mL), dried over magnesium sulfate, and evaporated to give an oil which slowly solidified. Crystallization using hot ethyl acetate – hexanes afforded white needles (30.9 mg, 82%), mp 81 to 82°C. Mass spectrum (CI, *m/z*): 382 (M+1). IR (KBr) (cm^{-1}): 3231, 1744, 1642. ^1H NMR ($CDCl_3$): 7.30 (6H, m, Ar), 7.24 (4H, m, Ar), 6.75 (1H, s, NH), 5.48 (1H, ddt, 7.4, 10.2, 16.9 Hz, =CH), 5.16, 5.10 (4H, ABq, 12.2 Hz, benzyl CH_2), 5.02 (1H, ddt, 1.0, 1.0, 10.2 Hz, =C*H*H), 4.97 (1H, ddt, 1.0, 1.0, 16.9 Hz, =CH*H*), 3.10 (2H, ddd, 1.0, 1.0, 7.4 Hz, allyl CH_2), 2.01 (3H, s, CH_3). ^{13}C NMR ($CDCl_3$): 169.00 (acetyl C=O), 167.44 (ester C=O), 134.94, 128.57, 128.52, 128.30 (aromatic), 131.08 ($CH_2CH=CH_2$), 119.96 ($CH_2CH=CH_2$), 68.14 (CO_2CH_2Ph), 66.51 (CH_3CONHC), 37.05 ($CH_2CH=CH_2$), 22.92 (CH_3CONH). Anal. calcd. for $C_{22}H_{23}NO_5$: C 69.28, H 6.08, N 3.67; found: C 69.23, H 6.08, N 4.40.

Hydrolysis of 19

A

A solution of **19** (79 mg, 0.19 mmol) in pyridine (12 mL) was cooled to –8°C and 0.99 M potassium hydroxide (0.4 mL, 22.2 mg, 0.40 mmol, 2.1 mol equiv) was added, with stirring. Stirring was continued for 2.5 h, and the solvent was then removed under reduced pressure. The residue was dissolved in water (20 mL) and the solution was extracted with ethyl acetate (2 × 20 mL). The organic layer was dried and evaporated to give unreacted diester (4 mg). The aqueous layer was acidified to pH 4 with 0.1 N hydrochloric acid and extracted with ethyl acetate (2 × 10 mL). The extract was dried over anhydrous sodium sulfate and evaporated to give a 7:1 mixture (by ^1H NMR) of 4-carboxy-Δ^2- and 4-carboxy-Δ^3-cephems.

Δ^2-Cephem: ^1H NMR (acetone-d_6): 8.17 (1H, d, 8.7 Hz, NH), 7.30 (2H,m, Ar), 7.00 (3H, m, Ar), 6.50 (1H, dd, 2.5, 10.4 Hz, H-2), 5.97 4.1 Hz, H-6), 4.94 (1H, d, 2.5, 4.4 Hz, H-4), 4.64 (2H, s, $PhOCH_2$).

Δ^3-Cephem: ^1H NMR (acetone-d_6): 8.00 (1H, d, 9.2 Hz, NH), 7.28 (2H, m, Ar), 6.94 (3H, m, Ar), 6.58 (1H, dd, 2.6, 6.4 Hz, H-3), 5.94 (1H, dd, 4.9, 9.2 Hz, H-7), 5.15 (1H, d, 4.9 Hz, H-6), 4.70 (2H, s, $PhOCH_2$), 3.65(1H, dd, 2.6, 19.1 Hz, SC*H*H), 3.51 (1H, dd, 6.4, 19.1 Hz, SCH*H*).

A solution of the mixed 4-carboxy-Δ^2- and 4-carboxy-Δ^3-cephems in dichloromethane (10 mL) was cooled to 0°C and diazomethane was added, followed after 5 min by one drop of acetic acid. The solvent was evaporated and the residue was purified by preparative layer chromatography, using ethyl acetate – hexanes (1:1), to give a 7:1 mixture of Δ^2- and Δ^3-esters (8 mg).

Δ^2-Ester: Mass spectrum (CI, *m/z*): 349 (M+1). IR (KBr) (cm^{-1}): 3408, 1784, 1751, 1697. ^1H NMR ($CDCl_3$): 7.40 (1H, d, 9.2 Hz, NH), 7.32 (2H, t, Ar), 7.04 (1H, t, Ar), 6.93 (2H, d, Ar), 6.32 (1H, dd, 2.5, 10.4 Hz, H-2), 5.87 (1H, dd, 4.3, 10.4 Hz, H-3), 5.81 (1H, dd, 4.2, 9.2 Hz, H-7), 5.23 (1H, d, 4.2 Hz, H-6), 4.95 (1H, dd, 2.5, 4.3 Hz, H-4), 4.5 (2H, s, $PhOCH_2$). ^{13}C NMR ($CDCl_3$): 168.50 (acetamido C=O), 167.55 (β-lactam C=O), 164.37 (ester C=O), 156.97, 129.79, 122.40, 114.82 (aromatic), 119.65 (C-2), 113.35 (C-3), 67.20 ($PhOCH_2$), 60.03 (C-7), 53.32 (C-6), 53.04 (CO_2CH_3), 49.33 (C-4). Anal. calcd. for $C_{16}H_{16}N_2O_5S\cdot0.25H_2O$: C 54.46, H 4.71, N 7.84; found: C 54.21, H 4.90, N 7.44.

Δ^3-Ester: Mass spectrum (CI, *m/z*): 349 (M+1). ^1H NMR ($CDCl_3$): 7.28 (1H, d, 9.4 Hz, NH), 7.31 (2H, t, Ar), 7.04 (1H, t, Ar), 6.93 (2H, d, Ar), 6.56 (1H, dd, 2.5, 6.3 Hz, H-3), 5.97 (1H, dd, 5.0, 9.4 Hz, H-7), 5.00 (1H, d, 5.0 Hz, H-6), 4.57 (2H, s, $PhOCH_2$), 3.60 (1H, dd, 2.5, 19.2 Hz, SC*H*H), 3.42 (1H, dd, 6.4, 19.2 Hz, SCH*H*).

B

A solution of **19** (80 mg, 0.23 mmol) in pyridine (1 mL) was cooled to –8°C, and 0.99 M potassium hydroxide (0.2 mL, 0.20 mmol, 0.9 mol equiv) was added, with stirring. Stirring was continued for 2.5 h, and the solvent was then removed under reduced pressure. The residue was dis-

© 2001 NRC Canada

solved in water (10 mL) and the solution was extracted with ethyl acetate (2 × 25 mL). The organic layer was dried and evaporated to give unreacted diester (3 mg). The aqueous layer was acidified to pH 4 with 0.1 N hydrochloric acid and extracted with ethyl acetate (2 × 10 mL). The extract was dried over sodium sulfat and evaporated to give a 5.4:1 Δ^3:Δ^2 mixture of 4-carboxycephems. A solution of this mixture in dichloromethane (10 mL) was cooled to 0°C and treated with diazomethane. After 5 min, one drop of acetic acid was added, and the solvent was evaporated. The residue was purified by preparatory layer chromatography, using ethyl acetate – hexanes (1:1), to give a 5.4:1 Δ^2:Δ^3 mixture of 4-methoxycarbonylcephems (7 mg).

C

A solution of **19** (24 mg, 0.06 mmol) in acetonitrile (4 mL) and water (2 mL) was cooled to –5°C, and treated, with stirring, with 0.99 M potassium hydroxide (1.2 mL, 6.7 mg, 0.12 mmol). Stirring was continued for 1.5 h, and the solvent was then evaporated under reduced pressure. The residue was dissolved in water (20 mL) and the solution was extracted with ethyl acetate (2 × 20 mL). The organic layer was dried and evaporated to give unreacted diester (4 mg). The aqueous layer was acidified to pH 4 with 0.1 N sulfuric acid and extracted with ethyl acetate (2 × 10 mL). The extract was dried over sodium sulfate and evaporated to give the 4-carboxy-Δ^2-cephem. A solution of this compound in dichloromethane (10 mL) was cooled to 0°C and treated with diazomethane. After 5 min, one drop of acetic acid was added and the solvent was then removed. The residue was purified by preparatory layer chromatography using ethyl acetate – hexanes (1:1) to give the Δ^2-ester (5 mg, 29%).

Deprotection of 24

A

A solution of the dimethyl ester (19 mg, 0.045 mmol) in pyridine (0.24 mL) was cooled to 0°C and treated with 1 M potassium hydroxide (0.048 mL, 1.9 mg, 0.045 mmol, 1 mol equiv). Stirring was continued for 2.5 h, and the solvent was then removed under reduced pressure. The residue was dissolved in water (20 mL) and this solution was extracted with ethyl acetate (2 × 20 mL). The organic layer was evaporated and dried to give unreacted diester (7 mg). The aqueous layer was acidified to pH 4 with 0.1 N hydrochloric acid and extracted with ethyl acetate (2 × 10 mL). The extract was dried over sodium sulfate and evaporated. The residue was dissolved in dichloromethane (7 mL), cooled to 0°C, and diazomethane was added. After 30 min, one drop of acetic acid was added, and the solvent was removed. Column chromatography of the residue, using ethyl acetate – hexanes (2:3), afforded the 4-methoxycarbonyl-Δ^2-ester. $[\alpha]_D^{20}$ +424.2° (c 0.165, $CHCl_3$). Mass spectrum (CI, *m*/*z*): 363 (M+1). HR-MS-CI calcd. for $C_{17}H_{18}N_2O_5S$: 363.1015 (M+1); found: 363.1018 (M+1). IR ($CHCl_3$) (cm^{-1}): 3412, 1778, 1751, 1694. ^1H NMR ($CDCl_3$): 7.36–7.30 (3H, m, Ar + NH), 7.04 (1H, t, Ar), 6.94 (2H, d, Ar), 5.81 (1H, dd, 4.1, 9.2 Hz, H-7), 5.62 (1H, dq, 1.3, 2.7 Hz, =CH), 5.23 (1H, dd, 0.4, 4.1 Hz, H-6), 4.96 (1H, ddq, 0.4, 2.0, 2.7 Hz, shows nOe with H-3 and CH_3 at 5.62 and 1.96 ppm, respectively, allyl CH), 1.96 (3H, dd, 1.3, 2.0 Hz, CH_3). ^{13}C NMR ($CDCl_3$): 168.52 (acetamido C=O), 168.37 (ester C=O), 164.74 (β-lactam C=O), 157.13, 129.82, 122.44, 114.96 (aromatic), 130.07 (C-2), 108.68 (C-3), 67.36 ($PhOCH_2$), 59.97 (C-7), 54.57 (C-6), 52.84 (ester CH_3), 50.07 (C-4), 24.28 (CH_3).

B

To a solution of the dibenzyl ester (26.5 mg, 0.046 mmol) in 95% ethanol (6.0 mL) and water (3.0 mL) were added sodium bicarbonate (8.9 mg, 0.106 mmol) and 10% palladium on carbon (82.3 mg). The apparatus was flushed thrice with nitrogen and thrice with hydrogen, and then stirred rapidly under hydrogen for 25 min. The mixture was filtered through Celite and the Celite was rinsed with water (3 × 5 mL). The filtrate was concentrated under reduced pressure to remove ethanol, and then lyophilized to give a white solid (16.9 mg). This material, in dimethylformamide (0.2 mL), was treated with methyl iodide (5.5 μL, 12.5 mg, 0.088 mmol). The mixture was stirred for 2.5 h and then diluted with dichloromethane (5 mL), washed successively with water (3 × 5 mL) and saturated sodium chloride (5 mL), dried over magnesium sulfate, and evaporated to give the methyl ester of 2-methyl-Δ^2-cephem V (3.5 mg, 91%).

C

To a solution of the dibenzyl ester (34.3 mg, 0.056 mmol) in glacial acetic acid (7.5 mL) and water (3.6 mL) was added 10% palladium on carbon (71.2 mg). The apparatus was purged in the usual manner and the mixture was stirred rapidly under hydrogen for 20 min and then centrifuged. The pellet was suspended in ice-cold 68% acetic acid (5.0 mL) and centrifuged again. The combined supernatants were lyophilized, and the white residue, in a mixture of absolute ethanol (2.0 mL) and dichloromethane (5.0 mL), was treated with diazomethane. The solution was stirred for 2 h and the solvent was then removed under reduced pressure. Chromatography of the residue using ethyl acetate – hexanes (1:1) gave two products, the 4-methoxycarbonyl-Δ^2-cephem (R_f 0.50, 4.3 mg, 21%) as a white solid, mp 125 to 126°C, and the 4-methoxycarbonyl-Δ^2-cepham (R_f 0.44, 1.5 mg, 2%) as a colourless film. $[\alpha]_D^{20}$ +160.0° (c 0.050, $CHCl_3$). Mass spectrum (CI, *m*/*z*): 365 (M+1). HR-MS-CI calcd. for $C_{17}H_{20}N_2O_5S$: 365.1171 (M+1); found: 365.1164. IR ($CHCl_3$) (cm^{-1}): 3414, 1778, 1751, 1694. ^1H NMR ($CDCl_3$): 7.31 (3H, m, Ar + NH), 7.05 (1H, t, Ar), 6.96 (2H, d, Ar), 5.76 (1H, dd, 4.5, 9.7 Hz, H-7), 5.27 (1H, d, 4.5 Hz, H-6), 4.80 (1H, dd, 2.0, 6.2 Hz, H-4), 4.55 (2H, s, $PhOCH_2$), 3.78 (3H, s, ester CH_3), 3.06 (1H, ddq, 2.0, 6.3, 6.8 Hz, $CHCH_3$), 2.25 (1H, ddd, 2.0, 2.0, 14.1 Hz, α-H-3), 1.69 (1H, ddd, 6.3, 12.0, 14.1 Hz, β-H-3), 1.25 (3H, d, 6.8 Hz, CH_3). ^{13}C NMR ($CDCl_3$): 169.75 (acetamido C=O), 168.36 (ester C=O), 165.39 (β-lactam C=O), 157.83, 129.78, 122.40, 115.03 (aromatic), 67.43 ($PhOCH_2$), 59.13 (C-7), 56.25 (C-6), 52.68 (ester CH_3), 50.26 (C-4), 34.86 (C-2), 31.81 (C-3), 21.34 (CH_3).

D

To a solution of isomer A (46 mg, 0.093 mmol) in glacial acetic acid (10 mL) and water (4.7 mL) was added 10% palladium on carbon (103 mg). The apparatus was purged in the

© 2001 NRC Canada

usual manner and the mixture was stirred rapidly under hydrogen for 20 min and then centrifuged. The pellet was suspended in ice-cold 67% acetic acid (5.0 mL) and centrifuged again. The combined supernatants were lyophilized, and the white residue, in a mixture of absolute ethanol (2.0 mL) and dichloromethane (5.0 mL), was treated with diazomethane. The solution was stirred for 2 h and the solvent was then removed under reduced pressure. Chromatography using ethyl acetate – hexanes (1:1) gave the 4-methoxycarbonyl-Δ^2-cephem (23.3 mg).

E

To a solution of isomer B (46 mg, 0.093 mmol) in glacial acetic acid (10 mL) and water (4.7 mL) was added 10% palladium on carbon (110 mg). The apparatus was purged in the usual manner and the mixture was stirred rapidly under hydrogen for 20 min and then centrifuged. The pellet was suspended in ice-cold 68% acetic acid (5.0 mL) and centrifuged again. The combined supernatants were lyophilized, and the residue, in a mixture of absolute ethanol (2.0 mL) and dichloromethane (5.0 mL), was treated with diazomethane. The solution was stirred for 2 h and the solvent was then removed under reduced pressure. Chromatography using ethyl acetate – hexanes (1:1) afforded the Δ^2-cephem (8.8 mg) and the cepham (7.0 mg).

Deprotection of model malonates

A

To a solution of dibenzyl acetamidomalonate (29.9 mg, 0.088 mmol) in glacial acetic acid (4.1 mL) and water (2.6 mL) was added 10% palladium on carbon (119.8 mg). The apparatus was flushed thrice with nitrogen, thrice with hydrogen and the mixture was then stirred rapidly under hydrogen for 55 min and centrifuged. While the supernatant was cooled in an ice bath, the pellet was suspended in ice-cold 61% acetic acid (4 mL) and centrifuged again. The combined supernatants were lyophilized to give acetamidomalonic acid as a fluffy white solid. An ice-cold solution of this material in a mixture of dichloromethane (1.8 mL) and 95% ethanol (0.3 mL) was treated, in 10 min intervals, with diazomethane, bubbled in from a DIAZALD reaction mixture using a stream of dry nitrogen. The solvent was removed under reduced pressure and the residue, in ethyl acetate, was filtered through a short layer of silica gel. Crystallization from hot methanol gave dimethyl acetamidomalonate as white needles (13.5 mg, 81%), mp 126–128°C. Mass spectrum (EI, *m*/*z*): 189 (M). IR (KBr) (cm^{-1}): 3304, 1750, 1740, 1651. ^{1}H NMR ($CDCl_3$): 6.47 (1H, d, 7.0 Hz, NH), 5.21 (1H, d, 7.0 Hz, CH), 3.82 (6H, s, ester CH_3), 2.08 (3H, s, acetamido CH_3). ^{13}C NMR ($CDCl_3$): 169.61 (acetamido C=O), 166.81 (ester C=O), 56.14 ($CH_3CONHCH$), 53.33 (CO_2CH_3), 22.68 (CH_3CONH). Anal. calcd. for $C_7H_{11}NO_5$: C 44.45, H 5.86, N 7.40; found: C 44.35, H 5.79, N 7.41.

