Phase behaviours and conductivity study of water/CPC/alkan-1-ol (C_4 and C_5)/1-hexane water/oil microemulsions with reference to their structure and related thermodynamics

S.P. Moulik, Wanda M. Aylward, and R. Palepu

Abstract: The microemulsion forming systems of water/cetylpyridinium chloride/butan-1-ol/*n*-hexane, and water/cetylpyridinium chloride/pentan-1-ol/*n*-hexane have been studied with respect to their phase behaviours and percolation of conductance to derive information on their droplet physicochemical characteristics (dimension, interfacial area and composition, and number density). This was carried out at different water contents at specific ratios of surfactant and cosurfactant and at various temperatures. From the information collected, the energetics of the transfer of the alkanol (butan-1-ol and pentan-1-ol) from the continuous oil-phase to the interfacial region (the interphase) have been estimated. At the conductance percolation threshold, the droplets cluster or associate, can be considered to form a pseudophase similar to surfactants forming micelles. Based on this concept, the energetics of the clustering process have been evaluated, and the results are discussed in comparison with other recently studied systems.

Key words: energetics of clustering, percolation, phase diagrams, microemulsions and thermodynamics of transfer.

Résumé : Afin de pouvoir déduire des informations sur les caractéristiques physicochimiques de leurs gouttelettes (dimension, surface et composition interfaciales et nombre de densité), on a déterminé les comportements des phases et la percolation de la conductance des systèmes eau/chlorure de cétylpyridinium/butan-1-ol/hexane et eau/chlorure de cétylpyridinium/pentan-1-ol/hexane qui forment des microémulsions. Cette étude a été effectuée à diverses teneurs en eau, à des rapports spécifiques d'agent de surface et de cosurfactant et à diverses températures. À partir des informations recueillies, on a évalué les énergies de transfert des alcools (butan-1-ol et pentan-1-ol) de la phase huileuse continue à la région interfaciale (interphase). Au seuil de percolation de la conductance, on peut considérer que les agrégats de gouttelettes forment une pseudophase semblable à celles des agents de surface qui forment des micelles. En se basant sur ce concept, on a évalué les énergies associées au processus de formation d'agrégats et on discute des résultats par comparaison avec d'autres systèmes étudiés récemment.

Mots clés : énergies impliquées dans la formation d'agrégats, percolation, diagrammes de phase, microémulsions et thermodynamique de transfert.

[Traduit par la Rédaction]

Introduction

Nanodispersions of water in oil or oil in water can be achieved by proper choice of surfactant and cosurfactant, and their combined addition at appropriate concentrations. When these dispersions are transparent, isotropic, thermodynamically stable and easily formed, they are called microemulsions (1, 2). The water/oil microemulsions can be considered as swollen reverse micelles having a distinct water pool in the core. Microemulsions have attracted the attention of scientists and technologists for their potential uses and applications in the forms of solvents, reaction media, liquid membranes, enhanced oil recovery fluids, media for nanoparticle synthesis, pharmaceutical and cosmetic preparations, etc., (3–8). The study of microemulsions in relation to the conditions of their formation, stability and structure is, therefore, of much current interest to both theoretical and experimental scientists.

For the determination of the internal structure and dynamics and the associated thermodynamics of microemulsions, nuclear magnetic resonance (NMR), small angle neutron scattering (SANS), dynamic light scattering (DLS), small angle X-ray diffraction (SAXRD), time resolved fluorescence quenching (TRFQ), dielectric relaxation, ultrasonic absorption, conductance, viscosity, positron annihilation technique, and calorimetric methods are mostly used (3). In recent years, the conductance method has been successfully, but infrequently, used on microemulsion systems, prepared with ionic surfactants, to elucidate their structural parameters and energetics of structural transitions with reference to both

volume induced and temperature induced percolation of conductance (9–16). The conductance of microemulsions is related to the effective medium theory that deals with the conductance of mixed systems of conductors and insulators and can be as well described by appropriate scaling equations. This area has received only limited investigations for water/oil microemulsions in which amphiphile-coated, dispersed, nano water droplets are the conductors and the oil is the insulator.

With this backdrop, we have made a detailed investigation of water/cetylpyridinium chloride/alkan-1-ol (butanol and pentanol)/*n*-hexane, water/oil microemulsion systems at several surfactant/cosurfactant mass ratios and temperatures. The pseudoternary phase diagram of the systems have been constructed. The volume induced percolation results have been analyzed to get the structural information of the droplets. The energetics of droplet association have been evaluated from the temperature effect on the process. The choice of the surfactant cetylpyridinium chloride (CPC) was made because it has a better water solubilization capability compared to cationic surfactants with quaternary ammonium head groups of equal chain length (17).

Experimental section

Materials

Cetylpyridinium chloride (CPC), butan-1-ol, pentan-1-ol, and *n*-hexane were obtained from Sigma–Aldrich. The alkanols were >99% pure. All materials were used as received except the CPC which was recrystallized from an acetone–ethanol mixture. Triply distilled quality water was used for making all solutions.

All measurements were performed in a thermostated water bath of accuracy ±0.01 K.

Method

For the construction of the phase diagrams, CPC/alkanol at a constant mass ratio (1:1) was mixed in different compositions in set *one* with water, and in set *two* with *n*-hexane. Each of the samples in the first set was titrated with *n*-hexane under constant stirring condition at 298 K until it became just cloudy. The same procedure was followed for the second set using water as the titer. The composition of each sample at the point of clouding was recorded and expressed in mass %. The data were then plotted using triangular coordinates to produce a boundary demarcating the biphasic and the monophasic zones comprising both oil/water and water/oil formulations. Several compositions falling well within the turbid region were selected, the components mixed, stirred, and kept overnight. It was visually observed that for all the combinations, there appeared only two phases, one rich in oil and the other rich in water. The occurrence of more than two phases was not observed.

The conductance measurements were taken with a YSI model 32 conductometer, U.S.A. using a cell with a 1.01 cm^{-1} cell constant. A jacketed beaker and an adjustable water bath were used to control and maintain temperature.

In the actual measurements, three surfactant/cosurfactant mass ratios (σ), 0.25, 0.33, and 0.50 were used in the study. A mixture of known masses of CPC, alkanol, and *n*-hexane was placed in the jacketed beaker with the conductivity cell and the temperature was set to a desired value. The initial value of conductance was recorded and water was then successively added to the beaker, with constant stirring. The conductance was recorded at each addition when it stabilized after temperature equilibration. The measurements were continued until a significant rise in conductance followed by a levelling off tendency was observed. The same measurement procedure was followed for different surfactant/cosurfactant/oil compositions and at different temperatures. The observations with successive addition of water to surfactant/cosurfactant/oil systems at a constant temperature is called volume-induced percolation of conductance. In the temperature-induced percolation study, the conductance of a microemulsion sample at a fixed composition was measured with increasing temperature until a rapid rise in the conductance was observed. The conductance measurement was made after careful equilibration of the system at each temperature. Similar sets of measurements were taken on samples of different compositions.

Theoretical background

Conductance method for structure elucidation

For microemulsions, structure elucidation i.e., determination of droplet dimension, interfacial area, and interfacial composition dependency on system composition and temperature, is important. The method of conductance is an indirect but potential method to obtain this information. The basic principle of the method and the related relations are briefly presented below. We are herein concerned with volume-induced percolation of conductance (10–13). The analysis is based on the effective medium theory (EMT) of conductance on binary inclusions (conductors and insulators) (18–20) and has been used very limitedly on microemulsion systems (10–12). It is a potential method and its efficacy has been established in the recent past (10–12). It is used in this study to derive interfacial information, droplet dimensions, and the thermodynamics of cosurfactant transfer.

In the EMT, the conductance equation of Böttcher (19) for a percolating system of isolated spherical dispersion has the following form,

$$[1] \qquad \frac{k - k_c}{k_d - k_c} = \frac{3k}{k_d + 2k}\,\phi_d$$

where k, k_c, and k_d are the conductances of the solution, the continuous medium, and the disperse phase, respectively, and ϕ_d is the volume fraction of the latter. In water/oil microemulsion, the continuous oil-phase is essentially nonconducting (insulator type) and hence $k_c = 0$, so that eq. [1] takes the form

$$[2] \qquad k = 1.5\,k_d(\phi_d - 0.333)$$

From the plot of k vs. ϕ_d or ($\phi_d - 0.333$), the k_d value can be evaluated.

This equation has been used for water/oil microemulsion systems to derive structural information. One basic condition that needs to be fulfilled is the dispersed entities should be of spherical form. Nonspherical dispersions and dispersions forming distinct aggregates should not obey the Böttcher's conductance equation. The EMTDD of Granqvist and Hunderi (21) can be applied to these systems. In that case, a

© 2001 NRC Canada

nonlinear plot between k and ϕ_d with an intercept on the axis at $\phi_d < 0.333$ would be obtained.

The analysis on the conductance of a microemulsion in the light of the EMT for spherical dispersions and EMTDD for chain and cluster forming dispersions has been recently presented and discussed (12). For low conducting water/oil microemulsions produced with different surfactants and oils, spherical dimensions of the droplets at low and even high concentrations have been reported. This has been mentioned and discussed by us (22). In line with this, we herein also consider spherical identities of the droplets for the present percolating systems, and eq. [2] was used to derive the desired information on the water/CPC/alkan-1-ol (C_4 and C_5)/*n*-hexane systems.

It is important to note that to use eq. [2], the volume fraction of the dispersion needs to be known. This is different from the volume fraction of water, for the associated surfactant and cosurfactant molecules become a part of the dispersion. Therefore, unless the proper value of ϕ_d is used, the k vs. ϕ_d plot or k vs. ($\phi_d - 0.333$) plot would not show 0.333 or 0 as the intercept on the x-axis to be in agreement with eq. [2]. Defining the average ratio of cosurfactant and surfactant in the droplet interfacial region (henceforth to be called the interphase) as the structure factor (r) and considering it to be invariable at a constant surfactant /cosurfactant ratio (σ), and independent of the weight fraction of water for a constant temperature in the microemulsion, it can be presented as

$$[3] \qquad r = \frac{N_{cs}}{N_s}$$

where N_{cs} and N_s are the number of cosurfactant and surfactant molecules in the interphase, respectively. At a constant temperature, a fixed concentration of surfactant and of cosurfactant (producing a constant surfactant/cosurfactant ratio), and an unchanging oil content, the effective head group areas, provided by the amphiphle molecules, determine the number and size of the dispersed water droplets. With changing amounts of water, the size and number of droplets adjust to maintain a constant effective interfacial area. The change in the number of amphiphile molecules in the interphase due to solubility requirements is considered to be minor. The aqueous solubilities of the alkanols used in this study are known to be low as well. Thus, for a particular system at a constant temperature, the distribution of the alkanol between the water, interphase, and oil remains essentially constant. The constancy of the structure factor (r) follows from the above and is supported by the good linear plots between k_d and ϕ_d calculated according to eq. [4]. By the principle of mass balance, the effective volume fraction of the disperse phase (10, 11) is given by the relation,

$$[4] \qquad \phi_d = \frac{\rho_t}{\rho_d}\left[W_s\left(1 + r\frac{M_{cs}}{M_s}\right) + W'_{cs} + W_w\right]$$

where ρ_t and ρ_d are the densities of the total solution and the disperse phase respectively; W_s, W'_{cs} and W_w are the mass fractions of surfactant, cosurfactant in the aqueous phase and the water, respectively, and the M_{cs} and M_s are the molar masses of the cosurfactant and the surfactant respectively. W'_{cs} has a contribution when the cosurfactant has appreciable water solubility; here, butan-1-ol has a contribution whereas pentan-1-ol contributes negligibly due to its poor aqueous solubility, and for it $W'_{cs} = 0$.

To obtain the effective ϕ_d, a correct value of r is required to be used in eq. [4]. The following procedure can be followed for a practical solution to obtain r. Several reasonable values of r can be assumed, and for each r, ϕ_d values are calculated for the different levels of water addition in the conductance experiment. These ϕ_d values are then used in eq. [2] to produce plots of k and ($\phi_d - 0.333$) to obtain an intercept on the x-axis. These intercepts are then plotted against the r values, and the r corresponding to the zero intercept is obtained from the plot which is the required structure factor (r) for the studied system.

The radius of the droplet (R_w) and the effective droplet number per unit volume of solution (N_e) are then obtained from the relations (11)

$$[5] \qquad R_w = \frac{3[M_s + rM_{cs} + \{(W_w + W'_{cs})/W_s\}M_s]}{N\rho_d(a_s + ra_{cs})}$$

and

$$[6] \qquad N_e = \frac{3\phi_d}{4\pi R_w^3}$$

where the new terms N, a_s and a_{cs} are Avogadro's number, the cross sectional areas of the surfactant and of the cosurfactant, respectively.

The effective volume of a microemulsion droplet (υ) is given by the relation (11)

$$[7] \qquad \upsilon = \left(\frac{4}{3}\right)\pi R_w^3 + \frac{A_s M_s}{\rho_s N} + \frac{A_{cs} M_{cs}}{\rho_{cs} N}$$

where the new terms A_s and A_{cs} represent the aggregation number of the surfactant and the cosurfactant molecules per droplet, respectively. A_{cs} can be obtained in terms of r and A_s using eq. [3].

The effective radius of the droplets (radius including the length of the interphase) can then be obtained from the relation

$$[8] \qquad R_e = \left(\frac{3\upsilon}{4\pi}\right)^{1/3}$$

The surface area of the droplets per unit volume can be estimated from the relation

$$[9] \qquad A_t = 4\pi R_w^2 N_e$$

Thermodynamics of cosurfactant transfer from oil to the interphase

The structure factor (r) relates the concentration of the cosurfactant in the interphase in terms of the surfactant. The cosurfactant remains distributed between the interphase and the oil phase, apart from the fraction that remains soluble in the aqueous pool satisfying the solubility requirement. From the knowledge of r and the concentrations of the surfactant and cosurfactant in the experimental solution, the standard Gibbs free energy of transfer of cosurfactant from the oil

© 2001 NRC Canada

phase to the interphase in the unitary scale can be estimated from the relation,

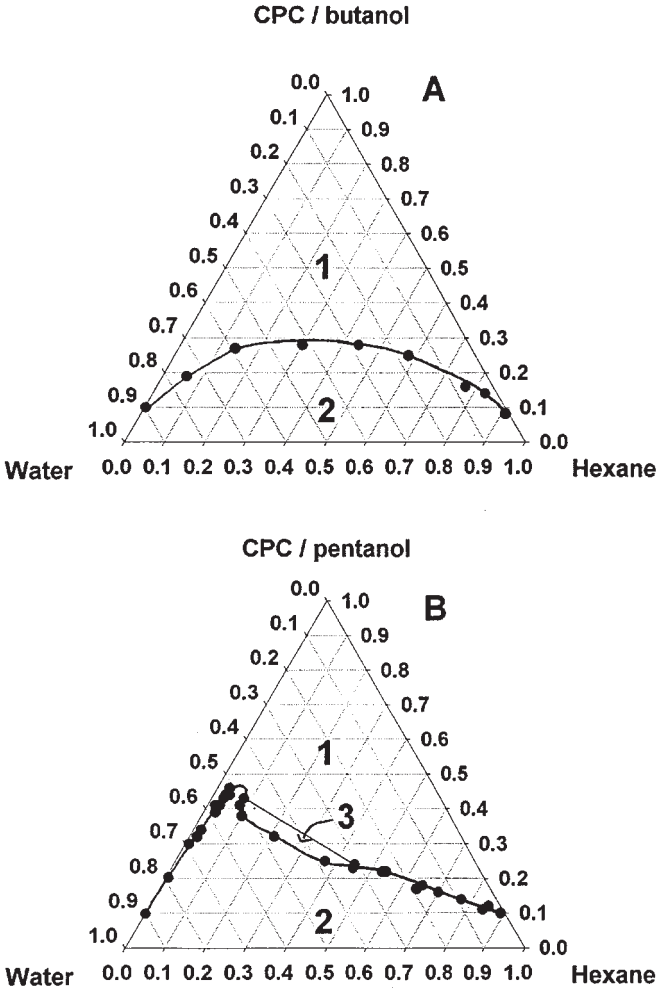
$$[10] \quad \Delta G_t^\circ = -RT \ln \frac{n_{cs}^i/(n_{cs}^i + n_s^i)}{n_{cs}^o/(n_{cs}^o + n_o)} = -RT \ln \frac{X_{cs}^i}{X_{cs}^o}$$

where X_{cs}^i and X_{cs}^o are the mol fractions of the cosurfactant in the interphase and oil phase respectively; n_s^i and n_{cs}^i are the number of mol of surfactant and cosurfactant, respectively, in the interphase; n_{cs}^o is the number of mol of cosurfactant in the oil phase; and n_o is the number of mol of oil in the sample. Normally, the thermodynamic distribution constants are obtained from the activities of the components distributed between the phases. However, estimation of the interfacial and bulk activities of the amphiphiles in the present context is complex and, since the species in question have comparable molecular architectures, mol fraction concentration terms can be substituted. Thus, we have used mol fractions in place of activities in our calculations. As a consequence, the subsequently calculated transfer parameters are not derived using a completely rigorous thermodynamic approach; they are good estimations, but they are not exact.

The first derivative of the ΔG_t° with respect to temperature gives the standard entropy of transfer (ΔS_t°) and the corresponding enthalpy of transfer (ΔH_t°) is obtained from the Gibbs–Helmholtz equation.

Thermodynamics of droplet association or clustering

In the process of percolation, the droplets assemble and ion-transfer takes place either by the mechanism of "hopping" or by "transient fusion and mass transfer" or by both (3). In this process, the overall geometry of the droplets is considered to remain more or less unaltered, except that they are physically close to facilitate efficient ion transfer. In the volume-induced percolation, at a sufficient level of water addition, bigger sized droplets promote easier transfer of materials (ions) producing a large change in conductance. The droplets must grow to the right size for this phenomenon to start, often to a radius of 0.5–1.0 nm. In the temperature percolation process, droplet motion increases with temperature, and at some threshold temperature, depending on concentration, they come sufficiently close to exchange or transfer mass (ions) resulting in a rapid increase in the conductance. The process occurs efficiently at a [water]/[amphiphile] mol ratio approximately in the range of 15–35.



At the percolation threshold, it is convenient to assume that the droplets are in close contact in the form of clusters but maintaining their individual spherical geometry. This is the onset of a pseudophase (14, 16) as envisaged in micelles forming from the association of surfactant monomers.

The standard Gibbs energy change for the clustering process can be obtained from the relation (14, 15).

$$[11] \quad \Delta G_{cl}^\circ = RT \ln X_d$$

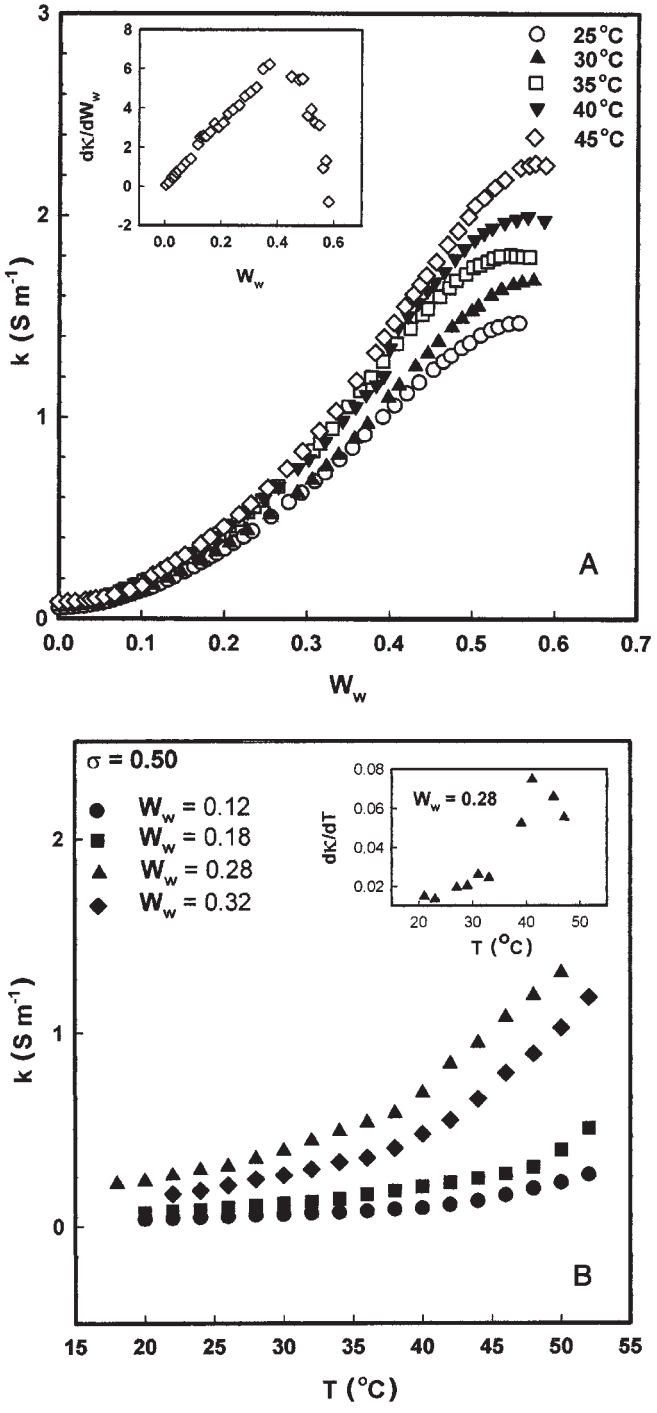
where X_d is the mol fraction of the droplets in the microemulsion at the point of the percolation threshold. This equation is comparable with the standard Gibbs energy of micellization ($\Delta G_m^\circ = RT \ln X_{CMC}$) where X_{CMC} is the mol fraction concentration of the surfactant at the critical micellar concentration (CMC). The X_d can be computed from the following equation

Fig. 1. Pseudoternary phase diagrams for the studied microemulsion systems at σ = 0.50 at 298 K. (*a*) water/CPC–butanol/*n*-hexane system; (*b*) water/CPC–pentanol/*n*-hexane system. Regions 1, 2, and 3 represent mono-, bi- and clear-gel phase, respectively.

$$[12] \quad X_d = \frac{N_e}{N_e + n_0' N}$$

where the new term n_0' is the number of mol of oil per unit volume of the microemulsion solution.

The other thermodynamic parameters, standard entropy and enthalpy changes of clustering, then follow from the first derivative of ΔG_{cl}° with respect to temperature and the Gibbs–Helmholtz equation.



Results

Phase diagrams

The phase behaviours observed at 298 K for the water/CPC/ butan-1-ol/*n*-hexane system and water/CPC/pentan-1-ol/*n*-hexane system at CPC–alkanol mass ratio 1:1 are presented in Fig. 1 as pseudoternary phase diagrams. It is observed that the diagram for butan-1-ol is symmetric, and at the maximum point on the boundary 30% (by mass) of the CPC–butanol mixture dissolves 35% of each of water and hexane. This supports the observation (17), that surfactants such as pyridinium salts are better microemulsion forming

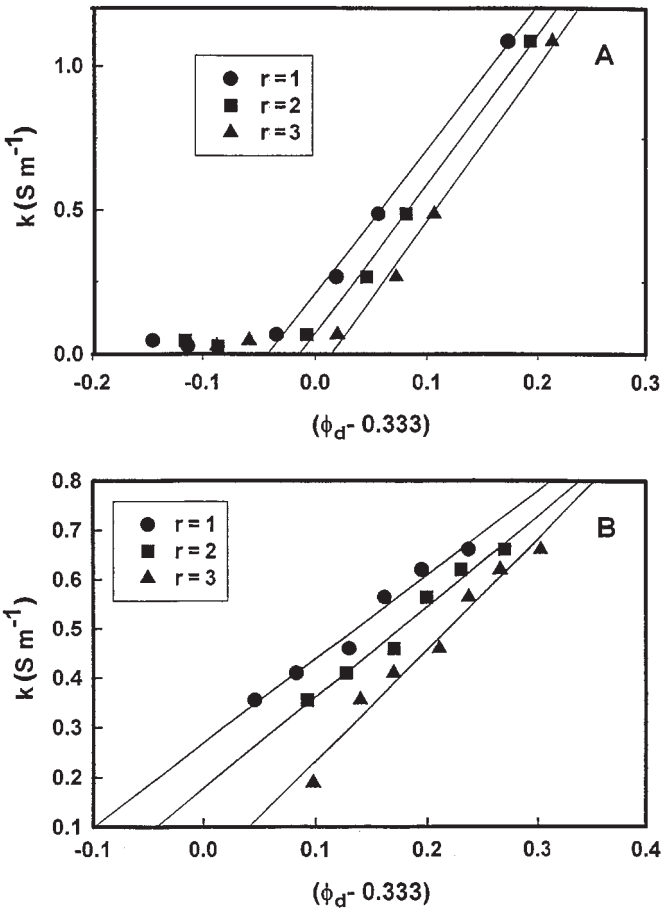
agents for alkanol–alkane systems than the quaternary ammonium representatives (better water solubilizer). The phase diagram for pentan-1-ol as the co-surfactant (Fig. 1*b*) is different and unsymmetric compared to that of butan-1-ol. The phase boundary course is almost triangular in shape; the shortest arm of the triangle extends up almost along the base line of the oil. From the apex to half-way down towards the right, there is a clear gel region identified by the loss of flow. At 30% CPC–pentan-1-ol, nearly 40% of oil and 30% of water make a low viscous microemulsion solution. The composition of the vertical apex is 48:47:5, water/CPC–pentanol/hexane. The difference in the phase behaviour between the two systems is considered to arise from the difference in the aqueous solubility of butan-1-ol and pentan-1-ol. The former is much more soluble (1.061 *m*) than the latter (0.255 *m*) at 298 K, and homogenization leading to better microemulsion formation is easier. The better performance of butan-1-ol does not comply with the mixing model of Bansal et al. (23) which proposes that for a stable water/oil microemulsion, the sum of the chain lengths of the cosurfactant and the oil must be comparable to the chain length of the surfactant. Using this rationale, butan-1-ol is shorter than pentan-1-ol by one unit of the chain length and is expected to be less efficient than the latter. Similar inconsistencies in this mixing model have been reported in the past (11).



Conductance percolation (r) and k_d.

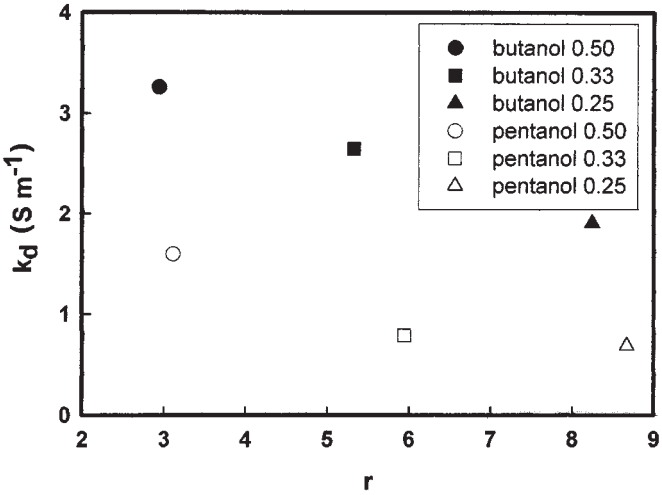
In Fig. 2*a*, a graphical representation of conductance percolation for the water/CPC/butan-1-ol/*n*-hexane system with $\sigma = 0.50$ weight ratio of surfactant:cosurfactant at five different temperatures is presented. The curves are sigmoidal in nature, and the conductance at all W_w increases systematically with temperature like an electrolyte solution. A first derivative plot of conductance with respect to W_w is shown in the inset at 45°C to demonstrate the transition point at $W_w = 0.371$. At higher temperature, droplets rapidly associate at lower W_w due to their increased kinetic motion. This results in an efficient transfer of ions among themselves resulting in a rapid rise in conductance. The temperature percolation at $\sigma = 0.50$ for four different W_w for the water/CPC/pentan-1-ol/*n*-hexane system is illustrated in Fig. 2*b*. The efficiency of the process for $W_w \geq 0.28$ can be inferred from the figure. The transition temperature for percolation can be obtained from the first derivative plot between k and T (see inset). It is observed that the transition temperature decreases with increasing W_w. Larger droplets associate at relatively lower temperature to exhibit conductance enhancement by the rapid ion-transfer mechanism as suggested above.

In light of eqs. [2]–[4], the representative plots of k and $[\phi_d - 0.333]$ are exhibited in Fig. 3, for the two types of percolating systems studied at $\sigma = 0.50$. In the percolation region, the plots are fairly linear and the least-squares method has been used for obtaining the intercepts on the x-axis for different r values. The plot between the intercept and the r has been observed to be linear (not shown here) with a correlation coefficient of 0.9995 from which the r value with the zero intercept has been obtained. The k_d value has been obtained from the slope of the k vs. $[\phi_d - 0.333]$ plot corresponding to the correct value of r. The r and k_d values obtained at different temperatures and σ values for the percolating systems studied are presented in Table 1. It is observed that at a constant temperature, r decreases with σ and k_d increases. For the system with butan-1-ol, both r and k_d

© 2001 NRC Canada

Fig. 3. (*a*) $k - [\phi_d - 0.333]$ profiles for water/CPC–butanol/*n*-hexane system at 298 K according to eq. [2] for three *r* values 1, 2, and 3; (*b*) $k - [\phi_d - 0.333]$ profiles for the water/CPC–pentanol/*n*-hexane system at 298 K according to eq. [2] for three *r* values 1, 2, and 3.

increase with temperature with a minor deviation; whereas for the pentan-1-ol system, *r* decreases and k_d increases with temperature without any deviation. The microemulsion system with pentan-1-ol is more systematic in conductance behaviour than with butan-1-ol. In the past (11) an inverse relation between the k_d and *r* has been observed which is also observed in this study. At a constant temperature (298 K), a linear trend between k_d and *r* is illustrated in Fig. 4; the two alkanols constitute two lines, pentan-1-ol follows the lower course. The *r* and k_d values obtained in this study are higher than that for the systems studied earlier (11) with CTAB, SDS, and AOT. It appears that individual systems have their specific characteristics of *r* and k_d. It is reasonable to state that a higher value of *r* corresponds to a higher proportion of cosurfactant in the interfacial region to lower the conductance of the disperse phase.



Droplet dimension, number density, and surface aggregation

The structure and related parameters of the two percolating systems studied are presented in Tables 2 and 3 at σ = 0.50 for different weight fractions of water (W_w) and temperature. The results in the tables indicate that the conductance method is suitable to obtain different structural parameters

of water/oil microemulsion. The trends of the parameters with W_w and *T* are readily revealed. At a comparable condition (e.g., W_w = 0.05), the droplet dimension (R_w) for the system with butan-1-ol is lower, droplet surface area per mL of solution (A_t) is higher, number density (N_e) is higher, and the aggregation number (A_{cs}) is higher compared to that for pentan-1-ol. With respect to temperature, the parameters vary oppositely between the two systems. For butan-1-ol (Table 2), $R_w(R_e)$ increases with temperature, A_t decreases,

[a]The cross sectional areas of CPC and butan-1-ol used for calculation are 0.71 and 0.20 nm^2, respectively.
[b]The error limits of R_w (R_e), A_t, N_e, and A_{cs} (A_s) are within ±5, ±6, ±6, and ±8%, respectively.

N_e decreases, and the A_{cs} tends to increase; and for pentan-1-ol (Table 3) except for A_{cs}, a reverse trend is observed with temperature. The A_{cs} values presented in Tables 2 and 3 are all greater than A_s under all conditions. Both $A_{cs} > A_s$ and $A_{cs} < A_s$ have been observed in the previous study (11) working with microemulsions comprising different classes of surfactants, cosurfactants, and oils. The R_e:R_w ratio is on the whole independent of the system composition and temperature. The average value of this ratio obtained in the temperature range of 298–318 K for the butan-1-ol system is 1.180 and that for the pentan-1-ol system is 1.142, giving a combined average of 1.161. This agrees well with our previous report (11), (1.150) and the value of (1.180) reported by Lagourette et al. (24).

The R_w and R_e profiles as a function of W_w at different σ and at 298 K for both the studied microemulsion systems are presented in Fig. 5. It is seen in the figure that both R_w and R_e increase curvilinearly with W_w and the difference between them decreases with increasing σ; for the butan-1-ol system at σ = 0.50, both R_w and R_e almost merge. At higher σ, the size of the waterpool becomes larger and the contribution of the thickness of the interphase is relatively low. The system with pentan-1-ol produces smaller droplets and the contribution of the interphase is still visible at σ = 0.50. Comparable variation in R_w with W_w on the other microemulsion systems was observed in the past (10, 11). In Fig. 6, the number density of the droplets (N_e) are plotted against W_w at different σ values at 298 K. The decline in N_e with W_w is exponential and the value of N_e with butanol is greater than N_e with pentanol in accordance with the R_w relationship between the two alkanols. The N_e values obtained in this study are appreciably higher than those reported earlier (10, 11) with CTAB, SDS, and AOT as surfactants, butan-1-ol and hexylamine as cosurfactants, and using different types of oil.

The A_{cs} and A_s relationship with W_w at different σ values at 298 K (Fig. 7) are also curvilinear; both the parameters increase with W_w and the spread between the two decreases with σ. The cosurfactant, pentan-1-ol gives more spread at each σ compared to butan-1-ol. Such a comparison was not done in our past study but, as mentioned earlier, A_{cs} has been found to be both higher and lower than A_s for a single surfactant:co-surfactant ratio, σ = 0.50 at 293 and 303 K. The more efficient crowding of pentan-1-ol compared to butan-1-ol in the interphase due to its better hydrophobicity (lower aqueous solubility) lowers the interfacial tension more for efficient nanodispersion of water with lower droplet size and increased droplet number. It may be stated here that the dependence of A_t with W_w at different σ values at a constant temperature has been observed to be nearly linear

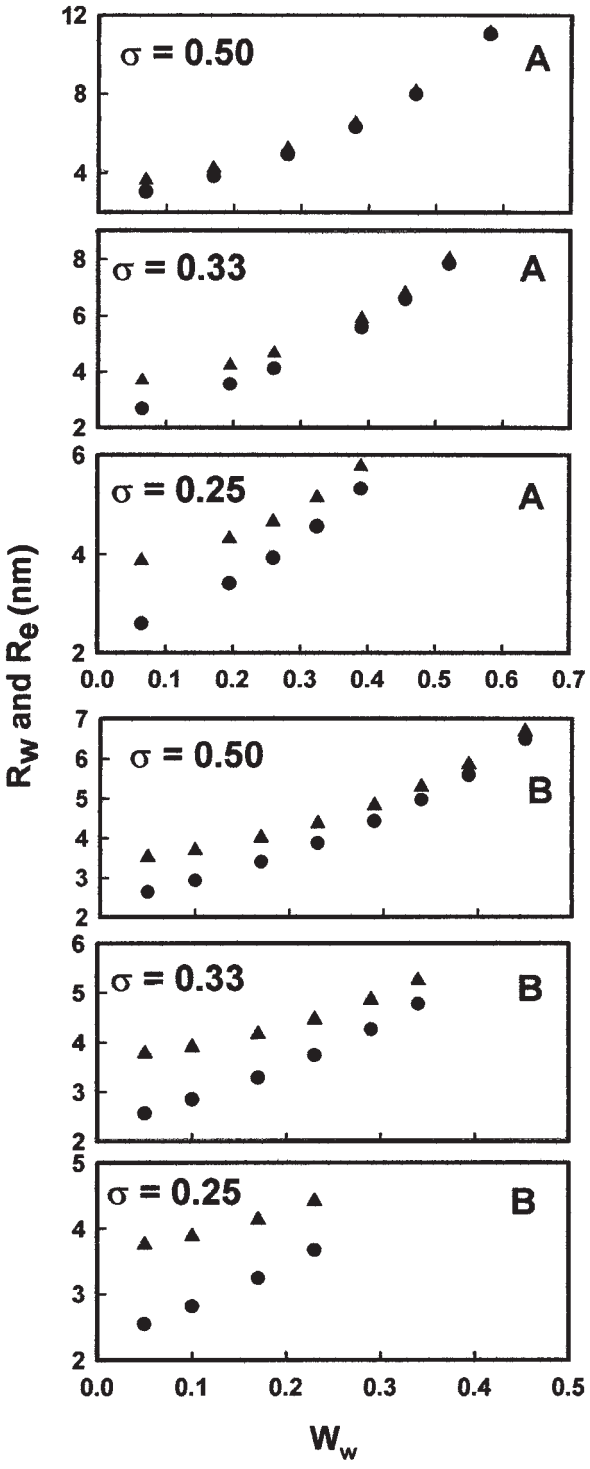
with mild curvature here and there in line with our previous study (11).



Temperature dependence of structural parameters

In the literature, conflicting results on the dependence of droplet dimension on temperature obtained by different methods are reported. Both decreased and increased droplet size for AOT stabilized water/oil microemulsions in long chain alkanes as oils have been reported from SANS and TRFQ methods (25–27). A change in the droplet dimension of 20–35% (decrease or increase) for a temperature range of 25–35°C has been observed. In the previous report (11) for a 10° rise in temperature we have observed R_w to decrease to the extents of 1, 5, 8, 3, 4, and 8% for CTAB-butanol, SDS-butanol, AOT-butanol, CTAB-hexylamine, SDS-hexylamine, and AOT-hexylamine with 1-heptane as the oil. This, on the whole, agrees with the 20% decrease observed by Rouviere et al. (27) for a temperature increase of 23°. In the present study, for a temperature rise of 20°, we have observed a max decrease of 12% in R_w for the CPC–pentanol case; for the CPC–butanol system, R_w increases instead and maximizes at 4%. These results manifest the differences in the activities of the two alkanols used in this study. The dependence of R_w on temperature for the two systems are presented in Fig. 8 at different W_w and σ values. Small increases and decreases in R_w are observed. More changes in R_w with temperature at higher W_w for the CPC–butanol system (not shown in Fig. 8) have been observed.

The dependence of the aggregation numbers, A_{cs} and A_s (with each droplet in the microemulsion) on temperature is an important aspect of microemulsion stability. For butanol and hexylamine, a max decrease in A_s of 27% and an increase in A_{cs} of 32% have been observed by us for a 10° rise in temperature by the conductance method (11). An increase in the aggregation number of AOT by 50% for a 18° temperature increase has been reported by Lang et al. (26) by the TRFQ method and they have shown an increase of more than 100% for AOT in 1-decane for a temperature rise of 40°. In this study, we have observed a 35% increase in A_{cs} and 16% decrease in A_s for the CPC–pentanol combination, and 2 and 7% increases in A_{cs} and A_s, respectively, for the CPC–butanol pair. The percentage increase in A_{cs} and decrease in A_s observed was also found earlier by us (11) with butan-1-ol as the cosurfactant. For both the studied systems, we find that the total aggregation number A_{scs} ($=A_{cs} + A_s$) within the limits of experimental errors remains virtually independent of temperature. Working at only two temperatures, a decrease in A_{scs} with increasing temperature was

revealed earlier (11). Although A_{scs} is relatively constant, the contributions from the two components (A_{cs} and A_s) are self-adjusting to maintain the observed trend in R_w.

theoretical background. The results realized for the two microemulsion systems at different σ and temperature values are presented in Table 4. It is observed from the results that ΔG_t° has a mild dependence on both σ and temperature for the system with CPC–butanol. For the other system with CPC–pentanol, the magnitude of ΔG_t° decreases with increasing σ but the temperature dependence is even more mild. On the whole, the transfer process for the second system is slightly more spontaneous than the first. The ΔH_t° values for the second are very small and exothermic, but are endothermic and higher in magnitude for the first. The ΔS_t° are all positive, the second system is less disordered for the transfer process than the first. The exothermic, with a lower ΔS_t°, transfer of pentan-1-ol from the oil to the interphase speaks in favor of an interfacial stabilization which is greater than for the transfer of butan-1-ol.

It may be mentioned here that the magnitudes of the transfer parameters of the alkanols herein obtained are mostly different from those reported by the method of dilution (28, 29). A recent calorimetric method reported that the ΔH_t° and ΔS_t° are both negative (30). These are not in line with the present observations. The ΔG_t° values, however, agree with the earlier findings of Gerbacia and Rosano (31). A comparative study using both the conductivity and the dilution methods under similar experimental conditions would be a worthwhile physicochemical endeavor. This area has been only minimally explored.

Thermodynamics of droplet clustering (association)

On consideration of formation of a pseudophase by the clustering of the droplets at the threshold of conductance percolation (comparable with the formation of micellar pseudophase), the thermodynamics of the said clustering

[b]Mass % compositions are given in the parentheses.

(association) process have been evaluated in terms of eqs. [11], [12]. The results for different microemulsion compositions and σ values at 298 K are presented in Table 5. It is observed from the ΔG_{cl}° values that the process of clustering is fairly spontaneous, the CPC–butanol system more so than the CPC–pentanol system. The dependence of ΔG_{cl}° on σ is not systematic. The ΔH_{cl}° values are all reasonably large and negative, and the ΔS_{cl}° values are small and positive; the latter is relatively much larger for the system with butan-1-ol than with pentan-1-ol. The thermodynamics of the clustering of droplets in microemulsion have been recently studied by us (14, 15) and Alexandradis et al. (16) exploiting the method of conductance as herein presented with AOT as the surfactant (which nicely forms microemulsion without a cosurfactant). The ΔH_{cl}° values obtained were all positive, and the corresponding ΔS_{cl}° values were large and positive. The results of this study are at variance with the above with respect to ΔH_{cl}° and ΔS_{cl}°.

It is considered (16) that during clustering, spherical droplets make mutual contacts and become to some extent flattened with absorption of heat (a process that acts against the bending energy that opposes deformation) manifested as the positive enthalpy change. The removal of the solvent molecules between the clustering droplets and the dissimilarities between the free volume of the mobile solvent molecules and the fixed surfactant molecules in the interphase contribute to the positive entropy change. In the present study, the free volume difference between the molecules of hexane (solvent) and the surfactant (CPC) is large, while these differences with butan-1-ol and pentan-1-ol (the cosurfactants) are minor so that the entropy change for the overall process of droplet clustering is also small. It should be also considered that $A_{cs} >> A_s$ (Tables 2 and 3) so that the contributions to ΔS_{cl}° coming from the free volume consideration of the alkanol is much more than from the CPC. It is also seen in Table 5 that ΔS_{cl}° with pentan-1-ol is appreciably lower than ΔS_{cl}° with butan-1-ol although the molecular size difference of the alkanols with *n*-hexane is less for the former than the latter. Since the $+\Delta S_{cl}^\circ$ values are low, the $T\Delta S_{cl}^\circ$ term cannot surpass the $-\Delta G_{cl}^\circ$ in the Gibbs–Helmholtz equation (meant for mutual adjustments among the energetic parameters) to produce a positive enthalpy change for the clustering

© 2001 NRC Canada

process. The association process appears to be a normal one occurring with the release of heat. Thus, although the flattening of the spherical nanodroplets during mutual contact in clustering (as envisioned for the cosurfactant-less microemulsion system with AOT) has been considered to produce positive ΔH_{cl}°, other steric factors may have a significant influence on the process when cosurfactant and oil of comparable size exist in the system. The cosurfactant may even make the interphasial region rigid (3) so that during clustering the interface is mildly or hardly flattened (32) to make the process enthalpy disfavorable. The rigidification of the interface is more with pentan-1-ol than butan-1-ol (33) so that ΔH_{cl}° is more favorable for the latter than the former. The contact between the droplets occur by the interplay of long range van der Waals forces of attraction to essentially become an enthalpy driven process.

The aforesaid analysis of the thermodynamics of the studied clustering process is only tentative. A systematic study using different surfactant–cosurfactant combinations and different types of oil is needed for a pragmatic understanding of the roles of the components in guiding the thermodynamics of the clustering process.

Conclusions

(1) The phase boundary in the ternary phase diagram of the water/CPC/butan-1-ol/*n*-hexane system is symmetric and dome-shaped whereas that of the water/CPC/pentan-1-ol/*n*-hexane system is triangular in shape at 298 K. The latter shows a gel region near the middle.

(2) The above microemulsion forming systems exhibit fair degrees of both volume- and temperature-induced percolations.

(3) The structure factor (r) and the conductance of the disperse phase (k_d) decrease and increase, respectively with the surfactant:cosurfactant mass ratio, σ at a constant temperature. At comparable conditions, r is higher and k_d is lower for pentan-1-ol compared to butan-1-ol as the cosurfactant.

(4) The waterpool diameter of the droplets and the ratio of the interfacial aggregation number (A_{cs}/A_s) are lower and higher with pentan-1-ol than butan-1-ol at comparable conditions. The size of the droplet increases mildly with temperature when butan-1-ol is the cosurfactant and decreases when it is pentan-1-ol.

(5) The free energies of transfer of the alkanols from the oil phase to the interphase (ΔG_t°) are lower than the limited data available in the literature on different systems, except for that of Gerbacia and Rosano (31). The transfer process is entropy-controlled.

(6) The thermodynamics of droplet clustering reported with the combined presence of surfactant and cosurfactant differ with respect to the enthalpy and entropy obtained for systems stabilized with AOT without a cosurfactant. The clustering of the studied system is an enthalpy driven process.

IR Spectroscopy of aqueous alkali halides. Factor analysis

Jean-Joseph Max, Serge de Blois, Alain Veilleux, and Camille Chapados

Abstract: The infrared spectra of ten salts in aqueous solutions were obtained in their solubility range using attenuated total reflection (ATR). The salts are: LiCl, NaCl, KCl, CsCl, $MgCl_2$, NaBr, KBr, NaI, KI, and CsI. The salts, which are completely ionized in water, do not absorb in the IR. Only their interactions with water are observed and analyzed. Factor analysis (FA) applied to the spectra showed that two principal species are present in the solutions: pure water and salt-solvated water. The modifications of the water spectrum are dependent on the nature of the salts, their concentrations and are mainly of first-order. Second-order effects were observed but, being weak, were not investigated. The modifications of the IR-ATR spectrum from pure water to a salt solution are proportional to the modifications of the imaginary part of the refractive index spectrum ($k(\nu)$). This indicates that the anomalous dispersion effects do not interfere with the chemical analysis of the IR-ATR spectra. In every salt studied, the two main species present in the solutions remained stable throughout the salt solubility ranges. Comparison between the IR spectra of the different salts solutions indicates that both anions and cations are in strong interaction with water molecules and are solvated together in stable clusters.

Key words: IR spectroscopy, ATR, liquid, aqueous solutions, factor analysis, principal spectra, LiCl, NaCl, KCl, CsCl, NaBr, KBr, NaI, KI, CsI, $MgCl_2$.

Résumé : Les spectres infrarouges de dix sels en solutions aqueuses dans la gamme de leur solubilité ont été obtenus par réflexion totale atténuée (ATR). Ces sels sont : LiCl, NaCl, KCl, CsCl, $MgCl_2$, NaBr, KBr, NaI, KI et CsI. Les sels qui sont complètement ionisés n'absorbent pas dans l'infrarouge, seules leurs interactions avec l'eau qui en modifie le spectre peuvent être observées et analysées. L'analyse par facteurs (FA) des spectres a montré que deux espèces principales sont présentes dans les solutions: l'eau liquide et l'eau de solvatation du sel. Les modifications du spectre de l'eau dépendent de la nature du sel, de sa concentration et sont principalement du premier ordre. Des effets du second ordre ont été observés, mais compte tenu de leur faible amplitude, ils n'ont pas été pris en compte. Les modifications du spectre IR-ATR de l'eau en présence de sel dans la solution sont proportionnelles aux modifications du spectre de la partie imaginaire de l'indice de réfraction, $k(\nu)$. Ceci démontre que les effets dus à la dispersion anormale sont stables et n'empêchent pas l'analyse chimique directe des spectres IR-ATR, sans la nécessité de passer en spectres $k(\nu)$. Dans chacun des sels étudiés, les deux espèces principales sont stables dans toute la gamme de solubilité. La comparaison des divers spectres d'eau de solvatation indique que les deux ions solubilisés sont en interaction forte avec des molécules d'eau et qu'ils sont solvatés ensemble (par paire) formant avec quelques molécules d'eau des agrégats stables.

Mots clés : spectroscopie IR, ATR, liquide, solutions aqueuses, analyse par facteurs, spectres principaux, LiCl, NaCl, KCl, CsCl, NaBr, KBr, NaI, KI, CsI, $MgCl_2$.

Introduction

In previous papers, we studied at 26.5°C aqueous solutions of NaCl, KCl, and CsCl (1–4) over the solubility range of the salts (as given in ref. 5) by attenuated total reflection infrared spectroscopy (IR-ATR). By applying factor analysis (FA) to the series of spectra, we found that all the spectra for each series could be represented by the sum of two spectra: one for pure water and one for the highest concentration of salt in the series, each spectrum being multiplied by a multiplying factor (MF). Finally, it was found that the MFs were proportional to the salt concentration, indicating that: (*i*) two types of water are present in the solutions; (*ii*) the spectrum of each sample is a linear combination of the spectra of the two types of water; (*iii*) for each type of water, the intensity of aqueous salt solutions follows the Beer–Lambert law. Based on these properties, a simple method of subtracting the water spectra from the IR spectra of aqueous solutions was developed (1, 6).

The spectrum of water is strongly modified when a binary salt, a strong acid, or a strong base is added to it (1–4, 6–10). ATR configuration provides easy sample manipulations and high reproducibility (1–4, 6, 7, 11–17). We previously reported that the modification of the ATR absorbance spectrum

of water when a solute is added to the solution is almost proportional to the modification of the spectrum of the imaginary part of the refractive index of water ($k(\nu)$) (2, 4). This property of the ATR spectrum of water is valid only when: (*i*) a substantial difference exists between the refractive index of the crystal and that of the sample; (*ii*) the angle of incidence is higher than the crystal critical angle. The validity remains even when the concentration of water in the solutions is lowered by 35% compared to pure water. When both of these conditions are met, the direct ATR absorbance spectra reflect the chemical changes of the system (2, 4).

In the systems studied, the spectroscopic modifications depended on the species dissolved in water. The species studied — chloride salts (NaCl, KCl, CsCl), a strong acid (HCl), or a strong base (NaOH) — are completely ionized in water and the ions are either nonabsorbing or weakly absorbing compared to water (1–4, 6, 7). The spectroscopic modifications thus reflected the chemical modifications of water (8–10, 18). The changes in the ATR spectrum of water were proportional to the amount of ionic species. In the solutions analyzed, four different types of species of water were identified: pure water, salt-solvated water, HCl- and NaOH-solvated waters. While NaCl-solvated water is very similar to KCl-solvated water, CsCl-solvated water is different. This fact indicates that the cation plays a role in cluster organization. All four types of water remain unchanged in one another's presence except when a reaction occurs. For example, consider the titration of NaOH by HCl which gives NaCl (7). At the outset, pure water and NaOH-solvated water were identified. As the titration proceeded both types of water persisted until neutralization with the formed NaCl-solvated water. After neutralization, the latter was present, at almost constant amounts, with pure water and HCl-solvated water in increasing amounts as HCl was added to the solution. The presence of NaCl did not modify the structure of HCl- or NaOH-solvated waters. From an IR point of view, the ions of each of these species were not solvated separately or independently from their respective counter ions. These results do not support the usual concept of hydration shells of isolated ions (19–21) but are in conformity with previous observations establishing the cooperative action of anions and cations in spectral changes (22).

The groups led by Williams (9, 10) reported experimental values of the optical IR characteristics of aqueous solutions of several binary salts obtained by reflection measurements. Draegert and Williams (10) compared their far-IR results on salt solutions with the results reported by Bernal and Fowler (21) on pure water at different temperatures. The far-IR results on salts solutions were interpreted in terms of structure-makers and structure-breakers produced by solvated ions. The modifications varied with the size and charge of the ions (10). Subsequent results obtained by Rhine et al. (9) in the 5000–350 cm^{-1} region did not support this idea. Rather, they suggested that ion clustering may be a better interpretation of the IR spectra of salt solutions. The results these authors obtained were qualitative due to the low accuracy of the method used and the spectra not being normalized for the number of water molecules. FTIR-ATR sampling is a better method because the path length is fixed, the water bands do not saturate, and the spectra are reproducible.

The purpose of this paper is to obtain the IR-ATR spectra of aqueous solutions at several concentrations up to the solubility limit of several alkali halides (LiCl, NaCl, KCl, CsCl, NaBr, KBr, NaI, KI, and CsI) and one alkaline-earth halide ($MgCl_2$). The latter was added to the alkali series for the purpose of comparison. From the series of spectra we will: (*i*) determine the number of species present in the solutions; (*ii*) obtain the spectra of the species; (*iii*) determine the abundance of the species as a function of the salt concentration; (*iv*) compare the results to detect similarities and dissimilarities on the basis of ion sizes and types of halogens; (*v*) evaluate the optical effects produced by ATR sampling to determine if they prevent the direct chemical analysis of the IR-ATR spectra; (*vi*) evaluate the clustering effects of these salts.

Calculation methods

Factor analysis (FA)

Factor analysis is a method that can sort the principal spectra in series of evolving spectra as a function of one of the system's perturbing parameters such as temperature, pressure, concentration, etc. Within a set of experimental spectra, some spectra may represent pure or almost pure species. In such cases, these spectra can be used as principal spectra for FA (6, 7, 14–17) When the principal spectra can be easily and directly obtained from a set of experimental spectra, FA can be simply performed using a personal computer. Otherwise, a more demanding procedure has to be applied (23). For the salt solutions studied here we used the direct procedure. Each principal spectrum is multiplied by its MF and the results are added. The resulting spectrum is subtracted from the experimental one and the MFs are varied until the difference spectrum is minimized. The best fit is monitored by using the least-squares fit procedure. In the case of aqueous salt solutions, neither principal factor necessary for the procedure is orthogonal to the others since the solution with the highest salt concentration used as the second principal spectrum contains some water organized as in pure water (1–4). However, orthogonality is not required in the FA procedure.

Calculation of sample composition from MFs

The composition of a sample is calculated from the MFs obtained by FA by the method detailed in ref. 4. The concentration of each species present in the solution is obtained by multiplying the MF by the concentration of the corresponding species in the solution used for the principal spectrum. When the principal spectra used in applying FA are not orthogonal, the sample's solvent content is obtained by multiplying the amount of solvent in each solution used for the eigenspectra by its respective MF in the sample and calculating the sum of the values obtained.

Optical effects

Compared to transmission spectra, ATR sampling is known to produce stronger optical effects which modify the spectrum (24–27). These optical effects increase with a decreasing difference between sample and substrate refractive indices, and with a decreasing incidence angle (24, 25, 27). Furthermore, the optical effects are enhanced by the proximity

of two strong absorption bands (26). However, as we recently reported, with appropriate ATR sampling the optical effects in the IR spectrum of water are hardly modified when a binary salt is added to the solution. When NaCl, KCl, or CsCl is added to water, the modification of the ATR spectrum is almost proportional to the modification of the $k(\nu)$ spectrum (2, 4).

To evaluate the optical effects in an ATR spectrum, it is necessary to transform it into $k(\nu)$ and $n(\nu)$ spectra. Refractive indices n and k were calculated from the ATR spectra following the method detailed in ref. 2 and used in ref. 4. The value of n was calculated using the Kramers–Krönig transform of k, which was obtained by using an FFT algorithm twice with the proper modifications of the input data parity function. The ATR spectra were recalculated with equations provided in ref. 11 using the substrate and sample complex refractive indices. The excellent fit between experimental and calculated ATR spectra was the validity criterion.

Experimental

Chemicals and solutions

Deionized water was used to prepare the aqueous solutions. Dried salts (24 h at 65°C) of LiCl, NaCl, KCl, CsCl, NaBr, KBr, NaI, KI, CsI, and $MgCl_2$ (all from Aldrich, purity 99%) were used to prepare the aqueous solutions up to their concentration limits. Homogeneous solutions were obtained by weighing the salts in 10 mL volumetric flasks and completing with water. The resulting total mass was measured. The density of the solutions was obtained and compared to the literature data (5, 28).

Density and refractive index of salt solutions

The density of the aqueous solutions as a function of salt concentration c (in mol L^{-1}) of the 10 salts are well approximated by linear relationships. The experimental results obtained by this study are similar to available reported values to within 0.6% (Table 1) (5, 28). The refractive index at the sodium D line (n_D, 17 000 cm^{-1}) (29) as a function of salt concentration of the salt aqueous solutions were obtained from the literature (5) and proven to be well approximated by linear functions with only a negligible second order variation (Table 1).

The value of n_∞ is needed to calculate $k(\nu)$ and $n(\nu)$ (2, 4). We used the n_D values for that purpose. The latter may be considered to be near infinite frequency because it is far from any vibrational and electronic absorption bands (9). The n_D values not available in handbooks were obtained by extrapolation on the basis that, for ions in water, refractivity (n_D) is additive (21). The values are listed in Table 1. The n_D values of 6.03 M KI and 8.19 M NaI obtained using that mode agreed with the literature values (9, 30).

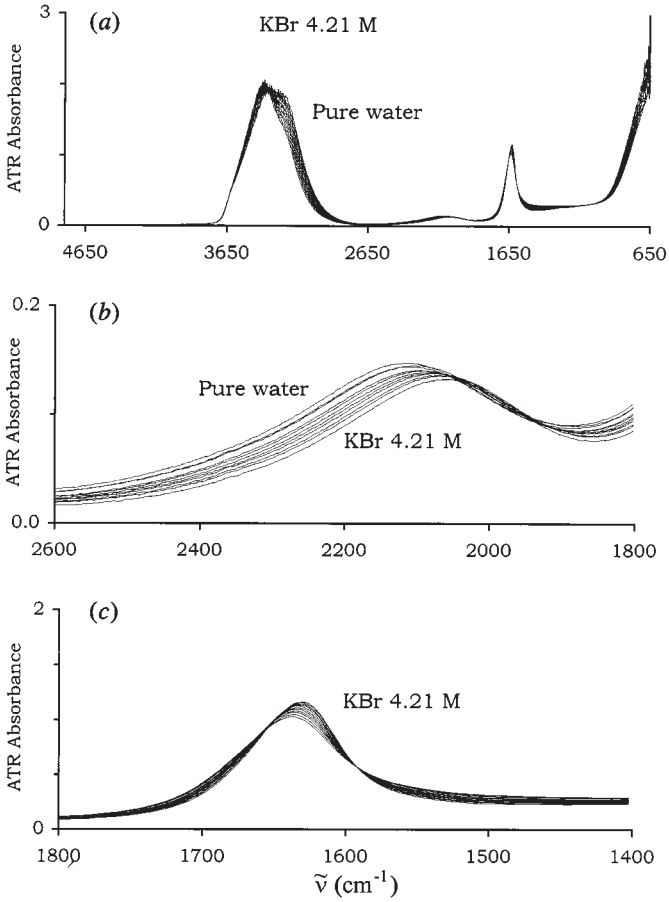
IR measurements

The IR measurements were obtained using a model 510P Nicolet FT-IR spectrometer with a TGS detector. Two KBr windows isolated the measurement chamber from the outside.

© 2001 NRC Canada

The samples were contained in a "Circle cell" (SpectraTech, Inc.) equipped with a ZnSe crystal rod in an ATR configuration (the incident beam is at an angle of 45° with respect to the rod's axis). The spectral range of the ZnSe rod in the spectrophotometer is situated between 6500 and 630 cm^{-1}. The spectra taken at 26.5 ± 0.3°C with a resolution of 4 cm^{-1} were obtained under a flow of nitrogen to ensure a low residue of CO_2 and water vapors in the spectrometer. For the series of NaI, CsCl, CsI, and $MgCl_2$ salt solutions an accumulation of 200 scans were obtained. For the series of LiCl, NaCl, KCl, NaBr, KBr, and KI salt solutions, 20 scans were obtained. The spectrum of pure water and the highest concentrated salt solutions were obtained with an accumulation of 1000 scans from 6500 to 630 cm^{-1}. The cell was carefully washed and dried prior to each measurement. Model 510P is a single-beam spectrometer. A background with the empty cell was taken before the measurement of each sample.

The IR measurements consisted of obtaining the ATR background intensity (R_0) and the ATR sample intensity (R). The R/R_0 ratio produced intensity I for the spectral range studied. Thereafter, the data points {I ($\tilde{\nu}$) vs. $\tilde{\nu}$ (in cm^{-1})} of each spectrum were transferred to a Microsoft Excel spreadsheet program on a personal computer where the numerical treatments were performed. Then intensities I were transformed in absorbance (log (1/I)). A small baseline shift was made to obtain a null mean absorbance in the 4600–4450 cm^{-1} or 6500–6150 cm^{-1} region, depending on the range studied. The reported values of $k(\nu)$ in these regions are approximately 2×10^{-4} and 4×10^{-5} (12), corresponding to 3×10^{-3} and 6×10^{-4} ATR au, respectively. The ATR cell's effective number of reflection (m) as determined by the pure water spectrum and the $k(\nu)$ values from the literature (12) is 6.6.



Factor analysis

The principal spectra needed to analyze the series of spectra of aqueous salts were determined from the experimental spectra: pure water and the highest concentrated salt solution. The absorbance of water in the 3450–3150 cm^{-1} region and below 750 cm^{-1} was near saturation, resulting in a noisy signal in these frequency ranges. The region below 700 cm^{-1} was eliminated in the least-squares procedure. The noise in the 3450–3150 cm^{-1} region somewhat reduced the accuracy of FA, but was kept in the minimization procedure. For a few of the salts, minimization produced a sigmoid flexure in certain regions due to a small band displacement.

Transforming ATR spectra into *k* and *n* spectra

The Kramers–Krönig transform is used in the transformation of the ATR spectra into k and n spectra with the use of a FFT algorithm (2, 11). The spectrophotometer supplied 3044 data points from 6500 to 630 cm^{-1}. Data from 0 to 630 cm^{-1} were not available and could not be found in the literature. We used a 8192-point FFT algorithm, thus requiring 4097 experimental data points for the input $k(\nu)$ function (4). The wave number interval between experimental data points was 1.92906 cm^{-1} with which the FFT calculation covered the 0–7900 cm^{-1} region. Values of k in the 6500–7900 and 0–630 cm^{-1} regions were put to 10^{-5}, which incidentally introduced an error below 1000 cm^{-1} (2, 4).

Results and discussion

FA applied to the ATR spectra

FA applied to the IR spectra of NaCl, KCl, and CsCl aqueous solutions have been previously reported (1–4). The following provides two examples of FA applied to the IR spectra of salt solutions. KBr was used to illustrate the solutions that behaved like NaCl (NaCl, KCl, NaBr, KBr, and CsI) and NaI for those that behaved differently (LiCl, CsCl, NaI, KI, $MgCl_2$). The FA procedure is the same and was applied to every salt solution presented here.

ATR spectra of aq KBr and NaI solutions

The experimental spectra of the KBr (0–4.21 M) and NaI (0–8.19 M) solutions are presented in Figs. 1 and 2, respectively. Expanded views of the principal regions are shown in Frames (*b*) and (*c*). When KBr and NaI are added to water, the ν_2 band shifts from 1637 to 1632 and 1617 cm^{-1}, respectively, (Figs. 1*c* and 2*c*). The displacement on the ν_2 band of NaI solutions is the greatest displacement observed on all the salts presented here (Table 1). These displacements concur with the data reviewed in ref. 31.

Factor analysis results of the series of ATR spectra

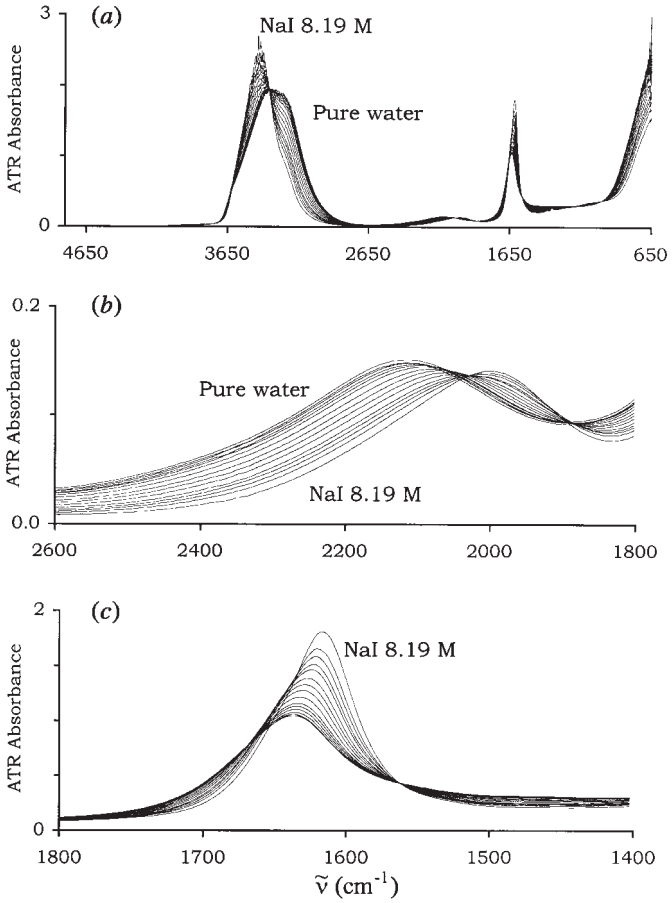
Fig. 2. Experimental IR-ATR absorbance spectra of NaI aqueous solutions (0–8.19 M). (*a*) Complete spectra; Expanded view of (*b*) 2100 cm^{-1} region; (*c*) HOH deformation region.



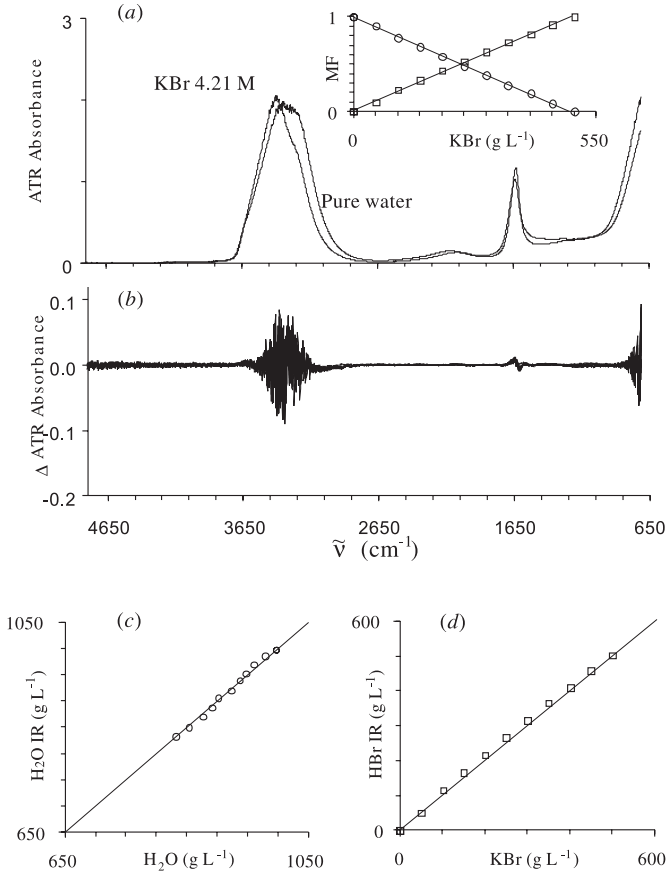


Fig. 3. Result of FA on the KBr aqueous solution spectra. (*a*) Principal spectra used in FA: pure water and 4.21 M KBr. Insert, MFs retrieved; (*b*) Residue spectra. Correlation between the concentration retrieved by IR and that obtained by gravimetry for: (*c*) water; and (*d*) KBr.

Figs. 1 and 2, respectively. The spectra of pure water and those of 4.21 M KBr (Fig. 3*a*) and 8.19 M NaI (Fig. 4*a*) were used as principal spectra in the FA procedure. The linear regressions (full lines in the inserts) of the MFs show that they are nearly proportional to the salt concentration.

The difference between experimental spectra and those retrieved from FA are presented in Figs. 3*b* and 4*b*, respectively. For KBr, compared to the intensity of the experimental spectra (Fig. 1), the residues are less than ±1% at maximum intensity in the strong absorption regions of the KBr solution spectrum and less than ±0.1% in the rest of the spectrum (Fig. 3*b*). For NaI, the residues are less than ±10% at maximum intensity in the ν_2 region of the NaI solution spectrum and less than ±1% in the rest of the spectrum (Fig. 4*b*). The latter percentages apply to the worst situations: the solution containing half the amount of salt of the more concentrated solution. Since the residues for the NaI solutions showed a progression with the salt concentration, we tried unsuccessfully to introduce a third species in the FA procedure. The sigmoid flexure seen in the residue spectra of NaI (Fig. 4*b*), which is due to the displacement of the ν_2 vibration of water, cannot come from the contribution of a stable species and does not result from optical effects (see the section on the optical effects evaluated by the ATR/$k(\nu)$ spectra). We attributed the residue spectra to second-order effects. Of the ten salts studied here, NaI exhibited the strongest second-order effects (Table 1). The residue spectra observed in the KBr solutions (Fig. 3*b*) are typical of what is observed in the other solutions. In Table 1, we report the worst cases in each series, that is the characteristics of the greatest difference spectra (difference between experimental and calculated spectra). The second-order effects are not very strong, even in the worst case. Although neglected in the present study, they are the object of ongoing research.

The two principal factors obtained by FA are sufficient to describe the entire series of KBr and NaI spectra (inserts, Figs. 3*a* and 4*b*). The same FA procedure applied to the rest of the salt solutions gave similar results. We previously obtained similar results for NaCl, KCl, and CsCl aqueous solutions (1–4). This indicates that two types of species of water are present in the samples: pure water and salt-solvated water.

Correlation between IR and gravimetry results

The MFs of Figs. 3*a* and 4*a* (inserts) were transformed into concentrations by the method found in the calculation of sample composition from MFs section. The plots of the concentrations obtained by IR as a function of those obtained by gravimetry are given in Figs. 3*c* and 3*d* for water and KBr, respectively. Those of NaI are given in Figs. 4*c* and 4*d*. The results indicate that all the points are near the solid line, which is the theoretical slope for a perfect one to one correlation. Although well within experimental error, a

small deviation from this theoretical one to one correlation which seems statistically significant is observed in Fig. 4*d* for the NaI concentration. This small deviation may stem from second-order effects (1, 4).

The correlation plots between the salt and water concentrations retrieved from the IR spectra and those obtained by gravimetry for all the salts are presented in Fig. 5*a* and 5*b*, respectively. The correlations are very good for the concentrations of both water (Fig. 5*a*) and salt (Fig. 5*b*), although the latter shows small deviations on the CsCl (Δ) and NaI (O) values. These results reinforce the idea that the alkali halides solutions are made up of two types of species, pure water and salt-solvated water, and that these species are stable throughout the entire solubility range, their concentrations depending on the amount of salts in the solutions.

Experimental ATR spectra and optical effects

The IR-ATR spectra are affected by AD, which may cause optical effects that could influence the direct relation between the spectra and the solutions. In particular, the second-order effects that we mentioned previously might have originated from these effects. In this section we address these issues by evaluating the ratio between the ATR and $k(\nu)$ spectra.

The experimental spectra

The experimental IR-ATR spectra of concentrated salt solutions are presented in Fig. 6 for NaCl-like spectra: 5.13 M NaCl, 4.03 M KCl, 6.82 M NaBr, 4.20 M KBr, and 3.00 M CsI. To these spectra we added the water spectrum (trace a). The slight differences observed between these spectra are mostly due to differences in salt concentration and water content.

The spectra which differ from NaCl are presented in Fig. 7 along with the spectrum of water: 14.16 M LiCl, 7.15 M CsCl, 8.19 M NaI, 6.03 M KI, and 4.29 M $MgCl_2$. These spectra not only differ from that of 5.13 M NaCl but are also very different one from the other.

Influence of the optical effects evaluated by the ATR/k(ν) spectra

For pure water and KCl- and CsCl-solvated water, we recently reported that IR-ATR and $k(\nu)$ spectra were related by (4):

$$[1] \qquad \frac{\mathrm{ATR}(\nu)_{\mathrm{solution}}}{k(\nu)_{\mathrm{solution}}} = \left(\frac{n_{\infty\,\mathrm{solution}}}{n_{\infty\,\mathrm{pure\ water}}}\right)^4 \frac{\mathrm{ATR}(\nu)_{\mathrm{pure\ water}}}{k(\nu)_{\mathrm{pure\ water}}}$$

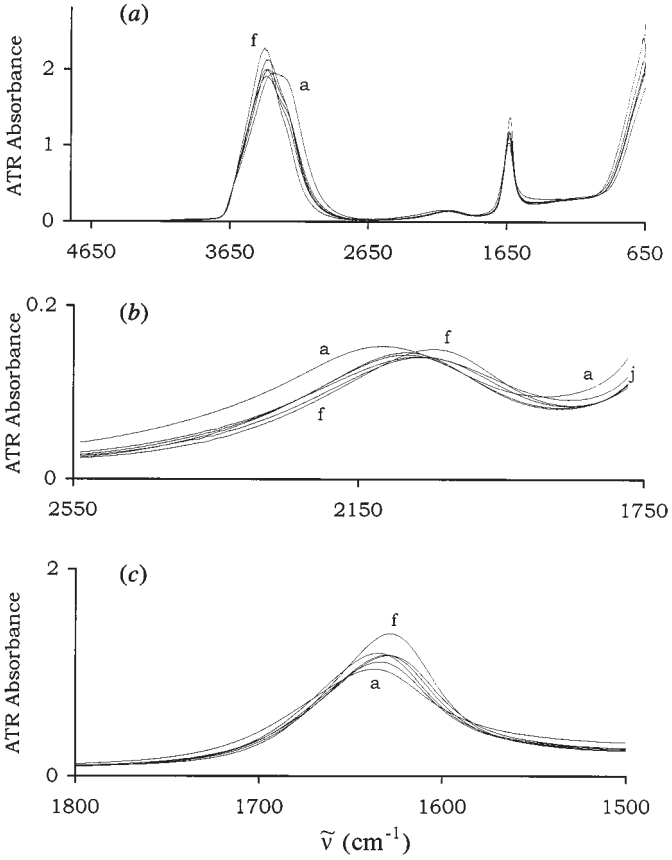
Fig. 6. IR-ATR spectra of aqueous solutions of salts with spectral features similar to those of NaCl: (*a*) pure water; (*c*) 5.14 M NaCl; (*d*) 4.03 M KCl; (*f*) 6.81 M NaBr (g) 4.21 M KBr; and (j) 3.00 M CsI. (*a*) Complete spectra; Expanded view of (*b*) 2100 cm^{-1} region; (*c*) HOH deformation region.



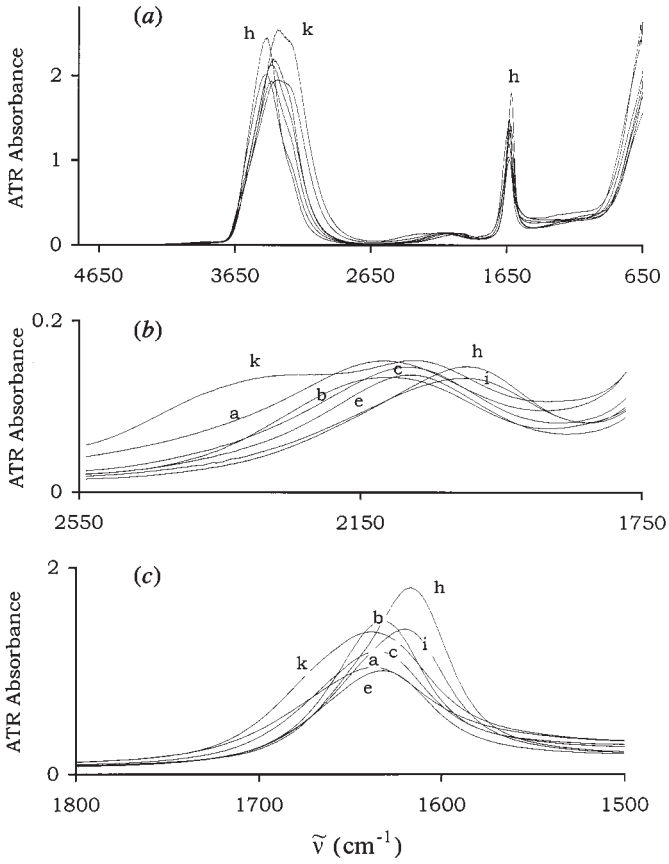


Fig 7. IR-ATR spectra of aqueous solutions of salts with spectral features different from those of NaCl: (*a*) pure water; (*b*) 14.16 M LiCl; (*c*) 5.14 M NaCl (for comparison); (*e*) 7.15 M CsCl; (h) 8.19 M NaI; (*i*) 6.03 M KI; and (k) 4.29 M $MgCl_2$. (*a*) Complete spectra; Expanded view of (*b*) 2100 cm^{-1} region; (*c*) HOH deformation region.

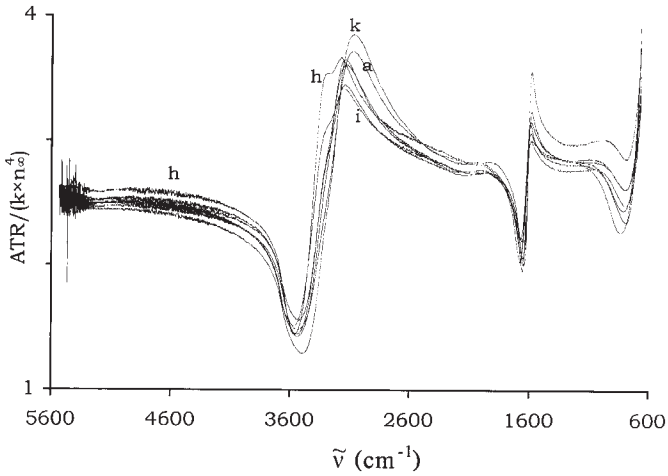

where n_∞ is the refractive index value at infinite wave number (taken as n_D). The correction for the amount of water molecules (1–3) can be omitted because it would be applied to both ATR and *k* spectra and hence is canceled in eq. [1], which is rewritten as follows:

$$[2] \qquad \frac{\mathrm{ATR}(\nu)_{\mathrm{solution}}}{k(\nu)_{\mathrm{solution}}(n_{\infty\,\mathrm{solution}})^4} = \frac{\mathrm{ATR}(\nu)_{\mathrm{pure\ water}}}{k(\nu)_{\mathrm{pure\ water}}(n_{\infty\,\mathrm{pure\ water}})^4}$$

To confirm the validity of eq. [2], the relation of ATR over ($k \times n_\infty^4$) for pure water and for each of the concentrated salt solutions of Fig. 7 were obtained and are presented in Fig. 8. In the latter, only salts that are not NaCl-like are presented because the NaCl-like salts gave overlapping results. The seven curves in Fig. 8 being close together indicates that eq. [2] is valid. The slight variations between the curves as opposed to exact equality are attributed to minor changes in AD effects (4). These results confirm that the modification of the ATR spectrum when a binary salt is added to pure water is proportional to the modification of the imaginary part of the refractive index (*k*) (eq. [1]). Therefore, the optical effects are not responsible for: (*i*) the modification of the ATR spectrum of salt-solvated water compared to that of pure water; (*ii*) the second-order effects observed (Figs. 3*b* and 4*b*).

Fig. 8. Ratios of the IR-ATR spectrum over that of the imaginary part of the refractive index $k(\nu)$ divided by n_∞^4 for the solutions indicated in Fig. 7 (See text, eq. [2]).

© 2001 NRC Canada

Furthermore, the mean value of ATR/($k \times n_\infty^4$) in the 5300 –5450 cm^{-1} region was found to be 2.52 ± 0.09, which can be compared to the square root of the effective number m of reflections in the ATR crystal ($m^{1/2} = 6.6^{1/2} = 2.57$). Work is in progress to substantiate this relation.

Ion pairing in salt-solvated water

The spectrum of NaI is different from that of CsCl (Fig. 7), and both of them are different than that of NaCl. The latter is similar to the spectrum of CsI (Fig. 6). Therefore, no combination of the spectra of NaI and CsCl solutions can give the spectra of NaCl and CsI, which would be the case if the ions were solvated independently. This result does not support previous interpretations that considered monoatomic ions to be solvated independently (8–10, 19, 32–35). Rather, it strengthens our previous interpretation that each pair of ions (monoatomic ions) are bound together, solvated by a fixed number of water molecules to form a cluster (1–4, 7). FA results show that the spectra of aqueous salt solutions are linear combinations of two principal spectra, one for pure water and one for salt-solvated water (refs. 1–4 and present work). Therefore, the clusters made up of one set of salt ions and a fixed number of water molecules are stable throughout the solubility range of these salts. The clusters behave as strongly bound units where the cations and anions are close together in each cluster (3, 4). The differences observed in the spectra (Fig. 7) are the manifestation of the differences in the strong interaction between the ion pairs and water. These conclusions shed new light onto the water solvation process and may be useful for the interpretation of neutron scattering experiments on aqueous solutions (32, 33). Work is in progress which will determine the hydration numbers from the IR spectra.

$MgCl_2$ solutions

The spectrum of 4.29 M $MgCl_2$, an alkaline–earth chloride salt (Fig. 7k) is very different from all other alkaline chloride salts presented in Fig. 7. The intensity of the OH stretching band's low-frequency wing is greatly increased, contrary to the others. This cannot be attributed to the Mg^{2+} solvated ion alone, because the spectrum reported for 7.7 M $Mg(NO_3)_2$ does not exhibit a low-frequency wing as intense as for $MgCl_2$ (36). Therefore, the comparison between the spectrum of aqueous $MgCl_2$ and that of aqueous $Mg(NO_3)_2$ is additional evidence of ion pairing in aqueous solution.

Conclusion

Using adequate ATR sampling, the changes in the ATR spectrum of water are proportional to the changes in its k spectrum. This proves unambiguously that the optical effects do not vary much and that the IR-ATR technique is highly reliable for quantitative chemical analysis of aqueous solutions made directly from the experimental IR-ATR spectra. The elimination of the optical effects is only needed to extract exact optical characteristics of samples.

Factor analysis showed that the IR spectra of aqueous binary salt solutions, and one ternary salt solution, are proportional to the salt concentration. For all the salts studied, two main types of species of water were obtained: pure water and salt-solvated waters. These types of water are stable in the whole solubility range of the salt. These results are added proof of ion pair clustering in water (3, 4, 9). When an alkali halide salt and $MgCl_2$ is dissolved in water, it forms clusters with a finite number of water molecules per ion pair. These clusters are stable throughout the solubility range of the salt. Second-order effects and the behavior of other alkaline earth halides besides $MgCl_2$ are the objects of ongoing research.

Theoretical study on the influence of H_2O for the 1,2-hydrogen shift from hydrogen peroxide (H_2O_2) to water oxide (O-OH_2)

Toshiya Okajima

Abstract: Theoretical calculation was performed to study the solvent effect for the 1,2-hydrogen shift from hydrogen peroxide (H_2O_2) (**1**) to water oxide (O-OH_2) (**2**). Stationary points including transition structures (TSs) were optimized with no geometrical constraint at Becke3LYP/6–311++G** level. All stationary points were tested by frequency analysis and IRC calculation. The activation energies ($\Delta E^{\neq}$) and heats of reaction (ΔH_0) were evaluated at Becke3LYP/6–311++G**//Becke3LYP/6–311++G** level of theory. The following points were clarified: (*i*) inclusion of polarization function (*) and diffusion function (+) for calculation hardly affected the energetic of the reaction; (*ii*) judging from the change of $\Delta E^{\neq}$ and ΔH_0 values, the reaction is predicted to be accelerated by the increase of involving H_2O; (*iii*) proton-relaying mechanism considerably reduced $\Delta E^{\neq}$ values; (*iv*) the endothermicity became monotonically small as the number of solvating H_2O molecules increased. The calculation suggests that the formation of water oxide (O-OH_2) (**2**) from H_2O_2 (**1**) is promoted by a proton-relaying pathway in protic media (such as H_2O).

Key words: theoretical calculation, ab initio, transition structure, 1,2-hydrogen shift, water oxide.

Résumé : On a effectué des calculs théoriques pour étudier l'effet de solvant sur le déplacement 1,2 d'hydrogène à partir du peroxyde d'hydrogène (H_2O_2) (**1**) ver l'oxyde d'eau (O-OH_2) (**2**). On a optimisé les points stationnaires, y compris les structures de transition (ST), en n'imposant aucune contrainte géométrique au niveau Becke3LY/6-311++G**. Tous les points stationnaires ont été vérifiés par l'analyse de fréquence et par des calculs IRC. On a évalué les énergies d'activation ($\Delta E^{\neq}$) et les chaleurs de réaction (ΔH_0) au niveau Becke3LYP/6-311++G**//Becke3LYP/6-311++G** de la théorie. On a clarifié les points suivants: (*i*) l'inclusion, dans les calculs, de la fonction de polarisation (*) et de la fonction de diffusion (+) n'influence pratiquement pas les énergies de la réaction ; (*ii*) en se basant sur les changements dans les valeurs de $\Delta E^{\neq}$ et de ΔH_0, on peut prédire que la réaction est accélérée par l'augmentation de l'eau impliquée; (*iii*) le mécanisme impliquant un relais du proton réduit les valeurs de $\Delta E^{\neq}$ et de ΔH_0 de façon considérable; (*iv*) le caractère endothermique devient faible et monotonique avec l'augmentation du nombre de molécules d'eau de solvatation. Les calculs suggèrent que, dans des milieux protiques (tels que l'eau), la formation d'oxyde d'eau (O-OH_2) (**2**) à partir de H_2O_2 (**1**) est facilitée par une voie impliquant un relais de proton.

Mots clés : calculs théoriques, ab initio, structure de transition, déplacement d'hydrogène 1,2, oxyde d'eau.

[Traduit par la Rédaction]

Introduction

The oxygen atom transfer involving oxygen–oxygen σ bond cleavage (oxo transfer) (1–6) is known to be one of the most important oxidation pathways. Water oxide (O-OH_2) (**2**), which is produced from hydrogen peroxide (H_2O_2) (**1**) by a 1,2-hydrogen shift (see Table 1), is predicted to decompose to H_2O and atomic oxygen [O] easily, and therefore, to be a powerful oxidant (7–9). However, high activation barriers for the conversion of **1** into **2** have been reported (10–13). On the other hand, the studies strongly supporting the involvement of **2** in the oxidation pathway by **1** have also been reported (14–16). Shaefer and co-workers (14, 15) reported the activation energy for this isomerization of **1** into **2** is only 3.3 kcal mol^{-1}. Furthermore, Bach and co-workers (2, 3, 7) and Bach and Andres (12) reported that the coordination of H_2O molecules to **2** drastically raises the oxidizing ability of it. Based on these theoretical works, the author has investigated the role of H_2O involving in this 1,2-type hydrogen shift from the mechanistic point of view. The study is also expected to clarify the role of **2** in the oxidation of biomolecules existing in a hydrophilic environment, such as the living body. In this report, the proton-relaying mechanism involving coordinating H_2O for 1,2-hydrogen shift from **1** to **2**, in which solvating $n$$H_2O$ molecule(s) (n = 0–3) was implicated in, was especially focused on (Scheme 1).

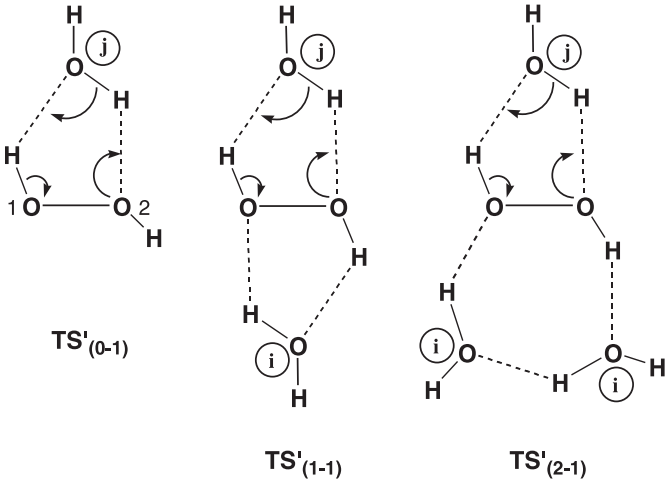

Scheme 1.

Becke3LYP/6–311++G** level (18). Activation energies ($\Delta E^{\neq}$) and heats of reaction (ΔH_0) were evaluated at the Becke3LYP/6–311++G**//Becke3LYP/6–311++G** level. For stationary points, an energy min and max point (TS) were characterized by the correct number of negative eigenvalues of its Hessian matrix, that is, the former and the latter have zero and a single imaginary frequency, respectively. The atomic disposition in the TS are collected in Scheme 1 (in these TSs one hydrogen atom on O^2 in **2** is supplied from *H*-O^1 in **1**) and in Schemes 2 and 3 (proton-relaying mechanism, in which one hydrogen atom in **2** is delivered from the hydrogen bonding H_2O molecule). For two or more H_2O solvating systems, some coordinating modes to the substrate are possible. For example, when two H_2O molecules are involved in the reaction, two types of solvating mode (such as $H_2O_{2(2-0)}$ shown in Fig. 1 and $H_2O_{2(1-1)}$ in Fig. 2 are possible. The TSs expressed by the symbol with a prime mark (′), such as "**TS′**," are proton-relaying TSs. The

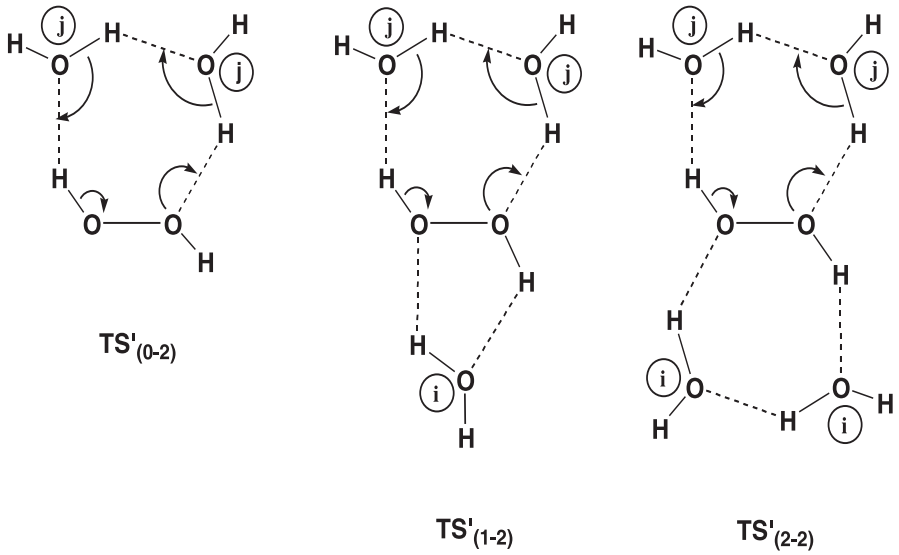

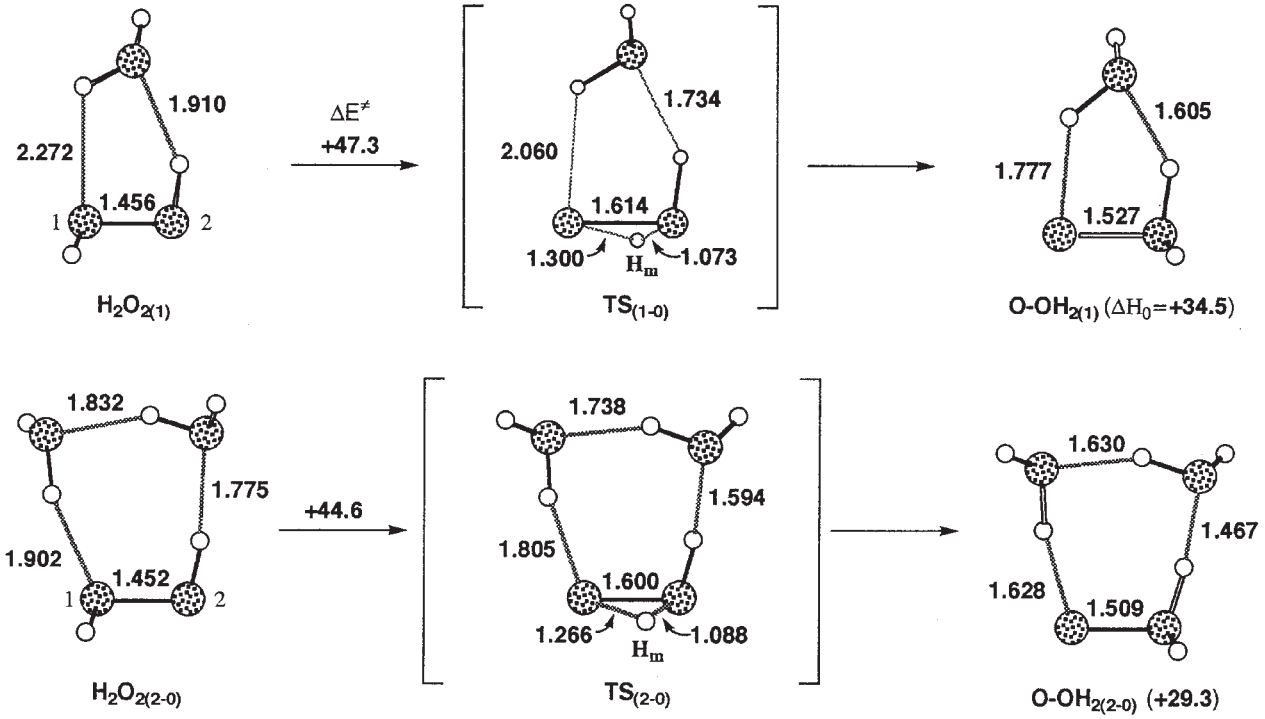

Fig. 1. The critical geometries including $\mathbf{TS}_{(i-0)}$ (i = 1, 2) and geometrical parameters optimized at Becke3LYP/6–311++G** for the 1,2-hydrogen migration between hydrogen peroxide (**1**) and water oxide (**2**). Atomic distances are in angstroms (Å). The energy differences (Becke3LYP/6–311++G**// Becke3LYP/6–311++G**) are in kcal mol^{-1}. $\Delta E^{\neq} = E(\mathrm{TS}) - E(H_2O_2)$ and $\Delta H_0 = E(\mathrm{O\text{-}OH_2}) - E(H_2O_2)$.

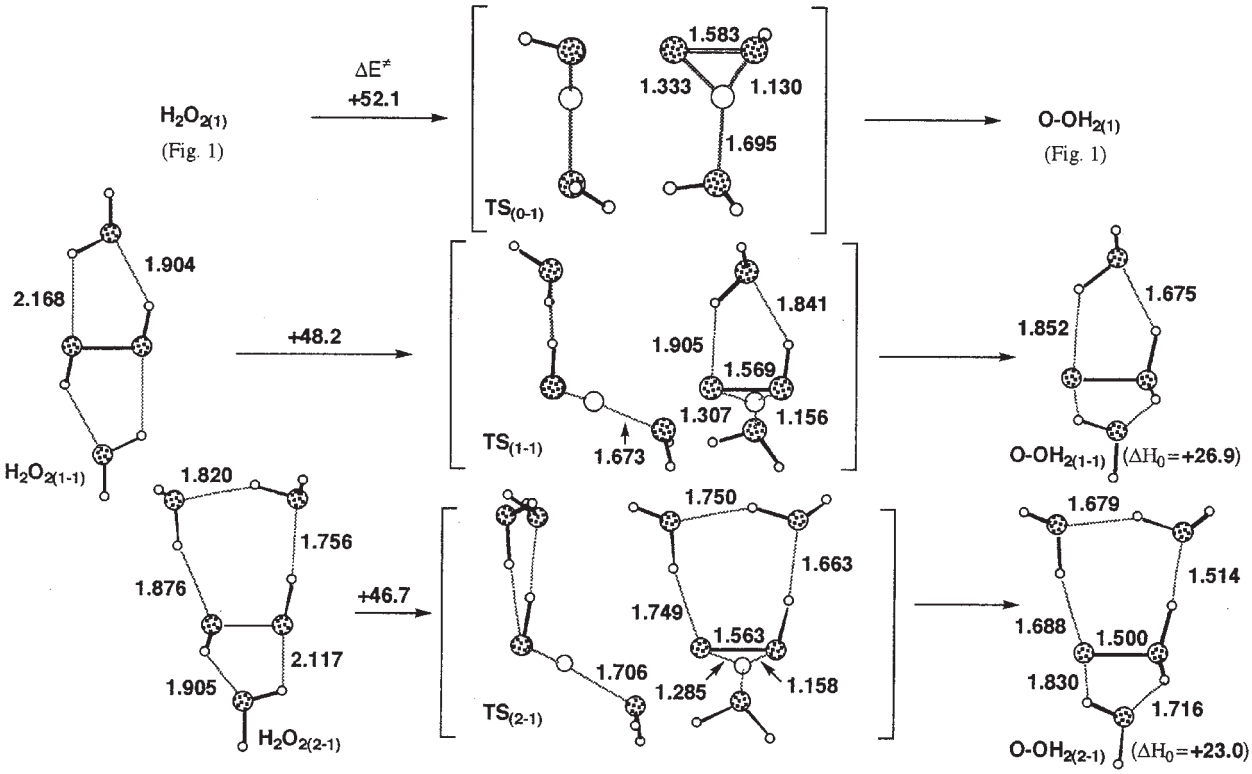

characters "*i*" and "*j*" in the symbols $X_{(i-j)}$ (X = H_2O_2, TS(′), and O-OH_2) seen in the schemes and figures, mean that all H_2O molecules involved in the reaction ($(H_2O)_{i+j}$) are divided into two groups of H_2O clusters, which are marked by i ($(H_2O)_i$) and by j ($(H_2O)_j$), respectively, as shown in Schemes 1–3. These two groups of H_2O molecules coordinate to the substrate from different directions with respect to the O^1—O^2 bond. One group indicated by $(H_2O)_j$ involves in the coordination to H_m in **TS** and in the proton-relay in **TS′**, respectively. The other groups of H_2O ($(H_2O)_i$) appear to play an simple role to the reaction, in which the hydrogen bonding network between $(H_2O)_i$ and the substrate is maintained all through the reaction.

Results and discussion

Table 1 collects the activation energies ($\Delta E^{\neq}$) and heats of reaction (ΔH_0) for the 1,2-hydrogen shift from (HO-OH) (**1**) to water oxide (O-OH_2) (**2**) (Scheme 1) under the consideration of polarization function (marked with an asterisk (*)) and of diffusion function (+). Judging from the critical geometrical parameters of the TSs (*b*, *c*, and *d* in Scheme 1),

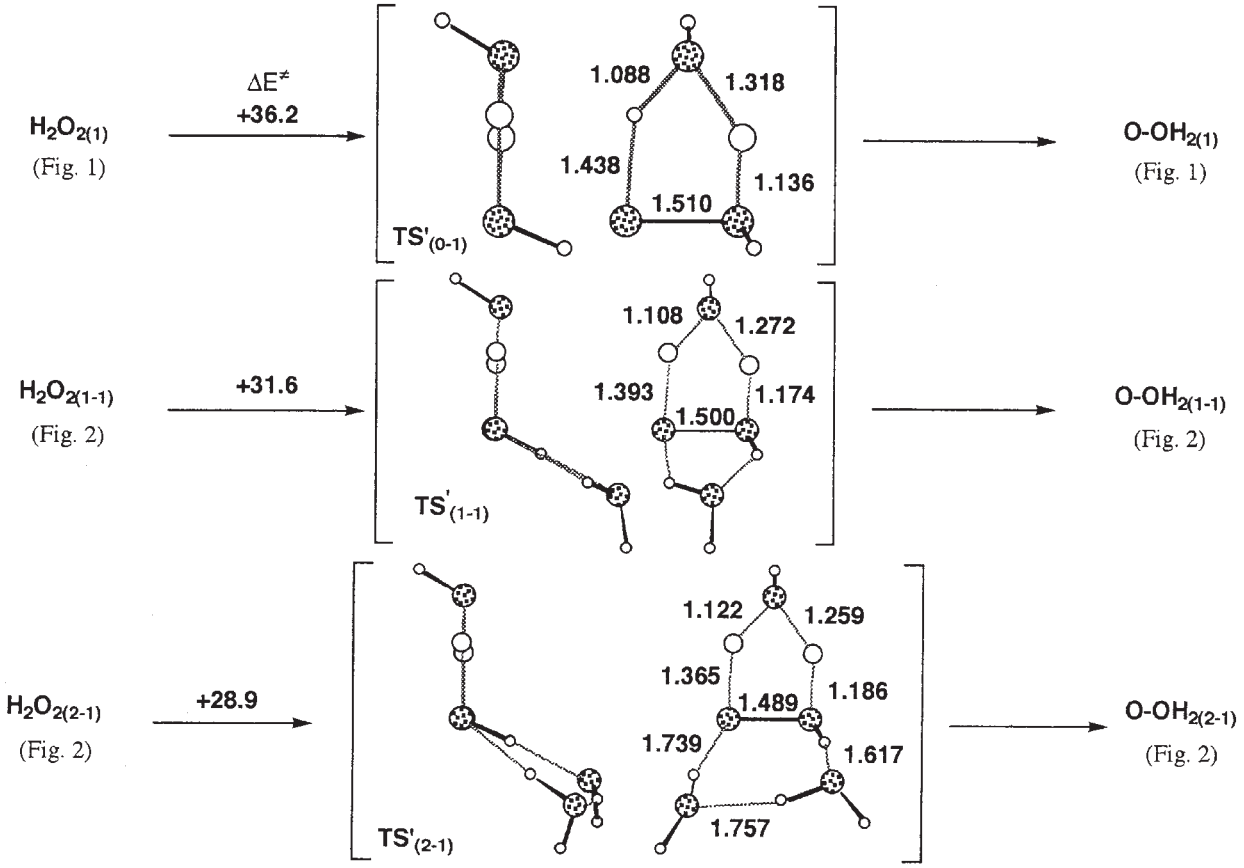
Fig. 2. The critical geometries including $\mathbf{TS}_{(i-1)}$ (i = 0–2) and geometrical parameters (Å) optimized at Becke3LYP/6–311++G** for the 1,2-hydrogen migration between **1** and **2**. A single H_2O coordinates to migrating hydrogen atom (H_m). The side view of each TS is also shown. Energies at Becke3LYP/6–311++G**//Becke3LYP/6–311++G** are in kcal mol^{-1}. $\Delta E^{\neq} = E(\mathrm{TS}) - E(H_2O_2)$ and $\Delta H_0 = E(\mathrm{O\text{-}OH_2}) - E(H_2O_2)$.



the TSs optimized at the MP2 and Becke3LYP level of theory are very late (atomic distances for breaking $O^1\cdots H$ ranges in 1.3–1.4 Å and those for forming $O^2\cdots H$ in 1.0–1.1 Å) and the RHF structures are rather faster than those optimized at the above mentioned two levels (the atomic distances of breaking $O^1\cdots H_m$ and forming $O^2\cdots H_m$ both range in 1.1–1.2 Å at RHF level). The O^1—O^2 bond lengths in **2** are quite longer than those in **1**, which implies the easy cleavage of the O—O bond of **2** to give water (H_2O) and atomic oxygen [O], and consequently, the strong oxidizing ability of **2**. $\Delta E^{\neq}$ values of the reaction are very high and the reaction is generally quite endothermic and these critical values were not changed very much by considering polarization and diffusion functions for calculation. Consequently, high $\Delta E^{\neq}$ and ΔH_0 values were calculated at all levels of calculation considered here, strongly indicating that the parent reaction from **1** to **2** is fundamentally difficult to proceed under no assistance of H_2O solvent (2).

Figure 1 shows the Becke3LYP/6–311++G** TSs ($\mathbf{TS}_{(i-0)}$, i = 1,2) and some critical geometrical parameters for the 1,2-hydrogen shift from **1** to **2**. In these two TSs, solvating H_2O molecule(s) do not get involved with migrating hydrogen (H_m) directly and coordinate(s) to the substrate from the opposite direction to H_m with respect to the O^1—O^2 bond. In other words, in this path one hydrogen atom (H_m) on **1**, to which none of H_2O coordinates, migrates and all coordinating H_2O plays a simple role as the hydrogen bonding species to the substrate. The breaking $O^1\cdots H$ and forming $O^2\cdots H$ bond lengths became shorter and longer (1.300 and 1.073 Å for $\mathbf{TS}_{(1-0)}$ and 1.266 and 1.088 for $\mathbf{TS}_{(2-0)}$, as compared with those (1.365 and 1.044 Å) for the parent reaction shown in Fig. 1 at Becke3LYP/6–311++G**, respectively, indicating that TSs became early by involving H_2O in the reaction. The H_2O molecules indicated by i (i = 1,2) coordinated to the H_2O_2 moiety ($H_2O_{2(1)}$ and $H_2O_{2(2-0)}$) stay almost on the same position until reaching the product ($\mathrm{O\text{-}OH_{2(1)}}$ and $\mathrm{O\text{-}OH_{2(2-0)}}$, respectively). The $\Delta E^{\neq}$ values calculated at Becke3LYP/6–311++G**//Becke3LYP/6–311++G** (+47.3 and +44.6 kcal mol^{-1} for $\mathbf{TS}_{(1-0)}$ and $\mathbf{TS}_{(2-0)}$, respectively) are considerably smaller than that (+52.9) for the parent reaction. Heats of reaction (ΔH_0) (+34.5 kcal mol^{-1} for $\mathbf{TS}_{(1-0)}$ and +29.3 for $\mathbf{TS}_{(2-0)}$) also became smaller than that (+ 45.6). Moreover, as the coordinating H_2O molecules increase the activation energy and the endothermicity of the reaction became small. Nevertheless, the calculation still predicts the large activation energy and endothermicity for the 1,2-hydrogen shift.

Figure 2 shows the Becke3LYP/6–311++G** TSs for the 1,2-hydrogen shift from **1** to **2** under the consideration of H_2O coordination to migrating hydrogen (H_m). A single H_2O coordinates to H_m (j = 1) and the solvating H_2O is considered to be up to two molecules (i = 0 ($\mathbf{TS}_{(0-1)}$, i = 1 ($\mathbf{TS}_{(1-1)}$), and i = 2 ($\mathbf{TS}_{(2-1)}$)). In $\mathbf{TS}_{(2-1)}$, two of the three coordinating H_2O molecules ($(H_2O)_i$) construct the hydrogen bonding network linking H^2 and O^1 terminals and stays on almost the same position throughout the migration reaction. The other one H_2O molecule coordinates to migrating H_m. As well as the TSs ($\mathbf{TS}_{(1-0)}$ and $\mathbf{TS}_{(2-0)}$) shown in Fig. 1, these three

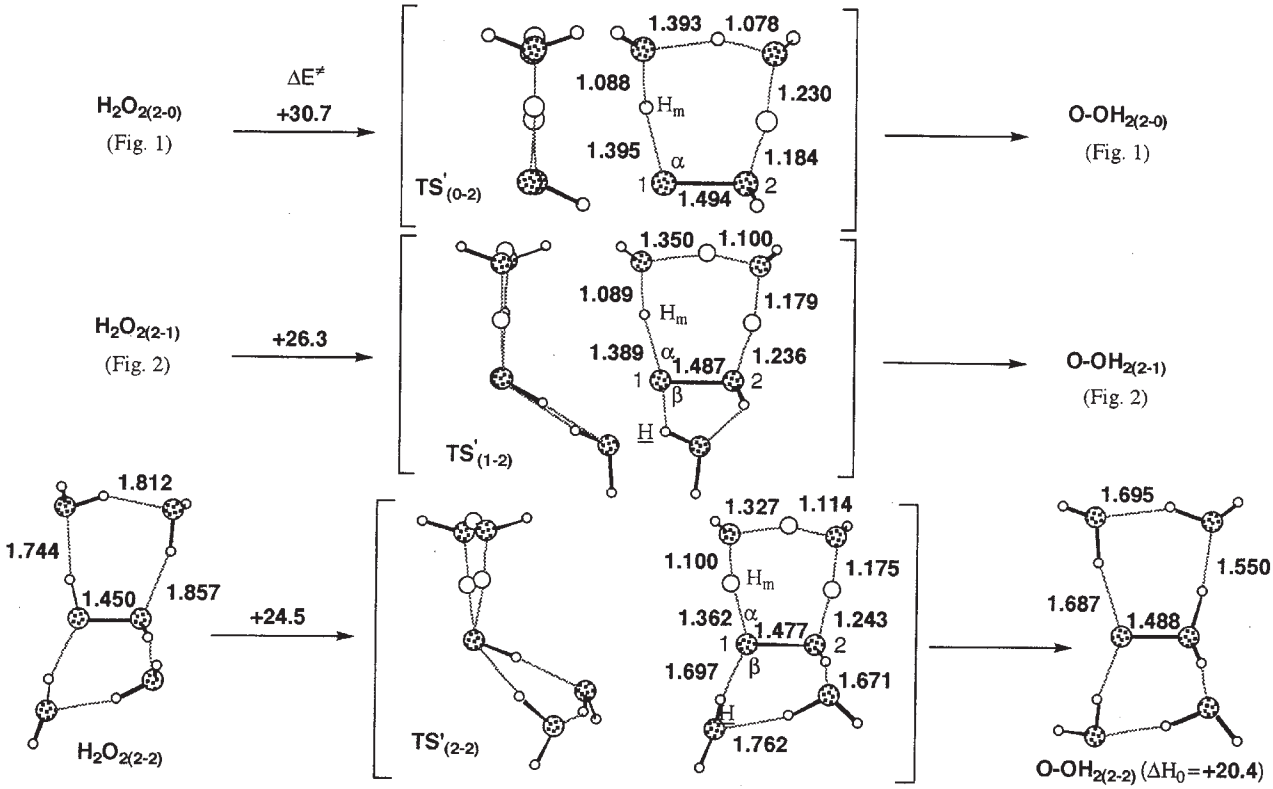
Fig. 3. The TS geometries including $\mathbf{TS'}_{(i-1)}$ (i = 0, 2) and geometrical parameters (Å) optimized at Becke3LYP/6–311++G** for the 1,2-hydrogen migration between **1** and **2**. The schematic representation for these three TSs are shown in Chart 2. In these three TSs, a single H_2O involves directly in proton-relay between **1** and **2**. The side view of each TS is also shown. Energies at Becke3LYP/6–311++G**//Becke3LYP/6–311++G** are in kcal mol^{-1}. $\Delta E^{\neq} = E(\mathrm{TS}) - E(H_2O_2)$ and $\Delta H_0 = E(\mathrm{O\text{-}OH_2}) - E(H_2O_2)$.



TSs are also earlier than the TS for the reaction of parent **1**. For example, the breaking $O^1\cdots H_m$ and the forming $O^2\cdots H_m$ bond length changes from 1.365, *1.044* (Fig. 1), to 1.300, *1.073* ($\mathbf{TS}_{(1-0)}$), 1.266, *1.088* ($\mathbf{TS}_{(1-0)}$), 1.333, *1.130* ($\mathbf{TS}_{(0-1)}$), 1.307, *1.156* ($\mathbf{TS}_{(1-1)}$), and 1.285, *1.158* ($\mathbf{TS}_{(2-1)}$). In this path, the hydrogen atom (H_m), which is coordinated by a single H_2O, migrates and one hydrogen bond between O^1 and ***H***-OH in **1** is broken and new $O^2\cdots$***H***-OH hydrogen bond is formed in **2**. During the migration, the H_2O molecule rotates around the pivotal migrating hydrogen (H_m). The $\Delta E^{\neq}$s are +52.1 ($\mathbf{TS}_{(0-1)}$), +48.2 ($\mathbf{TS}_{(1-1)}$), and +46.7 kcal mol^{-1} ($\mathbf{TS}_{(2-1)}$), which values are almost the same with the corresponding $\Delta E^{\neq}$s for the TSs having no coordinating H_2O on H_m (+47.3 ($\mathbf{TS}_{(1-0)}$) and +44.6 kcal mol^{-1} ($\mathbf{TS}_{(2-0)}$)), respectively, indicating that the direct coordination of H_2O to H_m has little effect to accelerate the hydrogen migration.

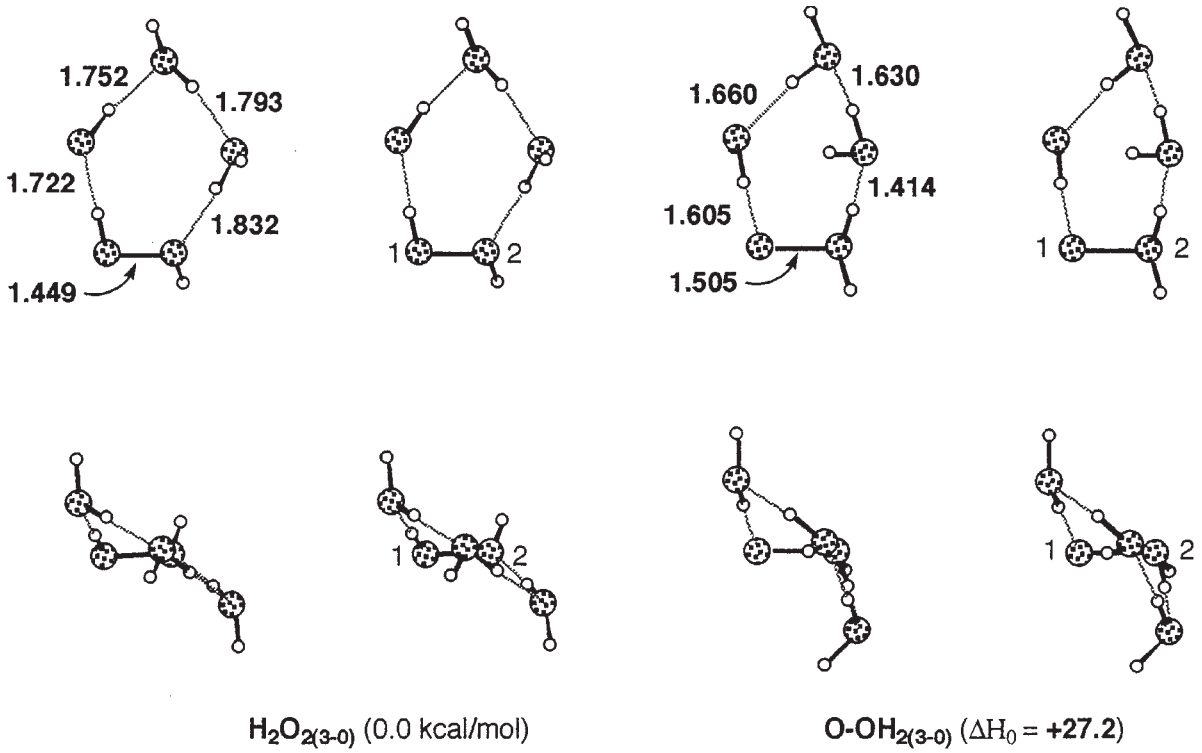
Figures 3 and 4 present Becke3LYP/6–311++G** TSs for the proton-relaying mechanism for the 1,2-hydrogen shift from **1** to **2** involving H_2O molecules. All these TSs are the ones corresponding to the concerted proton-relaying mechanism having single TS on the energy potential surface connecting **1** with **2**. The $\Delta E^{\neq}$ values calculated at Becke3LYP/6–311++G**//Becke3LYP/6–311++G** are in the range +24 ~ +36 kcal mol^{-1}, which are drastically smaller than those (+44 ~ +52) for the pathways proceeding through three-membered TSs (1,2-shift), as shown in Figs. 1 and 2. Focusing on the role of $(H_2O)_i$, hydrogen bonding $(H_2O)_i$ appears to play a simple role in the reaction, however, $\Delta E^{\neq}$ values became monotonically small as the number of $(H_2O)_i$ increases. Considering the fact that atomic disposition in hydrogen bonding $(H_2O)_i$ appears to be maintained on almost the same position all through the reaction, and the fact that there exists little steric congestion between $(H_2O)_i$ and the other parts of the species, the accelerating effect by coordinating $(H_2O)_i$ is considered to be mainly attributing to electronic factors, reducing the fluctuation of the charge on O^1 and O^2 as the reaction proceeds, rather than steric factors. Next, the role of $(H_2O)_j$ in a series of **TS′** was considered. It is plausible that the leaving ability (namely, ability to be eliminated by H_2O) of ***H*** in ***H***O^1-OH is enhanced because of the stabilizing effect of the negative charge growing on O^1 by H_2O coordinating to it. In this case, the leaving and the attacking direction of the proton to O^1 is clearly important. The direct 1,2-hydrogen shift (such as **TS** in Scheme 1 and $\mathbf{TS}_{(i-0)}$ in Fig. 1 suffers severe steric strain because of the proceedings through three-membered ring TSs, which clearly results in the increase of activation energy, and therefore, lowering the reactivity. In proton-relaying $\mathbf{TS'}_{(i-2)}$ (i = 0–2), bond angles of O^2-O^1-H_m designated by α and O^2-O^1-***H***(-OH) by β in Fig. 4 are 104.3° for $\mathbf{TS'}_{(0-2)}$, 107.4, 101.0 for $\mathbf{TS'}_{(1-2)}$, and 105.0, 108.4 for $\mathbf{TS'}_{(2-2)}$, respectively,

© 2001 NRC Canada

Fig. 4. The critical geometries including $\mathbf{TS'}_{(i-2)}$ (i = 0–2) and geometrical parameters (Å) optimized at Becke3LYP/6–311++G** for the 1,2-hydrogen migration between **1** and **2**. The schematic representation for these three TSs are shown in Scheme 3. In these three TSs, two H_2O involves directly in proton-relay between **1** and **2**. The side view of each TS is also shown. Energies at Becke3LYP/6–311++G**//Becke3LYP/6–311++G** are in kcal mol^{-1}. $\Delta E^{\neq} = E(\mathrm{TS}) - E(H_2O_2)$ and $\Delta H_0 = E(\mathrm{O\text{-}OH_2}) - E(H_2O_2)$.

indicating that leaving of $\mathbf{H}^1(\text{-}O^1)$ and H_2O coordination to O^1 occurs at almost ideal angles so as to maintain favorable interaction with lone pairs spread out around O^1. The least $\Delta E^{\neq}$ value (+24.5 kcal mol^{-1}) and the smallest endothermicity (ΔH_0 = +20.4) could be obtained as the reaction path proceeding through $\mathbf{TS'}_{(2-2)}$. These values suggest that the1,2-hydrogen shift from **1** to **2** could be clearly promoted when the assistance of H_2O solvent works effectively.

Finally, Fig. 5 presents Becke3LYP/6–311+G** optimized geometries of H_2O_2 and O-OH_2 having three H_2O molecules ($\mathbf{H_2O_2}_{(3-0)}$ and $\mathbf{O\text{-}OH_2}_{(3-0)}$). Both geometries have a nine-membered hydrogen bonding network linking three H_2O and the substrate. It is also likely that the conversion between H_2O_2 and O-OH_2 proceeds through successive proton transfer along these solvating H_2O molecules. Unfortunately, concerted TSs, in which proton transfer occurs along linking three H_2O could not be located. Considering the larger energy difference between $\mathbf{H_2O_2}_{(3-0)}$ and $\mathbf{O\text{-}OH_2}_{(3-0)}$ (+27.2 kcal mol^{-1}) than that (+20.4) for $\mathbf{TS'}_{(2-2)}$, it is concluded that the proton-relaying mechanism under the involvement of *two* hydrogen bonding H_2O molecules ($\mathbf{TS'}_{(2-2)}$, in this study) is the most favorable pathway.



Summary

Theoretical calculation was performed to study the solvent effect for the 1,2-hydrogen shift from hydrogen peroxide (H_2O_2) (**1**) to water oxide (O-OH_2) (**2**) by considering up to four H_2O molecules as the solvent. Geometries including transition structures (TSs) were located by using density functional theory (DFT) at the Becke3LYP/6–311++G** level of theory. Energies were calculated at Becke3LYP/6–311++G** based on the Becke3LYP/6–311++G** geometries. The calculations clarified the following points: (*i*) the inclusion of polarization (*) and diffusion functions for calculation (+) hardly affected the geometries and the energetic of the 1,2-hydrogen shift from **1** to **2**; (*ii*) the involvement of protic solvent to the reaction considerably reduced the activation energies ($\Delta E^{\neq}$) and endothermicity; (*iii*) the activation energy and the endothermicity were considerably reduced as the number of involving H_2O increases, suggesting that the 1,2-hydrogen shift is able to be promoted in the protic media, such as H_2O; (*iv*) the proton-relaying mechanism (the reaction pathway proceeding through **TS′**s) is considered to be the most plausible one for the formation of **2** from **1** in H_2O.

Water oxide (**2**) is a candidate to become a powerful oxidant. However, the activation energy ($\Delta E^{\neq}$) and the endothermicity of the conversion of **1** into **2** are still large to exist for **2** in potential concentration as oxygen donor even in protic media (in H_2O). However, these calculational results could clarify the importance of proton-relaying pathway as the lowering factor of $\Delta E^{\neq}$ for the isomerization of **1** to **2**. Considering this result with Schaefer's works (14, 15) to clarify low activation energy for this isomerization evaluated at high level calculations and with Bach's (2, 3, 7, 8)

Fig. 5. The Becke3LYP/6–311++G** optimized geometries of $\mathbf{H_2O_{2(3-0)}}$ and $\mathbf{O\text{-}OH_{2(3-0)}}$ and Becke3LYP/6–311++G** energy difference between **1** and **2** having three H_2O molecules. Plus sign of the energy means that 1,2-hydrogen migration from **1** to **2** is endothemic ($\Delta H_0 = E(\text{O-OH}_2) - E(\text{H}_2\text{O}_2)$).

works to clarify the role of the coordination of H_2O to raise the oxidizing ability of **2** together, it is suggested that oxidizing species **2** is short-lived but viable and plays an unmarked role for the oxidation of various (bio)molecules especially existing in hydrophilic environments. Considering the unstability of **2**, toxicity of **2** is serious but might be definite, for instance when **2** is just formed in the close proximity to sensitive biomolecules to the oxidants. This situation is quite similar to the behavior of a hydroxyl radical (·OH) that is the strongest activated oxygen and has a very short lifetime.

New chaotic behavior and its effective control in Belousov–Zhabotinsky reaction

Yan-Ni Li, Hao Song, Zun-Sheng Cai, Lan Chen, Zhe Hou, Qing-Li Wei, Ben-Xiang Wu, and Xue-Zhuang Zhao

Abstract: A new "spiral-in-to-spiral-out" mixed-mode type chaos of the Belousov–Zhabotinsky (BZ) reaction in a continuous flow stirred tank reactor (CSTR) is observed. We discussed its evolution and characterization in detail. We controlled the new chaos into steady periodic behavior by two control methods: (*i*) a self-adaptive delayed feedback controlling scheme; and (*ii*) a linear self-interacting feedback controlling scheme.

Key words: BZ-CSTR reaction, chaos, control.

Résumé : On a observé un nouveau type de chaos « spirale-interne-spirale-externe » à mode mixte pour la réaction de Belousov–Zhabotinsky (BZ) dans une cuve de réaction avec agitation et à écoulement continue. On discute en détail de son évolution et de sa caractérisation. On a fait appel à deux méthodes pour contrôler le nouveau chaos en comportement périodique régulier: (*i*) un schéma de contrôle impliquant une rétroaction retardée auto-adaptable et (*ii*) un schéma de contrôle à rétroaction linéaire auto-interdépendante.

Mots clés : réaction BZ-CSTR, chaos, contrôle.

[Traduit par la Rédaction]

Introduction

There are various nonlinear chemical dynamic behaviors in the Belousov–Zhabotinsky (BZ) reaction system, such as multi-stability (1), simple period oscillation (2), quasi-period oscillation (3), mix-mode oscillation (4), and chaos (5). Also, several routes to chaos have been found in the BZ system, such as by the period-doubling bifurcation (6), quasi-period bifurcation (3), intermittent bifurcation (7, 8), and complex bifurcation (9) (such as the interaction of a local subcritical Hopf bifurcation with a global homoclinic bifurcation). Here, we show new spiral-in-to-spiral-out mixed-mode type chaos and its evolution from P1 at the experimental conditions. Also, the four-variable Montanator model (10) has been used for modeling this new phenomenon.

In addition, the control of chaos has received increasing attention. Because chaos is very sensitive to initial conditions, people thought that chaos could not be controlled at first. Over the past few years, however, great progress has been made in developing techniques for control of chaos. Out of the methods which were mostly proposed by physicists (11–16), here we have successfully applied two schemes to control the chaos in this chemical reaction.

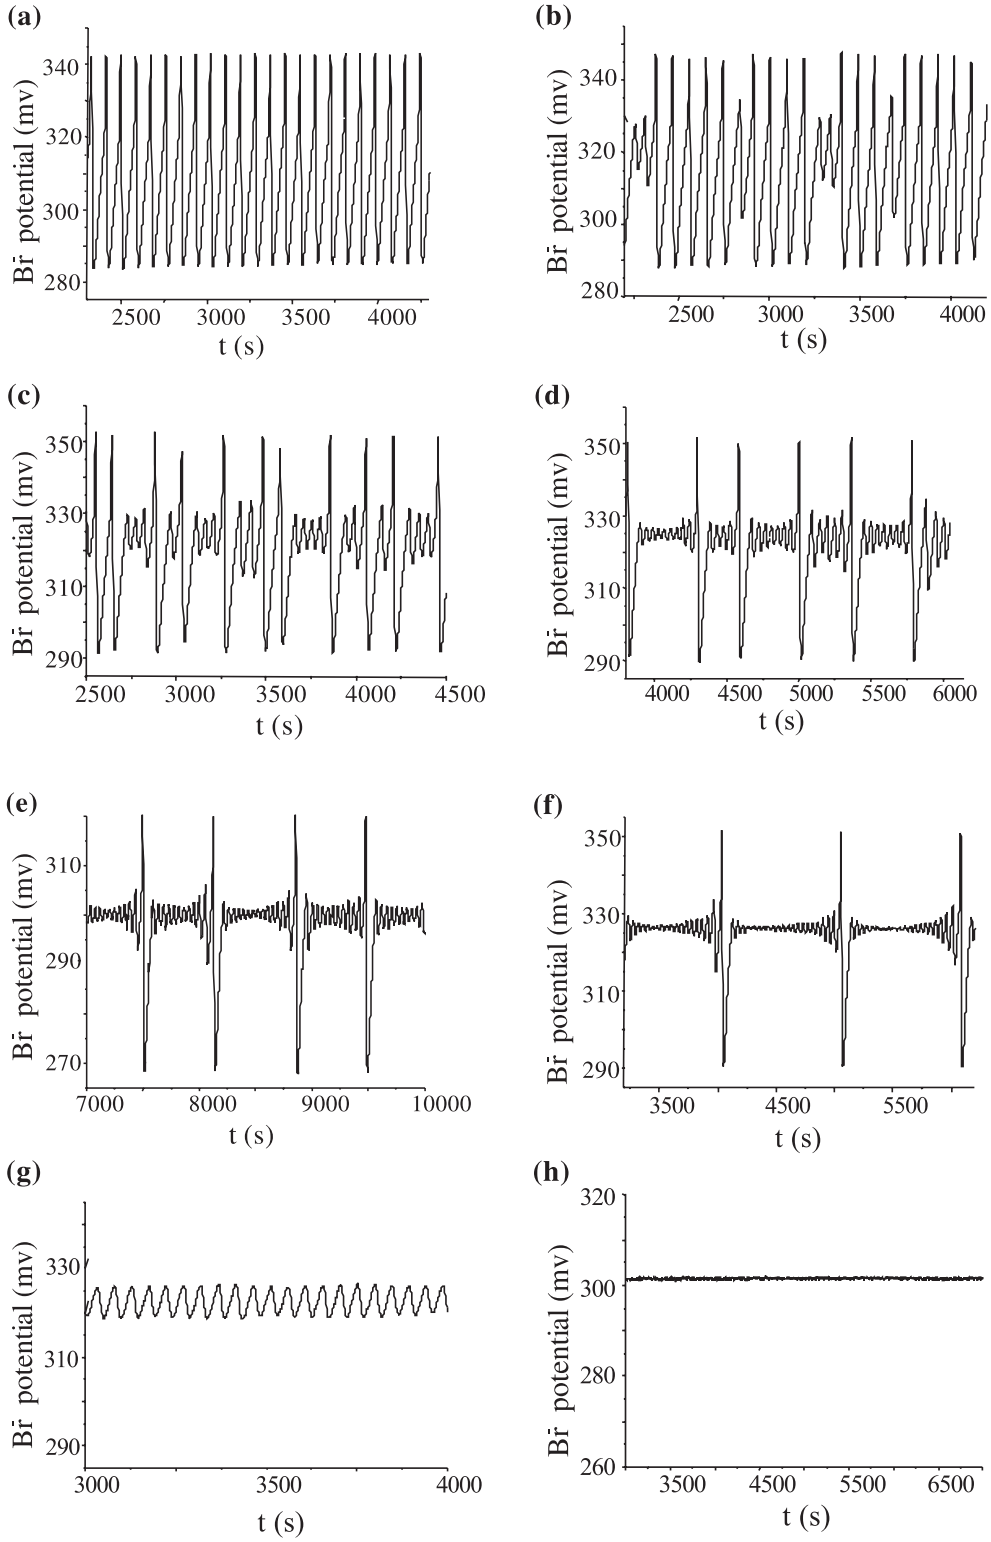
Experimental

Experimental method



Reaction was carried out in a continuously stirred tank reactor (volume 12.5 mL, stirring rate 1200 rpm). The temperature we used is 28.0 ± 0.1°C, which is different from the temperature of 41°C which gives the quasi-period bifurcation (3). Reagents were fed with separate solutions of malonic acid (MA), sodium bromate (BrO_3^-), and cerous sulphate (Ce^{3+}); the later two solutions are acidified with sulphuric acid (H^+). These three solutions are delivered by a peristaltic pump at a flow regulated on-line by a computer. Although the peristaltic pump generates an oscillating flow while the syringe pump does not, there are no effects in the position of the bifurcation points of the BZ system (10). After mixing, [MA] = 0.25 mol L^{-1}, [BrO_3^-] = 0.1 mol L^{-1}, [Ce^{3+}] = 8.6 × 10^{-4} mol L^{-1}, [H^+] = 0.30 mol L^{-1}. The potential of a bromide-ion-selective electrode was monitored, collected, and stored with 1 Hz, after averaging 10 consecutive measurements at 0.1 s intervals.

Dynamical behavior evolution

The experimental results are summarized in Fig. 1. In brief, at the indicated reaction solution and temperature conditions, when the flow is high, the reaction shows P1 oscillation with large amplitude (Fig. 1*a*). By decreasing the flow, the time series of the normal P1 oscillation is occasionally interrupted by several small amplitude oscillations, and the ratio of the number of small to large oscillations increases with the further decreasing of flow (Fig. 1*b*, 1*c*, and 1*d*). Chaotic behavior is possibly in the making, because at least for Fig. 1*d* we get its Lyapunov exponent (17) to be 0.005 bits s^{-1}. At this point, a slight decreasing of the flow

 DOI: 10.1139/cjc-79-1-29 © 2001 NRC Canada

Fig. 1. Evolution process of experimental new chaos time series. From (*a*)–(*h*), the flow for each solution is 0.12, 0.115, 0.09, 0.07, 0.055, 0.05, 0.04, and 0.03 mL min^{-1}, respectively.

leads to a transition to the spiral-in-to-spiral-out chaos (Fig. 1*e* and 1*f*). Upon further lowering of the flow, this chaos gives way to small amplitude oscillation behavior (Fig. 1*g*). After a further decreasing of the flow, the system crosses a Hopf bifurcation and settles into an equilibrium state (Fig. 1*h*).

Characterization of the new chaos

Analysis of the time series (Fig. 1*e*) provides evidence for the assignment of chaos. The Lyapunov exponent is evaluated, and is 0.0032 bits $s^{-1} > 0$, so that it maybe a chaotic behavior. Phase space (Fig. 2*a*) is reconstructed by time-delay

© 2001 NRC Canada

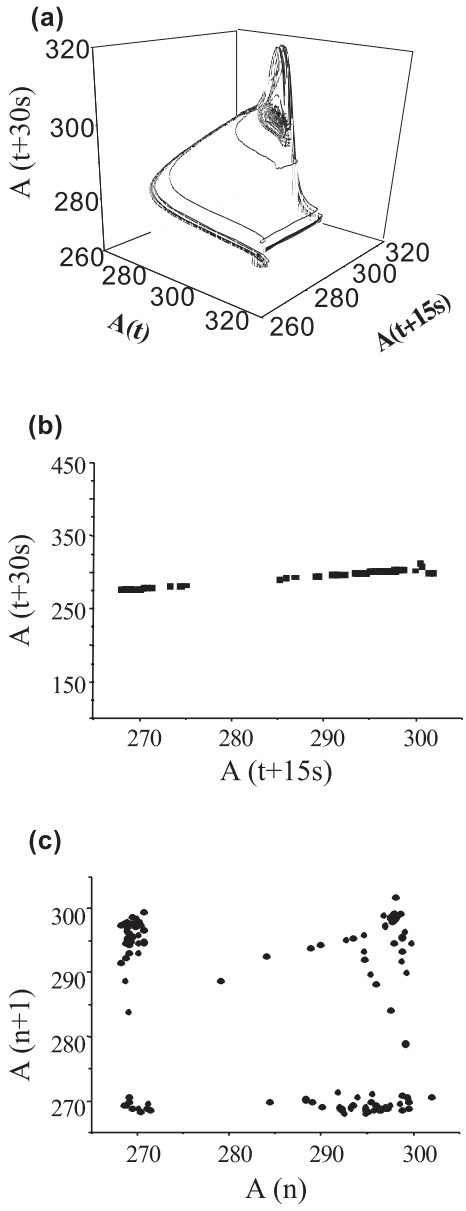
method (18). The obtained attractor is then further studied, and found that the object in the Poincare Surface of Section (PSS) (Fig. 2*b*) is a smooth linear manifold rather than random distributed points. Also, the one-dimension return map (Fig. 2*c*) constructed from the PSS is an object with order structure, rather than random distributed points. So we have further evidence of the existence of chaos. Seen from the time series (Fig. 1*e*), the differences in amplitudes between large and small oscillations are distinctive. The amplitude of small oscillation changes with time, first decreasing, then increasing. Moreover, the number of the small oscillations between two large amplitude oscillations is not always the same. This indicates that the chaos we obtain is the type of spiral-in-to-spiral-out.

Model simulation

We use the four-variable Montanator model (see Table 1) at about the same conditions as in the experiment to describe the spiral-in-to-spiral-out feature of the time series. The corresponding differential equations are as follows:

[1]
$$\frac{d[Br^-]}{dt} = -k_{D1}[H^+][Br^-][HBrO_2] - k_{D2}[BrO_3^-][H^+]^2[Br^-] + k_{D7}[Ce(IV)][BrMA] + k_{D8}[MA\cdot]_{QSS}[BrMA] + k_f([Br^-]_{mf} - [Br^-])$$

$$\frac{d[HBrO_2]}{dt} = -k_{D1}[H^+][Br^-][HBrO_2] + k_{D2}[BrO_3^-][H^+]^2[Br^-] - 2k_{D3}[HBrO_2]^2 + 0.5k_{D4}[H^+]([Ce]_{tot} - [Ce(IV)])[BrO_2\cdot]_{est} - 0.5k_{D5}[HBr0_2][Ce(IV)] + k_f([HBrO_2]_{mf} - [HBrO_2])$$



$$\frac{d[Ce(IV)]}{dt} = k_{D4}[H^+]([Ce]_{tot} - [Ce(IV)])[BrO_2\cdot]_{est} - k_{D5}[HBrO_2][Ce(IV)] - k_{D6}[MA][Ce(IV)] - k_{D7}[Ce(IV)][BrMA] + k_f([Ce(IV)]_{mf} - [Ce(IV)])$$

$$\frac{d[BrMA]}{dt} = 2k_{D1}[H^+][Br^-][HBrO_2] + k_{D2}[BrO_3^-][H^+]^2[Br^-] + k_{D3}[HBrO_2]^2 - k_{D7}[Ce(IV)][BrMA] - k_{D8}[MA\cdot]_{QSS}[BrMA] + k_f([BrMA]_{mf} - [BrMA])$$

where

$$[MA\cdot] = \frac{\{-k_{A15}[BrMA] + \{(k_{A15}[BrMa])^2 + 8k_{A13}k_{A18}[MA][Ce^{4+}]\}^{0.5}\}}{4k_{A18}}$$

Fig. 2. Dynamic analysis of the time series of Fig. 1*e*. (*a*) The reconstructed attractor using the time delay method; (*b*) PSS at plane of (t + 15 s) and (t + 30 s) containing the center of the attractor; (*c*) one-dimensional return map constructed from the PSS.

$$[BrO_2\cdot]_{est} = [BrO_2\cdot]_{EQ} = \left(\frac{k_{A7}[HBrO_2]}{k_{A8}}\right)^{0.5}$$

and

k_{A15} = 2.4 × 10^4 L mol^{-1} s^{-1}

k_{A13} = 0.3 L mol^{-1} s^{-1}

k_{A18} = 3.0 × 10^9 L mol^{-1} s^{-1}

k_{A7} = 0.858 s^{-1}

k_{A8} = 4.2 × 10^7 L mol^{-1} s^{-1}

Table 1. Four-variable Montanator model of BZ-CSTR reaction.

Reaction steps	Rate constant
D1: $Br^- + HBrO_2 + \{H^+\} \rightarrow 2BrMA^a$	$k_{D1} = 2.0 \times 10^6\ M^{-2}\ s^{-1}$
D2: $Br^- + \{BrO_3^-\} + \{2H^+\} \rightarrow BrMA + HBrO_2$	$k_{D2} = 2.0\ M^{-3}\ s^{-1}$
D3: $2HBrO_2 \rightarrow BrMA$	$k_{D3} = 3.0 \times 10^3\ M^{-1}\ s^{-1}$
D4: $0.5HBrO_2 + \{BrO_3^-\} + \{H^+\} \rightarrow HBrO_2 + Ce(IV)$	$k_{D4} = 6.2 \times 10^4\ M^{-2}\ s^{-1}$
D5: $HBrO_2 + Ce(IV) \rightarrow 0.5HBrO_2$	$k_{D5} = 7.0 \times 10^3\ M^{-1}\ s^{-1}$
D6: $Ce(IV) + \{MA^b\} \rightarrow$	$k_{D6} = 0.3\ M^{-1}\ s^{-1}$
D7: $BrMA + Ce(IV) \rightarrow Br^-$	$k_{D7} = 30.0\ M^{-1}\ s^{-1}$
D8: $BrMA \rightarrow Br^-$	$k_{D8} = 2.4 \times 10^4\ M^{-1}\ s^{-1}$

[a] $BrMA = BrCH(COOH)_2$.
[b] $MA = CH_2(COOH)_2$.

where subscript "mf" refers to mixed-feed concentration of that component, which is assumed to be zero in the model. The reagent concentrations are: $[BrO_3^-] = 0.10$ mol L^{-1}, $[H^+] = 0.32$ mol L^{-1}, $[MA] = 0.25$ mol L^{-1}, $[Ce^{3+}] = 8.6 \times 10^{-4}$ mol L^{-1}. We use the Gear algorithm (19) to integrate the differential equations. The initial values for the four variables are: $[Br^-]_0 = 2.8260 \times 10^{-6}$ mol L^{-1}, $[HBrO_2]_0 = 2.8420 \times 10^{-5}$ mol L^{-1}, $[Ce(IV)]_0 = 1.1405 \times 10^{-5}$ mol L^{-1}, $[BrMA]_0 = 1.27154 \times 10^{-3}$ mol L^{-1}). Through the numerical study, we also obtained the corresponding evolution process (bifurcation diagram). In addition, we characterize the time series of Fig. 3*a*. The results of characterization (Fig. 3*b*–3*d*) seem to qualitatively agree with the experimental results (Fig. 2), and the Lyapunov exponent calculated is 0.0028 bits s^{-1}, which is also comparable with the experimental value. However, the major difference between the experiment and the model is that there are several periodic windows in the model bifurcation diagram (not shown), but it cannot be seen in experiment evolution investigation (Fig. 1).

Chaos controlling

After discovering the new type of chaos, whether it can be controlled is an open question we were faced with. The following section of the paper is concerned with the control of this new chaotic behavior.

By self-adapted delay feedback controlling scheme

The delay feedback controlling scheme was proposed by Pyragas (20) in 1992. The method deals with a chaotic system that can be presented by a set of ordinary differential equations:

$$[2] \qquad dy/dt = P(y, x) + F(t, p)$$
$$dx/dt = Q(y, x)$$

Variable $y(t)$ can be measured as a system output, while vector x describes the remaining variables of the system that are not available or not of interest for observation. $F(t, p)$ denotes an external perturbation (or controlling rule) on system parameter p, and $F(t, p) = k[y(t - \tau) - y(t)]$ (k is the adjustable parameter). Therefore the difference between the delayed output signal $y(t - \tau)$ and the output signal itself $y(t)$ is used as a control signal. This feedback performs the function of self-control. When the delay time (τ) coincides with the period of the UPO (unstable periodic orbit) which is embedded in the strange attractor, the perturbation vanishes and the chaotic dynamic system is driven to the desired UPO. This method does not require any priori dynamic analysis of the chaotic system and has been applied to the BZ reaction (21) and PO reaction (22). Since the choice of τ is particularly difficult, Pyragas and co-workers (14) modified this scheme in 1995 and proposed the self-adapted delay feedback controlling scheme. Here $\tau_n = t^{(n)}_{max} - t^{(n-k)}_{max}$, where $t^{(n)}_{max}$ defines the moment the nth maximum appears in the output. The period-k UPO can be stabilized by choosing τ_n equal to the interval between k neighbor maxima of the output signal and varying it by computer automatically at each kth maximum. Using this method to control ordinary chemical chaos, we have successfully obtained P1, P2, P3, P4 periodic oscillation (23). The following are the controlling the new chaos with this method.

In the experiment, the controlling rule for the system parameter k_f is constructed as:

$$[3] \qquad k_f = k_f^0 + C\{E(Br^-)_{t-\tau} - E(Br^-)_t\}$$
$$\tau = (t^{(n)}_{max} - t^{(n-k)}_{max})k = \text{integer}$$

where k_f (mL min^{-1}) is the flow of the BZ-CSTR system, $k_f^0 = 0.055$ mL min^{-1} (which is in the chaotic regime), C is an adjustable parameter which reflects the feedback strength. The output signal is the concentration of Br^-($E(Br^-)$) which is monitored by a bromide-ion-selective electrode. τ is the delay time. As τ is changed automatically according to a simple algorithm by computer during the experiment, we need only to adjust C manually so as to regulate the flow k_f to bring the chaotic dynamic behavior onto the UPOs embedded in the strange attractor. Because of the behavior of the new type of chaos (See discussion and conclusion), we only obtained P1 oscillation. The result is shown in Fig. 4*a*.

By linear self-interacting feedback controlling scheme

This method was proposed by Chen et al. (15) in 1994. The main idea is to regulate the self-interacting parameter (the adjustable parameter) by the system output signal itself. Because of the adopting of a linear coupling between the output signal and the system parameter, this method is called the linear self-interacting feedback controlling scheme.

In the experiment, the controlling rule for the system parameter k_f is constructed as follows:

$$[4] \qquad k_f = k_f^0\{1 + C(E(Br^-)_t)\} + R$$

where C is the manually adjustable parameter, which reflects the self-interacting strength. R is a regulator, which may be set specifically for each experiment. In practice, both C and R are adjusted manually to bring the chaos onto UPO, and at

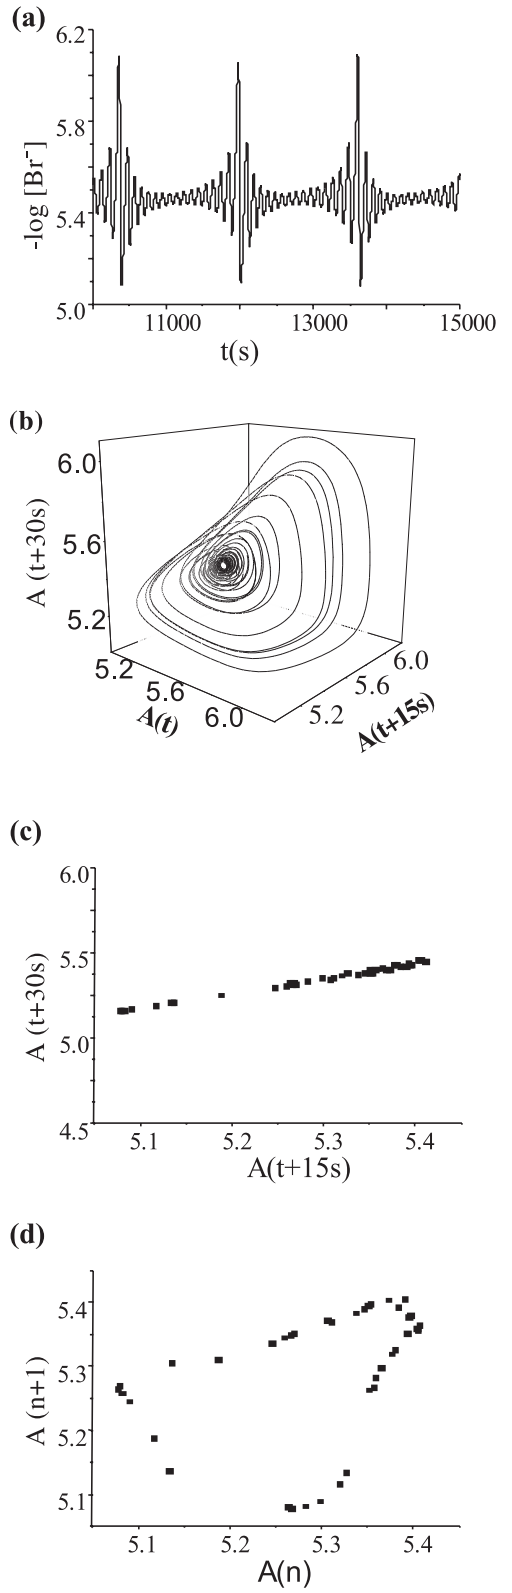

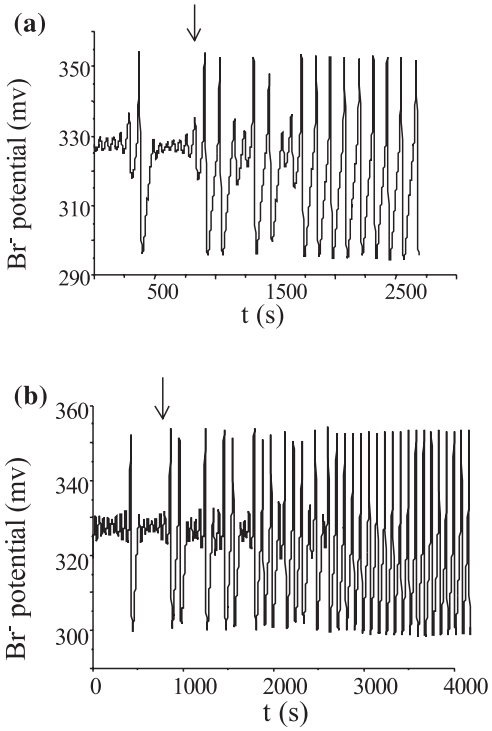

Fig. 4. The results of controlling the new chaotic behavior. Experimental conditions are the same as Fig. 1(*e*). The arrow indicates the time when the control perturbation is switched on. (*a*) Control results by using the self-adapted delay feedback controlling scheme (C = –0.1 mL mV^{-1} min^{-1}); (*b*) control results by using the linear self-interacting feedback controlling scheme (C= –0.10 mV^{-1}, R = 2.275 mL min^{-1}).

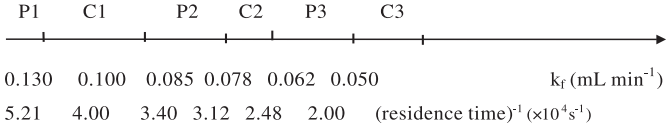

the same time guarantee the pump operating in a proper flow range to ensure the system in its chaotic behavior regime. The others are the same as above. Applying this method, we obtain several periodic oscillations from the ordinary BZ-CSTR chaos effectively (23, 24). For the new chaos, the result is shown in Fig. 4*b*.

Discussion and conclusion

We may assume that the new chaos that we obtained maybe the result of one of the following two types of the coupling of three bifurcations. Either by the coupling of subcritical Hopf bifurcation, supercritical Hopf bifurcation, and homoclinic bifurcation, or by the coupling of local divergent unstable foci, local convergent stable foci, and homoclinic bifurcation, but further work is needed.

In our experiment, applying two methods to control the new chaotic behavior, we get P1 oscillation only. The results do not seem not as good as those while operating on the ordinary chaos. However, thinking from the evolution process, it can be understood: for ordinary chaos in the BZ system, we have obtained the following bifurcation series (22):

© 2001 NRC Canada

It essentially coincides with the one in ref. 25. In such bifurcation series, every chaotic regime is sandwiched by two periodic orbits, which naturally become the dominating UPOs embedded in the strange attractor of the chaos between them. Therefore, the two UPOs that are adjacent with the chaotic regime can be controlled onto easily. However, concerning the new chaos, the evolution process is through the route by decreasing the number of large amplitude oscillations and increasing the number of small amplitude oscillations. During the process, regular behaviors of P*n* oscillations are not emerged. Only at the higher flow, there exists the P1 oscillation as mentioned before. Accordingly, it is the certain results that stable P1 oscillation can be obtained easily.

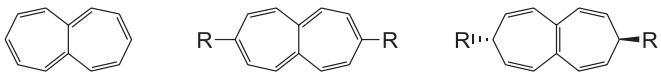
Synthesis of new substituted dihydroheptalene derivatives: SiO_2- and base-catalyzed rearrangement of dimethyl *trans*-3,8-dihydroheptalene-3,8-dicarboxylate

Nurullah Saraçoğlu, Abdullah Menzek, Armağan Kınal, and Metin Balci

Abstract: Dimethyl *trans*-3,8-dihydroheptalene-3,8-dicarboxylate (*trans*-**3**) isomerizes to dimethyl *cis*-3,8-dihydroheptalene-3,8-dicarboxylate (*cis*-**3**) upon treatment with SiO_2. On the other hand, base-catalyzed reaction of *trans*-**3** undergoes a direct 1,3-intramolecular proton shift to give **6** at room temperature in 5 min. Prolonged reaction time formed isomers **7** and **8** in a ratio of 4:1. AM1 calculations indicate that the isomer **8**, which is formed as minor product, has a lower heat of formation (–99.34 kcal mol^{-1}) than that of the major isomer **7** (–92.05 kcal mol^{-1}). However, when a similar reaction was performed at 100°C, the thermodynamically more stable isomer **8** was formed as the major product. Furthermore, cycloaddition reactions of these new dihydroheptalene derivatives **6** and **7** with different dienophiles have been studied. The mechanism has been discussed.

Key words: dihydroheptalene, cycloaddition, 1,3-hydrogen shift, cycloheptatriene–norcaradiene equilibrium.

Résumé : Le *trans*-3,8-dihydroheptalène-3,8-dicarboxylate de diméthyle (*trans*-**3**) s'isomérise en *cis*-3,8-dihydroheptalène-3,8-dicarboxylate de diméthyle (*cis*-**3**) par traitement avec du SiO_2. Par ailleurs, dans une réaction catalysée par les bases, le *trans*-**3** subit un transfert 1,3-intramoléculaire de proton qui, à la température ambiante, conduit directement au produit **6** en cinq minutes. Si le temps de réaction est prolongé, les isomères **7** et **8** se forment dans un rapport de 4:1. Des calculs AM1 indiquent que la chaleur de formation (–99,34 kcal mol^{-1}) l'isomère **8**, qui se forme comme produit mineur, est inférieure à celle (–92,05 kcal mol^{-1}) de l'isomère majeur. Toutefois, lorsqu'on effectue la même réaction à 100°C, il y a formation prédominante de l'isomère **8** qui est thermodynamiquement le plus stable. De plus, on a étudié les réactions de cycloaddition de ces nouveaux dérivés dihydroheptalènes **6** et **7** avec divers diénophiles. On discute du mécanisme.



Mots clés : dihydroheptalène, cycloaddition, déplacement 1,3 d'hydrogène, équilibre cycloheptatriène–norcaradiène.

[Traduit par la Rédaction]

Introduction

Heptalene **1** (1), which has been for a long time the subject of theoretical studies, was synthesized by Dauben and Bertelli (2) in 1961. However, it remained poorly accessible. Later Vogel et al. (3) have developed different elegant methods leading to the synthesis of heptalene **1** and its derivatives **2**. In recent years we have been concerned with the synthesis of *trans*-**3** (3*c*, 4*a*), which is dihydroheptalene derivative, in connection with our work on the synthesis of the pyramidalized double bonds (4).

Dihydroheptalene derivative *trans*-**3** consists of two fused cycloheptatriene units where the ester groups have *trans* configuration. We were interested in the isomerization of one ester group in *trans*-**3** to obtain the corresponding isomer *cis*-**3**. In this paper, we describe the SiO_2- and base-catalyzed reactions of *trans*-**3** and the cycloaddition reactions of the newly formed dihydroheptalene derivatives.

1 **2** *trans*-**3**

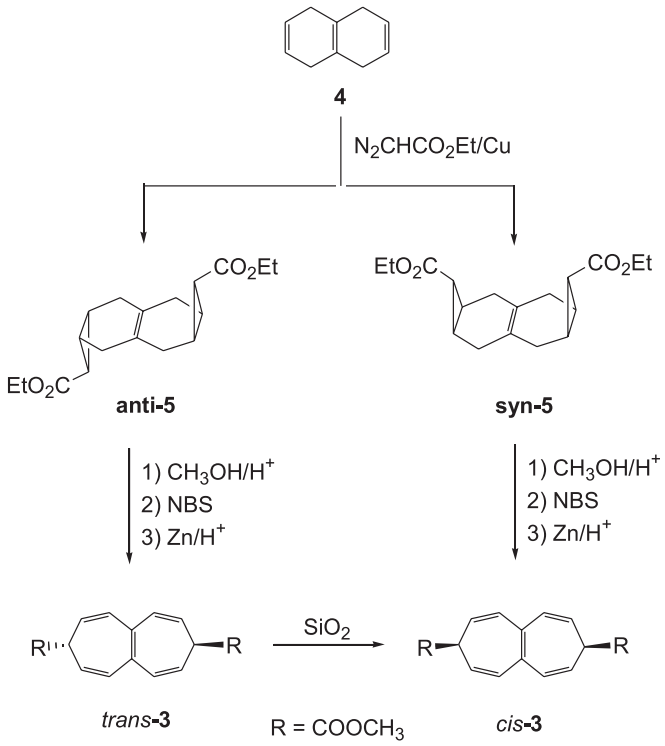
Results and discussions



trans-**3** *and cis*-**3** have been synthesized by addition of excess ethyl diazoacetate to isotetraline **4** to deliver bis-adducts *anti*-**5** (3*c*, 4*a*) and *syn*-**5** (4*c*) in 18 and 28% yields, respectively. Transesterification and NBS-bromination followed by Zn-AcOH elimination resulted in the formation of *trans*-**3** and *cis*-**3** (Scheme 1).

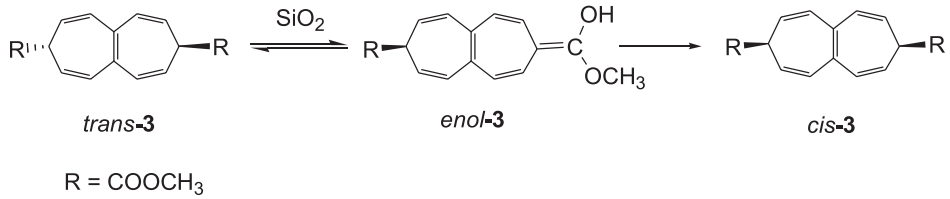
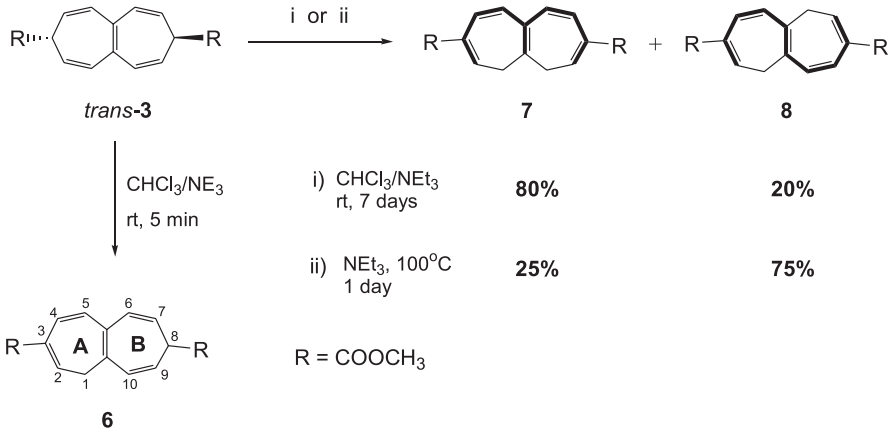
 *trans*-**3**	0.502	1.602	2.621

Scheme 1.



We have noticed that *trans*-**3** was isomerized partly to *cis*-**3** during column chromatography on silica gel. For that reason, *trans*-**3** was refluxed with silica gel in $CHCl_3$. After four days *trans*-**3** was completely rearranged to *cis*-**3** in yield of 61%, no other isomer being detected (Scheme 2). *cis*-**3** was characterized by its 200 MHz ^{1}H NMR spectrum. Its six-line ^{13}C NMR spectrum is particularly informative. Furthermore, structural assignment to compounds *trans*-**3** and *cis*-**3** has been supported by the formation of the cycloaddition products and their X-ray analysis (4). It is very interesting that *trans*-**3** isomerized completely to *cis*-**3**. In this isomerization, silica gel presumably acts as an adsorbent, since silica gel has numerous hydroxyl groups (Si-OH). Hydrogen bonding formed between these hydroxyl groups and the polar carbonyl group of *trans*-**3** seems to play an important role, in forming enol-**3**, which later converts to the thermodynamically more stable isomer *cis*-**3**.

To understand the driving force of this isomerization, firstly, optimized geometry and energies of all conformers were calculated in semiempirical method (AM1 (5)) by using HyperChem 5.01 for Windows. Then, they were optimized by using Hartree–Fock (HF) (6) and Density Functional Theory (DFT) (7) methods of the Gaussian 98 package program (8). The stable geometries of the conformers optimized by the AM1 method were used as input for the HF method calculation. For the DFT optimization method, the optimized geometries of the HF method were used as the input. As basis set, we employed the minimal basis set (STO-3G (9)) for both HF and DFT calculations. Results of these calculations show clearly that the *cis*-**3** isomer has a lower heat of formation than the *trans*-**3** isomer, which indicates that the *cis*-**3** isomer is thermodynamically the most stable one (Table 1).



Later, the base-catalyzed intramolecular proton transfer in cycloheptatriene units of *trans*-**3** has been investigated. *trans*-**3** was first treated with a catalytic amount of a proton-donating base, triethylamine in chloroform at room temperature. After 5 min, **6** was formed almost in quantitative yield. The structure of **6** was assigned by ^{1}H and ^{13}C NMR spectra. The most conspicuous features in the ^{1}H NMR spectra of

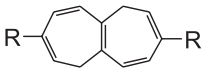
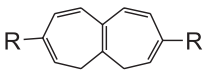
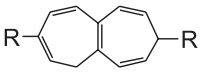
Scheme 2.

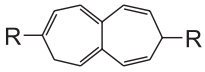
Scheme 3.

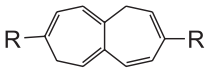
this new dihydroheptalene derivative **6** are three distinct AB-systems, which correspond to six olefinic protons. The olefinic proton H_2 resonates as triplet. ^{13}C NMR spectrum with 16 lines is also in agreement with the unsymmetrical structure.

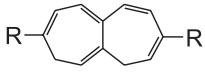












Base-catalyzed reaction of *trans*-**3** undergoes a direct 1,3-intramolecular proton shift. Takahashi et al. (10) have also observed a direct 1,3-proton shift in cycloheptatriene derivatives, the shift proceeding through a 1,3-hydrogen bond-bridged carbanion that is a transition state rather than an intermediate. The mechanism has been supported by MNDO calculations.

The treatment of *trans*-**3** with triethylamine in $CHCl_3$ for seven days afforded a mixture of two isomerization products (**7** (80%) and **8** (20%)) in accord with the usual 1,3-hydrogen transfer in cycloheptatriene derivatives. Attempted separation of this isomeric mixture by column chromatography failed. However, dihydroheptalene derivative **7** was isolated from the reaction mixture by fractional crystallization. The correct structural assignment of **7** was made especially by analysis of ^{13}C NMR. On the basis of the ^1H NMR data and splitting pattern one cannot distinguish between those isomers. A nine-line ^{13}C NMR is in agreement with the structure **7**. However, the isomer **8** gave an eight-line ^{13}C NMR spectrum as expected.

First, *trans*-**3** undergoes a 1,3-hydrogen shift to give **6**. The next hydrogen shift can take place only in the other cycloheptatriene unit (**B**), since the acidity of the methylenic protons in the ring **A** decreased. In the second cycloheptatriene system (**B**) a new 1,3-hydrogen shift can take place in two different directions due to the unsymmetrical structure of **6** providing **7** and **8**.

AM1 calculations indicate that the isomer **8**, which is formed as minor product, has a lower heat of formation (–99.34 kcal mol^{-1}, a fully conjugated system) than the major isomer **7** (–92.05 kcal mol^{-1}) which is cross-conjugated (Table 2). We assume that the activation energy leading to the thermodynamically most stable isomer **8** must be higher than that of **7**. To clarify the course of the migration, we have optimized the geometry of the transition states by the

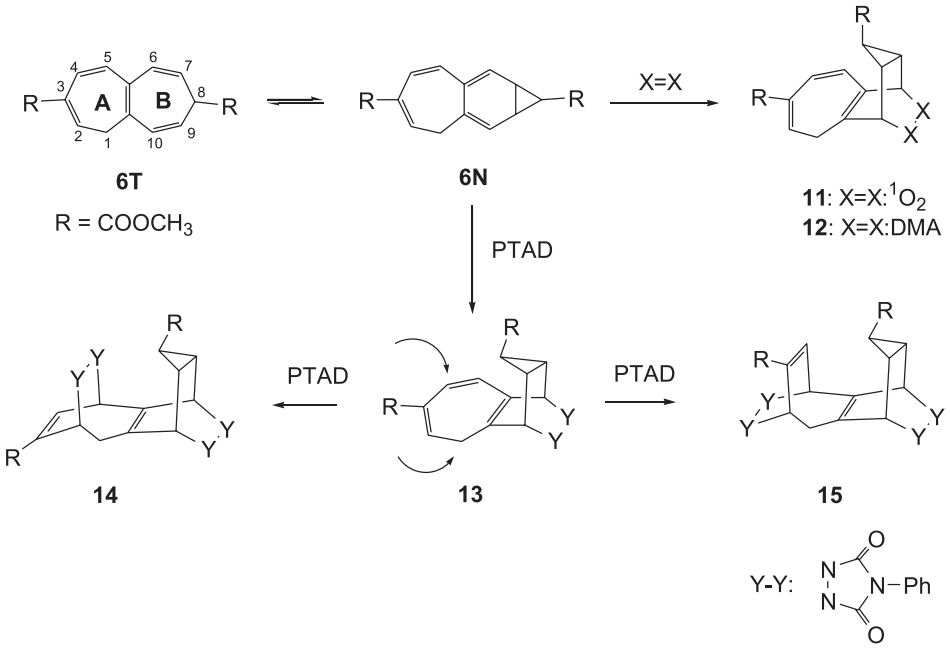
Scheme 4.

QST2 method in Gaussian 94 (11) and calculated the activation energies for the formation of **7** and **8** (in the absence of the base) starting from the isomer **6**. We found, that the activation barrier for the formation of **7** (E_a = 52.6 kcal mol^{-1}) is much lower than that for the formation of **8** (E_a = 92.6 kcal mol^{-1}).

This assumption was confirmed nicely by carrying out the base-catalyzed reaction at the elevated temperature. The treatment of *trans*-**3** with triethylamine for one day at 100°C afforded again the same isomeric mixture of **7** (25%) and **8** (75%), however in reversed yields. We conclude that the kinetically controlled product **7** is formed at lower temperatures, whereas at higher temperature the thermodynamically more stable isomer **8** is formed as the major product.

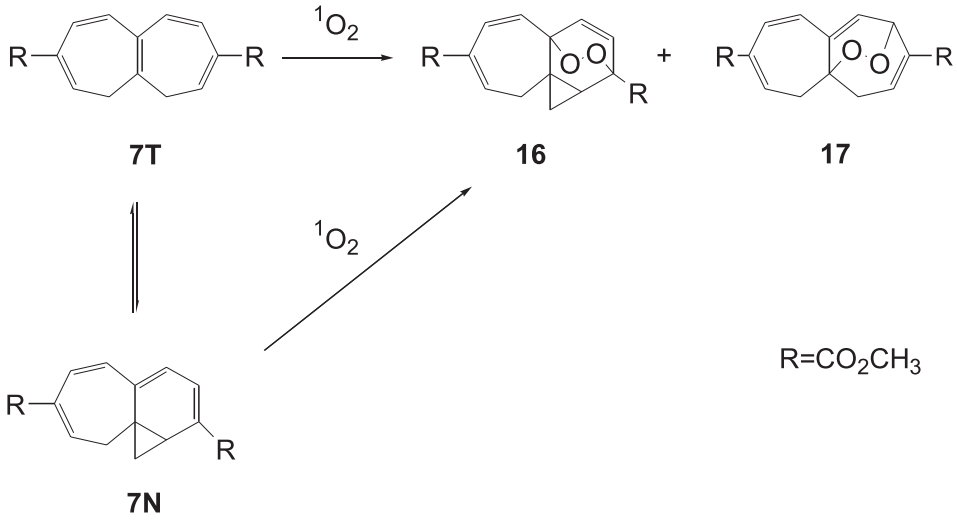
We reported that the cycloheptatriene units in *trans*-**3** and *cis*-**3** undergo easily cycloaddition reactions with dienophiles, such as benzyne, dimethyl acetylenedicarboxylate (DMAD), singlet oxygen ($^1O_2$), and *N*-phenyltriazolinedione (PTAD) to form adducts derived from norcaradiene which is in equilibrium with cycloheptatriene (12). The equilibrium for the symmetry-allowed valence isomerization of cycloheptatriene and norcaradiene has been demonstrated. Electron-accepting substituents, such as CHO, COOR, CN, etc., at C-7 tend to shift the equilibrium to the norcaradiene (**10**) side (Scheme 4) (13).



To investigate chemical behavior of cycloheptatriene units in **6** and **7**, they were reacted with some dienophiles. The reactions of (**6T** ⇆ **6N**) consisting of two different cycloheptatriene (CHT) rings with singlet oxygen and DMAD and gave only isolated NOR-adducts **11** and **12**, respectively. Careful examination of the ^{1}H and ^{13}C NMR spectra of the products showed exclusive formation of the norcaradiene adducts where the **B** ring in **6** was involved. Since **6T** is in equilibrium with its valence isomer **6N**, two types of norcaradiene adducts (*exo* and *endo*) are possible. We have revealed the presence of only the *exo* isomers **11** and **12** on the basis of the measured coupling constants at the cyclopropane ring. These results show that cycloheptatriene ring **B** bearing an ester group at C-8 carbon atom is more reactive (forms more norcaradiene isomer) than the cycloheptatriene unit **A** (Scheme 5). This is an expected result. In both cases we observe a strong regio- and stereoselectivity.

Furthermore, it was interesting to examine the behavior of the cycloheptatriene unit **A**. For this reason we have studied the cycloaddition reactions of **6** with 2 mol of triazolinedione (PTAD). Reaction of **6** with PTAD gave two bis-adducts **14** and **15** in a ratio of 1:1. The second mol of PTAD added exclusively to the cycloheptatriene unit.

The cycloheptatriene equilibrates with its valence isomer and forms norcaradiene. In the case of **7** the formation of the norcaradiene isomer is not favored because of the position of the ester group. The ester group can stabilize the norcaradiene structure much better if it is directly attached to an sp^3-carbon atom, which is not the case in **7**. Additionally, the formation of the norcaradiene structure **7N** will cause more strain in the molecule. To test the reactivity of this system, we have treated **7** with singlet oxygen and obtained NOR-product **16** and CHT-product **17** in ratio of 66 and 26%, respectively.



It is remarkable that the NOR-product **16** is formed as the major product. Clearly singlet oxygen intervenes in the cycloheptatriene–norcaradiene equilibrium in **7**. This is not surprising since kinetic studies confirm that the dienophilic reactivity of singlet oxygen toward [2 + 4]-cycloadditon is

Scheme 5.

Scheme 6.

enormous (14). We assume that the dynamic equilibrium in **7** is still on the side of the cycloheptatriene valence isomer. However, the activation barrier for the cycloaddition of singlet oxygen to cycloheptatriene unit in **7** must be significantly higher than the activation barrier for the **7T** ⇆ **7N** valance isomerization which in turn must be higher than the activation barrier for the cycloaddition of singlet oxygen to **7N** to give the adduct **16**. This is not surprising since the planar diene moiety in norcaradiene **7N** should be considerably more reactive towards dienophiles than the twisted diene moiety in cycloheptatriene **7T**.

General

All solvents were dried and distilled by standard procedures. Melting points were determined using a capillary melting point apparatus (Thomas–Hoover) and are uncorrected. IR spectra were obtained from KBr pellets or solution in 0.1 mm cells on an IR recording spectrophotometer. ^{1}H NMR spectra were recorded on a Varian 200 MHz spectrometer and are reported in δ units with TMS as internal standard. All column chromatography was carried out using Merck on silica gel (60-mesh).

Experimental

Dimethyl *cis*-3,8-dihydroheptalene-3,8-dicarboxylate (*cis*-3)

To a solution of *trans*-**3** (1088 mg, 4 mmol) in 70 mL of $CHCl_3$ was added 6.0 g of thin-layer silica gel (741-Kieselgel 60 $HF_{254+366}$). The reaction mixture was refluxed for four days and cooled to room temperature. The reaction mixture was filtered and washed with ethyl acetate. The combined organic solvents were evaporated, and the residue was purified by crystallization from ether, giving *cis*-**3** (660 mg, 61%, pale yellow crystals, mp 114–116°C). IR (KBr, cm^{-1}): 3000, 2950, 2820, 1735, 1615, 1433, 1300, 1205, 1170, 1040, 975, 915, 810, 720. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 6.32 (d, *J* = 9.9 Hz, 4H), 5.81 (dd, *J* = 9.9, 5.6 Hz, 4H), 3.80 (s, 3H), 2.53 (t, *J* = 5.6 Hz, 2H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 173.51, 139.97, 129.40, 124.40, 52.83, 44.55. Anal. calcd. for $C_{16}H_{16}O_4$: C 70.58, H 5.92; found: C 70.39, H 5.81.

Dimethyl 1,8-dihydroheptalene-3,8-dicarboxylate (6)

A mixture of *trans*-**3** (272 mg, 1 mmol) and NEt_3 (3 drops) in 15 mL of $CHCl_3$ was stirred at room temperature during 5 min and the mixture was diluted by adding 35 mL of $CHCl_3$. The organic phase was washed with a solution of HCl (2 × 20 mL, 5%) and then washed with water (2 × 40 mL), and dried over $MgSO_4$. The residue was purified by crystallization from ether, giving **6** (250 mg, 92%, mp 85–86°C). IR (KBr, cm^{-1}): 2980, 2930, 2830, 1740, 1700, 1610, 1430, 1300, 1250, 1170, 1050, 970. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 6.97 (bd, A part of AB system, *J* = 11.7 Hz, 1H), 6.88 (d, B part of AB system, *J* = 11.7 Hz, 1H), 6.65 (bt, *J* = 7.3 Hz, 1H), 6.27 (d, A part of AB system, *J* = 9.8 Hz, 1H), 6.24 (d, A part of AX system, *J* = 9.7 Hz, 1H), 5.77 (dd, B part of AB system, *J* = 9.8, 5.7 Hz, 1H), 5.50 (dd, X part of AX system, *J* = 9.7, 5.7 Hz, 1H), 3.72 (s, 6H), 3.03 (dd, A part of AB system, *J* = 11.8, 7.3, 1H), 2.37 (bt, *J* = 5.7 Hz, 1H), 2.80 (dd, X part of AX system, *J* = 11.8, 7.3 Hz, 1H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 173.49, 167.10, 137.82, 135.65, 133.78, 133.04, 130.36, 129.14, 127.21, 126.81, 123.75, 120.01, 52.76, 52.39, 44.87, 35.72. Anal. calcd. for $C_{16}H_{16}O_4$: C 70.58, H 5.92; found: C 70.45, H 5.96.

The reaction of *trans*-3 with NEt_3 for seven days: dimethyl 1,10-dihydroheptalene-3,8-dicarboxylate (7) and dimethyl 1,6-dihydroheptalene-3,8-dicarboxylate (8)

A solution of *trans*-**3** (272 mg, 1 mmol) and five drops NEt_3 in 15 mL of $CHCl_3$ was stirred at room temperature for seven days. To the reaction mixture was then added $CHCl_3$ (35 mL). The organic layer washed with a solution of HCl (2 × 20 mL, 5%) and then washed with water (2 × 40 mL), and dried over $MgSO_4$. The ^{1}H NMR spectrum showed that the reaction mixture consisted of a mixture of **7** (80%) and **8** (20%). The crystallization of this mixture from ether gave (**7**) (mp 142–143 °C). IR (KBr, cm^{-1}): 3000, 2960, 2920, 1700, 1610, 1420, 1340. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.10 (d, A part of AB system, *J* = 11.6 Hz, 2H), 6.90 (d, B part of AB system, *J* = 11.6 Hz, 2H), 6.64 (t, *J* = 7.6 Hz, 2

H), 3.78 (s, 6H), 2.52 (d, J = 7.6 Hz, 4H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 167.37, 133.33, 132.51, 129.77, 129.61, 126.81, 116.43, 52.46, 35.59. Anal. calcd. for $C_{16}H_{16}O_4$: C 70.58, H 5.92; found: C 70.69, H 5.67. (**8**): ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.08 (d, A part of AB system, J = 11.4 Hz, 2H), 6.70 (d, B part of AB system, J = 11.4 Hz, 2H), 6.47 (t, J = 7.7 Hz, 2 H), 3.72 (s, 6H), 2.57 (d, J = 7.7 Hz, 4H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 166.60, 133.14, 131.77, 130.36, 129.32, 126.86, 51.86, 33.11.

The reaction of *trans*-3 with NEt_3 at 100°C

A solution of *trans*-**3** (210 mg, 0.77 mmol) and 1.7 g of NEt_3 was heated at 100°C. After 24 h, the reaction mixture was cooled to room temperature. The residue was dissolved in $CHCl_3$ (75 mL) and washed with a solution of HCl (3 × 30 mL, 10%) and then washed with water (2 × 40 mL), and dried over $MgSO_4$. The solvent was removed under reduced pressure. According to the NMR spectrum, the reaction mixture consisted of a mixture of **7** (25%) and **8** (75%).

Photoxygenation of 6: dimethyl *cis*-13,14-dioxatetracyclo[7.3.2.0^{2,8}.0^{10,12}] tetradeca-2(8),3,5-triene-5,11-dicarboxylate (11)

To a stirred solution of **6** (272 mg, 1 mmol) in 30 mL of CCl_4 was added 10 mg of tetraphenyl porpyrine (TPP). The resulting mixture was irradiated with a projection lamp (50 W) while oxygen passed through solution and the mixture was stirred for 1.5 h. The solvent was removed by evaporation. Chromatography of the residue on a silica gel column eluting with $CHCl_3$–*n*-hexane (50 mL, 20:80) and $CHCl_3$ (200 mL) gave the cycloadduct **11** (250 mg, 83%, mp 89–90°C, crystallized from $CHCl_3$–ether). IR (KBr, cm^{-1}): 3000, 2940, 1720, 1705, 1430, 1260, 1160, 1075, 1050. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.19 (bd, A part of AX system, J = 11.4 Hz, 1H), 6.60 (d, X part of AX system, J = 11.4 Hz, 1H), 6.54 (t, J = 7.1 Hz, 1 H), 5.09 (bd, J = 4.3 Hz, 1H), 3.80 (s, 3H), 3.62 (s, 3H), 2.73 (dd, A part of AB system, J = 13.4, 7.1 Hz, 1H), 2.51 (dd, B part of AB system, J = 13.4, 7.1 Hz, 1H), 2.19 (m, 2H), 0.62 (t, J = 3.1 Hz, 1H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 171.83, 166.94, 132.21, 131.23, 130.39, 129.85, 128.94, 124.77, 77.77, 76.37, 52.70, 52.54, 30.06, 21.55, 15.89, 15.19. Anal. calcd. for $C_{16}H_{16}O_6$: C 63.13, H 5.30; found: C 62.94, H 5.19.

The cycloaddition of 6 with DMAD: tetramethyl *exo*-tetracyclo[7.3.2.0^{2,8}.0^{10,12}] tetradeca-2(8),3,5,13-tetraene-5,11,13,14-dicarboxylate (12)

A mixture of **6** (200 mg, 0.74 mmol) and DMAD (130 mg, 0.91 mmol) in 4 mL of $CHCl_3$ was placed into a glass tube, the tube was sealed and heated at 70–80°C. After 13 days, the mixture was cooled to room temperature. The solvent was roto-evaporated, the residue was submitted to column chromatography on silica gel eluting with $CHCl_3$–*n*-hexane (100 mL, 10:90) and cycloadduct **12** was obtained (190 mg, 62%, as pale-yellow liquid). IR (liquid, cm^{-1}): 3000, 2940, 1715, 1625, 1430, 1270, 1120, 1060, 940, 900. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 6.94 (bd, A part of AB system, J = 11.3 Hz, 1H), 6.56 (d, B part of AB system, J = 11.3 Hz, 1H), 6.37 (t, J = 7.5 Hz, 1 H), 4.22 (bd, J = 3.8 Hz, 1H), 4.10 (bd, J = 3.9 Hz, 1H), 3.77 (s, 3H), 3.76 (s, 3H), 3.75 (s, 3H), 3.56 (s, 3H), 2.50 (dd, A part of AB system, J = 13.2, 7.5 Hz, 1H), 2.47 (dd, B part of AB system, J = 13.2, 7.5 Hz, 1H), 2.16–2.02 (m, 2H), 1.14 (t, J = 2.8 Hz, 1H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 171.49, 167.21, 166.43, 166.39, 147.44, 147.36, 135.63, 130.74, 130.07, 128.98, 127.89, 127.44, 52.86, 52.82, 52.51, 52.26, 47.62, 44.95, 31.36, 30.79, 28.42, 27.88. Anal. calcd. for $C_{22}H_{22}O_8$: C 63.76, H 5.35; found: C 63.94, H 5.22.

The cycloaddition of 6 with 2 mol of PTAD

A solution of **6** (170 mg, 0.63 mmol) and PTAD (300 mg, 1.7 mmol) in 15 mL of $CHCl_3$ was stirred at room temperature for 17 h. The solvent was removed in vacuum and chromatography of the residue on silica gel eluting with $CHCl_3$ (100 mL) gave a mixture of **14** (50%) and **15** (50%). Crystallization of the mixture from CH_2Cl_2–*n*-hexane gave **14** as white crystals (180 mg) and then recrystallization of the residue from CH_2Cl_2–ether gave **15** as white crystals (168 mg).

14: (mp 248–249°C). IR (KBr, cm^{-1}): 3106, 2953, 1780, 1741, 1720, 1642, 1523, 1446, 1421, 1242, 1165, 1038, 936. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.55–7.24 (m, 11H), 5.67 (m, 1H), 5.35 (d, J = 4.8 Hz, 1H), 5.26 (d, J = 13.5 Hz, 1H), 4.97 (d, J = 4.7 Hz, 1H), 3.71 (s, 3H), 3.70 (s, 3H), 3.06 (dd, A part of AB system, J = 19.8, 4.4 Hz, 1H), 2.56 (dd, B part of AB system, J = 19.8, 2.5 Hz, 1H), 2.35–2.19 (m, 2H), 1.35 (t, J = 3.0 Hz, 1H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 172.08, 164.68, 159.96, 159.48, 154.38, 153.95, 141.26, 134.87, 133.18, 132.63, 131.93, 131.24, 131.16, 131.13, 130.83, 130.72, 130.50, 127.46, 59.79, 58.92, 54.69, 54.35, 52.90, 51.80, 37.05, 25.25, 18.29, 17.43. Anal. calcd. for $C_{32}H_{26}N_6O_8$: C 61.73, H 4.21, N 13.50; found: C 61.49, H 4.09, N 13.21.

15: (mp 176–177°C). Thermodynamic of metal complexation of the macrocyclic antibiotic rifampicin

I. Shehatta, I. Kenawy, A.H. Askalany, and Ayman A. Hassan

Abstract: The acid–base and complexation equilibria of rifampicin with H^+, Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+}, and Pb^{2+} were studied by means of potentiometry. The stoichiometric equilibrium constants were determined in 50% (v/v) methanol–water medium at different temperatures and constant ionic strength (0.05 M KCl). It was established that rifampicin has two proton-binding sites. The distribution diagram of the corresponding ionic species as a function of pH is given and indicated that rifampicin exists predominantly in the zwitterionic form at pH ≤ 5. The thermodynamic parameters of protonation and complexation were derived and discussed. The formation of the complexes is spontaneous, more favourable at lower temperatures, entropically unfavourable, and an enthalpy-driven process. The order of the changes in Gibbs energy and enthalpy accompanying the complexation was found to be $Mn^{2+} < Co^{2+} < Ni^{2+} < Cu^{2+} > Pb^{2+} > Zn^{2+} > Cd^{2+} > Hg^{2+}$ in accordance with the well-known sequence of Irving and Williams. The transition series contraction energy (E_r(Mn–Zn)), and the ligand field stabilization energy (δH) were calculated from the enthalpy changes.

Key words: rifampicin, thermodynamics, potentiometry, and complexation.

Résumé : Faisant appel à la potentiométrie, on a étudié les équilibres acide–base et de complexation de la rifampicine avec H^+, Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+} et Pb^{2+}. Les constantes d'équilibre stoechiométriques ont été déterminées dans un mélange méthanol–eau à 50 % (v/v), à diverses températures et à force ionique constante (0,05 M KCl). On a établi que la rifampicine possède deux sites de liaison. On a déterminé le diagramme de distribution des espèces ioniques correspondantes en fonction du pH; il indique que, à des pH ≤ 5, la rifampicine existe principalement sous la forme zwitterionique. On a dérivé les paramètres thermodynamiques de la protonation et de la complexation et on les discute. La formation des complexes est spontanée, plus favorable à faibles températures, défavorable d'un point de vue entropique et le processus est favorisé par l'enthalpie. On a trouvé que le changement dans l'énergie de Gibbs et dans l'enthalpie qui accompagnent la complexation est dans l'ordre $Mn^{2+} < Co^{2+} < Ni^{2+} < Cu^{2+} > Pb^{2+} > Zn^{2+} > Cd^{2+} > Hg^{2+}$, en accord avec la séquence bien connue d'Irving et Williams. À partir des changements d'enthalpie, on a calculé l'énergie de contraction de la série de transition (E_r(Mn–Zn)) ainsi que l'énergie de stabilisation du champ de ligand (δH).

Mots clés : rifampicine, thermodynamique, potentiométrie, complexation.

Introduction

Rifamycins are macrocyclic antibiotics. They belong to a class of molecules known as ansamycins. Rifamycins are unique among antibiotics in that they have a characteristic ansa structure, i.e., a ring structure or chromophore spanned by an aliphatic chain. Rifamycins differ from one another in the type and the substituent on their naphthohydroquinone ring. Rifampicin is one of the most semisynthetic compounds of the ansamycin group. Rifampicin is the drug of choice for chemoprophylaxis of meningococcal diseases and meningitis. It shows promise in the treatment of certain non-mycobacterial diseases when combined with β-lactam antibiotic or vancomycin. Furthermore, it has a rapid bactericidal effect on mycobacterium lepra and is used in leprosy.

The role of transition metal ions in the mechanism action of antibacterial drugs was reported (1). Moreover, when a therapeutically affective dose of antibacterial drug is administrated, the balance between the metal ions in vivo and their ligand environment can be considerably altered. This may have an influence on the activity of the drug against bacteria. Also, rifampicin–Pt complexes (2) were useful as antibiotic agents. They have stronger bactericidal effect (against *Staphylococcus aureus* 209p) and less toxicity than rifampicin, and show good H_2O-solubility. Thus, capsules were formulated containing rifampicin–Pt complex. Therefore, to enhance understanding of drug–metal interaction, and in continuation of our previous work (3–7), it is important to assess the reaction between rifampicin and a number of transition-metal ions. These metal ions may be present in the biological systems, or may be taken by an accident.

In this paper, we report the determination of the stability constants by pH-metric method for rifampicin complexes of H^+, Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+}, and Pb^{2+} at different temperatures. The thermodynamic functions for these systems were also calculated and correlated with the well-known properties of metal ions. This is done to observe how the different metal environments could affect the affinity of the drug for metal ion.

Experimental

Reagent and materials

Rifampicin (Structure 1) was obtained from El-Nasr Pharmaceutical Chemical Co., Egypt and used without any further purification. Other materials of analytical reagent grade were used, and supplied from different companies. Methanol was purified as described by Lund and Bjerrum (8). The metal salts were provided by BDH as nitrates. All solutions of metal ions were prepared using deionized water and standardized complexometrically by EDTA (9) using suitable indicators. Carbonate-free sodium hydroxide was prepared and standardized potentiometrically with potassium hydrogen phthalate solution.

Structure 1

Apparatus and procedure

Potentiometric measurements were performed using a Metrohm E536 potentiograph equipped with a 665 DOSIMAT (Metrohm, Herisau, Switzerland). The combined glass electrode was standardized before, and checked after each titration with buffer solutions produced by FISHER (New Jersey, U.S.A.). The electrode system was calibrated in terms of hydrogen ion concentrations instead of activities. Thus, all constants determined in this work are concentration constants. All titrations were carried out at 30, 35, and 40°C. This was adjusted to ±0.05°C by circulating water from an ultrathermostat (Köttermann 4130, Germany) through the annular space of a double-walled Pyrex titration cell of 100 mL capacity. Sodium hydroxide was added from the Dosimat and the content of the titration vessel was stirred magnetically. The following solution mixtures (A–C) were prepared and titrated potentiometrically with standard 0.02 M NaOH at constant ionic strength (0.05 M KCl) in 50% (v/v) methanol–water mixture:

(A) 2.5 mL (10^{-2} M) HCl + 2.5 mL (1 M) KCl
= 0.5 mM acid

(B) Solution (A) + 5 mL (5×10^{-3} M) drug
= 0.5 mM drug

(C) Solution (B) + 5 mL (1×10^{-3} M) metal ion
= 0.1 mM metal

All the above solution mixtures were made up to 50 mL with appropriate volumes of methanol and double-distilled water to keep at the 50% (v/v) methanol–water ratio. An Irving and Rossotti (10) pH titration technique was used to determine the protonation constants of rifampicin and formation constants of its complexes. Triplicate titrations have been performed for each system.

All calculations were performed using a computer program based on unweighted linear least-square fits. Moreover, the stability constants have been determined in the low pH region. Thus, the formation of hydroxy complexes could be neglected.

The pH readings were corrected, using the Van Uitert–Hass equation (11):

$$[1] \qquad -\log [H^+] = B + \log U_H^\circ - \log\left(\frac{1}{\gamma_\pm}\right)$$

The values of the correction factor ($\log U_H^\circ$) were obtained experimentally (12) and those of the mean activity coefficients ($\gamma_\pm$) were computed according to the equation given by Harned and Owen (13) assuming the activity coefficients are the same on both molal and molar scales.

$$[2] \qquad \log\left(\frac{1}{\gamma_\pm}\right) = \frac{\left[\dfrac{[Z_1 Z_2]1.29\times10^6\sqrt{2\mu}}{(\varepsilon T)^{3/2}}\right]}{\left[1+\dfrac{3556a^\circ\sqrt{2\mu}}{(\varepsilon T)^{1/2}}\right]}$$

where μ is the ionic strength (0.05 M), T is the absolute temperature (303.15, 308.15, or 313.15 K), Z_1 and Z_2 are the charges of ions in solution at equilibrium, $a°$ is the mean ionic diameter in Å (taken as 6 Å (14)) and ε is the dielectric constant of the medium. The values of $\log U_H^\circ$ were found to be –0.148, –0.153, and –0.157 at 303.5, 308.15, and 313.15 K, respectively, in agreement with the literature values (15).

Results and discussion

Proton–rifampicin system

The ionization constants (Table 1) for rifampicin were determined potentiometrically using the Irving–Rossotti technique (10) at different temperatures in 50% methanol–water mixture. The titrations were carried out at constant ionic strength (0.05 M KCl). The free acid (0.5 mM) and its mixture with rifampicin (0.5 mM) were titrated against carbonate-free sodium hydroxide (20 mM) solution and represented in Fig. 1.

The average number of protons attached per ligand ($\bar{n}_A$) was calculated (10) at different pH values, and was used to calculate the proton association constants of rifampicin applying different computational methods (16). The maximum $\bar{n}_A$ value is found to be ≈ 2 indicating that the investigated

drug has two dissociable protons. The first proton ionization is assigned to the peprazine group, in good agreement with that previously reported (17), while the other is assigned to the hydroxyl group at C-4. Since the initial pH reading in the drug titration curve was around 3.3, the ionization constant of rifampicin related to the hydroxyl at C-8 (pK_a = 1.7) (17) could not be calculated under the present experimental conditions.

The first association constant was calculated using the half- $\bar{n}_A$ values (16), i.e., at $\bar{n}_A$ = 1.5 from the $\bar{n}_A$–pH curve. This value is confirmed by least-quares method (16) by plotting log $(\bar{n}_A - 1)/(2 - \bar{n}_A)$ vs. pH. While the second association constant is evaluated by the midpoint method (16) using the following equation: log K_1K_2 = 2 pH (at $\bar{n}_A$ = 1)

Metal–rifampicin system

The stepwise formation constants of some divalent metal ions (Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+}, and Pb^{2+}) with rifampicin were calculated potentiometrically at different temperatures (303.15, 308.15, and 313.15 K), constant ionic strength (0.05 M KCl), and in 50% (v/v) methanol–water mixture.

An inspection of the titration curves shown in Fig.1, reveals that the metal–drug titration curves lie below and well separated from the drug titration one. This indicates that the complexation processes occurred with the liberation of hydrogen ions.

Values of $\bar{n}$ and pL are calculated (where $\bar{n}$ is the average number of ligand attached per metal ion and pL is the free ligand exponent). All metal ions form 1:1 and 1:2 (M:L) ratios in solution with rifampicin as gathered from $\bar{n}$, where $\bar{n}$ values extend between 0 and 2.

The stoichiometric stability constants (log K_1 and log K_2) are evaluated using the two well-known methods, namely: (*i*) the half-method (16) in which the formation curves are drawn between $\bar{n}$ and pL and the constants are evaluated at $\bar{n}$ = 0.5 and 1.5, respectively; and (*ii*) the least-squares method (16) using the equation:

$$[3] \qquad \frac{\bar{n}}{(1-\bar{n})[L^-]} = \frac{(2-\bar{n})[L^-]}{1-\bar{n}} K_1K_2 + K_1$$

The stability constant values (Table 1) calculated by the two different methods are in good agreement with each other.

Effect of the ionic strength of the medium on the stability of the complexes

In an attempt to know the possible effects of chloride complexation with the metals, the variation of log *K* values of rifampicin–Cu^{2+} complexes, as a representative example, with the ionic strength of the medium was investigated at 308.15 K in 50% (v/v) methanol–water mixture. The salt concentration have been chosen in the range where extended Debye–Hückel theory is suitable to be applied. Although the values of p*K* and log *K* decrease with increasing ionic strength of the medium (Table 2) in accordance with the Debye–Hückel equation (18), the values obtained in 0.05 M KCl are close to those calculated in absence of the salt.

Table 2. Acid ionization constants for rifampicin, and stability constants for its Cu^{2+} complexes, in different concentrations of KCl and 50% (v/v) methanol–water mixture at 308.15 K.

Concentration of KCl (M)	Ionization constants		Stability constants	
	pK_1	pK_2	log K_1	log K_2
0.20	7.07	11.01	8.92	6.60
0.10	6.99	10.91	8.85	6.52
0.05	6.94	10.85	8.79	6.47
0.00[a]	6.81	10.69	8.66	6.34

[a]These values were obtained by linear regression of pK or log K vs. $[KCl]^{1/2}$.

Distribution curves

Fractional compositions of the drugs are necessary to understand stability and transportation models in the gastrointestinal and biological membrane (19). Such transportation depends on the ionization degree of the drugs and their lipid solubility. These terms are dependent upon the pH of the absorptive medium and pK_a values of the drugs (20). In general, the absorption is pH-dependent when the pK_a values of acids are between 2.5 and 7.5. In contrast, for acids with pK_a > 7.5, the absorption is pH-independent (21). Therefore, rifampicin absorption in the intestinal tract is transported by the pH-dependent mechanism.

Rifampicin can exist in three possible forms: as an acidic cation (H_3L^+), uncharged form (H_2L^0) (in equilibrium with its zwitterionic form $H_2L^{\pm}$), and two anionic forms (HL^-) and (L^{2-}), depending on the given pH. At low pH, both the piperazinyl and hydroxyl groups are protonated. At high pH, neither is protonated. At each pH, the fractions of zwitterionic ($H_2L^{\pm}$), and the anionic species (HL^- and L^{2-}) can be calculated (22) and represented in Fig. 2. In solution, $H_2L^{\pm}$ and L^{2-} species approach the total concentration of rifampicin at low (≤5) and high (≥12) pH values, respectively. While HL^- species reach a maximum in the isoelectric pH (pI = [pK_1 + pK_2]/2 = 9). The pH regions where two curves overlap correspond to the pK_a value. Also, the distribution curves (Fig. 2) for metal ions – rifampicin complexes permit us to follow up the stepwise complex formation and to detect at which pH value the different species are formed and facilitate the calculation of the stability constants of ML and ML_2.

Effect of temperature and thermodynamic parameters

The effect of temperature on both stepwise protonation constants of rifampicin and the stability constants of its complexes with Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Pb^{2+}, Zn^{2+}, Cd^{2+}, and Hg^{2+} was investigated. The corresponding thermodynamic functions (ΔG, ΔH, and ΔS) were evaluated using the following relationships:

$$[4] \quad \Delta G = -2.303RT \log K = \Delta H - T\Delta S$$

$$[5] \quad \mathrm{d} \log K/\mathrm{d}(1/T) = \Delta H/2.303R$$

$$[6] \quad \Delta S = (\Delta H - \Delta G)/T$$

From the stability constants (Table 1) and the thermodynamic functions (Table 3) the following conclusions can be obtained: (*i*) pK_a values decrease with increasing temperature, i.e., the acidity of the drug increases with increasing temperature. However, the stepwise stability constants

decrease with an increase of temperature indicating that the complexation process is more favourable at lower temperatures; (*ii*) ΔG values for the dissociation of rifampicin are positive, i.e., the dissociation processes are nonspontaneous while for the metal–ligand, all ΔG values are negative, indicating the spontaneous character of chelation; (*iii*) the positive values of ΔH indicate that the dissociation processes are endothermic in nature and enhance with the rise of temperature. But the chelation processes are exothermic as gathered from the negative ΔH values, supporting that the complexation reactions are more favourable at lower temperatures; (*iv*) the positive values of ΔS for protonation are owing to the increasing disorder as a result of the solvation process. For dibasic acids, like rifampicin, protonation is accompanied by large positive entropy changes. The large increase in entropy on protonation is a result of the release of solvent molecules from the solvation sheath of the interacting species. Also, the complexation processes are entropically unfavourable, as indicated from the negative ΔS values of the complexation. Such negative entropies can be attributed to the extensive solvation of metal chelates in the aqueous–methanol medium, as a result of the exposure of the polar nitrogen, oxygen, and metal ion of the chelate to the solvent molecule (23). The high negative enthalpy and entropy changes are in good agreement with that obtained for similar naphthohydroquinone moieties (24–27).

It is apparent that the complexation of rifampicin with the investigated metal ions in 50% (v/v) methanol–aqueous solution

appears to be an enthalpy driven process. This is because both ΔH and ΔS are negative values; (*v*) the correlations of pK_a or log K values vs. $1/T$ are linear, suggesting that ΔC_p^o values for the dissociation and complexation processes are zero over the studied temperature range (303.15–313.15 K).

Factors affecting the stability of metal–rifampicin complexes

In an attempt to know how the different metal environments could affect the affinity of rifampicin for metal ion, it is necessary to correlate the thermodynamic parameters with the characteristic properties of the metal ions. Such study could help us to understand the role of metal ions in the mechanism of action of the drug.

Fig. 5. Variation of $-\Delta G_1$ (●), $-\Delta H_1$ (○), and $T\Delta S_1$ (▼) for rifampicin complexes with the enthalpy of hydration of the divalent metal ions.

The ΔG and ΔH values for rifampicin complexes with Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Pb^{2+}, Zn^{2+}, Cd^{2+}, and Hg^{2+} are correlated with the reciprocal of the metal ionic radius (Fig. 3), the total ionization enthalpy (Fig. 4) at 298 K for the process $M(g) \rightarrow M^{2+}(g) + 2e$, and the enthalpy of hydration (ΔH_H) (Fig. 5). The latter correlation reveals that most of the rifampicin complexes are similar in size and geometry of the coordination sphere to the corresponding aquo ions (28). Similar correlations are also obtained for zinc group (Zn^{2+}, Cd^{2+}, and Hg^{2+} ions) complexes of rifampicin.

The relatively small constant $-T\Delta S$ values ($T\Delta S_1 = -8.88 \pm 0.58$ kJ mol^{-1}) coupled with large values of ΔH support that the transition-metal complexes of rifampicin are stabilized by enthalpy changes.

The $-\Delta G$ and $-\Delta H$ values for rifampicin complexation with the investigated divalent metal ions follow the order:

$$Mn^{2+} < Co^{2+} < Ni^{2+} < Cu^{2+} > Pb^{2+} > Zn^{2+} > Cd^{2+} > Hg^{2+}$$

which is in agreement with the well-known sequence of Irving–Williams (29). This is in line with the fact that the greater the electron acceptor ability of a metal, the stronger will be the complexes that it forms, hence the more $-\Delta G$ and $-\Delta H$ values. In general, it is noted that the ΔG and ΔH values of Cu^{2+} complex do not fall in a straight line and deviates when those values for the metal chelates are plotted against the respective properties of the divalent metal ions. Because of the Jahn–Teller effect (30), Cu^{2+} complex will gain some extra stabilization due to the tetragonal distortion of the octahedral symmetry in its complexes. Also, the complete 3*d*-orbital of Zn^{2+} leads to decrease its ionic radius therefore it gains more stabilization and deviates from the straight lines when ΔG and ΔH values of the metal chelates are plotted vs. the properties of metal ions. The values of log K_1 are greater than those of log K_2 and the difference is

[b] $\Delta H° = \Delta H°_1 + \Delta H°_2$.
[c] $\Delta H_L = \Delta H_H + \Delta H°$.

Fig. 6. Values of ($\Delta H_C + \Delta H_H$) for rifampicin complexes of Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+} plotted against the number of 3*d* electrons.

usually positive (1.4–3.6 log units). This may be attributed to vacant sites of the metal ion are more freely available for the binding of the first ligand than the second. The large ($\log K_1 - \log K_2$) obtained, implies that in these systems not only the statistical effect, which gives $\log K_1 - \log K_2 = 0.68$ units, is considered but also the electrostatic effect and steric hindrance, due to the addition of the second chelating group, are significant. Furthermore, the second ligand (at least in part) may be bound to the central metal ion through a number of its donor groups less than of the first (31).

The effect of inner orbital splitting on the thermodynamic properties of the transition-metal rifampicin complexes

The presence of ligand gives more stability to the metal ion, except those with d^0, d^5, and d^{10} electronic configuration. The extra stabilization known by the ligand field stabilization energy (δH) which arises from the splitting of *d*-orbital and can be determined from the enthalpy change of complexation (32) using the following equation:

$$[7] \quad \delta H(M^{2+}) = \Delta H°(Mn^{2+}) - \left\{\frac{(n-5)}{5}\right\}E_r - \Delta H°(M^{2+}) + \Delta H_H(Mn^{2+}) - \Delta H_H(M^{2+})$$

where *n* is the number of the 3*d*-electrons, E_r is the transition series contraction energy, and $\Delta H°$ and ΔH_H are the complexation and hydration enthalpies, respectively. A plot of ($\Delta H_H + \Delta H°$) of rifampicin complexes as a function of the 3*d*-electrons is a humped curve (Fig. 6) rising to a maximum of about 160 kJ mol^{-1} above the line joining ($\Delta H_H + \Delta H°$) values for Mn^{2+} and Zn^{2+} complexes. The E_r ($Mn^{2+} - Zn^{2+}$) value was found to be 207.57 kJ mol^{-1}. The ligand field stabilization energy (Table 4) follows the order: $Co^{2+} < Ni^{2+} > Cu^{2+}$, which is in agreement with the ligand field theory.

Excess properties for acetophenone + butanols at 298.15 K

Roque Riggio, Juan F. Ramos, and Hector E. Martinez

Abstract: Densities, viscosities, and refractive indexes of binary systems acetophenone + *n*-butanol, + *sec*-butanol, and + 2-methyl-1-propanol have been measured at 298.15 K and atmospheric pressure, over the whole composition range. The excess values of molar volume, viscosity, Gibbs free energy of activation of viscous flow, and internal pressure were calculated from experimental measurements. Based on the variations of the excess functions with composition, conclusions about the molecular interactions in these kinds of mixtures were obtained.

Key words: excess properties, binary mixtures, butanols, acetophenone.

Résumé : Opérant à 298,15 K et à la pression ambiante, on a mesuré les viscosités et les indices de réfraction des systèmes binaires acetofenone + *n*-butanol, + *sec*-butanol et + 2-méthylpropan-1-ol, sur I'ensemble des compositions. Utilisant les données expérimentales, on a calculé les valeurs en excès du volume molaire, de la viscosité, de I'énergie libre d'activation de Gibbs de l'écoulement visqueux et de la pression interne. Sur la base des variations des fonctions d'excès avec la composition, on a tiré des conclusions concernant les interactions moléculaires de ces divers mélanges.

Mots clés : propriétés en excès, mélanges binaires, butanols, acetofenone.

Introduction

To investigate the effects of molecular structure of alcohol isomers on excess molar volumes and viscosity deviations, a series of density, refractive index and viscosity measurements were conducted in our laboratory.

In previous works, we studied several binary liquid solutions of alcohols with different kinds of ketones (1–5). In this contribution, we report the following excess properties: molar volumes (V^E), viscosity (η^E), molar free energy of activation of viscous flow (G^{*E}), and internal pressures (P_i^E), for the mixtures: acetophenone (APH) + *n*-butanol (BuOH), + *sec*-butanol (2-BuOH), and + 2-methyl-1-propanol (I-BuOH), which were calculated from the density, viscosity, and refractive index measured.

Experimental

Components were supplied by Merck–Darmstadt (A.R. grade). All species were dried with anhyd K_2CO_3 and fractionally distilled under a flow of nitrogen. The middle fractions were stored over 3 Å molecular sieve and acetophenone over 4 Å molecular sieve.

Received July 16, 1999. Published on the NRC Research Press Web site on January 24, 2001.

All solutions were prepared by weight using an H11 Mettler balance and were stored in air-tight stoppered bottles.

Density

Densities (ρ) were determined with an Anton Paar DMA46 density meter with a built-in thermostat, and were calibrated with air and doubly distilled water. The accuracy was estimated to be ±0.1 kg m^{-3}.

Viscosity

Viscosities (η) were measured with a Cannon–Fenske viscometer, which was calibrated with doubly distilled water and benzene. The accuracy was estimated to be ±0.5%.

Refractive index

Refractive indexes (n_D) of pure components, as well as mixtures (sodium D line), were measured with a Jena dipping refractometer with an accuracy of ±0.00002. For the viscosity and refractive index, a thermostatic water bath, whose temperature was controlled to ±0.01°C, was used.

The composition of mixture samples was checked frequently by gas chromatography after measurements; the variation was found to be minimal.

Results

In Table 1, we report the experimental physical properties of the pure liquids, along with some literature values for comparison purposes.

The excess functions of the binary systems can be represented by a Redlich–Kister type equation:

$$[1] \qquad X^E = x_i x_j \sum_{k=0}^{n} a_k (2x_i - 1)^k$$

	η	–3.38	2.90	–2.08	9.0×10^{-3}
	n_D	0.0372	–0.0037	0.0029	4.4×10^{-5}

Notes: Units for density ρ, kg m^{-3}; for viscosity η, mPa s^{-1}.

where X^E represents any of the properties V^E, η^E, G^{*E}, P_i^E; x_i and x_j are the mol fractions of components i and j, respectively; and a_k denotes the polynomial coefficients. In each case, the optimum number of coefficients was ascertained from an examination of the variation of the standard error of the estimate with n

$$[2] \qquad \sigma = \left[\sum \frac{(X^E_{obs} - X^E_{cal})^2}{n_{obs} - n} \right]^{1/2}$$

where n_{obs} is the number of measurements.

Table 2 shows the values of the coefficients a_k as well as their standard deviation, calculated by the method of least-squares (6).

The excess functions are defined by the following equations, previously used by several authors (7–11):

$$[3] \qquad V^E = V - (X_1 V_1 + X_2 V_2)$$

$$[4] \qquad \eta^E = \eta - (X_1 \eta_1 + X_2 \eta_2)$$

$$[5] \qquad G^{*E} = RT\,[\ln \eta V - (X_1 \ln \eta_1 V_1 + X_2 \ln \eta_2 V_2)]$$

$$[6] \qquad P_i^E = \frac{2^{1/6} RT}{2^{1/6} V - d \mathrm{N}^{1/3} V^{2/3}} - \left(X_1 \frac{2^{1/6} RT}{2^{1/6} V_1 - d_1 \mathrm{N}^{1/3} V_1^{2/3}} + X_2 \frac{2^{1/6} RT}{2^{1/6} V_2 - d_2 \mathrm{N}^{1/3} V_2^{2/3}} \right)$$

where V and η are the molar volumes and the viscosities of the mixtures; V_1, V_2, η_1, and η_2 are the molar volumes and viscosities of the pure components, respectively.

The excess internal pressures (P_i^E) of the liquid mixture were obtained (12) by the equation

$$[7] \qquad P_i^E = P_i - (x_1 P_{i1} + x_2 P_{i2})$$

where P_i, P_{i1}, P_{i2} are the internal pressures of the mixtures and the pure components, respectively, which can be obtained from the Buchler–Hirschfelder–Curtis equation of state (13):

$$[8] \qquad P_i = \frac{2^{1/6} RT}{2^{1/6} V - d \mathrm{N}^{1/3} V^{1/3}}$$

where N is Avogadro's number and d the molecular diameter of the mixture or the pure components, calculated by the equation (14)

$$[9] \qquad d = 2 \left(\frac{n_D^2 - 1}{n_D^2 + 2} V \frac{3}{4 \Pi \mathrm{N}} \right)^{1/3}$$

where n_D are the refractive indexes of the mixtures or the pure components.

The values of the coefficients a_k for the excess functions of the binary systems and their standard deviation, which were calculated by the method of least squares, are shown in Table 3.

Discussion

It is well known that when mixing a highly associated alcohol with a different polar solvent, certain phenomena occur (15–17). Firstly, breaking of the alcohol's associations due to hydrogen bonding takes place. Secondly, specific interactions appear in the mixtures, such as new hydrogen bonds, dispersion forces, keto–enol tautomerism, and steric freedom (18). For the particular systems studied in this contribution, these effects have been identified through analyses of the following excess properties: molar volume, viscosity, free energy of viscous flow, and internal pressure.

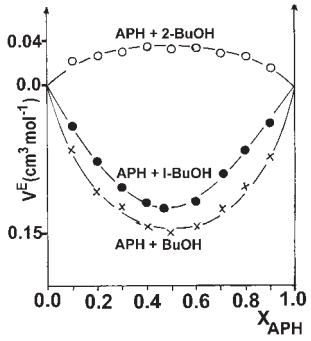

Figure 1 shows excess molar volumes against composition. From the isothermal curves at 298.15 K, the sterically

Fig. 1. Excess molar volumes of the systems at 298.15 K.

hindered effects on the excess molar volumes can be clearly noticed.

It can also be seen that the isothermal curve at 298.15 K is positive for the APH + 2-BuOH system, meanwhile, for the APH + BuOH and APH + I-BuOH systems, the isothermal curves are negative over the whole composition range. From these observations, we can conclude that for these systems the structure of the alcohol is broken when the mixture is formed. It appears that alcohols with OH-groups located at the very end of the molecular chain are more suitable to forming hydrogen bonds with acetophenone. Consequently, their excess molar volumes are lower than those for other binary systems, at near equimolar conditions. For the mixture containing secondary butanol (2-BuOH), there exists a slight possibility of geometric ordering due to the OH position. Meanwhile, for the APH + BuOH system and, to a lesser extent, for the APH + I-BuOH system, both containing primary alcohols, we believe that a compensating effect produces a negative contribution to the V^E values (19, 20).

The observed behaviour differences between the BuOH and I-BuOH mixtures, and the 2-BuOH mixture can be attributed to the higher steric freedom of the primary alcohols to form intermolecular association complexes through hydrogen bonds between the OH of the alcohol and the keto form to the ketone (21).

For the I-BuOH mixture, the lower V^E negative values are probably due to the steric effect of the α-methyl group and the small keto–enol–OH associates formed.

Fig. 2. Excess viscosities of the systems at 298.15 K.

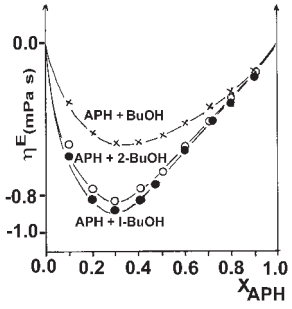

Fig. 3. Excess molar free energies of viscous flow activation by the systems at 298.15 K.

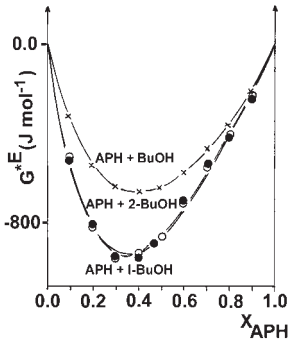

Figure 2 presents excess viscosities of the systems against composition at 298.15 K.

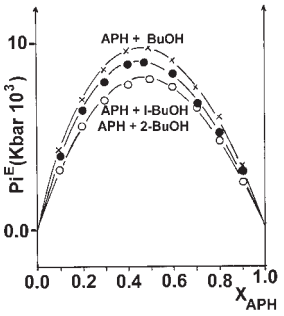
It is observed that all mixtures present negative excess viscosity values, whose decreasing order is the following:



APH + I-BuOH < APH + 2-BuOH < APH + BuOH

According to the above order, negative deviations occur when dispersion forces are preponderant (22). This is in full agreement with the conclusions reached for the V^E behaviour.

Figure 3 shows the dependence of the calculated G^{*E} values upon composition.

© 2001 NRC Canada

Fig. 4. Excess molar internal pressures by the systems at 298.15 K.

Increasing negative deviations with composition can be observed in the order:

$$\text{APH + 2-BuOH} < \text{APH + I-BuOH} < \text{APH + BuOH}$$

It is well known that the strength of molecular interactions increases as G^{*E} decreases. In particular, for the above systems, interactions decrease according to the given order, which is in full agreement with our previous conclusions.

On the other hand, Fig. 4 shows excess internal pressure vs. composition.

We can observe positive P_i^E deviations for all systems studied. For those mixtures showing positive deviations, the attraction forces are greater than the repulsion forces. We know that, in these conditions, acetophenone is present partially in enol form (23), although in tiny quantities (24) and, so, it could be expected that the addition of different alcohols to acetophenone would cause keto–enol interactions, preferably with keto form. Thus, our results may be in good agreement with those expected through predictions reported in the literature.

Structure and redox kinetics of nickel(II) tetraazamacrocycles containing pendant carboxylate groups

Robert Ivor Haines, Dean Reginald Hutchings, Rhonda Jane Lucas, and David Miller

Abstract: The nickel(II) complex of the deprotonated pendant-arm macrocycle 5,12-dimethyl-7,14-diphenyl-1,4,8,11-tetraazacyclotetradecane-4,11-diacetate $(L^2)^{2-}$ has been structurally characterized by X-ray crystallography. The Ni(II)L^2 complex crystallizes in the monoclinic system, space group $P2_1/c$, with a = 12.981(8), b = 16.474(6), c = 14.262(7) Å and β = 98.81(4)°. The complex shows a distorted *cis*-geometry about the metal centre, the macrocyclic ligand being folded about a N-Ni-N axis, with the pendant arms coordinated *cis* to one another. The Ni(II)L^1 (where $(L^1)^{2-}$ is *meso*-5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane-4,11-diacetate) and Ni(II)L^2 complexes undergo reversible one-electron oxidation, with redox potentials of 0.717 and 0.766 V (vs. S.H.E.), respectively. Chemical oxidation of the complexes by peroxodisulfate obey overall second-order rate laws. Enthalpies and entropies of activation for Ni(II)L^1 are 38 ± 3 kJ mol^{-1} and –106 ± 9 J K^{-1} mol^{-1}; and for Ni(II)L^2 the corresponding values are 41 ± 5 kJ mol^{-1} and –126 ± 15 J K^{-1} mol^{-1}. Outer-sphere oxidation of Ni(II)L^1 by bis-(triazacyclononane)nickel(III) ($[Ni(III)(tacn)_2]^{3+}$) has been studied, and a self-exchange rate constant for the $[Ni(II)L^1]^{0/+}$ system has been estimated at 55 mol^{-1} dm^3 s^{-1}.

Key words: peroxodisulfate, nickel(II), dicarboxylato-pendant arm macrocycles, bis-(triazacyclononane)nickel(III), self-exchange rate.

Résumé : Faisant appel à la diffraction des rayons X, on a déterminé la structure du complexe de nickel(II) du macrocycle à chaîne latérale déprotoné 5,12-diméthyl-7,14-diphényl-1,4,8,11-tétraazacyclotétradécane-4,11-diacétate $(L^2)^{2-}$. Le complexe Ni(II)L^2 cristallise dans le système monoclinique, groupe d'espace $P2_1/c$, avec a = 12,981(8), b = 16,474(6) et c = 14,262(7) Å et β = 98,81(4)°. Le complexe présente une géométrie *cis* déformée autour de l'atome central neutre, le ligand macrocyclique étant replié autour d'un axe N-Ni-N, avec les chaînes latérales coordinées de façon *cis* l'une par rapport à l'autre. Les complexes de Ni(II)L^1 (dans lequel $(L^1)^{2-}$ est le *méso*-5,5,7,12,12,14-hexaméthyl-1,4,8,11-tétraazacyclotétradécane-4,11-diacétate) et le Ni(II)L^2 subissent chacun une oxydation réversible impliquant un électron et les potentiels redox sont respectivement de 0,717 et de 0,766 V (vs. S.H.E.). L'oxydation chimique des complexes par le peroxodisulfate se fait globalement en fonction des lois de vitesse du deuxième ordre. Les enthalpies et les entropies d'activation sont respectivement de 38 ± 3 kJ mol^{-1} et –106 ± 9 J K^{-1} mol^{-1} pour le Ni(II)L^1 et de 41 ± 5 kJ mol^{-1} et –126 ± 15 J K^{-1} mol^{-1} pour le Ni(II)L^2. On a aussi étudié l'oxydation du Ni(II)L^1 dans la couche externe par le bis(triazacyclononane)nickel(III) ($[Ni(III)(tach)_2]^{3+}$) et on a évalué la constante de vitesse d'autoéchange du système $[Ni(II)L^1]^{0/+}$, qui est de 55 mol^{-1} dm^3 s^{-1}.

Mots clés : peroxodisulfate, nickel(II), macrocycles à chaînes latérales dicarboxylato, bis(triazacyclononane)nickel(III), vitesse d'autoéchange.

Introduction

There is significant interest in the synthesis and properties of transition-metal polyazamacrocycles bearing pendant arms, particularly those having arms attached at the nitrogen atoms of the macrocycles (1). Some of these appendages, if they contain ligating atoms, can coordinate to the central metal ion. Most such functionalized macrocycles are often prepared by elaborate multistep procedures, with synthesis of partially functionalized macrocycles being more difficult than fully functionalized ones (2, 3). More recently, a "one-pot" method for producing polyazamacrocycles with appended cyclodextrins has been reported (4). Such complexes find application in ion-selectivity (5), electrocatalysis (6), and tumor-targetting (7). Pendant-arm macrocyclic complexes, because of their thermodynamic stability and ex-

tremely slow acid-dependent dissociation, have important radioimmunotherapeutic value (8, 9). While many studies examine the properties of amino-, nitro-, and pyridyl-arms, the majority involve carboxylate pendant arms (10).

The ability of polyazamacrocycles to stabilize transition-metal ions in unusual oxidation states has been well known for many years (11). We are interested in the redox behaviour of transition-metal macrocycles that contain pendant carboxylate arms, since these appendages coordinate to the central metal ion and may provide an inner-sphere pathway for electron transfer to, or from, other metal centres. Such behaviour has application, for example, in reductive dissolution of iron(III)-bearing ferrites, which constitute corrosion films found in industrial boilers and nuclear reactors (12). The present work reports the kinetics of oxidation of the nickel(II) complexes of two deprotonated carboxylato-pendant arm macrocycles (*meso*-5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane-4,11-diacetate $(L^1)^{2-}$) and (5,12-dimethyl-7,14-diphenyl-1,4,8,11-tetraazacyclotetradecane-4,11-diacetate $(L^2)^{2-}$) to the nickel(III) forms, by peroxodisulfate anion, $S_2O_8^{2-}$. Oxidation of the Ni(II)L^1 complex by the bis-(triazacyclononane)nickel(III) cation $[Ni(tacn)_2]^{3+}$ has also been studied. The X-ray crystal structure of Ni(II)L^2, which has not been reported in the literature, is also described.

L^1H_2

L^2H_2

Experimental

Materials

AnalaR grade potassium peroxodisulphate (BDH) was first washed several times with distilled water, then recrystallized four times from cold water, rinsed with ice water, and dried over P_4O_{10} in vacuo. This procedure was found necessary to obtain reproducible, clean kinetics. All other reagents and solvents were of AnalaR grade and were used without further purification. All solutions were prepared using double-distilled, deionized water.

Synthesis of ligands and complexes

1,4,7-Triazacyclononane (tacn), and its nickel(II) perchlorate complex were synthesized by a modified literature method (13). The functionalized macrocycles *meso*-5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane-1,7-diacetic acid (L^1H_2) and 5,12-dimethyl-7,14-diphenyl-1,4,8,11-tetraazacyclotetradecane-4,11-diacetic acid, (L^2H_2) were prepared according to the literature (14–16). The nickel(II) complex of the deprotonated macrocycle Ni(II)L^1 was prepared by the literature method as the hydrobromide monohydrate (15) and recrystallized from aqueous ethanol prior to use. Yield 70%. IR (KBr cm^{-1}): 3396 (OH), 3124 (NH), 1623 (COO^-). Anal. calcd. for $NiC_{20}H_{41}N_4O_5Br$ (monohydrate): C 43.19, H 7.45, N 10.10; found: C 43.38, H 7.57, N 10.34.

The Ni(II)L^2 complex (isolated as the dihydrate), was prepared as follows: to 250 mg (0.500 mmol) of L^2H_2 dissolved in 20 mL of water was added 238 mg (1.00 mmol) of $NiCl_2 \cdot 6H_2O$. The pH was adjusted to pH 5 with 0.1 mol dm^{-3} NaOH and the mixture was heated to reflux for 24 h. The solution was concentrated to approximately 5 mL and violet crystals precipitated. The crystals were collected, washed with cold water, and air dried to give 177 mg (43%) of product. IR (KBr cm^{-1}): 3448 (OH), 3232 (NH), 1604 (COO^-). Anal. calcd. for $NiC_{28}H_{42}N_4O_6$ (dihydrate): C 57.06, H 7.18, N 9.51; found: C 57.20, H 7.21, N 9.72.

X-ray crystallography

Violet crystals of Ni(II)L^2 suitable for structure determination were obtained from water–ethanol using the vapour diffusion method. The data were collected at a temperature of 26 ± 1°C on a Rigaku AFC6S diffractometer (MoK_α radiation, graphite monochromator) in the ω-2Θ scan mode to 2Θ = 50.1°. Lorentz and polarization corrections were applied. The structure was solved by direct methods (17) using the teXsan crystallographic software package (18). Refined parameters were calculated using anisotropic thermal parameters for nonhydrogen atoms and isotropic factors for all hydrogen atoms. A summary of crystal data is given in Table 1. Atomic positional parameters are given in Table 2 and selected bond lengths and angles are given in Table 3. The full description of the structurally determined thermal parameters, hydrogen atom positional parameters, and a full listing of bond distances and angles have been deposited as supplementary data.[2]

Cyclic voltammetry

Cyclic voltammograms of Ni(II)L^1 and Ni(II)L^2 were measured using a Princeton Applied Research model 482 fast-scanning electrochemical apparatus, in aq 0.10 M trifluoromethanesulphonic acid, under an argon atmosphere. A 1 mm diameter Pt disk working electrode, a platinum wire counter electrode, and a Ag/AgCl (sat. KCl) reference electrode were used.

Kinetics

All kinetics were performed under pseudo-first-order conditions, using an excess of oxidant. Due to the low solubility of the neutral complexes in water, all kinetics were performed

in 20% by volume aqueous ethanol. Because of the relatively low solubility of potassium peroxodisulfate, particularly in binary aqueous mixtures, the concentration range possible using that oxidant was limited. The concentration of the nickel(II) complexes used in all experiments was 5.00×10^{-6} mol dm^{-3}. For the peroxodisulfate experiments, absorbance changes with time were measured using 1 cm path length quartz cells in the thermostatted cell compartment of a Beckman DU-65 recording spectrophotometer. Data were collected using Beckman Datacapture software on an EmPac 386 microcomputer. Ionic strength was kept constant at 0.300 mol dm^{-3} for all kinetic runs, using potassium sulfate. Absorbance measurements were made at 350 nm.

The oxidation kinetics using $[Ni(tacn)_2]^{3+}$ were carried out at a constant ionic strength of 0.100 M, using $NaClO_4$–$HClO_4$. Kinetic measurements were made using a Tritech Dynamics Instruments stopped-flow spectrometer, using a Bausch & Lomb light source and monochromator. The apparatus was thermostatted to ±0.05°C, using a Haake circulating water bath. All solutions were prepared with distilled, deionized water. First-order rate constants (k_{obs}) were calculated from the slopes of linear regression plots of ln ($A_\infty - A_t$) vs. time. Reported values of k_{obs} are the means of at least three measurements. For any given set of conditions, repetitive measurements gave observed rate constant values invariant within 1%.

Stock solutions of $[Ni(tacn)_2]^{3+}$ were prepared freshly in situ for each set of kinetic runs, by oxidation of the nickel(II) form with a stoichiometric deficiency of Co^{3+}(aq).

Results

Structure of Ni(II)L^2

The nickel complex Ni(II)L^2 was found to be only sparingly soluble in pure water and pure ethanol, but was soluble in binary mixtures of these solvents. The complex formed from the ligand L^2H_2 and nickel(II) chloride is a neutral species, containing the deprotonated ligand in a *cis*-configuration. The crystal structure was found to have two waters of crystallization in the lattice. These waters occur in channels between the complexes and are strongly hydrogen bonded with each other, but not to either the nitrogens or the oxygens of the macrocyclic ligand. Both pendant carboxylate arms are coordinated to the central nickel(II) ion, in a slightly distorted octahedral arrangement. An ORTEP diagram of the complex is shown in Fig. 1. All Ni—O and Ni—N bond lengths are very similar (Table 3), close to 2.080 Å.

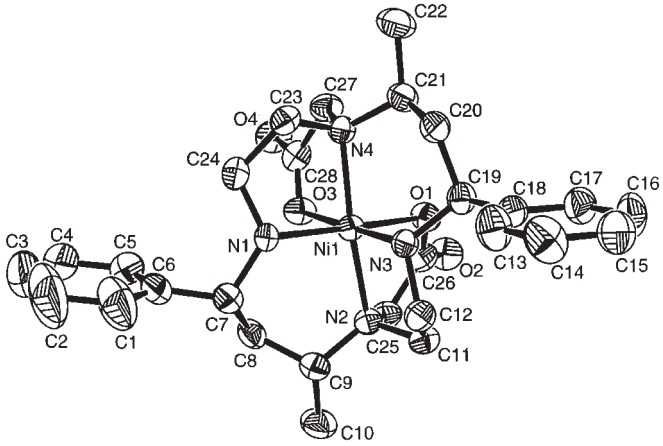
oxidations to the nickel(III) forms. The values of $E°$ for $Ni(II)L^1$ and $Ni(II)L^2$, respectively, are 0.717 V and 0.766 V (vs. S.H.E.) with peak separations of 64 ± 4 mV. The anodic and cathodic peak separations were independent of scan rate. The purity of these voltammograms, for both complexes, suggests that there is little change in geometry, and certainly no change in coordination, on oxidation. This is in keeping with the known tetragonally distorted octahedral coordination of nickel(III) macrocycles (11), and the known structures of the nickel(II) forms, as six-coordinate, high-spin d^8 systems. Addition of sulfate to the solution in the cyclic voltammetry experiments had no effect on redox potential or peak separation, indicating that the anion does not coordinate to either the oxidized or reduced form of the complex.

Kinetics



(a) Oxidation by $[Ni(tacn)_2]^{3+}$

The $Ni(II)L^1$ complex was oxidized by $[Ni(tacn)_2]^{3+}$ on the stopped-flow timescale. The reaction was found by spectrophotometric titration to have a 1:1 stoichiometry, and to obey a simple second-order rate law,

$$[1] \qquad \text{rate} = +d[Ni(III)L^1]/dt = k_1[Ni(tacn)_2{}^{3+}][Ni(II)L^1]$$

The reaction was found to be independent of acid over a range of added $[H^+]$ of 0–0.10 mol dm^{-3}. While this is quite a limited range, the ionic strength of the reaction solutions was 0.1 mol dm^{-3}, limiting the upper acid concentration. Separate experiments have shown that there are no spectral changes in solutions of $Ni(II)L^1$ in acid concentrations up to 0.50 mol dm^{-3}, suggesting no protonation–deprotonation equilibria are extant in these media. Hence, a lack of rate dependence on $[H^+]$ is not unexpected. The kinetic data are presented in Table 4. The activation enthalpy and entropy, calculated using the Eyring equation, were found to be 34 ± 4 kJ mol^{-1} and –63 ± 12 J K^{-1} mol^{-1}, respectively.

Fig. 1. ORTEP diagram of the $Ni(II)L^2$ molecule.

(b) Oxidation by $S_2O_8^{2-}$

The $Ni(II)L^1$ and $Ni(II)L^2$ complexes were oxidized smoothly to the tervalent state in 20% by volume aqueous ethanol. The ionic strength was maintained at 0.30 mol dm^{-3} using potassium sulfate. No acid dependence was examined, since the peroxodisulfate ion is known to protonate above $[H^+]$ = 0.01 mol dm^{-3} (19). Figure 3 shows the UV–vis spectral change during the oxidation of $Ni(II)L^1$. The strong peak at 300 nm (ε = 8000 mol^{-1} dm^3 cm^{-1}), with a shoulder at 400 nm (ε = 6000 mol^{-1} dm^3 cm^{-1}) is characteristic of nickel(III) polyazamacrocycles. An isosbestic point at 226 nm indicates that there is no build-up of intermediates during the oxidation. Excellent first-order kinetics were observed over at least five half-lives for the appearance of the nickel(III) products. Addition of the radical scavenger allyl acetate had no effect on the reaction rates. This gives further support for the lack of participation of sulfate radicals in the kinetics of the reactions. The overall reactions corresponds to:

$$[2] \qquad 2\ [Ni(II)L] + S_2O_8^{2-} \rightarrow 2\ [Ni(III)L]^+ + 2\ SO_4^{2-}$$

Tables 5 and 6 list the observed first-order rate constants for oxidation of the $Ni(II)L^1$ and $Ni(II)L^2$ complexes as a function of temperature and $S_2O_8^{2-}$ concentration. Figure 4 illustrates the linear dependence of k_{obs} on $S_2O_8^{2-}$ concentration for oxidation of the $Ni(II)L^1$ complex at several temperatures, showing the reaction to obey an overall second-order rate law. Eyring plots of the temperature-dependent data yielded $\Delta H^{\ddagger}$ = 38 ± 3 kJ mol^{-1}, $\Delta S^{\ddagger}$ = –106 ± 9 J K^{-1} mol^{-1} for $Ni(II)L^1$; and $\Delta H^{\ddagger}$ = 41 ± 5 kJ mol–1, $\Delta S^{\ddagger}$ = –126 ± 15 J K^{-1} mol^{-1} for $Ni(II)L^2$.

Discussion

Structures

A number of X-ray structures of transition-metals complexed by pendant-arm macrocycles similar to L^1 and L^2 are known. Xu et al. (15) have reported the structure of a *cis*-form of NiL^1. In that complex the Ni—N bonds were shorter (2.072, 2.073 Å) for the tertiary nitrogens than the secondary ones (2.091, 2.107 Å). The Ni—O bonds were quite different from each other (2.199, 2.065 Å). On inspection of the geometry about the metal centre, it may be surmised

that this difference is in part due to strain in the macrocycle on coordination to the metal. For example, the N-Ni-O angles, that would be 180° for a perfectly octahedral centre, are in fact 176.78° and 163.06°. For the *cis*-NiL^2 structure presented in the present paper, the metal—ligand bond lengths are all remarkably close to one another. For example, the two Ni—O lengths are 2.072 Å and 2.093 Å; the Ni—N lengths are 2.094, 2.078, and 2.084 Å. Also, there is

much less distortion from octahedral geometry, evidenced by the equatorial O-Ni-N angles of 178.6° and 174.6°.

Xu et al. (20) have also reported the structure of macrocycle and the aquanickel(II) complex of a mono-carboxylato-analogue of L^1. That complex takes up a *trans*-III configuration, with four nitrogens in a square plane and the carboxylato- and aqua-ligands in axial positions. In that case the Ni—N bonds were all similar (2.097, 2.093, 2.070, and 2.103 Å), and the Ni—O length (for the carboxylato-arm) was 2.065 Å, with only minor deviations from octahedral geometry. The mean Ni(II)—N bond length for octahedral NiN_6 moieties has been reported (21) to be 2.081 ± 0.026 Å. Hence, the bond lengths reported here for Ni(II)L^2 are not unusual.

The Ni(II)L^1 complex used for kinetic studies in this work has a *trans*-III conformation (22), similar to[3] $[CoL^1]^+$ and the Cu(II)L^2 complexes (15). Based on the electrochemical behaviour of Ni(II)L^1 and Ni(II)L^2, it is assumed that no major structural rearrangements occur on oxidation, and the nickel(III) forms of the two complexes are likely still *cis*- and *trans*-, respectively.

The possible structures and isomers of 14-membered hexamethyl tetraazamacrocycles have been thoroughly described in the past (22, 23). According to Curtis (22), *meso*-macrocycles form metal complexes in the *trans*-III configuration, i.e., the four nitrogen donor atoms are in a square planar arrangement, and the backbone of the macrocycle is in an overall chair conformation. Racemic forms of the macrocycle take up the *cis*-V conformation. Examples of complexes of L^1 and L^2, whose structures agree with Curtis' theory include the C-*meso*-[Cu(II)L^2] (*trans*-III) (16) and rac-[Ni(II)L^1] (*cis*-V). A seeming contradiction is the reported (24) rac-[Cu(II)L^1] complex, that has the *trans*-III configuration. Closer examination of the structure in that paper, however, reveals that the macrocycle was mislabelled, and is actually the *meso* form. In this work, we find that the rac-[Ni(II)L^2] occurs as the *cis*-V configuration, in agreement with Curtis' theory.

Redox mechanisms

$[Ni(tacn)_2]^{3+}$ is well known as an outer-sphere oxidant (25), whose redox reactions do not display acid dependence, unless the reductant undergoes protonation–deprotonation. Hence, this is a useful oxidant to probe the mechanism of electron-transfer from the nickel(II) pendant-arm macrocycles that are the focus of this study. The observed second-order rate law is expected for a system where both reactants are coordinatively saturated, in both oxidized and reduced forms. The measured activation parameters are typical of outer-sphere redox. Because the nickel(II) complexes are high-spin, six-coordinate and hence paramagnetic, and the nickel(III) form is necessarily paramagnetic (d^7), it is not possible to measure the self-exchange rates for the Ni(II)L^1 and Ni(II)L^2 complexes by the usual NMR (26) or EPR methods (27). However, we have been able to estimate the self-exchange rates, using Marcus Theory (28).

For an outer-sphere electron-transfer mechanism, the rate constant for the cross-reaction (k_{12}) is related to the rate constants for the self-exchange rates of the components (k_{11} and k_{22}) and the equilibrium constant K_{12} by the expression $k_{12} = (k_{11}\ k_{22}\ K_{12} f_{12})^{1/2} w_{12}$, where

$$\ln f_{12} = \frac{\left[\ln K_{12} + \left(\frac{w_{12} - w_{21}}{RT}\right)\right]^2}{4\left[\ln\left(\frac{k_{11}k_{22}}{A_{11}A_{22}}\right) + \left(\frac{w_{11} - w_{22}}{RT}\right)\right]}$$

$$w'_{12} = \exp\left[\left(\frac{-w_{12} + w_{21} - w_{11} - w_{22}}{2RT}\right)\right]$$

$$wij = \frac{Z_i Z_j\ e^2}{D_s \sigma_{ij}(1 + \beta\sigma_{ij}(\mu^{1/2}))}$$

$$A_{ij} = \frac{4\pi N \sigma^2 \upsilon b \gamma r}{1000_{ij}}$$

[3] R.I. Haines and R.J. Lucas. Unpublished observations.

w_{ij} is the work required to bring the ions i and j (with charges Z_i and Z_j, respectively) to the separation distance σ_{ij}. This distance is assumed to be equal to the sum of the radii of the ions i and j, β ($= 8\pi Ne^2/1000D_s kT)^{1/2}$, υb is the nuclear frequency that destroys an activated complex configuration, and γr is the thickness of the reaction layer (~0.8 Å); D_s is the dielectric constant of the medium. In the present reaction, where Ni(II)L^1 is neutral, the work terms will be negligible, so w'_{12} becomes unity. Hence, the cross-reaction rate constant may be estimated from the simplified Marcus relationship:

$$k_{12} = (k_{11}\ k_{22}\ K_{12}\ f_{12})^{1/2}$$

where, for small values of K_{12}, the term f is usually assumed to be unity (29). The value of k_{22}, the self-exchange rate for $[Ni(tacn)_2]^{3+}$, has been determined to be 6×10^3 s^{-1} (13). From the electrode potentials of Ni(II)L^1 and $[Ni(tacn)_2]^{2+}$, the K_{12} value is calculated to be 43. Using these values and the experimental value for the cross-reaction rate (k_{12}), the self-exchange rate for $[NiL^1]^{0/+}$ is calculated to be 55 mol^{-1} dm^3 s^{-1} (using $k_{11} = (k_{12}^2/k_{22}\ K_{22})$). For negligible work terms (vide supra) the value of f_{12} is estimated to be 1.13, using the expression $\ln f_{12} = (\ln K_{12})^2/4\ln(k_{11}k_{22})$. This has negligible effect on the estimate of k_{11}. The value for k_{11} is low compared to six-coordinate nickel(II/III) systems, containing the ligands tacn, 2,2′-bipyridyl (bipy), and 1,10-phenanthroline (phen), and their substituted derivatives (31). The self-exchange rates for these complexes have been estimated as 1500 mol^{-1} dm^3 s^{-1} for LL = bipy and phen (30). The self-exchange rate for $[Ni(cyclam)]^{2+/3+}$ has also been measured at 2000 mol^{-1} dm^3 s^{-1} (31). The value for $[NiL^1]^{0/+}$ estimated here is one to two orders of magnitude lower than other nickel systems. Such variations in self-exchange rates for metal complexes with different ligands has been considered reasonable (32). One significant difference between the complex in this study and those literature cases mentioned above is that the $[NiL^1]^{0/+}$ system contains a negatively charged ligand. Interestingly, the self-exchange rate for a nickel complex containing a deprotonated tripeptide has been estimated at 450 mol^{-1} dm^3 s^{-1} (33), which is much closer to that for $[NiL^1]^{0/+}$. We have assumed the reaction to be adiabatic, where the transmission coefficient (κ_{12}) is unity. Any nonadiabatic behaviour ($\kappa_{12} < 1$) would result in a higher calculated value of the self-exchange rate.

We have examined the kinetics of oxidation of both Ni(II)L^1 and Ni(II)L^2 complexes to their Ni(III) forms using peroxodisulfate. The general mechanism for oxidation of transition-metal complexes by the peroxodisulfate anion is well known (34). Reduction of peroxodisulfate characteristically proceeds via rate-determining fission of the peroxo-bond, a step that may be assisted by the presence of a metal ion. The general mechanism for oxidation of cationic nickel(II) macrocycles (35) by the peroxodisulfate anion is:

$$[3] \qquad [Ni(II)L]^{2+} + S_2O_8^{2-} \overset{K_{ip}}{\rightleftharpoons} \{Ni(II)L^{2+}, S_2O_8^{2-}\}$$

ion-pair

$$[4] \qquad \{Ni(II)L^{2+}, S_2O_8^{2-}\} \overset{k_4}{\rightarrow} [Ni(III)L]^{3+} + SO_4^{-} + SO_4^{2-}$$

$$[5] \qquad [Ni(II)L]^{2+} + SO_4^{-} \overset{\text{fast}}{\rightarrow} [Ni(III)L]^{3+} + SO_4^{2-}$$

For oxidation of nickel(II) complexes of neutral square planar macrocycles, the nickel(III) product is known to coordinate sulfate ion, forming the $[Ni(III)L(SO_4)]^+$ cation (36). In the present study, there are no vacant coordination sites at the metal, precluding the possibility of formation of a sulfato-adduct. The rate law derived from the above scheme is

$$[6] \qquad \text{Rate} = 2k_{obs}[Ni(II)L]_{tot} = \frac{2k_4K_{ip}[S_2O_8^{2-}][Ni(II)L]_{tot}}{1 + K_{ip}[S_2O_8^{2-}]}$$

Since the nickel(II) complexes are neutral there is expected to be little or no ion-pairing due to electrostatic effects. Under these conditions, the rate law simplifies to:

$$[7] \qquad \text{Rate} = 2k_7[Ni(II)L][S_2O_8^{2-}]$$

where $k_7 = k_4K_{ip}$. Tables 5 and 6 include values of the second-order rate constants for the two complexes, which differ by a factor of ca. 30 at similar temperatures. This may be attributable to differences in redox potentials, since Ni(II)L^1 is oxidized faster than Ni(II)L^2, and its redox potential is lower by 50 mV.

