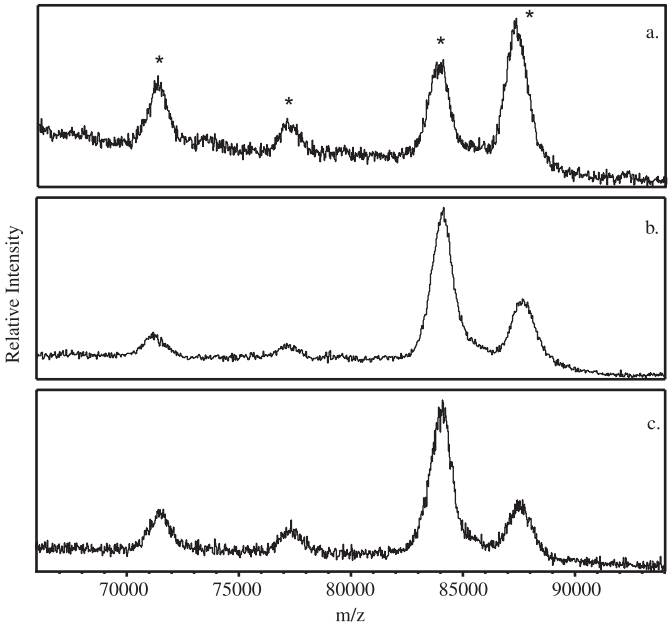
Results from the analysis of the HMW glutenin fraction are shown in Fig. 8. The quality of the spectra at first glance is similar for the three washed substrates. However, use of the PU membrane resulted in less noise in the mass spectra and both PU surfaces yielded good signals with fewer laser shots. Spectra were not obtained on any target without washing. With metal targets, only two useful spectra were obtained even after numerous attempts. When using the PU surfaces, useful spectra could be obtained on nearly every sample. More concentrated buffer components are present in the HMW fraction (1% DTT and 2 M urea in buffered 0.082 M trisHCL (pH = 7.0), see Fig. 1) than in the LMW glutenin and gliadin samples. Removal of buffers was necessary to generate spectra. The far right column of Table 1 shows ranges of standard deviations obtained for spectra recorded on single samples using four peaks (marked with asterisks in Fig. 8). These results are similar to those obtained with LMW glutenins. In general, spectra obtained on films were less reproducible in terms of peak heights than those acquired using PU membranes, which tended to be more reproducible than metal target data.



Sample-to-sample reproducibility with HMW glutenins on separate targets, same sample preparation method, and different days of analysis (within two weeks), resulted in correlations of ca. 90% in peak heights, with the exception of metal surfaces with only two spectra obtained. The best sample-to-sample spectral reproducibility with separate targets was obtained using the PU membrane, which gave correlations greater then 90% on peak heights.

There were significant variations in peak heights with PU supports vs. metal targets, as indicated in Table 4. In this case, the affinity of the PU surface for proteins played a significant role in controlling relative signals. The best correlations appear to result from similarities in the surface chemistry of PU film and membrane surfaces: PU-wash spectra correlate well with film-wash spectra. Because of different extents of interaction between analytes and substrate, relative intensities differed for spectra acquired on PU supports vs. metal, thus yielding low correlations.

This class of compounds was the most difficult to analyse in terms of probability of obtaining informative spectra on a given sample. When using the metal targets, several attempts

Fig. 8. MALDI-TOF mass spectra of HMW glutenins: (*a*) metal target; (*b*) PU membrane; (*c*) PU film. All spectra were acquired with sample washing. Peaks marked with an asterisk were used for statistical analysis.

were required for each sample and a large number of shots were required to obtain acceptable signal-to-noise ratios. It was also necessary to acquire spectra within a very short time frame once the samples were extracted, due to degradation in solution. Overall, PU supports allowed a significant increase in throughput. The samples, once applied to the PU supports, were stable for several days prior to analysis, allowing sufficient time for shipping if required. Once prepared, the bulk of the samples prepared on PU surfaces would easily yield informative MALDI spectra.

Conclusions

Comparing the two PU systems, the signals were slightly better with analysis on the nonporous PU membrane. This was attributed to an increase in surface area available for protein sorption on the membrane compared to the film, and differences in surface morphology. More noticeable was the difference between the relative intensities of the protein ion signals measured using the steel targets and the PU supports. Nevertheless, each spectrum contained the same information (*m*/*z*) regardless of the support used. We are currently investigating various factors that are believed to affect the type and extent of protein sorption that occurs onto PU membranes.

For gliadins, there was no improvement by using PU supports vs. traditional MALDI sample preparation methods. Gliadin samples were initially clean, and these proteins are relatively hydrophilic. On the other hand, there was no disadvantage in using PU supports. The main advantage of the PU supports for these proteins was the convenience of sample handling.

The washing procedures significantly improved the signal-to-noise ratios in the mass spectra, particularly for the

Table 4. Comparison of mean reproducibility of spectra obtained on HMW glutenin samples prepared using different methods.[a]

Sample preparation method	Correlation of mean peak intensities[b]

Metal target	—	—	—
PU-wash	0.1904	—	—
Film-wash	0.096	0.9995	—

[a]Useful spectra were not obtained on unwashed samples on metal or PU supports.
[b]Peaks as per Table 1 and Figs. 5–8.

LMW- and HMW-glutenin samples. Use of the PU supports allowed more vigorous sample washing due to the stronger interaction of the proteins with the PU surfaces compared with matrix and steel targets. Advantages of PU supports, which are not obvious from the spectra shown in this paper, are ease of sample manipulation, and ease of obtaining and storing samples prior to analysis. Once the wheat protein sample is placed onto the membrane or film, it is stable for at least two weeks prior to analysis. This was not the case with liquid samples of wheat proteins, which degraded rapidly during storage. The PU membranes were particularly useful as one large piece of membrane could be used to collect several samples outside of the laboratory and then store them prior to analysis. Spectra were obtained with greater ease and equivalent reproducibility on the PU supports, in particular the PU membrane, thus increasing the confidence that samples, once acquired, would yield informative spectra. Based on this work, we have incorporated the use of the PU supports for the routine analysis of the LMW- and HMW-wheat-glutenin proteins.

Tautomerization tendencies of 2-acetylcycloalkanones, 2-acetyl-1,3-cycloalkanediones, and cyclic β-keto esters of five- and six-membered rings

Antonio Rojas, Alfonso Perez-Encabo, Ignacio Herraiz-Sierra, and Carlos A. Blanco

Abstract: NMR and kinetics studies of the tautomeric equilibrium of 2-acetylcycloalkanones, 2-acetyl-1,3-cycloalkanediones, and methyl 2-oxocycloalkanecarboxylates of five- and six-membered rings have been carried out. By comparing ^{1}H NMR and ^{13}C NMR spectra recorded in D_2O–$DOCD_3$ and $CDCl_3$, with those results derived using a bromination kinetic procedure in dilute aqueous solution, information concerning tautomeric interconversion is provided. Some discussions considering ionisation equilibria and rate constants involved have also been considered. Solvent and concentration effects on keto–enol equilibria have also been discussed.

Key words: 2-acetylcycloalkanones, 2-acetyl-1,3-cycloalkanediones, methyl 2-oxocycloalkanecarboxylates, equilibrium, tautomerization, ionization.

Résumé : On a effectué des études RMN et cinétiques sur l'équilibre tautomère de 2-acétylcycloalcanones, de 2-acétylcycloalcane-1,3-diones et de 2-oxocycloalcanecarboxylates de méthyle de composés à cinq et à six chaînons. En comparant les spectres RMN du ^{1}H et du ^{13}C enregistrés dans le D_2O–$DOCD_3$ et $CDCl_3$ avec ceux obtenus à l'aide de la méthode cinétique de bromation dans des solutions aqueuses diluées, on en a tiré des informations relatives à l'interconversion tautomérique. On présente aussi quelques discussions relatives à l'équilibre d'ionisation et aux constantes de vitesse. On discute aussi des effets de solvant et de concentration sur l'équilibre cétoénolique.

Mots clés : 2-acétylcycloalcanones, 2-acétylcycloalcane-1,3-diones, 2-oxocycloalcanecarboxylates de méthyle, équilibre, tautomérisation, ionisation.

Introduction

Structure reactivity effects are important guidelines in the elucidation and interpretation of complexation mechanisms, since the structure of ligands can indeed affect their ligand equilibria (1) (tautomerization, ionization) as well as complexation processes.

Acyclic 1,3-dicarbonylic compounds having already been studied (1), our attention has now been focused on alicyclic ligands with different functionalities: 2-acetylcycloalkanones, 2-acetyl-1,3-cycloalkanediones, and cyclic β-keto esters. These structures present a common feature, the possibility of assuming *endo*-cyclic and *exo*-cyclic enol forms.

2-Acetylcycloalkanones, which are suitable substrates for metal chelation, have become quite useful, both with regard to current health issues (2) (intermediate in preparation of HIV inhibitors) and other industrial applications (3) (inhibitor for metal corrosion).

It is well known that 2-acetylcycloalkanones form enol isomers and that the extent of enolization is controlled mainly by the strong intramolecular hydrogen bond formed, apart from the concentration, solvents, and temperature (4). The relative stabilities of the two enol forms are strongly influenced by the ring size and it is accepted that the five-membered ring systems favour an *exo*-cyclic enol, whereas six-, seven-, and eight-membered ring systems favour an *endo*-cyclic enol.

The β,δ-tricarbonyl compounds are the higher analogues of the dicarbonyl compounds and can take triketo-, monoenol-, and bisenol-forms in their tautomeric equilibrium. Accordingly, they can behave as bidentate or terdentate ligands to form metal chelate complexes. The investigation of these keto-monoenol and -dienol equilibria has shown that the bisenol content of the heptane-2,4,6-trione increases with decrease in the polarity of the solvent used and a high percentage of the triketo-form was found in solvents of high

Scheme 1.

dielectric constant (5). 2-Acetyl-1,3-cycloalkanediones, are symmetrical cyclic β,β′-triketones, which present only one acidic protonizable hydrogen and subsequently can not form polynuclear coordination compounds with metal ions.

In order to understand the factors that affect the ligand chemical behaviour, in this contribution we extended the work to structurally similar *cyclic* β-*keto esters*, which exhibit also the phenomenon of keto–enol tautomerism and may present similar *endo*-cyclic as well as *exo*-cyclic enol forms (6, 7) (Scheme 1). In fact, these β-keto esters behave as bidentate ligands, and are able to form coordination compounds similar to those of the β-diketones with metal ions such as Mn(II), Fe(III), Co(II), Ni(II), Cu(II) and La(III), Ce(III) and Pr(III) (8, 9).

Furthermore, alkyl esters of 2-oxocycloalkanecarboxylic acids are receiving considerable attention, not only from the viewpoints of synthesis (10–13), reactivity (14–16), spectroscopic behaviour (17), but also because of their pharmacological and therapeutic properties, which make them useful lead compounds for the development of safer antiepileptic drugs (18) or derivatives with antiinflammatory effects (19).

Because of the lack of tautomerization studies of 2-acetylcycloalkanediones and β-keto esters, we now report a comparative study of equilibria on structurally similar 2-acetylcycloalkanones, 2-acetyl-1,3-cycloalkanediones, and methyl 2-oxocycloalkanecarboxylates. Five- and six-membered ring derivatives have been the major focus of our studies since the relative stabilities of the *endo*- and *exo*-cyclic enol form are strongly influenced by the ring size, and it has been found (7, 20) that the tendency is inverted from five- to six-membered ring systems.

Since these ligands are so important in aqueous complexation, the equilibria study is focused on diluted aqueous solutions although for sake of comparison, chloroform will also be used for comparison with a solvent of relatively low polarity. To our knowledge, this is the first work where an NMR tautomeric study concerning this kind of ligands in dilute aqueous solution has been reported.

Experimental

2-Acetylcyclopentanone, (Hacpt, H being the enolic hydrogen atom), 2-acetylcyclohexanone (Hacx), 2-acetyl-1,3-cyclopentanedione (Hacpd), 2-acetyl-1,3-cyclohexanedione (Hacxd), and methyl 2-oxocyclopentanecarboxylate (Hmcp) were obtained from Aldrich; methyl 2-oxocyclohexanecarboxylate (Hmcx), was purchased from Fluka, all of them reagent grade. All were purified by distillation under reduced pressure, except 2-acetyl-1,3-cyclopentanedione (Hacpd) which was purified by recrystallization. Stock solutions were standardized by titration with standard sodium hydroxide.

The source of hydrogen ions was perchloric acid (Merck). Unless otherwise indicated, all materials (D_2O, $DOCD_3$, etc.), were of analytical reagent grade, and were used without further purification.

pH measurements were made using a CRISON 2002 pH meter calibrated to read hydrogen ion concentration directly by titrating solutions of perchloric acid with standard sodium hydroxide solutions.

UV–vis spectra were recorded on a Hitachi U-3OOO spectrophotometer. A Spectronic 1201 UV–vis spectrophotometer which includes a kinetic resident program, was used to follow the kinetic runs.

^1H NMR and ^{13}C NMR spectra were recorded on a BRUKER AC-300. They were taken at 300 and 75 MHz, respectively, in D_2O–$DOCD_3$ and $CDCl_3$. The chemical shifts were given in ppm relative to TMS.

Results and discussion

Equilibria may be analysed on the basis of the speed with which equilibrium is attained and considering the final equilibrium concentrations (equilibrium constant). Both aspects of the equilibrium (speed of attainment and position) are important for a proper understanding of tautomeric equilibrium and subsequent ligand behaviour in chelation reactions in solution.

The position of the keto–enol equilibrium can be modified by several effects, one of the most important being the medium in terms of solvent polarity. Thus, in this work we have tried to avoid effects other than solvent but simultaneously focusing attention on solvent concentration ratios.

Since, interconversion between *endo*- and *exo*-cyclic enol tautomers is very fast these compounds exist as equilibrium mixtures of the keto and enol forms, and the tautomerism exhibited by the ligand (HL) is usually represented as in eq. [1]:

	$CDCl_3$	–	–	2.6	–
	D_2O	–	–	2.2	–
	$CDCl_3$	–	3.8	–	3.7
	D_2O	–	3.7	–	3.6

Note: In $CDCl_3$ medium δ (ppm) is given using TMS as internal reference. When D_2O was used, chemical shifts were measured with respect to the residual water signal at δ = 4.64 ppm.

$$[1] \quad HK \underset{k_k}{\overset{k_e}{\rightleftharpoons}} HE$$

where k_e is the rate of enolization, k_k the rate of ketonization, and HK and HE represent the keto and enol tautomers, respectively.

The advantages of NMR techniques in studies of tautomeric phenomena have been demonstrated (7, 21–23). In the keto–enol equilibria, in which the tautomers are only partially interconverted at room temperature, the proton and carbon signals of individual isomers (e.g., Fig. 1) may be easily distinguishable, which allows the calculation of the keto–enol ratio in the medium.

Since a major factor that cannot be overlooked is the medium effects in the tautomerization equlilibria, solvents consisting of a mixture of D_2O–$DOCD_3$ and $CDCl_3$ were utilized. Chemical shifts of both tautomers are included in Table 1 and Table 2.

Table 2. ^{13}C NMR chemical shifts (δ (ppm)) of carbonyl group in D_2O–CD_3OD.

	–	–	204;206	116	186
	220	176	–	103	179

Note: δ from TMS as external reference in $CDCl_3$.

In order to study the concentration effects over the tautomeric equilibria several NMR spectra were registered in the 0.002–0.2 mol dm^{-3} concentration range (Table 3). All keto–enol ratios are summarised in Table 3.

To allow us also to check the accuracy of the tautomeric equilibrium measurement in dilute aqueous solution, in addition to the mentioned NMR study, a kinetic procedure was also carried out.

The keto–enol interconversion in 2-acetyclcycloalkanones has been investigated by using a spectrophotometric method to measure the rate at which bromine is added (24) from which the ratio [HE]/[HK] which is equal to the quotient between enolization and ketonization rate constants may be easily determined. The enol tautomer reacts instantly with the bromine. To maintain equilibrium some of the keto

tautomer converts to the enol tautomer which then reacts with bromine. Hence, the rate of enolization parallels the rate of bromination, which will reach a limiting rate given by eq. [2]

$$[2] \qquad -d[Br_2]/dt = -d[HK]/dt = k_e[HK]$$

In this situation, the concentration of HK is given by eq. [3], where A is the absorbance due to bromine at any time t at the observation wavelength (452 nm), l is the path length, ε is the absorption coefficient of bromine at 452 nm, $[HL]_0$ and $[Br_2]_0$ are the total concentrations of 2-acetyclcycloalkanone (enol plus keto-forms) and bromine respectively at time zero.

$$[3] \qquad [HK] = A/\varepsilon l + [HL]_0 - [Br_2]_0$$

Substitution from eq. [3] into eq. [2] followed by integration gives eq. [4], where C is a constant,

$$[4] \qquad -\ln (A/\varepsilon l + [HL]_0 - [Br_2]_0) = k_e t + C$$

In eq. [4] the term in the parenthesis corresponds to the keto-tautomer concentration. A plot of the left-hand side of eq. [4] vs. time gives a straight line of slope k_e. Since k_e/k_k = [HE]/[HK] and [HL] = [HE] + [HK], the intercept values obtained in these plots were used to determine the enol fraction (y = [HE]/[HL]) allowing determination of ketonization rate constants k_k.

A small volume (100–200μl) of bromine stock solution was added to 2.5–3.0 mL of a previously standardized ligand solution placed in the thermostatted cell compartment of the spectrophotometer. The diketone concentrations in the cell ranged from 7.47×10^{-4} mol dm^{-3} to 2.45×10^{-3} mol dm^{-3} whereas bromine concentrations ranged from 7.88×10^{-4} mol dm^{-3} to 2.37×10^{-3} mol dm^{-3}. Changes in absorption at 452 nm were recorded at 0.5 s intervals. Each bromine solution contained 1×10^{-3} mol dm^{-3} NaBr in order to suppress hydrolysis of bromine.

Since the presence of OH^- might promote the interconversion between keto and enol tautomers catalytically, bromitation experiments have been carried out in acidic medium (0.1–0.001 mol dm^{-3}). It was shown that the H^+ concentrations had little or no effect on the tautomeric equilibrium.

The ketonization rate constant (k_k) was determined from graphical consideration (25) over the first-order bromination equation as indicated above, and secondly from acid treatment of a solution of 2-acetyclcycloalkanones in sodium hydroxide medium. In this latter case, the value of k_k was determined by reacting a solution of the diketone which had been adjusted to a pH of approximately 11 with sodium hydroxide and which contained the compound almost exclusively as enolate ion, with excess perchloric acid. The enolate ion is rapidly protonated and the subsequent readjustment of the equilibrium to the equilibrium concentrations of keto and enol tautomers was monitored spectrophotometrically at 290 nm. A first-order plot of these absorbance changes gives ($k_e + k_k$) from which k_k can be calculated. From this information and a consideration of the total concentration of reacting bromine, enol fraction values (y) have been determined.

The above mentioned halogenation procedure has been carried out for 2-acetyl-1,3-cycloalkanediones. In this case when bromine and triketone are in equimolecular conditions

© 2001 NRC Canada

all the bromine reacts instantaneously. These results suggest that the mentioned triketones are present only in monoenol form. When the bromine concentration is higher than the triketone, the subsequent rate of bromination is governed by the rate of a second enol formation in the previously monobrominated molecule. In fact, addition of a second bromine molecule results from the possibility of internal proton transfer arrangement within the molecule since the first brominated molecule still remains a β-dicarbonyl system.

Finally, although β-keto esters present different functionality than 2-acetylcycloalkanones, they can conventionally be regarded as compounds with a similar tautomeric equilibrium (7) for which a similar bromination procedure has been extended.

The ionization equilibrium, apart from its importance for predicting both stability constants (26) and decomplexation rate contants (27) of a wide range of 1,3-dicarbonylic monochelates, is also closely related to the tautomeric equilibrium analysed.

In fact, the enolization of 1,3-dicarbonylic compounds does not proceed by direct transfer of a proton from carbon to oxygen. Instead, the enolate ion is formed as an intermediate and eq. [5] is a more complete description of the actual mechanism.

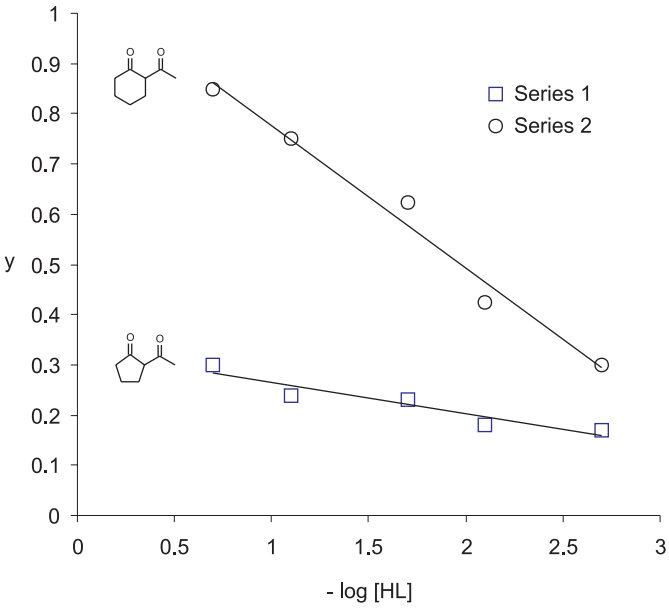
$$[5] \quad HK \underset{k_b}{\overset{k_a}{\rightleftharpoons}} H^+ + E^- \underset{k_d}{\overset{k_c}{\rightleftharpoons}} HE$$

In eq. [5], $k_{c\ kb}$ k_d k_a and k_c is diffusion-controlled (28) (≈3 × 10^{10} dm^3 mol^{-1} s^{-1}).

Moreover, the equilibrium constants for ionization may be partitioned as follows:

$$[6] \quad HL \overset{k_{HL}}{\rightleftharpoons} H^+ + E^-$$

In eq. [6] HL represents the carbonylic molecule and E^- the enolate ion (common product of the ionization of either keto or enol tautomers). This overall dissociation constant (K_{HL}) can be partitioned between the equilibrium constant K_{HE} and K_{HK}, the dissociation constants of the enol and keto tautomers respectively, eq. [7] and [8],



$$[7] \quad HK \overset{k_{HK}}{\rightleftharpoons} H^+ + E^-$$

$$[8] \quad HE \overset{k_{HE}}{\rightleftharpoons} H^+ + E^-$$

These constants can be related through the equation: $1/K_{HL} = 1/K_{HE} + 1/K_{HK}$. Taking into account that $K_{HE}/K_{HK} = [HE]/[HK]$, values of $K_{HE} = K_{HL}/y$ may be similarly calculated. Thus, in terms of the ionization scheme, $k_e = k_a$ and $k_k = K_{HE}k_b$ and the values of k_d may be calculated from the known values of K_{HE} and k_c, assuming that the k_c pathway is diffusion-controlled.

K_{HL} values were determined potentiometrically by titrating solutions of the mentioned carbonylic compounds having concentrations in the range 1.0×10^{-3} to 1.0×10^{-2} mol dm^{-3} with standard sodium hydroxide solutions in a double-walled titration cell under an atmosphere of nitrogen gas. Data treatment was carried out using the program SUPERQUAD (29). Since compounds of this class readily undergo hydrolysis or cleavage in alkaline solution, for the less acidic ligands it was thought desirable to check these results by the method of parallel straights (30) through spectrophotometric measurements. Standard buffer solutions were prepared in a pH range close to the *pK* of the ligand (6). The wavelengths were selected at regular intervals around the absorption max of the ligand associated with the $\pi \rightarrow \pi^*$ transition. The averaged p*K* of the ligands at 25°C are shown in Table 3.

Fig. 2. Enol fraction dependence on the 2-acetylcycloalkanone concentrations.

A first analysis of results in Table 3 shows a very good agreement between halogenation and NMR results when the solvent and ligand concentrations are similar.

In this case, the reaction medium plays a decisive role in the observed equilibrium position. These results also reveal the predomination of the less polar tautomer in nonpolar solvents and the more polar tautomer in polar solvents. It has been also verified that high D_2O concentrations shifted the equilibrium to the keto tautomeric form (Fig. 2). Thus concentration effects might be interpreted as an increase in medium polarity.

One important feature which emerges from Table 3 is that regardless of the solvent utilized, the keto-form in β-keto esters and the enol form in β,β′-triketones are the most stable.

In 2- acetylcycloalkanones, tautomer content has been determined from the integration of the methyl group signal on ^{1}H NMR (Table 1). Methyl groups in the enol tautomer appear upfield relative to the same methyl group in keto-form. In the ^{13}C NMR spectra, keto- and enol-forms can also be distinguished (Table 2).

These compounds show that the percentage of enol tautomer, especially the nature of the enol form, depends on ring size. Although the content of enol tautomer depends strongly on the solvent used (Table 1), five-membered ring systems

© 2001 NRC Canada

favours an *exo*-enol tautomer, while in six-membered rings systems the *endo*-enol form is the predominant. On dissolution in solvents of low polarity, the percentage of the less polar *cis*-enolic form increases and on the other hand, polar solvents displace the equilibrium towards the polar diketo-form.

Thus, in chloroform the enol tautomer is predominant and even in the case of Hacx the keto tautomer was undetected. On the other hand, in deuterium oxide the keto tautomer is predominant and its percentage depends on the carbonylic compound concentration (Fig. 2). This can be explained in terms of the solvation of the carbonyl groups by the polar solvent molecules, thus increasing the relative stability of the diketo-form (31, 32).

Analysis of ^{1}H and ^{13}C NMR spectra of β,β′-triketones indicated that the monoenol form was present in both solvents while the triketo-form was undetected. ^{1}H-NMR spectra shows a single signal for methyl group and in the ^{13}C NMR two carbonyl signals appear as well as an alkene group signal.

In β-keto esters, the percentage of enolic forms was determined from the integration of the methoxy signal (CH_3O) of keto and enol tautomers on the ^{1}H NMR (Table 1). The methyl signal in the enol tautomer is displaced towards high fields. This was confirmed by ^{13}C NMR (Table 2) where the enol form shows an alkene group, with two signals (δ = 180, 110 ppm).

The degree of enolization of cyclic keto esters seems to depend on ring size. Thus five-membered keto esters are completely in keto-form in chloroform and deuterium oxide. Six-membered keto esters show that keto-ester-form is prevalent but the enol content increases with the concentration of keto ester, as with Hacpt (Fig. 2).

All of this leads us to deduce that when an *endo*-enol form is close to a quasiaromatic H-bonded (7) system it increases the enol content. Therefore, in six-membered rings where "olefinic strain" (33) is less there is a higher enol content.

The ionization rate constants, are important not only per se but also due to their importance in establishing complexation mechanisms. In order to obtain an idea about ionization equlilibria, rate constants of ionization processes (k_a and k_d) have been determined (Table 3). The results obtained indicate that the rate constants for ionization of the keto and enol tautomers of Hacx are about three orders of magnitude less than the homologous five-membered rings. Considering both p*K* and ionization rate values, it can be assumed that ionisation in Hacpt is energetically and kinetically advantageous.

When comparing ionization rates of Hacx with other six-membered derivative compound rates (Hacxd and Hmcx) the former is at least one order of magnitude less than the next smallest value.

It can also be observed that the substitution of a carbonyl group in a second α-position at the acetyl group changes acidity of the ligand strongly (the K_{HL} of triketones is larger than the K_{HL} of its homologous diketones). There are two important effects that can influence a compound's acidity, the inductive effect and the resonance effect, although in the case of bulky molecules the steric effect may also be considered. Unfortunately, in most molecules, several effects are working simultaneously and it becomes extremely difficult and complex to interpret the observed differences in acidity or basicity in terms of a single structural feature. In this case the stabilisation of the anion as we go from dicarbonylic compounds to β,β′-tricarbonylic compounds, may be interpreted not only by three carbonylic groups over the same tertiary carbon through inductive and resonance effects, but also by intramolecular hydrogen bonding.

Since enolization equilibria and intermolecular proton transfer reactions in these ligands are particularly attractive even from a theoretical point of view (34), several parameters have been calculated at different semiempirical computational levels. AM1 calculations (35) have been performed with the Spartan Plus program.

Once the structures have been fully optimized, AM1-SM2 results reveal the predomination of the *exo*-cyclic enol form in Hacpt and the *endo*-cyclic enol form Hacx (Table 3). The relative stabilities of the two enol forms in 2-acetylcycloalkanones are influenced by the ring size, since five-membered ring systems favour an *exo*-cyclic enol, whereas six favour an *endo*-cyclic enol (36). The results observed in 2-acetylcyclopentanone (0.24 *exo*, 0.20 *endo*) might be explained on the basis of steric factors (37), and torsional and angle bending strains (38) which can cause deviations from the expected behaviour.

In the case of β,β′-triketones, these theoretical calculations which show that the triketo content is negligible are in good agreement with the data available from the mentioned kinetic and NMR methods.

Agreement between experiments and predictions is also very good when analysing β-keto ester results. In these compounds, only a really undetectable amount of the enol form (y = 0.04) is calculated for Hmcp and a slightly higher amount in the Hmcx (y = 0.12) as is the case. Furthermore, the *endo*-enolic form predicted is also in agreement with literature predictions (7, 20) which corroborate the semiempirical results obtained.

Potentiometric titration study of two novel polydenate ligands and investigations of their complexes

Dengke Cao, Hua-Kuan Lin, Zhi-Fen Zhou, Shou-Rong Zhu, Xun-Cheng Su, and Yun-Ti Chen

Abstract: Two novel linear polyamine ligands, *N*,*N*′-bis-(2-(*N*″-2-hydroxyl-5-bromobenzyl)aminoethyl) malondiamide (**L_1**) and *N*,*N*′-bis-(3-(*N*″-2-hydroxyl-5-bromobenzyl)aminopropyl) malondiamide (**L_2**), have been synthesized and fully characterized by elemental analysis (^{1}H NMR and IR spectroscopy) (Fig. 1). The binding ability of ligands **L_1** and **L_2** to metal ions such as Cu(II), Zn(II), Co(II), Mn(II), Mg(II), and Ca(II) has been investigated by the potentiometric method in 1,4-dioxane–water (v/v = 15:100) and KNO_3 (0.1 mol dm^{-3}) at 25.0°C. In view of the linear structures of **L_1** and **L_2**, binuclear metal complexes can be formed in solution by controlling Cu(II)-5-substituted *o*-phenanthroline (Rphen, R = CH_3, H, Cl, NO_2):**L** to a 2:1 molar ratio, whereas the mononuclear metal complexes form at molar ratio M(II):**L** of 1:1, where M(II) is Cu(II), Zn(II), Co(II), Mn(II), Mg(II), and Ca(II). The stability constants of metal complexes have been determined and further discussed. In addition, two manganic complexes have been synthesized and IR and electronic spectra showed their coordination nature.

Key words: linear polyamine ligand, 5-substituted *o*-phenanthroline, mononuclear and binuclear metal complex, stability, spectrum.

Résumé : On a réalisé la synthèse de deux nouveaux ligands polyamines linéaires, *N*,*N*′-bis-(2-*N*″-2-hydroxy-5-bromobenzyl)aminoéthyl)malondiamide (**L_1**) et *N*,*N*′-bis-(3-*N*″-2-hydroxy-5-bromobenzyl)aminopropyl)malondiamide (**L_2**) et on en a fait la caractérisation complète par analyses élémentaires, RMN du ^{1}H et par IR. Faisant appel à des mesures potentiométriques et opérant dans un mélange 1,4-dioxane–eau, à 25°C, dans des solutions contenant 0,1 mol dm^{-3} de KNO_3, on a étudié les possibilités de fixation des ligands **L_1** et **L_2** aux ions métalliques Cu(II), Zn(II), Co(II), Mn(II), Mg(II) et Ca(II). Compte tenu des structures linéaires des ligands **L_1** et **L_2**, il existe une possibilité de former des complexes métalliques binucléaires en solution si on contrôle le rapport molaire entre le sel de Cu(II) de l'*o*-phénanthroline substituée en position 5 (Rphen; R = CH_3, H, Cl, NO_2)/**L** (2:1) alors qu'il se forme des complexes métalliques mononucléaires lorsque le rapport molaire (M(II):**L**) est de 1:1 (M(II) = Cu(II), Zn(II), Co(II), Mn(II), Mg(II) et Ca(II)). On a déterminé et on discute des constantes de stabilité des complexes métalliques. De plus, on a synthétisé deux complexes manganiques et, sur la base de leurs spectres IR et électroniques, on en a déduit la nature de leur coordination.

Mots clés : ligand polyamine linéaire, *o*-phénanthroline substituée en position 5, complexes métalliques mononucléaires et binucléaires, stabilité, spectre.

[Traduit par la Rédaction]

Introduction

In recent years, the research of polynuclear metal complexes has increased dramatically due to the introduction of appropriate ligands such as linear polyamine that is able to form mononuclear or binuclear metal complexes by controlling the reaction conditions. Dominguez-Vera et al. (1) reported the ligand *N*,*N*′-bis(3-aminopropyl) oxamidate (oxpn), the mononuclear [Cu(cis-oxpn)], and the binuclear $[Cu_2(trans\text{-}oxpn)]^{2+}$ species were prepared by controlling pH and the Cu(II):oxpn molar ratio. Additionally, the synthesis of manganic complexes has been a subject of considerable importance, because manganic ions serves various important roles in biological systems (2), and to date, many metal enzymes containing manganic ions have been found (3).

In this paper, we report an attempt at preparing some novel ligands and metal complexes. Two novel linear ligands shown in Fig. 1, *N*,*N*′-bis-(2-(*N*″-2-hydroxyl-5-bromobenzyl)aminoethyl) malondiamide (**L_1**) and *N*,*N*′-bis-(3-(*N*″-2-hydroxyl-5-bromobenzyl)aminopropyl) malondiamide (**L_2**) have been synthesized and characterized. The potentiometric method has been used to investigate the formation of mononuclear and binuclear complexes in solution. The Mn**L_1** and Mn**L_2** complexes have been prepared and characterized by elemental analyses (IR and UV spectroscopy).

L

Experimental

Reagents

Dimethylmalonate, salicylaldehyde, ethylenediamine, and propylenediamine were of AR reagent grade and purified prior to use. *N*,*N*′-bis-(2-aminoethyl) malondiamide, *N*,*N*′-bis-(3-aminopropyl) malondiamide, and 5-Br-salicylaldehyde were synthesized according to the earlier reports (4, 5). $Mn(CH_3COO)_2{\cdot}4H_2O$ and $Mn(CH_3COO)_3{\cdot}2H_2O$ were used as received. Five-substituted *o*-phenanthroline (Rphen, R = CH_3, H, Cl, NO_2) were purchased from G. Friderik Smith Chemistry Corporation and used without further purification. In potentiometric experiments, all solutions were prepared from redistilled water. The Cu(II), Zn(II), Co(II), Mn(II), Mg(II), and Ca(II) nitrates were purchased from Tianjin Third Chemical Reagent Factory and recrystallized. All these metal ion solutions were standardized with EDTA.

Instruments

Elemental analyses were performed on a Perkin Elmer 240C elemental analyzer. IR spectra were obtained as KBr disks on a Nicolet 170 SX FT-IR spectrometer, and the ^{1}H NMR spectra were recorded with a Varian UNITY-plus 400 MHz spectrometer. The electronic absorption spectra of the complexes were measured in the range 190–500 nm using a Shimadzu UV-240 spectrometer.

Potentiometric measurements

The potentiometric technique was described in a previous paper (6), and the potentiometric measurements were carried out with a Beckman pH meter Model Φ71 equipped with a type 39841 combination electrode. Typical concentration of the experimental solutions for molar ratios M:**L** of 1:1 in binary systems and Cu(II):Rphen:**L** of 2:2:1 in ternary systems, was 5×10^{-4} mol dm^{-3}. The ionic strength was adjusted to 0.1 mol dm^{-3} with KNO_3. All the potentiometric measurements were carried out in a nitrogen atmosphere at 25.0 ± 0.1°C. The calculations of protonation and equilibrium constants were made using the SCMAR program (7) based on the improved TITFIT technique (8). For each system, at least three titrations were performed, and each titration contained ca. 50 experimental points.

Synthesis

Symmetric Schiff-base

5-Bromosalicylaldehyde (0.075 mol) and ethanol (50 cm^3) was placed in a 250 mL flask equipped with a magnetic stirrer. The solution of *N*,*N*′-bis-(2-aminoethyl)-malondiamide (0.026 mol) in water (40 mL) was added slowly at room temperature and a yellow precipitate was formed immediately. After the addition, the resulting solution was brought to reflux for 2 h and then allowed to cool. The precipitate was filtered off, washed with ethanol, and dried.

N,N′*-bis-(2-(*N″*-2-hydroxyl-5-bromobenzyl)aminoethyl) malondiamide (L_1)*

Solid $NaBH_4$ (0.76 g) was added in portions to solution at reflux of 0.005 mol (1.98 g) *N*,*N*′-bis-(2-(*N*″-5-bromosalicylaldehyde)aminoethyl) malondiamide in absolute methanol (30 mL). After heating an additional 2 h at reflux, the solution was cooled. The excess methanol was removed with a rotary evaporator and the pH was adjusted to about 8. The resulting solution was extracted with $CHCl_3$ three times. The removal of $CHCl_3$ gave a pale red powder as the crude product. It was then recrystallized as white powder from ethanol, 2.09 g (75%). IR (cm^{-1}): 3282.0 (N-H), 1637.9 (C=O), 814.3 (C-H benzene ring). ^{1}H NMR(DMSO) δ: 6.670–8.059 (6H), 2.506–3.740 (14H). Anal. calcd. for $C_{21}H_{26}N_4O_4Br_2$: C 45.16, N 10.03, H 4.67; found: C 45.17, N 9.83, H 4.60.

N,N′*-bis-(3-(*N″*-2-hydroxyl-5-bromobenzyl)aminopropyl) malondiamide (L_2)*

The method was similar to the synthesis of $\mathbf{L_1}$ and the yield was 73%. IR (cm^{-1}): 3288.0 (N-H), 1637.2 (C=O), 815.3 (C-H benzene ring). ^{1}H NMR (DMSO) δ: 6.648–8.004 (6H), 1.550–3.755 (18H). Anal. calcd. for $C_{23}H_{30}N_4O_4Br_2$: C 45.54, N 9.24, H 4.95; found: C 45.59, N 9.30, H 4.90.

MnL_1 complex

The ligand $\mathbf{L_1}$ (1.51 g, 2.7 mmol) was stirred with 2 equiv KOH (0.303 g, 5.4 mmol) for 30 min in methanol (40 cm^3) at room temperature. An aqueous solution of $Mn(CH_3COO)_2{\cdot}4H_2O$ (20 cm^3, 0.67 g, 2.7 mmol) was added slowly, and the solution gradually turned dark brown. The reaction mixture was allowed to reflux for 45 min, filtered, and then the product was washed with methanol and dried. The yield was 67%. The same product could be isolated in 58% yield by using $Mn(CH_3COO)_3{\cdot}2H_2O$ instead of the Mn(II) salt.

MnL_2 complex

A slightly different method was adopted for the synthesis of Mn$\mathbf{L_2}$. The methanol solution containing ligand $\mathbf{L_2}$ was stirred with 2 equiv of KOH for 30 min at 313 K, solid $Mn(CH_3COO)_2{\cdot}4H_2O$ (1 equiv) was added to the solution and the resulting solution turned dark brown. The reaction mixture was allowed to reflux for 45 min, then filtered at 313 K, washed with methanol and dried. The yield was 65%.

Results and discussion

Protonation constants of the ligands $\mathbf{L_1}$ and $\mathbf{L_2}$

The stepwise protonation of the ligands $\mathbf{L_1}$ and $\mathbf{L_2}$ have been studied by potentiometric titration in 1,4-dioxane–water (v/v = 15:100) at 25.0°C and I = 0.1 mol dm^{-3} in KNO_3. In a typical experiment, a solution containing the ligand and excess acid was titrated by the standard base. The equilibrium in the system can be written as in eq. [1], where β_{mlh} =

$[M_m\mathbf{L}_lH_h]/[M]^m[\mathbf{L}]^l[H]^h$ in which charges are omitted for the sake of simplicity, and square brackets denote equilibrium concentrations. The *m*, *l*, and *h* are the stoichiometric numbers of the metal ions, the ligand (**L**), and hydrogen ions, respectively, and h has a negative value when H^+ is released during coordination. The value of *m* is zero for protonation constants of the ligands (**L**).

[1] $$m\mathrm{M} + l\mathbf{L} + h\mathrm{H} \rightleftharpoons \mathrm{M}_m\mathbf{L}_l\mathrm{H}_h$$

Within the investigated pH range (2.7–10.5), protonation reactions were found to occur in four steps, and the results are listed in Table 1. In fact, the ligand containing two amines, two phenols, and two amide groups might experience six-step protonation, but the basicity of both amide groups is so weak that their protonation constants can not be determined in the investigated pH range (2.7–10.5). For ligands $\mathbf{L_1}$ and $\mathbf{L_2}$, log K_1 and log K_2 can be ascribed to the protonation constants of both phenolic groups. It can be observed that log K_1 is larger than log K_2 for ligands $\mathbf{L_1}$ and $\mathbf{L_2}$. The species (011) might have two types of structures as show in Fig. 2, the structure *b* seems much more reasonable than *a* because of the bulky effect of the bromine group. Log K_3 and log K_4 are the protonation constants of both amine groups. The log K_3 values for ligands $\mathbf{L_1}$ and $\mathbf{L_2}$ are somewhat lower than the corresponding first step protonation constants of ethylene diamine (9) (log K_1 = 9.93) and 1,3-propanediamine (9) (log K_1 = 10.62). The lower log K_3 values obtained for ligands $\mathbf{L_1}$ and $\mathbf{L_2}$ indicated that the basicity of the amine group became weak due to some electron transfer to the "super conjugative" system of the 2-hydroxyl-5-bromobenzyl group when the proton of the amine group was substituted by the 2-hydroxyl-5-bromobenzyl. After the third step protonation was completed, the two amine groups were bridged by the same proton. Under this condition, both of the two amine groups have difficulty to become protonated due to the effect of electrostatic interaction, so for the ligands $\mathbf{L_1}$ and $\mathbf{L_2}$, log K_4 is smaller than log K_3.

The comparison of protonation constants of $\mathbf{L_1}$ and $\mathbf{L_2}$ shows that the later is higher than the former. Log K_3 and log K_4 of ligand $\mathbf{L_2}$ are higher than the corresponding constants of $\mathbf{L_1}$. This is consistent with the reported results of log K_1 and log K_2 in 1,3-propanediamine (9) (log K_1 = 10.61, log K_2 = 8.64), which are higher than those in ethylene diamine (9) (log K_1 = 9.93, log K_2 = 6.85). Since some electrons of the amine group may transfer to the super conjugative system of the 2-hydroxy-5-bromobenzyl group, and the amine group basicity of the ligand $\mathbf{L_2}$ is stronger than that of the ligand $\mathbf{L_1}$, we obtained a higher log K_1 and log K_2 for the ligand $\mathbf{L_2}$ than $\mathbf{L_1}$. On the whole, the comparison of the four-step protonation constants of ligand $\mathbf{L_2}$ with those of ligand $\mathbf{L_1}$ shows that the protonation capability of ligand $\mathbf{L_2}$ is stronger than that of ligand $\mathbf{L_1}$, which can also be deduced from the distribution curves of the protonation of ligands $\mathbf{L_1}$ and $\mathbf{L_2}$ (Fig. 3 and 4).

Stability constants of ligands $\mathbf{L_1}$ and $\mathbf{L_2}$ with Cu(II), Zn(II), Co(II), Mn(II), Ca(II), and Mg(II)

For ligands $\mathbf{L_1}$ and $\mathbf{L_2}$, the stability constants (log β_{mlh}) of binary systems are listed in Table 2 and Table 3, respectively. In Fig. 5 (the distribution curves of the Cu(II)-**L** binary complexes), only 80% maximal formation of complex Cu$\mathbf{L_1}$, while almost 100% formation for the complex Cu$\mathbf{L_2}$ occurred in a wide pH range, indicating that for the same metal ion (Cu(II)) the coordination capability of the ligand $\mathbf{L_1}$ is weaker than that of the ligand $\mathbf{L_2}$. Comparing the stability constants of $\mathbf{L_2}$ with Zn(II), Co(II), Mn(II), Ca(II), and Mg(II) with the corresponding ones of $\mathbf{L_1}$, the results are in line with our expectations as follows:

For the ligand $\mathbf{L_1}$ and $\mathbf{L_2}$, the model species (111) of Zn(II) was not detected at the lower pH due to the weak coordination capability of Zn(II) compared to Cu(II), and coordination did not take place, as shown in Table 2 and 3. In addition, the model species (11–1) of Mn(II) did not occur, because the two protons of the amides that coordinate with Mn(II) tend to dissociate simultaneously at a higher pH. From the determined stability constants of $\mathbf{L_1}$ (in Table 2) and $\mathbf{L_2}$ (in Table 3), the coordination capabilities of metal ions for the ligands are Mn(II) < Co(II) < Cu(II) > Zn(II),

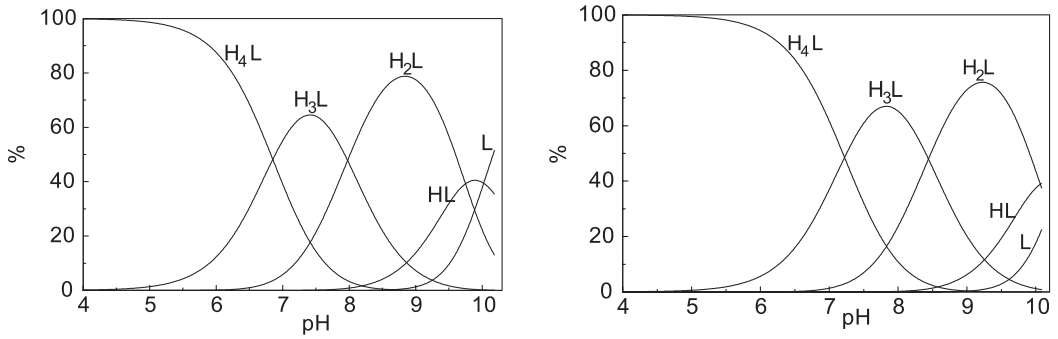

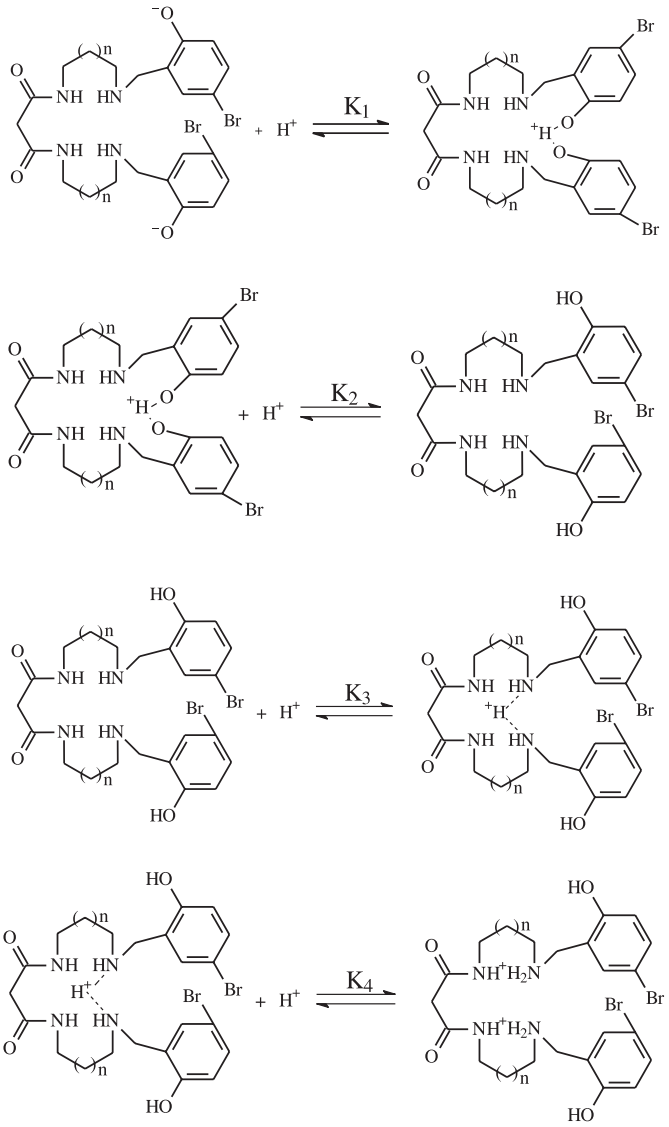

Fig. 4. Protonation style of $\mathbf{L_1}$ and $\mathbf{L_2}$.

which shows good agreement with the Irving–William sequence.

As expected, the ligands $\mathbf{L_1}$ and $\mathbf{L_2}$ have good deforming capability, so that for each ligand, not much difference appears between the corresponding log *K* for Mg(II)-**L** and Ca(II)-**L**, even though the radius of Mg(II) and Ca(II) differ greatly. In addition, the stability constants of Mg(II)-**L** or Ca(II)-**L** are not obviously smaller than for Co(II)-**L**, which may be due to the hard nature (from the hard-soft acid-base point of view) of coordination donors of ligands $\mathbf{L_1}$ and $\mathbf{L_2}$.

Stability constants of Cu-Rphen-L ternary (quasi-binary) complexes

It is well known (10) that Cu(II) can almost coordinate completely with Rphen in the pH range 2–7 due to the extremely strong coordination capability of Rphen. In this work, Cu(II)-Rphen binary complexes were prepared and employed in potentiometric measurements. The ligand $\mathbf{L_1}$ or $\mathbf{L_2}$ and Cu(II)-Rphen were mixed by a certain molar ratio and the system was defined as a quasi-binary system. In the above quasi-binary systems, the molar ratio of **L**:Cu(II)-Rphen may be 1:1 or 1:2. We failed to obtain rational results at molar ratio 1:1, but in contrast, we found that binuclear metal complexes formed at molar ratio 1:2 in quasi-binary systems. The stability constants obtained are summarized in Table 4. It seems that the appearance of **L** varied from a quasi-cycle to a torsional chain when coordinating with Cu(II)-Rphen, and binuclear complexes were formed as a result. The structure of binuclear complexes were determined only by the potentiometric method without separation. The structure of species 210 is suggested in Fig. 6*b*. Potentiometric titrations were performed in the pH range 2.7–6.7. Since the basicity of amide groups is too weak, only two amine groups and two phenolic donors coordinated with Cu(II) as shown in Fig. 6*b*. As shown in Table 4, the stability constant of the ligand $\mathbf{L_1}$ is lower than that of the ligand $\mathbf{L_2}$ for the same model species, which agrees with the weaker basicity of $\mathbf{L_1}$ vs. $\mathbf{L_2}$.

Comparing the stability constants for the Cu(II)-Rphen-**L** ternary (quasi-binary) systems in Table 4, it is found that the stability constants for Cu(II)-Rphen-**L** (R from CH_3 to NO_2) for $\mathbf{L_1}$ and $\mathbf{L_2}$ increase with corresponding increasing Hammett constant (–0.05, 0, 0.47, 0.63), and decreasing protonation constants of Rphen (5.028, 4.748, 4.125, 3.437) (11). The reasonable interpretation of the above phenomenon is that there exists a *d*–π feedback bond between Cu(II) and Rphen. Some *d* orbit electrons of Cu(II) feedback to Rphen and this decreases the density of the electron cloud around Cu(II). The lower the electron cloud density of Cu(II), the stronger the coordination of Cu(II) with **L**. From CH_3 to NO_2, the

Fig. 5. Distribution curves of the binary complexes (*a*) Cu$\mathbf{L_1}$ and (*b*) Cu$\mathbf{L_2}$.

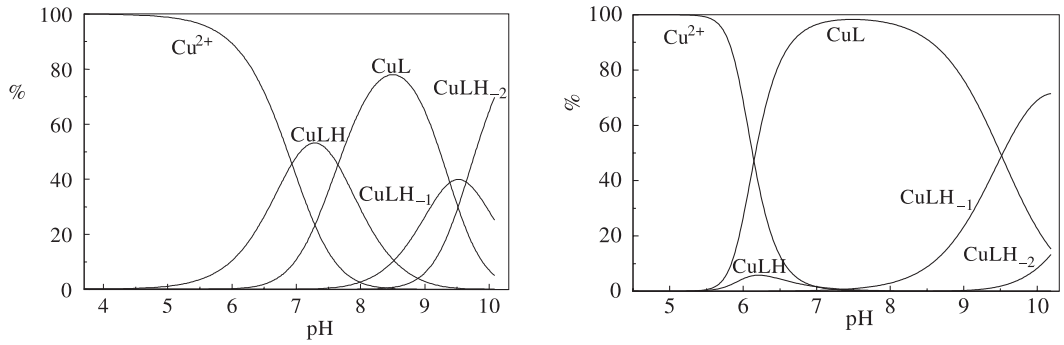

Table 3. Stability constants of the binary complexes for Cu(II), Zn(II), Co(II), Mn(II), Mg(II), and Ca(II) with the ligand $\mathbf{L_2}$.

	Cu(II)	Zn(II)	Co(II)	Mn(II)	Mg(II)	Ca(II)
log β_{111}	23.37	—	16.06	15.50	15.33	14.69
log β_{110}	15.14	9.26	7.20	6.41	5.55	4.26
log β_{11-1}	5.62	–1.23	–2.47	—	—	—
log β_{11-2}	–5.02	–11.54	–12.56	–13.10	–14.83	–16.47

Table 4. Stability constants of the ternary (quasi-binary) complexes for Cu(II)-Rphen with the ligand $\mathbf{L_1}$ and $\mathbf{L_2}$.

	CH_3	H	Cl	NO_2
$\mathbf{L_1}$				
log β_{212}	29.25	29.38	29.76	30.01
log β_{210}	16.01	16.10	16.37	16.54
$\mathbf{L_2}$				
log β_{212}	29.75	29.84	30.13	30.31
log β_{210}	16.57	16.62	16.90	17.10

density of the electron cloud of the ligand decreases gradually, *d*–π feedback increases, and the stability constants of the Cu(II)-Rphen-**L** ternary (quasi-binary) complexes (for the same model species) also increase gradually. In the quasi-binary systems studied, it was also found that linear relationships exists between log β_{212} or log β_{210} and the protonation contants of Rphen with the following equations:

for $\mathbf{L_1}$: $\log \beta_{212} = 31.72 - 0.49 \log \beta_{Rphen}$ $r = -0.994$
$\log \beta_{210} = 17.74 - 0.34 \log \beta_{Rphen}$ $r = -0.993$

and $\mathbf{L_2}$: $\log \beta_{212} = 31.58 - 0.36 \log \beta_{Rphen}$ $r = -0.992$
$\log \beta_{210} = 18.31 - 0.35 \log \beta_{Rphen}$ $r = -0.994$

In our work, linear relationship was also obtained between the Hammett constant (σ) and stability constants of complexes in quasi-binary system. The relevant equations are as follows:

for $\mathbf{L_1}$: $\log \beta_{212} = 29.33 + 1.02\sigma$ $r = 0.990$

and $\mathbf{L_2}$: $\log \beta_{212} = 29.81 + 0.76\sigma$ $r = 0.992$

The coordination nature of complexes

As shown in Table 5, for the complexes Mn$\mathbf{L_1}$ and Mn$\mathbf{L_2}$, analytical results agree well with theoretical calculations. In

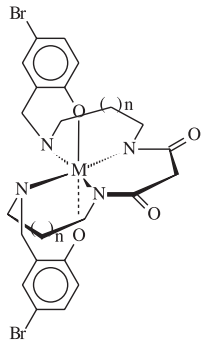
Table 5. Analytical data for the complexes of Mn(III) with the ligands $\mathbf{L_1}$ and $\mathbf{L_2}$.

		Analysis (%)[a]		
Compound	Color	C	H	N
Mn$\mathbf{L_1}$	Brown	40.89 (41.11)	3.70 (3.92)	9.10 (9.14)
Mn$\mathbf{L_2}$	Brown	42.95 (43.06)	4.12 (4.37)	8.23 (8.74)

[a]Calculated values are given in parentheses.

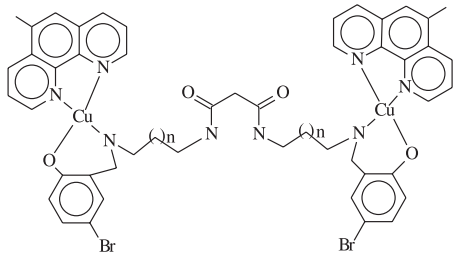
the two complexes, the valence state of manganese ion is +3 (12). We also studied solid powder ESR spectra of complexes Mn$\mathbf{L_1}$ and Mn$\mathbf{L_2}$ at room temperature and did not observe any peaks, which also supports our conclusion.

Infrared Spectroscopy



The spectra of the solid state complex Mn$\mathbf{L_1}$ and Mn$\mathbf{L_2}$ are assigned and given in Table 6. For the complex Mn$\mathbf{L_1}$, the phenol's coordination is suggested by the shift of ν (Ar-O) to 1271 cm^{-1} towards the peak of the ligand $\mathbf{L_1}$ at 1253 cm^{-1} (13). From comparison of the ν (CO) and δ (NH) of $\mathbf{L_1}$ with those of the complex Mn$\mathbf{L_1}$, the coordination of amide with Mn(III) could be determined. For the complex Mn$\mathbf{L_2}$, the coordination nature is suggested by the presence of absorption due to the metal-bound amide ν (CO) at 1654 cm^{-1}, δ (NH) at 1545 cm^{-1}, and stretching frequency ν (Ar-O) at 1272 cm^{-1} (14).

Electronic Spectroscopy



Electronic spectra in DMSO solution of $\mathbf{L_1}$, Mn$\mathbf{L_1}$, $\mathbf{L_2}$, and Mn$\mathbf{L_2}$ over the 190–500 nm region (298 K) are reported in Table 7. For the complex Mn$\mathbf{L_1}$, the σ(N) → Mn(III) LMCT transition occurs as a single broad band centering at 390 nm (15). Intense bands at 262 nm and 283 nm are assignable to absorptions of the benzene ring. Comparing these with the 287 nm band of $\mathbf{L_1}$, it was found that new absorptions of the benzene ring are due to phenolic group coordination with Mn(III). For the complex Mn$\mathbf{L_2}$ similar

$\mathbf{L_2}$	—	287	—
Mn$\mathbf{L_2}$	259	286	391

peaks appear. Additionally, each of the complexes also exhibit a broad absorption near 500 nm, which may be due to the ligand field transitions.

Conclusion

In summary, two novel linear ligands $\mathbf{L_1}$ and $\mathbf{L_2}$ have been synthesized. The thermodynamic properties of these ligands and their metal complexes have been studied in aqueous solutions using potentiometric methods. The results show that the ligands are of great interest in coordination to metal ions. In addition, two mangantic complexes have been prepared and their structures have been extensively studied. The amides coordinated complexes Mn$\mathbf{L_1}$ and Mn$\mathbf{L_2}$ are indicated by the blue shift of ν (CO) in IR spectra, so it is reasonable to conclude that amides coordinate with Mn(III) without dissociating protons. The complexes Mn$\mathbf{L_1}$ and Mn$\mathbf{L_2}$ are both of octahedral geometry and the possible structures are given in Figs. 6*a*, *b.*

Addendum

Bis(trimethylsilyl)methanesulfonyl and tris(trimethylsilyl)methanesulfonyl chlorides and their reactions by way of sulfenes: Addendum[1]

James F. King, Kim M. Baines, Matthew R. Netherton, and Vinod Dave

In footnote 4 of this paper we expressed reservations about the reliability of a report by Skrypnik and Lyashchuk in *Sulfur Letters* (ref. 10), on the preparation by reaction of Arduengo's carbene with sulfur dioxide of a sulfene "stable at low temperature." We now wish to note further that the editor of *Sulfur Letters* in an Editorial Note has concluded as follows with respect to the paper by Skrypnik and Lyashchuk: "In the absence of self-consistent convincing proof of the claims made in this paper we suggest that it should be stricken from the scientific record." (A. Senning, *Sulfur Letters*, **1996**, *20*, 105). We thank Professor Senning for drawing this Note to our attention.

Synthesis, characterization, and C—N bond cleavage of tungsten(VI)arylimido-calix[4]arene complexes

Martyn Brown and Chet Jablonski

Abstract: The tetradentate, partially flattened cone tungsten(VI) imido-calix[4]arene derivative $[W(NC_6H_5)(t\text{-BucalixH})]^+Cl^-$, **(4)**, is formed in good yield from reaction of *p-tert*-butyl-calix[4]arene (t-BucalixH_4), and $W(NC_6H_5)Cl_4$. A reaction mechanism involving a putative, bidentate calixarene intermediate $W(NC_6H_5)(t\text{-Bucalix}H_2)Cl_2$ (**3**), which partitions by reversible cleavage of the imido group to give the known tetradentate calixarene complex W(t-Bucalix)Cl_2 (**2**), and elimination of HCl to form the thermodynamic imido product **4** is proposed. A series of isostructural $[W(NAr)(t\text{-BucalixH})]^+Cl^-$ (Ar = C_6H_5 or *o,m,p*-$C_6H_4CH_3$) imido derivatives (**4**–**7**), which adopt a partially flattened cone conformation in solution has been prepared by reaction of dichloride **2** with H_2NAr (Ar = C_6H_5, *o,m,p*-$C_6H_4CH_3$). Reaction of W(t-Bucalix)Cl_2 with aliphatic amines affords a red product formulated as the nitrido complex, **9**, which results from facile cleavage of the imido C—N bond.

Key words: calix[4]arene complex, imido complex, nitrido complex, C—N bond cleavage, conformation, metallocalixarene.

Résumé : Le dérivé imidocalix[4]arène $[W(NC_6H_5)(t\text{-BucalixH}]^+Cl^-$ (**4**), un tétradentate du tungstène(VI) en cône partiellement aplati, se forme avec un bon rendement par réaction du *p-tert*-butyl-calix[4]arène, (t-BucalixH_4) et du $W(NC_6H_5)Cl_4$. On suggère que la réaction implique un mécanisme dans lequel un intermédiaire calixarène bidentate putatif, le $W(NC_6H_5)(t\text{-Bucalix}H_2)Cl_2$ (**3**), subit une partition par un clivage réversible du groupe imido pour conduire à la formation du complexe calixarène tétradentate connu W(t-Bucalix)Cl_2 (**2**) et à une élimination de HCl pour former le produit imido **4**. Faisant appel à la réaction du dichlorure **2** avec H_2NAr (Ar = C_6H_5 ou *o,m,p*-$C_6H_4CH_3$), on a préparé une série de dérivés imido isostructuraux $[W(NAr)(t\text{-BucalixH}]^+Cl^-$ (**4**–**7**) qui, en solution, adoptent une conformation en cone partiellement déformé. La réaction du W(t-Bucalix)Cl_2 avec des amines aliphatiques conduit à la formation d'un produit rouge dont la formule correspond à celle du complexe nitrido **9** qui résulte d'un clivage facile de la liaison C—N de l'imido.

Mots clés : complexe du calix[4]arène, complexe imido, complexe nitrido, clivage d'une liaison C—N, conformation, métallocalixarène.

Introduction

Interest in organotransition–imido complexes derives from their recognized ability to function as active homogeneous olefin metathesis catalysts, CVD thin-film metal nitride precursors, and as models for intermediates in catalytic oxidation–deoxygenation and hydro-denitrogenation (1–5). Imido ligands are excellent π-donors which can contribute 2–6 electrons depending on the geometry of the M—N—R bond, properties of the supporting ligands, oxidation state, and the relative energy levels of the nitrogen–metal frontier orbitals (3, 6–11). Our interest in the synthesis of nonracemic macrocyclic coordination complexes with conformationally stable cavities as host–guest models for biological systems led us to explore the possibility of employing asymmetric transition metal–imido functionalities as a route to the easy resolution of inherently chiral metallocalixarenes which are expected to have interesting supramolecular properties (12–16). In this report we describe the synthesis and spectroscopic characterization of a series of model tungsten(VI) tetradentate imido-calix[4]arene derivatives $[W(NAr)(t\text{-BucalixH})]^+Cl^-$ (Ar = C_6H_5, *o,m,p*-$C_6H_4CH_3$) (**4**–**7**) as well as an unusual, mild, reversible, imido C—N bond cleavage reaction which forms the nitrido complex $[W(N)(t\text{-BucalixH})]\cdot HCl$ (**9**).

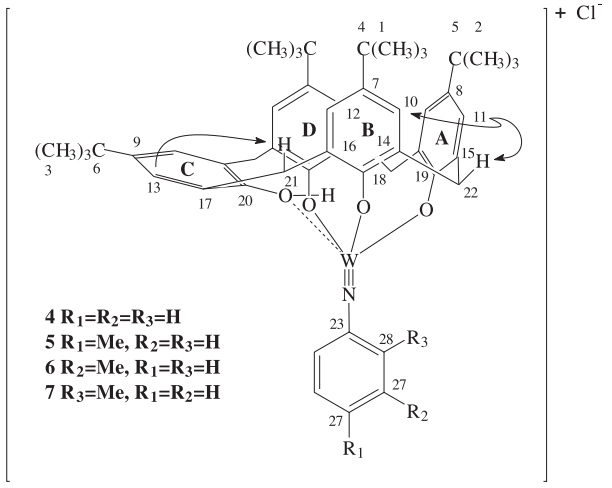
Experimental

Apparatus and procedures

Solvents were purified and dried by conventional methods and were distilled from an atmosphere of dry nitrogen. Reactions were carried out under a nitrogen atmosphere. Elemental analyses were performed by the MicroAnalytical Service Laboratory, Department of Chemistry, University

 DOI: 10.1139/cjc-79-5/6-463 © 2001 NRC Canada

of Alberta. Hexamethyldisiloxane, phenyl isocyanate and *p-tert*-butyl-calix[4]arene were purchased from Aldrich and used as received. Aniline, toluidines, and aliphatic amines were dried by refluxing over NaOH(s) and were distilled under nitrogen before use. Preparative radial, thick-layer chromatography separations were carried out unprotected from the ambient atmosphere on 2 or 4 mm silica gel (Merck TLC grade 7749) plates using a Chromatotron (Harrison Research). NMR spectra were measured on Varian INOVA 500 MHz (Palo Alto) or GE GN-300-NB instruments. NOe measurements were determined using steady-state difference (GE instrument) or selective excitation (Varian instrument) techniques. Chemical shifts are reported in ppm referenced to internal tetramethylsilane. IR spectra were measured on a Mattson Polaris instrument as Nujol mulls. $WOCl_4$, $W(NPh)Cl_4$, and W(*t*-Bucalix)Cl_2 were prepared using literature methods (7, 17, 18). Electrospray mass spectra (ESMS) were measured at DFO, St. John's, on a Micromass triple quadrupole mass spectrometer (OCP-v3.2–3-QUATT 4000) equipped with an electrospray ionization source. The temperature of the electrospray ionization source was maintained at 65°C. The capillary voltage was maintained at 3.50 kV. Cone voltage settings varied from 30 to 300 V. Samples were injected as methanol–chloroform solutions. X-ray data was collected at the University of Alberta on a Bruker P4/CCD system with graphite monochromated Mo-Kα radiation and a rotating anode generator.



Reaction of W(NPh)Cl_4 with p-tert-*butyl-calix[4]arene*

Solid $W(NPh)Cl_4$ (0.64 g, 1.54 mmol) was added to a stirred suspension of *p-tert*-butyl-calix[4]arene (1.0 g, 1.54 mmol) in toluene (20 mL)and refluxed for 12 h. The resulting black violet solution deposited black crystals of W(*t*-Bucalix)Cl_2 (**2**) at room temperature which were filtered and collected. δ_H ($CDCl_3$): 7.35 (s, 4H, calix[4]arene Ar), 7.13 (s, 4H, calix[4]arene Ar), 4.57 (d, 4H, J = 13.3, -CH_2-), 3.55 (d, 4H, -CH_2-), 1.40 (s, 18H, C(CH_3)$_3$), 1.22 (s, 18H, C(CH_3)$_3$). δ_C ($CDCl_3$): 164.4 (Ar ipso-O), 151.0 (Ar ipso-CH_2), 149.2 (Ar ipso-CH_2), 139.5 (Ar ipso-*t*-Bu), 131.9 (Ar ipso-*t*-Bu), 126.8 (Ar *C*H), 124.0 (Ar *C*H), 34.7 (*C*H_2), 34.1 (*C*H_2), 32.2 (C(*C*H_3)), 32.1 (C(*C*H_3)). Anal. calcd. for $C_{44}H_{52}O_4WCl_2$: C 58.7, H 5.7; found: C 58.7, H 5.9.

The remaining solution was reduced in volume and cooled. A purple powder precipitated which was determined by NMR analysis to be W(*t*-Bucalix)Cl_2·2($C_6H_5CH_3$). δ_H ($CDCl_3$): 7.41–7.27 (m, 18H, $C_6H_5CH_3$ + *t*-Bucalix Ar), 4.71 (d, 4H, J = 14.0 Hz, CH_2), 3.69 (d, 4H, CH_2), 2.51 (s, 6H, $C_6H_5CH_3$), 1.54 (s, 18H, C(CH_3)$_3$), 1.35 (s, 18H, C(CH_3)$_3$). δ_C ($CDCl_3$): 163.2 (Ar ipso-O), 158.2 (Ar ipso-O), 151.1 (Ar ipso-CH_2), 149.3 (Ar ipso-CH_2), 139.5 (Ar ipso-*t*-Bu), 132.0 (Ar ipso-*t*-Bu), 129.4 ($C_6H_5CH_3$), 128.5 ($C_6H_5CH_3$), 126.9 (*C*H-*t*-Bucalix), 125.2 ($C_6H_5CH_3$), 124.1 (*C*H-*t*-Bucalix), 35.1 (C(*C*H_3)$_3$), 34.8 (*C*H_2), 34.2 (C(*C*H_3)$_3$), 32.3(CH_2), 22.2 ($C_6H_5CH_3$).

Removal of solvent from the filtrate left a dark solid which was purified by preparative TLC using 4 mm silica gel plates and hexane as the initial elutant followed by increasing amounts of $CHCl_3$. An initial orange fraction was collected followed by a violet band of the dichloride, W(*t*-Bucalix)Cl_2 (**2**). Removal of solvent from the orange fraction left an orange solid, 20 mg, 1.2%, which analyzed

Fig. 1. Important nOe correlations for the imido complexes **4**–**7**.

for the imido complex [W(NPh)(*t*-BucalixH)]$^+Cl^-$ (**4**). Anal. calcd. for $C_{50}H_{58}O_4NClW$: C 62.8, H 6.1, N 1.5; found: C 62.3, H 6.3, N 1.6.

*Preparation of the aniline adduct, (**4**) ([W(NPh)(*t*-BucalixH)]$^+Cl^-$)*

Repetition of the reaction with a reflux time of 24 h resulted in a deep red – brown solution which gave orange **4** as the major product (1.1 g, 65.4%) upon removal of solvent. Although imido complexes have been reported (1) to hydrolyze readily, complex **4** appears stable to hydrolysis and can be purified by preparative TLC on silica gel plates. ESMS (-ve ion, *m*/*z* calculated for $^{180}W/^{37}Cl$ + $^{182}W/^{35}Cl$ isotopomers): *m*/*z* = 952 (M-H)$^-$, 875 (952-C_6H_5)$^{-\cdot}$, 861 (952-NC_6H_5)$^{-\cdot}$, 647 (*t*-BucalixH_4-H)$^-$. IR (Nujol) ν_{max} cm^{-1}: 1 193 (WN), 730 (aromatic C-H). δ_H ($CDCl_3$, see Fig. 1 for numbering scheme): 7.17 (d, 2H, J = 2.3 Hz, H_{10}), 7.04 (d, 2H, J = 2.1 Hz, H_{12}), 6.9 (t, 2H, J = 6.1 Hz, H_{25} + H_{27}), 6.72 (s, 2H, H_{11}), 6.73 (s, 2H, H_{13}), 6.63 (t, 1H, J = 6.2 Hz, H_{26}), 6.44 (d, 2H, J = 7.5 Hz, H_{24} + H_{28}), 5.62 (d, 2H, J = 12.2 Hz, H_{22} *syn* to W), 4.73 (d, 2H, J= 14.4 Hz, H_{21} *syn* to W), 3.43 (d, 2H, H_{22} *anti* to W), 3.35 (d, 2H, H_{21} *anti* to W), 1.21 (s, 18H, C(CH_3)$_3$), 1.07 (s, 9H, C(CH_3)$_3$), 0.88 (s, 9H, C(CH_3)$_3$). δ_C ($CDCl_3$): 167.7 (C_{23}), 161.1 (C_{20}), 154.3 (C_{18}), 150.4 (C_{19}), 146.1 (C_{17}), 145.1 (C_{16}), 133.9 (C_{14}), 133.6 (C_{15},), 129.5 (C_9), 129.0 (C_7), 128.9 (C_8), 126.7 (C_{24}), 125.7 (C_{26}), 124.4 (C_{25}), 124.0 (C_{12}), 123.7 (C_{10}), 122.6 (C_{11}), 36.4 (C_{21}), 34.3 (C_{22}), 33.8 (*C*-*t*-Bu) 31.8 (C(*C*H_3)$_3$), 31.5 ((C(*C*H_3)$_3$), 31.2 (C(*C*H_3)$_3$).

Crystallization from toluene over a period of two weeks gave **4** as red–orange plates which lost solvent readily when removed from the mother liquor and failed to diffract. Repeated attempts to generate and mount X-ray diffraction quality crystals failed.

*Reaction of W(*t*-Bucalix)Cl_2 (2) with aniline and* o-, m-, p-*toluidines*

Amine (7.5 mmol) was added via syringe to a stirred solution of W(*t*-Bucalix)Cl_2 (**2**) (2.25 g, 2.50 mmol) in 20 mL of toluene and refluxed for 24 h. The resulting deep red solution was cooled to room temperature and the precipitated [$ArNH_3$]$^+$ Cl^- (2.1–2.3 mmol) was removed by filtration.

© 2001 NRC Canada

Partial evaporation of solvent deposited a yellow solid which analyzed for W(O)(*t*-Bucalix)·H_2O (**8**). Yield: aniline 25.5%, *p*-toluidine 26.8%, *o*-toluidine 34.3%, *m*-toluidine 27.8%. IR (Nujol) ν_{max} cm^{-1} : 983 (W=O). ^1H NMR (C_6D_6) δ: 7.1 (s, 8H, calix aromatic), 4.98 (d, 4H, CH_2), 3.21 (d, 4H, CH_2), 1.22 (s, 36H, *t*-Bu). Anal. calcd. for $C_{44}H_{54}O_6W$: C 61.3, H 6.3%; found: C 61.0, H 6.0%.

The remaining solution was evaporated and the products separated by preparative TLC with hexane as the initial elutant followed by a steadily increasing $CHCl_3$ gradient. The orange imido adducts **4**–**7** were collected as the first fraction. With aniline, the product (isolated yield 35.5%) was identical to **4** obtained from the reaction of W(NPh)Cl_4 with *p-tert*-butylcalix[4]arene.

p-*Toluidine adduct (**5**) ([W(NC$_6$H$_4$CH$_3$)(*t*-BucalixH)]$^+$Cl$^-$)*: Yield 30.1%. A second, red fraction was collected in all cases. Evaporation gave [W(N)(*t*-BucalixH)]·HCl (**9**) as a red solid. ESMS (–ve ion, $^{180}W/^{37}Cl$ + $^{182}W/^{35}Cl$ isotopomers): *m*/*z* = 875 (M-H)$^-$, 647 (*t*-BucalixH_4-H)$^-$. ^1H NMR ($CDCl_3$, 60°C) δ (ppm): 7.27 (m, aromatic), 7.18 (m, aromatic), 7.12 (s, aromatic), 7.08 (s, aromatic), 7.05 (d, aromatic), 6.99 (d, aromatic), 6.93 (m, aromatic), 6.85 (m, aromatic), 6.38 (d, CH_2), 5.03 (d, CH_2), 4.42 (d, CH_2), 4.27 (d, CH_2), 3.93 (d, CH_2), 3.51 (d, CH_2), 3.44 (d, CH_2), 3.29 (d, CH_2), 3.27 (d, CH_2), 1.39 (s, *t*-Bu), 1.21 (s, *t*-Bu), 1.20 (s, *t*-Bu), 1.11 (s, *t*-Bu). ^{13}C NMR ($CDCl_3$) δ (ppm): 162.4, 161.8, 158.4, 156.3, 149.1, 147.1, 146.7, 146.3, 142.7, 135.7, 135.1, 134.8, 131.2 (CH), 130.6 (CH), 128.2 (CH), 127.4 (CH), 126.8 (CH), 16.5 (CH), 125.4 (CH), 125.1 (CH), 124.1 (CH), 123.9 (CH), 36.1 (*C*Me$_3$), 35.3 (CH_2), 35.1 (CH_2), 34.7 (CMe_3), 34.26 (CH_2), 34.1 (CH_2), 33.4 (CMe_3), 32.2 (Me), 32.0 (Me), 31.7 (Me). Anal. calcd. for $C_{44}H_{54}O_4NWCl$: C 60.0, H 6.2, N 1.6; found: C 60.5, H 6.1, N 1.5.

*Reaction of diisopropylamine, diethylamine, benzylamine, and (S)-(–)-α-methylbenzylamine with W(*t*-Bucalix)Cl$_2$ (**2**)*

The procedure was identical to that used for the aromatic amines. Amine (3 mmol) was added via syringe to a stirred solution of the dichloride **2** (1 mmol) under N_2 in 15 mL of toluene. After 24 h reflux, the cooled solution deposited crystals of the oxo compound (**8**), which were removed by filtration (yields: diisopropyl amine 35.5%, diethylamine 32.4%, benzylamine 38.6%, methylbenzylamine 45.3%). The filtrate showed a single spot on TLC (silica gel, hexane:$CHCl_3$, 10:1). Removal of solvent gave a red solid which was identical by NMR with complex **9** obtained as a trace product from the reaction with anilines. No imido-calixarene derivatives were isolated.

*Reaction of imido adduct **4** ([W(NPh)(*t*-BucalixH)]$^+$Cl$^-$) with AgPF$_6$*

0.1 mmol of the imido adduct **4** was dissolved in $CDCl_3$ (1 mL) in an NMR tube. $AgPF_6$ (0.1mmol) was then added as a solid. After initial dissolution, precipitation of a white solid took place. The ^1H NMR spectrum of the solution was identical with that of the starting [W(NPh)(*t*-BucalixH)]Cl complex (**4**).

*Reaction of imido adducts **4**–**7** ([W(NAr)(*t*-BucalixH)]$^+$Cl$^-$) with ClSiMe$_3$ and CH$_3$COCl*

1.0 mmol of the imido adduct and 1.1 mmol of $ClSiMe_3$ or CH_3COCl were refluxed in 20 mL of toluene. The orange solution turned violet after 3 h. After 24 h, the solvent was

© 2001 NRC Canada

removed to leave a black solid which was identified as W(*t*-Bucalix)Cl_2 (**2**) by NMR.

*Attempted reaction of imido adducts **4** ([W(NPh)(*t*-BucalixH)]$^+Cl^-$) with HCl*

Imido complex **4** (1 mmol) was dissolved in 20 mL of toluene and stirred under N_2. HCl(g) (3 mmol) was added via syringe and the mixture refluxed for 12 h. No reaction occurred, even upon addition of a total of 10 equiv of HCl(g).

*Crystal structure determination of **8** (W(O)(t-Bucalix)·H_2O)*

A pale yellow plate crystal of **8** having approximate dimensions of 0.36 × 0.03 × 0.37 mm was selected and mounted on a glass fibre. All measurements were made on a Bruker P4/CCD system with graphite monochromated Mo-Kα radiation and a rotating anode generator. The data were collected at a temperature of –80 ± 1°C. The full hemisphere of data was collected with 30 s, 0.3 deg. frames to a maximum 2θ value of 51.55°.

Of the 19 634 reflections which were collected, 2 382 were unique, R_{int} = 0.048). The linear absorption coefficient, μ, for Mo-Kα radiation is 28.1 cm^{-1}. The Siemens area detector absorption routine (SADABS) was used to correct the data with max and min effective transmissions of 0.942192 and 0.706867, respectively. The data were corrected for Lorentz and polarization effects. A correction for secondary extinction was applied (coefficient = 8.90850e-008).

Collection, solution, and refinement all proceeded normally. Hydrogens were introduced in calculated or difference map positions with isotropic thermal parameters set 20% greater than those of their bonding partners at the time of their inclusion. They were not refined. All non-hydrogen atoms were refined anisotropically with the exception of a second, disordered water molecule located near the upper rim of the calixarene. The structure was solved by direct methods (19, 20) and expanded using Fourier techniques (21). The final cycle of full-matrix least-squares refinement (least-squares function minimized: $\Sigma w(|F_o| - |F_c|)^2$ where $w = 1/[\sigma^2(F_o)] = [\sigma^2_c(F_o) + p^2F_o^2/4]^{-1}$; $\sigma_c(F_o)$ = esd based on counting statistics; p = p-factor) on F was based on 1329 observed reflections ($I > 2.00\sigma(I)$) and 123 variable parameters and converged (largest parameter shift was 0.00 times its esd) with unweighted and weighted agreement factors of: $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.045$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2]^{1/2} = 0.061$.

The standard deviation of an observation of unit weight $([\Sigma w(|F_o| - |F_c|)^2/(N_o - N_V)]^{1/2}$ where N_o = number of observations and N_V = number of variables) was 2.63. The weighting scheme was based on counting statistics. Plots of $\Sigma w(|F_o| - |F_c|)^2$ vs. $|F_o|$, reflection order in data collection, sin θ/λ and various classes of indices showed no unusual trends. The max and min peaks on the final difference Fourier map corresponded to 1.21 and –0.77 $e^-/Å^3$, respectively.

Neutral atom scattering factors were taken from Cromer and Waber (22). Anomalous dispersion effects were included in Fcalc (23); the values for Df′ and Df″ were those of Creagh and McAuley (24). The values for the mass attenuation coefficients are those of Creagh and Hubbell (25). All calculations were performed using the teXsan (26) crystallographic software package of Molecular Structure Corporation. The crystallographic data are summarized in Table 1.

Results

Synthesis and characterization

Our investigations began by studying model reactions of tungsten tetrachloro-aryl imido derivatives with *p-tert*-butylcalix[4]arene with the expected, direct formation of the tetradentate-calix[4]arene imido tungsten product (**1**) (Scheme 1). Instead, refluxing an equimolar suspension of W(NPh)Cl_4 and *p-tert*-butyl-calix[4]arene for 12 h in toluene afforded a black–violet solution which deposited black crystals, identified as the known (18) dichlorocalix[4]arene complex W(*t*-Bucalix)Cl_2 (**2**) on cooling. Continued reflux for an additional 12 h resulted in a deep red – brown solution which yielded an orange solid on removal of solvent. Complex **2** was shown to be an intermediate in the formation of the orange thermodynamic product which was spectroscopically characterized as the imido calix[4]arene complex [W(NPh)(*t*-BucalixH)]$^+Cl^-$ (**4**) (cf. discussion below).

Complex **4** along with a series of isostructural imido complexes, **5**–**7**, were rationally synthesized (1) by reaction of aniline or *o*-, *m*-, or *p*-toluidine with the dichlorocalix[4]arene complex **2** in refluxing toluene. The insoluble, yellow oxo complex W(O)(*t*-Bucalix)·H_2O (**8**) which was spectroscopically and structurally characterized, precipitated directly from the reaction mixture as a major by-product in all cases. Complex **8**, which has been previously prepared from the reaction of $WOCl_4$ and *p-tert*-butylcalix[4]arene (18), presumably results from hydrolysis of **2**. Chromatographic work-up of the toluene soluble fraction afforded the orange imido complexes **4**–**7** in reasonable yield. A second red, slower moving band which afforded trace quantities of a red solid, formulated as the nitrido species W(N)(*t*-BucalixH)·HCl (**9**) was also isolated in each case.

Reaction of the dichlorocalixarene complex **2** with aliphatic amines gave a very different result. Refluxing **2** with diisopropylamine, diethylamine, or (*S*)-(–)-α-methylbenzylamine gave the oxo complex **8**, and the nitrido species **9** as major products. No imido products were detected.

The toluene soluble, orange thermodynamic product isolated from the reaction of W(NPh)Cl_4 and *p-tert*-butyl-calix[4]arene or from the reaction of W(*t*-Bucalix)Cl_2 (**2**) with aniline was characterized by analysis and spectroscopic data as the cationic calix[4]arene phenol–phenolate imido complex [W(NPh)(*t*-BucalixH)]$^+Cl^-$ (**4**) (cf. experimental). An alternate, neutral structure [W(NPh)(*t*-Bucalix)]·HCl (**4′**) in which the HCl is present as an inclusion compound could not be ruled out. Negative ion ESMS showed a mass envelope corresponding to $[M-H]^-$ at m/z = 952 (calculated for $^{180}W/^{37}Cl + ^{182}W/^{35}Cl$ isotopomers) as well as major fragments at 875 $(952\text{-}C_6H_5)^-$, 861 $(952\text{-}NC_6H_5)^-$ and 647 (*t*-BucalixH_4-H)$^-$. Formulation as **4** or **4′** is supported by its +ve ion ESMS which gave a peak at m/z = 919 assigned to [M + H]-Cl^+ which was not present in the –ve ion ESMS data. Similarly, the negative ion ESMS spectra of the toluidine analogs **5**–**7** all showed characteristic fragments at m/z = 966 $(M-H)^-$, 875 $(966\text{-}C_6H_4CH_3)^-$, 861 $(M\text{-}NC_6H_4CH_3)^-$ and 647 (*t*-BucalixH_4-H)$^-$. Facile aryl cleavage (5) in the ESMS of the imido series gives a base peak at m/z = 875 assigned to the nitrido species.

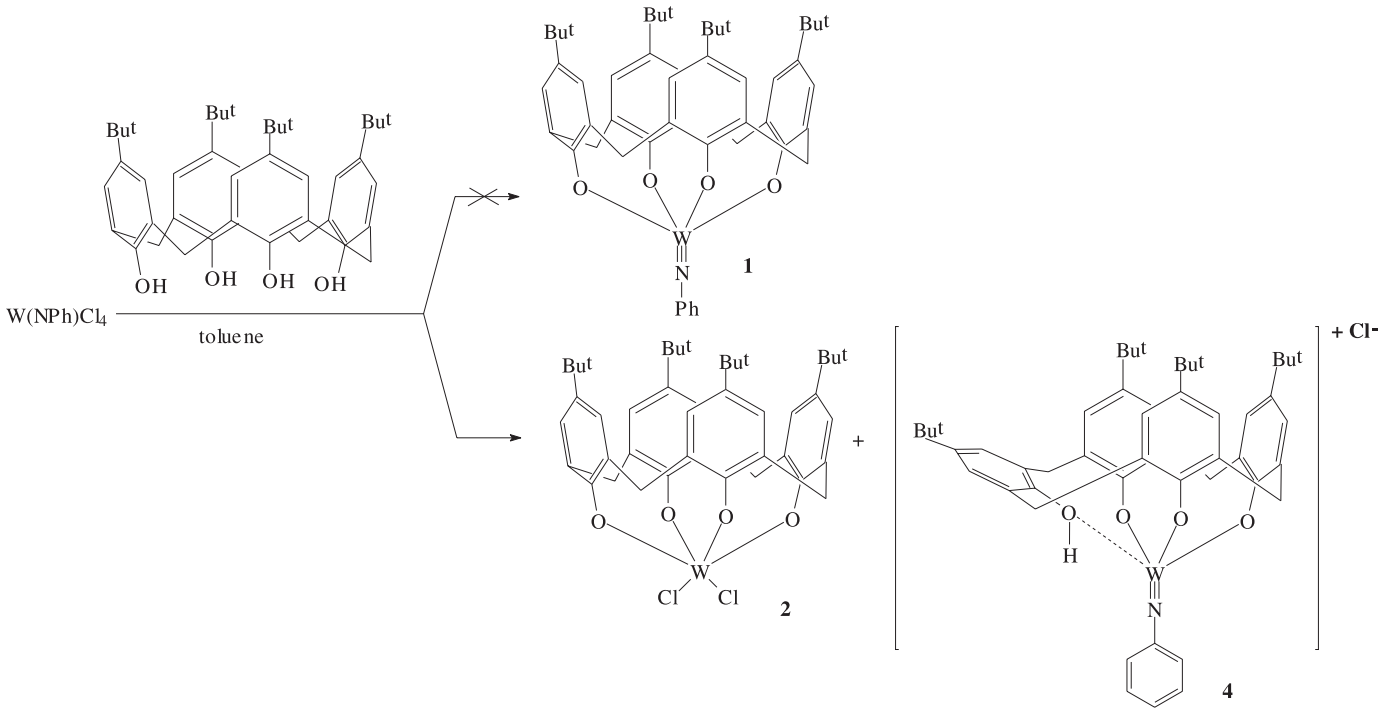
Proton NMR spectra of **4**–**4′** in $CDCl_3$ showed two characteristic pairs of calix[4]arene -CH_2-AB doublets and three *t*-Bu singlets which integrated in a 2:1:1 ratio. Very similar spectra were reported for tetradentate niobium (27) and tantalum (28) calix(4)arene complexes. The calixarene portion of the NMR spectra of the toluidine imido complexes **5**–**7** were nearly identical (cf. Experimental) and we therefore propose that they are isostructural with **4**–**4′**.

Two imido structures, which are difficult to distinguish on the basis of spectroscopic information, are reasonable for isostructural series **4**–**7**. We were, however, unable to distinguish between formulation as cationic phenol–phenolates, [W(NAr)(*t*-BucalixH)]$^+$Cl$^-$, or neutral hydrochlorides, [W(NAr)(*t*-Bucalix)]·HCl. For consistency in mechanistic arguments, we have selected the former (cf. Scheme 1).



Attempts to confirm the cationic structure on the basis of reactivity failed. For example, a similar phenol–phenolate tetra coordinate calix[4]arene complex had been successfully derivatized by Floriani and co-workers (27), hence we treated **4** with excess acetyl chloride or trichloromethylsilane but isolated only W(*t*-Bucalix)Cl_2 (**2**). The chloride in **4**–**7** was easily precipitated by reaction with $AgPF_6$ to give a soluble fraction which showed a ^{1}H NMR spectrum unchanged from the starting material. Although this result is more consistent with an ionic rather than a covalent (eg. W-Cl) and hence supports a tetra-coordinated calix[4]arene, it does not conclusively distinguish between the two structures (**4**, **4′**) in question.

Conformational analysis of 4–7 ([W(NAr)(*t*-BucalixH)]$^+$Cl$^-$)

Variable temperature ^{1}H NMR experiments on the imido complex **4** in toluene-d_8 and benzene-d_6 showed no substantive changes in the range –10 to 80°C and were therefore

Scheme 1.

congruent with the presence of a single, stable conformation. A cone, flattened cone, or partial cone conformation of **4** could conceivably give the ^{1}H spectrum observed (29–33) but ^{1}H nOe experiments and ^{13}C methylene shift arguments are more in accord with a partially flattened cone conformation.

In an nOe experiment, partial selective saturation of the singlet assigned to the two equivalent *t*-Bu groups at 1.21 ppm, $H_1/H_{1'}$, resulted in a positive enhancement of the signals assigned to the *ortho* aromatic doublets at 7.17 and 7.04 ppm on rings **B** and **D** respectively (cf. Fig. 4). Therefore, the remaining two closely spaced singlets at ca 6.7 ppm must be $H_{11}/H_{11'}$ and $H_{13}/H_{13'}$ on rings **A** and **C** respectively. Subsequent nOe experiments identified the remaining *t*-Bu groups. The fact that the *ortho* protons of rings **B** and **D** are nonequivalent requires that each side of the rings be in a distinctly different chemical environment, a result not consistent with a cone conformation but which does support a partial cone or partially flattened cone conformation.

Selective partial saturation of the ortho resonance at 7.17 ppm resulted in a positive enhancement of the 3.35 ppm doublet (-CH_2- *exo* to W) as well as the 6.73 ppm signal (ring $\mathbf{A}_{ortho}$). A parallel experiment on the ortho resonance at 7.04 ppm resulted in a positive enhancement of the 3.43 ppm doublet (-CH_2- exo to W) but had no effect on the aryl region. Clearly, the aromatic protons on ring **C** (cf. Fig. 4) are not proximal to the aromatic protons on rings **B** and **D**, a result which supports a flattened cone conformation. Ring **C** cannot be orthogonal to the axis of the cone as in a partial cone conformation since, if this were the case, both *anti* and *syn* methylene protons $H_{21}/H_{21'}$ would be expected to experience a +ve nOe enhancement on irradiation of the aromatic protons in ring **C**.

The empirical Mendoza and co-workers (34) formalism for determining calixarene conformations suggests that the methylene carbons bridging *syn*-oriented calixarene rings have a ^{13}C shift of 31–34 ppm and a shift closer to 37 ppm when the rings are *anti*. Applied to complex **4**, the observed chemical shifts of C_{21} (36 ppm) and C_{22} (34 ppm) suggest that rings **C**/**D**/**B** are not *syn*. These predictions must be viewed with caution, especially in the case of the metallo-calixarenes in this study. Nevertheless, both the partial cone and partially flattened cone conformations are consistent with ^{13}C chemical shift data.

Characterization of 9 ([W(N)(*t*-BucalixH)]·HCl)

Attempts to obtain a X-ray quality single crystal of the red complex isolated as the major toluene soluble product from the reaction of **2** with 1° or 2° aliphatic amines failed. It is formulated as the phenol–phenolate nitrido complex **9** (cf. Scheme 2) on the basis of analytical, NMR, and ESMS data. The latter shows a $(M-H)^-$ molecular ion at m/z = 875 ($^{180}W/^{37}Cl$ + $^{182}W/^{35}Cl$ isotopomers). An alternate, parent imido structure, W(NH)(*t*-Bucalix)·HCl, seems less likely since we were unable to detect a ^{1}H NMR signal assignable to the imido hydrogen.

The ^{1}H NMR spectrum of **9** in $CDCl_3$ is complex and our assignments are based on the assumption that several distinct conformations are present. A total of 10 calixarene -CH_2- doublets corresponding to three conformations **a**, **b**, **c** (cf. Fig. 2) were observed. The presence of three calixarene conformers is supported by variable temperature ^{1}H NMR experiments which showed a small but measurable dependence of the integrated ratio of the sets of resonances assigned to the conformers and by a 2-D COSY experiment which was consistent with three distinct, mutually coupled spin systems. A cone conformation was assigned to the two AB doublets at 5.03 and 3.44 ppm. Two sets of four doublets at 6.38, 3.93, 3.51, 3.27 ppm and at 4.42, 4.27, 3.29, and

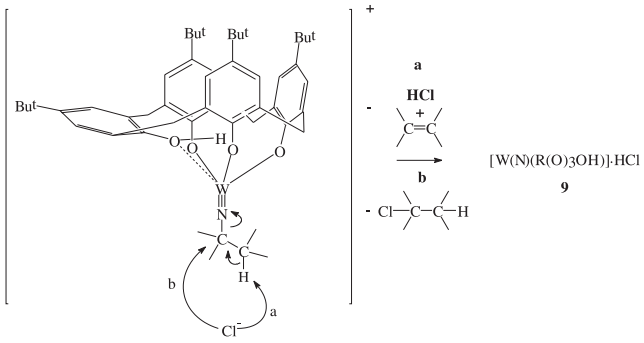
Scheme 2.



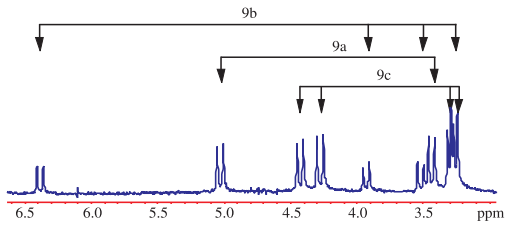


Fig. 2. Partial 300 MHz NMR spectrum (-CH_2- region) of **9** in $CDCl_3$ at 60°C showing three conformers.

3.27 ppm correspond to two partial cone or partially flattened cone conformations.