B

To a solution of dibenzyl allylacetamidomalonate (32.5 mg, 0.0852 mmol) in glacial acetic acid (4.2 mL) and water (2.7 mL) was added 10% palladium catalyst (116.3 mg). The mixture was purged thrice with nitrogen and thrice with hydrogen and then stirred under hydrogen for 1 h and centrifuged. The pellet was suspended in 61% acetic acid (4.0 mL), centrifuged again, and the combined supernatants were lyophilized to give the malonic acid. This was dissolved in a mixture of dichloromethane (1.8 mL) and 95% ethanol (0.3 mL), the solution was cooled in an ice bath, and excess diazomethane was introduced in a stream of dry nitrogen. The solution was stirred for 2 h, evaporated, and the residue, in ethyl acetate (2 mL), was flushed through a short column of silica gel. Evaporation and crystallization from ethyl acetate – hexanes afforded dimethyl *n*-propyl acetamidomalonate as white needles (19.2 mg, 82%) mp 127 to 128°C. Mass spectrum (CI, *m*/*z*): 232 (M+1). IR (KBr) (cm^{-1}): 3273, 1748, 1642. ^{1}H NMR ($CDCl_3$): 6.77 (1H, br s, NH), 3.77 (6H, s, ester CH_3), 2.29 (2H, m, CH_2), 2.03 (3H, s, acetamido CH_3), 1.12 (2H, m, CH_2), 0.90 (3H, t, 7.3 Hz, CH_3). ^{13}C NMR ($CDCl_3$): 168.89 (acetamido C=O), 168.75 (ester C=O), 66.62 ($CH_3CONHC(CO_2CH_3)_2$), 53.30 (CO_2CH_3), 34.52 ($CH_3CONHCCH_2CH_2CH_3$), 22.96 (CH_3CONH), 17.08 ($CH_3CONHCCH_2CH_2CH_3$), 13.74 ($NHCCH_2CH_2CH_3$). Anal. calcd. for $C_{10}H_{17}NO_5$: C 51.94, H 7.41, N 6.06; found: C 52.13, H 7.44, N 5.88.

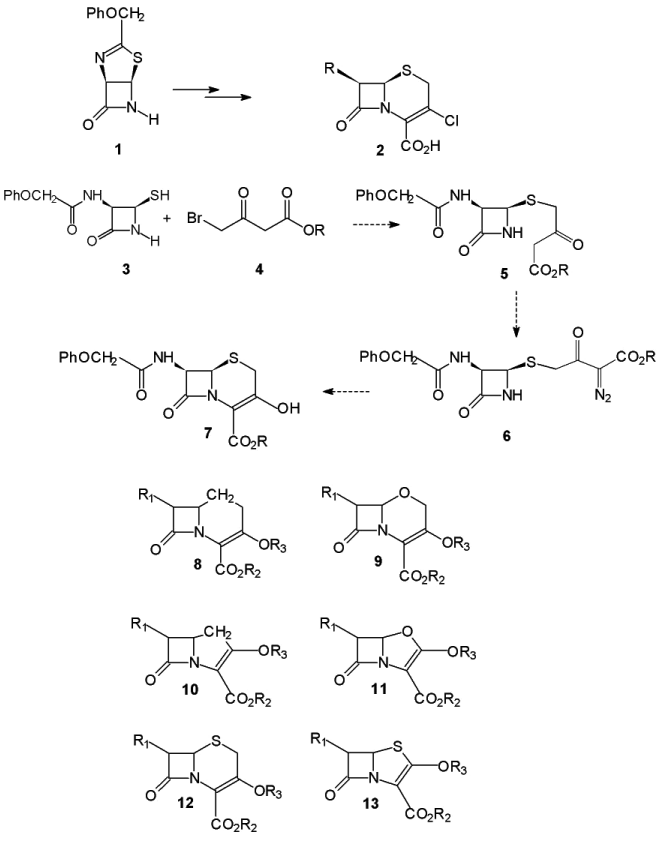
Generation, electrocyclic ring opening, and unprecedented conversion of a 3-acylaminoazetinone into *cis*-3,4-disubstituted azetidinones

Saul Wolfe, Stephen Ro, and Zheng Shi

Abstract: An attempt to synthesize the nucleus of cefaclor by insertion of an appropriately functionalized rhodium carbene into a β-lactam N—H bond leads instead to attack at sulfur, followed by fragmentation into a four-membered thietanone and a four-membered 3-acylaminoazetinone. The azetinone undergoes electrocyclic ring opening, with a calculated half-life of 11 s at 40°C, to a *trans*-disubstituted vinyl isocyanate, but can be trapped by saturated, unsaturated allylic and benzylic alcohols to form 3,4-disubstituted azetidinones in which the *cis*- isomer predominates.

Key words: rhodium carbene, torquochemical, azetinone, mercaptoazetidinone.

Résumé : Un essai de synthèse du noyau cefaclor, par insertion d'un carbène de rhodium fonctionnalisé de façon appropriée dans une liaison N—H d'un β-lactame, conduit plutôt à une attaque au niveau du soufre, suivie d'une fragmentation en une thiétanone à quatre chaînons et à une 3-acétylaminoazétinone à quatre chaînons. L'azétinone subit une ouverture de cycle électrocyclique, avec un temps de demi-vie de 11 s à 40°C, qui conduit à un isocyanate de vinyle *trans*-disubstitué; on peut toutefois la piéger à l'aide d'alcools saturés, insaturés et benzyliques qui avec formation d'azétidinones 3,4-disubstituées dans lesquelles l'isomère *cis* prédomine.



Mots clés : carbène de rhodium, torquochimique, azétinone, mercaptoazétidinone.

[Traduit par la Rédaction]

Introduction

The thiazoline azetidinone **1** (Cooper's compound), which is readily accessible from penicillin V (1), is a useful starting material for the partial synthesis of unnatural β-lactam-containing compounds (2). The work reported here began with the idea that **1** might serve as a precursor of the 3-chloro-Δ^3-cephem nucleus (2), which is a desirable synthetic target (3) because of the orally effective broad-spectrum antibacterial properties of cefaclor (**2**, R = D-PhCH(NH_2)CONH) (4).

It was thought that hydrolysis of **1** to the mercaptoazetidinone **3** (5), followed by reaction with a γ-bromoacetoacetate (**4**), diazotization of **5** (6), and cyclization of **6** via N—H insertion using rhodium acetate (7), would lead to a 3-hydroxycephem **7**, the precursor of **2**. Significantly, although this plan appeared to have ample precedent in the numerous reports of carbenoid insertion into β-lactam N—H bonds to produce carbacephems (**8**) (8), oxacephems (**9**) (9), carbapenems (**10**) (10), and oxapenems (**11**) (11), there were no reported examples of the successful application of this methodology to syntheses of cephems (**12**) or penems (**13**). A reason for this absence of (published) activity soon became clear.

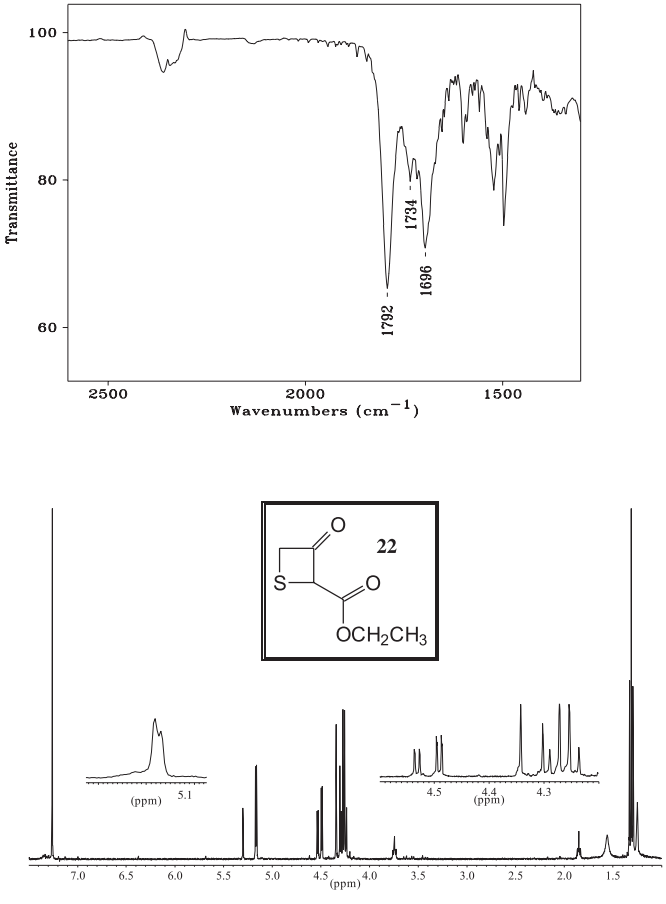
Scheme 1.

Scheme 2.

Serendipitous formation and electrocyclic ring opening of an acylaminoazetinone



The synthesis of **6** is summarized in Scheme 1. Bromination of ethyl acetoacetate in acetic acid produced the γ-bromide **4** (R = Et), which was converted to the α,γ-dibromide **14** with 1 equiv of pyrrolidone hydrotribromide (PHT) (12). With 1 and 2 equiv of PHT, ethyl acetoacetate gave, successively, the α-bromide **15** and the α,α-dibromide **16**. Following Osborne (13), who reported that **3** reacts with ethyl bromoacetate in hexamethylphosphoramide solvent (HMPA) to give **17** (R = OEt), stirring of **3** with **4** in HMPA afforded **17** (R = CH_2CO_2Et) in 53% yield. The same product was obtained from the α,γ-dibromide **14**. Diazo transfer to **17** (R = CH_2CO_2Et) to form **6** (mp 135–137°C) proceeded reproducibly in 70–75% yield using *p*-carboxybenzenesulfonyl azide and triethylamine in acetonitrile (14).[2]

Refluxing of **6** with rhodium acetate in benzene did not lead to **7**. Instead, a compound $C_{11}H_{10}N_2O_3$ was isolated as an oil, whose IR and ^{1}H NMR spectra showed the presence of $PhOCH_2$- and -CH=CH-, and the absence of a β-lactam ring. The structure considered initially was *N*-phenoxyacetylimidazolone (**18**), whose formation could be rationalized in terms of Scheme 2, which proposes attack of the metallocarbenoid **19** on sulfur to form the neutral sulfonium ylide **20** (16). Fragmentation of **20** into the neutral acylaminoazetinone **21** ($C_{11}H_{10}N_2O_3$) and the neutral thietanone **22**, ring opening of **21** to the *cis*-vinyl isocyanate **23** (17), and cyclization of **23** would lead to **18** (18).

Support for this mechanistic proposal was sought through a search for **22** among the products, and by an independent synthesis of the putative imidazolone **18**. Refluxing of **6** with rhodium acetate in methylene chloride afforded, in 32% yield, a fragrant oil $C_6H_8O_3S$, identified as **22** on the basis of its IR and ^{1}H NMR spectra (Fig. 1). In subsequent experiments, conducted in refluxing benzene, both the presumed imidazolone **18** (68%) and **22** were isolated as products.

The synthesis of **18** is summarized in Scheme 3. Reaction of aminoacetaldehyde diethyl acetal with potassium cyanate gave the ureidoacetal **24** (19) which, when refluxed with phenoxyacetyl chloride in acetonitrile containing 4 Å molecular sieves, underwent acylation and cyclization to **18**, a crystalline compound that melted with decomposition at 82°C and liquefied completely at 89°C. It was immediately apparent, from the isolation of a crystalline compound and from the IR and NMR spectra, that **18** was different from the rhodium acetate product; the latter exhibited, inter alia, a

Fig. 1. The IR and ^{1}H NMR spectra of **22**.

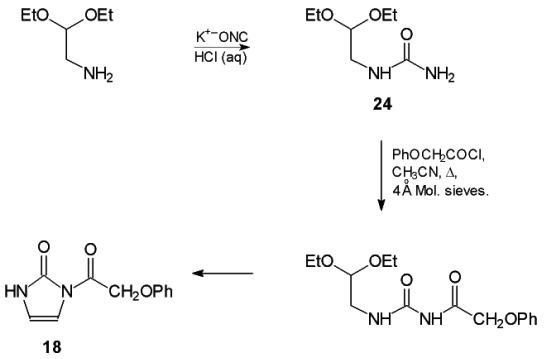
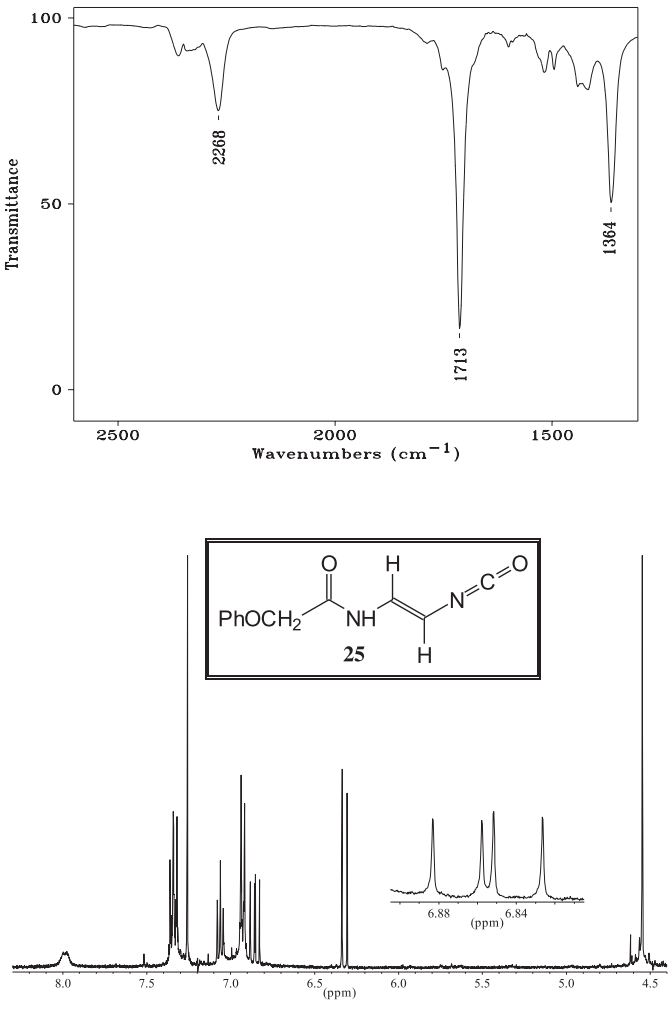
Scheme 3.





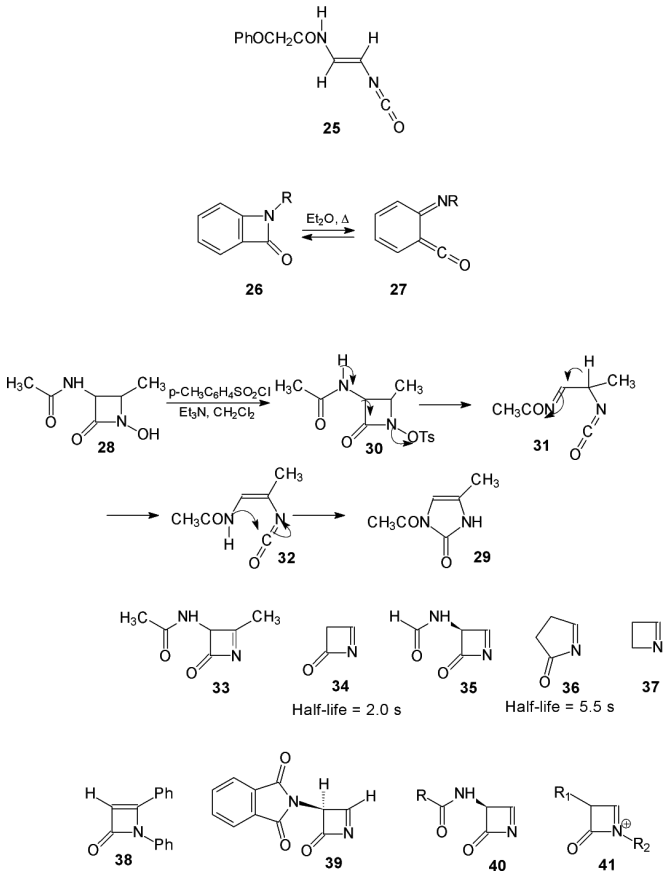


Fig. 2. The IR and ^{1}H NMR spectra of **25**.

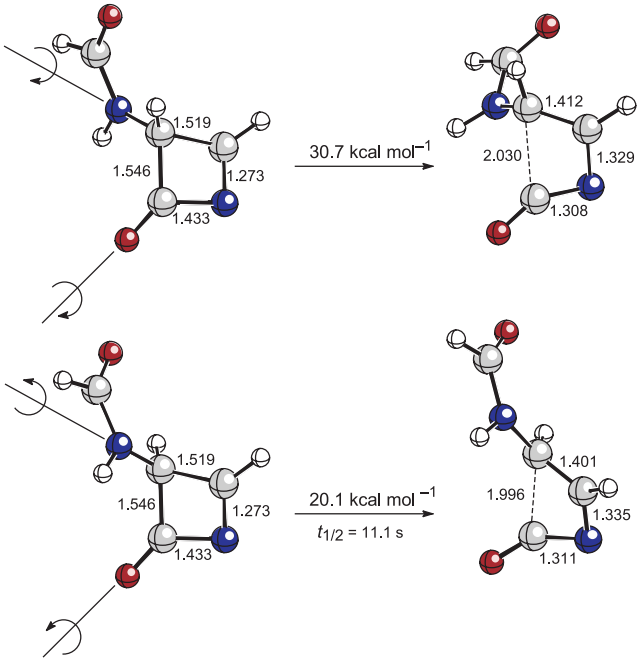
carbonyl stretch at 1713 cm^{-1}, while **18** showed peaks at 1732 and 1559 cm^{-1}.

A closer examination of the spectra of the rhodium acetate product (Fig. 2) then revealed a possible isocyanate absorption at 2268 cm^{-1} in the IR, previously (and erroneously) assigned by us to carbon dioxide, a possible isocyanate carbon at 123.33 ppm (20) in the ^{13}C NMR, previously interpreted as an aromatic carbon, and a 12.5 Hz H-C=C-H coupling constant in the ^{1}H NMR, which is compatible with the presence of a *trans*-double bond (21). All of these observations are consistent with the *trans*-substituted vinyl isocyanate **25** as the structure of the rhodium acetate product. This corresponds to the less-hindered torquochemical (22) sense of conrotatory ring opening of the putative azetinone **21**.