The activation parameters are very similar to one another, and follow the trend in activation parameters for oxidation of a wide range of transition-metal complexes by peroxodisulfate (35, 37–40), indicating a similar rate-determining step. This is primarily an outer-sphere electron transfer from the nickel(II) macrocycle to the oxidant, with concomitant peroxo-bond fissure. In this mechanism, electron transfer from the nickel complex will generate a positive charge on the neutral reductant, with concomitant increase in negative charge on the oxidant. The latter undergoes peroxo-bond elongation, forming a $^{-}O_3SO—SO_4^{2-}$ moiety in the transition-state, resulting in an increased charge separation. This will lead to increased electrostriction, resulting in a negative entropy. This prediction is supported by the experimentally determined activation entropy. An inner-sphere pathway, with electron transfer via the coordinated carboxylate arms, is not likely, since the oxidant is anionic and would not form a bridge. This is supported by the electrochemical experiments, which showed that the integrity of the six-coordinate environment about the nickel is unaffected by the presence of sulfate. Application of Marcus Theory is not feasible for peroxodisulfate oxidations since, while the oxidant's redox potential is very large (2.01 V) (41), predicting a very high reaction rate, the rates are actually slow, due to the dominant role played by peroxo-bond fissure in the process.

Complexes of L^1 and L^2 provide redox active systems where there is the facility for inner-sphere electron transfer to cationic oxidants, via a potentially bridging carboxylate pendant arm. Current studies in our laboratory are focussed on exploring the redox properties of these complexes with cationic oxidants, with application as inner-sphere reducing agents, for reductive dissolution of transition-metal oxides. Preliminary results on the oxidation of Fe^{II}(aq) and iodide ion by a mono-carboxylato-analogue of the $[Ni(III)L^1]^+$

The photochemistry of the 4-cyanobenzoic acid esters of *trans*- and *cis*-2-phenylcyclohexanol

J.A. Pincock, S. Rifai, and R. Stefanova

Abstract: Irradiation of *trans*-2-phenylcyclohexyl 4-cyanobenzoate (**4**) in methanol results in formation of the 1-phenylcyclohexene and 4-cyanobenzoic acid as the major products. The mechanism proposed for this example of the Norrish Type II-like reaction, normally inefficient for the π,π* state of esters, begins with intramolecular electron transfer in the excited singlet state. The next step, intramolecular proton transfer, is highly exergonic as a result of the increased acidity of the benzylic hydrogen of the radical cation and the increased basicity of the carbonyl oxygen of the radical anion. The final step is cleavage of the 1,4-biradical. This mechanism is proposed on the basis of product studies, absorption spectra, fluorescence spectra, oxidation and reduction potentials, and nanosecond laser flash photolysis spectra. The stereochemical requirements for the process have also been examined using solution NMR, the X-ray structure, and MM3 calculations. The stereoisomer, *cis*-2-phenylcyclohexyl 4-cyanobenzoate (**5**), undergoes *cis* to *trans* isomerization before photofragmentation. Photolysis of the *cis* isomer in methanol–OD demonstrated that the *cis* to *trans* isomerization occurred by inversion at C1.

Key words : Norrish Type II, aromatic esters, intramolecular electron transfer.

Résumé : Les produits majeurs qui se forment lors de l'irradiation du 4-cyanobenzoate de *trans*-2-phénylcyclohexyle (**4**) dans du méthanol sont le 1-phénylcyclohexène et l'acide 4-cyanobenzoïque. Le mécanisme proposé pour cet exemple de réaction de Norrish type II, normalement inefficace pour l'état π,π* des esters, débute par un transfert intramoléculaire d'électron dans l'état singulet excité. L'étape suivant, un transfert intramoléculaire de proton, est fortement exergonique en raison de l'augmentation de l'acidité de l'hydrogène benzylique du cation radical et d'une augmentation de la basicité de l'oxygène du carbonyle de l'anion radical. La dernière étape est un clivage du biradical-1,4. Ce mécanisme est proposé sur la base de l'étude des produits, des spectres d'absorption et de fluorescence, des potentiels d'oxydation et de réduction et des spectres de photolyse éclair au laser à nanoseconde. On a aussi examiné les exigences stéréochimiques du processus à l'aide de la RMN en solution, de la diffraction des rayons-X et de calculs MM3. Le stéréoisomère 4-cyanobenzoate du *cis*-phénylcyclohexyle (**5**) subit une isomérisation *cis* à *trans* avant la photofragmentation. La photolyse de l'isomère *cis* dans du méthanol–OD permet de démontrer que l'isomérisation *cis* à *trans* se produit par une inversion du C1.

Mots clés : Norrish Type II, esters aromatiques, transfert d'électron intramoléculaire.

[Traduit par la Rédaction]

Introduction

Recently, we have shown that the Norrish Type II-like[2] reaction, normally inefficient for the π,π* state of aromatic esters, proceeds readily if electron transfer in the excited state is favourable (1). Thus, 2-arylethyl 4-cyanobenzoates (**1a**–**c**) fragment on irradiation at 254 nm in either acetonitrile or methanol to give the styrene (**2a**–**c**) and 4-cyanobenzoic acid as the primary photoproducts (Scheme 1). The mechanism proposed proceeds through exergonic intramolecular electron transfer in the excited singlet state with the aryl ring being the donor and the aromatic ester the acceptor. Since the radical cation now has increased acidity and the radical anion increased basicity, proton transfer is now also exergonic. The 1,4-diradical (**3**), in parallel with the critical intermediate in the Norrish Type II reaction of aromatic ketones, then fragments into the two products. Thus, facile hydrogen atom transfer occurs by consecutive electron and proton transfer.

We now describe[3] the photochemistry of *trans*- and *cis*-2-phenylcyclohexyl 4-cyanobenzoate, (**4** and **5**), respectively, using the stereochemistry of these substrates as a probe to clarify the above mechanism. In addition, nanosecond laser

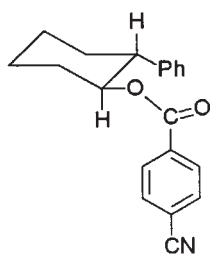
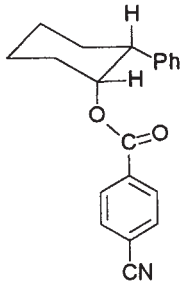
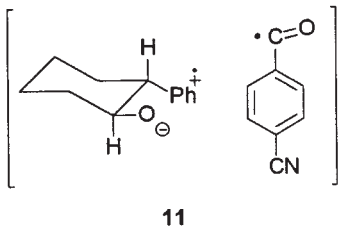
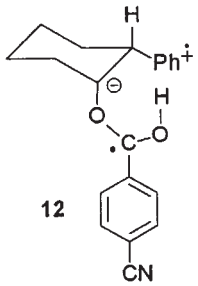


Scheme 1. Mechanism for the Norrish Type II reaction of aryl methyl esters induced by intramolecular electron transfer.





flash photolysis (LFP) results for both the cyclic (**4**) and acyclic (**1**) arylethyl esters will be described.



Results and discussion

Compounds **4** and **5** were synthesized from the corresponding alcohols (Aldrich) by condensation with 4-cyanobenzoic acid. In solution, the ^{1}H NMR spectra in $CDCl_3$ demonstrated that the phenyl group was equatorial for both compounds by observation of the axial–axial coupling (11.5 Hz) to two vicinal hydrogens for the hydrogen on the phenyl-substituted carbon in the *trans* isomer but only one (10.7 Hz) in the *cis*. The ester functionality is therefore equatorial in **4** but axial in **5**. X-ray structures of the two confirmed this observation for the solid state (Figs. 1 and 2).[4]

The UV spectra of these compounds indicated that there was essentially no interaction between these chromophores in the ground state. This was demonstrated by comparing an additive spectrum of toluene plus methyl 4-cyanobenzoate with *trans*-2-phenylcyclohexyl 4-cyanobenzoate (**4**), which has the same two chromophores. There is only a minor interaction between the two chromophores in the sense that the intensity of some vibrational modes are altered but there is no evidence for charge transfer absorption at longer wavelengths. The spectra for the *cis* isomer **5** were essentially the same.

In contrast to the absorption spectra, the fluorescence spectra of **4** and **5** are very much weaker than the model compound, toluene. The quantum yield of fluorescence at 280 nm for both is at least a factor of 1000 lower than that for toluene, suggesting intramolecular electron transfer quenching of the excited state. However, this observation cannot be interpreted easily because the 4-cyanobenzoate chromophore has a much higher extinction coefficient than the benzene ring and it does not fluoresce. For instance, the relative absorbance of the two is 7.9:1 at 267 nm, the excitation wavelength used for the fluorescence spectra. Therefore only about 11% of the light is absorbed by the emitting chromophore. Moreover, this emission at 280 nm will be reabsorbed by the 4-cyanobenzoate chromophore.

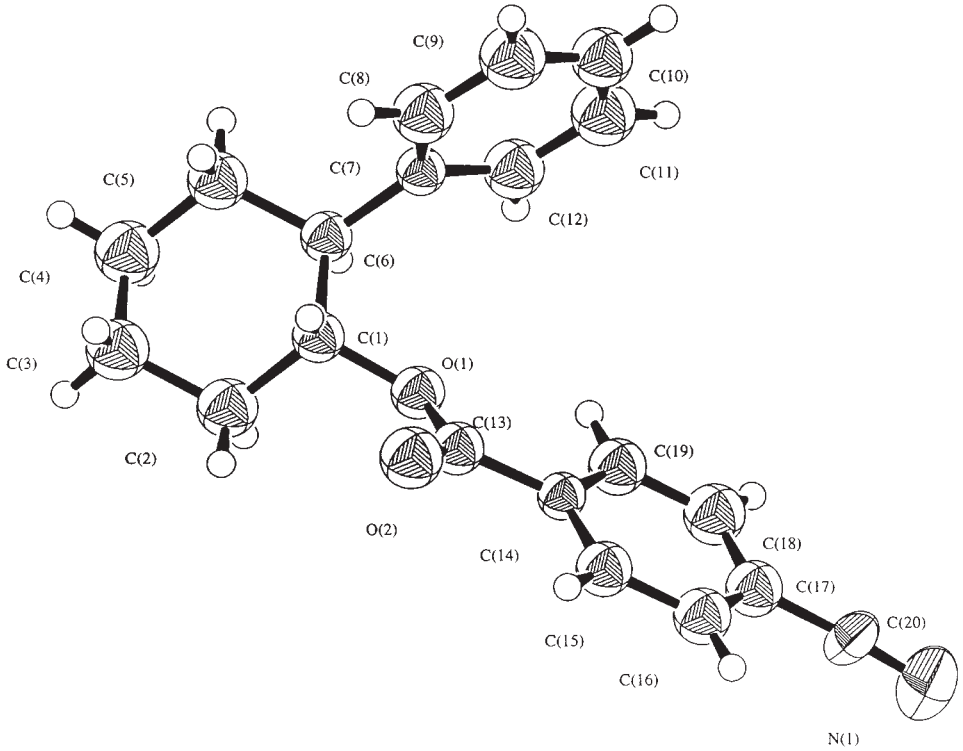

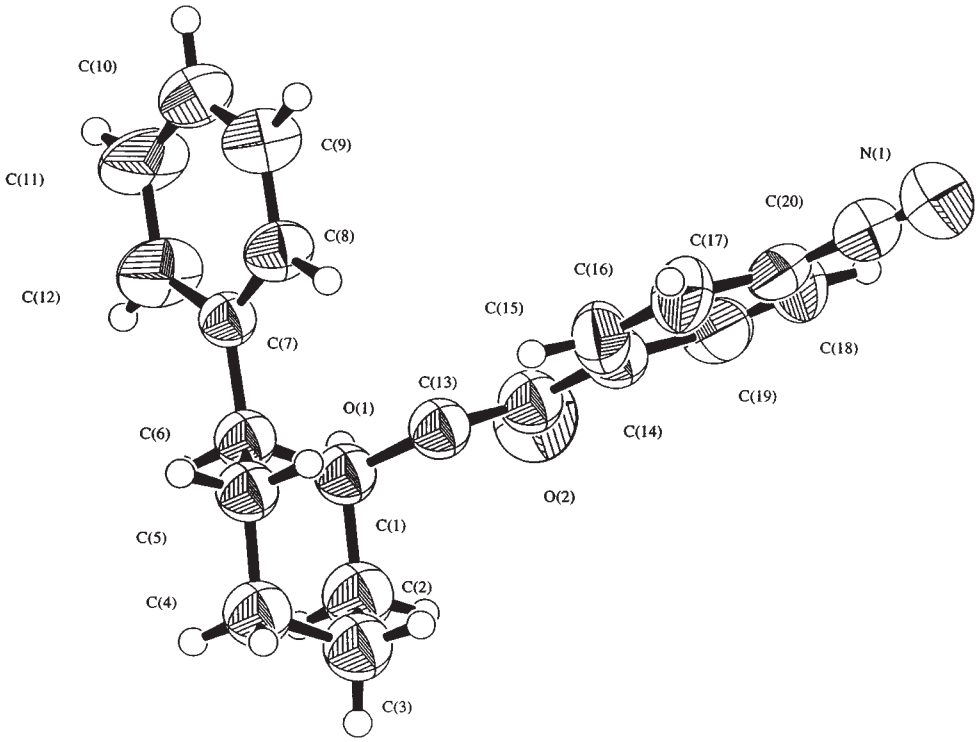

Fig. 2. X-ray crystal structures of **5**.

Since intramolecular electron transfer could not be demonstrated by flourescence quenching, redox potentials along with the Weller equation, eq. [1],[5] were used (2). The oxidation potential of the phenyl fragment of **4** and **5** was estimated at 2.4 V (vs. SCE), the value for toluene (3). The reduction potential of the 4-cyanobenzoate moiety was

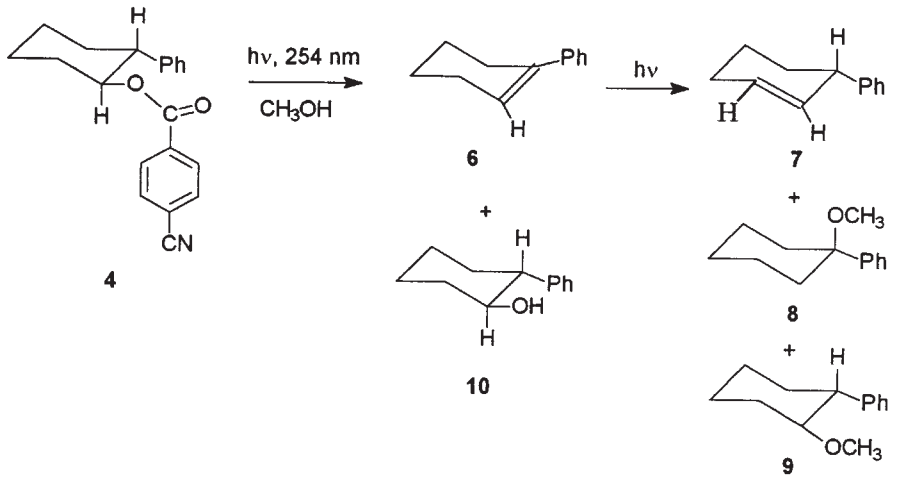
[5] Equation [1*a*] is the general equation, eq. [1*b*] to calculate ΔG_{et} in units of kcal mol^{-1} with the electrode potentials in V, the wavelength of excitation in nm, and the distance of separation of the ions in Å.

© 2001 NRC Canada

[1a] $\Delta G_{et} = (E_{ox} - E_{red}) - \Delta E_{o,o} - (NQ_1Q_2) / 4\pi\varepsilon_o\varepsilon r$

[1b] $\Delta G_{et}\,(\text{kcal/mol}) = 23.06(E_{ox} - E_{red}) - \frac{2.86 \times 10^{-4}}{\lambda\,(\text{nm})} - \frac{3.33 \times 10^{2}}{\varepsilon r\,(\text{Å})}$

estimated at 1.66 V (vs. SCE) on the basis of measured values (1) for the acyclic cases (**1a**–**c**). This value also agrees well with a value for methyl 4-cyanobenzoate (4) equal to 1.97 V (vs. $Ag/AgNO_3$) which can be corrected (5) to 1.67 V (vs. SCE). The singlet excitation energy (98.2 kcal mol^{-1}) was estimated from the first vibrational band in the absorption spectrum at 291 nm because the fluorescence emission was too weak to obtain a reliable (0,0) crossing. Using eq. [1], ΔG_{et} equals –4.8 kcal mol^{-1}, ignoring the Coulombic term (which will make the value more negative) because the distance (*r*) between the two charges is not certain. From the X-ray structures the centre-to-centre distance of the aromatic rings is 5.75 Å in **4** (the *trans* isomer) and 6.15 Å in **5** (the *cis* isomer) leading to values of the Coulombic term of –1.8 and –1.6 kcal mol^{-1}, respectively, using a value for the dielectric constant of methanol of 32.7 (6). However, molecular models indicate that these two rings can approach each other face-to-face to distances approaching contact for either of the isomers. The Coulombic term would now be –2.9 kcal mol^{-1} assuming a centre-to-centre distance of 3.5 Å, as estimated for the π-stacking distance in benzene itself (7). These geometries will be discussed further below.

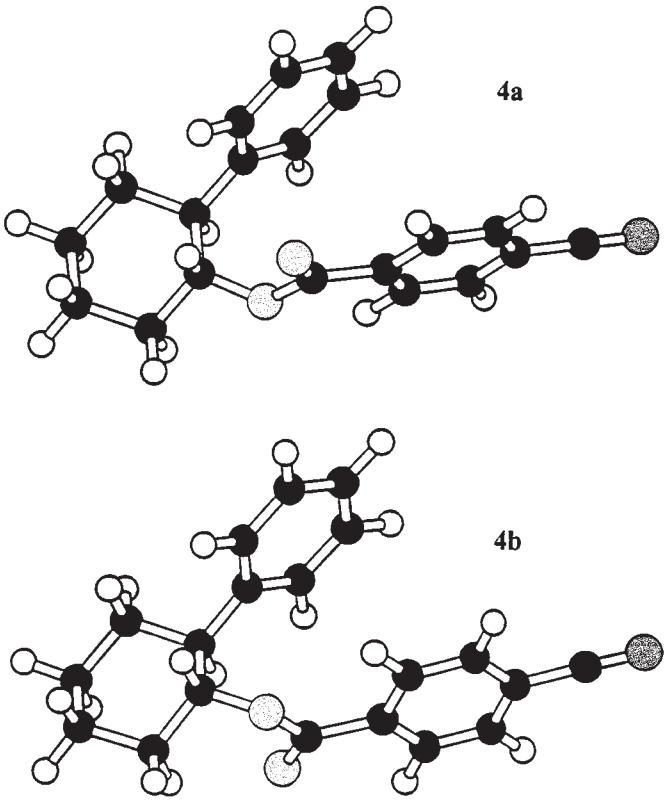


Photolysis of the *trans* isomer (**4**), in methanol (6.0 mM, 254 nm, N_2 purged, 25°C) resulted in a mixture of photoproducts **6**–**10** (eq. [2]) along with 4-cyanobenzoic acid and methyl 4-cyanobenzoate. To our surprise, the major expected product, 1-phenylcyclohexene (**6**), was observed in less than 1% yield even at very low conversions of **4**. That this was the major primary photoproduct was easily demonstrated by addition of 10 mol% of **6** to the reaction before photolysis began. Monitoring by GC indicated that the added **6** was converted to **7**, **8**, and **9**, before **4** began to disappear. This rapid secondary photochemistry of **6** is a result of the fact that **6** has a more strongly absorbing chromophore than the starting ester **4**. The ratio of (**7** + **8** + **9**):**10**, which reflects the ratio of the initial formation of **6**:**10**, was 3:1. The secondary products, **7**:**8**:**9**, were formed in the ratio of 52:34:14.

As expected, and as observed previously for the acyclic cases (**1**), the secondary photolysis of **6** is of three major types: (*i*) deconjugation to 3-phenylcyclohexene (**7**) by electron transfer sensitized formation of the radical cation as previously observed by Arnold and Mines (8) (the cyanobenzoate starting material or photoproducts are presumably the electron acceptor); (*ii*) photochemical *cis* to *trans* isomerization of **6** followed by Markovnikov addition of methanol to form **8** as discussed by Cozens et al. (9); (*iii*) electron transfer sensitized anti-Markovnikov addition of methanol to form **9**-*cis* and **9**-*trans* also as previously reported by Arnold and Shigemitsu (10).

The formation of the major primary photoproduct is consistent with our previously proposed mechanism (Scheme 1) of exergonic intramolecular electron transfer from the aryl ring to the 4-cyanobenzoate group followed by exergonic intramolecular photon transfer to form a 1,4-biradical which then cleaves to form **6**. In fact, photolysis of **4** in acetonitrile also lead to slow formation of **7**, again resulting from deconjugation of **6** by secondary photochemistry. The X-ray structure for the *trans* isomer (**4**) shown in Fig. 1, presents two stereochemical problems for this mechanism. First, the carbon—hydrogen bond at the benzylic carbon (C6—H)[6] has poor overlap with the SOMO of the radical cation of the aryl ring as a consequence of the almost parallel orientation of the π-orbitals of that equatorial group; the estimated dihedral angle (C=C-C6-H) is 13° in the solid. Arnold and coworkers (11) have previously shown that aryl methyl hydrogens in this orientation are not particularly acidic in the corresponding radical cations. Second, the carbonyl oxygen of the ester is remote from that hydrogen. Therefore, formation of 1-phenylcyclohexene by intramolecular hydrogen atom transfer should not be facile from this geometry.

In order to gain a better understanding of the conformation of **4** and **5** in solution, molecular mechanics calculations (MM3) were performed (Figs. 3 and 4). Three minima were obtained for rotation about the cyclohexyl carbon to ester oxygen single bond of **4** and two were found for **5**. For both compounds, these minima were very similar in energy indicating rather flat rotational surfaces. For the *trans* isomer, **4a** is the minimum, but only 0.5 kcal mol^{-1} lower than a structure that is essentially identical to the X-ray one. In addition,

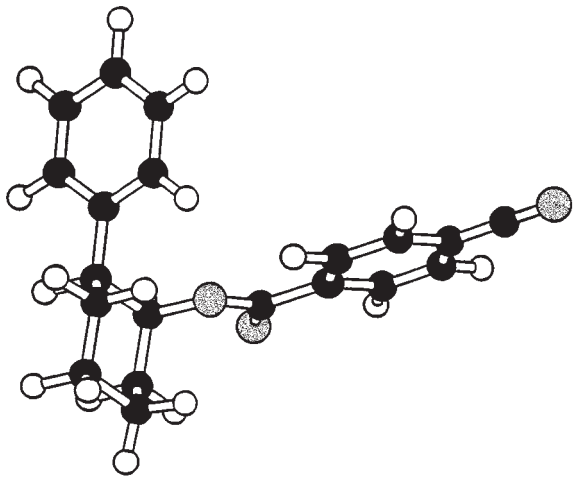


[2]

[6] Carbon atom numbering follows that of the X-ray strucures in Figs. 1 and 2.

© 2001 NRC Canada

Fig. 3. MM3 minimized geometries **4a** and **4b** with the phenyl group equatorial in both.



4b only 0.9 kcal mol^{-1} above the minimum, provides an ideal conformation for intramolecular abstraction of the aryl methyl hydrogen. Our conclusion for the mechanism of formation of 1-phenylcyclohexene is, therefore, that proton transfer occurs in the intramolecular radical ion pair created from S_1 of **4**. The formation of this radical ion pair by through-bond electron transfer is favoured by overlap of the π-system of the aryl methyl ring through the C6—C1 σ bond and then to the π-system of the cyanobenzoate moiety. The rotation from **4a** to **4b** may be aided by electrostatic attraction between the two aromatic rings ("harpooning") (12). Another possibility is that the population of the conformer **4b** is high enough to allow efficient reaction to occur. The activation energy for proton transfer is then lowered by the beginning of the rotation in the transition state of the aryl methyl ring as it approaches the geometry required for conjugation with the developing radical center at C6.

The other primary photoproduct for the photolysis of **4** is *trans*-2-phenylcyclohexanol (**10**). The fact that the original stereochemistry of the ester is maintained in this alcohol product suggests ester acyl C—O bond cleavage in the photochemical step. As has been observed previously (13), this reactivity is characteristic of the radical anions of esters, provided that the alkyl group does not form a stabilized radical. In the latter case, alkyl C—O bond cleavage occurs. The sequence of steps that converts the geminate pair **11** to **10** and methyl 4-cyanobenzoate is not known but may proceed by electron transfer to form the acylium cation and the alkoxide anion which are then trapped by methanol.

In order to strengthen these mechanistic arguments, nanosecond LFP experiments have been performed in methanol using a Nd:YAG laser with 266 nm excitation. For **1c**, **4**, and **5** strong transient absorbances at 300 nm were observed (Fig. 5 for **1c** and **4**) with very similar first order decays for **1c** (1.1×10^5 s^{-1}) and **4** (1.2×10^5 s^{-1}) but somewhat faster for **5** (7.7×10^5 s^{-1}). The same transient was observed for methyl 4-cyanobenzoate ($k_d = 1.4 \times 10^5$ s^{-1}) indicating that these species are not derived from the second chromophore in either **1c** or **4**. This absorbance was assigned to the triplet state of the cyanobenzoate chromophore on the basis of the observation that it was quenched by oxygen and by 2,3-dimethyl-1,3-butadiene. Stern–Volmer rate constants for the diene quenching of this transient derived from **1c** and methyl 4-cyanobenzoate were equal to 7.1×10^9 M^{-1} s^{-1} and 1.4×10^{10} M^{-1} s^{-1}, respectively, comparable to the estimated diffusional limit in methanol, 1.2×10^{10} M^{-1} s^{-1} (14).

Fig. 4. MM3 minimized geometry for **5**.

The radical anions of aromatic esters have been generated previously both by pulse radiolysis and photoinduced electron transfer using triethylamine as the donor (13). For instance, 266 nm excitation of ethyl benzoate in ethanol containing 0.1 M triethylamine gave a transient with maxima at 310 and 445 nm. It decayed with second order kinetics indicating that back electron transfer to the radical cation of triethylamine was the dominant pathway for its disappearance. We have also generated the radical anions of methyl 4-cyanobenzoate (**1c** and **4)** using 0.1 M triethylamine. A typical transient spectrum is shown for **4** in Fig. 6. The maxima have shifted to longer wavelength (360 and 490 nm) as a consequence of the nitrile group. The rate constant for first-order decay (inset) in methanol is 8.6×10^5 s^{-1}. We see no evidence for this signal on irradiation of any of the esters in the absence of the added donor, triethylamine.

Our conclusion from these LFP results is that the triplet state of methyl 4-cyanobenzoate is formed in the normal way by intersystem crossing from the singlet state. However, for the bichromophoric esters (**1c** and **4**) intramolecular electron transfer to form the radical ion pair from the excited singlet state is likely too fast to allow efficient intersystem crossing to the triplet state. As discussed above, this suggestion cannot be proven because intamolecular fluorescence quenching cannot be quantitatively monitored. However, the electron transfer is exergonic which normally guarantees that it will be rapid. Therefore, there must be competition in the

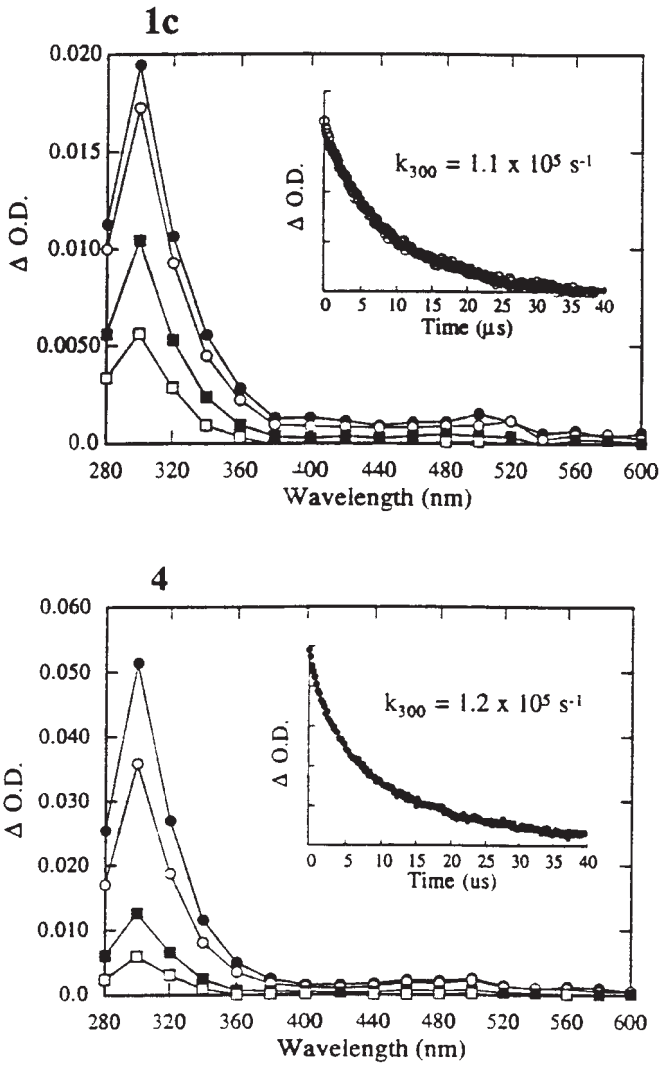
Fig. 5. Transient absorbance observed from **1c** and **4** after 266 nm excitation in methanol. Decay traces show first-order fits at 300 nm.



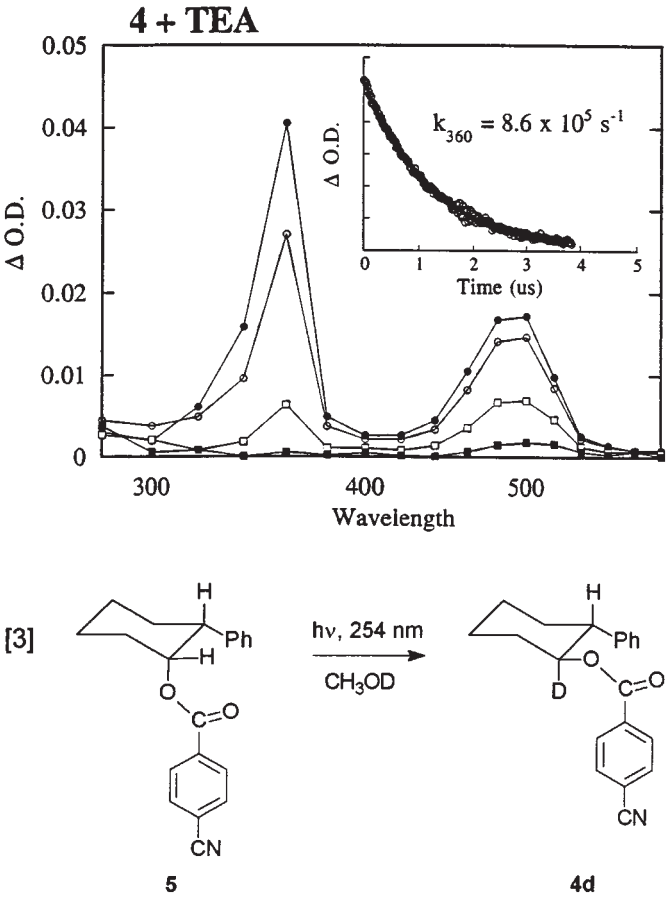


Fig. 6. Transient absorbance observed for **4b** + 0.1 M triethylamine after 266 nm excitation in methanol. Decay traces show first-order fit at 360 nm.

radical ion pair between proton transfer that leads to products and back electron transfer to form the triplet state. Back electron transfer to form triplet states has been observed previously in cases where it is energetically feasible (4, 15). This process is certainly possible for these esters because the excited singlet state, localized on the 4-cyanobenzoate chromophore, is at 98 kcal mol^{-1} and the radical ion pair at approximately 93 kcal mol^{-1} for **4** and 76 kcal mol^{-1} for **1c** (1). The excited triplet state of methyl 4-cyanobenzoate is at 72 kcal mol^{-1} (16) so that back electron transfer resulting in triplet state formation is highly exothermic for **1c** and slightly for **4**.

Finally, as expected on the basis of the X-ray structure (Fig. 2) and MM3 calculations (Fig. 4) for the *cis* isomer **5**, proton transfer in the intramolecular radical ion pair should be geometrically inhibited. In confirmation of this, photolysis of **5** resulted only in photoisomerization to the *trans* isomer **4** (eq. [3]) which then underwent the photochemistry described above. There are three likely mechanisms for this *cis* to *trans* isomerization process: (*i*) C—H bond cleavage at the ester carbon C1; (*ii*) C—H bond cleavage at the benzylic carbon C6; (*iii*) C1—C6 bond cleavage. Pathways 2 and 3 have been observed previously for the radical cations of phenyl substituted alkanes with oxygen substitution at the adjacent carbon (11); pathway 2 is preferred when the SOMO of the phenyl group has good overlap with the C—H bond and pathway 3 when the overlap occurs with the C—C bond. However, irradiation of the *cis* isomer **5** in methanol–OD resulted in formation of the *trans* isomer (**4d**) eq. [3] with deuterium incorporation at C1, that is, pathway 1, above. The fact that deuterium was being incorporated at C1 was initially determined by GC-MS. The molecular ions for these esters are very weak, but an ion corresponding to 1-phenylcyclohexene (*m*/*z* of 156) resulting from McLafferty fragmentation by loss of 4-cyanobenzoic acid, is quite strong. In the *trans* ester **4**, the ratio of *m*/*z* 158:159 = 5.7. After irradiation of the *cis* ester **5** in methanol–OD until the ratio of *trans*:*cis* was 23:77, the *trans* ester now had *m*/*z* 158:159 = 0.40 indicating a large increase in the deuterium content and an increased intensity for the M + 1 peak at 159. The mass spectral fragmentation requires abstraction of a hydrogen from C6, so the deuterium is most likely incorporated at C1. This was confirmed by ^{1}H NMR spectra of this mixture which indicated only the appearance of a signal for *trans* H6 at δ 2.8 but not H1 at δ 5.2. Moreover, the signal for H6 now showed only one large coupling constant to the

© 2001 NRC Canada

anti-hydrogen at C5 but not to the one at C1, which was now deuterium. A possible mechanism for isomerization and exchange is therefore abstraction of the hydrogen at C1 by the radical anion of the 4-cyanobenzoate group. This five-membered cyclic process leading to a distonic radical anion may be favoured by the bringing together of the two aromatic rings in the exciplex so that the ester carbonyl group is close to the C1 hydrogen. The mechanistic details of this exchange are not known but a species like **12** may rationalize the deuterium incorporation from methanol–OD and the *cis* to *trans* isomerization.

Experimental

1-Phenylcyclohexene, 1-phenylcyclohexanol, *trans*-2-phenylcyclohexanol and *cis*-2-phenylcyclohexanol were obtained from Aldrich. Authentic samples of 1-methoxy-1-phenylcyclohexane, *trans*- and *cis*-1-methoxy-2-phenylcyclohexane (**10**) were prepared by reaction of the alcohols with NaH in DMSO (dimethyl sulphoxide) followed by CH_3I. 3-Phenylcyclohexene was prepared by photochemical deconjugation of 1-phenylchclohexene as described previously (8).

Preparation of esters

The esters were prepared by the condensation of the corresponding alcohol (Aldrich) with 4-cyanobenzoic acid (Aldrich) using DCC in dichloromethane and DMAP as the catalyst as described by Neises and Steglich (17).

trans-*2-Phenylcyclohexyl 4-cyanobenzoate (**4**)*: mp 62–64°C (from dichloromethane–hexanes, 46% yield). GC-MS: *m/z* (%): 159 (12), 158 (100, 1-phenylcyclohexene), 143 (21), 131 (12), 130 (80), 129 (22), 115 (13) 102 (47), 91 (98), 75 (10). UV (CH_3OH) λ_{max} (ε): 239 nm (19 600 M^{-1} cm^{-1}), 282 (1470), 290 (1259). ^1H NMR (250 MHz, $CDCl_3$) δ: 7.86 (d, *J* = 8.4 Hz, 2H), 7.60 (d, *J* = 8.4 Hz, 2H), 7.2 (m, 3H), 7.25–7.10 (m, 3H), 5.19 (dt, *J* = 4.6, 10.5 Hz, 1H), 2.83 (dt, *J* = 3.8, 11.5 Hz, 1H), 2.28 (m, 1H), 2.05–1.77 (m, 3H), 1.75–1.30 (m, 4H). ^{13}C NMR ($CDCl_3$) δ: 164.2, 142.8, 134.4, 132.0, 129.8, 128.4, 127.4, 126.6, 118.0, 115.9, 78.0, 49.9, 33.7, 32.2, 25.8, 24.8. HR-MS calcd. for $C_{20}H_{19}NO_2$: 305.1416; found: 305.1421. X-Ray structure (Fig. 1).

cis-*2-Phenylcyclohexyl 4-cyanobenzoate (**5**)*: mp 92–94°C (from dichloromethane–hexane, 41% yield). GC-MS *m/z* (%): 158 (68, 1-phenylcyclohexene), 157 (12) 130 (60), 129 (14), 102 (37), 91 (100). UV (CH_3OH) λ_{max} (ε): 239 nm (22 100 M^{-1} cm^{-1}), 282 (1630), 290 (1340). ^1H NMR (250 MHz, $CDCl_3$) δ: 8.02 (d, *J* = 8.6 Hz, 2H), 7.71 (d, *J* = 8.6 Hz, 2H), 7.26–7.16 (m, 5H), 5.45 (bs, 1H), 2.93 (m, 2H), 2.4–2.1 (m, 2H), 2.02–1.50 (m, 6H). ^{13}C NMR ($CDCl_3$) δ: 163.9, 142.7, 134.6, 132.1, 129.8, 128.2, 127.5, 126.5, 118.0, 116.1, 75.1, 46.5, 30.7, 26.0, 25.8, 20.3. HR-MS calcd. for $C_{20}H_{19}NO_2$: 305.1416; found: 305.1405. X-Ray structure (Fig. 2).

Photolysis

In a typical reaction, 100 mg of **4** in 100 mL of HPLC grade methanol was irradiated in a quartz tube in a Rayonet reactor with 254 nm low-pressure mercury lamps while being purged with nitrogen. The reaction was thermostated at 25°C with an immersion circulating water tube. The reactions were monitored by GC on a 30 m × 0.25 mm J & W DB 200 column using helium as carrier gas (split) and temperature programming (60°C for 1 min, 15°C min^{-1} to 180°C, 180°C for 7 min). Standard samples of the products were used to monitor their appearance. Dark samples were checked for ground-state reactions but none were observed over the short times required for photolysis and analysis.

Laser flash photolysis

The nanosecond laser flash photolysis system at Dalhousie is of standard design using, as excitation source, the fourth harmonic from a Continuum Nd:Yag NY-61 laser (266 nm, ≤8 ns per pulse, ≤15 mJ per pulse).

X-Ray crystallographic analyses were performed on a AFC5R diffractometer with graphite monochromated Mo-K_α radiation and a rotating anode generator.

Thermodynamics of triaryltin chloride adduct complexes

Mozaffar Asadi and Khosrow Aein Jamshid

Abstract: The stability constants and the thermodynamic data were measured spectrophotometerically for 1:1 adduct formation of triaryltin chlorides, where aryl groups are *p*-chlorophenyl, phenyl, *p*-, *m*-, and *o*-tolyl, as Lewis acids, with chloride and bromide ions, as Lewis bases, in 50% v/v ethanol–water solvent. The stability constants and the thermodynamic parameters trend, confirmed the following softness trend of tin(IV) in the triaryltin chlorides:

$$(p\text{-}, m\text{-}, o\text{-tolyl})_3SnCl > (\text{phenyl})_3SnCl > (p\text{-chlorophenyl})_3SnCl$$

Key words: tin(IV) complexes, thermodynamic parameters, mixed solvent, adduct formation.

Résumé : Opérant dans des solutions aqueuses d'éthanol à 50 % v/v et faisant appel à la spectroscopie, on a mesuré les constantes de stabilité et les données thermodynamiques pour la formation de l'adduit 1:1 de chlorures de triarylétain (dans lesquels les groupes aryles sont *p*-chlorophényle, phényle, *p*-, *m*- et *o*-tolyle) agissant comme acides de Lewis avec les ions chlorure et bromure agissant comme bases de Lewis. Les constantes de stabilité et la tendance des paramètres thermodynamiques permet de confirmer la tendance suivante dans la mollesse de l'étain(IV) dans les chlorures de triarylétain:

$$(p\text{-}, m\text{- et } o\text{-tolyl})_3SnCl > (\text{phényl})_3SnCl > (p\text{-chlorophényl})_3SnCl$$

Mots clés : complexes d'étain(IV), paramètres thermodynamiques, solvant mixte, formation d'adduit.

[Traduit par la Rédaction]

Introduction

During the last decades there has been considerable interest in the behaviour of organotin halides as Lewis acids. While the tetraorganotin compounds show no evidence of Lewis acidity, the tin(IV) halides are strong Lewis acids which can produce 1:1 and 1:2 adducts in the presence of Lewis bases. The organotin halides R_nSnX_{4-n} are intermediate in Lewis acidity and found between R_4Sn and SnX_4. Generally the acidity is increased when the proportion of the halide is increased.

Recent studies have shown that mono-halides produce predominantly 1:1 adducts in solution with various monodentate bases such as TPPO, DMSO, and DMA (1), while di- and trihalides form a mixture of 1:1 and 1:2 adducts. The 1:1 adducts have been shown, by X-ray diffraction, to have trigonal bipyramid structures with the organo groups lying in the equatorial positions and the 1:2 adducts to have octahedral structures (2).

The thermodynamic data have been reported for 40 organotin compounds with Lewis bases in benzene solution at 30°C by means of calorimetric titration. It was shown that adduct stabilities enhance with increasing chloride substitution and in the order: Bu < Me < Ph (3).

Holecek et al. (4) have determined the stability constants and the thermodynamic parameters of complex formation of tri-*n*-butyl-, tribenzyl- and triphenyltin(IV) chlorides with pyridine, DMSO, and HMPA. Their studies showed that the stability of the complexes increases in the *R*-substituent series: *n*-butyl < benzyl < phenyl, and in the donor series: pyridine < DMSO < HMPA.

Fujiwara et al. (5) have investigated the reaction between Me_2SnCl_2 with DMF, DMSO, HMPA, and PINO. They have found that with DMF and DMSO (1:1), and HMPA and PINO (1:2) complexes have been formed in solution. The stability constants and $-\Delta H°$ values for these donors are depicted as following the order: DMSO > DMF and PINO > HMPA. The stability constants and $\Delta H°$ values for 1:2 complexes are larger than the 1:1 complexes.

In the present study, the stability constants and the thermodynamic parameters of complex formation of tri-*p*-chlorophenyl, triphenyl, tri-*p*-, tri-*m*- and tri-*o*-tolyltin(IV) chlorides with chloride and bromide bases in 50% v/v ethanol–water solvent have been obtained by using ultraviolet (UV) spectrophotometry in a effort to study the softness property of these triaryltin chlorides. The stability constants were recorded at 35, 45, 55, and 65°C spectrophotometrically

 DOI: 10.1139/cjc-79-1-70 © 2001 NRC Canada

by using Ketelaar's equation and the thermodynamic parameters were obtained by using the van't Hoff equation.

Experimental

Materials

Tetraphenyltin, *p*-bromotoluene, *m*-bromotoluene, *o*-bromotoluene, *p*-bromochlorophenyl, and all solvents were purchased from Merck and Fluka. Solvents that were used in the preparation of Grignard reagents were dried and distilled; all other materials were used without further purification. For the spectroscopy measurements pure NaCl, NaBr, and extra pure ethanol were used as obtained from Merck.

Instrumental

All of the scanning UV spectra were recorded by Philips PU 8750 spectrophotometer.

Synthesis of organotin compounds

The reaction of tintetrachloride with Grignard reagents gives the tetraaryltin compounds:

$$4RMgX + SnCl_4 \rightarrow R_4Sn + 4MgClX$$

The various triaryltin chlorides (Ar_3SnCl) were prepared in a similar manner to Kocheshkov et al. (6) and Stern and Becker (7) in which the tetraaryltin and tintetrachloride in the appropriate proportions are heated together and refluxed for a few hours at 200–210°C to give:

$$3R_4Sn + SnCl_4 \rightarrow 4R_3SnCl$$

The solid triaryltin chlorides were recrystallized from ethanol. The recorded melting point (7), UV (8) and ^{1}H NMR (9) spectra are in agreement with the literature reported values.

Preparation of solutions

The adduct complexes were obtained from the reaction of triaryltin chlorides with donors, according to the following reaction:

$$R_3SnCl + X^- \overset{\text{ethanol}-\text{water } 50\%}{\underset{X^- = Cl^-,\ Br^-}{\rightleftharpoons}} R_3SnClX^-$$

The solutions for spectroscopy measurements were prepared by dissolving 5×10^{-5} M of triaryltin chloride and 0.01–0.09 M of NaCl or NaBr, respectively, in 50% v/v ethanol–water. The triaryltin chloride concentration was kept constant in all solutions, while the donor concentrations varied with a coefficient of 20–200-fold of the acceptor for NaCl and NaBr, respectively. Solutions containing only donor species show no significant absorption.

The solution provided was allowed to stand at 35, 45, 55, and 65°C for 19, 10, 5, and 3 h, respectively. Ultimately, the solution was transferred into the thermostated cell compartment of the instrument, which was kept at constant temperature (±0.1°C) by circulating water, and absorption measurements were carried out at several fixed wavelengths. Scanning from 200 up to 350 nm using the PU-8750 spectrophotometer was performed at selected wavelengths. These wavelengths are listed for each system in Table 1. The fixed wavelengths which were chosen in the region that showed absorbance by the solutions. These absorptions varied with respect to wavelengths of the pure substrate alone. The adducts formed, and the Lewis acceptors show absorption in the same region, while donors show little or no absorption at all. The effect of ionic strength variations of the medium on the stability constants were found to be slight. All the syntheses and solutions preparation were carried out in a fume cupboard, because of to the toxicity of tin compounds.

Table 1. Wavelengths of Ar_3SnCl compounds.

Ar_3SnCl	λ_{nm} ($Ar_3SnClBr^-$)	λ_{nm} ($Ar_3SnCl_2^-$)
(p-Cl-C_6H_4)$_3$SnCl	226–232	226–230
(C_6H_5)$_3$SnCl	224–227	224–228
(p-CH_3-C_6H_4)$_3$SnCl	229–232	228–232
(m-CH_3-C_6H_4)$_3$SnCl	228–232	227–233
(o-CH_3-C_6H_4)$_3$SnCl	228–232	227–233

Results and discussion

The equilibrium constants of the various aryltin chloride complexes studied were calculated by using Ketelaar's (10) equation:

$$[1] \qquad \frac{C_A^\circ C_D^\circ}{A - A_A^\circ - A_D^\circ} = \frac{1}{\varepsilon_C - \varepsilon_A - \varepsilon_D} \times \left[\frac{1}{K} + (C_A^\circ + C_D^\circ)\right]$$

where C_A° and C_D° are the initial concentrations of the acceptor and the donor, respectively; A is the optical density of the solution including the acceptor and the donor, A_A° and A_D° are the optical densities of the pure acceptor and the pure donor in the solution of concentration C_A° and C_D°; ε_C, ε_A, and ε_D are the molar extinction coefficients of the complex, the acceptor, and the donor, respectively. K is the stability constant of the formed complex and the cell optical path length is 1 cm. A plot of $(C_A^\circ\ C_D^\circ)/(A - A_A^\circ - A_D^\circ)$ vs. $(C_A^\circ + C_D^\circ)$ should produce a straight line if only a 1:1 complex is formed, while a mixture of 1:1 and 1:2 or only 1:2 complex in a system would lead to a curve. The stability constants were calculated from the ratio of the slope to the intercept by least-square method using the Excel version 5 computer software. The variation of the stability constant values, particularly for the bromide ion, with the wavelength has led us to use the average value of K for a given system.

The thermodynamic parameters of the studied aryltin chloride complexes were calculated by use of the well known, van't Hoff equation.

$$[2] \qquad \ln K = \frac{-\Delta H^\circ}{RT} + \frac{\Delta S^\circ}{R}$$

where K is the stability constant, R is the gas constant and T is the temperature in degrees Kelvin. While, the thermodynamic parameters of the aryltin chloride complexes were obtained from the linear plots of ln K vs. 1/T. The values of ΔH° and ΔS° were obtained from the slope and the intercept, respectively, by using the Excel version 5 computer program.

The stability constants and the thermodynamic parameters data are collected in Tables 2, 3, 4. The mean of stability constants are given for the 1:1 adducts formation. The

formation of 1:1 adducts for triorganotin halides was supported by previous works (11, 12). Previous studies have also showed that triaryltin chlorides form 1:1 adducts with monodentate donors (13).

In the present studies of triaryltin chlorides, efforts were made to provide a quantitative measurement of the behaviour of tin in our compounds. In some of them, in addition to the resonance and electronegative inductive effects of substituted phenyl rings, steric interactions effect may also contribute to the stability constants of these compounds when chloride and bromide ions are used as Lewis bases. The experimental data are explained as follows:

The acceptor property of tin

In some of these aryltin chlorides, in addition to the resonance and electronegative inductive effects of the substituted phenyl rings, steric effects may also contribute to the stability constants of these compounds. The electron-withdrawing or electron-releasing property of substituent groups on a phenyl ring, in the substituted phenyltin chlorides, can influence the softness property of the corresponding central tin atom with respect to the triphenyltin chloride through *d—p* bonding. The presence of a Cl^- electron-withdrawing group causes the $Cl\text{-}C_6H_4^-$ to become a harder ligand than the $C_6H_5^-$ group. Therefore, the tin atom in $(p\text{-}Cl\text{-}C_6H_4)_3SnCl$ has more acceptor property than $(C_6H_5)_3SnCl$, and forms a more stable complex with the donors. Since the electron releasing group, CH_3, on the phenyl rings increases the electron releasing character of phenyl groups to the central tin atom (via induction, resonance, or both), the $(p\text{-}CH_3\text{-}C_6H_4)_3SnCl$ compound has less acceptor properties than $(C_6H_5)_3SnCl$ and hence, forms a less stable complex with the donors. On the basis of what has been described above, the following sequence can be proposed for the soft acid property of triaryltin chlorides which is confirmed with $\Delta G°$ (35°C) and K_{av} (35°C) values of the acceptors with Br^-:

$$(p\text{-}Cl\text{-}C_6H_4)_3SnCl < (C_6H_5)_3SnCl < (p\text{-}CH_3\text{-}C_6H_4)_3SnCl$$

Table 4. $\Delta H°$ and $\Delta S°$ values for Ar_3SnCl with Cl^-, Br^- in 50% v/v ethanol–water solvent.

Ar_3SnCl	$\Delta S°$ (J K^{-1} mol^{-1})	$\Delta H°$ (kJ mol^{-1})
$Ar_3SnCl_2^-$		
p-Chlorophenyl	64.90 ± 2.38	9.20 ± 0.77
Phenyl	72.92 ± 2.51	12.25 ± 0.81
p-Tolyl	77.23 ± 3.29	14.16 ± 1.06
m-Tolyl	76.45 ± 4.55	14.01 ± 1.47
o-Tolyl	75.67 ± 1.79	14.19 ± 0.58
$Ar_3SnClBr^-$		
p-Chlorophenyl	71.23 ± 1.04	10.25 ± 0.33
Phenyl	76.78 ± 4.80	12.70 ± 1.55
p-Tolyl	91.62 ± 7.82	17.86 ± 2.52
m-Tolyl	87.60 ± 6.71	16.67 ± 2.17
o-Tolyl	79.10 ± 7.55	14.41 ± 2.44

In the case of $(p\text{-}CH_3C_6H_4)_3SnCl$, $(m\text{-}CH_3C_6H_4)_3SnCl$, and $(o\text{-}CH_3C_6H_4)_3SnCl$, the existence of a methyl electron-releasing group caused the increasing extent of charge transfer, as the result of hyperconjugation and inductive effects, from the π-orbitals of the benzene ring to the *d*-orbitals of the tin atom. Therefore these compounds have less acceptor properties than $(C_6H_5)_3SnCl$ and form less stable complexes with donors. But according to steric effects, the stability of complexes decreases with increases in steric effects. On the basis of what has been described above the following sequence can be proposed for the complex formation of triaryltin chlorides which is confirmed by $\Delta G°$ (35°C) and K_{av} (35°C) values of the acceptor with Br^-:

$$(p\text{-}CH_3\text{-}C_6H_4)_3SnCl > (m\text{-}CH_3\text{-}C_6H_4)_3SnCl > (o\text{-}CH_3\text{-}C_6H_4)_3SnCl$$

$\Delta G°$ (kJ mol^{-1}) –10.37 : –10.32 : –9.97

K_{av} (M) 57.27 : 54.86 : 47.79

Effect of donors

In this work we have two donors (Cl^-) and (Br^-). In Pearson's classification, (14) Cl^- is a hard base and Br^- is a borderline base. According to Pearson's rules (14) soft acids such as triaryltin chlorides form more a stable complex with the softer base, Br^-. As far as the Sn-Cl hydrolysis is concerned, no experimental evidence is accessible. It is believed that in solutions of the substrates in the presence of high concentrations of Cl^- or Br^- ions (≥10-fold in excess to the substrate) the hydrolysis is so slow that it does not intervene in the experiments. This is probably attributed to the lower absolute hardness (η) of Cl^- and Br^- with respect to H_2O (15, 16). On the basis of this description the following sequence was confirmed by $\Delta G°$ (35°C) and K_{av} (35°C) values for the interaction of $(C_6H_5)_3SnCl$ with Cl^- and Br^-:

$$(C_6H_5)_3SnCl\text{-}Br^- > (C_6H_5)_3SnCl\text{-}Cl^-$$

$\Delta G°$ (kJ mol^{-1}) –10.96 : –10.22

K_{av} (M) 70.78 : 53.76

Effect of solvent

In this work we have used 50% v/v ethanol–water solvent, which is a hard solvent. According to Ahrland (17), a hard solvent binds strongly with hard acceptors and donors. On the other hand this solvent forms weak bonds with soft acceptors and donors. The formation of a complex requires that the bonds between solvent molecules with the acceptor and the donor have to be broken. Therefore, complex formation with the softer donor, Br^-, is preferred. This is confirmed by $-\Delta G°$ (35°C) values of $(C_6H_5)_3SnCl$ with Cl^- and Br^- shown above.

The $\Delta H°$ value and its sign is dependent on two factors: one of these factors is the solvation effect; the other one is the heat of the formation of the complexes (17). The solvation effect for triaryltin chlorides is not important due to the neutrality of these compounds. Since the donor in our series of compounds is constant, the solvation effect is also constant. In the case of $(p\text{-}Cl\text{-}C_6H_4)_3SnCl$, $(C_6H_5)_3SnCl$, and $(p\text{-}CH_3\text{-}C_6H_4)_3SnCl$, the $\Delta H°$ values are predominantly governed by the heat of formation and the solubility of the complexes. Their values increase with increasing softness of the compounds. This is confirmed by the following $\Delta H°$ values of triaryltin chlorides with Br^-:

$$(p\text{-}Cl\text{-}C_6H_4)_3SnCl < (C_6H_5)_3SnCl < (p\text{-}CH_3\text{-}C_6H_4)_3SnCl$$

$\Delta H°$ (kJ mol^{-1}) 10.25 : 12.70 : 17.86

In the case of $(p\text{-}CH_3\text{-}C_6H_4)_3SnCl$, $(m\text{-}CH_3\text{-}C_6H_4)_3SnCl$, and $(o\text{-}CH_3\text{-}C_6H_4)_3SnCl$, according to the first and second factors and also the solubility of the complexes, the $\Delta H°$ values decrease with increasing solubility of the complexes. This is confirmed by the following $\Delta H°$ values of triaryltin chlorides with Br^-:

$$(p\text{-}CH_3\text{-}C_6H_4)_3SnCl > (m\text{-}CH_3\text{-}C_6H_4)_3SnCl > (o\text{-}CH_3\text{-}C_6H_4)_3SnCl$$

$\Delta H°$ (kJ mol^{-1}) 17.86 : 16.67 : 14.41

The K_{av} and $\Delta H°$ values signify that the complex formation between the acceptors and the Br^- ion is preferred, $\Delta H°$ values of the complexes with Br^- are higher than ones with Cl^-. This is confirmed by the following $\Delta H°$ values of triphenyltin chloride with Cl^- and Br^- ions:

$$(C_6H_5)_3SnCl\text{-}Br^- > (C_6H_5)_3SnCl\text{-}Cl^-$$

$\Delta H°$ (kJ mol^{-1}) 12.70 : 12.25

The $\Delta S°$ value and its sign is also dependent on two factors: one of these factors is the difference in the number of particles of the initial substances and the product complexes; the other one is the liberation of solvent molecules from the solvation shells (17). With respect to the first factor, the net entropy change is great and has a positive sign. The solvation effect and, therefore, the liberation of solvent molecules from the solvation shells for triaryltin chlorides is not an important factor, due to the neutrality of these compounds. Since the donor in our series is constant, the solvation effect is constant too. From the above description and also from

© 2001 NRC Canada

the solubility of the complexes, the following order of $\Delta S°$ values for aryltin complexes is confirmed:

$$(p\text{-Cl-}C_6H_4)_3SnCl < (C_6H_5)_3SnCl < (p\text{-}CH_3\text{-}C_6H_4)_3SnCl$$

$\Delta S°$ (J K^{-1} mol^{-1}) 71.23 : 76.78 : 91.62

$$(p\text{-}CH_3\text{-}C_6H_4)_3SnCl > (m\text{-}CH_3\text{-}C_6H_4)_3SnCl > (o\text{-}CH_3\text{-}C_6H_4)_3SnCl$$

$\Delta S°$ (J K^{-1} mol^{-1}) 91.62 : 87.60 : 79.10

As a matter of fact the complex formation between the acceptors and the Br^- ion is more favourable and due to the second factor, $\Delta S°$ values of the complexes with Br^- are higher than with Cl^-. This is confirmed by the following $\Delta S°$ values for $(C_6H_5)_3SnCl$ with Cl^- and Br^- ions:

$$(C_6H_5)_3SnCl\text{-}Br^- > (C_6H_5)_3SnCl\text{-}Cl^-$$

$\Delta S°$ (J K^{-1} mol^{-1}) 76.78 : 72.92

Conclusions

In this work efforts were made to provide a quantitative measure of the softness character of tin(IV) in some triaryltin chlorides, such as tri-*p*-, -*m*-, -*o*-tolyl, triphenyl, and tri-*p*-chlorophenyltin chlorides, through adduct formation with Cl^- and Br^- ions in 50% v/v ethanol–water. The stability constants and the thermodynamic parameters obtained spectrophotometrically have shown the following softness trend of R_3SnCl:

R = *p*-, *m*-, *o*-tolyl > phenyl > *p*-chlorophenyl

Precipitation from alkaline aqueous aluminosilicate solutions

Michael R. North, M. Alejandra Fleischer, and Thomas W. Swaddle

Abstract: The longevity of metastable, highly alkaline Na and K aluminosilicate solutions has been examined over a wide range of Si/Al concentration ratios R ($0.04 \leq R \leq 20$) at 24°C and, in selected cases, at 50 and 75°C. In general, the longest solution lifetimes (t_{ppt}) (several weeks) were found at 24°C and for the highest alkalinities and (or) large R, but long t_{ppt} were also found for $R = 1.0$ at the lower alkalinities. Solution lifetimes generally shortened when the temperature was raised, but the opposite effect was observed with the smaller Al concentrations when $2 \leq R \leq 6$. These results are interpreted in terms of the requirement for ≡Si-OH groups for precipitate growth by condensation and of the relatively high solubility (few nuclei for gel growth) of the aluminosilicate solutes when $R = 1.0$.

Key Words: aluminosilicates, precipitation kinetics, aluminates, aqueous silicates, gelation, Bayer process, zeolite synthesis.

Résumé : Opérant à 24°C (et quelquefois à 50 et à 75°C) et à des rapports (R) de concentration de Si/Al allant de (0,04 à 20), on a déterminé la longévité de solutions métastables et fortement alcalines d'aluminosilicates de Na et de K. En général, les temps de vie en solution les plus longs, t_{ppt} (qui peuvent aller jusqu'à plusieurs semaines), sont observés à 24°C, avec les alcalinités les plus élevées et/ou des valeurs de R élevées; toutefois, aux alcalinités plus faibles, on a aussi observé des valeurs élevées de t_{ppt} lorsque $R = 1,0$. Une augmentation de la température a comme effet de raccourcir les temps de vie en solution; on a toutefois observé l'effet contraire à des concentrations plus faibles d'aluminium quand la valeur de R se situe entre 2 et 6. On interprète ces résultats en fonction de la taille des groupes ≡Si-OH sur la croissance du précipité par condensation et en fonction de la solubilité relativement élevée (peu de noyaux pour la croissance du gel) des solutés aluminosilicates quand $R = 1,0$.

Mots clés : aluminosilicates, cinétique de la précipitation, aluminates, silicates aqueux, gélation, processus de Bayer, synthèse de zéolites.

[Traduit par la Rédaction]

Introduction

Although aluminosilicates are generally very insoluble in water, metastable alkaline aluminosilicate solutions can be involved in many industrial processes (1); for example, in the Bayer process for refining bauxite for aluminum production (2, 3), scale formation in kraft papermaking (4), the setting of Portland cements (5), the exploitation of oil sands by steam injection (6), and the hydrothermal synthesis of zeolites (7–9). The mixing of alkaline aluminate and silicate solutions in particular concentrations typically brings about the formation of aluminosilicate gels (or, less commonly, granular precipitates) which, upon heating in contact with the supernatant solution, are converted to solid zeolites or related materials such as cancrinite (9). Gelation or precipitation may, however, be delayed for long periods depending upon the Al and Si concentrations, the pH, the temperature, and the nature of the cation(s) (10–13), with obvious implications for the carryover of Si in the Bayer process or aluminosilicate scaling. Like the parent aluminosilicate solutions, zeolites are themselves metastable, so that the solution-mediated synthesis of a particular zeolite is largely a matter of kinetic control, involving both the precipitation rate and the rates of silicate or aluminate exchange in the silicate and aluminosilicate solute species (14, 15).

Knowledge of the longevity of aluminosilicate solutions is therefore of intrinsic value, but has been of special interest to us as a prerequisite for study of the speciation and substitution kinetics of aqueous aluminosilicates by ^{29}Si or ^{27}Al NMR spectroscopy (1, 14, 15) for which the prepared solutions must remain stable over the often lengthy spectral accumulation times. For meaningful kinetic studies, it is necessary to limit the number of Si-containing solute species. This can be achieved by maintaining very high alkalinities and (or) elevated temperatures (1). The precipitation studies of Dent Glasser and Harvey (10–12) covered ambient-temperature cases in which the total alkali concentrations ranged up to 5 mol L^{-1} and the $[Si^{IV}]/[Al^{III}]$ ratio R varied from 1 to 8. We report here precipitation time measurements at 24°C for Na and K aluminosilicate solutions over extended ranges of pH with R values ranging from 0.04 to 20, and, in a few cases, at moderately elevated temperatures. These simple experiments involved noting the approximate time (t_{ppt})

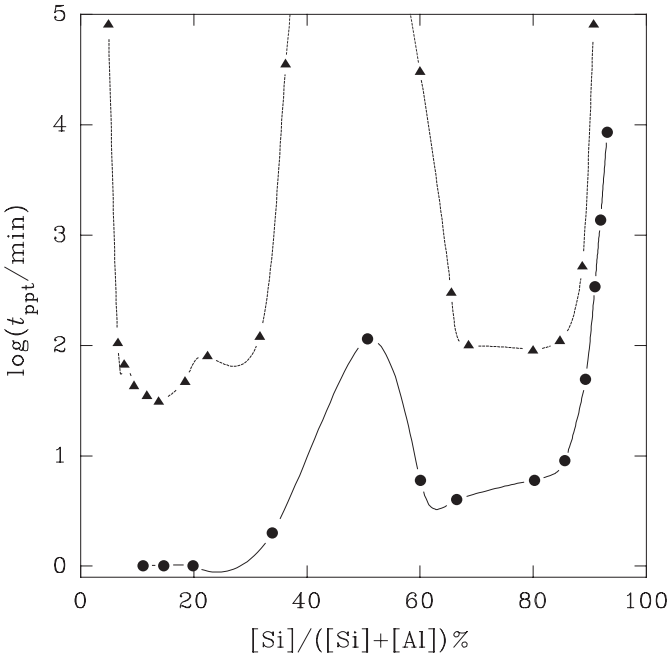
elapsed between mixing aluminate and silicate solutions and the first visible signs (if any) of gel or precipitate formation. No detailed kinetic analysis was intended; nevertheless, some useful generalizations emerged.

Experimental

All solutions were handled in polyethylene or Teflon™-FEP containers. Amorphous silica was prepared by dropwise hydrolysis of freshly distilled silicon tetrachloride (Fisher Scientific, technical grade) in water. The resultant gel was dried, crushed, washed with water, and oven dried at 250°C. Sodium and potassium hydroxides (BDH assured ACS reagent grade) and high-purity aluminum (Spex) were used as received. Stock NaOH and KOH solutions were prepared by dissolving the hydroxide pellets in freshly degassed deionized water and standardized by titration with potassium hydrogen phthalate. Stock silicate and aluminate solutions were prepared by dissolving silica or aluminum in portions of the stock hydroxide solutions. The use of glassware, which can dissolve in and contaminate highly alkaline media, was strictly avoided.

Test solutions were prepared in Teflon™ tubes by mixing a weighed amount of silicate stock solution with a prepared aluminate solution, the alkalinity of which had been adjusted by mixing with a known amount of stock NaOH or KOH solution. Solution compositions are definitively expressed in terms of the initial concentrations of M_2O (M = K or Na), SiO_2, and Al_2O_3 in mol kg^{-1} of H_2O, the latter including H from all sources to avoid ambiguities arising from the unknown degrees of deprotonation of the hydroxosilicate species. Following mixing, the aluminosilicate solutions were shaken vigorously and sealed. Precipitation times (t_{ppt}) to the visible formation of either a granular precipitate or a gel were then noted with the solution samples either standing on the bench (24.0 ± 1.5°C) or immersed in a thermostat bath (50.0 or 75.0 ± 0.1°C).



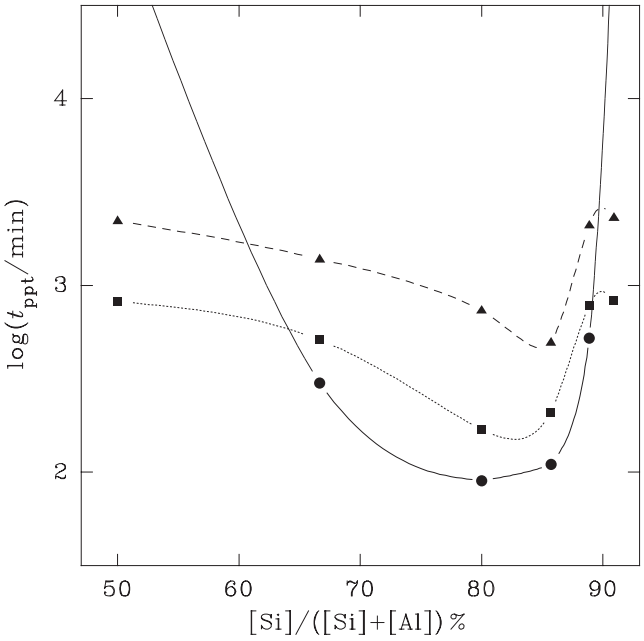
In some cases, the order of mixing the aluminate and silicate solutions was found to affect the measured t_{ppt}. The longer t_{ppt} were always obtained when the dominant reactant (silicate or aluminate) was added to the other, followed by thorough mixing. In the experiments described below, all solutions for which $R \geq 1.0$ were therefore prepared by adding the silicate solutions to the aluminate solutions, and vice versa for $R < 1.0$.

The Si-dominant side of each series was examined by preparing stock solutions of a fixed initial $[M_2O]$ and then performing a series of experiments at a constant $[Al_2O_3]$ while varying the [Si]/[Al] ratio R by varying $[SiO_2]$. In a similar fashion, the Al dominant side was explored by maintaining a constant $[SiO_2]$ while varying $[Al_2O_3]$. Alkali concentrations of 1, 3, 5, and 9 mol kg^{-1} K_2O, and 1, 3, 5, and 7 mol kg^{-1} Na_2O, were examined at room temperature at various concentrations of silicate and aluminate. A few experiments were also performed at 50 and 75°C with 5 mol kg^{-1} K_2O, and at 50°C with 5 mol kg^{-1} Na_2O.

Results and discussion

In general, the sodium solutions produced finely grained precipitates except at the lowest alkalinity studied ($[Na_2O]$ = 1.0 mol kg^{-1}) with $R \geq 1$, when massive gels were rapidly precipitated. The potassium solutions, however, gave gels except when $R > 6$. As the formation of identifiable crystalline products is known to require incubation at elevated temperatures (9, 12), no attempt was made to characterize the apparently amorphous precipitates formed at the relatively low temperatures of these experiments. Somewhat higher alkalinities were accessible with K^+ as the cation ($[K_2O]$ up to 9 mol kg^{-1}) than with Na^+ ($[Na_2O]$ up to 7 mol kg^{-1}). The salient features of the results are presented in Figs. 1–4, in which samples that formed permanent precipitates within the mixing time are arbitrarily given a precipitation time of 1 min.

Fig. 1. Dependence of log t_{ppt} on mol% Si for K^+ solutions with $[K_2O]$ = 3 mol kg^{-1} (●, solid curve) and 5 mol kg^{-1} (▲, dotted curve). For [Si]/([Al] + [Si]) ≤ 50%, [Si] = 0.1 mol kg^{-1}; for [Si]/([Al] + [Si]) ≥ 50%, [Al] = 0.1 mol kg^{-1}. Samples with 40–53 mol% Si at $[K_2O]$ = 5 mol kg^{-1} did not gel in 4 weeks at 24°C.



Potassium Solutions

Effect of alkalinity

It was generally found that t_{ppt} increased with increasing alkalinity. Silicate concentrations ranged from 0.1 to 4.0 mol kg^{-1} and $[Al_2O_3]$ from 0.05 to 1.0 mol kg^{-1} (i.e., [Al] from 0.1 to 2.0 mol kg^{-1}) and, at any particular [Si]/[Al] ratio R, t_{ppt} generally increased when the concentration of K_2O was increased (see, for example, the samples with R = 1 in Table 1). Dent Glasser and Harvey (10) noted that, although t_{ppt} for potassium aluminosilicate solutions with $1 \leq R \leq 3$ lengthened with increasing $[K_2O]$, t_{ppt} for samples with higher R and $[K_2O]$ up to 2.5 mol L^{-1} actually decreased with increasing alkalinity. This effect was also observed in the present study, but, at very high alkalinity (5 mol kg^{-1} K_2O or greater), t_{ppt} increased again, as can be seen in Table 1 for samples with R = 4 and 6.

© 2001 NRC Canada

Fig. 2. Dependence of log t_{ppt} on mol% Si and temperature for K^+ solutions with $[K_2O]$ = 5 and $[Al_2O_3]$ = 0.05 mol kg^{-1} at: (●, solid curve) 24°C; (▲, dashed curve) 50°C; (■, dotted curve) 75°C. Samples with 50 or ≥91 mol% Si did not gel in 4 weeks at 24°C.

Effect of [Si]/[Al] ratio

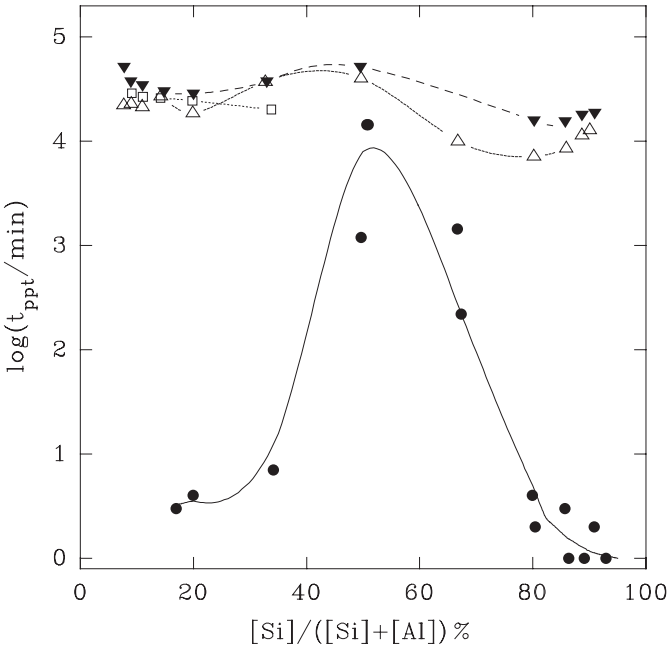
The variation of R at fixed concentrations of K_2O and either constant silicate or constant aluminate concentration had a pronounced effect on t_{ppt}, as shown in Fig. 1. Precipitation times passed through a local maximum for samples with R = 1.0, with the shortest t_{ppt} occurring at R = 0.25 and 4.0, that is, at 20 and 80 mol% Si, respectively, relative to mol (Si + Al). The nature of the precipitate was also found to vary with the R; solutions with more than ca. 85 mol% Si gave granular precipitates which settled out, whereas those of lower Si content tended to form gels, including cases where Al was dominant.

Figure 1 also shows that t_{ppt} increased on increasing $[K_2O]$ from 3 to 5 mol kg^{-1}. In accordance with this trend, gelation was faster at 1 mol kg^{-1} K_2O, whereas at 9 mol kg^{-1} K_2O no gelation was observed in over a month. Measurements with 9 mol kg^{-1} K_2O were restricted to the Si dominant side because stock aluminate solutions with $[Al_2O_3]$ > 0.3 mol kg^{-1} formed a white precipitate (presumably a potassium aluminate) during dissolution of the aluminum.

Although the Si-dominant side of Fig. 1 covers a wider range of $[K_2O]$ than the experiments of Dent Glasser and Harvey (10), trends in t_{ppt} when R was increased at a fixed $[K_2O]$ were similar. It was found that solutions with R > 10 and $[K_2O]$ > 3 mol kg^{-1} were indefinitely stable against gelation. In one instance in which $[K_2O]$ = 5, $[Al_2O_3]$ = 0.23, and R = 10, initial mixing gave immediate precipitation, but subsequent sonication of the sample for 1 h produced a solution which was indefinitely stable. At $[K_2O]$ = 3, however, it was found necessary to go to R = 19 to form an indefinitely stable solution.

It should be noted that although $[K_2O]$ does not change with R, the overall alkalinity does since as R increases the concentration of silicate increases, and therefore total alkalinity decreases.

Fig. 3. Dependence of log t_{ppt} on mol% Si for Na^+ solutions with $[Na_2O]$ = 1.0 mol kg^{-1} (●, solid curve), 3.0 mol kg^{-1} (△, short-dashed curve), 5.0 mol kg^{-1}(▼, long-dashed curve), and 7.0 mol kg^{-1}(□, dotted curve). For [Si]/([Al] + [Si]) ≤ 50%, [Si] = 0.05 mol kg^{-1}; for [Si]/([Al] + [Si]) ≥ 50%, [Al] = $2[Al_2O_3]$ = 0.05 mol kg^{-1}.



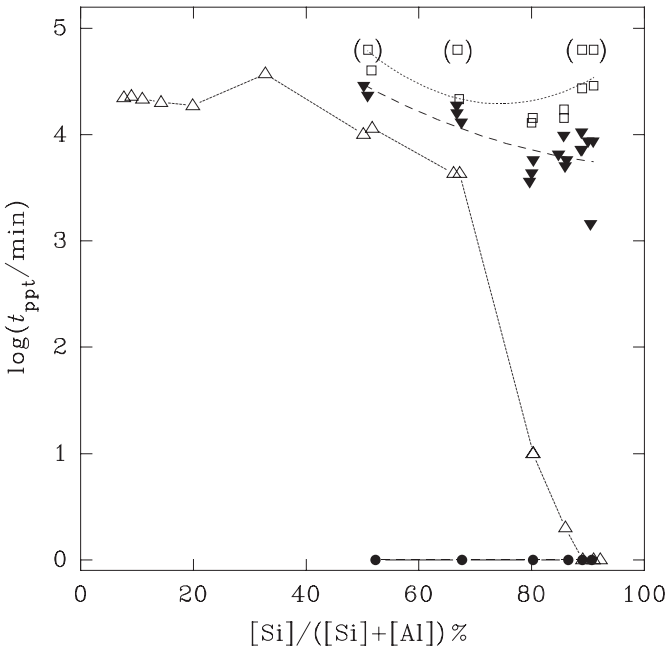


Fig. 4. Dependence of log t_{ppt} on mol% Si for Na^+ solutions as in Fig. 3, but with [Al] doubled. For [Si]/([Al] + [Si]) ≤ 50%, [Si] = 0.1 mol kg^{-1}; for [Si]/([Al] + [Si]) ≥ 50%, [Al] = $2[Al_2O_3]$ = 0.10 mol kg^{-1}. Legend as in Fig. 3. Symbols in parenthesis indicate that no precipitate was formed in 4 weeks.

$[K_2O]$ (mol kg^{-1})	t_{ppt} (min) at: R = 1	R = 4	R = 6
1.0	2	7	120
3.0	122	6	9
5.0	> 4 × 10^4 [a]	90	110
9.0	> 4 × 10^4 [a]	> 4 × 10^4 [a]	> 4 × 10^4 [a]

[a]No precipitation in one month.

Effect of absolute concentration of silicate and aluminate

In most cases, increasing the absolute concentrations of total silicate and aluminate for a fixed R and K_2O concentration caused t_{gel} to decrease. This effect is shown in Table 2 for samples with R = 1.0.

It was noted above that, when [Si] and the Si/Al ratio were low, increasing the alkalinity retarded gelation. Table 2 shows that t_{gel} decreased as the absolute concentrations of Al and Si increased for any given concentration of K_2O, but, because the concentration of free alkali must also have decreased, it is unclear whether the shortened gelation times were due to the increasing [Al] and [Si] or to the decrease in alkalinity. By the same token, the "unexpected" behaviour noted by Dent Glasser and Harvey (10) for K^+ solutions with high Si:Al ratios, where t_{ppt} can, in some cases, be increased by decreasing the alkalinity, is also suggested by measurements at 5 mol kg^{-1} K_2O; thus, t_{ppt} for samples with $R \approx 8$ increased from ca. 9 h at $[Al_2O_3]$ = 0.05 mol kg^{-1} ($[SiO_2]$ = 0.8 mol kg^{-1}) to 96 h at $[Al_2O_3]$ = 0.1 mol kg^{-1} ($[SiO_2]$ = 1.6 mol kg^{-1}).

Effect of temperature

The effect of increasing the temperature on t_{ppt} was examined for a series of samples with [Si] > [Al] at $[K_2O]$ = 5 mol kg^{-1}. It was expected that gelation times would decrease with increasing temperature because of faster nucleation or gel growth kinetics, and this was certainly found to be the case at $[Al_2O_3]$ = 0.1 mol kg^{-1}, as shown in Table 3. Similarly, at the lower $[Al_2O_3]$ of 0.05 mol kg^{-1}, solutions with R = 1 and 10 that would have remained clear for over a month at 24°C formed precipitates in a few hours at 50 and 75°C. Surprisingly, however, for $2 \leq R \leq 6$ with $[Al_2O_3]$ = 0.05 mol kg^{-1}, t_{ppt} was shorter at 24°C than at 50°C; at 75°C, t_{ppt} was again longer than at room temperature, but still significantly shorter than at 50°C. These results are summarized in Fig. 2. The solids formed in these cases were of a granular nature rather than the usual gels.

Sodium solutions

The behavior of sodium solutions was broadly similar to that of their potassium analogues, but some significant differences were noted. Comparison of Figs. 1 and 3 shows that sodium aluminosilicate solutions with relatively low [Al] or [Si] (0.05 mol kg^{-1}) and alkalinity ($[Na_2O]$ = 1.0 mol kg^{-1}), exhibited an anomalous longevity for $R \approx 1$, like that of their potassium counterparts with higher concentrations. This phenomenon was much less evident, however, when $[Na_2O]$ was increased to 3.0 mol kg^{-1} or higher, in which case t_{ppt} remained fairly constant at around 2–3 weeks over a wide range of R and alkalinity. Indeed, the reproducibility of t_{ppt} at high alkalinities, evident in Fig. 3, is an encouraging measure of the validity of the simple experimental approach.

Table 2. Precipitation times for sample of varying concentrations of aluminate and silicate at a constant [Si]/[Al] ratio R of 1.0.

$[K_2O]$ (mol kg^{-1})	t_{ppt} (min) for $[Al_2O_3]$ (mol kg^{-1}) = 0.05	0.10	0.15	0.20	0.25
1.0	2	0*	0*	0*	0*
3.0	122	0	0*	0*	0*
5.0	> 4 ×10^4	21	5	0*	0*
9.0	> 4 ×10^4	> 4 ×10^4	> 4 ×10^4	3.5 × 10^4	100

*Inferred from results at lower concentrations.

Table 3. Temperature dependence of precipitation times (t_{ppt}) for $[K_2O]$ = 5.0 mol kg^{-1} and $[Al_2O_3]$ = 0.1 mol kg^{-1}.

temp (°C)	t_{ppt} (min) at: R = 1	R = 2	R = 4	R = 6
24	21	11	27	120
50	6	4	4	8

When [Al] was increased to 0.10 mol kg^{-1} on the Si-dominant side (Fig. 4), precipitation of massive gels occurred promptly on mixing at the lowest alkalinity studied ($[Na_2O]$ = 1.0 mol kg^{-1}) for all R values ≥1, and on a time scale of minutes at moderate alkalinity ($[Na_2O]$ = 3.0 mol kg^{-1}) for $R \geq 4$, but, at higher alkalinities, the solutions were consistently long lived (several days to longer than four weeks). In particular, the conspicuous minima in t_{ppt} noted for K^+ solutions of comparable concentrations of alkali and reactants (Fig. 1) were much diminished or arguably absent (Fig. 4). For Na^+ solutions with R = 1, t_{ppt} was short when the alkalinity was low and [Al] was high.

Conclusions

In general, long solution lifetimes are favored by high $[Na_2O]$ or $[K_2O]$. This is attributable to the reduced numbers of ≡Si-OH functions in monomeric or oligomeric silicate ions as the alkalinity is increased, since the formation of a gel or precipitate via condensation reaction [1] requires the availability of ≡Si-OH groups (which are subject to deprotonation at high alkalinity) as well as ≡Al-OH (which are not) (15).

[1] ≡Al-OH + HO-Si≡ → ≡Al-O-Si≡ + H_2O

Reaction [1] also leads to the expectation that the precipitation process will be at least first order in each of [Si] and [Al], so that long solution lifetimes should be expected for high alkalinities and low reactant concentrations. This is borne out by the data of Table 1. Gelation times generally decreased with increasing absolute concentrations of silicate and aluminate. It is difficult, however, to distinguish the effect of increasing [Si] or [Al], as such, from that of the concomitant decrease in alkalinity because formation of silicate and aluminate ions from SiO_2 and Al_2O_3, respectively consumes OH^- (by an indefinite amount, in the former case).

© 2001 NRC Canada

We have shown elsewhere (15) that silicate and aluminosilicate ring or cage structures are much less reactive in condensation processes in solution than their small acyclic analogues. This is due partly to steric constraints, and partly to the reduced number of ≡Si-OH functions available in cyclic silicate anions. The long lifetimes of solutions with high [Si] (>5, right-hand side of Fig. 1) and hence high concentrations of cyclic oligomers (16, 17) can be understood on this basis. For Na^+ solutions, a similar but less pronounced effect can be discerned in Figs. 3 and 4. Solutions with very low [Al] can also be expected to be long lived, as the precipitation process can be viewed as the result of the insertion of Al into an extended silicate structure that would otherwise be soluble. According to Loewenstein's rule (18), Al—O—Al links are avoided in solid aluminosilicates, and presumably this will limit the ready formation of aluminosilicate precipitates to solutions where $R \geq 1.0$. The left-hand half of Fig. 4 is consistent with this expectation, as is the extreme left of Fig. 1.

It is less obvious, however, why there should be a local maximum in solution lifetimes at $R = 1$ for K^+ solutions (Fig. 1) and, at least at low alkalinity and low [Al], for Na^+ solutions also (Fig. 3, cf. Fig. 4). Probably, for $R \approx 1$, most of the Al and Si are present as the ions $(HO)_3AlOSiO_n(OH)_{(3-n)}^{(n+1)^-}$ (n = 1–3), which seem to be capable of existing in stable solution in substantial concentrations at high pH. Significantly, the precipitates that eventually formed from either K^+ or Na^+ aluminosilicate solutions at $R = 1.0$ were granular rather than gel-like, and further growth was slow, consistent with the view that $(HO)_3AlOSiO_n(OH)_{(3-n)}^{(n+1)^-}$ ions, though probably the major vehicles of growth of aluminosilicate precipitates (15), are themselves quite soluble indefinitely in NaOH or KOH media and provide few nuclei for gel growth.

For the most part, increasing the temperature resulted in faster precipitation from both Na^+ and K^+ aluminosilicate solutions. However, the gelation times of the less concentrated aluminosilicate solutions (i.e., $[Al_2O_3] = 0.05$ mol kg^{-1} with $2 \leq R \leq 6$) increased when the temperature was raised to 50°C, but decreased again when the temperature was increased further to 75°C (Fig. 2). Because of the interdependence of the several variables, a definitive assessment of the effect of temperature on t_{ppt} is probably not feasible, but it may be that the anomalous behaviour of the K^+ solutions containing less Al resulted from a reduction in the numbers of gel nuclei at 50°C because of increased solubility, hence retarding precipitation. The "unexpected" behavior of certain K^+ solutions first noted by Dent Glasser and Harvey (10; see above) may similarly have originated in a trade-off between numbers of nuclei and growth rates. The absence of parallel effects for Na^+ solutions is consistent with solubility as the cause of these phenomena. At the higher temperature of 75°C, the increased rate of gel growth may compensate for the reduction in numbers of nuclei and, thus, gelation times begin to decrease again. In any event, these observations imply that aluminosilicates may persist long enough in solution at high temperature and alkalinities to cause significant Si carryover in the Bayer process and to cause scaling in various industrial applications.

Excess electrons in aqueous glasses and crystalline ice

Hugh A. Gillis and Terence I. Quickenden

Abstract: Experimental studies of excess electrons in aqueous glasses and crystalline ice are reviewed. Emphasis is placed on studies of the two main optical absorption bands, the well known visible band, which is similar to that of the solvated electron in water, and the IR band which has $\lambda_{max} \geq 2950$ nm. Under some circumstances partial conversion of the IR-absorbing species to the visible-absorbing species has been observed. Evidence indicates that the two species are due to electrons trapped in distinctly different physical environments. Two mechanisms have been proposed for the formation of the visible-absorbing electron in crystalline ice, one involving naturally occurring vacancies and the other radiation produced vacancies. Studies of the UV and visible luminescence emitted when ice at low temperature is irradiated are summarized, and the mechanisms suggested for its production are discussed briefly. The studies on excess electrons in aqueous solids seem to the authors to be highly relevant to the more recent studies of electron solvation in water which are done on a much shorter time-scale. These latter studies are reviewed briefly with the aim of elucidating the relevance.

Key words: visible-absorbing electrons, IR-absorbing electrons, irradiation of aqueous glasses, irradiation of crystalline ice, electron solvation in water.

Résumé : On présente une revue des études expérimentales sur les électrons en excès dans des verres aqueux et dans de la glace cristalline. On met l'emphase sur les études des deux principales bandes d'absorption optique, la bande visible bien connue, qui est semblable à celle de l'électron solvaté dans l'eau et la bande infrarouge dont le $\lambda_{max} \geq$ 2950 nm. Dans certaines circonstances, on peut observer une conversion partielle des espèces qui absorbent dans l'infrarouge en espèces qui absorbent dans le visible. Les données indiquent que les deux espèces sont dues à des électrons piégés dans des environnements physiques différents. Deux mécanismes ont été proposés pour la formation de l'électron absorbant dans le visible dans la glace cristalline; l'une implique les vides qui existent normalement et l'autre ceux qui sont produits par des rayonnements. On présente un résumé des études faites sur la luminescence ultraviolette et visible émise quand on irradie de la glace à basse température et on discute brièvement des mécanismes suggérés pour sa production. Pour les auteurs, il semble que les études sur les électrons en excès dans des solides aqueux sont très pertinentes aux études plus récentes sur la solvatation des électrons dans l'eau qui s'effectue à une échelle de temps beaucoup plus courte. On passe brièvement ces dernières études en revue dans le but d'élucider leur pertinence.

Mots clés : électrons absorbant dans le visible, électrons absorbant dans l'infrarouge, irradiation de verres aqueux, irradiation de la glace cristalline, solvatation des électrons dans l'eau.

[Traduit par la Rédaction]

Introduction

Ever since the solvated electron was identified as the chemical species responsible for the blue colour of solutions of sodium in liquid ammonia (1), it has aroused great interest. This interest is due not only to its important role in radiation chemistry, photochemistry, and electrochemistry, but also because it is a very useful probe of solvent environment and solvation dynamics. The electron can be solvated in solid and liquid water, and in a wide variety of organic liquids and solids such as hydrocarbons, ethers, and alcohols.

Many studies of the solvated electron have been concerned with the dynamics of its formation, i.e., with the processes that take place between the injection of a quasi-free electron into a liquid or solid and the appearance of the comparatively stable solvated electron. The first time-resolved optical absorption studies of electron solvation were conducted in alcohols. Nanosecond pulse radiolysis studies of liquid and glassy alcohols at low temperatures showed an initial absorption in the IR due to trapped electrons (2). Subsequently, the absorption peak shifts continuously to the final spectrum with a peak in the 500–800 nm range; this shift is a reflection of the continuous adjustment of the solvent surrounding the electron to its presence. However, a stepwise mechanism is possible, particularly because the first-order decay observed in the IR corresponds quite well with

the absorption build-up at 550 nm for cold liquid *n*-propyl alcohol (2). A hybrid model has been proposed for electron solvation in methanol at room temperature (3); this involves two electron-solvent configuration states (a weakly bound and a strongly bound one) both of which relax via a continuous shift and between which there is a stepwise transfer.

This review is concerned primarily with excess electrons trapped in aqueous glasses and crystalline ice. These electrons do not show the dramatic shift of a single peak as seen in alcohols; however, they give two well separated absorption bands, and under some circumstances, weakly bound electrons are converted to strongly bound electrons. In the review emphasis is placed on evidence which indicates that the bands are due to electrons trapped in distinctly different environments, and on results which tell us something about those environments. Many of the papers reviewed reported optical absorption studies, but relevant studies of reactions of quasi-free electrons in ice followed by conductivity are also reviewed briefly, as is work on the luminescence emitted when aqueous glasses and ice are irradiated. Much of the work reviewed was done 20–25 years ago, though some has been reported in the past five years. In the opinion of the authors, this work is highly relevant to the current intense activity on the dynamics of the solvation of the electron in water, although it has been largely ignored in papers on this subject. The formation kinetics of the hydrated electron is covered briefly in this review with the aim of elucidating the relevance.

Aqueous glasses

In this section we emphasize the electron absorption band in the IR which is found in some aqueous glasses. The electron that gives the visible absorption band is very similar to the hydrated electron. From the dependence of the ratio of intensities of the two bands on the water content of glasses it was concluded that the IR band is due to an electron trapped in free water (not coordinated to ions or organic molecules), whereas the visible band is trapped in an environment of coordinated water. The two types of electron decay by different mechanisms, and decay of the IR-absorbing species in some glasses is accompanied by growth of the visible-absorbing species.

Visible band

It was first reported in 1962 that γ-irradiated aqueous NaOH glasses at 77 K give an optical absorption with λ_{max} near 585 nm (4, 5); subsequent work showed that the absorption was due to a trapped electron. In this review this species will be referred to as e^-_{vis}. Early work on it has been extensively reviewed (6).

Several published reports show that there is structure in the e^-_{vis} band. Pulse radiolysis studies of several aqueous glasses at ~76 K show that the band is considerably broader and has λ_{max} at longer wavelengths at short times ($<10^{-6}$ s) than at long times or in γ-irradiation experiments (7–9). This broadening is due to increased absorption on the red side of the band. As time elapses absorption at $\lambda > 575$ nm decays while absorption at $\lambda < 575$ nm remains constant or increases, and these changes account for the narrower and blue-shifted spectrum seen in γ-irradiation.

Substructure in the equilibrated e^-_{vis} band (after decay of the red wing) in aq BeF_2 glasses is seen in photobleaching experiments (10). A green band (λ_{max} 530–590 nm) seems to be bleached homogeneously, whereas the red side of the equilibrated e^-_{vis} band seems to bleach inhomogeneously as if it arises from electrons with a range of ground state energies.

Rice et al. (11) have shown that comparison of the photoconductivity spectra of trapped electrons with their optical absorption spectra leads to information about the nature of the optical transitions involved in the absorption band. Some aqueous glasses such as 10 M NaOH show a similar wavelength dependence of photoconductivity and optical absorption spectra for e^-_{vis} which implies the dominance of bound–continuum transitions. For other systems, such as 10 M LiCl, the photoconductivity spectra are somewhat blue-shifted from the absorption spectra; this indicates dominance of bound–bound transitions in the main part of the spectrum and dominance of bound–continuum transitions in the high-energy tail. Nguyen and Walker (12) made a careful measurement of the percentage of bound–continuum character in the optical transition at 694 nm for e^-_{vis} in aq 9.5 M LiCl glass at 77 K and found it to be (3.7 ± 1.8)%. Therefore, about 96% of the transition probability at this wavelength must be to bound excited states. This measurement took account of the number of photoreleased electrons which are retrapped and of those electrons which are bleached by indirect secondary processes.

Detailed geometric information on e^-_{vis} in aqueous glasses has come from various types of electron magnetic resonance studies (13, 14). The electron is shown to be surrounded by six approximately equivalent water molecules, with one OH of each molecule oriented towards the electron. The water molecules are thought to be in an octahedral arrangement. This geometry was originally established for an aq 10 M NaOH glass, but later work showed the same structure for e^-_{vis} in a matrix with less than 10^{-3} M NaOH formed by codepositing sodium atoms and water vapour. Thus the geometric structure proposed does not seem to require the presence of a high concentration of ions.

IR band

Blandamer et al. (15) produced e^-_{vis} by γ-irradiation of an aqueous alkali–metal hydroxide glass at 77 K, bleached it with visible light so that the band with λ_{max} at ~590 nm disappeared and found a new, broad absorption edge, strong in the near-IR and red parts of the spectrum and tailing into the visible. Kevan et al. (16) reported that for γ-irradiation of 10 M NaOH glasses at 77 K to doses greater than 10 Mrad, the trapped electron absorption at 585 nm decreases and a broad band grows in the near-IR with a maximum at approximately 1000 nm. The IR band was attributed to the dielectron; two electrons trapped in the same vacancy. A γ-irradiated mixture of ethylene glycol and water (50:50 by volume) at temperatures ≤30 K showed increasing absorption from 1200 nm out to at least 2000 nm, in addition to the well-known peak in the visible (17). Transient absorption at 1152 nm was produced by photoexcitation of the visible-absorbing trapped electron in some aqueous glasses with a ruby laser pulse (18). In 1976, Buxton et al. (9) reported finding an IR absorption band with a maximum beyond

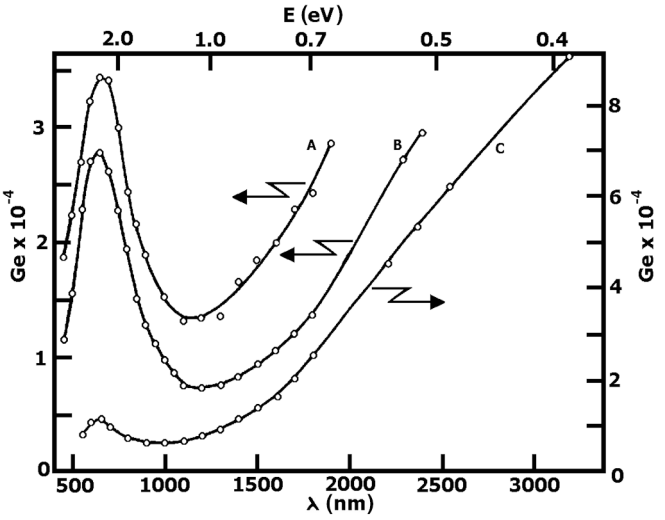

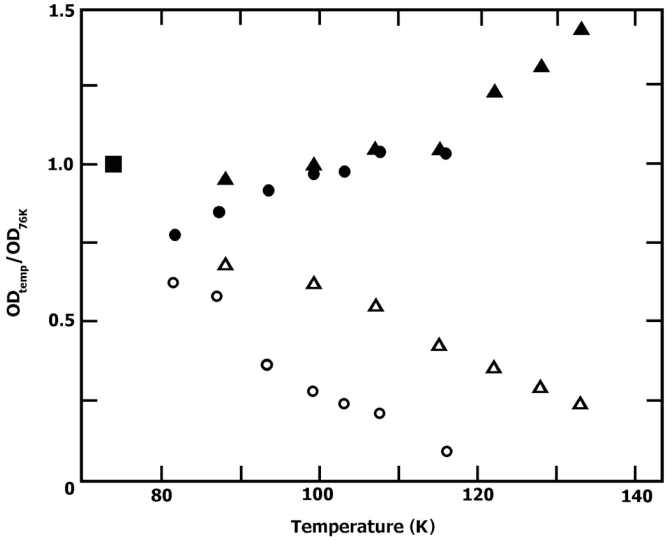

Fig. 2. Effect of temperature on the relative initial intensities of the visible and IR bands: LiCl, 2360 nm (○); LiCl, 650 nm (●); $MgCl_2$, 2360 nm (△); $MgCl_2$, 650 nm (▲); and one point common to all (■). From ref. 9.

3200 nm in the pulse radiolysis of D_2O glasses of ethylene glycol, $MgCl_2$, and LiCl, as well as the trapped electron band with a maximum around 650 nm. Because of the effects of electron scavengers on the IR band, they assigned it also to a trapped electron which they referred to as e^-_{ir}. We shall use the same nomenclature in this article. Absorbance per krad (1 rad = 10^{-2} Gy) at 2360 nm was found to be the same for 5 and 0.5 krad pulses, which strongly suggests that the band is not due to a dielectron. Later, e^-_{ir} was found also in H_2O glasses (19), but the species has been studied mainly in deuterated systems because of their greater transparency in the 1200–3200 nm range. Matrix absorption bands in this region in H_2O arising from overtones and combinations of the fundamental vibrational modes are shifted to higher wavelengths by deuterium substitution.

The absorption spectra observed in three aqueous glasses at about 73 K are shown in Fig. 1. The band due to e^-_{vis} and the partial band attributed to e^-_{ir} are quite distinct although they overlap in the 800–1300 nm region. The effects of temperature, electron scavengers, and glass composition on the two bands are different, and the bands decay at different rates (9). These facts indicate that the spectra refer to different species, and also permit the resolution of the bands in the overlap region.

The resolved IR band closely fits a Lorentzian function on the high energy side (9), and in this respect is similar to spectra observed by Jou and Dorfman (20) for solvated electrons in several ethers. The Lorentzian fit predicts λ_{max} to be 3600 nm for $MgCl_2$ glasses. For *tert*-butanol–D_2O glasses, for which 2500 nm was the highest wavelength at which measurements could be made, a similar Lorentzian fit gives λ = 4350 nm (21). The difference between these two extrapolated values of λ_{max} may not be significant.

Other aqueous glasses in which the IR band was found, in addition to the LiCl, $MgCl_2$, ethylene glycol, and *tert*-butanol glasses already indicated, are BeF_2 and LiBr (10), alkaline glasses (NaOD, KOD, RbOD, and CsOD) at 6 K but not at 76 K (22), $CaCl_2$ (23), and probably a 26.5 mol% H_2O–ethanol glass at 6 K (24). Aqueous glasses at 6 K in which an IR band was looked for and not found are: K_2CO_3, NaO_2CH, $NaClO_4$, $Mg(CH_3CO_2)_2$, and $Mg(ClO_4)_2$ (9). It is not known why the IR band is found in some glasses and not in others; however, Nguyen and Walker (25) concluded that e^-_{ir} is destroyed, or its formation is inhibited, by many of the solutes which are commonly used to make aqueous glasses. They came to this conclusion after studying mixed-solute glasses, specifically using $MgCl_2$ glasses with $CaCl_2$, $Mg(ClO_4)_2$, or ethylene glycol added as a second solute.

The decay of the IR band in ethylene glycol, LiCl, and $MgCl_2$ glasses at 76 K was independent of λ for λ > 1400 nm (9), but of course the decay of the red edge of the band or even of the maximum of the band was not measured.

The photoconductivity spectrum of e^-_{ir} is significantly blue-shifted from its absorption spectrum (11). This implies that e^-_{ir} has bound–bound transitions dominating in the region of the extrapolated optical absorption maximum, and bound–continuum transitions dominating in the high-energy tail of the spectrum (11).

Effects of temperature and scavengers on e^-_{vis} and e^-_{ir}

The effects of increasing the temperature of LiCl and $MgCl_2$ glasses on the intensities of the visible and IR absorption bands are shown in Fig. 2. The IR band steadily decreases in intensity while the visible band remains practically constant up to 120 K and then increases. Part of the decrease in intensity of the IR band is due to faster decay at higher temperatures, which results in more decay before the first measurement at about 100 ns. However, in the $MgCl_2$ glass this effect was negligible up to 114 K.

Buxton et al. (9) found that CrO_4^{2-} or acetone decreased the initial intensities of both e^-_{ir} and e^-_{vis} bands in aq LiCl, $MgCl_2$, and ethylene glycol glasses at 76 K, but the fractional decrease was always greater for e^-_{ir}. They found the addition of HCl to LiCl and $MgCl_2$ glasses scarcely affected

© 2001 NRC Canada

the intensity of either band. The addition of Ag^+ to an aqueous ethylene glycol glass decreased the initial intensities of the e^-_{vis} and e^-_{ir} bands, and a band due to Ag° was produced. In steady-state experiments Rice et al. (11) used nitrate as an electron scavenger for trapped electrons in aqueous 10 M LiCl glasses at 4.2 K, and found that the e^-_{ir} band was reduced much more markedly than the e^-_{vis} band. If electron scavengers merely intercepted quasi-free electrons before they became trapped in deep or shallow traps, their effect on the initial yields of e^-_{ir} and e^-_{vis} would be the same. A possible explanation of the greater reduction in e^-_{ir} yields is the formation of encounter pairs in which the electrons are trapped within the reaction volume of the scavenger and react before detection; the effect is expected to be much more important for shallowly trapped electrons then for deeply trapped ones (9).

Extinction coefficient for e^-_{ir}

The extinction coefficient for e^-_{ir} was determined from the experiments with Ag^+ in a 50:50 aqueous ethylene glycol glass (9). Measurements of the yields of Ag° and its extinction coefficient, and of the decrease in initial yields of e^-_{ir} and e^-_{vis}, and the known extinction coefficient of e^-_{vis} led to a calculated $\varepsilon_{1400} = (5.7 \pm 0.8) \times 10^3\ M^{-1}\ cm^{-1}$ which is convertible into $\varepsilon_{1800} = (1.08 \pm 0.15) \times 10^4\ M^{-1}\ cm^{-1}$. A similar procedure for estimating the extinction coefficient for e^-_{ir} from the irradiation of a 45:55 ethylene glycol–D_2O matrix with 0.01 M sodium salicylate at 6 K gave $\varepsilon_{1800} = (1.3 \pm 0.3) \times 10^4\ M^{-1}\ cm^{-1}$ (26). Another determination came from the photoionization of tryptophan in a 9.5 M LiCl–D_2O glass at 76 K, and it gave $\varepsilon_{1800} = 1.3 \times 10^4\ M^{-1}\ cm^{-1}$ (27). It is reassuring that similar extinction coefficients were found for e^-_{ir} for different glasses and temperatures.

Dependence of $G(e^-_{ir})/G(e^-_{vis})$ on glass composition

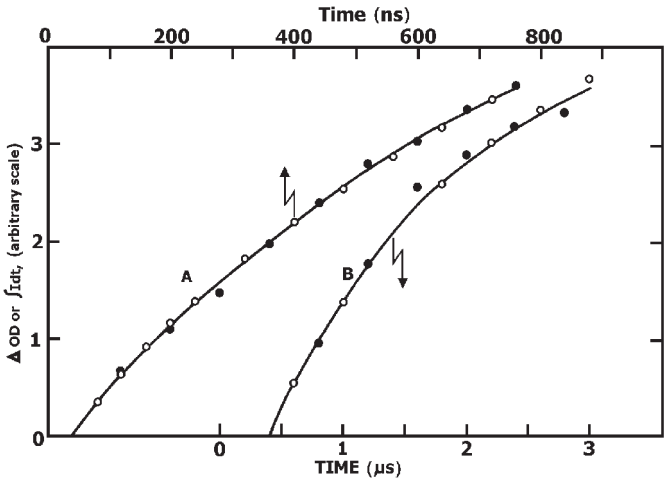
For aq LiCl (28), ethylene glycol (26), and BeF_2 glasses (10) at 76 K, increasing the concentration of the nonaqueous component decreases the ratio $G(e^-_{ir})/G(e^-_{vis})$ and to a good approximation does not change the sum $(G(e^-_{ir}) + G(e^-_{vis}))$. The same is true for ethylene glycol glasses at 6 K (26). For D_2O–KOD glasses irradiated at 6 K, the effect of increasing D_2O content is also to increase $G(e^-_{ir})$ and decrease $G(e^-_{vis})$ (22). This trend is not followed by aqueous *tert*-butanol glasses at 72 K, nor at 6 K (21). However, in the latter glasses e^-_{vis} is produced in very small yields even at 72 K, and possibly some of the absorption attributed to e^-_{ir} is due instead to electrons trapped in a glassy *tert*-butanol environment (21).

Studies by NMR techniques of the structure of LiCl glasses indicate that they consist of $(Li{\cdot}4H_2O)^+Cl^-$ units, with water in excess of that required to form $(Li{\cdot}4H_2O)^+$ existing as clusters of free water (not coordinated to ions) packed interstitially between the $(Li{\cdot}4H_2O)^+$ units, and probably amorphous rather than ice-like (29). The simple model proposed was that e^-_{ir} is an electron trapped in free water and e^-_{vis} is an electron trapped in $LiCl{\cdot}4D_2O$ structures, and that these preexisting trapping sites are in competition for quasi-free electrons which would otherwise recombine with geminate positive holes (28). A plot of $G(e^-_{ir})/G(e^-_{vis})$ against [free D_2O]/[$LiCl{\cdot}D_2O$] gives a straight line as expected from this model. This model should apply also to BeF_2 and ethylene glycol glasses.

Yields of e^-_{vis} and e^-_{ir} were measured in LiCl glasses at temperatures between 6 K and 72 K (21, 23, 27, 30, 31). If the model described above were strictly true, yields of the two species would not change much in this temperature range since the ratio of concentrations of the two kinds of traps would not be expected to change in these rigid matrices. However, as the temperature is decreased from 72 K the yields of e^-_{vis} decrease modestly, $(G(e^-_{ir}) + G(e^-_{vis}))$ increases modestly, and yields of e^-_{ir} increase dramatically, especially for the glasses with the highest concentrations of LiCl, that is, those with the lowest yields of e^-_{ir} at 76 K. Most of the results can be explained by adding to the model the assumption that there is an activation energy for electron trapping by deep traps which is slightly larger (perhaps 50–100 cal mol^{-1} larger (1 cal = 4.1868 J)) than any activation energy for trapping by shallow traps or for geminate reaction by quasi-free electrons with holes. This activation energy difference would have no effect at 76 K so that at this temperature the yields of e^-_{vis} and e^-_{ir} would simply reflect the relative numbers of deep and shallow traps available, but of course would have a large effect at 6 K.

Similar effects are seen when the temperature of aqueous ethylene glycol glasses is decreased from 72 to 6 K, i.e., $G(e^-_{ir})$ increases, $G(e^-_{vis})$ decreases, and $(G(e^-_{ir}) + G(e^-_{vis}))$ increases (26).

Bartczak et al. (32) have proposed a model to explain qualitatively the yields of e^-_{ir} and e^-_{vis} in aqueous ionic glasses. This model is based on the lattice theory of concentrated ionic solutions which assumes that the ions form distorted lattices and water molecules fill up empty regions in the lattices. Bartczak et al. (32) suggest that e^-_{ir} is an electron trapped at a cation in the distorted lattice. Because of the repulsive effects of the nearest neighbouring anions this trap is very shallow or even has no bonding level. The trap depth decreases with increased salt concentration, which explains the effects described above of salt concentration on $G(e^-_{ir})$. The model also gives a shallower trap for Na^+ than for Li^+, and no trap at all for K^+ glasses at 72 K, though e^-_{ir} has been seen in K^+ glasses at 6 K. Also, traps in Ca^{2+} glasses are predicted not to be bonding, as contrasted to traps in Mg^{2+} glasses. Measured yields of e^-_{ir} in $MgCl_2$ glasses at 80 K are much larger than for $CaCl_2$ glasses at the same temperature and concentration (23). This model is only applicable to e^-_{ir} in ionic aqueous glasses, and does not deal with this species in aqueous ethylene glycol, *tert*-butanol, or other alcohol glasses, nor with e^-_{ir} in crystalline ice.



According to the model of Bartczak et al. (32), electrons can also be trapped at anion vacancies; these are deep traps and the electron in one of these traps is e^-_{vis}. Just as for cationic traps, when the nearest neighbours are Li^+ the traps are deeper than when they are Na^+, but the difference is now negligible by comparison with the total trapping energy. This picture of e^-_{vis} seems to be incompatible with the geometric description of e^-_{vis} deduced by Kevan (13, 33) and Kevan and co-workers (14), that is given earlier in this article, that is, that the electron has six water molecules as nearest neighbours.

Decay reactions of e^-_{vis} and e^-_{ir}

In LiCl glasses at 76 K over a wide range of LiCl concentrations, e^-_{vis} decays after 100 ns almost entirely by reaction

© 2001 NRC Canada

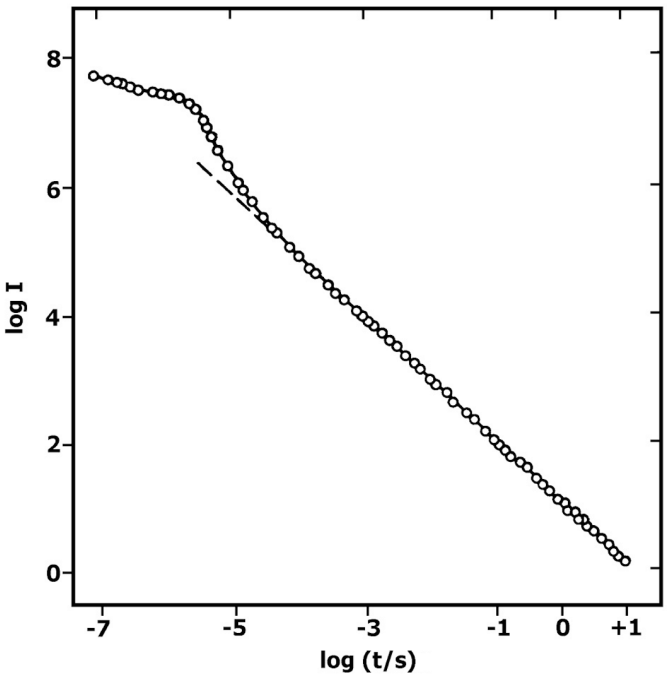
Fig. 3. Comparison of the change with time in: IR absorption (–ΔOD (●)) measured at 2350 nm, and integrated emission intensity; $\int I dt$ (○), measured at 425 nm after a 40 ns pulse in 2.5 M $MgCl_2$ glass at: 76 K (*A*); and 102 K (*B*). From ref. 9.

with Cl_2^-, both in the absence of light and during photobleaching (34). Reaction with Cl_2^- is not an important reaction for e_{ir}^- in these glasses.

Pulse radiolysis of LiCl and $MgCl_2$ glasses at 72 K results in light emission which persists after the pulse (9). The spectrum of the emission was found to have a maximum at about 410 nm. The reciprocal of the emission intensity is approximately linear in time. In Fig. 3 the change in optical density due in e_{ir}^- over a given period of time is compared to the integrated intensity of emitted light over the same period of time. The two correspond very closely after a normalization of the ordinate scale, and this correspondence was found to hold for both LiCl and $MgCl_2$ glasses, regardless of temperature. The correlation holds also in the presence of electron scavengers, even though in the case of $MgCl_2$ glasses e_{ir}^- decays more rapidly in the presence of these scavengers. No postpulse emission was detected at temperatures at which the IR band was absent, nor was it observed when 1 M acetone was added to a $MgCl_2$ glass to eliminate the IR band.

The correlation suggests that electron-hole recombination is mainly responsible for the decay of e_{ir}^-, and that recombination is the rate-determining step in the emission process, that is, that the emitting excited state is relatively short-lived (about 20 ns (12)). Tachiya and Mozumder (35) developed a model for geminate-ion recombination by tunnelling. For an exponential distribution of distances between reactants which give a short-lived luminescing product giving light intensity (*I*) in media in which the electron mobility is low, they derived the approximate relationship:

$$[1] \qquad I = k_1 t^{-1}$$



If *I* is also given by

$$[2] \qquad I = k_2 \frac{d}{dt}[e_{ir}^-]$$

it follows that

$$[3] \qquad [e_{ir}^-] = -k_3 \log t + \text{constant}$$

Fig. 4. Light emission at 450 nm from laser excitation of γ-irradiated 9.5 M LiCl glass at 77 K, plotted as the logarithm of the luminescence intensity (in arbitrary units) against the logarithm of time after the laser pulse. From ref. 37.

Buxton et al. (9) found eq. [1] was followed in their experiments, and that $[e_{ir}^-]$ was approximately linear with the logarithm of time over two and a half decades, in accordance with eq. [3].

Wypych and Kroh (36) similarly found good correlations between the change in optical density due to e_{ir}^- and the integrated intensity of emission for LiCl glasses at 6 K, 50 K, and 110 K, for $MgCl_2$ glasses at 6 K and 50 K, and for $CaCl_2$ glasses at 6 K; however, they found the integrated emission intensity correlates better with the change in optical density of e_{vis}^- for $CaCl_2$ glasses at 50 K and 110 K. It is worth noting that for $CaCl_2$ glasses $G(e_{ir}^-)$ is very low and $G(e_{vis}^-)$ is high at 110 K, and even at 50 K the ratio $G(e_{ir}^-)/G(e_{vis}^-)$ is much smaller for $CaCl_2$ glass than for the other two glasses.

When samples of trapped electrons in 9.5 M LiCl and 3.1 M $MgCl_2$ aqueous glasses were bleached by single pulses of 694 nm light from a Q-switched ruby laser, e_{ir}^- was produced and luminescence with λ_{max} around 410 nm was observed (37). The luminescence intensity was measured over eight decades of time (100 ns to 10 s) following the laser pulse. Over much of this period the intensity was inversely proportional to time, just as it was in the pulse radiolysis experiments with these glasses. The interpretation of the experiments is summarized as follows:

$$[4] \qquad e_{vis}^- \xrightarrow{h\gamma} e_{ir}^- \xrightarrow{R} R^{-*} \longrightarrow R^- + h\gamma(\sim 410 \text{ nm})$$

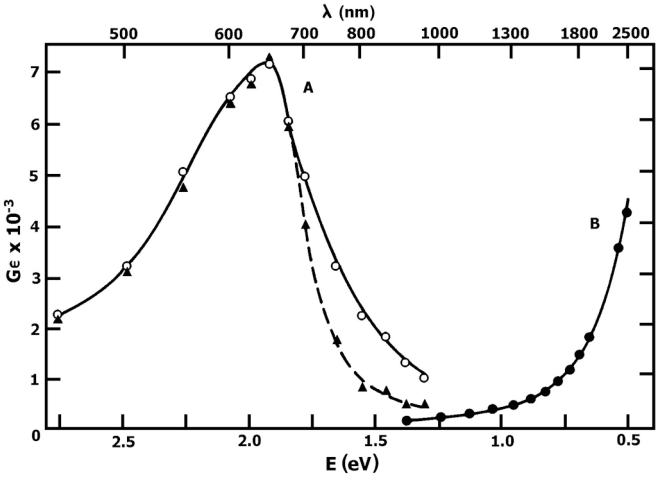
It has been suggested that the reaction centre R of eq. [4] is OH, so that the emission seen would then be fluorescence from excited hydroxide ions (9).

© 2001 NRC Canada

A plot of the logarithm of luminescence intensity (in arbitrary units) from a 9.5 M LiCl glass at 73 K against the logarithm of time after the laser pulse is shown as Fig. 4. Corrections were made for emission from a blank. The bulge for the period 10^{-7}–10^{-5} s after the pulse, corresponding to extra luminescence, is thought to arise from additional, laser-induced fluorescent processes. The straight-line part of the curve has a slope of –0.95, so that eq. [1] is obeyed quite well over six orders of magnitude in time.

Crystalline ice

In this section evidence is reviewed which indicates that e^-_{vis} in crystalline ice is an electron in a lattice vacancy, which is present at significant equilibrium concentration for $T \geq -30$°C or is produced by irradiation. The IR band may be due to electrons trapped in natural cavities that exist in perfect crystals of ice. The rates of decay of e^-_{vis} and e^-_{ir} are affected differently by changes in initial concentration, doping with NH_4F, preirradiation, and temperature, and these observations lead to suggestions for the decay reactions of both species. There is very little direct evidence for the transition $e^-_{ir} \rightarrow e^-_{vis}$ in ice, but the present authors interpret delayed formation of e^-_{vis} after irradiation of ice at –5°C as being due to this reaction.



Introduction

The absorption spectrum of electrons produced by pulse radiolysis of crystalline ice at 200, 235, and 263 K was first reported by Shubin et al. (38), who found a λ_{max} similar to that of the solvated electron in water. A short time later a similar trapped electron spectrum in γ-irradiated ice at 77 K was reported by Eiben and Taub (39) and the spectrum in pulse-irradiated ice at various temperatures was reported by Taub and Eiben (40) and Nilsson et al. (41). The half-width of the peak is smaller in ice than in water (41). Taub and Eiben (40) found that the absorption maximum for ice shifts towards the blue with decreasing temperature, and that on a plot of λ_{max} against temperature for both ice and water, the solid-phase line intercepts the liquid-phase line near the freezing point. The absence of a discontinuity indicates strongly that the electron in ice and the electron in water are the same species.

In the early studies the yields of the trapped electron in pulse-irradiated ice were found to decrease markedly with decrease in temperature from –5 to –40°C, but only slowly thereafter (40, 41). Pulse lengths in these experiments were in the range 0.4–200 μs. The *G* (trapped electron) for γ-irradiated ice at 77 K was only about 2×10^{-4}, and a rough pulse experiment at this temperature gave an approximately three-fold larger yield (40). The *G* at –5°C was estimated as 0.3 as a lower limit (40), and at –10°C as 0.3 (41).

Kawabata et al. (42) reported on a pulse radiolysis study of crystalline D_2O ice at 123 K. They found, in addition to the visible band with a peak around 630 nm due to trapped electrons, a broad IR absorption with a peak at 1000 nm which they ascribed to electrons in a shallow trap. Ice doped with 10^{-2} M NH_4F gave higher yields and slower decays for both bands. Absorbance in the visible band increased by about 10% in the first 0.4 ms after the pulse, while the IR absorption was decaying. At longer times the visible band also showed some decay.

Fig. 5. Absorption spectra at 76 K in crystalline D_2O ice. For the visible band (*A*), points were measured at the end of a 30 ns pulse. Points ▲ refer to measurements made 400 ns after the start of the pulse and multiplied by 1.90. For the IR band (*B*), the line is a Lorentzian curve fitted to the experimental points ●, which refer to the end of a 30 ns pulse and were obtained by a short extrapolation from 100 ns. Points for both bands between 1.0 and 1.5 eV have been corrected for contributions from the other band (see text). From ref. 44.

e^-_{vis} and e^-_{ir}

Buxton et al. (43, 44) in a pulse radiolysis study of crystalline D_2O ice over a range of temperatures, found an intense IR absorption band with $\lambda > 2350$ nm, in addition to the well known visible absorption band of the trapped electron. These bands seemed to be similar in some respects to the bands they found in aqueous glasses, so they referred to them also as e^-_{vis} and e^-_{ir}. This convention will also be used in this article.

Absorption spectra for irradiated D_2O ice are shown in Fig. 5. The low-energy side of the e^-_{vis} band decays much faster than the band as a whole. The band-width at half-height is 0.75 and 0.67 eV at 30 ns and 400 ns, respectively. The band-width following γ-irradiation is about 0.58 eV, so further narrowing occurs after 400 ns. The spectrum of irradiated NH_4F-doped (~4×10^{-3} M) crystalline D_2O was found to be very similar to that shown in Fig. 5 but for the doped sample the lifetime of the IR band is much longer than that of the visible band. This permits resolution of the spectrum into two bands, and the points shown in Fig. 5 for both bands at energies between 1.0 and 1.5 eV were obtained in this way.

The experimental points for the e^-_{ir} band fit a Lorentzian function very well; the best fit, shown by the line for band B in Fig. 5, predicts $\lambda_{max} = 2950$ nm. As indicated above, the Lorentzian fit for the e^-_{ir} band for a $MgCl_2$ glass at 76 K gives a predicted λ_{max} of 3600 nm, but this difference may not be experimentally significant. At 151 K the e^-_{ir} band has the same shape as band B of Fig. 5. The visible band at the end of the pulse at 151 K is intermediate between the 30 ns

© 2001 NRC Canada

and 400 ns points of band A in Fig. 5, as expected because of the faster decay of the red edge at the higher temperature.

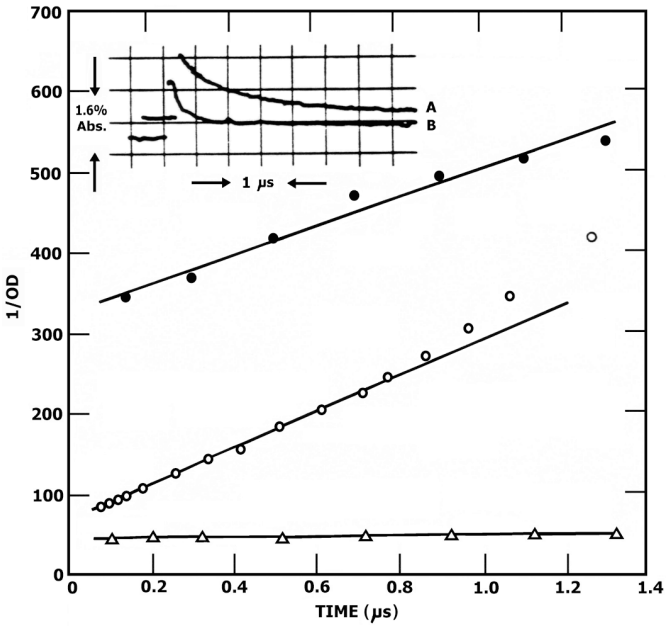
Effects of dose/pulse and solutes for ice at 76 K

$G\varepsilon$ for both bands was constant within experimental error (±10%) for a variation of dose/pulse at a constant pulse width. The range of dose/pulse was a factor of 8.1 for measurements of e^-_{vis} (45) and 4.5 for measurements of e^-_{ir} (44).

The yields of e^-_{vis} changed little when ice was doped with NH_4F, but those of e^-_{ir} increased strongly with concentration of NH_4F and the decay rate decreased markedly, as indicated in Fig. 6. For a crystal doped with 6.7×10^{-4} M NH_4F, the decay of e^-_{ir} had a half-life of about 25 ms. The effect of accumulated dose on yields of the two types of electrons in pure ice was small, but a previous irradiation of 180 krad doubled the yield of e^-_{ir} for a sample doped with 1.5×10^{-2} M NH_4F and had only a small effect on e^-_{vis} yields.

Decay kinetics for e^-_{vis} and e^-_{ir}

The decay of e^-_{vis} in pure D_2O ice at 76 K does not obey simple first- or second-order kinetics. However, a plot of $OD/(OD)_0$ (where OD_0 is OD at mid-pulse, obtained by extrapolation) against time gives the same curve for a four-fold variation of initial concentration. This strongly suggests that e^-_{vis} decays by reaction with a geminate partner. By contrast, the half-life for decay of e^-_{ir} depends strongly on dose, and therefore, on initial concentration. Figure 6 shows that for previously unirradiated samples at 76 K, the initial decay follows second-order kinetics although deviations from second-order occur at later times. More significantly, the initial slopes for the second-order plots are the same within experimental error for a four-fold variation in initial concentrations. This means that e^-_{ir} and its reaction partner are homogeneously distributed. At higher temperatures (up to 149 K) the half-life for decay of e^-_{ir} still depends strongly on the dose per pulse, though it seems the concentration of e^-_{ir} is always lower than that of its reaction partner (45).



The most likely decay reaction of e^-_{ir} which accounts for homogeneous second-order kinetics in previously unirradiated pure ice is neutralization by D_2O^+:

$$[5] \qquad e^-_{ir} + D_2O^+ \rightarrow D_2O \text{ or } D + OD + \square$$

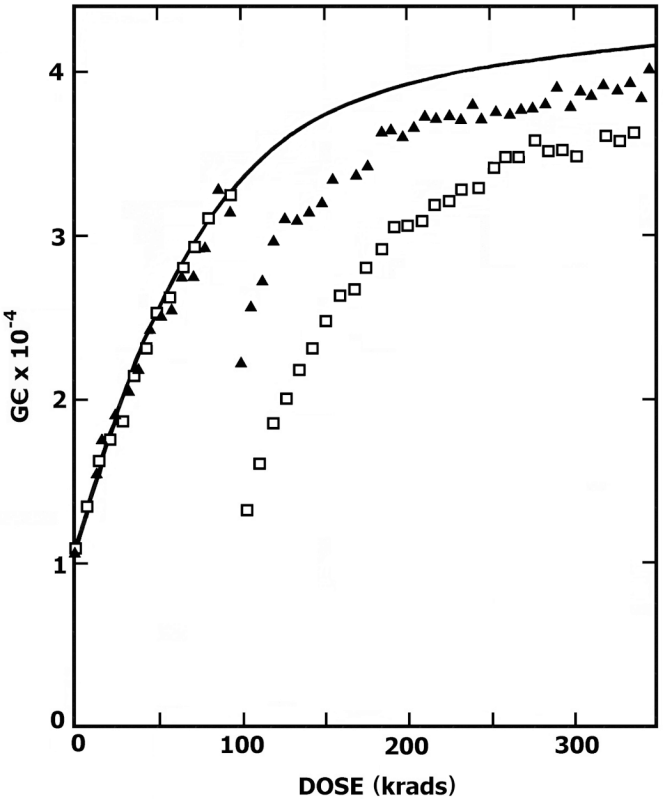
where $\square$ is a vacancy. This requires that e^-_{qf}, the quasi-free electron which is the precursor of e^-_{ir}, is trapped sufficiently far from the site of ionization that e^-_{ir} has a homogeneous distribution with respect to D_2O^+. In view of the high mobility of e^-_{qf}, this requirement is probably met.

The long life-time of e^-_{ir} ($t_{1/2} \cong 25$ ms) in NH_4F-doped crystals at 73 K implies that it has a low mobility; a mobile e^-_{ir} would be expected to react quickly with trapped OD radicals, for example. However, the second-order rate constant at 73 K is calculated as 4×10^{12} M^{-1} s^{-1} from the straight line for pure ice of Fig. 6 and an estimated extinction coefficient for e^-_{ir} at 2350 nm (see below) (44). This rate constant corresponds to a sum of mobilities of e^-_{ir} and its reaction partner of 1.1×10^{-2} cm^2 V^{-1} s^{-1} (44), which seems reasonable for D_2O^+ moving by a resonant charge transfer process. The mobility of D_3O^+ has been measured as only 1×10^{-3} cm^2 V^{-1} s^{-1} at 95 K and should be rather similar at 73 K (46), so e^-_{ir} is probably not decaying by reaction with D_3O^+.

Fig. 6. Decay of absorption at 2350 nm in crystalline D_2O at 76 K, without additives (○) and (●), and doped with 9.6×10^{-4} M NH_4F (△). All three curves are for the first pulse for a sample. Inset: *A*, oscilloscope trace of absorption at 2350 nm for a previously unirradiated crystal without additives at 76 K; *B*, oscilloscope trace of absorption at 2350 nm for a pure crystal that had received an accumulated dose of 100 krads. From ref. 44.

In ice at a nominal temperature of 6 K (the heat input from the pulse increases the temperature momentarily to an observed 13 K), e^-_{ir} undergoes geminate decay, probably by a tunnelling mechanism (47). Two explanations may be offered for the difference from the second-order decay at 73 K and higher temperatures: (*i*) the Onsager radius, that is, the distance from a charged particle at which the Coulombic energy is equal to kT, is much greater at 6 K than at 73 K; and (*ii*) the rate of geminate recombination might be much slower at 6 K so that we observe geminate electrons that would have disappeared before the shortest observation time at 73 K. In keeping with these ideas, for previously unirradiated samples $G(e^-_{ir})$ is estimated to almost triple when the temperature is lowered from 73 to 6 K.

Preirradiation of crystalline D_2O at a nominal 6 K results in a large increase in $G(e^-_{ir})$, as seen in Fig. 7 (47). This effect may be annealed by heating; Fig. 7 shows the decrease of the preirradiation effect brought about by annealing to two temperatures. The effect was completely eliminated by heating to 120 K. It was proposed that the effect of accumulated dose on ice at 6 K is due to the buildup of products which can trap mobile D_2O^+, the most significant of which is probably the D atom which can react as follows:



$$[6] \qquad D + D_2O^+ \rightarrow D_3O^+$$

Reaction [6] would compete with a very rapid recombination of the quasi-free electron (e^-_{qf}) with the geminate positive ion

$$[7] \qquad e^-_{qf} + D_2O^+ \rightarrow D_2O^*$$

and hence favour the trapping of e^-_{qf}:

[8] e^-_{qf} + ir-trap → e^-_{ir}

Trapped hydrogen atoms in irradiated ice have been found to react over a large temperature range; some react slowly at 60 K whereas others react rapidly at 15 K (48); however, no hydrogen atoms are stabilized at 73 K, so it was proposed that product OD radicals can undergo a reaction similar to rxn. [6]:

[9] $OD + D_2O^+ \rightarrow D_3O^+_2$

This would account for the necessity to heat ice to a temperature at which OD radicals become mobile, about 110 K, to restore a crystal to its original condition.

Nature of trap for e^-_{vis}

The results on the visible band absorption can be interpreted on the basis that it is due to electrons trapped in vacancies in the crystal lattice, but there are two distinctly different origins of these vacancies. At 76 K these vacancies do not exist before a crystal has been irradiated, as indicated by the following calculation. The equilibrium concentration of vacancies at any temperature may be calculated from the Boltzmann equation if the energy required to form a vacancy is known. Estimates of this quantity are 0.3–0.4 eV from the rate of self-diffusion in ice (49) and 0.28 ± 0.07 eV from an investigation of the annealing behavior of γ-irradiated ice by positron annihilation techniques (50). As a crystal is cooled down, a temperature will be reached at which vacancies become frozen in, that is, equilibrium is no longer attained. Radiation-produced vacancies become mobile and disappear in the region of 100–120 K (50, 51) and therefore they must be at equilibrium concentrations at higher temperatures. The maximum concentration of vacancies in unirradiated ice at 76 K is that calculated for 120 K by assuming the heat of formation is 0.3 eV, and that concentration is about 1.3×10^{-11} M. For a pulse typical of those used to obtain the data of Fig. 5, the concentration of e^-_{vis} at the end of the pulse was about 2×10^{-6} M, so the concentration of preexisting vacancies at 76 K is not high enough to account for the results.

Irradiation of ice produces vacancies (50, 52). The following mechanism was proposed as the origin of e^-_{vis} at low temperature (44):

[10] $2D_2O \rightarrow (2D_2O^+ + 2\ e^-_{qf})$

[11] $(2D_2O^+ + 2e^-_{qf}) \rightarrow (D + OD + D_2O^+ + e^-_{qf} + \square)$

[12] $(e^-_{qf} + \square) \rightarrow e^-_{vis}$

Here parentheses around reactants are intended to indicate that the reaction takes place in a spur. Reaction [11] is a neutralization reaction that produces the vacancy, and rxn. [12] is the trapping of a quasi-free electron in the same spur. $G(e^-_{vis})$ in D_2O ice around 76 K was reported as ~0.4 (44) and ~0.6 (53); the latter determination was done with a shorter pulse (6 ns) and is presumably better. These yields mean that 10–15% of e^-_{qf} become e^-_{vis}. This seems plausible for the mechanism proposed since the percentage of spurs containing two or more ion pairs in which the successive rxns. [11] and [12] would occur is expected to be rather low.

The narrowing of the visible absorption band with time, as seen in Fig. 5, is easily explained in terms of a vacancy model. If one water molecule is removed from the tetrahedral structure of ice and an electron occupies this vacancy, then protons from only two of the four water molecules in the first shell point towards the electron. Calculations of the optical transition energy for an electron in a vacancy in ice agree with experiment only if two of the molecules at the corners of the tetrahedron can rotate so that four O—H bonds point to the center, and by assuming also that the OH bond length and the H-O-H angles can change from their values in the perfect crystal (54). Therefore, the narrowing of the visible band seen in Fig. 5 is likely a reflection of the orientation of the OD dipoles and (or) a preferential decay of the less stably trapped electrons.

e^-_{vis} and e^-_{ir} in H_2O ice

Both e^-_{vis} and e^-_{ir} are seen in H_2O ice at temperatures of 6 and 73 K (19). The biggest isotope effect seen is in the lifetime of e^-_{vis}. In D_2O ice around 77 K, $t_{1/2}$ for e^-_{vis} is about 120 ns, and in H_2O ice at the same temperature it is 8 ns (53). Several pieces of evidence indicate that the decay occurs in a spur. The decay reaction is not a reaction with OH; it may be migration of H_3O^+ to e^-_{vis} followed by reaction (53). At 6 K in D_2O ice $t_{1/2}$ for e^-_{vis} decay is about 5 μs (53) and in H_2O ice it is ≤75 ns (19). Thus, the ratio of half-lives

© 2001 NRC Canada

is very high at about 15 around 77 K and ≥67 at 6 K. The fast decay of e^-_{vis} at temperatures around 77 K, especially in H_2O ice, accounts for the very low yields of e^-_{vis} seen in early pulse experiments on ice which used 0.4–200 μs pulses.

e^-_{vis} at temperatures near 273 K

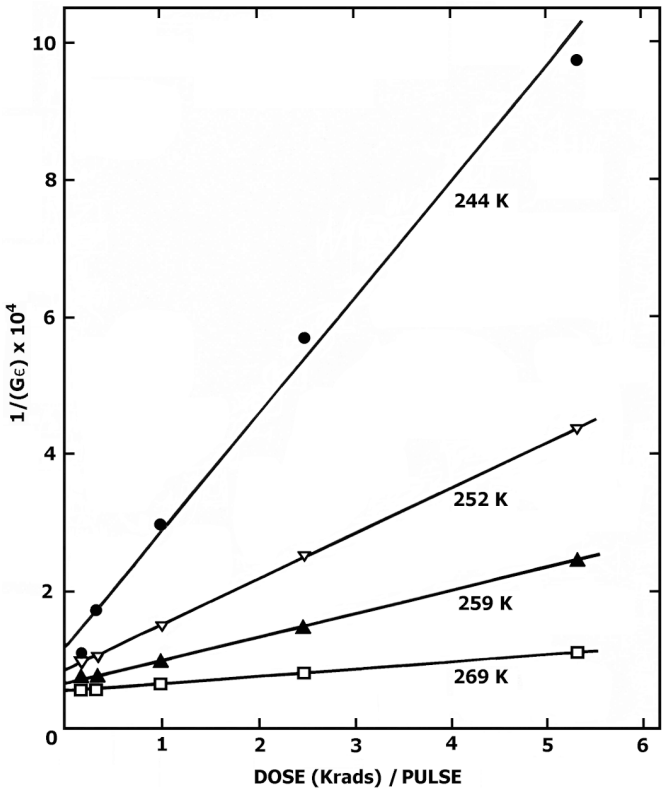
At these higher temperatures e^-_{vis} no longer decays predominantly by geminate recombination as it does at lower temperatures. Rather, the initial half-life for decay depends strongly on the dose in the pulse. A strong dependence of yield of e^-_{vis} in crystalline D_2O at temperatures between 244 and 273 K on dose per pulse has been found (45, 55). This suggests that the precursor of e^-_{vis}, that is, the quasi-free electron e^-_{qf}, undergoes a competition between dropping into a trap such as a vacancy (□) to form e^-_{vis}, or reaction with a radiation product which we designate as X:

[13] $e^-_{qf} + \square \rightarrow e^-_{vis}$

[14] $e^-_{qf} + X \rightarrow$ no e^-_{vis}

It follows that

$$[15] \quad \frac{1}{G(e^-_{vis})} = \frac{1}{G(e^-_{qf})} + \frac{k_{14}[X]}{G(e^-_{qf})\,k_{13}[\square]}$$



For [X] = a*i*, where *i* is the current during the pulse and a is a proportionality constant

$$[16] \quad \frac{1}{G(e^-_{vis})} = \frac{1}{G(e^-_{qf})} + \frac{k_{14}ai}{G(e^-_{qf})\,k_{13}[\square]}$$

Equation [16] indicates that a plot of $1/G(e^-_{vis})$ or $1/G(e^-_{vis})\varepsilon$ against *i* or dose per pulse for constant pulse length should be a straight line, and Fig. 8 shows that in fact for 40 ns reasonably linear plots are obtained for temperatures between 244 and 269 K. A plot of log (intercept/slope) for the plots of Fig. 8 against $1/T$ gives a reasonably straight line, from the slope of which the Arrhenius parameter *E* was calculated as 0.46 eV. This *E* should be close to the heat of formation of a vacancy, and agrees reasonably with literature values for this quantity (45).

Warman and co-workers (56, 57) irradiated H_2O ice with 25 ps electron pulses and found an absorbing species produced immediately in the pulse, which they designated as species X. They also found the e^-_{vis} absorption spectrum which grew in over a few hundred ps at –5°C. The spectrum of species X is similar to that of e^-_{vis} except that it shows relatively greater absorption on the red side of λ_{max}. Its yield ($G\varepsilon_{660} \cong 9 \times 10^3$) at –5°C is approximately the same as that reported at 80 K (53). Species X is most likely the same as e^-_{vis} seen at 73 K. Warman et al. (57) measured $k = 1.2 \times 10^9\ s^{-1}$ for the decay of this species at 245 K (this rate constant means that species X could not have been seen in the nanosecond pulse radiolysis experiments of Buxton et al. (44)). Combination of this rate constant with $t_{1/2} = 8$ ns (53) for e^-_{vis} in H_2O ice at 80 K gives an activation energy of 27 meV, which is not greatly different from that of 20 meV measured by Kawabata et al. (53) between 80 and 100 K. The similar yields for species X at –5°C and e^-_{vis} near 80 K at first seems surprising in view of the report by Buxton et al. (44) that the yield of e^-_{vis} in D_2O decreases as temperature is increased from 73 to 200 K; however, the apparent decrease is likely due to the limited response time of detection. The measurements for $t_{1/2}$ of e^-_{vis} in D_2O ice by Kawabata et al. (53) of 120 ns at 80 K and 76 ns at 100 K suggest that the yields measured by Buxton et al. (44) at temperatures above 73 K were not initial yields.

Fig. 8. Reciprocals of yields of e^-_{vis} in pure crystalline D_2O, measured at 650 nm, as a function of dose per pulse at different temperatures. The pulse length was 40 ns. From ref. 45.

Warman et al. (57) suggested that species X or low-temperature e^-_{vis} seen by them and Buxton et al. (44) might be an exciton state rather than e^-_{vis}. However, Kawabata et al. (53) found that the decay of e^-_{vis} at 80 K follows Hummel's (58) empirical equation for decay by geminate ion recombination in a spur, and they reported other pieces of evidence which indicate that decay occurs in a spur. We believe that the weight of evidence strongly suggests that species X (which is the same as the low-temperature e^-_{vis}) and e^-_{vis} which grows in over a few hundred picoseconds in ice near 0°C are essentially the same species, though they are produced by different mechanisms, and this species is very similar to the hydrated electron.

Warman et al. (57) found that the build-up of visible absorption could be described by the following reaction scheme:

[17] $H_2O \rightarrow e^-, H_3O^+, X$

[18] $e^- + H_3O^+ \xrightarrow{k_R} H_2O + H$

[19] $e^- + T \xrightarrow{k_T N_T} e^-_T$

© 2001 NRC Canada

[20] $e_T^- \xrightarrow{k_{rel}} e_{sol}^-$

[21] $X \xrightarrow{k_X}$ products

Reaction [19] is the reaction of a quasi-free electron with a naturally occurring trap, and reaction [20] is that of a trapped electron to give a solvated (hydrated) electron. The values of k_R and $k_T N_T$ were determined from conductivity measurements (see below) and, as indicated above, k_X was found to be 1.2×10^9 s^{-1}. The growth curves in the temperature range –5 to –30°C were fitted to give $G\varepsilon$ and k_{rel}. The values found for $G\varepsilon$ are in good agreement with those reported by Nilsson and Pagsberg (55) and Gillis et al. (45), and k_{rel} was found to be 2.2×10^9 s^{-1} at –5°C. The absolute magnitude of k_{rel} is much larger than would be expected on the basis of the bulk dielectric relaxation time for fixed charge.

By doping ice with NH_4F, Warman et al. (57) were able to observe clearly the initial decrease in absorption at λ_{max} of 660 nm followed by growth of absorption due to rxn. [20] (e_{sol}^- is e_{vis}^- in our terminology). This separation of the timescales of decay and growth is good evidence that species X is not a direct precursor of e_{vis}^-. It is unfortunate that these authors did not extend their wavelength range beyond 1000 nm, to attempt the measure the spectrum of e_T^-. Presumably they could not do so because of the low intensity at higher wavelengths of the Cerenkov light which they used for measurements. The species e_T^- is unrelaxed and might have a spectrum similar to that of e_{ir}^-.

Nature of site for e_{ir}^- in ice

Buxton et al. (44) suggested that the IR band in crystalline ice is due to electrons trapped in natural cavities that exist in perfect crystals. In crystals of ordinary ice (ice I_h), molecules form sheets of crinkled six-membered rings normal to the *c* axis. Rings from two adjacent sheets form dodecahedral cavities that are joined together along the *c* axis to form long shafts. It was suggested that electrons trapped in these cavities give rise to the IR band. Before e_{ir}^- had been observed in aqueous solids, Nilsson (59) carried out calculations on this ice-cavity model to see if agreement could be found with the optical transition energy of e_{vis}^-. He found agreement was reasonable if it was assumed that the dipoles of the first coordination shell have time to line up with the electric field during the lifetime of e_{ir}^-. The dipole relaxation times would have to be much less than the dielectric relaxation time of ice which is about 1 ms at –40°C and decreases with temperature (60). Without this assumption the calculated optical transition in the Nilsson treatment is at about 800 nm for ice at –10°C, which of course is at a much higher energy than the extrapolated experimental λ_{max} of 2950 nm.

Kevan (61) calculated an optical absorption peak for the polaron in ice at ~77 K in the 3100–2100 nm region, which agrees nicely with the extrapolated experimental λ_{max}. Julienne and Gary (62) also carried out calculations based on the polaron model. If the dipolar medium molecules are unable to orient themselves with respect to the charge, the optical absorption maxima are calculated to be 2300, 2100, and 1800 nm for cavity sizes of 3.0, 2.5, and 2.0 A°, respectively (62).

We conclude that the polaron model leads to a calculated λ_{max} for e_{ir}^- in reasonable agreement with experiment.

Decay kinetics of quasi-free electrons in ice as followed by conductivity

The decay kinetics of the highly mobile quasi-free electrons formed by nanosecond pulse radiolysis of crystalline ice were studied from –10 to –190°C by using the microwave conductivity method (63). In the temperature range $0°C > T > -40°C$ the lifetime of the quasi-free electron is comparable to the response time of detection, but accurate kinetic data were obtained by using a long (50 ns) pulse and fitting the data in the pulse. Reactions [18] and [19] were the main reactions included in the fitting, but a slight complication arose because of a small conductivity signal that decays over a relatively long period ($t_{1/2} \cong 50$ ns); this signal was attributed to mobile protons and was incorporated into the kinetic fits. The values of $k_T N_T$ obtained in this way should be quite reliable. Arrhenius plots of $k_T N_T$ obtained in this way show a linear dependence above about –70°C for both H_2O and D_2O ice with an activation energy of 0.55 ± 0.05 eV (64).

Warman et al. (63) consider that the trap of eq. [19] is a combination of a D defect and a vacancy, called a dressed vacancy. They point out that in view of the large repulsive force between neighbouring H atoms in a lattice D defect, quite a large fraction of D defects might be expected to reside at vacancy positions where the stress is released.

In the temperature range $-80°C > T > -140°C$, the first half-life of the conductivity signal is inversely proportional to the total dose in the pulse, which indicates that electron decay in this range is mainly by reaction with a product or products which are also formed in the pulse (63). The dominance of this reaction should be even greater for the pulses of much higher dose that were used in the optical absorption studies. However, the conductivity results would seem to be compatible with the small yields of e_{ir}^- found in this temperature range.

The decay rate of quasi-free electrons increases as the temperature is lowered from –140°C. Warman et al. (63) suggest that in the temperature range $-140°C > T > -190°C$ mobile electrons are localized at a trapping site from which they are readily emitted thermally

[22] $S + e^- \leftrightarrow S^-$

Luminescence from ice

UV and visible luminescences are emitted when ice at low temperature is exposed to ionizing radiation. The intensity of the luminescence at some wavelengths from ice at 88 K increases with successive pulses of electrons and reaches a plateau level (65). Studies (66) of such dose accumulation effects have allowed separation of the luminescence into three bands. For H_2O ice at 88 K these bands have the following luminescence yields (G_p) in photons/100 eV: the 280–340 nm band, $G_p = 2 \times 10^{-7}$; the 320–600 nm band, with $\lambda_{max} \cong 385$ nm, $G_p = 1 \times 10^{-5}$ after 50 krad of irradiation but rising to a plateau value of 2×10^{-4} after a total of 1.2–1.5 Mrad; the 500–600 nm band, $G_p = 1 \times 10^{-5}$. The intensities of the 280–340 nm and 500–600 nm bands to a

© 2001 NRC Canada

good approximation are independent of dose in the range 0.50–1.5 Mrad (65, 66).

Decay of the 385 nm luminescence was analyzed into a long-lived first-order component ($t_{1/2}$ = 690 ns for H_2O and 1820 ns for D_2O) and a superimposed short-lived decay which obeys second-order kinetics (67). The ratio of the first-order rate constants, $k(H_2O)/k(D_2O)$ was 2.7 ± 0.3, which agrees with the ratio (2.7) of the mobilities of protons and deuterons in their respective ices in one report (68), though a later report by the same authors gives a smaller ratio of $2 > M(H^+)/M(D^+) \geq 1.3$ (69). Studies of the effect of temperature on the 385 nm luminescence band showed that from 79 to 101 K, the luminescence intensity did not change greatly with temperature (70); however, the intensity fell sharply between 101 and 117 K, which parallels the behaviour of trapped OH (71). The mechanism suggested for the 385 nm luminescence at 88 K is (70):

[23] $H_2O \rightarrow H + OH + H_2O^+ + OH^- + e^-$

[24] $OH \rightarrow OH_t$

[25] $OH_t + e^- \rightarrow OH^-$

[26] $OH^- + H^+ \rightarrow H_2O^* (C^1B_1)$

[27] $H_2O^* (C^1B_1) \rightarrow H_2O (A^1B_1) + h\nu$

As the position of the 385 nm luminescence peak does not change when the early second-order luminescence is followed by the long-lived, first-order emission, it can be concluded that both the early and late emissions arise from the same excited species. The short-lived 385 nm decay may, however, proceed by a different mechanism which does not produce H_2O in the C^1B_1 state. Alternatively, it may proceed by the same mechanism, OH^- again reacting with H^+, but at a different type of location where the $[OH^-]/[H^+]$ ratio is closer to unity.

Emission from irradiated ice has also been studied over the lower temperature range 8–77 K (72). It was found that the emission intensity at 77 and 40 K has a max around 380 nm (very similar to the λ_{max} from the earlier work (65, 66) on ice at 88 K) while the luminescences from ice at 20 and 8 K both show maxima around 330 nm. The emission intensity at 8 K is about 40 times higher than at 77 K. The 330 nm emission at 8 K increases with increasing accumulated dose, as does the peak around 385 nm at 88 K (66). This indicates that trapped irradiation products are implicated in the origin of these peaks. The accumulated dose effect on the 8 K emission is not eliminated by warming to 40 K, but is wiped out by warming to 77 K. The following mechanism is proposed by Miyazaki et al. (72):

[28] $H_2O \rightarrow H_2O_t^+ + e_t^-$

[29] $H_2O_t^+ + e_t^- \rightarrow H_2O^*$

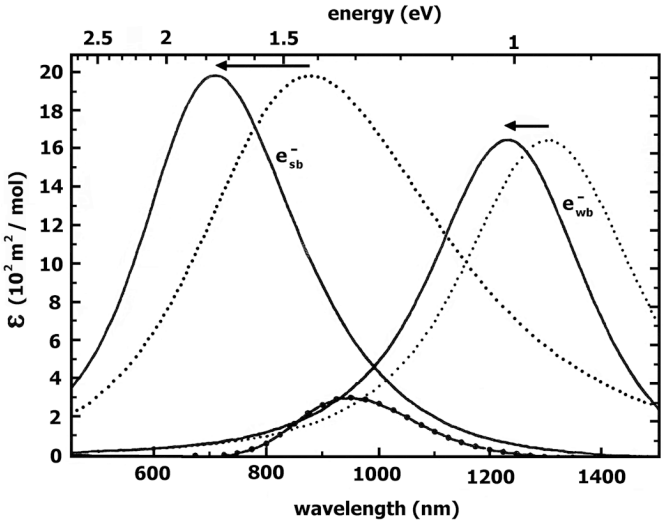
[30] $H_2O^* \rightarrow OH^* (A^2\Sigma^+) + H$

It is concluded by Miyazaki et al. (73) that the trapped electron in rxn. [29] is e_{ir}^-. They chose this mechanism partly because of the effects on luminescence of adding NaOH, HCl, or C_2H_5OH to the water from which ice samples were grown (73). However, these solutes are rather insoluble in ice and the first two form clusters in ice (74), so their effective concentration in the ice samples may have been extremely low. The conclusion was based also on an approximate correspondence between the emission lifetimes and the lifetimes of e_{ir}^-. The correspondence has to be approximate because the emission kinetics are approximately first-order after an initial faster decay, whereas e_{ir}^- decay seems to be geminate and follows a tunnelling mechanism (47).

Further studies are necessary to confirm this or another mechanism, and to provide reasons why the mechanism for production of luminescence should change between 40 and 20 K.

Electron solvation in water

Over the past 25 years many reports have been published of experimental, theoretical, and simulation studies of the solvation kinetics of electrons in water and other polar liquids. In alcohols the time dependence of the spectroscopic changes which accompany the solvation process correlate well with the monomeric dielectric relaxation time of the alcohol (75), and these times are of the order of 10–50 ps. The molecular relaxation time in water is less than 1 ps, and direct observation of the solvation process was only possible after lasers with pulse lengths less than 1 ps became available. Studies of electron solvation in water have been summarized recently by Pépin et al. (76).



Recent experimental studies on electron solvation in pure water or aqueous salt solutions have been of two types: (*i*) photoionization via two- or multi-photon absorption, followed by a variably delayed probe pulse at a selected wavelength which monitors the induced changes in transmission; and (*ii*) three-pulse experiments: the first preparation pulse generates solvated electrons, which after an equilibration time of typically 1–4 ns are excited by a second pulse to upper states, and a probe pulse monitors changes as in (*i*).

According to Pépin et al. (76), it is generally agreed that a large number of trap states are available to quasi-free electrons in polar media. At very short times the quasi-free electron is trapped to form a weakly-bound species (e_{wb}^-) which absorbs chiefly in the IR. This species undergoes a stepwise transition to a strongly bound species (e_{sb}^-) that absorbs in the visible and which relaxes to become the well-known hydrated electron at long times. Some authors consider the weakly bound species (e_{wb}^-) to be the *p*-like excited states of the hydrated electron (77, 78). Some of the matters on which the various studies disagree are: (*i*) the existence of a direct solvation channel which allows the quasi-free electron to go to the e_{sb}^- state without passing through the e_{wb}^- state; (*ii*) the existence of another species absorbing in the IR due to transient encounter pairs; and (*iii*) the role played by solvent relaxation in the spectral evolution of the absorbing species.

Pépin et al. (76) studied electron solvation in liquid D_2O by the two-pulse method at 20 different wavelengths in the 450–1450 nm range. On the basis of the following picture they were able to get good fits to kinetic traces at all wavelengths: (*i*) trapping starting 0.15 ps after the passage of the excitation pulse's maximum intensity; (*ii*) a stepwise transition with a characteristic time of 0.4 ps between the major species e_{wb}^- and e_{sb}^-; (*iii*) a blue shift of the spectra of both e_{wb}^- and e_{sb}^-, concomitant with the stepwise transition and with a characteristic time of 0.5 ps; (*iv*) magnitudes of

Fig. 9. Molar extinction coefficients ε (SI units are used: 1 m^2 mol^{-1} = 10 M^{-1} cm^{-1}) of the various species that are included in the fit of the observed solvation kinetics of electrons in pure liquid D_2O. The dotted lines represent the spectra of e^-_{wb} and e^-_{sb} before any continuous shift has occurred. The solid lines represent the spectra in the long-time limit, that is, when the continuous shift is completed. The arrows indicate the amplitude of the blue shifts. One should note that, on the energy scale, the widths of the spectra remain constant. From ref. 76.

the blue shifts of e^-_{wb} and e^-_{sb} of 0.06 and 0.34 eV, respectively; (*v*) a probability of direct trapping into the e^-_{sb} configuration of 0.34; and (*vi*) a weak source of absorption in the near-IR (800–1100 nm) with a characteristic decay time of 2.0 ps. The spectra of e^-_{wb}, e^-_{sb}, and the near-IR component are shown in Fig. 9.

The above analysis of electron solvation in liquid D_2O is similar to an analysis of electron solvation in methanol at room temperature by the same authors (3), except that in the latter case the characteristic relaxation times were much greater. These authors (79) used a similar model to reanalyze three-pulse experiments in water (80) and alcohols of various chain lengths (81) and found that the general features of the results could be explained in terms of their hybrid model, by using the kinetic and spectral parameters they found in their own two-pulse experiments (3, 76). However, there are several parameters that are fitted in the model of Pépin et al. (76), and likely other models and parameters would also explain the results. Certainly other authors have used different models and parameters to explain their own results. For example, the two-pulse experiments of Eisenthal and co-workers (82) were interpreted on the basis of a two-state model, but the upper state (referred to as the "wet electron" and considered likely to be a *p*-like excited state) was found to have a broad maximum near 900 nm. Assel et al. (83) consider on the basis of their experiments that the wet electron discussed by Eisenthal and co-workers (82) is really a ground state electron in a hot solvent cavity. Assel et al. (84) reported very recently on three-pulse experiments with pure water; they find the first intermediate (e^-_{wb} in the terminology of Pépin et al. (76)) has λ_{max} = 1000 nm. Similarly, Hertwig et al. (85) on the basis of their two-pulse experiments consider that their initial (~350 fs) spectrum, the maximum of which is red-shifted by about 0.5 eV with respect to that of the thermally relaxed spectrum, is due to hot solvated electrons. They find no evidence for transient electronically excited states of solvated electrons.

Recently Pastina et al. (86) measured hydrogen yields following γ-radiolysis of aqueous solutions with a variety of scavengers of the hydrated electron and its precursor. They concluded that a common precursor is responsible for both molecular hydrogen and the hydrated electron. The mechanism for producing molecular hydrogen is unknown, but a suggestion is the capture of the precursor by water to give the molecular anion, which then either gives molecular hydrogen directly, or decomposes to give a hydride anion which reacts with water to produce molecular hydrogen (86). Presumably the precursor to the hydrated electron considered by Pastina et al. (86) is the same as the e^-_{wb} discussed by Pépin et al. (76); however, the analysis by Pépin et al. (76) assumes that all e^-_{wb} becomes e^-_{sb}, except for the small fraction that undergoes geminate recombination, and the extinction coefficients of Fig. 9 are calculated on this assumption.

Connection between electron solvation in water and in aqueous solids

Very shortly after injection of electrons into water, two major species seem to be present: a weakly bound species e^-_{wb} (sometimes considered to be the *p*-state of the solvated electron) which absorbs mainly in the near-IR, and a strongly bound species (e^-_{sb}) which absorbs in the visible. Some researchers consider that there is another, less important species which also absorbs in the near-IR. A first-order transition $e^-_{wb} \rightarrow e^-_{sb}$ occurs, as well as concomitant blue shifts of both species. The magnitude of the blue shift is greater for e^-_{sb} than for e^-_{wb}, and e^-_{sb} becomes the hydrated electron at long times. A study of hydrogen yields from the γ-radiolysis of aqueous solutions suggests that the precursor of the hydrated electron is also a precursor of molecular hydrogen.

After injection of an electron into ice or some aqueous solids, again two major species are produced: the very weakly bound e^-_{ir}, and the strongly bound e^-_{vis} which at long times is essentially the same as the hydrated electron. The traps for the two species seem to be physically different; therefore, e^-_{ir} does not appear to be an excited state of the hydrated electron. At short times e^-_{vis} undergoes a blue shift, which is much smaller than the blue shift of e^-_{sb} in water. Evidence is strong that the transition $e^-_{ir} \rightarrow e^-_{vis}$ occurs in some glasses under some circumstances, but in crystalline ice the transition has only been observed directly once, at 4 K. It is likely that the transition is slow in aqueous solids, such that reaction of e^-_{ir} with other radiation-produced species is sometimes faster, or such that decay of e^-_{vis} with other radiation-produced species is sometimes faster than its production by the transition.

In both water and aqueous solids there is a direct channel for the transition from quasi-free electrons to the strongly bound state (e^-_{sb} or e^-_{vis}) without going through the weakly bound state, e^-_{wb} or e^-_{ir}.

Thus there are strong similarities between e^-_{ir} and e^-_{wb} and we suggest they are essentially the same species, although

© 2001 NRC Canada

the absorption spectrum of e^-_{wb} is significantly blue-shifted as compared to e^-_{ir}.

Scope and limitations in the use of *N*-(PhF)serine-derived cyclic sulfamidates for amino acid synthesis

Lan Wei and William D. Lubell

Abstract: Ring-opening of *N*-(PhF)serine-derived cyclic sulfamidate **17** was achieved with different nucleophiles (β-keto esters, β-keto ketones, dimethyl malonate, nitroethane, sodium azide, imidazole, and potassium thiocyanate) to prepare a variety of amino acid analogs. Two different pathways for ring opening of **17** were elucidated: direct nucleophilic displacement, as well as β-elimination followed by Michael addition. Furthermore, β-keto ester and β-keto ketone products **18k**, **18m**, and **18i** were converted to prolines and pyrazole amino acids.

Key words: glutamate, amino acid, cyclic sulfamidate, proline.

Résumé : L'ouverture des sulfamidates cycliques dérivés de la serine a été explorée avec différents nucléophiles (β-céto esters, 1,3-dicétones, diméthyle de malonate, nitroéthane, azidure de sodium, imidazole et thiocyanate de potassium) pour préparer une variété d'analogues d'acides aminés. Deux voies différentes ont été proposées pour l'ouverture du cycle à cinq membres du sulfamidate **17**: le déplacement nucléophile et l'élimination β suivie de l'addition de Michael. De plus, les β-céto ester **18k**, **18m** et 1,3-dicétone **18i** ont été respectivement convertis en prolines et en acides aminés pyrazoyle.

Mots clés : glutamate, acide aminé, sulfamidate cyclique, proline.

Introduction

Serine-derived cyclic sulfamidates have served in syntheses of a series of amino acid analogs (Fig. 1) (1–3). For example, β-substituted alanines **1**–**11** have been prepared by ring opening of sulfamidate with oxygen, nitrogen, sulfur, and fluorine nucleophiles (1–3). Aspartate analogs **12** and **13** have also been prepared by nucleophilic opening of sulfamidate with a cyanide ion (1, 3). Moreover, γ-acyl pyroglutamate **14** was furnished on treatment of sulfamidate with diethyl malonate (1). These examples demonstrate that serine-derived cyclic sulfamidates are versatile chiral building blocks with complementary reactivity to related β-alanine cation equivalents such as serine-derived β-lactones (4, 5) and aziridines (6, 7).

Interested in harnessing its power to construct peptide mimics and glutamate receptor ligands, we have explored the reactivity of cyclic-sulfamidate **17** derived from *N*-(PhF)serine methyl ester (Scheme 1), because of the proven effectiveness of the PhF protecting group for preserving configurational integrity during manipulations of α-amino carbonyl compounds (PhF = 9-(9-phenylfluorenyl)) (8, 9). Sulfamidate **17** reacted with a series of heteroatomic as well as carbon nucleophiles to provide the desired amino acid analogs; however, careful examination of the configurational integrity of these products revealed that racemization occurred during reactions of **17** with carbon nucleophiles (10). Although enantiopure serine has often been employed as starting material, to the best of our knowledge, the enantiomeric purity of the products from ring opening of its cyclic sulfamidates had been previously reported in only two examples (2). Pyrazole **7** and piperidine **8** were checked for racemization after conversion to diastereomeric amides using, respectively, (*R*)-α-methoxy-α-trifluoromethylphenylacetyl chloride and (–)-menthyl chloroformate. A comparison of the diastereomeric amides with material prepared from racemic serine using proton nuclear magnetic resonance (^{1}H NMR) spectroscopy led the authors to conclude that "no apparent racemization occurred in the course of both the ring opening and the hydrolysis" reactions involved in the preparation of **7** and **8**. This claim contrasted with our discovery of racemization in the reactions of sulfamidate **17** with carbon nucleophiles and provoked a detailed investigation of the enantiomeric purity of the various products from nucleophilic ring opening of sulfamidate **17**.

In reactions with different nucleophiles, sulfamidate **17** was found to undergo additions via two different mechanisms. In the case of weakly basic (conjugate acid $pK_a \leq 7$) nucleophiles, direct nucleophilic displacement occurred to provide enantiopure (>97% ee) β-substituted alanines. On the other hand, carbon nucleophiles, such as the enolates of 1,3-dicarbonyl compounds, added to sulfamidate **17** by a mechanism featuring β-elimination to provide a

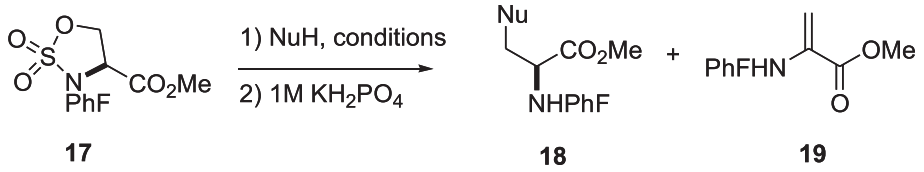
dehydroalanine intermediate that underwent subsequent Michael addition and afforded racemic product. In addition, several nucleophiles were found that caused β-elimination, yet failed to react with the dehydroalanine intermediate in a conjugate addition. This spectrum of reactivity and the utility of the addition products have been evaluated to better define the scope and limitations of *N*-(PhF)serine-derived sulfamidate **17** as a chiral educt for amino acid synthesis.

Results and discussion

Synthesis of cyclic sulfamidate 17

Sulfamidate derivatives of β-amino alcohols permit protection of the nitrogen moiety and conversion of the hydroxyl group into a leaving group. The most direct approach for their construction has been the reaction of the respective β-amino alcohol with sulfuryl chloride; however, this process has usually led to the corresponding aziridines, presumably due to ring closure of the corresponding -OSO_2Cl intermediate (11–13). Because of the difficulties encountered when using sulfuryl chloride, most cyclic sulfamidates have been prepared by oxidation of the corresponding sulfamidites (1–3, 11–22). Following this protocol, (4*S*)-methyl 2,2-dioxo-3-PhF-1,2,3-oxathiazolidine-4-carboxylate (**17**) was synthesized initially by treating *N*-(PhF)serine methyl ester **15** (23) with thionyl chloride, triethylamine, and imidazole in dichloromethane to furnish quantitatively a 1:2 mixture of diastereoisomeric sulfamidites **16** (Scheme 1). Cyclic sulfamidate **17** was then prepared by subsequent oxidation of sulfamidites **16** with sodium periodate and catalytic ruthenium trichloride in acetonitrile and water at 0°C.

Scheme 1. Synthesis of cyclic sulfamidate **17**.



Diastereoisomers (2*R*)-**16** and (2*S*)-**16** could be separated by chromatography and independently converted into five-membered sulfamidate **17**. The assignment of the configuration at sulfur for the diastereoisomers (2*R*)-**16** and (2*S*)-**16** was initially attempted by comparisons of their ^{1}H NMR spectra with that of their oxidation product sulfamidate **17** (Table 1), as well as with spectral data for other cyclic sulfamidites (24). Comparing the spectra of **16** and **17**, we concluded that the (2*R*)-sulfamidite ((2*R*)-**16**), would exhibit similar steric as well as anisotropic effects as sulfamidate **17** (25, 26). For example, in the spectra of (2*R*)-**16** and **17**, the C-4 proton appeared as a doublet of doublets as the result of steric interactions between the exocyclic oxygen atom on sulfur and the PhF group, which twisted the five-membered ring such that significantly different dihedral angles existed between the C-4 and C-5 protons. In contrast, the C-4 proton in (2*S*)-**16** appeared as a triplet indicative of a conformation with similar dihedral angles between the C-4 proton and each of the C-5 protons. The magnetic anisotropy of the S—O bond (26) shifted downfield the resonances of proximal PhF protons as well as the C-4 proton in the spectra of (2*R*)-**16** and **17** relative to the respective signals in the spectrum of (2*S*)-**16**.

The configurational assignments for **16**, which were made based on the ^{1}H NMR chemical shift and coupling constant

values, were confirmed by X-ray crystallographic analysis of (2*R*)-**16** (Fig. 2). Single-crystal X-ray analysis showed that the dihedral angle between the C-4 proton and the C-5α proton was 25.4°, and the dihedral angle between the C-4 proton and the C-5β proton was 82.6°. The crystal structure of (2*R*)-**16** exhibits a conformation in which the α-proton and the α-acid carbonyl are nearly coplanar (159.5°). Since α-deprotonation from the coplanar geometry is stereoelectronically less favoured than from an orthogonal geometry, this arrangement has been suggested to contribute to the configurational stability of PhF amino carbonyl compounds (27, 28).

Ring opening of five-membered cyclic sulfamidate 17

With cyclic sulfamidate **17** in hand, we next examined nucleophilic ring opening using different nucleophiles (Scheme 2, Table 2). Cyclic sulfamidate **17** reacted with heteroatomic nucleophiles to provide products from both nucleophilic displacement at C-5 and proton abstraction at C-4. For example, KSCN, NaN_3, and imidazole, all opened regioselectively the sulfamidate ring to afford, respectively, thioether **18d**, azide **18e**, and imidazole **18f**. Other nucleophiles, such as TBAF, MeONa, diethyl amine, and piperidine, gave mainly dehydroalanine **19** and recovered starting material as observed by NMR spectral analysis of the crude product after aqueous work-up.

Ring opening of sulfamidate **17** was also examined using *C*-nucleophiles including β-keto esters, β-keto ketones, dimethyl malonate, and nitroethane. Treatment of sulfamidate **17** with a premixed solution containing 400 mol% of either β-keto ester, β-keto ketone, or dimethyl malonate and 220 mol% of sodium hydride in DME, followed by heating at 60°C caused ring opening to form the polar sulfamic acid intermediate. Hydrolysis of the reaction mixture with 1 M KH_2PO_4 furnished the desired amino acid derivatives **18i**–**o** after chromatography (Table 2). Since β-keto ester **18k** and β-keto ketone **18i** were difficult to separate from methyl acetoacetate and 2,4-pentanedione, respectively, the crude material was used without purification in the next step towards the preparation of heterocyclic amino acids. Nitroethane reacted with **17** using similar conditions to provide γ-nitro-α-amino pentanoate **18o** in 52% yield as a 10:1 mixture of diastereomers.

β-Keto esters **18k** and **18m** were next converted, respectively, to 5-methylproline **23** and δ-keto α-amino ester **20m**, an intermediate in the synthesis of 5-*tert*-butylproline (29) (Scheme 3). Their respective δ-oxo-α-*N*-(PhF)amino acids were first obtained from hydrolysis and decarboxylation of β-keto esters **18k** and **18m** with sodium hydroxide in ethanol heated at a reflux. Esterification with iodomethane and potassium carbonate in acetonitrile provided methyl 5-oxo-2-[*N*-(PhF)amino]hexanoate (**20k**) and methyl 6,6-dimethyl-5-oxo-2-[*N*-(PhF)amino]heptanoate (**20m**) in 71% and 52% overall yields, respectively, from **17**. Hydrogenation of δ-oxoheptanoate with palladium-on-carbon and di-*tert*-butyl dicarbonate in methanol proceeded by cleavage of the PhF protection, *N*-acylation, imine formation, and hydrogenation of the imine intermediate on the face opposite the methyl ester to furnish *N*-(BOC)-5-methylproline methyl ester (**21**) as the *cis*-diastereomer. Hydrolysis of methyl ester *cis*-**21** with potassium trimethylsilanolate in Et_2O furnished *cis*-*N*-(BOC)-5-methylproline (*cis*-**22**) in 96% yield. In addition, removal of the BOC protecting group with trifluoroacetic acid in dichloromethane provided *cis*-5-methylproline **23** (30, 31).

The utility of β-keto ketone **18i** was illustrated by its conversion to pyrazole amino acid **26** (Scheme 3). Methyl 2-[*N*-(PhF)amino]-3-(3,5-dimethyl-2*H*-pyrazol-4-yl)propanoate (**24**) was initially prepared by treatment of β-keto ketone **18i** with

[2] The structure of (2*R*)-**16** was solved at l'Université de Montréal X-ray facility using direct methods (SHELXS 96) and refined with SHELXL 96: $C_{23}H_{19}NO_4S$, Mr = 405.452, orthorhombic, colourless crystal, space group $P2_12_12_1$, unit cell dimensions (Å) a = 9.5587(2), b = 9.7736(2), c = 21.0498(4), volume of unit cell (Å^3) 1966.53(7), Z = 4, R_1 = 0.0659 for $F^2 > 2\sigma(F^2)$, wR_2 = 0.1613 for all data; GOF = 1.048. The author has deposited the atomic coordinates for the structure of (2*R*)-**16** with the Cambridge Crystallographic Data Centre. The coordinates can be obtained, free of charge, on application to the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, U.K. (Fax: 44-1223-336033 or e-mail: deposit@ccdc.cam.ac.uk). Scheme 3. Synthesis of 5-alkylproline **23** and amino-3-(3,5-dimethyl-1*H*-pyrazol-4-yl) propionic acid **26**.

© 2001 NRC Canada

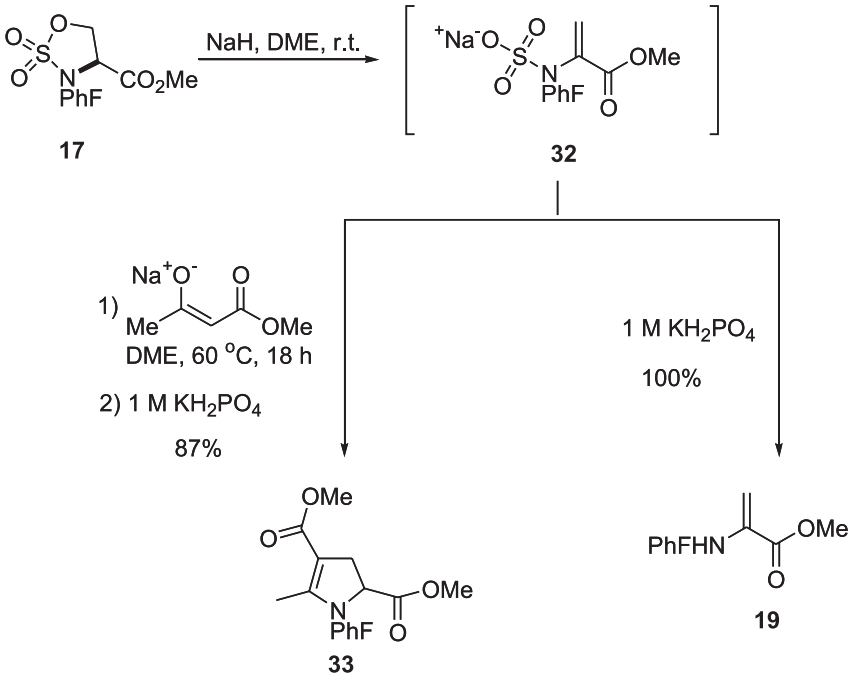
Fig. 3. Evaluation of enantiomeric purity of amino acids **28**, **29**, and *cis*-**22**.

hydrazine hydrate. Hydrolysis of methyl ester **24** with 1 N NaOH in EtOH then furnished 2-[*N*-(PhF)amino]-3-(3,5-dimethyl-1*H*-pyrazol-4-yl)propionic acid (**25**) as a solid after chromatography. Removal of the PhF group was cleanly accomplished by heating **25** with trifluoroacetic acid in dichloromethane at a reflux for 18 h and furnished **26** in 88% yield.

Enantiomeric purity

Enantiomeric purity was evaluated for two products by conversion to diastereomeric derivatives and analysis of the isomeric signals in their ^{1}H NMR spectra. In the case of (2*S*)-*N*-PhF-*S*-cyanocysteine methyl ester (**18d**), conversion to *N*-PhF-L-alanine (**28**) and comparison of its specific rotation with the literature value was used to estimate purity. Cleavage of the S—C bond with Raney nickel in EtOAc at reflux for 6 h gave *N*-PhF-L-alanine methyl ester (**27**). Hydrolysis of *N*-PhF-L-alanine methyl ester (**27**) with 1 N NaOH in ethanol for 1 h gave *N*-PhF-L-alanine (**28**) in 74% overall yield from **18d** (Fig. 3). The specific rotation of *N*-PhF-L-alanine (**28**) and comparison with its literature value (9) ($[\alpha]_D^{20}$ 150° (*c* 0.2, $CHCl_3$), lit. (9) $[[\alpha]_D^{20}$ 163° (*c* 1, $CHCl_3$)) demonstrated that the material from sulfamidate opening was significantly enriched with one enantiomer.



The enantiomeric purity of (2*S*)-methyl 3-(1-imidazol)-2-[*N*-(PhF)amino]propionate (**18f**) was determined after conversion to diastereomeric amides **30**, and subsequent spectral analysis. (2*S*)-3-(1-Imidazol)-2-[*N*-(PhF)amino]propionic acid (**29**) was first synthesized by ester hydrolysis in 86% yield using 1 N NaOH in EtOH. Acid **29** was coupled to L- and D-phenylalanine methyl ester in MeCN with TBTU and DIEA, respectively, at room temperature. Measurement of the methyl ester singlets at 3.71 and 3.76 ppm in $CDCl_3$ by 400 MHz ^{1}H NMR spectroscopy demonstrated **30** to be of >97% diastereomeric excess. Hence, (2*S*)-methyl 3-(1-imidazol)-2-[*N*-(PhF)amino]propionate (**18f**) is presumed to be of >97% enantiomeric purity. We consider, therefore, that no racemization occurred during nucleophilic substitution on cyclic sulfamidate **17** with imidazole nor with potassium thiocyanate nor with azide ion as nucleophiles.

The enantiomeric purity of *cis*-*N*-(BOC)-5-methylproline (*cis*-**22**) was studied after conversion to diastereomeric α-methylbenzylamides **31** by coupling, respectively, to *R*- and *S*-α-methylbenzylamine in MeCN with TBTU followed by removal of the BOC group with 10% TFA in CH_2Cl_2 (Fig. 3). In the ^{1}H NMR spectra of α-methylbenzylamides **31**, the diastereomeric methyl doublets were resolved and came at 1.50 and 1.49 ppm, as well as at 1.46 and 1.42 ppm. Integration of these doublets indicated that **31** was of only 10% diastereomeric excess.

In contrast to the amino acid syntheses using less basic nucleophiles, racemization had evidently occurred during the preparation of *cis*-*N*-(BOC)-5-methylproline **22**. The source of the loss of configurational integrity was narrowed down to the ring opening step after measurement of the specific rotation of δ-keto α-amino ester **20m**, which showed a considerable drop in optical purity ($[\alpha]_D^{20}$ –1.2° (*c* 0.8, $CHCl_3$), lit. (29) $[\alpha]_D^{20}$ –137.7° (*c* 1, MeOH)). Because hydrolysis and decarboxylation of β-keto ester **18m**, prepared from a route featuring acylation of *N*-(PhF)glutamate γ-methyl ester (32), produced enantiopure **20m** ($[\alpha]_D^{20}$ –139° (*c* 0.8, MeOH)), we considered that racemization occurred prior to or during the nucleophilic addition to cyclic sulfamidate **17** and not at the hydrolysis and decarboxylation steps.

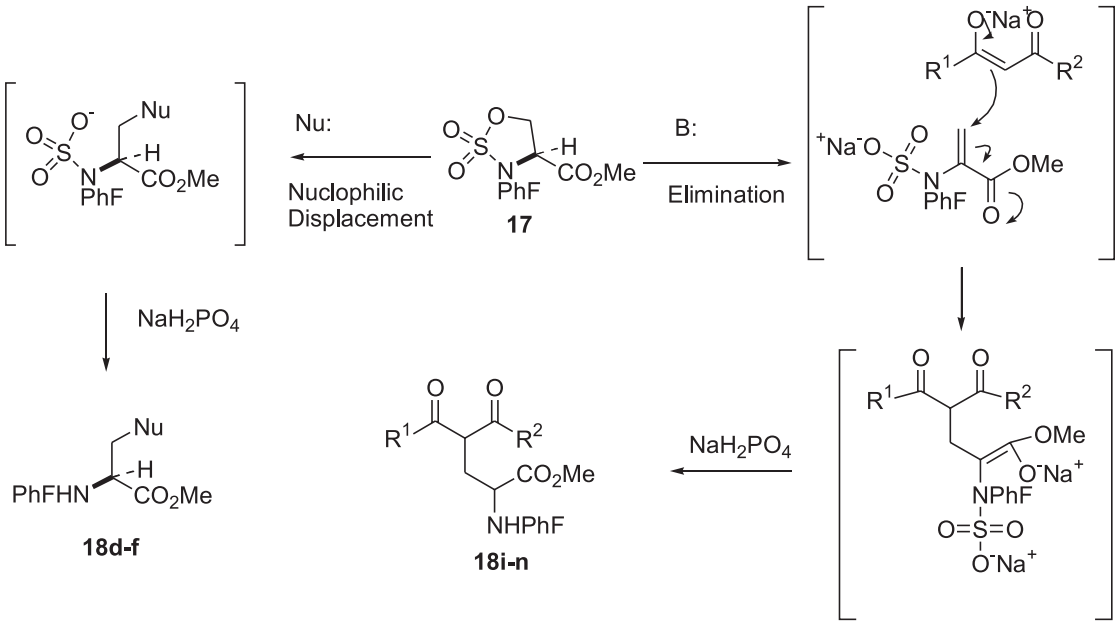
© 2001 NRC Canada

Scheme 4. Michael addition of methyl acetoacetate enolate to dehydroalanine sulfamic acid **33**.

Low specific rotation values were also recorded for δ-keto α-amino ester **20k** ($[\alpha]_D^{20}$ –4.8° (*c* 0.15, $CHCl_3$)), pyrazole amino acid **25** ($[\alpha]_D^{20}$ –9.5° (*c* 0.2, MeOH)), and malonate **18i** ($[\alpha]_D^{20}$–4.3° (*c* 0.1, $CHCl_3$)). Because of the characteristically high specific rotations of *N*-(PhF)-α-amino carboxylates (9, 23, 27–29, 32, 33), racemization may be inferred to have occurred in these cases.

Dehydroalanine **19** was formed on ring opening of cyclic sulfamidate **17** by β-elimination induced with a variety of nucleophiles (Table 2). Postulating that the presumed dehydroalanine intermediate **32** could serve as a Michael acceptor for the formation of racemic β-keto ester, we treated sulfamidate **17** with 200 mol% of sodium hydride in DME to induce elimination (Scheme 4). A premixed solution of methyl acetoacetate (300 mol%) and NaH (400 mol%) in DME was then added to the reaction mixture which was heated at 60°C for 18 h. Hydrolysis of the polar sulfamic acid intermediate with 1 M KH_2PO_4 furnished (5*RS*)-methyl *N*-PhF-2-methyl-3-(methyloxy)carbonyl-Δ^2-pyrroline (**33**) in 87% yield. Previously, pyrroline **33** was encountered in the direct ring opening of sulfamidate **17** with the preformed enolate of methyl acetoacetate when the hot reaction mixture was quenched with 1 M KH_2PO_4. Its formation can be avoided by cooling the reaction mixture to room temperature prior to hydrolysis of the sulfamic acid; however, we elected to form pyrroline **33** in the present sequence because it was easier to characterize. Formation of **33** demonstrated that dehydroalanine **19** could serve as a prochiral intermediate for the formation of racemized amino acid product. To verify if sulfamidate racemized prior to ring opening, aliquots were taken at different time intervals from the reaction mixture containing **17** and the preformed enolate of methyl acetoacetate in DME at 60°C. No loss of configurational integrity of sulfamidate **17** was detected after 1 and 2 h of reaction as ascertained by measurement of its specific rotation after isolation by chromatography. Hence, α-deprotonation triggers β-elimination prior to reprotonation and racemization of **17**.

A mechanism that may explain the cause of racemization involves the nucleophile acting as base and removing the α-proton to trigger ring opening with elimination. A second nucleophile may then attack **32** to furnish β-keto ester by a Michael addition (Scheme 5). On the other hand, because (2*S*)-methyl 4-(1-imidazol)-2-[*N*-(PhF)amino]propionate (**18f**) was shown to be of >97% enantiomeric purity, ring opening of cyclic sulfamidate **17** with less basic nucleophiles should involve only nucleophilic displacement.



The formation of *N*-(PhF)dehydroalanine **19** by β-elimination on sulfamidate **17** is remarkable in light of a previous report in which the PhF group was found to completely suppress elimination during Mitsunobu reactions on the alcohol of *N*-(PhF)serine methyl ester **15** (34). The related β-*N*-(PhF)enamino ester has previously been reported; however, removal of the α-proton was not required for its formation via base induced rearrangement of dimethyl *N*-(PhF)-3,4-didehydroglutamate (33). In the X-ray crystal structure of cyclic sulfamidite **16**, the α-proton and β-hydroxyl group from serine are constrained in a nearly coplanar geometry within the five-membered ring. Most likely, sulfamidate **17** adopts a similar geometry that can favour orbital overlap facilitating β-elimination. Finally, pyroglutamate **14** should also be considered to be of suspect enantiomeric purity, because dehydoalanine product was encountered in its synthesis using sulfamidate derived from *N*-(Bn)serine *tert*-butyl ester (1).

Conclusion

Five-membered cyclic sulfamidate **17** was synthesized from serine in good yield. Ring opening of five-membered cyclic sulfamidate was achieved using a variety of nucleophiles

© 2001 NRC Canada

Scheme 5. Proposed mechanisms for the ring opening of sulfamidate **17.**

including β-keto esters, β-keto ketones, dimethyl malonate, nitroethane, sodium azide, imidazole, and potassium thiocyanate. A careful analysis of the enantiomeric purity of the products from ring opening of five-member cyclic sulfamidate **17** was performed using optical measurements as well as conversion of particular products to diastereomeric derivatives that were analyzed by NMR spectroscopy. Direct nucleophilic displacement and β-elimination followed by Michael addition were both found to be favoured mechanisms for the additions of different nucleophiles to **23**, which formed enantiopure and racemic amino acid product, respectively. Verification of product enantiomeric purity is thus essential when using serine-derived cyclic sulfamidates as chiral educts for amino acid synthesis.

Supporting information available: ^{1}H and ^{13}C NMR spectra for key compounds.[2]

Experimental section

General

Unless otherwise noted, all reactions were run under nitrogen atmosphere and distilled solvents were transferred by syringe. Tetrahydrofuran (THF) and ether were distilled from sodium–benzophenone immediately before use; 1,1,1,3,3,3-hexamethyldisilazane (HMDS) and CH_2Cl_2 were distilled from CaH_2; Et_3N was distilled from BaO. Final reaction mixture solutions were dried over Na_2SO_4. Chromatography was on 230–400 mesh silica gel; thin layer chromatography (TLC) on aluminum-backed silica plates. Melting points are uncorrected. Mass spectral data, HRMS (EI and FAB), were obtained by the Université de Montréal Mass Spectroscopy facility. ^{1}H NMR (300 and 400 MHz) and ^{13}C NMR (75 and 100 MHz) spectra were recorded in $CDCl_3$. Chemical shifts are reported in ppm (δ units) downfield of internal tetramethylsilane ($(CH_3)_4Si$). Coupling constants are given in Hz. Chemical shifts for aromatic PhF carbons are not reported.

*(2*R*,4*S*)-Methyl 2-oxo-3-(PhF)-1,2,3-oxathiazolidine-4-carboxylate ((2*R*)-**16**) and (2*S*,4*S*)-methyl 2-oxo-3-(PhF)-1,2,3-oxathiazolidine-4-carboxylate ((2*S*)-**16**)*

A solution of *N*-PhF-L-serine methyl ester ((*S*)-**15**, 3.57 g, 10 mmol, prepared according to ref. 23) in 150 mL of dichloromethane was cooled to 0°C, treated with imidazole (2.7 g, 40 mmol) followed by triethylamine (2.8 mL, 20 mmol), stirred for 10 min, then treated with thionyl chloride (0.8 mL, 11 mmol). After stirring an additional 45 min, water (100 mL) was added and the phases were separated. The aqueous phase was extracted with dichloromethane (3 × 50 mL) and the combined organic fractions were washed with water (2 × 50 mL), dried, filtered, and evaporated. The residue was normally used without purification in the next reaction. Purification of the residue by chromatography on silica gel with an eluant of 20–30% EtOAc in hexane provided 4 g (99%) of a 1:2 mixture of diastereomers ((2*R*)-**16** and (2*S*)-**16**). First to elute was (2*R*)-**16**: mp 83–84°C. $[\alpha]_D^{20}$ 121° (*c* 0.14, $CHCl_3$). TLC: R_f = 0.54 (30% EtOAc in hexanes). ^{1}H NMR δ: 3.42 (s, 3H), 3.51 (dd, 1H, *J* = 1.4, 7.1), 4.41 (dd, 1H, *J* = 1.4, 9.4), 4.75 (dd, 1H, *J* = 7.1, 9.4), 7.17–8.17 (m, 13H). ^{13}C NMR δ: 52.1, 59.0, 72.2, 75.2, 171.4. HRMS calcd. for $C_{23}H_{20}O_4NS$ (MH^+): 406.1113; found: 406.1130. Next to elute was (2*S*)-**16**: mp 71–72°C. $[\alpha]_D^{20}$ 243° (*c* 0.38, $CHCl_3$). TLC: R_f = 0.37 (30% EtOAc in hexanes). ^{1}H NMR δ: 3.37 (t, 1H, *J* = 7.9), 3.57 (s, 3H), 4.32 (t, 1H, *J* = 7.9), 4.95 (t, 1H, *J* = 7.9), 7.19–7.77 (m, 13H). ^{13}C NMR δ: 52.5, 61.3, 73.5, 76.2, 170.3. HRMS calcd. for $C_{23}H_{19}O_4NS$ (M^+): 405.1035; found: 405.1046.

*(4S)-Methyl 2,2-dioxo-3-PhF-1,2,3-oxathiazolidine-4-carboxylate (**17**)*

A solution of 2-oxo-1,2,3-oxathiazolidine **16** (1.25 g, 3.1 mmol) in 100 mL of acetonitrile was cooled to 0°C, treated with ruthenium(III) chloride monohydrate (10 mg) followed by sodium periodate (1.28 g, 6 mmol), stirred 10 min, and quenched with water (100 mL). After stirring for 4 h, the reaction mixture was diluted with ether

© 2001 NRC Canada

(100 mL) and the phases were separated. The aqueous phase was extracted with ether (3 × 60 mL). The combined organic fractions were washed with saturated aqueous sodium bicarbonate (100 mL) and brine (50 mL), dried, filtered, and evaporated to a residue that was purified by chromatography on silica gel with an eluant of 10–20% EtOAc in hexane. Evaporation of the collected fractions provided 1.14 g (87%) of **17**: mp 155–156°C. $[\alpha]_D^{20}$ 244° (*c* 0.1, $CHCl_3$). ^{1}H NMR δ: 3.64 (dd, 1H, *J* = 4.0, 8.2), 3.69 (s, 3H), 4.02 (dd, 1H, *J* = 8.2, 8.7), 4.38 (dd, 1H, *J* = 4.0, 8.7), 7.19–8.22 (m, 13H). ^{13}C NMR δ: 52.9, 58.8, 66.8, 77.9, 169.2. HRMS calcd. for $C_{23}H_{19}O_5NS$ (M^+): 421.0984; found: 421.0997.

*(2*S*)-*N*-*PhF*-*S*-cyanocysteine methyl ester (**18d**)*

A solution of (4*S*)-methyl 2,2-dioxo-3-PhF-1,2,3-oxathiazolidine-4-carboxylate (**17**, 48 mg, 0.12 mmol) in 5 mL of DMF was treated with potassium thiocynate 35 mg (0.36 mmol), stirred at room temperature for 36 h, poured into 1 M KH_2PO_4 (20 mL), and extracted with EtOAc (3 × 20 mL). The combined organic phase was washed with brine (20 mL), dried, filtered, and evaporated to a residue that was chromatographed on silica gel eluting with a gradient of 15–20% EtOAc in hexane. Concentration of the collected fractions provided 34.8 mg (72%) of **18d**: mp 149–150°C. $[\alpha]_D^{20}$ –287° (*c* 0.4, $CHCl_3$). ^{1}H NMR δ: 2.88 (dd, 1H, *J* = 4.7, 12.6,), 3.02 (dd, 1H, *J* = 4.7, 5.8), 3.13 (dd, 1H, *J* = 5.8, 12.6), 3.44 (brs, 1H), 3.48 (s, 3H), 7.23–7.75 (m, 13H). ^{13}C NMR δ: 39.5, 52.6, 54.9, 72.8, 112.8, 172.6. HRMS calcd. for $C_{24}H_{21}O_2SN_2$ (MH^+): 401.1324; found: 401.1339.

*(2*S*)-*N*-*(PhF)-3-azido-alanine methyl ester (**18e**)*

A solution of (4*S*)-methyl 2,2-dioxo-3-PhF-1,2,3-oxathiazolidine-4-carboxylate (**17**, 49 mg, 0.12 mmol) in 5 mL of DMF was treated with sodium azide (24 mg, 0.37 mmol), stirred at room temperature for 1 h, poured into 1 M KH_2PO_4 (20 mL), and extracted with EtOAc (2 × 10 mL). The combined organic phase was washed with brine (10 mL), dried, filtered, and evaporated to a residue that was chromatographed on silica gel eluting with a gradient of 10–20% EtOAc in hexane. Concentration of the collected fractions provided 40.3 mg (90%) of **18e** as a thick clear oil. $[\alpha]_D^{20}$ –294° (*c* 0.12, $CHCl_3$). ^{1}H NMR δ: 2.85 (dd, 1H, *J* = 4.7, 5.3), 3.07 (dd, 1H, *J* = 4.7, 12.3), 3.18 (dd, 1H, *J* = 5.3, 12.3), 3.42 (s, 3H), 7.21–7.73 (m, 13H). ^{13}C NMR δ: 52.2, 54.5, 56.4, 73.0, 173.6. HRMS calcd. for $C_{23}H_{21}O_2N_4$ (MH^+): 385.1664; found: 385.1677.

*(2*S*)-Methyl 3-(1-imidazol)-2-[*N*-(PhF)amino]propionate (**18f**)*

A solution of (4*S*)-methyl 2,2-dioxo-3-PhF-1,2,3-oxathiazolidine-4-carboxylate (**17**, 100 mg, 0.24 mmol) in 15 mL of DME was treated with imidazole (49 mg, 0.72 mmol), heated at 80°C for 18 h, poured into 1 M KH_2PO_4 (30 mL), and extracted with EtOAc (3 × 20 mL). The combined organic phase was washed with brine (20 mL), dried, filtered, and evaporated to a residue that was chromatographed on silica gel eluting with a gradient of 5–10% MeOH in EtOAc. Concentration of the collected fractions provided 83.2 mg (85%) of **18f**: mp 146–147°C. $[\alpha]_D^{20}$ –241° (*c* 0.1, $CHCl_3$). MS (*m*/*z*): 410.2 (M + 1), 307.1, 289.1, 257.1, 241.1, 154.1. ^{1}H NMR δ: 2.85 (m, 1H), 3.16 (brs, 1H), 3.35 (s, 3H), 3.83 (dd, 1H, *J* = 4.9, 14.0), 3.94 (dd, 1H, *J* = 6.7, 14.0), 7.01–7.72 (m, 16H). ^{13}C NMR δ: 50.8, 52.3, 56.7, 72.9, 119.7, 128.4, 137.5, 173.4.

General procedure for ring opening of cyclic sulfamidate 17 with β-keto esters, β-keto ketones, and dimethyl malonate

A solution of sodium hydride (prewashed with hexane, 60 wt% in oil, 85 mg, 2.1 mmol) in DME (15 mL) was treated with the respective β-keto ester, β-keto ketone, or dimethyl malonate (3.6 mmol), stirred for 10 min, treated with (4*S*)-methyl 2,2-dioxo-3-PhF-1,2,3-oxathiazolidine-4-carboxylate (**17**, 380 mg, 0.9 mmol), heated at 60°C for 18 h, cooled to room temperature, and poured into 1 M NaH_2PO_4 (50 mL). The mixture was extracted with EtOAc (3 × 50 mL). The combined organic phases were washed with brine (2 × 30 mL), dried, filtered, and evaporated to a residue.

*Methyl 5-oxo-4-(methylcarbonyl)-2-[*N*-(PhF)amino]hexanoate (**18i**)*

Methyl 5-oxo-4-(methylcarbonyl)-2-[*N*-(PhF)amino]hexanoate (**18i**) was prepared from 2,4-pentanedione and used directly in next step. HRMS calcd. for $C_{28}H_{28}O_4N$ (MH^+): 442.2018; found: 442.2033.

*Methyl 5-oxo-4-(phenylcarbonyl)-2-[*N*-(PhF)amino]hexanoate (**18j**)*

Methyl 5-oxo-4-(phenylcarbonyl)-2-[*N*-(PhF)amino]hexanoate (**18j**) was prepared from 1-benzoyl acetone and isolated by chromatography on silica gel eluting with a gradient of 10–20% EtOAc in hexane as a 1.1:1 mixture of diastereomers in 45% yield. ^{1}H NMR δ: 2.00 (s, 3H), 2.07 (m, 4H), 2.17 (s, 3H), 2.58 (m, 2H), 3.26 (s, 3H), 3.28 (s, 3H), 4.78 (t, 1H, *J* = 6.0), 4.83 (dd, 1H, *J* = 4.8, 7.4), 6.70–8.26 (m, 36H). ^{13}C NMR δ: 28.0, 28.7, 33.0, 33.2, 51.69, 51.73, 53.8, 54.5, 59.1, 59.3, 72.7, 72.8, 176.0 (2C), 195.0, 196.1, 202.9, 203.6. HRMS calcd. for $C_{33}H_{30}O_4N$ (MH^+): 504.2175; found: 504.2153.

*Methyl 5-oxo-4-(methyloxycarbonyl)-2-[*N*-(PhF)amino]hexanoate (**18k**)*

Methyl 5-oxo-4-(methyloxycarbonyl)-2-[*N*-(PhF)amino]hexanoate (**18k**) was prepared from methyl acetoacetate and used directly in next step. HRMS calcd. for $C_{28}H_{28}O_5N$ (MH^+): 458.1968; found: 458.1982.

*Methyl 5-oxo-4-(ethyloxycarbonyl)-2-[*N*-(PhF)amino]heptanoate (**18l**)*

Methyl 5-oxo-4-(ethyloxycarbonyl)-2-[*N*-(PhF)amino]heptanoate (**18l**) was prepared from ethyl propionylacetate and isolated as an inseparable 1.1:1 mixture of diastereomers by chromatography on silica gel eluting with a gradient of 10–20% EtOAc in hexane in 82% yield. ^{1}H NMR δ: 0.98 (t, 3H, *J* = 7.2), 1.11 (t, 3H, *J* = 7.2), 1.19 (t, 3H, *J* = 7.2), 1.28 (t, 3H, *J* = 7.2), 1.91–1.99 (m, 4H), 2.32–2.39 (m, 2H), 2.52–2.68 (m, 4H), 3.24 (s, 3H), 3.25 (s, 3H), 3.67 (t, 1H, *J* = 6.4), 3.89–4.10 (m, 3H), 4.23 (dd, 2H, *J* = 7.2, 14.1), 7.14–7.70 (m, 26H). ^{13}C NMR δ: 7.35, 7.59, 13.8, 13.9, 32.5, 32.7, 35.1, 35.3, 51.3, 51.6, 53.6, 54.1, 54.9, 55.6, 61.1, 61.4, 72.6, 72.7, 169.0, 169.7, 175.9, 176.0, 204.6, 205.5. HRMS calcd. for $C_{30}H_{31}O_5NNa$ (M^+ + Na): 508.2100; found: 508.2116.

*Methyl 6,6-dimethyl-5-oxo-4-(ethyloxycarbonyl)-2-[*N*-(PhF)amino]heptanoate (**18m**)*

Methyl 6,6-dimethyl-5-oxo-4-(ethyloxycarbonyl)-2-[*N*-(PhF)amino]heptanoate (**18m**) was prepared from ethyl pivaloylacetate and isolated as an 1:1 mixture of diastereomers by chromatography on silica gel eluting with a gradient of 10–20% EtOAc in hexane in 63% yield. ^{1}H NMR δ: 1.10 (s, 9H), 1.13 (t, 3H, *J* = 7.1), 1.27 (t, 3H, *J* = 7.1), 1.31 (s, 9H), 1.48 (m, 1H), 1.58 (m, 1H), 2.03 (m, 1H), 2.33 (m, 1H), 2.60 (m, 2H), 3.26 (s, 6H), 3.81–3.98 (m, 3H), 4.24 (q, 2H, *J* = 7.1), 4.45 (dd, 1H, *J* = 2.4, 10.4), 7.14–7.71 (m, 26H). ^{13}C NMR δ: 13.7, 14.0, 26.0, 26.2, 33.5, 34.4, 45.3, 45.6, 47.9, 49.8, 51.5, 51.7, 53.6, 54.6, 60.8, 61.2, 72.6, 72.8, 168.9, 169.5, 175.4, 176.5, 209.9, 210.5. HRMS calcd. for $C_{32}H_{35}O_5NNa$ (M^+ + Na): 536.2413; found: 536.2392.

*4-(Methyloxycarbonyl)-2-[*N*-(PhF)]glutamate dimethyl ester (**18n**)*

4-(Methyloxycarbonyl)-2-[*N*-(PhF)]glutamate dimethyl ester (**18n**) was prepared from dimethyl malonate and isolated as a 1:1 mixture of diastereomers by chromatography on silica gel eluting with a gradient of 10–20% EtOAc in hexane in 65% yield. ^{1}H NMR δ: 2.03 (m, 2H), 2.61 (dd, 1H, *J* = 4.7, 8.9), 3.20 (s, 3H), 3.36 (s, 3H), 3.57 (s, 3H), 3.73 (m, 1H), 7.11–7.67 (m, 13H). ^{13}C NMR δ: 33.3, 48.3, 51.5, 52.3, 52.5, 53.7, 72.6, 166.8, 169.0, 169.8. HRMS calcd. for $C_{28}H_{27}O_6NNa$ (M^+ + Na): 496.1736; found: 496.1728.

*Methyl 4-nitro-2-[*N*-(PhF)amino]pentanoate (**18o**)*

A solution of sodium hydride (prewashed with hexane, 60 wt% in oil, 40 mg, 1 mmol) in DME (12 mL) was treated with nitroethane (0.2 mL, 2.8 mmol), stirred at 60°C for 3 h, treated with (4*S*)-methyl 2,2-dioxo-3-PhF-1,2,3-oxathiazolidine-4-carboxylate (**17**, 100 mg, 0.24 mmol), heated at 60°C for 36 h, cooled to room temperature, and poured into 1 M NaH_2PO_4 (30 mL). The mixture was extracted with EtOAc (3 × 30 mL), and the combined organic phases were washed with brine (2 × 30 mL), dried, filtered, and evaporated. Purification of the residue by chromatography on silica gel with an eluant of 0–20% EtOAc in hexane provided 52 mg (52%) of a 10:1 mixture of diastereomers **18o**. The spectra data for the major isomer was as follows. ^{1}H NMR δ: 1.51 (d, 3H, *J* = 6.9), 1.73 (ddd, 1H, *J* = 3.4, 9.4, 14.8), 2.16 (ddd, 1H, *J* = 4.2, 9.1, 14.8), 2.64 (dd, 1H, *J* = 3.4, 9.1), 3.25 (s, 3H), 4.92 (m, 1H), 7.15–7.71 (m, 13H). ^{13}C NMR δ: 20.3, 39.1, 51.8, 52.6, 72.6, 79.4, 175.6. HRMS calcd. for $C_{25}H_{25}O_4N_2$ (MH^+): 417.1814; found: 417.1826.

*Methyl 5-oxo-2-[*N*-(PhF)amino]hexanoate (**20k**)*

Crude methyl 5-oxo-4-(methyloxycarbonyl)-2-[*N*-(PhF)amino]hexanoate (**18k**) was dissolved in EtOH (10 mL), treated with 1 N NaOH (10 mL), and heated at a reflux for 5 h. The mixture was cooled to room temperature and adjusted to pH 5 using 10% HCl. The solution was extracted with EtOAc (3 × 30 mL) and the combined organic phases were washed with brine (30 mL), dried, filtered, and evaporated to a residue that was dissolved in acetonitrile (20 mL), treated with K_2CO_3 (300 mg, 2.2 mmol) and iodomethane (0.3 mL, 4.8 mmol), and stirred at room temperature for 18 h. Brine (50 mL) was added to the reaction mixture, which was extracted with EtOAc (3 × 30 mL). The organic phases were combined, washed with 0.65 M sodium thiosulfate (50 mL) and brine (50 mL), dried, filtered, and evaporated to a residue that was purified by chromatography on silica gel using a gradient of 10–20% EtOAc in hexane. Evaporation of the collected fractions gave 259 mg (71% overall from **17**) of **20k**. ^{1}H NMR δ: 1.71 (m, 2H), 2.11 (s, 3H), 2.45–2.61 (m, 3H), 3.29 (s, 3H), 7.18–7.73 (m, 13H). ^{13}C NMR δ: 28.6, 29.8, 39.6, 51.5, 54.6, 72.8, 176.3, 207.8. HRMS calcd. for $C_{26}H_{26}O_3N$ (MH^+): 400.1913; found: 400.1905.

cis-N-*(BOC)-5-methylproline methyl ester (*cis-***21***)*

A solution of methyl 5-oxo-2-[*N*-(PhF)amino]hexanoate (**20k**, 400 mg, 1 mmol) and di-*tert*-butyldicarbonate (670 mg, 3 mmol) in MeOH (50 mL) was placed into a hydrogenation vessel and treated with palladium-on-carbon (10 wt%, 65 mg). The vessel was filled, vented and filled three times with hydrogen, and the mixture was stirred under 4 atm of hydrogen for 48 h. The mixture was filtered on Celite™ and washed with MeOH (50 mL). The combined organic phase was evaporated to a residue that was purified by chromatography on silica gel using a gradient of 10–15% EtOAc in hexane. Evaporation of the collected fractions gave 225 mg (92%) of *cis*-**21** as an oil. ^{1}H NMR δ (showed a mixture of carbamate isomers): 1.24 (d, 6H, *J* = 6.2), 1.38 (s, 9H), 1.42 (s, 9H), 1.58 (m, 2H), 1.97 (m, 4H), 2.14 (m, 2H), 3.68 (s, 6H), 3.86 (m, 1H), 3.98 (m, 1H), 4.16 (m, 1H), 4.27 (m, 1H). ^{13}C NMR δ (showed a mixture of carbamate isomers): 19.7, 20.5, 28.3, 28.7, 31.6, 32.4, 51.9, 53.9, 59.7, 60.0, 79.5, 158.2, 159.0, 173.0, 173.9. HRMS calcd. for $C_{12}H_{22}O_4N$ (MH^+): 244.1549; found: 244.1556.

cis-N-*(BOC)-5-methylproline (*cis-***22***)*

Methyl ester **21** (110 mg, 0.45 mmol) was dissolved in 10 mL of Et_2O, treated with $KOSi(Me)_3$ (70 mg, 0.55 mmol) and stirred for 18 h at room temperature. The reaction mixture was extracted with water (5 × 20 mL), and the aqueous phases were combined, acidified with acetic acid to pH 2, saturated with NaCl, and extracted with EtOAc (3 × 30 mL). The organic phases were combined, dried, filtered, and evaporated to give 99.4 mg (0.43 mmol, 96%) of *cis*-**22**. ^{1}H NMR (CD_3OD) δ (showed a mixture of carbamate isomers): 1.27 (d, 3H, *J* = 6.2), 1.42 (brs, 9H), 1.65 (m, 1H), 2.02 (m, 2H), 2.23 (m, 1H), 3.96 (m, 1H), 4.18 (m, 1H). ^{13}C NMR (CD_3OD) δ (showed a mixture of carbamate isomers): 20.1, 20.9, 28.6, 28.8, 29.3, 29.8, 32.7, 33.4, 49.6, 49.8, 55.4, 55.7, 61.2, 61.5, 81.2, 81.3, 155.4, 155.8, 176.6, 176.8. HRMS calcd. for $C_{11}H_{20}O_4N$ (MH^+): 230.1392; found: 230.1385.

Enantiomeric purity of cis-N-*(BOC)-5-methylproline (*cis-***22***)*

A room-temperature solution of *cis-N*-(BOC)-5-methylproline (*cis*-**22**, 20 mg, 0.09 mmol) and either (*R*) or (*S*)-α-methylbenzylamine (28 μL, 0.22 mmol) in 1 mL of acetonitrile was treated with benzotriazol-1-yl-1,1,3,3-tetramethyluronium tetrafluoroborate (30 mg, 0.09 mmol) and stirred for 2 h when TLC showed complete disappearance of the starting acid. Brine (2 mL) was added to the reaction mixture, which was then extracted with EtOAc (2 ×

© 2001 NRC Canada

3 mL). The combined organic phase was extracted with 2 N HCl (2 × 2 mL) and $NaHCO_3$ (2 × 2 mL), washed with H_2O (2 × 2 mL) and brine, dried, filtered, and evaporated to a residue that was dissolved in CH_2Cl_2 (5 mL), treated with 0.5 mL TFA, and stirred at room temperature for 1 h. The solution was concentrated, dried, and directly examined by ^{1}H NMR spectroscopy. When (*S*)- and (*R*)-α-methylbenzylamine of 99% diastereomeric purity were used, respectively, the same mixture of diastereomers were obtained. Examination of the methyl doublets at 1.50, 1.49, 1.46, and 1.42 ppm in the ^{1}H NMR spectra in $CDCl_3$ demonstrated **31** to be of 1.1:1 mixture of diastereomers. Hence, *cis*-**22** is presumed to be of 10% enantiomeric excess.

5-Methylproline N′-α-*methyl-benzylamide trifloroacetate (**31**)*

^{1}H NMR (CD_3OD) δ: 1.42 (d, 3H, *J* = 6.6), 1.46 (d, 3H, *J* = 6.6), 1.49 (d, 3H, *J* = 7.0), 1.50 (d, 3H, *J* = 7.0), 1.60 (m, 1H), 1.73 (m, 1H), 2.04 (m, 1H), 2.19 (m, 3H), 2.42 (m, 2H), 3.74 (m, 2H), 4.31 (m, 2H), 5.04 (m, 2H), 7.22–7.37 (m, 10H).

*Methyl [*N*-(PhF)amino]-3-(3,5-dimethyl-2*H*-pyrazol-4-yl)propanoate (**24**)*

Crude methyl 5-oxo-4-(methylcarbonyl)-2-[*N*-(PhF)amino]hexanoate (**18i**) was dissolved in dioxane (10 mL), treated with hydrazine hydrate (60 μL, 1.7 mmol), stirred for 1.5 h, and poured into 1 M NaH_2PO_4 (30 mL). The mixture was extracted with EtOAc (3 × 20 mL), and the combined organic phase was washed with brine (2 × 30 mL), dried, filtered, and evaporated. The residue was normally used without purification in the next reaction. Purification of the residue by chromatography on silica gel with an eluant of 20–30% EtOAc in hexane provided 169 mg (43% overall from **17**) of **24**. ^{1}H NMR δ: 1.99 (s, 6H), 2.50 (m, 2H), 2.58 (m, 1H), 3.22 (s, 3H), 6.73–7.69 (m, 13H). ^{13}C NMR δ: 10.5, 28.8, 51.4, 56.0, 72.9, 111.1, 142.8, 176.6. HRMS calcd. for $C_{28}H_{28}O_2N_3$ (MH^+): 438.2181; found: 438.2189.

*2-*N*-(PhF)Amino-3-(3,5-dimethyl-1*H*-pyrazol-4-yl)propionic acid (**25**)*

Crude methyl [*N*-(PhF)amino]-3-(3,5-dimethyl-2*H*-pyrazol-4-yl)propanoate (**24**) was dissolved in EtOH (5 mL), treated with 1 N NaOH (5 mL), heated at 60°C for 3 h, cooled to room temperature, and then poured into 1 M NaH_2PO_4 (50 mL). The mixture was extracted with EtOAc (2 × 30 mL). The combined organic phases were extracted with 1 N NaOH (2 × 30 mL), the aqueous phase was combined, acidified with citric acid to pH 2, and extracted with EtOAc (2 × 30 mL). The organic phases were combined, dried, filtered, and evaporated to a residue that was purified by chromatography on silica gel with a gradient of 10–20% MeOH in EtOAc as eluant. Evaporation of the collected fractions gave 143 mg (37% over all from **17**) of **25**. ^{1}H NMR (CD_3OD) δ: 1.95 (s, 6H), 2.50–2.54 (m, 3H), 6.61–7.72 (m, 13H). ^{13}C NMR (CD_3OD) δ: 10.5, 29.9, 57.7, 74.3, 112.6, 144.1, 179.1. HRMS calcd. for $C_{27}H_{26}N_3O_2$ (MH^+): 424.2025; found: 424.2043.

*Amino-3-(3,5-dimethyl-1*H*-pyrazol-4-yl)propionic acid (**26**)*

2-[*N*-(PhF)Amino]-3-(3,5-dimethyl-1*H*-pyrazol-4-yl)propionic acid (**25**, 143 mg, 0.34 mmol) was dissolved in 10 mL of CH_2Cl_2, treated with 2 mL of CF_3CO_2H, and heated at a reflux for 18 h. The volatiles were evaporated, and the residue was treated with 10 mL of H_2O and filtered. The aqueous solution was washed with hexanes (2 × 20 mL), and then evaporated to a solid 55 mg (88%) of **26**. ^{1}H NMR (CD_3OD) δ: 2.39 (s, 6H), 3.07 (dd, 1H, *J* = 7.2, 15.3), 3.19 (dd, 1H, *J* = 7.2, 15.3), 4.13 (t, 1H, *J* = 7.2). ^{13}C NMR (CD_3OD) δ: 9.7, 24.6, 53.4, 113.2, 146.1, 170.9. HRMS calcd. for $C_8H_{14}N_3O_2$ (MH^+): 184.1086; found: 184.1090.

*(2*S*)-*N*-PhF-Alanine methyl ester (**27**)*

(2*S*)-*N*-(PhF)-*S*-Cyanocysteine methyl ester (**18d**, 35 mg, 0.09 mmol) was dissolved in EtOAc (10 mL) and treated with Raney nickel (50% slurry in water, ≈ 200 mg). The mixture was heated at a reflux for 6 h, cooled to room temperature, and filtered through Celite™ to remove the catalyst. The filtrate was concentrated. The residue was used without purification in the next reaction. ^{1}H NMR δ: 1.14 (d, 3H, *J* = 7.0), 2.79 (dd, 1H, *J* = 7.0, 14.1), 3.31 (s, 3H), 7.17–7.73 (m, 13H).

*(2*S*)-*N*-PhF-Alanine (**28**)*

Crude (2*S*)-*N*-PhF-alanine methyl ester (**27**) was dissolved in ethanol (5 mL), treated with 1 N NaOH (5 mL), and heated at 75°C for 1 h. The mixture was cooled to room temperature, poured into 1 M KH_2PO_4 (20 mL), and extracted with EtOAc (3 × 20 mL). The combined organic phase was washed with brine (2 × 10 mL), dried, filtered, and evaporated to a residue. Purification of the residue by chromatography on silica gel with an eluant of 60–70% EtOAc in hexane provided 22 mg (74% overall from **18d**) of **28**. $[\alpha]_D^{20}$ 150° (*c* 0.2, $CHCl_3$), lit. (9) $[\alpha]_D^{20}$ 163° (*c* 1, $CHCl_3$). ^{1}H NMR δ: 1.13 (d, 3H, *J* = 7.2), 2.71 (q, 1H, *J* = 7.2), 7.18–7.75 (m, 13H). ^{13}C NMR δ: 19.7, 52.2, 73.0, 175.9.

*(2*S*)-3-(1-Imidazol)-2-[*N*-(PhF)amino]propionic acid (**29**)*

Ester hydrolysis was performed on **18f** (83 mg, 0.2 mmol) using the same conditions described for the preparation of **28** and provided 69 mg (86%) of **29**: mp 156–157°C. $[\alpha]_D^{20}$ –149° (*c* 0.42, $CHCl_3$). ^{1}H NMR δ: 2.97 (t, 1H, *J* = 4.1), 3.94 (dd, 1H, *J* = 4.1, 13.6), 4.23 (dd, 1H, *J* = 4.1, 13.6), 7.18–7.70 (m, 15H), 8.86 (brs, 1H). ^{13}C NMR δ: 52.7, 56.4, 73.2, 119.4, 122.1, 135.6, 172.7. HRMS calcd. for $C_{25}H_{21}O_2N_3$ (M^+): 395.1634; found: 395.1644.

*Enantiomeric purity of (2*S*)-3-(1-imidazol)-2-[*N*-(PhF)amino]propionic acid (**29**)*

A solution of **29** (10 mg, 0.025 mmol) in acetonitrile (1 mL) was treated with D- or L- phenylalanine methyl ester hydrochloride (11 mg, 0.05 mmol), TBTU (16 mg, 0.05 mmol), and diisopropylethylamine (35 μL, 0.20 mmol) at room temperature. After stirring for 1 h, the solution was diluted with ethyl acetate (5 mL), washed with water (2 × 5 mL) and brine (5 mL), dried, and concentrated in vacuo to a crude oil, which was directly examined by ^{1}H NMR spectroscopy. The limits of detection were determined by measuring the diastereomeric methyl ester singlets at 3.71 and 3.76 ppm in $CDCl_3$ in the 400 MHz ^{1}H NMR spectra. Purification by chromatography using a gradient of 5–10%

© 2001 NRC Canada

methanol in EtOAc as eluant gave dipeptides having the following spectra.

*(2*S*)-3-(1-Imidazol)-2-[*N*-(PhF)amino]propionyl-*D*-phenylalanine methyl ester (2′*R*) (**30**)*

^{1}H NMR δ: 2.73 (m, 1H), 2.97 (dd, 1H, *J* = 8.1, 14.1), 3.16 (dd, 1H, *J* = 5.3, 14.1), 3.49 (dd, 1H, *J* = 4.1, 14.6), 3.76 (s, 3H), 4.09 (m, 1H), 4.49 (m, 1H), 7.01–7.68 (m, 21H).

*(2*S*)-3-(1-Imidazol)-2-[*N*-(PhF)amino]propionyl-*L*-phenylalanine methyl ester (2′*S*) (**30**)*

^{1}H NMR δ: 2.80 (m, 1H), 2.88 (dd, 1H, *J* = 6.0, 13.7), 3.11 (dd, 1H, *J* = 5.3, 13.7), 3.56 (dd, 1H, *J* = 4.3, 13.9), 3.71 (s, 3H), 4.21 (m, 1H), 4.73 (m, 1H), 6.80–7.72 (m, 21H).

*Methyl 1-*N*-PhF-2-methyl-3-[(methyloxy)carbonyl]-*Δ^2*-pyrroline (**33**)*

A solution of (4*S*)-methyl 2,2-dioxo-3-PhF-1,2,3-oxathiazolidine-4-carboxylate (**17**, 60 mg, 0.14 mmol) in 8 mL of DME was treated with NaH (40 mg, 1 mmol), stirred at room temperature for 30 min. A 0.5 mL aliquot was taken, poured into 1 M KH_2PO_4, and extracted with EtOAc (2 × 10 mL). The combined organic fractions were concentrated, dried on vacuum, and examined directly by ^{1}H NMR spectroscopy, which showed complete conversion to dehydroalanine **19**. ^{1}H NMR δ: 3.76 (s, 3H), 4.63 (brs, 1H), 5.62 (brs, 1H), 7.20–7.74 (m, 13H)). In a separate flask, a solution of methyl acetoacetate (50 μL, 0.46 mmol) in 3 mL of DME was treated with NaH (25 mg, 0.6 mmol) and stirred at room temperature for 1 h. The enolate solution was then added to the remaining solution of dehydroalanine, stirred at a reflux for 18h, poured into 40 mL of 1 M KH_2PO_4, and extracted with EtOAc (3 × 30 mL). The combined organic phases were washed with brine (2 × 30 mL), dried, filtered, and evaporated to a residue that was chromatographed on silica gel eluting with a gradient of 10–15% EtOAc in hexane. Concentrated of the collected fractions provided 49.6 mg (87%) of **33**. ^{1}H NMR δ: 2.08 (s, 3H), 2.48 (dd, 1H, *J* = 6.8, 12.8), 2.82 (t, 1H, *J* = 12.8), 3.47 (dd, 1H, *J* = 6.8, 12.8), 3.48 (s, 3H), 3.61 (s, 3H), 7.12–7.77 (m, 13H). ^{13}C NMR δ: 13.4, 33.8, 50.8, 52.2, 61.9, 103.5, 161.9, 166.7, 174.7, 174.8. HRMS calcd. for $C_{28}H_{26}O_4N$ (MH^+): 440.1862; found: 440.1870.

Solvation of a water molecule in cyclohexane and water

Giuseppe Graziano

Abstract: Reliable values for the thermodynamic functions associated with the solvation of a water molecule in its own liquid phase and in cyclohexane, at 25°C, are obtained using experimental data from different investigations. They are successfully rationalized by means of a general theory of solvation. The standard Gibbs energy change is given by the balance of two contrasting terms: the work to create a cavity in the solvent suitable to host the water molecule; and the work to turn on the water–solvent interactions. It proves that the work of cavity creation is largely overwhelmed by the formation of two H-bonds in liquid water, whereas it is almost exactly counterbalanced by the establishment of van der Waals interactions in liquid cyclohexane.

Key words: water, cavity creation, H-bonds, van der Waals interactions.

Résumé : En se basant sur des données expérimentales obtenues au cours d'études diverses, on a déterminé des valeurs fiables pour les fonctions thermodynamiques associées à la solvatation d'une molécule d'eau dans sa propre phase liquide ainsi que dans le cyclohexane, à 25°C. On peut les rationaliser facilement à l'aide d'une théorie générale de solvatation. Le changement d'énergie standard de Gibbs est donné par l'équilibre entre deux termes en opposition: le travail nécessaire pour créer une cavité dans le solvant approprié pour servir d'hôte à la molécule d'eau et le travail pour déclencher les interactions eau–solvant. Ce changement démontre que le travail de création de la cavité est très assujetti à la formation de deux liaisons hydrogènes dans l'eau liquide alors que, dans le cyclohexane liquide, elle est pratiquement exactement contrebalancée par la création d'interactions de van der Waals.

Mots clés : eau, création d'une cavité, liaisons hydrogènes, interactions de van der Waals.

[Traduit par la Rédaction]

Introduction

Currently there is great interest in solvation processes in view of the pivotal role played by the solvent medium in the stabilization of the native structure of biological macromolecules, and in the kinetics and thermodynamics of chemical and biochemical reactions (1–3). To avoid dangerous ambiguities, however, the meaning of the term solvation has to be precisely defined. We adopt the general definition proposed by Ben-Naim (4): solvation refers to the transfer of a solute molecule from a fixed position in the ideal gas-phase to a fixed position in the liquid phase, at constant temperature and pressure. The corresponding standard thermodynamic quantities, referred to the molar concentration scale, do not contain the effects of the difference in density between the two phases, and account solely for the solute–solvent coupling work; they are denoted by a superscript filled circle.

The solvation of nonpolar, polar, and charged species in water has been largely and deeply investigated, both experimentally and theoretically (5–8), because water is, by far, the most important and widely used solvent. However, it would be interesting to compare the solvation of a water molecule in its own liquid phase and in a standard nonpolar solvent such as cyclohexane. The solvation of water in nonpolar media merits attention in its own right (9), and for its implication in several molecular recognition phenomena (10), and in the transport mechanism of water across biological membranes (11).

By combining the data compiled by Ben-Naim and Marcus (12), and the detailed solubility measurements by Wolfenden and Radzicka (13), it is possible to determine the Ben-Naim standard enthalpy, entropy and Gibbs energy changes, at 25°C, associated with the following processes: (*i*) solvation of a water molecule in liquid water ($H_2O(g) \rightarrow H_2O(l)$); (*ii*) solvation of a water molecule in liquid cyclohexane ($H_2O(g) \rightarrow H_2O(chx)$); (*iii*) transfer of a water molecule from liquid water to liquid cyclohexane ($H_2O(l) \rightarrow H_2O(chx)$). The determined values are collected in Table 1.

The process $H_2O(g) \rightarrow H_2O(l)$ is spontaneous because the Gibbs energy change is large and negative ($\Delta G^{\bullet} = -26.3$ kJ mol^{-1}) and is enthalpy-driven since $\Delta H^{\bullet} = -41.7$ kJ mol^{-1} and $\Delta S^{\bullet} = -51.7$ J K^{-1}mol^{-1}. For the process $H_2O(g) \rightarrow H_2O(chx)$, $\Delta G^{\bullet}$ amounts to –0.2 kJ mol^{-1}, indicating that for a water molecule it is practically the same to stay in the gas-phase or to dissolve in liquid cyclohexane. This is an important result, as stressed by Wolfenden and Radzicka (13), who proposed a qualitative explanation without, however, performing a complete theoretical analysis. It should be

Table 1. Ben-Naim standard enthalpy, entropy, and Gibbs energy changes, at 25°C, associated with the following processes: (*i*) solvation of a water molecule in liquid water ($H_2O(g) \rightarrow H_2O(l)$); (*ii*) solvation of a water molecule in liquid cyclohexane, ($H_2O(g) \rightarrow H_2O(chx)$); (*iii*) transfer of a water molecule from liquid water to liquid cyclohexane, ($H_2O(l) \rightarrow H_2O(chx)$). The values are obtained by combining the data reported in refs. 12 and 13.

	$\Delta H^\bullet$ (kJ mol^{-1})	$\Delta S^\bullet$ (J K^{-1} mol^{-1})	$\Delta G^\bullet$ (kJ mol^{-1})
$H_2O(g) \rightarrow H_2O(l)$	–41.7	–51.7	–26.3
$H_2O(g) \rightarrow H_2O(chx)$	–5.9	–19.1	–0.2
$H_2O(l) \rightarrow H_2O(chx)$	35.8	32.6	26.1

underscored that both solvation processes are exothermic and lead to an entropy decrease, but the changes are significantly larger in magnitude in the case of liquid water.

For the process $H_2O(l) \rightarrow H_2O(chx)$, $\Delta G^\bullet$, $\Delta H^\bullet$, and $\Delta S^\bullet$ are all large and positive, indicating that the transfer is not spontaneous, as expected, and it is dominated by enthalpic effects. A water molecule strongly prefers to stay in liquid water rather than in liquid cyclohexane.

It would be desirable to rationalize the experimental data within a unified approach; this is exactly the aim of the present work.

Results and discussion

For a solvation process, the following equation has general validity (14–17):

$$[1] \qquad \Delta G^\bullet = \Delta G_c + E_a$$

ΔG_c is the work of cavity creation, involving the exclusion of solvent molecules from the region of space that has to be occupied by the solute molecule; it is a positive quantity that contrasts solvation. E_a is a negative quantity and represents the solute–solvent energetic interactions. We would like to show that this equation works well also for the solvation thermodynamics of a molecule like water.

Reliable estimates of ΔG_c in any solvent can be obtained by means of scaled particle theory (SPT) (14, 18). In SPT calculations, we assume that both water and cyclohexane molecules are spherical, with a hard-sphere diameter of 2.80 Å and 5.63 Å (19), respectively. The value selected for water is physically sound, because it is close to the location of the first max in the oxygen–oxygen radial distribution function of water, as determined from X-ray and neutron scattering measurements (20). In addition, the actual densities of water and cyclohexane are used in SPT calculations (at room temperature the volume packing density is 0.383 for water and 0.517 for cyclohexane). For the creation of a cavity of 2.80 Å diameter at 25°C, the following values are obtained: ΔG_c = 14.7 kJ mol^{-1} in water, and 10.9 kJ mol^{-1} in cyclohexane. The value of ΔG_c in water is significantly larger than that in cyclohexane due to the small size of water molecules. This geometrical feature amplifies the excluded volume effect upon solute insertion into liquid water with respect to all other solvents (15, 16, 21).

The SPT value of ΔG_c in cyclohexane appears to be accurate because SPT works well for nonpolar liquids owing to its fundamental assumptions (18). Also the SPT estimate of ΔG_c in liquid water appears to be accurate because Monte Carlo and molecular dynamics computer simulations (22), using both the test particle insertion method and perturbation approaches, resulted in ΔG_c values of about 15 kJ mol^{-1} for a cavity of 2.80 Å diameter at 25°C. The latter investigations used sophisticated water models with explicit information on H-bonds, whereas SPT completely neglects orientational order and H-bonds. As a consequence, the fact that the estimates of ΔG_c in liquid water are so close is a strong indication that the work of cavity creation does not depend on the existence of H-bonds, when the solvent density is fixed (23).

For the evaluation of E_a we have to consider that: (*i*) a water molecule entering liquid water forms an average of two H-bonds with the surrounding water molecules (i.e., in liquid water, assuming an ideal tetrahedral coordination, each water molecule is engaged in four H-bonds; each H-bond, however, is shared between two molecules, so that the net number of H-bonds a water molecule forms is two); (*ii*) a water molecule entering liquid cyclohexane cannot form H-bonds and establishes solely van der Waals interactions with the surrounding cyclohexane molecules.

For the first case, Pauling (24), with simple arguments, determined that the average effective strength of a H-bond in water $< \varepsilon(\text{H-bond}) > = -21$ kJ mol^{-1}, so that $E_a = -42$ kJ mol^{-1} for a water molecule in its own liquid phase. The latter value is in satisfactory agreement with theoretical results, as can be verified by looking at the figures of the intermolecular energy for a set of widely used models of liquid water, quoted in the second line of Table III in ref. 25. Actually, Pauling's estimate of $< \varepsilon(\text{H-bond}) >$ can be derived in a slightly more rigorous way, as it is shown below. According to the Landolt-Börnstein tables (26), the enthalpy of liquid water at 25°C amounts to –34.1 kJ mol^{-1}. For a liquid phase, the enthalpy can be equated to the internal energy, which is the sum of kinetic and potential energies. As a first approximation, the potential energy of liquid water can be considered equal to the average effective strength of two H-bonds per molecule, while, at room temperature, the kinetic energy contains both translational and rotational contributions. In the reliable assumption that liquid water can be treated by classical statistical mechanics, each translational and rotational degree of freedom contributes (1/2)*RT* to the kinetic energy, so that:

$$[2] \qquad H \approx U = (3/2)RT + (3/2)RT + 2 < \varepsilon(\text{H-bond}) >$$

where *H* and *U* are the enthalpy and internal energy per molecule, respectively, of liquid water, and *R* is the gas constant. Performing the calculations, one readily obtains $< \varepsilon(\text{H-bond}) > = -20.8$ kJ mol^{-1} at 25°C, and $E_a = -41.6$ kJ mol^{-1} for a water molecule in its own liquid phase.

Alternatively, following the proposal by Walrafen et al. (27), one can imagine that, for each hydrogen atom of a water molecule, there is a general energetic contribution independent of the orientations of neighboring molecules ($E_a(g)$) and a specific contribution orientation-dependent ($E_a(s)$). $E_a(g)$ arises from dipole–dipole, dispersive and dipole-induced dipole interactions among neighboring water molecules and is always turned on and favorable. Adopting the

© 2001 NRC Canada

procedure devised by Walrafen et al. (27), $E_a(g) = -13.0$ kJ per mol of hydrogen atoms. $E_a(s)$ is related to the formation of a specific H-bond interaction between two water molecules correctly oriented. According to theoretical calculations and simulations (28), a two-state mechanism can be assumed for each H-bond, and so for $E_a(s)$, it is turned on or turned off, depending on the relative orientation of the two water molecules (i.e., the energy distribution is discrete and bimodal). As a consequence, for each temperature, there is a fraction of H-bonds broken (f_b) and a fraction intact ($1 - f_b$). According to the Muller's model (29), $E_a(s) = -9.8$ kJ per mol of hydrogen atoms and $f_b = 0.205$ at 25°C. Therefore, $E_a = 2(-13.0) + 2(0.795)(-9.8) = -41.6$ kJ mol^{-1} for a water molecule in its own liquid phase. It is pleasing that the obtained estimates are very close.

In the second case, the van der Waals interactions of a water molecule in liquid cyclohexane consist solely of dispersive and dipole-induced dipole contributions. We assumed that the latter contribution, arising from the interaction of water dipole with the polarizable cyclohexane molecules, can be absorbed into the parameterization of the dispersive contribution. This assumption is reasonable because both terms depend on the inverse sixth power of distance (30), and is usually employed in molecular mechanics force fields (31). We performed calculations using Pierotti's formula (14), which employs the Lennard–Jones potential and considers the radial distribution function of solvent molecules to be unit around the central solute molecule. The dipole-induced dipole contribution is taken into account by increasing the ε/k value of water, where ε is the well-depth in the Lennard–Jones potential and k is the Boltzmann constant. We used $\varepsilon/k = 573$ K for cyclohexane, as determined by Wilhelm and Battino (19), and $\varepsilon/k = 145$ K for water. The latter is larger than the customary values of about 80 K, but is in the middle of the values for argon (125 K) and krypton (169 K) (14, 16). In this respect, it is worth noting that the dipole-induced dipole contribution should be substantial in view of the large values of both the dipole moment of water and the polarizability of cyclohexane. The selected ε/k values lead to $E_a = -11.1$ kJ mol^{-1} for a water molecule in liquid cyclohexane.

This estimate illustrates that there is no phobia of a water molecule for nonpolar solvents: the energetic interactions are attractive. Actually, E_a is even larger and negative for a water molecule in *n*-heptane or benzene, because, at 25°C, $\Delta G^\bullet = -1.3$ kJ mol^{-1} for the solvation of water into *n*-heptane, and $\Delta G^\bullet = -7.3$ kJ mol^{-1} for the solvation of water into benzene (13). In particular, since the SPT estimate for a cavity of 2.80 Å diameter in benzene, at 25°C, is $\Delta G_c = 11.7$ kJ mol^{-1}, the water-benzene interaction energy should be $E_a = \Delta G^\bullet - \Delta G_c = -7.3 - 11.7 = -19.0$ kJ mol^{-1}, which is a large negative quantity.

The fundamental point is that for both the solvation processes the sum $\Delta G_c + E_a$ closely corresponds to the experimental $\Delta G^\bullet$ values. For $H_2O(g) \rightarrow H_2O(l)$, $\Delta G_c + E_a = 14.7 - 41.6 = -26.9$ kJ mol^{-1}, while for $H_2O(g) \rightarrow H_2O(chx)$, $\Delta G_c + E_a = 10.9 - 11.1 = -0.2$ kJ mol^{-1}. This is a confirmation of the general validity of eq. [1], and has to be widely recognized. In liquid cyclohexane the work of cavity creation is practically balanced by the van der Waals interaction energy, whereas in liquid water the energy gain for the formation of two H-bonds largely counterbalances the work of cavity creation. It is worth noting that the same equation works equally well for the solvation of a water molecule in its own liquid phase and in cyclohexane, as well as for the solvation of a cyclohexane molecule in its own liquid phase and in water (32).

For the transfer $H_2O(l) \rightarrow H_2O(chx)$, it results $\Delta\Delta G_c + \Delta E_a = -3.8 + 30.5 = 26.7$ kJ mol^{-1}, in fair agreement with the experimental value. Clearly, the loss of two H-bonds dominates the transfer energetics, largely overwhelming the difference in the work of cavity creation and the establishment of van der Waals interactions in liquid cyclohexane.

We turn now to the enthalpy and entropy changes; for a solvation process they are given by the following general relations (33, 34):

$$[3] \qquad \Delta H^\bullet = E_a + \Delta H_r$$

$$[4] \qquad \Delta S^\bullet = \Delta S_x + \Delta S_{nx}$$

ΔH_r is the enthalpy contribution due to solvent reorganization upon solute insertion; ΔS_x is the entropy contribution owing to the excluded volume effect associated with cavity creation, and is calculated as $\Delta S_x = -\Delta G_c/T$ (i.e., ΔG_c is a purely entropic quantity (35), being a direct measure of the probability that a certain region of space is devoid of solvent molecules); ΔS_{nx} is the nonexcluded volume entropy contribution.

For $H_2O(g) \rightarrow H_2O(l)$, $E_a = -41.6$ kJ mol^{-1}, close to $\Delta H^\bullet$, so that ΔH_r is negligible; $\Delta S_x = -49.3$ J K^{-1}mol^{-1}, close to $\Delta S^\bullet$, so that ΔS_{nx} is vanishingly small (see Table 1). This means that there is very little reorganization of the water H-bonded network upon insertion of a water molecule. Such a result is the expected one, in view of the well-established plasticity of the H-bonded network of liquid water (6, 36).

For $H_2O(g) \rightarrow H_2O(chx)$, $E_a = -11.1$ kJ mol^{-1} and $\Delta H_r = \Delta H^\bullet - E_a = 5.2$ kJ mol^{-1}; $\Delta S_x = -36.6$ J K^{-1} mol^{-1} and $\Delta S_{nx} = \Delta S^\bullet - \Delta S_x = 17.5$ J K^{-1}mol^{-1}. Therefore, the insertion of a water molecule in liquid cyclohexane causes a significant structural reorganization, affording positive contributions to both the enthalpy and entropy changes. Such contributions, however, cancel each other in the Gibbs energy balance because enthalpy-entropy compensation holds for the solvent structural reorganization (37).

A last point merits attention. The analysis shows that the negative entropy changes associated with both solvation processes are not caused by a poorly defined ordering of solvent molecules around the inserted solute. The physical cause of such negative values is the excluded volume effect upon solute insertion, which leads to a significant reduction in the configuration space accessible to solvent molecules. This mechanism is operative in all liquids because they are a condensed state of the matter, and each molecule possesses a finite volume.

In conclusion, the present work indicates that a unified theoretical approach is able to rationalize the solvation thermodynamics of water as well as noble gases, hydrocarbons and aliphatic alcohols (15, 16, 32–34). It is simply necessary to recognize that: (*i*) energy has to be spent to create a cavity in the solvent suitable to host the solute molecule; (*ii*) energy is gained by turning on the solute–solvent interactions, which may consist of H-bonds, as well as van der Waals

© 2001 NRC Canada

interactions. The balance of these two opposing contributions governs the solvation thermodynamics of every noncharged solute.

Appendix

It should be noted that both ΔG_c and E_a are not directly measurable quantities; only their sum can be tested against experimental ΔG^* values. This basic fact cannot be circumvented or eluded. Estimates of ΔG_c and E_a are calculated using ad hoc assumptions that cannot be considered valid in general (this statement is entirely true also with regard to computer simulations). The validity and reliability of the assumptions have to be verified by comparing the calculated sum $\Delta G_c + E_a$ with experimental ΔG^* data.