Solid state structure of 8 (W(O)(*t*-Bucalix)·H_2O)

The solid state structure of complex **8** was determined from a single crystal X-ray study. Tables 1, 2, and 3 list crystallographic data, positional parameters, and selected bond distances and angles for **8**. As Fig. 3 shows, the coordination sphere of the tungsten atom in the oxo-complex **8** establishes a distorted MO_6 octahedral coordination geometry. The O_2-W-O_1 angles of 99.7° allow the tungsten atom to ride slightly above the calixarene O_4 plane. The loosely coordinated clathrate water shows a long W—O(3) bond length of 2.37(1) Å compared to the 1.910(6) Å value for the four calixarene oxygen atoms. Atypically for tetradentate complexes of calixarenes in the cone conformation (2, 18), **8** retains C_{4v} symmetry. Accordingly, unlike the elliptically distorted parent W(O)(calix[4]arene) complex (18) which shows *para* carbon atom distances for opposing phenyl rings of 9.04 Å/7.88 Å, the calixarene cavity of **8** is spherical with a corresponding distance of 8.60 Å and identical O1-C1-C6-C7 dihedral angles of 4.4°.

Discussion

Mechanistic considerations

Figure 4 shows the % mol fraction vs. reaction time for the ^{1}H NMR observed species formed from the reaction of $W(NPh)Cl_4$ with *p-tert*-butylcalix(4)arene in toluene-d_8 at 80°C. The dichloride species W(*t*-Bucalix)Cl_2 (**2**), rapidly forms initially and, subsequent to an induction period, remains essentially constant as the thermodynamic imido product [W(NPh)(*t*-BucalixH)]$^+$Cl$^-$ (**4**) begins to accumulate. Clearly, the formation of **2** from the starting complex $W(NPh)Cl_4$ requires an imido W—N cleavage. There is precedent for imido cleavage in a related reaction of $Mo(NAr)_2(OR)_2$ with *t*-BucalixH_4 (35). We propose a similar mechanism which involves initial replacement of two equiv of chloride to form a putative, bidentate, calix[4]arene imido intermediate W(NPh)(*t*-BucalixH_2)Cl_2 (**3**) which subsequently partitions by reversible imido cleavage to give **2** and loss of a third equiv of chloride as HCl to give **4** as depicted in Scheme 3. The conversion of **3** → **4** is essentially irreversible since **2** is not present at the end of the reaction and attempts to react **4** with HCl failed.

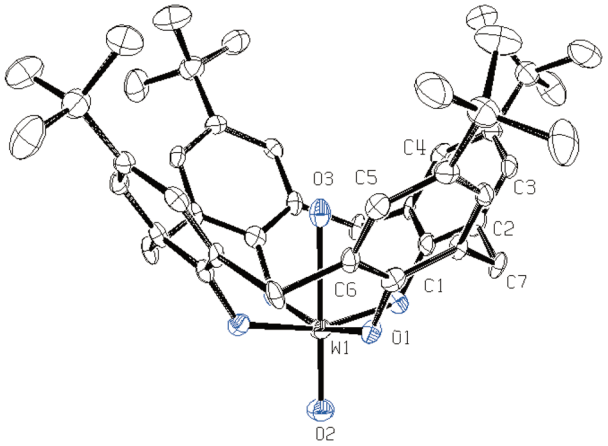
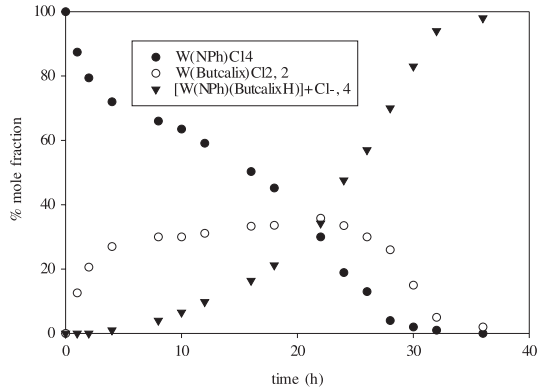
Fig. 3. ORTEP representation of the solid-state structure of W(O)(*t*-Bucalix)·H_2O (**8**).





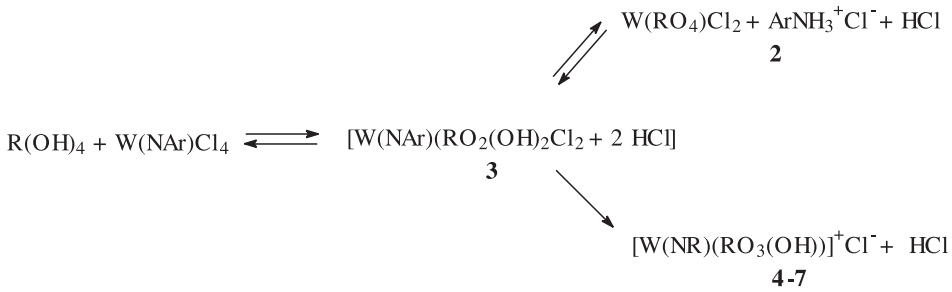


Fig. 4. Mol fraction $W(NPh)Cl_4$, **2** and **4** vs. time at 80°C in toluene-d_8.

Scheme 3.

Early transition metal – imido ligands are typically nucleophilic and are readily cleaved by HCl to produce the corresponding metal dichloride and the ammonium salt (3, 10, 36). It can be argued that the imido link in the tungsten complex, **3**, would be particularly susceptible to protonation since coordination of two π-donor oxygen atoms increase electron density on the imido nitrogen atom. Although we are unable to provide direct structural evidence establishing the geometry of the imido link in these complexes, imido reactivity would be enhanced by bending the imido bond (9, 10, 37) which forces the lone pair to reside on nitrogen, thereby making it more nucleophilic. Further, calculations by Nugent et al. (8) support enhanced imido nucleophilicity for early 5*d* metals since the LUMO is essentially localized on the nitrogen *p* orbital.

Figure 4 and the mechanism shown in Scheme 3 require a reversible W—N imido cleavage. Such reactions are well-known and indeed imido formation by reaction of metal chlorides with amines (1, 3, 38) represents a general synthetic route. Excess base is often required to remove the HCl produced. Consistent with this requirement, reaction of the calixarene dichloride complex W(*t*-Bucalix)Cl_2 (**2**) with 2 equiv of aniline, gave the partial cone adduct **4** in 35% yield, presumably via facile, sequential amine and amido deprotonation (3). The conformational properties of the putative bidentate calixarene intermediate W(NPh)(*t*-BucalixH_2)Cl_2 (**3**) are unknown. However, significant ligand preorganization may present the metal—imido bond in such a way that reversible cleavage is facilitated. Similar results were obtained for reactions with *o*-, *m*-, and *p*-toluidines.

In contrast, **4** survives extended reflux in toluene or reaction with HCl and therefore appears to be the thermodynamic product under the reaction conditions investigated. The fact that the imido complexes **4**–**7** carry a formal positive charge may account for the observed resistance toward protonation and the failure to form derivatives with $ClSiMe_3$ or MeCOCl (cf. experimental).

Formation of the proposed nitrido-derivative W(N)(*t*-BucalixH) (**9**) as a major toluene soluble product from the reaction of W(*Bu*^{t}calix)Cl_2 (**2**) with aliphatic 1° and 2° amines but not from aniline or toluidines requires explanation. Literature precedent for related C—N bond cleavage reactions, which form the basis for use of imido complexes as CVD sources of metal nitrides (39), derives from a thermal, Hoffman-like β-elimination (40, 41) observed for the conversion of the amido $Ta(NEt_2)_5$ to the imido–amido product (EtN) = $Ta(NEt_2)_3$ and ethylene. The proposed mechanism for the aliphatic analogs of **4**–**7** is illustrated in Scheme 3. Further examples involving an alternative S_N, N—C cleavage of $Os(O)_3$(N*t*-Bu) can be found in Nugent and Mayer's (42) anthology on metal—ligand multiple bonds. Alternatively, the C—N bond cleavage may be viewed as the reverse of nitrido alkylation (1) in which S_N2 nucleophilic attack (42) (cf. Scheme 3) of chloride at C_α results in formation of alkyl halide and **9**. The observation that benzylamine also provides **9** in good yield suggests that the S_N2 mechanism may in fact be more likely in the present case.

Clearly, either mechanism is impossible for the aniline-and toluidine-derived imido complexes **4**–**7** hence **9** is only observed in trace amounts.

© 2001 NRC Canada

Conclusion

A tetradentate tungsten(VI) imido calix[4]arene complex $[W(NPh)(t\text{-BucalixH})]^+Cl^-$ (**4**) has been isolated from the reaction of $W(NPh)Cl_4$ with *p-tert*-butyl-calix[4]arene (t-BucalixH_4) as the thermodynamic product in a series of reactions involving formation of a putative bidentate calix[4]arene tungsten-imido intermediate $W(NPh)(t\text{-Bu calix}H_2)Cl_2$ (**3**) which partitions by reversible cleavage of the W-imido link to form $W(t\text{-Bucalix})Cl_2$ and HCl, and elimination of a further equiv of HCl to form the isolated imido product **4**. Imido complex **4** and an isostructural series of cationic tetradentate tungsten-imido species of the type $[W(NAr)(t\text{-BucalixH})]^+Cl^-$ (**5**–**7**) with a partially flattened cone conformation have been rationally synthesized from the reaction of $W(t\text{-Bucalix})Cl_2$ (**2**) and NH_2Ar. The imido substituent determines the stability of the imido adduct and reaction of **2** with aliphatic 1° and 2° amines results in an unstable imido complex which cleaves the C—N bond to form the nitrido adduct **9**.

On the reduction of rhodium trichloride in the presence of triisopropylphosphine

David C.D. Butler, Duncan W. Bruce, Philip Lightfoot, and David J. Cole-Hamilton

Abstract: The reduction of $RhCl_3 \cdot 3H_2O$ by sodium amalgam in the presence of P-*i*-Pr_3 has been reexamined. Reaction of $RhCl_3 \cdot 3H_2O$ with P-*i*-Pr_3 in THF gives *i*-Pr_3PO and $[RhHCl_2(P\text{-}i\text{-}Pr_3)_2]$ or $[RhDCl_2(P\text{-}i\text{-}Pr_3)_2]$ if D_2O is added. Further reaction of $[RhHCl_2(P\text{-}i\text{-}Pr_3)_2]$ with P-*i*-Pr_3 gives $[i\text{-}Pr_3PH][RhHCl_3(P\text{-}i\text{-}Pr_3)_2]$, which reversibly dissociates to $[RhHCl_2(P\text{-}i\text{-}Pr_3)_2]$ and $[i\text{-}Pr_3PH]Cl$ at high temperatures in solution. Sodium amalgam reduction of $[RhHCl_2(P\text{-}i\text{-}Pr_3)_2]$ in THF containing P-*i*-Pr_3 gives $[RhH(P\text{-}i\text{-}Pr_3)_3]$ if water is rigorously excluded, but $[RhH_2Cl(P\text{-}i\text{-}Pr_3)_2]$ if water is present.

Key words: rhodium, trisiopropylphosphine, hydride, reduction.

Résumé : On a réétudié la réduction du $RhCl_3 \cdot 3H_2O$ par l'amalgame de sodium en présence de P-*i*-Pr_3 . La réaction du $RhCl_3 \cdot 3H_2O$ avec le P-*i*-Pr_3 dans le THF conduit à la formation de $[RhHCl_2(P\text{-}i\text{-}Pr_3)_2]$ ou au $[RhDCl_2(P\text{-}i\text{-}Pr_3)_2]$ si on ajoute du D_2O. Une réaction subséquente de $[RhHCl_2(P\text{-}i\text{-}Pr_3)_2]$ avec un excès de P-*i*-Pr_3 conduit à la formation de $[i\text{-}Pr_3PH][RhHCl_3(P\text{-}i\text{-}Pr_3)_2]$ qui, en solution à haute température, se dissocie de façon réversible en $[RhHCl_2(P\text{-}i\text{-}Pr_3)_2]$ et $[i\text{-}Pr_3PH]Cl$. La réduction du $[RhHCl_2(P\text{-}i\text{-}Pr_3)_2]$ par l'amalgame de sodium dans du THF qui contient du P-*i*-Pr_3 conduit à la formation de $[RhHCl(P\text{-}i\text{-}Pr_3)_3]$ si le milieu est strictement anhydre; toutefois, si le solvant contient de l'eau, il y a formation de $[RhH_2Cl(P\text{-}i\text{-}Pr_3)_2]$.

Mots clés : rhodium, trisisopropylphosphine, hydrure, réduction.

[Traduit par la Rédaction]

Introduction

$[RhH(P\text{-}i\text{-}Pr_3)_3]$ has been shown to be an active catalyst for the water gas shift reaction (WGSR) (1, 2) and for the photochemical dehydrogenation of alcohols (3, 4). It also reacts oxidatively with water (5), and ketones (6). It has generally been prepared from the reaction of $RhCl_3 \cdot 3H_2O$ with P-*i*-Pr_3 under nitrogen, followed by evaporation to dryness and reduction with sodium amalgam in dry THF (7). The source of the hydride was believed to be the THF. During the course of studies of a variety of catalytic reactions using low-valent rhodium trialkylphosphine complexes (3, 4, 8), we have reexamined this reaction, as well as a number of similar reactions carried out under related conditions. We now report the results of these studies. An alternative synthesis of $[RhH(P\text{-}i\text{-}Pr_3)_3]$ by reaction of $[RhH_2Cl(P\text{-}i\text{-}Pr_3)_2]$ with KO-*t*-Bu has been reported (9).

Experimental

Microanalyses were done by the Universities of Liverpool's and St. Andrews' Microanalytical Services. NMR spectra were recorded on a Varian Gemini 2000 or a Brüker Associates AM 300 spectrometer operating in the Fourier transform mode with, for ^{31}P, broadband proton decoupling, and FT IR spectra were recorded as Nujol™ mulls between CsI plates on Nicolet Protégé 460 Magna or PerkinElmer PE 1710 spectrometers.

All manipulations were carried out using standard Schlenk line catheter tubing techniques under nitrogen purified by passing through a glass column containing Cr(II) absorbed onto silica. Petroleum ether (boiling range 40–60°C), diethylether, and THF were distilled over sodium diphenylketyl and degassed before use. Dichloromethane was dried by refluxing over CaH_2.

$RhCl_3 \cdot 3H_2O$ (Johnson Matthey, Royston, England), and other commercial chemicals were used as received. P-*i*-Pr_3 was either purchased from Strem, Royston, England or prepared by a standard method (10).

Dichlorohydridobis(triisopropylphosphine)rhodium(I)

$RhCl_3 \cdot 3H_2O$ (0.49 g, 1.86 mmol) was refluxed in THF (35 cm^3) with P-*i*-Pr_3 (0.8 cm^3, 4 mmol) for 3 h. On cooling, the orange solution was filtered, reduced in vacuo and cooled to –30°C for 72 h. The resulting orange crystals were recovered by filtration and washed with light petroleum (2 × 10 cm^3) to remove any free P-*i*-Pr_3. Recrystallization was from CH_2Cl_2–light petroleum. Yields of this reaction are very variable (20–50%). Anal. calcd. for $C_{18}H_{43}Cl_2P_2Rh$ (%): C 43.7, H 8.7, P 12.5, Cl 14.3; found: C 43.6, H 8.7,

 DOI: 10.1139/cjc-79-5/6-472 © 2001 NRC Canada

P 12.5, Cl 14.8. It was identified by comparison with a sample prepared by lit. method (11).

An increased yield could be obtained as follows: $RhCl_3 \cdot 3H_2O$ (1.04 g, 4.97 mmol) was dissolved in THF (50 cm^3). Water (10 cm^3), P-*i*-Pr_3 (2.5 cm^3, 12.5 mmol), and HCl (4 drops, concd) were added and the mixture was refluxed with stirring for 18 h under argon. The resulting red solution was dried in vacuo at 45°C to remove residual water, then washed with diethyl ether (2 x 15 cm^3) and water (2 × 5 cm^3) before drying thoroughly. Yield: 2.4 g, 99%. The spectroscopic data from samples prepared in this way were identical to those from samples prepared as above, but the microanalytical data suggests some contamination with HCl. Anal. calcd. for $C_{18}H_{43}Cl_2P_2Rh$ (%): C 43.7, H 8.7; found: C 41.5, H 8.5. Anal. cald. for $C_{18}H_{44}Cl_3P_2Rh$ (%): C 40.6, H 8.2.

Dichlorodeuteridobis(triisopropylphosphine)rhodium(I)

Prepared as above but using $RhCl_3 \cdot 3H_2O$ (0.49 g, 1.86 mmol), P-*i*-Pr_3 (1.2 cm^3, 6 mmol), and D_2O (5 cm^3) containing DCl (1 cm^3, 20% in D_2O) in THF (35 cm^3). The final product was not washed with H_2O. FT IR λ_{max} (cm^{-1}): 1380 (RhD). ^{2}D NMR (46.076 MHz, CH_2Cl_2) δ: –30.1 (RhD).

Triisopropylphosphonium trichlorohydridobis(triisopropylphosphine)rhodium(I) tetrahydro-uran

$[RhHCl_2(P\text{-}i\text{-}Pr_3)_2]$ (0.14 g, 0.28 mmol) prepared by the higher yield method described above, and therefore containing HCl, was refluxed for 3 h in THF (4 cm^3) containing P-*i*-Pr_3 (0.3 cm^3, 1.5 mmol). On cooling slowly, orange crystals separated. These were stored under the mother liquors to prevent decomposition and collected by filtration to obtain the NMR spectra. The instability of this complex and the requirement to store it under the mother liquors means that the yield has not been measured. FT IR λ_{max} (cm^{-1}): 1943 (RhH). ^{1}H NMR (300.13 MHz, CD_2Cl_2) δ: (298 K): –30.3 (br s, RhH), 8.1 (d, $J_{P,H}$ = 492 Hz, PH); (193 K) δ: –21.0 (br s, RhH), 8.1 (d, $J_{P,H}$ = 492 Hz, PH); (308 K): –30.3 (dt, $J_{Rh,H}$ = 12.8, $J_{P,H}$ = 31.3 Hz, RhH), 8.1 (d, $J_{P,H}$ = 492 Hz, PH). ^{31}P NMR (121.497 MHz, CD_2Cl_2) δ: (298 K): 43.5 (br d, $J_{Rh,P}$ = 96 Hz, RhP), 32.7 (s, HP); (183 K): 29.2 (d, $J_{Rh,P}$ = 97 Hz, RhP), 32.2 (s, HP); (308 K): 44.5 (br d, $J_{Rh,P}$ = 97 Hz, RhP), 32.8 (s, HP). Microanalytical data were variable, but an example is: anal. calcd. for $C_{31}H_{68}Cl_3OP_3Rh$ (%): C 50.0, H 9.1; found: C 47.4, H 9.5.

Reduction of $[RhHCl_2(P\text{-}i\text{-}Pr_3)_2]$ in dry THF

A suspension of $[RhHCl_2(P\text{-}i\text{-}Pr_3)_2]$ (0.5 g, 1.01 mmol), prepared by lit. method (11), in THF containing P-*i*-Pr_3 (1.5 cm^3, 7.5 mmol) was stirred with Na–Hg (140 g, 0.7%) for 18 h. The resulting solution was decanted from the amalgam, which was washed with THF (5 cm^3), and the washing combined with the original solution. The solvent was removed in vacuo and the resulting yellow-brown tar was extracted with light petroleum (3 × 5 cm^3) to give a yellow solution, which was filtered through Celite. The volume was reduced to 3 cm^3 and P-*i*-Pr_3 (15 drops) added, prior to cooling to –30°C for 24 h. The yellow crystals that formed were collected by filtration and washed with cold light petroleum. The crystals were unstable to air and slowly melted in the solid state even under argon when stored at 4°C. Solutions in light petroleum were more stable.

The spectroscopic properties of the product from this reaction were identical to those of a batch obtained by the reaction of $[RhH_2Cl(P\text{-}i\text{-}Pr_3)_2]$ with KO-*t*-Bu (9), but differed from the literature values. FT IR λ_{max} (cm^{-1}): 1960 (RhH) (lit. 7 value 1975). ^{1}H NMR (300.13 MHz, CD_2Cl_2) δ: (298 K): –11.6 (dd on a br hump, RhH) (lit. 7 value –10.5, complex multiplet); (213 K): –11.2 (second order pattern, resembles dddd, RhH). ^{31}P NMR (121.497 MHz, CD_2Cl_2) δ: (298 K): 53.6 (d, $J_{Rh,P}$ = 157 Hz) (lit. 5 value 58.8 (d, $J_{Rh,P}$ = 157 Hz)) (lit. 12 value 32.2 (d, $J_{Rh,P}$ = 157 Hz)). The properties of the compound including the exchange of Rh-H for D in C_6D_6 or in $C_6D_4CD_3$ (5), make us confident that the product is $[RhH(P\text{-}i\text{-}Pr_3)_3]$.

Chlorodihydridobis(triisopropylphosphine)rhodium(I)

A suspension of $[RhHCl_2(P\text{-}i\text{-}Pr_3)_2]$ (1.44 g, 2.90 mmol), prepared by lit. method (11), in THF containing P-*i*-Pr_3 (0.4 cm^3, 2 mmol) and water (0.2 cm^3, 11 mmol) was stirred with Na–Hg (60 g, 0.3%) under argon until the solution turned yellow (ca. 2 h). This solution was worked up as for $[RhH(P\text{-}i\text{-}Pr_3)_3]$ to give light yellow crystals contaminated with a darker material. This solid was collected by filtration and recrystallized from light petroleum at –30°C. The resulting pale yellow crystals were collected by filtration at –78°C. Yield: 0.7 g, 52%. The complex was identified crystallographically and by comparison of its spectroscopic properties with those in the literature (13). FT IR λ_{max} (cm^{-1}): 2140.

X-ray crystallography

X-ray data were collected at 220 K on a Rigaku AFC7S diffractometer using graphite-monochromated Mo Kα radiation (λ = 0.71069 Å). The structures were solved using direct methods (14) and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically. For $[RhH_2Cl(P\text{-}i\text{-}Pr_3)_2]$, the hydrogen atoms on Rh were refined isotropically, the rest were included in fixed positions. For $[i\text{-}Pr_3PH][RhHCl_3(P\text{-}i\text{-}Pr_3)_2]$, hydrogen atoms were included but not refined. Neutral atom scattering factors were taken from the literature (15). Anomolous dispersion effects, Lorentz, and polarization corrections were applied. All calculations were performed using the teXsan (16) crystallographic software package. Crystal data, along with the structure solution and refinement parameters are listed in Table 1. CCDC reference numbers: $[RhH_2Cl(P\text{-}i\text{-}Pr_3)_2]$ 163 735, $[i\text{-}Pr_3PH][RhHCl_3(P\text{-}i\text{-}Pr_3)_2]$ 163 736.[2]

Results and discussion

Reaction of $RhCl_3 \cdot 3H_2O$ with excess P-*i*-Pr_3 in THF produces $[RhHCl_2(P\text{-}i\text{-}Pr_3)_2]$, which has also been prepared by refluxing $RhCl_3 \cdot 3H_2O$ with P-*i*-Pr_3 in wet propan-2-ol (11, 17), and shown crystallographically to be square pyramidal with an apical hydride (18). *i*-Pr_3PO is also a product,

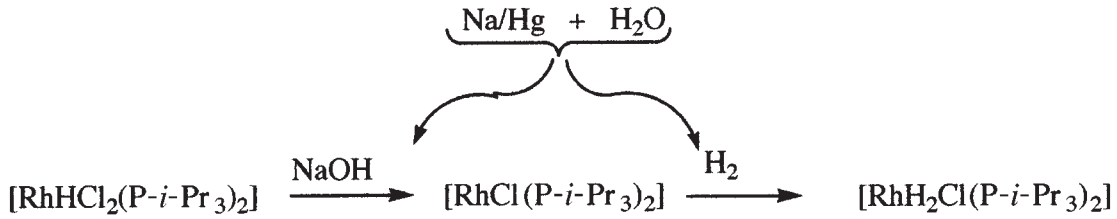
Fig. 1. X-ray structure and numbering scheme for [*i*-Pr_3PH][$RhHCl_3$(P-*i*-$Pr_3)_2$]·THF.

suggesting that the reaction may proceed via reduction of the rhodium by P-*i*-Pr_3. The final product is then formed by oxidative addition of HCl. That the hydride comes from the water in $RhCl_3·3H_2O$ rather than from THF is confirmed by carrying out the reaction in THF in the presence of D_2O to give [$RhDCl_2$(P-*i*-$Pr_3)_2$] (FT IR: 1380 cm^{-1} (RhD) ($\nu_{Rh,H}$ / $\nu_{Rh,D}$ = 1.41), ^{2}D NMR δ: –30.1 (RhD)).[3] The need for water and excess P-*i*-Pr_3 in this reaction means that the yield of [$RhHCl_2$(P-*i*-$Pr_3)_2$] can be increased by carrying out the reaction in the presence of excess P-*i*-Pr_3, added water, and HCl, but it is difficult to remove the last traces of HCl.

Further reaction of [$RhHCl_2$(P-*i*-$Pr_3)_2$], produced from the reaction of $RhCl_3·3H_2O$ with P-*i*-Pr_3 in THF containing aqueous HCl, produced a yellow solution, from which yellow-orange crystals could be isolated. The NMR spectra of this compound were broad at room temperature (see below), but an X-ray structural determination (Fig. 1, Table 2) showed it to be [*i*-Pr_3PH][$RhHCl_3$(P-*i*-$Pr_3)_2$] with an octahedral rhodium centre and mutually *trans* phosphine ligands. At room temperature, the ^{1}H NMR spectrum shows a doublet at δ 8.1 ($J_{P,H}$ = 492 Hz) from the H of the phosphonium ion, and a broad hydride signal at δ –30.3, a position similar to that of [$RhHCl_2$(P-*i*-$Pr_3)_2$], whilst the ^{31}P NMR spectrum consists of a broad doublet at δ 43.5 ($J_{Rh,P}$ = 95.5 Hz). Variable-temperature ^{31}P and ^{1}H NMR studies (Figs. 2 and 3) show the phosphonium cation does not exchange with the bound P-*i*-Pr_3, resonating as a singlet (δ = 32–34 at all temperatures). The broadening of this signal in the spectrum measured at 308 K may indicate that exchange would occur at higher temperatures. Changes do occur, however, in the resonance due to the rhodium bound phosphines, which exhibit a doublet at δ –29.2 ($J_{Rh,P}$ = 97 Hz) at –183 K. On warming, this doublet broadens and shifts to lower field before sharpening to a doublet at δ 43 ($J_{Rh,P}$ = 95.6 Hz). The hydride resonance in the ^{1}H NMR spectrum at 193 K is a singlet at δ –21, but this also broadens on warming and moves to higher field sharpening to a doublet of triplets at δ –30.3 (dt, $J_{Rh,H}$ = 12.8, $J_{P,H}$ = 31.3 Hz). The high-temperature limiting spectrum of the rhodium containing



[3] It is also possible that D could be incorporated by exchange of [$RhHCl_2$(P-*i*-$Pr_3)_2$] with D_2O after its formation, but the increased yield in the presence of water suggests that water is the direct source of the hydride.

Scheme 1. Proposed reactions involved in the formation of [RhH_2Cl(P-*i*-Pr_3)$_2$] from Na–Hg reduction of [$RhHCl_2$(P-*i*-Pr_3)$_2$] in the presence of water.

species is the same as that for [$RhHCl_2$(P-*i*-Pr_3)$_2$] (18), so that [*i*-Pr_3PH][$RhHCl_3$(P-*i*-Pr_3)$_2$] is only stable at lower temperatures, losing Cl^- from the rhodium on warming.

Reduction of [$RhHCl_2$(P-*i*-Pr_3)$_2$] with Na–Hg in THF containing P-*i*-Pr_3 leads to the formation of [RhH(P-*i*-Pr_3)$_3$] as might be expected. However, the reaction shows poor reproducibility and variable yield, and is better carried out under argon. If the reaction is carried out under nitrogen, spectroscopic studies show the presence of a mixture of compounds, possibly [RhH(P-*i*-Pr_3)$_2$] or [RhH(P-*i*-Pr_3)$_2$]$_2$ (μ-N_2) (δ = 66 (d, $J_{P,Rh}$ = 162 Hz, P); δ = –15.0 (dt, $J_{Rh,H}$ = 17.0, $J_{P,H}$ = 20.8 Hz, RhH)) (7) and [RhH(N_2)(P-*i*-Pr_3)$_2$] (δ = 67 (d, $J_{P,Rh}$ = 158 Hz, P); δ = –13.6 (dt, $J_{Rh,H}$ = 18.4, $J_{P,H}$ = 18.2 Hz, RhH)) (7), but [RhH(P-*i*-Pr_3)$_3$] can be recovered from this solution by evaporation to dryness and recrystallization from light petroleum in the presence of excess P-*i*-Pr_3.

On some occasions, attempts to prepare [RhH(P-*i*-Pr_3)$_3$] from the reaction of $RhCl_3$·$3H_2O$ with P-*i*-Pr_3 followed by evaporation to dryness and reduction with sodium amalgam led to a different yellow complex, which crystallizes as yellow plates, for which the spectroscopic properties suggest [RhH_2Cl(P-*i*-Pr_3)$_2$]. This formulation has been confirmed crystallographically, although a different polymorph is obtained from that described previously (18). Detailed studies have shown that this product arises if water remains after evaporation of the solution formed in the first step of the reaction to "dryness". The probable mechanism of formation of the dihydrido complex is shown in Scheme 1 and involves NaOH formed from the reaction of water with Na–Hg, removing HCl from [$RhHCl_2$(P-*i*-Pr_3)$_2$] to give [RhCl(P-*i*-Pr_3)$_2$] (13), which reacts with hydrogen, also produced from water and Na–Hg, to give the final product. This mechanism is supported by the reports that [$RhHCl_2$(P-*i*-Pr_3)$_2$] reacts with H_2 in 50% NaOH–benzene mixtures under phase transfer conditions to give [RhH_2Cl(P-*i*-Pr_3)$_2$] (19), and that [RhCl(P-*i*-Pr_3)$_2$] gives the same product on reaction with H_2 in benzene (13). We find the yield from these reactions can be quite low and variable, but a reproducible synthesis of the dihydride, which occurs in 50% yield, involves reaction of [$RhHCl_2$(P-*i*-Pr_3)$_2$], prepared by the lit. method (11), over sodium amalgam in the presence of THF, P-*i*-Pr_3, and water for 2 h. Prolonged stirring leads to a green solution, from which we have not isolated any pure complexes.

X-ray crystal and molecular structure of [RhH_2Cl(P-*i*-Pr_3)$_2$]

A previous structure of [RhH_2Cl(P-*i*-Pr_3)$_2$] (18) showed it to be triclinic with space group *P*1 and containing two independent molecules in the asymmetric unit. One of these had a pseudo-twofold axis passing through the Rh and Cl atoms, whilst in the other, this axis was destroyed by different orientations in the P-*i*-Pr_3 groups. Samples of [RhH_2Cl(P-*i*-

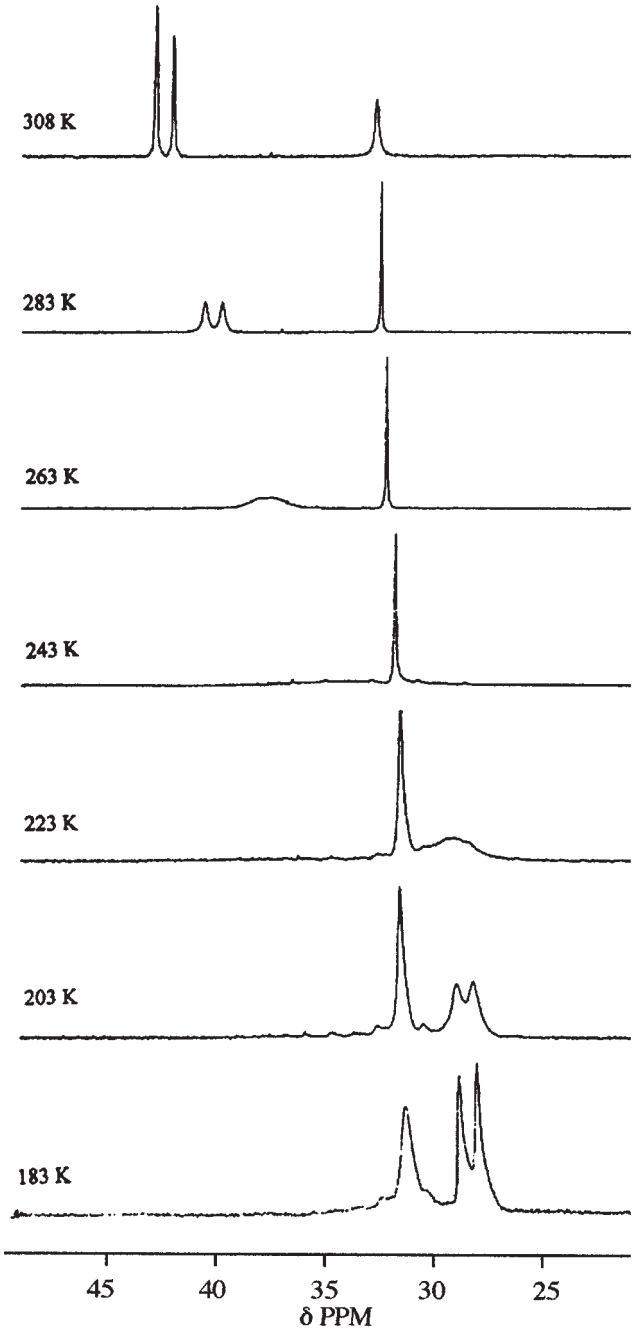
Fig. 2. Variable temperature ^{31}P NMR spectra for [*i*-Pr_3PH][$RhHCl_3$(P-*i*-Pr_3)$_2$] (in CD_2Cl_2).



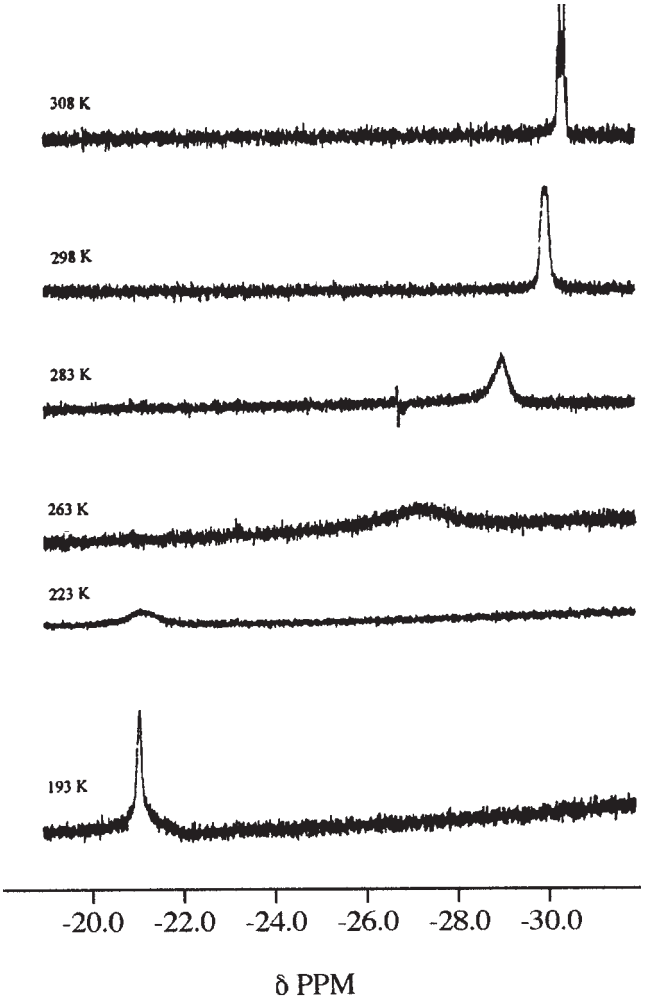


Fig. 3. Variable temperature ^1H NMR spectra for [*i*-Pr_3PH][$RhHCl_3$(P-*i*-Pr_3)$_2$] (in CD_2Cl_2).

$Pr_3)_2$] prepared from the reaction of $RhCl_3 \cdot H_2O$ with P-*i*-Pr_3 in THF crystallized in a different space group ($P2_1/n$) and contained only one type of molecule with no pseudo-twofold axis (Fig. 4 and Table 3). The H-Rh-H angle (71°) is slightly more obtuse and the Rh—H distances (1.45(4), 1.51(3) Å) are similar to but less unequal than those previously reported. The amount of "T"-square pyramidal geometry character in our structure is slightly greater, as indicated by the relatively acute Cl-Rh-H(43) angle of 132° and the rather more obtuse Cl-Rh-H(44) angle of 155°. This results in a noticeable distortion of H(43) away from the Cl-Rh-H(44) plane towards one of the P-*i*-Pr_3 ligands. The H—H distance is 1.74 Å, confirming the complex to be a dihydride. The P-Rh-P angle (176.6°) is very similar to those reported for the two independent molecules of the triclinic system (176.6, 175.6°), so it can be concluded that the slight "T"-distortion in our structure is responsible for the longer Rh—Cl, Rh—P, and Rh—H bond lengths (see Table 3).

Crystal and molecular structure of [*i*-Pr_3PH][$RhHCl_3$(P-*i*-Pr_3)$_2$]

The X-ray crystal structure and numbering scheme for [*i*-Pr_3PH][$RhHCl_3$(P-*i*-Pr_3)$_2$] are shown in Fig. 4, with selected bond lengths and angles in Table 2. The crystals are triclinic, space group *P*1 (no. 2). The complex is octahedral with meridional chlorides and Rh-Cl *trans* to hydride being longer by 0.21 Å than those for the mutually *trans* chlorides (which are similar to those observed for [$RhHCl_2$(P-*i*-Pr_3)$_2$]), as expected on account of the large *trans* influence of hydride and possibly weak H-bonding of this Cl atom to the phosphonium cation (see below). The similarity between the structural parameters for [*i*-Pr_3PH][$RhHCl_3$(P-*i*-Pr_3)$_2$], omitting the chloride *trans* to H, and those for [$RhHCl_2$(P-*i*-Pr_3)$_2$] (18) (Table 2) is striking and consistent with the ready loss of Cl^- observed by NMR spectroscopy (see above). The [*i*-Pr_3PH]$^+$ cation is orientated in such a way that the H atom is directed towards the Cl atom *trans* to H, but the P—Cl

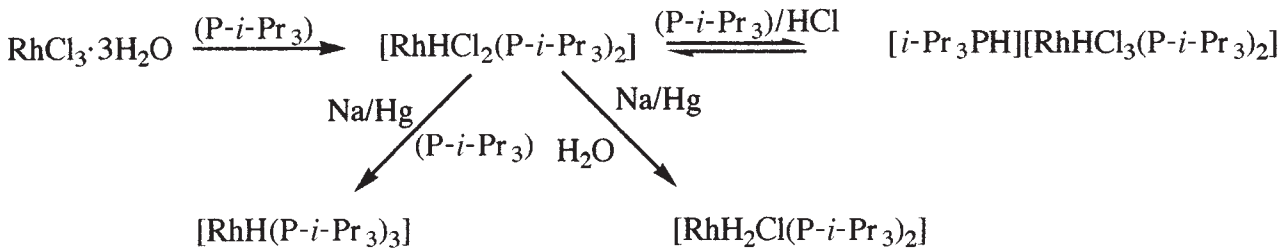

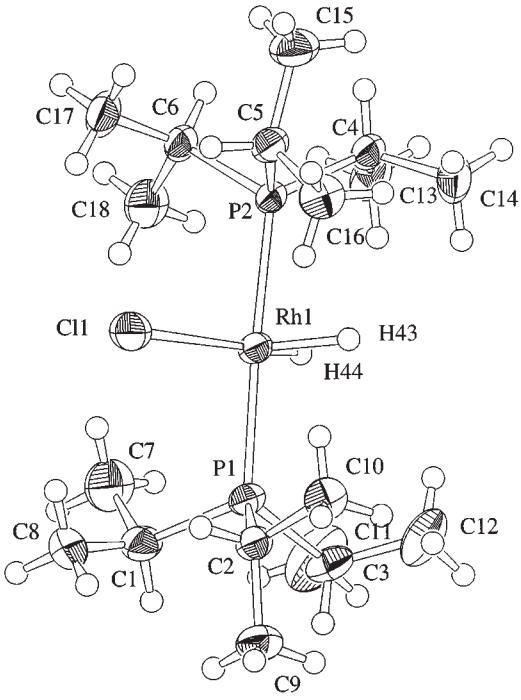

Fig. 4. X-ray structure and numbering scheme for $[RhH_2Cl(P\text{-}i\text{-}Pr_3)_2]$.

distance is 3.88 Å, suggesting that if hydrogen-bonding occurs in the solid state, it is very weak. The reactions discussed in this paper are outlined in Scheme 2.

Conclusions

We conclude that reaction of $RhCl_3 \cdot 3H_2O$ with P-*i*-Pr_3 in THF can lead to $[RhHCl_2(P\text{-}i\text{-}Pr_3)_2]$ or $[i\text{-}Pr_3PH][RhHCl_3(P\text{-}i\text{-}Pr_3)_2]$, depending upon the conditions, with the hydride being derived from the water in $RhCl_3 \cdot 3H_2O$. A better synthesis of $[RhHCl_2(P\text{-}i\text{-}Pr_3)_2]$ involves carrying out the reaction in propan-2-ol (11). Sodium amalgam reduction of in-situ prepared $[RhHCl_2(P\text{-}i\text{-}Pr_3)_2]$ in the presence of excess P-*i*-Pr_3 leads to $[RhH(P\text{-}i\text{-}Pr_3)_3]$ only if water has been rigorously removed. If water is present, $[RhH_2Cl(P\text{-}i\text{-}Pr_3)_2]$, which crystallizes in a different polymorph from that previously reported (18), is obtained.

In-depth NMR and IR study of the proton transfer equilibrium between [{(MeC(CH_2PPh_2)$_3$}Ru(CO)H_2] and hexafluoroisopropanol

Vladimir I. Bakhmutov, Ekaterina V. Bakhmutova, Natalia V. Belkova, Claudio Bianchini, Lina M. Epstein, Dante Masi, Maurizio Peruzzini, Elena S. Shubina, Evgenii V. Vorontsov, and Fabrizio Zanobini

Abstract: The (carbonyl)dihydride complex [(triphos)Ru(CO)H_2] (**2**) has been synthesized by reaction of the ruthenate [(triphos)RuH_3]K (triphos = MeC(CH_2PPh_2)$_3$) with ethanol saturated with CO. A single crystal X-ray analysis and IR and NMR experiments have shown that **2** adopts in both the solid state and solution an octahedral coordination geometry with a *facial* triphos ligand, two *cis* terminal hydrides, and a terminal carbonyl. The reaction of hexafluoro-2-propanol (HFIP) with **2** has been studied in CH_2Cl_2 solution by IR and NMR spectroscopy. The proton donor interacts with a terminal hydride of **2** forming a rather strong hydrogen bond. The resulting H-bonded adduct [{(triphos)Ru(CO)(H)H}$\cdots${HOCH(CF_3)$_2$}] (**2a**) has fully been characterized by in situ NMR and IR techniques. Compound **2a** is in equilibrium with the nonclassical η^2-H_2 complex [(triphos)Ru(CO)H(H_2)]$^+$ (**2b**), which can independently be prepared by protonation of **2** with a strong protic acid at low temperature. Unequivocal characterization of the dihydrogen complex (**2b**) has been achieved by a multifaceted spectroscopic investigation (T_{1min}^{obs} = 0.005 s (200 MHz), $J_{H,D} \approx$ 30 Hz, DQCC = 78.3 kHz). A combined IR and NMR study of the proton transfer reaction involving **2** and HFIP in CH_2Cl_2 to give, first, the H-bonded adduct (**2a**) and, then, the dihydrogen complex (**2b**) has demonstrated that all these species are in equilibrium in the temperature range from 190 to 260 K. The thermodynamic parameters for the formation of **2a** have independently been determined by NMR and IR methods, while those for the formation of **2b** have been obtained by IR spectroscopy. An energetic profile for the reaction sequence **2** $\rightarrow$ **2a** $\rightarrow$ **2b** is proposed and discussed.

Key words: hydrides, hydrogen bonding, ruthenium, IR spectroscopy, NMR spectroscopy.

Résumé : On a synthétisé le complexe [(triphos)Ru(CO)H_2] (**2**) (triphos = MeC(CH_2PPh_2)$_3$), un (carbonyl)dihydrure, en faisant réagir le ruthénate [(triphos)RuH_3]K avec de l'éthanol saturé de CO. La diffraction des rayons X sur un cristal unique et des expériences d'IR et de RMN ont permis de montrer que le composé **2**, tant à l'état solide qu'en solution, adopte une géométrie de coordination octaédrique comportant un ligand triphos *facial*, deux hydrures terminaux *cis* et un carbonyle terminal. Faisant appel à la spectroscopie IR et RMN, on a étudié la réaction du composé **2** avec l'hexafluoropropan-2-ol (HFIP) en solution dans le CH_2Cl_2. Le donneur de proton interagit avec un hydrure terminal du composé **2** en formant une liaison hydrogène relativement forte. Faisant appel in situ d'IR et de RMN, on a fait un caractérisation complète de l'adduit à liaison hydrogène qui en résulte [{(triphos)Ru(CO)(H)H}$\cdots${HOCH(CF_3)$_2$}] (**2a**). Le composé **2a** est en équilibre avec le complexe non classique η^2-H_2, [(triphos)Ru(CO)(H_2)]$^+$ (**2b**) que l'on peut préparer de façon indépendante en procédant à la protonation du composé **2** à l'aide d'un acide protique fort, à basse température. On a effectué la caractérisation non ambiguë du complexe dihydrogéné, **2b**, en faisant appel à une étude spectroscopique à multiples facettes (T_{1min}^{obs} = 0,005 s (200 MHz), $J_{H,D} \approx$ 30 Hz, DQCC = 78,3 kHz). Faisant appel à une combinaison de techniques d'IR et de RMN, on a étudié la réaction de transfert de proton du composé **2** avec l'HFIP, dans le CH_2Cl_2, qui donne premièrement l'adduit à liaison hydrogène **2a** et ensuite le complexe dihydrogéné **2b**; ces études ont démontré que toutes ces espèces sont en équilibre sur toute la plage de températures allant de

[Traduit par la Rédaction]

Introduction

The occurrence of intra- and intermolecular hydrogen bonds between transition-metal hydride complexes and Brønsted acids has recently been established for a variety of metals and proton donors (1). It is proposed that such M-H···H-X interactions in solution may lead to the formation of dihydrogen (η^2-H_2) complexes; however, well-documented examples of proton transfers involving the formation of η^2-H_2 metal complexes via M-H···H-X intermediates are still very scarce (2). This scarcity of data is essentially due to the low temperature at which the M-H···H-X ⇆ $M(H_2)^+$ + X^- equilibrium becomes spectroscopically visible (2*b*, *d*, *f*). Nonetheless, the energetic profile associated with the M-H + ROH ⇆ M-H···HOR ⇆ $M(H_2)^+$ + RO^- sequence relative to the reaction of the rhenium(I) complex [(triphos)Re$(CO)_2$H] (triphos = MeC$(CH_2PPh_2)_3$) (**1**) with perfluoro-*tert*-butanol has recently been estimated using a combined NMR–IR approach (2*e*). In particular, the H-bonded adduct [(triphos)Re$(CO)_2$H···HOR] (**1a**) was unambiguously intercepted by in situ IR and NMR experiments before degradation to the thermodynamically stable dihydrogen complex [(triphos)Re$(CO)_2(\eta^2$-$H_2)]^+$ (**1b**) (2*b*). The energy associated with each step of the conversion of **1a** to **1b** was determined, and a neat energy profile for the whole proton transfer process was obtained (2e). Prior to the rhenium study, thermodynamic parameters relative to the (M-H + HOR ⇆ M-H···HOR)→ M-(η^2-H_2) step had been reported exclusively for the reaction of the dihydride *trans*-[RuH_2(dppm)$_2$] (dppm = bis-diphenylphosphinomethane) with phenol in toluene (2*a*).

This paper is aimed at expanding our knowledge on proton-transfer reactions involving transition metal hydrides, as well as showing the reliability and wide applicability of the combined NMR–IR approach to study M-H + ROH ⇆ M-H···HOR ⇆ $M(H_2)^+$ + RO^- solution equilibria. To this purpose, the new dihydride complex [(triphos)Ru$(CO)H_2$] (**2**) has been synthesized, and the energetic profile associated with the formation of the hydrogen-bonded adduct [{(triphos)Ru(CO)(H)H}···{HOCH$(CF_3)_2$}] (**2a**) and of the dihydrogen complex [(triphos)Ru(CO)H$(H_2)]^+$ (**2b**) has been determined by means of low-temperature NMR and IR experiments.

Experimental

General procedures

Tetrahydrofuran (THF) was purified by distillation under nitrogen over $LiAlH_4$. All other reagents and chemicals were reagent grade and, unless otherwise stated, were used as received by commercial suppliers. All reactions and manipulations were routinely performed under a dry nitrogen atmosphere by using standard Schlenk-tube techniques. The solid complexes were collected on sintered glass-frits and washed with ethanol and light petroleum ether (bp 40–60°C) before being dried with a stream of nitrogen. The complex [(triphos)RuH(η^2-BH_4)] (**3**) was prepared as described in the literature (3).

NMR studies were carried out in standard 5-mm-NMR tubes in either CD_2Cl_2 or THF-d_8. The deuterated solvents were dried by using conventional procedures and were freshly distilled under inert atmosphere prior to use. ^{1}H and ^{2}H NMR spectra were recorded on Bruker AC200, WP-200 or AMX-400 spectrometers and were calibrated with respect to tetramethylsilane. ^{31}P NMR spectra were recorded on the Bruker AC200 instrument operating at 81.01 MHz. Chemical shifts were measured relative to external 85% H_3PO_4 with downfield values taken as positive. ^{13}C NMR spectra were recorded on Varian VXR 300 or Bruker AC200 spectrometers operating at 75.42 or 50.32 MHz, respectively. Peak positions are relative to tetramethylsilane and were calibrated against the residual solvent resonance. The conventional inversion-recovery method (180-τ-90) was used to determine the variable-temperature longitudinal-relaxation time (T_1). The relaxation times were calculated using the nonlinear three-parameter fitting routine of the spectrometers. In each experiment, the waiting period was five times larger than the expected relaxation time and 16–20 variable delays were employed. The duration of the pulses were controlled at every temperature. The errors in T_1 determinations were lower than 5% (this was checked with different samples). The proton donor-hydride reactions were carried out in cold (195–250 K) CD_2Cl_2 solutions in 5-mm-NMR tubes and all the NMR experiments were run starting at low temperature with precooled probe-heads.

Infrared spectra were recorded as Nujol™ mulls on a PerkinElmer 1600 series FT-IR spectrometer between KBr plates or in CH_2Cl_2 solutions on a Specord M82 spectrometer using 0.01–0.2 cm CaF_2 cells. The latter measurements were performed under a dry argon atmosphere. Low-temperature IR measurements were carried out in CH_2Cl_2 solutions using a Carl Zeiss Jena cryostat. The accuracy of the experimental temperature was ±0.5 K. The cells width was 0.04–0.12 cm.

Elemental analyses (C, H) were performed at ISSECC CNR using a Carlo Erba model 1106 elemental analyzer.

Preparation of [(triphos)Ru(CO)H_2] (2)

A vigorously stirred suspension of [(triphos)RuH(η^2-BH_4)] (**3**) (600 mg, 0.81 mmol) in THF (30 mL) was treated with solid KO-*t*-Bu (270 mg, 2.41 mmol) added in small portions. After 30 min stirring, the starting pale yellow complex dissolved to yield a colorless solution which was layered with absolute ethanol (20 mL) saturated with carbon monoxide (CO). After 15 min, the CO flow was stopped and a brisk stream of nitrogen was passed throughout the solution until ivory colored crystals of **2** separated. Yield: 415 mg (78%). Slow crystallization of the mother liquor in the air gave a second crop of **2** (80 mg, 15%). Ivory-colored truncated prisms of **2** suitable for an X-ray crystal analysis

were obtained by slow evaporation of the solvent from a diluted CH_2Cl_2–EtOH solution (2:1 v/v). IR (KBr, Nujol™) (cm^{-1}): 1920 (CO), 1884 (RuH), 1859; (CH_2Cl_2 solution) 1934 (CO), 1871 (RuH). $^{31}P\{H\}$ NMR (22°C, CD_2Cl_2, 81.01 MHz) δ: 34.71 (AM_2 spin system, t, $^2J_{P_A,P_M}$ = 32.9 Hz, P_A), 27.07 (d, $^2J_{P_M,P_A}$ = 32.9 Hz, P_M). ^1H NMR (22°C, CD_2Cl_2, 200.13 MHz) δ: 7.8–6.9 (m, 30H, aromatic protons), 2.4–2.1 (m, 6H, $CH_{2(triphos)}$), –1.48 (q, $^4J_{H,P}$ = 2.9 Hz, 3H, $CH_{3(triphos)}$), –7.32 (AA′XX′Y, $^2J_{H_A,H_{A'}}$ = 6.0 Hz, $^2J_{H_A,P_X}$ = 18.2 Hz, $^2J_{H_A,P_{X'}}$ = 66.1 Hz, $^2J_{H_A,P_Y}$ = 18.0 Hz, $^2J_{P_X,P_{X'}}$ = 38.0 Hz, 2H, RuH). $^{13}C\{H\}$ NMR (22°C, CD_2Cl_2, 50.32 MHz) δ: 209.98 (dt, $^2J_{C,P_{trans}}$ = 77.5 Hz, $^2J_{C,P_{cis}}$ = 7.8 Hz, CO), 142, 138 (m, aromatic ipso carbons), 134–128 (m, aromatic *meta*, *ortho*, and *para* carbons), 39.36 (q, $^3J_{C,P}$ = 9.4 Hz, CH_3), 39.11 (q, $^2J_{C,P}$ = 7.0 Hz, CCH_3), 35.71 (td, $J = J_{C,P_{equat}} + J_{C,P'_{equat}}$ = 12.5 Hz, $J_{C,P_{axial}}$ = 4.7 Hz, CH_2P_{equat}), 33.98 (dt, $J_{C,P_{axial}}$ = 20.3 Hz, $J_{C,P_{equat}}$ = 6.2 Hz, CH_2P_{axial}). Anal. calcd. for $C_{42}H_{41}OP_3Ru$: C 66.8, H 5.5; found C 66.4, H 5.6.

Preparation of [(triphos)Ru(CO)D_2] (2-d_2)

The perdeuterated isotopomer [(triphos)Ru(CO)D_2] (**2b**-d_2) was prepared as described above using [(triphos)RuD(η²-BD_4)] (**3**-d_4) in the place of **3** and C_2H_5OD instead of ethanol. IR (KBr) (cm^{-1}): 1349 (m) (RuD). ^1H NMR analysis confirmed an isotopic purity higher than 95%.

Preparation of [(triphos)Ru(CO)H(H_2)]$^+$ (2b)

A 5-mm screw-cap NMR tube was charged with **2** (40 mg, 5.3×10^{-2} mmol) and degassed dichloromethane-d_2 (0.8 mL). Into this solution, cooled to –78°C with a dry ice–acetone bath, was added via syringe an excess of $HBF_4 \cdot OMe_2$ (20 μL, 0.16 mmol). The tube was immediately inserted into the spectrometer precooled at –80°C and a $^{31}P\{H\}$ NMR spectrum, immediately recorded at this temperature, revealed the quantitative transformation of **2** into **2b**. $^{31}P\{H\}$ NMR (–80°C, CD_2Cl_2, 81.01 MHz) δ: 20.19 (AM_2 spin system, t, $^2J_{P_M,P_A}$ = 35.3 Hz, P_A), 22.90 (d, $^2J_{P_A,P_M}$ = 35.3 Hz, P_M). ^1H NMR (–80°C, CD_2Cl_2, 200.13 MHz) δ: 7.7–7.0 (m, 30H, aromatic protons), 2.7–2.1 (m, 6H, $CH_{2(triphos)}$), 1.58 (br, 3H, $CH_{3(triphos)}$), –5.39 (br, 3H, RuH).

Monitoring the reaction between 2 and HFIP

Interception of the hydrogen-adduct [{(triphos)Ru(CO)(H)H}···{HOCH(CF_3)$_2$}] (2a)

Under similar experimental conditions, two equiv of HFIP (11.2 μL, 0.11 mmol) were added via syringe to a solution of **2** prepared as described above. Low temperature NMR spectra showed the complete conversion of **2** into the hydrogen-adduct **2a**. $^{31}P\{H\}$ NMR (–80°C, CD_2Cl_2, 81.01 MHz) δ: 30.95 (AM_2 spin system, t, $^2J_{P_M,P_A}$ = 34.5 Hz, P_A), 24.47 (d, $^2J_{P_A,P_M}$ = 34.5 Hz, P_M). ^1H NMR (–80°C, CD_2Cl_2, 200.13 MHz) δ: 8.1–6.8 (m, 30H, aromatic protons), 2.4–2.0 (m, 6H, $CH_{2(triphos)}$), 1.43 (br, 3H, $CH_{3(triphos)}$), –7.79 (br, 2H, RuH).

Transformation of the hydrogen-adduct into [(triphos)Ru(CO)H(H_2)]$^+$ (2b)

Addition of a large excess of HFIP (12 equiv, 67 μL) to the above solution at –80°C immediately transformed the hydrogen-adduct **2a** into the molecular hydrogen complex **2b**. ^{31}P NMR spectroscopy showed that the transformation of **2a** in **2b** occurred in almost quantitative yield. Complex **2b** was also obtained by addition 10–12 equiv of HFIP to a dichloromethane-d_2 solution of **2** (NMR tube experiment carried out at –80°C).

Preparation of [(triphos)Ru(CO)$_2$H](BPh$_4$) (5)

A solution of **2** (250 mg, 0.33 mmol) in THF (15 mL) was saturated with CO and then 1 equiv of MeOTf (40 μL, 0.36 mmol) was added via syringe under stirring. After 15 min, CO was replaced by nitrogen, and $NaBPh_4$ (300 mg, 0.88 mmol) in ethanol (15 mL) was added. Slow concentration of the resulting colorless solution gave off-white crystals of **5** in ca. 95% yield. The IR and NMR characteristics of **5** are fully coincident with those reported in the literature for the same compound prepared by a different route (4).

X-ray diffraction study of [(triphos)Ru(CO)H$_2$] (2)

An ivory-colored crystal of **2** with the dimensions 0.22 × 0.12 × 0.17 mm was chosen for an X-ray analysis. A summary of crystal and intensity data for the compound is presented in Table 1. Experimental data were recorded at room temp on a PHILIPS PW1100-FEBO diffractometer using a graphite-monochromated Cu Kα radiation. A set of 25 carefully centered reflections in the range $10° \le \theta \le 15°$ was used for determining the lattice constants. As a general procedure, the intensity of three standard reflections was measured periodically every 2 h for orientation and intensity control. This procedure did not reveal any decay of intensities. The data were corrected for Lorentz and polarization effects. Atomic scattering factors were those tabulated by Cromer and Waber (5) with anomalous dispersion corrections taken from ref 6. An empirical absorption correction was applied via Ψ scan with transmission factors in the range 1.8794–1.0042. The computational work was performed with a Pentium-II™ personal computer using the programs SHELXL 93 (7) and ZORTEP (8). Final atomic coordinates with equivalent isotropic thermal parameters of all atoms and structure factors are available as supplementary material.

The structure was solved via the heavy atom technique using the program SIR 92 (9) and all the non-hydrogen atoms were found through a series of F_0 Fourier maps. Refinement was done by full-matrix least-squares calculations, initially with isotropic thermal parameters, and then, in the last least-squares cycle, with anisotropic thermal parameters for ruthenium, phosphorus, and carbon and oxygen atoms of the carbonyl ligand. All of the phenyl rings were treated as rigid bodies with D_{6h} symmetry and C—C distances fixed at 1.39 Å. Hydrogen atoms of the triphos ligand were introduced in calculated positions, but not refined. At an advanced stage of the refinement, two hydrogen atoms were located in the Fourier map and successfully refined as ruthenium coordinated hydrides.

Results and discussion

Synthesis and characterization of the dihydride complex [(triphos)Ru(CO)H$_2$] (2)

Treatment of the known (tetrahydroborate)hydride complex [(triphos)RuH(η²-BH_4)] (**3**) with a slight excess of KO-*t*-Bu in anhydrous THF at room temp gave a yellow-orange solution of the trihydride [(triphos)RuH_3]K (**4**) as the only Ru-containing product (Scheme 1) (10). Although **4** can be

isolated as potassium salt in the presence of a 18-crown-6 ether, its difficult storage, due to remarkable sensitivity to water and protic solvents, makes freshly prepared THF solutions excellent vehicles to study the chemistry of the ruthenate **4** and, in particular, to generate the 16e$^-$ fragment [(triphos)Ru(H)$_2$]. As a matter of fact, a THF solution of **4** reacts with protic solvents such as water or alcohols to give quantitatively the tetrahydrido complex [{(triphos)RuH}$_2$(μ-H)$_2$] and H_2 via spontaneous dimerization of the coordinatively unsaturated fragment [(triphos)RuH$_2$].[3] In the presence of σ-donor ligands, this 16e$^-$ system can be intercepted to form stable octahedral complexes of the formula [(triphos)Ru(L)H$_2$] (L = nitriles, phosphines, arsines, CO, etc.).[3] With carbon monoxide, the new carbonyl dihydride complex [(triphos)Ru(CO)H$_2$] (**2**) was readily obtained by simply adding ethanol saturated with CO to a THF solution of **4**. Once formed, **2** is stable in THF and can be isolated in the solid state. Compound **2** is air-stable in both the solid state and solution (THF, halocarbons, acetone) and has been characterized by multinuclear (^{1}H, ^{31}P, and ^{13}C) NMR and IR spectroscopy, and elemental and X-ray diffraction analyses (vide infra).

The AM$_2$ pattern featured in the ^{31}P NMR spectrum of **2** and the typical AA′XX′Y (X, X′, Y = ^{31}P) pattern of the high-field hydride resonance (δ = –7.32) are consistent with the presence of two *cis*-disposed hydride ligands in an octahedral coordination with three positions taken by a *facial* (*fac*) triphos and three other positions occupied by two hydrides and one carbon monoxide ligand (11). A narrow doublet of triplets is contained in the ^{13}C NMR spectrum at δ 209.98 for the CO carbon atom, which agrees with the proposed structural formulation for **2**.

Complex **2** is stereochemically rigid on the NMR time scale; neither the ^{31}P nor the ^{1}H NMR spectrum show significant changes over the temperature window of dichloromethane. In keeping with a classical dihydride nature, a variable-temperature analysis of the spin-lattice relaxation time (T_1) of the isochronous hydride ligands gave a quite long minimum value of 0.178 s at 200 K using a 200 MHz instrument (12). The solid state IR spectrum contains a ν(CO) band at 1920 cm^{-1} and two ν(RuH) bands at 1884 and 1859 cm^{-1}. The observation of a medium intensity absorption at ca. 1350 cm^{-1} in the spectrum of the deuterated isotopomer **2b-*d*$_2$** confirmed the correctness of our ν(RuH) assignment ($k_{H/D}$ = 1.39). The IR spectrum in CH_2Cl_2 solution shows ν(CO) at 1934 cm^{-1} and ν(RuH) at 1871 cm^{-1}. This latter band is a combination of both ν_s(RuH) and ν_{as}(RuH), which are well-resolved in the solid state (ν_s(RuH) 1884 cm^{-1} and ν_{as}(RuH) 1859 cm^{-1}).

Well-shaped crystals of **2** were grown from a dilute dichloromethane–ethanol solution. Figure 1 shows a ORTEP view of the complex molecule, while crystallographic data and selected bond distances and angles are presented in Tables 1 and 2, respectively. The results of a single crystal

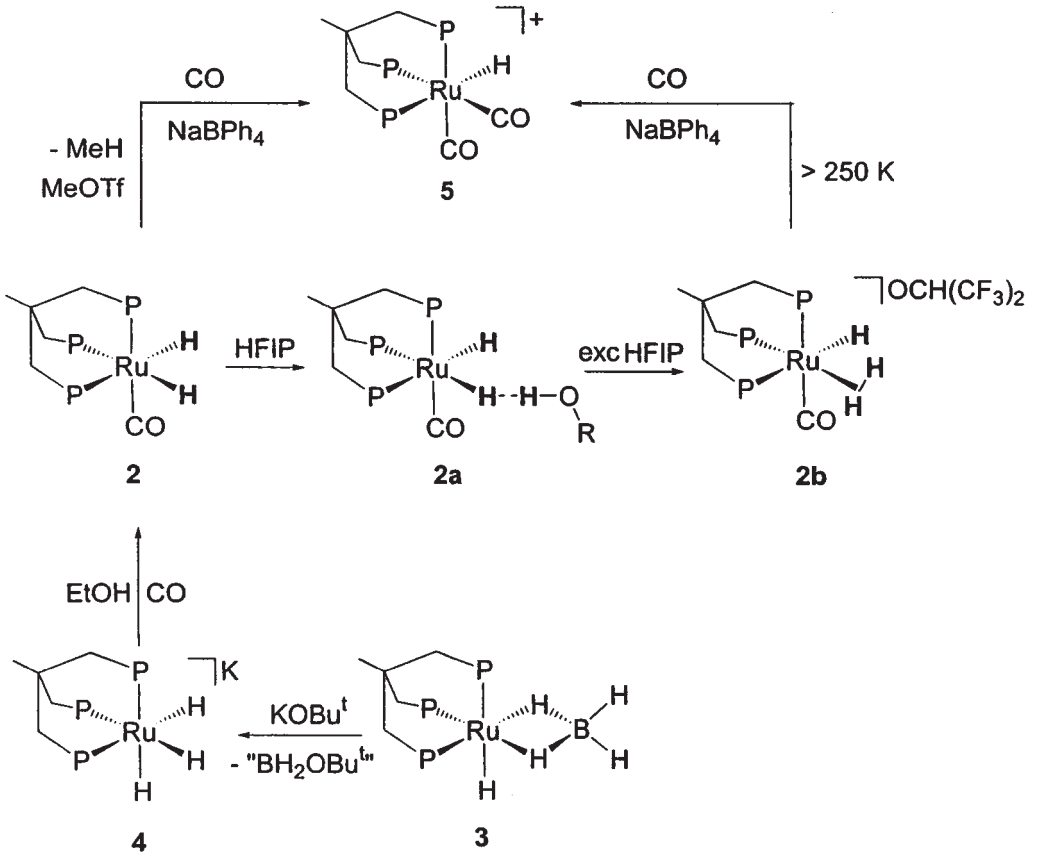
Scheme. 1.



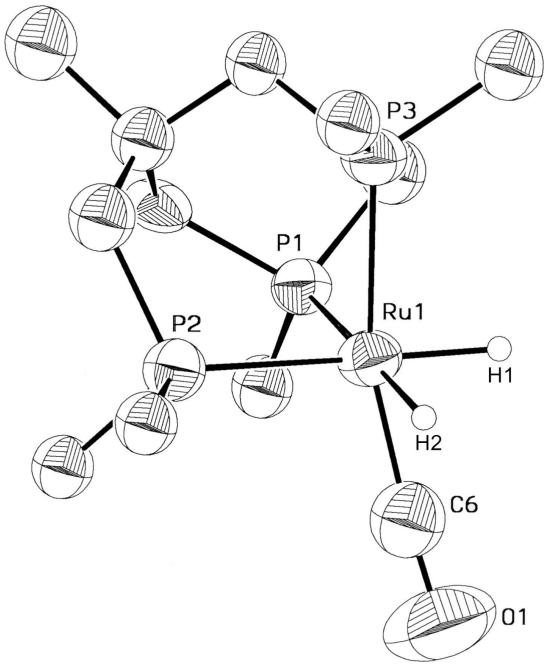


Fig. 1. ORTEP drawing of the molecular structure of **2**. Only the ipso carbons of the six triphos phenyl rings are shown.

X-ray diffraction analysis are consistent with the solution structure determined by NMR spectroscopy.

The ruthenium atom is octahedrally coordinated by a *fac* triphos ligand, by two *cis* hydrides, and by a terminal carbonyl. The observed distortions from a regular octahedron are typical of triphos complexes containing hydride ligands (13). The three Ru—P distances are very similar to each other (average Ru—P = 2.34 Å), and reflect comparable *trans* influence exerted by the hydride and the carbonyl ligands. The Ru—CO distance of 1.84(2) Å is typical for ruthenium(II) carbonyl complexes (14). The two hydride ligands were located in the difference Fourier maps and refined as isotropic atoms together with the rest of the non-hydrogen atoms of the structure, giving Ru—H(1) and Ru—H(2) separations of 1.46(18) and 1.50(11) Å, respectively.

Synthesis and spectroscopic characterization of the dihydrogen complex [(triphos)Ru(CO)(H)(H_2)]$^+$ (2b)

Treatment of **2** with strong protic acids (HBF_4, $HOSO_2CF_3$) at room temp gave a mixture of products that denied first-order analysis, thus indicating that the molecular hydrogen complex [(triphos)Ru(CO)(H)(H_2)]$^+$ (**2b**), which actually forms upon protonation of **2** (vide infra), is unstable at room temp. This behavior agrees with the results by Michos et al. (15) for the protonation of [{PhP($CH_2CH_2PPh_2$)$_2$}RuH_2L] (L = CO, P(OCH_2)$_3$CEt, PMe_2Ph), which did not afford isolable molecular hydrogen complexes, although the spectroscopic data were provided. However, when the protonation was repeated in the presence of carbon monoxide, the known octahedral hydrido dicarbonyl complex [(triphos)Ru($CO)_2$H]$^+$ was quantitatively produced and isolated as the tetraphenylborate salt [(triphos)Ru($CO)_2$H](BPh_4) (**5**). Complex **5** has previously been synthesized by oxidation of the ruthenium(0) complex

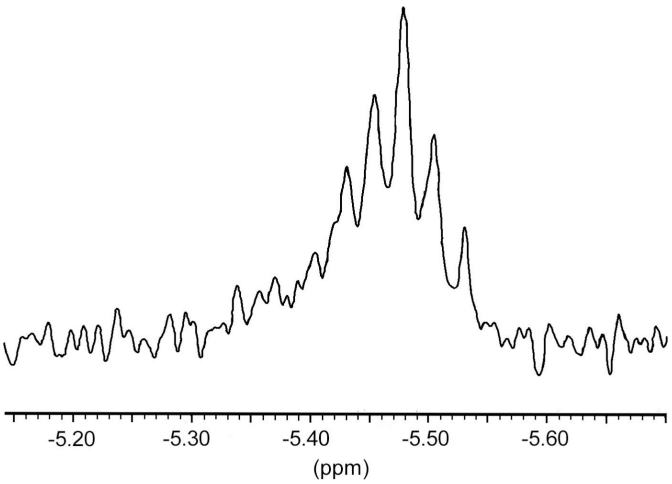
[(triphos)Ru(CO)$_2$] with HCl or MeCOCl (4). To intercept the molecular hydrogen complex **2b**, the protonation of **2** was then carried out in CH_2Cl_2 solution at low-temperature (200 K) using either a stoichiometric amount of strong acid or a large excess (10–12 equiv) of a medium-strength proton donor such as the activated alcohol hexafluoroisopropanol (HFIP). Indeed, the addition of 12 equiv of HFIP to a CD_2Cl_2 solution of **2** in a 5 mm NMR tube cooled to 195 K generated a new broad hydride resonance centered at ca. –5.4 ppm (3H) featured by a very short T_{1min} value of 0.005 s at 190 K (200 MHz), which is typical for a nonclassical dihydrogen structure (16, 17). The appearance of the η^2-H_2 resonance in the proton spectrum of **2b** was paralleled by that of a well-resolved AMM′ pattern with δ_{P_A} 20.19 and δ_{P_M} 22.90 ppm (J_{P_A,P_M} = 35.3 Hz) in the ^{31}P NMR spectrum. The P_A donor atom, *trans* to the CO ligand, undergoes a significant high-field shift ($\Delta\delta \approx 14.5$ ppm) in line with the formation of a cationic carbonyl complex. Figure 2 collects the NMR spectra illustrating the stepwise transformation of **2** into **2b** via the H-bonded adduct [{(triphos)Ru(CO)(H)H}$\cdots${HOCH(CF$_3$)$_2$}] (**2a**). Indeed, this latter compound is formed in very low concentration when a large excess of HFIP is employed (Fig. 2*c*), while it is the only product visible on the ^{31}P NMR timescale when **2** is reacted with two equiv of alcohol (vide infra).

Fig. 2. ^{31}P NMR spectra (81.01 MHz) illustrating the stepwise transformation of **2** (4.63×10^{-5} M solution in CD_2Cl_2) (top trace), into **2a** (middle trace) upon addition of HFIP (2 equiv) and, eventually, into **2b** (bottom trace) upon addition of further 10 equiv of HFIP. All the spectra were taken at 193 K.



The dihydrogen complex **2b** is highly fluxional in CD_2Cl_2 solution as a consequence of a fast hydride-dihydrogen exchange occurring even at the lowest temperature investigated (180 K). Compound **2b** is quite stable in solution below 250 K but slowly eliminates H_2 above this temperature as shown by the appearance of the typical H_2 resonance at 4.56 ppm in the proton NMR spectrum. The decomposition of **2b** is not chemoselective; in fact, a single, well-defined product was obtained only in the presence of external ligands, like carbon monoxide, which are capable of trapping the 16e$^-$ fragment [(triphos)Ru(CO)H]$^+$.

The nonclassical nature of **2b** was confirmed by deuterium labeling experiments. A ^{1}H{^{31}P} NMR spectrum, recorded after addition of excess CF_3COOD to a solution of **2** in CD_2Cl_2 at 200 K, exhibits a poorly resolved resonance at –5.48 ppm, which, upon increasing the temperature to 250 K, transforms into a nonbinomial quintet with a line separation of ca. 10 Hz. Accordingly, this resonance can

© 2001 NRC Canada

Fig. 3. Hydride region of the $^1H\{^{31}P\}$ NMR spectrum of the **2-*d*$_2$** isotopomer (250 K, 400 MHz) prepared by low-temperature protonation of **2** with an excess of CF_3COOD in CD_2Cl_2.

safely be assigned to the bis-deuterated isotopomer $[(triphos)Ru(CO)HD_2]^+$ (**2b-*d*$_2$**) (Fig. 3). In the ^1H NMR spectrum, the typical 1:1:1 triplet of free HD is also observed at 4.51 ppm. In agreement with the formation of a deuterated isotopomer of **2b**, the deuteration results in a high-field isotopic shift of the "HD_2" signal of 120 ppb. Similar isotopic shifts are commonly observed for HD metal complexes (17) and may be due to the IPR effect. A $J_{H,D}$ constant of ca. 30 Hz can be calculated for **2b** assuming a very fast H–H_2 exchange (17). Introducing this value in the empirical correlation, $r_{(HH)} = (1.42 - 0.0167)J_{H,D}$ Å, recently proposed by Morris and co-workers (18) for dihydrogen complexes, a rather elongated H—H distance of 0.92 Å may be figured out for the nonclassical ligand in **2b**.

An independent estimation of the H—H separation can also be obtained from the relaxation data. The T_{1min} measured for both the hydride signals in **2** (T_{1min} (**2**$_{Ru,H2}$) = 0.178 s) and **2b** (T^{obs}_{1min} (**2b**$_{Ru,H3}$) = 0.005 s) allows one to calculate the T_{1min} for the dihydrogen ligand in **2b** by means of eq. [1], and hence the T_{1min} ($Ru(H_2)$) applying eq. [2].

$$[1]\qquad 1/T^{obs}_{1min}(\mathbf{2b}_{Ru,H3}) = (1/3)/T_{1min}\ (\mathbf{2}_{Ru,H2}) + (2/3)/T^{obs}_{1min}(\mathbf{2b}_{Ru(H2)})$$

$$[2]\qquad 1/T^{obs}_{1min}\ (\mathbf{2b}_{Ru(H2)}) = 1/T_{1min}\ (\mathbf{2}_{Ru,H2}) + 1/T_{1min}\ (\mathbf{2b}_{Ru(H2)})$$

As a result, a T_{1min} (**2b**$_{Ru(H2)}$) value of 0.0035 s, exclusively occasioned by hydride–hydride dipole–dipole interactions in the dihydrogen ligand, is obtained, which ultimately gives an H—H distance ranging from 0.74 to 0.94 Å depending on the spinning model adopted (fast or slow rotation) for the motion of the dihydrogen ligand (19*a*). As the separation of 0.94 Å calculated using the low-spinning model is very close to the distance determined from the $J_{H,D}$ coupling constant in **2b-*d*$_2$**, it is conceivable that **2b** contains, as usually, a rather "immobile" H_2 ligand (19*b*).

Since the relaxation properties of the deuterium nucleus are a powerful tool to investigate the dynamic behavior of dihydrogen ligands (16*b*, 21), ^2H-T_1 spin-lattice measurements were carried out on complexes **2b-*d*$_2$** and **2b-*d*$_3$** in CH_2Cl_2. The perdeuterated isotopomer **2b-*d*$_3$** has been prepared by low-temperature protonation of **2b-*d*$_2$** with CF_3COOD. The ^2H NMR spectrum of **2b-*d*$_3$** contains a broad resonance at ca. –5.4 ppm that can safely be assigned to the three freely exchanging deuterides. Like **2b**, the ^2H resonance of **2b-*d*$_3$** remains unchanged even at 180 K due to fast deuteride–deuterium exchange.

The ^2H-T_1 relaxation experiments on the parent classical deuteride **2b-*d*$_2$** give a T_{1min} (**2**$_{Ru,D2}$) value of 0.0149 s at 61.402 MHz. By applying eq. [3] and introducing therein $\eta = 0$ (21), a deuterium quadrupole coupling constant (DQCC) (22) as large as 78.3 kHz can be calculated for **2b-*d*$_2$**

$$[3]\qquad DQCC = 1.2201(1 + \eta^2/3)^{-1/2}\ (\nu/T_{1min})^{1/2}$$

where DQCC, ν, and T_{1min} are given in kHz, MHz, and s, respectively.

The DQCC value for **2-*d*$_2$** is very close to those recently determined for classical deuteride ligands in the related complexes $[(dppe)_2RuD(D_2)]BPh_4$ (dppe = $PPh_2CH_2CH_2PPh_2$) (DQCC = 79 kHz) (20*b*) and $[(PP_3)RuD_2]$ (PP_3 = $P(CH_2CH_2PPh_2)_3$) (DQCC = 73–76 kHz) (20*a*). The average ^2H resonance in **2b-*d*$_3$** exhibits a T_{1min} (**2b**$_{Ru,D3}$) time of 0.0174 s. Taking into account a fast D–D_2 exchange (see eq. [1]), it is then possible to calculate a T_{1min} value of 0.0190 s for the nonclassical D_2 ligand in **2b-*d*$_3$**. Nonclassical transition metal hydride complexes have been reported to display longer ^2H-T_{1min} times as compared to classical polyhydrides due to motions of the dihydrogen ligands (20). The elongation observed on going from **2b-*d*$_2$** to **2b-*d*$_3$**, however, is very weak, which may be due to a slow-rotating dihydrogen ligand. Thus, the evaluation of ^2H-T_{1min} (or DQCC) is important because it provides an additional support for the genuine nonclassical nature of **2b**.

The IR spectrum of the dihydrogen complex **2b**, obtained by treatment of **2** with HBF_4 at 200 K in dichloromethane solution, shows a ν(CO) band at 2023 cm^{-1}, which is shifted at higher energy as compared to the ν(CO) band of the initial complex. Such high-frequency shifts are commonly observed for transformations of hydride(carbonyl) complexes into cationic nonclassical molecular hydrogen-carbonyl derivatives (2*b*, *f*).

Synthesis and spectroscopic characterization of the H-bonded adduct [{(triphos)Ru(CO)(H)H}···{HOCH(CF$_3$)$_2$}] (2a)

Upon addition of **2** (0.07 M) to a CH_2Cl_2 solution of trifluoroethanol (TFE), HFIP, MeOH, or monofluoroethanol (MFE) at 298 K, significant changes were observed in the ν_{OH} region of the corresponding IR spectrum. To avoid self-association, proton-donor concentrations in the range 0.01–0.03 M were used, so as to work with an excess of **2**. Irrespective of the proton donor, the changes affecting the OH stretching region (Table 3) were indicative of a hydrogen bonding interaction between the alcohol and the hydride ligands in the ruthenium complex.[4] Indeed, the intensity of the

[4] A hydrogen-bonding interaction between the activated alcohol and the oxygen atom of the carbonyl ligand was ruled out in view of the high-frequency shift encompassed by ν_{CO} upon addition of HFIP (1*d*, 2*b*).

© 2001 NRC Canada

Table 3. Spectral characteristics of the H-bonded adducts [{(triphos)Ru(CO)(H)H}···{HOR}] and enthalpy values ($-\Delta H$) relative to their formation in CH_2Cl_2.

ROH	ν_{OH}^{bonded} (cm^{-1})	$\Delta\nu_{OH}$ (cm^{-1})	$-\Delta H$ (kcal mol^{-1})	E_j
CH_3OH	3415	212	4.1	1.41
MFE	3355	254	4.7	1.38
TFE	3254	346	5.8	1.40
HFIP	3160	420	6.6	1.37

band due to the free OH groups decreased, while a new broad and intense band was formed at lower frequency. As previously observed (1*d*, 2*f*), the frequency shifts ($\Delta\nu = \nu_{OH}^{free} - \nu_{OH}^{bonded}$) increase with the proton-donor ability of the alcohol in the order MeOH < MFE < TFE < HFIP.

The Iogansen correlation shown in eq. [4] may be used to estimate the hydrogen-bonding enthalpy values at 298 K from the experimental frequency shifts listed in Table 3 (1*d*, 2*b*).

$$[4] \qquad -\Delta H^\circ = 18\ \Delta\nu/(720 + \Delta\nu)$$

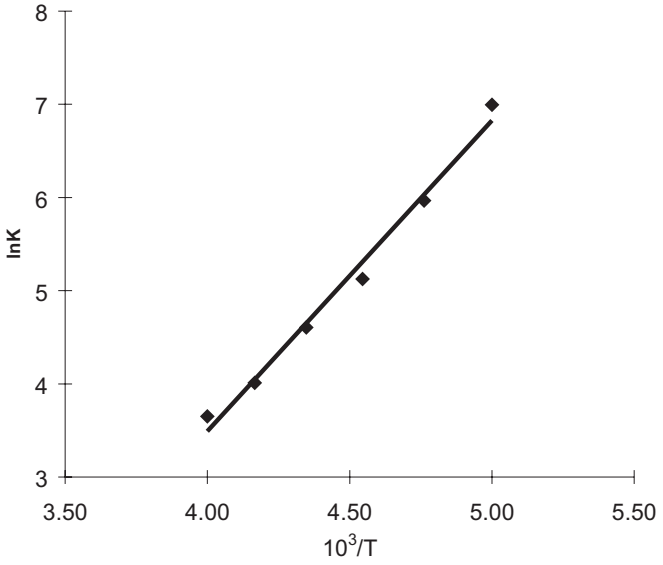
On decreasing the temperature, the band shift ($\Delta\nu_{CO}$) gradually moved to high-frequency reaching a maximum of +15 cm^{-1} at 190 K for a 10-fold excess of alcohol, while a band shift to low-frequency was displayed by the Ru—H stretching of **2**. Indeed, after addition of HFIP (2 to 3 equiv) and cooling down the solution, the ν_{RuH} band at 1871 cm^{-1} moved to low-frequency by 20 cm^{-1}, which is consistent with a hydrogen bonding interaction between the alcohol and a hydride ligand of **2** (1*d*, 2*f*). This behavior led us to assign the two bands at 1949 (ν_{CO}) and 1851 (ν_{RuH}) cm^{-1} to the H-bonded complex **2a**. In contrast, when both the parent hydride **2** and the H-bonded adduct **2a** were contemporaneously present in solution, a unique ν_{CO} and ν_{RuH} band was observed in a position intermediate between the two limits and depending on the molar fraction of **2a** (p(**2a**)). This latter can readily be calculated from eq. [5]

$$[5] \qquad p(\mathbf{2a}) = \frac{\nu_{CO}(\mathbf{2} + \mathbf{2a}) - \nu_{CO}(\mathbf{2})}{\nu_{CO}(\mathbf{2a}) - \nu_{CO}(\mathbf{2})}$$

Using the p(**2a**) data obtained in this way, the formation constants $K_{\mathbf{2-2a}} = [\mathbf{2a}]/[\mathbf{2}][\text{HFIP}]$ have been determined in the temperature range from 200 to 260 K, and hence the enthalpy and entropy values associated with the formation of **2a** have been calculated by the van't Hoff method. The corresponding temperature dependence of ln $K_{\mathbf{2-2a}}$ vs. $1/T$ shown in Fig. 4 gave a $-\Delta H^\circ_{\mathbf{2a}}$ value of 6.7 kcal mol^{-1} in fairly good agreement with the value calculated from eq. [4]. A $-\Delta S^\circ_{\mathbf{2a}}$ value of 19.6 eu was similarly determined from the plot.

Following the method reported by Iogansen (23), the basicity factor (E_j) of the hydride ligand in **2** was calculated as 1.39 ± 0.02 (1*d*, 2*b*). It is worth noticing that this parameter, which characterizes the absolute proton accepting ability of the hydride ligand, irrespective of both proton donor partner and solvent, is significantly greater than those reported for rhenium hydride **1** (E_j = 0.97) and other metal hydride complexes (2*b*) as well as organic bases such as Et_2O (E_j = 1.0) and DMSO (E_j = 1.27) (23). The relatively high E_j value of **2** might explain why this dihydride complex is easily protonated to give the dihydrogen complex **2b** even with relatively weak proton donors such as HFIP and PFTB.

Fig. 4. Temperature-dependence of the equilibrium constant ($K_{\mathbf{2-2a}}$) for the formation of **2a** from **2** and HFIP in CH_2Cl_2 (obtained from IR data).



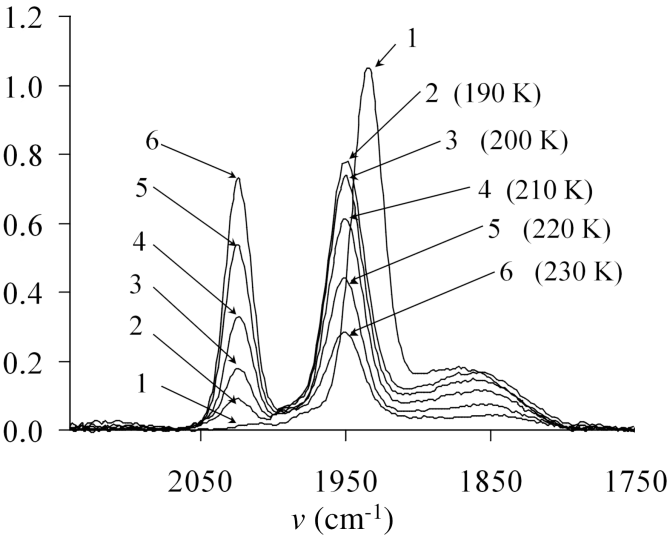


Fig. 5. Variable-temperature IR spectra (ν_{CO} range) of complex **2** (0.006 M) in CH_2Cl_2 at 190 K (curve 1) and in the presence of a 10-fold excess of HFIP in the temperature range between 230 and 190 K (curves 2–6).

Variable-temperature IR and NMR studies of the proton transfer reactions between 2 and HFIP

The reaction of **2** with HFIP (10–12 equiv) was followed by IR spectroscopy in CH_2Cl_2 starting from 200 K. Selected variable-temperature spectra in the ν_{CO} region are reported in Fig. 5. The spectrum at 200 K showed the presence of the dihydrogen complex **2b**, with ν_{CO} at 2023 cm^{-1}, and of the H-bonded adduct **2a** with ν_{CO} at 1949 cm^{-1}. When the temperature was increased to 260 K, the ν_{CO} band of **2b** decreased in intensity while that of **2a** increased.

[a]Determined from NMR data.
[b]Determined from IR data.

Concomitantly, an enhancement of the ν_{RuH} band due to **2a** at ca. 1855–1860 cm^{-1} was observed.

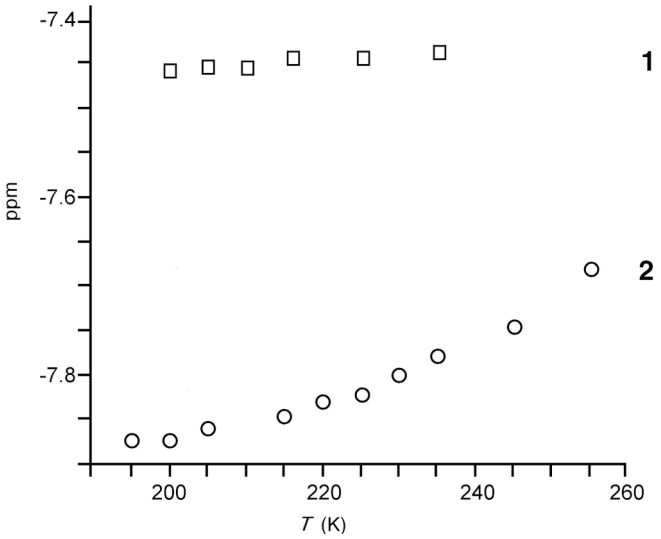
Since the equilibrium between **2a** and **2b** is reversible in the temperature range from 200 to 260 K, the IR spectra allowed us to determine the equilibrium constants $K_{\mathbf{2a-2b}}$ = [**2b**]/[**2a**] and the overall constant $K_{\mathbf{2-2b}}$ = [**2b**]/[**2**][HFIP] for the proton transfer from HFIP to a terminal hydride of **2** to give the dihydrogen complex **2b** via the intermediate H-bonded complex **2a**.

The equilibrium concentrations [**2b**] were obtained directly from the IR experiments. The equilibrium concentrations [**2**], [**2a**], [**2b**], and [HFIP] are related to each other and to the total concentration of hydride (c_2) and proton donor (c_{HFIP}) by the mass-balance eqs. [6*a*] and [6*b*].

$$[6a] \quad c_2 = [\mathbf{2}] + [\mathbf{2a}] + [\mathbf{2b}]$$

$$[6b] \quad c_{HFIP} = [HFIP] + [\mathbf{2a}] + [\mathbf{2b}]$$

Substituting for [**2**] and [HFIP] from eqs. [6*a*] and [6*b*] into equation for $K_{\mathbf{2-2a}}$ and rearranging, eq. [7] was obtained whose solution gave [**2a**].



$$[7] \quad [\mathbf{2a}]^2 + [\mathbf{2a}]\left\{2[\mathbf{2b}] - c_2 - c_{HFIP} - \frac{1}{K_{\mathbf{2-2a}}}\right\} + \{c_2 c_{HFIP} + [\mathbf{2b}]^2 - [\mathbf{2b}](c_2 + c_{HFIP})\} = 0$$

Once the concentrations of each species participating in the proton transfer equilibrium were known, the calculation of the equilibrium constants $K_{\mathbf{2a-2b}}$ and $K_{\mathbf{2-2b}}$ in the temperature range from 200 to 230 K was straightforward (Table 4).

The temperature dependencies of the equilibrium constants with inverse temperature (1/T) are linear and provide the following thermodynamic parameters: $-\Delta H^\circ_{\mathbf{2a-2b}}$ = 8.7 kcal mol^{-1}, $-\Delta S^\circ_{\mathbf{2a-2b}}$ = 42 eu for the formation of **2b** from **2a** and $-\Delta H^\circ_{\mathbf{2-2b}}$ = 16.1 kcal mol^{-1}, $-\Delta S^\circ_{\mathbf{2-2b}}$ = 65 eu for the overall proton transfer. Since the formation of **2a** has been found to involve a $-\Delta H^\circ_{\mathbf{2-2a}}$ value of 6.7 kcal mol^{-1}, it is apparent that the formation of **2a** plays the major role in the proton transfer reaction.

The proton transfer reaction for the system (**2** + HFIP) has also been studied by NMR spectroscopy. The low-temperature addition (200 K) of a twofold excess of HFIP to a CH_2Cl_2 solution of **2** results in a high-field shift of the hydride resonance to –7.86 ppm. Figure 6 illustrates the temperature dependence of the hydride chemical shift observed

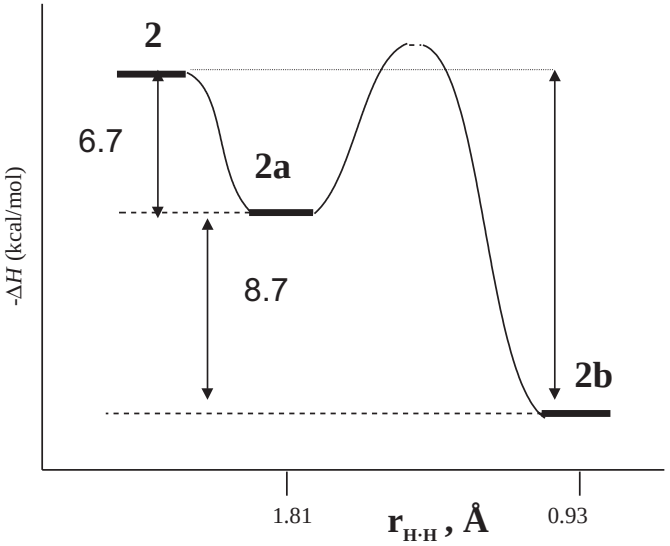
Fig. 6. Temperature-dependence of the chemical shift of the hydride resonance of **2** in CD_2Cl_2 (□), and in the presence of a twofold excess of HFIP (○).

for this solution. The hydride chemical shift of **2** is practically independent from the temperature in the absence of the proton donor (curve 1), while it reaches a plateau at –7.87 ppm below 200 K (curve 2). Therefore, the resonance at –7.87 ppm can be assigned to the H-bonded adduct **2a**. Obviously, the observed hydride resonance is averaged between two nonequivalent positions and, therefore, the chemical shift of the hydride involved in hydrogen bonding can be calculated as –8.29 ppm by eq. [8].

$$[8] \quad \delta(RuH)^{obs} = 0.5\ \delta(RuH^{free}) + 0.5\ \delta(RuH\cdots HOR)$$

From curve 2 in Fig. 6, the molar fractions of **2** (p_{free}) and **2a** (p_{bonded}) were obtained at different temperatures (eq. [9]) and the corresponding equilibrium constants for the formation of the H-bonded complex could be calculated (Table 4). Finally, the $-\Delta H°$ (7.1 kcal mol^{-1}) and $-\Delta S°$ (19.0 eu) values relative to the formation of **2a** were obtained from a standard ln K vs. 1/T plot.

$$[9] \quad \delta(RuH)^{obs} = p_{free}\ \delta(RuH^{free}) + p_{bonded}\ \delta(RuH^{bonded})$$



It is worth noticing that the thermodynamic parameters calculated using variable-temperature NMR and IR experiments are in good agreement with each other.

Positive enthalpy and entropy changes ($\Delta H°$ = 17 kcal mol^{-1}, $\Delta S°$ = 75.8 eu) obtained by NMR methods have been reported for the proton transfer from phenol to the hydride ligand in [RuH_2(dppm)$_2$] (2*a*), while the thermodynamic parameters for the proton transfer to [RuH_2(dmpe)$_2$] (dmpe = bis(dimethylphosphino)ethane) in ethanol (the H-bonded complex was not observed, however) exhibit a negative sign and are only slightly smaller than ours ($-\Delta H°$= 6.0 kcal mol^{-1}, $-\Delta S°$ = 19.9 eu) (24).

It is also worth noticing that the H-bonded complex (**2a**) is thermodynamically more stable than corresponding rhenium complex (**1a**) ($-\Delta H°$ = 4.8 kcal mol^{-1}) (2*b*), which

Scheme 2.

reflects the lower basicity of the hydride ligand in **1** (see the E_j factor).

The variable-temperature spin-lattice relaxation data for a CH_2Cl_2 solution of **2** in the presence of a twofold excess of HFIP showed that the relaxation time of the observed hydride resonance reaches a minimum at 200 K (T_{1min}^{obs} = 0.119 s at 200 MHz). As it is evident from Fig. 5, under these conditions the equilibrium is completely shifted towards the formation of **2a**. Using eq. [10], the observed T_{1min}^{obs} value was employed to calculate T_{1min}^{obs} (RuH···HFIP) (0.0894 s) for the H-bonded hydride ligand in **2a**. Finally, the combination of T_{1min}^{obs} (RuH···HFIP) and of T_1 (0.178 s) measured for **2** (see above) provided a T_{1min} (H···H) value of 0.183 s for **2a**, which is exclusively due to hydride–proton dipole–dipole interactions (12).

$$[10] \quad 1/T_{1min}^{obs} = 0.5/0.178 + 0.5/T_{1min}^{obs} \ (\mathrm{RuH\cdots H})$$

Using the procedure described by Halpern and co-workers (12), the T_{1min} (H···H) relaxation time has been employed to calculate a hydride—proton distance of 1.81 Å in **2a**, which is quite comparable to the value reported for the rhenium system (**1** + PFTB) (1.83 Å) (2*b*). This H—H distance lies in the expected range (1.7–2.0 Å) for transition metal hydride complexes with either intra- (1*a–c*) or intermolecular hydrogen bonds (1*d*, *e*).