There is precedent for such an electrocyclic reaction in the behaviour of the benzoazetinones **26**, which equilibrate with iminoketenes **27** (23). In related work, Li and Miller (24) have reported that tosylation of the 1-hydroxy-2-azetidinone **28** leads to the imidazolone **29**, possibly via intermediates **30**–**32**. The cyclization **32** → **29** is analogous to **23** → **18** but, in view of ref. 23 and the present findings, it can be proposed that the precursor of **32** is the azetinone **33**, whose preferred mode of electrocyclic ring opening leads to a *trans*-relationship between the methyl and acylamino groups.

The *tert*-butyl- and adamantyl-substituted benzoazetinones **26** exhibit carbonyl stretching bands at 1812 and 1825 cm^{-1}, respectively, (23). The calculated (HF/6-31G*) C=O stretch of the parent azetinone **34** is at 1895 cm^{-1}, and the calculated (6-31G*) C=O stretch of the acylaminoazetinone **35** is at 1889 cm^{-1} (see *Experimental*). Since no IR peak higher than 1800 cm^{-1} can be detected during the reaction of **6** with rhodium acetate, the acylaminoazetinone **21** is presumed to have an extremely short lifetime. In retrospect, this is not surprising: **34** has a half-life of 2.0 ± 0.5 s at 35°C (25), the homologous 1-pyrrolin-5-one **36** has a half-life of 5.5 ± 0.5 s (25), and at-

Fig. 3. Conrotatory ring opening of a 3-acylaminoazetinone (6-31G*//6-31G* calculations). Upper: reactant and transition structure leading to the *Z*-isomer. Lower: reactant and transition structure leading to the *E*-isomer.

tempts to synthesize 1-azetine (**37**) lead instead to 2-azabutadiene (26).

Figure 3 shows the transition structures of the two conrotatory modes of electrocyclic ring opening of the acylaminoazetidinone **35**, calculated at the MP2/6-31G*//6-31G* level (27). The pathway leading to the *trans*-substituted vinyl isocyanate is 10 kcal mol^{-1} lower in energy. From the calculated 20.1 kcal mol^{-1} barrier and the Eyring equation, the estimated half-life of **35** is 11 s at 40°C.

An unprecedented result — Trapping the 3*S*-acylaminoazetinone with alcohols leads to *cis*-disubstituted azetidinones

Substituted 2-azetin-4-ones (**38**) are isolable and, in some cases, crystalline compounds (28). In contrast, with the exception of the phthalimido compound **39**, claimed in the patent literature (29), 1-azetin-4-ones (**40**) and 1-azetidinium cations (**41**) are known only as the often-proposed but never-observed intermediates in C-4-substitution reactions of 2-azetidinones (30). With compounds containing a C-3-substituent, all previous work involving the generation and capture of these putative intermediates has led (31) to *trans*-3,4-disubstituted azetidinones. In contrast, *cis*-3-phenoxyacetamido-4-alkoxyazetidinones have now been found to be produced as the major isomers (32) when saturated, unsaturated, and aromatic alcohols are included in reaction mixtures containing **6** and rhodium acetate.

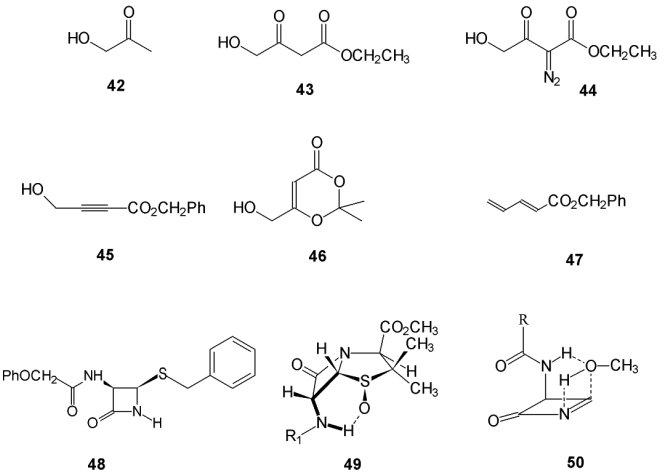

Table 1 summarizes the results of these trapping experiments. The yields shown in this table refer to isolated yields of pure *cis*- and (or) *trans*-isomers.

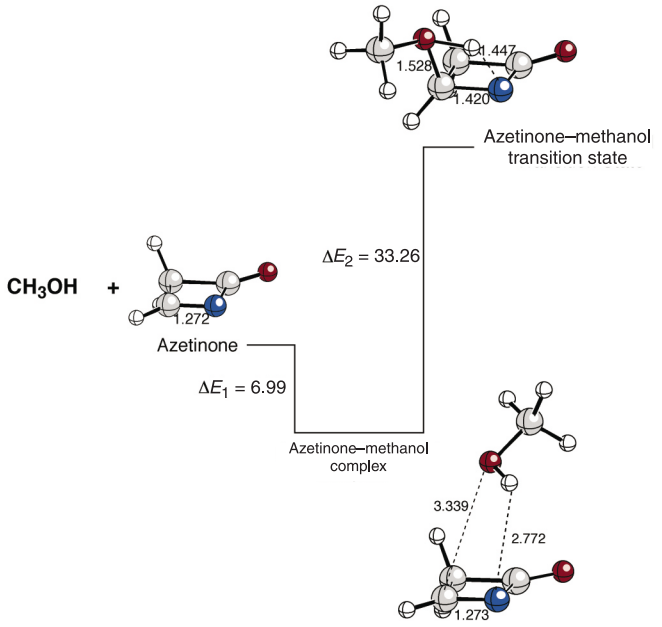
Table 1. Reaction of **6** with rhodium acetate in methylene chloride in the presence of RXH to form 3-phenoxyacetylamino-4-XR-substituted azetidinones.

RXH	Temperature (°C)	Yield of *cis*-isomer	Yield of *trans*-isomer
EtOH	20	15	nd[a]
IpOH	20	41	12
$PhCH_2OH$	40	70	22
$Me_2C{=}CHCH_2OH$	40	69	24
$HC{\equiv}CCH_2OH$	40	26	12
$CH_2{=}CHCH_2OH$	40	36	14
Furfuryl alcohol	40	50	nd
$PhCH_2SH$	40	12	4

[a]Not detected.

More complex alcohols, including hydroxyacetone (**42**), ethyl γ-hydroxyacetoacetate (**43**) (33), ethyl α-diazo-γ-hydroxyacetoacetate (**44**), benzyl 4-hydroxy-2-propynoate (**45**) (34), and 6-hydroxymethyl-1,3-dioxin-4-one (**46**) (35) did not react with the azetinone. In the case of **43**, the product was the 4-ethoxyazetidinone, presumably via prior lactonization, with liberation of ethanol, under the reaction conditions. Benzylamine, *N*-benzylamine, and benzyl pentadienoate (**47**) (36) also did not react. Benzyl mercaptan gave the *cis*-benzyl sulfide **48** in low yield (Table 1).

Theoretical considerations



The oxidation of penicillins leads to *S*-sulfoxides **49**, in which the sulfoxide oxygen occupies the concave (β) face, and is *syn* to the acylamino side chain (37). The evidence strongly suggests (37) that the oxidant is delivered to the more hindered face of the bicyclic system by hydrogen bonding to the amide N—H.

In the present work, using no more than a two-fold excess of an alcohol in the relatively nonpolar solvent methylene chloride, the alcohol is delivered *syn* to the acylamino group of the putative 3-acylaminoazetinone. With the earlier oxidation experiments as a precedent, the chair-like hydrogen-bonded transition state **50** could be proposed to account for the trapping results. This idea was pursued computationally.

Figure 4 summarizes the results of 3-21G calculations of the four-centred *cis*-addition of methanol to the parent

Fig. 4. *cis*-Addition of methanol to 1-azetin-4-one (3-21G calculations). Energy differences are in kcal mol^{-1}; bond lengths are in Å.

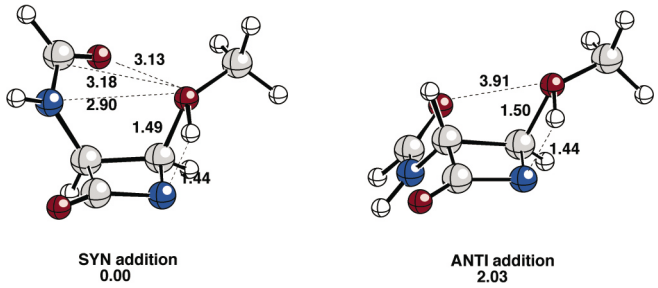
azetinone. Figure 5, which is more interesting, shows the 6-31G* transition structures for the four-centred addition of methanol *syn* and *anti* to the acylamino group of an acylamino-substituted azetinone. The *syn* structure shows no evidence of the intramolecular hydrogen bond postulated in **50**. Nevertheless, based on single point MP2/6-31G* calculations, the energy of this structure is 2.03 kcal mol^{-1} lower than that of the *anti*. In addition, the developing C···O bond is rather short, suggesting a product-like transition state. If this were the case, the *products* of the addition might also show a *syn*-preference. This is indeed the case; as seen in Fig. 6, the *gauche* conformation of MeO-CH_2CH_2-NHCHO is significantly more stable than the *anti*. Finally, the calculated MP2/6-31G*//6-31G* barrier for the *syn* addition of Fig. 5 is 20.6 kcal mol^{-1}, almost the same as that shown in Fig. 3 for the electrocyclic ring opening (20.1 kcal mol^{-1}).

Experimental

3-Phenoxyacetamido-4-mercapto-2-azetidinone (3)

A 40% aqueous solution of *p*-toluenesulfonic acid hydrate (13 mL) was added to a solution of the thiazoline azetidinone **1** (5.03 g, 21.5 mmol) in a mixture of dichloromethane (100 mL) and acetone (100 mL). The mixture was stirred for 2 h, and the mercaptoazetidinone was then collected by filtration and dried in vacuo. A second crop was recovered by evaporation of the filtrate and trituration with a minimum amount of water (4.93 g, 91%), mp 138–140°C (lit. (38) 133–135°C). MS (CI, *m*/*z*): 219 ((M + 1)-H_2S). IR (KBr) (cm^{-1}): 3283, 3210, 1761, 1659. ^{1}H NMR (DMSO-d_6): 8.93 (1H, d, 9.3 Hz, NH), 8.79 (1H, s, NH), 7.29 (2H, t, Ar), 6.98 (3H, m, Ar), 5.32 (1H, dd, 4.7, 9.3 Hz, H-3), 5.00 (1H, 4.7, 10.2 Hz, H-4), 4.61 (1H, d, 15.1 Hz, C*H*H), 4.58 (1H, d, 15.1 Hz, CH*H*), 3.19 (1H, d, 10.3 Hz, SH). ^{13}C

Fig. 5. Transition structures for the four-centered *cis*-addition of methanol *syn* (left) and *anti* (right) to 3-formylamino-1-azetin-4-one. Geometries have been optimized at 6-31G*. Relative energies refer to single point MP2/6-31G* calculations at the 6-31G* optimized geometries.



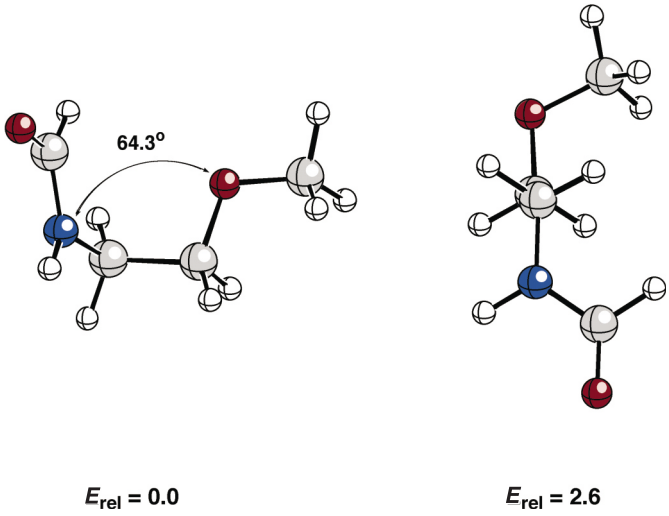


Fig. 6. The gauche effect in MeO-CH_2CH_2-NHCHO (MP2/6-31G*//6-31G*) calculations. The gauche conformation is 2.6 kcal mol^{-1} more stable than the *anti*.

NMR (DMSO-d_6): 166.59 (acetamido C=O), 161.90 (β-lactam C=O), 157.33, 129.47, 121.46, 114.86 (aromatic), 150.11 (C-3), 124.76 (C-4), 66.35 ($PhOCH_2$). Anal. calcd. for $C_{11}H_{12}N_2O_3S$: C 52.37, H 4.79, N 11.10; found: C 52.24, H 5.00, N 11.30.

Ethyl γ-bromoacetoacetate (4) (39)

A solution of bromine (1.4 mL, 4.34 g, 27.1 mmol) in glacial acetic acid (4 mL) was added dropwise, with stirring at 0°C, to a solution of ethyl acetoacetate (3.2 mL, 3.3 g, 25.1 mmol) in glacial acetic acid (9 mL). After the addition was complete, the ice bath was removed and stirring was continued overnight. The yellow solution was then diluted with ether (30 mL) and washed successively with water (3 × 30 mL), saturated sodium bicarbonate (4 × 40 mL), water (40 mL), and saturated sodium chloride (40 mL), dried over magnesium sulfate, and evaporated to afford the product as a yellowish-green liquid (3.99 g, 76%). The compound was characterized spectroscopically, and used directly in the next step. MS (CI, *m*/*z*): 209 (M + 1, for ^{79}Br), 211 (M + 1, for ^{81}Br). IR (KBr) (cm^{-1}): 1744, 1726. ^{1}H NMR ($CDCl_3$): 4.20 (2H, q, 7.1 Hz), 4.05 (2H, s), 3.70 (2H, s), 1.29 (3H, t,

7.1 Hz). ^{13}C NMR ($CDCl_3$): 194.44 (acetyl C=O), 166.52 (ester C=O), 61.73 (ester methylene), 46.05 (C-4), 33.66 (C-2), 14.03 (methyl).

Ethyl α,γ-dibromoacetoacetate (14)

A solution of ethyl γ-bromoacetoacetate (12.5 mg, 0.060 mmol) in tetrahydrofuran (0.2 mL) was treated with a solution of pyrrolidone hydrotribromide (20.5 mg, 0.060 mmol) in tetrahydrofuran (0.7 mL). Stirring was continued for 3 h, and the solids were then removed by filtration. The filtrate was diluted with ethyl acetate (5 mL), washed successively with water (5 mL) and saturated sodium chloride, dried over magnesium sulfate, and evaporated to afford the product as a yellow oil (15.8 mg, 91%). ^{1}H NMR ($CDCl_3$): 5.17 (1H, s), 4.30 (2H, q, 7.2 Hz), 1.31 (3H, t, 7.2 Hz). IR (neat) (cm^{-1}): 1748, 1728.

Ethyl α-bromoacetoacetate (15)

A solution of pyrrolidone hydrotribromide (49.5 mg, 0.099 mmol) in tetrahydrofuran (0.8 mL) was added dropwise to a solution of ethyl acetoacetate (0.012 mL, 12.3 mg, 0.095 mmol) in tetrahydrofuran (0.4 mL). After 30 min, the reaction mixture was diluted with ether (4 mL) and maintained overnight at –5°C. The mixture was then filtered and the filtrate was evaporated to dryness. The residue was dissolved in ethyl acetate (5 mL), and this solution was washed successively with saturated sodium bicarbonate (5 mL) and water (5 mL), dried over magnesium sulfate, and evaporated to afford the product as a colourless oil. ^{1}H NMR ($CDCl_3$): 4.77 (1H, s), 4.30 (2H, q, 7.3 Hz), 2.45 (3H, s), 1.32 (3H, t, 7.3 Hz).

Ethyl α,α-dibromoacetoacetate (16)

A solution of pyrrolidone hydrotribromide (77.1 mg, 0.158 mmol) in tetrahydrofuran (0.9 mL) was added dropwise, with stirring, to a solution of ethyl acetoacetate (0.011 mL, 10.9 mg, 0.084 mmol) in tetrahydrofuran (0.3 mL). The mixture was stirred for 3 h and the filtrate was then diluted with ethyl acetate (5 mL), washed successively with saturated sodium bicarbonate (50 mL), water (50 mL), and saturated sodium chloride (50 mL), dried over magnesium sulfate, and evaporated to give the product (12.2 mg, 51%). ^{1}H NMR ($CDCl_3$): 4.38 (2H, q, 7.2 Hz), 2.60 (3H, s), 1.35 (3H, t, 7.2 Hz).

Coupling of 3 with ethyl bromoacetate

Ethyl bromoacetate (3.4 μL, 5.1 mg, 0.03 mmol) was added to a solution of **3** (6.5 mg, 0.03 mmol) in hexamethylphosphoric triamide (0.06 mL). The solution was stirred for 23 h. Ethyl acetate (10 mL) was then added and the resulting solution was washed successively with water (2 × 10 mL) and saturated sodium chloride (10 mL), dried over magnesium sulfate, and evaporated. The residue was crystallized from chloroform–ether to give **2**, 5.8 mg (66%) (13). ^{1}H NMR ($CDCl_3$): 7.44 (1H, d, 8.9 Hz, NH), 7.24 (2H, t, Ar), 7.03 (1H, t, Ar), 6.94 (2H, t, Ar), 6.65 (1H, br s, NH), 5.62 (1H, dd, 4.5, 8.9 Hz, H-3), 5.14 (1H, d, 4.5 Hz, H-4), 4.57 (2H, s, $PhOCH_2$), 4.17 (2H, q, 7.2 Hz, ester CH_2), 3.27 (1H, d, 11.5 Hz, SC*H*H), 3.24 (1H, d, 11.5 Hz, SCH*H*), 1.27 (3H, t, 7.2 Hz, ester CH_3). ^{13}C NMR ($CDCl_3$): 170.32 (acetamido C=O), 168.84 (ester C=O), 165.35 (β-lactam C=O), 157.22, 129.81, 122.41, 114.92 (aromatic), 67.44 ($PhOCH_2$), 62.03 (C4), 61.93 ($CO_2CH_2CH_3$), 60.44 (C-3), 32.91 (SCH_2CO), 14.05 ($CO_2CH_2CH_3$).