In principle, SPT enables the calculation of the work to create a spherical cavity in a solvent without making use of any adjustable parameter (18). However, SPT results depend significantly upon the value of the hard-sphere diameter selected for the solute and solvent molecules (38). For instance, we can select σ = 2.75 Å for H_2O molecules. It results: ΔG_c = 10.6 kJ mol^{-1} and 13.2 kJ mol^{-1} to create a cavity of 2.75 Å diameter at 25°C in liquid cyclohexane and

© 2001 NRC Canada

liquid water, respectively; and E_a = –10.9 kJ mol^{-1} in cyclohexane, using the same parameters reported in the text. The insertion of these estimates in eq. [1] leads to a slightly worse agreement with experimetal data. For $H_2O(g) \rightarrow H_2O(chx)$, $\Delta G_c + E_a = 10.6 - 10.9 = -0.3$ kJ mol^{-1} compared to $\Delta G^{\bullet} = -0.2$ kJ mol^{-1}; for $H_2O(g) \rightarrow H_2O(l)$, $\Delta G_c + E_a = 13.2 - 41.6 = -28.4$ kJ mol^{-1} compared to $\Delta G^{\bullet} = -26.3$ kJ mol^{-1}. Clearly, a very small reduction in the σ value of H_2O molecules has a little effect on the ΔG_c estimate in liquid cyclohexane, but an appreciable effect on the ΔG_c estimate in liquid water.

The sensitivity of SPT should not be a problem if the molecular diameters could be accurately determined. This is feasible for spherical or nearly spherical molecules, but there is no reliable recipe to assign the hard-sphere diameter to nonspherical molecules. From a physicochemical point of view, the best procedure is to use as hard-sphere diameter the distance value at which occurs the first maximum in the radial distribution function for the center-of-mass of the molecules of the selected liquid, as determined by X-ray and (or) neutron scattering measurements (i.e., the oxygen–oxygen radial distribution function for water, and the ring center-ring center radial distribution function for benzene). This is the procedure adopted in the present work. The following point, however, merits attention.

A water molecule should have two sizes depending on the interactions in which it is involved (23). When it is H-bonded to other water molecules σ = 2.80 Å, as revealed by the location of the first peak in the oxygen–oxygen radial distribution function of liquid water. When it is not H-bonded to neighbor molecules σ = 3.17 Å, that is the van der Waals diameter of an oxygen atom. As a consequence, the latter value of σ should be the correct one for a water molecule dissolved in liquid cyclohexane. Using the same parameters reported in the text, except σ = 3.17 Å for H_2O, it proves that: ΔG_c = 12.9 kJ mol^{-1} and E_a = –12.6 kJ mol^{-1} in liquid cyclohexane at 25°C. The latter estimates differ from those reported in the text, but, unequivocally confirm the practically complete cancellation of ΔG_c and E_a contributions for the $H_2O(g) \rightarrow H_2O(chx)$ process, in agreement with experimental data.

It is evident that all the above concerns and calculations do not detract anything from the qualitative general validity of our approach and derived conclusions.

Epoxide of a ketene acetal. The first 2,2-dialkoxyoxirane to be isolated

Małgorzata Dawid, Paul C. Venneri, and John Warkentin

Abstract: Dimethoxycarbene, generated at 110°C in benzene by thermolysis of 2,2-dimethoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline, reacted with cyclohexanone to afford 2,2-dimethoxyspiro[2.5]-1-oxaoctane. It is the first oxirane of a ketene acetal that could be isolated and characterized by ^{1}H NMR-, ^{13}C NMR-, and IR spectroscopy. The identical oxirane might be expected from conrotatory cyclization of the appropriate carbonyl ylide. That ylide was generated under identical conditions by thermolysis of an oxadiazoline precursor (3,4-diaza-2,2-dimethoxy-1-oxaspiro[4.5]dec-3-ene) (**14**). The ylide could either cyclize or fragment to dimethoxycarbene and cyclohexanone. Addition of 4-*tert*-butylcyclohexanone, to trap dimethoxycarbene in competition with the cyclohexanone generated from **14** and, to leave the ylide closure pathway as the only route to the oxirane, showed that the carbonyl ylide does cyclize. However, fragmentation of the carbonyl ylide is relatively fast compared to its cyclization and most of it fragments to dimethoxycarbene and cyclohexanone. Oxirane formation from the carbene and ketone is probably either a concerted cycloaddition or it occurs in two steps, by nucleophilic attack at the carbonyl carbon to form the C—C bond first, prior to ring closure. If the carbene is bonded first to O of the carbonyl group, as it is in the carbonyl ylide, subsequent formation of the C—C bond is too slow, relative to fragmentation of the ylide, to afford the oxirane ring efficiently.

Key words: carbonyl ylide, dialkoxyoxirane, dimethoxycarbene, oxadiazoline, oxirane.

Résumé : Le diméthoxycarbène, généré à 110°C dans le benzène par thermolyse de la 2,2-diméthoxy-5,5-diméthyl-Δ^3-1,3,4-oxadiazoline, réagit avec la cyclohexanone pour conduire à la formation du 2,2-diméthoxyspiro[2,5]-1-oxooctane. Il s'agit du premier oxirane d'un acétal de cétène à être isolé et caractérisé par RMN du ^{1}H et du ^{13}C et par spectroscopie IR. On pourrait s'attendre à la formation d'un oxirane identique par cyclisation conrotatoire de l'ylure de carbonyle approprié. On a généré l'ylure dans des conditions identiques par thermolyse d'un précurseur oxadiazoline, le 3,4-diaza-2,2-diméthoxy-1-oxospiro[4,5]déc-3-ène (**14**). Cet ylure peut donner lieu soit à une cyclisation ou à une fragmentation en diméthoxycarbène et cyclohexanone. L'addition de 4-*tert*-butylcyclohexanone, pour piéger le diméthoxycarbène en compétition avec la cyclohexanone générée à partir du composé **14** et pour s'assurer que la voie réactionnelle impliquant une fermeture de l'ylure est la seule voie disponible à l'oxirane, a permis de démontrer que l'ylure de carbonyle se cyclise. Toutefois, la fragmentation de l'ylure de carbonyle est relativement rapide par rapport à sa cyclisation et elle conduit à la formation de fragments diméthoxycarbène et cyclohexanone. La formation de l'oxirane à partir du carbène et de la cétone se produit probablement par le biais d'une cycloaddition concertée ou en deux étapes, par une attaque nucléophile sur le carbone du carbonyle conduisant en premier lieu à la formation d'une liaison C—C avant la fermeture du cycle. Si le carbène commençait par se lier à l'oxygène du carbonyle, comme c'est le cas dans l'ylure de carbonyle, la formation subséquente de la liaison C—C est trop lente, en comparaison avec la fragmentation de l'ylure, pour conduire de façon efficace à la formation du cycle oxirane.

Mots clés : ylure de carbonyle, dialkoxyoxirane, diméthoxycarbène, oxadiazoline, oxirane.

[Traduit par la Rédaction]

Introduction

2,2-Dialkoxy-, 2-alkoxy-2-aryloxy-, 2,2-diaryloxy- and analogous trioxy- or tetraoxyoxiranes have never been isolated. 2,2-Dialkoxyoxiranes may also be viewed as strained orthoformates or as carbonyl-group-protected α-lactones. While oxiranes are well-known (1) and easily prepared with a variety of substituents, α-lactones are generally too unstable to be isolated unless they have electron-withdrawing groups at C2 (2). Presumably ring strain in the ground state, and carboxylate-like stabilization of the transition state, drives the ring opening, and destabilization of the positive end of the dipole is required to make α-lactones persistent (Scheme 1).

2,2-Dialkoxyoxiranes could, in principle, undergo thermal conrotatory ring opening to a carbonyl ylide (3) or else the alkoxy groups might cause cleavage of a different bond, with the cationic entity delocalized (Scheme 2). The latter process had been suggested earlier by Kopecky et al. (4). They, and Hoffmann and Schneider (5), studied the ozonolysis

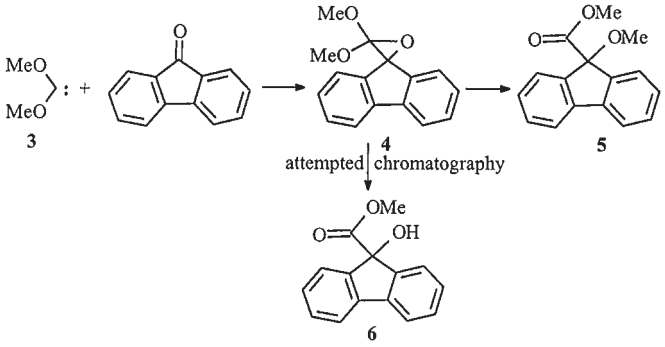
Scheme 1.

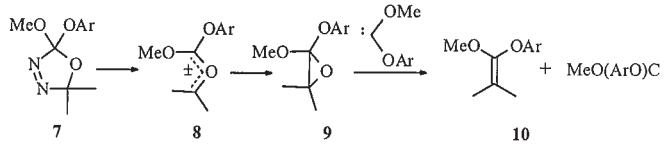


Scheme 2.

(The ozonide and other intermediates are not shown)

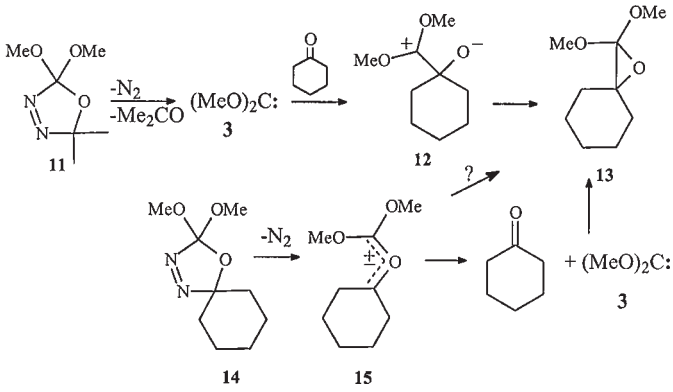
Scheme 3.

of tetramethoxyethylene, which gave methyl trimethoxyacetate.



The ester appeared to be derived from opening of oxirane **1** to a dipolar intermediate (**2**) that rearranged (Scheme 2) (4). An oxirane intermediate (**4**) was indicated in another case by the fact that dimethoxycarbene (**3**), generated at 110°C in the presence of fluorenone, afforded **5** (Scheme 3) (6). Although **4** could not be isolated, because it was converted into **6** during chromatography, it was possible to glean the ^{13}C NMR spectrum of **4** from the spectrum of a mixture (6). Moreover, Couture et al. (7) inferred the intermediacy of 2-methoxy-2-aryloxy oxiranes (**9**) on a path from oxadiazolines **7** to ketene acetals **10** (Scheme 4) although such intermediates were not actually observed.

We now report the isolation, spectroscopic characterization, and hydrolysis of the first 2,2-dialkoxyoxirane (**13**) that could be isolated. It was obtained by the thermolysis of oxadiazoline **11** in the presence of cyclohexanone. Thermolysis of **11** generates dimethoxycarbene (**3**) by sequential loss of N_2 and acetone (8), and the carbene reacted with the ketone in a [2 + 1] cycloaddition, either directly or via intermediate **12**. With the oxirane in hand, we were able to assess whether or not it can also arise from thermolysis of oxadiazoline **14**, via cyclization of the corresponding carbonyl ylide (**15**) under the same conditions (Scheme 5).



Results and discussion

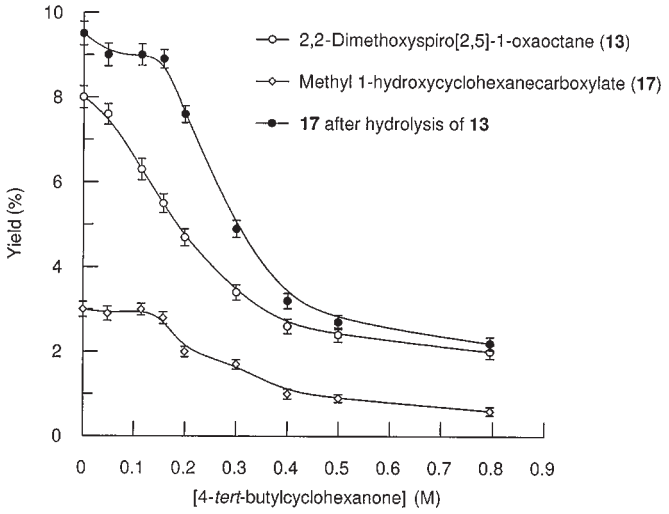
Thermolysis of 2,2-dimethoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline **11** (8, 9) in the presence of cyclohexanone gave a mixture from which **13** was isolated by means of gas chromatography, in ca. 12% yield. The crude reaction mixture did not appear to contain the product of ring expansion

Scheme 4.

Scheme 5.

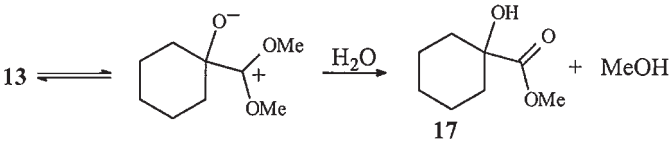
(2,2-dimethoxycycloheptanone) which we would have recognized and isolated, based on experience with ring expansion of cycloalkanones with dimethoxycarbene. The products of ring expansion of cyclobutanones and cyclopropanones were readily isolated and identified (10).

Reasonable mechanisms for the formation of **13** from **14** are in Scheme 5, which includes successive fragmentation of oxadiazoline **14** to carbonyl ylide **15** (7, 11), which could close directly (the question mark in Scheme 5) or fragment to form cyclohexanone and dimethoxycarbene (**3**). Dimethoxycarbene could then attack cyclohexanone to afford **13**. To answer the mechanistic question the known reaction between dimethoxycarbene and cyclohexanone (above) was suppressed by including 4-*tert*-butylcyclohexanone (**16**), to act as a competitor to any cyclohexanone formed from **15**. Any **13** formed at a high concentration of **16** would have to be attributed to cyclization of **15**, if the yield of **13** were to become independent of the concentration of **16** at higher values of [**16**].



The results show that the yield of **13** drops as the concentration of **16** is increased, from an initial value near 10% to a limiting value that is near 2% (Fig. 1). Thus, most of the **13** arises from attack of dimethoxycarbene on cyclohexanone (both formed by fragmentation of **15**) rather than from cyclization of **15**. In other words, **15** cyclizes slowly at 110°C compared to the rate at which it fragments to **3** and cyclohexanone, and it is primarily these products that then react to afford **13** in the absence of **16** (Scheme 5).

We assume that **16** actually captures dimethoxycarbene to form the diastereomeric *tert*-butyl analogues of **13**, but separation of those product from the reaction mixture was not attempted.



Attempts to isolate **13** by either column or radial chromatography on silica led invariably to the α-hydroxy ester (**17**) (Scheme 6). Isolation of **13** by means of gas chromatography, but not by chromatography on silica, implies that hydrolysis normally destroys such compounds. Deliberate

Fig. 1. Yields of **13** and **17**, from thermolysis of **14**, as a function of the concentration of 4-*tert*-butylcyclohexanone (M), and yields of **17** after hydrolysis of **13**. The error bars are standard deviations from five injections into the GC.

Scheme 6.

hydrolysis of **13**, dissolved in C_6D_6 in an NMR tube, by addition of a drop of water and a drop of trifluoroacetic acid also afforded **17**. Water alone, added to a solution of **13** in benzene, also caused hydrolysis but the reaction took two days. The instability of **13** in the presence of water is not surprising. Opening of the oxirane ring in a polar environment is probably fast and unidirectional (Scheme 6), even without acid catalysis, because of the *gem* dialkoxy substituents, as Kopecky et al. (4) had surmised.

We suspect that analogous dialkoxyoxiranes may, in general, be intermediates when dialkoxycarbenes attack ketones, and that some of them are more labile than **13** at the temperature (100–110°C) that is commonly used for fragmentation of the oxadiazoline source of **3**. Subtle differences in the ground state stabilities of a dialkoxyoxirane (such as **13**) and in the barriers to ring expanded products, or to carbene and ketone starting materials, could determine whether or not an analogue of **13** accumulates sufficiently for its detection and potential isolation. At this time we do not know whether the cyclohexyl ring of **13** is critical or whether there will be other dialkoxyoxiranes that are stable enough to be isolated.

Experimental

Synthesis of 11

Compound **11** was prepared according to published procedures (8, 12).

Thermolysis of 11 and isolation of 13

In a sealed tube, a degassed solution of **11** (0.100 g, 0.625 mmol) in benzene (5 g) containing cyclohexanone at 0.22 M concentration (0.123 g, 1.25 mmol) was heated with an oil bath at 110°C for 24 h. The solution was concentrated in vacuo and the concentrate was subjected to semipreparative gas chromatography on a 6′ × ¼″ glass column packed with OV-17. The column temperature was initially at 60°C for 3 min and it was then raised at 5° min^{-1} to 200°C. 2,2-Dimethoxyspiro[2.5]1-oxaoctane (**13**) was isolated in ca. 12% yield as a clear liquid. IR (CCl_4) cm^{-1}: 2990–2850, 1450. ^{1}H NMR (200 MHz, C_6D_6) δ: 1.52–1.89 (m, 10H), 3.25 (s, 6H). ^{13}C NMR (50 MHz, C_6D_6) δ: 21.7, 26.4, 32.1, 51.4, 77.9, 113.3. EI-MS *m*/*z* (rel. intensity): 173 ($M^{\cdot+}$ + 1, 9), 141 (4), 105 (100), 81 (12), 59 (14).

Hydrolysis of 13 to methyl 1-hydroxycyclohexanecarboxylate (17)

Addition of water and catalytic trifluoroacetic acid to a solution of **13** gave **17** (13) as a clear liquid. IR (CCl_4) cm^{-1}: 3542 (br), 2900–2850, 1730. ^{1}H NMR (200 MHz, C_6D_6) δ: 1.35–1.80 (m, 10H), 3.23 (s, 3H), 3.70 (s, br, 1H). ^{13}C NMR (50 MHz, C_6D_6) δ: 21.5, 25.6, 35.1, 52.0, 73.7, 177.7. EI-MS *m*/*z* (rel. intensity): 99 ($M^{\cdot+}$-CO_2Me, 21), 84 (38), 75 (4), 49 (100). Failure to generate a significant molecular ion signal, because of loss of the CO_2R fragment, is a characteristic of α-hydroxy esters and their hydroxyl-group derivatives (14).

Preparation of authentic methyl 1-hydroxycyclohexanecarboxylate (17)

The hydroxyester was prepared according to a procedure from the literature (15).

Preparation of 3,4-diaza-2,2-dimethoxy-1-oxaspiro[3,4]dec-3-ene (14)

Compound **14** was prepared by oxidative cyclization of the methoxycarbonyl hydrazone of cyclohexanone using lead tetraacetate as described previously for analogues (8). To a stirred, ice-cooled solution of lead(IV) acetate (31.92 g) in anhyd MeOH (75 mL) under dry N_2 was added, by drops, a solution of the methoxycarbonylhydrazone of cyclohexanone (10.19 g) in MeOH (75 mL). When addition of the hydrazone solution was complete, the ice bath was removed and the mixture was stirred for 4 h as the temperature rose to that of the room. Aqueous NaOH (10%, 30 mL) was added and stirring was continued for 45 min. About one-third of the MeOH was removed with a rotary evaporator before CH_2Cl_2 (25 mL) was added for extraction with a separatory funnel. After three more extractions with CH_2Cl_2 the combined extract was washed three times with 5% $NaHCO_3$. The organic layer was dried over $CaCl_2$ and, after evaporation of the solvent, the crude product was purified by column chromatography (hexane/ethyl acetate, 24:1) to afford **14** as a clear liquid, in 66% yield. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.50 – 2.04 (m, 10H), 3.47 (s, 6H). ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 22.7, 24.6, 33.5 (CH_2 groups), 51.7 (CH_3), 120.9 (C5), 136.1 (C2). EI-MS *m*/*z*: (mol. ion not observed), 169 $[M\text{-}OMe]^{\cdot+}$, 113, 91, 90, 81, 67, 59 (100%), 41.

© 2001 NRC Canada

Thermolysis of 14 with added 4-*tert*-butylcyclohexanone

Samples of 1 mL of solutions containing **14** (0.1 M) and 4-*tert*-butylcyclohexanone (0.05, 0.10, 0.15, 0.20, 0.30, 0.40, 0.50, and 0.80 M) in dry benzene were sealed into thermolysis tubes and heated with an oil bath at 110°C for 72 h. The crude mixtures were analysed by GC–FID (megabore capillary column, DB-1, 0.53 mm × 30 m) with 1,4-dimethoxybenzene as internal standard. For analysis of **17**, which was always present (presumably from adventious water), the GC was calibrated with the authentic ester. Hydrolysis after the analysis gave a solution that no longer contained **13**. That solution was then analysed for **17**. As Fig. 1 shows, the sum of the yields of **13** and **17** before hydrolysis are in good agreement with the yield of **17** after hydrolysis.

Photochemical preparation of cyclopropanes from cyclobutanones

Jailall Ramnauth and Edward Lee-Ruff

Abstract: A general method for the preparation of cyclopropanes is reported. Triplet-photosensitized reactions of a series of cyclobutanones give cyclopropanes as the major product. Part 1 describes the synthesis of substituted cyclobutanones used in this study. In Part 2, the photo-reactions of cyclobutanones are reported. Triplet-sensitized reactions of cyclobutanones using acetone as a sensitizer give cyclopropanes as the major non-polar products. The extent of photodecarbonylation seems to be dependent on α-substitution. Electron-donating groups promote decarbonylation while electron-withdrawing groups favour cycloelimination.

Key words: photodecarbonylation, cyclobutanones, cyclopropanes, triplet-sensitization.

Résumé : On décrit une méthode générale de préparation des cyclopropanes. Les réactions photosensibilisées de triplets d'une série de cyclobutanones conduisent à des cyclopropanes comme produits majeurs. Dans la première partie, on décrit la synthèse des cyclobutanones substituées utilisées dans cette étude. Dans la deuxième partie, on décrit les photoréactions des cyclobutanones. Les réactions sensibilisées de triplets de cyclobutanones utilisant de l'acétone comme sensibilisateur conduisent à la formation de cyclopropanes comme produits non polaires principaux. Le degré de photodécarbonylation semble dépendre de la substitution en α. Les groupes électrodonneurs favorisent la décarbonylation alors que les groupes électroattracteurs favorisent la cycloélimination.

Mots clés : photodécarbonylation, cyclobutanones, cyclopropanes, sensibilisation triplet.

[Traduit par la Rédaction]

Introduction

Small ring compounds have become more than just a curiosity to chemists. In particular, cyclopropane-containing compounds have played an important role in organic synthesis (1). In contrast to simple alkanes and cycloalkanes, such as cyclopentane and cyclohexane, cyclopropanes participate in a variety of reactions under mild conditions. This increased reactivity of cyclopropanes has been attributed to the deformation of bond angles from normal values as well as torsional effects. Cyclopropane derivatives are also known to constitute the basic framework of biologically active compounds present in animals, plants, and microorganisms, or to be generated as intermediates in primary and secondary metabolic processes (2).

A variety of methods are available for the synthesis of cyclopropanes, but only a few of these have been reported from ring-contraction reactions of cyclobutane derivatives (3). In conjunction with our work on the synthesis and photochemistry of cyclobutanones (4, 5), we are interested in the photodecarbonylation of cyclobutanones as a potential route to cyclopropanes. Preliminary studies have indicated that cyclopropane formation is dominant from a triplet-excited cyclobutanone (6). The triplet-sensitized photochemistry of cyclobutanones appears to take a completely different course of events compared to its singlet state chemistry and is an area that has been relatively unexplored. The impetus for this work is the increasing availability of cyclobutanones in both chiral and achiral forms (7). With three centres amenable to functionalization, cyclobutanones could be valuable precursors to substituted cyclopropanes.

In this paper, we report the synthesis and triplet-photosensitized reactions of a series of substituted cyclobutanones to assess substitution patterns towards photodecarbonylation.

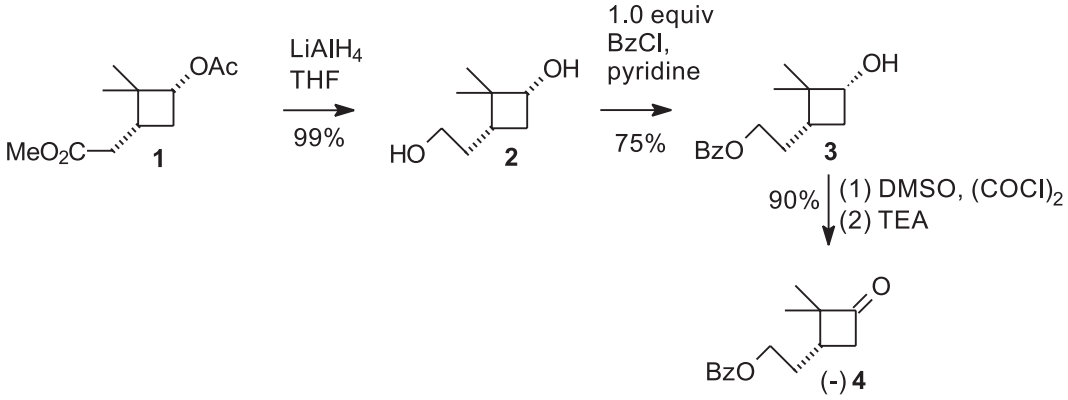
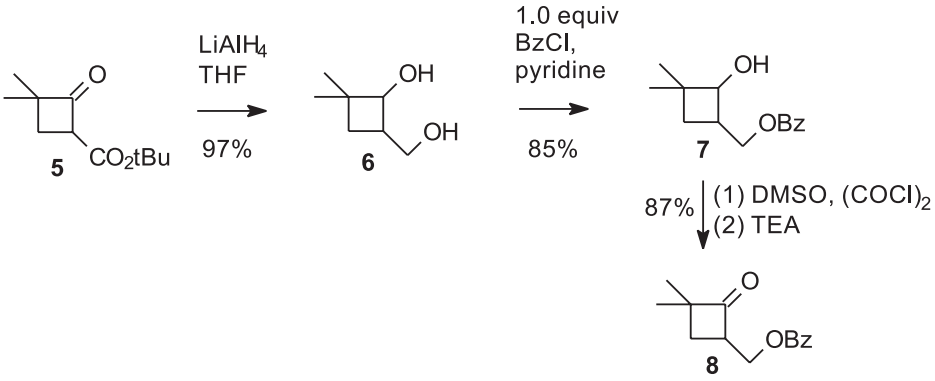
Results and discussion



Synthesis of cyclobutanones

The optically active cyclobutanone **((–)-4**) was prepared from the cyclobutane diester (**1**), which was obtained from *cis*-pinonic acid of 92% optical purity (8). The latter compound is an oxidation product of the naturally occurring (+)-α-pinene. The synthesis of (–)-**4** was carried out according to Scheme 1. The diester (**1**) was reduced with $LiAlH_4$ to the diol (**2**) in quantitative yield. This crude diol was then monoprotected with 1.0 equiv of benzoyl chloride at 0°C to hydroxy benzoate (**3**) in 75% yield. This alcohol was then oxidized under Swern conditions to give cyclobutanone ((–)-**4**) in 90% yield after flash column chromatography. The structure of (–)- **4** was ascertained from its spectral and analytical data.



The racemic 2,2,4-trisubstituted cyclobutanone (**5**) was synthesized according to a literature procedure; the key step

involved a [2 + 2] cycloaddition of *t*-butyl acrylate to *N*,*N*-dimethylisobutenylamine (9). This compound was then converted to cyclobutanone **8** according to Scheme 2. The synthesis of **8** involved the reduction of **5** to diol **6** in quantitative yield followed by protection of its primary hydroxyl group with 1 equiv of benzoyl chloride at –20°C in a yield of 85%. This alcohol was then oxidized under Swern conditions to give the targeted compound **8** in a yield of 87%. The structure of this ketone was confirmed by spectral and analytical data.

Cyclobutanone derivatives (**11a**–**e**) were prepared according to Scheme 3. The olefins (**9a**–**e**) were prepared by esterification of the corresponding alcohol with benzoyl chloride in pyridine in yields ranging from 90–95%. These olefins were then treated with dichloroketene (generated in situ from activated zinc with trichloroacetyl chloride) in the presence of DME (10) to give the cycloadducts (**10a**–**e**) in yields of 80–85%. In all cases, only one regio- and (or) stereoisomer was obtained as determined by ^1H and ^{13}C NMR. The regioisomer of the dichloroketene adduct **10c** was also ascertained by X-ray crystallography (11).

These dichlorocyclobutanones were dechlorinated with zinc powder in acetic acid to give cyclobutanones (**11a**–**e**) in high yields ranging from 85–95%. The structures of all cyclobutanones were confirmed by spectral and analytical data. Cyclobutanone **11a** showed 9 peaks in the ^{13}C NMR spectrum and a symmetrical pattern for the cyclobutyl protons in the ^1H NMR spectrum. A similar analysis was made for **11b** to confirm its regioisomeric structure. The structures of the regioisomers **11c** and **11d** were confirmed by 2-D ^1H COSY experiments. The splitting patterns in the ^1H NMR spectra were consistent with the assigned structures. The

Scheme 4.

stereochemistry of **11d** and **11e** was assigned based on the starting olefins. Also, ^{13}C and ^{1}H NMR data showed that there is no interconversion of the two isomers under the acidic conditions used in the dechlorination reaction.

Photolyses of cyclobutanones

Photolyses were performed using a medium-pressure mercury arc lamp with a Pyrex filter. Photolyses were conducted in acetone for the triplet sensitized reactions while comparative non-sensitized irradiations were carried out in THF. The samples were thoroughly degassed with argon prior to irradiation. The samples were photolyzed for 4 h and the crude photolysis products were purified by chromatography. Conversions were on average >90%. In cases where mixtures of olefins and cyclopropanes were obtained, relative yields were determined by ^{1}H NMR or HPLC analysis.

The products derived from the photolysis of the different substituted cyclobutanones are illustrated in Scheme 4. The yields for the photolyses in acetone are tabulated (Table 1). For photoreactions in THF, the major products were the olefins for all of the cyclobutanones except for cyclobutanone **8**. For this cyclobutanone, an intractable polymeric mixture was obtained. This suggests that the initial photoproducts were not stable under these conditions leading to oligomerization.

The structures of all photoproducts were assigned based on spectral and analytical data. It is evident from the results that under triplet-sensitized conditions cyclopropanes are the

Scheme 5.

major products while olefins are the major products under non-sensitized conditions. The photodecarbonylation reaction seems to be quite general.

It is apparent that the extent of photodecarbonylation is dependent on the α-substituent. We compared the ratio of cyclopropane to olefin to look at the efficiency of the decarbonylation pathway with varying substituents (Table 1). The results indicate that electron-donating groups promote decarbonylation. (–)-Cyclobutanone **4** with two electron-donating methyl groups at the α-position gave cyclopropane **12** as the only product. The lowest ratio of cyclopropane to olefin was obtained for cyclobutanone **11c** which has a weak electron-withdrawing benzoyloxymethyl group at the α-position. In the extreme case, with α,α-dichlorocyclobutanones **10a** and **10b**, cycloelimination to give 1,1-dichloroalkene is the only reaction (12).

The stereoisomeric cyclobutanones **11d** and **11e** provide examples of cyclobutanones with methyl substituents at the α-position. But more importantly, they provide a stereochemical probe for epimerization in the photodecarbonylation reaction. Under triplet-sensitized conditions these two cyclobutanones gave similar product distributions as determined by ^{1}H NMR analyses. It was surprising to see that the products showed no memory effect of the starting cyclobutanone stereochemistry unlike the photochemical ring-expansion under non-sensitized conditions (5).

In general, the extent of epimerization at the α-carbon in the decarbonylation of cyclobutanones will depend on the lifetimes of the intermediate acyl-alkyl diradical **19** and the 1,3-diradical **20** (Scheme 5). A thermodynamic equilibration of these intermediates would give an epimeric mixture of cyclopropanes. After 1 h of irradiation under triplet-sensitized conditions, analysis of the unreacted cyclobutanones **11d** and **11e** showed that about 10% of the other epimer was formed. It is likely that the decarbonylation products undergo equilibration at the 1,4-diradical stage. This stereochemical scrambling of starting materials does not occur under non-sensitized conditions. This indicates the presence of a stereochemically labile triplet 1,4-acyl-alkyl diradical intermediate under the triplet-sensitized conditions. The triplet 1,3-diradical formed after decarbonylation would be expected to undergo rapid epimerization relative to ring closure which would also allow for equilibration of the final products.

The cyclopropane photoproducts are photochemically inert under the acetone sensitized conditions, e.g., irradiation of **16** for 4 h showed no epimerization with complete recovery eliminating the possibility for stereochemical equilibration at the cyclopropane stage.

Conclusion

It has been shown that triplet-sensitized reactions of cyclobutanones, using acetone as a sensitizer, gave cyclopropanes as the major non-polar products. Under non-sensitized conditions, the photochemistry of cyclobutanones gave mostly cycloelimination products. The extent of photodecarbonylation seems to be dependent on the nature of the α-substituents. Electron-donating groups promote decarbonylation while electron-withdrawing groups favour cycloelimination. The triplet-sensitized photoreactions of *E*-3-benzoyloxymethyl-2,3-dimethylcyclobutanone (**11d**) and *Z*-3-benzoyloxymethyl-2,3-dimethylcyclobutanone (**11e**), a pair of epimeric cyclobutanones, gave a similar product distribution. The distribution of products does not show any memory effect of the starting ketone stereochemistry. In both

© 2001 NRC Canada

cases, the major product was *E*-1-benzoyloxymethyl-1,2-dimethylcyclopropane, along with its stereoisomer and minor elimination products. It is evident from these results that the photodecarbonylation reaction is not stereoselective and bond rotation in the diradical intermediates occurs faster than ring closure. Since the cyclobutanones are prepared from [2 + 2] cycloadditions of alkenes and ketene or ketene equivalents, this two step process represents an alternate route for cyclopropanations under neutral conditions which could find many applications. The reaction can also be a potential route to sterically congested cyclopropanes.

Experimental

Melting points (mp) were determined on a Reichert melting point apparatus and were uncorrected. NMR spectra were recorded on a Bruker ARX 400 (400 MHz) spectrometer in $CDCl_3$ containing 1% TMS unless otherwise noted. Chemical shifts are quoted in delta (δ) values in parts per million (ppm) downfield from TMS (δ = 0). Mass spectra (MS) were recorded at 70 eV electron impact mode on a Kratos profile mass spectrometer. Optical rotations were measured using a Perkin–Elmer 241 polarimeter at 22°C. Fourier transform infrared spectra (FT-IR) were recorded on a Pye Unicam SP3–200 spectrometer as thin films or KBr pellets. HPLC analysis was performed on a Waters M6000A instrument with a Lamda-Max model 481 LC detector using UV detection (254 nm), a Hewlett–Packard integrator, and a Spherisorb Silica analytical column from Sigma–Aldrich. Elemental analyses were performed by Guelph Chemical Laboratories Ltd.

Photolyses were carried out using a Hanovia 450 W medium-pressure mercury arc lamp in a water-cooled quartz immersion well. Pyrex tubes containing the samples were strapped around this well and the assembly immersed in an ice water bath. The samples were purged with argon for 30 min prior to irradiation. All solvents used in these reactions were dried and distilled.

Analytical thin layer chromatography (TLC) was performed on commercially prepared silica gel 60F 254 plastic sheets (E. Merck & Co.). Preparative TLC was performed on Aldrich silica gel 60F 254 precoated glass plates. For column chromatography, Silicycle silica gel (flash chromatography grade, 20–45 μm) was used.

Synthesis of (–)-3-[2-(benzoyloxy)ethyl]-2,2-dimethylcyclobutanone (4)

To a stirred suspension of $LiAlH_4$ (2.5 g, 65.2 mmol) in dry Et_2O (100 mL) at 0°C under argon was added **1** (8) (7.0 g, 32.6 mmol) in 60 mL dry Et_2O dropwise over a period of 30 min. The reaction mixture was then heated to reflux for 4 h. After cooling in an ice-water bath the following were added dropwise in sequence: (*i*) 2.4 mL H_2O in 7.6 mL THF; (*ii*) 2.4 mL 15% aq. NaOH; and, (*iii*) 7.2 mL H_2O. The resulting mixture was stirred at ambient temperature for an additional 30 min after which it was filtered and washed with Et_2O (3 × 100 mL). The ether extracts were combined and dried over anhyd Na_2SO_4 and concentrated to give 4.7 g (99.7%) of **2**. This crude diol was dissolved in dry pyridine (50 mL) and cooled to 0°C. To this solution was added dropwise benzoyl chloride (4.4 g, 31.3 mmol, 0.95 equiv) in dry pyridine (20 mL) over a period of 30 min. The reaction was kept at this temperature for 4 h and then allowed to warm to room temperature. After this time, the reaction mixture was concentrated and diluted with CH_2Cl_2 (300 mL). The organic phase was washed with H_2O (3 × 50 mL), 1% HCl (3 × 50 mL), sat. aq $NaHCO_3$ (3 × 50 mL), H_2O (2 × 50 mL) and dried over Na_2SO_4. Evaporation of the solvent, followed by flash silica gel chromatography (6:1, hexane:ethyl acetate), gave 5.8 g (75%) of **3**. MS *m/z*: 249 (M + 1). FT-IR (neat) cm^{-1}: 3410, 1719. ^1H NMR ($CDCl_3$) δ: 8.04–7.42 (m, 5H), 4.29–4.22 (m, 2H), 3.75–3.70 (m, 1H), 2.39–2.14 (m, 1H), 1.88–1.50 (m, 5H), 1.09 (s, 3H), 0.99 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 166.7, 133.0, 130.3, 129.6, 128.4, 74.1, 64.1, 43.9, 34.5, 34.4, 29.1, 28.1, 15.2. The crude product was used for the next step.

A solution of oxalyl chloride (1.25 mL, 15 mmol) in dry CH_2Cl_2 (60 mL) was cooled to –60°C with constant stirring under argon. To this mixture, DMSO (2.0 g, 25 mmol) in dry CH_2Cl_2 (12 mL) was added over a 5 min period. After an additional 10 min of stirring, **3** (2.5 g, 10.1 mmol) in CH_2Cl_2 (25 mL) was added over a 5 min period. After 15 min, TEA (7.0 mL) was added over a 5 min period, and the resulting mixture was allowed to warm to room temperature. The reaction mixture was treated with H_2O (30 mL) and stirred for 10 min to separate the two layers. The organic layer was separated and the aqueous layer was extracted with CH_2Cl_2 (2 × 50 mL). The combined organic extract was washed with 2% HCl (2 × 50 mL), H_2O (50 mL), sat. aq $NaHCO_3$ (50 mL), sat. aq NaCl (50 mL), and dried over $MgSO_4$. Purification by flash silica gel chromatography (6.25:1, hexane:ethyl acetate) gave 2.2 g (90%) of the title compound as a colourless oil. $[\alpha]_D^{22}$ = –23.0° ($CHCl_3$, *c* 1.5). MS *m/z*: 246. FT-IR (neat) cm^{-1}: 1777.1, 1718.3. ^1H NMR ($CDCl_3$) δ: 8.05–7.27 (m, 5H), 4.40–4.36 (m, 2H), 3.21 (dd, *J* = 8.9, 8.7 Hz, 1H), 2.84 (dd, *J* = 7.7, 9.9 Hz, 1H), 2.23–2.10 (m, 2H), 1.93–1.85 (m, 1H), 1.22 (s, 3H), 1.15 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 214.3, 166.6, 133.1, 130.1, 129.6, 128.5, 63.9, 61.1, 48.6, 33.6, 29.9, 23.4, 17.3. Anal. calcd. for $C_{15}H_{18}O_3$: C 73.14, H 7.37; found: C 72.94, H 7.76.

Synthesis of (±)-2-benzoyloxymethyl-4,4-dimethylcyclobutanone (8)

The keto-ester **5** (9) was reduced according to the procedure described for the reduction of diester **1** to give compound **6** (mixture of isomers) in a yield of 98%. ^1H NMR of major isomer δ: 4.06 (d, *J* = 7.3 Hz, 1H), 3.86 (t, *J* = 10.9 Hz, 1H), 3.74 (dd, *J* = 4.2, 6.8 Hz, 1H), 3.20 (br s, 1H), 3.05 (br s, 1H), 1.62–1.54 (m, 2H), 1.11 (s, 3H), 1.06 (s, 3H). ^{13}C NMR ($CDCl_3$) of major isomer δ: 76.4, 63.2, 37.9, 35.4, 32.3, 28.8, 22.3. This crude diol was used in the next step without further purification. The hydroxy ester **7** was prepared in 85% yield by a slightly modified procedure as described for the preparation of **3**. This reaction was conducted at –20°C instead of 0°C. ^1H NMR ($CDCl_3$) of major isomer δ: 8.04–7.26 (m, 5H), 4.73 (dd, *J* = 1.7, 9.8, Hz, 1H), 4.18 (dd, *J* = 4.8, 6.6 Hz, 1H), 3.97–3.95 (m, 1H), 2.84 (d, *J* = 3.5 Hz, 1H), 2.77–2.73 (m, 1H), 1.76–1.73 (m, 1H), 1.68–1.61 (m, 1H), 1.14 (s, 3H), 1.08 (s, 3H). This compound was oxidized under Swern conditions as before to give **8** as a colourless oil in a yield of 87% after flash silica

General procedure for the preparation of dichlorocyclobutanones 10a–e

A two-neck round-bottom flask, equipped with a magnetic stirrer, dropping funnel, and argon inlet was charged with activated zinc (4 equiv) and the olefin (1 equiv) in anhyd ether (2 mL $mmol^{-1}$ of olefin). To this vigorously stirred suspension was added dropwise a mixture of trichloroacetyl chloride (2 equiv), 1,2-dimethoxyethane (DME) (2 equiv), and anhyd ether (1 mL $mmol^{-1}$) over a period of about 30 min. This mixture was stirred overnight at room temperature. After this time, hexane was added (~50 mL) and the suspension stirred for 5 min to precipitate the zinc salts. The solution was then decanted and treated sequentially with H_2O (100 mL), sat. aq $NaHCO_3$ (3 × 100 mL), sat. aq NaCl (100 mL), and dried over Na_2SO_4. The syntheses of compounds **10a** and **10b** have been reported previously (12).

*4-Benzoyloxymethyl-2,2-dichloro-3,3-dimethylcyclobutanone (**10c**)*

Prepared from olefin **9 c** in 82% yield. The crude product was recrystallized from hexane to give creamish coloured crystals, mp 61–62°C. FT-IR (KBr) cm^{-1}: 1801, 1716. ^1H NMR ($CDCl_3$) δ: 8.02–7.44 (m, 5H), 4.62 (dd, *J* = 5.0, 6.8 Hz, 1H), 4.46 (dd, *J* = 3.1, 8.7 Hz, 1H), 3.94 (dd, *J* = 3.2, 5.6 Hz, 1H), 1.58 (s, 3H), 1.36 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 192.3, 166.0, 133.4, 129.6, 129.4, 128.6, 91.9, 62.6, 59.0, 45.1, 24.5, 21.1. Anal. calcd. for $C_{14}H_{14}Cl_2O_3$: C 55.85, H 4.69; found: C 56.00, H 4.81.

E-*3-Benzoyloxymethyl-2,2-dichloro-3,4-dimethylcyclobutanone (**10d**)*

Prepared in 81% yield from olefin **9d**. The crude product was passed through a short plug of silica gel to give a white solid, mp 99–100°C. FT-IR (neat) cm^{-1}: 1800, 1726. ^1H NMR ($CDCl_3$) δ: 8.26–7.65 (m, 5H), 4.87 (d, *J* = 11.6 Hz, 1H) 4.81 (d, *J* = 11.6 Hz, 1H), 3.93 (q, *J* = 7.1 Hz, 1H), 1.55 (s, 3H), 1.39 (d, *J* = 7.0 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 194.9, 166.0, 133.4, 129.7, 129.5, 128.6, 90.2, 68.5, 56.0, 47.4, 16.9, 8.6. Anal. calcd. for $C_{14}H_{14}Cl_2O_3$: C 55.85, H 4.69; found: C 55.80, H 4.83.

Z-*3-Benzoyloxymethyl-2,2-dichloro-3,4-dimethylcyclobutanone (**10e**)*

Prepared in 81% yield from olefin **9e**. The crude product was passed through a short plug of silica gel to give a viscous yellow oil which solidified on standing at –10°C overnight, mp 75–76°C. FT-IR (neat) cm^{-1}: 1800, 1726. ^1H NMR ($CDCl_3$) δ: 8.03–7.52 (m, 5H), 4.63 (d, *J* = 11.9 Hz, 1H) 4.51(d, *J* = 11.9 Hz, 1H), 3.71 (q, *J* = 7.5 Hz, 1H), 1.65 (s, 3H), 1.37 (d, *J* = 7.0 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 194.9, 166.0, 133.4, 129.7, 129.5, 128.6, 90.2, 68.5, 56.0, 47.4, 16.9, 8.6. Anal. calcd. for $C_{14}H_{14}Cl_2O_3$: C 55.85, H 4.69; found: C 55.81, H 4.66.

General procedure for the dechlorination of cyclobutanones 11a–e

A one-neck round-bottom flask was charged with zinc powder (5 equiv) and glacial acetic acid (1.5 mL/equiv). To this vigorously stirred suspension was slowly added the dichlorocyclobutanone (1 equiv) in glacial acetic acid (1 mL/equiv). After addition, the mixture was heated to 60°C for 30 min. The reaction mixture was cooled, diluted with anhyd ether (100 mL) and then filtered. The filtrate was then treated with sat. aq $NaHCO_3$ (5 × 100 mL), sat. aq NaCl (1 × 100 mL), and dried over Na_2SO_4. In general, the crude products contained very little impurity and were purified using a short plug of silica gel with 4:1 (hexane:ethyl acetate). Compounds **11c**–**e** were purified by flash silica gel chromatography, using methylene chloride as the eluent.

*3-Benzoyloxymethylcyclobutanone (**11a**)*

Prepared in 95% yield from compound **10a**. FT-IR (neat) cm^{-1}: 1787, 1719. ^1H NMR ($CDCl_3$) δ: 8.04–7.26 (m, 5H), 4.50 (d, *J* = 6.1 Hz, 2H), 3.29–3.21 (m, 2H), 3.04–2.89 (m, 3H). ^{13}C NMR ($CDCl_3$) δ: 205.9, 166.4, 133.2, 129.8, 129.6, 128.5, 67.2, 50.1, 23.0. Anal. calcd. for $C_{12}H_{12}O_3$: C 70.58, H 5.92; found: C 70.65, H 5.76.

*3-[2-(Benzoyloxy)ethyl]cyclobutanone (**11b**)*

Prepared in 93% yield from **10b**. FT-IR (neat) cm^{-1}: 1786, 1718. ^1H NMR ($CDCl_3$) δ: 8.04–7.43 (m, 5H), 4.40 (t, *J* = 6.1 Hz, 2H), 3.28–3.20 (m, 2H), 2.86–2.79 (m, 2H), 2.60–2.56 (m, 1H), 2.12–2.07 (m, 2H). ^{13}C NMR ($CDCl_3$) δ: 207.2, 166.5, 133.1, 130.1, 129.5, 128.4, 63.7, 52.7, 35.0, 21.4. Anal. calcd. for $C_{13}H_{14}O_3$: C 71.55, H 6.47; found: C 71.73, H 6.37.

*2-Benzoyloxymethyl-3,3-dimethylcyclobutanone (**11c**)*

Prepared in 95% yield from compound **10c**. FT-IR (neat) cm^{-1}: 1779, 1720. ^1H NMR ($CDCl_3$) δ: 8.02–7.42 (m, 5H), 4.54 (dd, *J* = 4.9, 6.8 Hz, 1H), 4.45 (dd, *J* = 3.0, 8.8 Hz, 1H), 2.97–2.91 (m, 1H), 2.70 (dd, *J* = 2.5, 14.5 Hz, 1H), 2.66 (dd, *J* = 1.3, 16.1 Hz, 1H), 1.49 (s, 3H), 1.29 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 205.5, 166.2, 133.1, 129.9, 129.6, 128.5, 66.2, 59.9, 58.5, 30.0, 29.6, 22.8. Anal. calcd. for $C_{14}H_{16}O_3$: C 72.39, H 6.95; found: C 72.34, H 6.84.

E-*3-Benzoyloxymethyl-2,3-dimethylcyclobutanone (**11d**)*

Prepared in 85% yield from **10d**. FT-IR (neat) cm^{-1}: 1780, 1720. ^1H NMR ($CDCl_3$) δ: 8.04–7.44 (m, 5H), 4.42 (s, 2H), 3.32 (m, 1H), 3.16 (d, *J* = 19.6 Hz, 1H), 2.59 (d, *J* = 16.8 Hz, 1H), 1.24 (s, 3H), 1.09 (d, J = 7.5 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 208.6, 166.4, 133.3, 129.8, 129.6, 128.6, 58.9, 54.0, 32.5, 18.2, 8.5. Gaussian basis sets for the atoms from K through Xe

R. Centoducatte, E.V.R. de Castro, and F.E. Jorge

Abstract: An improved generator coordinate Hartree–Fock (IGCHF) method is used to generate Gaussian basis sets for the atoms from K (Z = 19) through Xe (Z = 54). The Griffin–Hill–Wheeler–HF equations are integrated using the integral discretization technique. The ground state HF total energies obtained by us are compared with those calculated with the original GCHF method and with other approaches reported in the literature. The largest difference between our energy values and the corresponding ones computed with a numerical HF method is equal to 6.003 mhartree for Kr (Z = 36).

Key words: improved generator coordinate Hartree–Fock method, Gaussian basis sets, total energies.

Résumé : On a utilisé une méthode de Hartree–Fock avec générateur de coordonnées amélioré (IGCHF) pour générer des ensembles de base gaussiens pour les atomes allant de K (Z = 19) à Xe (Z = 54). On a intégré les équations de Griffin–Hill–Wheeler–HF en faisant appel à une technique de discrétisation intégrale. Les énergies totales de HF que l'on a obtenues pour l'état fondamental sont comparées à celles calculées par la méthode de GCHF originale et avec celles obtenues par d'autres approches rapportées dans la littérature. La plus grande différence entre les valeurs d'énergies que l'on a obtenues et celles obtenues par des calculs à l'aide d'une méthode de HF numérique est égale à 6,003 mhartree pour le Kr (Z = 36).

Mots clés : méthode de Hartree–Fock avec générateur de coordonnées amélioré, ensembles de base gaussiens, énergies totales.

[Traduit par la Rédaction]

Introduction

Hartree–Fock (HF) wave functions for atoms and atomic ions can be constructed numerically (1). However, practical convenience dictates a very frequent use of Roothaan–HF (RHF) wave functions (2) in which the radial parts of the atomic orbitals are algebraically approximated by expansion in a set of basis functions such as Slater-type functions (STFs) or Gaussian-type functions (GTFs). The majority of contemporary molecular quantum chemical calculations use basis sets composed of GTFs. There are good reviews and compendia (3–6) of GTF basis sets either in uncontracted or contracted form.

In 1986, Mohallem et al. (7) developed the generator coordinate HF (GCHF) method and applied this methodology in the generation of universal basis sets (UBSs) of STFs and GTFs (8,9). In the last three years, Jorge and co-workers (10–14) have used with success the GCHF method in the generation of UBSs and of adapted Gaussian basis sets for light and heavy atoms.

[1]Corresponding author (e-mail: jorge@cce.ufes.br).

Recently, Jorge and de Castro (15) developed an improved GCHF (IGCHF) method that was used to generate accurate Gaussian basis sets (GBSs) for the first-row atoms (15) and second-row atoms and atomic ions (16). From these basis sets (15,16) we have generated contracted GBSs which were used to calculate various physical and chemical properties of first- (17) and second-row (18) diatomic molecules.

In this work, we report GBSs for the third- and fourth-row atoms in their ground state generated with the IGCHF method (15). Our total energy results are compared with the corresponding values obtained with the original GCHF method (7), with the fully optimized basis sets (19) of STFs and with a numerical HF (NHF) (20) approach.

Improved generator coordinate Hartree–Fock method

The GCHF method (7) has been used to describe the electronic structure of atoms and molecules. This model describes the one-electron functions as an integral transform

$$[1] \qquad \psi_i(1) = \int \phi_i(1,\alpha)\, f_i(\alpha)\, d\alpha \qquad i = 1, \ldots, n$$

where the ϕ_i are the generator functions (in this work are GTFs), the f_i are the weight functions, and α is the generator coordinate. The application of eq. [1] to calculate expectation values using Slater determinant leads to the Griffin–Hill–Wheeler–HF (GHWHF) eqs. (7). These are a set of integral equations of the form

 DOI: 10.1139/cjc-79-2-121 © 2001 NRC Canada

$$[2] \qquad \int [F(\alpha,\beta) - \varepsilon_i S(\alpha, B)] f_i(\beta) d\beta = 0 \qquad i-1,\ldots,n$$

where the ε_i are the HF eigenvalues, and the Fock ($F(\alpha, \beta)$) and overlap ($S(\alpha, \beta)$) kernels are defined in ref. 7. An analytic solution of eq. [2] for multieletronic systems is not possible and, thus, it is integrated numerically through a technique called integral discretization (ID) (21). This technique is implemented through a relabelling of the generator coordinate space, i.e.,

$$[3] \qquad \Omega = \ln\alpha / A \qquad A > 1$$

where A is a scaling parameter determined numerically. The new generator coordinate space (Ω) is discretized for each *s*, *p*, *d*, and *f* symmetry in an equally spaced mesh $\{\Omega_i\}$ so that:

$$[4] \qquad \Omega_k = \Omega_{\min} + (k-1)\Delta\Omega \qquad k = 1,\ldots,N$$

In eq. [4] N corresponds to the number of discretization points defining the basis set size, $\Omega_{\min}$ is the initial point, and $\Delta\Omega$ an increment. Thus, the original GCHF method (7) corresponds to the use of only one arithmetic sequence (eq. [4]) of equally spaced points $\{\Omega_i\}$ to generate single-optimized GBSs (SOGBSs).

Recently, Jorge and de Castro (15) have introduced a simple modification in the GCHF method that produces improvements in the HF atomic energy values without adding more functions (GTFs in our case); this procedure has been named as IGCHF method. In this new approach (15) the new generator coordinate space, Ω, is discretized for each *s*, *p*, *d*, and *f* symmetry in three independent arithmetic sequences,

$$[5] \qquad \Omega_k = \begin{cases} \Omega_{\min} + (k-1)\Delta\Omega & k = 1,\ldots,j \\ \Omega'_{\min} + (k-1)\Delta\Omega' & k = j+1,\ldots,M \\ \Omega''_{\min} + (k-1)\Delta\Omega'' & k = M+1,\ldots,N \end{cases}$$

For a given value of N, the number of parameters now to be optimized for each symmetry when we use eq. [5] is three times that of the original GCHF method (see eq. [4]). In ref. 15, we named the GBSs generated through the eqs. [3] and [5] as triple-optimized GBSs (TOGBSs).

We call attention to the fact that when eq. [5] is used there is no longer an equally spaced mesh $\{\Omega_i\}$, because now there are three arithmetic sequences to generate the basis function exponents for each symmetry.

Results and discussion

We have used an IGCHF method (15) presented in the last section to calculate the total energies for the atoms from K (Z = 19) through Xe (Z = 54). Throughout the calculations the scaling parameter value A (see eq. [3]) is equal to 6.0. All calculations were carried out using a modified version of the ATOMSCF program (22). For each atom studied here, the optimization process of each approach (GCHF and IGCHF) is repeated until the total energy value is stabilized within 10 significant figures.

Table 1 displays the ground state HF total energies (in hartree) computed with the SOGBSs and TOGBSs, and with a NHF (20) approach. For the GCHF (7) and IGCHF (15) methods, we choose GTF basis sets of the same size (see the fifth column of Table 1) with the purposes to compare the energy values. From this table, we can notice that, for all atoms studied here, our results are always more stable than those computed with the SOGBSs, and that the largest improvement in the energy is 2.755 mhartree for In. Beside this, the errors in the energy values computed with our TOGBSs relatively to the NHF limits, are always smaller than 6.004 mhartree.

The good performance of the TOGBSs is attributed to the IGCHF (15) method, because since we have now three independent arithmetic sequences for each *s*, *p*, *d*, … symmetry (see eq. [5]), it is possible to describe independently the inner, intermediate and outer electrons of a given symmetry. On the other hand, the SOGBSs generated with the original GCHF method (7) have only one arithmetic sequence (see eq. [4]) to describe these three different regions of each atomic symmetry. It is important to mention here that for the *d* symmetry of all third- and fourth-row atoms we have used the same set of exponents of the SOGBSs, because there are no large exponents for this symmetry, that is, the electrons of the *d* orbitals are far from the nucleus. Thus, for these atoms we have optimized, with the IGCHF method (15), only the GTF exponents of *s* and *p* symmetries.

The widely used RHF wave functions of Clementi and Roetti (23) for the atoms from He through Xe were improved by reoptimization (19) of the STF exponents. For the third-row and Te and I atoms the energies computed with our TOGBSs are larger than those obtained with fully optimized basis sets of STFs (19), whereas for the atoms from Rb through Sb and for Xe, the opposite occurs.

Conclusions

We have constructed accurate GBSs with the IGCHF method (15) for the third- and fourth-row atoms. These wave functions are appropriated to be used in HF atomic and molecular calculations of physical and chemical properties.

Our total energies are closer to the NH*F* values (20) than the corresponding values calculated with the original GCHF method (7) using GBSs of same size. For the atoms from Rb through Xe (except for Te and I) the present results are better than those calculated with the fully optimized basis sets (19) of STFs. The total energy errors do not exceed 6.003 mhartree.

An application of the TOGBSs generated in this work in calculations of some properties of third- and fourth-row diatomic molecules is in progress. Full details about the wave functions reported here are available upon request to the e-mail address: jorge@cce.ufes.br.

Possible structures for H-Cu-CH_3 molecules

Martyn C.R. Symons and Raymond E. March

Abstract: EPR spectra for H-Cu-CH_3 molecules in glasses at 77 K show ^{63}Cu hyperfine splitting that accords with a $d^1_{x^2-y^2}$ orbital for the semi-occupied molecular orbital (SOMO) rather than a $d^1_{z^2}$ SOMO. The *g*-values also strongly imply a $d^1_{x^2-y^2}$ configuration. The estimated spin densities on the H- and -CH_3 ligands are small. It is argued that the molecule must be strongly bent in order to favour this SOMO and that this bending may be induced by weak solvation.

Key words : H-Cu-CH_3, EPR spectra, molecular structure, hyperfine splitting.

Résumé : Les spectres RPE de molécules de H-Cu-CH_3 dans des solides à l'état vitreux, à 77 K, présentent des dédoublements hyperfins du ^{63}Cu qui sont plutôt en accord avec la présence d'une orbitale $d^1_{x^2-y^2}$ moléculaire semi-occupée (OMSO) que d'une OMSO $d^1_{z^2}$. Les valeurs de *g* impliquent aussi fortement une configuration $d^1_{x^2-y^2}$. Les évaluations des densités de spin sur les ligands H- et CH_3- indiquent que celles-ci sont faibles. On suggère que, pour favoriser une telle OMSO, la molécule doit être fortement déformée et que cette déformation pourrait être induite par une faible solvatation.

Mots clés : H-Cu-CH_3, spectre RPE, structure moléculaire, dédoublement hyperfin.

[Traduit par la Rédaction]

Introduction

Most Cu^{II} complexes have four strongly bonded ligands arranged, commonly, in a square planar configuration with two weakly bonded axial ligands. A few such complexes, especially in constrained protein ligand structures, tend towards structures with four nearly tetrahedral ligands such as in the blue copper proteins. In contrast, Cu^{I} complexes are bonded normally to four tetrahedrally bonded ligands where the bonding is sp^3 hybridized on copper to a first approximation. Hence, it seemed of interest to study the EPR spectrum of the unusual copper derivative H-Cu-CH_3. When the ligands are considered as H^- and CH_3^-, this complex can be regarded as a Cu^{II} complex.

Experimental

The photochemical reaction of methane with copper atoms isolated in a matrix was reported originally by Billings et al. (1). Ozin et al. (2) identified H-Cu-CH_3 from a narrow-band photolysis study of the Cu/CH_4 system. A detailed study of the formation and photochemistry of $HCuCH_3$ was reported by Parnis et al. (3). The best results were obtained using dilute solutions (ca. 0.1 M) in methyltetrahydrofuran at 77 K. EPR spectra were measured at 77 K using a Varian E109 X-band spectrometer. Microwave powers were in the 1–5 mW range. Modulation frequencies were ca. 100 kHz. The spectra were the same within these ranges.

Results and discussion

A typical EPR spectrum is shown in Fig. 1; the data taken from this spectrum are listed in Table 1. Both the ^{63}Cu hyperfine splitting and the *g*-values are typical of a $d^1_{x^2-y^2}$ semi-occupied molecular orbital (SOMO). Hence, perhaps surprisingly, the complex must be strongly bent, rather than linear, since a $d^1_{z^2}$ configuration is ruled out by the data. Before discussing the reasons for our choice of the $d^1_{x^2-y^2}$ SOMO, we considered the structures of related species, specifically, the $PbCH_3^{\bullet 2+}$ centre (4), $AgH^{\bullet +}$(5), and the recently discovered $HHgCH_3^{\bullet +}$ radical cation (6). The $PbCHCH_3^{\bullet 2+}$ centre was formed by exposing $Pb^{2+}(CH_3CO_2^-)_2$ to ionizing radiation at 77 K. The centre was identified by its EPR spectrum (4). The data extracted from the EPR spectrum of the centre are included in Table 1. They show that a monomethyl centre Pb-CH_3^{2+} was formed. It was suggested that this centre was formed by electron loss from acetate ions, to give CH_3CO_2• radicals, which readily lose CO_2 to give CH_3• radicals. These radicals then added to the relatively weakly coordinated lead cations to yield the $(Pb\text{-}CH_3)^{2+}$ centre.

The ^{207}Pb hyperfine coupling ($A_{//}$ = 1928 G; $A_{\perp}$ = 1700 G) (G = 10^{-4} T) shows that the 6*s*-orbital character is very large (≈25%), whilst the purely anisotropic hyperfine coupling due to population of the outer 6*p*-orbital gives a population of ≈43%. Hence, the spin-density on Pb is ≈ 68%. These values, determined in the usual way (7), are very approximate but always give good qualitative structures.

At first glance, the spin-density on the protons of the –CH_3 group, as gauged from the isotropic proton hyperfine couplings, is very high, since the splitting compared to methyl radicals is ≈ 23%. However, •CH_3 radicals are planar,

whereas in Pb-CH_3 the –CH_3 group should be pyramidal. As a •CH_3 radical starts to become pyramidal, the originally negative coupling caused by spin polarisation of the C-H σ-electrons passes through zero and becomes positive because direct delocalization onto the protons becomes allowed. Hence, in this case, with a considerable share of the bonding electrons, the groups must be strongly pyramidal with quite large spin-density on the carbon, by difference, this is ≈32%.

The $AgH^{\bullet+}$ radical centres are similar. They were first formed by irradiating aqueous sulphuric acid glasses containing silver perchlorate. The ejected electrons added to Ag^+ to give Ag• atoms that have very well defined EPR features. On annealing, the trapped hydrogen atoms reacted with Ag^+ to give $AgH^{\bullet+}$. A range of other diatomic σ^*-radicals have also been prepared (8).

We have also studied the $(Ag_2H)^{\bullet 2+}$ radical formed similarly on annealing in concentrated sulphuric acid (9). In contrast with $HCuCH_3^{\bullet 2+}$, these radicals were clearly linear, with high spin-density on all three atoms. This condition arises because there are now two extra electrons with the result that the *d*-manifold is full. Now the two ligands can avoid each other using the outer 6*s* orbital on silver, with some contributions from the 6*p* and $5d_z^2$ orbitals.

Another radical that has been studied recently is H-Hg-$CH_3^{\bullet+}$ (6). This centre, together with $(CD_3)_2Hg^{\bullet+}$, $(C_2H_5)_2Hg^{\bullet+}$ and $(C_2H_5)_2Cd^{\bullet+}$ (10), were prepared by exposing very dilute solutions of the parent compound in freon ($CFCl_3$) to ionizing radiation at 77 K. Under these conditions, it is well established that only electron-loss processes occur (11, 12). Only the H-Hg-$CH_3^{\bullet+}$ radical-cations are considered here, and the data are given in Table 1. Two distinct centres were detected at 77 K. One had a very large ^1H hyperfine splitting (462 G) and there was nothing detectable from the methyl protons. The other had a very small proton coupling to the hydride ligand but a relatively large coupling to the methyl protons (15 G). No coupling to ^{199}Hg or to ^{201}Hg could be detected. These results have been interpreted in terms of two alternative limiting structures. For (*a*), it is

© 2001 NRC Canada

suggested as $(H\bullet\text{---}HgCH_3)^+$ while for (*b*), it is suggested as $(H\text{-}Hg\text{---}\bullet CH_3)^+$, with the positive charge primarily on mercury.

As suggested above, the limiting structure for the copper derivative is $(H–Cu^{2+}–CH_3^-)$ with a bond angle of ≈90°, and a high spin-density in the $d^1_{x^2-y^2}$ orbital. The explanation appears to lie in the relative electron affinities of Cu^{2+} and Hg^{3+} (that is, for $H–Hg^{3+}–CH_3^-$). For this species, the electron affinity of the Hg^{3+} cation is, relatively, very high. This condition is due, in part, to the 3+ charge and, in part, to the large *d*–*s* gap for mercury. Hence, electron loss occurs primarily from the ligands since the electron affinities of hydrogen and carbon (*sp* hybridized) are comparable. There is no clear preference for $(C_2H_5)_2Cd^{\bullet+}$ radical cations, the two ethyl groups are equivalent, both with high spin-densities (10) and typical *g*-values. It is concluded that the $H\text{-}Hg\text{-}CH_3^{\bullet+}$ radical-cation can exist in two stable forms, one being close to H• and the other close to $\bullet CH_3$. Indeed, both these radicals were also detected in high yields. This situation is very rare. Another example, is that of the $SnH_4^{\bullet+}$ radical cation (13). Again, at 77 K, two alternative structures were detected. In one case, a σ^* type of species $(H\text{-}\bullet SnH_3)^+$ was found. However, in the other, bond angles had changed as for $CH_4^{\bullet+}$, with two strongly coupled protons and two very weakly coupled protons.

There remains the problem as to why the $d^1_{x^2-y^2}$ configuration is favoured for $HCuCH_3$ over the near linear $d^1_{z^2}$ configuration. It is suggested tentatively that this configuration arises because of weak coordination of solvent molecules in the two positions.

Conclusions

We conclude that the $H\text{-}Cu\text{-}CH_3$ molecule does not have a linear structure with a $d^1_{z^2}$ ground state. This suggests that the molecule is strongly bent such that the $d^1_{x^2-y^2}$ structure is favoured. We suggest tentatively that this bent structure occurs, at least in part, because of the coordination of two solvent molecules along the *x*- and *y*-axes.

Potassium borohydride reducing route to phase-pure nanocrystalline InSb at low temperature

Jun Lu, Yi Xie, Xuchuan Jiang, Wei He, Ping Yan, and Yitai Qian

Abstract: The phase-pure III–V binary antimonide (InSb) was first prepared through a novel solution route at a temperature of 200°C:

$$2InCl_3 + 6KBH_4 + 2Sb \xrightarrow{en} 2InSb + 6KCl + 6BH_3 + 3H_2\uparrow$$

Mean crystallite dimensions of 40 nm were determined from X-ray powder diffraction. Transmission electron microscopy images showed that the spherical grains with a diameter of 40–60 nm and the rodlike grains with a size of 120 × 1500 nm coexisted in the same product. The reaction proceeds with indium as the intermediate and a solution–liquid–solid mechanism is proposed for the one-dimensional growth.

Key words: indium antimonide, nanorod, phase-pure, solvothermal, solution–liquid–solid mechanism.

Résumé : On a réalisé la première préparation de l'antimoniure binaire III–V en phase pure en opérant à 200°C et en faisant appel à une nouvelle voie de synthèse en solution

$$2InCl_3 + 6KBH_4 + 2Sb \xrightarrow{en} 2InSb + 6KCl + 6BH_3 + 3H_2\uparrow$$

Sur la base du diagramme de poudre de la diffraction des rayons X, on a déterminé que les dimensions moyennes de la cristallite sont de 40 nm. Les images obtenues par microscopie électronique de transmission montrent que, dans le même produit, des grains sphériques d'un diamètre de 40 à 60 nm coexistent avec des grains en forme de tiges mesurant 120 × 1500 nm. La réaction implique la formation d'indium comme intermédiaire et on propose un mécanisme solution–liquide–solide pour la croissance unidirectionnelle.

Mots clés : antimoniure d'indium, nanotige, phase pure, solvothermique, mécanisme solution–liquide–solide.

[Traduit par la Rédaction]

Introduction

The discovery of markedly different properties from the bulk materials and the promise of exploiting these properties for making devices has led to widespread research activity in the field of nanocrystalline materials for both scientific and technological applications (1). Among these nanocrystalline materials, the III–V (13–15) group of compound semiconductors are well-known electronic and optoelectronic materials (2). Compared with II–VI semiconductors, the III–V conductors have a greater degree of covalent bonding, a decreased ionic lattice and larger excition diameters (the excition diameter in GaAs is 190 Å, compared with 60 Å for CdS) (3). For this reason, quantum size effects on the optical spectra have been predicted to be more pronounced in the III–V class of materials than in the II–VI group (4). To date, the majority of work has been focused on II–VI materials (5), while III–V semiconductors, including an important direct band gap semiconductor (InSb) have been studied relatively little due to the numerous difficulties encountered in their preparations.

The present zeal for new routes to the III–V compound semiconductors is motivated by several goals such as safe precursors and low reaction temperatures (6). Several new strategies have emerged in the last decade (for a recent review see ref. 7) including, dehalosilylation and related reactions (8), metathesis reactions (9), metal organic precursors' alcoholysis (10), and pyrolysis of single-source precursors that incorporate the elements of a compound in a single molecule (11). Although these methods are very useful and mild in comparison with traditional solid-state reactions (usually above 1000°C), they still require relatively high processing or post-treatment temperatures (200–500°C) to obtain fully crystallized products. Very recently, a solution–liquid–solid (SLS) mechanism was developed to grow well-crystallized III–V semiconductor fibers at much lower temperatures (111–203°C for InP; 203°C for InAs and GaAs) (12). The SLS is closely analogous to the well known vapor–liquid–solid (VLS) mechanism (13), where whisker crystals are grown from flux droplets that are fed from the vapor phase rather than the solution phase.

To our knowledge, no phase-pure antimonide has been obtained using the above methods, while elemental antimony has often coexisted in the final products (9*a*, 14). There may

 DOI: 10.1139/cjc-79-2-127 © 2001 NRC Canada

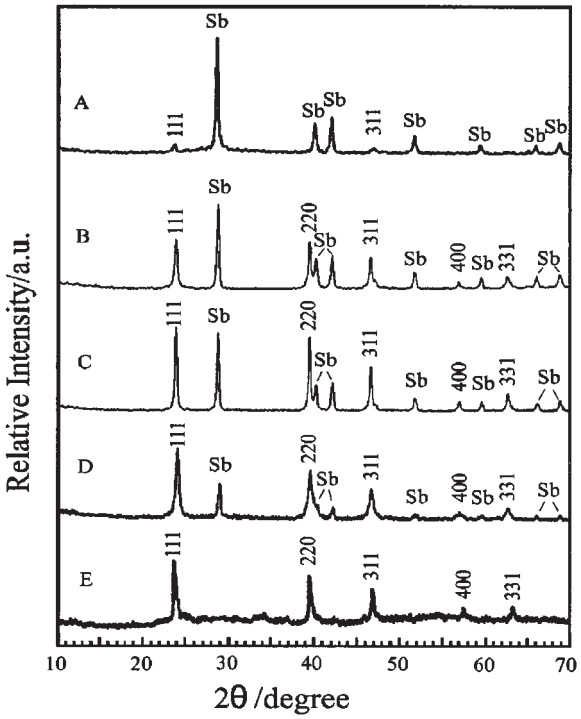
be two reasons why preparing phase-pure antimonides are so difficult. One is that the formation of SbH_3 and the metal organic precursors of antimony is more difficult than As and P. The other is that the relatively strong metallicity of elemental antimony is not favoring the formation of antimonides. The development of a synthetic method for preparing phase-pure antimonides, especially III–V antimonides, is an ultimate challenge for material scientists. In this paper, we describe a novel route to phase-pure InSb nanocrystals at temperatures as low as 200°C.

KBH_4 and its derivatives have been used to prepare finely divided powders of metals and alloys by reducing the metal salts in an organic solvent, such as THF and hydrocarbons (15). We have extended it to prepare nanocrystals of MSe (M = Cd) (16) at room temperature, and InP (17) and InAs (18) at 160°C. In this paper, we successfully produced phase-pure InSb nanocrystals via exploiting the potassium borohydride reducing route at relatively low temperature as follows:

$$[1]\qquad 2InCl_3 + 6KBH_4 + 2Sb \xrightarrow{en} 2InSb + 6KCl + 6BH_3 + 3H_2\uparrow$$

Experimental section

All reagents were of analytical grade or better, and the indium chloride was purified by mixing it in thionyl chloride ($SOCl_2$) at reflux for 45 min before being used. Reactions were carried out in a Teflon-lined autoclave. A mixture of ethylenediamine (40 mL), Sb (0.609 g, 5 mmol), $InCl_3$ (4.428 g, 20 mmol), and KBH_4 (3.228 g, 60 mmol) were added to a 50 mL flask. The mixture was ultrasonically mixed for 4 h before being transferred into a Teflon-lined autoclave. The autoclave was kept at 100, 120, 160, or 200°C for 36 h and then cooled to room temperature. The products were filtered off, washed with absolute alcohol, HCl (1 M), and distilled water, then dried in a vacuum at room temperature for 4 h.



Powder X-ray diffraction (XRD) patterns were performed on a Japan Rigaku D/Max γA rotating anode X-ray diffractometer with Ni-filtered Cu Kα radiation (λ = 1.54178 Å). Transmission electron microscopy (TEM) measurements were made on a Hitachi H-800 transmission electron microscope with an accelerating voltage of 200 kV. Samples were deposited from ethanol solutions of the products onto thin amorphous carbon films supported by copper grids.

Purity and composition of the product were detected by X-ray photoelectron spectra (XPS) on an ECSALab MKII instrument with Mg Kα radiation as the exciting source. The binding energies obtained in the XPS analysis were corrected by referencing the C 1 s peak to 284.60 eV.

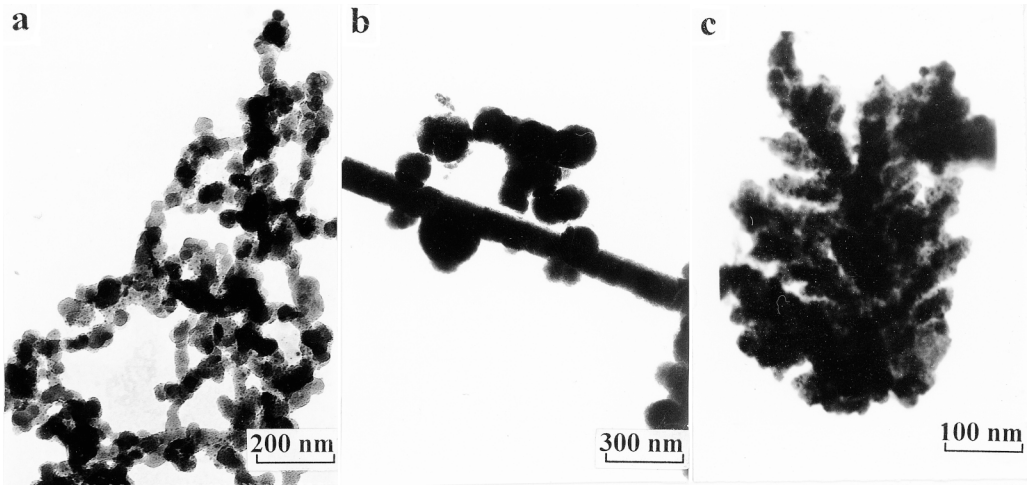
Results and discussion

The reaction of $InCl_3$, antimony (molar ratio: $InCl_3/Sb = 4$), and potassium borohydride at 200°C in ethylenediamine resulted in a black precipitate, which was washed with HCl (1 M) (here, HCl was used to dissolve the excessive indium reduced by KBH_4) and dried. The XRD pattern (Fig. 1*e*) of the sample agrees with the bulk InSb reflections, indicating the same cubic blende lattice structure

Fig. 1. XRD patterns of the products with the molar ratio of $InCl_3/Sb = 4$ after 1 M HCl treatment at: (*a*) room temp. (*b*) 100°C, (*c*) 120°C, (*d*) 160°C, (*e*) 200°C.

(19). Average crystallite sizes are about 40 nm, as estimated by the Scherrer equation.

The molar ratios of the reactants ($InCl_3/Sb$) and the temperature played important roles in preparing a phase-pure product. In our experiments we found that if the molar ratio of $InCl_3/Sb$ was lower than 4, no phase-pure InSb was obtained, even if the temperature was raised to 300°C. When the molar ratio of $InCl_3/Sb$ was as high as 4, the yield of InSb increased, while the antimony content decreased with the temperature, as seen over the range of 100–200°C (Fig. 1*b*–*e*). Moreover, the reaction did not initiate at all at room temperature. These facts led us to believe the chemical pathway is as follows:



$$[2]\qquad 2InCl_3 + 6KBH_4 + 2Sb \longrightarrow 2In + 6KCl + BH_3 + 3H_2\uparrow$$

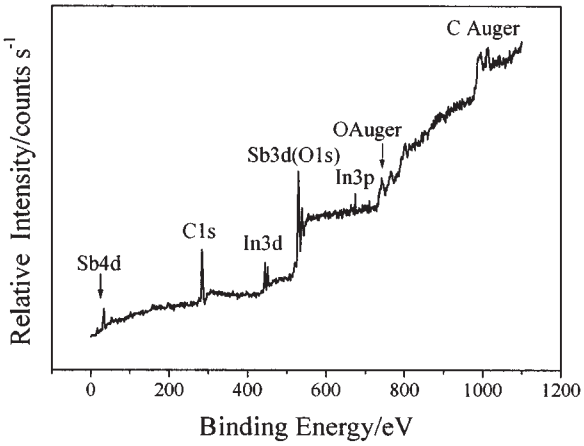
$$[3]\qquad 2In + 2Sb \longrightarrow 2InSb$$

All of the above facts can be rationalized as follows: it is very difficult to obtain phase-pure InSb due to the relatively strong metallicity of elemental antimony, whilst the atmosphere of rich indium is benefited by the formation of phase-pure InSb. To prepare phase-pure InSb, the molar ratio of $InCl_3/Sb$ should be as high as 4. On the other hand, the first step cannot take place at room temperature. When the reaction temperature was as low as 100°C, the freshly formed indium only reacted with antimony to a very small extent, however, when the temperature is raised to 160°C, which is above the melting point of indium (mp = 156.4°C), the reaction is almost complete and only trace amounts of antimony

© 2001 NRC Canada

Fig. 2. TEM images for InSb nanocrystals prepared at 200°C with the reactant molar ratio ($InCl_3$/Sb = 4).

coexisted in the product. When the temperature is raised to 200°C, the reaction is complete and phase-pure InSb is obtained, which is confirmed by XRD patterns (Fig. 1*e*). These results indicate that the reaction temperature plays a very important role for the synthesis of phase-pure InSb when the ratio of $InCl_3$/Sb is as high as 4.



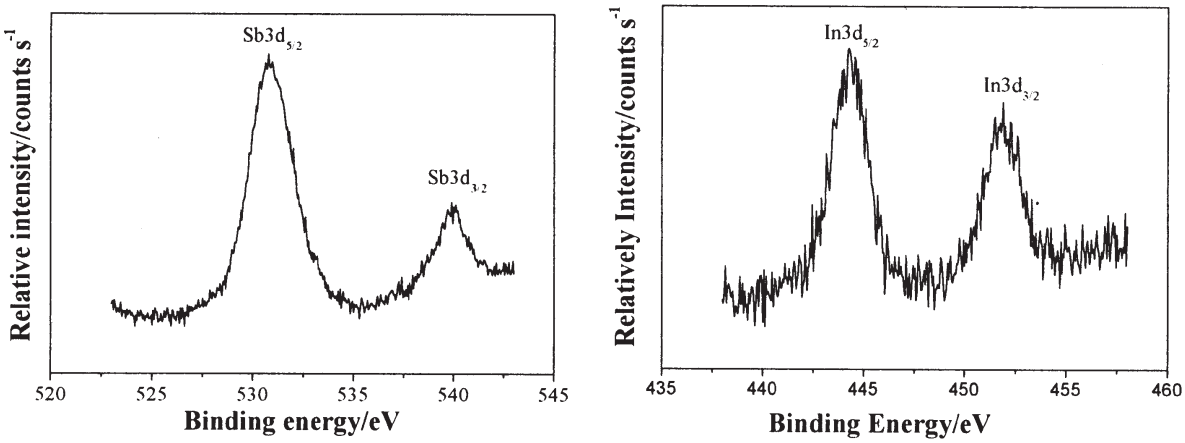
Transmission electron microscopy images for sample D (molar ratio: $InCl_3$/Sb = 4, prepared at 200°C) are shown in Fig. 2. The spherical particles (Fig. 2*a*) with the average diameter of about 50 nm are obtained. A nanorod (120 × 1500 nm) is also clearly seen from the same sample (Fig. 2*b*). More careful observation showed that the nanorod itself is composed of small particles. Another interesting feature is that the products have a crystalline growth extinction of dendritic crystals (Fig. 2*c*). The dendritic structure is a fractal object, which had been proved by Nittmann and Stanley (20). The ratio of In:Sb in the final product is 1.058:1 as measured by energy-dispersion X-ray (EDX) analysis.

According to the melting point of indium (156.4°C), the reaction can be regarded as a two-stage process, one is where the range of temperature is 100 to ~156.4°C, the other is 156.4 to ~200°C. Among the three well-known whisker-growth mechanisms, i.e., VLS, vapor–solid (VS), and SLS, the formation of InSb nanorods in our reaction is most similar to the SLS mechanism under the second-stage conditions. Such a system, which includes liquid indium and an organic solvent, is favorable for the formation of rodlike InSb particles. Otherwise, the formation of the product cannot be explained by the SLS mechanism. Although the reaction occurs, no rodlike products were obtained below 120°C, which provides a strong evidence for the SLS mechanism. We considered that the spherical particles of the product (Fig. 2*a*) formed at the first stage of the reaction process, and the rodlike particles (Fig. 2*b*) formed at the second stage, which further confirmed the proposed SLS mechanism.

As to the crystalline growth extinction of dendritic crystal (Fig. 2*c*), we cannot explain it at present, but we are conducting more experiments to investigate this.

Ethylenediamine also played a key role in the formation of InSb nanocrystals. Experiments show that it can disperse antimony powder and readily dissolve KBH_4, thereby increasing the surface area of reactants and promoting the reaction at relatively low temperatures. When benzene was used as the solvent, the reaction did not take place, presumably due to the poor solubility of KBH_4 in benzene.

Fig. 3. XPS survey spectrum for InSb nanocrystals prepared at 200°C.



X-ray photoelectron spectroscopy has been used to measure the elemental composition of the nanocrystals. A survey spectrum is shown in Fig. 3. The survey indicates the presence of In and Sb, as well as C and O (from reference absorbed gaseous molecules). There are no peaks for Cl or N (from starting material) in the survey spectrum.

Higher resolution spectra were also taken of the In3*d* and Sb3*d* regions (Fig. 4). The binding energy is 444.7 eV for In3$d_{5/2}$ and 539.95 eV for Sb3$d_{5/2}$, which is in agreement with the literature (21).

Peak areas of these high-resolution scans were measured and used to calculate the In:Sb ratio for the nanocrystals. Quantification of the peaks gives a ratio of In:Sb of 1.075:1, which closely agrees with the formula of InSb. As a result of our EDX and XPS analyses, we conclude that the nanocrystals are close to stoichiometric InSb.

© 2001 NRC Canada

Fig. 4. High-resolution XPS scans of the In3*d* and Sb3*d* cores.

Conclusion

In summary, phase-pure III–V binary antimonide, InSb, was prepared through a new solution route. Nanocrystalline InSb was successfully synthesized via a novel solvothermal reaction of $InCl_3$ with antimony and KBH_4 in ethylenediamine at a temperature of 200°C for 36 h. The reaction proceeds through a metallic indium intermediate, and an SLS mechanism is proposed for the one-dimensional growth. By choosing a suitable system, it is reasonable to expect that this safe mild route can be extended to the preparation of other metal antimonides.

A spectrophotometric study of Fe(II)-chloride complexes in aqueous solutions from 10 to 100°C

Renhai Zhao and Pujing Pan

Abstract: The absorption spectra of Fe(II)-chloride solutions were measured in both the UV (ultraviolet) and near-IR (near infrared) regions at temperatures ranging from 10 to 100°C with chloride concentrations from 0.1 to 16 mol kg^{-1}. The stability constants of all Fe(II)-chloride complexes were derived from the spectra using a non-negative nonlinear least-squares computer program (SQUAD). Earlier work on this system reported in the literature was rigorously reassessed. The activity coefficients of the ionic species were calculated using both the Pitzer model and the Helgeson model. The results obtained with UV and near-IR spectra and with different activity coefficient calculation models are in general agreement. Other useful thermodynamic data, including the Gibbs energies, enthalpies, and entropies for complex formation, were also obtained. It was found that the Fe(II)-chloride complexes gradually undergo a configuration transformation from octahedral to tetrahedral coordination as the temperature and (or) chloride concentration increases. This coordination change is of significant importance to the nuclear reactors, as the presence of the tetrahedral complex can increase the solubility of iron in steam generator crevices.

Key words: Fe(II)-chloride complexes, stability constants, solution thermodynamics, spectrophotometry, reactor chemistry.

Résumé : Opérant à des températures allant de 10 à 100°C, à des concentrations de chlorure allant de 0,1 à 16 mol/kg, on a mesuré les spectres d'absorption UV (ultraviolet) et proche infrarouge (proche-IR) de solutions de chlorure de Fe(II). Sur la base des spectres obtenus et faisant appel à un programme informatique des moindres carrés non linéaires non négatifs, on a évalué les constantes de stabilité de tous les complexes de chlorure de Fe(II). On a réévalué d'une façon rigoureuse un travail antérieur sur ce système rapporté dans la littérature. On a calculé les coefficients d'activité des espèces ioniques à l'aide du modèle de Pitzer et du modèle dHelgeson. Les résultats obtenus à l'aide des spectres UV et proche infrarouge et avec différents modèles de calcul des coefficients d'activité sont généralement en bon accord. On a aussi évalué d'autres données thermodynamiques utiles, y compris les énergies de Gibbs, les enthalpies et les entropies de formation des complexes. On a trouvé que l'augmentation de température et/ou de concentration en chlorure provoque une transformation graduelle des complexes de Fe(II) alors que la configuration passe d'une coordination octaédrique à tétraédrique. Ce changement de coordination revêt une importance significative dans les réacteurs nucléaires puisque la présence du complexe tétraédrique peut augmenter la solubilité du fer dans les crevasses des générateurs de vapeur d'eau.

Mots clés : complexes de chlorure de Fe(II), constantes de stabilité, thermodynamique de solutions, spectrophotométrie, chimie des réacteurs.

Introduction

Water is used as the heat transfer medium in nuclear steam generators. Its corrosiveness depends on a number of parameters, including pH, E_h, temperature, and the impurities it contains such as chloride, sulfate, and carbonate ions. The complex formation due to the presence of these impurities is important in stabilizing dissolved metal ions and, therefore, can enhance the solubility of metals by a few orders of magnitude. In tight crevices and deep sludge piles, solutes may be concentrated by a factor as high as 10^4 due to differential evaporation. The chloride concentration predicted for such an environment was in the range of 1–15 *m* (mol kg^{-1}). Typically, the stability of a metal complex in aqueous solutions increases with an increase in temperature. Much of the CANDU® steam generator and feedtrain are made of carbon steel. Corrosion products from carbon steel would, therefore, predominate in the secondary system. The most abundant anionic impurity usually observed in the steam generator system is chloride. Concentration of the dissolved impurities, in the presence of iron oxides from carbon steel corrosion, may be expected to lead to the formation of concentrated chloride solutions and complexes of iron ions with chloride. This study focuses on the stability of

Fe(II)-chloride complexes. The resulting information is considered to be of importance in understanding and predicting steam generator chemistry, particularly in crevices.

Because the Fe(II)-chloride complexes are very weak and it is difficult to avoid fast oxidation of Fe(II) in the presence of trace oxygen, few studies on Fe(II)-chloride complexation in aqueous solutions have been reported. There is a large scatter in the early values of stability constants of Fe(II)-chloride complexes. One important reason for this scatter is that indirect studies through solubility measurements (1, 2), kinetic measurements (3, 4), complexation with organics (5), and isocoulombic estimation methods (6) were used for stability constant determination. In spectrophotometric studies (7, 8) the spectral measurements were usually limited to a limited range of wavelengths (cf. ref. 9 for a more thorough review of the literature on Fe(II)-chloride complexes).

The most recent spectrophotometric study on stability constants of Fe(II)-chloride complexes was carried out by Heinrich and Seward (10), in aqueous solutions from 25 to 200°C with chloride concentration from 0.01 to 3.4 *m*. The tetrahedral complexes, however, were neglected in their work. Previous work (11, 12) has clearly demonstrated that Fe(II)-chloride complexes undergo a configuration transformation from octahedron to tetrahedron at high temperatures (near or above 100°C) and (or) high chloride concentrations. The complex configuration change is also apparent from the measured spectra of Heinrich and Seward (10). The neglect of tetrahedral complexes in Heinrich and Seward (10) could have caused appreciable errors in the final fitted stability constants.

Recently, Palmer and Hyde (13) investigated the formation of the monochloroiron(II) complex in aqueous solutions using potentiometry, from 125 to 295°C at I = 1.0 *m*. The formation of tetrahedral Fe(II)-chloride complexes in the solutions was also completely neglected over the entire temperature range in this work.

The present study was designed to obtain reliable stability constants of Fe(II)-chloride complexes in aqueous solution, by means of improved experimental and computational techniques.

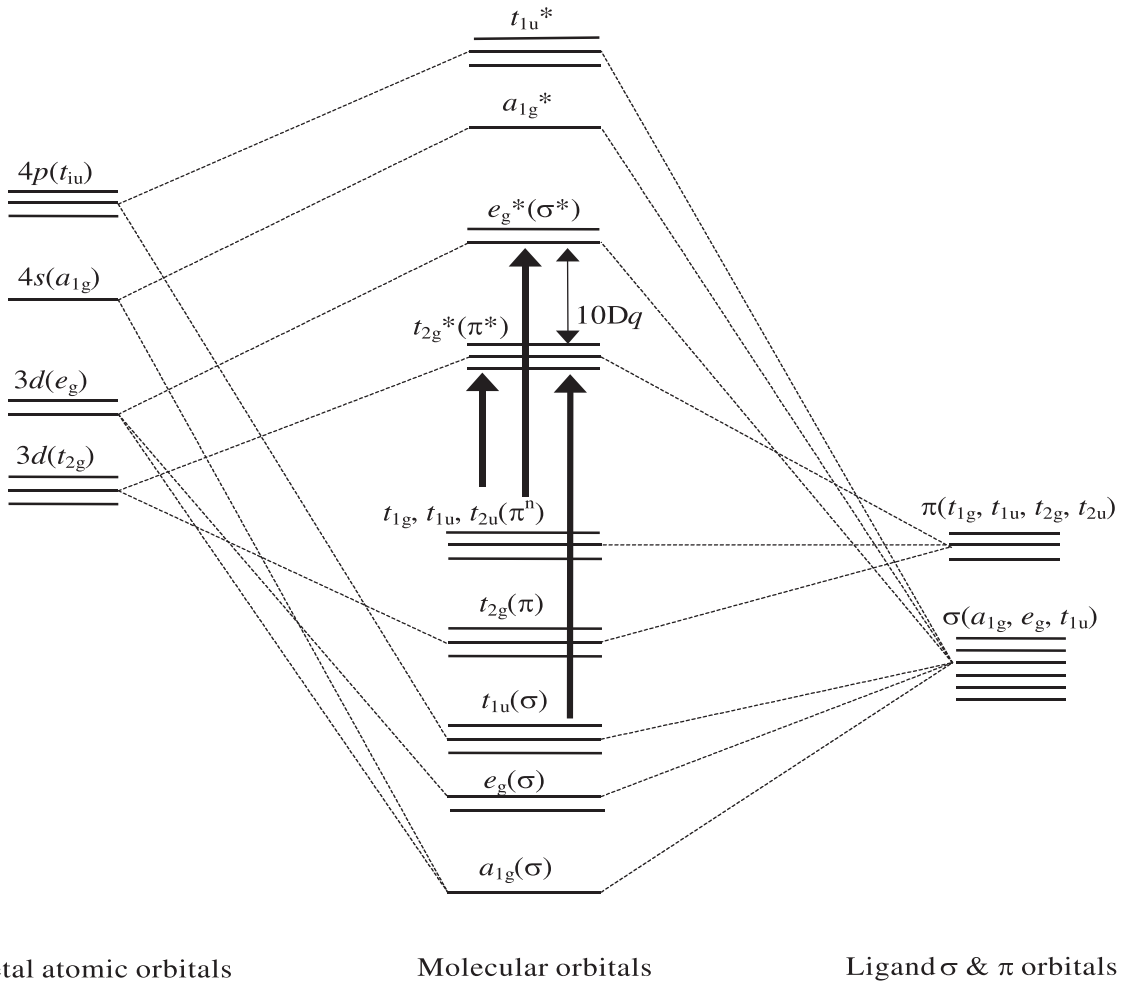
Experimental

Chemicals used in this work were mainly from Aldrich Chemicals (Fe(II)-chloride tetrahydrate 99.995%; deuterium oxide 99.9 at.% D; deuterium chloride 37 wt.%, 99.5 at.% D; platinum black, 10 μm powder; iron powder 99.99+%). They were used as received without further purification. Doubly distilled and deionized water (resistivity > 13.0 × 10^6 Ω cm) was used for preparing solutions. Crystals of NaCl or LiCl were heated at 150°C for over 2 h to remove moisture before they were added into solutions for adjusting chloride concentrations.

Each solution was prepared immediately before use and all sample weighing and transfer were performed in a glove box purged with nitrogen gas. The solution preparation system was slightly pressurized (<6 psig, 1 psi = 6894.757 Pa) with hydrogen gas to generate a reducing atmosphere and facilitate sample loading. Thus, solutions were in a closed system throughout the entire preparation process. About 0.01 g of platinum black was added before the solution was purged with hydrogen. The solution was gently heated to about 50°C for about 30 min to allow complete reduction of Fe(III) to Fe(II) under hydrogen atmosphere (5 psig). The cell was purged with hydrogen and the solution and platinum black were then loaded into the cell at the same time. About 20% of total cell volume was allowed for liquid expansion upon heating.

A total of 15 solutions were made for each wavelength region (UV or near-IR) for spectral measurements. For the UV region, solutions (about 0.10 *m* Fe(II)) were made by dissolving hydrated $FeCl_2$ directly in water, with no HCl added, because there is little hydrolysis of Fe(II) ions in neutral solutions over the temperatures covered in this study (less than 0.001% at 25°C (14)). NaCl was then added to make solutions of 0.2–5.8 *m* chloride.

In the near infrared (near-IR) region, water interferes severely with the Fe(II) bands of interest. Fe(II) solutions were prepared using D_2O and DCl so that the upper limit of the useful wavelength was extended from about 1350 nm (7407 cm^{-1}) to about 1850 nm (5405 cm^{-1}) with 10 mm pathlength, and the whole *d–d* transition band of the Fe(II) octahedral complexes could be observed. Pure iron powder was dissolved in a mixture of DCl and D_2O, and the calculated amount of D_2O was added to make a Fe(II) stock solution of 0.5031 *m*. The desired chloride concentration (1.15–5.43 *m)* for each solution used was achieved by adding the calculated amount of NaCl.



The solutions used for investigating the configuration transformation from octahedral to tetrahedral complexes in both regions were prepared by adding LiCl to obtain much higher chloride concentrations (7.68–16.28 *m*). The corresponding blank solutions that contained the same chloride concentrations and no Fe(II) ions were prepared in the same way as the sample solutions.

In neutral to slightly acidic aqueous solutions, the Fe(III) species have two absorption bands in the UV region centered at 49 505 and 33 898 cm^{-1}, respectively. Our measured spectra with different Fe(III) solutions show that the Fe(III) band at 33 898 cm^{-1}, which is somewhat remote from the Fe(II) band at 41 667 cm^{-1}, is about 105 times stronger than the Fe(II) band at 41 667 cm^{-1}. Therefore, any trace amount of Fe(III) species in solution should be easily detected based on spectral scans in the UV region (27 778–33 898 cm^{-1}). Solutions were checked before and after experiments and showed a flat background absorption in this region, indicating that Fe(III) contamination was undetectable. Fe(III) species used in this work, have no absorption bands in the near-IR region.

A UV-vis near-IR spectrophotometer (Cary 5E, Varian) was employed for absorption spectral measurement in the regions from 27 778 to 57 143 cm^{-1} (UV) and from 5263 to 16 667 cm^{-1} (near-IR). The instrument is equipped with a 6 × 6 thermostatic cell-holder mounted on a sample transport accessory. The cell-holder block with solutions can be cooled down to –10°C and heated up to 100°C in 2 to 3 min with an accuracy of ±0.3°C, and the temperature gradient between the block and the solution was less than 0.5°C. A spectrophotometric cell (NSG Precision Cells Inc.) with a nominal 10 mm pathlength was connected with a solution preparation system through Teflon tubing and valves which have near zero oxygen permeability to prevent oxygen ingression. The same cell was used for the measurements of

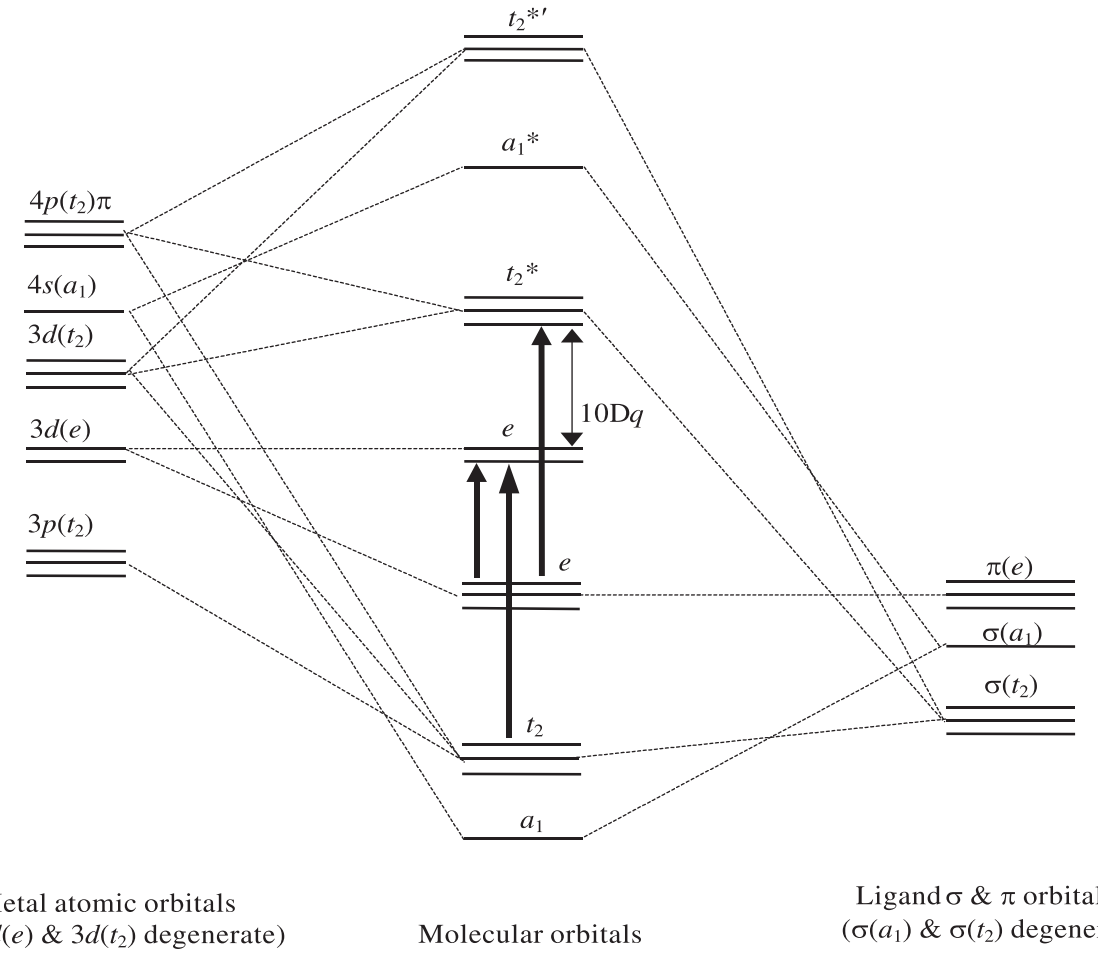
Fig. 1. Schematic molecular orbital diagram for octahedrally coordinated Fe(II)-chloride complexes. The d → d transition is shown as a light double arrow and possible charge transfer transitions are shown as heavy arrows. This diagram and Fig. 2 were constructed based on refs. 10, 13, and 15.

both Fe(II) and blank solutions to eliminate variations in pathlength and absorbance by the cell. An oxygen remover (Oxiclear from Aldrich Chemical Co.) was connected to the hydrogen cylinder to reduce oxygen to below 50 ppb.[3]

In the UV region, all spectra were collected at 10 cm^{-1} intervals with a scan rate of 1500 cm^{-1}/min, from 28 000 to 57 100 cm^{-1}. In the near-IR region, all spectra were collected at 0.25 nm intervals with a scan rate of 90 nm/min, from 600 to 1900 nm (16 667 to 5263 cm^{-1}). The spectral bandwidth (SBW) was set to 1.5 nm and the slit was fully open. All solutions, including the blank solutions, were run using a double beam mode with water (UV region) or heavy water (near-IR region) as the reference material. The absorptions due to solvent and chloride were then eliminated by subtraction.

The spectra were collected in the same order for each solution, starting from 25°C, then from 100 to 80, 60, 40, 25, and 10°C sequentially. A comparison of the two spectra measured at 25°C would indicate if there was a concentration change of solution after heating it up to 100°C. The chloride concentration for each solution at each temperature was corrected individually. Typically, a correction factor of 0.5–1.5% was applied to the solution concentrations after heating, assuming that the concentration changes arose from differential water evaporation only.



Coordination chemistry of Fe(II)

Transition metal chemistry is largely governed by its *d*-electron configuration. With a d^6 configuration, Fe(II) has the greatest possible ligand field stabilization energies (LFSE) in octahedrally (O_h) coordinated strong (low spin) ligand fields. Even in weak (high spin) ligand fields, octahedral Fe(II) complexes are still favored in terms of 10Dq[4] decrease. However, tetrahedral (T_d) complexes are often favored at higher temperatures and (or) higher chloride concentrations because of the vibrational stretching of the metal–ligand bond and steric requirements. Schematic molecular orbital energy levels for Fe(II) octahedral and tetrahedral complexes are shown in Figs. 1 and 2 (cf. refs. 11, 15, 16). For both octahedral and tetrahedral Fe(II) complexes, the spin-allowed *d–d* transitions, being orbitally forbidden and weak, occur in the near-IR region. Other

[3] More experimental details can be found in ref. 9.
[4] For a definition of 10Dq, see ref. 17.

Fig. 2. Schematic molecular orbital diagram for tetrahedrally coordinated Fe(II)-chloride complexes. The d → d transition is shown as a light double arrow and possible charge transfer transitions are shown as heavy arrows.

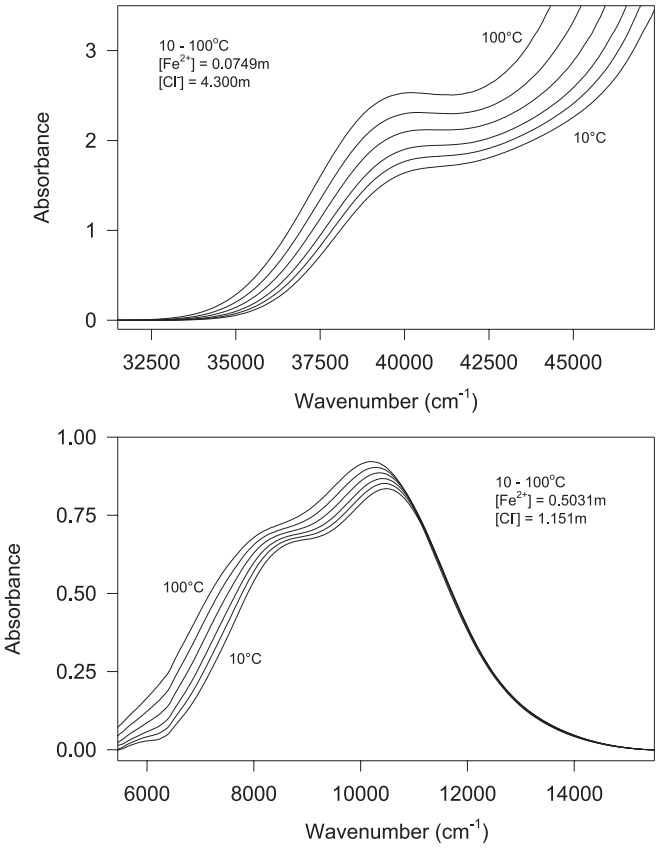
transitions, both spin and Laporte allowed charge transfers, are intense and occur in the UV region. All these transitions are closely related to the strength of the applied ligand field (10Dq).[4]

The spin allowed $d \rightarrow d$ transition for a Fe(II) ion in an octahedral ligand field ($t_{2g} \rightarrow e_g$) is at about 10 000 cm^{-1} with a maximum molar extinction coefficient (ε_{max}) ~1.1 L mol^{-1} cm^{-1} (17). This transition corresponds directly to the 10Dq for a d^6 ion in an O_h field (17). Because of tetragonal distortion of O_h symmetry when non-equivalent ligands surround the metal ion, or Jahn–Teller distortion in the case of six equivalent ligands (H_2O), either a split band with two components or a broad and asymmetric band may be observed for this transition (18). The separation of Jahn–Teller distorted splitting is about 2300 cm^{-1}, varying with temperature (12, 18).

At room temperature, Fe(II) ion, resembling other first-row transition metal ions, exists as the hexaaquo complex in dilute aqueous solutions (11). Water is replaced stepwise by Cl^- as the chloride concentration or temperature increases. Correspondingly, a tetragonal splitting will gradually become dominant over the Jahn–Teller effect. The 10Dq of these mixed ligand complexes (e.g., 9000 cm^{-1} for the monochloroiron(II) complex) will be slightly less than that of the hexaaquo ion because Cl^- ion is a weaker ligand compared to H_2O in the spectrochemical series (17). The 10Dq of a complex also decreases (red shift) with an increase of temperature because the vibrational stretching of the metal–ligand bond increases and ligand field strength decreases accordingly at higher temperatures. Strictly speaking, the conversion from hexaaquo to chloroaquo complexes changes the O_h symmetry (removal of center of symmetry) and relaxes orbital forbiddenness of the $d \rightarrow d$ transition, and therefore, the ligand field band is more intense (12).

When temperature or chloride concentration is sufficiently high, the distorted octahedral structure of Fe(II) complexes may undergo a coordination change to a tetrahedral geometry (T_d). A tetrahedral Fe(II) complex will also exhibit only one spin-allowed transition, $e \rightarrow t_2$, at about 4/9 the energy of the $t_{2g} \rightarrow e_g$ transition in an O_h field with the same ligands (17). It was suggested that this band should lie near 4160 cm^{-1} (12) and was 10–100 times stronger than that of a similar octahedral complex because it is partially orbitally allowed because of d–p mixing in T_d coordination (17).

In octahedrally coordinated Fe(II) complexes, there are potentially four charge transfer transitions $u \rightarrow g$ for two groups of orbitals: t_{1g}, t_{2u}, t_{1u}, t_{2g} (π orbitals) and t_{1u}, e_g, a_{1g} (σ orbitals). Therefore, four bands might occur from t_{1u}, t_{2u} (π), and t_{1u}(σ) to e and t. Three of them have been clearly observed for $FeCl_2$ solid crystal at 10 K (19, 20).



© 2001 NRC Canada

In our experiments, the absorption spectra of aqueous solutions of Fe(II)-chloride show unresolved bands around 40 000–45 000 cm^{-1} and a stronger band around 50 000 cm^{-1}. Unlike the spectra of solid crystals, these bands have severe overlapping with solvent absorption. They might be assigned to the transitions: t_{1u}, $t_{2u}(\pi) \rightarrow t_{2g}^*$, $t_{1u}(\sigma) \rightarrow t_{2g}^*$, and t_{1u}, $t_{2u}(\pi) \rightarrow e_g^*$, as shown in Fig. 1.

As in the case of octahedral complexes, tetrahedral complexes have three possible charge transfer transitions (Fig. 2): $t_2(\sigma) \rightarrow e$ (Fe 3*d*), *e* (Cl lone pair π) $\rightarrow e$ (Fe 3*d*), and *e* (Cl lone pair π) $\rightarrow t_2$* (16). At least two of those transitions were observed in our spectra under the current experimental conditions (centered around 37 000 and 44 000 cm^{-1}).

Several studies on the ligation number for Fe(II)-chloride complexes indicate that $Fe(H_2O)_6^{2+}$ was present predominantly in aqueous solution at 25°C even at chloride concentrations up to 8 *m* (21, 22), and that the maximum ligation number is 2 at temperatures ranging from 25 to 90°C (11). However, Vogel Koplitz et al. (12) studied the Fe(II)-chloride complexes spectrophotometrically with chloride concentrations ranging from 1 to 11 *m* and at temperatures from 25 to 82°C, and found that octahedral complexes with chloride ligation numbers up to 4 were present over this range, as determined by principal factor analysis and from the rule of average environment. At higher temperatures and (or) chloride concentrations, the formation of some tetrahedral complexes, possibly $FeCl_4^{2-}$, was also reported by the authors (12). Most of the other work on Fe(II)-chloride complexes in aqueous solution (e.g., refs. 6, 13) was based on the assumption that only the monochloroiron(II) complex was present in solution and, therefore, only the first stability constant was obtained.

Fig. 3. Absorption spectra of 0.07491 *m* $FeCl_2$ in 4.300 *m* NaCl aqueous solution in the UV region (top), and 0.5031 *m* Fe(II) in aqueous solution with 1.151 *m* chloride (bottom) in the near-IR region at 10, 25, 40, 60, 80, and 100°C (from bottom to top).

Spectra

Each spectrum was five-point-smoothed, 261 points selected at 50 cm^{-1} (UV) and 4.5 nm (near-IR) intervals, and formatted into the input data set for SQUAD (a FORTRAN program originally written by Leggett and co-workers (23–26)). At each temperature, the input data set for SQUAD consists of 15 spectra with 3915 data points in total, covering a spectral range from 34 000 to 47 000 cm^{-1} (UV) or from 5484 to 15 302 cm^{-1} (near-IR) with slight variations because absorbance bands shift with temperature. Some representative spectra, with constant chloride concentration at varied temperature, are shown in Fig. 3.

The equilibria between Fe^{2+}(aq) and chloride ions in aqueous solution can be generalized as:

$$[1] \qquad Fe(H_2O)_6^{2+} + nCl^- \rightleftharpoons Fe(H_2O)_{6-n}Cl_n^{2-n} + nH_2O$$

$$[2] \qquad Fe(H_2O)_6^{2+} + mCl^- \rightleftharpoons Fe(H_2O)_{4-m}Cl_m^{2-m} + (m+2)H_2O$$

where the coordination numbers of chloride are $0 \le n \le 6$ and $0 \le m \le 4$. The activity of water under our experimental conditions is nearly constant and was considered unity. According to Susak and Crerar (11), the chloride ligation number of Fe(II) octahedral complexes is less than or equal to 2 ($n \le 2$ in eq. [1]). It was shown (12) that the stoichiometry of Fe(II) tetrahedral complex appeared to be $FeCl_4^{2-}$. These observations were confirmed in this work, and are consistent with those on the cobalt(II) chloride system (27). Therefore, eqs. [1] and [2] may be combined and simplified to:

$$[3] \qquad Fe^{2+} + nCl^- \rightleftharpoons FeCl_n^{2-n}$$

with $n = 4$ referring to the tetrahedral complex. Then the stability constant β for a Fe(II)-chloride complex may be written as:

$$[4] \qquad \beta_n = \frac{[FeCl_n^{2-n}]\gamma_n}{[Fe^{2+}]\gamma_{Fe^{2+}}[Cl^-]^n\gamma_{Cl^-}^n}$$

where the square brackets [ ] represent molalities (mol kg^{-1}) and γ is the individual ion activity coefficient. Sodium chloride is essentially dissociated in aqueous solutions at temperatures up to 150°C (28) and, therefore, the NaCl concentrations in the solutions were not corrected in this work.

Beer's law states that at a given wavelength

$$[5] \qquad A = \sum_n (FeCl_n^{2-n})\varepsilon_n l$$

where *A* and ε are absorbance and molar absorptivity, respectively, at a given wavelength, *l* is the path length, round brackets () denote molar concentration (mol L^{-1}). Combining eqs. [4] and [5] yields:

$$[6] \qquad A = \sum_n \beta_n Y_n [Fe^{2+}][Cl^-]^n \varepsilon \gamma_{Fe^{2+}} \gamma_{Cl^-}^n \gamma_n^{-1} l$$

© 2001 NRC Canada

where Y_n is a factor to convert the concentration of the *n*th complex from molality (mol kg^{-1}) to molarity (mol L^{-1}), and can be calculated using the following equation:

$$[7] \qquad Y_n = \frac{1000d}{1000 + m_1W_1 + m_2W_2 + \ldots}$$

where m_1, m_2, W_1, and W_2 are the molalities and formula weights of solutes 1 and 2 in solution, respectively, d is the solution density.

Because of the lack of data, the same eq. [7] was also used to convert molalities to molarities for heavy water solutions with the following relationship assumed:

$$[8] \qquad \frac{d_H}{d_H^\circ} = \frac{d_L}{d_L^\circ}$$

where d_H, d_L, d_H°, and d_L° are the densities of D_2O solution, H_2O solution, pure D_2O and pure H_2O, respectively.

Thus, given sufficient absorbance values A, the βs and molar absorptivities for various Fe(II) species can be obtained from eq. [6] using numerical methods.

The nonlinear least-squares program SQUAD searches for the combination of apparent formation constants (activity coefficients were not considered) and molar absorptivities which best describe the supplied total concentrations of metal and ligand, and data of absorbance. The program was modified in this work to be used in a PC environment with activity coefficient calculations incorporated in an iterative process so that true thermodynamic stability constants could be obtained.

It is noted that no isosbestic point is present in any of the spectra measured (Fig. 3); therefore, there were more than two major species present in the system when either the temperature or ligand concentration changed. However, if more than two octahedral complexes were assumed or the tetrahedral complex was included, no meaningful convergence could be achieved with our data using SQUAD. We conclude that the concentrations of the octahedral complexes with chloro coordination number >2, if any, are insignificant and below detection in most of the solutions (tetrahedral complex will be discussed later). Extensive work on cobalt(II) chloride complexes suggests that, over a wide range of temperature and chloride concentration, the ligation does not exceed 4 and that $CoCl(H_2O)_5^+$ and $CoCl_2(H_2O)_4^0$ are the major complexes in most cases (27, 29, 30).

For all Fe(II) containing species, the absorption bands in the near-IR region due to *d–d* transitions are relatively weak compared to the charge transfer bands in the UV region. Therefore, results obtained with the near-IR spectra are intended to serve as cross-checks for those obtained with the UV spectra.

Activity coefficients

The ionic interaction model of Pitzer (31) is one of the most widely used methods for electrolyte activity calculations. But, few Pitzer parameters are currently available for complexed species. For the purpose of comparison, a semi-empirical method by Helgeson et al. (32) was also used in this work. A comparison of the data obtained independently using the two different methods with relevant discussions follows.

Pitzer model

Pitzer and co-workers (31, 33, 34) developed a theoretical model for electrolyte solutions by combining the Debye–Hückel equation with additional terms in the form of virial coefficients. This model has successfully provided an alternate formulation of statistical mechanics for a number of multicomponent solution systems (35, 36).

The Pitzer equations for the natural logarithms of the activity coefficients of cations (M) and anions (X) are given as (31):

$$[9] \qquad \ln\gamma_M = z_M^2F + \sum_a m_a(2B_{Ma} + ZC_{Ma}) + \sum_c m_c(2\Phi_{Mc} + \sum_a m_a\psi_{Mca}) + \sum_{a<a'}\sum m_a m_{a'}\psi_{Maa'} + z_M\sum_c\sum_a m_c m_a C_{ca} + 2\sum_n m_n\lambda_{nM} + \ldots$$

$$[10] \qquad \ln\gamma_X = z_X^2F + \sum_c m_c(2B_{cX} + ZC_{cX}) + \sum_a m_a(2\Phi_{Xa} + \sum_c m_c\psi_{cXa}) + \sum_{c<c'}\sum_a m_c m_{c'a}\psi_{cc'X} + |z_X|\sum_c\sum_a m_c m_a C_{ca} + 2\sum_n m_n\lambda_{nM} + \ldots$$

where

$$[11] \qquad F = f^\gamma + \sum_c\sum_a m_c m_a B'_{ca} + \sum_{c<c'}\sum m_c m_{c'}\Phi'_{cc'} + \sum_{a<a'}\sum m_a m_{a'}\Phi'_{aa'}$$

$$[12] \qquad f^\gamma = -A_\phi\left[\frac{I^{1/2}}{1+bI^{1/2}} + \frac{2}{b}\ln(1+b\sqrt{I})\right]$$

$$[13] \qquad Z = \sum_i m_i|z_i|$$

A_ϕ is the Debye–Hückel limiting law constant and taken from Archer and Wang (37), b is a universal parameter with the value of 1.2 $kg^{1/2}$ $mol^{-1/2}$, I is the ionic strength, m_i and z_i are the molality and charge of species i, respectively, B and C are adjustable parameters derived from experimental data of single salt solutions, Φ is related to short range interactions between like charged ions and long range electrical forces due to unsymmetrical mixing where the charges on c and c' (or a and a') differ, Φ′ is the ionic strength derivative of Φ, ψ accounts for the short range interactions between one ion of one sign and two dissimilar ions of opposite sign, λ represents the short range interactions between neutral solute species and charged ions, and subscripts c and a represent cations and anions and the sums are over the various cations c, c' or over the anions a, a'.

The parameters C_{MX} are related to the tabulated parameters derived from data on aqueous single salt systems

$$[14] \qquad C_{MX} = \frac{C^\Phi_{MX}}{2\sqrt{z_M z_X}}$$

All coefficients B_{MX} in the Pitzer equations are expressed as functions of ionic strength I

$$[15] \qquad B_{MX} = \beta^{(0)}_{MX} + \beta^{(1)}_{MX}g(\alpha I^{1/2})$$

$$[16] \qquad B'_{MX} = [\beta^{(1)}_{MX}g'(\alpha I^{1/2})]/I$$

where

© 2001 NRC Canada

$$[17] \quad g(x) = \frac{2[1-(1+x)e^{-x}]}{x^2}$$

$$[18] \quad g'(x) = \frac{-2\left[1-\left(1+x+\frac{x^2}{2}\right)e^{-x}\right]}{x^2}$$

and α has the value of 2.0 $kg^{1/2}$ $mol^{-1/2}$ for the most common salts.

The Pitzer model has the advantage of being able to account for all the possible interactions between all pairs and triplets of solute species that may exist in those multicomponent solutions. However, the higher order terms involving interactions between ions of like sign and an unsymmetrical mixing (Φ), interactions between one ion of one sign and two dissimilar ions of opposite sign (Ψ), and interactions between ions and neutrals (λ) are usually trivial, and were ignored in this work.

As shown in eqs. [14]–[16], the B_{MX} and C_{MX} functions incorporate ion interaction parameters, i.e., Pitzer parameters $\beta^{(0)}_{MX}$, $\beta^{(1)}_{MX}$, C^{Φ}_{MX}, which are specific to the particular salt MX, representing short-range interactions specific to the interacting ions M^{z+} and X^{z-} in solution. Therefore, the single salt parameters $\beta^{(0)}_{MX}$, $\beta^{(1)}_{MX}$, and C^{Φ}_{MX} for all the solutes are required to calculate the activity coefficients of ionic species using the Pitzer equations.

The Pitzer parameters for NaCl (Na^+-Cl^-) were from Pitzer (38), the values for the other solutes are discussed as follows.

$FeCl_2$ (Fe^{2+}-Cl^-): The Pitzer parameters for $FeCl_2$ (Fe^{2+}-Cl^-) at 25°C were taken from Pitzer (31), but no data are available at other temperatures. However, temperature derivatives of the Pitzer parameters are available for $CoCl_2$ (39). Based on the fact that all the Pitzer parameters for $CoCl_2$ are very similar to those for $FeCl_2$ at 25°C, it was reasonable to use the temperature derivatives for $CoCl_2$ to calculate the Pitzer parameters for $FeCl_2$ at temperatures other than 25°C. The increments calculated from temperature derivatives were then added to the corresponding values of Pitzer parameters for $FeCl_2$ at 25°C (9).

$FeCl_2$ ($FeCl^+$-Cl^-): The Pitzer parameters for this system are not available at any temperature. It is noted that many physical parameters including crystal and ionic radii, effective electrostatic radius, and Born constants are very close for the two metal ions Fe(II) and Cu(II) (16, 32). Thus, as a good approximation, the Pitzer parameters ($\beta^{(0)}$ = 0.0651, $\beta^{(1)}$ = 0.554, and C^{ϕ} = 0.0244) for the ion-pair $CuCl^+$-Cl^- (36) could be used as initial values in SQUAD for the $FeCl^+$-Cl^- ion pair.

Assuming only the monochloro complex in solution, eq. [4] can be rearranged to

$$[19] \quad \ln\beta_1 - \ln K^* + \ln\gamma_{Fe^{2+}} = \ln\gamma_{FeCl^+} - \ln\gamma_{Cl^-}$$

where K^* is the concentration quotient. Substituting $\ln\gamma_{Cl^-}$ in eq. [19] with eqs. [9] and [10] and consolidating all terms without $\beta^{(0)}_{FeCl^+,Cl^-}$, $\beta^{(1)}_{FeCl^+,Cl^-}$, and $C^{\Phi}_{FeCl^+,Cl^-}$ into an *f*-term yields:

$$[20] \quad \ln\beta_1 - \ln K^* + \ln\gamma_{Fe^{2+}} + f(m_{Cl^-}, m_{Fe^{2+}}, m_{FeCl^+}) = \beta^{(0)}_{FeCl^+,Cl^-} 2(m_{Cl^-} - m_{FeCl^+})$$

$$[21] \quad \ln\beta_1 - \ln K^* + \ln\gamma_{Fe^{2+}} + f'(m_{Cl^-}, m_{Fe^{2+}}, m_{FeCl^+}) = \beta^{(1)}_{FeCl^+,Cl^-} 2(m_{Cl^-} - m_{FeCl^+})g$$

$$[22] \quad \ln\beta_1 - \ln K^* + \ln\gamma_{Fe^{2+}} + f''(m_{Cl^-}, m_{Fe^{2+}}, m_{FeCl^+}) = C^{\Phi}_{FeCl^+,Cl^-} 2(m_{Cl^-} - m_{FeCl^+})Z$$

In eqs. [20]–[22], the left-hand side terms are known, and the Pitzer parameters $\beta^{(0)}_{FeCl^+,Cl^-}$, $\beta^{(1)}_{FeCl^+,Cl^-}$, and $C^{\Phi}_{FeCl^+,Cl^-}$ can be calculated in an iterative process (9). In a given cycle, one parameter was calculated at a time with the other two fixed, and the calculated data were then used as input values for the next round of calculations.

Helgeson model

In the Debye–Hückel equation, the charging process, omitting all the direct effects of short range forces, is used as an approximation to obtain thermodynamic properties. Adding the effects of the short range forces to the Debye–Hückel equation, Helgeson (28) presented extended equations that were used to describe the electrolyte behavior for the relatively minor species in aqueous solutions with a high chloride concentration. The equation of Helgeson et al. (32) gives a close approximation of individual ion activity coefficients over a wide range of chloride concentration, temperature, and pressure (9).

Results and discussion

Complex configuration transition

Although the amount of tetrahedral complex is insignificant in the solutions used for SQUAD analysis, it can be important or even dominant at around 100°C with higher chloride concentrations, such as those found in steam generator crevices under lay-up or shutdown conditions. Therefore, the tetrahedral Fe(II)-chloride complex cannot be ignored and has to be investigated even at relatively low temperatures (<100°C). In our study the absorbance of the tetrachloroiron(II) complex ($FeCl_4^{2-}$) was observed in solutions with high chloride concentrations, in both the UV and near-IR regions.

Near-IR region

The *d–d* transition of a Fe(II)-chloride tetrahedral complex is expected to appear in the near-IR region centered at around 4160 cm^{-1}, with molar absorptivities 10–100 times greater than those of octahedral complexes (17). Even with heavy water and DCl, only the tail of this band was observed in the region from 5405 to 6250 cm^{-1}. This tail becomes more pronounced as the chloride concentration or temperature increases (Fig. 4). In Fig. 4, the intensities of the band centered near 10 000 cm^{-1} (which is primarily due to the octahedral complexes) decrease while those centered near 4160 cm^{-1} (of which only the tail is visible and which are primarily due to the tetrahedral complex) increase as the temperature or chloride concentration increases. This indicates that the amount of the tetrahedral complex increases at the expense of the octahedral complexes.

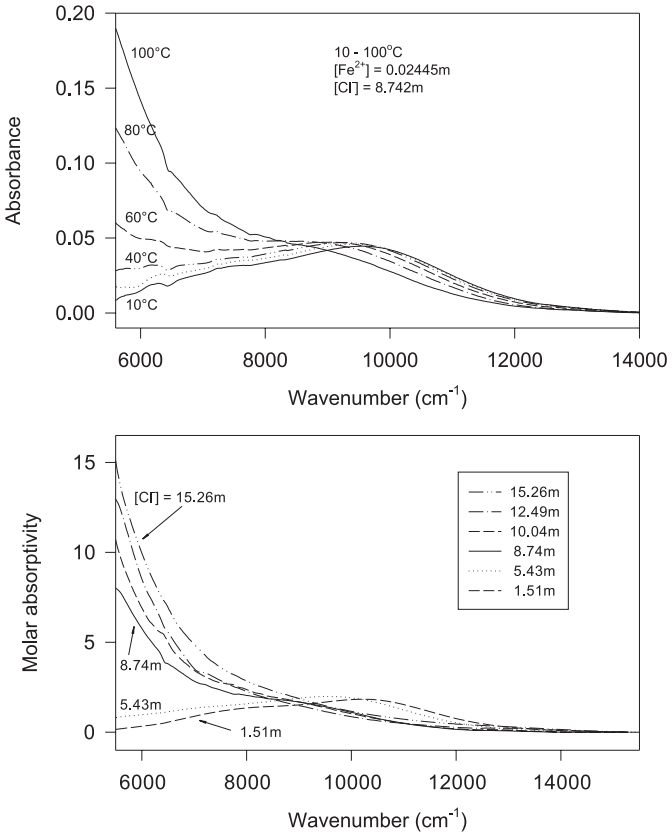
Fig. 4. Top: near–IR absorption spectra of 0.02445 *m* Fe(II) in 8.742 *m* chloride (added as LiCl and DCl) aqueous solution at 10, 25, 40, 60, 80, and 100°C (from bottom to top at 6000 cm^{-1}); Bottom: near–IR absorption spectra of Fe(II)-chloride solutions at 100°C. Solution concentrations are (from bottom to top at 6000 cm^{-1}): 1.51, 5.43, 8.74, 10.04, 12.49, and 15.26 *m*.



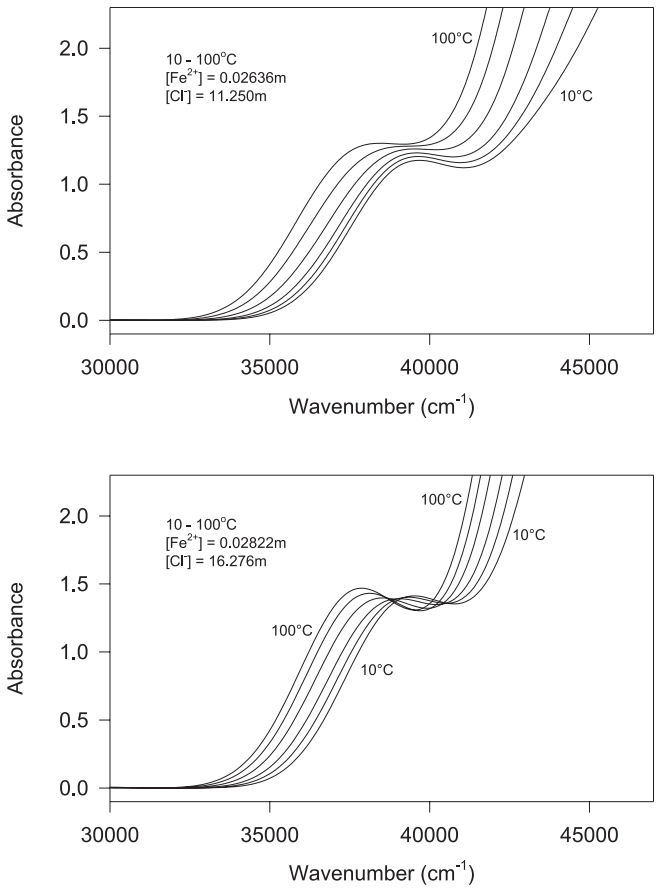


Fig. 5. Variation of absorption spectra with temperature (10, 25, 40, 60, 80, and 100°C, from bottom to top) for 0.02636 *m* $FeCl_2$ in 11.250 *m* total chloride (added as LiCl) (top graph), and for 0.02822 *m* $FeCl_2$ in 16.276 *m* total chloride (bottom graph), in the UV region. Note that the band due to tetrahedral complex (37 500 cm^{-1}) increases at the expense of the octahedral complex band (39 500 cm^{-1}) as temperature increases.

UV region

It was expected that the charge transfer bands for tetrahedrally coordinated Fe(II)-chloride complexes would appear in the UV region. Figure 5 shows the absorption spectra for 0.027 *m* $FeCl_2$ in solutions of varying total chloride concentrations and at various temperatures from 10 to 100°C. It demonstrates that the band at 39 500 cm^{-1} at a low total chloride concentration and low temperature decreases, and a new band at 37 500 cm^{-1} increases with an increase of chloride concentration and (or) temperature.

The band at 37 500 cm^{-1} was assigned to one of the charge transfers of the tetrahedral Fe(II)-chloride complex, because for the solutions whose UV spectra show a well-defined band at 37 500 cm^{-1}, the near-IR spectra show clearly that the tetrahedral complex is predominant in the solutions.

As can be seen from Figs. 4 and 5, octahedral and tetrahedral Fe(II)-chloride complexes coexist in solutions over a wide range of temperature and chloride concentration. In Fig. 6, however, the tetrahedral band at about 37 500 cm^{-1} remains in the same position over a chloride concentration range approximately from 12.46 to 16.28 *m*, with the molar absorptivities little changed. The unsaturated shoulder portion of a strong band at high wavenumbers (cutoff at about 42 000 cm^{-1} in Fig. 6) shows a similar characteristic; there is little further red shift with an increase of chloride concentration from 12.46 to 16.28 *m*. These observations suggest that: (*i*) the tetrahedral complex becomes predominant when the chloride concentration and (or) the temperature are sufficiently high; (*ii*) the band at high wavenumbers can be attributed to the tetrahedral complex; and (*iii*) there is probably only one tetrahedral complex in solution. Following Vogel Koplitz et al. (12), we assume that the only tetrahedral Fe(II)-chloride complex in solution is $FeCl_4^{2-}$. This assumption is consistent with the work by Pan and Susak (27) on Co(II)-chloride complexes.

For this equilibrium

$$[23] \quad Fe(H_2O)_6^{2+} + 4Cl^- \rightleftharpoons FeCl_4^{2-} + 6H_2O$$

we have

$$[24] \quad K_T = \frac{[FeCl_4^{2-}]}{[Fe^{2+}][Cl^-]^4} \frac{\gamma_{FeCl_4^{2-}}}{\gamma_{Fe^{2+}}\gamma_{Cl^-}^4}$$

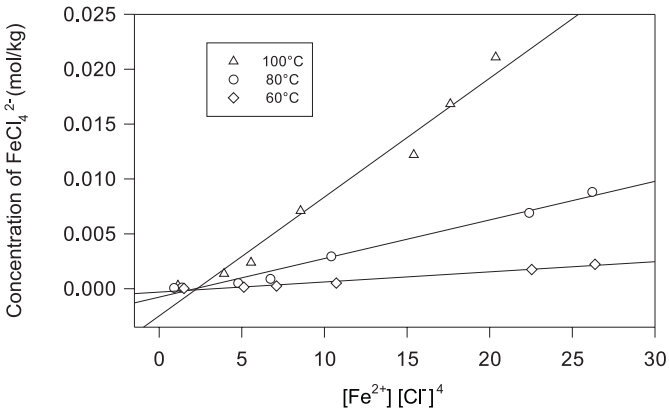
[a]Values obtained using the UV spectra.
[b]Values obtained using the near-IR spectra.

Fig. 6. Absorption spectra of about 0.025 *m* $FeCl_2$ aqueous solutions with chloride concentrations from 7.68 to 16.28 *m* (added as LiCl) at 100°C in the UV region. Chloride concentrations for the discernible three spectra at the bottom are 7.68, 9.52, and 11.25 *m*.



$$[25] \quad [FeCl_4^{2-}] = K_T[Fe^{2+}][Cl^-]^4 \frac{\gamma_{Fe^{2+}}\gamma^4_{Cl^-}}{\gamma_{FeCl_4^{2-}}}$$

where K_T is the equilibrium constant for the configuration transition reaction (H_2O activity was assumed unity). Using the approximation method of Vogel Koplitz et al. (12), the fraction of tetrahedral complex in a solution can be estimated. Because $\gamma_{Fe^{2+}}$ and $\gamma_{FeCl_4^{2-}}$ largely cancel out and γ_{Cl^-} does not deviate appreciably from unity over a large concentration range (40), as a further approximation, the activity term on the right hand side of eq. [25] was taken as unity. The plots of $[FeCl_4^{2-}]$ as a function of $[Fe^{2+}][Cl^-]^4$ show straight lines at 60, 80, and 100°C (Fig. 7). The linear relationship is a convincing evidence that equilibrium [25] is adequate for describing the octahedral–tetrahedral complex transformation in solutions. The equilibrium constant of eq. [24] is obtained from the slopes in Fig. 7 as 9.23×10^{-4} at 60°C, 3.51×10^{-4} at 80°C, and 1.08×10^{-3} at 100°C.

Stability constants

The stability constants for the octahedrally coordinated complexes refined in SQUAD with activity coefficients calculated using the Helgeson and Pitzer models, are listed in Table 1. No convergence could be achieved using the near-IR spectra with the Helgeson model. Generally, better results with smaller standard deviations were obtained using the UV spectra, regardless of the activity calculation model used. These stability constants are averaged and listed in Table 2 as the accepted values.

Fig. 7. Concentration of the tetrahedral complex $FeCl_4^{2-}$ against $[Fe^{2+}][Cl^-]^4$ at 60, 80, and 100°C. Solutions with chloride concentrations greater than 2.2 *m* were used for the plot.

Our determined value of β_1 at 25°C (0.394) falls in the middle range of literature values (9). Our data are also compared with the other two high-temperature studies of Fe(II)-chloride complexes in Table 3. As stated by Palmer and Hyde (13), their reported values for β_1 are in very good agreement with those of Heinrich and Seward (10). Whereas the β_1 values determined in this work differ appreciably from these two earlier works (Table 3). However, this and previous work (11, 12) clearly demonstrate that tetrahedrally coordinated chloro-Fe(II) complexes are present in significant amounts at or near room temperatures at sufficiently high chloride concentrations, and that they are predominant at elevated temperatures (near and above 100°C) even at moderately low chloride concentrations. Obviously, the tetrachloroiron(II) complex cannot be ignored in Heinrich and Seward's work (10), given that their experimental conditions ranged from 25 to 200°C and 0.01 to 3.4 *m* chloride concentration. Even though the chloride concentrations are relatively low (<0.11 *m*) in the solutions of Palmer and Hyde (13), at temperatures near 300°C the tetrachloroiron(II) complex can be important (9). Besides, because very acidic solutions (0.01 to 3.4 *m* HCl) were used by Heinrich and Seward (10), substantial water molecules would exist in the form of H_3O^+, and this could change water's properties as a ligand and affect the coordinating ability of the chloride ions

accordingly. Finally, real systems encountered in industrial applications are not well represented by either the Fe(II)-H_2O-HCl (10) or the diluted Fe(II)-H_2O-NaCl (13) system.

Complexation thermodynamics

Thermodynamic parameters $\Delta_r G°$, $\Delta_r H°$, and $\Delta_r S°$ for the complexation reactions between Fe(II) and Cl^- can be obtained from the temperature dependence of the stability constants. The free energy change for a reaction can be calculated using

$$[26] \quad \Delta_r G° = -RT \ln K$$

where K is the equilibrium constant (Table 2) for one of the following equilibria

$$[27] \quad Fe^{2+} + Cl^- \rightleftharpoons FeCl^+$$

$$[28] \quad FeCl^+ + Cl^- \rightleftharpoons FeCl_2^0$$

$$[29] \quad Fe^{2+} + 4Cl^- \rightleftharpoons FeCl_4^{2-}$$

Because the present experiments cover a relatively small range of temperature (10–100°C), $\Delta_r H°$ and $\Delta_r S°$ were assumed constant, so that

$$[30] \quad \ln K = \frac{\Delta_r S°}{R} - \frac{\Delta_r H°}{RT}$$

Both $\Delta_r H°$ and $\Delta_r S°$ can be derived from a linear fit of ln K against $1/T$ as shown in Fig. 8. The fitted results are tabulated in Table 4.

Both of our obtained enthalpy and entropy changes for the first Fe(II)-chloride complex formation are positive and larger than those reported previously (10, 13). In fact, all the entropy and enthalpy values obtained for Fe(II)-chloride complex formations as listed in Table 4 are positive, indicating that these complex formations are more like hard–hard interactions. The obtained data also indicate that replacement of water by chloride in the complexes is endothermic, and the driving force for complex formation is the overall increase of entropy through releasing water molecules into the bulk solution.

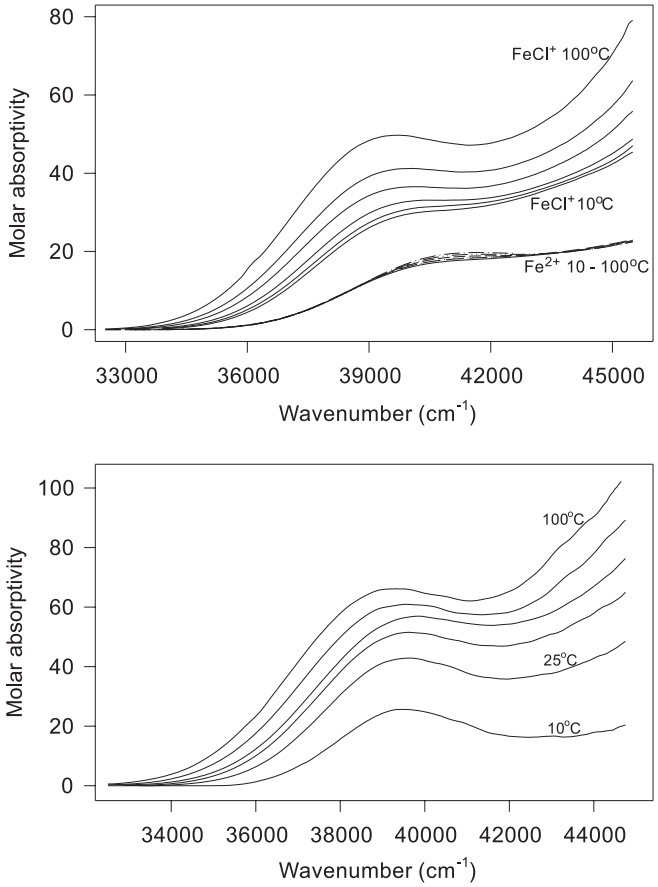
Note: Subscripts/reactions 1, 2, 4 refer to reactions [27], [28], and [29] in the text, respectively.



The tetrachloroiron(II) complex is relatively weak with a large positive enthalpy and hence energetically not favored with respect to octahedral complexes at room temperatures. The configuration transition from octahedrally to tetrahedrally coordinated complexes is, therefore, driven by an entropy increase and thus favored at higher temperatures, in addition to being favored stoichiometrically by an increase of chloride concentration.

Molar absorptivities and complex distributions

Increased molecular vibrations and rotations at elevated temperature relax ligand fields, resulting in a decrease in 10Dq. This is shown by the slight band shifts towards lower energies at higher temperatures observed in Figs. 9 and 10

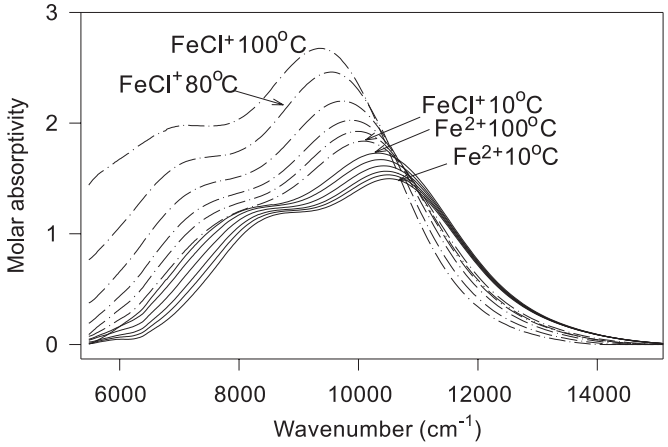
© 2001 NRC Canada

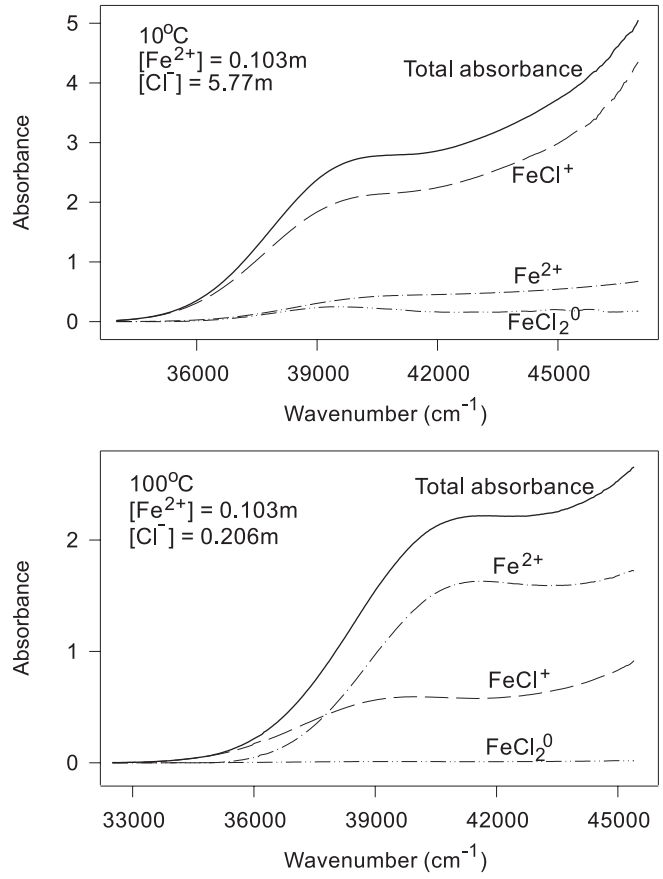
Fig. 9. Molar absorptivities of Fe^{2+}(aq) and $FeCl^+$ (top graph) and $FeCl_2^0$ (bottom graph) at 10, 25, 40, 60, 80, and 100°C (from bottom to top) in the UV region, derived from SQUAD refinements.

for Fe(II)-chloride complexes in both the UV and near-IR regions. These stronger molecular vibrations and rotations at higher temperatures can partially remove the center of symmetry of an O_h coordination, and the Laporte selection rule is partially overcome to yield stronger absorptivities for Laporte forbidden bands. These absorptivities increase with increase of temperature as shown in Figs. 9 and 10 for Fe(II)-chloride species.

As water molecules in $Fe(H_2O)_6^{2+}$ are replaced stepwise by chloride ions, the absorption bands of $FeCl^+$ and $FeCl_2^0$ become more intense at a given temperature (Figs. 9 and 10) because of the removal of center of symmetry of the complexes. The absorption bands of the complexes $FeCl^+$ and $FeCl_2^0$ also shift to lower wavenumbers at a given temperature, indicating that replacement of H_2O by Cl^- decreases the octahedrally coordinated ligand field strength. This observation was expected because Cl^- is a weaker ligand than H_2O. It is noted that at higher temperatures (near 100°C), molar absorptivities in the region from 5556 to 7142 cm^{-1} for $FeCl^+$ increase greatly with temperature (Fig. 10), erratically deviating from the trend shown at lower temperatures. This is due to the formation of the tetrahedral complex. To minimize this problem, spectra with chloride concentrations higher than 4.45 *m* (tetrahedral complex >4.5% for [Cl^-] >4.45 *m* at 100°C) were removed from the data set for SQUAD at 100°C.

Fig. 10. Molar absorptivities of Fe^{2+}(aq) and $FeCl^+$ at 10, 25, 40, 60, 80, and 100°C (from bottom to top) in the near-IR region, derived from SQUAD refinements.





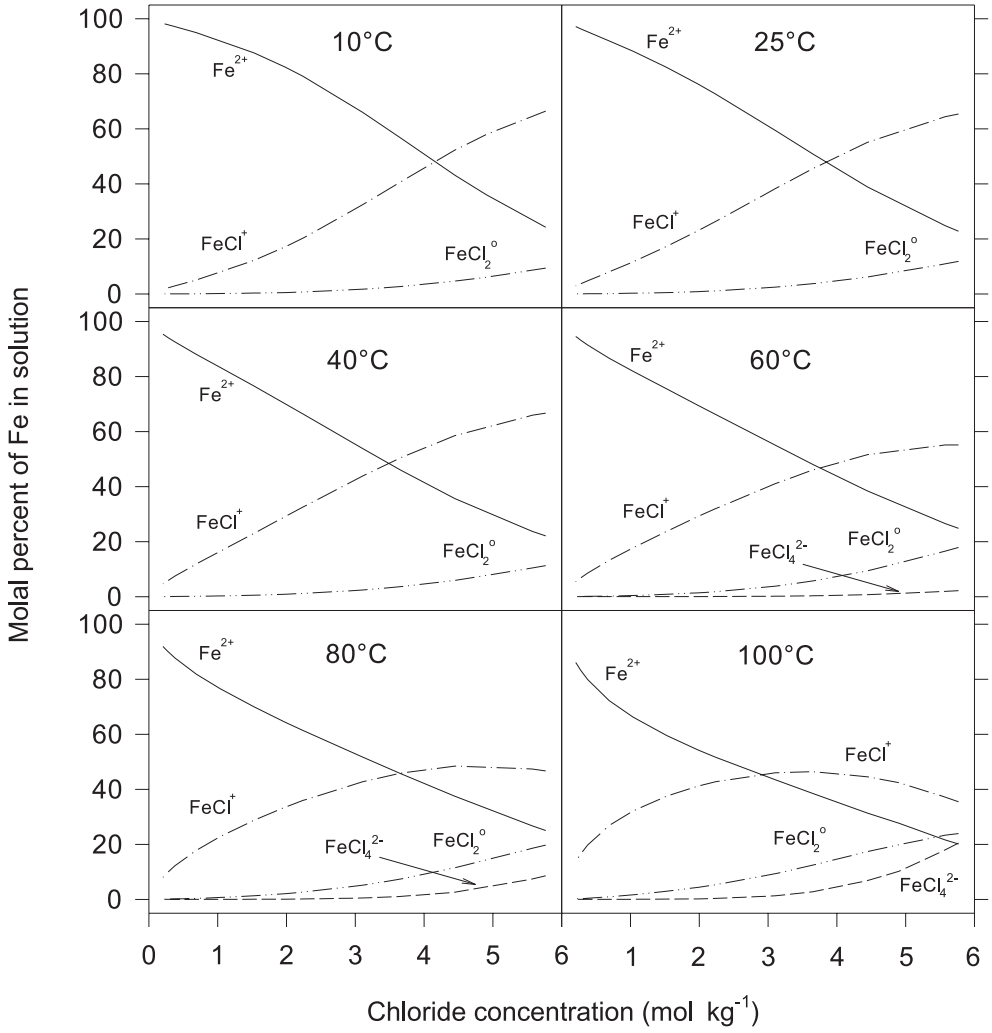


Fig. 11. Total absorbance and contributions from the individual Fe(II) species in high chloride solution at 10°C (top) and in low chloride solution at 100°C (bottom), derived from SQUAD refinements.

When the molar absorptivities and stability constant of each Fe(II) complex are derived from SQUAD at a specific temperature, the absorbance and concentration of the species can be easily calculated for a solution of known Fe(II) and chloride concentrations. Representative absorption spectra with the specific contributions of each Fe(II) containing species, are shown in Fig. 11 at temperatures of 10 and

© 2001 NRC Canada

Fig. 12. Percentage molal contribution of Fe^{2+}(aq), $FeCl^{+}$, $FeCl_2^0$, and $FeCl_4^{2-}$ in aqueous solution as a function of total chloride concentration at 10, 25, 40, 60, 80, and 100°C, derived from SQUAD refinements in the UV region.

100°C. Not surprisingly, the absorption band of free Fe(II) ion dominates the absorption spectra of solutions with low Fe(II) concentrations and at low temperatures. When chloride concentration or temperature gets sufficiently high, the absorption bands of complexes $FeCl^+$ and $FeCl_2^0$ contribute more to the observed spectra (Fig. 11).

In Fig. 12, the percentages of all Fe(II) species are plotted as a function of total chloride concentration in solution at 10, 25, 40, 60, 80, and 100°C. It is noted that the free Fe^{2+}(aq) ion predominates in solutions from 10 to 100°C with chloride concentration less than 3 *m*. The monochloroiron(II) complex, $FeCl^+$, becomes important in solutions with chloride concentrations greater than 1.0 *m*. The dichloroiron(II) complex, $FeCl_2^0$, is always a minor species in solutions (<20%), and the tetrachloroiron(II) complex becomes important only at 100°C and when the chloride concentration exceeds 4 *m* (Fig. 12).

Applications to steam generator systems

To quantitatively assess the effect of hydrolysis and chloro-complex formation on the extent of dissolution of Fe(II) iron, a log [Cl^-] vs. pH diagram depicting the predominance of Fe(II) species at 25 and 100°C was constructed (Fig. 13). The hydrolysis constants of Fe(II) have been reported by several groups (14, 41, 42); the most recent values by Ziemniak et al. (14) were used in this work.

Figure 13 shows that at 25°C in solutions with low chloride concentrations (<1.0 *m*), the free Fe(II) ion (Fe^{2+}(aq)) is predominant over a wide pH range. Only when pH > 9 does the first hydrolyzed Fe(II) species, $FeOH^+$, become predominant. At low temperatures, the higher order hydrolyzed Fe(II) species are relatively unimportant. However, at higher temperatures (near 100°C), the free ion is predominant over a much narrower range of pH, while the second hydrolyzed species ($Fe(OH)_2^0$) becomes more important. At 100°C, the predominance region of the first hydrolysis species ($Fe(OH)^+$) shrinks considerably and the third hydrolysis species ($Fe(OH)_2^0$) gains some importance.

At 25°C, the monochloroiron(II) complex ($FeCl^+$) does not dominate over the free Fe(II) ion until the chloride concentration approaches 2.5 *m*. At 100°C, $FeCl^+$ becomes predominant at chloride concentrations below 0.5 *m*. As the temperature further increases, the Fe(II)-chloride complexes are expected to be even more important.

In steam generators, dissolved impurities can concentrate in crevices and other local areas with restricted coolant flow

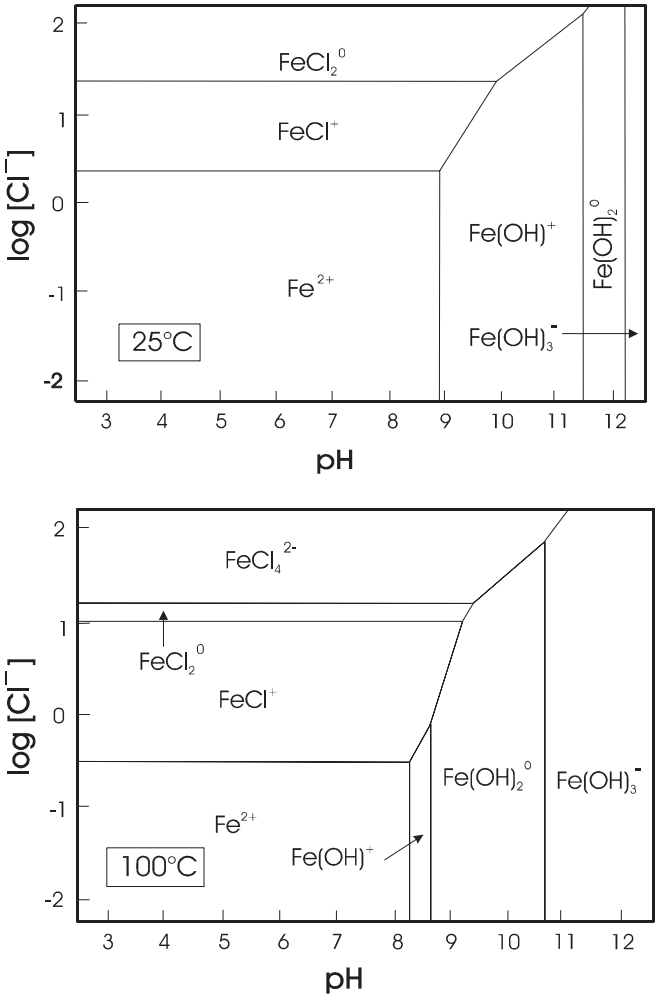
Fig. 13. Log [Cl^-] against pH diagrams showing predominance of Fe(II) species at 25°C (top) and 100°C (bottom). The boundaries represent conditions where two species are equal in molar concentrations. Data for chloride species were determined in this work, while those for hydrolyzed species were from Ziemniak et al. (14). The same data were also used for Fig. 14.



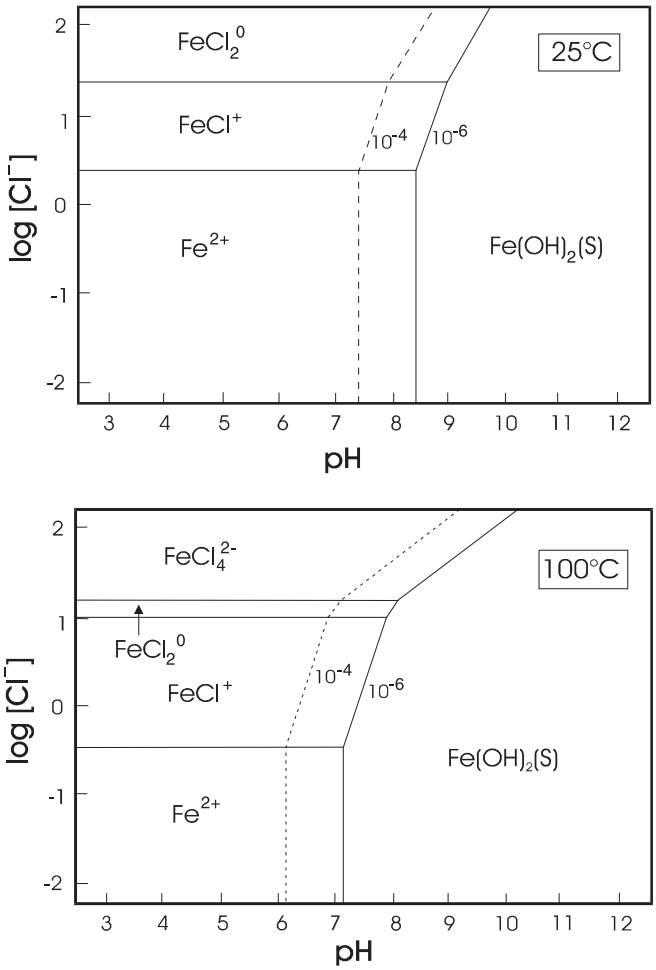


Fig. 14. Diagrams showing the solubility of $Fe(OH)_2$(s) as a function of pH and log [Cl^-] at 25°C (top) and 100°C (bottom). Solid lines between aqueous species and the solid are the 10^{-6} *m* (56 ppb Fe) contours, and the dashed lines are 10^{-4} *m* (5.6 ppm Fe) contours. The boundaries between aqueous species represent conditions where two species are equal in molar concentrations.

because of differential evaporation of water. This hideout process may generate a highly concentrated corrosive solution next to the heat transfer surface. Laboratory tests show that the high temperature pH values of the crevice solutions were slightly higher than or near the neutral point (pH 4–9), and the chloride concentrations were predicted to be in the range of 1–15 *m*. Under such conditions, it is obvious that the monochloroiron(II) complex is the predominant dissolved form of iron at or near 100°C (Fig. 13).

During reactor lay-up or shutdown, local boiling in areas of restricted flow will stop because of the temperature decrease along the heat transfer interface, and the "hidden" impurities will return back to the bulk system. This process may increase the concentrations of chloride and other anions substantially in the bulk water in some local areas; the predominant Fe(II) species in water may change from the free ion to the monochloroiron(II) complex ($FeCl^+$) and result in increased corrosion of the secondary heat transfer system due to complex formation (Fig. 13). However, it should be pointed out that this scenario does not appear to be supported by the station chemistry data. Even with the hideout return, the bulky secondary system is likely still sufficiently clean to prevent significant Fe(II)-chloride complex from forming.

Recently, Ziemniak et al. (14) showed that over a temperature range of 20–80°C, magnetite solubility was independent of the dissolved hydrogen level. They suggested that magnetite solubility behavior at low temperatures up to 83°C is controlled by a surface layer of hydrous Fe(II) oxide at a dissolved hydrogen concentration of 234 μ*m*; at a hydrogen partial pressure of 1 atm (1 atm = 101 325 Pa), this hydrous Fe(II) oxide is stable up to 116°C.

Assuming $Fe(OH)_2$(s) to be the controlling solid phase in steam generator systems at temperatures of 25–100°C, we plot Fe(II) solubilities as a function of chloride concentration and pH in Fig. 14. Comparing the two diagrams in Fig. 14, it is noticed that an increase in temperature from 25 to 100°C will actually moderately decrease the level of dissolved Fe(II) in solution over a wide range of pH and chloride concentration. For example, assuming dissolved chloride to be 5.0 *m* in solution and pH (at 25°C) to be 9.0,

© 2001 NRC Canada

the dissolved Fe(II) concentrations at 25 and 100°C are calculated to be 8.8 ppb and 0.36 ppb, respectively. However, if the chloride concentration gets sufficiently high so that the tetrachloroiron(II) complex becomes predominant, the formation of the tetrachloroiron(II) complex will greatly increase the solubility of Fe(II) hydroxide (Fig. 14). At 100°C and a pH of 8.0, an increase in chloride concentration from 0.0 *m* to 17.0 *m* will enhance the dissolved Fe(II) in solution from 0.89 to 93 ppb. Such a high chloride concentration is rare even at extreme conditions in crevices; it is used in the calculation to illustrate that when the tetrachloroiron(II) complex does form, its enhancement effect to iron dissolution is substantial. Such an enhancement effect is less of an issue at low temperatures (<100°C), but will be much more pronounced at higher temperatures, where the tetrachloroiron(II) complex forms at much lower chloride concentrations. It should be pointed out that these discussions are based on the assumption that the system is in chemical equilibrium. In reality, there may not be sufficient time for chemical equilibrium to be attained, and kinetics may play a vital role in the generator systems.

Conclusions

The stability constants of all Fe(II)-chloride complexes were derived from the measured UV and near-IR absorption spectra using a non-negative nonlinear least-squares computer program (SQUAD), with the activity coefficients of the ionic species calculated using both the Pitzer model and the Helgeson model. The results obtained with UV and near-IR spectra and with different activity coefficient calculation models are generally in good agreement. It was found that the Fe(II)-chloride complexes gradually undergo a configuration transformation from octahedral to tetrahedral coordination when the temperature and (or) chloride concentration increase. This coordination change is governed by mass balance, and driven by an increase in entropy.

At steam generator crevice conditions, the presence of high concentration of chloride ion will enhance the corrosion of carbon steel and other Fe-bearing alloys by forming Fe(II)-chloride complexes. The occurrence and predominance of the tetrachloroiron(II) complex at higher temperatures and chloride concentrations will further enhance the solubility of iron in steam generator systems. Further work at temperatures up to 300°C is required to fully assess the effect of Fe(II)-chloride complex formation on the corrosion of carbon steel and other Fe-bearing alloys under steam generator conditions, and is presently in progress.

Intervalence transfer in a new benzotriazolate bridged ruthenium–iron complex

Reginaldo C. Rocha and Henrique E. Toma

Abstract: The unsymmetrical dinuclear ruthenium–iron complexes $[(NH_3)_5Ru–bta–Fe(CN)_5]^n$ (where bta = benzotriazolate; n = –2, –1, 0) were prepared as solid sodium salts from $[Ru^{II}(NH_3)_5(bta)]^+$ or $[Ru^{III}(NH_3)_5(bta)]^{2+}$ and $[Fe^{II}(CN)_5(H_2O)]^{3–}$ and characterized in aqueous solution by means of electrochemical and spectroelectrochemical methods. UV-vis, near-infrared, IR, and cyclic and differential pulse voltammetry data suggest that the related mixed valent species belong to a valence trapped formulation, featuring localized Ru(III) and Fe(II) oxidation states. In spite of the class II categorization in the Robin and Day scheme, this system shows a remarkable metal–metal electronic coupling, as deduced from an intense, low-energy, and very broad intervalence band in the near-IR region. In addition, the mixed valence state displays enhanced stabilization in relation to the isovalent state. The intervalence transfer properties are discussed on the basis of Hush's theory.

Key words: ammineruthenium complexes, cyanoiron complexes, mixed valence, intervalence, benzotriazole, benzotriazolate.

Résumé : En faisant réagir $[Ru(II)(NH_3)_5(bta)]^+$ ou $[Ru(III)(NH_3)_5(bta)]^{2+}$ avec $[Fe(II)(CN)_5(H_2O)]^{3–}$, on a obtenu les complexes dinucléaires, non symétriques, de ruthénium–fer $[(NH_3)_5Ru\text{-}bta\text{-}Fe(CN)_5]^n$ (dans lesquels bta = benzotriazolate; n = –2, –1, 0) et on les a caractérisés par des méthodes électrochimiques et spectroélectrochimiques. Les spectres UV-vis, IR et proche IR et les données de voltampérométrie pulsée différentielle suggère que l'espèce apparentée à valences mixtes appartient à une formulation piégée de valence typique caractérisée par des états d'oxydation localisés pour le Ru(III) et le Fe(II). En dépit d'une caractérisation comme classe II dans le schéma de Robin et Day, ce système présente un couplage électronique métal-métal remarquable sur la base d'une bande d'intervalence intense, de faible énergie et très large dans la région du proche infrarouge. De plus, son état de valence mixte présente une grande stabilisation par rapport aux états isovalents. On discute des propriétés de transfert intervalence en se basant sur la théorie de Hush.

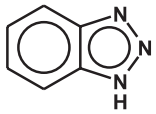
Mots clés : complexes ammineruthénium, complexe cyanofer, valence mixte, intervalence, benzotriazole, benzotriazolate.

[Traduit par la Rédaction]

Introduction

Dinuclear mixed valency complexes (1) have been extensively studied (2–4) due to their importance as simple models for inter and (or) intramolecular electron transfer related processes (5–9). One approach, in order to verify the electronic coupling parameters in such systems as a function of their donor-acceptor configuration, can be performed by conveniently choosing the nature of the metal and (or) ancillary ligands of each moiety, i.e., by designing unsymmetrical systems. This is one of the reasons why an enormous variety of synthetic heteronuclear bi, tri, and polymetallic complexes have been reported in the literature (1–4, 10–33).

Dinuclear complexes based on the Ru^{III}/Ru^{II} (2, 3, 14, 34) and (or) Fe^{III}/Fe^{II} (2, 35–39) couples have played a central role in the study of mixed valence chemistry because of their rich and versatile redox chemistry, in association with their d^5/d^6 configuration. They also present favorable kinetic properties and are thermodynamically stable. The similarity between the pentacyanoferrate(II)/(III) and pentaammineruthenium(II)/(III) moieties (35), has been exploited in the study of the mixed valence chemistry of the neutral heterodinuclear $(NH_3)_5Ru^{III}(pz)Fe^{II}(CN)_5$ complex (where pz = pyrazine) (40, 41).



Aromatic *N*-heterocycles, on the other hand, have proven to be suitable ligands and bridging groups in coordination chemistry (42–44). The triazole derivatives, for instance, have been largely studied in ruthenium and osmium chemistry of discrete compounds or supermolecules (19, 45–52). In particular, benzotriazole (btaH) which is a *N*-heterocyclic species exhibiting three vicinal coordinating N-atoms for the formation of mono and dinuclear complexes with transition metal ions. In addition, btaH has been employed as an efficient corrosion inhibitor for copper and its alloys (53) and provides an interesting model species in bioinorganic chemistry. Nevertheless, except for an investigation on the linkage isomerism in $[Fe^{II,III}(CN)_5]^{3–/2–}$ (54) and $[Ru^{II,III}(NH_3)_5]^{2+/3+}$ (55) complexes, the coordination chemistry of benzotriazole with first- or second-row transition metals has not been readily explored up to the present time.

benzotriazole
(**btaH**)

In order to improve the understanding of electronic interactions and intervalence transfer in benzotriazole ruthenium-ammine and iron-cyano complexes, we carried out a detailed investigation on the novel unsymmetrical dinuclear species $[(NH_3)_5Ru(bta)Fe(CN)_5]^n$ (n = –2, –1, or 0 for the fully reduced [II,II], mixed valent [III,II], and isovalent oxidized [III,III] species, respectively). Analogous to the pyrazine derivative (40), the mixed valent molecule exhibited the $Ru^{III}Fe^{II}$ oxidation states for its individual acceptor–donor metal centers, whose formulation was based on electrochemical and spectroscopic investigations for the starting mononuclear and dinuclear complexes. To our surprise, this species showed an unusually strong metal–metal electronic communication, through the benzotriazolate bridging ligand, in comparison with other similar complexes in the $[(NH_3)_5Ru(L)Fe(CN)_5]^n$ series (e.g., L = pyrazine (40, 41), 4,4′-bipyridine (41), cyanide (56), 1,2-bis(4-pyridyl)ethane (57), pyridinecarboxamido (58), imidazolate (59), 4- and 3-cyanopyridine (60), and 4,4′-dipyridylamine (61)). However, analysis of the intervalence band parameters, in light of the Hush formalism (62–64) and the Robin–Day classification (2, 3, 65), revealed that the $[(NH_3)_5Ru^{III}(bta)Fe^{II}(CN)_5]^-$ complex possesses localized charges and is categorized as a valence trapped class II system.

Experimental

Syntheses and preparation of compounds

Starting materials

$[Ru(NH_3)_6]Cl_3$ (Johnson Matthey; recrystallized), $Na_2[Fe(CN)_5(NO)]\cdot 2H_2O$ (J.T.Baker). All other chemicals and organic solvents employed in the syntheses were analytical reagent grade (Aldrich, J.T.Baker, Merck, or Sigma) and were used without further purification. High purity, deoxygenated water was used through out the experiments. Deionized water was obtained by passing distilled water through a Nanopure (Barnstead) purification system.

btaH/bta⁻ ligands

Benzotriazole (btaH) was purchased from Aldrich and recrystallized from ethanol/water. The lithium benzotriazolate [Li(bta)] salt was prepared by mixing equimolar amounts of btaH and lithium hydroxide, followed by slow evaporation to dryness at room temperature. The UV spectra of the neutral ligand and its corresponding deprotonated anion, in aqueous solutions, gave absorption bands as follows λ (nm) (ε (mol^{-1} dm^3 cm^{-1})): btaH, 257 (4560), 274 (3800, sh); bta^-, 273 (6990). The pK_a values, to be used in this work, for the benzotriazole free ligand were extracted from literature (66): 1.17 ($btaH_2^+$/btaH) and 8.38 ± 0.03 (btaH/bta^-).

$[Ru(NH_3)_5Cl]Cl_2$

The preparation of pentaammine(chloro)ruthenium(III) chloride was based on the classical literature procedure (67).

$Na_3[Fe(CN)_5(NH_3)]\cdot 3H_2O$

The sodium amminepentacyanoferrate(II) complex was prepared as previously described (68). Anal. calcd. for $C_5H_9N_6O_3FeNa_3$ (MW = 326.0): C 18.42, H 2.78, N 25.78; found: C 18.25, H 2.93, N 25.92.

$[Ru^{II}(NH_3)_5(btaH)](PF_6)_2\cdot 3H_2O$

$[Ru(NH_3)_5Cl]Cl_2$ (58.6 mg, 0.2 mmol) was dissolved in water (5 mL) and reduced for 30 min with zinc amalgam, under an argon atmosphere. Then the solution was transferred by syringe techniques or via Teflon® tubing to a recipient containing benzotriazole (238.2 mg, 2.0 mmol). The orange solution was treated with concentrated solution of ammonium hexafluorophosphate (5 mL) yielding a yellow precipitate. The solid product was collected on a filter, washed with a small volume of ethanol and dried in vacuum in the presence of anhyd calcium chloride. Yield: 85–90%. Anal. calcd. for $C_6H_{26}F_{12}N_8O_3P_2Ru$ (MW = 649.3): C 11.10, H 4.04, N 17.26; found: C 10.95, H 4.11, N 17.04.

$[Ru^{III}(NH_3)_5(btaH)](PF_6)_3\cdot 2H_2O$

The yellow $[Ru(NH_3)_5(btaH)](PF_6)_2$ solid (prepared as described above) was redissolved in water and completely oxidized by passing a flow of O_2 gas through the solution. The reddish product was isolated from the slow evaporation of a concentrated solution with excess of NH_4PF_6. Anal. calcd. for $C_6H_{24}F_{18}N_8O_2P_3Ru$ (MW = 776.3): C 9.28, H 3.12, N 14.43; found: C 9.39, H 3.24, N 14.47.

$Na_3[Fe^{II}(CN)_5(btaH)]\cdot 3H_2O$

The mononuclear iron complex was prepared similarly to the published procedure (54). $Na_3[Fe(CN)_5(NH_3)]\cdot 3H_2O$ (326.0 mg, 1.0 mmol) was added to a deoxygenated H_2O/ethanol (3:1) solution (20 mL) containing benzotriazole (178.7 mg, 1.5 mmol). After ~20 min, the yellow mixture was evaporated under vacuum to a volume of 3–5 mL. Then, cold acetone (15 mL) was dripped on the solution. The solid was collected by filtration, washed with a mixture acetone/ethanol (2:1) and dried under vacuum in the presence of anhyd calcium chloride. Yield: 80–85%. Anal. calcd. for $C_{11}H_{11}N_8O_3FeNa_3$ (MW = 428.1): C 30.86, H 2.59, N 26.18; found: C 30.93, H 2.66, N 26.13.

$Na_2[(NH_3)_5Ru^{II}(bta)Fe^{II}(CN)_5]\cdot 4H_2O$

The fully reduced dinuclear compound was obtained by adding $Na_3[Fe(CN)_5(NH_3)]\cdot 3H_2O$ (65.6 mg, 0.20 mmol) to 5.0 mL of an argon saturated, neutral solution of $[Ru(NH_3)_5(btaH)](PF_6)_2\cdot 3H_2O$ (129.6 mg, 0.20 mmol). The initially pale yellow mixture became immediately orange colored. After 30 min, cold deaerated ethanol/acetone (1:3) (20 mL) was added to the mixture and a dark yellow precipitate was formed. The solid was filtered off, washed with a cold ethanol/acetone (1:3) mixture and dried under vacuum over anhyd calcium chloride. Yield: 80–90%. Anal. calcd. for $C_{11}H_{27}N_{13}O_4FeNa_2Ru$ (MW = 608.3): C 21.72, H 4.47, N 29.93; found: C 21.65, H 4.64, N 29.96.

Alternatively, this dinuclear complex was freshly prepared and characterized in aqueous solution by means of spectroscopic and electrochemical methods, as described below.[2,3]

Cyclic voltammetry: In the electrochemical measurements the complex solution was obtained by adding $Na_3[Fe(CN)_5(NH_3)]\cdot 3H_2O$ (8.2 mg, 0.025 mmol) to 5.0 mL of a deaerated 0.05 mol dm^{-3} acetate buffer solution (pH 4.7) containing $[Ru(NH_3)_5(btaH)](PF_6)_2\cdot 3H_2O$ (16.2 mg, 0.025 mmol). Then, the pH of the mixture was adjusted to 8.8–9.0 through the controlled addition of 3.0 mol dm^{-3} sodium hydroxide solution.

Spectroelectrochemistry: In the spectroelectrochemical measurements, the complex was also prepared according to the above procedure. However, it used $Na_3[Fe(CN)_5(NH_3)]\cdot 3H_2O$ (18.4 mg, 0.050 mmol) and $[Ru(NH_3)_5(btaH)](PF_6)_3\cdot 3H_2O$ (32.5 mg, 0.050 mmol) instead. In order to avoid/minimize the electronic absorption by water in the near-IR region of the spectra, D_2O was employed as solvent.

Sodium trifluoroacetate (NaTFA) and potassium nitrate (both 0.25 mol dm^{-3}) were employed as supporting electrolytes in the cyclic voltammetry and spectroelectrochemical measurements, respectively.

$Na[(NH_3)_5Ru^{III}(bta)Fe^{II}(CN)_5]\cdot 5H_2O$ [4]

The mixed valent dinuclear complex was prepared by two different methods: (*a*) by mixing equimolar amounts (0.20 mmol) of $Na_3[Fe^{II}(CN)_5(NH_3)]\cdot 3H_2O$ and $[Ru^{III}(NH_3)_5(btaH)](PF_6)_3\cdot 2H_2O$ in neutral aqueous solutions, under argon; (*b*) by treating a solution of $Na_2[(NH_3)_5Ru^{II}(bta)Fe^{II}(CN)_5]\cdot 4H_2O$ with 1 equiv of sodium peroxydisulfate. In both cases, further handling of the brownish product was carried out in the same way as for the reduced complex. Yield: 85–90%. Anal. calcd. for $C_{11}H_{29}N_{13}O_5FeNaRu$ (MW = 603.3): C 21.90, H 4.84, N 30.18; found: C 21.99, H 5.02, N 30.20.

$(NH_3)_5Ru^{III}(bta)Fe^{III}(CN)_5\cdot 6H_2O$ [4]

The fully oxidized neutral compound was obtained by adding excess (about 3 equiv) of $Na_2S_2O_8$ to the $Na[(NH_3)_5Ru^{III}(bta)Fe^{II}(CN)_5]\cdot 5H_2O$ complex (0.2 mmol) in water (5 mL). After reacting, the resulting violet solution was cooled to 0°C and left in the ice bath for 30 min. Then, the precipitate was handled as before. Yield: 75–80%. Anal. calcd. for $C_{11}H_{31}N_{13}O_6FeRu$ (MW = 598.4): C 22.08, H 5.22, N 30.43; found: C 21.95, H 5.40, N 30.33.

Instrumentation and methods

The electronic spectra in the ultraviolet–visible (UV–vis) and near-infrared (near-IR) regions were recorded on a Hewlett-Packard model 8453 diode-array spectrophotometer (1 cm or 0.025 cm quartz cells) and on a Guided-Wave model 260 fiber-optics instrument (adjustable optical path length; measured by reflectance), respectively.

Cyclic and differential pulse voltammetry measurements were carried out by using a Princeton Applied Research–PAR model 283 potentiostat (from EG&G Instruments, Inc.). A conventional three-electrode arrangement was employed in the measurements; it consists of a glassy carbon working electrode, a Luggin capillary with Ag/AgCl (KCl 1.0 mol dm^{-3}) reference electrode ($E°$ = 0.222 V vs. SHE), and a platinum wire as the auxiliary electrode, in aqueous solutions containing sodium trifluoroacetate (NaTFA) or potassium nitrate (0.10 or 0.25 mol dm^{-3}) as supporting electrolyte. All solutions were thoroughly degassed with argon prior to beginning the experiments, and before each measurement the solutions were purged with argon gas. Working electrodes were polished by using alumina paste (Struers). All potential values in this paper are uncorrected for junction potentials and given in V vs. standard hydrogen electrode (SHE).

Spectroelectrochemical measurements in the UV–vis region were carried out with a Princeton Applied Research–PAR model 173 potentiostat or a model 366 bi-potentiostat in parallel with the diode-array spectrophotometer. A three-electrode system was designed for a rectangular quartz cell of 0.025 cm internal optical path length (69). A gold minigrid was used as a transparent working electrode, in the presence of a small Ag/AgCl reference electrode and a platinum auxiliary electrode. The cell was located directly in the spectrophotometer, and the absorption change was monitored during the electrolysis.

Spectroelectrochemistry measurements in the near-IR region were performed by using a fiber-optic probe for in situ measurements in a specially designed quartz, flat bottom electrochemical cell, as used in earlier works (70, 71). In this case, the fiber-optic probe was placed perpendicular to the mirror surface of the platinum electrode, which was kept approximately 0.020 cm from the bottom, providing a constant optical pathlength. This cell was then filled with the D_2O solution.

The vibrational spectra of the solid dinuclear compounds in KBr pellets were measured with a Shimadzu model 8300 Fourier Transform infrared (FT-IR) spectrophotometer.

The pK_a evaluations were made by means of electrochemical measurements as a function of pH. A cell was specially designed in order to combine simultaneous pH measurements with cyclic voltammetry. pH measurements were carried out with a MD21 digital pH meter from Digimed Ltd. Calibration of the pH meter was performed using pH 4.00, 7.00 and 10.00 commercial standard buffers, at 25°C.

Elemental analyses were conducted by Analytical Center Laboratory of the Instituto de Química, Universidade de São Paulo.

Molecular mechanics calculations were performed by using the MM+ module, a modified MM2 force field (72) within the HyperChem 5.1 program (Hypercube, Inc., Gainesville, Florida, U.S.A., 1999). Geometry optimizations were carried out with a gradient of 1×10^{-5} kcal $Å^{-1}$ mol^{-1}

[2] The freshly prepared solutions from either the isolated solid or directly from the mixture of the starting mononuclear complexes show identical cyclic voltammograms and electronic spectra.

[3] All prolong-time measurements involving the photo-sensitive $[Fe(CN)_5]^{2-/3-}$ derivatives were run in the absence of light. This procedure avoids further substitution processes involving the cyanide ligands.

[4] This oxidized complex was also generated by electrolysis (vide infra). In both chemical and electrochemical synthetical procedures, the same electronic spectrum was obtained, as well as cyclic voltammogram for their corresponding solutions of the complex.

Results and discussion

Mononuclear complexes

In spite of our emphasis on the mixed valent complex, we found it necessary to characterize some aspects of the mononuclear species in order to understand the properties of the dinuclear complexes. Although their properties are partially reported elsewhere (54, 55), the relevant data are summarized in Table 1 along with, for comparison purposes only, the data concerning the starting materials (73–80).

Dinuclear complexes $[(NH_3)_5Ru(bta)Fe(CN)_5]^n$ (n = –2, –1, or 0)

In aqueous solution, the amminepentacyanoferrate(II) ion ($[Fe(CN)_5(NH_3)]^{3-}$) undergoes substitution of NH_3 to form the corresponding aquacomplex, $[Fe(CN)_5(H_2O)]^{3-}$ (81) which, in turn, readily reacts with *N*-heterocyclic ligands (36). The reaction of $[Ru^{II}(NH_3)_5(bta)]^+$ and $[Fe^{II}(CN)_5(NH_3)]^{3-}$ (equimolar ratio) in aqueous solution at pH ~ 9.0, under an argon atmosphere, produced an orange color complex, analogous to the one isolated in the solid form (the reaction of oxidized $[Ru^{III}(NH_3)_5(bta)]^{2+}$ and reduced $[Fe^{II}(CN)_5(NH_3)]^{3-}$ species was also followed at pH 6.0, generating a brownish product; see Experimental section). It is worthy to note that, at the experimental pH, deprotonation of the monocoordinated benzotriazole takes place (Table 1), making binding of this species to the cyanoiron(II) unit (from the $[Fe(CN)_5(H_2O)]^{3-}$ ion) possible.

The cyclic and differential pulse voltammograms of this new species exhibit two well-defined reduction processes at E_1 = 0.390 V and E_2 = –0.090 V vs. SHE (Fig. 1), providing the first piece of evidence for the formation of the new unsymmetrical dinuclear complex, $[(NH_3)_5Ru(bta)Fe(CN)_5]^{2-}$. Another important indication of its existence is the presence of a strong electronic absorption band in the NIR region after the addition of 1 equiv of a chemical oxidant (i.e., peroxydisulfate), which is consistent with the generation of the mixed valent species, $[(NH_3)_5Ru^{III}(bta)Fe^{II}(CN)_5]^-$. The formulation of the Ru(III) and Fe(II) oxidation states was initially based on comparison of the reduction potentials, E_1 and E_2, of the Fe^{III}/Fe^{II} and Ru^{III}/Ru^{II} redox couples, respectively, in the starting mononuclear complexes (Table 1). This

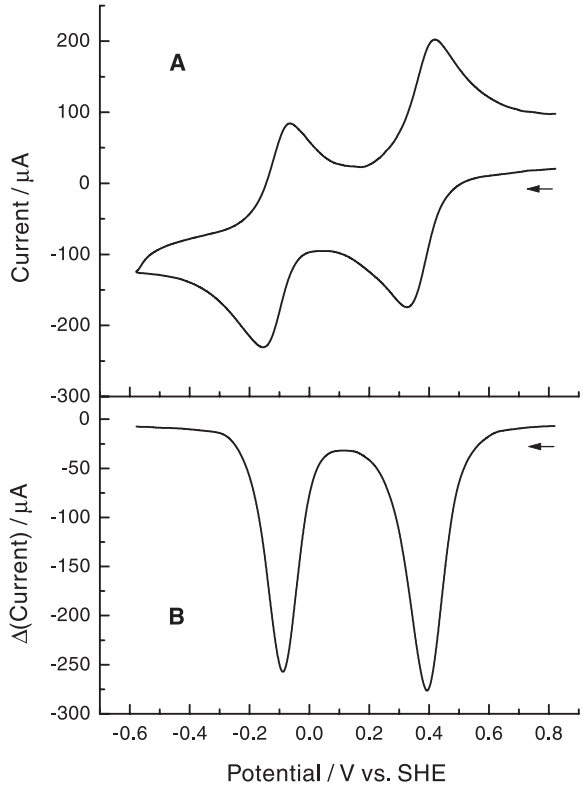
Fig. 1. Cyclic voltammograms (*a*) and differential pulse voltammogram (*b*) of the $[(NH_3)_5Ru(bta)Fe(CN)_5]^-$ complex in an aqueous solution (C = 5.0 × 10^{-3} mol dm^{-3}; I = NaTFA 0.25 mol dm^{-3}; pH 6.5). (DPV working conditions: pulse height = 0.025 V; pulse width = 0.005 s; scan rate = 100 mV s^{-1}; step/droptime = 0.020 s).



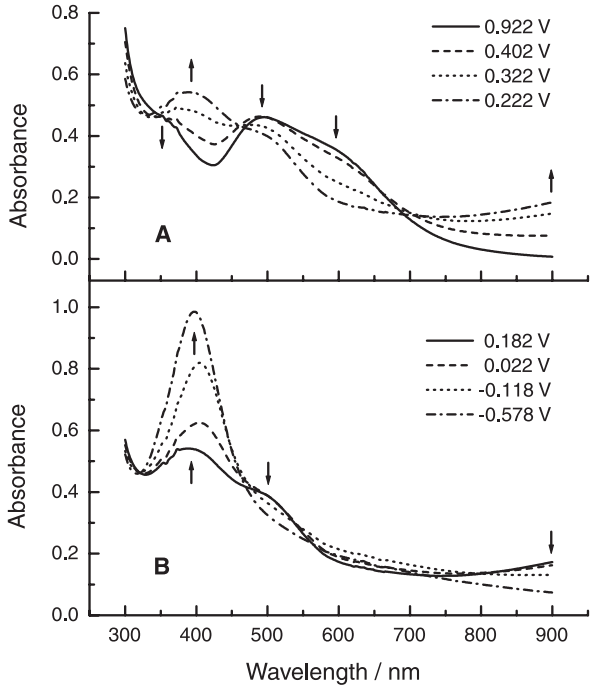


Fig. 2. Electronic spectra of the $[(NH_3)_5Ru(bta)Fe(CN)_5]^n$ complexes (n = –2, –1, 0) under application of potentials (C = 5.0 × 10^{-3} mol dm^{-3}; l = 0.025 cm; I = NaTFA 0.25 mol dm^{-3}; pH 6.5; applied potentials vs. SHE are indicated in the figure).

type of assignment must take into account an important feature of Fe–L–Ru related complexes, since their oxidation states can be formulated as Fe^{II}–Ru^{III} (as is the case in the majority of the literature examples (40, 41, 56–59, 61)), Fe^{III}–Ru^{II} (60), or even a mixture of both electronic isomers (60). In order to give support for the preliminary assignment simply from their potentials analysis, infrared spectra (see below) and UV–vis spectroelectrochemical (Fig. 2) measurements were carried out.

As reported before (40), comparison among the infrared spectra of the three dinuclear complexes (reduced isovalent [II,II], oxidized isovalent [III,III], and mixed valent [II,III] species) shows that they are nearly the same, except for the CN^- and NH_3 absorption bands. It is known (82) that the frequencies associated with the vibrations of the CN^- and NH_3 groups depend on the nature and charge of the metal ions to which they are coordinated. The symmetric deformation and rocking vibrational modes of the coordinated NH_3 group occur at frequencies which usually increase with the oxidation state and electronegativity of the central ion in the complex (83, 84). For ruthenium hexaammines in the II and III oxidation states, they appear at 1220 and 769 cm^{-1} (85) and 1316–1362 and 788 cm^{-1} (86), respectively. Therefore, the observed shifts from 1263 cm^{-1} ($\delta_{NH_3(sym)}$; strong) and 754 cm^{-1} (ρ_{NH_3}; medium) in the totally reduced (II,II) complex to 1308 cm^{-1} (s) and 795 cm^{-1} (m) in the mixed valent (II,III) complex are indicative of the oxidation of the ruthenium(II) center. This hypothesis is corroborated by the fact that practically no changes were observed in these bands from the mixed valent to the completely oxidized (III,III) species (1315 cm^{-1} (s) and 804 cm^{-1} (m)).

The cyanide stretching frequency (ν_{CN}), however, is seen at 2055 cm^{-1} (s) for both the (II,II) and (II,III) species and is diagnostic of cyanoferrate(II) complexes (82, 87). In the case of cyanoiron(III) complexes the cyanide stretching frequency is usually observed in the 2100–2150 cm^{-1} region, which is in accordance with the absorption for the fully oxidized [III,III] species (2117 cm^{-1} (s) and 2161 cm^{-1} (m)). These results, therefore, agree with a valence trapped system in which the oxidized acceptor center is mainly localized on the ruthenium ammine moiety.

The UV–vis electronic spectra of the oxidized isovalent complex (Ru^{III}-bta-Fe^{III}) (generated at potentials higher than 0.4 V; Fig. 2*a*) show two absorption bands at 495 nm (3700 mol^{-1} dm^3 cm^{-1}) and 590 nm (sh; 2800 mol^{-1} dm^3 cm^{-1}). These bands were assigned to the ligand-to-metal charge transfer (LMCT) transitions involving the ruthenium and iron centers, i.e., $\{bta^-\}\pi \rightarrow d_\pi\{Ru^{III}(NH_3)_5\}$ and $\{bta^-\}\pi \rightarrow d_\pi\{Fe^{III}(CN)_5\}$. The analogous bands for the mononuclear complexes occur at 467 nm (2060 mol^{-1} dm^3 cm^{-1}) and 582 nm (2180 mol^{-1} dm^3 cm^{-1}), respectively (Table 1). The fact that the LMCT transition to Fe(III) appears at lower energy with respect to the one centered on Ru(III) is consistent with the stronger oxidizing ability of iron. A shoulder is also seen around 360 nm and can be tentatively assigned to a $(CN^-) \rightarrow d_\pi(Fe^{III})$ LMCT transition (59, 88, 89).

When the mixed valent species (Ru^{III}-bta-Fe^{II}) is electrolytically produced by applying potentials between E_1 and E_2 (Fig. 1), two bands can be seen in the spectra (Figs. 2*a* and

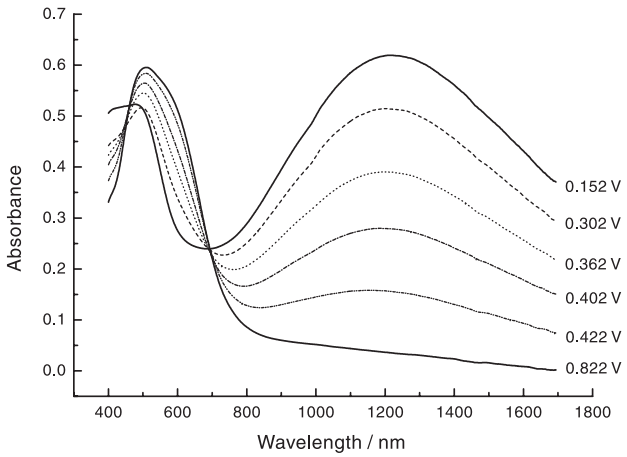
Note: The bridging ligand (L_b) is given in the Table as: **1** = pyrazine; **2** = 4,4′-bipyridine, **3** = cyanide, **4** = 1,2-bis(4-pyridyl)ethane, **5** = pyridinecarboxamido, **6** = imidazolate, **7** = 4-cyanopyridine, **8** = 3-cyanopyridine, **9** = 4,4′-dipyridilamine, and **10** = benzotriazolate.

[a]Refers to the iron(III/II) couple.

[b]Refers to the ruthenium(III/II) couple.

[c]Potential vs. SHE.

[d]Unsymmetrical system; the redox separation and the corresponding global ΔG_c does not reflect the stabilization by electron delocalization, since there is an intrinsic $\Delta E_{1/2}$ between the redox potentials associated to the non-equivalent ammineruthenium and cyanoiron moieties (see details in the text).



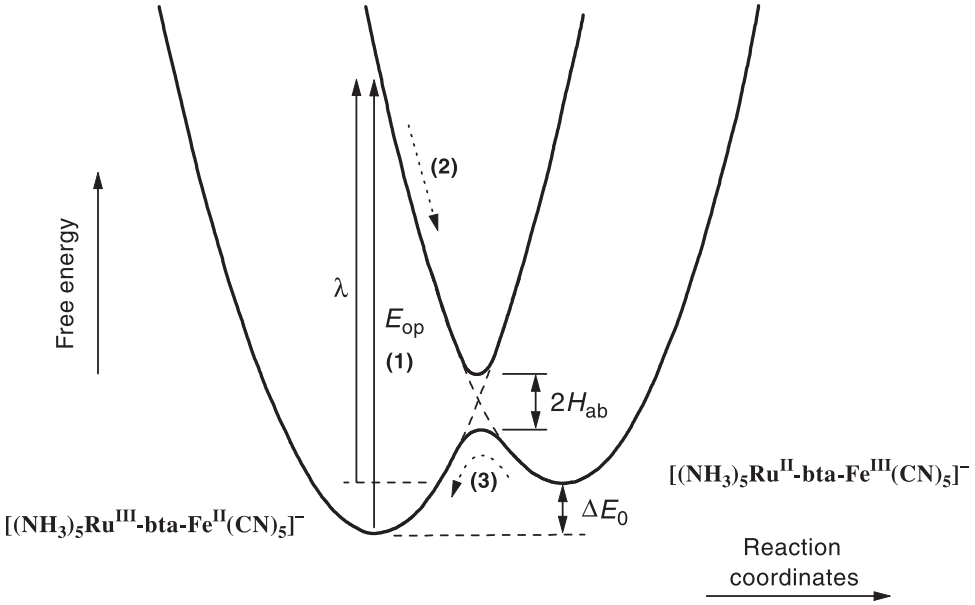
[e]The oxidation states for the mixed valent complex were proposed according to the Ru^{II}–Fe^{III} formulation.

2*b*): one around 500 nm, which refers to the already mentioned LMCT involving the $\{Ru^{III}(NH_3)_5\}$ moiety; and a new one that appears at 390 nm (4300 mol^{-1} dm^3 cm^{-1}), corresponding to the metal-to-ligand charge transfer (MLCT) transition on the iron unit, $\{Fe^{II}(CN)_5\}d_\pi \rightarrow \pi^*\{bta^-\}$. In the mononuclear cyanoiron complex, an analogous band was observed at 350 nm (2100 mol^{-1} dm^3 cm^{-1}) and 388 nm (4440 mol^{-1} dm^3 cm^{-1}) for the deprotonated and protonated species, respectively, reflecting the π-acceptor effect of the ruthenium(III) moiety to the iron(II) π-donor center in the mixed valent dinuclear complex. This comparison suggests that the hydrogen ion (H^+) and the $[Ru^{III}(NH_3)_5]^{3+}$ fragment exert similar electronic effects when bound to the benzotriazolate ligand in $[Fe^{II}(CN)_5(bta)]^{4-}$, since the MLCT energy in the mixed valent Ru^{III}-Fe^{II} species and the reduction potential for the Ru^{III}-$Fe^{III/II}$ couple are close to those observed in the protonated $[Fe(CN)_5(btaH)]^{3-}$ monomer (Table 1).

With potentials below 0 V vs. SHE, the completely reduced species Ru^{II}-bta-Fe^{II} is generated and the spectra (Fig. 2*b*) show only an intense (7800 mol^{-1} dm^3 cm^{-1}) and broad band around 400 nm. In light of the corresponding bands in the mononuclear species at 389 and 350 nm, this envelope consists of both $Ru^{II} \rightarrow bta^-$ and $Fe^{II} \rightarrow bta^-$ MLCT transitions (Table 1).[5]

Based on the above discussion, the alternative formulation (Ru^{II}-Fe^{III}) can be ruled out, and the complex can be unambiguously identified as having the $[(NH_3)_5Ru^{III}(bta)Fe^{II}(CN)_5]^-$ configuration. In order to investigate the intervalence transfer (IT) related processes for this mixed valent species, a spectroelectrochemical study in the vis–near-IR region was performed (Fig. 3). The results confirm that the intense (ε = 3900 ± 200 mol^{-1} dm^3 cm^{-1})[6] and broad ($\Delta\nu_{1/2}$ = 6500 cm^{-1})[7] band at 1210 nm (or 8265 cm^{-1}) only occurs when the system is submitted to a potential between 0.4 and –0.1 V (Figs. 1 and 3, Table 2). The maximum absorption intensity is reached when the applied potential approaches 0.15 V vs. SHE (Fig. 3), which is the middle point between the two

Fig. 3. Spectroelectrochemistry of the dinuclear complex $[(NH_3)_5Ru(bta)Fe(CN)_5]^{n-}$ in a D_2O solution (C = 1.0 × 10^{-2} mol dm^{-3}; l = 0.016 ± 0.001 cm; I = KNO_3 0.25 mol dm^{-3}; pD 6.0; applied potentials vs. SHE are indicated in the figure).



[5]In the spectroelectrochemical measurements, all species were practically 100% recovered.

[6]This uncertainty comes from the experimental error associated to the optical pathlength, which is not known and has to be indirectly determined through a standardized solution; see *Experimental* section for details on the employed reflectance apparatus.

[7]The near–IR absorption band was deconvoluted from the CT bands in the visible region by assuming that the IT transition results in a single symmetrical Gaussian band (spectrum in cm^{-1}) and no change in the vis-bands' profiles. Such deconvolution methods have already been discussed in details elsewhere (90).

Scheme 1.

reversible wave couples shown in the cyclic voltammograms (Fig. 1). Potential values above or below this point show that the absorptivity gradually decreases until the band completely disappears at the positive (>0.5 V) and negative (< – 0.2 V) extremes of the range. At these extremes the oxidized and reduced isovalent species should be fully generated (Fig. 1).[5]

The behavior described above clearly reveals the presence of an oxidized (acceptor) and another reduced (donor) site in the E_1 to E_2 range, whose observed low-energy band is consistent with a metal-metal charge transfer (MMCT) and is characteristic of mixed valence complexes (1–9). Therefore the two redox pairs established by the electrochemical data may be ascribed as follows:

[1*a*] $(NH_3)_5Ru^{III}-bta-Fe^{III}(CN)_5 \overset{E_1 = 0.390V}{\rightleftharpoons} [(NH_3)_5Ru^{III}-bta-Fe^{II}(CN)_5]^-$

[1*b*] $[(NH_3)_5Ru^{III}-bta-Fe^{III}(CN)_5]^- \overset{E_2 = -0.090V}{\rightleftharpoons} [(NH_3)_5Ru^{II}-bta-Fe^{II}(CN)_5]^{2-}$

In addition, the band at 1210 nm originates from the intervalence transition from the donor {$(CN)_5Fe^{II}$–} to the acceptor {–$Ru^{III}(NH_3)_5$} unit, as shown in eq. [2]:

[2] $[(NH_3)_5Ru^{III}(d\pi_3^1)-bta-(d\pi_3^2)Fe^{II}(CN)_5]^- \xrightarrow{h\nu} [(NH_3)_5Ru^{II}(d\pi_3^2)-bta-(d\pi_3^1)Fe^{III}(CN)_5]^-$

where $d\pi_3$ is the highest $d\pi$ energy level among the three nearly degenerated t_{2g}-type metal orbitals.

In a subsequent step an inverse electron transfer (ET) process, following a thermal path (eq. [3]), should take place (see representation in the diagram of Scheme 1) since the system is unsymmetrical and, at the equilibrium state, there is a driving force, ΔE_0, favoring the thermodynamically stable electronic isomer, $[(NH_3)_5Ru^{III}(bta)Fe^{II}(CN)_5]^-$.

[3] $[(NH_3)_5Ru^{II}(d\pi_3^2)-bta-(d\pi_3^1)Fe^{III}(CN)_5]^- \xrightarrow{\Delta, k_{th}} [(NH_3)_5Ru^{III}(d\pi_3^1)-bta-(d\pi_3^2)Fe^{II}(CN)_5]^-$

In Hush's model (2–9, 62–64), configurational-coordinate energy diagrams (or simply potential energy diagrams) have been used as a powerful tool (91) for describing light-induced electron transfer reactions, as shown in Scheme 1 for the unsymmetrical $[(NH_3)_5Ru(bta)Fe(CN)_5]^-$ ion. Thus, the energy of the IT transition (E_{op}) for this type of systems will equal the sum of λ, the reorganizational energy (i.e., Franck-Condon energy), and the ΔE_0 (where ΔE_0 is the difference in internal energy between the thermally equilibrated ion Ru^{III}-bta-Fe^{II} and its higher-energy redox isomer Ru^{II}-bta-Fe^{III}, which is the product of optical ET after having undergone vibrational and rotational relaxation). The meaning and magnitude of H_{ab}, the resonance energy between the reagent and product states at the curves intersection, will be explored below.

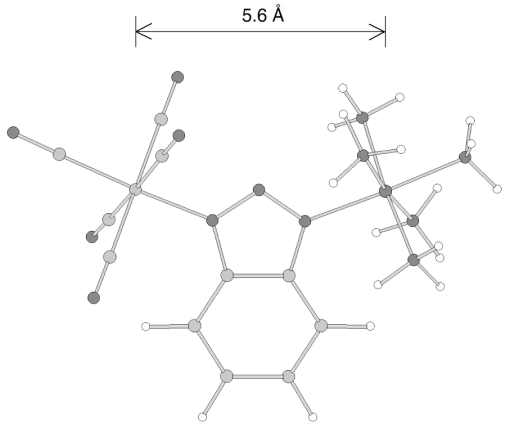
The thermodynamic stability of the mixed valent complex relative to the isovalent species can be estimated (92–94) from the comproportionation constant (K_c) associated with the equilibrium in eq. [4].

[4] $(NH_3)_5Ru^{III}-bta-Fe^{III}(CN)_5 + [(NH_3)_5Ru^{II}-bta-Fe^{II}(CN)_5]^{2-} \Downarrow K_c$

$2[(NH_3)_5Ru^{III}-bta-Fe^{II}(CN)_5]^-$

By assuming that $\Delta G_c = -RT\ln(K_c) = -nF(\Delta E_{1/2})$ for the comproportionation reaction, then K_c can be calculated (92, 93) based on the potential separation, where $\Delta E_{1/2} = |E_1 - E_2| =$ 480 mV. For $\Delta E_{1/2}$ given in mV, at 298 K, the expression for K_c becomes eq. [5].

© 2001 NRC Canada



$$[5] \qquad K_c = \frac{[Ru^{III}Fe^{II}]^2}{[Ru^{III}Fe^{III}][Ru^{II}Fe^{II}]} = \exp\left(\frac{\Delta E_{1/2}}{25.69\ mV}\right)$$

The calculated value of K_c for this system was 1.30×10^8, giving a ΔG_c value of –11.1 kcal mol^{-1} (3870 cm^{-1}) (Table 2).[8] In spite of the high magnitude of the comproportionation constant, which is typical of complexes with relatively strong electronic coupling, it is important to remember that the system is not symmetric and there is an intrinsic ΔE associated with the difference of formal reduction potentials of the starting moieties ($E_{1/2}$ values for $[Ru(NH_3)_5(bta)]^{2+}$ and $[Fe(CN)_5(bta)]^{3-}$ are 0.025 and 0.215 V vs. SHE, respectively, in such a way that $\Delta E_{(mono)}$ = 190 mV). Thus the magnitude of ΔG_c is not totally related to the stabilization of the complex by electron delocalization at the mixed valence state (95–97).

In fact, the $\Delta E_{(mono)}$ value could be taken as rough approximation of ΔE_0,[9] which, in this case, would be near 0.19 eV (~1530 cm^{-1}) and refers to an approximation of $\Delta G°$ (2, 3), the driving force of the thermodynamically favorable ET reaction (see eq. [5] and Scheme 1), i.e., the released energy in the back electron transfer reaction $[(NH_3)_5Ru^{II}(bta)Fe^{III}(CN)_5]^- \rightarrow [(NH_3)_5Ru^{III}(bta)Fe^{II}(CN)_5]^-$. In addition, the Franck-Condon principle imposes that the optical (light-induced) intramolecular ET reaction occurs with $E_{op} = \nu_{max} = \lambda + \Delta E_0$ (2–9). Hence, within the limitation of this approach,[9] the reorganization energy (λ) was estimated as 6735 cm^{-1}, from the thermodynamic barrier (ΔE_0) and the IT absorption energy (ν_{max}).

Although some efforts have been made to determine the isolated contribution of delocalization energy in unsymmetrical systems (97–99), no theoretical treatment including a normalization of $\Delta E_{1/2}$ ($E_2 - E_1$ in the dinuclear species) as a function of the intrinsic difference of potential ($\delta(\Delta E)$) for the distinct starting moieties is known. As an approximation, however, in order to compare with the results from symmetrical mixed valence systems, $\Delta E_{(mono)}$ should be subtracted from $\Delta E_{1/2}$ (i.e., 480 – 190 mV), yielding an effective stabilization of 290 mV (from the monomers to the dimer). This resulting stabilization (referred here as $\Delta G'_c$) would contribute 2340 cm^{-1} to the comproportionation energy. Even so, it is important to recognize that this energy is a sum of, at least (97), four terms (2, 3, 95, 96): $\Delta G_{en} + \Delta G_{el} + \Delta G_s + \Delta G_d$, where ΔG_{en} is an entropic factor which reflects the statistical distribution of eq. [4] (evaluated as 1/2RT ln 1/4); ΔG_{el} is an electrostatic factor arising from the repulsion of the two charged metal centers joined by the bridge; ΔG_s is the synergistic factor, arising from the stabilization by charge transfer and outer-sphere donor effects; and ΔG_d (delocalization or resonance factor), is the stabilization energy component originating from the electron delocalization. For weakly coupled systems, the magnitude of ΔG_d can be estimated by $\Delta G_d = H_{ab}^2/\lambda$ (2, 3), from the Franck-Condon energy (λ) and the mixed valence resonance stabilization energy (H_{ab}) which can be extracted from the IT band parameters (see sections below).

Fig. 4. Molecular structure of the $[(NH_3)_5Ru(bta)Fe(CN)_5]^-$ complex, calculated by molecular mechanics geometry optimization.

In the bta-system, the calculated value of ΔG_d is 417 cm^{-1}. Considering that ΔG_d is generally ~ 1% (<20 mV) of H_{ab} in most class II reported cases (2–4), the obtained value (~25%) reflects a significant delocalization in this complex, even though it represents only about 50 mV of 340 mV corresponding to $\Delta G'_c$. This also means that the most of the comproportionation stabilization in the mixed valent dinuclear complex comes from the combined $(Fe^{II})d_\pi \rightarrow \pi_L^*$ and $\pi_L \rightarrow d_\pi(Ru^{III})$ charge-transfer and electrostatic effects.

Molecular structure

The molecular structure of the unsymmetrical dinuclear $[(NH_3)_5Ru(bta)Fe(CN)_5]^-$ complex, based on MM+ molecular mechanics geometry optimization calculations, is illustrated in Fig. 4. The two metal ions and the bridging ligand are located in the same plane, exhibiting a metal-metal distance of 5.6 Å.

In previous work involving the symmetrical $[\{Ru(edta)\}_2\text{-}\mu\text{–}L]^{4-}$ complexes (L = benzotriazolate or benzimidazolate) (70), we proposed that their contrasting IT properties could be partially explained by the fluxional coordination mode of the benzotriazolate one (54, 55, 100). Theoretical calculations revealed, however, that {Ru(edta)} terminal units offer a special situation where a steric vacancy (101) makes the metal-metal approximation through the benzotriazolate feasible to an intermediate binding position where the Ru–Ru distance should be shorter than the one resulting from the conventional N1–N3 coordination. On the other hand, in this system, this type of behavior is not expected due to the more sterically hindered structure associated with the rather larger pentacyano and pentaammine moieties. Thus, the unsymmetrical benzotriazolate derivative will have a metal–metal separation very close to that observed for the symmetrical

[8] The dimer investigated herein has sufficiently large $\Delta E_{1/2}$ value that corrections for comproportionation to the observed extinction coefficients (95, 96) were ignored.

[9] ΔE_0 has usually been obtained from the reduction potentials of model compounds or directly from $\Delta E_{1/2}$, the difference between the (III,III) and (III,II) reduction potentials of the dimer itself (where the electronic coupling is negligible). However, the latter method suffers from the fact that synergistic effects, stabilization of M(II) by M(III), electron delocalization, etc., cannot be appropriately assessed. In this way, it seems that, although the method adopted here does not provide an accurrate value of ΔE_0, it is more realistic for the type of investigated system than others.

benzimidazolate one, where the fluxional mechanism does not take place. Consequently, one can consider the ruthenium-iron distance as being slightly shorter than the one calculated for the edge-to-edge model, $[(NH_3)_5Ru\text{-}N1\text{-}bta\text{-}N3\text{-}Fe(CN)_5]^-$, i.e., 5.6 Å, whose value will be used as the ET ratio in the electronic coupling evaluation (see next section).

Intervalence transfer properties

It is interesting to note that the IT band for this mixed valent complex is much broader and stronger than the ones observed previously for the symmetrical diruthenium species (70). These intensities are reflected in the oscillator strength ($f_{os} = 0.117 \pm 0.005$) and in the transition dipole moment ($\mu = 1.14 \pm 0.03$) related to this heterodinuclear complex, which were given by eqs. [6] and [7] (102–105).

$$[6] \qquad f_{os} = 4.61\times10^{-9}\,(\varepsilon_{max})\,(\Delta\bar{\nu}_{1/2})$$

$$[7] \qquad \mu = [\,f_{os}/(1.08\times10^{-5}\,(\bar{\nu}_{max}))]^{1/2}$$

Three classes of systems may be distinguished depending on the magnitude of the interaction between the donor–acceptor sites (65). Using the Mulliken formalism (106, 107), Hush showed that the electronic coupling element and the extent of electron delocalization in the mixed valence species can be estimated from the IT band parameters (62–64). However, according to this model, the theory applies only for class II systems (65), where the electronic interaction is weak or moderately strong and can be treated as a discrete perturbation. Hence, a criterion for evaluating or classifying the degree of electronic coupling is given by the Hush model (2–4, 62–64), through the calculation of the spectral half-bandwidth $\Delta\nu_{1/2}$ for the IT band, by using the eq. [8]:

$$[8a] \qquad \Delta\bar{\nu}_{1/2} = [16\,(\ln 2)\,RT(E_{op} - \Delta E_0)]^{1/2}$$

$$\Downarrow$$

$$[8b] \qquad \Delta\bar{\nu}_{1/2} = [2310\,(E_{op} - \Delta E_0)]^{1/2} \quad \text{(at 298K)}$$

where the calculated $\Delta\nu_{1/2}$ value corresponds to the limiting value for a class II mixed valence complex. The experimental values below this limiting $\Delta\nu_{1/2}$ value are typical of systems exhibiting substantial electronic coupling between the metal centers, as is the case for valence delocalized complexes (class III).

The theoretical value of $\Delta\nu_{1/2}$ for the $[(NH_3)_5Ru(bta)Fe(CN)_5]^-$ complex is 4060 cm^{-1}. As a consequence of the estimated values being much lower than the observed one (6500 cm^{-1}), it was confirmed that this system can be properly described as a localized class II mixed valence model, in terms of the Robin and Day categorization (2–4, 65). Application of eqs. [9] and [10] for evaluation of electronic coupling matrix element and delocalization from the IT parameters (2–9, 62–64) may, therefore, appropriately provides the magnitude of the interaction between the metal centers.

$$[9] \qquad H_{ab} = 2.05\times10^{-2}\left(\frac{(\varepsilon_{max})(\Delta\bar{\nu}_{1/2})\,(\bar{\nu}_{max})}{d^2}\right)^{1/2}$$

$$[10] \qquad \alpha = \frac{H_{ab}}{E_{op}}$$

The energy of the optical absorption ($\nu_{max} = E_{op}$), its molar absorptivity (ε_{max}), and the corresponding bandwidth at half-height ($\Delta\nu_{1/2}$) values for the IT band of the mixed valent species, $[(NH_3)_5Ru^{III}(bta)Fe^{II}(CN)_5]^-$, are 8265 cm^{-1}, 3900 mol^{-1} dm^3 cm^{-1}, and 6500 cm^{-1}, respectively. The electron transfer distance (d) is usually taken to be the intermetallic separation (2–9) and it was extracted to be 5.6 Å from molecular geometry optimizations (see *Molecular calculations* above or *Experimental* section for computational details).

The H_{ab} and α^2 parameters for electronic coupling energy and ground state electron delocalization degree were calculated to be 1675 cm^{-1} and 0.041, respectively. Even though this benzotriazolate species contains an "nonlinear" bridging ligand, to our surprise, their magnitude is superior to the pyrazine-analogue (40, 41), and reflects the efficient metal-metal communication through the apparently more conductive bta-bridge. As in this case the fluxional mobility in the benzotriazolate should not be significant, the unexpected differences in intervalence properties between the pyrazine and benzotriazolate unsymmetrical systems are better interpreted in terms of π-electronic character of the bridging ligand, which in turn dictates the superexchange mechanism (8, 9). While benzotriazole acts as either a slight π-acceptor or a weak donor ligand (relatively electron rich), pyrazine behaves as a strong π-acceptor ligand (electron poor), such that the hole-transfer and electron-transfer mechanisms (108), respectively, should take place in their corresponding pentaammineruthenium(III)-pentacyanoferrate(II) dinuclear complexes. Therefore, since the cyanoiron(II) fragment also behaves as a partial π-donor unit (since it is stabilized through π-backdonation) and the pentaammineruthenium(III) as a π-acceptor (Lewis acid) group in the mixed valent species, the benzotriazolate π-levels approach, in energy, the metal $d\pi$ orbitals, and consequently, can better distribute–communicate the extra charge from iron to ruthenium. By extrapolation of this reasoning, it would seem obvious that ligands with strong σ,π-donor character should promote an enhanced intermetallic coupling. Interestingly, the imidazolate derivative of the type $[(NH_3)_5Ru^{III}\text{–}L\text{–}Fe^{II}(CN)_5]^-$ (59), shows about half of the resonance energy involved in the benzotriazolate system reported herein (it should be pointed out that imidazolate and benzotriazolate bridges have actually almost the same metal-to-metal electron transfer distance). If the same superexchange mechanism is operating in both systems, then some other characteristic is making the latter special, as we have observed before (70, 109).

Conclusions

From the discussion, one can conclude that the features of the $[(NH_3)_5Ru^{III}(bta)Fe^{II}(CN)_5]^-$ species are quite remarkable for this type of mixed valence complex, where these results approach those previously reported for class III systems

© 2001 NRC Canada

(2, 3) even though their electronic charges are valence trapped. A more illustrative comparison is provided by the analogous dinuclear complexes of the series $[(NH_3)_5Ru(L)Fe(CN)_5]^n$ that have emerged in recent years (L = pyrazine (40, 41), 4,4′-bipyridine (41), cyanide (56), 1,2-bis(4-pyridyl)ethane (57), pyridinecarboxamido (58), imidazolate (59), 3- and 4-cyanopyridine (60), and 4,4′-dipyridilamine (61)), for which the mixed valence and comproportionation properties (Table 2) are rather modest as compared to the observed ones in this communication. Indeed, these literature examples possess H_{ab} values up to ~750 cm^{-1} (59) while the one for the benzotriazole derivative is higher than 1600 cm^{-1}. The unusual interaction observed in this study is even more exceptional when one takes into account the non-linearity of the bridging ligand employed in this work, as many symmetrical or unsymmetrical examples of dimers comprehend μ-symmetrical and linear bridges of similar structural dimensions (2–4).

A favorable aspect for the relatively strong metal-metal electronic coupling, as well as for the high stability of the electronic (or redox) isomer formulated as Ru^{III}-Fe^{II} is the existence of the (donor bridging ligand) $\pi \rightarrow d_\pi$ (acceptor Ru^{III} ion) charge-transfer interaction, which is reinforced by the π-donor ability of the $[Fe^{II}(CN)_5]^{3-}$ moiety. This statement is supported by the fact that the redox potential at the ruthenium center is more negative in the dinuclear complex (– 0.090 V) than in the protonated $[Ru^{III/II}(NH_3)_5(btaH)]^{3+/2+}$ (0.210 V), or even in the deprotonated $[Ru^{III/II}(NH_3)_5(bta)]^{2+/+}$ (0.025 V) monomers. From the same reasoning, this unidirectional π-conjugation can eventually decrease the stability of some isovalent Ru^{II}-Fe^{II} species with strong π-donor ligands (59), where the π-donor effect takes place on both the ruthenium(II) and the iron(II) units, but in the opposite direction. Conversely, in the fully oxidized state (Ru^{III}-Fe^{III}) the acceptor $M^{III}X_5$ moieties compete for the poor π-donor ability of the benzotrizolate bridge.

Although benzotriazole is not typically a strong σ,π-donor ligand, as it is the case of imidazole (59) and its derivatives (110), the facts observed herein corroborate the hypothesis of benzotriazolate acts primarily as a donor (relative to the acceptor property) bridge. The Fe^{III}/Fe^{II} couple in the benzotriazolate complexes, for instance, have lower potentials than $[Fe^{III/II}(CN)_5(H_2O)]^{2-/3-}$ (Table 1), which indicates the weak π-acceptor ability of this ligand.

The superexchange mechanism operating in the charge conduction through the bridges is better rationalized, in the present example, by hole-transfer rather than electron-transfer. The electron-transfer mechanism is well established in pyrazine or pyridine derivatives with low-energy π* orbitals, but, as demonstrated in this study, this is not the case for benzotriazolate. On the contrary, hole-transfer is favored by the energy match between the metal d_π and the populated π ligand levels.

Catalytic pathways in the ethanolysis of fenitrothion, an organophosphorothioate pesticide. A dichotomy in the behaviour of crown/cryptand cation complexing agents[1]

Vimal K. Balakrishnan, Julian M. Dust, Gary W. vanLoon, and Erwin Buncel

Abstract: The rates of displacement of 3-methyl-4-nitrophenoxide ion from the pesticide, fenitrothion, by alkali metal ethoxides in anhydrous ethanol were followed spectrophotometrically. Through product analysis experiments, which included ^{31}P NMR and GC-MS, as well as spectrophotometric analysis, three reaction pathways were identified: nucleophilic attack at the phosphorus centre, attack at the aliphatic carbon, and a minor S_NAr route (≤7%). Furthermore, a consecutive process was found to occur on the product of attack at the phosphorus centre. For purposes of kinetic treatment, the processes at the aliphatic and aromatic carbon were combined (i.e., the minor S_NAr pathway was neglected), and the observed reaction rate constants were dissected into rate coefficients for nucleophilic attack at phosphorus and at aliphatic carbon. Attack at phosphorus was found to be catalyzed by the alkali metal ethoxides in the order KOEt > NaOEt > LiOEt. Catalysis arises from alkali metal ethoxide aggregates in the base solutions used (0–1.8 M); treatment of the system as a mixture of free ethoxide, ion-paired metal ethoxide, and metal ethoxide dimers resulted in a good fit with the kinetic data. An unexpected dichotomy in the kinetic behaviour of complexing agents (e.g., DC-18-crown-6, [2.2.2]cryptand) indicated that the dimers are more reactive than free ethoxide anions, which are in turn more reactive than ion-paired metal ethoxide. The observed relative order of reactivity is explained in the context of the Eisenman theory in which the free energy of association of the metal ion with the rate-determining transition state is largely determined by the solvent reorganization parameter. In contrast with displacement at the phosphorus centre, attack at the aliphatic carbon was not found to be catalyzed by alkali metals. In this case, the free ethoxide anion was more reactive than either the ion-paired metal ethoxide or the dimeric aggregate. The differing effects of alkali metals on the two pathways is ascribed largely to the leaving group pK_a. For carbon attack, the pK_a value estimated for demethyl fenitrothion, 2.15, is sufficiently low that metal ions are not required to stabilize the rate-determining transition state. In contrast, for phosphorus attack, 3-methyl-4-nitrophenoxide, with a pK_a of 7.15, requires stabilization by metal ion interactions. Hence, alkali metal ions catalyze attack at phosphorus, but not attack at the carbon centres.

Key words: organophosphorothioate, pesticide, fenitrothion, ethanolysis, alkali metal ethoxide, ion-pair reactivity, dimers, catalysis, competitive pathways.

Résumé : Faisant appel à la spectrophotométrie, on a déterminé les vitesses de déplacement de l'ion 3-méthyl-4-nitrophénolate à partir du pesticide, fénitrothion, sous l'influence d'éthylates de métaux alcalins, dans l'éthanol anhydre. Sur la base d'analyses des produits qui ont impliqué la RMN du ^{31}P et la SM–CG ainsi que des analyses spectrophotométriques, on a pu identifier trois voies réactionnelles: une attaque nucléophile sur le centre phosphoré, une attaque au niveau du carbone aliphatique et une voie S_NAr mineure (inférieure à 7%). De plus, on a observé que le produit résultant d'une attaque au niveau du phosphore donne lieu à un processus consécutif. Pour les besoins du traitement cinétique, on a combiné les processus au niveau des atomes de carbone aliphatique et aromatique (c'est-à-dire que l'on néglige la voie S_NAr mineure) et on a disséqué les constantes de vitesse réactionnelles observées en coefficients d'attaque nucléophile au niveau du carbone aliphatique et du phosphore. On a trouvé que l'attaque au niveau du phosphore est catalysée par les éthylates de métaux alcalins dans l'ordre KOEt > NaOEt > LiOEt. Dans les solutions basiques utilisées (0–1,8 M), la catalyse provient d'agrégats d'éthylate du métal alcalin; si l'on traite le système comme un mélange d'éthylate libre, d'éthylate formant une paire d'ions avec le métal et de dimères d'éthylate métallique, on obtient un bon ajustement avec les données cinétiques. Une dichotomie inattendue dans le comportement des

agents complexants (par exemple, le cryptand-[2.2.2], DC-18-couronne-6) indique que les dimères sont plus réactifs que les anions éthylates libres qui, de leur côté, sont plus réactifs que l'éthylate métallique sous la forme de paire d'ions. On explique l'ordre de réactivité relative observé en faisant appel à la théorie d'Eisenman selon laquelle l'énergie libre d'association de l'ion métallique avec l'état de transition de l'étape cinétiquement déterminante est déterminée principalement par le paramètre de réorganisation du solvant. Par opposition avec la réaction de déplacement au centre phosphoré, on a trouvé que l'attaque au niveau du carbone aliphatique n'est pas catalysée par les métaux alcalins. Dans ce cas, l'anion éthylate libre est plus réactif que l'éthylate métallique sous la forme de paire d'ions ou sous la forme d'agrégat dimère. Les effets différents des métaux alcalins sur les deux voies réactionnelles sont attribués en grande partie au pK_a du groupe partant. Dans le cas de l'attaque sur l'atome de carbone, la valeur du pK_a estimée pour le desméthylfénitrothion, 2,15, est tellement base qu'il n'est pas nécessaire de faire intervenir des ions métalliques pour stabiliser l'étape cinétiquement déterminante de l'état de transition. Par ailleurs, pour l'attaque au niveau du phosphore, la stabilisation par des interactions avec l'ion métallique est nécessaire pour le 3-méthyl-4-nitrophénolate dont le pK_a est de 7,15. En conséquence, les ions des métaux alcalins catalysent l'attaque au niveau du phosphore, mais pas l'attaque au niveau des centres carbonés.

Mots clés : organophosphorothioate, pesticide, fénitrothion, éthanolyse, éthylate de métal alcalin, réactivité de la paire d'ions, dimères, catalyse, voies réactionnelles en compétition.

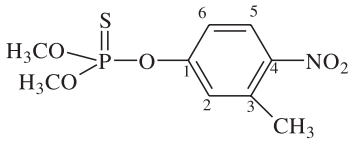
Introduction



Due to their biological and environmental importance, the degradation of organophosphorus compounds has been studied extensively over the past several decades (1–5). In addition to investigations of the pathways and mechanisms of degradation, research has highlighted the role played by metal ions and surfaces in the abiotic degradation process (6).

From a mechanistic viewpoint, organophosphorus esters are known to undergo a variety of degradation processes. For a phosphorus phenolate ester containing both alkyl and aryl substituents, three decomposition pathways can be envisaged: attack at phosphorus, resulting in P—OAr cleavage; attack at the aliphatic carbon with C—O cleavage; and attack on the aromatic moiety with Ar—O cleavage (2–4).

In aqueous reactions with weakly nucleophilic phenolate ions, Kirby and Younas (4*a*) have shown that aryl methylphosphate anion ($(^{-}O)(MeO)P(O)$-OAr) reacts at the phosphorus and aromatic centres at approximately equal rates, and that C—O bond fission was not significant. In the case of tetrabenzylpyrophosphate ($(PhCH_2O)_2(O)P$-O-$P(O)(OCH_2Ph)_2$), reaction with *n*-propoxide ion occurred competitively at both the phosphorus centre and the aliphatic carbon. In reactions with hydroxide anion, phosphate esters are found to undergo only P—OAr cleavage via an S_N2 (P) mechanism (3). In their studies on the reaction of a series of phosphinate esters with alkali metal ethoxides, Buncel and co-workers (7–11) found that reaction occurred exclusively at the phosphorus centre of the P=O compounds investigated.

The present work represents a continuation of the previous studies conducted in this laboratory on nucleophilic substitution at phosphorus and sulfur centres and catalysis–inhibition by alkali metal ethoxides in ethanol (7–11). The studies showed that for the phosphorus-based esters, alkali metal ions were uniformly catalytic, with reactivities following the order: LiOEt > NaOEt > KOEt > CsOEt > EtO^{-}. However, with sulfonate esters, the reactivities were in the order: CsOEt > KOEt > NaOEt > $^{-}$OEt > LiOEt, with LiOEt acting as an inhibitor.

As an extension of the studies with a variety of P=O and O=S=O compounds, it was deemed logical to proceed to P=S compounds, which comprise the majority of organophosphorus pesticides in use today. Specifically, the compound studied is fenitrothion (*O*,*O*-dimethyl-*O*-(3-methyl-4-nitro)phenylphosphorothioate (**1**), a broad-spectrum insecticide used extensively throughout the world for the control of agricultural and forest pests (12). In Canada, its main application, since 1969, is in the control of the spruce budworm in the forests of the Atlantic provinces (13).

1

In the present paper, kinetic data are described for displacement not only at the P=S centre, but also for reaction via two other competitive pathways of fenitrothion ethanolysis (S_N2 (C) and S_NAr). Alkali metal ethoxides were found to catalyze reaction at phosphorus, but not at the aliphatic or aromatic carbon centres.

Results and discussion

Reaction pathways

The reaction of fenitrothion with alkali metal ethoxides in ethanol was studied spectrophotometrically by following, over time, the formation of 3-methyl-4-nitrophenoxide, the product of attack at the phosphorus centre. It was soon noted, however, that the absorbance at infinite time of the aryloxide product (A_{inf}) was lower than that predicted when the reaction occurred solely via nucleophilic displacement at phosphorus. The expected A_{inf} value at 398 nm, given an initial fenitrothion concentration of 7.72×10^{-5} M and a cuvette pathlength of 1 cm, was 1.45; the observed A_{inf} values ranged over 0.68–1.39 (see Table S1 of the supplementary

data).[3] The data show that, in general, the observed A_{inf} values increase in tandem with increasing $[MOEt]_o$.

The significant deviation of A_{inf} values from the expected value suggested the intervention of alternative reaction pathways, leading to additional products. Two likely possibilities were an S_N2 process involving nucleophilic attack at the aliphatic methoxy carbon and an S_NAr process in which ethoxide attacked at the C-1 position of the electron-deficient aromatic moiety.

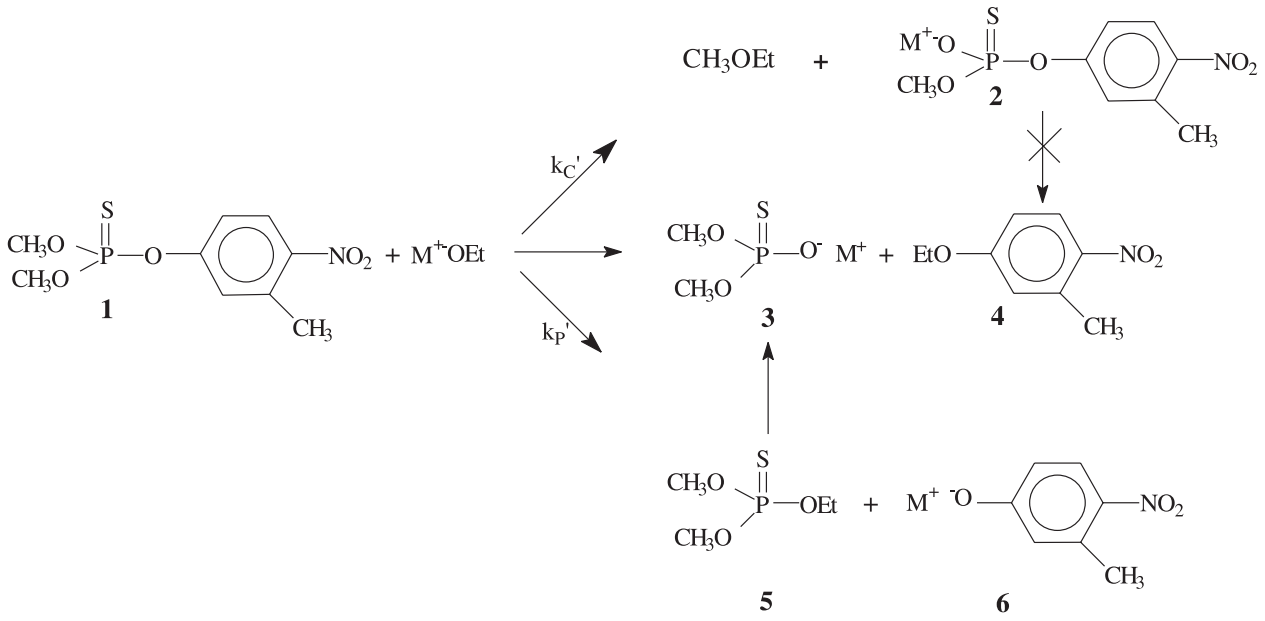
Further evidence on this aspect was obtained through ^{31}P NMR and GC-MS experiments. The degradation of a 0.020 M solution of fenitrothion in 0.898 M KOEt was followed via ^{31}P NMR over a period of 18 days. The initial reading showed a single peak at 67 ppm, corresponding to the chemical shift of **1**. As the reaction proceeded, two product peaks were observed: the first, at 72.6 ppm, was attributed to *O*-ethyl-*O*,*O*-dimethylphosphorothioate (**5**), the product of attack at the phosphorus centre, and the second, at 54.9 ppm, demethyl fenitrothion (**2**) from competitive nucleophilic attack at the methoxy carbon. These three peaks were monitored until no fenitrothion remained (ca. 6 h) at which point only the products were monitored.

Over the next 17 days, it was found that a consecutive reaction occurred involving **5**, which was seen to gradually disappear, while a new peak appeared at 58.6 ppm and was identified as dimethylphosphorothioic acid (**3**). The concentration of **2** remained constant throughout this interval. While **3** appears to be largely formed as a product of the consecutive reaction of **5** with KOEt, it is also possible that some amount of **3** may arise from a competitive S_NAr process occurring on **1**. Moreover, a consecutive reaction between **2** and KOEt could also give rise to **4**.

Unfortunately, the sensitivity of the ^{31}P NMR experiments was insufficient to conclusively determine whether or not S_NAr products were formed; if they were formed, the product concentration was below that observable using ^{31}P NMR. To determine whether or not an S_NAr process occurs, and if so, whether it occurs as a competitive or consecutive reaction, another product analysis experiment was undertaken using GC-MS.

The underlying principle of this experiment was that if **4** could be detected, the existence of an S_NAr pathway would be confirmed. Furthermore, given that **2** was found to be stable to KOEt (within the detection limits of NMR) for 17 days, following the disappearance of **1**, any consecutive process would be slow. Therefore, if **4** were to be detected while **1** was still in solution then the S_NAr process would indeed be competitive.

The results of this experiment are presented in Table 1. Importantly, the presence of **4** is detected within 30 min of initiation of the reaction, at which time **1** remains present in the reaction mixture. After 6 h, when **1** had disappeared from solution, the concentrations of both **2** and **4** remain almost constant, proving that **4** does not arise from a consecutive process on **2**. Therefore, fenitrothion is clearly subject to a competitive S_NAr process. Hence, it can be unambiguously concluded that the ethanolysis of fenitrothion entails a minor ($\leq$7%) S_NAr route taking place at the C-1 position of the aromatic ring. Furthermore, a slow consecutive process occurs on the phosphorus product of the S_N2 (P) pathway. The reaction processes are summarized in Scheme 1.



As the products of the S_NAr process accounted for not more than 7% of reaction (as determined by GC-MS), for the purposes of kinetic treatment the contribution of the S_NAr process to the overall rate is deemed to be essentially negligible, and for the sake of simplicity the kinetics are treated in terms of competitive processes arising from the S_N2 (C) and S_N2 (P) pathways. Thus the observed rate constants are dissected into an observed rate of attack at phosphorus (k'_P) and an observed rate of attack at the aliphatic carbon (k'_C), according to eqs. [1] and [2]:

$$[1] \qquad k_{obs} = k'_P + k'_C$$

[3] Tables of absorbances and rate constants (Tables S1–S3) and the derivation of eq. Scheme 1.

[2] $$\frac{k'_P}{k'_C} = \frac{[\mathbf{6}]}{[\mathbf{2}]}$$

The concentration of 3-methyl-4-nitrophenoxide ion (**6**) was determined directly from spectrophotometric measurements, while the concentration of **2** was determined by subtracting $[\mathbf{6}]_{inf}$ from $[\mathbf{1}]_o$.

The S_N2 (P) process: catalytic pathways revealed by a dichotomy in the behaviour of complexing agents

Phenomenology

To investigate the effect of aggregation of alkali metal ethoxides on the degradation processes, experiments were conducted with different concentrations of LiOEt, NaOEt, and KOEt (Table 2). While the concentration ranges that could be studied depended on the respective solubilities of the given alkali metal ethoxide in anhyd ethanol, it is evident that the effect of increasing [MOEt] is most pronounced with $M^+ = K^+$, and least pronounced where $M^+ = Li^+$.

It can be seen from the plots of k'_P vs. $[MOEt]_o$ (Fig. 1*a*, and expanded plot in Fig. 1*b*) that the apparent reactivity of these nucleophiles towards fenitrothion increases in the order LiOEt < NaOEt < KOEt (although the difference in reactivity between NaOEt and KOEt is not readily distinguished until higher concentrations are used). Note that, while reaction of fenitrothion with LiOEt yielded a linear plot of k'_P vs. $[LiOEt]_o$, *upward curvature* is seen in similar plots of k'_P vs. [NaOEt] and [KOEt], respectively. This upward curvature is more pronounced with KOEt than with NaOEt.

In previous studies investigating metal ion catalysis of reactions of phosphinate and sulfonate compounds with ethoxide ion in ethanol at 25°C (7–11), such upward curvature was attributed to the higher reactivity of the metal ethoxide ion pair compared with the free ethoxide anion. In such a scenario, the addition of macrocyclic complexing agents to the reaction system should result in a decrease in the rate of reaction at phosphorus. However, as can be seen in Fig. 2, at low concentrations of MOEt the addition of crown/cryptand complexing agents resulted in an *increase* in

Fig. 2. The effect of complexing agents on the reaction of fenitrothion with alkali metal ethoxides at 25°C. For attack at the phosphorus centre: ◆ 0.179 M KOEt in the presence of 18-C-6; ▲ 0.0535 M KOEt and [2.2.2] cryptand; ● 0.119 M LiOEt and [2.1.1] cryptand. The analogous open symbols (◇, △, ○) represent the observed rate of attack at the carbon centre under the same conditions.

the rate of attack at the phosphorus centre (Table S2, supplementary data). Thus, at low $[MOEt]_o$ free ethoxide is found to be *more reactive* than the metal ethoxide ion pair. Since the relative amount of free ethoxide decreases with increasing $[MOEt]_o$, the addition of complexing agents had a greater effect in the more concentrated MOEt solutions, where they allowed for the release of a proportionately larger quantity of free ethoxide. The low solubility of the complexing agents limited these experiments to situations where the initial concentration of MOEt used was below the level at which upward curvature is seen in Fig. 1. To accommodate both the low solubility of the complexing agents and the need to work at concentrations of KOEt where curvature was present, these experiments were repeated at 50°C (Table S3, supplementary data).[3]

Figure 3 shows the effect of KOEt on attack at phosphorus and at the aliphatic carbon at 50°C. At this temperature, note that for the trace representing attack at phosphorus, upward curvature begins at approximately 0.6 M KOEt (in contrast with the onset of curvature at 25°C, which occurs at about 0.3 M). Figure 4 depicts the effect of the macrocyclic complexing agent, dicyclohexyl-18-crown-6 (DC-18-C-6) on the ethanolysis reaction at 50°C in both 0.404 and 0.898 M KOEt. At 0.404 M KOEt, where the plot of k'_P vs. [KOEt] is essentially linear, the addition of DC-18-C-6 results in a *rate enhancement*, prior to the attainment of a plateau. The behaviour is similar to that observed at low concentrations of KOEt at 25°C. On the other hand, when the concentration of KOEt was increased to 0.898 M, the addition of DC-18-C-6 resulted in a *decreased rate* of attack at phosphorus (Fig. 4).

For the displacement reaction at the phosphorus centre, the fact that upward curvature in plots of k'_P vs. [MOEt] becomes apparent only at high [MOEt] (Fig. 3, at 50°C), coupled with the rate decrease observed upon addition of DC-18-C-6 (to sequester K^+ ions) to the reaction of fenitrothion with 0.898 M KOEt (Fig. 4), suggests that at high $[KOEt]_o$ an aggregative species of alkali metal ethoxide acts to catalyze the reaction. However, as noted above, addition of the same complexing agent to a lower concentration of KOEt (0.404 M) reacting with fenitrothion resulted in a rate increase, consistent with the results presented in Fig. 2 (using low concentrations of MOEt at 25°C).

The upward curvature observed in the plot showing rate dependence on alkali metal ethoxide concentration prompted an evaluation of the rate data using the H_M and J_E basicity functions (14, 15). The H_M scale refers to the basicity of alkali metal methoxide ions in methanol, at 25°C, and was developed using various weak acid indicators (e.g., 2-*tert*-butyl substituted phenols and 2,6-di-*tert*-butyl substituted phenols). On the other hand, Gold and Toullec's J_E scale was developed from equilibrium measurements of Meisenheimer adduct formation between 2,4-dinitrophenetole and alkali metal ethoxides in ethanol, at 25°C. Typically, when the enhanced basicity of the medium is responsible for increased reaction rates, a linear relationship between the acidity function and rate is observed. Under ideal circumstances, the

© 2001 NRC Canada

plots would not only be linear, but would have a slope of unity. However, there have been circumstances reported where the relationship was *linear with a nonunity slope* (14). In such cases, it was determined that the assumption that solvent activity remained constant was incorrect, and so solvent activity was corrected for, thus giving a unit slope. In the present study, plots of H_M and J_E vs. rate took the form of a gentle S-shaped curve, with initial slope 0.45 and a final slope of 0.58. From the overall nonlinearity of the plot, it was concluded that no correlation existed between the rate data reported here and either acidity function.

In summary, on the basis of the kinetic data described above for the complexing agents, we propose that the mechanism of ethanolysis involves the reactivity of three species of alkali metal ethoxides: free ethoxide, ion-paired alkali metal ethoxide, and a metal ethoxide aggregate present in equilibrium. In the following sections, the nature, reactivity, and role of the aggregate in the reaction under study will be carefully examined.