We have already shown that **2** (0.008 M) is converted to **2b** in the presence of a 12-fold excess of HFIP in CD_2Cl_2. The dihydrogen complex is clearly observed in the ^{1}H NMR spectrum at 183 K (see above), which also contains an averaged hydride resonance for **2** and **2a**. Consistent with the IR data, it has been found that increasing the temperature leads to a completely reversible redistribution of integral intensities of both signals, thus indicating that all these species are in equilibrium.

An energetic profile for the overall hydrogen-transfer reaction is illustrated in Scheme 2. It is worth noticing that: (*i*) the hydride—proton distance represents the reaction coordinate (determined by NMR spectroscopy); (*ii*) the energy of **2a** is obtained by IR and NMR data; (*iii*) the depth of the second well corresponds to the enthalpy value obtained from the IR data; and (*iv*) the energy level of the transition state for the proton transfer **2a** → **2b** has a purely qualitative character.

Notwithstanding the qualitative character of the profile, the proposed energy levels are quite reasonable. Indeed, it is well known that the formation of H-bonded adducts is a diffusion-controlled process with no energy barrier (25). The observation of separated signals for the hydride ligands in **2a** and **2b**, with no broadening of the resonances at low-temperature, is consistent with a lifetime longer than 10 s for this reaction (26). Accordingly, an upper limit of 10^{-1} s^{-1} can be envisaged for the corresponding rate constant. The bottom limit of rate constant may roughly be estimated considering that our IR technique does not allow one to monitor band-intensity changes for processes faster than 1×10^{-2} s^{-1} (2*e*). Since no intensity change with time is observed, it may be assumed that the lifetime of the proton transfer is shorter than 1 to 2 min, which provides a lower limit of 1×10^{-2} s^{-1} for the rate constant. It may be thus concluded that the transformation of **2a** into **2b** has an activation barrier $-\Delta G^{\ddagger}$ (200 K) of ca. 12 to 13 kcal mol^{-1}, which is in nice agreement with the barrier previously calculated for the related rhenium system [(triphos)Re(CO)$_2$H] with PFTB (2*e*) as well as other literature data. In particular, theoretical studies of proton transfer to Re- and Ru-hydrides have recently shown that the proton-transfer barriers depend on both the metal complex basicity and the strength of the acid and may vary from 10 to 0.7 kcal mol^{-1} (27). On the other hand, rather low rates of proton transfer and dihydrogen complex generation (varying from 1×10^6 to 1×10^{-1} s^{-1} with corresponding activation barriers of ca. 6.5–12 kcal mol^{-1}) have been reported for the reactions of Fe- and Ru-hydrido complexes with strong acids (28).

Conclusions

The (carbonyl)dihydride complex [(triphos)Ru(CO)H$_2$] (**2**) has been found to react with hexafluoro-2-propanol to give the new dihydrogen complex [(triphos)Ru(CO)H(H$_2$)]$^+$ (**2b**) through the H-bonded adduct [{(triphos)Ru(CO)(H)H}···{HOCH(CF$_3$)$_2$}] (**2a**). All these compounds have been characterized by in situ NMR and IR techniques. Variable-temperature IR and NMR studies in CH_2Cl_2 solution have shown that **2**, **2a**, and **2b** are in equilibrium in the temperature range from 190 to 260 K. An energetic profile describing the formation of the dihydrogen complex via the H-bonded adduct has been proposed on the basis of thermodynamic parameters determined experimentally. The proposed energy profile suggests that, at least in thermodynamic terms, the formation of the H-bonded adduct contributes substantially to the overall proton transfer leading to the dihydrogen complex.

Acknowledgments

Thanks are due to NATO (contract "^{2}H-relaxation as a tool to study hydrogen transfer reactions", grant HTECH-CRG 972 135), CNR (Italy) – RAS (Russian Federation) agreement, and RFBR (project No 99–03–33270) for financial support. Support from COST Chemistry Action D17/WG003 is also acknowledged.

Iron complexes of the $N(CH_2CH_2S)_3^{3-}(NS_3)$ ligand with isocyanide co-ligands.

Lyndsey Cooper, Sian C. Davies, Jonathan R. Dilworth, David L. Hughes, Marcin Konkol, Raymond L. Richards, J. Roger Sanders, and Piotr Sobota

Abstract: The complexes $NEt_4[Fe(NS_3)(CNR)]$ (**1**), $[Fe\{Fe(NS_3)(CNR)\}_2\text{-}S,S']$ (**2**), $[Co\{Fe(NS_3)(CNMe)\}_2\text{-}S,S']$ (**3**), and $[Ni\{Fe(NS_3)(CNMe)\}_2\text{-}S,S']$ (**4**) (R = Me, *t*-Bu, or C_6H_{11}(Cy)) have been prepared and the X-ray crystal structures of $NEt_4[Fe(NS_3)(CNMe)]$ (**1a**) and $[Fe\{Fe(NS_3)(CNCy)\}_2\text{-}S,S']$ (**2c**) have been determined. Mössbauer and IR spectroscopic data and room temperature magnetic moments for these complexes are reported.

Key words: iron, cobalt, nickel, thiolate, isocyanide.

Résumé : On a préparé les complexes de $NEt_4[Fe(NS_3)(CNR)]$ (**1**), $[Fe\{Fe(NS_3)(CNR)\}_2\text{-}S,S']$ (**2**), $[Co\{Fe(NS_3)(CNMe)\}_2\text{-}S,S']$ (**3**) et $[Ni\{Fe(NS_3)(CNMe)\}_2\text{-}S,S']$ (**4**) (R = Me, *t*-Bu ou C_6H_{11} (Cy)) et on a déterminé les structures de $NEt_4[Fe(NS_3)(CNMe)]$ (**1a**) et de $[Fe\{Fe(NS_3)(CNCy)\}_2\text{-}S,S']$ (**2c**) par diffraction des rayons X. Pour chacun de ces complexes, on a déterminé les spectres de Mössbauer et IR ainsi que les moments magnétiques à la température ambiante.

Mots clés : fer, cobalt, nickel, thiolate, isocyanure.

[Traduit par la Rédaction]

Introduction

We have been exploring the chemistry of the tripodal NS_3 ligand $N(CH_2CH_2S)_3^{3-}(NS_3)$ in order to investigate the ability of metal sites carrying this ligand to mimic the behaviour of metal–sulfur sites in enzymes such as hydrogenases and nitrogenase. In the former study, some of us have shown that sulfur-bridged, binuclear complexes containing the $\{Fe(\mu\text{-}NS_3)Ni\}$ unit model structural aspects of iron–nickel hydrogenase (1). Recently a rich chemistry of the tripodal nitrogen-donor ligand $[N(CH_2CH_2NSiMe_3)_3]^{3-}(NN_3)$, and its analogues has been developed, including the preparation of the tris(μ-dinitrogen) complex $[Fe\{N_2Mo(NN_3)\}_3]$ as well as the monomer $[Mo(NN_3)(N_2)]$ (2). This prompted us to investigate the ability of metal sites carrying the (NS_3) ligand to bind species on the route from N_2 to NH_3 such as N_2H, N_2H_2, and N_2H_4 and their derivatives, and alternative substrates to N_2 such as CO, cyanides, isocyanides, and azide. We have already reported or communicated some of our results for Mo (3), V (4), and Fe (5). The $Fe(NS_3)$ site is able to bind CO with biologically relevant values of ν(C=O) (5). We, therefore, searched for interactions of this site with other small molecules which are able to function as alternative substrates for dinitrogen, and have developed chemistry of isocyanides as detailed below.

Results and discussion

The blue, mononuclear, terminal RNC complexes $NEt_4[Fe(NS_3)(CNR)]$ (R = Me (**1a**); *t*-Bu (**1b**); or C_6H_{11} (Cy) (**1c**)) were obtained either by treatment of $[Fe(acac)_3]$ and NS_3H_3 with RNC in presence of $Et_4N(OAc)$, or by reduction of $NEt_4[FeCl(NS_3)]$ (5) with sodium amalgam in presence of RNC (rxn. [1]). Compounds **1a** and **1b** form blue crystals, but **1c** could not be crystallized, nor obtained analytically pure, although its spectroscopic data show it clearly to be the analogue of **1a** and **1b**. In the solid, compounds **1** are moderately stable to air, decomposing over 2 to 3 days, but they are more sensitive in solution.

[1] $NEt_4[FeCl(NS_3)] + Na + RNC \rightarrow NEt_4[Fe(NS_3)(CNR)] + NaCl$
(R = Me (**1a**), *t*-Bu (**1b**), or Cy **(1c)**)

The complexes have the RNC ligand bound to five-coordinated Fe in the linear mode as revealed by the X-ray crystal structure of **1a**. The structure (Fig. 1) is similar to that of the carbonyl analogue (5), and consists essentially of a trigonal bipyramid with the terminal MeNC ligand linearly bound in the position *trans* to the apical N atom of the NS_3 ligand, with the three S atoms lying in the equatorial plane.

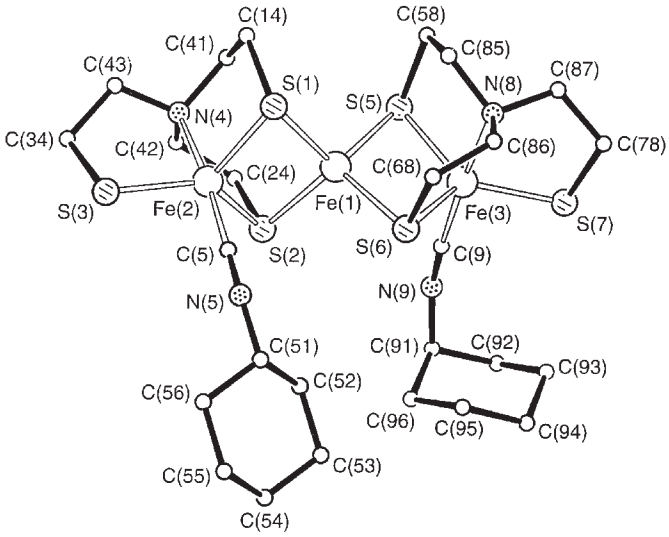
Table 1. Selected molecular dimensions in complex **1a**.



(*a*) About the iron atom			
Fe—S(1)	2.2953(5)	Fe—N(4)	2.049(2)
Fe—S(2)	2.2908(5)	Fe—C(5)	1.805(2)
Fe—S(3)	2.2926(6)		
S(2)-Fe-S(1)	119.09(2)	N(4)-Fe-S(2)	87.24(5)
S(3)-Fe-S(1)	118.73(2)	C(5)-Fe-S(2)	90.48(6)
N(4)-Fe-S(1)	87.87(5)	N(4)-Fe-S(3)	87.37(5)
C(5)-Fe-S(1)	92.35(6)	C(5)-Fe-S(3)	94.69(6)
S(2)-Fe-S(3)	121.61(2)	C(5)-Fe-N(4)	177.51(7)
(*b*) In the isocyanide ligand			
C(5)—N(51)	1.169(3)	N(51)-C(5)-Fe	178.2(2)
N(51)—C(52)	1.411(3)	C(5)-N(51)-C(52)	169.3(2)

Note: Bond lengths are in angstroms (Å), angles in degrees (°), Esds are in parentheses.

Principal structural parameters are presented in Table 1 and show that the Fe—N distance (2.049(2) Å) and average Fe—S distances (2.2929(14) Å) are close to those of the CO analogue, 2.035(7) and 2.274(5) Å respectively (5). The iron atoms are displaced similarly toward the apical C atom, 0.1003(2) and 0.0893(11) Å in **1a** and the CO analogue, respectively, from the 3S equatorial plane. The Fe—C distance 1.805(2) Å and Fe-C-N angle 178.2(2)° are in the expected ranges for linear RNC at an Fe(II) site.

As expected, compounds **1** have NC stretching frequencies in the terminal range (2061–1940 cm^{-1}). These values are lower than those of the corresponding free ligands, in keeping with the lowering of the CO stretching frequency on binding CO to this site, which is clearly electron releasing. The lowering of the NC frequency caused by binding to the d^6 $Fe(NS_3)^-$ site is similar to that produced by binding the analogous d^4 $Re(NS_3)$ site e.g., both **1b** and $[Re(NS_3)(CN\text{-}t\text{-}Bu)]$ (6) have ν(N≡C) at 1975 cm^{-1}, some 162 cm^{-1} lower than the value for the free ligand. The d^3 complex analogues $[V(NS_3)(CNR)]$ (R = *t*-Bu or Cy) do not show such a lowering of the CN stretching frequency (ν(N≡C) = 2173 cm^{-1} in both cases) (4). The electron-releasing properties of the

Fig. 2. View of the trinuclear complex $[Fe\{Fe(NS_3)(CNCy)\}_2]$ (**2c**) with the pseudo-twofold symmetry axis vertical in the plane of the paper. Only the major components of the disordered NS_3 ligands are shown.

V(NS_3) site is clearly less than that of the iron and rhenium systems, in keeping with the inability of the vanadium site to bind CO (4).

Compounds **1** are paramagnetic, with μ_{eff} values in the range 2.61–2.58 μ_B corresponding to an S = 1 state, as observed for the CO analogue (μ_{eff} = 2.79 μ_B) (5). Like the CO analogue, their Mössbauer spectra show a doublet, but the parameters (in the ranges: IS 0.36–0.32, QS 1.27–1.30 mm s^{-1}), are somewhat larger than those of the CO analogue (IS 0.22, QS 0.99 mm s^{-1}) (5).

In addition to the mononuclear complexes, the paramagnetic homo- and hetero-metallic linear cluster complexes $[Fe\{Fe(NS_3)(CNR)\}_2\text{-}S,S']$ (**2**), $[Co\{Fe(NS_3)(CNR)\}_2\text{-}S,S']$ (**3**), and $[Ni\{Fe(NS_3)(CNR)\}_2\text{-}S,S']$ (**4**) have been obtained by two routes. The first route, which involves treatment of $[Fe(acac)_3]$ with RNC and NS_3H_3, gives the very dark green "all iron" complexes (**2 a**–**c**). The second and more general route exploits the donor properties of the ligating S-atoms of complexes **1** and allows the controlled synthesis of the green-black hetero-atom linear clusters **3** and **4**, as shown in rxn. [2].

[2] $2NEt_4[Fe(NS_3)(CNR)] + MCl_2 \rightarrow [M\{Fe(NS_3)(CNR)\}_2\text{-}S,S'] + 2NEt_4Cl$

(M = Fe, R = Me (**2a**), *t*-Bu (**2b**), Cy **(2c)**;
M = Co, R = Me (**3)**; M = Ni, R = Me (**4**))

The linear structure of complexes **2a**–**c** is proven by the X-ray crystal structure of **2c**, shown in Fig. 2. The structure consists of two trigonal bipyramidal $Fe(NS_3)(CNCy)$ units, each of which bridges through two of its S atoms to a central Fe, which has distorted tetrahedral symmetry and lies on an approximate twofold symmetry axis. Principal structural parameters are presented in Table 2. Within the $Fe(NS_3)(CNCy)$ units, the Fe—S distances involving the four bridging S atoms average 2.265(4) Å, but those to the non-bridging S atoms are shorter, mean 2.221(4) Å. The

Note: Bond lengths are in angstroms (Å), angles in degrees (°), Esds are in parentheses.

Fe—S distances about the central Fe have a mean value of 2.307(6) Å. The iron atoms Fe(2) and Fe(3) are displaced from the planes of their three equatorially-arranged sulfur atoms by 0.0805(11) and 0.0696(10) Å, respectively, similar to the values above for complex **1a** and its CO analogue. The apical N-Fe-C-N-C units are basically linear, with dimensions resembling those in **1a**. The isocyanide C-N-C angles in both ligands of **2c** however, essentially identical at 160.25(1)°, deviate more from linearity than in **1a** where the angle is 169.3(2)°. Even greater deviations have been noted in the Re^{III} complexes $[Re(NS_3)(CN\text{-}t\text{-}Bu)]$ and $[Re(NS_3)(CNCH_2COOMe)]$ where the C-N-C angles are 154.0(10) and 150.8(9)°, respectively (6). The limit of the pseudo-symmetry is reached at the cyclohexyl ring junction; both Cy rings have the chair conformation but the C(51)—N(5) bond is equatorial with respect to the ring in one isocyanide ligand, whereas, in the second, C(91)—N(9) is axially orientated.

All the Fe atoms can be regarded as formally in oxidation state two, but solid **2c** has μ_{eff} = 1.72 μ_B per molecule at 20°C showing considerable electronic coupling, and **2a**, **2b**, **3**, and **4** also show similar behaviour (see *Experimental*). The detailed magnetic and electrochemical properties of these and related complexes will form a separate study.

The Mössbauer spectrum of complex **2c** is in accord with its structure, showing resonances corresponding to two different iron(II) sites, one having twice the intensity of the other (*Experimental*). Since the Mössbauer spectra of **2a**, **2b**, **3**, and **4** all have similar IS and QS values to those of **2c**, all of these complexes are considered to have an analogous linear cluster structure. The CO analogue has the same linear structure also (5) and the members of this class of complex have structural similarities to the linear clusters $[NEt_4]_3[Fe_3S_4(SPh)_4]$ (7) and $[NEt_4]_3[VFe_2S_4Cl_4]$ (8).

The NC stretching frequencies of **2**, **3**, and **4** are increased relative to the corresponding monomeric precursors (*Experimental*). A similar increase was observed for the CO analogue on passing from the monomer to the linear cluster complexes (5). Clearly the ability of the $Fe(NS_3)$ site to release electron density to CO or RNC is reduced in the linear clusters as a consequence of the loss of anionic charge and by two of its sulfur ligands utilising lone pairs to bind a central metal atom.

Conclusions

The $Fe(NS_3)$ site is able to support a number of co-ligands including isocyanides, and its tendency to bridge through sulfur can be used to synthesise linear cluster complexes. The stretching frequencies of CO at mononuclear and linear cluster $Fe(NS_3)$ sites have values which are similar to those observed in stop-flow IR studies of *Klebsiella pneumoniae* nitrogenase (5). Corresponding data for RNC interactions with the enzyme are not yet available to ascertain how extensively the behaviour of the $Fe(NS_3)$ sites resembles that of the enzyme.

Experimental

General

All operations were carried out under a dry dinitrogen atmosphere, using standard Schlenk techniques. Solvents were distilled under dinitrogen from the appropriate drying agents prior to use. Starting materials were obtained from Aldrich Chemical Co. and used without further purification unless stated otherwise. Methyl isocyanide was made by the reaction of *N*-methylformamide with *p*-toluenesulfonyl chloride in quinoline at 75°C and purified by trap-to-trap distillation at 15 mm Hg (1 mm Hg = 133.222 Pa). NS_3H_3 was made by a modification of the literature method (4, 9–11) via tris(chloroethyl)amine hydrochloride (CAUTION-VESICANT) This work was carried out in an enclosed Schlenk apparatus whilst wearing heavy duty gloves and a face mask.

$[FeCl_2(MeCN)_2]$, $[FeCl_2(DMSO)_3]$ (DMSO = dimethylsulfoxide), and their cobalt and nickel analogues were made by heating the anhydrous metal chlorides in MeCN or DMSO until they dissolved and crystallizing by adding diethyl ether. IR spectra were recorded on PerkinElmer 883 or Shimadzu FT-IR 810M instruments in Nujol™ mulls. Mössbauer parameters were determined at 77 K by Dr D.J. Evans and Mrs E. Barclay of this laboratory, using an ES-technology MS105 spectrometer having a 925 MBq ^{57}Co source in a rhodium matrix at ambient temperature, referenced against a 25 μm iron foil at 295 K. Magnetic moment determinations at 293 K were in the solid state, using a

Johnson Matthey Gouy balance. Microanalyses were by Mr A. Saunders of the University of East Anglia (CHN) or by Southern Science, Falmer Laboratories, East Sussex (metals).

Syntheses

*Preparation of $Et_4N[Fe(NS_3)(CNMe)]\cdot MeCN$ (**1a**)*

$[Fe(acac)_3]$ (0.71 g, 2.0 mmol), $Et_4NOAc\cdot 4H_2O$ (0.65 g, 2.5 mmol), and MeNC (0.4 g, 10 mmol) were stirred in MeCN (10 mL) for a few minutes, then NS_3H_3 (0.6 g, 3 mmol) in MeCN (5 mL) was added, whereupon the solution turned blue. After 1 h it was filtered and MeCN (5 mL) and ether (20 mL) were added as a layer. After 3 days large blue crystals deposited, which were filtered off, washed with MeCN:ether and then ether, and dried in a vacuum; yield 0.35 g (38%). Mössbauer (mm s^{-1}): IS 0.36, QS 1.27. μ_{eff} = 2.61 μ_B (S = 1). IR (cm^{-1}): 2291, 2246 (C≡N), 2061 (N≡C). Anal. calcd. for $C_{18}H_{38}FeN_4S_3$: C 46.8, H 8.2, N 12.1; found: C 46.3, H 8.2, N 11.7.

*Preparation of $Et_4N[Fe(NS_3)(CN\text{-}t\text{-}Bu)]$ (**1b**)*

$Et_4N[FeCl(NS_3]$ (0.83 g, 2 mmol) was treated with sodium amalgam (70 g, 0.5% Na) in MeCN (20 mL). After 20 min the solution became yellow and was filtered through Celite™. *t*-BuNC (0.8 g, 10 mmol) was added immediately to the filtrate, which became blue. Ether (60 mL) was then added as a layer to give, after 2 h, dark blue microcrystals (0.14 g, 15%), which were filtered off, washed with ether, and dried in a vacuum. Mössbauer (mm s^{-1}): IS 0.32, QS 1.30. μ_{eff} = 2.58 μ_B (S = 1). IR (cm^{-1}): 1975 (N≡C). Anal. calcd. for $C_{19}H_{41}FeN_3S_3$: C 49.2, H 8.9, N 9.1; found: C 48.1, H 8.9, N 8.7.

*Preparation of $Et_4N[Fe(NS_3)(CNCy)]$ (**1c**)*

This was made similarly from reduced $Et_4N[FeCl(NS_3)]$ by treatment with CyNC, in 35% yield. A good analysis was not obtained (see text). Mössbauer (mm s^{-1}): IS 0.33, QS 1.29. IR (cm^{-1}): 2023, 1940 (N≡C). Anal. calcd. for $C_{21}H_{43}FeN_3S_3$: C 51.5, H 8.8, N 8.6; found: C 49.1, H 8.2, N 9.1.

*Preparation of $[Fe\{Fe(NS_3)(CNMe)\}_2$-S,S′] (**2a**)*

$[Fe(acac)_3]$ (0.71 g, 2 mmol) and MeNC (0.4 g, 10 mmol) were dissolved in MeCN (40 mL), and NS_3H_3 (0.6 g, 3 mmol) in MeCN (5 mL) was added. The solution turned dark red, but within 30 min it turned dark green and deposited black needles after 3 h which were filtered off, washed with ether, and dried in a vacuum (yield: 0.13 g, 0.2 mmol, 30% with respect to iron). Mössbauer (mm s^{-1}): IS 0.59, QS 2.06 (rel. intensity 1); IS 0.33, QS 1.38 (rel. intensity 2). μ_{eff} = 2.92 μ_B. IR (cm^{-1}): 2099 (N≡C). Anal. calcd. for $C_{16}H_{30}Fe_3N_4S_6$: C 30.1, H 4.6, N 8.8; found: C 30.1, H 4.6, N 8.9.

*Preparation of $[Fe\{Fe(NS_3)(CN\text{-}t\text{-}Bu)\}_2$-S,S′] (**2b**)*

$[Fe(acac)_3]$ (2.13 g, 6 mmol) and *t*-BuNC (3 g, 36 mmol) were dissolved in ether (40 mL) and NS_3H_3 (1.2 g, 6 mmol) was added. The mixture was stirred overnight and a brown precipitate was formed which turned dark green on standing overnight. It was filtered off, washed with ether, and dried in a vacuum; yield 1.0 g (70% with respect to Fe). Mössbauer (mm s^{-1}): IS 0.58, QS 2.04 (rel. intensity 1); IS 0.32, QS 1.39 (rel. intensity 2). μ_{eff} = 1.72 μ_B. IR (cm^{-1}): 2098, 2065 (N≡C). Anal. calcd. for $C_{22}H_{42}Fe_3N_4S_6$: C 36.6, H 5.8, N 7.8; found: C 36.7, H 5.6, N 7.7.

*Preparation of $[Fe\{Fe(NS_3)(CNCy)\}_2$-S,S′] (**2c**)*

This was made similarly using CyNC in ether, in 82% yield with respect to Fe. Mössbauer (mm s^{-1}): IS 0.67, QS 2.01 (rel. intensity 1); IS 0.30, QS 1.47 (rel. intensity 2). μ_{eff} = 1.72 μ_B. IR (cm^{-1}): 2084, 2060 (N≡C). Anal. calcd. for $C_{26}H_{46}Fe_3N_4S_6$: C 40.3, H 5.9, N 7.2; found: C 40.4, H 5.9, N 7.4.

*Preparation of $[Co\{Fe(NS_3)(CNMe)\}_2$-S,S′] (**3**)*

$[CoCl_2(DMSO)_3]$ (0.10 g, 0.3 mmol) in methanol (10 mL) was added to $Et_4N[Fe(NS_3)(CNMe)]$ (0.24, 0.6 mmol) in methanol (20 mL). A black precipitate formed. The next day this was filtered off, washed with methanol and ether, and dried in a vacuum (yield: 0.06 g, 34%). Mössbauer (mm s^{-1}): IS 0.29, QS 1.52. IR (cm^{-1}): 2105 (N≡C). Anal. calcd. for $C_{16}H_{30}CoFe_2N_4S_6$: C 30.0, H 4.7, N 8.7, Co 9.2, Fe 17.5; found: C 29.7, H 4.9, N 8.2, Co 9.9, Fe 17.3.

*Preparation of $[Ni\{Fe(NS_3)(CNMe)\}_2$-S,S′] (**4**)*

This was made similarly from $[NiCl_2(DMSO)_3]$ in 76% yield. Mössbauer (mm s^{-1}): IS 0.27, QS 1.61. μ_{eff} = 2.26 μ_B. IR (cm^{-1}): 2103 (N≡C). Anal. calcd. for $C_{16}H_{30}Fe_2N_4NiS_6$: C 30.0, H 4.7, N 8.7, Fe 17.5, Nil 9.2; found: C 30.0, H 4.9, N 8.2, Fe 15.6, Nil 9.1.

Crystal structure analyses

*$NEt_4[Fe(NS_3)(CNMe)]\cdot MeCN$ (**1a**)*

Crystal data: $C_8H_{20}N\cdot C_8H_{15}FeN_2S_3\cdot C_2H_3N$, MW = 462.5. Orthorhombic, space group $P2_12_12_1$ (No. 19), a = 16.664(2), b = 14.2340(12), c = 9.929(2) Å, V = 2355.1(6) $Å^3$, Z = 4, D_c = 1.31 g cm^{-3}, $F(000)$ = 992, T = 140 K, μ (Mo Kα) = 9.2 cm^{-1}, λ (Mo Kα) = 0.71069 Å.

Crystals are black, irregular octahedra; in thin section they are blue, decomposing in air to orange over two to three days. Most are twinned, and from preliminary photographic examination, some crystals show small variations in cell parameters and diffraction intensities. One, ca. 0.83 × 0.48 × 0.48 mm, sealed in a capillary tube, was mounted on an Enraf–Nonius CAD4 diffractometer (with monochromated radiation) for determination, at room temperature, of accurate cell parameters (from the settings of 25 reflections, θ = 10 to 11°, each centred in four orientations). The sample, shown to be twinned, was then cooled to 140 K, the cell parameters were re-determined, and diffraction intensities of the major twin were recorded. Of the 3825 unique reflections to θ_{max} = 30°, 3537 were "observed" with $I > 2\sigma_I$; the 00l reflections, common to both twins, were removed from the data set, leaving 3819 and 3532 reflections, respectively.

During processing, corrections were applied for Lorentz polarization effects, absorption (by semi empirical ψ-scan methods), and to eliminate negative net intensities (by Bayesian statistical methods). No deterioration correction was necessary. The structure was determined by the direct methods routines in the SHELXS program (12) and refined by full-matrix least-squares methods, on F^2's, in SHELXL (13). There is disorder in the N-bonded methylene groups in

© 2001 NRC Canada

the NS_3 ligand, with occupancy ratio of 0.736:0.264(2). All the non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included in idealised positions; later, the parameters of those in the cation, the major component of NS_3 ligand and the solvent molecule were refined freely, while the remainder were set to ride on those of the parent carbon atoms. At the conclusion of the refinement, $wR_2 = 0.051$ and $R_1 = 0.026$ (13) for all 3819 reflections weighted $w = [\sigma^2(F_o^2) + 0.180P]^{-1}$ with $P = (F_o^2 + 2F_c^2)/3$; for the observed data only, $R_1 = 0.022$. In the final difference map, the highest peaks (to ca. 0.2 e Å^{-3}) were close to a methylene group in the cation. Scattering factors for neutral atoms were taken from ref. 14. Computer programs used in this analysis have been noted above or in Table 4 of ref. 15, and were run on a DEC-Alpha Station 200 4/100 in the Department of Biological Chemistry, John Innes Centre.

[Fe{Fe(NS$_3$)(CNCy)}$_2$-S,S′]·nH$_2$O ***(2c)***

Crystal data: $C_{26}H_{46}Fe_3N_4S_6{\cdot}n(H_2O)$, with *n* ca. 0.2, MW = 778.2. Monoclinic, space group $P2_1/n$ (equiv. to No. 14), $a = 17.112(2)$, $b = 11.3486(8)$, $c = 17.313(2)$ Å, $\beta = 97.693(8)°$, $V = 3331.7(5)$ Å^3, $Z = 4$, $D_c = 1.551$ g cm^{-3}, $F(000) = 1624$, $T = 293$ K, μ (Mo Kα) = 16.9 cm^{-1}, λ (Mo Kα) = 0.71069 Å.

Crystals are black polyhedra. One, ca. 0.36 × 0.21 × 0.17 mm, was mounted on a glass fibre and coated with epoxy resin. Following a similar procedure to that described above, 4058 unique reflections to $\theta_{max} = 22°$ were measured at room temperature; 2523 were observed with $I > 2\sigma_I$. One reflection, whose intensity measurement was suspect, was not included in the refinement process.

During refinement, both NS_3 ligands were both found to have two alternative conformations; these were refined independently, each with its complement of hydrogen atoms included in idealised positions and with temperature factors riding on those of the parent carbon atoms. Hydrogen atoms were included similarly in the cyclohexyl groups. The non-hydrogen atoms, except for those in the minor components in the disordered ligands, were refined with anisotropic thermal parameters. A persistent difference peak was included as a partially occupied water molecule. At the conclusion of the refinement, $wR_2 = 0.132$ and $R_1 = 0.086$ (12) for the 4057 reflections weighted $w = [\sigma^2(F_o^2) + (0.0593P)^2]^{-1}$; for the observed data only, $R_1 = 0.051$. In the final difference map, the highest peaks (to ca. 0.8 e Å^{-3}) were all in the region of the iron-sulfur core of the molecule.

Acknowledgments

We thank the BBSRC and the EU (SOCRATES programme) for support and Dr A. Trzeciak for helpful discussions.

Synthesis, characterization, and reactivity of manganese(II) and iron(II) trifluoroacetates. Crystal and molecular structure of two linkage isomers of polynuclear $[Mn(CF_3COO)_2(THF)_2]_n$

Fausto Calderazzo, Ulli Englert, Guido Pampaloni, Vincenzo Passarelli, Giovanna Serni, and Ruimin Wang

Abstract: The trifluoroacetates of manganese(II) and iron(II) have been prepared as THF or DMF adducts by reaction of metallic manganese or pentacarbonyliron(0) in THF or DMF, respectively, with CF_3COOH–$(CF_3CO)_2O$. Crystals of two linkage isomers of polynuclear $[Mn(CF_3COO)_2(THF)_2]_n$ have been obtained differing in the distribution of the bridging trifluoroacetato groups within the repeating units, namely $[(THF)_2Mn(\mu\text{-}CF_3COO)_3Mn(THF)_2(\mu\text{-}CF_3COO)]$ and $[(THF)_2Mn(\mu\text{-}CF_3COO)_2Mn(\mu\text{-}CF_3COO)_2(THF)_2]$. Photolysis of $Fe(CO)_5$ in CF_3COOH–$(CF_3CO)_2O$ mixtures or in neat $(CF_3CO)_2O$ gives the trifluoroacetato of iron(II) $Fe(CF_3COO)_2$, whose formation may occur through the intermediacy of $Fe_2(CO)_9$.

Key words: linkage isomers, manganese, iron, carboxylates, X-ray structure.

Résumé : Par réaction du manganèse métallique ou du pentacarbonylfer(0) avec du CF_3COOH–$(CF_3CO)_2O$, en solution dans le THF ou le DMF, il est possible de préparer les trifluoroacétates de manganèse(II) ou de fer(II) sous la forme d'adduits avec du THF ou du DMF. On a obtenu des cristaux pour deux isomères de liaison de l'entité polynucléaire $[Mn(CF_3COO)_2(THF)_2]_n$; ils ne diffèrent que par la distribution des groupes trifluoroacétato qui forment les ponts dans les motifs de la chaîne, soit le $[(THF)_2Mn(\mu\text{-}CF_3COO)_3Mn(THF)_2(\mu\text{-}CF_3COO)]$ et $[(THF)_2Mn(\mu\text{-}CF_3COO)_2Mn(THF)_2(\mu\text{-}CF_3COO)_2(THF)_2]$. La photolyse du $Fe(CO)_5$ dans des mélanges de CF_3COOH–$(CF_3CO)_2O$ ou dans du $(CF_3CO)_2O$ pur conduit à la formation du trifluoroacétatofer(II), $Fe(CF_3COO)_2$, dont la formation peut se produire par l'intermédiaire de $Fe_2(CO)_9$.

Mots clés : isomères de liaison, manganèse, fer, carboxylates, structure par diffraction des rayons X.

Introduction

Carboxylates of transition- and nontransition elements occupy a central position in coordination chemistry (1). More recently, the discovery of new applications has increased the interest in the chemistry of metal carboxylates. Trifluoroacetates are important in the production of ferroelectrics, and in the thin-film coating of complex oxides in the high-T_c superconductor field (2).

Moreover, trifluoroacetates offer a number of advantages with respect to unsubstituted carboxylates: they are generally more soluble in common organic solvents and in some cases they can be sublimed at relatively low temperature. Moreover, trifluoroacetic acid being a relatively strong acid, the conjugated base ($[CF_3COO]^-$) is weakly basic and may be easily displaced from the coordination sphere of a metal or at least can easily behave as a monodentate ligand, leaving a free coordination position.

In continuation of our recent work (3) on triflato- or trifluoracetato complexes of vanadium(II), it was believed that homoleptic[3] trifluoroacetato derivatives should be further explored, as these derivatives of transition metals are limited in

[3]In the context of this paper, a homoleptic derivative is a compound which contains trifluoroacetato ligands only, their number corresponding to the formal oxidation state of the metal.

 DOI: 10.1139/cjc-79-5/6-495 © 2001 NRC Canada

number. A few compounds have been crystallographically characterized, namely $M_2(CF_3COO)_4$, M = Mo (4), W (5), $Ru_2(CF_3COO)_5$ (6), $Rh_2(CF_3COO)_4$ (7), $Pd_n(CF_3COO)_{2n}$, n = 3 (8), 4 (9), and $Ag(CF_3COO)$ (10). We therefore decided to study the manganese(II) and iron(II) carboxylato systems and in this paper we report the synthesis of the trifluoroacetates of manganese(II) and iron(II) and their complexes with Lewis bases. In the course of this work we have encountered an unusual type of linkage isomerism for the manganese(II) derivatives.

Experimental

All operations were carried out using standard Schlenk-tube techniques, under an atmosphere of prepurified nitrogen. The reaction vessels were oven dried prior to use. Solvents were dried by conventional methods.

Elemental analyses were performed with a Carlo Erba Mod. 1106 elemental analyzer. Infrared spectra were recorded with a PerkinElmer mod. FT 1725X instrument on solutions or Nujol or polychlorotrifluoroethylene mulls of the compounds prepared under rigorous exclusion of moisture and oxygen. The presence of solvent (THF, DMF, or trifluoroacetic acid) in the compounds reported in this paper was qualitatively established by IR spectroscopy and quantitatively confirmed by gravimetric determination of the liquid collected at liquid nitrogen temperature upon thermal decomposition at about 250°C/10^{-1} torr (1 torr = 133.322 Pa). Photolytic reactions were performed in a quartz apparatus equipped with a 150 W mercury lamp.

Pentacarbonyliron (Fluka) and finely divided manganese (Fluka) were commercially available and were used without further purification. Di-iron enneacarbonyl ($Fe_2(CO)_9$) was prepared according to literature (11).

Synthesis of $Mn(CF_3COO)_2 \cdot n$THF

A mixture of CF_3COOH (60 mL) and $(CF_3CO)_2O$ (10 mL) was treated with finely divided manganese (2.58 g, 46.96 mmol) at room temperature. Evolution of gas and formation of a colourless solid were observed. After 12 h stirring at room temperature, the mixture, still containing unreacted manganese, was refluxed for 6 h. The volatiles were evaporated to dryness in vacuo and the colourless residue (with broad absorptions above 3000 and at 1781(s) cm^{-1} due to trifluoroacetic acid) was dissolved in THF (100 mL). After filtration, the volatiles were removed in vacuo at room temperature and the residue was heated at 120°C/10^{-2} torr (1 torr = 133.322 Pa) for 5 h obtaining 12.4 g (76% yield) of $Mn(CF_3COO)_2 \cdot 0.9$ THF.[4] IR (Nujol – polychlorotrifluoroethylene mull) $\bar{\nu}$ (cm^{-1}): 2964 m-w, 2915 m-w, 1721 s, 1685 vs (ν_{as} (COO)), 1663 w, 1462 m-s (ν_s (COO)), 1375 w, 1211 vs (ν_{as} (CF_3)), 1151 s (ν_s (CF_3)), 1027 m (ν_{as} (COC)), 920 w, 875 m-s (ν_s (COC)), 851 m-s, 798 s, 726 s, 616 w, 524 w, 475 w. Magnetic data: $\chi_M^{corr} = 1.1 \times 10^{-2}$ cgsu, diam. corr. = -1.36×10^{-4} cgsu, μ_{eff} (293 K) = 5.08 BM. Anal. calcd. for $C_{7.6}H_{7.2}F_6MnO_{4.9}$: C 26.4, H 2.1, Mn 15.9; found: C 26.0, H 2.4, Mn 16.0. The compound was recrystallized from THF–heptane affording colourless crystals.

Crystal structure solution and refinement $(Mn(CF_3COO)_2(THF)_2)$[5]

Crystals suitable for the X-ray structural determination were chosen within the mother liquor (heptane + THF) to avoid their collapse upon filtration and drying in vacuo. Crystal data, data collection parameters, and refinement results are in Table 1.

Structure solution based on direct methods (12) and refinement on structure factors (13) were straightforward. Highly anisotropic displacement parameters for the trifluoromethyl groups and the five-membered THF rings are considered to be responsible for the relatively high R factors.

[4] On several preparations, the amount of THF retained by the compound depends on the drying time in vacuo. The THF content of the solid was determined by collecting the volatiles (THF by IR spectroscopy) in a liquid nitrogen trap upon heating the sample at 250°C/10^{-2} torr (1 torr = 133.322 Pa). The compound darkens at ca. 220°C without melting.

While choosing the crystals for the X-ray diffractometric experiment, it was noted that some of them had a different shape. The low quality of these crystals prevented a conventional refinement of the structure, although it was possible to establish the atom connectivity.[6]

Synthesis of $Fe(CF_3COO)_2 \cdot n$DMF from $Fe(CO)_5$

A golden yellow solution of $Fe(CO)_5$ (2 mL, 15.2 mmol) in DMF (25 mL) was treated with a mixture of CF_3COOH (2.34 mL, 30.4 mmol) and $(CF_3CO)_2O$ (0.43 mL, 3.04 mmol). After 15 h reflux, no carbonyl derivatives were detected in the solution (IR spectrum in the carbonyl stretching region). The colourless solution was evaporated at 80°C/10^{-2} torr (1 torr = 133.322 Pa), thus obtaining a pale yellow liquid residue. After addition of toluene (25 mL) the mixture was evaporated (80°C/10^{-2} torr (1 torr = 133.322 Pa)) affording a colourless solid. In some instances, this operation should be repeated at least three times to obtain a microcrystalline solid. The residue was suspended in heptane (25 mL). After filtration and washing with heptane (2 × 5 mL), the solid was dried in vacuo at room temperature affording 4.0 g (67% yield) of $Fe(CF_3COO)_2 \cdot 1.5$DMF.[7] IR (Nujol – polychlorotrifluoroethylene mull) $\bar{\nu}$ (cm^{-1}): 2943 m-w, 1729 m, 1646 vs (ν_{as} (COO)), 1496 m-s, 1456 m-s (ν_s (COO)), 1435 m-s, 1376 s, 1208 vs (ν_{as} (CF_3)) 1144 s ($\nu_s(CF_3)$), 844 m-s, 795 m-s, 724 s, 670 m-w, 453 s, 409 m-w. Magnetic data: χ_M^{corr} = 1.1 × 10^{-2} cgsu, diam. corr. = –1.60 × 10^{-4} cgsu, μ_{eff} (293 K) = 5.08 BM. Anal. calcd. for $C_{8.5}H_{10.5}F_6FeN_{1.5}O_{5.5}$: C 26.1, H 2.7, N 5.4, Fe 14.3; found: C 25.7, H 2.4, N 5.1, Fe 14.5.

The compound was heated in vacuo at 120°C for 4 h which caused partial loss of DMF and gave $Fe(CF_3COO)_2 \cdot 0.9$DMF as established by elemental analysis. Attempts to remove DMF completely produced darkening and decomposition.

Synthesis of $Fe(CF_3COO)_2 \cdot n CF_3COOH$

By photolysis of $Fe(CO)_5$ in CF_3COOH–$(CF_3CO)_2O$

A golden yellow solution of $Fe(CO)_5$ (2 mL, 15.2 mmol) in CF_3COOH (100 mL) and $(CF_3CO)_2O$ (2 mL) was photolyzed at 20°C for 2 h. Evolution of gas and formation of a colourless solid were observed. The solid was filtered off and dried in vacuo at room temperature affording 4.54 g (58.5% yield) of $Fe(CF_3COO)_2.2CF_3COOH$. IR (Nujol – polychlorotrifluoroethylene mull) $\bar{\nu}$ (cm^{-1}): 3200 m-br, 1781 m, 1697 vs (ν_{as} (COO)), 1450 m-s (ν_s (COO)), 1204 vs (ν_{as} (CF_3)), 1140 s ($\nu_s(CF_3)$), 855 m-s, 820 w, 796 m-s, 728 s, 705 m-s, 522 m-w, 458 m-w, 420 m-w. Magnetic data: χ_M^{corr} = 1.04 × 10^{-2} cgsu, diam. corr. = –1.69 × 10^{-4} cgsu, μ_{eff} (293 K) = 4.94 BM. Anal. calcd. for $C_8H_2F_{12}FeO_8$: C 18.9, H 0.4, Fe 10.8; found: C 18.3, H 0.3, Fe 10.7. The solution was evaporated to dryness at 60°C/10^{-2} torr (1 torr = 133.322 Pa) and 1.1 g of $Fe(CF_3COO)_2 \cdot CF_3COOH$ was thus obtained. Anal. calcd. for $C_6HF_9FeO_6$: C 18.2, H 0.2 Fe 14.1; found: C 17.7, H 0.1, Fe 13.8.

By photolysis of $Fe(CO)_5$ in CF_3COOH

A golden yellow solution of $Fe(CO)_5$ (2 mL, 15.2 mmol) in CF_3COOH (100 mL), was photolyzed at 20°C. Evolution of gas (H_2 and CO by gas chromatography) took place. After 9 h, an IR spectrum of the solution showed unreacted $Fe(CO)_5$ as the only carbonyl species. The solution was evaporated to dryness in vacuo at room temperature affording 1.87 g (28% yield) of $Fe(CF_3COO)_2 \cdot 1.4CF_3COOH$. IR (Nujol – polychlorotrifluoroethylene mull) $\bar{\nu}$ (cm^{-1}): 3200 m-br, 1785 m, 1698 vs (ν_{as} (COO)), 1455 m-s (ν_s (COO)), 1204 vs ($\nu_{as}(CF_3)$), 1140 s ($\nu_s(CF_3)$), 855 m-s, 820 w, 796 m-s, 728 s, 705 m-s, 522 m-w, 458 m-w. Anal. calcd. for $C_{6.8}H_{1.4}F_{10.2}FeO_{6.8}$: C 18.5, H 0.3, Fe 12.6; found: C 18.3, H 0.4, Fe 12.6.

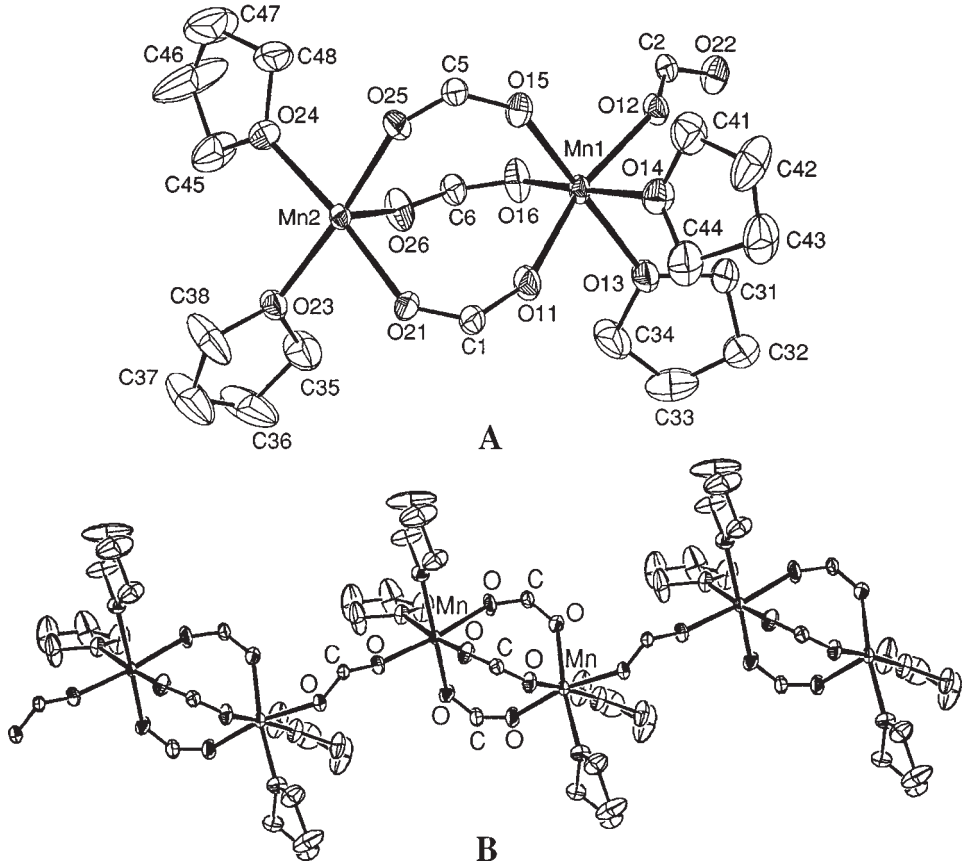
By photolysis of $Fe(CO)_5$ in $(CF_3CO)_2O$

A golden-yellow solution of $Fe(CO)_5$ (2 mL, 15.2 mmol) in $(CF_3CO)_2O$ (45 mL), was photolyzed at 20°C. Evolution of gas (CO by gas chromatography) and separation of a colourless solid took place during photolysis (7 h). The mixture was filtered and the solid was dried in vacuo at room temperature affording 2.3 g (48% yield) of $Fe(CF_3COO)_2 \cdot 0.3CF_3COOH$. IR (Nujol – polychlorotrifluoroethylene mull) $\bar{\nu}$ (cm^{-1}): 3200 w-br, 1751 w, 1694 vs (ν_{as} (COO)), 1455 m-s (ν_s (COO)), 1206 vs (ν_{as} (CF_3)) 1160 s (ν_s (CF_3)), 858 m-s, 797 m-s, 729 s, 614 m-w, 523 m-w, 461 m-w. Magnetic data: χ_M^{corr} = 1.17 × 10^{-2} cgsu, diam. corr. = –1.00 × 10^{-4} cgsu, μ_{eff} (293 K) = 5.26 BM. Anal. calcd. for $C_{4.6}H_{0.3}F_{6.9}FeO_{4.6}$: C 17.5, H 0.1, Fe 17.7; found: C 17.5, H 0.0, Fe 17.6. The mother liquor was evaporated at 80°C/10^{-2} torr (1 torr = 133.322 Pa) in a trap cooled at liquid nitrogen temperature and the distillate showed (GC–MS) the presence of hexafluoro–2,3-butanedione ($(CF_3CO)_2$).

By reaction of $Fe_2(CO)_9$ in CF_3COOH–$(CF_3CO)_2O$

An orange suspension of $Fe_2(CO)_9$ (0.651 g, 1.8 mmol) in a 85:15 mixture (v/v) of CF_3COOH–$(CF_3CO)_2O$ (30 mL) was stirred in the dark for 12 h at room temperature, thus obtaining a pale yellow solution (free from absorptions in the carbonyl stretching region) which was evaporated to dryness in vacuo at room temperature. The pale yellow $Fe(CF_3COO)_2 \cdot 0.8CF_3COOH$ (0.43 g, 64%) was obtained as a microcrystalline solid. IR (Nujol – polychlorotrifluoroethylene mull) $\bar{\nu}$ (cm^{-1}): 3210 w-br, 1783 w, 1694 vs-br (ν_{as} (COO)), 1457 m-s (ν_s (COO)), 1203 vs (ν_{as} (CF_3)), 1166 s (ν_s (CF_3)), 852 m-s, 797 m-s, 729 s, 702 w, 615 m-w, 522 w, 455 m-w. Anal. calcd. for $C_{5.6}H_{0.8}F_{8.4}FeO_{5.6}$: C 18.0, H 0.2, Fe 15.0; found: C 17.7, H 0.1, Fe 15.0.

Reaction of $Fe(CF_3COO)_2 \cdot 2CF_3COOH$ with THF



A solution of $Fe(CF_3COO)_2 \cdot 2CF_3COOH$ (1.273 g, 2.5 mmol) in THF (10 mL) was stirred at room temperature for 4 h. The solid which formed on addition of heptane (30 mL) was filtered off, washed with heptane (2 × 10 mL), and dried in vacuo at room temperature affording 0.80 g

[6] Crystal data: MW = 425.19; crystal system: monoclinic; space group: $P2_1/c$ (no. 14); a = 8.21(5) Å, b = 10.88(5) Å, c = 19.52(5) Å; V = 1743(1) Å^3; Z = 4; D_c = 1.62 g cm^{-3}; μ = 8.09 cm^{-1}; $F(000)$ = 860; T = 203 K. The structure was solved by direct methods. 1164 independent reflections with $I > 2\,\sigma(I)$ and 101 variables were used in the refinement which converged at values of R = 0.216 and Rw = 0.238.

[7] On several preparations, the amount of DMF retained by the compound was found to depend on the isolation procedure. The DMF content of the solid was determined by collecting the volatiles (DMF by IR spectroscopy) in a liquid nitrogen trap upon heating the sample at 250°C/10^{-2} torr (1 torr = 133.322 Pa).

Results and discussion

Manganese

The reaction of finely divided manganese with CF_3COOH in the presence of $(CF_3CO)_2O$ (see rxn. [1]) gives a colourless solid containing CF_3COOH as suggested by the broad absorption above 3000 cm^{-1} and the strong absorption at 1781 cm^{-1}. The product is massively soluble in THF (concentrations as high as 12% w/w can be obtained at 20°C) and from the colourless solution the highly moisture sensitive THF adduct crystallizes out on addition of heptane. The treatment of the crude material with THF is also important to eliminate small amounts of unreacted metallic manganese. Depending on the drying procedure, compounds with THF–Mn molar ratios lower than 2 were isolated. The THF-containing species decompose at ca. 210°C (14) without melting (15; this paper reports that the reaction of manganese with CF_3COOH gives $Mn(CF_3COO)_2$ as a colourless solid melting at 63°C).

[1] $$Mn \xrightarrow[2)\ THF]{1)\ CF_3COOH/(CF_3CO)_2O} Mn(CF_3COO)_2 * n\text{THF}$$

The IR spectrum of the THF adduct of $Mn(CF_3COO)_2$ shows strong bands at 1670 (ν_{as} (COO)) and 1470 (ν_s (COO)) cm^{-1}, the difference between the two absorptions being typical of chelating bridging trifluoroacetato groups (16). The presence of THF in this species is indicated by the two absorptions of medium intensity at 1027 and 851 cm^{-1}.

Colourless crystals of $Mn(CF_3COO)_2(THF)_2$ were obtained by recrystallization from THF–heptane and used for the crystallographic study. The compound is polynuclear with bridging trifluoroacetato groups giving a sequence of one-three bridges between neighboring metal centres. Consequently, two different intermetallic distances are observed along the chain (Mn1···Mn2 = 4.371 Å ; Mn2···Mn1 = 6.128 Å) (Fig. 1A) and the asymmetric unit contains two manganese atoms. The two manganese atoms are bonded in a distorted octahedral coordination to the oxygen atoms of the triple bridge, to two oxygen atoms of two THF ligands, and to one oxygen atom of the single trifluoroacetato bridge (see Fig. 1B). The chain is therefore constituted by the $[(THF)_2Mn(\mu\text{-}CF_3COO)_3Mn(\mu\text{-}CF_3COO)(THF)_2]$ repeating unit. Table 2 reports a selection of bond distances and angles of this compound.

The trifluoroacetato groups of the triple bridge are arranged in a *syn-syn* bidentate mode; nevertheless, one of the bridges is substantially symmetric (Mn—O distances: 2.133(3) and 2.135(3) Å), while the remaining two groups

form two asymmetric bridges (Mn—O distances: 2.151(3) and 2.126(3); 2.116(3) and 2.130(3) Å). The mean C—O bond distance (1.224 Å) is in agreement with a bidentate coordination of the ligand (17). The single trifluoroacetato bridge shows two significantly different Mn—O bond distances (Mn1—O12 = 2.148(3), Mn2—O22 = 2.124(3) Å); moreover, the O12-C2-O22 bond angle (127.3(4)°) is smaller than the average O-C-O bond angles of the triple bridge (131°).

The two THF groups occupy *cis*-positions around the manganese at Mn—O bond distances comprised between 2.213(3) and 2.239(3) Å, in agreement with the Mn—O bond distances observed in THF-adducts of manganese(II) (some selected examples are found in ref. 18).

Fig. 2. View of the atom connectivity in $[(THF)_2Mn(\mu\text{-}CF_3COO)_2Mn(\mu\text{-}CF_3COO)_2(THF)_2]$. The THF ligands have been omitted for clarity.

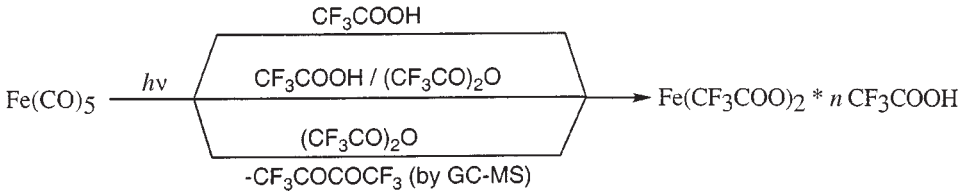
Crystals of a different shape were noticed and found to correspond to a *linkage isomer* of $Mn(CF_3COO)_2(THF)_2$ with the symmetric repeating unit $[(THF)_2Mn(\mu\text{-}CF_3COO)_2\text{-}Mn(\mu\text{-}CF_3COO)_2(THF)_2]$. The low quality of the crystals prevented a conventional refinement of the structure; nevertheless, the atom connectivity was established, as reported in Fig. 2. The Mn···Mn distance was found to be 4.87 Å, to be compared with the Mn···Mn distances of 4.371 and 6.128 Å observed in the asymmetric isomer.

It is interesting to note that the manganese centres show a similar coordination sphere (six oxygen atoms belonging to two *cis*-THF groups and four bridging trifluoroacetates), the difference between the two isomers consisting of the different distribution of the trifluoroacetates along the polynuclear chain. Thus, the two species represent an interesting case of linkage isomerism which is rather uncommon in the literature, previous examples being bis(hydrotris(1,2,4-triazolyl)borato)zinc (19), and $[Rh_2(CF_3COO)_4(TCNE)]_x$ (20).

Although many carboxylato derivatives of manganese(II) exist (21), trifluoroacetato complexes are not common. Examples of structurally characterized derivatives are: the mononuclear $Mn(CF_3COO)_2(pyridine)_4$ (15), $Mn(CF_3COO)_2(tmen)_2$ (tmen = *N,N,N′N′* -tetramethylethylenediamine (22)), $Mn(CF_3COO)_2(2,2'\text{-dipyridyl})_2$ (22), the trinuclear $Mn_3(CF_3COO)_6(C_6H_5CN)_6$(15), and the polynuclear chain of the 1,10-phenanthroline adduct $[Mn(CF_3COO)_2(1,10\text{-phenanthroline})]_n$ (23) whose structure is reminiscent of the more symmetric linkage isomer of $[Mn(CF_3COO)_2(THF)_2]_n$.

Iron

Iron(II) trifluoroacetate was obtained many years ago by reacting $Ba(CF_3COO)_2$ with $FeSO_4$ in water (24). According to an earlier report, $Fe(CO)_5$ slowly reacts with acetic acid in boiling DMF to give high yields of $Fe(CH_3COO)_2$ (25). The reaction with the stronger acid CF_3COOH is faster and after some hours at the boiling point of the mixture, no IR carbonyl absorptions were detected in solution and DMF-solvated $Fe(CF_3COO)_2$ was isolated (see rxn. [2]).



$$[2]\qquad Fe(CO)_5 \xrightarrow[DMF]{CF_3COOH/(CF_3CO)_2O} Fe(CF_3COO)_2{}^{*}\, n\ DMF$$

Some DMF was retained by the product, the amount depending on the drying conditions (see *Experimental*).

The IR spectrum of the solid has strong absorptions at 1729 and 1645 cm^{-1}; additional absorptions were observed at 1435 (ν_{sym} (COO)), 1208 (ν_{asym} (CF_3)), and 1144 (ν_{sym} (CF_3)) cm^{-1}. The magnetic moment of 5.08 BM at room

Scheme 1.

temperature is in agreement with the presence of high-spin d^6 iron(II) (26).

Having shown that $Fe(CO)_5$ is oxidized thermally to iron(II) by CF_3COOH in DMF, it was of interest to see which products are obtained in the reaction of $Fe(CO)_5$ with neat CF_3COOH. As a matter of fact, it is known that the photolysis of $Fe(CO)_5$ in acetic acid or in acetic anhydride gives quantitative yields of $Fe_2(CO)_9$ (11). Unexpectedly, we have found that $Fe(CO)_5$ is easily converted into $Fe(CF_3COO)_2$ by photolysis in neat CF_3COOH, in CF_3COOH–$(CF_3CO)_2O$ mixtures, or in neat $(CF_3CO)_2O$ (see Scheme 1). No traces of $Fe_2(CO)_9$ were observed, although that this species may be an intermediate cannot be excluded. As a matter of fact, an independent experiment has shown $Fe_2(CO)_9$ to react with CF_3COOH in the dark at room temperature to give $Fe(CF_3COO)_2 \cdot nCF_3COOH$ (see rxn. [3]).

[3] $$Fe_2(CO)_9 \xrightarrow{CF_3COOH/(CF_3CO)_2O} Fe(CF_3COO)_2 * n\,CF_3COOH$$

The presence of CF_3COOH in the iron-containing product obtained from $Fe(CO)_5$–$(CF_3CO)_2O$ is presumably due to some adventitious acid present in the reaction mixture. Moreover, the detected formation of $CF_3COCOCF_3$ suggests cleavage of the anhydride, i.e., an oxidative addition process through the C—O bond of $(CF_3CO)_2O$. Our data are in agreement with the observation that $Ni(CF_3COO)_2$ can be obtained from $(CF_3CO)_2O$ and $Ni(CO)_4$ (27).

Bis(trifluoroacetato)iron(II) was isolated as a CF_3COOH adduct with quantities of acid depending on the drying procedures. It is a colourless microcrystalline solid, soluble in water and DMF, slightly soluble in hydrocarbons and THF. It is paramagnetic (magnetic moments about 5 BM, see *Experimental*) in agreement with the value expected for a high-spin d^6 ion in an octahedral field (26). The IR spectrum in the solid-state shows strong absorptions at 1697 (ν_{as} (COO)) and 1450 (ν_s (COO)) cm^{-1} suggesting the presence of bridging trifluoroacetato groups (16). A strong multiple absorption at 1781 cm^{-1} and a broad one above 3000 cm^{-1} are diagnostic of the presence of CF_3COOH in our compound. As a matter of fact, these absorptions disappear upon treatment with THF (see rxn. [4]) and the THF-adduct $Fe(CF_3COO)_2 \cdot n$THF has been isolated in good yields.

[4] $$Fe(CF_3COO)_2 * 2CF_3COOH + n\,THF \longrightarrow Fe(CF_3COO)_2 * n\,THF + 2CF_3COOH$$

Conclusions

Metallic manganese or iron pentacarbonyl are useful precursors in the preparation of the corresponding trifluoroacetates, $M(CF_3COO)_2$. In the case of the polynuclear THF-adduct of $Mn(CF_3COO)_2$, the existence of linkage isomerism has been observed. For donor atoms of the same type (oxygen in this case) linkage isomerism is a rather uncommon phenomenon. As a matter of fact, the two isomers essentially differ in the distribution of the bridging ligands along the polynuclear chain. As far as iron is concerned, the results of the present work have established that, at variance with the $Fe(CO)_5$–CH_3COOH system under photolytic conditions, $Fe_2(CO)_9$ is not the product when the photolysis of $Fe(CO)_5$ is carried out in CF_3COOH. The higher autoionization constant of CF_3COOH with respect to CH_3COOH may be responsible for the present experimental findings.

Synthesis, characterization, and properties of some cyclopentadienyl molybdenum nitrosyl benzyl complexes

Peter Legzdins, Kevin M. Smith, and Steven J. Rettig

Abstract: Reaction of $CpMo(NO)(CH_2Ph)Cl$ with Me_2Mg, Ph_2Mg, or PhCCLi reagents in THF affords the corresponding alkyl, aryl, or alkynyl $CpMo(NO)(CH_2Ph)R$ (R = hydrocarbyl) complexes as orange powders in good yields. Unlike related 16-electron $CpMo(NO)R_2$ complexes, these 18-electron species exhibit good thermal stability due to their η^2-benzyl-Mo interactions. Treatment of $CpMo(NO)(CH_2Ph)Cl$ with Na(DME)Cp provides dark green $Cp_2Mo(NO)(CH_2Ph)$, whose solid-state molecular structure has been established by a single-crystal X-ray crystallographic analysis. The two Cp rings display different binding modes to the Mo atom, while the benzyl ligand is coordinated to the metal centre in an η^1 fashion. The triflate complex, $CpMo(NO)(CH_2Ph)(OTf)$, is obtained by addition of AgOTf to the benzyl chloride precursor. The covalent Mo—OTf bond in this compound can be disrupted by the addition of Lewis bases (L) such as PPh_3 or pyridine, leading to the corresponding $[CpMo(NO)(CH_2Ph)(L)][OTf]$ salts. Attempts to generate neutral benzylidene complexes by deprotonation of $[CpMo(NO)(CH_2Ph)(PPh_3)][OTf]$ have not yet been successful.

Key words: nitrosyl, molybdenum, benzyl, hydrocarbyl, triflate.

Résumé : La réaction du $CpMo(NO)(CH_2Ph)Cl$ avec les réactifs Me_2Mg, Ph_2Mg et PhCCLi dans le THF conduit aux complexes alkyles, aryles ou alkynyles correspondants, $CpMo(NO)(CH_2Ph)R$ (R = hydrocarbyle), des poudres oranges obtenues avec des bons rendements. Contrairement à ce qui se produit avec les complexes à seize électrons du type $CpMo(NO)R_2$, ces espèces à dix-huit électrons présentent une bonne stabilité thermique en raison de leurs interactions η^2-benzyl-Mo. Le traitement du $CpMo(NO)(CH_2Ph)Cl$ par du Na(DME)Cp conduit au $Cp_2Mo(NO)(CH_2Ph)$ vert foncé dont on a déterminé la structure moléculaire à l'état solide par une analyse cristallographique réalisée par diffraction des rayons X par un cristal unique. Les deux noyaux Cp présentent des modes de liaison avec le Mo qui sont différents alors que le ligand benzyle est coordiné au centre métallique de façon η^1. On a obtenu le complexe au triflate, $CpMo(NO)(CH_2Ph)(OTf)$ en additionnant du AgOTf au précurseur avec du chlorure de benzyle. La liaison covalente Mo—OTf de ce composé peut être perturbée par l'addition de bases de Lewis (L), telles que la PPh_3 ou la pyridine, qui conduisent à la formation des sels $[CpMo(NO)(CH_2Ph)(L)][OTf]$ correspondants. Les essais effectués en vue de générer des complexes benzylidènes neutres par déprotonation de $[CpMo(NO)(CH_2Ph)(PPh_3)][OTf]$ se sont avérés infructueux jusqu'à maintenant.

Mots clés : nitrosyle, molybdène, benzyle, hydrocarbyle, triflate.

Introduction

We (1) recently reported the intermolecular C—H bond activation of alkane substrates by thermolysis of the 16-electron (16e) bis(hydrocarbyl) complexes, $Cp^*W(NO)(CH_2CMe_3)_2$ and $Cp^*W(NO)(CH_2CMe_3)(CH_2Ph)$. Labeling and kinetic studies established that these reactions proceed via initial elimination of CMe_4 to form the unsaturated alkylidene complexes, $Cp^*W(NO)(=CHCMe_3)$ and $Cp^*W(NO)(=CHPh)$, respectively. However, the generation of these reactive alkylidene species requires reaction temperatures in the range of 70–80°C, and little control can be exerted on the steps following the initial, rate-determining α-hydrogen abstraction step. This practical limitation could be avoided by either lowering the activation barrier of the neopentane elimination process or by finding an alternative route to the reactive alkylidene compounds.

Previous studies in these laboratories have demonstrated that the related $CpMo(NO)(=CHCMe_3)$ fragment is readily produced by the *room temperature* transformation of the 16e $CpMo(NO)(CH_2CMe_3)_2$ compound (2), or by the facile loss of pyridine (py) from the 18e adduct $CpMo(NO)(=CHCMe_3)(py)$ (3). Like the Cp*W analogues, $CpMo(NO)(=CHCMe_3)$ can also activate element—hydrogen bonds. Thus, isolable $CpMo(NO)(CH_2CMe_3)(ER)$ complexes are obtained when the ER group can act as a π-donor

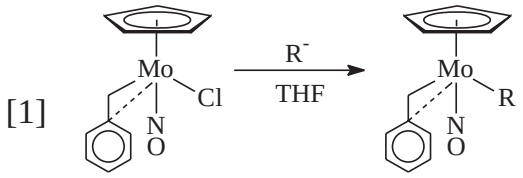
ligand (e.g., HER = HOPh, H_2NCMe_3, $HSCMe_3$), thereby resulting in 18e products (3). However, stable $CpMo(NO)(CH_2CMe_3)R$ compounds resulting from activation of hydrocarbon RH substrates have not yet been observed, and this may well be a manifestation of the marked thermal instability of 16e $CpMo(NO)(R)_2$ complexes. For instance, diaryl species can be observed in situ when $[CpMo(NO)Cl_2]_2$ is treated with $(aryl)_2Mg$ reagents at low temperature, but these 16e complexes decompose at ambient temperatures even in the presence of trapping agents (4). The differing reactivities of Mo and W cyclopentadienyl nitrosyl alkyl complexes have recently been analyzed using density functional theoretical techniques (5).

The current study was undertaken with a view to developing a non-thermolytic route to an electronically unsaturated alkylidene species, specifically the benzylidene fragment [CpMo(NO)(=CHPh)] (**A**). As shown in the retrosynthetic strategy outlined below in Scheme 1, the reactive 16e species **A** should be accessible by loss of a labile, neutral ligand L from the 18e CpMo(NO)(=CHPh)(L) complex (**B**). The neutral benzylidene compound could be formed by deprotonation of the cationic complex $[CpMo(NO)(CH_2Ph)(L)]^+$ (**C**). The cationic complex could, in principle, be synthesized by nucleophilic displacement of a weakly bound anionic ligand X from $CpMo(NO)(CH_2Ph)(X)$ (**D**), which in turn would be derived by salt metathesis from the known $CpMo(NO)(CH_2Ph)(Cl)$ compound (**E**) (6).

Scheme 1.



Benzyl chloro complex **E** also provides a metathetical route to the benzyl hydrocarbyl complexes expected to result from the C—H bond activation of RH substrates by the [CpMo(NO)(=CHPh)] target species. Indeed, the prototypal complex, $CpMo(NO)(CH_2Ph)(CH_2SiMe_3)$, has previously been synthesized using just this methodology (6). The independent synthesis of additional $CpMo(NO)(CH_2Ph)R$ compounds was thus undertaken to assess their thermal stability and to establish their diagnostic spectroscopic properties. It was anticipated that these alkyl complexes, as well as compounds **C** and **D**, might well be stabilized as 18e species by the η^2-benzyl-metal interactions characteristic of other $Cp'M(NO)(CH_2Ph)(X)$ complexes (Cp′ = Cp or Cp*, M = Mo or W) (6, 7), some of which are analogues of those depicted above in Scheme 1.

This paper describes the synthesis of several $CpMo(NO)(CH_2Ph)R$ compounds by salt metathesis and outlines their spectroscopic and physical properties. The solid-state molecular structure of one of these compounds, namely $Cp_2Mo(NO)(CH_2Ph)$, as determined by X-ray crystallography is described. The synthesis and characterization of $CpMo(NO)(CH_2Ph)(OTf)$, (OTf = triflate, OSO_2CF_3) and $[CpMo(NO)(CH_2Ph)(L)]^+[OTf]^-$, corresponding to target molecules **D** and **C** in Scheme 1, respectively, are also presented. Finally, the various attempts to generate alkylidene complexes from these precursors are summarized.

Results and discussion

Direct synthesis of $CpMo(NO)(CH_2Ph)R$ complexes

As shown in eq. [1] above, $CpMo(NO)(CH_2Ph)Cl$ is a useful precursor to a range of $CpMo(NO)(CH_2Ph)R$ complexes, where R is methyl **1**, phenyl **2**, phenylalkynyl **3**, or cyclopentadienyl **4**. The metathesis reactions proceed cleanly in THF as determined by monitoring the change in ν (NO) during the course of the reaction by solution IR spectroscopy. The conversions can be accomplished using a diverse range of hydrocarbylating reagents, including organolithium and organosodium species as well as the more typical organomagnesium reagents. Analytically pure, crystalline samples of the $CpMo(NO)(CH_2Ph)R$ complexes may be obtained by chromatography of the crude products on Alumina I using toluene as eluant, followed by recrystallization from toluene:hexanes solvent mixtures. The colour, yield, and elemental analysis data for the new compounds are listed in Table 1. Their IR and mass spectral data are collected in Table 2, and Table 3 contains their ^1H and ^{13}C NMR data.

The replacement of the electronegative Cl ligand with more covalently bound hydrocarbyl groups has the expected effect on the electron density at the metal centres. This is indicated by the ν(NO) bands in the Nujol mull IR spectra of the $CpMo(NO)(CH_2Ph)R$ compounds which are from 14 to 44 cm^{-1} lower in energy than the 1620 cm^{-1} value exhibited by $CpMo(NO)(CH_2Ph)Cl$ (6). The magnitude of this decrease in ν (NO) follows the trend C≡CPh < Cp ~ Ph ~ CH_2Ph < CH_2SiMe_3 ~ Me, which is consistent with the electron-donating abilities of these hydrocarbyl ligands. The IR spectrum of **3** also displays a ν(C≡C) band at 2091 cm^{-1} (8).

In their ^1H NMR (C_6D_6) spectra, the C_5H_5 signals of compounds **1**–**4** lie in the 4.80–5.20 ppm region and are diagnostic indicators of these complexes. Also useful is the signal at –0.88 ppm characteristic of a Me ligand in the ^1H NMR (C_6D_6) spectrum of **1**. The ^{13}C NMR spectra of complexes **1**–**3** are important chiefly for the ipso carbon signals of the CH_2Ph ligands which fall in the 110–113 ppm range indicative of η^2-benzyl-molybdenum interactions (6, 7). In contrast, complex **4** does not appear to possess a η^2-benzyl ligand according to its ^1H and ^{13}C NMR spectra. The benzyl methylene ^1H NMR signal appears as a singlet at room

temperature, and the ipso carbon signal occurs at 152.3 ppm in the ^{13}C NMR spectrum of **4**. There is also only a single ^1H NMR peak for the two Cp ligands at room temperature. Consequently, a single-crystal X-ray crystallographic analysis of **4** was undertaken to establish definitively its solid-state molecular structure. The results of this analysis are discussed in the next section.

Solid-state molecular structure of $Cp_2Mo(NO)(CH_2Ph)$

The nature of the Cp—Mo bonds in $Cp_2Mo(NO)X$ complexes has been the subject of debate since their initial synthesis over 30 years ago (9, 10). If these compounds possessed two η^5-Cp groups and a linear nitrosyl ligand, they would have a formal valence electron count of 20 (11*e*). Early suggestions that this unfavourable situation might be avoided by the complexes adopting an asymmetric η^5-Cp/η^3-Cp binding mode (11*a*, *b*) were *not* supported by subsequent X-ray crystallographic studies. The solid-state molecular structures of $Cp_2Mo(NO)(\eta^1$-Cp) (11*c*), $Cp_2Mo(NO)(CH_3)$ (11*d*), and Cp*(Cp)Mo(NO)(CH_3) (11*f*) all exhibit linear Mo-N-O angles (>172°) and essentially planar but skewed Cp′ groups with all 10 multihapto ring C atoms lying within bonding distance of the Mo centres. This observation contrasts with the situation in $Cp_2W(CO)_2$ which possesses distinct η^5-Cp and η^3-Cp ligands (12). The η^3-Cp group contains a localized C—C double bond, with the two unique C atoms bent 20° away from the plane containing the three Cs bound to the W centre. Calhorda and co-workers (13) have recently investigated via DFT calculations the phenomenon of ring slippage in Cp_2MoL_2 species and related Cp and indenyl complexes of Mo(II).

The solid-state molecular structure of $Cp_2Mo(NO)(CH_2Ph)$ **4** (Fig. 1) exhibits features intermediate between those displayed by $Cp_2W(CO)_2$ and the previously reported $Cp_2Mo(NO)R$ structures. All 10 Cp carbons in **4** are within 2.336–2.700 Å (avg = 2.475 Å) of the Mo centre, and the

Fig. 1. The solid-state molecular structure of $Cp_2Mo(NO)(CH_2Ph)$ (**4**); 50% probability thermal ellipsoids are shown.

[a]The H—H coupling constants of the diastereotopic benzyl hydrogens, while not specifically measured, appear to be in the normal 4.5–7.0 Hz range expected for these complexes (6).

difference between the two Cp groups is not as marked as in the $Cp_2W(CO)_2$ structure. However, the C(1)-C(5) ring exhibits characteristics more typical of an η^3-Cp ligand than previously observed for any other structurally characterized $Cp_2Mo(NO)R$ species. The C(4) and C(5) atoms are 2.700(3) and 2.667(3) Å away from the Mo atom, respectively, and the C(4)—C(5) bond length of 1.317(5) Å is significantly shorter than the other C—C distances in the ring (1.392(5)–1.407(5) Å, avg = 1.401 Å). The C(1)-C(2)-C(3)-C(4) and C(3)-C(2)-C(1)-C(5) torsion angles of 7.0(4)° and 8.0(4)°, respectively, are also reminiscent of, if less pronounced than, those found in $Cp_2W(CO)_2$. The crystallographic and experimental data for **4** are presented in Table 4. Table 5 lists the positional and thermal parameters of its constituent atoms, while selected bond lengths and angles are collected in Tables 6 and 7, respectively.

Stabilizing effects of η^2-CH_2Ph ligands

The coordinative and electronic saturation imparted by their η^2-benzyl ligands is deemed to be responsible for the thermal stability of compounds **1**–**3**. Of the known $Cp'M(NO)R_2$ (Cp′ = Cp, Cp*; M = Mo, W) complexes, the CpMo-containing species are the most Lewis acidic, the most prone to M—C bond hydrolysis, and the most thermally sensitive (14). The general fragility of the 16e $CpMo(NO)R_2$ species is in marked contrast to the robust 18e complexes shown below.

These latter compounds achieve a saturated electronic configuration via additional σ-donor ligation (15), lower oxidation state (9), or multihapto ancillary ligand bonding (11, 14). All of the species shown above are thermally stable at ambient temperature, and several are remarkably tolerant of air and (or) water. The range of hydrocarbyl ligands available to these 18e complexes extends to groups which are difficult to synthesize (e.g., Me, Ph) or entirely unknown

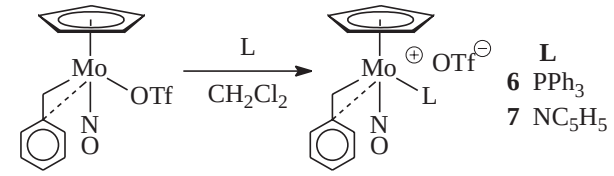
Synthesis of [CpMo(NO)(CH$_2$Ph)(L)][OTf]

The stabilizing influence of the η^2-benzyl ligand is also of critical importance to the target molecule CpMo(NO)(CH$_2$Ph)(OTf) **5** which can be synthesized in high yields as illustrated below in eq. [2].



[2] 

5

Silver salts have been previously utilized to abstract halide ligands from Cp′M(NO)$_x$-containing complexes. For instance, if the abstraction from CpMo(NO)(CH$_2$Ph)Cl is performed using $AgBF_4$ in acetonitrile, NCMe-solvated organometallic cations can be isolated (16). Furthermore, treatment of Cp′M(NO)$_2$Cl with $AgBF_4$ in CH_2Cl_2 generates the reactive Cp′M(NO)$_2$(FBF$_3$) species (17) which have been used to synthesize lactones (17*b*) and pyrones (17*c*). Halide-abstraction reactions with AgO_2CR (R = 2-phenylbutyrate) (16e) or AgO_3SR (R = *p*-tolyl, camphor) (18) in CH_2Cl_2 afford neutral nitrosyl complexes with covalent M—O bonds.

As shown in eq. [2], the synthesis of **5** is best accomplished in a 1:1 solvent mixture of CH_2Cl_2 and Et_2O. The thermal stability of CpMo(NO)(CH$_2$Ph)(OTf), which is isolable as a orange powder that can even be handled briefly in air without deleterious effects, can be contrasted with that of CpMo(NO)(η^3-(*Z*)-crotyl)(OTs) (which was not isolated, but was generated at low temperature and used in situ) (18*a*) and that of Cp*W(NO)(CH$_2$SiMe$_3$)(OTf) (which decomposes upon being generated in non-coordinating arene or chlorinated solvents).[4] The existence of a covalent Mo—OSO_2CF_3 bond in **5** is inferred from its solubility in poor ion-supporting solvents such as toluene, C_6D_6 and Et_2O, and by its IR spectrum (Nujol) (19). The highly electron-withdrawing nature of the OTf group in **5** is evidenced by the ν(NO) (Nujol) value of 1654 cm^{-1} which is much higher in energy than that exhibited by the hydrocarbyl products **1**–**4** or the benzyl chloride starting material.

As shown above in eq. [3], reaction of isolated or in situ generated CpMo(NO)(CH$_2$Ph)(OTf) with PPh_3 or pyridine

[3] 

L	
6	PPh_3
7	NC_5H_5

results in the formation of complexes **6** and **7**, respectively. As expected, these [CpMo(NO)(CH$_2$Ph)(L)][OTf] salts display decreased solubility as compared to the neutral complexes **1**–**5**. Thus, **6** and **7** are only moderately soluble even in THF, and dissolve readily only in good ion-supporting solvents such as CH_2Cl_2 and CH_3NO_2. As solids, **6** and **7** appear to be relatively inert with respect to O_2 and water, since the yellow powders may be handled briefly in air without noticeable decomposition. The decrease in the highest frequency ν(SO) band of the triflate group from 1321 cm^{-1} in the IR spectrum of **5** to ~1260 cm^{-1} in **6** and **7** is consistent with the displacement of the OTf group from the Mo centre (19). The ^{1}H and ^{13}C NMR spectra of **6** and **7** help demonstrate that only one L ligand is present in each molecule and that the η^2-benzyl-molybdenum interaction is preserved in each complex.

Attempted deprotonation of [CpMo(NO)(CH$_2$Ph)(PPh$_3$)][OTf]

In an attempt to form a benzylidene compound such as CpMo(NO)(=CHPh)(PPh_3) or [CpMo(NO)(=CHPh)]$_2$, cationic complex **6** was treated with a variety of Brønsted bases (e.g., KO-*t*-Bu, LiN(SiMe$_3$)$_2$, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), NEt_3, HN-*i*-Pr$_2$) in THF and CH_2Cl_2. In each case, monitoring of the reaction by solution IR spectroscopy revealed the complete consumption of starting material and the formation of a broad band at ~1600 cm^{-1}. However, ^{1}H NMR spectra of the crude reaction mixtures resulting from these reactions were devoid of signals characteristic of alkylidene Hs. None of the attempts to purify, chromatograph, crystallize, or precipitate the products from

the attempted deprotonation reactions resulted in any tractable material.

Related attempts to form alkylidene complexes by deprotonation of neutral $Cp^*M(NO)(CH_2CMe_3)(PMe_3)Cl$ (M = Mo, W) (16*a*) or $Cp^*Mo(NO)(CH_2SiMe_3)_2$ (20) complexes with $LiNR_2$ reagents have been shown to result in metallated η^5,η^1-$C_5Me_4CH_2$ species due to attack on the Cp* methyl groups. From the reaction of LiN-*i*-Pr_2 with $Cp^*Mo(NO)(CH_2SiMe_3)_2$, the anionic "tucked-in" compound goes on to rearrange to $[Cp^*Mo(NO)(=CHSiMe_3)(CH_2SiMe_3)]_2[Li_2(THF)_3]$ (20).

Experimental

Methods

All reactions and subsequent manipulations were conducted under anaerobic conditions using an atmosphere of N_2. $CpMo(NO)(CH_2Ph)Cl$ (6) and the $R_2Mg{\cdot}x$(dioxane) (6) and Na(DME)Cp (21) reagents were prepared according to the published procedures. All other reagents were used as received from commercial suppliers. Filtrations were performed through Celite (1 × 2 cm) supported on a medium-porosity glass frit unless specified otherwise. For the low-temperature alkylation reactions, solvents were transferred via trap-to-trap distillation from the drying reagent directly onto the reactants contained in a flask cooled by a liquid nitrogen bath.

Synthesis of $CpMo(NO)(CH_2Ph)R$ (R = Me (1), Ph (2), C≡CPh (3), Cp (4))

All four complexes were prepared in a similar manner, and the synthesis of $CpMo(NO)(CH_2Ph)Me$ (**1**) is described as a representative example.

THF (~25 mL) was vacuum transferred onto $CpMo(NO)(CH_2Ph)Cl$ (0.186 g, 0.59 mmol) and $Me_2Mg{\cdot}x$(dioxane) (0.089 g, 0.59 mmol). The mixture was stirred while being allowed to warm slowly to room temperature. After ~1 h, the solvent was removed from the final red

© 2001 NRC Canada

solution in vacuo. The residue was extracted with a 2:1 solvent mixture of Et_2O:CH_2Cl_2, and the extracts were filtered. The solvent was again removed from the filtrate in vacuo, and the residue was triturated with Et_2O twice to obtain CpMo(NO)(CH_2Ph)Me (**1**) as an orange powder (0.110 g, 63% yield). Analytically pure samples of **1** were obtained by extraction of the crude powder with a 1:1 solvent mixture of THF:toluene, followed by chromatography using an Alumina I column with toluene as eluant. The resulting orange eluate was then reduced in volume in vacuo, hexanes were added, and the solution was chilled to –30°C overnight to induce the deposition of orange crystals.

CpMo(NO)(CH_2Ph)Ph (**2**), CpMo(NO)(CH_2Ph)(C≡CPh) (**3**), and Cp_2Mo(NO)(CH_2Ph) (**4**) were synthesized from CpMo(NO)(CH_2Ph)(Cl) in an analogous manner, using $Ph_2Mg{\cdot}x$(dioxane), LiC≡CPh, and Na(DME)Cp, respectively, instead of $Me_2Mg{\cdot}x$(dioxane) as the hydrocarbylating reagent.

Synthesis of CpMo(NO)(CH_2Ph)(OTf) (5)

First CH_2Cl_2 (20 mL) and then Et_2O (20 mL) were added via syringe to CpMo(NO)(CH_2Ph)Cl (0.433 g, 1.36 mmol) and AgOTf (0.350 g, 1.36 mmol). After ~10 min, a flocculent white precipitate had formed in the orange solution. The mixture was filtered, and the Celite plug was washed with Et_2O (3 × 5 mL). The combined filtrates were taken to dryness in vacuo, and the residue was triturated twice with Et_2O (10 mL) to obtain CpMo(NO)(CH_2Ph)(OTf) (**5**) as an orange powder (0.529 g, 83% yield).

Synthesis of [CpMo(NO)(CH_2Ph)(L)][OTf] (L = PPh_3 (6), NC_5H_5 (7))

Both triflate salts **6** and **7** may be obtained from either isolated or in situ generated **5**. The two-step synthesis of [CpMo(NO)(CH_2Ph)(PPh_3)][OTf] from CpMo(NO)(CH_2Ph)Cl is described as a representative example.

First CH_2Cl_2 (10 mL) and then Et_2O (10 mL) were added to CpMo(NO)(CH_2Ph)Cl (0.115 g, 0.36 mmol) and AgOTf (0.092 g, 0.36 mmol). After ~10 min, the mixture was filtered through Celite onto solid PPh_3 (0.096 g, 0.36 mmol). The solution was stirred briefly, and then hexanes (10 mL) were added. The total volume of the solution was reduced to ~25 mL, and it was chilled to –30°C overnight to obtain [CpMo(NO)(CH_2Ph)(PPh_3)][OTf] **6** as a yellow powder (0.198 g, 79% yield).

X-ray crystallographic analysis of Cp_2Mo(NO)(CH_2Ph) (4)

A green/black plate of **4** having approximate dimensions of 0.50 × 0.40 × 0.10 mm was mounted in a glass capillary. All measurements were made on a Rigaku/ADSC CCD area detector with graphite monochromated Mo Kα radiation. Data were collected in 0.50° oscillations with 60.0 s exposures. A sweep of data was done using ϕ oscillations from 0.0 to 190.0° at χ = –90° and a second sweep was performed using ω oscillations between –23.0 and 18.0° at χ = –90°. The crystal-to-detector distance was 39.20(3) mm. The detector swing angle was –10°. The data were corrected for Lorentz and polarization effects.

The structure was solved by heavy-atom Patterson methods (22) and expanded using Fourier techniques (23). The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were fixed in calculated positions with C—H = 0.98 Å. Neutral atom scattering factors were taken from Cromer and Waber (24). Anomalous dispersion effects were included in *F*calc (25); the values for $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley (26). The values for the mass attenuation coefficients are those of Creagh and Hubbell (27). All calculations were performed using the teXsan (28) crystallographic software package of Molecular Structure Corp.

Synthesis of 5-fluoro-β-D-glucopyranosyluronic acid fluoride and its evaluation as a mechanistic probe of *Escherichia coli* β-glucuronidase

Alexander W. Wong, Shouming He, and Stephen G. Withers

Abstract: Synthesis of the potential mechanism-based inactivator of β-D-glucuronidases (5-fluoro-β-D-glucopyranosyluronic acid fluoride) was accomplished via a six-step process from D-glucuronic acid that involved radical bromination at C-5 and displacement of the bromide by fluoride. A key step in this process was the masking of the carboxylic acid as a phenacyl ester. This group is uniquely stable to conditions of photobromination and fluoride displacement, yet removable under very mild conditions. Incubation of the *Escherichia coli* β-glucuronidase with 5-fluoro-β-D-glucopyranosyluronic acid fluoride resulted in time-dependent inactivation of the enzyme through the accumulation of a covalent 5-fluoro-α-D-glucopyranosyluronic acid-enzyme. Peptic digestion of the 5-fluoro-α-D-glucopyranosyluronic acid-enzyme intermediate and subsequent analysis by liquid chromatography coupled to an electrospray ionization triple quadrupole mass spectrometer indicated the presence of a 5-fluoro-α-D-glucopyranosyluronic acid-modified peptide. This peptide was partially purified by HPLC and its sequence determined by tandem mass spectrometry in the daughter ion scan mode, permitting the identification of Glu504 as the catalytic nucleophile within the sequence IT**E**YGVD. This new reagent is therefore useful for the specific, mechanism-based inactivation of glycuronidases and has good potential in other studies of enzymes of this general class.

Key words: β-glucuronidase, catalytic nucleophile, 5-fluoro-β-D-glucopyranosyluronic acid fluoride, electrospray MS.

Résumé : Utilisant une voie en six étapes au départ de l'acide D-glucuronique qui implique une bromation radicalaire en C-5 et une substitution du brome par du fluor, on a réalisé la synthèse du fluorure de l'acide 5-fluoro-β-D-glucopyranosyluronique, un inhibiteur potentiel des β-D-glucuronidases en raison du mécanisme. Dans une étape clé de la synthèse, on masque l'acide carboxylique sous la forme d'ester phénacyle. Ce groupe, particulièrement stable dans les conditions de photobromation et de déplacement par le fluorure, peut facilement être enlevé dans des conditions très douces. L'incubation de la β-glucuronidase de l'*Escherichia coli* avec du fluorure de l'acide 5-fluoro-β-D-glucopyranosyluronique donne lieu à une inactivation de l'enzyme qui dépend du temps et qui résulte d'une accumulation d'un dérivé covalent l'acide 5-fluoro-α-D-glucopyranosyluronique-enzyme. L'hydrolyse peptique de cet intermédiaire et l'analyse subséquente du produit par chromatographie liquide couplée à un spectromètre de masse quadripolaire à triple ionisation par électronébulisation met en relief la présence d'un peptide modifié par l'acide 5-fluoro-α-D-glucopyranosyluronique. Ce peptide a été partiellement purifié par CLHP et on a déterminé sa séquence par spectrométrie de masse en tandem dans le mode de balayage de l'ion fille qui a permis d'identifier le Glu504 comme nucléophile catalytique dans la séquence IT**E**YGVD. Ce nouveau réactif est donc utile pour les inactivations spécifiques de glycuronidases liées à des mécanismes et il offre de bons potentiels dans d'autres études d'enzymes de cette classe générale.

Mots clés : β-glucurononidase, nucléophile catalytique, fluorure de l'acide 5-fluoro-β-D-glucopyranosyluronique, SM par électronébulisation.

[Traduit par la Rédaction]

Introduction

β-Glucuronidases are enzymes responsible for the cleavage of the β-glucuronide linkages that occur in a number of contexts, of which the most prevalent are probably the glycosaminoglycans. β-Glucuronides are also formed as conjugates with toxins to assist in their clearance from the body. Gene sequences for a number of β-glucuronidases have been determined and on this basis these enzymes have been assigned to glycoside hydrolase family 2 (1) (see also the following Web site http://afmb.cnrs-mrs.fr/~pedro/CAZY). This is a large family also containing β-galactosidases and β-mannosidases. Three-dimensional structures of several enzymes from this family have been determined, including that

Fig 1. Proposed mechanism for a retaining β-glucuronidase.

of the human lysosomal β-glucuronidase (2), an enzyme whose deficiency results in Sly syndrome (3). Members of this family are all retaining enzymes, which catalyze glycosidic bond cleavage with net retention of anomeric configuration. Such enzymes employ a two step mechanism involving the formation and hydrolysis of a covalent glycosyl-enzyme intermediate via oxacarbenium ion-like transition states. Two carboxylic acids at the active site play direct roles in the mechanism, one acting as an acid and (or) base catalyst and the other functioning as the nucleophile that attacks at the substrate anomeric centre to form the intermediate (Fig. 1).

Inhibitors of these enzymes are useful in several ways, and of particular value are those that function by trapping the enzyme in its glycosyl-enzyme intermediate form. Such reagents can be used to identify the catalytic nucleophile at the active site, and to allow the determination of the three-dimensional structure of this key species along the reaction coordinate. They also have potential value as therapeutic agents, for example as inhibitors of the heparanase (a β-glucuronidase) associated with cancer metastasis (4). They are also of interest to us in our efforts to develop positron emission tomographic (PET) imaging agents for the in vivo localization and quantitation of glycosidase activity. Two such classes of inhibitor have been developed, the 2-deoxy-2-fluoroglycosides and the 5-fluoroglycosides. Both classes function by the same mechanism, the fluorine substituent serving to inductively destabilize the oxacarbenium ion-like transition states for both the formation and the hydrolysis of the glycosyl-enzyme intermediate, thereby slowing *both* steps. The presence of a good leaving group (typically fluoride) at the anomeric centre accelerates the first step, thereby ensuring that the intermediate is kinetically accessible, thus that it accumulates.

The synthetic strategy employed for the 5-fluorosugar inhibitors hinges upon a radical bromination reaction at C-5, followed by fluoride displacement of the bromide so installed. It is important that the anomeric substituent be correctly installed prior to bromination since these C-5 halo derivatives actually contain two reactive anomeric centres, thus are quite labile. In addition, once the C-5 fluorine substituent has been installed it is not possible to generate intermediates with free hemiacetals at C-1 since they would rapidly decompose via ring opening and elimination of HF. This synthetic approach has been applied to the generation of 5-fluoro glucosides, galactosides, mannosides, and even *N*-acetylhexosaminides, but has never been used to generate 5-fluoroglucuronyl derivatives. Indeed, glucuronides are particularly attractive candidates for such chemistry since generation of a radical at C-5 should be considerably facilitated by the adjacent acid and (or) ester functionality.

We report here the synthesis of 5-fluoro-β-D-glucopyranosyluronic acid fluoride (5FGlcAF), the kinetic analysis of its interaction with the *Escherichia coli* β-glucuronidase, and the identification of the active site nucleophile so labelled via proteolysis of the tagged enzyme and subsequent sequencing of the labelled peptide via liquid chromatography – tandem mass spectrometry (LC–MS–MS).

Experimental procedures

General procedures

All buffer chemicals and other reagents were obtained from Sigma and (or) Aldrich unless otherwise noted. *E. coli* β-glucuronidase (EBG) was purchased from Sigma in lyophilized form. Pepsin (from porcine gastric mucosa) was obtained from Boehringer Mannheim. Dichloromethane and carbon tetrachloride were distilled from calcium hydride under dry nitrogen. Methanol was distilled from magnesium hydride under dry nitrogen.

^{1}H NMR spectra chemical shifts are externally referenced to tetramethylsilane and for samples dissolved in D_2O, the spectra are externally referenced to 2,2-dimethyl-2-silapentane-5-sulfonate (δ = 0.015 ppm). ^{19}F NMR shifts are referenced to $CFCl_3$, although the samples were externally referenced to trifluoroacetic acid (δ = –76.53 ppm).

Syntheses

1,2,3,4-Tetra-O-*acetyl*-β-D-*glucuronic acid (2)*

D-Glucuronic acid (20 g, 103 mmol) was suspended in 200 mL acetonitrile. To it was added acetic anhydride (60 mL, 636 mmol, 6.2 equiv) and concentrated sulfuric acid (1 mL). The mixture was stirred at room temperature for 16 h. The solvent was then removed in vacuo and the remaining acetic acid was removed by coevaporation with toluene. To the concentrated syrup was added 100 mL of water and the mixture stirred at room temperature for 2 h. The

© 2001 NRC Canada

resulting white solids were filtered off, rinsed with water, and dried over P_2O_5 under vacuum. The yield of the product was 23 g (62%). ^{1}H NMR data (CD_3OD, 200 MHz) δ: 5.89 (d, 1 H, $J_{1,2}$ = 8.0 Hz, H-1), 5.39 (t, 1 H, $J_{3,2}$ = 9.0 Hz, $J_{3,4}$ = 9.4 Hz, H-3), 5.19 (t, 1 H, $J_{4,3}$ = 9.4 Hz, $J_{4,5}$ = 9.6 Hz, H-4), 5.06 (t, 1 H, $J_{2,1}$ = 8.0 Hz, $J_{2,3}$ = 9.0 Hz, H-2), 4.35 (d, 1 H, $J_{5,4}$ = 9.6 Hz, H-5), 1.97–2.09 (4 s, 12 H, -OAc).