Coupling of 3 with 4

Ethyl γ-bromoacetoacetate (2.01 g, 9.64 mmol) was added dropwise with stirring during 15 min to a solution of **3** (2.14 g, 8.49 mmol) in hexamethylphosphoric triamide (30 mL). The pale yellow solution was stirred for 24 h, diluted with ethyl acetate (50 mL) and washed successively with water (3 × 50 mL) and saturated sodium chloride (50 mL), dried over magnesium sulfate, and evaporated. The resulting foam (**5**) crystallized upon trituration with anhydrous ether, 1.84 g (57%), mp 106–108°C. $[\alpha]_D^{20}$ +69.6° (c 0.115, chloroform). MS (EI, *m*/*z*): 380 (M). HR-MS-EI calcd. for $C_{17}H_{20}N_2O_6S$: 380.1042 (M); found: 380.1044. IR (KBr) (cm^{-1}): 3304, 1762, 1735, 1701, 1675. ^{1}H NMR ($CDCl_3$): 7.38 (1H, d, 8.7 Hz, NH), 7.32 (2H, t, Ar), 7.04 (1H, t, Ar), 6.96 (2H, d, Ar), 6.66 (1H, s, NH), 5.56 (1H, dd, 4.7, 8.7 Hz, H-3), 5.00 (1H, d, 4.7 Hz, H-4), 4.58 (1H, d, 15.2 Hz, PhOC*H*H), 4.57 (1H, d, 15.2 Hz, PhOCH*H*), 4.19 (2H, q, 7.2 Hz, ester CH_2), 3.66 (1H, d, 16.0 Hz, SC*H*H), 3.54 (1H, d, 16.0 Hz, SCH*H*), 3.48 (1H, d, 15.5 Hz, COC*H*HCO), 3.45 (1H, d, 15.5 Hz, COCH*H*CO), 1.28 (3H, t, 7.2 Hz, ester CH_3). ^{13}C NMR ($CDCl_3$): 198.00 (C=O), 168.85 (acetamido C=O), 166.93 (ester C=O), 165.16 (β-lactam C=O), 157.20, 129.82, 122.41, 114.97 (aromatic), 67.41 (PhOCH), 61.89 (C-4), 61.59 ($CO_2CH_2CH_3$), 60.60 (C-3), 47.07 ($COCH_2CO$), 40.46 (SCH_2CO), 14.06 ($CO_2CH_2CH_3$). ***p*-Carboxybenzenesulfonyl azide**

A suspension of the potassium salt of *p*-carboxybenzenesulfonic acid (10.00 g, 41.6 mmol) in chlorosulfonic acid (14.0 mL) was heated for 3 h at 100°C. The reaction mixture was then cooled to room temperature and cautiously poured onto ice (40 g). The white precipitate was collected, air dried, dissolved in acetone (125 mL), and treated with a solution of sodium azide (3.11 g, 47.8 mmol) in water (20 mL). After warming at 40°C for 2.5 h, with addition of water as necessary to maintain one phase, the solution was immersed in ice, water was added to the cloud point, and crystallization was allowed to proceed. The crystals were collected, triturated with ether (50 mL), and dried to give the product (4.89 g, 52%), mp 177–179°C (lit. (40) mp 180°C (dec)). MS (EI, *m*/*z*): 227 (M). IR (KBr) (cm^{-1}): 3100–2554, 2151, 1703, 1377. ^{1}H NMR ($CDCl_3$, triethylamine salt): 10.06 (1H, br s, NH), 8.23 (2H, d, 8.8 Hz, Ar), 7.91 (2H, d, 8.8 Hz, Ar), 2.61 (6H, q, 7.2 Hz, CH_2), 1.05 (9H, t, 7.2 Hz, CH_3). ^{13}C NMR ($CDCl_3$, triethylamine salt): 170.49 (carboxylate), 143.98, 139.09, 130.49, 126.93 (aromatic), 45.26 (CH_3CH_2N), 8.71 (CH_3CH_2N).

Diazo transfer to 5

p-Carboxybenzenesulfonyl azide (845 mg, 3.72 mmol) was added to a solution of the azetidinone (1.29 g, 3.39 mmol) in acetonitrile (28 mL). The suspension was stirred in an ice bath while triethylamine (1.4 mL, 1.02 g, 10.04 mmol) was added dropwise. The suspension dissolved

© 2001 NRC Canada

initially and, after 10 min, a precipitate reappeared. The ice bath was removed and the mixture was stirred for 3 h and then filtered. The filtrate was evaporated and the yellow residue, in dichloromethane (80 mL), was washed with saturated sodium bicarbonate (2 × 80 mL) and water (80 mL), dried over magnesium sulfate, and evaporated. Trituration with ethyl acetate – ether (1:5) and cooling overnight at 5°C afforded **6** as a pale yellow solid (0.98 g, 71%), mp 135–137°C. $[\alpha]_D^{20}$ +55.0° (c 0.109, chloroform). MS (CI, *m*/*z*): 161, 219. IR (KBr) (cm^{-1}): 3310, 3192, 2145, 1765, 1719, 1663, 1645. ^1H NMR ($CDCl_3$): 7.38 (1H, d, 11.9 Hz, NH), 7.34 (2H, m, Ar), 7.03 (1H, t, Ar), 6.94 (2H, d, Ar), 6.48 (1H, br s, NH), 5.62 (1H, ddd, 1.0, 4.7, 9.1 Hz, H-3), 5.13 (1H, d, 4.7 Hz, H-4), 4.56 (2H, s, $PhOCH_2$), 4.28 (2H, dq, 7.1, 7.2 Hz, nonequivalent protons of ester methylene), 4.02 (1H, d, 14.5 Hz, SC*H*H), 3.61 (1H, d, 14.5 Hz, SCH*H*), 1.31 (3H, t, 7.1 Hz, ester CH_3). ^{13}C NMR ($CDCl_3$): 188.02 (acetyl C=O), 168.68 (acetamido C=O), 165.39 (β-lactam C=O), 161.40 (ester, C=O), 157.21, 129.81, 122.40, 114.99 (aromatic), 67.44 ($PhOCH_2$), 61.99 (C4), 61.58 ($CO_2CH_2CH_3$), 60.35 (C-3), 36.97 (SCH_2CO), 14.26 ($CO_2CH_2CH_3$). Anal. calcd. for $C_{17}H_{18}N_4O_6S\cdot0.5H_2O$: C 49.15, H 4.61, N 13.49; found: C 48.90, H 4.51, N 12.55.

Rhodium(II) acetate (41)

A solution of rhodium(III) chloride trihydrate (126.3 mg, 0.48 mmol) and sodium acetate trihydrate (259.1 mg, 1.90 mmol) in absolute ethanol (2.5 mL) and glacial acetic acid (2.5 mL) was heated at 105°C for 1.5 h. The green reaction mixture was then cooled and filtered. Recrystallization from hot methanol and drying at 35°C in vacuo yielded emerald green crystals (87.1 mg, 33%). IR (KBr) (cm^{-1}): 1588, 1439, 1433. ^1H NMR (acetone-d_6): 1.74 (s). Anal. calcd. for $Rh_2C_8H_{12}O_8$: C 21.74, H 2.74; found: C 21.98, H 2.86.

Reaction of 6 with rhodium acetate — Isolation and characterization of the thietanone 22

Rhodium(II) acetate (5.1 mg, 0.015 mmol) was added to a solution of **6** (20 mg, 0.049 mmol) in dichloromethane (2 mL). The solution was stirred for 23 h and then flushed through a 5-cm column of silica gel, using dichloromethane, to give unreacted diazoketone (5 mg) and **22** as a colourless, fragrant film (2.5 mg, 32%). MS (CI, *m*/*z*): 161 (M + 1). HR-MS-CI calcd. for $C_6H_8O_3S$: 161.0262 (M + 1); found: 161.0267. IR ($CHCl_3$) (cm^{-1}): 3412, 1790, 1691. ^1H NMR ($CDCl_3$): 7.32 (3H, m, Ar + NH), 7.03 (1H, t, Ar), 6.92 (2H, d, Ar), 6.54 (1H, br s, NH), 5.52 (1H, ddd, 1.4, 3.9, 9.5 Hz, H-3), 5.17 (1H, d, 3.9 Hz, H-4), 4.59 (1H, d, 15.1 Hz, PhOC*H*H), 4.53 (1H, d, 15.1 Hz, PhOCH*H*), 3.61 (1H, dq, 7.0, 14.0, OC*H*H), 3.48 (1H, dq, 7.0, 14.0 Hz, OCH*H*), 1.17 (3H, t, 7.0 Hz, CH_3). ^{13}C NMR ($CDCl_3$): 168.30 (acetamido C=O). 167.24 (β-lactam C=O), 157.63, 129.80, 122,32, 114.85 (aromatic), 81.09 (C4), 67.47 ($PhOCH_2$), 64.61 (OCH_2CH_3), 59.76 (C-3), 14.92 (OCH_2CH_3).

(ii) With isopropanol

Rhodium(II) acetate (1 mg, 0.002 mmol) was added to a solution of the diazoketone (14.1 mg, 0.035 mmol) and 2-propanol (0.003 mL, 2.4 mg, 0.039 mmol) in dichloromethane (1 mL). The red solution was stirred overnight under nitrogen and then evaporated. The residue was chromatographed using dichloromethane to elute the thietanone and a blue film, which decolourized upon washing with water to afford a white solid. Fractional crystallization from ethyl acetate – pentane afforded the *cis*-isomer as white crystals (4.0 mg, 41%), mp 93–95°C, and the *trans*-isomer (1.2 mg, 12%). *cis*-Isomer: $[\alpha]_D^{20}$ +29.3° (c 0.205, chloroform. MS (CI, *m*/*z*): 279 (M + 1). HR-MS-EI calcd. for $C_{14}H_{18}N_2O_4$: 278.1267 (M); found: 278.1266. IR (KBr) (cm^{-1}): 3410, 1792, 1690. ^1H NMR ($CDCl_3$): 7.38 (1H, d, 9.6 Hz, NH), 7.32 (2H, m, Ar), 7.03 (1H, t, Ar), 6.93 (2H, d, Ar), 6.60 (1H, br s, NH), 5.54 (1H, ddd, 1.4, 3.9, 9.6 Hz, H-3), 5.27 (1H, d, 3.9 Hz, H-4), 4.60 (1H, d, 15.1 Hz, PhOC*H*H), 4.54 (1H, d, 15.1 Hz, PhOCH*H*), 3.77 (1H, septet, 6.2 Hz, CH), 1.19 (3H, d, 6.2 Hz, methyl), 1.12 (3H, d, 6.2 Hz, methyl). ^{13}C NMR ($CDCl_3$): 168.22 (acetamido C=O), 167.57 (β-lactam C=O), 154.93, 129.81, 122.29, 114.85 (aromatic), 79.76 (C4), 71.90 (isopropyl CH), 67.44 ($PhOCH_2$), 59.89 (C-3), 22.59, 22.25 (isopropyl methyls). *trans*-Isomer: ^1H NMR ($CDCl_3$) 7.32 (2H, m Ar), 7.09 (1H, d, 7.6 Hz, N*H*), 7.04 (1H, t, Ar), 6.92 (2H, d, Ar), 6.33 (1H, br s, N*H*), 5.22 (1H, d, 1.2 Hz, H-4), 4.54 (2H, s, $PhOCH_2$), 4.59 (1H, dd, 1.2, 7.6 Hz, H-3), 3.87 (1H, sept, 5.6 Hz, Ip H), 1.23 (3H, d, 5.6 Hz, Me), 1.21 (3H, d, 5.6 Hz, Me).

(iii) With benzyl alcohol

A solution of the diazoketone (19.7 mg, 0.048 mmol) and benzyl alcohol (0.011 mL, 11.5 mg, 0.106 mmol) in dichloromethane (2.6 mL) was stirred briefly with rhodium (II) acetate (3.1 mg, 14 mol%), and then immersed in a preheated oil bath at 50°C. The red solution was refluxed for 28 h and evaporated to give a red residue with a fragrant odour. The residue was chromatographed, using dichloromethane (20 mL) to elute the thietanone, followed by dichloromethane – ethyl acetate (1:1) to isolate a crystalline *cis*-benzyloxyazetidinone (15.9 mg, 70%), mp 128–131°C, and an oily *trans*-benzyloxyazetidinone (5 mg, 22%). *cis*-Isomer: $[\alpha]_D^{20}$ +26.7° (c 0.15, chloroform). MS (CI, *m*/*z*): 327 (M + 1). IR (CH_2Cl_2) (cm^{-1}): 3414, 1792, 1692. ^1H NMR ($CDCl_3$): 7.39 (1H, d, 9.6 Hz, NH), 7.32–7.26 (7H, m, Ar), 7.02 (1H, t, Ar), 6.87 (2H, d, Ar), 6.65 (1H, br s, NH), 5.51 (1H, ddd, 1.4, 3.9, 9.6 Hz, H-3), 5.26 (1H, d, 3.9 Hz, H-4), 4.57 (2H, s, $PhOCH_2$), 4.53 (1H, d, 15.0 Hz, benzyl C*H*H), 4.50 (1H, d, 15.0 Hz, benzyl CH*H*). ^{13}C NMR ($CDCl_3$): 168.57 (acetamido C=O), 168.05 (β-lactam C=O), 138.61, 130.44, 129.25, 128.55, 128.51, 122.55, 115.83 (aromatic), 81.61 (C-4), 70.82 (OCH_2Ph), 68.13 ($PhOCH_2$), 60.68 (C-3). Anal. calcd. for $C_{18}H_{18}N_2O_4 \cdot H_2O$: C 62.78, H 5.85, N 8.13; found: C 62.25, H 5.41, N 7.92. *trans*-Isomer: ^1H NMR ($CDCl_3$): 7.36–7.30 (8H, m, Ar + NH), 7.04 (1H, m, Ar), 6.92 (2H, d, Ar), 6.91 (1H, d, 7.1 Hz, NH), 6.83 (1H, br s, NH), 5.27 (1H, d, 1.0 Hz, H-4), 4.95 (1H, dd, 1.0, 7.1 Hz, H-3), 4.87 (1H, d, 11.8 Hz, OC*H*HPh), 4.70 (1H, d, 11.8 Hz, OCH*H*Ph), 4.67 (1H, d, 14.9 Hz, PhOC*H*H), 4.63 (1H, d, 14.9 Hz, PhOCH*H*).

(iv) With dimethallyl alcohol

A solution of the diazoketone (181 mg, 0.45 mmol) and 3-methyl-2-butenol (0.12 mL, 102 mg, 1.2 mmol) in dichloromethane (34 mL) was stirred with rhodium(II) acetate (20 mg, 0.05 mmol) and placed in a preheated oil bath at 50°C. The red solution was refluxed for 11 h and the solvent was then removed. The residue was chromatographed, using dichloromethane (100 mL), to isolate the thietanone, followed by dichloromethane – ethyl acetate (1:1) to yield the *cis*- and *trans*-disubstituted azetidinones as blue solids. These was dissolved in dichloromethane (20 mL), and the solutions were washed with water (20 mL), dried over magnesium sulfate, and evaporated to give the crystalline *cis*-disubstituted azetidinone (94 mg, 69%), mp 79–83°C, and the *trans*-disubstituted azetidinone (33 mg, 24%). *cis*-Isomer: $[\alpha]_D^{20}$ –8.6° (c 0.116, chloroform). MS (CI, *m*/*z*): 305 (M + 1). HR-MS-CI calcd. for $C_{16}H_{20}N_2O_4$: 305.1502 (M + 1); found: 305.1504. IR (CH_2Cl_2) (cm^{-1}): 3412, 1790, 1692. ^1H NMR ($CDCl_3$): 7.32 (3H, m, Ar + NH), 7.03 (1H, t, Ar), 6.93 (2H, d, Ar), 6.49 (1H, br s, NH), 5.49 (1H, ddd, 1.2, 3.8, 9.4 Hz, H-3), 5.25 (1H, m, OCH_2CH=), 5.18 (1H, d, 3.8 Hz, H-4), 4.57 (1H, d, 15.0 Hz, PhOC*H*H), 4.52 (1H, d, 15.0 Hz, PhOCH*H*), 4.06 (1H, dd, 6.9, 11.5 Hz, OC*H*HCH=), 4.00 (1H, dd, 6.9, 11.5 Hz, OCH*H*CH=), 1.76 (3H, s, methyl), 1.64 (3H, s, methyl). ^{13}C NMR ($CDCl_3$): 168.31 (acetamido C=O), 167.20 (β-lactam C=O), 157.25, 129.77, 122.29, 114.91 (aromatic), 138.69 (OCH_2CH=*C*), 119.46 (OCH_2CH=C), 80.67 (C4), 67.45 ($PhOCH_2$), 65.63 (OCH_2CH=), 59.80 (C3), 25.70 (methyl), 18.03 (methyl). *trans*-Isomer: MS (CI, *m*/*z*): 305 (M + 1). IR (CH_2Cl_2) (cm^{-1}): 1786, 1696. ^1H NMR ($CDCl_3$): 7.32 (2H, t, Ar), 7.16 (1H, d, 7.6 Hz, NH), 7.04 (1H, t, Ar), 6.91 (2H, d, Ar), 6.54 (1H, br s, NH), 5.34 (1H, m, OCH_2CH=), 5.13 (1H, d, 1.2 Hz, H-4), 4.65 (1H, 1.2, 7.6 Hz, H-3), 4.53 (2H, s, $PhOCH_2$), 4.18 (1H, dd, 7.3, 11.3 Hz, OC*H*HCH=), 4.11 (1H, dd, 7.3, 11.3 Hz, OCH*H*CH=), 1.76 (3H, s, methyl), 1.70 (3H, s, methyl). ^{13}C NMR ($CDCl_3$): 169.01, 165.70, 157.08, 138.69, 129.74, 122.18, 114.73, 119.58, 83.94, 67.12, 65.14, 63.64, 25.71, 18.01. Anal. calcd. for $C_{16}H_{20}N_2O_4$: C 63.14, H 6.62, N 9.20; found: C 63.37, H 6.68, N 8.98.