Catalysis by alkali metal alkoxide aggregates

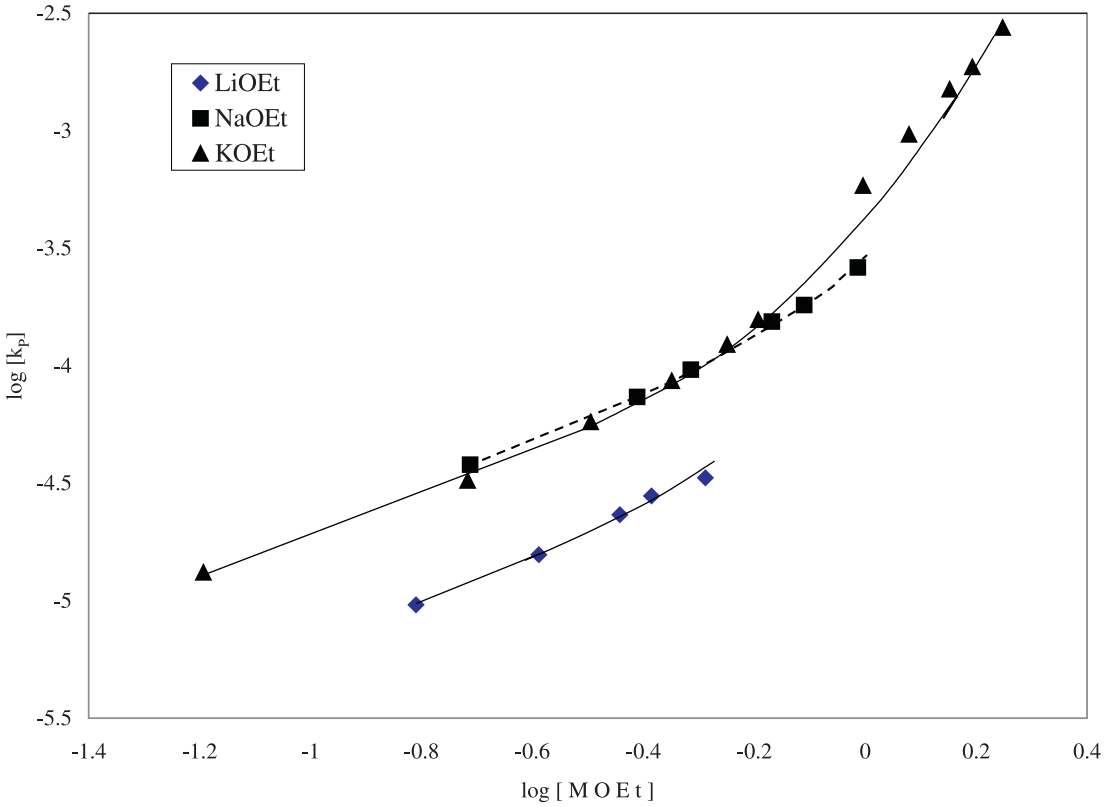
A variety of studies have shown that alkali metal alkoxides not only form ion pairs in solution but also are able to organize themselves into higher order aggregates (16–24). Dinnebier et al. (16*a*) reported on powder diffraction studies of alkali metal phenoxides in which a hexameric structure was assigned for C_6H_5OK, while Chisholm et al. (17) likewise showed the single-crystal X-ray structure of $LiOCMe_2Ph$ to be consistent with hexameric structures. In addition, using cryoscopy they showed that lithium *tert*-butoxide had a degree of aggregation of 6 in benzene. Generally, the smaller alkali metal *tert*-alkoxides form higher order aggregates than do larger alkali metals (K, Rb, Cs), which tend to adopt a tetrameric structure in benzene solution (18). Jackman and Rakiewicz (19), too, have documented cases of aggregate formation in solutions of lithium 2,6-dimethylphenolate and its isomer, lithium 3,5-dimethylphenolate (20), in THF, dioxolane, and diethyl ether. The former was found to exist as a dimer, whereas the latter formed tetrameric species.

The existence of these aggregates in solution cannot be regarded as inconsequential, as studies have shown that these clusters can be the primary reactants responsible for controlling reactivity (21–24). DePue and Collum (21) investigated the *N*-alkylation of lithium diphenylamide with *n*-butyl bromide in THF–hydrocarbon mixtures and found that the reaction could be explained in terms of catalysis by lithium diphenylamide monomers, in equilibrium with less reactive dimers. Furthermore, evidence of reaction involving free ions was inferred from the existence of a competitive elimination pathway which produced 1-butene. More recently, Streitwieser and co-workers (22, 23) investigated the alkylation of the cesium and lithium enolates of *p*-phenylisobutyrophenone in THF and found that the cesium enolate consisted of a mixture of monomeric, dimeric, and tetrameric species in THF solution, with monomers being most reactive. The lithium enolates, meanwhile, were found to exist in monomeric and tetrameric forms, again with monomers making the largest contribution to rate, even in situations where the tetramer was the predominant species. Although the preceding studies generally found monomeric forms to be more reactive than higher order aggregates, the recent study by Gagne and co-workers (24) of the ester metathesis reaction between *tert*-butyl acetate and various methyl esters in hexane showed that alkali metal *tert*-butoxides possessing a higher degree of aggregation (i.e., hexamers) can be more reactive than their less aggregated counterparts (i.e., tetramers).

It is critical to note that these previous kinetic studies involving aggregated alkali metal alkoxides have generally been performed in nonpolar, aprotic solvents. How then can these studies be applied to the behaviour of alkali metal ethoxides in ethanol?

The speciation of the alkali metal ethoxide in solution spans the general continuum given in eq. [3] (25, 26).

$$[3]\quad \underset{\text{(Free ions)}}{M^+ + {}^-OEt} \rightleftharpoons \underset{\text{(SSIP)}}{M^+ \,//\, {}^-OEt} \rightleftharpoons \underset{\text{(CIP)}}{(M^+\,{}^-OEt)} \rightleftharpoons \underset{\text{(Dimer)}}{(M^+\,{}^-OEt{:}\,M^+\,{}^-OEt)} \rightleftharpoons \underset{\text{(Higher order aggregate)}}{(M^+\,{}^-OEt)_n}$$



The position of the equilibrium in this continuum is significantly affected by the ability of the solvent to support charge separation. Aprotic donor solvents such as THF might reasonably be expected to better solvate cationic species than aprotic, nondonor, nonpolar solvents such as hexane. Consequently, it is not surprising that aggregates of higher order (i.e., hexamers (24)) are present in hexane than are normally found in THF (in which dimeric and tetrameric aggregates predominate (19–23)). Extending this rationale to polar, protic solvents such as ethanol, the ability to support charge separation is enhanced via hydrogen-bonding interactions, leading to the reasonable expectation that charge separated, rather than highly aggregated, species will be favoured and that the maximum aggregate size will be lower than in nonpolar, aprotic solvents.

It has been suggested that in *dilute* alkali metal ethoxide solutions in ethanol, contact (or solvent separated) ion pairs are the dominant associated species (25, 26). However, as the total base concentration increases, the equilibrium depicted in eq. [3] shifts to the right (i.e., towards higher order aggregates). Conversely, an increase in temperature results in a leftward shift in the aforementioned equilibrium, towards free ethoxide. In ethanol, at concentrations of less than 0.3 M, at 25°C, the two alkali ethoxide species present in solution are considered to be free ions and monomeric alkali metal ion pairs (SSIP and CIP).

Consequently, in the low-concentration range of MOEt used in this study, the main species in solution are known to be free ions in equilibrium with ion-paired alkali metal ethoxide. However, as $[MOEt]_o$ is increased, higher order aggregates would be expected to form. Plots of log k'_P vs. log $[MOEt]_o$ can be used to provide evidence of this type of behaviour (24). Upon examination of these plots (Fig. 5), one observes that the slope is generally near unity when $[MOEt]_o < 0.45$ M. However, above this concentration the plots begin to exhibit curvature, with LiOEt reaching a final slope of 1.3, NaOEt attaining a value 1.7, and KOEt achieving a slope of 3.1. Once again, it should be noted that the

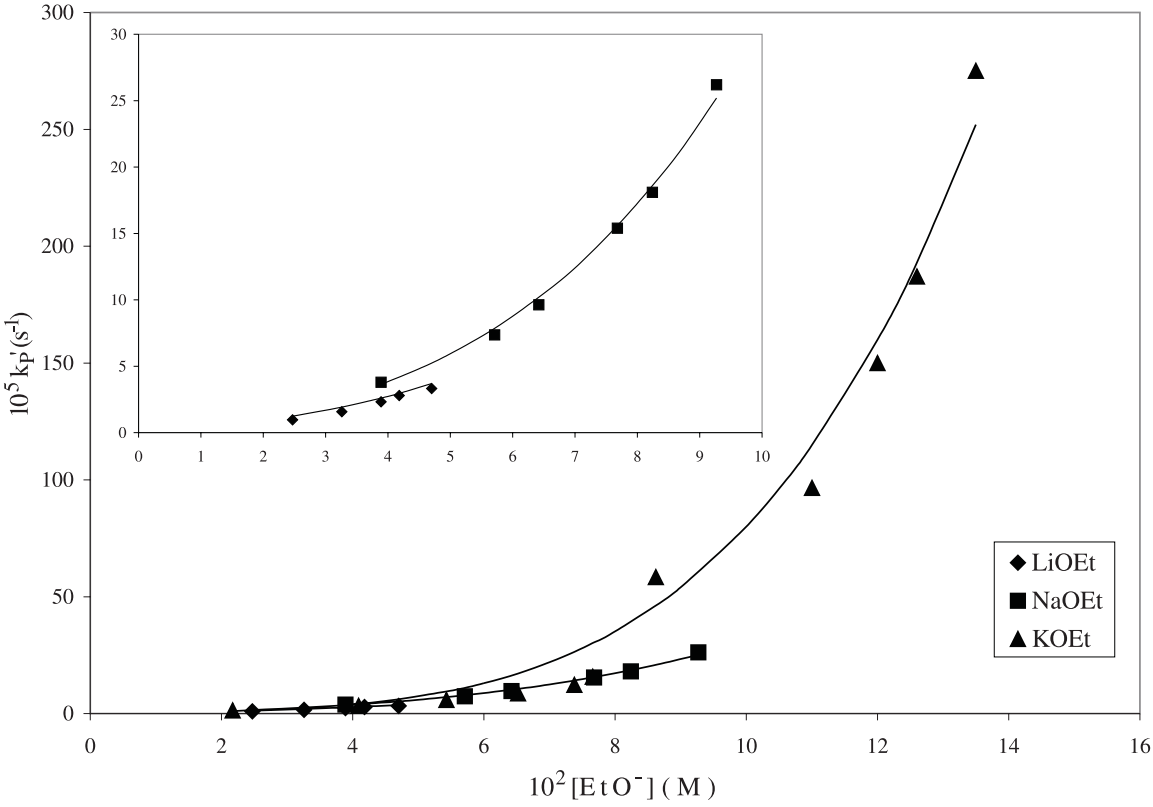
Fig. 5. Graph showing the variation of reaction order with MOEt concentration in order to detect the participation of alkali metal ethoxide aggregates in the ethanolysis of fenitrothion.

lower solubilities of both LiOEt and NaOEt precluded their use at higher concentrations (as were used with KOEt), where one expects that the slopes of the curves would continue to increase in the same manner as that observed with KOEt.

The non-unity orders in MOEt may be explained in terms of the equilibrium between the reacting species depicted in eq. [3]. If one of the kinetically active species is present in a smaller concentration than another, a perturbation in the log–log plot ensues (24). Gagne and co-workers (24) used such an argument in rationalizing the nonunity slope of log–log plots of the ester metathesis reaction, concluding that in hexane, NaO-*t*-Bu exists predominantly as a tetramer in equilibrium with a more reactive hexamer. Applying a similar argument to the system under study here, it appears reasonable that the upward curvature seen in the high-concentration region of plots of log k'_P vs. log $[MOEt]_o$ can be attributed to the formation of alkali metal ethoxide clusters that are more reactive than either the free ethoxide or ion-paired metal ethoxide. If the dimers depicted in eq. [3] are taken to be the said species of clustered alkali metal ethoxide, the overall reaction order would approach 4.0, a point worth bearing in mind in the subsequent discussion.



The significance of the behavioural dichotomy of crown/cryptand complexing agents

To further investigate the hypothesis that the formation of reactive alkali metal ethoxide aggregates was responsible for catalyzing fenitrothion ethanolysis, varying concentrations of the macrocyclic complexing agent DC-18-C-6 were added to the reaction of fenitrothion and KOEt, where [KOEt] was high enough that curvature was present in Fig. 3. As stated earlier, this required performing the experiment at 50°C in order to be able to add sufficiently high concentrations of DC-18-C-6. It should be noted that at 50°C, curvature is observed in plots of k'_P vs. $[KOEt]_o$ only when $[KOEt]_o$ > 0.6 M (Fig. 3). This observation is itself consistent with the idea that alkali metal ethoxide aggregates play a role in the reaction, since an increase in temperature would shift the equilibrium away from aggregate formation (26). When the 50°C experiment was performed at 0.404 M KOEt (where plots of k'_P vs. $[KOEt]_o$ are not curved), it was found that the addition of increasing amounts of DC-18-C-6 resulted in a *rate increase* for attack at phosphorus, up to a maximum rate at which a plateau resulted. However, at 50°C and 0.898 M KOEt (where curvature is present), addition of increasing amounts of DC-18-C-6 resulted in a *decreased rate* of attack at the phosphorus centre, once again, culminating in a plateau. *These findings confirm the existence of two regimes of reactivity: a low-concentration regime where free ethoxide anions are more reactive than ion-paired metal ethoxide, and a high-concentration regime where free ethoxide anions are less reactive than are the alkali metal ethoxide clusters.*

Considering that polar, protic solvents are better able to support charge separation than nonpolar, aprotic solvents and that aggregation numbers in alcoholic solutions tend to decrease with decreasing alkyl chain length (26), taken together with the fact that the plot of log k'_P vs. log $[KOEt]_o$

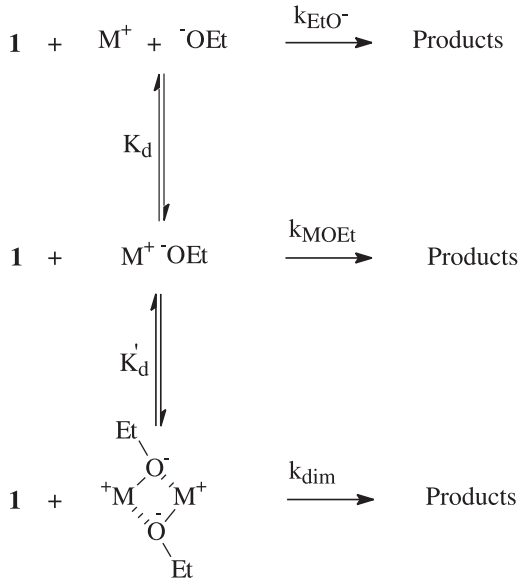
Fig. 6. The fit of the data to eq. [4] for reaction at the phosphorus centre (k'_P) of fenitrothion with MOEt. The inset omits overlapping data from KOEt, leaving only the data for LiOEt and NaOEt.

(Fig. 5) shows a reaction order greater than 3, we suggest that the two regimes of reactivity are as follows. At low concentrations of MOEt, the metal ethoxide is largely present as ion-paired ethoxide in equilibrium with free ethoxide (25, 26), but as the concentration of MOEt increases, the contribution of alkali metal ethoxide dimers to the rate of ethanolysis becomes significant. Based on the dichotomy in the behaviour of the complexing agents, the following relationships hold in terms of reactivity: $k^P_{dim} > k^P_{EtO^-} > k^P_{MOEt}$.

Thus, the reaction of fenitrothion with MOEt is depicted in Scheme 2, where k'_P is expressed as:



$$[4] \qquad k'_P = \frac{k^P_{dim}}{K'_d K_d}[EtO^-]^4_{eq} + \frac{k^P_{MOEt}}{K_d}[EtO^-]^2_{eq} + k^P_{EtO^-}[EtO^-]_{eq}$$

A full derivation of eq. [4] is given in the Appendix, supplementary data.[3] The fit of the data (using GraphPad Prism, a nonlinear least-squares-fitting program) to eq. [4] is shown in Fig. 6. For both LiOEt and NaOEt, the fits are good with correlation coefficients (R^2) of 0.987 and 0.995, respectively, while for KOEt also a reasonable fit (R^2 = 0.981) was obtained.

The terms in eq. [4] are as follows:

K_d represents the dissociation constant for ion-paired metal ethoxide in ethanol at 25°C and is available from the literature (27).

Scheme 2.

K'_d represents the dissociation constant for the alkali metal ethoxide dimer, and k^P_{dim} denotes the reactivity of the dimer for attack at the phosphorus centre of fenitrothion. The ratio k^P_{dim}/K'_d was obtained using GraphPad Prism. For KOEt, $k^P_{dim}/K'_d = 7.94 \times 10^{-2}$ M^{-2} s^{-1}; for NaOEt, 1.31×10^{-2} M^{-2} s^{-1}; and for LiOEt, 5.00×10^{-3} M^{-2} s^{-1}.

k^P_{MOEt} is defined as the reactivity of ion-paired metal ethoxide towards attack at the phosphorus centre. With

Note: The values are calculated based on the fit obtained to eq. [4], and the calculated values are compared to the k_P' values determined experimentally at 25°C.

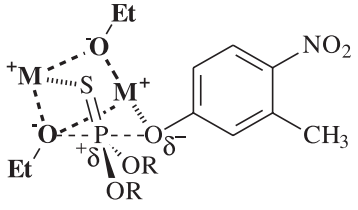
[a]Due to the low solubilities (at 25°C) of LiOEt and NaOEt, experiments could not be run at these concentrations. However, theoretical values were obtained by calculation from eq. [4].

KOEt, it was determined from the various experiments involving complexing agents as being 6.45×10^{-5} M^{-1} s^{-1}. This was done by first determining the value for $k^P_{EtO^-}$ (as outlined below), and since dimers are not present at the low $[KOEt]_o$ at which $k^P_{EtO^-}$ was determined, the first term on the right-hand side of eq. [4] becomes negligible. Using the value for k^P_{obs} obtained in the absence of complexing agent, the resulting simplified version of eq. [4] was solved for k^P_{MOEt}. In the case of NaOEt and LiOEt, this parameter was determined using GraphPad Prism. For NaOEt, k^P_{MOEt} was 1.46×10^{-4} M^{-1} s^{-1}, while for LiOEt a value of 4.01×10^{-5} M^{-1} s^{-1} was obtained.

$k^P_{EtO^-}$, the reactivity of free ethoxide anion towards the phosphorus centre, was experimentally determined from the complexing agent studies to be 2.76×10^{-4} M^{-1} s^{-1}. This was done by dividing the rate constant (k_P') at the plateau observed in Fig. 2 by $[MOEt]_o$. The concentration of free ethoxide at equilibrium is given as $[EtO^-]_{eq}$ in eq. [4].

Although differences in solubility limited the range over which LiOEt and NaOEt could be used in comparison with KOEt, the theoretical curves for both metals are calculated to cover the same range as covered using KOEt (Table 3).

It is seen from Table 3 that for all three metal ethoxide systems, the reactivity proceeds in the order: dimer > free ethoxide ion > ion-paired metal ethoxide, with dimerized KOEt being more reactive than dimerized NaOEt, which is in turn more reactive than dimerized LiOEt. The contribution made by each species to the observed rate of nucleophilic displacement at phosphorus is itemized in Table 3. It is readily apparent from the Table that at lower concentrations of MOEt, the putative contribution of the alkali metal ethoxide dimer is much less than that of the free



© 2001 NRC Canada

ethoxide or ion-paired metal ethoxide. However, at higher concentrations of MOEt, the contribution of the dimer to the overall rate becomes much more significant, which in the case of LiOEt causes the *relative* contribution of ion-paired metal ethoxide to decrease from an apparent maximum.

Further evidence of metal ion involvement in accelerating fenitrothion ethanolysis was found by carrying out reactions in the presence of additional K^+ ions, in the form of an unreactive salt, potassium acetate (Table 4). In this case, there was an *increase in the rate of attack at phosphorus*. We suggest then that the addition of KOAc shifts the equilibrium towards the more reactive dimer, resulting in the observed rate increase. The nature of the aggregate itself is unclear at this time, given that not only are pure KOEt dimers possible but so too are mixed dimers involving both KOEt and KOAc (19, 20). Regardless of the nature of the dimer, it is certain that ethoxide (not acetate) acts as the nucleophilic species, since a mixture of fenitrothion and KOAc (such that the total K^+ concentration used was equivalent to that at the highest ratio of [KOAc]/[KOEt] reported in Table 4) did not result in any reaction over 7 days. In fact, since the pK_a of acetic acid in ethanol is 10.32 (28) and the autoprotolysis constant for ethanol (at 25°C) is 3×10^{-20} (29), the equilibrium constant for the reaction of acetate with ethanol is calculated to be 1.5×10^{-10}. Therefore, the expected concentration of ethoxide would be 1.58×10^{-5} M, giving an estimated rate constant of 4.35×10^{-9} s^{-1} (i.e., a half-life of approximately 5 years)!

Structure of the fenitrothion-dimeric metal ethoxide transition state

The greater reactivity of the alkali metal ethoxide dimers can be rationalized upon consideration of structure **7**, depicting the transition state (TS) for the reaction of fenitrothion with the MOEt dimer species. Although structure **7** depicts a TS for a concerted S_N2 (P) process (2), it should be noted that previous studies on similar phosphorus-centred systems have found that reaction can occur as a two-stage process, via a penta-coordinate intermediate, with nucleophilic attack being rate-determining (8). However, as both scenarios have identical rate laws, structure **7** was chosen for simplicity. In this structure, the dimer plays several roles which contribute to stabilization of the incipient negative charge of the transition state. First, alkali metal interaction with the aryl oxygen neutralizes the developing charge on the leaving group, thus enhancing its nucleofugality. Second, alkali metal can bind to the polarizable sulfur atom, leading to increased electrophilicity at the phosphorus centre. Finally, the transition state depicted in structure **7** allows one metal ethoxide ion pair in the dimer to align the ethoxide of the other pair in the best orientation for backside nucleophilic attack.

7

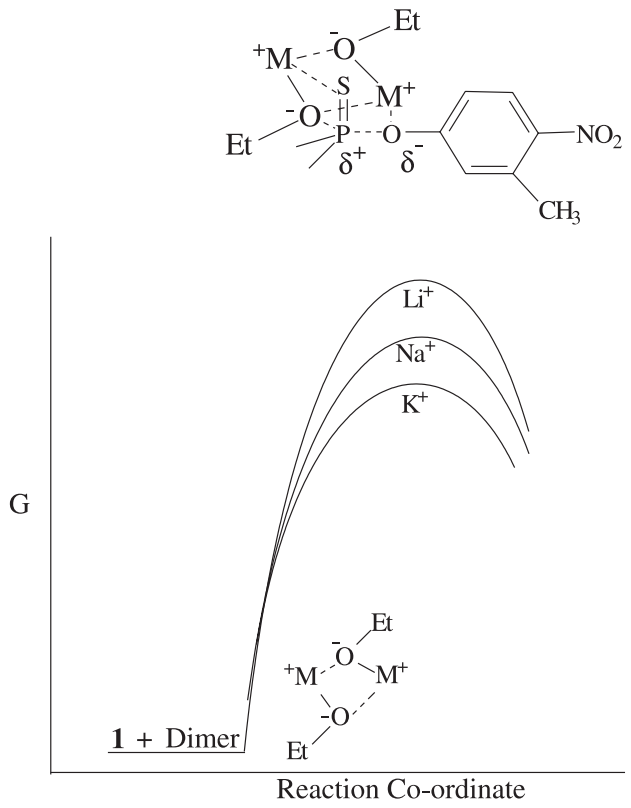
Table 4. Pseudo-first-order rate constants for the reaction of fenitrothion with 0.025 M KOEt in the presence of added KOAc, at 25°C. k_{obs} are dissected as shown in eqs. [1] and [2].

[KOAc]/[KOEt]	$10^6 k_{obs}$ (s^{-1})	$10^6 k'_P$ (s^{-1})	$10^6 k'_C$ (s^{-1})
0	8.30	4.37	3.93
2.32	8.30	5.22	3.08
4.20	8.80	5.92	2.88
6.96	10.3	7.32	2.98
8.82	12.2	9.17	3.03
11.2	13.8	11.3	2.50

The multiple points of attachment afforded by the dimers are not available with either the singly ion-paired metal ethoxide or the free ethoxide anion, and thus the dimer is more reactive than both. The finding that free ethoxide is more reactive than ion-paired metal ethoxide is consistent with conventional wisdom, which suggests that in nucleophilic displacement reactions, the free (dissociated) nucleophile should be more reactive than an ion-paired species. Note, however, that such is not always the case, as previous studies using phosphorus- and sulfur-centred esters (7–11) have found. Ion-paired alkali metal ethoxide in fact served to catalyze the ethanolysis reaction. We will return to the contrast between catalysis in P=O systems and P=S systems later in this discussion.

Selectivities of alkali metal ethoxides (Eisenman theory)

An explanation for the relative ordering in metal reactivities arises from Eisenman theory, which was originally posited to explain alkali metal ion selectivity patterns for ion-exchange resins and glass electrodes (30). According to Eisenman, two competing factors govern the nature of cation interactions with a fixed anionic species. The first is the attractive electrostatic interaction, which is the energy gained when ions of opposite charge approach one another. The second factor is the free energy expended to rearrange the solvent molecules around the ions to allow for close approach (or contact) of the two ionic species. The free energy involved in the latter would be closely related to the standard free energy of hydration for the ions involved. Therefore, the free energy required for the displacement of cation 2 by cation 1 ($\Delta G^\circ_{1/2}$) on a fixed anion grouping can be expressed as



$$[5] \qquad \Delta G^\circ_{1/2} = \left(\frac{e^2}{r_A + r_2} - \frac{e^2}{r_A + r_1} \right) - (\Delta G_2 - \Delta G_1)$$

where r_A is the radius of the anion, r_1 and r_2 are the ionic radii of cations 1 and 2, respectively, ΔG_1 and ΔG_2 are the solvation energies of the cations, and e is the electronic charge. If $\Delta G^\circ_{1/2}$ has a negative value, the anion exhibits selectivity towards cation 1, and conversely, a positive value for $\Delta G^\circ_{1/2}$ results in selectivity towards cation 2.

Consider now a case where r_A is large (i.e., low field strength anion or an anion with delocalized charge). In such a scenario, the first bracketed term in eq. [5] will be small, and $\Delta G^\circ_{1/2}$ will be determined by the solvation energy term of eq. [5]. Hence, one expects the selectivity to decrease in the order $K^+ > Na^+ > Li^+$. However, for high electric field

© 2001 NRC Canada

Fig. 7. Free energy reaction profile for the reaction at the phosphorus centre of fenitrothion with MOEt dimers, with the relative ordering of both the ground state and transition state energies being determined using Eisenmann theory. Note that the transition state structure has a more dispersed negative charge than present in the ground state, which accounts for the reversal of the transition state stabilities.

strength anions (i.e., r_A is small and charge is localized) electrostatic attraction overcomes cation solvation and selectivity proceeds as $Li^+ > Na^+ > K^+$, as predicted by Coulomb's law. As the electric field strength of the anion is varied between these extremes, intermediate selectivity sequences are observed. Although originally designed for predicting anion interactions with ion-exchange resins, Buncel and co-workers (11) showed that the principles of Eisenman theory could be applied to chemical kinetics. In their study, the reaction of a variety of phosphinate and sulfonate esters (PO and SO_2 centres) with alkali metal ethoxides was described. It was found that the sequences for the transition states for reaction with the phosphinates were all located at the high electric field strength end of the spectrum, while the sulfonate esters exhibited selectivities at the opposite extreme.

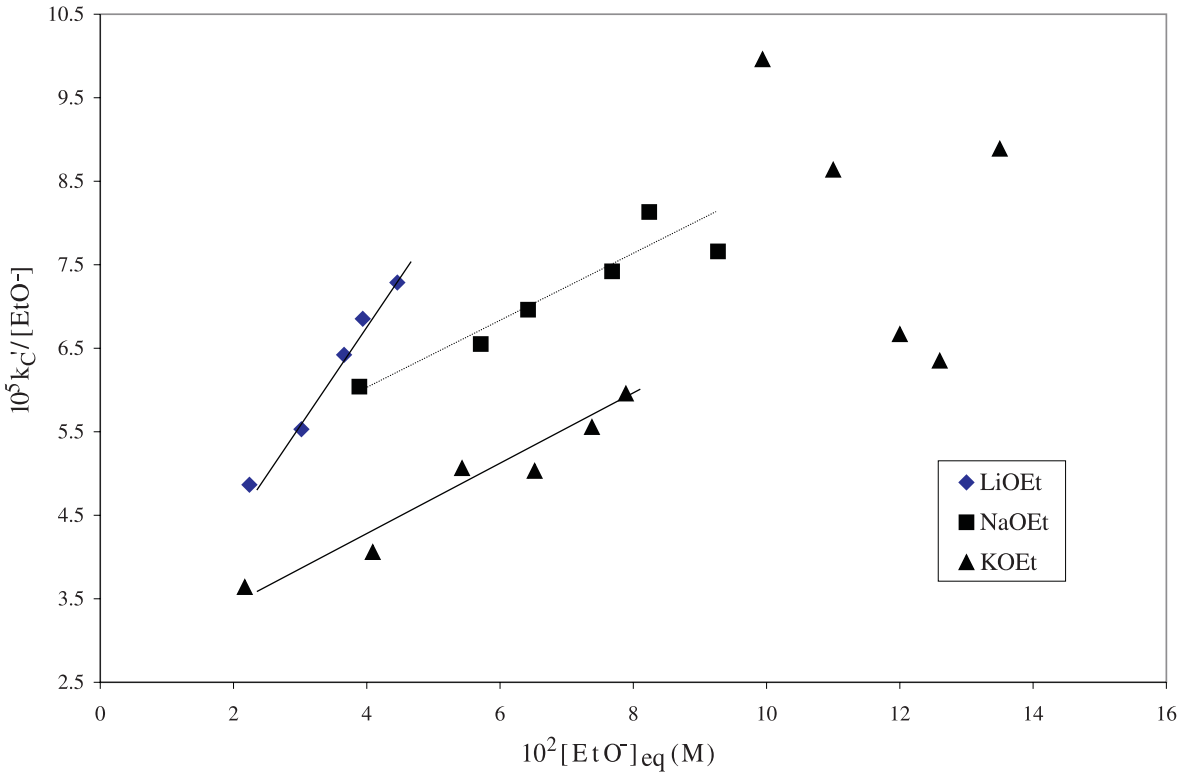
Returning once again to structure **7**, a comparison of the transition states based on Eisenman theory predicts the following. In the transition state, a negative charge is delocalized amongst the dimeric nucleophile, sulfur, and leaving group oxygen. Consequently, Eisenman theory predicts that the transition state stabilization depicted in Fig. 7 proceeds as: KOEt > NaOEt > LiOEt, and therefore, the rate of reaction at the phosphorus centre of fenitrothion with dimerized alkali metal ethoxides should proceed in the observed order, i.e., KOEt > NaOEt > LiOEt.

A comparison of P=S and P=O systems

Previous studies (7–11) have found that singly ion-paired metal ethoxide species are more reactive than the free ethoxide anion with respect to attack at P=O centres. However, in this work we report that the opposite holds true at the P=S centre of fenitrothion, indicating that ion-paired alkali metal ethoxide is *less* associated with the transition state in the P=S system than in the P=O system.

A possible explanation of this reversal arises from Hard–Soft Acid Base (HSAB) theory (31). According to this theory, Li^+, Na^+, and K^+ ions are classified as "hard". In the P=O system, the $P^+–O^-$ canonical form makes a significant contribution to the overall hybrid. Consequently, the P centre bears significant positive charge and would be considered hard, while the corresponding negative charge on the oxygen renders the oxygen hard as well. Since ethoxide anion is also deemed hard, it would have a favourable interaction with the formally positive phosphorus atom. Furthermore, the hard metal cation would preferentially associate with the hard phosphoryl oxygen. In the case of EtO^- alone, there is only the hard–hard interaction with the P centre, and thus the ion-paired metal ethoxide has more favourable interactions with the P=O centre than does free ethoxide alone.

However, in the P=S system, the comparable $P^+–S^-$ form would not be expected to contribute as significantly; there would be good *p–p* overlap between P and S bonding orbitals. As a π-bonded moiety, P=S would be more polarizable than P=O, and the less electronegative sulfur, therefore, would be considered "soft". The P centre, by contrast, is bonded to three attached oxygen substituents that effectively withdraw electron density from the P centre so that it remains hard, although arguably less hard than the P site of the comparable P=O system. Consequently, the interaction of the ethoxide anion (hard) with the phosphorus atom remains favoured, but the interaction between alkali metal cation and the sulfur atom is not. Therefore, ion-paired metal ethoxide is predicted to be *less* reactive than free ethoxide at a P=S centre, exactly as was observed here.



The S_N2 (C) process

In their studies of the reaction between methyl 2,4-dinitrophenyl phosphate monoanion and a variety of weakly nucleophilic phenolates, Kirby and Younas (4*a*) found all three reaction pathways (S_N2 (C), S_N2 (P), and S_NAr) to be operative. In contrast to what is reported here, Kirby reported that the S_N2 (C) pathway was not significant in comparison to the S_N2 (P) and S_NAr processes. However, in their studies using 2-(substituted phenyl)-2-oxo-1,3,2-dioxaphosphorinans, Kirby and Khan found that reaction proceeded exclusively via cleavage of the P—OAr bond (4*b*). Thus, it may be that the S_NAr process observed with methyl 2,4-dinitrophenyl phosphate monoanion was a consequence of electrostatic repulsion between the nucleophile and the phosphorus centre that would reduce reactivity at P, coupled with an aromatic ring which was activated towards S_NAr reaction by the presence of two nitro groups.

In the case of fenitrothion, since there is only one electron-withdrawing nitro group on the aromatic ring, the ring-carbon

© 2001 NRC Canada

Fig. 8. The fit of the data for the S_N2 (C) reaction of fenitrothion with LiOEt, NaOEt, and KOEt to eq. [7].

is unlikely to be sufficiently electron deficient to favour an S_NAr reaction (32). Consequently, the S_NAr process on fenitrothion becomes a minor reaction pathway.

On the other hand, reaction at the aliphatic methoxy carbon was observed by Greenhalgh et al. (5*b*) in fenitrothion hydrolysis under acidic conditions. Under alkaline conditions, Me—O bond fission was not observed.

The observed rate behaviour for S_N2(C) displacement reactions at the aliphatic centre of fenitrothion (Figs. 1*c* and 3) shows no evidence of metal ion catalysis with any of the nucleophiles used. In fact, the plots of k_c' vs. $[MOEt]_o$ exhibit, within experimental error, downward curvature. It should be noted that the error bars are larger at higher $[MOEt]_o$, owing mainly to uncertainty in the concentration of **2**, which was determined by subtracting the measured concentration of **6** (the product of attack at phosphorus) from the initial fenitrothion concentration. For example, when $[KOEt]_o$ = 1.56 M, the measured absorbance for the phenoxide product was 1.39 ± 0.01. For the reaction to proceed exclusively by attack at phosphorus, the expected infinity absorbance is 1.45. The difference, then, is due to products arising from the S_N2(C) pathway, and accounts for 0.06 ± 0.01 absorbance units, a relative uncertainty of ca. 17%. With this level of uncertainty in some of the data points, one might be tempted to state that plots of k_c' vs. $[MOEt]_o$ are, within error, linear. In principle, a linear second-order plot would suggest that all forms of the nucleophile (i.e., free ethoxide, ion-paired metal ethoxide, and dimers) are equally reactive, contradicting the observed findings from the addition of complexing agents (Figs. 2 and 4), which showed that for attack at the aliphatic centre, *free ethoxide is more reactive* than either ion-paired or dimerized alkali metal ethoxide.

The suggested downward curvature in Figs. 1*c* and 3 is not unprecedented. For other S_N2 reactions at carbon, downward curvature in a second-order plot has been shown to indicate that dissociated anions are more reactive than are ion-paired anions (33, 34), exactly as is observed in this study. The addition of KOAc to the reaction of fenitrothion with 0.025 M KOEt (Table 4), which results in a right-ward shift of the equilibrium depicted in Scheme 3, confirms this finding, as evidenced by the corresponding decrease in the values for k_c'.

For reaction at the aliphatic centre, Scheme 2 continues to apply except that where the reactivity order for reaction at phosphorus was dimers > free ethoxide > ion-paired metal ethoxide, as discussed above, the S_N2(C) reaction proceeds in the order: free ethoxide > dimers, ion-paired metal ethoxide (with no distinction possible between the reactivities of these latter two species). The experimental data should fit eq. [6] (derived in the same manner as eq. [4]):

$$[6] \qquad \frac{k_c'}{[EtO^-]_{eq}} = \frac{k_{dim}^C}{K_d' K_d}[EtO^-]_{eq}^3 + \frac{k_{MOEt}^C}{K_d}[EtO^-]_{eq} + k_{EtO^-}^C$$

where k_{dim}^C is the rate of reaction due to dimerized metal ethoxide, and K_d' is the dissociation constant of said dimers. Since k_{dim}^C is less than $k_{EtO^-}^C$, and the values for $[EtO^-]^3$ are much smaller than those for $[EtO^-]$, the first term on the

© 2001 NRC Canada

right-hand side of eq. [6] is treated here as being negligible, and eq. [6] reduces to a convenient linear equation, eq. [7].

$$[7] \qquad \frac{k'_c}{[EtO^-]_{eq}} = \frac{k^C_{MOEt}}{K_d}[EtO^-]_{eq} + k^C_{EtO^-}$$

The essentially linear fit of the data to eq. [7] is shown in Fig. 8.

The average $k^C_{EtO^-}$ value obtained from the plots is 3.18×10^{-4} M^{-1} s^{-1}, whereas the experimentally determined $k^C_{EtO^-}$ value is $(2.39 \pm 0.53) \times 10^{-4}$ M^{-1} s^{-1}. Given that the experimentally determined value for k^C_{EtO-} was obtained at low $[MOEt]_o$ (i.e., where the relative error in the final absorbance measurements was smaller than at the higher $[MOEt]_o$ included in the fitting to eq. [7]), it can be stated that the theoretical and experimental $k^C_{EtO^-}$ values are largely in agreement.

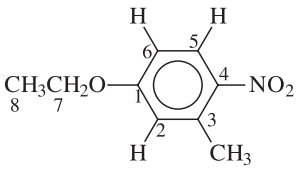
Leaving group pK_a values can largely explain why no metal ion catalysis is observed for the $S_N2(C)$ process yet is observed for attack at phosphorus. For metal ion catalysis to be observed, the metal ion (either as an ion pair with ethoxide or as a dimer) must participate in stabilizing the rate-determining transition state. For the $S_N2(C)$ pathway, the estimated pK_a of demethyl fenitrothion of 2.15 (based on the pK_a of H_3PO_4 (35)) is sufficiently low that metal ions are not required to stabilize the rate-determining transition state, whereas the conjugate acid of the aryl oxide leaving group for the reaction at phosphorus has a pK_a of 7.15, and can thus be stabilized by metal ion interactions.

The fact that higher MOEt concentrations favour attack at phosphorus further suggests that the geometry of the dimer (as shown in **7**) is better suited for attack at the phosphorus centre rather than the aliphatic carbon. A significant part of the catalytic role of the dimer thus appears to be the ability to orient the nucleophile towards nucleophilic attack, a function the dimer cannot perform for the $S_N2(C)$ degradation pathway.

Experimental

Materials

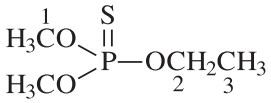
Anhydrous ethanol was obtained by refluxing absolute ethanol with magnesium turnings in the presence of iodine followed by distillation. Solutions of potassium or sodium ethoxide were prepared by dissolving clean potassium or sodium metal (Aldrich) in anhyd ethanol at 0°C, under nitrogen. Lithium ethoxide solutions were prepared in a similar manner by dissolving lithium hydride (Alfa–Aesar) in dry ethanol. If required, the ethoxide solutions were filtered at the end of the reaction in the glove box under nitrogen to remove any insoluble materials. The concentration of base was determined by titration with anhyd potassium hydrogen phthalate (KHP, VWR). All other chemicals were purchased from Aldrich unless otherwise indicated.



The macrocyclic complexing agents that were purchased from Aldrich were dicyclohexyl-18-crown-6 (DC-18-C-6), 18-C-6, [2.2.2] cryptand, and [2.1.1] cryptand. Potassium acetate (KOAc) was purchased from VWR. All were used without further purification.

The fenitrothion (96.7%) used in this study was a gift from Sumitomo Chemicals (Japan) and was purified as follows. Fenitrothion was loaded directly onto the head of a column (34 × 5 cm) of silica gel (wet-packed with hexane) and eluted using successive volumes of hexane (800 mL, discarded) and toluene (1600 mL). The toluene fraction was collected in a round-bottom flask and the solvent removed under reduced pressure, at a temperature not greater than 40°C in order to avoid the possible isomerization of fenitrothion (36, 37). The purity of the product was verified by both GC-MS and NMR (13).

Synthesis of authentic standards

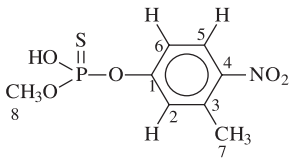


3-Methyl-4-nitro-ethoxybenzene

To 5-fluoro-2-nitrotoluene (0.500 g, 3.22×10^{-3} mol) was added DABCO (1,4-diazabicyclo[2.2.2]octane, 1.1 equiv) and KOEt (0.896 M, 1.1 equiv) in anhyd ethanol (95 mL), and the solution was allowed to stir overnight in a nitrogen dry box. Iced 20% v/v HCl (200 mL) was added, and the cloudy solution was reduced by rotary evaporation at which point the flask was left in a refrigerator overnight. The crystals were then filtered, recrystallized from water, and dried in an Abderhalden drying pistol, yield 20%: mp 54–54.3°C (lit. (38): 53–55°C). EI-MS (solvent: chloroform) *m/z*: 181.2. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.43 (t, $^3J_{H7–H8}$ = 7.00 Hz, 3H, C*H*$_3$CH$_2$O-), 2.61 (s, 3H, 3-C*H*$_3$ aryl ring), 4.09 (q, $^3J_{H8–H7}$ = 7.00 Hz, 2H, CH$_3$C*H*$_2$O-), 6.78 (m, 2H, *H*-2, -6), 8.06 (dd, $^3J_{H6–H5}$ = 8.60, $^4J_{H2–H5}$ = 2.68 Hz, 1H, *H*-5).

O-Ethyl-O,O-dimethylphosphorothioate

To *O,O*-dimethylthiophosphoryl chloride (3.966 g, 0.0247 mol) was added KOEt (0.898 M, 1.1 equiv) in anhyd ethanol (47 mL), and the solution was allowed to stir overnight. The precipitate (KCl) was removed by filtering the mixture through a bed of celite, and the remaining ethanol was removed under reduced pressure without the application of heat. The resulting pale yellow oil was purified by flash chromatography using 4:1 diethyl ether : chloroform as eluent. The final product was a pale yellow oil. EI-MS (solvent: chloroform) *m/z*: 170.0. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.33 (td, $^3J_{H2–H3}$ = 9.20, $^4J_{P–H}$ = 0.40 Hz, 3H, C*H*$_3$CH$_2$O-), 3.74 (d, C*H*$_3$O-, $^3J_{P–H}$ = 9.00 Hz, 6H), 4.13 (qd, $^3J_{H3–H2}$ = 9.20, $^3J_{P–H}$ = 1.80 Hz, 2H, CH$_3$C*H*$_2$O-). ^{13}C NMR (400 MHz, $CDCl_3$) δ: 16.19 (C-3), 54.76 (C-1), 64.85 (C-2). ^{31}P NMR (400 MHz, DMSO-d_6, relative to 85% H_3PO_4) δ: 72.78.



Demethyl fenitrothion

Following the procedure of Chambers and Matthews (39), fenitrothion (1.3227 g, 4.77×10^{-3} mol, Sumitomo Chemicals) was added to KBr (0.596 g, 1.05 equiv) in methanol (25 mL), and the solution was brought to reflux for 20 h, with stirring,

© 2001 NRC Canada

while argon was passed through the solution to ensure that the methyl bromide byproduct was removed (thus preventing *S*-methylation of demethyl fenitrothion). The methanol was then removed under reduced pressure at which point the residual fenitrothion was dissolved in diethyl ether, and the demethyl fenitrothion salt was extracted into water. The water was acidified using an excess of HCl, and another extraction with diethyl ether was performed. The diethyl ether was then removed under reduced pressure, yielding a pale yellow oil. GC-MS(EI) (solvent: $CDCl_3$; using GC parameters outlined below) *m*/*z*: 263 (GC peak at 20.65 min). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.63 (s, 3H, aryl-C*H*$_3$), 3.92 (d, $^3J_{P-H}$ = 14.1 Hz, 3H, C*H*$_3$O-), 6.15 (s, 2H, -O*H*), 7.21 (d, $^3J_{H5-H6}$ = 9.0 Hz, 2H, *H*-2,-6), 8.05 (d, $^3J_{H6-H5}$ = 9.0 Hz, 1H, *H*-5,). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 21.2 (C-7), 55.5 (C-8), 119.6, 125.1, 127.1 (C-2,5,6), 136.8, 146.2, 153.9 (C-1,3,4). ^{31}P NMR (300 MHz, DMSO-d_6, relative to 85% H_3PO_4) δ: 54.8, 16.4 (impurity, ~12%).

Kinetic measurements

General

Duplicate kinetic runs by UV–vis spectrophotometry were followed using either a Varian CARY3, a Hewlett–Packard 8452A, or Perkin–Elmer λ-5 spectrophotometer. The instruments were equipped with thermostatted cell-holders, and the temperature inside the 10 mm quartz cuvette was maintained at 25.0°C. All reactions were carried out under pseudo-first-order conditions in which the concentration of base was at least 100 times greater than the initial substrate concentration. All solutions were transferred from the round-bottom flasks to the quartz cuvettes, under nitrogen, using gas-tight syringes.

The reactions were followed by one of two methods. The first method involved using the HP8452A spectrophotometer for repeat scanning between 200 and 650 nm. This provided information pertaining to the rate of product appearance and substrate disappearance. The second method involved monitoring the appearance of product at a fixed wavelength, corresponding to the maximum absorption of the product (λ_{max}), as determined by the first method. In the case of fenitrothion degradation in basic ethanol, λ_{max} for the 3-methyl-4-nitrophenoxide ion was found to be 398 nm.

In general, each reaction was followed for 3 half lives, and the infinity absorbance value (A_{inf}) was taken after 10 half lives. Pseudo-first-order rate constants, k_{obs}, were determined from linear plots of log ($A_{inf} - A_t$) versus time, where A_t is the absorbance value at time *t*. Specifically, the slope of the plot was equal to $2.303k_{obs}$.

Product analysis experiments

Two types of product analysis experiments were performed.

The first method involved the use of ^{31}P NMR, in a pseudo-first-order kinetic experiment. An NMR sample was prepared such that it contained 0.898 M KOEt and 0.02 M fenitrothion, in anhyd ethanol. A sealed capillary tube containing DMSO-d_6 was placed into the NMR sample tube as signal lock, and spectra were acquired on a 300 MHz Bruker NMR instrument every 15 min for the first 15 h of reaction, and then obtained periodically over the next 17 days in order to monitor possible consecutive reactions. By comparisons with both authentic standards and literature values, the peaks observed throughout this reaction were determined to be those for **1** (67.0 ppm), **5** (72.6 ppm), and **2** (54.9 ppm). **3** (58.6 ppm) was identified from the available literature value (40).

The second method of product analysis involved the use of GC-MS. As described above, a reaction was initiated between 0.898 M KOEt and 0.02 M fenitrothion in anhyd ethanol. A 0.1 mL aliquot of the reaction mixture was removed at various time intervals. To this aliquot was added 1.14 equiv of HCl, which quenched the reaction, and the quenched aliquot was then extracted with $CHCl_3$ (2 × 1 mL). The $CHCl_3$ extract was dried over $MgSO_4$, transferred to a vial, and stored in a refrigerator until analysis by GC-MS was performed, using a Fisons 8000 gas chromatography instrument equipped with a MD800 mass spectrometer. The GC was equipped with a DB-5 capillary column and used helium as the carrier gas at a flowrate of 6 psig. At the start of the injection, the oven temperature was set to 85°C for 3 min and ramped at a rate of 10°C/min until reaching 215°C. Particular attention was paid to the peak for 3-methyl-4-nitro-ethoxybenzene, which was quantitated by comparison to the GC-MS results of the authentic compound.

Two-photon absorption of styryl-quinolinium, -pyridinium, and -barbituric acid derivatives, and intramolecular charge transfer

XiaoMei Wang, Chun Wang, WenTao Yu, YuFang Zhou, Xian Zhao, Qi Fang, and MinHua Jiang

Abstract: A series of new chromophores, styryl-parent end-capped with various donors, and with barbituric acid, methyl-pyridinium, and methyl-quinolinium as the acceptors, have been synthesized and characterized by element analysis or X-ray diffraction. Using the *Z*-scan system, their two-photon absorption (TPA) cross-section values (δ) have been determined under excitation with 10 Hz, and 1064 nm, 35 ps mode-locked Nd:YAG laser pulse in DMF with d_0 = 0.05 M. The effective δ value is as high as 10.9×10^{-48} cm^4 s per photon for *trans*-4-(4′-*N*,*N*-diphenyl amino) styryl-*N*-methyl quinolinium iodide (DPASQI). The δ value increases from barbituric acid- to pyridinium- to quinolinium-derivatives apparently due to the increase in both the conjugated degree and planarity; however, when the acceptor is fixed, the δ value increases from dialkyl amino groups to diphenyl amino groups even though the latter is a weaker donor than the dialkyl amino groups. Theoretical calculations confirm that the increased distortion from planarity for the barbituric acid derivative makes its δ value decrease. The relatively large δ value for quinolinium- or pyridinium-derivatives originates from larger intramolecular charge transfer, which can be characterized by the difference of dipole moment ($\Delta\mu_{ge}$) between the S_0 and S_1, and the transition dipole moment ($M_{ee'}$) between S_1 and S_2.

Key words: two-photon absorption, intramolecular charge transfer, styryl-quinolinium, styryl-pyridinium, styryl-barbituric acid.

Résumé : On a synthétisé une série de nouveaux chromophores, un styryle de base recouvert de divers donneurs et des accepteurs comme l'acide barbiturique et les ions méthylpyridinium et méthylquinoléinium et on les a caractérisés par analyse élémentaire ou diffraction des rayons X. Faisant appel à un système à balayage Z et opérant dans le DMF avec d_0 0,05 M, une excitation de 10-Hz et une pulsation laser Nd:YAG de 35 ps en mode bloqué, on a déterminé les valeurs, δ, des sections efficaces de leur absorption de deux photons. Dans le cas de l'iodure du *trans*-4-((4′-*N*,*N*-diphénylamino) styryl-*N*-méthylquinoléinium (« DPASQI »), la valeur δ effective s'élève jusqu'à $10{,}9 \times 10^{-48}$ cm^4 s/photon. Par ailleurs, la valeur de δ augmente en passant de l'acide barbiturique, puis aux dérivés pyridinium et quinoléinium; il semble que cette situation résulte d'une augmentation tant du degré de conjugaison que de la planarité. De plus, lorsque l'accepteur est fixé, la valeur de δ augmente des groupes dialkylamino aux groupes diphénylamino même si ces derniers sont des donneurs plus faibles que les groupes dialkylamino. Des calculs théoriques confirment que, dans le cas de l'acide barbiturique, l'augmentation de la distorsion par rapport à la planarité provoque une diminution de la valeur de δ. La valeur relativement élevée de δ pour les dérivés quinolinéinium et pyridinium trouverait son origine dans un important transfert de charge intramoléculaire qui peut être caractérisé par la différence du moment dipolaire ($\Delta\mu_{ge}$) entre S_0 et S_1 et la transition du moment dipolaire ($M_{ee'}$) entre S_1 et S_2.

Mots clés : absorption à deux photons, transfert de charge intramoléculaire, styryl-quinoléinium, styryl-pyridinium, styryl-acide barbiturique.

[Traduit par la Rédaction]

Introduction

Organic conjugated chromophores with a large two-photon absorption (TPA) cross-section emerge as very attractive elements for use in a number of optical applications such as optical data storage, up-converted lasing, and optical power limiting (1–10). Numerous organic compounds have been investigated experimentally and theoretically in order to understand the structure–property relationship of materials with large TPA cross-sections (11–17). Some general structural parameters for increasing the molecular TPA cross-section values (δ) have gradually been drawn in several laboratories (11–15). For example: (*i*) increasing the donor and acceptor strength; (*ii*) changing the character of the conjugated bridge; (*iii*) increasing the planarity of the chromophores; and (*iv*) extending the conjugated length. The results of theoreti-

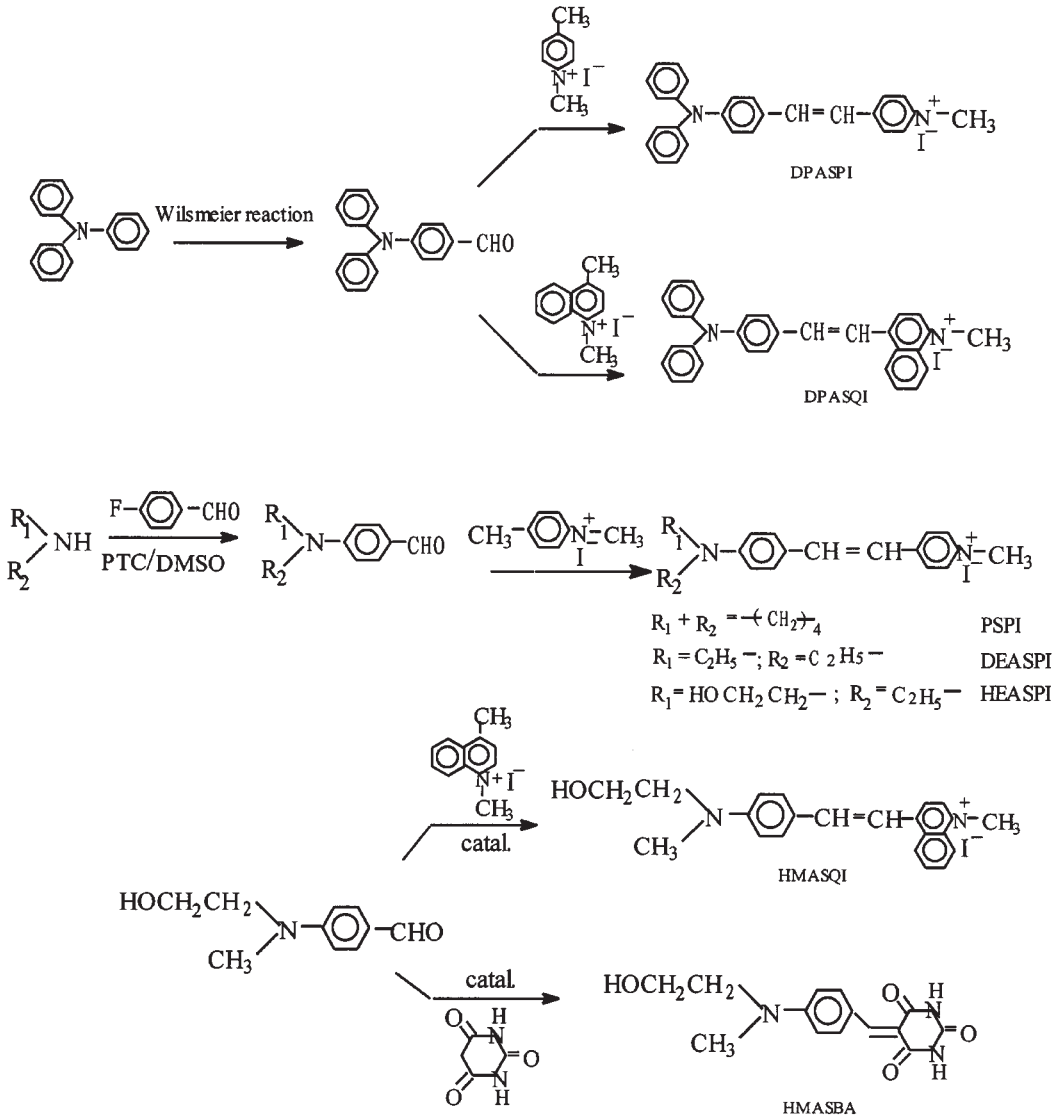
cal studies further reveal that the TPA δ value is related to the imaginary part of the third-order polarizability (16),

$$[1] \qquad \delta(\omega) = \frac{4\pi h\omega^2}{n^2 c^2} L^4 \,\mathrm{Im}\ \gamma(-\omega;\omega,\omega,-\omega)$$

where h is Planck's constant, n is the index of refraction of the medium, L is a local field factor (equal to 1 for vacuum), and c or ω is the speed of light or the frequency of light. When the frequency (ω) is left out of consideration, the third-order polarizability (γ) can be expressed as eq. [2] (17–18),

$$[2] \qquad \gamma_{xxxx} = 24\frac{M_{ge}^2}{E_{ge}^2}\left[\frac{\Delta\mu^2{}_{ge}}{E_{ge}} + \sum_{e'}\frac{M_{ee}^2}{E_{ge'}} - \frac{M_{ge}^2}{E_{ge}}\right]$$



where $\Delta\mu_{ge}$ is the difference of dipole moment between the ground state (S_0) and the first excited state (S_1); M_{ge} or $M_{ee'}$ is the transition dipole moment between S_0 and S_1 or between the two lowest excited states, that is, S_1 and S_2, and E_{ge} or $E_{ge'}$ is the difference between ground and excited state energy or between the two excited states. The first two terms in eq. [2] make a positive contribution to the TPA process (17).

It is evident that the TPA δ value is dependent not only on the difference between the ground- and excited-state dipole moment but also the transition dipole moment between two excited states. It is rational to deduce that materials with large $\Delta\mu_{ge}$ and $M_{ee'}$ must have exhibited high δ values due to stronger intramolecular charge transfer.

Based on this idea, we calculated structural parameters, such as $\Delta\mu_{ge}$ and $M_{ee'}$, for π-donor–acceptor compounds. One of the better candidate groups for generating a larger intramolecular charge shift is the substituted styryl-pyridinium cations. Other promising candidates are the substituted styryl-quinolinium cations. These kinds of salts possess the fused aromatic heterocyclic ring that may improve π-electron delocalization and result in better TPA properties. In addition the structural parameters for the barbituric acid derivative have also been calculated to examine the influence planarity and conjugated length upon TPA property. The calculation results are shown in Table 1.

Scheme 1.

methyl-pyridinium and further to methyl-quinolinium moiety, and also by varying the donor strengths in the order of: dialkylamino group > diphenylamino group. On the basis of correlated quantum-chemical calculation and experimental measurement results, we further demonstrate that large $\Delta\mu_{ge}$ and $M_{ee'}$ can result in large intramolecular charge transfers, which have contributed to enhance the two-photon absorption cross-section.

Experimental

Synthesis

The decomposition temperatures were measured on a Perkin–Elmer TGS-2 thermogravimetric analyzer at a rate of 20°C min^{-1} under nitrogen atmosphere. Element analyses were performed on a Perkin 2400. Mass spectra were recorded with an HP5989 apparatus. NMR spectra were determined on FX-90Q NMR spectrometer (TMS as standard).

Synthesis of donor and acceptor components

4-Pyrrolidinyl benzaldehyde, 4-(*N*,*N*-diethyl amino)benzaldehyde, 4-(*N*,*N*-diphenyl amino)benzaldehyde, 4-(*N*-hydroxyethyl-*N*-ethyl amino)benzaldehyde and 4-(*N*-hydroxyethyl-*N*-methyl amino)benzaldehyde were synthesized according to ref. 11.

4-Methyl-*N*-methylquilinonium iodide was synthesized by the reaction of lepidine (4.3 g, 30 mmol) and methyl iodide (4.4 g, 31 mmol) in ethanol (30 mL) at reflux temperature for 2 h. After cooling, the solution was filtered and recrystallized in ethanol. Yellow needle crystals were obtained with yield 80%.

Synthesis of chromophores

Chromophores were synthesized by the Knoevenagel condensation reaction of the appropriate substituted benzaldehyde and the acceptor components such as 4-methyl-*N*-methylpyridinium iodide and 4-methyl-*N*-methylquinolinium iodide with a catalytic amount of piperidine. For example, a mixture of equal molar 4-(*N*,*N*-diphenyl amino)benzaldehyde (3.5 g, 13 mmol) and 4-methyl-*N*-methylquinolinium iodide (3.7 g, 13 mmol) were stirred in ethanol (20 mL) at reflux temperature overnight in the presence of 4–5 drops piperdine. After cooling, the crude product of DPASQI

(*trans*-4-[(4′-*N*,*N*-diphenyl amino) styryl]-*N*-methyl quinolinium iodide) was filtered then purified by column chromatography on silica gel using acetone–ethanol (1:1) as the eluent. Needle deep-rose crystals were obtained after evaporation with a yield of 55% and the decomposition temperature (*T*d) = 254.87°C. Element analysis: Anal. calcd.: C 66.67, H 4.66, N 5.18; found: C 66.03, H 4.59, N 5.12.

trans-4-[(4′-*N*-Hydroxyethyl-*N*-methyl amino) styryl]-*N*′-methyl quinolinium iodide (HMASQI) was synthesized by the same method. Purified by column chromatography on silica gel using acetonitrile–water (1:1) as the eluent. Strip-like purple crystals were obtained after evaporation. Yield 60% and *T*d = 278.11°C. Element analysis: Anal. calcd.: C 56.51, H 5.19, N 6.28; found: C 56.48, H 5.13, N 6.38. (See Table 3 for bond lengths and angles).

Using the same method mentioned above, we synthesized the chromophores of pyridinium derivatives.

trans-*4-[4′-(*N,N-*Diphenylamino) styryl]*-N-*methyl pyridinium iodide (DPASPI)*: The crude product was purified by column chromatography on silica gel using ethane–chloroform (1:1) as the eluent. Yield 82% and *T*d = 260.2°C. Element analysis: Anal. calcd.: C 63.68, H 4.73, N 5.71; found: C 63.63, H 4.85, N 5.67. See Table 4 for bond lengths and angles.

trans-*4-(4′-Pyrrolidinyl styryl)*-N-*methyl pyridinium iodide (PSPI)*: The crude product was purified by column chromatography on silica gel with ethanol as the eluent. Yield 82% and *T*d = 260.6°C. Element analysis: Anal. calcd.: C 55.11, H 5.35, N 7.14; found: C 55.0, H 4.84, N 7.59.

trans-*4-[4′-(*N,N-*Diethylamino) styryl]*-N-*methyl pyridinium iodide (DEASPI)*: Purified by column chromatography on silica gel with ethanol as the eluent. Yield 84% and *T*d = 264.7°C. Element analysis: Anal. calcd.: C 54.84, H 5.88, N 7.10; found: C 54.34, H 5.46, N 6.98.

trans-*4-[4′-(*N-*Hydroxyethyl*-N-*ethyl) amino)styryl]*-N-*methyl pyridinium iodide (HEASPI)*: Purified by column chromatography on silica gel with ethanol as the eluent. Yield 85% and *T*d = 286.7°C. Element analysis: Anal. calcd.: C 52.69, H 5.69, N 6.83; found: C 52.43, H 5.21, N 6.45.

*5-(4-*N-*Hydroxyethyl*-N-*methylamino tyryl) barbituric acid (HMASBA)*: A mixture of equal molar 4-(*N*-hydroxyethyl-*N*-methyl amino) benzaldehyde (3.58 g, 20 mmol) and barbituric acid (2.56 g, 20 mmol) was refluxed in the presence of Et_3N (3.2 g, 32 mmol) in water–ethanol (15:15 mL) until a clear solution was obtained. The reaction was kept at reflux for an additional 2 h, then the solvent was removed by evaporation. After 2–3 days the resulting precipitate was washed several times with water and acetone, then dried. Red microcrystals with a yield of 80% and *T*d = 245.49°C were obtained. MS *m*/*z*: 289 (M^+), 258, 120. ^{1}H NMR δ: 10.73 (d, *J* = 11.46 Hz, 2H), 8.24 (d, *J* = 8.6 Hz, 2H), 7.98 (s, 1H), 6.68 (q, *J* = 8.6 Hz, 2H), 4.71 (1H, s), 3.53 (4H, s), 3.07 (3H, s). Element analysis: Anal. calcd.: C 58.12, H 5.23, N 14.53; found: C 57.64, H 4.85, N 14.38.

Crystal structure determination

Crystal data and other information on structure determination are given in Tables 2–4. X-ray diffraction data were made on a Bruker P4 four-cycle diffractometer and graphite-monochromated Mo Kα radiation was used (λ = 0.71073 Å). The structures were solved by direct method and refined by full-matrix least-squares on F^2. The refinement was on F^2 of reflections with $F_0 \geq 4\sigma(F_0)$ to minimize $\Sigma w(|F_0| - |F_c|)^2$. Anisotropic displacement parameters were refined for all nonhydrogen atoms, and isotropic hydrogen atoms were constrained to ride on their parent carbon atoms with fixed bond lengths and idealized bond angles.

Linear optical property

The λ_{max} values for all chromophores in DMF with d_0 = 1.00×10^{-5} M have been measured with a Hitachi U-3500

Linear optical property

The λ_{max} values for all chromophores in DMF with d_0 = 1.00×10^{-5} M have been measured with a Hitachi U-3500 recording spectrophotometer from quartz curettes of 1 cm path.

Measurement of the two-photon absorption cross section (δ value)

The *Z*-scan system with an open aperture ($S = 1$), which is insensitive to the nonlinear refraction, can be used to measure the nonlinear absorption cross-section. Such *Z*-scan traces with open apertures are expected to be symmetrical with respect to the focus ($Z = 0$), where they have a minimum transmittance (e.g., multiphoton absorption) or a maximum transmittance (e.g., saturation of absorption). In fact, the nonlinear absorption coefficient (β) that is due to TPA can be easily calculated from the transmittance curves.

For a temporally Gaussian pulse, the normalized energy transmittance can be given as (19),

$$[3] \qquad T(z, S = 1) = \frac{1}{\sqrt{\pi}\, q_0(z,0)} \int_{-\infty}^{+\infty} \ln (1 + q_0)(z,0) e^{-\tau^2} \mathrm{d}\tau$$

where $q_0(z,t) = \beta I_0 L_{\mathrm{eff}} / (1 + z^2/z_0^2)$. When there is no linear absorption, $L_{eff} = L$. L is the sample thickness, z_0 and $\pm z$ are the position of focus point and the range of scanning, respectively, and I_0 is the peak irradiance.

For $| q_0 | 1$, the transmittance (T) can be expressed in terms of the peak irradiance in a summation form more suitable for numerical evaluation,

$$[4] \qquad T(z, S = 1) = \sum_{m=0}^{\infty} \frac{[-q_0(z,0)]^m}{(m+1)^{3/2}} = \sum_{m} \frac{\beta I_0 L / (1 + z^2/z_0^2)}{(m+1)^{3/2}}$$

Thus, once an open-aperture *Z*-Scan ($S = 1$) is performed, the TPA coefficient β can be unambiguously deduced and if the concentration d_0 (in units of mol L^{-1}) of the solution is known, the molecular TPA cross section δ (in units of cm^4 s per photon) can be determined by using the following relationship,

$$[5] \qquad h\nu\beta = \delta N_0 = h\nu\delta N_A d_0 \times 10^{-3}$$

where $h\nu$ is the energy of the incident photon. N_A is Avogadro's constant.

We have accomplished TPA cross-section measurement for all chromophores with the sample thickness of 2 mm and a relatively high concentration of $d_0 = 0.05$ M, using a focussed 35 ps, 1064 nm mode-locked Nd:YAG laser. Using the above equations, we can get the TPA coefficient (β) and TPA δ value, which are presented in Table 1. The final measured results of all samples are given in Table 1 with an experimental uncertainty of ±15%. The typical open aperture *Z*-scan curves are shown in Fig. 1, which depicts the open-aperture trace at peak irradiance $I_0 = 3.64$ GW cm^{-2}.

Calculation of the structures

Charge density distribution in both ground and excited states, the difference between the ground and excited state dipole moment ($\Delta\mu_{ge}$), the transition dipole moment between two lowest states ($M_{ee'}$), and the dihedral angle between two rings of the backbone ($\theta^{d/0}$) were all calculated with the PM3 and ZINDO semiempirical methods.

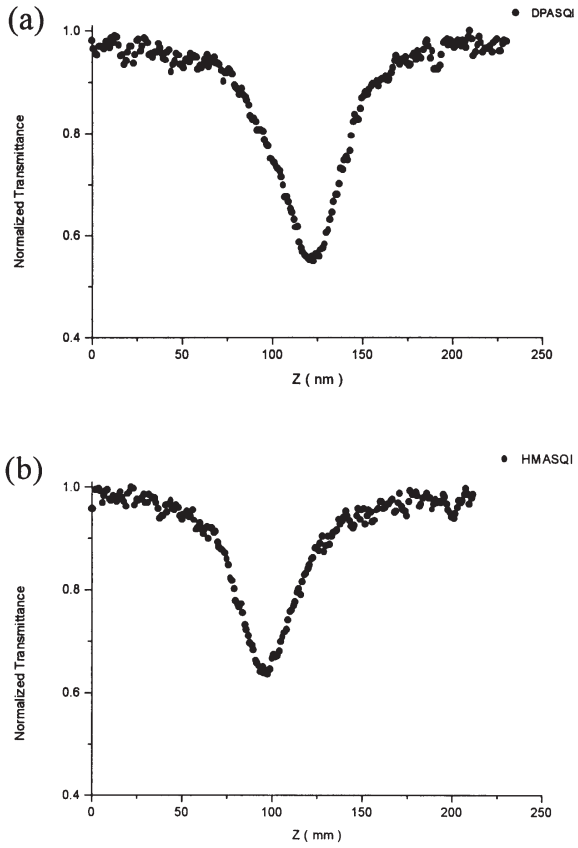
Fig. 1. Normalized *Z*-scan transmittance of: (*a*) DPASQI and (*b*) HMASQI, measured using ps pulses at λ = 1064 nm with I_0 = 3.64 GW cm^{-2}.



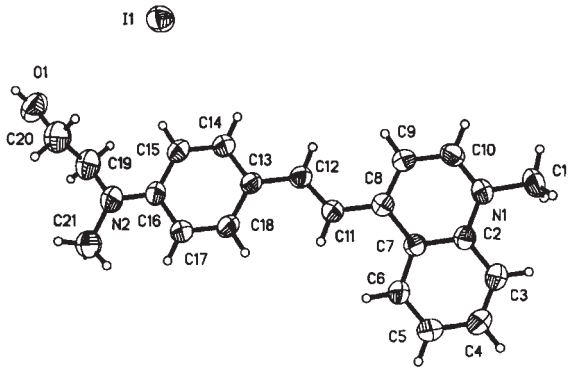


Fig. 2. Molecular structure of HMASQI.

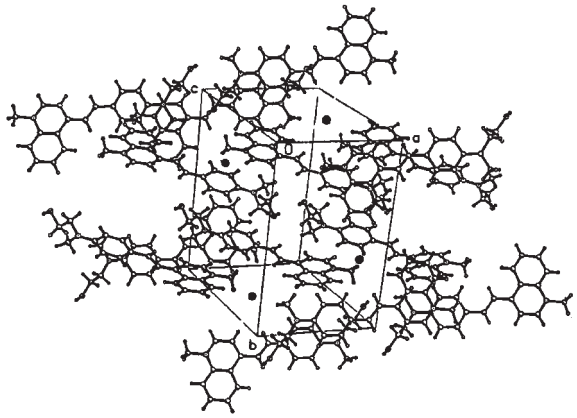
monoclinic crystal system of the centrosymmetric space group $P2_1/n$ with the unit cell parameters of a = 10.0512(11) Å, b = 16.2879(12) Å, c = 12.3328(8) Å, β = 102.307(6)°. Bond lengths of C8—11, C11—12, and C12—13 are 1.436(5), 1.352(5), and 1.442(5) Å, respectively owing to strong π-electron conjugation between the substituted phenyl ring and quinolinium ring. Bond angles of ∠C6-7-8, ∠C2-7-8, ∠N1-C2-C3, and ∠N1-C2-C7 are 122.4(4)°, 120.3(3)°, 120.4(4)°, and 119.2(3)°, respectively, which shows that the quinolinium ring possesses excellent planarity. The packing diagram shows that HMASQI molecules stack to form a layer-like structure along the *b*-axis. The donor-end of one

Fig. 3. Packing diagram of HMASQI.



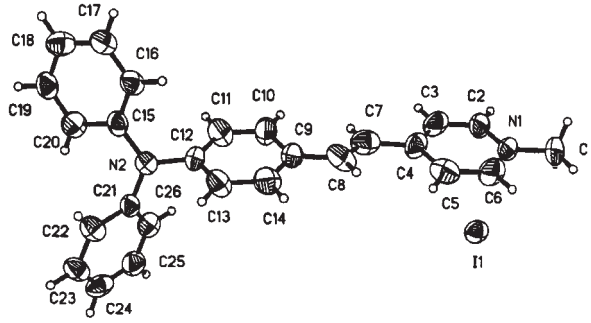


Fig. 4. Molecular structure of DPASPI.

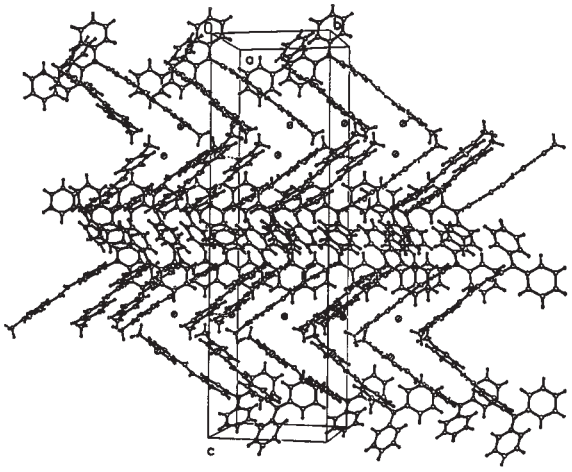
molecule is overlapped with the acceptor-end of the other molecule along the *a*-axis. The anions (I^-) fill in the space among the cations.



The structures of DPASPI are shown in Figs. 4 and 5. This crystal belongs to the orthorhombic crystal system of centrosymmetric space group *Pbca* with eight molecules in the unit cell. The two phenyl rings of the backbone are almost in the identical plane with the dihedral angle of 3.6°, while the other two phenyl rings on the donor-end deviate from this plane. From the packing diagram of DPASPI (shown in Fig. 5), one can see that the donor groups overlap, or stagger, each other while the acceptor-ends align face to face with the definite degree. Along the *c*-axis, the donor- and acceptor-groups present chain-like channels among the space filling in the anions.

Two-photon absorption and intramolecular charge transfer

Linear absorption for all chromophores is shown in Fig. 6. The influences from the quartz liquid cell and the solvent DMF have been subtracted. One can see that maximum absorption bands are 463 nm for the barbituric acid derivative and 458 ~ 482 nm for the pyridinium derivatives. Upon replacing the acceptor group with a larger conjugated fragment (*N*-methyl-quinolinium) one can observe a bathochromic shift of the long-wave absorption band to 514 ~ 554 nm. This suggests that the electronic interactions between the donor and acceptor groups induce the spectral shift to lower energy in the order of: quilidinium derivatives > pyridinium derivatives > barbituric acid derivatives.

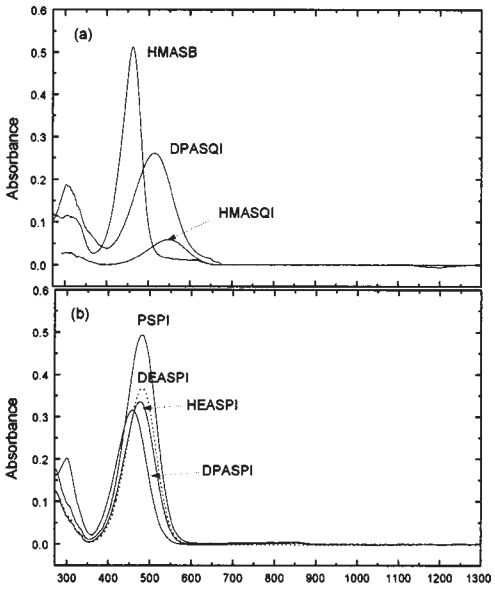
Fig. 5. Packing diagram of DPASPI.



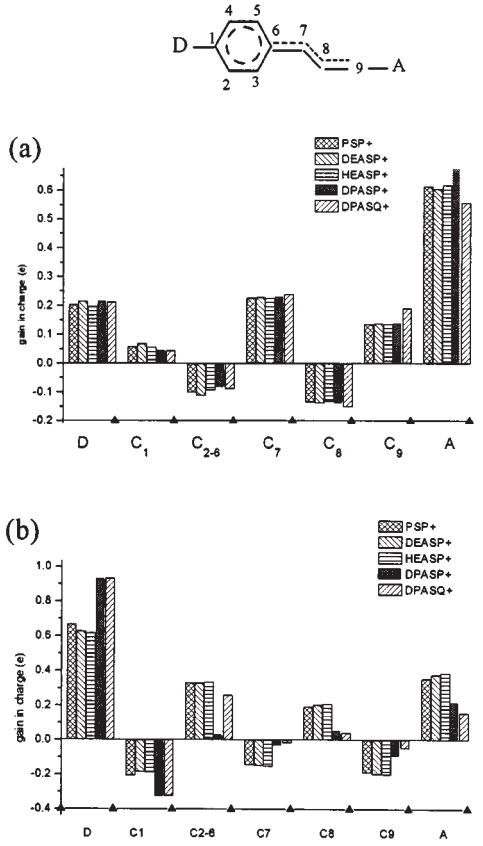
It must be noted that there is no linear absorption for all chromophores in the region from ~700 to ~1300 nm. So pumped by a 1064 nm laser pulse, the linear absorption can be excluded because two-photon excitation via virtual intermediate state can proceed, consistent with the fact that the nonlinear absorption occurs at a frequency in the region of one-photon transparency. It should be stressed that valid structure–property relationships can only be ascertained for those molecules that have their two-photon absorption peak at approximately the same wavelength. If the two-photon absorption peak shifts greatly from the wavelength that is away from the experimental wavelength of 1064 nm, then the comparison of absolute cross-sections is misleading. From Fig. 6, one can see that the maximum absorption wavelengths of all chromophores do not deviate too much. It is for this reason that the structure–property relationships deduced from the experimental data in this work are valid at 1064 nm.

Two-photon absorption cross-sections measured in DMF for the newly synthesized chromophores are summarized in Table 1. From Table 1, one can see that when the acceptor is fixed to the *N*-methyl pyridinium moiety, while the donor strength decreases, the δ values increase from 5.7×10^{-48} cm^4 s per photon for PSPI, to 7.0×10^{-48} cm^4 s per photon for HEASPI, to 8.8×10^{-48} cm^4 s per photon for DPASPI. This suggests that the δ value is not always proportional to the donor strength. Similar results can be observed in quinolinium moiety. When acceptor is fixed to *N*-methyl quinolinium moiety, with the decrease in donor strength, the two-photon absorption cross-section values change from 8.8×10^{-48} cm^4 s per photon for HMASQI to 10.9×10^{-48} cm^4 s per photon for DPASQI.

It is clear that with the acceptor structural factor changing from barbituric acid to pyridinium and further to quinolinium, δ values are gradually enhanced, in the range of $3.8 \times 10^{-48} \sim 10.9 \times 10^{-48}$ cm^4 s per photon. The barbituric acid derivative exhibits a relatively small cross-section, which can be explained as the molecular planarity seems to be critical in enhancing TPA cross-section values. Calculation shows that the dihedral angle between the benzene ring and the barbituric acid (70° for HMASBA) distorts the planarity and reduces the conjugated length, which is a disadvantage with respect to intramolecular charge transfer.

Fig. 6. Vis-IR absorption spectra of all chromophores in DMF with $d_0 = 1.00 \times 10^{-5}$ M.

Replacing barbituric acid by a pyridinium or a quinolinium fragment, greatly decreases the dihedral angle between two aromatic rings so as to be negligible. Consequently, a relatively large value for the cross-section was obtained.



In a comparison of these newly synthesized compounds with some other chromophores recently reported (13, 20), we found that the δ value of 10.9×10^{-48} cm^4 s per photon for DPASQI is remarkable considering the limited conjugation length. For example, the TPA δ value for DPASQI is nearly same as that of 6-(4-pyridyl)-*N*,*N*-diphenyl-2-naphthylamine ($\delta = 12.9 \times 10^{-48}$ cm^4 s per photon) (13), but almost twice that of the nitro-containing fluorescent derivative ($\delta = 6.5 \times 10^{-48}$ cm^4 s per photon) (20). The difference of their TPA cross-section resulting from the variation of both the acceptor group and the character of the conjugated bridge shows that the quinolinium ring is a good acceptor group and that the TPA δ value can be significantly enhanced if a better planar moiety (as a conjugated bridge) is inserted in a donor-quinolinium ring pair. Since the quinolinium ring possesses better planarity, as confirmed by the crystallographic data of HEASQI mentioned above, this characteristic has to contribute to the intramolecular charge transfer that can be measured by such structural parameters as $\Delta\mu_{ge}$ and $M_{ee'}$ or the change of charge distribution on each atom between the ground and the excited state.

The structural parameters calculated by the PM3 and ZINDO methods are presented in Table 1. From this table, one can conclude that the chromophores with large $\Delta\mu_{ge}$ and $M_{ee'}$ values possess relatively high δ value. For example, $M_{ee'}$ values in pyridinium derivatives change in the order of $DPASP^+ > HEASP^+ \sim PSP^+ \sim DEASP^+$, while $\Delta\mu_{ge}$ values change in the order of $DPASP^+ > HEASP^+ \sim DEASP^+ >> PSP^+$. The measured δ values, with the order of DPASPI > HEASPI ~ DEASPI > PSPI, confirmed that the experimental results are in agreement with the calculation.

Charge density (e) distribution for part of the chromophore cations in the ground state (shown in Fig. 7(*a*)), and in the

© 2001 NRC Canada

Fig. 7. Histogram of the π-charge distribution (e) in the: (*a*) ground state and (*b*) in the excited state, for part of the chromophores.

excited state (shown in Fig. 7(*b*)), are plotted in histogram form. One can see that in the ground state there is no alternation of charge density distribution. For example, the charge densities over D (donor) and atom C1 are both positive, and the charge densities over A (acceptor) and atom C9 are both positive too. Once in the excited state, the great charge redistribution occurs, accompanying with the significant charge positive–negative alternation, where the positive charge increases on the donor-end (D), and in the meantime, decreases on the acceptor-end (A). For example, one can see that in the ground state, the charge distribution of the $DPASP^+$ cation is in such a way: Q_D = +0.21 e and Q_A = +0.83 e; while in the excited state, Q_D = +0.93 e and Q_A = +021 e, indicating a large charge redistribution on the two-terminals occurs. It is interesting to note that such a π-charge transfer degree is consistent with the $\Delta\mu_{ge}$ and $M_{ee'}$ values and also in accordance with the enhancement of δ value. So DPASPI exhibits relatively large δ values among pyridinium derivatives because of its larger $\Delta\mu_{ge}$ (11.8 debye) and $M_{ee'}$ (9.8 debye) values. HMASBA exhibits smaller δ value because of its small change of dipole moment (0.8 debye). Its charge distribution is also small: Q_{ami} = +0.04 e, Q_{bar} = –0.27 e in the ground state, and Q_{ami} = +0.25 e, Q_{bar} = –0.28 e in the excited state, which shows that only a weak charge transfer between the ground and the excited state has occurred.

Conclusions

A series of new chromophores, styryl-parent end-capped with various substituted amino groups as donors, and barbituric acid, methyl-pyridinium, and methyl-quinolinium as the acceptors, has been synthesized and characterized by element analysis or X-ray diffraction.

We confirm both theoretically and experimentally that the TPA cross-section is strongly influenced by intramolecular charge transfer, which is characterized by the difference between the ground and excited state dipole moment ($\Delta\mu_{ge}$) and the transition dipole moment between the excited states ($M_{ee'}$) or the change of charge distribution on each atom between ground and excited state. Based on above point of view, the structure–property relationships of two-photon absorption (TPA) property can be interpreted reasonably, which can provide some useful information for molecular design with large TPA cross-sections.

The barbituric acid derivative possesses a relatively small TPA cross-section value due to its being heavily distorted from planarity and short conjugated length, which hinders intramolecular charge transfer. In contrast to this, quinolinium derivatives exhibit relatively large TPA cross-section due to its excellent planarity.

Both the *N*,*N*-diphenylamino group and the quinolinium ring are effective groups for enhancing TPA cross-sections, although the *N*,*N*-diphenylamino group is not a strong donor in comparison with the *N*,*N*-diakylamino group. Quantum chemical calculation shows that when the *N*,*N*-diphenylamino group and the quinolinium ring are matched, a relatively large charge transfer is produced ($\Delta\mu_{ge}$ = 12.1 debye), which confirms that TPA cross-section is not proportional to electron-donating strength, but dominated by intramolecular charge transfer.

Novel polyfluoroalkylated pyrazoles from 2-polyfluoroacylcycloalkanones and hydrazines: syntheses and unequivocal molecular structure assignment

D.V. Sevenard, O.G. Khomutov, M.I. Kodess, K.I. Pashkevich, I. Loop, E. Lork, and G.-V. Röschenthaler

Abstract: The reaction between 2-trifluoroacetylcycloalkanones and methylhydrazine or phenylhydrazine exclusively yields 3-CF_3-pyrazoles. When the chain length of the polyfluorinated substituent in $R^FC(O)$ group increases, 5-R^F-pyrazoles are isolated. The reaction of 2-trifluoroacetylcyclohexanone with 2-hydrazinopyradine gives 5-hydroxypyrazoline, an intermediate in the formation of 5-CF_3-pyrazoles. The regiochemistry of the condensation is probably controlled by the nucleophilicity of the terminal nitrogen in the mono substituted hydrazines and by the steric requirements of the R^F group in the 1,3-diketones. Polymethylene chain containing pyrazoles obtained from the 1,3-diketones in question and hydrazine prefer the 3-R^F tautomeric form, irrespective of carbocyclic ring size and polyfluoroalkyl group chain length.

Key words: polyfluorinated 1,3-diketones, hydrazines, isomeric pyrazoles, molecular structure.

Résumé : Les 2-trifluoroacétylcyclohexanones réagissent de façon avec la méthyl- ou la phénylhydrazine pour donner exclusivement des 3-CF_3-pyrazoles. Une augmentation de la longueur de la chaîne du substituant polyfluoré du groupe $R^FC(O)$ conduit à une augmentation de la quantité de 5-R^F-pyrazoles produite. La réaction de la 2-trifluoroacétylcyclohexanone avec la 2-hydrazinopyradine conduit à la formation de la 5-hydroxypyrazoline, un intermédiaire dans la formation des 5-CF_3-pyrazoles. La régiochimie de la condensation est contrôlée par le caractère nucléophile de l'azote terminal des hydrazines monosubstituées et les facteurs stériques du groupe R^F dans les 1,3-dicétones. Les pyrazoles comportant une chaîne polyméthylène obtenus à partir des 1,3-dicétones en question et de l'hydrazine favorisent la forme tautomère du 3-R^F, quelle que soit la grandeur du cycle carboné et de la longueur de la chaîne du groupe polyfluoroalkyle.

Mots clés : 1,3-dicétones polyfluorées, hydrazines, pyrazoles isomères, structure moléculaire.

[Traduit par la Rédaction]

Introduction

Pyrazoles, a class of compounds with biological activity (1–9), are available from the reaction of hydrazines with 1,3-diketones. In the case of unsymmetrical 1,3-diketones and mono substituted hydrazines, the formation of regioisomeric pyrazoles is possible (Scheme 1).

A regiospecific pathway has been discussed (4–8, 10) for reactions involving 2-acylcycloalkanones, but only the 4,5-polymethylene (5, 8, 10) or the 3,4-polymethylene structure (4, 6, 7) have been reported. A mixture of regioisomers has also been found (11, 12). Introducing polyfluorinated groups into 1,3-diketones substantially increases the steric and electronic inequivalence of the electrophilic centers, allowing an unequivocal course of the reaction to obtain only *one* of the two possible pyrazoles, e.g., as in the case of mono (het)aryl substituted hydrazines (9, 13–19). Nevertheless, both regioisomeric products have also been mentioned (7, 19, 20). If the hydrochloride salt of arylhydrazine is used, the reaction is regioselective, while for the respective free arylhydrazine, a mixture of isomers has been obtained (21). In the case of methylhydrazine, no regiospecificity has been observed (16, 22).

For hydrazines with acyl-, (thio)carbamoyl-, and some hetaryl-substituents, the reaction pathway is different. In the case of the non-fluorinated substrate, pyrazoles not only are obtained (23), but also a variety of intermediates. For example, mono- or bis-hydrazones (23, 24) and 2-pyrazolines (23–25), while with polyfluorinated 1,3-diketones, mostly 5-hydroxy-2-pyrazolines are formed (3, 26–30). Their molecular structures have been determined by X-ray diffraction (26, 27) and ^{13}C NMR spectroscopic studies (28, 29). On the

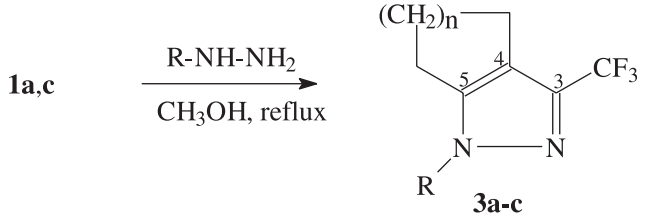
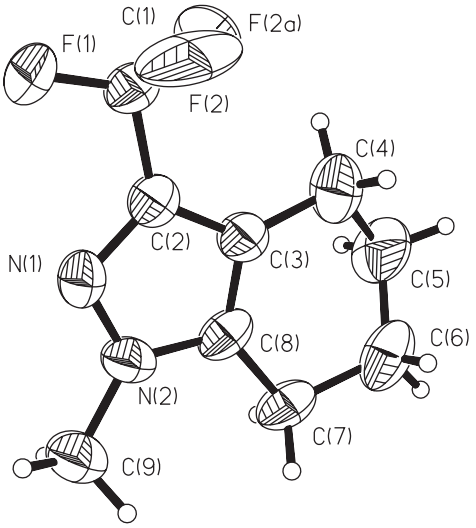
basis of the NMR data, the isomeric structure of some 5-hydroxy-3-pyrazolines reported (16) was, in our opinion, assigned ambiguously.



The question still remains: what is the structure of the pyrazoles synthesized from polyfluoralkyl 1,3-diketones and hydrazine (3, 13, 16, 20, 31) or from the dehydration of the 5-hydroxy-5-R^F-pyrazolines, which were isolated in some cases (3, 20, 32) and can exist in two tautomeric forms (Scheme 1, R = H) (33, 34)? Here we investigate the reaction of 2-polyfluoroacylcycloalkanones with hydrazine, and its mono-substituted derivatives, to unambiguously determine the structures of the new products.

Results and discussion

The reaction of 1,3-diketones (**1a**–**e**) and hydrazine furnish solid pyrazoles (**2a**–**e**) (Scheme 2) as the only products, which exist in only one tautomeric form at 25°C in $CDCl_3$ according to the ^1H, ^{13}C, and ^{31}P NMR data (one set of signals, Tables 1 and 2). A possible fast 1*H*–2*H* equilibrium, on the NMR time scale, (33) is unlikely, since the temperature-dependent ^{13}C NMR spectra of compound **2c** (Table 3) taken at 25, –10, and –50°C show no significant difference of the respective δ_C values, e.g., 0.01 ppm/°C for carbon-bearing CF_3 groups and 0.0005 ppm/°C for carbon C5 (similar deviations, where no tautomeric equilibria are in effect, were found, cf. ref. 35).



Heating, in methanol, (also in benzene for **3c**) the reaction between trifluoromethyl substituted 1,3-diketones (**1a**,**c**) and methylhydrazine or phenylhydrazine yields regiospecifically 3-trifluormethylpirazoles (**3a**–**c**) (Scheme 3), where the NH_2 moiety attacks the trifluoroacetyl group followed by subsequent heterocyclization.

Fig. 1. Molecular structure of compound **3a** (for clarity, the disordering is not depicted).

Analysis of the X-ray crystal structure reveals the unit cell of compounds **3a** and **3b** to contain two molecules (four for **3c**). Supplementary material for **3a**–**c** has been deposited.[2] The molecular structures of **3a**–**c** (Figs. 1–3, Table 4) are characterized by a planar pyrazolic ring featuring a pentagon with angles between 104.1° and 112.6°. The fused cyclohexene ring in **3c** displays a twist conformation, with C5 being 27.8 pm above and with C6 being 47.5 pm below the plane (C4-C3-C8-C7). The methyl and CF_3 groups of **3a** are in the pyrazol plane. Both are slightly disordered, forming two positions from rotations around the C—C and C—N bonds, respectively. The tetramethylene moiety is creating the two possible twist conformations by disordering in a 1:1 ratio. Atoms C4, C3, C8, and C7 are located on the crystallographic mirror plane, whereas C5 and C6 lie 45.4 pm above and 31.0 pm below the plane, respectively. The

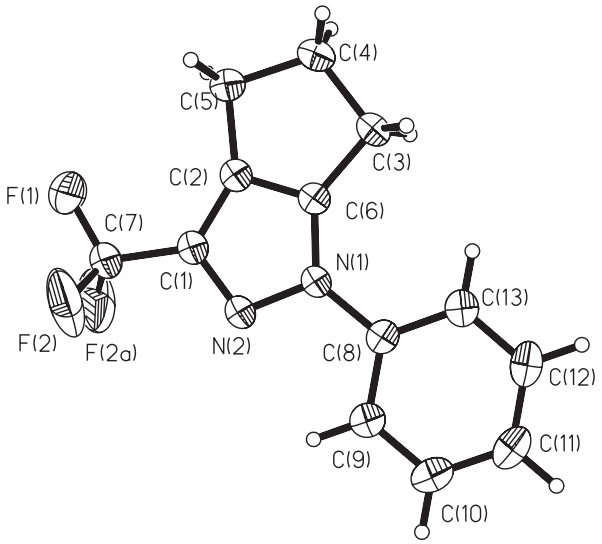

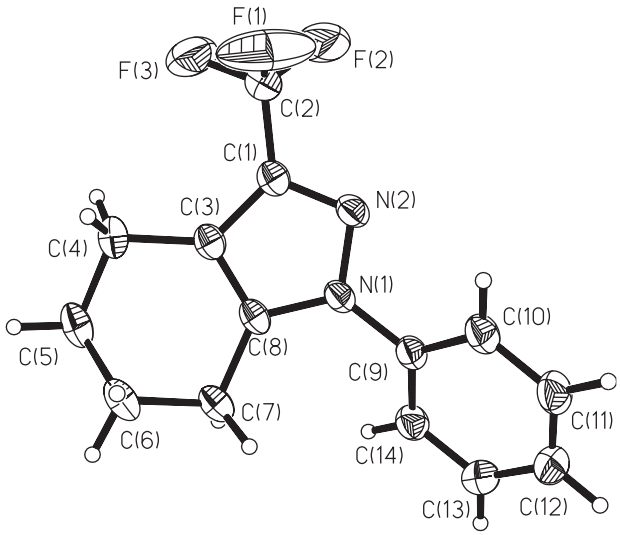

Fig. 3. Molecular structure of compound **3c**.

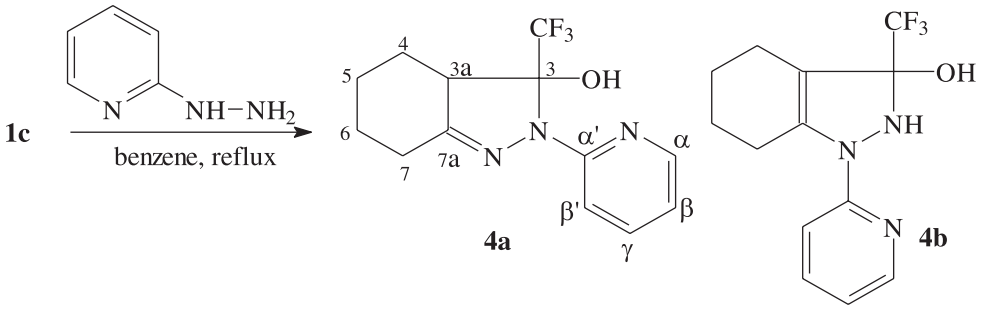
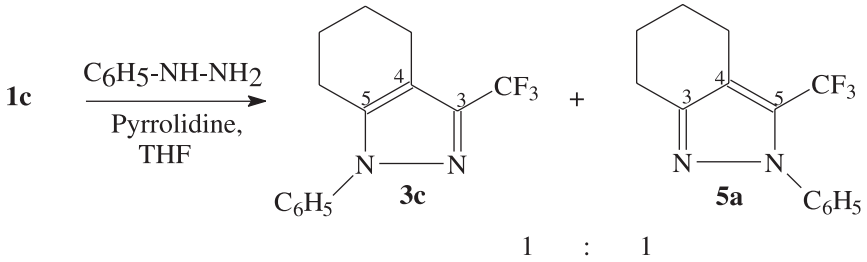


the CH_3 and CF_3 group. In a $^1H\{^{19}F\}$ NMR experiment, the quartet for the CH_3 at 3.76 ppm ($^6J_{H-F}$ = 0.6 Hz) was transformed into a singlet, while the CF_3 multiplet, at –62.60 ppm in the ^{19}F NMR spectrum, was transformed into a triplet (with CH_2 protons, $^5J_{F-H}$ = 0.9 Hz) by irradiating the CH_3 resonance.

When 2-hydrazinopyridine was used instead of phenylhydrazine, the reaction pathway changed. Molecule **1c** furnished, as in the case of (thio)semicarbazides (27, 28), the 2-*R*-indazole derivative **4a** (Scheme 4) as indicated by the two chiral carbon atom signals (97:3) in the ^{19}F NMR spectrum, representing the two possible diastereomers. The ^{13}C NMR data (δ_c (C^3) = 92.36, $^2J_{C-F}$ = 32.3 Hz, which indicates sp^3-hybridization), supports the proposed structure (see also refs. 36–38). The constitutional isomer **4b**, assigned to similar compounds (16, 39), could be ruled out because of the presence of a resonance representing the methylidyne proton at δ_H = 3.15 (dd, $^3J_{H-H}$ = 10.7, 6.3 Hz).



Two pyrazoles with a vicinal arrangement between R^F and a 2,4-difluorophenyl group were obtained from condensation of the 1,3-diketones and hydrazine in the presence of equimolar amounts of pyrrolidine, giving 5-hydroxypyrazolines, which were subsequently dehydrated (11). According to ref. 38, a semi-aminal is formed in the first step, which is a product of the addition of the pyrrolidine nitrogen to the polyfluoroacyl group (cf. ref. 40) and then a reaction with phenylhydrazine proceeds. However, 1,3-diketones and amines form ammonium salts at ambient temperatures, which produce β-aminoenones upon heating (41). The semi-aminals described in ref. 38 are probably pyrrolidinium salts. Obviously, the synthetic procedure of the aforementioned pyrazoles is based on the variation of the relative

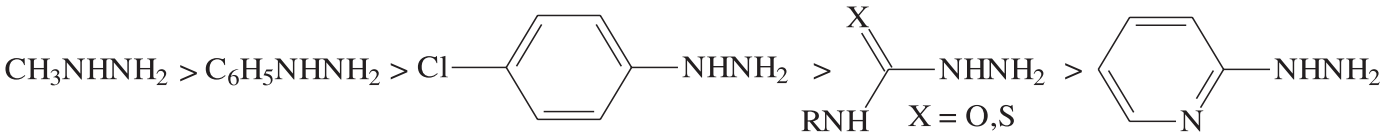
reactivity of the 1,3-diketone electrophilic centers by in situ generation of the respective β-aminoenones (11). Applying the same conditions for the reaction of **1c** with phenylhydrazine, an isomeric mixture of pyrazoles **3c** and **5a** (1:1) was found (Scheme 5), which could be separated by column chromatography. The formation of hydroxypyrazoline intermediate was not observed, the relative stability was probably controlled not only by the presence of a polyfluoroalkyl substituent (42) but also by the presence of a hydrogen-bridge acceptor as in the case of **4a**, where the OH proton probably interacted with the pyridine nitrogen atom, as confirmed by IR absorption in the 3000–3400 cm^{-1} region.

In the ^{13}C NMR spectrum of compound **5a**, a quartet (J = 1.1 Hz) appeared in one of the phenyl carbon signals, presumably due to a "through-space" coupling of the *ortho*-carbon nuclei with the CF_3 group fluorine nuclei, as also seen in ref. 11.



Increasing the chain length of the polyfluoroalkyl moiety R^F in the 1,3-diketone changed the direction of the non-catalyzed reaction with methylhydrazine and phenylhydrazine. For **1a**, **c** (R^F = CF_3), 3-trifluoromethylpyrazoles

Scheme 7.

Scheme 8.

were obtained exclusively; for **1d** (R^F = CF_2CF_2H) and **1f** (R^F = C_3F_7), a mixture of the isomeric pyrazoles, **3d**, **5b** (5:6) and **3e**, **5c** (5:2) (as determined by comparing NMR integral intensities of the reaction mixtures), were obtained, respectively (Scheme 6). For **1e**, **g** (R^F = C_4F_9, C_6F_{13}), only 2-indazole derivates **5d**, **e** were found, where the NH_2 group attacked the cyclohexanone keto carbon. Like **3a**, compounds **3e** and **5c** are featuring CH_3-CF_2 through-bond coupling. For **3e**, a broad triplet was observed with $^6J_{H-F} \approx$ 0.7 Hz ($\Delta\nu_{1/2} \approx$ 2.0 Hz); for **5c**, a broad multiplet ($\Delta\nu_{1/2}$ = 3.6 Hz) was observed due to $^5J_{H-F}$ and $^7J_{H-F}$ coupling with the $CF_2CF_2CF_3$ system, as confirmed by $^1H\{^{19}F\}$ NMR experiments (see Table 1).

The pyrazoles **2c**–**e**, **3d**, **e**, and **3a**, **c** investigated by X-ray diffraction show similar ^{13}C NMR features (Table 2), but differ significantly from the spectrum of the 5-CF_3-pyrazole **5a**. This prompted us to assume a 3-CF_3-structure for cyclohexane ring containing compounds **2c**–**e**, **3d**, **e**. The same argument applies for the trimethylene substituted pyrazoles **2a**, **b** for which ^{13}C NMR data (Table 2) are comparable with those of compound **3b** (see its molecular structure, Fig. 2). The similarity of ^{13}C NMR spectra of compounds **5b**–**e** with those of pyrazoles **5a** and compounds mentioned in ref. 11 led us to propose a 5-CF_3-pyrazole structure.

When 1,3-diketone **1h** was reacted with perfluoroglutaric dihydrazide in a 2:1 ratio, surprisingly the *N*-H pyrazole **2f** (Scheme 7) was obtained, indicating hydrolytical cleavage.

The reactions of asymmetric binucleophiles with trifluoroacetyl group containing bielectrophiles mentioned above can be qualitatively characterized as acid–base interactions according to the Pearson concept (43, 44). The decrease in hardness of the terminal nitrogen in the binucleophiles from left to right (see Scheme 8) alters the position of the NH_2 attack. The NH_2-group of the first two hydrazines interacts with the harder electrophilic center, namely in the $CF_3C(O)$ group, the last two compounds interact with the softer keto carbon in the cycloalkane ring. Compound 4-chlorophenylhydrazine furnished a mixture of the two possible pyrazoles (7).

When 1,3-diketones with longer polyfluoroalkyl substituents were treated, the attack of the NH_2 group was probably controlled by steric factors (45); as in the case of R^F = CF_2CF_2H and C_3F_7,where a mixture of isomers was found. In the case of R^F = C_4F_9, C_6F_{13}, only 5-R^F-pyrazoles were obtained, where the NH_2 group interacted with the cyclohexane keto carbon.

Our results show that structural assignment based solely on whether spin–spin couplings between the substituents at pyrazole are observed or absent would lead to erroneous conclusions. Following the arguments in ref. 16, compound **3a** should have the 2-CH_3-indazole structure because of the spin–spin interaction between the CH_3 and CF_3. This could subsequently let one assume the wrong geometry of compounds **2c**–**e**, **3c**–**e**, since they have similar ^{13}C NMR parameters. Therefore, it appears as if the trimethylene and tetramethylene substituted compounds **3b** and **3a**, **c**–**e** were derivatives of the isomeric pyrazole, although the ^{13}C shift difference of the respective nuclei reflect probably only the ring strain difference of the corresponding bicyclic systems.

There is one case where the structures of 5-CF_3 pyrazoles and their 3-CF_3 isomers, which were obtained as well, were unequivocally assigned based on chemical transformations and NMR data (18, 19, 29, 30, 32). The ^{13}C NMR signals of CF_3-C^3 were found at ca. δ_C = 145, and of CF_3-C^5 at δ_C = 133. However, this rule is not general and cannot be applied for the CF_3 substituted pyrazoles in this work, where for CF_3-C^3 δ_C = 137.95 (**3a**), 137.02 (**3b**), 140.11 (**3c**), and for CF_3-C^5 δ_C = 128.34 (**5a**) have been observed. The ^{19}F NMR shift values found for CF_3 group containing pyrazoles (29, 32), δ_F (3-CF_3) ≈ –62 and δ_F (5-CF_3) ≈ –58, applies also for **2a**, **c**, **3a**–**c**, **5a** (see Table 1) but only for $CDCl_3$ solutions. This has to be taken into account for ref. 32 where ^{19}F NMR data from a solution of *N*-H pyrazoles in a DMSO-d_6–$CDCl_3$–CF_3COOH mixture were used for the structure determination. In this case, the ^{13}C NMR parameters indicate the CF_3 group at C^3 with δ_C (C^3) = 141.61, whereas the ^{19}F NMR data (δ_F = –57.35) correspond to the 5-CF_3-pyrazole.

Obviously, the δ_F value for the difluoromethylene group connected with the pyrazole ring is also indicative for the structural assignment. In the ^{13}C NMR data of 3-CF_2CF_2H isomer **3d** the respective signal was observed at δ_F = –114.8; in case of 5-CF_2CF_2H isomer **5b**, δ_F = –109.7 (solvent $CDCl_3$). These findings correspond to the δ_F value of compound **2d** (δ_F = –114.6, nitrogen is not substituted), where a

3-R^F structure is assumed due to the ^{13}C NMR data. From the literature and this work, the following typical ^{19}F and ^{13}C NMR data for the 3-R^F- or 5-R^F geometry of the polyfluoroalkyl group substituted pyrazoles could be defined (as reference structures compounds whose geometry unequivocally were determined by X-ray diffraction or by specific chemical reactions were taken).

3-R^F isomer

(1) δ_F (CF_3) = ca. –62, for pyrazoles from the respective linear (29, 37, 38) and carbocyclic 1,3-diketones;
(2) δ_F (CF_2CF_2H) = ca. –115, for pyrazoles from carbocyclic 1,3-diketones;
(3) δ_C (C^3) and δ_C (C^5) are similar: δ_C = 136–141, for pyrazoles with any R^F from cyclohexane containing 1,3-diketones; and δ_C = 140–145, for pyrazoles with R^F = CF_3 from linear 1,3-diketones (18, 19, 29, 30);
(4) δ_C (C^3) = ca. 135 and δ_C (C^5) = ca. 152, for pyrazoles from 2-trifluoracetylcyclopentanone.

5-R^F isomer

(1) δ_F (CF_3) = ca. –58, for pyrazoles from the respective linear (29, 32, 38) and carbocyclic 1,3-diketones;
(2) δ_F (CF_2CF_2H) = ca. –110, for pyrazoles from carbocyclic 1,3-diketones;
(3) δ_C (C^3) = ca. 150, δ_C (C^5) = ca. 130, for pyrazoles from 2-polyfluoroacylcyclohexanones; δ_C (C^3) = ca. 149, δ_C (C^5) = 133, for pyrazoles from linear 1,3-diketones (19, 29, 30).

Experimental

Mass spectra (EI, 70 eV) were carried out on a MAT 8200 spectrometer (Table 5). IR spectra were recorded on a Specord-75 IR spectrophotometer as suspensions in nujol. NMR spectra were recorded in deuterochloroform solutions on a Tesla BS-587A instrument operating at 80.1 MHz (^1H, standard: TMS), 20.1 MHz (^{13}C, standard: TMS), and 75.3 MHz (^{19}F, standard: CCl_3F) and on a Bruker DPX-200 spectrometer operating at 200.1 MHz (^1H), 50.3 MHz (^{13}C), and 188.3 MHz (^{19}F). Double resonance experiments $^1H\{^{19}F\}$ and $^{19}F\{^1H\}$ were performed on a Tesla 587A supplied with a specially designed decoupler unit operating on ^{19}F frequency (46). Chromatography was performed with a silica gel column (normal phase, MATREX, Grace GmbH). 2-Polyfluoroacylcycloalkanones **1a** (47), **c** (11, 47), **f**, **g** (48), **d**, **e** (49), **h** (50) were synthesized by a Claisen-type condensation of cyclopentanone or cyclohexanone and alkylpolyfluoroacylates in the presence of lithium hydride in dried benzene (49).

2-Perfluoropentanoylcyclopentanone (1b)

To a stirred suspension of sodium methoxide (3.2 g, 60 mmol) in diethyl ether (100 mL) was added dropwise the mixture of cyclopentanone (4.8 g, 58 mmol) and methyl perfluoropentanoate (16.0 g, 58 mmol). The mixture was stirred for 24 h at room temp, then quenched by the addition of 10% H_2SO_4 (60 mL). The organic layer was separated and the water phase additionally extracted with diethyl ether (2 × 20 mL) and the combined extracts were dried over $MgSO_4$. The solvent was evaporated and the crude product distilled at reduced pressure with Vigreaux column to yield 13.5 g (71%) of a colorless liquid: bp 52°C (0.5 torr). ^1H NMR (major enol-tautomer) δ: 1.91–2.06 (m, 2H, CH_2), 2.47–2.56 (m, 2H, CH_2), 2.74–2.84 (m, 2H, CH_2), 13.0 (br s, 1H, O*H*). MS *m*/*z* (%): 330 (M^+, 18), 169 ($C_3F_7^+$, 3), 119 ($C_2F_5^+$, 3), 111 ($[M - C_4F_9]^+$, 100) and other fragments. HRMS *m*/*z* calcd. for $C_{10}H_7F_9O_2$: 330.0302; found: 330.0300.

General procedure for preparing compounds 2a–e, 3a–c, 5d, e (for 2d, 3c: method A)

A mixture of **1** (10 mmol) and hydrazine (10 mmol) (for **2**: 80% hydrazine hydrate (1.2 g, 30 mmol) in methanol (20 mL) (for **5e**: in 20 mL ethanol) was heated at reflux for 4 h (for **2b**: 10 h, for **2c**: 5 h, for **3a**: 6h), cooled to ambient temp, and diluted with water (100 mL). For **2a**–**e**, the mixture was extracted with $CHCl_3$ (3 × 10 mL). The combined extracts were dried with $MgSO_4$. After removal of the solvent, the solid residue was recrystallized (Table 6) to afford **2a**, **c**–**e** as colorless crystals (**2b**: pale yellow crystals). For **3a**, the precipitated solid was dried and recrystallized (Table 6) to afford product as colorless crystals. For **3b**, **c**, **5d**,

and **e**, the reaction mixture was extracted with $CHCl_3$ (3 × 10 mL). The combined extracts were dried using $MgSO_4$. After removal of the solvent, the residue was purified by column chromatography ($CHCl_3$) and recrystallized (Table 6) to give **3b**, **c**, and **5e** as colorless crystals (**5d**: yellow crystals).

Preparation of 2d (method B)

A mixture of **1d** (3.0 g, 13 mmol), hydrazine dihydrochloride (1.4 g, 13 mmol), and triethylamine (2.7 g, 27 mmol) in methanol (30 mL) was heated at reflux for 4 h. The cooled mixture was diluted with water (100 mL). Mixture was extracted with $CHCl_3$ (3 × 10 mL). The combined extracts were dried with $MgSO_4$; removal of the solvent gave a solid residue which was recrystallized (Table 6).

Preparation of 3c (method B)

A mixture of **1c** (1.0 g, 5 mmol) and phenylhydrazine (0.6 g, 5 mmol) in benzene (20 mL) was heated at reflux for 4 h. After removal of the solvent, the residue was purified by column chromatography ($CHCl_3$) and recrystallized (Table 6).

Reaction of 1d with phenylhydrazine

A mixture of **1d** (1.4 g, 6 mmol) and phenylhydrazine (0.7 g, 6 mmol) in methanol (15 mL) was heated at reflux for 4 h. The cooled mixture was diluted with water (100 mL). Mixture was extracted with $CHCl_3$ (3 × 10 mL). The combined extracts were dried with $MgSO_4$. After removal of the solvent, the residue was purified by chromatography ($CHCl_3$:*n*-pentane) to yield **3d** (higher R_f, 0.1 g, yellow oil) and **5b** (lower R_f, 0.05 g, colorless oil) (Table 6).

Reaction of 1f with methylhydrazine

A mixture of **1f** (4.9 g, 17 mmol) and methylhydrazine (0.8 g, 17 mmol) in methanol (30 mL) was heated to reflux for 4 h. After removal of the solvent, the residue was purified by column chromatography ($CHCl_3$) to yield a mixture of **3e** and **5c** as a colorless oil (Table 6).

Reaction of 1c with phenylhydrazine in the presence of pyrrolidine

To a solution of **1c** (2.0 g, 10 mmol) in THF (10 mL) was added pyrrolidine (0.7 g, 10 mmol) followed by separation using 1.0 g molecular sieves (3 Å). After stirring at 0°C for 30 min, a solution of phenylhydrazine (1.1 g, 10 mmol) in THF (5 mL) was added, and the mixture was allowed to warm slowly to room temp for 12 h. The mixture was diluted with water (100 mL) and extracted with $CHCl_3$ (3 × 10 mL). The combined extracts were dried with $MgSO_4$ and concentrated to 5 mL, followed by flash chromatography

4,5,6,7-Tetrahydro-3-(1,1,2,2,3,3,4,4-octafluorobutyl)-1*H*-indazole (2f)

A mixture of **1h** (1.0 g, 3 mmol) and perfluoroglutaric dihydrazide (0.4 g, 1.5 mmol) in 2-propanol (15 mL) was heated at reflux for 12 h. The cooled mixture was diluted with water (50 mL) and extracted with $CHCl_3$ (3 × 10 mL). The combined extracts were dried with $MgSO_4$. Removal of the solvent gave a residue which was purified by column chromatography ($CHCl_3$) and recrystallized, affording **2f** (0.15 g) as colorless crystals (Table 6).

X-ray crystal structure parameters

The X-ray structure studies of compounds **3a–c** were performed at –100°C on a Siemens P4 diffractometer with low-temperature device LT2, using graphite-monochromated Mo Kα radiation (λ = 71.073 pm). Full-matrix least-squares refinement has been carried out with the SHELX-97 program system (51). Details of crystal data, measurement of intensities, and data processing are summarized in Table 7. Atomic coordinates are summarized in Tables 8–10. All structures were solved by direct methods. All non-hydrogen atoms were refined anisotropically, and the positions of the hydrogen atoms were calculated as a riding model. The

Synthesis, X-ray crystal structure, and solid-state ^{13}C NMR study of tris(9-crown-3)triphenylene

Gerald W. Buchanan, Majid F. Rastegar, and Glenn P.A. Yap

Abstract: Benzo-9-crown-3 ether trimerizes in the presence of $FeCl_3$ and aqueous H_2SO_4 to produce tris(9-crown-3)triphenylene in 25.4% yield. This compound crystallizes in the monoclinic $P2_1/c$ space group: a = 13.759(2) Å, b = 13.318(2) Å, c = 13.399(2) Å, β = 96.883(2)°, with Z = 4. The three 9-crown-3 ether units of the trimer possess different geometries and there is substantial deviation from coplanarity in the three aromatic rings. ^{13}C NMR chemical shifts in the solid state are consistent with this lack of symmetry and are discussed in terms of the X-ray crystal-structure data.

Key words: crown ether, trimerization, stereochemistry.

Résumé : Dans l'acide sulfurique aqueux ou en présence de $FeCl_3$, l'éther benzo-9-couronne-3 se trimérise pour conduire à la formation du tris(9-couronne-3)triphénylène avec un rendement de 25,4 %. Ce composé cristallise dans le système monoclinique, groupe d'espace $P2_1/c$, avec a = 13,759(2) Å, b = 13,318(2) Å et c = 13,399(2) Å, β = 96,883(2)° et Z = 4. Les trois unités d'éthers 9-couronne-3 du trimère possèdent des géométries différentes et les trois noyaux aromatiques sont loin d'être coplanaires. Les déplacements chimiques en RMN du ^{13}C à l'état solide sont en accord avec ce manque de symétrie et on en discute en fonction des données structurales obtenues par diffraction des rayons X.

Mots clés : éther couronne, trimérisation, stéréochimie.

[Traduit par la Rédaction]

Introduction

Hexaalkoxy-substituted triphenylenes show liquid-crystal properties if the side chains are of sufficient length. Hence, these molecules are important models for discotic liquid crystals (1, 2). Recently, a procedure for preparing 2,3,6,7,10,11-hexamethoxytriphenylene in near-quantitative yield was reported (3) using oxidative trimerization of 1,2-methoxybenzene. Herein, we report the application of this method to the synthesis of a novel tris(9-crown-3)triphenylene.

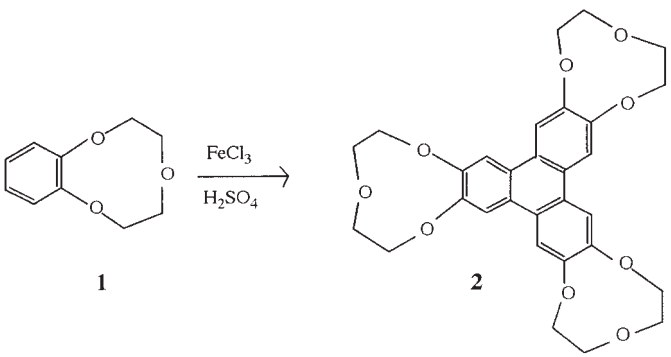
The X-ray crystal structure has been determined, and a comparison of the solution and solid-phase ^{13}C NMR spectra is included. The observed multiplicity in the ^{13}C NMR spectrum clearly shows the lack of any symmetry elements in the crystal structure. The chemical shifts in the solid state are discussed in light of the X-ray crystal structure data.

Results and discussion

The synthesis, NMR spectra, and X-ray crystal structure of benzo-9-crown-3 ether (**1**) have been reported previously (4). In the presence of $FeCl_3$ and H_2SO_4, **1** trimerizes in 25.4% yield to the triphenylene system (**2**) depicted in Fig. 1.

Figure 2 shows the ORTEP diagram for **2**, while the solid-state ^{13}C NMR spectra are shown in Fig. 3. Table 1 contains atomic bond lengths and angles. Torsion angles involving non-hydrogen atoms are collected in Table 2, while the crystallographic data are presented in Table 3. Atomic coordinates and equivalent isotropic displacement factors are in Table 4. Anisotropic temperature factors are available as supplementary data.[2]

X-ray crystal structure



In discussing the conformations of the three nine-membered rings of **2**, it is useful to compare these with the torsion angles for the parent benzo-9-crown-3 system (**1**). Also, when viewing the ORTEP plot of **2** (Fig. 2), it is clear that there is a "northern" ring (i.e., C3–C8), an "eastern" ring (i.e., C13–C18), and a "western" ring (i.e., C23–C28). A comparison of torsion angles is presented in Table 5, and it is evident that the three nine-membered rings of **2** have

substantially different geometries and that the structure lacks any element of symmetry. Interestingly, the "eastern" nine-membered (C13–C18) ring has a conformation that is essentially identical to that of **1**, with the torsion angles differing on the average by only approximately 4°.

Another feature of note in the geometry of **2** is the non-planarity observed in the region containing the four fused

aromatic rings. The most pronounced effect is in the C19-C20-C21-C22 region where the torsion angle is –13.8(4)°. The C9-C10-C11-C12 torsion angle is 7.9(3)°, while the smallest deviation from planarity occurs in the C2-C1-C30-C29 region, with a torsion angle of 3.3(4)°.

Finally, it is of interest to observe that there are two aromatic C—O—C bonds that have a remarkably large bond angles. Specifically, the C13-O4-C14 angle is 124.9(2)° and the C28-O9-C27 angle is 124.7(2)°. These values are approximately 10° larger than the values for the other four units of this type in **2** and most likely arise from intermolecular crystal-packing influences. Consistent with these large bond angles are the relatively short O4—C13 and O9—C28 bond lengths (Table 1*a*), which suggest substantial double bond character in these units.

^{13}C NMR Spectra

The solution ^{13}C spectrum ($CDCl_3$ solvent) contains only five resonances, as expected from the three-fold symmetry element present in the planar depiction of **2**, which arises from sufficiently rapid conformational interconversions at room temperature. The aromatic C-O appears at 158.9 ppm. In contrast, the solid-state ^{13}C cross-polarized magic angle spinning (CPMAS) NMR spectrum shown in Fig. 3*a* shows six resolved resonances for the aromatic carbons bearing oxygen, with the chemical shifts ranging from 151.1 to 156.5 ppm. This is consistent with the observed lack of symmetry in the crystal structure. One can tentatively assign these resonances to specific carbons of solid **2**, from an examination of the C—O bond lengths (Table 1). The underlying tenet here is that the shortest C—O bond will have the most double-bond character and hence be the most deshielded (i.e., highest δ_c value). Thus, we assign the most deshielded resonance at 156.5 ppm to C28, since the O9—C28 bond length is the shortest (1.371(3) Å). The O4—C13 bond is 1.375(3) Å, and thus, the line at 155.0 ppm is attributed to C13. The O1—C3 bond length is 1.378(3) Å and the O7—C23 bond is 1.379(3) Å, so the lines at 153.4 and 152.6 ppm, respectively, can be associated with these carbons. Finally, the O6—C18 bond is 1.384(3) Å long, and the O3—C8 is the longest bond at 1.395(3) Å. Thus, the resonances at 151.6 and 151.1 ppm are attributed to these carbons, respectively. The uncertainty of 0.003 Å in the experimental measurements of bond lengths must be noted, hence some interchange of assignments for C—O bonds whose lengths differ by < 0.006 Å may be possible.

The six quaternary carbons of the central ring of **2** (i.e., C1, C10, C11, C20, C21, and C30) are clearly evident in the dipolar dephased (DPD) version of the ^{13}C CPMAS NMR spectrum (Fig. 3*b*). Due to peak overlap, rather than the six resonances, there are four peaks in the ratio of 1:2:2:1 at

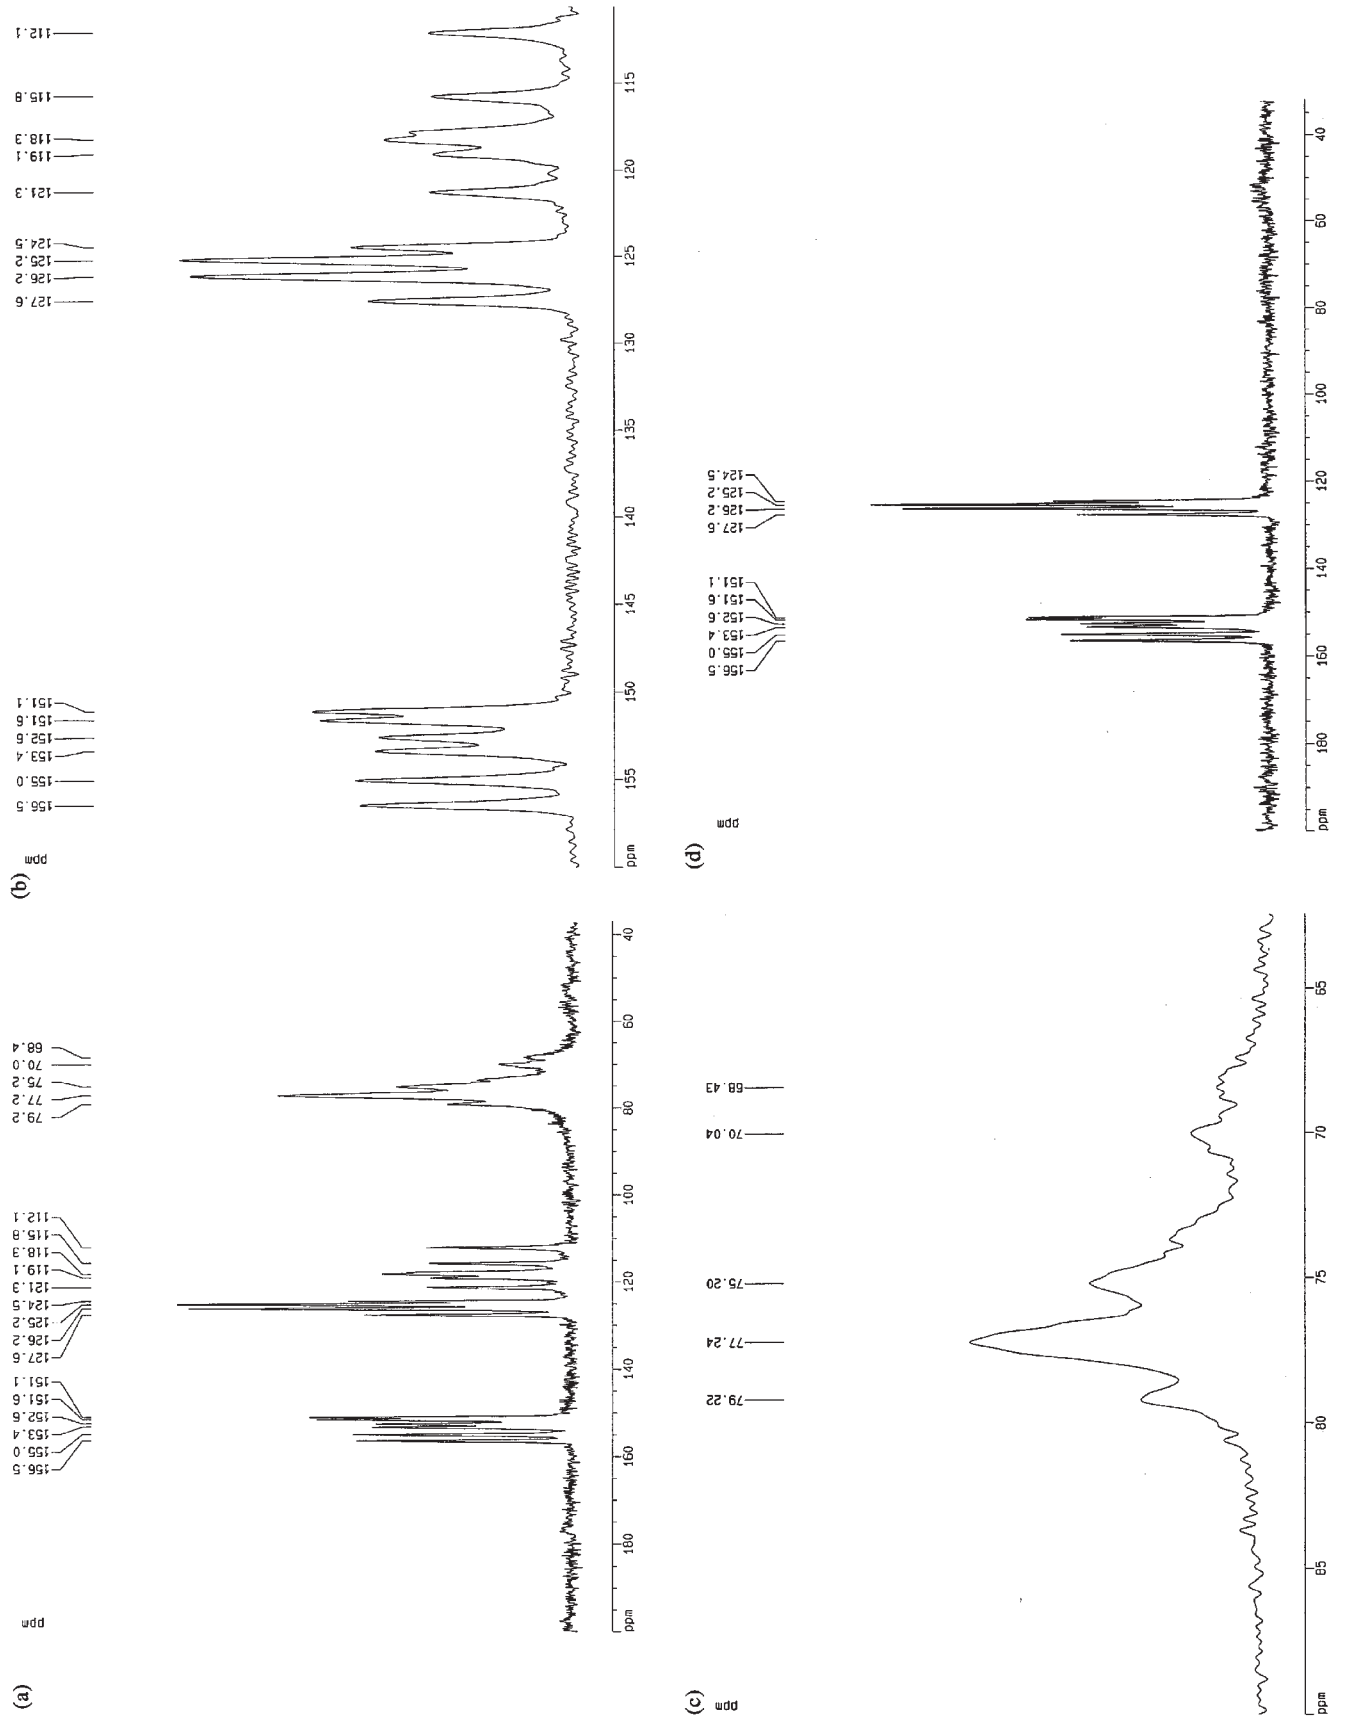
C8-O3-C7-C6	98.7	95.3	103.6	95.9
C6-O2-C5-C4	108.7	–110.5	114.8	114.1

124.5, 125.2, 126.2, and 127.6 ppm. In solution a single peak is observed for these carbons at 125.9 ppm.

For the aromatic CHs (i.e., C2, C9, C12, C19, C22, and C29), a single peak at 116.2 ppm is seen in solution. In contrast, the solid-phase spectrum shows six resonances with a range of chemical shifts from 112.1 to 121.3 ppm. Again, this multiplicity in the solid-state spectrum is consistent with the lack of symmetry in the crystal structure. There are several factors contributing to the observed solid-state chemical shift differences for these carbons. Our analysis of these factors will concentrate on differences in two torsion angles for networks involving these carbons as terminal atoms (Table 6). For example, for the C2 site, the C2-C1-C30-C29 angle is 3.3(4)°, while the C2-C3-O1-C4 angle is 60.0(3)°. For C29, a common angle of 3.3° occurs for the C29-C30-C1-C2 network, but the C29-C28-O9-C27 angle is 159.6(3)°. Thus, a substantial chemical shift difference is expected between C2 and C29. Indeed, the angular dependence of the isotropic ^{13}C NMR shielding tensor for anisole has been calculated (5), and using these calculations as a model, one would anticipate that C29 would be shielded by approximately 4 ppm relative to C2.



The other factor that is expected to influence the ^{13}C shieldings for the aromatic CH of **2** is the degree of planarity that exists between the adjacent aromatic rings. Any deviations from planarity will reduce the steric interactions and lead to deshielding effects. Thus, there will be enhanced shielding contributions to C2 and C29 from this effect (θ = 3.3(4)°) relative to C9 and C12 (θ = 7.9(3)°), and in turn, relative to C19 and C22 (θ = 13.8(4)°). Taking both factors into account for each of the six carbons, one can arrive at a predicted order of shielding as follows: C29 > C12, C2 > C9 > C19, C22.

For the aliphatic carbons of **2**, the chemical shift range in the solid-state ^{13}C NMR spectrum is approximately 9 ppm, with five clearly resolved lines in the approximate ratio of 1:1:3:5:2 (from high to low field). In solution there are just two lines at 72.0 and 73.7 ppm. For solid **1**, the range is approximately 8 ppm. Although it is expected that torsional effects will play a part in determining the chemical shifts of the 12 unique aliphatic carbons of **2**, it is difficult to make any unambiguous assignments. However, if one uses the angular dependence of the ^{13}C shifts of anisole as a model and examines the torsion angles in **2**, one would predict that C7 would be the most deshielded aliphatic carbon of **2** and that C14 would be the most shielded.

The central carbons C5, C6, C15, C16, C25, and C26 (i.e., those most remote from the aromatic rings) are likely to have similar chemical shifts and probably give rise to the largest peak around 77 ppm in the solid phase spectrum.

C29-C28-O9-C27	–159.6(3)

The dipolar dephased version of the ^{13}C CPMAS NMR spectrum is shown in Fig. 3*d* where the resonances for all the carbons bearing hydrogen have disappeared. This is normal behaviour and indicates that there is no large-amplitude molecular motion in the crown ether portions of **2**. This is in contrast to the case for some larger macrocyclic systems, such as complexes of 12-crown-4, 15-crown-5, and 18-crown-6, where substantial residual intensity has been observed in the dipolar dephased solid-state ^{13}C NMR spectra due to at least partial motion averaging of the dipolar C-H interactions (6).

Experimental

Materials

Synthesis of **2** was carried out as follows. A 1 L double-necked round-bottom flask was fitted with a dropping funnel and a condenser. The flask had a gas outlet tube going into a dilute NaOH solution. To a mixture of $FeCl_3$ (48.7 g, 0.3 mol), CH_2Cl_2 (400 mL) and concentrated H_2SO_4 (1 mL) in this flask was added **1** (17.9 g, 0.1 mol) in CH_2Cl_2 (100 mL), dropwise with vigorous stirring. The mixture was brought to reflux for 24 h. Then methanol (150 mL) was added, and the mixture was brought to reflux for another 3 h. After cooling, CH_2Cl_2 (300 mL) was added to the mixture and washed with distilled water (3 × 300 mL). The combined organic layers were dried over anhyd Na_2SO_4, and the solvent was removed by rotary evaporation to yield 16.0 g of a black oil. ^1H NMR indicated that this was a mixture of **1** and **2** in a ratio of ca. 3:1.

The black oil was boiled in hexane (3 × 400 mL) to produce a deep-brown precipitate. This solid was collected by filtration and washed further with boiling hexane (200 mL) to yield a dark-brown powder. Final purification was carried out via flash column chromatography on silica gel, with 1:1 acetone:petroleum ether as eluent. The resulting light-brown solid was dissolved in a minimum quantity of absolute ethanol and boiled with activated charcoal. Upon cooling of the light-yellow filtrate, colourless needles of **3** were obtained. Total yield was 4.5 g (25.4%) (mp 264–266°C). ^{13}C NMR (400 MHz, $CDCl_3$) δ: 72.0, 74.7, 116.2, 125.9, 151.1.

^{13}C NMR spectra

The solution ^{13}C NMR spectra were recorded at 100.6 MHz using a Bruker AMX-400 instrument with complete ^1H noise decoupling. An Aspect 3000 processing controller was employed, and all standard microprograms used are in the Bruker software library.

The solid phase ^{13}C NMR spectra were recorded at 50.3 MHz using a Bruker ASX-200 solid-state NMR spectrometer equipped with a Bruker 7 mm triple resonance probe. The magic angle was set accurately using the ^{79}Br resonance of KBr and maximizing the number of rotational echoes in the FID. Magic angle spinning rates were approximately 5 kHz. ^1H 90° pulses were 3.5–3.8 μs with contact times of 1 s. Chemical shifts were referenced to the ^{13}C resonance of $Si(Si(CH_3)_3)_4$, which has a chemical shift of 3.7 ppm relative to TMS. Dipolar dephased spectra were obtained via interruption of the ^1H decoupling for 40 μs immediately following the cross-polarization pulse.

X-ray crystallographic studies and structure refinement

Suitable crystals were selected and mounted on thin glass fibres using viscous oil. Data were collected on a Bruker AX SMART 1k CCD diffractometer using 0.3° scans at 0, 90, and 180°. Unit cell parameters were determined from 60 data frames collected at different sections of the Ewald sphere. Semi-empirical absorption corrections based on equivalent reflections were applied (7).

Unit cell parameters and systematic absences in the diffraction data are consistent with the space group $P2_1/c$. The structure was solved by direct methods, completed with difference Fourier syntheses and refined with full-matrix least-squares procedures based on F^2. All non-hydrogen atoms were refined with anisotropic displacement parameters and hydrogen atoms were treated as idealized contributions. All scattering factors and anomalous dispersion factors are contained in the SHEXTL 5.1 program library.

Factors limiting oxygen delignification of kraft pulp

Leonid G. Akim, Jorge Luiz Colodette, and Dimitris S. Argyropoulos

Abstract: Softwood kraft pulp was subjected to a laboratory one- and three-stage oxygen delignification process. Pulp and liquor samples were collected at different stages of the process with particular attention being paid to the early and late stages. A novel residual lignin isolation method extracted about 65% of the oxidized residual lignins at a purity exceeding 90%. Using this methodology coupled to quantitative ^{31}P NMR, ^{13}C NMR, 2D heteronuclear (HMQC) NMR spectroscopic and analytical pyrolysis techniques allowed a thorough characterization of the residual and solubilized lignin fractions at the various stages of the process. Our conclusions do not point to a single factor as being responsible for the limits confronting oxygen delignification. Amongst the major factors impeding the effectiveness of oxygen delignification are: (*i*) the accumulation of relatively inert 5,5′ biphenyl structures originally present in kraft lignin from dibenzodioxocin ring opening reactions; and (*ii*) the accumulation of considerably less reactive *p*-hydroxyphenyl structures. Detailed quantitative information was obtained and discussed in relation to the presence and role of these unreactive phenolic fractions on the residual oxidized lignins. As such we arrived at important conclusions as to why and how these structures remain and accumulate on the fiber. In addition, issues related to the profiles of the total phenolic hydroxyl content of the residual lignins and the remaining arylglycerol β-*O*-4 structures are discussed.

Key words: analytical pyrolysis, biphenyl structures, HMQC, NMR, oxidation mechanism, oxygen delignification, *p*-hydroxyphenyl moieties, quantitative ^{13}C NMR, quantitative ^{31}P NMR, residual lignin, solubilized lignin, total phenolic hydroxyls.

Résumé : De la pâte au sulfate (pâte kraft) provenant de bois résineux a été soumise en laboratoire à un processus de délignification par l'oxygène, à une ou trois étapes. Les échantillons de pâte et de liqueurs ont été recueillies à différents stades du processus, en portant une attention particulière aux stades du début et de la fin. Une nouvelle méthode d'isoler la lignine résiduelle a permis d'extraire environ 65 % des lignines résiduelles oxydées, avec un degré de pureté supérieur à 90 %. Faisant appel à cette technologie couplée à des techniques spectroscopiques [RMN du ^{31}P, RMN du ^{13}C, RMN hétéronucléaire en deux dimensions (« HMQC »)] ou d'analyses pyrolytiques, il a été possible de faire une caractérisation complète des fractions de lignines résiduelles et solubilisées, à divers stades du processus. Nos résultats ne permettent pas d'attribuer à un seul facteur les limites auxquelles on doit faire face lors de la délignification par l'oxygène. Parmi les facteurs qui limitent l'efficacité de la délignification par l'oxygène, les plus importants sont: (*i*) l'accumulation de structures 5,5′ biphényles relativement inertes qui sont originalement présentes dans la lignine de la pâte kraft et qui proviennent de réactions d'ouverture de cycles des dibenzodioxocines et; (*ii*) l'accumulation de structures *p*-hydroxyphényles qui sont beaucoup moins réactives. On a obtenu des informations quantitatives détaillées et on en discute en termes de la présence et du rôle de ces fractions phénoliques non réactives sur les lignines oxydées résiduelles. Sur cette base, on est arrivé à d'importantes conclusions sur le pourquoi et comment ces structures se maintiennent et s'accumulent sur la fibre. De plus, on discute des questions apparentées aux profils en contenu en hydroxyles phénoliques totaux des lignines résiduelles et en structures β-*O*-4-arylglycérol résiduelles.

Mots clés : pyrolyse analytique, structures biphényles, HMQC, RMN, mécanisme d'oxydationm délignification par l'oxygène, portions *p*-hydroxyphényles, RMN du ^{13}C quantitative, RMN du ^{31}P quantitative, lignine résiduelle, lignine solubilisée, hydroxyles phénoliques totaux.

[Traduit par la Rédaction]

Introduction

Regulatory and economic pressures have driven the pulp and paper industry to implement new delignification and bleaching practices. A major transition is the partial replacement of chlorine or chlorine dioxide delignification stages with oxygen delignification. The environmental, technical and economic benefits of oxygen delignification include lower chemical requirements in subsequent bleaching sequences, higher brightness with equivalent amount of chemicals, lower rejects and lower water consumption and subsequent effluent discharge due to the greater recycling potential of

oxygen stage effluents (1, 2). The effectiveness of an oxygen delignification stage is however limited to 50% delignification. Beyond this level, severe cellulose degradation takes place, resulting in the deterioration of pulp viscosity and strength characteristics (3, 4). This selectivity issue is a drawback of oxygen delignification.

A number of approaches aimed at extending oxygen delignification have been proposed and implemented in the industry. Double stage oxygen delignification has shown some potential (5, 6). However, even under idealized laboratory conditions, the effectiveness of double stage oxygen delignification with thorough interstage washing failed to exceed 70% delignification (7). Chirat and Lachenal (8) in their study of multistage oxygen delignification showed that a significant fraction of the residual lignin remains within the pulp even after four stages of oxygen delignification.

Finding ways to obtain lower kappa numbers, using oxygen delignification would curtail the expensive chemicals needed in subsequent bleaching stages. However, achieving a viable "extended" oxygen delignification process is more likely if the mechanisms responsible for limiting the process are better understood. During the past decade a number of studies have addressed lignin oxidation with molecular oxygen under alkaline conditions. The early efforts centered on elucidating the reaction mechanism of oxygen delignification using lignin model compound under homogeneous reaction conditions (9, 10). Moieties bearing free phenolic hydroxyls groups exhibited a higher reactivity toward oxidation than their etherified counterparts (11–13). Based on the accumulated data Gierer (14) proposed a reaction mechanism which involves the phenolate anions, formed under the alkaline conditions of the process, being converted into phenoxy radicals followed by the formation of hydroperoxides and the eventual degradation of aromatic rings to muconic acids.

Further developments in this area have been associated with structural studies of residual lignin isolated from oxygen delignified pulp using either acidolysis (15, 16) or enzymatic digestion (17). In the early papers of this series, Gellerstedt et al. (15) reported that the residual lignin, in an oxygen-delignified pulp "has few remaining phenolic hydroxyl groups." However, ensuing efforts by Sun and Argyropoulos (18) and Johansson et al. (19) did not confirm such a drastic depletion.

Aromatic condensation reactions have also been thought to decrease the reactivity of lignin moieties toward oxygen delignification (20, 21). The reactivity of various condensed units present in kraft pulp were explored using degradation techniques. Condensed structures such as diphenylmethane and biphenyls were found to be resistant during oxygen delignification and were held responsible for the slow phase of oxygen delignification (20). The phenylcoumaran structures were pronounced to be the least stable amongst the resistant condensed moieties (20). The reactivity of the condensed structures within residual kraft lignin under oxygen delignification conditions was recently evaluated in detail (21). Even under homogeneous oxidative conditions with no mass transfer limitations operated, the 5,5′ biphenyl condensed structures were found to be fairly stable toward the oxidation.

Despite the many research efforts the question of which structures are responsible for activation and which are responsible for lignin deactivation during oxygen delignification still remains unanswered. Our continuing efforts to address this question are now focused at systematically examining the residual lignins within an oxygen delignified fiber. To do this a newly developed residual lignin isolation method which provided residual lignin in high yield was coupled with a systematic sampling of delignified pulp and spent liquor at different stages of oxygen delignification. The isolated residual and solubilized lignins were then subjected to detailed spectroscopic analyses. This approach allowed a systematic assessment of the structural changes occurring within the lignin during the oxidation process. To strengthen our conclusions and augment our data, lignins isolated from a multistage treatment were also examined.

Experimental

Oxygen delignification

Black spruce softwood (*Picea mariana*) kraft pulp of kappa no. 29.9 was chelated with DTPA for 30 min at 50°C and thoroughly washed before the oxygen delignification process.

A custom-made 2.5 L kettle reactor was used for oxygen delignification. The reactor was equipped with a central shaft and impellers for effective pulp mixing at medium consistencies. An elaborate computer interface provides a precise control of all major process parameters and of any desired process scenarios.

In all experiments the amount of pulp used in the oxygen delignification stage (oven-dry basis) at a consistency of 10%, an oxygen pressure of 0.68 MPa, and at 90°C was 50 g. At the beginning of each experiment the NaOH charge was 2.5% (on oven-dry pulp). A 1% charge (on oven-dry pulp) of $MgSO_4$ was also added at this time to ensure optimum stabilization of the carbohydrates. The pulp was mixed with the chemicals and placed in the preheated reactor. After reaching 90°C, oxygen pressure was applied. At the end of the desired reaction time the pressure was released, the reactor opened, and the pulp was discharged and filtered. The spent liquor was collected and the pulp was washed thoroughly with de-ionized water. For the second and third stages the washed pulp was remixed with the same amount of fresh chemicals and loaded into the preheated reactor using the same procedure and conditions described above. Kappa no., viscosity, and Klason lignin contents of the pulps were measured according to the PAPTAC standard methods (22).

Homogeneous oxidation of spent liquor

The spent liquor from a 20-min oxygen delignification stage was collected, filtered without dilution, and placed in a glass-lined 1 L Parr reactor. To avoid metal ion contamination all interior parts of the reactor were coated with Teflon®. The system was then heated to 90°C and an oxygen pressure of 0.68 MPa was applied upon reaching temperature. The time of oxidation at temperature and pressure was 60 min with continuous mixing. After the treatment, the solubilized lignin was isolated according to the procedure

described in ref. 27, ensuring that the yields of lignin recovery were near quantitative.

Lignin isolation

Solubilized lignins were precipitated from the spent liquor by acidification with 1 M solution of HCl to pH 1.5. The precipitated lignin was then centrifuged, washed repetitively with acidified water (pH 2.0), and freeze-dried.

The residual lignins were isolated using a method recently developed in our laboratory (23). The method initially requires a mild enzymatic hydrolysis step with cellulase. The solubilized lignin was then precipitated by acidification and combined with the undissolved residue remaining after the enzymatic treatment. This mixture was then subjected to a very mild acidolytic treatment (0.05 M of HCl solution in dioxane–water (85:15) mixture). The lignin-containing solution was acidified with 1 M HCl to pH 2.0, the precipitated lignin was then centrifuged, repetitively washed with 0.01 M HCl, and freeze-dried. At the end of the isolation procedure the lignin was extracted with dichloromethane to remove accumulated extractives. The yield of the extracted lignin ranged from 55 to 70% (Table 1). The protein contamination was calculated based on the nitrogen content (Table 1) and further calculations of functional groups content within the residual lignin were made taking this into account. Elemental and methoxyl analyses were carried out by the Schwarzkopf Microanalytical Laboratories, Woodside, New York.

Oxidation of lignin model compounds

Two lignin model compounds were oxidized: 4-methylphenol (*p*-cresol) and 2-methoxy-4-methylphenol. Both compounds were purchased from Aldrich and used without purification. In preparation for the oxidation process, *p*-cresol (0.54 g, 0.005 mol) and 2-methoxy-4-methylphenol (0.69 g, 0.005 mol) were dissolved in 0.625 M NaOH (250 mL). The mixture was then placed in a glass-lined Parr reactor and oxidized at an oxygen pressure of 0.68 MPa at 90°C for 60 min with continuous agitation. After the treatment an internal standard (3,4-dimethylphenol) (0.154 g, 0.001 mol) was added, the mixture was acidified with 2 M HCl to pH 2.0 and repetitively extracted with ethylacetate. The combined extracts were then dried over $MgSO_4$ and quantitatively analyzed using a Hewlett–Packard HP 5890A gas chromatograph, equipped with a DB 5 30 m × 0.25 mm packed silica capillary column (film thickness 0.25 μm) and a flame ionization detector. The injection port temperature was 280°C and the oven temperature was raised from 70°C to 200°C with a gradient of 15°C min^{-1}.

NMR spectroscopy

Quantitative ^{31}P NMR spectra of the lignins were acquired using a Varian Unity 500 spectrometer operating at 202.3 MHz according to the method described by Granata and Argyropoulos (24). Prior to the analysis the lignin was phosphitylated with 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane and cholesterol was employed as an internal standard. An inverse gated decoupling sequence was employed with a pulse width of 90° and a relaxation delay between pulses of 5 s. About 300 transients were acquired to ensure high signal–noise ratio. For each lignin sample at least two spectra were recorded to ensure reproducibility with low standard error. The spectra were integrated and the amounts of the different functional groups were calculated as described elsewhere (24).

Quantitative ^{13}C NMR spectra of the lignins were acquired on a Varian Unity 500 NMR spectrometer operating at 125.7 MHz with an inverse gated decoupling sequence using a newly developed acquisition protocol described by Zia et al. (25). The weighed amount of lignin (400–450 mg) was placed into a 10 mm (o.d.) NMR tube and dissolved in DMSO-d_6 (2.7 mL). A measured amount of 1,3,5-trioxane (30–35 mg) was added as an internal standard and $Cr(acac)_3$ (2 mg) was added as a relaxation agent. The sweep width of the spectra was 59 970 Hz, the pulse width was 14.1 μs, and the relaxation delay was 12.5 s. For each spectrum about 7000–8000 scans were accumulated. The resulting spectra were integrated and the integrals compared with those of the internal standard as described elsewhere (25).

One-bond ^{13}C–^{1}H heteronuclear quantum coherence (HMQC) correlation spectra were recorded using a Varian Unity 500 NMR spectrometer with a 5 mm inverse geometry probe. To record the spectra 100 mg of lignin was dissolved in 0.7 mL of DMSO-d_6 in a 5 mm (o.d.) sample tube. The

© 2001 NRC Canada

spectra were acquired using 170 scans over 256 increments of 2 K data points over 10 ppm in F2 (^{1}H) and 140 ppm in F1 (^{13}C). To suppress the ^{1}H–^{13}C magnetization, a BIRD presaturaration sequence was used. The polarization transfer delay between ^{1}H and ^{13}C was set to 140 Hz and the relaxation delay was 0.8 s. After processing with F1 zero filling, $\pi/2$ shifted squared sinebell apodization and Fourier transformation were applied. The resulting matrix was 1024(F2) × 1024(F1) real points.

Analytical pyrolysis (Py-GC-MS)

The isolated residual lignin sample (0.5 mg) was placed into the pyrolysis chamber of a pyroprobe 2000 (Chemical Data System) and purged with helium through the chamber for 10 s prior to pyrolysis to minimize oxidation. The interface starting temperature was 250°C. The temperature was then increased at a rate of 20°C ms^{-1} to 550°C, and it was held at this temperature for 10 s. The GC-MS analyses were carried out on a Hewlett–Packard 5972 mass spectrometer interfaced to a Hewlett–Packard HP 5890A gas chromatograph equipped with a DB-5 30 m × 0.25 mm packed silica capillary column with a film thickness of 0.25 μm. The column temperature was held at 70°C for 4 min and it was then increased by 4°C min^{-1} to 280°C. The pyrolysis products were identified by their mass spectra fragmentation pattern. The relative content of *p*-hydroxyphenyl structures was calculated as a ratio of peak area assigned to these structures, to the total peak area.

Results and discussion

The lignin content in the oxygen-delignified pulp and the elemental analysis of the isolated residual and spent liquor lignins are shown in Table 1. The pulp and spent liquors were sampled at different intervals within a 160-min first stage delignification and at the end of a 60-min (3 × 20) three-stage and also a 120-min (2 × 20 and 1 × 120) three-stage process. During this effort the residual lignin was isolated using a mild enzymatic hydrolysis protocol, followed by a mild acidolytic treatment (23). In this novel isolation procedure the primary cellulolytic treatment digests most of the carbohydrates thus exposing the residual lignin and the mild acidolytic treatment ensures minimum secondary condensation reactions. This method supplies an excellent yield of residual lignins even for heavily oxidized pulps, i.e., an oxygen-delignified pulp after three stages (about 62 to 63%, Table 1). More details of the procedure and detailed lignin analyses and purity data have been described by Argyropoulos et al. (23). This represents a major improvement over previous reports that implied that conventional methods of enzymatic hydrolysis could not provide an acceptable yield for such heavily oxidized pulps (26).

The isolated lignins were studied using a broad range of NMR spectroscopic techniques, namely quantitative ^{31}P NMR, ^{13}C NMR, and 2D heteronuclear (HMQC) NMR spectroscopy. Quantitative information on the different types of functional groups in the lignins was collected and analyzed to follow the changes occurring within the kraft pulp lignin during multistage oxygen delignification.

The kappa no. measured after various time intervals of the oxygen delignification shows that after 50–60 min of oxidation the delignification had significantly slowed. Attempts to use a multistage approach only marginally reduced the lignin content (to kappa no. 12.5) (representing about 60% delignification). As anticipated, the introduction of the multistage approach showed no significant improvement in the effectiveness of oxygen delignification, in agreement with various large scale industrial operations (7). Recent claims by industry suppliers in relation to extending these limits, most likely, rest with lignin leaching effects at the second stage and not on actual degradation by oxygen (6).

The role of phenolic hydroxyl groups

Most early efforts attempted to unravel the mechanism of oxygen delignification using lignin model compounds (9, 10). These studies suggested that the reactivity of the phenylpropane units bearing free phenolic hydroxyl groups far surpassed that of non-phenolic structures. To this effect Gierer (14) regards the role of free phenolic units as the centers of radical formation. Consequently, amongst all the lignin functional groups we focused our attention on the free phenolic hydroxyl groups because of the evidence pointing to their important role in the chemistry of oxygen delignification.

In two earlier accounts the extreme depletion of phenolic groups during oxygen delignification has been cited as the factor responsible for the limits of the process (15, 16). Chirat et al. (26) and Johansson and Ljunggren (12) however, reported that the decrease of the amount of free phenolic hydroxyls is significant but even after extensive multistage delignification there is still an abundance of such groups within the lignin. In addition, our earlier research on oxidation of isolated residual kraft lignin (27), pointed out that even under extreme and idealized oxidation conditions (140°C, 80 min, homogeneous solution, and thorough mixing) about 50% of the initial amount of the total phenolic OH remained within the lignin structure. Our data was also later supplemented and supported by that of Moe and Ragauskas (28) who showed free phenolic hydroxyl content within residual kraft lignin decreased by only about 30–40% after oxygen delignification.

The amount of phenolic hydroxyls present in the residual lignin of oxidized kraft pulp was determined by quantitative ^{31}P NMR spectroscopy (Table 2). The residual lignins isolated from the delignified pulps show a rapid depletion of the total free phenolic hydroxyl units during the initial 10 min of oxygen delignification from 1.87 to 1.42 mmol g^{-1}, which represents a 24% decline. Then after 50 min of treatment, the amount of the phenolic hydroxyl units was seen to stabilize at approximately 60% and did not further decrease (Fig. 1). Application of three stages of delignification with thorough interstage washing did not result in any significant additional decrease of the phenolic hydroxyl level (Table 2). More specifically, even after two 20-min stages and a third 120-min stage the amount of phenolic units within the residual lignin was 1.21 mmol g^{-1}. This figure is marginally lower than the corresponding amount within the residual lignin from the pulp delignified in a single 160-min stage (1.31 mmol g^{-1}).

While it is very likely that the decrease of phenolic OH units is a consequence of lignin oxidation reactions, our data indicates that factors other than the lack of phenolic OH

groups cause the oxygen delignification to reach a ceiling. Our continuing efforts to locate these factors prompted further investigation of the structural features of isolated residual lignins.

The role of condensation reactions

In earlier work we demonstrated that under homogeneous oxidative conditions the rate of elimination of condensed phenolic units in residual kraft lignin was slower than the rate of elimination of uncondensed guaiacyl phenolic units (21). Amongst the condensed structures, 5,5′ biphenolic structures showed the highest resistance. They decreased in the initial phase of oxidation but after about 40 min of treatment their content did not further decrease. This resulted in a significant accumulation of the condensed hydroxyl content within the oxidized residual lignin (21). The origin of 5,5′ biphenolic moieties in kraft lignin are the eight-membered dibenzodioxocins ring structures recently discovered by Brunow and co-workers (29). Recent work in our laboratory has shown that they constitute about 10% of the phenyl propane units in lignin, or about 10 such rings are present per 100 phenyl propane units (30, 31). Dibenzodioxocins, under kraft pulping conditions open quantitatively to release large amounts of 5,5′ biphenolic moieties, making the presence of these units abundant in residual kraft lignin (31).

Consequently, we paid particular attention to the behavior of the condensed phenolic structures, and more specifically on the development of 5,5′ biphenyl structures within the residual lignins as a function of intensity of oxygen delignification. Within the solubilized lignins the condensed

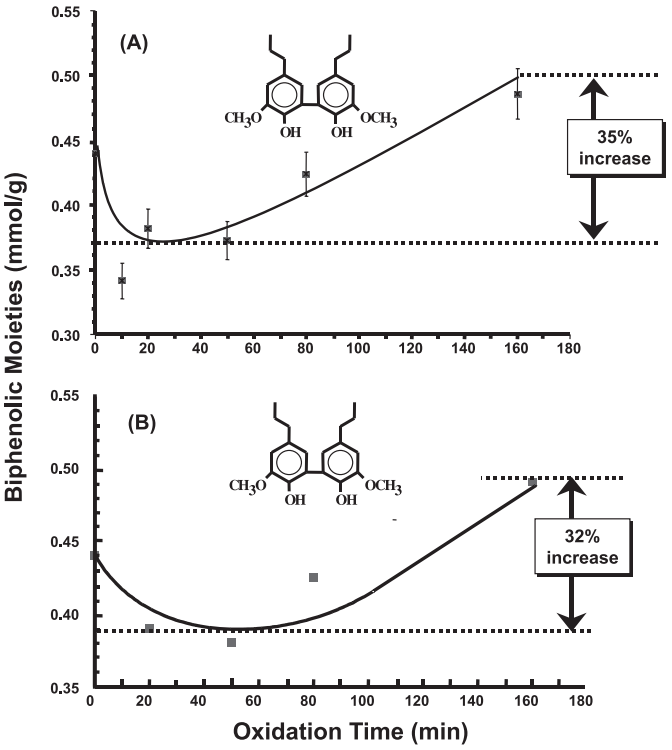

Fig. 1. Total phenolic hydroxyl group content measured in isolated residual lignin at various intervals along an oxygen delignification process.

phenolic OH content was found to decrease by about 25–30% during the initial stages of delignification (20 min) and then remained essentially constant (Table 2). In the residual lignins, however, the 5,5′ biphenolic condensed structures were found to decrease from 0.44 to 0.38 mmol g^{-1} during the early phases of oxygen delignification, and then started to build up again to a value of 0.49 mmol g^{-1} level (Fig. 2*a*). However, when the liquor coexisting with the pulp was replaced in a series of multistage experiments, the content of

Fig. 2. 5,5′-Biphenyl moieties present within the residual lignin at various points along a conventional oxygen delignification process. The upper plot (2*a*) shows the data derived from quantitative ^{31}P NMR of analyses of the lignins, while the lower plot (2*b*) shows the data for the same moieties derived from quantitative ^{13}C NMR analyses.

5,5′ biphenyls did not increase. Even after a prolonged three-stage delignification the level of 5,5′ hydroxyls remained at 0.44 mmol g^{-1}, which is lower than the 0.49 mmol g^{-1} level reached in the corresponding one-stage oxygen delignification (Table 2).

In an effort to further support our measurements of 5,5′ biphenolic structures we measured them using an independent method. For this purpose we developed a quantitative ^{13}C NMR protocol (25) (using an internal standard) and as such we were able to measure the precise amounts of 5,5′ etherified and non-etherified biphenyl moieties and their development within residual oxidized lignins as a function of the extent of oxidation. The data of Fig. 2*b* confirmed that the content of non-etherified 5,5′ biphenyl structures after 80 min increased over the overall time scale of the oxidation. In addition, the etherified 5,5′ structures were also seen to increase (Table 4, see C3 in the last column). The inert nature of such moieties under oxygen delignification conditions could be held responsible for this enrichment.

Our observations so far correlate well with earlier experiments attempting to understand the mechanism of oxygen delignification, using isolated residual kraft lignin oxidized under homogeneous conditions (21, 27). These accounts coupled with the present findings support the idea that the etherified and even non-etherified 5,5′ biphenolic structures are unreactive under oxygen delignification conditions. The accumulation of these groups during oxygen delignification could be another factor imposing limits to the process while the role of lignin–carbohydrate linkages still remains unclear.

Table 3. Relative content of *p*-hydroxyphenyl moieties present in the products of analytical pyrolysis of oxidized residual lignins (%), as determined by oxygen delignification.

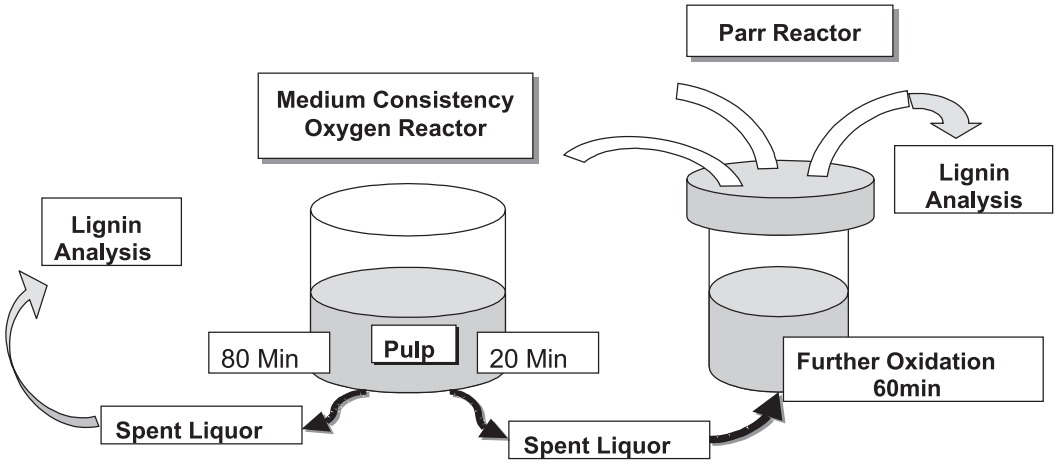
Time of oxidation (min)	Relative content of *p*-hydroxyphenyl (%)
0	2.3
20	2.5
50	3.4
80	3.5
160	4.0

The observed increase of 5,5′ biphenyl hydroxyls could be attributed to secondary condensation reactions. Such reactions, which are likely to occur between phenoxy radicals forming on the mobile solubilized fraction and the radicals forming on immobilized residual lignin could generate new 5,5′ condensed structures. Earlier efforts in our laboratory have demonstrated and quantified that these coupling reactions occur with catechol and 3-methoxy-4-hydroxy toluene (32). These compounds were shown to produce significant quantities of 5,5′ related products under oxidative conditions.

In an effort to further support and substantiate this rationalization we carried out the following series of experiments, schematically represented in Fig. 3.

After 20 min of pulp oxidation in the medium-consistency oxygen delignificaton reactor, the extracted liquor was quantitatively collected and further oxidized for an additional 60 min (without dilution) in a Parr reactor (see Fig. 3). After the oxidation, the lignin was recovered quantitatively and subjected to detailed analyses (Table 2). The amount of 5,5′ condensed phenolic units formed by this liquor treatment in the absence of fiber were found to be 0.55 mmol g^{-1}. This figure was found to be 22% higher than experiments where the fiber was present throughout the oxidation for a total treatment time of 80 min (Table 2).

It is thus reasonable to assume that phenols liberated from the lignocellulosic matrix could form highly mobile and reactive radicals which may recombine with similar moieties present on the fiber. This process could lead to the formation of new 5,5′ unreactive biphenolic moieties present on the fibre, explaining the ^{31}P and ^{13}C NMR data of Fig. 2 and Table 3, respectively.



Noncondensed phenolic hydroxyls

Other functional groups that require attention are the noncondensed phenolic hydroxyls. Studies with lignin model compounds (12, 33) and residual lignin have shown that under oxygen delignification conditions such moieties are much more reactive than biphenyl structures (20).

The noncondensed guaiacyl units in the solubilized lignins decreased monotonically from 0.85 (at 10 min) to 0.25 mmol g^{-1}, as the delignification time was extended and the oxidation intensified (Table 2). However, the changes that occurred to the noncondensed phenolic moieties were different within the residual lignin. As delignification proceeded, the guaiacyl phenolic hydroxyl content in the residual

© 2001 NRC Canada

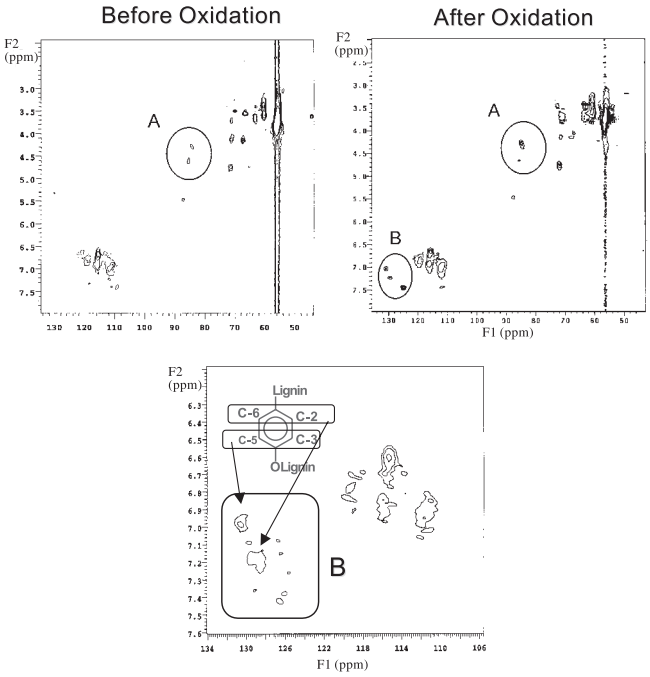


Fig. 3. A schematic showing the series of experiments carried out aimed at confirming the occurrence of 5,5′ linkages between mobile phenoxy radicals and immobilized residual fibre lignin.

lignin also decreased but in a different fashion (Table 2). During the initial rapid phase of delignification the level of noncondensed phenols within the residual lignin was reduced by about 50%. This level was then maintained throughout the rest of the process irrespective of the intensity of oxidation. Only after a series of prolonged delignification stages, one may observe a decrease of these moieties to about 40% of the initial level.

Based on these data it is clear that noncondensed units bearing free phenolic hydroxyls possess excellent reactivity under oxygen delignification conditions. However, the fact that the delignification stops well in advance from the total depletion of these units casts a reasonable doubt to the claim that their depletion is responsible for the ceiling of oxygen delignification.

Fig. 4. HMQC spectra and specific signal assignments for residual lignin isolated from a pulp before and after 80 min of oxygen delignification. Where: (*a*) 4-hydroxy-3-methoxyphenol correlations and (*b*) *p*-hydroxyphenyl correlations.

Accumulation of *p*-hydroxyphenyl units

A comparison of the HMQC (one-bond ^{13}C–^{1}H correlation technique, which displays the signals of carbon atoms directly linked to protons) NMR spectra of the initial residual lignin and the sample isolated after 80 min of delignification (Fig. 4) revealed that a new group of signals appeared in the spectra of the oxidized lignin. These signals appear in the downfield region assigned to aromatic nuclei (Fig. 4, region B) characteristic of *p*-hydroxyphenyl structures (34) while region A is characteristic of guaiacyl correlations. In the spectrum of residual kraft lignin (Fig. 4) before oxidation the *p*-hydroxyphenyl signals are below the detection limit and could not be identified.

To further confirm and quantify the presence of these structures within the residual lignin we examined the quantitative ^{31}P NMR spectra of the isolated residual lignins. The *p*-hydroxyphenyl OH gives rise to a well-resolved peak at 137.8 ppm in the spectra of the oxidized lignin (35). As such their amount within the residual lignin was quantified and was shown to progressively increase by more than three-fold during oxygen delignification (from 0.04 mmol g^{-1} at 0 min to 0.15 mmol g^{-1} at 160 min (Table 2, Fig. 5)). When the content of these structures was calculated on a per g of pulp basis it was found that their content remained essentially constant throughout the delignification process. This clearly indicates that these units accumulate and do not form during oxygen delignification.

A series of isolated residual lignin samples was subjected to further analyses using a combination of analytical pyrolysis coupled to a gas chromatographic and a mass spectroscopic detector (Py-GC-MS). The results in Table 4 show that the relative content of p-hydroxyphenyl units within the pyrolysis products increased with increasing delignification time.

It is a known fact that softwood lignin contains small amounts of *p*-hydroxyphenyl units. Estimates for their abundancy vary from 5% (*Picea abies* (36)) to 13% (*Pinus taeda* (37)). If *p*-hydroxyphenyl units survive oxygen

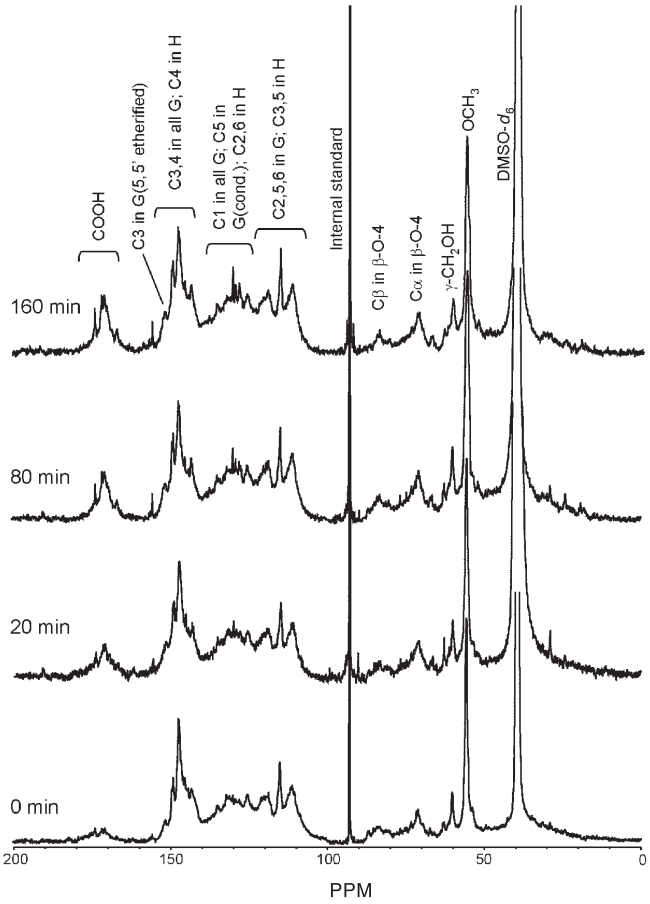
delignification, or at least undergo only limited degradation compared to the guaiacyl units, such moieties may accumulate within the residual lignin. Additional support of this contention arises from literature accounts claiming the accumulation of *p*-hydroxyphenyl units during the process of oxidative delignification with peroxyacids or laccase-mediator systems (38, 39).

Since three independent analytical techniques corroborate the presence and accumulation of such units within the oxygen delignified pulp, this represents convincing evidence for their presence and role in the process. Unfortunately, however there are no literature accounts of directly comparing the oxidative reactivity of *p*-hydroxyphenyl structures with their guaiacyl counterparts. To address this issue we designed a set of experiments where two model compounds, namely: 4-hydroxy toluene and its guaiacyl counterpart (3-methoxy-4-hydroxy toluene) were oxidized under conditions resembling those of oxygen delignification. The products of the oxidation were then quantified by gas chromatography. It was found that 45% of 4-hydroxy toluene remained unreacted while only 12% of the guaiacyl phenol remained in the reaction mixture. This experiment demonstrated the higher stability of *p*-hydroxyphenyl moieties under oxygen delignification conditions. This provides additional evidence that their accumulation contributes to impairing the rate of the process as oxidation intensifies. Since considerably higher amounts of *p*-hydroxyphenyl units exist in hardwood than in softwood, the accumulation of such units could be even more pronounced during oxygen delignification of hardwood pulps. This may, in part, explain the tendency of hardwood pulps to be more difficult than softwood pulps to delignify with oxygen (4).

Other lignin structural changes

The quantitative ^{13}C NMR spectra of the residual lignins isolated from the pulp at different oxidation times are shown in Fig. 6.



Notably, these spectra were similar to those of an oxidized residual lignin recently published by Gellerstedt et al. (40). The only visible difference is the peak at 171.8 ppm assigned to carboxylic carbon atoms. This peak significantly increases as the time of delignification increases. This increase correlates well with the amount of protein contaminants present in the residual lignins and could be attributed to signals of amidic carbonyl group present in proteins. A group of signals due to *p*-hydroxyphenyl structures and probably signals from olefinic carbons at 130.2–129.3 ppm, also progressively increased in size as the oxidation intensified.

A comparison of the ^{13}C spectra of Fig. 6 brings to light that all the changes in the residual lignin structure are of a quantitative rather than qualitative character. In this respect, our quantitative ^{13}C NMR acquisition conditions significantly facilitated the extraction of information and the comparison of the spectra.

There are a number of reports demonstrating that residual β-*O*-4 structures present within kraft lignin are stable under oxygen delignification conditions (13, 28, 40). The signal area between 89.2–67.3 ppm was assigned to Cα and Cβ signals of the atoms involved in β-*O*-4 bonds based on our HMQC spectra and previous accounts (41). The data supplied by quantification of these areas showed that the abundancy of these moieties does not change during the initial 80 min of oxidation (Table 4), i.e., it remained at about 1.20 mmol g^{-1}. This amount decreased to 1.07 mmol g^{-1} when the total oxygen delignification time reached 160 min.

© 2001 NRC Canada

Fig. 6. Quantitative ^{13}C NMR spectra of residual lignins at various points along a conventional oxygen delignification process.

Under extensive oxygen delignification conditions the oxidative degradation of aliphatic side-chains may also become pronounced. This is confirmed by the amount of the γ-CH_2OH groups which significantly decreased during the process (Table 4). A possible mechanism operating could be that of a reverse aldol condensation reaction causing γ-carbon elimination.

The methoxyl content of all residual oxidized lignins gradually decreased during oxygen delignification ranging from 4.1 to 2.8 mmol g^{-1} (Table 4). The difference between the two extreme values is about 32%. This data correlate well with published accounts (16) and our elemental analyses data (Table 1) and can be rationalized on the basis of demethoxylation reactions occurring prior to aromatic ring cleavage (11, 27).

To further assess the differences between the solubilized and residual kraft lignins the quantitative ^{13}C NMR spectra of lignins isolated after 80 min of oxygen delignification were compared. Unfortunately, minor carbohydrate contaminants within the sample of the solubilized lignin prevented a reliable quantification of the aliphatic region. However, data obtained by quantification of the aromatic region (Table 4) revealed that at the same stage of oxygen delignification, (23.4 and 20.5 mmol g^{-1}, respectively) the solubilized lignin was of higher aromaticity compared to its residual lignin counterpart.

Conclusions

A number of factors are responsible for imposing limits usually encountered in oxygen delignification. While phenolic hydroxyl groups are reactive under oxygen delignification conditions their presence is not essential for continuing reactivity at latter stages of the process. 5,5′ Biphenyl structures are relatively inert toward oxidation and accumulate within the residual lignin. Radical coupling reactions are also likely to occur between phenoxy guaiacyl radicals in the liquor and on the fiber, resulting in the formation of 5,5′ structures. Considerably less reactive *p*-hydroxyphenyl structures were also observed to accumulate within the residual lignin. However, the nature of the linkage of the remaining lignin moieties to the fiber still remains unclear. The likelihood of lignin–carbohydrate linkages being formed during oxygen delignification, anchoring lignin moieties on the fibre is currently under investigation in our laboratory.

Acknowledgments

The authors would like to express their gratitude to Mr. Ernst Palus and Mr. Tibor Kristof for their assistance with residual lignin isolation and pulp analyses. In addition, Dr. Anna-Stiina Jaaskelainen also deserves our gratitude for carrying out the Py-GC-MS analyses, Mr. Yujun Sun for participating in a number of valuable discussions, and Mrs. Barbara van Lierop for reviewing the manuscript.

Classical analysis of intermolecular potentials for Ar–CO_2 rotational collisions[1]

J.C. Belchior, J.P. Braga, and N.H.T. Lemes

Abstract: Classical trajectory calculations have been performed for four potential energy functions to describe Ar–CO_2 collisions. A comparison is given between classical cross sections calculated using the two most recent potential surfaces and two older intermolecular potential surfaces based on the electron gas model. The two-dimensional atom ellipsoid model has also been applied for the study of multiple collisions. The model was able to predict such a phenomenon in agreement with quantum scattering results previously published for an ab initio potential surface in the region of very low collision energy. On the other hand, the two older potentials showed multiple collision effects at very high energies. The comparison of the cross sections showed some deviations from the experimental data. By introducing two parameters, a modified surface is proposed by changing the most recent intermolecular potential. In this case the agreement with experimental measurements and theoretical scattering cross sections was considerably improved. It is concluded that global potential surfaces for describing Ar–CO_2 interaction are not well established. To achieve the requirement of reproducing all properties of this system, the present work suggests that one needs further experimental and theoretical investigations.

Key words: classical trajectories, dynamics, cross sections, Ar–CO_2 collisions, potentials.

Résumé : Afin de décrire les collisions Ar–CO_2, on a effectué des calculs de trajectoire classique pour quatre fonctions d'énergie potentielle. On présente une comparaison des sections efficaces classiques calculées d'une part à l'aide les surfaces de potentiel les plus récentes et d'autre part avec deux surfaces de potentiel intermoléculaire plus anciennes basées sur le modèle du gaz électronique. On a aussi appliqué le modèle de l'atome bidimensionnel ellipsoïdal à l'étude des collisions multiples. Le modèle a pu prédire un tel phénomène en accord avec des résultats de diffusion quantique publiés antérieurement pour une surface de potentiel ab initio dans la région de très faible énergie de collision. Par ailleurs, les deux potentiels les plus vieux ne permettent de mettre en évidence les effets de collisions multiples qu'aux énergies très élevées. La comparaison des sections efficaces met en évidence des déviations par rapport aux données expérimentales. En introduisant deux paramètres, on propose une surface modifiée résultant du changement du potentiel intermoléculaire le plus récent. Dans ce cas, l'accord entre les mesures expérimentales et les sections efficaces de diffusion théoriques est grandement amélioré. On conclut que les surfaces de potentiel global permettant de décrire l'interaction Ar–CO_2 n'est pas bien établie. Afin d'atteindre les conditions requises pour reproduire toutes les propriétés de ce système, il découle de notre travail que de nouvelles études expérimentales et théoriques sont nécessaires.

Mots clés : trajectoires classiques, dynamique, sections efficaces, collisions Ar–CO_2, potentiels.

[Traduit par la Rédaction]

Introduction

During the past few years, considerable attention has been focused on the study of the Ar–CO_2 system, as has been discussed in refs. 1 and 2. However, the Ar–CO_2 intermolecular interaction has not yet been fully understood (1), since according to Roche et al. (3) "the only potential that gives a satisfactory account of the line-broadening coefficients is the modified electron gas potential of Preston and Pack" (4), while this same potential provides very poor agreement with van der Waals spectra. The disagreement with the van der Waals spectra suggests that the long-range forces can be improved.

Several types of experimental data are available for the Ar–CO_2 interaction, all measured with a high degree of accuracy (5). Second virial coefficients were obtained for Ar–CO_2 mixtures, and for several temperatures, comparisons with the experimental results of Lichtenthaler and Schafer (6) and of Cottrell et al. (7) show satisfactory agreement. However, for dynamic studies, generally the most informative data from which details of the intermolecular potential can be deduced are obtained from crossed molecular beam experiments. Usually such measurements allow for the extraction of information about the anisotropy of the interaction (8). For the Ar–CO_2 interaction, crossed molecular beam scattering data were obtained by Kalinin et al. (9) and by Loesch (10).

In particular, the experimental measurements of Loesch, which are based on high-resolution molecular beam techniques, have provided state-to-state rotational total cross sections for three collision energies, namely 0.069, 0.11, and 0.19 eV. Classical trajectory calculations were also performed (10) for a simple model potential, and qualitative agreement with the experimental results (i.e., the cross sections) was found. As indicated by Loesch, the state-to-state rotational cross sections are very sensitive to the anisotropy of the repulsive interaction, in particular, and satisfactory agreement was found for a speci-

fied geometric anisotropy. Simultaneously and independently, Parker et al. (11) proposed an intermolecular potential energy function based on an electron gas model that included correlation, Coulomb, and exchange contributions to the interaction energy. A full potential surface was obtained with contributions of both short- and long-range terms. Use of this potential surface for the calculation of the second virial coefficients gave rise to reasonable agreement between the calculated and experimental values. As has been pointed out in ref. 1, this surface, referred to hereafter as surface 1, was the first realistic potential with both short- and long-range components available for the study of $Ar-CO_2$ collisions. Later, Preston and Pack (4) considered another potential surface, obtained by modifying the long-range van der Waals interaction. This potential surface is referred to hereafter as surface 2. Classical trajectory (~30 000) calculations have been performed for both potentials, and in general, acceptable agreement has been found with the experimental measurements of Loesch (10). Small deviations were observed between the calculated and experimental values for differential cross sections corresponding to small Δj transitions. However, as indicated by Preston and Pack (4), such disagreement would be possible since the angular distribution for low Δj values could be unreliable. They noted that surface 1, which gave satisfactory agreement with the experiments, was the most reliable potential and was preferable for studying $Ar-CO_2$ rotational collisions.

Very recently, an ab initio intermolecular potential was obtained using the Møller–Plesset perturbation theory with a large basis set (12), and the data were fitted using procedures recommended by Buckingham et al. (13). This potential has qualitative features of the anisotropy that are comparable to the exchange-quadrupole model of Cooper and Hutson (14). Later, extensive classical and quantum scattering calculations were carried out (2) using this potential energy function. It was pointed out by ter Horst and Jameson that orbital resonances are to be expected for low total energy; this was confirmed on the basis of quantum and classical trajectory calculations. However, no comparison with experimental state-to-state differential or total rotational cross sections was performed, and therefore it appears that such effects have not been fully analysed. This will be discussed in more detail in the present work in light of the two-dimensional atom ellipsoid model.

In an independent study, Roche et al. (3) have utilized nine different $Ar-CO_2$ potential energy functions available in the literature to carry out quantum scattering calculations and to test the ability of these potentials to reproduce the spectra of such a system. Both IOS (15, 16) and CS (16) approximations were used to calculate the pressure-broadening cross sections, but none of the nine potentials gave a satisfactory account of the spectroscopic properties analysed. The goal of Hutson et al. (1) was to obtain an intermolecular potential capable of providing a quantitative potential which was able to reproduce a wide range of the spectrum. Their new potential energy function is based on a nonlinear least-squares method of fitting to both high-resolution van der Waals spectra and second virial coefficients. The new surface was able to reproduce the spectra of the $Ar-CO_2$ interaction with high accuracy, and the relative average error for almost all properties compared was found to be very small. As pointed out by Preston and Pack (4) a correct intermolecular potential would be intermediate to the two potentials used in refs. 4 and 11. This was an important conclusion of Hutson et al. (1), i.e., "...the shape of the repulsive wall in the electron gas potentials is actually quite good and our value for the depth of the minimum at $\theta = 90^o$ is between surface 1 and surface 2." As previously quoted (1), these two surfaces (1 and 2) have a poor representation of the attractive wall, while other fitted potentials (17, 18) provide better representation in the attractive region but provide unsatisfactory representations of the repulsive wall.

The ab initio potential energy function of Marshall et al. (12) was used to study $Ar-CO_2$ collisions and extensive classical and quantum calculations were carried out, but no state-to-state rotational total cross sections were evaluated. Virial coefficients were calculated for several potential energy surfaces, and a comparison with the experimental data for several temperatures was done. Moreover, transport properties were calculated, and an extensive comparison of several types of spectroscopic data was carried out for all available $Ar-CO_2$ potentials. However, it was concluded (2) that "...the ab-initio surface fitted by Marshall et al. (12) provided a disappointing representation of the potential."

Most of the studies of the $Ar-CO_2$ system have been carried out for spectroscopic or thermodynamic phenomena. Very recently, Roche et al. (19) carried out an accurate analysis of the potential surface proposed in ref. 1. They tested the potential for reproducing collisional properties such as line-broadening cross sections. However, even with several intermolecular potentials available, the important features for understanding the $Ar-CO_2$ interaction without also considering cross sections may be still unsatisfactory. We have also very recently used surface 4 for analysing scattering cross sections; these studies have suggested new experiments for new fitting procedures in order to calculate accurate potential energy functions (20).

The present study analyses the two oldest potentials (1 and 2) and the two latest surfaces (3 and 4). A full comparison of classical trajectory calculations for these surfaces and the new ab initio potential (surface 3) will be carried out with the experimental state-to-state rotational total cross sections of Loesch (10). Moreover, the two-dimensional (2D) atom-ellipsoid model (21) will be used to analyse the importance of multiple collisions. Finally, calculations based on the latest surface of Hutson et al. (1), surface 4, will be compared with the experimental state-to-state rotational total cross sections of Loesch (10) and also with the results obtained using the other three surfaces.

The intermolecular potentials

Although several intermolecular potentials have been proposed to study $Ar-CO_2$ collisions, the present work considers only four of them. The surface of Parker et al. (11), surface 1, is written as

$$[1] \qquad V(r,\gamma) = \sum_{n=0,2,\ldots} V_n(r) P_n(\cos\gamma)$$

$$= v^{HF}(r,\gamma) + v^{COR}(r,\gamma)$$

in which v^{HF} and v^{COR} are the short- and long-range contributions, each with a corresponding Legendre expansion. Surfaces 1 and 2 differ mainly in the long-range terms. The functional form for the short-range component is common, and is written as

$$[2] \qquad v_n^{\mathrm{HF}}(r) = A_{n1}^{(1)} \exp(A_{n2} r + A_{n3} r^2)$$

with the $A_{n1}^{(1)}$, A_{n2}, and A_{n3} values provided in Table 1 ($A_{n1}^{(1)}$ is replaced by $A_{n1}^{(2)}$ for surface 2). For surface 1 the long-range terms are given by

$$[3] \qquad v_n^{\mathrm{COR}}(r) = -B_{n1}^{(1)} \exp(B_{n2} r + B_{n3} r^2) \qquad r \le r_n$$

$$v_n^{\mathrm{COR}}(r) = -C_6(n) r^{-6} - C_8(n) r^{-8} \qquad r > r_n$$

with r_n, $B_{n1}^{(1)}$, B_{n2}, B_{n3}, $C_6(n)$, and $C_8(n)$ all given in Table 1. Surface 2, which is more anisotropic than surface 1, has a different exponential prefactor $B_{n1}^{(2)}$ for $r \le r_n$, and has the form

$$[4] \qquad v_n^{\mathrm{COR}}(r) = -(B_{n1}^{(2)} - B_{n1}^{(1)}) \exp(B_{n2} r + B_{n3} r^2) - C_6(n) r^{-6} - C_8(n) r^{-8}$$

for $r > r_n$ with the parameters also given in Table 1.

The ab initio surface of Marshall et al. (12) (surface 3) can be summarized as a sum of several terms, short-range energy (v_{sr}), the dispersion energy (v_{disp}), and the induction energy (v_{ind}). The complete intermolecular potential is written as

$$[5] \qquad V(r, \gamma) = v_{\mathrm{sr}} + v_{\mathrm{disp}} + v_{\mathrm{ind}}$$

where

$$[6] \qquad v_{sr}(r, \gamma) = A \exp\{-\beta(\gamma)[r - r_{ref}(\gamma)]\}$$

with both $\beta(\gamma)$ and $r_{\mathrm{ref}}(\gamma)$ expanded in Legendre series as

$$[7] \qquad \beta(\gamma) = \sum \beta_L P_L(\cos\gamma)$$

Table 2. Parameters for surface 3 (values are in atomic units).

v_{sr}	v_{ind}	v_{disp}
A = 4.35889E+01	$C_{8,0}^{\mathrm{ind}}$=202.945	$C_{6,0}^{\mathrm{disp}}$=186.178
$r_{\mathrm{ref},0}$=1.49681	$C_{8,2}^{\mathrm{ind}}$=231.937	$C_{6,2}^{\mathrm{disp}}$=106.532
$r_{\mathrm{ref},2}$=1.35945	$C_{8,4}^{\mathrm{ind}}$=173.953	$C_{8,0}^{\mathrm{disp}}$=0.0
$r_{\mathrm{ref},4}$=0.103711	$C_{10,0}^{\mathrm{ind}}$=4257.40	$C_{8,2}^{\mathrm{disp}}$=0.0
$r_{\mathrm{ref},6}$=-0.232085	$C_{10,2}^{\mathrm{ind}}$=2359.70	$C_{8,4}^{\mathrm{disp}}$=0.0
$r_{\mathrm{ref},8}$=0.1741	$C_{10,4}^{\mathrm{ind}}$=2356.01	$C_{10,0}^{\mathrm{disp}}$=293258
β_0=1.85782	$C_{10,6}^{\mathrm{ind}}$=6.86952	$C_{10,2}^{disp}$=528639
β_2=0.0209364		$C_{10,4}^{\mathrm{disp}}$=0.0
β_4=0.101625		$C_{10,6}^{\mathrm{disp}}$=0.0
β_6=-0.0964734		
β_8=0.0698541		

Note: Multiply the dispersion coefficients by 1.012 (see table VI of this ref. 12 for more details).

$$r_{\mathrm{ref}}(\gamma) = \sum r_{\mathrm{ref}_L} P_L(\cos\gamma)$$

The dispersion energy is also represented as a Legendre expansion,

$$[8] \qquad v_{\mathrm{disp}}(r, \gamma) = -\sum_{n=6}^{\mathrm{even}} \sum_{L=0}^{n-4} \frac{D_n(\beta(\gamma), r) C_{n,L}^{\mathrm{disp}} P_L(\cos\gamma)}{r^n}$$

with

$$[9] \qquad D_n(\beta, r) = 1 - \mathrm{e}^{-\beta r} \sum_{k=0}^{n} \frac{[\beta r]^k}{k!}$$

Finally, the induction energy contribution is written as

$$[10] \qquad v_{\mathrm{ind}}(r, \gamma) = -\sum_{n=8}^{\mathrm{even}} \sum_{L=0}^{n-4} \frac{C_{n,L}^{\mathrm{ind}} P_L(\cos\gamma)}{r^n}$$

The parameters in eqs. [6]–[10] are found in Table 2.

The latest surface available for $Ar-CO_2$ collision is that proposed by Hutson et al. (1) by fitting a wide range of spectroscopic data. Actually, they have proposed two slightly different potential energy functions, but as later pointed out (1), the difference between these potentials is not particularly significant.

Therefore, only the surface referred to in ref. 1 as the "single repulsion" potential has been considered here. It is a site–site potential, which can be written in the form (surface 4)

$$[11] \quad V(r,\gamma) = \sum_{i=1}^{3}\left[\sum_{L} S_{iL}(r_i)P_L(\cos\gamma_i) - \sum_{n=6,8,10}\sum_{L=0,2,4} C_{in}^{L}P_L(\cos\gamma_i)r_i^{-n}D(r_i)\right]$$

in which i is summed over the three sites on the CO_2 molecule, $S_{iL}(r_i)$ is given by

$$[12] \quad S_{iL}(r_i) = A_{iL}\exp[-\beta_{iL}(r_i - r_{\text{ref}})]$$

where r_{ref} was fixed to $7.0a_0$ and the damping function , $D(r_i)$, is given by

$$[13] \quad D_i(r_i) = \begin{cases} 1 & \text{for } i \geq r_i^d \\ \exp[-0.4((r_i^d/r_i)-1)^2] & \text{for } r_i < r_i^d \end{cases}$$

where r^d is equal to $12.85a_0$. The parameters of this surface are given in Table 3. More details of the parameters of surface 1, 2, 3, and 4 may be found in refs. 4, 12, and 1.

The key equations for classical trajectory calculations

The classical trajectory method is well detailed elsewhere (22), and therefore it will be only summarized here. The Hamiltonian of an atom-linear molecule system can be written as

$$[14] \quad H = \frac{1}{2\mu}\left[P_X^2 + P_Y^2 + P_Z^2\right] + \frac{1}{2I}\left[P_\theta^2 + \frac{P_\phi^2}{\sin^2\theta}\right] + V(r,\cos\gamma)$$

in which μ is the reduced mass of the system; I is the moment of inertia of the linear molecule; P_X, P_Y, and P_Z are the components of the linear momentum of the incoming atom; P_θ and P_ϕ are the components of the angular momentum of the molecule; θ and ϕ are describing the orientation of the molecule; and $V(r,\gamma)$ is the intermolecular potential. The relative angle γ is given by

$$[15] \quad \cos\gamma = \frac{(X_A\sin\theta\cos\phi + Y_A\sin\theta\sin\phi + Z_A\cos\theta)}{r}$$

where X_A, Y_A, and Z_A are the coordinates of the incoming atom. Following the usual procedure, the set of 10 coupled equations given in ref. 22 can be obtained, and by defining a set of initial conditions the Runge–Kutta method can be used to integrate the classical coupled equations. The total energy was conserved to better than eight digits. Scattering cross sections $\sigma_{jj'}$ can be calculated using the Monte Carlo statistical method as

$$[16] \quad \sigma_{jj'} = \pi b_{\max}^2 P_{jj'}$$

in which $P_{jj'}$ is the transition probability. The latter has been calculated by boxing the calculated final rotational angular momentum. In the present case it has been truncated to the next even final j, i.e., for values smaller than an odd integer number this is truncated to the smallest even value otherwise to the next greatest even value.

Table 4. The dynamical parameters used in the classical trajectory calculations (40 000 trajectories performed for all surfaces).

Surfaces	$r_{\max}$ (Å)	$b_{\max}$ (Å)
Surface 1 (Parker et al. (11))	30	15
Surface 2 (Preston and Pack (4))	30	15
Surface 3 (Marshall et al. (12))	18	15
Surface 4 (Hutson et al. (1))	18	15

The maximum impact parameter, $b_{\max}$, was chosen as described in Table 4, and each one was selected randomly from the distribution $b = b_{\max}(\xi)^{1/2}$, where ξ is a random number ranging between 0 and 1. The angles, θ and ϕ were also generated randomly between 0 and π and 0 and 2π, respectively.

Results and discussion

Ellipsoid model

The two-dimensional (2D) atom-ellipsoid model is well detailed elsewhere (21), and the theory will not be described here. The analysis based on such a model can give qualitative information concerning the anisotropy of a particular system (23). In the present analysis, two sets of calculations will be carried out for each potential described in section 2 by considering firstly the repulsive component of a surface and then the full potential surface.

Resonance effects were recently analysed by ter Horst and Jameson (2), using the ab initio potential of Marshall et al. (12), namely surface 3. However, although comparisons of classical trajectory and close coupling calculations were made, no direct comparison was made with state-to-state scattering cross sections for any of the energies used by Loesch (10). Moreover, most of the analyses in ref. 2 were carried out based on comparisons with second virial coefficient data, spectroscopic constants, and transport properties. As was pointed out in ref. 2,

©2001 NRC Canada

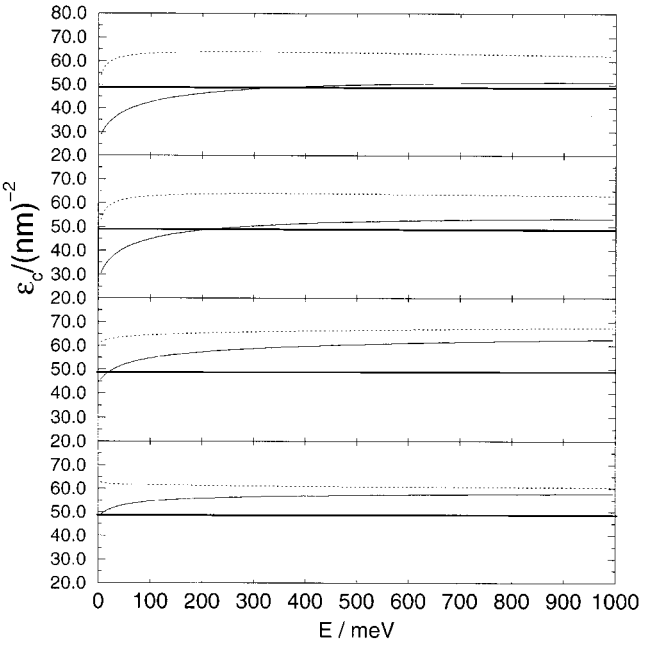
potential 1 can reproduce most of those experimental data, and surface 2 shows good agreement for some but not for all data: as stated by ter Horst and Jameson (2), "the only surface that gave a satisfactory account of the line broadening coefficients was surface 2." It is interesting that in ref. 2 the collision energy used for analysing the resonances was 40 cm^{-1} (4.96 meV). Such an energy is too low to provide any comparison with the experiments of Loesch (10), for which the lowest energy is 69 meV.

According to ref. 24 the occurrence of multiple rotational collisions can be determined by a comparison between $\epsilon \equiv \mu/I$ and ϵ_c, which is evaluated from

[17] $$\epsilon_c = \frac{\beta - \alpha}{(A-B)\left[2B(\sqrt{2A-B} - \sqrt{A}) + (A-B)(\beta-\alpha)\right]}$$

with

[18] $$\beta = \pi - \cos^{-1}\left(\frac{A-B}{A}\right)$$



[19] $$\alpha = \frac{1}{2}\cos^{-1}\left(\frac{A-B}{A+B}\right)$$

and the parameters A and B are defined by $A = r$ when $V(r, 0) - E = 0$ and $B = r$ when $V(r, \pi/2) - E = 0$, where E is the collision energy. If ϵ_c is smaller than ϵ, then multiple collisions will be present. Figure 1 shows ϵ_c as a function of the collision energy for the potentials described in section 2. The contributions of the repulsive component and the full surface are illustrated separately. The repulsive component of surfaces 1, 2, and 3 are almost the same, as can be seen from comparisons between the dotted curves in this figure. Notice that for the first three surfaces ϵ_c increases with collision energy and becomes constant at high energies, while surface 4 shows a different behaviour, especially for very low collision energy. This indicates that multiple-collision effects can be associated with long-range forces. In addition, according to this model, surface 3 gives rise to multiple-collision effects only for collision energies below 20 meV, while for surfaces 1 and 2 such effects can be expected for much higher collision energies of order 200 meV. This may explain the analysis of resonances in ref. 2 where the collision energy used was 40 cm^{-1} (4.96 meV) in concordance with the conclusions of this effect stated there. It appears that the 2D model has failed in the case of surface 4, as it predicts the complete absence of multiple collisions.

Classical trajectory analysis

Classical trajectory calculations have been performed using the potentials of Parker and co-workers (surface 1), Preston and Pack (surface 2), Marshall et al. (surface 3) and Hutson and collaborators (surface 4). Although Preston and Pack have also carried out classical trajectories, the present calculations provide additional details for their surfaces by splitting out the short- and long-range contributions and comparing the classical results with those obtained using more recent potential

Fig. 1. From the top, ϵ_c (multiple collision effects) as a function of the collision energy E for surfaces 1, 2, 3, and 4. The thicker solid lines correspond to the value of ϵ, while the dotted curves show ϵ_c corresponding to the repulsive components of the surfaces and the solid curves show ϵ_c for the full surfaces.

energy functions (surfaces 3 and 4). The analyses of all present calculations are predicted upon treating the experimental measurements of Loesch (10) as the exact results.

Each intermolecular potential comparison made with the experimental results of Loesch is based upon 40 000 classical trajectory calculations carried out with the CO_2 molecule initially in rotational state $j_i = 6$. The classical cross sections calculated using the two oldest potentials are compared with the results obtained using the two latest surfaces for the Ar−CO_2 interaction. The collision energies 0.069, 0.11, and 0.19 eV are those used for the experimental measurements of Loesch (10). Figure 2 shows the results for surfaces 1 and 2 (the two oldest) and surface 4 (ref. 1), while Fig. 3 compares the calculations for surfaces 3 and 4. In both Figs. 2 and 3, only the short-range forces have been taken into account. In Fig. 4 the classical trajectory calculations for the three energies used are compared considering the whole intermolecular potentials.

Figure 2 shows the state-to-state rotational total cross sections. The repulsive intermolecular potentials 1 and 2 are very similar, with slight differences only in the values of the parameter $A_{n1}^{(1)}$ of eq. [2]. Hence, the cross sections in Fig. 2 are almost the same, but as can be seen, small differences do exist. For example, at collision energy 0.069 eV, the cross sections calculated using surface 2 rise up slightly for $j' = 22$, while for surface 1 this is not observed. The greatest difference can be observed at energy 0.19 eV for j' between 30 and 40. As can be seen in this figure, the experimental data are in reasonable agreement with the theoretical results, as has been found previously for surfaces 1 and 2. These surfaces are better for the lowest collision energy and become worse as the energy increases. The repulsive component of surface 4 provides better

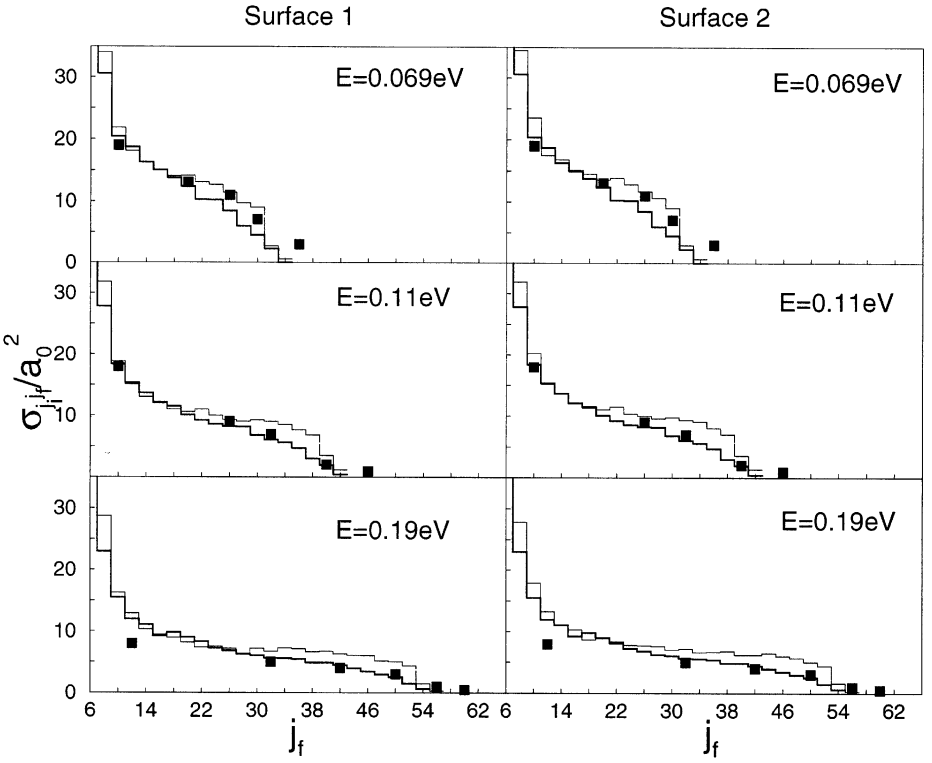
Fig. 2. State-to-state rotational cross sections for repulsive potentials (surfaces 1, 2, and 4). The experimental results of Loesch (10) are shown by the filled squares and the cross sections calculated for surface 4, illustrated by the thick lines, have also been included for comparison.



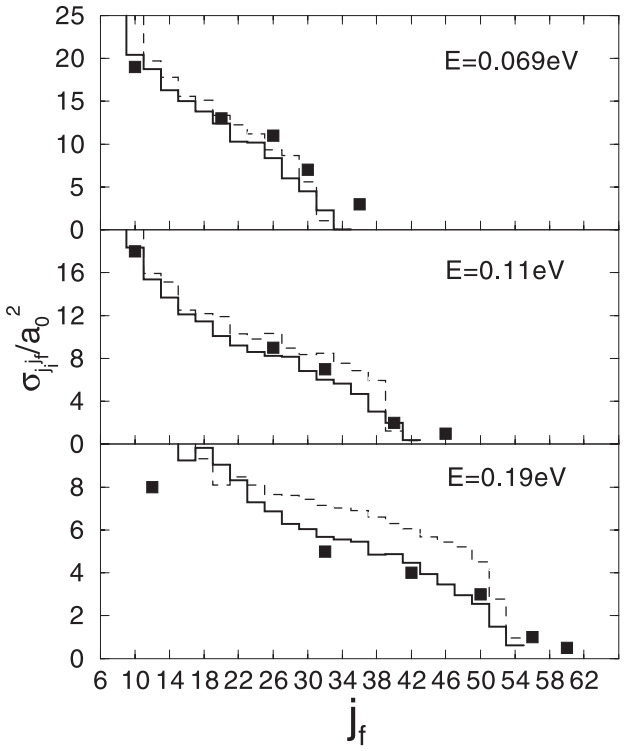


Fig. 3. Comparison of state-to-state rotational cross sections for surface 3 (dashed lines), surface 4 (solid lines), and the experimental data (filled squares).

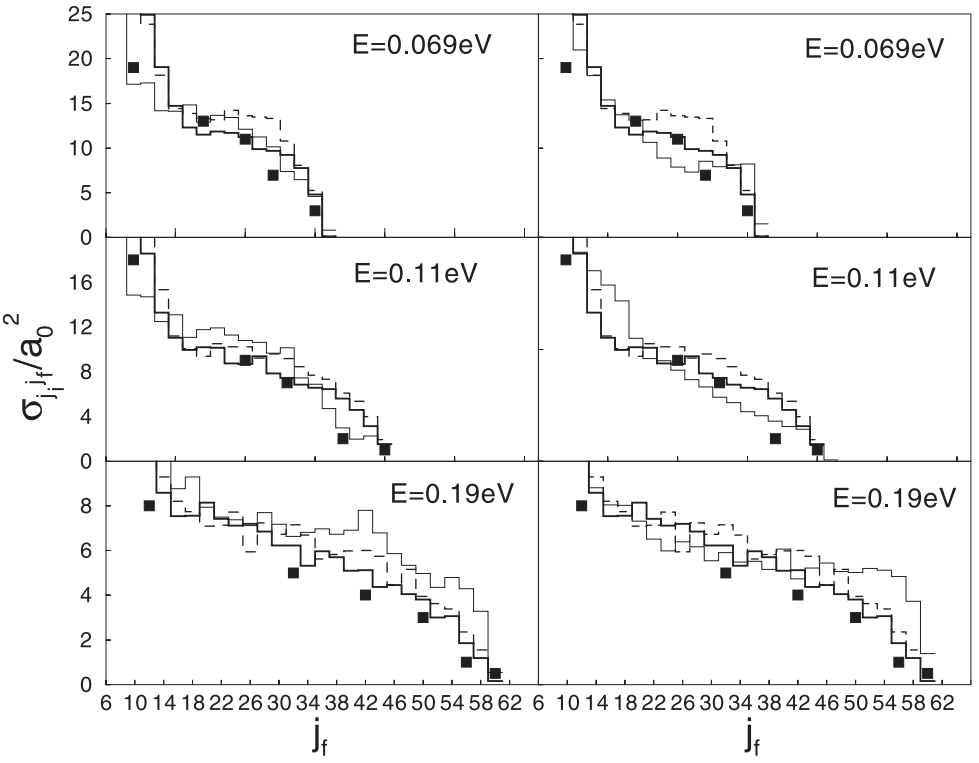

results for the two higher energies, and it does not deviate much from the experimental data, even at the lowest energy.

In general, a full potential contains components of short- and long-range forces. In this case, if there is no charge involved, the core of the particles will contribute to the repulsive term of the potential, while the attractive component, due to the dispersion and induction energies, will mainly contribute to the tail of the surface. If one models the interaction considering only repulsive forces, the tail will certainly be present but it will describe only how the interaction goes to zero. These two quantities are important for increasing or decreasing the rotational transition probability. An analysis of the tail of the potential when only repulsive forces are involved was previously investigated for rotational collisions through quantum mechanics (25). When attractive forces are present the tail of the potential will have two contributions: one from the repulsive component and the other from the attractive term. The results compared in Fig. 2 were calculated by considering only repulsive forces, and hence the tail of these surfaces will only be due to the repulsive component. When no attractive forces are involved only contributions due to the core are present. At lower collision energy the tail may be more important than at higher energies. As can be observed, the results in this figure show that surfaces 1 and 2 provide better agreement with almost all the experimental data at low energies, while surface 4 provides good agreement for small Δj transitions. As the collision energy increases, there is better agreement between the results obtained using surface 4. This is more evident at 0.11 eV collision energy. A unique deviation is observed for the latest transition, i.e., at $j' = 46$, which

©2001 NRC Canada

Fig. 4. Comparison of experimental (filled squares) and calculated state-to-state rotational cross sections for full potentials. Thin solid lines, surface 1 (left panels), surface 2 (right panels); dashed lines, surface 3; thick solid line, surface 4.

may be attributed to the absence of the long-range component of the surfaces. At the highest collision energy, the agreement is improved for surface 4, while it is much worse for surfaces 1 and 2. A small deviation is also observed at $j' = 12$, which is unexpected since the other small transitions are in good agreement when only the repulsive term of the potential is included. Therefore, the analysis considering only the short-range contribution by comparing surfaces 1 and 2 and surface 4, shows that the core contribution of the repulsive force of surface 4 is accurate for low collision energy and even better for higher collision energies where, as expected, the core contribution increases. Although there is some satisfactory agreement with the experimental results of Loesch (10), the short-range contribution of surface 4 may be improved further, especially its tail, for low collision energies.

The cross sections calculated using surfaces 3 and 4 are compared (also only short-range contributions) in Fig. 3. The results for the highest $\Delta j'$s are not reproduced when only the contribution of repulsive potentials is taken into account. Although both surfaces show deviations at the lowest collision energy, especially for high Δj transitions, the agreement improves as the energy increases. As can be seen, the ab initio potential of Marshall et al. (12) (surface 3) fares better than surface 4 for the lowest collision energy, especially for high Δj's. The surface of Hutson and co-workers gives much better agreement with experiment at higher energies (0.11 and 0.19 eV) and for almost all rotational transitions. In particular, at 0.11 eV (the middle figure), there is no deviation at all for any of the results. It seems that the tail of the short-range component of surface 3 is better than that of surface 4, while the core of the latter is better than that of surface 3. In summary, the results shown in Figs. 2 and 3 may provide sufficient information to confirm that the short-range contribution, either of surface 3 or surface 4, may sufficiently explain the Ar−CO_2 repulsive interaction with surface 4 showing better agreement than surface 3.

Figure 4 compares the state-to-state cross sections for all surfaces (see Table 1) considering the full intermolecular potential, i.e., the contributions of both short- and long-range forces. On the whole, some improvements are observed in the agreement between the calculated and experimental cross sections. For example, at the lowest energy (top figure) surfaces 1 and 2 provide better agreement for the highest j' compared to the same cross section in Fig. 2. On the other hand, the cross section for $j' = 30$ (surface 1) has decreased in intensity, while at $j' = 24$ (surface 2) it has increased. At 0.11 eV, both surfaces 1 and 2 show improved agreement when compared to Fig. 2. However, at the highest collision energy the level of agreement is worse when the long-range contribution is taken into account. For surface 3 not only was there no marked improvement in agreement found when the long-range term was included, but also the level of agreement was decidedly worse at all collision energies. At low collision energies, especially, one should expect an improvement on the level of agreement, and the fact that this was not seen suggests that the attractive component of surface 3 may be incorrect. This confirms the conclusion in ref. 2 that this ab initio potential "provides a disappointing representation of the potential energy surface." For surface 4 there is improved agreement for the σ_{6-34} cross section at 0.069 eV, but the level of agreement worsens for other cross sections: for example, the cross section for $j' = 18$ is now worse than the result shown in

©2001 NRC Canada

Fig. 5. State-to-state rotational cross sections for experimental data (filled squares), surface 4 (solid line), and modified surface 4 (dot-dashed line) at the collision energy of 0.069 eV.

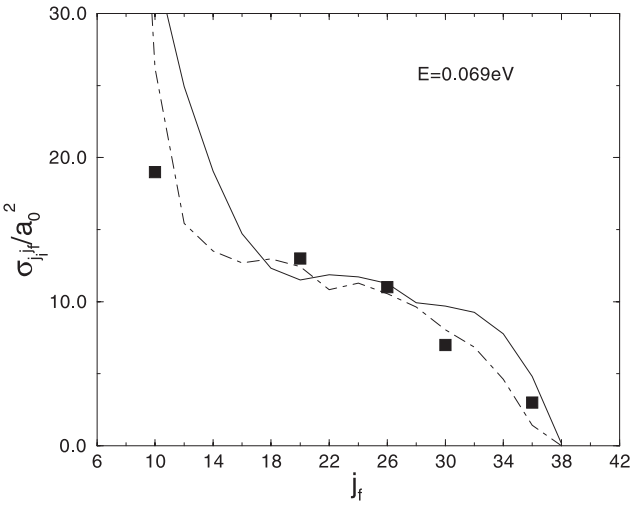

Fig. 6. State-to-state rotational cross sections for experimental data (filled squares), surface 4 (solid line), and modified surface 4 (dot-dashed line) at the collision energy of 0.19 eV.

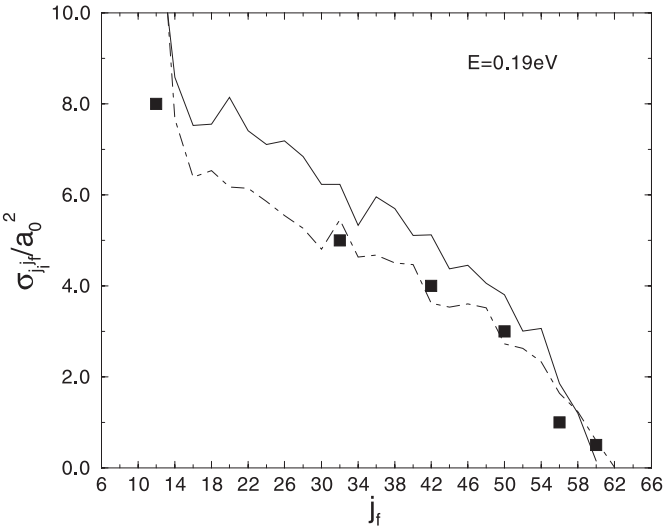

Fig. 2, as is also the case for $j' = 20$, $j' = 28$, and $j' = 30$. For each of these transitions the deviations between the calculated and experimental values are larger. Thus, the expectation that the level of agreement between the calculated and experimental results should be improved when the long-range component is taken into account has not been observed, and it appears that the long-range contribution of surface 4 is too strong. This is clearly observed for the three highest transitions, i.e., $j' = 26$, $j' = 30$, and $j' = 36$ at $E = 0.069$ eV. The values calculated for these cross sections using surface 4 lie below the experimental results in Fig. 2 while, in Fig. 4, the calculated cross sections calculated using the full surface 4 lie above the experimental cross sections. This suggests that better agreement might be achieved if the long-range component of surface 4 was to be modified.

For 0.11 eV, the calculated results are in good agreement with experimental with only one deviation, i.e., for $j' = 38$. The calculated value for this cross section was drastically reduced with the inclusion of the long-range component of the potential. While it appears again that the long-range contribution is too strong, it is less so than was observed for the collision energy 0.069 eV. For collision energy 0.19 eV an upwards shift is observed for all cross sections, but with the results remaining close to the experimental data of Loesch. Comparison of the cross sections for this energy in Figs. 2 and 4 indicates that the results using only the repulsive component of the potential were actually much better, with almost all calculated transitions in quantitative agreement with the experimental data. Inclusion of the long-range component in the calculations at the other two collision energies also gives worse comparisons. However, as stated in ref. 19, "no further work on improving the potentials at present" may be necessary, referring to surface 4. What is important to point out is that such a surface, obtained by fitting high-resolution spectroscopic data, seems to be the best surface available for reproducing a wide range of experimental data. This should also hold for scattering cross section data, but the results shown in Fig. 4 may indicate that the surface should be modified in order to obtain accurate state-to-state rotational cross sections as well, especially at higher collision energies.

We propose a modification of the surface of ref. 1 by introducing two additional parameters, specifically a short-range and a long-range parameter, in order to provide a surface that incorporates state-to-state rotational cross section data. A trial and error procedure discussed previously (26) has been applied to obtain values for these two parameters. Although we have not found a general surface with the present modification, much better agreement has been achieved for the rotational cross sections.

For analysing the agreement between the calculated scattering cross sections and the experimental data, surface 4 was chosen to be slightly modified, as described above. Although any modification of it may not be correct, especially if the attractive component of it is also changed, this modification may show that a simple modification of the fitting procedure of this surface may provide a global potential energy surface for completely describing the Ar–CO_2 interaction.

Figures 5 and 6 compare classical trajectory state-to-state rotational total cross sections for collision energies 0.069 and 0.19 eV, respectively. Calculations have been performed using the original surface 4 and a modification of it. As can be seen from Fig. 5, a single parameter introduced into the long-range contribution suffices to improve agreement with the experimental state-to-state rotational cross sections of Loesch (10) at 0.069 eV. The parameter reduces the Hutson et al. (1) long-range contribution by a factor 1.574 in order to produce the agreement shown in the figure: for example, at $j' = 20$ surface 4 (original) gives a calculated cross section of $11.5a_0^2$, while the modified surface 4 gives $12.4a_0^2$, which is in much better agreement with the experimental results. Further, the results obtained using surface 4 (original) show a small minimum in the cross sections between $j' = 18$ and $j' = 22$, whereas the results obtained using the modified surface show a small maximum that provides better agreement with the cross section at $j' = 20$. Moreover, while the cross sections calculated using surface 4 (original) show a broad maximum for $j' > 28$, those

©2001 NRC Canada

calculated using the modified surface 4 lie closer to the experimental measurements of Loesch (10): for example, the cross section calculated using the modified potential 4 is now much closer to the experimental cross section for $j' = 30$ than is that obtained with the original surface 4. As observed in this figure, there is a very good improvement in the potential 4. Therefore, if this single number was enough to provide better agreement, and if the collision energy increases, one might expect a lesser influence of the long-range component, hence a small number should be expected for 0.19 eV collision energy. Moreover, the present analysis seems to show that the short-range component of surface 4 is correct, since it was not modified at low energy.

Figure 6 compares the cross sections at collision energy 0.19 eV using surface 4 (original) and the modified surface 4. A preliminary analysis using only one parameter, as was done to generate the results shown in Fig. 5, did not provide accurate results, and it was deemed necessary to introduce a second parameter to control the short-range component of the interaction. In this case the short-range contribution was increased by 0.274, while the long-range force was reduced by a factor of 1.3. In general, the contribution of the attractive part of the potential decreases with increasing collision energy. However, by comparing the results in Fig. 5 (0.069 eV) and Fig. 6 (0.19 eV), such a behaviour appears to be not observed for the original potential (surface 4): it appears as if the long-range interaction has provided an upwards shift with increasing collision energy.

At this collision energy (0.19 eV), however, a change to the short-range component was also required. This collision energy is about 175% greater than the lowest collision energy (0.069 eV). The latter corresponds to approximately three times greater than the dissociation energy of the surface 4 for the T configuration and even greater at the linear approach. These values are certainly much greater at higher collision energies. Therefore, less influence of the long-range component for the higher energies would be expected. It is observed that there is a very small difference between the two multipliers. It is exactly the difference between the short-range parameter (1.574) used in the case of the results shown in Fig. 5 and the new value, 1.3, i.e., 0.274. The latter was needed to correct the short-range component of surface 4. Therefore, these multipliers show that as of yet there is no global potential energy surface for fully described Ar–CO_2 interaction. Although such a surface can describe several spectroscopic properties.

Normally, either the tail or the core contribution of the repulsive component could be responsible for such a shift. The inclusion of two parameters allowed better agreement to be attained between the experimental measurements of Loesch (10) and the classical trajectory state-to-state cross sections. As can be seen with the modified surface 4, all the classical trajectory results are in quantitative agreement with the experimental data. Moreover, the short-range factor introduced was able to increase the repulsive force, and this has pushed cross sections down, and hence, closer to the experimental results.

Finally, it is important to note that the modified surface has certainly changed the entire long-range contribution and, for the highest collision energy, also the short-range contribution, and as a consequence, the modified surface may no longer be able to reproduce most of the spectroscopic properties. One possibility, given that this modified potential was obtained by fitting to high-resolution experimental state-to-state rotational cross section data measured by Loesch (10), is to calculate spectroscopic properties with a high level of accuracy using the original surface or to perform collision studies using the modified version of the potential. When dealing with Ar−CO_2 rotational collisions at low energies, one can reduce only the long-range contribution by a factor of 1.574 or at high energies, one can use the short-range parameter (0.274) and also the long-range factor (1.3). This shows that the whole surface 4 was changed, and indeed it will not describe spectroscopic data, but it also shows that a simple modification during the fitting procedure may be done in order to improve the agreement with the scattering cross section experiments.

Although surface 4 has been shown to be highly accurate for spectroscopic properties (19), the present work shows that it is not accurate enough to reproduce some of rotational cross sections that are also sensitive to the potential as well as those properties shown in ref. 1. For example, the rainbow positions and the final rotational states of the molecule are drastically affected by the long-range terms of the interaction (27). Hence, a sensitive analysis of the angular distribution of the state-resolved differential cross sections may also contribute to improve the attractive term of the potential. The latter may not be sensible to the transport properties, but it is very sensitive to the repulsive and attractive components of the surface (27). Therefore, for almost all properties the surface of Hutson and co-workers is accurate enough, but it does not provide quantitative reproduction of all Ar−CO_2 rotational cross sections as analysed in the present study.

Concluding remarks

This work has mainly been concerned with analysing two recent potential energy functions (3 and 4) for describing the Ar–CO_2 system. Although a slight modification of the Hutson et al. (10) surface for studying rotational collisions was proposed, it is important to point out that their potential energy function may be the best surface available up to now without any modification for studying spectroscopy properties (19). On the other hand, for cross sections, the actual work has provided a critical analysis of the latest surfaces, with special attention given to the potentials 3 and 4.

The potential of Hutson and co-workers (19) is based on fitting procedures, and very recently a new potential has been calculated by Misquitta et al. (28) based on ab initio methods. Calculations of spectroscopic properties using the latter produced the same level of accuracy in some spectroscopic properties as the potential proposed in ref. 19. Therefore, according to the analysis shown in this paper, it is expected that this new ab initio potential will also produce poor results for rotational cross sections, but this needs to be tested.

Although it has been shown in this contribution that the agreement of scattering cross sections can be improved by introducing two parameters to multiply the short- and long-range components, it is clear that it is not the right suggestion, since the spectroscopic data will also change. This is even more drastically effected if the modification is mainly done in the attractive part of the surface. Nevertheless, the modified potential can better match the experimental measurements, and hence, one can see that it is indeed necessary to carry out further detailed analyses for future fitting procedures for the Ar–CO_2 system.

©2001 NRC Canada

Therefore, the present study may indicate that a new potential energy function could be fitted to match all the available data, i.e., spectroscopy and state-to-state cross sections. Nevertheless, a general surface has not been proposed, and it is clear that other studies are needed. The present paper showed that potential 4 can also be improved to match state-to-state cross sections with only two parameters.

Acknowledgements

We would like to thank Professor Jeremy Hutson and Professor M. Szczęśniak for providing their subroutines to calculate the potential energy functions. We are also in indebted to the unknown referee who pointed out many mistakes in our manuscript.

Studies on the synthesis and properties of bischelating dioxotetraamine macrocycle, its metal complexes and thermodynamic stability in aqueous solution

Xun-Cheng Su, Zhi-Fen Zhou, Hua-Kuan Lin, Shou-Rong Zhu, Hong-Wei Sun, Guang-Hua Zhao, and Yun-Ti Chen

Abstract: A new route to obtain *C*-functionalized dioxotetraamine, in which two independent chelating groups 8-quinolinol and dioxotetraamine are included, is described. In addition, two trinuclear metal complexes are synthesized and fully characterized. The thermodynamic properties of the ligand and its respective metal complex were investigated by a potentiometric titration method. Coupled with UV spectra, the difference in affinities for copper ion between dioxotetraamine and 8-quinolinol in the new ligand are investigated and the results show that 8-quinolinol is a stronger donor group than the dioxotetraamine macrocycle in an aqueous solution. Over pH 3~11, 8-quinolinol interacts 100% with the copper ions while dioxotetraamine is only partially coordinated.

Key words: macrocycle, dioxotetraamine, 8-quinolinol, copper ion, stability constants.

Résumé : On décrit une nouvelle façon d'obtenir de la dioxotétraaamine *C*-fonctionnalisée dans laquelle on a inclus deux groupes chélatants indépendants, le 8-quinoléinol et la dioxotétraamine. De plus, on a synthétisé et complètement caractérisé deux complexes métalliques trinucléaires. Faisant appel à une méthode de titrages potentiométriques, on a étudié les propriétés thermodynamiques de chaque ligand et celles du complexe métallique correspondant. En se basant sur ces résultats et sur les spectres UV, on a étudié la différence dans les affinités pour l'ion cuivre entre la dioxotétraamine et le 8-quinoléinol dans le nouveau ligand; les résultats montrent que, en solution aqueuse, le 8-quinoléinol est un groupe donneur plus fort que le macrocycle dioxotétraamine. À des pH allant de 3 à environ 11, le 8-quinoléinol interagit à 100% avec l'ion cuivre alors que la dioxotétraamine n'est que partiellement coordiné.

Mots clés : macrocycle, dioxotétraamine, 8-quinoléinol, ion cuivre, constantes de stabilité.

[Traduit par la Rédaction]

Introduction

Macrocyclic polyamines are of great interest in the field of coordination chemistry and have been studied intensively in recent years (1) because they possess cavities capable of providing a favorable environment for transition metal ions. The strength of the ion binding is determined by ion size, macrocyclic cavity size, and ligand conformation (1b). Macrocyclic oxopolyamines are unique metal chelators, and their structure bears the dual features of macrocyclic polyamines and oligopeptides (2). Because of their important biological functions and some unusual properties, oxopolyamines have been extensively studied and their structural features in biological significance are well recognized (2). The two amide groups in macrocyclic dioxotetraamines, for example, are equivalent, but when coordinated to a 3*d* metal ion they can be dissociated successively. Furthermore, dioxotetraamines can stabilize higher states of some transition metals and have been developed as effective oxidants and biomimetic redox catalysts. The functionalization of macrocycles allows us to modify or introduce new properties into a ligand such that: (*i*) it can make the ligand more selective toward a metal ion; (*ii*) it can increase or decrease the thermodynamic stability and the kinetic inertness; (*iii*) it can change the solubility and extractability into an organic phase; or (*iv*) it can covalently attach the macrocycle to a polymeric support or to a protein (3). Functionalization can be achieved using either a carbon or a nitrogen atom of the ring as an attaching point. Generally, the modifications based on such macrocyclicmolecules have been focused on *N*-substituted pendant-arm groups, while the *C*-substituted research is relatively rare (4). The *C*-substituted derivatives have the advantage of not influencing the nature of the heteroatomic donor group and are ideal substituents. 8-Quinolinol is known to be a good chelating ligand and can form stable complexes with most metal ions. Moreover, being a fluorescent active group, the pendent-arm 8-quinolinol can facilitate the modification of macrocyclic hosts for easy detection by methods such as UV or fluorescence spectroscopy

Fig. 1. The structures of ligand (**L**) and its metal complexes.

(5). Therefore, in this paper we report a simple method to obtain an 8-quinolinol functionalized dioxotetraamine **(L)** (Fig. 1).

At given conditions two trinuclear metal complexes were prepared and fully characterized by FAB-MS, IR and electron paramagnetic resonance (EPR) spectroscopy, and elemental analysis. The stability constants of the ligand complexes with a proton and with copper(II) were studied by means of pH titration, along with UV spectroscopy. The affinity of 8-quninolinol and dioxotetraamine in the new ligand (**L**) to the copper(II) ion was compared and the results show that for Cu^{2+}, 8-quninolinol is a stronger donor group than dioxotetraamine macrocycle, and at 1:1 molar ratio (M:**L**) the former binds 100% to the metal ions while the dioxotetraamines are only partially coordinated.

Experimental

Synthesis

8-Quinolinol and diethyl malonate were purchased from Aldrich and The Chinese Academy of Martial and Medical Science, respectively. All other chemicals were of analytical reagent grade, and were used without further purification. The Fourier-transform IR spectra were taken on a FT-IR 170SX (Nicolet) spectrometer. Elemental analyses were made on a Perkin-Elmer 240C analyzer. MS was conducted on VG ZAB-HS instrument. Proton NMR spectra were recorded on a Bruker AC-P200 spectrometer operating at 200 MHz at 25°C in $CDCl_3$ or DMSO-d_6 solution with tetramethylsilane as the internal reference. Electronic absorption spectra were obtained from a Shimadzu UV-240 spectrophotometer. The compound 5-chloromethyl-8-quinolinol hydrogen chloride was prepared according to literature (6).

5-[(2,2-Bisethoxycarbonyl)ethyl]-8-quinolinol: A mixture of 5-chloromethyl-8-quinolinol hydrogen chloride (1.56 g, 6.8 mmol), diethyl malonate (1.07 g, 8.2 mmol), and anhyd K_2CO_3 (2.35 g, 17 mmol) in dry DMF (30 mL) was stirred at room temperature under a nitrogen atmosphere. After three days, the mixture was filtered, and the residue was thoroughly washed with DMF. The combined organic extracts were concentrated in vacuum to afford a light yellow oil, which was purified by column chromatography over silica gel eluting with EtOAc–C_6H_{12} (1:4) to give **2**, as colorless crystals (yield ≈ 40%), mp 77.5–78.0°C. FT-IR (KBr pellet) cm^{-1}: 3356, 1729 ($\nu_{C=O}$), 1256, 1202. ^1H NMR ($CDCl_3$) δ: 1.12–1.19 (br s, 6H), 3.54–3.68 (m, 3H), 4.07–4.14 (m, 4H), 7.03–8.77 (m, 6H). Anal. calcd. for $C_{18}H_{19}NO_5$: C 64.35, H 5.99, N 4.41; found: C 64.62, H 6.16, N 4.47.

Ligand L: 5-[2,2-bis(ethoxycarbonyl)]ethyl]-8-quinolinol (2.57 g, 8 mmol) was dissolved in absolute ethanol (300 mL) and then an equivalent amount of polyamine was added slowly with constant stirring. The resulting mixture was kept of reflux under N_2 for about two weeks. Then the reaction solution was concentrated to 20 mL and the product was precipitated in the refrigerator. The isolated yellow solid was washed with cold ethanol three times to afford the pure ligand (yield 24%). CI-MS *m*/*z*: 386.3 $[M + 1]^+$. FT-IR (KBr pellet) cm^{-1}: 3340, 2931, 1672 ($\nu_{C=O}$), 1624, 1473. ^1H NMR (DMSO-d_6) δ: 1.50 (m, 2H), 2.49–2.83 (br s, 4H), 3.33–3.60 (br s, 11H), 6.95 (m, 1H), 7.18 (m, 1H), 7.54 (m, 2H), 8.42 (m, 1H), 8.80 (m, 1H). Anal. calcd. for $C_{20}H_{27}N_5O_3 \cdot 0.5H_2O$: C 60.90, H 7.15, N 17.75; found: C 61.12, H 7.45, N 17.55.

Complex 1 ($L_2 \cdot Cu_3$): A solution of $Cu(OOCMe)_2$ (0.136 g, 0.75 mmol) in H_2O (10 mL) was added dropwise over 20 min to the methanol solution of **L** (0.197 g, 0.5 mmol) with constant stirring and the pH was adjusted to pH 6~7 with NaOH. The mixture was stirred for another hour and then concentrated to 10 mL. After cooling the product was filtered off and washed with acetone three times and dried in vacuum (yield 50%). FAB-MS *m*/*z*: 956 $[Cu_3L_2 + H]^+$. FT-IR (KBr pellet) cm^{-1}: 3396, 3243, 1640, 1581 ($\nu_{C=O}$), 1506. UV (ε, mol dm^{-3} cm^{-1}): 5.69×10^3 (400 nm, MeOH), 2.27×10^3 (340 nm, MeOH). Conductivity (Ω^{-1} dm^{-3} cm^{-1}): 3.43 (10^{-3} mol dm^{-3} in DMSO at 25°C). Anal. calcd. for $C_{40}H_{54}N_{10}O_6Cu_3 \cdot 9H_2O$: C 42.99, H 5.91, N 12.54; found: C 42.82, H 5.60, N 12.65.

Complex 2 ($L_2 \cdot Cu \cdot Ni_2$): A solution of $Cu(OOCMe)_2$ (0.045 g, 0.25 mmol) in H_2O (10 mL) was added to the 20 mL methanol solution of **L** (0.195 g, 0.5 mmol) with stirring. After 10 min, $Ni(ClO_4)_6 \cdot 6H_2O$ (0.186 g, 0.5 mmol) in H_2O (10 mL) was added dropwise and then a small amount of NaOH was added. The stirring was continued for 10 h and then pH was adjusted to about 8.0. The resulting solution was concentrated to 10 mL and the product was precipitated. The yellow-green solid was filtered and washed with acetone and dried in vacuum (yield 54%). FAB-MS *m*/*z*: 944 $[CuNi_2L_2 + H]^+$. FT-IR (KBr pellet) cm^{-1}: 3386, 3215, 1640, 1576 ($\nu_{C=O}$), 1556. UV (ε, mol dm^{-3} cm^{-1}): 5.70×10^3 (400 nm, MeOH), 3.29×10^3 (340 nm, MeOH). Conductivity (Ω^{-1} dm^{-3} cm^{-1}): 6.61 (10^{-3} mol dm^{-3} in DMSO at 25°C). Anal. calcd. for $C_{40}H_{54}N_{10}O_6CuNi_2 \cdot 6H_2O$: C 45.59, H 5.74, N 13.29; found: C 45.59, H 5.96, N 13.49.

Potentiometric titrations

Potentiometric equilibrium measurements of the ligands in the absence or presence of Cu(II) ions were carried out with a Beckman pH meter (Model Φ71) equipped with a type 39841 combination electrode. Typical concentrations of

experimental solutions were 1 × 10^{-3} mol dm^{-3} of ligand with equal molar concentrations of metal ion. The ligand was dissolved in an adequate amount of dilute HNO_3 (about 3 equiv) and then titrated with 0.1 mol dm^{-3} NaOH. Redistilled (in quartzware) H_2O was used for preparing all the solutions. $NaNO_3$ and $Cu(NO_3)_2$ were recrystallized with redistilled H_2O before use. The concentrations of Cu^{2+} in the stock solution were analyzed by EDTA titration methods. The ionic strength was adjusted to 0.1 mol m^{-3} with $NaNO_3$. All titrations were carried out under N_2 at 25°C. Computations of equilibrium constants were made using a program based on the improved TITFIT technique (7). Species-distribution curves were calculated and plotted with the DP program (7). For each system at least two titrations were performed, and each titration contained about 45 experimental points. Table 1 illustrates the protonation constants of the ligand **L**.

Coordinating tendencies of **L** toward aq Cu(II) ions was investigated by means of pH titrations with a standard base solution containing the ligand and $Cu(NO_3)_2$ in equivalent amounts plus excess acid (about 3 equiv). The titration curves were simulated with a computer program and the complex species present at equilibrium were chosen and their equilibrium constants were refined to the best curve fitting. In the following text, each species will be denoted by (p, q, r) where: p is the stoichometric coefficient of the metal in the complex, q that of the ligand, and r that of the hydrogen ions. A negative value of r indicates that the complex has released a proton (for instance, from the amide group of the ligand or from the coordinated H_2O). The stability constants of the ligands with the metal ion (Cu(II)) are listed in Table 2, and titration and distribution curves are shown in Figs. 3 and 4.

Results and discussion

Synthesis of ligand and metal complexes

Starting from 5-chloromethyl-8-quinolinol hydrogen chloride that is easily prepared, the preparation of **L** involves two simple steps and does not require the use of chromatography. In our work, the novel preparation of cyclic dioxotetraamine has a significant advantage in that any desirable substituent can be introduced on the carbon atom of the macrocyclic skeleton. In addition, the size of the macrocycle can be changed easily by judicious choice of the linear tetraamine. Moreover, the 8-quinolinol substituted macrocycle has two independent chelating groups and both can form metal complexes; therefore, the modified macrocycle possesses advantageous properties over the dioxotetraamine in coordination chemistry, especially for the generation of polymeric complexes.