Phenacyl 2,3,4-tri-O-*acetyl*-α-D-*glucopyranuronate (**3**)*

1,2,3,4-Tetra-*O*-acetyl-D-glucuronic acid **2** (7.59 g, 20.9 mmol) was dissolved in 70 mL HPLC-grade acetonitrile. To this solution was added hydrazine acetate (3.86 g, 41.8 mmol, 2 equiv). The resulting suspension was warmed until most of the solid had dissolved and the solution then stirred at room temperature for 15 min. The reaction was quenched with the addition of 100 mL 0.5 M HCl, the acetonitrile was evaporated in vacuo, and the aqueous layer extracted with ethyl acetate (8 × 50 mL). The organic layer was dried over magnesium sulfate, filtered, and evaporated. The crude gum was dissolved in 100 mL ethyl acetate and 2-bromoacetophenone (4.62 g, 23.2 mmol, 1.1 equiv) followed by addition of triethylamine (4 mL, 28.7 mmol, 1.4 equiv). After stirring at room temperature overnight, the mixture was washed with 1 M HCl and saturated sodium bicarbonate, dried with magnesium sulfate, filtered, and evaporated. The crude material was purified by flash chromatography using 1:1 ethyl acetate:petroleum ether to yield **3** as a white solid (4.3 g, 47% over 2 steps). ^{1}H NMR data (CD_3OD, 400 MHz) δ: 7.82–7.90 (m, 2 H, H-2′, H-6′), 7.56–7.62 (m, 1 H, H-4′), 7.42–7.51 (m, 2 H, H-3′, H-5′), 5.57–5.63 (m, 2 H, H-1, H-3), 5.41 (d, 1 H, *J* = 16.4 Hz, -CH-*H*-), 5.35 (d, 1 H, *J* = 16.4 Hz, -CH-*H*-), 5.29 (dd, 1 H, $J_{4,3}$ = 9.5 Hz, $J_{4,5}$ = 10.0 Hz, H-4), 4.94 (dd, 1 H, $J_{2,1}$ = 3.5 Hz, $J_{2,3}$ = 10.1 Hz, H-2), 4.80 (d, 1 H, $J_{5,4}$ = 10.0 Hz, H-5), 3.60 (s, -OH), 1.98–2.10 (3 s, 9 H, -OAc).

Phenacyl (2,3,4-tri-O-*acetyl*-β-D-*glucopyranosyl fluoride)uronate (**4**)*

Hemiacetal **3** (4.3 g, 9.8 mmol) was dissolved in 100 mL dry dichloromethane, cooled to –30°C under N_2, then DAST (2.5 mL, 18.9 mmol, 1.9 equiv) was added dropwise to the stirring solution. After the addition, the solution was allowed to warm gradually to room temperature. When the reaction was complete, as determined by TLC, the solution was cooled to 0°C and methanol (5 mL) was added dropwise and the solution stirred for 15 min. The mixture was then worked up according to the general procedure. The crude material was passed through a silica gel plug using 1:1 ethyl acetate:petroleum ether. The β-anomer was selectively crystallized using dichloromethane and petroleum ether to yield white needles of **4** (2.41 g, 56%). ^{1}H NMR data ($CDCl_3$, 200 MHz) δ: 7.82–7.92 (m, 2 H, H-2′, H-6′), 7.56–7.68 (m, 1 H, H-4′), 7.42–7.53 (m, 2 H, H-3′, H-5′), 5.54 (t, 1 H, $J_{4,3}$ = 8.5 Hz, $J_{4,5}$ = 9.2 Hz, H-4), 5.48 (dd, 1 H, $J_{H1\text{-}F}$ = 51.0 Hz, $J_{1,2}$ = 4.9 Hz, H-1), 5.42 (s, 2 H, -CH_2-), 5.26 (t, 1 H, $J_{3,2}$ = 7.1 Hz, $J_{3,4}$ = 8.5 Hz, H-3), 5.13 (ddd, 1 H, $J_{2,1}$ = 5.0 Hz, $J_{2,3}$ = 7.1 Hz, $J_{2,F}$ = 9.4 Hz, H-2), 4.49 (d, 1 H, $J_{5,4}$ = 9.2 Hz, H-5), 2.00–2.18 (3 s, 9 H, OAc). ^{19}F NMR data ($CDCl_3$, 188 MHz) δ: –57.87 (dd, 1 F, $J_{H1\text{-}F}$ = 51.1 Hz, $J_{H2\text{-}F}$ = 9.4 Hz, F-1).

Phenacyl (5-bromo-2,3,4-tetra-O-*acetyl*-β-D-*glucopyranosyl fluoride)uronate (**5**)*

Phenacyl (2,3,4-tri-*O*-acetyl-β-D-glucopyranosyl fluoride)uronate **4** was suspended in dry CCl_4 (50 mL), recrystallized *N*-bromosuccinimde (3.23 g, 4 equiv) added, and the mixture irradiated with two 200 W light bulbs. After 2 h, the resulting orange mixture was filtered through glass wool, washed with saturated sodium bicarbonate, dried with magnesium sulfate, filtered, and evaporated. The crude material was purified by flash chromatography using 1:5 ethyl acetate:petroleum ether to yield **5** as a gum (1.02 g, 43%). ^{1}H NMR data ($CDCl_3$, 200 MHz) δ: 7.82–7.92 (m, 2 H, H-2′, H-6′), 7.56–7.68 (m, 1 H, H-4′), 7.42–7.53 (m, 2 H, H-3′, H-5′), 5.70 (dd, 1 H, $J_{1,2}$ = 7.5 Hz, $J_{1,F}$ = 51.3 Hz, H-1), 5.38–5.54 (m, 4 H, H-3, H-4, -CH_2-), 5.26 (ddd, 1 H, $J_{2,1}$ = 7.5 Hz, $J_{2,3}$ = 2.3 Hz, $J_{2,F}$ = 13.5 Hz, H-2), 1.94–2.08 (3 s, 9 H, -OAc). ^{19}F NMR data ($CDCl_3$, 188 MHz) δ: –74.42 (dd, 1 F, $J_{H1,F}$ = 51.3 Hz, $J_{H2,F}$ = 13.5 Hz, F-1).

Phenacyl (5-fluoro-2,3,4-tri-O-*acetyl*-β-D-*glucopyranosyl fluoride)uronate (**6**) and phenacyl (5-fluoro-2,3,4-tri*-O-*acetyl*-α-L-*idopyranosyl fluoride)uronate (**7**)*

Phenacyl (2,3,4-tri-*O*-acetyl-5-bromo-β-D-glucopyranosyl fluoride)uronate **5** (0.176 g, 0.339 mmol) was dissolved in dry diethyl ether (3.5 mL) and cooled to 10°C. To this solution was added silver tetrafluoroborate (0.166 g, 0.850 mmol, 2.5 equiv). After stirring the mixture at room temperature in the dark for 1 h, the mixture was diluted with ethyl acetate (10 mL), and washed with water. The aqueous phase was extracted once more with ethyl acetate, then the organic phase was washed with brine, dried with magnesium sulfate, filtered, and evaporated. The crude material was purified by flash chromatography using 1:3 ethyl acetate:petroleum ether to yield **6** as a white solid (0.0192 g, 12%) and **7** as a gum (0.0512 g, 32%). ^{1}H NMR data of **6** ($CDCl_3$, 400 MHz) δ: 7.82–7.90 (m, 2 H, H-2′, H-6′), 7.58–7.64 (m, 1 H, H-4′), 7.44–7.51 (m, 2 H, H-3′, H-5′), 5.81 (dd, 1 H, $J_{4,3}$ = 9.4 Hz, $J_{4,F5}$ = 22.4 Hz, H-4), 5.72 (dd, 1 H, $J_{1,2}$ = 5.7 Hz, $J_{1,F1}$ = 51.7 Hz, H-1), 5.53 (d, 1 H, *J* = 16.1 Hz, -CH-*H*-), 5.43 (dd, 1 H, $J_{3,2}$ = 6.8 Hz, $J_{3,4}$ = 9.4 Hz, H-3), 5.39 (d, 1 H, *J* = 16.1 Hz, -CH-*H*-), 5.27 (ddd, 1H, $J_{2,1}$ = 5.7 Hz, $J_{2,3}$ = 6.8 Hz, $J_{2,F1}$ = 10.6 Hz, H-2), 2.00–2.21 (3 s, 9 H, -OAc). ^{19}F NMR data of **6** ($CDCl_3$, 188 MHz) δ: –51.11 (dd, 1 F, $J_{F5,H4}$ = 22.4 Hz, $J_{F5,F1}$= 9.4 Hz, F-5), –64.67 (dt, 1 F, $J_{F1,H1}$ = 51.7 Hz, $J_{F1,H2}$ = 10.6 Hz, $J_{F1,F5}$ = 9.4 Hz, F-1). ^{1}H NMR data of **7** ($CDCl_3$, 400 MHz) δ: 7.83–7.89 (m, 2 H, H-2′, H-6′), 7.57–7.62 (m, 1 H, H-4′), 7.44–7.51 (m, 2 H, H-3′, H-5′), 5.75 (d, 1 H, $J_{1,F1}$ = 50.1 Hz, H-1), 5.61–5.67 (m, 1 H, H-4), 5.58 (d, 1 H, *J* = 16.1 Hz, -CH-*H*-), 5.39 (d, 1 H, *J* = 16.1 Hz, -CH-*H*-), 5.31–5.36 (m, 1 H, H-3), 5.21–5.29 (m, 1 H, H-2), 2.05–2.20 (3 s, 9 H, -OAc). ^{19}F NMR data of **7** ($CDCl_3$, 188 MHz) δ: –30.40 (dd, 1 F, $J_{F5,H4}$ = 9.4 Hz, $J_{F5,F1}$= 15.6 Hz, F-5), -47.77 (ddd, 1 F, $J_{F1,H1}$ = 50.1 Hz, $J_{F1,H2}$ = 9.1 Hz, $J_{F1,F5}$ = 15.6 Hz, F-1).

(5-Fluoro-2,3,4-tri-O-*acetyl*-β-D-*glucopyranosyl fluoride)uronic acid (**8**)*

The phenacyl ester **6** (0.050 g, 0.109 mmol) was dissolved in 4:1 methanol:water (5 mL). To this solution was added a spatula tip of 10% Pd/C. The mixture was stirred under an atmosphere of hydrogen gas at room temperature for 1 h.

© 2001 NRC Canada

The suspension was then filtered through a plug of Celite 545 and the filtrate concentrated in vacuo. The crude material was purified by flash chromatography using initially 1:1 ethyl acetate:petroleum ether, followed by 4:1 ethyl acetate:methanol to yield **8** as a gum (0.033 g, 90%). ^{1}H NMR data (CD_3OD, 400 MHz) δ: 5.69 (dd, 1 H, $J_{1,2}$ = 6.6 Hz, $J_{1,F1}$ = 53.0 Hz, H-1), 5.69 (dd, 1 H, $J_{4,3}$ = 9.8 Hz, $J_{4,F5}$ = 22.0 Hz, H-4), 5.35 (t, 1 H, $J_{3,2}$ = 8.7 Hz, $J_{3,4}$ = 9.8 Hz, H-3), 5.23 (ddd, 1 H, $J_{2,1}$ = 6.6 Hz, $J_{2,3}$ = 8.7 Hz, $J_{2,F1}$ = 12.6 Hz, H-2), 1.96–2.12 (3 s, 9 H, -OAc).

*(5-Fluoro-β-D-glucopyranosyl fluoride)uronic acid (**9**)*

5-Fluoro-2,3,4-tri-*O*-acetyl-β-D-glucopyranosyl fluoride)uronic acid (0.033 g, 0.097 mmol) was dissolved in 5 mL dry methanol and cooled to 0°C. Anhydrous ammonia was bubbled through the solution until it was saturated. The solution was allowed to warm to room temperature and stirred for 30 min. The solution was then concentrated in vacuo. The crude material was purified by flash chromatography using 17:2:1 ethyl acetate:methanol:water to yield a gum (0.019 g, 90%). This was then dissolved in minimal ddH_2O and eluted through a column of Bio-Rad AG 1X-8 resin (H^+ form) using ddH_2O as the eluant. Fractions obtained were lyophilized to yield a white powder (0.016 g, 85%). ^{1}H NMR data (D_2O, 400 MHz) δ: 5.48 (dd, 1 H, $J_{1,2}$ = 7.3 Hz, $J_{1,F1}$ = 53.9 Hz, H-1), 3.95 (dd, 1 H, $J_{4,3}$ = 9.6 Hz, $J_{4,F5}$ = 22.8 Hz, H-4), 3.76 (t, 1 H, $J_{3,2}$ = 9.4 Hz, $J_{3,4}$ = 9.6 Hz, H-3), 3.67 (ddd, 1 H, $J_{2,1}$ = 7.3 Hz, $J_{2,3}$ = 9.4 Hz, $J_{2,F1}$ = 14.8 Hz, H-2). ^{19}F NMR data (D_2O, 188 MHz) δ: –30.40 (dd, 1 F, $J_{F5,H4}$ = 22.8 Hz, $J_{F5,F1}$= 15.6 Hz, F-5), -47.77 (ddd, 1 F, $J_{F1,H1}$ = 53.9 Hz, $J_{F1,H2}$ = 14.8 Hz, $J_{F1,F5}$ = 15.6 Hz, F-1). Anal. calcd. for $C_6H_8O_6F_2 \cdot 0.5H_2O$: C 32.30, H 4.07; found: C 32.33, H 4.09.

Enzyme kinetics

All studies on *E. coli* β-glucuronidase were performed in 30 mM potassium phosphate buffer, pH 6.8 (buffer A) at 37°C. A continuous spectrophotometric assay based on the hydrolysis of *p*-nitrophenyl-β-D-glucuronide (pNPGlcA) was used to monitor enzyme activity by measurement of the rate of *p*-nitrophenolate release upon hydrolysis (λ = 400 nm, ε = 7.28 × 10^3 M^{-1} cm^{-1}) using a UNICAM 8700 UV–vis spectrophotometer equipped with a circulating water bath. Michaelis–Menten parameters for the substrate, previously undetermined with this enzyme, were determined by measuring initial rates at a series of substrate concentrations and fitting these data to the Michaelis–Menten equation using the program GraFit (5). Values of K_m = 87 (±10) μM and k_{cat} = 226 (±20) s^{-1} were determined.

Inactivation studies

The inactivation of EBG by 5FGlcAF was monitored by incubation of the enzyme (~25 ng μL^{-1}) under the above conditions in the presence of various concentrations (30–500 μM) of 5FGlcAF at 37°C in a total volume of 100 μL. Residual enzyme activity was determined at the appropriate time intervals by addition of a 5 μL aliquot of the inactivation mixture to a solution of pNPGlcA (1 mM, 700 μL) in 30 mM potassium phosphate buffer and measurement of rates of *p*-nitrophenolate release over a period of 1 min. Pseudo-first-order inactivation rate constants at each inactivator concentration (k_{obs}) were determined by fitting each curve to a first-order equation using the program GraFit. Values of the inactivation parameters (k_i and K_i) for the kinetic model eq. [1] shown below, were determined by fitting values of k_{obs} and inactivator concentration [*I*] to eq. [2] shown below using the program GraFit:

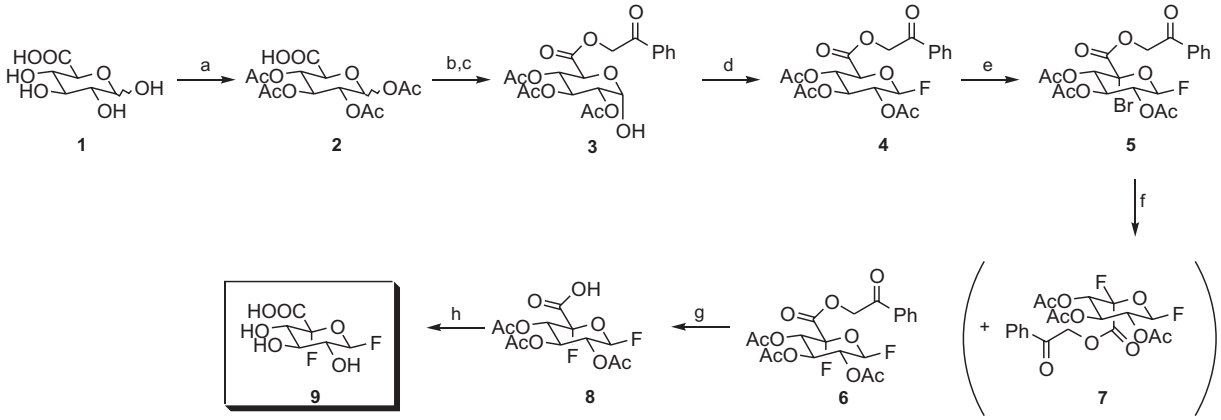
$$[1] \qquad E + I \overset{K_i}{\rightleftharpoons} E \cdot I \xrightarrow{k_i} E\text{-}I$$

$$[2] \qquad k_{obs} = \frac{k_i [I]}{K_i [I]}$$

Turnover (reactivation) of the 5-fluoro-glucuronyl-enzyme intermediate

5-Fluoro-α-D-glucuronyl enzyme was generated by incubating EBG in the presence of 500 μM 5FGlcAF in buffer A at 37°C for 10 min. The trapped intermediate (100 μL, ~8 μg mL^{-1}) was freed of excess inactivator by dilution of the inactivated enzyme with buffer A to a final volume of 2000 μL followed by concentration to a volume of ~200 μL using 10 kDa nominal molecular weight cut-off centrifugal concentrators (Amicon Centricon-10). Fourfold repetition of this process ensured a 1000-fold (>99%) reduction in the free 2FGlcAF concentration. The inactivated enzyme, freed from 5FGlcAF, was then incubated at 37°C in buffer A. Reactivation was monitored by removing aliquots (5 μL) at several time intervals and assaying for activity as described above.

Labeling and proteolysis



EBG (36 μL, 4.2 mg mL^{-1}) was incubated with 5FGlcAF (4 μL, 10 mM) or 2FGlcAF (4 μL, 50 mM) at 37°C for 15 min in buffer A; complete inactivation (>99%) was confirmed by enzyme assay as above. These mixtures were immediately subjected to peptic digestion: the samples were mixed with pepsin (40 μL, 1.2 mg mL^{-1} in 2.1 M sodium phosphate buffer, pH 1.6) followed by 2.1 M sodium phosphate, pH 1.6 buffer (40 μL). The mixture was incubated at 37°C for 30 min, frozen, and analyzed immediately by liquid chromatography – mass spectrometry (LC–MS) upon thawing.

Electrospray mass spectrometry

Mass spectra were recorded on a PE-Sciex API 300 triple quadrupole mass spectrometer (Sciex, Thornhill, Ontario, Canada) equipped with an Ionspray ion source. Peptides were separated by reverse phase HPLC on an Ultrafast Microprotein Analyzer (Michrom BioResources Inc., Pleasanton, California) directly interfaced with the mass spectrometer. In each of the MS experiments, the proteolytic digest was loaded onto a C18 column (Reliasil, 1 × 150 mm) equilibrated with solvent A (solvent A: 0.05% trifluoroacetic acid (TFA), 2% acetonitrile in water). Elution of the peptides was accomplished using a gradient (0–60%) of solvent B over 60 min followed by 100% solvent B over 2 min (solvent B: 0.045% TFA, 80% acetonitrile in water). Solvents were pumped at a constant flow rate of 50 μL min^{-1}. Spectra were obtained in the single quadrupole scan mode (LC–MS) or the tandem MS product ion scan mode (MS–MS).

Fig 2. Reaction scheme used in the synthesis of 5-fluoro-glucopyranosyluronic acid fluoride (**8**): (*a*) acetic anhydride, acetonitrile, H_2SO_4 (cat.); (*b*) hydrazine acetate, DMF; (*c*) phenacyl bromide, triethylamine, ethyl acetate; (*d*) DAST, CH_2Cl_2; (*e*) NBS, CCl_4; (*f*) $AgBF_4$, diethyl ether; (*g*) 10% Pd-C, H_2; (*h*) NH_3, MeOH; AG 1X-8 (H^+) resin.

In the single quadrupole mode (LC–MS), the quadrupole mass analyzer was scanned over a mass to charge ratio (*m*/*z*) range of 400–2200 Da with a step size of 0.5 Da and a dwell time of 1.0 ms per step. The ion source voltage (ISV) was set at 5.5 kV and the orifice energy (OR) was 45 V. In the tandem MS daughter ion scan mode, the spectrum was obtained by selectively introducing the parent ion (*m*/*z* = 974 or 990) from the first quadrupole (Q1) into the collision cell (Q2) and observing the product ions in the third quadrupole (Q3). Thus, Q1 was locked on *m*/*z* = 974 or 990; Q3 scan range was 50–1000; the step size was 0.5; dwell time was 2.0 ms; ion source voltage (ISV) was 5 kV; orifice energy (OR) was 45 V; Q0 = –10 V; IQ2 = –48 V.

Results and discussion

Synthesis of the 5-fluoro inactivators

The synthesis of 5-fluoroglycosyl fluorides is generally achieved via a route involving radical bromination of an acyl-protected sugar at C-5 (6), displacement of the bromide by fluoride (7), and then deprotection using methoxide in methanol. A major stumbling block in the synthesis of 5FGlcAF was the choice of protecting group for the acid functionality. Simple alkyl esters such as a methyl ester are unsuitable since the conditions required for their removal result in decomposition of the difluoride product. Benzyl esters, which could be removed hydrogenolytically, are also of no use, being incompatible with the photobromination conditions. Silicon-based protecting groups are also out of the question since fluoride would rapidly remove them at the displacement stage. The protecting group ultimately employed was the phenacyl ester, which is compatible with all the reaction conditions employed, and removable by hydrogenolysis (8).

As illustrated in Fig. 2, acetylation of D-glucuronic acid was carried out with acetic anhydride under acidic conditions to yield the 1,2,3,4-tetra-*O*-acetate. Selective anomeric deprotection was achieved by the use of hydrazine acetate, the product partially purified by extraction, and then directly converted to the phenacyl ester via reaction with 2-bromoacetophenone in the presence of triethylamine. Conversion of this protected hemiacetal (**3**) to the β-glycosyl fluoride (**4**) was achieved by reaction with DAST, yielding a mixture of the β- and α-anomers, of which the β-anomer was the predominant species. Bromination at C-5 to yield **5** was performed under radical conditions using *N*-bromosuccinimide and light. While this reaction proceeds slowly for the per-*O*-acetylated β-glucosyl fluoride (over 4 h), bromination of the phenacyl 2,3,4-tri-*O*-acetyl-β-D-glucopyranosyluronic acid fluoride is complete within two hours, presumably reflecting captodative stabilization of the radical generated at C-5 by the adjacent carbonyl group (electron-withdrawing) and the adjacent oxygen atom (electron-donating) (6).

Reaction of the 5-bromo sugar with silver tetrafluoroborate in diethyl ether afforded a mixture of the 5-fluoro D-gluco and L-ido uronic acid fluorides (**6** and **7**), but unfortunately only in low yields (12 and 32%, respectively). Use of silver fluoride in acetonitrile yielded only the ido-epimer. However, the bromide displacement step provided sufficient material for deprotection, characterization, and testing as an inactivator. Deprotection was achieved via a two-step process: the phenacyl protecting group was removed via hydrogenolysis in methanol:water to give **8** while the acetate groups were cleaved using ammonia in methanol to yield the desired final product **9**.

Inactivation kinetics

Incubation of EBG with 5FGlcAF resulted in inactivation of the enzyme in a time dependent manner according to pseudo-first-order kinetic behaviour, allowing measurement of pseudo-first-order rate constants for inactivation at each concentration of 5FGlcAF (Fig. 3A). A plot of these observed rate constants versus inactivator concentration revealed that full saturation of the enzyme was not achieved, even at the highest inactivator concentrations studied (Fig. 3B). Unfortunately, higher concentrations could not be investigated due to the rapidity of inactivation, which precluded accurate sampling. Nevertheless, approximate values for the inactivation rate constant of $k_i = 4.8 \pm 0.6$ min^{-1} and of the reversible dissociation constant $K_i = 455 \pm 95$ μM were determined, and an accurate value of the second-order rate constant $k_i/K_i = 10.4 \pm 1.9$ min^{-1} mM^{-1} was extracted from the initial slope of this plot (obtained by performing a linear regression on the first three points of the data).

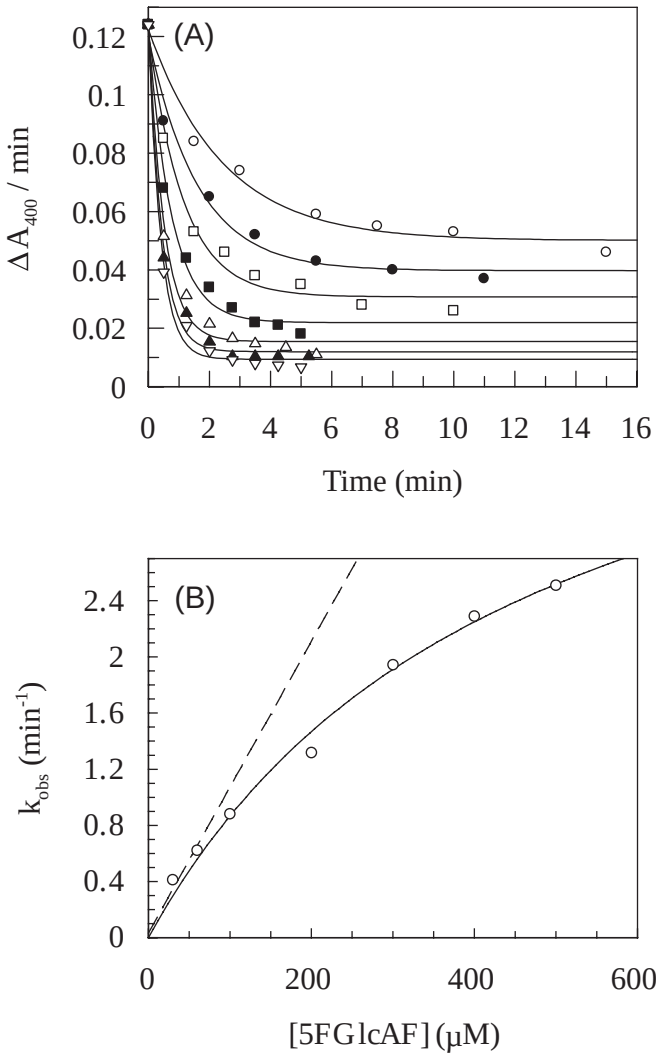
The dashed line represents the initial slope of the plot.



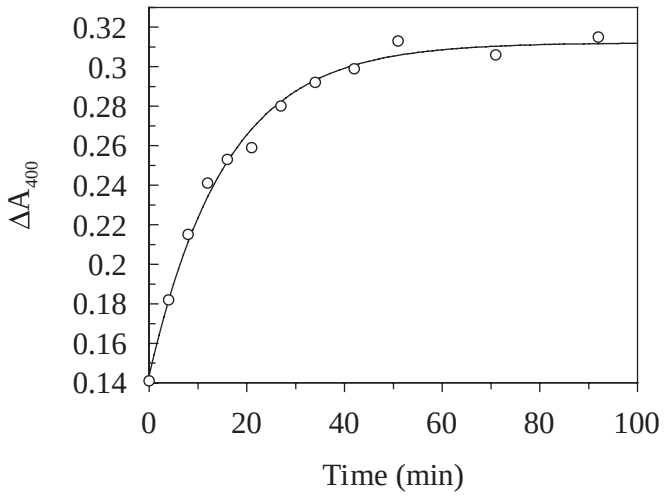


Fig 4. Reactivation of 5F-glucuronyl glucuronidase. Plot of enzyme activity vs. time.

Catalytic competence

Further evidence supporting the trapping of a relevant covalent 5F-glucuronyl-enzyme arises from demonstration of the catalytic competence of the trapped intermediate. Following removal of excess inactivator from the labelled enzyme, the sample was incubated at 37°C in the presence of buffer A and the recovery of activity associated with the regeneration of the free enzyme was monitored. Reactivation of the 5F-glucuronyl-enzyme in buffer followed a first order process with an apparent rate constant of k_{re} = 0.0642 ± 0.0045 min^{-1} ($t_{1/2}$ = 10.8 ± 0.8 min) (Fig. 4).

Identification of the labelled active site peptide by ESMS

The strategy for identification of the active site nucleophile involved first labelling a sample of EBG with 5FGlcAF, then carrying out comparative LC–MS analyses of samples of labelled and unlabelled enzyme that had been subjected to proteolytic digestion. Searching of these chromatograms for a pair of unique peptides differing in mass by exactly the mass of the 5-fluoroglucuronyl moiety (195 Da) should identify a candidate peptide, which could then be sequenced by tandem mass spectrometry.

Peptic hydrolysis of native EBG or 5F-glucuronyl-enzyme resulted in a mixture of peptides that were separated by reverse-phase HPLC using the ESMS as detector. When scanned in the normal LC–MS mode, the total ion chromatograms (TIC) showed a large number of peaks, each corresponding to one or more peptides in the digest mixture. The masses under each peak in the labelled sample were compared with the masses of the corresponding peptides in the native sample, searching for a peptide present only in the labelled sample that was 195 Da greater than a peptide present only in the unlabelled sample. However, no peptide was found matching this criterion.

The absence of such a match did not rule out the presence of a labelled peptide in the treated sample since it was possible that the presence of the sugar moiety could modify the cleavage pattern of pepsin, thereby masking the mass difference. Comparative mapping was therefore performed between EBG labelled with 5FGlcAF and EBG labelled with the previously synthesized 2FGlcAF (9). The latter reagent has previously been shown to label human glucuronidase and was shown here to also inactivate EBG. The difference in mass between 5FGlcAF and 2FGlcAF is 16, allowing for comparative searching of the chromatograms from proteolytic digests of the two labelled samples. These samples would likely have very similar proteolytic digestion profiles, thereby sidestepping the problem of different digestion patterns. Only one pair of peaks with this difference in mass was found, these being a peak with *m*/*z* 990 in the 5FGlcAF-treated sample, which was not observed in the 2FGlcAF-treated sample (Fig. 5) and a peak with *m*/*z* 974 in the 2FGlcAF-treated sample that was not observed in that of the 5FGlcAF-treated sample (Fig. 5). The labelled parent ions (*m*/*z* 974 and 990) thus appear as singly charged species. Subtracting 179 and 195 (the masses of the 2FGlcAF and

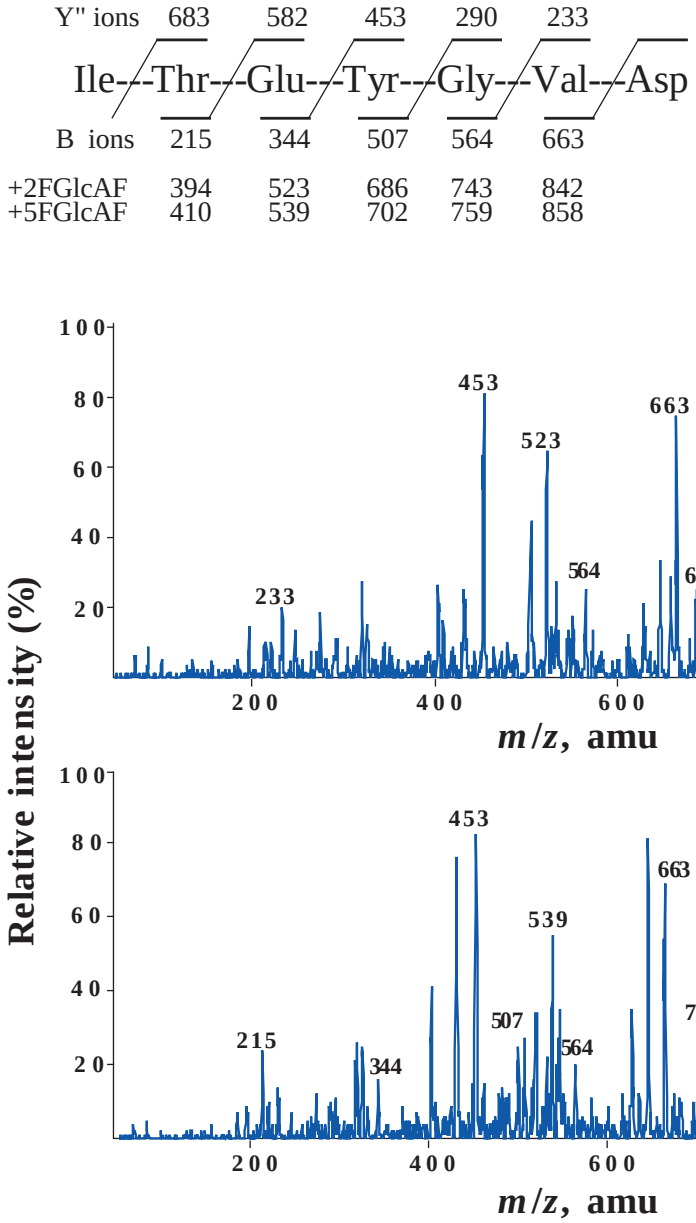
Note: The enzymes are grouped according to substrate specificity.

5FGlcAF labels) from these observed masses gives the molecular weight of the native peptide as 795.



Candidate peptides with a mass of 795 ± 1 Da were then identified by inspection of the amino acid sequence of the enzyme and searching for all possible peptides with this mass. Three such peptides were identified, but one of these was eliminated because its sequence did not contain either an aspartate or a glutamate residue. Precedent with retaining glycosidases to date would predict that the nucleophile should be one of these two amino acids (10). The candidate peptides are $_{115}$EADVTPY$_{121}$ and $_{502}$ITEYGVD$_{507}$. The sequence of the peptide was then unambiguously determined by tandem mass spectrometry.

Peptide sequencing

Information on the sequence was obtained by additional fragmentation of the peptides of interest (*m/z* 974 and 990) in the daughter ion scan mode (Fig. 6). The parent ion of interest was selected in the first quadrupole and subjected to collision-induced fragmentation, and then the masses of the

Fig 6. Electrospray tandem MS daughter ion spectrum of labelled peptides. (A) Observed fragments for peptide labelled with 2FGlcAF; (B) observed fragments for peptide labelled with 5FGlcAF. The sizes of the observed B and Y″ series fragments are shown above.

daughter ions were detected in the third quadrupole. In each sample, peaks with a mass difference of 16 arising from B ions bearing either a 2FGlcAF or a 5FGlcAF label include ITE (*m*/*z* 523 and 539), ITEY (*m*/*z* 686 and 702), ITEYG (*m*/*z* 743 and 759), and ITEYGV (*m*/*z* 842 and 858). Because the B ions bearing the label include only a glutamic acid, we can infer that the label is linked to Glu504. This information, in conjunction with the mass of the labelled peptide and the primary sequence of the enzyme, permits identification of the peptide containing the active site nucleophile as $_{502}$ITEYGVD$_{507}$. Comparison of this sequence with those of the other Family 2 glycosidase sequences shows that the dipeptide EY is conserved throughout the known family members (Table 1). However, the amino acids around this dipeptide are conserved only within a particular glycosidase category, i.e., galactosidase vs. glucuronidase vs. mannosidase. From this we can assign Glu504 as the catalytic nucleophile.

Conclusion

Synthesis of a new mechanism-based inactivator for β-glucuronidases (5-fluoro-β-D-glucuronosyl fluoride) is described and the reagent shown to be an effective inactivator of the β-glucuronidase from *E. coli*. The reagent functions via the formation of a stable, catalytically competent 5-fluoroglucuronosyl-enzyme intermediate. Proteolysis of this labelled enzyme coupled with tandem mass spectrometric analysis revealed the labelled residue as Glu504 within the sequence ITEYGVD.

Homobinuclear Ru–Ru and heterobinuclear Ru–Rh complexes with alkynyl and vinylidene ligands as molecular units

Helmut Werner, Petra Bachmann, and Marta Martin

Abstract: The chelate complex [$RuCl_2\{\kappa^2(P,O)$-*i*-$Pr_2PCH_2CH_2OMe\}_2$] (**1**) reacted, in the presence of CF_3SO_3Ag, with 1 equiv of $C_6H_4(C{\equiv}CH)_2$-*p* (**4**) to afford the mononuclear vinylidene compound [$RuCl(C{=}CHC_6H_4$-*p*-$C{\equiv}CH)\{\kappa^2(P,O)$-*i*-$Pr_2PCH_2CH_2OMe\}_2](CF_3SO_3)$ (**3**). From **1** and 0.5 equiv of **4**, the binuclear bis(vinylidene) complex [$RuCl\{\kappa^2(P,O)$-*i*-$Pr_2PCH_2CH_2OMe\}_2(C{=}CHC_6H_4$-*p*-$CH{=}C)RuCl\{\kappa^2(P,O)$-*i*-$Pr_2PCH_2CH_2OMe\}_2](CF_3SO_3)_2$ (**6**) was obtained. The related compound [$RuCl\{\kappa^2(P,O)$-*i*-$Pr_2PCH_2CH_2OMe\}_2(C{=}CHC_6H_4$-*m*-$CH{=}C)RuCl\{\kappa^2(P,O)$-*i*-$Pr_2PCH_2CH_2OMe\}_2](CF_3SO_3)_2$ (**7**) was prepared from **1**, 0.5 equiv of $C_6H_4(C{\equiv}CH)_2$-*m* (**5**), and silver triflate. The reaction of **2** or **3** with $[RhCl(P$-*i*-$Pr_3)_2]_2$ (**8**) in the molar ratio of 2:1 yields, by addition of the 14-electron fragment [$RhCl(P$-*i*-$Pr_3)_2$] to the uncoordinated C—C triple bond, the heterobinuclear complexes [$RuCl\{\kappa^2(P,O)$-*i*-$Pr_2PCH_2CH_2OMe\}_2(C{=}CHC_6H_4$-*m*/*p*-$C{\equiv}CH)RhCl(P$-*i*-$Pr_3)_2](CF_3SO_3)$ (**9**, **10**) which slowly rearrange at room temperature to give the bis(vinylidene) isomers [$RuCl\{\kappa^2(P,O)$-*i*-$Pr_2PCH_2CH_2OMe\}_2(C{=}CHC_6H_4$-*m*/*p*-$CH{=}C)RhCl(P$-*i*-$Pr_3)_2](CF_3SO_3)$ (**11**, **12**).

Key words: ruthenium, rhodium, vinylidene complexes, alkyne complexes, phosphine complexes.

Résumé : En présence de CF_3SO_3Ag, le chélate complexe [$RuCl_2\{\kappa^2(P,O)$-*i*-$Pr_2PCH_2CH_2OMe\}_2$] (**1**) réagit avec un équivalent de $C_6H_4(C{\equiv}C)_2$-*p* (**4**) pour conduire à la formation du composé vinylidène mononucléaire [$RuCl(C{=}CHC_6H_4$-*p*-$C{\equiv}C)\{\kappa^2(P,O)$-*i*-$Pr_2PCH_2CH_2OMe\}_2](CF_3SO_3)_2$ (**3**). À partir de **1** et d'un demi-équivalent de **4**, on obtient le complexe bis(vinylidène) binucléaire [$RuCl\{\kappa^2(P,O)$-*i*-$Pr_2PCH_2CH_2OMe\}_2(C{=}CHC_6H_4$-*p*-$C{=}C)RuCl\{\kappa^2(P,O)$-*i*-$Pr_2PCH_2CH_2OMe\}_2](CF_3SO_3)_2$ (**6**). On a préparé le composé apparenté [$RuCl\{\kappa^2(P,O)$-*i*-$Pr_2PCH_2CH_2OMe\}_2(C{=}CHC_6H_4$-*m*-$C{=}C)RuCl\{\kappa^2(P,O)$-*i*-$Pr_2PCH_2CH_2OMe\}_2](CF_3SO_3)_2$ (**7**) en faisant réagir le composé **1** un demi-équivalent de $C_6H_4(C{\equiv}CH)_2$-*m* (**5**) en présence de triflate d'argent. Par le biais d'une addition du fragment à quatorze électrons [$RhCl(P$-*i*-$Pr_3)_2$] à la triple liaison qui n'est pas coordinée, les réactions des composés **2** ou **3** avec le $[RhCl(P$-*i*-$Pr_3)_2]_2$ (**8**), dans un rapport molaire de 2:1, conduisent aux complexes hétérobinucléaires [$RuCl\{\kappa^2(P,O)$-*i*-$Pr_2PCH_2CH_2OMe\}_2(C{=}CHC_6H_4$-*m*/*p*-$C{\equiv}C)RhCl(P$-*i*-$Pr_3)_2](CF_3SO_3)_2$ (**9**, **10**) qui se réarrangement lentement à la température ambiante pour conduire aux isomères bis(vinylidènes) [$RuCl\{\kappa^2(P,O)$-*i*-$Pr_2PCH_2CH_2OMe\}_2(C{=}CHC_6H_4$-*m*/*p*-$C{=}C)RhCl(P$-*i*-$Pr_3)_2](CF_3SO_3)_2$ (**11**, **12**).

[Traduit par la Rédaction]

Introduction

Recently, we (1) described an efficient method for the preparation of the chelate complex [$RuCl_2\{\kappa^2(P,O)$-*i*-$Pr_2PCH_2CH_2OMe\}_2$] (**1**) using $[(1.5\text{-}C_8H_{12})RuCl_2]_n$ as the starting material. Due to the *hemilabile* coordination mode of the two phosphinoether ligands (for the term hemilabile see ref. 2*a*; for reviews see ref. 2*b*), compound **1** is quite reactive and affords with CO or PhC≡CH by cleavage of one of the Ru—O bonds the corresponding carbonyl and vinylidene complexes, [$RuCl_2(CO)\{\kappa^1(P)$-*i*-$Pr_2PCH_2CH_2OMe\}\{\kappa^2(P,O)$-*i*-$Pr_2PCH_2CH_2OMe\}$] and [$RuCl_2(C{=}CHPh)\{\kappa^1(P)$-*i*-$Pr_2PCH_2CH_2OMe\}\{\kappa^2(P,O)$-*i*-$Pr_2PCH_2CH_2OMe\}$], respectively, (3). Moreover, treatment of **1** with terminal alkynes RC≡CH, in the presence of silver triflate, led to the formation of the cationic compounds [$RuCl(C{=}CHR)\{\kappa^2(P,O)$-*i*-$Pr_2PCH_2CH_2OMe\}_2](CF_3SO_3)$ which reacted with base by deprotonation of the vinylidene ligand to give the alkynyl derivatives [$RuCl(C{\equiv}CR)\{\kappa^2$-$(P,O)$-*i*-$Pr_2PCH_2CH_2OMe\}_2$] (1). Since we used in the course of these studies apart from alkynes RC≡CH with *R* = H, Ph, and C_6H_4Me-*p* also the diyne $C_6H_4(C{\equiv}CH)_2$-*m* as a substrate, we isolated a cationic complex with a ligand containing an uncoordinated C≡CH unit in the side chain.

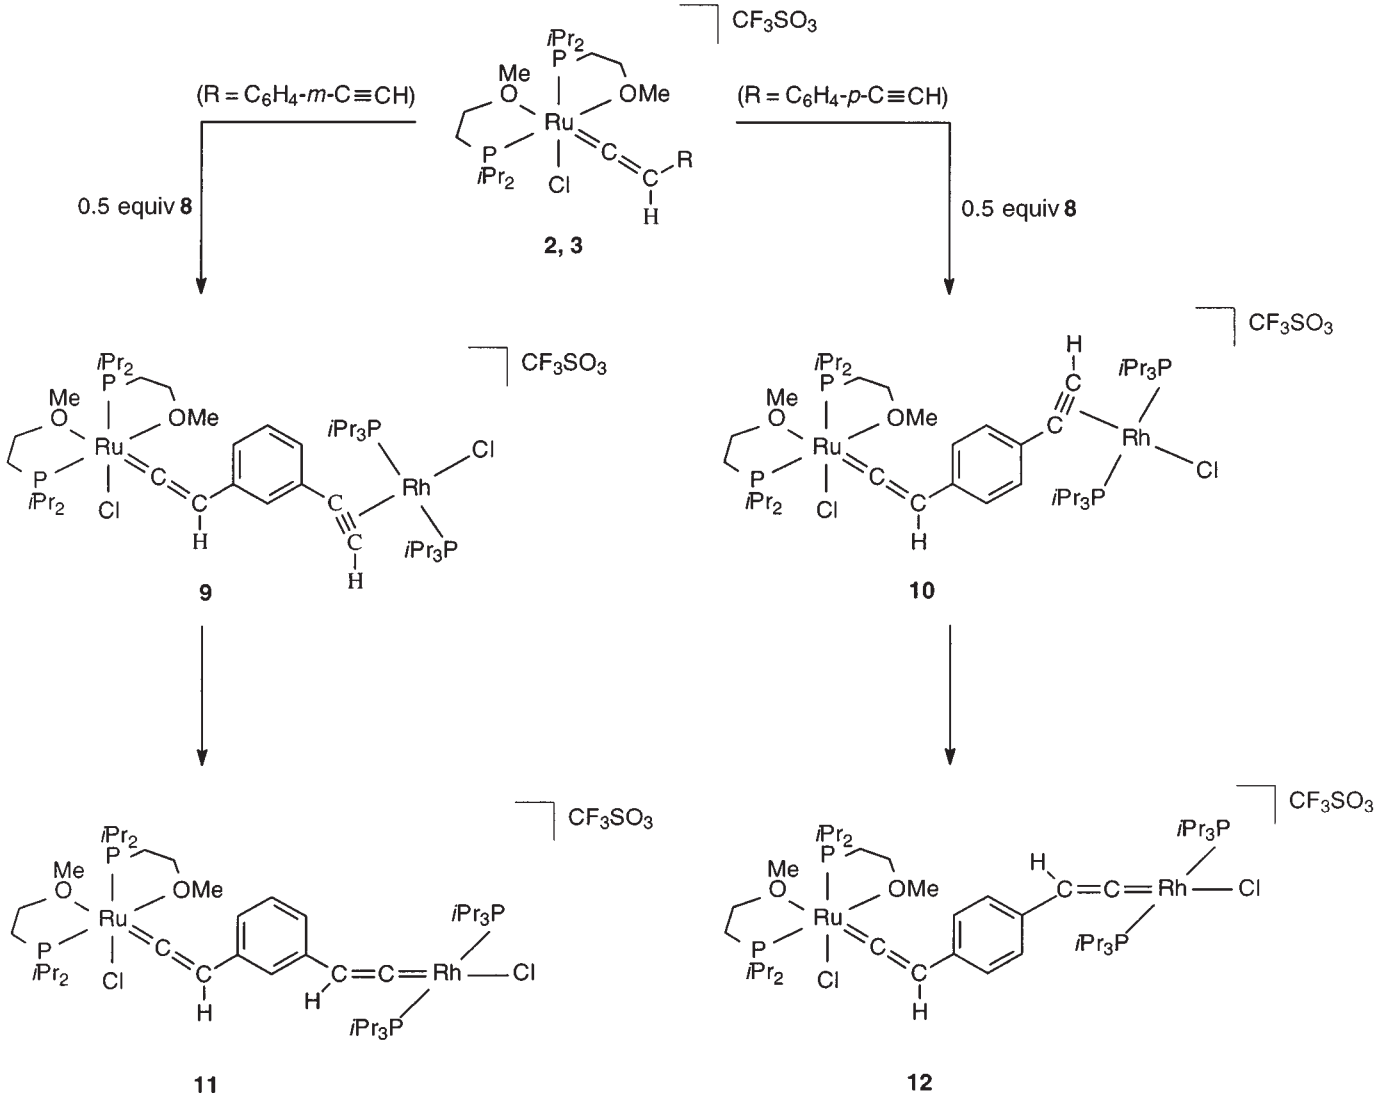
Scheme 1.

Based on this result, the question arose whether this ruthenium cation behaves like an ordinary terminal alkyne and reacts with coordinatively unsaturated precursors to give bimetallic products.

In answering this question, we report in the present paper the synthesis of some homo- and hetero-binuclear Ru–Ru and Ru–Rh complexes, the latter of which revealing different coordination spheres around the two metal centers.



Results and discussion

The preparation of the mononuclear complex **3** (see Scheme 1) followed the route which we had already used for the analogous compound **2** (1). Stepwise treatment of the starting material **1** in acetone with the diyne **4** and silver triflate led, after separation of AgCl, to the formation of a yellow solution from which **3** was isolated in 72% yield. The proposed structure with the *cis*-disposed P-*i*-Pr_2 groups is supported by the ^{31}P NMR spectrum which displays the typical pattern of an AB spin system showing two doublets with a small P—P coupling constant of 24.1 Hz. Further characteristic features are the triplet resonance for the =C*H*R proton in the ^1H NMR spectrum at δ 5.09 and the low-field signals at δ 355.5 and 117.2 in the ^{13}C NMR spectrum which, in agreement with DEPT measurements, are assigned to the α- and β-C atoms of the vinylidene unit. The resonances for the ^{13}C NMR nuclei of the uncoordinated C≡C bond appear as singlets at δ 83.8 and 77.4, respectively.

The reaction of **1** with an equimolar amount of CF_3SO_3Ag but with 0.5 equiv instead of 1 equiv of the diyne **4** led, under the same conditions as used for the preparation of **3**, to the binuclear complex **6** (see Scheme 1). Similarly to **3**, compound **6** is also an orange, only slightly air-sensitive solid which is easily soluble in polar solvents such as acetone or dichloromethane. In contrast to **3**, the IR spectrum of **6** shows no stretching vibrations in the regions at about 3200 and 2100 cm^{-1}, indicating that no C≡CH unit is present. The ^{13}C NMR spectrum of **6** displays the signals for the vinylidene carbon atoms at almost the same positions as found for the mononuclear complex **3**.

Scheme 2.

The starting material **1** reacts not only with **4** but also with the *meta*-isomer **5** of the diyne $C_6H_4(C{\equiv}CH)_2$ in the molar ratio of 2:1 to give the binuclear compound **7**. Due to the related structure of **6** and **7**, it is not surprising that both the chemical properties and the spectroscopic data of the two isomers are in most respects quite similar. The slightly lower symmetry of **7** compared to **6** is indicated, inter alia, by the appearance of a broad multiplet instead of a singlet for the protons of the C_6H_4 fragment and equally by the observation of eight instead of two singlet resonances for the carbon atoms of the phenylene ring. We also note that apart from **6** and **7**, three isomeric binuclear rhodium complexes with the *ortho*-, *meta*-, and *para*-isomers of the bis(vinylidene) unit $C{=}CHC_6H_4CH{=}C$ have been prepared in our laboratory (4).

The uncoordinated alkyne functionality of both **2** and **3** can also be used for the preparation of the mixed-metal ruthenium–rhodium compounds **9**–**12** shown in Scheme 2. The mononuclear precursors react, analogously as terminal alkynes RC≡CH (5), with the dimer $[RhCl(P\text{-}i\text{-}Pr_3)_2]_2$ (**8**) under mild conditions to give the Ru–Rh complexes **9** and **10** as orange microcrystalline solids in ca. 60% yield. In the IR spectra of **9** and **10**, the ν (≡CH) and ν (C≡C) modes appear at significantly lower wave numbers than in the spectra of **2** and **3** which is in agreement with the coordination of the triple bond to the rhodium center. The proposed *trans*-disposition of the two triisopropylphosphine ligands at Rh is supported by the ^{1}H NMR spectra of **9** and **10**, each of which displays two doublets of virtual triplets for the protons of the diastereotopic methyl groups of the P-*i*-Pr_3 units.

Both **9** and **10** slowly rearrange, in toluene at room temperature, to the isomeric species **11** and **12** which are isolated as green, relatively air-stable solids in ca. 70% yield. The ^{13}C NMR spectra of **11** and **12** exhibit in the low-field region two signals for the metal-bound carbon atoms at about δ 355 and 292 which is consistent with the presence of two different carbene-like vinylidene units in the molecule. Another characteristic feature in the ^{31}P NMR spectra of **11** and **12** is the appearance of two doublets for the phosphorus atoms linked to ruthenium and of one doublet for the phosphorus atoms linked to rhodium, the latter showing a rather large Rh—P coupling of ca. 135 Hz. With regard to the course of the rearrangement of **9** and **10** to **11** and **12**, we

failed to find any evidence for the generation of an intermediate containing an alkynyl(hydrido)rhodium moiety RhH(C≡CR)Cl(P-*i*-Pr_3)$_2$ as a building block, and therefore a concerted mechanism is most likely (6). This result is in contrast to that for the isomerization reaction of *trans*-[RhCl(HC≡C*t*Bu)(P-*i*-Pr_3)$_2$] to *trans*-[RhCl(=C≡CH-*t*-Bu)(P-*i*-Pr_3)$_2$] for which a five-coordinate intermediate [RhH(C≡C-*t*-Bu)Cl(P-*i*-Pr_3)$_2$] could not only be detected but even isolated (7).

Experimental

All experiments were carried out under an atmosphere of argon by using standard Schlenk techniques. The starting materials [$RuCl_2${κ^2(*P,O*)-*i*-$Pr_2PCH_2CH_2OMe$}$_2$] (**1**) (1), C_6H_4(C≡CH)$_2$-*p* and -*m* (**4**, **5**) (8), [RuCl-(C=CHC_6H_4C≡CH-*m*){κ^2(*P,O*)-*i*-$Pr_2PCH_2CH_2OMe$}$_2$](CF_3SO_3) (**2**) (1), and [RhCl(P-*i*-Pr_3)$_2$]$_2$ (**8**) (9) were prepared as described previously. IR spectra were recorded on a PerkinElmer 1420 IR spectrometer and NMR spectra on Bruker AC 200 and WM 400 instruments. Melting points (dec. temp.) were determined by DTA.

Preparation of [RuCl(C=CHC_6H_4-*p*-C≡CH){κ^2(*P,O*)-*i*-$Pr_2PCH_2CH_2OMe$}$_2$](CF_3SO_3) (3)

A solution of **1** (262 mg, 0.50 mmol) and **4** (63 mg, 0.50 mmol) in 10 mL of acetone was cooled to 0°C and then treated with CF_3SO_3Ag (128 mg, 0.50 mmol). After the reaction mixture was stirred for 20 min in the dark, the precipitate (AgCl) was separated by filtration through Kieselgur and the filtrate concentrated to ca. 0.5 mL in vacuo. A yellow microcrystalline solid was formed which was washed twice with ether and dried. Yield: 275 mg (72%). IR (KBr) (cm^{-1}): ν(≡CH) 3200, ν(C≡C) 2080, ν(C=C) 1620, 1590. ^{1}H NMR (400 MHz, CD_2Cl_2) δ: 7.37, 7.30 (AB spin system, *J* (HH) = 7.8 Hz, C_6H_4), 5.09 (t, *J* (PH) = 3.2 Hz, =CH), 4.18, 4.13, 4.04, 3.80 (all m, C*H*$_2$OCH$_3$), 3.84, 3.65, (both s, OCH$_3$), 3.10 (s, ≡CH), 2.88, 2.50, 2.40, 2.34, 2.30, 2.00, 1.85 (all m, PC*H*CH$_3$ and PCH$_2$), 1.53–1.29 (br m, PCHC*H*$_3$). ^{13}C NMR (100.6 MHz, CD_2Cl_2) δ: 355.5 (dd, *J* (PC) = 18.1 and 15.1 Hz, Ru=C), 132.7, 130.5, 126.5, 119.9 (all s, C_6H_4), 121.4 (q, *J* (FC) = 320.9 Hz, CF_3), 117.2 (s, =*C*HR), 83.8 (s, C≡*C*H), 77.4 (s, *C*≡CH), 72.8, 71.7 (both s, *C*H$_2$OCH$_3$), 63.2, 63.1, 61.7, 61.6 (all s, OCH$_3$), 37.7 (d, *J* (PC) = 33.2 Hz, P*C*HCH$_3$), 29.5 (d, *J* (PC) = 26.0 Hz, P*C*HCH$_3$), 26.6 (d, *J* (PC) = 28.6 Hz, P*C*HCH$_3$), 25.8 (d, *J* (PC) = 20.0 Hz, P*C*HCH$_3$), 25.4 (d, *J* (PC) = 22.0 Hz, PCH$_2$), 23.2 (d, *J* (PC) = 24.0 Hz, PCH$_2$), 20.1, 19.8, 19.7, 19.65, 19.6, 19.5, 19.1, 19.0 (all s, PCH*C*H$_3$). ^{31}P NMR (162.0 MHz, CD_2Cl_2) δ: 67.9, 56.3 (both d, *J* (PP) = 24.1 Hz). ^{19}F NMR (376.5 MHz, CD_2Cl_2) δ: –78.6 (s). Preparation of [RuCl{κ^2(*P,O*)-*i*-Pr$_2$PCH$_2$CH$_2$OMe}$_2$(C=CHC$_6$H$_4$-*p*-C≡CH)RhCl(P-*i*-Pr$_3$)$_2$](CF$_3$SO$_3$) (10)

The procedure was analogous to that described for **9**, using **3** (153 mg, 0.20 mmol) and **8** (94 mg, 0.10 mmol) as starting materials. An orange microcrystalline solid was obtained. Yield: 147 mg (60%), mp 120°C (dec.). IR (CH_2Cl_2) (cm^{-1}): ν(≡CH) 3070, ν(C≡C) 1780, ν(C=C) 1570. ^{1}H NMR (200 MHz, CD_2Cl_2) δ: 7.65–6.78 (br m, C_6H_4), 5.08 (t, *J* (PH) = 3.0 Hz, =CH), 4.13, 4.11, 4.01, 3.81 (all m, C*H*$_2$OCH$_3$), 3.78, 3.68 (both s, OCH$_3$), 3.67 (d, *J* (RhH) = 2.7 Hz, ≡CH), 2.87, 2.50, 2.35, 2.34, 2.31, 2.10, 1.88 (all m, RuPC*H*CH$_3$ and PCH$_2$), 2.73 (m, RhPC*H*CH$_3$), 1.49–1.37 (br m, RuPCHC*H*$_3$), 1.23 (dvt, *N* = 15.8, *J* (HH) = 7.3 Hz, RhPCHC*H*$_3$), 1.02 (dvt, *N* = 13.7, *J* (HH) = 6.5 Hz, RhPCHC*H*$_3$). ^{31}P NMR (81.0 MHz, CD_2Cl_2) δ: 66.2, 55.6 (both d, *J* (PP) = 24.3 Hz, RuP), 31.5 (d, *J* (RhP) = 116.8 Hz, RhP). ^{19}F NMR (376.5 MHz, CD_2Cl_2) δ: –78.6 (s). Anal. calcd. for $C_{47}H_{90}Cl_2F_3O_5P_4RhRuS$: C 46.16, H 7.42, S 2.62; found: C 46.23, H 7.51, S 2.74.

Preparation of [RuCl{κ^2(*P,O*)-*i*-Pr$_2$PCH$_2$CH$_2$OMe}$_2$(C=CHC$_6$H$_4$-*m*-CH=C)RhCl(P-*i*-Pr$_3$)$_2$](CF$_3$SO$_3$) (11)

A solution of **9** (162 mg, 0.13 mmol) in 15 mL of toluene was stirred for 4 h at room temperature. A change of colour from orange to dark brown occurred. The solvent was removed in vacuo, the remaining residue was dissolved in 2 mL of toluene, and the solution was chromatographed on Al_2O_3 (neutral, activity grade V, height of column = 7 cm). With toluene, a green fraction was eluted which was evaporated to dryness in vacuo. The green solid was washed twice with 2 mL portions of pentane (0°C) and dried in vacuo. Yield: 113 mg (71%), mp 105°C (dec.). IR (CH_2Cl_2) (cm^{-1}): ν(C=C) 1610, 1570. ^{1}H NMR (200 MHz, CD_2Cl_2) δ: 7.55–6.74 (br m, C_6H_4), 4.80 (t, *J* (PH) = 3.1 Hz, Ru=C=CH), 4.17, 4.15, 4.02, 3.85 (all m, C*H*$_2$OCH$_3$), 3.80, 3.63 (both s, OCH$_3$), 2.88, 2.48, 2.39, 2.35, 2.31, 2.14, 1.92 (all m, RuPC*H*CH$_3$ and PCH$_2$), 2.74 (m, RhPC*H*CH$_3$), 1.53–1.42 (br m, RuPCHC*H*$_3$), 1.30 (dvt, *N* = 12.8, *J* (HH) = 6.3 Hz, RhPCHC*H*$_3$), the signal of Rh=C=CH could not be exactly located. ^{13}C NMR (100.6 MHz, CD_2Cl_2) δ: 355.3 (dd, *J* (PC) = 17.9 and 14.8 Hz, Ru=C), 292.7 (dt, *J* (RhC) = 59.6, *J* (PC) = 15.5 Hz, Rh=C), 133.8, 130.0 127.3, 122.2 (all s, C_6H_4), 119.6 (q, *J* (FC) = 319.1 Hz, CF_3), 117.9 (s, Ru=C=*C*), 112.2 (dt, *J* (RhC) = 15.3, *J* (PC) = 7.0 Hz, Rh=C=*C*), 62.3, 61.3 (both s, OCH$_3$), 36.9 (d, *J* (PC) = 31.8 Hz, RuP*C*HCH$_3$), 29.0 (d, *J* (PC) = 24.2 Hz, RuP*C*HCH$_3$), 26.0 (d, *J* (PC) = 28.0 Hz, RuP*C*HCH$_3$), 25.6 (d, *J* (PC) = 24.2 Hz, PCH$_2$), 25.5 (d, *J* (PC) = 20.5 Hz, PCH$_2$), 25.4 (d, *J* (PC) = 20.3 Hz, RuP*C*HCH$_3$), 24.0 (vt, *N* = 17.8 Hz, RhP*C*HCH$_3$), 20.4 (s, RhPCH*C*H$_3$), 20.2, 20.1, 19.8, 19.6, 19.5, 19.4, 19.3, 19.1 (all s, RuPCH*C*H$_3$). ^{31}P NMR (81.0 MHz, CD_2Cl_2) δ: 68.6, 57.7 (both d, *J* (PP) = 24.7 Hz, RuP), 43.2 (d, *J* (RhP) = 135.1 Hz, RhP); ^{19}F NMR (376.5 MHz, CD_2Cl_2) δ: –77.5 (s). Mechanistic study of ligand substitution processes in TpIr(III) complexes

David M. Tellers and Robert G. Bergman

Abstract: The synthesis of the cationic hydridotris(pyrazolyl)borate iridium(III) complex [Tp(PMe_3)IrMe($ClCH_2Cl$)][BAr_f] (**2-CH_2Cl_2**) is reported. Spectroscopic characterization of **2-CH_2Cl_2** in CH_2Cl_2 solution indicates that exchange of bound CH_2Cl_2 with free CH_2Cl_2 is slow on the NMR time scale. Under 50 atm (1 atm = 101.325 kPa) of N_2, the CH_2Cl_2 in **2-CH_2Cl_2** is displaced by N_2 to yield [Tp(PMe_3)IrMe(N_2)][BAr_f] (**2-N_2**). The stronger nucleophile CH_3CN reacts rapidly with **2-CH_2Cl_2** to produce [Tp(PMe_3)IrMe($NCCH_3$)][BAr_f] (**4**). A kinetic study was performed on CH_2Cl_2 substitution in **2-CH_2Cl_2** by CD_3CN. The data are most consistent with dissociative loss of CH_2Cl_2 to generate the unsaturated species ([Tp(PMe_3)IrMe][BAr_f]) which then reacts with CD_3CN to generate [Tp(PMe_3)IrMe($NCCD_3$)][BAr_f]. Further evidence for a dissociative mechanism was obtained by comparison of ligand substitution rates for the Tp complexes with the analogous Tp^{Me2} complexes (Tp^{Me2} = hydridotris(3,5-dimethylpyrazolyl)borate). The relevance of these substitution experiments to C—H activation by cationic iridium(III) complexes is discussed.

Key words: iridium, hydridotris(pyrazolyl)borate, methylene chloride and dinitrogen complexes, dissociative substitution.

Résumé : On a réalisé la synthèse du complexe cationique hydridotris(pyrazolyl)borate d'iridium(III) ([Tp(PMe_3)IrMe($ClCH_2Cl$)][BAr_f]) (**2-CH_2Cl_2**). Une caractérisation spectroscopique du **2-CH_2Cl_2** en solution dans le CH_2Cl_2 indique que l'échange des CH_2Cl_2 liés et libres est lente sur l'échelle de temps de la RMN. Sous 50 atm (1 atm = 101.325 kPa) de N_2, le CH_2Cl_2 du **2-CH_2Cl_2** est déplacé par le N_2 pour conduire à la formation de [Tp(PMe_3)IrMe(N_2])[BAr_f] (**2-N_2**). Le CH_3CN, un nucléophile plus puissant, réagit rapidement avec le **2-CH_2Cl_2** pour conduire à la formation de [Tp(PMe_3)IrMe($NCCH_3$)][BAr_f] (**4**). On a réalisé une étude cinétique sur la vitesse de remplacement du CH_2Cl_2 de **2-CH_2Cl_2** par du CD_3CN. Les données sont plutôt en accord avec une perte dissociative du CH_2Cl_2 générant l'espèce insaturée [Tp(PMe_3)IrMe][BAr_f] qui réagit alors du CH_3CN pour générer le [Tp(PMe_3)IrMe($NCCD_3$)][BAr_f]. On a obtenu d'autres données favorisant un mécanisme dissociatif en comparant les vitesses de substitution des complexes Tp avec celles des complexes analogues Tp^{Me2} (Tp^{Me2} = hydridotris(3,5-diméthylpyrazolyl)borate). On discute de la pertinence de ces expériences de substitution sur l'activation des liaisons C—H par les complexes cationiques de l'iridium(III).

Mots clés : iridium, hydridotris(pyrazolyl)borate, complexes avec le chlorure de méthylène et le diazote, substitution dissociative.

We recently reported the synthesis of [Tp^{Me2}(PMe_3)IrMe(L)][BAr_f] (L = CH_2Cl_2 (**1-CH_2Cl_2**); L = N_2 (**1-N_2**); BAr_f = $B[3,5\text{-}C_6H_3(CF_3)_2]_4$) salts of a cationic complex that is capable of activating the C—H bonds of arenes and aldehydes (1). We envision these reactions occurring by one of the pathways illustrated in Scheme 1. The first mechanism involves dissociative loss of L and subsequent reaction with the hydrocarbon while the second involves an associative displacement of L by the hydrocarbon. Notably, complex **1** activates C—H bonds at rates slower than those reported for the corresponding Cp* compounds (2). Interest in understanding these differences prompted us to undertake a detailed study of the mechanism of substitution of L in these TpIr(III) complexes. Additional impetus was provided by the fact that relatively few mechanistic studies have been carried out on TpM-ligand exchange reactions (3–6; for a general review on Tp chemistry see ref. 7). Herein we communicate the synthesis of two new cationic hydridotris(pyrazolyl)borate iridium complexes, [Tp(PMe_3)IrMe(L)][BAr_f] (L = CH_2Cl_2 (**2-CH_2Cl_2**); L = N_2 (**2-N_2**)), and provide evidence that these complexes undergo substitution in a dissociative manner.

Preliminary kinetic experiments with the Tp^{Me2} system **1-CH_2Cl_2** were too fast to monitor. As a result, we shifted our focus to the hydridotris(pyrazolyl)borate analogue in hopes that it might prove easier to study. The synthesis of [Tp(PMe_3)IrMe(L)][BAr_f] (**2**) is illustrated in Scheme 2 and is analogous to a method reported by Heinekey and coworkers (8) for the synthesis of Tp(PMe_3)IrH_2. Dissolution of Cp*(PMe_3)$IrMe_3OTf$ (9) in CH_3CN produces

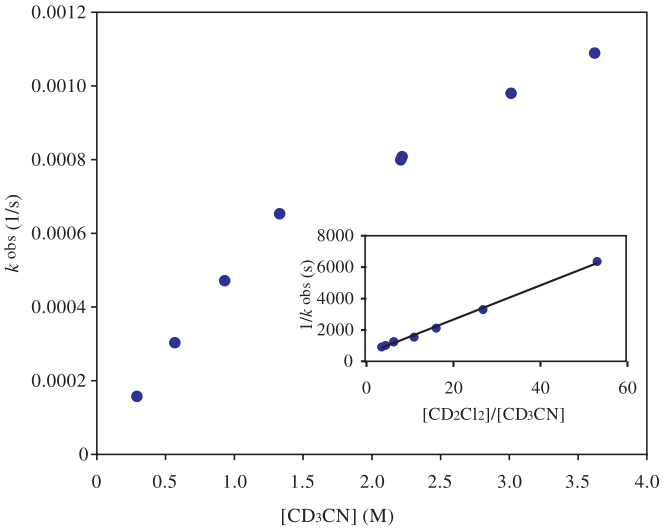
$[(CH_3CN)_3(PMe_3)IrMe_2][OTf]$ and hexamethylcyclopentadiene (C_5Me_6).[2] Subsequent addition of KTp to $[(CH_3CN)_3(PMe_3)IrMe_2][OTf]$ yields $Tp(PMe_3)IrMe_2$ (87%). Protonolysis of this product with HOTf yields $Tp(PMe_3)Ir(Me)OTf$ (**3**) (53%). Treatment of **3** with $NaBAr_f$ in CH_2Cl_2 under a dinitrogen atmosphere produces *only* **2-CH_2Cl_2** (40%). This was unexpected since under identical conditions the preparation of the Tp^{Me2} analogue yields only **1-N_2**. The identity of **2-CH_2Cl_2** was confirmed by ^{13}C NMR spectroscopy. In CH_2Cl_2 a triplet is observed at 61.3 ppm ($^1J_{C\text{-}H}$ = 183 Hz; free CH_2Cl_2 = 54.0 ppm, $^1J_{C\text{-}H}$ = 180 Hz). This resonance is assigned to the dichloromethane molecule bound to the cationic iridium center. The fact that it does not disappear at elevated temperatures (60°C) indicates that exchange with the solvent is slow on the NMR time scale. The slow rate of exchange appears to be unique to **2-CH_2Cl_2** since other cationic dichloromethane complexes, including **1-CH_2Cl_2**, require the use of low-temperature NMR spectroscopy to observe the bound dichloromethane resonance (for leading references see refs. 10 and 11).

Consistent with the observation that CH_2Cl_2 is bound to iridium relatively strongly, the synthesis of the dinitrogen complex **2-N_2** from **2-CH_2Cl_2** necessitates the use of high dinitrogen pressures. Placing a dichloromethane solution of **2-CH_2Cl_2** under 50 atm (1 atm = 101.325 kPa) of dinitrogen for 12 h yields **2-N_2** (60%, ν_{NN} (KBr) = 2237 cm^{-1}). Interestingly, **2-N_2** is thermodynamically more stable than **2-CH_2Cl_2**; **2-N_2** does not react to form **2-CH_2Cl_2** after 5 days in CH_2Cl_2 (1 atm N_2 (1 atm = 101.325 kPa)). The slow rate of formation of **2-N_2** compared to that of **1-N_2** is therefore the result of a relatively large kinetic barrier to dichloromethane loss. Stronger nucleophiles, however, displace CH_2Cl_2 from **2-CH_2Cl_2** at a more rapid rate. For example, treatment of **2-CH_2Cl_2** with 1 equiv of acetonitrile at 22°C yields $[Tp(PMe_3)IrMe(NCCH_3)][BAr_f]$ (**4**) ($t_{1/2}$ = 5 min, 74% yield).

As demonstrated above, it was more convenient to carry out exchange kinetics with **2-CH_2Cl_2** as it is significantly less reactive than the Tp^{Me2} complex **1-CH_2Cl_2**. We therefore elected to investigate the mechanism of formation of **4** from **2-CH_2Cl_2** and acetonitrile. A kinetic study was performed in CD_2Cl_2 at 0°C using ^1H NMR spectroscopy to monitor the reaction between **2-CH_2Cl_2** (0.004 M) and excess concentrations of CD_3CN (0.29–3.6 M).[3] A plot of k_{obs} vs. $[CH_3CN]$ is shown in Fig. 1. For an associative mechanism, we would expect a strictly linear relationship between k_{obs} and $[CH_3CN]$. As illustrated in Fig. 1, the reaction begins to deviate from linear behavior at high $[CH_3CN]$.[4] While this deviation may be the result of a solvent effect caused by the high $[CH_3CN]$, we believe the data are most consistent with the dissociative mechanism shown in Scheme 3, which leads to the rate law shown in eq. [1]. The



$$[1] \qquad \frac{d[\mathbf{4}]}{dt} = \frac{k_1 k_2[\mathbf{2\text{-}CH_2Cl_2}][CD_3CN]}{k_{-1}[CH_2Cl_2] + k_2[CD_3CN]}$$

first step (k_1) involves dichloromethane loss to generate the unsaturated 16-electron cation $[Tp(PMe_3)IrMe]$. This complex is subsequently trapped by added acetonitrile to

[2] Spectroscopic and analytical data can be found in the supplementary material.
[3] Deuterated material was used to avoid saturating the NMR receiver by the acetonitrile proton signals.
[4] Reactions at much higher concentrations were not run because the reaction rates became too fast to measure.

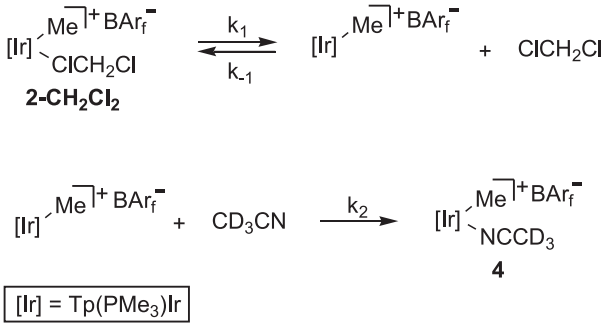
Fig. 1. Plot of k_{obs} vs. [CD_3CN] for the reaction of **2-CH_2Cl_2** with acetonitrile-d_3 to produce **4** at 0 ± 0.1°C. The inset is a plot of $1/k_{obs}$ vs. [CD_2Cl_2]/[CD_3CN]. This solid line is a linear least squares fit of the data (R^2 = 0.997).

generate **4**. As predicted by eq. [2], a linear plot is ob-



$$[2] \qquad \frac{1}{k_{obs}} = \left(\frac{k_{-1}}{k_2 k_1}\right)\frac{[CH_2Cl_2]}{[CD_3CN]} + \frac{1}{k_1}$$

tained when $1/k_{obs}$ is plotted against [CD_2Cl_2]/[CD_3CN] (Fig. 1). The rate constant for methylene chloride dissociation (k_1) from **2-CH_2Cl_2** at 0°C can be determined from the value of the *y*-intercept of this plot, which is equal to $1/k_1$. The value of k_1 is 2.1 ± 0.2 × 10^{-3} s^{-1} at 0°C.

Because of our inability to experimentally reach the limiting dissociation rate of **2-CH_2Cl_2**, the reaction of **1-CH_2Cl_2** with acetonitrile ([CD_3CN] = 0.27 M) to produce [Tp^{Me2}(PMe_3)IrMe($NCCD_3$)][BAr_f] (**6**) (1) was also examined. At 0°C, this reaction was too fast to monitor by NMR spectroscopy ($t_{1/2} \leq 5$ s). Under identical conditions, the Tp analogue (**2-CH_2Cl_2**) was found to have a $t_{1/2} \approx 75$ min. The difference in reaction rates between the Tp and Tp^{Me2} complexes for this reaction and for dichloromethane substitution by dinitrogen (vide supra) also supports the dissociative mechanism shown in Scheme 3. If substitution were to occur by an associative mechanism (i.e., via a seven-coordinate complex or transition state), the less sterically congested Tp compound should react at a faster rate.[5] Instead, the Tp^{Me2} ligand, which is more sterically encumbering and a stronger electron donor than the Tp ligand (12), serves to increase the rate of ligand loss at the metal center, as would be expected for a dissociative mechanism.

Our results are consistent with recent work done by Kirchner and co-workers (3) who demonstrated that the iso-

Scheme 3. Proposed dissociative mechanism for the formation of **4**.

electronic Ru(II) compound [$TpRu(NCCH_3)_3$]$^+$ undergoes dissociative exchange with free acetonitrile. Furthermore, displacement of $OPPh_3$ by pyridine on $TpReCl_2(OPPh_3)$ was shown to be dissociative by Seymore and Brown (5). It seems likely that the Tp ligand's ability to enforce an octahedral geometry about the metal center, coupled with its steric bulk, prevents the formation of a transient seven-coordinate species (i.e., an associative mechanism) (3). It should be noted, however, that Mayer and co-workers (4) recently demonstrated that triflate displacement from Tp(Ph)Re(NtBu)OTf by various dative ligands occurs via an associative mechanism. Consistent with this, and in constrast to our results, they observed that substitution in the Tp complex was *faster* than that observed for the more sterically encumbered Tp^{Me2} complex.[6]

In conclusion, we have synthesized two cationic iridium complexes and demonstrated that complex **2-CH_2Cl_2** undergoes ligand substitution by initial dissociation of CH_2Cl_2. Based upon this work, it is likely that the Tp-containing compounds **1** and **2** and the corresponding Cp* analogue react with the C—H bonds of hydrocarbons in a similar manner (Scheme 1, Dissociative pathway). Current work is focused on understanding the differences in the relative rates of C—H activation by these complexes.[7]

[5] Our experiments do not rule out a mechanism involving rate-determining dechelation of one pyrazole arm. It is unlikely, however, that dissociation of a Tp arm is more favorable than dissociation of what should be a relatively weakly bound methylene chloride molecule.

[6] In the TpRe system, the imido group can potentially serve to shuttle electron density away from the metal center as the nucleophile attacks prior to ligand substitution (similar to the mechanism of organic carbonyl substitution reactions). This type of mechanism would also generate an associative rate law.

Evaluation of ruthenium-based complexes for the controlled radical polymerization of vinyl monomers

François Simal, Dominique Jan, Lionel Delaude, Albert Demonceau, Marie-Rose Spirlet, and Alfred F. Noels

Abstract: New complexes of the type $RuCl_2$(*p*-cymene)L where the ligand L is either a phosphine or a stable triazolinylidene carbene have been tested and compared to the Grubbs' benzylidene complex $RuCl_2(=CHPh)(PCy_3)_2$ as catalyst precursors for the controlled atom transfer radical polymerization (ATRP) of methyl methacrylate and of various *para*-substituted styrenes. Kinetic data and Hammett ρ constants are reported, as well as the X-ray structure of the *ortho*-metallated triazolinylidene-ruthenium(II) complex RuCl(*p*-cymene)[1,2-phenylene[3,4-diphenyl-1*H*-1,2,4-triazol-1-yl-5(4*H*)-ylidene]].

Key words: ruthenium, carbene, chelate complex, homogeneous catalysis, atom transfer radical polymerization.

Résumé : De nouveaux complexes du type $RuCl_2$(*p*-cymène)L où le ligand L désigne une phosphine ou un carbène triazolinylidène ont été testés et comparés au complexe benzylidène de Grubbs $RuCl_2(=CHPh)(PCy_3)_2$ comme précurseurs de catalyseurs pour la polymérisation radicalaire contrôlée par transfert d'atome (ATRP) du méthacrylate de méthyle et de divers styrènes *para*-substitués. Des données cinétiques et les constantes de Hammett ρ sont rapportées ainsi que la structure cristallographique du complexe ruthénium(II)-triazolinylidène *ortho*-métallé RuCl(*p*-cymène)[1,2-phénylène[3,4-diphényl-1*H*-1,2,4-triazol-1-yl-5(4*H*)-ylidène]].

Mots clés: ruthénium, carbène, complexe chélaté, catalyse homogène, polymérisation radicalaire par transfert d'atome.

Introduction

The advent of well-defined organometallic complexes which may be used as initiators for controlled radical polymerization has opened new vistas in macromolecular synthesis. A major advance in this field came from the development of the so-called atom transfer radical polymerization (ATRP), which takes advantage of the redox properties of transition-metals (1–3). ATRP is based on a dynamic equilibration between active propagating radicals and dormant species. This equilibrium is established through the reversible transition-metal-catalyzed homolytic cleavage of the covalent carbon—halogen bond in the dormant species (Scheme 1) (4).

Catalytic engineering at the metal center aims to shift this equilibrium toward the dormant species. Thus, the concentration of propagating radicals remains low thorough the whole polymerization process and a high degree of control ensues, allowing not only the synthesis of polymers of predictable molecular weights and low polydispersities, but also the preparation of novel, functionalized, block copolymers amenable to further transformations (5, 6).

Polymerization systems utilizing the ATRP concept have been developed with complexes of Cu, Ru, Ni, Pd, Rh, and Fe during the last five years (7–10). We recently reported on the exceptional efficiency and versatility of new catalysts based on $RuCl_2$(*p*-cymene)(PR_3) (**1**) for promoting the ATRP of vinyl monomers (*p*-cymene is 4-isopropyltoluene) (11). The choice of the phosphane ligand proved to be crucial. Only phosphanes which were both strongly basic and which possessed a well-defined steric bulk led to both high catalytic activity and high control of the polymerization process (high initiation efficiency f and narrow molecular weight distribution, M_w/M_n = 1.1). Along these guidelines, the most suitable phosphines in our hands were tricyclohexylphosphine (PCy_3) and triisopropylphosphine (P-*i*-Pr_3). The corresponding catalyst precursors **1** are conveniently and quantitatively prepared by reacting the ruthenium dimer $[RuCl_2$(*p*-cymene)$]_2$ with 2 equiv of the phosphine (12, 13). They exhibit a high tolerance to heteroatom functionality in

Surprisingly, the best catalysts for ATRP were also the most active ones for the ring-opening metathesis polymerization (ROMP) of cycloolefins, a reaction where metal–carbene moieties (in equilibrium with metallacyclobutanes) are known to play a key role (14). This prompted us to test preformed metal–carbene complexes such as $RuCl_2(=CHPh)(PCy_3)_2$ (**2**) — a ruthenium-benzylidene catalyst precursor commonly used for olefin metathesis (15) — under ATRP conditions (16). The results were most gratifying and we further expanded our investigations in this field by substituting *N*-heterocyclic stable carbenes for the phosphine ligands (17).

In this article, we present further studies on the scope and limitations of: (*i*) new arene–ruthenium(II)-phosphine complexes; and (*ii*) new arene–ruthenium(II)-triazolinylidene complexes as potential catalysts for the controlled radical polymerization of methyl methacrylate (MMA) and of substituted styrenes.

Results and discussion

Polymerization of MMA with $RuCl_2$(*p*-cymene)PR_3 catalyst precursors

In a previous communication from our group, the catalytic activity of numerous $RuCl_2$(*p*-cymene)PR_3 complexes based on trialkyl-, triaryl-, or mixed alkylarylphosphines was investigated under ATRP conditions. Methyl methacrylate was chosen as a model substrate and polymerizations were initiated by ethyl 2-bromo-2-methylpropanoate at 85°C (11). Ruthenium–arene complexes containing the tricyclohexylphosphine (**1a**) and, to a slightly lesser extent, triisopropylphosphine (**1b**) emerged from this study as the most efficient catalyst precursors.

To complement our initial screening, we have tested new complexes based on tricyclopentylphosphine (**1c**), *tert*-butyldicyclohexylphosphine (**1d**), and dicyclohexylphosphine (**1e**) using the same experimental conditions for MMA polymerization. The results are summarized in Table 1. For comparison sake, data previously obtained with **1a** (PR_3 = PCy_3) and **1b** (PR_3 = P-*i*-Pr_3) are also included.

Table 1. Polymerization of methyl methacrylate with various $RuCl_2$(*p*-cymene)PR_3 catalyst precursors.[a]

Catalyst	PR_3	Polymer yield (%)	M_n (kg mol^{-1})[b]	M_w/M_n	f [c]
1a	PCy_3	100	41.5	1.12	0.95
1b	P-*i*-Pr_3	80	40.5	1.10	0.8
1c	PCp_3	99	66	1.12	0.6
1d	PCy_2-*t*-Bu	99	63	1.14	0.65
1d[d]	PCy_2-*t*-Bu	84	45	1.11	0.75
1e	PCy_2H	32	150	1.8	0.1

[a] Reaction conditions: MMA 1 mL, initiator (ethyl 2-bromo-2-methylpropanoate) 0.0234 mmol, catalyst 0.0117 mmol, 16 h at 85°C.
[b] Determined by size-exclusion chromatography with PMMA calibration.
[c] Initiation efficiency $f = M_{n,\,theor.}/M_{n,\,exp.}$ with $M_{n,\,theor.} = ([monomer]_0/[initiator]_0) \times MW\ (monomer) \times conversion$.
[d] Reaction at 60°C.

Both PCp_3 and PCy_2-*t*-Bu fulfill the requirements previously defined for achieving a high catalytic activity, namely a strong basicity and a well-defined steric bulk (160° < θ < 170°, θ = cone angle of the phosphine). Accordingly, complexes **1c** and **1d** are more than satisfactory catalyst precursors for MMA polymerization. On the other hand, PCy_2H is a much less efficient ligand, probably because of its smaller cone angle (θ = 143°) (18) and weaker basicity (pK_a $H_2PCy_2^+$ = 4.55) (19) compared to PCy_3 (θ = 170°, pK_a $HPCy_3^+$ = 9.70).

A detailed examination of the polymerization kinetics reveals that complexes based on the PCy_3 or PCp_3 ligands deserve the title of best catalyst precursors, because they display slightly faster reaction rates and afford better molecular weight control than the ones ligated to P-*i*-Pr_3 or PCy_2-*t*-Bu. For instance, the apparent propagation constants k_p^{app} calculated for **1a** and **1d** are 1.05×10^{-4} s^{-1} and 7.9×10^{-5} s^{-1}, respectively. Data analysis also confirms the living nature of the polymerization process with the most efficient catalytic systems. The plots of ln ($[M]_0/[M]$) and of M_n vs. monomer conversion are linear (not shown), and polymerization resumes when a second feed of MMA is added to an (almost) completely polymerized reaction mixture. Last but not least, the polymer samples were all colorless after a single precipitation step, a feature that catalytic systems based on other types of transition-metal complexes often lack (10, 20).

Polymerization of styrene and of *p*-substituted styrenes with $RuCl_2$(*p*-cymene)PR_3 catalyst precursors

To broaden the scope of our study on ruthenium(II)-phosphine complexes, a comparison of various catalyst precursors for the polymerization of different *para*-substituted styrenes was carried out. Prior reports strongly suggest that the same stereoelectronic requirements for the phosphine ligand apply to the polymerization of styrene and of MMA (11,21). Therefore, we have tested only three $RuCl_2$(*p*-cymene)PR_3 complexes which contain sterically demanding basic phosphines, viz. **1a** (PR_3 = PCy_3), **1b** (PR_3 = P-*i*-Pr_3), and **1d** (PR_3 = PCy_2-*t*-Bu). The polymerization of unsubstituted styrene initiated by ethyl 2-bromopropanoate at 110°C served as a model reaction in a first set of experiments. A comparative run in the presence of the Grubbs' benzylidene catalyst **2** was included and the results are summarized in Table 2.

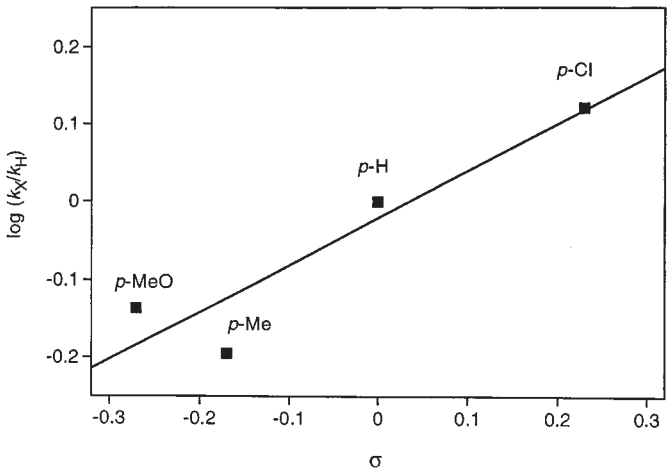
1d	PCy_2-*t*-Bu	57	23.5	1.85	0.95
2	PCy_3	61	27	1.38	0.9

[a]Reaction conditions: styrene 1 mL, initiator (ethyl 2-bromopropanoate) 0.0234 mmol, catalyst 0.0117 mmol, 16 h at 110°C.
[b]Determined by size-exclusion chromatography with PS calibration.
[c]See footnote *c*, Table 1 for a definition of *f*.

Table 3. Polymerization of styrene and of *p*-substituted styrenes with $RuCl_2$(*p*-cymene)PCy_3 as catalyst precursor.[a]

Monomer	Polymer yield (%)	M_n (kg mol^{-1})[b]	M_w/M_n	k_p^{app} (1×10^5 s^{-1})
4-Chlorostyrene[c]	68	18	1.27	2.01
Styrene	58	27	1.25	1.52
4-Methylstyrene	45	16	1.38	0.97
4-Methoxystyrene[c]	51	1.4	2.5	1.11



[a]Reaction conditions: 4-X-styrene 1 mL, initiator (ethyl 2-bromopropanoate) 0.0234 mmol, catalyst (**1a**) 0.0117 mmol, 16 h at 110°C.
[b]Determined by size-exclusion chromatography with PS calibration.
[c]Reaction time 24 h.

Although styrene is less prone to ATRP than MMA, catalysts **1a**, **b**, **d**, and **2** permit a moderate to satisfactory control of its polymerization. The narrowest molecular weight distribution was obtained with complex **1b**, while Grubbs' benzylidene complex **2** displayed the fastest reaction kinetics. Thus, the apparent propagation constants k_p^{app} (expressed in 10^5 s^{-1}) follow the order: 1.85 (**2**) > 1.52 (**1a**) > 1.25 (**1d**) > 1.16 (**1b**). In all cases, a linear relationship was observed between the number-average molecular weight (M_n) of the polystyrene samples and the monomer conversion.

To gain further insight into the reaction mechanism and kinetics, the polymerization of various *para*-substituted styrenes was carried out at 110°C with ethyl 2-bromopropanoate as initiator. The results obtained with styrene, 4-chloro-, 4-methyl-, and 4-methoxystyrene are listed in Table 3. They clearly show that the polymerization process is favored when an electron-withdrawing group is present on the aromatic ring. The relative reaction rates k_X/k_H follow the sequence: 1.32 (4-chlorostyrene) > 1 (styrene) > 0.73 (4-methoxystyrene) > 0.63 (4-methylstyrene). The decrease in rates is furthermore associated with an increase in the polydispersity ratio M_w/M_n.

No high molecular weight polymer was formed with 4-methoxystyrene, although the monomer conversion reached ca. 50%. This indicates that transfer reactions take over propagation, a likely consequence of competing ionic processes induced by the electron-donating substituent on styrene that could favor the heterolytic cleavage of the carbon—halogen bond in the active species. Yet, we opted for not excluding the data acquired with *p*-methoxystyrene from the Hammett plot presented in Fig. 1. With all four points, the correlation between log (k_X/k_H) and the substituent σ constant (22) leads to a ρ value of 0.60 and a correlation coefficient of 0.93. The ρ value becomes 0.78 when the 4-methoxy point is discarded, but the conclusion remains the same: one is dealing with a *nucleophilic* active radical species which favors the polymerization of electron-poor olefins.

Fig. 1. Hammett plot for the polymerization of *p*-substituted styrenes initiated by ethyl 2-bromopropanoate and mediated by $RuCl_2$(*p*-cymene)PCy_3 at 110°C.

Synthesis and evaluation of new RuCl(*p*-cymene)(triazolinylidene) catalyst precursors

In this section, we describe our attempts at further improving the ATRP of vinyl monomers by replacing the phosphine ligands in ruthenium complexes with *N*-heterocyclic carbenes (NHC). These new, stable, nucleophilic divalent carbon species are increasingly used in organometallic synthesis (23). They are very strong σ-donating ligands, while the extent of their π-back-bonding is negligible. Many representatives of this new class of compounds isolated so far also bear large substituents, such as benzyl or mesityl groups, on the ring nitrogen atoms. Because of these combined electron-donating properties and steric bulkiness, *N*-heterocyclic carbenes seemed to us to be promising alternatives to strongly basic, sterically crowded phosphines as ligands in our catalyst precursors.

Presently, derivatives of the imidazole and of the triazole ring systems constitute the most widely studied NHC. Our investigations concerning the diaza heterocyclic ligands have been reported elsewhere (17) and we shall focus here solely on the use of a commercially available triazolinylidene carbene, viz. 1,3,4-triphenyl-4,5-dihydro-1*H*-1,2,4-triazol-5-ylidene (**3**) (24). The stoichiometric reaction between this ligand and the ruthenium dimer $[RuCl_2(p\text{-cymene})]_2$ is depicted in Scheme 2. The addition of a base (EtN-*i*-Pr_2 in excess) is required to obtain selectively and quantitatively a single adduct. Indeed, the reaction proceeds via the opening of the μ-chloro bridges of the dimer and the coordination of the incoming carbene to the ruthenium atom. An *ortho*-metallation of the phenyl substituent in position 1 occurs and 1 equiv of HCl is released. It is trapped by the base, which therefore helps driving the reaction to its completion and prevents side-reactions between the protic acid and the highly reactive free carbene species.

Table 4. Selected bond distances (Å) and bond angles (°) for complex **4**.

Bond distances (Å)					
Ru—Cl	2.4187(8)	Ru—C(4)	2.284(3)	Ru—C(7)	2.198(3)
Ru—C(1)	2.004(3)	Ru—C(5)	2.185(3)	Ru—C(8)	2.267(3)
Ru—C(3)	2.300(3)	Ru—C(6)	2.207(3)	Ru—C(30)	2.071(3)
Bond angles (°)					
Cl-Ru-C(1)	84.06(8)				
Cl-Ru-C(30)	87.63(8)				
C(1)-Ru-C(30)	76.77(11)				

Fig. 2. Molecular structure of complex **4** showing the numbering system; ORTEP diagram with 50% probability ellipsoids.

Complex **4** was isolated as a yellow, air- and water-stable powder and its structure in the solid state was determined by X-ray crystallography. A plot of its molecular structure and a listing of selected bond distances and bond angles are reported in Fig. 2 and Table 4, respectively.

The structure of **4** is close to that reported by Enders et al. (25) for similar complexes. The ruthenium atom lies in a *pseudo*-tetrahedral environment, and the C(1)-Ru-C(30) angle formed between the metal and the two carbon atoms from the chelating ligand equals 76.11(11)° (see Fig. 2 for atom numbering). The triazolinylidene ring is planar and the interatomic distances are in agreement with those observed in other ruthenium–nucleophilic carbene complexes (26, 27). The ruthenium-carbene carbon bond length is 2.004(3) Å, and the *ortho*-metallation takes place with the phenyl ring located at N(3) rather than N(1). At 2.071(3) Å the ruthenium-carbon σ bond to the phenyl ring (Ru—C(30)) is comparable to the values obtained for other *ortho*-metallated *N*-arylcarbenes (25). Furthermore, the *p*-cymene ligand is tilted, the distances ruthenium to C(8), C(3), and C(4) (2.267(3)–2.300(3) Å) are longer than the distances ruthenium to C(7), C(6), and C(5) (2.185(3)–2.207(3) Å). We attribute this distortion to a relatively important *trans* effect of the *ortho*-metallated carbene ligand.

^{1}H and ^{13}C NMR spectra corroborate the X-ray analysis and bring over additional structural information on complex **4** (see *Experimental section* for detailed assignments). The carbene-carbon resonates at 192.8 ppm, a typical value for this type of complex. Due to chirality, all aromatic hydrogen and carbon atoms from the *p*-cymene ligand are inequivalent. The aromatic protons appear as 2 AB systems and the aromatic carbons as 6 different singlets in ^{1}H and proton-decoupled ^{13}C NMR spectra, respectively. The two methyls from the isopropyl group give rise to two doublets (^{1}H NMR) or two singlets (^{13}C NMR). No changes in the NMR spectra were observed even at temperatures as high as 110°C, indicating that dissociation of the *p*-cymene ligand does not take place under these conditions.

Addition of 1 equiv of silver tetrafluoroborate to the neutral complex **4** led to the corresponding cationic species **5** ligated to an extra molecule of solvent (CH_3CN) (Scheme 3). As expected, the cationic complex displayed after purification the same NMR characteristics than its neutral precursor, i.e., inequivalent C and H atoms for the arene ligand.