(v) With propargyl alcohol

A solution of **6** (20.2 mg, 0.050 mmol) and propargyl alcohol (0.006 mL, 5.8 mg, 0.10 mmol), in dichloromethane (2.4 mL), was stirred with rhodium(II) acetate (2 mg, 0.005 mmol) and placed in a preheated oil bath at 50°C. The

© 2001 NRC Canada

red solution was refluxed for 15 h, and the solvent was then evaporated. The red residue was chromatographed, using dichloromethane, to isolate the thietanone, followed by dichloromethane – ethyl acetate (1:1) to give the products as blue solids. These were dissolved in dichloromethane (10 mL) and washed successively with water (10 mL) and saturated sodium chloride (10 mL), dried over magnesium sulfate, and evaporated to give the *cis*-isomer (4.3 mg, 26%) and the *trans*-isomer (2 mg, 12%). *cis*-Isomer: $[\alpha]_D^{20}$ –29.4° (c 0.340, chloroform). MS (CI, *m*/*z*): 275 (M + 1). HR-MS-CI calcd. for $C_{14}H_{14}N_2O_4$: 275.1032 (M + 1); found: 275.1035. IR ($CHCl_3$) (cm^{-1}): 3420, 3306, 2402, 1790, 1690. ^{1}H NMR ($CDCl_3$): 7.32 (3H, m, Ar + NH), 7.03 (1H, t, Ar), 6.93 (2H, m, Ar), 6.79 (1H, br s, NH), 5.55 (1H, ddd, 1.4, 4.0, 9.6 Hz, H-3), 5.36 (1H, d, 4.0 Hz, H-4), 4.56 (1H, d, 15.1 Hz, PhOC*H*H), 4.53 (1H, d, 15.1 Hz, PhOCH*H*), 4.23 (1H, dd, 2.4, 16.2 Hz, OC*H*H), 4.18 (1H, dd, 2.4, 16.2 Hz, OCH*H*), 2.50 (1H, t, 2.4 Hz, (C=C-H). ^{13}C NMR ($CDCl_3$): 168.45 (acetamido C=O), 166.94 (β-lactam C=O), 157.21, 129.78, 122.34, 114.95 (aromatic), 81.02 (C-4), 78.35 (OCH_2C=CH), 75.93 (OCH_2C=*C*H), 67.44 ($PhOCH_2$), 59.96 (C-3), 56.50 (OCH_2C=CH). *trans*-Isomer: ^{1}H NMR ($CDCl_3$): 7.35–7.30 (3H, m, Ar + NH), 7.05 (1H, t, Ar), 6.93 (2H, d, Ar), 6.50 (1H, br s, NH), 5.31 (1H, d, 1.1 Hz, H-4), 4.66 (1H, dd, 1.1, 7.2 Hz, H-3), 4.54 (2H, s, $PhOCH_2$), 4.37 (1H, dd, 1.2, 2.4 Hz, OC*H*HC=CH), 4.36 (1H, dd, 1.2, 2.4 Hz, OCH*H*C=CH), 2.49 (1H, t, 2.4 Hz, OCH_2C=CH).

(vi) With allyl alcohol

To **6** (14.7 mg, 0.036 mmol) and allyl alcohol (0.006 mL, 5.1 mg, 0.81 mmol), in dichloromethane (2.6 mL) was added rhodium(II) acetate (2 mg, 0.005 mmol). The mixture was immersed in a preheated oil bath at 50°C and refluxed for 11 h. The solvent was then removed and the red residue chromatographed using dichloromethane, to elute the thietanone, followed by dichloromethane – ethyl acetate (1:1) to give the products as blue films. These were dissolved in dichloromethane (10 mL) and the solutions were washed successively with water (10 mL) and saturated sodium chloride (10 mL), dried over magnesium sulfate, and evaporated to give the *cis*-isomer (3.6 mg, 36%) and the *trans*-isomer (1.4 mg, 14%) as colourless oils. *cis*-Isomer: $[\alpha]_D^{20}$ –14.3° (c 0.070, $CHCl_3$). MS (CI, *m*/*z*): 277 (M + 1). HR-MS-CI calcd. for $C_{14}H_{16}N_2O_4$: 277.1188 (M + 1); found: 277.1189. IR ($CHCl_3$) (cm^{-1}): 3418, 1788, 1692. ^{1}H NMR ($CDCl_3$): 7.37 (3H, m, Ar + NH), 7.03 (1H, m, Ar), 6.92 (2H, m, Ar), 6.55 (1H, br s, NH), 5.87 (1H, ddt, 5.6, 10.4, 17.2 Hz, =CH), 5.53 (1H, ddd, 1.4, 3.9, 9.6 Hz, H-3), 5.33 (1H, dq, 1.4, 17.2 Hz, =C*H*H), 5.22 (1H, dq, 1.4, 10.4 Hz, =CH*H*), 5.21 (1H, d, 3.9 Hz, H-4), 4.58 (1H, d, 15.1 Hz, PhOC*H*H), 4.53 (1H, d, 15.1 Hz, PhOCH*H*), 4.22 (1H, ddt, 1.4, 5.6, 12.7 Hz, OC*H*H), 4.13 (1H, ddt, 1.4, 5.6, 12.7 Hz, OCH*H*). ^{13}C NMR ($CDCl_3$): 168.90 (acetamido C=O), 168.40 (β-lactam C=O), 157.25, 129.87, 122.33, 115.00 (aromatic), 133.19 (OCH_2CH=CH_2), 118.28 (OCH_2CH=*C*H_2), 81.01 (C-4), 70.06 (OCH_2CH=CH_2), 67.46 ($PhOCH_2$), 59.88 (C-3). *trans*-Isomer: ^{1}H NMR ($CDCl_3$): 7.33 (2H, t, Ar), 7.12 (1H, d, 7.0 Hz, NH), 7.04 (1H, t, Ar), 6.91 (2H, d, Ar), 6.47 (1H, br s, NH), 5.93 (1H, m, OCH_2C*H*=CH), 5.33 (1H, dq, 1.4, 3.0, 16.7 Hz, CH=C*H*H), 5.25 (1H, dq, 1.4, 2.6, 10.4 Hz, CH=CH*H*), 5.16 (1H, d, 1.2 Hz, H-4), 4.67 (1H, dd, 1.2, 7.4 Hz, H-3), 4.53 (2H, s, $PhOCH_2$), 4.22 (1H, ddt, 1.4, 5.4, 12.7 Hz, OC*H*HCH=CH_2), 4.12 (1H, ddt, 1.4, 6.1, 12.7 Hz, OCH*H*CH=CH_2).

(vii) With furfuryl alcohol

A solution of **6** (31 mg, 0.076 mmol) and furfuryl alcohol (0.014 mL, 0.162 mmol) in dichloromethane (4 mL) was heated to reflux under nitrogen and rhodium(II) acetate (5 mg, 0.01 mmol) was added. Refluxing was continued for 14 h, and the solvent was then removed. The residue was chromatographed on silica gel; elution with 7:3 ethyl acetate:hexanes gave 12.1 mg (50%) of the *cis*-product. ^{1}H NMR ($CDCl_3$): 7.39–7.29 (4H, m, Ph + furfuryl + NH), 7.03 (1H, t, Ph), 6.92 (2H, d, Ph), 6.34 (2H, d, 1.4 Hz, furfuryl), 6.32 (1H, br s, NH), 5.51 (1H, ddd, 1.3, 3.9, 9.6 Hz, H-3), 5.28 (1H, d, 3.9 Hz, H-4), 4.57 (1H, d, 13.2 Hz, OC*H*H), 4.54 (1H, d, 14.9 Hz, PhOC*H*H), 4.52 (1H, d, 13.2 Hz, OCH*H*), 4.50 (1H, d, 14.9 Hz, PhOCH*H*).

With hydroxyacetone (42)

To bromoacetone (2.06 g, 15.1 mmol), in dimethylformamide (80 mL), was added sodium formate (2.11 g, 31.00 mmol). The solution was stirred for 6 h, diluted with ethyl acetate (100 mL), washed successively with water (2 × 100 mL) and saturated sodium chloride (100 mL), dried over magnesium sulfate, and evaporated at room temperature to give the formate ester (900 mg, 59%). IR (neat) (cm^{-1}): 1726, 1678. ^{1}H NMR (100 MHz, $CDCl_3$): 8.16 (1H, s, aldehyde CHO), 4.76 (2H, s, OCH_2), 2.20 (3H, s, CH_3).

The formate ester (900 mg, 8.82 mmol), in absolute ethanol (10 mL), was stirred for 72 h with *p*-toluenesulfonic acid hydrate (5 mg, 0.03 mmol). The solution was evaporated at room temperature and the residue was chromatographed, using dichloromethane–ether (3:7), to give **42** as a pale yellow oil. MS (EI, *m*/*z*): 73 (M – 1), 74 (M). HR-MS-EI calcd. for $C_3H_6O_2$: 74.0368 (M); found: 74.0369. IR (neat) (cm^{-1}): 3424, 1724. ^{1}H NMR ($CDCl_3$): 4.25 (2H, s), 3.12 (1H, br s), 2.18 (3H, s). ^{13}C NMR ($CDCl_3$): 206.91 (C=O), 68.67 (CH2), 25.18 (CH_3).

Hydroxyacetone (6.9 mg, 0.093 mmol) was dried azeotropically with chloroform, and added to a solution of **6** (20.5 mg, 0.051 mmol) in dichloromethane (3 mL). The solution was stirred, rhodium(II) acetate (2.0 mg, 0.005 mmol) was added, and the mixture was refluxed for 16 h with continuous monitoring by TLC. Although **22** was produced, no β-lactam-containing product was detected. The same result was obtained when the reaction was repeated at room temperature.

With ethyl γ-hydroxyacetoacetate (43)

Sodium formate (2.82 g, 41.5 mmol) was added to a solution of ethyl γ-bromoacetoacetate (**4**) (4.33 g, 20.7 mmol) in dimethylformamide (80 mL). The solution was stirred rapidly for 2 h and then diluted with ethyl acetate (200 mL), washed successively with water (2 × 200 mL), and saturated sodium chloride (200 mL), dried over magnesium sulfate, and evaporated to afford the formate ester as a bright yellow oil (2.83 g, 78%). ^{1}H NMR (100 MHz, $CDCl_3$): 8.16 (1H, s, aldehyde CHO), 4.91 (2H, s, OCH_2CO), 4.26 (2H, q, 7.1 Hz,

© 2001 NRC Canada

ester CH_2), 3.53 (2H, s, $COCH_2CO$), 1.30 (3H, t, 7.1 Hz, ester CH_3). This oil was dissolved in absolute ethanol (100 mL) and stirred for 20 h with *p*-toluenesulfonic acid hydrate (232.3 mg, 1.2 mmol). The solvent was evaporated and the residue, in ethyl acetate (50 mL), was washed successively with water (50 mL) and saturated sodium chloride (50 mL), dried over magnesium sulfate, and evaporated. Purification of the product by column chromatography using ethyl acetate – hexanes (3:7) gave **43** as a yellow oil (1.14 g, 48%). MS (CI, *m*/*z*): 147 (M + 1). IR (neat) (cm^{-1}): 3472, 1732, 1626. ^1H NMR ($CDCl_3$): 4.38 (2H, d, 5.0 Hz, $HOCH_2CO$), 4.20 (2H, q, 7.2 Hz, ester CH_2), 3.49 (2H, s, $COCH_2CO$), 3.01 (1H, br. t, 5.0 Hz, $HOCH_2$), 1.28 (3H, t, 7.2 Hz, ester CH_3). ^{13}C NMR ($CDCl_3$): 202.29 (hydroxyacetyl C=O), 166.33 (acetate C=O), 68.49 ($HOCH_2COCH_2$), 61.74 ($CO_2CH_2CH_3$), 45.38 ($HOCH_2COCH_2CO_2CH_2CH_3$), 13.98 ($CH_2CO_2CH_2CH_3$). Anal. calcd. for $C_6H_{10}O_4$: C 49.31, H 6.90; found: C 49.21, H 6.81.

To a solution of **6** (18.4 mg, 0.045 mmol), in dichloromethane (4.0 mL), were added ethyl γ-hydroxyacetoacetate (14.5 mg, 0.099 mmol) (dried azeotropically with chloroform (3×)), and rhodium(II) acetate (3 mg, 0.007 mmol). The solution was refluxed for 7 h and then evaporated. The residue was subjected to chromatography using a dichloromethane – ethyl acetate gradient to yield **22** and a white solid identical to the product from trapping with ethanol.

With ethyl γ-hydroxy-α-diazoacetoacetate (44)

To ethyl γ-hydroxyacetoacetate (0.59 g, 4.04 mmol), in acetonitrile (10 mL), was added *p*-carboxybenzenesulfonyl azide (1.04 g, 4.57 mmol) followed, during 10 min at 0°C, by triethylamine (1.7 mL, 1.2 g, 2.20 mmol). The pale yellow solution was stirred at 0° for an additional 15 min and DBU (0.6 mL, 0.61 g, 4.01 mmol) was added to precipitate a yellow solid. After an additional 3 h of stirring at 0°, the mixture was filtered and the filtrate was evaporated. The residue was dissolved in ethyl acetate (50 mL) and the solution was washed successively with water (2 × 50 mL), saturated sodium bicarbonate (50 mL) and saturated sodium chloride (50 mL), dried over magnesium sulfate, and evaporated to give a red oil (309 mg). Purification by column chromatography, using ethyl acetate – hexanes (2:3), gave **44** as a yellow oil (178.5 mg, 26%). MS (CI, *m*/*z*): 173 (M + 1). IR (neat) (cm^{-1}): 3488, 2986–2911, 2145, 1721, 1659. ^1H NMR ($CDCl_3$): 4.61 (2H, d, 5.1 Hz, $HOCH_2$), 4.28 (2H, q, 7.1 Hz, ester CH_2), 3.40 (1H, 5.1 Hz, OH), 1.33 (3H, t, 7.1 Hz, ester CH_3). ^{13}C NMR ($CDCl_3$): 191.79 (hydroxyacetyl C=O), 160.82 (acetate C=O), 66.97 ($HOCH_2CO$), 61.97 ($CO_2CH_2CH_3$), 14.31 ($CO_2CH_2CH_3$). Anal. calcd. for $C_6H_8N_2O_4$: C 41.87, H 4.68, N 16.27; found: C 42.51, H 4.88, N 15.83.

To a solution of **6** (17.8 mg, 0.044 mmol) in dichloromethane (2.8 mL), was added ethyl γ-hydroxy-α-diazoacetoacetate (14.8 mg, 0.086 mmol) (dried azeotropically with chloroform (3×)). The solution was stirred, rhodium(II) acetate (3 mg, 0.007 mmol) was added, and the mixture was refluxed for 10 h. Although the thietanone **22** was detected, no β-lactam-containing product was found. The same result was obtained when the reaction was repeated at room temperature.

With benzyl 4-hydroxyprop-2-ynoate (45)

A solution of 3,4-dihydro-2*H*-pyran (28.0 mL, 25.82 g, 0.307 mol) in dichloromethane (100 mL) was cautiously added, at 0°C, to a solution of propargyl alcohol (16.5 mL, 15.90 g, 0.283 mol) and *p*-toluenesulfonic acid hydrate (159 mg, 0.089 mmol) in dichloromethane (80 mL). The solution was stirred for 2 h at 25° and then washed successively with water (100 mL), saturated sodium bicarbonate (100 mL), and saturated sodium chloride (100 mL), dried over magnesium sulfate, and evaporated. Purification by vacuum distillation afforded tetrahydro-2-(2-propynyloxy)pyran as a colourless oil (32.9 g, 83%), bp 63–65°C/9 torr (1 torr = 133.322 Pa). MS (CI, *m*/*z*): 141 (M + 1). IR (cm^{-1}): 3293, 2118. ^1H NMR ($CDCl_3$): 4.80 (1H, t, 3.3 Hz, OCHO), 4.27 (1H, dd, 2.4, 15.7 Hz, OC*H*HC=CH), 4.21 (1H, d, 2.4, 15.7 Hz, OCH*H*C=CH), 3.82 (1H, m, CH_2*H*HCHO), 3.49 (1H, m, CH_2CH*H*OCHO), 2.40 (1H, t, 2.4 Hz, C=C-H), 1.84–1.72 (6H, m, $OCH_2CH_2CH_2CH_2CH$). ^{13}C NMR ($CDCl_3$): 96.85 (OCHO), 79.81 (OCH_2C=CH), 73.90 (OCH_2C=*C*H), 61.97 ($OCH_2CH_2CH_2CH_2CH$), 53.97 (OCH_2C=CH), 30.22 ($OCH_2CH_2CH_2CH_2CH$), 25.35 ($OCH_2CH_2CH_2CH_2CH$), 19.00 ($OCH_2CH_2CH_2CH_2CH$).