It is known that when dioxotetraamine reacts with a transition metal ion such as Cu^{2+} or Ni^{2+}, each amide group will dissociate a proton in an effort to form more stable complexes (2). The absorption spectra of metal oxinate complexes have been studied extensively (8) and, therefore, the absorption spectra can be used to investigate whether the metal ion is coordinated to 8-quinolinol and if it is chelated to the macrocycle. In our work, the electronic absorption of these metal complexes (λ ~ 400 nm) is characteristic of a copper oxinate complex and it can be concluded that in the two trinuclear complexes each metal ion binds two 8-quinolinol moieties. IR results show that the C=O absorption decreases from 1672 cm^{-1} in the free ligand to 1581 and 1576 cm^{-1} in the complexes $[CuL_2]$ and $[CuNi_2L_2]$, respectively, indicating that the protons dissociate from the amide groups, and the amido nitrogen atoms coordinate to the metal ion. The molar conductivities in DMSO at 25°C for the trinuclear metal complexes **1** and **2** are 3.43 × 10^{-3} and 6.61 × 10^{-3} mol dm^{-3}, respectively, demonstrating that both metal complexes are neutral (9). FAB-MS results (956.2 [**1** + H]$^+$ and 944.2 [**2** + H]$^+$) further establish the formation of the trinuclear metal complexes. The EPR spectra of $[Cu_3L_2]$ and $[CuNi_2L_2]$ are similar, with $[Cu_3L_2]$ exhibiting much broader peaks, indicating a similar coordinating structure of the copper complex (Fig. 2). In methanol glass at 110 K, the EPR spectrum of $[Cu_3L_2]$ is too broad and no characteristic absorption is observed. This probably indicates that there is dipole–dipole coupling between the metal centers in $[Cu_3L_2]$ spectrum, which is different from that of $[CuNi_2L_2]$. These result reveals that the dioxotetraamine macrocyclic groups in metal complexes such as $[Cu_3L_2]$ are not parallel but instead

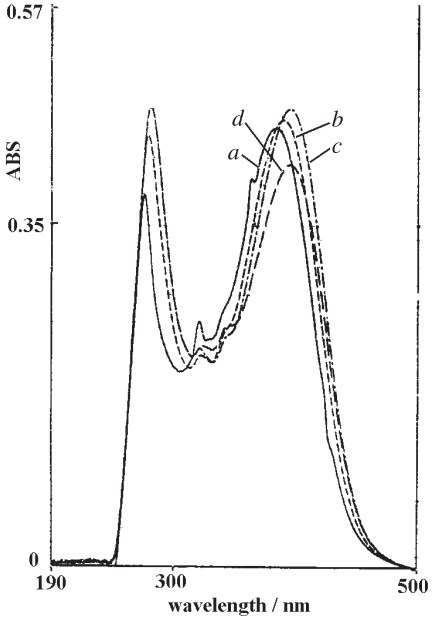
are at an angle and interact with each other through dipole–dipole forces (10).

Thermodynamic properties

The acid-base behavior of the ligand in aq $NaNO_3$ (0.1 mol dm^{-3}) at 25°C has been investigated through pH titration. Figure 3 shows the titration curves of **L** and its copper(II) complex. Figure 4 shows the distribution curves of metal complex species. In the pH range investigated (ca. 3–11), the dioxotetraamine can bind four protons, presumably two at the amine groups and two at the oxygen and nitrogen atoms of 8-quinolinol. The stepwise protonation equilibria constants have been determined and are shown in Table 1. For comparison, log *K* values of the stepwise protonation equilibra of a similar 14 membered macrocycle, dioxocyclam (2*e*), are also reported.

For macrocyclic dioxotetraamine, K_1 is the protonation constant for the phenolate. The value is somewhat lower

Fig. 5. UV–vis absorption spectra (25°C) of **L** (2.975×10^{-4} mol dm^{-3}) at different pH: (*a*) 2.82, (*b*) 4.88, (*c*) 7.29, (*d*) 10.04.



than that of free 8-quinolinol (log K_1 = 11.20) (11), which can be attributed to solvent effects since the free 8-quinolinol is insoluble in water and its protonation constants were determined in 1,4-dioxane–water. K_2 and K_3 are assigned to be the protonation constants of the macrocycle, which are similar to those of dioxocyclam, while K_4 can be attributed to the nitrogen atom of 8-quinolinol.

The incorporation of Cu(II) by the ligand (**L**) in aqueous solution was studied to identify the species formed and to evaluate the complexation constants of these compounds (Fig. 4). In fact, 8-quinolinol and the dioxotetraamine macrocycle are both strong chelating agents for many transition metal ions, especially copper(II), however, the two chelators cannot bind simultaneously to the same metal ion. In other words, if the metal ion lies in the dioxotetraamine cavity, 8-quinolinol can not act as a bidentate ligand and bind to the same metal ion due to the intrinsic strain of **L**. Likewise if 8-quinolinol chelates to a metal ion, the same metal ion can not promote the deprotonation of the dioxotetraamine amide to enter into its cavity. Therefore, if the ligand:metal molar ratio is 1:1, there are two possible modes of coordination: (*i*) 8-hydroxyquinoline is 100% coordinated to the copper ion; (*ii*) dioxotetraamine is incorporating the copper ion. Since the UV absorption of 8-quinolinolato copper complex differs greatly from that of free 8-quinolinol, the complex can be easily detected using UV spectroscopy. Consequently, the UV spectra of free ligand (**L**) and its copper complex were studied by varying the pH. Titrations, monitored by UV–vis spectroscopy, of free ligand (**L**) and its copper complex are shown in Figs. 5 and 6, respectively. The UV–vis absorption of **L** varies with

© 2001 NRC Canada

Fig. 6. UV–vis absorption spectra (25°C) of **L** (2.081×10^{-4} mol dm^{-3}) and Cu(II) (2.081×10^{-4} mol dm^{-3}) at different pH: (*a*) 3.02, (*b*) 4.84, (*c*) 7.50, (*d*) 10.01.

an increase in pH, which implies that the depronation of 8-quinolinol affects the electronic spectrum (Fig. 5). In case of the copper(II) complex, the UV–vis absorption is very similar to that of 8-quinolinol copper complex and exhibits only small changes with an increase in pH (Fig. 6), implying that in a 1:1 (molar ratio) metal complex, 8-quinolinol acts as bidentate group and chelates 100% to the copper ion over pH 3~10. Consequently, the dioxotetraamine can only be partially coordinated, and hence, 8-hydroxyquinoline is a stronger donor group than the dioxotetraamine macrocycle in **L**. And thus, it can be concluded that while titrating 8-quinolinol is 100% coordinated. The pH titrations provide a better tool for indicating the relative affinity of the ligand for H^+ or Cu^{2+}. If the metal's binding affinity to ligand is stronger than that of proton, the protonation constant of the ligand in the metal complex will be smaller than that of free ligand. From Tables 1 and 2, it is evident that the sum of the dioxotetraamine's protonation constants ($\log (\beta_{112}/\beta_{110}) = 9.08$) in the copper complex is much smaller than that of free **L** ($\log (K_2K_3) = 15.14$), implying that the dioxotetraamine behaves as a donor group. As discussed above, the dioxotetraamine actually interacts with copper ion, but the copper ion does not promote the deprotonation of dioxotetraamines's amides to enter into its cavity. Using these results, along with the UV–vis spectra, we can speculate as to the structure of the species at different stages of the pH titration. In the positively charged complex $(CuLH_2)^{3+}$ (112), 8-quinolinol chelates to the copper ion and the dioxotetraamine is doubly protonated. As the pH increases, the protonated amine groups in dioxotetraamine will be deprotonated and interact with Cu through a coordination bond, resulting in the formation of CuL (110) (pH ca. 4.5). When the pH is increased further, CuLOH (11–1) and $CuL(OH)_2$ (11–2) will be formed, which can be attributed to the deprotonation of coordinated water molecules. Notably, the CuLOH, in which OH^{-1} coordinates to copper ion, is very stable over pH 6–8 where metal catalysts play their role most efficiently.

In conclusion, we present a new route to obtain the *C*-functionalized macrocycles that include an 8-quinolinol group as a bidentate pendant arm. The results show that the new ligand can form trinuclear complexes using two independent chelators: 8-quinolinol and dioxotetraamine. 8-Quinolinol is a stronger donor group than dioxotetraamine and at a metal:ligand molar ratio of 1:1, where 8-quinolinol is 100% bound to copper ion while dioxotetraamine is only partially interacting with copper through coordination bonds.

Formation of heterocyclic arylboronates by thermally induced 1,4-aryl migration in diarylboron chelates of *C*-(1-hydroxyalkyl)nitrones. Crystal and molecular structures of some of the rearrangement products and of one of the educts[1]

Wolfgang Kliegel, Gottfried Lubkowitz, Jens O. Pokriefke, Steven J. Rettig, and James Trotter

Abstract: Synthesis of heterocyclic arylboronates has been carried out by thermally induced rearrangement of diarylboron chelates of *C*-(1-hydroxyalkyl)nitrones. The structures have been determined from spectroscopic data and from X-ray analyses. Thermoanalytical and time-dependent NMR measurements give information on the nature of the isomerization reaction. Crystal data (at 293 K for **2j**, 180 K for the others): **1m**, monoclinic, $P2_1/n$, a = 14.059(3), b = 12.5531(13), c = 14.8531(6) Å, β = 95.8067(12)°, Z = 4; **2j**, triclinic, $\bar{P}1$, a = 10.4729(11), b = 13.5896(11), c = 9.5803(7) Å, α = 104.764(6), β = 103.279(7), γ = 107.278(7)°, Z = 2; **2m**, monoclinic, $P2_1/n$, a = 14.9442(13), b = 11.990(2), c = 16.0613(4) Å, β = 114.0153(7)°, Z = 4; **9**, monoclinic, $P2_1/n$, a = 11.123(2), b = 18.433(3), c = 13.4852(4) Å, β = 108.2075(7)°, Z = 4. The structures were solved by direct methods and refined by full-matrix least-squares procedures to $R(F, I \geq 3\sigma(I))$ = 0.036, 0.052, 0.043, and 0.040, respectively, for AFC6 data for **2j** and CCD data for **1m**, **2m**, and **9**. All four molecules contain six-membered OBONCC rings, with an approximately planar ON=CC segment in the educt **1m** and approximately planar OBOC segments in the rearrangement products. A probable transition state geometry is derived for the isomerization process.

Key words: diarylboron chelates, *C*-(1-hydroxyalkyl)nitrones, heterocyclic arylboronates, organoboron compounds, rearrangement, crystal structures.

Résumé : On a réalisé la synthèse d'arylboronates hétérocycliques par le biais d'un réarrangement induit de façon thermique de chélates diarylbores de *C*-(1-hydroxyalkyl)nitrones. On a déterminé les structures à l'aide de données spectroscopiques et d'analyses de diffractions des rayons X. Des mesures thermoanalytiques et de RMN faites en fonction du temps permettent d'obtenir des informations sur la nature de la réaction d'isomérisation. Données cristallographiques (à 293 K pour **2j** et 180 K pour les autres): **1m**, monoclinique, $P2_1/n$, a = 14,059(3), b = 12,5531(13) et c = 14,8531(6)Å, β = 95,8067(12)°, Z = 4; **2j**, triclinique, $\bar{P}1$, a = 10,4729(11), b = 13,5896(11) et c = 9,5803(7)Å, α = 104,764(6), β = 103,279(7) et γ = 107,278(7)°, Z = 2; **2m**, monoclinique, $P2_1/n$, a = 14,9442(13), b = 11,990(2) et c = 16,0613(4)Å, β = 114,0153(7)°, Z = 4; **9**, monoclinique, $P2_1/n$, a = 11,123(2), b = 18,433(3) et c = 13,4852(4)Å, β = 108,2075(7)°, Z = 4. On a résolu les structures par des méthodes directes et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de ($R(F, I \geq 3\sigma(I))$ = 0,036, 0,052, 0,043 et 0,040 respectivement pour les données AFC6 pour **2j** et pour les données CCD pour **1m**, **2m** et **9**. Les quatre molécules comportent des cycles OBONCC à six chaînons pour lesquels l'éduit **1m** comporte un segment ON=CC approximativement planaire et des segments OBOC approximativement planaires dans les produits de réarrangement. On a déduit une géométrie probable de l'état de transition du processus d'isomérisation.

Mots clés : chélates diarylbores, *C*-(1-hydroxyalkyl)nitrones, arylboronates hétérocycliques, composés organiques du bore, réarrangement, structures cristallines.

Introduction

In previous work (1), we described the synthesis of various diarylboron chelates derived from *N*-alkylnitrones of 2-hydroxycarbaldehydes and 2-hydroxyketones. The six-membered cyclic B,N-betaine structure **1** was postulated from elemental analyses and spectroscopic data of the crystalline compounds. Some of these compounds were very sensitive towards thermal stress and could not be recrystallized from heated solvents; nuclear magnetic resonance (NMR) spectra of solutions of these materials also indicated the presence of some rearrangement products. Other examples of **1**, however, were stable and could be recrystallized even from boiling solvents.

In this work, we describe the results of an investigation of this rearrangement and its products. The supposed molecular structure of educts and products is corroborated by X-ray crystallographic analyses of one of the diarylboron chelates **1** and several of the isomeric arylboronates **2**.

Experimental

General procedures

The synthesis of the compounds **1** was described previously (1), with the exception of **1k** and **1n**, which were obtained as mixtures with the corresponding rearrangement products (see below).[3] All reactions were carried out under normal conditions, without protective gas atmosphere. Melting points (uncorrected): Linström apparatus and Büchi SMP 20. IR: PYE-Unicam SP 3–200, Philips PU 9800 FT-IR Spectrometer, V 3.00, and ATI Mattson Genesis Series FT-IRTM Rev. I. ^{1}H NMR: Varian EM 390 and Bruker AM 400. ^{11}B NMR: Bruker AC 200. Elemental analyses: Carlo Erba CHNO elemental analyzer 1106; boron and chlorine titrimetrically after Schöniger-oxidation with Methrom Potentiograph E 536/Dosimat 655. Differential scanning calorimetry: Perkin Elmer DSC 2 with standard measuring head 319–0006 and Thermal Analysis DATA Station 3600, N_2 gas (1.5 bar; 1 bar = 100 kPa) for rinsing; Seiko DSC 220 with disk station SSC 5200 H; measurement of test samples (3–5 mg) in cold-welded aluminum pots, standard heating rate of 5°C min^{-1}; calibration with In and Sn; diagram: mW (y), temp.°C (x); sample time 0.4 s. Thermo-Gravimetry and Differential Thermoanalysis: Seiko TG/DTA 220 with disk station 5200 H; measurement of test samples (2–3 mg) in open aluminum pots, heating rate of 5°C min^{-1}; calibration with In and Sn; diagram: DTA μV (y_1), TG % mass loss (y_2), temp. °C (x); sample time 0.4 s.

4,6-Dimethyl-2,5-diphenyl-1,3-dioxa-4-aza-2-boracyclohexane (2a)

1a (1) (0.53 g, 2 mmol) is refluxed in 30 mL of toluene for about 10 min until test samples of the solution no longer gave a blue color reaction with diphenylcarbazone, indicating absence of an intact diphenylboron moiety (1, 2).[4] The solvent is distilled off in vacuo, and the remaining colored oil is dissolved in a small amount of ethanol. Upon cooling, down to –18°C, colorless crystals are obtained and recrystallized from absolute ethanol. Yield: 0.31 g (58%) of colorless needles, mp 77–78°C. IR (KBr, cm^{-1}): 1600 (C=C), 1310 (B-O); ^{1}H NMR (90 MHz, $CDCl_3$–TMS) δ: 1.08 (d, J = 7 Hz, C-CH_3), 2.56 (s, N-CH_3), 3.18 (d, J = 9 Hz, N-CH-C), 4.39 (m, O-CH), 7.07–7.31 (m, 8 aromatic H), 7.58–7.73 (m, 2 aromatic H). Anal. calcd. for $C_{16}H_{18}BNO_2$: C 71.94, H 6.79, B 4.05, N 5.24; found: C 71.83, H 6.83, B 4.10, N 5.25.

4-*tert*-Butyl-6-methyl-2,5-diphenyl-1,3-dioxa-4-aza-2-boracyclohexane (2b)

1b (0.31 g, 1 mmol) is reacted as described above for **2a** (about 15 min). Yield: 0.20 g (65%) of colorless needles, mp 122–123°C. IR (KBr, cm^{-1}): 1600 (C=C), 1310 (B-O); ^{1}H NMR (90 MHz, $CDCl_3$–TMS) δ (ppm): 1.02 (d, J = 7 Hz, CH_3C-O), 1.06 (s, C(CH_3)$_3$), 3.66 (d, J = 8 Hz, N-CH), 4.42 (m, O-CH), 7.19–7.42 (m, 8 aromatic H), 7.68–7.88 (m, 2 aromatic H). Anal. calcd. for $C_{19}H_{24}BNO_2$: C 73.80, H 7.82, N 4.53; found: C 73.82, H 7.83, N 4.41.

4-Benzyl-6-methyl-2,5-diphenyl-1,3-dioxa-4-aza-2-boracyclohexane (2c)

1c (0.34 g, 1 mmol) is reacted as described above for **2a** (about 20 min). Yield: 0.22 g (64%) of colorless crystals, mp 119°C. IR (KBr, cm^{-1}): 1600 (C=C), 1308 (B-O); ^{1}H NMR (90 MHz, $CDCl_3$–TMS) δ: 1.09 (d, J = 7 Hz, CH_3C-O), 3.48 (d, J = 9 Hz, O-C-CH), 3.60 (d, J = 14 Hz, N-CH_2), 4.50 (m, O-CH), 7.24–7.43 (m, 13 aromatic H), 7.68–7.74 (m, 2 aromatic H). Anal. calcd. for $C_{22}H_{22}BNO_2$: C 76.99, H 6.46, B 3.15, N 4.08; found: C 77.04, H 6.54, B 3.16, N 4.05.

4-Benzhydryl-6-methyl-2,5-diphenyl-1,3-dioxa-4-aza-2-boracyclohexane (2d)

1d•C_2H_5OH (0.23 g, 0.5 mmol) is reacted as described above for **2a** (about 20 min). Yield: 0.18 g (86%) of colorless crystals, mp 144–145°C. IR (KBr, cm^{-1}): 1600 (C=C), 1310 (B-O). ^{1}H NMR (90 MHz, $CDCl_3$–TMS) δ: 1.02 (d, J = 7 Hz, CH_3C-O), 3.41 (d, J = 8 Hz, O-C-CH), 4.48 (m, O-CH), 5.03 (s, N-CH(aryl)$_2$), 7.10–7.51 (m, 18 aromatic H), 7.58–7.75 (m, 2 aromatic H). Anal. calcd. for $C_{28}H_{26}BNO_2$: C 80.20, H 6.25, N 3.34; found: C 80.30, H 6.27, N 3.43.

4, 5, 6-Trimethyl-2,5-diphenyl-1,3-dioxa-4-aza-2-boracyclohexane (2e)

1e (0.56 g, 2 mmol) is reacted in 10 mL of benzene as described above for **2a**. The oily residue is dissolved in a small amount of ethanol and mixed with a few drops of petroleum ether for crystallization. If necessary, the solution is cooled. Yield: 0.34 g (61%) of colorless crystals, mp 74°C. IR (KBr, cm^{-1}): 1600 (C=C), 1308 (B-O). ^{1}H NMR (90 MHz, $CDCl_3$–TMS), δ: 0.97 (d, J = 7 Hz, CH_3C-O), 1.37 (s, N-C-CH_3), 2.50 (s, N-CH_3), 4.60 (q, J = 7 Hz, O-CH), 7.17–8.10 (m, 10 aromatic H). ^{11}B NMR (64 MHz, $CDCl_3$–Et_2OBF_3) δ: 27.0 ($w_{1/2}$ = 385 Hz). Anal. calcd. for $C_{17}H_{20}BNO_2$: C 72.62, H 7.17, B 3.85, N 4.98; found: C 72.70, H 7.25, B 3.88, N 4.92.

[3] The boron chelate **1l** could not be isolated because of an immediate complete rearrangement to **2l** proceeding under various conditions.
[4] The compounds **2** give a red-violet colored solution upon addition of diphenylcarbazone, indicating the monoarylboron moiety (2*a*).

5,6-Dimethyl-2,5-diphenyl-4-propyl-1,3-dioxa-4-aza-2-boracyclohexane (2f)

1f (0.62 g, 2 mmol) is reacted as described above for **2e**. Yield: 0.51 g (82%) of colorless crystals, mp 62°C. IR (KBr, cm^{-1}): 1599 (C=C), 1307 (B-O). ^1H NMR (90 MHz, $CDCl_3$–TMS) δ: 0.87 (d, J = 7 Hz, CH_3C-O), 0.97 (m, CH_3C-C-N), 1.47 (s, N-C-CH_3), 1.77 (m, C-CH_2-C-N), 2.00–2.87 (m, N-CH_2), 4.60 (q, J = 7 Hz, O-CH), 7.20–8.13 (m, 10 aromatic H). ^{11}B NMR (64 MHz, $CDCl_3$–Et_2OBF_3) δ: 27.1 ($w_{1/2}$ = 428 Hz). Anal. calcd. for $C_{19}H_{24}BNO_2$: C 73.80, H 7.82, B 3.50, N 4.53; found: C 73.76, H 7.92, B 3.51, N 4.69.

4-Isopropyl-5,6-dimethyl-2,5-diphenyl-1,3-dioxa-4-aza-2-boracyclohexane (2g)

1g (0.62 g, 2 mmol) is reacted as described above for **2e**. Yield: 0.38 g (62%) of colorless crystals, mp 131°C. IR (KBr, cm^{-1}): 1598 (C=C), 1305 (B-O). ^1H NMR (90 MHz, $CDCl_3$–TMS) δ: 0.90 (d, J = 7 Hz, CH_3C-O), 1.13 and 1.20 (d and d, J = 7 Hz, $C(CH_3)_2$), 1.47 (s, N-C-CH_3), 2.97 (sept, J = 7 Hz, N-CH), 4.57 (q, J = 7 Hz, O-CH), 7.20–8.10 (m, 10 aromatic H). ^{11}B NMR (64 MHz, $CDCl_3$–Et_2OBF_3) δ: 27.3 ($w_{1/2}$ = 428 Hz). Anal. calcd. for $C_{19}H_{24}BNO_2$: C 73.80, H 7.82, B 3.50, N 4.53; found: C 73.78, H 7.76, B 3.52, N 4.83.

4-Cyclohexyl-5,6-dimethyl-2,5-diphenyl-1,3-dioxa-4-aza-2-boracyclohexane (2h)

1h (1.03 g, 3 mmol) is reacted as described above for **2e**. Yield: 0.63 g (60%) of colorless crystals, mp 122°C. IR (KBr, cm^{-1}): 1599 (C=C), 1308 (B-O). ^1H NMR (90 MHz, $CDCl_3$–TMS) δ: 0.80–2.23 (m, $(CH_2)_5$), 0.90 (d, J = 7 Hz, CH_3C-O), 1.53 (s, N-C-CH3), 2.63 (m, N-CH), 4.60 (q, J = 7 Hz, O-CH), 7.17–8.13 (m, 10 aromatic H). ^{11}B NMR (64 MHz $CDCl_3$–Et_2OBF_3) δ: 27.0 ($w_{1/2}$ = 428 Hz). Anal. calcd. for $C_{22}H_{28}BNO_2$: C 75.65, H 8.08, B 3.10, N 4.01; found: C 75.54, H 8.08, B 3.07, N 3.86.

4-Benzyl-5,6-dimethyl-2,5-diphenyl-1,3-dioxa-4-aza-2-boracyclohexane (2i)

1i (1.07 g, 3 mmol) is reacted in 10 mL of ethanol as described above for **2e**. Crystallization may start during the refluxing or upon cooling of the solution. Yield: 0.47 g (44%) of colorless crystals, mp 135°C. IR (KBr, cm^{-1}): 1598 (C=C), 1304 (B-O); ^1H NMR (90 MHz, $CDCl_3$–TMS) δ: 1.00 (d, J = 7 Hz, CH_3C-O), 1.53 (s, N-C-CH_3), 3.63 (s, N-CH_2), 4.67 (q, J = 7 Hz, O-CH), 7.03–7.87 (m, 15 aromatic H). ^{11}B NMR (64 MHz, $CDCl_3$–Et_2OBF_3) δ: 27.0 ($w_{1/2}$ = 385 Hz). Anal. calcd. for $C_{23}H_{24}BNO_2$: C 77.33, H 6.77, B 3.03, N 3.92; found: C 77.38, H 6.88, B 3.13, N 3.68.

4-Benzhydryl-5,6-dimethyl-2,5-diphenyl-1,3-dioxa-4-aza-2-boracyclohexane (2j)

1j (0.87 g, 2 mmol) is reacted as described above for **2i**. Yield: 0.48 g (56%) of colorless crystals, mp 158°C. IR (KBr, cm^{-1}): 1601 (C=C), 1314 (B-O). ^1H NMR (90 MHz, $CDCl_3$–TMS) δ: 0.90 (d, J = 7 Hz, CH_3C-O), 1.00 (s, N-C-CH_3), 4.80 (q, J = 7 Hz, O-CH), 4.97 (s, N-CH), 7.08–7.93 (m, 20 aromatic H). ^{11}B NMR (64 MHz, $CDCl_3$–Et_2OBF_3) δ (ppm): 26.8 ($w_{1/2}$ = 514 Hz). Anal. calcd. for $C_{29}H_{28}BNO_2$: C 80.38, H 6.51, B 2.49, N 3.23; found: C 80.36, H 6.52, B 2.54, N 3.03.

Single crystals suitable for X-ray analysis were obtained by very slow crystallization from absolute ethanol.

4-Benzhydryl-5,6-dimethyl-2,5-di(4′-methylphenyl)-1,3-dioxa-4-aza-2-boracyclohexane (2k)

3-Hydroxy-2-butanone (0.88 g, 10 mmol) and di(4-methylphenyl)borinic acid (**3**) (2.10 g, 10 mmol) are dissolved in 10 mL of absolute ethanol, if necessary under slight warming. A solution of *N*-benzhydrylhydroxylamine (1.99 g, 10 mmol) in 10 mL of ethanol is added without stirring, after pre-cooling of both solutions. At –18°C crystallization starts spontaneously or after rubbing with a glass stick. The crystals are filtered off and are washed rapidly with a small amount of ethanol and small portions of ether. Yield: 2.63 g (55%) of colorless crystals of **4-benzhydryl-5,6-dimethyl-2,2-di(4′-methylphenyl)-1,3-dioxa-4-azonia-2-borata-4-cyclohexene (1k)**[5]; mp 120°C (rearrangement to **2k**). IR (KBr, cm^{-1}): 1604 (C=N/C=C). ^1H NMR (400 MHz, CD_2Cl_2–TMS, at –17°C), δ: 1.58 (d, J = 7 Hz, O-C-CH_3), 2.14 (s, N=C-CH_3), 2.18 (s, 2 aryl-CH_3), 4.76 (q, J = 7 Hz, O-CH), 6.53 (s, N-CH), 6.56–7.27 (m, 18 aromatic H). ^1H NMR (90 MHz, $CDCl_3$–TMS, at ambient temp.) δ: 0.90 (d, J = 7 Hz, O-C-CH_3, 30% of 3 H), 2.10 (s, N=C-CH_3, 70% of 3 H), 2.27 (s, 2 aryl-CH_3, 30% of 6 H), 2.40 (s, 2 aryl-CH_3, 70% of 6 H), 4.60–4.97 (m, O-CH), 5.00 (s, N-CH, 70% of 1 H), 6.43 (s, N-CH, 30% of 1 H), 6.70–7.83 (m, 18 aromatic H). ^{11}B NMR (64 MHz, $CDCl_3$–Et_2OBF_3, at ambient temp) δ: 5–7 (very weak, broad), 28.0 ($w_{1/2}$ = 590 Hz). Anal. calcd. for $C_{31}H_{32}BNO_2$: C 80.70, H 6.99, B 2.34, N 3.04; found: C 80.65, H 7.27, B 2.34, N 2.96. **1k** (0.92 g, 2 mmol) is reacted as described above for **2i**. Yield: 0.62 g (67%) of colorless crystals, mp 180°C. IR (KBr, cm^{-1}): 1609 (C=C), 1308 (B-O). ^1H NMR (90 MHz, $CDCl_3$–TMS) δ: 0.90 (d, J = 7 Hz, O-C-CH_3), 0.97 (s, N=C-CH_3), 2.40 (s, 2 aryl-CH_3), 4.87 (q, J = 7 Hz, O-CH), 5.07 (s, N-CH), 7.17–7.97 (m, 18 aromatic H). ^{11}B NMR (64 MHz, $CDCl_3$–Et_2OBF_3) δ: 28.0 ($w_{1/2}$ = 520 Hz). Anal. calcd. for $C_{31}H_{32}BNO_2$: C 80.70, H 6.99, B 2.34, N 3.04; found: C 80.64, H 7.04, B 2.35, N 2.92.

4-Benzhydryl-2,5-di(4′-methoxyphenyl)-5,6-dimethyl-1,3-dioxa-4-aza-2-boracyclohexane (2l)

1-Hydroxy-2-butanone (0.88 g, 10 mmol) and di(4-methoxyphenyl)borinic acid (obtained by hydrolysis (3) from the 2-aminoethyl ester (**4**)) (2.42 g, 10 mmol) are dissolved in 10 mL of absolute ethanol, if necessary under slight warming. A solution of *N*-benzhydrylhydroxylamine (1.99 g, 10 mmol) in 10 mL of ethanol is added after pre-cooling of both solutions. After 5 h at –18°C crystals precipitate that do not give the blue color reaction with diphenylcarbazone, which would have indicated an Ar_2B-moiety of the intermediate **1l** (2), but rather a reddish color indicating the complete rearrangement to **2l**. Yield: 2.35 g (48%) of colorless crystals, mp 163°C. IR (KBr, cm^{-1}): 1603

[5] The product gives a blue-colored solution upon the addition of diphenylcarbazone in ethanol, indicating the presence of the chelated diarylborenium (Ar_2B^+) ion (2).

(C=C), 1306 (B-O). ^{1}H NMR (90 MHz, $CDCl_3$–TMS) δ: 0.90 (d, J = 7 Hz, O-C-CH_3), 0.97 (s, N-C-CH_3), 3.77 (s, 2 OCH_3), 2.73 (q, J = 7 Hz, B-O-CH), 4.97 (s, N-CH), 6.53–8.00 (m, 18 aromatic H). ^{11}B NMR (64 MHz, $CDCl_3$–Et_2OBF_3) δ: 27.8 ($w_{1/2}$ = 813 Hz). Anal. calcd. for $C_{31}H_{32}BNO_4$: C 75.46, H 6.54, B 2.19, N 2.84; found: C 75.40, H 6.67, B 2.14, N 2.71.

4-Benzhydryl-2,2-di(4′-chlorophenyl)-5,6-dimethyl-1,3-dioxa-4-azonia-2-borata-4-cyclohexene (1m)

The compound was prepared as described in the preceding paper (1). Single crystals suitable for X-ray analysis were obtained by very slow crystallization from dichloromethane/petroleum ether (bp 30–70°C) using the liquid diffusion method (5).

4-Benzhydryl-2,5-di(4′-chlorophenyl)-5,6-dimethyl-1,3-dioxa-4-aza-2-boracyclohexane (2m)

1m (1.01 g, 2 mmol) is reacted as described above for **2i**. Yield: 0.52 g (52%) of colorless crystals, mp 180°C. IR (KBr, cm^{-1}): 1590 (C=C), 1308 (B-O); ^{1}H NMR (90 MHz, $CDCl_3$–TMS) δ: 0.93 (d, J = 7 Hz, O-C-CH_3), 1.03 (s, N-C-CH_3), 4.77 (q, J = 7 Hz, O-CH), 4.97 (s, N-CH), 7.17–7.90 (m, 18 aromatic H). ^{11}B NMR (64 MHz, $CDCl_3$–Et_2OBF_3)δ: 24.1 ($w_{1/2}$ = 642 Hz). CI-MS (isobutane, 100°C, pos. mode) m/z: 502 (2%, M^+). Anal. calcd. for $C_{29}H_{26}BCl_2NO_2$: C 69.35, H 5.22, B 2.15, Cl 14.12, N 2.79; found: C 69.27, H 5.19, B 2.22, Cl 14.13, N 2.71.

Single crystals suitable for X-ray analysis were obtained by very slow crystallization from absolute ethanol.

5,6-Dimethyl-4-(4′-methylphenyl)-2,5-diphenyl-1,3-dioxa-4-aza-2-boracyclohexane (2n)

3-Hydroxy-2-butanone (0.44 g, 5 mmol) and oxybis(diphenylborane) (0.87 g, 2.5 mmol) are dissolved in 5 mL of absolute ethanol, if necessary under slight warming. A solution of *N*-(4-methylphenyl)hydroxylamine (0.62 g, 5 mmol) in 5 mL of absolute ethanol is added without stirring, after pre-cooling of both solutions. During storage at –18°C, crystals are forming that are separated and washed rapidly with a small amount of cooled ethanol and small portions of ether. Yield: 1.21 g (68%) of colorless crystals containing 95% of **2n** and 5% of the intermediate **1n**; mp 70°C (complete rearrangement to **2n**). IR (KBr, cm^{-1}): 1615 (C=N/C=C). ^{1}H NMR (90 MHz, $CDCl_3$–TMS, at ambient temp.) δ: 1.06 (d, J = 7 Hz, O-C-CH_3, 95% of 3H), 1.43 (s, N-C-CH_3, 95% of 3H), 1.73 (q, J = 7 Hz, O-C-CH_3, 5% of 3H), 1.86 (s, N=C-CH_3, 5% of 3H), 2.23 (s, aryl-CH_3, 95% of 3H), 2.43 (s, aryl-CH_3, 5% of 3H), 5.03 (q, J = 7 Hz, O-CH), 6.63–8.06 (m, 14 aromatic H). ^{11}B NMR (64 MHz, $CDCl_3$–Et_2OBF_3, at ambient temp.) δ: 5–7 (very weak broad signal, partially hidden under the ground signal), 28.0 ($w_{1/2}$ = 420 Hz). Anal. calcd. for $C_{23}H_{24}BNO_2$: C 77.33, H 6.77, B 3.03, N 3.92; found: C 77.24, H 6.86, B 3.13, N 3.75. The mixture **1n**/**2n** is reacted as described above for **2i** to give **2n**. Yield: 0.44 g (64%) of colorless crystals, mp 111°C. IR (KBr, cm^{-1}): 1601 (C=C), 1311 (B-O). ^{1}H NMR (90 MHz, $CDCl_3$–TMS) δ: 1.07 (d, J = 7 Hz, O-C-CH_3), 1.43 (s, N-C-CH_3), 2.23 (s, aryl-CH_3), 5.03 (q, J = 7 Hz, O-CH), 6.63–8.05 (m, 14 aromatic H); ^{11}B NMR (64 MHz, $CDCl_3$–Et_2OBF_3) δ: 28.0 ($w_{1/2}$ = 390 Hz). Anal. calcd. for $C_{23}H_{24}BNO_2$: C 77.33, H 6.77, B 3.03, N 3.92; found: C 77.03, H 6.73, B 3.13, N 3.82.

4-Benzhydryl-5,6-dimethyl-2-(1′-naphthyl)-2-phenyl-1,3-dioxa-4-azonia-2-borata-4-cyclohexene (8) (mixture of diastereomers)

3-Hydroxy-2-butanone (0.88 g, 10 mmol) and *B*-naphthyl-*B*-phenylborinic acid (**6**) (2.32 g, 10 mmol) are dissolved in 10 mL of absolute ethanol. A solution of *N*-benzhydrylhydroxylamine (1.99 g, 10 mmol) in 10 mL of ethanol is added without stirring, after precooling of both solutions. During storage of the mixture at –18°C, crystallization starts spontaneously or after rubbing with a glass stick. The crystals are filtered off and are washed rapidly with a small amount of absolute ethanol and small portions of ether. Yield: 2.89 g (60%) of colorless crystals,[5] mp 130–131°C (rearr.). IR (KBr, cm^{-1}): 1590 (C=N/C=C). ^{1}H NMR (400 MHz, $CDCl_3$–TMS) δ: 1.56 (d, J = 7 Hz, O-C-CH_3, 60% of 3H), 1.57 (d, J = 7 Hz, O-C-CH_3, 40% of 3H), 2.04 (s, N=C-CH_3, 60% of 3H), 2.13 (s, N=C-CH_3, 40% of 3H), 4.55 (q, J = 7 Hz, O-CH, 60% of 1H), 4.81 (q, J = 7 Hz, O-CH, 40% of 1H), 6.59 and 6.60 (s and s, ratio of peak areas 1:1, N-CH, 40% of 1H), 6.99–8.54 (m, 22 aromatic H). ^{11}B NMR (64 MHz, $CDCl_3$–Et_2OBF_3) δ: 8.3 ($w_{1/2}$ = 342 Hz). Anal. calcd. for $C_{33}H_{30}BNO_2$: C 81.99, H 6.25, B 2.24, N 2.90; found: C 81.89, H 6.35, B 2.26, N 2.78.

4-Benzhydryl-5,6-dimethyl-2-(1′-naphthyl)-5-phenyl-1,3-dioxa-4-aza-2-boracyclohexane (9)

8 (0.97 g, 2 mmol) is reacted as described above for **2i**. Yield: 0.43 g (45%) of colorless crystals,[6] mp 181°C. IR (KBr, cm^{-1}): 1599/1574 (C=C), 1304 (B-O). ^{1}H NMR (90 MHz, $CDCl_3$–TMS) δ: 0.97 (d, J = 7 Hz, O-C-CH_3), 1.07 (s, N-C-CH_3), 4.97 (q, J = 7 Hz, O-CH), 5.07 (s, N-CH), 7.03–8.60 (m, 22 aromatic H); ^{11}B NMR (64 MHz, $CDCl_3$–Et_2OBF_3) δ: 27.0 ($w_{1/2}$ = 513 Hz). Anal. calcd. for $C_{33}H_{30}BNO_2$: C 81.99, H 6.25, B 2.24, N 2.90; found: C 82.01, H 6.37, B 2.22, N 2.83.

Single crystals suitable for X-ray analysis were obtained by slow crystallization from dichloromethane/petroleum ether (bp 30–70°C) using the liquid diffusion method (5).

X-ray crystallographic analyses of 2j, 2m, 9, and 1m

Crystallographic data appear in Table 1. The final unit-cell parameters were obtained by least-squares based on 25 reflections (2θ = 90–110°) for **2j**, and 17642, 17505, and 17 642 (2θ = 5–64°) for **2m, 9,** and **1m**, respectively. The data were processed,[7] corrected for Lorentz and polarization effects, and absorption (based on a ψ-scan for **2j**, and analysis of symmetry-equivalent data for the others).

The structures were solved by direct methods, the coordinates of the non-hydrogen atoms being determined from *E*-maps or from subsequent difference Fourier syntheses.

[6] The compound **9** gives a reddish solution upon addition of diphenylcarbazone in ethanol, indicating the monoarylboron moiety (2a).

[b]Temperature 294 K, Rigaku/AFC6 diffractometer, Cu Kα (λ = 1.54178 Å), graphite monochromator, takeoff angle 6.0°, aperture 6.0 × 6.0 mm at a distance of 285 mm from the crystal, ω–2θ scan at 32°/min (in ω) (up to 9 scans), scan width (1.10 + 0.20tanθ)°, crystal decay 2.6%, $\sigma^2(F^2) = (C + B)/\mathrm{Lp}^2$ (C = scan count, B = background count), function minimized $\Sigma w(|F_o| - |F_c|)^2$, where $w = 1/\sigma^2(F_o)$, $R(F) = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w(F) = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, and gof = $[\Sigma w(|F_o| - |F_c|)^2/(m - n)]^{1/2}$.

[c]Includes crystal decay (if any), absorption, and scaling corrections performed in a single step.

[d]Absorption based on ψ scan.

The non-hydrogen atoms were refined with anisotropic thermal parameters, and the hydrogen atoms were refined with isotropic thermal parameters for **9** and fixed in idealized positions for the others. Corrections for secondary extinction were needed only for **2j** and **2m** (coefficients 2.96(3) and 0.23(1) × 10^{-5}, respectively). Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International Tables for X-Ray Crystallography*. Ring torsion angles are listed in Table 2, and selected bond lengths and angles in Table 3. Complete tables of atomic coordinates, bond lengths and angles, hydrogen atom parameters, anisotropic thermal parameters, torsion angles, and intermolecular contacts are included in supplementary material[8] as a Crystallographic Information File (CIF).

Isothermal long-time ^{1}H NMR measurements of 1/2 e, j, k, m, and n

A test sample of **1** (0.05 mmol) was dissolved in ice-cooled CD_2Cl_2, and the ^{1}H NMR spectra (400 MHz) was recorded at the operating temperature of the NMR spectrometer (25°C), repeatedly at fixed time-intervals dependent upon the rate of the rearrangement reaction, which had been determined roughly beforehand. The decrease of concentration of the educt **1** (and the increase of concentration of the rearrangement product **2**) was calculated from the changing peak

areas of corresponding signals. From the log (conc.% educt) vs. time (min) plots, the rate constants (*k*), the half-life ($t_{1/2}$), and the correlation coefficient (*r*) were calculated by standard methods.

Results and discussion

Synthesis and spectroscopy of 2

The thermally induced rearrangement of the diarylboron chelates **1** to the cycloboronates **2** had been detected as a more-or-less partial process during attempts to recrystallize and during NMR experiments with solutions of **1** (1). Complete transformation to **2** was achieved by refluxing **1** in solvents such as benzene, toluene, or ethanol, while monitoring the progress of the reaction by the color reaction with diphenylcarbazone (2).[4,5] An immediate synthesis of **2** was also possible without the preformation of the diarylboron chelate **1**, if a three-component one-pot reaction of carbonyl compound, the hydroxylamine, and the diarylborinic acid was conducted in a heated solvent. Certain compounds, like **2l**, could be obtained only by this method, because of the high tendency of isomerization of the preceding diarylboron chelate **1l**, which we were not able to isolate even without applying heat. Other chelates, like **1k** or **1n**, were obtained only as mixtures with **2k** and **2n**, respectively. Heating of these mixtures in ethanol resulted in complete rearrangement to **2k** and **2n**, respectively.

The infrared spectra of the crystalline compounds **2** are generally characterized by the disappearance of the N=C vibration, a distinctive mark in most of the spectra of the boron chelates **1** (1). In addition, a strong absorption band between 1304 and 1314 cm^{-1}, which is not present in the spectra of **1**, is conspicuous in the spectra of **2**. This band has been assigned formerly to the B—O stretching vibration of borates and boronates (7).[9] Another striking phenomenon can be observed in comparing the 1600 cm^{-1} region of the spectra of the educt **1** and the rearrangement product **2**, if **1** contains a diphenylboron moiety and no further aromatic ring system, as in **1a**, **1b**, and **1e**–**h**. In these cases, the diphenylboron chelates **1** do not show a considerable or detectable ν_{16}-ring stretching vibration of the *B*-aryl residues, whereas the corresponding isomerization products **2** display distinct ν_{16} bands, typical for mono-substituted benzene derivatives with an increased perturbation of the ring π-system (8). The low intensity of the ν_{16} bands in the diphenylboron compounds **1** might indicate the decreased interaction between the phenyl ring π-system and the tetra-coordinated (sp^3) boron atom. On the other hand, the trivalent phenylboronate moiety of **2** allows an increased interaction between the phenyl ring π-system and the (sp^2) boron atom, thus intensifying the ν_{16} band given by the migrated phenyl residue, now positioned at C5 of the cycloboronate ring.[10]

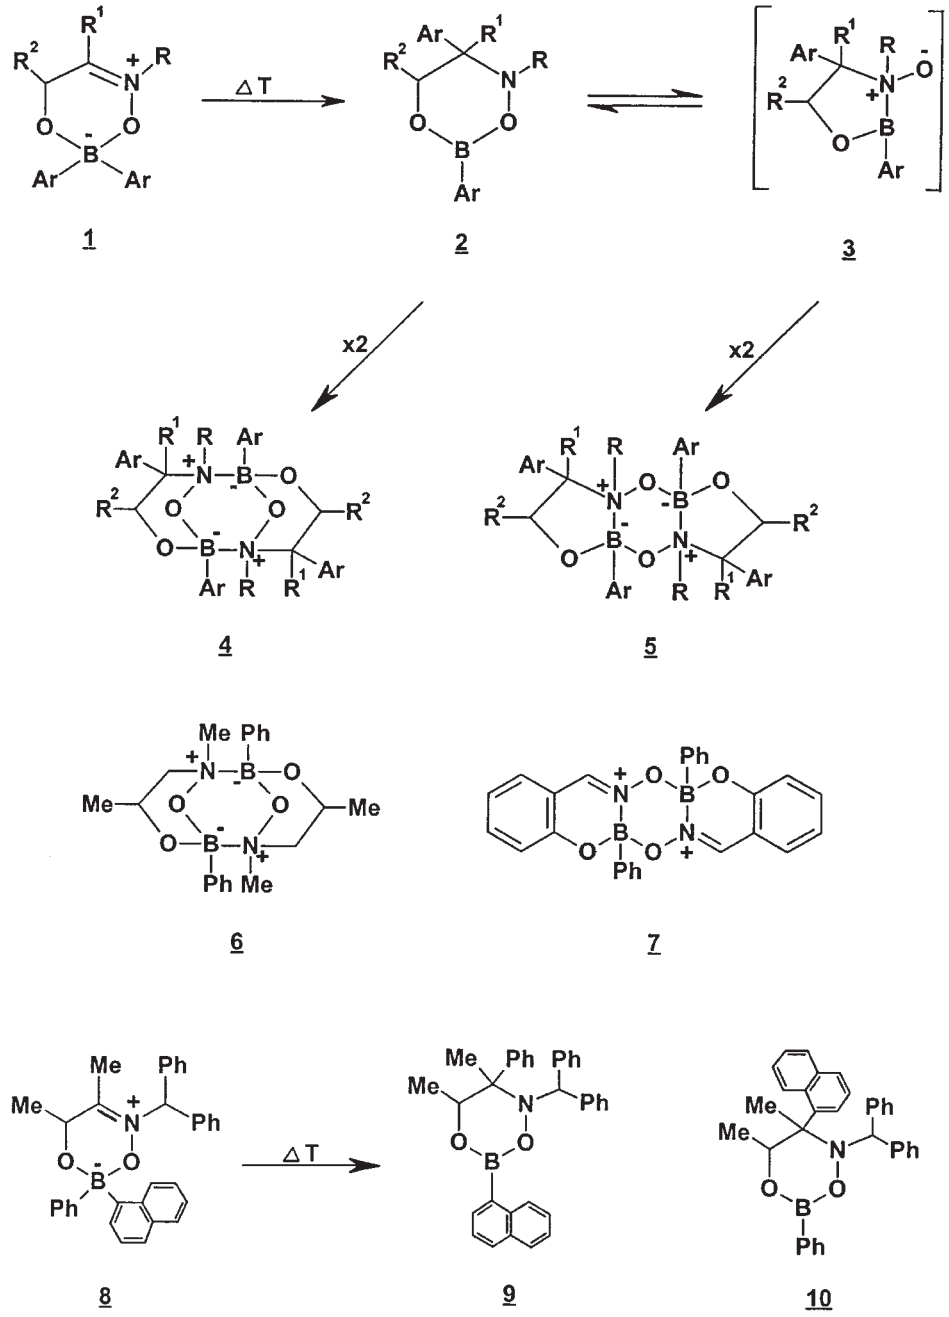
C-O-B	113.0	121.0	120.1	120.7

In the ^{1}H NMR spectra of **2**, generally all signals of the aliphatic protons of residues R, R^1, and R^2 are shifted to a higher field compared to the corresponding signals of the educts **1**, a consequence of the transformation of the N=C double bond into a N—C single bond ring segment and the deshielding effect caused thereby. The largest change occurs, as expected, in the N=CH methine-proton signal of compounds **1a–d**, which are shifted about 3.4 ppm upfield after the rearrangement to **2a**–**d**.

Additional proof for the isomerization comes from the ^{11}B NMR spectra of some examples of **2**, which display resonance signals between (Et_2OBF_3) = 26 and 28 ppm, indicating the (sp^2) boron atom of the cycloboronate, whereas the ^{11}B signals of the boron chelates **1** range between 3 and 9 ppm (1), typical for tetracoordinate (sp^3) boron nuclei (10).



The spectroscopic data, together with the elemental analyses and the red color reaction with diphenylcarbazone,[4] suggest the molecular structure **2** exists, at least in solution, but cannot exclude unambiguously the presence of dimers like **4** or **5** in the solid state. These types of BONBON dimers resemble the BONBON compounds **6** (11) or **7** (12), which have been fully characterized by X-ray crystallographic structure analyses and demonstrate the possibility of the formation of such dimers. An EI mass spectrum of **2m** gave as the highest mass feature the molecular ion of the monomer **2m**, but this observation could result from a complete dissociation of one of the possible dimers, **4** or **5**. However, the

[9] The strength of the band and its stability of position can be ascribed to the partial double bond character of the B—O bond by pp (π)-back donation (7*a*, *b*).

[10] A similar increase of intensity of the ν_{16} ring stretching band had been observed after the thermal rearrangement of another type of diphenylboron chelate having one of the *B*-phenyl ligands transformed into a *B*-phenyloxy ligand (9*a*, *b*).

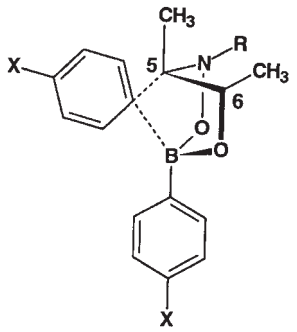
Scheme 1.

X-ray crystallographic analyses of **2j** and **2m** prove unambiguously the monocyclic arylboronate structure **2** (see below).

Synthesis and spectroscopy of 9



The thermally induced isomerization was not achieved with derivatives of dinaphthylborinic acid. The compounds **1** (Ar = 1-naphthyl) could be recrystallized unchanged even from high boiling solvents (1). To test the different migration tendency of *B*-phenyl and *B*-naphthyl residues, we synthesized compound **8**, a derivative of a "mixed" diarylborinic acid. Compound **8** was obtained as a mixture of stereoisomers. The ^{1}H NMR spectrum of the isolated batch of crystals points to a 3:2 mixture of the two possible racemates, by exhibiting a 3:2 ratio of corresponding peak areas.[11] We did not succeed in separating the diastereomers, the physical properties of which seem to differ only slightly.[12] In the ^{11}B NMR spectrum, for instance, only one broad signal at 8.3 ppm is registered for the tetracoordinate boron nucleus of the obviously present diastereomers. Thus, **8** (as a mixture of stereoisomers) was brought to reflux in ethanol and yielded 45% of a crystalline product which gave the red color-reaction with diphenylcarbazone,[6] and had the elemental analysis and the spectroscopic data of a monoarylboronate **9** or **10**. These data closely resembled those of the cycloboronates **2** in all respects, but did not distinguish between the alternative constitutions, **9** or **10**. An X-ray crystallographic analysis (see below) confirms the molecular

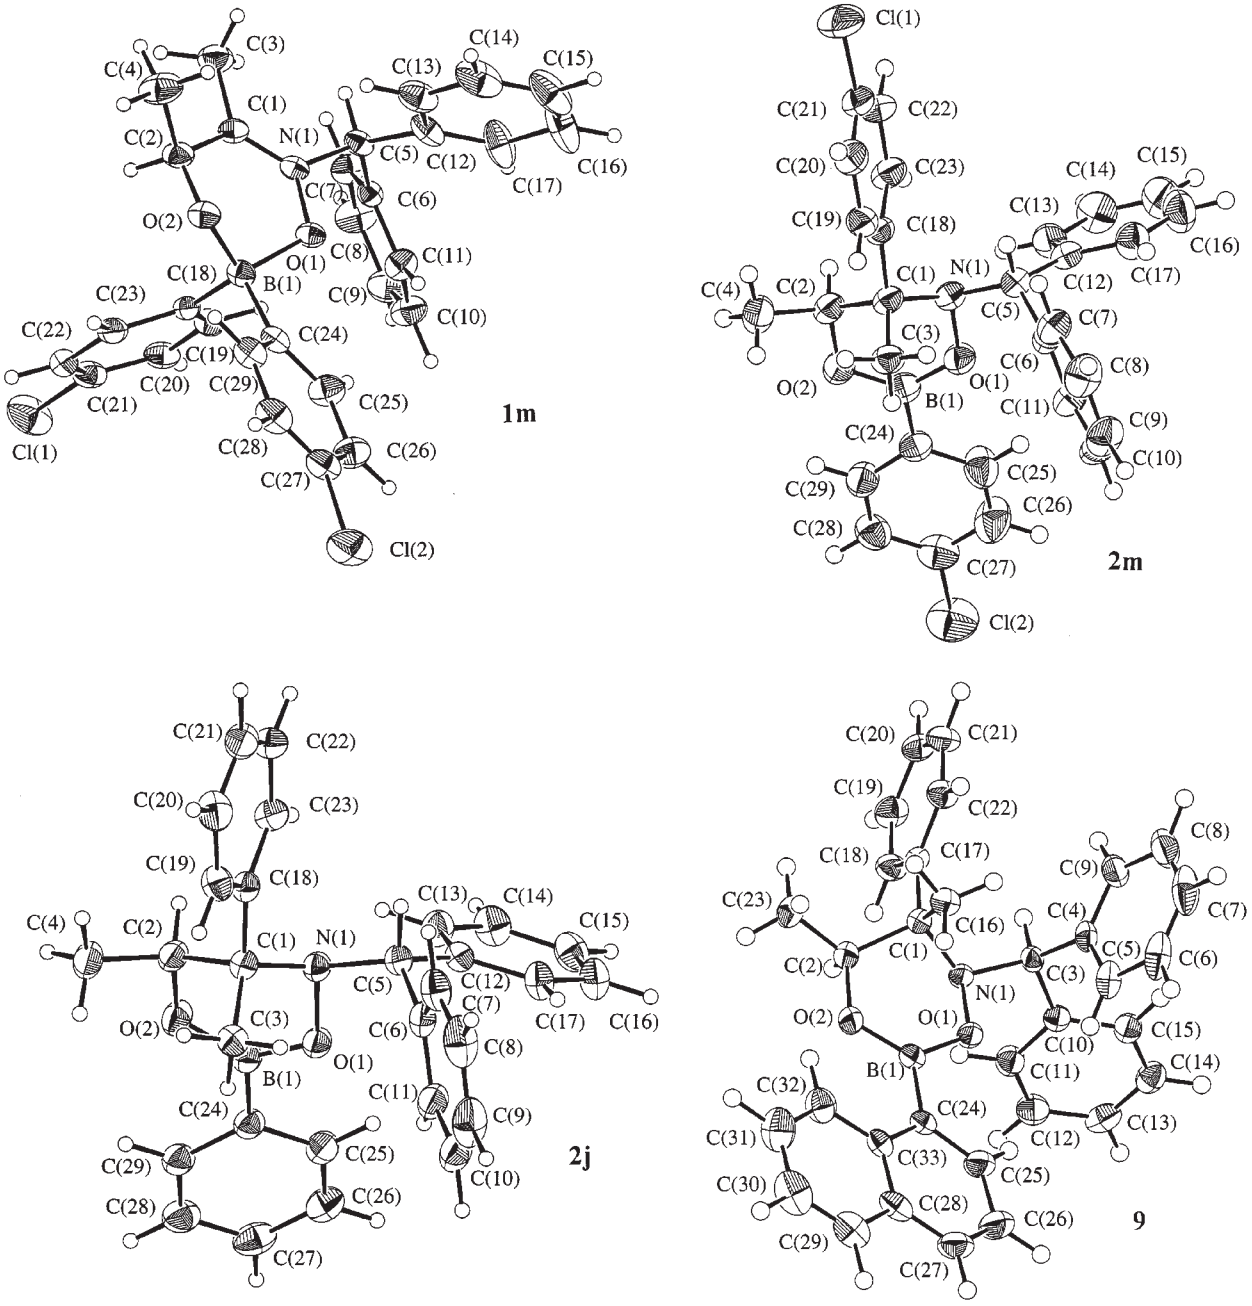
11

structure **9**, demonstrating the expected preferential migration of the phenyl group. This might explain the thermal stability of the dinaphthylboron chelates, on the basis of an impeded migration of the comparatively bulky naphthyl residue.



X-ray cyrstal structure analyses of 1m, 2j, 2m, and 9

The X-ray analyses confirm the postulated molecular structures of the rearrangement products **2j**, **2m**, and **9** (Fig. 1), proving the aryl-1,4-migration in each case, with an impediment for migration of the bulkier naphthyl residue. In addition, the structure of **2m** furnishes evidence for the identity of the scission and recombination site of the migrating aryl ring. For direct comparison of the rearrangement product with its educt, an additional analysis was carried out for **1m** that bears 4-chlorophenyl groups, allowing location of the linking position before and after the aryl migration.

The six-membered BONCCO ring of **1m** (Fig. 1) possesses an approximately planar O(1)-N(1)=C(1)-C(2) grouping (dihedral angle = 6.2° (Table 2)), with B displaced by about 0.4 Å from this plane and O(2) displaced by a smaller amount in the opposite direction. The conformation may thus be described as a distorted half-chair (an alternative description is as a distorted envelope, with a roughly planar five-atom section, with B at the flap). The tetrahedral arrangement of the ligands around the boron atom is typical for all diarylboron chelates of bidentate ligands. As expected, the pseudo-axial *B*-aryl bond B(1)—C(18) (1.624 Å) is somewhat longer (by 0.025 Å) than the pseudo-equatorial B(1)—C(24) bond (1.599 Å). The difference between the two O—B bond lengths indicates the better donor quality of the alcoholate ligand, which makes a stronger O—B bond (O(2)—B(1) = 1.461 Å), compared to that of the nitrone ligand with the weaker O—B bond (O(1)—B(1) = 1.556 Å). This (nitrone) O—B bond, however, seems to possess an increased binding strength relative to that of a seven-membered analogous diphenylboron chelate with a (nitrone) O—B distance of 1.593 Å reported previously (1). The mean C—B (1.612 Å) and O—B (1.509 Å) distances with a mean C—B/O—B bond length ratio of 1.068, in the upper range of values estimated for this kind of compound (15), suggest a slightly stronger ligand binding to the diarylboron nucleus in **1m** compared to the seven-membered analog (C—B/O—B ratio of 1.059) (1). The endocyclic C=N double bond

Fig. 1. Views of the molecules of **1m**, **2j**, **2m**, and **9**; 25% (**1m**, **2j**) and 50% (**2m**, **9**) probability ellipsoids are shown for the non-hydrogen atoms.

(C(1)—N(1) = 1.286 Å) and the nitrone N—O bond (N(1)—O(1) = 1.368 Å) are about normal and are in accord with the corresponding bond distances in seven-membered boron chelates with endocyclic nitrone moieties (1, 16). To the best of our knowledge **1m** is the first example of the type **1** boron chelates (1) structurally characterized by an X-ray crystallographic analysis.

The heterocyclic structures of **2j**, **2m**, and **9** contain in each case a trigonal planar sp^2-hybridized boron atom, whcih is typical for six-membered cycloboronates (17, 18). The ring geometry in each molecule is again a half-chair, with an approximately planar OBOC grouping (dihedral angle = 0.1–6.6°, Table 2), with displacement by ca. 0.5 Å on opposite sides of this plane of N and C-5 (C(1) in the ORTEP diagrams, Fig. 1).

Assuming that all of the rearrangement products presented here, **2** and **9**, have an identical BONCCO ring skeleton, they possess the same heterocyclic structure that had been established previously for the reaction products of various 2-(*N*-alkylhydroxylamino)alkanols with arylboronic acids (19), for *N*-unsubstituted analogs of **2** derived from bulky arylboronic acids (18) and also for *N*-acyl derivatives (20). In accordance with the near planarity at the sp^2-hybridized boron atoms in all three compounds, **2j**, **2m**, and **9**, there are

© 2001 NRC Canada

the relatively short O—B bonds (between 1.349 and 1.372 Å, Table 3), indicating the partial double bond character that results from O—B *pp* (π) back donation. In each case, the (C)O—B bond is distinctly shorter (by 0.008–0.019 Å) than the (N)O—B bond, indicating the better *p* (π) donor quality of the alcoholate ligand compared to the hydroxylamine ligand. The increased double bond character of the (C)O—B bonds is also reflected by the interior angles at O(2) and B(1) between 120.1 and 122.7° in all three compounds, whereas the interior angle at O(1) is somewhat compressed (114.3–117.7°), as a result of less double bond character. The B—C(aryl) distance in **2j**, **2m**, and **9** ranges between 1.544 and 1.561 Å, and is typical for many cyclic arylboronates (17, 18). Even though in (sp^2) B—C(aryl) bonds a *pp* (π) interaction seems to play a minor role (17, 18), the aryl rings in **2j**, **2m**, and **9** are not far from coplanar with the OBOC ring portion of the cycloboronate, with rotations of about 20, 1, and 18°, respectively (the exact values depend on which plane or dihedral angle is used to define the rotation). The deviation in **9** from coplanarity between the naphthyl ring and the OBOC plane is presumably due to intramolecular steric reasons, as in mesitylboronates (17, 18); there may be a weak C-H···O interaction (C(32)-H···O(2) in Fig. 1, H···O = 2.29(1) Å). The deviation in **2j** is likely an intermolecular effect.

The comparison of the structural features of the educt **1m** and the product **2m** points out some essential geometrical changes as a consequence of the chemical transformation, which might be generally applicable for the educt/product pair **1**/**2**. The aryl 1,4-migration from the (sp^3) boron atom B(1) to the nitrone carbon atom C(1) converts the short C=N double bond (C(1)—N(1) = 1.286 Å) of the nitrone function in **1m** into a long C—N single bond (C(1)—N(1) = 1.495 Å) of the dialkylhydroxylamine moiety in **2m**.[13] The nitrone reduction is accompanied by the oxidation of the borinic to a boronic acid function, transferring the double bond character of the nitrone bonds into the O-B-O segment of the ring, causing the shortening of the O—B bonds from the mean value of 1.509 Å in **1m** to a mean value of 1.366 Å in **2m**. This change includes the widening of the O-B-O angle from 106.1° in the (sp^3) boron complex **1m** to 121.9° in the trigonal (sp^2) boron compound **2m**. All of the remaining bonds in the BONCCO ring are elongated by 0.05–0.08 Å going from **1m** to **2m**, in particular the N—O bond, which loses its partial double bond character still present in the nitrone function of **1m**. The angles at N(1) in **2m** (106.0–117.6, average 111.5°) indicate tetrahedral geometry at the (sp^3) N atom (lone-pair pseudo-axial); the (sp^2) N atom in **1m** has nearly planar geometry (angles = 110.5–123.1, average, 118.2°). Considering the conformational change of the six-membered ring system, the aryl 1,4-migration results in a displacement of the planar part within the BONCCO ring, by transferring planarity from the ON=CC segment in **1m** to the OBOC segment in **2m**.

In all crystallographically analyzed rearrangement products, **2** and **9**, the vicinal methyl groups at ring positions C5 and C6 are in *cis*-configuration This indicates that, in each case, the migrating aryl residue seems to be that one that is positioned *trans* to the methyl group at C6 in the educt **1** and **8**, respectively. Examination of the ORTEP diagrams (Fig. 1) of the educt/product pair **1m**/**2m** shows that the aryl residue (with C(18)-C(23) and Cl(1)), which is *trans* to 6-CH_3 in the educt **1m** (C(4) in Fig. 1), migrates to C5 (C(1) in Fig. 1), via the supposed transition state **11**, and that consequently the methyl groups at C5 and C6 (C(3) and C(4) in Fig. 1) of the product **2m** are in a *cis*-configuration.

Preliminary thermoanalyses

The melting behaviour of certain specimens of **1** (e.g., **j**, **k**, **m**, and **n**) gave the first hints of a thermally induced transformation reaction: a sudden liquefaction of the substance at temperatures between 70 and 130°C was followed by recrystallization at the same or even higher temperature, until the final melting or decomposition at a still higher temperature.[14] This could be interpreted as a primary exothermic rearrangement reaction of **1** to result in the isomer **2**, which melts and decomposes at further raised temperatures. In those cases, with a melting point of **2** lower than the rearrangement temperature, only a single "liquefaction point" was observed, as to be expected. For **1m** and **2m**, the molecular structure of each was unambiguously established by X-ray crystallography (see above), the rearrangement point was observed at about 130°C, and the melting temperature of the rearrangement product at 180°C. In a differential scanning calorimetry (DSC) experiment, the transformation process showed two peaks, one at 130.5°C representing the exothermic isomerization of the B,*N*-betainic heterocycle **1m** to the energetically favored cycloboronate **2m**, including the negative recrystallization enthalpy,[15] and another at 179.8°C representing the positive fusion enthalpy of **2m** (Fig. 2). Approximately the same reaction progress was registered in a differential thermoanalytical/thermogravimetric (DTA/TG) experiment with **1m**. The DTA-curve showed approximately coinciding peaks, as displayed by the DSC-thermogram, for rearrangement/recrystallization (132.8°C) and fusion (183.3°C), and was in accordance with the TG-curve, indicating mass constancy up to the rearrangement point and no loss of mass during the transformation to **2m**. Rapid mass decrease at the fusion point of **2m** showed the decomposition of the compound (Fig. 2). The DSC data gave an isomerization/ recrystallization enthalpy of $\Delta H_{iso} + \Delta H_{rcr} = -179.3$ J g^{-1} (–90.05 kJ mol^{-1}) and a fusion enthalpy of $\Delta H_{fus} = 47.7$ J g^{-1} (23.96 kJ mol^{-1}) for the solid state transition from **1m** to **2m**. Similar values were gathered from the DSC data of **1**/**2i**–**k** and **8**/**9** (Table 4). In the DSC thermogram of **1j**/**2j** (see supplementary material)[8] the first exothermic reaction peak was split into two separate peaks at 103 and 112°C,

[13]The same type of thermally induced 1,4-shift of one *B*-phenyl group had been observed previously with open-chain nitrone–triphenylborane adducts (21) and with diphenylboron chelates of salicylaldonitrones (16, (*a*) W. Kliegel, D. Nanninga, S.J. Rettig, and J. Trotter. Can. J. Chem. **62**, 845 (1984); (*b*) W. Kliegel, D. Nanninga, and U. Lauterbach. Unpublished results). It represents fundamentally another kind of reductive arylation, like nitrone reductions by organometallic reagents (22).

[14]Similar observations are known for diarylboron chelates that undergo another type of thermal rearrangement (aryl-1,2-migration) (9).

[15]Possibly the rearrangement (liquefaction) and recrystallization might be registered as two separate peaks for chronologically resolved processes by measuring with considerably lower heating rates to those applied in this first experiment (5°C min^{-1}).

very likely the rearrangement reaction and the recrystallization process. The endothermic fusion peak at 152°C possessed approximately the same peak area as the crystallization peak at 112°C, which would be consistent. A preliminary idea of the thermal behaviour of those compounds **1** that rearrange at temperatures near or above the melting point of **2** was given by the DTA/TG thermogram of **1g**/**2g** (see supplementary material)[8]. In this case, the presence of only one single peak indicated the isomerization reaction at 142°C, and the loss of mass started as this temperature was approached. This should be equivalent to an instantaneous decomposition of the emerging rearrangement product **2g**, the fusion point of which has been found at lower temperatures of about 131°C.

Time-dependent NMR measurements

Since many of the boron compounds **1** isomerize even at room temperature or during the ^{1}H NMR mearsurements (at 25°C) and even ice cold solvents could not prevent partial rearrangement, a low-temperature ^{1}H NMR experiment has been carried out. It demonstrated, however, that the reaction rate from –40°C to 0°C seems to be very slow and that a progressively faster isomerization can be detected at higher temperatures up to 25°C (from the changing ratio of peak areas between educt **1** and product **2** during the increase of temperature). To obtain more specific information on the rate of transformation, the ^{1}H NMR spectra of variously substituted compounds **1** (or **1** containing a portion of already generated isomer **2**) were recorded at 25°C over an extended period of time (several half-life periods). For this purpose, on the one hand, a series of diphenylboron chelates with *N*-methyl- (**1e**), *N*-benzhydryl- (**1j**), and *N*-tolyl-substitution (**1n**), and on the other hand, a series of *N*-benzhydryl derivatives of di(4-chlorophenyl)- (**1m**), diphenyl- (**1j**), and di(4-tolyl)-boron chelates (**1k**) were selected to investigate the influence of the *N*-substitution and of the *B*-aryl residues on the reaction rate. The ^{1}H NMR spectra were recorded, using CD_2Cl_2 as a solvent, with periodic registration of the decrease and increase, respectively, of the signal intensities of **1** and **2**. Suitable, sufficiently separated marker signals for comparison of the peak areas were the quadruplet of the C6 single proton and additionally, in case of the *N*-benzhydryl derivatives, the singlet of the N-CH methine proton.

The concentration vs. time plots (Fig. 3) indicate an influence of both the *N*-substituent R and the *B*-substituent Ar on the rate of isomerization. The linearity of the log (conc. of educt) vs. time plots of **1** indicates a first-order reaction and suggests an intramolecular aryl 1,4-shift, which might include a transition state like **11**, as has been postulated for the

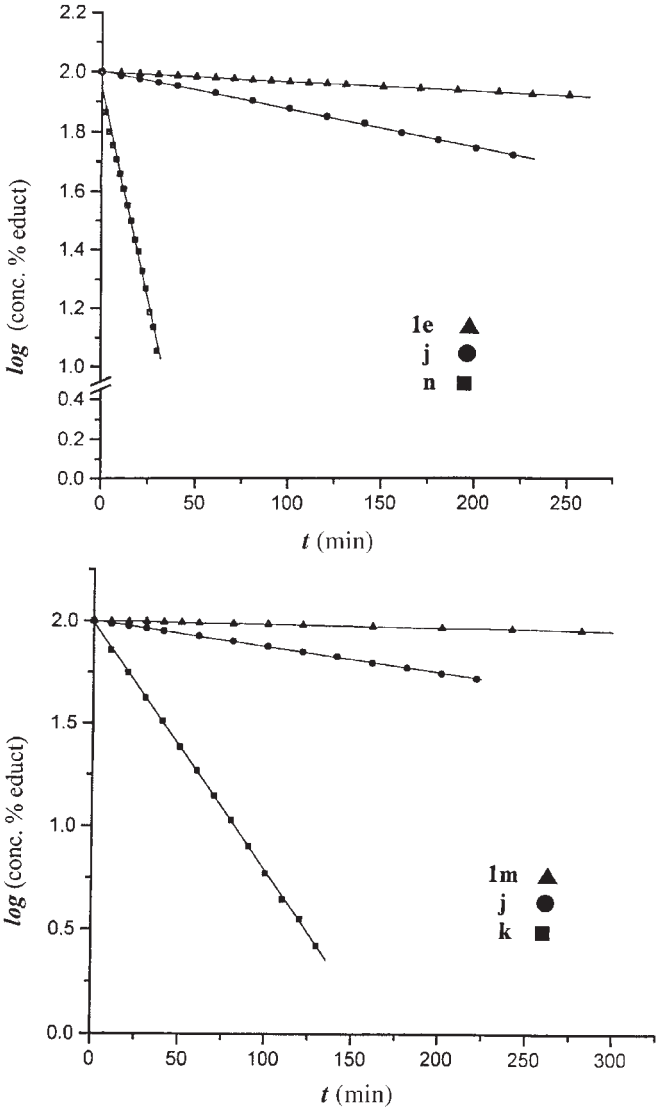

Fig. 2. Differential scanning calorimetry (DSC) and thermogravimetry and differential thermoanalysis (TG/DTA) thermograms of **1/2m**.

1,4-shift in the diarylboron chelates of salicyaldonitrones (16). From the kinetic parameters (Fig. 3, Table 5), it is clearly apparent that the reaction rate is increased by diminishing the electron density at C5 to enable or facilitate the formation of the transition state (**11**) of the aryl migration, in the order *N*-methyl < *N*-benhydryl < *N*-tolyl. Considering the influence of the *B*-aryl residues, the 4-chlorophenyl substiutent is a comparatively poor leaving group, with the order of the rate of migration, 4-chlorophenyl < phenyl < 4-tolyl, indicating the increase of electron density at the leaving position of the aryl ring by inductive effects, which facilitates the formation of the transition state **11** (X = Cl, H, CH_3) and accelerates the rearrangement.

The syntheses of 6-*C*-alkyl derivatives of methyl α-isomaltoside for a study of the mechanism of hydrolysis by amyloglucosidase

Ulrike Spohr, Nghia Le, Chang-Chun Ling, and Raymond U. Lemieux

Abstract: The epimeric (6a*R*)- and (6a*S*)-*C*-alkyl (methyl, ethyl and isopropyl) derivatives of methyl α-isomaltoside (**1**) were synthesized in order to examine the effects of introducing alkyl groups of increasing bulk on the rate of catalysis for the hydrolysis of the interunit α-glycosidic bond by the enzyme amyloglucosidase, EC 3.2.1.3, commonly termed glucoamylase (AMG). It was previously established that methyl (6a*R*)-*C*-methyl α-isomaltoside is hydrolysed about 2 times faster than methyl α-isomaltoside and about 8 times faster than its *S*-isomer. The kinetics for the hydrolyses of the ethyl and isopropyl analogs were also recently published. As was expected from molecular model calculations, all the *R*-epimers are good substrates. A rationale is presented for the catalysis based on conventional mechanistic theories that includes the assistance for the decomposition of the activated complex to products by the presence of a hydrogen bond, which connects the 4a-hydroxyl group to the tryptophane and arginine units. It is proposed that activation of the initially formed complex to the transition state is assisted by the energy released as a result of both of the displacement of perturbed water molecules of hydration at the surfaces of both the polyamphiphilic substrate and the combining site and the establishment of intermolecular hydrogen bonds, i.e., micro-thermodynamics. The dissipation of the heat to the bulk solution is impeded by a shell of aromatic amino acids that surround the combining site. Such shields are known to be located around the combining sites of lectins and carbohydrate specific antibodies and are considered necessary to prevent the disruption of the intermolecular hydrogen bonds, which are of key importance for the stability of the complex. These features together with the exquisite stereoelectronic dispositions of the reacting molecules within the combining site offer a rationalization for the catalysis at ambient temperatures and near neutral pH. The syntheses involved the addition of alkyl Grignard reagents to methyl 6-aldehydo-α-D-glucopyranoside. The addition favoured formation of the *S*-epimers by over 90%. Useful amounts of the active *R*-isomers were obtained by epimerization of the chiral centers using conventional methods. Glycosylation of the resulting alcohols under conditions for bromide-ion catalysis, provided methyl (6a*S*)- and (6a*R*)-*C*-alkyl-hepta-*O*-benzyl-α-isomaltosides. Catalytic hydrogenolysis of the benzyl groups afforded the desired disaccharides. ^{1}H NMR studies established the absolute configurations and provided evidence for conformational preferences.

Key words: amyloglucosidase (AMG), *exo*-anomeric effect, 6-*C*-alkyl-α-D-glucopyranosides and isomaltosides, mechanism of enzyme catalysis.

Résumé : On a réalisé la synthèse des dérivés (6a*R*) et (6a*S*)-*C*-alkyles (méthyle, éthyle et isopropyle) de l'α-isomaltoside de méthyle (**1**) afin d'étudier les effets provoqués par l'introduction de groupements alkyles de plus en plus volumineux sur la catalyse de l'hydrolyse de la liaison glycosidique α par l'enzyme amyloglucosidase, EC 3.2.1.3, que l'on dénomme souvent glucoamylase (AMG). Il a été établi antérieurement que le (6a*R*)-*C*-méthyl-α-isomaltoside de méthyle s'hydrolyse environ deux fois plus rapidement que l'α-isomaltoside de méthyle et environ huit fois plus rapidement que son isomère *S*. Les mesures cinétiques pour les hydrolyses des analogues éthyle et isopropyle ont aussi été publiées récemment. Tel qu'on pouvait s'y attendre sur la base de calculs sur des modèles moléculaires, tous les épimères *R* sont de bons substrats. On propose une rationalisation de la catalyse qui est basée sur la théorie mécanistique conventionnelle mais qui, pour la décomposition du complexe activé en produits, implique une aide apportée par la présence dans le complexe d'une liaison hydrogène reliant le groupe 4a-hydroxyle aux unités de tryptophane et d'arginine qui se trouvent loin du centre réactionnel. Il est suggéré que le passage du complexe qui se forme initialement à état de transition se produit avec l'aide de l'énergie libérée en raison à la fois du déplacement des molécules d'eau d'hydratation perturbées sur les surfaces tant du substrat polyamphiphile que du site qui se combine ainsi ce que celle qui résulte de la création de liaisons hydrogènes intermoléculaires, de la microthermodynamique. On indique qu'il y a eu empêchement à la dispersion de la chaleur vers l'ensemble du milieu réactionnel causé par une sorte de coquille

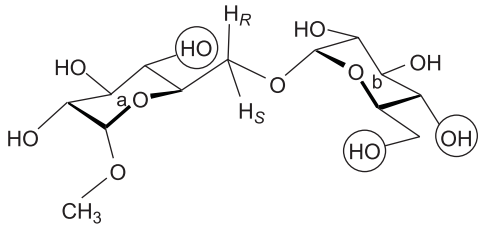
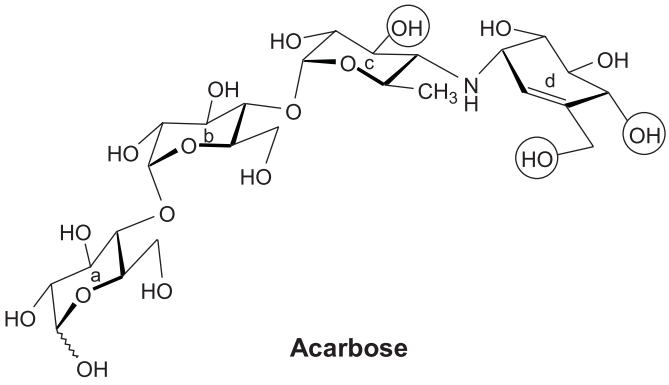
formée d'acides aminés aromatiques qui entoure le site où se produit la combinaison. De tels coquilles ont déjà été observées autour des sites où se produit la combinaison des lectines et des anticorps spécifiques aux hydrates de carbone et ils sont considérés comme nécessaires pour empêcher l'interruption des liaisons hydrogènes d'importance capitale à la stabilité du complexe. Ces caractéristiques ainsi que les dispositions stéréoélectroniques exquises des molécules qui réagissent à l'intérieur du site où se produit la combinaison permettent de rationaliser la catalyse à la température ambiante et à un pH pratiquement neutre. Les synthèses impliquent l'addition des réactifs de Grignard alkylés sur le 6-aldéhydo-α-D-glucopyranoside de méthyle. L'addition conduit à la formation préférentielle (90%) des épimères *S*. On a obtenu des quantités utiles des isomères actifs, *R*, par épimérisation des centres chiraux à l'aide de méthodes conventionnelles. La glycosylation des alcools qui en résultent, dans des conditions de catalyse par l'ion bromure, a permis d'obtenir les (6a*R*) et (6a*S*)-*C*-alkyl-*O*-benzyl-α-isomaltosides de méthyle. L'hydrogénolyse catalytique des groupes benzyles fournit ensuite les disaccharides désirés. Des études de RMN du ^{1}H ont permis de déterminer les configurations absolues et ont permis d'obtenir des données relatives aux préférences conformationnelles.

Mots clés : amyloglucidase (AMG), effet anomère *exo*, α-D-glucopyranosides et isomaltosides 6-*C*-alkylés, mécanisme de catalyse enzymatique.

[Traduit par la Rédaction]



Nomenclature and conventions: The nomenclature follows the general rules of organic chemistry. Thus, the introduction of a methyl group at *C*-6 of methyl α-D-glucopyranoside gives methyl (6*R*)-*C*-methyl-α-D-glucopyranoside not methyl 7-deoxy-β-L-glycero-D-gluco-heptopyranoside. For reasons of clarity and convenience, the so-called "reducing unit" of a disaccharide is termed the *a*-unit. The nonreducing unit is the *b*-unit. The 6a-epimers are given the same compound number but distinguished by their absolute configurations (*R* or *S*). The m, e and i letters that follow the number of a compound are to identify the alkyl substituent: methyl, ethyl or isopropyl, respectively. The rings of glucopyranosides are taken as residing in an essentially rigid $^4C_1$-conformation. The three flexible bonds that link the two glucose units at the 6a-position of an isomaltoside, namely, C-1b-O-6a, O-6a-C-6a and C-6a-C-5a, describe three torsion angles $\phi° =$ O-5b/C-6a, $\psi° =$ C-1b/C-5a, and $\omega° =$ O-6a/O-5a, respectively.



Introduction

The long known (1) industrially important enzyme, amyloglucosidase (EC 3.2.1.3), referred to herein as AMG, is an anomeric-centre inverting exoglycosidase that catalyzes the release of β-D-glucopyranose from the non-reducing end of starch and other related poly- and oligosaccharides (2, 3). AMG catalyzes the hydrolysis of the $1 \rightarrow 4$ linkage of maltose 30–50 times more rapidly than the $1 \rightarrow 6$ linkage of isomaltose. For both substrates three hydroxyl groups were found virtually indispensable, by means of chemical mapping (4, 5), for high enzyme activity. These essential hydroxyl groups circled in Fig. 1 for **1** are located at the 4a, 4b, and 6b positions for both the β- (5) and α- (6) methyl isomaltosides. For methyl β-maltoside these key hydroxyls are located at positions 3a, 4b, and 6b (4). As seen in Table 1, deoxygenation of the 4a-hydroxyl of methyl α-isomaltoside decreases the rate of hydrolysis by about a thousand-fold (6). It is conceivable that the enzyme recognizes the conformation of these substrates that have OH-4a of an isomaltoside (**1**) and OH-3a of a maltoside, which are in similar spatial relationship to the OH-4b and OH-6b of the nonreducing *b*-unit (5).

Chemical mapping (6) of the interaction of methyl α-isomaltoside with AMG proved to be in total agreement with both the kinetic data reported by Bock and co-workers (4, 5)

Fig. 1. The structure of methyl α-isomaltoside that displays the pro-*R* and pro-*S* hydrogen atoms at the *C*-6a position. Acarbose is a strong inhibitor ($\Delta G = -16.3$ kcal mol^{-1}) of the hydrolysis of **1** by the enzyme AMG.

and the X-ray crystal structure of the acarbose–AMG complex (7, 8). Substantially weaker interactions involve the hydroxyl groups at the 3a, 2b, and 3b positions (6). As expected from the X-ray crystal structure of the acarbose–AMG complex the OH-2a (see Table 1) and the aglycon at the 1a position remain in the aqueous phase. The fact that methyl (6a*R*)-*C*-methyl-α-isomaltoside (***R*-2m**) (9) is hydrolyzed 8 times faster than the *S*-epimer (***S*-2m**) suggests, as previously noted (9), that the *C*-methyl group of the *R*-isomer does not impede complex formation. Indeed, Frandsen et al. (10) found that the 6a-*C*-methyl group of ***R*-2m** projects into a surrounding aqueous phase to become hydrophobically associated to the enzyme. In the simulated complex of isomaltoside with AMG (6), it is the pro-*R* hydrogen that

	B	–45	167	163	1.56	7.3

[a]Conformers A are the preferred conformations established by GEGOP calculation. These were found to not be compatible with the combining site of the acarbose–AMG complex. Consequently, the values of the φ, ψ, and ω torsion angles were changed in order to achieve a fit. An acceptable fit could not be achieved keeping the *b*-unit in the chair-conformation. However, a fine fit was obtained on changing the conformation of the *b*-unit to the half-chair conformer. The Δ*E* values refer to the differences in energy that are expected to arise from relaxation of the φ, ψ, and ω torsion angles of the B conformers to those of the A conformers.

projects into the channel of water, which in supports the statement that only the *R*-isomers are good substrates (10). Furthermore, this data suggests that a substantial body of bulk water extends from near the 6a-CH_2 group on the side of the complex that includes the catalytic water molecule. It was on this basis that it had seemed likely that the (6a*R*)-*C*-methyl group of ***R*-2m** could be replaced by bulkier groups and still retain good substrate activity. To test this hypothesis, the ***R*-** and ***S*-2e** (6a-*C*-ethyl) and ***R*-** and ***S*-2i** (6a-*C*-isopropyl) analogs were synthesized and made available to Frandsen et al. (10) for kinetic studies.

We considered that should these compounds (***R*-2e** and ***R*-2i**) prove to be good substrates for AMG that it would also follow that all are accepted into the active site with similar φ, ψ, and ω torsion angles for the inter-unit bonds. It was also thought that the effect of the bulky alkyl groups on the rate of hydrolysis could provide insight to the structure of the transition state since the bulkier groups can be expected to better define the conformational requirements for the inter-unit *C*-5a to *C*-1b linkages.

Discussion

Theoretical discussion

GEGOP calculations (11) were used to estimate the preferred conformations for compounds **1**, ***R*-2m**, and ***R*-2i**. The results are presented in Table 2 as conformers A (see also Fig. 6) and are compared against reference compound methyl α-isomaltoside (**1**). It is seen that the different alkylating groups do not have a large effect on the orientation of the agluconic carbon (*C*-6a) (φ torsion angles range from –51° to –54°). The conformational preferences for the more rigid compounds (***R*-2m** and ***R*-2i**) appear to be similar but are significantly different as compared to the global minimum energy conformation of **1**. This inference is supported by the nuclear Overhauser enhancement (NOE) data presented in Table 3. As expected from the GEGOP calculations (Table 2), saturation of H-1b enhanced the signal for H-6a almost equally for the three 6a-alkylated compounds. The NOE data for the *S*-isomers are also recorded in Table 3, but the *S*-isomers are not further discussed because of their poor performance as substrates for AMG (10).

Prior to a consideration of conformers B, a brief review, for the more salient features of the mechanism for the hydrolysis of an α-D-glucopyranoside by AMG, is useful. An outline is presented in Fig. 2.

The mechanism (Fig. 2) has been established as an acid-base catalyzed reaction. The X-ray crystal structure of the acarbose–AMG complex (7, 8) displays a well situated "catalytic" water molecule for nucleophilic attack at the anomeric centre of the *b*-unit which results in the displacement of the *a*-unit (see Fig. 3). The nucleophilicity of this water molecule is enhanced by the involvement of both of its hydrogen atoms in hydrogen bonds with two oxygen atoms

(see Fig. 3), one with the carboxylate group of Glu 400 and the other with OH-6b. The OH-6b is also hydrogen bonded to the carboxylate of Asp 55 (7, 8). Experimental evidence in support of this type of delocalization of electron density in conjugated hydrogen bonds was established by Lemieux and Pavia (12) and now termed the "cooperativity effect" (13). These and other interactions expected to be present in the transition state were reviewed in a recent publication (6). The acid catalysis is promoted by proton donation from Glu 179 (Fig. 3), where the acidity of the carboxyl group of Glu 179 is expected to be enhanced by electron donation to a proton on Glu 124 (not shown in Fig. 3). It is to be noted (Table 1) that deoxygenation of OH-2b caused little change in the kinetic parameters. This suggestion that OH-2b is not involved in assisting the leaving of the *a*-unit must take into consideration that 2-deoxyglycosides are much more prone to hydrolysis when the 2-substituent is more electronegative, such as a hydroxyl group. Also, in the case of the 2b-deoxy compound, a water molecule may assist in relaying the electrophilicity of the Arg 305 to the 6a-oxygen atom (6). Certainly, a hydrogen bond between OH-2b and the leaving group can be expected to strengthen as the C-1b—O-6a bond is stretched to achieve the transition state.

The conformation of the valienamine moiety of acarbose (Fig. 1), as previously pointed out (6), provides an acceptable working model for the construction of the transition state where the C-5b, O-5b, C-1b, and C-2b atoms of the *b*-unit are coplanar and the oxygen of the catalytic water molecule, C-1b and the leaving O-6a atoms are colinear. Evidence in support of the structure of the transition state for inversions at anomeric centres was obtained in 1955 (14). The X-ray structure also can serve as a model for the structure of the complex displayed in Fig. 2. Although the mole fraction of the half-chair conformation for the *b*-unit of **1** is undoubtedly very small, its formation once **1** is complexed with AMG must be virtually spontaneous, especially since the active site conforms for the acceptance of acarbose. The B conformers listed in Table 2 are based on this consideration. Accordingly, it is expected that formation of the half-chair conformer will substantially weaken the *endo*- and *exo*-anomeric effects (15) and, thereby, render the anomeric centre more susceptible to nucleophilic attack.

As already mentioned, hydrogen bonding of OH-4a to Trp 178 (assisted by Arg 305) greatly enhances the rate of catalysis. Our attempts to establish these hydrogen bonds using both the *a*- and *b*-units in the $^4C_1$ chair conformation proved

© 2001 NRC Canada

unattractive. However, when the *b*-unit was placed in the half-chair conformation (see Table 2 and Figs. 3 and 6), the same hydrogen-bond networks presented in the acarbose–AMG complex (7, 8) are well established.

As seen in Table 2 the ϕ, ψ, and ω torsion angles for the *b*-unit are the same for each compound. However, large differences in conformational energy are indicated and, therefore, complex formation involving substrate ***R*-2m** should be slightly favored over complexation with **1** and much more than with substrate ***R*-2i**. As seen in Table 1, the kinetically determined K_m values are 20 (**1**), 0.7 (***R*-2m**), and 47 (***R*-2i**). The increase in complexation of AMG with ***R*-2m** as compared to AMG with **1** can be attributed to hydrophobic association of the 6a-C-methyl group with both Trp 120 and Trp 52, as shown in Fig. 4. This hydrophobic association is not present during formation of the **1**–AMG complex. Also, the conformational energy of ***R*-2m** in the complex is expected (Table 2) to be about 0.9 kcal mol^{-1} less than that for substrate **1**. These considerations support an increase in the rate of hydrolysis of ***R*-2m** (10). However, this is not the case for ***R*-2i**. As seen in Table 1, the equilibrium for complex formation (K_m) for ***R*-2i** is much less favorable than it is for ***R*-2m** (K_m = 0.71 for ***R*-2m** vs. 47 for ***R*-2i**). This difference is mainly due to the large conformational strain required to form the ***R*-2i**–AMG complex (Table 2). This resistance to complex formation is undoubtedly strongly moderated by important hydrophobic associations of the two methyl groups of the isopropyl group as is illustrated in Fig. 4*b*. Frandsen et al. (10) employed, in part, this synthetically imposed hydrophobic association in a study of site-specific mutagenic changes in the structure of AMG to conclude that "the versatility of AMG catalysis….emphasizes the significance of hydrophobic interactions in protein-carbohydrate complexation." We suggest that this is not necessarily the case with respect to the classical definition of the driving force for hydrophobic associations which involves the release of ordered water molecules to bulk. The strength of hydrophobic interactions was recently observed in the binding of *N*-acetyllactosamine by the lectin, *Erythrina corallodendron* (16). The X-ray crystal structure of the complex shows a strong association of the H-2, H-4, and H-5 on the α-side of the β-D-galactose unit with the appropriately positioned phenylalanine group. In this regard, although Monte Carlo simulations (17) for the hydration of the β-D-Gal unit of the Lewis b-OMe tetrasaccharide suggest that the formation of a shell of disordered perturbed water molecules extends over the hydrophobic α-side, some ordering of the water molecules cannot be discounted. In either event, the association of complementary surfaces should be energetically favorable in aqueous solution whether ordered or perturbed water molecules are released to bulk.

As seen in Table 2, the *b*-unit of the B conformers are highly strained. We suggest that the relaxation of this conformational strain energy provides the necessary assistance for the stretching of the C-1b—C-6a glycosidic bond and thereby promotes decomposition to the products. This structural feature is key for the catalysis of the hydrogen bonds of OH-4a to Trp 178 and Arg 305. Indeed, as previously noted (10), the k_{cat} values for **1**, ***R*-2m**, ***R*-2e**, and ***R*-2i** are remarkably similar.

Prior to a consideration of hydrophobic forces involved in the binding of **1** by AMG, it is of interest to examine the thermodynamics of the binding of the H-type 2-OMe trisaccharide by the lectin, *Ulex europaeus* (UE-1) (18, 19). The main driving force for binding is enthalpic, ΔH = –29 kcal mol^{-1}, which is countered by a large *decrease* in entropy, $T\Delta S$ = –20.5 kcal mol^{-1} (18). Inspection of the X-ray crystal structure for the UE-I–H-type 2-OMe complex reveals, as seen in Fig. 5, that two hydrophobic interactions are present: one involves Tyr 220 with the C-6 methylene group of the GlcNAc unit and the other involves valine 134 with the *C*-6 methyl group of the α-L-Fuc unit. These interactions, if truly hydrophobic in character, are obviously not compatible with the aforesaid thermodynamic parameters that show a decrease in entropy rather than an increase in entropy as expected for hydrophobic association. The proximity of these groups to the trisaccharide requires the displacement of water. Judging from the thoroughly polyamphiphilic surface (20) of the H-type 2-OMe molecule (19), perturbed water molecules must have been displaced, as in the case of Tyr 220. The interaction of Val 134 with the *C*-6-methyl group of the fucosyl group may result in an increase in entropy from the disordering of water molecules in an endothermic process. However, these contributions, if present, are strongly obscured by the large decreases in both enthalpy and entropy that are expected to arise mainly from the return of perturbed water molecules from both the combining site and the epitope of the trisaccharide to bulk (21, 22). This process has been termed the *hydraphobic* effect.

The binding of **1** with AMG is similar in that along with the establishment of numerous attractive polar interactions one hydrophobic group comes into close contact with disaccharide **1**. As seen in Fig. 4, the only nonpolar contact of less than 2.5 Å (omitting the interactions with the *R*-6a-methyl and *R*-6a-isopropyl groups) is between Trp 317 and H-2b. The presence of this large aromatic amino acid unit in the epitope is expected to contribute to the stability of the complex, since, along with the release of the ordered water molecules at its surface, it is also expected to participate in the release of perturbed water molecules from the polyamphiphilic surface of the substrate (**1**). This is clearly evident from the CPK molecular models displayed in Fig. 6.

The thermodynamic parameters for the hydrolysis of **1** catalyzed by AMG are not known. However, in view of the extensive polyamphiphilic surface of **1** and that of the complementary combining site, it is expected that complexation involves the release of a large number of perturbed water molecules (21). The decrease in enthalpy that is expected to result is amplified by the formation of nine intermolecular hydrogen bonds (see Fig. 3). In view of this large polar contribution and the paucity of hydrophobic interactions, the formation of the complex must result in a substantial (perhaps as great as 60 kcal mol^{-1}) decrease in enthalpy. As will be discussed below, the liberation of this heat is expected, as previously discussed (21), to participate in promoting the complex to the transition state (6) (see Fig. 2).

However, Sigurskjold et al. (23) have determined that the binding of the inhibitor acarbose by AMG is driven by both enthalpic (ΔH = –9.7 kcal mol^{-1}) and entropic ($T\Delta S$ = 6.6 kcal mol^{-1}) values. The increase in entropy is expected to arise from an important hydrophobic contribution. This is

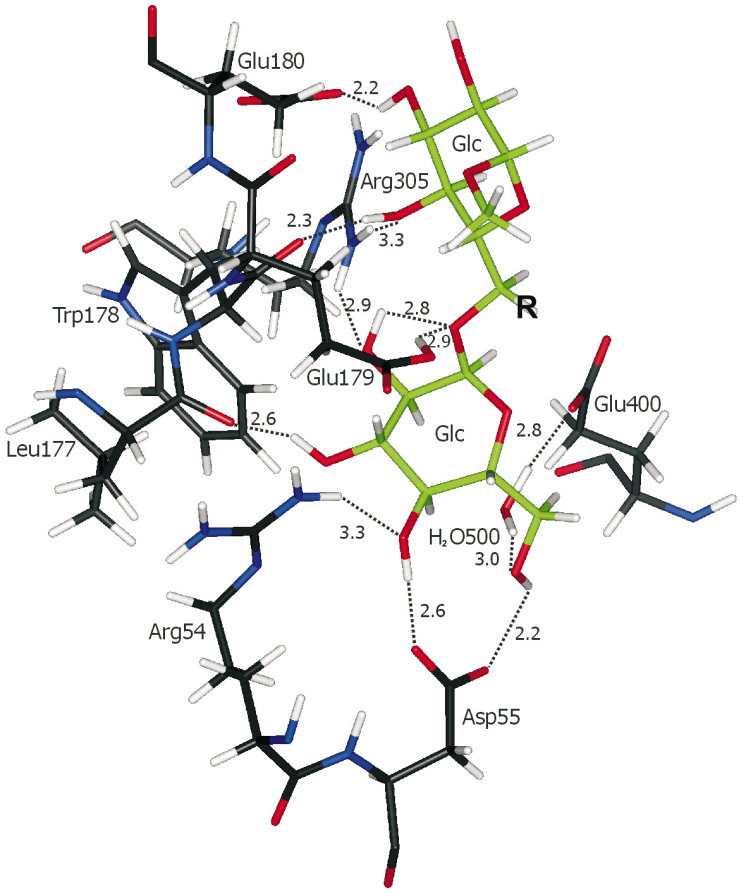
Fig. 3. A display of the intermolecular hydrogen bonds that are formed during the binding of **1** in the half-chair conformation and *C*-6a-alkyl derivatives (R = H, Me, Et, or *i*-Pr) into the site occupied by the *c*- and *d*-units of acarbose.



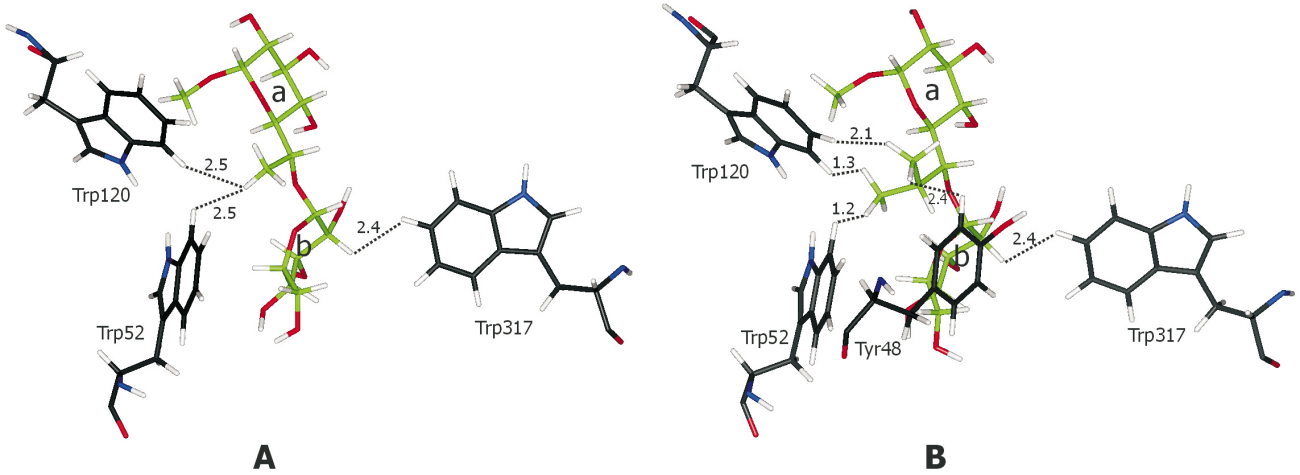


Fig. 4. Display of the near van der Waals' contacts of hydrophobic groups of AMG with nonpolar hydrogen atoms of 6a-alkyl derivatives of **1**. The hydrophobic associations of the methyl group of ***R*-2m** and the isopropyl group of ***R*-2i** are not present in the complex formed with **1**. Consequently, it appears that the only van der Waals contact with **1** involves a hydrogen of Trp 317 that is 2.4 Å away from *H*-2b.

not surprising since the terminal unit of the pseudo-tetrasaccharide (Fig. 1) is a derivative of cyclohexene, which along with the *C*-6a-methyl group of the neighboring 6-deoxy glucose the cyclohexene like unit offers a substantial hydrophobic surface to the aqueous phase (see Fig. 1). The ordered water molecules, along with disordered water molecules hydrogen bonded to the binding site, must be displaced during the binding process. Evidently, the increase in entropy caused by the hydrophobic component dominates the decrease in entropy expected from hydrophobic contributions.

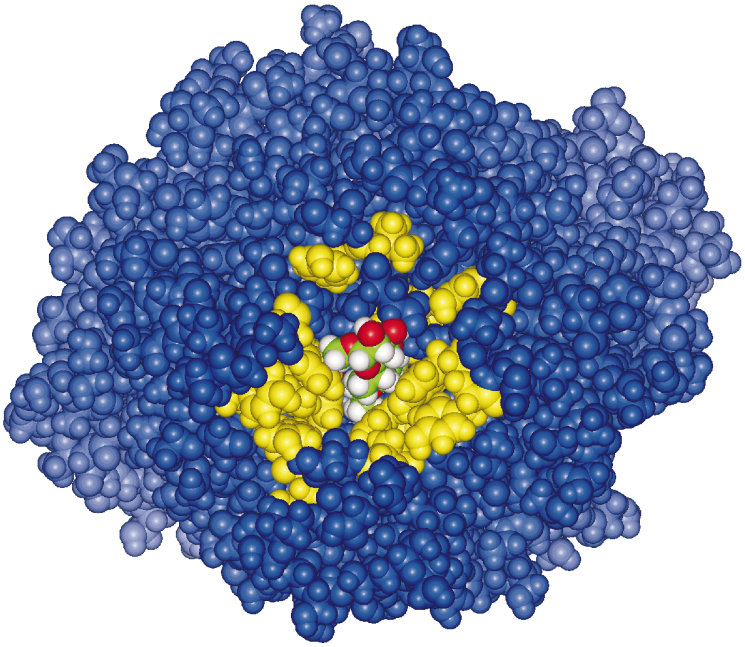
Fig. 7. This graphic is of AMG looking down to the combining site that is occupied by ***R*-2m** (white–hydrogens, green–carbons, and red–oxygen atoms). It is seen that a channel exists for water molecules to access the OH-3a region of the active site. The 6a-methyl group, which remains in the aqueous phase, is visible just below the methoxy group. The yellow atoms belong to aromatic side chains of amino acids that surround the active site, as shown in Fig. 8.



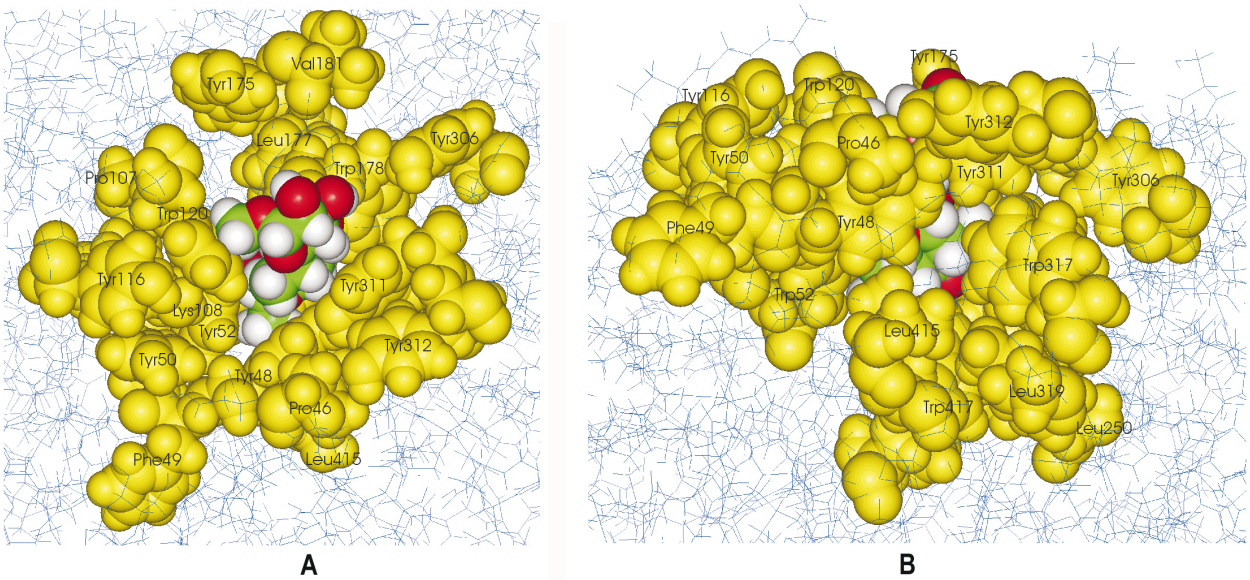


Fig. 8. The aromatic shield that protects the polar interactions (Fig. 2) in the complex from being disrupted by water: (*a*) is a close-up (amino acids are removed for clarity); (*b*) is a side view of the shield of largely nonpolar aromatic groups that is expected to provide thermal insulation of the heat of dehydration to assist achievement of the transition state. The slit in the shield through which a position of the substrate can be viewed does not exist but is occupied by other nonaromatic amino acid residues. The apparent close-packing is not real. However, their proximities are sufficient to provide effective protection of the polar interaction of the complex.

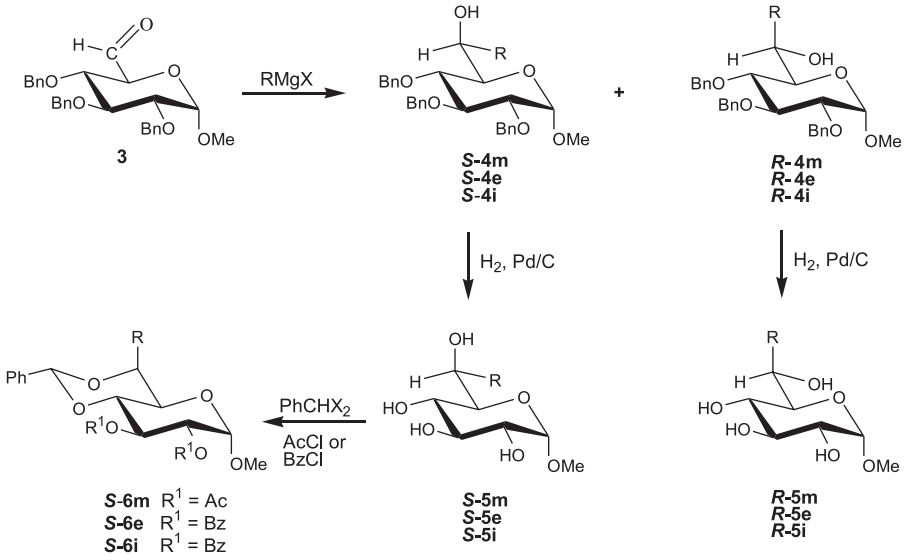

The heat liberated from the latter effect is large enough to cancel the endothermicity of the hydrophobic contribution by 9.7 kcal mol^{-1} and, consequently, the strong exothermicity of the binding of **1** by AMG is supported. Recall that this is the source of heat required to activate the complex to the transition state.

In 1990, Delbaere et al. (24) noted that for the Lewis b–*Griffonia simplicifolia* complex many of the amino acids, except for the diglycine bridge, near the periphery of the polar receptor site have aromatic side chains. These structural features were also observed for antibodies (25) and appear to be necessary for the combining site of all carbohydrate-binding

Scheme 1.

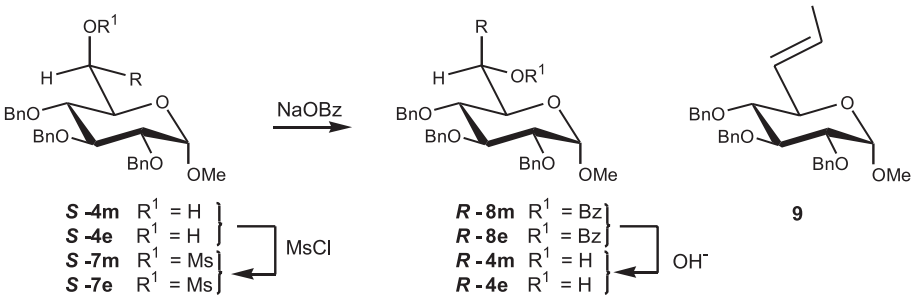
proteins. In general, carbohydrates are held in the cavity mainly by attractive polar interactions in the form of intermolecular hydrogen bonds. Hydrophobic associations are present and important, especially in the case of antibodies (25), but are of minor importance for the binding of oligosaccharides by many lectins. In this regard, the driving force for association is provided by a strong *decrease* in enthalpy and a slight *decrease* in entropy. Clearly, binding occurs in cavities in order to avoid disrupting the association of polar bonds with the bulk water. We suggest that the purpose of the largely aromatic coating surrounding of the polar complex is to provide a strong shield from the bulk water. Not surprisingly, therefore, the active site of the enzyme AMG that binds isomaltose is surrounded by amino acids that contain aromatic side chains (see Fig. 7). These large hydrophobic groups are expected to act as a shield and thus, at high concentrations, prevent water from seeping into the complex. It has been proposed that lower dielectric constants in the binding in a cavity favor the formation of the polar bonds. However, this stabilization of polar bonds must also apply to the water molecules that are displaced by the carbohydrate.

Finally, we propose that the shield of hydrophobic aromatic groups that surround the catalytic site of AMG (see Fig. 8) also serves as thermal insulation to lower the rate of the dissipation of the heat of complex formation (the hydraphobic effect) to bulk. This energy is expected to be the main source of activation for the **1**–AMG complex to the transition state (Fig. 2). This concept of heat being liberated from reacting molecules and being maintained in a suitable submicro-environment to eventually serve as the activation energy for another reaction may be a general feature of enzyme catalysis. This proposal is similar to the energy dissipation in enzyme catalysis proposed by Cramer and Freist (26).

Synthesis

The syntheses of the 6-*C*-alkyl glucosides **4m**, **4e**, and **4i** (Scheme 1) started from the known methyl 6-aldehydo-α-D-glucopyranoside (**3**) (27) that was prepared by oxidation of methyl 2,3,4-tri-*O*-benzyl-α-D-glucopyranoside (28). Molecule **3** was then reacted with the methyl, ethyl and isopropyl Grignard reagents in the usual fashion to yield mixtures of the *R*- and *S*-epimers, namely, the 6-*C*-methyl, 6-*C*-ethyl, and 6-*C*-isopropyl glucosides, (**4m**, **4e**, and **4i**). In agreement with Cram's rule (29), the *S*-isomers were produced in excess. The ratio of the *S*- to *R*-epimers was about 10:1 for **4m** and **4e** and 20:1 for **4i**.

In the case of the methyl Grignard, procedures to prepare ***R*,*S*-4m**, involved converting the crude product into a mixture of 6-*O*-(3,5-dinitrobenzoyl) esters from which the *S*-isomer crystallized and was purified by recrystallization. Zemplen methanolysis then provided the pure ***S*-4m**. The crude products obtained from the ethyl and isopropyl Grignard reagents could be separated by column chromatography into the pure *R*- and *S*-isomers. As will be described below (Schemes 2 and 3) larger amounts of the *R*-isomers, in each case, were obtained by inversion of the C-6 chiral centres of the *S*-compounds.



Both the *R*- and *S*-epimers of **4m**, **4e,** and **4i** were debenzylated by catalytic hydrogenolysis to obtain pure preparations of both the *R*- and *S*-*C*-6-epimers, **5m**, **5e**, and **5i (**Scheme 1).

For the configurational assignments, the *S*-isomers, (***S*-5m**, ***S*-5e**, and ***S*-5i**), were converted into the 4,6-*O*-benzylidene derivatives (***S*-6m**, ***S*-6e**, and ***S*-6i**) by reaction with α,α-dibromo- or α,α-dichlorotoluene in pyridine at elevated temperature followed by acylation. The absolute configuration of compound ***S*-6m** was unequivocally established by the NOE's obtained by saturation of the axial C-6 methyl group (see Table 4). The configurations of compounds ***S*-6e** and ***S*-6i** are assigned on the basis that the $J_{5,6}$ coupling constants (reported in Table 4). The coupling constant of 6.0 Hz is too small for coupling of antiperiplanar hydrogen atoms. Furthermore, the value of $J_{5,6}$ of ***S*-6m**, a compound of known configuration, is essentially the same as those for ***S*-6e** and ***S*-6i**, indicates that all three compounds are configurationally related. It is also relevant that these three *S*-compounds were the major products of the Grignard reactions and, therefore, are surely configurationally related.

For the preparation of larger amounts of ***R*-4m** and ***R*-4e** (Scheme 2), mesylated ***S*-7m** and ***S*-7e** were prepared and reacted with sodium benzoate in *N*,*N*-dimethylformamide at

$CH_{(1,2)}$	—	2.18, 1.79	2.62

[a]NOE experiments performed by irradiation of the CH_3-C6 doublet at 1.48 ppm caused enhancements of the *H*-6, *H*-4, and C*H*Ph signals by 6.2%, 2.9%, and 4.1%, respectively.

120°C followed by saponification of the products. Dehydromesylation of ***S*-7e** also resulted in compound **9**. Its *E*-configuration was assigned by the large $J_{5,6}$ coupling constant (14.5 Hz) (30).

The inversion of configuration at *C*-6 of ***S*-4i** (Scheme 3) to obtain ***R*-4i** was achieved by reduction of ketone **10** with sodium borohydride. Ketone **10** was prepared by oxidation of ***S*-4i** with dimethylsulfoxide and acetic anhydride (31). The crude product was mixture of ketone **10** and methylthiomethylene ether **11** (3:2). The borohydride reduction of **10** provided an epimeric mixture of ***R*-4i** and ***S*-4i** (5:1).

Preparation of the α-linked disaccharides ***R*-2m**, ***R*-2e**, and ***R*-2i** is outlined in Scheme 4. Bromide-ion catalyzed glycosylation conditions using 6-*O*-acetyl-2,3,4-tri-*O*-benzyl-α-D-glucopyranosyl bromide (**12**), tetraethylammonium bromide (32) and alcohol ***R*-4m** produced ***R*-14m**. Coupling of tetra-*O*-benzyl-α-D-glucopyranosyl bromide (**13**) with alcohols ***R*-4e** and ***R*-4i** was achieved in the presence of the cupric bromide–*N*,*N*-dimethylformamide complex (33). The protecting groups were removed in the usual manner to yield the desired compounds. The *C*-6a epimeric disaccharides ***S*-2m**, ***S*-2e**, and ***S*-2i** were prepared by similar procedures.

The ^{1}H NMR data for the disaccharides are presented in Table 5. The large ^{1}H coupling constants for $J_{2,3}$, $J_{3,4}$, and $J_{4,5}$ confirm the $^4C_1$-conformations of the pyranose rings. The $J_{5,6}$ coupling constants are ≤2.5 Hz. This suggests that a positive synclinal (+g) relationship exists between H-5a and H-6a, which is in agreement with the calculated ω angles for the two conformers A and B presented in Table 2.

Experimental

General methods

The ^{1}H NMR spectra were measured at 300 MHz and 360 MHz (Bruker AM 300 and WM 360) with tetramethylsilane as internal standard for $CDCl_3$ solutions. Reference standard for D_2O solutions was acetone (2.23 ppm). The ^{13}C NMR spectra were recorded at 75 MHz

[a]Spectra recorded in D_2O with acetone as internal reference set at 2.23 ppm at 360 MHz.

with dioxane (67.4 ppm) as reference for D_2O solutions and the $CDCl_3$ signal (77.0 ppm) as reference in $CDCl_3$ solutions. Optical rotations were measured at room temperature (23 ± 1°C) in a 1 dm cell on a Perkin–Elmer 241 polarimeter. Thin-layer chromatography was performed on precoated plates of silica gel (60-F254, E. Merck, Darmstadt) and visualized by spraying with 5% sulfuric acid in ethanol followed by heating. For column chromatography, silica gel 60 (230–400 mesh, E. Merck, Darmstadt) and distilled solvents were used. All solvents and reagents were purified and dried according to standard procedures. Melting points are uncorrected.

The molecular modeling was carried out on an SGI Indigo II. A suite of software from Molecular Simulations Inc., San Diego, was used to build and minimize the (6*R*)-*C*-alkylated glucopyranosyl units using AMBER forcefield. The coordinates of these (6*R*)-*C*-alkylated glucopyranosyl units were then exported to the GEGOP program[4] (11) for use in grid searchs, minimizations, and Monte-Carlo simulations.

Methyl 6-aldehydo-2,3,4-tri-*O*-benzyl-α-D-glucopyranoside (3)

Dried chromium trioxide (25.9 g, 259 mmol) was added to a solution of pyridine (40.9 g, 517 mmol) in dichloromethane (400 mL). The mixture was mechanically stirred at room temperature for 30 min. A solution of methyl 2,3,4-tri-*O*-benzyl-α-D-glucopyranoside (28) (10.0 g, 21.6 mmol) in dichloromethane (22 mL) was rapidly added and the resulting mixture stirred at room temperature for 10 min. The reaction mixture was then decanted and the black tarry precipitate was extracted with ether several times. The combined organic solutions were filtered through a pad of silica gel-G to provide a colorless slightly yellow oily residue which was co-evaporated with toluene (2 × 200 mL) to remove residual pyridine. The oily residue was dried under vacuum overnight before use to give crude **3** (6.94 g, 70%). The relative intensity of the singlet at 9.65 ppm (^{1}H NMR) attributed to H-6 indicated an about 90% content of **3**. $[\alpha]_D$ + 8.2° (*c* 1.0, chloroform), lit. (27) 13.6° (*c* 2.6, chloroform). IR (cm^{-1}): 1741 (CHO). ^{1}H NMR ($CDCl_3$) δ: 9.65 (s, 1H, *H*-6), 7.40–7.10 (m, 15H, 3*Ph*), 5.05–4.50 (m, 7H, 3CH_2Ph, *H*-1), 4.17 (d, $J_{4,5}$ = 10.0 Hz, 1H, *H*-5), 4.08 (dd, $J_{3,4}$ = 9.0 Hz, $J_{2,3}$ = 9.5 Hz, 1H, *H*-3), 3.57 (dd, $J_{3,4}$ = 9.0 Hz, $J_{4,5}$ = 10.0 Hz, 1H, *H*-4), 3.50 (dd, $J_{1,2}$ = 3.5 Hz, $J_{2,3}$ = 9.5 Hz, 1H, *H*-2), 3.38 (s, 3H, CH_3O).

Methyl 2,3,4-tri-*O*-benzyl-(6*S*)-*C*-methyl-α-D-glucopyranoside (*S*-4m)[5]

A solution of the crude aldehyde **3** (6.94 g, 15.0 mmol) in ether (30 mL) was added dropwise to a 0.6 N methylmagnsesium iodide solution in ether (50 mL, 30 mmol) and the reaction mixture was stirred at room temperature for 2 h. The reaction was quenched by the dropwise addition of aq sat. ammonium chloride. The mixture was diluted with water, extracted with ether and the organic solution was dried and evaporated to provide a yellow oil (5.96 g). The ^{1}H NMR spectrum was consistent with the presence of the desired compounds ***S*-4m** and ***R*-4m** in the ratio of about 10:1.

The crude mixture of ***S*-4m** and ***R*-4m** (0.59 g, 1.2 mmol) was reacted in pyridine (10 mL) with 3,5-dinitrobenzoyl chloride (0.51 g, 2.25 mmol) in the presence of a catalytic amount of 4-dimethylaminopyridine (few milligrams). The reaction mixture was stirred at room temperature until analysis by TLC indicated the reaction was completed. The usual work-up provided a yellow residue which crystallized spontaneously and was recrystallized from methanol. The compound characterized as the 6-*O*-(3,5-dinitrobenzoyl) derivative of ***S*-4m**, namely methyl 2,3,4-tri-*O*-benzyl-6-*O*-(3,5-dinitrobenzoyl)-(6S)-*C*-methyl-α-D-glucopyranoside, was obtained in 74% yield (0.612 g), mp 68–70°C. $[\alpha]_D$ + 52.2° (c 0.85, chloroform).

The 6-*O*-(3,5-dinitrobenzoyl) derivative of ***S*-4m** (1.00 g, 1.49 mmol) was dissolved in dioxane (50 mL) followed by the addition of 1 N sodium hydroxide solution (20 mL). After stirring for 1 h, the mixture was diluted with dichloromethane and filtered over a pad of silica gel-G, the organic solution was washed with water, dried and evaporated to give ***S*-4m** (0.69 mg, 97%) as a solid, mp 82–84°C. $[\alpha]_D$ + 26.9° (c 1.0, chloroform). ^{1}H NMR ($CDCl_3$) δ 7.40–7.20 (m, 15H, 3*Ph*), 5.01–4.63 (3ABq, 6H, 3CH_2Ph), 4.58 (d, $J_{1,2}$ = 3.5 Hz, 1H, *H*-1), 4.05 (dq, $J_{5,6}$ = 1.5 Hz, $J_{6,CH3}$ = 6.5 Hz, 1H, *H*-6), 3.99 (dd, $J_{3,4}$ = 9.0 Hz, $J_{2,3}$ = 9.5 Hz, 1H, *H*-3), 3.62 (dd, $J_{4,5}$ = 10.0 Hz, $J_{3,4}$ = 9.0 Hz, 1H, *H*-4), 3.50 (dd, $J_{2,3}$ = 9.5 Hz, $J_{1,2}$ = 3.5 Hz, 1H, *H*-2), 3.42 (dd, $J_{5,6}$ = 1.5 Hz, $J_{4,5}$ = 10.0 Hz, 1H, *H*-5), 3.34 (s, 3H, CH_3O), 1.25 (d, $J_{6,7}$ = 6.5 Hz, 3H, CH_3C-6). Anal. calcd. for $C_{29}H_{34}O_6$: C 72.78, H 7.16; found: C 72.94, H 6.82.

Methyl 2,3,4-tri-*O*-benzyl-(6*S*)-*C*-ethyl-α-D-glucopyranoside (*S*-4e) and -(6*R*)-C-ethyl-α-D-glucopyranoside (*R*- 4e*)*

A solution of crude methyl 6-aldehydo-2,3,4-tri-*O*-benzyl-α-D-glucopyranoside (**3**) (1.6 g, 3.46 mmol) in tetrahydrofuran (20 mL) was transferred slowly into a 0.5 N ethylmagnesium chloride solution in tetrahydrofuran (21 mL, 10.1 mmol) with stirring. After 1 h, the reaction was processed as described for ***S*-4m**. The crude material was applied to a column of silica gel (hexane–ethyl acetate, 5:1, 4:1) to provide in the main fraction the title compound ***S*-4e** (1.043 g, 61%) as a syrup. $[\alpha]_D$ + 12° (c 1.4, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.38–7.22 (m, 15H, 3*Ph*), 5.01–4.64 (3ABq, 6H, 3CH_2Ph), 4.56 (d, $J_{1,2}$ = 3.5 Hz, 1H, *H*-1), 3.99 (t, $J_{2,3} \sim J_{3,4}$ = 9.0 Hz, 1H, *H*-3), 3.70 (m, *H*-6), 3.66 (t, $J_{3,4} \sim J_{4,5}$ = 9.5 Hz, 1H, *H*-4), 3.53 (br d, $J_{5,6}$ < 1 Hz, 1H, *H*-5), 3.49 (dd, $J_{1,2}$ = 3.5 Hz, $J_{2,3}$ = 9.5 Hz, 1H, *H*-2), 3.35 (s, 3H, CH_3O), 1.67 (m, 1H, CH_2CH$_3$), 1.50 (m, 1H, CH_2CH$_3$), 0.95 (t, *J* = 7.5 Hz, 3H, CH_3CH$_2$). Anal. calcd. for $C_{30}H_{36}O_6$: C 73.15, H 7.37; found: C 73.26, H 7.32. Continued development of the column eluted epimer methyl 2,3,4-tri-*O*-benzyl-(6*R*)-*C*-ethyl-α-D-glucopyranoside (109 mg, 6.4%) as a crystallizing syrup. $[\alpha]_D$ + 35° (*c* 0.4, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.20 (m, 15H, 3*Ph*), 5.04–4.61 (3ABq, 6H, 3CH_2Ph), 4.55 (d, $J_{1,2}$ = 3.5 Hz, 1H, *H*-1), 4.02 (t, $J_{2,3} \sim J_{3,4}$ = 9.0 Hz, 1H, *H*-3), 3.70–3.63 (m, 1H, *H*-5, *H*-6), 3.50 (dd, $J_{1,2}$ = 3.5 Hz, $J_{2,3}$ = 9.5 Hz, 1H, *H*-2), 3.49 (t, $J_{3,4} \sim J_{4,5}$ = 9.0 Hz, 1H, *H*-4), 3.38 (s, 3H, CH_3O), 1.54 (m, 1H, CH_2CH$_3$), 1.42 (m, 1H, CH_2CH$_3$), 0.93 (t, *J* = 7.5 Hz, 3H, CH_3CH$_2$). Anal. calcd. for $C_{30}H_{36}O_6$: C 73.15, H 7.37; found: C 72.47, H 7.47.

Methyl 2,3,4-tri-*O*-benzyl-(6*S*)-*C*-isopropyl-α-D-glucopyranoside (*S*-4i) and -(6*R*)-*C*-isopropyl-α-D-glucopyranoside (*R*-4i*)*

Crude aldehyde **3** (2.47 g, 5.34 mmol) in tetrahydrofuran (30 mL) was reacted with isopropylmagnesium chloride as described for the preparation of ***S*-4e** The crude reaction product was purified on a column of silica gel (hexane–ethyl acetate, 5:1 → 3:1) to provide in the first fraction the minor epimer ***R*-4i** (73.8 mg, 2.7%) as a slowly crystallizing syrup. $[\alpha]_D$ + 26.4° (*c* 0.4, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.23 (m, 15H, 3*Ph*), 5.06–4.62 (3ABq, 6H, 3CH_2Ph), 4.53 (d, $J_{1,2}$ = 3.5 Hz, 1H, *H*-1), 4.03 (t, $J_{2,3} \sim J_{3,4}$ = 9.5 Hz, 1H, *H*-3), 3.69 (dd, $J_{4,5}$ = 9.5 Hz, $J_{5,6}$ = 6.0 Hz, 1H, H-5), 3.60 (t, $J_{3,4} \sim J_{4,5}$ = 9.0 Hz, 1H, *H*-4), 3.53 (dd, $J_{6,CH}$ = 4.0 Hz, $J_{5,6}$ = 6.0 Hz, 1H, *H*-6), 3.50 (dd, $J_{1,2}$ = 3.6 Hz, $J_{2,3}$ = 9.5 Hz, 1H, *H*-2), 3.40 (s, 3H, CH_3O), 1.96 (m, 1H, C*H*(CH$_3$)$_2$), 0.95 (d, *J* = 7.0 Hz, 3H, CH(CH_3)$_2$), 0.89 (d, *J* = 7.0 Hz, 3H, CH(CH_3)$_2$). General procedure for the catalytic hydrogenolysis of *O*-benzyl derivatives

A mixture of the benzyl derivative (200 mg, 0.2–0.4 mmol) and 5% palladium-on-carbon (200 mg) in methanol (10–15 mL) was hydrogenated in the hydrogen stream until completion (TLC). The catalyst was removed by filtration and the solvent evaporated. The resultant material was applied to a column of Iatrobeads® (chloroform-methanol-water) followed by gel filtration on a column of Sephadex LH 20 (50% ethanol) to provide the deprotected material.

*Methyl (6*S*)*-C-*methyl*-α-D-*glucopyranoside (***S*-5m**)

Compound ***S*-5m** was prepared from ***S*-4m** in quantitative yield by catalytic hydrogenolysis following the general procedure. The solid material could be recrystallized from 98% ethanol/hexane to give needle like crystals; mp 136–137°C; $[\alpha]_D$ + 150° (*c* 0.2, water). ^{1}H NMR (D_2O) δ: 4.80 (d, $J_{1,2}$ = 3.5 Hz, 1H, *H*-1), 4.16 (dq, $J_{5,6}$ = 1.5 Hz, $J_{6,CH3}$ = 6.5 Hz, 1H, *H*-6), 3.62 (dd, $J_{2,3}$ = 10.0 Hz, $J_{3,4}$ = 9.0 Hz, 1H, *H*-3), 3.55 (dd, $J_{1,2}$ = 3.5 Hz, $J_{2,3}$ = 10.0 Hz, 1H, *H*-2), 3.46 (dd, $J_{4,5}$ = 10.0 Hz, $J_{3,4}$ = 9.0 Hz, 1H, *H*-4), 3.39 (s, 3H, CH_3O), 3.38 (dd, $J_{4,5}$ = 10.0 Hz, $J_{5,6}$ = 1.5 Hz, 1H, *H*-5), 1.29 (d, *J* = 6.5 Hz, 3H, CH_3C-6). ^{13}C NMR (D_2O) δ: 100.24 (C-1), 74.49, 74.41, 72.31, 70.74, 65.26, 55.89 (CH_3O), 19.72 (*C*H_3C-6). Anal. calcd. for $C_8H_{16}O_6$: C 46.15, H 7.75; found: C 46.04, H 7.46.

*Methyl (6*S*)*-C-*ethyl*-α-D-*glucopyranoside (***S*-5e**)

Compound ***S*-5e** was prepared from ***S*-4e** by catalytic hydrogenolysis following the general procedure and obtained as a white solid (89%) after lyophilization of the aq solution. $[\alpha]_D$ + 150° (*c* 0.2, water). ^{1}H NMR (D_2O) δ: 4.80 (d, $J_{1,2}$ = 3.5 Hz, 1H, *H*-1), 3.85 (m, 1H, *H*-6), 3.64 (dd, $J_{2,3}$ = 9.5 Hz, $J_{3,4}$ = 9.0 Hz, 1H, *H*-3), 3.55 (dd, $J_{1,2}$ = 3.5 Hz, $J_{2,3}$ = 9.5 Hz, 1H, *H*-2), 3.53 – 3.50 (m, 2H, *H*-4, *H*-5), 3.41 (s, 3H, CH_3O), 1.64 (m, 2H, CH_2CH$_3$), 0.95 (t, *J* = 7.5 Hz, 3H, CH_3CH$_2$); ^{13}C NMR (D_2O) δ: 100.17 (C-1), 74.27, 72.60, 72.06, 70.47, 70.30, 55.87 (CH_3O), 26.70 (CH_3CH_2), 10.67 (*C*H_3CH$_2$).

*Methyl (*6S*)*-C-*isopropyl*-α-D-*glucopyranoside (***S*-5i**)

Compound ***S*-5i** was prepared from ***S*-4i** by catalytic hydrogenolysis following the general procedure and obtained as a white solid (95%) after lyophilization of its aq solution. $[\alpha]_D$ + 150° (*c* 0.3, water). ^{1}H NMR (D_2O) δ: 4.79 (d, $J_{1,2}$ = 3.5 Hz, 1H, *H*-1), 3.70 (dd, $J_{4,5}$ = 9.5 Hz, $J_{5,6}$ < 1 Hz, 1H, *H*-5), 3.64 (dd, $J_{3,4}$ = 8.5 Hz, $J_{2,3}$ = 9.5 Hz, 1H, *H*-3), 3.56 (dd, $J_{3,4}$ = 8.5 Hz, $J_{4,5}$ = 9.5 Hz, 1H, *H*-4), 3.54 (dd, $J_{1,2}$ = 3.5 Hz, $J_{2,3}$ = 9.5 Hz, 1H, *H*-2), 3.47 (dd, $J_{6,CH}$ = 9.5 Hz, $J_{5,6}$ < 1 Hz, 1H, *H*-6), 3.44 (s, 3H, CH_3O), 1.92 (m, 1H, CH(CH_3)$_2$), 1.01 (d, *J* = 6.5 Hz, 3H, CH(CH_3)$_2$), 0.91 (d, *J* = 6.5 Hz, 3H, CH(CH_3)$_2$). ^{13}C NMR (D_2O) δ: 100.48 (C-1), 74.36, 74.14, 71.99, 71.13, 70.39, 56.50 (CH_3O), 30.61 (*C*H(CH_3)$_2$), 19.84, 19.32 (*C*H_3)$_2$CH).

*Methyl (*6R*)*-C-*methyl*-α-D-*glucopyranoside (***R*-5m**)

Compound ***R*-5m** was prepared from ***R*-4m** in quantitative yield by catalytic hydrogenolysis following the general procedure; mp 135–136°C. $[\alpha]_D$ + 148° (*c* 1.0, water). ^{1}H NMR (D_2O) δ: 4.82 (d, $J_{1,2}$ = 4.0 Hz, 1H, *H*-1), 4.20 (dq, $J_{5,6}$ = 2.5 Hz, $J_{6,CH3}$ = 6.0 Hz, 1H, *H*-6), 3.71 (dd, $J_{4,5}$ = 10.0 Hz, $J_{5,6}$ = 2.5 Hz, 1H, *H*-5), 3.68 (dd, $J_{3,4}$ = 9.0 Hz, $J_{2,3}$ = 10.0 Hz, 1H, *H*-3), 3.58 (dd, $J_{1,2}$ = 4.0 Hz, $J_{2,3}$ = 10.0 Hz, 1H, *H*-2), 3.44 (s, 3H, CH_3O), 3.38 (dd, $J_{3,4}$ = 9.0 Hz, $J_{4,5}$ = 10.0 Hz, 1H, *H*-4), 1.25 (d, *J* = 6.5 Hz, 3H, CH_3C-6). ^{13}C NMR (D_2O) δ: 100.02 (C-1), 74.17, 74,12, 72.07, 71.73, 67.14, 55.76 (*C*H_3O), 15.85 (*C*H_3C-6). Anal. calcd. for $C_8H_{16}O_6$: C 46.15, H 7.75; found: C 45.99, H 7.50.

*Methyl (*6R*)*-C-*ethyl*-α-D-*glucopyranoside (***R*-5e**)

Compound ***R*-5e** was prepared from ***R*-4e** by catalytic hydrogenolysis following the general procedure and obtained as a foam after freeze-drying its aqueous solution (87%). $[\alpha]_D$ + 152° (*c* 0.4, water). ^{1}H NMR (D_2O) δ: 4.78 (d, $J_{1,2}$ = 3.5 Hz, 1H, *H*-1), 3.78 (m, 1H, *H*-6), 3.69 (dd, $J_{4,5}$ = 10.0 Hz, $J_{5,6}$ = 1.5 Hz, 1H, *H*-5), 3.64 (dd, $J_{3,4}$ = 8.5 Hz, $J_{2,3}$ = 9.5 Hz, 1H, *H*-3), 3.54 (dd, $J_{1,2}$ = 3.5 Hz, $J_{2,3}$ = 9.5 Hz, 1H, *H*-2), 3.43 (dd, $J_{3,4}$ = 8.5 Hz, $J_{4,5}$ = 10.0 Hz, 1H, *H*-4), 3.41 (s, 3H, CH_3O), 1.64 (m, 1H, CH_2CH$_3$), 1.53 (m, 1H, CH_2CH$_3$), 0.98 (t, *J* = 7.5 Hz, 3H, CH_3CH$_2$). ^{13}C NMR (D_2O) δ: 100.00 (C-1), 74.26, 74.05, 73.39, 72.01, 71.55, 55.78 (*C*H_3O), 23.94 (*C*H_2CH$_3$), 10.84 (*C*H_3CH$_2$).

*Methyl (*6R*)*-C-*isopropyl*-α-D-*glucopyranoside (***R*-5i**)

Compound ***R*-5i** was prepared from ***R*-4i** by catalytic hydrogenolysis following the general procedure and obtained as a white solid (85%) after lyophilization of its aqueous solution. $[\alpha]_D$ + 123.4° (*c* 0.2, water). ^{1}H NMR (D_2O) δ: 4.78 (d, $J_{1,2}$ = 3.5 Hz, 1H, *H*-1), 3.74 (dd, $J_{4,5}$ = 9.5 Hz, $J_{5,6}$ = 4.0 Hz, 1H, *H*-5), 3.67 (dd, $J_{3,4}$ = 9.0 Hz, $J_{2,3}$ = 9.5 Hz, 1H, *H*-3), 3.58 (dd, $J_{3,4}$ = 9.0 Hz, $J_{4,5}$ = 9.5 Hz, 1H, *H*-4), 3.57 (dd, $J_{6,CH} \sim$ 6.5 Hz, *J* = 40 Hz, 1H, *H*-6), 3.54 (dd, $J_{1,2}$ = 3.5 Hz,$J_{2,3}$ = 9.5 Hz, 1H, *H*-2), 3.42 (s, 3H, CH_3O), 2.04 (m, 1H, CH(CH_3)$_2$), 0.96 (d, *J* = 6.5 Hz, 3H, CH(CH_3)$_2$), 0.95 (d, *J* = 6.5 Hz, 3H, CH(CH_3)$_2$). ^{13}C NMR (D_2O) δ: 100.10 (C-1), 78.63, 74.16, 72.33, 71.86, 71.49, 56.12 (*C*H_3O), 30.11 (*C*H(CH_3)$_2$), 20.09, 17.96 ((*C*H_3)$_2$CH).

Methyl 2,3-di-*O*-acetyl-4,6-*O*-benzylidene-(6*S*)-*C*-methyl-α-D-glucopyranoside (*S*-6m)

A stirred solution of ***S*-5m** (16 mg, 0.053 mmol) and α,α-dibromotoluene (112 mg, 0.45 mmol) in pyridine (15 mL) was heated at reflux for 2 h. The mixture was cooled and then acetic anhydride (3 mL) was added. After 48 h at room temperature, the mixture was poured into ice water followed by extraction with chloroform, washing and drying of the organic solution and evaporation. The resultant product was purified by thin layer chromatography on silica gel (hexane–ethyl acetate, 3:2) to give ***S*-6m** (15 mg, 51%) as a solid, mp 132–134°C. $[\alpha]_D$ + 50.2° (*c* 0.3, chloroform). The ^{1}H NMR

© 2001 NRC Canada

data are reported in Table 4. ^{13}C NMR ($CDCl_3$) δ: 170.48, 169.76 (2CO), 137.40, 128.92, 128.22, 126.24 (Ph), 97.59 (C-1), 94.07 (*C*HPh), 72.74, 71.50, 70.49, 69.66 (C-2, C-3, C-4, C-5), 64.45 (C-6), 55.34 (CH_3O), 20.79, 20.65 ($2CH_3CO$), 11.28 (CH_3C-6). Anal. calcd. for $C_{19}H_{24}O_8$: C 59.99, H 6.36; found: C 59.55, H 6.06.

Methyl 2,3-di-*O*-benzoy-4,6-*O*-benzylidene-(6*S*)-*C*-ethyl-α-D-glucopyranoside (*S*-6e)

A solution of ***S*-5e** (49 mg, 0.22 mmol) and α,α-dichlorotoluene (100 μL, 0.78 mmol) in pyridine (7 mL) was heated at reflux for 4 h. Then more reagent (75 μL, 0.58 mmol) was added and heating was continued for 4.5 h. The mixture was cooled to ice bath temperature and benzoyl chloride (100 μL, 0.86 mmol) was added. After 2 h at this temperature, the mixture was poured into ice water, extracted with dichloromethane, followed by washing of the organic solution with water, drying and evaporation. The resultant material was purified on a column of silica gel (hexane-ethyl acetate, 9:1, 0.05% triethylamine) to provide labile, solid ***S*-6e** (56 mg, 49%) which was not analytically pure and was only characterized by ^{1}H NMR spectroscopy. The ^{1}H NMR data are reported in Table 5.

Methyl 2,3-di-*O*-benzoyl-4,6-*O*-benzylidene-(6*S*)-*C*-isopropylidene-α-D-glucopyranoside (*S*-6i)

***S*-5i** (37 mg, 0.16 mmol) was converted into ***S*-6i (**41 mg, 49%) as described for the preparation of ***S*-6e.** Labile ***S*-6i** contained a minor component (13%) that could not be removed. The ^{1}H NMR data are reported in Table 4.

Methyl 2,3,4-tri-*O*-benzyl-6-*O*-methanesulfonyl-(6*S*)-*C*-methyl-α-D-glucopyranoside (*S*-7m*)*

To a solution of ***S*-4m** (135 mg, 0.28 mmol) in pyridine (5 mL) at 0°C was added methanesulfonyl chloride (87 mg, 0.76 mmol). After 2 h at room temperature, the mixture was poured into ice-water, extracted with dichloromethane and the organic solution washed with saturated aqueous sodium bicarbonate and water, followed by drying and evaporation. Purification of the resultant material on a column of silica gel (toluene–acetone, 6:1) provided mesylate ***S*-7m** (104 mg, 66%) as a syrup. $[\alpha]_D$ + 9.3° (*c* 1.2, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.25 (m, 15H, 3*Ph*), 5.32 (dq, J_{6,CH_3} = 6.5 Hz, $J_{6,5}$ = 1.0 Hz, 1H, *H*-6), 5.06–4.62 (m, 7H, $3CH_2$Ph, *H*-1), 4.02 (m, 1H, *H*-5), 3.65–3.53 (m, 3H, *H*-3, *H*-4, *H*-2), 3.36 (s, 3H, CH_3O), 3.04 (s, 3H, CH_3SO_2), 1.53 (d, *J* = XX Hz, 3H, CH_3C-6). ^{13}C NMR ($CDCl_3$) δ: 138.54–127.74 (Ph), 98.26 (C-1), 82.30, 79.71, 77.17, 73.55, 72.38 (C-2, C-3, C-4, C-5, C-6), 75.74, 75.31, 75.00 ($3CH_2$Ph), 55.33 (CH_3O), 39.54 (CH_3SO_2-), 17.73 (CH_3C-6). Anal. calcd. for $C_{30}H_{36}O_8S$: C 64.73, H 6.52, S 5.76; found: C 64.85, H 6.55, S 5.52.

Methyl 2,3,4-tri-*O*-benzyl-(6*S*)-*C*-ethyl-6-*O*-methanesulfonyl-α-D-glucopyranoside (*S*-7e)

***S*-4e** (419 mg, 0.85 mmol) was reacted with methanesulfonyl chloride (100 μL, 1.29 mmol) as described for the preparation of ***S*-7m**. Purification of the resultant material on a column of silica gel (toluene–ethyl acetate, 10:1) provided mesylate ***S*-7e** (439 mg, 90%) as a syrup. $[\alpha]_D$ – 15.2° (*c* 0.4, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.20 (m, 15H, 3*Ph*), 5.12 (br t, J_{6,CH_2} = 7.5 Hz, 1H, *H*-6), 5.06–4.63 (3ABq, 6H, $3CH_2$Ph), 4.62 (d, $J_{1,2}$ = 3.5 Hz, 1H, *H*-1), 4.02 (t, $J_{2,3} \sim J_{3,4}$ = 9.5 Hz, 1H, *H*-3), 3.76 (br d, $J_{4,5}$ = 9.5 Hz, 1H, *H*-5), 3.64 (t, $J_{3,4} \sim J_{4,5}$ = 9.5 Hz, 1H, *H*-4), 3.55 (dd, $J_{1,2}$ = 3.5 Hz, $J_{2,3}$ = 9.5 Hz, 1H, *H*-2), 3.38 (s, 3H, CH_3O), 3.07 (s, 3H, CH_3SO_2), 1.94 (m, 2H, CH_2CH_3), 0.99 (t, *J* = 7.5 Hz, 3H, CH_3CH_2). Anal. calcd. for $C_{31}H_{38}O_8S$: C 65.24, H 6.71; found: C 64.86, H 7.03.

Methyl 2,3,4-tri-*O*-benzyl-(6*R*)-*C*-methyl-α-D-glucopyranoside (*R*-4m)

A stirring mixture of mesylate ***S*-7m** (600 mg, 1.08 mmol) and sodium benzoate (1.0 g, 7.0 mmol) in *N*,*N*-dimethylformamide (20 mL) was heated at 120° for 17 h. It was diluted with dichloromethane, filtered and the solution washed with water, dried and evaporated. The resultant material was purified by HPLC (hexane–acetone, 10:1) to give methyl 6-*O*-benzoyl-2,3,4-tri-*O*-benzyl-(6*R*)-*C*-methyl-α-D-glucopyranoside (***R*-8m**) (294 mg, 47%) as a syrup. $[\alpha]_D$ + 9.8° (*c* 1.04, chloroform). ^{1}H NMR ($CDCl_3$) δ: 8.40–7.20 (m, 20H, 3*Ph*, *Bz*), 5.47 (dq, $J_{5,6}$ = 2.0 Hz, J_{6,CH_3} = 7.0 Hz, 1H, *H*-6), 5.03–4.65 (m, 6H, $3CH_2$Ph), 4.64 (d, $J_{1,2}$ = 4.0 Hz, 1H, *H*-1), 4.04 (dd, $J_{2,3}$ = 9.5 Hz, $J_{3,4}$ = 9.0 Hz, 1H, *H*-3), 3.93 (dd, $J_{4,5}$ = 10.0 Hz, $J_{5,6}$ = 2.0 Hz, 1H, *H*-5), 3.52 (dd, $J_{1,2}$ = 4.0 Hz, $J_{2,3}$ = 9.5 Hz, 1H, *H*-2), 3.42 (dd, $J_{3,4}$ = 9.0 Hz, $J_{4,5}$ = 10.0 Hz, 1H, *H*-4), 3.38 (s, 3H, CH_3O), 1.18 (d, *J* = 7.0 Hz, 3H, CH_3C-6). Anal. calcd. for $C_{36}H_{38}O_7$: C 74.20, H 6.57; found: C 74.33, H 6.55.

Benzoate ***R*-8m** (137 mg, 0.24 mmol) was dissolved in dioxane (10 mL) and 1 N sodium hydroxide solution (6 mL) was added. After stirring for 48 h at 60°C, the mixture was diluted with dichloromethane and filtered over a pad of silica gel-G. The dichloromethane solution was washed with water, dried and evaporated to give solidifying ***R*-4m** (80 mg, 71%), mp 89–90°C. $[\alpha]_D$ + 28° (*c* 0.4, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.34–7.16 (m, 15H, 3*Ph*), 4.98–4.53 (m, 6H, $3CH_2$Ph), 4.50 (d, $J_{1,2}$ = 3.5 Hz, 1H, *H*-1), 3.95 (dd, $J_{2,3}$ = 9.5 Hz, $J_{3,4}$ = 9.0 Hz, 1H, *H*-3), 3.88 (m, 1H, *H*-6), 3.55 (dd, $J_{4,5}$ = 10.0 Hz, $J_{5,6}$ = 4.5 Hz, 1H, *H*-5), 3.43 (dd, $J_{1,2}$ = 3.5 Hz, $J_{2,3}$ = 9.5 Hz, 1H, *H*-2), 3.35 (dd, $J_{3,4}$ = 9.0 Hz, $J_{4,5}$ = 10.0 Hz, 1H, *H*-4), 3.31 (s, 3H, CH_3O), 2.49 (d, $J_{6,OH}$ = 6.0 Hz, 1H, OH), 1.05 (d, J_{6,CH_3} = 6.5 Hz, 3H, CH_3C-6). Anal. calcd. for $C_{29}H_{34}O_6$: C 72.78, H 7.16; found: C 72.81, H 7.07.

Methyl 2,3,4-tri-*O*-benzyl-(6*R*)-*C*-ethyl-α-D-glucopyranoside (*R*-4e)

A stirring mixture of mesylate ***S*-7e** (430 mg, 0.75 mmol) and sodium benzoate (600 mg, 4.16 mmol) in *N*,*N*-dimethylformamide (20 mL) was heated at 120° for 20 h. The solution was diluted with dichloromethane, filtered and the solution washed with water, dried and evaporated. The resultant material (methyl 6-*O*-benzoyl-2,3,4-tri-*O*-benzyl-(6*R*)-*C*-ethyl-α-D-glucopyranoside (***R*-8e**)) and potassium hydroxide (2.5 g) in 90% ethanol (50 mL) was kept at reflux for 3 h. The mixture was neutralized with acetic acid, evaporated, and the remainder taken up in dichloromethane. Washing of the solution with water, drying and evaporation was followed by column chromatography of the crude product on a column of silica gel (hexane–ethyl acetate, 4:1 → 3:1). Evaporation of the first fraction provided (*E*)-methyl

2,3,4-tri-*O*-benzyl-6,7,8-trideoxy-α-D-gluco-oct-6-enopyranoside (**9**) (105 mg, 22%) as a crystallizing syrup. $[\alpha]_D$ + 1.8°, $[\alpha]_{365}$ –33.4° (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.20 (m, 15H, 3*Ph*), 5.85 (m, 1H, *H*-7), 5.42 (ddd, $J_{6,5}$ = 7.5 Hz, J_{6,CH_3} = 1.5 Hz, $J_{6,7}$ = 14.5 Hz, 1H, *H*-6), 4.98–4.59 (3ABq, 6H, 3CH_2Ph), 4.56 (d, $J_{1,2}$ = 3.5 Hz, 1H, *H*-1), 4.01 (m, 1H, *H*-5), 3.96 (t, $J_{2,3} \sim J_{3,4}$ = 9.5 Hz, 1H, *H*-3), 3.51 (dd, $J_{1,2}$ = 3.5 Hz, $J_{2,3}$ = 9.5 Hz, 1H, *H*-2), 3.37 (s, 3H, CH_3O), 3.23 (t, $J_{3,4} \sim J_{4,5}$ = 9.5 Hz, 1H, *H*-4), 1.73 (m, 3H, CH_3CH=CH). Anal. calcd. for $C_{30}H_{34}O_5$: C 75.92, H 7.22; found: C 76.05, H 7.31. Continued development eluted ***R*-4e** (159 mg, 43%), identical to the minor Grignard product of aldehyde **3**.

Methyl 2,3,4-tri-*O*-benzyl-7,8-dideoxy-7-*C*-methyl-α-D-gluco-octopyranos-6-uloside (10)

A solution of ***S*-4i** (100 mg, 0.20 mmol) in dimethylsulfoxide (1.5 mL) and acetic anhydride (0.75 mL) was kept at room temperature for 15 h. The solution was evaporated and the residue was taken up in dichloromethane, washed with water, and evaporated to dryness. The ^{1}H NMR spectrum indicated a product mixture of ketone **10** and ether **11** in the ratio 1.6:1. Column chromatography on silica gel (toluene–ethyl acetate, 49:1) provided pure ketone **10** (55 mg, 55%) as an oil. However, a crude product mixture was used for the subsequent reduction because of the difficult separation. $[\alpha]_D$ + 6.4° (*c* 0.6, chloroform). IR ($CHCl_3$) cm^{-1}: 1730 (CO). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.15 (m, 15H, 3*Ph*), 5.00–4.50 (3ABq, 6H, 3CH_2Ph), 4.58 (d, $J_{1,2}$ = 3.5 Hz, 1H, *H*-1), 4.35 (d, $J_{4,5}$ = 9.5 Hz, 1H, *H*-5), 4.02 (t, $J_{3,4} \sim J_{2,3}$ = 9.5 Hz, 1H, *H*-3), 3.72 (t, $J_{3,4} \sim J_{4,5}$ = 9.5 Hz, 1H, *H*-4), 3.54 (dd, $J_{1,2}$ = 3.5 Hz, $J_{2,3}$ = 9.5 Hz, 1H, *H*-2), 3.42 (s, 3H, CH_3O), 2.85 (m, 1H, CH(CH_3)$_2$), 1.12 (d, *J* = 6.5 Hz, 3H, CH(CH_3)$_2$), 1.07 (d, *J* = 6.5 Hz, 3H, CH(CH_3)$_2$). Anal. calcd. for $C_{31}H_{36}O_6$: C 73.79, H 7.19; found: C 73.45, H 7.11.

Methyl 2,3,4-tri-*O*-benzyl-(6*R*)-*C*-isopropyl-α-D-glucopyranoside (*R*-4i)

To a solution of crude ketone **10** (0.40 mmol) in methanol (10 mL) was added, with stirring, sodium borohydride (65 mg, 1.72 mmol) at ice bath temperatures. After 30 min, the solution was evaporated, and the residue was taken up in dichloromethane, washed with water, dried, and evaporated. The product mixture was applied to a column of silica gel (hexane–ethyl acetate, 6:1 → 5:1 → 4:1) to provide in the first fraction methyl 2,3,4-tri-*O*-benzyl-(6*S*)-*C*-isopropyl-6-*O*-methylthiomethylene-α-D-glucopyranoside (**11**) (63 mg, 28%). $[\alpha]_D$ + 30° (*c* 0.8, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.20 (m, 15H, 3*Ph*), 5.06–4.58 (m, 8H, CH_2S, 3CH_2Ph), 4.65 (d, $J_{1,2}$ = 3.5 Hz, 1H, *H*-1), 4.02 (dd, $J_{2,3}$ = 9.5 Hz, $J_{3,4}$ = 9.0 Hz, 1H, *H*-3), 3.83 (br d, $J_{4,5}$ = 9.5 Hz, 1H, *H*-5), 3.73 (br d, $J_{6,CH}$ = 7.0 Hz, 1H, *H*-6), 3.65 (dd, $J_{3,4}$ = 9.0 Hz, $J_{4,5}$ = 9.5 Hz, 1H, *H*-4), 3.56 (dd, $J_{1,2}$ = 3.5 Hz, $J_{2,3}$ = 9.5 Hz, 1H, *H*-2), 3.43 (s, 3H, CH_3O), 2.20 (br s, 3H, CH_3S), 2.17 (m, 1H, CH(CH_3)$_2$), 1.01 (d, *J* = 6.5 Hz, 3H, CH(CH_3)$_2$), 0.99 (d, *J* = 6.5 Hz, 3H, CH(CH_3)$_2$). Anal. calcd. for $C_{33}H_{42}O_6S$: C 69.94, H 7.47, S 5.66; found: C 69.81, H 7.65, S 5.73. Continued elution afforded *R*-epimer ***R*-4i** (90 mg, 44%) identical to the minor Grignard product of aldehyde **3**. Further development eluted *S*-epimer ***S*-4i** (22 mg, 11%) identical to the major Grignard product of aldehyde **3**.

Methyl 6-*O*-(6-*O*-acetyl-2,3,4-tri-*O*-benzyl-α-D-glucopyranosyl)-2,3,4-tri-*O*-benzyl-(6*R*)-*C*-methyl-α-D-glucopyranoside (*R*-14m)

A solution of 6-*O*-acetyl-2,3,4-tri-O-benzyl-α-D-glucopyranosyl bromide (**12**) (34) (2.1 mmol) in dichloromethane (5 mL) was added to a stirring mixture of ***R*-4m** (500 mg, 1.04 mmol), tetraethylammonium bromide (420 mg, 2.00 mmol), *N*,*N*-dimethylformamide (1 mL) and 4 Å molecular sieves (powdered, 2 g) in dichloromethane (5 mL). The mixture was stirred under nitrogen for several days until completion (TLC), diluted with dichloromethane and filtered. The solution was washed with sat. aq $NaHCO_3$ and water, followed by drying and evaporation. The crude product was applied to a column of silica gel (hexane–ethyl acetate, 4:1) to provide ***R*-14m** (587 mg, 59%). $[\alpha]_D$ + 78.2° (*c* 1.1, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.20 (m, 30H, 6*Ph*), 5.00 (d, $J_{1b,2b}$ = 3.5 Hz, 1H, *H*-1b), 4.67 (d, $J_{1a,2a}$ = 3.5 Hz, 1H, *H*-1a), 5.03–4.51 (m, 12H, 6CH_2Ph), 4.27 (dd, $J_{5b,6b}$ = 4.5 Hz, $J_{6b,6b'}$ = 11.5 Hz, 1H, *H*-6b), 4.21 (dd, $J_{5b,6b'}$ = 2.5 Hz, $J_{6b,6b'}$ = 11.5 Hz, 1H, *H*-6b′), 4.08–3.91 (m, 4H, *H*-3a, *H*-3b, *H*-6a, *H*-5b), 3.78 (dd, $J_{5a,6a}$ = 0.5 Hz, $J_{4a,5a}$ = 10.0 Hz, 1H, *H*-5a), 3.57–3.43 (m, 3H, *H*-4a, *H*-4b, *H*-2a), 3.41 (dd, $J_{2b,3b}$ = 9.5 Hz, $J_{1b,2b}$ = 3.5 Hz, 1H, *H*-2b), 3.29 (3, 3H, CH_3O), 1.99 (s, 3H, CH_3CO), 1.16 (d, $J_{6a,CH3}$ = 6.5 Hz, 3H, CH_3C-6a). Anal. calcd. for $C_{58}H_{64}O_{12}$: C 73.09, H 6.77; found: C 73.46, H 6.61.

2,3,4,6-Tetra-*O*-benzyl-α-D-glucopyranosyl bromide (13) (32)

Oxalyl bromide (190 μL, ~1.8 mmol) was added to a stirring solution of 2,3,4,6-tetra-*O*-benzyl-D-glucopyranose (650 mg, 1.20 mmol) in dichloromethane (10 mL) and *N*,*N*-dimethylformamide (0.5 mL, 7.0 mmol). After 20 min at room temperature, the mixture was poured into ice water and the organic solution was washed twice with ice-cold water, dried and evaporated to provide **13** (quant.) as a syrup.

Methyl 2,3,4-tri-*O*-benzyl-(6*R*)-*C*-ethyl-6-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-α-D-glucopyranoside (*R*-14e) and -β-D-glucopyranoside

A solution of bromide **13** (1.12 mmol) in 1,2-dichloroethane (4 mL) was transferred into a stirring mixture of ***R*-4e** (159 mg, 0.32 mmol), copper(II) bromide (260 mg, 1.16 mmol), *N*,*N*-dimethylformamide (350 μL, 4.93 mmol) in 1,2-dichloroethane (2 mL) containing powdered 4 Å molecular sieves (1 g). After 44 h, toluene (15 mL) and moist pyridine (7.5 mL) were added. After stirring for 30 min, the mixture was filtered and the solvent evaporated. The resultant material was applied to a column of silica gel (hexane–ethyl acetate, 5:1) to first provide the β-anomer of ***R*-14e** (50 mg, 15%) as a syrup. $[\alpha]_D$ + 26.4° (*c* 0.6, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.15 (m, 35H, 7*Ph*), 5.01–4.51 (m, 35H, 7CH_2Ph), 4.60 (d, overlapped, *H*-1a), 4.45 (d, $J_{1b,2b}$ = 7.5 Hz, 1H, *H*-1b), 4.00 (t, $J_{2a,3a} \sim J_{3a,4a}$ = 9.5 Hz, 1H, *H*-3a), 3.48 (dd, $J_{1a,2a}$ = 3.5 Hz, $J_{2a,3a}$ = 9.5 Hz, 1H, *H*-2a), 3.40 (s, overlapped, CH_3O), 1.63 (m, 1H, C$H_2$$CH_3$), 1.40 (m, 1H, C$H_2$$CH_3$), 0.88 (t, *J* = 7.5 Hz, 3H, C$H_3$$CH_2$). Anal. calcd. for $C_{64}H_{70}O_{11}$: C 75.71, H 6.95; found: C 75.40, H 6.91.

© 2001 NRC Canada

Continued elution of the column provided the α-anomer ***R*-14e** (240 mg, 73%) as a syrup. $[\alpha]_D$ + 57° (*c* 1.0, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.10 (m, 35H, 7*Ph*), 5.12 (d, $J_{1b,2b}$ = 3.5 Hz, 1H, *H*-1b), 4.97–4.42 (m, 14H, 7CH_2Ph), 4.52 (d, overlapped, $J_{1a,2a}$ = 3.5 Hz, 1H, *H*-1a), 4.01 (t, $J_{2b,3b} \sim J_{3b,4b}$ = 9.5 Hz, 1H, *H*-3b), 3.97 (t, $J_{2a,3a} \sim J_{3a,4a}$ = 9.5 Hz, 1H, *H*-3a), 3.93 (m, 1H, *H*-5b), 3.85 (br d, $J_{4a,5a}$ = 9.5 Hz, $J_{5a,6a}$ < 1 Hz, 1H, *H*-5a), 3.73 (m, 3H, *H*-4a, *H*-6a, *H*-6b), 3.64 (t, $J_{3b,4b} \sim J_{4b,5b}$ = 9.5 Hz, 1H, *H*-4b), 3.60 (dd, $J_{6b,6b'}$ = 11.0 Hz, $J_{6b',5b}$ = 1.5 Hz, 1H, *H*-6b′), 3.53 (dd, $J_{1b,2b'}$ = 3.5 Hz, $J_{2b,3b}$ = 9.5 Hz, 1H, *H*-2b), 3.35 (dd, $J_{1a,2a}$ = 3.5 Hz, $J_{2a,3a}$ = 9.5 Hz, 1H, *H*-2a), 3.32 (s, 3H, CH_3O), 1.61 (m, 2H, CH_2CH$_3$), 0.89 (t, *J* = 7.5 Hz, 3H, *C*H$_3$CH_2). Methyl (6*R*)-*C*-ethyl-6-*O*-(α-D-glucopyranosyl)-α-D-glucopyranoside (*R*-2e)

Compound ***R*-2e** was prepared from ***R*-14e** by catalytic hydrogenolysis following the general procedure and obtained as a white solid (89%) after lyophilization of an aqueous solution. $[\alpha]_D$ + 182.5° (*c* 0.3, water). The ^{1}H NMR data are reported in Table 5. ^{13}C NMR (D_2O) δ: 100.36 (C-1a), 97.01 (C-1b), 78.21, 73.94, 73.73, 73.10, 72.09, 71.89, 71.28, 70.92, 70.47, 61.43 (C-6b), 56.46 (CH_3O), 22.73 (CH_2CH_3), 11.48 (CH_3CH_2).

Methyl 6-*O*-(α-D-glucopyranosyl)-(6*R*)-*C*-isopropyl-α-D-glucopyranoside (*R*-2i)

Compound ***R*-2i** was prepared from ***R*-14i** by catalytic hydrogenolysis following the general procedure and obtained as a white solid (87%) after lyophilization of an aqueous solution. $[\alpha]_D$ + 190.5° (*c* 0.2, water). The ^{1}H NMR data are reported in Table 5. ^{13}C NMR (D_2O) δ: 100.23 (C-1a), 97.86 (C-1b), 82.69, 73.99, 73.64, 73.27, 72.36, 71.88, 71.73, 71.34, 70.47, 61.45 (C-6b), 56.39 (CH_3O), 30.23 ($CH(CH_3)_2$), 20.75, 19.94 ($CH(CH_3)_2$).

Methyl 6-*O*-(α-D-glucopyranosyl)-(6*S*)-*C*-methyl-α-D-glucopyranoside (*S*-2m)

Compound ***S*-14m** (292 mg, 0.31 mmol) was deacetylated as described for ***R*-14m** to provide methyl 2,3,4-tri-*O*-benzyl-(6*S*)-*C*-methyl-6-*O*-(2,3,4-tri-*O*-benzyl-α-D-glucopyranosyl)-α-D-glucopyranoside (269 mg, 96%) as an oil. $[\alpha]_D$ + 47.6° (*c* 2.0, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.10 (m, 30H, 6*Ph*), 5.03 (d, $J_{1b,2b}$ = 3.5 Hz, 1H, *H*-1b), 5.01–4.57 (m, 13H, 6CH_2Ph, *H*-1a), 4.32 (dq, $J_{5a,6a}$ = 1.5 Hz, J_{6a,CH_3} = 6.5 Hz, 1H, *H*-6a), 4.01 (dd, $J_{2b,3b}$ = 9.5 Hz, $J_{3b,4b}$ = 9.0 Hz, 1H, *H*-3b), 3.98 (dd, $J_{2a,3a}$ = 9.5 Hz, $J_{3a,4a}$ = 10.0 Hz, 1H, *H*-3a), 3.84–3.72 (m, 2H, *H*-5b, *H*-4a), 3.66–3.49 (m, 5H, 2*H*-6a, *H*-5a, *H*-4b, *H*-2a), 3.46 (dd, $J_{1b,2b}$ = 3.5 Hz, $J_{2b,3b}$ = 9.5 Hz, 1H, *H*-2b), 3.36 (s, 3H, CH_3O), 1.32 (d, J_{6a,CH_3} = 6.5 Hz 3H, CH_3C-6). Anal. calcd. for $C_{56}H_{62}O_{11}$: C 73.82, H 6.86; found: C 73.20, H 6.95.

The deacetylation product of ***S*-14m**, namely methyl 2,3,4-tri-*O*-benzyl-(6*S*)-*C*-methyl-6-*O*-(2,3,4-tri-*O*-benzyl-α-D-glucopyranosyl)-α-D-glucopyranoside, (126 mg, 0.138 mmol) was debenzylated following the general procedure to give crystalline ***S*-2m** (40 mg, 78%), mp 127–128°. $[\alpha]_D$ + 175.3° (*c* 0.3, water). The ^{1}H NMR data are reported in Table 5. ^{13}C NMR (D_2O) δ: 100.03 (C-1a), 95.56 (C-1b), 74.49, 74.15, 73.68, 73.04, 72.25, 71.99, 70.24, 68.50, 61.17, 55.67 (CH_3O), 14.76 (CH_3-6a).

Methyl-(6*S*)-*C*-ethyl-6-*O*-(α-D-glucopyranosyl)-α-D-glucopyranoside (*S*-2e)

Compound ***S*-2e** was prepared from ***S*-14e** by catalytic hydrogenolysis following the general procedure and obtained as a white solid (94%) after lyophilization of an aqueous solution. $[\alpha]_D$ + 198° (*c* 0.2, water). The ^{1}H NMR data are reported in Table 5. ^{13}C NMR (D_2O) δ: 100.31 (C-1a), 96.31 (C-1b), 74.77, 74.47, 73.85. 73.15, 72.37, 72.01, 70.93, 70.29, 70.14, 61.21 (C-6b), 56.38 (CH_3O), 21.67 (CH_2CH_3), 10.02 (CH_3CH_2).

Methyl 6-*O*-(α-D-glucopyranosyl)-(6*S*)-*C*-isopropyl-α-D-glucopyranoside (*S*-2i)

Compound ***S*-2i** was prepared from ***S*-14i** by catalytic hydrogenolysis following the general procedure and obtained as a white solid (98%) after lyophilization of an aqueous solution. $[\alpha]_D$ + 192° (*c* 0.2, water). The ^{1}H NMR data are reported in Table 5. ^{13}C NMR (D_2O) δ: 100.63 (C-1a), 96.52 (C-1b), 76.45, 74.20, 73.70, 73.05, 72.67, 71.90, 70.86, 70.51, 70.33, 61.15 (C-6b), 57.43 (CH_3O), 28.42 ($CH(CH_3)_2$, 19.04, 17.72 ($CHCH_3)_2$).

Réaction compétitive de la substitution homolytique intramoléculaire : décomposition de peroxydes allyliques dans le thioglycolate de méthyle

Marie-Josèphe Bourgeois, Marianne Vialemaringe, Monique Campagnole et Evelyne Montaudon

Résumé : La décomposition des peroxydes allyliques dans le thioglycolate de méthyle conduit toujours à un mélange d'époxyde et de peroxyde adduit. Selon la nature de la chaîne allylique, l'un ou l'autre est formé très majoritairement, sinon exclusivement. C'est le premier exemple où la réaction de transfert d'un atome d'hydrogène peut l'emporter sur la substitution homolytique intramoléculaire. Les facteurs influençant la compétition sont étudiés.

Mots clés : peroxydes allyliques, époxydes, substitution homolytique intramoléculaire, transfert.

Abstract: The decomposition of allylic peroxides in methyl thioglycolate always leads to both epoxide and adduct peroxide. According to the nature of the allylic chain, either epoxide or peroxide is the predominant product, if not the only one. It is the first example where the hydrogen transfer is as fast as the intramolecular homolytic substitution. The influence of different factors upon the competition is studied.

Key words: allylic peroxides, epoxides, intramolecular homolytic substitution, transfer.

Introduction

L'addition radicalaire de substrats Z-H à des peroxydes allyliques, substitués ou non (**1a**), conduit toujours à l'époxypropanation de ces substrats, à l'exclusion de tout produit d'addition (1). Le radical adduit issu de la fixation de Z˙ à la double liaison n'évolue que par substitution homolytique intamoléculaire S_Hi (schéma 1, voie *a*, Z = radical alkyle et X = H).

Tous nos essais en vue d'établir une base de comparaison pour l'évolution de la constante de vitesse de la S_Hi — utilisation de substrats susceptibles de donner facilement une réaction de transfert ou mise en jeu de peroxydes conduisant à des radicaux adduits particulièrement fragiles susceptibles de se réarranger — sont restés vains. Ainsi, lorsque ZX est le tétrachlorure de carbone, la constante de vitesse du transfert de l'atome de chlore est encore insuffisante pour concurrencer la S_Hi; s'il s'agit du bromotrichlorométhane, seule la réaction de transfert est observée (schéma 1, voie *b*, Z = CCl_3 et X = Br) (1). Nous pensions que cette dernière réaction l'emporterait également lorsque le thioglycolate de méthyle, connu pour être un excellent agent de transfert (2, 3) au même titre que le bromotrichlorométhane, est opposé au peroxyde de *t*-butyle et de *trans*-pinocarvéyle, **1g**. Or, il n'en est rien et dans ce cas, seul l'époxyde **2g** est obtenu, ni le transfert d'hydrogène ni éventuellement la β–scission du radical adduit n'étant observés (schéma 2) (4).

Ne pouvant comparer les résultats issus de peroxydes de structures aussi différentes, nous avons opposé au thioglycolate de méthyle le peroxyde d'allyle et de *t*-butyle, **1a**, et des homologues diversement substitués. Le choix de ce substrat, dont la réactivité est analogue à celle des autres thiols, s'explique par la simplicité des signaux qui le caractérisent dans les spectres RMN ^1H et ^{13}C des produits formés. Cette publication décrit les résultats de cette étude.

Choix des méthodes et conditions d'étude

Les peroxydes testés sont rassemblés dans le schéma 3.

Les premiers essais sur le peroxyde **1g** montrent que les conditions habituelles (chauffage à 110°C d'un mélange contenant un équivalent de peroxyde, un excès de substrat et 0,1 équivalent de peracétate de *t*-butyle) sont à proscrire : en effet, la décomposition du peroxyde est rapide et brutale. La présence d'un amorceur est inutile, la réaction se produisant même dans l'obscurité; le thioglycolate de méthyle a du reste été additionné avec succès au styrène à 100°C, sans amorçage (5). Le mélange mis en jeu est uniquement constitué du peroxyde et du thiol pris dans le rapport molaire 1/1,05. La réaction est effectuée à différentes températures n'excédant pas 80°C et entraînant des durées de réaction adaptées (voir partie expérimentale).

Résultats et discussion

Le tableau 1 regroupe les résultats obtenus : rendements en époxyde **2** et (ou) adduit **3** susceptibles de se former (schéma 4), proportions relatives de l'époxyde par rapport à l'ensemble époxyde–peroxyde adduit. On observe que le taux de transformation des peroxydes est toujours très important, voire même total (74 à 100 %), sauf cas particulier de **1f**.

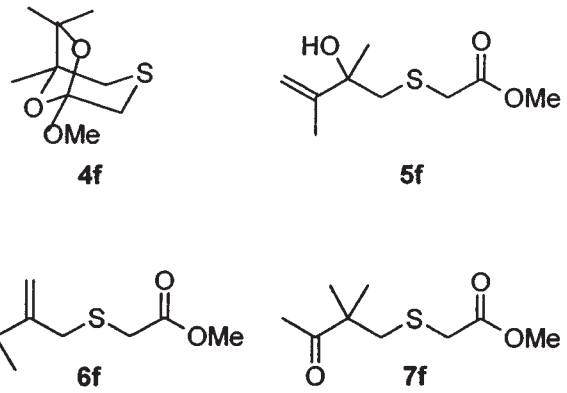
Proportions relatives époxyde/peroxyde adduit

L'époxyde et le peroxyde adduit sont tous les deux présents, sauf dans le cas du peroxyde de pinocarvéyle, **1g**. Pour les peroxydes linéaires, la proportion d'époxyde (par rapport à l'ensemble époxyde–peroxyde adduit) varie de 4 à 98 %.

Deux configurations sont possibles pour les époxydes **2b** et **2e**. **2b** est effectivement formé sous les formes *cis* et *trans* dans le rapport 15/85 (détermination effectuée par chromatographie en phase gazeuse (CPG) et résonance magnétique nucléaire (RMN)), régi par la stabilité relative des radicaux conformères impliqués dans l'étape de S_Hi (6). L'attribution *cis–trans* est possible grâce à la RMN ^{13}C : dans un cycle époxyde disubstitué en 1, 2, les carbones liés au cycle sont plus blindés lorsque les deux substituants sont en *cis* que lorsqu'ils sont en *trans* (6). **2e** est également présent sous ses deux formes isomères *cis–trans*, relativement aux carbones 4 et 7, dans les proportions 55/45 (évaluation effectuée par RMN).

Le degré de substitution du peroxyde initial, la classe du radical adduit et la température de l'expérience influencent l'orientation de la réaction : (*i*) la présence et l'accumulation de substituants sur le peroxyde initial favorisent la S_Hi : la proportion d'époxyde est maximale pour **f** et **e**, diminue pour **d**, **c** et **b**, et devient très minoritaire pour **a**. Ceci va dans le sens d'une formation plus rapide des petits cycles les plus substitués. (*ii*) La présence de un ou plusieurs substituants sur le site radicalaire initialement formé favorise la S_Hi : pour le même nombre de substituants sur la chaîne alkyle, il se forme plus d'époxyde avec **c** qu'avec **b**; avec **e** qu'avec **d**. Un radical tertiaire conduit plus facilement qu'un radical secondaire à un époxyde de même degré de substitution. (*iii*) L'élévation de la température favorise également la S_Hi. Il est en effet connu que les processus monomoléculaires sont, dans ces conditions, plus accélérés que les processus bimoléculaires.

Stabilité des époxydes



Les résultats obtenus à partir des peroxydes **1d**, **1e**, **1g** et surtout **1f** montrent une chute anormale du rendement en époxydes aux fortes températures : les époxydes tri- et surtout tétra-substitués semblent peu stables dans le milieu. La stabilité de l'époxyde **2f** a été plus particulièrement testée.

Traité à 80°C, le peroxyde **1f** conduit, à côté de l'époxyde **2f** et du peroxyde adduit **3f**, à des composés absents des décompositions réalisées à –10°C, à savoir l'orthoester **4f**, le mélange d'alcools **5f** et **6f** et la cétone **7f** (schéma 5), dans les proportions relatives 28, 60 et 12 %.

Une réaction normalement effectuée à –10°C, puis portée 1 h à 80°C, ne contient plus l'époxyde **2f**, mais les produits secondaires précédents dans les mêmes proportions. L'époxyde **2f** pur n'est pas transformé par un chauffage à 80°C durant 5 h en présence d'un équivalent de RSH; par contre, il disparaît totalement en donnant le mélange précédent dans les mêmes proportions s'il est chauffé à 80°C, soit en présence de 0,1 équivalent de RSH et un équivalent de *t*-butanol durant 5 h, soit en présence de 1 équivalent de

© 2001 CNRC Canada

Schéma 5.

t-butanol durant 15 h. Le *t*-butanol, éventuellement associé au thiol, facilite donc le processus de réarrangement thermique déjà observé à partir de δ,ε-époxycétones et d'acétates de 3,4-époxyalkyle (7).

Comparaison avec le peroxyde de *t*-butyle et de pinocarvéyle, 1g

Le modèle le plus proche de **1g** est le peroxyde **1e** : ils comportent tous les deux un substituant sur un carbone sp^2 et un autre sur le carbone allylique. Si **1e** ne donne que très peu de peroxyde adduit (<5 %), **1g** n'en donne pas du tout. Même avec un rapport molaire thiol/**1g** de 10/1 ou à –10°C (conditions favorisant le transfert), le peroxyde adduit **3g** est toujours absent. On peut estimer que les peroxydes **1e** et **1g** ont un comportement tout à fait analogue, l'encombrement du composé bicyclique rendant encore plus difficile une réaction de transfert déjà défavorisée.

Conclusion

Cette étude de décomposition des peroxydes allyliques dans les thiols nous a permis de trouver la réaction étalon de la substitution homolytique intramoléculaire que nous recherchions. Alors qu'avec tous les agents bons donneurs d'hydrogène par coupure d'une liaison C—H seul l'époxyde se forme, avec les thiols les réactions de transfert et de substitution homolytique intramoléculaire deviennent compétitives. En série peroxyde allylique linéaire, l'époxyde et le peroxyde adduit coexistent toujours. Le pourcentage d'époxyde par rapport au mélange époxyde – peroxyde adduit varie de 4 à 98 %, en fonction de la température, de la substitution de la chaîne allylique initiale et de la classe du site radicalaire. Dans le cas particulier du peroxyde d'allyle et de *t*-butyle, le peroxyde adduit est même obtenu avec le très bon rendement de 80 %. La réactivité du peroxyde de *t*-butyle et de *trans*-pinocarvéyle, qui semblait a priori très surprenante, s'explique donc logiquement en fonction des résultats obtenus en série linéaire.

Partie expérimentale

Techniques utilisées

Les analyses et déterminations de structure ont été réalisées sur les appareils suivants : (*i*) chromatographie en phase gazeuse : chromatographe DELSI DI 200 équipé d'une colonne CP SIL-8 CB (longueur 25 m, diamètre intérieur 0,25 mm, épaisseur du film 0,25 μm). Les dosages ont été effectués par la méthode de l'étalon interne. (*ii*) Spectres de RMN ^{1}H et ^{13}C : appareil Brucker AC 250 fonctionnant à 250 MHz et 62,9 MHz respectivement, en solution dans du chloroforme deutérié; les déplacements chimiques sont en ppm par rapport au tétraméthylsilane. Des expériences 2D de corrélation ont été réalisées quand cela était nécessaire. (*iii*) Spectres de masse : spectromètres éventuellement couplés à un chromatographe en phase gazeuse : FISONS-Instrument type Autospec-EQ en impact électronique (SMIE) (70 eV) ou en ionisation chimique (SM-IC) (NH_3), ou spectromètre à trappe ionique Varian Saturn 4D en impact électronique. Les intensités sont en pourcentage relatif par rapport au pic de base (100 %). Les masses moléculaires exactes sont déterminées, chaque fois que possible, par analyse en haute résolution.

Les purifications sont faites par chromatographie sur gel de silice ou par chromatographie liquide haute performance sur un appareil Millipore Waters Delta Prep 3000 équipé d'une colonne TW PREP-PAK Porasil 15 μm.

Matières premières

Certains peroxydes sont déjà décrits : **1a** et **1c** (8), **1b**, **1d** et **1g** (9). Les peroxydes **1e** et **1f** proviennent de la réaction du trichloroacétimidate de *t*-butyle (10) avec les hydroperoxydes correspondants issus de la photooxygénation du 2-méthyl-but-2-ène et du diméthyl-but-2-ène respectivement (11). Le peroxyde **1e** n'a pu être obtenu pur, il est accompagné de l'isomère **1d**, les hydroperoxydes précurseurs se formant simultanément (dans les proportions 53/47) lors de la photooxygénation; une chromatographie sur silice permet d'enrichir **1e** : rdt = 70 %; pureté = 85 %. Le peroxyde **1f** est obtenu pur : rdt= 85 %.

Peroxyde de 3-méthyl-but-3-èn-2-yle et de t*-butyle (**1e**) (en mélange avec **1d** : 85/15)*

RMN ^{1}H δ : 4,9–4,7 (m, 2H, *H*-4), 4,5–4,2 (m, 1H, *H*-2), 1,6 (s, 3H, Me-3), 1,19 (d, *J* = 13,4 Hz, 3H, Me-2), 1,15 (s, 9H, *t*-Bu). RMN ^{13}C δ : 145,4 (C-3), 111,9 (C-4), 82,7 (C-2), 78,4 (*C*Me$_3$), 26,3 (C*Me*$_3$), 24,4 (Me-3), 17,4 (C-1).

Peroxyde de 2,3-diméthyl-but-3-èn-2-yle et de t*-butyle (**1f**)*

RMN ^{1}H δ: 4,95–4,8 (m, 2H, *H*-4), 1,81 (s, 3H, Me-3), 1,33 (s, 6H, *H*-1, Me-2), 1,25 (s, 9H, *t*-Bu). RMN ^{13}C δ : 149,8 (C-3), 110,3 (C-4), 81,4 (C-2), 78,3 (*C*Me$_3$), 26,6 (C*Me*$_3$), 24,5 (C-1, Me-2), 18,7 (Me-3).

Addition du thioglycolate de méthyle

La décomposition des peroxydes insaturés dans les thiols à 110°C (conditions habituelles pour les autres substrats ZH) étant brutale, la réaction est effectuée à 80°C (1 h), 60°C (2 h), 30°C (18 h) et même à –10°C (4 jours). L'addition d'un amorceur radicalaire est inutile; on peut même procéder dans l'obscurité. Le rapport thiol/peroxyde est de 1,05/1 sauf études préparatives particulières où pour favoriser l'époxyde ou le peroxyde adduit on utilise respectivement les rapports 0,5/1 et 2/1.

Nota : Le rapport molaire peroxyde **1**/thiol = 1/1,05.
[a]Quatre jours dans l'obscurité à –10°C; 18 h à 30°C; 2 h à 60°C; 1 h à 80°C.
[b]Dosés par CPG par la méthode de l'étalon interne.
[c]Présent sous deux formes diastéréoisomères *cis*/*trans* : 15/85.
[d]Présent sous deux formes diastéréoisomères *cis*/*trans* (relativement aux carbones 4 et 7) : 55/45.

Études analytiques

Elles sont réalisées à partir de 1,5 mmol de peroxyde. Le mélange est introduit dans un tube à vis placé dans un bain thermorégulé ou dans le congélateur du réfrigérateur pendant le temps voulu. Les produits de réaction sont ensuite dosés en chromatographie en phase gazeuse.

Études préparatives

On opère dans un ballon muni d'un réfrigérant à partir de 10 mmol de peroxyde. Après avoir chassé les produits légers sous le vide de la trompe à eau, on sépare les produits de réaction par HPLC (éluant : éther de pétrole – éther 80/20 ou 70/30).

Étude de la stabilité de l'époxyde 2f

Après avoir réalisé la réaction d'addition du thiol à –10°C, on dose l'époxyde formé puis on porte le mélange réactionnel à 80°C pendant 1 h et on dose en CPG les nouveaux composés. On les isole par chromatographie sur colonne de silice.

Produits de réaction

*5,6-Époxy-3-thiahexanoate de méthyle (**2a**)*

SM-IC : 180 $[M + NH_4]^+$, 163 $[M + H]^+$. Non isolé, détecté par quelques signaux RMN ^{1}H δ : 3,3 (s, 2H, *H*-2), 2,9 (m, 3H, *H*-5,6).

*6-t-Butylperoxy-3-thiahexanoate de méthyle (**3a**)*

SM-IC : 254 $[M + NH_4]^+$. RMN ^{1}H δ : 3,9 (t, *J* = 6 Hz, 2H, *H*-6), 3,7 (s, 3H, OCH_3), 3,2 (s, 2H, *H*-2), 2,7 (t, *J* = 7 Hz, 2H, *H*-4), 2,0–1,7 (m, 2H, *H*-5), 1,2 (s, 9H, *t*-Bu). RMN ^{13}C δ : 170,6 (C-1), 79,6 (*C*Me_3), 79,3 (C-6), 51,9 (OCH_3), 33,0 (C-2), 29,1 (C-4), 27,3 (C-5), 26,1 (Me_3).

*5,6-Époxy-3-thiaheptanoate de méthyle (**2b**)*

Mélange de deux diastéréoisomères. SM-IC : 194 $[M + NH_4]^+$, 177 $[M + H]^+$. RMN ^{1}H δ : 3,62 (s, 3H, OCH_3), 3,22 (s, 2H, *H*-2), 2,9–2,6 (m, 4H, *H*-4, 5, 6), 1,2 (d, *J* = 5 Hz, 3H, *H*-7). RMN ^{13}C (*cis*/*trans*) δ : 170,6 (C-1), 56,0/58,4 (C-5), 52,8/54,4 (C-6), 52,4 (OCH_3), 30,2/33,9 (C-4), 33,4 (C-2) 13,2/17,3 (C-7). M calc. pour $C_7H_{12}O_3S$: 176,0507; tr. 176,0509.

*6-t-Butylperoxy-3-thiaheptanoate de méthyle (**3b**)*

SM-IC : 268 $[M + NH_4]^+$. RMN ^{1}H δ : 4,2–4 (m, 1H, *H*-6), 3,66 (s, 3H, OCH_3), 3,17 (s, 2H, *H*-2), 2,65 (t, *J* = 7 Hz, 2H, *H*-4), 2,0–1,6 (m, 2H, *H*-5), 1,16 (s, 9H, *t*-Bu), 1,13 (d, *J* = 6,3 Hz, 3H, *H*-7). RMN ^{13}C δ : 170,9 (C-1), 79,8 (*C*Me_3), 78,0 (C-6), 52,3 (OCH_3), 34,2 (C-5), 33,4 (C-2), 28,8 (C-4), 26,4 (Me_3), 18,5 (C-7).

*5,6-Époxy-5-méthyl-3-thiahexanoate de méthyle (**2c**)*

SM-IC : 194 $[M + NH_4]^+$, 177 $[M + H]^+$. RMN ^{1}H δ : 3,7 (s, 3H, OCH_3), 3,3 (s, 2H, *H*-2), 2,75 (s, 2H, *H*-4), 2,72 et 2,58 (AB, *J* = 5 Hz, 2H, *H*-6), 1,4 (s, 3H, Me). RMN ^{13}C δ : 170,5 (C-1), 56,1 (C-5), 52,9 (C-6), 52,2 (OCH_3), 38,6

Bis(1-phenyl-1-propyne) complexes of tungsten(II): crystal structures of $[WI_2(CO)(NCR)(\eta^2\text{-}MeC_2Ph)_2]$ (R = Me, Et, or Ph)

Paul K. Baker, Michael G.B. Drew, and Deborah S. Evans

Abstract: Reaction of $[WI_2(CO)_3(NCMe)_2]$ with two equivalents of 1-phenyl-1-propyne (MeC_2Ph) in CH_2Cl_2, and in the absence of light, gave the bis(1-phenyl-1-propyne) complex $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Ph)_2]$ (**1**) in 77% yield. Treatment of equimolar quantities of **1** and NCR (R = Et, *i*-Pr, *t*-Bu, Ph) in CH_2Cl_2 afforded the nitrile-exchanged products, $[WI_2(CO)(NCR)(\eta^2\text{-}MeC_2Ph)_2]$ (**2**–**5**) (R = Et (**2**), *i*-Pr (**3**), *t*-Bu (**4**), Ph (**5**)). Complexes **1**, **2**, and **5** were structurally characterized by X-ray crystallography. All three structures have the same pseudo-octahedral geometry, with the equatorial sites being occupied by *cis* and parallel alkyne groups, which are *trans* to the *cis*-iodo groups. The *trans* carbon monoxide and acetonitrile ligands occupy the axial sites. In structures **1** and **2**, the methyl and phenyl substituents of the 1-phenyl-1-propyne ligands are *cis* to each other, whereas for the bulkier NCPh complex (**5**), the methyl and phenyl groups are *trans* to one another. This is the first time that this arrangement has been observed in the solid state in bis(alkyne) complexes of this type.

Key words: bis(1-phenyl-1-propyne), carbonyl, nitrile, diiodo, tungsten(II), crystal structures.

Résumé : La réaction du $[WI_2(CO)_3(NCMe)_2]$ avec deux équivalents de 1-phénylprop-1-yne (MeC_2Ph), dans le CH_2Cl_2, en absence de lumière, conduit à la formation du complexe bis(1-phénylprop-1-yne) $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Ph)_2]$ (**1**) avec un rendement de 77%. La réaction de quantités équimolaires de **1** et de NCR (R = Et, *i*-Pr, *t*-Bu, Ph) conduit à la formation de produits d'échange avec les nitriles, $[WI_2(CO)(NCR)(\eta^2\text{-}MeC_2Ph)_2]$ (**2**–**5**) (R = Et (**2**), *i*-Pr (**3**), *t*-Bu (**4**), Ph (**5**)). On a déterminé les structures des composés **1**, **2** et **5** par diffraction des rayons X. Les trois structures comportent la même géométrie pseudo-octaédrique dans laquelle les sites équatoriaux sont occupés par des groupes alcynes *cis*- et parallèles qui sont *trans* par rapport aux groupes *cis*-iodo. Le monoxyde de carbone *trans* et les ligands acétonitriles occupent des sites axiaux. Dans les structures des composés **1** et **2**, les groupes méthyle et phényle des ligands 1-phénylprop-1-yne sont *cis* l'un par rapport à l'autre alors que dans le complexe **5** plus encombré, les groupes méthyle et phényle sont *trans* l'un par rapport à l'autre. C'est la première fois qu'un tel arrangement peut être observé à l'état solide dans des complexes bis(alcyne) de ce type.

Mots clés : bis(1-phénylprop-1-yne), carbonyle, nitrile, diiodo, tungstène(II), structures cristallines.

[Traduit par la Rédaction]

Introduction

Over the past 30 years, extensive developments of the chemistry of alkyne complexes of molybdenum(II) and tungsten(II) have been made (1, 2). To date, the majority of the literature work on bis(alkyne) complexes of Mo(II) and W(II) containing halogens and (or) carbonyl ligands has involved symmetrical alkynes such as 2-butyne (3–11), diphenylacetylene (3–5, 7, 8, 11), hexafluoro-1-butyne (6, 12, 13) and 3-hexyne (7, 14). Complexes of the general type $[MXX'(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (3, 8, 10, 14) and $[\{M(\mu\text{-}X)X'(CO)(NCMe)(\eta^2\text{-}RC_2R)\}_2]$ (X = Br or I) (8, 10, 11) have been well-established by Baker and co-workers (2, 3, 8, 10, 11).

Complexes containing unsymmetric alkynes (RC_2R') are less common. Dimeric complexes, such as $[\{M(\mu\text{-}I)I(CO)(NCMe)(\eta^2\text{-}RC_2R')\}_2]$ (M = Mo, W; R = Ph, R′ = Me, CH_2OH; R = Me, R′ = PhS, *p*-TolS) (11), $[\{W(\mu\text{-}I)Br(CO)(NCMe)(\eta^2\text{-}MeC_2Ph)\}_2]$ (10), and $[WBr_2(CO)(\eta^2\text{-}MeC_2Ph)_2]$ (15), and monomeric complexes, including $[WXX'(CO)(NCMe)(\eta^2\text{-}PhC_2Me)_2]$ (8, 10), $[Mo(CO)(\eta^2\text{-}RC_2R')_2(\eta^5\text{-}C_5H_5 \text{ or } C_9H_7)][BF_4]$ (R = H, R′ = Me; R = H, R′= *t*-Bu; R = Me, R′ = Ph) (4), and $[Mo(NCMe)(\eta^2\text{-}RC_2R')_2(\eta^5\text{-}C_5H_5 \text{ or } C_9H_7)][BF_4]$ (R = R′ = Me; R = H, R′ = *t*-Bu; R = H, R′ = *i*-Pr; R = Me, R′ = Ph) (5), have been reported.

In this work, we describe a modified synthesis of $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Ph)_2]$ (**1**) and the nitrile exchange reactions of **1** with NCR to give four new complexes, $[WI_2(CO)(NCR)(\eta^2\text{-}MeC_2Ph)_2]$ (R = Et (**2**), *i*-Pr (**3**), *t*-Bu (**4**), Ph (**5**)). The crystal structures of **1**, **2**, and **5** are also reported, with the structure for complex **5** being the first reported example of bis(unsymmetrical alkyne) complexes of

this type to have *cis* and parallel alkyne ligands with *trans* Me and Ph groups.

Experimental

General procedures

All reagents were purchased from Lancaster Synthesis or Aldrich–Sigma and were used as received. The starting material used in the preparation of **1**, namely $[WI_2(CO)_3(NCMe)_2]$, was prepared according to literature methods (16, 17). Elemental analyses (C, H, N) were determined using a Carlo Erba Elemental Analyser MOD 1108 (using Helium as a carrier gas). IR spectra were obtained using a Perkin–Elmer 1600 FT-IR spectrometer. ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded on a Bruker AC 250 MHz NMR spectrometer and referenced to tetramethylsilane ($SiMe_4$).

Preparation of $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Ph)_2]$ (1)

To a solution of $[WI_2(CO)_3(NCMe)_2]$ (3.007 g, 4.980 mmol) in dichloromethane (30 cm^3), in a foil-covered Schlenk tube, was added 1-phenyl-1-propyne (1.250 mL, 1.160 g, 9.986 mmol) and the solution was stirred for 24 h. Filtration of the resultant gold-brown solution over celite, followed by removal of the solvent in vacuo gave the product $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Ph)_2]$ (**1**) as a bright gold solid. Recrystallization from dichloromethane–diethyl ether solution (2/3 by volume) and cooling to –17°C, gave single yellow crystals suitable for X-ray crystallography. Yield of pure product was 2.836 g (77 %).

Preparation of $[WI_2(CO)(NCPh)(\eta^2\text{-}MeC_2Ph)_2]$ (5)

To a solution of $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Ph)_2]$ (0.540 g, 0.731 mmol) in dichloromethane (30 cm^3) was added benzonitrile (PhCN) (0.080 mL, 0.081 g, 0.781 mmol) and the solution was stirred for 22 h. Filtration of the resultant gold-brown solution over celite, followed by removal of the solvent in vacuo gave the product $[WI_2(CO)(NCPh)(\eta^2\text{-}MeC_2Ph)_2]$ (**5**) as a yellow solid. Recrystallization from dichloromethane–diethyl ether solution (2/3 by volume) and cooling to –17°C, gave single yellow crystals suitable for X-ray crystallography. Yield of pure product was 0.433 g (74 %).

Similar reactions of equimolar quantities of **1** and NCR in CH_2Cl_2 at room temp gave the acetonitrile exchanged products $[WI_2(CO)(NCR)(\eta^2\text{-}MeC_2Ph)_2]$ (R = Et (**2**), *i*-Pr (**3**), and *t*-Bu (**4**)). Complexes **1**–**5** were fully characterized by elemental analysis (C, H, N) (Table 1), IR spectrosopy (Table 2), ^1H NMR spectroscopy (Table 3) and ^{13}C NMR spectroscopy (Table 4).

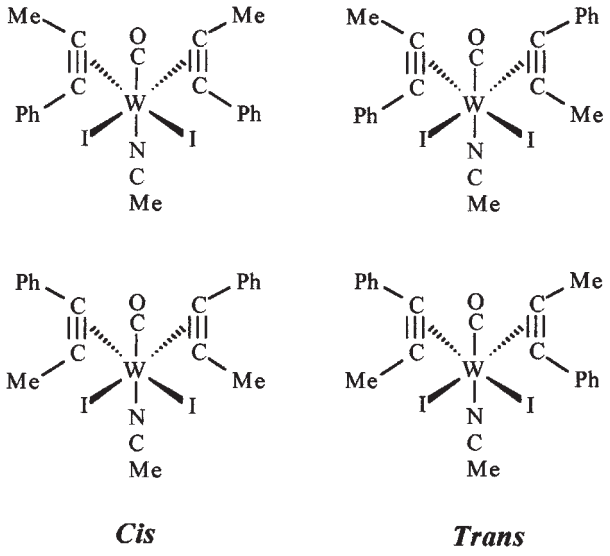
X-ray crystallographic experimental details for 1, 2, and 5

Crystal data were collected with Mo Kα radiation using the MARresearch Image Plate System. The crystals were positioned at 70 mm from the Image Plate. One hundred frames were measured at 2° intervals with a counting time of 2 min. Data analysis was carried out with the XDS program (18). The structures were solved using direct methods with the SHELXS 86 program (19). Complexes **1** and **2** are isomorphous. The non-hydrogen atoms were refined with aniostropic thermal parameters. The hydrogen atoms were included in geometric positions and given thermal parameters equivalent to 1.2 times those of the atom to which they were attached. Empirical absorption corrections were carried out using the DIFABS program (20). The structures were refined on F^2 using SHELXL (21). Crystal data and structure refinements for **1**, **2**, and **5** are given in Table 5. Bond lengths (Å) and angles (°) for **1**, **2**, and **5** are given in Tables 6 and 7, respectively.



Results and discussion

Modified synthesis, structural characterization, and detailed NMR spectroscopic analysis of the bis(1-phenyl-1-propyne) complex $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Ph)_2]$ (1)

The complex $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Ph)_2]$ (**1**) has been synthesized by a modified procedure to the literature method (8), with both the *cis*- and *trans*-isomers of product **1** being identified by ^1H and $^{13}C\{^1H\}$ NMR spectroscopy. Two equivalents of 1-phenyl-1-propyne were added to a solution of $[WI_2(CO)_3(NCMe)_2]$ in dichloromethane, in a foil-covered Schlenk tube, and the solution was stirred for 24 h at room temperature. Filtration of the resultant gold-brown solution over celite, followed by removal of the solvent in vacuo gave the product $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Ph)_2]$ (**1**) as a bright gold solid. Recrystallization from dichloromethane–diethyl ether solution (2/3 by volume) and cooling

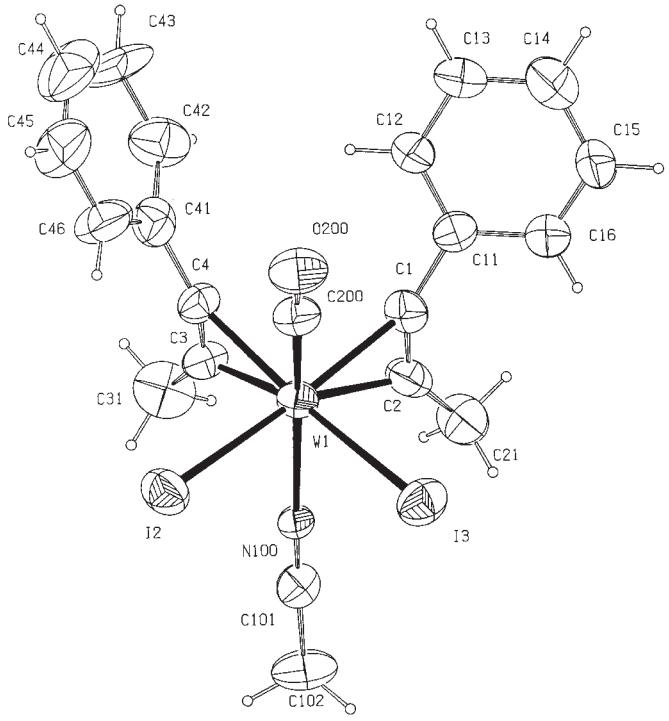
Fig. 1. Representation of the arrangement of substituents on each alkyne ligand to give *cis*- and *trans*-isomers.



to –17°C, gave single yellow crystals of **1** suitable for X-ray crystallography.

Complex **1** has been fully characterized by elemental analysis (C, H, N), IR spectroscopy, ^{1}H NMR, and ^{13}C{^{1}H} NMR spectroscopy (Tables 1–4). The complex is soluble in chlorinated solvents and acetonitrile, but is insoluble in diethyl ether and hydrocarbon solvents such as hexane. The complex is air stable for up to 15 min and can be stored for up to two months at –17°C with no obvious signs of deterioration. Solutions of **1** showed decomposition within 24 h upon exposure to air.

The IR spectrum for **1** (Table 2) shows a strong carbonyl stretching frequency at 2076 cm^{-1}, a weak acetonitrile stretching band at 2296 cm^{-1}, and a weak alkyne band at 1594 cm^{-1}. The ν(C≡C) stretching band for the coordinated alkyne was found at a lower wavenumber than for uncoordinated alkynes (typically at 2260–2190 cm^{-1} for unsymmetrical alkynes (22)) and can be mainly attributed to the σ–π-donation of the bonding electrons of the alkyne to the tungsten atom and also the back-bonding between anti-bonding π*-orbitals of the alkyne and the filled *d*-orbitals of tungsten. Although two isomers have been observed in solution (see next section), the difference electronically at the metal centre is small and is not expected to affect the IR stretching frequency to any significant degree.

The crystal data obtained for complex **1**, coupled with the proton and carbon NMR data, showed that two isomers were present for the bis(1-phenyl-1-propyne) complex [WI_2(CO)(NCMe)(η^2-MeC_2Ph)$_2$] (**1**). To aid interpretation of data, the isomers were designated *cis* and *trans* with respect to the substituents of the alkyne groups (Fig. 1). Faller and Murray (23) reported similar isomeric forms for cationic bis(alkyne) complexes of the type [Mo(CO)(η^2-HC_2R)$_2$(η^5-C_5H_5)]$^{+}$, where three isomers were possible (C_s symmetry): (*i*) the two R groups can be *trans* to one another; (*ii*) mutually *cis* proximal to the carbonyl; or (*iii*) mutually *cis* distal to the carbonyl. For complex **1**, four isomers are possible

Fig. 2. Crystal structure of [WI_2(CO)(NCMe)(η^2-MeC_2Ph)$_2$] (**1**).

(Fig. 1) however, only the *cis*-isomer with the larger phenyl group proximal to the carbonyl is obtained (Fig. 2).

The ^{1}H NMR spectrum of **1** (Table 3) showed a broad resonance at 7.55–7.22 ppm (m, 20H, *Ph*C_2Me, *cis* and *trans*) and five other resonances found further upfield. The *cis*-isomer displayed resonances at 3.14 ppm (s, 6H, PhC_2*Me*) and 2.25 ppm (s, 3H, NC*Me*), while the *trans*-isomer showed resonances at 3.18 ppm (s, 3H, PhC_2*Me*), 3.10 ppm (s, 3H, PhC_2*Me*), and 2.52 ppm (s, 3H, NC*Me*). Variable temperature ^{1}H NMR studies of single crystals of **1** in CD_2Cl_2 between 0°C and –80°C showed little change in the chemical shifts compared to the spectrum recorded at +25°C, with only a slight broadening and diminution of signal size observed. This suggests that there is no change in the isomer ratio as the temp of the solution is decreased and that neither isomer is preferred at lower temperatures. Single crystals of **1** were dissolved in d_8-toluene and a series of ^{1}H NMR spectra were obtained from +25°C to +100°C. Although broadening of the signals was observed, which suggests that the complex is fluxional, no coalescence temperature could be obtained.

The ^{13}C{^{1}H} NMR spectrum of **1** (Table 4) was assigned for both the *cis*- and *trans*-isomers. The carbonyl signal, the acetonitrile (*C*≡N) resonance, and the signal for the methyl group of the acetonitrile were observed at 203.59, 135.29, and 4.37 ppm, respectively, for the *cis*-isomer and at 202.96, 137.49, and 4.72 ppm, respectively, for the *trans*-isomer, which shows, as expected, only a subtle difference between the two isomers. From the integral ratios of the methyl groups of both the 1-phenyl-1-propyne and acetonitrile ligands, the *cis*- to *trans*-isomer ratio was determined to be approximately 55:45.

The most obvious difference between the two isomers was the number of alkyne contact carbon resonances. The *trans*

complex has four resonances at 175.77 (Ph*C*≡CMe), 168.56 (Ph*C*≡CMe), 161.56 (PhC≡*C*Me), and 160.31 (PhC≡*C*Me) ppm, due to their unequal environments, whereas the *cis*-isomer has only two alkyne contact carbon resonances at 168.70 (2 × Ph*C*≡CMe) and 162.93 (2 × PhC≡*C*Me) ppm. This difference was also supported by the presence of two methyl group signals for the alkynes of the *trans*-isomer (PhC$_2$*Me*) (21.43 and 17.75 ppm) and the presence of only one signal for the equivalent alkynes of the *cis*-isomer (PhC$_2$*Me*) (20.90 ppm). In both cases, the alkynes are donating an average of three electrons each to the tungsten centre, determined from Templeton and Ward's correlation (24) of the number of electrons donated by an alkyne and the alkyne contact carbon chemical shift, which also enables complex **1** to obey the effective atomic number rule.

The solid state structure of **1** was determined by X-ray crystallographic methods (Fig. 2). The formal geometry is eight-coordinate, however, if each alkyne is regarded as occupying one coordination site, the complex can be described as six-coordinate, which is more convenient when considering the local geometry of each ligand. The carbonyl ligand is *trans* to the acetonitrile group, the two alkyne moieties are mutually *cis*, and each alkyne is *trans* to an iodine atom. This arrangement is characteristic of bis(alkyne) complexes

I(2)-W(1)-I(3)	83.45(6)	I(3)-W(1)-I(2)	83.03(4)	I(2)-W(1)-I(3)	83.30(8)

of this type and is comparable to those of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me, Ph) (8). The structure of **1** (Fig. 2) shows the opposite arrangement of alkyne ligands to that proposed by Baker and co-workers (8), in which the methyl groups of the 1-phenyl-1-propyne ligand were thought to be *cis* to the carbonyl moiety due to intramolecular effects in the structures of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me, Ph) (8). The alkyne and CO ligands are competing for the same π-electron density as the tungsten atom (1), which is why the W—C(CC) bonds nearest the W-CO unit are longer than the W—C(CC) bonds *cis* to the poor π-acceptor NCMe ligand.

The W—I bond lengths for **1** are 2.842(2) and 2.875(2) Å, respectively (Table 6), which are similar to those of analogous complexes $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ (2.843(1) and 2.859(1) Å) and $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ (2.848(1) and 2.862(2) Å) (8). The internal angle for **1** (I(2)-W(1)-I(3)) of 83.45(6)° (Table 7) is comparable with those of $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ and $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ at 83.51(4) and 83.96(4)°, respectively (8). The bond lengths of the two alkyne carbons with the methyl substituents of **1** (W(1)—C(2) and W(1)—C(3)) were found to be 2.048(10) and 2.058(10) Å, respectively, and are slightly longer than the analogous bond lengths for $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$, but comparable to those of $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ (8). It has been previously observed (1) that the C≡C bond lengths are insensitive to whether the alkyne ligand is donating 2, 3, or 4 electrons to the metal in these systems.

The alkyne carbons with phenyl substituents were found to have bond lengths to W of 2.099(9) and 2.101(9) Å for W(1)—C(1) and W(1)—C(4), respectively, which are comparable with related carbons of $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ (2.099(15) and 2.119(15) Å) and $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ (2.070(16) and 2.083(15) Å) (8). In complex **1**, the two carbons C(1) and C(4), which are closest to the carbonyl group, have a longer bond than that between C(2) and C(3), which are closer to the nitrile substituent. This difference is probably due to steric effects between the alkyne substituents and the carbonyl group, and is also observed for the 2-butyne and diphenylacetylene analogues (8). The tungsten—carbonyl bond length in **1** (W(1)—C(200)) of 2.012(10) Å compares with that of $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ (8) at 2.018(17) Å, rather than $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ (8) at 1.937(14) Å, which is expected as the immediate environments of the carbonyl carbon (*cis* to alkynes with phenyl substituents) are more alike.

The data for complex **1** is slightly different to that previously reported (8) due to both *cis* and *trans* isomers being identified and the data being assigned by careful comparison with the series of analogues (**2**–**5**). This has enabled a more accurate assignment of data such that individual isomers can be distinguished rather than just the *cis*-isomer, as originally reported (8).

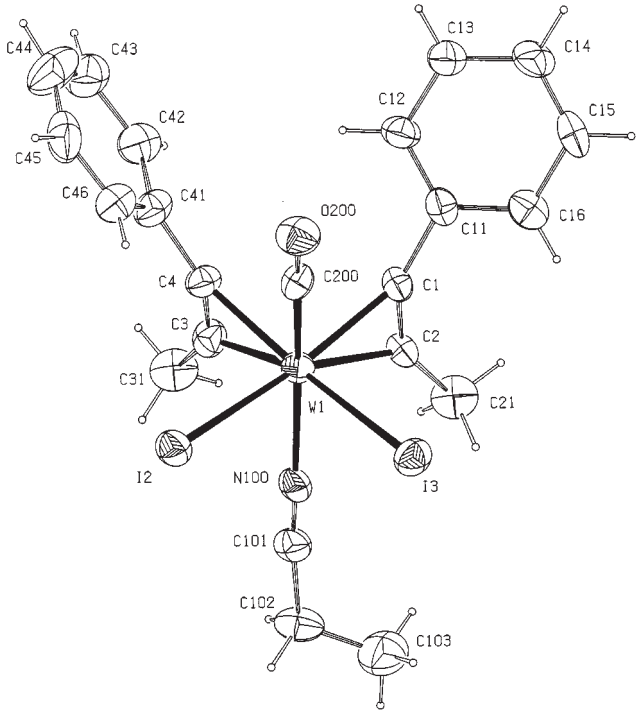
Fig. 3. Crystal structure of $[WI_2(CO)(NCEt)(\eta^2\text{-}MeC_2Ph)_2]$ (**2**).



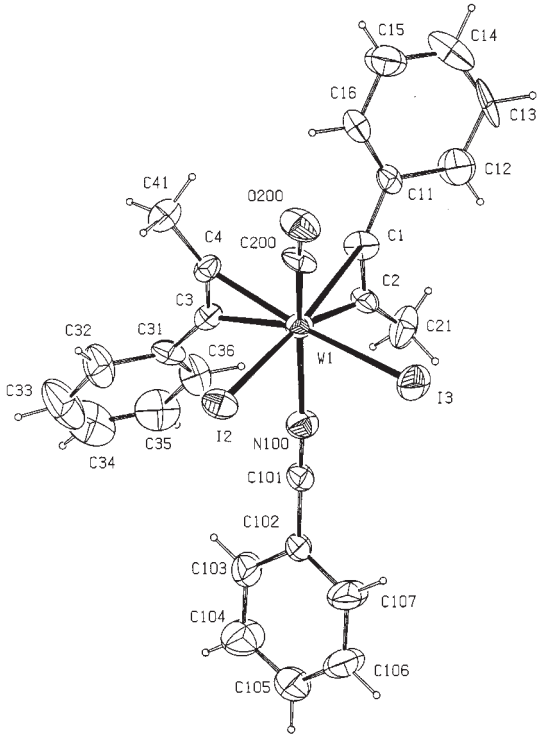


Fig. 4. Crystal structure of $[WI_2(CO)(NCPh)(\eta^2\text{-}MeC_2Ph)_2]$ (**5**).

Preparation and characterization of the nitrile exchanged bis(1-phenyl-1-propyne) complexes $[WI_2(CO)(NCR)(\eta^2\text{-}MeC_2Ph)_2]$ (R = Et, *i*-Pr, *t*-Bu, and Ph) (2–5)

Equimolar quantities of **1** and NCR (R = Et, *i*-Pr, *t*-Bu, Ph) were mixed in CH_2Cl_2 at room temp to give the acetonitrile-exchanged products $[WI_2(CO)(NCR)(\eta^2\text{-}MeC_2Ph)_2]$ (**2**–**5**) in high yield. In all four complexes, complete exchange of the acetonitrile ligand was observed, with no residual peaks attributable to the acetonitrile group detected in any of the spectroscopic data of complexes **2**–**5**. Complete nitrile exchange occurs with the reaction of one equivalent of NCR because acetonitrile is the most labile ligand in the complex and,hence, is completely exchanged. At room temp, the addition of excess NCPh, for example, to **1** for 6 h affords only **1** and NCPh.

Complexes **2**–**5** were fully characterized by elemental analysis (C, H, and N), IR spectroscopy, ^{1}H NMR spectroscopy, and $^{13}C\{^1H\}$ NMR spectroscopy (Tables 1–4). The complexes are soluble in chlorinated solvents and acetonitrile, but insoluble in diethyl ether and hydrocarbon solvents. All four complexes are less stable than **1**, in the solid state, with deterioration apparent in solid samples stored at –17°C for over six weeks.

The IR spectra of complexes **2**–**5** (Table 2) all show a strong carbonyl stretching band between 2081 and 2074 cm^{-1}, a weak nitrile stretching band between 2294 and 2274 cm^{-1}, and a weak alkyne band at either 1594 or 1595 cm^{-1}. The ^{1}H NMR spectra of **2**–**5** (Table 3) show multiplets at around 7.75–6.96 ppm due to the phenyl group of both *cis*- and *trans*-isomers and, in the case of complex **5**, the phenyl moiety of benzonitrile for both isomers. The methyl groups of 1-phenyl-1-propyne and the expected signals for each nitrile substituent were detected as distinct signals for each isomer of **2**–**4** (Table 3). Using integral ratios from the ^{1}H NMR spectra, the *cis*:*trans* isomer ratio for all four complexes (**2**–**5**) was determined to be approximately 55:45, which is similar to the isomer ratio obtained for the acetonitrile complex (**1**). This suggests that there is a common equilibrium of isomeric forms in solution, regardless of which isomer is preferred in the solid state.

The $^{13}C\{^1H\}$ NMR spectra of **2**–**5** (Table 4) were also assigned for both the *cis*- and *trans*-isomers, as described earlier for complex **1**, but with the presence of signals associated with each of the nitrile ligands. For complexes **2**–**5**, the chemical shifts of the alkyne contact carbons show an average of three-electron donation per 1-phenyl-1-propyne to the tungsten centre (24), thus enabling all the complexes to obey the effective atomic number rule.

Complexes **2** and **5** were structurally characterized by X-ray crystallography as the *cis*- and *trans*-isomers, respectively (Figs. 3 and 4) using suitable single crystals grown from dichloromethane–diethyl ether solution (3/8 by volume, cooled to –17°C for 48 h (**2**), 2/3 by volume, cooled to –17°C for 24 h (**5**)). It is probable that the bulky phenyl group of benzonitrile in complex **5** favours the *trans*-isomer in the solid state, with both isomers being detected in solution, as previously described. The molecular structure of **5** contains one molecule of dichloromethane, which was not apparent in subsequent elemental analyses or in ^{1}H or $^{13}C\{^1H\}$ NMR data performed using solid collected from the mother liquor (rather than crystals themselves, as only enough crystals for X-ray crystallography were obtained).

As for **1**, both **2** and **5** are formally eight-coordinate, but can be regarded as six-coordinate by considering each alkyne as occupying one coordination site. For **2**, which is isomorphous with **1**, the carbonyl ligand was found to be *trans* to the propionitrile group, with the two alkyne moieties

© 2001 NRC Canada

mutually *cis* and each alkyne *trans* to one iodine atom, as observed for complex **1**, and the previously described complexes $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me, Ph) (8).

The W—I bond lengths for **2** (2.8666(12) and 2.9021(11) Å) (Table 6) are slightly longer than those of **1**, and the internal angle (I(2)-W(1)-I(3)) of 83.03(4)° (Table 7) is less than that of **1**. The W—N bond lengths for **1** and **2** of 2.164(8) and 2.169(12) Å, respectively, are comparable, and the bond length between the nitrogen and its adjacent carbon atom (C≡N) were shown to be 1.088(12) Å for **1** and 1.129(19) Å for **2**.

The crystal structures of two similar complexes, $[WI_2(CO)(NC\textit{t}\text{-}Bu)(\eta^2\text{-}MeC_2Me)_2]$ (25) and $[WI_2(CO)(NCPh)(\eta^2\text{-}MeC_2Me)_2]$ (26), have been previously reported. These complexes were obtained from the addition of excess 2-butyne to $[WI_2(CO)_3(NC\textit{t}\text{-}Bu)_2]$ and $[WI_2(CO)_3(NCPh)_2]$, respectively. The nitrile exchange complex $[WI_2(CO)\{NCCH_2(C_3H_4S\text{-}3)\}(\eta^2\text{-}MeC_2Me)_2]$ (27) has also been structurally characterized. The W—N bond lengths for $[WI_2(CO)(NCR)(\eta^2\text{-}MeC_2Me)_2]$ (R = *t*-Bu, Ph, and $NCCH_2(C_3H_4S\text{-}3)$) are 2.175(9), 2.15(2), and 2.13(4) Å, respectively, which are sufficiently similar to conclude that the nature of the R substituent does not affect the length of W—N bond to any significant degree. The crystal structure of **5** shows the *trans* arrangement of alkynes (Fig. 1) and is the first bis(alkyne) tungsten(II) complex of the type $[WI_2(CO)(NCR)(\eta^2\text{-}R'C_2R'')]$ (R = alkyl or aryl group; $R' \neq R''$) to be crystallographically characterized for the *trans*-isomer, which was initially thought to be unfavoured (8). In complex **5**, the carbonyl ligand was found to be *trans* to the benzonitrile group, with the two alkyne moieties mutually *cis*, and each alkyne *trans* to one iodine atom, as observed for complexes **1** and **2** and the literature complexes $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me, Ph) (8). The major difference between **1**, **2**, and **5** is the position of the alkyne substituents. In **1** and **2**, the two phenyl groups of 1-phenyl-1-propyne are next to one another (*cis*-isomer), whereas in **5** the two phenyl groups are opposite one another (*trans*-isomer).

The crystal structure of the bis(2-butyne) complex $[WI_2(CO)(NCPh)(\eta^2\text{-}MeC_2Me)_2]$ has been reported by Baker and co-workers (26) and, due to the symmetric alkyne, has no isomeric forms as encountered for **1**, **2**, and **5**. The W—I bond lengths for **5** (2.872(3) and 2.909(3) Å) are comparable with those of $[WI_2(CO)(NCPh)(\eta^2\text{-}MeC_2Me)_2]$ (2.8613(13) and 2.8407(13) Å), and the internal angle (I(2)–W(1)–I(3)) of 83.30(8)° is similar to that of $[WI_2(CO)(NCPh)(\eta^2\text{-}MeC_2Me)_2]$ at 83.53(4)°. The W—N bond length (2.171(14) Å) and the bond length between the nitrogen and its adjacent carbon atom (C≡N) (1.12(2) Å) for **5**, are also in good agreement with those of $[WI_2(CO)(NCPh)(\eta^2\text{-}MeC_2Me)_2]$ (W—N = 2.15(2) and C≡N = 1.12(2) Å). These similarities suggest that the different alkynes do not overly affect the other tungsten—ligand bonds in complexes **5** and $[WI_2(CO)(NCPh)(\eta^2\text{-}MeC_2Me)_2]$ (26).

The tungsten—carbon(carbonyl) bond length for **5** (2.054(16) Å) shows that the *trans*-isomer compares well with analogous bond lengths for complexes **1** and **2** (2.012(10) and 2.043(15) Å, respectively). The alkyne carbon—tungsten bond lengths for **5** (2.04(2), 2.117(15) (*Me*), 2.145(17), and 2.110(18) (*Ph*) Å) are all quite similar, with the W—C(R) bond (for R = Me) being shorter than the W—C(R′) bond (for R = Ph), which can explained in terms of the electron withdrawing–donating properties of the different substituents. Despite the fact that **5** is the *trans*-isomer, there is very little difference in the angles subtended at the metal centre compared to the *cis*-forms of **1** and **2**, as is apparent from Table 7. We found no evidence that intermolecular effects, including π-stacking, were a significant factor in the preference of isomer formed.

In the three crystallographically characterized complexes **1**, **2**, and **5**, the average back bend angle (β) (28) was calculated from the R–C≡C and R′–C≡C angles, and all were in the region of 30–40°, as expected (1, 2, 27). The angles were found to be: **1** (36.5 (Me) and 34.2° (Ph)), **2** (35.8 (Me) and 37.0° (Ph)), and **5** (36.4 (Me), 41.0 (Me), 32.9 (Ph), and 34.8° (Ph)).

N′-tert-Butyl-*N′*-aroyl-*N*-(alkoxycarbonylmethyl)-*N*-aroylhydrazines, a novel nonsteroidal ecdysone agonist: syntheses, insecticidal activity, conformational, and crystal structure analysis

S. Cao, X. Qian and G. Song

Abstract: Seventeen *N′-tert*-butyl-*N′*-aroyl-*N*-(alkoxycarbonylmethyl)-*N*-aroylhydrazines were synthesized, and their insecticidal activities against armyworm (*Leucania separata* (Walker)) were tested. The conformation and structure of compound **1b** was studied by ^{1}H NMR spectroscopy and X-ray crystallography. The crystal structure belongs to the orthorhombic system and the N—N bond adopts a *gauche* conformation, which was assumed to be the active conformation, with a dihedral angle of 69.9°.

Key words: N′-tert-butyl-*N′*-aroyl-*N*-(alkoxycarbonylmethyl)-*N*-aroylhydrazine, syntheses, insecticidal activity, conformation, crystal structure.

Résumé : On a effectué la synthèse de dix-sept *N′-tert*-butyl-*N′*-aroyl-*N*-(alkoxycarbonylméthyl)-*N*-aroylhydrazines et on a évalué leur activités insecticides contre la légionnaire uniponctuée (*Leucania separata* (Walker)). On a étudié la conformation et la structure du composé **1b** par RMN du ^{1}H et par diffraction des rayons X. La structure cristalline fait partie du système orthorhombique et la liaison N—N adopte une conformation *gauche*, qui devrait être la conformation active, avec un angle dièdre de 69,9°.

Mots clés : *N′-tert*-butyl-*N′*-aroyl-*N*-(alkoxycarbonylméthyl)-*N*-aroylhydrazine, synthèse, activité insecticide, conformation, structure cristalline.

[Traduit par la Rédaction]

Introduction

RH-5849 and RH-5992 are two well-known synthetic nonsteroidal ecdysone agonists mimicking the molting hormone (20-hydroxyecdysone) in larval insects, and exhibiting insecticidal activity by inducing premature and incomplete molting of larvae, but show low toxicity to nontarget species (1–3). Researchers use RH-5849 as a prototype compound and then introduce various substituents on phenyl rings or the nitrogen atoms of the compound to optimize moulting hormone, as well as insecticidal activity (4, 5).

In the course of our studies on diacylhydrazine (6), we were interested in *N*,*N′*-disubstituted diacylhydrazines because, up to now, there was no clear explanation as to why when the hydrogen of the second nitrogen atom of diacylhydrazine was replaced with other groups the compound still retained its activity. In this paper, we introduce a polar group (an ester group to the atom of another nitrogen) in order to enhance the lipophilicity and broaden the spectrum of insecticidal activity of *N-tert*-butyl diacylhydrzide (Fig. 1). The preliminary bioassay tests show that some compounds exhibited good insecticidal activity on armyworm (*Leucania separata* (Walker)). The lowest LC_{50} was 6 ppm.

Experimental

All chemicals were obtained from Shanghai Chemical Reagent company Ltd. and used without further purification. Infrared spectra were done using a Nicolet 20SX FT-IR instrument. Mass spectra were recorded on a HITACHI M80 mass spectrometer using electron impact (EI) as the ion source and reported as *m*/*z*. Proton NMR spectra were obtained on a Bruker-AC 500 (500 MHz) spectrometer using $CDCl_3$ or DMSO-d_6 as the solvent and were reported in parts per million (δ) downfield from tertramethylsilane (internal reference). The analyses for elemental composition were undertaken with an Italy MOD-1106 analyzer. Isolation and purification were done by column chromatography on silica gel 60 (300–400 mesh). Analytical thin layer chromatography (TLC) was carried out on precoated plates (silica gel 60 F_{254}), and melting points were uncorrected.

Scheme 1.

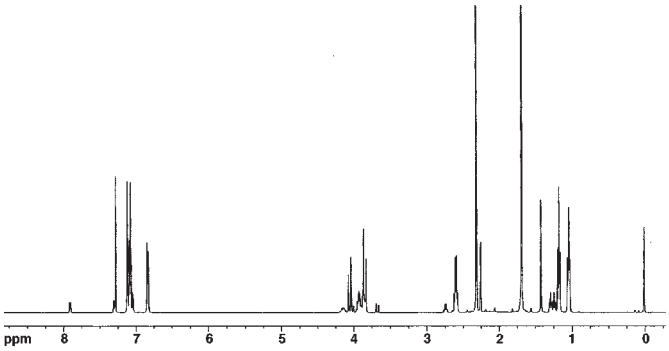
General synthetic procedures

Synthesis of symmetrical N-tert-*butyl diaroylhydrazines (2a–9a, 11a)*

tert-Butylhydrazine hydrochloride (4.98 g, 4 mmol) was dissolved in methylene chloride (20 mL). To this solution was added 10% aqueous sodium hydroxide (4.8 mL, 12 mmol). A solution of appropriate acid chloride (8 mmol) in methylene chloride was then added at 0–5°C to the rapidly stirring two-phase system. A white precipitate was formed in 4 h. The mixture was filtered and recrystallized from ethanol–water to give the desired compound in good yield, generally in the range of 70–90%.

Synthesis of unsymmetrical N-tert-*butyl diaroylhydrazines (1a, 10a, 12a–17a)*

N-tert-Butyl aroylhydrazine (25 mmol) was stirred vigorously in a two-phase system of methylene chloride (50 mL) and 10% aqueous sodium hydroxide (25 mL, 63 mmol) until all dissolved. To this solution was added a solution of acid chloride (25 mmol) in methylene chloride (25 mL). After 4–6 h at room temp, the solid was removed and washed with water. Recrystallization from ethanol gave the desired compound in high yield (70–90%).



Synthesis of N′-*tert-butyl*-N′-*aroyl*-N-*(alkoxycarbonylmethyl)-N-aroylhydrazines (1b–17b)*

A mixture of *N-tert*-butyl diaroylhydrazine (3 mmol, **1a–17a**), sodium hydride (3.2 mmol, 60% suspension in paraffin oil), and dry DMF (15 mL) was stirred at room temp for 2 h. To the mixture was added ethyl bromoacetate or methyl bromoacetate (3 mmol) and dry DMF (2 mL). The reaction mixture was stirred at 35–40°C for 8–10 h. After cooling the mixture was treated with water (30 mL) and extracted with chloroform (3 × 15 mL). The organic layer was washed with water, dried $MgSO_4$, and concentrated. The residue was chromatographed over a column of silica gel and eluted with petroleum ether–ethyl acetate (2:1) (60–90°C). The title compounds were obtained (Scheme 1). The preparative and spectral data of **1a–17a** and **1b–17b** are listed in Tables 1–4.

Synthesis of N-*(ethoxycarbonylmethyl) dibenzoylhydrazine (18)*

Ethyl hydrazinoacetate hydrochloride ($NH_2NHCH_2CO_2C_2H_5 \cdot HCl$) (0.62 g, 4 mmol) was dissolved in methylene chloride (20 mL). To this solution was added 10% aqueous sodium hydroxide (4.8 mL, 12 mmol). A solution of benzoyl chloride (1.12 g, 8 mmol) in methylene chloride was then added at 0–5°C to the rapidly stirring two-phase system. A white precipitate was formed in 6 h. The mixture was filtered and recrystallized from ethyl acetate. A colourless solid was obtained in a yield of 74%, mp 108–109°C. EI-MS *m/z* (%): 327 ($[M+1]^+$, 19), 309 (78), 253 (19), 122 (28), 105 (46), 77 (100). FT-IR (KBr) (cm^{-1}): 1745, 1680, 1650. ^{1}H NMR ($CDCl_3$) δ: 1.28 (t, J = 7.2 Hz, 3H), 4.20 (t, J = 7.2 Hz, 2H), 4.64 (br s, 2H), 7.27–7.62 (m, 10H), 8.60 (s, NH). Anal. calcd. for $C_{18}H_{18}N_2O_4$: C 66.25, H 5.56, N 8.58; found: C 66.06, H 5.44, N 8.52.

Fig. 1. ^{1}H NMR spectrum of compound **1b**.

Results and discussion

Chemical

When the crude products (**1b–17b**) were purified by column chromatography, *N-tert*-butyl substituted benzamide by-products were also obtained (yield 10–15%), including *N-tert*-butyl benzamide, *N-tert*-butyl-4-fluoro-benzamide, *N-tert*-butyl-4-ethylbenzamide, and *N-tert*-butyl-4-methoxy benzamide (structures were determined by ^{1}H NMR). Reaction at higher temperature (50–60°C) yielded 20–25% of these by-products. When the substituted group attached to the aromatic ring was a strong electron-releasing or -withdrawing group, such as CH_3O- or $-NO_2$, the main product was *N-tert*-butyl substituted benzamide; the desired product was not obtained. The results showed that the N—N bond was easily cleavaged in a NaH–DMF system.

The ^{1}H NMR spectrum (in $CDCl_3$) of **1b** clearly showed that there exist two conformational isomers (Fig. 1). The ratio of isomer **A** (major) to isomer **B** (minor) is approximately 85:15. In the ^{1}H NMR spectrum of **1b**, the signals for most of the protons of minor isomer are shifted downfield as compared to the corresponding signals of the major isomer (**A**), while the signals of $(CH_3)_3$, CH_3Ar, and NCH_2CO_2 are upfield shifted. The geminal hydrogens of NCH_2CO_2 are not magnetically equivalent and, therefore, are coupled with each other (J = 17.9 Hz). Similarly, each line of the methylene hydrogens quartet ($CO_2CH_2CH_3$) is further split to a doublet due to the methylene hydrogens having different magnetic environments. Similar results were observed from the ^{1}H NMR spectra of **2b–17b**. ^{1}H NMR

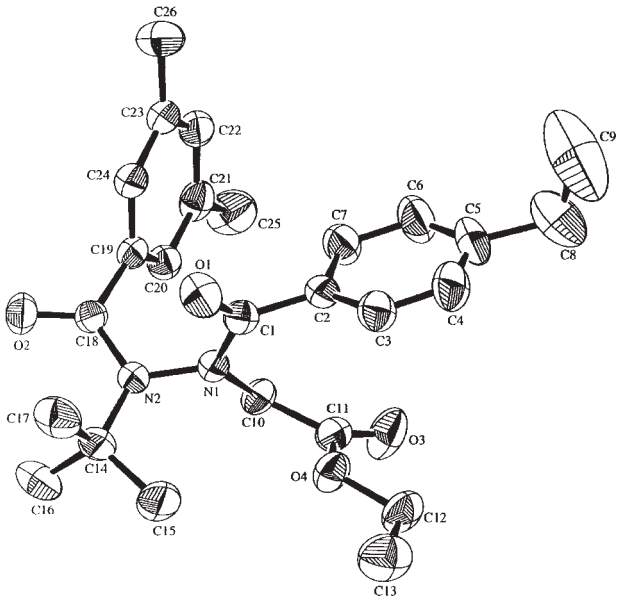
spectra of **2b**–**17b** reveal that the introduction of an ester group to another nitrogen may cause the molecular rotations around the N—N bond to be "frozen" sufficiently for these differences to be detected.

Biological Activities



Insecticidal activity was assessed with third-instar larvae of *Leucania separata* (Walker). The method was similar to the procedure described in the literature (11). Compounds were dissolved in DMF, and water was serially diluted to achieve the desired range of concentrations (ppm). For each concentration, 20–40 insects were used and at least six different concentrations were applied in order to calculate LC_{50} values (ppm). Insecticidal activities of the new 10 compounds (**1**–**3b**, **7b**, **13**–**17b**) were shown in Table 5. Of the other eight compounds (**4b**, **5b**, **8**–**12b**, **18b**), the LC_{50}

Fig. 2. X-ray crystal structure of compound **1b**.

values were not determined as they showed no, or attenuated, biological activity at concentrations as high as 500 ppm.

In general, unsymmetrical *N′-tert*-butyl-*N*-(alkoxycarbonylmethyl)-*N′*,*N*-diaroylhydrazines are more active than symmetrical *N′-tert*-butyl-*N*-(alkoxycarbonylmethyl)-*N′*,*N*-diaroylhydrazines, and the activitives of halogen-containing symmetrical compounds are higher than those of non halogen-containing compounds. Comparison of the observed activity values of **1b**, **5b**, **8b**–**15b**, and **17b** with their parent compound (**2b**) showed that the activity of multialkyl-substituted compounds varied drastically, with activity dependent on the type, number, and position of substituents. Although **1b** was found to be one of the most active compounds, exchange of the position of the *tert*-butyl and ester groups (**13b**) resulted in a significant loss of activity. Replacement of the *tert*-butyl group on the hydrazine (**2b**) by a hydrogen atom gave an inactive compound (**18**). These results suggest that the bulky *tert*-butyl group and its position is critical to the activity. This is in agreement with observations of Chan et al. (9) and Hsu et al. (10).

X-ray crystal structure of 1b

Three of the products (**1b, 3b**, and **15b**) showed potent insecticidal activity on armyworm. They were weaker than tebufenozide (RH-5992), but they were more potent than RH-5849. These results are not inconsistent with the literature (10), which suggest that when the hydrogen of the secondary nitrogen atom (NH) was substituted with an unhydrolyzable group the compound tends not to be active.

The X-ray crystal structure of RH-5849 was reported previously by Chan et al. (9), who suggested that the N—N bond in RH-5849 adopts a *gauche* conformation with a dihedral angle of –71.8 or –58.1°, and that this conformation is essential to the activity of the molecule. In order to explain why replacement of the hydrogen on the nitrogen of *N-tert*-butyl diaroylhydrazine by an ester group (or another group) still gave an active compound, we studied the X-ray crystal structure of **1b** (Fig. 2). Different from the two conformations of **1b** observed in a $CDCl_3$ solution (^{1}H NMR of **1b**, see Fig. 1), only one conformation exists in the crystalline state. Structure analysis reveals that the N—N bond in **1b** also adopts a *gauche* conformation. A dihedral angle of 69.9° for C(1)-N(1)-N(2)-C(18) is also observed, but its direction of rotation is opposite to that of RH-5849. Similar to the crystal of RH-5849, the amide bearing the *N*-ester group has an *s-cis* conformation, whereas the amide bearing the *N-tert*-butyl group has an *s-trans* conformation, with the steric bulk of the *tert*-butyl group causing the phenyl group to be directed away from the molecule. The dihedral angle between two phenyl rings is 96.11°, which is much larger, compared to the data of RH-5849 (66.3 or 60.8°), due to the ester group pushing the phenyl ring upward. To further

elucidate structural details of **1b**, we studied the conformations and energies of this compound using the PCMODEL method. The energy minimum conformation of **1b** is similar to that obtained from the X-ray crystal structure of **1b**. Therefore, based on the results from X-ray crystal structure analysis and the PCMODEL method, we can suggest that the major conformational isomer in solution may also adopt the *gauche* conformation.

Crystallographic experimental details

Crystal data for **1b** ($C_{26}H_{34}N_2O_4$). MW = 438.57 g mol^{-1}. Recrystallized from ethyl acetate. Orthorhombic space group, *a* = 21.842(3), *b* = 24.375(4), *c* = 9.559(3) Å. *V* = 5089(1) $Å^3$, space group *Pbca* (no. 61), *Z* = 8, D_{calcd} = 1.14 g cm^{-3}, *F*(000) = 1888.00, μ (Mo Kα) = 0.77 cm^{-1}, *T* = 293 K. Of the 5028 unique reflections measured, 1735 [I 2.50σ(I)] were used in refinement. *R* = 0.055, *wR* = 0.059. The experimental data were collected on a Rigaku AFC7R diffractometer using graphite monochromated Mo K α radiation (λ = 0.71069 Å). The structure was solved by direct methods and expanded using Fourier techniques. All calculations were performed using the teXan crystallgraphic software package of Molecular Structure Corporation.

Conclusions

Good insecticidal activities were obtained when the ester group was introduced to the hydrazine linkage. The crystal structure showed that the introduction of the ester group at the second nitrogen may cause the steric repulsion between the ester and the *tert*-butyl group, but the basic conformation (active conformation) is unchanged. These results can give a clear explanation to the fact why many *N′-tert*-butyl-*N*-substituted-N, *N′*-diaroylhydrazines are still active, and have encourage us to pursue the search of new, more effective analogues as promising pesticidal candidate through the modification of the second nitrogen of hydrazine.

Overtone intensities in neopentane and tetramethylsilane

Michael W. P. Petryk and Bryan R. Henry

Abstract: The CH vibrational overtone transitions of vapour phase neopentane-d_0, -d_6, -d_9, and tetramethylsilane (TMS) are investigated via conventional absorbance spectroscopy and intracavity laser photoacoustic spectroscopy (ICL-PAS). The CH stretching overtones of neopentane-d_0 are observed in the energy range $\Delta v_{CH} = 3$–9 (8 400 to 22 000 cm^{-1}) and in the range $\Delta v_{CH} = 3$–8 for the remaining neopentanes and TMS. While we have extended the range of previous studies, our main focus in this work has been on overtone intensities. The oscillator strengths of the neopentane-d_0 overtone transitions are determined directly by conventional absorbance spectroscopy for $\Delta v_{CH} = 3$–6 and via ICL-PAS with methane as an internal standard for $\Delta v_{CH} = 4$–7. The correspondence of measured intensities for the two techniques demonstrates the usefulness of the latter for higher overtone ICL-PAS spectra. The experimentally determined Morse parameters $\widetilde{\omega}$ and $\widetilde{\omega}x$ as well as the harmonically coupled anharmonic oscillator (HCAO) model are used in conjunction with dipole moment functions that are derived from ab initio computations to calculate overtone transition intensities for the neopentanes and TMS.

Key words: local mode, overtone transition, absolute intensity, photoacoustic spectroscopy.

Résumé : Faisant appel à la spectroscopie d'absorbance conventionnelle et à la spectroscopie photoacoustique laser intracavité (SPA-LIC), on a étudié les transitions harmoniques vibrationnelles du CH, en phase vapeur, des néopentanes-d_0, -d_6, -d_9, et du tétraméthylsilane (TMS). Les harmoniques d'élongation du CH du néopentane-d_0 ont été observées sur la plage d'énergie $\Delta v_{CH} = 3$–9 (8,400 à 22,000 cm^{-1}) alors qu'on les observe sur la plage d'énergie $\Delta v_{CH} = 3$–8 pour les autres néopentanes et pour le TMS. Même si on a élargi les connaissances déjà acquises dans des études antérieures, le but principal du présent travail était d'examiner les intensités des harmoniques. On a déterminé les forces de l'oscillateur des transitions harmoniques pour le néopentane-d_0 soit directement par spectroscopie d'absorbance conventionnelle $\Delta v_{CH} = 3$–6 soit par le biais de la (SPA-LIC) $\Delta v_{CH} = 4$–7. La correspondance des intensités mesurées par les deux techniques démontre l'utilité de la dernière pour les harmoniques plus élevées des spectres de SPA-LIC. On a utilisé les paramètres de Morse obtenus expérimentalement, $\widetilde{\omega}$ et $\widetilde{\omega}x$, le modèle de l'oscillateur anharmonique couplé de façon harmonique ainsi que les fonctions de moment dipolaire dérivées de calculs ab initio pour calculer les intensités de la transition harmonique des néopentanes et du TMS.

Mots clés : mode local, transition harmonique, intensité absolue, spectroscopie photoacoustique..

[Traduit par la Rédaction]

Introduction

The vibrational overtone stretching transitions of XH bonds (X = C, N, O, etc.) are dominated by transitions to states whose components have all of the vibrational energy localized within one of a series of equivalent XH oscillators. This apparent localization of energy in a single bond makes the overtone spectra of large molecules appear very simple. In the absence of coupling, one transition peak is observed for each non-equivalent XH bond. Furthermore, the localization of energy in XH oscillators makes overtone spectroscopy an extremely sensitive probe for detecting changes in molecular environment (1, 2) which can manifest themselves as small changes in structural parameters such as bond length (3–5), and conformation (2, 6).

In the absence of very strong coupling we would expect the overtone transitions of neopentane-d_0 ($C(CH_3)_4$), -d_6 ($C(CH_3)_2(CD_3)_2$), and -d_9 ($C(CH_3)(CD_3)_3$) to be simple, with only one transition peak. In fact, the overtone transitions of neopentane have complicated structures and the CH overtone transitions themselves are much broader than those of other $M(CH_3)_4$ homologues (7, 8). This investigation has been undertaken to obtain more accurate, higher energy CH stretching overtone spectra of neopentane-d_0, -d_6, -d_9, and tetramethylsilane (TMS) ($Si(CH_3)_4$) than are currently available as a first step towards determining which factors might contribute to the anomalous profiles of the neopentanes.

Previously, the vibrational overtones of gas (7–11) and liquid (7, 12, 13) phase neopentane-d_0, as well as neopentane-d_6 and -d_9 (10, 11) have been studied with conventional absorption spectroscopy (7, 9–14), Raman spectroscopy (13), and intracavity laser photoacoustic spectroscopy (ICL-PAS) techniques up to seven quanta of stretching excitation (8) in the vapour phase. The overtone spectra of TMS have been studied in the vapour (7, 8, 15, 16) and liquid (7, 17–21) phases with conventional absorption spectroscopy (7, 15), ICL-PAS (8, 16), and piezoelectric detection (18–21) methods at energies of up to seven quanta of CH stretching excitation (8) in the vapour phase.