Both **4** and **5** were tested as ATRP catalysts. Cationic complex **5** was practically inactive at promoting the polymerization of MMA and of styrene, whereas its neutral counterpart **4** proved to be an active catalyst precursor for the ATRP of vinyl monomers. Because a reversible oxidation of Ru(II) into Ru(III) is central to the ATRP mechanism (cf. Scheme 1), one could argue that the already charged species **5** is less prone to oxidation than its neutral counterpart **4**, thus explaining the large difference in reactivity between the two of them. Results obtained with MMA, styrene, and two *para*-substituted styrenes using complex **4**

as catalyst precursor are summarized in Table 5. Standard polymerization conditions were applied with ethyl 2-bromo-2-methylpropanoate and (1-chloroethyl)benzene as initiators for MMA and styrenes, respectively.

The molecular weight distributions are slightly narrower for polystyrenes than for PMMA. However, the *ortho*-metallated triazolinylidene complex **4** does not afford a better control of the polymerization than the phosphine-based catalysts **1a**–**d**. It also loses more rapidly its efficiency when the reaction temperature is lowered, since the polymer yield drops to 16% when MMA is reacted at 75°C instead of 85°C and no more PMMA is isolated when the reaction is carried out at 60°C. Thus, catalyst **4** is presently no match for complexes **1** and **2**, whose synthesis is also more straightforward. Further studies concerning the relationship between ATRP and ATRA (atom transfer radical addition, Kharasch reaction) as a function of the electronic tuning and other variations of the carbene ligand are in progress.

Experimental Section

General information

All the solvents and monomers were dried, distilled, and degassed prior to use. They were stored under nitrogen at –20°C in the absence of light. NMR spectra were recorded on a Brucker AM 400 spectrometer (400 and 100 MHz for ^{1}H and ^{13}C NMR, respectively). Chemical shifts are listed in ppm downfield from TMS with the solvent as the internal standard. Infrared spectra were recorded on a PerkinElmer 1720X series FT-IR spectrometer from KBr discs. Elemental analyses were performed at the Laboratory of Pharmaceutical Chemistry, University of Liège.

Materials

Complexes **1a**–**e** were prepared according to the literature (12, 13). $RuCl_2(=CHPh)(PCy_3)_2$ (**2**) was used as received from Strem. 1,3,4-Triphenyl-4,5-dihydro-1*H*-1,2,4-triazol-5-ylidene (**3**) was purchased from Acros.

*Chloro[(1,2,3,4,5,6-η)-1-methyl-4-(1-methylethyl) benzene][1,2-phenylene[3,4-diphenyl-1*H*-1,2,4-triazol-1-yl-5(4*H*)-ylidene]]ruthenium (**4**)*

A 0.44 g sample of 1,3,4-triphenyl-4,5-dihydro-1*H*-1,2,4-triazol-5-ylidene **3** (0.48 mmol) was weighted in a glove box and dissolved in 15 mL of THF. This solution was added via a cannula to a mixture of $[RuCl_2(p\text{-cymene})]_2$ (0.40 g, 0.65 mmol) and *N*,*N*-diisopropylethylamine (0.75 g, 5.74 mmol) in 40 mL of THF under inert atmosphere. The initial red suspension was stirred 4.5 h at room temperature. It progressively turned into an orange then a yellow solution. After 4.5 h the solvent was removed on a rotary evaporator and the yellow residue was purified by column chromatography on silica gel with CH_2Cl_2. The eluate was washed with H_2O (3 × 20 mL) to remove the ammonium salt, dried over sodium sulfate, and evaporated. The residue was rinsed with Et_2O (2 × 10 mL) and *n*-pentane (2 × 15 mL) to afford the title compound as a bright yellow powder. Yield: 0.59g (79%); mp 215°C (dec.). X-ray crystallography

Crystals of **4** suitable for X-ray diffraction analysis were obtained by slow diffusion of *n*-pentane in a CH_2Cl_2 solution at –18°C. A summary of the crystal data and parameters for data collection is given in Table 6. Data were collected at 293 K on a four circle Brucker P4 diffractometer using monochromated Mo K_α radiation (0.71073 Å). The structure was solved by direct method and refinement was performed on F^2 using the SHELXL-96 solution package programs (28). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located on difference Fourier map and refined isotropically. Complete tables of bond distances and angles, final atomic coordinates, and anisotropic displacement parameters have been deposited as supplementary material.[2]

Typical polymerization procedure

A ruthenium complex (0.0117 mmol) was placed in a glass tube containing a magnet bar and capped by a three-way stopcock. Air was expelled by three vacuum–nitrogen cycles before methyl methacrylate (1 mL, 9.35 mmol) and the initiator solution (0.1 M in toluene, 0.234 mL) were added. All liquids were handled with dried syringes under nitrogen. The reaction mixture was heated for 16 h at 85°C under inert atmosphere. After cooling, it was diluted with THF and poured in *n*-heptane (600 mL) under vigorous stirring. The precipitated polymer was filtered with suction and dried overnight at 80°C under vacuum.

Styrene and the *p*-substituted styrenes were polymerized according to the same procedure and precipitated from methanol. In all experiments, 1 mL of monomer was used (see the Tables for further information on the initiator, the temperature, and the reaction time).

Polymer characterization

Molecular weight distributions were determined by SEC in THF at 40°C using a Hewlett–Packard 1090 liquid chromatograph equipped with a Hewlett–Packard 1037A refractive index detector. PMMA and PS standards (Polymer Laboratories) were used for calibration. Before SEC analysis, the polymers were purified by passing solutions through a short Al_2O_3-filled column. ^{1}H NMR spectra were recorded at room temperature in $CDCl_3$ with TMS as internal reference on a Brucker AM 400 apparatus.

Conclusions

A major advantage of utilizing transition-metal complexes as catalysts is the possibility to fine tune their electronic and steric properties through the design of their ligands. Our research on the potential of various ruthenium(II)-phosphine or ruthenium(II)-triazolinylidene complexes to promote atom transfer radical polymerization of vinyl monomers nicely illustrates this concept. Polymerizations of methyl methacrylate and of styrene were chosen as model reactions with ethyl 2-bromo-(2-methyl)propanoate or (1-chloroethyl)benzene serving as initiators. Very efficient catalyst precursors were

[2] Copies of material on deposit may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Ontario, Canada K1A OS2 ((http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically). Formation and reactivity of the zirconium ethylene complexes [η^5-C_5H_3-1,3-($SiMe_2CH_2PR_2$)$_2$]Zr(η^2-CH_2=CH_2)(X) (R = Me, Pr^i; X = Br, C_5H_5)

Michael D. Fryzuk, Paul B. Duval, and Steven J. Rettig

Abstract: The formation and reactivity of the zirconium ethylene complexes ^{R}[P_2Cp]Zr(η^2-CH_2=CH_2)(X) (**2a**: R = Pr^i, X = Br; **2b**: R = Me, X = Br; **4a**: R = Pr^i, X = C_5H_5; ^{R}[P_2Cp] = (η^5-C_5H_3-1,3-($SiMe_2CH_2PR_2$)$_2$)) are described. Ethylene complexes **2a** and **2b** are prepared from a reaction of ^{R}[P_2Cp]ZrCl_3 (**1a**: R = Pr^i; **1b**: R = Me) with 2 equiv of EtMgBr, presumably via β-H elimination from the diethyl intermediate ^{R}[P_2Cp]ZrCl(CH_2CH_3)$_2$. The structure of **2b** was determined by X-ray crystallography. Addition of carbon monoxide to 16-electron **2** displaces the ethylene ligand to generate the carbonyl complex ^{R}[P_2Cp]Zr(CO)$_2$Br (**5a**: R = Pr^i; **5b**: R = Me), which is stable only under an atmosphere of CO. The corresponding CO reaction with 18-electron **4a** to give the metallocene monocarbonyl analogue ^{Pr}[P_2Cp]Zr(η^5-C_5H_5)(CO) (**6a**) is considerably slower. **2a** exhibits fluxional exchange of one carbonyl ligand with bulk ^{13}CO in solution; the kinetic parameters for this exchange process are $\Delta H^{\ddagger}$ = 9.2(5) kcal mol^{-1} and $\Delta S^{\ddagger}$ = –17(2) cal mol^{-1} K^{-1}. The addition of diphenylacetylene to **2a** yields the alkyne complex ^{Pr}[P_2Cp]Zr(η^2-PhCCPh)Br (**7a**), which exists in solution as two isomers in equilibrium. A solid-state X-ray structure determination for the minor isomer ***syn*-7a** was performed.

Key words: zirconium, cyclopentadienyl phosphine, alkyne, metallocyclopropane.

Résumé : On décrit la formation et la réactivité de complexes de l'éthylène zirconium ^{R}[P_2Cp]Zr(η^2-CH_2=CH_2)(X) (**2a** : R = *i*Pr, X = Br; **2b** : R = Me, X = Br; **4a** : R = *i*Pr, X = C_5H_5; ^{R}[P_2Cp] = (η^5-C_5H_3-1,3-($SiMe_2CH_2PR_2$)$_2$)). On a préparé les complexes **2a** et **2b** par réaction du ^{R}[P_2Cp]ZrCl_3 (**1a** : R = *i*Pr; **1b** : R = Me) avec deux équivalents de EtMgBr, probablement par le biais d'une élimination β d'hydrogène à partir de l'intermédiaire diéthylé ^{R}[P_2Cp]ZrCl(CH_2CH_3)$_2$. On a déterminé la structure du complexe **2b** par diffraction des rayons X. L'addition de monoxyde de carbone au complexe **2** à seize électrons conduit à un déplacement du ligand éthylène et à la formation du complexe carbonylé ^{R}[P_2Cp]Zr(CO)$_2$Br (**5a**: R = *i*Pr; **5b**: R = Me) qui n'est stable que sous une atmosphère de CO. La réaction correspondante du CO avec le complexe **4a** à dix-huit électrons, qui conduit à la formation du métallocène monocarbonylé analogue, ^{R}[P_2Cp]Zr(η^5-C_5H_5)(CO) (**6a**) est beaucoup plus lente. Le complexe **2a** donne lieu à un échange fluxionnel d'un ligand carbonyle avec le ^{13}CO qui se trouve dans l'ensemble de la solution; les paramètres cinétiques pour ce processus d'échange sont $\Delta H^{\ddagger}$. = 9,2(5) kcal mol^{-1} et $\Delta S^{\ddagger}$ = –17,2 cal mol^{-1} K^{-1}. L'addition de diphénylacétylène au complexe **2a** conduit à la formation de ^{R}[P_2Cp]Zr(η^2-PhCCPh)Br (**7a**) qui, en solution, existe sous la forme de deux isomères à l'équilibre. Faisant appel à la diffraction des rayons X, on a effectué une détermination de la structure en phase solide de l'isomère mineur, le ***syn*-7a**.

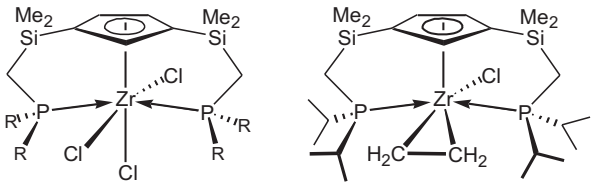
Mots clés : zirconium, cyclopentadiényl phosphine, alcyne, métallocyclopropane.

[Traduit par la Rédaction]

Introduction

The coordination of ethylene to transition metal centers is one of the foundations of organometallic chemistry (1) and dates back to the synthesis of Zeise's salt (K[Pt(η^2-CH_2=CH_2)Cl_3]) in 1827. Currently, the chemistry of metal-alkene complexes encompasses numerous important catalytic industrial processes, such as alkene polymerization using Ziegler–Natta catalysts, olefin metathesis (2, 3) (which includes both ring-opening (4) and ring-closing (5) metathesis type processes), alkene hydrogenation (6), and the Wacker process (7). In addition, there is continued interest in the bonding aspects of the metal-alkene interaction (8), which has been the focus of theoretical studies (9).

Received September 5, 2000. Published on the NRC Research Press Web site at http://canjchem.nrc.ca on May 23, 2001.



Dedicated to Professor B. R. James, in recognition of his distinguished contributions to homogeneous catalysis, on the occasion of his 65th birthday.

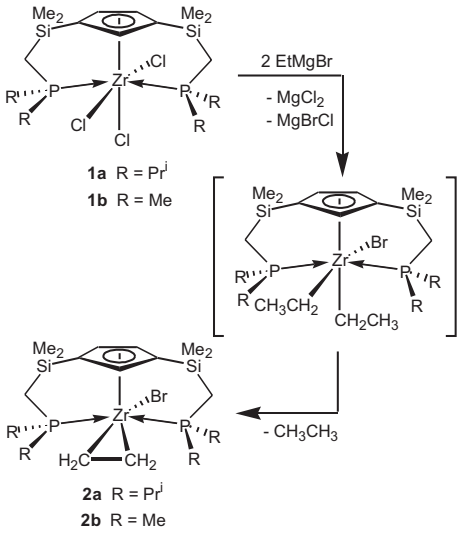
We have been examining the reactivity of zirconium complexes stabilized by the hybrid donor ancillary ligand η^5-C_5H_3-($SiMe_2CH_2PR_2$)$_2$ (^{R}[P_2Cp], R = Pr^i, Me). Deployment of bulky isopropyl substituents on the side-arm phosphines has enabled the isolation of Zr(IV) alkylidene complexes, ^{Pr}[P_2Cp]Zr=CHR(Cl), (10, 11) from which reaction with ethylene yields the ethylene adduct ^{Pr}[P_2Cp]Zr(η^2-CH_2=CH_2)Cl (**2c**) (11). An interest in studying the reactivity of this product as a probe into the nature of the metal-alkene bonding in this formally Zr(II) species led to a more direct synthetic route from the starting chloride ^{Pr}[P_2Cp]$ZrCl_3$ (**1a**). One advantage of this alternate preparation is the ability to obtain the analogous but less bulky ^{Me}[P_2Cp]Zr ethylene derivative (^{Me}[P_2Cp]Zr(η^2-CH_2=CH_2)Br (**2b**)) directly from ^{Me}[P_2Cp]$ZrCl_3$ (**1b**).

1a R = Pr^i
1b R = Me

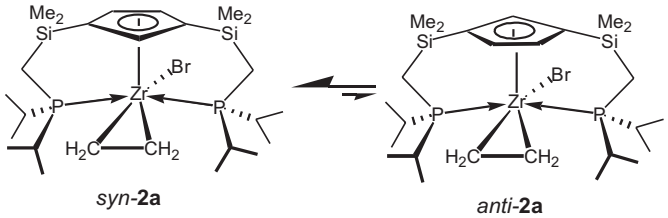
2c



Although zirconium–alkene complexes are proposed as intermediates in several important synthetic transformations, (12, 13) the number of characterizable species has been restricted to a few metallocene-type systems, (14–17) the majority of which are isolated by the use of a trapping donor (typically a phosphine) to stabilize these complexes. The ethylene derivatives introduced in this report expand this sample to include 16-electron mono(cyclopentadienyl) complexes and a related 18-electron metallocene analogue; in addition, some substitution studies are included.

Preparation of ^{R}[P_2Cp]Zr(η^2-CH_2=CH_2)Br (R = Pr^i, Me)

A toluene solution of the starting Zr(IV) trichloride **1** reacts with 2 equiv of EtMgBr at –78°C to give a bright yellow solution, which upon warming to room temperature produces the ethylene complex ^{R}[P_2Cp]Zr(η^2-CH_2=CH_2)Br (**2a**: R = Pr^i; **2b**: R = Me) in excellent yield, either as dark purple (**2a**) or dark red (**2b**) crystals (Scheme 1). The yellow precursor is presumed to be the diethyl species ^{R}[P_2Cp]$ZrBr(CH_2CH_3)_2$, although no direct proof of its existence was obtained. The putative reaction sequence is completed by a β-H abstraction reaction with the elimination of ethane to generate the ethylene product. A quantitative halide exchange incorporates a bromide ligand in the final product, based on elemental analyses and an X-ray structural determination for **2b** (see below).



The ^{1}H and ^{31}P NMR spectra of purple **2a** are nearly identical to that of the crystallographically characterized chloro derivative ^{Pr}[P_2Cp]Zr(η^2-CH_2=CH_2)Cl (**2c**), a red product formed from the reaction of either alkylidene complex ^{Pr}[P_2Cp]Zr=CHR(Cl) (R = Ph, $SiMe_3$) with ethylene (18). As with **2c**, the NMR spectra for **2a** show the presence of two species in a 9:1 ratio assigned as *syn* (major) and *anti* (minor) isomers, designated according to the orientation of the ethylene ligand as being directed either *syn* or *anti* with respect to the unique carbon of the cyclopentadienyl (Cp) ring, as shown below (eq. [1]). Each isomer of **2a** displays a separate singlet in the ^{31}P NMR spectrum and corresponding resonances in the ^{1}H NMR spectrum.

Scheme 1.

1a R = Pr^i
1b R = Me

2a R = Pr^i
2b R = Me

syn-**2a** *anti*-**2a**

The ethylene protons give rise to a complex multiplet centred near 1.0 ppm in the ^{1}H NMR spectrum, originating from an AA′BB′XX′ spin system due to additional $^3J_{PH}$ coupling from the side-arm phosphines. The upfield location of these resonances in the ^{1}H NMR spectrum is indicative of an ethylene fragment coordinated to Zr. As with **2c**, definitive assignment of stereochemistry was unfortunately not possible (via ^{1}H NMR NOEDIFF experiments, for example) and so our designation of *syn* or *anti* is presumed.

In contrast to **2a**, only a single species is seen in solution for the ^{Me}[P_2Cp] derivative **2b**; we speculate that the reduced steric hindrance from the smaller methyl substituents at phosphorus reduces the tendency for phosphine dissociation which in turn discourages a *syn*/*anti* exchange process in this complex. The solid-state molecular structure of **2b** is shown in Fig. 1, along with the atom numbering scheme. A summary of the crystallographic data is given in Table 1; selected bond distances and bond angles are listed in Table 2. The structure reveals that the ethylene unit is coordinated parallel to the Cp ring and oriented *syn* to the unique Cp carbon atom C(2), precisely as found for the solid state structure for **2c** (18). Presumably, this orientation reduces steric interactions between the bound ethylene molecule and the Cp ring; moreover, it situates the ethylene π*-orbital to overlap favorably with the filled metal d_{xy} orbital (in this

representation the *z*-axis passes through the Cp-centroid). Previous investigations into bonding interactions in electron-rich complexes with piano-stool geometries suggest that the metal d_{xy} orbital offers the best electron donation to a π-acceptor ligand (19, 20). The C(16)—C(17) bond distance of 1.431(6) Å in **2b** is comparable to the corresponding value of 1.433(17) Å for **2c**, which illustrates that the degree of

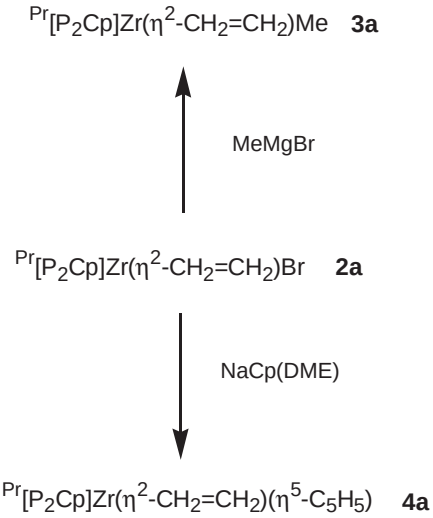
backbonding is not significantly altered upon substituting either the halide (Br for Cl) or the groups attached to the phosphines (methyl for isopropyl). However, the phosphines are bound considerably closer to the metal in **2b**, with Zr—P bond distances averaging 2.72 Å in comparison to 2.86 Å for **2c**. The C—C bond distance of the ethylene ligand is similar in these complexes to that found for other monomeric Zr(II) ethylene complexes (14, 16, 21). The lengthening of this bond compared to 1.337 Å found in free ethylene (22) is indicative of significant back-bonding from the metal as represented in the Dewar–Chatt–Duncanson model (23, 24) and supports a Zr(IV) metallacyclopropane bonding depiction (**A**). Also consistent with this formalism are the short Zr—C bond lengths (average 2.30 Å) in **2b**, which are within the range of typical Zr—C single bonds

© 2001 NRC Canada

(12) and considerably shorter than the Zr—C distance of 2.68 (2) in a cationic Zr(IV) olefin complex in which *d*-π* back-bonding is unavailable (25).

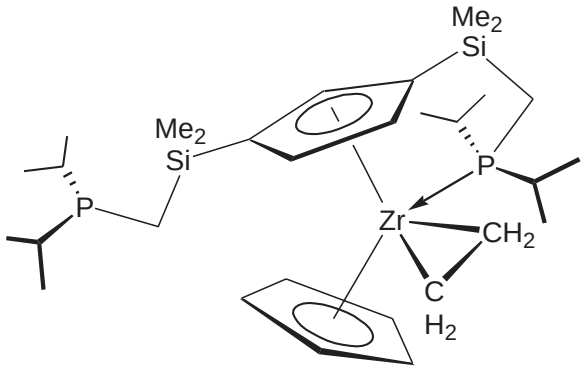
By NMR spectroscopy, only one isomer is seen for **2b** in solution, thus it is assumed that it corresponds to the *syn* structure observed in the solid state. The similarities between the ^{1}H NMR spectrum of the major isomer of **2a** with that of the single species seen for **2b**, particularly in the distinctive Cp region, suggests that the major isomer of **2a** is the *syn* isomer as well.

The formation of the ethylene complexes **2a** and **2b** directly from the respective starting trichlorides offers a facile alternative to the multistep approach to **2c** (i.e., via an alkylidene complex) (18). This general synthetic route has been employed elsewhere to obtain a number of early metal alkene complexes (15). Unfortunately, this procedure could not be extended to other Zr alkene complexes with this system. For example, propylene complexes could not be isolated by using Grignard reagents such as Pr^{n}MgBr or Pr^{i}MgCl, nor was Bu^{n}Li effective in obtaining a coordinated butene species. All of these attempts resulted in complete consumption of the starting materials, but no isolable alkene complexes were forthcoming; this is reminiscent of the reactions of substituted alkenes with the related alkylidene complexes (18). The apparent instability of these complexes incorporating higher alkenes may be due to a combination of greater steric hindrance from the bulky ancillary ligand along with weaker bonding of these alkenes relative to ethylene.



Preparation of ^{Pr}[P$_2$Cp]Zr(η^2-CH$_2$=CH$_2$)R′ (R′ = Me, C$_5$H$_5$)

In an attempt to expand the scope of ethylene complexes for which reactivity studies could be compared, we examined the preparation of alkyl-ethylene derivatives by standard metathesis reactions involving the bromide ligand (Scheme 2).



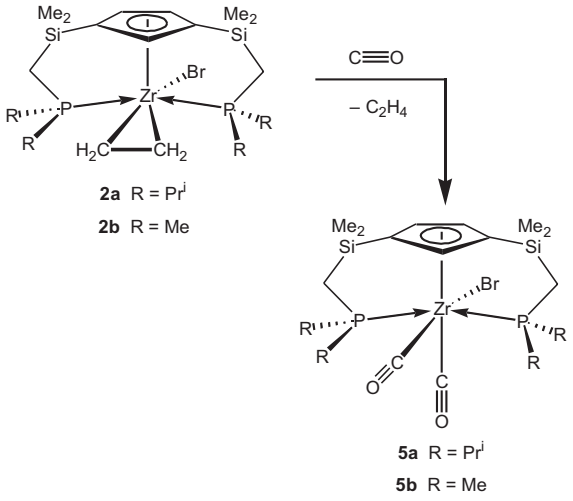
The characteristic spectroscopic feature of the methyl derivative **3a** is the triplet ($^3J_{PH}$ = 10 Hz) at –0.67 ppm in the ^{1}H NMR spectrum for the methyl group attached to Zr. The distinctive Cp region of this spectrum is nearly identical to that of the major *syn* isomer of **2**, suggesting that the solution structure of **3a** (only one species is seen) is exclusively the *syn* isomer. Unfortunately this complex was only characterized in solution as it could not be isolated as a solid, despite many attempts; decomposition with the elimination of ethylene to give unidentified products was observed.

The Cp derivative **4a** could be isolated as reddish-orange crystals. There are two equal intensity singlets in the ^{31}P NMR spectrum for **4a** at –5.3 ppm and 42.3 ppm; the peak

Scheme 2.

at –5.3 ppm for this ligand system is indicative of an uncoordinated phosphine, while the other resonance at 42.3 corresponds to a bound phosphine donor. The ^{1}H NMR spectrum shows a doublet ($^3J_{PH}$ = 2 Hz) at 5.20 ppm for the five protons of the C_5H_5 ring; the downfield chemical shift suggests that this ligand is coordinated in an η^5-mode. As the array of ligands in this complex is similar to that found in the structurally characterized metallocene derivative Cp$_2$Zr(η^2-CH$_2$=CH$_2$)(PMe$_3$), (14, 21) it is reasonable to consider an analogous structure for **4a** as shown below.

4a

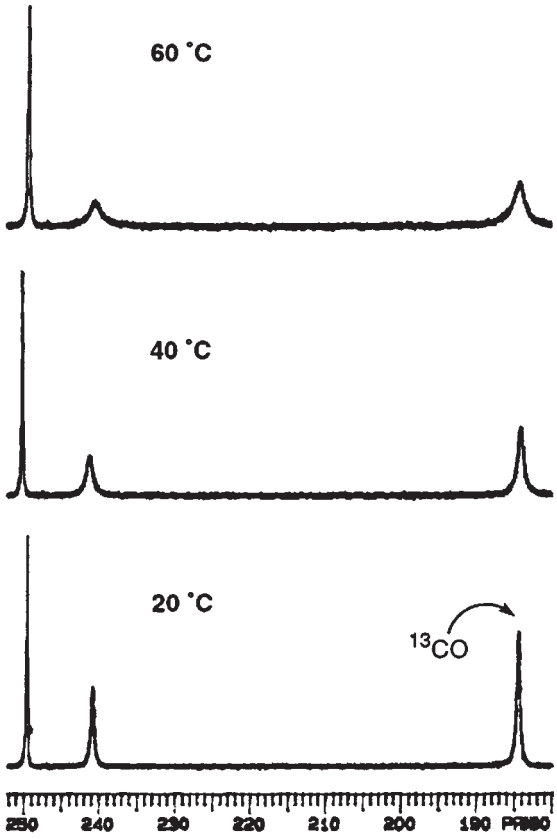


The asymmetric geometry renders all four ethylene protons inequivalent, thus generating a complicated second order splitting pattern in the ^{1}H NMR spectrum (with additional coupling to the coordinated phosphine). This asymmetry is also evident from the three separate resonances observed for the cyclopentadienyl portion of the P$_2$Cp ancillary ligand. The presence of only one coordinated phosphine in **4a** supports the view of the C_5H_5 ligand as η^5-bound; the steric and electronic saturation provided by this coordination mode yields an 18-electron species which would force one side-arm to remain dangling, as observed. The ethylene unit and the coordinated phosphine thus can be

© 2001 NRC Canada

considered to be occupying the metallocene wedge, with the other side-arm left out of the coordination sphere.

Ligand substitution reactions with CO

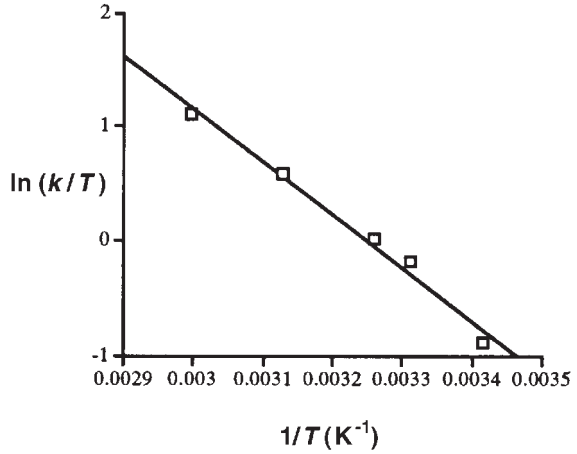


A purple toluene solution of the ethylene complex **2a** reacts instantly under an atmosphere of CO to generate a dark greenish-orange solution that shows a single resonance in the ^{31}P NMR spectrum at 29.1 ppm. In the ^{1}H NMR spectrum the only resonances observed are attributed to the ancillary ligand, and a sealed NMR tube reaction reveals a singlet at 5.25 ppm for the evolution of free ethylene. A similar result is obtained in the reaction with **2b**. Therefore, it is apparent in both instances that the coordinated ethylene unit has been replaced by CO in a ligand substitution reaction to give a carbonyl complex (eq. [2]).

For the reaction of **2a** with ^{13}CO the downfield region of the ^{13}C NMR spectrum displays two carbonyl peaks at 241 and 249 ppm for **5a** in addition to a third resonance at 184 ppm for excess free ^{13}CO, indicating that an 18-electron dicarbonyl species has been formed from the 16-electron precursor. In **5b** the carbonyl resonances are located at 240 and 245 ppm, respectively. These complexes have a ligand arrangement that is similar to known derivatives such as $CpZr(CO)_2(dmpe)Cl$ (26). The presence of a carbonyl ligand is supported by absorptions in the IR spectra at 1890 and 1898 cm^{-1} for **5a** and **5b**, respectively, which shift to 1865 and 1855 cm^{-1} for the ^{13}C labeled isotopomers. The low ν_{CO} values of the coordinated carbonyl ligands in comparison to free CO (ν_{CO} = 2143 cm^{-1}) are due to strong back-bonding from the electron-rich Zr(II) centre to the π^* orbital of the CO ligand and is consistent with the stretching frequency in analogous Zr(II) carbonyls (i.e., $CpZr(CO)_2(dmpe)Cl$, ν_{CO} = 1940 cm^{-1}) (26). Unfortunately, although both carbonyl complexes **5a** and **5b** are stable indefinitely in solution in the presence of excess CO, attempts to isolate these species in the absence of CO led to decomposition. This instability outside of a protective CO atmosphere has been noted with other Zr carbonyl derivatives (26–28), demonstrating the labile nature of these ligands with early metals.

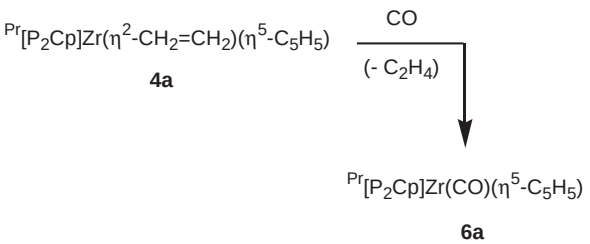
A notable feature of the ambient temperature ^{13}C NMR spectrum of **5a** is that the peak for free CO at 184 ppm is broadened, as is the carbonyl peak at 241 ppm. This observation suggests that this CO ligand is undergoing an exchange process with free CO in solution; the remaining ligand is either not involved in this process or is at the slow exchange limit at this temperature, since the peak for this ligand at 249 ppm is quite sharp in comparison. This exchange process was monitored by variable temperature ^{13}C NMR spectroscopy and a selection of the spectra are shown in Fig. 2; these spectra demonstrate an increase in line broadening as the temperature is raised, in agreement with an increase in the exchange rate between free CO and the exchanging carbonyl ligand.

Fig. 2 Variable temperature ^{13}C NMR spectra of $^{Pr}[P_2Cp]Zr(CO)_2Br$ (**5a**).



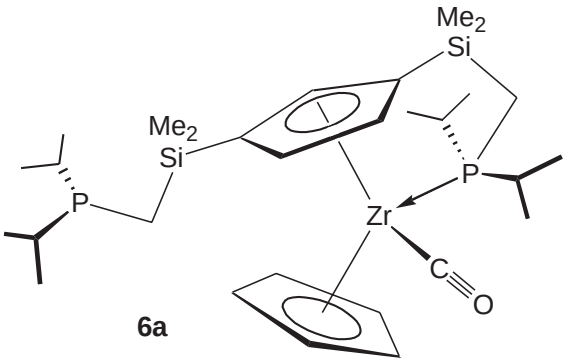
The NMR spectra were simulated (using DNMR-5)® to obtain rate constants at each temperature, which were used in the resulting Eyring plot shown in Fig. 3. The kinetic parameters $\Delta H^{\ddagger}$ = 9.2(5) kcal mol^{-1} and $\Delta S^{\ddagger}$ = –17(2) cal mol^{-1} K^{-1} were calculated from this plot. The negative entropy term is unexpected, as ligand exchange from this saturated 18-electron species is anticipated to proceed in a dissociative mechanism that should produce a positive entropy term for a less ordered transition state. A concerted mechanism involving dissociation of a pendant phosphine may therefore be a factor in this exchange. An associative process has also been suggested from a separate kinetic study into similar CO ligand exchange in other 18-electron Zr carbonyl species (27, 28).

Ligand exchange is common for early metal carbonyl complexes. In the related complex $Cp^*Hf(CO)_2(dmpe)Cl$ (28) both CO ligands are observed to rapidly and quantitatively exchange with excess ^{13}CO. One can speculate as to



© 2001 NRC Canada

Fig. 3 Eyring plot for the CO ligand exchange process in $^{Pr}[P_2Cp]Zr(CO)_2Br$ (**5a**).



why only one carbonyl ligand in **5a** undergoes this exchange. If we assume that the quasioctahedral geometry shown in eq. [2] holds here, then for such mono(cyclopentadienyl) type complexes the ligand located *trans* to the Cp donor is typically weakly bound, (29) with labile coordination observed in some instances (30). Thus for **5a**, it is the carbonyl ligand located at this labile site that undergoes exchange while the other *trans* to the bromide remains unaffected. To rationalize this observation, one can invoke two complementary effects: first, the strong labilizing trans effect of the Cp donor contrasts with the weak trans effect of the electron withdrawing bromide, and second, and as noted for **2b**, backbonding from the zirconium in monocyclopentadienyl complexes is optimized by the d_{xy} orbital (and to a lesser extent the d_z2 orbital), which is well suited to stabilize the carbonyl *trans* to the bromide but of negligible use for the other carbonyl ligand *trans* to the Cp group.

The reactivity of the 18-electron ethylene complex **4a** with CO was examined to compare with the results observed for the 16-electron analogue **2a**. As opposed to **2a**, which coordinates CO almost instantly, the reaction of **4a** with CO is considerably slower, requiring more than two weeks for completion under the same reaction conditions (eq. [3]). This remarkable difference in reaction times can be traced to the electronic saturation in **4a**, adding further evidence that the C_5H_5 donor in this complex is η^5-coordinated. As a result, in lieu of a 20-electron intermediate in this reaction, either a ligand must dissociate or alternatively the Cp ring must undergo η^5-η^3 ring slippage, prior to the coordination of a CO molecule.

The eventual product from the above reaction is the carbonyl species $^{Pr}[P_2Cp]Zr(CO)(\eta^5\text{-}C_5H_5)$ (**6a**), which is accompanied by the evolution of free ethylene as observed with the analogous reaction that forms carbonyl **5**. The ^{31}P NMR spectrum of **6a** is similar to that of the precursor **4a**, with one singlet at 58.7 ppm and another at –4.8 ppm. In the ^1H NMR spectrum only resonances attributed to the ancillary ligand and the Cp ligand are evident. The presence of the carbonyl ligand is indicated in the ^{13}C NMR spectrum by a single downfield resonance at 308 ppm ($^2J_{PC}$ = 2 Hz) in the reaction of **4a** with ^{13}CO. As an analogue of the 18-electron metallocene carbonyl species $Cp_2Zr(CO)(PMe_3)$ (31), the proposed structure of **6a** is depicted as shown below.

6a

In contrast to **5a**, the line width of the carbonyl peak for **6a** is very narrow, with no evidence for exchange with the narrow peak at 184 ppm due to excess ^{13}CO. The difference in the respective lability of the carbonyl ligands in **5a** vs. **6a** may originate from the presence of one less CO ligand in **6a**, which is not in competition for backbonding and hence is less labile. The contrasting rapid CO exchange observed for the similar metallocene analogue $Cp_2Zr(CO)_2$ (27) is in accord with this view, where two carbonyl ligands are in competition for backbonding from the same filled donor orbital (32).

Preparation of $^{Pr}[P_2Cp]Zr(\eta^2\text{-PhCCPh})Br$

Given the facile ligand substitution reaction observed for the ethylene derivatives **2a** and **2b** with CO, and the observed tendency for early metal alkene complexes to undergo substitution reactions with alkynes, (33, 34) the reaction with diphenylacetylene was examined with this system. A toluene solution of ethylene **2a** reacts with 1 equiv of diphenylacetylene (PhCCPh) under ambient conditions to displace the ethylene ligand and generate the alkyne complex $^{Pr}[P_2Cp]Zr(\eta^2\text{-PhCCPh})Br$ (**7a**), which can be isolated as pale yellow crystals (Scheme 3). In contrast to the immediate displacement of ethylene by CO to give carbonyl **5a**, the corresponding ligand substitution reaction of **2a** with diphenylacetylene is slower, requiring 24 h for completion. This observation is consistent with steric factors inducing a slower rate for the bulky alkyne in comparison to the small linear CO molecule, and points to a probable requirement that a phosphine must dissociate to allow room for the incoming alkyne.

In solution alkyne **7a** exists as two isomers in a 3:2 ratio, based on the ^1H and ^{31}P NMR spectra. There are two singlets in the ^{31}P NMR spectrum, one each for the major (8.5 ppm) and minor isomer (11.6 ppm), respectively, and a

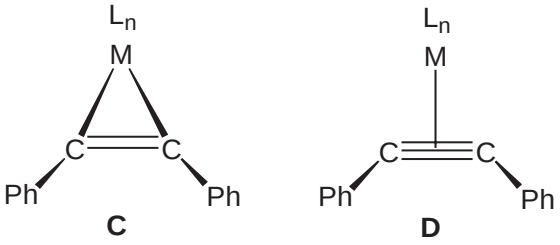
C(24)—C(25)	1.322(6)	Zr(1)-C(24)-C(26)	111.0(1)
C(24)—C(26)	1.471(4)	C(25)-C(24)-C(26)	126.8(2)



corresponding set of resonances in the ^{1}H NMR spectrum for each species. As found with other complexes having this ancillary ligand system (18) and observed for **2a**, the two species seen for **7a** are likely the *syn* and *anti* stereoisomers. A variable temperature NMR study indicates that these isomers interconvert, as evidenced by increased line broadening in both peaks in the ^{31}P NMR spectrum as the temperature is raised. Curiously, a change in the equilibrium ratio of these species was not detected from this experiment. A ^{1}H NOEDIFF NMR experiment was performed, from which it was determined that the *anti* isomer is the major species in solution. Irradiation of the resonance assigned to the two equivalent protons in the Cp ring of the major isomer showed an enhancement of the signals for the ortho protons of the phenyl ring; no effect was detected when the unique Cp proton resonance was irradiated.

The molecular structure of alkyne **7a** was determined by an X-ray crystal structure analysis and is shown in Fig. 4. Selected bond lengths and bond angles are listed in Table 3. The solid-state structure corresponds to the minor *syn* isomer, with the alkyne coordinated parallel to the Cp ring as found for the ethylene ligand in **2b**. However, in ***syn*-7a** the alkyne unit is tilted from this parallel orientation by approximately 9°. The short Zr(1)—C(24) and Zr(1)—C(25) bond lengths of 2.20 Å and 2.18 Å, respectively, are indicative of strong back-bonding from the metal. This is also reflected in the C(25)-C(24)-C(26) bond angle of 127° that illustrates the

Fig. 4 Molecular structure of $^{Pr}[P_2Cp]Zr(\eta^2\text{-PhCCPh})Br$ (***syn*-7a**); 33% probability thermal ellipsoids are shown. Hydrogen atoms are omitted for clarity.

degree to which the phenyl rings are pulled back from the metal as a result of this back-donation. This geometry of the coordinated alkyne resembles that of a metallacyclopropene **C**, rather than a simple π-bound alkyne as shown in **D** (6). The double bond character of the coordinated alkyne is indicated by the C(24)—C(25) bond distance of 1.322(6) Å. These structural parameters are similar to those of the structurally characterized Zr alkyne complex $Cp_2Zr(\eta^2\text{-PhCCPh})(PMe_3)$ (34).

A comparison of the bonding in ***syn*-7a** with that of the ethylene complex **2b** shows in each case that back-bonding from the metal induces lengthening of the coordinated C—C bond (compared to the free substrate). In addition, alkynes have a second π-orbital that can overlap with a metal *d* orbital of suitable symmetry to form a π-bond, such that this ligand can potentially be represented as a four-electron donor. However, in **7a** this interaction is in competition with one of the π-donor orbitals from the Cp ring, which diminishes the ability of the alkyne to donate electron density from this second π-orbital. But the observation that alkyne

© 2001 NRC Canada

7a is unreactive in the presence of CO is in direct contrast to the rapid reaction seen for ethylene **2a**, which otherwise has the same ligand coordination sphere. Assuming that steric considerations are minimal for a small nucleophile such as CO, this difference in reaction times suggests that the alkyne complex **7a** is a fully saturated 18-electron species, implying that there is at least some component present to the additional π-bond from the alkyne to the metal centre.

Experimental section

General considerations

Unless otherwise stated all manipulations were performed under an atmosphere of prepurified nitrogen in a Vacuum Atmospheres HE-553–2 glove box equipped with a MO-40–2H purification system or in standard Schlenk-type glassware on a dual vacuum–nitrogen line. Reactions involving gaseous reagents were conducted in Pyrex vessels (bombs) designed to withstand pressures up to 10 atm (1 atm = 101.325 kPa). ^{1}H NMR spectra (referenced to either C_6D_5H or $C_6D_5CD_2H$ for benzene and toluene, respectively) were performed on one of the following instruments depending on the complexity of the particular spectrum: Bruker WH-200, Varian XL-300, or a Bruker AM-500. ^{13}C NMR spectra (referenced to solvent peaks) were run at 50.323 MHz on the Bruker WH-200 or at 75.429 MHz on the XL-300 instrument, and ^{31}P NMR spectra (referenced to external $P(OMe)_3$ at 141.0 ppm) were run at 121.421 MHz and 202.33 MHz, on the XL-300 and Bruker AM-500 instruments, respectively. All chemical shifts are reported in ppm and all coupling constants are reported in Hz. Infrared spectra were recorded on a BOMEM MB-100 spectrometer. Solution samples were recorded on a 0.1 mm KBr cell and solid samples were recorded as pellets. Elemental analyses (Mr. P. Borda) and GC–MS were performed within this department.

Reagents

Ethylene and carbon monoxide were obtained as lecture bottles from Matheson and dried over P_2O_5 before use. Labeled ^{13}CO (Cambridge Isotopes) was used as received. Diphenylacetylene (Aldrich) was sublimed before use. MeMgBr (1.4 M solution in THF–toluene) and EtMgBr (3.0 M solution in ether) were purchased from Aldrich and used as received. NaCp(DME) (DME = dimethoxyethane) was prepared according to published literature procedure (35). Hexanes, tetrahydrofuran (THF), and toluene were predried over CaH_2 followed by distillation under argon from either sodium metal or sodium-benzophenone ketyl; pentane was distilled from sodium-benzophenone ketyl. The deuterated solvents C_6D_6 and $C_6D_5CD_3$ were dried over sodium, vacuum transferred to a bomb, and degassed by freeze–pump–haw technique before use. The procedures for the preparation of $^R[P_2Cp]ZrCl_3$ (**1a**: R = Pr^i (36); **1b**: R = Me[3]) have been described elsewhere.

*$^{Pr}[P_2Cp]Zr(\eta^2$-CH_2=$CH_2)Br$ (**2a**)*

A solution of 3.0 M EtMgBr (2.15 mL, 6.45 mmol) was diluted in 20 mL of toluene and added dropwise with stirring to a cooled (–78°C) solution of **1a** (2.06 g, 3.23 mmol) dissolved in 100 mL of toluene. The pale yellow colour of the solution turned to bright yellow upon addition. The mixture was stirred at –78°C for 1 h and allowed to slowly warm to room temperature, whereupon the colour of the solution gradually changed to a dark reddish purple. The volatiles were then removed under vacuum and the residue extracted with pentane and filtered. Dark purple crystals of **2a** were obtained from a cold (–40°C) concentrated pentane solution. Yield: 1.86 g (90%). ^{1}H NMR (20°C, C_6D_6) δ: 0.21 and 0.23 (s, 6H, $Si(CH_3)_2$), 0.82 and 0.85 (d, 2H, $^2J_{PH}$ = 8 Hz, $SiCH_2P$), 0.98 and 1.01 (m, 2H, $^3J_{PH}$ = 7 Hz, CH_2=CH_2), 1.08, 1.15, 1.26, and 1.31 (dd, 6H, $^2J_{HH}$ = 7 Hz, $^2J_{PH}$ = 7 Hz, $CH(CH_3)_2$), 2.23 and 2.35 (sept, 2H, $^3J_{HH}$ = 7 Hz, $CH(CH_3)_2$), 4.37 (t, 1H, $^4J_{HH}$ = 1 Hz, Cp-*H*), 6.31 (d, 2H, $^4J_{HH}$ = 2 Hz, Cp-*H*). ^{31}P NMR (20°C, C_6D_6) δ: 19.5 (s). Anal. calcd. for $C_{25}H_{51}BrP_2Si_2Zr$: C 46.85, H 8.02; found: C 46.89, H 8.06.

*$^{Me}[P_2Cp]Zr(\eta^2$-CH_2=$CH_2)Br$ (**2b**)*

A solution of 3.0 M EtMgBr (1.50 mL, 4.50 mmol) was diluted in 20 mL of toluene and added dropwise with stirring to a cooled (–78°C) solution of **1b** (1.19 g, 2.26 mmol) dissolved in 40 mL of toluene. The reaction mixture was allowed to warm to room temperature and stirred for 3 h, during which a dark reddish brown colour was generated. The solvent was removed and the residue extracted with hexanes and filtered. Reducing this solution to 5 mL permitted the isolation of dark red crystals at –40°C, which were washed with cold pentane and dried. Yield: 0.93 g (79%). ^{1}H NMR (20°C, C_6D_6) δ: 0.09 and 0.16 (s, 6H, $Si(CH_3)_2$), 0.84 and 1.15 (d, 2H, $^2J_{HH}$ = 12 Hz, $SiCH_2P$), 0.88 and 1.33 (d, 2H, $^3J_{PH}$ = 9 Hz, CH_2=CH_2), 1.24 and 1.27 (d, 6H, $^2J_{PH}$ = 7 Hz, $P(CH_3)_2$), 4.15 (t, 1H, $^4J_{HH}$ = 1 Hz, Cp-*H*), 6.02 (d, 2H, $^4J_{HH}$ = 1 Hz, Cp-*H*). ^{31}P NMR (20°C, C_6D_6) δ: 0.0 (s). Anal. calcd. for $C_{17}H_{35}BrP_2Si_2Zr$: C 38.62, H 6.67; found: C 38.54, H 6.74.

*$^{Pr}[P_2Cp]Zr(\eta^2$-CH_2=$CH_2)Me$ (**3a**)*

A solution of 1.4 M MeMgBr (0.75 mL, 1.05 mmol) was diluted in 10 mL of toluene and added dropwise with stirring to a cooled (–78°C) solution of **2a** (620 mg, 0.97 mmol) dissolved in 30 mL of toluene. The mixture was allowed to slowly warm to room temperature, during which the colour of the solution gradually changed from a deep purple to a dark reddish orange. The reaction mixture was stirred for another 24 h, the volatiles were then removed under vacuum and the residue extracted with hexanes and filtered. An impure pale pink solid was obtained by slow evaporation of the filtrate, which gradually decomposed with the evolution of free ethylene. ^{1}H NMR (20°C, C_6D_6) δ: –0.67 (t, 3H, $^3J_{PH}$ = 10 Hz, $ZrCH_3$), 0.24 and 0.26 (s, 6H, $Si(CH_3)_2$), 0.86 (m, 4H, $^2J_{PH}$ = 8 Hz, $SiCH_2P$), 1.05 (m, 2H, $^3J_{PH}$ = 8 Hz, $Zr(CH_2$=$CH_2)$), 1.10 (m, 24H, $CH(CH_3)_2$), 2.09 (sept, 4H, $^3J_{HH}$ = 7 Hz, $CH(CH_3)_2$), 4.61 (t, 1H, $^4J_{HH}$ = 2 Hz, Cp-*H*), 6.32 (d, 2H, $^4J_{HH}$ = 2 Hz, Cp-*H*). ^{31}P NMR (20°C, C_6D_6) δ: 20.1 (s).

*$^{Pr}[P_2Cp]Zr(\eta^2$-CH_2=$CH_2)(\eta^5$-$C_5H_5)$ (**4a**)*

A solution of NaCp(DME) (106 mg, 0.59 mmol) in 30 mL of toluene was added dropwise with stirring to a cooled (–78°C) solution of **2a** (410 mg, 0.59 mmol) dis-

solved in 50 mL of toluene. The mixture was stirred at –78°C for 2 h, then allowed to slowly warm to room temperature and stirred for another 24 h The colour of the solution gradually changed from a deep purple to a orange-red. The volatiles were then removed under vacuum and the residue extracted with hexanes and filtered. Orange crystals were obtained from a cold (–40°C) concentrated hexamethyldisiloxane–hexanes mixture. The crystals were washed with cold hexamethyldisiloxane and dried. Yield: 310 mg (84%). ^{1}H NMR (20°C, C_6D_6) δ: 0.08, 0.13, 0.52 and 0.58 (s, 3H, Si(CH_3)$_2$), 0.42, 0.75, and 0.85 (ddt, 1H, $^3J_{HH}$ = 10 Hz (*cis* and *trans*), $^3J_{PH}$ = 6 Hz, CH*H*=CH$_2$), 0.74 and 0.81 (dd, 2H, $^2J_{HH}$ = 15 Hz, $^2J_{PH}$ = 4 Hz, SiCH_2P), 0.94, 1.00, 1.02, 1.03, 1.04, 1.05, 1.05, and 1.13 (dd, 3H, $^3J_{HH}$ = 7 Hz, $^3J_{PH}$ = 7 Hz, CH(CH_3)$_2$), 1.59 and 1.60 (sept, 1H, $^3J_{HH}$ = 7 Hz, C*H*(CH$_3$)$_2$), 1.74 (d of sept, 1H, $^3J_{HH}$ = 7 Hz, $^2J_{PH}$ = 3 Hz, C*H*(CH$_3$)$_2$), 1.98 (d of sept, 1H, $^3J_{HH}$ = 7 Hz, $^2J_{PH}$ = 7 Hz, C*H*(CH$_3$)$_2$), 5.21 (t, 1H, $^4J_{HH}$ = 2 Hz, Cp-*H*), 5.35, (s, 5H, $^3J_{PH}$ = 1 Hz, C$_5H_5$), 5.61 and 5.62 (dd, 1H, $^3J_{HH}$ = 6 Hz, $^4J_{HH}$ = 2 Hz, Cp-*H*). ^{31}P NMR (20°C, C_6D_6) δ: –5.3 (s), 42.3 (s). Anal. calcd. for $C_{30}H_{56}P_2Si_2Zr$: C 57.55, H 9.01; found: C 57.25, H 9.15.

^{Pr}[P_2Cp]Zr(CO)$_2$Br (**5a**)

A benzene-d_6 solution of **2a** was placed in a sealable NMR tube and affixed to a dual vacuum–nitrogen line. A small portion of solvent was removed under vacuum, and an atmosphere of carbon monoxide introduced at –78°C. The colour of the solution instantly changed from dark purple to dark green. ^{1}H NMR spectroscopy revealed the evolution of free ethylene and the formation of one clean product with resonances associated solely with the ancillary ligand, while the ^{31}P NMR spectrum showed a single new resonance. Repeating the reaction in a sealed tube with the addition of ^{13}CO yielded diagnostic peaks for the carbonyl ligands in the ^{13}C NMR spectrum. Conducting the reaction on a larger scale in toluene generated the same colour change in solution as noted before upon addition of CO, although removal of the volatiles induced a subtle degradation of the green colour to this solution. A hydrocarbon-soluble, thermally labile dark orange-green oil was obtained after workup in hexanes. IR (C_6D_6) ν_{CO} (cm^{-1}): 1890, 1865 (^{13}CO). ^{1}H NMR (20°C, C_6D_6) δ: 0.12 and 0.28 (s, 6H, Si(CH_3)$_2$), 0.51 and 0.82 (dd, 2H, $^2J_{HH}$ = 15 Hz, $^2J_{PH}$ = 9 Hz, SiCH_2P), 0.97, 1.22, 1.29 and 1.32 (dd, 6H, $^3J_{HH}$ = 7 Hz, $^3J_{PH}$ = 7 Hz, CH(CH_3)$_2$), 1.95 and 2.48 (sept, 2H, $^3J_{HH}$ = 7 Hz, C*H*(CH$_3$)$_2$), 5.16 (d, 2H, $^4J_{HH}$ = 1 Hz, Cp-*H*), 5.19 (t, 1H, $^4J_{HH}$ = 1 Hz, Cp-*H*). ^{13}C NMR (20°C, C_6D_6) δ: 241.1 (br s, Zr(*C*O)), 249.1 (s, Zr(*C*O)). ^{31}P NMR (20°C, C_6D_6) δ: 29.1 (s).

^{Me}[P_2Cp]Zr(CO)$_2$Br (**5b**)

The procedure followed was similar to that for **5a**, reacting ethylene **2b** in an atmosphere of CO. The colour of the solution gradually changed from dark red to a dull purplish red after the addition of CO. Once again, a scaled up version of this reaction permitted only the isolation of a thermally labile oil. IR (C_6D_6) ν_{CO} (cm^{-1}): 1898, 1855 (^{13}CO) ^{1}H NMR (20°C, C_6D_6) δ: 0.09 and 0.18 (s, 6H, Si(CH_3)$_2$), 0.57 and 1.03 (d, 2H, $^2J_{PH}$ = 7 Hz, SiCH_2P), 1.41 and 1.50 (t, 6H, $^2J_{PH}$ = 5 Hz, P(CH_3)$_2$), 4.82 (d, 2H, $^4J_{HH}$ = 1 Hz, Cp-*H*), 5.08 (t, 1H, $^4J_{HH}$ = 1 Hz, Cp-*H*). ^{13}C NMR (20°C, C_6D_6) δ: 240.5 and 245.1 (s, Zr(*C*O)). ^{31}P NMR (20°C, C_6D_6) δ: –12.0 (s).

^{Pr}[P_2Cp]Zr(η^5-C_5H_5)(CO) (**6a**)

A benzene-d_6 solution of **4a** was placed in a sealable NMR tube and affixed to a dual vacuum–nitrogen line. A small portion of solvent was removed under vacuum, and an atmosphere of carbon monoxide introduced at –78°C. The contents within the sample were continually mixed under ambient temperature by a constant inversion of the sample by mechanical method. The reaction was monitored by ^{1}H and ^{31}P NMR spectroscopy until the reaction was complete (approximately 2 weeks). There was no obvious colour change associated with this reaction. **6a** was observed to be the major product (90%) based on the NMR spectra. Repeating the procedure in a sealed tube with the addition of ^{13}CO yielded a strong diagnostic peak at 308 ppm for the carbonyl ligand in the ^{13}C NMR spectrum. Conducting the reaction on a larger scale in toluene generated a thermally sensitive hydrocarbon-soluble orange oil after workup that gradually decomposed at –40°C. ^{1}H NMR (20°C, C_6D_6) δ: 0.13, 0.24, 0.35, and 0.47 (s, 3H, Si(CH_3)$_2$), 0.42 and 0.63 (dd, 1H, $^2J_{HH}$ = 11 Hz, $^2J_{PH}$ = 9 Hz, SiCH_2P), 0.69 (d, 2H, $^2J_{PH}$ = 7 Hz, SiCH_2P), 0.75, 0.78, 0.90, and 0.91 (dd, 3H, $^3J_{HH}$ = 7 Hz, $^3J_{PH}$ = 7 Hz, CH(CH_3)$_2$), 1.05 (m, 12H, CH(CH_3)$_2$), 1.29 and 1.55 (sept, 1H, $^3J_{HH}$ = 7 Hz, C*H*(CH$_3$)$_2$), 1.59 (sept, 2H, $^3J_{HH}$ = 7 Hz, C*H*(CH$_3$)$_2$), 4.95 (s, 5H, $^3J_{PH}$ = 1 Hz, C$_5H_5$), 5.08, 5.55, and 5.62 (dd, 1H, $^4J_{HH}$ = 1 Hz, Cp-*H*). ^{13}C NMR (20°C, C_6D_6) δ: 308.0 (d, $^2J_{PC}$ = 3 Hz, Zr(*C*O)). ^{31}P NMR (20°C, C_6D_6) δ: –4.8 and 58.7 (s).

^{Pr}[P_2Cp]Zr(η^2-PhCCPh)Br (**7a**)

Diphenylacetylene (106 mg, 0.59 mmol) was dissolved in 30 mL of toluene and added dropwise with stirring to a cooled (–78°C) solution of **2a** (410 mg, 0.59 mmol) dissolved in 50 mL of toluene. The mixture was slowly warmed to room temperature and stirred for another 24 h. The colour of the solution gradually changed from a deep purple to a dark brown. The volatiles were then removed under vacuum and the residue extracted with hexanes and filtered. Pale yellow crystals were obtained from slow evaporation of a concentrated hexamethyldisiloxane–hexanes mixture. The crystals were washed with two aliquots of cold hexamethyldisiloxane and dried. Yield: 313 mg (67%). Anal. calcd. for $C_{37}H_{57}P_2Si_2Zr$: C 56.18, H 7.26; found: C 56.15, H 7.31.

Major isomer (60%): ^{1}H NMR (20°C, C_6D_6) δ: 0.27 and 0.46 (s, 6H, Si(CH_3)$_2$), 0.84 and 1.28 (dd, 2H, $^2J_{HH}$ = 15 Hz, $^2J_{PH}$ = 4 Hz, SiCH_2P), 0.80, 0.98, 1.04, and 1.13 (dd, 6H, $^3J_{HH}$ = 7 Hz, $^3J_{PH}$ = 7 Hz, CH(CH_3)$_2$), 1.74 and 2.53 (sept, 2H, $^3J_{HH}$ = 7 Hz, C*H*(CH$_3$)$_2$), 6.75 (d, 2H, $^4J_{HH}$ = 1 Hz, Cp-*H*), 6.86 (t, 1H, $^4J_{HH}$ = 1 Hz, Cp-*H*), 7.00 (t, 2H, *p*-C_6H_5), 7.24 (t, 4H, *m*-C_6H_5), 7.45 (d, 4H, *o*-C_6H_5). ^{31}P NMR (20°C, C_6D_6) δ: 9.3 (s).

Minor isomer (40%): ^{1}H NMR (20°C, C_6D_6) δ: 0.21 and 0.33 (s, 6H, Si(CH_3)$_2$), 0.67 and 1.14 (dd, 2H, $^2J_{HH}$ = 14 Hz, $^2J_{PH}$ = 5 Hz, SiCH_2P), 0.75, 1.19, 1.29, and 1.35 (dd, 6H, $^3J_{HH}$ = 7 Hz, $^3J_{PH}$ = 7 Hz, CH(CH_3)$_2$), 2.10 and 2.15 (sept, 2H, $^3J_{HH}$ = 7 Hz, C*H*(CH$_3$)$_2$), 6.46 (t, 1H, $^4J_{HH}$ = 1 Hz, Cp-*H*), 6.80 (d, 2H, $^4J_{HH}$ = 1 Hz, Cp-*H*), 6.94 (t, 2H, *p*-C_6H_5),

7.18 (t, 4H, *m*-C_6H_5), 7.35 (d, 4H, *o*-C_6H_5). ^{31}P NMR (20°C, C_6D_6) δ: 6.9 (s).

Concluding remarks

In this paper a series of zirconium complexes stabilized by the ancillary P_2Cp ligand are presented in which the formal oxidation state can be regarded as Zr(II). The ethylene complexes **2** and **4a** react with CO via loss of ethylene to generate carbonyl derivatives, and **2a** undergoes a similar reaction with diphenylacetylene to produce alkyne **7a**. The slow reaction of the saturated 18-electron complex **4a** with CO demonstrates that phosphine dissociation is required to provide a reactive site. The lack of reactivity of alkyne **7a** with CO presumably originates from the same electronic saturation of that species. In comparison, the immediate incorporation of CO by the 16-electron ethylene complexes **2a** or **2b** suggests an associative mechanism. The displacement of a coordinated ethylene molecule by CO is a rare occurrence in early metal complexes (33). It might have been anticipated that strong back-bonding should confer a degree of Zr(IV) metallacycle character in the metal—ethylene bonding as shown in **A**; however, it is apparent from the resulting ligand substitution reactions that considerable Zr(II) character is still present in these ethylene derivatives.

Molecular characterization of petroporphyrins in crude oil by electrospray ionization Fourier transform ion cyclotron resonance mass spectrometry

Ryan P. Rodgers, Christopher L. Hendrickson, Mark R. Emmett, Alan G. Marshall, Mark Greaney, and Kuangnan Qian

Abstract: Petroporphyrin compositional analysis of a heavy crude oil has been realized by isolation and subsequent ESI–FT-ICR mass spectrometric analysis of the porphyrin-containing fractions. Vanadium octaethyl (V=O(II)OEP) and nickel octaethyl (Ni(II)OEP) porphyrin standards were analyzed to determine favorable electrospray ionization conditions and provide insight as to the molecular species present (e.g., adducts, multimers). Standard V=O(II)OEP and Ni(II)OEP solutions revealed the presence of both monomer and dimer species with a greater relative abundance of monomers. In contrast, mass spectral analysis of a porphyrin fraction from Cerro Negro crude oil was dominated by dimeric species. MS^3 analysis identified a dioctylphthalate (DOP) contaminant, likely introduced during fractionation of the crude oil. DOP-porphyrin complexes and porphyrin–porphyrin dimers were then identified. Infrared multiphoton dissociation (IRMPD) of dimeric species produced the corresponding monomers with minimal fragmentation. The monomeric petroporphyrins were analyzed to reveal the metal (Ni(II) or V=O(II)), porphyrin type (e.g., etio vs. DPEP), and distribution of alkylation.

Key words: petroporphyrin, porphyrin, petroleum, electrospray ionization, mass spectrometry, Fourier transform, ion cyclotron resonance, ICR, FT-ICR, FTMS.

Résumé : On a réalisé une analyse de la composition en pétroporphyrines d'une huile brute lourde en procédant à l'isolement et à une analyse subséquente des fractions contenant des porphyrines par spectrométrie de masse par la technique « ESI–FT-IRC.» Dans le but de déterminer les conditions les plus favorables pour obtenir une ionisation par électronébulisation ainsi que pour évaluer la nature des espèces moléculaires présentes (par exemple, adduits, multimères), on a procédé à l'analyse d'échantillons de référence d'octaéthylvanadium- (V=O(II)OEP) et d'octaéthylnickel-(Ni(II)OEP) porphyrines. Des solutions de référence d'échantillons de V=O(II)OEP et de Ni(II)OEP montrent la présence d'espèces monomères ainsi que dimères; l'abondance relative des espèces monomères est plus importante que celle des dimères. Par ailleurs, l'analyse par spectrométrie de masse d'une fraction de porphyrines d'une huile brute de Cerro Negro est dominée par les espèces dimères. Une analyse par la méthode MS^3 révèle la présence de phtalate de dioctyle (« DOP ») comme contaminant introduit vraisemblablement durant le fractionnement de l'huile brute. On a alors identifié des complexes de DOP-porphyrine et des dimères porphyrine–porphyrine. Une dissociation multiphotonique par infrarouge (« IRMPD ») des espèces dimères a conduit aux monomères correspondants avec un minimum de fragmentation. Les pétroporphyrines monomères ont été analysées et ont mis en évidence la nature du métal (Ni(II) ou V=O(II)), le type de porphyrine (par exemple, etio vs. DPEP) ainsi que la distribution de l'alkylation.

Mots clés : pétroporphyrine, porphyrine, pétrole, ionisation par électronébulisation, spectrométrie de masse, transformation de Fourier, résonance gyromagnétique des ions, ICR, FT-CR, FTMS.

Fig. 1. Structures of two common types of petroporphyrins.

Introduction

The presence of petroporphyrins (also known as geoporphyrins) in crude oils is significant to the petroleum industry in both upstream (exploration and production) and downstream (refinery) sectors of the business. Petroporphyrins originate from the degradation of biological materials and are regarded as important biomarkers. The distribution of porphyrin types, such as the ratio of etioporphyrin (etio) (i.e., porphyrins that bear no exocyclic ring) to deoxophyllerythro-etioporphyrin (DPEP) (see Fig. 1) is widely used as a measure of the maturity of a crude oil (1, 2). For example, degradation of the heme, from hemoglobin or the cytochromes, by decarboxylation of the acids and reduction of the vinyl groups generates etioporphyrin-III. Similarly, degradation of chlorophyll can generate the five-membered ring of the DPEP family. DPEP is an example of the more general classification of cycloalkanoporphyrins (CAP), which may contain one or more five-, six-, or seven-membered rings (3).

Petroporphyrins are also an important class of metal-containing compounds in crude oil. Metals are known to poison catalysts in various catalytic refinery processes, such as catalytic cracking, hydrocracking, etc. (4–6). As world-wide petroleum supplies become richer in heteroatomic content, research on processing such heavy petroleum becomes increasingly important. Knowledge of the molecular composition of metal-containing species, including petroporphyrins in crude, is important to the development of an effective demetallation process for heavy petroleum processing.

Characterization of petroporphyrins, developed over the past several decades, traditionally involves separations of petroporphyrins by open column, thin-layer, or reverse-phase HPLC (7–10). Demetallation by methane sulfonic acid is often performed to facilitate spectroscopic analysis, including mass spectrometric analysis. Various petroporphyrin types, such as etio, DPEP, Di-DPEP, rhodo-etio and rhodo-DPEP, have been identified in petroleum products (1).

Mass spectrometry provides molecular weight and elemental composition of porphyrin homologs, from which porphyrin "type" (rings plus double bonds) may be determined. Additional structural information may be obtained by tandem mass spectrometry (3). Direct mass spectrometric characterization of petroporphyrins in crude oil without prior chromatographic separation remains difficult and a subject of continued research interest. Direct analysis would not only avoid potential modification of petroporphyrin structures during chromatography, but also make it possible to track directly molecular transformations of porphyrin structures in crude oil processing. The latter is critical to the understanding of fundamental chemistry occurring in the refinery process. Direct mass spectrometric analysis is difficult for at least two reasons. First, the low concentration and high-boiling nature of petroporphyrins render traditional vaporization and ionization methods ineffective. Second, the complexity of the hydrocarbon matrix in the high-boiling region demands ultra-high mass resolving power that cannot be met by traditional mass spectrometric methods. The development of electrospray ionization high-field Fourier transform ion cyclotron resonance mass spectrometry (ESI–FT-ICR–MS) technology offers an opportunity to characterize polar molecules, such as petroporphyrins in heavy petroleum, at an unprecedented level of detail.

In an effort to develop a strategy to speciate directly petroporphyrins in crude oil, we have evaluated the use of ESI–FT-ICR–MS for petroporphyrin characterization. Here, we report elemental compositional analyses of two petroporphyrin standards (nickel and vanadyl octaethyl porphyrins (Ni(II)OEP and V=O(II)OEP) and two petroporphyrin fractions isolated from Cerro Negro extra heavy crude oil. Cerro Negro was selected not only for its high VO/Ni content, but also because it has been previously characterized by other researchers (11). High-resolution ($m/\Delta m_{50\%} \approx 100\,000$) broadband (200 m/z 1200) mass analysis allows for resolution and identification of ~300 distinct elemental compositions in a complex mass spectrum. Furthermore, IRMPD of dimeric species present in the broadband mass spectrum allows for the detection and subsequent identification of the monomer petroporphyrins present in the crude despite strong signals from dioctylphthalate contamination. Both porphyrin:porphyrin and porphyrin:DOP dimers could be dissociated into their respective monomers in the ICR ion trap, leading to a much simplified mass spectrum.

Experimental

Sample preparation

Vanadyl octaethyl porphyrin (V=O(II)OEP) and nickel octaethyl porphyrin (Ni(II)OEP) were purchased from Aldrich Chemical Co. and used as received. Standard solutions of Ni(II)OEP and V=O(II)OEP were prepared by dissolution in either methanol (V=O(II)OEP) or acetonitrile (ACN) (Ni(II)OEP) to a concentration of 10 μM, with the addition of acetic acid (1% v/v). Preparation of the isolated petroporphyrin fractions went as follows. The basic procedure used for petroporphyrin isolation is a slightly modified version of that described by Grigsby and Green (11). The isolation scheme is illustrated in Fig. 2. Six grams of extra heavy crude oil from Cerro Negro, Venezuela was diluted with 10 mL of toluene and loaded onto a dry packed column of neutral aluminum oxide (Alfa, 60 mesh, 100 g). Three dark bands were eluted with 100 mL of toluene, then 100 mL of a 1:1 toluene–methylene chloride (CH_2Cl_2)

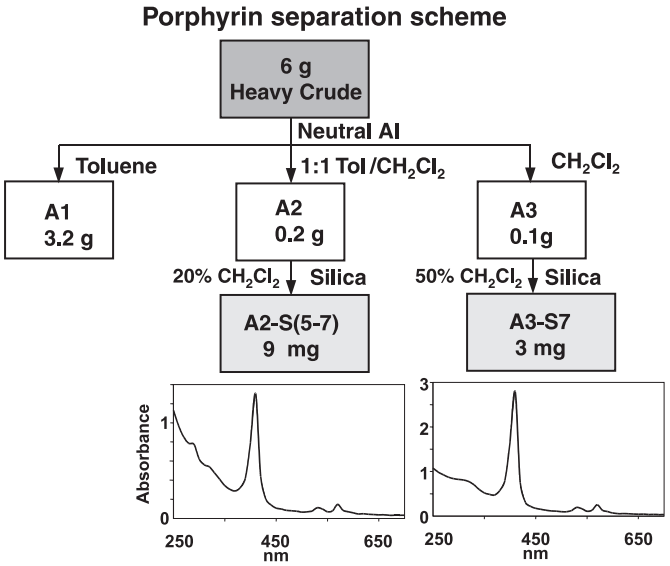
Fig. 2. Separation scheme employed to isolate the petroporphyrin fractions from Cerro Negro crude oil. The second and third bands (A2 and A3 fractions) exhibited Soret peaks at 408 nm in their UV–vis absorption spectra, indicating the presence of petroporphyrins. Therefore, both A2 and A3 were further processed to yield the A2-S(5–7) and A3-S7 fractions, whose UV–vis spectra are shown at the bottom of the diagram.



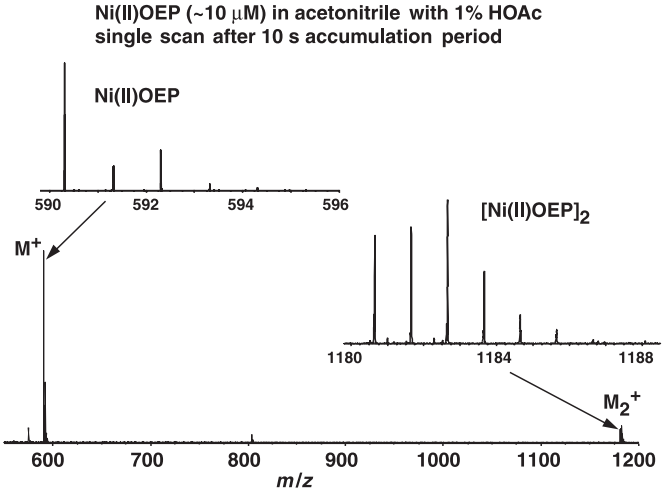


Fig. 3. Broadband single-scan ESI–FT-ICR mass spectrum of a 10 μM Ni(II) octaethyl porphyrin solution in acetonitrile with 1% acetic acid (v/v) at an average mass resolving power ($m/\Delta m_{50\%} \approx 100\,000$) and a signal-to-noise ratio (S/N) > 1000). The two dominant isotopic distributions at m/z = 590 (left zoom inset) and 1180 (right zoom inset) are the Ni(II)OEP monomer and dimer.

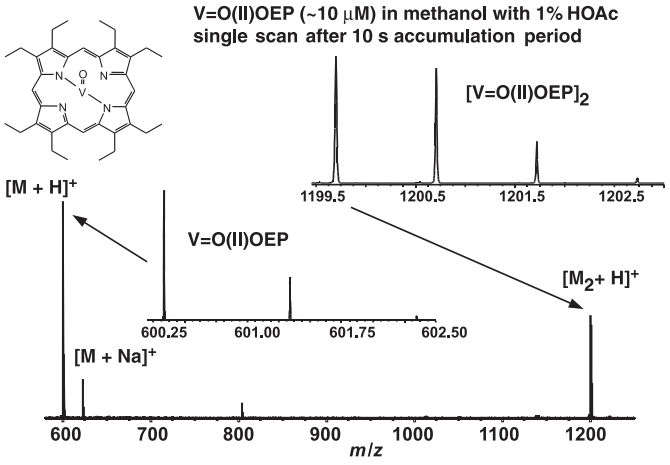
mixture and finally with 50 mL of pure CH_2Cl_2. The second and third bands (A2 and A3 fractions) exhibited Soret peaks at 408 nm in their UV–vis absorption spectra indicating the presence of petroporphyrins. A2 and A3 fractions were dried under a nitrogen stream and weighed 200 and 100 mg, respectively.

Further purification was achieved by passing A2 and A3 fractions through silica gel (J.T. Baker, 60–200 mesh, 40 g) that was slurried into the column after mixing with 200 mL of 10 vol% CH_2Cl_2 in hexane. The column was eluted sequentially with 10, 20, 30, 40, and 50% CH_2Cl_2. For A2, elution with 20% CH_2Cl_2 led to isolation of a red-pink band, with a UV–vis spectrum characteristic of a porphyrin, with absorbance maxima at 408, 537, and 573 nm. The fraction was labeled as A2-S(5–7) and weighed 9 mg after solvent evaporation. A3 was separated by a similar scheme. A red band was isolated by elution with 50% CH_2Cl_2 in hexane. The fraction was labeled as A3-S7 and weighed 3 mg after solvent evaporation. It exhibited absorbance maxima in the UV–vis region at 408, 533, and 572 nm, and a shoulder peak at 588 nm. Portions of the dried Cerro Negro fractions (both A2-S(5–7) and A3-S7) were first dissolved in a small amount of methylene chloride (~500 μL) and then added to 10 mL of methanol with 1% (v/v) acetic acid. If precipitation occurred, methylene chloride was added dropwise until the solution cleared. The samples were then microelectrosprayed into the FT-ICR mass spectrometer.



Instrumentation

All mass analyses were carried out on a homebuilt FT-ICR mass spectrometer (12) equipped with a 22 cm horizontal room temperature bore 9.4 Tesla magnet (Oxford Corp., Oxney Mead, England) and a modular ICR data station (13). Positive ions were generated from a microelectrospray source (14) at a flow rate of 300 nL min^{-1} and a source potential of ~2.2 kV before external accumulation (5–30 s) in a 67 cm long octopole (15). Ions were then transferred through a 200 cm long rf-only octopole into an open cylindrical ICR cell (10 cm i.d. × 30 cm long) prior to broadband frequency chirp excitation (50 kHz – 1.44 MHz at a sweep rate of 150 Hz s^{-1} and amplitude, $V_{p\text{-}p}$ = 210 V) and direct mode image current detection to yield 512 K word time-domain data. The data were processed by an in-house FT-ICR–MS analysis package (13). The time-domain data was Hanning-apodized, followed by a single zero-fill before FFT and magnitude calculation. Frequency-to-mass conversion was based on assumed three-dimensional axial quadrupolar trapping potential (16, 17), to generate the spectra shown in Figs. 3–6. For the Cerro Negro fractions, VOEP served as an internal calibrant. External calibration was used for the two porphyrin standards, VOEP and NiOEP. IRMPD studies were performed by irradiation for 2 s by a Synrad (Mukilteo, WA) 50 W cw CO_2 (λ = 10.6 μm) laser aligned on-axis with the ion cloud. The laser was operated at 20 W and focused to a ~1 cm beam diameter at the center of the Penning trap.

Mass spectral data were converted to the Kendrick mass scale to facilitate separation and identification of pseudohomologous series (i.e., a series of compounds differing in mass by 14.01565 Da (CH_2) from one member to the next). In the Kendrick mass scale (18), each mass value is multiplied by (14.00000/14.01565), so that the Kendrick mass of CH_2 becomes 14.00000. With this convention, members of a homologous series differing by multiples of CH_2 each have identical mass defect. All of the Kendrick mass values may then be scanned to find each series of ions differing by (say) 14.000 ± 0.001 Kendrick mass units. The type for each such series is then determined from the z-value

Fig. 4. Broadband single-scan ESI–FT-ICR mass spectrum of a 10 μM V=O(II) octaethyl porphyrin solution in methanol with 1% acetic acid (v/v) at an average mass resolving power ($m/\Delta m_{50\%} \approx 100\,000$) and a signal-to-noise ratio (S/N) > 1000). The two dominant isotopic distributions at m/z = 600 (left zoom inset) and 1200 (right zoom inset) are the V=O(II)OEP monomer and dimer.

(C_nH_{2n+z}) to locate porphyrins containing V=O, Ni, and Na (see below).

Results and discussion

Porphyrin standards analysis

Solutions of Ni(II)OEP and V=O(II)OEP (each ~10 μM) were separately electrosprayed (19, 20) into the FT-ICR mass spectrometer to yield in each case a relatively simple positive ion mass spectrum. Figure 3 shows the ESI–FT-ICR mass spectrum of the Ni(II)OEP stock solution at an average mass resolving power ($m/\Delta m_{50\%} \approx 100\,000$ (in which $m_{50\%}$ denotes the magnitude-mode peak full-width at half-maximum peak height)) and a signal-to-noise ratio (S/N) 1000. The two prominent isotopic distributions centered about m/z 590 and 1180 correspond to the singly charged Ni(II)OEP monomer molecular ion and its (proton-bound) dimer. The experimental nominal mass isotopic relative abundance distributions (not shown) for Ni(II)OEP monomer and dimer match the theoretical distributions quite well, and are quite diagnostic because of the distinctive isotopic distribution of Ni (68.3% ^{58}Ni, 26.1% ^{60}Ni).

Similarly, Fig. 4 shows the ESI–FT-ICR mass spectral analysis of the V=O(II)OEP stock solution at an average mass resolving power $m/\Delta m_{50\%} \approx 100\,000$ and a S/N 1000. Again, the two prominent isotopic distributions (m/z = 600 and 1200, shown in the zoom mass insets) represent both the VOEP monomer and dimer. Interestingly, whereas Ni(II)OEP monomer and dimer become positively charged by loss of an electron, V=O(II)OEP and its dimer gain positive charge by addition of H^+ (or Na^+). The tendency of the porphyrins to dimerize is important for the analysis of the crude oil extracts (see below).

Petroporphyrin fraction analysis

Both A2-S(5–7) and A3-S7 porphyrin-containing fractions isolated from Cerro Negro crude were micro-

Fig. 5. Broadband ESI–FT-ICR mass spectrum of A3-S7 fraction isolated as in Fig. 1, shown before (top) and after (bottom) infrared multiphoton dissociation. Top: Three dimer distributions in the range, 800 < m/z < 1100. The species at m/z 800 was identified by MS^3 experiments as dioctyl phthalate (DOP) dimer. The remaining two dimer distributions were then identified as petroporphyrin:dioctyl phthalate (900 < m/z < 1000) and petroporphyrin:petroporphyrin (1000 < m/z < 1100) dimers. Bottom: broadband mass spectrum of the same isolated petroporphyrin fraction after IRMPD. IRMPD dissociates the dimers to yield solely monomers. Each spectrum was the result of 20 co-added time-domain transients, and the sample was spiked with V=O(II)OEP as an internal mass calibrant.

717.5769	717.5770	–0.1	–0.1	0.4
731.5773	731.5770	+0.3	+0.4	0.3
745.5774	745.5770	+0.4	+0.6	0.2

Note: Kendrick mass increases by exactly 14 mass units for every additional CH_2 group, making it easy to recognize such a series of alkylated molecules.

will be presented. Figure 5 (top) shows the broadband mass spectrum of the isolated porphyrin fraction spiked with the V=O(II)OEP standard solution to provide an internal calibrant. Petroporphyrins in the mass range 500 *m*/*z* 600 are barely observable. However, the V=O(II)OEP dimer is clearly evident at 1200 Da as are many other dimeric species from 800–1100 Da. Two separate groups of dimers are apparent in the mass range spanning 900–1000 Da and 1000–1100 Da. A third homodimer of large relative abundance at *m*/*z* 800 was SWIFT-isolated (21, 22) and fragmented by IRMPD for identification. Subsequent MS^3 experiments identified the dimer species as a dioctyl phthalate (DOP) contaminant, most likely introduced (e.g., from bottle cap lining) in the fractionation of the Cerro Negro crude oil. Identification of the DOP contaminant led to the assignment of the two heterodimer distributions as petroporphyrin:dioctyl phthalate (900–1000 Da) and petroporphyrin–petroporphyrin (1000–1100 Da) dimer series. The laser power and duration were varied in an attempt to dissociate the dimer complexes so as to reveal the true petroporphyrin monomer distributions present in the Cerro Negro crude oil. Figure 5 (bottom) shows the broadband mass spectrum of the same isolated porphyrin fraction (Fig. 5, top) after IRMPD to yield both the petroporphyrin, DOP, and VOEP monomers at a mass resolving power of ~200 000 and S/N 1000.

Petroporphyrin type and alkylation analysis

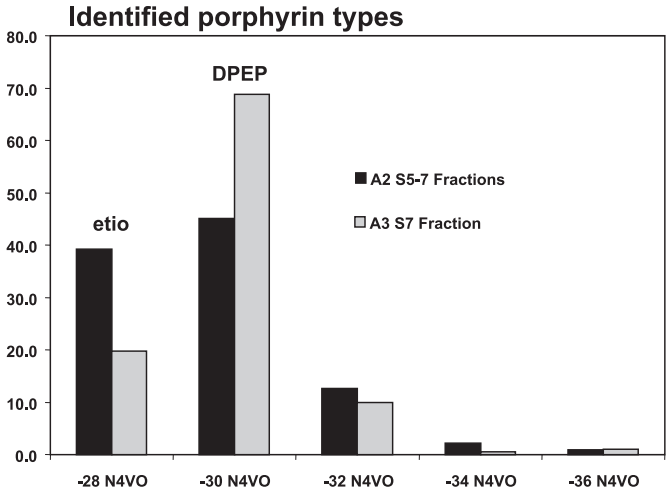

Table 1 shows how the members of a particular vanadyl petroporphyrin family are identified. First, the masses of all resolved peaks are converted to Kendrick mass scale. For a particular petroporphyrin ion type (in this case, $C_nH_{2n-30}N_4VONa$) the mass values calculated from the elemental composition constitute a series of masses separated by 14.000 Kendrick mass units, with identical Kendrick mass defect. Examination of the experimental masses then immediately results in identification of all of the members of the $C_nH_{2n-30}N_4VONa$ (DPEP) porphyrin family shown in the table.

Two types of petroporphyrin homolog series (VO(II)etio and VO(II)DPEP) identified in this way are shown in Fig. 6, for A2-S(5–7) and A3-S7 fractions isolated as shown in Fig. 1. The average molecular weight (MW) of petroporphyrins in A2-S(5–7) is higher than that in A3-S7. Molecular ions with mass up to 700 Da were observed. This observation is consistent with the higher polarity of the A3-S7 fraction compared to the A2-S(5–7) fraction. The MW profile reflects the distribution of alkylation of the porphyrins: for example, the most probable carbon number observed for the DPEP family in A3-S7 is 31. Given that the porphyrin skeleton itself (including the five-membered ring) contains 22 carbons, the most probable number of alkyl carbon substituents is nine. It is satisfying to note that both the M+H and the M+Na ion series yield very similar alklyation patterns, suggesting that the mass spectrometric ion relative abundances may well correlate to the relative abundances of the petroporphyrins in solution. Figure 6 also suggests that short chain porphyrins have a higher tendency to form Na adducts than do long chain porphyrins. Moreover, etio-type form Na adducts to a greater degree than the DPEP-type. Grigsby and Green (11) have characterized by low-voltage high-resolution mass spectrometry a vanadyl fraction isolated from the 700°C residual of Cerro Negro heavy crude oil. Their carbon number distribution for the etio type accords with our observation. Their carbon number distribution for the DPEP type, however, is about two carbon higher than our result. It is also interesting to note that the average number of carbon atoms in vanadyl petroporphyrins from another heavy crude (Boscan) oil (35–40) (23) is somewhat higher than the value (33) that we observe for Cerro Negro heavy crude oil.

Listings like that in Table 1 reveal additional homolog series for the petroporphyrins in Fig. 6. The results are conveniently summarized in Fig. 7, which shows the relative

Fig. 7. Relative abundances of various porphyrin types identified by ESI–FT-ICR mass analysis. The indicated type is denoted according to its elemental composition, in which the carbon and hydrogen values are abbreviated by their "*z*"-value in the formula, $C_nH_{2n+z}N_4VO$. Thus, ETIO and DPEP porphyrins have $z = -28$ and $z = -30$, respectively. The species with $z = -32$, –34, and –36 presumably contain 2, 3, and 4 additional rings.

abundances of different petroporphyrins according to type and isolated fraction. For example, the etio and DPEP porphyrins are comparably abundant in the A2 S(5–7) fraction, whereas the DPEP porphyrins are much more abundant in the A3-S7 fraction.

In conclusion, we are able to resolve and classify petroporphyrins from extracts of a heavy crude oil by ESI–FT-ICR–MS. First, we can identify the metal (Ni(II) or V=O(II)) in the porphyrin. Second, we can determine the porphyrin type (i.e., rings plus double bonds). Third, for each type, we can determine the distribution of alkylation of the porphyrin skeleton. Finally, tandem mass spectrometry, previously available only for pure porphyrins (3), should now be available for petroporphyrins from crude oil isolates, making it possible to determine the chain lengths of individual alkyl substituents. In summary, petroleum chemists now have access to a much higher level of compositional and structural detail in characterizing metallopetroporphyrins. This work provides a valuable reference base for direct speciation of petroporphyrins in crude oil.

Structural, electronic and spectroscopic features of the dihydride $Pd_4(dppm)_4(H)_2^{2+}$ cluster catalyst

Daniel Meilleur and Pierre D. Harvey

Abstract: ^{1}H NMR, vibrational, and UV–vis spectroscopic measurements for $Pd_2(dppm)_2Cl_2$ (dppm = $Ph_2PCH2PPh_2$), $[Pd_4(dppm)_4(X)_2](BF_4)_2$ (X = Cl, H), and $[Pd_4(dmpm)_4(H)_2](Br)_2$ (dmpm = $Me_2PCH_2PMe_2$) were performed to address the structure of the recently identified title cluster. Its dmpm analogue was prepared from the reaction between $Pd_2(dmpm)_2Br_2$ and $NaBH_4$ in methanol under inert atmosphere, and exhibits the expected nonet (rel. int. 1:8:28:56:70:56:28:8:1) at –5.21 ppm (in $(CD_3)_2CO$), contrasting with that of $Pd_4(dppm)_4(H)_2^{2+}$ (δ + 5.15 ppm, $(CD_3)_2CO$). This significant difference is explained by the presence of the PdH residues in the deshielding region of the dppm-phenyl groups. The vibrational spectra in the low-frequency region are consistent with a centrosymmetric structure, and a scattering at 144 cm^{-1} in the FT-Raman spectra is observed; a peak that is assigned to $\nu(Pd_2)$ on the basis of a comparison with the well established M_2-bonded $Pd_2(dppm)_2Cl_2$ data ((Pd_2) = 149 cm^{-1}). On the basis of the qualitative temperature behavior of the band maxima and width, the two lowest energy absorption bands in the UV–vis spectra are assigned to $d\sigma \rightarrow d\sigma^*$ type transition. EHMO computations predict four well-isolated frontier MO levels, defined as $d\sigma^*(Pd_2)/d\sigma^*(PdH)$ (LUMO + 1), $d\sigma^*(Pd_2)$ (LUMO), $d\sigma^*(Pd_2)/d\sigma^*(PdH)$ (HOMO), and $d\sigma$ (Pd_2) (HOMO –1), and simple selection rules ($u \leftrightarrow g$) indicate that only two low-energy electronic transitions are orbitally allowed, consistent with the UV–vis findings. Computer modelings show the presence of large cavities above and under the Pd_4 plane, described by inner-cavity nonbonded H···H distances of ~5–8 Å.

Key words: cluster, palladium, hydride, structure, spectroscopy.

Résumé : Afin de pouvoir étudier la structure du composé mentionné dans le titre, qui a récemment été identifié comme un agrégat, on a déterminé les spectres RMN du ^{1}H et les spectres vibrationnels et UV–vis du $Pd_2(dppm)_2Cl_2$ (dppm = $Ph_2CH_2PPh_2$), $[Pd_4(dppm)_4(X)_2](BF_4)_2$ (X = Cl, H) et du $[Pd_4(dmpm)_4(H)_2](Br)_2$ (dmpm = $Me_2PCH_2PMe_2$). L'analogue dmpm a été préparé par réaction d $Pd_2(dmpm)_2Br_2$ avec du $NaBH_4$ dans du méthanol, dans une atmosphère inerte; son spectre RMN comporte le nonet attendu (int. rel. 1:8:28:56:70:56:28:8:1) à –5,21 ppm (dans le $(CD_3)_2CO$); ce résultat est en contraste avec les résultats obtenus avec le $Pd_4(dppm)_4(H)_2^{2+}$ pour lequel la valeur de δ est de +5,15 ppm dans le $(CD_3)_2CO$. Cette différence significative est expliquée par la présence de résidus PdH dans la région de déblindage des groupes dppm-phényles. Les spectres vibrationnels dans la région des basses fréquences sont en accord avec une structure centrosymétrique et on observe un étalement de 144 cm^{-1} dans les spectres Raman à TF; on attribue un pic à la vibration $\nu(Pd_2)$ en se basant sur une comparaison avec des données bien établies de M_2-lié dans $Pd_2(dppm)_2Cl_2$ ($(Pd)_2$ = 149 cm^{-1}). Sur la base du comportement qualitatif des maxima et des largeurs de bandes en fonction de la température, on a attribué les deux bandes d'absorption de basse énergie du spectre UV–vis à une transition de type $d\sigma \rightarrow d\sigma^*$. Des calculs d'OM "EH" permettent de prédire quatre niveaux d'OM frontières bien isolées qui sont définies comme $d\sigma^*(Pd_2)/d\sigma^*(PdH)$ (BV + 1), $d\sigma^*(Pd_2)$ (HO), $d\sigma^*(Pd_2)/d\sigma^*(PdH)$ (HO) et $d\sigma(Pd_2)$ (HO –1) et des règles de sélection simple (u $\leftrightarrow$ g) indiquent qu'il n'y a que deux transitions électroniques de basse énergie qui sont permises, ce qui est en accord avec ce qui a été observé dans les spectres UV–vis. Des modélisations à l'ordinateur montrent la présence de larges cavités au-dessus et en-dessous du plan Pd_4 qui est décrit par des distances H···H non liées dans la cavité interne d'environ 5 à 8 Å.

Mots clés : agrégat, palladium, hydrure, structure, spectroscopie.

Introduction

In 1983, Kirss and Eisenberg (1) reported the preparation of a new material arising from the reaction of $Pd_2(dppm)_2Cl_2$ with sodium borohydride which analysed as C 57.28%, H 4.68%, P 11.57%, Pd 19.84%, and correctly identified the presence of a hydride species. Although the analysis did not add to 100%, the authors proposed the general formula "PddppmH$_x$". In 1998, our group in collaboration with Mugnier's group (2) in Dijon, more appropriately reformulated the description of this purple compound as

 DOI: 10.1139/cjc-79-5/6-552 © 2001 NRC Canada

$Pd_4(dppm)_4(H)_2Cl_2$. This discovery was important because the cluster is a catalyst or precatalyst for various reactions. Interestingly, the title compound can be electrochemically generated from the reduction of $Pd_2(dppm)_2Cl_2$ in the presence of carbon dioxide in protic media (3). In aprotic media, this reaction leads to the known cluster $Pd_3(dppm)_3(CO)^{2+}$, and carbonate (4). The title cluster can be electrochemically reduced to its neutral form, which in turn catalyses the hydrogen evolution, via the generation of the $Pd_4(dppm)_4(H)_3^+$ species (5). This same trihydride species can also electrocatalytically decompose the formate ion into dihydrogen and carbon dioxide, under oxidation conditions. Kirss and Eisenberg (1) also briefly described experiments on *para*-H_2 during the catalytical hydrogenation of phenylacetylene using this same cluster. Our group[2] recently reported a more complete description of this catalytical activity, and some new interesting and important features. First, under mild conditions, styrene is the only product observed at a turnover rate of ~67 h^{-1}, but at 100 atm, ethylbenzene is obtained selectively and quantitatively. Upon increasing the temperature, a similar behavior is seen, but cluster decomposition interfers with the catalyst. More importanly, no hydrogenation of diphenylacetylene occurs at room temperature and 1 atm. This regioselectively (internal vs. external) is tentatively explained by steric hindrance, which is governed by host–guest interactions somewhat similar to that described for the cyclic $M_3(dppm)_3(CO)^{2+}$ species (M = Pd, Pt) (6, 7). However, upon increasing the pressure to ~8 atm, 1,2-diphenylethane is unexpectedly obtained quantitatively. These surprising new results suggest the presence of a dissociative equilibrium between these $Pd_4(dppm)_4(H)_2^{2+}$ and a hypothetical active intermediate formulated as $Pd_2(dppm)_2(H)(solvent)^+$. Unfortunately, the X-ray structure for the title cluster has never been reported, despite the numerous attempts to obtain single crystals of suitable quality (5).

We now wish to report some key spectroscopic features (electronic, vibrational, NMR) in comparison with related clusters, along with some qualitative EHMO calculations and computer modeling. We will address both the electronic and molecular structures of this important species, in more detail, to corroborate and explain new and important experimental results.

Experimental section

Materials

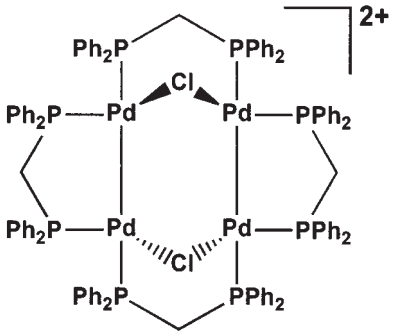
$Pd_2(dppm)_2X_2$ (X = Cl, Br) (8), $Pd_2(dmpm)_2Br_2$ (9), $[Pd_4(dppm)_4(H)_2](BF_4)_2$ (5), and $[Pd_4(dppm)_4(Cl)_2](BF_4)_2$ (10, 11) have been prepared according to literature procedures. The solvents methanol (BDH), ethanol (BDH), tetrahydrofuran, and 2-methyltetrahydrofuran (both from Aldrich Chemical Co.) were purified according to standard procedures (12).

$Pd_4(dmpm)_4(H)_2(Br)_2$

This compound was prepared using the same methodology employed for $Pd_4(dppm)_4(H)_2(Br)_2$ (2), except dmpm (Aldrich) was used instead of dppm. 100 mg (0.18 mmol) of $Pd_2(dmpm)_2Br_2$ was dissolved in 10 mL of methanol in a cold bath maintained in an ice bath (~4°C) and under inert atmosphere. The Br-derivative was selected because previous works on $Pd_4(dppm)_4(H)_2(X)_2$ (X = Cl, Br)(2) indicated better stability. To this solution, 68 mg (1.8 mmol) of $NaBH_4$ was dissolved in 5 mL of degassed ethanol, and added dropwise by canular to the $Pd_2(dmpm)_2Br_2$ solution. Over a period of 1 h, the bright yellow solution turned dark blue, and a deep purple product was obtained from evaporation to dryness. Yield: 85 mg (83%). UV–vis (MeOH): 500 (m), 570 nm (sh). ^{1}H NMR $(CD_3)_2CO$: 2.81 ppm (br, fwhm = 13.5 Hz, 8H, PCH_2P), 1.72 ppm (s, 48 H, CH_3), –5.21 ppm (nonet, rel. int. = 1:8:28:56:70:56:28:8:1, ^2J (H,P) = 13.5 Hz, 2H, Pd-H). ^{31}P NMR $(CD_3)_2CO$: –10.12 (s). FAB mass obs.: 658, 637, 621, 605, 582, 559, 488; calcd. for: $Pd_2(dmpm)_2Br_2(O)$ 660.8, $Pd_2(dmpm)_3(O)$ 637.2, $Pd_2(dmpm)_3$ 621.2, $Pd_3(dmpm)_2(O)$ 607.6, $Pd_2(dmpm)(Br)(O)$ 580.9, $Pd_2(dmpm)_2Br$ 564.9, $Pd_2(dmpm)_2$ 485.1. The compound proved air-sensitive, and unstable in solutions at room temperature and decomposed slowly with time. The presence of oxide fragments in the mass spectra is not surprising when the samples are handled in air.