A solution of the tetrahydropyranyl ether (2.06 g, 14.73 mmol) in tetrahydrofuran (15 mL), was treated, at –78°C, with a 2.5 M solution of *n*-butyllithium in hexane (5.9 mL, 0.94 g, 14.75 mmol). The resulting yellow solution was stirred for 1.5 h at –78°, and benzyl chloroformate (2.0 mL, 2.39 g, 14.01 mmol), in a solution of tetrahydrofuran (2.0 mL) and hexamethylphosphoramide (3.5 mL), was then added dropwise. The reaction mixture was warmed to –65° for 2 h and then to room temperature during 7.0 h, cooled to 0°, and treated with water (30 mL). The mixture was diluted with ether (60 mL) and the organic phase was separated and washed successively with water (60 mL) and saturated sodium chloride (60 mL), dried over magnesium sulfate, and evaporated. Purification by column chromatography using ethyl acetate – hexanes (1:9) afforded the tetrahydropyranyl ether of **45** as a colourless oil. ^1H NMR (100 MHz, $CDCl_3$): 7.39 (5H, s, Ar), 5.32 (1H, s, OCHO), 5.17 (2H, s, benzyl CH_2), 4.82 (2H, s, OCH_2C=CH), 3.93–3.47 (2H, m, $OCHOCH_2CH_2$), 1.73 (6H, m, $OCH_2CH_2CH_2CH_2$). A portion of this oil (50 mg, 0.18 mmol), in dry methanol (3.8 mL), was treated with trifluoroacetic acid (0.07 mL, 104 mg, 0.91 mmol). The solvent was evaporated after 30 min, and the product was purified by column chromatography using ethyl acetate – hexanes (1:4) to yield **45** as white crystals (12 mg, 35%), mp 102–104°C. MS (CI, *m*/*z*): 191 (M + 1). IR (KBr) (cm^{-1}): 3468, 1742. ^1H NMR (100 MHz, $CDCl_3$): 7.41 (5H, s, Ar), 5.21 (1H, br s, OH), 5.09 (2H, s, benzyl CH_2), 4.70 (2H, s, $HOCH_2$). ^{13}C NMR ($CDCl_3$): 178.86 (ester C=O), 173.15 ($HOCH_2C$=*C*CO_2CH_2Ph), 133.83, 129.19, 128.93, 128.01 (aromatic), 89.87 ($HOCH_2C$=C), 74.57 ($HOCH_2C$=C), 67.88 (CO_2CH_2Ph). Anal. calcd. for $C_{11}H_{10}O_3 \cdot 0.25H_2O$: C 67.86, H 5.44; found: C 67.83, H 5.28.

Rhodium(II) acetate (1 mg, 0.002 mmol) was added to a solution of **6** (12.0 mg, 0.030 mmol) and **45** (8.5 mg, 0.045 mmol) (dried azeotropically with chloroform (3×)), in dichloromethane (2.5 mL). The red solution was refluxed for 10 h while being monitored by TLC. Purification by column chromatography, using a dichloromethane – ethyl acetate

© 2001 NRC Canada

elution gradient, afforded **22** and unreacted **45**. The same result was obtained when the reaction was repeated at room temperature.

With 6-hydroxymethyl-2,2-dimethyl-4*H*-1,3-dioxin-4-one (46)

To 2,2,6-trimethyl-4*H*-1,3-dioxin-4-one (0.93 mL, 1.01 g, 7.12 mmol) in carbon tetrachloride (25 mL), were added *N*-bromosuccinimide (1.26 g, 7.08 mmol) and benzoyl peroxide (3 mg, 0.012 mmol). The mixture was heated to reflux with a heat gun and irradiated for 60 min with a 500 W Photoflood No. 2 bulb mounted beside the flask. The mixture was then cooled to 0°, filtered, and the filtrate was evaporated. The residue, in hexanes (20 mL), was washed successively with water (20 mL), saturated sodium bicarbonate (20 mL), water (20 mL), and saturated sodium chloride (20 mL), dried over magnesium sulfate, and evaporated to give 6-bromomethyl-2,2-dimethyl-4*H*-1,3-dioxin-4-one (300 mg, 19%) as a pale yellow oil. ^{1}H NMR (100 MHz, $CDCl_3$): 5.55 (1H, s, =CH), 3.90 (2H, s, $BrCH_2$), 1.74 (6H, s, CH_3).

A solution of this bromide in dimethylformamide (3.5 mL) was treated with sodium formate (206.5 mg, 3.04 mmol). The solution was stirred for 5 h and was then diluted with ether (25 mL), washed successively with water (25 mL) and saturated sodium chloride (25 mL), dried over magnesium sulfate, and evaporated to give the formate ester as a yellow oil. A solution of this compound in dry methanol (9.0 mL) was cooled to 0°, and a solution of anhydrous potassium carbonate (198.5 mg, 1.44 mmol) in water (2.3 mL) was added during 10 min. The solvent was evaporated after an additional 30 min of stirring. The residue, in dichloromethane (20 mL), was washed successively with 0.2 M hydrochloric acid (20 mL), water (20 mL), and saturated sodium chloride (20 mL), dried over magnesium sulfate, and evaporated. The product was purified by column chromatography using ethyl acetate – hexanes (3:7) to yield **46** as a yellow oil (37.9 mg). MS (CI, *m*/*z*): 159 (M + 1). IR (neat) (cm^{-1}): 3418, 1713. ^{1}H NMR ($CDCl_3$): 5.56 (1H, t, 1.2 Hz, =CH), 4.19 (2H, d, 1.2 Hz, $HOCH_2$), 2.35 (1H, br s, OH), 1.70 (6H, s, CH_3). ^{13}C NMR ($CDCl_3$): 169.85 (C=O), 161.02 (CO*C*H=C), 107.06 (H_3CCCH_3), 92.37 ($HOCH_2CCH$), 60.99 ($HOCH_2C$), 25.01 (CH_3). Anal. calcd. for $C_7H_{10}O_4 \cdot 0.5H_2O$: C 50.30, H 6.63; found: C 50.71, H 6.49.

To a solution of **6** (10.1 mg, 0.025 mmol) in dichloromethane (2.3 mL) was added **46** (11.1 mg, 0.059 mmol), which had been dried azeotropically with chloroform (3×). The resulting solution was stirred, rhodium(II) acetate (2 mg, 0.005 mmol) was added, and the mixture was refluxed for 9 h while being monitored by TLC. Although the thietanone **22** was formed, no β-lactam-containing product was isolated after evaporation of the solvent and chromatography of the residue. The same result was obtained when the reaction was repeated at room temperature.

With benzyl *trans*-2,4-pentadienoate (47)

To finely ground *trans*-2,4-pentadienoic acid (39.8 mg, 0.41 mmol), in dry dimethylformamide (6.0 mL), was added anhydrous potassium carbonate (56.3 mg, 0.41 mmol). The mixture was stirred for 10 min, and benzyl bromide (0.05 mL, 71.9 g, 0.42 mmol) was then added, with stirring, over a 5 min period. Additional dimethylformamide (5.0 mL) was added after 3 h, and the solution was stirred for 18 h, diluted with ethyl acetate (20 mL), and washed successively with water (4 × 20 mL) and saturated sodium chloride (20 mL), dried over magnesium sulfate, and evaporated to give a yellow oil (30.5 mg). Purification by column chromatography using ethyl acetate – hexanes (1:7) gave **47** as a colourless oil (13.8 mg, 18%). MS (CI, *m*/*z*): 189 (M + 1). HR-MS-CI calcd. for $C_5H_6O_2$: 189.0915 (M + 1); found: 189.0921. IR (neat) (cm^{-1}): 1716, 1642, 1600. ^{1}H NMR ($CDCl_3$): 7.40–7.26 (6H, m, Ar + H-3), 6.46 (1H, ddt, 0.6, 7.0, 10.0 Hz, H-4), 5.96 (1H, dd, 0.6, 15.4 Hz, H-2), 5.62 (1H, dt, 0.6, 17.0 Hz, =C*H*H), 5.50 (1H, dt, 0.6, 10.0 Hz, =CH*H*), 5.20 (2H, s, benzyl CH_2). ^{13}C NMR ($CDCl_3$): 166.57 (ester C=O), 145.10 (CH_2=*C*H-CH), 136.18, 128.56, 128.40), 125.57 (*C*H_2=CH-CH), 121.97 (CH_2=CH-CH-*C*H), 66.23 (CH-CH-CO_2CH_2Ph).

The ester (11.1 mg, 0.059 mmol) was dried azeotropically with chloroform and added to a solution of **6** (17.2 mg, 0.042 mmol) in dichloromethane (5.0 mL). The solution was stirred, rhodium(II) acetate (3 mg, 0.007 mmol) was added, and the mixture was refluxed for 4.5 h. Other than the thietanone **22** and unreacted **47**, isolated after chromatography using dichloromethane followed by dichloromethane – ethyl acetate (1:1), no β-lactam-containing product was detected. The same result was obtained when the reaction was repeated at room temperature.

With benzyl mercaptan

To a solution of **6** (48.9 mg, 0.12 mmol) and benzyl mercaptan (0.025 mL, 26.5 mg, 0.213 mmol), in dichloromethane (3 mL), was added rhodium acetate (6.3 mg, 0.014 mmol). The mixture was heated to reflux for 9 h, cooled to room temperature, diluted with dichloromethane (10 mL), and washed with water (2 × 13 mL). The dichloromethane layer was dried over sodium sulfate, evaporated, and purified by column chromatography using ethyl acetate – hexanes (2:1) to give the *cis*-benzyl sulfide (5.0 mg, 12%) and the *trans*-benzyl sulfide (1.5 mg, 4%). *cis*-Isomer: ^{1}H NMR ($CDCl_3$): 7.41–7.27 (8H, m, Ar + NH), 7.03 (1H, t, Ar), 6.94 (2H, d, Ar), 6.60 (1H, br s, NH), 5.58 (1H, dd, 4.6, 9.1 Hz, H-3), 4.91 (1H, d, 4.6 Hz, H-4), 4.55 (1H, d, 15.0 Hz, PhOC*H*H), 4.51 (1H, d, 15.0, PhOCH*H*), 3.72 (1H, d, 13.7 Hz, SC*H*HPh), 3.69 (1H, d, 13.7 Hz, SCH*H*Ph). *trans*-Isomer: ^{1}H NMR ($CDCl_3$): 7.35–7.27 (7H, m, Ar), 7.03 (1H, t, Ar), 7.01 (1H, d, 7.7 Hz, NH), 6.90 (2H, d, Ar), 5.59 (1H, br s, NH), 4.82 (1H, d, 2.3 Hz, H-4), 4.60 (1H, dd, 2.3, 7.7 Hz, H-3), 4.50 (2H, s, $PhOCH_2$), 3.90 (1H, d, 13.8 Hz, SC*H*HPh), 3.89 (1H, d, 13.8 Hz, SCH*H*Ph).

Theoretical

Calculations were performed using Gaussian 98 (42). Stationary points were optimized fully at the level indicated, and characterized by frequency analysis. For the calculations of C=O stretching frequencies of azetinones, calculated frequencies were scaled by 0.89 (43).

A topochemical rearrangement with multiple inversions of configuration

Saul Wolfe, Yih-Huang Hsieh, Raymond J. Batchelor, Frederick W.B. Einstein, and Ian D. Gay

Abstract: Crystalline 2-benzyloxypyridine-1-oxide rearranges slowly at room temperature to crystalline 1-benzyloxy-2-pyridone. No intermediates are detected when the process is followed by solid-state ^{13}C NMR. The crystal structure of the pyridine-1-oxide strongly suggests that a topochemically controlled intramolecular process, in which the benzyl group migrates with retention of configuration, is not feasible. On the other hand, although somewhat disfavoured by initial solid-state O···C···O angles significantly less than the ideal 180°, intermolecular topochemically controlled processes can be envisaged that lead, with multiple inversions of configuration, either to net retention of configuration or to net inversion of configuration in the benzyl group. In contrast to the 50–80% inversion observed in solution, in the solid state only inversion is observed experimentally when chirally labelled α-deuteriobenzyloxypyridine-1-oxide is allowed to rearrange.

Key words: X-ray crystallography, solid-state ^{13}C NMR, benzyl-α-D-alcohol, 2-benzyloxypyridine-1-oxide, 1-benzyloxy-2-pyridone.

Résumé : Le 1-oxyde de 2-benzyloxypyridine à l'état cristallin se réarrangement lentement, à la température ambiante, pour conduire à la 1-benzyloxypyrid-2-one. Lorsqu'on a suivi cette transformation par RMN du ^{13}C à l'état solide, on n'a pas pu détecter d'intermédiaires. La structure cristalline du 1-oxyde de pyridine suggère fortement qu'il n'est pas possible de suggérer l'existence d'un processus intramoléculaire contrôlé de façon topochimique dans lequel le groupe benzyle migrerait avec rétention de configuration. Par ailleurs, même s'il est légèrement défavorisé à l'état solide par des angles initiaux O···C···O inférieurs à la valeur idéale de 180°, il est possible d'envisager des processus intermoléculaires contrôlés de façon topichimique qui conduiraient après de multiples inversions de configuration à une rétention ou à une inversion nette de configuration dans le groupe benzyle. Par opposition aux degrés d'inversion de 50 à 80% observés expérimentalement en solution, le réarrangement du 1-oxyde de l'α-deutérobenzyloxypyridine à l'état solide ne donne lieu qu'à de l'inversion.

Mots clés : diffraction des rayons X, RMN du ^{13}C à l'état solide, alcool α-D-benzylique, 1-oxyde de 2-benzyloxypyridine, 1-benzyloxypyrid-2-one.

[Traduit par la Rédaction]

We recently reported (1) that the Tieckelmann reaction, the conversion of a 2-alkoxypyridine-1-oxide (**1**) into a 1-alkoxy-2-pyridone (**2**) (2), is not an intramolecular [1*s*,4*s*] sigmatropic rearrangement (3), as some workers had previously believed (4), but a two-step intermolecular process. In the first step (see Fig. 1), an alkyl group R* is transferred, with inversion of configuration, from one molecule of **1** to the *N*-oxide of a second molecule, to form the anion of 2-hydroxypyridine-*N*-oxide (**3**) and a 1,2-dialkoxypyridinium cation (**4**). In the second step, the nature of which depends upon the alkyl group and the solvent, one of the alkyl groups of **4** is transferred, also with inversion of configuration, to one of the oxygens of **3**. The product is then formed, without crossover and with net retention of configuration, by a double inversion of one alkyl group, or with crossover and net inversion of configuration, by single inversions of two alkyl groups.

Although four channels are, in principle, possible for the second step, only two have so far been observed. Based on kinetic studies, crossover experiments and measurement of the secondary H/D isotope effect, in dimethylformamide (DMF) at 140°C **1** (R = methyl) reacts exclusively via channel A. In the case of **1** (R = benzyl), crossover experiments and kinetic and stereochemical studies showed that channels A and B compete in DMF at 140°C, with channel A comprising about 80% of the reaction. In chloroform at 140°C, channels A and B compete equally.

Ollis and co-workers (5) have made the interesting observation that **5** undergoes quantitative Tieckelmann rearrangement to **6** in the solid state during 13 months at –15°C. The topochemical nature (6) of this reaction was not examined, but there are numerous related examples of intermolecular methyl transfer which proceed under topochemical control in the solid state (7). In each case, the crystal structure exhibits an intermolecular X···CH3···Y angle close to linearity

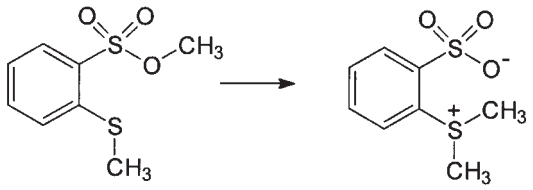
Fig. 1. Rearrangement of **1** (R = benzyl) to **2** (R = benzyl) with net inversion of configuration in the benzyl group (channel A) or with net retention of configuration in the benzyl group (channel B).



and an X···Y distance of 4 to 5 Å, and the reaction occurs exclusively, or is much faster, in the solid state than in solution or in the melt.

There is also an example of an intermolecular solid state rearrangement that is observable within 1 week at 40°C, but which, because of the molecular packing in the crystal, cannot proceed under topochemical control (8). This is the celebrated reaction **7** → **8** which, as a paradigm of linear methyl transfer (9), had previously been found to be intermolecular in solution (10). To account for the non-topochemical nature of the solid state reaction, Venugopalan et al. (8) have suggested that intermolecular methyl transfer can take place at defects such as microcavities, surfaces, and other irregularities in the ordered crystal arrangement.

5 **6**

7 **8**

2-Methoxypyridine-1-oxide (**1**, R = methyl) is reported to crystallize in two forms (11): anhydrous needles, mp 78 to 79°C, and hydrated prisms, mp 66.5 to 67.5°C. In our hands, despite considerable effort, only a hydrate, mp 73–76°C, was observed (1), as needles from ethyl acetate, and as tabular prisms after boiling in toluene, followed by cooling. The tabular prisms were employed for the determination of the crystal structure. Figure 2 shows a portion of this crystal structure, including relevant geometrical parameters. The molecules in the set that includes **A**, **B**, and **C** are mutually related by simple translations in the *x*-direction, as are the molecules of the crystallographically distinct set that includes **D** and **E**. The figure displays an edge-viewed cross section of a sheet structure, two-dimensionally extended parallel to the *xy*-plane, which is the result of the formation of chains cross-linked by hydrogen bonds from water molecules to nitroxide oxygen atoms.

Since the methyl group is positioned *anti* to the C—N bond,[2] Fig. 2 strongly suggests that an intramolecular transfer of this group in the solid state is improbable. However, there are several potential pathways for an intermolecular, topochemically controlled Tiekelmann rearrangement: for example, a transfer of methyl groups from **A** to **B** and from **B** to **C** would convert **B** to product. Alternatively, a transfer of methyl groups from **A** to **D** and from **D** to **B**, or from **A** to **D** and **D** to **E**, etc., would convert **D** to product. The relevant O···O distances in the crystal, which range from 4.322(2)–4.451(2) Å, are close to the calculated gas phase value of 4.32 Å for the bimolecular complex, shown in Fig. 5 of ref. 1; however, the O···C···O angles in the crystal, which range from 107.5(2)–121.6(2)°, deviate substantially from linearity and from the calculated gas phase angle of 174.2°, also shown in Fig. 5 of ref. 1. This is one possible reason for our inability to observe an intermolecular solid-state reaction (9). A second is that, in the solid, each nitroxide oxygen is hydrogen-bonded to one or two water molecules, and it is known that the solvation of a nucleophile by just one water molecule greatly reduces the rate of an intermolecular *gas-phase* S_N2 reaction (12).