For CH stretching the off-diagonal coupling terms of the molecular Hamiltonian (represented in a local mode basis) are small compared to the diagonal cubic and quartic terms (22). Furthermore, the differences in magnitude between the energy

contributions from the cubic and quartic terms and the off-diagonal coupling terms increase with increasing vibrational excitation. The net result is that the potential of a molecule with a number of anharmonic oscillators is effectively separable, and the molecule can be treated as a collection of diatomic Morse potentials, in which, couplings are taken as perturbations (23). Morse potentials have an advantage over some more generalized functions in that their wave functions can be solved analytically (23). The basis states for a series of XH Morse oscillators can be conveniently written as $|\upsilon_1\rangle|\upsilon_2\rangle, \ldots, |\upsilon_i\rangle, \ldots$ or simply as $|\upsilon_1\upsilon_2 \ldots \upsilon_i \ldots\rangle$,where υ_i is the number of vibrational quanta in the i^{th} XH oscillator. Spectrally "bright" states, i. e., those states which carry intensity from the $\upsilon = 0$ vibrational state, are pure local mode states which are well described by a linear combination of components in which all of the vibrational energy is localized ($|\upsilon 0 \ldots 0\rangle$, $|0\upsilon \ldots 0\rangle$, etc.). The pure local mode wave functions of three coupled, identical XH oscillators of local C_{3v} symmetry arising from the linear combination of these basis states may be denoted as $|\upsilon 00\rangle_{A_1}$ and $|\upsilon 00\rangle_E$. The various symmetrized components for these bright states approach degeneracy with increasing excitation so that symmetry effects are generally not observed for $\Delta v_{CH} \geq 3$. In cases where it is impossible to resolve the nearly degenerate states, it is useful to refer to them collectively as $|\upsilon 00\rangle_{A_1E}$. The local mode description (24–28) has been extended to multi-oscillator systems in the harmonically coupled anharmonic oscillator (HCAO) model (13, 28–30).

Absolute overtone transition intensities can be calculated from the transition dipole moment and vibrational wave functions. The wave functions of the ground and excited vibrational states are calculated from the experimental values of the local mode parameters (23, 28) $\widetilde{\omega}$, $\widetilde{\omega}x$, and γ' (the interoscillator coupling parameter for XH oscillators on the same atom X) within the HCAO model. A dipole moment function (DMF) is derived from ab inito calculations (31–33). The calculated intensities will be compared to measured values that are obtained both photoacoustically and by conventional absorption spectroscopy.

Experimental

Sample preparation

Neopentane-d_0 (Matheson Gas Products, 99.87%) was used without further purification. A gas chromatograph–mass spectrometer analysis revealed that the neopentane-d_0 contained no significant levels of impurities. Both neopentane-d_6 and neopentane-d_9 (Fisher, 99.9+%) were also used without further purification.

NMR grade tetramethylsilane (TMS) was obtained as a liquid (Aldrich, 99.9+%) and was degased by repeated freeze-pump-thaw cycles. Prior to its introduction into a spectrometric gas cell, TMS was dried by passing it through molecular sieves.

Conventional absorbance spectroscopy

A Varian Cary 5e UV–vis–near-IR conventional absorption spectrometer equipped with a gas cell was used to record overtone transitions in the range $\Delta v_{CH} = 3$–6. The spectral resolution of the Cary 5e is wavelength dependent: 0.7 cm^{-1} at 8 300 cm^{-1} ($\Delta v_{CH} = 3$), 1.2 cm^{-1} at 11 000 cm^{-1} ($\Delta v_{CH} = 4$), 1.8 cm^{-1} at 13 400 cm^{-1} ($\Delta v_{CH} = 5$), and 2.5 cm^{-1} at 15 900 cm^{-1} ($\Delta v_{CH} = 6$). The vacuum line and gas cells were evacuated to a pressure of about 10^{-2} torr (1 torr = 133.32 Pa) for at least 4 h prior to introducing the sample into a Wilks variable length gas cell fitted with Melles Griot BK7 Schott glass windows.

Intracavity laser photoacoustic spectroscopy

ICL-PAS is a technique which exploits the photoacoustic effect, i. e., ICL-PAS relies on the thermal generation of sound waves from an absorbing sample exposed to *modulated* incident light. An output coupler is chosen which nearly completely reflects the laser radiation back into the cavity, thereby maximizing intracavity power. The photoacoustic (PA) sample cell is positioned within the laser cavity to take advantage of the higher intracavity power levels and the longer effective path length. Intense laser excitation, combined with the essentially zero background noise of this technique, results in high sensitivity. Extraneous noise is further suppressed by referencing the acoustic detector to the excitation source modulator via a lock-in amplifier.

ICL-PAS has certain shortcomings. In particular, it is difficult to obtain absolute absorption intensities as the dependence of photoacoustic signal strength ($S(\nu)$) on various parameters cannot be easily extended to subtly different experimental conditions. At a frequency (ν), the relationship between the photoacoustic signal strength ($S(\nu)$), the incident light intensity ($I(\nu)$), the absorbance of the sample ($A(\nu)$), and $k(\nu)$ (some unknown component(s) accounting for numerous factors such as coupling gas pressure and temperature, cell dimensions, microphone location and sensitivity) can be expressed as (34, 35)

$$[1] \qquad S(\nu) = k(\nu)I(\nu)A(\nu)$$

Since the factor $k(\nu)$ depends upon so many variables it is impractical to evaluate experimentally for all possible experimental conditions, therefore, PA spectra typically yield only absorption intensities of a chromophore relative to other chromophores within the cell. The inferential assumption here is that $k(\nu)$ is invariant to changes in ν over the narrow range of frequencies encountered during a given spectral scan. This assumption is generally valid as typical ICL-PAS scanning ranges are 100 nm or less owing to instrumental limitations.

Our ICL-PAS setup has been described in detail elsewhere (36–38), and only a brief summary is supplied here. A 20 W Coherent Innova 200 argon ion laser is used to pump a Coherent 599 tunable dye laser or a broadband Coherent 890 Ti:sapphire (Ti:sapph) laser. The pump laser beam is mechanically chopped, and the output signal is referenced to the chopper and amplified, digitized, and exported to a personal computer where it is later normalized to the intracavity power. The Ti:sapph laser has three sets of optics (short wave, mid wave, and long wave) which enable it to scan a region from 9 300 to 14 700 cm^{-1} ($\Delta v_{CH} = 3$–5). By varying the dyes and the optics, the dye laser can access the region from 12 300 to 23 900 cm^{-1} ($\Delta v_{CH} = 5$–9). Tuning is accomplished via birefringent filters, which have resolutions of approximately 0.4 cm^{-1}.

The gas line and PA cell are evacuated to a pressure of 10^{-3} to 10^{-4} torr (1 torr = 133.32 Pa) for at least four hours prior to sample introduction to ensure complete dryness.

Table 1. The methane transitions which were used to obtain the absolute intensities of the neopentane-d_0 pure local mode transitions.

Normal mode transition	Energy[a] (cm^{-1})	Oscillator strength[b,c]	Nearest neopentane-d_0 local mode transition[a]
$3\nu_1+\nu_3$	11 250	$(1.92 \pm 0.05) \times 10^{-9}$	$\|400\rangle \leftarrow \|000\rangle$
$4\nu_1+\nu_3$	13 750	$(3.47 \pm 0.03) \times 10^{-10}$	$\|500\rangle \leftarrow \|000\rangle$
$5\nu_1+\nu_3$	16 160	$(6.01 \pm 0.06) \times 10^{-11}$	$\|600\rangle \leftarrow \|000\rangle$
$5\nu_1+\nu_3+(\nu_2$ or $\nu_4)$	17 360	$(4.71 \pm 0.06) \times 10^{-12}$	$\|700\rangle \leftarrow \|000\rangle$

[a] From ref. 40. The four fundamental CH_4 vibrations are the $\nu_1 = 2914\ cm^{-1}$ symmetric stretch, the $\nu_3 = 3020\ cm^{-1}$ asymmetric stretch, and the $\nu_2 = 1526\ cm^{-1}$ and $\nu_4 = 1306\ cm^{-1}$ bending modes.
[b] The conversion factor from intensity (I) expressed in (km amagat cm)$^{-1}$ to dimensionless oscillator strength (f) is $f = I \times 4.204 \times 10^{-13}$ (km amagat cm) (60).
[c] The oscillator strength for the $3\nu_1 + \nu_3$ transition (40) has been divided by 1.4 to account for intensity ascribed to unresolved rovibrational transitions (vide infra).

Absolute Oscillator Strength via ICL-PAS

As noted above, ICL-PAS allows the determination of the relative absorbances of chromophores within a sample, but does not allow *direct* determination of absolute absorbances. In order to obtain absolute absorbances with ICL-PAS, Perry et al. (39) have used the published methane absorbances of Giver (40) to calibrate their PA cell. An intracavity configuration is extremely sensitive to the alignment of the PA cell within the laser cavity. Thus their determination of the oscillator strengths of various deuterated methanes was only approximate.

It would be preferable in an intracavity configuration to employ an internal standard to assuage the limitations imposed by the dependence of intracavity power levels on cell alignment.

Previous determinations of absolute oscillator strengths via ICL-PAS have been carried out by Gutow et al. (41), who determined the absolute absorbances of the $\Delta v_{CH} = 5, 6$ transitions of ethane and ethylene with reference to the published absorption strengths of HD (42). Wong and Moore (43) have used methane as an internal standard to determine the $\Delta v_{CH} = 6$ overtone transition intensities of numerous alkanes, alkenes, and haloalkanes. Manzanares et al. (8) have used methane and ethylene as internal standards to determine the intensities of the $\Delta v_{CH} = 5, 6$ overtones of $M(CH_3)_4$ where M = C, Si, Ge, and Sn.

The choice of methane as an internal standard in the determination of the $\Delta v_{CH} = 4$–7 overtone transition intensities of neopentane (38) is an appropriate one as both molecules have overtone transition energies which are disparate enough that they will not overlap significantly, yet these gases have CH overtone transition energies which are similar enough to allow their overtone transition to be recorded in one continuous scan.

In order to compare the PA intensities of neopentane and methane in an ICL-PAS experiment it is important that both gases be exposed to identical spectral intensities within the laser cavity. Unlike intracavity laser absorption spectroscopy (ICLAS) where some 10^4 modes are active (44), the presence of a birefringent filter in the ICL-PAS laser cavity (vide supra) restricts the number of active modes to approximately fifteen. With only a few closely spaced modes oscillating around the center of the gain line, variations in inversion (and therefore in intensity) will be smeared out owing to the presence of spatially shifted standing wave patterns of these modes (45) within the (homogeneous) laser. The intracavity spectral intensities of modes whose wavelengths correspond to methane rovibrational transitions will not be different from those of neopentane, which is a broad bandwidth absorber.

The tacit assumption which is made when methane is used as an internal standard for neopentane in a phase-sensitive photothermal technique, such as ICL-PAS, is that both gases have similar deactivation efficiencies. Since our phase-sensitive detection scheme locks onto only one signal, mismatched deactivation efficiencies could lead to the loss of signal intensity and subsequent erroneous results.

The deactivation efficiencies of neopentane and methane are expected to be different. Large molecules such as neopentane and benzene undergo rapid and complete intramolecular vibrational energy redistribution (IVR) and, thus, are expected to have efficient vibrational deactivations. On the other hand, small molecules such as methane and methane-d_3 undergo IVR on a much longer time scale and, therefore, should have lower deactivation efficiencies than neopentane. The criterion for being able to use methane as an internal standard for neopentane is that both gases have comparable deactivation efficiencies *on the time scale of our experiment*.

The effect of the different deactivation efficiencies of methane and neopentane on our ICL-PAS system was investigated using phase-sensitive detection. In our laboratory setup, phase-sensitive detection is achieved by referencing the microphone to the mechanical chopper via a lock-in amplifier. The phase angle at which the PA signal is collected can be varied from 0° to 360° in increments of 0.025° relative to the duty cycle of the mechanical chopper. The signal maxima arising from the two different gases will occur at the same phase angle if the deactivation efficiencies of neopentane and methane are equivalent on the time scale of our ICL-PAS experiment.

The ratio of methane and neopentane was chosen to give comparable absorbances by the two gases. The laser was tuned to the excitation frequency of a neopentane overtone maximum and the phase angle was determined for maximum absorption. Similarly, the phase angle at the methane overtone maximum was determined. It was found that the phase difference was less than 3 degrees at each overtone and, thus, any difference in the deactivation efficiencies of the two gases is a negligible source of error in our experiment.

The methane transitions that were used to determine the neopentane-d_0 overtone intensities are listed in Table 1. The

[a] See ref. 40

intensities of these transitions were taken from Giver (40). It is important to note that in Giver's work, the rovibrational structure of the methane $3\nu_1+\nu_3$ transition was not resolved. However, our ICL-PAS instrumentation does resolve this structure. The effect of the unresolved rovibrational structure in Giver's work increases the apparent intensity of the $3\nu_1+\nu_3$ transition by 30%. This increase was calculated through a comparison of our resolved spectrum and its associated area with the corresponding area where rotational lines were broadened to produce a spectrum similar in appearance to that of Giver (40). Therefore, we have revised the intensity for the $3\nu_1+\nu_3$ transition in methane in Table 1 by dividing it by a factor of 1.4 (vide infra).

Giver (40) determined the absorption intensities by using the absorption minima between adjacent bands to define the limits of the integration. He made no attempt to correct for the overlap of adjacent bands. Correction factors (see Table 2) had to be determined to enable us to relate the area determined through a deconvolution of a spectrum in our work to the area obtained by a minimum to minimum integration.

Theory and calculations

Local modes of vibration and the HCAO model

The XH stretching overtone spectra can be interpreted within the local mode model of molecular vibration (24, 25). Within this model the XH stretching potential is often described as a Morse potential. The energy eigenvalues of a Morse oscillator can be rearranged to give the frequency ($\tilde{\nu}$) (in cm^{-1}) of an overtone transition from the ground state $\upsilon' = \upsilon \leftarrow \upsilon'' = 0$ in the form (46)

$$[2] \qquad \tilde{\nu} = \upsilon\tilde{\omega} - (\upsilon^2 + \upsilon)\tilde{\omega}x$$

The values of the Morse parameters $\tilde{\omega}$ and $\tilde{\omega}x$ are obtained from a fit of eq. [2]. The eigenstates are obtained within the HCAO model (9, 13, 28–30) in terms of Morse oscillator wave functions with the assumption of harmonic coupling between the CH oscillators (28).

Overtone intensities

Experimental intensities are conveniently expressed in terms of the dimensionless oscillator strength (f) (47). By applying the ideal gas law and using the appropriate physical constants (48) we obtain an expression for f in the form

$$[3] \qquad f = 8.0267 \times 10^{-7}(\text{torr m cm})\frac{1}{p\,l}\int A(\tilde{\nu}_{eg})\mathrm{d}(\tilde{\nu}_{eg})$$

[b] The spectrum was obtained by coadding two spectra.
[c] The spectrum was obtained by coadding six spectra.

where p is the gas pressure expressed in torr (1 torr = 133.32 Pa), l is the path length expressed in meters, and $A(\tilde{\nu}_{eg})$ is the absorbance as a function of frequency in wavenumbers (cm^{-1}), all at 298 K.

The intensity of a vibrational overtone transition can be calculated from HCAO wave functions and a suitable dipole moment function (DMF). The coupling between the methyl CH oscillators is treated within the HCAO model as pairwise interactions between the i^{th} and j^{th} internal displacement coordinates, which are q_i along CH_i and q_j along CH_j, respectively. Ab initio calculations have been used (31–33, 49, 50) to obtain discrete values for the dipole moment as a function of q_i and q_j. In the present paper, the values of the dipole moment were calculated as the bonds q_1 and q_2 were stretched or compressed about the equilibrium XH bond length r_e by ±30 pm in increments of 10 pm with all other molecular coordinates constant at their equilibrium values. The continuous DMF of two coupled XH oscillators is approximated by a fourth order Taylor series expansion along their internal stretch coordinates q_1 and q_2

$$[4] \qquad \boldsymbol{\mu}(q_1, q_2) = \sum_{i,j=1}^{i+j=4} \boldsymbol{\mu}_{ij} q_1^i q_2^j$$

where $\boldsymbol{\mu}_{ij}$ are the DMF derivatives

$$[5] \qquad \boldsymbol{\mu}_{ij} = \frac{1}{i!j!}\frac{\partial^{i+j}\boldsymbol{\mu}}{\partial q_1^i \partial q_2^j}$$

which were obtained by fitting an interpolating polynomial of degree $n-1$ to n ab inito values of the dipole moment. Terms up to fourth order were retained in eq. [4], including the pairwise mixed derivatives $\partial^2\boldsymbol{\mu}/\partial q_1^1 \partial q_2^1$, $\partial^3\boldsymbol{\mu}/\partial q_1^1 \partial q_2^2$, and $\partial^3\boldsymbol{\mu}/\partial q_1^2 \partial q_2^1$. It is especially important to include terms beyond linear as the second order derivatives $\partial^2\boldsymbol{\mu}/\partial q_1^2$ and $\partial^2\boldsymbol{\mu}/\partial q_2^2$ contribute significantly more intensity to overtone transitions than do the linear terms. As the methyl groups in neopentane and TMS are assumed to have local C_{3v} symmetry, the interactions of q_i or q_j with the remaining CH stretch coordinate q_k is generated by rotating the $\boldsymbol{\mu}(q_1, q_2)$ grid with a similarity transformation.

[b]The full width at half-maximum of the central peak from the deconvolution.
[c]The spectrum was obtained by coadding two spectra.

With the appropriate physical constants (48), the oscillator strength of an overtone transition can be expressed as

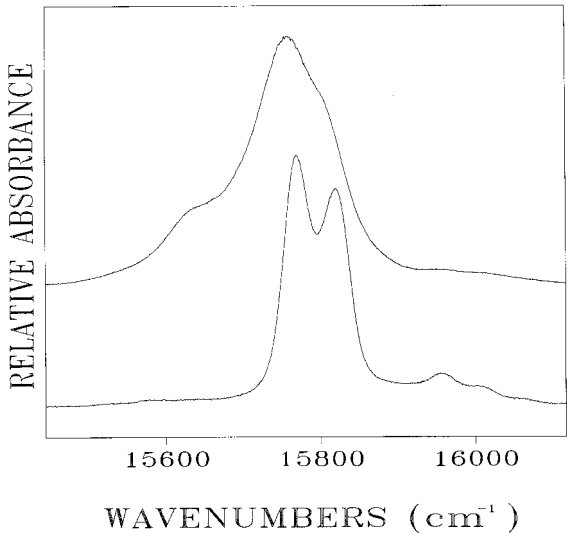
$$[6] \qquad f = 4.70175 \times 10^{-7} (\text{cm D}^{-2}) \tilde{\nu}_{eg} |\boldsymbol{\mu_{eg}}|^2$$

where $\tilde{\nu}_{eg}$ is the transition frequency in wavenumbers (cm^{-1}), and $\boldsymbol{\mu_{eg}}$ is the transition dipole moment function in Debye

$$[7] \qquad \boldsymbol{\mu_{eg}} = \langle e|\boldsymbol{\mu}|g\rangle$$

where e and g are the excited and ground state wave functions, respectively, and $\boldsymbol{\mu}$ is the DMF.

Results and discussion



Experimental spectra

Experimental spectra were deconvoluted in SpectraCalc[2] with the least number of peaks required to reasonably reproduce the experimental spectrum. It was found that Lorentzian profiles led to the best deconvolutions for most of the overtone spectra. In cases where more than one Lorentzian was required to deconvolute a vibrational overtone transition, the dominant Lorentzian is chosen to represent the pure local mode transition. In cases where there exist two dominant Lorentzians (which have comparable intensities), the Lorentzian that is chosen to represent the pure local mode transition is the one that gives the most linear Birge–Sponer plot (vide infra). Summaries of the spectrometers (lasers), the sample pressures, the transition energies, and the FWHM values of neopentane-d_0 and TMS are given in Tables 3 and 4.

As we have noted, we have measured the spectra of neopentane-d_0, -d_6, and -d_9. The -d_6 and -d_9 spectra are similar to the -d_0 spectrum, although there are subtle differences that probably arise from coupling between CH stretching local modes and methyl torsion (51). In the present paper, we report local mode parameters and intensities for all three neopentanes. In a future publication we will compare the spectral structure in neopentane-d_0, -d_6, and -d_9.

[2]SpectraCalc is commercially available software from Galactic Industries Corporation.

Fig. 1. The ICL-PAS (DCM dye) $\Delta v_{CH} = 6$ regions of the vapour phase overtone spectra of neopentane (top) and TMS (bottom). Gas pressures were 200.0 and 70.2 torr (1 torr = 133.32 Pa), respectively, at room temperature.

A Fermi resonance (52, 53) is observed in TMS in the range $\Delta v_{CH} = 4$–6 (see Fig. 1). The $|\upsilon - 1, 0, 0\rangle|2\upsilon_b\rangle$ states (where υ_b refers to a CH bending mode) steal intensity from the unresolved $|\upsilon, 0, 0\rangle_{A_1E}$ transitions. Since the $|\upsilon - 1, 0, 0\rangle|2\upsilon_b\rangle$ states are nearly resonant with the $|\upsilon, 0, 0\rangle_{A_1E}$ pure local mode states, the former act as "doorway states" into the vibrational bath which facilitate IVR (11, 54, 55). The $|\upsilon - 1, 0, 0\rangle|2\upsilon_b\rangle$ states do not have any appreciable intrinsic intensity. At $\Delta v_{CH} = 6$ (see Fig. 1 and compare to Fig. 2) the nearly identical intensities of the resonant $|5, 0, 0\rangle|2\upsilon_b\rangle$ and $|6, 0, 0\rangle_{A_1E}$ states indicate a very strong coupling.

In order to measure the $\Delta v_{CH} = 8$ spectra of neopentane-d_0, -d_6, -d_9, and TMS, the dye Coumarin 102 was employed and two spectra were coadded. Gas pressures were approximately 450 torr (1 torr = 133.32 Pa). Asymmetries in the CH stretching overtone transitions of the neopentanes persist.

Poor signal to noise ratios coupled with the short life span of the Stilbene 3 dye made it impractical to study the $\Delta v_{CH} = 9$ transitions of the deuterated neopentanes. Only neopentane-d_0 was recorded in this region. Six spectra were coadded to produce the profile in Fig. 3.

The low intensities of these signals made the detection of neopentane-d_0 overtone transitions above $\Delta v_{CH} = 9$ unattainable.

Local mode parameters

Values of $\widetilde{\omega}$ and $\widetilde{\omega}x$ were obtained from both Birge–Sponer plots and from quadratic fits of the transition energy vs. υ (eq. [2]) for vapour phase neopentane-d_0, -d_6, -d_9, and TMS. Birge–Sponer plots tend to underemphasize the contributions of higher overtone transitions, however, the results obtained via

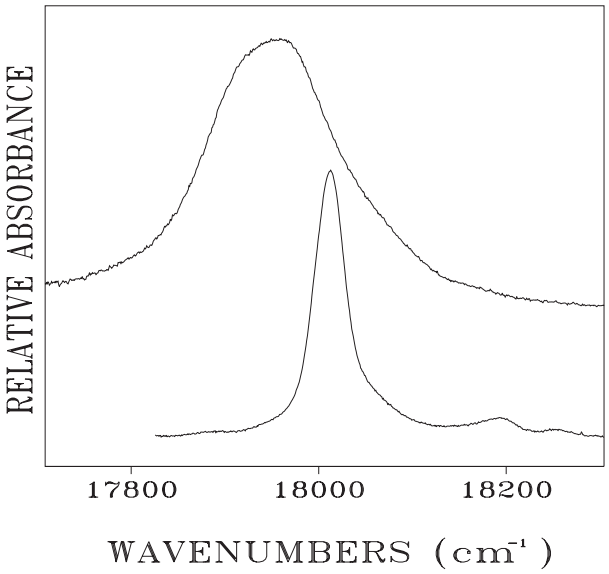
[c]TMS analysis accounts for Fermi resonance at $\Delta v_{CH} = 4$–6.

Fig. 2. The ICL-PAS (Coumarin 6 dye) $\Delta v_{CH} = 7$ regions of the vapour phase overtone spectra of neopentane (top) and TMS (bottom). Gas pressures were 200.0 and 161.8 torr (1 torr = 133.32 Pa), respectively, at room temperature.



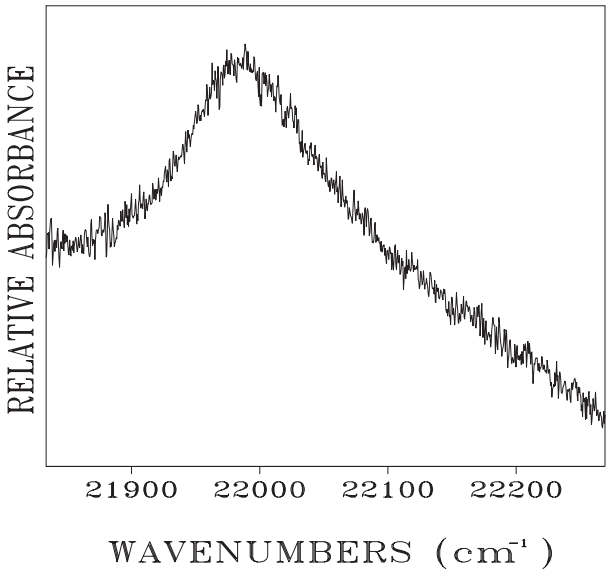


Fig. 3. The ICL-PAS (Stilbene 3 dye) $\Delta v_{CH} = 9$ regions of the vapour phase overtone spectra of neopentane. The spectral region is the sum of six coadded spectra. Gas pressures were approximately 850 torr (1 torr = 133.32 Pa) at room temperature.

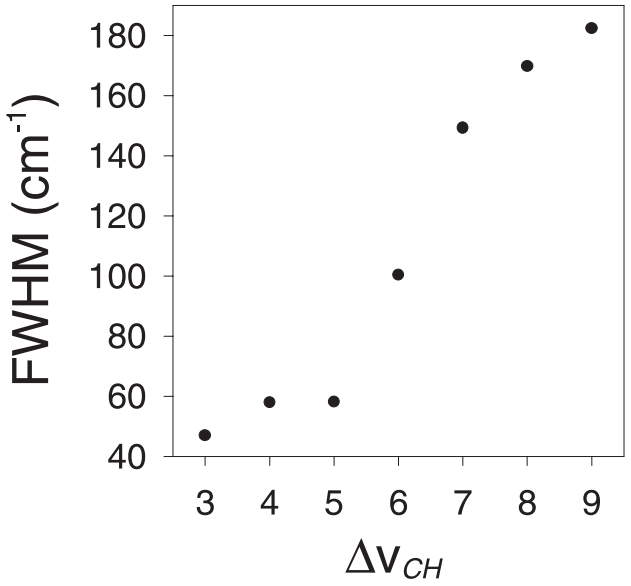
both methods are the same within experimental error. Birge–Sponer plots of TMS and the neopentanes were linear, which indicates that in the higher energy regimes ($\Delta v_{CH} \geq 3$) the CH stretching vibrations of the neopentanes and TMS are well described as uncoupled anharmonic Morse oscillators. Those values of $\widetilde{\omega}$ and $\widetilde{\omega}x$ determined via a quadratic fit are compared to literature values in Table 5. Accurate values of local mode frequency ($\widetilde{\omega}$) and anharmonicity ($\widetilde{\omega}x$) have been obtained. Contrary to previous work (7, 8), the $\widetilde{\omega}$ value of TMS was found to be slightly lower than that of neopentane-d_0. The magnitude of the anharmonicity of neopentane-d_0 was found to be larger than that of TMS, in agreement with previously published data (7, 8). The anharmonicities of the neopentanes are identical within experimental error.



Full width at half-maximum

In agreement with previous work (7), we found that the FWHM values of neopentane are larger than those of TMS. A monotonic increase in the FWHM values of the pure local mode transitions of neopentane-d_0 with increasing excitation can be seen in Table 3 and in Fig. 4. Of particular interest is the fact that the most pronounced increases in the FWHM values of neopentane-d_0 occur in going from $\Delta v_{CH} = 5$ to $\Delta v_{CH} = 6$ and from $\Delta v_{CH} = 6$ to $\Delta v_{CH} = 7$.

The assumption, which is implicit in the interpretation of the overtone spectra of neopentane-d_0 and TMS, is that we are observing a central CH local mode excitation, i. e., we are not simply observing the excitation of several molecular eigenstates which correspond to a global excitation of the molecule. It is assumed that these pure CH local modes are the only "bright" states. To justify our assumption that we are observing bright CH stretching local mode overtones, we refer to the three principles that Sage and Jortner (23) have used to support the concept of XH stretching local modes. The first of these principles is *energetics*; a Morse oscillator adequately describes the $\Delta v_{CH} =$ 2–6 region of aromatic and aliphatic hydrocarbons (56, 57). In

©2001 NRC Canada

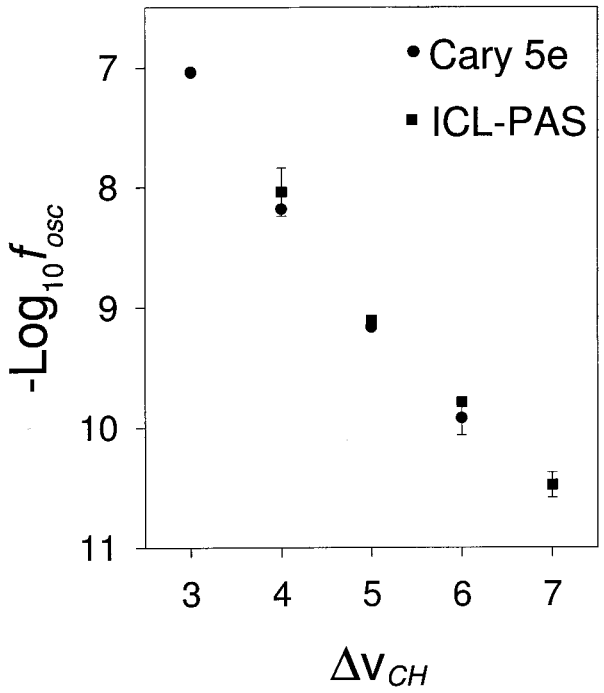
Fig. 4. The full-width at half maximum of the pure local mode transitions of neopentane as a function of the number of vibrational quanta.

the present paper we find that a Morse oscillator adequately describes the $\Delta v_{CH} = 3$–9 region of neopentane-d_0 and the $\Delta v_{CH} = 3$–8 regions of neopentane-d_6, -d_9, and TMS. The second principle is that of *relative intensities* in which the intensity of the $\Delta v_{CH} = 6$ CH overtone of C_6H_6 is roughly six times that of C_6D_5H (57). Again, in the present paper it was found that the overtone intensity of neopentane-d_0 is approximately twice that of neopentane-d_6 and four times that of neopentane-d_9 at each overtone. The final principle is *absolute intensities*. The intensity of higher CH vibrational overtones can be approximated by additively equal contributions from all local CH bond modes (17, 51). Our intensity calculations successfully account for the observed absolute intensities (vide infra) and are based on additivity.

Observed overtone transition intensities

Dimensionless oscillator strengths for neopentane-d_0, -d_6, -d_9, and TMS (see Table 6 and Fig. 5) were obtained from spectra that were measured with a conventional Cary 5e spectrometer over the energy ranges indicated in Table 6. Within the Born–Oppenheimer approximation, the intensities of neopentane-d_0, -d_6, and -d_9 are expected to be proportional to the number of CH oscillators in the sample if there are no large changes in the transition frequency $\tilde{\nu}_{eg}$ or in the transition dipole moment function $\boldsymbol{\mu}_{eg}$ (see eq. [6]). The oscillator strength of neopentane-d_0 at any given overtone is twice that of neopentane-d_6 within 5%, reflecting the relative number of CH oscillators in the two molecules. A similar relationship is observed between the oscillator strengths of neopentane-d_0 and neopentane-d_9, where the former is four times more intense than the latter to within 2%. The oscillator strengths of TMS at various overtones were found to be approximately 70% larger than for the corresponding overtones of neopentane-d_0 owing primarily to much larger fourth order derivatives in the DMF, $\boldsymbol{\mu}_{40}$ and $\boldsymbol{\mu}_{04}$ (see eq. [5]).

Fig. 5. The negative logarithms of the absolute oscillator strengths of various overtone transitions in neopentane obtained with a Cary 5e conventional absorbance spectrometer or with ICL-PAS using methane as an internal standard. The gas pressures and temperatures for the conventional absorbance spectrometer are given in Table 6.



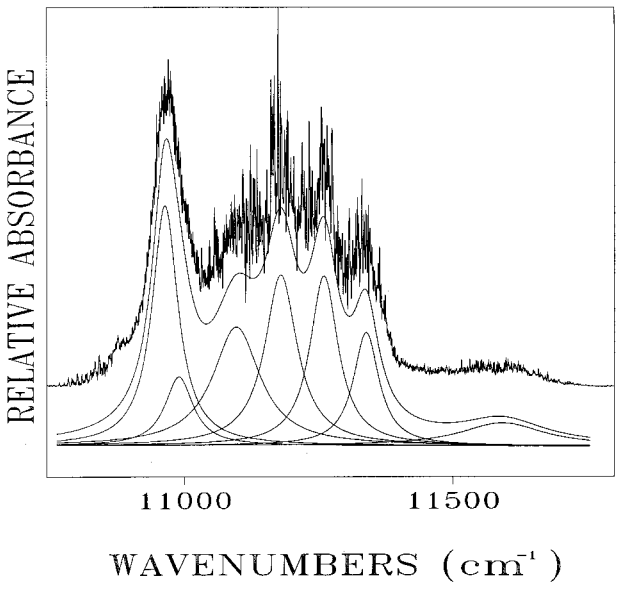


Fig. 6. The Ti:sapph (mw) ICL-PAS $\Delta v_{CH} = 4$ region of the overtone spectrum of a mixture of neopentane and methane. The experimental spectrum (top) has been vertically offset for clarity. The individual Lorentzian functions and the linear base line fit to the experimental spectrum are also shown. The sum of these two curves is also included. The χ^2 value for the fit was 6.062×10^{-8}.

[a]Measured intensity of the total band (see text).

[a]Errors represent a "worst case" estimated uncertainty in our deconvolution areas of 20%.

The $\Delta v_{CH} = 4$ region of the ICL-PAS spectrum of a mixture of methane and neopentane-d_0 was obtained with a Ti:sapph laser equipped with mid wave (mw) optics and is presented in Fig. 6. The methane $3\nu_1 + \nu_3$ transition required four Lorentzians while the unresolved neopentane $|400\rangle_{A_1E}$ transitions were approximated by two Lorentzians. The spikes on the neopentane transition correspond well to known water vapour lines while the most intense spikes on the methane transition do not. The methane structure has been attributed to congested rovibrational transitions by Perry et al. (39). The intracavity power levels (which are recorded simultaneously with the PA signal) varied smoothly and showed no evidence of the selective absorption of intensity from modes whose frequencies correspond with methane rovibrational transitions.

The intensity of the unresolved neopentane-d_0 $|400\rangle_{A_1E}$ transitions relative to the methane transition is obtained by dividing the sum of the areas of its deconvoluted peaks by the sum of the areas of the methane deconvoluted peaks. The absolute oscillator strength of the neopentane-d_0 $|400\rangle_{A_1E}$ transitions (see Table 7) was then obtained by factoring in the pressures of the two gases, as well as the known oscillator strength of methane and the scaling factor (which relates Giver's (40) integrated areas to our deconvolution areas, vide supra) for the methane $3\nu_1 + \nu_3$ transition. As we have noted, we have revised Giver's $3\nu_1 + \nu_3$ intensity (see Table 1) by a factor of 1.4 to account for the comparison between resolved and unresolved rotational structure (vide supra). The uncertainty introduced in revising Giver's $3\nu_1+\nu_3$ intensity makes our ICL-PAS value for $\Delta v_{CH} = 4$ more uncertain than the corresponding values for $\Delta v_{CH} = 5$ and 6. In addition to this error, the propagation of experimental errors was approximated by assuming an error in the area of each constituent Lorentzian to be 10%. Other sources of experimental error such as pressure gauge fluctuations were taken into account and found to be negligible.

A Ti:sapph laser equipped with short wave (sw) optics was used to obtain the ICL-PAS spectrum of a mixture of neopentane-d_0 and methane in the $\Delta v_{CH} = 5$ region. Figure 7 shows the rich structure of the methane transition, which is attributed to congested rovibrational transitions. The $4\nu_1 + \nu_3$ transition of methane is deconvoluted as a single Lorentzian while the unresolved $|500\rangle_{A_1E}$ transitions in neopentane-d_0 require four Lorentzians. The combined absolute oscillator strength of neopentane-d_0 in this region is given in Table 7. It was obtained from the pressures and the relative absorbances of the two gases, the known oscillator strength of the methane $4\nu_1+\nu_3$ transition, and the associated scaling factor (vide supra) for this transition. As at $\Delta v_{CH} = 4$, the intracavity power levels varied smoothly and showed no evidence of the selective mode absorption (vide supra).

The absolute oscillator strength of the unresolved $|600\rangle_{A_1E}$ transitions in neopentane-d_0 were arrived at by comparison to the methane $5\nu_1 + \nu_3$ transition. The $\Delta v_{CH} = 6$ region was obtained with a DCM dye laser and is shown, along with its deconvolution, in Fig. 8. Congested rovibrational transitions are again observed in methane. The combined absolute oscillator strength of the neopentane-d_0 $|600\rangle_{A_1E}$ transitions is given in Table 7. This value was obtained in a manner identical to that for the $|500\rangle_{A_1E}$ transitions (vide supra).

The unresolved neopentane $|700\rangle_{A_1E}$ transitions and the $5\nu_1+\nu_3 + (\nu_2$ or $\nu_4)$ transitions of methane were observed with a Rhodamine 110 dye laser and are presented in Fig. 9. Some of the methane structure is caused by congested rovibrational transitions, however, traces of water vapour are also present and absorb in this range. The methane transition is deconvoluted as a single Lorentzian. The combined absolute oscillator strength of the neopentane-d_0 $|700\rangle_{A_1E}$ transitions was obtained in a manner identical to that for the $|500\rangle_{A_1E}$ transitions (vide supra) and is given in Table 7.

The absolute oscillator strengths of neopentane-d_0 which were obtained from ICL-PAS are compared with those from a conventional spectrometer in Table 7. These values are represented graphically in Fig. 5. Aside from the problem at $\Delta v_{CH} = 4$ with the PA value, the most significant source of experimental uncertainty in the oscillator strengths is in the deconvoluted

peak areas. In the region of the spectrum where the two techniques overlap, i. e., $\Delta v_{CH} = 4$–6, we observe good agreement to within experimental error. This agreement establishes the reliability of the photoacoustic intensity measurements. Moreover, it supports the use of correction factors for the internal standard.

Calculated overtone transition intensities

Previous work (58–60) has shown that electron correlation in the DMF does not play an important role in determining overtone transition intensities for most molecules. We found the same result in this work. Overtone transition intensities that used HCAO vibrational wave functions and ab inito DMFs from dipole moments calculated with levels of theory, which included electron correlation (i. e., MP2, QCISD, etc.), showed no improvement over intensities from DMFs at the Hartree–Fock level. However, unlike the general trend observed in our previous work (58, 59), calculated intensities of neopentane-d_0 did not asymptotically approach experimentally determined overtone intensities from above with the use of progressively larger basis sets. Kjaergaard et al. (59) had previously observed that increasing the basis set size did not always lead to improved agreement between calculated and observed overtone intensities in the case of methane. They postulated that the HCAO model may not adequately describe all the significant coupling modes of methane. The same situation is likely to be true for the neopentanes.

We carried out calculations for a number of ab inito DMFs which combined different levels of theory and basis set size (38) using Gaussian 98 (61). DMFs calculated at both HF and MP2 levels of theory with basis sets which varied in size from 6-31G to 6-311++G(2d,2p) all led to intensities which were in reason-

[a]Values at $\Delta v_{CH} = 3$–4 are from a Cary 5e conventional absorbance spectrometer while values at $\Delta v_{CH} = 5$–7 are from ICL-PAS with methane as an internal standard.

ably good agreement with experimental neopentane-d_0 intensities in the energy range $\Delta v_{CH} = 3$–7. In order of decreasing correspondence, the best agreements between calculated and experimental neopentane-d_0 intensities in this energy range were realized with DMFs calculated from the following combinations of theory and basis set (see Table 8 and Fig. 10):

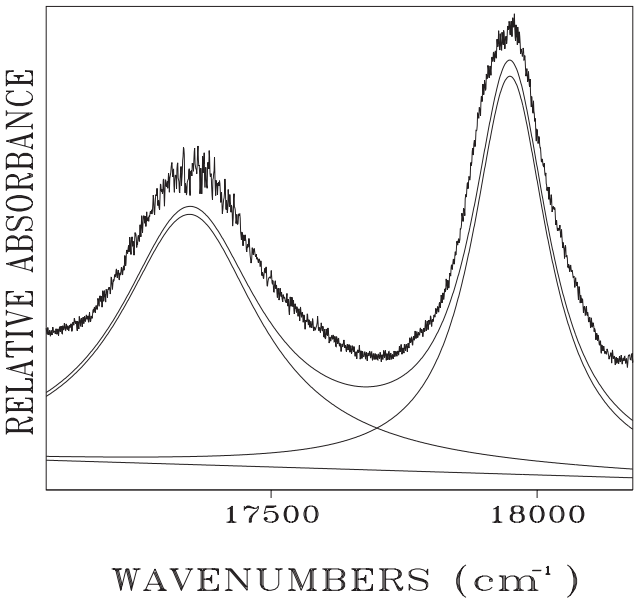
HF / 6-311++G(d,p) > HF / 6-311+G(d,p) >

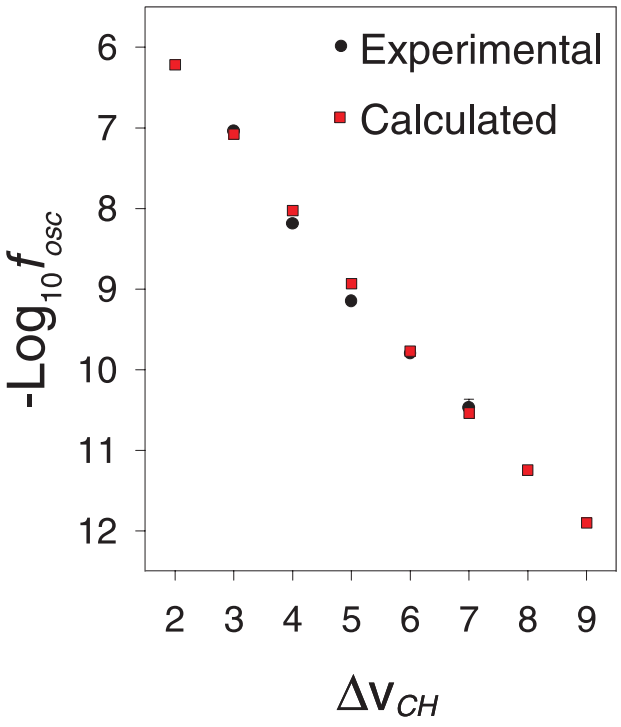
HF / 6-311++G(2d,2p) ≈ MP2 / 6-31G(d,p)

The oscillator strengths of TMS were calculated in a similar manner and these values are compared to experimental intensities in Table 9 and Fig. 11. Once again, the same basis sets at both HF and MP2 levels of theory led to DMFs which gave reasonably good agreement with experimental TMS intensities in the energy range $\Delta v_{CH} = 3$–5.

In decreasing order, the best agreement between calculated and experimental TMS intensities in this energy range were realized with DMFs calculated from the following combinations of theory and basis set:

Fig. 9. The ICL-PAS (R110 dye) $\Delta v_{CH} = 7$ region of the overtone spectrum of a mixture of neopentane and methane. The experimental spectrum (top) has been vertically offset for clarity. The individual Lorentzian functions and the linear base line fit to the experimental spectrum are also shown. The sum of these two curves is also included. The χ^2 value for the fit was 3.181×10^{-10}.





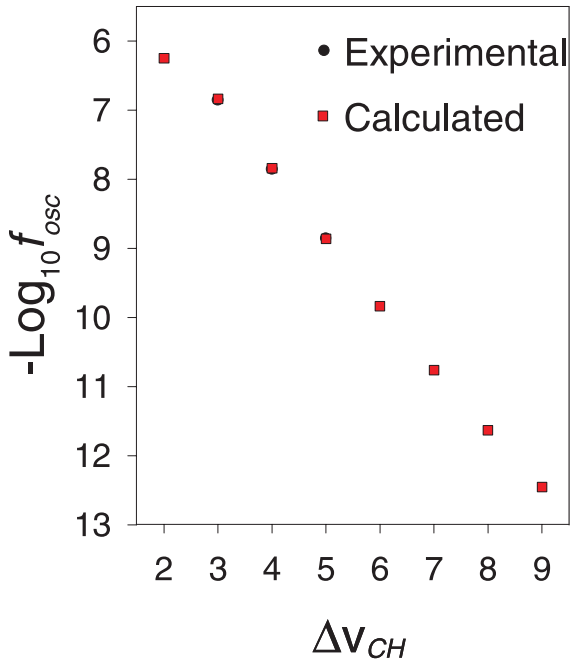


Fig. 10. The negative logarithm of experimental and calculated (HF / 6-311++G(d,p)) oscillator strengths of overtone transitions in neopentane.

©2001 NRC Canada

Fig. 11. The negative logarithm of experimental and calculated (HF / 6-31G(d,p)) oscillator strengths of overtone transitions in TMS.

HF / 6-31G(d,p) > HF / 6-31G ≈ MP2 / 6-31G > MP2 / 6-31G(d,p)

In particular, those levels of theory and basis set which worked well to predict the overtone intensities of neopentane-d_0 also gave good results in TMS.

Conclusions

The vibrational overtone spectrum of gas phase neopentane-d_0 was studied in the energy range 8 400 cm^{-1} ($\Delta v_{CH} = 3$) to 22 000 cm^{-1} ($\Delta v_{CH} = 9$), while the overtone spectra of gas phase neopentane-d_6, -d_9, and vapour phase TMS were studied in the energy range of 8 400 cm^{-1} ($\Delta v_{CH} = 3$) to 20 100 cm^{-1} ($\Delta v_{CH} = 8$). Conventional absorbance spectroscopy was used to access the lower energy overtones ($3 \leq \Delta v_{CH} \leq 6$) while ICL-PAS techniques were used in the higher energy regions ($4 \leq \Delta v_{CH} \leq 9$). Birge–Sponer plots for TMS and the neopentanes were linear across this energy range which indicates that the vibrational CH stretching overtones of the neopentanes and TMS are well described as uncoupled Morse oscillators. A splitting which arises from Fermi resonance was observed in the TMS spectra in the range $\Delta v_{CH} = 3$–6. Asymmetries have been observed in the spectra of neopentane at $\Delta v_{CH} = 4$–8 which indicate a coupling of the unresolved $|\upsilon 00\rangle_{A_1E}$ states to methyl torsion.

ICL-PAS spectroscopy was used with methane as an internal standard to obtain the absolute absorbance intensities of neopentane-d_0 in the energy range $\Delta v_{CH} = 4$–7. Good agreement was realized between these intensities and those obtained via conventional absorbance spectroscopy in the region of $\Delta v_{CH} = 4$–6. This is a useful result since very weak high-energy overtone transitions can only be observed by intracavity laser techniques.

[a]Values at $\Delta v_{CH} = 3$–5 are from a Cary 5e conventional absorbance spectrometer.

The absolute overtone intensities of neopentane-d_0 and TMS were accurately predicted by calculations which used the HCAO model and the experimental parameters $\widetilde{\omega}$, $\widetilde{\omega}x$, and γ' to obtain the vibrational wave functions, and ab inito calculations to obtain the DMFs. In the case of neopentane-d_0, the combination of theory and basis set, which gave a DMF that led to the best agreement between observed and calculated overtone intensities in the energy range $\Delta v_{CH} = 3$–7, was HF / 6-311++G(d,p). The best agreement for TMS was achieved with an ab inito DMF calculated at the HF / 6-31G(d,p) level. However, all calculations led to satisfactory agreement with the absolute experimental intensities, despite the fact that the only parameters in the theory were obtained directly from the overtone transition energies.

Synthesis of the diborylated ferrocene 1,1′-bis-(bis-pentafluorophenylboryl)ferrocene and the X-ray structure of its trimethylphosphine adduct

Bryon E. Carpenter, Warren E. Piers, and Robert McDonald

Abstract: The diborylated ferrocene compound 1,1′-Fc[B(C_6F_5)$_2$]$_2$ (**2**) was prepared via a transmetallation reaction involving 1,1′-Fc(HgCl)$_2$ and two equivalents of ClB(C_6F_5)$_2$. Although this reaction is very clean spectroscopically, isolated yields of **2** were never greater than 40% owing to the high solubility of the compound in non-donor solvents. Compound **2** is similar in its properties to the related monoborylated complex FcB(C_6F_5)$_2$ (**1**) reported previously, particularly the UV–vis spectrum, which exhibits an intense charge transfer absorption (λ_{max} = 233 nm, $\varepsilon = 1.64 \times 10^4$) assignable to an $Fe_{dz^2/dx^2-y^2} \rightarrow B_p$ transition. However, **2**, is significantly more Lewis acidic than **1**, reacting with weak donors such as acetonitrile at room temperature, and effecting methide abstraction from Cp_2ZrMe_2 under mild conditions. Complex **2** also forms a bis(trimethylphosphine) adduct (**3**), which was structurally characterized via X-ray crystallography.

Key words: organoboranes, ferrocene derivatives, multidentate Lewis acids.

Résumé : On a préparé le ferrocène diborylé 1,1′-Fc[B(C_6F_5)$_2$]$_2$, **2**, par une réaction de transmétallation impliquant le 1,1′-Fc(HgCl)$_2$ et deux équivalents de ClB(C_6F_5)$_2$. Même si d'un point de vue spectroscopique cette réaction est propre, les rendements en produit **2** isolé n'ont jamais dépassé 40% en raison de la grande solubilité du composé dans les solvants non donneurs. Les propriétés du composé **2** sont semblables à celles du complexe monoborylé apparenté, FcB(C_6F_5)$_2$ (**1**), dont on a rapporté la synthèse antérieurement, particulièrement le spectre UV–vis qui présente une absorption de transfert de charge intense (λ_{max} = 233 nm; $\varepsilon = 1{,}64 \times 10^4$) que l'on peut attribuer à une transition $Fe_{dz^2/dx^2-y^2} \rightarrow B_p$. Toutefois, **2** est beaucoup plus acide que **1**; il réagit à la température ambiante avec les donneurs faibles, tel l'acétonitrile, et il peut effectuer l'enlèvement d'un méthide à partir du Cp_2ZrMe_2 dans des conditions douces. Le complexe **2** forme aussi un adduit bis(tripméthylphosphine), **3**, dont on a caractérisé la structure par diffraction des rayons X.

Mots clés : organoboranes, dérivés du ferrocène, acides de Lewis multidentate.

Introduction

Borylated ferrocenes (1) and perfluoroaryl substituted boranes (2) are two important classes of boron compounds. The former group is of interest for probing fundamental bonding questions (3), and because they act as precursors to unique coordination (4) or covalent (5) ferrocene containing polymeric materials. The latter class has found application as Lewis acid activators for olefin polymerization processes involving single site catalysts (6) and in the arena of organic synthesis (7), due to their superior Lewis acid strength and hydrolytic stability.

Recently we have explored the chemistry of ferrocenyl derivatives borylated with -B(C_6F_5)$_2$ groups, bringing these two classes of borane compounds together. In a previous paper (8), we described in detail the synthesis and chemistry of the monoborylated ferrocene FcB(C_6F_5)$_2$ (**1**). Here we describe the diborylated complex 1,1′-Fc[B(C_6F_5)$_2$]$_2$ (**2**), which represents a new member in a growing family of highly electrophilic diboranes (9), and contrast its chemistry with that of **1**.

Results and discussion

Whereas the monoborylated ferrocenyl compound Fc[B(C_6F_5)$_2$] (**1**), was readily prepared by direct borylation (8) of ferrocene with HB(C_6F_5)$_2$ (10), reaction of the metallocene with two to three equivalents of the borane did not proceed to a clean diborylated product. Instead, only mixtures of **1** (≈30%) and the target diborylated ferrocene 1,1′-Fc[B(C_6F_5)$_2$]$_2$ (**2**) (≈70%), were produced. Since the solubility properties of these compounds are similar, **2** proved inseparable from the monoborylated **1** via crystallization. The high sensitivity of the Fc—B bond towards proteolysis precluded chromatographic methods for separation.

Therefore, to produce the desired diborane, we turned to a metathetical route utilizing 1,1′-Fc(HgCl)$_2$ (11) and 2 equiv of ClB(C$_6$F$_5$)$_2$ (12) (eq. [1]). This method is also viable for preparing ferrocenyl borane **1**, so to obtain clean samples of **2**, highly pure 1,1′-Fc(HgCl)$_2$ was required. A modified preparation of this compound using 1,1′-FcLi$_2$·TMEDA (13) and HgCl$_2$ fulfilled this need, giving 1,1′-Fc(HgCl)$_2$, which was free from FcHgCl. The reaction shown in eq. [1] proceeds slowly owing to the poor solubility of 1,1′-Fc(HgCl)$_2$, but produces **2** essentially quantitatively, as judged by spectrocopy. However, due to the extreme solubility of **2** in both hexanes and aromatic solvents, isolated yields of analytically pure material were only 25–40% depending on the scale of the reaction.

Complex **2** is intensely maroon colored when dissolved in common non-donor solvents, and is isolated as a waxy solid when crystallized from saturated solutions in hexamethyldisiloxane at –35°C. Although single crystals of **2** are obtainable from Me$_3$SiOSiMe$_3$ solution, severe disorder problems precluded satisfactory refinement of the data set; nonetheless, this experiment was consistent with the connectivity required by **2**.[2] The ^{1}H NMR spectrum shows two signals, a broadened one at 4.39 ppm for the protons α to the boryl group, and a sharper multiplet at 4.75 ppm for the β protons. Cyclic voltammetric measurements on **2** (1 mM in α,α,α-trifluorotoluene with [Bu$_4$N][B(C$_6$F$_5$)$_4$] (100 mM) as supporting electrolyte (14), scan rate = 100 mV s^{-1}) reveals a quasi-reversible one-electron oxidation at +820 mV relative to ferrocene–ferrocenium ($E_{1/2}$ Fc–Fc$^+$ = 0 mV), which is roughly double the potential observed for monoborylated ferrocene (**1**) (+450 mV). The intense color of the compound is similar to that observed for **1** and arises from a charge transfer absorption (λ_{max} = 233 nm, ε = 1.64 × 10^4) assignable to an $Fe_{dz^2/dx^2-y^2} \rightarrow B_p$ transition from the metallocene-based HOMO into the empty *p* orbitals of the boryl groups (3). In our previous paper (8), we argued that the ^{19}F NMR data for monoborylated **1** was consistent with a significant Fe → B interaction since the chemical shift separation between the *meta* and *para* fluorine atoms was midway between that observed for free, unligated boranes and Lewis base adducts of these boranes. A similar phenomenon is observed in **2**, but the difference in the chemical shifts observed for the *meta* and *para* fluorine atoms of the C$_6$F$_5$ rings ($\Delta_{m,p}$) is a measure of the electron density on boron (15); the boron centers in **2** have less electron density ($\Delta_{m,p}$ = 10.7 ppm) than **1** ($\Delta_{m,p}$ = 9.2 ppm). Thus, because the Fe → B interaction is spread over two boryl groups, the individual interactions are attenuated somewhat as the extent of borylation grows (3).

This is also manifested in the compound's behavior as a Lewis acid, in comparison to **1**, since the weaker Fe → B interaction leads to stronger Lewis acidity for the boron centers in **2**. For example, on the Child's scale (16), monoborylated **1** scored a very low value of 0.37 ± 0.03 relative to BBr$_3$ at 1.00. In comparison, diborylated **2** measures a Lewis acidity of 0.70 ± 0.03, which is closer to the value of 0.77 found for B(C$_6$F$_5$)$_3$ itself (17). Furthermore, whereas acetonitrile binds to the boron center in **1** only at low temperatures (reversibly), it complexes to the boron centers in **2** at room temperature, as evidenced by the immediate decolorization of benzene solutions of **2** in the presence of 2 to 3 equiv of the Lewis base. Soon thereafter, a yellow solid precipitates from these solutions. The loss of the deep maroon color is indicative of a disruption of the Fe → B interaction upon complexation of the boron centers by CH$_3$CN. Based on the single set of resonances observed in the ^{19}F NMR spectrum of this yellow solid, it is probably the bis(acetonitrile) adduct of **2**, although it was not fully characterized due to its insolubility.

Exposure of maroon solutions of **2** to a slight excess of the stronger Lewis base PMe$_3$ again led to an immediate decolorization of the solution to a yellow color, from which a precipitate consisting of the bis(trimethylphosphine) adduct (**3**) soon developed (eq. [2]). This compound proved more amenable to analysis, and the ^{1}H and ^{19}F NMR data for **3** are fully consistent with formation of the C_{2v} symmetric bis(phosphine) adduct. The ^{11}B (–13.4 ppm) and ^{31}P (–14.5 ppm) NMR spectral data are similar to those found for **1**·PMe$_3$ and also indicate that the two boryl fragments are related by symmetry. This was confirmed by X-ray analysis of single crystals of **3**; the solid state structure is shown in Fig. 1, along with selected metrical data. Further details on this structure can be found in the Supporting Information.[3] The two -B(C$_6$F$_5$)$_2$·PMe$_3$ moieties are oriented differently with respect to the ferrocenyl core of the molecule. For example, the P(1)-B(1)-C(1)-C(5) torsion angle of –11.1(4)° indicates that the P(1)-B(1) vector lies essentially in the C(1)-C(5) plane. In contrast, the P(2)-B(2)-C(6)-C(10) dihedral angle is 70.8(3)°, such that this P—B bond is oriented nearly perpendicular to the corresponding Cp ring plane. Presumably, these differences are due to packing effects. While the bond angles within these fragments differ somewhat as a consequence, bond distances are

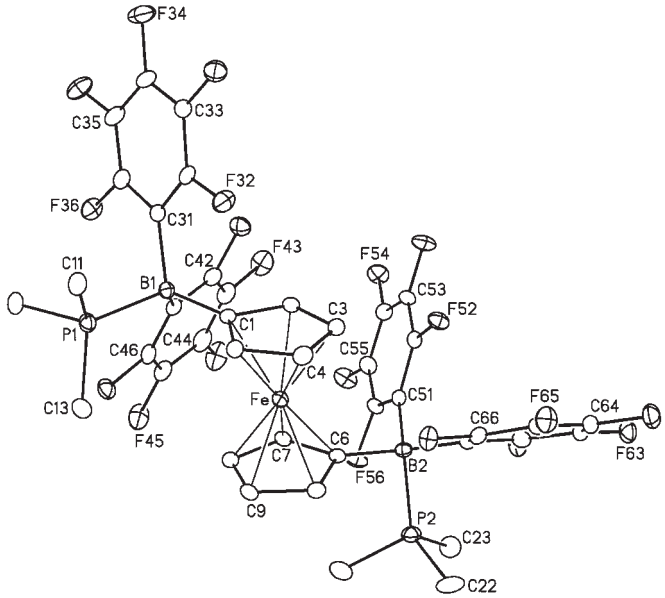
comparable and also similar to those found in the PMe_3 adduct of **1**. The Cp rings in **3** are almost eclipsed with respect to one another, deviating by 12.5° from a fully eclipsed conformation.

The enhanced Lewis acidity of diborane **2** relative to **1** is also shown in its observed reactivity with the metallocene Cp_2ZrMe_2. Perfluoroaryl substituted boranes of various types are capable of abstracting methide anions from metallocenes such as this, a reaction which constitutes an activation of the dialkyl metallocene in olefin polymerization reactions. Thus, it was surprising that monoborylated ferrocene (**1**) underwent absolutely no reaction with the dimethylzirconocene reagent. In contrast, diborylated **2** is observed to undergo a slow reaction with Cp_2ZrMe_2, as indicated in eq. [3]. Although a stable ion pair is not observed,

such a species is likely an intermediate on the way to the observed products, which form after rapid back-transfer of a $-C_6F_5$ group from the putative ion pair $[Cp_2ZrCH_3]^+[\mathbf{2}\cdot CH_3]^-$. Similar back-transfer reactions have been observed in ion pairs formed from boranes of general formula $RB(C_6F_5)_2$ (R = aliphatic group) (18). Although the behavior of this ion pair is not ideal, these observations do indicate that **2** is Lewis acidic enough to effect methide abstraction, unlike monoboryl ferrocene (**1**).

In conclusion, we have prepared a diborylated ferrocene incorporating $-B(C_6F_5)_2$ units in the 1,1′ positions. Although it is not an effective olefin polymerization initiator due to the facile aryl back-transfer reaction, the diborylated compound is demonstrably more Lewis acidic than the monoborylated species due mainly to the weaker Fe → B interactions in the more heavily borylated acid.

Experimental Section



General

General procedures have been described in detail elsewhere (8). Reagents employed were prepared from literature procedures cited in the text.

Modified preparation of 1,1′-Fc(HgCl)$_2$

To a solution of $FcLi_2\cdot$TMEDA (1.60 g, 5.90 mmol) dissolved in THF (50 mL) was added a solution of mercuric chloride (3.53 g, 13.0 mmol, 2.2 equiv) in THF (15 mL) via cannula transfer. The clear orange solution immediately turned chalky orange upon addition of mercuric chloride. The orange suspension was stirred for 24 h under argon. The orange solid was collected by filtration and washed with

THF. Removal of the solvent under vacuum afforded an insoluble orange product. Yield 3.23 g (4.90 mmol, 83%). There was no trace of FcHgCl by ^{1}H NMR spectroscopy.

Preparation of 2

1,1-Bis(chloromercuric)ferrocene (1.47 g, 2.24 mmol) and $ClB(C_6F_5)_2$ (1.70 g, 4.48 mmol) were placed into a 100 mL bomb, and dry hexanes (50 mL) were added via vacuum transfer. The vessel was warmed slowly to 60°C in an oil bath and stirred for 72 h. The orange suspension changed to a dark maroon solution with a grey precipitate. The warm product mixture was cannula transferred to a 100 mL flask fitted with a frit assembly, and filtered. The solid was washed with hexanes until the washings were colourless. The solvent was removed under vacuum and the resulting oily maroon solid was recrystallized from a minimum amount of hexamethyldisiloxane at –35°C. Yield: 537 mg (0.605 mmol, 27%). UV (trifluorotoluene) λ_{max} (nm) (ε ($M^{-1}cm^{-1}$)): 233 (1.64×10^4). ^{1}H NMR (C_6D_6) δ: 4.75 (m, (AA'XX') $^3J_{H,H}$ = 1.6 Hz, 4H, H_β), 4.39 (br m, WHM = 5.4 Hz, 4H, H_α). ^{13}C NMR (C_6D_6) δ: 145.7 (d, $^1J_{C,F}$ = 244 Hz), 142.5 (d, $^1J_{C,F}$ = 256 Hz, C_p), 137.8 (d, $^1J_{C,F}$ = 253 Hz), 114.1 (br s, $C_{ipso}(C_6F_5)$), 80.0 (s, C_β), 79.1 (s, C), 75.1 (br s, $C_{ipso}(C_5H_4)$). ^{11}B NMR (d_8-toluene) δ: signal too broad to observe. ^{19}F NMR (C_6D_6) δ: –129.8 (d, 8F, F_o), –150.0 (t, 4F, F_p), –160.7 (dt, 8F, F_m). Anal. calcd. for $C_{34}H_8B_2F_{20}Fe$: C 46.73, H 0.92; found: C 46.35, H 0.61.

Preparation of 3

A solution of **2** (100 mg, 0.114 mmol) in hexanes was cooled to –78°C and a slight excess of trimethylphosphine (0.285 mmol, 2.5 equiv) in a 35.1 cm^3 bulb, was vacuum transferred (150 mm Hg (1 mm Hg = 133.322 Pa)) into the vessel. Upon warming to room temperature, the maroon solution quickly turned colour to a yellow suspension; stirring continued for an additional 60 min. The solvent was removed along with the unreacted PMe_3 under vacuum to afford 107 mg (85%) of a yellow powder. A single crystal was obtained from toluene solution. ^{1}H NMR (d_8-toluene) δ: 4.29 (br m, 4H, *H*), 3.62 (br m, 4H, H_α), 0.41 (d, $^2J_{P,H}$ = 10.6 Hz, 18H, CH_3). ^{13}C NMR (d_8-toluene) δ: 147.9 (d, $^1J_{C,F}$ = 239 Hz), 139.6 (d, $^1J_{C,F}$ = 246 Hz, C_p), 137.6 (d, $^1J_{C,F}$ = 264 Hz), 120.1 (br s, $C_{ipso}(C_6F_5)$), 73.9 (*C*), 72.2 (*C*), 9.1 (d, $^1J_{C,P}$ = 37 Hz, *C*H$_3$), $C_{ipso}(C_5H_4)$ not found. ^{11}B NMR (d_8-toluene) δ: –13.4 (d, WHM = 190 Hz). ^{19}F NMR (d_8-toluene) δ: –127.5 (d, 8F, F_o), –157.3 (t, 4F, F_p), –163.3 (dt, 8F, F_m). ^{31}P NMR (d_8-toluene) δ: –14.5 (br s).

Reaction of 2 with Cp_2ZrMe_2

In the dry box **2** (30 mg, 0.034 mmol, 1.08 equiv) and Cp_2ZrMe_2 (8 mg, 0.032 mmol) were loaded into a dry NMR tube and dissolved in d_8-toluene (ca. 0.5 mL). The NMR tube was flame sealed and shaken. The ^{1}H NMR spectrum was monitored until the reaction was complete (≈6 h). ^{1}H NMR (d_8-toluene) δ: 5.69 (s, 10H, Zr(C_5H_5)), 4.62 (m, J = 1.8 Hz, 2H, H_β for one C_5H_4B ring), 4.52 (m, J = 1.8 Hz, 2H, H_β for one C_5H_4B ring), 4.37 (m, 2H, H_α for one C_5H_4B ring), 4.14 (m, 2H, H_α for one C_5H_4B ring), 0.82 (s, 3H, BCH_3), 0.26 (t, $^2J_{H,F}$ = 4.0 Hz, 3H, ZrCH_3).

X-ray crystallography

Crystals of **3** were coated in Paratone–8277 oil; one of these was mounted on a glass fiber for diffraction measurements. Data were collected using a Bruker P4/RA diffractometer with a SMART 1000 CCD detector[4], using monochromated Mo Kα radiation at –80°C. Data were integrated to a maximum 2θ value of 52.80°, and were corrected for absorption through use of the SADABS procedure[4]. The structure of **3** was solved using the program SHELXS 86 (19), and the structure was refined using full-matrix least-squares methods (SHELXL 93) (20)[5] 2σ (F_o^2) is used only for calculating R_1, and is not relevant to the choice of reflections for refinement. *R*-factors based on F_o^2 are statistically about twice as large as those based on F_o, and *R*-factors based on all data will be even larger.[5] All nonhydrogen atoms were refined anisotropically and all hydrogen atoms were placed in idealized positions as suggested by the sp^2 or sp^3 hybridizations of their attached carbons. Details of crystal data, data collection, and structure refinement have been provided in Table 1.

Acknowledgments

Cobalt-59 chemical shift and quadrupolar tensors of simple octahedral cobalt(III) complexes

Christopher W. Kirby and William P. Power

Abstract: Analysis of the solid-state powder ^{59}Co NMR spectra of ten simple inorganic cobalt(III) complexes at 11.75, and in most cases, 4.7 T have permitted the assignment of specific ligand planes to ranges of values of the observed chemical shift principal components. The relevant chemical shift components were determined from the simulations of the powder line shapes. These simulations also provided the relative orientations of the chemical shift (CS) and electric field gradient (efg) tensors, as well as magnitude and asymmetry of the ^{59}Co quadrupolar coupling. Using symmetry arguments and ab initio calculations, as appropriate or necessary, the orientations of the efg tensors in the molecular frame were deduced. This allowed the determination of the CS tensors in the molecular frame and thus assignment of the ligand planes responsible for the observed values of chemical shifts.

Key words: cobalt, chemical shift, quadrupolar coupling, solid state NMR.

Résumé : L'analyse des spectres RMN du ^{59}Co de poudres à l'état solide de six complexes inorganiques simples du cobalt(III), déterminés à 11,75 T et, dans la plupart des cas à 4,7 T, on permit d'attribuer des plans de ligand spécifique à des plages de valeurs des composants principaux des déplacements chimiques observés. On a déterminé les composantes des déplacements chimiques appropriés en faisant appel à des simulations des formes de raies des poudres. Ces simulations ont aussi permis de déterminer les orientations relatives des tenseurs du déplacement chimique et du gradient du champ électrique ainsi que l'amplitude et l'asymétrie du couplage quadripolaire du ^{59}Co. Utilisant des arguments de symétrie et des calculs ab initio, suivant les cas et les nécessités, on a pu déduire les orientations des tenseurs du gradient du champ électrique dans l'environnement moléculaire. Ceci a permis de déterminer les tenseurs du déplacement chimique dans l'environnement moléculaire et finalement l'attribution des plans de ligand responsables des valeurs observées pour les déplacements chimiques.

Mots clés : cobalt, déplacement chimique, couplage quadripolaire, RMN à l'état solide.

Introduction

In the past few years, there has been a renewed interest in ^{59}Co chemical shielding with the advent of computational methods using density functional theory (DFT) to predict shielding in heavy atoms (1–6). Chan and Au-Yeung (5) have reported calculated chemical shielding (CS) tensors of five simple octahedral cobalt(III) complexes. Godbout and Oldfield (6) have also performed a DFT study on six cobalt(III) complexes of which four are the same studied by Chan and Au-Yeung. With the increasing availability and power of these new theoretical methods, more experimental data concerning the magnitude and orientation of the chemical shift and quadrupolar coupling tensors is needed to aid in their improvement and refinement.

The first reports of ^{59}Co CS tensor determinations were provided by single-crystal NMR (7–12). These experiments were carried out at low magnetic fields, and, therefore, the precision of the experiments, in terms of CS data, is low. The first high-field single-crystal ^{59}Co NMR experiment was completed on $Co(acac)_3$ (acac = acetylacetonate) at 9.4 T (13). In this study, the orientations of the CS and electric field gradient (efg) tensors were unambiguously determined as well as the orientation of these tensors in the molecular frame. Chan and Au-Yeung (5) as well as Godbout and Oldfield (6) have calculated the CS tensor for this complex. The span ($\Omega = \delta_{11} - \delta_{33}$) of the shift tensor reported in the single-crystal ^{59}Co NMR study more closely agrees with the computations of Chan and Au-Yeung.

The first report of powder ^{59}Co NMR spectra of highly symmetric cobalt(III) complexes by Eaton et al. (14) appeared before a general theory for powder NMR line shape simulations for quadrupolar nuclei in low symmetry sites was available. This limited their ability to comment quantitatively on the interactions responsible for the observed anisotropic line shapes. Shortly thereafter (in 1990) two groups independently reported techniques for the analysis of powder line shapes of half-integer-spin quadrupolar nuclei ($I = n/2$ where $n = 3$, 5, 7, or 9), which had chemical shielding and quadrupolar tensors that were both non-axially symmetric and non-coincident (15, 16). Since then, the chemical shift and quadrupolar tensors of only three anionic cobalt complexes have been completely determined using this more

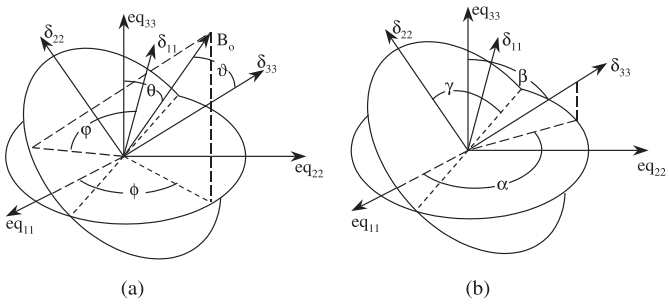
general NMR line shape theory (17, 18). Other classes of complexes that have been studied using solid-state powder ^{59}Co NMR include cobalt clusters (19, 20), battery materials (21), and biologically relevant cobalt complexes (22–24). We have also performed a single-crystal ^{59}Co NMR on vitamin B_{12} (25), and our results agree quite closely with those of the powder ^{59}Co NMR study (23).

In this report, we present the ^{59}Co solid-state powder NMR spectra of ten octahedral inorganic cobalt(III) complexes. The CS and efg tensors have been determined, as well as the relative orientations of the two tensors in each complex. Specific ligand planes were assigned to the observed values of the chemical shift principal components, by using the orientation of the two tensors and symmetry arguments or ab initio calculations, to determine the orientation of the efg tensor in the molecular frame. We believe these results will provide important experimental comparison for ongoing efforts aimed at improving theoretical methods for prediction of transition-metal chemical shielding.

Theory



For a quadrupolar nucleus, only the Zeeman, quadrupolar, and chemical shielding interactions need to be considered, and the nuclear-spin Hamiltonian is given as

$$[1] \qquad \hat{H}_T = \hat{H}_Z + \hat{H}_Q + \hat{H}_{CS}$$

There are two situations that arise depending on the strength of the quadrupolar coupling with respect to the Zeeman interaction: first-order (Q_1) or second-order (Q_2) quadrupolar effects. Q_1 is sufficient to describe the response of the quadrupolar nucleus when the quadrupolar interaction is only a first-order perturbation of the Zeeman interaction (similar to all other NMR interactions that are only first order perturbations). If the quadrupolar effects are larger, Q_2 must be considered as well. As a guide for ^{59}Co NMR, at 11.75 T, a χ of 1.5 MHz or greater is required before Q_2 needs to be considered; at 4.7 T, a χ of only 950 kHz necessitates consideration of Q_2. Using the estimates of χ from previous ^{59}Co relaxation studies in solution (26), we observe that all of the complexes described in this study fall into the second-order regime (i.e., Q_2 must be considered) if the solution and solid-state χs are equivalent. Hence, the central $m = +1/2 \leftrightarrow -1/2$ transition should dominate the observed ^{59}Co NMR spectra. If the satellite transitions are observed, Q_2 will shift them but the splitting between any pair of satellite transitions will be determined solely by Q_1.

The theory describing the origin of NMR powder line shapes for quadrupolar nuclei in general crystal sites, has been described in detail elsewhere (15, 16). Figure 1*a* uses the angles θ and ϕ to describe the orientation with respect to the magnetic field (B_o) of the efg tensor, where $|eq_{33}| \geq |eq_{11}| \geq |eq_{22}|$ are the three orthogonal components of this tensor in its principal axis system (PAS). The angles ϑ and φ describe the orientation with respect to B_o of the CS tensor, where $\delta_{11} \geq \delta_{22} \geq \delta_{33}$ are the three principal components of this tensor in its PAS. In general, powder NMR line shapes of the central ($+1/2 \leftrightarrow -1/2$) transition of quadrupolar nuclei with half-integer spin are described by the following equation:

Fig. 1. (*a*) Orientation of the CS and efg tensors with respect to B_o; (*b*) the Euler angles (α, β, and γ) orient the CS tensor in the PAS of the efg tensor.

$$[2] \qquad \nu = \nu_o(\delta_{11} \sin^2 \vartheta \cos^2 \varphi + \delta_{22} \sin^2 \vartheta \sin^2 \varphi + \delta_{33} \cos^2 \vartheta) + \frac{\nu_Q^2\left[I(I+I) - \frac{3}{4}\right]}{6\nu_o}[A(\phi) \cos^4 \theta + B(\phi) \cos^2 \theta + C(\phi)]$$

where

$$[3] \qquad \nu_Q = \frac{3\chi}{2I(2I-1)}$$

I is the nuclear spin quantum number, ν_o is the Larmor frequency, and $\chi = eq_{33}eQ/h$ is the quadrupolar coupling constant, with eq_{33} the largest or so-called "principal" component of the electric field gradient (efg) tensor and eQ the nuclear quadrupole moment,

$$[4] \qquad A(\phi) = -\frac{27}{8} - \frac{9}{4}\eta_Q \cos 2\phi - \frac{3}{8}\eta_Q^2 \cos^2 2\phi$$

$$[5] \qquad B(\phi) = -\frac{30}{8} - \frac{1}{2}\eta_Q^2 + 2\eta_Q \cos 2\phi + \frac{3}{4}\eta_Q^2 \cos^2 2\phi$$

$$[6] \qquad C(\phi) = -\frac{3}{8} - \frac{1}{3}\eta_Q^2 + \frac{1}{4}\eta_Q \cos 2\phi - \frac{3}{8}\eta_Q^2 \cos^2 2\phi$$

and η_Q is the asymmetry of the efg tensor ($\eta_Q = (eq_{22} - eq_{11}) / eq_{33}$). However, it is only possible to obtain the orientations of the tensors with respect to the molecule using single-crystal NMR, a dipolar interaction, or in systems where there is high crystal symmetry (orthorhombic or higher point-symmetry). Therefore, to simulate solid-state ^{59}Co NMR spectra, the relative orientations of the two tensors are described via the Euler angles (α, β, and γ, as seen in Fig. 1*b*) using the following expressions:

$$[7] \qquad \sin \vartheta \cos \varphi = \cos \gamma \cos \beta \cos (\phi - \alpha) + \sin \gamma \sin \theta \sin (\phi - \alpha) - \cos \gamma \sin \beta \cos \theta$$

$$[8] \qquad \sin \vartheta \sin \varphi = -\sin \gamma \cos \beta \sin \theta \cos (\phi - \alpha) + \cos \gamma \sin \theta \sin (\phi - \alpha) + \sin \gamma \sin \beta \cos \theta$$

$$[9] \qquad \cos \vartheta = \sin \beta \sin \theta \cos (\phi - \alpha) + \cos \beta \cos \theta$$

Hence, in general, eight variables are needed to fully describe the interactions responsible for the anisotropic NMR

line shape of a quadrupolar nucleus in the solid-state: the three principal components of the CS tensor, the quadrupolar coupling constant (χ), its asymmetry (η_Q), and the Euler angles relating the fixed orientations of the two tensors in the molecular frame. To establish accurate values for the eight parameters used in describing such a powder NMR line shape, it is normally necessary to obtain spectra at two or more magnetic field strengths.

Experimental

The cobalt(III) complexes were made by standard literature procedures, were commercially available, or were graciously provided by a colleague, as seen in Table 1. All samples were referenced to 1.0 M $K_3[Co(CN)_6]$ (aq). Solid-state ^{59}Co NMR spectra were acquired at 11.75 T on a Bruker AMX-500 NMR spectrometer and at 4.7 T on a Bruker DSX-200 NMR spectrometer where possible (vide infra). Samples were prepared by crushing the sample with a mortar and pestle and packing them into 5 mm NMR tubes. Samples were limited to the central region of the rf coil. At 4.7 T, a spin-echo pulse sequence was used for all spectra. At 11.75 T, a simple one pulse experiment was attempted to obtain all spectra except for Na[Co(edta)] (edta = ethylenediamine tetraacetate), which has a very broad line shape. In some spectra, Lorentzian "tails" were present due to the probe's finite dead time.

Calculations of the ^{59}Co NMR powder line shapes were performed on a Pentium computer using a Windows-based software package[3] that incorporates the POWDER routine (27) with additions for quadrupolar nuclei (15). The values of the three principal components of the chemical shift tensor, the quadrupolar coupling constant, the asymmetry of the efg tensor, and the Euler angles were optimized to maximize the agreement (visually) between the experimental and calculated line shapes of the central transition, with particular emphasis placed on the positions of critical frequencies (peaks and shoulders) in the spectra. Crystal structures were used to determine whether any constraints on the CS or efg tensors were necessary due to nuclear site symmetry.

The orientations of the efg tensors were estimated by consideration of local symmetry arguments or obtained using Gaussian 94 (28) for *cis*-$[Co(NH_3)_4(NO_2)_2]NO_3$ running on a SGI Indigo^2 XL workstation. For this complex, no crystal structure has been published, hence Gaussian 94 was used to obtain an optimized structure of the cation only and the resulting efg tensor. The calculations were performed using the LanL2DZ basis set with Hartree–Fock methods.

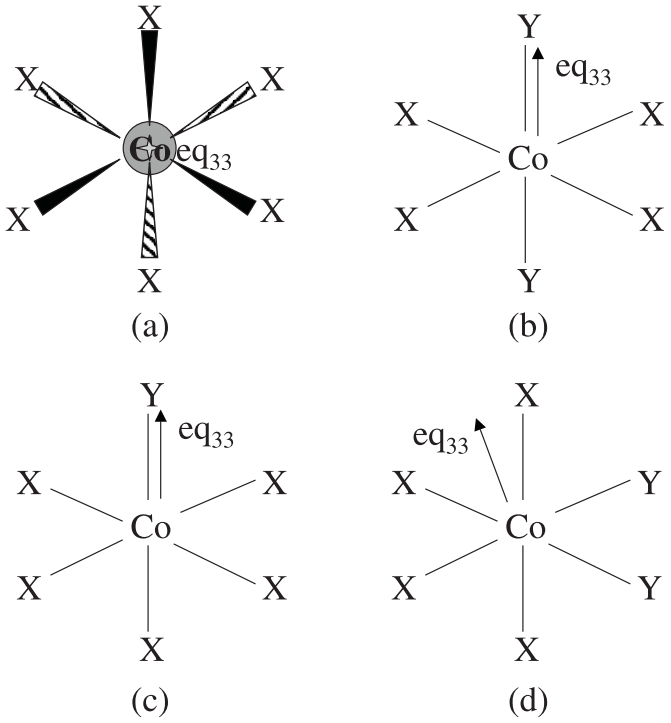
Results and Discussion

Simulations of the ^{59}Co NMR spectra were performed for all of the spectra at 11.75 T as well as for the complexes for which spectra were obtained at 4.7 T. The results of the simulations are summarized in Table 1. Any values in Table 1 without "±" indicated are parameters that must be exactly 0 or 90° under crystallographic symmetry constraints.

For most compounds, only the central transition (m = +1/2 ↔ −1/2) was observed due to the large quadrupolar splitting causing the satellites to fall outside the observable spectral window. One example where the satellites as well as the central transition was observed was $[Co(en)_3]Cl_3$ (en = ethylenediamine). The crystal structure of $[Co(en)_3]Cl_3$ (29) indicated that the compound crystallizes in the trigonal space group *P*3*c*1. Therefore, the cobalt CS and efg tensors were required to be both axially symmetric and coincident, placing constraints on the analysis of the spectra of this complex. As seen in Table 1, the CS tensor was axially symmetric with $\delta_{11} = \delta_{22}$ and the principal components of the CS and efg tensors were aligned such that δ_{33} and eq_{33} were coincident (i.e., $\beta = 0$). Figure 2 shows the calculated spectra of this compound at 11.75 T; considering in turn: only the chemical shift tensor, only the efg tensor, the resulting full simulation including both interactions, and the experimental spectrum. The experimental spectrum shows some phase distortion due to the dead time of the probe. It is impossible to refocus all of the central and satellite transitions simultaneously with a single echo sequence. This complex is the only one in this series where all of the satellites are observed because whenever χ was larger and (or) the tensors were not aligned, the central transition dominated the spectrum, and the satellites fell outside the spectral window or became obscured under the central transition.



The only other complex that had constraints dictated by its crystal structure was $Na_3[Co(NO_2)_6]$, which crystallizes in the rhombohedral space group $R\bar{3}m$ (30); the cobalt nuclei sit on sites of threefold symmetry. All other complexes studied here did not have any constraints placed on the cobalt sites by their crystallographic symmetry, hence all eight parameters had to be used to obtain suitable simulations of the spectra.

At 4.7 T, the solid-state ^{59}Co NMR spectra of $[Co(NH_3)_5Cl]Cl_2$ and Na[Co(edta)] were difficult to obtain due to the large χs associated with these complexes, therefore, useful spectra were not obtained. A spectrum of *cis*-$[Co(NH_3)_4(NO_2)_2]NO_3$ was not obtained at the lower magnetic field due to the small amount of compound (approximately 5 mg), which was insufficient for sensitivity reasons. Cobalt-59 spectra of the other seven complexes were obtained at both 4.7 and 11.75 T, and the spectra at both fields were used to obtain unambiguous simulations.

Chemical shift tensors are of greatest interest when it is possible to identify trends that are present from similar compounds. Plots of the chemical shift tensors only (i.e., no quadrupolar interaction) of the complexes in this study are shown on the chemical shift scale (with respect to 1.0 M $K_3[Co(CN)_6]$ (aq)) at the bottom of Fig. 3. The magnitudes of the CS components alone are not sufficient; it is also important to consider the orientation of the tensors. Using basic symmetry arguments, as well as results from Gaussian 94 (28), it is possible to predict, or at least suggest, the orientation of the ^{59}Co efg tensors in each complex. Since absolute magnitudes of the efg tensor were not desired, and the orientations are dictated predominantly by local symmetry, the orientations of the efg tensor provided by calculations at this modest level of theory (HF/LANL2DZ) should be instructive nonetheless. These orientations of the efg tensors, in turn,

Fig. 4. The orientation of the principal component of efg tensors in the four classes of compounds in this study: (*a*) CoX_6, (*b*) *trans*-CoX_4Y_2, (*c*) CoX_5Y, and (*d*) *cis*-CoX_4Y_2.

permit the orientation of the CS tensor in the molecular frame to be deduced using the Euler angles.

We will introduce two definitions to simplify the ensuing discussion of chemical shielding tensor orientations and trends: eq_{33} will be called the "principal component" of the efg tensor, and the principal component of the CS tensor that is furthest from δ_{iso} will be termed the "principal director" of the CS tensor. The complexes will be discussed in four basic frameworks: CoX_6, CoX_5Y, *trans*-CoX_4Y_2, and *cis*-CoX_4Y_2. The orientation of the efg tensors of these four types of ligand arrangements is given in Fig. 4, and representative spectra of a complex from each of these categories are displayed in Fig. 5.

CoX_6

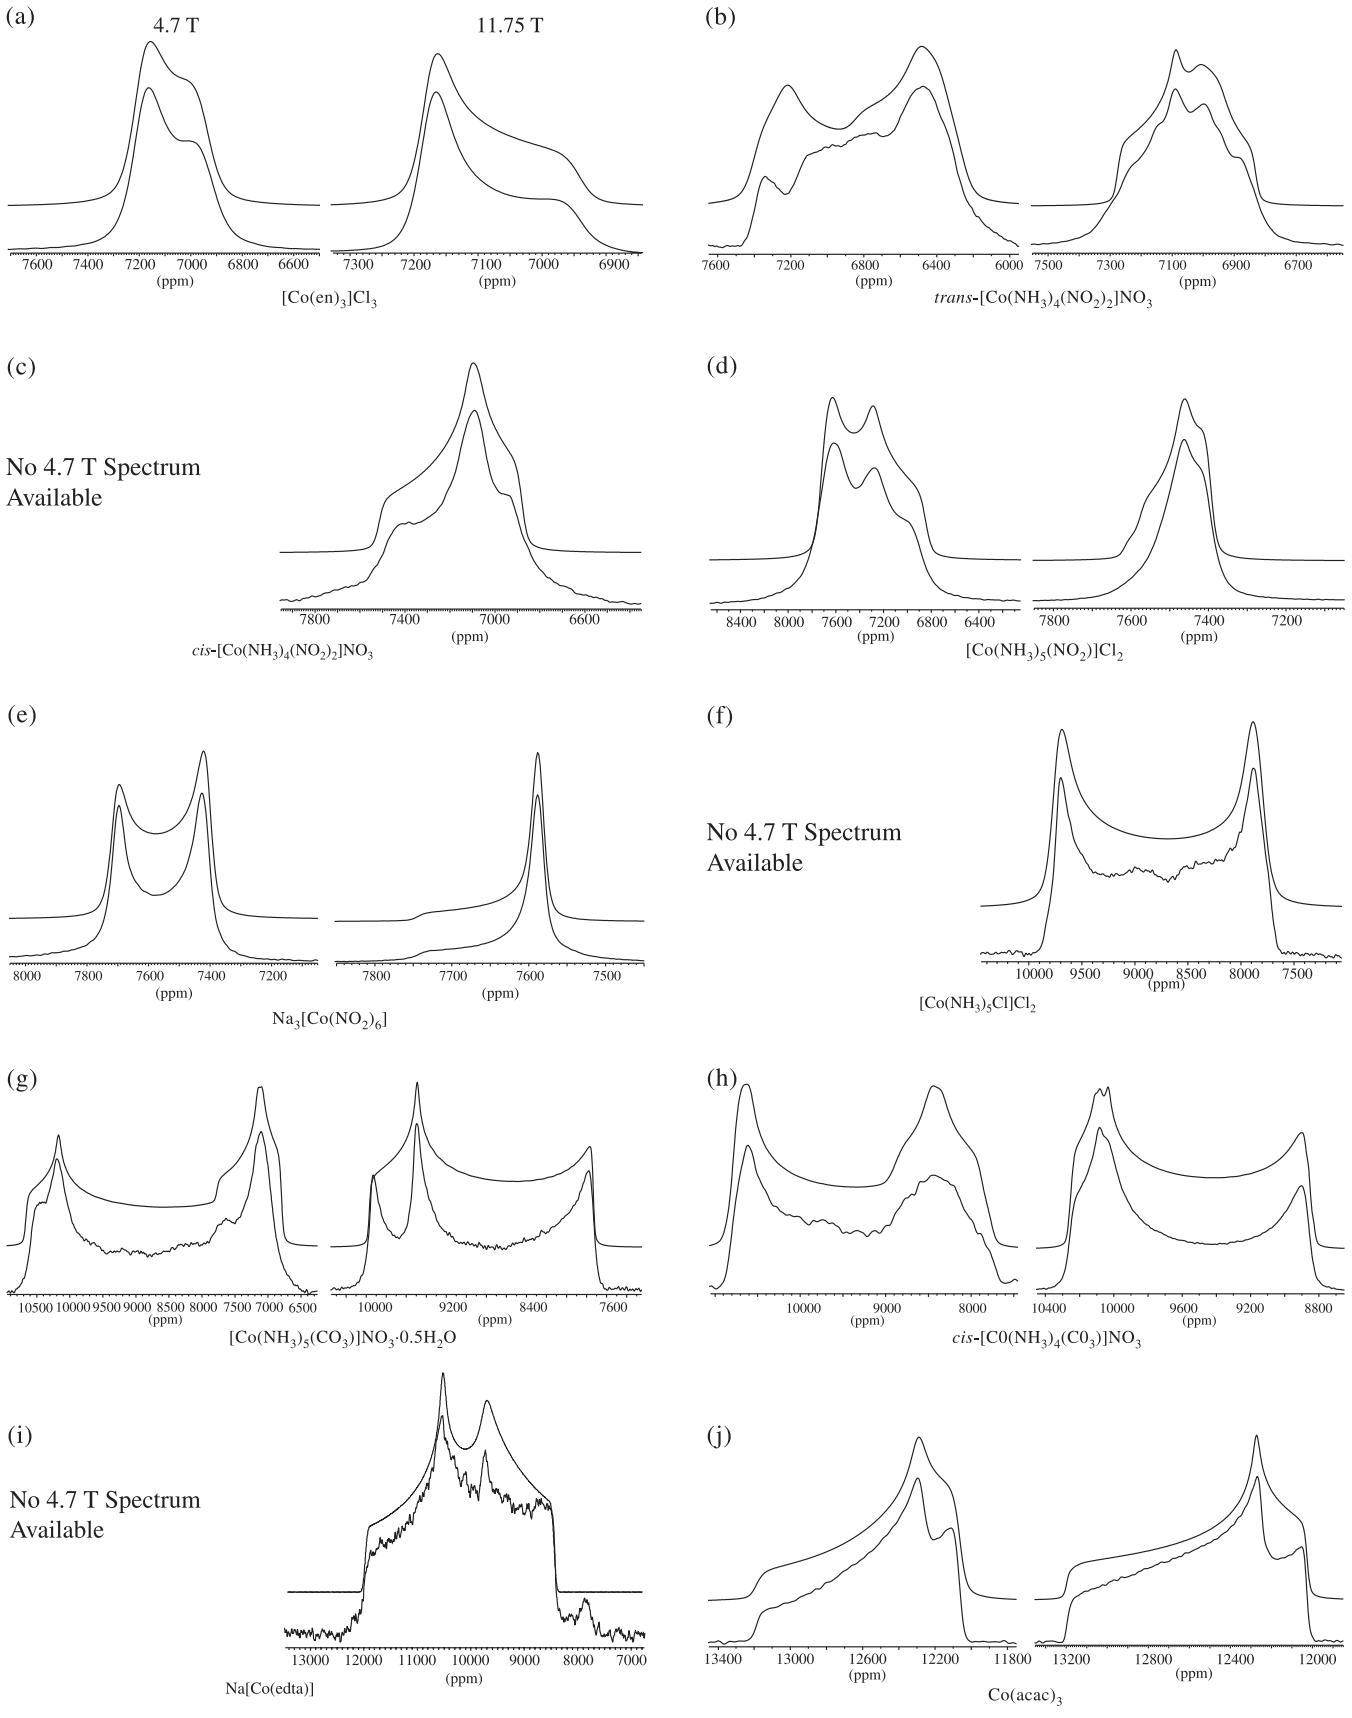
This group consists of three complexes: $[Co(en)_3]Cl_3$, $Na_3[Co(NO_2)_6]$, and $Co(acac)_3$. $Na_3[Co(NO_2)_6]$ crystallizes in a rhombohedral space group with the cobalt nucleus at the origin of the rhombohedral cell (30). The principal component of the efg tensor must lie along the threefold axis, and since β was 90°, it lies along δ_{11} (the principal director) with $\delta_{22} = \delta_{33}$. These results agree closely with those obtained previously via powder ^{59}Co NMR (17). $Co(acac)_3$ is similar to $Na_3[Co(NO_2)_6]$ in that the principal component of the efg lies along the normal to one face of the octahedron which is closest to a threefold axis ($Co(acac)_3$ does not have a true threefold axis since it crystallizes in the space group $P2_1/c$) (31). A β value of 86° was found for this complex, which would put the principal component of the efg approximately along δ_{11}. The orientation of the two tensors in this study, as well as the span of the CS tensor, agree quite well with those of a recent single-crystal ^{59}Co study of $Co(acac)_3$ (13). For $[Co(en)_3]Cl_3$, β was 0° and δ_{33} lies along the principal component of the efg tensor. The principal component of the efg would lie along the threefold axis of this molecule that crystallizes in a trigonal space group (29).

CoX_5Y

This group also comprises three complexes: $[Co(NH_3)_5Cl]Cl_2$, $[Co(NH_3)_5CO_3]NO_3{\cdot}2H_2O$, and $[Co(NH_3)_5NO_2]Cl_2$. For the first two of these complexes, β was small (6° or less). Therefore, the unique component of the efg should lie close to δ_{33}. If eq_{33} lies along δ_{33}, δ_{33} would have to be the principal director of the chemical shift tensor. This is observed for both complexes even though the spans vary between the two. In $[Co(NH_3)_5NO_2]Cl_2$, β was 90°, and thus, eq_{33} should lie close to δ_{11}. The principal director in $[Co(NH_3)_3NO_2]Cl_2$ was observed to be δ_{11} in agreement with the observed β value of 90°.

trans-CoX_4Y_2

trans-$[Co(NH_3)_4(NO_2)_2]NO_3$ was unique because it was the only complex in this study with a *trans* arrangement of ligands. The principal component of the efg tensor was expected to lie along a Co—NO_2 bond. Since the Euler angles for this complex were all nonzero and non-90°, the efg and the chemical shift tensors did not have any components that were coincident. The principal director of the chemical shift tensor was observed to be δ_{11}, but in fact, there was not a true principal director in this complex since the chemical shift tensor was far from axial symmetry.



cis-CoX_4Y_2

This last group contained the following complexes: Na[Co(edta)], *cis*-$[Co(NH_3)_4(NO_2)_2]NO_3$, and *cis*-$[Co(NH_3)_4CO_3]NO_3$. From a Gaussian 94 calculation of the efg tensor of *cis*-$[Co(NH_3)_4(NO_2)_2]^+$, the principal component of the efg tensor was predicted to lie close to a Co—NH_3 bond that was perpendicular to the ligand plane containing the two nitro groups, and slightly tilted away from the nitro groups (see Fig. 4). A similar orientation was assumed for the other two complexes, in that the efg lies close to one of the Co—X bonds and perpendicular to the ligand plane containing the two Y groups. The principal director of the chemical shift tensors of Na[Co(edta)] and *cis*-$[Co(NH_3)_4(NO_2)_2]NO_3$ was δ_{11} while it was δ_{33} for *cis*-$[Co(NH_3)_4CO_3]NO_3$. With a β value of 4° for *cis*-$[Co(NH_3)_4CO_3]NO_3$, the principal component of the efg lies close to the principal director of the chemical shift tensor, and may, in fact, lie along a Co—NH_3 bond. In the other two complexes, the principal director of the chemical shift tensor does not lie along the principal component of the efg tensor. For Na[Co(edta)], a similar case to that of *trans*-$[Co(NH_3)_4(NO_2)_2]NO_3$ was observed, in that the chemical shift tensor was not symmetric and there was not a true principal director in the complex. For *cis*-$[Co(NH_3)_4(NO_2)_2]NO_3$ the principal component of the efg was not very different from eq_{11} since η_Q is 0.9. Therefore, the principal component of the efg and the principal director of the chemical shift tensor are not relevant to these two complexes.

In attempting to understand the origin of chemical shift tensors, it is beneficial to determine planes that are responsible for specific magnitudes of the principal components of

the chemical shift tensors. Each principal component of a chemical shift tensor depends on electronic excitations, specifically magnetic-dipole-allowed *d–d* transitions, in the plane perpendicular to its axis. Using the data from this study, the following ligand planes have been determined to give rise to specific values of chemical shifts: (*i*) a four-nitrogen (4-N) plane gives rise to shifts between 6910–7890 ppm, (*ii*) a 3-N 1-O or 3-N 1-Cl plane gives rise to shifts between 8860–9805 ppm, (*iii*) a 2-N 2-O plane gives rise to shifts between 9910–10165 ppm, and (*vi*) a 4-O plane gives rise to shifts between 12030–13185 ppm. The range of the 2-N 2-O plane may be increased as high as 11870 ppm if one assumes that of the chemical shift tensor of Na[Co(edta)] was a result of a 2-N 2-O plane; however, it is not clear that this orientation for the δ_{11} component can be assigned from the results presented in Table 1.

As stated earlier, with DFT calculations now available, experimental data of this quality are needed to aid in the improvement of the calculations. Of the ten complexes studied here, ab initio calculations have been reported for four: $Co(NO_2)_6^{3-}$, $Co(en)_3^{3+}$, $Co(acac)_3$, and *cis*-$Co(NH_3)_4CO_3^+$ (5, 6). The first three of these complexes should be readily calculated because all of the ligands of Co are the same (either six nitrogens or oxygens). Both Chan and Au-Yeung (5) as well as Godbout and Oldfield (6) have calculated the chemical shielding tensors of $Co(acac)_3$. The calculations of the span of the chemical shift tensor by Chan and Au-Yeung agree reasonably well with our experimental CS tensor (approximately 10% too small), while Godbout and Oldfield's is smaller by almost 25%. Both groups have also calculated the shielding tensor of *cis*-$Co(NH_3)_4CO_3^+$, however, they both report spans (Ω) that are greater than those measured experimentally (contrary to both groups predicting smaller spans for the compound) and Godbout and Olfield's calculations are significantly better in this case. This discrepancy may result from the different counterion (Br^-) present in the experimental single-crystal diffraction goemetries (32) used in the calculations and the NO_3^- counterion in the complex characterized experimentally by solid-state NMR here. Godbout and Oldfield have also calculated the tensors of $Co(NO_2)_6^{3-}$ and $Co(en)_3^{3+}$; however, their calculated tensors are not axially symmetric (which they have to be by crystal symmetry) and differ by approximately 200 ppm in both cases (too small for $Co(NO_2)_6^{3-}$ while too large for $Co(en)_3^{3+}$).

A comparison between the solution and solid-state ^{59}Co NMR results is also instructive. The solid-state isotropic chemical shifts (δ_{iso}) can be obtained from the average of the principal components of the chemical shift tensors. Table 2 shows the solution and solid-state NMR δ_{iso}s, χs, and Ωs. From Table 2 one can see that the isotropic chemical shifts in solution and in the solid-state are all within approximately 100 ppm, which is close considering the large chemical shift range for cobalt. There is no trend observed between the isotropic shifts and the χs, but Ω, in general, increases with increasing χ. For convenience in this discussion, we will assume that the values of χ are positive in both solution and solid-state; the only real consequence of this is the assumption that their values will be of *the same sign* in solution and solid, which appears to be reasonable. The solid-state χs are much larger than those measured in solution. This could be due to several factors, including a change in geometry and (or) conformation between solution and solid states, or that the solid-state values in Table 2 are measured directly from a spectrum while the solution values are measured indirectly from the relaxation studies. In fact, the value of $\chi_{solution}$ includes any contribution from asymmetry in the quadrupolar coupling constants, via the term $(1 + \eta_Q^2/3)^2$ in the spin-lattice relaxation expression (26); since η_Q lies in a range from 0 to 1, estimates of χ from solution relaxation data are upper-bound estimates, with the "true" χ up to 13.3% less. In addition, $\chi_{solution}$ is only as good as the correlation time measured, which, in the relaxation studies, was obtained from the carbon T_1s of two complexes since T_1 minima could not be reached due to temperature limitations of the solvent. Another possible origin of the differences between solution and solid-state data is changes in either intramolecular, intermolecular, or both contributions to observed values. Since the isotropic shifts are consistent between solution and solid-state, and chemical shielding is predominantly a local phenomenon, the intramolecular term should be constant between phases. Intermolecular effects could arise from interactions between two (or more) solute molecules, or between a solute molecule and a solvent molecule. Since $\chi_{solution}$ is less than χ_{solid}, one might take this as evidence that the intermolecular χ has a negative sign, but if one uses the arguments of Osten and Jameson (33), one would expect that intermolecular effects would increase as concentration increases, as observed in the ^{59}Co relaxation of Na[Co(edta)] (26). At maximum concentration (a solid) the largest χ is observed, and, therefore, the intermolecular χ is positive between solute molecules. Thus, if there is an influence from the solvent on χ, it must be negative.

Conclusions

Solid-state ^{59}Co NMR spectra of ten simple inorganic cobalt(III) complexes have been obtained at 11.75 and, in most cases, at 4.7 T as well. From the spectra, their ^{59}Co CS and efg tensors have been determined. The isotropic chemical shifts in the solid-state are close to those found in solution considering the large chemical shift range for cobalt. The quadrupolar coupling constants determined from the solid-state spectra were all larger than those determined from the ^{59}Co relaxation studies, but the spans of the CS tensors were, in general, found to increase with increasing quadrupolar coupling constants. Several ligand planes responsible for specific chemical shifts have been determined. The planes are (*i*) 4-N plane gives rise to shifts between 6910–7890 ppm, (*ii*) 3-N 1-O or 3-N 1-Cl plane gives rise to shifts between 8860–9805 ppm, (*iii*) 2-N 2-O plane gives rise to shifts between 9910–10165 ppm (possibly up to 11870 ppm), and (*vi*) 4-O plane gives rise to shifts between 12030–13185 ppm.

Acknowledgments

We thank Dr. Arthur J. Carty (National Research Council of Canada) for his gift of $[Co(NH_3)_5(NO_2)]Cl_2$ and Dr. Patricia Aroca-Ouellette (University of Toronto) for her assistance in using the DSX-200. We are also grateful to the Natural Sciences and Engineering Research Council of Canada (NSERC) for financial assistance in the form of operating and equipment grants.

The reduction of I_2 by H_2O_2 in aqueous solution

J.M. Ball and J.B. Hnatiw

Abstract: The reduction of I_2 by hydrogen peroxide, a primary water radiolysis product, has been identified as a key reaction that would influence iodine volatility in nuclear reactor accident conditions (1–3). Although there have been a number of studies of the reduction of I_2, there exists a great degree of controversy regarding the intermediates involved, the effect of buffers, and the general rate law (1–9). Because the rates and the mechanism of this reaction are important in predicting the pH dependence of iodine behaviour in reactor containment building after a postulated reactor accident, we have undertaken a kinetic study of I_2 reduction by H_2O_2 in aqueous solution over a pH range of 6–9. The experiments were performed using stopped-flow instrumentation and monitoring the decay of I_3^- spectrophotometrically. The effects of buffer catalysis have been examined by comparison of kinetic data obtained in sodium barbital (5,5-diethylbarbituric acid), disodium citrate, and disodium hydrogen phosphate buffers. The effect of buffers, combined with the complex acid dependence of the rate law, explains many of the discrepancies reported in earlier literature.

Key words: hydrogen peroxide, molecular iodine, kinetics, iodine volatility.

Résumé : On a identifié la réduction de I_2 par le peroxyde d'hydrogène, un produit de radiolyse primaire de l'eau, comme une réaction clé qui pourrait influencer la volatilité de l'iode dans des conditions d'accident d'un réacteur nucléaire (1–3). Même s'il y a déjà eu plusieurs études de la réduction, il y a encore un grand degré de controverse concernant les intermédiaires impliqués, l'effet des tampons et la loi générale de vitesse (1–9). Compte tenu du fait que les vitesses et le mécanisme de cette réaction sont importants pour prédire la relation entre le comportement de l'iode et le pH dans un édifice permettant de contenir un réacteur après un accident de réacteur présumé, on a entrepris une étude cinétique de la réduction du I_2 par H_2O_2, en solution aqueuse, à des pH allant de 6 à 9. On a réalisé les expériences à l'aide d'instruments à flux stoppé et on a suivi la disparition de l'ion I_3^- de façon spectrophotométrique. On a étudié les effets de catalyse par des tampons en faisant une comparaison des données cinétiques obtenues dans des tampons de barbital sodique (acide 5,5-diéthylbarbiturique), de citrate disodique et de phosphate d'hydrogène disodique. L'effet des tampons, combiné à la relation complexe entre le degré d'acidité et la loi de vitesse, permet d'expliquer beaucoup de disparités rapportées dans la littérature antérieure.

Mots clés : peroxyde d'hydrogène; iode moléculaire; cinétique; volatilité de l'iode.

[Traduit par la Rédaction]

Introduction

Iodine species are important in the assessment of the radiological consequences of a nuclear reactor accident because the radiologically toxic ^{131}I is one of the most abundant fission products that would be released from fuel. Iodine also has the potential to form numerous volatile species, which, once airborne in containment, could be released to the atmosphere through containment leakage or during controlled venting.

The reduction of iodine by peroxide in aqueous solutions has been recognized as an important process that would govern iodine volatility in containment after a reactor accident. The reaction has,therefore, been recently investigated as part of a number of reactor safety research programs (1–3). A large body of early literature also exists regarding the iodine–peroxide couple because of its role in the Bray–Liebhafsky oscillatory reactions, which were discovered in 1921 (4–8). Unfortunately, there is no consensus in the literature on a mechanism for the reaction, and in cases where the same general rate law is reported, calculated rate constants vary by two orders of magnitude (5, 6). Moreover, much of the experimental data obtained to date has been in acidic or neutral solutions, conditions which may not be representative of containment in a reactor accident scenario.

Studies of the kinetics of iodine reduction by peroxide in the pH range 2–7 have been performed by Shiraishi et al. (1), Abel (4), and Liebhafsky (5). Abel (4) and Liebhafsky (5) derived general rate laws in which iodine reduction exhibited a $1/[H^+]^2$ dependence, consistent with their proposed reaction scheme in which peroxide, or the peroxodyl anion (HO_2^-) reacts with either the hypoiodite anion (OI^-), or with hypoiodite (HOI).[2]

$$[1] \quad I_2 + H_2O \rightleftharpoons HOI + I^- + H^+$$

$$[2] \quad HOI \rightleftharpoons OI^- + H^+$$

[2]The effect of oxidation of I^- by H_2O_2 ($H_2O_2 + I^- \rightarrow HOI + OH^-$) on the kinetics of reduction of I_2 were accounted for by Liebhafsky, but were negligible in the other studies. In neutral to basic solution, with $[I^-]$ less than 10^{-2} M the reaction is slow, since the rate constant is small (0.012 M^{-1} s^{-1} (1)).

[a]Ionic strength was maintained at 0.2 M with $NaClO_4$.
[b]Calculated from eq. [10] and confirmed spectrophotometrically.

[3] $HOI + HO_2^- \rightarrow I^- + O_2 + H_2O$

[4] $OI^- + H_2O_2 \rightarrow I^- + O_2 + H_2O$

Deviations from the $1/[H^+]^2$ rate law derived from the above equations were reported by Shiraishi et al. (1) who measured the overall rate of the reduction by observing the rate of loss of I_3^- from solutions containing I_2 and I^- at pH 6 to 7. He explained his observation by incorporating rxns. [5]–[7] to the above reaction scheme.

[5] $I_2 + I^- \rightleftharpoons I_3^-$

[6] $I_2 + OH^- \rightleftharpoons I_2OH^- \rightleftharpoons HOI + I^-$

[7] $I_2OH^- + H_2O_2 \rightarrow 2I^- + O_2 + H_3O^+$

In experiments performed at pH 7 and 9, Kessi-Rabia et al. (6) observed that the rate of iodine reduction exhibited a $1/[H^+]$ dependence. His proposed reaction scheme was identical to that reported by Liebhafsky (5) (see rxns. [1]–[5]), but he suggested that the simple inverse dependence upon $[H^+]$ arose as a result of the forward rate of rxn. [1] becoming rate determining at pH 7 and above (i.e., a rapid equilibrium cannot be assumed for the hydrolysis of iodine represented in rxn. [1]).

Preliminary stopped-flow studies performed in our laboratories (9) confirmed that the rate law for the reduction of I_2 by H_2O_2 in the pH range of 6–9 deviates from the $1/[H^+]^2$ relationship reported in refs. 1, 5, and 6. However, the peroxide and buffer dependencies of the rates observed in ref. 9 were not accounted for by the reaction scheme suggested by Kessi-Rabia et al. (7). We, therefore, performed a more complete study of the kinetics of the reduction as a function of acid, peroxide, iodide, and buffer concentration in three buffers to attempt to derive a rate law that describes the reduction over a large range of conditions.

Experimental

Iodine (I_2) (99.999%), sodium hydroxide (99.99%), and dihydrogen sodium phosphate (99.99%) were used as purchased from Aldrich. Sodium iodide (99.99%) was purchased from Aldrich and dried at 100°C overnight prior to use. Sodium citrate (99.99%) was standardized by titration with sodium hydroxide. Sodium perchlorate (99.99%) was standardized by passing a 2 M solution through an ion exchange resin, and titrating the resulting acid. Hydrogen peroxide was purchased as a 30% solution from Mallinkrodt and standardized by titration with potassium permanganate solution. Sodium barbital (97.5%) was purchased from BDH and dried overnight prior to use. All reagents and reaction solutions were diluted in water purified with a Milli-Q reagent grade water system.

Kinetic studies were performed using a Hi-Tech Scientific SF-61MX stopped-flow multi mixing unit and a Hi-Tech Scientific M300 monochromator spectrophotometer. Stock solutions containing I_2 and I^- were prepared, and the desired concentration of the resulting I_3^- solution obtained by dilution with water purged with argon. I_3^- solutions were analyzed spectrophotometrically prior to each use (adsorption 353 nm, $\varepsilon = 27500\ M^{-1}\ cm^{-1}$). They were then placed in one of the stopped-flow solution reservoirs. For every measurement, the I_3^- solution was mixed in the stopped flow apparatus with equal volumes of pH adjusted solutions containing peroxide and buffer, adjusted to 0.2 M ionic strength with sodium perchlorate, and purged with argon. Solution reservoirs drive syringes and observation cells were temperature controlled using a circulating water bath. All solutions were

© 2001 NRC Canada

temperature stabilized to the desired temperature (±0.2°C) prior to each test run.

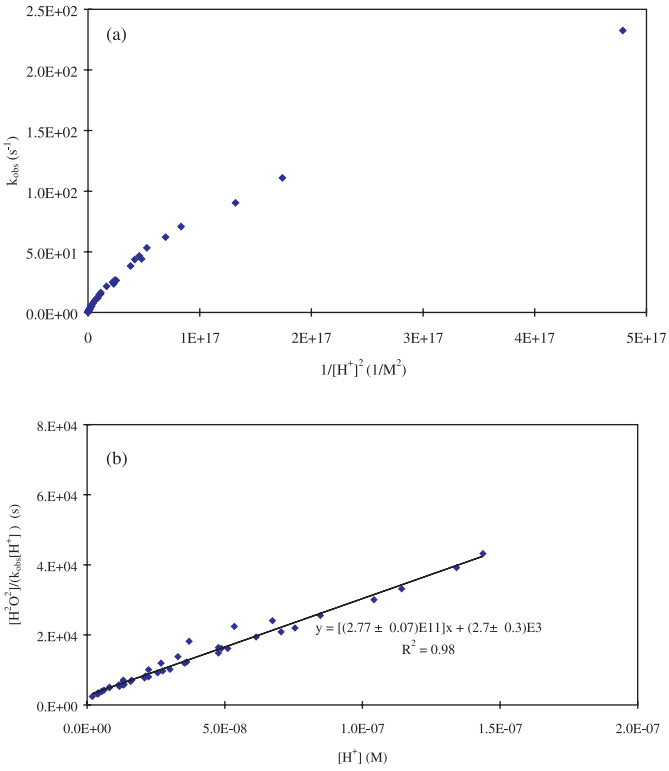
Reactant concentrations were chosen such that the reaction was pseudo first-order in I_2 (i.e., an excess of H_2O_2 and I^- were used). The decay of I_3^- (which is assumed to be in rapid equilibrium with I_2 and its hydrolysis products (1, 11)) was monitored at various pH values for a given set of conditions by measuring its absorbance at 353 nm using a tungsten light source. Initial concentrations and conditions for each experiment are presented in Table 1.

At each pH, six to twelve repetitive runs using the same solution and operating conditions were averaged and fitted with a built-in fitting function to obtain a first-order decay rate constant (k_{obs}). All of the decay curves obeyed first-order kinetic behaviour up to about three half-lives. The variance of each decay profile with the mean absorbance vs. time plot ranged from about 1–10% of the total absorbance. However the deviation of individual first-order decay rates from the average decay rate was less than 5%.

Results and discussion

Derivation of a rate law

Figure 1 shows the $[H^+]$ dependence of the observed pseudo-first-order rate constant for decay of I_3^- (k_{obs}) from solutions initially containing I_3^- (2.6×10^{-6} M) and H_2O_2 (1×10^{-3} M) buffered with 5×10^{-3} M barbital buffer. A plot of k_{obs} vs. $1/[H^+]^2$ (Fig. 1*a*) demonstrates that the overall rate constant deviates significantly from a $1/[H^+]^2$ dependence. This would not be the case if the reaction schemes, proposed in refs. 1, 5, and 6, were valid. A more convenient plot for extracting kinetic information is shown in Fig. 1*b* where $[H_2O_2]/k_{obs}[H^+]$ is plotted against $[H^+]$. To a first approximation, $1/k_{obs}[H^+]$ varies linearly with $[H^+]$. From Fig. 1*b*, the relationship in eqs. [8] and [9] are evident.



$$[8] \qquad \frac{1}{k_{obs}[H^+]} \propto k'[H^+] + k''$$

$$[9] \qquad \frac{1}{k_{obs}} \propto k'[H^+]^2 + k''[H^+]$$

The effects of the peroxide and the iodide concentrations on the rate of reduction of I_2 by peroxide are shown in Figs. 2 and 3. The dependence of the reduction rate on the concentrations of these species implies that the rate-determining step must have both an iodide and peroxide concentration dependence. The mechanism proposed by Kessi-Rabia et al. (6), in which the forward rate of the iodine hydrolysis equilibrium (rxn. [1]) is the rate-determining step, is, therefore, ruled out as a possible mechanism.

The qualitative behaviour exhibited in Figs. 1–3 can be accounted for by a reaction mechanism analogous to that proposed by Connick (10) for the reduction of Cl_2 by H_2O_2.

Fig. 1. Plots of (*a*) k_{obs} (the psuedo-first-order rate constant for loss of I_3^- from solutions containing H_2O_2) vs. $1/[H^+]$ and (*b*) $[H_2O_2]/k_{obs}[H^+]$ vs. $[H^+]$ for initial concentrations of 1×10^{-5} M I_2, 5×10^{-4} M I^-, 5×10^{-3} M sodium barbital, and 1×10^{-3} M H_2O_2 at 25°C. A linear least-squares fit of the data is shown in (*b*).

The mechanism involves the formation of IO_2H as an intermediate, and could occur by reaction of molecular iodine or one of its hydrolysis products (I_2OH^- or HOI) with peroxide, or perhydroxy radical. For example:

Scheme 1[2]

$$[10] \qquad I_2 + I^- \rightleftharpoons I_3^-$$

$$[11a] \qquad I_2 + OH^- \rightleftharpoons I_2OH^-$$

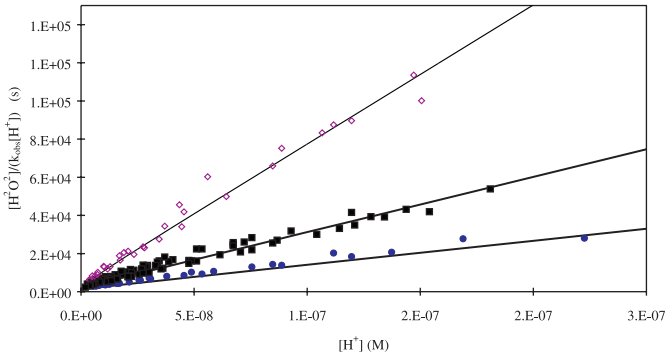
$$[11b] \qquad I_2OH^- \rightleftharpoons HOI + I^-$$

$$[12] \qquad I_2OH^- + H_2O_2 \rightleftharpoons I^- + IO_2H + H_2O$$

$$[13] \qquad IO_2H + OH^- \rightarrow I^- + H_2O + O_2$$

Alternatively, reaction of the I_2 hydrolysis product (HOI) with H_2O_2 to form the intermediate IO_2H could occur, in which case rxn. [12] would be replaced by:

[2] The direct reaction of I_2 with HO_2^- could also be invoked. In this kinetically equivalent scheme rxns. [11*a*], [11*b*], and [12] in Scheme 1 could be replaced with:



Scheme 1′

$$[11] \qquad H_2O_2 \rightleftharpoons HO_2^- + H^+$$

$$[12] \qquad I_2 + HO_2^- \rightleftharpoons IO_2H + I^-$$

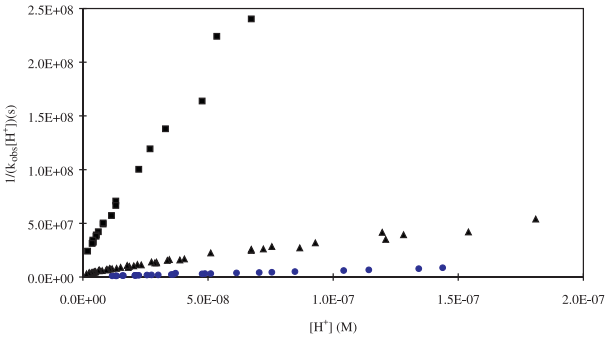
Fig. 2. Iodide concentration dependence of $[H_2O_2]/k_{obs}[H^+]$ vs. $[H^+]$ at 25°C. Initial concentrations used were: 1×10^{-5} M I_2, 5×10^{-3} M sodium barbital, and 1×10^{-3} M H_2O_2 with 2.5×10^{-4} (●), 5×10^{-4} (■), and 1×10^{-3} (◇) M I^-. Unbroken lines represent values calculated using the rate law from Scheme 1 and the rate constants from Table 2.

Scheme 2

[12′] $HOI + H_2O_2 \rightleftharpoons IO_2H + H_2O$

Scheme 2 leads to rate expression that is slightly different from that of Scheme 1 because the concentration of the iodine species (HOI) in the rate-determining step has an iodide dependence due to *both* equilibrium rxns. [10] and [11b].



For either Scheme 1 or 2, the overall rate of reduction of I_2 by peroxide ($d[O_2]/dt$) may be expressed as the sum of loss of I_2, I_3^-, I_2OH^-, and HOI from solution. Assuming a rapid equilibrium between I_2, its hydrolysis products (I_2OH^- and HOI), and I_3^- (3), the overall rate can be expressed in terms of the measured rate of loss of I_3^- ($-d[I_3^-]/dt$ or $k_{obs}[I_3^-]$)[3]:

$$[14] \quad \frac{dO_2}{dt} = -k_{13}[IO_2H][OH^-] = \left(1 + \frac{1}{K_{10}[I^-]} + \frac{k_{11a}[OH^-]}{K_{10} - [I^-]} + \frac{K_{11a}K_{11b}[OH^-]}{K_{10}[I^-]^2}\right)\frac{d[I_3^-]}{dt}$$

The values of K_{10} (700 (13)), K_{11a} (2.9×10^4 (11)), and K_{11b} (1.7×10^{-3} (1)) are such that, for the pH range 6–9 and iodide concentrations from 2.5×10^{-4} to 1×10^{-3} M employed in these experiments, the second two terms in brackets on the right side of eq. [14] can be ignored to give:

$$[15] \quad \frac{d[O_2]}{dt} = \left(1 + \frac{1}{K_{10}[I^-]}\right)k_{obs}[I_3^-] = k_{13}[IO_2H][OH^-]$$

Fig. 3. Peroxide concentration dependence of $1/k_{obs}[H^+]$ vs. $[H^+]$ at 25°C. Initial concentrations used were: 1×10^{-5} M I_2, 5×10^{-4} M I^-, and 5×10^{-3} M sodium barbital with 5×10^{-3} (●), 1×10^{-3} (▲), and 1×10^{-4} (■) M H_2O_2.

Assuming the reaction proceeds via Scheme 1, and using a steady state approximation to solve for the concentration of IO_2H leads to the expression:

$$[16] \quad k_{obs} = \frac{K_w^2 K_{11} k_{12} k_{13}}{k_{13}K_w[H^+] + k_{-12}[I^-][H^+]^2}\left(\frac{[H_2O_2]}{1 + K_{10}[I^-]}\right)$$

where K_w is the dissociation constant for water, and K_{11} is either the formation constant for I_2OH^- (K_{11a}, Scheme 1) or the dissociation constant for H_2O_2 (Scheme 1′, footnote 2). The equation may be rearranged to give the plotting form used in Figs. 1–3:

$$[17] \quad \frac{[H_2O_2]}{k_{obs}} = (1 + K_{10}[I^-])\left(\frac{k_{-12}[I^-][H^+]}{K_w^2 K_{11} k_{12} k_{13}} + \frac{1}{k_{12}K_{13}K_w}\right)$$

A plot of $[H_2O_2]/k_{obs}[H^+]$ vs. $[H^+]$ should, therefore, give a straight line with:

$$[18] \quad \text{slope} = \frac{(1 + k_{10}[I^-])(k_{-12}[I^-])}{K_w^2 K_{11} k_{12} k_{13}}$$

$$[19] \quad \text{intercept} = \frac{1 + K_{10}[I^-]}{K_{11}k_{12}K_w}$$

If Scheme 2 is the mechanism, the rate law is :

$$[20] \quad \frac{[H_2O_2]}{k_{obs}[H^+]} = (1 + K_{10}[I^-])\left(\frac{k_{-12}[I^-][H^+]}{K_w^2 K_{11} k_{12} k_{13}} + \frac{[I^-]}{k_{12}K_{10}K_w}\right)$$

where K_{11} is $K_{11a} \times K_{11b}$. A plot of $[H_2O_2]/k_{obs}[H^+]$ vs. $[H^+]$ should give a straight line with

[3] The substitutions used are:

$$-\frac{d[I_2]}{dt} = \frac{1}{K_{10}[I^-]}\frac{d[I_3^-]}{dt},$$

$$\frac{d[I_2OH^-]}{dt} = K_{11a}[OH^-]\frac{d[I_2]}{dt} = \frac{K_{11a}[OH^-]}{K_{10}[I^-]}\frac{d[I_3^-]}{dt}$$

$$\frac{d[HOI]}{dt} = K_{11a}K_{11b}\frac{[OH^-]}{[I^-]}\frac{d[I_2]}{dt} = \frac{K_{11a}K_{11b}[OH^-]}{K_{10}[I^-]^2}\frac{d[I_3^-]_4}{dt}$$

Table 2. Estimated rate constants[a] (using Scheme 1 as a mechanism) for the reduction of I_2 by H_2O_2 in aqueous solution.

Buffer	Barbital	Citrate	Phosphate	ΔE_a (kJ M^{-1})
k_{12} (M^2 s^{-1}) [a]	(2.25 ± 0.27) × 10^6	(2.25 ± 0.27) × 10^6	(2.25 ± 0.27) × 10^6	31 ± 3
k_{-12} (M^2 s^{-1}) [b]	(1 ± 0.4) × 10^7	(1 ± 0.4) × 10^7	(1 ± 0.4) × 10^7	92 ± 10
k_{13} (M^2 s^{-1}) [b]	(2 ± 0.8) × 10^9	(2 ± 0.8) × 10^9	(2 ± 0.8) × 10^9	54 ± 6
k_{23} (M^2 s^{-1})[b]	(3 ± 1) × 10^5	(2 ± 1) × 10^4	(7 ± 2) × 10^4	91 ± 10 (phosphate)[c]

[a]From a linear least-squares fit of all of the data obtained with 2.5 × 10^{-4} and 5 × 10^{-4} M barbital buffer.
[b]Rate constants reported are those that provide a best fit to *all* of the available data. Rate constants obtained from non-linear least-squares fits to individual data sets (i.e., data obtained for a given set of conditions in Table 1) deviated from these values. The deviations are reported in brackets.
[c]From a linear least-squares fit of ln k vs. $1/T$ obtained at various temperatures in phosphate buffer.

Fig. 4. A plot of $[H_2O_2]/k_{obs}[H^+]$ vs. $[H^+]$ for1 × 10^{-5} M I_2, 1 × 10^{-3} M H_2O_2, and 5 × 10^{-3} M barbital buffer with 2.5 × 10^{-4} (●) and 1 × 10^{-3} (■) M I^- at 25°C. Linear least-squares fits to the data are shown.

$$[21] \quad \text{slope} = \frac{(1 + K_{10}[I^-])\, k_{-12}[I^-]}{K_w K_{11} k_{12} k_{13}}$$

$$[22] \quad \text{intercept} = \frac{[I^-] + K_{10}[I^-]^2}{K_{11} k_{12} K_w}$$

One can distinguish between Scheme 1 and 2 by the iodide dependence of the intercept value of plots of $[H_2O_2]/k_{obs}[H^+]$ vs. $[H^+]$. For citrate and phosphate buffer measurements, which used buffer concentrations of 0.01–0.05 M (to provide kinetic data comparable to that obtained in earlier investigations (1, 4, 5)), these plots deviated significantly from linearity at high pH values. The deviation, which arose due to the effect of buffer catalysis (see below), made it difficult to assign an "intercept" value to the experimental data. Fortunately, plots of data obtained using barbital buffer at lower concentrations (0.005 M) did not significantly deviate from linearity, and a linear least-squares fit of the data provided a reasonable estimate of the intercept. The linear least-squares fit of the data in Fig. 4 shows that the intercept values from data obtained using iodide concentrations of 2.5 × 10^{-4} and 1 × 10^{-3} M differ by a factor of about 2 (note that the ratio of the intercept values depends only upon the value used for $[I^-]$). This is much closer to the ratio of the intercept values expected for Scheme 1 (1.45) than for Scheme 2 (5.8). It should also be noted that it was not possible to use Scheme 2 to fit all of the data obtained from the three different buffer types, and various iodide and peroxide concentrations. For this reason, we believe the reaction proceeds via Scheme 1 and (or) the kinetically equivalent Scheme 1′ (footnote 2).

Fig. 5. Barbital buffer concentration dependence of $[H_2O_2]/k_{obs}[H^+]$ vs. $[H^+]$ at 25°C. Initial concentrations were: 5 × 10^{-4} M I^-, 1 × 10^{-5} M I_2, 1 × 10^{-3} M H_2O_2 with 2.5 × 10^{-3} (□) and 1 × 10^{-2} (×) M barbital buffer. Unbroken lines represent values calculated using the rate law from Scheme 1 and the rate constants from Table 2.

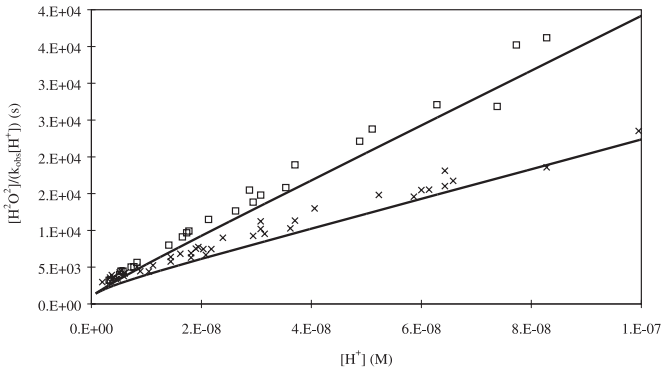

Figure 5 shows the effect of barbital buffer concentration on the rate of disappearance of I_3^- from a solution initially containing I_2 and I^- when mixed with H_2O_2. The plot of $[H_2O_2]/k_{obs}[H^+]$ vs. $[H^+]$, for two buffer concentrations demonstrates that the slope (eq. [18]) is sensitive to buffer concentration, whereas the intercept (eq. [19]) is not. Because the intercept is proportional to $1/K_{11}k_{12}K_w$, the data implies that neither rxn. [11] nor [12] can be participating in the catalysis step. Buffer catalysis by sodium barbital must therefore be due to catalysis of rxn. [13] alone. General base catalysis of the reaction by:

$$[23] \quad IO_2H + B^- \rightarrow I^- + BH + O_2$$

may be accommodated in the rate expression of eq. [16] by substituting:

$$k_{13}K_w = k_{13}K_w + k_{23}K_b[BH]:$$

where K_b is the buffer dissociation constant and B^- and BH are the basic and acidic forms of the buffer, respectively.

When buffer catalysis is included in eq. [17], the formulation for the slope and intercept of plots of $[H_2O_2]/k_{obs}[H^+]$ vs. $[H^+]$ become:

$$[24] \quad \text{slope} = \frac{(1 + K_{10}[I^-])(k_{-12}[I^-])}{K_w K_{11} k_{12}(k_{13}K_w + k_{23}K_b[BH])} = k_{ov}$$

$$[25] \quad \text{intercept} = \frac{1 + K_{10}[I^-]}{K_{11} k_{12} K_w}$$

Evaluation of rate constants

Values for k_{12}, k_{-12}, k_{13}, and k_{23} were estimated from the data. Literature values of 700 M^{-1} (13), 2.9×10^4 M^{-1} (11, 12), and 1×10^{-14} (14) were used for K_{10}, K_{11}, and K_w, respectively. An estimate for k_{12} was obtained from the intercept values of linear least-squares fits of $[H_2O_2]/k_{obs}[H^+]$ vs. $[H^+]$ for mixtures of $I_2/I^-/I_3^-$ and H_2O_2 in barbital buffer. Scheme 1 was assumed to be the mechanism. The ratio $k_{-12}/k_{12}k_{13}$ was then estimated by plotting the gradients (eq. [24]) of a series of $[H_2O_2]/k_{obs}[H^+]$ vs. $[H^+]$ plots against barbital buffer concentration (2.5×10^{-3}, 5×10^{-3}, 7.5×10^{-3}, and 1×10^{-2} M) and extrapolating to zero buffer concentration. Individual values for the rate constants k_{-12}, k_{13}, and k_{23} were then estimated by obtaining a best fit to all of the experimentally observed first-order decay rates of $[I_3^-]$ (k_{obs} $[I_3^-]$) using a numerical integration package for solving chemical kinetics.[4] In addition to the reaction set for Scheme 1, reactions describing the dissociation of HOI (1), and the disproportionation of HOI and OI^- (12, 14) were used. Numerical solutions for the concentration of I_2, I_2OH^-, HOI, I_3^-, and IO_2H were obtained, and a first-order decay rate for I_3^- was calculated for various pH values.

The rate constants k_{12}, k_{-12}, and k_{13} determined for barbital buffer were then used to estimate values for k_{23} for citrate and phosphate buffers. Values for individual rate constants are presented in Table 2. Comparisons of calculated (using the rate law for Scheme 1 and the constants in Table 2) vs. experimental plots of $[H_2O_2]/k_{obs}[H^+]$ vs. $[H^+]$ are presented in Figs. 2, 5, 6, and 7 for selected data obtained in barbital, citrate, and phosphate buffers, respectively. Note that the values for the rate constants presented in Table 2 were used in the calculations shown in the figures. These values represent the rate constants that provided a best fit to *all* of the available data. Rate constants obtained by non-linear least-squares optimization of individual data sets deviated from these mean values. This deviation is also indicated in Table 2.

The agreement between calculated and experimental values over a wide range of conditions supports the assignment of the rate law to the mechanism presented in Scheme 1. The assumptions that I_2, its hydrolysis products, and I_3^- are in rapid equilibrium, and that IO_2H can be treated by a steady-state approximation, were also verified by obtaining numerical solutions for k_{obs} using a numerical integration package.[4] The individual decay rate constants obtained by numerical

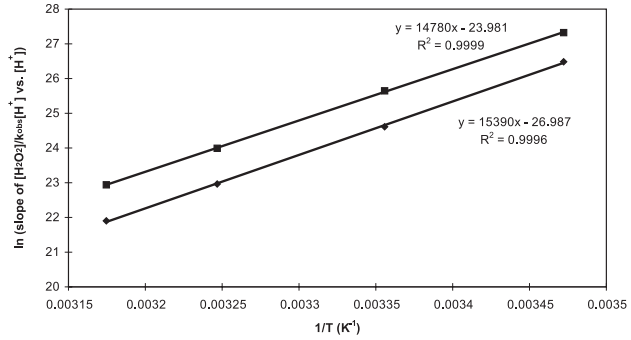
Fig. 8. A plot of ln (slope $H_2O_2/k_{obs}[H^+]$ vs. $[H^+]$) vs. $1/T$ for 1×10^{-5} M I_2, 1×10^{-3} M H_2O_2, 0.05 M phosphate buffer, and 5×10^{-4} (◆) and 1×10^{-3} (■) M I^-. Linear least-squares fits to the data are shown as unbroken lines with the value for the slope in *K*.



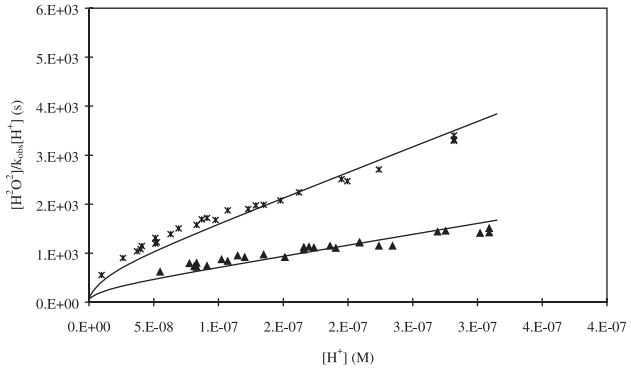


Fig. 9. A comparison of observed and calculated values for $H_2O_2/k_{obs}[H^+]$ vs. $[H^+]$ at 42°C. Initial concentrations were: 1×10^{-5} M I_2, 1×10^{-3} M H_2O_2, 0.05 M phosphate buffer, and 5×10^{-4} (▲) and 1×10^{-3} (×) M I^-. Unbroken line represents calculated values.

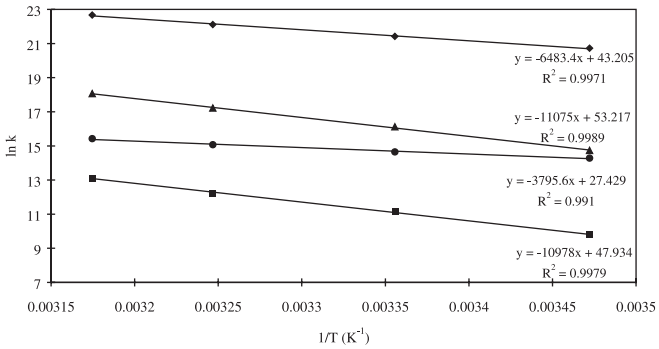
solution for each condition differed by less than 10% to those calculated using the steady state approximation.

The temperature dependence of the reduction of I_2 by H_2O_2



The temperature dependence of the reaction rate constants k_{12}, k_{-12}, k_{13}, and k_{23} were obtained by performing measurements of the rate of loss of I_3^- in peroxide solutions at 15, 25, 35, and 42°C in phosphate buffer. Measurements were obtained using 1×10^{-5} M I_2, 1×10^{-3} M H_2O_2, and 0.05 M phosphate buffer with both 5×10^{-4} and 1×10^{-3} M I^-. Plots of $[H_2O_2]/k_{obs}[H^+]$ vs. $[H^+]$ were generated for each set of conditions. The overall rate constant,

$$k_{ov} = \frac{(1 + K_{10}[I^-])(k_{-12}[I^-])}{K_w K_{11} k_{12}(k_{13}K_w + k_{23}K_b[BH])}$$

was estimated from the slope of these plots. A plot of ln k_{ov} vs. $1/T$, as shown in Fig. 8, gives an estimated activation energy for the overall rate constant of 125 kJ mol^{-1}.

Solutions for eq. [24] were calculated using trial values for k_{-12}, k_{12}, k_{13}, and k_{23}, and using the appropriate values for K_w (14), K_{10} (15), K_{11} (16), and K_b (14) as a function of temperature, with the constraints being that the overall activation energy be approximately 125 kJ mol^{-1}, and that the individual rate constants were consistent with values previously determined from data obtained at 25°C. These solutions were compared with experimental data obtained at 15, 25, 35, and 42°C to obtain a best fit to the data. A comparison of the calculated values of $H_2O_2/k_{obs}[H^+]$ vs. $[H^+]$ to the values observed at 42°C is shown in Fig. 9. The agreement between calculated and observed values is typical. Individual values of k_{12}, k_{-12}, k_{13}, and k_{23} that were selected on the basis of providing the best fit (non-linear least-squares regression analysis) to the data were also found to follow the Arrhenius law (See Fig. 10). Activation energies estimated from linear least-squares fits of ln *k* vs. $1/T$ for the individual rate constants are tabulated in Table 2.

Fig. 10. A plot of ln *k* vs. $1/T$ for individual values of k_{12} (●), k_{-12} (▲), k_{13} (◆), and k_{22} (■) used to obtain a best fit to the data. Linear least-squares' equations used to fit the data to straight lines are indicated.

Conclusions

The kinetic data obtained in these experiments support the formulation of the rate law derived for Scheme 1. It should be noted that this rate law is also consistent with data obtained in earlier investigations. Discrepancies in the rate laws previously reported for this reduction resulted from the different pH conditions (1, 5) or iodide concentrations (7) under which the experiments were performed, whereas variations in reported rates (1, 2, 6) of reaction could be accounted for by the effects of buffer catalysis. Thus, our observed overall rates of reduction of I_2 in phosphate and citrate buffers are similar to those reported by Liebhafsky (5) and Shiraishi et al. (1) under the same conditions. The rate law derived from Scheme 1 is also consistent with the findings of Kessi-Rabia et al. (6). Furthermore, the overall temperature dependence of the iodine hydrolysis–peroxide reduction is similar to that measured by Liebhafsky (16).

Cyclopropanation of benzylidenemalononitrile with dialkoxycarbenes and free radical rearrangement of the cyclopropanes

Nadine Merkley, Paul C. Venneri, and John Warkentin

Abstract: Thermolysis of 2-cinnamyloxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**1a**) and the analogous 2-benzyloxy-2-methoxy compound (**1b**) at 110°C, in benzene containing benzylidenemalononitrile, afforded products of apparent regiospecific addition of methoxycarbonyl and cinnamyl (or benzyl) radicals to the double bond. When the thermolysis of **1a** was run with added TEMPO, methoxycarbonyl and cinnamyl radicals were captured. Thermolysis of the 2,2-dibenzyloxy analogue (**1c**) in the presence of benzylidenemalononitrile gave an adduct that is formally the product of addition of benzyloxycarbonyl and benzyl radicals to the double bond. In this case, a radical addition mechanism could be ruled out, because the rate constant for decarboxylation of benzyloxycarbonyl radicals is very large. A mechanism that fits all of the results is predominant cyclopropanation of benzylidenemalononitrile by the dialkoxycarbenes derived from the oxadiazolines, in competition with fragmentation of the carbenes to radical pairs. The cyclopropanes so formed then undergo homolytic ring-opening to the appropriate diradicals. Subsequent β-scission of the diradicals to afford radical pairs, and coupling of those pairs, gives the final products. Thus, both carbene and radical chemistry are involved in the overall processes.

Key words: cyclopropane, dialkoxycarbene, β-scission, oxadiazoline, radical.

Résumé : La thermolyse de la 2-cinnamyloxy-2-méthoxy-5,5-diméthyl-Δ^3-1,3,4-oxadiazoline (**1a**) et du composé analogue, 2-benzyloxy-2-méthoxy (**1b**), à 110°C, dans du benzène contenant du benzylidènemalononitrile, conduit à la formation des produits provenant d'une addition apparemment régiospécifique des radicaux méthoxycarbonyles et cinnamyles (ou benzyles) sur la double liaison. Lorsqu'on a effectué la thermolyse de **1a** en présence de TEMPO, les radicaux méthoxycarbonyles et cinnamyles sont piégés. La thermolyse de l'analogue 2,2-dibenzyloxy (**1c**), en présence de benzylidènemalononitrile, conduit à la formation d'un adduit qui est formellement le produit d'addition des radicaux benzyloxycarbonyles et benzyles sur la double liaison. Dans ce cas, on peut éliminer la possibilité d'un mécanisme d'addition radicalaire en raison de la valeur élevée de la constante de vitesse de décarboxylation des radicaux benzyloxycarbonyles. Un mécanisme qui permet d'expliquer tous les résultats implique une cyclopropanation prédominante du benzylidènemalononitrile par les dialkoxycarbènes dérivés des oxadiazolines qui serait en compétition avec la fragmentation des carbènes en paires de radicaux. Les cyclopropanes ainsi formés subissent alors une ouverture de cycle homolytique conduisant aux biradicaux appropriés. Une scission subséquente β des biradicaux fournit des paires de radicaux et le couplage de ces paires conduit aux produits finaux. Ainsi, les processus globaux impliqueraient à la fois de la chimie des radicaux et de celle des carbènes.

Mots clés : cyclopropane, dialkoxycarbène, scission β, oxadiazoline, radical.

[Traduit par la Rédaction]

Introduction

Fragmentations of dialkoxycarbenes to radical pairs in the gas-phase have been known for some time (1, 2), but the analogous homolyses in solution are still relatively new (3–5). Thermolysis of cinnamyloxy(methoxy)- (3), benzyloxy(methoxy)- (4), and dibenzyloxy-oxadiazolines (**1**) (5) in benzene led primarily to formation of the appropriate dioxycarbenes (**3**) through carbonyl ylides (**2**). The carbenes fragmented to corresponding radical pairs (Scheme 1). A minor side reaction of **1** was a dipolar cycloreversion to the carbonate and 2-diazopropane (not shown). Carbene intermediates were trapped with *tert*-butyl alcohol (3–5), and radical intermediates were trapped with TEMPO (3–5). In the absence of TEMPO, the radical pairs (**4** and **5a**) coupled to esters (**6a** and **7)**, whereas **4** and **5b** afforded **6b** (Scheme 2).

Evidence for the sequential formation of carbenes and radicals raised some interesting questions regarding the consequences of generating the carbenes in the presence of an olefinic trap with the potential for reaction with both the carbenes and the radicals. For instance, could the carbenes be trapped fast enough as cyclopropanes, by suitably substituted olefins, to suppress carbene fragmentation to radicals?

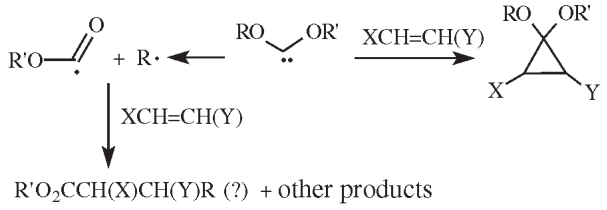
Scheme 1.

Scheme 2.



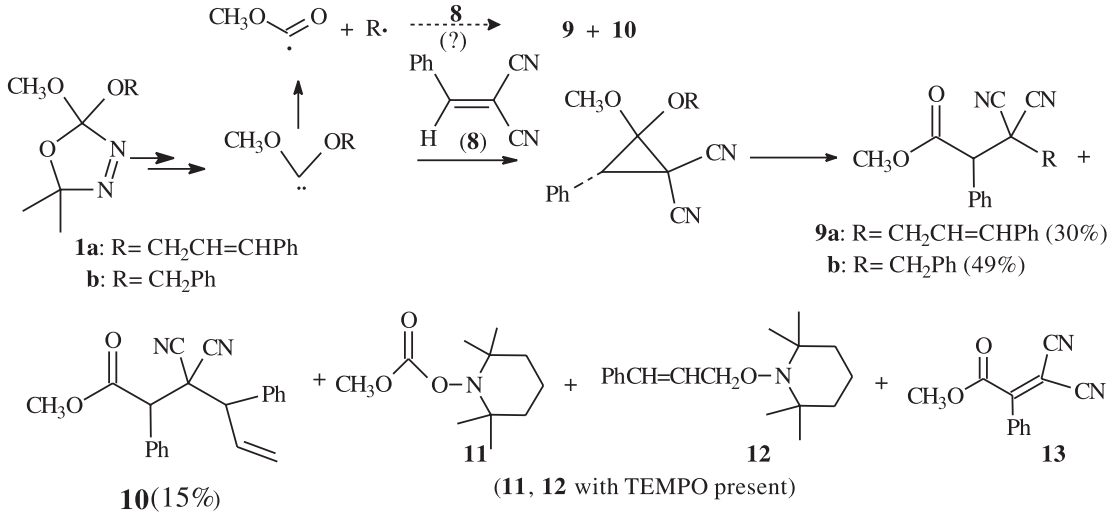
Alternatively, if cyclopropanation were slow enough to make carbene fragmentation predominant, could the very different radicals (e.g., methoxycarbonyl and benzyl) possibly be trapped with some regioselectivity (Scheme 3)?

We now report the thermolysis of **1a**–**c** in the presence of **8**, showing that cyclopropanation of the benzylidenemalononitrile by the first-formed carbene is the fastest reaction (at [**8**] = 0.16–0.20 M) (Scheme 4). Thereafter, radical pairs are indeed involved but they originate primarily from ring-opening of the cyclopropanes and not from fragmentation of the carbenes.

Results and discussion

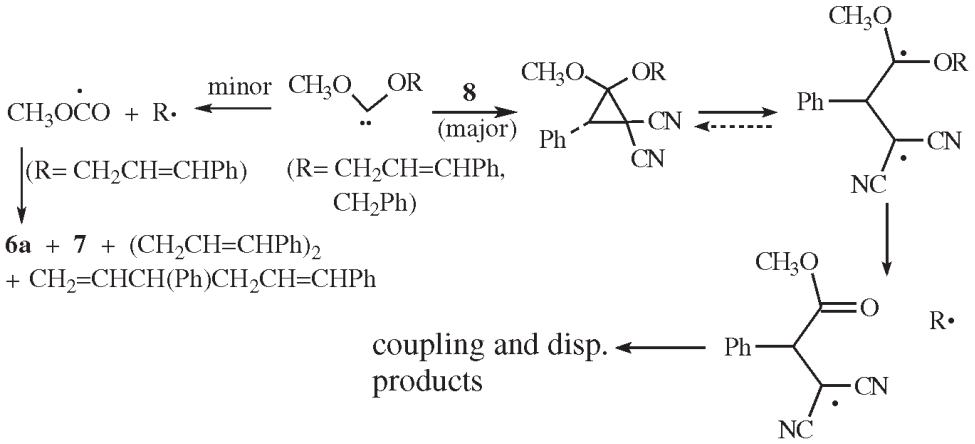
Thermolysis of 2-cinnamyloxy-2-methoxy oxadiazoline (**1a**) in the presence of benzylidenemalononitrile (**8**) in benzene at 110°C for 24 h afforded products **9a** and **10** in 2:1 ratio in a combined yield of 45**%** (isolated) (Scheme 4). A sequential ylide → carbene → radical-pair mechanism was considered in view of the evidence described above for formation of radical pairs from **1a** (3), although the other three potential products from addition of the radicals to benzylidenemalononitrile were not found. To probe for radical intermediates, a stable free radical (TEMPO) was included with **1a** and **8**. The yields of **9a** and **10** were reduced and new products **11** and **12**, generated from radical-coupling of the methoxycarbonyl and phenylallyl radicals with TEMPO, were obtained (Scheme 4). The alternative product of trapping of the phenylallyl radical by TEMPO was not observed; we assume that it is more sterically hindered, and, therefore, less stable than **12**, and is eventually converted to **12** at 110°C by dissociation–recoupling. The yields of **9a** and **10**, estimated by GC, were depressed about

Scheme 3.



fourfold by TEMPO as would be expected if they had arisen from radicals. The yield of disproportionation product **13**, estimated in the same way, rose about fivefold when TEMPO was present.

These facts can probably be accounted for as follows: TEMPO does not interfere with cyclopropanation by the carbene, but it does scavenge diffusively separated radicals arising from carbene fragmentation. Adducts **11** and **12** are products of such scavenging. Compounds **9a**, **10**, and **13** come primarily from ring-opening of the cyclopropane and subsequent β-scission, with the radical pairs either coupling or disproportionating in the solvent cage, or else diffusing apart (Scheme 5). Again, TEMPO captures the radicals that become free but not radicals from a caged pair. The increased yield of **13** in the presence of TEMPO could be the result of disproportionation between TEMPO and the methyl 1,1-dicyano-2-phenylpropanoyl radical (Scheme 5), which presumably couples reversibly with TEMPO and, therefore, leads to **11** eventually.



The alternative interpretation that **9a** and **10** of Scheme 4 came from sequential additions of carbene-derived methoxycarbonyl and phenylallyl radicals to **8** must be rejected. It would require that those additions be both regio- and order-selective, the methoxycarbonyl radical adding first (faster) to **8**. Moreover, in the second step, there would have to be a considerable selectivity for the adduct radical to couple with the phenylallyl radical, rather than with the methoxycarbonyl radical. That apparent selectivity, favouring phenylallyl over methoxycarbonyl radicals, is not obviously in keeping with a radical mechanism, because coupling reactions do not have appreciable activation energies, but are, in many cases, essentially diffusion controlled. Moreover, although radical additions of small molecules (XY) to multiple bonds are well-known, they do not involve sequential reactions of X• and Y• with the alkene. Instead, they normally proceed by addition of X• to one atom of the multiple bond, followed by a radical–molecule reaction (chain trans-

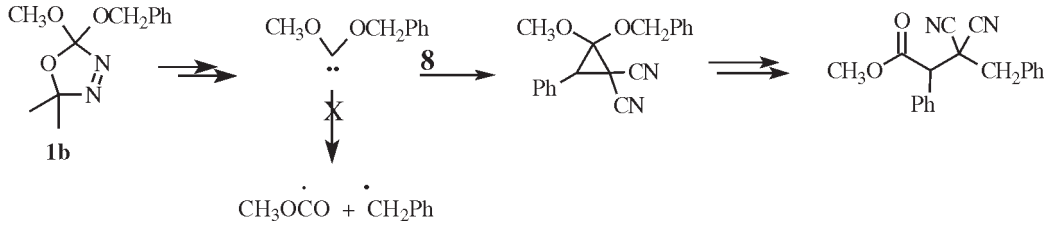
Scheme 4.

Scheme 5.

fer by abstraction of Y• from XY) that attaches Y• to the other atom of the former multiple bond, and regenerates X•.

On the other hand, the cyclopropanation mechanism, followed by rearrangement via β-scission of a diradical (Scheme 5), is attractive. Cyclopropane formation from nucleophilic carbenes and **8** is easy to envision, and subsequent rearrangement of the cyclopropane seemed likely, given that 1,1-dialkoxycyclopropanes undergo thermal ring-opening readily (6–8). Such ring-openings of cyclopropanes have generally been described with a heterolytic mechanism (9)[2], presumably because cyclopropanes with vicinal electron withdrawing and donating groups undergo the opening most easily (6, 7, 9[2]). The fact that the formation of **9a** and **10** was suppressed when TEMPO was present with **8**, requires that at least a fraction of **9a** and **10** come from free radicals that are capable of being trapped, and suggests that those compounds arise from homolytic, rather than heterolytic, ring-opening. Homolytic ring-opening of cyclopropanes is a tenable alternative to heterolytic cleavage, for Baldwin (10) has shown that there is a correlation of the rates of thermal enantiomerization of 1,2-disubstituted cyclopropanes with radical stabilization energies.



Additional products from the thermolysis of **1a** with **8** (Scheme 5) that were detectable in trace amounts by GC–MS were the esters **6a** and **7** as well as two products with masses appropriate for dimers of phenylallyl radicals. The esters are presumably derived from nonscavengeable caged radical pairs formed from the carbene. Dimers of phenylallyl are not surprising as products from diffusion out of the solvent cage. This result indicates that most, but not all, of the carbene from **1a** is captured by **8** before it can fragment (Scheme 5).

Under the same conditions, different results were obtained with **1b** and **8**. In that case, the ester (methyl phenylacetate) expected from in-cage-coupling of methoxycarbonyl and benzyl radicals was not detected. Failure to find it presumably means that benzyloxy(methoxy)carbene fragments more slowly to a radical pair than cinnamyloxy(methoxy)carbene (Scheme 6). The alternative explanation that the former carbene adds more rapidly to **8**, is less likely.

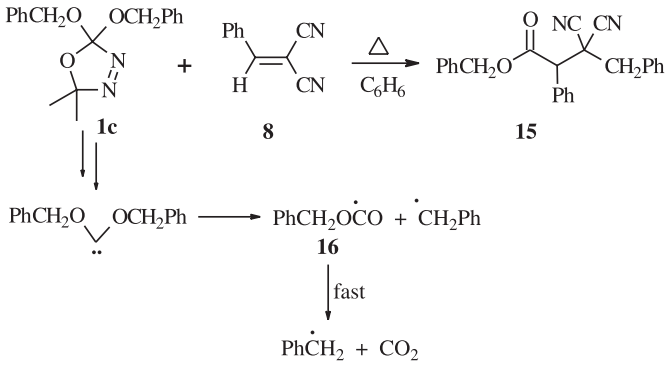
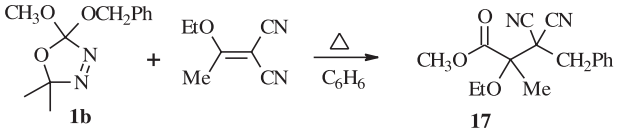


Scheme 6.



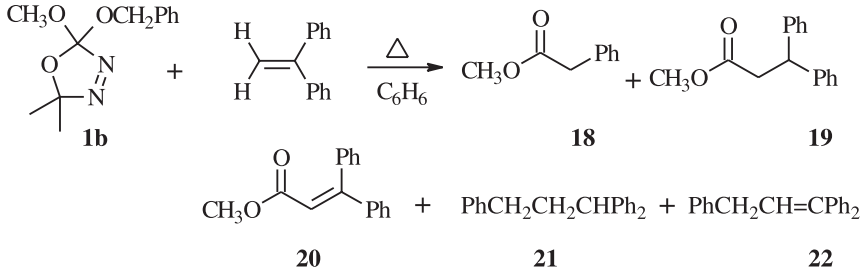
Scheme 7.

Scheme 8.

Scheme 9.

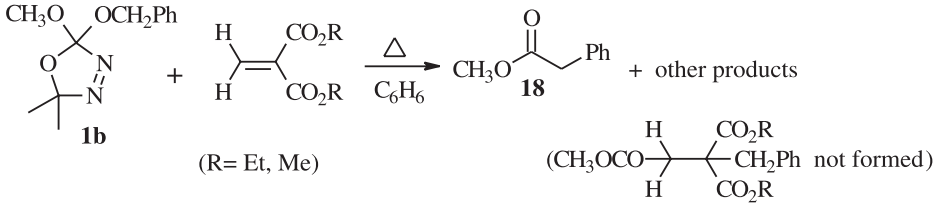
With both **8** and TEMPO present, **1b** afforded disproportionation product **13** and the product of trapping of benzyl radicals with TEMPO (**14**) (Scheme 7). Adduct **12**, from trapping of the methoxycarbonyl radical with TEMPO, was not identified in this case.

Experiments with **1c** and **8** were particularly revealing as confirmation of the cyclopropanation mechanism of Scheme 7. A major product was **15** (Scheme 8), which could not have arisen from addition of benzyloxycarbonyl radicals (**16**) and benzyl radicals to **8,** because **16** decarboxylates very rapidly, with $k_{110°C} \approx 10^9$ s^{-1} (extrapolated from Arrhenius parameters) (11). A carbene mechanism must, therefore, be invoked to account for **15** (Scheme 8), and the use of analogy to assign the same mechanism to the reactions of **1a** and **1b** with **8** seems to be reasonable.



1,1-Diphenylethylene was known to react with dimethoxycarbene to afford the expected cyclopropane in good yield (12), and the same carbene reacted similarly with ethyl cinnamate (12). To look for similar cycloadditions with benzyloxy(methoxy)carbene, thermolyses of **1b** in the presence of 1,1-diphenylethylene, (1-ethoxyethylidene)malononitrile, and both dimethyl and diethyl benzalmalonate were also investigated. (1-Ethoxyethylidene)malononitrile behaved like benzylidenemalononitrile (Scheme 9), although it produced **17** in quite low yield (ca. 17%), but the other alkenes reacted too slowly with benzyloxy(methoxy)carbene to afford cyclopropane intermediates. Instead the carbene fragmented to radicals, and those radicals reacted with the alkenes. For example, a complex mixture of products was obtained from 1,1-diphenylethylene, and not all components were identified. It was possible, by means of GC and with authentic compounds in hand, to identify the major products as **18**–**22** (Scheme 10). Methyl phenylacetate is presumably the result of cage-coupling of the radical pair from benzyloxy(methoxy)carbene. Methyl 3,3-diphenylpropanoate and methyl 3,3-diphenylpropenoate must come from addition of the methoxycarbonyl radical to 1,1-diphenylethylene and subsequent disproportionation. Similarly, 1,1,3-triphenylpropane and 1,1,3-triphenyl-1-propene are derived from addition of benzyl radical to 1,1-diphenylethylene and subsequent disproportionation. The disproportionations could be between both identical and nonidentical radicals, of course. The malonic ester derivatives were investigated in less detail. A major product in each case was methyl phenylacetate (Scheme 11). Analysis by GC–MS showed that products expected from cyclopropanation and subsequent ring-opening were absent. Thus, the geminal nitrile groups of **8** appear to be necessary for fast cyclopropanation by dialkoxycarbenes that fragment to radicals in the absence of a good trapping agent.

Summary



At 110°C benzylidenemalononitrile and 1-ethoxy(ethylidene)malononitrile at ca. 0.16–0.20 M capture benzyl-

Scheme 11.

oxy(methoxy)carbene and analogues, in [1 + 2] cycloadditions before they can fragment to radical pairs, such as methoxycarbonyl and benzyl. The resulting cyclopropanes undergo ring-opening, probably reversibly, to diradicals that then undergo β-scission to radical pairs. Such pairs couple (primarily) or disproportionate. Some alkenes lacking the *gem* dicyanoalkenyl functional group (such as 1,1-diphenylethylene) as well as diethyl and dimethyl benzylidenemalonates, are not cyclopropanated fast enough by the carbenes under the same conditions, and they react instead with the radicals from carbene fragmentation.

The sequence involving cyclopropanation could be useful, affording complex products in modest yield in a one-pot reaction. On the other hand, radical pair additions to alkenes that are not cyclopropanated rapidly by dialkoxycarbenes have very little potential utility.

Experimental

General

Chemical shifts for ^{1}H NMR spectra are relative to TMS or $CHCl_3$ (in $CDCl_3$, δ = 7.24) or C_6HD_5 (in C_6D_6, δ = 7.15). Those for ^{13}C NMR spectra are relative to the C_6D_6 triplet (δ = 128.0) or the $CDCl_3$ triplet (δ = 77.0). Mass spectra were recorded with a VGH ZAB-E double focusing instrument or with a Hewlett–Packard MSD GC–MS. Analytical GC work was done with a Varian Vista 600 instrument equipped with a flame ionization detector and a DB1 Megabore capillary column (0.53 mm × 30 m).

Thermolysis of 1a in the presence of 8

A solution of oxadiazoline **1a** (300 mg, 1.15 mmol) and **8** (300 mg, 1.95 mmol) in benzene (10 mL) in a 25 mL thermolysis tube was heated to distill out 2.5 mL of benzene together with adventitious water. The sample was then freed of gases by means of three freeze–pump–thaw cycles before the tube was sealed and heated at 110°C for 21 h. The crude sample was analyzed by GC and GC–MS before it was concentrated and the residue was subjected to flash chromatography on 25 g of basic alumina (Fisher Brockman 1), which had been activated by heating to 120°C for 24 h. The column dimensions were 2 × 15 cm and elution was with 30% ethyl acetate in hexanes. Two major fractions were collected.

*Methyl 3,3-dicyano-2,4-diphenyl-5-hexenoate (**10**)*

Clear liquid, 15% yield (isolated). CI-MS (NH_3) *m*/*z*: 348 $[M + 18]^+$. ^{1}H NMR (500 MHz, C_6D_6) δ: 3.10 (s, 3H), 3.70 (s, 1H), 4.08 (d, ^3J = 9.0 Hz, 1H), 5.05 (dt, ^3J = 10.2 Hz, ^2J = 1.0 Hz, 1H), 5.12 (dt, ^3J = 16.8 Hz, ^2J = 1.0 Hz, 1H), 6.25 (ddd, ^3J = 16.8 Hz, ^3J = 10.2 Hz, ^3J = 9.0 Hz, 1H), 6.94–7.38 (m, 10H). ^{13}C NMR (125 MHz, C_6D_6) δ: 47.3, 52.3, 54.1, 54.4, 113.9, 114.4, 121.8, 129.0, 129.1, 129.3, 129.4, 129.8, 130.4, 131.8, 133.8, 136.2, 169.0.

Thermolysis of 1a in the presence of 8 and TEMPO

A similar thermolysis, except for omission of the azeotropic distillation and the inclusion of TEMPO (300 mg, 1.92 mmol), gave a solution that was analyzed by GC to reveal small amounts of the esters **9a** and **10**. Chromatography gave, as major products, the adducts of the methoxycarbonyl and the phenylallyl radical with TEMPO (**11** and **12**).

Clear liquid. EI-MS *m/z*: 274 $[M + 1]^+$ (11), 156 $[M - 117]^+$ (100), 117 $[M - 156]^+$ (52), 69 (22), 41 (19). ^{1}H NMR (200 MHz, C_6D_6) δ: 1.31 (s, 6H), 1.38 (s, 6H), 1.27–1.59 (m, 6H), 4.60 (d, ^3J = 5.8 Hz, 1H), 4.61 (d, ^3J = 5.8 Hz, 1H), 6.36 (dt, ^3J = 16.0, 5.8 Hz, 1H), 6.69 (d, ^3J = 16.0 Hz, 1H), 7.11–7.34 (m, 5H). ^{13}C NMR (25 MHz, C_6D_6) δ: 17.5, 20.3, 33.3, 40.0, 59.9, 78.5, 126.0, 126.8, 127.6, 128.9, 131.8, 137.6. HRMS: calcd. for $C_{18}H_{27}NO$: 273.2093; found: 273.2081.

In a second run, aimed at finding additional products, a solution of 2-cinnamyloxy-2-methoxy oxadiazoline (**1a)** (106.2 mg, 0.40 mmol), **8** (125.8 mg, 0.82 mmol), and TEMPO (157.0 mg, 1.0 mmol) in benzene (5 mL) was heated as described above. Analysis by GC–MS indicated **9a** and **10** in low yields, as well as **13** (below) and **12**.

Thermolysis of 1b in the presence of 8

A solution of 2-benzyloxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**1b**) (106 mg, 0.45 mmol) and benzylidenemalononitrile (**8**) (130 mg, 0.84 mmol) in benzene (5 mL) was sealed into a thermolysis tube (after a freeze–pump–thaw cycle), which was then heated for 24 h at 110°C with an oil bath. The benzene was removed by distillation and the crude residue was chromatographed on silica (Chromatotron, 30% EtOAc–hexanes) to afford **9b**. Methyl phenylacetate was not found.

Methyl 3,3-dicyano-2,4-diphenylbutanoate (9b)

White solid, 49% yield (isolated), mp 127 to 128°C. EI-MS *m/z* (%): 305 $[M + H]^+$ (1), 150 (78), 121 (27), 91 (100), 65 (22). ^{1}H NMR (200 MHz, C_6D_6) δ: 2.77 (d, ^2J = 13.6 Hz, 1H), 2.85 (d, ^2J = 13.6 Hz, 1H), 3.15 (s, 3H), 3.67 (s, 1H), 6.99–7.11 (m, 6H), 7.19–7.23 (m, 2H), 7.30–7.34 (m, 2H). ^{13}C NMR (50 MHz, C_6D_6) δ: 41.59, 42.89, 52.42, 56.03, 114.25, 114.69, 128.29, 128.84, 128.98, 129.39, 129.78, 130.69, 131.52, 132.26, 168.90. HRMS: calcd. for $C_{19}H_{17}N_2O_2$: 305.1290; found: 305.1297.

Thermolysis of 1b in the presence of 8 and TEMPO

A solution of **1b** (112.9 mg, 0.4787 mmol), **8** (113.9 mg, 0.739 mmol), and TEMPO (188.9 mg, 1.21 mmol) in benzene (5 mL) was heated as described above. Separation of the crude product mixture by radial chromatography (Chromatotron, 30% EtOAc–hexanes) gave a fraction containing mostly methyl 3,3-dicyano-2,4-diphenylbutanoate. It was chromatographed again with 100% hexanes as eluent to give methyl 3,3-dicyano-2,4-diphenylbutanoate (**9b**) (37.3 mg, 0.1227 mmol, 26%) and methyl 3,3-dicyano-2-phenylpropenoate (**13**) as a yellow oil (2.7 mg, 0.0125 mmol, 2.6%). EI-MS *m/z* (%): 212 $[M]^+$ (70), 197 (89), 153 (73), 127 (100), 100 (35), 77 (89), 51 (92). ^{1}H NMR (200 MHz, C_6D_6) δ: 3.18 (s, 3H), 6.82–6.86 (m, 5H). HRMS: calcd. for $C_{12}H_8N_2O_2$: 212.0586; found: 212.0583. The product of coupling of benzyl radicals with TEMPO was identified by GC–MS. It had been isolated and characterized previously (4, 13).

Thermolysis of 1c in the presence of 8

A solution of 2,2-dibenzyloxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (5) (**1c**) (102.3 mg, 0.328 mmol) and **8** (106.9 mg, 0.694 mmol) in benzene (5 mL) gave a mixture that was partially separated by radial chromatography (Chromatotron, 30% EtOAc–hexanes). The fractions collected were purified by further chromatography (30% EtOAc–hexanes) to collect a fraction rich in benzyl 3,3-dicyano-2,4-diphenylbutanoate. Rechromatography of that fraction, with 100% hexanes as eluent, gave pure benzyl 3,3-dicyano-2,4-diphenylbutanoate.

Benzyl 3,3-dicyano-2,4-diphenylbutanoate (15)

Yellow oil, 37% yield (isolated). EI-MS *m/z* (%): 381 $[M + H]^+$ (3), 245 (7), 226 (3), 91 (100), 65 (11). ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.24 (s, 2H), 3.96 (s, 1H), 5.15 (d, ^2J = 12.0 Hz, 1H), 5.31 (d, ^2J = 12.0Hz, 1H), 7.24–7.41 (m, 15H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 41.57, 42.59, 55.46, 68.05, 113.77, 114.07, 128.61, 128.74, 128.86, 128.93, 129.32, 129.39, 129.83, 130.33, 130.67, 131.42, 134.48, 168.05. HRMS: calcd. for $C_{25}H_{21}N_2O_2$: 381.1603; found 381.1604.

Thermolysis of 1b in the presence of (1-ethoxyethylidene)malononitrile

A solution of **1b** (109.75 mg, 0.465 mmol) and (1-ethoxyethylidene)malononitrile (113.7 mg, 0.836 mmol) in benzene (5 mL) was heated as described above. The crude ester was separated by means of radial chromatography (Chromatotron, 20% EtOAc–hexanes), and it was purified by rechromatography with 100% hexanes as eluent. The regiochemistry of the product was determined by 2D NMR spectroscopy (HMBC). A three-bond correlation was observed between the ^{13}C signal at 172.65 ppm and the methyl proton signal at 2.23 ppm.

Methyl 3,3-dicyano-2-ethoxy-2-methyl-4-phenylbutanoate (17)

Yellow oil, 17% yield (isolated). EI-MS *m/z* (%): 287 $[M + H]^+$ (3), 179 (12), 151 (16), 91 (100). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.29 (t, ^3J = 7.0 Hz, 3H), 2.23 (s, 3H), 3.30 (s, 3H), 3.50 (dq, ^2J = 9.6 Hz, ^3J = 7.0 Hz, 1H), 3.55 (dq, ^2J = 9.6 Hz, ^3J = 7.0 Hz, 1H), 4.53 (d, ^2J = 11.7 Hz, 1H), 4.56 (d, ^2J = 11.7 Hz, 1H), 7.31–7.34 (m, 1H), 7.34–7.37 (m, 4H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 14.62, 19.40, 50.43, 59.29, 65.48, 90.45, 111.38, 112.15, 127.95, 128.39, 128.71, 136.02, 172.65. HRMS: calcd. for $C_{16}H_{19}N_2O_3$: 287.1396; found: 287.1381.

Thermolysis of 1b in the presence of diethyl benzalmalonate

A solution of **1b** (84.7 mg, 0.359 mmol) and diethyl benzalmalonate (0.198 g, 0.798 mmol) in benzene (5 mL) was heated as described above. Analysis by GC–MS indicated that there were many products, methyl phenylacetate was a major one. A component with a mass appropriate for $C_{23}H_{26}O_6$ (formally the adduct of methoxycarbonyl and benzyl radicals with diethyl benzalmalonate) was absent. The reaction mixture was not analyzed further.

© 2001 NRC Canada

Thermolysis of 1b in the presence of dimethyl benzalmalonate

A solution of **1b** (115.6 mg, 0.489 mmol) and dimethyl benzalmalonate (14) (18.06 mg, 0.821 mmol) in benzene (5 mL) was heated as described above. Analysis by GC–MS indicated that there were many products, methyl phenylacetate was a major one. A compound with a mass appropriate for $C_{21}H_{22}O_6$ (formally the adduct of methoxycarbonyl and benzyl radicals with dimethyl benzalmalonate) was absent. The products were not analyzed further.

Thermolysis of 1b in the presence of 1,1-diphenylethylene

A solution of **1b** (100 mg, 0.42 mmol) and 1,1-diphenylethylene (152 mg, 0.84 mmol) in benzene (5 mL) was heated as described above. The crude reaction mixture was analyzed by means of GC with authentic compounds for comparison of retention times. The compounds identified and the approximate relative amounts (as determined by integration of the GC traces), are listed as follows: (*i*) methyl phenylacetate, 3.3 parts; (*ii*) methyl 3,3-diphenylpropanoate (**19**) (15), 1.2 parts; (*iii*) methyl 3,3-diphenylpropenoate (**20**) (16), 1.0 part; (*iv*) 1,1,3-triphenylpropane, 1.2 parts; and (*v*) 1,1,3-triphenylpropene, 1.1 parts.

Synthesis of reference samples

1,1,3-Triphenylpropene (**22**) was synthesized from ethyl hydrocinnamate by analogy to a procedure in the literature (17). 1,1,3-Triphenylpropane (**21**) was synthesized by catalytic hydrogenation of the crude 1,1,3-triphenylpropene. Methyl 3,3-diphenylpropenoate (**20**) (16) and methyl 3,3-diphenylpropanoate (**19**) (15) were isolated together from the appropriate thermolysis experiment and a composite spectrum was obtained that agreed well with the sum of the individual spectra in the literature. The mixture was used for coinjection onto the GC column.

Diaryloxycarbenes from oxadiazolines

Xiaosong Lu, Darren L. Reid, and John Warkentin

Abstract: Symmetric and unsymmetric 2,2-diaryloxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazolines were synthesized by oxidative cyclization of aryloxycarbonyl hydrazones of acetone with lead tetraacetate and subsequent treatment of the product mixture with a phenol in acidic solution. Thermolysis of the oxadiazolines in benzene solution at 110°C afforded carbonyl ylide intermediates that cyclize, in part, to the corresponding 2,2-diaryloxyoxirane intermediates. The oxiranes, which were not observed, are required to account for the 1,1-diaryloxy-2-methylpropenes (ketene acetals) that were isolated. Most of the carbonyl ylides fragment to acetone and diaryloxycarbenes. The latter form dimers (tetraaryloxyethenes) or they can be trapped with phenols to form orthoformates. Diphenoxycarbene was also trapped with dimethyl acetylenedicarboxylate (DMAD). The method appears to be the first for generating the parent diphenoxycarbene under relatively mild conditions in solution, and the only one to date for generating unsymmetrically substituted diaryloxycarbenes. Minor competing fragmentations of the oxadiazolines to 2-diazopropane and the appropriate diaryl carbonates, were also observed.

Key words: diarylcarbonate, diaryloxycarbene, diaryloxy oxadiazoline, ketene acetal, orthoformate.

Résumé : On a synthétisé des 2,2-diaryloxy-5,5-diméthyl-Δ^3-1,3,4-oxadiazolines symétriques et non-symétriques par cyclisation oxydante d'aryloxycarbonylhydrazones de l'acétone avec du tétraacétate de plomb et par traitement subséquent du mélange réactionnel à l'aide d'un phénol en solution acide. La thermolyse des oxadiazolines, dans le benzène, à 110°C, conduit à la formation d'intermédiaires ylures de carbonyle qui se cyclisent, en partie, pour donner les intermédiaires 2,2-diaryloxyoxiranes correspondants. Les oxiranes, que l'on n'a pas observés, sont nécessaires pour expliquer la formation des 1,1-diaryloxy-2-méthylpropènes (acétals du cétène) qui ont été isolés. La plupart des ylures de carbonyle se fragmentent en acétone et ne diaryloxycarbènes. Ces derniers forment des dimères (tétraaryloxyéthènes) ou on peut les piéger avec des phénols avec lesquels ils conduisent à la formation d'orthoformiates. On a aussi piégé le diphénoxycarbène avec l'acétylènedicarboxylate de diméthyle (ACDM). Il semble que la méthode est la première qui permette de générer le diphénoxycarbène parent dans des conditions relativement douces, en solution, et c'est la première à avoir été utilisée pour générer des diaryloxycarbènes substitués de façon non symétrique. On a aussi observé des fragmentations mineures, des oxadiazolines, en compétition avec la réaction principale, qui conduisent au 2-diazopropane et aux carbonates de diaryle appropriés.

Mots clés : carbonate de diaryle, diaryloxycarbène, diaryloxyoxadiazoline, acétal du cétène, orthoformiate.

[Traduit par la Rédaction]

Introduction

There are now many methods for generating a variety of carbenes in solution for studies of their chemistry (1). They include carbenes with an alkyl, alkoxyl, amino, aryl, halogen, or vinyl substituent, to name only a few (2). Various bis(heteroatom) carbenes have also been generated. The latter, with amino or alkoxyl substituents are distinctly nucleophilic (3). Aryloxy- or diaryloxycarbenes should be comparatively less nucleophilic than alkoxy analogues, because an aryl group competes conjugatively with the carbenic virtual orbital for electron density from the oxygen atom, and because phenyl is inductively electron-withdrawing, relative to alkyl. Their lower (and tunable) nucleophilicity, and the fact that an aryloxy group of aryloxymethoxycarbenes can undergo ipso-substitution (4) during reaction with dimethyl acetylenedicarboxylate (DMAD), suggests that aryloxy- and diaryloxy-carbenes could show other new chemistry.

Unsymmetric diaryloxycarbenes ((ArO)Ar′OC:) remain unreported, although many dialkoxycarbenes and alkoxyphenoxycarbenes have been studied thoroughly. Diphenoxycarbene has been reported several times (5–7). It was generated by treating chlorodiphenoxymethane with a strong base or with silver glycinate, and more recently, by thermolysis of an oxadiazoline (7) (Scheme 1). The former methods for generating the carbene limit the study of the chemistry of diaryloxycarbenes, especially those with different substituents in the two rings, not only because the conditions can lead to competing reactions, but also because the precursors are not readily accessible.

We now report the preparation of seven 2,2-diaryloxy oxadiazolines (**1**) and the thermolysis of the parent

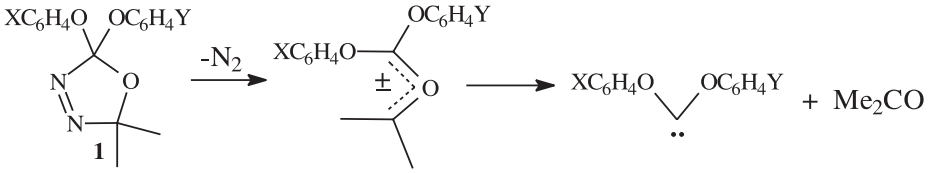
diphenoxy compound, as well as some substituted analogues, in solution at 110°C to generate diaryloxycarbene intermediates (Schemes 2 and 3). Oxadiazolines (**1**) are not more difficult to prepare than corresponding 2-aryloxy-2-methoxy oxadiazolines or 2,2-dialkoxy oxadiazolines, they are thermally stable compounds at room temperature, and they represent the most convenient source of diaryloxycarbenes that is currently available.

Results and discussion

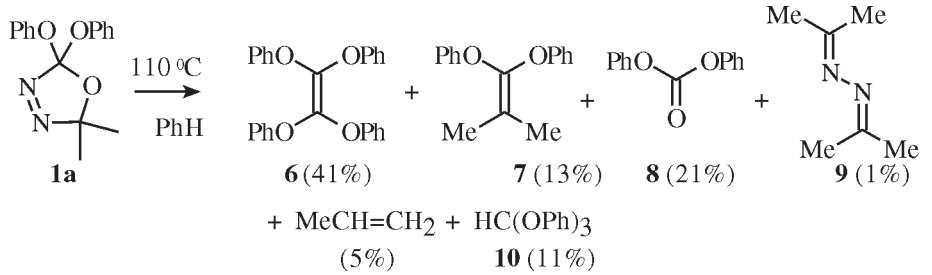
2,2-Diaryloxy-Δ^3-1,3,4-oxadiazolines were prepared from appropriate diaryl carbonates according to Scheme 3. Diphenyl carbonate is commercially available and other carbonates were prepared either from a phenol and 1,1′-carbonyldiimidazole or by transesterification of diphenyl carbonate (not shown). Hydrazinolysis of the diaryl carbonates, in contrast to that of dimethyl carbonate, requires some care to minimize displacement of both aryloxy groups. Condensation of **3** with acetone and subsequent oxidative cyclization (6) to **4** were straightforward, as was the exchange step (8).

Thermolysis of oxadiazoline **1a** in benzene-d_6 occurred with first order kinetics, with $k_{110°C} = 1.17 \times 10^{-4}$ s^{-1}, about tenfold faster than thermolysis of the 2,2-dimethoxy analogue (8). Rate constants for four of the diaryloxy oxadiazolines are gathered in Table 1. It is evident that a *p*-substituent has only a small effect on the rate constant for thermolysis, and both the sense of the effect (*p*-CN, *p*-OMe) and its magnitude fit a mechanism in which 1,3-dipolar cycloreversion to N_2 and a carbonyl ylide is the rate-limiting step (Scheme 4). The preferred sense of the cycloreversion, to place either XC_6H_4O or YC_6H_4O into the *endo* position, is not known. The intermediacy of a carbonyl ylide was also indicated strongly by the formation of a ketene acetal (vide infra).



a: X=Y= H; **b**: X= H, Y= *p*-CN; **c**: X= H, Y= p-OMe; **d**: X= H, Y= *p*-Me; **e**: X= *p*-OMe, Y= *p*-CN; **f**: X= *p*-CN, Y= *p*-Me; **g**: X= *o*-OMe, Y= H.

To demonstrate that a carbene is formed upon thermolysis, **1a** was heated in benzene alone or in benzene containing a phenol. From thermolysis of **1a** in the absence of a trapping agent, the carbene dimer tetraphenoxyethene (**6**) was formed in ca. 41% yield, together with **7**–**10** (Scheme 5). Ketene acetal **7** is most likely derived from a carbonyl ylide intermediate (**11**) that closes to oxirane **12** (9). Neither the ylide nor the oxirane arise from attack of the carbene on acetone, as added acetone-d_6 did not result in deuterium incorporation into any of the products. Attack on **12** by carbene **13**, to transfer the oxirane oxygen, leads to **7** and carbonate **8** (Scheme 6). Deoxygenation of oxiranes and desulfurization of thiiranes by carbenes is known (10).



Some of the carbonate is also derived from a competing cycloreversion of **1a** to afford **8** and 2-diazopropane. That process, which would seem to account for the acetone azine (**9**) and propene, must be relatively minor, because of the low total yield of products that are probably derived from 2-diazopropane. In the presence of traces of phenol (presumably derived from reaction of an intermediate or product with adventitious water) 2-diazopropane is expected to be protonated to afford 2-propyl cation–phenoxide ion pairs, which could lead to both propene and isopropyl phenyl ether. The possibility that most of the propene arises from dimethylcarbene, by fragmentation of the carbonyl ylide intermediate to dimethylcarbene and diphenyl carbonate in competition with its fragmentation to diphenoxycarbene and

Scheme 6.

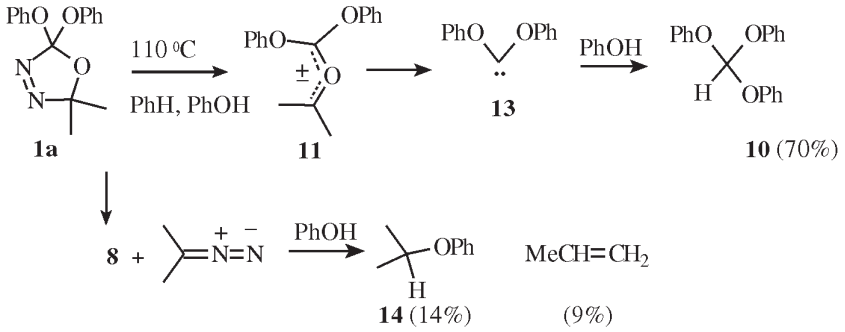
acetone, can be excluded. Although dimethylcarbene would certainly afford propene, the rate constant for 1,2 H-migration is very large (10^7 s^{-1} at room temp) (11) and detection of isopropyl phenyl ether from carbene insertion into phenol at low concentrations of phenol should be difficult. Orthoformate **10** (Scheme 5) is probably derived from the trapping of carbene **13** by phenol. A trace of phenyl formate, detected by GC–MS only, can be attributed to the capture of some of the carbonyl ylide intermediate by water, to generate an intermediate that would lead to phenyl formate (plus acetone and phenol) (Scheme 6). Deliberate addition of water prior to thermolysis of **1a** in benzene did lead to phenyl formate, and other products. Thermolyses of **1c** and **1e** were studied less thoroughly, but the appropriate ketene acetal and the expected carbene dimers were obtained.

Thermolysis of **1a** in benzene with added phenol led to orthoformate (**10**) in 70% yield (Scheme 7). Diphenyl carbonate was a coproduct, and isopropyl phenyl ether (**14**) as well as propene, but not acetone azine, were found. A likely source of **14** is 2-diazopropane, which is expected to react efficiently with phenol in excess to prevent the formation of acetone azine and give **14** instead.

Finally, thermolysis of **1a** in the presence of DMAD gave a product of ipso-aromatic substitution (**15**, Scheme 8), analogous to a product from monoaryloxycarbenes and DMAD (4), as well as bicyclo[1.1.0]butanes **16** and **17**. Those products have been reported in a preliminary communication (7).

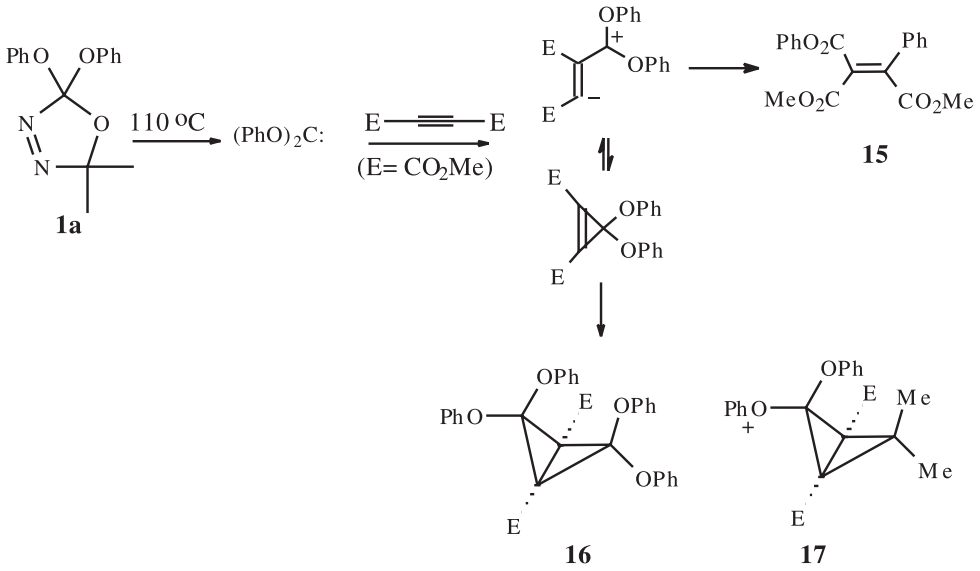
Experimental

General methods



NMR spectra were recorded on a Bruker AC-200 or AC-300 NMR spectrometer. IR spectra were recorded with a Biorad FTS-40 spectrophotometer, with the sample in CCl_4. The IR bands are labeled qualitatively with the symbols br, s, or m for broad, strong, or medium intensities, respectively. Weak bands are omitted. Melting points were recorded on a Thomas–Hoover capillary melting point apparatus, and are uncorrected.

Synthesis of diaryl carbonates



Diphenyl carbonate is commercially available. The other diaryl carbonates were prepared by treating *N*,*N*′-carbonyl diimidazole with a substituted phenol or by *trans*-esterification of diphenyl carbonate.

Scheme 7.

Scheme 8.

Di-p-*cresyl carbonate (**2d**)*

Compound **2d**, mp 113 to 114°C (lit. (12) mp 113°C), was obtained as a white solid (41.8 g, 69%) by refluxing a solution of 53.5 g (0.25 mol) of diphenyl carbonate with *p*-cresol (162 g, 1.5 mol) in toluene (300 mL) containing triethylamine (151.5 g, 1.5 mol). ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.35 (s, 6H), 7.11–7.25 (m, 8H).

Di-p-*methoxyphenyl carbonate (**2c**)*

Carbonate **2c**, mp 93 to 94°C (lit. (13) mp 95.5–96°C), was prepared in 66% yield by the reaction of *N*,*N*′-carbonyl diimidazole (16.2 g, 0.10 mol) with *p*-methoxy phenol (49.6 g, 0.40 mol). ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.80 (s, 6H), 6.88–7.20 (m, 8H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 55.6, 114.5, 121.7, 144.7, 152.8, 157.6.

Aryl hydrazinocarboxylates

A solution of diaryl carbonate and hydrazine hydrate (1.2 equiv) in dichloromethane was stirred for 24 h. After evaporation of all the volatile components, including part of the excess hydrazine hydrate, enough diethyl ether was added to form a clear solution before hexane was added dropwise to crystallize the hydrazide.

Phenyl hydrazinocarboxylate

Mp 104 to 105°C (lit. (14) mp 105 to 106°C), was prepared by reaction of diphenyl carbonate with hydrazine hydrate at 0°C. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.88 (s, 2H, NH_2), 6.40 (s, 1H, NH), 7.26 (m, 5H, ArH).

p-*Tolyl hydrazinocarboxylate*

This was obtained in 53% yield by the reaction of 27.5 g (0.114 mol) of di-*p*-tolyl carbonate with hydrazine *mono*-hydrate (6.80 g, 0.136 mol) in CH_2Cl_2 (100 mL). White solid, mp 116 to 117°C (lit. (14) mp 115–117°C). EI-MS *m*/*z*: 166 $[M]^+$ (8), 108 $[MeC_6H_4O]^+$ (100), 91 (8), 77 (16), 65 (7), 51 (9). CI-MS (NH_3) *m*/*z*: 184 $[M+18]^+$ (28), 167 $[M+1]^+$ (100). IR (CCl_4) (cm^{-1}): 3457 (m), 1753 (s), 1549 (m), 1510 (m), 1462 (s), 1255 (m), 1220 (s), 1206 (s), 1024 (m). ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.33 (s, 3H), 3.86 (s, 2H, NH_2), 6.39 (s, 1H, NH), 6.99–7.26 (m, 4H). ^{13}C NMR (50 MHz) δ: 20.8, 121.0, 129.9, 135.2, 148.5, 157.1.

Other aryl hydrazinocarboxylates were not isolated but were used directly in the next step.

(Phenoxycarbonyl)hydrazone of acetone

Phenyl hydrazinocarboxylate (5.74 g, 37.7 mmol) was stirred with $NaSO_4$ (~6 g) in acetone (150 mL) for 12 h. The

© 2001 NRC Canada

crude reaction mixture was filtered and concentrated to give the (phenoxycarbonyl)hydrazone compound of acetone (6.87 g, 35.7 mmol) in 64% overall yield, as a white solid, mp 125 to 126°C. EI-MS *m/z*: 192 $[M]^+$ (2), 98 $[M\text{-}PhOH]^+$ (30), 94 $[PhOH]^+$ (100), 66 (22), 65 (20), 56 $[N{=}C(CH_3)_2]^+$ (13). CI-MS (NH_3) *m/z*: 210 $[M+NH_4]^+$, 193 $[M+H]^+$. ^1H NMR (200 MHz, $CDCl_3$) δ: 1.84 (s, 3H), 2.06 (s, 3H), 6.79–7.40 (m, 5H), 7.98 (s, 1H, NH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 16.2, 25.2, 115.4, 121.5, 125.6, 129.3.

p-Cresoxycarbonyl hydrazone of acetone

In an analogous reaction, di-*p*-tolyl carbonate (27.5 g, 0.113 mol) gave 11.4 g (61%) of the *p*-cresoxycarbonyl hydrazone of acetone as a white solid, mp 122–124°C. EI-MS *m/z*: 206 $[M]^+$ (7), 108 $[MeC_6H_4O]^+$ (100), 99 (15), 77 (7), 6 (6), 41 (4). CI-MS (NH_3) *m/z*: 207 $[M+1]^+$ (53). IR (CCl_4) (cm^{-1}): 3250 (m), 2922 (m), 1781 (m), 1735 (m), 1720 (s), 1508 (m), 1491 (m), 1390 (m), 1361 (s), 1253 (m), 1216 (s), 1202 (s), 1018 (m). ^1H NMR (200 MHz, $CDCl_3$) δ: 1.87 (s, 3H), 2.09 (s, 3H), 2.33 (s, 3H), 7.03–7.26 (m, 4H), 7.79 (s, 1H, NH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 16.2, 20.8, 25.4, 121.2, 129.8, 135.3, 148.5, 152.3.

Other carbonyl hydrazones of acetone were synthesized according to the above procedure.

Oxidation of hydrazones to 2-acetoxy-2-aryloxy oxadiazolines

The general procedure involved dropwise addition, over 1 to 2 h, of a solution of an aryloxycarbonyl hydrazone of acetone (5 g, 0.02 mol) in CH_2Cl_2 (60 mL) under dry nitrogen, to a stirred solution of 1.2 equiv (ca. 10 g) of lead tetraacetate at 0°C. After the addition, the solution was kept in the ice bath for 2 h and then at room temperature overnight. The solution was washed with 10% aq $NaHCO_3$ (4 × 50 mL) and the organic layer was dried with anhyd $MgSO_4$. Filtration and evaporation of the solvent left a yellow oil containing the desired oxadiazoline (about 70%) and an acyclic isomer ($ArOCON{=}NC(OAc)Me_2$, about 30%), estimated by means of integration of the ^1H NMR spectrum. Unlike 2-acetoxy-2-methoxy oxadiazolines, the 2-acetoxy-2-aryloxy oxadiazolines can be isolated by chromatography on SiO_2 (radial or column) with 5% ethyl acetate in hexane as the eluting solvent.

2-Acetoxy-5,5-dimethyl-2-phenoxy-Δ^3-1,3,4-oxadiazoline

To a stirred and ice cooled solution of lead tetraacetate (12.69 g, 28.62 mmol, 1.0 M) in methylene chloride (10 mL) under nitrogen was added (by drops over 20 min) a solution of the (phenoxycarbonyl)hydrazone of acetone (15) (5.0 g, 26.00 mmol, 0.9 M) in methylene chloride (20 mL). The reaction solution, which changed colour from yellow to brown, was stirred for an additional 2 h during which time the ice melted. A small amount of a brown precipitate was observed. Water (~10 mL) and CH_2Cl_2 (~10 mL) were added to the reaction mixture that was then filtered through a pad of Celite. The filtrate was washed with aqueous sodium bicarbonate (5%) until the bubbling stopped and extracted with CH_2Cl_2. Drying over anhyd $MgSO_4$, filtration, and concentration gave 4.48 g of a mixture containing 58% of the oxadiazoline and 42% of $PhOCON{=}NC(OAc)Me_2$. Composite ^1H NMR (200 MHz, $CDCl_3$) δ: 1.35 (s, Me), 1.66 (s, Me), 1.71 (s, Me_2), 2.10 (s, OCOMe of oxadiazoline), 2.02 (s, OCOMe), 7.28 (m).

*2-Acetoxy-5,5-dimethyl-2-phenoxy-Δ^3-1,3,4-oxadiazoline (**5a**)*

The title compound was isolated by chromatography as a pale yellow oil, in 72% yield. ^1H NMR (200 MHz, $CDCl_3$) δ: 1.35 (s, 3H), 1.66 (s, 3H), 2.09 (s, 3H), 7.15–7.31 (m, 5H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 21.2, 22.6, 23.9, 121.7, 123.4, 125.0, 129.1, 133.1, 151.3, 165.9. (In 2,2-dialkoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazolines the C5 and C2 signals in the ^{13}C NMR spectrum are near 119 and 137 ppm, respectively) (9).

The other 2-acetoxy-2-aryloxy oxadiazolines were not separated from their acyclic isomers but the crude products from oxidation were used directly for preparation of diaryloxy oxadiazolines.

Synthesis of diaryloxy oxadiazolines (1)

In general, both symmetric and unsymmetric 2,2-diaryloxy oxadiazolines were synthesized by exchanging the acetoxy group of a 2-acetoxy-2-aryloxy oxadiazoline for a second aryloxy group. A solution of a 2-acetoxy-2-aryloxy oxadiazoline (ca. 5 g) and 3 equiv (ca. 7 g) of a substituted phenol in CH_2Cl_2 was acidified with catalytic trifluoroacetic acid. After refluxing for 16 h, the solution was extracted with three 30 mL portions of 10% NaOH to remove excess phenol and to destroy the acyclic acetoxy compound. Separation of the organic layer, drying with anhyd $MgSO_4$, and filtration resulted in a solution of the 2,2-diaryloxy oxadiazoline in CH_2Cl_2. Evaporation of the solvent and purification of the residue by chromatography afforded the oxadiazoline in pure form.

*5,5-Dimethyl-2,2-diphenoxy-Δ^3-1,3,4-oxadiazoline (**1a**)*

The procedure for the synthesis of 5,5-dimethyl-2,2-diphenoxy-Δ^3-1,3,4-oxadiazoline is typical. A 50 mL round-bottom flask was charged with 1.05 g of a mixture of 2-acetoxy-2-phenoxy oxadiazoline (ca. 57%) and its acyclic isomer (ca. 43%), phenol (0.412 g, 4.38 mmol, 0.5 M), a catalytic amount of trifluoroacetic acid (0.06 mL, 0.74 mmol), and CH_2Cl_2 (8.5 mL). The solution was stirred for 24 h at room temperature before aq NaOH (10 mL, 10% w/v) was added and stirring was continued for 3 h. Dichloromethane was added and the organic layer was separated and extracted with water. Drying ($MgSO_4$), filtration, and concentration gave the 2,2-diphenoxy oxadiazoline (**1a**, 51%) as a white solid, mp 59.5–60.5°C. EI-MS *m/z* (%): $[M]^+$ not observed, 215 (11), 191 $[M\text{-}OPh]^+$ (100), 135 (37), 119 (78), 105 (46), 77 $[Ph]^+$ (43). General method for thermolyses

All thermolyses were carried out by immersing the sealed thermolysis tubes containing the samples (ca. 0.2 mol in 10–15 mL of benzene, dried by refluxing over CaH_2) in a constant-temperature oil bath at 110.0 ± 0.2°C for 24 h. Spectroscopic data of pure compounds came from chromatographically isolated products. Radial chromatography, with ethyl acetate in hexanes for elution, was used for small-scale reactions, and column chromatography for larger scale reactions (0.2–1 g of oxadiazoline).

Thermolysis products from 5,5-dimethyl-2,2-diphenoxy-Δ^3**-1,3,4-oxadiazoline in the absence of trapping agents**

5,5-Dimethyl-2,2-diphenoxy-Δ^3-1,3,4-oxadiazoline (**1a**) (0.82 g, 2.88 mmol) was heated at 110°C in benzene (25 mL). The solvent was evaporated and the residue was chromatographed (Chromatotron) to give carbene dimer **6a** (41%), ketene acetal **7** (13%), and diphenyl carbonate (21%). The yields came from a thermolysis experiment carried out in a sealed NMR tube containing *p*-dimethoxybenzene as internal standard. After the thermolysis, the ^{1}H NMR spectrum (300 s relaxation delay) was integrated without opening the tube. The solution was also analysed by GC–FID to estimate the yields of the products.

IR (CCl_4) (cm^{-1}): 3004 (m), 2932 (m), 2838 (m), 2232 (m), 1781 (s), 1717 (m), 1605 (s), 1505 (s), 1465 (m), 1296 (m), 1225 (s), 1183 (s), 1041 (m). ^1H NMR (200 MHz, $CDCl_3$) δ: 3.79 (s, 3H, OMe), 6.88–7.72 (m, 8H, Ar). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 55.5, 110.1, 114.5, 117.9, 121.5, 121.9, 133.7, 144.2, 151.4, 153.8, 157.7.

Thermolyses of diphenoxy oxadiazoline in the presence of acetone-d_6

A solution of **1a** (15.2 mg, 0.053 mmol) in benzene-d_6 (0.5 mL) containing acetone-d_6 (36.8 μL, 0.500 mmol) and dimethoxybenzene (internal standard, 7.4 mg, 0.054 mmol) was heated at 110°C for 24 h. Analysis by GC–MS showed that none of the products contained deuterium.

Thermolyses of di(aryloxy) oxadiazolines in the presence of phenols

Oxadiazoline (**1a**) (1 g, 3.50 mmol) was heated at 105°C for 24 h in benzene (25 mL) containing phenol (3.3 g, 35 mmol). The only product that could be isolated was triphenyl orthoformate (mp 73 to 74°C, lit. (17) mp 75°C), as a white solid in 76% yield. EI-MS *m/z* (%): 199 (100), 171 (7), 153 (31), 141 (4), 94 (17), 77 (72), 65 (20), 51 (31). CI-MS (NH_3) *m/z* (%): 199 $[M\text{-}OPh]^+$ (93). IR (CCl_4) (cm^{-1}): 3069 (m), 3046 (m), 1784 (m), 1597 (s), 1491 (s), 1363 (m), 1289 (m), 1228 (s), 1206 (s), 1061 (s), 1028 (m), 997 (m). ^1H NMR (200 MHz, $CDCl_3$) δ: 6.81 (s, 1H, $(PhO)_3CH$), 7.06–7.33 (m, 15H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 110.9, 118.2, 123.6, 129.6, 153.9.

Thermolyses of diaryloxy oxadiazolines in the presence of *p*-cresol

A solution of oxadiazoline **1a** (1.14 g, 4.02 mmol) in benzene (25 mL) containing *p*-cresol (4.32 g, 40 mmol) was heated at 105°C for 24 h. *p*-Tolyl diphenyl orthoformate was isolated as a white solid, mp 82 to 83°C, in 65% yield. EI-MS *m/z* (%): 213 $[M\text{-}OPh]^+$ (98), 199 $[M\text{-}OC_6H_4OMe]^+$ (100), 167 (16), 153 (21), 108 (16), 91 (46), 77 (85), 55 (40), 51 (28). CI-MS (NH_3) *m/z* (%): 213 $[M\text{-}OPh]^+$ (100), 199 $[M\text{-}OC_6H_4OMe]^+$ (81). IR (CCl_4) (cm^{-1}): 3069 (m), 3043 (m), 2927 (m), 2869 (m), 1596 (s), 1495 (s), 1363 (m), 1288 (m), 1194 (s), 1171 (s), 1032 (s). ^1H NMR (200 MHz, $CDCl_3$) δ: 2.27 (s, 3H), 5.56 (s, 1H, CH), 6.98–7.31 (m, 14H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 20.5, 111.0, 118.0, 123.4, 129.6, 130.0, 133.0, 151.5, 153.8. By GC–MS it was possible to detect traces of *p*-cresyl isopropyl ether and diphenyl carbonate.

Similarly, a solution of **1b** (0.2 g, 0.65 mmol) and *p*-cresol (0.56 g, 5.18 mmol) in benzene (25 mL) was heated at 105°C for 24 h. *p*- Tolyl *p*-cyanophenyl phenyl orthoformate was isolated as a pale yellow oil, in 84% yield. EI-MS *m/z* (%): 238 $[M\text{-}OPh]^+$ (55), 224 $[M\text{-}OC_6H_4Me]^+$ (88), 213 $[M\text{-}OC_6H_4CN]^+$ (93), 196 (19), 185 (9), 167 (9), 153 (7), 123 (5), 107 (17), 91 (62), 77 (100), 65 (45), 51 (21). Thermolysis of 1a in the presence of DMAD

A solution of **1a** (0.49 g, 1.73 mmol) in benzene (8.5 mL) containing DMAD (0.223 g, 1.57 mmol) was heated at 110°C for 24 h. Evaporation of the benzene followed by column chromatography afforded **15** and diphenyl carbonate (32.5%) as well as two new products, **16** and **17**.

*Phenyl (*E*)-2,3-bis(methoxycarbonyl)-3-phenyl propionate (**15**)*

Yield 40%, clear oil. EI-MS *m*/*z* (%): 341 $[M+1]^+$ (8), 309 $[M\text{-}31]^+$ (16), 247 (100), 219 (62), 175 (25), 151 (31), 129 (100), 105 (26), 59 (100). HRMS: Anal. calcd. for $C_{32}H_{26}O_8$: 538.1628; found: 538.1629.

*Dimethyl 4,4-dimethyl-2,2-diphenoxybicyclo[1.1.0]butane-1,3-dicarboxylate (**17**)*

Yield 4%, oil. EI-MS *m*/*z* (%): 382 $[M]^+$ (25), 351 $[M\text{-}31]^+$ (22), 323 (12), 289 (100), 261 (50), 229 (16), 197 (27), 169 (15), 77 (23), 49 (28). CI-MS (NH_3) *m*/*z* (%): 400 $[M+18]^+$ (10), 382 (4), 351 (100). IR (CCl_4) (cm^{-1}): 2954 (m), 1729 (br), 1593 (m), 1550 (m), 1494 (s), 1439 (m), 1334 (m), 1266 (s), 1206 (s), 1081 (s), 1013 (m). ^{1}H NMR (200 MHz, C_6D_6) δ: 1.35 (s, 3H, Me), 1.65 (s, 3H, Me), 3.29 (s, 6H, OMe), 6.70–7.52 (m, 10H, OPh). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 21.3, 21.8, 42.2, 48.6, 52.0, 117.2, 117.4, 122.4, 123.0, 128.3, 129.1, 129.8, 154.5, 154.8, 164.8. HRMS: Anal. calcd. for $C_{22}H_{22}O_6$: 382.1416; found: 382.1426.

A similar thermolysis with **1a** (1.674 g, 5.90 mmol) and DMAD (0.230 g, 1.60 mmol) in benzene (8.5 mL), gave **16** in 32% yield. Compound **17** was apparently not formed in an appreciable amount; none could be isolated.

Thermolysis rate constants

The rates of decomposition of the oxadiazolines were monitored by ^{1}H NMR spectroscopy at 300 MHz. A sample, typically containing 1.25×10^{-4} mol of an oxadiazoline and 7 mg of *p*-xylene (internal standard) in C_6D_6 (0.5 mL), was degassed and sealed into a medium-walled NMR tube. At appropriate time intervals during thermolysis, the tube was removed from the oil bath and quickly chilled to room temperature to record the ^{1}H NMR spectrum. All oxadiazoline thermolyses were run simultaneously. Linear regression analyses of the data (ln (I / I_0) vs. time, where I and I_0 are the normalized integrals of a given resonance at time t and at time zero, respectively), gave first-order decomposition rate constants from the slopes of the calculated best fits including the origin. Rate constants for thermolysis of four members of the family **1** are in Table 1.

Investigation of two-component mixed self-assembled monolayers on gold

Zhen Wang, Yan-Li Shi, and Hu-Lin Li

Abstract: Two-component mixed self-assembled monolayers (SAMs) composed of 2-mercapto-5-methyl-1,3,4-oxadiazole (MMO) and 1-dodecanethiol ($C_{12}SH$) in various molar percentages were prepared on gold surfaces by self-assembly. X-ray photoelectron spectroscopy (XPS) and wettability results gave evidence that the coverage of MMO was controlled by the composition of MMO in the assembling solution. The monolayer coverage and apparent rate constant of the redox active probes in solution of different molar ratios of mixed SAMs could be calculated using impedance measurements. The cyclic voltammetry reveals that the probes are selectively passed through the mixed SAMs depending upon their properties.

Key words: self-assembled monolayers (SAMs), X-ray photoelectron spectroscopy (XPS), electrochemistry, electrochemical impedance analysis.

Résumé : On a préparé des monocouches autoassemblées mixtes à deux composants (MAA) de 2-mercapto-5-méthyl-1,3,4-oxadiole (MMO) et de dodécane-1-thiol ($C_{12}SH$), à divers pourcentages molaires, par autoassemblage sur des surfaces d'or. La spectroscopie photoélectronique des rayons X (SPX) et les propriétés de mouillage ont permis d'obtenir des données indiquant que la couverture de MMO est contrôlée par la composition de MMO dans la solution qui conduit à l'assemblage. La couverture de monocouche et les constantes de vitesse apparentes des sondes redox actives en solution de divers rapports molaires de multicouches autoassemblées mixtes peuvent être calculées par des mesures d'impédance. La voltampérométrie cyclique révèlent que, suivant leurs propriétés, les sondes peuvent passer de façon sélective à travers des multicouches autoassemblées mixtes.

Mots clés : monocouches autoassemblées (MSA), spectroscopie photoélectronique des rayons X, électrochimie, analyse d'impédance électrochimique.

Introduction

The development of self-assembled monolayers (SAMs) has received particular attention. SAMs prepared from the long chain alkanethiols are well-known examples of two-dimensional ordered structures in which the chains appear to approach the ideal rigid–rod limit of all-trans conformations with a uniform tilt angle (1–3). However, defects will always be present, even for maximum coverage films on atomically flat substrates. Furthermore, a larger number of partially disordered structure phases will arise from homogeneous films of uniform density to heterogeneous films of macroscopic patches of organized adsorbates (4, 5). Recently, controlling surface properties by heterogeneity in monolayer has attracted increasing attention (6–8). Multi-component SAMs derived from the adsorption of organosulfur compounds on gold are useful in fundamental studies of wetting (9, 10), electron transfer (11–13), and also provide elements for the fabrication of molecular-based devices and sensors (14, 15).

Two-component SAMs have been widely investigated (12, 16–19). Mixed monolayers that incorporate molecular "gate" sites are developed to obtain monolayers with molecular recognition properties (20–22). However, the factors governing the formation of mixed SAMs are not well understood. It is generally accepted that the long-chain alkanethiols are always preferentially adsorbed compared to short-chain alkanethiols, and that monolayer composition appears to be thermodynamically controlled (17, 23). For example, Chidsey et al. (12) showed that two-component SAMs could be enriched slightly in one component by equilibrating the monolayer in a solution containing the desired component. On the basis of this result, the authors concluded that molecules adsorbed at the defect sites are labile and can exchange with solution phase species, while molecules adsorbed at terraces were stable and did not exchange to any significant extent. Rowe and Creager (24) and Bain and Whitesides (25) have confirmed this founding.

The 1,3,4-oxadiazole compound is one of various very useful materials in modern technology such as the flash counting materials of nucleus physics, neutron physics, and atomic energy physics. In this paper, we introduce the thiol-substituted oxadiazole compound into the self-assembly system to supply a new method to draw the defect into the surface. We characterized the two-component mixed SAMs using X-ray photoelectron spectroscopy (XPS) and impedance measurements. One of these two components, which

 DOI: 10.1139/cjc-79-3-328 © 2001 NRC Canada

we call the framework component, is an *n*-alkanethiol about 25 Å long. The other, much shorter organo-mercaptan (MMO), which we call the template, induces defects within the much longer, kelp-forest-like framework. Two different probe molecules were applied to investigate the monolayer properties in terms of the theory developed by Amatore et al. (26).

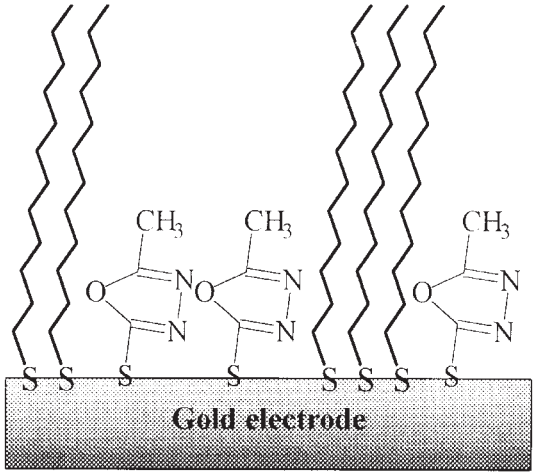
Within the context of this theory, monolayers that contain either many closely spaced small defects or a few large defects, give rise to voltammograms that have shapes defined by linear diffusion of a bulk-phase redox species. Monolayers that contain only a few very small defects spaced sufficiently far apart that their diffusion layers do not overlap, give rise to voltammograms that are characterized by radial diffusion.

Experimental

2-Mercapto-5-methyl-1,3,4-oxadiazole (MMO) was synthesized according to literature (27). All other chemicals were analytical reagents and used as received.

X-ray photoelectron spectroscopy (XPS)

XPS measurements were carried out using an Escalab 220iXL system (VG Scientific Inc.) with a monochromatic Mg Kα X-ray source (1284.6 eV). The pressure in the chamber during analysis was approximately 2×10^{-10} torr (1 torr = 133.322 Pa). The binding energies were corrected using the Au ($4f_{2/7}$) peak energy standard. A take-off angle of 50° from the surface was employed. Spectra were recorded with 50 eV pass energy, 1 mm spot, and 300 W electron beam power with an acquisition time of 5 min. The acquisition time used was sufficiently short that sample damage did not affect the spectra significantly.



Wettability measurements

Contact angle measurements were performed with a JJC-II contact-angle goniometer under ambient conditions (21–23°C, 50–60% relative humidity) using yellow light to illuminate the liquid droplet. The contact angles were obtained by expanding a droplet from a microsyringe until it advanced smoothly across the surface, and then measured 10–20 s after expansion. At least four results were read for each sample.

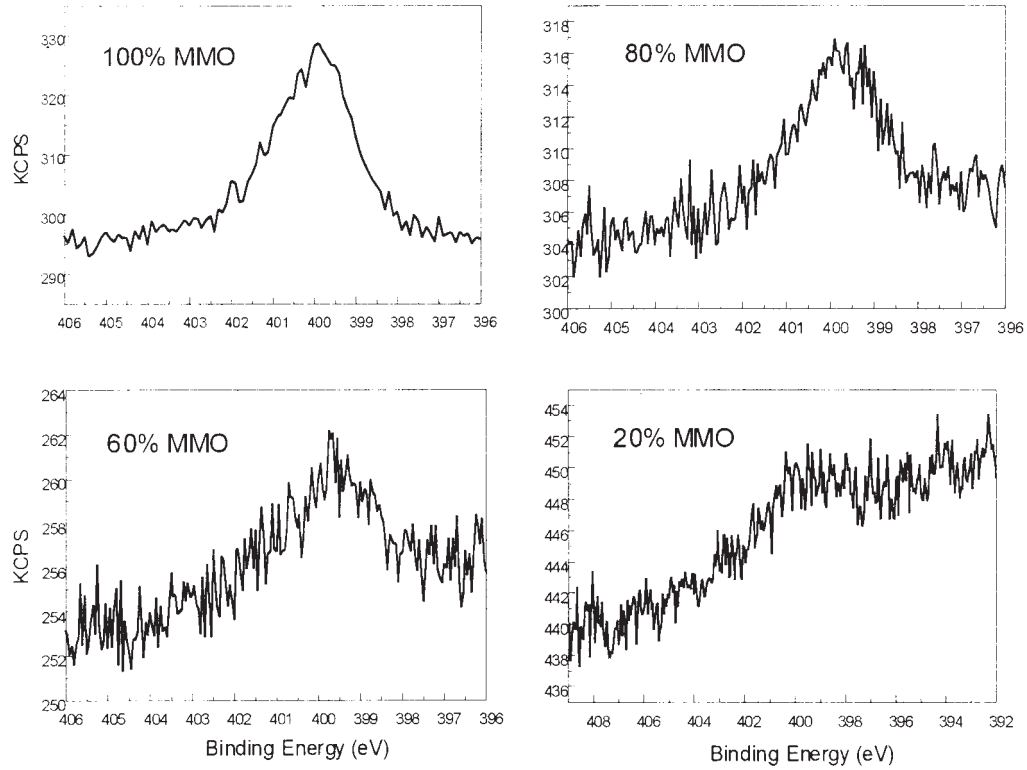
Electrochemical measurements

The cyclic voltammograms were carried out with BAS-100B electrochemical analyzer. Electrochemical impedance spectroscopy was performed using CHI Model 660A Electrochemical Workstation. The conventional three-electrode system was used throughout the experiment. All potentials were reported versus a Ag–AgCl (3 mol L^{-1} KCl) reference electrode. A platinum foil was employed as the counter electrode. The working electrode was a bare or SAMs-modified gold-disk electrode (geometric area: 0.03799 cm^2). The gold electrode was cleaned by potential-scanning in H_2SO_4 (0.5 mol L^{-1}) between –200 mV and +1400 mV until a stable cyclic voltammogram was obtained. After the cleaning process, the substrates were rinsed with distilled water and ethanol, then immediately immersed into the assembling solution. Cyclic voltammetry was performed in a solution containing only one oxidation state of the redox couple, such as $Ru(NH_3)_6Cl_3$ (1 mmol L^{-1}) or $K_3Fe(CN)_6$ (1 mmol L^{-1}) in KCl (0.1 mol L^{-1}). The solutions used for impedance measurements always contained equal concentrations of the oxidized and reduced forms of the redox couple, such as 1 mmol L^{-1} $K_3Fe(CN)_6$ and $K_4Fe(CN)_6$ in KCl (0.1 mol L^{-1}), and measurements were conducted in a wide frequency range from 100 kHz to 0.05 Hz. In impedance experiments, the DC applied potential is held at an open circuit potential, and a small amplitude AC potential is applied. All the experiments were carried out at room temperature.

Fig. 1. The schematic diagram of mixed self-assembled monolayers of $C_{12}SH$ and MMO adsorbed on the gold surface.

Substrate preparation

The substrates employed in the XPS and wettability measurements were prepared by evaporating 200 nm gold (99.99%) onto a glass slide (7.5 × 2.5 cm) precoated with chromium (10–15 nm) at the evaporation rate of 0.1 nm s^{-1}. The base pressure was always $<3.5 \times 10^{-6}$ torr (1 torr = 133.322 Pa) and the evaporation pressure $<5.5 \times 10^{-6}$ torr. The gold slides were cleaned in a heated and freshly prepared "piranha solution" (3:1 concentrated H_2SO_4:30% H_2O_2) for 5 min, and then rinsed with distilled water and ethanol (caution: piranha solution reacts violently with organic compounds, and it should be handled with extreme care). SAMs were prepared by immersing clean gold substrate into a series of ethanol solutions (1.0 mmol L^{-1}) containing 1-dodecanethiol ($C_{12}SH$) and MMO with different molar percentages over 24 h to reach a saturated and steady coverage. Afterwards, the substrates were washed with ethanol and dried in N_2 atmosphere prior to characterization. The schematic diagram of mixed self-assembled monolayers of $C_{12}SH$ and MMO adsorbed on the gold surface is shown in Fig. 1.



Results and discussion

X-ray photoelectron spectroscopy (XPS)

In an XPS experiment, the samples are exposed to monochromic X-ray radiation and the properties of inner-shell electrons are probed. Figure 2 shows typical XPS spectra of mixed monolayers with different molar percentages in which the N_{1s} region at 399.5 eV is clearly observed (KCPS

© 2001 NRC Canada

Fig. 2. XPS spectra (the N_{1s} region) of SAMs derived from ethanol solutions containing mixtures of $C_{12}SH$ and MMO on gold. The compositions of the assembling solution are illustrated as molar percentage of MMO in solution.

is kilo counts per second). The MMO coverage in SAMs could be directly estimated from the peak area of the N_{1s} region. The N_{1s} peak area increased with increasing MMO ratio in the assembly solution (Fig. 2), indicating that the coverage of MMO could be controlled by the solution composition. According to Whitesides (9), the composition of the relative component of acid-terminated thiol incorporated in the monolayers could be obtained from normalizing the ratio of O_{1s}:S_{2p}. In the SAMs under consideration, for simplicity, we assumed that the part of the SAMs above the sulfur tail group could be represented by a total, and then the S_{2p} counts could be considered to represent the total SAMs coverage. Usually, in the SAMs system, the signal intensity of an element will be represented by the formula:

$$[1] \qquad I = I_0 b \mathrm{e}^{-\mathrm{d}l(\lambda \sin \theta)}$$

where I is the signal intensity observed in the SAMs, I_0 is the signal intensity of the element on the surface, b is a correction factor, l is the depth of the element in the SAMs, λ is the attenuation level of the photo-electron in this system, and θ is the angle between the detector and the surface. But the values of I_0, b, and λ are not obtained in the experiment, and the two nitrogen atoms were present at different depths, so we simplified the ratios of nitrogen to sulphur taking the sensitivity factor into consideration (0.42 and 0.54 for N_{1s} and S_{2p}, respectively):

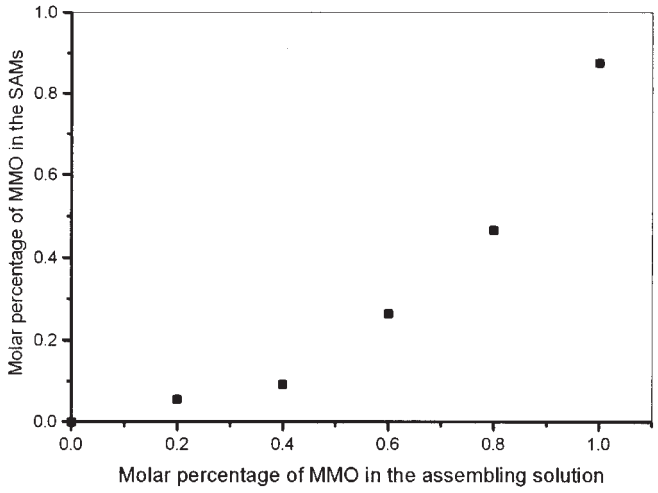
$$[2] \qquad \frac{N'_{\mathrm{MMO}} \times 0.54}{S'_{\mathrm{MMO}} \times 0.42} = k \frac{N_{\mathrm{MMO}}}{S_{\mathrm{MMO}}}$$

N' and S' represent the relative atomic numbers detected in the XPS, N and S represent the realistic atomic numbers in the MMO molecule, and k is the constant related to the depth of the nitrogen atom. If we consider that the orientation of MMO in the pure MMO SAMs is similar to that in the mixed SAMs, and distribution of sulphur elements changed little, the value of k is constant:

$$[3] \qquad \frac{N'_{\mathrm{Mix}} \times 0.54}{S'_{\mathrm{Mix}} \times 0.42} = k \frac{xN_{\mathrm{MMO}}}{xS_{\mathrm{MMO}} + (1-x)S_{\mathrm{C_{12}SH}}}$$

x is the molar percentage of MMO in the SAMs. For the molar percentages of MMO in the mixed SAMs, the x values obtained from the above two equations are used as the y-axis of Fig. 3.

Wettability



The quality and microscopic structure of the mixed SAMs were also estimated from wetting measurements. Young described the relationship (29) between the free energy of the surface and a unique contact angle, under ideal conditions, for a system in equilibrium as:

$$[4] \qquad \gamma_{\mathrm{LV}} \cos\theta = \gamma_{\mathrm{SV}} - \gamma_{\mathrm{SL}}$$

where θ is the contact angle at the three-phase interface, while γ_{LV}, γ_{SV}, and γ_{SL} are surface-free energies at the liquid-vapor, solid-vapor, and solid-liquid interfaces, respectively. Monolayers containing exposed polar groups and disordered monolayers have much lower contact angles. If the mixed monolayers containing two components are homogeneous, and the two components affect surface wettability

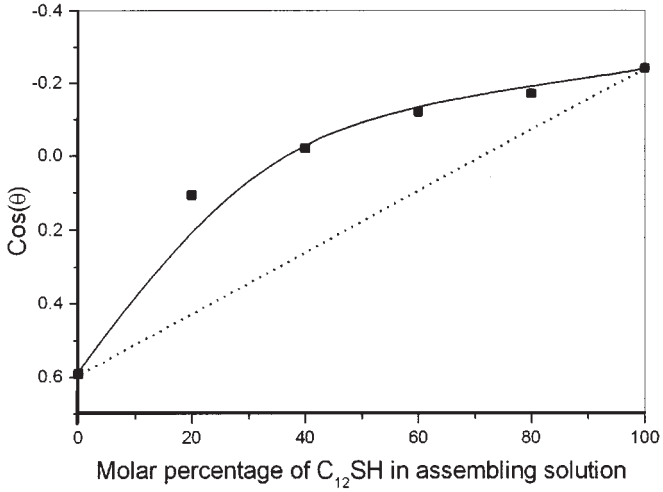
Fig. 3. Plot of the molar percentage of MMO in the SAMs as a function of the molar percentage of MMO in the assembling solution.



independently, the Cassie equation is appropriate for interpretation of wettability results (30, 31):

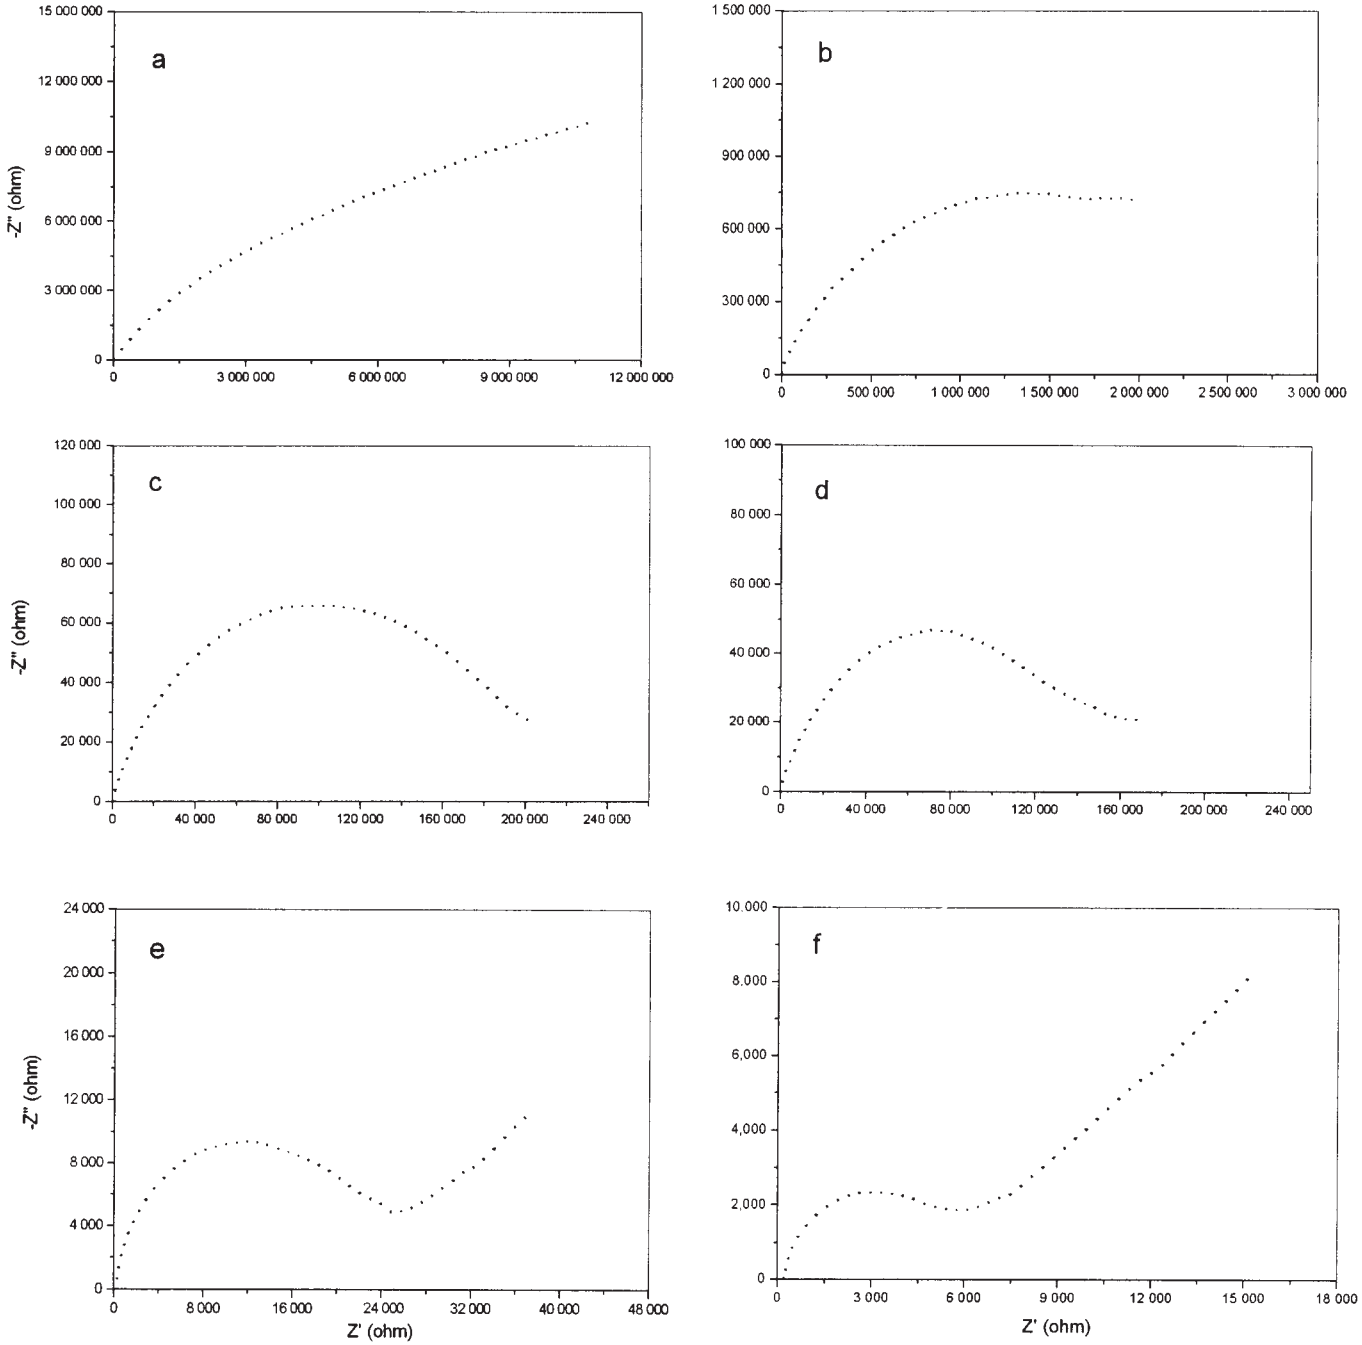
$$[5] \qquad \cos\theta = f_1 \cos\theta_1 + f_2 \cos\theta_2$$

where θ is the contact angle of a liquid on the heterogeneous surface, f_1 and f_2 are the fractions of the two types of chemical groups at the surface, and θ_1 and θ_2 are the contact angles of this liquid on the pure homogeneous surfaces of the two function groups, respectively. Consequently, changes in cos θ are linearly dependent on the composition of the surface for an ideal surface (32–39). Hence, the composition and quality of a monolayer are usually checked quickly and easily with this technique.

The cosine of contact angles of pure water on freshly prepared monolayers composed of mixtures of MMO and $C_{12}SH$ are shown as a function of the surface composition. The SAMs become more hydrophobic as the percentage of $C_{12}SH$ in the assembling solution increases because $C_{12}SH$ SAMs are more hydrophobic than MMO SAMs. The obviously nonlinear behavior displayed in Fig. 4 indicate that the wettability of SAMs mixed with $C_{12}SH$ and MMO is highly nonideal. The relation between surface wettability and the surface composition of the mixed SAMs demonstrates the complexity of the interactions at the film–air–probe-liquid three-phase interface. Bain and his colleagues (8, 9, 25) studied the wettability of SAMs mixed with methyl groups and other polar-group-terminated alkanethiols that have similar chain length. They found that the curve of cos θ vs. surface composition usually appeared concave rather than convex. The mixed SAMs considered here are also consistent with a polar component (MMO) and a low surface energy component ($C_{12}SH$). However, in contrast with that observed by Bain, Fig. 4 demonstrates a convex curve, which indicates that the SAMs mixed with MMO and $C_{12}SH$ are more hydrophobic than predicted by Cassie's equation (eq. [5]). The major differences of our system compared to Bain's (25) is that the lengths of the two components studied here are very different, and the $C_{12}SH$ molecule is about two times larger than the MMO molecule.

Fig. 4. The cosines of contact angle (θ) of pure water on SAMs-modified surfaces as a function of the percentage of $C_{12}SH$ in assembling solution. The solid line shows the tendency as a guide, and the dashed line represents an expected linear relationship.

Electrochemical impedance measurements



Impedance measurements have been applied successfully to investigate these types of assembled monolayers and electron transfer through the monolayers, as impedance can provide valuable information about the surface coverage of the monolayer and apparent rate constant of the redox-active probes in solution.

In impedance experiments, the DC applied potential is held at an open circuit potential, and a small amplitude of AC potential is applied. The response is often shown in a complex impedance presentation and results are interpreted in terms of an equivalent electrical circuit. According to Randles' equivalent circuit (40), two frequency regions can be distinguished to understand the change in faradic impedance due to the presence of electroactive species at the electrode–SAM–electrolyte interface. In the low frequency region, mass transfer via diffusion has to be taken into account, whereas the microarray behavior of the defect within the passivating monolayer disturb the $\omega^{-1/2}$ depedence of the Warburg impedence (41). The deviation from semi-infinite diffusion is due to the defects in the monolayers, which are far apart from each other. In this type of situation, the overlap of diffusion fields is not achieved and radial diffusion seems to be valid (42). We focused our attention on the more interesting part of the Nyquist plot at the high frequencies, where the electrode reaction is purely kinetically controlled, and the heterogeneous charge transfer resistance (R_{ct}) is expected to increase due to the inhibition of the electron transfer by the monolayer present on the electrode surface (43). From this increase in the charge transfer resistance, one can calculate the approximate fractional coverage of the gold electrode (Γ) (44), assuming that the current is due to the defects within the monolayer:

$$[6] \qquad \Gamma = 1 - \left[\frac{R_{ct}}{R'_{ct}}\right]$$

© 2001 NRC Canada

Fig. 5. The Nyquist plots obtained from SAMs modified with a mixture of $C_{12}SH$ and MMO for 24 h. Molar percentages in solution, with $K_3Fe(CN)_6$ (1 mmol L^{-1}) and $K_4Fe(CN)_6$ (1 mmol L^{-1}) in aq KCl solution (0.1mol L^{-1}): (*a*) 100% $C_{12}SH$, (*b*) 80% $C_{12}SH$, (*c*) 60% $C_{12}SH$, (*d*) 40% $C_{12}SH$, (*e*) 20% $C_{12}SH$, and (*f*) 100% MMO. 100 kHz–50 Hz frequency ranges used.

where R_{ct} indicates the charge transfer resistance of pure gold electrode and R'_{ct} is the corresponding term of the passivated electrode covered by the monolayers containing various molar percentages of $C_{12}SH$ and MMO.

Several Nyquist plots for a gold electrode modified by various molar percentages in solution are shown in Figs. 5*a–f*. Figure 5*a* shows a Nyquist plot obtained from an apparently defect-free $C_{12}SH$ monolayer. The resistance was too large to measure in this experiment. The relative molar percentages of the two components were changed steadily, and the obvious occurances of the different processes are displayed in the other five Nyquist plots (Figs. 5*b–f*). The impedance in Fig. 5*c* is observed to be substantially smaller than in Fig. 5*b*, which is due to the larger amount of defects existing in the mixed monolayers of 5*c* compared to 5*b*. With the increase of the concentration of MMO, the Nyquist plot could be an intermediate system. The Nyquist plot is a semi-circle at high frequencies (kinetic control) and changes to a

Table 1. Different parameters obtained for mixed SAMs on a gold electrode from impedance measurements.

	Molar percentage (C_{12}SH:MMO)				
	8:2	6:4	4:6	2:8	0:10
Charge transfer resistance (R_{ct}) (Ω cm^2)	106 000	7220	5600	911	220
Apparent electrode coverage (Γ) (%)	99.96	99.40	99.20	95.25	80.40
Apparent rate constant of $Fe(CN)_6^{3-}$:$Fe(CN)_6^{4-}$ (k_{app}) (cm s^{-1})	2.5×10^{-6}	4.1×10^{-5}	4.7×10^{-5}	2.9×10^{-4}	1.2×10^{-3}

straight line at low frequencies (diffusion control). It is known that the lower intercept on the Z' axis is at $Z' = R_\Omega$ (R_Ω = solution resistance) and the higher intercept is at $Z' = R_\Omega + R_{ct}$. The frequency that gives the largest -Z″ value on the semi-circle is equal to $1/R_{ct}C_{dl}$ (C_{dl} = double layer capacitance). The rate constant of the $K_3Fe(CN)_6$:$K_4Fe(CN)_6$ ratio could be calculated from the impedance plot of the gold electrode modified with different molar percentages of the two components, since the monolayer behaves as a microelectrode assembly leading to an expected decrease in the rate constant (40). Thus, from eq. [7], for a one-electron first-order reaction with $c_o = c_r = c$ and unit geometric area:

$$[7] \qquad R_{ct} = \frac{RT}{j_0 F}$$

and

$$[8] \qquad j_0 = Fk_{app}c$$

Combination of eqs. [7] and [8] gives

$$[9] \qquad k_{app} = \frac{RT}{F^2 R_{ct} c}$$

Based on these formulas, Nyquist plots, and impedance measurements, different parameters obtained for the mixed SAMs on a gold electrode are shown in Table 1. From the data listed in the table, one can see that the apparent electrode coverage decreased with the increase of molar ratio of MMO because the degree of order and close-packed structure in the MMO monolayer is less than that of the C_{12}SH monolayer. The apparent rate constant of the $Fe(CN)_6^{3-}$–$Fe(CN)_6^{4-}$ couple increased with the increase of molar ratio of MMO in solution. The apparent rate constant of $Fe(CN)_6^{3-}$–$Fe(CN)_6^{4-}$ at a bare gold electrode was taken as 2.6×10^{-2} cm s^{-1} (45, 46). The rate constant of $Fe(CN)_6^{3-}$–$Fe(CN)_6^{4-}$ of pure MMO obtained in the experiments is smaller than 2.6×10^{-2} cm s^{-1}, because the formation of MMO monolayers on the gold surface has the effect of preventing the probe molecule's penetration.