Apparatus

The UV–vis spectra were acquired on a Hewlett–Packard 8452A diode array spectrophotometer. The emission spectra were obtained on a PTI LS-100 spectrophotometer. The phosphorescence lifetime measurements were performed on the same PTI instrument using the phosphorimeter assembly. The solid state Raman data were acquired using a Bruker IFS 66/CS FT-IR spectrometer coupled with an FRA 106 FT-Raman module and using a Nd:YAG laser (1064 nm excitation) and a Notch filter (cut off ~50 cm^{-1}). The mass spectra were measured on a Krator MS-50 TCTA spectrometer using an Iontech model FAB 11NF saddle field source operating at 70 kV with 2 mA current. The samples were in thiolglycerol matrices. The NMR data were obtained on a Bruker instrument 300 MHz (^{1}H NMR: 300.15 MHz, ^{31}P NMR: 121.497 MHz). The reference was the residual nondeuterated solvent. The chemical shifts are reported with respect to TMS (^{1}H NMR) and H_3PO_4 (^{31}P NMR).



EHMO computations

All the molecular orbital calculations were of the extended Hückel type (13) using a modified version of the Wolfsberg–Helmholz formula (14). The atomic parameters used for C (12), H (12), P (14), and Pd (15, 16) were from the literature. Because of the size of the molecules handled, dppm was replaced by 2 PH_3 groups to simplify the resulting MO diagram. In this case the $P(C_6H_5)_2$ fragments do not contribute to the frontier orbitals and complicate needlessly the MO diagram. This methodology is standard (17). The bond distances and angles are close to those reported in the X-ray structures of the related $Pd_4(dppm)_4(Cl)_2^{2+}$ cluster (10, 11), and are as follows: d (Pd_2) = 2.64 Å, d (Pd···Pd) = 3.60 Å, d (Pd—P_{axial}) = 2.35 Å, and d (Pd—$P_{equa.}$) = 2.23 Å. The d (Pd—H) value was set at 1.80 Å, an average value known for Pd—H species (18).

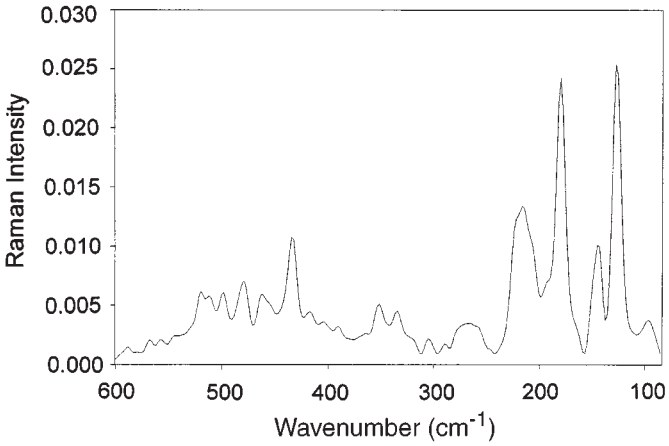
Scheme 2.

Computer modelings



The computer modelings were performed using a commercially available program called PC-Model version 7.0. On occasion, some distances, notably the *d* (Pd_2) and *d* (PdH) values, were fixed to retain the planar structure of the cluster.

Results and discussion

Hydride ^{1}H NMR data

The $Pd_4(dppm)_4(H)_2^{2+}$ cluster exhibits a nonet signal at +5.15 ppm in $(CD_3)_2CO$ of relative intensity 1:8:28:56:70:56:28:8:1 in the ^{1}H NMR spectra (2), which suggests that the cluster has a four-fold symmetry. The T_1 data (0.5 s) (2) confirms the presence of hydrides (19), but the formulation of μ^4-bridging coordinates over and under the Pd_4 plane appears inconsistent as computer models indicate that the H···H separation would be close or within the H_2 bond length (≤0.74 Å) (20), assuming Pd—Pd distances of 2.60–2.70 Å generally encountered for Pd_2 single bonds (21). The highly deshielded hydride ^{1}H NMR signal is also curious, and suggests that the hydrides are located within the deshielding region of the anisotropy cones of the dppm-phenyl substituents. Kirss and Eisenberg (1) noted that the surprisingly deshielded signal was not unprecedented. Indeed Lloyd and Puddephatt (22) reported the hydride resonance for the $[Pt_3(\mu^3\text{-}H(dppm)_3]^+$ cluster at δ 4.16 ppm. To prove this point the dmpm analogue was prepared using the $NaBH_4$ procedure published by Kirss and Eisenberg (1), adapted for dmpm using the $Pd_2(dmpm)_2Br_2$ starting material. This compound exibits the same nonet signal, but appears in the normally expected region for hydride species (at –5.21 ppm in $(CD_3)_2CO$). As with the highly related cluster $Pd_4(dppm)_4(Cl)_2^{2+}$ (Scheme 1) reported by Braunstein et al. (10, 11), the hydrides must be placed more closely to the Pd_4 plane to be within the deshielding region of the phenyl groups. To explain the four-fold symmetry recurrently deduced from the ^{1}H NMR spectra, one should consider a rapid fluxionnality process of the bridged Pd-H-Pd fragments, as shown in Scheme 2. The nonet signal remains even at –70°C.

Fig. 1. Low-frequency FT-Raman (up) and FT-IR (down) spectra of solid $[Pd_4(dppm)_4(H)_2](BF_4)_2$ at room temperature. Experimental conditions: FT-Raman, resolution = 4 cm^{-1}, number of scans = 500.

The ν (Pd_2) data

The IR, Raman and resonance Raman spectra of the Pd_2-bonded dimers $M_2(dppm)_2X_2$ (M = Pd, Pt; X = Cl, Br, $SnCl_3$) and $Pd_2(dppm)_2(SnCl_3)Cl$ have been fully interpretted by Sourisseau and co-workers (23). Using resonance Raman, the authors have securely assigned ν (M_2) which appears between 140 and 150 cm^{-1} in all cases, except for $Pd_2(dppm)_2Br_2$ (ν (Pd_2) = 120 cm^{-1}) (23). $[Pd_4(dppm)_4(H)_2](BF_4)_2$ proved to be extremely laser sensitive in solutions, and resonance Raman spectra could not be acquired in this case. Using FT-Raman, lower laser power, and multi-scan conditions, Raman data for solid samples have been obtained and are shown in Fig. 1 and Table 1. For comparison purposes, both $Pd_2(dppm)_2Cl_2$ and $[Pd_4(dppm)_4(Cl)_2]$-$(BF_4)_2$ are investigated in this work. The comparison of the IR and Raman data, particularly in the low-frequency region associated with skeleton deformations, illustrates clearly the centrosymmetric geometry of the molecules. ν (Pd_2) is easily localized at 144 cm^{-1} as expected, except that the relative intensity is somewhat lower than anticipated. Such behavior is however, not uncommon, and not shocking for 4*d* row elements (24, 25). The structure indicated in Scheme 2 exhibits two independent Pd_2 vibrators (i.e., no coupling between the two should occur), and therefore the symmetric and assymmetric stretches should have about the same frequency. This frequency predicts that the Pd_2 bond length should be in the same order of magnitude as what is generally encountered in the literature for "Pddppm" fragments

[a]The far-IR spectrum of $[Pd_4(dppm)_4(Cl)_2](BF_4)_2$ was not acquired. Code: s (strong), m (medium), w (weak), sh (shoulder), br (broad), ν (stretching), δ (deformation), Γ (torsion), ass (assymmetric), sym (symmetric).

[b]This cluster proved very laser sensitive and the power was reduced to 10 mW at the sample. This peaks are broad, and ν (Pd_2) expected at ~150 cm^{-1} was not observed, presumably hidden under the stronger and broad scattering at 165 cm^{-1} associated with the ν (Pd-P) modes.

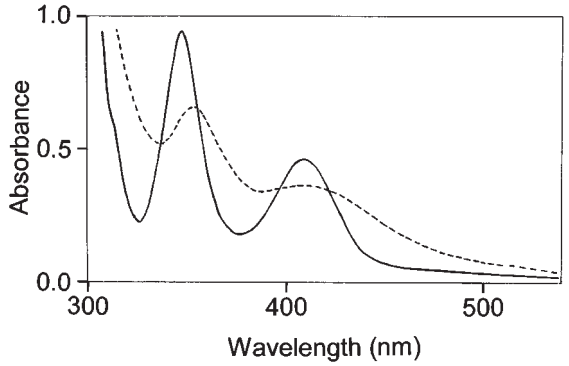

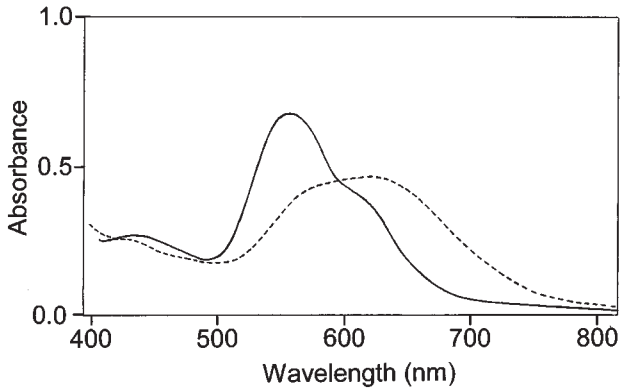

Fig. 3. Uv–vis spectra of $[Pd_4(dppm)_4(H)_2](BF_4)_2$ at 293 K (---) and 77 K (___) in 2-MeTHF.

(2.6 to 2.7 Å) (10, 11, 26, 27). The spectra are provided in the Supporting information.[2]

Numerous attempts to locate ν (Pd-H) in both the IR and Raman spectra were made, but were unsuccessful.

Absorption spectra

Electronic bands associated with $d\sigma \rightarrow d\sigma^*$ electronic transitions for M_2-bonded species generally exhibit low energies, high intensities ($\varepsilon > 10\,000\ M^{-1}\ cm^{-1}$), and are often narrow ($2000 < FWHM < 4000\ cm^{-1}$ at room temperature) (20). The most striking piece of evidence for such a band in the UV–vis spectra is the high sensitivity of the λ_{max} and FWHM, with the temperature. Upon cooling the samples, either in the solid state or in solutions, the $d\sigma \rightarrow d\sigma^*$ bands experience a significant blue shift and decrease in FWHM. This well-known phenomena is due to lower energy "hot bands" of vibronic origin, which disappear upon cooling (28). The presence or absence of such hot bands depends upon the vibrational frequency of the Franck–Condon active modes in the electronic transitions. For $d\sigma \rightarrow d\sigma^*$ transitions, this mode is ν (M_2), which is generally of low frequency, leading to significant hot bands contributions in the $d\sigma \rightarrow d\sigma^*$ spectral envelope. For MLCT or *d*—*d* transitions, higher frequency Franck–Condon active modes are generally present, such as intraligand and M–L stretches. Because of their greater energy gap, the higher vibrational levels are not heavily populated. As a consequence, there is no or little intensity arising from hot bands and upon cooling the samples, the band shape does not change greatly and the hot bands' intensity is weak or nil. For comparison purposes and reference point, the $Pd_2(dppm)_2Cl_2$ UV–vis spectra at 77 and 293K are investigated (Fig. 2). Sourrisseau and co-workers (23) used resonance Raman to demonstrate the $d\sigma \rightarrow d\sigma^*$ assignment of the lowest energy absorption band at ~420 nm. Indeed, there is a ~10 nm blue shift (408 vs. 418 nm) and a notable 2800 cm^{-1} decrease in FWHM (1200 vs. 4000 cm^{-1}, at 77 and 293 K, respectively). Such values are comparable to other Pd_2-bonded species (21). The UV–vis spectra for $[Pd_4(dppm)_4(H)_2](BF_4)_2$ under the same experimental conditions are presented in Fig. 3 in which a drastic change in band shape is depicted for the lowest

[a]Contributions less than 1% per atom are not included.

Fig. 4. MO diagrams of the frontier orbitals for the model compounds $Pd_2L_4^{2+}$, $(Pd_2L_4)_4^{4+}$ (intermolecular distance = 3.60 Å), and $Pd_4L_8H_2^{2+}$ (L = PH_3).

energy absorption bands. The blue shifts of the two features are striking (615 vs. 629 nm, and 557 vs. 583 nm, at 77 and 293 K, respectively), and the decrease in FWHM is easily noted as well. Based on these observations $d\sigma \rightarrow d\sigma^*$ assignments can be made for these bands.

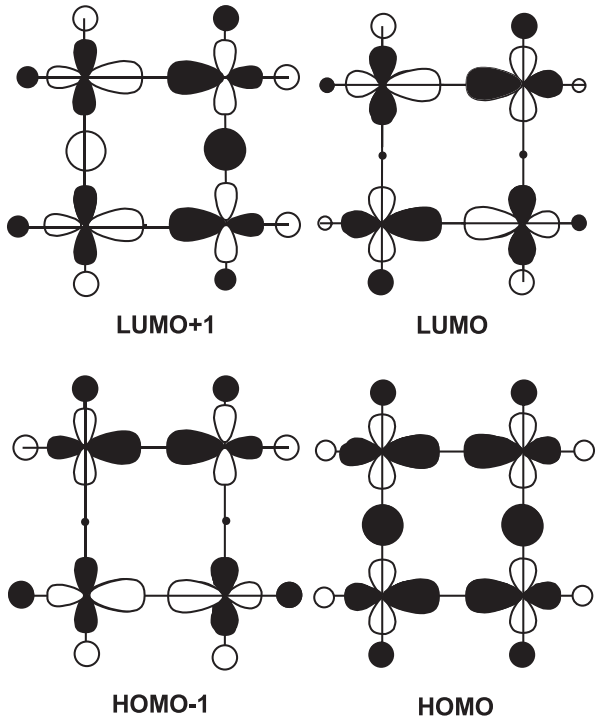
Frontier MOs

Scheme 2 best describes the $Pd_4(dppm)_4(H)_2^{2+}$. The static molecule exhibits two Pd_2 single bonds and two Pd-H-Pd bridges, and is very probably planar. Using d (PdH) = 1.80 Å (an average value found for other Pd—H species) (19) and d (Pd2) = 2.64 Å, the model compound $Pd_4(\mu\text{-}H)_2(PH_3)_8^{2+}$ is designed for EHMO computational purposes.

The analysis indicates the presence of four well-separated frontier MO levels depicted as LUMO +1, LUMO, HOMO, and HOMO –1. They originate from interactions between the HOMO and the LUMO of two double-T shaped $Pd_2L_4^{2+}$ fragments (L = PH_3), as shown in Fig. 4. These precursor MOs exhibit atomic contributions primarily localized within the metal centers (~75%), using the d_{x2-y2}, p_x, and p_y orbitals. Minor contributions from the nonbonding lone pairs of the phosphine ligands (either as p_x or p_y depending upon the molecular axis), are also calculated. The $Pd_2L_4^{2+}$ HOMO and LUMO show the expected bonding $d\sigma$ and antibonding $d\sigma^*$ M_2 interactions, respectively, in agreement with previous studies on similar systems (21, 29).

The side-by-side dimerization of the $Pd_2L_4^{2+}$ fragments provides the intermediate species $Pd_2L_4^{4+}$. These are placed at 3.60 Å from each other allowing the hydrides to occupy the vacant sites half way between the two dimers. At such a distance, practically no or very weak Pd···Pd interactions are anticipated (30). Indeed, the $(Pd_2L_4)_2^{4+}$ MO diagram consists of two degenerated HOMO and LUMO levels (Fig. 4).

The addition to the two hydride centers in this $(Pd_2L_4)_2^{4+}$ frame lead to six MO levels. The bonding PdHPd interactions (+++ and —-) generate two strongly stabilized MOs (not shown in Fig. 4). Similarly, the antibonding PdHPd interactions (+-+ and -+-) produce two destabilized MOs (HOMO and LUMO +1). The remaining two MOs are the HOMO –1 and LUMO and do not involve any atomic contribution from the hydrides (Table 2). Their interactions are essentially nonbonding, and therefore have no effect on either the atomic contributions of three MOs, nor their relative energies (Fig. 4). The overall result is that the lowest electronic transition energy should be smaller in the title compound than that of the dimeric $Pd_2L_4^{2+}$. This observation is readily corroborated by the UV–vis spectra of the $Pd_2(dppm)_2Cl_2$ and $Pd_4(dppm)_4(H)_2^{2+}$ complexes, where the lowest energy absorptions are located at 420 and 600 nm, respectively. In addition, for a $D2h$ local symmetry, the LUMO +1, LUMO, HOMO, HOMO –1 possess the u, g, u and g symmetry, respectively. Selection rules indicate that only two orbitally allowed $u \leftrightarrow g$ transitions are possible (HOMO –1 $\rightarrow$ LUMO +1, and HOMO $\rightarrow$ LUMO), and therefore only two bands should be observed. This is obviously the case (Fig. 3). The atomic contributions are listed in Table 2, and orbital drawings are presented in Fig. 5.



Upon the one- or two-electron reduction of the title cluster, this MO diagram predicts a weakening in the Pd_2 bond, as the bond order decreases formally by a half with no influence to the hydrides. There should be no cluster dissociation due to the dppm ligands and the presence of Pd2 bonding during reductive electrolysis to $Pd_4(dppm)_4(H)_2^0$. This is indeed the case as the reductive waves are found electrochemically reversible (2) and that this neutral species could be characterized from ^{31}P NMR (5). In addition, the related $Pd_4(dppm)_4(S)$ which also contains a Pd_4^{2+} core, has successfully been characterized crystallographically (31) and exhibits a rectangular geometry with longer Pd—Pd bonds (2.675(1) Å) in comparison to that reported for $Pd_4(dppm)_4(Cl)_2^{2+}$ (2.594(2) Å).

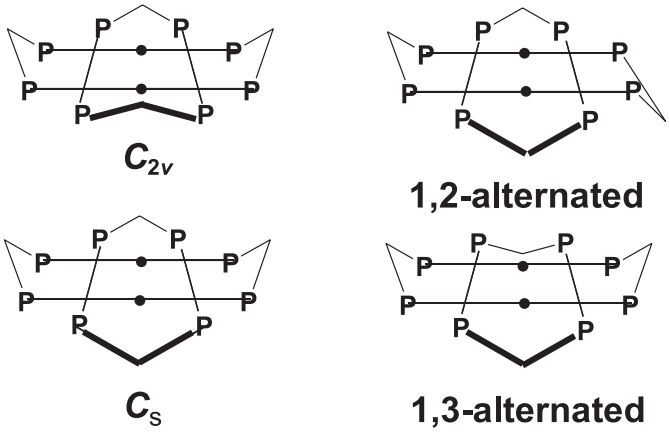

Fig. 5. MO drawings of the LUMO +1, LUMO, HOMO and HOMO –1 for $Pd_4L_8H_2^{2+}$ model compound (L = PH_3). The atomic contributions are listed in Table 2.

A two-electron oxidation of the title cluster should, on one hand, also decrease the Pd—Pd bond order by a half as well, but more importantly it should also remove electrons from an MO exhibiting some significant hydride character. One can also predict that a two-electron oxidation should not lead to cluster dissociations for the same bridging ligand and Pd_2-bonding, but H_2 loss is highly anticipated. The cyclic voltammograms do indeed exhibit an irreversible two-electron wave for $Pd_4(dppm)_4(H)_2^{2+}$ (2), and the FAB analysis of the bulk electrolysis product, provides clear evidence that the Pd_4 cluster is not dissociated, as expected (Supporting information)[2].

Under these frontier orbitals lie many other MO levels which are close in energy to each other (16 MOs within 1 eV). These are the expected $d\pi$, $d\pi^*$, $d\delta$, and $d\delta^*$ orbitals issued from M_{2-} bonding interactions. Below these levels are the two $d\sigma(Pd_2)/d\sigma(PdH)$ and $d\sigma^*(Pd_2)/d\sigma^*(PdH)$ MOs briefly mentionned above. None of these sublevels will be discussed in this work.

Scheme 3.

Molecular modelings

The title cluster may exist under four different conformations depending upon the relative orientation of the dppm-methylene groups (Scheme 3). These are called the C_{2v}, C_s, 1,2-alternated, and 1,3-alternated structures in this work. The $Pd_4(dppm)_4(Cl)_2^{2+}$ (10, 11) and $Pd_4(dppm)_4(S)$ (31) clusters are found in their 1,2- and 1,3-alternated structures, respectively, in the solid state. The ^1H NMR data do not exhibit the presence of a coupling constant ^2J (HCH) as the ^{31}P-irradiated CH_2 signal exhibits a singlet of 1.5 width (2). The results clearly indicate that these protons have the same chemical environment, and must be fluxional as well. This behavior is not uncommon for $Pt_4(dppm)_4$ clusters (32).

All four structures were modelized, and a comparison between the known compound ($Pd_4(dppm)_4(Cl)_2^{2+}$) and its computer modeling was made (Table 3). A positive charge of +1 was added to the Pd atoms, and a fixed distance of 3.60 Å between the non-Pd_2-bonded atoms, was set. After minimization, this fixed distance was removed, and the model was reminimized. The comparison between the X-ray and computed data is reasonable as the bond distances of the skeleton are all within ±0.06. The Pd-Cl-Pd fragment was somewhat poorly modeled (Table 3), as the program does not include the ionic character of the Pd—Cl coordination bond. As a result the computed Pd···Pd, and Pd—Cl distances, and Pd-Cl-Pd angles were smaller than expected. For the $Pd_4(dppm)_4(H)_2^{2+}$ structures, the computed data are very similar in all four conformations and only one typical example is provided in Table 2. The interrelated Pd—H and Pd···Pd distances are shorter than expected, but are not disturbing as the 1.65 Å distance for a bridged palladium

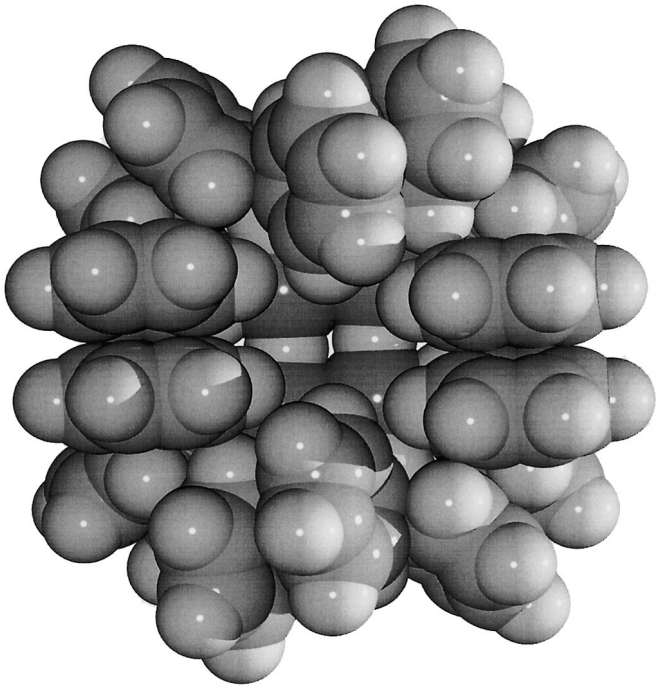
Fig. 6. CPK model of the 1,3-alternated structure. This geometry provides the smallest opening to the Pd_4H_2 center, on one face.



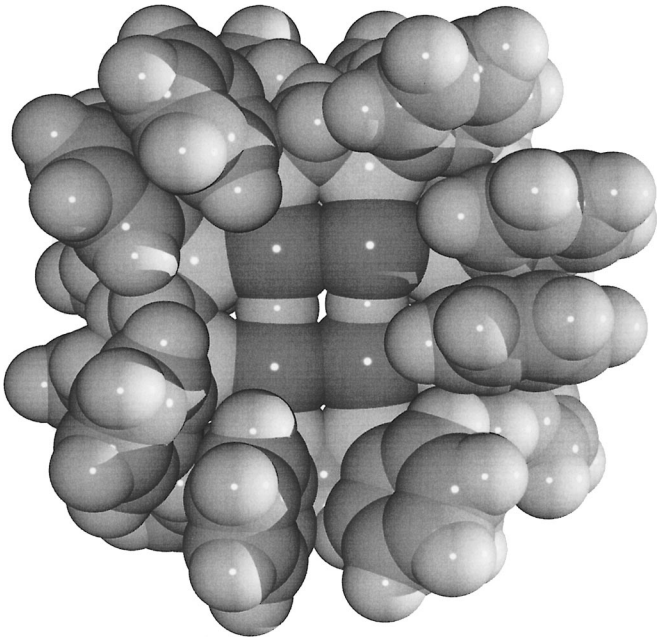


Fig. 7. CPK model of the C_s structure. This geometry provides the largest openings to the Pd_4H_2 center, for both faces.

hydride bond lies at the lower end of what is known in the literature (18).

All four models exhibit two quasiplanar unsaturated Pd_4H_2 faces located well inside picket-fence cavities described by the dppm-phenyl groups, similar to that described for the $Pd_3(dppm)_3(CO)^{2+}$ species (6, 7). Depending on the structure, the cavity openings vary expectedly, where the C_s geometry offers the greatest access to the Pd_4H_2 center, while the 1,3-alternated one, provides the least for one face. Inner-cavity nonbonded H···H distances in the order of 5.5–8.7 Å (typically 6.5–7.5 Å), are computed for the C_s structure. The 1,3-alternated structure exhibits two different cavities: a large and a small one. The inner-cavity nonbonded H···H distances are in the order of 7.6–8.0 Å for the large cavity, while separations of 4.6–5.1 Å are calculated for the smaller one. The two other structures exhibit large cavities somewhat similar in dimensions to that of the C_s model. Typical examples are shown in Figs. 6 and 7 for the two cases discussed. Taking into account the uncertainties of the calculated models, the computation results clearly show the presence of large openings allowing substrates of about 5–6 Å in size to penetrate the cavities, and leaving access for interactions with the Pd_4H_2 faces.

Concluding remarks

This work has compiled spectroscopic results which rationalize the $Pd_4(dppm)_4(H)_2^{2+}$ structure, and based upon that structure simple EHMO analysis has reassuringly confirmed, or supported, many of the experimental findings. The most important feature is undoubtedly the presence of unsaturated sites at the Pd centers, somewhat analoguous to the well known reactive Pd—Pd bonded $Pd_2(dppm)_2Cl_2$ dimer. The presence of cavities above and under the Pd_4 plane is also evident, and explains in part, the selectivity for catalytical hydrogenation of phenylacetylene vs. diphenylacetylene under mild conditions. Further attemps to obtain suitable crystals for X-ray structure determination, and a full investigation on the reactivity and catalytical activity are clearly in order.

Study of the hydroformylation of 2,5-dihydrofuran catalyzed by rhodium diphosphine complexes

Inmaculada del Río, Piet W.N.M. van Leeuwen, and Carmen Claver

Abstract: Rhodium diphosphine systems, including chiral ones, were used as catalyst precursors for the hydroformylation of 2,5-dihydrofuran. The effect of the reaction conditions and the bite angle on the activity and selectivity of the reaction were studied. The solution structures of the species present have been investigated spectroscopically through HP-NMR experiments during the hydroformylation reaction.

Key words: hydroformylation, dihydrofuran, rhodium complexes, diphosphines, HP-NMR.

Résumé : On a utilisé des systèmes diphosphines de rhodium, y compris des systèmes chiraux, comme précurseurs de catalyseurs pour l'hydroformylation du 2,5-dihydrofurane. On a étudié l'effet des conditions de la réaction et l'angle d'accès sur l'activité et la sélectivité de la réaction. On a étudié les structures des espèces présentes en solution à l'aide de la spectroscopie, impliquant des expériences de RMN du phosphore et de l'hydrogène au cours de la réaction d'hydroformylation.

Mots clés : hydroformylation, dihydrofurane, complexes du rhodium, diphosphines, RMN du phosphore et de l'hydrogène.

[Traduit par la Rédaction]

Introduction

Considerable effort has been made to synthesize derivatives of heterocyclic compounds such as tetrahydrofuran and tetrahydropyran (1–3). These derivatives are of interest for the preparation of intermediates for the synthesis of natural products or pharmaceuticals (4).

The great development of the rhodium-catalyzed hydroformylation is shown for the amount of modified systems using monofunctional and chelate phosphorus ligands. Furthermore, the hydroformylation reactions have been applied for different substrates to obtain intermediates in organic syntheses (5–7). The hydroformylation of heterocyclic olefins would provide a potential synthetic tool for preparing derivatives of tetrahydrofuran and tetrahydropyran.

Few systems have proved to be successful in the hydroformylation of internal cyclic alkenes. In most cases, selectivities are only moderate, probably because of the drastic reaction conditions required (8, 9).

In the case of the hydroformylation of dihydrofurans with rhodium/phosphine catalysts, high pressures and temperatures have been used and low selectivities towards tetrahydrofuran-2-carbaldehyde were obtained (10, 11).

In recent years, the use of bulky phosphites in rhodium–phosphorus catalytic systems has been found to be useful in the hydroformylation of cycloalkenes (12–15).

We reported on the hydroformylation of 2,3-dihydrofuran and 2,5-dihydrofuran under mild conditions using rhodium systems with PPh_3 and tris(*o*-*tert*-butylphenyl)phosphite ($P(OC_6H_4$-2-*t*-$Bu)_3$) as catalyst precursors (16, 17). By modifying the reaction conditions we succeeded in selectively introducing a formyl group in the 2- or 3-position of tetrahydrofuran, starting from 2,3- and 2,5-dihydrofuran (16). The influence of the phosphorus co-catalyst, pressure, and temperature on the reaction selectivity has also been studied and a reaction mechanism proposed (17).

Although only the tetrahydrofuran-3-aldehyde would be expected to form in the hydroformylation of 2,5-dihydrofuran, it has been shown (16) that the tetrahydrofuran-2-aldehyde can also form through an isomerization process (Scheme 1). This isomerization is taking place simultaneously with the hydroformylation reaction. When the 2,5-dihydrofuran reacts with the rhodium hydride complex, the 3-alkyl intermediate is formed, which can evolve to the 2,3-dihydrofuran via the β-hydride elimination reaction. This new substrate can evolve to give either of the metal alkyl intermediates, 2-alkyl or 3-alkyl. The 3-alkyl intermediate is thermodynamically favoured according to Ojima et al. (18) because the metal—carbon bond is formed at the carbon with the highest electron density regardless of the phosphorus ligand used. However, because the C-2—metal bond in the 2-alkyl intermediate is more polarized than the C-3—metal bond in the 3-alkyl intermediate, the acyl complex forms more quickly from the 2-alkyl than from the 3-alkyl rhodium intermediate (Scheme 1).

Scheme 1.

Therefore, according to the proposed model, there is a fast preequilibrium between the metal alkyl species, via the β-elimination process. The selectivity is dominated by the rate of formation of the acyl complex, provided that the hydrogen pressure is high enough for the hydrogenolysis of the metal–acyl complex not to be the rate-determining step (Scheme 1).

The asymmetric hydroformylation of heterocyclic olefins has been studied very little and enantiomeric excesses below 10% ee have been published (19, 20). Only a successful enantioselective hydroformylation of oxygen- and nitrogen-containing internal cyclic olefins was reported in which phosphine-phosphite ((*R*,*S*)-BINAPHOS and (*R*,*S*)-BIPHEMPHOS) were used as ligands (21). Enantiomeric excesses between 60–70% were obtained in the hydroformylation of 2,5-dihydrofuran, using these rhodium phosphine-phosphite systems.

If diphosphines are used as ligands in homogeneous catalysis, not only is there the possibility of chiral control but also the possibility of stabilizing a specific geometry that depends on the bite angle of the diphosphine. In recent years a correlation has been observed between the bite angle of the diphosphines and the catalytic activity or selectivity in rhodium-catalyzed hydroformylation (22–25), nickel hydrocyanation (26, 27), palladium-catalyzed allylic alkylation (28), cross coupling reactions of Grignard reagents with organic halides (29, 30), and palladium hydroxycarbonylation (31). In hydroformylation, ligands with wider bite angles tend to give little isomerization of the alkenes at relatively low ligand-to-metal ratios, while retaining a high activity.

Nowadays high-pressure NMR is often used to identify organometallic compounds under high pressure, although the reaction intermediates during rhodium-catalyzed hydroformylation have scarcely been characterized (32–37).

We report here a study of the hydroformylation of 2,5-dihydrofuran using rhodium diphosphine systems as the catalytic precursor. We studied the effect of the bite angle on the activity of the system and tested different chiral diphosphines. We performed in situ HP-NMR experiments during the catalysis to determining the nature of the catalytic species.

Experimental section

General techniques

Rhodium complexes were synthesized using standard Schlenk techniques under a nitrogen atmosphere. The diphosphines DPEphos and Xantphos were synthesized via published methods (23). Solvents were distilled and deoxygenated before use. All other reagents were commercial samples and were used as purchased. Gas chromatography analyses were performed on a Hewlett–Packard 5840A, a gas chromatograph with a flame ionization detector and an Ultra-2 (5% diphenylsilicone:95% dimethylsilicone) (25 m × 0.2 mm Ø) capillary column.

Catalysis

Hydroformylation experiments were carried out in a specially designed autoclave with magnetic stirring and electrical heating. The catalytic solution was contained in a glass vessel. The inside part of the cover was made from Teflon® to protect the solution from direct contact with the stainless steel. These experiments were not performed at constant pressure, but for the amount of substrate used the drop of pressure was never more than 3 bar.

Standard experiment

A solution of the substrate (5 mmol) (previously stirred with alumina for 24 h), the catalyst (0.05 mmol), and the diphosphine were placed in the evacuated autoclave. The gas mixture ($CO–H_2$) was introduced, the system was heated, and the stirring initiated when the thermal equilibrium was reached. Conversion and regioselectivities were determined by GC analysis of the crude samples.

Determination of the enantiomeric excess

The reaction mixture was treated to obtain the corresponding carboxylic acids as has been previously reported (21). The crude acid was dissolved in ether and treated with diazomethane in an Aldrich MNNG diazomethane generation apparatus (38) to afford the methyl ester. The enantiomeric excess was determined by ^{1}H NMR spectroscopy using $Eu(hfc)_3$ as the chiral shift reagent. The absolute configuration of the enantiomers was previously determined by comparing the optical rotation of the corresponding alcohol by reduction of the methyl ester (21).

The in situ HP-NMR experiments

In a typical experiment, the in situ HP-NMR experiments were carried out in a sapphire tube (ϕ = 10 mm). The rhodium complex $[Rh(\mu\text{-}OMe)(COD)]_2$ (0.04 mmol), dppb (0.08 mmol), and substrate (0.05 mmol) were dissolved in toluene-d_8 (2 mL) under nitrogen, and the sapphire tube was

© 2001 NRC Canada

closed. After pressurizing the mixture with H_2–CO, the tube was placed in the NMR spectrometer and the spectra were recorded.

Results and discussion

Catalysis experiments

The catalytic species were prepared in situ by mixing $[Rh(\mu\text{-OMe})(COD)]_2$ with the corresponding diphosphine. After a screening with different diphosphines, the diphosphine dppb (bis(diphenylphosphino)butane) was chosen to study the effect of the parameters and the reaction conditions on the hydroformylation of 2,5-dihydrofuran with Rh–diphosphine systems.

Preliminary experiments were undertaken to establish how the P-P:[Rh] molar ratio affected the hydroformylation of 2,5-dihydrofuran with dppb (Table 1).

It is important to note that when the rhodium precursor was used without the phosphorus ligand, conversion into aldehyde was high but the reaction was not regioselective (Table 1, entry 1). A P-P:[Rh] molar ratio of 1 was required to obtain high conversion and regioselectivity in the tetrahydrofuran-3-aldehyde (Table 1, entry 3). When the P-P:[Rh] ratio was increased the regioselectivity increased to 100% but the conversion decreased (Table1, entries 4, 5). This effect contrasts with previous results in the hydroformylation styrene where an excess of phosphine is required to allow the active species to be formed (39, 40).

The fact that the regioselectivity increased as the P-P:[Rh] molar ratio increased can be explained in terms of ligand dissociation phenomena (Scheme 1). Since an excess of ligand shifts the equilibrium toward coordinatively saturated species, the β-elimination processes are not favoured.

The effects of pressure and temperature were examined using dppb as the ligand (Table 2). At 30 bar, the conversion decreased when the temperature decreased. However, the regioselectivity in tetrahydrofuran-3-carbaldehyde increased (Table 2, entries 6–9). To obtain total regioselectivity in the 3-formyl derivative of the tetrahydrofuran, the temperature had to be 40°C but conversion was only 51% (Table 2, entry 9). There was a slightly increase in conversion when the total pressure of the system was increased (Table 2, entries 9, 10). Finally, conversion and of regioselectivity were 96 and 99%, respectively at 34 bar of CO–H_2 pressure, 50°C of temperature, and substrate:Rh = 100. The substrate:Rh ratio was increased to 200 but the conversion fell to 84% and the regioselectivity to 90:10.

The effect of pressure and temperature on the hydroformylation of this substrate can be explained in terms of the proposed mechanism for the hydroformylation of 2,5-dihydrofuran (Scheme 1). When the temperature was decreased, selectivity for the formation of the tetrahydrofuran-3-aldehyde was higher (Table 2, entries 6–9). Thus, in the range of temperatures explored it seems that only the β-elimination is significantly affected. Therefore by increasing the temperature, a fast preequilibrium is established between the metal alkyl species, via the β-elimination process, and the regioselectivity towards the tetrahydrofuran-3-aldehyde decreases. At constant temperature (Table 2, entries 9, 10) the total pressure increased from 30 to 60 bar, and the rate of formation of the rhodium acyl species increased because of the higher partial pressure of CO. In this situation, CO insertion is much faster than β-elimination. In our case, the temperature was relatively low (40°C) and the β-elimination was not predominant so the regioselectivity was not affected, and there was only a slight increase in conversion into aldehydes.

Once the conditions allowing high conversion and regioselectivity had been selected, the effect of the bite angle of different diphosphines was studied (Table 3).

Diphosphines with bite angles smaller than 90° such as dppe and dppp (Table 3, entries 12, 13) provided low conversions to aldehyde. Systems containing diphosphines with a wider bite angle such as dppb, 1,1′-bis(diphenylphosphino)ferrocene (dppf), and 9,9-dimethyl-4,6-bis(diphenylphosphino)xanthene (Xantphos) provided high conversions (Table 3, entries 14–16). After 6 h of reaction activity was seen to increase with the bite angle (Table 3).

[b]% Tetrahydrofuran-3-carbaldehyde.

Xantphos-type diphosphines have been shown to give excellent regioselectivities in the rhodium-catalyzed hydroformylation of 1-octene (23). In the hydroformylation of 2,5-dihydrofuran under the conditions chosen, it seems that the bite angle has no influence on the regioselectivity (Table 3) as for all ligands tested the selectivity is high. Within the Xantphos series of ligands one also observes an increase of the rate at wider bite angles, which is ascribed to the stabilization of the unsaturated species obtained after CO dissociation (25).

We tested several chiral diphosphines in the asymmetric hydroformylation of 2,5-dihydrofuran (Scheme 2).

Conversions into aldehydes were higher than 90% with regioselectivities as high as 99% in the tetrahydrofuran-3-aldehyde. However, only in the case of BDPP the enantiomeric excess was 14% (Table 4). It has been previously found that [Rh]–BDPP systems provide enantiomeric excesses that are higher than other rhodium diphosphine systems in the hydroformylation of styrene (39, 40).

Rhodium systems with DIOP and related ligands have previously been used in the hydroformylation of 2,5-dihydrofuran at higher pressures and temperatures. The enantiomeric excesses observed were in the same range (3 to 4%) (19, 20).

It has been reported that an excess of chiral ligand may increase the enantiomeric excess (33–37). However, when the same experiments were performed with P-P:Rh = 1.25 conversions into aldehydes were very low. It seems that an excess of ligand quenches the system forming species that are not active in the hydroformylation reaction.

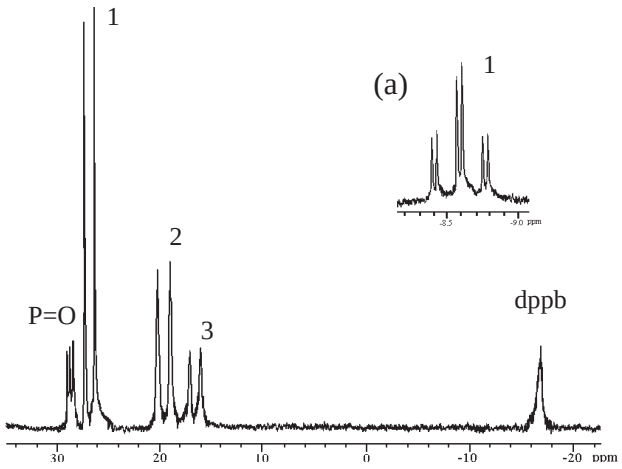
1	26.7	116	–8.8	11	49
2	19.6	147	–9.3	—	—
3	16.7	131	—	—	—
4	13.7	155	—	—	—

[a]Conditions: 0.04 mmol [Rh(μ-OMe)(COD)]$_2$, in 2 mL of toluene-d_8, P = 30 bar CO–H_2, T = 25°C, dppb:Rh = 1.

High-pressure NMR study



HP-NMR experiments were performed with dppb under hydroformylation conditions with and without 2,5-dihydrofuran to observe the species present during the hydroformylation reaction.

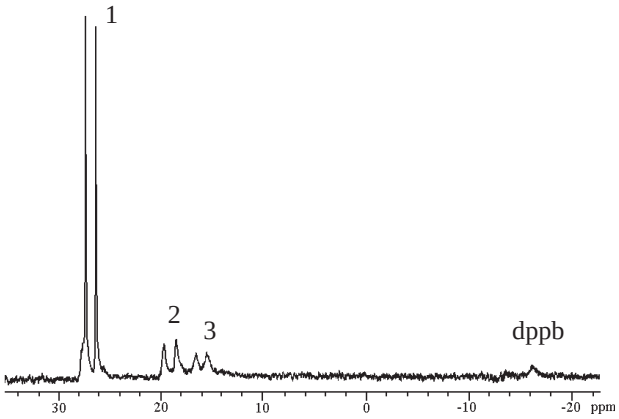
The HP-NMR spectroscopic study was performed at 30 bar H_2–CO, room temperature, and a dppb:Rh ratio of 1 in toluene-d_8, which has been found to provide the same catalytic behaviour as dichloroethane. The ^{31}P NMR spectrum of the solution has four doublets at δ 26.7 ($^{1}J_{Rh-P}$ = 116 Hz), 19.6 ($^{1}J_{Rh-P}$ = 147 Hz), 16.7 ($^{1}J_{Rh-P}$ = 131 Hz), and 13.7 ($^{1}J_{Rh-P}$ = 155 Hz) (Table 5). The ^{1}H NMR of this solution revealed a double triplet in the hydride region at –8.8 ppm ($^{1}J_{Rh-H}$ = 11 Hz, $^{2}J_{P-H}$ = 49 Hz), which is indicative of the coupling of a hydride with the rhodium and with two equivalent phosphorus nuclei. The ^{1}H NMR spectrum also shows a broad signal at –9.3 ppm (Table 5).

We assigned the doublet at 26.7 ppm and the double triplet in the hydride region to the mononuclear rhodium complex [HRh(dppb)(CO)$_2$] (**1**) (Scheme 3) in accordance with data for BDPP from the literature (32). We suggest that this species has trigonal–bipyramidal geometry with the dppb coordinated to the rhodium centre. In the present case, the intermediate phosphorus-hydride coupling constant ($^{2}J_{P-H}$ = 49 Hz) and the averaged coupling constant ($^{1}J_{Rh-P}$ = 115 Hz) suggest that there is an apical–equatorial coordination of the diphosphine with an exchange of the phosphorus atoms (32, 34, 41, 42), although small amounts of the equatorial–equatorial isomer cannot be discounted. The doublet at 19.6 ppm with $^{1}J_{Rh-P}$ = 147 Hz and the broad hydride observed in the ^{1}H NMR were attributed to the mononuclear rhodium complex **2**, which has four equivalent phosphorus

© 2001 NRC Canada

Fig. 1. ^{31}P NMR spectrum during hydroformylation of 2,5-dihydrofuran at room temperature. (*a*) Hydride region of the ^{1}H NMR.

atoms with an average coupling constant (43). The doublet at 16.7 ppm is attributed to a square-planar rhodium complex **3** with two dppb coordinating to the metal (Scheme 3) (44). Finally, the doublet at 13.7 ppm had previously been observed by James et al. (45) and assigned to the carbonyl diphosphine dimer $[Rh(CO)_2dppb]_2$ (**4**) which has a Rh—Rh bond and two CO groups bridging the metal atoms.



When the temperature was increased to 50 and 90°C, the ^{31}P NMR spectrum showed a major signal at 26.7 ppm, which was attributed to complex **1**. Two minor doublets were observed at 19.6 and 16.7 ppm and assigned to compounds **2** and **3**. The hydrides of complexes **1** and **2** were also observed in the ^{1}H NMR. No formation of the dinuclear rhodium complex **4** was observed in the ^{31}P NMR spectrum.

The HP-NMR tube was then depressurized at room temperature and the 2,5-dihydrofuran was added (0.05 mL) under nitrogen. The HP-NMR spectrum at 30 bar $CO–H_2$ and room temperature remained unchanged (Fig. 1). Three doublets at δ 26.7, 19.6, and 16.7 ppm were assigned to complexes **1**, **2**, and **3**, respectively. The resonance of the free dppb was observed at –17 ppm and three singlets were attributed to oxidized phosphine at δ 29 ppm. In the ^{1}H NMR spectra the double triplet was assigned to complex **1** (Fig. 1).

The temperature was increased to 80°C to reach hydroformylation conditions, and the formation of the aldehydes was observed in the ^{1}H NMR during the hydroformylation reaction. Simultaneously the species observed in the ^{31}P NMR were the ones that had previously been observed without the addition of substrate at these temperatures (Fig. 2). Complex **1** was the major compound observed and the other two doublets were assigned to complexes **2** and **3**. Since complexes **2** and **3** are not active under hydroformylation conditions, complex **1** can be considered as one of the species present in the catalytic cycle of the hydroformylation reaction.

It is well known that diphosphines containing at least one alkyl substituent are prone to oxidation. The three signals for oxidized diphosphine observed at room temperature (Fig. 1) indicate the possible presence of rhodium species with partially oxidized monocoordinated diphosphine. This oxidation

Fig. 2. ^{31}P NMR spectrum during hydroformylation of 2,5-dihydrofuran at 80°C.

can be due to the difficulty to avoid the presence of oxygen in these HP-NMR experiments.

At higher P-P:Rh ratios, conversion into aldehydes decreases drastically. In the case of dppb, this can be because in the presence of high P-P:[Rh] ratios inactive species **2** and **3** can be easily formed, as was observed in the HP-NMR experiments.

Conclusions

The effect of pressure and temperature was explained in terms of the described isomerization process via β-elimination during the hydroformylation of 2,5-dihydrofuran.

The rhodium–diphosphine systems provide high activity by using diphosphines with wider bite angles. The regioselectivity depends on the pressure and temperature conditions. High pressures and low temperatures favour the selective formation of the tetrahydrofuran-3-carbaldehyde.

HP-MR experiments performed with and without the substrate during the hydroformylation of 2,5-dihydrofuran show that the rhodium hydride $[HRh(dppb)(CO)_2]$ (**1**) is the predominant species during the hydroformylation.

The addition of an excess of ligand decreased conversion because inactive species **2** and **3** were formed with two coordinated diphosphines in the case of dppb.

An easy-to-use heterogeneous catalyst for the Knoevenagel condensation

Bernd Siebenhaar, Bruno Casagrande, Martin Studer, and Hans-Ulrich Blaser

Abstract: Physical mixtures of alkali and earth alkali metal carbonates and commercially available zeolites were investigated as solid catalysts for the Knoevenagel condensation. Best results for the model reaction between benzaldehyde and ethyl cyanoacetate were obtained for a 1:4 mixture of Na_2CO_3 with 4 Å molecular sieves (MS). The effects of the following parameters were investigated: structure of substrate, type and basicity of metal carbonate and zeolite, and temperature. Between 50 and 90°C chemical yields up to >90% were obtained without continuous removal of water and with reasonable catalyst activities and reaction times. Na_2CO_3 – MS 4 Å proved to be active for the condensation of several aldehydes and ketones with a variety of active methylene components.

Key words: Knoevenagel condensation, solid basic catalysts, zeolite – sodium carbonate mixtures.

Résumé : On a évalué la possibilité d'utiliser des mélanges physiques de carbonates de métaux alcalins ou alcalinoterreux et de zéolites commercialement disponibles comme catalyseurs solides pour des condensations de Knoevenagel. Les meilleurs résultats pour la réaction modèle entre le benzaldéhyde et le cyanoacétate d'éthyle ont été obtenus avec un mélange 4:1 de Na_2CO_3 avec du MS 4 Å. On a étudié les effets des paramètres suivants: structure du substrat; type et basicité du carbonate métallique et du zéolite; température. Entre 50 et 90°C, on a obtenu des rendements chimiques allant jusqu'à plus de 90 % sans nécessité d'enlever l'eau de façon continue, avec des activités catalytiques et des temps de réaction raisonnables. Le mélange Na_2CO_3 – MS 4 Å s'avère actif pour la condensation de plusieurs aldéhydes et cétones avec une grande variété de composés comportant un méthylène actif.

Mots clés : condensation de Knoevenagel, catalyseurs basiques solides, mélanges de zéolite – carbonate de sodium.

[Traduit par la Rédaction]

Introduction

The Knoevenagel condensation is a valuable tool in synthetic chemistry (1, 2). Starting from aldehydes or ketones and activated methylene compounds the synthesis of a wide variety of tri- or tetra-substituted olefins is possible (usually *trans* products are favored). This type of reaction is classically carried out in presence of an organic bases such as pyridine and piperidine and water is removed continuously. While yields are generally good, relatively high temperatures are needed and work up can be cumbersome (Fig. 1).

To overcome some of these problems, solid basic catalysts were developed using zeolites (3, 4), clays (5, 6), alumina (7, 8), as well as amines immobilized on montmorillonite (9), silica (10, 11), and ion exchanged resins (12, 13). Although many of these catalysts indeed have helped to solve some of the problems mentioned above, they are not very practical for the synthetic organic chemist. Most of them are not available commercially, many are difficult to prepare, and even though there are cases where the reaction occurs at room temperature (14), some catalysts are not very active. In this contribution we describe the application of a physical mixture of molecular sieves (MS) and sodium carbonate as very effective solid catalysts for the Knoevenagel condensation of several types of starting materials. The catalysts are easy to prepare starting from commercially available materials, are highly active and selective, and lead to very pure condensation products at relatively low temperatures.

Results and discussion

As already pointed out, zeolites have been used as solid catalysts before (3, 4). However, in order to get reasonable activities, quite elaborate modification of the commercially available materials is usually necessary. On the other hand, alkaline carbonates have also been used with good activity , but due to various side reactions, selectivities were reported to be rather low (1, 15). We thought that a combination of a metal carbonate with a readily available zeolite might eliminate these deficiencies and a catalyst screening was carried out with different carbonates and zeolites using the reaction of benzaldehyde with ethyl cyanoacetoactetate as model reaction. The results were very promising and selected results are presented in Table 1 and Fig. 2. The most important finding was that with several catalyst combinations, conversions up to 99% and selectivities of 98 to 99% of ethyl cyanocinnamate were reached at low temperature within reasonable reaction times. No further Michael addition

SiO_2	K	50	—	70[a]	[a]	2 g SiO_2, 0.45 g K_2CO_3

Note: Reaction conditions: 0.1 mol substrates, 0.55 g metal carbonate.
[a]Reaction time 15 min.

reactions to the product molecules were ever observed. As expected, the strongest correlation was found between catalyst activity (expressed as mmol/g catalyst * h) and the basicity of the two components (see Fig. 3), but the amount of zeolite also plays a role. Similar dependencies have been reported before (3). The overall preferred combination used for further investigations was the easily available MS 4 Å and K_2CO_3 at a weight ratio of ca. 1:4, respectively. This means that the molecular sieve can absorb about 50% of the water formed (pore volume of 0.45 mL g^{-1}) (16), which seems to be enough to allow high conversions under these conditions. Control experiments in absence of molecular sieves gave similar conversions but much lower yields due to side reactions, confirming the documented observations (1, 15) mentioned above.

To determine the scope and limitations of the new catalyst system we investigated the effect of variations in the substrate structure. On the one hand, this is important for the preparative applications of the catalysts, and on the other hand the dependence on the pK_a of the methylene component allows an indirect catalyst characterization (3, 5, 6). The best results for each combination of starting materials are listed in Table 2 and the following trends are noteworthy: (*i*) The scope of the Na_2CO_3 – MS 4 Å combination is quite broad, and a variety of different substrates can be condensed with moderate to very high conversions and low to very high yields. (*ii*) For the reaction with benzaldehyde, the catalyst activity (see Fig. 3), as well as the product yields, are related to the pK_a of the starting methylene compound with a limiting value of ca. 13; this is inferred to correspond to an approximate pK_a value for the solid catalyst. (*iii*) As for the classical version of the Knoevenagel condensation, products are predominantly *trans*, and aldehydes are much more reactive than ketones, which give generally low conversions but acceptable selectivities.

Conclusions

As a result of their ready availability and very good overall catalytic performance, a 1:4 physical mixture of Na_2CO_3 with MS 4 Å is a very useful catalyst for the preparative Knoevenagel condensation for a variety of aldehydes and ketones with different active methylene compounds. The most important parameters affecting the catalytic performance were the structure of starting materials and the catalyst basicity. From the correlation between the catalyst activity and the pK_a of different methylene components, it is concluded that the Na_2CO_3 – MS 4 Å catalyst has a pK_a of approximately 13. Optimal reaction temperatures are between 50 and 90°C, and chemical yields of up to >90% can be obtained without continuous removal of water and with reasonable catalyst activities and reaction times.

Experimental

All organic starting materials were obtained from Fluka (purum) and were used without further purification. The following reference compounds were used: benzylidenemalononitrile (Aldrich), ethyl cyanocinnamate (Aldrich), diethyl benzylidenemalonate (Fluka). The inorganic salts

were p.A. grade and supplied by Fluka or Merck. The zeolites used were obtained from Strem (H-mordenite, zeolite X and Y) and from Merck (MS 4 Å).

Fig. 3. Condensation of benzaldehyde with different methylene compounds using a mixture of Na_2CO_3 and MS 4 Å at 70–90°C; correlation between pK_a and catalyst activity.

General procedure for Knoevenagel condensations

In a 50 mL three-necked flask with reflux condenser the carbonyl compound (0.1 mol) and the methylene compound (0.1 mol) were heated to reaction temperature. A mixture of carbonate (0.45 g) and MS 4 Å (2.0 g) was added and the reaction started immediately. After 0.25–4 h (depending on the nature of the carbonyl and methylene compound) the hot reaction mixture was filtered to remove the catalyst and yields were determined by GLC. In many cases the crude product was obtained with high yield and purity and did not need further purification. Otherwise the crude product was dissolved in hot ethanol and slowly cooled down to room temperature. Crystals of the product appeared and after filtration and drying under vacuum the product was obtained with high yield and purity.

Analytics

The course of reaction was monitored by GLC (OV 101, 40°C, 10°C min^{-1}; 220°C, 5°C min^{-1}). Conversion was calculated on the basis of peak area of the carbonyl compound,

© 2001 NRC Canada

the product peak, and byproduct areas. The selectivity was defined as %desired product/%all products. To verify the GLC results, an ^{1}H NMR analysis of the crude product mixture was carried out directly after filtration on a Bruker ARX 250 instrument in $CDCl_3$ at room temperature.

Procedure for the determination of the pH values of catalyst slurries

To the inorganic compound (0.5g) (zeolite or carbonate–zeolite mixture) was added de-ionized water (10 mL). The flask was shaken from time to time, and after 24 h the pH of the water phase was measured with a glass electrode.

Synthesis and spectroscopic (^{1}H NMR, ESR) characterization of new aryloxy–Mn(II) complexes: steric control over *O*– vs. phenyl–π-coordination of ArO^- ligands (ArO^- = $C_6H_5O^-$, 4-methyl-$C_6H_4O^-$, 3,5-dimethyl-$C_6H_3O^-$, 2,6-di-*tert*-butyl-$C_6H_3O^-$, 2,6-dimethyl-$C_6H_3O^-$) to the "Mn(II)Cp" moiety, and their reactivity with carbon dioxide

M. Aresta, I. Tommasi, C. Dileo, A. Dibenedetto, M. Narracci, J. Ziolkowski, and A. Jezierski

Abstract: The coordination chemistry of phenoxide ligands, such as $C_6H_5O^-$, 4-(CH_3)-$C_6H_4O^-$, 3,5-$(CH_3)_2$-$C_6H_3O^-$, 2,6-(*tert*-butyl)$_2$-$C_6H_3O^-$, 2,6-$(CH_3)_2$-$C_6H_3O^-$, to Mn(II) has been investigated because of the possible implication of Mn(II)–phenoxide complexes as intermediates in the phenylphosphate carboxylase enzyme, a protein which catalyses the selective carboxylation of phenylphosphate to 4-OH-benzoic acid using CO_2. We report here the synthesis and characterization of $[CpMn(\mu\text{-}OAr)(THF)]_2$ (ArO = $C_6H_5O^-$, 4-(CH_3)-$C_6H_4O^-$, 3,5-$(CH_3)_2$-$C_6H_3O^-$, 2,6-$(CH_3)_2$-$C_6H_3O^-$) and $[CpMn(\eta^5\text{-}ArO)]$ (ArO = 2,6-(*tert*-butyl)$_2$-$C_6H_3O^-$ and 2,6-$(CH_3)_2$-$C_6H_3O^-$) complexes, the first examples of mixed-sandwich complexes with Cp and phenate as π-ligands. The latter bear the 2,6-substituted phenoxide π-coordinated to the $[Mn(Cp)]^+$ moiety. The different mode of bonding of the phenoxide ligands to Mn(II), substantiated by ^{1}H NMR and electron spin resonance (ESR) spectroscopy, is controlled by the steric hindrance of substituents at the 2- and 6-position. The reactivity of the π-bonded ligand towards CO_2 is also reported as a quite rare example of nucleophilic attack at the cumulene by the ring-carbon of the phenoxide, which is driven by electron density localization at the 4-position generated upon π-coordination to Mn(II).

Key words: Mn(II)-complexes, phenoxide ligands, ^{1}H NMR spectroscopy, ESR spectroscopy, reaction with carbon dioxide.

Résumé : On a étudié la chimie de coordination des ligands phénolates, tels que $C_6H_5O^-$, 4(CH_3)-$C_6H_4O^-$, 3,5-$(CH_3)_2$-$C_6H_3O^-$, 2,6-(*tert*-butyl)$_2$-$C_6H_3O^-$ et 2,6-$(CH_3)_2$-$C_6H_3O^-$, avec le Mn(II) en raison de l'implication possible des complexes Mn(II)-phénolates comme intermédiaires dans l'enzyme carboxylase du phosphate de phényle, une protéine qui catalyse la carboxylation sélective du phosphate de phényle en 4-HO-C_6H_4-C(O)OH à l'aide de CO_2. On a synthétisé et caractérisé les complexes $[CpMn(\mu\text{-}OAr)(THF)]_2$ (ArO = $C_6H_5O^-$, 4(CH_3)-$C_6H_4O^-$, 3,5-$(CH_3)_2$-$C_6H_3O^-$ et 2,6-$(CH_3)_2$-$C_6H_3O^-$) et $[CpMn(\eta^5\text{-}ArO)]$ (ArO = 2,6-(*tert*-butyl)$_2$-$C_6H_3O^-$ et 2,6-$(CH_3)_2$-$C_6H_3O^-$), le premier exemple d'un complexe sandwiche mixte comportant un Cp et un phénate comme ligands π. Dans le dernier, le phénolate 2,6-disubstitué est fixée par une coordination π à la partie $[Mn(Cp)]^+$. Les différents modes de fixation des ligands phénolates au Mn(II), tels que confirmés par RMN du ^{1}H et par spectroscopie RPE, sont contrôlés par l'encombrement stérique des substituants en positions 2 et 6. On a aussi déterminé la réactivité des ligands fixés d'une façon π vis à vis du CO_2; il s'agit d'un rare exemple d'attaque nucléophile au niveau du cumulène par l'atome de carbone du cycle du phénolate alors que celle-ci est amenée par la localisation de la densité électronique en position 4 sous l'influence d'une coordination π avec le Mn(II).

Mots clés : complexes du Mn(II), ligands phénolates, spectroscopie RMN du ^{1}H, spectroscopie RPE, réaction avec le bioxyde de carbone.

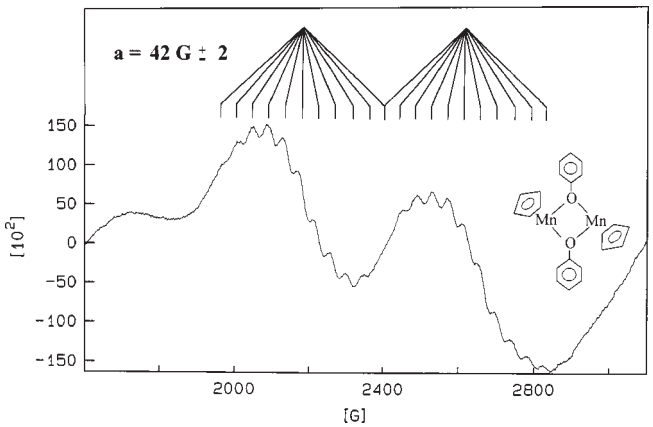
Introduction

Phenol and its derivatives have been shown to act as ligands to transition metal systems (1) through either the *O*-atom or the phenyl π-electron system. Bulky substituents in both 2- and 6-position of the phenyl ring, as well as an unsaturated coordination of the metal, may force π-phenyl bonding to the metal center (2). Such a situation has been structurally documented for diamagnetic Rh(I) complexes (3). Although both diamagnetic and paramagnetic phenoxide-complexes are extensively described in the literature, no examples of phenoxide π-coordination to a paramagnetic center have been reported to date.

Iron(III) complexes bearing phenol or substituted phenols, which are exclusively η^1–*O*-bonded, have been extensively studied as model compounds of catechol oxidase (4). The importance of Mn(II) systems in several biosystems (5) and in material science has prompted investigatations of complexes or clusters bearing the η^1–*O*-bonded phenoxide anion (6). Only a single case of π-bonded phenate to Mn(I) is reported in the literature (7). Despite this interest practically no reports are available in the literature that describe both modes of bonding of phenol and (or) its substituted forms to manganese(II).

Very recently we have extracted a phenol carboxylase enzyme from the anaerobic bacteria *Thauera aromatica* (8). The extracted enzyme was supported onto an organic matrix and shown to catalyse very selectively the conversion of phenylphosphate into 4-OH-benzoic acid in mesophilic conditions (9) with significant turnover frequency (TOF) and turnover number (TON). While information about the structure of the active site is still not available, it is known that the enzymatic activity is Mn(II) dependent (8) and that if the enzyme is incubated with phenol this activity is strongly retained. This finding prompted us to investigate the coordination of phenol and its derivatives to Mn(II) in order to gain information about the relevance of the mode of bonding to reactivity. Therefore, we decided to investigate the reaction of $Mn(Cp)_2$ with C_6H_5OH, 4-(CH_3)-C_6H_4OH, 3,5-$(CH_3)_2$-C_6H_3OH, 2,6-(*tert*-butyl)$_2$-C_6H_3OH, and 2,6-$(CH_3)_2$-C_6H_3OH.



In this paper, we report the synthesis of complexes of the formula [CpMn(ArO)(THF)] (ArO = $C_6H_5O^-$, 4-(CH_3)-$C_6H_4O^-$, 3,5-$(CH_3)_2$-$C_6H_3O^-$, 2,6-(*tert*-butyl)$_2$-$C_6H_3O^-$, and 2,6-$(CH_3)_2$-$C_6H_3O^-$), which are quite rare examples of paramagnetic complexes bearing one Cp and one phenoxide ligand. The different mode of bonding of phenoxide anion to Mn(II) is substantiated by ^{1}H NMR, electron spin resonance (ESR), and IR spectroscopy, and by the reactivity of Mn–phenoxides with CO_2. A unique example of ring carboxylation of phenol derivatives to substituted 4-OH-benzoic acid under ambient conditions, which is fully mimetic of the above mentioned biological carboxylation of phenol, is also reported.

Results and discussion

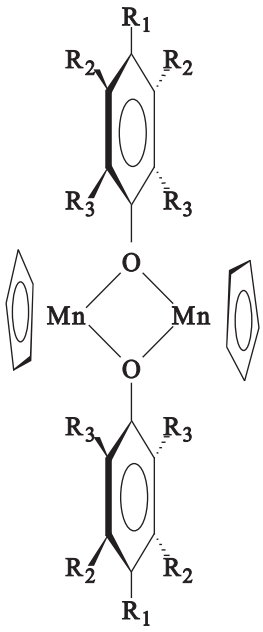
Synthesis and characterization of the [Cp(THF)Mn(μ-*O*-C_6H_5)]$_2$ complex (1)

Cp_2Mn reacts with PhOH (in THF) in a 1:1 molar ratio at room temp to afford a white solid (**1**), which separates quantitatively from the reaction mixture (eq. [1]). This reaction is very clean and can be followed by GC that allowed the reaction stoichiometry to be determined for eq. [1].

Fig. 1. ESR sectrum of [Cp(THF)Mn(μ-*O*-C_6H_5)]$_2$ (in THF, *T*= 77 K, mod amplitude: 2.299 G, frequency: 9.4247866 GHz, power: 2.00e + 01 mW).

[1] $2Cp_2Mn + 2C_6H_5OH \xrightarrow[298K]{THF} [Cp(THF)Mn(\mu\text{-}O\text{-}C_6H_5)]_2 + 2C_5H_6$

GC analysis of the reaction solution after precipitation of the solid, shows that one mol of C_5H_6 per mol of Cp_2Mn is released after addition of phenol. Residual phenol is not found in solution.



Complex **1** is very oxygen- and moisture-sensitive. The white solid is pyrophoric and could not be correctly characterized by conventional elemental analysis techniques. In spite of this, it was possible to ascertain its composition by acidolysis of the compound and quantitative determination, via GC, of the ligands released (see *Experimental*). Analysis of **1**, by this methodology, ascertained that Cp and PhO^- are coordinated to the metal in a 1:1 ratio and that one mol of solvent (THF) per mol of Cp and PhO^- is also present in the metal coordination sphere. Quantitative determination of Mn was achieved by atomic absorption after acidolysis of the compound in aqueous solution and was determined to be present in a 1:1 ratio with the other ligands (PhOH, Cp, THF). When **1** was suspended in pentane under continuous stirring for approximately two days, the analysis of the recovered compound, after acidolysis, still gave a 1:1:1:1 ratio for Cp, THF, phenol, and Mn, respectively, indicating that the THF ligand remains quite strongly bound to the metal when the solid is suspended in non-coordinating solvents.

Complex **1** has been also characterized by spectroscopic techniques (ESR, IR, ^{1}H NMR) and by magnetic measurements. The IR spectrum (Nujol™ suspension) shows bands at 1587 (s, (C=C)) and 1260 (m, (C-O)) cm^{-1}. The ESR spectrum of **1** (Fig. 1), measured at 77 K in frozen THF, shows several not well resolved absorptions in the range 0–5000 G.

The two transitions in the range 1800–2800 G show an hyperfine structure consisting of 11 lines with a hyperfine coupling constant of 42 ± 2 G, in which the intensities follow quite well the 1:2:3:4:5:6:5:4:3:2:1 ratio. The observed value (42 G) is approximately half the value (85–90 G) found for monomeric complexes (10). Preliminary theoreti-

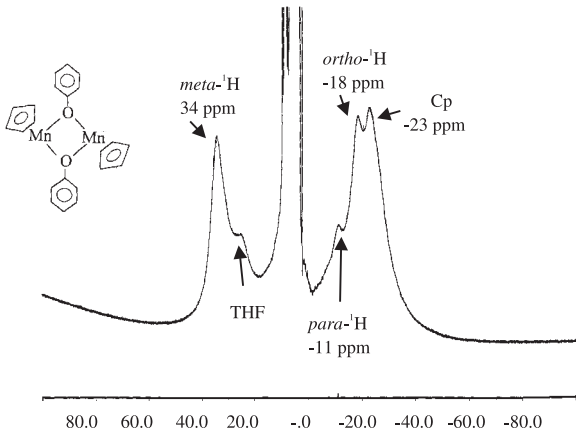
Fig. 2. Proposed structure of dimeric Mn-complexes.

Compound **1** $R_1 = H, R_2 = H, R_3 = H$
Compound **2** $R_1 = CH_3, R_2 = H, R_3 = H$
Compound **3** $R_1 = H, R_2 = CH_3, R_3 = H$
Compound **5** $R_1 = H, R_2 = H, R_3 = CH_3$



cal calculations[2] also support the presence of a dimeric system. The above reported spectral features indicate the presence of two ^{55}Mn centers ($I = 5/2$) with strong electron spin exchange interaction through the bridging *O*-bonded phenoxide ligands. Such features are common to other Mn(II)-complexes bearing *O*-bridging ligands (11). The proposed structure for compound **1** is shown in Fig. 2 and accounts for a 17 electron-system.

Complex **1** has a magnetic moment of $\mu_{eff} = 5.35\ \mu_B$ per Mn atom measured at room temp and $4.54\ \mu_B$ at 80 K. The product $(\chi_m \cdot \theta)$ is almost constant over the entire range of temperature. This value may indicate the presence of high spin antiferromagnetically coupled Mn(II) centers (12).

Unfortunately, it was not possible to obtain the ^{13}C NMR spectrum of **1**. The ^1H NMR spectrum of **1** (Fig. 3), however, shows a very complex pattern with broad signals (half-widths of ca. 4 kHz) at 34, 24, –11, –18, and –23 ppm. The ^1H NMR spectra reported throughout this paper are quite rare examples of proton NMR spectra of Mn(II) complexes, for which very often it is reported that it was not possible to obtain the ^1H NMR spectrum due to sensivity reasons.

The observed pattern in the ^1H NMR spectra strongly indicates the dominance of the spin density polarisation effect through the aromatic ring (5). As the integral and the chemical shifts were not helpful for the assignment of the resonances for the phenoxide, THF, and Cp protons, a systematic study of the ^1H NMR spectra of half-sandwich Mn(II) complexes with *ortho*-, *meta*-, and *para*-substituted phenols ($4\text{-}(CH_3)\text{-}C_6H_4OH$, $3,5\text{-}(CH_3)_2\text{-}C_6H_3OH$, $2,6\text{-}(tert\text{-butyl})_2\text{-}C_6H_3OH$), and $2,6\text{-}(CH_3)_2\text{-}C_6H_3OH$) was undertaken. This study was reputed useful for the following reasons. (*i*) As

Fig. 3. ^1H NMR spectrum of $[Cp(THF)Mn(\mu\text{-}O\text{-}C_6H_5)]_2$ in THF-d_8, $T = 298$ K.

documented in the literature, the ^1H NMR signals of CH_3-protons attached to aromatic systems in paramagnetic complexes are narrower with respect to the signals of protons directly attached to the carbon atoms of the phenyl ring and, thus, they can be more easily recognized in the spectrum. (*ii*) If strong spin density polarisation is taking place through the aromatic ring, the substitution of H with a CH_3 group is expected to significantly shift the proton resonance. This feature is often very helpful in proton assignment.

In fact, a comparative analysis of the variation of the CH_3-proton shifts with the position of the substituents in the ring made possible the assignment of almost all resonances for the complexes with the different ligands listed above; the results are reported in Table 1.

On the basis of the total spectral assignments for the complexes bearing coordinated phenoxide and its substituted forms, we can, for complex **1**, attribute the signal at 34 ppm to phenolate-*meta*-protons and the signals at –18 and –11 ppm to the phenolate *ortho*- and *para*-protons, respectively. The signal at –23 ppm is assigned to the coordinated Cp protons. This value is in agreement with the data reported in the literature for half-sandwich complexes with facial coordination of the Cp ligand (13). The band at 24 ppm is assigned to the coordinated THF molecule. When the spectrum was registered in THF-d_8 this signal was not observed, because of the exchange with the deuterated solvent. By adding small amounts of THF directly to the solution in the NMR tube, the resonance at 24 ppm did finally appear.

Reaction of Cp_2Mn with $4\text{-}CH_3\text{-}C_6H_4OH$

The reaction of Cp_2Mn with $4\text{-}(CH_3)\text{-}C_6H_4OH$ in a 1:1 molar ratio in THF affords compound **2**, which is soluble in THF and can be separated from a very concentrated solution.

$$[2] \quad 2Cp_2Mn + 2(4\text{-}CH_3\text{-}C_6H_4OH) \xrightarrow[298\ K]{THF} [Cp(THF)Mn(\mu\text{-}O\text{-}4\text{-}(CH_3)\text{-}C_6H_4)]_2 + 2C_5H_6$$

[a]Tentative assignment.

In this case, GC analysis of the reaction solution is not helpful for monitoring the amount of Cp released upon the reaction of Cp_2Mn with 4-(CH_3)-C_6H_4OH. In fact, because the product is soluble in the reaction solvent, the GC technique cannot distinguish the free Cp in solution from that generated upon decomposition of the complex in the injector. It was, however, possible to follow the reaction by monitoring the IR spectrum of the reaction solution. In fact, just minutes after the addition of 4-CH_3-(C_6H_4)OH, the band at 3600 cm^{-1} due to the free phenol ν(OH) completely disappears, allowing one to conclude that the added substituted phenol has completely reacted with Mn(II). Complex **2** was analyzed by GC and atomic absorption analysis after acidolysis of the solution (see *Experimental*) and shown to bear Mn in a 1:1 ratio to Cp, THF, and 4-(CH_3)-C_6H_4OH. The analytical data do not change if complex **2** is suspended in pentane (even for 2 days), indicating that THF is always strongly bound to the metal. The ESR spectrum of **2** measured at 77 K, as a frozen THF solution, is very similar to that of **1**, including the presence of the 11 line hyperfine structure for bands in the range 1800–2800 G with hyperfine coupling of 42 ± 2 G. These features suggest a dimeric structure for complex **2**, with μ-*O*-bonded phenoxide ligands. The ^{1}H NMR spectrum of **2** shows only two intense signals at 31 and –26 ppm, assigned to the CH_3-*para*-protons of the phenoxide ligand and the cyclopentadienyl protons, respectively. The shift towards lower fields of the CH_3-*para*-phenoxide protons is in agreement to what is observed for CH_3-*para*-protons of 4-(CH_3)-$C_6H_4O^-$ coordinated to Fe(III)–salen complexes (5), and the observed value of –26 ppm, is in the correct range for Cp protons. The signals of the *ortho*- and *meta*-protons of the phenoxide ligand are probably obscured by the two large signals reported above. The structure for compound **2** is shown in Fig. 2.

Reaction of Cp_2Mn with 3,5-(CH_3)$_2$-C_6H_3OH

The reaction of Cp_2Mn with 3,5-dimethylphenol (1:1 molar ratio) in THF closely matches the reaction reported for **2**. A white powder is isolated from a very concentrated solution, which was analyzed to be [Cp(THF)Mn(μ-*O*-3,5-(CH_3)$_2$-C_6H_3)]$_2$ (**3**).

[3] $$2Cp_2Mn + 2(3,5\text{-}(CH_3)_2\text{-}C_6H_3OH) \xrightarrow[298\ K]{THF} [Cp(THF)Mn(\mu\text{-}O\text{-}3,5(CH_3)_2\text{-}C_6H_3)]_2 + 2C_5H_6$$

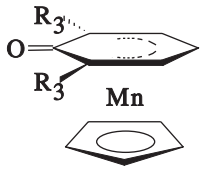
THF is strongly bound as shown by the stability of **3** in pentane even for a long period of time (2 days).

The ESR spectrum of **3** in frozen THF solution at 77 K consists of bands in the range 1800–2800 G, with a hyperfine structure comprised of 11 lines, and hyperfine coupling of 42 ± 2 G. A dimeric structure is also assigned to complex **3** (Fig. 2).

The ^{1}H NMR spectrum of compound **3** in THF-d_8 shows that the CH_3-*meta*-protons (–5 ppm) and the Cp protons (–26 ppm) almost overlap the signals found at –2.5 and –18 ppm, which are assigned to the *para*- and *ortho*-phenoxide protons, respectively, in the dimeric μ-*O*-bonded phenoxide complex (compound **3**, Fig. 2). This is in agreement with a negative spin density delocalization on the CH_3-*meta*-protons of the μ-*O*-coordinated phenoxide anion and confirms the spectral analogies between Mn(II)– and Fe(III)–phenoxide complexes (5). In fact, the pattern of the isotropic shifts of CH_3-*meta*- or *para*-protons in compound **3** or **2,** respectively, is very similar to what observed for (salen)Fe(III) – methyl-substituted-phenoxide complexes, and demonstrates the presence of a strong spin polarization through the aromatic ring. On this basis, a positive spin density delocalization is expected and revealed for protons of CH_3-group *ortho*- or *para*- in the phenoxide ligand, as found also in relevant (salen)Fe(III) complexes.

Reaction of Cp_2Mn with 2,6-(*tert*-butyl)$_2$-C_6H_3OH

When Cp_2Mn is reacted in anhydrous THF with 2,6-(*tert*-butyl)$_2$-C_6H_3OH in a 1:1 molar ratio a white solid product (**4**) is isolated. (eq. [4])



[4] $$Cp_2Mn + 2,6\text{-}(tert\text{-butyl})_2\text{-}C_6H_3OH \xrightarrow[298\ K]{THF} [CpMn(\eta^5\text{–}2,6\text{-}(tert\text{-butyl})_2\text{-}C_6H_3O)] + C_5H_6$$

Again, the reaction cannot be followed by GC analysis because of the solubility of the reaction product, but can be isolated and analyzed by GC after acidolysis. The ligands (Cp, THF, and 2,6-(*tert*-butyl)$_2$-C_6H_3OH) are determined to be in a 1:1:1 reciprocal ratio and each in 1:1 ratio to Mn. If **4** is suspended in pentane for 12 h, analysis of the solid shows that THF has been released almost quantitatively (less than 5% of product still contains coordinated THF, as demonstrated by GC analyses).

The ESR spectrum of **4** measured at 77 K, in a frozen THF solution, shows only one large signal at g = 2.003 G due to a low spin Mn(II) with a six line hyperfine structure. The coupling constant (A = 85 ± 3 G) and the six lines clearly indicate the presence of a monomeric species (10). When 2,6-(*tert*-butyl)$_2$-C_6H_3OH is added in a 1:1 ratio to a

Fig. 4. Proposed structure of monomeric [CpMn(η^5–2,6-(*tert*-butyl)$_2$-C_6H_3O)].

R_3 = *t*-Bu; Compound **4**
R_3 = CH_3; Compound **6**

solution of Cp_2Mn and the ESR spectrum of the reaction mixture is measured at low temperature (80 K) with time, several changes are observed. Immediately after the addition of 2,6-(*tert*-butyl)$_2$-C_6H_3OH, a complex pattern of signals appears, similar to that observed for compounds **1**–**3**. If the solution is allowed to warm to room temp, and after 30 min the spectrum is repeated at low temperature (80 K), one single signal is observed as specified above. These features indicate the initial formation of a high spin species (most probably, the *O*-bonded phenoxide complex is the kinetic product), which in a short time converts into a low spin species. The complex bearing the phenol moiety π-bonded to the metal is the thermodynamic product.

Since, Cp_2Mn and substituted cyclopentadienyl manganocenes show a spin cross-over effect at temperature close to room temp that depends on the matrix that contains the compound, a detailed analysis of the dependence of the high spin ⇄ low spin equilibrium for **4** is in progress.

Complex **4** is soluble enough in benzene at room temp for preparing a 1×10^{-2} M solution, which was not possible for dimeric compounds described above, to allow for molecular mass determination of **4** by cryoscopy (14). The molecular mass of **4** was found to be 355 g mol^{-1} (calculated 325 g mol^{-1}), thus, confirming the monomeric structure of the complex. The ^{1}H NMR of **4** in THF-d_8 shows a signal at 10 ppm for the *tert*-butyl-protons. As the *tert*-butyl-protons are one C—C bond further away from the aromatic ring with respect to the CH_3-protons, the slight shift to lower fields confirms that in this complex the same mechanism of spin density delocalization is operative as described for the other complexes in this paper. The signal due to Cp protons overlaps with that of the solvent and is found around 3 ppm. The ^{1}H NMR spectrum of **4** in C_6D_6 shows the same features of that measured in THF-d_8, demonstrating that both benzene and THF do not coordinate to the metal center and, thus, validates the cryoscopic measurement of the molecular mass made in C_6H_6. The monomeric structure of **4**, as shown by ESR and cryoscopic measurements, can be explained by considering a π-coordination of the aromatic ring to the metal center (Fig. 4).

A single *O*-bonded phenoxide to the CpMn moiety should, in fact, give a coordinatively unsaturated 13e$^-$ species. While in the literature, one example of a dimeric Mn–phenoxide complex (15) which formally accounts for 11e$^-$, is reported, all known momeric cyclopentadienyl complexes account for 17–19e$^-$.

Reaction of Cp_2Mn with 2,6-$(CH_3)_2$-C_6H_3OH

The reaction of Cp_2Mn with 2,6-$(CH_3)_2$-C_6H_3OH in a 1:1 molar ratio in THF affords a mixture of solid products. Analysis shows the ligands and Mn to all be in a 1:1 ratio. However, the suspension of the white solid in pentane for 12 h allows for isolation of a powder showing, after acidolysis, a Cp:THF:phenoxide ratio of 1:0.5:1, indicating that THF is released from the coordination sphere even in non-coordinating solvents. Such finding must be related to a possible change of the coordination mode of the ligand.

Spectroscopic data of the white solid clearly show the presence of two products (**5** and **6**) (see discussion below) formed according to eq. [5]:

$$[5]\quad 3Cp_2Mn + 3(2,6\text{-}(CH_3)_2\text{-}C_6H_3OH) \xrightarrow[298\ K]{THF} [Cp(THF)Mn(\mu\text{-}O\text{-}2,6\text{-}(CH_3)_2\text{-}C_6H_3)]_2 + [CpMn(\eta^5\text{-}2,6\text{-}(CH_3)_2\text{-}C_6H_3O)] + 3C_5H_6$$

Such data can be rationalized considering the features of complexes **1**–**4** described above. The ESR spectrum of the reaction product measured at 77 K in a frozen THF solution shows a quite complex pattern of signals, only in part similar to the ESR spectrum of compound **1**. The most important differences are related to: (*i*) the absence of the hyperfine structures in the bands in the range 1800–2800 G; and (*ii*) the presence of hyperfine splitting in the region of 500 G. In this region a six-line pattern is observed. Such a hyperfine structure suggests the presence of a monomeric species, as found for complex **4**. The analysis of the ^{1}H NMR spectrum (in THF-d_8) shows two broad and partially overlapping signals at 35 and 28 ppm. One very broad strong signal appears at –28 ppm with two less intense signals in the high field region at –18 and –24 ppm. The signals at 28 and –24 ppm are easily recognized as CH_3-protons on the basis of their half-width of ca. 1 kHz. The signal at 28 ppm is assigned to CH_3-protons of a dimeric compound (compound **5**, Fig. 1). The difference in the absolute value of the isotropic shift for the *tert*-butyl-protons of compound **4** compared with the CH_3-protons of compound **6** is due to the absence of the strong hyperconjugation effect operative in the case of the CH_3-protons. While the presence of the CH_3-proton signal at 28 ppm is in agreement with the above discussed pattern, the signal at –24 ppm deviates strongly if a μ-*O*-structure is considered. The latter signal is assigned to a species bearing the *O*-2,6-$(CH_3)_2$-C_6H_3 moiety π-coordinated to the Mn(II) center. The signals at 35 and –18 ppm are assigned to the *meta*- and *para*-protons, respectively, of compound **5**. The Cp ligand in this complex is found at –29 ppm. In **6** the Cp signal is shifted to lower field (2 ppm), and partially overlaps with the solvent signal.

Both the ESR and ^{1}H NMR spectra and the analytical data support the conclusion that two products (**5** and **6**) are formed as shown in eq. [5]. The experimental evidence that half of the coordinated THF is released after suspension of the solid in pentane, indicates that approximately half of the solid is a species in which THF is not strongly bound to the metal and can be removed by the action of a non-coordinating solvent. By simply taking into account electron-counting, compound **5** can reach a 17e$^-$ configuration by being a dimer with a molecule of THF in the coordination

© 2001 NRC Canada

sphere. The monomeric species (**6**), which on the basis of the analytical data is composed of Mn, Cp, and phenoxide in 1:1:1 ratio, does not need THF to reach the $17e^-$ configuration as it bears the π-coordinated phenoxide ligand. In compound **6**, the presence of two methyl groups in the 2- and 6-positions, forces the η^5-coordination of the substituted phenoxide, but the steric hindrance is not such to afford the π-coordination as the only form, as observed in the case of **4**. Attempts to isolate compounds **5** and **6** as pure solids have been done. By crystallization from benzene or toluene it is possible to obtain a compound richer in **6**, but not totally free of **5**. The interconversion (**5** ⇄ **6**) is not operating at room temp or lower.

Reaction of 4 and 6 with CO_2

When complex **4** (or **6**) is exposed to CO_2, 4-OH-3,5-di-*tert*-butyl-benzoic acid (or 4-OH-3,5-dimethyl-benzoic acid) is isolated (yield ca. 10%). When Mn-complexes bearing *O*-bonded phenols are used, ring-carboxylation is not observed. The behaviour of μ-*O*- and π-bonded phenols can be explained by taking into account that the π-coordination forces electron-dislocation in the 4-position to facilitate nucleophilic attack on CO_2. This produces the ring carboxylation, as also observed for similar Rh-complexes (4*a*), and benzene electro-carboxylation, via electron-transfer, to the ring coordinated Cr(0)-system upon electrochemical reduction of the metal center (16). Conversely, the μ-*O*-bonded phenols undergo CO_2 insertion into the Mn—O bond. Subsequent acidolysis produces the semi-carbonate (ROC(O)OH), which promptly decomposes into ROH and CO_2.

Experimental

General procedure

Unless otherwise stated, all reactions and manipulations were conducted under a nitrogen (N_2) atmosphere by using vacuum-line techniques. Samples for ESR studies were prepared using a Brown glove-box under N_2 atmosphere. All solvents were dried as described in the literature (17) and stored under nitrogen. FT-IR spectra were recorded using a Bruker 113V Fourier transform interferometer. Frequencies are accurate to ±1 cm^{-1}. Solid samples were studied as Nujol™ mulls (Nujol™ was previously dried on sodium wires and bubbled with argon). GC analyses were performed with a Dani 3800 gas chromatograph equipped with a FID detector and a packed SE30 column. Quantitative Mn determination was performed with an PerkinElmer 3110 atomic absorption spectrometer equipped with Mn lamp.

NMR spectra were recorded using a AM 500 Bruker spectrometer. ESR spectra were recorded at 9.4247866 GHz (power = 2.00×10^1 mW) on a Bruker ESP300E spectrometer, which has a 100 kHz magnetic field modulation and is equipped with a Bruker NMR gaussmeter (ER 035M) and a Hewlett–Packard microwave frequency counter (HP 5350B).

Acidolysis, GC, and atomic absorption analysis of compounds

All described compounds were pyrophoric and could not be analysed by conventional analytical techniques. The following methodology allowed for compositional analysis: (*i*) 20–30 mg of the compound, carefully weighted out of the contact with air, was put in a Schlenck tube cooled to 0°C with an ice water bath and, under vigorous stirring, was added dry toluene (2 mL) previously saturated with dry, gaseous HCl. A brown solid immediately separated. After deposition of the solid, the liquid fraction was analysed by GC using a temperature program, which allowed for the separation of cyclopentadiene (1.07 min), THF (1.72 min), toluene (7.8 min), and phenols (C_6H_5OH, 10.40 min; 4-CH_3-C_6H_4OH, 12.38 min; 3,5-$(CH_3)_2$-C_6H_3OH, 14.5 min; 2,6-(*tert*-butyl)$_2$-C_6H_3OH, 15.3 min; 2,6-$(CH_3)_2$-C_6H_3OH, 12.87 min). (*ii*) Alternatively, the solid sample was treated with a large (>100 molar ratio) excess of propionic acid. The solution was analysed by the same GC procedure (propionic acid retention time is 5.5 min in the reaction conditions and does not interfere with other species).

For the quantitative determination of Mn, the following procedure was applied: to 15–20 mg of carefully weighted compound was put in a Schlenck tube under N_2 and was added, under vigorous stirring, distilled water (2 mL) and concentrated H_2SO_4 (analytical grade) (1 mL). The light pink solution obtained was quantitatively transferred into a 50 mL analytical flask and diluted with distilled water. The solution was then analysed by atomic absorption spectroscopy.

Synthesis of [Cp(THF)Mn(μ-*O*-C_6H_5)]$_2$ (1)

To a solution of Cp_2Mn (400 mg, 2.1 mmol) in anhydrous THF (30 mL) under a N_2 atmosphere was added, with vigorous stirring, phenol (200 mg, 2.1 mmol) dissolved in THF (10 mL). A white solid immediately precipitated. After stirring for 1 h, the mixture was filtered and the white solid washed with THF (10 mL), pentane (20 mL), and finally dried in vacuo. The compound was isolated in 95% yield. The GC and atomic absorption analysis, carried out after acidolysis of **1** (as previously described), revealed the presence of Cp, THF, phenol, and Mn in a 1:1:1:1 ratio.

Compound **1** was suspended in anhydrous pentane (30 mL) under a N_2 atmosphere with vigorous stirring for 2 days. The solvent was eliminated and the complex washed and dried in vacuo. Analysis, after acidolysis, of the isolated product showed the same composition as reported above. FT-IR (Nujol/KBr) (cm^{-1}): (PhO-ligand) 1587 (vs) (C=C), 1260 (m) (C-O), 753 (s) (γC-H), 693 (s) (γC-H); (cyclopentadienyl ligand) 1025 (vs) (δC-H), 1006 (s) (δC-H), 760 (s) (γC-H). ^{1}H NMR (THF-d_8) δ: 34 (H-*meta*), –11 (H-*para*), –18 (H-*ortho*), –23 (Cp).

Synthesis of [Cp(THF)Mn(μ-*O*-4-(CH_3)-C_6H_4)]$_2$ (2) and [Cp(THF)Mn(μ-*O*-3,5-(CH_3)$_2$-C_6H_3)]$_2$ (3)

(*i*) A solution of 4-CH_3-C_6H_4OH (292 mg, 2.7 mmol) dissolved in anhydrous THF (15 mL) was added to Cp_2Mn (500 mg, 2.7 mmol) in THF (35 mL) (under N_2 atmosphere) with stirring. The resulting mixture was stirred for 4 h and then concentrated in vacuo to 5–7 mL. A light-brown solid separated from the solution and the organic phase was removed. The solid was washed anhydrous THF (2 × 5 mL), anhydrous pentane (10 mL), and dried in vacuo. The compound, isolated as a grey powder in 90% yield, was determined to be [Cp(THF)Mn(μ-*O*-4-(CH_3)-C_6H_4)]$_2$ by GC analysis after acidolysis (as previously described).

Compound **2** was suspended in anhydrous pentane following the same procedure as described for compound **1**. Analysis,

© 2001 NRC Canada

showed that no change had occurred. FT-IR (Nujol/KBr) (cm^{-1}): (4-CH_3-$C_6H_4O^-$ ligand) 1589 (s) (C=C), 1260 (vs) (C-O), 750 (s) (γC-H), 700 (s) (γC-H); (cyclopentadienyl ligand) 1025 (vs) (δC-H), 1006 (s) (δC-H), 770 (s) (γC-H). ^{1}H NMR (THF-d_8) δ: 26 (H-*meta*), 31 (CH_3-*para*), –26 (Cp).

(*ii*) A solution of 3,5-$(CH_3)_2$-C_6H_3OH (278 mg, 2.28 mmol) in anhydrous THF (10 mL) was added, under N_2 flow and vigorous stirring, at room temp to a flask containing Cp_2Mn (420 mg, 2.28 mmol) dissolved in THF (30 mL). The mixture was worked up as described above and [Cp(THF)Mn(μ-*O*-3,5-$(CH_3)_2$-C_6H_3)]$_2$ was isolated in 90% yield.

Compound **3** in anhydrous pentane did not change its composition after two days. FT-IR (Nujol/KBr) (cm^{-1}): (3,5-$(CH_3)_2$-$C_6H_3O^-$ ligand) 1585 (s) (C=C), 1155 (vs) (C-O), 750 (s) (γC-H), 690 (s) (γC-H); (cyclopentadienyl ligand) 1025 (vs) (δ C-H), 1006 (s) (δC-H). ^{1}H NMR (THF-d_8) δ: –5 (CH_3-*meta*), –2 (H-*ortho*), –18 (H-*para*), –26 (Cp).

Synthesis of [CpMn(η^5-2,6-(*tert*-butyl)$_2$-C_6H_3O)] (4)

A solution of Cp_2Mn (300 mg, 1.62 mmol) dissolved in anhydrous THF (20 mL) under a N_2 atmosphere was added to 2,6-(*tert*-butyl)$_2$-C_6H_3OH (334 mg, 1.62 mmol) dissolved in THF (10 mL). The mixture was stirred for 4 h and then worked up as for **2**. A white solid compound was isolated in 90% yield which analysis, after acidolysis, showed Cp, THF, 2,6-(*tert*-butyl)$_2$-C_6H_3OH, and Mn to be in a 1:1:1:1 ratio. Compound **6** was suspended in anhydrous pentane (30 mL) and stirred for 12 h. The solvent was eliminated and the product obtained was dried in vacuo. The analysis after acidolysis of the obtained complex showed Cp, THF, phenoxide, and Mn to be in a 1:0.05:1:1 ratio. FT-IR (Nujol/KBr) (cm^{-1}): (2,6-(*tert*-butyl)$_2$-$C_6H_3O^-$ ligand) 1575 (s) (C=O and C=C), 1181 (vs) (C-O), 840 (m) (γC-H), 610 (m) (γC-H); (cyclopentadienyl ligand) 1000 (s) (δC-H), 775 (s) (γC-H). ^{1}H NMR (THF-d_8) δ: 31 (H-*meta*), –22 (H-*para*), 10 (*t*-Bu-*ortho*), 3 (Cp).

Synthesis of [Cp(THF)Mn(μ-*O*-2,6-$(CH_3)_2$-C_6H_3)]$_2$ (5) and [CpMn(η^5-2,6-$(CH_3)_2$-C_6H_3O)] (6)

To a solution of Cp_2Mn (450 mg, 2.4 mmol) in THF (35 mL) was added 297 mg (2.4 mmol) of 2,6-$(CH_3)_2$-C_6H_3OH dissolved in 10 mL of the same solvent. The mixture was stirred for 4 h and then worked up as for **2**. A white powder was isolated in 90% yield. GC analysis, carried out after acidolysis, revealed the presence of Cp, THF, 2,6-$(CH_3)_2$-C_6H_3OH, and Mn in a 1:1:1:1 ratio. The white solid obtained was suspended in anhydrous pentane (30 mL) under N_2 atmosphere with vigorous stirring for 12 h. The solvent eliminated and the complex dried in vacuo. Analysis, after acidolysis, of the obtained product showed the Cp, THF, phenoxide, and Mn in a 1:0.5:1:1 ratio. FT-IR (Nujol/KBr) (cm^{-1}): (2,6-$(CH_3)_2$-$C_6H_3O^-$ ligand) 1585(s) (C=O and C=C), 1250 (vs) (C-O), 750(s) (γC-H), 690(s) (γ C-H); (cyclopentadienyl ligand) 1025(w) (δC-H), 995(s) (δC-H), 760(s) (γC-H).

Crystallization from benzene–pentane allowed separating almost pure samples of **5** and **6**. ^{1}H NMR (THF-d_8) δ: (compound **5**) 35 (H-*meta*), –18 (H-*para*), 28 (CH_3-*ortho*), –29 (Cp); (compound **6**) 25 (H-*meta*), –18 (H-*para*), –24 (CH_3-*ortho*), 2 (Cp).

Reaction of 4 and 6 with CO_2

Complex **4** (180 mg, 0.5 mmol) (180 mg (0.7 mmol) for **6**) was dissolved in THF and the solution exposed to 0.1 MPa of CO_2 at room temp. After 6 h stirring, the solution was dried in vacuo and the residual solid treated with BF_3–CH_3OH. Water was added to eliminate the excess of BF_3 and the mixture extracted with diethyl ether. The GC analysis of the resulting ether solution showed the formation of the methyl ester of 4-OH-3,5-(*tert*-butyl)-benzoic acid if starting from **4** (or of 4-OH-3,5-$(CH_3)_2$-benzoic acid if starting from complex **6**).