A distinction between these possibilities became possible when one of us (Y.H.) discovered that a sample of crystalline 2-benzyloxypyridine-1-oxide (**1**, R = benzyl), which had been maintained at room temperature for some time, had undergone partial rearrangement to **2** (R = benzyl).

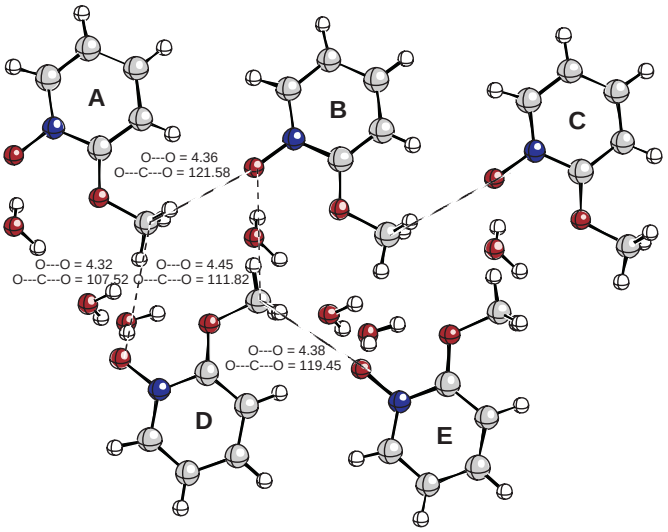


Figure 3 shows a portion of the crystal structure of **1** (R = benzyl).

It can be seen that, except for the absence of water molecules and the substitution of a phenyl group for one of the methyl hydrogens, there is a similar arrangement of the mol-

[2] The N-C-O-C torsion angles are 178.9(2)° and –178.5(3)°.

Fig. 2. A portion of the crystal structure of **1** (R = methyl), showing intermolecular O···O distances and O···C···O angles.

ecules of the methyl and benzyl compounds. Consequently, the possibilities for intermolecular topochemical rearrangement are also similar.

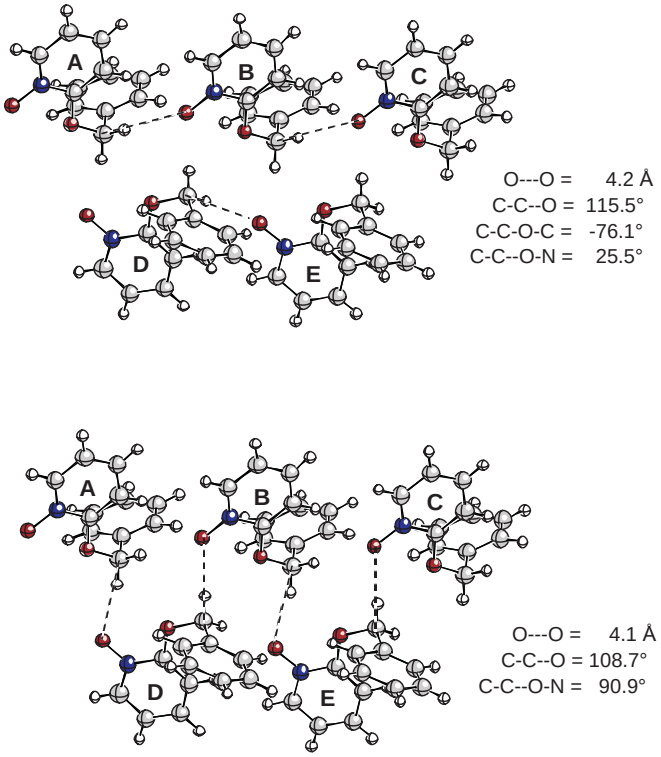
Referring to Fig. 3, molecules **A**, **D**, **B**, **E**, and **C** are sequentially related by a 2_1-screw operation. There is a second crystallographically unique molecule in the structure which shows a closely similar arrangement about an alternate screw axis. One can visualize numerous combinations of relatively small rotations of molecules and (or) internal rotations about CH_2—O, CH_2—C, or C^{ring}—O bonds which would produce the 180° angle required for the concerted transfer of a benzyl group, with inversion of configuration. For example: (*i*) transfer from **A** to **B** and **B** to either **C** or **E**, or from **A** to **D** and **D** to either **B** or **E** could produce **2** (R = benzyl) with net inversion of configuration in the benzyl group; alternatively, (*ii*) transfer from **A** to **D**, with inversion of configuration, followed by counterclockwise rotation of **A**, and return of the benzyl group to **A** with inversion of configuration will produce **2** with net retention of configuration in the benzyl group.

Figure 4 shows a portion of the crystal structure of **2** (R = benzyl).

Molecules, related by simple translations in *x*, are shown, and the nearest approaches between neighbouring NO and methylene groups are indicated. The N-O-C-C dihedral angle is 175.4(5)°. It is noteworthy that the much smaller intermolecular C-C···O-N torsion angles listed in Fig. 3 permit neither (*i*) nor (*ii*) above to produce this conformation initially, so that subsequent conformational rearrangement of **2** (R = benzyl) within the host crystal of **1** (R = benzyl) may be expected to lead to degradation of the crystal as the solid-state reaction proceeds.

The foregoing analyses of the two crystal structures permit the following tentative predictions: (*i*) the initial step of a solid-state Tieckelmann rearrangement of **1** (R = methyl, benzyl) will be slow, because of the substantial deviation of the entering and leaving groups from linearity; (*ii*) in the case of **1** (R = methyl), rearrangement is slowed further by

Fig. 3. The crystal structure of **1** (R = benzyl), showing intermolecular O···O distances and O···C···O angles.



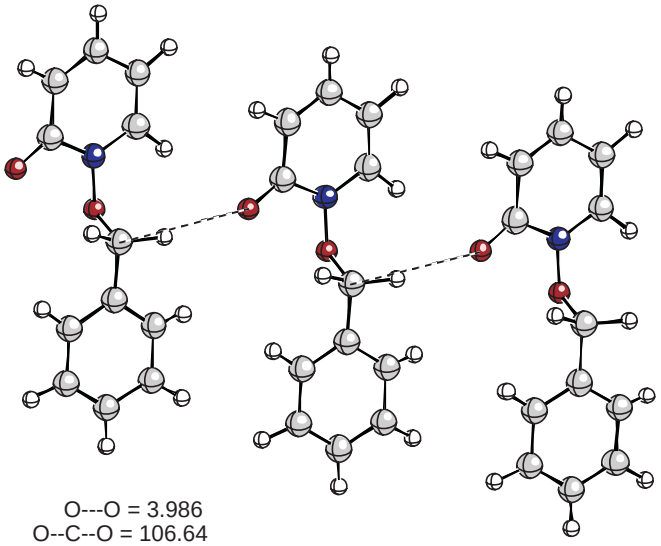


Fig. 4. The crystal structure of **2** (R = benzyl).

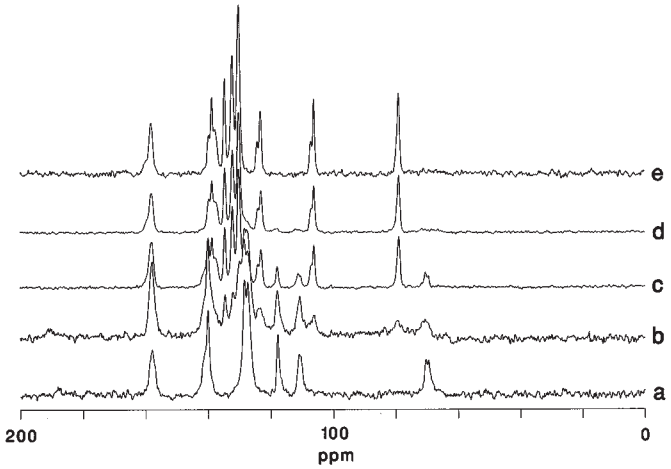

the presence of the water molecules;[3] (*iii*) depending on the nature of the intramolecular and intermolecular librations in the crystal, the solid-state rearrangement of **1** (R = benzyl) could potentially produce **2** with net inversion of configuration, or with net retention of configuration; (*iv*) since the antiperiplanar N-O-C-C conformation of **2** (R = benzyl) can probably not be accommodated within the host lattice of **1** (R = benzyl), the reaction likely proceeds at domain boundaries or packing defects and will be accompanied by a loss

[3] The intermolecular RCH_2···O distances are from 0.15–0.36 Å larger in **1** (R = methyl, hydrate) than in **1** (R = benzyl).

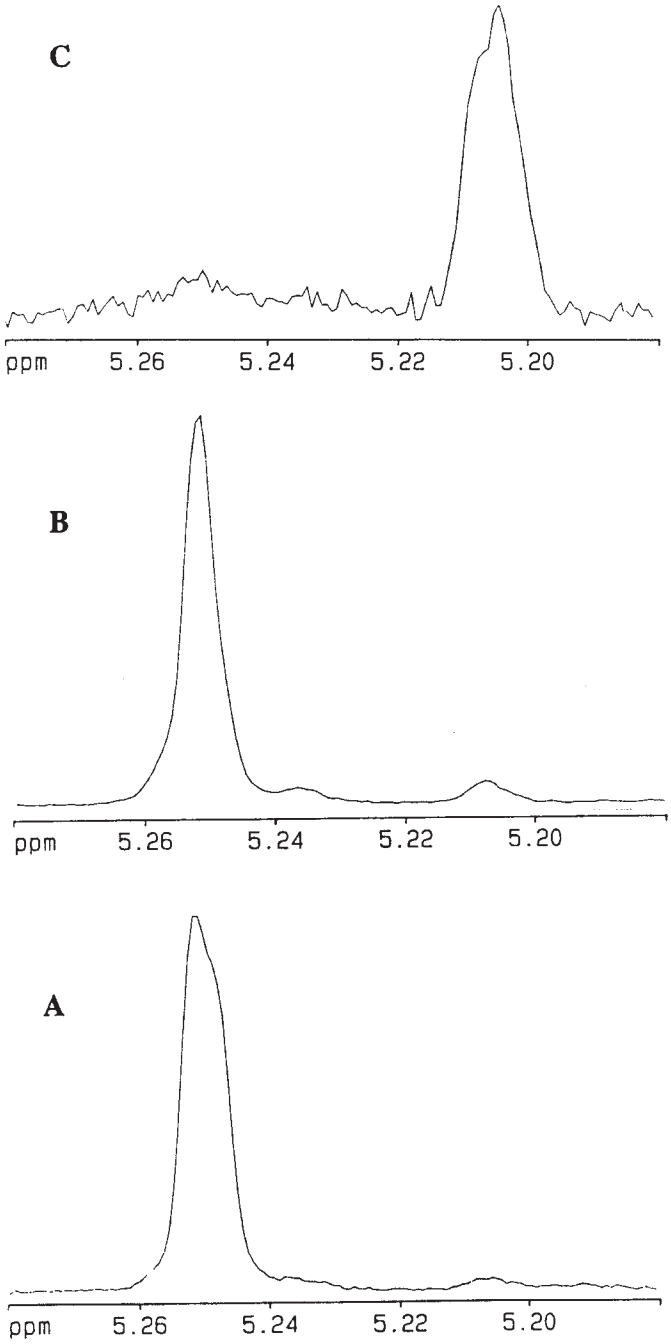
Fig. 5. (*a*) The solid-state ^{13}C NMR spectrum of a fresh sample of **1** (R = benzyl); (*b*) the spectrum after 10 months; (*c*) the spectrum after 25 months; (*d*) the spectrum after 36 months; (*e*) the spectrum of an authentic sample of **2** (R = benzyl).

of crystallinity. Indeed, the crystal of **1** (R = benzyl) used for the X-ray structure determination decayed on a time scale of months; remeasurement of selected reflections showed that all had dropped to 28% of their original intensities after 130 days.



The conversion of **1** to **2** (R = benzyl) was also followed at room temperature by solid-state ^{13}C NMR, and was also found to occur on a time scale of months. Figure 5 shows: (a) the spectrum of a fresh sample of **1**; (*b*) the spectrum after 10 months; (*c*) the spectrum after 25 months; (*d*) the spectrum after 36 months; (*e*) the spectrum of an authentic sample of **2**. While not all carbon resonances are resolved in the solid, the occurrence of the reaction is easily seen from the decay of the peaks at 70, 110, and 118 ppm, and the growth of peaks at 79, 106, 132, and 135 ppm. There is a steady conversion of **1** to **2**, and no peaks corresponding to intermediates are observed. Unfortunately, **1** has a long spin-lattice relaxation time, necessitating a repolarization delay of 90 s. This makes it impractical to signal average to a significantly better signal-to-noise ratio than shown. Consequently the presence of intermediates at levels up to a few percent of the total cannot be excluded.

Assuming that the rearrangement occurs in more than one step, with each step slow for the reasons already stated, transient formation of **3** and **4** can be expected, but these would only have been observable in the initial stages of the reaction.

To determine the stereochemical course of the rearrangement, a sample of optically active 2-(α-deuteriobenzyloxy)-pyridine-1-oxide was synthesized as described previously (1, 13), carefully crystallized from ethyl acetate, and allowed to stand for 11 months. At this time the rearrangement was found to be 85% complete. The reactant and product were separated, benzyl alcohol was released from each, by treatment with sodium methoxide in the case of **1**, and by treatment with zinc and acetic acid in the case of **2**, and the alcohols were converted to their Mosher esters (1, 14) for determination of their ^{1}H NMR spectra.

Figure 6 shows the deuterium-decoupled ^{1}H NMR spectra of the benzyl protons of the Mosher esters of: (A) the benzyl-α-d-alcohol employed to prepare the initial sample of **1**; (B) the benzyl-α-D-alcohol recovered from **1** following rearrangement; (C) the benzyl-α-D-alcohol recovered from **2** following rearrangement. Samples (A) and (B) are identical; sample (C) is the epimer of (A).

Fig. 6. Deuterium-decoupled ^{1}H NMR spectra of the benzyl protons of the Mosher esters of: (*a*) chirally labelled benzyl-α-D-alcohol; (*b*) chirally labelled benzyl-α-D-alcohol recovered from **1** (R = benzyl), after partial rearrangement to **2**; (*c*) chirally labelled benzyl-α-D-alcohol recovered from **2** after partial rearrangement.

It follows that the solid-state rearrangement of **1** (R = benzyl) proceeds with essentially complete inversion of configuration, in contrast to the 50–80% inversion observed in

© 2001 NRC Canada

solution. Based on our earlier examination of Fig. 3, it can be concluded that the topochemical rearrangement is an intermolecular process that proceeds by transfer of a benzyl group from **A** to **B** and **B** to **C**, etc., or by transfer from **A** to **D**, **D** to **B**, **B** to **E**, and **E** to **C**, etc., with inversion of configuration in every step.

Experimental

NMR Studies

The sample used for NMR experiments was supplied as a powder of fine crystals. This was loosely packed into a segment of 5 mm NMR tubing, and remained in this tube over the course of all measurements. The sample had a tendency to "clump" over time, and was occasionally stirred with a spatula and repacked. During the whole course of the NMR experiments, the sample was exposed to the atmosphere, and was maintained at ambient laboratory temperature, 23 ± 5°C. Probe temperatures during NMR experiments were also within this range.

Solid-state ^{13}C NMR spectra were recorded at 37.56 MHz on a 3.5T instrument. ^{1}H–^{13}C cross-polarization was used, with a contact time of 2 ms and a relaxation delay of 90 s. The sample was spun at the magic angle at 2.4 kHz; at this speed and field, small spinning sidebands are seen for the *sp* carbons. These were suppressed, in the spectra shown, by a phase-cycled TOSS pulse sequence. Proton decoupling fields of 50–85 kHz were used, the higher fields giving a slight improvement in line width. Resonances were referred to TMS using solid adamantane as a secondary standard, taking the shift of the high-frequency line to be 38.56 ppm.

Stereochemical studies

Full details of the synthesis of chirally deuterated **1**, of the recovery of benzyl-α-D-alcohol from **1** and **2**, of the conversion of these alcohols to Mosher esters, and of the NMR analyses of these esters can be found in ref. 1.

X-ray crystallography

One large crystal of **1** (hydrate, R = methyl)[4] (obtained from toluene solution and believed to be anhydrous) was exposed to a dry nitrogen atmosphere in a crystallographic glove box while it was cleaved to produce the fragment used for crystallographic analysis. When the crystal was exposed to the dry atmosphere it appeared to begin to liquefy. Nonetheless a fragment was successfully sealed in a capillary tube, after which time it ceased to "melt" while the remaining fragments liquefied completely. It seems likely that the sample was undergoing dehydration in the glove box to produce a lower melting substance or mixture. Full-matrix least-square refinement, on *F*, of 254 parameters for 1558 data ($I_o > 2.5\ \sigma(I_o)$) included independent coordinates for all atoms, anisotropic displacement parameters for the non-hydrogen atoms, and a single isotropic thermal parameter for each of the following three groups of hydrogen atoms: those on the C_5N-rings, those of the methyl groups, and those of the water molecules.

A crystal of **1** (R = benzyl)[5] obtained from ethyl acetate solution was mounted on a glass fiber using epoxy adhesive. While less than 1% decays of the intensity standards were observed during data acquisition, remeasurement of three of the stronger reflections showed a systematic decay over a period of 130 days, by which time the net intensities had all dropped to 28% of their original values. This net loss of intensity appeared to apply equally to all the reflections tested. A peak search at the end of that time revealed only reflections indexed on the original cell and orientation. Full-matrix least-squares refinement, on *F*, of 273 parameters for 1728 data ($I_o > 2.5\sigma(I_o)$) included independent coordinates and anisotropic displacement parameters for the non-hydrogen atoms. Hydrogen atoms were riding in calculated positions (C—H, 0.95 Å) and were initially assigned isotropic thermal parameters proportionate to the equivalent isotropic parameter of the respective carbon atoms. Subsequently, all hydrogen atom isotropic thermal parameters were constrained to have equivalent shifts.