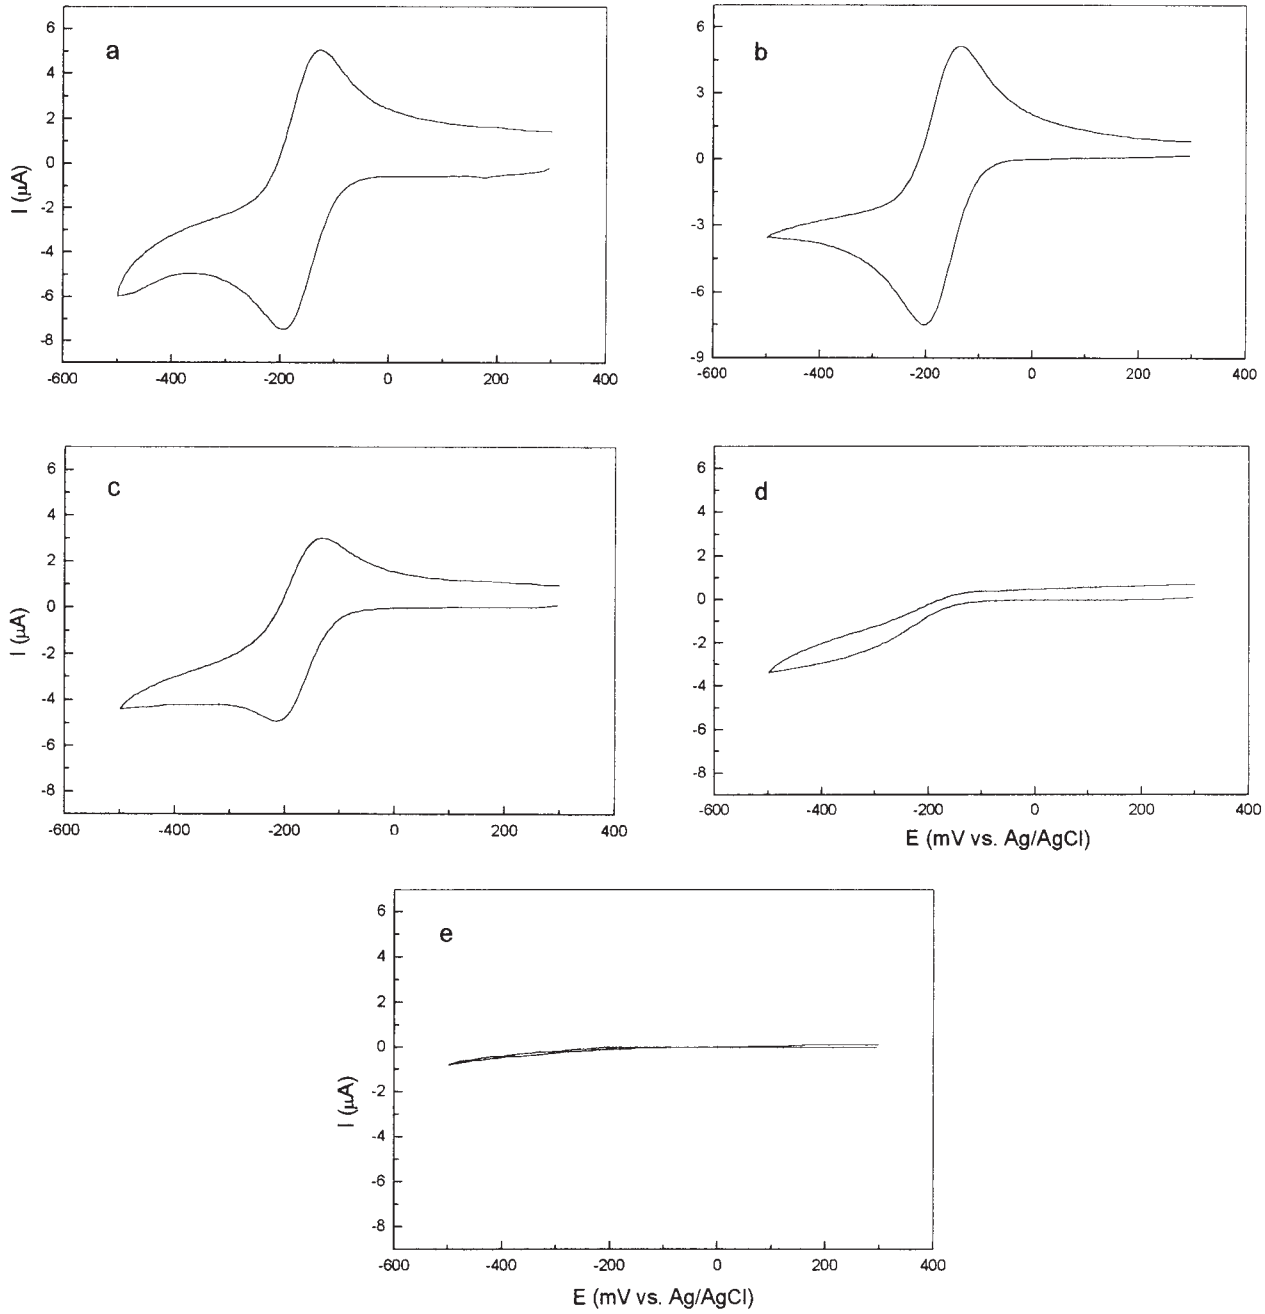
Electrochemical investigation

XPS and wettability results demonstrated that binary composite monolayers have been prepared. The film composition, which was affected by the composition of the assembling solution, changed the film structure dramatically. Next we examined the electrochemical properties of the mixed SAMs using two different probe molecules to access the gold surface.

Electrochemical response of $Ru(NH_3)_6^{3+}$ on SAMs

The cyclic voltammograms shown in Fig. 6 are obtained from an electrode prepared by soaking a gold electrode in ethanol solutions containing various molar percentages of MMO and C_{12}SH. We were able to reproduce the data shown in Fig. 6 four times within 10%. Following modification, the electrode potential was cycled between +300 mV and –500 mV at 100 mV s^{-1} in an aqueous electrolyte solution consisting of $Ru(NH_3)_6Cl_3$ (1 mmol L^{-1}) and KCl (0.1 mol L^{-1}). In the presence of defect sites that have the correct combination of size and interaction energies, the $Ru(NH_3)_6^{3+}$ probe molecule should penetrate the inert frame work and undergo electron exchange with the underlying gold surface. The electron transfer should be facile since the electron-transfer rate constant for $Ru(NH_3)_6^{3+}$ is large (21, 47). If the probe molecules cannot penetrate the monolayer framework, they can only be reduced by electrons that tunnel through the C_{12}SH layer. Since the distance of closest approach of the probe to the electrode surface is approximately the thickness of the monolayer, about 21–25 Å (48, 49), the tunneling current should be small relative to that arising from direct electron transfer at defect sites.

Figure 6*e* shows the results obtained for a nominally defect-free C_{12}SH monolayer surface. The roughly exponential shape of the cyclic voltammogram is consistent with electron tunneling through the film (21, 50–52). The voltammogram shape of Fig. 6*d* arises from radial diffusion of $Ru(NH_3)_6^{3+}$ to small, widely dispersed defect sites (defect sites include the domain formed by the MMO molecules) on the electrode surface. As the concentration of the template molecules in the assembling solution increases relative to the framework, the charging current increases, and there is a clear departure from pure radial to a mixed linear–radial regime. Mixed diffusion behavior is shown in Fig. 6*c*. Figure 6*b* is indistinguishable from that of a bare gold electrode.



Electrochemical response of $Fe(CN)_6^{3-}$ on SAMs

Figure 7 presents data analogous to that shown in Fig. 6, except that the solution-phase redox-probe molecule is $K_3Fe(CN)_6$. This set of data follows the general trend discussed for $Ru(NH_3)_6^{3+}$. The only difference between the cyclic voltammograms shown in Figs. 6 and 7 is that the transition from radial to linear diffusion occurs at a higher MMO concentration for $Fe(CN)_6^{3-}$ than for $Ru(NH_3)_6^{3+}$. Since the monolayers used to generate Figs. 6 and 7 are the same, and the size of the two probe molecules are approximately the same on the basis of their diffusion coefficients[2], there is

[2] For $Fe(CN)_6^{3-}$: $D = 7.6 \times 10^{-6}$ cm^2 s^{-1}, see D. T. Sawyer and J. L. Roberts Jr. Experimental electrochemistry for chemistry. Wiley, New York. 1974. p. 77; for $Ru(NH_3)_6^{3+}$: $D = 7.1 \times 10^{-6}$ cm^2 s^{-1}, see A.J. Bard, J.A. Crayston, G.P. Kttleson, T.V. Shea, and M.S. Wrighton. Anal. Chem. **58**, 2321 (1986).

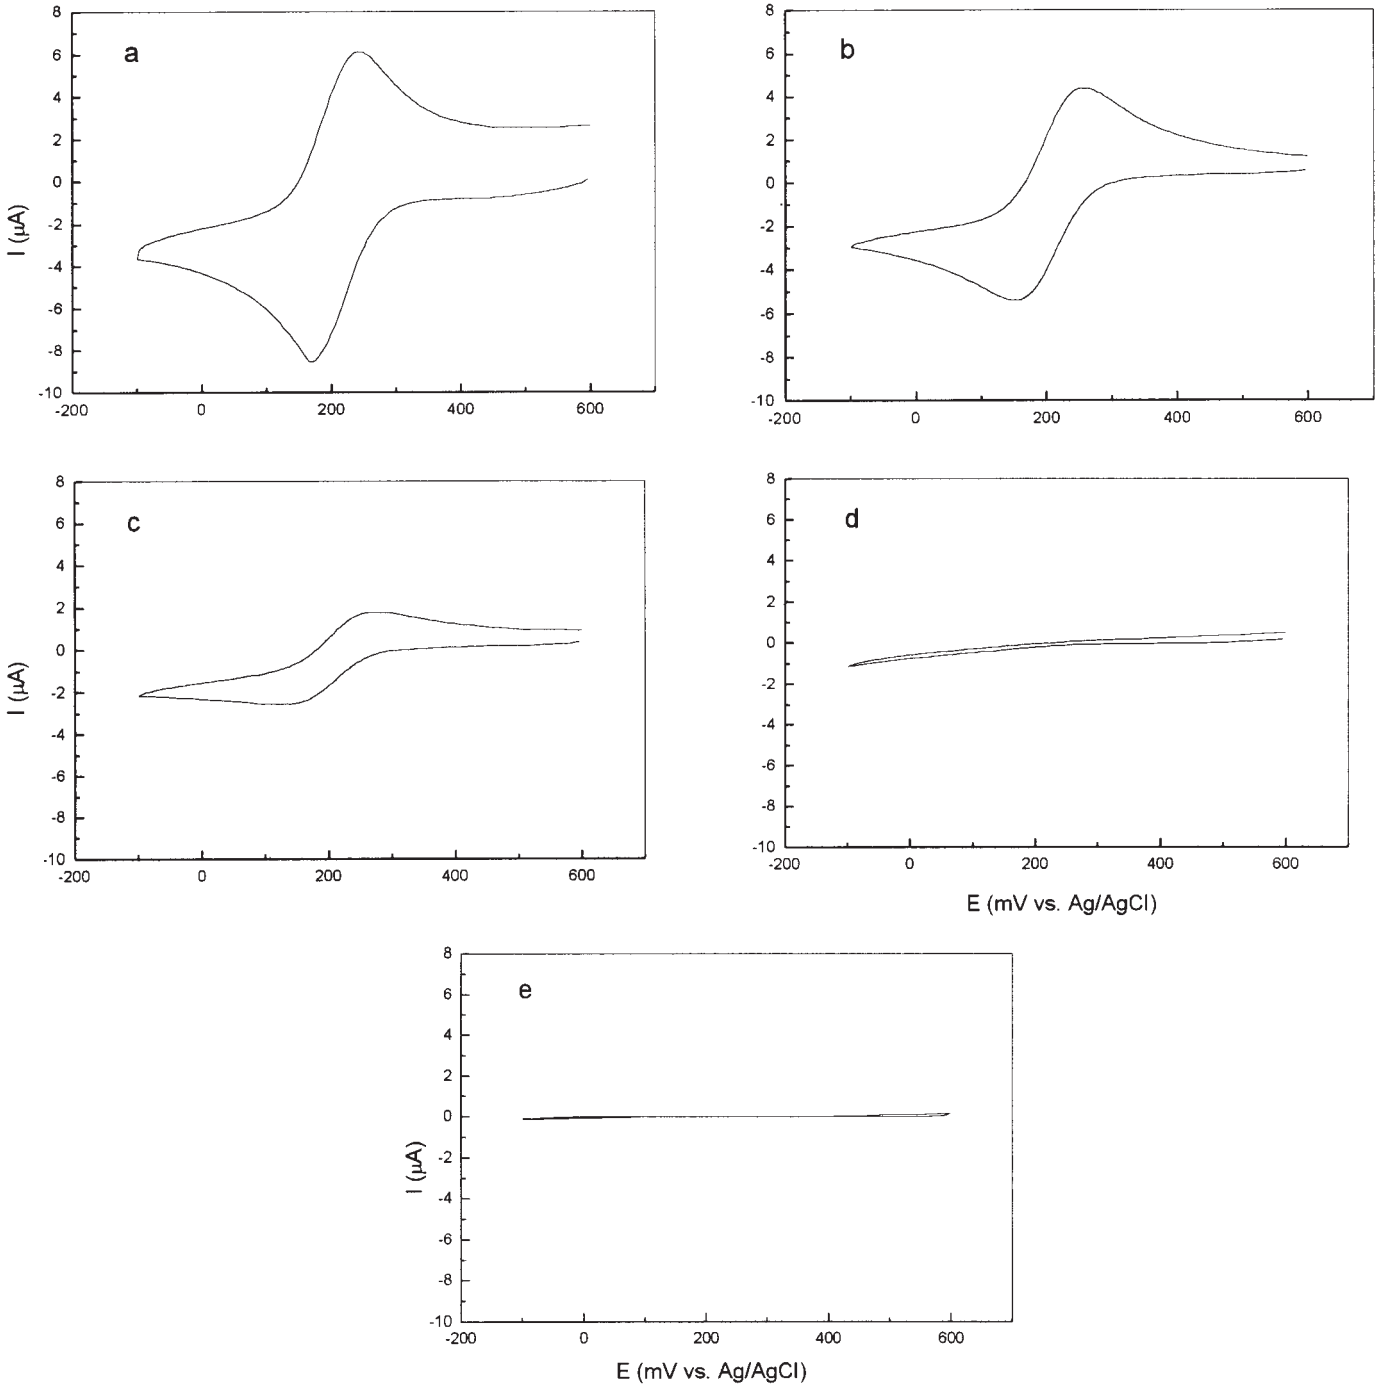
Fig. 6. Cyclic voltammetric response of $Ru(NH_3)_6Cl_3$ (1 mmol L^{-1}) on (*a*) bare gold, and mixed SAMs with: (*b*) 90% MMO, (*c*) 80% MMO, (*d*) 70% MMO, and (*e*) 100% $C_{12}SH$ (molar percentage in solution). The supporting electrolyte was KCl solution (0.1 mol L^{-1}), and scan rate was 100 mV s^{-1}.



only one possible explanation for this behavior: some of the defect sites that admit $Ru(NH_3)_6^{3+}$ do not admit $Fe(CN)_6^{3-}$. That is, although the total number and average size of the defects are fixed, there are differences in the nature of the intermolecular interactions between the probe molecules and the mercaptan component of short length in this system.

Conclusions

Self-assembled monolayers composed of MMO and $C_{12}SH$ with various molar percentages were prepared and characterized on a gold surface. Our experiments prove that the composition of the mixed monolayers could be controlled by the ratio of MMO and $C_{12}SH$ in the assembling solution. The chemical nature of the template–framework ratio of the assembling solution control the size and chemical properties of the defects. Impedance measurements supply some related parameters, such as apparent electrode coverage and apparent rate constant of the redox couple. When the molar ratio of MMO is 80%, $Ru(NH_3)_6^{3+}$ penetrates the monolayer easily, but $Fe(CN)_6^{3-}$ does not. This phenomenon resulted from the differences in the nature of

Flow injection-chemiluminescent assay for the determination of superoxide dismutase activity

Hong Yeob Choi, Jin Hyang Song, Yong Sung Park, Gabriel Lord, and Dong Ki Park

Abstract: Superoxide dismutase (SOD) activity was measured using a flow injection-chemiluminescent assay (FI-CLA) based on xanthine–xanthine oxidase dependent superoxide ($O_2^{\bullet -}$) formation. The mobile phase consists of 50 mM potassium phosphate buffer (pH 7.4) containing lucigenin (5 μM) and xanthine (0.3 mM). Under optimum conditions, bovine albumin did not affect chemiluminescence at concentrations of 1–1000 μg mL^{-1} and KCN inhibited 100% of the Cu, Zn-SOD activity using 5 μL of a 0.23 mM concentration. The analysis of one sample was done in less than 30 s with a relative standard deviation of ±3.1%. SOD activity in the biological samples was correlated to the amount of exogenously applied SOD. The FI-CLA method reported here appears to be one of the faster and more useful tools used to assay SOD activity.

Key words: superoxide dismutase, flow injection-chemiluminescent assay, superoxide, xanthine oxidase, lucigenin.

Résumé : L'activité de la dismutase du superoxyde (SOD) a été mesurée par chimiluminescence à injection continue (FI-CLA) basée sur la formation de superoxyde ($O_2^{\bullet -}$) par l'oxydase de xanthine. La phase mobile était constituée de 50 mM de phosphate de potassium (solution-tampon de pH 7.4), de lucigénine 5 μM et de xanthine 0.3 mM. Dans des conditions optimales, l'albumine de bovins n'affectait pas la chimiluminescence à des concentrations de 1 jusqu'à 1000 μg mL^{-1} et le KCN inhibait l'activité du SOD-Cu,Zn à 5 μL de solution 0.23 mM. L'analyse d'un échantillon s'effectuait en moins de 30 s avec une déviation standard de ±3.1 %. L'activité du SOD dans les échantillons biologiques a été corrélé à la quantité appliquée exogéniquement au SOD. La méthode FI-CLA mentionée ici s'avère l'une des méthodes les plus rapides et un des outils les plus précieux pour évaluer l'activité du SOD

Mots clés : dismutase du superoxyde, évaluation par chimiluminescence à injection continue, superoxyde, oxydase de xanthine, lucigénine.

[Traduit par la Rédaction]

Introduction

The detection and measurement of superoxide anion ($O_2^{\bullet -}$) flow within cells is of critical importance for investigating the physiological and pathological roles of $O_2^{\bullet -}$. The short-lived and reactive radical ($O_2^{\bullet -}$) can be considered as a nonclassical messenger molecule, i.e., the signal transduction is mediated via its chemical reactivity. Acting on one hand as defense against viral or bacterial attack, it can, on the other hand, cause oxidative damage to proteins, DNA, and lipids.

Superoxide dismutases (SOD) catalyze the dismutation of two molecules of $O_2^{\bullet -}$ into hydrogen peroxide and molecular oxygen (1). It is generally accepted that SOD play a major protective role in living cells and have been widely used as pharmacological tools in the study of pathophysiological mechanisms. Since the discovery of SOD, numerous direct and indirect methods for the activity assay have been developed; many methods for the determination of SOD activity have emerged based on enzymatically or chemically produced superoxide (2–9) and on immunochemistry (10). Amongst these methods, the use of lucigenin-amplified chemiluminescence (CL) (6) has been gaining popularity largely because of its simplicity and sensitivity in usage. However, the validity of lucigenin as a detecting probe has recently been questioned because $O_2^{\bullet -}$ is generated by lucigenin itself in several in vitro enzymatic systems (11, 12). More recently, however, Skatchkov et al. (11) demonstrated that the concentration of lucigenin is a critical parameter affecting the probe's validity, and their spin-trapping studies revealed that lucigenin at 250 μM increased $O_2^{\bullet -}$ production severalfold while 5 μM lucigenin did not stimulate $O_2^{\bullet -}$ production (11, 13). Thus, lucigenin at a concentration of 5 μM is a valid probe for assessing $O_2^{\bullet -}$.

In this paper, we present a simple and continuous one-step flow injection system based on lucigenin-amplified CL for the assay of SOD activity using a concentration of 5 μM lucigenin. The reaction of lucigenin-derived CL is initiated by interaction between the lucigenin cation radical and xanthine–xanthine oxidase (XOD) derived $O_2^{\bullet -}$ to yield an unstable dioxetane intermediate. The lucigenin dioxetane decomposes to produce two molecules of *N*-methylacridone, one of which is in an electronically excited state, which upon relaxation to the ground state emits a photon (13). The presence of SOD activity is, therefore, determined by a reduction in $O_2^{\bullet -}$ concentration and, hence, reduced CL intensity.

Materials and methods

Materials

Lucigenin (*bis*-*N*-methylacridinium nitrate), xanthine, xanthine oxidase (EC 1.1.3.22, from buttermilk, 0.69 U mg^{-1} protein), superoxide dismutase (EC 1.15.1.1), Cu, Zn-SOD (from bovine erythrocytes, 4000 U mg^{-1} protein), Mn-SOD (from E. coli, 4000 U mg^{-1} protein), catalase (EC 1.11.1.6, from bovine liver, 58 000 U mg^{-1} protein), glutathione reductase (EC 1.6.4.2, from bovine intestinal mucosa, 100 U mg^{-1} protein), bovine albumin, ascorbic acid, potassium phosphate, glutathione, adrenaline, and cysteine were purchased from Sigma Chemical Co. (St. Louis, Mo). Potassium cyanide (KCN) was obtained from Fluka (Buchs, Switzerland) and all other chemicals were reagent grade.

Tissue preparation

Following 24 h of starvation and anesthesia by diethyl ether inhalation, guinea pigs were perfused through the aorta with ice cold 0.9% NaCl until the heart and major organs were visibly blanched. Liver, heart, kidney, lung, and brain were excised, snap-frozen, and stored at –80°C. For the tissue homogenate preparation, frozen tissue was thawed in ice cold 50 mM potassium phosphate buffer (pH 7.4), blotted, weighed, and minced (14). Each tissue was homogenized on ice in a 10 mL volume of the buffer with a Teflon™-homogenizer (Iwaki Co., Japan). Homogenates (10%) were then subjected to three sonication cycles of 30 pulses, on ice, with a 1 min interval between cycles, in a Bransonic sonifier (Branson Co., Shelton, CT). The resultant extract was clarified by centrifugation. The supernatant was diluted 10-fold using 50 mM potassium phosphate buffer (pH 7.4).

Flow injection-chemiluminescent assay

The CL was measured with a spiral flow cell and filter-equipped photon counting spectrophotometer (CLD-110, Tohoku Electronic Industry, Sendai, Japan) connected to a pump (Gilson Model 303) and a sample injection valve (Rheodyne Model 7125, 20 μL). The tubing diameter and length between injector and detector was 0.25 mm ID and 40 cm, respectively. The dispersed light from the grating was simultaneously detected on the photocathode with the image sensor in the range of 300–650 nm. The photons counted in the range of 300–650 nm were computed as total spectral intensity. The mobile phase consisted of 50 mM potassium phosphate buffer (pH 7.4) containing lucigenin (5 μM) and xanthine (0.3 mM); the flow rate was maintained at 1 mL min^{-1} using the pump. In order to measure SOD activity, the mixture of XOD (15 mU, according to manufacture's information) and SOD and (or) test samples were injected. The 15 mU XOD was used as a reference for measurement of changes in CL intensity and the XOD amount could be readily varied by changing the experimental conditions. The injected volumes of XOD, SOD, and test samples used were dependent upon each concentration, and only very small amounts (1–5 μL) were needed. The reduced CL intensities of the mixtures were compared to those of the CL intensities of 15 mU of XOD. SOD activities of test samples were measured based on a standard curve, using a purified SOD preparation (according to manufacture's information). The percentage reduction of CL can be calculated using the equation:

$$[1] \qquad \% \text{ reduction of CL} = [(A - B)/A] \times 100$$

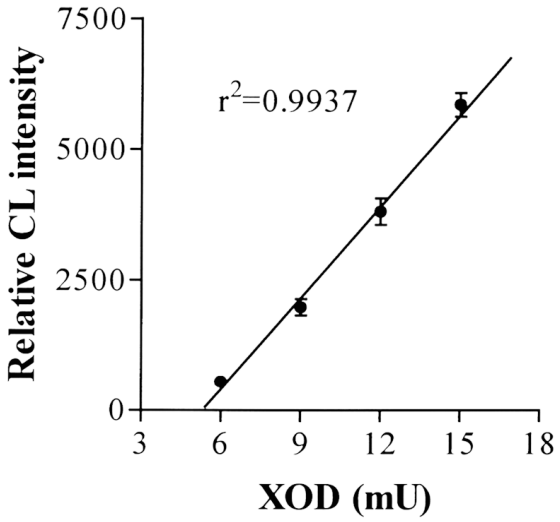
where *A* is the CL intensity generated from the injection of the 15 mU XOD only and *B* is the CL intensity generated from the injection of XOD (15 mU) and SOD and (or) test sample.

Optimization tests

The action of xanthine oxidase on CL intensity was tested. The optimum pH for the xanthine–XOD dependent CL was examined using 50 mM potassium phosphate buffer with a 5.4–8.4 pH range. The effect of temperature was measured in the range of 25–55°C. Bovine albumin was injected in concentrations of 1–1000 μg mL^{-1} in order to test the interference of protein. The inhibition of Cu, Zn-SOD activity was tested by the addition of KCN. Cyanide anion binds Cu, thereby causing the inhibition.

Results

Optimization



XOD concentrations related directly and linearly to CL intensity (Fig. 1). As shown in Fig. 2, the intensity of the CL signal increased with an increase in the reaction pH and temperature of the detector. For standard assays, suboptimal physiological condition (pH 7.4, 38°C) were chosen to construct a system with which to assess the SOD activity of tissues and cells. Bovine albumin, injected as a mixture of 15 mU XOD and albumin (5 μL), did not affect CL at concentrations of 1–1000 μg mL^{-1}. KCN, injected as a mixture of 15 mU XOD, KCN (5 μL), and 75 mU SOD, inhibited 50 and 100% of Cu, Zn-SOD activity at concentrations of 0.15 and 0.23 mM, respectively.

Calibration curve of standard SOD

By transforming the values of CL intensities into logarithms, it was found that, under optimum conditions, the pure Cu, Zn-SOD linearly inhibited the xanthine–XOD dependent CL. The linear regression equation was $y = 3.8299 - 0.2018x$; the correlation coefficient (r^2) was 0.9931 (Fig. 3). A log-plot (inset of Fig. 3) demonstrates that the reduction was not directly proportionate to Cu, Zn-SOD concentrations, but rather follows an exponential function. A 50% reduction of CL was detected at 18.56 mU of Cu, Zn-SOD against 15 mU XOD. The results of 10 consecutive runs with the mixture of 15 mU XOD and 14.8 mU of Cu,

Fig. 1. Effect of XOD concentration on lucigenin CL induced by xanthine–XOD. All concentrations of XOD were injected using the optimized conditions as described under *Results*. Each point denotes mean ±SD of three determinations.

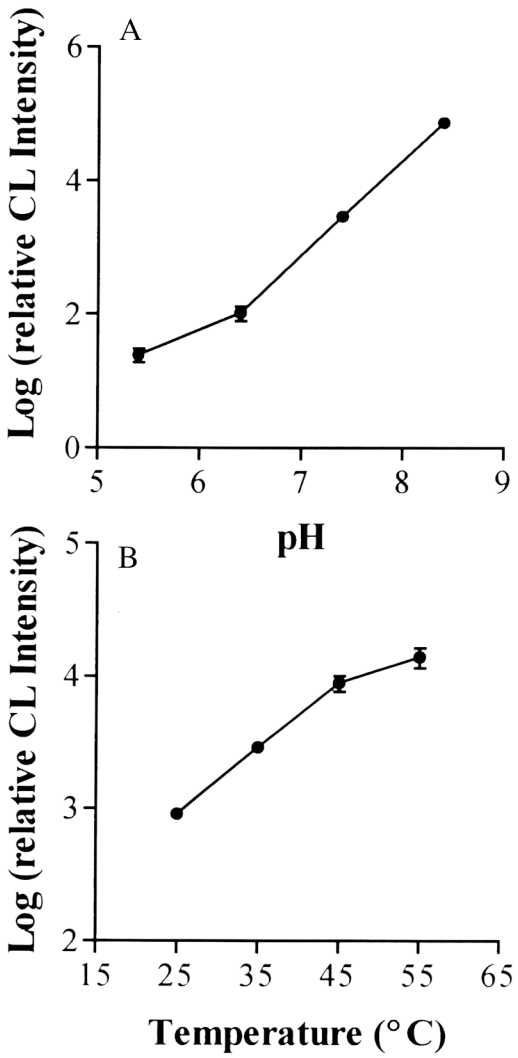
Zn-SOD showed high analysis speed and reproducibility (Fig. 4). We achieved a relative standard deviation of ±3.1%, and each run was performed in less than 30 s.

SOD activity in tissues and standard addition

To test the applicability and validity of this system to the determination of SOD activity in tissues, tissue samples of guinea pigs were used. The mixture of 15 mU XOD and 5 μL of tissue extracts diluted by 1:10 was injected with or without exogenous SOD. The total SOD activity varied amongst the tissues, with the activity in the liver being much higher than in other tissues. The results of the standard addition experiment show that the degree of reduced CL intensity correlates to the amount of exogenously applied SOD (Table 1).

Specificity evaluation

The present study was done to assess the specificity and sensitivity of the assay. Glutathione, adrenaline, and cysteine, which are well-known natural reductants in tissues, inhibited the CL intensity in a dosage-dependent manner. A 50% reduction of CL was detected using 5 μL of 4.64 mM glutathione, 0.38 mM adrenaline, and 6.44 mM cysteine, respectively. Catalase also showed a dosage-dependent behavior, but it was about 1.3×10^4 times less efficient than SOD; giving a 50% reduction at 237.8 U. Glutathione reductase did not affect the intensity of CL signal with additions up to 300 U. Ascorbic acid, one of the strongest reductants and radical scavengers and a major antioxidative substance against aqueous radicals in the blood (15), demonstrated a different pattern of activity. Ascorbic acid increased the CL at 0.01 and 0.1 mM concentrations, but reduced the CL by 82.3 and 95.4% at 1 and 10 mM, respectively (Fig. 5).



Discussion

Although the CL probe (lucigenin) has been shown to be suitable for detecting $O_2^{\bullet -}$ (6, 16), a more sensitive and useful method is required for application in a wide range of clinical uses. The method must permit a low concentration (5 μM) of lucigenin to be used effectively, while precluding the possible generation of superoxide by lucigenin itself. In these respects, several important advantages over the currently available methods are apparent with the use of the flow injection-chemiluminescent assay (FI-CLA) for CL-based SOD activity utilizing xanthine–XOD dependent $O_2^{\bullet -}$ formation.

First, the instrumentation is simple, and the highly sensitive detector (CLD-110) makes possible the use of small amounts of sample in very small volumes as well as requiring low concentrations of lucigenin. Also, there is no need for incubation steps or the addition of any other reagents for amplifying the lucigenin-enhanced CL.

Second, the dynamic range for detection of SOD activity is adhered to. The concentration of SOD that gives a 50% reduction of CL is often used as an indicator of sensitivity in assay protocols. Our FI-CLA system reaches this level with 18.56 mU of Cu, Zn-SOD against 15 mU XOD. However,

Fig. 2. Effects of (*a*) assay pH and (*b*) temperature on CL responses with the injection of 15 mU XOD. Each point denotes mean ±SD of three determinations. SD bars shown only when they are bigger than the symbol used.

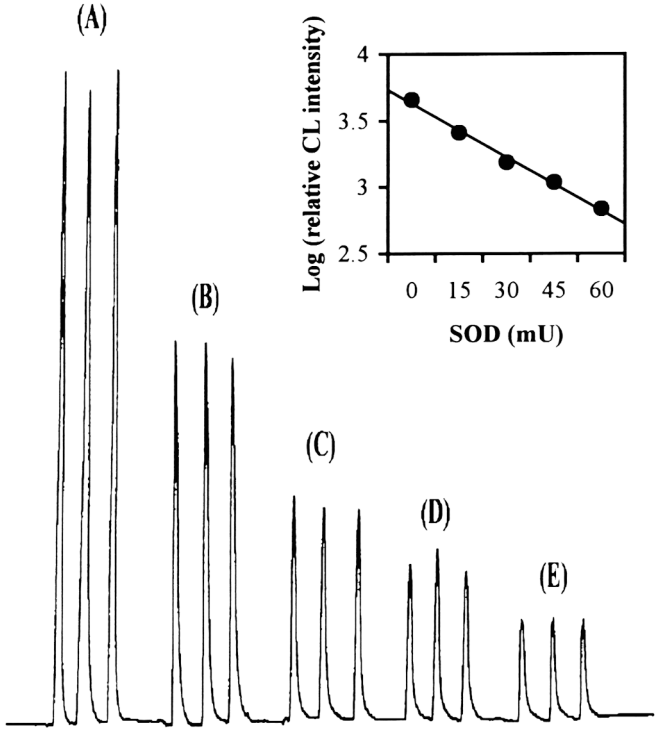
Fig. 3. Inhibition of xanthine–XOD dependent CL by Cu, Zn-SOD. The different concentrations of Cu, Zn-SOD were injected with the mixture of 15 mU XOD. The concentration of SOD: (*a*) 0 mU, (*b*) 15 mU, (*c*) 30 mU, (*d*) 45 mU, and (*e*) 60 mU.



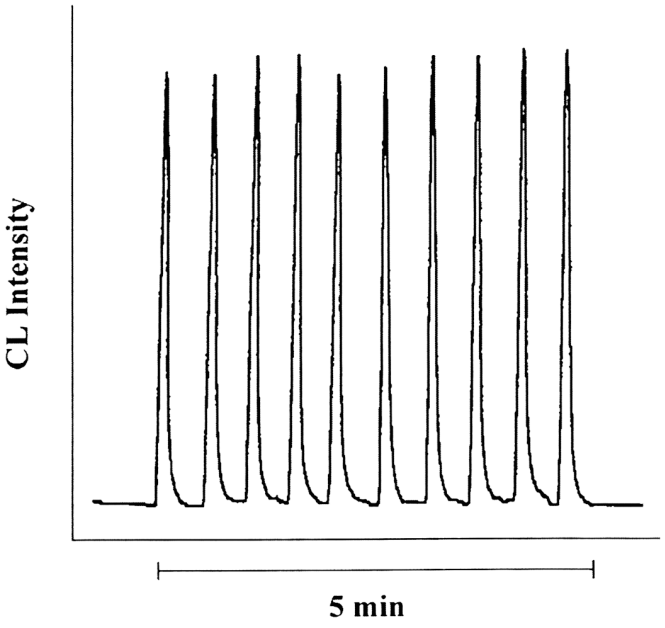


Fig. 4. Ten consecutive runs of the mixture of 15 mU XOD and 14.8 mU of Cu, Zn-SOD.

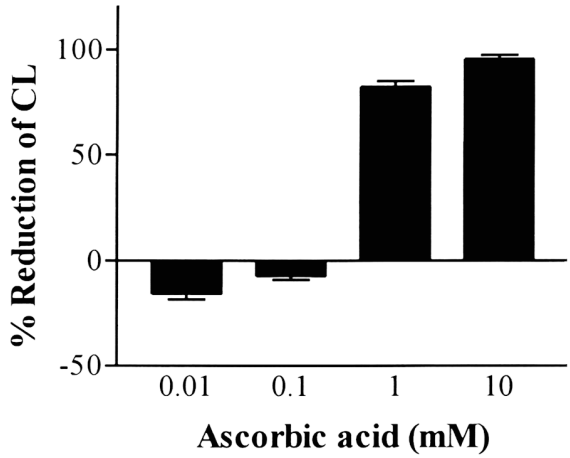

the concentration of SOD to get the 50% reduction of CL can be lowered by reducing the amount of XOD which controls the amount of $O_2^{\bullet -}$ produced. As described in the *Materials* section, the injected amounts of XOD, SOD, and test sample were readily varied in this system.

Table 1. Measurement of SOD activities in tissue extracts.

Tissue	SOD added (ng)	SOD activity[a] (ng 5 μL^{-1} ± 3 SD)
Brain	—	4.35 ± 0.13
	1.0	5.40 ± 0.11
Heart	—	5.46 ± 0.07
	1.0	6.38 ± 0.08
Kidney	—	9.58 ± 0.30
	1.0	10.51 ± 0.33
Lung	—	6.94 ± 0.12
	1.0	7.88 ± 0.25
Liver	—	26.38 ± 0.17
	1.0	27.11 ± 0.11

[a]SOD activity was based on standard curve.

Fig. 5. Changes in inhibition of CL by ascorbic acid concentrations. Each concentration was injected with the mixture of XOD (15 mU) and ascorbic acid (5 μL). Vertical bars denote mean ±SD of three determinations.

Third, a highly reproducible and rapid analysis can be carried out very conveniently by direct injection of the mixture of XOD and SOD and (or) a test sample, allowing a wide clinical application (Fig. 4).

The kinetics of CL are mainly dependent upon pH and temperature (17). Increasing pH through the pH range of 5.4–8.4 and temperature through the range of 22–55°C, increased CL intensity, which did not reach a maximum in our system. The use of suboptimal physiological conditions (pH 7.4, 38°C) has a distinct advantage in the application to biological samples. In fact, physiological pH is the most suitable for optimal activity of Mn-SOD, which is not reliably assayed at the elevated pH values that are required by other sensitive methods (18, 19). The standard curve of Mn-SOD was essentially identical with Cu, Zn-SOD under the same conditions (data not shown).

The exponential behavior of SOD activity agrees well with previous studies (19, 20). SOD that was thermally inactivated at 100°C for 5 min did not affect the intensity of the CL signal (data not shown), proving that no residual loss of CL occurred. KCN is able to completely restore CL by inhibiting Cu, Zn-SOD, proving that CL specifically originated from the superoxide radical (21).

© 2001 NRC Canada

Tissue samples can be readily analysed using this method. SOD activity in tissue homogenates is correlated to the amount of exogenously applied purified SOD (Table 1). However, it must be kept in mind that natural reductants and radical scavengers might also have a role in the activities of the tissue samples, even if their reaction specificity is much lower than that of SOD. Therefore, the activity should be regarded as a total SOD-like activity of a given sample. To avoid all interference by the compounds mentioned above, we recommend that samples be dialyzed against suitable media, or rapidly desalted through a small Sephadex G-25 (coarse) column prior to the assay (22).

Ascorbic acid leads to either positive (reducing CL intensity) or negative (enhancing CL intensity) effects depending on the concentration (Fig. 5). The dual role of ascorbic acid as an anti- and pro-oxidant has been repeatedly documented (23–25). It is assumed that ascorbic acid potentiates the formation of the lucigenin cation radical or $O_2^{\bullet -}$ is generated by the autoxidation of ascorbic acid at low concentrations.

Based on the above data, we conclude that FI-CLA is a simple, rapid, and reliable method for determining SOD activity. In particular, this new system is expected to be applied to a wide range of biochemical and clinical examinations.

Synthesis and characterization of an homologous series of bis(amido)diazadipnictetidines (Pnict = P, As, Sb, Bi)

Neil Burford, T. Stanley Cameron, Kim-Chung Lam, Daren J. LeBlanc, Charles L.B. Macdonald, Andrew D. Phillips, Arnold L. Rheingold, Laura Stark, and Denise Walsh

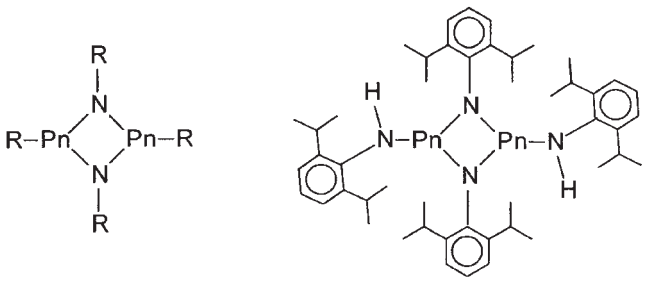
Abstract: Spectroscopic and structural features are presented for the first homologous series of diazadipnictetidines, which have the general formula $[DipNPnN(H)Dip]_2$ (Pn = P, As, Sb, Bi; Dip = 2,6-diisopropylphenyl). The compounds are obtained from a general reaction of the corresponding halopnictine with excess LiN(H)Dip, which was previously reported for $[DipNBiN(H)Dip]_2$. However, isolation is improved by the introduction of LiN(H)-*t*-Bu (at the appropriate stoichiometry) following the addition of LiN(H)Dip. The intermediate steric presence of the Dip substituent is suitable to support the heterocatenate framework for all homologues. This is in contrast to the small substituents (e.g. alkyl), which enable both bis- and tris-amination, and the larger substituent (Mes* = tri-*tert*-butylphenyl), which can impose coordinative unsaturation (aminoiminopnictine) for the smaller congeners (P and As).

Key words: phosphorus, arsenic, antimony, bismuth, phosphazanes, phosphetidines, synthesis, structures, spectroscopic characterization.

Résumé : On a déterminé les caractéristiques spectroscopiques et structurales de la première série d'homologues des diazadipnictétidines de formules générales $[DipNPhN(H)Dip]_2$ (Pn = P, As, Sb, Bi; Dip = 2,6-diisopropényllphényle). Les composés ont été obtenus par une réaction générale de l'halopnictine correspondante avec du LiN(H)Dip en excès, telle que rapportée antérieurement pour le $[DipNBiN(H)Dip]_2$. Toutefois, il est plus facile d'isoler les produits si l'on introduit une quantité stoechiométriquement appropriée de LiN(H)-*t*-Bu à la suite de l'addition du LiN(H)Dip. La présence stérique intermédiaire du substituant Dip est appropriée pour supporter le squelette hétérocaténate pour tous les homologues; cette propriété contraste avec celles des petits substituants (par exemple, alkyles) qui permettent de faire aussi bien des bis- que des tris-aminations et avec celle du substituant plus encombrant (Mes* = tri-*tert*-butylphényle) qui peut imposer une insaturation coordinatrice (aminoiminopnictine) aux congénères plus petits (P et As).

Mots clés : phosphore, arsenic, antimoine, bismuth, phosphazane, phosphétidine, synthèse, structure, caractérisation spectroscopique.

[Traduit par la Rédaction]



Introduction

Cyclodiphosphazanes (**1P**) (more commonly known as diazadiphosphetidines (1) or cyclo-1,3-diaza-2,4-diphosphabutanes) represent a prominent component of established nitrogen–phosphorus chemistry (2, 3). They are distinguished by the ubiquitous four-membered heterocatenated ring structure, which contrasts the more flexible and varied ring sizes observed for the formally unsaturated phosphazenes (4). Although analogous pnictetidine heterocycles involving the heavier elements of group 15 (P, As, Sb, Bi) have been structurally characterized (5–17), each represents a unique derivative and many involve cage or cluster structures

incorporating the pnictetidine moiety, thereby impeding direct structural or spectroscopic comparison. In this context, the structural report for the first unsupported bismetidine derivative (**2Bi**) (18) and the spectroscopic characterization of the arsenic analogue (**2As**) (19) prompted us to exploit the use of the 2,6-diisopropylphenyl (Dip) substituent and extrapolate the synthetic procedures to isolate and characterize the first phosphetidine, arsetidine, stibetidine, and bismetidine (homologous) series (**2Pn**).

Experimental procedures

General

Diethyl ether was obtained from ACP Chemicals Inc., hexane from Van Waters & Rogers, and arsenic(III) chloride from Kodak Chemicals. All other chemicals and reagents were obtained from Aldrich. Sample handling and reactions were performed under oxygen and moisture free conditions (20). *n*-Butyllithium (1.6 M in hexanes) and 2,6-diisopropylaniline ($DipNH_2$) were used as supplied. *tert*-Butylamine was dried at reflux over KOH and CaH_2. Dichloromethane was dried at reflux over CaH_2 and P_4O_{10}. Diethylether and hexane were dried over sodium–benzophenone. Deuterated solvents were dried over CaH_2. PCl_3 and $AsCl_3$ were distilled, and $SbCl_3$ was sublimed in vacuo prior to use. $BiCl_3$ was used as received. Lithium amides were prepared in situ under an atmosphere of nitrogen by adding an equimolar quantity of *n*-BuLi via a septum to a stirred solution (diethyl ether) at room temp of the amine, followed by stirring for at least 8 h. Melting points were obtained on samples sealed in glass capillaries under dry nitrogen using a Fisher–Johns apparatus. FT-IR spectra were recorded as Nujol™ mulls on CsI plates using a Nicolet 510P spectrometer. FT-Raman spectra were recorded on powder samples sealed in 1 mm diameter glass tubes with a laser power of 166 mW using a Bruker RFS-100 spectrometer. Vibrational spectra are presented as wavenumber (cm^{-1}) maxima with ranked intensities for each absorption, the most intense given a ranking of 1. Chemical analyses were performed by Beller Laboratories, Göttingen, Germany. Solution (CD_2Cl_2) ^{31}P and ^{1}H NMR data were recorded at room temp on samples sealed in evacuated Pyrex™ tubes using a Bruker AC-250 spectrometer (working at 250.13 MHz for ^{1}H and 101.26 MHz for ^{31}P). Chemical shifts are reported in ppm relative to external standards (TMS for ^{1}H, 85% aq. H_3PO_4 for ^{31}P). UV–vis spectra were obtained on a Varian Cary 100Bio UV–vis spectrometer at room temp.

Preparative procedures and spectroscopic characterization data

*[DipNPN(H)Dip]$_2$ (**2P**)*

In an evacuated vessel, a solution of LiN(H)Dip (18.5 mmol) was added over a period of ca. 30 min to a stirred solution of PCl_3 (0.84 g, 6.1 mmol) in Et_2O (20–30 mL) to give a bright yellow solution and a white precipitate. After stirring for 2 days the mixture was filtered through a fine fiberglass frit and all volatiles were removed in vacuo to give a yellow oil and pale yellow cube-shaped crystals. The oil was decanted from the crystals, which were washed three times by cold spot back-distillation (20) to afford 0.34 g (0.88 mmol, 14%) of yellow crystals, mp 125–138°C. UV–vis λ_{max} (nm) (ε (M^{-1} cm^{-1})): 230–250, 360 (3000), 430 (600). FT-IR (cm^{-1}) (ranked intensity): 3370 (22), 3057 (23), 1436 (1), 1381 (4), 1327 (5), 1263 (12), 1248 (10), 1242 (15), 1191 (8), 1186 (9), 1105 (17), 1097 (18), 1043 (21), 936 (26), 899 (6), 881 (7), 867 (3), 798 (2), 785 (13), 746 (11), 738 (19), 717 (24), 532 (20), 518 (25), 480 (14), 430 (16). IR-Raman (cm^{-1}) (ranked intensity): 3059 (5), 3021 (9), 2958 (1), 2912 (2), 2865 (3), 1590 (6), 1441 (8), 1269 (4), 1109 (16), 1044 (11), 954 (18), 884 (12), 684 (10), 521 (14), 442 (17), 292 (15), 147 (7), 78 (13). ^{1}H NMR (CD_2Cl_2) δ: 1.03 (d, J = 7 Hz, 24H), 1.27 (d, J = 7 Hz, 24H), 3.10 (sept, J = 7 Hz, 4H), 3.91 (sept, J = 7 Hz, 4H), 5.43 (s, 2H), 6.9–7.3 (m, 12H). ^{31}P NMR (CD_2Cl_2) δ: 118. Anal. calcd. for $C_{24}H_{35}N_2P$: C 75.36, H 9.22, N 7.32; found: C 75.30, H 9.33, N 7.25.

*[DipNAsN(H)Dip]$_2$ (**2As**)*

Under an atmosphere of nitrogen, $AsCl_3$ (0.8 mL, 9.1 mmol) was added to a cooled (0°C) solution of LiN(H)Dip (27 mmol) in Et_2O (50 mL) over a period of 10 min to give an orange solution and a white precipitate. After stirring at room temperature for 2 days, the solution was frozen and the vessel was evacuated. After thawing, LiCl was filtered from the solution and volatiles were slowly removed under static vacuum to leave a red oil, which was dissolved in hexane and filtered. Slow removal of solvent under static vacuum gave a pale yellow crystalline solid with an oil, which was decanted, and the crystals were washed three times by cold spot back-distillation (20) to yield 0.67 g (0.78 mmol, 17 %), mp 166–169°C. UV–vis λ_{max} (nm) (ε (M^{-1} cm^{-1})): 230–250, 323 (1000). IR-Raman (cm^{-1}) (ranked intensity): 3056 (11), 3020 (18), 2958 (3), 2925 (2), 2865 (9), 1589 (4), 1460 (17), 1433 (13), 1328 (24), 1263 (6), 1249 (1), 1180 (20), 1160 (29), 1108 (15), 1042 (16), 954 (28), 885 (14), 843 (26), 669 (19), 605 (25), 539 (23), 507 (30), 448 (22), 364 (12), 274 (21), 223 (27), 145 (8), 102 (10), 84 (7), 71 (5). ^{1}H NMR (CD_2Cl_2) δ: 1.08 (d, J = 7 Hz, 24H), 1.25 (d, J = 7 Hz, 24H), 2.99 (sept, J = 7 Hz, 4H), 4.02 (sept, J = 7 Hz, 4H), 5.57 (s, 2H), 6.7–7.2 (m, 12H), additional minor signals speculatively assigned to As[N(H)Dip]$_3$. Anal. calcd. for $C_{24}H_{35}N_2As$: C 67.59, H 8.27, N 6.57; found: C 68.06, H 8.01, N 6.45.

*[DipNSbN(H)Dip]$_2$ (**2Sb**)*

Under an atmosphere of nitrogen, a solution of LiN(H)Dip (12 mmol) was added via cannula to a cooled (–78°C) solution of $SbCl_3$ (1.33 g, 5.83 mmol) in Et_2O (20 mL) to give a yellow solution and a white precipitate. After stirring for less than 5 min, a solution of LiN(H)-*t*-Bu (5.9 mmol) was added. The reaction mixture was stirred for 60 min at –78°C and then at room temperature for 4 h. The solution was frozen and the vessel was evacuated. After thawing, the reaction mixture was filtered and the volatile components were removed in vacuo to leave a peach coloured oil, from which a bright yellow powder precipitated on addition of hexane (20 mL). Filtration and slow removal

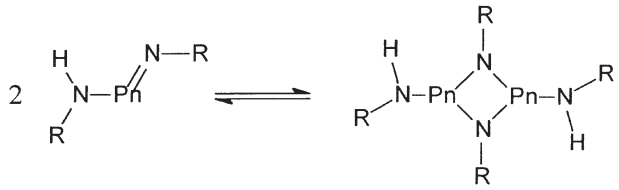
X-ray crystallography



Crystals were obtained as described above and mounted in Pyrex™ capillaries in a drybox, except for **2P**, which was immersed in fluorolube oil and attached to a glass pin and immediately frozen in the cold stream of the diffractometer.

For **2P**, unit cell determination and data collection were performed, with graphite monochromated radiation (Mo Kα, λ = 0.71073 Å) by Φ and ω scans, on a Siemens P4 diffractometer equipped with a Bruker AXS SMART CCD detector (21). Structure solution and refinement were performed with the SHELX-97 (22) and SHELXTL (23) software packages. All nonhydrogen atoms were refined anisotropically, while the hydrogen atoms, which were placed geometrically in idealized positions, were allowed to ride on the heavy atom to which they were bonded with U_{iso} equal to 1.2 U_{eq} of the heavy atom.

For **2As** and **2Sb**, unit cell determination and data collection were performed, with graphite monochromated radiation (Cu Kα, λ = 1.54178 Å) and $\omega - 2\theta$ scans, on a Rigaku AFC5R diffractometer. The data were corrected for Lorentz and polarisation effectsas absorption (psi scans) and a secondary extinction coefficient were refined in each case. Structure solution and refinement were performed with use of the teXsan crystallographic software package (24). The structures were solved by direct methods. All nonhydrogen atoms were refined anisotropically. Hydrogen atoms were included at calculated positions but were not refined (C—H = 0.95 Å). Crystallographic details are summarized in Table 1 and selected bond lengths and angles are presented in Table 2.[2]

Results and discussion

Phosphazanes are readily synthesised by a variety of procedures, the most common being the reaction of an amine with a halophosphine. Although applicable to some arsines (25, 26), amination of the heavier pnictines (As, Sb, Bi) is generally complicated by the weaker and more labile N—Pn bond (as compared to N—P), which results in multiple products. More effective procedures have involved the introduction of lithium amides or silylated amines at the appropriate stoichiometry and in the presence of a base to effect the dehydrohalogenation reaction responsible for dimerization, however, stoichiometric combinations can be unpredictable. For example, the reaction of $BiCl_3$ with 3 equiv of LiN(H)Dip provides the pnictetidine **2Bi** (18), presumably with concomitant formation of 2 equiv of H_2NDip. Contrary to intuitive appreciation of steric factors, the corresponding reaction of $BiCl_3$ with 3 equiv of LiN(H)Mes* (Mes* = 2,4,6-tri-*tert*-butylphenyl, a bulkier substituent) effects quantitative amination to $Bi[N(H)Mes^*]_3$, as it does for $SbCl_3$ (27). In contrast, the reactions of PCl_3 or $AsCl_3$ with 3 equiv of LiN(H)Mes* give the aminoiminopnictines (28), which can be considered as the monomers (**3P** and **3As**) of the pnictetidine dimers (**4P** and **4As**), respectively.

3Pn **4Pn**

The number and variety of known derivatives for **1** indicate that the pnictetidine frame is favorable for all members of group 15, making **1** a key representative of the developing N–Pn chemistry. Comparisons between pnictetidines with different pnictogen centers are currently restricted by the diversity of substitution formats that have been reported. We

[2] Supporting information available: thermal ellipsoid diagrams for each of the structures, tables of crystallographic data, atomic coordinates, isotropic and anisotropic displacement parameters, bond lengths, and angles, and a CIF file for **2P**. have now prepared the first homologous series of diaminodiazapnictetidines employing the 2,6-diisopropylphenyl (Dip) substituent, with bis-1,3-(2,6-diisopropylphenyl)-bis-2,4-(2,6-diisopropylphenylamino)-cyclo-1,3-diaza-2,4-di-p- nictabutanes (**2**) being derived from the previously reported arsenic **2As** (19) and bismuth **2Bi** (18) derivatives.

Although the title compounds (**2**) are all likely present in the reaction mixtures of the respective halopnictine with H_2NDip, these compounds have been isolated from reactions of $PnCl_3$ with LiN(H)Dip, thereby generalizing the synthetic approach first employed for **2As** (19) and **2Bi** (18). By using 2 equiv of LiN(H)Dip with $PnCl_3$ followed by the introduction of 1 equiv of LiN(H)-*t*-Bu, which enables in vacuo removal of the by-product (H_2N-*t*-Bu), we have isolated **2Sb** and improved the isolation procedure for **2Bi**. The reactions of $PnCl_3$ with 3 equiv of LiN(H)Dip produce one equiv of H_2NDip (low volatility and viscous oil readily identified, as an impurity, in the ^{1}H NMR spectrum), which is difficult to separate from the reaction mixture and hinders isolation of crystalline samples of **2**.

The four homologues of **2** have been comprehensively characterized. Solution NMR data (^{1}H and ^{31}P) are distinctive and can be interpreted in terms of the substitution pattern of **2**, and the compounds are clearly distinguished by vibrational spectra (IR and Raman). The N—H stretch is obvious (cf. 3397cm^{-1} for **2As**) (19), and a consistent three-band pattern at 1250, 1425, and 1600 cm^{-1}, evident in the Raman spectra, is tentatively assigned to vibrations associated with the Dip substituents. Further assignments are hindered by the complexities associated with the organic substituents. The distinctive colours of the solids **2P** (pale yellow), **2As** (cream), **2Sb** (bright yellow), and **2Bi** (red) are correlated with two weak bands in the visible region of the electronic spectra, which we tentatively assign to $n \rightarrow \pi^*$ transitions. Two additional intense, high-energy bands (230 and 250 nm) are analogous to those observed for the parent amine (H_2NDip) and are assigned to transitions involving the aryl substituents.

Selected solid state structural features for the derivatives of **2** are presented for comparison in Table 2. Representative

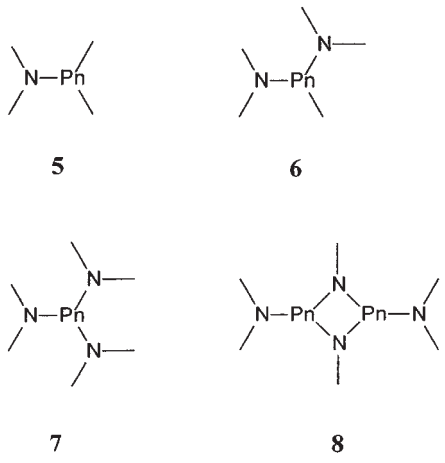
views of the molecular structures of **2As** and **2Sb** are shown in Fig. 1. A variety of crystal structures are observed despite the uniform substitution pattern and the essentially symmetric four-membered molecular ring present in all four cases. Isolated samples of **2Sb** and **2Bi** are isostructural involving a *trans*-configuration about the centrosymmetric planar heterocycle. In contrast, **2P** and **2As** have symmetric (*C*2/*c*) and asymmetric ($P2_1/c$) *cis*-configured molecular structures, respectively. Both display substantial folding of the heterocycle (Pn–Pn vector fold angles: P 154.5(1)°, As 150.4(2)°). Within each derivative of **2**, the endocyclic N—Pn bond lengths are essentially indistinguishable. The exocyclic N—Pn bonds are slightly shorter for Pn = P and As, but are identical to the endocyclic bonds when Pn = Sb and Bi. A slight increasing trend in Pn-N-Pn angle and a decreasing trend in N-Pn-N angle in the order P, As, Sb, Bi are evident. The N(*exo*)-P-N(*endo*) angles are anomalously large in comparison with the more routine angles observed for the other derivatives (Pn = As, Sb, and Bi), indicating that steric interactions between the substituents may be partly responsible for the nonplanarity of the heterocycle. Nevertheless, the planarity of the *trans*-configuration and puckering of the *cis*-configurations are consistent with observations for the numerous structural reports for diazadiphosphetidine derivatives (3). The consistency of the four-membered heterocyclic frame, in spite of the substituent steric influences, is possibly responsible for the observed configurational distinctions imposed by the relative atomic sizes of the pnictogen elements.



The data presented for compounds **2P**, **2As**, and **2Sb** complement the spectroscopic data previously reported for **2As** (19) and the structural and spectroscopic data for **2Bi** (18) to complete the first homologous series of diazadipnictetidines. We attribute the preferential isolation and general stability of these systems to the intermediate steric influences of the Dip substituent. The degree of amination of a pnictine is understandably limited by the spatial (steric) requirements of both the number of substituents on nitrogen and steric bulk of those substituents. Depending on reaction stoichiometry and conditions, small substituents (e.g., Me, Ph, *t*-Bu) generally enable all three degrees of amination (mono-**5**, bis-**6**, and tris-**7**) of pnictines, as well as oligomeric arrangements resulting from condensation reactions, for which the pnictetidine **1** (or **4**/**8**) is the most obvious product. In the context of the data available for NMes* substitution, the sterically smaller Dip substituent may be expected to allow for trisamination. For Sb and Bi, however, the observations

© 2001 NRC Canada

Fig. 1. Crystallographic views of **2As** (top) and **2Sb** (bottom) with 30% probability displacement ellipsoids. For clarity, hydrogen atoms have been omitted.

reveal that slightly lower steric strain imposed by the Dip substituent (relative to Mes*) favours condensation to the diazadipnictetidine **4** over trisamination.

Conclusions

The intermediate steric presence of the Dip substituent is suitable to support all heterocatenate frameworks for the first homologous series of diazadipnictetidines. The generally applicable synthetic procedure involves the reaction of LiN(H)Dip with the corresponding chloropnictine; isolation is enhanced using an equivalent of LiN(H)-*t*-Bu. Consistent structural features are evident throughout the series except for configurational differences, which may be of minimal energetic significance.

Acknowledgments

We thank the Natural Sciences and Engineering Research Council of Canada (NSERC), the Killam Trust and the Sumner Foundation for funding, the Atlantic Regional Magnetic Resonance Centre and Dr. F. Cozens for the use of instrumentation, Natasha Zwarun for obtaining the UV–vis spectra, and Katherine Robertson for help with processing the crystallographic data for **2As** and **2Sb**.

In the footsteps of Pasteur: asymmetric induction in the photochemistry of crystalline ammonium carboxylate salts

John R. Scheffer

Abstract: This review describes the development of a new, synthetically useful method of asymmetric synthesis in organic photochemistry. Similar in many ways to the Pasteur procedure for resolving racemic carboxylic acids and organic amines, the method relies on the use of crystalline organic salts in which the enantioselectivity of a photochemical reaction of an achiral organic ion (for example, a carboxylate anion) is governed in the solid state by the presence of an optically pure counterion (for example, an optically active ammonium ion). Such optically pure counterions are termed ionic chiral auxiliaries. Salts containing ionic chiral auxiliaries are required to crystallize in chiral space groups, which provide the asymmetric environment necessary for chiral induction. Using this methodology, we have obtained near-quantitative optical yields in a wide variety of photochemical reactions.

Key words: photochemistry, solid state, chiral auxiliaries, asymmetric synthesis, crystal structure–reactivity relationships.

Résumé : Cet article de revue décrit le développement d'une nouvelle méthode, utile, de synthèse asymétrique en photochimie organique. Semblable à plusieurs points de vue à la méthode de Pasteur de dédoubler les acides carboxyliques et les amines organiques racémiques, la méthode est basée sur l'utilisation de sels organiques cristallins dans lesquels l'énantiosélectivité d'une réaction photochimique d'un ion organique achiral (par exemple, un ion carboxylate) est régie à l'état solide par la présence d'un contre-ion optiquement pur (par exemple, un ion ammonium optiquement actif). De tels contre-ions optiquement purs sont dénommés auxiliaires chiraux ioniques. Des sels contenant des auxiliaires chiraux ioniques sont nécessaires pour obtenir une cristallisation dans des groupes spatiaux chiraux qui fournissent l'environnement asymétrique nécessaire à l'induction chirale. À l'aide de cette technologie, nous avons pu obtenir des rendements optiques pratiquement quantitatifs dans un grand nombre de réactions photochimiques.

Mots clés : photochimie, état solide, auxiliaires chiraux, synthèse asymétrique, relations structure cristalline–activité.

[Traduit par la Rédaction]

Introduction

Before embarking on a description of our work dealing with asymmetric synthesis in the crystalline state, a few words are in order concerning the title of this presentation. Without in any way trying to equate our work with that of Pasteur's in terms of significance, there are, nonetheless, some interesting connections. One of these is that several of the ideas presented in this review were developed in 1997 while I was on sabbatical leave at the University of Strasbourg. At the same university, approximately 150 years earlier, Louis Pasteur carried out much of his most famous and important research dealing with the isolation of optically active substances (1), and it was genuinely inspiring to think that one might literally, as well as figuratively, be following in the great man's footsteps. The scientific relationship between Pasteur's work and ours will be presented later in the review.

Origin of the ionic chiral auxiliary concept

In the mid-1980s, one of my graduate students, Miguel Garcia-Garibay, discovered that the achiral compound diisopropyl 9,10-dihydro-9,10-etheno-anthracene-11,12-dicarboxylate (**1**) spontaneously crystallizes in the chiral space group $P2_12_12_1$, and that irradiation of enantiomorphously pure single crystals of this substance leads to the di-π-methane rearrangement product **2** in near quantitative enantiomeric excess (Scheme 1) (2). The critical importance of a chiral space group to this so-called absolute asymmetric reaction was highlighted by the fact that a dimorph of diester **1** in the achiral space group *Pbca* rearranged in the solid state to give racemic **2**. While absolute asymmetric syntheses had been documented prior to this time for bimolecular solid state reactions ((3) and for the first example of an absolute

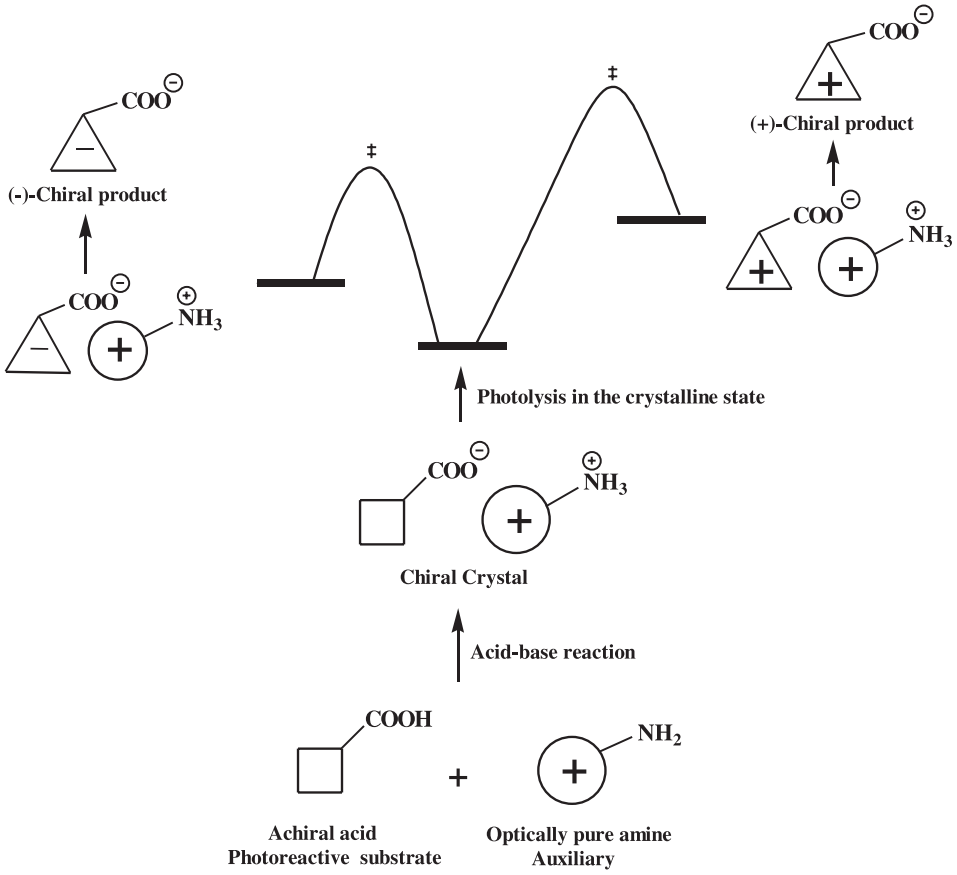
asymmetric synthesis see, ref. 3*a*), this was the first reported example of a *unimolecular* absolute asymmetric photorearrangement.

Encouraged by the high optical yield obtained in this reaction, we set out to devise a more general method by which the crystalline state could be used to achieve asymmetric induction in photochemical reactions. For reviews on asymmetric induction in organic photochemistry, see ref. 4. One problem with absolute asymmetric synthesis as a general method is that the great majority of achiral compounds do *not* crystallize in one of the 65 chiral space groups (of 230 total space groups) that are essential for success (5). For a more recent discussion of space group frequencies see ref. 5*b*. A second major obstacle is that, at present, there is no general understanding of the relationship between molecular structure and crystal structure. In other words, it is virtually impossible to predict when an achiral molecule will crystallize in a chiral space group. It is clear, therefore, that what is needed is a method of *guaranteeing* the presence of a chiral space group, and that absolute asymmetric synthesis, while fascinating and perhaps of relevance to theories of the prebiotic origins of optical activity on earth (6), will never be synthetically useful in the general sense.

How is it possible to guarantee the presence of a chiral space group? The simple answer is to equip the reactant with an optically pure chiral auxiliary. Such compounds are *required* to crystallize in chiral space groups because the molecules of which the lattice is composed cannot pack in mirror-symmetric or centrosymmetric arrangements. Incidentally, for those wondering how achiral molecules can also crystallize in chiral space groups (albeit rarely and unpredictably), a good way to visualize this is to imagine a right or left-handed spiral staircase constructed of achiral building blocks (e.g., bricks).

Two types of chiral auxiliary can be envisaged: covalent and ionic (Fig. 1). In the covalent type (Fig. 1*a*), the optically pure chiral auxiliary is tethered to the achiral reactant by a covalent bond, typical examples being via ester or amide formation between a carboxylic acid and an alcohol or an amine. In contrast, ionic chiral auxiliaries are attached by means of salt bridges between ions (Fig. 1*b*). At the time we began this work (1989) the use of ionic chiral auxiliaries in asymmetric synthesis was unknown, and for this reason we concentrated our efforts in this area. Since then Zhang and Corey (7) have shown that optically active quaternary ammonium ions can be used successfully in enantioselective alkylation, Michael addition, nitroaldol, and epoxidation reactions.

Fig. 1. Covalent (*a*) and ionic (*b*) chiral auxiliaries.



In addition to novelty, there were a number of practical reasons for choosing to work with ionic chiral auxiliaries. Chief among these is the fact that salts tend to have much higher melting points than purely covalent compounds of comparable molecular weight. This is important when conducting reactions in the crystalline state, since salts are less likely to melt as the reaction proceeds and, as a result, higher conversions are possible. Melting, of course, leads to loss of topochemical control of reaction selectivity as the periodic, three-dimensional regularity of the crystal lattice is degraded. We also hoped that, because of their strong lattice forces, ionic compounds might be more prone to undergo single crystal-to-single crystal or topotactic solid state photochemistry. Reactions of this type represent the Holy Grail of solid state chemistry, because they allow the reacting crystal to be monitored by X-ray diffraction throughout the course of the transformation. This is not possible for the great majority of solid state reactions, which are nontopotactic in nature and involve formation of the product in polycrystalline form (8). The beauty of topotactic reactions for asymmetric induction studies is that they permit the absolute configuration of the starting material to be correlated with that of the product through X-ray crystallography of partially reacted crystals. For a review of absolute configuration correlation studies in topotactic as well as nontopotactic solid state photoreactions, see ref. 9. For salts, this works best when the absolute configuration of the chiral auxiliary is known, which is usually the case. We shall see an example of such a study later in the paper.

Another practical advantage of salts for asymmetric induction studies is that they are readily prepared by simple acid-base chemistry, and once the asymmetric induction is complete, the ionic chiral auxiliary can be easily removed, typically by diazomethane workup to form the methyl ester of the carboxylate anion component. Finally, it is important to mention that it is not necessary to work with single crystals in the case of substrates containing ionic or covalent chiral auxiliaries. This is because all crystals in such

materials have the same chirality. As a result, one can photolyze polycrystalline samples weighing dozens or even hundreds of milligrams, an important feature if the method is to become synthetically useful.

Scientific connection with Pasteur

The solid state ionic chiral auxiliary approach to asymmetric synthesis has close parallels to the procedure devised by Pasteur to resolve racemic carboxylic acids. In this procedure, first used in 1853 to resolve racemic tartaric acid (10), the racemic carboxylic acid is treated with an optically pure amine (cinchonicine or quinicine in Pasteur's case) to form a pair of diastereomerically related salts. These are then separated by fractional crystallization, and subsequent acidification of each diastereomerically pure salt regenerates the carboxylic acid in optically pure form.

What we are proposing to do in the ionic chiral auxiliary method is to generate a chiral carboxylic acid in situ by photolysis of an achiral precursor in the presence of an optically pure amine (Fig. 2). Such reactions proceed through ionic transition states that are diastereomerically related, and given a sufficiently large difference in activation energy for a kinetically controlled process, can in principle lead to near-quantitative yields of a single product enantiomer. This method has an advantage over the conventional Pasteur resolution procedure in terms of yield, since the maximum yield of a given enantiomer that can be obtained in the latter case is 50% (and in practice is often considerably less) (11). Furthermore, the ionic chiral auxiliary approach allows either optical antipode of the photoproduct to be prepared by simply changing the configuration of the auxiliary. This is a relatively easy matter these days given the commercial availability of a wide variety of chiral auxiliaries in both enantiomeric forms.

Test reaction requirements

In order to be suitable for testing the solid state ionic chiral auxiliary approach to asymmetric synthesis, photochemical reactions must meet the following requirements: (*i*) the reaction must be one in which an achiral starting material is converted into a chiral photoproduct; high quantum yields are desirable. (*ii*) The reactant must contain an acidic or basic functional group that allows for salt formation with a suitable chiral auxiliary. In nearly all of the systems we have investigated, the reactant contains a carboxylic acid group and the chiral auxiliary is an optically pure amine. The reason for this is that diazomethane workup of the reaction mixture affords the photoproduct as the corresponding methyl ester, which is relatively easy to chromatograph, isolate and analyze for ee. (*iii*) The reactant must crystallize in a conformation favorable for reaction. Hydrogen abstraction reactions, for example, only work in the solid state if the C=O···H distance is of the order of 2.8 ± 0.2 Å (for a discussion of the geometric requirements for intramolecular hydrogen atom transfer in the solid state, see ref. 12). Since most conformationally flexible molecules crystallize in or near

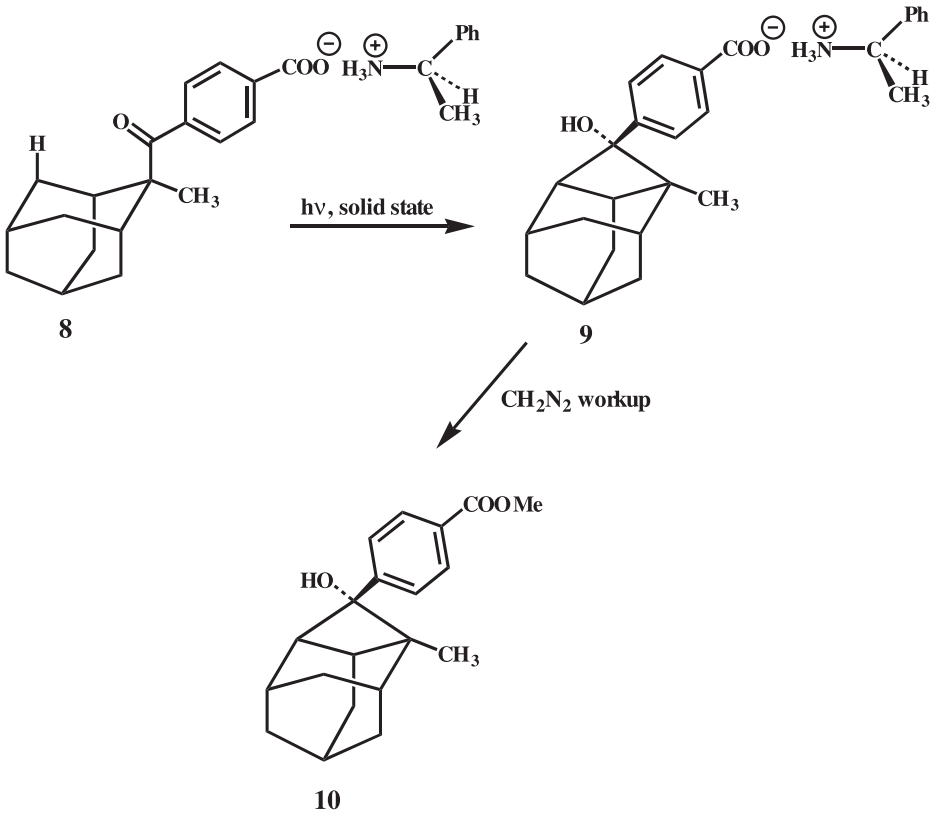
their lowest energy conformations (13), molecular mechanics calculations give a good indication of the conformation to be found in the solid state.

Examples of the solid state ionic chiral auxiliary method

cis-4-*tert*-Butyl-1-benzoylcyclohexane derivatives



In 1974, Lewis et al. (14) showed that solution phase irradiation of achiral ketone **3** affords excellent yields of the corresponding racemic cyclobutanol **4** (Scheme 2). This reaction, an example of Yang photocyclization (see ref. 15 for examples of Norrish type II photochemistry), seemed ideal for our purposes since it fulfills all the requirements outlined above. In particular, molecular mechanics calculations indicated a feasible hydrogen atom abstraction geometry for the lowest energy conformer, and all that was required was to introduce a carboxylic acid group into compound **3** without disturbing its plane of symmetry; this was readily accomplished through synthesis of the corresponding *p*-carboxylic acid **5** (16).

Treatment of keto-acid **5** with (*R*)-(+)-1-phenylethylamine gave salt **6**, and photolysis of polycrystalline samples of this material followed by diazomethane workup gave (–)-**7** in optical yields as high as 97% (Table 1) (16). As shown in the table, the enantiomeric excess (ee) decreased slightly with increasing conversion, a feature that appears to be general to the method. We attribute this decrease in ee to crystal breakdown resulting from defect sites generated by product molecules that do not fit into the reactant lattice. Despite this, the pleasant fact is that >90% ee is maintained even at conversions as high as 85%. As predicted, use of the enantiomeric chiral auxiliary (*S*)-(–)-1-phenylethylamine gave essentially the identical ee of (+)–**7**. These results clearly indicate the considerable synthetic potential of the ionic chiral auxiliary approach to asymmetric induction. Finally, irradiation of salt **6** in solution was found to afford racemic cyclobutanol **7**, a result that highlights the importance of the crystalline state for asymmetric induction.

Several additional ionic chiral auxiliaries were investigated in the case of keto-acid **5**, and the results are summarized in Table 2. Clearly, not all chiral auxiliaries work equally well, and an important task was to try to understand why some salts give much higher ees than others. We have recently solved this problem and shall address this question later in the review. For now, suffice it to say that for every photochemical reaction that we have studied via the solid

(–)-Prolinamide	51	(+)-68.2

state ionic chiral auxiliary method, it has always been possible to find at least one and often two or three chiral auxiliaries that give ees of 90% or more. More often than not, for reasons that we do not understand, the 1-phenylethylammonium ion has proven to give the highest ees.

Fig. 3. Molecular structure of the *same crystal* prior to (**8**) and following (**9**) irradiation in the solid state. The hydrogen atoms have been omitted for clarity.

Single crystal-to-single crystal photorearrangement of a 2-benzoyladamantane derivative

As an extension of our work with the *cis*-4-*tert*-butyl-1-benzoylcyclohexane system discussed above, we investigated the solid state photochemistry of a series of 2-benzoyladamantane derivatives (16). During these studies, we noticed that irradiation of crystals of salt **8** (Scheme 3) led to excellent yields of photoproduct salt **9** without any noticeable change in the appearance of the crystals. Treatment of the irradiated crystals with diazomethane afforded methyl ester **10** in ees that varied from a high of 88% ee at 3.5% conversion to 82.4% ee at 82.3% conversion. These results suggested that the conversion of salt **8** into photoproduct salt **9** was a single crystal-to-single crystal (topotactic) process, and this possibility was, therefore, investigated further.

Accordingly, a single crystal of salt **8** was subjected to X-ray diffraction analysis and then photolyzed for a sufficient time (2 h) to convert it quantitatively into salt **9**, whereupon a second data set was collected. Both data sets refined successfully in space group $P2_12_12_1$ to final R values of 4.6 and 4.9%, thus verifying that the solid state photorearrangement is indeed a topotactic process. Figure 3 shows the molecular structures of the salts before and after photolysis. As is

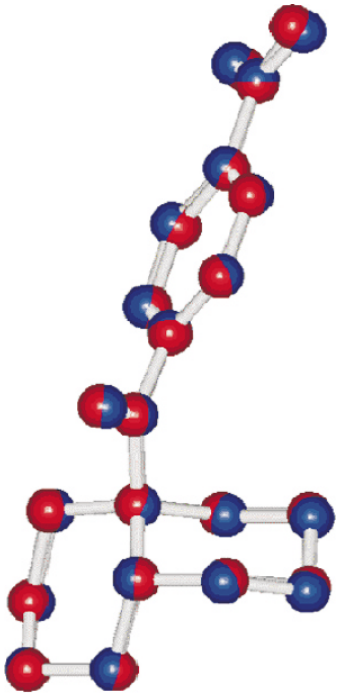
Scheme 4.

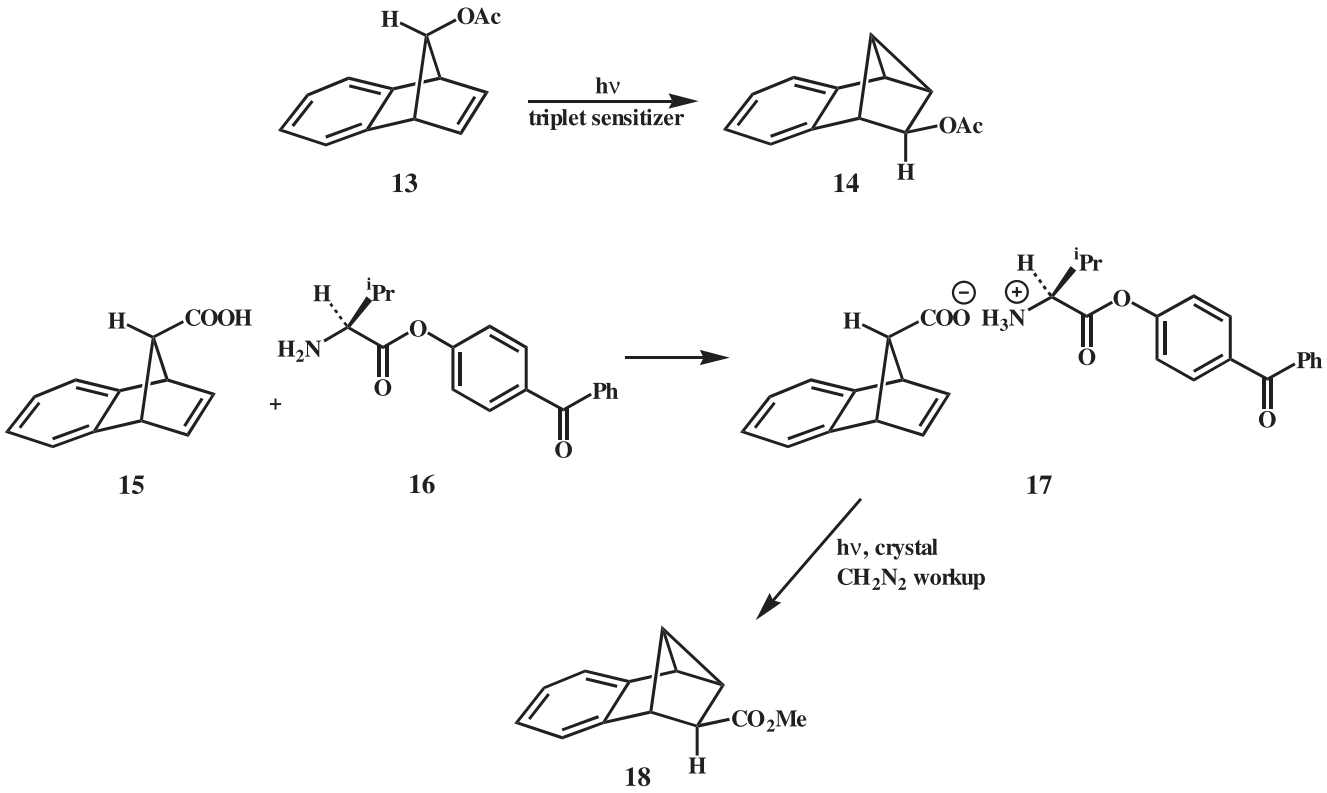


11 **12**

evident, the reactant and product have similar shapes and sizes. This is reflected by a root mean-square error of only 0.53 Å calculated for the overlap of the two structures (17), which is undoubtedly the reason for the single crystal-to-single crystal nature of the reaction, i.e., the photoproduct fits very well into the lattice site of the reactant.

Furthermore, because the absolute configuration of the 1-phenylethylammonium ion is known, the absolute configuration of the anion is established, and this allows us to determine whether γ-hydrogen atom H_X or H_Y was abstracted. The experimental results clearly show that H_X is the reactive hydrogen atom, and this is consistent with its closer proximity (2.60 Å) to the carbonyl oxygen, as compared to H_Y (3.59 Å) (for an example where a difference in C=O···H_γ distance of only 0.27 Å leads to exclusive abstraction of the closer hydrogen in the solid state, see ref. 18). The crystal structures shown in Fig. 3 also reveal the reason for the high diastereoselectivity of the conversion of salt **8** into salt **9**. Following abstraction of H_X, the 1,4-hydroxybiradical intermediate finds itself in a conformation ideally suited for least motion closure to the observed *endo*-aryl photoproduct. Formation of the *exo*-aryl cyclobutanol would require an approximately 180° rotation of the –Ċ(OH)Ar substitutent, a large amplitude motion that is impossible in the crystalline state. The same explanation applies to the diastereoselective conversion of salt **6** into *endo*-aryl cyclobutanol photoproduct **7** (Scheme 2) (16).

Fig. 4. RMS overlay of chiralty-matched conformational enantiomers of salt **11** (cations not shown). The red spheres correspond to one conformational enantiomer, the blue spheres to the other.



cis-9-Decalyl aryl ketone derivatives

Next we discuss the use of the ionic chiral auxiliary method in the photochemistry of *cis*-9-decalyl aryl ketone derivatives. Consider the example shown in Scheme 4. In a Yang photocyclization reaction (15) that is simultaneously regio-, diastereo-, and enantioselective, irradiation of crystals of salt **11** leads to chiral cyclobutanol **12** with an ee of 98% at 85% conversion (19). Similar results were obtained with the (*R*)-bornyl ammonium salt. As in the cases discussed above, X-ray diffraction studies revealed that the molecular conformation of the reactant is responsible for the remarkable selectivity observed. Salt **11** crystallizes in a conformation that brings the axial γ-hydrogen atom at C4 (shown in Scheme 4) into close proximity with the carbonyl oxygen atom (2.62 Å). Abstraction of this hydrogen leads to a biradical that closes with "retention of configuration" at the carbonyl carbon to afford cyclobutanol **12**. As in the case of salts **6** and **8** discussed above, formation of the alternative diastereomer requires a topochemically forbidden 180° bond rotation of the bulky –Ċ(OH)Ar group, and is, therefore, not observed. Serving once again to highlight the importance of the crystalline state to the success of the ionic chiral auxiliary method, irradiation of salt **11** in solution led to racemic **12**. We have yet to observe a measurable ee in solution for any of our chiral salts.

One of the ionic chiral auxiliaries investigated in the *cis*-decalyl aryl ketone system led to relatively low ees. This was the (1*R*,2*S*)-norephedrine salt, which gave photoproduct **12** in 30% ee at 55% conversion. In this case we were able to obtain an X-ray crystal structure of the starting salt, which allowed us to pinpoint the structural features responsible for the low ees observed. The key feature of this salt, which distinguishes it from those that lead to high ees, is that it crystallizes with equal amounts of two crystallographically independent ion pairs in the asymmetric unit. Remarkably, the two independent photoreactive carboxylate anions were found to exist as near-perfect enantiomers, reaction of which give rise to opposite product enantiomers, thus accounting

© 2001 NRC Canada

Scheme 5.

for the low ees observed. Because the independent enantiomers are conformers of one another, they are termed conformational enantiomers (19). When only one conformational enantiomer of the reactive ion is present in the crystal, as in the 1-phenylethylammonium salt **11**, high ees are observed.

Figure 4 represents the superposition of the two conformational enantiomers of the reactive anion of the norephedrine salt, one as found in the crystal, and the other as its mirror image. As can be seen there is a nearly perfect atom-for-atom overlap of the two structures (root-mean-square error of 0.08 Å). This sort of packing arrangement may turn out to be fairly common. To date, we have identified six other examples in widely different systems, and in every case low but measurable ees are observed (20). This raises the interesting question of why *any* ee is observed at all, since all other factors being equal, irradiation of crystals containing equal amounts of two conformational enantiomers might be expected to lead to racemic photoproducts. We believe the answer lies in the fact that the two conformational enantiomers reside in structurally different reaction cavities, and that one of these cavities allows the reaction to proceed at a slightly faster rate than the other (for an example of a solid state reaction in which two independent molecules in the asymmetric unit react at measurably different rates, see ref. 21). Viewed another way, the conformational enantiomers form diastereomeric salts with the common optically pure amine, and should, therefore, not react at exactly the same rate.

Benzonorbornadiene derivatives

As a final example of the use of the ionic chiral auxiliary method for asymmetric synthesis, we describe our work with benzonorbornadiene derivatives. In solution, such compounds are well known to undergo triplet-sensitized di-π-methane photorearrangement (22) to afford tetracyclic products, a typical example being the conversion of the achiral acetoxy derivative **13** into chiral photoproduct **14** (23) (Scheme 5).

This and similar reactions require the use of triplet energy sensitizers, which leads to problems in the crystalline state because of the difficulty in preparing two component solid solutions of sensitizer and substrate (24). Previous work from our research group has shown that ionic auxiliaries can function as solid state photosensitizers (25), and we, therefore, decided to go one step further and design an ionic auxiliary that could play two roles simultaneously; the first as chiral auxiliary and the second as triplet energy sensitizer. Carboxylic acid **15** (Scheme 5) was chosen as the achiral reactant and amine **16** was synthesized in optically pure form to serve as the chiral photosensitizer (26). These two compounds were combined to afford salt **17**, which was then irradiated in the crystalline state and subsequently treated with diazomethane to form ester **18**. Under conditions of 100% conversion at –20°C, this compound was formed in a gratifying 91% ee, a remarkable result given the fact that salt **17** is not conformationally biased toward formation of one photoproduct enantiomer over the other.

Factors responsible for asymmetric induction

Unlike the majority of ground state reactions involving asymmetric induction, where the chiral agent is intimately associated in the transition state, the role of the ionic chiral

© 2001 NRC Canada

auxiliary in the solid state photochemical reactions described above is simply to ensure that the salts crystallize in chiral space groups. This means that the chiral auxiliary can be attached to any part of the reactive molecule and does not need to be close to the site of reaction. In the case of salts **6**, **8**, and **11**, the role of the ionic chiral auxiliary is to preorganize the reactant anions in a single, homochiral conformation that permits abstraction of only one of two possible enantiotopic hydrogen atoms. Once hydrogen abstraction takes place, the enantioselectivity of the process is determined. Cyclization of the 1,4-hydroxybiradical can occur only at the carbon atom from which the hydrogen was removed, leading to a single enantiomer of each of the two possible diastereomers. In every case studied so far, biradical closure occurs in the solid state with "retention of configuration" at the carbonyl carbon such that only the least-motion diastereomer is formed. Thus, in addition to being enantioselective, these ionic chiral auxiliary-mediated reactions are diastereoselective.

In the case of the di-π-methane photorearrangement of salt **17**, reactant conformation plays little or no role in determining enantioselectivity, since to all intents and purposes, the reactive species is symmetrical except for twisting in the carboxylate group. The first step of the mechanism in this case is vinyl-benzo bridging (22), which can occur in two different ways leading to opposite enantiomers. In such circumstances, it is the shape and size of the solid state "reaction cavity," i.e., the space occupied by a single molecule in a crystal whose walls are composed of the neighboring molecules in the lattice (27), which governs enantioselectivity. Such *environmental* control of enantioselectivity is more difficult to pin down than conformational control. Visual inspection of the packing diagram often provides no obvious clue to reaction selectivity, which is the cumulative result of a large number of small interactions and requires detailed computational analysis. The approach taken is to construct a computationally amenable "mini-lattice" of 50–100 molecules based on the X-ray crystal structure of the reactant. The central molecule in the mini-lattice is then replaced with a transition state analogue and the energy of the resulting ensemble calculated using molecular mechanics. For recent progress in this area, the interested reader is referred to the work of Zimmerman and co-workers (28) as well as that of Houk and co-workers (29). Such calculations were not possible in the case of salt **17** because we were unable to obtain a crystal structure. We were, however, able to utilize this approach to rationalize the enantioselectivity of a different, non-ionic solid state photorearrangement (30).

Epilogue

The focus of this article has been to outline the general principles underlying the use of ionic crystals in bringing about asymmetric induction in photochemical reactions. Owing to space restrictions, the success of the ionic chiral auxiliary approach could be illustrated with only a few examples, and the purpose of this epilogue is to point out that the method has been applied with equal success to several additional systems (31–43). As a result, there seems little doubt that this technique can now be classified as one of the most general and useful methods of asymmetric synthesis in organic photochemistry.

Acknowledgments

Acknowledgment is made to the donors of the Petroleum Research Fund, administered by the American Chemical Society, for partial support of this research. Financial support by the Natural Sciences and Engineering Research Council of Canada (NSERC) is also gratefully acknowledged. I would also like to acknowledge funding by NATO in the form of a Senior Guest Fellowship (1997–98), as well as thank Jean-Marie Lehn, Université Louis Pasteur, Strasbourg, France for hospitality during a sabbatical visit. Finally, I would like to dedicate this paper to the members of my research group, past and present, whose hard work, dedication, and perspicacity were responsible for bringing this project to fruition.

Synthesis and spectroscopic properties of benzo- and naphthofuryl-3-hydroxychromones

Andrey S. Klymchenko, Turan Ozturk, Vasyl G. Pivovarenko, and Alexander P. Demchenko

Abstract: With the focus of designing new fluorescent probes, four new 3-hydroxy-chromone derivatives bearing benzofuran and naphthofuran groups were synthesized. They show bathochromic absorption shifts relative to 3-hydroxyflavone with the ability of retention to display the excited-state proton transfer. Disruption of the planarity by the methyl group in the furan ring leads to a decrease of both the extinction coefficient and the contribution of long wavelength absorption band, while molecules without a methyl group showed two distinct absorption bands. Shifts to longer wavelengths are also observed in fluorescent spectra, and the absence of the methyl group results in a dramatic increase of fluorescence quantum yield and lifetime. Of the extended 3-hydroxychromone derivatives, 3-hydroxy-2-naphtho[2,1-*b*]furan-2-yl-chromone has shown comparable, and in some cases better, absorption and fluorescence properties than the 3-hydroxychromones synthesized so far, which make it a highly promising candidate as molecular probe for analytical chemistry, biophysics, and cellular biology.

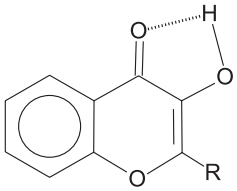
Key words: benzo- and naphthofuryl-3-hydroxyflavone, synthesis, electronic spectra, fluorescence, excited state proton transfer.

Résumé : Dans le but de développer de nouvelles sondes fluorescentes, on a synthétisé quatre nouveaux dérivés de la 3-hydroxychromone portant des groupes benzofurane et naphtofurane. Par rapport à la 3-hydroxyflavone, ils présentent des déplacements bathochromes d'absorption tout en conservant leur habilité à donner lieu à un transfert de proton dans l'état excité. La présence du groupe méthyle dans le noyau furane conduit à un manque de planéité qui provoque une diminution du coefficient d'extinction ainsi que de la contribution de la bande d'absorption de grande longueur d'onde alors que les molécules sans groupe méthyle présentent deux bandes d'absorption distinctes. On observe aussi des déplacements vers les longueurs d'onde plus élevées dans les spectres de fluorescence et l'absence du groupe méthyle conduit à une augmentation dramatique du rendement quantique de fluorescence et du temps de vie. Parmi les dérivés de la 3-hydroxychromone allongés, il a été démontré que, comparées à celles des 3-hydroxychromones synthétisés jusqu'à maintenant, l'absorption et les propriétés de fluorescence de la 3-hydroxy-2-naphto[2,1-*b*]furan-2-ylchromone sont au moins comparables et, quelquefois meilleures; il s'agit donc d'un candidat plein de promesses comme sonde moléculaire pour la chimie analytique, la biophysique et la biologie cellulaire.

Mots clés : benzo- et naphtofuryl-3-hydroxyflavone, synthèse, spectres électroniques, fluorescence, transfert de proton dans l'état excité.

Introduction

3-Hydroxyflavones (**1a**–**d**) have interesting specific spectroscopic properties, which make them important chromophores for the preparation of new fluorescence probes and molecular sensing devices for applications in analytical chemistry, biophysics, and cellular biology (1, 2). They exhibit dual fluorescence due to excited state intramolecular proton transfer (ESIPT) from the 3-hydroxy moiety to the carbonyl group. The latter is characterized by a significant Stokes shift of about 10 000 cm^{-1} (3). This results in the isomerization of the normal excited form of the flavonol to a phototautomer. These two excited isomers return to the ground state with the emission of photons of different energies separated by 5000–6000 cm^{-1} (60–80 nm). The positions and the ratio of intensities of these two bands exhibit strong dependence on solvent polarity (4) and hydrogen bonding with the solvent molecules (2, 4, 5). These particular features suggest that 3-hydroxyflavones can be effectively used as fluorescence probes to investigate the structure and physical properties of biological membranes such as polarity, hydration, transmembrane potential, and the transformations of their structure under various conditions (6, 7). For example, interdigitated gel phase formation of lipid membrane bilayer in the presence of alcohols (8, 9) can be followed by 3-hydroxyflavone probes (10).



So far, 4-amino derivatives of 3-hydroxyflavone (**1a**–**d**) have been widely investigated as fluorescent membrane probes and fluorescent chelators (11, 12). However, most modifications of the structure were focused on extensions of 3-hydroxyflavone system at the chromone fragment, while extensions of phenyl side have not been extensively explored.

6

To modify and improve the chromophore properties, we have synthesized four new chromones bearing benzofuran (**3** and **4**) and naphtofuran groups (**5** and **6**). It is expected that such systems may display improved fluorescent properties due to the following reasons: (*i*) their conjugation systems are larger than 3-hydroxyflavone, therefore, absorption and emission bands are expected to shift to longer wavelengths; (*ii*) furan oxygen might compete for the 3-hydroxy group's proton, which should increase the sensitivity of the molecule to hydrogen bonding interactions with the surrounding molecules; (*iii*) the presence of methyl group in the furan ring should lead to a decrease of planar structure stability, which is a crucial factor for fluorescence properties; and (*iv*) the furan ring is a π-electron-abundant system, and it is known that an electron donor in position two of the chromone ring increases the transfer of electron density to the carbonyl group in the excited state, which usually leads to the enhancement of the proton transfer and stabilizes the proton transferred tautomeric form. Furthermore, having shifted the absorption and emission bands to longer wavelengths, such heterocyclic systems are expected to serve better in biological systems, since most cells respond poorly to short wavelength excitation (13), and intrinsic cellular pigments interfere with the analysis. Therefore, it is highly desirable to locate the emission peaks in a region where background fluorescence (auto-fluorescence) from cellular pigments is very low. It is, also, well known that longer wavelength light is much less attenuated, and reduced Raleigh and Raman scattering with longer wavelength would yield much lower background signal. Obviously, having extended conjugation systems would be advantagous to reach these goals.

Although all the chromones (**2**–**6**) have shown absorption and fluorescence spectra at longer wavelengths compared with the 3-hydroxyflavone (**1a**), naphthofurylhydroxychromone **5** exhibits superior properties of both higher quantum yields and relatively longer wavelength absorption and fluorescence spectra. These properties make it one of the best fluorescence probe candidates among the 3-hydroxychromones synthesized so far.

Experimental

Melting points were determined on a Kofler hostage microscope melting point apparatus and are uncorrected. Microanalyses were performed with a Carlo Erba 1106 Elemental Analyzer. Proton NMR spectra were recorded at 200 MHz on JEOL PMX 270 MHz spectrometer. Tetramethylsilane (TMS) was used as the internal standard in all NMR spectra run in $CDCl_3$ or DMSO-d_6. Mass spectra were recorded on a Kratos MS-25 mass spectrometer with an ionization potential of 70 eV. All column chromatography were performed on silica gel (Merck, Kieselgel 60H, Art 7736). Absorption spectra were recorded on a Cary 3 Bio-spectrophotometer (Varian) in the concentration range of 10^{-5} M. Fluorescence measurements were recorded on a Quanta Master spectrofluorometer (Photon Technology International). Quantum yields were measured by reference to 3-hydroxyflavone (ϕ_F = 0.046 in acetonitrile, 0.024 in ethanol, 0.29 in toluene). Fluorescence lifetimes with ≈0.5 ns resolution were recorded on Strobe Master time-resolved fluorometer (Photon Technology International), which has nitrogen-filled pulsed lump as a light source (excitation

380 nm) and stroboscopic principle for registration of emission decay curves.

3-Hydroxy-2-(benzo[*b*]furan-2-yl)chromone (**2**) was synthesized using the procedure described elsewhere (15).

3-Hydroxy-2-(3-methylbenzo[*b*]furan-2-yl)chromone (3)

To a solution of 3-methylbenzo[*b*]furan-2-carbaldehyde (**9**) (0.1 g, 0.63 mmol) and 2-hydroxyacetophenone (**7**) (0.085 mL, 0.71 mmol) in ethanol (5 mL) was added 70% potassium hydroxide (0.11 g, 2 mmol) dropwise. The mixture was left stirring at room temp for 24 h, and to the resultant red (*E*)-1-(2-hydroxyphenyl)-3-(3-methylbenzo[*b*]furan-2-yl)-2- propen-1-one (**14**) solution was added 30% hydrogen peroxide (0.5 mL, 4.4 mmol). After stirring for an additional 2 h, the precipitate was filtered, washed with ethanol (5 mL), and crystallized from ethanol to obtain **2** (40 mg, 22%), mp 172°C. EI-MS *m*/*z*: 292.1 (M^+), 275.0, 263.1, 249.0, 235.1, 221.0, 171.0, 144.0, 121.0, 115.0. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.58 (s, 3H), 6.90 (s, 1H, H-exchangeable), 7.29–7.78 (m, 7H), 8.28 (dd, *J* = 8.0, 1.3 Hz, 1H). Anal. calcd. for $C_{18}H_{12}O_4$: C 73.97, H 4.14; found: C: 73.75, H: 4.14.

General procedure for synthesis of 1-(2-hydroxyphenyl)-2-propen-1-one derivatives

To a solution of appropriate benzo- or naphtho[*b*]furan-2-carbaldehyde (0.57 mmol) and 2-hydroxyacetophenone (**7**) (0.07 mL, 0.58 mmol) in ethanol (5 mL) was added 70% potassium hydroxide (0.07 g, 1.25 mmol) dropwise, and the mixture was left stirring for 24 h. In the case of the naphtho-derivatives, the mixture was heated in water bath at 50°C for the same time. Then, the mixture was poured into water (20 mL), neutralized with dilute HCl, and the resultant precipitate was filtered and washed with water to yield the product, which is pure enough to use for the next step.

*(*E*)-3-(6-Ethoxy-3-methylbenzo[*b*]furan-2-yl)-1-(2-hydroxyphenyl)-2-propen-1-one (**15**)*

Purified over silica gel column (hexane–ethyl acetate, 5:1), yield 49%, mp 106°C. EI-MS *m*/*z*: 322.1 (M^+), 305.1, 276.1, 265.1, 229.1, 202.1, 189.1, 174.1, 161.0, 147.0, 133.0, 121.0. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.48 (t, *J* = 7.1 Hz, 3H), 2.41 (s, 3H), 4.11 (q, *J* = 7.1 Hz, 2H) 6.87–7.05 (m, 4H), 7.41–7.55 (m, 4H), 7.65 (d, *J* = 14.8 Hz, 1H), 7.89 (d, *J* = 14.8 Hz, 1H), 8.00 (dd, *J* = 8.0, 1.1 Hz, 1H), 13.05 (s, 1H, H-exchangeable). Anal. calcd. for $C_{20}H_{18}O_4$: C 74.52, H 5.63; found: C 73.8, H 5.56.

*(*E*)-1-(2-Hydroxyphenyl)-3-naphtho[2,1-*b*]furan-2-yl-2-propen-1-one (**16**)*

Crystallized from acetonitrile, yield 95%, mp 198°C. EI-MS *m*/*z*: 314.1 (M^+), 297.1, 285.1, 257.1, 239.1, 221.0, 194.1, 181.1, 165.1. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 6.99 (d, *J* = 15.9 Hz, 1H), 7.03 (d, *J* = 15.9 Hz, 1H), 7.30–8.18 (m, 10H,), 8.15 (d, *J* = 8.0 Hz, 1H), 12.91 (s, 1H, H-exchangeable). Anal. calcd. for $C_{21}H_{14}O_3$: C 80.24, H 4.49; found: C 80.03, H 4.44.

*(*E*)-1-(2-Hydroxyphenyl)-3-(1-methylnaphto[2,1-*b*]furan-2-yl)-2-propen-1-one (**17**)*

Crystallized from butanol, yield 64%, mp 174°C. EI-MS *m*/*z*: 328.1 (M^+), 310.1, 235.1, 208.1, 195.1, 178.1, 121.0. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.83 (s, 3H) 6.98 (d, *J* = 15.9 Hz, 1H), 7.02 (d, *J* = 15.9 Hz, 1H), 7.48–8.07 (m, 9H), 8.40 (d, *J* = 8.1 Hz, 1H), 13.03 (s, 1H, H-exchangeable). Anal. calcd. for $C_{22}H_{16}O_3$: C 80.47, H 4.91; found: C 80.30, H 4.87.

General procedure for synthesis of 3-hydroxychromone derivatives

To a solution of appropriate 1-(2-hydroxyphenyl)-2-propen-1-one derivative (**15**–**17**) (0.22 mmol) in ethanol (5 mL) was added subsequently 70% potassium hydroxide (0.1 g, 1.8 mmol) and 30% hydrogen peroxide (0.4 mL, 3.5 mmol). The mixture was then heated at reflux for 1 h, cooled to room temp, and the precipitate was filtered, washed with water, and crystallized from appropriate solvent.

*2-(6-Ethoxy-3-methylbenzo[*b*]furan-2-yl)-3-hydroxychromone (**4**)*

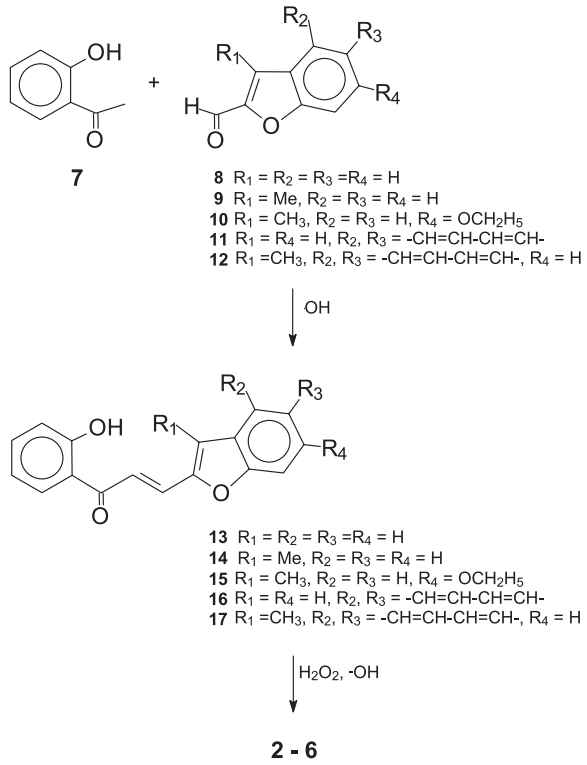
Crystallized from acetonitrile, yield 31%, mp 186°C. EI-MS *m*/*z*: 336.1 (M^+), 307.1, 265.1, 251.1, 237.1, 223.1, 187.1, 165.1, 160.1, 154.1, 140.1, 131.1, 121.0, 77.0. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.46 (t, *J* = 7.1 Hz, 3H), 2.55 (s, 3H), 4.09 (q, *J* = 7.1 Hz, 2H), 6.85 (s, 1H, H- exchangeable), 6.94 (dd, *J* = 8.6, 2.1 Hz, 1H), 7.09 (d, *J* = 2.0 Hz, 1H), 7.39–7.59 (m, 2H), 7.72 (td, *J* = 6.8, 1.4 Hz, 1H), 8.26 (dd, *J* = 8.1, 1.4 Hz, 1H). Anal. calcd. for $C_{20}H_{16}O_5$: C 71.42, H 4.79; found: C 71.38, H 4.73.

*3-Hydroxy-2-naphtho[2,1-*b*]furan-2-yl-chromone (**5**)*

Crystallized from acetic acid, yield 40%, mp 253°C. EI-MS *m*/*z*: 328.1 (M^+), 299.1, 271.1, 215.1, 164.1, 152.1. ^{1}H NMR (200 MHz, DMSO-d_6) δ: 7.47–8.01 (m, 7H), 8.09 (d, *J* = 7.8 Hz, 1H), 8.16 (d, *J* = 7.8 Hz, 1H), 8.30 (s, 1H), 8.43 (d, *J* = 7.8 Hz, 1H), 10.35 (s, 1H, H-exchangeable). Anal. calcd. for $C_{21}H_{12}O_4$: C 76.82, H 3.68; found: C 76.61, H 3.69.

*3-Hydroxy-2-(1-methylnaphtho[2,1-*b*]furan-2-yl)-chromone (**6**)*

Crystallized from acetic acid, yield 31%, mp 187°C. EI-MS *m*/*z*: 342.1 (M^+), 299.1, 285.1, 271.1, 185.1. ^{1}H NMR (200 MHz, DMSO-d_6) δ: 2.77 (s, 3H) 7.47–8.00 (m, 7H), 8.11 (d, *J* = 8.0 Hz, 1H), 8.17 (d, *J* = 8.0 Hz, 1H), 8.52 (d, *J* = 8.2 Hz, 1H), 9.68 (s, 1H, H-exchangeable). Anal. calcd. for $C_{22}H_{14}O_4$: C 77.19, H 4.12; found: C 77.1, H 4.05.



Results and discussion

The syntheses of the target molecules **2**–**6** were carried out by employing the well-established Algar–Flynn–Oyamada reaction (14). Condensation of 2-hydroxyacetophenone (**7**) with the aldehydes **8**–**12**, synthesized as described elsewhere (15–19), in basic solution gave the intermediates **13**–**17**, respectively (Scheme 1). Treatment of these intermediates with hydrogen peroxide in basic ethanol solution led to the formation of 3-hydroxychromones **2**–**6**, respectively.

All the 3-hydroxychromones (**2**–**6**) possess absorption spectra at longer wavelengths compared with 3-hydroxyflavone (**1a**) in various solvents (Fig. 1: acetonitrile (*A*), ethanol (*E*), toluene (*T*)), and of all the 3-hydroxychromones (**2**–**6**), 3-hydroxy-2-naphthofurylchromone (**5**) is found to

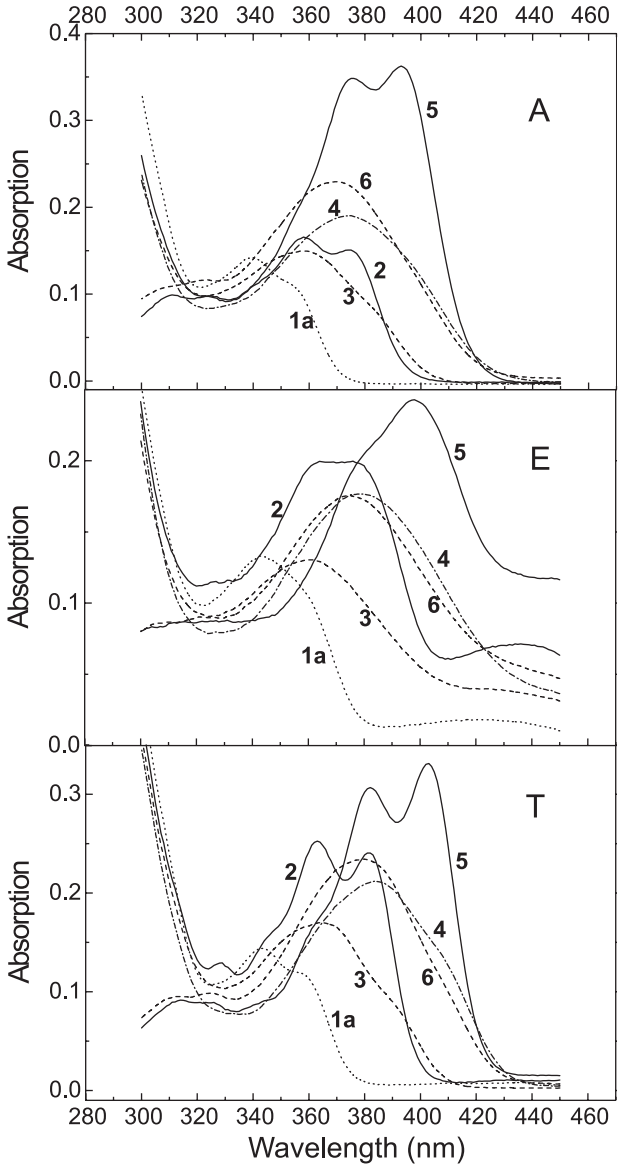

Scheme 1.

have the longest wavelength position of absorption spectrum. This result is related to the extension of the π-conjugation system. The effect of addition of methyl group at C-3 position of the furan ring can be observed as decrease of absorption at long-wavelength part of the spectra. Thus, the absorption spectra of chromones **3**, **4**, and **6** bearing methyl group at C-3 position of the furan ring, show only one absorption band at shorter wavelengths, with a small shoulder at longer wavelengths, while compounds without a methyl group (**2** and **5**) show two distinct absorption bands. One of the possible suggestions for these observed differences could be that the methyl group dramatically effects the hydrogen bonding capabilities of 3-OH group with solvent, but it is unlikely in view of the following reasons. First, this cannot explain the presence of long-wavelength band in absorption spectra of compounds **2** and **5** for all the solvents, including nonpolar toluene. Second, it is in contradiction with observed small differences between absorption spectra of chromones **2** and **5** in toluene and in acetonitrile, where the blue shift is correlated with the increase of polarity (Figs. 1*A* and *T*). The latter means that hydrogen bonding of 3-OH group with acetonitrile is either very weak, even for the case of non-methylated chalcones, or unimportant for energetic profile of the molecules. The critical role of methyl group in absorption of compounds **3**, **4**, and **6** can be explained by a steric factor that may lead to statistical non-planarity between benzo- and naphthofuran and chromone rings, which has been already studied on 2′-, 3′-, and 4′-methyl-3-hydroxyflavones (20). Therefore, it can be suggested that planarity of the chromone molecule is the necessary condition for existence of the long-wavelength band.

In the light of the previous studies (20) we can assume that the absorption at short-wavelength is due to the normal

Fig. 1. Absorption spectra of chromones **1a**, **2**–**6** in different solvents: acetonitrile (*A*); ethanol (*E*); and toluene (*T*).

excitation of 3-hydroxychromone ring, and the long wavelength absorption, as in the case of planar compounds **2** and **5**, is the result of charge transfer from the benzo- and naphthofuran part to the 3-hydroxychromone system. Small long-wavelength absorption shoulders in the spectra of **3**, **4**, and **6** can be explained by less efficient π-electron delocalization between the furan and chromone parts as a result of distortion of the planarity. Non-planarity results not only in a decrease of intensity of the long-wavelength absorption band, but also in a decrease of the extinction coefficient (Table 1), while the introduction of a strong electron donating group, such as ethoxy, to the benzofuryl group (**4**), shifts the absorption band to longer wavelengths in comparison with its analogues (**2** and **3**) (Figs. 1*A*, *E*, and *T*).

Fluorescence spectra of **2**–**6** showed dual fluorescence in all solvents which were used for the absorption measurements (Figs. 2*A*, *E*, and *T*). Dual fluorescent behavior is well explained to be due to the excited state intramolecular proton

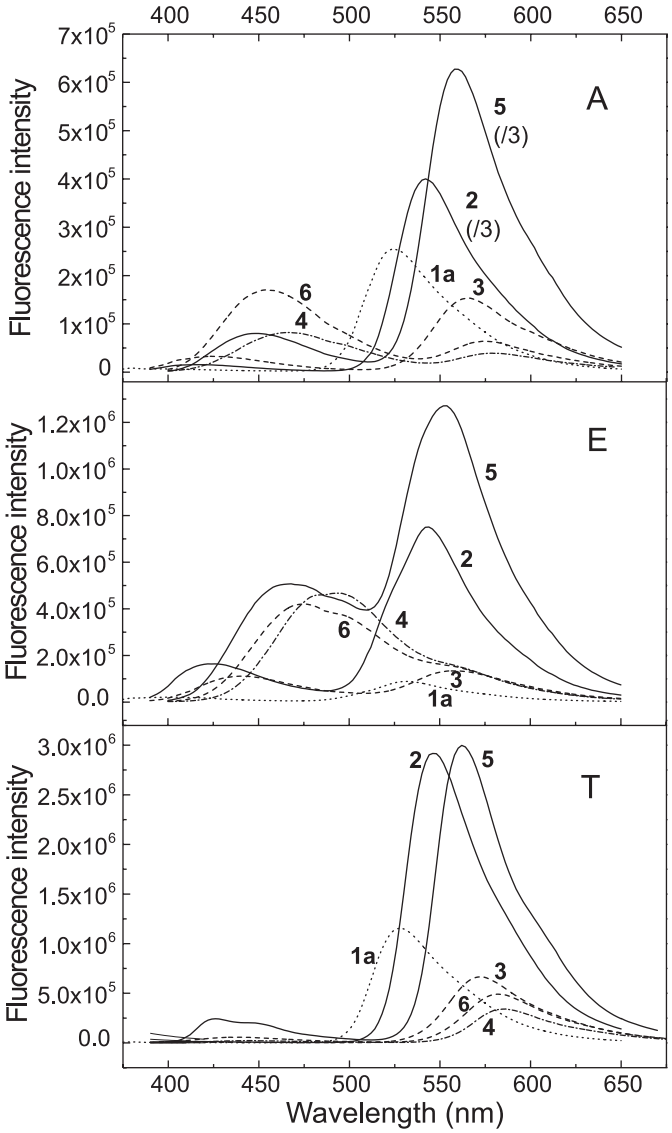
transfer (ESIPT), which is the result of the partial isomerization of the excited normal isomer to a phototautomer. These two forms, then, return to the ground state with the emission of different energies exhibiting two fluorescent bands, at short and long wavelengths for the normal and phototautomer excited forms, respectively.



Fluorescent measurements of compounds **2**–**6** indicate that replacement of the phenyl group of 3-hydroxyflavone (**1a**) for longer aromatic systems, such as benzo- or naphthofuryl, leads to a significant red shift (ca. 50 nm) (Table 1). In polar solvents, such as acetonitrile and ethanol, two distinctive fluorescent bands are observed, while only the long-wavelength band is recorded in nonpolar solvent (toluene). The exception is naphthofurylchromone **5**, which showed considerable short-wavelength fluorescence band in both polar and nonpolar solvents. It appears that the strongest among the solvent effects is the change in ratio of intensities of normal excited form emitting at shorter wavelength to phototautomer form emitting at longer wavelength (I_{N^*}/I_{T^*}). This can be explained as the preference of hydrogen bonding of the 3-OH group with the solvent as compared to intramolecular hydrogen bonding of 3-OH with the carbonyl group. However, in acetonitrile this ratio is still very small, especially for the case of non-methylated chromones (**2** and **5**), which supports the above statement based on absorption data that hydrogen bonding of 3-OH group of the chromones with acetonitrile is very weak and does not significantly change the energetic profile of the molecules.

The fluorescence quantum yield of compounds **2** and **5**, was found to be higher than that of 3-hydroxyflavone, and the addition of methyl group in C-3 position decreases the fluorescence quantum yield considerably (Table 1). Furthermore, the effect of methyl group was found to cause an increase in the I_{N^*}/I_{T^*} ratios for compounds **3**, **4**, and **6**. These results correspond to the increased I_{N^*}/I_{T^*} ratio for 3-hydroxyflavone with a methyl group at position 2 of the phenyl ring (20).

It is interesting to note that the molecules with methyl group in furan ring (**3**, **4**, and **6**) demonstrate stronger red shifted (by 22–28 nm, which is 670–880 cm^{-1}) fluorescent bands compared with the corresponding non-methylated derivatives (**2** and **5**) (Table 1). Taking into account that the position of the long-wavelength maximum of 3-hydroxyflavones is not very sensitive to 2- or 3- substituents of the phenyl ring, the fact of the red shift, caused by such a weak electron donor as methyl group, is important and requires further investigation. Since a red shift is observed in both polar and nonpolar solvents arguments regarding the differences in hydrogen bonding between solvent and molecules **2** and **3**, and **5** and **6** do not explain this effect. It could be suggested that the non-planar molecules, with the steric hindrance of the methyl group, relax to a more stable planar excited conformation characterized by lower energies with an emission at longer wavelengths. Red shifts in fluorescence due to flattening of a molecule in an excited state is known for some heterocyclic compounds (21). Since, fluorescence of the phototautomer of 3-hydroxychromones requires a planar conformation between the 2-aryl and chromone rings (20), it is understandable that the red shift, caused by flattening of the non-planar chromones with the methyl group in furan ring **3**, **4**, and **6**, is much stronger for the long-wavelength fluorescence band. For instance, in acetonitrile the long-wavelength band of **3** (compared with **2**) is red shifted by 24 nm (782 cm^{-1}), whereas the short-wavelength band is red shifted by just 6 nm (339 cm^{-1}).

Fig. 2. Fluorescence spectra of chromones **1a**, **2**–**6** in different solvents: acetonitrile (*A*); ethanol (*E*); and toluene (*T*) (excitation for: **1a** (340 nm); **2** and **3** (360 nm); **4**–**6** (390 nm)).

Furthermore, the methyl group causes the decrease of fluorescence lifetime (Table 1) and lowers the fluorescence intensity, which also indicates its dramatic influence on relaxation pathways.

In conclusion, we have synthesized a series of 3-hydroxychromones, which have comparable, and in some respects better, absorption and fluorescence properties than the 3-hydroxychromones synthesized so far. They have comparably higher quantum yield, display absorption and fluorescence at longer wavelengths in different solvents, and some of them have longer fluorescent lifetimes. These properties make benzo- and naphthofuryl-3-hydroxychromones highly promising candidates for fluorescence probes design. Currently, the preparation of membrane probes and fluorescent chalators using the chromophoric systems **2** and **5** are underway, and the results will be published in due course.

Mechanism of ipso aromatic substitution by reaction of aryloxy(methoxy)carbenes and diaryloxycarbenes with DMAD

Xiaosong Lu and John Warkentin

Abstract: Some aryloxy(methoxy)carbenes and diaryloxycarbenes attack dimethyl acetylenedicarboxylate (DMAD) with aryl group transfer to an alkyne carbon of DMAD. In this study diaryloxycarbenes with different aryl groups that could be transferred competitively, were generated in the presence of DMAD to probe for the mechanism of that ipso aromatic substitution. It was found that a *para* electron-withdrawing substituent, relative to an electron-donating substituent, facilitated migration of an aryl group. Mechanisms in accord with these findings involve initial nucleophilic attack by the carbene at an alkyne carbon of DMAD. That step is followed by either nucleophilic, ipso attack on the aromatic ring or by electron transfer, from the side chain of the aromatic ring into the ring itself.

Key words: aromatic substitution, diaryloxycarbene, DMAD, ipso, nucleophilic.

Résumé : Quelques aryloxy(méthoxy)carbènes et diaryloxycarbènes attaquent l'acétylènedicarboxylate de diméthyle (ACDM) avec un transfert de groupe aryle vers un atome de carbone alcyne du ACDM. Dans le présent travail, dans le but d'étudier le mécanisme de cette réaction de substitution aromatique ipso, on a généré en présence du ACDM des diaryloxycarbènes portant divers groupes aryles qui peuvent être en compétition pour un transfert. On a trouvé que, par opposition à un substituant électrodonneur, un substituant électroaffinitaire facilite la migration d'un groupe aryle. Les mécanismes qui correspondent à ces faits impliquent une attaque nucléophile initiale par le carbène au niveau du carbone de l'alcyne du ACDM. Cette étape est suivie par une attaque nucléophile ipso du noyau aromatique ou par un transfert d'électron à partir de la chaîne latérale du noyau aromatique vers le cycle lui-même.

Mots clés : substitution aromatique, diaryloxycarbène, ACDM, ipso, nucléophile.

Introduction

Recently, we (1) reported the results of thermolysis of bis-oxadiazoline **1** in benzene containing dimethyl acetylenedicarboxylate (Scheme 1). The multifunctional product (**2**) must have arisen from a cascade of reactions, including transfer of the aryl ring from oxygen to carbon. Analogous substitution reactions were also observed with a simpler oxadiazoline (**3a**) (1), and with 5,5-dimethyl-2,2-diphenoxy-Δ^3–1,3,4-oxadiazoline (**3b**) (2, 3) (Scheme 2). The only related reaction that we are aware of is that between an aminothiocarbene and diethyl acetylenedicarboxylate, reported by Scherowsky et al. (4) in 1977 (Scheme 3). Although a variety of ipso substitutions on benzene derivatives are known (5), oxy-substituents are not generally among the leaving groups unless there are activating nitro groups in the ring also. It was therefore of interest to try to establish the mechanism of the substitution reactions of Schemes 1 and 2. We now report that competition reactions, with diaryloxycarbenes ((ArO)(Ar′O)C:), gave evidence for preferential transfer of the more electron-deficient aryl group from oxygen to an alkyne carbon atom of DMAD.

Methods, results, and discussion

The strategy for determining the effect of aryl substituents involved generation of unsymmetric diarylcarbenes (**5**) so as to have internal competition, between the aryl groups in a dipolar (or other) intermediate (**6a**, **7a**), in the step that generates *isomeric* esters (Scheme 4). In all but one case the substituents in the aryl groups were in the *p*-position, and it was assumed that a conformational preference (**6a**, **7a**) would be small at most. It is probably irrelevant because the Curtin–Hammett principle is expected to apply (6). Although intermediates **6a** and **7a** presumably epimerize to **6b** and **7b**, through a small barrier, that too should be irrelevant because intramolecular substitution cannot occur with the ester groups *trans*, as in **6b** and **7b**.

5,5-Dimethyl-2,2-diphenoxy-Δ^3-1,3,4-oxadiazoline (**11**, Ar = Ar′ = Ph), the first 2,2-diaryloxy oxadiazoline (2), was prepared by hydrazinolysis of diphenyl carbonate, subsequent reaction of the hydrazide (**8**) with acetone to afford **9**, oxidative cyclization of **9** to **10** with lead tetraacetate (LTA) in CH_2Cl_2, and acid-catalyzed reaction of **10** with phenol (Scheme 5) (3, 7). Unsymmetric analogues (**11**, one or both aryl groups bearing a substituent) were prepared similarly (3).

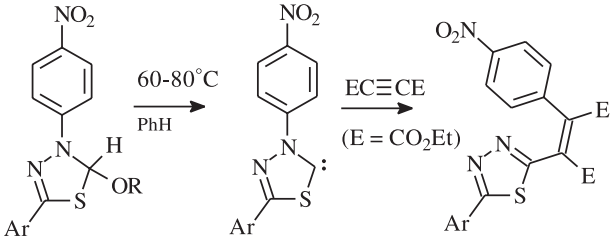
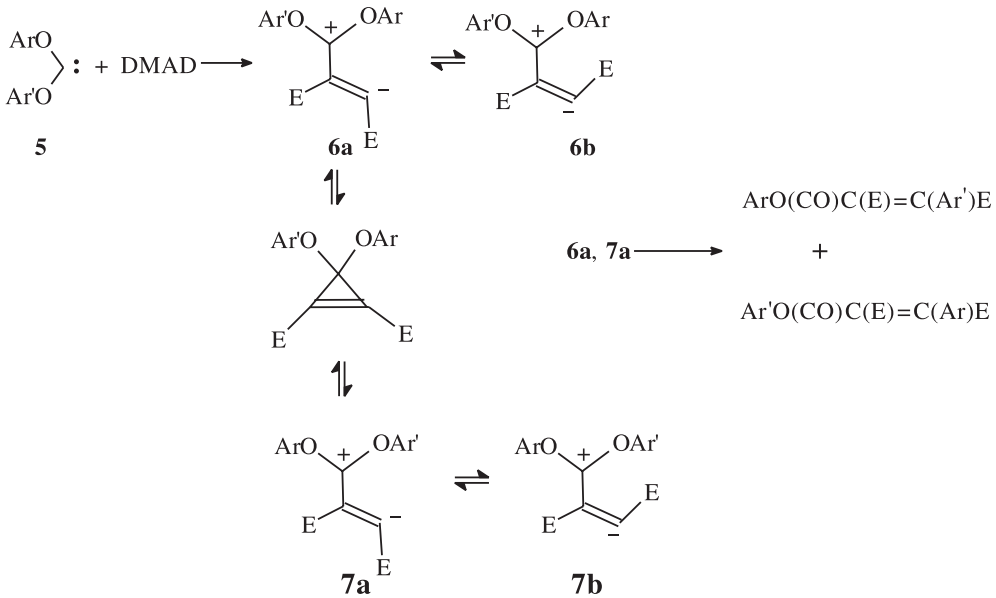


Scheme 2.

(a) R= Me, Ar= *o*-$MeOC_6H_4$; (b) R = Ar = Ph
(DMAD = dimethyl acetylenedicarboxylate;
E = CO_2Me)

Thermolysis of oxadiazolines **11** as benzene solutions containing DMAD, at 110°C in sealed tubes, gave one or both of the isomeric esters (**12**, **13**) in yields (or composite yields) between 28 and 37% (of isolated material) and a diaryl carbonate (**14**) in 25–35% yield (Scheme 6). The esters were separated from other products by means of radial chromatography, which also separated the isomers in the one case that gave both. Assignment of structure followed from the NMR spectra of the products and from the GC–MS patterns. In their EI mass spectra, aryl esters afford base peaks from loss of the fragment ArO in the case of ArOCOC(E)=C(Ar′)E, and from loss of Ar′O in the case of Ar′OCOC(E)=C(Ar)E. It was therefore easy to assign the gross structures of the esters from **11a**–**d** and of the isomeric

Scheme 3.



(R = H, Me)

esters from **11e** (Scheme 6). The geometry (ArOCO and CO_2Me groups *trans*) was established for **12a** by single crystal X-ray diffraction and that geometry was assumed for the other triesters **12**, and for **13e**, on the basis of analogy.

The effects of substituents on the ease of ipso substitution, given by the yield ratios (**13**:**12**) rather than by the absolute yields, are in the order *p*-CN >> *o*-MeO > H > Me > *p*-MeO (Table 1).

It is clear from Table 1 that an electron-withdrawing group in the *p*-position increases the migratory aptitude of an aryl group whereas an electron-donating group decreases it. Unfortunately, most substrates gave only one of the two possible esters and it was not possible to construct a Hammett plot and to estimate the value of ρ. However, the sense of the substituent effect is unmistakable, and the effect cannot be small. We suggest that a likely mechanism to account for the migratory aptitudes is that illustrated with Scheme 7, for the case X=H, Y=CN. The steps to the carbene are well-precedented (8), as are the attack of nucleophilic carbenes on DMAD and other alkynes (9–12) and the reversible ring-opening and ring-closing of cyclopropenes and (or) vinylcarbenes (13–16). Moreover, Boger et al. (17) and Boger and Brotherton-Pleiss (18) have reported reactions of an intermediate (a π-delocalized vinylcarbene) analogous to **15** in Scheme 7. We assume that **15** is equilibrated with cyclopropene **16**, in view of the fact that diphenoxy

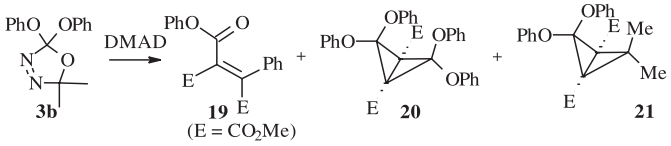
Scheme 7.



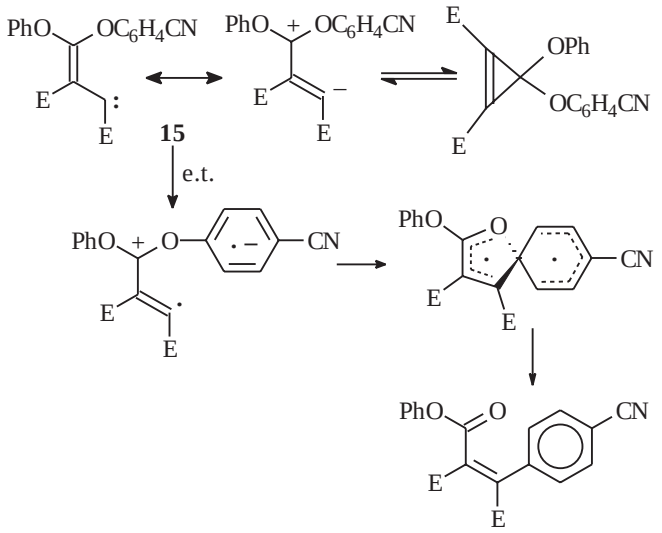
oxadiazoline **3b**, when thermolyzed in the presence of DMAD, affords not only **19** but also **20** and **21** (2) (Scheme 8).

Intermediate **15** also affords **18**, presumably via **17**, which is analogous to the intermediate usually invoked in describing nucleophilic aromatic substitutions (5). Dipolar intermediates in ipso nucleophilic aromatic substitution have been demonstrated many times (19).

A concerted reaction, leading directly from the carbene and DMAD to the product, is unlikely given that aromatic substitutions generally occur through intermediates. However, a more complex stepwise process, involving electron transfer (e.t.) *before* ring closure but leading to the observed

Scheme 8.

result (Scheme 9) cannot be ruled out with confidence. Some intermolecular chemistry of intermediates similar to **15** is thought to involve electron transfer from a π-delocalized vinylcarbene intermediate, and subsequent coupling of a radical cation and radical anion pair (Scheme 10) (20).



A special interaction must be invoked for the *o*-methoxy substituent, which promoted migration whereas the *p*-methoxy group was not effective. Given that a likely mechanism (Scheme 7) involves a dipolar intermediate, it is logical to propose that the *o*-methoxy group exerts its effect through space, rather than through bonds (Scheme 11). A through-space interaction of the *ortho* methoxy group with the positive center of a dipolar intermediate would help to orient the aryl group for attack, as shown in Scheme 11. Such an involvement would differentiate strongly between the *o*- and *p*-methoxy groups, which presumably have similar conjugative effects.

Summary

Diaryloxycarbenes attack DMAD to afford unsaturated triesters, by attack at the *sp*-carbon and migration of an aryl group from oxygen to the other *sp*-carbon of DMAD. If the aryloxy groups are *para*-substituted, the aryl group that is transferred preferentially is the one that is more

Scheme 9.

electron-deficient. The *ortho*- but not the *para*-methoxy group also promotes migration, presumably by stabilizing an electrophilic site by donation of electron density from the oxygen atom through space. Aryloxymethoxycarbenes (1) probably react with DMAD by an analogous mechanism.

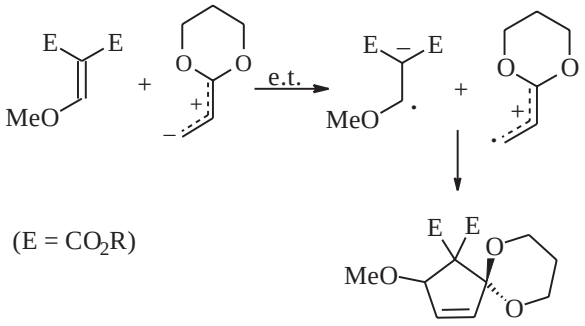
Experimental section

General

NMR spectra were recorded with a Bruker AC-200 or AC-300 NMR spectrometer and IR spectra were obtained with a Biorad FTS-40 spectrophotometer, with the sample in CCl_4. The IR bands are labeled qualitatively with the symbols br, s, and m for broad, strong, and medium intensity bands. Weak bands are not listed. The eluting solvent for radial chromatography was a gradient of ethyl acetate (2.5–10 vol. %) in hexanes. Melting points were obtained with a Thomas Hoover capillary melting point apparatus, and are uncorrected.

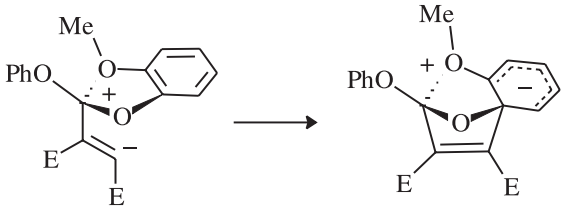
Synthesis of diaryl carbonates

Diphenyl carbonate is commercially available. The other diaryl carbonates were prepared as described earlier (3).



Thermolysis of 11a with DMAD

The procedure described below for thermolysis of **11a** with DMAD is typical.



2-(*p*-Cyanophenoxy)-2-(*p*-methoxyphenoxy)-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (1.03 g, 3.04 mmol) was heated in the presence of DMAD (0.52 g, 3.66 mmol) in 25 mL of benzene (sealed tube) at 110°C for 24 h. Radial chromatography following evaporation of the solvent gave **12a** (37%) and **14a** (29%).

Abstract: The possible removal of copper(II), nickel(II), or lead(II) by an insoluble crosslinked poly(acrylic acid) was investigated in dilute aqueous solution. The binding properties of the polymer were examined at pH = 6.0 or 4.0 with an ionic strength of the medium μ = 0.1 or 1.0 M ($NaNO_3$) using differential pulse polarography as an investigation means. The highest complexing capacity of the polyacid was obtained with lead(II) at pH = 6.0 with μ = 0.1 M, 4.8 mmol Pb(II)/g polymer. The conditional stability constants of the complex species formed were determined using the method proposed by Ruzic assuming that only the 1:1 complex species was formed; for lead(II) at pH = 6.0 and μ = 0.1 M, log K' = 5.3 ± 0.2. It appeared that the binding properties of the polymer increased, depending on the metal ion, in the following order: Ni(II) < Cu(II) < Pb(II). The complexing capacity and log K' values decreased with the pH or with an increase of the ionic strength. These results were in agreement with the conclusions of our previous studies of the hydrosoluble linear analogues. Finally, with the insoluble polymer, the log K' values were comparable to those previously obtained with the linear analogue whereas the complexing capacity values expressed in mmol g^{-1} were slightly lower.

Key words: insoluble crosslinked poly(acrylic acid), copper(II), nickel(II), and lead(II) complexation.

Résumé : La possibilité d'éliminer le cuivre(II), le nickel(II) ou le plomb(II) par un acide polyacrylique réticulé insoluble a été étudiée en solution aqueuse diluée. Les propriétés complexantes du polymère ont été examinées à pH 6,0 ou 4,0 et avec une force ionique du milieu μ valant 0,1 ou 1,0 M ($NaNO_3$) en utilisant la polarographie impulsionnelle différentielle. La capacité complexante la plus élevée du polyacide a été obtenue avec le plomb (II) à pH 6,0 et avec μ = 0,1 M, 4,8 mmol Pb (II)/g de polymère. Les constantes de stabilité conditionnelles des espèces complexes formées ont été déterminées à l'aide de la méthode proposée par Ruzic qui suppose la seule formation du complexe 1:1 ; pour le plomb(II) à pH 6,0 et pour μ = 0,1 M, log K' = 5,3 ± 0,2. Il est apparu que les propriétés complexantes du polymère étaient accrues, selon la nature du cation métallique, dans l'ordre suivant : Ni(II) < Cu(II) < Pb(II). Les valeurs de la capacité complexante et de log K' décroissent avec le pH ou avec une augmentation de la force ionique du milieu. Ces résultats sont en accord avec les conclusions de nos précédentes études relatives aux homologues linéaires hydrosolubles. Enfin, les valeurs de log K' obtenues avec le polymère insoluble sont comparables à celles obtenues précédemment avec l'homologue linéaire alors que les valeurs de la capacité complexante, exprimées en mmol g^{-1}, sont légèrement plus faibles.

Mots clés : acide polyacrylique réticulé insoluble, complexation (cuivre(II), nickel(II) et plomb(II)).

Introduction

Some insoluble crosslinked polymers, called superabsorbents, present many industrial applications which are linked to their important water-absorbing capacity (10 to several hundred times their dry weight) (1–3). Although the bulk of the research and development effort has been placed on disposable absorbent products, numerous other applications have been developed (water-retention of soils for agricultural applications, water-absorbing construction materials, electronics and cabling, food packaging, thickeners (2, 3)). Some interesting new applications of superabsorbents are emerging, for example in the cosmetic industry, to develop new sensors or for the controlled release of substances such as pharmaceuticals, pesticides, or fertilizers (3).

In our (4–7) previous studies of metal complexation with linear hydrosoluble poly(acrylic acids) (HPAAs) of high molecular weight, we showed that HPAAs were able to trap different metal ions. There is some literature relative to this field of research but there is a complete lack of data for their insoluble crosslinked analogues, i.e., superabsorbents of a carboxylic nature.

The aim of this work was to study the metal complexation properties of an insoluble crosslinked PAA (Aquakeep® SAP X 50 R superabsorbent) in dilute aqueous solution and to compare these properties with those previously obtained with HPAAs, their linear analogues. The metal ions copper(II),

nickel(II), and lead(II) are investigated. Copper(II), often mentioned in the literature, constitutes a reference ion that can be used for comparison purposes. Nickel(II) and lead(II) are metal cations representative of highly pollutant substances. The choice of the analytical technique used (differential pulse polarography) as well as the choice of the pH range considered (pH = 4.0–6.0) were justified in a previous paper (6). We also studied the effect of the ionic strength of the medium (μ = 0.1 or 1.0 M) on the binding properties of Aquakeep®.

The previous potentiometric study carried out with Aquakeep® in dilute aqueous solution provided us with fundamental information on the binding properties of the polymer towards copper(II), nickel(II) (8), and lead(II) (9). However, no quantitative estimation of the specific amount of metal ion that can be fixed by the polyacid could be made from these experimental results. Compared to potentiometry, the polarographic approach and the data treatment methods we used allow not only the determination of the stability constants of the complex species formed with Aquakeep® but also the estimation of its complexing capacity at a constant pH value.

The two methods we used to treat the experimental data have been applied by numerous authors to determine the metal-binding capacity of the bulk organic matter of natural waters of different origins (10–13). However, apart from our own previous results, there is no available data relative to the determination of the complexing capacity of PAAs, hydrosoluble or not.

Theory

As previously explained (4), molar concentration has little meaning for polymer compounds. Thus, we shall define for polycarboxylic acids the total content of titratable acid functions of the sample under study (C_A, expressed in equiv L^{-1}). C_A corresponds to the total reactive site (potentially complexing site) concentration of the polymer introduced in the analysis cell as used next for the complexation study.

The binding properties of a given polymer can be described in terms of the saturation of its complexing sites (10, 11). The macromolecule may be considered as the central group which is able to fix a certain number of metal ions. The complexing capacity of the ligand (C') may then be defined as the maximum ability of the molecule to fix a given metal ion. The complexing capacity of Aquakeep® was determined through the titration of the ligand with the metal ion of interest at a fixed pH (10, 11). From the graph of the measured current i (i corresponds to the free metal ion concentration (m)) vs. the total metal ion concentration introduced (C_M), one can estimate the value of C'_{obs}; C'_{obs} corresponds to the value of C_M at which the break in the titration curve occurs. The C'_{obs} value is needed to obtain the saturation of the ligand. Therefore, the value of $C_M - m$ represents the maximum concentration of the metal ion which can be bound to the complexing agent studied. The value of $C_M - m$ corresponds to the horizontal segment between the curves i vs. C_M obtained in the absence and in the presence of the ligand.

The same sets of experimental data were also treated using the method described by Ruzic (14). This method allows the calculation of C' (C'_{calc} throughout our work) and K', the conditional stability constant of the MA (metal–ligand) complex species formed, from the graph of $m/(C_M - m)$ vs. m. All the definitions and assumptions needed for this study have already been described (6).

Table 1. Main characteristics of Aquakeep® SAP X 50 R.

Residual humidity	5.5 ± 0.2%	
Water retention after 30 min	31 ± 3 g g^{-1}	
Absorption capacity with 0.9% NaCl	57 g g^{-1}	
Gelling time	85 s	

Experimental

Reagents

The poly(acrylic acid) used was Aquakeep® SAP X 50 R superabsorbent, Elf-Atochem Co. (Levallois-Perret, France). All the experiments were carried out using the same batch of polymer which was stored in a polyethylene flask, at room temperature (20°C) and in the dark. It was used without any further treatment. Its main characteristics are presented in Table 1.

The previous potentiometric study of the acid–base properties of Aquakeep® (8) showed that the polymer exhibits both a weak and a very weak acidity (specific values: 6.7 ± 0.1 and 2.1 ± 0.1 mequiv g^{-1}, respectively). The weak acidity of Aquakeep® is characterized by a pK_m^H value of 5.40 ± 0.05. This study also showed that the carboxylic groups accounting for the very weak acidity of Aquakeep® dissociate at pH values above 7.5. This acidity was thus not considered for the study of metal complexation carried out at pH ≤ 6.0.

All the other reagents were of analytical grade. Metal ion stock solutions (0.2 M) were prepared from copper nitrate (Prolabo, France), nickel or lead nitrate (Fluka Chemika, Switzerland), and then standardized using an EDTA disodium salt solution (Merck, Germany). The stock solution of supporting electrolyte ($NaNO_3$ (Fluka Chemika)) was 1 M. All the solutions were prepared with freshly distilled water.

Apparatus and procedure

We used the apparatus described in ref. 6. The instrumental parameters used to perform the differential pulse polarography (DPP) measurements are presented in Table 2.

All the samples were treated in the same way. The measurements were performed at 25.0 ± 0.1°C under a nitrogen atmosphere and with a 50 mL total volume of solution in the analysis cell. The response of the polarographic system in the DPP mode was calibrated (in the absence of polymer) for each of the metal ions, at each of the two pH values. The pH was adjusted at 4.0 or 6.0 ± 0.1 by the addition of microquantities of dilute solutions of nitric acid or sodium hydroxide. It was also calibrated at each of the two ionic

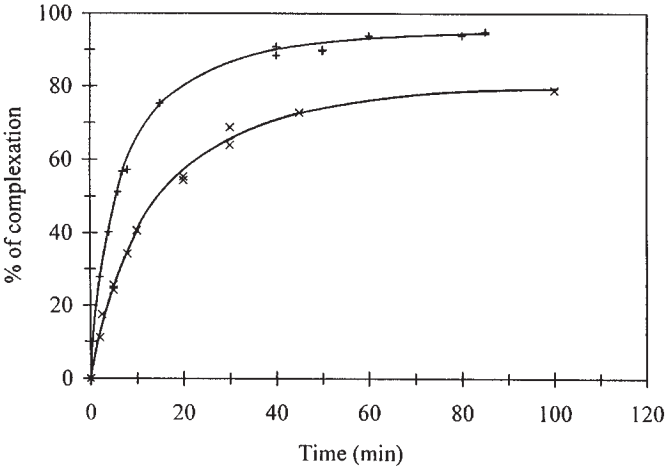
strengths examined (μ = 0.1 or 1.0 M). The curves *i* vs. C_M were obtained for corrected metal ion final concentrations in the 4×10^{-5} to 8×10^{-4} M range. The responses of the different systems were recorded after the deaeration of the samples by a 5 min nitrogen bubbling. These calibrations were then verified for a few values of C_M before each experiment.

Each experiment of progressive saturation of Aquakeep® was carried out with 10.0 ± 0.1 mg of the polyacid (C_A = 1.34 ± 0.02 mequiv L^{-1}). After a 20 min nitrogen bubbling at the desired values of pH and ionic strength, a blank was systematically recorded. The titration of Aquakeep® was then carried out at pH 6.0 or 4.0 with μ = 0.1 or 1.0 M. The successive 30 µL additions of the metal ion stock solution (C_M in the 1.2×10^{-4} to 1.2×10^{-3} M range, i.e., C_A/C_M in the 1.1–11.2 range) were performed while Aquakeep® was maintained in suspension in the analysis cell by a vigorous stirring (500 rpm). The pH of the medium was continuously verified and corrected if necessary. The reproducibility of both metal ion complexations was determined by carrying out the same experiment twice. Direct current polarograms were recorded, both in the absence and in the presence of Aquakeep®, to check the shape of the polarographic waves.

The complexation of metal ions by Aquakeep® proved not to be a fast phenomenon and preliminary experiments were needed to determine the contact time under stirring required before the polarographic analysis could be performed, that is time to reach the equilibrium state. The study of the complexation rate of Aquakeep® was carried out at pH 6.0 with μ = 0.1 or 1.0 M. Two hundred µL of the metal ion stock solution were added to the Aquakeep® suspension ($C_M = 8 \times 10^{-4}$ M) and the response of the system (corresponding to the free metal ion residual concentration (*m*)) was then recorded at different times. The pH of the medium was continuously checked.

Results and discussion



Using the formula proposed by Baes and Mesmer (15) and taking into account the maximum value of C_M examined, we ensured that neither soluble nor insoluble metal hydroxides were significantly formed at any of the pH values considered during the experiments.

The Aquakeep® blanks always presented null or negligible values of *i* at the peak potentials of the different metal ions examined. The response of the polarographic systems investigated was linear over all the metal concentration range considered, in the absence and in the presence of Aquakeep®.

Complexation rate of Aquakeep®

Figure 1 shows the evolution of the complexation yield vs. time for Aquakeep® with lead(II) at pH 6.0 and for μ = 0.1 or 1.0 M. Very similar curves were obtained with the other metal ions examined. From these results, the maximum complexation yields were obtained at μ = 0.1 M for Pb(II) > Cu(II) >> Ni(II) at 95, 90, and 50%, respectively. The complexation of nickel(II) was the most affected by an increase in the ionic strength of the aqueous medium. For nickel(II) there was a 37% decrease in the signal, whereas for copper(II) and lead(II) it was only 13% and 17%, respectively.

Fig. 1. Complexation yield vs. time for Aquakeep® ($C_A = 1.34 \times 10^{-3}$ equiv L^{-1}) with lead(II) at pH 6.0 and μ = 0.1 M (+) or 1.0 M (x).

All the curves reached a plateau but after a 45 min contact time under continuous stirring, the complexation yield was less than 5% below its max value. This stirring time was thus chosen for the following experiments of progressive saturation of Aquakeep® by the different metal ions; it would allow the measurement of *m* at a quasiequilibrium state while avoiding a long time between subsequent additions of the metal ion.

Complexation properties of Aquakeep®

The curves *i* vs. C_M obtained for nickel(II) at pH 6.0 and μ = 0.1 M and for copper(II) at pH 4.0 and μ = 1.0 M, both in the absence or in the presence of Aquakeep®, are shown in Figs. 2 and 3, respectively. The other curves obtained in the presence of Aquakeep® presented very similar shapes. However, for nickel(II) in all experimental conditions examined except the one above, the curves did not present any change in their slope and were very close, if not identical, to the calibration curves (obtained in the absence of Aquakeep®) indicating a very poor complexation. Therefore, no value of C'_{obs} was measurable in this case. The same phenomenon had also been observed previously with HPAAs in the same conditions of pH and ionic strength (6). For copper(II) in the presence of Aquakeep® at pH 4.0 and μ = 0.1 M, the first part of the graph *i* vs. C_M, observed for $C_M < C'_{obs}$, had an anomalous shape. The same phenomenon had been observed previously with HPAAs (6). The value of C'_{obs} estimated in this case was a maximum value.

The values of C'_{obs} and $C_M - m$ (the bound metal concentration) estimated for the different systems Aquakeep®/metal ion are presented in Tables 3 and 4 for pH 4.0 and 6.0,

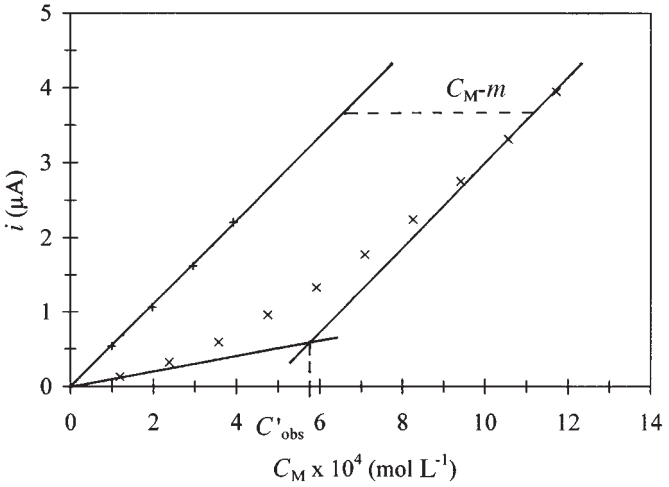
Fig. 2. Curves *i* vs. C_M obtained for Aquakeep® (C_A = 1.34 × 10^{-3} equiv L^{-1}) with nickel(II) at pH 6.0 and μ = 0.1 M ((+): in the absence of Aquakeep®; (x): in the presence of Aquakeep®).



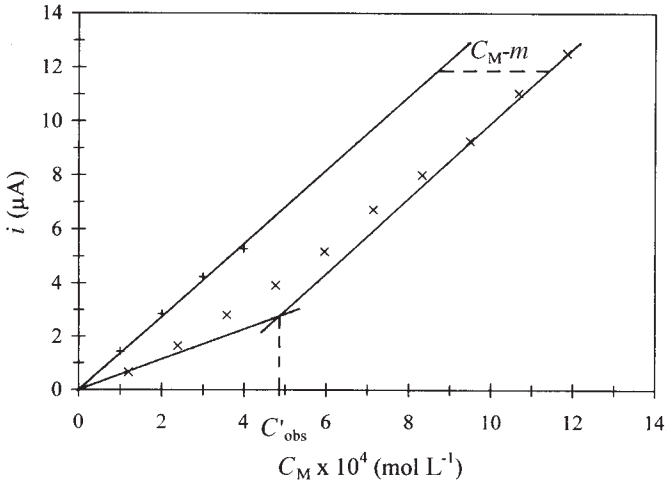


Fig. 3. Curves *i* vs. C_M obtained for Aquakeep® (C_A = 1.34 × 10^{-3} equiv L^{-1}) with copper(II) at pH 4.0 and μ = 1.0 M ((+): in the absence of Aquakeep®; (x): in the presence of Aquakeep®).

respectively. As C'_{obs} and $C_M - m$ are conditional values, which depend on the experimental conditions such as aqueous medium characteristics and especially the amount of Aquakeep® added to the solution, they were expressed in mmol of metal/g of polymer. The values of C_M and $C_M - m$ were calculated at the point where the representation becomes linear again. The experimental error on the values of C'_{obs} and $C_M - m$ was estimated at ± 4 × 10^{-5} M or 0.2 mmol g^{-1}.

The same sets of experimental data were also treated using the method described by Ruzic (14). Figures 4 and 5 show the curves of $m/(C_M - m)$ vs. *m* corresponding to the experimental points obtained in Figs. 2 and 3, respectively. The values of C'_{calc} and log K' were calculated from the slope and intercept of the linear regressions applied to all the experimental points of these graphs. Except for copper(II) at pH 4.0 and μ = 0.1 M, there was good agreement between the experimental points and the plot of the linear regression applied to these points, indicated by a high value of the correlation coefficient (r^2). This showed that the method proposed by Ruzic (14) could be successfully used for the different systems Aquakeep®/metal ion considered here.

Tables 5 and 6 present the values of C'_{calc}, log K', r^2, and *n* (number of observations) obtained for the different systems Aquakeep®/metal ion considered at pH 4.0 and 6.0, respectively. As C'_{calc} and K' are conditional value, C'_{calc} was expressed in mmol of metal/g of polymer. The experimental error on the values of C'_{calc} and log K' was estimated at ± 4 × 10^{-5} M (or 0.2 mmol g^{-1}) and ±0.2, respectively. However, for copper(II) at pH 4.0 and μ = 0.1 M, the dispersion of the experimental points led to a larger uncertainty on the estimation of C'_{calc} and log K'; these values are given in brackets in Table 5.

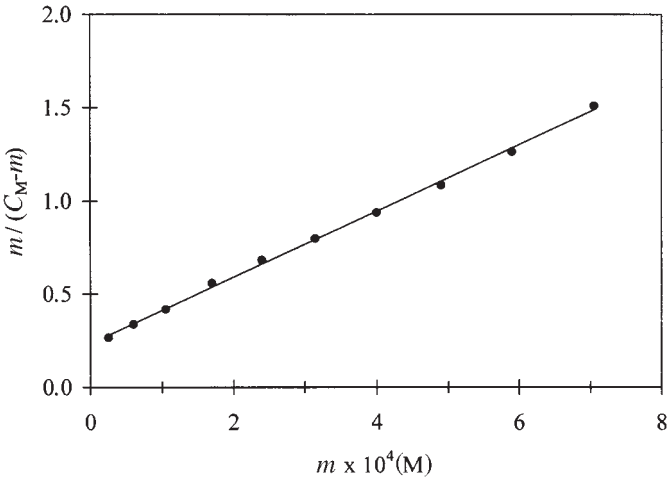
Fig. 4. Curves $m/(C_M - m)$ vs. m obtained for Aquakeep® ($C_A = 1.34 \times 10^{-3}$ equiv L^{-1}) with nickel(II) at pH 6.0 and μ = 0.1M.



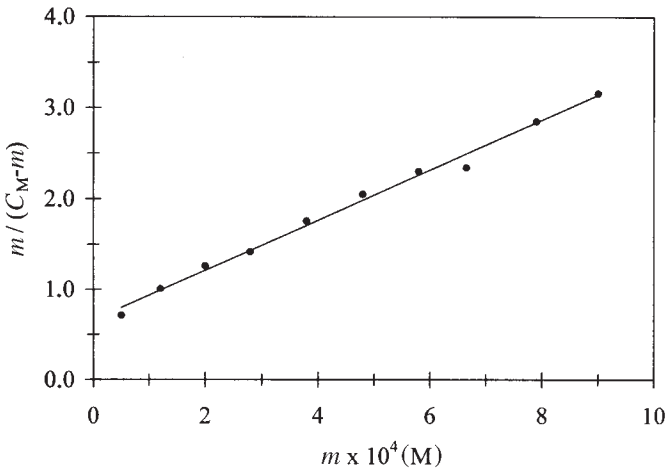


Fig. 5. Curves $m/(C_M - m)$ vs. m obtained for Aquakeep® ($C_A = 1.34 \times 10^{-3}$ equiv L^{-1}) with copper(II) at pH 4.0 and μ = 1.0 M.

If we compare the values of all the parameters estimated during this work, i.e., C'_{obs}, $C_M - m$, C'_{calc}, and log K', we can draw the following conclusions: (*i*) for one metal ion and for given values both of pH and ionic strength of the aqueous medium, the values of C'_{obs}, $C_M - m$, and C'_{calc} are of the same order of magnitude; (*ii*) the four parameters show that lead(II) tends to be more readily bound to Aquakeep® than copper(II) and much more than nickel(II) for the same values of pH and ionic strength; and (*iii*) finally, for all the metal ions examined, each of the four parameters is significantly lowered by a decrease of the pH or by an increase of the ionic strength of the medium. For copper(II) and lead(II) this decrease, as expected, is more pronounced when the two parameters are varied simultaneously.

We also calculated the values of C_M/C_A (metal to ligand concentration ratio) and $(C_M - m)/C_A$ (the occupation rate of the ligand complexing sites) at the point where the saturation of the polyacid with the metal ion was reached (Tables 3 and 4). At pH 6.0 and for μ = 0.1 M, the value of $(C_M - m)/C_A$ was around 70% for copper(II) and lead(II) and it was around half this value for nickel(II). This would indicate that when the ligand is saturated not all the potentially available complexing sites of the polyacid are occupied. In every case, the value of $(C_M - m)/C_A$ decreased with the pH of the medium or with an increase of μ.

Explanations, summarised in a previous paper, on the large influence of pH on the binding properties of polyacids in general (6), observed that the deprotonated form of the reactive sites (i.e., carboxylate groups) is primarily responsible for the binding of metal ions onto polymers of a carboxylic nature (16–19). The pH of the medium influences the binding of metal ions via the change in the degree of dissociation of the polyacid (α_A). A previous potentiometric study of Aquakeep® (8) carried out with μ = 0.1 M allowed the determination of the evolution of α_A vs. pH: α_A = 0.18 and 0.58 for pH = 4.0 and 6.0, respectively.

Table 7. $(C_M - m)/C_A$ values obtained with the HPAA ($C_A = 1.0 \times 10^{-3}$ equiv L^{-1}) and with Aquakeep® ($C_A = 1.34 \times 10^{-3}$ equiv L^{-1}) at pH = 6.0 and $\mu = 0.1$ M.

	HPAA		Aquakeep®	
	(mmol mequiv^{-1})	(mg g^{-1})	(mmol mequiv^{-1})	(mg g^{-1})
Cu(II)	0.46	370	0.69	300
Ni(II)	0.19	140	0.34	140
Pb(II)	0.50	1300	0.71	980

All the results obtained with Aquakeep® can be compared with those obtained previously with a linear, hydrosoluble poly(acrylic acid) having a high average molecular weight (3×10^6) (6, 7). The experiments with the HPAA were carried out at pH = 6.0 ± 0.1, with $\mu = 0.1$ M ($NaNO_3$) and using the same analytical procedure. The total content of titratable acid functions in the analysis cell was $C_A = 1.0 \times 10^{-3}$ equiv L^{-1}.

The metal complexation with HPAA was a fast reaction with only a short time before reaching an equilibrium state (about 1 min). The polarographic analysis could be carried out almost immediately. The delay observed with Aquakeep® can be explained by a steric effect of the reticulous structure of the polymer, limiting the accessibility of some of its inner complexing sites. Clearly, for the four parameters considered, the same stability order was found for the complexes formed with HPAA. Nickel(II) was weaker bound to the polymer than copper(II) and lead(II) (this was much more visible on the C' and $C_M - m$ values). The values of log K' are not significantly different between HPAA and Aquakeep® for nickel(II) and lead(II); however, the value of log K' obtained for the system HPAA/copper(II) (log $K' = 5.2 \pm 0.2$) was significantly higher than that determined for the system Aquakeep®/copper(II). The same effect of pH of the medium on the complexing properties (C' and log K' values) was also observed with HPAA (6, 7).

The values of $(C_M - m)/C_A$, when expressed in mmol mequiv^{-1}, are systematically higher with Aquakeep® than those found with HPAA. However, when expressed in mg g^{-1} of polymer, comparable or slightly lower values of $(C_M - m)/C_A$ are found with Aquakeep® (Table 7). For example, for comparable ligand concentrations, Aquakeep® is able to fix a maximum (obtained with lead(II)) of 0.71 mol of metal ion per equiv of complexing sites at pH = 6.0 and $\mu = 0.1$ M, whereas HPAA in the same conditions could only fix a max (also obtained with lead(II)) of 0.50 mol of metal ion per equiv (7). However, still in the same conditions, 1 g HPAA was able to complex 1.30 g lead(II) (7) whereas Aquakeep® only complexed 0.98 g.

We did not find any data in the literature relative to this study of complexing properties of an acrylic acid derivated polymer gel using voltammetric methods. However, we did find work relative to the complexing properties of methacrylic acid derivated polymer gels using potentiometry (20–22). These studies had not been carried out in conditions of saturation of the polymer ligand and therefore their stability constants could not be compared to those we determined. We did not consider studies relative to natural substances or natural waters as the complexing material in this case is not well-defined and not comparable with our studies.

Conclusion

The binding capacity of Aquakeep®, as well as the stability constant of the complex species formed with copper(II), nickel(II), or lead(II) were calculated in dilute aqueous solution. The results obtained with this insoluble crosslinked poly(acrylic acid) (stability order of the complexes formed and the influence of pH and ionic strength of the aqueous medium) were in very good agreement with those we previously obtained from the potentiometric or the polarographic studies of its linear hydrosoluble analogues (4–7). In both cases, the highest values of C' and log K' were obtained with lead(II), at pH 6.0 and $\mu = 0.1$ M. This shows that there is no significant difference in the complexing properties of Aquakeep® and HPAA.

Synthesis and evaluation of novel β-lactam inhibitors of human leukocyte elastase

K.P. Koteva, André M. Cantin, W.A. Neugebauer, and E. Escher

Abstract: A series of β-lactam derivatives were synthesized and tested to determine the structure–activity relationship for inhibition of human leukocyte elastase (HLE), a serine protease involved in several degenerative lung and tissue diseases. The most potent IC_{50} values were obtained with neutral hydrophobic 7α-methoxy cephalosporanic acid derivatives. Tryptophanyl-9-fluorenylmethyl ester and *N*-benzhydryl piperazine derivatives of 7α-methoxy cephalosporanic acid represent two novel HLE inhibitors, with length of action persisting beyond 24 h.

Key words: β-lactams, neutrophil elastase, protease inhibitors, peptides.

Résumé : Une série de dérivés de molécules β-lactames fut synthétisée et analysée afin de déterminer la relation structure-activité en tant qu'inhibiteurs de l'élastase neutrophilique humaine (ENH), une protéase impliquée dans plusieurs maladies pulmonaires et tissulaires. Les valeurs inhibitrices (IC_{50}) les plus puissantes furent obtenues avec des dérivés neutres hydrophobes de l'acide 7α-methoxy cephalosporanique. Les dérivés tryptophanyl-9-fluorenylmethyl ester et *N*-benzhydrylpiperazine de l'acide 7α-methoxy cephalosporanique représentent deux nouveaux inhibiteurs de l'ENH, dont l'effet persiste plus de 24 heures.

Mots clés : β-lactames, élastase neutrophilique, inhibiteurs de protéases, peptides.

Introduction

Elastin is a proteinaceous part of the extracellular matrix, commonly called connective tissue. It gives coherence and elasticity to many tissues, such as lung, yellow tendon, and cartilage of joints. Elastin remodeling is controlled by a fine balance between continuous elastin synthesis and breakdown by neutrophil and tissue elastases. Human leukocyte (neutrophil) elastase (HLE, EC 3.4.21.37) secreted by polymorphonuclear neutrophils (PMN) has been considered over two decades as one of the most interesting therapeutic targets in several lung diseases (1). One of the main functions of HLE is the degradation of structural proteins, such as elastin, fibronectin, and collagen (2). Under normal physiological conditions, the lungs are protected from excessive HLE elastolytic activity by endogenous inhibitors such as α1-protease inhibitor (α1-PI) and α2-macroglobulin (α2-M). However, the rate of elastin (and collagen) degradation is greatly enhanced under a variety of clinical conditions. In particular, pulmonary emphysema, rheumatoid arthritis, acute respiratory distress syndrome (ARDS), and cystic fibrosis (CF) (3–5) are characterized by an excessive destruction of connective tissue of the lung and joints. Neutrophil elastase is believed to participate in this process (6). Although α1-PI is present in the CF-lung, it is inactive in most patients, apparently due to oxidative and proteolytic processes (7, 8). Myeloperoxidase present in CF respiratory secretions converts Cl^- to OCl^- in the presence of hydrogen peroxide, inducing a large oxidant burden in the airways (9, 10). Moreover, bronchial secretions from CF-patients can directly inactivate α1-PI through elastase-mediated proteolysis (11). Therefore, individuals with CF have a functional deficiency of airway α1-PI (11, 12). They are especially susceptible to the early development of lung disease. It is reasonable to expect that a selective inhibitor of HLE might be useful for the treatment of emphysema, rheumatoid arthritis, CF, and other diseases. This provides a rationale for developing such inhibitors of low molecular weight for the evaluation of their efficacy to supplement natural inhibitors in diseases involving HLE (13). Several classes of HLE inhibitors have been reported in the past, including *N*-arylbenzylisothiazolinone 1,1-dioxide (14), fatty acids (15), sulfonyl fluorides (16), 4*H*-3,1-benzoxazin-4-one, 4-chloroquinazolines (17), azapeptide *p*-nitrophenyl esters (18), and cephalosporin derivatives. The discovery that neutral cephalosporins are inhibitors of mammalian serine proteinases led Zimmerman and co-workers (19) to evaluate the activity of clavulanic acid and its benzyl esters as inhibitors of HLE. The free acid, known to inhibit the bacterial β-lactamase, was inactive against HLE, but its benzyl ester had good activity against HLE. This observation prompted several investigators to select a large number of β-lactams for evaluation as inhibitors of HLE and other mammalian serine proteases (20–28).

Reagents: (a) $NaNO_2 \cdot H_2SO_4$; (b) Br_2; (c) $KMnO_4$ / 85% H_3PO_4; (d) EEDQ/DMF; (e) *R*-piperazine

Our objective was to develop a series of novel HLE synthetic inhibitors, including hydrophobic residues covalently linked to β-lactam structures (dibromopenicillanic acid, sulbactam, and 7α-methoxycephalosporin sulfone). Our first approach was to choose three different *N*-substituted piperazines: *N*-methylpiperazine, *N*-benzylpiperazine, and *N*-benzhydrylpiperazine (*N*-Bhpip). They were covalently linked to 6,6-dibromopenicillanic acid-(*S*,*S*)-dioxide (**5**–**7**) and penicillanic acid-(*S*,*S*)-dioxide (sulbactam) (**8**–**10**) (Scheme 1). From this group, *N*-Bhpip was detected as the most potent substituent. Based on the knowledge that *tert*-butyl 7α-methoxycephalosporanate 1,1-dioxide is a potent inhibitor of HNE, we hypothesized that replacing the *tert*-butyl group with hydrophobic amino acids would yield novel potent HNE inhibitors. With a 4-mer combinatorial peptide library, we have shown earlier that hydrophobic amino acids have definite anti-elastase effect (29). The selected amino acids and amino acid esters were covalently linked to 7α-methoxy cephalosporin sulfone (**20**–**31**) and tested for anti-elastase effect.

Experimental

General methods: chemistry

Melting points were measured on a Thomas–Hoover capillary melting point apparatus and were uncorrected. FT-IR spectra were recorded by using PerkinElmer Model 1600 spectrophotometer in chloroform. ^{1}H NMR spectra were recorded on a Bruker 300 spectrophotometer in DMSO-d_6 or $CDCl_3$ referenced to tetramethylsilane as an internal standard at 0.00 ppm. MS spectra were recorded on a high resolution mass spectrophotometer Z AB-IF (electron ionization, 70 eV) and Voyager Biospectrometry Workstation^{TM} based on matrix assisted laser desorption ionization mechanism (MALDI-TOF). Molecular ion peaks for compounds **5**–**10** were obtained. The MS of products **19**–**25**, except product **22**, revealed no molecular ion peak. However, a characteristic homologue $[M]^+$ ion series, subsequently missing – SO_2, – OCH_3, and – $CO\text{-}CH_3COO$, could be assigned. Chromatography generally refers to flash silica gel 60 200–400 mesh (SiliCycle, Quebec, QC, Canada) and TLC plates (Merck Kieselgel 60 F_{254}) with detection using UV or ninhydrine. Thin-layer chromatograms were developed in the following solvent systems: (a) $CHCl_3$:MeOH:AcOH, 95:5:3; (b) BuOH:AcOH:H_2O, 5:2:3; (c) BuOH:pyridine:H_2O, 4:1:1; (d) EtOAc:BuOH:AcOH:H_2O, 2:1:1:1; (e) $CHCl_3$:MeOH:AcOH, 5:3:1; (f) EtOAc:hexane, 8:2; (g) MeOH:$CHCl_3$, 8:2; (h) $CHCl_3$:MeOH, 7:3; or (i) $CHCl_3$:MeOH, 5:5. HPLC wt% analysis was performed on a Waters System 600E Controller at the following conditions: column C18 Bondpack (3.9 × 300 mm), eluent 95:5 (A:B isocratic at 1.0 mL min^{-1}, A = H_2O (0.05% TFA v/v), B = CH_3CN (0.05% TFA v/v)), UV detector at 254 nm. Dimethylformamide (DMF) was distilled over ninhydrine. Dry dichloromethane (DCM) was obtained after filtration over basic alumina. Dicyclohexylcarbodiimide (DCC) was used as 8% solution in DCM. 6,6-Dibromopenicillanic acid-(*S*,*S*)-dioxide was prepared according to refs. 30 and 31. 6-Aminopenicillanic acid (6-APA) and penicillanic acid-(*S*,*S*)-dioxide (sulbactam) were purchased from Sigma-Aldrich (ON, Canada). 7-Aminocephalosporanic acid (7-ACA) was purchased from Fluka (Ronkonkoma, NY). Abbreviations for amino acids follow the recommendations of the IUPAC-IUB Commission on Biochemical Nomenclature (32). Other abbreviations are described as follow: *tert*-butyloxycarbonyl (Boc), 9-fluorenylmethyl ester (OFm), benzyl ester (OBz), *tert*-butyl ester (O-*t*-Bu), *o*-nitrophenyl ester (ONp), 9-aminofluorene (NFm), 7α-methoxycephalosporanic acid 1,1-dioxide (CA).

Synthesis of the compounds 5–10 (Scheme 1)

Method A

To a stirred solution of dibromopenicillanic acid-(*S,S*)-dioxide (0.5 g, 1.2 mmol) in DCM (1 mL) was added DCC (1.5 mL, 0.6 mmol) at 0°C. The reaction mixture was then stirred for 20 min. After the filtration of dicyclohexylurea, the solution was used immediately in the next step. *N*-Methylpiperazine (0.55 g, 6.0 mmol) was added and the reaction was carried out at –5 to 0°C for 2 h. Then ice cold water was added and the mixture was stirred for 15 min. The organic layer was separated and the aqueous phase was extracted three times with DCM. The combined DCM extracts were washed with water, citric acid (10%), and brine. After drying over anhydrous sodium sulfate, the solvent was evaporated off under reduced pressure.

Method B

The synthesis was carried out using the method of mixed anhydrides. For this purpose 1-ethoxycarbonyl-2-ethoxy-1, 2-dihydroquinoline (EEDQ) (33) was used as a coupling reagent. *N*-Benzylpiperazine (0.7 g, 4 mmol) was added to a DMF solution of 6,6-dibromopenicillanic acid-(*S,S*)-dioxide (1.5 g, 4 mmol) followed by EEDQ (1.1 g, 4 mmol). The reaction mixture was then stirred for 48 h at room temp. Then ethyl acetate was added and the organic solution was extracted with water, citric acid (10%), and sodium bicarbonate (1 M). After drying over anhydrous sodium sulfate, the ethyl acetate solution was concentrated under vacuum and purified.

Method C

To a DMF solution of 1-methylpiperazine (0.4 g, 4 mmol), *N*-hydroxybenzotriazole (HOBt) (0.65 g, 4 mmol), 2-(1*H*-benzotriazole-1-yl)-1,1,3,3- tetramethyluronium tetrafluoroborate (TBTU) (1.37 g, 4 mmol), and *N*-methylmorpholine (NMM) (8 mmol) were added, followed by sulbactam (1 g, 4 mmol). The reaction mixture was stirred at room temp for 16 h. Then the mixture was diluted with water (70 mL) and extracted three times with ethyl acetate (100 mL). The organic layer was concentrated under reduced pressure and the isolated product purified.

*(2S)-6,6-Dibromo-3,3-dimethyl-7-oxo-4-thia-1-azabicyclo[3.2.0] heptane-2-(4′-methylpiperazine-4′-yl-1′-amido)-4,4-dioxide (**5**)*: Compound **5** was obtained according to method A and purified by preparative thin layer chromatography. Yield: 28%. EI-MS *m/z* ($C_{13}H_{19}Br_2N_3O_4S$, MW 473.19): 473. FT-IR (cm^{-1}): 3400, 1808, 1753, 1672. ^1H NMR (DMSO-d_6) δ: 3.6 (m, 8H) 2.4 (m, 3H), 1.2 (s, 3H), 1.0 (s, 3H).

*(2S)-6,6-Dibromo-3,3-dimethyl-7-oxo-4-thia-1-azabicyclo[3.2.0] heptane-2-(4′-benzylpiperazine-4′-yl-1′-amido)-4,4-dioxide (**6**)*: The synthesis was carried out using method B. Yield: 30%. EI-MS *m/z* ($C_{19}H_{23}Br_2N_3O_4S$, MW 549.28): 550. FT-IR (cm^{-1}): 1802, 1734, 1649, 1633, 1570. ^1H NMR (DMSO-d_6) δ: 7.60 (m, 5H), 4.72 (t, *J* = 6.1 Hz, 2H), 3.61 (m, 8H), 2.43 (s, 3H), 1.60 (s, 3H), 1.39 (s, 3H).

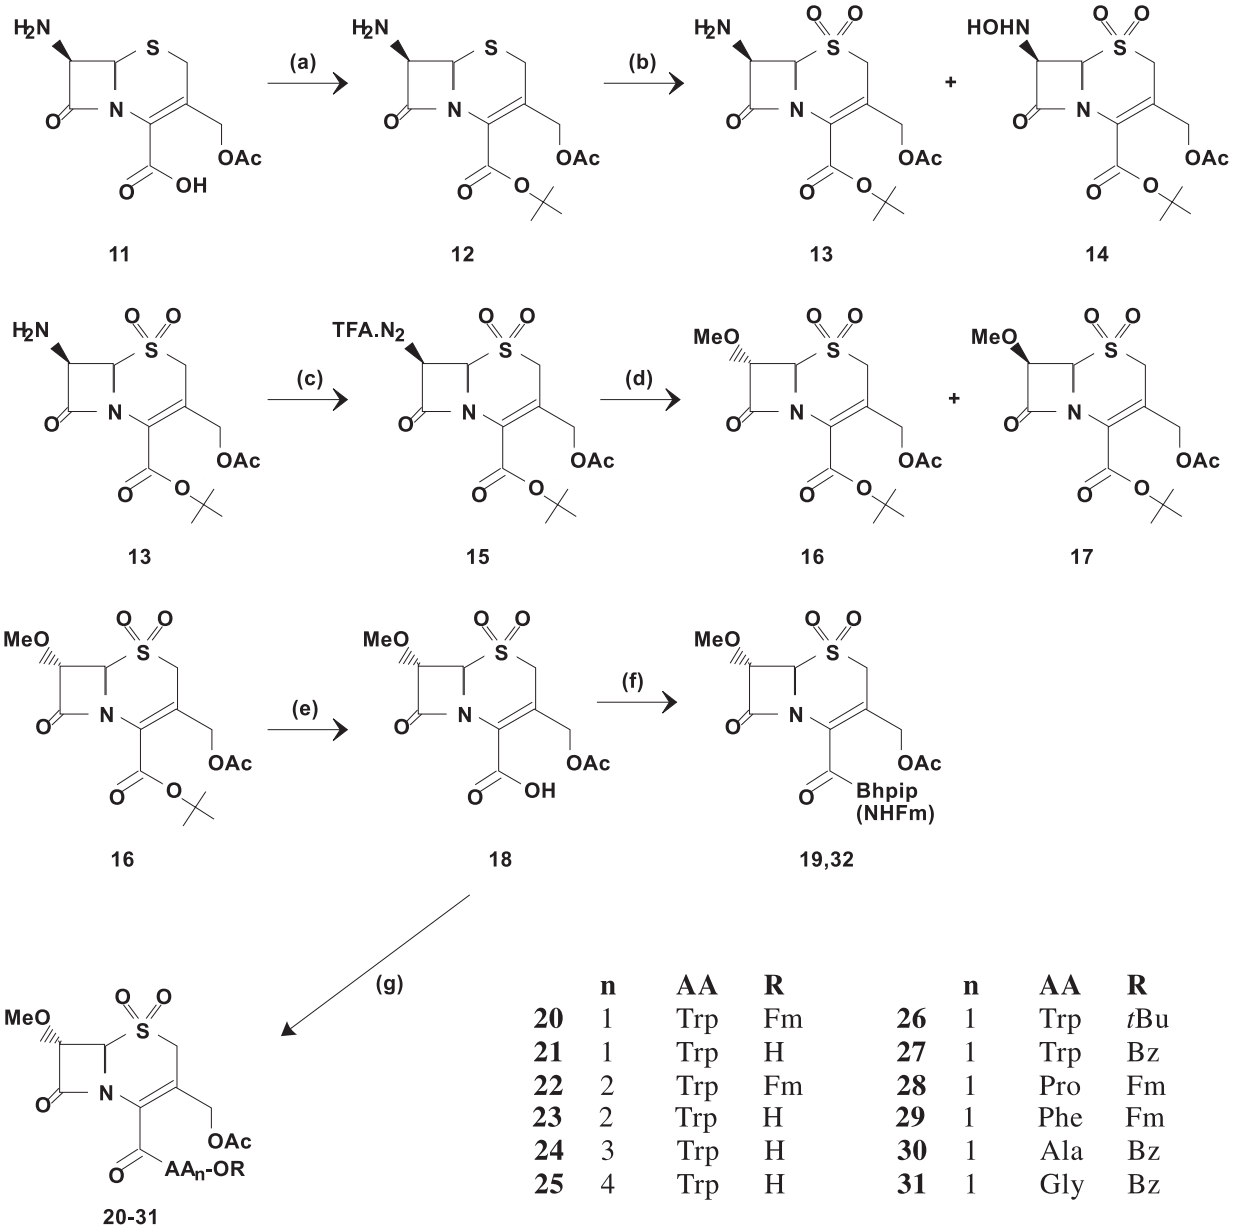
*(2S)-6,6-Dibromo-3,3-dimethyl-7-oxo-4-thia-1-azabicyclo[3.2.0] heptane-2-(4′-benzhydrylpiperazine-4′-yl-1′-amido)-4,4-dioxide (**7**)*: Compound **7** was obtained using method A. Yield: 45%. EI-MS *m/z* ($C_{25}H_{27}Br_2N_3O_4S$, MW 625.38): 625. FT-IR (cm^{-1}): 2982, 2808, 2760, 1817, 1757, 1690, 1662, 1599, 1551. ^1H NMR (DMSO-d_6) δ: 7.35 (m, 10H), 4.20 (t, *J* = 8.2 Hz, 2H), 3.61 (m, 8H), 2.38 (s, 3H), 1.59 (s, 3H), 1.42 (s, 3H).

*(2S)-3,3-Dimethyl-7-oxo-4-thia-1-azabicyclo[3.2.0]heptane-2-(4′-methylpiperazine-4′-yl-4′-amido)-4,4-dioxide (**8**)*: Compound **8** was obtained according to method C. Yield: 18%. EI-MS *m/z* ($C_{13}H_{21}N_3O_4$ S, MW 315.39): 315. FT-IR (cm^{-1}): 3460, 1790, 1667. ^1H NMR (DMSO-d_6) δ: 3.4–3.8 (m, 8H), 2.4–2.6 (m, 3H), 1.58 (s, 3H), 1.37 (s, 3H).

*(2S)-3,3-Dimethyl-7-oxo-4-thia-1-azabicyclo[3.2.0]heptane-2-(4′-benzylpiperazine-4′-yl-1′-amido)-4,4-dioxide (**9**)*: The synthesis of compound **9** was carried out using method A. Yield: 20%. EI-MS *m/z* ($C_{19}H_{25}N_3O_4S$, MW 391.49): 391. FT-IR (cm^{-1}): 3465, 1789, 1666. ^1H NMR (DMSO-d_6) δ: 7.2–7.4 (m, 5H), 4.88 (s, 1H), 4.73 (s, 1H), 3.4–3.8 (m, 8H), 2.4–2.6 (m, 3H), 1.61 (s, 3H), 1.38 (s, 3H).

*(2S)-3,3-Dimethyl-7-oxo-4-thia-1-azabicyclo[3.2.0]heptane-2-(4′-benzhydrylpiperazine-4′-yl-1′-amido)-4,4-dioxide (**10**)*: Compound **10** was prepared using method C. Yield: 40%. EI-MS *m/z* ($C_{25}H_{29}N_3O_4S$, MW 467.59): 467. FT-IR (cm^{-1}): 3479, 1790, 1681, 1651. ^1H NMR (DMSO-d_6) δ: 7.30 (m, 10H), 4.91 (s, 1H), 4.68 (s, 1H), 3.4–3.8 (m, 8H), 2.4–2.6 (m, 3H), 1.62 (s, 3H), 1.42 (s, 3H).

Chemistry of 7-methoxy cephalosporanic acid-1,1-dioxide *tert*-butyl-7β-aminocephalosporanate (12) (Scheme 2)



Dry dioxan was freed from peroxides by passage through a column of neutral alumina. To 100 mL of this solvent was added, by turns, ice cooled sulfuric acid (10 mL), 7-ACA (**11**) (10 g, 0.036 mol), and isobutylene (78.8 mL, 0.73 mol). The mixture was sealed in a pressurized bottle, stirred at room temp for 2 h, and then poured into an excess of ice cooled sodium bicarbonate solution (500 mL). Vigorous release of CO_2 occurred. The pH of the aqueous layer was checked during the quenching to maintain a basic pH (pH 8–9) Extraction with ethyl acetate and evaporation of the solvent gave a brown oil residue, which was then purified through a column of silicagel G 60 A (100 g) with chloroform as the eluent. Yield: 41%, mp 110°C. EI-MS *m/z* ($C_{14}H_{20}N_2O_5S$, MW 328.39): 272 [M – $C(CH_3)_3]^+$, 240 [M – $CO\text{-}CH_3COO]^+$. FT-IR (cm^{-1}): 3459, 2975, 1785, 1723, 1526. ^1H NMR ($CDCl_3$) δ: 5.03 (d, *J* = 13.5 Hz, 1H), 4.94 (d, *J* = 5.2 Hz, 1H), 4.79 (d, *J* = 13.5 Hz, 1H), 4.76 (d, *J* = 5.2 Hz, 1H), 3.55 (d, *J* = 18.3 Hz, 1H), 3.35 (d, *J* = 18.3 Hz, 1H), 2.09 (s, 3H), 1.70 (br s, 2H, NH_2), 1.54 (s, 9H).

tert-*Butyl-7β-aminocephalosporanate-1,1-dioxide (**13**)*

In a 250 mL three-necked round-bottomed flask, equipped with a stirrer and device for external cooling–heating was dissolved **12** (5 g, 0.015 mol) in ethyl acetate (100 mL) at 25°C. The solution was stirred quickly while solid sodium tungstate dihydrate (0.5 g, 0.001 mol) and 30% hydrogen peroxide (6.25 mL, 0.061 mol) were added. The temperature of this biphasic mixture was maintained at 20–25°C with cooling for 2 h. The reaction mixture took on a yellow cast due to the

Reagents: (a) isobutylene/H_2SO_4; (b) H_2O_2/Na_2WO_4; (c) isopropylnitrite/TFA/EtOAc;
(d) MeOH/rhodium octanoate dimer / Et_3N; (e) TFA/thioanisol/water;
(f) DCC/HOBT/benzhydrylpiperazine(Bhpip)or 9-N_2H-fluorene; (g) H-$(Trp)_n$-OR (R = Fm or H)

formation of the oxidizing species, sodium pertungstate. After 2 h, an additional amount of 30% hydrogen peroxide (1.25 mL, 0.012 mol) was added. After 18 h, an additional hydrogen peroxide amount was added and the batch was left until completion (21 h). When the reaction was deemed complete (TLC), the mixture was diluted with ethyl acetate (150 mL) and cooled to 10°C. The reaction mixture was well stirred while a solution of sodium sulfite (5 g, 0.037 mol) in water (100 mL) was added slowly to decompose any remaining hydrogen peroxide. After 10 min a test for residual peroxide was performed (starch iodide). The biphasic mixture was further cooled to 5°C, and a cold (5°C) solution of aqueous sodium bicarbonate solution (5%) was added to decompose any oxime by-product (**14**). The reaction mixture was stirred for 10 min at 5°C. Stirring was discontinued until the layers were ready to be separated (30 min). The lower aqueous layer was removed and discarded. The upper ethyl acetate product layer was then washed with saturated sodium chloride solution (100 mL). The organic layer was dried over sodium sulfate (5 g), filtered, and cake washed with ethyl acetate (50 mL). The combined filtrate and liquid phases from washing were concentrated under vacuum to give an oily residue, which was further purified through a silicagel G 60A column, using chloroform–methanol (0 → 50% MeOH). Yield: 18.5%. EI-MS

m/z ($C_{14}H_{20}N_2O_7S$, MW 360.51): 273 [M – SO_2 – $C(CH_3)_3$]$^+$, 196 [M – SO_2 – $COOC(CH_3)_3$]$^+$. FT-IR (cm^{-1}): 3360, 2978, 1798, 1731, 1643, 1359, 1154, 1128. ^1H NMR ($CDCl_3$) δ: 5.12 (d, *J* = 14.0 Hz, 1H), 4.91 (d, *J* = 5.2 Hz, 1H), 4.79 (d, *J* = 14.0 Hz, 1H), 4.76 (d, *J* = 4.9 Hz, 1H), 3.66 (d, *J* = 18.6 Hz, 1H), 2.33 (br s, 2H), 2.09 (s, 3H), 1.54 (s, 9H).

tert-*Butyl-7-diazocephalosporanate-1,1-dioxide (**15**)*

A 500 mL three-necked round-bottomed flask equipped with a mechanical agitator and nitrogen bubbler was charged with **13** (0.5 g, 0.0014 mol) in ethyl acetate (15 mL). A freshly prepared solution of isopropyl nitrite (0.16 g, 20 mmol) in DCM (33) was added to the stirred solution at 15–20°C, followed by a catalytic amount of TFA. The batch temperature rose to 31°C over 15 min and the reaction mixture was stirred for 1 h at this temperature. When the diazotization was complete, the batch was diluted with ethyl acetate and concentrated under reduced pressure at 30°C or less to the previous volume (NB: in isolated form the diazo compound may be explosive, however, previous investigators have suggested that this material may be handled safely as a dilute solution in ethyl acetate. Therefore, it was important that the product did not crystallize near the neck of the flask during concentration. The above flash concentration removed most of the excess unreacted isopropyl nitrite, isopropyl alcohol by-product, and methylene chloride.). Afterwards, the batch was diluted with fresh ethyl acetate and used immediately in the next step.

tert-*Butyl-7α-methoxycephalosporanate-1,1-dioxide (**16**)*

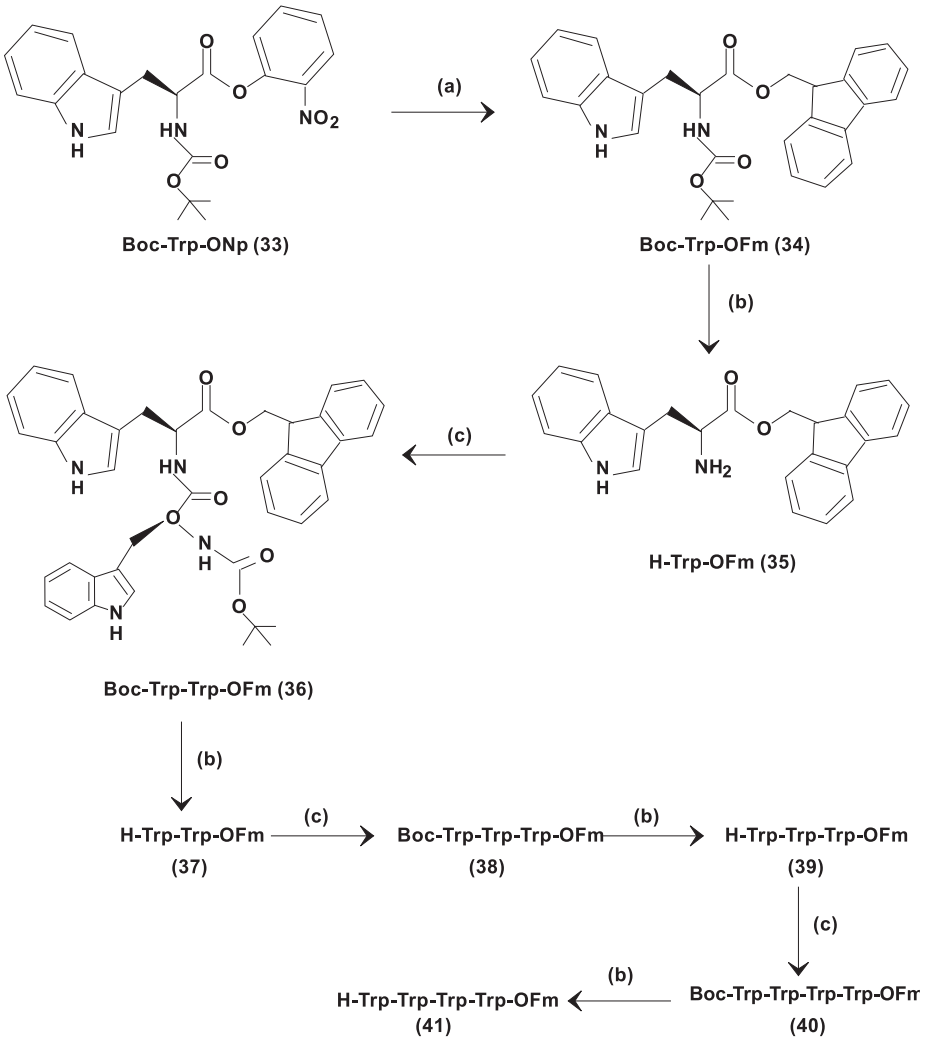
Simultaneously to the preparation of the diazocephalosporanate (**15**), rhodium octanoate dimer (20 mg, 0.02 mmol) was dissolved in methanol (1.7 mL) and diluted with ethyl acetate (13 mL). The solution was let to cool. The mixture from the previous step, containing **15**, was cooled to –5°C and vacuum was purged three times with nitrogen. Before the reaction with the compound **15**, triethylamine (0.05 mL) was added to the catalyst mixture, and the solution was stirred for 5 min. The color changed from blue green to purple, probably due to ligand exchange and (or) complexation of the rhodium octanoate dimer with triethylamine. The catalyst solution was added to the solution of diazocompound for about 1 h. The reaction was carried out in an open flask to eliminate nitrogen gas. After 1 h, the batch was concentrated in vacuo, washed with deionized water, containing sodium chloride and phosphoric acid, and then washed with a solution of 10% sodium chloride. The ethyl acetate layer was dried over anhydrous sodium sulfate and then passed through a bed of silicagel G 60A. The silicagel was then washed with ethyl acetate. The batch and wash were combined and concentrated in vacuo to 40 mL. Hexane (8 mL) was slowly added, the crystallization occurred progressively. The crystallization mixture was further concentrated to 5 mL, diluted with hexane (12 mL) over 4 h, let with stirring 4 h at 25°C, and then for 24 h at 0–5°C. The batch was filtered and cake washed with 6 mL of hexane. The residue was dried completely in vacuo. The major product fraction contained 220 mg (24%) of a white crystalline solid, mp 130 to 131°C (EtOAc–hexane), and was identified as *tert*-butyl-7α-methoxycephalosporanate-1,1-dioxide (**16**) on the basis of its spectral characteristics. EI-MS *m/z* ($C_{15}H_{23}NO_8S$, MW 377.42): 273 [M – $COOC(CH_3)_3$]$^+$, 208 [M – SO_2 – $COOC(CH_3)_3$]$^+$, 180 [M – SO_2 – $COOC(CH_3)_3$ – CO]$^+$, 150 [M – SO_2 – $COOC(CH_3)_3$ – CO – OCH_3]$^+$. FT-IR (cm^{-1}): 2978, 1797, 1723, 1693, 1513, 1369, 1157, 1128. ^1H NMR ($CDCl_3$) δ: 5.20 (d, *J* = 14.1 Hz, 1H), 4.99 (d, *J* = 5.0 Hz, 1H), 4.88 (d, *J* = 12.0 Hz, 1H), 4.34 (d, *J* = 13.2 Hz, 1H), 3.99 (d, *J* = 18.8 Hz, 1H), 3.70 (d, *J* = 18.8 Hz, 1H), 3.60 (s, 3H), 2.10 (s, 3H), 1.55 (s, 9H).

*7α-Methoxycephalosporanic acid-1,1-dioxide (**18**)*

A solution of **16** (50 mg, 0.1 mmol) and thioanisol (0.8 mL) in TFA (4 mL) was stirred at 0°C for 30 min and was then evaporated in vacuo. Two additional aliquots of DCM were added and then evaporated to remove most of the residual TFA. The compound was used directly in the next amidation step.

Synthesis in solution of H-Trp-Trp-Trp-Trp-OH (Boc-Trp-OFm) (34), Boc-strategy (Scheme 3)

9-Fluorenylmethanol (5.07 g, 0.0258 mol) and imidazol (2.35 g, 0.0345 mol) were added to tetrahydrofurane (40 mL). The suspension was stirred at room temp and *t*-Boc-Trp-ONp (**33**) (10 g, 0.23 mol) was added. Stirring was continued for 18 h. The solvent was then removed under reduced pressure. The residue was dissolved in ethyl acetate, and the solution washed with 2% citric acid solution, sodium bicarbonate solution (0.5 N), and water. The ethyl acetate solution was dried over anhydrous sodium sulfate and evaporated to dryness. The compound was purified by flash chromatography silicagel G 60A, using chloroform as an eluent. Yield 80%. R_f^a: 0.55, R_f^b: 0.84, t_R: 13.6 min. EI-MS *m/z* ($C_{30}H_{30}N_2O_4$, MW 482.58): 482, 178, 130. FT-IR (cm^{-1}): 3409, 3328, 3007, 2979, 2930, 1736, 1699, 1664, 1617, 1590.



*H-Trp-OFm·HCl (**35**)*: Boc-Trp-OFm (**34**) (2.5g, 5 mmol) was dissolved in ether and HCl gas was passed through the solution until precipitation was observed. The amino acid ester hydrochloride was filtered, washed several times with hexane and dried. Yield 95%, mp 200°C. R_f^a: 0.12, R_f^b: 0.80, t_R: 15.4 min. EI-MS *m/z* ($C_{25}H_{22}N_2O_2$, MW 382.47): 382, 178, 152, 130.

*Boc-Trp-Trp-OFm (**36**)*: To a solution of **35** (0.650 g, 1.5 mmol) and HOBt (0.3 g, 1.9 mmol) in DMF (15 mL) was added NMM (0.2g, 1.9 mmol) followed by **33** (0.8 g, 1.9 mmol). The solution was stirred for 4 h at room temp. A 10-fold excess of water was then added, and the obtained suspension was extracted with ethyl acetate. The organic layer and extracts were combined, washed with 0.1% sodium bicarbonate solution, and evaporated under vacuum. The process was followed by TLC and HPLC. The product was further purified by flash chromatography, using silicagel G 60A and $CHCl_3$–MeOH (0 → 50% MeOH) as the eluent. After the purification step, the obtained compound was 1g (91%), mp 88–90°C. R_f^a: 0.60, R_f^b: 0.83, t_R: 20 min. EI-MS *m/z* ($C_{41}H_{40}N_4O_5$, MW 668.80): 669, 569. FT-IR (cm^{-1}): 3409, 3328, 3007, 2977, 2931, 1736, 1697, 1664, 1617, 1591.

*H-Trp-Trp-OFm·HCl (**37**)*: The deprotection was carried out using the procedure already described for **35**. Yield 78%, mp 164 to 165°C. R_f^a: 0.15, R_f^b: 0.78, t_R: 16.5 min. EI-MS *m/z* ($C_{36}H_{32}N_4O_3$, MW 568.68): 569. FT-IR (cm^{-1}): 3409, 3007, 1736, 1697, 1664, 1516.

Reagents: (a) 9-fluorenylmethanol/imidazol/THF; (b) ether/HCl(gas); (c)**26**/HOBt/NMM/DMF

*Boc-Trp-Trp-Trp-OFm (**38**)*: The synthesis was carried out using the method described above for **36**. Yield 90%, mp 93–95°C. R_f^a: 0.64, R_f^b: 0.80, t_R: 21.5 min. EI-MS *m*/*z* ($C_{52}H_{50}N_6O_6$, MW 855.01): 855, 475, 374, 146. FT-IR (cm^{-1}): 3404, 3318, 2928, 1736, 1690, 1663, 1509.

*H-Trp-Trp-Trp-OFm·HCl (**39**)*: The Boc-deprotection was carried out according to the method described above. Yield 70%. R_f^a: 0.04, R_f^b: 0.81, t_R: 17.4 min. EI-MS *m*/*z* ($C_{47}H_{42}N_6O_4$, MW 754.90): 755.

*Boc-Trp-Trp-Trp-Trp-OFm (**40**)*: The reaction was carried out according to the method described above. After 16 h water was added and then the extraction with ethyl acetate was done. After purification, the peptide fractions were pooled together and submitted to TLC, HPLC, and EI-MS analysis. The first and major product was Boc-$(Trp)_4$-OFm (M^+ = 1041, MW 1040), and the second one was *tert*-butylated Boc-$(Trp)_4$-OFm (M^+ = 1097, MW 1096). R_f^a: 0.30, R_f^b: 0.70, t_R: 22 min. EI-MS *m*/*z* ($C_{63}H_{60}N_8O_7$, MW 1041.23): 1040, 941, 740, 569, 474, 375.

Solid phase synthesis of H-Trp-Trp-Trp-Trp-OH, Fmoc-strategy

Synthesis was performed using Fmoc-Trp(Boc)-Wang resin, substitution Fmoc-Trp-(Boc)-OH (0.4 mmol g^{-1}, 2.5 eq), DCC (2.5 eq), and HOBt (5 eq), and NMM as a base. The resin cleavage was carried out with TFA–ethanedithiol–water (95:2.5:2.5) for 1 h at room temp. The following compounds were synthesized:

*H-Trp-Trp-Trp-OH (**39**)*: EI-MS *m*/*z* ($C_{33}H_{35}N_6O_4$, MW 576.66): 577.

*H-Trp-Trp-Trp-Trp-OH (**41**)*: EI-MS *m*/*z* ($C_{44}H_{42}N_8O_5$, MW 762.88): 763.

7α-Methoxycephalosporanic acid-1,1-dioxide derivatives (19–31) (Scheme 2)

*CA-Bhpip (**19**)*

To a solution of **18** (42.5 mg, 0.1 mmol) in DMF (3 mL) was added NMM to pH 8, followed by HOBt (19 mg,

© 2001 NRC Canada

0.1 mmol) and DCC (0.5 mL, 0.1 mmol). The mixture was stirred over 30 min at 0°C. *N*-Bhpip (44 mg, 0.17 mmol) was added and the stirring continued overnight. When the reaction was complete DCM was added, followed by water, and the layers were allowed to separate. The organic layer was washed with citric acid solution (2%), water, and brine. After drying over anhydrous sodium sulfate the solvent was removed under reduced pressure. The compound was then purified by column chromatography on silicagel G60 A using chloroform–methanol (0 → 50% MeOH) as a mobile phase. EI-MS *m/z* ($C_{28}H_{31}N_3O_7S$, MW 553.64): 458 [M – SO_2 – CH_3CO]$^+$, 208 [M – SO_2 – CH_3CO – Bhpip]$^+$. FT-IR (cm^{-1}): 3387, 2936, 1791, 1735, 1682, 1522. ^{1}H NMR ($CDCl_3$) δ: 7.60 (m, 10H), 5.20 (d, *J* = 1.6 Hz, 1H), 4.99 (d, *J* = 14.0 Hz, 1H), 4.88 (d, *J* = 1.6 Hz, 1H), 4.34 (d, *J* = 14.0 Hz, 1H), 3.99 (d, *J* = 19.0 Hz, 1H), 3.4–3.8 (m, 8H), 2.10 (s, 3H).

*CA-Trp-OFm (**20**)*

To a solution of **35** (47 mg, 0. 1mmol), HOBt (19 mg, 0.1 mmol), and TBTU (40 mg, 0.1mmol) in DMF (2 mL) was added NMM to pH 8 followed by **18** (40 mg, 0.1 mmol). The reaction was checked using TLC. After 7 h the reaction was stopped and 10-fold excess of water was added. The solution was then extracted with ethyl acetate. The ethyl acetate layer was dried over anhydrous sodium sulfate and the solvent was removed under reduced pressure. EI-MS *m/z* ($C_{36}H_{33}N_3O_9S$, MW 683.74): 273 [M – CO – Trp-OFm]$^+$, 208 [M – SO_2 – CO – Trp-OFm]$^+$. FT-IR (cm^{-1}): 1797, 1789, 1769, 1745, 1738, 1731, 1713, 1681, 1667, 1573. ^{1}H NMR (DMSO-d_6) δ: 7.2–7.8 (m, 12H), 6.82 (d, *J* = 2.5 Hz, 1H), 5.18 (d, *J* = 1.6 Hz, 1H), 4.80 (s, 2H), 4.67 (d, *J* = 12.8 Hz, 2H), 4.42 (s, 2H), 4.09 (s, 2H), 3.24 (s, 3H), 2.09 (s, 3H).

*CA-Trp-OH (**21**)*: The compound was obtained after deprotection of carboxyl function with 15% piperidine in DMF. EI-MS *m/z* ($C_{22}H_{25}N_3O_9S$, MW 507.52): 369 [M – SO_2 – CH_3CO – OCH_3]$^+$, 183 [M – SO_2 – CH_3CO – OCH_3 – CO – Trp]$^+$. FT-IR (cm^{-1}): 2925, 2854, 1789, 1734, 1714, 1667, 1557, 1519.

*CA-(Trp)$_2$-OFm (**22**)*: The synthesis was carried out according to the method described above. Yield: 31%. EI-MS *m/z* ($C_{47}H_{43}N_5O_{10}S$, MW 869.96): 870. FT-IR (cm^{-1}): 2925, 2854, 1789, 1729, 1714, 1667, 1557, 1519.

*CA-Trp-Trp-OH (**23**)*: Yield 56%. EI-MS *m/z* ($C_{33}H_{33}N_5O_{10}S$, MW 691.72): 413 [M – SO_2 – Trp – OCH_3]$^+$, 199 [M – SO_2 – OCH_3 – CO – Trp]$^+$. FT-IR (cm^{-1}): 2925, 2854, 1789, 1734, 1714, 1667, 1557, 1519.

*CA-(Trp)$_3$-OH (**24**)*: 7α-Methoxycephalosporanic acid-1,1-dioxide (**18**) (37 mg, 0.1 mmol) in DMF was added to peptide-resin (250 mg, 0.4 mmol g^{-1}), followed by DCC (0.65 mL, 0.1 mmol), HOBt (17 mg, 0.1 mmol), and a drop of NMM. The synthesis was carried out overnight. After washing and drying, the resin was cleaved with a mixture of TFA–thioanisol–water (3.5:25:0.25) for 1 h at room temp. The peptide was further precipitated in ice cooled ether (200 mL). The solvent was then evaporated and the product lyophilised (purity 98%, HPLC). EI-MS *m/z* ($C_{44}H_{45}N_7O_{11}S$, MW 879.95): 783 [M – SO_2 – OCH_3]$^+$. FT-IR (cm^{-1}): 1790, 1771, 1742, 1670, 1653, 1637, 1593, 1532, 1510.

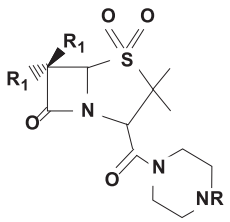
*CA-(Trp)$_4$-OH (**25**)*: Yield: 10%. EI-MS *m/z* ($C_{55}H_{55}N_9O_{12}S$, MW 1066.17): 969 [M – SO_2 – OCH_3]$^+$. FT-IR (cm^{-1}): 2926, 2852, 1794, 1774, 1736, 1701, 1666, 1654, 1560, 1523, 1509.

*CA-Trp-O-t-Bu (**26**)*: Yield: 12%. EI-MS *m/z* ($C_{26}H_{31}N_3O_9S$, MW 561.62): 563, 228 [M – CH_3 – $OCOCH_2$ – Trp-O-*t*-Bu]$^+$, 136 [M – CH_3OCOCH_2 – Trp-O-*t*-Bu – SO_2]$^+$. FT-IR (cm^{-1}): 3370, 1787, 1735, 1679, 1508, 1458, 1385, 1157. ^{1}H NMR (DMSO-d_6) δ: 7.18 (m, 4H), 6.80 (d, *J* = 2.5 Hz, 1H), 5.19 (d, *J* = 1.6 Hz, 1H), 4.81 (t, *J* = 6.4 Hz, 1H), 4.75 (s, 2H), 4.40 (d, *J* = 2.5 Hz, 1H), 4.08 (s, 2H), 3.32 (s, 3H), 2.12 (s, 3H), 1.45 (s, 9H).

*CA-Trp-OBz (**27**)*: Yield: 10%. EI-MS *m/z* ($C_{29}H_{29}N_3O_9S$, MW 595.63): 596, 484 [M – OCH_3 – SO_2 – CH_3]$^+$, 277 [M – CO – Trp-OBz]$^+$, 137 [M – CO – Trp-OBz – SO_2 – CH_2OCOCH_3]$^+$. FT-IR (cm^{-1}): 3378, 1795, 1741, 1666, 1571, 1135. ^{1}H NMR (DMSO-d_6) δ: 7.20 (m, 5H), 7.18 (m, 4H), 6.80 (d, *J* = 2.8 Hz, 1H), 5.21 (d, *J* = 1.4 Hz, 1H), 4.81 (t, *J* = 7.1 Hz, 1H), 4.75 (s, 2H), 4.42 (d, *J* = 2.5 Hz, 1H), 4.08 (s, 2H), 3.33 (s, 3H), 2.07 (s, 3H).

*CA-Pro-OFm (**28**)*: Yield: 8%. EI-MS *m/z* ($C_{30}H_{30}N_2O_9S$, MW 594.64): 595, 564 [M – OCH_3]$^+$, 286 [M – Pro-OFm]$^+$. FT-IR (cm^{-1}): 3410, 2960, 1794, 1550. ^{1}H NMR (DMSO-d_6) δ: 7.3–7.8 (m, 8H) 5.21 (d, *J* = 1.4 Hz, 1H), 4.75 (s, 2H), 4.70 (d, *J* = 12.8 Hz, 2H), 4.46 (d, *J* = 15.8 Hz, 1H), 4.21 (t, *J* = 7.0 Hz, 1H), 4.08 (s, 2H), 3.32 (t, *J* = 6.3 Hz, 2H), 3.24 (s, 3H), 2.09 (s, 3H), 1.87 (t, *J* = 7.5 Hz, 2H), 1.60 (m, 2H).

*CA-Phe-OFm (**29**)*: Yield: 10%. EI-MS *m/z* ($C_{34}H_{32}N_2O_9S$, MW 644.70): 645, 614 [M – OCH_3]$^+$. FT-IR (cm^{-1}): 3401, 1790, 1731, 1679, 1391, 1185. ^{1}H NMR (DMSO-d_6) δ: 7.8–7.1 (m, 13H), 5.22 (d, *J* = 1.4 Hz, 1H), 4.81 (t, *J* = 7.5 Hz, 1H), 4.75 (s, 2H), 4.40 (d, *J* = 12.8 Hz, 1H), 4.13 (s, 2H), 3.3 (s, 3H), 2.11 (s, 3H).



*CA-Ala-OBz (**30**)*: Yield: 12%. EI-MS *m/z* ($C_{20}H_{22}N_2O_9S$, MW 466.47): 466, 407 [M – $COOCH_3$]$^+$, 343 [M – $COOCH_3$ – SO_2]$^+$, 233 [M – $COOCH_3$ – SO_2 – OBz]$^+$, 135 [M – $COOCH_3$ – SO_2 – CO – Ala-OBz]$^+$. FT-IR (cm^{-1}): 3370, 2983, 1786, 1739, 1662, 1384, 1227, 1156. ^{1}H NMR (DMSO-d_6) δ: 7.4–7.6 (m, 5H), 5.22 (d, *J* = 1.2 Hz, 1H), 4.75 (d, *J* = 12.8 Hz, 2H), 4.43 (d, *J* = 12.0 Hz, 1H), 4.07 (d, *J* = 5.8 Hz, 2H), 4.08 (s, 2H), 3.24 (d, *J* = 18.6 Hz, 3H), 2.10 (s, 3H).

*CA-Gly-OBz (**31**)*: Yield: 30%. EI-MS *m/z* ($C_{19}H_{20}N_2O_9S$, MW 452.44): 452, 355 [M – $COOCH_3$ – SO_2]$^+$, 261 [M – $COOCH_3$ – SO_2 – OBz]$^+$, 107 (OBz), 135 [M – $COOCH_3$ – SO_2 – CO – Gly-OBz]$^+$. FT-IR (cm^{-1}): 3408, 1786, 1738, 1710, 1665, 1385, 1134. ^{1}H NMR (DMSO-d_6) δ: 7.4–7.6 (m, 5H), 5.22 (d, *J* = 1.2 Hz, 1H), 4.75 (d, *J* = 12.8 Hz, 2H), 4.4 (d, *J* = 12.8 Hz, 1H), 4.13 (d, *J* = 6.9 Hz, 2H), 4.08 (s, 2H), 3.24 (d, *J* = 18.6 Hz, 3H), 2.10 (s, 3H).

*CA-NFm (**32**)*: Yield: 40%. EI-MS *m/z* ($C_{24}H_{22}N_2O_7S$, MW 482.51): 451 [M – OCH_3]$^+$. FT-IR (cm^{-1}): 3411, 2874, 1788, 1726, 1665, 1368, 1187. ^{1}H NMR (DMSO-d_6) δ: 7.3–7.8 (m, 8H), 5.21 (s, 1H), 4.75 (s, 2H), 4.46 (s, 1H), 4.42 (d, *J* = 12.8 Hz, 1H), 3.35 (s, 3H), 2.01 (s, 3H).

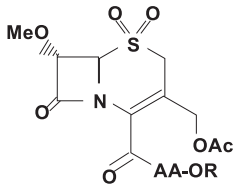
Elastase inhibition assay

Neutrophil elastase (HNE) activity was determined with the specific human neutrophil elastase substrate *N*-methoxy-succinyl-alanyl-alanyl-prolyl-valyl-*p*-nitroanilide (MeO-Succ-Ala-Ala-Pro-Val-pNA, Sigma, St. Louis) as described in ref. 12. HNE inhibitory capacity was determined by incubating 20 nM HNE with 0–1 μM inhibitor for 1–24 h at room temp. Residual elastase activity was assayed with MeO-Succ-Ala-Ala-Pro-Val-pNA by measuring the change in absorbance 1 min at 410 nm in a spectrophotometer (model DU7, Beckman Instruments Inc., Montreal, Qc).

Results and discussion

Chemistry

Penicillin derivatives



The commercially available 6-APA, (**1**) (Scheme 1) was first converted to 6,6-dibromopenicillanic acid (**2**) using a diazotization–halogenation procedure (30). A high-yield conversion of **1** to **2** was achieved since the diazo intermediate, once formed, was more easily brominated. The biphase of the diazotization–bromination reaction exploited the solubility of bromine and the 6,6-dibromopenicillanic acid intermediate in organic solvents and the solubility of hydrogen bromide in water. Following Scheme 1, **1** was added to a cooled DCM–sulfuric acid mixture, containing sodium nitrite and bromine, and was converted to the desired 6,6-dibromopenicillanic acid (**2**) in high yield (80%). 6,6-Dibromopenicillanic acid (**2**), once formed, was converted in a very high yield (more than 90%) to the corresponding sulfone (**3**) by a potassium permanganate oxidation (31). The synthesis of the final compounds **5**–**10** was achieved using three different methods: (A) method of symmetrical anhydrides, using dicyclohexylcarbodiimide (DCC) as a coupling reagent, (B) method of mixed anhydrides with the use of EEDQ (33) as a coupling reagent, and (C) amidation via HOBt active ester procedure, using the activating agent TBTU or with DCC. The compounds having formula **5**–**10** obtained after synthesis were 93–99% pure as evidenced by HPLC and TLC analysis (Table 1). They were isolated as micro-crystalline solids or oils. FT-IR, EI-MS, and ^{1}H NMR spectroscopy confirmed the structures.

*Synthesis of 7α-methoxy-cephalosporanic acid-1,1-dioxide (**18**) (Scheme 2)*

The synthesis was carried out according to Scheme 2. 7-ACA (**11**) was used as a starting material. It was apparent that any synthesis of **18** must involve two key chemical transformations, i.e., oxidation of 1-sulfide to the corresponding 1-sulfone and conversion of the 7β-amino group to the 7α-methoxy group. For this reason our preparation followed the procedure described by Blackock et al. (34). Following Scheme 2, the carboxylic function of **11** was protected by esterification with isobutylene, using the method of Stedmann (35). Compound **12** was then oxidized to *tert*-butyl-7-aminocephalosporanate-1,1-dioxide (**13**). Direct oxidation of 7-ACA *tert*-butyl ester to the corresponding sulfone caused some unique problems due to the potential for *N*-oxidation of the 7-amino group. As in step one, we believed that protection from *N*-oxidation might come via protonation of the amine prior to the oxidation step. Our initial attempts to oxidize compound **12** using *m*-chloroperoxybenzoic acid (*m*-CPBA) were unsuccessful. However, using sodium tungstate as a catalyst and 30% hydrogen peroxide solution we managed to obtain the sulfone, but in very low yield (18.5%). Some *N*-oxidation occurred to form 20% of a nearly insoluble and crystalline by-product, 7-hydroxyimino sulfone derivative (**14**) of 7-ACA *tert*-butyl ester. Synthesis of *tert*-butyl-7α-methoxycephalosporanate-1,1-dioxide (**16**) was the next step. For the diazotization–methoxylation procedure we followed the method previously described (34). The use of isopropyl nitrite as the diazotizing reagent facilitated the workup, as the by-product (isopropyl alcohol) reaction could be readily removed from the reaction mixture by vacuum replacement concentration. The fast reaction rate of methoxylation ensured a higher insertion yield, but slowing down the rate with a reduced methanol and catalyst charge increased stereoselectivity. For this reason cold (0°C) ethyl acetate solution, containing rhodium octanoate dimer, methanol, and thriethylamine was added slowly over 1 h to the cold solution of the diazocomponent. *tert*-Butyl-7β-methoxy-cephalosporanate (**17**) was also obtained as a by-product.

[a]TLC solvent systems are described in *General methods* section.

The free acid **18** was obtained by cleavage of *tert*-butyl ester group with TFA–thioanisol. Compound **18**, a light yellow oil, was used without isolation in the next amidation step.

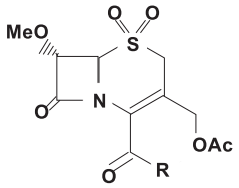
Synthesis in solution of H-Trp-Trp-Trp-Trp-OH, Boc-strategy (Scheme 3)

A method for the synthesis of tetra-tryptophanyl-9-fluorenylmethyl ester was developed. From numerous methods proposed for the preparation of amino acids esters, we selected the imidazol-catalyzed transesterification of a commercially available protected amino acid active ester, Boc-Trp-ONp (33). Following Scheme 3, in the first step the *o*-nitrophenylester group was substituted with the 9-fluorenylmethyl ester group using the method of Bednarek and Bodansky (36). The *tert*-butyloxycarbonyl amino protection of **34**, **36**, **38**, and **40** could be cleaved either by TFA or by gaseous HCl as the fluorenylmethyl ester group remains unaffected under these conditions. For the synthesis we chose gaseous HCl Boc-cleavage. The next tryptophanyl residue was then attached using Boc-Trp-ONp ester. The coupling was carried out using HOBt–active ester in situ formation in the presence of NMM as a base. It is interesting to note that the fluorenylmethyl group contributes to the solubility of the protected peptides in organic solvents. Thus, fluorenylmethyl esters might offer some advantages in peptide synthesis, particularly because they are readily removable under mild conditions (15% piperidine in DMF).

Solid phase synthesis of H-Trp-Trp-Trp-Trp-OH, Fmoc-strategy

Synthesis was performed using Fmoc-Trp(Boc)-Wang resin, substitution Fmoc-Trp(Boc)-OH (0.4 mmol g^{-1}, 2.5 eq), DCC (2.5 eq), HOBt (5 eq), and MMM as a base. The cleavage from the resin was carried out with TFA–ethanedithiol–water (95:2.5:2.5) for 1 h at room temp. The final product (**41**) was purified by HPLC.

7α-Methoxycephalosporanic acid derivatives (19–32) (Scheme 2)



The synthesis of the compounds with the formula **19**–**32** was achieved in low to moderate yield using the method of active esters. The predicted structures were confirmed by FT-IR, NMR, and EI-MS spectroscopy. Physico-chemical data for the compounds from this series are shown in Tables 2 and 3.

In vitro activity

In vitro inhibition of HLE activity by the target compounds is shown in Tables 1, 2, and 3 as nominal IC_{50} values (μM). From the results in Table 1, it can be seen that the compounds prepared on the basis of the penicillin structures (dibromopenicillanic acid and sulbactam) are very poor time-dependant inhibitors of HLE. From this series of compounds, we chose *N*-Bhpip as the most promising substituent and it was determined that compound **19**, on the basis of cephalosporin structures, had a strong anti-elastase effect (IC_{50} = 0.8 μM) (Table 3). Substitution of *N*-Bhpip with 9-aminofluorene gave compound **32**, which exhibited poor anti-elastase activity. Biological data for the compounds with amino acids and amino acid esters covalently linked to the cephalosporin (structures **20**–**31**) are shown in Table 2. Replacement of the *tert*-butyl ester group in **16** with tryptophanyl-9-fluorenylmethyl ester gave compound **20**, possessing the same anti-elastase activity as **19**. The free carboxylic group on **21** gave a diminished anti-elastase effect. The addition of more tryptophanyl residues gave poor HLE inhibitors (**22**–**25**), as demonstrated by the absence of activity in the compound with up to four tryptophanyl residues. Both the tryptophanyl residue and the Fm ester group were found to be essential for anti-HLE activity. Replacement of the Fm ester group in **20** with *t*-Bu (**26**) and benzyl (Bz) (**27**) ester groups gave poor anti-elastase inhibitors. Furthermore, the importance of tryptophanyl was

Table 3. Physico-chemical data and antielastase activity of cephalosporin sulfones.

	R	% yield	mp (°C)	R_f[a]	t_R (min)	IC_{50}	Formula
16	O-*t*-Bu	24	130 to 131	[a]0.53, [f]0.55	—	1.0	$C_{15}H_{23}NO_8S$
19	Bhpip	42	foam	[a]0.15, [b]0.54	10.9	0.8	$C_{28}H_{31}N_3O_7S$
32	NHFm	30	oil	[f]0.29, [g]0.73	—	<40	$C_{24}H_{22}N_2O_7S$

[a]TLC solvent systems are described in *General methods* section.

demonstrated by the substitution of tryptophanyl 9-fluorenylmethyl ester with prolyl-9-fluorenylmethyl ester and phenylalanyl-9-fluorenylmethyl ester yielding compounds **28** and **29**, respectively, with reduced anti-elastase activity. Finally, the substitution of tryptophanyl-9-fluorenylmethyl ester with commercially available alanyl benzyl ester (**30**) and glycyl benzyl ester (**31**) gave the same results.

Conclusion

We have demonstrated that replacement of *t*-butyl ester group in 7α-methoxycephalosporanic acid 1,1-dioxide with tryptophanyl-9-fluorenylmethyl ester (compound **20**) yields a strong HLE inhibitor with a length of action beyond 24 h. Deprotection of the carboxylic function resulted in loss of activity. Replacement of tryptophan with tetra-tryptophan or other amino acids, as well as replacement of tryptophanyl-9-fluorenylmethyl ester with other tryptophanyl-esters led to compounds with diminished anti-elastase effect. However, replacement of tryptophanyl-9-fluorenylmethyl ester with the hydrophobic *N*-Bhpip gave compound **19** having the same inhibitory effect as **20**, both of which are novel HLE inhibitors.

Excess enthalpies of the ternary mixtures: ethyl *tert*-butylether + *n*-heptane + (*n*-decane or *n*-dodecane) at 298.15 K

Zhaohui Wang, Yoshiteru Horikawa, George C. Benson, and Benjamin C.-Y. Lu

Abstract: Excess molar enthalpies, measured at 298.15 K in a flow microcalorimiter, are reported for the two ternary systems, ethyl *tert*-butylether + *n*-heptane + *n*-decane and ethyl *tert*-butylether + *n*-heptane + *n*-dodecane. Smooth representations of the results were used to construct constant enthalpy contours on Roozeboom diagrams. It is shown that useful estimates of the ternary enthalpies can be obtained from the Liebermann–Fried model using only the physical properties of the components and their binary mixtures.

Key words: excess enthalpies, ternary mixtures, ethyl *tert*-butylether, *n*-alkanes, Liebermann–Fried model.

Résumé : Utilisant un microcalorimètre à écoulement, on a mesuré les enthalpies molaires en excès, à 298,15 K, de deux systèmes ternaires, oxyde d'éthyle et de *tert*-butyle + *n*-heptane + *n*-décane et oxyde d'éthyle et de *tert*-butyle + *n*-heptane + *n*-dodécane. On a utilisé des représentations aplanies des résultats pour construire des contours de constante d'enthalpie sur des diagrammes de Roozeboom. On a démontré que l'on peut obtenir des évaluations utiles des enthalpies ternaires à l'aide du modèle de Liebermann–Fried en n'utilisant que les propriétés physiques des composants et de leurs mélanges binaires.

Mots clés : enthalpies en excès, mélanges ternaires, oxyde d'éthyle et de *tert*-butyle, alcanes linéaires, modèle de Liebermann–Fried.

[Traduit par la Rédaction]

Introduction

In view of the use of ethers as oxygenating agents in gasoline technology, the properties of ether + hydrocarbon systems are of considerable interest. A recent paper (1) from our laboratory described measurements of the excess molar enthalpies of the two ternary mixtures (ethyl *tert*-butylether + *n*-hexane + *n*-heptane and ethyl *tert*-butylether + *n*-hexane + *n*-octane). As a continuation of that investigation, we have made similar measurements for the analogous systems (ethyl *tert*-butylether + *n*-heptane + (either *n*-decane or *n*-dodecane)).

Experimental

Ethyl *tert*-butylether (ETBE), with mol fraction purity exceeding 0.97, was purchased from TCI America. The *n*-heptane (nC7), *n*-decane (nC10), and *n*-dodecane (nC12) were obtained from Sigma-Aldrich. The *n*-alkanes had purities of at least 99 mol%. Apart from partial degassing, all of the component liquids were used without further purification. Their densities, measured at 298.15 K, were 735.39, 680.14, 726.26, and 745.29 kg m^{-3} for ETBE, nC7, nC10, and nC12, respectively. These values are in reasonable agreement with the literature (2–4).

An LKB-Produkter AB (Bramma, Sweden) flow microcalorimeter (Model 10700-1) was used to measure excess molar enthalpies (H^E_m) at 298.150 ± 0.003 K. Details of this equipment and its operation have been described previously (5). The excess molar enthalpies of the ternary mixtures were investigated by measuring the excess molar enthalpies ($H^E_{m,1+23}$) for several pseudo-binary mixtures, in which component 1 (ETBE) was added to binary mixtures of components 2 (nC7) and 3 (either nC10 or nC12), having a fixed mol ratio x_2/x_3. These binaries were prepared by weighing. The excess molar enthalpy ($H^E_{m,123}$) of the ternary mixture was then obtained from the relation:

$$[1] \qquad H^E_{m,123} = H^E_{m,1+23} + (1 - x_1) H^E_{m,23}$$

where $H^E_{m,23}$ is the excess molar enthalpy of the particular binary mixture. Over most of the mol fraction range, the errors in the excess molar enthalpies are estimated to be less than ±0.5%. Errors in the mol fractions of the ternary mixtures are estimated to be less than 5×10^{-4}.

Results and discussion

Excess molar enthalpies ($H^E_{m,ij}$ $(i < j)$) at 298.15 K for four of the five constituent binaries of present interest, have been reported in the literature: ETBE + nC7 (6), ETBE + nC10 and ETBE + nC12 (7), and nC7 + nC12 (8). Table 1 summarizes the present experimental measurements for the binary system nC7 + nC10. The smoothing function:

[a]Ternary term for representation of $H^E_{m,1+23}$ by eqs. [3] and [4]: $H^E_{m,T}$ (J mol^{-1}) = $(x_1x_2x_3/(1 - x_1 + x_2))(456.81 - 484.35x_1 - 661.81x_2)$, s = 2.06.

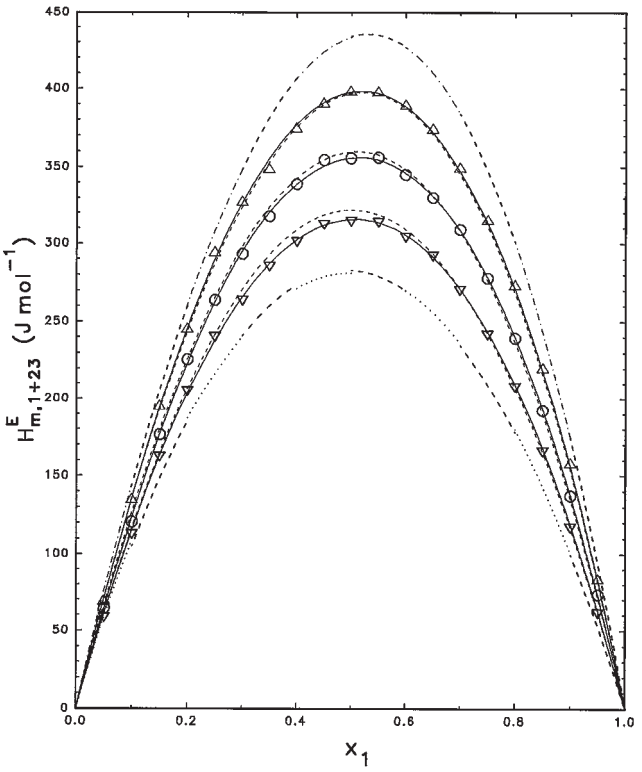

Fig. 3. Excess molar enthalpies ($H^E_{m,1+23}$) at 298.15 K, for the addition of ETBE to binary mixtures of nC7 + nC12 to form $x_1CH_3CH_2OC(CH_3)_3 + x_2CH_3(CH_2)_5CH_3 + x_3CH_3(CH_2)_{10}CH_3$. Experimental results: x_2/x_3 = 0.3335 (△); x_2/x_3 = 0.9999 (○); x_2/x_3 = 3.0029 (▽). Curves: x_2 = 0, (·—·—) Wang et al. (7); x_3 = 0 (····), Peng et al. (6); calculated from the representation of the results by eqs. [3] and [4], using the ternary term $H^E_{m,T}$ given in the footnote of Table 4 (—); estimated from the Liebermann–Fried model (- - - -).

are the values of the standard deviation (s) for each of the representations. Plots of the experimental results in Table 1 and their representation by eq. [2] are presented in Fig. 1.

The experimental results for $H^E_{m,1+23}$ and the corresponding values of $H^E_{m,123}$ are listed in Tables 3 and 4 for the nC10 and nC12 ternary systems, respectively. Plots of $H^E_{m,1+23}$ vs. the mol fraction (x_1) of ETBE are given in Figs. 2 and 3. Also included in these figures are the smooth representations of the excess molar enthalpies of the constituent-binaries, corresponding to the cases x_2 = 0 and x_3 = 0. These were calculated from eq. [2] using the coefficients in Table 2. In all cases, the maximum values of $H^E_{m,1+23}$ and $H^E_{m,123}$ occur near x_1 = 0.5, and for comparable values of x_2/x_3, the maximum is larger for the mixture with nC12. For both systems at constant x_1, the enthalpies decrease as x_2/x_3 increases.

[a]Ternary term for representation of $H^E_{m,1+23}$ by eqs. [3] and [4]: $H^E_{m,T}$ (J mol^{-1}) = $x_1x_2x_3(16.07 + 3483.96x_1 - 1654.81x_2 - 8496.55x_1^2 - 244.63x_1x_2 + 1461.44x_2^2 + 5442.69x_1^3)$, s = 1.94.

As in our previous work (1), the values of $H^E_{m,1+23}$ were represented as a sum of binary terms with an added ternary correction:

$$[3] \qquad H^E_{m,1+23} = \left[\frac{x_2}{1-x_1}\right] H^E_{m,12} + \left[\frac{x_3}{1-x_1}\right] H^E_{m,13} + H^E_{m,T}$$

where the values of the $H^E_{m,ij}$ were calculated from the appropriate smoothing functions. The form (which was adopted for the latter contribution):

$$[4] \qquad \frac{H^E_{m,T}}{\text{J mol}^{-1}} = \left[\frac{x_1x_2x_3}{1+b(x_2-x_1)}\right](c_0 + c_1x_1 + c_2x_2 + c_3x_1^2 + c_4x_1x_2 + c_5x_2^2 + c_6x_1^3 + c_7x_1^2x_2 + \ldots)$$

is similar to the form used by Morris et al. (9) but with the possibility of incorporating an extra skewing factor $(1 + b(x_2 - x_1))^{-1}$. Values of b = 1 and b = 0 were used for the nC10 and nC12 systems, respectively. The values of the parameters (c_k) were obtained from least-squares analyses, in which eqs. [3] and [4] were fitted to the experimental $H^E_{m,1+23}$ in Tables 3 and 4. The results of these analyses are given in the footnotes of the tables, where the standard deviations (s) of the representations are also indicated. The solid curves in Figs. 2 and 3 were calculated from these representations.

Table 5. Values of the interaction parameters A_{ij} and A_{ji}, standard deviation (s) (J mol^{-1}), and isobaric thermal expansivity (α_p) (kK^{-1}) at 298.15 K.

Component					α_p	
i	j	A_{ij}	A_{ji}	s	i	j
ETBE	nC7	0.8726	0.9305	2.10	1.401	1.256
ETBE	nC10	0.9596	0.7906	2.43	1.401	1.051
nC7	nC10	1.0218	0.9622	0.13	1.256	1.051
ETBE	nC12	0.9680	0.7418	2.06	1.401	0.960
nC7	nC12	1.0637	0.9008	0.12	1.256	0.960

Equations [1]–[4] were also used to calculate the constant $H^E_{m,123}$ contours plotted on the Roozeboom diagrams in Figs. 4*a* and 5*a*. The general characteristics of these plots are very similar and are comparable to those found in our earlier work (1). All of the contours extend to the edges of the triangle and there is no indication of an extremum lying within the triangle.

Recently, it has been found that the Liebermann–Fried model (10) can be extended to provide estimates of the thermodynamic properties of multicomponent systems using only the properties of the pure components and interaction parameters derived from analyses of the excess enthalpies of their constituent-binaries. This approach was investigated for the present systems. Reference can be made to the work of Wang et al. (1) for the equations used in this application.

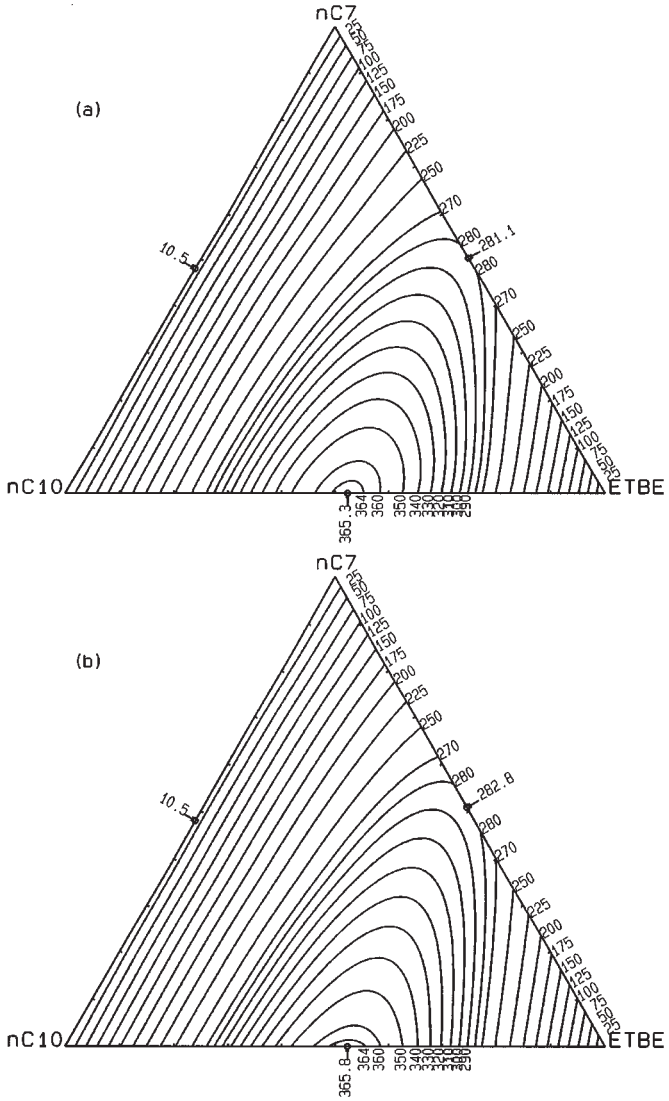
Fig. 4. Contours for constant values of $H^{E}_{m,123}$ /(J mol^{-1}) for the system ETBE + nC7 + nC10 at 298.15 K. (*a*) Calculated from the representation of the experimental results by eqs. [1]–[4] with $H^{E}_{m,T}$ from the footnote of Table 3. (*b*) Estimated from the Liebermann–Fried model.



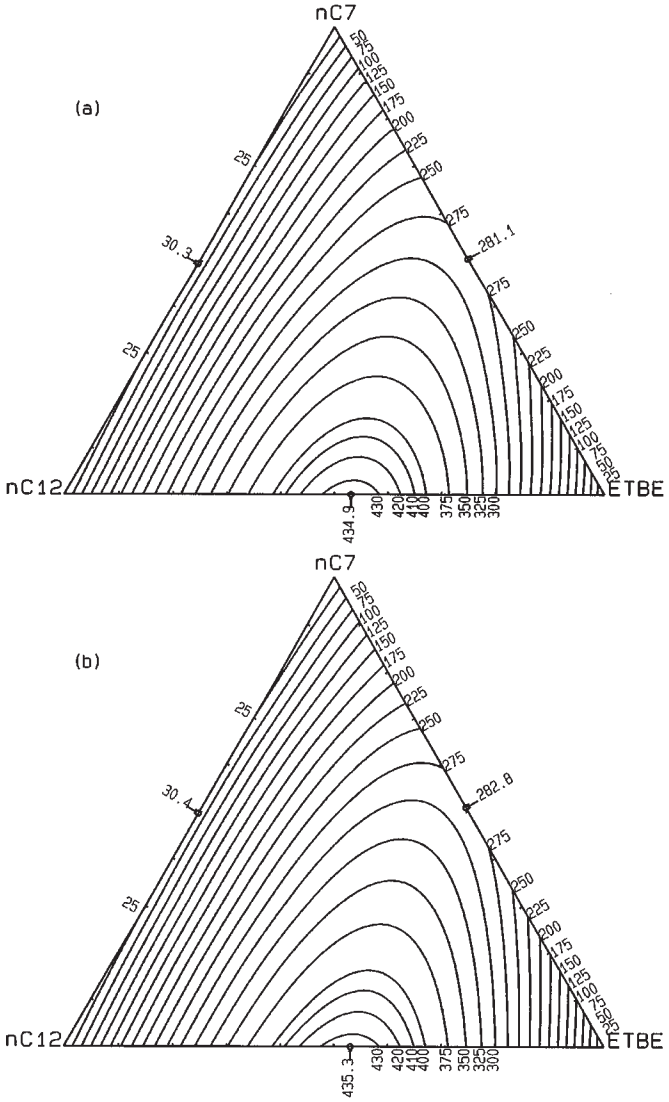


Fig. 5. Contours for constant values of $H^{E}_{m,123}$ /(J mol^{-1}) for the system ETBE + nC7 + nC12 at 298.15 K. (*a*) Calculated from the representation of the experimental results by eqs. [1]–[4] with $H^{E}_{m,T}$ from the footnote of Table 4. (*b*) Estimated from the Liebermann–Fried model.

The Liebermann–Fried interaction parameters (A_{ij} and A_{ji}) for the constituent-binaries are given in Table 5. These values were obtained by fitting the Liebermann–Fried formula for H_{ij} to the primary experimental data for the excess molar enthalpies given in Table 1 and refs. 6–8. Also included in the table are the standard deviations obtained in the fitting process, and values of the isobaric thermal expansivity (α_p) (2, 11), used in evaluating the contributions due to the different sizes of the molcules.