Conclusions

The results reported above demonstrate that bulky substituents at the 2,6-positions of the phenyl ring may force the η^5-coordination to Mn(II) of substituted phenoxides. Coupling ESR and ^{1}H NMR spectroscopy proved to be a useful tool for structure determination in solution. The η^5-coordination of the phenol prompts the phenyl-ring to a nucleophilic attack of CO_2, which produces the ring carboxylation.

$Rh_2Cl_2(CO)_4$ adsorbed and tethered on gold powder: IR spectroscopic characterization and olefin hydrogenation activity

Hanrong Gao and Robert J. Angelici

Abstract: Catalysts were prepared by adsorbing $Rh_2Cl_2(CO)_4$ directly on gold powder or on gold that contained the tethered ligands 2-(diphenylphosphino)ethane-1-thiol (DPET) or methyl 2-mercaptonicotinate (MMNT). Infrared (IR) studies (diffuse reflectance infrared Fourier transform (DRIFT)) of the catalyst Rh–Au prepared by adsorbing $Rh_2Cl_2(CO)_4$ directly on Au indicate that a $Rh^I(CO)_2$ species is present. IR studies of Rh–DPET-Au suggest that tethered *cis*-Rh(DPET)$(CO)_2$Cl is the major species at relatively high $Rh_2Cl_2(CO)_4$ loadings, but *trans*-Rh$(DPET)_2$(CO)Cl is observable at low $Rh_2Cl_2(CO)_4$ loadings. Spectral investigations of the catalyst Rh–MMNT-Au prepared by adsorbing $Rh_2Cl_2(CO)_4$ on MMNT-Au suggest that tethered [*cis*-Rh$(MMNT)_2(CO)_2]^+Cl^-$ and (or) Rh(MMNT)$(CO)_2$Cl are the major species at low $Rh_2Cl_2(CO)_4$ loadings, while a new unidentified species predominates at high $Rh_2Cl_2(CO)_4$ loadings. All three catalysts are active 1-hexene hydrogenation catalysts under the mild conditions of 40°C and 1 atm of H_2; they are much more active than Au powder or $Rh_2Cl_2(CO)_4$ in solution. Of the three catalysts, Rh–Au is the most active with a maximum turnover frequency (TOF) of 800 mol H_2 per mol Rh per min while its turnover (TO) is 29 600 mol H_2 per mol Rh during a 2-hour run. Under the conditions of 1-hexene hydrogenation, the catalysts lose their CO ligands. Thus, it appears that a form of Rh metal on Au is the catalytically active species.

Key words: catalysis, olefin hydrogenation, gold powder, tethered rhodium complexes, infrared studies, adsorption, rhodium complexes.

Résumé : On a préparé les catalyseurs mentionnés dans le titre en faisant absorber du $Rh_2Cl_2(CO)_4$ directement sur de l'or en poudre ou sur de l'or qui contient les ligands fixés 2-(diphénylphosphino)éthane-1-thiol (DPET) ou 2-mercaptonicotinate de méthyle (MMNT). Des études infrarouges («DRIFT») du catalyseur (Rh–Au) préparé par adsorption de $Rh_2Cl_2(CO)_4$ directement sur de l'or indiquent la présence d'une espèce $Rh^I(CO)_2$. Les études IR du Rh–DPET-Au suggèrent que, pour des chargements relativement élevés de $Rh_2Cl_2(CO)_4$, le *cis*-Rh(DPET)$(CO)_2$Cl est l'espèce fixée principale; on peut toutefois observer la formation de *trans*-Rh$(DPET)_2$(CO)Cl avec des chargements faibles de $Rh_2Cl_2(CO)_4$. Des études spectrales du catalyseur (Rh–MMNT-Au) préparé par adsorption de $Rh_2Cl_2(CO)_4$ sur du MMNT-Au suggèrent que, pour des chargements faibles de $Rh_2Cl_2(CO)_4$, le [*cis*-Rh$(MMNT)_2(CO)_2]^+Cl^-$ et (ou) le Rh(MMNT)$(CO)_2$Cl sont les espèces fixées principales; toutefois, pour des chargements élevés de $Rh_2Cl_2(CO)_4$, l'espèce principale est une nouvelle espèce qui n'a pas été identifiée. Les trois catalyseurs sont des catalyseurs actifs pour l'hydrogénation de l'hex-1-ène dans des conditions douces, soit 40°C et 1 atm. de H_2; en solution, ils sont beaucoup plus actifs que l'or en poudre ou le $Rh_2Cl_2(CO)_4$. Des trois catalyseurs, le Rh–Au est le plus actif avec une valeur maximale de "TOF" de 800 mol H_2/mol Rh·min alors que son "TO" est de 29,600 mol H_2/mol Rh pour une expérience de deux heures. Dans les conditions d'hydrogénation de l'hex-1-ène, les catalyseurs perdent leurs ligands CO. Il semble donc que l'espèce catalytiquement active soit une forme métallique de Rh sur de l'or.

Mots clés : catalyseur, hydrogénation d'oléfines, poudre d'or, complexes de rhodium fixés, études infrarouges, complexes de rhodium.

[Traduit par la Rédaction]

Introduction

Heterogenized transition-metal complex catalysts, which offer distinct advantages over their homogeneous counterparts, have been extensively studied in the past few decades (1). Much work in this area has been dedicated to tethering organometallic complexes to insoluble organic polymers or inorganic oxides (2). Little information, however, has been reported on transition-metal complexes tethered to metallic surfaces (3).

The adsorption of organic molecules on solid metal surfaces has been extensively studied in recent years (4). Gold

metal has been investigated extensively because it does not form a surface oxide under atmospheric conditions at room temperature (5, 6). Among the organic compounds (7, 8) that adsorb on gold are thiols (RSH) and disulfides (RSSR), which produce RS groups on the surface (9). For example, terminal alkyl thiols, $X(CH_2)_nSH$ ($n \geq 1$ and X = COOH, $CONH_2$, CN, CH_2NH_2, etc.) adsorb on gold films as $X(CH_2)_nS$ groups (10).

Various transition-metal complexes have been tethered on polymer or inorganic oxide supports using a ligand that coordinates to the transition-metal complex through a donor ligand at one end and to the support through a surface-reactive group at the other end (11). Some of these tethered complexes have been used as catalysts (2). In our previous studies, we formed catalysts by tethering complexes on silica that also contained a supported metal, e.g., Pd (12). These tethered complex on a supported metal (TCSM) catalysts are unusually active for the hydrogenation of arene substrates. In the present report, we describe catalysts that are prepared by tethering a Rh complex directly to the surface of a metal (Au). The tethering ligand is attached to the Au through a thiol group and to the Rh complex by a phosphine or pyridine donor group. It was hoped that an unsaturated organic substrate would be activated by coordination to the Rh complex and hydrogen would be activated by Au to give a catalyst that was more active than either the complex or the Au metal separately. Although gold is generally considered to be a poor catalyst, small-particle gold has recently been reported (13) to be active for alkene hydrogenation. Although there are a few examples (14) of metal complexes tethered on gold, none have been used in catalytic hydrogenation reactions.

In this study, the tethering ligands, methyl 2-mercaptonicotinate (MMNT) or 2-(diphenylphosphino)ethane-1-thiol (DPET), were adsorbed on gold powder to give the ligand-modified gold powders MMNT-Au and DPET-Au (Scheme 1). These modified gold powders were reacted with $Rh_2Cl_2(CO)_4$ to give Au powders with tethered rhodium-carbonyl complexes. We also observed that $Rh_2Cl_2(CO)_4$ could be adsorbed directly onto Au powder without a tether. All three of these rhodium-complex – Au-metal materials were characterized by diffuse reflectance infrared Fourier transform (DRIFT) spectroscopy and evaluated for their catalytic activities in the hydrogenation of 1-hexene under the mild conditions of 40°C and 1 atm of H_2.

Scheme 1.

Experimental

Materials

$Rh_2Cl_2(CO)_4$ and $HAuCl_4{\cdot}xH_2O$ (Au, 49%) were purchased from Strem. The 2-(diphenylphosphino)ethane-1-thiol (DPET) (15) and methyl 2-mercaptonicotinate (MMNT) (16) tethers were prepared by the literature methods. Toluene was dried over CaH_2 before use, while THF, ethanol, and olefin substrates were used directly as commercial products without further purification.

The gold powder was prepared by reducing anhyd $AuCl_3$ (17) with $Li[(C_2H_5)_3BH]$ in THF using the following modified literature procedures (18). Hydrogen tetrachloroaurate ($HAuCl_4{\cdot}3H_2O$) (2.00 g) was heated under reflux with $SOCl_2$ (20 mL) in a 250 mL flask connected to a mineral oil bubbler in order to prevent moisture from contaminating the reaction mixture. Evolution of SO_2 and HCl was observed while the suspension was heated at reflux, and a red precipitate of anhyd gold(III) chloride was visible in the reaction flask. When the evolution of SO_2 and HCl ceased, the remaining $SOCl_2$ was removed by syringe and the red solid was dried in vacuum (1 mm Hg, 1 mm Hg = 133.322 Pa) at 65°C for 4 h. Then THF (100 mL) was added to the reaction flask, and 20 mL (1.0 M) of a THF solution of $Li[B(C_2H_5)_3H]$ was added dropwise with stirring at room temperature. After stirring for 12 h at room temperature, the mixture was filtered and the solid was washed successively with 80 mL aliquots of THF, methanol, THF, pentane, and water, and then dried under vacuum (0.02 mm Hg) at 80°C. The resulting Au powder was cleaned with freshly prepared "piranha" solution (20 mL) composed of a 50:50 mixture of concd H_2SO_4 and 30% aq H_2O_2 (caution: carefully add the H_2SO_4 to the H_2O_2) in a 250 mL beaker with slow stirring. Nitrogen was blown over the mixture to reduce gold loss due to foaming. The mixture was stirred for 10 min, filtered on a coarse frit, washed with water (10 × 50 mL) and ethanol (2 × 20 mL), and dried under a nitrogen stream. The Au powder was then baked in an oven at 120°C overnight. Routine BET surface area measurements were performed on a Micromeritics AccuSorb 2100 E instrument. With Kr as the adsorbate gas at 77 K, the surface area of the resulting Au powder was determined to be 0.96 ± 0.07 m^2 g^{-1}. An XPS analysis (on an AEI 200B spectrometer) of the Au powder showed it to be pure Au(0). Neither Au(I) nor other impurities such as lithium and boron were detected.

Infrared spectroscopy

All FT-IR and DRIFT spectra were recorded on a Nicolet 710 spectrophotometer equipped with a TGS detector in the main compartment and a MCT detector in the auxiliary experimental module (AEM). The AEM housed a Harrick diffuse reflectance accessory. All solution IR spectra were recorded using a NaCl cell (0.50 mm thickness) in the main compartment with the instrument set for 4 cm^{-1} resolution and 128 scans. All DRIFT spectra were recorded with samples in the Harrick microsampling cup using 600 scans and 4 cm^{-1} resolution. The background spectrum used for the DRIFT spectra was clean gold powder. Spectra were routinely baseline and purge corrected. The abscissa of the spectra were recorded and are reported in absorbance units even though the radiation collected is actually reflectance. Kubelka–Munk transformations of the spectra were not possible because of the low intensities of all bands; the bands were eliminated by the transformation. The pseudo-absorbance units used do appear to obey Beer's law, at least approximately.

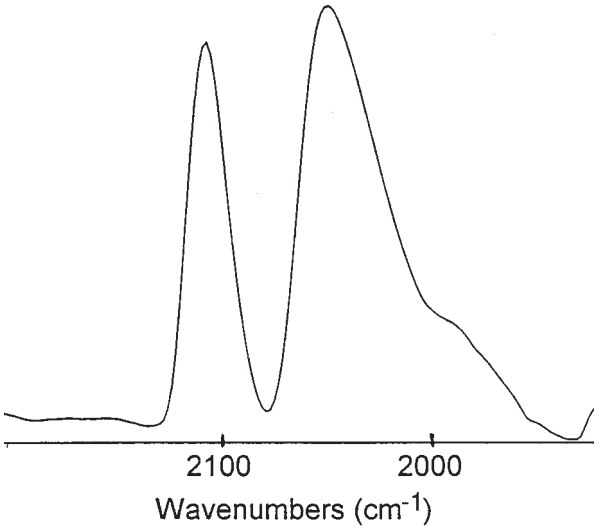
Preparation of ligand-modified Au powders

MMNT-Au

The Au powder (300 mg) was mixed with a THF solution (1 mL) of methyl 2-mercaptonicotinate (MMNT) (3 mM) in a test tube and shaken for 2 min on a Genie Vortex mixer. After allowing the mixture to stand overnight at room temperature, the solution was separated by centrifugation and analyzed for the amount of MMNT by measuring the intensity of the ester ν(C=O) absorption at 1720 cm^{-1} and converting it to MMNT concentration using Beer's law. Subtracting this concentration from the original concentration of the MMNT solution gave the amount of MMNT (0.30 μmol) adsorbed on the 300 mg sample of Au powder. Increasing the original concentration of MMNT in the THF solution did not change the amount of MMNT adsorbed on the Au powder. The Au solid was washed with THF (1 mL) and dried in vacuum at room temperature to give the MMNT-modified Au powder (MMNT-Au). The DRIFT spectrum of MMNT-Au shows a carbonyl band at 1728 cm^{-1}. This 8 cm^{-1} increase from that of free MMNT (1720 cm^{-1}) is similar to that observed in the adsorption of $MeO_2C(CH_2)_nSH$ on a Au film (10*a*, 19).

DPET-Au



The Au powder (300 mg) was mixed with a 1,2-dichloroethane (DCE) solution (1 mL) of 2-(diphenylphosphino)ethane-1-thiol (DPET) (5 mM). After being shaken for 2 min on a Genie Vortex mixer, the mixture was allowed to stand at room temperature overnight. The solution was separated by centrifugation and analyzed for the amount of DPET by measuring the intensity of the C-H stretching absorption at 3073 cm^{-1} and converting it to DPET concentration using Beer's law. Subtracting this concentration from the original concentration of the DPET solution gave the amount (0.63 μmol) of DPET adsorbed on the 300 mg sample of Au powder. Increasing the original concentration of DPET in the DCE solution did not change the amount of DPET adsorbed on the Au powder. The Au solid was washed with DCE (1 mL) and dried in vacuum at room temperature to give the modified Au powder, DPET-Au.

Preparation of $Rh_2Cl_2(CO)_4$-modified Au powder catalysts

$Rh_2Cl_2(CO)_4$ adsorbed on Au powder (Rh–Au)

The Au powder (300 mg) was mixed with a toluene solution (1 mL) of $Rh_2Cl_2(CO)_4$ (0.6 mM), and the mixture was stirred at room temperature overnight under an N_2 atmosphere. The solution was separated by centrifugation and analyzed for the amount of $Rh_2Cl_2(CO)_4$ by measuring the intensity of the ν(CO) band at 2088 cm^{-1} and converting it to $Rh_2Cl_2(CO)_4$ concentration using Beer's law. Subtracting this concentration from the original concentration of the $Rh_2Cl_2(CO)_4$ solution gave the amount of $Rh_2Cl_2(CO)_4$ (0.72 μmol) adsorbed on the 300 mg sample of Au powder. The gold powder was washed with toluene (4 × 1 mL) and dried at room temperature under vacuum to give the catalyst Rh–Au. IR (DRIFT) (cm^{-1}): 2105 (s) (CO), 2045 (s) (CO) (Fig. 1).

Fig. 1. DRIFT spectrum of Rh–Au.

$Rh_2Cl_2(CO)_4$ tethered on MMNT-Au (Rh–MMNT-Au)

A mixture of MMNT-Au (300 mg) and a toluene solution (1 mL) of $Rh_2(CO)_4Cl_2$ of the desired concentration was stirred at room temperature overnight under an N_2 atmosphere. The mixture was centrifuged for 5 min to separate the toluene solution. The separated toluene solution was analyzed by the same IR method that was used in the preparation of the Rh–Au catalyst to determine the amount of $Rh_2Cl_2(CO)_4$ adsorbed on the 300 mg of MMNT-Au powder. The Au solid was washed (4 × 1 mL) with toluene and dried in vacuum at room temperature to give the tethered $Rh_2Cl_2(CO)_4$ catalyst Rh–MMNT-Au. The mol of tethered $Rh_2Cl_2(CO)_4$, and the DRIFT spectra of the Rh–MMNT-Au catalysts prepared by using different concentrations of $Rh_2Cl_2(CO)_4$ solutions are shown in Table 1 and Fig. 2.

$Rh_2Cl_2(CO)_4$ tethered on DPET-Au (Rh–DPET-Au)

Rh–DPET-Au was prepared by the same procedure as that used for the preparation of Rh–MMNT-Au using DPET-Au instead of MMNT-Au. The mol of tethered $Rh_2Cl_2(CO)_4$, and DRIFT spectra of the Rh–DPET-Au catalysts prepared by using different concentrations of $Rh_2Cl_2(CO)_4$ solutions are shown in Table 2 and Fig. 3.

Hydrogenation reactions

The hydrogenation reactions were carried out in a 50 mL three-necked jacketed glass-vessel closed with a self-sealing silicon rubber cap and connected to a vacuum–hydrogen line and a constant pressure (1 atm) gas buret. The temperature of the ethylene glycol circulating through the jacket was maintained at 40.0°C by a constant temperature bath. After the catalyst was added and the atmosphere in the vessel was replaced with hydrogen, solvent was added and the mixture was stirred for about 5 min. Then, the substrate was added and the hydrogen volume uptake was followed by the constant-pressure gas buret. The products were analyzed by gas chromatography on a Varian 3400 GC using a 25 m HP-1 capillary column with a FID detector. When the catalyst was used in several successive 1-hexene hydrogenations, the reaction mixture after the first cycle was filtered, and the solid

Fig. 2. DRIFT spectra of the Rh–MMNT-Au samples containing various amounts of rhodium (μmol) per 300 mg catalyst: (*a*) 0.56; (*b*) 0.56; (*c*) 0.42; (*d*) 0.30; (*e*) 0.15.

catalyst was washed with ethanol, dried under vacuum, and used for the hydrogenation of the second batch of 1-hexene by following the same procedure as that used in the first cycle. After the second cycle, the catalyst was treated as after the first cycle; the isolated catalyst was then used for the third cycle.

Results and discussion

IR characterization of catalysts consisting of $Rh_2Cl_2(CO)_4$ adsorbed or tethered on Au powder

Rh–Au

After stirring a mixture of $Rh_2Cl_2(CO)_4$ and Au powder in toluene at room temperature overnight, IR analyses of both the solution and the Au solid showed that rhodium-carbonyl species were present on the Au powder surface. A DRIFT spectrum (Fig. 1) of the resulting Au powder (Rh–Au) shows two ν(CO) bands at 2105 (s) and 2045 (s) cm^{-1}. The DRIFT spectrum of Rh–Au remained the same after it was washed with toluene several times, which indicates that the rhodium-carbonyl species is strongly adsorbed on the Au surface. Although the ν(CO) bands of Rh–Au are similar to those of $Rh_2Cl_2(CO)_4$ (2115 (w), 2095 (s), and 2045 (s) cm^{-1} in Nujol™ mull (20)), they are also similar to those of $Rh^I(CO)_2$ (approximately 2095 (s) and 2032 (s) cm^{-1}) on SiO_2 or Al_2O_3 (21). Thus, the Rh carbonyl group on Rh–Au appears to be some type of $Rh^I(CO)_2$ species, perhaps associated with Cl^- ligands in some way. The broadness of the 2045 cm^{-1} absorption suggests that other species, perhaps monocarbonyl $Rh^I(CO)$ species, are also present. It is unlikely that any of these species is associated with CO adsorbed on Au as CO does not adsorb on pure Au powder under these conditions.

Rh–MMNT-Au

The tethered $Rh_2Cl_2(CO)_4$ catalyst Rh–MMNT-Au was obtained by stirring a mixture of $Rh_2Cl_2(CO)_4$ and MMNT-Au in toluene at room temperature overnight. Table 1 gives the number of mol of rhodium anchored on 300 mg of MMNT-Au when 1 mL toluene solutions of $Rh_2Cl_2(CO)_4$ in concentrations ranging from 0.075 to 1.0 mM were used. The MMNT:Rh ratio on the Au surface ranges from 0.53 to 2.0. In Table 1, it is evident that the number of mol of rhodium anchored on 300 mg of MMNT-Au increases as the initial concentration of $Rh_2Cl_2(CO)_4$ in the toluene solution increases. When the initial concentration of $Rh_2Cl_2(CO)_4$ in the toluene solution reaches 0.60 mM (Table 1, entry *b*), the amount of Rh anchored on 300 mg of MMNT-Au is 0.56 μmol and does not increase further when the initial concentration of $Rh_2Cl_2(CO)_4$ in the toluene solution is increased to 1.0 mM. To gain some insight into the structure of the rhodium species, DRIFT spectra (Fig. 2) were recorded on the five Rh–MMNT-Au samples. When the amount of Rh on the MMNT-Au is relatively low (Table 1, entries *d* and *e*), the DRIFT spectra (Fig. 2*d* and *e*) show one relatively sharp ν(CO) band at 2120 (s) cm^{-1} and one broad band in the region 2060–2000 cm^{-1}; these absorptions are somewhat similar to those of the Rh–Au catalyst (2105 (s) and 2045 (s) cm^{-1}). Although this suggests that the structure of the major rhodium-carbonyl species formed on these two Rh–MMNT-Au samples might be similar to that on Rh–Au, the two ν(CO) bands at 2120 (s) and 2060–2000 (vs, br) could also be assigned to the square planar $[(cis\text{-}Rh(MMNT)_2(CO)_2]^+Cl^-$; the related $cis\text{-}Rh(py)_2(CO)_2^+$ complex is known to have ν(CO) bands at 2095 (vs) and 2020 (vs) cm^{-1} in $CHCl_3$ solution (22*a*). In pyridine solution under a CO atmosphere, $cis\text{-}Rh(py)_2(CO)_2^+$ has bands at 2100 and 2038 cm^{-1} (22*b*). Still another possible assignment for the species with bands at

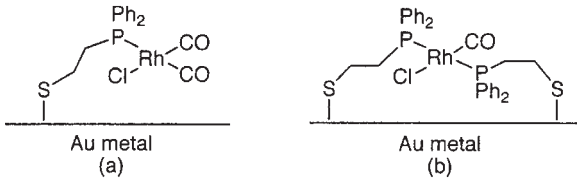
[b]On 300 mg of DPET-Au.
[c]Ratio on Rh–DPET-Au.

2120 (s) and 2060–2000 (vs, br) cm^{-1} is $Rh(MMNT)(CO)_2Cl$; this assignment is based on the ν(CO) spectrum of $Rh(py)(CO)_2Cl$ which has bands at 2090 (s) and 2020 (s) cm^{-1} in $CHCl_3$ solution (23). In fact, there may be an equilibrium (eq. [1]) between $[Rh(MMNT)_2(CO)_2]^+Cl^-$ and $Rh(MMNT)(CO)_2Cl$ as the MMNT:Rh ratio on the surface decreases from 2.0 to 1.0. This equilibrium may account for the change in band shapes between spectra in Fig. 2*d* and *e*. The shoulder on the low-energy side of the 2060–2000 cm^{-1} absorption in Rh–MMNT-Au might be attributed to a $[Rh(MMNT)_3(CO)]^+Cl^-$ species based on a 1993 cm^{-1} band reported for $Rh(py)_3(CO)^+$, which was observed in pyridine (22*b*).

$$[1]\quad [Rh(MMNT)_2(CO)_2]^+Cl^- + 1/2Rh_2Cl_2(CO)_4 \rightleftarrows 2Rh(MMNT)(CO)_2Cl$$

When the initial mol ratio of Rh–MMNT increases to 2, the Rh–MMNT-Au sample (Table 1, entry *d*) has ν(CO) absorptions at 2120 (s), 2095 (m), and 2030 (s) cm^{-1}. As the initial mol ratio of Rh–MMNT increases further, the relative intensity of the ν(CO) band at 2120 cm^{-1} decreases, but the relative intensity of the ν(CO) band at 2095 cm^{-1} increases. The growth of the 2095 cm^{-1} band (Fig. 2*a*–*c*) is in samples in which the MMNT:Rh ratio is less than 1.0, which means that there is less than one MMNT ligand per Rh. A species with only one MMNT per two Rh atoms is $Rh_2Cl_2(CO)_3(MMNT)$; however, the model complex $Rh_2Cl_2(CO)_3(py)$ for this species is unknown. Another possible species for the 2095 cm^{-1} band (and probably a companion band at 2030 cm^{-1}) is one in which Rh is bonded to the sulfur atom tethered to the surface. At this point, it is not possible to make an assignment to these new bands. It was also observed that when the Rh–MMNT-Au sample (Table 1, entry *d*) was stirred in a toluene solution (1 mL) of $Rh_2Cl_2(CO)_4$ (0.60 mM), an additional 0.24 μmol of $Rh_2Cl_2(CO)_4$ was tethered on the Au powder, giving a sample with 0.56 μmol of Rh, which is the same as that of the Rh–MMNT-Au (0.56 μmol) sample used in Table 1, entry *b*. The DRIFT spectra of these two Rh–MMNT-Au samples are similar as well. Because of the broadness of the ν(CO) bands, these assignments are tentative, and it is not possible to exclude the presence of the $Rh^I(CO)_2$ species resulting from the adsorption of $Rh_2Cl_2(CO)_4$ directly on the Au.

Fig. 3. DRIFT spectra of the Rh–DPET-Au samples containing various amounts of rhodium (μmol) per 300 mg catalyst: (*a*) 0.52; (*b*) 0.48; (*c*) 0.45; (*d*) 0.28.



Rh–DPET-Au

The tethered $Rh_2Cl_2(CO)_4$ catalyst Rh–DPET-Au was prepared by reacting DPET-Au with toluene solutions (1 mL) of $Rh_2Cl_2(CO)_4$ ranging in concentration from 3.0 to 0.15 mM to give Au powders (Rh–DPET-Au) containing different amounts of tethered $Rh_2Cl_2(CO)_4$. The data in Table 2 show that the amount of rhodium anchored on 300 mg of DPET-Au increases with an increase in the amount of $Rh_2Cl_2(CO)_4$ in the initial toluene solution; the DPET:Rh ratio on the Au surface increases from 1.2 to 2.3 in the samples. Figure 3 shows that the DRIFT spectra of the four Rh–DPET-Au samples (Table 2) change as the DPET:Rh ratio increases. All of the samples exhibit one relatively sharp ν(CO) band at about 2070 cm^{-1} and one broad ν(CO) band in the region 2025–1975 cm^{-1}, and as expected, the intensities of the bands increase as the loading of $Rh_2Cl_2(CO)_4$ increases. The reaction of $Rh_2Cl_2(CO)_4$ with PPh_3 in solution is known (24) to give a complicated distribution of various mononuclear $[RhCl(CO)_{3-n}(PPh_3)_n]$ and dinuclear $[Rh_2(\mu\text{-}Cl)_2(CO)_{4-m}(PPh_3)_m]$ complexes depending on the ratio of reactants. The complex *cis*-$Rh(PPh_3)(CO)_2Cl$ is assigned to the two ν(CO) absorptions at 2090 (s) and 2005 (s) cm^{-1}, which are in a

Scheme 2.

similar position (2070 and 2025–1975 cm^{-1}) to those (Fig. 3*a*–*c*) of the samples in which the DPET:Rh ratio is near unity (1.2–1.4). In the spectrum (Fig. 3*d*), in which the DPET:Rh ratio is higher (2.3), there is evidence of another band at lower energy, which is similar in position to that reported for *trans*-$Rh(PPh_3)_2(CO)Cl$ (1959 cm^{-1}) (24). Thus, the spectra in Fig. 3 are consistent with *cis*-$Rh(DPET)(CO)_2Cl$ (Scheme 2*a*) as the predominant species at high $Rh_2Cl_2(CO)_4$ loadings where the DPET:Rh ratio is 1.2–1.4, whereas *trans*-$Rh(DPET)_2(CO)Cl$ (Scheme 2*b*) becomes a contributing species when the DPET:Rh ratio is higher (24). It should be noted that none of the four Rh–DPET-Au samples exhibit ν(CO) bands that are characteristic of $Rh^I(CO)_2$ resulting from the adsorption of $Rh_2Cl_2(CO)_4$ directly on Au.

Decarbonylation of $Rh_2Cl_2(CO)_4$ adsorbed and tethered on Au powder

The decarbonylation of the Rh–Au and Rh–DPET-Au catalysts was examined by heating under vacuum. Figure 4 shows changes in the ν(CO) bands for the Rh–Au catalyst as a function of treatment under vacuum (0.1 mm Hg) and at different temperatures (no absorptions in the 1700–1900 cm^{-1} range were observed in the DRIFT spectra of any of the heat-treated samples). After treatment at 50–60°C under vacuum for 1.5 h, the ν(CO) band at 2105 cm^{-1} disappeared but the band at 2045 cm^{-1} remained, although its intensity decreased (Fig. 4*b*); this suggests that the original $Rh^I(CO)_2$ species has been lost and small amounts of perhaps a monocarbonyl $Rh^I(CO)$ species remain. After further treatment at 70–80°C for 1.5 h, the ν(CO) band at 2045 cm^{-1} shifted to about 2025 cm^{-1} and broadened (Fig. 4*c*). After this sample was further treated at 100–110°C for 1.5 h, only a weak, broad band at 2005 cm^{-1} remained (Fig. 4*d*). However, when this final sample was stirred in toluene under a CO atmosphere at room temperature overnight, the DRIFT spectrum (Fig. 4*e*) of the resulting sample was similar to that of the original Rh–Au catalyst, although the ν(CO) bands are at slightly lower values, which suggests the formation of a $Rh^I(CO)_2$ species that is not identical to the original $Rh^I(CO)_2$ species.

After a sample of Rh–DPET-Au containing 0.45 μmol Rh per 300 mg of DPET-Au was heated at 60°C under vacuum (0.1 mm Hg) for 1.5 h, the DRIFT spectrum showed only three weak ν(CO) bands at 2105 (sh), 2076 (s), and 2007 (s, br) cm^{-1} (Fig. 5*b*). When the heat-treated sample was stirred in toluene under a CO atmosphere at room temperature overnight, the sample exhibited ν(CO) bands at 2105 (sh), 2076 (s), and 2007 (s, br) cm^{-1}. The absorptions at 2076 (s) and 2007 (vs, br) indicate that at least some of the original Rh–DPET-Au (2076 (s) and 2008 (s) cm^{-1}) has been regenerated. The ν(CO) band at 2105 (sh) corresponds to a $Rh^I(CO)_2$ species with ν(CO) bands at 2105 and 2045 cm^{-1} (the band at 2045 cm^{-1} would overlap with that of *cis*-$RhCl(CO)_2(DPET)$ (Scheme 2). Thus, it appears that during the heat treatment, some of the rhodium is deposited on the Au surface and is carbonylated to $Rh^I(CO)_2$ under CO.

Hydrogenation of 1-hexene with catalysts consisting of $Rh_2Cl_2(CO)_4$ adsorbed and tethered on Au powder

The Rh–Au, Rh–MMNT-Au, and Rh–DPET-Au materials were used to catalyze the hydrogenation of 1-hexene under the conditions of 40°C and 1 atm of H_2. Table 3 gives hydrogenation activities for the homogeneous $Rh_2Cl_2(CO)_4$ and

$Rh_2Cl_2(CO)_4$-PPh_3 (1:1) catalysts, Au powder, Rh–Au, Rh–DPET-Au (0.48 μmol Rh per 300 mg of DPET-Au), and Rh–MMNT-Au (0.42 μmol Rh per 300 mg of MMNT-Au). From the data in Table 3, it can be seen that the homogeneous rhodium complex catalysts $Rh_2Cl_2(CO)_4$ and $Rh_2Cl_2(CO)_4$-PPh_3 are inactive for 1-hexene hydrogenation under these mild conditions. The Au powder exhibits a very low activity for the hydrogenation. However, Rh–Au, Rh–MMNT-Au, and Rh–DPET-Au are all active for the hydrogenation of 1-hexene under these reaction conditions. Their activities decrease in the following order: Rh–Au > Rh–DPET-Au > Rh–MMNT-Au. The maximum turnover frequency (TOF) and turnover (TO) values for the Rh–Au catalyst are 800 mol H_2 per mol Rh per min and 29600 mol H_2 per mol Rh in 2 h. To the best of our knowledge, this activity is greater than that of any homogeneous or immobilized rhodium complex catalyst for the hydrogenation of 1-hexene reported in the literature (11*f*, 25–27). For the Rh–DPET-Au and Rh–MMNT-Au catalysts, substantial amounts of isomerization to the 2-hexenes also occur.

Table 4 gives the results of hydrogenation of 1-hexene over Rh–MMNT-Au catalysts with different amounts of rhodium, prepared as described in Table 1. It can be seen that the activities (per mol of Rh) of the Rh–MMNT-Au catalysts decrease as the amount of rhodium on the catalyst increases. This decrease may be due to changes in the catalyst precursor complexes present on the surface at different Rh loadings. Table 5 shows the durability of the Rh–Au and Rh–DPET-Au catalysts during repeated use in the hydrogenation of 1-hexene. The activities of both catalysts in the second cycle are lower than in the first cycle. The DRIFT spectra of the used Rh–Au and Rh–DPET-Au catalysts, which were isolated from the reaction mixtures after Rh–Au was used for three cycles and Rh–DPET-Au was used for two cycles, show no ν(CO) absorptions. Even after these two used catalysts were stirred in toluene under CO (1 atm) overnight, no ν(CO) bands were observed in the DRIFT spectra of the samples. Thus, the nature of the Rh species on the Au has changed dramatically during the hydrogenation. It seems unlikely that all of the rhodium has leached from the surface since the catalysts still have appreciable activity after two or three runs even though they exhibit no ν(CO) absorptions.

Conclusions

Although the original goal of this investigation was to probe the hydrogenation activities of catalysts that consist of metal complexes tethered on a gold surface, we find that the most active catalyst is Rh–Au in which $Rh_2Cl_2(CO)_4$ is simply adsorbed on gold. This catalyst is far more active than Au metal or $Rh_2Cl_2(CO)_4$ separately. While the initial rhodium species on the Au appears to be some type of $Rh^I(CO)_2$ unit, it loses CO under 1-hexene hydrogenation conditions (40°C, 1 atm H_2). Thus, the active catalyst is a noncarbonyl Rh species, which also does not adsorb CO. Although the active form of the Rh is not known, it is possibly small Rh metal aggregates. The formation of this active Rh species is

© 2001 NRC Canada

apparently facilitated in some manner by the Au. This is supported by the observation that Rh–Au and Rh–DPET-Au undergo decarbonylation even at 55°C under vacuum (0.1 mm Hg), as described above. In contrast, Bhaduri and Khwaja (26*c*) reported that the catalyst prepared by the reaction of a phosphinated polystyrene with $Rh_2Cl_2(CO)_4$ does not undergo decarbonylation even when heated at 120°C under vacuum (1×10^{-3} mm Hg) for 24 h. It has also been reported that the intensities and positions of the ν(CO) bands for a material prepared by adsorbing $Rh_2Cl_2(CO)_4$ from toluene solution onto Al_2O_3 do not change when it is heated at 80°C under 1 atm of H_2 for 1 h (2l). This suggests that the Au powder facilitates the decarbonylation of the rhodium carbonyl complex adsorbed or tethered on it. Another possible role played by the Au powder support is the creation of an unusually active form of Rh for 1-hexene hydrogenation.

While less active, the tethered Rh complex catalysts, Rh–DPET-Au and Rh–MMNT-Au, also catalyze the hydrogenation of 1-hexene. Under the hydrogenation conditions, the Rh complexes that are present in the unused catalysts lose their CO ligands to generate a noncarbonyl form of Rh, perhaps the same as that formed from Rh–Au, which is the catalytically active species. The activities of the Rh–Au and Rh–DPET-Au catalysts decrease upon repeated use. This decrease may be due to migration of the Rh(0) into the Au to form an inactive alloy.

These studies demonstrate that it is possible to form active hydrogenation catalysts by adsorbing Rh complexes on Au metal. Although Au is too expensive to be used as a catalyst support for most studies, the results do suggest that the adsorption of metal complexes on less expensive metal supports may lead to unusually active hydrogenation catalysts.

Palladium-catalyzed alternating copolymerization of carbon monoxide with olefins bearing carbamate and amide functionalities

Christophe Moineau, Giuseppe Mele, and Howard Alper

Abstract: The copolymerization of carbon monoxide with different olefins bearing carbamate and amide functionalities was effected using $[Pd(CH_3CN)_4](BF_4)_2$ as the catalyst and (*R*,*R*)-Me-DUPHOS (2:1 (v/v) $MeNO_2$–MeOH or CH_2Cl_2 as the solvent). The products constitute a new class of functionalized copolymers, and were found to be optically active with a mixture of 1,4-ketone and spiroketal repeating units in the backbone. The influence of different parameters on the copolymerization of methyl *N*-(3-butenyl)carbamate with carbon monoxide was examined.

Key words: copolymerization, carbon monoxide, olefins bearing carbamate and amide functionalities.

Résumé : On a réalisé la copolymérisation du monoxyde de carbone avec diverses oléfines portant des fonctions carbamate et amide en utilisant du $[Pd(CH_3CN)_4](BF_4)_2$ en présence de (*R*,*R*)-Me-DUPHOS comme catalyseur et du CH_2Cl_2 ou un mélange 2:1 (v/v) de $MeNO_2$–MeOH comme solvant. Les produits constituent une nouvelle classe de copolymères fonctionnalisés et on a observé qu'ils sont optiquement actifs avec un squelette comportant un mélange de motifs 1,4-dicétone et spirocétal. On a évalué l'influence de divers paramètres sur la copolymérisation du *N*-(but-3-ényl)carbamate de méthyle avec le monoxyde de carbone.

Mots clés : copolymérisation, monoxyde de carbone, oléfines portant des fonctions carbamate et amide.

Introduction

Since 1982, there has been great interest in the development of the metal-catalyzed alternating copolymerization reaction of alkenes with carbon monoxide (1). The reasons for this interest are the low monomer costs, the potential photodegradability of the copolymers (2), and the possibility to modify them (3). Another important area is the use of functional alkenes as monomers. This is an interesting strategy to obtain highly functionalized copolymers which can find a large number of applications.

The advantage of the palladium complex as a catalyst is the greater stability when compared with early transition-metal complexes which allow the polymerization of a limited number of polar monomers due to their sensitivity to electron-donating functional groups (4). However, few papers describe the alternating copolymerization of functional alkenes with carbon monoxide using a palladium catalyst. In these studies (5), olefins bearing alcohol and acid functionalities were used but it had been observed that the copolymerization stopped or became very slow when the functional group and the C=C bond were proximate to each other. This was due to a strong coordination between the functional group and the metal. This problem was recently addressed by using a bulky chelate phosphine such as Me-DUPHOS (Fig. 1), instead of a classic bidentate phosphine, which allowed the formation of chiral functionalized copolymers with isotactic sequences (6).

To our knowledge there have been no studies concerning the copolymerization of alkenes bearing amide and carbamate functionalities with carbon monoxide catalyzed by metal complexes. Herein we present some interesting results for the copolymerization, with novel features of the reaction such as an excess of ligands, or reactions without solvent.

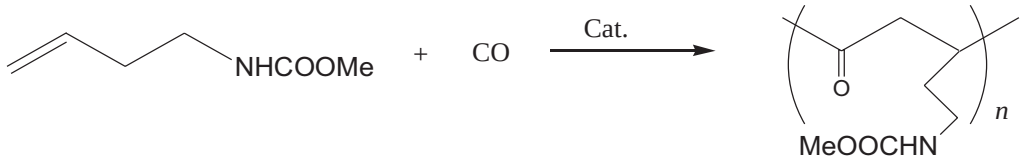
Results and discussion



Copolymerization of methyl *N*-(3-butenyl)carbamate with carbon monoxide

The copolymerization with carbon monoxide of methyl *N*-(3-butenyl)carbamate was investigated under various conditions. The catalyst used for the reaction was the dicationic complex $[Pd(CH_3CN)_4](BF_4)_2$ with added bidentate phosphine ((*R*,*R*)-Me-DUPHOS). Other synthetic procedures and different kinds of palladium catalysts were not effective in giving the desired copolymer.

We first examined the reaction using a 2:1 (v/v) $MeNO_2$–MeOH solvent mixture (Table 1). In all cases the formed

[a]Reaction conditions: olefin 10 mmol, catalyst Pd/L = $[Pd(CH_3CN)_4](BF_4)_2$/(*R*,*R*)-Me-DUPHOS, solvent CH_3NO_2–CH_3OH 2:1 (v/v) 3 mL, time 48 h.
[b]The molecular weight of the polymers were measured by GPC using Styragel HT columns (HPLC-grade THF as eluant) and based on calibration with polystyrene standards.

Fig. 1. 1,2-Bis((2*R*,5*R*)-2,5-dimethylphospholano)benzene((*R*,*R*)-Me-DUPHOS).

copolymer was found to be a mixture of 1,4-ketone and spiroketal repeating units in the polymer backbone. The structure of the polymer was characterized by IR and NMR spectroscopy and was supported by elemental analysis results.

The ^{13}C NMR spectrum (in $CDCl_3$) of the product showed resonances at 212.4 ppm due to the carbonyl group and at 114.2 ppm due to the ketal group. We also observed two resonances at 157.1 and 154.2 ppm due to carbamate groups branched on the 1,4-polyketone and on the polyketal backbone. The methylene and methine carbons in the polymer displayed resonances at 46.1, 40.1, and 29.1 ppm, and the signal for the methyl carbon occurred at 51.8 ppm. The ^1H NMR spectrum in $CDCl_3$ displayed a signal at 3.58 ppm due to the methyl group and broad resonances at 6.50–4.50 ppm due to the NH unit, and at 3.11 and 2.75–1.05 ppm for the $CH_2CHCH_2CH_2$ units.

These polymers showed some optical rotation (Table 1). The magnitude of the optical rotation may depend on the ratio of ketone to spiroketal units present in the backbone. These copolymers appeared as amorphous white solids soluble in $CHCl_3$, THF, CH_3OH, CH_2Cl_2, and CH_3COCH_3, and insoluble in diethyl ether, hexane, and toluene. The molecular weight and the yield of the copolymer are significantly increased if an excess of (*R*,*R*)-Me-DUPHOS is used ([Pd]/L = 1/1.5) relative to palladium. For example, at 40°C and under 1000 psi CO-pressure, the use of 0.4% of the catalytic system [Pd]/Me-DUPHOS = 1/1.5 (entry 4) gave a copolymer with a molecular weight of 13 200 g mol^{-1} in 78% yield, compared with a molecular weight of 9700 g mol^{-1} and a yield of 66% for 1/1 [Pd]/Me-DUPHOS. The same enhancement can be seen with entries 3, 7 and 5, 8. To our knowledge, this is the first obsrvation of the increase in molecular weight resulting from the addition of more phosphine. Note, however, that no copolymer forms when too much (*R*,*R*)-Me-DUPHOS is used (entry 1). We assume, in the latter case, that the result is a consequence of bis-ligand complex formation.

Increasing the amount of catalyst afforded a slight increase in molecular weight (entries 2–5 and 8, 9). The temperature has an important effect on the molecular weight as well as on the yield (entries 2, 4). At 40°C the molecular weight is approximately double that at 25°C (13 200 g mol^{-1} compared to 6800 g mol^{-1}). However, higher temperatures have a detrimental effect on the reaction: at 80°C (entry 6) the molecular weight was only 3900 g mol^{-1} with a polymer yield of 40%. The influence of the CO-pressure was also analyzed (entries 8, 10). At lower pressure (800 psi instead of 1000 psi), a lower molecular weight of copolymer was obtained (5500 g mol^{-1} instead of 9200 g mol^{-1}).

Table 2 shows the influence of dilution on the reaction. Reaction at higher dilution appreciably lowers the yield (to 5%), and the molecular weight decreases significantly (3800 g mol^{-1}). The copolymerization reaction was also run neat and in CH_2Cl_2 (Table 3). A polar olefin such as methyl *N*-(3 butenyl)carbamate is capable of solubilizing the palladium catalyst. At 40°C and 1000 psi of CO, the copolymer was obtained in 30% yield with a molecular weight of 60 500 g mol^{-1} (entry 1). Higher temperatures (80°C, entry 2) gave essentially the same yield and also had a significant effect in lowering the molecular weight. The limitation of this reaction may be the solubility of the polymer in the

[c]T_m = melting temperature.

monomer. One can also use CH_2Cl_2 as the solvent with the yield of the functionalized polyketone being 80% and a molecular weight of 30 400 g mol^{-1}. Note that unreacted monomer was recovered without isomerization of the double bond, in contrast with isomerization observed using 2:1 (v/v) $MeNO_2$–MeOH mixture as the solvent.

Copolymerization of other olefins bearing carbamate and amide functionalities

The methodology described for the copolymerization of methyl *N*-(3-butenyl)carbamate and carbon monoxide, was applied to different unsaturated carbamates and amides using CH_2Cl_2 or 2:1 (v/v) $MeNO_2$–MeOH as the solvent. The results are summarized in Table 4. All copolymers were found to be a mixture of 1,4-ketone and spiroketal repeating units in the polymer backbone.

One cannot predict, a priori, which solvent would give the best results for the copolymerization of unsaturated carbamates and amides with carbon monoxide. For example, when 2:1 (v/v) $MeNO_2$–MeOH is used, no polymer was obtained with methyl *N*-(2-propenyl)carbamate (entry 1) and only an oligomer with a molecular weight less than 1000 g mol^{-1} was formed (30% yield, entry 5) with methyl *N*-(3-butenyl)amide. Also, using phenyl *N*-(2-propenyl)amide

© 2001 NRC Canada

as the olefin (entry 9), a copolymer with molecular weight of 3400 g mol^{-1} was obtained with a yield of only 20%. On the other hand, when CH_2Cl_2 is used as the solvent, no polymer was formed with methyl *N*-(3-butenyl)amide (entry 6) and only an oligomer with a molecular weight less than 1000 g mol^{-1} was obtained with phenyl *N*-(3-propenyl)carbamate (55% yield, entry 4).

Concerning the other cases, copolymers were obtained in moderate molecular weight, and in good yield (44–75%). All copolymers melted without decomposition, and were optically active. Concerning the latter, two interesting results merit comment: the copolymer obtained with methyl *N*-(3-propenyl)carbamate and carbon monoxide (entry 2) showed a high optical rotation, especially when compared with the other results. Also, it was observed for the first time that the copolymerization of phenyl *N*-(3-butenyl)amide in two different solvents (entries 7 and 8) gave two chiral copolymers with specific rotations of opposite sign.

Experimental section

Materials

Most chemicals were purchased from Aldrich Chemical Co. and were used as received. $[Pd(CH_3CN)_4](BF_4)_2$ and 1,2-bis((2*R*,5*R*)-2,5-dimethylphospholano)benzene ((*R*,*R*)-Me-DUPHOS) were purchased from Strem Chemicals. Solvents were appropriately dried and distilled (under nitrogen if necessary) before use.

General methods

Methyl *N*-(2-propenyl)carbamate, phenyl *N*-(2-propenyl)carbamate, methyl *N*-(3-butenyl)carbamate, phenyl *N*-(2-propenyl)amide, methyl *N*-(3-butenyl)amide, and phenyl *N*-(3-butenyl)amide were prepared according to literature methods (7, 8).

All ^1H and ^{13}C NMR spectra were recorded on either a Gemini-200 or Bruker AMX 500 NMR spectrometer using $CDCl_3$, CD_3OD, or DMSO-d_6 as solvent and TMS as the internal standard. Infrared spectra were recorded on a Bomem-100 FT-IR spectrometer. Gel permeation chromatography (GPC) was run using a Waters 510 HPLC pump operating on a 1 mL min^{-1} flow rate with three consecutive Styragel HT columns effective from 5×10^2 to 4×10^6 and detected using a Waters 410 differential refractometer detector. HPLC-grade THF was used as the eluant. The molecular weight for the polymers are based on calibration with polystyrene standards. Optical rotation measurements of chiral polymers were performed on a PerkinElmer 241 polarimeter using a sodium lamp.

Methyl *N*-(2-propenyl)carbamate

Allyl amine (5.0 g) afforded methyl *N*-(2-propenyl)carbamate (5.6 g, 55%) as a colorless oil, $bp_{0.3}$ = 39°C. IR (neat) (cm^{-1}): 3340, 3084, 2952, 1712, 1537, 1258, 1021, 994, 921, 780. ^1H NMR ($CDCl_3$) (ppm): 5.79 (1H, ddt, *J* = 17.2, 10.2, 5.4 Hz), 5.13 (1H, d, *J* = 17.2 Hz), 5.07 (1H, d, *J* = 10.2 Hz), 4.90 (1H, br), 3.75 (2H, br), 3.63 (3H, s). ^{13}C NMR ($CDCl_3$) (ppm): 157.6, 135.2, 116.4, 52.7, 44.0. Anal. calcd.: C 52.16, H 7.88, N 12.17; found: C 52.01, H 7.91, N 12.10.

Phenyl *N*-(2-propenyl)carbamate

Allyl amine (5.0 g) afforded phenyl *N*-(2-propenyl)carbamate (10.9 g, 70%) as a colorless oil. R_f = 0.16 (hexane – ethyl acetate, 10:1). IR (neat) (cm^{-1}): 3332, 3073, 1731, 1646, 1594, 1537, 1487, 1205, 1024, 990, 931, 758, 689. ^1H NMR ($CDCl_3$) (ppm): 7.35 (2H, dl, *J* = 7.4 Hz), 7.27–7.08 (3H, m), 5.88 (1H, ddt, *J* = 16.2, 10.3, 6.5 Hz), 5.23 (1H, d, *J* = 16.2 Hz), 5.17 (1H, d, *J* = 10.3 Hz), 5.29–5.10 (1H, br), 3.86 (2H, br). ^{13}C NMR ($CDCl_3$) (ppm): 155.2, 134.6, 130.0, 129.9, 126.0, 122.2, 117.2, 44.3. Anal. calcd.: C 67.78, H 6.26, N 7.90; found: C 68.03, H 6.51, N 7.46.

Methyl *N*-(3-butenyl)carbamate

3-Butenylamine (7) (5.0 g) afforded methyl *N*-(3-butenyl)carbamate (6.0 g, 66%) as a colorless oil, $bp_{0.1}$ = 37°C. IR (neat) (cm^{-1}): 3347, 2953, 1710, 1535, 1263, 1144, 1034, 917, 779. ^1H NMR ($CDCl_3$) (ppm): 5.68 (1H, m), 5.01 (1H, d, *J* = 16.7 Hz), 5.00 (1H, d, *J* = 10.4 Hz), 3.58 (3H, s), 3.20 (2H, m), 2.18 (2H, m). ^{13}C NMR ($CDCl_3$) (ppm): 156.9, 135.1, 117.2, 52.0, 40.0, 34.1. Anal. calcd.: C 55.80, H 8.58, N 10.84; found: C 55.91, H 8.64, N 10.72.

Phenyl *N*-(2-propenyl)amide

Allyl amine (5.0 g) afforded phenyl *N*-(2-propenyl)amide (7.8 g, 55%) as a light yellow oil. R_f = 0.15 (hexane – ethyl acetate, 10:1). IR (neat) (cm^{-1}): 3317, 3084, 3067, 1633, 1556, 1488, 1308, 993, 804, 694. ^1H NMR ($CDCl_3$) (ppm): 7.76 (2H, d, *J* = 7.8 Hz), 7.47–7.33 (3H, m), 6.48 (1H, br), 5.88 (1H, ddt, *J* = 17.2, 10.2, 5.6 Hz), 5.22 (1H, d, *J* = 17.2 Hz), 5.14 (1H, d, *J* = 10.2 Hz), 4.04 (2H, br). ^{13}C NMR ($CDCl_3$) (ppm): 168.2, 135.0, 134.8, 132.0, 129.1, 127.7, 117.0, 43.0. Anal. calcd.: C 74.51, H 6.88, N 8.69; found: C 74.40, H 6.83, N 8.50.

Methyl *N*-(3-butenyl)amide

3-Butenylamine (7) (5.0 g) afforded methyl *N*-(3-butenyl)amide (4.8 g, 60%) as a colorless oil, $bp_{0.3}$ = 85°C. IR (neat) (cm^{-1}): 3333, 3084, 2952, 1698, 1538, 1258, 994, 921. ^1H NMR ($CDCl_3$) (ppm): 5.84–5.62 (2H, m), 5.06 (1H, d, *J* = 16.1 Hz), 5.05 (1H, d, *J* = 10.3 Hz), 3.28 (2H, dt, *J* = 5.9, 6.7 Hz), 2.22 (2H, dt, *J* = 6.7 Hz), 1.93 (3H, s). ^{13}C NMR ($CDCl_3$) (ppm): 172.7, 135.6, 117.8, 39.1, 34.3, 23.9. Anal. calcd.: C 63.68, H 9.79, N 12.38; found: C 63.60, H 9.80, N 12.35.

Phenyl *N*-(3-butenyl)amide

3-Butenylamine (7) (5.0 g) afforded phenyl *N*-(3-butenyl)amide (7.4 g, 60%) as a light yellow oil, R_f = 0.33 (hexane – ethyl acetate, 2:1). IR (neat) (cm^{-1}): 3318, 3077, 2979, 2933, 1642, 1543, 1311, 1150, 1076, 992, 917, 803, 695. ^1H NMR ($CDCl_3$) (ppm): 7.73 (2H, d, *J* = 7.9 Hz), 7.50–7.24 (3H, m), 6.34 (1H, br), 5.80 (1H, *J* = 17.1, 10.2, 6.9 Hz), 5.11 (1H, d, *J* = 17.1 Hz), 5.10 (1H, d, *J* = 10.2 Hz), 3.50 (2H, dt, *J* = 6.9, 6.7 Hz), 2.35 (2H, dt, *J* = 6.7, 6.7 Hz). ^{13}C NMR ($CDCl_3$) (ppm): 168.2, 135.9, 135.3, 132.0, 129.1, 127.4, 117.9, 39.5, 34.4. Anal. calcd.: C 75.40, H 7.48, N 7.99; found: C 75.79, H 7.46, N 7.89.

Copolymerization of methyl *N*-(3-butenyl)carbamate

To a solution containing 4.0×10^{-2} mmol of $[Pd(CH_3CN)_4](BF_4)_2$ and 6.0×10^{-2} mmol of (*R*,*R*)-Me-

© 2001 NRC Canada

DUPHOS in 3 mL of a 2:1 (v/v) mixture of CH_3NO_2 and MeOH was added 10 mmol of methyl *N*-(3-butenyl)carbamate. The resultant solution was place in a 45 mL autoclave and charged with 1000 psi of CO. After stirring for 48 h at 40°C, the excess carbon monoxide was released and the solution was diluted with CH_2Cl_2 and filtered. Diethyl ether was added to the filtrate to precipitate out the polymer (1.2 g). The polymer was washed with diethyl ether and dried under vacuum. The formed polymer was found to be a mixture of 1,4-ketone and spiroketal repeating units in the polymer backbone. $[\alpha]_D^{25}$ = +8 (c = 0.9, MeOH). $M_w = 1.3 \times 10^4$, M_w/M_n = 1.4. T_m = 145–155°C. IR (KBr) (cm^{-1}): 3342, 2982, 1706, 1534, 1448, 1374, 1259, 1139, 1034, 835, 781. ^{1}H NMR ($CDCl_3$) (ppm): 6.50–4.50 (1H, br), 3.58 (3H, s), 3.11 (2H, br), 2.75–1.05 (5H, m). ^{13}C NMR ($CDCl_3$) (ppm): 212.4, 157.1, 154.2, 114.2, 51.8, 46.1, 40.1, 29.1. Anal. calcd. for the poly(spiroketal–1,4-ketone): C 53.49, H 7.05, N 8.91; found: C 53.73, H 7.06, N 8.73.

Copolymerization of methyl *N*-(2-propenyl)carbamate

The copolymerization was carried out following the same procedure as the one employed for *N*-(3-butenyl)carbamate using 10 mmol of methyl *N*-(2-propenyl)carbamate in 1.3 mL of CH_2Cl_2. The formed polymer (1.1 g) was a mixture of 1,4-ketone and spiroketal repeating units in the polymer backbone. $[\alpha]_D^{25}$ = +83 (c = 1.1, CH_2Cl_2). $M_w = 6.3 \times 10^3$, M_w/M_n = 1.3. T_m = 190–200°C. IR (KBr) (cm^{-1}): 3349, 2954, 1709, 1536, 1449, 1262, 1195, 1147, 824. ^{1}H NMR ($CDCl_3$) (ppm): 7.0–5.0 (1H, br), 3.62 (3H, s), 3.40 (2H, br), 2.88–1.40 (3H, m). ^{13}C NMR ($CDCl_3$) (ppm): 215.0, 158.0, 115.1, 52.9, 47.5, 43.5, 40.8. Anal. calcd. for the poly(spiroketal–1,4-ketone): C 50.35, H 6.34, N 9.79; found: C 50.05, H 6.53, N 9.49.

Copolymerization of phenyl *N*-(2-propenyl)carbamate

The copolymerization was carried out following the same procedure as the one employed for *N*-(3-butenyl)carbamate using 10 mmol of phenyl *N*-(2-propenyl)carbamate in 3 mL of a 2:1 (v/v) mixture of CH_3NO_2 and MeOH. The formed polymer (0.9 g) was a mixture of 1,4-ketone and spiroketal repeating units in the polymer backbone. $[\alpha]_D^{25}$ = +44 (c = 1.2, CH_2Cl_2). $M_w = 4.5 \times 10^3$, M_w/M_n = 1.2. T_m = 180–190°C. IR (KBr) (cm^{-1}): 3352, 2942, 1736, 1491, 1376, 1206, 952, 826, 762, 689. ^{1}H NMR ($CDCl_3$) (ppm): 7.60–6.60 (5H, m), 5.96 (1H, br), 3.36 (2H, br), 3.00–1.40 (3H, m). ^{13}C NMR (DMSO-d_6) (ppm): 209.9, 154.4, 151.0, 129.2, 124.9, 121.7, 47.5, 43.7, 41.2. Anal. calcd. for the poly(spiroketal–1,4-ketone): C 64.38, H 5.40, N 6.83; found: C 64.59, H 5.47, N 6.62.

Copolymerization of methyl *N*-(3-butenyl)amide

The copolymerization was carried out following the same procedure as the one employed for *N*-(3-butenyl)carbamate using 10 mmol of methyl *N*-(3-butenyl)amide in 3 mL of 2:1 (v/v) CH_3NO_2–MeOH. The formed polymer (0.4 g) was a mixture of 1,4-ketone and spiroketal repeating units in the polymer backbone. $[\alpha]_D^{25}$ = +24 (c = 1.2, MeOH). $M_w < 10^3$. T_m = 145–155°C. IR (KBr) (cm^{-1}): 3289, 3093, 2936, 1708, 1655, 1560, 1440, 1374, 1297, 1212, 1149, 1096, 1040, 954, 823. ^{1}H NMR (CD_3OD) (ppm): 7.72 (1H, br), 2.79 (2H, br), 1.56 (3H, s), 2.30–0.94 (5H, m). ^{13}C NMR (CD_3OD) (ppm): 172.9, 135.1, 114.9, 42.7, 41.9, 39.2, 29.8, 22.5. Anal. calcd. for the poly(spiroketal–1,4-ketone): C 63.68, H 9.80, N 12.38; found: C 63.40, H 9.91, N 12.51.

Copolymerization of phenyl *N*-(3-butenyl)amide

The copolymerization was carried out following the same procedure as the one employed for *N*-(3-butenyl)carbamate using 10 mmol of phenyl *N*-(3-butenyl)amide in 1.3 mL of CH_2Cl_2. The formed polymer (1.3 g) consisted of a mixture of 1,4-ketone and spiroketal repeating units in the polymer backbone. $[\alpha]_D^{25}$ = +40 (c = 0.2, DMSO). $M_w = 6.4 \times 10^3$, M_w/M_n = 1.2. T_m = 155–170°C. IR (KBr) (cm^{-1}): 3318, 3066, 2930, 1638, 1542, 1309, 1148, 955, 822, 694. ^{1}H NMR (DMSO-d_6) (ppm): 8.42 (1H, br), 7.75 (2H, br), 7.60–7.00 (3H, br), 3.16 (2H, br), 2.47 (1H, br), 2.05 (2H, br), 1.73 (2H, br). ^{13}C NMR (DMSO-d_6) (ppm): 166.8, 134.7, 130.8, 128.1, 127.0, 38.1, 30.7, 41.0. Anal. calcd. for the poly(spiroketal–1,4-ketone): C 70.92, H 6.45, N 6.89; found: C 70.51, H 6.25, N 7.01.

Copolymerization of phenyl *N*-(2-propenyl)amide

The copolymerization was carried out following the same procedure as the one employed for *N*-(3-butenyl)carbamate using 10 mmol of phenyl *N*-(2-propenyl)amide in 1.3 mL of CH_2Cl_2. The formed polymer (1.0 g) was a mixture of 1,4-ketone and spiroketal repeating units in the polymer backbone. ^{1}H NMR (DMSO-d_6) (ppm): 8.58 (1H, br), 8.15–6.80 (5H, m), 3.17 (2H, br), 2.92–1.00 (3H, m). ^{13}C NMR (DMSO-d_6) (ppm): 209.9, 166.5, 134.3, 131.2, 128.3, 127.2, 46.1, 43.5, 41.7. IR (KBr) (cm^{-1}): 3353, 3066, 2939, 1647, 1541, 1308, 823, 712. Anal. calcd. for the poly(spiroketal–1,4-ketone): C 69.83, H 5.86, N 7.40; found: C 69.40, H 5.71, N 7.31.

Conclusion

The solubilization of the palladium catalyst in unsaturated carbamates and amides enables copolymerization with carbon monoxide to take place without any solvent. While the yield may be only 30%, the fact that the unreacted olefin can be recovered without isomerization of the C=C bond is of interest. For the first time, an excess of phosphine was found to be effective for obtaining polyketones in higher molecular weight. Finally the new copolymers formed may be of value for subsequent modification of the polymer (*e-g* polyurethane-polyketone).

Alternating copolymerization of ω-perfluoroalkyl-1-alkenes with carbon monoxide catalyzed by homogeneous and polymer-supported Pd-complexes

Kyoko Nozaki, Fumitoshi Shibahara, Stephan Elzner, and Tamejiro Hiyama

Abstract: Alternating copolymerization of fluorinated olefins $(C_nF_{2n+1})(CH_2)_mCH=CH_2$ (**1**) and carbon monoxide was carried out using cationic Pd(II)-(*R*,*S*)-BINAPHOS complexes (**2**) as catalysts. To obtain polymeric products sufficiently, existence of at least two methylenes in **1** were essential ($m \geq 2$). The products thus obtained formed polyspiroketal (**4**) rather than polyketone (**3**), the structures being determined by solid- and solution-state NMR and IR analyses. The water contact angle was 108° for a sample of **4f** when it was casted on a glass surface from C_6F_6 solution.

Key words: copolymer, fluoroalkene, carbon monoxide, palladium, contact angle.

Résumé : Utilisant des complexes cationiques Pd(II)-(*R*,*S*)-BINAPHOS (**2**) comme catalyseurs, on a effectué une copolymérisation alternative d'oléfines fluorées $(C_nF_{2n+1})(CH_2)_mCH=CH_2$ (**1**) et de monoxyde de carbone. Pour obtenir des quantités suffisantes de polymères, il est essentiel que **1** comporte au moins deux méthylènes ($m \geq 2$). Les produits ainsi obtenus forment des polyspirocétals (**4**) plutôt que des polycétones (**3**); les structures ont été déterminées par analyses IR et par RMN à l'état solide et en solution. L'angle de contact avec l'eau est de 108° pour un échantillon de **4f** déposé sur une surface de verre à partir d'une solution de C_6F_6.

Mots clés : copolymère, fluoroalcène, monoxyde de carbone, palladium, angle de contact.

[Traduit par la Rédaction]

Introduction

The Pd(II)-catalyzed alternating copolymerization of alkenes with carbon monoxide provides polyketones whose carbonyl groups are potentially convertible to other functional groups (1). Meanwhile, employment of alkenes bearing functional groups is also of interest to obtain highly functionalized polymers. For example, Sen and co-workers (2) successfully applied alkenols and alkenoic acids to the copolymerization. We put a trialkoxysilyl group to the alkene, that opens the possibility of silane coupling of the polyketones on silica gels (3). In the course of our study, we became interested in the introduction of perfluoroalkyl groups into the polyketone. While our research was going on, Sen and co-workers (4) reported elegant success in the alternating copolymerization of fluorinated allylbenzenes with carbon monoxide catalyzed by a Me-DuPHOS complex of Pd(II) (for another example of fluoroalkene–CO copolymerization see ref. 5). Potential utility of the copolymer was suggested as new materials to alter the surface properties when blended with polar polymers. Here, we report the alternating olefin–CO copolymerization catalyzed by Pd(II)-(*R*,*S*)-BINAPHOS employing ω-perfluoroalkyl-1-alkenes. Our attempt to produce the copolymer using a polymer-supported catalyst is also described. Supercritical CO_2 was examined as a solvent in addition to the conventional CH_2Cl_2 because CO_2 is known to possess high affinity with perfluoroalkyl groups.

Results and discussions

Monomer synthesis

Other than commercially available 3,3,3-trifluoropropene, we synthesized fluoroalkenes which have either one or two methylene groups between the C=C double bond and the perfluoroalkyl groups. 3-Perfluoroalkyl-1-propenes (**1b**–**d**) were prepared from perfluoroalkyl halides and allyl(trimethyl)silane according to the literature (eq. [1]). Between the two catalysts proposed in the literature (6), $Ru_3(CO)_{12}$ was preferably used rather than $Fe_3(CO)_{12}$ because of its easy separation from the products by simple filtration. 4-Perfluoroalkyl-1-butenes **1e** and **1f** were prepared from (2-perfluoroalkyl)ethyl

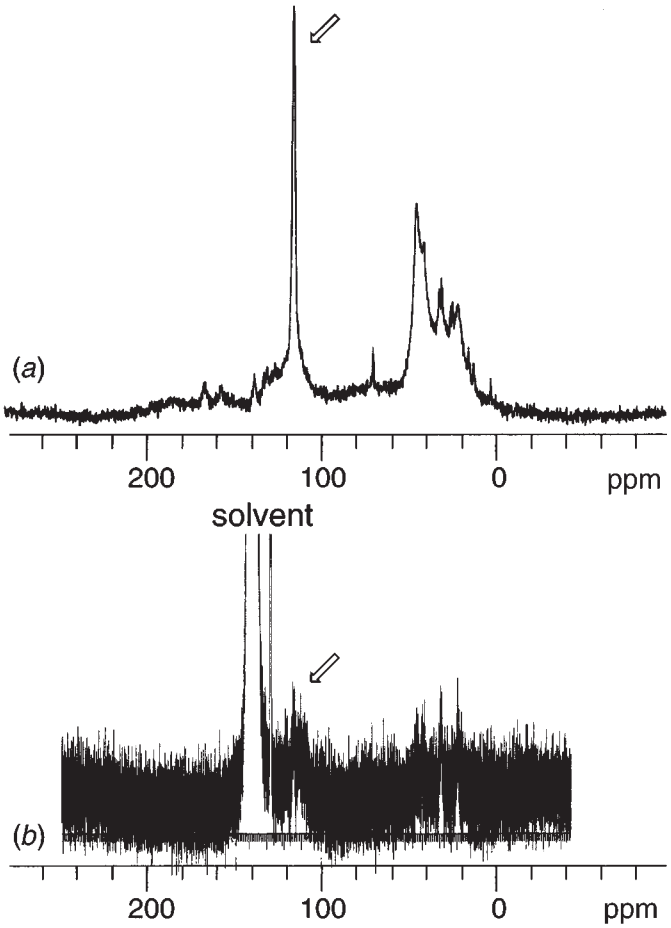
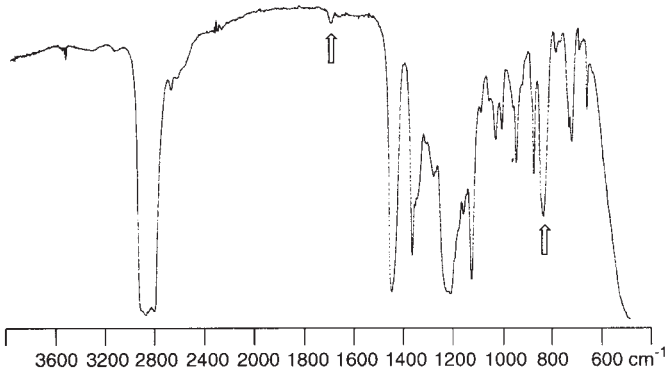
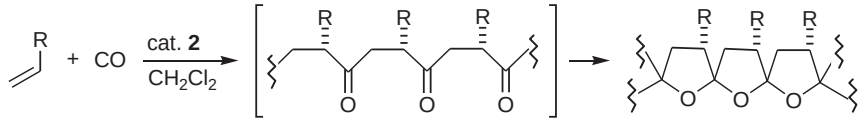
Alternating copolymerization of fluoroalkenes with CO in CH_2Cl_2

Fluorinated alkenes were subjected to the alternating copolymerization with carbon monoxide. The employed catalyst was a cationic Pd(II) complex of a chiral phosphine-phosphite ([PdMe(MeCN){(*R*,*S*)-BINAPHOS}][B{3,5-$(CF_3)_2C_6H_3$}$_4$] (**2a**)) (8). In the presence of **2a**, a CH_2Cl_2 solution of fluoroalkenes (**1a**–**f**) were treated under CO pressure in an autoclave. The product polymers were allowed to precipitate from methanol. The results are summarized in Table 1. With 3,3,3-trifluoropropene (**1a**), no polymeric material was produced. Starting from 3-perfluoroalkyl-1-propenes (**1b**–**d**), insoluble products were obtained in low yields as shown in runs 2–5. With 4-perfluoroalkyl-1-butenes (**1e**–**f**), the products were given in higher yields. The polymers thus obtained were insoluble in most of organic solvents, except for hexafluorobenzene (C_6F_6). In THF, which was reported to dissolve poly(fluorine-substituted allylbenzene-*alt*-CO) (4), only oligomers with low molecular weights were soluble and most of the polymeric materials remained insoluble. Accordingly, the copolymers here obtained were characterized on the basis of solid-state and solution-state (in C_6F_6) NMR and IR spectra. The representative spectra of poly(**1f**-*alt*-CO) are shown in Figs. 1 and 2. Solid-phase ^{13}C NMR (Fig. 1(*a*)) shows a peak at 114 ppm suggesting the presence of spiroketal **4f** (9). No peak was detectable around 213 ppm where polyketone **3f** would exhibit a peak due to C=O, with the S/N ratio of 32. The solution NMR chart taken in C_6F_6 (Fig. 1(*b*)) is essentially superimposable on the solid-state NMR Fig. 1(*a*). By IR, an extremely weak absorption was observed at 1710 cm^{-1}, attributed to carbonyl. The peak at 840 cm^{-1} may be assigned as the C—O—C bond of spiroketal **4f**. Thus, the polymer exists mainly as spiroketal

Fig. 1. (*a*) Solid-phase ^{13}C NMR (CP-MAS) of poly(**1f**-*alt*-CO). The peak at 114 ppm suggests the presence of spiroketal **4f**. No peak is detectable around 213 ppm where polyketone **3f** would exhibit a peak due to C=O. (*b*) Solution-phase ^{13}C NMR (C_6F_6). The chart is essentially superimposable on (*a*).







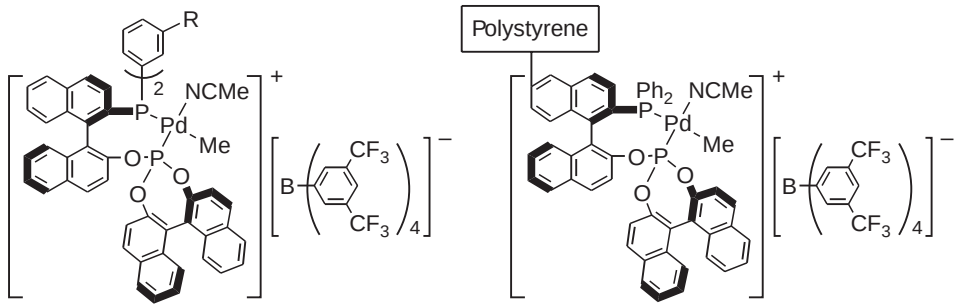


Fig. 2. Infrared spectrum (Nujol) of poly(**1f**-*alt*-CO). A small peak is observed at 1710 cm^{-1}, attributed to the C=O absorption due to polyketone **3f**. Absorption around 840 cm^{-1} may be assigned as the C—O—C of spiroketal **4f**.

4f, and at max, 3% of the polymer may form polyketone **3f** (the **4f**/**3f** ratio was estimated from the S/N ratio of the solid-state ^{13}C NMR). This is unchanged when the polymer is dissolved in C_6F_6. Also, characterization by IR was carried out for the copolymers obtained from **1b–e** to reveal that all of them exist as spiroketals **4b–e** but not polyketones **3b–e**.

Alternating copolymerization of fluoroalkenes with CO in supercritical CO_2

Fluorinated compounds are known to have strong affinity with supercritical (sc.) CO_2 (10) (for examples of fluoroalkene polymerization in sc. CO_2 see ref. 11). In sc. CO_2, no polymeric material was obtained in the attempted copolymerization of **1f** with CO when Pd-complex **2a**, which was insoluble in sc. CO_2, was employed as a catalyst. Meanwhile **2b**, a perfluoroalkyl-substituted analog of **2a**, (12*a*; for fluoroalkyl-substituted complexes in general see ref. 12*b*) was soluble in sc. CO_2 and the corresponding copolymer **4f** was produced in 3% yield. Polymer production with polymer-supported catalyst was also possible (for preparation of alternating olefin–CO copolymers under heterogeneous conditions, e.g., see ref. 13). A cationic Pd(II) complex of polystyrene-supported (*R*,*S*)-BINAPHOS (14), complex **2c**, was treated with olefin **1f** and CO in sc. CO_2 for 72 h at 50°C. After removal of the residual monomers by filtration, the product polymer **4f** was obtained in 0.08% yield when it was separated from the catalyst polymer **2c** by extracting the filter cake with C_6F_6.

Water contact angle

Taking advantage of the hydrophobic nature of the perfluoroalkyl side chain, the water contact angle was measured for a sample of **4f** by casting on glass surface. The observed contact angle of 108° is larger than the value 96° reported by Sen (4) for a related polymer (poly[(allyl)pentafluorobenzene-*alt*-CO]). The value 108° is even comparable to that of poly(tetraflueoroethylene) (PTFE).

Experimental

General

All manipulations involving the air- and moisture-sensitive compounds were carried out using standard Schlenk techniques under an argon purified by passing through a hot column packed with BASF catalyst R3-11. Solid-state ^1H–^{13}C CP-MAS NMR at 67.94 MHz was measured by a JEOL GSX270 spectrometer. Infrared spectra were recorded by a Jasco IR810 spectrometer after mixing the polymers with Nujol. Most of reagents were purchased from Wako Pure Chemical Industries Ltd., Daikin Fine Chemical, or Aldrich Chemical Co. Inc., and were used without further purification unless otherwise specified. Solvents were purified by distillation under argon after drying over standard drying agents. Carbon monoxide (99.9%) was obtained from Teisan Co.

Alternating copolymerization of 3-perfluoroalkyl-1-propenes 1a–d with CO in CH_2Cl_2

A solution of Pd(Me)(Cl){(*R*,*S*)-BINAPHOS} (23.8 mg, 26 μmol) in CH_2Cl_2 (1.5 mL) was added to a solution of Na[B(3,5-$(CF_3)_2C_6H_3$)] (24.9 mg, 28 μmol) in MeCN (0.5 mL). After the solution was stirred at 20°C for 1 h, the solvents were removed in vacuo to give [Pd(Me)(MeCN){(*R*,*S*)-BINAPHOS}]·[B{3,5-$(CF_3)_2C_6H_3$}$_4$] (**2**). The resulting NaCl was not removed from **2**. Palladium complex **2** was dissolved in 2 mL of CH_2Cl_2 and to this, fluoroalkenes **1** (13 mmol) were added. The solution was

© 2001 NRC Canada

degassed by three freeze–thaw cycles and transferred into an autoclave. In the case of highly volatile olefin (**1a**), the olefin was directly introduced into the autoclave. The solution was stirred with a stirring bar in the atmosphere of CO at 50°C. After removal of the volatile materials in vacuo, the residual trace amounts of waxy compounds were analyzed by IR without separation of the catalyst. For the samples of runs 2–5, IR absorptions were observed both at 1710 cm^{-1} (C=O of polyketone **3b**–**d**) and 840 cm^{-1} (C—O—C of spiroketal **4b**–**d**).

Alternating copolymerization of 4-perfluoroalkyl-1-butenes 1e and 1f with CO in CH_2Cl_2

The procedure used for **1b**–**d** was employed for the copolymerization process. When reactions were completed, the CO pressure was released, and the products were reprecipitated from MeOH–CH_2Cl_2. For characterization of **4f**, solid-state ^{13}C NMR, solution-phase ^{13}C NMR (C_6F_6), and IR spectrum were taken and the charts are shown in Figs. 1(*a*), 1(*b*), and 2. Due to the limited solubility of the polymer in C_6F_6, the S/N could not be improved further. **4f**: $[\alpha]_D^{23}$ –62.9 (*c* 0.5, C_6F_6). Polymer **4e** was less soluble in C_6F_6 and was characterized by IR. Absorptions were observed both at 1710 cm^{-1} (C=O of polyketone **3e**) and 840 cm^{-1} (C—O—C of spiroketal **4e**).

Attempted copolymerization of 1f with CO in sc. CO_2 catalyzed by 2a

In a 33-mL autoclave equipped with a window, complex **2a** (4.9 μmol) was prepared by the method mentioned above. The autoclave was charged with olefin **1f** (2.5 mmol) and CO (20 atm), and then cooled down to –78°C. After introduction of liquid CO_2, the system was heated up to 50°C whereupon the total pressure reached 125 atm. The catalyst did not get dissolved and stayed at the bottom of the autoclave. The monomers were soluble in sc. CO_2. After stirring for 20 h at 50 C, the autoclave was cooled down to –78°C and the pressure was slowly released. No polymeric products were obtained.

Copolymerization of 1f with CO in sc. CO_2 catalyzed by perfluoroalkyl-substituted complex 2b

The same reaction as mentioned above was repeated with complex **2b** (0.005 mmol). The catalyst was soluble in CO_2 in this case. After 3 days at 50°C, 3% of the monomer was converted into a black waxy solid whose IR showed peaks at 1710 cm^{-1} (C=O of polyketone **3f**) and 840 cm^{-1} (C—O—C of spiroketal **4f**).

Copolymerization of 1f with CO in sc. CO_2 catalyzed by polymer-supported complex 2c

Polymer-supported (*R*,*S*)-BINAPHOS (14) (0.55 g as a polymer, corresponding to 0.10 mmol of the ligand) was allowed to swell in 5.0 mL of benzene in a Schlenk tube. To this was added a benzene (3.0 mL) solution of Pd(Me)(Cl)(cod) (0.10 mmol). After standing for 4 h at 25°C, the solvents were removed in vacuo, and the polymers were freeze-dried, washed with CH_2Cl_2 and Et_2O. Polymer-supported neutral Pd complex thus prepared was placed in a Schlenk tube and was allowed to swell in 5.0 mL of CH_2Cl_2. To this was added a solution of Na[B(3,5-$(CF_3)_2C_6H_3$)] (0.10 mmol) in MeCN (4.0 mL). The mixture was stirred for ca. 10 min and then allowed to stand for 20 h at 25°C. The solvents were removed in vacuo to produce polymer-supported cationic Pd complex **2c**. Complex **2c** was placed at the bottom of a 33-mL autoclave, equipped with a window. The autoclave was charged with a solution of **1f** (11 mmol) in C_6F_6 (5 mL) and CO (20 atm at 25°C), and then cooled down to introduce CO_2 at –78°C. At 50°C, the total pressure was 110 atm. After stirring by a stirring bar for 81 h at 50°C, the pressure was slowly released at –78°C, and then the autoclave was charged with 0.5 mL of methanol and CO (20 atm at 25°C). After stirring for 1 h at 50°C, the pressure was released, and the resulting mixture was poured into 50 mL of methanol, filtered through a Celite pad, washed with methanol and CH_2Cl_2, and then extracted with C_6F_6. The extracts were evaporated and dried under vacuum to yield **4f** as a white waxy solid (3.5 mg, 0.08% yield).

Contact angle measurement

Polymer **4f** (19.0 mg) was dissolved in C_6F_6 (0.50 mL) and an aliquot (0.1 mL) was placed on the surface of a piece of slide glass (MATSUNAMI precleaned micro slide glass, thickness 0.8 ~ 1.0 mm). The solution was spread over the glass by the aid of a gas blow (HFC 134a, OKEN Bioden gas spray)) and air-dried at room temperature. Contact angle was measured by dropping 3.5 μL of water drops on the surface. Contact angles were measured on either side of eleven drops and averaged to be 108°.

Conclusion

The olefin–CO copolymerization resulted in low conversion with monomers in which a carbon-carbon double bond and a perfluoroalkyl chain is either directly attached or separated only by one methylene group. On the other hand, when they were separated by two methylenes, the corresponding alternating copolymers were obtained in satisfactory yields. Apparently, two methylenes were required to cancel the influence of the perfluoroalkyl group upon the electronic nature of the C=C double bond. The polymers thus produced contain substantial amount of polyspiroketal structure **4** as was characterized by solid-state and solution-phase ^{13}C NMR and IR. The high density of fluorine in **4f** endowed the polyspiroketal with a hydrophilic nature. The highest level of water contact angle of 108° was observed when **4f** was cast on a glass surface. By using super critical CO_2 as a solvent, a small amount of copolymer was obtained from fluoroalkene **1f** and CO employing either a CO_2-soluble Pd complex **2b** or a polymer-supported catalyst **2c**.

Studies on transition-metal nitrido and oxo complexes. Part 20. Oxoruthenates and oxo-osmates in oxidation catalysis; *cis*-$[Os(OH)_2O_4]^{2-}$ as a catalytic oxidant for primary amines and for alcohols

William P. Griffith and Maria Suriaatmaja

Abstract: *cis*-$[Os(OH)_2O_4]^{2-}$ with $[Fe(CN)_6]^{3-}$ and other co-oxidants has been studied as a catalytic reagent for the oxidative dehydrogenation of primary aromatic and aliphatic amines to nitriles, the oxidation of primary alcohols to carboxylic acids and of secondary alcohols to ketones. Electronic and Raman spectroscopy have been used to elucidate the nature of the oxoruthenates and oxo-osmates present in a number of reported organic oxidations catalyzed by ruthenium and osmium species.

Key words: oxidation catalysis, ruthenium, osmium, amine dehydrogenation, alcohol oxidation.

Résumé : On a évalué les possibilités d'utiliser le *cis*-$[Os(OH)_2O_4]^{2-}$, avec le $[Fe(CN)_6]^{2-}$ ou d'autres cooxydants, comme réactif catalytique pour la déshydrogénation oxydante d'amines aromatiques et aliphatiques primaires en nitriles, pour l'oxydation d'alcools primaires en acides carboxyliques et d'alcools secondaires en cétones. On a fait appel aux spectroscopies électronique et Raman pour élucider la nature des oxoruthénates et oxo-osmates présents dans un certain nombre de réactions d'oxydations connues, catalysées par des espèces contenant du ruthénium et de l'osmium.

Mots clés : oxydation, catalyse, ruthénium, osmium, déshydrogénation d'amine, oxydation d'alcool.

Introduction

Homogeneous oxidation reactions catalyzed by transition metal complexes are a subject of much current interest, and those catalyzed by ruthenium and osmium complexes have been much studied in recent years (for Part 19 see ref. 1) (2, 3). The reagent *trans*-$[Ru^{VI}(OH)_2O_3]^{2-}$ – $S_2O_8^{2-}$ is effective in aqueous base for a fairly unusual catalyzed reaction, the oxidative dehydrogenation of primary amines to nitriles at room temperatures (4), a reaction also studied by the dedicatee of this paper using ruthenium porphyrinato complexes (5). We have reported that *cis*-$[Os^{VIII}(OH)_2O_4]^{2-}$ – $[Fe(CN)_6]^{3-}$ in aqueous base at room temperatures will oxidize primary alcohols and primary alkyl halides to aldehydes (6). Here we show that *cis*-$[Os(OH)_2O_4]^{2-}$ – $[Fe(CN)_6]^{3-}$ is, in the presence of CH_3CN, comparable in efficacy with *trans*-$[Ru(OH)_2O_3]^{2-}$ – $S_2O_8^{2-}$ for oxidative amine dehydrogenation, and is much more effective for the oxidations of secondary alcohols than we had previously observed (6) in the absence of CH_3CN.

A second purpose of this paper is to use spectroscopic methods, principally electronic spectroscopy but also Raman solution studies, to establish the nature of the active catalytic intermediates, or their precursors, in systems described in a number of reports of organic oxidations catalyzed by ruthenium and osmim complexes with a variety of co-oxidants. Since in some cases the procedures are used for organic preparations a knowledge of the nature of the catalyst (or its active precursor) is of value.

Received August 30, 2000. Published on the NRC Research Press Web site at http://canjchem.nrc.ca on May 30, 2001.

This paper is dedicated to Brian James, a good friend for many years and a continuing source of inspiration for his catalytic and ruthenium work in particular, on the occasion of his 65th birthday.

Results and discussion

I. Oxidations catalyzed by *cis*-$[Os^{VIII}(OH)_2O_4]^{2-}$ with $[Fe(CN)_6]^{3-}$ and other co-oxidants

(i) Oxidative dehydrogenation of primary amines

In earlier work we attempted, with very limited success, to use *cis*-$[Os(OH)_2O_4]^{2-}$ with $S_2O_8^{2-}$, BrO_3^-, and $[Fe(CN)_6]^{3-}$ as co-oxidants for the oxidative dehydrogenation of amines to nitriles (6). Here we examine the utility of *cis*-$[Os(OH)_2O_4]^{2-}$ as a catalyst for the oxidative dehydrogenation of primary amines to nitriles with a variety of co-oxidants in the presence of CH_3CN. Acetonitrile is

Table 1. Oxidative dehydrogenation of primary amines to nitriles by *cis*-$[Os^{VIII}(OH)_2O_4]^{2-}$ – $[Fe(CN)_6]^{3-}$.

Substrate	Product	Yield (%) [Turnover]	Time (h)
Benzylamine	Benzonitrile	94 [24]	2
4-Methoxybenzylamine	4-Methoxybenzonitrile	81 [21]	1.5
2-Chlorobenzylamine	2-Chlorobenzonitrile	75 [19]	1.5
4-Chlorobenzylamine	4-Chlorobenzonitrile	74 [19]	1.5
2-Bromobenzylamine·HCl	2-Bromobenzonitrile	82 [21]	1.5
3-Bromobenzylamine·HCl	3-Bromobenzonitrile	80 [20]	1.5
4-Bromobenzylamine·HCl	4-Bromobenzonitrile	80 [20]	1.5
Octylamine	Octanenitrile	84 [22]	1.5
With BrO_3^- co-oxidant the following were obtained:			
Benzylamine	Benzonitrile	51 [13]	2
Octylamine	Octanenitrile	63 [16]	2

Note: Conditions: 2 mmol of the amine in 25 cm^3 of the *cis*-$[Os^{VIII}(OH)_2O_4]^{2-}$ – $[Fe(CN)_6]^{3-}$ or the *cis*-$[Os^{VIII}(OH)_2O_4]^{2-}$ – BrO_3^- reagent, each with 5 cm^3 of CH_3CN at room temperature.

known to improve yields in a number of ruthenium-catalyzed reactions (7, 8).

We tried the three co-oxidants used previously with *cis*-$[Os(OH)_2O_4]^{2-}$, viz. $S_2O_8^{2-}$, BrO_3^-, and $[Fe(CN)_6]^{3-}$. Persulfate gave rather poor yields of nitriles (ca. 15%) as was the case with *trans*-$[Ru(OH)_2O_3]^{2-}$ with $S_2O_8^{2-}$ (4). Ferricyanide gave the best results while bromate was of intermediate efficiency (Table 1). The success of $[Fe(CN)_6]^{3-}$ is perhaps not surprising since with *cis*-$[Os^{VIII}(OH)_2O_4]^{2-}$ for oxidation of alcohols, aldehydes, and alkyl halides it was the most effective co-oxidant (6) (and the related *trans*-$[OS^{VI}O_2(OH)_4]^{2-}$ is widely used in the asymmetric *cis*-hydroxylation of alkenes (3, 9)). Results in terms of product yields, turnovers and times for amine dehydrogenations by *cis*-$[Os(OH)_2O_4]^{2-}$ – $[Fe(CN)_6]^{3-}$ are comparable with those found (4) for *trans*-$[Ru(OH)_2O_3]^{2-}$ – $S_2O_8^{2-}$.

In the absence of $[Fe(CN)_6]^{3-}$, addition of benzylamine to the orange *cis*-$[Os(OH)_2O_4]^{2-}$ in base gives an immediate purple colour of *trans*-$[OsO_2(OH)_4]^{2-}$, identified by its electronic spectrum. Reaction of *trans*-$[Ru(OH)_2O_3]^{2-}$ with benzylamine gave a transient green amine complex (4), but there is no evidence of such a species being formed with *cis*-$[Os(OH)_2O_4]^{2-}$ or *trans*-$[OsO_2(OH)_4]^{2-}$. In the presence of excess $[Fe(CN)_6]^{3-}$ with *cis*-$[Os(OH)_2O_4]^{2-}$ in base the colour darkens on addition of amine, but when the reaction is complete the original orange returns, so the reagent is self-indicating. Comparisons of the electronic spectra of $[Fe(CN)_6]^{3-}$ and of a mixture of $[Fe(CN)_6]^{3-}$ with *cis*-$[Os(OH)_2O_4]^{2-}$ in molar NaOH show, in addition to bands due to $[Fe(CN)_6]^{3-}$, maxima at 225, 325, and 380 nm due to *cis*-$[Os(OH)_2O_4]^{2-}$. Raman spectra of a similar mixture show the symmetric Os=O stretch (ν^s (OsO_4)) of *cis*-$[Os(OH)_2O_4]^{2-}$ known[2] to lie at 915 cm^{-1} in addition to bands from $[Fe(CN)_6]^{3-}$. Electronic spectra also show that excess $[Fe(CN)_6]^{3-}$ with *trans*-$[Os^{VI}O_2(OH)_4]^{2-}$ gives *cis*-$[Os^{VIII}(OH)_2O_4]^{2-}$, as shown by appearance of bands due to the latter at 325 and 380 nm, and again Raman spectra confirm this by the appearance of the same 915 cm^{-1} band. It thus seems clear that $[Fe(CN)_6]^{3-}$ oxidizes *trans*-$[OsO_2(OH)_4]^{2-}$ to *cis*-$[Os(OH)_2O_4]^{2-}$, and we conclude that this is the effective catalyst precursor in the system.

As indicated above the yields of nitriles are much improved by addition of CH_3CN. It has long been known that acetonitrile substantially improves yields, selectivities, and catalytic turnovers in ruthenium-catalyzed reactions (7), and we have recently observed a similar effect in the $RuCl_3.nH_2O$–$IO(OH)_5$ system for alkene and alkyne cleavage (8). The action of CH_3CN is not clear; Sharpless and co-workers (7) have suggested, in the case of ruthenium complexes, that CH_3CN, itself resistant to oxidation, may stabilize intermediate lower oxidation states of ruthenium involved in the catalytic cycle, and it is possible that there is a similar effect with osmium.

Attempts were made to use *N*-methylmorpholine-*N*-oxide (nmo) as a co-oxidant since this is very effective in nonaqueous solutions for alcohol oxidations with $[RuO_4]^-$ (10, 11). Although some oxidation of 4-methoxybenzylamine to the nitrile was observed, black OsO_2 was formed during the reaction, so such dehydrogenation as did occur was probably via a heterogeneously catalyzed route. With hypochlorite as co-oxidant primary aromatic amines gave only ca. 15% of nitriles. GC–MS studies on the oxidation products of benzylamine, 2-methoxy-, 2-methyl-, 4-methylbenzylamine, and octylamine showed in all cases a clean conversion to the nitrile. For benzylamine no formation of the imine ($PhCH_2N{=}CHPh$) was observed, though this was a significant side-product (4) in the oxidation of benzylamine by *trans*-$[Ru(OH)_2O_3]^{2-}$ – $S_2O_8^{2-}$.

(ii) Oxidation of primary and secondary alcohols

Our earlier use of *cis*-$[Os(OH)_2O_4]^{2-}$ as a catalyst for alcohol oxidations with $[Fe(CN)_6]^{3-}$, BrO_3^-, and $S_2O_8^{2-}$ as co-oxidants showed that $Fe(CN)_6]^{3-}$ was the most efficient co-oxidant, but no acetonitrile was added to the reaction mixture (6). In the presence of CH_3CN (Table 2) we again find that $[Fe(CN)_6]^{3-}$ is the most effective co-oxidant, and secondary alcohols (found to give relatively poor yields of ketones in our earlier work in the absence of acetonitrile (6))

Table 2. Oxidations of alcohols by *cis*-$[Os^{VIII}(OH)_2O_4]^{2-}$ – $[Fe(CN)_6]^{3-}$.

Substrate	Product	Yield (%) [Turnover]	Time (h)
Benzyl alcohol	Benzoic acid	81 [21]	2
1-Hexanol	1-Hexanoic acid	70 [18]	2
Cyclopentanol	Cyclopentanone	>99 [25]	2
Cylohexanol	Cyclohexanone	66 [17]	0.5
Cylohexanol	Cyclohexanone	69 [18]	1
Cylohexanol	Cyclohexanone	>99 [25]	2
Cycloheptanol	Cycloheptanone	>99 [25]	2
Cyclooctanol	Cyclooctanone	>99 [25]	2
2-Hexanol	2-Hexanone	>99 [25]	2
2-Octanol	2-Octanone	90 [23]	0.5
2-Octanol	2-Octanone	>99 [25]	2
4-Methylcyclohexanol	4-Methylcyclohexanone	>99[25]	2
Citronellol	Citronellal	90 [24]	2
Geraniol	Citral	91 [24]	2

Note: Conditions: 2 mmol of the alcohol in 25 cm^3 of the *cis*-$[Os^{VIII}(OH)_2O_4]^{2-}$ – $[Fe(CN)_6]^3$ reagent with 25 cm^3 of CH_3CN at room temperature.

gave good yields and turnovers if CH_3CN is used. Thus cyclopentanol, cyclohexanol, cycloheptanol, cyclooctanol, 2-methyl-cyclohexanol, 2-hexanol, and 2-octanol give the corresponding ketones in >99% yield with catalytic turnovers of ca. 25 over a two-hour period. With primary alcohols however, the yields and turnovers of carboxylic acids are only slightly improved by addition of acetonitrile. Unsaturated alcohols (citronellol, geraniol) do not suffer competing double bond cleavage and give the corresponding unsaturated aldehydes in good yield. The same colour changes as with amines are observed when alcohols are added to orange *cis*-$[Os(OH)_2O_4]^{2-}$ in base, without and with $[Fe(CN)_6]^{3-}$.

II. Identification of ruthenium and osmium catalyst precursors in published oxidation procedures

Over the past 20 years there have been numerous reports on oxidations catalyzed by ruthenium and, in a smaller number of cases, osmium complexes. Usually $RuCl_3 \cdot nH_2O$ or OsO_4 are the reagents initially used, but there is often doubt about the nature of the species involved in the catalysis. We have tried (Table 3) to establish the nature of such species by measuring the electronic and, in some cases, Raman spectra of the solutions used in typical literature reports. Often, particularly in kinetic studies, a range of concentrations was used by the original investigators. We have used conditions typical of these and they are listed (catalyst and its concentration, co-oxidant, substrate, solvent and solutes, pH). In the last two columns of Table 3 the active catalyst precursor is given as suggested by the literature and that which we favour from spectra which we have measured of the reaction solutions. Occasionally our catalyst concentrations differ from those in the cited publications to be able to obtain reasonable spectra.