A fragment cleaved from a crystal of **2** (R = benzyl)[6] obtained from hexane solution was mounted on a glass fiber using epoxy adhesive. Full-matrix least-squares refinement, on *F*, of 138 parameters for 570 data ($I_o > 2.5\sigma(I_o)$) was conducted analogously to that of **1** (R = benzyl).

All data were acquired at room temperature using an Enraf–Nonius CAD-4F diffractometer and with graphite-monochromatized Mo K_α radiation. Complex scattering factors for neutral atoms (15) were used in the calculation of structure factors. The programs used for data reduction, structure solution, and graphical output were from the NRCVAX Crystal Structure System (16). The program suite CRYSTALS (17) was employed in the refinement. Full details of the X-ray crystallographic structure determinations have been deposited as hardcopy and in CIF format.[7]

The ozonolysis of *ortho*-xylene and its relevance to the history of the benzene problem

Saul Wolfe and Zheng Shi

Abstract: Using B3LYP density functional theory in conjunction with the 6-311++G** basis set, the relative rates of the initial rate-determining attack of ozone upon the carbon—carbon bonds of *o*-xylene are found to be 4,5- ≅ 3,4- > 2,3- > 1,2-. With the assumption that the final products glyoxal (G), methylglyoxal (M), and dimethylglyoxal (D) are determined by the site of the initial attack, and taking statistical factors into account, the ratio G:M:D is calculated to be 3:2:1. This is close to the value found experimentally, and identical to the result predicted by the contention that two nearly equivalent Kekulé–Pauling valence bond (resonance) structures of *o*-xylene exist and each localized carbon—carbon double bond of these structures is oxidized at the same rate. Although Frontier Molecular Orbital theory also predicts a 3:2:1 ratio of G:M:D, this theory incorrectly predicts that the initial attack of ozone will take place at the 1,2- and 4,5- bonds, with 1,2-attack slightly preferred. These results are discussed in relation to a recent historical analysis of the benzene problem, and it is concluded that since the products of ozonolysis of *o*-xylene are determined by the relative energies of the transition states leading to the four possible primary ozonides, these transition states should be the focus of theory.

Key words: Kekulé structure, resonance, frontier orbital theory, density functional theory, kinetics.

Résumé : Faisant appel à la théorie de la densité fonctionnelle B3LYP en relation avec l'ensemble de base 6-311++G**, on a trouvé que les vitesses relatives des attaques initiales, qui déterminent la vitesse de la réaction de l'ozone sur les doubles liaisons carbone-carbone du 1,2-diméthybenzène varient dans l'ordre 4,5- ≅ 3,4- > 2,3- > 1,2-. Si on fait l'hypothèse que les produits finaux, glyoxal (G), méthylglyoxal (M) et diméthylglyoxal (D) sont déterminés par le site de l'attaque initiale, et tenant compte des facteurs statistiques, le rapport G:M:D calculé est égal à 3:2:1. Cette valeur se rapproche de la valeur expérimentale et elle est identique à la valeur que l'on peut prédire en se basant sur l'existence de deux structures de Kekulé–Pauling pratiquement équivalentes pour le 1,2-diméthylbenzène à partir desquelles les doubles liaisons carbone-carbone localisées seraient oxydées à la même vitesse. Même si la théorie des orbitales frontières conduit aussi à une prédiction d'un rapport G:M:D de 3:2:1, cette théorie conduit à la prédiction incorrecte que l'attaque initiale de l'ozone se fera au niveau des liaisons 1,2- et 4,5-, avec une légère préférence pour l'attaque 1,2. On discute de ces résultats en relation avec une analyse historique récente du problème du benzène et on en conclut que, puisque les produits d'ozonolyse du 1,2-diméthylbenzène sont déterminés par les énergies relatives des états de transition conduisant aux quatre ozonides primaires possibles, la théorie devrait être orientée vers l'étude de ces états de transition.

Mots clés : structure de Kekulé, résonance, théorie des orbitales frontières, théorie de la densité fonctionnelle, cinétique.

Introduction

In an absorbing two-part account of the history of the benzene problem, Brush (1) has drawn attention to the title reaction, which at one time (2 (ref. 1*a*, footnotes)) was thought to lend experimental support to Kekulé's oscillation theory (3) and its reformulation by Pauling (4). In Pauling's terminology, *o*-xylene is a resonance hybrid of the two nearly equivalent valence-bond (VB) structures **1** and **2**, and complete ozonolysis, followed by decomposition of the ozonide, should yield methylglyoxal (**3**) and glyoxal (**4**) in the ratio 2:1 from **1**, butanedione (**5**) and **4** in the ratio 1:2 from **2**, and an overall **3**:**4**:**5** ratio of 2:3:1.

To test Kekulé's theory, Levene and Cole (5) examined the ozonolysis of *o*-xylene in acetic anhydride at –30°C. After treatment of the ozonide with ice, they identified the *p*-nitrophenylosazones of **3**, **4**, and **5** among the products. Since the total yield of these products was less than 2%, and their proportions had not been determined, the reaction was reexamined by Haaijman and Wibaut (6) using chloroform as the solvent and work-up with sodium bisulfite or hydroxylamine. In addition to copious amounts of formic acid, acetic acid, and oxalic acid, Haaijman and Wibaut obtained dimethylglyoxime, methylglyoxime, and glyoxime in a total yield of 19–26% of the theoretical, based on *o*-xylene, and in the proportions 19–24% dimethylglyoxime (≡**5**), 32–37% methylglyoxime (≡**3**), and 42–47% glyoxime (≡**4**).

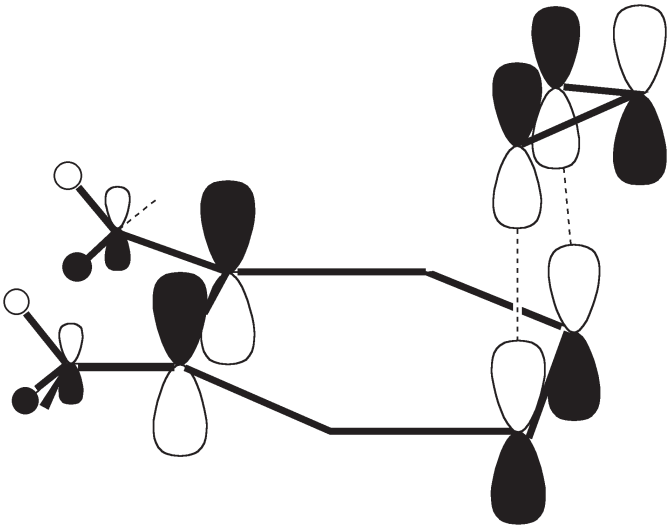
Fig. 1. The HOMO–LUMO (FMO) treatment of the attack of ozone upon the 4,5-bond (channel *a*) of *ortho*-xylene.



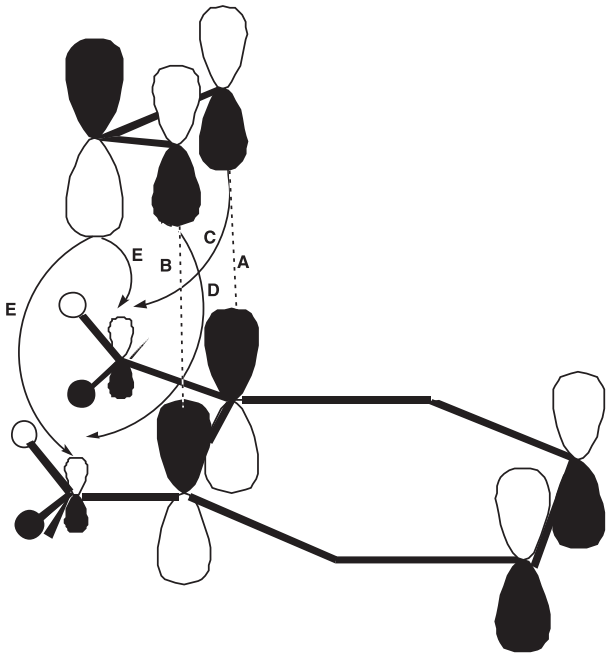


Fig. 2. The HOMO–LUMO (FMO) treatment of the attack of ozone upon the 1,2-bond (channel *b*) of *ortho*-xylene.

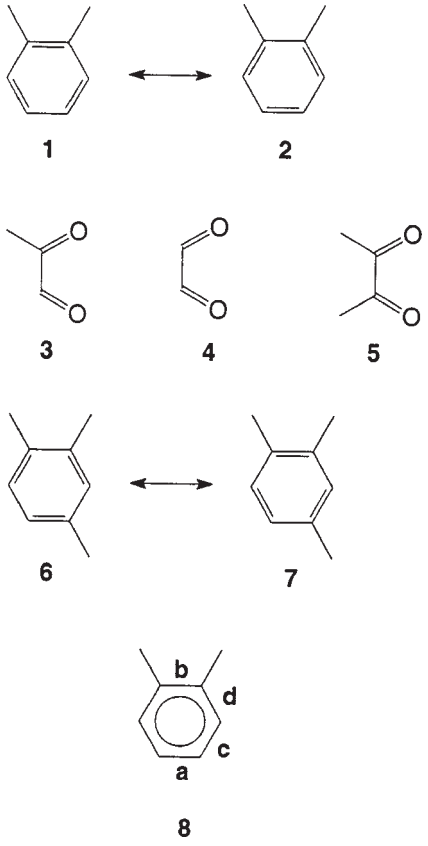


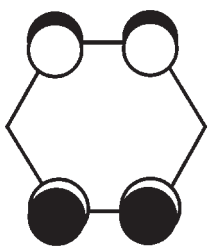
These relative yields are close to the predicted values, but Haaijman and Wibaut could not yet reach a definitive conclusion, because the degree of steric hindrance by the methyl groups was uncertain and the experiment had afforded only one-quarter of the theoretical yield of the products. Accordingly, they also examined the ozonolysis of 1,2,4-trimethylbenzene. In this case, if the compound is written as a hybrid of **6** and **7**, the products would still be **3**, **4**, and **5**, but in the new proportions 4:1:1. Although the total yield of **3**–**5** was reduced to 11–13%, the relative amounts, 66.2% (**3**), 14.2% (**4**), and 17.9% (**5**), were in excellent agreement with the theoretical prediction. Haaijman and Wibaut concluded that "it is certain that *o*-xylene reacts with ozone according to the two canonical structures proposed by Kekulé."

The current status of this conclusion is examined in some detail by Brush (1), in an analysis of how the VB treatment of benzene, including reference to the ozonolysis of *o*-xylene, eventually came to be superseded by the "superior" (7) molecular orbital (MO) method. Nonetheless, Brush concludes, although the (Levene–Cole) experiment "has … dropped out of the textbooks," one could still ask "how MO explains (the result)." "I do not doubt that a modern quantum chemist could provide such an explanation if necessary, but so far I have not found one in print."

The present work was stimulated by the foregoing remarks.

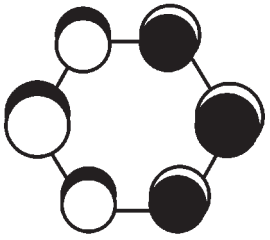
Results and discussion

The application of qualitative FMO (frontier molecular orbital) theory (8) to the problem requires several assumptions: (*i*) the initial attack of ozone to form a 1,2,3-trioxolane, the primary ozonide, is both rate-determining and product-determining (9). For example, referring to structure **8**, initial attack at bond *a* is equivalent to initial attack at bond *d*, and leads to the same result as the complete ozonolysis of **2**. Likewise, initial attack at bond *b* is equivalent to attack at bond *c*, and leads to the same result as the complete ozonolysis of **1**; (*ii*) since ozonolysis is an oxidative process, the rate-determining electron transfer takes place between the *o*-xylene donor and the ozone acceptor so that the principal focus is on the interaction between the HOMO of xylene and the LUMO of ozone; (*iii*) in its nodal character the LUMO of ozone (**9**) resembles ψ_3 of the Hückel treatment of allyl. Calculations at all levels (extended Hückel,



© 2001 NRC Canada

semiempirical, ab initio) confirm this point; (*iv*) the attachment of two methyl groups removes the degeneracy of the *E*-type π-MOs of benzene (**10ab**) and produces a $^2B_1$ π-HOMO (**11**) and a $^2A_2$ π-NHOMO (**12**) (**11** and **12** refer to 6-31G* calculations (10)). Since, from photoelectron spectroscopy (11), the energy difference between **11** and **12** is 0.52 eV (11.99 kcal), **11** is employed in the analysis.



It is immediately apparent, upon inspection of **11**, that the FMO treatment predicts the initial attack of ozone to take place primarily at *a* and at *b*, since overlap with the ozone LUMO is possible only at these sites. From (*i*) above, it follows that, if the coefficients at *a* and *b* are the same, the qualitative MO and qualitative VB treatments are equivalent. However, upon closer examination, this first-order MO treatment seems to be incomplete, because the coefficients at *a* and *b* are not the same. Calculations at all levels (extended Hückel, semiempirical, ab initio) find the *p*-atomic orbital coefficients at *b* to be slightly larger than those at *a*.

10b

11

12

Figures 1 and 2 show the origin of **11** schematically, and also the primary and secondary overlaps in the HOMO–LUMO interactions associated with reaction at *a* and at *b*; **11** is formed from the out-of-phase interaction between **10a** and **13**, the *E*′ combination of two π-type methyl group orbitals. Since **10a** lies higher than **13**, **10a** makes the larger contribution to the HOMO, as depicted in the figures.

13

Figure 1, which refers to attack at *a*, is straightforward. Figure 2, which depicts attack at *b*, requires comment. The primary HOMO–LUMO overlap is shown in the dotted lines A and B. If this were the only criterion, the larger coefficients at the ring carbons of *b* would permit the prediction that attack at *b* is slightly preferred over attack at *a*. However, Fig. 2 also exhibits secondary overlap, shown by the curved arrows C, D, and E. Whether this secondary overlap is rate-enhancing or rate-retarding is difficult to predict from qualitative considerations alone, because C and D are out-of-phase (retarding), and E is in-phase (enhancing). Thus, at this level of treatment, Haaijman and Wibaut's "steric hindrance by the methyl groups" may or may not exist. A more rigorous analysis is necessary.

Figure 3 is the 6-31G* (10) HOMO of *cis*-2-butene. The out-of-phase relationship between π_{cc} and π_{Me} is reminiscent of that seen in **11**. Figure 4 shows the 6-311++G** transition structures calculated using Gaussian 98 (12) for the attack of ozone *syn* to the methyl groups and *anti* to the methyl groups. Geometrical parameters of interest are the C···O distances (Å) and the attack and tilt angles (deg). These angles are defined as explained in Fig. 5, where **a** is the C-C=C-C (*anti*) or H-C=C-H (*syn*) plane, **b** is the O_3 plane, and **c** is the plane that includes C=C and the termini of ozone. The attack angle is the angle between planes **a** and **c**; the tilt angle is the angle between planes **a** and **b**. In the *syn* attack the attack angle is 105.8°, the tilt angle is 46.0°, and the C···O distances are 2.36 Å; the corresponding parameters for *anti* attack are 78.2 and 21.4°, and 2.19 Å. These geometries suggest that *syn* attack is significantly more encumbered. The relative unimportance of interaction E is reflected in the free energies of the *syn* and *anti* transition structures: the *anti* structure is lower by 1.911 kcal mol^{-1}, corresponding to k_{anti}/k_{syn} = 25 at 298 K. If the attack of ozone at *b* of *o*-xylene were to be similarly retarded relative to attack at *a*, the FMO treatment would then predict attack at *a* to be the dominant reaction channel. This would be equivalent to the bizarre assertion that only VB structure **2** is oxidized. At this (second-order) level, the HOMO–LUMO FMO treatment has, therefore, failed. A possible reason for this failure is that FMO theory assumes a reactant-like transition state, but ozonolysis of an aromatic compound will proceed via a high energy product-like transition state which is not properly patterned by the HOMO of the reactant. This point was pursued by examination of the transition structures for attack at *a*, *b*, *c*, and *d* of *o*-xylene.

The calculations were performed (12) at the Hartree–Fock (HF) level with the 6-311++G** basis set (HF/6-311++G**//HF/6-311++G**), and also using density functional theory (DFT) with the B3LYP functional (13) and the same basis set (B3LYP/6-311++G**//B3LYP/6-311++G**). For the calculation of the free energies at 243 K and at 298 K, vibrational frequencies were scaled using the 298 K scaling

factors recommended in ref. 14: for HF calculations: ΔH_{vib}, 0.8951; ΔS_{vib}, 0.9021; for DFT calculations: ΔH_{vib}, 0.9989; ΔS_{vib}, 1.0015. Tables 1 and 2 summarize the results for 298 K and 243 K, respectively, and Fig. 6 shows the DFT transition structures of the four reaction channels.

Since each channel begins from the same reactants, the free energy differences can be equated to $\Delta\Delta G^{\ddagger}$. This allows the relative rates to be calculated.

As expected from the *cis*-2-butene calculations, channel *b* is the least favourable and, at 298 K, reaction via this channel is 25 times slower than reaction via channel *a*. On the other hand, channel *c*, which leads to the same products as channel *b*, is kinetically competitive with channel *a*. Neither the unimportance of channel *b* nor the importance of channel *c* was predicted by qualitative FMO theory.

From the free energies of the four transition structures the relative proportions of **3**, **4**, and **5** can be calculated. The rates of formation are:

[1] $V_3 = 2V_b + 2V_c$

[2] $V_4 = 2V_a + V_b + V_c + 2V_d$

[3] $V_5 = V_a + V_d$