Using the values of the parameters given in Table 5, $H^{E}_{m,1+23}$ and $H^{E}_{m,123}$ were estimated for the present ternary mixtures. The Liebermnn–Fried fits of $H^{E}_{m,ij}$ and the results for $H^{E}_{m,1+23}$ are shown as dashed curves in Figs. 1–3. In general, the fits of $H^{E}_{m,ij}$ are quite good, but there is a tendency to over-estimate the values of $H^{E}_{m,1+23}$. The mean absolute relative deviations of the 58 points for the nC10 system in Table 3 and the 57 points for the nC12 system in Table 4 amount to 1.1% and 1.3%, respectively.

Constant $H^{E}_{m,123}$ contours were also estimated on the basis of the Liebermann–Fried model. For both systems, the overall characteristics of these are quite similar to those derived from the representations of the experimental data by eqs. [1]–[4]. The results of the estimations are shown on the Roozeboom diagrams in Figs. 4*b* and 5*b*. It is clear from a comparison of parts (*a*) and (*b*) in these figures, that for the present type of systems the model provides useful estimates of $H^{E}_{m,123}$ without requiring the direct investigation of the excess enthalpies of any ternary mixtures.

Demethoxylation and hydroxylation of methoxy- and hydroxybenzoic acids by OH-radicals. Processes of potential importance for food irradiation

Birgit Gaisberger and Sonja Solar

Abstract: The hydroxylation process for methoxy- and hydroxy-benzoic acids (MBA, HBA) induced by γ-radiation is compared. 2-, 3-, and 4-methoxybenzoic acid as well as 3-hydroxybenzoic acid have been irradiated in N_2O and aerated solutions up to 1.5 kGy. The products were analyzed by HPLC. The results for 2- and 4-HBA have been taken from literature data. The $OH^{\bullet}$-adduct distribution is generally the same for the hydroxy- as well as for the methoxy-benzoic acid isomers. With both 4-HBA and 4-MBA more than 65% C3-adducts and about 15% C4-adducts are formed, which could be proved by their reactions with $K_3Fe(CN)_6$. Oxidation of the nonipso-adducts of 3-HBA and 3-MBA results in 84 and 87% of the corresponding phenols. Whereas in N_2O-saturated solutions only part of the $OH^{\bullet}$-radicals leads to substrate decomposition, in the presence of air, the degradation of both kinds of compounds is equivalent to $[OH^{\bullet}]$. The nonipso $OH^{\bullet}$-adducts of the HBAs are converted into 68–77% hydroxylation products. With the MBAs, the hydroxylation process is ≤10%. This is attributed to different decay pathways of the peroxyl radicals, intermediates formed by O_2 addition to the $OH^{\bullet}$-adducts. The hydroxyperoxycyclohexadienyl radicals of the HBAs decay mainly by $HO_2^{\bullet}$ elimination to the corresponding phenols, those of the MBAs decay predominantly by fragmentation of the benzene ring, yielding to nonidentified aliphatic products. The replacement of $-OCH_3$ by -OH is practically not influenced by the presence of oxygen, it increases in the sequence 3-MBA < 4-MBA < 2-MBA. For 2-MBA, yields of more than 15% are obtained. Both processes, hydroxylation as well as demethoxylation, might be of importance for the recognition of radiolytical changes in foodstuff.

Key words: γ-radiolysis, methoxybenzoic acids, hydroxybenzoic acids, phenolic acids, food components, reaction mechanisms, product analysis, HPLC analysis.

Résumé : On a fait une étude comparative des processus d'hydroxylation, induits par un rayonnement γ, des acides méthoxy- et hydroxy-benzoïques (AMB, AHB). On a irradié les acides 2-, 3- et 4-méthoxybenzoïques ainsi que l'acide 3-hydroxybenzoïque en solutions saturées en N_2O et en solutions aérées, jusqu'à 1,5 kGy. On a analysé les produits par CLHP. Les résultats pour les acides 2- et 4-AHB correspondent aux données que l'on peut retrouver dans la littérature. La distribution de l'adduit $OH^{\bullet}$ est généralement la même pour les isomères des acides hydroxy- ainsi que méthoxy-benzoïques. Avec les acides 4-AHB et 4-AMB il se forme dans chaque cas plus de 65% d'adduits C3 et environ 15% d'adduits C4 ce qui a pu être démontré par leurs réactions avec le $K_3Fe(CN)_6$. L'oxydation des adduits non ipso des acides 3-AHB et 3-AMB conduit à la formation de 84 et de 87% des phénols correspondants. Lors des réactions en solutions saturées en N_2O, il n'y a qu'une partie des radicaux $OH^{\bullet}$ qui conduit à une décomposition du substrat; par ailleurs, en présence d'air, la dégradation des deux types de composés est équivalent à la $[OH^{\bullet}]$. Les adduits de $OH^{\bullet}$ non ipso des AHB sont transformés à 68–77% en produits d'hydroxylation. Avec les AMB, le processus d'hydroxylation est ≤ 10%. Ceci est attribué à divers modes de décomposition des radicaux peroxyles qui se forment de façon intermédiaire par l'addition de O_2 aux adduits $OH^{\bullet}$. Les radicaux hydroxyperoxycyclohexadiényles des AHB se décomposent principalement par une élimination de $HO_2^{\bullet}$ conduisant aux phénols correspondants alors que ceux des AMB se décomposent principalement par une fragmentation du noyau benzénique en conduisant à des produits aliphatiques non identifiés. Le remplacement d'un $-OCH_3$ par un -OH n'est pratiquement pas influencé par la présence d'oxygène; il augmente dans la séquence 3-AMB < 4-AMB < 2-AMB. Pour le 2-AMB, on obtient des rendements de plus de 15%. Les deux processus, l'hydroxylation ainsi que la déméthoxylation, peuvent présenter de l'intérêt pour la reconnaissance des changements radiolytiques dans les aliments de nature végétale.

Introduction

Hydroxybenzoic acids and their derivatives are ubiquitous in plant material. The phenolic groups of these compounds are often methoxylated or present as glycoside (1–3). Upon irradiation of aqueous aromatic compounds, the main primary process is the electrophilic addition of $OH^{\bullet}$-radicals to activated ring positions, which can eventually result in hydroxylation of the initial material. Such radiolytically formed hydroxylated compounds can be used as markers for irradiated food, as is the case with *o*-tyrosine, originating from phenylalanine in protein rich food (4–7). The detection of hydroxylation products from phenolic acid-food components was proposed in 1989 as a promising chemical method for the detection of irradiation treatment of fruits and vegetables (8, 9), but no marker compounds have been found so far.

For methoxybenzoic acids, it has been reported that upon irradiation in the presence of N_2O and at pH ≤ 3, radical cations and phenoxyl radicals are generated. Radical cations are formed from the nonipso $OH^{\bullet}$-adducts by an acid-catalysed water elimination. The phenoxyl radicals result from methanol elimination from the ipso adduct carrying the methoxyl group (10, 11). The work of these authors concentrated on the detection of these radical intermediates by pulse radiolysis and on the determination of methanol. There are, however, no data concerning the formation of the phenolic products from methoxylated benzoic acids. Upon radiolysis of *ortho*- and *para*-hydroxybenzoic acid, the formation of phenolic products has been found to be the major reaction path (12–15).

This study focuses on a comparison of γ-radiation-induced degradation and hydroxylation processes of benzoic acids with free as well as methoxylated OH-groups, and its importance for the detection of radiation-chemical changes of phenolic components in food of plant origin. Priority was given to the influence of oxygen on the product distribution.

Experimental

Chemicals and preparation of the solutions

All chemicals were of the highest purity commercially available: 4-methoxybenzoic acid (4-MBA) (*p*-anisic acid) (Aldrich, 99%), 3-MBA (*m*-anisic acid) (Aldrich, 99%), 2-MBA (*o*-anisic acid) (Fluka, 99%), 2-hydroxybenzoic acid (2-HBA) (Merck, 98%), 3-HBA and 4-HBA (Merck, 98%), 3,4-dihydroxybenzoic acid (3,4-DHBA) (Aldrich, 97%), 2,3-DHBA (Aldrich, 99%), 2,5-DHBA (Aldrich, 97%), 4-hydroxy-3-methoxybenzoic acid (vanillic acid (VA)) (Aldrich, 97%), 3-hydroxy-4-methoxybenzoic acid (isovanillic acid (iso-VA)) (Sigma, 97%), 2-hydroxy-3-methoxybenzoic acid (3-methoxysalicylic acid (3-MSA)) (Aldrich, 97%), 4-MSA (Aldrich, 97%), 5-MSA (Aldrich, 97%), sodium hydroxide (Fluka, 98%), $K_3Fe(CN)_6$ (Fluka, 98%), and phosphoric acid (Aldrich, 98%). Solutions were made with triple-distilled water. To obtain oxidizing conditions, the solutions were saturated with high purity N_2O or oxygen (5.0, Messer Griessheim) prior to irradiation.

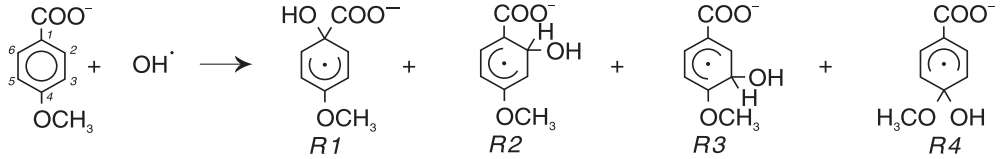
Gamma radiolysis

γ-Radiolysis experiments (Gammacell 220, MDS Nordion International Inc., Kanata, Ontario, Canada) were carried out at a dose rate of 160 Gy min^{-1}, which was determined by Fricke dosimetry using a radiation chemical yield of *G*-value[2] *G* (Fe^{3+}) = 15.6 = 1.617 μmol J^{-1} (16).

Product analysis

Product analysis was carried out by high-performance liquid chromatography (HPLC) using a Hewlett–Packard 1050 chromatograph (column: 125 × 4 mm Spherisorb ODS 2 RP-18 (5 μm), Lichrosorb precolumn, flow rate 1.0 ml min^{-1}) equipped with a multiple wavelength detector. The mobile phase consisted of water (Millipore® filtered) and methanol (Promochem, HPLC grade), the binary gradient was water–methanol 10–35%. (The gradient was 1–5 min: H_2O:CH_3OH = 90:10, 5–10 min: H_2O:CH_3OH = 85:15, 10–20 min: H_2O:CH_3OH = 65:35 per volume). As for 3-HBA the mobile phase was H_2O:CH_3OH = 90:10. The individual compounds were detected by measuring their absorptions at 210, 235, and 255 nm. Concentrations were determined by calibration with standard solutions. The identity of the products was confirmed by comparing the retention time and the UV spectra to that of the corresponding standards. Irradiations were carried out at least in duplicate, the HPLC analyses were reproducible within 10%.

Results and discussion



Radiolysis in the presence of N_2O

In the first step of the investigations, the seven products obtained as a consequence of the $OH^{\bullet}$-radical reactions with the isomers of MBA (anisic acids) were studied. These compounds were used as model substrates for derivatives of hydroxybenzoic acids having the phenol group linked with other residues. 3-HBA was investigated for comparison.

Exposure of water or dilute aqueous solutions to γ-radiation leads to the primary species e^-_{aq}, $OH^{\bullet}$, $H^{\bullet}$, H_2, and H_2O_2. In the presence of N_2O, the e^-_{aq} are converted into $OH^{\bullet}$ (eq. [1]), yielding a *G* ($OH^{\bullet}$) = 5.5, which corresponds to a concentration of 0.57 μmol J^{-1}.

[1] $$e^-_{aq} + N_2O \rightarrow OH^{\bullet} + OH^- + N_2$$

By addition of $OH^{\bullet}$ to methoxylated benzoic acids, isomeric methoxyhydroxycyclohexadienyl radicals (demonstrated for 4-MBA in eq. [2]) are formed, which after several

[2] 

[2] *G*-value is the number of molecules reacting per 100 eV of absorbed energy. Conversion into SI-units: a *G*-value of 1 molecule per 100 eV corresponds to a radiation-chemical yield of 0.10364 μmol J^{-1}.

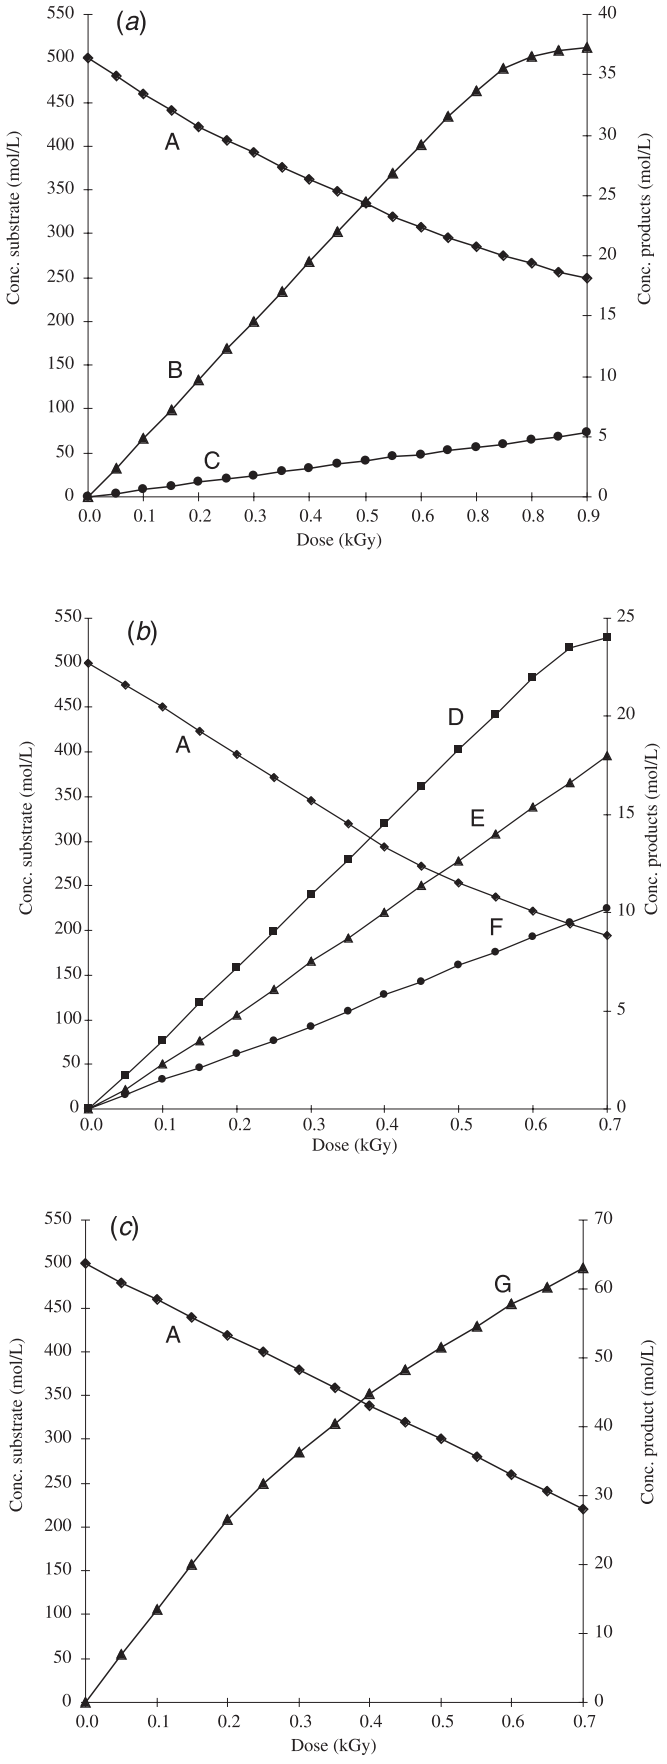

Fig. 1. Concentration–dose dependence curves obtained from irradiated N_2O-saturated aqueous solutions of 5×10^{-4} M of (*a*) 4-MBA, (*b*) 3-MBA, and (*c*) 2-MBA at pH = 8 to 9. List of symbols: (A) decrease of the substrates, (B) formation of iso-VA and 4-HBA, (C) formation of 3,4-DHBA, (D) formation of 3-HBA, (E) formation of VA, (F) formation of 3-MSA, and (G) formation of 2-HBA.

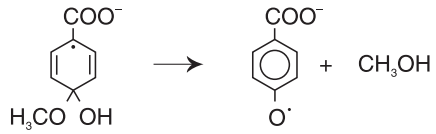
reaction steps, may lead to hydroxylation and oxidative demethoxylation.



The substrates degradation and product formations obtained on radiolysis of aqueus N_2O-saturated 5×10^{-4} M 2-, 3-, and 4-MBAs (pH 8–9) as a function of dose (50 Gy steps) are presented in Figs. 1*a–c*. The irradiations were carried out up to an absorbed dose that gives rise to about 50% substrate decomposition. Representative chromatograms are given in Figs. 2*a–c*.

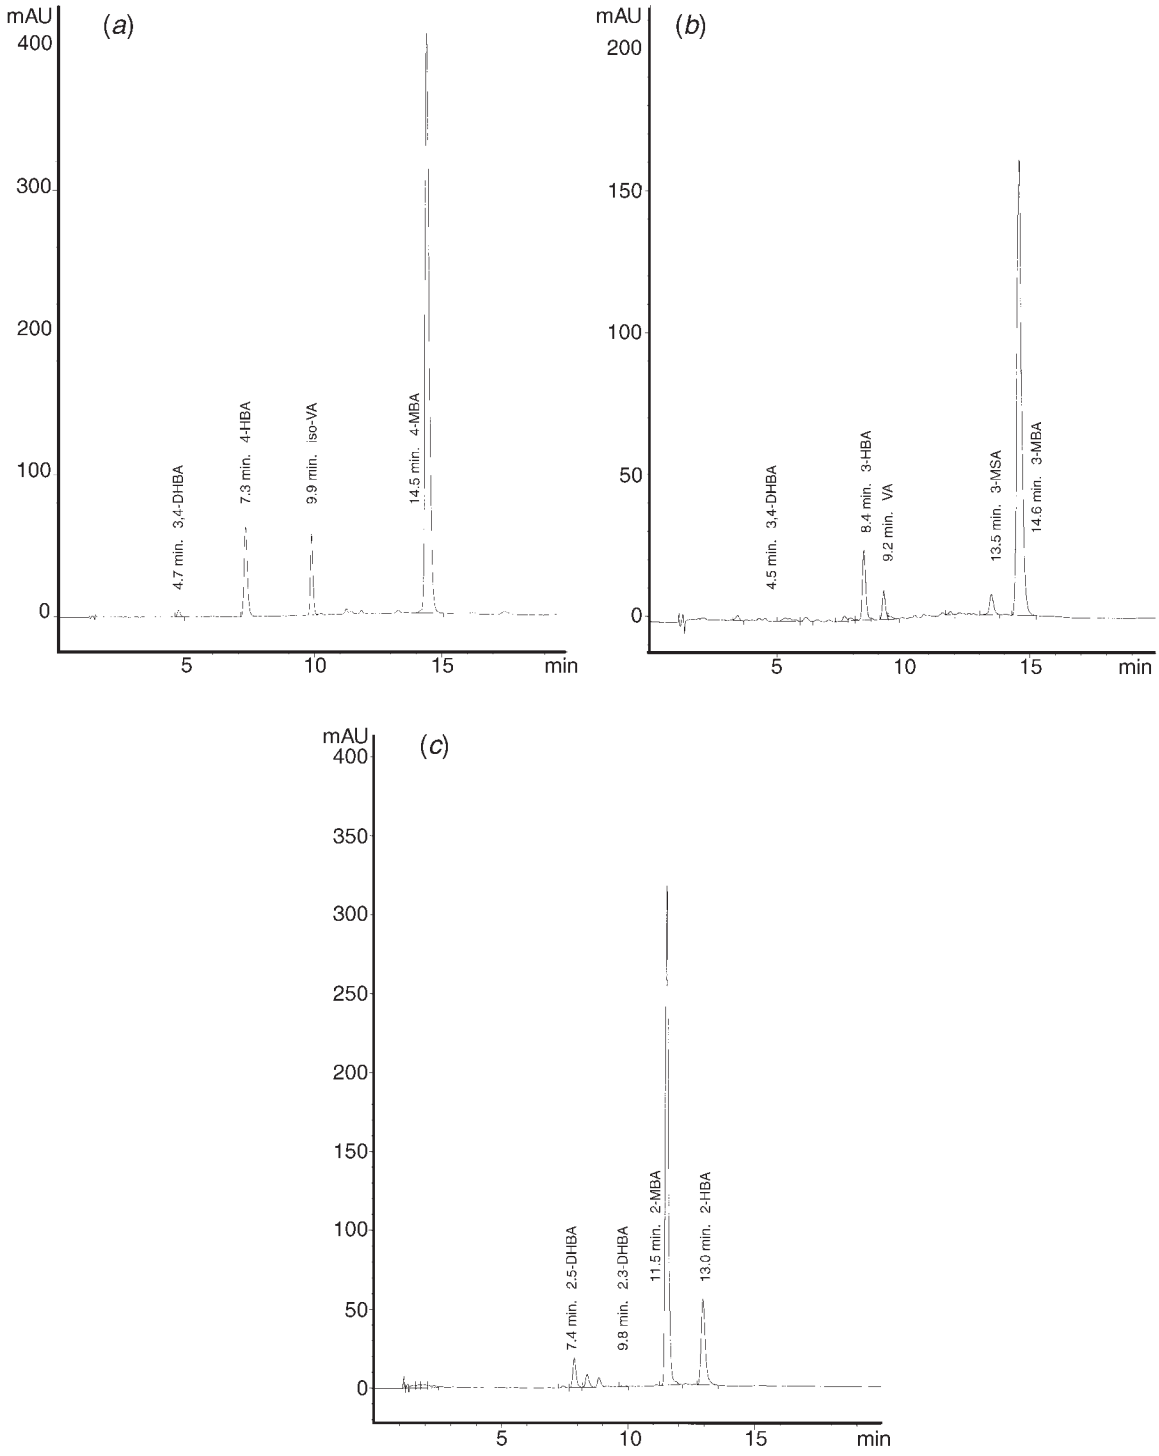
Degradation

The initial degradation yields (G_i)[3], are similar for 4-MBA and 2-MBA (G_i = 3.9 and 4.0), which corresponds to about 70% $OH^{\bullet}$-radical consumption, with the *meta*-isomer 91% of the $OH^{\bullet}$-radicals giving rise to decomposition. The linearity of degradation with dose (up to 300 and 400 Gy for 4-MBA and 3-MBA, respectively), and to more than 700 Gy for 2-MBA, is given in Figs. 1*a–c*. The highest dose for a 50% degradation is required for 4-MBA (0.9 kGy). The HBAs are decomposed to a clearly smaller extent: G_i (-2-HBA) = 2.4 and G_i (-4-HBA) = 2.8 (14, 15). For 3-HBA a decomposition yield of G_i (-3-HBA) = 2.1 was obtained, the 50% degradation is at 1.3 kGy (Table 1). The low initial degradation yields of the HBAs indicate the occurrence of reactions leading to a reformation of the substrates.

Product formation

In the case of 4-MBA, two products could be detected by HPLC (Figs. 1*a* and 2*a*): iso-VA resulting from R3, and 4-HBA which has R4 as precursor (the $OH^{\bullet}$-adduct formed by attachment of $OH^{\bullet}$ to the ring carbon carrying the methoxyl group). Such ipso-adducts have been found to decay by acid- and base-catalyzed or uncatalyzed elimination of CH_3OH producing phenoxyl radicals, the rate constant at pH = 7 was found to be $k \approx 5 \times 10^4$ s^{-1} (10, 11). In the case of radical R4 the 4-carboxyphenoxyl radical is formed (eq. [3]).

[3] 



R4

The yield of the demethoxylation product 4-HBA (G_i = 0.5), accounts for about 10% of the total $OH^{\bullet}$-radicals. This is more than twice as much as reported by O'Neill et al. (10), who used methanol determinations for quantification. The product arising from an $OH^{\bullet}$ attack on the *meta*-position of 4-MBA, is only detectable in traces. The finding of hydroxylation products in *ortho*- and *para*-positions, and the lack of products in *meta*-position to the *ortho–para*-directing

[3] Initial *G*-values (G_i) are calculated from the linear part of dose–yield plots before secondary reactions occur.

Fig. 2. Chromatograms of 5×10^{-4} M N_2O-saturated aqueous solutions of (*a*) 4-MBA irradiated with 0.5 kGy at pH = 9.0, 255 nm; (*b*) 3-MBA irradiated with 0.7 kGy at pH = 8.6, 235 nm; (*c*) 2-MBA irradiated with 0.7 kGy at pH = 8.5, 235 nm.

methoxyl group is in line with the electrophilic nature of the $OH^{\bullet}$-radical (17, 18). The production of the hydroxylation product iso-VA is very low (G_i = 0.46, 8.4% of $OH^{\bullet}$). The formation of the secondary product 3,4-DHBA can also be observed (Fig. 1*a*). It results from the reaction of $OH^{\bullet}$ with the primary final substances 4-HBA and iso-VA. In contrast to 4-MBA, the hydroxylation of 4-HBA is quite efficient; 33% of $OH^{\bullet}$ resulted in 3,4-DHBA with G_i = 1.8 (14, 15) (Table 1).

With 2-MBA, the replacement of the -OCH_3-group by -OH is more effective (G_i (2-HBA) = 1.3), it corresponds to more than 20% of $OH^{\bullet}$. This value is nearly five times higher than that found by methanol determinations (10). The yield of the expected hydroxylation products 2-methoxy-3-

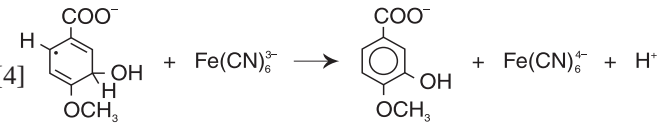
3-HBA	2.1	1.3	1.3	24	—	—	0	0
4-HBA[a]	2.8	0.7	1.8	33	—	—	0.6	11

Note: G ($OH^•$) = 5.5 or 0.57 μmol J^{-1}.
[a]Taken from the literature (14, 15).

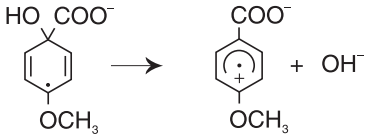


hydroxybenzoic acid and 2-methoxy-5-hydroxybenzoic acid is very low (Figs. 1*c* and 2*c*). Since these compounds were not available for calibration, their yields could only be estimated to approximately $G_i < 0.5$. Comparing this result with the hydroxylation of the corresponding HBA, it is again obvious that in the case of the latter, the hydroxylation process is distinctly higher (Table 1). For salicylic acid, an 83% conversion of the decomposed acid (G_i (-2-HBA) = 2.4) into 2,3- and 2,5-DHBA (G_i = 1.6 and 0.4, respectively), has been reported (13, 14). This selective reaction of $OH^•$ enables the detection of the hydroxylation products of salicylic acid as an indicator for the appearance of $OH^•$ radical in vivo (19).

Irradiation of the *meta*-isomer of anisic acid produces about 6.5% demethoxylation (G_i (3-HBA) = 0.35) and 7% total hydroxylation (G_i (VA) = 0.24 and G_i (3-methoxysalicylic acid) = 0.14) (Figs. 1*b* and 2*b*). The compound 5-methoxysalicylic acid, expected from the $OH^•$ adduct in *para*-position to -OCH_3, could not be detected. Under the conditions used, it has a retention time of 15.5 min. In this time range there is, however, no compound detectable (Fig. 2*b*). Radiolytic products of 3-HBA have been determined in the course of this work. Thirty-eight percent of the $OH^•$-radicals contribute to its degradation (G_i (-3-HBA) = 2.1), the 50% decomposition dose is 1.3 kGy. The hydroxylation products 2,3-, 2,5-, and 3,4-DHBA are formed with G_i = 0.37, 0.43, and 0.52, respectively (Figs. 3*a* and *b*).

The total hydroxylation attributed to substrate degradation is 60%, which is comparable to that of 4-HBA. In contrast to 2- and 4-HBA, no replacement of the carboxyl group is observable. This may be attributed to the *meta*-positioning of the *ortho–para*-directing -OH-group vs. -COO^-, which reduces the probability of $OH^•$-attachment at the carboxyl group.

The yields of degradation, and product formation for the methoxy- and hydroxy-benzoic acids, are summarized in Table 1. Hydroxylation is assigned to the total amount of products resulting from $OH^•$-adducts where $OH^•$ is attached to ring carbons not carrying methoxyl-, hydroxyl-, or carboxyl-groups.



To elucidate whether the pronounced differences in hydroxylation of hydroxy- compared to methoxy-benzoic acids could at least partly be attributable to a different pattern of $OH^•$-radical addition to these substrates, irradiations in the presence of $K_3Fe(CN)_6$ have been performed. $K_3Fe(CN)_6$ and the quinones *p*-benzoquinone and 2-methylbenzoquinone, which have a somewhat lower redox potential, are frequently used to oxidize hydroxycyclohexadienyl radicals, for example, from anisole (17) and phenol (18), to the corresponding phenols. The rate constant for the electron transfer from the isomeric methoxyhydroxycyclohexadienyl radicals of anisole to $K_3Fe(CN)_6$ has been found to be $k(ox)_{o,p} = 2.4 \times 10^9$ M^{-1} s^{-1} for the *ortho*- and *para*-isomer and $k(ox)_m = 2 \times 10^7$ M^{-1} s^{-1} for the *meta*-isomer (17). The distribution of the isomeric hydroxycyclohexadienyl radicals was determined for 4-MBA, 3-MBA, and 3-HBA. For 2-MBA this process could not be carried out because of the lack of

[4] 

hydroxylation products for calibration. The oxidation step is demonstrated for the C3-adduct of 4-MBA (eq. [4]).

The detected oxidation products together with those reported for 4-HBA, obtained by using various quinones as oxidants (12), are summarized in Tables 2*a* and *b*.

The result clearly shows, that the MBAs and HBAs exhibit a similar $OH^•$-adduct distribution. The yields of hydroxylation products primarily formed on the nonipso $OH^•$-adducts are practically the same. 4-MBA and 4-HBA result in 68 and 69% total hydroxylation, respectively, with 3-MBA and 3-HBA 87 and 84% phenolic compounds are produced, respectively, (Tables 2*a* and *b*). For anisole the demethoxylation process has been found to be independent of the presence of an oxidant (17), but it is influenced by pH (11). Radiolysis of 4-MBA without oxidants at pH > 10 showed an increase of 4-HBA formation to 17%, which improves the material balance to about 85%. 4-Methoxyphenol and 3-methoxyphenol, the decarboxylation analogoues to hydroquinone and resorcinol, could not be detected (Tables 2*a* and *b*). Nevertheless, in the case of 4-MBA, the remaining 15% of $OH^•$ presumably adds to the C-1 position; this adduct probably decays by elimination of OH^- forming radical cations (eq. [5]).

[5] 

Since the yields of the nonipso $OH^•$-adducts of methoxy- and hydroxy-benzoic acids are equivalent (Tables 2*a* and *b*),

their diverse hydroxylation can be attributed to the different decay pathways of the $OH^{\bullet}$-adducts. Principally, these transients can undergo unimolecular (eqs. [6] and [7]), and bimolecular reactions (eqs. [8], [9], and [10]):

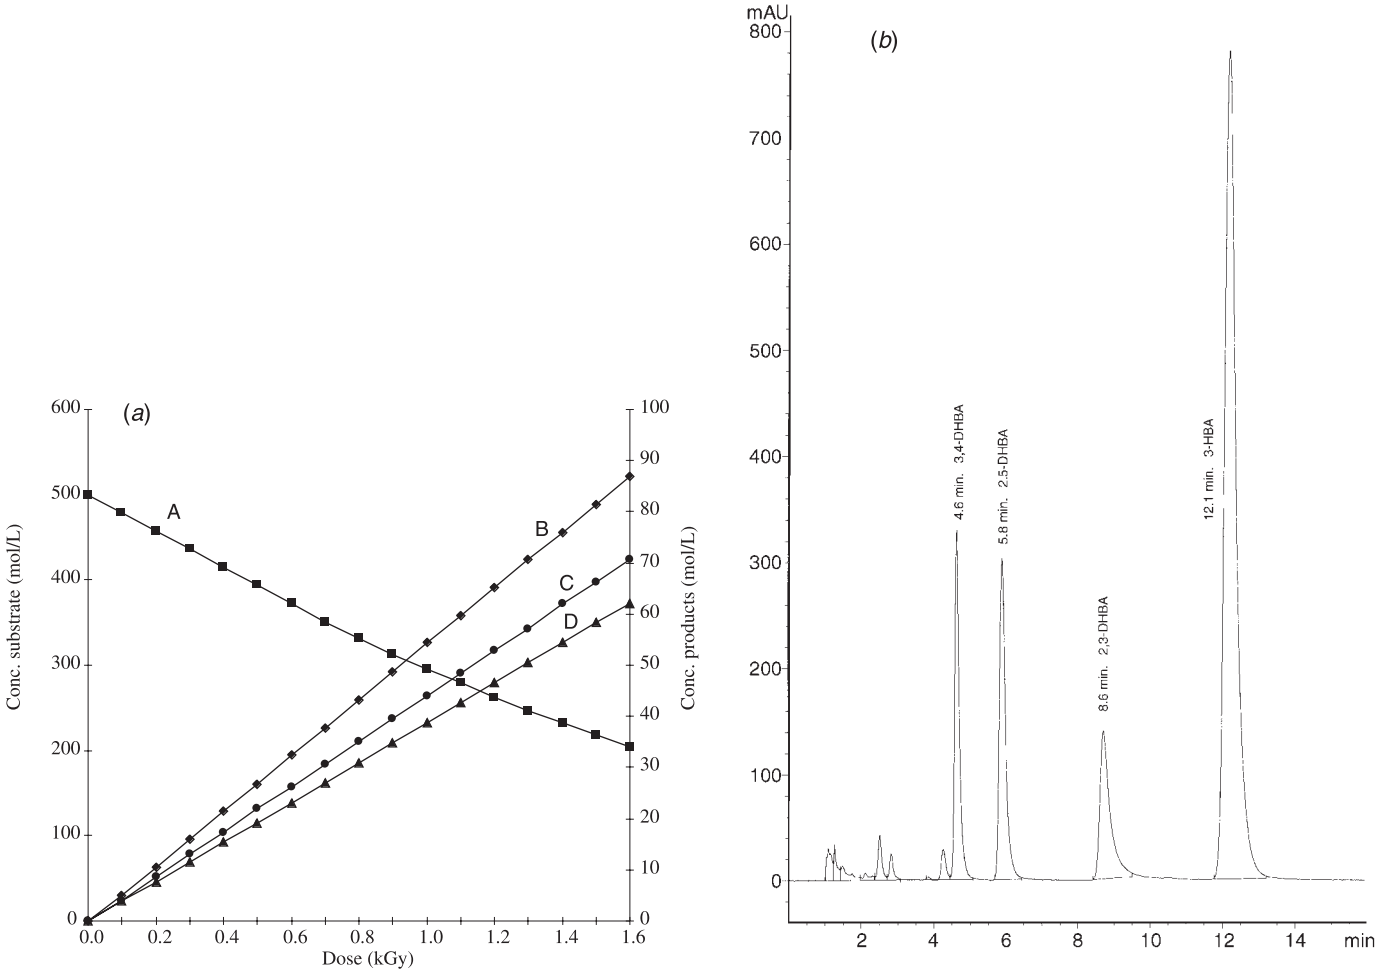
[6] 

[7] 

[8] 

[9] 

[10] dimerisation



In acid solutions in the case of methoxylated benzoic acids (R = CH_3), the formation of radical cations (eq. [6]), has been found to be the major path. Their production have been followed for di- and tri-methoxylated benzoic acids in the pH range 1–3 using optical and conductometric pulse radiolysis (10). For HBAs (R = H, eq. [7]), an acid- and base-catalyzed water-splitting takes place (12–15). During γ-radiolysis the concentration of radicals is very low, and first-order reactions are likely to proceed faster than second-order ones. Thus the radicals formed initially may be altered by first-order processes (eqs. [6] and [7]), before radical centers are finally removed by second-order dismutation and dimerization (eqs. [8], [9], and [10]). Cross reactions (eq. [8]) between phenoxyl radicals (e.g., resulting from ipso-adducts, eq. [3]) and hydroxycyclohexadienyl radicals, seem quite probable because of the driving force exerted by the different redox potentials. For the MBAs, phenoxyl radical production is restricted to eq. [3]. Therefore hydroxylation- and demethoxylation-products formed via eq. [8], are generated in the same proportion as can be seen for 3- and 4-MBA (>6 and 8% each) (Table 1). In the case of HBAs, besides hydroxylation, the starting compound is regenerated. The latter is reflected in the lower initial degradation yield of the HBAs (Table 1).

Radiolysis in the presence of $SO_4^{-\bullet}$

Degradation rates of 4-MBA initiated by its radical cation have not yet been reported. The generation of $4\text{-MBA}^{+\bullet}$ is achieved by oxidation of 4-MBA with $SO_4^{-\bullet}$ (k_{13} = 3.5 ×

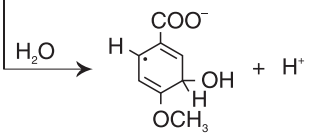
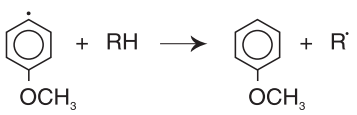
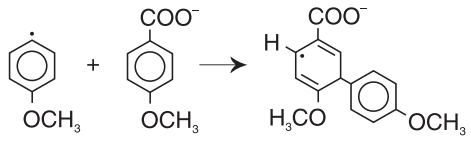
10^9 M^{-1} s^{-1}) (20), which is formed by reduction of $S_2O_8^{2-}$ with e_{aq}^- in air-free solutions ($k_{12} = 1.1 \times 10^{10}$ M^{-1} s^{-1}) (21). The $OH^{\bullet}$-radicals are scavenged by 2-methyl-2-propanol (*t*-BuOH) ($k_{11} = 6 \times 10^8$ M^{-1} s^{-1}) (22) (eqs. [11], [12], and [13]). Concentrations used were 500 μmol 4-MBA, 5 mmol $K_2S_2O_8$, and 100 mmol *t*-BuOH (pH = 6.5, Ar saturation). Since k (e_{aq}^- + 4-MBA) = 2×10^9 M^{-1} s^{-1}) (23) 5 mmol $K_2S_2O_8$ are sufficient to scavenge 98% of the e_{aq}^-.



[11] $(CH_3)_3COH + OH^{\bullet} \rightarrow H_2O + (CH_3)_2C^{\bullet}H_2COH$



[12] $e_{aq}^- + S_2O_8^{2-} \rightarrow SO_4^{-\bullet} + SO_4^{2-}$



[13] $SO_4^{-\bullet} + \text{4-MBA} \rightarrow \text{4-MBA}^{+\bullet} + SO_4^{2-}$

Radical cations of benzoic acid have been found to decay by decarboxylation, giving rise to phenyl radicals, and (or) by addition of water to hydroxycyclohexadienyl radicals. For benzoate the distribution of these radicals is 70%:30% (24). Phenyl radicals are known to decay by H-abstraction, for example, from donors such as alcohols or by addition to an aromatic system resulting in the formation of substituted cyclohexadienyl radicals. The rate constants for both processes are in the range of 10^6–10^7 M^{-1} s^{-1} (25). The cyclohexadienyl radicals can be oxidized, thus giving stable biphenylic products, which has been demonstrated for halogenated benzoic acids (26). On the basis of these results, the following decay reactions of 4-$MBA^{+\bullet}$ are likely to proceed:

[14]

Note: G ($OH^•$) = 2.8 or 0.29 μmol J^{-1}.
[a]Taken from the literature (14, 15).

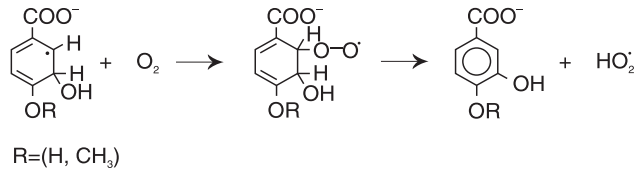
If water addition (eq. [15]) is of importance, hydroxylated compounds may be formed after fixing of the hydroxyl moiety on the ring via e.g., eqs. [8] and [9]. Methoxyphenyl radicals (eq. [14]) should result in anisole (eq. [16]), and (or) in various methoxylated biphenyls, having e.g., eq. [17] as precursor. Since such biphenyl compounds were not available as reference substances, their formation could not be confirmed by HPLC.

The degradation rate is rather slow (G_i (-4-MBA) = 0.6), which corresponds to 22% of e^-_{aq}. No hydroxylation products could be detected, demonstrating that water addition to the radical cation (eq. [15]) plays a minor role. Anisole is not produced either, therefore, presumably, biphenyls formed via eq. [17], can be expected to be the major products in the decay process of the radical cations of 4-MBA. Since no radiolytic products were detectable, the concentration vs. dose plot, as well as the HPLC chromatogram, are not presented. The data were of similar quality to those in earlier figures.

Radiolysis in the presence of oxygen

Oxygen is present in plant tissue, and, therefore, its influence on radiolytic product formation has to be taken into account. The substrates have been irradiated in aerated solutions ($[O_2] = 0.25 \times 10^{-3}$ M). In the presence of oxygen, the reducing radicals $H^•$ and e^-_{aq} are scavanged, forming $HO_2^•$ and $O_2^{-•}$:

[18] $H^• + O_2 \rightarrow HO_2^•$ $k = 2.1 \times 10^{10}\ M^{-1}\ s^{-1}$ (20)



[19] $e^-_{aq} + O_2 \rightarrow O_2^{-•}$ $k = 2.0 \times 10^{10}\ M^{-1}\ s^{-1}$ (20)

[20] $H^+ + O_2^{-•} \leftrightarrows HO_2^•$ pK = 4.8

The rates of reactions of superoxide radicals with organic substances have been found to be rather slow (27), thus $OH^•$-radicals remain the most reactive species. As the main difference to the N_2O conditions, the addition of oxygen to the primarily formed $OH^•$-adducts is to be expected. The peroxyl radicals formed thereby may undergo various decay processes. The most ubiquitous are $HO_2^•$ or $O_2^{-•}$ elimination, especially by those radicals which carry the peroxyl radical function in *ortho*-position to the H-atom to be eliminated (28).

This reaction course is demonstrated on the C3-$OH^•$-adducts of 4-MBA and 4-HBA:

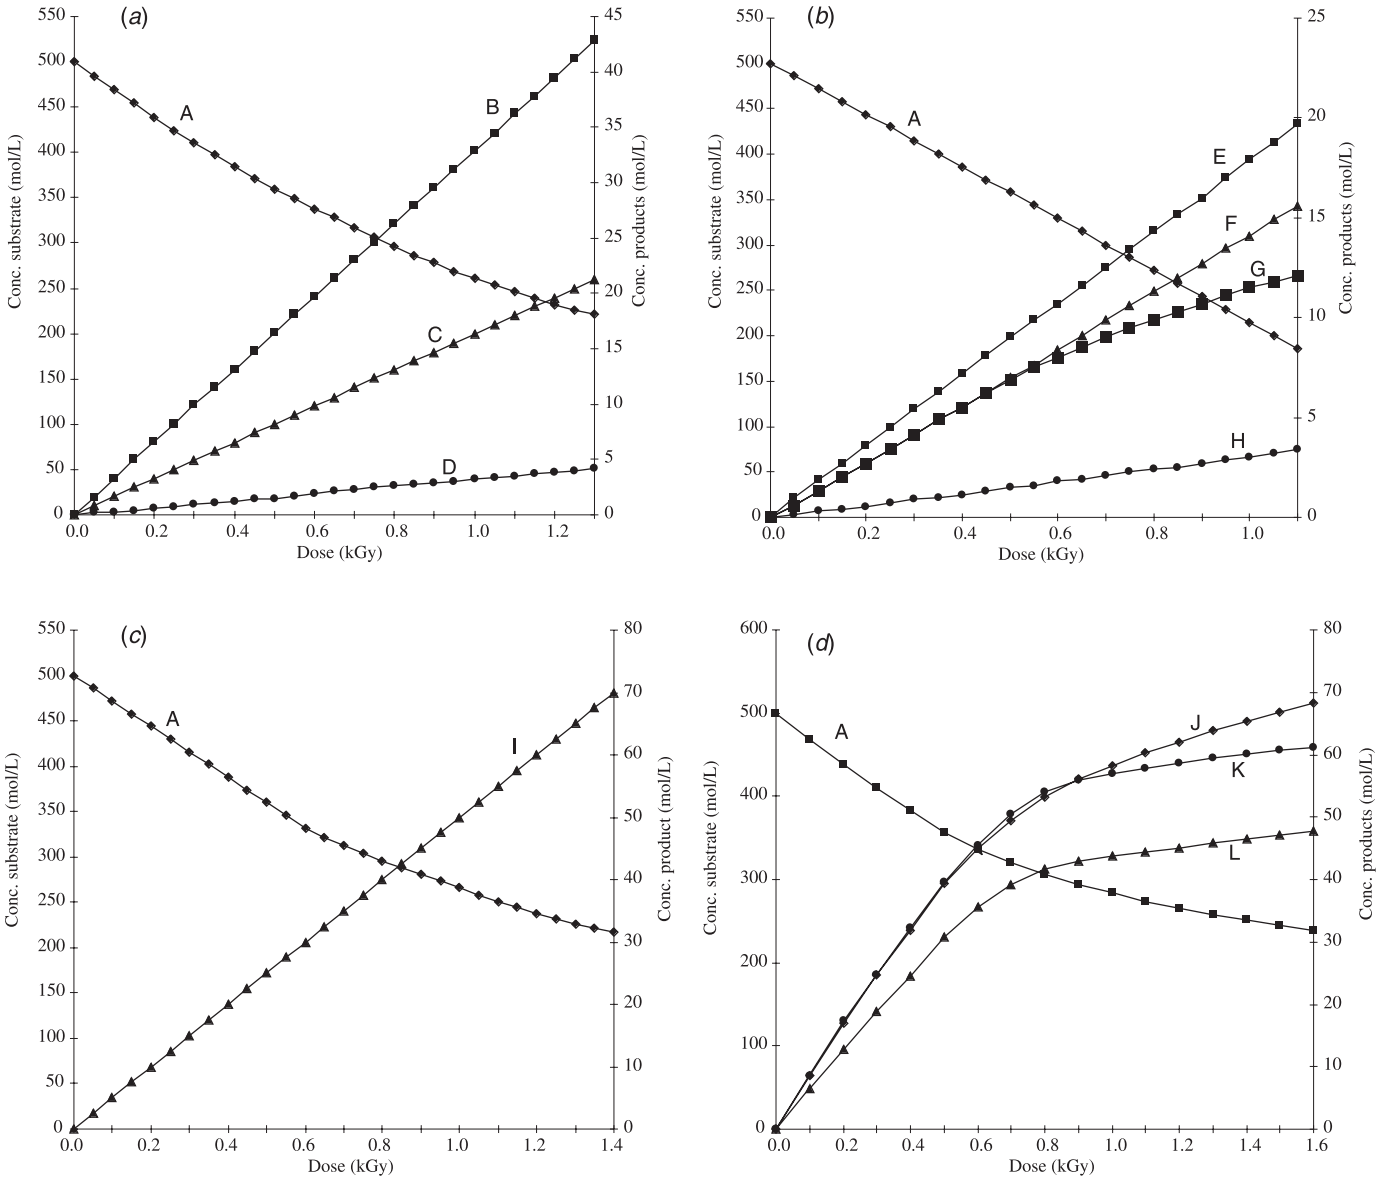
[21]

It was of particular interest whether the presence of oxygen would enhance the formation of hydroxylation products of the MBAs as was the case in the presence of the oxidant $K_3Fe(CN)_6$ and as has been reported for 2- and 4-HBA (14, 15). As a consequence, this would enhance the probability for using hydroxylated products of phenolic acids as markers for irradiation treatment of food-vegetables, as has been suggested previously (8, 9).

Aerated solutions of 500 μmol 2-, 3-, and 4-MBA as well as 3-HBA (pH 8), have been irradiated in 50 Gy steps. The substrate degradation and the concentration of the phenolic products are presented in Figs. 4*a–d* as a function of dose. Characteristic chromatograms are given for 3-MBA and 3-HBA in Figs. 5*a* and *b.*

The initial yields of degradation, phenolic product formation, as well as the 50% decomposition dose for the isomers of MBA and HBA are summarized in Table 3.

Decomposition



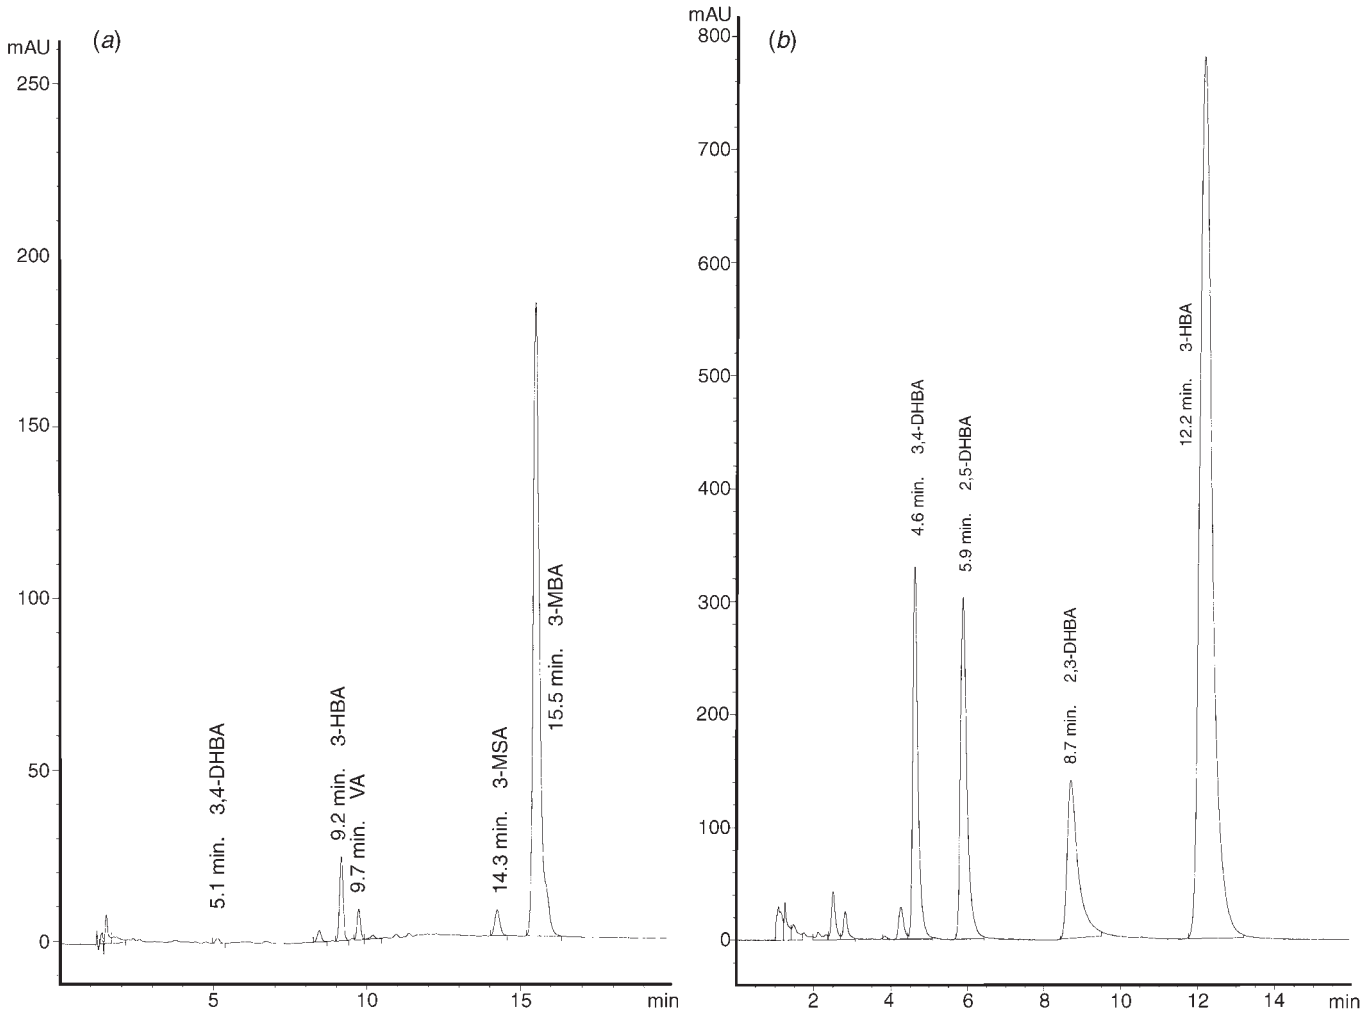
In contrast to the N_2O saturated solutions in the presence of air, no substrate reversion takes place. All $OH^•$-radicals contribute to the degradation of the hydroxy- and methoxybenzoic acids, indicating the addition of O_2 to the $OH^•$-adducts. Their decomposition rates are comparable, a dose of about 1 kGy is required for 50% degradation. 2-HBA and 3-HBA exhibit a somewhat higher radiation resistance; their half-life dose is 1.4 kGy.

Product formation

Upon radiolysis of the HBAs in the presence of air, a considerable amount of phenolic products has been found. For salicylic acid: 2,3-DHBA (G_i = 0.85) and 2,5-DHBA (G_i = 1.1) (13, 14), this corresponds to a conversion of 69% of the $OH^•$-radicals into hydroxylation of the substrate. In the case of 4-HBA, 3,4-DHBA is formed with G_i = 1.9 (i.e., 68% of $OH^•$) (12, 14). 3-HBA yields three hydroxylation products: 2,3-DHBA (G_i = 0.61), 2,5-DHBA (G_i = 0.77), and 3,4-DHBA (G_i = 0.77), in total this amounts to 77% of the $OH^•$-radicals. Whereas the conversion factor of $OH^•$ to

© 2001 NRC Canada

Fig. 4. Concentration–dose dependence curves obtained from irradiated aerated aqueous solutions of 5×10^{-4} M of (*a*) 4-MBA, (*b*) 3-MBA, (*c*) 2-MBA, and (*d*) 3-HBA at pH = 7–9. List of symbols: (A) decrease of the substrates, (B) formation of 4-HBA, (C) formation of iso-VA, (D) formation of 3,4-DHBA, (E) formation of 3-HBA, (F) formation of VA, (G) formation of 3-MSA, (H) formation of 3,4-DHBA, (I) formation of 2-HBA, (J) formation of 3,4-DHBA, (K) formation of 2,5-DHBA, and (L) formation of 2,3-DHBA.



hydroxylation was 0.3 ± 0.06 for the HBAs in N_2O, in aerated solutions its value is 0.75 ± 0.05, which confirms the proceeding of eq. [21] as major reaction pathway at radiolysis of HBAs in aerated solutions.

For the MBAs, the presence of air is not reflected in an enhancement of $OH^{\bullet}$ conversion, either into hydroxylation or into the oxidative replacement of the methoxyl group (Tables 1 and 3). The yields of both product types about 10%, except the demethoxylation of 2-MBA, which is >15%. The hydroxylation product for 4-MBA (iso-vanillic acid) is formed with $G_i = 0.16$. The products expected for 2-MBA, 2-methoxy-3-hydroxybenzoic acid and 2-methoxy-5-hydroxybenzoic acid, which were not available for calibration, could be estimated to be <10% (Fig. 4*c*). From the *meta*-isomer 3-MBA, only two of three possible substances were detectable, VA and 3-MSA with $G_I = 0.14$ each. The product with -OH in *para*-position to the $-OCH_3$ group (5-methoxysalicylic acid), is not formed, as was the case in N_2O-saturated solutions (Table 3). In addition, experiments in oxygen-saturated solutions ($[O_2] = 1.25 \times 10^{-3}$ M) have been carried out. Even a level of oxygen which was five times higher did not influence the yield of the hydroxylation products.

The rate constants of the $OH^{\bullet}$-adducts of the MBAs and HBAs with oxygen are not known, but it can be assumed that they are comparable. For anisole and benzoate this rate constant has been found to be $k = 8 \times 10^8$ M^{-1} s^{-1} and $k = 2 \times 10^8$ M^{-1} s^{-1}, respectively, (28, 29). Thus it can be deduced that the rate constant for oxygen addition to the $OH^{\bullet}$-adducts of the MBAs is sufficiently large to ensure a quantitative

Fig. 5. Chromatograms of 5×10^{-4} M aerated aqueous solutions of (*a*) 3-MBA irradiated with 1.0 kGy at pH = 8.4, 235 nm; (*b*) 3-HBA irradiated with 1.2 kGy at pH = 6.9, 210 nm.

conversion into peroxyl radicals, as is the case with the HBAs. The decay, however, takes different courses. As could be shown for benzene and substituted benzenes, if O_2 instead of $K_3Fe(CN)_6$ is used as oxidant, the conversion of the hydroxycyclohexadienyl radicals into the corresponding phenols is no longer quantitative (29, 30). There are mainly two competitive decay pathways for hydroxycyclohexadienylperoxyl radicals: (*i*) $HO_2^{\bullet}$ elimination leading to phenols, and (*ii*) a formation of *endo*-peroxidic structures, which in turn are converted into peroxyl radicals and subsequently undergo fragmentation (29–31). Apparently fragmentation is the dominant reaction path with the MBAs. This is confirmed by the fact that no aromatic products are detectable by HPLC. Presumably aliphatic aldehydes and acids are the radiolytic products.

The yields for the products resulting from $-OCH_3$ replacement did not change in aerated solutions. This independence of demethoxylation on the presence of an oxidant is in line with the data obtained for anisole (17). The dominant reaction for the ipso-adducts carrying the methoxyl group is a prompt methanol elimination under formation of phenoxyl radicals. Since the decay of the latter is not influenced by the presence of oxygen, the product partition in aerated and N_2O solutions is comparable (Tables 1 and 3).

Conclusions

Although the primarily formed $OH^{\bullet}$-adducts are present in the same concentration for both the hydroxy- and methoxybenzoic acids, their final hydroxylation product yields are distinctly different. Whereas 68–77% of the $OH^{\bullet}$-adducts of the HBAs are converted to hydroxylation products in the presence of air, only about 10% hydroxylation occurs with the $OH^{\bullet}$-adducts of the MBAs. This fact is attributable to different decay pathways of the intermediate peroxyl radical.

The detection of hydroxylation products of phenolic acids has been suggested as a promising method for the identification of irradiated food of plant origin. Free HBAs, in the nonmethoxylated form, will produce sufficient amounts of hydroxylation products. If the OH-groups of phenolic acid derivatives are, however, linked to other residues (e.g., present as ether, ester, or glycoside) the hydroxylation process can expected to be of less significance.

© 2001 NRC Canada

The oxidative replacement of the -OCH_3 by -OH amounts to between 10–20%. Such addition–elimination reactions may be of importance for e.g., the release of glycoside residues. Preliminary radiolysis results from chlorogenic acid (3-(3,4-dihydroxycinnamoyl)quinic acid) showed the formation of caffeic acid (3,4-dihydroxycinnamic acid), indicating the occurrence of this process.

Glutathione radical: Intramolecular H abstraction by the thiyl radical

A. Rauk, D.A. Armstrong, and J. Berges

Abstract: Ab initio computations (B3LYP/6-31G(D)) were used to predict transition structures and energies of activation for intramolecular H atom transfer to a thiyl radical ($RS^{\cdot}$) from the α-C—H bonds of glutathione (**1**) and from the model compounds, *N*-formylcysteinylglycine (**2**) and *N*-(2-thioethanyl)-γ-glutamine (**3**). For each compound, transition structures were located by in vacuo calculations on the neutral non-zwitterionic system. Thermodynamic functions derived at the same level and single point calculations at the B3LYP/6-311+G(3df,2p) level, were used to derive free energies of activation ($\Delta G^{\neq}$) and reaction ($\Delta G°$). For abstraction of the α-C—H (Gly) by the thiyl radical in the gas phase, $\Delta G^{\neq}$ = 134 kJ mol^{-1} if the amide link to Gly is in the more stable (*Z*)-configuration, and $\Delta G^{\neq}$ = 52 kJ mol^{-1} if it is in the less stable (*E*)-configuration. The isomerization of the amide group requires about 95 kJ mol^{-1}. Previous studies had indicated that for intramolecular reaction of the thiyl radical at α-C—H (Cys), $\Delta G^{\neq}$ = 110 kJ mol^{-1}. The lowest energy pathway for intramolecular H-transfer to the thiyl radical is from α-C—H (Gln), $\Delta G^{\neq}$ = 37–42 kJ mol^{-1}, and corresponds rather well with experimental results in solution ($\Delta G^{\neq}$ = 43 kJ mol^{-1}). The calculated free energy change for the equilibrium between thiyl and α-C forms of the glutathione radical is $\Delta G°$ = –54 kJ mol^{-1}. The value estimated from experimental data is $\Delta G°$ = –37 kJ mol^{-1}. The agreement between the energies from theory in the gas phase and experiment in solution suggests that the free energies of solvation of reactant thiyl radical, transition structures for H abstraction, and the product α-C-centred radical, are very similar. The effects of solution were estimated by two continuum models (SCIPCM and COSMO). The SCIPCM model yields results very similar to the gas phase, predicting a modest lowering of the activation free energy. The results from the COSMO method were inconclusive as to whether a rate enhancement or decrease could be expected.

Key words: glutathione, thiyl radical, α-C-radical, hydrogen transfer.

Résumé : On a effectué des calculs ab initio (B3LYP/6-31G(D)) pour prédire les structures de transition et les énergies d'activation pour le transfert intramoléculaire d'un atome H à un radical thiyle ($RS^{\cdot}$) à partir des liaisons α-C—H du glutathion (**1**) et de composés modèles (*N*-formylcystéinylglycine (**2**) et *N*-(2-thioéthanyl)-γ-glutamine (**3**)). Pour chacun des composés, on a localisé les structures de transition par des calculs dans le vide au même niveau et on a utilisé des calculs ponctuels au niveau B3LYP/6-311+G(3df,2p) pour en tirer les énergies libres d'activation ($\Delta G^{\neq}$) et de réaction ($\Delta G°$). Pour l'enlèvement du α-C—H (Gly) par le radical thiyle en phase gazeuse, $\Delta G^{\neq}$ = 134 kJ mol^{-1} si la liaison amide du Gly est dans la configuration la plus stable (*Z*) et $\Delta G^{\neq}$ = 52 kJ mol^{-1} si elle est dans la configuration (*E*) qui est moins stable. L'isomérisation du groupe amide nécessite environ 95 kJ mol^{-1}. Des études antérieures avaient suggéré que pour la réaction intramoléculaire du radical thiyle avec le α-C—H (Cys), $\Delta G^{\neq}$ = 110 kJ mol^{-1}. La voie réactionnelle de plus faible énergie pour le transfert intramoléculaire vers le radical thiyle à partir de α-C—H (Gln), $\Delta G^{\neq}$ = 37–42 kJ mol^{-1}, et cette valeur correspond assez bien avec les résultats expérimentaux en solution, $\Delta G^{\neq}$ = 43 kJ mol^{-1}. La valeur calculée pour le changement d'énergie libre pour l'équilibre entre le thiyle et les formes α-C du radical glutathion est $\Delta G°$ = –37 kJ mol^{-1}. L'accord entre les énergies calculées de façon théorique en phase gazeuse et les valeurs expérimentales en solution suggère qu'il y existe une grande similarité entre les énergies libres de solvatation du radical thiyle qui réagit, des structures de transition pour l'enlèvement de H et du produit à radical centré sur le α-C. On a évalué les effets de solution par deux modèles continus, SCIPCM et COSMO. Le modèle SCIPCM conduit à des résultats qui sont très semblables à ceux obtenus en phase gazeuse et il prédit un faible abaissement de l'énergie libre d'activation. Les résultats obtenus grâce à la méthode COSMO ne permettent pas de conclure si l'on peut s'attendre à une augmentation ou à une diminution de la vitesse de réaction.

Mots clés : glutathion, radical thiyle, radical α-C, transfert d'hydrogène.

Fig. 1. The three pathways for intramolecular H atom transfer in GSH thiyl radical.

Introduction

Glutathione (γ-glutamylcysteinylglycine, GSH **1**) is a ubiquitous tripeptide which plays a number of vital roles in cell metabolism, including repair of oxidative damage in red blood cells and elsewhere (1). In the central nervous system, as well as being a free radical scavenger, GSH has been suggested to function as redox modulator of ionotropic receptor activity, and possibly as a neurotransmitter (2). Decreased GSH levels have been associated with increased oxidative stress in various neurological disorders, including Lou Gehrig's disease (ALS), Parkinson's disease, and Alzheimer's disease (2).

1

The side group of the cysteine residue reacts rather rapidly with all oxidizing agents, including $OH^{\bullet}$ (3–5), $Br_2^{(-\bullet)}$, and $N_3^{\bullet}$, forming the thiyl radical ($RS^{\bullet}$), which, in experiments involving glutathione, has been shown to abstract a hydrogen atom intramolecularly from the α-carbon centre of the glutamyl residue (6, 7). Indeed it has been concluded that at physiological pH, under conditions of both low GSH and O_2 concentration, where the product $[O_2][GSH]\ 1 \times 10^{-7}$, the intramolecular H-transfer pathway becomes the main controlling route for processing of the initially formed thiyl radical (7).

The cysteine residue is present in most proteins and in a number of them, plays a central active role in oxidation–reduction reactions where free radicals can be involved. In thioredoxin reductase and similar enzymes, cysteines appear in pairs of the type -Cys-X-X-Cys- and reduction is effected through electron transfers which cycle between disulfide and sulfhydryl forms (1, 8). The reactivity and ultimate fate of the thiyl radical of GSH serves as a realistic model for parallel processes which can occur in proteins.

In a more general sense, the site of radical formation causing oxidative damage to proteins is a matter of great interest, since such damage is implicated in numerous pathological disorders (3) and in the process of aging. Oxidation is generally initiated by $OH^{\bullet}$ radicals or other radicals created from enzyme reactions (3, 9–12), or by ultraviolet and ionizing radiation (13). The α-carbon center of amino acid residues is also a major point of direct attack (3, 14, 15).

In previous work (16), we have established the methodology for the accurate determination of α-C—H bond dissociation energies (BDEs). We showed explicitly in the case of glycine, alanine, serine, and threonine residues (17), and the anhydrides of glycine and alanine (18), that the α-C—H BDEs are lower than for RS—H, and therefore could potentially be damaged by thiyl radicals. We (17) also established that some site specificity of such oxidative damage is expected, namely that these residues in disordered or β-sheet (glycine only) regions of the protein may be most readily damaged, but that the α-helical secondary structure confers some protection.

The present work addresses the modes of internal transfer of oxidative damage from the cysteine thiyl radical of GSH. The three potential pathways of H atom abstraction from the α-C-centers (rxn. [1]) are shown in Fig. 1. Experimental observations by pulse-radiolysis–EPR have been interpreted as following path **c**, i.e., H-transfer from the α-C site of the glutamyl moiety (19).

An examination is made of the effects of aqueous solution on the energetics of the H atom transfer pathways using continuum models. For the large molecules considered here, it is not possible to optimize structures in the presence of the

© 2001 NRC Canada

solvent reaction field. Since the initial structures must be optimized in the "gas phase," we have used the neutral species rather than the anionic species, which predominate at the conditions of the experiment (pH above 7), but which yield nonrepresentative self-solvated conformations in vacuum.

Computational details

All ab initio calculations presented here were performed with the Gaussian-94 (G94) and Gaussian-98 (G98) molecular orbital packages (20). The geometry optimizations and frequency calculations were carried out at the B3LYP/6-31G(d) level by the hybrid HF–DFT procedure implemented in the Gaussian molecular orbital packages. The vibrational frequencies were scaled by a factor of 0.98 in considering the zero-point energy (ZPE) (21) and in the calculation of thermodynamic functions (($H^\circ_{298} - H^\circ_0$) and S°_{298}). The latter were calculated in the rigid rotator-harmonic oscillator approximation (22). All internal motions were considered as vibrations. The gas phase partition functions for molecular rotation and translation were considered to be unchanged in solution.

Single point calculations at the B3LYP/6-31G(d,p) level with keyword SCRF=SCIPCM (23), and at the B3LYP/6-311+G(3df,2p) level with keyword SCRF=CPCM (the continuum model, COSMO (24), using Pauling radii (25, 26)) were carried out to evaluate the free energy of solution in water. The implementation (called CPCM in G98) provides an analysis of the total free energy of solvation (ΔG (solv)) in terms of electrostatic and nonelectrostatic contributions (ΔG (es) and ΔG (nes), respectively), while the SCIPCM model as implemented in G94, contains only the electrostatic terms (23, 26).

The energies (E) and ZPE results of B3LYP calculations, and derived "relative" quantities (ΔH°_0, ΔH°_{298}, ΔS°_{298}, and ΔG°_{298}) are collected in Table 1. Relative quantities are relative to the most stable conformer of each species. The quantities in columns 11, 12, and 14 (ΔG (es) and ΔG (nes)) are not relative quantities. ΔG (es) in column 11 is the electrostatic part of the free energy of aqueous solvation (ΔG (solv)) as reported by G98 using SCRF=CPCM and Pauling radii. ΔG (ns) in column 12 is the nonelectrostatic part of ΔG (solv). ΔG (es) in column 14 is taken as the difference between B3LYP energies calculated with and without the presence of the reaction field specified as SCRF=SCIPCM.

The relative enthalpy at 0 K (ΔH°_0 (column 4)), is identified with the relative vibrationally corrected Born–Oppenheimer energy (eq. [1]):

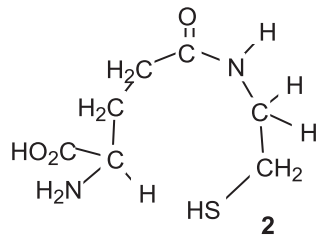
$$[1] \qquad \Delta H^\circ_0 = \Delta E + \Delta ZPE$$

The relative enthalpies at 298 K (ΔH°_{298} (columns 5 and 9)) are calculated according to eq. [2]):

$$[2] \qquad \Delta G^\circ_{298} = \Delta H^\circ_0 + \Delta(H^\circ_{298} - H^\circ_0)$$

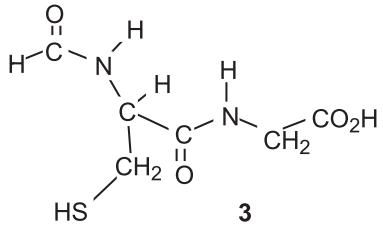
The relative gas phase free energies at 298 K (ΔG°_{298} (columns 7 and 10)) are calculated according to eq. [3]), using ΔS°_{298} from column 6:

$$[3] \qquad \Delta G^\circ_{298} = \Delta H^\circ_{298} - 298.15 \times \Delta S^\circ_{298}$$



Finally, the relative free energies in aqueous solution (columns 13 and 15) are obtained by adding the relative electrostatic part of ΔG (solv) (ΔG (es) from columns 11 and 14) to the gas phase ΔG°_{298} at the B3LYP/6-311+G(3df,2p)// B3LYP/6-31G(d) level (column 10) (eq. [4]):

$$[4] \qquad \Delta G^\circ_{298}(\text{aq}) = \Delta G^\circ_{298}(\text{g}) + \Delta\Delta G \text{ (es)}$$



The reasons for using only the electrostatic part of ΔG (solv) from the CPCM calculations are discussed below.

Results and discussion

The parent compound (**1**) and its radical derivatives exist in numerous conformational forms. A full search of the conformational space was not attempted for the parent, nor any of the free radical minima or transition structures. Instead, only fully optimized structures close to the geometry of the TSs for H-transfer and some structures for the parent molecules which should be among the most stable, were considered. The computational details are provided in Table 1. The B3LYP/6-31G(d) structures of representative neutral non-zwitterionic conformers of **1**, and of compounds *N*-formylcysteinylglycine (**2**) and *N*-(2-thioethanyl)-γ-glutamine (**3**), which were chosen as models for the larger GSH system, are shown in Fig. 2.

2

3

As illustrated in Fig. 3, **1** and **2** have two amide linkages (groups *Amide1* and *Amide2*). Subsequent figures show the structures of the S-centred (thiyl) and α-C-centred radicals, and the connecting transition structures (TSs). The labelling is transparent. Thus, the thiyl radical of one of the conformations of (*Z*)-**2** (labelled (*Z*)-**2a**_S) is connected to the α-C-centred radical ((*Z*)-**2a**_α-C) by TS ((*Z*)-**2**_TS) (Fig. 4). The reaction, which corresponds to intramolecular H-transfer from the Gly moiety to the Cys moiety, is discussed below. In the discussion that follows, energy related references are to the relative free energies at 298 K in the gas phase (column 10, Table 1) and in aqueous solution (column 15, Table 1) unless specified otherwise. These are shown in bold in Table 1.

The solution model

We chose two continuum models in an attempt to simulate the effect of solvation on the activation parameters for

intramolecular H-transfer reaction. Polarizable continuum models (PCM) have been widely used since their introduction in 1981 (27) for the study of chemical processes in solution. These models require the definition of a molecular surface across which the mutual electrostatic response of the solute and solvent can be calculated. For complex molecules, the surface is defined by overlapping spheres, taking cognizance of the physical size of solvent molecules as well (26). The "self-consistant isodensity polarizable continuum model" (SCIPCM) (23), defines the surface as an isodensity contour derived from the molecular wave function in the presence of the solvent reaction field. We also chose the "conductor" PCM method (CPCM) on the basis of favorable results in the literature (25, 28), and opted to use Pauling radii rather than the default UAHF radii since we were dealing with H-transfer TSs (25). As well as the electrostatic part of the solute–solvent interaction calculated by SCIPCM, the CPCM method evaluates the "nonelectrostatic" contribution which originates from formation of the molecular cavity (defined by overlapping spheres) in the solvent. The electrostatic and nonelectrostatic components of the computed free energies of solvation by CPCM, ΔG (es) and ΔG (ns), respectively, for all species are listed separately in columns 11 and 12 of Table 1. The electrostatic terms are derived directly from the SCRF wave function as mapped onto the surface of the cavity occupied by the molecule. The nonelectrostatic terms originate from the shape of the cavity, which may be problematic for large molecules which have concave surfaces and holes. It seems reasonable that isomeric substances should have similar values for ΔG (ns). To within a few kJ mol^{-1}, this is the case for most of the species listed in Table 1. Thus ΔG (ns) for the conformers of each of the parent systems differ by less than 3 kJ mol^{-1}. The radical species for the most part show only slightly wider variation. However, the two successfully converged **1b**_ radicals differ by about 30 kJ mol^{-1} from the structurally similar **1a**_ series and a similar variability is seen in two of the **3b**_ series compared to the **3a**_ group. We have concluded that the extreme variations in ΔG (ns) are not physically reasonable and therefore base our estimates of the differential effects of solvation (namely the data in Column 13 of Table 1) solely on ΔG (es). Where ΔG (ns) is indeed nearly constant, its omission has only a minor effect on the relative free energies in solution. Experimental evidence (29) supports the notion that since parent and radical differ only by a single H atom from a relatively nonpolar C—H bond, the free energy of solution of the parent and the radical should be similar. This approximation would appear to be valid also in the case of GSH and its thiyl- and α-C-centered radicals since both S—H and α-C—H bonds are relatively nonpolar. In short, the differential effects of solvation should not be dramatic and the solution phase relative energies should be similar to the gas phase values. Comparison of the gas phase values and the SCIPCM- and CPCM-derived solution values will provide a basis for the assessment of the applicability of the latter to large polar molecules.

Structures of the parent molecules

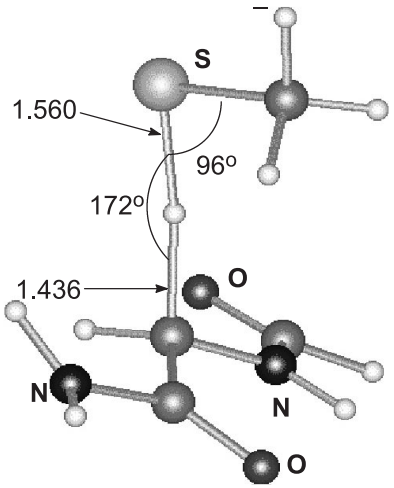
the parent molecules considered in this study are given beside the structures in Fig. 2. In **1a**, **1b**, **1c**, and (*Z*)-**2** both *Amide1* and *Amide2* (see Fig. 3) are in their more stable *anti*- (*Z*) configurations and the two are oriented relative to each other so as to be linked by an H-bonding interaction between the N—H bond of *Amide1* and the carbonyl O atom of *Amide2*. This interaction, which exists in the "extended" conformation of the protein backbone, is missing in **3** which lacks the *Amide2* group. An indication of the relative importance of the additional intramolecular H-bonding interactions may be gained by examination of the relative energies of the conformations of **3**. Conformations **3a** and **3b** are similar in energy. **3b** has the amino NH_2 and COOH groups in a bifurcated arrangement, as does the most stable gas phase structure of glycine (30), and an additional H-bond between the amino group and the N—H of *Amide1*. **3a** has the amino NH_2 and COOH groups in an orientation which may be regarded as the precursor to the zwitterionic form which would exist in solution at neutral pH. This form in glycine (in the gas phase) is 6 kJ mol^{-1} less stable than the bifurcated form (30). It has the largest dipole moment. **3a** also has an additional H-bond between the amino NH_2 and the carbonyl O of *Amide1*. **3a** is more stable than **3b** by 2 kJ mol^{-1} in the gas phase and this difference increases to 4 kJ mol^{-1} in solution. Conformation **3c**, in which the amino group only acts as a weak H-bond donor, is substantially less stable in both phases.

Conformation **1a**, which lacks the secondary H-bonding interaction of **3a**, is less stable by 4 kJ mol^{-1} than **1b** in the absence of solvent but is predicted by the SCIPCM (and CPCM) procedure to be the most stable structure in solution, probably due to its large dipole moment (9.4 D). It should be emphasized that of the many conformations of GSH **1**, only extended structures which have the SH group in proximity to the α-C—H of the glutamyl moiety were considered. The corresponding thiyl radical would be poised to directly abstract the α-C H atom, as discussed below.



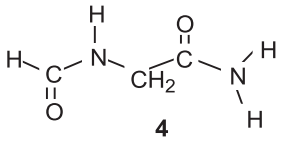
The model system **2** was chosen to examine H-abstraction from the glycine moiety of GSH **1**. Only two structures with the *Amide1–Amide2* interaction noted above were selected, differing by the configuration at *Amide2*. (*E*)-**2**, which has a *cis* transit of the backbone through the amide group, is 13 kJ mol^{-1} less stable than (*Z*)-**2** both in the presence and absence of solvent. A TS for interconversion of (*Z*)-**2** and (*E*)-**2**, **2**_TS (Table 1) was located. The isomerization at *Amide2* is predicted to be hindered by about 95 kJ mol^{-1} relative to (*Z*)-**2**, independent of phase.

α-C—H bond dissociation enthalpies (BDEs)

As a means of assessing the thermodynamic feasibility for the three pathways shown in Fig. 1, the magnitudes of the C—H BDEs for each of the α-C sites are compared to the S—H BDE. Feasibility is evident when BDE α-C—H BDE S—H. The α-C—H bond of the Cys residue is flanked by amide groups. Thus, on the basis of studies on model peptides, α-C—H BDE(Cys) = 346 kJ mol^{-1}, and S—H BDE (Cys) = 366 kJ mol^{-1} (31). Unfortunately, the model peptide studies do not apply directly to the Gly or Gln residues. The Gly residue has an amide linkage through the N atom but a free COOH group. One may expect that the α-C—H BDE (Gly)

© 2001 NRC Canada

Fig. 5. Transition structure for H abstraction by methanethiyl radical from *N*-formylglycinamide **4**.

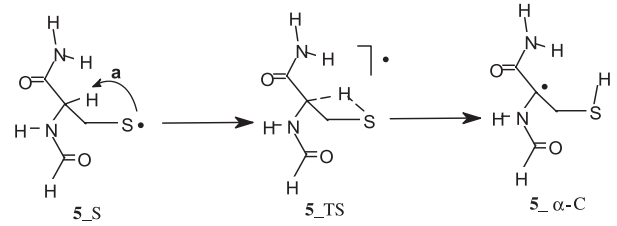


≤ 350 kJ mol^{-1}, the value estimated for a Gly residue in a peptide environment (31), since the COOH group is a better electron acceptor than the CONHR group and would enhance the captodative stabilization (32) of the radical. In the case of the Gln residue, the α-C—H is flanked by an NH_2 group and a neutral COOH group. As for Gly, the α-C—H BDE of Gln may be as much as 20 kJ mol^{-1} lower than the value (334 kJ mol^{-1}) calculated for the Gln residue in a peptide (31). The α-C—H BDE of the Gln residue of GSH has been estimated from experimental data to be no higher than 329 kJ mol^{-1} (7). Here the carboxyl flanking group is ionized and the stabilization would be slightly less effective than for the present calculations.

Approximate bond dissociation enthalpies for the α-C—H bond may be obtained from the present calculations by the isodesmic procedure (31), using the isodesmic partner (glycine) and the most stable structures for the parent systems and the corresponding radicals at the B3LYP/6-31G(d) level of theory. The isodesmic procedure would normally entail an uncertainty of ±10 kJ mol^{-1}. However, the uncertainty is greater in this case because without an exhaustive conformational search, we cannot be sure that the most stable conformers have been located. Using **1b** and **1a**_α-C, a value of 320 kJ mol^{-1} is derived for α-C—H BDE(Gln). Using **3a** and **3b**_α-C, a second estimate of α-C—H BDE(Gln) (313 kJ mol^{-1}) may be derived. These values are consistent with the maximum value of 329 kJ mol^{-1} derived from experiments (7). Using (*Z*)-**2** and (*Z*)-**2b**_α-C, α-C—H BDE(Gly) = 344 kJ mol^{-1}. Similarly, three identical values of 356 kJ mol^{-1} may be derived for the S—H BDE: for **1**, using **1b** and **1b**_S; for **2**, using (*Z*)-**2** and (*Z*)-**2b**_S; and for **3**, using **3a** and **3a**_S. For determination of S—H BDEs, the isodesmic partner is methanethiol. For the isodesmic reactions, the theoretically derived value (331 kJ mol^{-1}) for the BDE(α-C—H) of glycine (16) and the experimental value (360 kJ mol^{-1} for the BDE (S—H) of methanethiol (33), respectively, were used. The calculated BDE (S—H) of GSH **1** is in good agreement with the predicted value (367 kJ mol^{-1}) for Cys model peptide (34). Thus the α-C—H bonds of all three of the residues of GSH **1** involved in the H abstraction pathways in Fig. 1 are weaker than the S—H bond of the Cys residue and in principle, the thiyl radical could abstract an H atom from any of the α-C-sites.

Intermolecular H-transfer

We have previously predicted that the transfer of an α-C—H atom to thiyl in neutral glycine or the model system (*N*-formylglycinamide **4** + methanethiyl radical) entails a free energy of activation of approximately 60 kJ mol^{-1} at 298 K. This value may be taken as the reference for an unconstrained H-transfer of this type. The reaction proceeds via the transition structure shown in Fig. 5 (34). The principal features of the unstrained prerequisite geometry for α-C to S transfer are illustrated here, namely near collinearity of



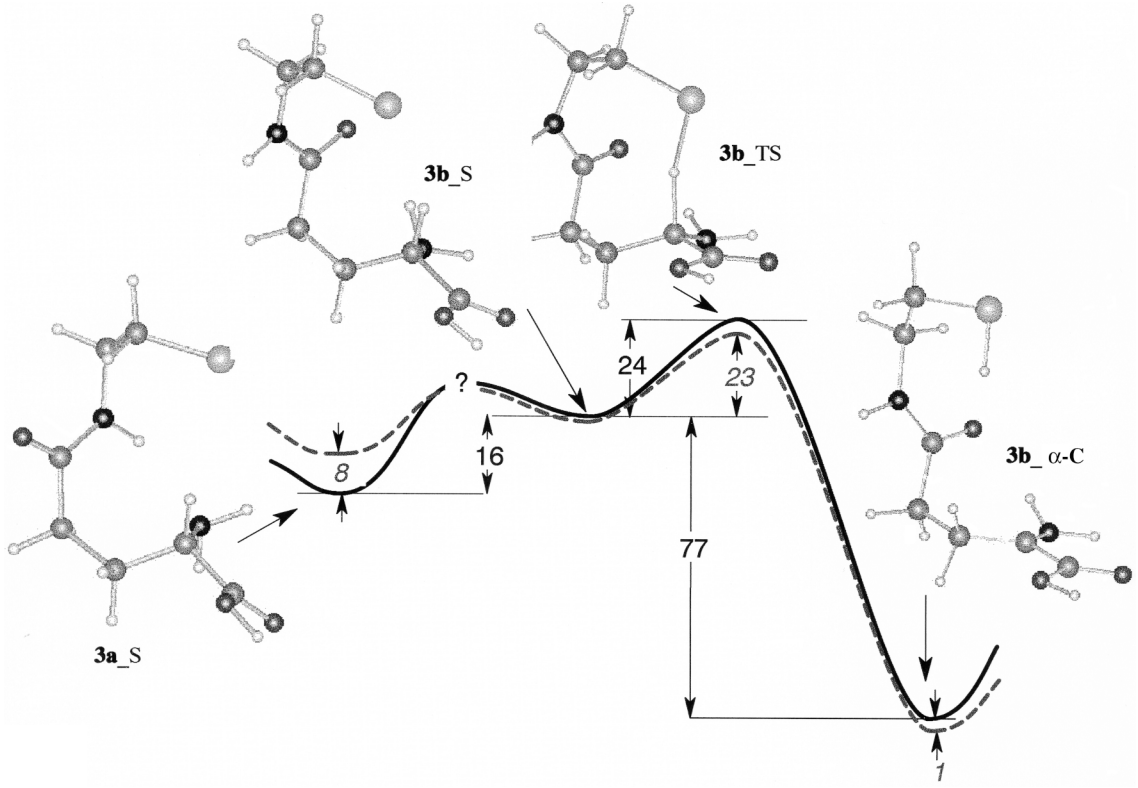
4

the α-C-H-S angle, an approximate angle of 90° at S and a trajectory more or less along the original α-C—H bond.

Intramolecular H-transfer in GSH 1: α-C—H (Cys) to S

The intramolecular α-C to S transfer of an H atom with the Cys residue has previously been examined in the model peptide system (*N*-formylcysteinamide (**5**) (eq. [5])): it is hindered by an enthalpy of activation of 115 kJ mol^{-1} (34). In this case, the cyclic transition state, consisting of only four atoms, cannot achieve the ideal geometry shown in Fig. 5. This value (115 kJ mol^{-1}) should be very similar in GSH **1** itself. We do not examine it further.

[5]



Intramolecular H-transfer in GSH 1 (modelled by 2): α-C—H (Gly) to S

Transfer of H from the α-C of the glycyl moiety would involve a seven-membered ring with an embedded amide group (Amide2, Fig. 3). Because an amide group is quasi-planar, its incorporation into a seven-membered ring would incur severe steric strain if it is in the normal (*Z*)-configuration, but would be relatively strain free if it is in the less favourable (*E*)-configuration (see Fig. 2). We have examined the possibility of H-transfer to thiyl radical from the α-C of the Gly residue using *N*-formylcysteinylglycine **2** as a model compound. Model **2** has both *Amide1* and *Amide2* groups, with *Amide2 endo* to the seven-membered ring of the TS. The structures of the S- and α-C-centered radicals and the TSs are shown in Fig. 4 along with the gas phase free energy profile plotted relative to the most stable structure ((*Z*)-**2b**_α-C). It is immediately clear that H-transfer in the (*Z*) compound is hindered by a very high barrier (134 kJ mol^{-1})

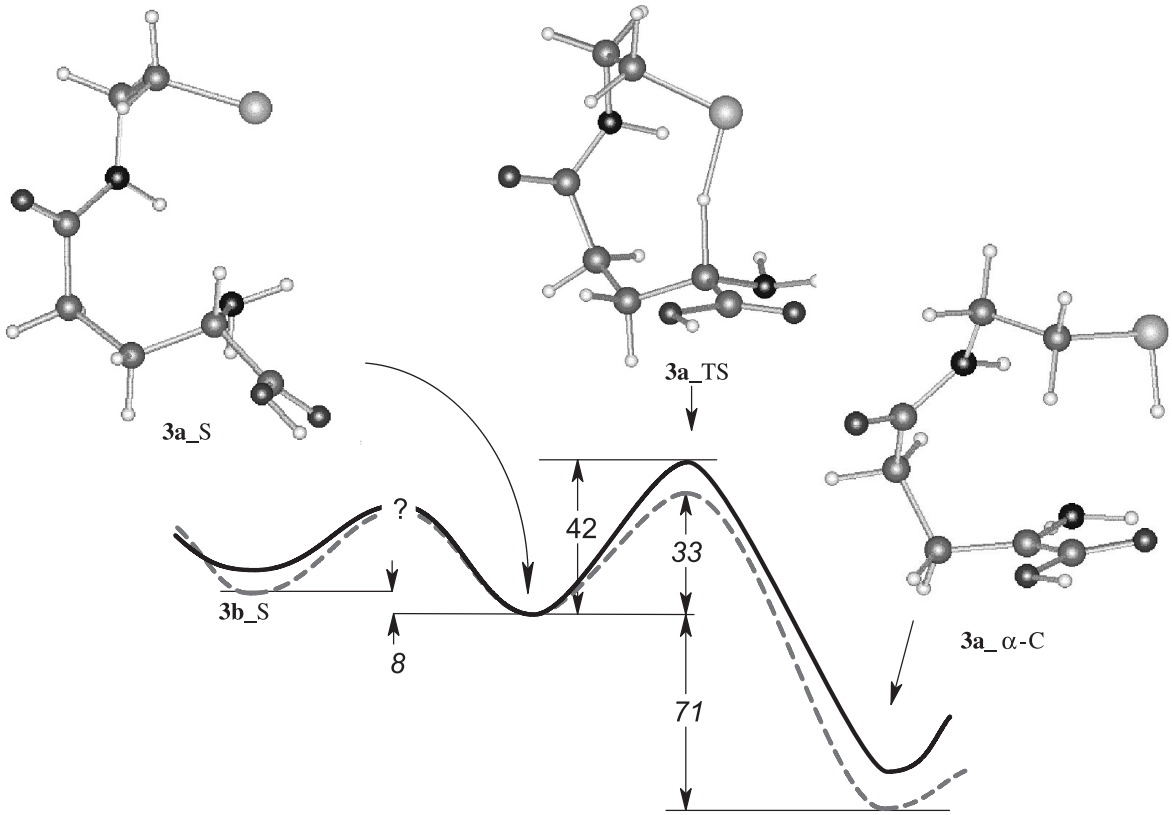
© 2001 NRC Canada

Fig. 6. Free energy (kJ mol^{-1}) profile for intramolecular H abstraction by **3b**_S in the gas phase (solid line, normal numbers) and solution (dashed line, italics).

and entails a 75° distortion from planarity of the *Amide2* group in (*Z*)-**2**_TS. H-transfer from the less stable (*E*) conformer ((*E*)-**2**_S) is hindered by a barrier (52 kJ mol^{-1}) which is actually less than the acyclic case, modelled by reaction of *N*-formylglycinamide (**6**) with methanethiyl radical ($\Delta G^{\neq}$ = 63 kJ mol^{-1} (34)). However, since the parent compound is in the (*Z*) conformation (compare (*Z*)-**2** and (*E*)-**2**, Table 1), the thiyl radical initially formed ((*Z*)-**2**_S) is 69 kJ mol^{-1} below the (*E*)-**2**_TS barrier. Furthermore, conversion of (*Z*)-**2**_S to (*E*)-**2**_S would be hindered by a barrier of about 95 kJ mol^{-1}, as is the case with the parent system. The situation in solution is predicted to be very similar to that shown in Fig. 4.

Intramolecular H-transfer in 3: α-C—H (Gln) to S

The most plausible site of H atom abstraction is the α-C—H site of the Gln residue of GSH **1** as deduced experimentally (6, 7, 19). The TS has a nine-membered ring with sufficient flexibility to readily accommodate the ideal TS requirements shown in Fig. 5. The normal (*Z*) configuration of *Amide1* is readily incorporated into the large ring with minimal distortion. Two orientations of *Amide1* are possible, depending on which face is turned into the ring. These approximately correspond to the **a** and **b** conformations of the parent system **3** (Fig. 2). This reaction was investigated in model system **3**, and in GSH **1**, itself. We discuss first the model system **3**, and conclude with GSH **1**.



Of the two conformations of the thiyl radical of **3** considered here, **3a**_S is more stable than **3b**_S by 16 kJ mol^{-1} in the absence of solvent and by 8 kJ mol^{-1} in water. The free energy reaction profile of the conversion of **3b**_S to **3b**_α-C via **3b**_TS in the presence and absence of solvent is shown in Fig. 6. The aqueous free energy of activation ($\Delta G^{\neq}$) is only 23 kJ mol^{-1} in water, and 24 kJ mol^{-1} in the gas phase, starting from **3b**_S, the immediate precursor to the TS. From the lower energy conformer (**3a**_S) the values are 31 kJ mol^{-1} and 40 kJ mol^{-1}, respectively. The aqueous profile for the conversion of **3a**_S to **3a**_α-C via **3a**_TS in the presence and absence of solvent is shown in Fig. 7. The free energy of activation ($\Delta G^{\neq}$) is predicted to be 33 kJ mol^{-1} in water and 42 kJ mol^{-1} in the gas phase.

Intramolecular H-transfer in GSH 1: α-C—H (Gln) to S

Two conformations of the thiyl radical of GSH (**1a**_S and **1b**_S) were considered here. The latter (**1b**_S) is predicted to be more stable by 20 kJ mol^{-1} in the absence of solvent and by 16 kJ mol^{-1} in water by the SCIPCM method. It was not possible to converge the SCRF calculations for **1b**_S for any basis set (6-31G(d), 6-31G(d,p), 6-311+G(3df,2p) were attempted) in the model CPCM with Pauling radii. With the 6-31G(d,p) basis set, SCRF=CPCM with the default united atom radii *did* converge, however. At this level, **1a**_S is predicted to lie 13 kJ mol^{-1} above **1b**_S in water. The gas phase reaction profile of the more stable conformer (**1b**_S) is shown in Fig. 8: $\Delta G^{\neq}$ = 40 kJ mol^{-1} and $\Delta G°$ = – 45 kJ mol^{-1}. The exothermicity of the reaction is somewhat greater than that deduced experimentally in water ($\Delta G°$ = –37 kJ mol^{-1}) (7). As shown in Fig. 9, $\Delta G^{\neq}$ for the reaction with the less stable conformers (**1a**_S → [**1a**_TS] → **1a**_α-C) is somewhat lower: $\Delta G^{\neq}$ = 34 kJ mol^{-1} and $\Delta G°$ = –56 kJ mol^{-1} in the gas

© 2001 NRC Canada

Fig. 7. Free energy (kJ mol^{-1}) profile for intramolecular H abstraction by **3a**_S in the gas phase (solid line, normal numbers) and solution (dashed line, italics).

phase, and $\Delta G^{\neq}$ = 31 kJ mol^{-1} and $\Delta G°$ = – 49 kJ mol^{-1} in water. However, **1a**_S is less stable than **1b**_S, yielding an overall greater activation free energy for this pathway.

Effect of solvation

The present solution modelling results with the SCIPCM method (shown in Figs. 6–9) are consistent with a lowering of $\Delta G^{\neq}$ in solution relative to the gas phase. Inspection of the ΔG (es) data for the radicals of **1** and **3** in column 14 of Table 1 reveals that the lowering is due to a small preference for solvation of the TS relative to the thiyl radical. On the other hand, the results for the CPCM method shown in column 13 of Table 1 are inconclusive as to the effect of solvation on the activation free energy. The results for the reaction (**1a**_S → [**1a**_TS] → **1a**_α-C) suggest that solvation may raise the free energy of activation by a small amount (2 kJ mol^{-1}). This is also true for the reaction ((*Z*)-**2a**_S → [(*Z*)-**2a**_TS] → (*Z*)-**2a**_α-C (Table 1)) while for the reaction ((*E*)-**2**_S → [(*E*)-**2**_TS] → (*E*)-**2**_α-C (Table 1)) the barrier is raised by a more substantial amount, 20 kJ mol^{-1}. On the other hand, the results for the model systems (**3a**_S → [**3a**_TS] → **3a**_α-C and **3b**_S → [**3b**_TS] → **3b**_α-C) suggest a lowering of the barrier in water. The reason for such divergent results in such closely related systems is not at all obvious. We must conclude that single point SCRF=CPCM methodology applied to systems of the size considered here cannot distinguish the trends for the effects of solvation.

The most reliable predictors of the free energy changes for the reaction of GSH thiyl radical are the gas phase results shown in Fig. 8. These results ($\Delta G^{\neq}$ = 40 kJ mol^{-1}, $\Delta G°$ = – 45 kJ mol^{-1}) are applicable to solution under the assumption stated above that differential effects of solvation should be small. Direct evaluation of the effect of solvation by the SCIPCM methodology suggest that the free energy of activation should be lower ($\Delta G^{\neq}$ = 35 kJ mol^{-1}) and the exothermicity should be higher ($\Delta G°$ = –54 kJ mol^{-1}).

Entropy of mixing

The data in Table 1 refer to individual components of a complex mixture. Where one conformer dominates the mixture of the reactant (thiyl radical in this case), and one TS is clearly the most stable, the free energy of activation of the reaction may be computed as the difference of the free energies of just these two species. For GSH thiyl radical, one may choose **1b**_S and **1b**_TS and obtain $\Delta G^{\neq}$ = 35 kJ mol^{-1} from the solution phase results (Fig. 8). In the general case, the entropy of a substance composed of a number (n) of components (i) is given by eq. [6]:

$$[6] \qquad S = \Sigma_i^n \chi_i S_i - R\Sigma_i^n \chi_i \ln \chi_i$$

where χ_i and S_i are the mol fraction and entropy, respectively, of conformer i. and R is the gas constant. The last term is the entropy of mixing, which is approximately equal to R ln n in the event that there are n low-energy conformations which are approximately equally populated. For a highly flexible molecule, this may be significant. Consider the case of **1b**_S → [**1b**_TS], shown in Fig. 10. The five single bonds specifically labelled are in the part of the molecule which forms the cyclic TS for thiyl abstraction of the H atom from the Gln moiety. Bonds b_1, b_2, and b_5 are threefold

Fig. 10. Definition of bonds involved in the process, **1b**_S → [**1b**_TS] (see text).

1b_S **1b**_TS

rotors, while b_3 and b_4 are twofold rotors. Independent rotations about these may generate as many as 108 conformations, one of which is **1a**_S, another **1b**_S. These rotational degrees of freedom are affected by the necessity to make a cyclic TS. For instance, rotation about b_3 is accompanied by rotation about b_4, and only certain *gauche* conformations are permitted for the threefold rotors (b_1, b_2, and b_5). The number of conformations available to the TS is reduced to about eight, two of which are **1a**_TS and **1b**_TS. This restriction in the conformational freedom would raise the free energy of activation by $-RT$ (ln 8 – ln 108) = 6.7 kJ mol^{-1} at 298 K, corresponding to an order of magnitude reduction in reaction rate. Even if there were only one other conformation as important as **1b**_S, and if **1b**_TS were the only accessible TS, the increase in the free energy of activation due to the entropy of mixing is almost 2 kJ mol^{-1}. Thus the entropy of mixing would have the effect of raising the free energy of activation into the range 37–42 kJ mol^{-1}.

The rate of H atom transfer

In the case of a unimolecular reaction, the rate constant for the reaction (k_T) is related to the free energy of activation ($\Delta G^{\neq}$) by eq. [7] (35):

$$[7] \qquad k_T = (k_B T/h)\ \exp(-\Delta G^{\neq}/RT)$$

Two independent experimental determinations place the rate of the thiyl to α-C radical transformation in the range 1.5 to 1.8 × 10^5 s^{-1} at 298 K (6, 19). This implies that $\Delta G^{\neq}$ = 43 kJ mol^{-1}. Both experiments were carried out at pH 10, where all acidic groups of GSH (including the Gln amino group) are deprotonated. At this pH, the SH group will also be deprotonated after H-transfer, but that should not affect the barrier height. The present calculations were carried out on the neutral system. Protonation of the Gln carboxyl may have a small effect on the barrier height, but the Gly carboxyl group will be sufficiently removed so as not to perturb the thermochemistry at the thiyl and α-C centres to a significant extent. Indeed, the experimental value is in remarkable agreement with the gas phase value for the lowest energy process ($\Delta G^{\neq}$ = 40 kJ mol^{-1} (Fig. 8)) and with the solution phase value which falls in the same range after inclusion of a contribution from the entropy of mixing. Addition of the free energy contribution from the entropy of mixing will have a lesser effect on the free energy change for the reaction since both reactants and products have similar conformational flexibility.

Conclusions

The bond dissociation enthalpies of the S—H bond and the α-C—H bonds of the three residues of glutathione (GSH), calculated by the method of isodesmic reactions, are (in kJ mol^{-1}): S—H 356, α-C—H (Gly) 344, α-C—H (Cys) 346 (31), α-C—H (Gln) 320. The last value is consistent with expectations based on experiment (7). Calculations on the radicals derived from GSH **1** and two model systems (*N*-formylcysteinylglycine (**2**) and *N*-(2-thioethanyl)-γ-glutamine (**3**)) suggest that the free energy of activation for abstraction of the α-C—H (Gly) by the thiyl radical in the gas phase is hindered by a barrier of 134 kJ mol^{-1} if the amide link to Gly is in the more stable (*Z*)-configuration, but is reduced to 52 kJ mol^{-1}, if it is in the less stable (*E*)-configuration. However, the isomerization of the amide group requires about 95 kJ mol^{-1}. Previous studies had indicated that intramolecular reaction of the thiyl radical at α-C—H (Cys) would encounter a barrier of 110 kJ mol^{-1} (34). The lowest energy pathway for intramolecular H-transfer to thiyl radical is from α-C—H (Gln). The gas phase barrier ($\Delta G^{\neq}$ = 40 kJ mol^{-1}) for the lower energy pathway and the solution phase barrier for the mixture of conformers ($\Delta G^{\neq}$ = 37– 42 kJ mol^{-1}) are in excellent agreement with that expected from the experimentally observed rate of reaction (6, 19) in solution ($\Delta G^{\neq}$ = 43 kJ mol^{-1}). The calculated free energy change ($\Delta G°$ = –54 kJ mol^{-1}) is higher than that estimated from experimental observations of solution equilibria ($\Delta G°$ = –37 kJ mol^{-1}) (7). The good agreement between theory in the gas phase and experiment in solution suggests that the free energies of solvation of reactant thiyl radical, transition structures for H abstraction, and the product α-C-centred radical, are very similar. This has direct support within the SCIPCM model (see ΔG (es) values in column 14 of Table 1). However, attempts to model the effects of solvation using the continuum self-consistent reaction field and the COSMO procedure (SCRF=CPCM) with Pauling radii, were inconclusive even as to whether a rate enhancement or decrease could be expected. This is possibly due to artefacts originating from complex cavities for these large molecules.

Incorporation of ^{13}C glucose into nicotinamide in *E. coli* and in *S. cerevisiae*

Ram Nath Gupta, Thomas Hemscheidt, Brian G. Sayer, and Ian D. Spenser

Abstract: The mode of incorporation into nicotinamide of label from ^{13}C-labeled samples of D-glucose, in *Escherichia coli* and *Saccharomyces cerevisiae*, was determined by means of ^{13}C NMR spectroscopy. The results, which confirm and extend early studies with radioactive tracers, permit a definitive choice to be made between alternative biogenetic proposals.

Key words: nicotinic acid, nicotinamide, biosynthesis, glucose incorporation, ^{13}C NMR.

Résumé : Faisant appel à la spectroscopie RMN du ^{13}C, on a déterminé le mode d'incorporation du ^{13}C d'échantillons de D-glucose marqué dans le nicotinamide d'*Escherichia coli* et de *Saccharomyces cerevisiae*. Les résultats, qui confirment et qui étendent la portée d'études antérieures à l'aide de marqueurs radioactifs, permettent de faire un choix définitif entre les diverses propositions biogénétiques.

Mots clés : acide nicotinique, nicotinamide, biosynthèse, incorporation du glucose, RMN du ^{13}C.

[Traduit par la Rédaction]

Introduction

Two major de novo pathways of nicotinic acid biosynthesis are known (for a review see ref. 1). The key intermediate of both routes is quinolinic acid which in the two pathways originates from different precursors.

The first of the pathways to the vitamin to be described is found in mammalian tissues, in molds and fungi, in yeasts under aerobic conditions, and in some higher plants. The primary precursor of this pathway is tryptophan. The steps and the enzymology of this route are well established (for a review see ref. 1).

That another route to the vitamin must exist became probable when it was shown that nicotinic acid in *Escherichia coli* (2) and trigonelline, the methylbetaine of nicotinic acid, in a higher plant (3), were not derived from tryptophan. This second pathway, which would appear to be more widely distributed than the route from tryptophan,[2] is found in prokaryotes in general, e.g., *E. coli* (5), *Mycobacterium tuberculosis* (6) and other bacteria, and also in yeasts under anaerobic conditions (7, 8). This route generates nicotinic acid by condensation of a triose phosphate with a dicarboxylic acid related to aspartic acid. The mechanism whereby these two precursors combine to yield the skeleton of nicotinic acid has not been established.

The first detailed incorporation studies related to this alternative pathway of nicotinic acid biosynthesis were carried out with higher plants.[3] This early work with ^{14}C-labeled substrates established incorporation of label from glycerol, and from dicarboxylic acids related to succinic acid (for summary see ref. 13). It is certain from tracer work with ^{14}C-labeled substrates that glycerol (and hence triose phosphate) supplies C-4, C-5, and C-6 of the ring. Label from [1,3-^{14}C]glycerol was found predominantly, and approximately equally, at C-4 and C-6, whereas label from [2-^{14}C]glycerol entered C-5 of the pyridine ring (13). Label from D-[3-^{14}C]glyceraldehyde entered mainly C-4 (55 ± ?[4]%), with the rest of the radioactivity spread throughout the molecule (14).

The dicarboxylic acid supplies carbon atoms C-2, C-3 of the ring system, and the two carboxylic acid groups of quinolinic acid (and thence of nicotinic acid, after decarboxylation of the carboxyl group at C-2). ^{14}C from [2,3-^{14}C]succinate as well as from [2-^{14}C]acetate labeled C-2 and C-3 of the pyridine ring approximately equally, while label from [1-^{14}C]acetate, [1,4-^{14}C]succinate, as well as from [4-^{14}C]aspartic

[2]The view that nicotinic acid (niacin) and its congener, nicotinamide, components of NAD and related coenzymes, was universally derived from tryptophan was firmly held until the mid-1950ies. But even today, current textbooks of biochemistry (4), if they refer to niacin biosynthesis at all, persist in stating categorically that the sole route to nicotinic acid starts from tryptophan.

[3]Results, showing the precise distribution of label from ^{14}C-labeled substrates within the pyridine ring of the alkaloids nicotine and anabasine in intact tobacco plants and within ricinine in the castor bean plant, can be extrapolated to the origin of the nicotinic acid ring system, since it has been demonstrated that the intact ring of nicotinic or of quinolinic acid serves as the precursor of the pyridine ring of the tobacco alkaloids (9–11) and of ricinine (12).

Fig. 1. ^{13}C NMR spectrum of nicotinamide derived from D-[$^{13}C_6$]glucose: (A) from *E. coli* (expt 1); and (B) from *S. cerevisiae* (expt 2).

acid entered solely into the carboxyl carbon of nicotinic acid. It is noteworthy that label from [3-^{14}C]aspartic acid, as well as from [3-^{14}C]malic acid, entered both C-2 (38 ± ?[4]% of the total specific activity of the labeled product) and C-3 (57 ± ?[4], 61 ± ?[4]%), rather than being confined to C-3 (15), as would have been expected if aspartic acid had been incorporated intact.

In *E. coli*, label from [1-^{14}C]glycerol entered C-4 (57 ± ?[4]%) and C-6 (40 ± ?[4]%) of quinolinic acid (16), while label from [1-^{14}C]dihydroxyacetone 1-phosphate entered C-4 exclusively (17). Label from D-[1-^{14}C]glucose (and probably also from D-[6-^{14}C]glucose) was spread over the whole molecule, with preferential entry into C-4 (24 ± ?[4]%) and C-6 (25 ± ?[4]%) whereas label from D-[2-^{14}C]glucose entered C-5 preferentially (78 ± ?[4]%) (16).

All available evidence thus points to the derivation of the ring system of quinolinic acid, and hence of that of nicotinic acid, from a triose plus a compound related to aspartic acid (18).

Two genes, *nadA* and *nadB*, that control the biosynthesis of nicotinic acid in *E. coli* and *S. typhimurium*, have been mapped and expressed (for a review see ref. 19, 20) and the corresponding gene products have been characterized (20, 21). The *nadB* gene product ("B protein"), L-aspartic acid oxidase (EC 1.4.3.16), is present not only in *E. coli* (22) but also in a higher plant (cotton) (23). It catalyzes the dehydrogenation, in the presence of FAD, of L-aspartic acid to yield 2-iminobutanedioic acid (2-iminosuccinic acid, referred to incorrectly as iminoaspartic acid) (24). However, there appears to be some question whether or not in *E. coli* the C-N fragment of aspartic acid is incorporated intact into the vitamin (25). Certainly, 2-iminosuccinic acid is generated also from oxalacetic acid plus ammonium sulfate (24).

The *nadA* gene product ("A protein"), quinolinate synthase (26), catalyzes the condensation of 2-iminosuccinic acid as the source of the fragment N-1,C-2,3,CO_2H of nicotinic acid, with the triose phosphate as the source of the fragment C-4,5,6. Both dihydroxyacetone phosphate and glyceraldehyde phosphate react readily in this condensation reaction. The identification of the former as the actual substrate for the condensation reaction rests on a single experiment with an inhibitor of triose phosphate isomerase (26).

The disposition of the triose on entry into the C_3 unit C-4,5,6 differs in alternative biogenetic proposals.

In a recently published hypothetical biogenetic sequence, the carbon atom of the phosphotriose that bears the phosphate ester group is postulated to yield C-6 of nicotinic acid (27). A similar disposition of the triose phosphate on entry into nicotinic acid had been advanced earlier (21, 28, 29). Alternatively, the phosphate ester carbon atom of the triose was postulated to generate C-4 of the niacin ring system (1, for a review see ref. 11, 14, 22, 30).

We now present results which establish that the latter alternative is the correct one.

Results and discussion

We have employed NMR spectroscopy to examine the mode of incorporation of ^{13}C-labeled D-glucose into nicotinamide in *E. coli* B WG2 (a *pdxH*$^-$ auxotroph) and in *S. cerevisiae* strain ATTC 7752 (IFO 1234). These are the micro-organisms that we had employed in our previous investigations of pyridoxine (31) and thiamin biosynthesis (32).

The ^{13}C NMR method had not hitherto been applied in the study of niacin biosynthesis. To do so, a method of isolation with minimal carrier dilution had to be developed. The method that eventually proved successful, described in the experimental section, was based on the isolation of nicotinamide, a weak base that can be isolated from the cell hydrolysate by solvent extraction and can then be further purified by liquid chromatography. Nicotinamide is quite stable. There is no significant hydrolysis of nicotinamide when it is heated in 0.1 M HCl solution for 1 h. In earlier investigations of niacin biosynthesis with ^{14}C, significant carrier dilution was required when either quinolinic acid or nicotinic acid, amphoteric compounds, were isolated. To test the utility of the method, D-[$^{13}C_6$]glucose was selected as the substrate whose incorporation was examined. Incorporation into nicotinamide of multicarbon units derived from this bond-labeled substrate[5] was indeed observed both in

[5] These experiments cannot differentiate between the two pathways since the distribution of D-[$^{13}C_6$]glucose-derived label within niacin in both pathways is predicted to be identical: In triose–aspartate-derived niacin the C_3 unit C-4,5,6 is generated via a triose while the C_2 unit C-2,3 arises via a dicarboxylic acid that is ultimately also derived via a triose, but can randomize its label by tricarboxylic acid cycling. In the aerobic route to niacin from glucose via tryptophan, a C_3 unit of glucose is incorporated into C-4,5,6 of niacin via erythrose while the C_2 unit C-2,3 arises via phosphoenolpyruvate.

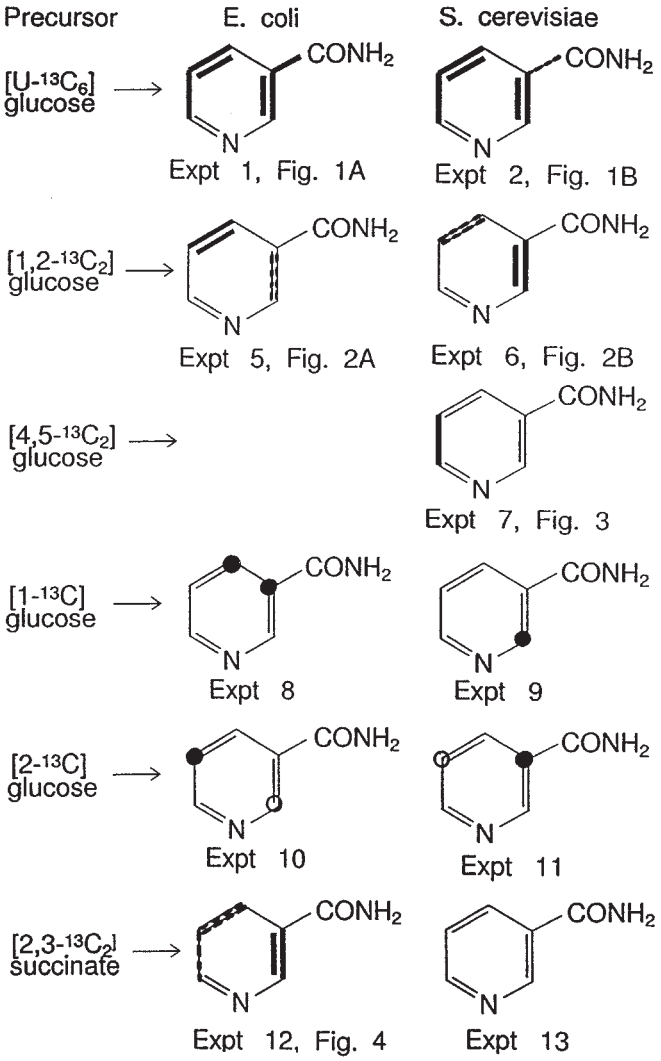
Table 1. ^{13}C NMR spectrum of nicotinamide: chemical shifts and coupling constants.

Chemical shift[a] (ppm)	Carbon atom no.	Coupling constants (±0.5 Hz) ^{13}C-^{13}C	
124.7	C-5	$^1J_{C\text{-}5,C\text{-}4}$	54.4
		$^1J_{C\text{-}5,C\text{-}4} + {}^1J_{C\text{-}5,C\text{-}6}$	108.8
129.2	C-3	$^1J_{C\text{-}3,C\text{-}2}$	58.1
		$^1J_{C\text{-}3,C=O}$	64.0
		$^1J_{C\text{-}3,C\text{-}2} + {}^1J_{C\text{-}3,C=O}$	122.1
136.8	C-4	$^1J_{C\text{-}4,\ C\text{-}5}$	54.4
147.7	C-2	$^1J_{C\text{-}2,C\text{-}3}$	58.1
151.8	C-6	$^1J_{C\text{-}6,C\text{-}5}$	54.4
170.9	C=O	$^1J_{C=O,C\text{-}3}$	64.0

[a]Chemical shift (ppm) relative to dioxane as internal standard (66.6 ppm with respect to TMS at 0 ppm).



E. coli (expt 1, Fig. 1A) and in yeast (expt 2, Fig. 1B). ^{13}C NMR chemical shifts and coupling constants are summarized in Table 1.

The appearance of multiplets straddling the signals due to C-4 (136.8 ppm, $^1J_{C\text{-}4,\ C\text{-}5}$ = 54.4 Hz), C-5 (124.7 ppm, $^1J_{C\text{-}5,\ C\text{-}4} + {}^1J_{C\text{-}5,\ C\text{-}6}$ = 108.8 Hz), and C-6 (151.8 ppm, $^1J_{C\text{-}6,\ C\text{-}5}$ = 54.4 Hz) and of doublets at the signals due to C-2 (147.7 ppm, $^1J_{C\text{-}2,\ C\text{-}3}$ = 58.1 Hz) and C-3 (129.2 ppm, $^1J_{C\text{-}3,\ C\text{-}2}$ = 58.1 Hz) that were observed in the ^{13}C NMR spectrum of nicotinamide from *E. coli* (expt 1, Fig. 1A) confirmed that a C_3 unit and a C_2 unit derived from D-[$^{13}C_6$]glucose had been incorporated. Some scrambling of label had taken place during the incubation period, as indicated by the presence of a low intensity doublet around the carbonyl signal, showing low level labeling of the $CONH_2$ carbon atom and coupling with C-3 of the ring. The labeling patterns observed in these and subsequent experiments are summarized in Scheme 1.

The fact that ^{13}C incorporation into nicotinamide was detected served to show that the experimental procedure can be employed in the investigation of nicotinamide biosynthesis.

Using this method, an experiment was then carried out to establish the disposition of the triose phosphate upon its entry into the C_3 fragment C-4,5,6 of the pyridine ring of nicotinamide in *E. coli*. The distribution pattern of label from D-[1,2-$^{13}C_2$]glucose (expt 5, Fig. 2A) distinguished among the two possible modes of entry of the triose into the C_3 unit C-4,5,6 of the ring. The spectrum of the nicotinamide sample derived from D-[1,2-^{13}C]glucose (Fig. 2A) shows that the C-5 signal (124.7 ppm, $^1J_{C\text{-}5,\ C\text{-}4}$ = 54.4 Hz) is coupled to the signal due to C-4 (136.8 ppm, $^1J_{C\text{-}5,\ C\text{-}4}$ = 54.4 Hz). As before, low intensity satellites are present at other carbon signals, due to some scrambling of label. Since the signal due to bond-labeling at C-5 (124.7 ppm) shows coupling to only one other carbon, C-4, whereas in the spectrum of D-[$^{13}C_6$]glucose-derived nicotinamide the signal for C-5 had shown coupling to two other carbon atoms ($^1J_{C\text{-}5,\ C\text{-}4} + {}^1J_{C\text{-}5,\ C\text{-}6}$ = 108.8 Hz), this coupling pattern shows that a C_2 unit derived from the precursor was incorporated into C-4,5 of the nicotinamide.

Scheme 1. Observed incorporation of ^{13}C into nicotinamide (see Figs. 1–4).

Upon glycolysis, C-1 and C-2 of glucose give rise, respectively, to the phosphohydroxymethyl carbon and the carbonyl carbon atom of dihydroxyacetone phosphate and then, by triosephosphate isomerization, to the phosphohydroxymethyl carbon atom and the central carbon atom of D-glyceraldehyde phosphate. The incorporation pattern of ^{13}C from D-[1,2-^{13}C]glucose proves that incorporation of the phosphotriose takes place in such a way that C-4, but not C-6, of nicotinamide is derived from the phosphohydroxy carbon atom, as had been proposed by Gholson and coworkers (22) and others (1, 11, 14, 30).

Incorporation of label from D-[$^{13}C_6$]glucose and from D-[1,2-$^{13}C_2$]glucose into the C_2 fragment C-2,3 of nicotinamide in *E. coli* must now be examined. This fragment, together with the carbonyl carbon atom is derived from 2-iminosuccinic acid, the *nadB* gene product (see *Introduction*).

Since aspartic acid and related dicarboxylic acids originate from glucose-derived triose phosphates in several steps, via [$^{13}C_3$]phosphoenolpyruvate and thence by carboxylation to [1,2,3-$^{13}C_3$]oxaloacetate, an intact C_2 unit derived from D-[$^{13}C_6$]glucose was expected to enter C-2,3 of nicotinamide.

© 2001 NRC Canada

Fig. 2. ^{13}C NMR spectrum of nicotinamide derived from D-[1,2-$^{13}C_2$]glucose: (A) from *E. coli* (expt 5); and (B) from *S. cerevisiae* (expt 6).

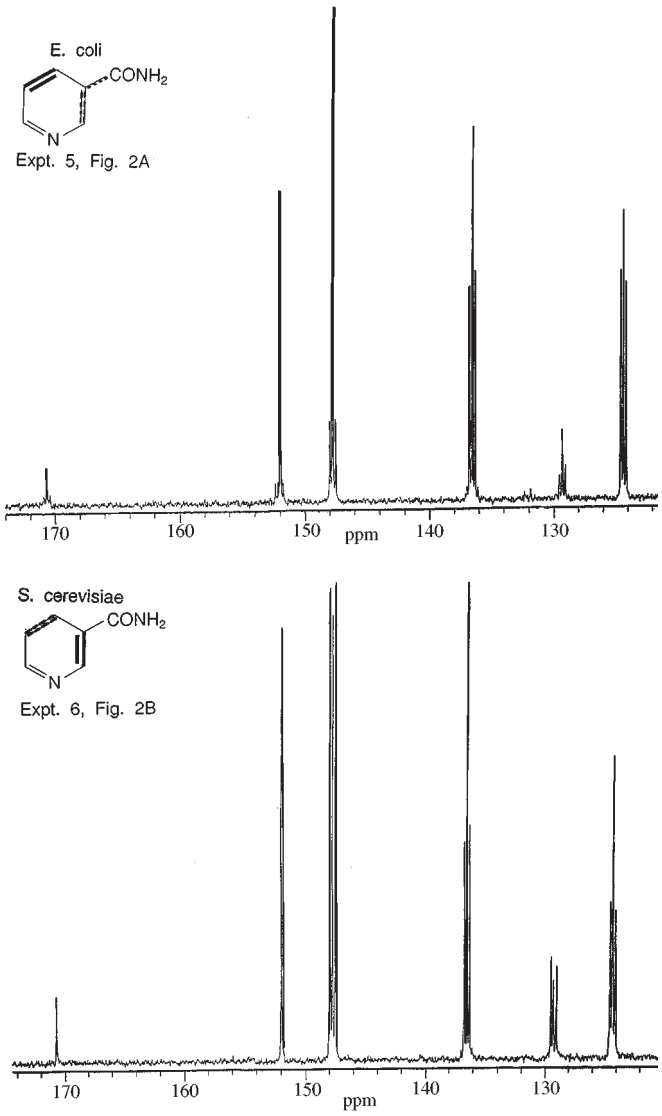


Fig. 3. ^{13}C NMR spectrum of nicotinamide derived from D-[4,5-$^{13}C_2$]glucose (expt 7).

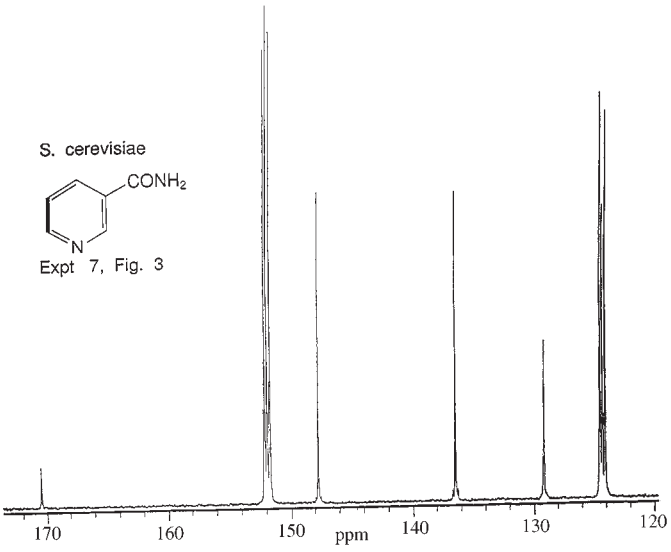

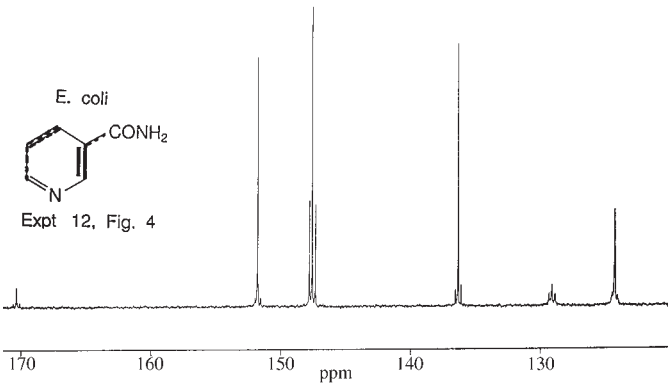

Fig. 4. ^{13}C NMR spectrum of nicotinamide derived from sodium [2,3-$^{13}C_2$]succinate (expt 12).

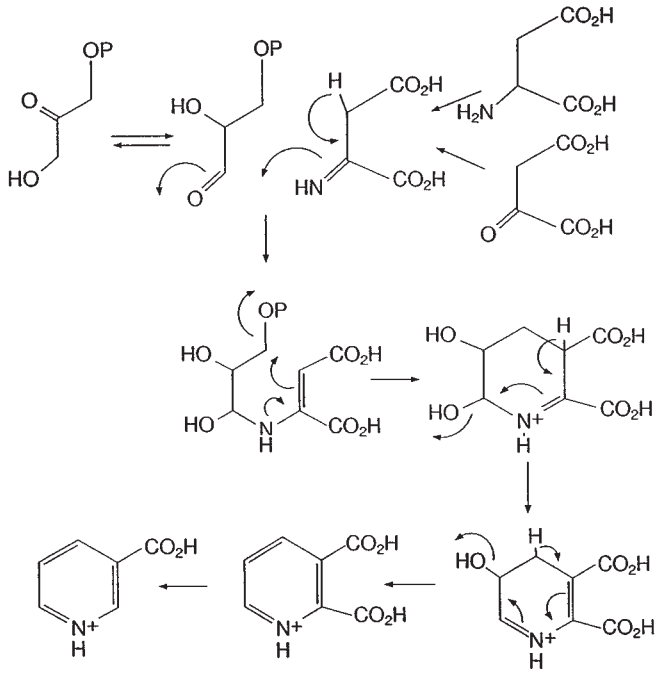

The appearance of doublets at the signals due to C-2 (147.7 ppm, $^1J_{C\text{-}2,\ C\text{-}3}$ = 58.1 Hz) and C-3 (129.2 ppm, $^1J_{C\text{-}3,\ C\text{-}2}$ = 58.1 Hz) (Fig. 1A) showed that this had indeed occurred. Incorporation of label from glucose by this multistep route had presumably taken place via quinolinic acid, followed by decarboxylation, i.e., with loss of the labeled oxaloacetate carboxyl group derived from C-3 of glucose. The low-intensity multiplet around C-3 (129.2 ppm, $^1J_{C\text{-}3,\ C\text{-}2}$ + $^1J_{C\text{-}3,\ C=0}$ = 122.1 Hz), indicating incorporation of an intact C_3 unit into C-2,3,CO, is explicable on the basis of [1,2,3-$^{13}C_3$]oxaloacetate recycling through the tricarboxylic acid cycle to yield [2,3,4-$^{13}C_3$]oxaloacetate, which upon entry into nicotinamide, loses the unlabeled carboxyl group.

Another indication for involvement of an intermediate derived from aspartate was the observation that when incubation with D-[$^{13}C_6$]glucose was carried out in the presence of excess unlabeled aspartic acid (expt 3), incorporation of ^{13}C into the C_2 unit C-2,3 of the ring was lowered, relative to the ^{13}C incorporation into the C_3 unit C-4,5,6. This was shown by the observation that the ratios of the intensities of the doublets C-6:C-2 and C-4:C-2 (5.3 and 5.1, respectively), in the nicotinamide spectrum from the latter incubation, were found to be more than twice as large as the corresponding ratios in the spectrum of the sample obtained from the incubation with glucose alone (expt 1) (C-6:C-2 = 2.1, C-4:C-2 = 2.3). It should be mentioned, parenthetically, that in a similar set of experiments with yeast (expts 4 and 2, respectively), in which nicotinamide showed an incorporation pattern similar to that of the nicotinamide derived from D-[$^{13}C_6$]glucose in *E. coli*, these ratios were unaffected by the presence of aspartic acid. This confirms that in yeast under aerobic conditions the triose–aspartic acid route to nicotinamide is at best of minor importance.

This conclusion is borne out by the results of incorporation experiments with sodium [2,3-$^{13}C_2$]succinate. In *E. coli* (expt 12, Fig. 4) label from this precursor was found in the C_2 unit C-2,3 (C-2: 147.7 ppm, $^1J_{C\text{-}2,\ C\text{-}3}$ = 58.2 Hz; C-3:

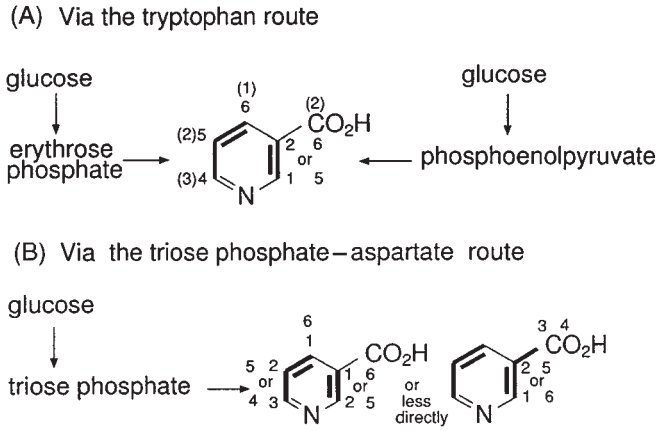
Scheme 2. A possible mechanism of the triose phosphate–aspartate pathway of nicotinic acid biosynthesis.



129.2 ppm, $^{1}J_{C\text{-}3,\ C\text{-}2}$ = 58.2 Hz) of nicotinamide.[6] In the spectrum of yeast nicotinamide, from the same precursor (expt 13), incorporation of ^{13}C was not detectable.

A mechanism for the biosynthesis of quinolinic acid (and hence of nicotinic acid), based on the condensation of 2-iminosuccinic acid with dihydroxyacetone phosphate, was advanced by Gholson and co-workers in 1982 (22). In order to arrive at the desired target, quinolinic acid, from these precursors, the proposed mechanism included steps that were equivalent to an isomerization of dihydroxyacetone phosphate into D-glyceraldehyde phosphate. Derivation of quinolinic acid by condensation of 2-iminosuccinic acid with D-glyceraldehyde phosphate rather than with dihydroxyacetone phosphate offers a much simpler path to the product (Scheme 2). It would be desirable to confirm by further experiment that the gene product of *nadA*, quinolinate synthase, is indeed specific for dihydroxyacetone phosphate, as seems to be generally assumed on the basis of a single experimental observation (26), or whether D-glyceraldehyde phosphate serves as the substrate.

As already mentioned,[5] the triose–aspartate route cannot be distinguished from the tryptophan route on the basis of the incorporation pattern of label derived from ^{13}C bond-labeled samples of D-glucose, since the sites of entry of multicarbon units from glucose are similar in the two pathways (Fig. 1). But even though the distribution of the multicarbon fragments is similar, the relative efficiency of entry into the two sites of nicotinamide, C-4,5 and C-2,3, was found to differ: Comparison of the spectra of nicotinamide derived from D-[1,2-$^{13}C_2$]glucose (Fig. 2) shows that in the triose–aspartate-derived *E. coli* sample (expt 5) the triose-derived C_2 unit C-4,5 was much more highly enriched than the aspartate-derived C_2 fragment C-2,3 (Fig. 2A). By contrast, in the tryptophan-derived aerobic *S. cerevisiae* sample (expt 6) the C_2 fragment C-2,3, derived via phosphoenolpyruvate, was much more highly enriched than the erythrose-derived C_2 unit C-4,5 (Fig. 2B). In the case of the samples derived from D-[U-$^{13}C_6$]glucose (Fig. 1) the quantitative difference in the incorporation of multicarbon units was minor. In nicotinamide derived from D-[4,5-$^{13}C_2$]glucose in *S. cerevisiae* (expt 7, Fig. 3) coupling was confined to C-5,6 (Scheme 3A).

Scheme 3. Incorporation of carbon atoms of glucose into nicotinic acid. Solid lines represent incorporation of multicarbon fragments. Numbers refer to the carbon atoms of glucose from which indicated sites within nicotinic acid are derived.

When singly ^{13}C-labeled samples of glucose are used as substrates, differentiation of the two pathways is possible. The distribution of label observed in the nicotinamide obtained in these experiments is shown in Scheme 1.

On the basis of well-established evidence (4) the tryptophan route is predicted to deliver label from D-[1-^{13}C]glucose into C-2 of niacin, while label from D-[2-^{13}C]glucose is predicted to enter C-3 as well as the carbonyl carbon. The triose–aspartate route is expected to deliver C-1 of glucose mainly into C-4 and C-3 of niacin, with some minor amount entering C-2. By contrast, C-2 of glucose is delivered into C-5 and C-2 of niacin, with a minor quantity entering C-3. Niacin generated by the two different pathways should thus be ^{13}C-enriched at different sites (Scheme 3).

To determine which of the nicotinamide carbon atoms of the samples derived from D-[1-^{13}C]- and D-[2-^{13}C]-glucose in *E. coli* (expts 8 and 10) and in *S. cerevisiae* (expts 9 and 11) had been significantly enriched, peak areas of each of the signals in the ^{13}C NMR spectra of these four samples were compared with those of the corresponding signals in a spectrum of a standard nicotinamide sample. The signal areas in the spectra of the ^{13}C-enriched samples were normalized using the signal of C-6 of nicotinamide as a baseline, since, from the experiments with D-[1,2-$^{13}C_2$]glucose, the C-6 signal was known to be unenriched in each case. The signals with maximum enrichment were thus identified. The differences

[6] The additional low level incorporation of C_2 units into C=O,C-3; C-4,5 and C-5,6 shown in Fig. 4 is presumably due to tricarboxylic acid cycle recycling of [2,3-$^{13}C_2$]succinate and due to gluconeogenesis, in the course of the 18 h incubation that was required to reach the desirable cell density in expt 12.

in the distribution of label from D-[1-^{13}C]- and D-[2-^{13}C]glucose in the samples derived by the triose–aspartate route (*E. coli*) and the tryptophan route (aerobically grown *S. cerevisiae*) are manifest (Scheme 1).

Experimental

^{13}C-labeled compounds

All but one of the ^{13}C-labeled compounds were purchased from Cambridge Isotope Laboratories, Andover, MA. The exception was D-[4,5-$^{13}C_2$]glucose, which was obtained from Isotech Inc., Miamisburg, OH.

Micro-organisms

E. coli B WG2 and *S. cerevisiae* ATTC 7752 (IFO 1234) were cultured and worked up as described earlier (32). *E. coli* cultures grown to a cell density of 1.0 at 620 nm (12–15 h) were found to contain ca. 60–80 μg L^{-1} nicotinamide. Yeast cultures grown to a cell density of 1.6 or greater (12–24 h) contained ca. 300–400 μg L^{-1}. Incubations with labeled compounds in *E. coli* cultures were carried out with 5 × 1 L cultures. Yeast incubations were performed with 1 L or with 2 × 1 L yeast cultures (Table 2).

Isolation of nicotinamide

The cells were harvested by centrifugation (10 min at room temp) and the cells from the multiflask incubations were pooled. The separated cells were suspended in dilute HCl (0.1 M, 10 mL per 1 L batch of cells) and the mixture was autoclaved for 1 h at 121°C. After cooling, acetate buffer (1 M, pH 5.5) was added to adjust the pH of the suspension to pH 4.7.

The suspension was centrifuged for 10 min at room temp. The cell debris was sonicated twice in water (20 mL) and the clear supernatant collected. The pH of the combined supernatant was adjusted (if necessary) with acetate buffer (0.2 M, pH 4.7).

The cell hydrolysate was spiked with 1 mL of an aqueous solution containing 3 mg per mL nicotinamide. The solution was centrifuged if necessary to remove suspended solids. The supernatant was applied to a 80 mm × 10 mm column of Amberlite CG50 (H^+ form) and the drainings were

© 2001 NRC Canada

collected. The column was washed with water (120 mL). The drainings and washings were combined and evaporated at 50°C under vacuum.

The residue was treated with 100 μL portions of a saturated solution of sodium carbonate (total sodium carbonate solution ca. 0.4–0.5 mL), until the pH was 9, followed by dichloromethane (25 mL). After mixing, anhydrous sodium sulfate (5 g) was added and the mixture allowed to stand overnight. The organic layer was separated and filtered through a small column with a filter disc, containing ca. 2 g anhydrous sodium sulfate.

The solid cake was stirred twice with dichloromethane (15 mL), filtered and the combined filtrates evaporated. The residue was dissolved in water (2 mL), treated with 1M HCl (20 μL), and the solution applied to a 500 mg column of SCX (a silica based strong cation exchange resin, Varian, Harbor City, CA), which had been washed in turn with column volumes (ca. 10 mL) of 1M NH_4OH, methanol, 1M HCl, and methanol, followed by a water wash, until the eluate was neutral. All the washings were carried out at a medium flow rate by applying suction. However, the sample was passed through the column at a slow rate by reducing the suction. The column was drained completely by increasing the suction to a maximum. The column was then washed with water (5 mL) and methanol (2.5 mL) at a medium rate and the product was then eluted with a mixture of dichloromethane (20 mL), methanol (2 mL), and concd. NH_4OH (0.2 mL). The elution was carried out by gravity or under mild positive pressure of nitrogen.

The eluate was evaporated to dryness to yield nicotinamide, sufficiently pure for NMR. The recovery and purity of nicotinamide was monitored by liquid chromatography (HPLC) using a Beckman Ultrasphere (5 μm, 25 cm × 4.6 mm) ODS column. The column was eluted with a mobile phase containing formic acid (400 μL), concd. NH_4OH (800 μL), and acetonitrile (15 mL) per L of water, at a flow rate of 1 mL min^{-1}. The peaks were detected at 254 nm. Under these conditions nicotinamide eluted at 13 min. The average recovery of spiked nicotinamide was ca. 90%. When traces of impurities accompanied the nicotinamide sample, it was purified by HPLC, using a Beckman Ultrasphere (5 μm, 25 cm × 10 mm) semipreparative column, using the same mobile phase that was used with the analytical column, at a flow rate of 2.5 mL min^{-1}.

Isolation of nicotinamide from the cell hydrolysate of *S. cerevisiae* was carried out by the same procedure used for the isolation from the *E. coli* cell hydrolysate.

NMR Spectroscopy

NMR spectra were acquired at McMaster and at the University of Hawaii. At McMaster: Bruker DRX 500 spectrometer operating at 11.74 T, using a Bruker 2.5 mm microprobe; pulse width 90° (8 μs); spectral width 28 985.5 Hz; recycle delay 4.6 s; digital resolution 0.88 Hz per data point. At University of Hawaii: GE Omega 500 spectrometer, using a Nalorac 3 mm microtube; pulse width 60°; recycle delay 2 s; 32 k data points. Spectra were 125.776 Hz proton decoupled ^{13}C NMR spectra of nicotinamide in D_2O (100 μL). Approximately 50 000 transients were required to generate the ^{13}C spectra showing satellites.

Chelated fluoroboron cations. III. Spectroscopic evidence for ring size and steric limitations to chelate formation by amine chelating donors

J. Stephen Hartman and James A.W. Shoemaker

Abstract: Factors affecting the ability of potentially chelating amine ligands to form chelated fluoroboron cations are explored by ^{19}F and ^{11}B NMR spectroscopy and fast atom bombardment mass spectrometry (FAB-MS). Five-membered chelate rings form much more readily than six-membered. Some potentially chelating ligands give rise to additional fluoroboron species by various redistribution and decomposition reactions.

Key words: chelated fluoroboron cations, ^{19}F NMR, ^{11}B NMR; FAB-MS, *N,N,N′,N′*-tetraethylethylenediamine.

Résumé : Faisant appel à la spectroscopie RMN du ^{19}F et du ^{11}B et la spectrométrie de masse par bombardement avec des atomes rapides, on a étudié les facteurs qui affectent la facilité de former des cations fluoroborés chélatés à partir de ligands aminés pouvant éventuellement donner lieu à de la chélation. Les chélates avec cycles à cinq chaînons se forment beaucoup plus facilement que ceux à six chaînons. Certains des ligands pouvant éventuellement donner lieu à de la chélation conduisent à d'autres espèces fluoroborés impliquant diverses réactions de redistribution et de décomposition.

Mots clés : cations fluoroborés chélatés, RMN du ^{19}F, RMN du ^{11}B, FAB-MS, *N,N,N′,N′*-tétraéthyléthylènediamine.

[Traduit par la Rédaction]

Introduction

We have recently reported the formation of chelated fluoroboron cations $(DD)BF_2^+$ involving substituted ethylenediamine (en) ligands, notably *N,N,N′,N′*-tetramethylethylenediamine (Me_4en) and *N,N,N′,N″,N″*-pentamethyldiethylenetriamine (Me_5dien) (1). There are various possible routes to these species (1, 2): (*i*) displacement of a donor and a heavy halide ion from $py{\cdot}BF_2Cl$ or $ISOX{\cdot}BF_2X$ (X = Cl or Br; py = pyridine; ISOX = isoxazole (a very weak donor));

ISOX

(*ii*) stepwise displacement of py from $(py)_2BF_2^+$; and (*iii*) reaction of the ligand with $Et_2O{\cdot}BF_3$. Routes (*i*) and (*ii*) are effective for *t*-amine chelating ligands such as Me_4en and Me_5dien, while route (*iii*) gives only BF_3 adducts, in which each donor site is coordinated to a separate BF_3 molecule. This is in accord with earlier work in which others had tried and failed to obtain the chelated $(Me_4en)BF_2^+$ by this route (3). However, $Et_2O{\cdot}BF_3$ does react to form chelated fluoroboron cations with some rigid donor molecules such as 1,10-phenanthroline (2, 4), in which the donor sites are geometrically constrained to favour chelation, i.e., there is donor preorganization (5). Most of the few known chelated fluoroboron cations have five-membered chelate rings except for 1,8-bis(dimethylamino)naphthalene (DMAN) (2) which gives rise to a six-membered ring. However boron forms a wide range of five- and six-membered ring chelate compounds (6), and there are even some 7-membered-ring chelate compounds (7). Hence there is no evident reason why fluoroboron chelates should not form with a similarly wide range of ligands.

We now report an extension of our studies of the formation of chelated fluoroboron cations (1, 2) to a wider range of amine chelating ligands, with emphasis on the effects of increased steric hindrance and chelate ring size, using the ligands *N,N,N′,N′*-tetraethylethylenediamine (Et_4en), *N,N,N″,N″*-tetraethyldiethylenetriamine (Et_4dien), di-(2-picolyl)amine (DPA) (8), 1,3-bis(dimethylamino)propane (*N,N,N′,N′*-tetramethylpropylenediamine) (Me_4pn), *N,N,N″,N″*-tetraethyldipropylenetriamine (Et_4dipn), and bis(dimethylamino)methane (*N,N,N′,N′*-tetramethylmethylenediamine) (Me_4mn). Although none of the chelated fluoroboron cations of these ligands have precipitated cleanly as single species as in our previous studies (1, 2), much has been learned about these systems from spectroscopic studies.

Scheme 1.

Experimental

Materials and methods

Materials were handled with standard inert-atmosphere Schlenk line and glove bag techniques. The chelating ligands, all from Aldrich, were stored over 3 Å Molecular Sieve that had been heated in a muffle furnace at 400°C for more than 3 h and cooled over a period of 0.5 h in a vacuum desiccator, and were used without further purification. Boron trifluoride (Aldrich, 99.5%), boron trifluoride etherate (Aldrich), boron trichloride (Matheson, 99.5%) boron tribromide (Aldrich, 99.9%), isoxazole (ISOX, Aldrich 99%), ammonium hexafluorophosphate (Aldrich, 95+%), and pyridine (Aldrich, 99.5%) were all handled as described previously (1). Acetone (Caledon, HPLC grade), chloroform (Caledon, hydrocarbon stabilized, 99.8%), chloroform-d_1 (Cambridge Isotope Laboratories, 99.8%), and nitromethane (Fisher Scientific) were dried over 3 Å Molecular Sieve, and were used without further purification.

The $py{\cdot}BF_nX_{3-n}$, $ISOX{\cdot}BF_nCl_{3-n}$, and $ISOX{\cdot}BF_nBr_{3-n}$ adduct systems were prepared in Schlenk vessels by methods described previously (9, 10) and handled as described in the previous paper in this series (2). $(py)_2BF_2^+$ was prepared as described previously (2) and precipitated as its PF_6^- salt with ammonium hexafluorophosphate. Subsequent reactions were carried out on 20 mg mL^{-1} solutions of $(py)_2BF_2^+{\cdot}PF_6^-$ in acetone. Reactions of $Et_2O{\cdot}BF_3$ with the chelating donors were carried out by adding neat $Et_2O{\cdot}BF_3$, dissolved in benzene, chloroform, acetone, or diethyl ether, to 1–15 mL of solution containing 20–100 mg of the chelating donor in the same solvent.

Most ^{19}F and ^{11}B NMR spectra were obtained on a Bruker AC-200 4.7 T multinuclear FT-NMR spectrometer operating at 188.31 (^{19}F) and 64.20 MHz (^{11}B), using 5 mm NMR tubes. ^{19}F NMR spectra were obtained with 16K FID's, 16K zero-filling, spectral windows of up to 35 000 Hz, with between 256 and 4096 30° pulses, and a relaxation delay of 1.0 s. The 90° pulse durations were 6.6 (^{19}F) and 17.1 μs (^{11}B). ^{19}F NMR chemical shifts are accurate to ±0.1 ppm and were internally referenced to C_6F_6 as a secondary standard (–162.7 ppm from $CFCl_3$), and are reported in ppm from $CFC1_3$. ^{11}B spectra were obtained with 16K FID's and spectral windows of up to 6400 Hz, and were referenced to external $Et_2O{\cdot}BF_3$. Some ^{19}F and ^{11}B NMR spectra were obtained at 30°C on a Bruker DRX-500 11.7 T multinuclear FT-NMR spectrometer (McMaster University) operating at 470.53 (^{19}F) and 160.46 MHz (^{11}B) using between 40 and 128 30° pulses with 32K FID's. The 90° pulse durations were 7.5 (^{19}F) and 15.0 μs (^{11}B). Spectral windows of 42 016 (^{19}F) and 40 000 Hz (^{11}B) were used. ^{11}B solid state magic angle spinning (MAS) NMR spectra were obtained on a Bruker DPX-300 7.4 T multinuclear FT-NMR spectrometer, as described previously (2), using trimethyl borate as the external standard (chemical shift 18.3 ppm from $Et_2O{\cdot}BF_3$).

Positive ion fast atom bombardment (FAB) mass spectra were obtained on a Concept 1S double beam mass spectrometer, with 8 KV accelerating voltage using Xe collision gas at 7.5 W power. 3-Nitrobenzyl alcohol (NBA) was normally used as the liquid matrix. Data were collected on a Kratos DART data system with SUN Spectrostation 10, using XMACH3 software.

Specific reactions

Et_4en plus $py{\cdot}BF_nCl_{3-n}$

Et_4en displaces py from its BF_3 adduct but does not react with the other py adducts, which is consistent with its high steric hindrance and analogous to the behaviour of Et_3N (9). The displaced py proceeds to form $(py)_2BF_2^+$.

Et_4en plus $ISOX{\cdot}BF_nCl_{3-n}$

Addition of Et_4en to a chloroform solution of the $ISOX{\cdot}BF_nCl_{3-n}$ adducts ($ISOX:BF_3:BCl_3:Et_4en$ = 4:1:3:4 mol equiv) gave rapid displacement of ISOX to form the $Et_4en{\cdot}BF_nCl_{3-n}$ adducts, according to ^{19}F and ^{11}B NMR (Table 1). Upon standing, new NMR signals appeared that arise from the $BF_nCl_{4-n}^-$ anions (11), and ^{19}F 1:1:1:1 quartets at –150.1 and –139.4 ppm that we attribute to chelated $(Et_4en)BF_2^+$ and $(Et_4en)BFCl^+$, respectively. In addition, two overlapping 1:1:1:1 quartets at –159.8 and –159.9 ppm are seen, both with $^1J_{BF}$ = 47 Hz, which appear after different lengths of time in different samples. Positive ion FAB-MS spectra of the chloroform solution, obtained using an NBA matrix, confirm the presence of $(Et_4en)BF_2^+$ (*m*/*z* 221, 100%) and $(Et_4en)BFCl^+$ (*m*/*z* 237, ~2%, with the correct isotope pattern). A further FAB-MS peak that occurs at *m*/*z* 270 (~20%) possibly arises from loss of HF from $(Et_4en)(ISOX)BF_2^+$; it also appears in the FAB-MS spectrum of the Et_4en plus $ISOX{\cdot}BF_nBr_{3-n}$ reaction mixture. This peak gives rise to metastable peaks at 173.2 (11%), 172.2 (13%), 171.2 (72%), 101.1 (5%), 100.1 (100%), and 86.1 (16%).

Et_4en plus $ISOX{\cdot}BF_nBr_{3-n}$

On addition of Et_4en to $ISOX{\cdot}BF_nBr_{3-n}$ a brown solid, insoluble in nitromethane, separates from the orange-brown chloroform solution. The positive ion FAB-MS spectrum of the solid shows the presence of $(Et_4en)BF_2^+$ (*m*/*z* 221, 100%), $(Et_4en)BFBr^+$ (*m*/*z* 281, 15.8%, higher than the

[a]Determined from reaction of the base with $Et_2O{\cdot}BF_3$ in diethyl ether:chloroform solution (1:5).
[b] ^{19}F chemical shifts in chloroform are –161.6 and –159.3 ppm for $Me_4mn{\cdot}BF_3$ and $Me_4mn{\cdot}(BF_3)_2$, respectively.

signal intensities previously seen for (*t*-amine)$BFBr^+$ species (1)), and the *m*/*z* 270 species noted above (10.2%), as well as the ion cluster $[(Et_4en{\cdot}H_2)^{2+}{\cdot}Br^-]^+$ (*m*/*z* 253, ~2%).

This is typical of many of the following reactions. Solids often appear due to saturation of the mother liquor by one or more of the reaction products. Typically, FAB-MS and (or) NMR spectroscopy show that these solids consist of mixtures of haloboron cation salts.

Et_4dien plus ISOX·BF_nCl_{3-n}

Excess Et_4dien added to a chloroform solution of the ISOX·BF_nCl_{3-n} adducts (ISOX:BF_3:BCl_3:Et_4en = 4:1:3:4 mol equiv) readily forms (Et_4dien)BF_2^+, as confirmed by positive ion FAB-MS (in NBA matrix) on both the chloroform mother liquor, and on the brown solid generated by removing the chloroform: (Et_4dien)BF_2^+ (*m*/*z* 264, 32.3 and 83.4%, respectively)), ($C_{12}H_{28}N_3$)BF^+ (loss of HF from (Et_4dien)BF_2^+) (*m*/*z* 244, 17.1 and 33.8%), and Et_4dien·H^+ (*m*/*z* 216, 31.0 and 100%). The ^{19}F NMR spectrum of the chloroform solution included two equal-intensity signals at –153.1 and –160.0 ppm, consistent with the nonequivalent BF_2 fluorines expected from (Et_4dien)BF_2^+, in which coordination is by the central nitrogen and one terminal nitrogen (1). There are many additional ^{19}F NMR signals (less than 20% of the total ^{19}F peak intensity) from unknown species, including singlets at –122.3 (broad), –131.2 (broad), and –148.8 ppm, and 1:1:1:1 quartets at –143.4 ($^1J_{BF}$ = 50 Hz), –150.5 ($^1J_{BF}$ = 62 Hz), and –151.8 ppm (probably a quartet, but poorly resolved). The ^{19}F spectrum of the brown solid, dissolved in nitromethane, gave major signals for (Et_4dien)BF_2^+ and a small BF_4^- signal at –150.5 ppm, as well as a broad singlet at –137.3 ppm and a 1:1:1:1 quartet at –131.3 ppm ($^1J_{BF}$ ~ 26 Hz, poorly resolved). The ^{11}B NMR spectrum of the chloroform mother liquor had the (Et_4dien)BF_2^+ signal as 40% of the total peak intensity, BCl_4^- 30%, ISOX·BCl_3 8%, and unknown species (broad signal from 1 to –1 ppm) 22%, but no chlorofluoroborate anion signals were observed.

DPA plus ISOX·BF_nCl_{3-n}

DPA added to a chloroform solution of the ISOX·BF_nCl_{3-n} adducts (ISOX:BF_3:BCl_3:DPA = 4:1:3:4 mol equiv) apparently gives (DPA)BF_2^+, on the basis of positive ion FAB-MS results (in NBA matrix). The yellow chloroform mother liquor and the brown oil, generated by removing the chloroform under vacuum, both gave very low intensity FAB mass spectra, which included peaks arising from DPA·H^+ (*m*/*z* 200, 7.3 and 100%, respectively) and a peak at *m*/*z* 55 (100 and 22%). The brown oil gave an additional peak corresponding to ($C_{12}H_{12}N_3$)BF^+ (*m*/*z* 228, 20%), consistent only with loss of HF from (DPA)BF_2^+. The chloroform solution gives many ^{19}F NMR peaks, including broad singlets at –149.8, –150.9, –153.4, –154.6, and 156.5 ppm, a BF_4^- signal, and a 1:1:1:1 quartet at –147.8 ppm ($^1J_{BF}$ = 52 Hz). The brown oil, dissolved in nitromethane, gives a ^{19}F NMR spectrum with a much larger BF_4^- peak, broad singlets at –138.7, –144.4, –145.2, –153.4, and –155.5 ppm, and a 1:1:1:1 quartet at –151.7 ppm ($^1J_{BF}$ = 42 Hz). A few of these peaks may arise from boron trihalide adducts of DPA.

Me_4pn plus py·BF_nCl_{3-n}

Me_4pn, added in small portions to the py·BF_nCl_{3-n} adducts in chloroform solution, gives a yellow solution. ^{19}F and ^{11}B NMR spectra show that py·BF_3 and py·BF_2Cl react over several hours to give $Me_4pn{\cdot}BF_3$, $(py)_2BF_2^+$, and (py)(Me4en)BF_2^+. py·$BFCl_2$ and py·BCl_3 are much less reactive, although a small amount of $(py)_2BFCl^+$ does form after several hours by attack of py (displaced from its BF_3 adduct) on py·$BFCl_2$. Further reactions occur over several days. FAB mass spectra confirm the presence of (py)(Me_4pn)BF_2^+ (*m*/*z* 258) in solution. Addition of a single large portion of Me_4pn,

© 2001 NRC Canada

instead of several small portions, gives immediate separation of a white foam-like material at the top of the mixture, identified as primarily $Me_4pn \cdot BF_3$ by ^{19}F NMR.

Me_4pn plus $ISOX \cdot BF_nCl_{3-n}$

Addition of Me_4pn to chloroform solutions of $ISOX \cdot BF_nCl_{3-n}$ ($ISOX:BF_3:BCl_3:Me_4pn$ = 2:1:1:2 and 4:1:3:4 mol equiv) gives immediate formation of a red solid at the top, and the colourless solution turns orange. NMR spectra of the solution show the presence of $Me_4pn \cdot BF_3$, $Me_4pn \cdot BFCl_2$, $Me_4pn \cdot BFCl_2$, and $Me_4pn \cdot BCl_3$ (Table 1), with the chlorine-containing species being more abundant in the 4:1:3:4 sample. The red solid gives positive ion FAB-MS spectra showing the presence of $Me_4pn \cdot H^+$ (*m/z* 131, 100%), but no fluoroboron cations. The ^{11}B and ^{19}F NMR spectra of the red solid, dissolved in 3:1 acetone:sulpholane (slightly soluble) or nitromethane (more soluble) indicate the presence of the same species as in the orange solutions, and again there is no indication of the presence of fluoroboron cations.

Me_4pn plus $ISOX \cdot BF_nBr_{3-n}$

Addition of Me_4pn to chloroform solutions of $ISOX \cdot BF_nBr_{3-n}$ ($ISOX:BF_3:BBr_3:Me_4pn$ = 5:2:3:5 and 4:1:3:4 mol equiv) gives immediate precipitation, and only a small amount of $Me_4pn \cdot BF_3$ was detected in the mother liquor by ^{19}F NMR. As with the corresponding Me_4en and Me_5dien systems (1), the precipitates are insoluble in various solvents. After drying, they give FAB mass spectra showing the presence of $Me_4pn \cdot H^+$ (*m/z* 131, 100%) and $[(Me_4pn \cdot H_2)^{2+} \cdot Br^-]^+$ (*m/z* 211, 12%), but there are no signals corresponding to fluoroboron cations. ^{11}B MAS NMR spectra of the precipitates are broad and poorly resolved, with most of the signal intensity in the BF_nBr_{3-n} adduct range (+2 ppm to –10 ppm) and little in the fluoroboron cation range (+10 to +2 ppm) (1).

Me_4dipn plus $ISOX \cdot BF_nCl_{3-n}$

Me_4dipn added to a chloroform solution of the $ISOX \cdot BF_nCl_{3-n}$ adducts ($ISOX:BF_3:BCl_3:Me_4dipn$ = 4:1:3:4 mol equiv) gives an orange solution from which a brown solid gradually precipitates. One sample remained supersaturated and no precipitate appeared until after the ^{19}F NMR spectrum was obtained. This spectrum included two equal-intensity ^{19}F peaks at –164.7 and –170.9 ppm, as well as many singlets: –128.1 (broad), tentatively $Me_4dipn \cdot BFCl_2$; –138.3 (broad), tentatively $Me_4dipn \cdot BF_2Cl$; –158.9, –160.0, and –161.0 ppm (one of which probably arises from $Me_4dipn \cdot BF_3$), and broad peaks at –168.0, –174.3, and –176.4 ppm. Positive ion FAB mass spectra on the chloroform solution and on the brown solid gave only $Me_4dipn \cdot H^+$ (*m/z* 188) and its fragments.

Me_4mn plus $py \cdot BF_nCl_{3-n}$

Me_4mn displaces py from its BF_3 adduct but does not react with the other py adducts. The displaced py proceeds to form $(py)_2BF_2^+$.

Me_4mn plus $ISOX \cdot BF_nCl_{3-n}$

Me_4mn readily displaces ISOX from the $ISOX \cdot BF_nCl_{3-n}$ adducts in chloroform to form the $Me_4mn \cdot BF_nCl_{3-n}$ (*n* = 0–3) adducts, as shown by ^{11}B and ^{19}F NMR (Table 1). A number of further reactions occur on standing, as shown by NMR monitoring and discussed below, but no evidence for the chelated cation could be obtained by FAB mass spectrometry under various conditions, running the reaction solution neat or mixed with the matrix liquids NBA, NOPE, sulpholane, or glycerol, which have been effective in other difficult cases (1,2). The principal FAB-MS peaks correspond to $Me_2NH_2^+$ (*m/z* 46) and $Me_2N{=}CH_2^+$ (*m/z* 58).

Me_4mn plus $ISOX \cdot BF_nBr_{3-n}$

On reacting Me_4mn with $ISOX \cdot BF_nBr_{3-n}$ in chloroform a yellow solid precipatates, which is insoluble in nitromethane. Positive ion FAB-MS of the solid does not indicate the presence of any fluoroboron cations.

Reactions with $Et_2O \cdot BF_3$

Reacting Et_4en, Me_4pn, and Me_4mn with $Et_2O \cdot BF_3$ in chloroform (1:1 mol ratio of base to $Et_2O \cdot BF_3$) gives white precipitates, and the ^{19}F NMR spectra of the supernatant liquids contain 1:1:1:1 quartets arising from the mono- and bis-BF_3 adducts (Table 1), in addition to a small BF_4^- signal. The white precipitates, dissolved in nitromethane, give ^{19}F NMR signals of the mono- and bis-BF_3 adducts. When the bases are reacted with excess $Et_2O \cdot BF_3$ in chloroform (1:2 and 1:3 mol ratios of base to $Et_2O \cdot BF_3$), the supernatant liquid contains only a very small ^{19}F NMR signal of the base$\cdot(BF_3)_2$ adduct, most of which had precipitated, as well as an $Et_2O \cdot BF_3$ signal at –153.9 ppm. These precipitate too consist of the mono- and bis-BF_3 aducts. With Me_4mn an additional fluorine-containing species is present in the supernatant liquid from all three mol ratios of Me_4mn to $Et_2O \cdot BF_3$, giving a small ^{19}F NMR 1:1:1:1 quartet at –157.5 ppm ($^1J_{BF}$ = 20 Hz), which is reasonably consistent with $Me_2NH \cdot BF_3$. FAB mass spectra gives no evidence for fluoroboron cations.

Reactions with $(py)_2BF_2^+$

Of the six ligands in Scheme 1, only Me_4pn and Me_4dipn (2 to 10 molar excess) undergo substitution reactions with $(py)_2BF_2^+$, giving new ^{19}F NMR 1:1:1:1 quartets over several hours that we assign to $(py)(Me_4pn)BF_2^+$ and $(py)(Me_4dipn)BF_2^+$ on the basis of their chemical shifts and $^1J_{BF}$ values (Table 2). The yield of $(py)(Me_4pn)BF_2^+$ increases as the excess of Me_4pn increases, up to about 40% at ambient temperature or 30% at 50°C. Positive ion FAB mass spectra confirm the existence of $(py)(Me_4pn)BF_2^+$, but there is no evidence for chelated $(Me_4pn)BF_2^+$. With Me_4dipn the new ^{19}F NMR quartet is very small, and $(py)(Me_4dipn)BF_2^+$ could not be confirmed by FAB-MS. The larger the excess of Me_4dipn, the smaller the size of this ^{19}F quartet, and it was not detectable in samples that had been allowed to stand at 50°C.

Results

The best-behaved systems are Et_4en, Me_4pn, and Me_4mn, which give clean displacement of ISOX from its BF_nCl_{3-n} and BF_nBr_{3-n} adducts. The other systems, each having an N—H bond, give additional products that are apparently related to loss of hydrogen halide from the reactive N—H and B—Cl or B—Br bonds. The more detailed studies were therefore carried out on Et_4en, Me_4pn, and Me_4mn. None of

these react with $Et_2O{\cdot}BF_3$ to give fluoroboron cations, but only form the 1:1 and 1:2 BF_3 adducts except for Me_4mn,which forms these plus an additional species, apparently $Me_2NH{\cdot}BF_3$. Me_4pn and Me_4dipn displace only a single py from $py_2BF_2^+$, while none of the other systems can displace even one py.

Five-membered ring chelating ligands

Et_4en and Et_4dien react with the ISOX·BF_nX_{3-n} (n = 0–3) adducts much like the less sterically hindered Me_4en and Me_5dien (1), with rapid displacement of the weakly basic ISOX from its adducts by the chelating base and subsequent closure of the chelate ring by heavy halide ion displacement. A major difference is formation of the tetrahaloborate anions $BFCl_3^-$, $BF_2Cl_2^-$, and especially BCl_4^- as major products, as shown by ^{11}B and ^{19}F NMR (11). The ^{19}F spectrum of a sample, in which insufficient Et_4en is available to displace all of the ISOX from its adducts, shows strong $BFCl_3^-$ and $BF_2Cl_2^-$ signals (Fig. 1), while the ^{11}B spectrum of the same sample has an intense BCl_4^- peak (Fig. 2). This sample had been allowed to stand for a day, and all of the Et_4en·BF_2Cl had reacted to give chelated (Et_4en)BF_2^+ (^{19}F NMR 1:1:1:1 quartet at –151 ppm; its $^1J_{BF}$ value of 35 Hz distinguishes it from Et_4en·BF_3 which has a similar chemical shift but a much smaller $^1J_{BF}$ value of 18 Hz.) Several additional ^{19}F NMR signals, most having low intensity, gain in intensity very slowly over time (Fig. 1). The largest of these, at –159.8 ppm, resembles two overlapping 1:1:1:1 quartets, both with $^1J_{BF}$ = 47 Hz.

^{19}F NMR shows that the potentially tridentate Et_4dien, on addition to a chloroform solution of the ISOX·BF_nCl_{3-n} adducts, forms bidentate (Et_4dien)BF_2^+ with the centre and one terminal nitrogen coordinated to boron. The similarity of the ^{19}F NMR spectrum to that of (Me_5dien)BF_2^+, which we have previously studied in detail (1), is striking. The two equal-intensity ^{19}F peaks, split by $^1J_{BF}$ and $^2J_{FF}$ couplings (Fig. 3), can be assigned to the prochiral and nonequivalent BF_2 fluorines, the nonequivalence arising from chirality of the central nitrogen, as in (Me_5dien)BF_2^+ ($^1J_{BF}$ = 34 Hz and $^2J_{FF}$ = 62 Hz, compared to $^1J_{BF}$ = 33 Hz and $^2J_{FF}$ = 61 Hz for (Me_5dien)BF_2^+ (1)). The parent ion FAB-MS peak at m/z 264 confirms the presence of (Et_4dien)BF_2^+, while the peak at m/z 244 is consistent with loss of HF due to the presence of the reactive N—H proton.

DPA probably reacts with ISOX·BF_nCl_{3-n} to give the desired chelated (DPA)BF_2^+, on the basis of the m/z 228 FAB peak, which corresponds to loss of HF from (DPA)BF_2^+ as seen with (Et_4dien)BF_2^+. However no parent ion peak is detected. This system has low stability and undergoes multiple reactions, and no spin-spin splittings are visible, preventing unambiguous assignments of adduct and cation ^{19}F resonances from among the many signals present. Every sample does give two equal-intensity broad peaks (–154.6 and –156.6 ppm in chloroform; –153.4 and –155.5 ppm in nitromethane), which is consistent with bidentate coordination and nonequivalent fluorines, as seen with Et_4dien and Me_5dien.

Potential six-membered ring chelating ligands

Me_4pn displaces Cl^- from py·BF_2Cl to form the nonchelated (py)(Me_4pn)BF_2^+, but differs from the five-membered ring chelating ligands in that the coordinated Me_4pn does not displace the second pyridine to form the chelate complex. The inability of Me_4pn to undergo chelation allows us to study the conditions for maximization of (py)(DD)BF_2^+ without complications due to further reactions. ^{19}F NMR monitoring of the reaction of Me_4pn with py·BF_nCl_{3-n} (mol ratio of Me_4pn:py:BF_3:BCl_3 = 3:4:2:2) (Fig. 4*a*) shows that Me_4pn displaces py from about 80% of the py·BF_3 within 2.4 h, while only 25% of the py·BF_2Cl has reacted. The py released from py·BF_3 competes effectively with Me_4pn in attacking py·BF_2Cl, so that the predominant fluoroboron cation formed is $(py)_2BF_2^+$ (25% of the total ^{19}F NMR signal intensity, vs. only 5% for (py)(Me_4pn)BF_2^+). The low-steric-hindrance py is evidently a much more

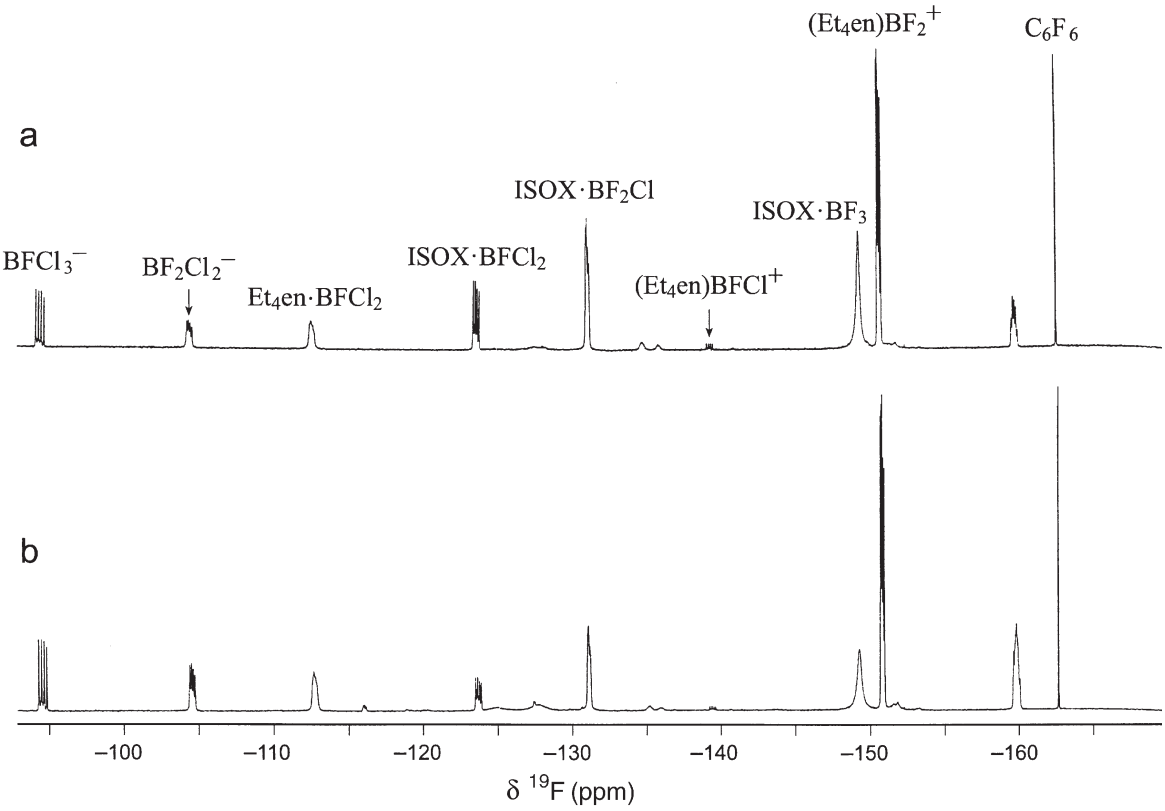
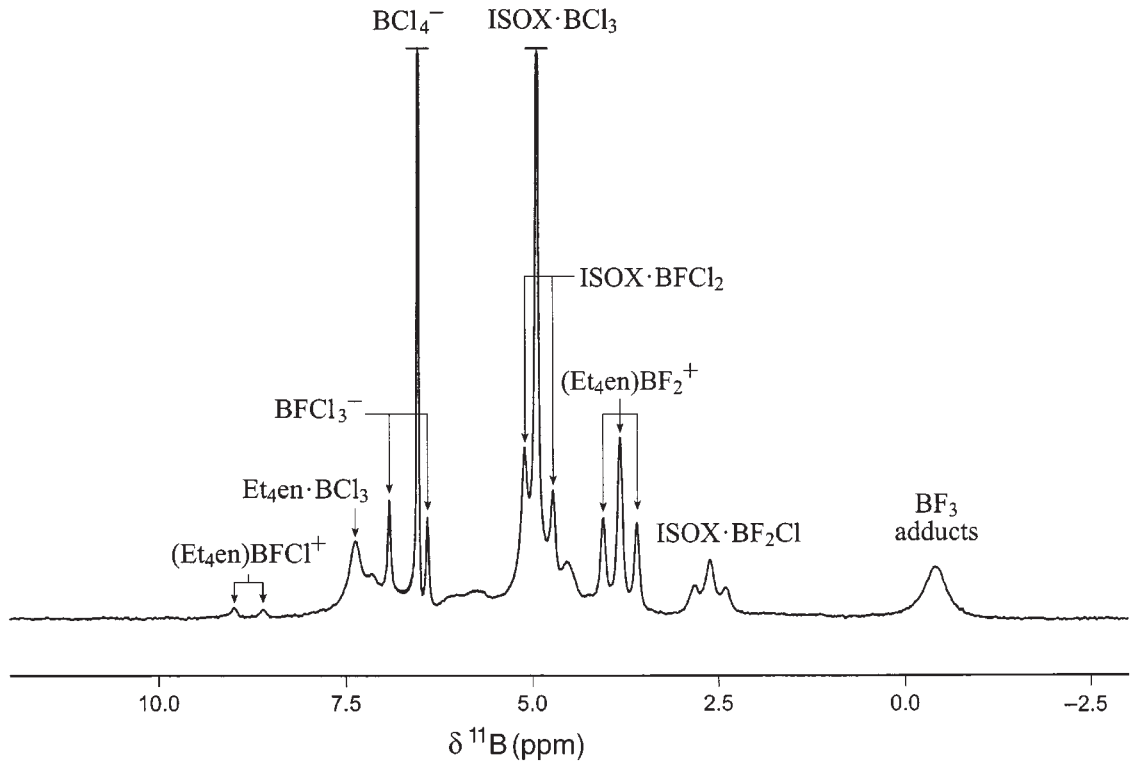
Fig. 1. 470.59 MHz ^{19}F NMR spectra of a $CDCl_3$ solution of ISOX·BF_nCl_{3-n} (ISOX:BF_3:BCl_3 = 4:1:3 mol ratio) to which Et_4en (insufficient to displace all the ISOX) had been added, after standing for: (*a*) one day; and (*b*) 4 days, at ambient temperature.





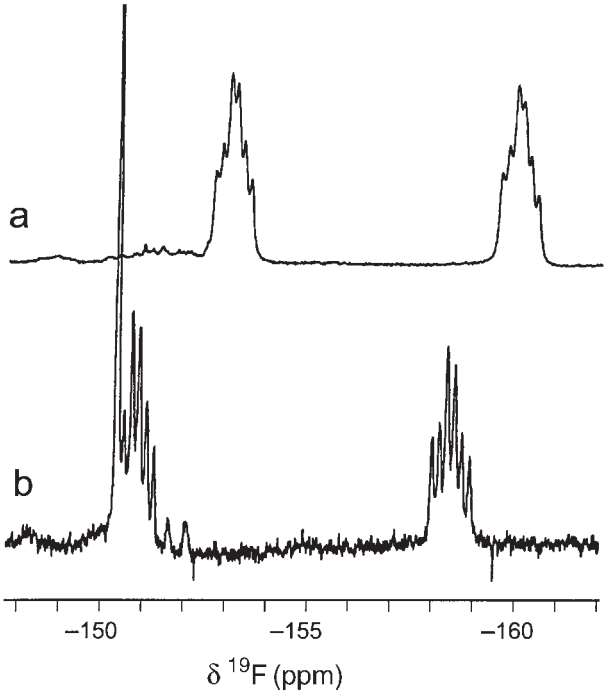


Fig. 2. 160.46 MHz ^{11}B NMR spectrum of the same sample as Fig. 1, after standing for one day at ambient temperature.

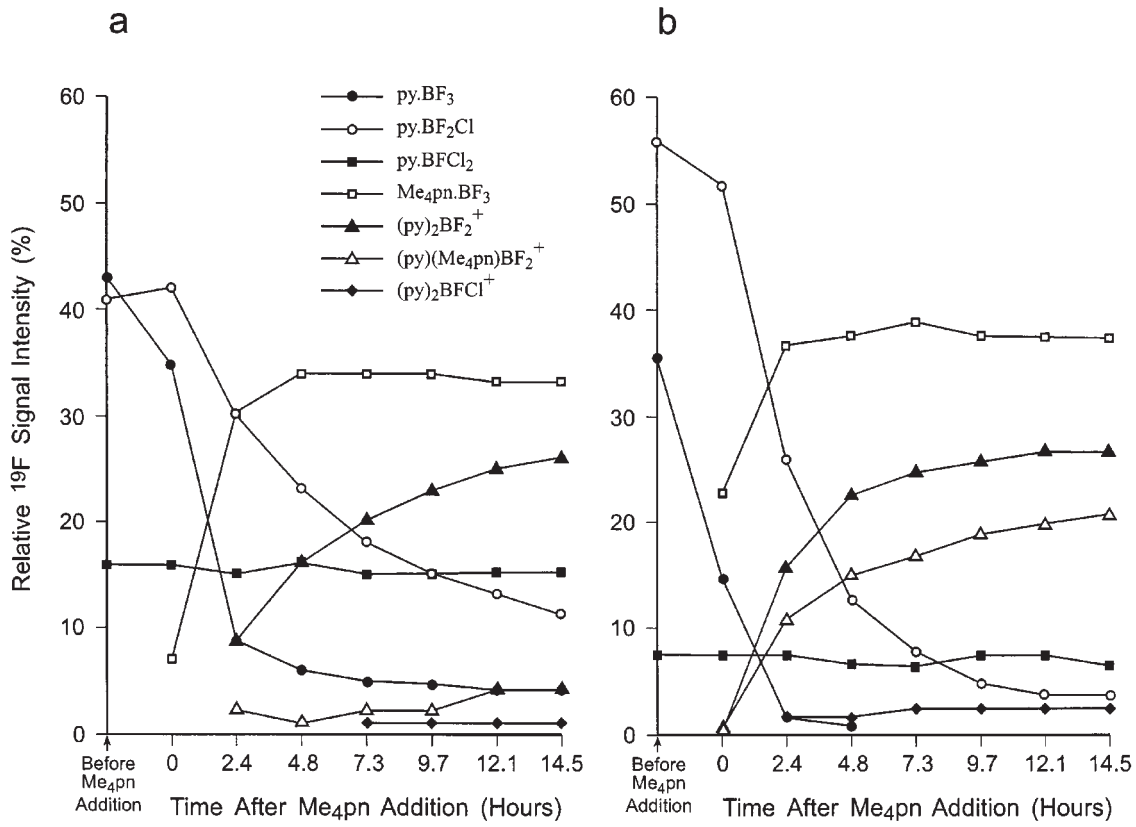
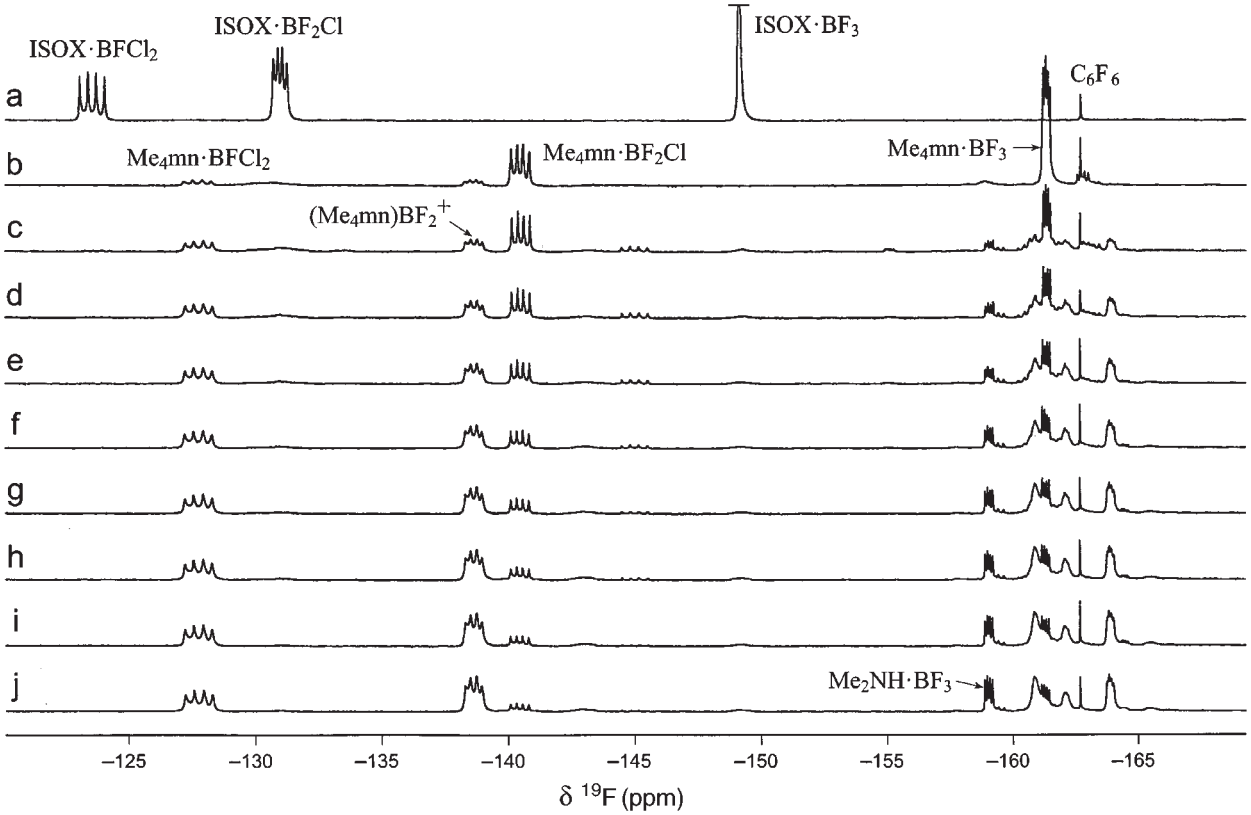
© 2001 NRC Canada

Fig. 3. 188.31 MHz ^{19}F NMR spectra (–148 to –162 ppm region only) of a $CDCl_3$ solution of ISOX·BF_nCl_{3-n} (4:1:3 mol ratio) to which Et_4dien had been added (*a*) in chloroform, and (*b*) in nitromethane. The spin-spin splittings, better resolved in nitromethane, are consistent with BF_2 nonequivalence in chelated $(Et_4dien)BF_2^+$.



effective nucleophile despite its much lower basicity (pK_b 8.8 compared to $pK_b \approx 4$ for *t*-amines such as Me_4pn).

The formation of $(py)(Me_4pn)BF_2^+$ can be optimized by (*i*) increasing the concentration of Me_4pn so it can compete more effectively with the displaced py, and (*ii*) using a py·BF_nCl_{3-n} solution that is richer in Cl than in F, since this minimizes the amount of py·BF_3 which is the only adduct which readily releases py. A Me_4pn:py:BF_3:BCl_3 mol ratio of 5:5:2:3 optimizes both of these factors to give a much larger $(py)(Me_4pn)BF_2^+$ signal (20% of the total ^{19}F NMR signal intensity), although the $py_2BF_2^+$ signal remains large (Fig. 4*b*).



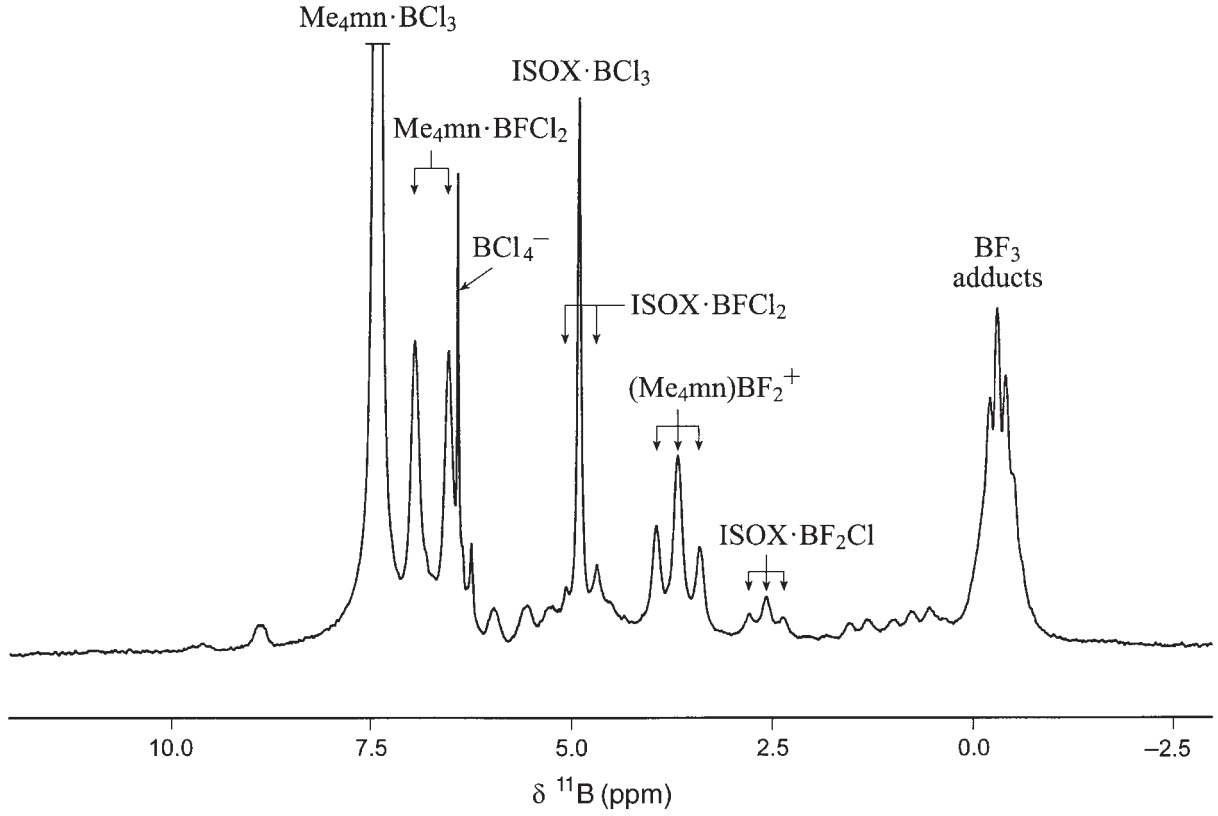
Further reactions occur over several days. Me_4pn very slowly displaces py from py·BF_2Cl to form Me_4pn·BF_2Cl (unusual since most ligands displace Cl^- rather than py from py·BF_2Cl (9, 10, 12)). Me_4pn also reacts very slowly with $(py)_2BF_2^+$ to give more $(py)(Me_4pn)BF_2^+$, and with py·$BFCl_2$ to give primarily $(py)(Me_4pn)BFCl^+$ but also some Me_4pn·$BFCl_2$. Thus the initial reactions of Fig. 4 occur under kinetic control, but the greater basicity of Me_4pn eventually wins out, with more Me_4pn becoming coordinated as the system moves very slowly toward thermodynamic equilibrium. However even on prolonged standing Me_4pn does not displace pyridine from $(py)(Me_4pn)BF_2^+$ or $(py)(Me_4pn)BFCl^+$ to give the bis(Me_4pn) cations, and no chelated $(Me_4pn)BF_2^+$ can be detected even when the concentration of $(py)(Me_4pn)BF_2^+$ is optimized.

Fig. 4. Plots of changes in ^{19}F NMR (188.31 MHz) signal intensity with time in the ambient-temperature reaction of Me_4pn with py·BF_nCl_{3-n}, in chloroform, for samples with Me_4pn:py:BF_3:BCl_3 mol ratios of (*a*) 3:4:2:2 and (*b*) 5:5:2:3. The proportions in the latter sample are optimized for formation of $(py)(Me_4pn)BF_2^+$ (20% of the total ^{19}F intensity compared to 5% in (*a*)).

© 2001 NRC Canada

Fig. 5. 188.31 MHz ^{19}F NMR spectra of: (*a*) a chloroform solution of ISOX·BF_nX_{3-n} (ISOX:BF_3:BX_3 = 4:1:3 mol ratio); (*b*) the same solution a few minutes after addition of sufficient Me_4mn to displace all of the ISOX; (*c*) the same solution as spectrum (*b*) after standing at ambient temperature for 5.4 h; (*d–j*) after further standing at room temperature for successive 5.7-hour intervals, up to a total time of 45.2 h. Small 1:1:1:1 quartets arising from $BFCl_3^-$ and $BF_2Cl_2^-$ are also present at –94.6 and –104.4 ppm, respectively, in spectrum (*b*), and their intensities diminish and disappear over a day.

Me_4pn, like other potentially chelating ligands (1, 2), reacts far more readily with ISOX·BF_nCl_{3-n} and ISOX·BF_nBr_{3-n} than with py·BF_nCl_{3-n}, with ISOX being rapidly displaced to give $Me_4pn·BF_3$, $Me_4pn·BFCl_2$, $Me_4pn·BFCl_2$, and $Me_4pn·BCl_3$. Also the displaced ISOX, unlike py, is too weak a base to compete in forming cations. However, under conditions which readily give the five-membered chelated fluoroboron cations, there is no displacement of chloride to give chelated $(Me_4pn)BF_2^+$ or $(Me_4pn)BFCl^+$. Even on reaction with ISOX·BF_nBr_{3-n} no fluoroboron cations form, despite Br^- displacement being much easier than Cl^- displacement.



Although rapid decomposition occurs in the Me_4dipn-ISOX·BF_nCl_{3-n} system and there is no FAB-MS evidence for chelated $(Me_4dipn)BF_2^+$, there is convincing ^{19}F NMR evidence. As with Et_4dien and DPA, two equal-intensity ^{19}F NMR peaks appear at high field (–164.7 and –170.9 ppm), consistent with nonequivalent BF_2 fluorines and hence with chelation by the central nitrogen and one end nitrogen in $(Me_4dipn)BF_2^+$. The –164.7 ppm chemical shift value is consistent with a fluorine in a six-membered ring (2), *cis* to a methyl group and a longer hydrocarbon chain on the adjacent nitrogens, while the peak at –170.9 ppm is consistent with a fluorine that is *cis* to a methyl group and to a hydrogen atom on the adjacent nitrogens, since lower steric hindrance causes a shift to higher field. The chemical shift difference of 6.2 ppm is very similar to the difference of 6.9 ppm described above for $(Et_4dien)BF_2^+$ for which the FAB-MS evidence is conclusive, and consistent with the 5.5 ppm difference observed previously in $(Me_5dien)BF_2^+$ (1). The spin-spin splittings, consistent with $^1J_{BF}$ ~ 32 and $^2J_{BF}$ ~ 70 Hz, support this interpretation.

Me_4mn, a possible four-membered ring chelating ligand

^{19}F NMR spectra of a chloroform solution of the ISOX·BF_nCl_{3-n} adducts, before and after the addition of sufficient Me_4mn to displace all of the ISOX, are shown in Fig. 5. Me_4mn rapidly displaces ISOX to form all four of the $Me_4mn·BF_nCl_{3-n}$ adducts (Fig. 5*b*), and many further changes occur over two days (Figs. 5*c* to 5*j*). Also, small ^{19}F NMR 1:1:1:1 quartets at –95.0 and –104.8 ppm arising from $BFCl_3^-$, and $BF_2Cl_2^-$, respectively (11) (off scale in Figs. 5*c–g*), appear shortly after the addition of Me_4mn, and then diminish and disappear over about a day. As is usual in such systems, the $Me_4mn·BF_2Cl$ 1:1:1:1 quartet diminishes in intensity and is replaced by a new quartet at –138.9 ppm ($^1J_{BF}$ = 41 Hz), with the rate of growth of the new quartet matching the rate of shrinkage of $Me_4mn·BF_2Cl$, while the intensity of the $Me_4mn·BFCl_2$ quartet remains essentially unchanged. The loss of the BF_2Cl adduct signal is normally due to Cl^- displacement by a neutral base molecule, so the new quartet normally arises from a difluoroboron cation, and in this case the most plausible product is the chelated cation $(Me_4mn)BF_2^+$. Its ^{19}F chemical shift is consistent with a

© 2001 NRC Canada

Fig. 6. 160.46 MHz ^{11}B NMR spectrum of a $CDCl_3$ solution of ISOX·BF_nCl_{3-n} (ISOX:BF_3:BCl_3 = 4:1:3 mol ratio) to which Me_4mn (insufficient to displace all the ISOX) had been added, after standing for one day.

trend related to ring size: the six-membered (DMAN)BF_2^+ species absorbs at –164.4 ppm (2) and the five-membered (DD)BF_2^+ species absorbs in the –146 to –157 ppm range (1, 2), so a four-membered (DD)BF_2^+ species could well absorb at –138.9 ppm. However, we have not detected a FAB-MS signal corresponding to this ion (or to any other fluoroboron cation), so its identification remains tentative.

The high-field ^{11}B NMR spectrum of a sample to which insufficient Me_4mn had been added to displace all the ISOX, and which had been allowed to stand for a day (Fig. 6), is consistent with Fig. 5 and shows that unmixed-halogen species predominate. By far the largest ^{11}B NMR signal arises from $Me_4mn·BCl_3$. There is also a sharp but low-intensity BCl_4^- signal and a moderately large 1:2:1 triplet corresponding to the –138.9 ppm ^{19}F NMR signal, as well as small mixed-halogen adduct and chlorofluoroborate anion signals, and signals from several unidentified minor species.

However, many additional reactions occur. The $Me_4mn·BF_3$ ^{19}F signal diminishes on standing and many new ^{19}F signals appear, especially in the –158 to –166 ppm region (Figs. 5*c*–*j*). Trace amounts of about 30 unidentified species can be detected over the entire spectral range by high-field (11.7 T) ^{19}F NMR. This complexity is consistent with the expected sensitivity of Me_4mn to traces of acid. Me_4mn is a formaldehyde derivative and can be used as a reagent in the Mannich reaction (13). Protonation gives Me_2NH and $Me_2N{=}CH_2^+$, and Lewis acids should react similarly. These reactions have not been studied in detail but it is noteworthy that the prominent 1:1:1:1 quartet at –159.0 ppm ($^1J_{BF}$ = 18 Hz), which continues to grow over two days, is consistent with the formation of $Me_2NH·BF_3$ (lit. in CH_3CN: ^{19}F chemical shift = –158.8 ppm, $^1J_{BF}$ = 16 Hz; ^{11}B chemical shift = 0.5 ppm (14)). A 1:1:1:1 quartet with similar chemical shift and $^1J_{BF}$ value also appears on reaction of Me_4mn with $Et_2O·BF_3$ and with $py_2BF_2^+$, so $Me_2NH·BF_3$ apparently forms in these systems as well.

Discussion

Factors affecting chelation

While all of the potentially chelating ligands of Scheme 1 rapidly displace ISOX from its adducts, in contrast to slow displacement of pyridine from its BF_nCl_{3-n} adducts (Fig 4), this step is readily followed by chelate formation if the chelate rings are five-membered rather than six-membered. We had anticipated that Et_4en, more hindered than Me_4en and Me_5dien (1), might form the chelate only very slowly or not at all, on the basis of the huge differences in ease of heavy halide ion displacement and fluoroboron cation formation across the series Me_3N, Me_2NEt, $MeNEt_2$, NEt_3 (12). Nevertheless Et_4en readily forms chelated (Et_4en)BF_2^+, (Et_4en)$BFCl^+$, and (Et_4en)$BFBr^+$ from (Et_4en)·BF_2X and (Et_4en)·BFX_2 (X = Cl, Br). In contrast, Me_4pn forms only the $Me_4pn·BF_nX_{3-n}$ adducts, with no subsequent heavy halide ion displacement even on prolonged standing. The BF_2Cl adduct of the potentially four-membered ring chelating ligand Me_4mn, like the potentially five-membered ring chelating ligands, does give rise to a major new species which may be (Me_4mn)BF_2^+. However, the formation of Me_2NH by decomposition of Me_4mn, as described above,

© 2001 NRC Canada

raises additional possibilities for the identity of the new ^{19}F and ^{11}B NMR signals tentatively assigned to $(Me_4mn)BF_2^+$ in Figs. 5 and 6. Further studies of this system would be desirable. We note however that four-membered $(BN)_2$ rings are known to exist as dimers of many $R_2N{=}BX_2$ systems (15), as do four-membered $(BO)_2$ rings, although examples are scarce (16). Hence there is nothing implausible about a four-membered-ring chelated $(Me_4mn)BF_2^+$.

The only clear-cut exception to date to the preference for five- over six-membered fluoroboron cation chelate rings is the formation of the six-membered-ring cation $(DMAN)BF_2^+$ (DMAN = 1,8-bis(dimethylamino)naphthalene) (2), in which there is effective preorganization (5) of the ligand, the two nitrogens being constrained to be close together in the free ligand. In fact, with DMAN no intermediate with only one nitrogen coordinated, analogous to $Me_4pn{\cdot}BF_2Cl$, could be detected (2), due to extreme crowding at the donor sites; DMAN cannot coexist with two fluorines and a heavy halogen about boron. Me_4dipn apparently gives a second case of a fluoroboron cation with a six-membered chelate ring, whose formation is favoured relative to Me_4pn by the decreased steric hindrance of the secondary-amine central nitrogen. However the N—H bond also favours decomposition, so that the presence of $(Me_4dipn)BF_2^+$ could not be confirmed by FAB-MS.

The preference for five- over six-membered fluoroboron chelate rings is unexpected because many six-membered as well as five-membered ring chelate complexes involving boron are known (6). The preference for five-membered ring formation might be a kinetic or a thermodynamic effect. Both entropy and kinetic effects should favour closure of five-membered chelate rings over six-membered, but a molecular modelling approach indicates that, with small atoms such as beryllium(II) and boron(III), enthalpy should favour six-membered chelate rings over five-membered (5, 17). The bite angle of the chelating ligand is of crucial importance in determining the stability of chelate complexes (18). The preference for five- over six-membered ring formation suggests that kinetic rather than thermodynamic effects are predominant. Ready formation of the four-membered fluoroboron cation chelate system ($(Me_4mn)BF_2^+$) would be consistent with this. Molecular modeling studies of the fluoroboron cations would be desirable.

Observation of FAB-MS peaks corresponding to the chelated fluoroboron cation parent ion does not rigorously exclude the possibility that the solution species are actually oligomeric open-chain adducts $(\text{–N—NBF}_2^+\text{–})_n$. However such oligomeric species are more likely to form as the separation of the nitrogen atoms increases, i.e., with Me_4pn rather than with the potentially five-membered ring chelating donors. Since the Me_4pn-containing systems do not give a FAB-MS peak corresponding to the chelated fluoroboron cation parent ion, the possibility is remote that any of the other potentially chelating donors generate their chelated fluoroboron cation parent ion peak from oligomeric open-chain adducts.

Potentially tridentate ligands such as Et_4dien and Me_5dien, when coordinated in a bidentate fashion as in their difluoroboron cations, have the possibility of being fluxional, undergoing rapid dissociation of the coordinated end nitrogen and attachment of the other end nitrogen atom (19). We can exclude this process for $(Et_4dien)BF_2^+$ and $(Me_5dien)BF_2^+$ since it would racemize the cation and collapse the nonequivalent BF_2 fluorine NMR signals, whether the reaction is dissociative or is associative with inversion at boron.

Chlorofluoroborate anion formation and halogen redistribution reactions

Displacement reactions on the $ISOX{\cdot}BF_nCl_{3-n}$ adducts can lead to formation of large amounts of $BF_nCl_{4-n}^-$ ions, provided that the amount of displacing ligand added is sufficient to react with only a fraction of the $ISOX{\cdot}BF_nCl_{3-n}$ adducts, and that Cl^- as well as ISOX is displaced. The chloride ion so generated is a sufficiently strong base to displace ISOX from its adducts to form the chlorofluoroborate anions, which survive indefinitely in solution in the absence of a sufficiently strong base to displace Cl^- and regenerate fluoroboron adducts and cations. This occurs for example when sufficient Et_4en is added to react with only a fraction of the $ISOX{\cdot}BF_nCl_{3-n}$ adducts (Fig. 1). However if an excess of a chelating donor or other strong donor is added to the $ISOX{\cdot}BF_nCl_{3-n}$ system, Cl^- cannot compete effectively with the strong donor in displacing ISOX, and the chlorofluoroborate anions are either undetectable or are formed in only small amounts. Thus we have detected the mixed chlorofluoroborate anions in only a few of our previously studied systems, most notably with the highly hindered DMAN (2).

The same behaviour is not observed on reaction with the $ISOX{\cdot}BF_nBr_{3-n}$ system. There are severe solubility limitations, and even if the $BF_nBr_{4-n}^-$ ions were to form they would not be detectable by ambient-temperature NMR because halogen redistribution among the $BF_nBr_{4-n}^-$ ions is rapid and would collapse their NMR signals (11).

We have previously observed $BF_nCl_{4-n}^-$ formation in some mixed boron trihalide adduct systems that do not involve the ISOX adducts notably with amidines (20) and tetramethylurea (21), which have low steric hindrance, and also to a small extent with 2-(methylthio)-2-thiazoline (10). A different mechanism is required here because there is no weak donor analogous to ISOX that can be easily displaced by Cl^- from its adducts, and we previously suggested a carbene mechanism for $BF_nCl_{4-n}^-$ formation in the amidine systems (20). Although neither amidines nor DMAN, when present alone in solution, are sufficiently basic to displace HCl from chloroform to generate dichlorocarbene, this carbene can be generated from chloroform by anhydrous fluoride ion (22), traces of which might form in our systems. Further work to determine the mechanisms of chlorofluoroborate anion generation in these systems is desirable.

Fluorine and chlorine tend to "unscramble" from mixed chlorofluoroboron species on prolonged standing in many of our systems (20), as is evident from ^{11}B NMR signal intensities, e.g., Figs. 2 and 6. Typically, the mother liquor from the reaction of Et_4dien with $ISOX{\cdot}BF_nCl_{3-n}$ gave ^{11}B NMR signal intensities of 40% for $(Et_4dien)BF_2^+$, 30% for BCl_4^-, 8% for $ISOX{\cdot}BCl_3$, and 22% for a broad hump from 1 to –1 ppm, which apparently arises from various BF species, and little else. However ^{11}B NMR spectra, even at 11.7 T, often give only limited information because the 4-coordinate chloro- and fluoroboron compounds have a very narrow chemical shift range. ^{19}F is a far more sensitive nucleus than ^{11}B and has vastly superior chemical shift dispersion in these

© 2001 NRC Canada

systems, but reliance on ^{19}F can lead to a distorted picture since it cannot detect the non-fluorine-containing boron species which are often major components. Despite its poor resolution, ^{11}B NMR clearly shows how small a fraction of the total boron in equilibrated solutions has both chlorine and fluorine substitutents.

Further reactions

These are highly reactive systems with unexplored chemistry, and there are hints of intriguing new species which merit further study. For example when Et_4en is reacted with either $ISOX{\cdot}BF_nCl_{3-n}$ or $ISOX{\cdot}BF_nBr_{3-n}$, a major ^{19}F NMR signal appears, which resembles two overlapping 1:1:1:1 quartets at –159.8 and –159.9 ppm, both with $^1J_{BF}$ = 47 Hz (Fig 1).

Our attempts to isolate PF_6^- salts of chelated fluoroboron cations, by methods that have been successful with non-chelated fluoroboron cations (9, 10, 12, 20), have not been successful. We have been able to isolate a few chelated fluoroboron cations as their Cl^- and BF_4^- salts in earlier studies (1, 2), but the ligands in the present study have been less favourable. Further work is desirable on isolation of salts of these systems.

Conclusions

A few generalizations are possible. (*i*) Five-membered ring chelated fluoroboron cations form far more readily than six-membered. (*ii*) The presence of an N—H bond greatly increases the rate of decomposition, forming HCl and HBr in the presence of B—Cl and B—Br bonds, and this interferes with the desired reactions. *N*-Methylation of Et_4dien, DPA, and Me_4dipn would be desirable to eliminate this side reaction. (*iii*) The presence of an N—H bond allows facile HF loss in FAB-MS, and this can prevent FAB-MS detection of the parent fluoroboron cation.

These are very reactive systems, with many reactions occurring simultaneously. Success in forming fluoroboron cations is dependent on competition of desirable reactions with undesirable ones, and the relative rates apparently depend on various factors. Despite being more stable than many of the other species present, the fluoroboron cations themselves are prone to hydrolysis and decomposition. We will report elsewhere our studies of the reactions of $py_2BF_2^+$ and related fluoroboron cations.[3]

Application of nonporous polyurethane (PU) membranes and porous PU thin films as sample supports for MALDI-MS of wheat proteins

Mark E. McComb, Richard D. Oleschuk, Art Chow, Hélène Perreault, Ragnar G. Dworschak, Marek Znamirowski, Werner Ens, Kenneth G. Standing, and Ken R. Preston

Abstract: Non-porous polyurethane (PU) membranes and porous PU thin films are used as sample supports for MALDI-TOFMS. Mass spectra obtained are compared with those acquired using metal targets and the crushed matrix method. The compounds characterized are wheat proteins which consist of moderately water-soluble gliadins, and of water-insoluble low molecular weight (LMW) and high molecular weight (HMW) glutenins. Mass spectra obtained using the PU supports are in general of good quality, and this method of sample preparation is the most convenient for sample handling. In the case of gliadins and LMW glutenins, the spectra obtained on PU are comparable with those obtained using metal supports. Isolation of the LMW and HMW wheat proteins characterized in this study requires the use of buffers incompatible with MALDI. Spectra of samples containing buffer components on PU supports are of better quality than those obtained using the crushed matrix method. This effect is attributed to stronger protein binding onto the PU supports, which allows for extensive washing and removal of water soluble buffer components. The PU film, when cast onto a MALDI probe, is porous and flat in topology. The differences in surface characteristics between the PU film and the PU membrane result in slight variations in the mass spectra. The extent of surface charging, observed significantly using 50 μm thick PU membranes, decreases with 25 μm membranes and becomes insignificant with PU thin films. An important advantage of using the PU supports is the possibility of preparing samples on the film or membrane in the field and of analysing them at a later time. This is especially important when samples are susceptible to chemical degradation in solution. These proteins are known to degrade while stored in solution. We have thus incorporated the use of PU membrane–film supports into our routine analysis of these proteins.

Key words: gliadins, glutenins, MALDI, membrane supports, polymeric supports, time-of-flight analysis.

Résumé : On utilise des membranes non poreuses de polyuréthane (PU) et des films minces poreux de PU comme supports échantillons pour la « MALDI-TOFMS ». On a comparé les spectres de masse obtenus par cette méthode avec ceux obtenus en utilisant des cibles métalliques et par la méthode des matrices broyées. Les composés caractérisés sont des protéines de blé formées de gliadines modérément solubles dans l'eau et de gluténines insolubles dans l'eau de faibles poids moléculaires (« LMW ») et de poids moléculaires élevés (« HMW »). En général, les spectres de masse obtenus en utilisant les supports de PU sont de bonne qualité et cette méthode de préparation des échantillons est la plus commode pour le maniement de l'échantillon. Dans le cas des gliadines et des gluténines LMW, les spectres obtenus sur des supports de PU sont comparables à ceux obtenus en utilisant des supports métalliques. L'isolement des protéines de blé de LMW et de HMW caractérisées dans cette étude nécessite l'utilisation de tampons incompatibles avec la MALDI. Les spectres d'échantillons contenant des composants de tampons, réalisés sur des supports de PU, sont de meilleure qualité que ceux obtenus en faisant appel à la méthode de la matrice broyée. Cet effet est attribué à la fixation plus forte de la protéine sur les supports de PU, ce qui permet d'effectuer des meilleurs lavages et l'élimination des composants de tampons solubles dans l'eau. Le film de PU fixé sur une sonde MALDI est poreux et de topologie plane. Les différences dans les caractéristiques de surface entre le film de PU et la membrane de PU conduisent à de légères variations dans les spectres de masse. Le niveau de formation de charge à la surface, qui est relativement élevé lorsqu'on utilise des membranes de PU de 50 μm d'épaisseur, diminue avec les membranes de

25 μm et il devient pratiquement nul avec les films minces de PU. Un avantage important d'utiliser des supports de PU est la possibilité de préparer des échantillons sur le film ou la membrane sur le terrain et de les analyser plus tard. Ceci est particulièrement important quand les échantillons sont susceptibles aux dégradations chimiques si ils restent en solution. Il est connu que ces protéines se dégradent lorsqu'on les conserve en solution. On a donc incorporé l'utilisation de supports membrane–film de PU dans l'analyse de routine de ces protéines.

Introduction

Matrix-assisted laser desorption–ionization time-of-flight mass spectrometry (MALDI-TOFMS), first introduced in 1988 by Karas et al., provides a rapid and convenient means for the characterization of proteins and peptides (1). Since its introduction, MALDI-TOFMS has been used for a large number of applications for the characterization of several types of biological molecules (2–6). The method is relatively tolerant of impurities, such as salts and buffers, even at concentrations which hamper other ionization processes such as electrospray ionization (ESI).

Numerous experimental parameters, such as sample preparation, may affect the sensitivity, resolution, and accuracy of measurements. Several methods of sample preparation using different matrices have thus been developed for MALDI-TOFMS applications (7). In spite of the relative tolerances, one main concern is the presence of interfering components such as salts, buffers, and detergents which may result in adduct formation and widening of peaks. Techniques for sample purification prior to MALDI-TOFMS analysis have thus been developed. Many of these are based on traditional separation techniques including dialysis, filtration, and chromatography. Another approach is to purify the sample directly on the surface of the MALDI probe. By incorporating the sample-purification step with the addition of matrix, the time frame of analysis may be reduced and only a minimal amount of sample is required.

Various approaches to on-probe sample-purification based on a common theme have been explored. In all of these a substrate is first deposited onto the surface of the MALDI probe, either by mechanical adhesion to the surface (i.e., polymeric membranes and films), or by covalent attachment to the surface. The substrate possesses a chemical or physical property which allows it to selectively bind the analyte of interest. Once the analyte is bound, it is possible to remove other components from the surface by washing procedures. Addition of the matrix to the probe, in a suitable solvent, releases the bound analyte, which then may cocrystallize with the matrix for analysis by MALDI. This overall approach is easy and cost effective. Moreover, it makes sample preconcentration possible through application of successive sample aliquots to the probe.

Surface enhanced affinity capture (SEAC), introduced by Hutchens and Yip (8), was an early example of sample pretreatment directly on the MALDI probe. The SEAC probe surface was modified with a functional group (agarose) used to selectively bind the analyte of interest. Another similar example involved the use of a small amount of powdered chromatographic packing placed on the MALDI target (9). Also, C-18-derivatized targets have been prepared using self-assembled monolayers of octadecyl mercaptan placed on a gold-coated probe (10).

An alternative technique involves modifying the probe surface by the addition of a polymeric membrane or film which binds to the sample protein and allows washing of buffer components. This approach, based on the use of membranes for automatic protein sequencing, is now used routinely for sample purification and introduction into the mass spectrometer (2, 3, 6). Hydrophobic–ionic interactions between the sample and the film or membrane, allow the selective removal of interfering buffer components. Addition of matrix solution directly onto the surface promotes partitioning of the analyte and salts- or buffer-components between the liquid phase and the surface of the film or membrane. Derivatization and proteolytic digestion may be performed on the surface of the film or membrane. Membranes, which are readily available in large quantities and various sizes, are very convenient for transporting samples from the preparation site to the MALDI-TOFMS laboratory. A number of different polymeric supports have been examined for use with MALDI. An early example by Mock et al. (11) used an electrosprayed surface of nitrocellulose to create a thin film on a gold surface. Since then, a number of other membranes and films have been used. These include nitrocellulose (12–14), polyethylene (15, 16), Nafion (perfluorosulfonated ion exchange membrane) (17), nylon (18), cellulose (14), poly(vinylidene difluoride) (PVDF) (19), polypropylene (16), paraffin wax (20), Teflon® (poly(tetrafluoroethylene)) (21), and polyurethane (22, 23). Recently, there have been reports on the use of nonporous Teflon® surfaces for MALDI, which are now available as commercial targets from Bruker Daltonics, Bremen, Germany (24–26).

Our laboratory was first to introduce the use of nonporous polyurethane (PU) membranes as sample supports for MALDI-TOFMS characterization of peptides and proteins derived from biological samples (22, 23). In our first report on the subject, we focused on the analysis of low molecular weight proteins and peptides. We observed that the nonporous surface of the membrane provided improved mass spectra in comparison with a porous membrane surface, and sample purification could be performed easily, directly on the membrane surface. Additionally, the nonporous membrane surface proved to be useful for on-probe proteolytic digestion and (or) purification of proteins for peptide mass-mapping. We also observed that qualitative aspects of spectra, such as peak shape and peak width, depended on the laser fluence and repetition rate of data acquisition, consistent with electrostatic charging occurring near or on the membrane surface. This motivated our investigation on the use of thinner PU membranes (25 μm thickness) and thin PU films for use as sample supports.

© 2001 NRC Canada

In this paper, we report the use of nonporous PU membranes and porous PU thin films for MALDI-TOFMS, particularly in the analysis of wheat proteins. MALDI-MS has been used to accurately and quickly determine the masses of specific glutenin subunits of wheat (27, 28), and our laboratory has recently characterized gliadins and glutenin subunits by MALDI-MS on metal targets as part of an ongoing collaborative project with the Canadian Grain Commission, Grain Research Laboratory (29). Gliadins have limited solubility in water, and glutenins are insoluble. The wheat gliadins consist of a group of ca. 100 proteins, with a low molecular weight range of 30–40 kDa. The glutenins are large polymeric proteins composed of two groups of subunits: low molecular weight (LMW) (30–40 kDa) and high molecular weight (HMW) (65–90 kDa) subunits. These subunit proteins are heterogeneous and are thought to have some degree of post-translational modification (i.e., glycosylation). The reagents required for their isolation (i.e., 1% DTT, 2 M urea, 0.082 M trisHCl) are not favourable for analysis by MALDI. We discuss the ease of sample preparation, time frame of analysis, and show comparisons between spectra obtained using nonporous membranes, porous thin films, and steel targets. Statistical figures are used for spectral comparisons at different levels e.g., spectrum-to-spectrum reproducibility on the same sample, on different samples from the same batch prepared with a given method, and on samples from the same batch prepared with different methods. These results are meant to demonstrate the overall usefulness and advantages of PU substrates. With this robust approach and its easy sample preparation schemes, PU membranes and films as supports yielded spectra as reproducible as obtained with steel targets and other recently developed nonporous substrates (26).

Experimental

All chemicals used in this study were of reagent grade unless otherwise stated. High performance liquid chromatography (HPLC) grade acetonitrile, dithiothreitol (DTT), and ethanol were from Fisher Scientific (Fair Lawn, NJ). Trifluoroacetic acid (TFA) was from Sigma (St. Louis, MO). HPLC grade deionized water, prepared with a Milli-Q® plus-TOC water purification system (Millipore, Bedford, MA), was employed in all solutions.

PU sample supports

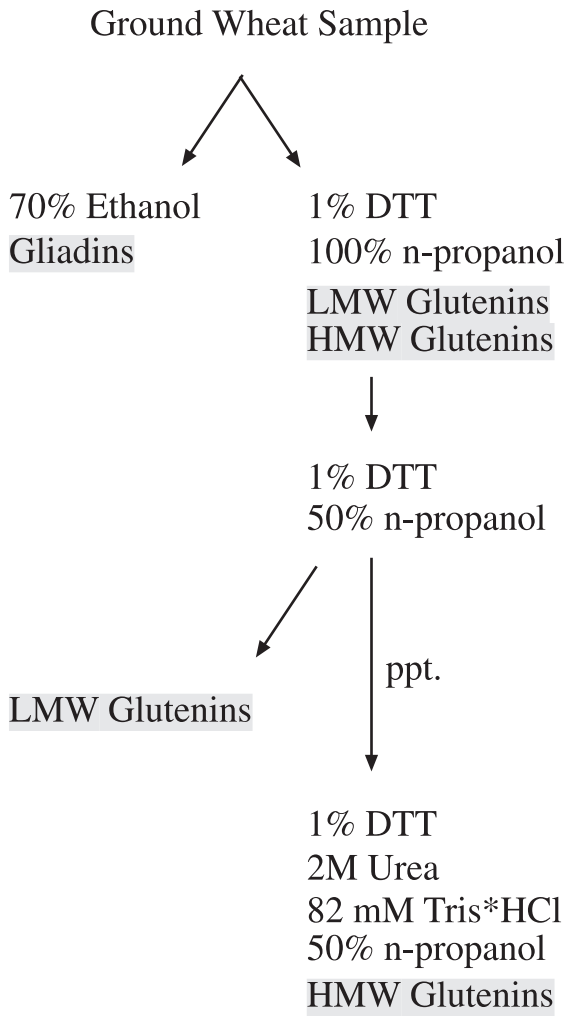
The nonporous ether-type PU membrane (25 μm in thickness (XPR625-FS)), was supplied by Stevens Elastomerics (Northampton, MA). Complete details on the preparation of PU membranes for sample supports are available elsewhere (23). In brief, the PU membrane was rinsed in methanol prior to the addition of sample. After rinsing and matrix application, the membrane was trimmed to the size of the MALDI probe and affixed to it using 3M® Spray Mount adhesive (3M, London, ON). Porous PU thin films were prepared by first dissolving the solid PU membrane in tetrahydrofuran and then depositing ca. 10 μL of the liquid onto the probe surface, spreading it around, and then allowing it to dry.

Scanning electron microscopy

The PU membrane and film were characterized by scanning electron microscopy (SEM). Scanning electron micrographs were obtained on a Cambridge Instruments microscope located in the Department of Geological Sciences, University of Manitoba. Samples prepared on PU membranes and on metallic surfaces were coated with gold and palladium by plasma deposition prior to analysis. Images were recorded with magnifications of 30× and 300×.

Protein extraction

Pure samples of the Biggar wheat variety from the Canada Prairie Spring commercial class were obtained from stocks maintained at the Grain Research Laboratory in Winnipeg, MB, Canada. Wheat samples (25 g) were ground in a UDY cyclone sample mill equipped with a 1 mm sieve. Gliadins were extracted from ground grain (1.0 g) into 70% (v/v) ethanol (6 mL) at room temperature for 60 min. Glutenins were then extracted from the remaining grist with 1% DTT in 100% *n*-propanol (29, 30). The LMW glutenin fraction was extracted by precipitating out the HMW glutenins with the addition of 1% DTT in 50% *n*-propanol to bring the final concentration to ca. 65% *n*-propanol. The HMW glutenin precipitate was washed with 1% DTT in 65% *n*-propanol and then resolubilized in 1% DTT and 2 M urea in buffered (0.082 M trisHCl, pH = 7.0) 50% *n*-propanol (30). Extracts were then centrifuged at 20 000 *g* for 10 min. The extraction procedure is outlined in Fig. 1. Typically, the samples were deposited onto the MALDI targets within one day to minimize sample loss and degradation. Samples on metal targets were analyzed by MALDI-MS within one day while samples on PU surfaces were analyzed within 14 days.



Sample preparation

The stock wheat protein solutions had concentrations varying from 30 to 600 mM. The matrix solution used in all analyses was a saturated solution of 3,5-dimethoxy-4-hydroxycinnamic acid (sinapinic acid) in 0.1% TFA and acetonitrile (2:1 v/v). For samples on steel probes, the crushed matrix method was used (31). A 2 μL aliquot of the matrix solution was first applied to the sample probe, allowed to dry, and then crushed. The stock solution was then mixed (1:10 v/v) with the matrix solution and a few microlitres of the mixture were applied to the crushed spot on the sample probe. When a visible film began to form (ca. 10–60 s), the spot was rinsed with cold deionized water for 10 s and then allowed to dry thoroughly prior to analysis. This process was repeated if necessary to deposit enough protein onto the surface of the probe to acquire MALDI mass spectra.

Samples were prepared on PU substrates by first depositing 2 μL of the protein solution onto the film or membrane surfaces. After the samples were completely dried, 2 μL of methanol were added to enhance protein sorption onto PU. For sample preparation without a washing step, 2 μL of the saturated matrix solution were added and allowed to dry prior to analysis. For preparation with a washing step, 25 μL of deionized water were deposited on the surface of each sample and allowed to stand for 1 min to solubilize as much material as possible. This large droplet was then removed with a pipette. This step was repeated once more to ensure

that the protein samples were as free from water soluble material as possible. The matrix was added just prior to analysis.

Matrix assisted laser desorption–ionization

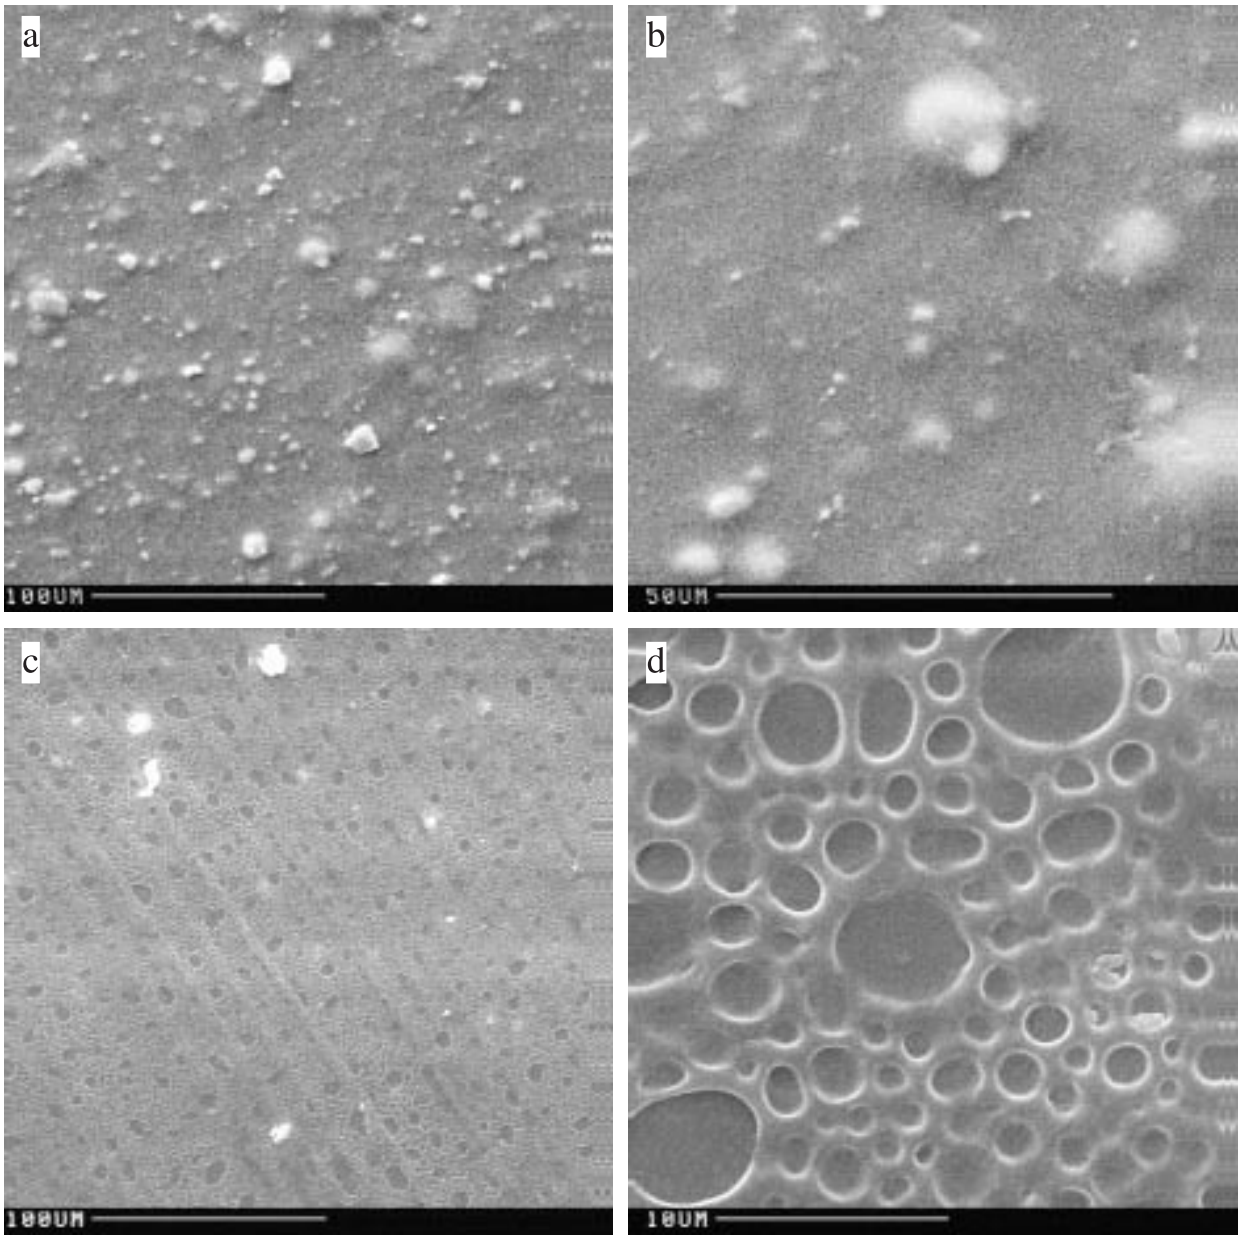
Positive-ion mass spectra were obtained in the linear mode on a MALDI-TOF mass spectrometer built in-house (32). A nitrogen laser (VSL 337 ND, Laser Science Inc., Cambridge, MA, U.S.A.) was used with intensity set just above threshold. For some of the gliadin and LMW glutenin subunits, a two-grid delayed extraction system (33) was employed, with a 25 kV DC accelerating potential on the probe and first grid, and a 3 kV pulse applied to the probe 1.2 μs after the laser pulse. The 3 kV pulse was supplied by a high voltage switch (Behlke, Frankfurt, Germany). For the HMW glutenin fraction, DC extraction was employed with the target and first grid potentials of 30 kV and 18 kV, respectively. Following desorption and acceleration, ions drifted through a field-free region of 1.2 m in which the nominal pressure was 3×10^{-7} torr (1 torr = 133.322 Pa). The ions were detected with microchannel plates and the signal was recorded with a LeCroy 9350AM 500 MHz digital oscilloscope from which the spectra were summed by a UMAX Supermac C600 computer. Approximately 150–200 shots were accumulated per spectrum on samples prepared on the steel targets while ca. 50 shots were sufficient for samples on PU supports. The gliadin- and LMW-glutenin-subunit spectra were calibrated externally with carbonic anhydrase (29021 Da), while the HMW-glutenin-subunit spectra were calibrated externally with human transferrin (79549 Da). Improved mass accuracy would have been possible with internal calibration, however the emphasis in this work was on the examination and evaluation of PU films and membranes for sample analysis.

Results and discussion

Characterization of polyurethane films and membranes

Membranes and films have different advantages when used as sample supports for MALDI analysis of proteins. While films may be directly deposited onto the surface of the MALDI target, membranes must be attached, usually with an adhesive, which introduces an additional step into the analytical scheme. Because films are thin, the possibility of surface charging is reduced or eliminated. One distinct advantage of membranes is that the sample may be applied prior to affixing the membrane onto the probe surface. This allows samples to be collected directly on the surface of the membrane outside the MALDI laboratory. A number of different polymeric film and membrane supports are available, thus a specific type may be chosen for a selected class of analyte.

For preparation of PU thin films, some PU membrane material was dissolved in THF, cast onto the surface of the MALDI probe and allowed to dry under ambient conditions. Fig. 2 compares SEM images taken on the 25 μm thick PU membrane (*a* and *b*), and the PU film (*c* and *d*). The surface topology of both the membrane and film was flat, unlike the uneven rough surfaces typical of other membranes examined previously (15). Unexpectedly, the surface of the PU film was porous as shown in Figs. 2*c* and *d*. Porosity is introduced when the film dries on the probe after casting. The extent of porosity varies with rate of drying and solvent volatility, among other parameters. The pore sizes ranged from ca. 1 μm to 8 μm in diameter, with most pores being in the 2–3 μm range. The film was less than 1 μm thick, i.e., thinner than ca. 1 μm as calculated from the amount of material deposited and the surface area of the probe.



In general, thinner conductive surfaces (e.g., metal targets) or porous surfaces, such as PU films, reduce the time frame of static discharge of an insulating surface on a MALDI target. However, porous surfaces result in greater extent of analyte adsorption away from the surface, thus making it unavailable for laser desorption or resulting in a spread in the flight-time measurements (22). Nonporous flat surfaces allow a maximal extent of protein sorption at the surface, yielding better MALDI signals and better resolution than porous surfaces. An ideal substrate material would be a PU thin film with flat topology, either nonporous or with very small pores (e.g., <1 μm).

Charging

MALDI spectra of bovine insulin were obtained using PU membranes and thin films and compared qualitatively with those obtained using steel targets. With the laser intensity set just above threshold, all three surfaces produced similar

spectra in terms of resolution and mass accuracy, which were typical of the instrument (32) (see overlap of first data point of each set in Fig. 3, and two sample spectra, bottom of Fig. 4). Comparisons between spectra of myoglobin and bovine insulin obtained using PU membranes and steel targets had shown the same trends (22). Charging of the membrane, sometimes observed in MALDI (18), occurred with the 25 μm and 50 μm thick PU membranes at laser intensities two to three times above threshold using a laser pulse rate of ca. 2 Hz on the laser (22). Charging was not observed with the PU thin films, nor with the steel targets. We attributed this to the thinness and surface porosity of the film, which would be expected to facilitate dispersal of static charge. To overcome the charging observed with the membrane, it was necessary to reduce the pulse rate of the laser to ca. 0.5 Hz to allow dispersal of the static charge. Figure 4 shows the effect of charging on the spectrum of bovine insulin on a PU film. All six spectra result from summing 50 shots, and were acquired at a shot frequency of 1 Hz using 35 pmol of bovine insulin in sinapinic acid matrix. The film thickness was ca. 1 μm. The laser intensity was decreased from Spectrum 1 to Spectrum 6. The variation in time-of-flight was of the order of only ca. 0.1%.

Qualitative measurements of the charging observed are shown in Fig. 3. The time-of-flight of bovine insulin $[M+H]^+$ ions was measured as a function of laser intensity on the three surfaces employed. With the 25 μm PU membrane, the time-of-flight increased by nearly 1.5% at higher laser intensity, relative to the value measured at threshold. Spectra obtained using the PU film were less influenced by the laser intensity, and charging occurred only at maximum intensity. Spectra obtained using the steel target were not

influenced. It is noted that the maximum laser fluence used was about six times above threshold, and would not normally be used in MALDI analysis.

Proteins from wheat

Our laboratory has recently characterized some wheat gliadins and LMW- and HMW-glutenin subunits on metal targets by MALDI-MS (29). The spectra obtained on wheat gliadins in the 70% ethanol fraction (see *Experimental*) were in general of good quality, informative, and relatively easy to acquire. This was not the case for the spectra of LMW and HMW wheat glutenins. Extraction of the glutenin proteins requires buffers that are incompatible with the usual MALDI protocol. Using the crushed matrix method, successive applications of protein were necessary, followed by washing, to obtain informative spectra. With this method, a spectrum was not obtained for every target, even for samples from the same preparation on separate targets. For example, for HMW glutenins, only two significant spectra were obtained out of numerous attempts. PU films and membranes as supports produced informative spectra for every target prepared, and were thus more reliable than metal targets. Addition of

Fig. 4. MALDI-TOF mass spectra of bovine insulin on a 1 μm-thick PU film, with increasing laser intensity from Spectrum 6 (just above threshold) to Spectrum 1, showing that charging causes a time-of-flight shift of only ca. 0.1% on film surfaces.

methanol as an organic modifier appeared to enhance the extent of analyte binding by partitioning salts away from the surface and favoring interactions of the surface with hydrophobic peptides and proteins.

Stability and time-reproducibility considerations

It was important to consider the elapsed time between sample extraction and MALDI analysis. The general trend observed in our laboratory is that dried protein samples, when placed onto the PU surfaces, are stable for up to several weeks prior to analysis by MALDI-TOFMS. In the specific case of the wheat proteins, several samples of each class of protein were analyzed in replicate, without observing any detrimental effects from up to 14 days of storage. In essence there was no observable change in their mass spectra, and reproducibility was as good as for spectra acquired the same day (see discussion on sample-to-sample reproducibility below).

More importantly, we observed that glutenins were not stable in solution and necessitated to be deposited on substrates within one day following extraction. Once on PU substrates, these proteins could be analyzed by MALDI without detectable spectral deterioration, again within 14 days. Solution instability is a serious limitation in a laboratory without a dedicated MALDI instrument, and necessitates immediate use of solution methods for analysis. Prolongation of the possible analysis time frame to up to two weeks following extraction therefore constitutes a real advantage of using our method. For both glutenins and gliadins, no samples were analyzed past two weeks of storage. It is however generally accepted that once deposited on polymer substrates, dried protein samples can be stored for prolonged periods of time.

Gliadins

To demonstrate that the membrane surfaces did not adversely contribute to the mass spectra of the wheat samples, initial spectra were obtained without the use of the washing protocol. Figure 5 shows MALDI mass spectra of wheat gliadins obtained using the different sample supports, without washing. All three types of targets employed produced similar spectra. These results are not surprising as this fraction of wheat proteins did not necessitate the use of involatile buffer components during extraction and thus resulted in relatively clean samples. For comparison, Fig. 6 shows spectra of the same class of proteins prepared on a metal target and PU supports while incorporating sample washing.

In an attempt to determine the best sample preparation method for MALDI-MS of gliadins, standard deviations on heights of peaks indicated in Figs. 5 and 6 with asterisks were calculated for each sample. At least three MALDI spectra were used for each calculation, and each spectrum was the sum of 50–150 shots obtained over the entire surface of the target. Ideally the whole spectrum should be used for comparison, however, this would not necessarily be more useful, unless a specific low-concentration substance was targeted. We have already demonstrated that peak areas provide for better statistical treatment of data on the PU surfaces (34). Here, due to peak overlap of the many proteins within the gliadin sample, it was not possible to adequately calculate peak areas. For relatively clean samples, the standard deviations of peak heights obtained with the crushed matrix method were lower than those obtained with PU supports. This is in agreement with the higher standard deviations observed with the dried droplet method of crystallization compared with fast crystallization (35). The

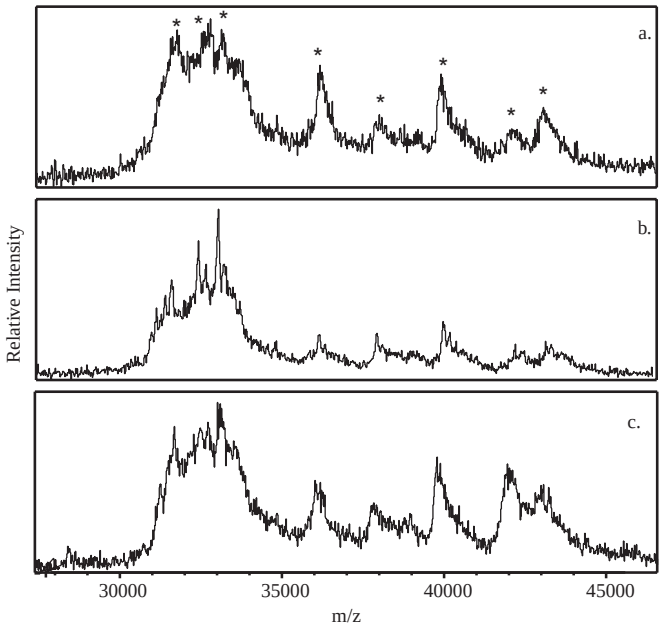
[a]Peaks as per Table 1 and Figs. 5–8.

results, presented in part of Table 1 (Gliadins column), indicate that for this class of wheat proteins, washing has a negative effect on reproducibility, while changing substrates has a consistent effect of decreasing the extent of reproducibility in the order metal > PU > film. The negative effect of washing may be expected, because the gliadin samples were clean to begin with, moderately water soluble, and thus not entirely compatible with the hydrophobic surfaces of PU membranes and films. It is possible that some of the sample was removed from the membrane surface during the washing step. For comparing spectral reproducibility for samples of the same class, prepared using the same method but on different consecutive samples and analyzed on different days (within 2 weeks), statistical correlations were used, and found to be greater then 90% for gliadins, indicating a relatively reproducible sample preparation method. A statistical comparison was also made between spectra prepared using the different methods. The results are shown in Table 2 for gliadins. These indicate that both the physical nature of the surface and the chemical interaction of the sample with the surface influence spectral features. In terms of surface influence, PU-wash spectra (see definition of abbreviated terms at the foot of Table 1) correlate well with those obtained using PU-neat. Also, film-wash spectra correlate well with film-neat results. PU-neat substrates have a surface topology similar to that of metal targets, and a high correlation is observed between spectra acquired using these two methods. There is also correlation dependence on washing or nonwashing of the sample, e.g., PU-wash spectra correlate well with film-wash results.

The overall pattern of relative intensities for the protein ions was different for PU and steel sample substrates. This may be due to a difference in protein affinity between the PU and the crushed matrix on the steel probe, as the degree of surface hydrophobicity will influence the extent of protein and peptide binding. Different degrees of sorption would thus result in the release of variable amounts of protein during the washing and matrix application steps. These findings are similar to results obtained in our laboratory for comparison of PU and steel supports for peptide mixtures (22, 23). Walker et al. (19) have made similar observations with the use of polymeric supports for protein analysis. They suggested that some protein is removed during washing and not all of it may be released from the polymer surface after applying the matrix solution.



Low molecular weight glutenins

The benefit of using PU substrates is more apparent in the analysis of the LMW glutenins as shown in Fig. 7. For these proteins, it was not possible to record spectra using the steel targets without washing, possibly due to the presence of 1% DTT and other components required for their extraction. Spectra were more easily obtained using the PU supports, which yielded better signal uniformity and shot-to-shot reproducibility than metal targets. The washed samples on film and membrane also yielded better signal-to-noise ratios than unwashed samples. Spectra could be obtained from the entire surface of samples prepared on PU supports, while samples prepared on the steel targets required rastering of the target to find useful ionization sites. Between 150–200 shots were required to obtain spectra on the steel targets compared with ca. 50 shots with PU supports. The spectra of best quality were obtained on PU membranes, with better definition of the 30 000–33 000 *m*/*z* range due, presumably, to removal of buffer components, which resulted in broadened peaks in the other samples.

An indication of the extent of reproducibility on single samples of this class of proteins is given in the central

column of Table 1. Eight peaks were used to obtain standard deviations. These results show no significant improvement owing to PU substrates compared with metal surfaces, although they are transparent to the fact that many metal targets needed to be prepared to produce only a few spectra, while most PU targets produced informative data. Table 1 shows that reproducibility in peak heights obtained on film surfaces was slightly worse than on membranes, which in turn produced spectra as reproducible as, or more reproducible, than metal targets.

Sample-to-sample reproducibility with LMW glutenins on separate targets, same sample preparation method, and different day of analysis (within 2 weeks), resulted in correlations of ca. 90% in peak heights. There were slight variations in peak heights when using different supports. These results are shown in Table 3. These correlations appear to depend on both surface chemistry and topology, similar to results obtained with the gliadin proteins. These factors have been known to affect the formation of matrix crystals. Following this idea, PU-wash spectra correlate well with film-wash data, showing similar surface chemistry. Metal spectra correlate well with PU-wash spectra, both surfaces being nonporous. Differences in the surface morphology of the film vs. membrane may contribute to some of the variations observed. The PU surface composition depends on the method of fabrication (e.g., casting, extrusion) and on the type of contact surface during casting of the polymer (36). Changing the proportions of hard (crystalline) and soft (amorphous) segments at the polymer surface leads to different protein sorption characteristics (37). In this application, casting the PU onto the MALDI probe may alter the surface composition of the polymer, leading to different affinities for the different wheat proteins present. In addition, as the membrane is nonporous, the surface area available for protein

binding would be expected to be greater than that of the film, which would influence the amount of protein available for analysis by MALDI. With nonporous surfaces, all the sample is likely to remain on the top and easily accessible to the UV laser.

High molecular weight glutenins