In most cases the ruthenium precursors are likely to be the oxo species ruthenium tetroxide ($Ru^{VIII}O_4$), perruthenate ($[Ru^{VII}O_4]^-$), or ruthenate (*trans*-$[Ru^{VI}(OH)_2O_3]^{2-}$); these are easily distinguished by their electronic (13–15) or Raman[2] (15, 16) spectra. For the osmium-catalyzed reactions, likely intermediates are osmium tetroxide ($Os^{VIII}O_4$), perosmate (*cis*-$[Os^{VIII}(OH)_2O_4]^{2-}$), or osmate (*trans*-$[Os^{VI}O_2(OH)_4]^{2-}$). These can be distinguished by their electronic (17–19) or Raman[2] (6, 15) spectra, and here again we use electronic spectra to help in the identification of such species in published procedures. An earlier paper of ours (20) covered some literature for oxoruthenate but not oxo-osmate species up to 1994.

A. Oxidations with ruthenium catalysts

(i) Electronic spectra of oxoruthenates

In Fig. 1 we reproduce the electronic spectra of: (*a*) RuO_4, (*b*) $[RuO_4]^-$, and (*c*) of *trans*-$[Ru(OH)_2O_3]^{2-}$ in aqueous media; they are close to those reported earlier for all three species (12), for $[RuO_4]^-$ (13), and of *trans*-$[Ru(OH)_2O_3]^{2-}$ (13, 14).

(ii) Hypochlorite as co-oxidant

Recently Mills and Holland (21) studied the oxidation of 2-octanol to 2-octanone by RuO_4 using ClO^- as co-oxidant, and gave a speciation diagram for the oxoruthenates produced from RuO_4 at different pH. From pH 5–7 RuO_4 is the predominant species, $[RuO_4]^-$ from pH 7.5–10.5, and *trans*-$[Ru(OH)_2O_3]^{2-}$ at higher pH, essentially in agreement with the classic work of Connick and Hurley (12)). They noted for oxoruthenates in hypochlorite solutions that, although at pH 11–14 the orange *trans*-$[Ru(OH)_2O_3]^{2-}$ might be expected to be present, in fact the yellow-green $[RuO_4]^-$ is the predominant species. This was ascribed to a kinetic effect, the oxidation of *trans*-$[Ru^{VI}(OH)_2O_3]^{2-}$ to $[Ru^{VII}O_4]^-$ by ClO^- being much more rapid than the reduction of RuO_4 to *trans*-$[Ru^{VI}(OH)_2O_3]^{2-}$ by OH^-, unless the pH is very high (>5 M OH^-). However, they did not show spectroscopically that $[RuO_4]^-$ is present in such hypochlorite solutions. Here we demonstrate both with electronic and Raman spectroscopies that this is the case.

In Table 3 (entries 1–7 (22–26)) we list a number of ruthenium-catalyzed oxidations with hypochlorite, all used as preparative methods and thus of particular interest. The electronic spectra of both aqueous and organic layers were mea-

© 2001 NRC Canada

Fig. 1. Electronic spectra in aqueous solutions of: (*a*) RuO_4 in water at pH 7 (ca. 2.6×10^{-4} M RuO_4); (*b*) $[Ru^{VII}O_4]^-$ in water at pH 10; 0.09 g dm^{-3} (3.5×10^{-4} M) $RuCl_3 \cdot 3H_2O$ in 0.2 M $NaBrO_3$ and molar Na_2CO_3; (*c*) *trans*-$[Ru^{VI}(OH)_2(O_3]^{2-}$ in water at pH 14; 0.15 g dm^{-3} (6×10^{-4} M) $RuCl_3 \cdot 3H_2O$ in 0.05 M $K_2S_2O_8$ and molar KOH.

sured. In the organic solvent RuO_4 is always present, clearly shown by its bands at 315 and 385 nm with attendant vibrational fine structure particularly for the 385 nm band. The aqueous layer could contain RuO_4, $[RuO_4]^-$ or *trans*-$[Ru(OH)_2O_3]^{2-}$, depending on the pH. Unfortunately for such layers the electronic spectrum of ClO^- obscures the 315 nm band and part of the 385 nm band of $[RuO_4]^-$. Nevertheless the latter is visible as a shoulder without the fine structure always observed on this band for RuO_4, as well as the weak shoulder near 480 nm present in the spectrum of $[RuO_4]^-$ but not RuO_4. Study of the Raman spectra of more concentrated solutions of $RuCl_3 \cdot nH_2O$ (0.01 M) in 0.3 M hypochlorite clearly show the ν^s (RuO_4) band of $[RuO_4]^-$ at 853 cm^{-1}, close to the literature values for this mode in the perruthenate ion (15, 16).

For entries 1 and 2, RuO_4 was suggested as the oxidant (22, 23), but certainly for the aqueous layers our electronic spectra showed $[RuO_4]^-$ to be present, although no phase-transfer reagent was used in our measurements. For entries 3 (24), 4, and 5 (25) the pH of the aqueous layers are 13 and our electronic spectra show that they contain $[RuO_4]^-$ rather than the RuO_4 which we had earlier suggested (20). For the solution at 60°C this is still the case for entry 5. For entry 6 (26) $[RuO_4]^-$ is clearly present rather than the claimed "$[RuO_4]^{2-}$".

In entry 7 $Ca(OCl)_2$ is used in a small quantity of concentrated water – CH_3CN (27). Little of the co-oxidant dissolves under the conditions described and the mixture separates into two layers. The upper, predominantly acetonitrile, layer contains RuO_4 and the lower, predominantly aqueous layer $[RuO_4]^-$.

Thus in all the solutions studied with hypochlorite as the co-oxidant we observe $[RuO_4]^-$ in the aqueous layer and RuO_4 in the organic layer ($[RuO_4]^-$, being a charged species, does not extract into the organic layer in the absence of a phase-transfer agent).

(iii) With periodate as co-oxidant

We have isolated salts of *trans*-$[Ru^{VI}O_2\{I(OH)O_5\}_2]^{6-}$ from reaction of $RuCl_3 \cdot nH_2O$ with periodates and persulfate (28, 29) and have shown that with excess periodate these function as catalysts for the oxidation of primary alcohols and alkyl halides to carboxylic acids, and for secondary alcohols and halides to ketones (29). The X-ray crystal structure of *trans*-$NaK_5[Ru^{VI}O_2\{I(OH)O_5\}_2] \cdot 8H_2O$ was determined (28), and the electronic spectrum of *trans*-$[RuO_2\{I(OH)O_5\}_2]^{6-}$ in aqueous base has bands at 221 and 389 nm (29). Rozovskii et al. (30) have proposed the formation of a ruthenium(VII) periodato complex from *trans*-$[Ru(OH)_2O_3]^{2-}$ and periodate in base (0.04–2 M KOH) and such a species, possibly *trans*-$[Ru^{VII}O_2\{I(OHO)O_5\}_2]^{5-}$, seems to be associated with a band near 380 nm.

For those oxidations effected in neutral solution (entries 8, 9 (24, 27)) it is clear that RuO_4 is produced, as expected. At 60°C, at which some of these oxidations (entry 8) were conducted (24), electronic spectra show that there is surprisingly still some RuO_4 remaining in both layers. Raman spectra also show, in addition to bands due to $(IO_4)^-$, the ν^s (RuO_4) and ν^{as} (RuO_4) bands at 883 and 915 cm^{-1}, in agreement with the literature data (15).

At high pH (entries 10 and 11 (31, 32)) problems arise from the very low solubilities of $NaIO_4$ or KIO_4 at such pH. We observe inflections in the electronic spectra of the

© 2001 NRC Canada

solutions near 380 nm which could well arise from *trans*-$[RuO_2\{I(OH)O_5\}_2]^{6-}$ which has a band near this wavelength and is an effective catalytic oxidant with periodate as co-oxidant (29). Unfortunately, Raman spectra could not be recorded owing to the low concentrations at this pH. We believe the effective oxidation precursor to be the periodato species abbreviated as $[RuO_2(HIO_6)_2]^{6-}$ in Table 3.

(iv) With bromate and iodate as co-oxidant

Aqueous bromate is an effective co-oxidant at pH 10 for $[RuO_4]^-$ and *trans*-$[Ru(OH)_2O_3]^{2-}$ at pH 14 (13). For entry 12 our electronic spectra show that RuO_4 is produced, as expected, since the pH ~ 7. The substrate was "Bordeaux" (disodium-2-hydroxy-4-(1-naphthylazo)-naphthalen-3,6-disulphonate) being oxidized to an unspecified product; the effective oxidant was not identified (33). Raman spectra also show the ν^s (RuO_4) and ν^{as} (RuO_4) bands of RuO_4 at 883 and 915 cm^{-1} in addition to those due to bromate. Entry 13 involves the initial use of *trans*-$[Ru(OH)_2O_3]^{2-}$ (incorrectly formulated in (34) as $[RuO_4]^{2-}$) with BrO_3^- in 0.01 M OH^-. Bands in the electronic spectra at 385 and 460 nm show that *trans*-$[Ru(OH)_2O_3]^{2-}$ is indeed the effective oxidant precursor.

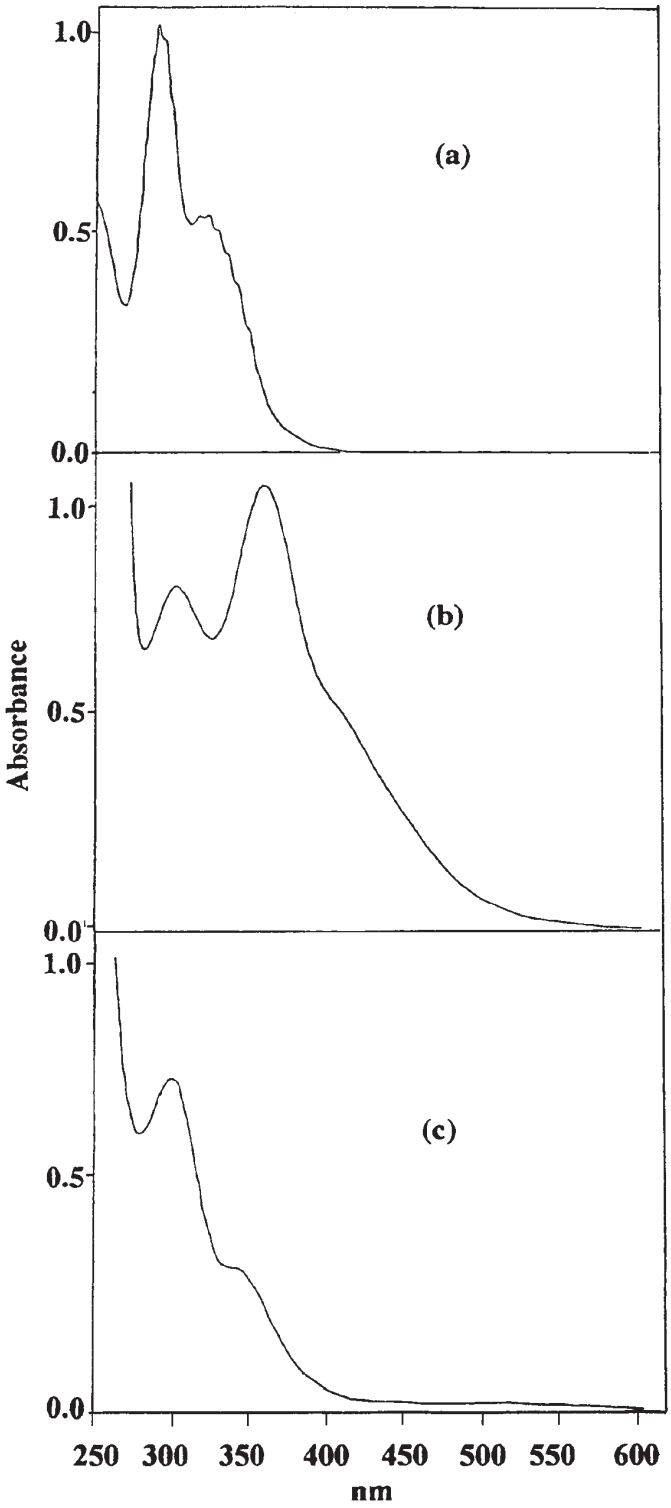
There are references to the use of iodate (IO_3^-) as a co-oxidant with $RuCl_3{\cdot}nH_2O$ as the catalyst for kinetic data on certain oxidations (35). However, under the conditions reported, we found no evidence of electronic spectral change on addition of iodate to $RuCl_3{\cdot}nH_2O$.

(v) With ferricyanide as co-oxidant

We have shown the viability of using $[Fe(CN)_6]^{3-}$ on a preparative scale for the oxidation of primary alcohols to aldehydes and carboxylic acids and for secondary alcohols to ketones with *trans*-$[Ru(OH)_2O_3]^{2-}$ as the catalyst (20) and, above (section I), with *cis*-$[Os(OH)_2O_4]^{2-}$. Three recent reports concern oxidations with $RuCl_3{\cdot}nH_2O$ with $[Fe(CN)_6]^{3-}$ as co-oxidant (entries 14–16). As before (20), there is no evidence of formation of oxoruthenates in such mixtures in the absence of organic substrate. It is likely, as the authors suggest (36–38), that a ruthenium(III) species is responsible for the catalysis.

(vi) With cerium(IV) sulfate

With cerium(IV) sulfate as co-oxidant and $RuCl_3{\cdot}nH_2O$ (entries 17, 18 (39, 40)) a strong electronic absorption at 315 nm in the aqueous layer is observed, but extraction of the solutions with CCl_4 shows RuO_4 to be present in the organic layer. It may be that the band at 315 nm arises from a ruthenium(IV) chloro-aquo complex, the existence of which was suggested by Giddings and Mills (41) from their studies on cerium(IV) sulfate at pH 5 with $RuO_2{\cdot}nH_2O$.



B. Oxidations reported catalyzed by osmium complexes

There is an early but comprehensive review of reactions catalyzed by OsO_4 in base by a variety of co-oxidants (42).

(i) Electronic spectra of oxo-osmates

In Fig. 2 we give the spectra of: (*a*) OsO_4, (*b*) *cis*-$[Os^{VIII}(OH)_2O_4]^{2-}$, and (*c*) *trans*-$[Os^{VI}O_2(OH)_4]^{2-}$; again these are close to those reported for these species (17–19). No molar extinction coefficients (ε) values have been given in the literature (17) for OsO_4 in aqueous solution, but for the 251 and 288 nm bands we measured the ε values to be 1905 and 1048 mol^{-1} cm^{-1}, respectively. For *trans*-$[Os^{VI}O_2(OH)_4]^{2-}$ we measured the spectrum of a known

Fig. 2. Electronic spectra in aqueous solutions of: (*a*) $Os^{VIII}O_4$ in water at pH 7 (0.13 g dm^{-3} (5.2×10^{-4} M) OsO_4); (*b*) *cis*-$[Os^{VIII}(OH)_2O_4]^{2-}$ (0.11 g dm^{-3} (4.5×10^{-4} M) OsO_4 in molar NaOH); (*c*) *trans*-$[Os^{VI}O_2(OH)_4]^{2-}$ (0.165 g dm^{-3} (4.5×10^{-4} M) *trans*-$K_2[OsO_2(OH)_4$ in 0.1 M NaOH).

© 2001 NRC Canada

amount of *trans*-$K_2[Os^{VI}O_2(OH)_4]^{2-}$ dissolved in 0.1 M NaOH. Essentially identical spectra were obtained by reduction of *cis*-$[Os^{VIII}(OH)_2O_4]^{2-}$ in molar KOH with 2-propanol.

(ii) Oxidations by OsO_4 with no co-oxidant

Entry 19 concerns stoichiometric oxidations by OsO_4 in base. *cis*-$[Os(OH)_2O_4]^{2-}$ was suggested as the catalyst precursor (43) and our spectra, showing bands at 325 and 375 nm, confirm this.

(iii) Oxidations with hypochlorite as co-oxidant

Foglia et al. (44) report oxidations with OsO_4 in alkaline hypochlorite (entry 20) and implied that OsO_4 is the active species. We observe a shoulder at 380 nm which probably arises from *cis*-$[Os(OH)_2O_4]^{2-}$ which has a band here (its 300 nm band would be obscured by absorption from hypochlorite).

(iv) With periodate as co-oxidant

The complex *trans*-$Na_6[Os^{VI}O_2\{I(OH)O_5\}_2]\cdot 18H_2O$ is made from *trans*-$K_2[OsO_2(OH)_4]$ and $NaIO_4$ in NaOH (45). Its electronic spectrum in aqueous base shows bands at 325 and 385 nm and it functions as a catalyst, with periodate as co-oxidant, for the oxidation of primary alcohols and alkyl halides to carboxylic acids and of secondary alcohols to ketones (29).

For entries 21–23 (27, 46, 47) in which oxidations are carried out at high pH our electronic spectra show a clearly pronounced shoulder at 380 nm which could arise either from *trans*-$[Os^{VI}O_2\{I(OH)O_5\}_2]^{6-}$ or *cis*-$[Os(OH)_2O_4]^{2-}$. We think it likely that, from the known ease of oxidation of osmium(VI) to (VIII), that the latter is the more likely effective catalyst precursor. Again, as was the case with the analogous ruthenium system, low solubilities prevent Raman spectra being obtained.

(v) With ferricyanide as co-oxidant

The use of $[Fe(CN)_6]^{3-}$ with *trans*-$[Os^{VI}O_2(OH)_4]^{2-}$ at pH 10 is common in organic synthesis for the *cis*-hydroxylation of alkenes (3, 9); in our earlier work (6) we showed that *cis*-$[Os^{VIII}(OH)_2O_4]^{2-}$ is not present in such mixtures at that pH. In entries 24 and 25 (48, 49) the oxidations were carried out at high pH, and our electronic spectra show a band at 325 nm in addition to bands due to $[Fe(CN)_6]^{3-}$. We ascribe this (as discussed above in section I) to *cis*-$[Os(OH)_2O_4]^{2-}$; the 380 nm band of the latter is obscured by the broad 425 nm band of $[Fe(CN)_6]^{3-}$. The Raman data alluded to above also suggest that that *cis*-$[Os(OH)_2O_4]^{2-}$ is present in these mixtures.

C. Oxidations reported catalyzed by osmium and ruthenium complexes

The last entries in Table 3 (26, 27 (47, 50)) concern oxidations with a mixture of OsO_4 and $RuCl_3\cdot nH_2O$ with periodate in base. The mixtures show electronic spectral bands at 325 and 385 nm; it is possible that a mixture of *trans*-$[RuO_2\{I(OH)O_5\}_2]^{6-}$ (which has a band at 389 nm (29)) and *cis*-$[Os(OH)_2O_4]^{2-}$ (bands at 325 and 385 nm (6)) is present in both cases. Unfortunately, low solubilities prevented the collection of Raman data.

Experimental

Materials

Chemicals were purchased from Aldrich (hydrated ruthenium trichloride and osmium tetroxide were obtained from Johnson, Matthey) and used without further purification.

The use of *cis*-$[Os^{VIII}(OH)_2O_4]^{2-}$ as a catalyst for oxidative amine dehydrogenation and alcohol oxidations.

Preparation of the cis-*$[Os(OH)_2O_4]^{2-}$ – $[Fe(CN)_6]^{3-}$ reagent*

OsO_4 (0.02 g, 0.08 mmol) was dissolved in 25 cm^3 of aqueous molar NaOH and excess $K_3[Fe(CN)_6]$ (9.9 g, 30 mmol) was added to give an orange solution.

Preparation of cis-*$[Os(OH)_2O_4]^{2-}$ – $S_2O_8^{2-}$ and* cis-*$[OsO_4(OH)_2]^{2-}$ – BrO_3^-*

OsO_4 (0.02 g, 0.08 mmol) was dissolved in 25 cm^3 of aqueous molar NaOH to give an orange solution of *cis*-$[OsO_4(OH)_2]^{2-}$. Excess $K_2S_2O_8$ (9.9 g, 30 mmol) or 1.5 g (10 mmol) of $NaBrO_3$ was then added.

Catalytic dehydrogenation of amines to nitriles

The reactions (Table 1) were performed at room temperature by dropwise addition of the amines (RCH_2NH_2, 2 mmol) over a period of 5 min to a vigorously stirred solution (25 cm^3) of the *cis*-$[Os(OH)_2O_4]^{2-}$ – $[Fe(CN)_6]^{3-}$ reagent and acetonitrile (25 cm^3). Subsequent work with benzylamine and 2-chlorobenzylamine shows that the same results were obtained with only 5 cm^3 of CH_3CN. The initial colour of the reaction mixture is orange; on addition of amine the solution darkens and some pale-yellow $K_4[Fe(CN)_6]$ is deposited. When the reaction is complete the original orange colour of the mixture reappears. The mixture was then extracted with chloroform (3 × 25 cm^3), these extracts dried over anhyd $MgSO_4$, and the chloroform removed. Products were characterized by ^1H NMR, IR spectra, and melting points of solids; liquids were characterized by GC–MS.

Catalytic oxidation of alcohols

Reactions (Table 2) were carried out at room temperature, and the oxidation of cyclohexanol is typical. To 25 cm^3 of the *cis*-$[Os(OH)_2O_4]^{2-}$ – $[Fe(CN)_6]^{3-}$ reagent made as described above was added 0.22 g (2 mmol) of cyclohexanol and 25 cm^3 of acetonitrile, and the mixture stirred for the stated time. The colour changes are similar to those observed for the amine dehydrogenations. The mixture was then extracted with chloroform (3 × 25 cm^3), the extracts combined and dried over anhyd $MgSO_4$, the chloroform evaporated off, and the product characterized by GC or, in the cases of carboxylic acids, by isolation.

The nature of oxoruthenates or oxo-osmates present in solutions

In all cases (Table 3) the cited literature procedure was followed but no substrate added. The solvent after mixture of the ruthenium or osmium precursor, co-oxidant and buffer (if appropriate) was diluted if necessary, using the same solvent or solvent mixture at the same pH as in the literature so that good quality electronic spectra could be obtained.

© 2001 NRC Canada

Spectroscopic data

In general the optimum ruthenium or osmium concentrations for measurements of electronic spectra were ca. 4×10^{-4} M (see also legends for Figs. 1 and 2. Note that for Fig. 1(*a*) the concentration of RuO_4 given is approximate since the solution was made by passing RuO_4 vapour into water). For the less sensitive Raman technique the ruthenium or osmium concentrations had to be substantially higher: for *cis*-$[Os(OH)_2O_4]^{2-}$ in $[Fe(CN)_6]^{3-}$ 0.02 M of the former and 0.6 M of the latter in molar NaOH was used, while for Raman spectral demonstration of the oxidation of *trans*-$[OsO_2(OH)_4]^{2-}$ to *cis*-$[OsO_4(OH)_2]^{2-}$ by $[Fe(CN)_6]^{3-}$ in base the same concentrations were used. For detection of $[RuO_4]^-$ in hypochlorite 0.01 M $RuCl_3 \cdot nH_2O$ was used in aqueous 0.3 M hypochlorite. For detection of RuO_4 in periodate and also in bromate, 0.25 M $RuCl_3 \cdot nH_2O$ was used in molar aq $NaIO_4$ and in 2 M aq $NaBrO_3$, respectively.

Instrumentation

Electronic spectra were measured in 1 cm quartz cuvettes on a PerkinElmer Lambda 2 instrument. Raman spectra were measured on a PerkinElmer 1760X Fourier Transform Raman instrument with 1064 nm Nd-YAG excitation with a power of 2 W, and on a Dilor LabRam Infinity instrument with 632 nm. He–Ne excitation and 532 nm frequency-doubled Nd-YAG excitations, as appropriate, each at 5 mW.

Mass spectra were measured on a PerkinElmer Autosystem instrument with a PerkinElmer stainless-steel column packed with 5% Carbowax 20M on Chromosorb (DCMS treated). GC–MS characterization was carried out on a Micromass Autospec with a Hewlett–Packard 5890 gas chromatograph and an SGE BPX5 column.

Conclusions

The *cis*-$[Os(OH)_2O_4]^{2-}$ – $[Fe(CN)_6]^{3-}$ reagent will, in the presence of acetonitrile, oxidatively dehydrogenate primary amines to nitriles and oxidise primary alcohols to carboxylic acids and secondary alcohols to ketones at room temperatures. Ferricyanide is the best co-oxidant while others (persulfate, bromate, hypochlorite) are less effective.

Studies by electronic and Raman spectroscopies of solutions in a wide variety of procedures in the literature using ruthenium or osmium catalysts with a number of co-oxidants (hypochlorite, periodate, bromate, iodate, ferricyanide, and cerium(IV)) were made to identify the nature of the catalyst or catalyst precursor.

Acknowledgements

We thank the University of London Intercollegiate Research Service (ULIRS) for the Raman facilities, Mr. John Barton for the GC–MS studies, and Johnson Matthey for loan of ruthenium trichoride and osmium tetroxide.

Synthesis and molecular structures of monooxo aryl complexes of osmium(VI)

Man-Kit Lau, Joyce L.C. Chim, Wing-Tak Wong, Ian D. Williams, and Wa-Hung Leung

Abstract: Reaction of [OsO_4] with C_7H_7MgBr (C_7H_7 = 2-methylphenyl) followed by column chromatography afforded the reported osmium tetraaryl [$Os(C_7H_7)_4$] along with the oxo-osmium(VI) ([$OsO(C_7H_7)_4$]) (**1**) (13%) and the dioxo-osmium(VI) ([$OsO_2(C_7H_7)_2$]) (**2**) (25%) complexes. Treatment of [OsO_4] with C_8H_9MgBr (C_8H_9 = 2,5-dimethylphenyl) gave a mixture of [$Os(C_8H_9)_4$] (**3**) (34%) and [$OsO(C_8H_9)_4$] (**4**) (4%) while that with C_8H_9OMgBr (C_8H_9O = 4-methoxy-2-methylphenyl) afforded [$OsO(C_8H_9O)_4$] (**5**) in 20% yield. Oxidation of **3** with 3-chloroperoxybenzoic acid afforded **4** in good yield. The solid-state structures of **1** and **4** have been established by X-ray crystallography. Crystals of **1** are tetragonal with a = 13.080(1) and c = 6.6506(5) Å, V = 1137.9(1) Å^3, Z = 2, and space group of $P4/n$; while those of **4** are tetragonal with a = 13.593(2) and c = 7.377(2) Å, V = 1363.0(5) Å^3, Z = 4, and space group of $P4/n$. The geometry around osmium in both complexes is square pyramidal with the oxo ligand occupying apical position. The Os—O and Os—C distances in **1** are 1.652(2) and 2.084(1) Å, respectively, while those in **4** are 1.688(7) and 2.088(4) Å, respectively. The cyclic voltammograms of the monooxo aryl osmium(VI) compounds show reversible Os(VI/V) couple at around –1.4 V vs. ferrocene/ferrocenium couple.

Key words: osmium(VI), oxo aryl complexes.

Résumé : La réaction du [OsO_4] avec du C_7H_7MgBr (C_7H_7 = 2-méthylphényle), suivie d'une chromatographie sur colonne permet d'isoler le tétraarylosmium attendu [$Os(C_7H_7)_4$] aux côtés de complexes oxo-osmium(VI) [$OsO(C_7H_7)_4$] (**1**) (13%) et dioxo-osmium(VI) [$OsO_2(C_7H_7)_2$] (**2**) (25%). Le réaction du [OsO_4] avec du C_8H_9MgBr (C_8H_9 = 2,5-diméthylphényle) conduit à un mélange de [$Os(C_8H_9)_4$] (**3**) (34%) et de [$OsO(C_8H_9)_4$] (**4**) (4%) alors que celle avec C_8H_9MgOBr (C_8H_9 = 4-méthoxy-2-méthylphényle) conduit au [$OsO(C_8H_9O)_4$] (**5**) avec un rendement de 20%. L'oxydation du produit **3** par de l'acide 3-chloroperbenzoïque conduit au produit **4** avec un bon rendement. Les structures des composés **1** et **4** ont été déterminées à l'état solide par diffraction des rayons X. Les cristaux de **1** sont tétragonaux, groupe d'espace $P4/n$, avec a = 13,080(1) et c = 6,6506(5) Å, V = 1137,9(1) Å^3 et Z = 2 alors que ceux du composé **4** sont tétragonaux, groupe d'espace $P4/n$, avec a = 13,593(2) et c = 7,3776(2) Å et Z = 4 V = 1363,0(5) Å^3. Dans chacun des complexes, la géométrie autour de l'osmium est de type pyramide carrée de laquelle le ligand oxo se trouve en position apicale. Les distances Os—O et Os—C dans le composé **1** sont respectivement de 1,652(2) et 2,084(1)Å alors que celles dans le composé **4** sont respectivement de 1,688(7) et 2,088(4) Å. Dans les voltampérogrammes cycliques des composés monooxo aryl osmium(VI), on observe le couple réversible Os(VI/V) aux environs de –1,4 V par rapport au couple ferrocène/ferrocénium.

Mots clés : osmium(VI), complexes oxo aryles.

[Traduit par la Rédaction]

Introduction

Organometallic oxides are of interest due to their relevance to the active intermediates in metal-catalyzed oxidation of organic compounds (1, 2). Some transition metal oxo alkyls, notably [$Re(CH_3)O_3$], are also used as stoichiometric and catalytic reagents for organic transformations (2). While oxo alkyls of oxophilic early transition metals are well-documented, there are relatively few examples of the later transition-metal congeners. Wilkinson and co-workers (3, 4) first reported the synthesis of high-valent osmium aryls and oxo aryls by arylation of [OsO_4] with Grignard reagents ArMgBr (Ar = aryl). It was found that the *ortho*-methyl substituent in Ar has a significant effect on the nature of the arylation products. Thus, reaction of [OsO_4] with di*ortho*-substituted mesMgBr (mes = 2,4,6-trimethylphenyl) afforded [$OsO_2(mes)_2$] (3) whereas interactions of [OsO_4] with mono*ortho*-substituted or unsubstituted ArMgBr (e.g., Ar = 2-methylphenyl or phenyl) gave homoleptic Os(IV) aryls [$Os(Ar)_4$] (4). However, to our knowledge, no oxo(tetraaryl)osmium(VI) complexes have been isolated al-

though oxo(tetraalkyl)osmium(VI) complexes have been prepared by alkylation of [OsO_4] (5) or oxo-osmium glycolates (6). In view of the low yield for the synthesis of [$Os(C_7H_7)_4$], we suspect that there may be other unidentified product(s) for the arylation of [OsO_4]. To this end, we set out to reinvestigate the reaction between [OsO_4] and ArMgBr, and to separate the products by column chromatography. We here describe the isolation, molecular structures, and electrochemistry of the first monooxo aryl complexes of osmium(VI).

Experimental

All manipulations, unless otherwise stated, were carried out in air. Solvents were purified, dried, and distilled prior to use. [OsO_4] was obtained from Strem Ltd. ArMgBr in Et_2O were prepared from commercially available aryl bromides and Mg.

Spectrometers used were as follows: IR spectra (in KBr discs) PerkinElmer 16 PC FT IR; mass spectra on a Finnigan TSQ 7000; UV–vis spectra Milton-Roy Spectronic 3000 diode array; 300 MHz ^{1}H NMR spectra Bruker ALX 300 (chemical shifts in ppm relative to $SiMe_4$). Cyclic voltammetry was performed with a Princeton Applied Research (PAR) Model 273A potentiostat. The working and reference electrodes were glassy carbon and $Ag/AgNO_3$ (0.1 M in acetonitrile), respectively, and the scan rate was 100 mV s^{-1}. Formal potentials ($E_{1/2}$) were measured in CH_2Cl_2 solutions with 0.1 M [*n*-NBu_4][PF_6] as supporting electrolyte and reported with reference to the ferrocenium/ferrocene couple ($Cp_2Fe^{+/0}$). Elemental analyses were performed by Medac Ltd., Surrey, U.K.

[$OsO(C_7H_7)_4$] (1) and [$OsO_2(C_7H_7)_2$] (2) (C_7H_7 = 2-methylphenyl)

These complexes were synthesized using a modification of the Wilkinson's procedure. To a solution of [OsO_4] (1 g, 3.94 mmol) in THF (30 mL) at –78°C were added 7 equiv of 2-methylphenylmagnesium bromide (17.3 mL of a 1.6 M solution in Et_2O), and the mixture was stirred for 45 min. The resulting purple mixture was then warmed to room temperature, stirred for a further 2 h, and evaporated to dryness. The residue was extracted into CH_2Cl_2 in air and subjected to column chromatography (silica gel). Elution with hexane, CH_2Cl_2–hexane (1:4), and acetone afforded purple [$Os(C_7H_7)_4$] (10%), orange **1** (13%), and green **2** (25%), respectively. Recrystallization of **1** from CH_2Cl_2–hexane led to isolation of orange blocks, which were suitable for X-ray diffraction.

*Characterization data for **4***

FT IR (KBr, cm^{-1}): 986 (Os=O). FAB-MS *m*/*z*: 572 (M^+). UV–vis (CH_2Cl_2) λ_{max} (nm) (ε_{max} (M^{-1} cm^{-1})): 248 (22 000), 350 (8250). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.99 (s, 12H, CH_3), 2.25 (s, 12H, CH_3), 5.78 (s, 4H, H_o), 6.75 (d, J = 7.5 Hz, 4H, H_p), 7.13 (d, J = 7.5 Hz, 4H, H_m). $E_{1/2}$ (V): –1.35 [Os(VI/V)]. Anal. calcd. for $C_{32}H_{36}OOs$: C 59.0, H 4.9; found: C 58.3, H 4.9.

*Preparation of **4** from **3***

To a solution of **3** (0.5 g, 0.08 mmol) in CH_2Cl_2 (10 mL) was added 1.5 equiv of 3-chloroperoxybenzoic acid or *t*-BuOOH at room temperature. The reaction mixture was stirred for 2 h, evaporated to dryness, and subjected to column chromatography (silica gel). The product was eluted with hexane and recrystallized from CH_2Cl_2–hexane to give orange crystals (80% yield), which was identified as **4** by ^{1}H NMR spectroscopy and mass spectrometry. Recrystallization of **4** from CH_2Cl_2–hexane afforded orange blocks, which were suitable for X-ray diffraction study.

[$OsO(C_8H_9O)_4$] (5)

To a solution of [OsO_4] (0.5 g, 2.0 mmol) in Et_2O (20 mL) at –40°C was added 7 equiv of 4-methoxy-2-methylphenylmagnesium bromide (20.6 mL of a 0.67 M solution in Et_2O), and the mixture was slowly warmed to room temperature and stirred for 2 h. The solvent was pumped off and the residue was extracted into CH_2Cl_2 in air. Column chromatography (silica gel, eluant: CH_2Cl_2–Et_2O (1:5)) followed by recrystallization from CH_2Cl_2–hexane afforded a brown solid. Yield: 0.25 g, 20%. FAB-MS *m*/*z*: 693 [M + 1]$^+$. FT IR (KBr, cm^{-1}): 982 (OsO). UV–vis (CH_2Cl_2) λ_{max} (nm) (ε_{max} (M^{-1} cm^{-1})): 254 (26 700), 350 (11 700). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.28 (s, 12H, CH_3), 3.76 (s, 12H, OCH_3), 5.77 (d, J = 8.8 Hz, 4H, H_o), 6.41 (d, J = 8.8 Hz,

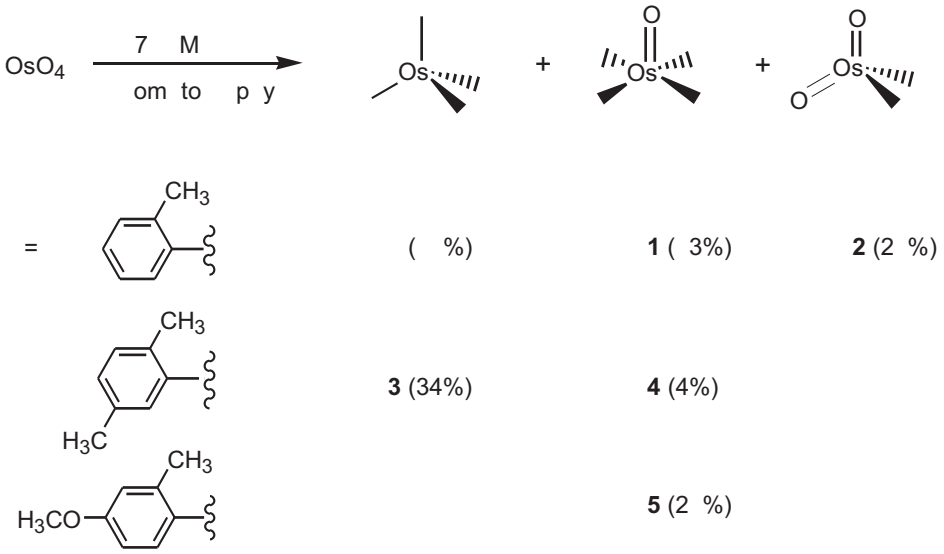
X-ray crystallography

Pertinent crystallographic data and other experimental details for complexes **1** and **4** are summarized in Table 1. Data for **1** and **4** were collected on a Bruker CCD diffractometer and a Siemens P4 diffractometer, respectively, at room temperature using graphite-monochromated Mo K_α radiation (λ = 0.71073 Å). Data were corrected for Lorentz and polarization effects. Absorption corrections are semiempirical based on ψ-scan data. Structures **1** and **4** were solved by direct methods and refined by full-matrix least-squares on *F* and F^2, respectively. Hydrogen atoms were included and fixed in their idealized positions (C-H 0.95 Å). Calculations were carried out using the teXsan (7) (for **1**) and SHELXL (8) (for **4**) crystallographic software packages. Complete listings of bond lengths and angles, final atomic coordinates of non-hydrogen atoms with thermal parameters, and anisotropic thermal parameters are included as supplementary material.[2]

Results and Discussion



Synthesis

The preparations of osmium oxo aryl complexes are summarized in Scheme 1. Wilkinson and co-workers (4*a*) first reported the synthesis of $[Os(C_7H_7)_4]$ by the reaction of $[OsO_4]$ with C_7H_7MgBr. The osmium tetraaryl was obtained in 29% yield after extraction into light petroleum and subsequent recrystallization under nitrogen. However, we found that when the reaction mixture was exposed to air and then chromatographed (silica gel) in air, in addition to $[Os(C_7H_7)_4]$, the oxo-osmium species $[OsO(C_7H_7)_4]$ (**1**) and $[OsO_2(C_7H_7)_2]$ (**2**) species were isolated in 13 and 25% yield, respectively. The relative yields of $[Os(C_7H_7)_4]$, **1**, and **2** for the reaction were, however, found to be dependent on reaction conditions, workup procedure, and some unknown factors that have not been optimized yet. It appears that the oxo complexes **1** and **2** were derived directly from reaction of $[OsO_4]$ with C_7H_7MgBr, instead of via aerobic oxidation of $[Os(C_7H_7)_4]$, because $[Os(C_7H_7)_4]$, **1**, and **2** are all air stable in solution and under chromatographic conditions. Like $[Os(C_7H_7)_4]$ (3*a*), complex **1** exhibits a symmetric ^{1}H NMR spectrum featuring a single *ortho*-methyl resonance at δ 2.32 at room temperature, indicating that the 2-methylphenyl ligands are free to rotate around the Os—C bonds at the NMR timescale. The UV–vis spectrum of **1** in CH_2Cl_2 displays absorption bands at ca. 350 (ε_{max} = 8700 M^{-1} cm^{-1}) and 248 nm (sh, ε_{max} = 23 000 M^{-1} cm^{-1}). The former band is tentatively attributed to a charge transfer transition due to the Os=O moiety while the latter probably arises from an intraligand transition because a similar absorption was also found for $[Os(C_7H_7)_4]$. The IR Os—O

[2] Crystal data for **1** and **4** may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada DUD No. 3276. For information on obtaining material electronically go to http://www.nrc.ca/cisti/irm/unpub_e.shtml. This supplementary material has also been deposited with the Cambridge Crystallographic Centre (deposition nos. 148 810 and 148 809, respectively), and can be obtained on request from: The Director, Cambridge Crystallographic Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

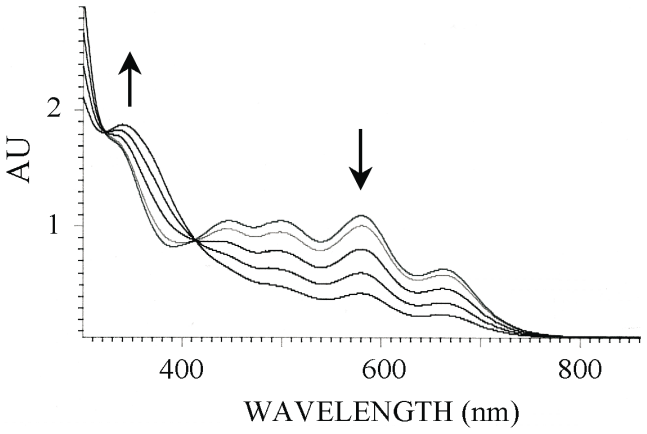


Scheme 1.

stretching frequency for **1** was observed at 990 cm^{-1}, which is comparable to that for $[OsO(CH_3)_4]$ (994 cm^{-1}) (6*a*) but is lower than that for $[OsO(CH_2SiMe_3)_4]$ (1054 cm^{-1}) (5*b*). Complex **2**, which presumably has a similar tetrahedral geometry as $[OsO_2(mes)_2]$ (4*a*), exhibits $\nu(OsO)_{as}$ at 1000 and 980 cm^{-1}. Neither **1** nor **2** reacted with oxygen abstractors such as tertiary phosphines and Si_2Cl_6. Attempts to reduce **2** by cobaltocene led to recovery of the starting material.

To further investigate the substituent effect of Ar on the arylation of $[OsO_4]$, disubstituted phenyl Grignard were used as the alkylation agents. Treatment of $[OsO_4]$ with 7 equiv of 2,5-dimethylphenylmagnesium bromide (C_8H_9MgBr) in Et_2O afforded purple $[Os(C_8H_9)_4]$ (**3**) (33%) and orange $[OsO(C_8H_9)_4]$ (**4**) (4%), which were separated by column chromatography. On the other hand, reaction of $[OsO_4]$ with 4-methoxy-2-methylphenylmagnesium bromide (C_8H_9OMgBr) in Et_2O gave the oxo-Os(VI) compound $[OsO(C_8H_9O)_4]$ (**5**) as the sole isolable product in 20% yield. Complexes **3**–**5** are soluble in common organic solvents including hexanes, ether, and methanol. They are air-stable in solution and could be chromatographed in air without decomposition. It appears that the presence of the 5-methyl substituent in the aryl group enhances the production of Os(IV) tetraaryl while the 4-methoxy substituent favors oxo-Os(VI) formation although the origin of such a substituent effect is not well understood. The ^1H NMR spectrum of **3** shows two singlets at δ 2.22 and 2.27 due to the *ortho*- and *meta*-methyl protons. Oxidation of **3** with $[Ag(CF_3SO_3)]$ afforded the osmium(V) species $[Os(C_8H_9)_4]^+$, which exhibits an isotropic EPR signal at $g = 2.04$ at –120°C. A similar *g* value was found for the structurally characterized osmium(V) complex $[Os(C_7H_7)_4][CF_3SO_3]$ (3*b*, 9). Treatment of **3** with single-oxygen donors such as 3-chloroperoxybenzoic acid and *t*-BuOOH gave **4** in good yield. Figure 1 shows a spectral trace for the reaction of **3** with *t*-BuOOH in CH_2Cl_2. Upon addition of ca. 1 equiv of *t*-BuOOH, the d-d bands for **3** centered at 447, 579, and 662 nm disappeared and concomitantly an absorption at 352 nm attributable to the charge transfer band for **4** appeared. The observation of isosbestic points at ca. 325 and 420 nm suggests that the oxo transfer

Fig. 1. Optical spectral trace for the reaction between $[Os(C_8H_9)_4]$ (**3**) and *t*-BuOOH in CH_2Cl_2.

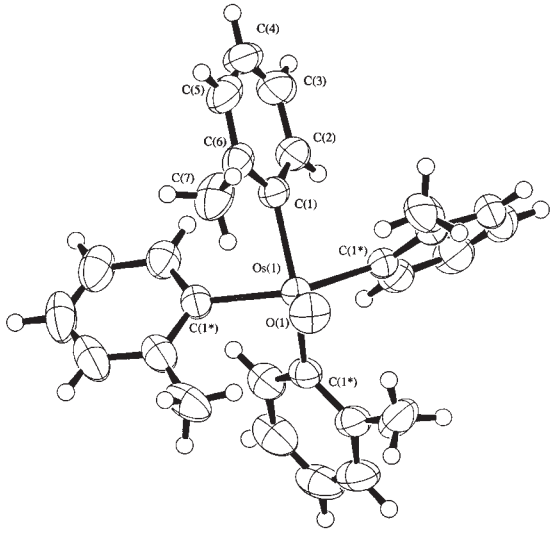
from *t*-BuOOH to **3** is a clean, single-step process. The charge transfer band for methoxy-substituted **5** (385 nm) was found at a longer wavelength relative to those for **4** (352 nm) and **1** (350 nm). The ^1H NMR spectrum of **4** shows two singlets at δ 1.99 and 2.25 due to the *meta*- and *ortho*-methyl protons while the methyl and methoxy proton signals for **5** were observed at δ 2.28 and 3.76, respectively. The IR Os—O stretching frequencies for **4** and **5** (982 and 986 cm^{-1}, respectively) are comparable to that for **1**.

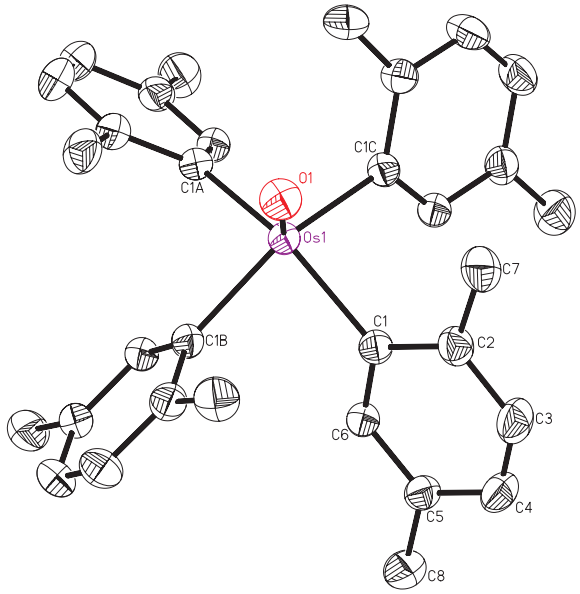
Crystal structures

Complexes **1** and **4** have been unambiguously characterized by X-ray crystallography. The corresponding molecular structures with selected bond lengths and angles are shown in Figs. 2 and 3. Complex **1** is isostructural with the previously reported Re(VI) analogue $[ReO(C_7H_7)_4]$, which also exhibits a fourfold molecular symmetry (10). The geometry around osmium in **1** and **4** is pseudo-square pyramidal with the oxo ligand occupying the apical position. The Os atoms are situated above the C4 plane with the O-Os-C angles of 110.4(4) and 110.82(12)° for **1** and **4**, respectively, (cf.

© 2001 NRC Canada

Fig. 2. Molecular structure of $[OsO(C_7H_7)_4]$ (**1**). Selected bond lengths and angles are: Os(1)—O(1) 1.652(2) and Os(1)—C(1) 2.084(1) Å; O(1)-Os(1)-C(1) 110.04(4), C(1)-Os(1)-C(1*) 82.59(3), and C(1)-Os(1)-C(1*) 137.91(8)°.





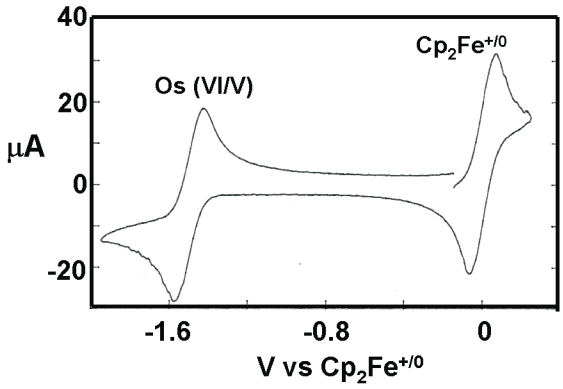


Fig. 3. Molecular structure of $[OsO(C_8H_9)_4]$ (**4**). Selected bond lengths and angles are: Os(1)—O(1) 1.688(7) and Os(1)—C(1) 2.088(4) Å; O(1)-Os(1)-C(1) 110.82(12), C(1)-Os(1)-C(1B) 82.74(8), and C(1)-Os(1)-C(1A) 138.4(2)°.

106.0(2)° for $[ReO(C_7H_7)_4]$ (10)). Like $[ReO(C_7H_7)_4]$, the *ortho*-methyl groups in **1** and **4** are found on the same side as the oxo function possibly due to steric reasons. The Os—O and average Os—C distance for **1** are 1.652(2) and 2.084(1) Å, respectively, while those for **4** are 1.688(7) and 2.088(4) Å, respectively. The Os—C distances are comparable to those in $[OsO(CH_2SiMe_3)_4]$ (average 2.078 Å) (5*b*) and $[ReO(C_7H_7)_4]$ (2.063 Å) (10) but is slightly shorter than that in $[Os(C_7H_7)_4]$ (average 1.997 Å) (4*a*). The Os—O distances are short and similar to that in $[OsO(CH_2SiMe_3)_4]$ (1.692(6) Å) (5*b*).

Fig. 4. Cyclic voltammogram of $[OsO(C_8H_9)_4]$ (**4**) in CH_2Cl_2 at a glassy carbon electrode. Scan rate = 100 mV s^{-1}.

Electrochemistry

The formal potentials for the osmium aryl complexes have been determined by cyclic voltammetry in CH_2Cl_2. The tetraaryl complex **3** exhibits reversible couples at 0.24 and –1.48 V vs. $Cp_2Fe^{+/0}$, which are assigned to the metal-centered Os(V/IV) and Os(IV/III) couples, respectively. The $E_{1/2}$ ([Os(V/IV)]) for **3** is less anodic than that for $[Os(C_7H_7)_4]$ (0.33 V) due to inductive effect of *meta*-methyl substitutents in the aryl groups. The cyclic voltammogram of **4** (Fig. 4) shows a reversible reduction couple at –1.35 V, which is assigned to the Os(VI/V) couple. Similarly, the Os(VI/V) couples for **1** and **5** were observed at –1.41 and –1.37 V, respectively. An irreversible oxidation wave at 0.93 V, which is tentatively assigned to the Os(VII/VI) oxidation, was also found for **5**. For comparison, the Os(VII/VI) couple for $[Os(O)(CH_2SiMe_3)_4]$ was observed at 1.19 V vs. Ag/AgCl (5*b*). The dioxo-osmium(VI) complex **2** exhibits the Os(VI/V) couple at –1.14 V, which is similar to that for $[OsO_2(mes)_2]$ (–1.28 V) (4*b*). In general, the $E_{1/2}$ ([Os(VI/V)]) for $[OsO(aryl)_4]$ are more negative than those for $[OsO_2(aryl)_2]$, indicating that the σ-aryls are very strong donor ligands.

Conclusions

In summary, we found that depending on the nature of aryl ligand, reaction of $[OsO_4]$ with arylmagnesium bromide produced a mixture of osmium(IV) tetraaryl, oxo(tetraaryl)osmium(VI), and dioxo(diaryl)osmium(VI) complexes, which could be separated by column chromatography. It appears that the presence of the 5-methyl substituent in the aryl ligand enhances the formation of Os(IV) tetraaryl while the 4-methoxy substituent favors the formation of $[OsO(aryl)_4]$. Oxidation of $[Os(C_8H_9)_4]$ with 3-choroperoxybenzoic acid gave $[OsO(C_8H_9)_4]$ in good yield. The oxo(tetraaryl)osmium(VI) complexes exhibit reversible Os(V/IV) couples at ca. –1.4 V while the Os(VI/V) couples for dioxodiarylosmium(VI) occur at ca. –1.1 V vs. $Cp_2Fe^{+/0}$.

One-electron reduction of the γ*-isomer of $[S_2W_{18}O_{62}]^{4-}$ leads to isolation of the α-isomer

Peter J.S. Richardt, Jonathon M. White, Peter A. Tregloan, Alan M. Bond, and Anthony G. Wedd

Abstract: Bu_4N^+ salts of $[S_2W_{18}O_{62}]^{5-}$ and $[S_2W_{18}O_{62}]^{6-}$ can be isolated by electro reduction of γ*-$(Bu_4N)_4[S_2W_{18}O_{62}]$ in MeCN. α-$(Bu_4N)_5[S_2W_{18}O_{62}]\cdot 4MeCN$ crystallizes in space group *C*2/*c* with *a* = 26.226(2) Å, *b* = 15.570(2) Å, *c* = 38.407(2) Å, β = 115.59(2)°, *V* = 14 145(2) Å^3, and *Z* = 8. The observations indicate that a γ* ↔ α isomerization is associated with the $[S_2W_{18}O_{62}]^{4-}$– $[S_2W_{18}O_{62}]^{5-}$ couple. However, the transformation could not be detected on the timescale of cyclic voltammetry up to a scan rate of 10 V s^{-1}. The available data suggest that either: (*i*) the γ* ↔ α equilibrium favors one of the isomers in solution for both redox states, or (*ii*) the isomerization is slow on the cyclic voltammetric timescale but the differences in $E_{1/2}$ values for the α-$[S_2W_{18}O_{62}]^{4-}$–$[S_2W_{18}O_{62}]^{5-}$ and γ*-$[S_2W_{18}O_{62}]^{4-}$–$[S_2W_{18}O_{62}]^{5-}$ couples cannot be resolved by cyclic voltammetry.

Key words: polyoxometalates, synthesis, electrochemistry, isomerization.

Résumé : On peut isoler les sels de Bu_4N^+ de $[S_2W_{18}O_{62}]^{5-}$ et de $[S_2W_{18}O_{62}]^{6-}$ par électroréduction du γ*-$(Bu_4N)_4[S_2W_{18}O_{62}]$ dans le MeCN. Le α-$(Bu_4N)_5[S_2W_{18}O_{62}]\cdot 4MeCN$ cristallise dans groupe d'espace *C*2/*c*, avec *a* = 26,226(2) Å, *b* = 15,570(2) Å et *c* = 38,407(2) Å, β = 115,59(2)°, *V* = 14 145(2) Å^3 et *Z* = 8. Les observations indiquent qu'une isomérisation γ* ↔ α est associée au couple $[S_2W_{18}O_{62}]^{4-}$–$[S_2W_{18}O_{62}]^{5-}$. Toutefois, il n'est pas possible de détecter cette transformation à l'échelle de temps de la voltampérométrie cyclique jusqu'à des vitesses de balayage de 10 V s^{-1}. Les données disponibles suggèrent (*i*) que, en solution, l'équilibre γ*↔ α favorise l'un des isomères pour les deux états redox ou (*ii*) que l'isomérisation est lente à l'échelle de temps de la voltampérométrie cyclique, mais que les différences dans les valeurs de $E_{1/2}$ pour les couples α-$[S_2W_{18}O_{62}]^{4-}$–$[S_2W_{18}O_{62}]^{5-}$ et γ*-$[S_2W_{18}O_{62}]^{4-}$–$[S_2W_{18}O_{62}]^{5-}$ ne peuvent pas être résolues par voltampérométrie cyclique.

Mots clés : polyoxométalates, synthèse, électrochimie, isomérisation.

Introduction

The $[S_2Mo_{18}O_{62}]^{4-}$ ion as its Bu_4N^+ salt exists as the α-isomer of nominal D_{3h} point symmetry (Fig. 1) (1). In contrast, the equivalent tungsten salt contains the γ*-isomer (Fig. 1, D_{3d}) (2), derived formally from the α-form by 60° rotation of one half of the ion relative to the other, followed by 60° rotation of both trinuclear "caps" (3). The two hexanuclear "belts" are eclipsed in the α-form but staggered in the γ*-form.

The rich electrochemistries of both α-$[S_2Mo_{18}O_{62}]^{4-}$ and γ*-$[S_2W_{18}O_{62}]^{4-}$ have been explored recently (2, 4, 5). These studies have provided an understanding of the complex but highly reversible electrochemical behavior characteristic of these anions and those of polyoxometalate systems in general (6). Multiple pathways for correlated reduction and protonation are present in both the molybdenum and tungsten systems, but only a single fast oxidation pathway is available. As the reduced forms of $[S_2W_{18}O_{62}]^{4-}$ are weaker bases than those of $[S_2Mo_{18}O_{62}]^{4-}$, the individual oxidation pathways are different (2).

A number of reduced forms of $[S_2Mo_{18}O_{62}]^{4-}$ have been isolated in substance[2] (4, 7, 8). The α-isomer is present in structurally characterized salts of the oxidized form and (2 e$^-$, H$^+$)- and (4 e$^-$, 3H$^+$)-reduced forms[2] (8).

The present work reports synthesis and characterization of Bu_4N^+ salts of 1 e$^-$- and 2 e$^-$-reduced forms of $[S_2W_{18}O_{62}]^{4-}$. Intriguingly, one-electron reduction of the γ*-isomer of $[S_2W_{18}O_{62}]^{4-}$ converts it to the α-isomer. A number of systems that exhibit reversible changes in molecular geometry upon simple electron-transfer are known (9, and refs. therein), but not with the multiple breaking and making of bonds characteristic of the present example.

Experimental

Reagents

$Na_2WO_4\cdot 2H_2O$ and $Na_2MoO_4\cdot 2H_2O$ were reagent grade chemicals from APS Ajax Finechem, Melbourne, Australia.

 DOI: 10.1139/cjc-79-5/6-613 © 2001 NRC Canada

Fig. 1. Ball-and-stick and polyhedral representations of the α- and γ*-isomers of $[S_2W_{18}O_{62}]^{4-}$.

CH_3CN, Et_2O, and EtOH were analytical grade chemicals from APS Ajax Finechem. Bu_4NBr was purchased from Aldrich, Milwaukee, WI. The Bu_4N^+ salt of γ*-$[S_2W_{18}O_{62}]^{4-}$ was synthesized as described previously (2).

Synthesis

α-$(Bu_4N)_5[S_2W_{18}O_{62}]$·4MeCN

Controlled potential electrolysis was carried out at a carbon-tube- or mercury-pool-working electrode. A solution of γ*-$(Bu_4N)_4[S_2W_{18}O_{62}]$ (2.0 mM, 1×10^{-4} mol) in MeCN (50 cm^3, 0.1 M Bu_4NClO_4) was electrolyzed at –0.40 V vs. Fc^+/Fc. The reduction was monitored by coulometry, and the average oxidation state of the product confirmed by the position of zero current in a rotating-disk electrode-voltammogram (RDEV). Complete precipitation of the dark blue product occurred upon addition of EtOH with vigorous stirring. The solid was filtered off, washed with EtOH (× 2) and Et_2O, and dried under vacuum (0.46 g, 82%). Recrystallization from hot MeCN yielded dark blue microcrystals. Anal. calcd. for $C_{80}H_{180}N_5O_{62}S_2W_{18}$ (%): C 17.23, H 3.25, N 1.26, S 1.15, W 59.33; found: C 17.46, H 3.13, N 1.30, S 1.18, W 59.60. The MeCN molecules of crystallization detected by X-ray crystallography (see below) appear to be absent in the analytical samples, which were dried under vacuum. UV–vis (MeCN) λ_{max} (nm) (ε (M^{-1} cm^{-1})): 855 (4.2×10^3), 740 (3.7×10^3). FT-IR (KBr pellet) (cm^{-1}): 1175 (m) (WOS), 1075 (m) (WOS), 975 (vs) (W=O), 960 (sh) (W=O), 880 (sh) (WOW), 840 (s) (WOW), 740 (sh) (WOW).

$(Bu_4N)_6[S_2W_{18}O_{62}]$

This salt was prepared similarly via electrolysis at –0.80 V. Isolation was also similar except that anaerobic techniques were employed due to the oxygen sensitivity of the product. Recrystallization from MeCN yielded dark blue microcrystals (0.14 g, 26%). UV–vis (MeCN) λ_{max} (nm) (ε (M^{-1} cm^{-1})): 685 (1.5×10^4). FT-IR (KBr pellet) (cm^{-1}): 1165 (w) (WOS), 1155 (sh) (WOS), 1110 (vw) (WOS), 965 (vs) (W=O), 950 (sh) (W=O), 880 (sh) (WOW), 830 (s) (WOW), 735 (sh) (WOW). Anal calcd. for $C_{96}H_{216}N_6O_{62}S_2W_{18}$ (%): C 19.81, H 3.74, N 1.44, S 1.10, W 56.86; found: C 20.01, H 3.83, N 1.33, S 1.04, W 56.75.

Instrumental techniques

Elemental analysis was performed by the Analytische Laboratorien, Elbach, Germany. Electronic spectra were recorded on a Cary 1C UV–vis spectrophotometer. IR spectra of pressed KBr discs were recorded on a Bio-Rad FTS-165 Fourier-transform spectrometer. Data collection employed a generic 486 PC running Cary ver. 2.50 software on an OS/2 WARP ver. 3 operating platform. The spectrometric cells were quartz with a 1 cm path length. A rectangular OTTLE cell (path length 1 mm) with a 3 mL solution reservoir was utilized for spectro-electrochemistry (10). A Pt gauze (ca. 4 cm^2, ca. 75% transmission) working electrode was used to generate reduced species. A silver-wire quasireference electrode and Pt counter electrode were separated from the electroactive solution by salt bridges located in the upper reservoir of the cell. Electrolysis was performed with a PAR 273A potentiostat. Potentials were held at about 200 mV more negative than the half-wave potential of the appropriate redox process. All spectra were corrected for background electrolyte absorption.

Voltammograms were obtained using a Cypress Systems model CS1087E electroanalysis system. The standard three-electrode arrangement was employed with a Pt-wire auxiliary electrode, glassy-carbon working electrode and Ag/AgCl reference electrode for both rotating-disk voltammetry and cyclic voltammetry. The reference electrode was calibrated against the ferricenium/ferrocene (Fc^+/Fc) couple. All potentials are quoted relative to this standard. The glassy-carbon working electrodes (dia 2.8 mm) were polished with alumina (3 μm) on LECO Inc. polishing pads, then rinsed with distilled water and dried before each experiment. The cell was purged with N_2 for at least ten minutes before each experiment. Rotating-disk voltammetric measurements were undertaken with a Metrohm 2.8 mm diameter glassy-carbon working electrode that was rotated by a variable speed Metrohm 628–10 rotator.

X-ray crystallography

Crystal data

Large hexagonal shaped plates were grown by dissolving $(Bu_4N)_5[S_2W_{18}O_{62}]$ in MeCN (ca. 0.01 M) at 40°C, allowing the solution to cool to room temperature and then stand at 4°C. The large crystals could not be cut without causing significant damage and so large uncut crystals were selected for data collection. The crystals decomposed rapidly during room temperature data collection using Mo Kα radiation. Instrument problems in our laboratories at the time dictated that low-temperature data could be collected only with a Cu

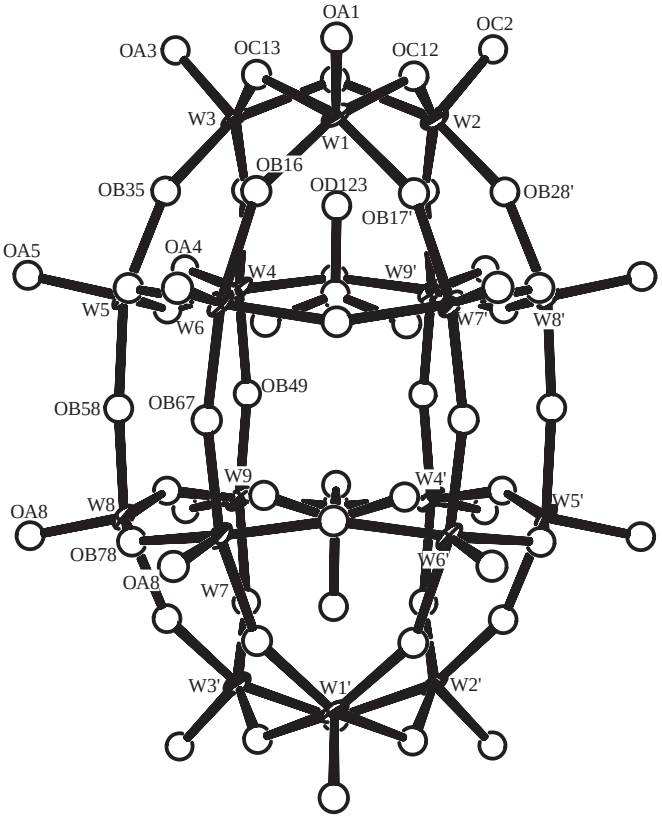
radiation source with the attendant problems of absorption. However, the crystal faces were well-formed and easily measured and indexed. Crystals were mounted on a drop of paraffin oil and flash cooled to 130 K using an Oxford Cryostream low-temperature device. Although the reflection peaks showed high mosaicity, data collection was continued. Intensity data were collected using an Enraf–Nonius CAD-4 MachS single crystal X-ray diffractometer using the ω:2θ scan method, with Cu Kα (Ni filtered) λ = 1.5418. Accurate values of the unit cell parameters and crystal orientation were obtained by a least-squares procedure from the angular settings of 25 carefully centered reflections. The crystal showed a deterioration of ca. 5% during the data collection. A total of 10 553 reflections were collected $2 < \theta < 60$, with 10 284 unique (*R* (int) = 0.1299), and used in the subsequent solution and refinement. Crystallographic data are summarized in Table 1. Three different crystals selected from different crops exhibited the same crystallographic parameters.

The structure was solved by a combination of direct methods and difference synthesis (11, 12). It was refined using a full-matrix least-squares refinement procedure based on F^2 and with ansiotropic displacement parameters assigned to all nonhydrogens excluding the oxygen atoms in the cluster. The anion and one of the Bu_4N^+ cations lie on a crystallographic twofold axes while the remaining Bu_4N^+ cations are in general positions. The latter four cations in general positions, were relatively well-ordered while the terminal carbon atoms of the fifth Bu_4N^+ cation and the MeCN solvent showed large temperature factors suggesting disorder. Hydrogen atoms were constrained to idealized positions. The largest peaks in the difference map were in the vicinity of the tungsten cage and may reflect some disorder in the anion. The molecular structure of the anion is shown in Fig. 2, while selected interatomic distances and angles are included in Table 2.[3]

Results and discussion



Electrosynthesis and characterization

The first four redox processes (**I**–**IV**) observed for

Fig. 2. Molecular structure and labelling scheme of the anion in $(Bu_4N)_5[S_2W_{18}O_{62}]\cdot 4MeCN$. Primed atoms are related to the unprimed atoms by the symmetry operator $1 - x, y, 1/2 - z$.

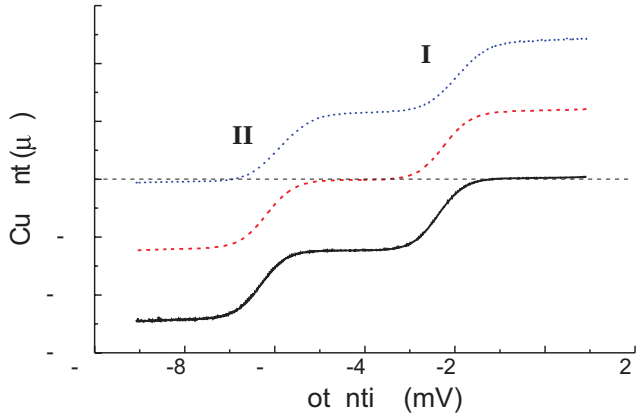
γ^*-$(Bu_4N)_4[S_2W_{18}O_{62}]$ in MeCN are reversible one-electron processes (2). Controlled potential electrolysis was carried out in MeCN at potentials slightly more negative than those of processes **I** and **II** until the current had decayed to zero (Fig. 3). Coulometry indicated that, respectively, 1.03 and 1.92 electron equiv were transferred. The positions of zero current in RDEV confirmed the presence of stable 1 e^-- and 2 e^--reduction products (Fig. 3). Intense absorption bands characteristic of reduced polyoxo anions appeared in the wavelength range 400–2000 nm (Fig. 4) (13). Quantitative oxidation of the 2 e^--reduction product cleanly regenerated the spectra of the 1 e^--product and of the oxidized anion. In addition, the 2 e^--reduction product was oxidized quantitatively to the 1 e^--level upon exposure to air. Solutions of the latter were stable in air.

This information defined conditions for the isolation in substance of Bu_4N^+ salts of the 1 e^-- and 2 e^--reduced anions $[S_2W_{18}O_{62}]^{5-}$ and $[S_2W_{18}O_{62}]^{6-}$ (see *Synthesis*). Solutions of these salts in MeCN reproduced the spectra of Fig. 4 quantitatively.

X-ray crystal structure of α-$(Bu_4N)_5[S_2W_{18}O_{62}]\cdot 4MeCN$

The 1 e^--reduced anion $[S_2W_{18}O_{62}]^{5-}$ adopts the α-isomeric structure (D_{3h}, Fig. 3), rather than the γ^*-structure (D_{3d}) seen in the oxidized form (2). Upon electrolytic reduction by one electron, γ^*-$[S_2W_{18}O_{62}]^{4-}$ undergoes isomerization to α-$[S_2W_{18}O_{62}]^{5-}$. Attempts to confirm the physical reversibility of this process by X-ray powder diffraction of α-$(Bu_4N)_5[S_2W_{18}O_{62}]\cdot 4MeCN$ and its 1 e^- oxidation product were frustrated by loss of crystallinity caused by solvent loss.

Fig. 3. Rotating-disk electrode voltammograms for: γ^*-$[S_2W_{18}O_{62}]^{4-}$ (——); its 1 e^--reduced (——); and 2 e^--reduced (·····) electrolysis products (2×10^{-3} M in MeCN, 0.1 M Bu_4NClO_4, ν 0.010 V s^{-1}, N_r 2000 min^{-1}).



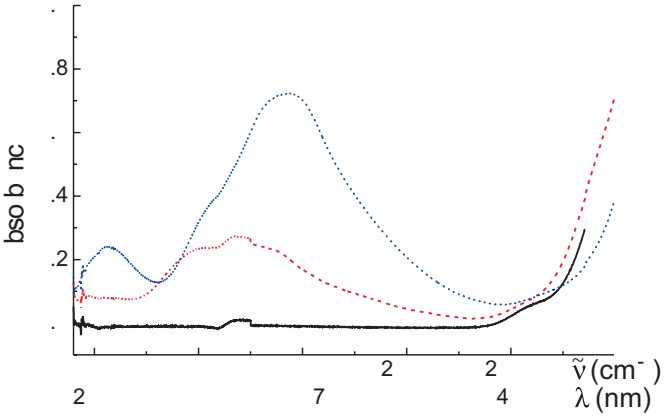


Fig. 4. Electronic spectra generated by electrolysis of γ^*-$(Bu_4N)_4[S_2W_{18}O_{62}]$ (5×10^{-4} M) in MeCN (0.1 M Bu_4NClO_4): before reduction (——); after reduction by 1 e^- equiv (——-); after reduction by 2 e^- equiv (·····). Note baseline artefact at 800–900 nm.

Comparison of structural parameters of α-$[S_2W_{18}O_{62}]^{5-}$ with γ^*-$[S_2W_{18}O_{62}]^{4-}$ and α -$[S_2Mo_{18}O_{62}]^{4-}$ may be made from Tables 2 and 3. The most significant differences between the tungsten isomers are the changes in the ranges observed in bond angles M(μ-O)M at the oxygen atoms O_{b2}, which link the caps with the belts (e.g., W3OB35W5: $\gamma^* = 161 \pm 1°$, $\alpha = 154 \pm 1°$), and at the oxygen atoms O_{b3}, which link the two belts (e.g., W5OB58W8: $\gamma^* = 179 \pm 1°$, $\alpha = 167 \pm 1°$). These differences occur in the regions of major topological change induced by the relative rotation of the belts and caps (2, 3). Table 3 details the O···O nonbonded separations in these anions. The smaller hexagons of bridging atoms (O_{b1}), which link the belts with the caps each feature alternating shorter and longer nonbonding separations. The difference is more pronounced in the α-isomers. On the other hand, the larger hexagon of bridging atoms (O_{b3}),

[a]The observed values are indicated as a ± range. Data taken from references footnoted in Table 2.
[b]The larger hexagon is formed by atoms O_{b3}, which bridge the two hexanuclear belts; the smaller hexagon is formed by atoms O_{b1}, which bridge the hexanuclear belts and the trinuclear caps (see Fig. 2).
[c]Esd values for O···O distances are typically 0.02 Å.

which link the two halves of the molecules, have similar separations in the γ*-isomer but alternating shorter and longer separations in the α-isomers.

It is surprising to find that upon reduction by a single electron, γ*-$[S_2W_{18}O_{62}]^{4-}$ undergoes relative rotation of both caps and belts, which would require the breaking of multiple W—O bonds. In particular, the two hexanuclear belts are eclipsed in the α form but staggered in the γ* form (Fig. 1).

Resonance and spectroscopic data on the 1 e^-- and 2 e^--reduced forms of α-$[P_2M_{18}O_{62}]^{6-}$ (M = Mo, W) indicate that the additional electrons are localized on the metal atoms of the belts (14–18). There is now direct structural evidence of this phenomenon in the series of α-anions $[S_2Mo_{18}O_{62}]^{4-}$ (oxidized), $[HS_2Mo_{18}O_{62}]^{5-}$ (reduced by 2 e^-, 1H^+), and $[H_3S_2Mo_{18}O_{62}]^{5-}$ (reduced by 4 e^-, 3H^+)[2] (8). As two and then four electrons are added, the average Mo···Mo distance across the belts decreases. As equivalent octahedra in each belt are linked by a bridging O_{b3} ligand, the conclusion is consistent with the known stability of the spin-paired $[Mo^VO]_2(\mu\text{-}O)$ fragment, stabilized by exchange correlations

[a]Potentials relative to the Fc^+/Fc couple.

mediated by the bridging O_{b3} atom (19). EPR investigations of 1 e^--reduced α-$[S_2Mo_{18}O_{62}]^{5-}$ indicate that the unpaired electron is delocalized over the entire molecular framework (7). However, cyclic voltammetry in MeCN revealed pairs of 1 e^--reductions (separation ~0.2 V) with a larger separation between pairs (~0.6 V) (4). This result suggests a significant contribution from exchange via M_2^V pairs.

The presence of additional electron density on the belts of $[S_2W_{18}O_{62}]^{5-}$ may lower the activation energy for rotation of the belts from the staggered (γ*) to the eclipsed (α) conformation (Fig. 1). Such rotation converts the similar O···O nonbonding separations in the large central hexagons of O_{b3} atoms in γ*-$[S_2W_{18}O_{62}]^{4-}$ to the alternating long and short distances characteristic of an α-isomer (Table 3). The effect of this conversion on the smaller, upper hexagon of the belt is to invert the pattern of long and short O···O separations. This would destabilize the caps in their original orientation and favor rotation to that characteristic of the α-isomer.

Fig. 5. Cyclic voltammogram of α-$(Bu_4N)_5[S_2W_{18}O_{62}]$ (1.0×10^{-3} M) in MeCN (0.1 M Bu_4NClO_4, ν 0.100 V s^{-1}).

Electrochemistry in MeCN

RDE voltammetry for the isolated reduced salts $(Bu_4N)_5[S_2W_{18}O_{62}]$ and $(Bu_4N)_6[S_2W_{18}O_{62}]$ in MeCN mimics that of the electrolyzed solutions (Fig. 3). The reversible half-wave potential ($E_{1/2}$) and diffusion coefficient (D_f) were the same, within experimental error, for each salt and the same as those observed for $(Bu_4N)_4[S_2W_{18}O_{62}]$ (2). Cyclic voltammetry operates on a faster timescale. Results for the two reduced salts revealed four one-electron processes that are essentially reversible (Fig. 5, Table 4). A comparison of data for processes **I**–**IV** of 1 e^--reduced α-$[S_2W_{18}O_{62}]^{5-}$ with those (2) of oxidized γ*-$[S_2W_{18}O_{62}]^{4-}$ indicate that all parameters are the same within experimental error. No evidence of interconversion of α- and γ*-isomers could be detected on the timescale of the cyclic voltammetry. Addition of acid in MeCN–H_2O (95:5 v/v) solutions also allowed no discrimination. Processes **III** and **IV** coalesced as the acid concentration increased to produce the new 2 e^--process *III*. This was accompanied at higher acid concentrations by new 2 e^--process *IV*. This is clearly evident in RDE

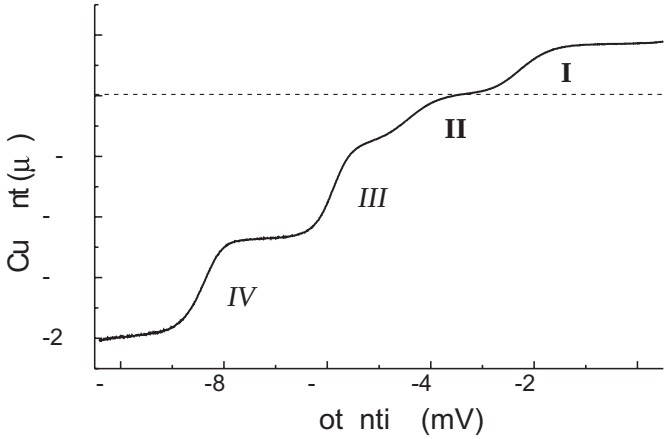
Fig. 6. RDE voltammogram of α-$(Bu_4N)_5[S_2W_{18}O_{62}]$ (1.0×10^{-3} M) in MeCN:H_2O (95:5 v/v, 0.1 M Bu_4NClO_4, N_r 2000 min^{-1}) with 100 mol equiv $HClO_4$.



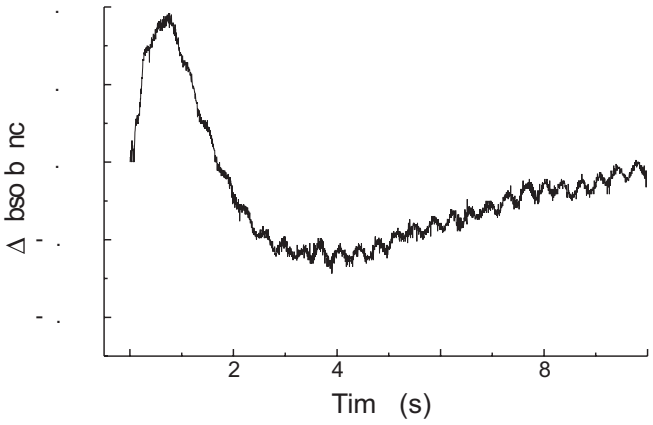


Fig. 7. Plot of absorbance difference vs. time for α-$(Bu_4N)_4[S_2Mo_{18}O_{62}]$ (3.2×10^{-5} M) and α-$(Bu_4N)_5[S_2W_{18}O_{62}]$ (9.8×10^{-5} M) in MeCN (λ = 410 nm).

voltammetry, where the ratios of limiting currents for processes **I**:**II**:*III*:*IV* = 1:0.96:1.96:1.93 (Fig. 6). Again the behavior mimics that of oxidized γ*-$[S_2W_{18}O_{62}]^{4-}$ under equivalent conditions (2).

Isomerization

Reduction of γ*-$[S_2W_{18}O_{62}]^{4-}$ by 1 e^--equiv by electrolysis leads to the isolation of α-$[S_2W_{18}O_{62}]^{5-}$ as the Bu_4N^+ salt. This transformation was not detected on the timescale of cyclic voltammetry, even at the fast scan rate of 10 V s^{-1}. The $E_{1/2}$ values derived by cyclic voltammetry were the same, within experimental error, for γ*-$[S_2W_{18}O_{62}]^{4-}$ and α-$[S_2W_{18}O_{62}]^{5-}$. This observation may be attributed to one of three possibilities: (*i*) the γ* ↔ α equilibrium favors one of the isomers in solution (presumably the α-form) for both redox states and the electrochemistry accesses that form; (*ii*) the isomerization is fast on the voltammetric timescale; or (*iii*) the isomerization is slow on that timescale but the difference in $E_{1/2}$-values for processes **I**–**IV** cannot be resolved by the techniques available up to the present work.

In the only comparable system available, RDE voltammetry (carbon-working electrode) examined $[As_2W_{18}O_{62}]^{6-}$ in aq solution at pH 1 (NaCl 0.9 M, HCl 0.1 M) (3). The voltammetries of the β- and γ*-isomers were indistinguishable within the resolution limit of 20 mV. Three processes were reported for each of the α- and γ*-isomers. The differences in $E_{1/2}$-values were 30 mV for each process, close to the resolution limit, with those for the γ*-isomer being more positive. However, the second process was reported as a 1 e^--process for the α-isomer and as a 2 e^--process for the γ*-isomer. In nonaqueous systems, Bu_4N^+ salts of the α-, β-, and γ-isomers of the Keggin system $[SiW_{12}O_{40}]^{4-}$ are available (20, 21). Cyclic voltammetry in MeCN demonstrated that the α- and β-isomers can be distinguished on the basis of $E_{1/2}$-values (three 1 e^--processes that are 80–110 mV more positive for the α-isomer), and that 1 e^--reduction of the γ-isomer converts it to the α-isomer on the voltammetric timescale (22).

Examination of the half potentials for the $[S_2W_{18}O_{62}]^{4-}$–$[S_2W_{18}O_{62}]^{5-}$ and α-$[S_2Mo_{18}O_{62}]^{4-}$–α-$[S_2Mo_{18}O_{62}]^{5-}$ couples (Table 5 and ref. 2) indicated that the following reaction would proceed to completion:

$$\alpha\text{-}[S_2W_{18}O_{62}]^{5-} + \alpha\text{-}[S_2Mo_{18}O_{62}]^{4-} \rightarrow [S_2W_{18}O_{62}]^{4-} + \alpha\text{-}[S_2Mo_{18}O_{62}]^{5-}$$

Mixing experiments confirmed this prediction as the electronic spectra of each of the four species is known (see *Synthesis* and ref. 2). Exploratory stopped-flow experiments were carried out in the wavelength range 820–340 nm at a range of relative concentrations of reactants. Typical results are presented in Fig. 7. Data fitting was not attempted due to the complex nature of the system. However, different transformations are occurring on time scales of about ~1 s, ~2 s, and >10 s. The simplest interpretation is that electron transfer is completed in the first process and that the slower processes are associated with subsequent relaxation of the product anions. Whether this includes isomerization of initial product α-$[S_2W_{18}O_{62}]^{4-}$ to final product γ*-$[S_2W_{18}O_{62}]^{4-}$ cannot be discerned.

The available data suggest that either: (*i*) the γ* ↔ α equilibrium favors one of the isomers in solution (presumably the α-form) for both redox states, or (*ii*) the γ* ↔ α isomerization associated with the $[S_2W_{18}O_{62}]^{4-}$–$[S_2W_{18}O_{62}]^{5-}$ couple is slow on the cyclic voltammetric timescale and that the differences in $E_{1/2}$ values for the α-$[S_2W_{18}O_{62}]^{4-}$– α-$[S_2W_{18}O_{62}]^{5-}$ and γ*-$[S_2W_{18}O_{62}]^{4-}$–γ*-$[S_2W_{18}O_{62}]^{5-}$ couples cannot be resolved by cyclic voltammetry.

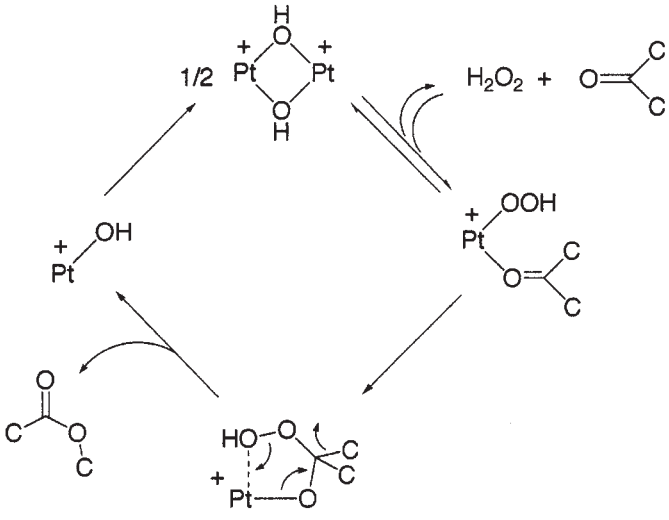
Thioacetalization of aldehydes and ketones in the presence of hydroxo complexes of platinum(II): An example of Lewis acid catalytic activity

Lorenzo Battaglia, Francesco Pinna, and Giorgio Strukul

Abstract: The complex $[(dppb)Pt(\mu\text{-}OH)]_2(BF_4)_2$ displays high catalytic activity in the thioacetalization of a variety of aldehydes and ketones with mercaptoethanol under very mild conditions. The reaction rate is greatly enhanced by the addition to the reaction mixture of magnesium perchlorate as drying agent and molar turnovers as high as 9700 can be observed. The effect of different desiccating agents is also reported. The reactivity pattern observed, the similarity with other reactions and NMR spectroscopic investigations confirm the possible role of the complex as Lewis acid catalyst in promoting the reaction.

Key words: thioacetalization, catalysis, aldehydes, ketones, platinum complex.

Résumé : Le complexe $[(dppb)Pt(\mu\text{-}OH)]_2(BF_4)_2$ présente une activité catalytique élevée dans les réactions de thioacétalisation d'une grande variété d'aldéhydes et de cétones par réaction avec le mercaptoéthanol, sous des conditions expérimentales douces. La vitesse de la réaction est augmentée par l'addition au mélange réactionnel de perchlorate de magnésium comme agent desséchant; on peut alors observer des taux de renouvellement chimique qui peut aller jusqu'à 9,700. On rapporte aussi l'effet de divers agents desséchant. Le type de réactivité observé, la similarité avec d'autres réactions et les études par spectroscopie RMN confirment la possibilité que le complexe agit comme un catalyseur acide de Lewis pour promouvoir la réaction.



Mots clés : thioacétalisation, catalyseur, aldéhydes, cétones, complexe du platine.

[Traduit par la Rédaction]

Introduction

The acetalization reaction is a process that is widely used in organic synthesis to protect the carbonyl group of aldehydes and ketones (1) and for the synthesis of end products (acetals), including enantiomerically pure compounds (see for example ref. 2), that find practical application in the field of synthetic carbohydrate (3), steroids (4), pharmaceuticals and fragrances (5), and as polymers and copolymers (6). This reaction is normally acid catalyzed, although the use of transition-metal complexes as Lewis acid catalysts has been occasionally reported in the literature (7). In the past two decades we have extensively studied the properties of cationic Pd(II) and Pt(II) complexes in a variety of oxidation reactions using hydrogen peroxide as oxidant (for reviews on this subject see ref. 8). A typical feature displayed by the metal in the latter reactions is the ability to increase the reactivity of the substrate by coordination thereby making it more prone to attack by the peroxidic oxidant. An essential requirement to promote this kind of reactivity is the presence of a positive charge on the metal which, therefore, possesses a significant Lewis acidity. An example of this behavior is shown in Scheme 1 which illustrates the mechanism of the Baeyer–Villiger oxidation of ketones catalyzed by $[(P\text{-}P)Pt(\mu\text{-}OH)]_2^{2+}$ complexes [9] (P-P = a variety of different disphosphines, including chiral ones for asymmetric transformations (10)). The Lewis acidity of these complexes

Scheme 2.

has been recently exploited to catalyze the acetalization of a variety of aldehydes and ketones (11), where some unusual selectivities with respect to ordinary Brønsted acids were observed, especially in the case of α,β-unsaturated substrates (12).

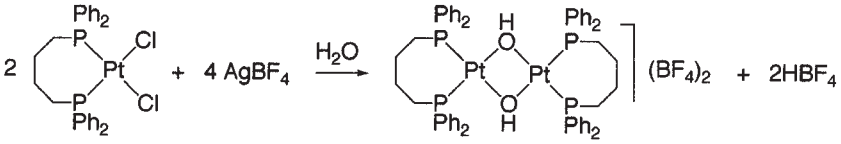
In this paper we wish to report the first example of a transition-metal catalyzed thioacetalization reaction. This reaction is potentially very useful in organic synthesis as, for example, the use of 2-mercaptoethanol as the acetalizing agent leads to the formation of 1,3-oxathiolanes (Scheme 2) and opens an easy access to a class of chiral compounds that can be obtained starting from every aldehyde or unsymmetrically substituted ketones.

Results and discussion

The complex used as catalyst in the present study is $[(dppb)Pt(\mu\text{-}OH)]_2(BF_4)_2$. This cationic complex displays a significant Lewis acidity as was already observed in the catalysis of the above mentioned acetalization reactions (11, 12) and in the Baeyer–Villiger oxidation of ketones with hydrogen peroxide (9). The choice of this complex is due to the fact that it proved to be the most active among the homologous complexes of Pt in both the acetalization and the Baeyer–Villiger oxidation. Moreover, compared to homologous complexes of Pd, it is more thermally stable and can be used as catalyst up to 90°C without any problems. It can be easily obtained starting from the corresponding dichloro complex by addition of 2 equiv of $AgBF_4$ in acetone (13) according to eq. [1]. However, we found that the reported synthetic procedure (13) may lead to the adsorption of significant amounts of HBF_4 on the complex upon precipitation. To avoid possible ambiguities in the catalytic tests, the complex, dissolved in CH_2Cl_2, was extracted several times with water until neutrality was attained.

Initially, the search for the best reaction conditions in the thioacetalization reaction was carried out. To this purpose, 2-mercaptoethanol was tested in the reaction with benzaldehyde and a summary of the results obtained is reported in Table 1. Initial tests were carried out with benzaldehyde at 25°C using 0.05% equivalents of the dimeric catalyst with respect to the substrate corresponding to 0.1% Pt. At room temperature, no activity was observed even increasing the equivalents of Pt to 1% (run 2). Upon increasing the reaction temperature to 82°C, a quick reaction takes place leading to about 60% conversion in about 10 h and to the neat formation (>99% selectivity) of 2-phenyl-1,3-oxathiolane. During the same reaction time, a blank reaction without catalyst shows no conversion. Similar results were observed using other aldehyde and ketone substrates, with the exception of acetophenone where a much lower conversion was observed (Table 1). Since no attempt was made to remove water formed during the reaction (Scheme 2), in all cases the reaction stops at equilibrium concentration, preventing the achievement of higher conversions.

Table 1. Thioacetalization of different substrates with 2-mercaptoethanol catalyzed by $[(dppb)Pt(\mu\text{-}OH)]_2\ (BF_4)_2$.



Run	Substrate	Temperature (°C)	Max conversion (%)	Time (min)
1	Benzaldehyde	25	0	1440
2		25[a]	0	1450
3		82	62	600
4	Propanal	82	57	500
5	Acetophenone	82	9	1800
6	*p*-Anisaldehyde	82	80	300
7	Cyclohexanone	82	58	350
8	2-Hexanone	82	21	1500

Note: Experimental conditions: Pt (5 μmol), substrate (5 mmol), 2-mercaptoethanol (5 mmol), 1,2-dichloroethane (2.2 mL).
[a]Pt (0.05 mmol).

For this reason the reaction was tested in the presence of a desiccating agent. This is not unusual for equilibrium reactions forming water, for example Gorla and Venanzi (7*e*) in their study on catalyzed acetalization reactions found the use of molecular sieves very useful to maximize conversions and reaction rates. In the present case, $Mg(ClO_4)_2 \cdot 2H_2O$ was added to the initial reaction mixture in 20% excess with respect to the theoretical amount of water formed at full conversion. At the reaction temperature used in the previous experiments (82°C) the thioacetalization reaction is extremely fast (>99% conversion in 1 min) both for the catalyzed and the non-catalyzed blank reaction. For this reason a new series of catalytic tests was carried out at 25°C. The results for a variety of aldehydes and ketones are shown in Tables 2 and 3 where a comparison with the non-catalyzed reaction is also reported.

As can be seen, in the case of aldehydes the reaction is always very fast and catalyst amounts as low as 0.01% with respect to the substrate were used. A comparison with the non-catalyzed reactions indicate that the catalytic effect is not very pronounced except in the case of *p*- and *m*-anisaldehyde, where the non-catalyzed reaction is considerably slower. The case of ketones is different. In all cases the catalytic effect is very strong (perhaps with the exception of cyclohexanone). In a few hours a variety of ketones can be converted almost quantitatively with the catalyst performing 8500–9700 turnovers, opening some interesting synthetic perspectives.

Other desiccating agents have been tested in the thioacetalization of 2-butanone taken as the test reaction, namely sodium sulfate, magnesium sulfate, and molecular

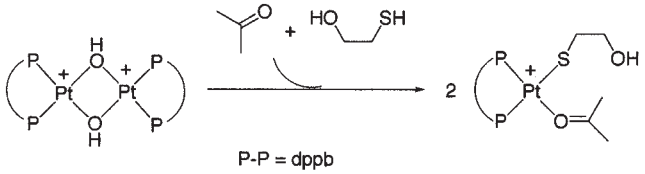
Note: Comparison between the catalyzed (by $[(dppb)Pt(\mu\text{-}OH)]_2(BF_4)_2$) and the non-catalyzed reaction. Experimental conditions: Pt (2 μmol), substrate (20 mmol), 2-mercaptoethanol (20 mmol), $Mg(SO_4)_2\cdot 2H_2O$ (1.555 g), 1,2-dichloroethane (8.78 mL).

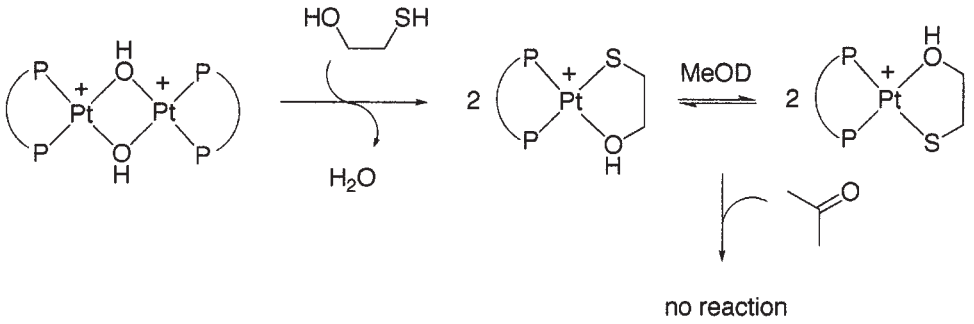


sieves. The results are summarized in Fig. 1 and show that $Mg(ClO_4)_2\cdot 2H_2O$ is by far the most effective desiccating agent. Since all desiccants tested are based on poorly coordinating anions, an interpretation of the data of Fig. 1 on this basis seems unlikely. Indeed, they differ significantly in the water absorption rate and, to a minor extent, in the water absorption capacity, in this respect magnesium perchlorate being the best option (14). This view may constitute a possible explanation for the behavior shown in Fig. 1, where the different rates correlate with the absorption rate, while the maximum conversions could be associated to different amounts of residual water at the equilibrium. The possible direct involvement of Mg^{2+} through the formation of soluble species similar to the complex $[(PPh_3)_2Pt(\mu\text{-}O)]_2LiBF_4$ as reported by Sharp and co-workers (13*a*) seems less likely in view of the very different behavior between magnesium perchlorate and magnesium sulfate observed in Fig. 1.

From Table 3, it appears that aliphatic ketones are more reactive and their reactivity can be correlated to the inductive effect of substituents as for example in the sequence: 2-butanone > phenylacetone > acetophenone. This seems to suggest that the role of the catalyst can be associated to Lewis acidity, where the electrophilicity of the carbonyl compound is increased by coordination making it more prone to nucleophilic attack by the alcohol (thiol). In this respect, Scheme 1 provides a rationale for the understanding of the mechanism with which the thioacetalization reaction occurs. The similarities between the formation of the

Fig. 1. Effect of four desiccating agents on the thioacetalization of 2-butanone with 2-mercaptoethanol in the presence of $[(dppb)Pt(\mu\text{-}OH)]_2(BF_4)_2$ as catalyst. $Mg(ClO_4)_2\cdot 2H_2O$ (circles), Na_2SO_4 (diamonds), molecular sieves (triangles), $MgSO_4$ (squares). Experimental conditions: Pt (2 μmol), 2-butanone (20 mmol), 2-mercaptoethanol (20 mmol), 1,2-dichloroethane (8.8 mL), $Mg(ClO_4)_2\cdot 2H_2O$ (1.555 g), Na_2SO_4 (0.341 g), molecular sieves (3.6 g), $MgSO_4$ (0.413 g).

Scheme 3.



hydroperoxyplatinum ketone complex and the process depicted in Scheme 3 are evident.

We tried to find some experimental evidence for the formation of the intermediate indicated in Scheme 3. First of all, the reaction between $[(dppb)Pt(\mu\text{-}OH)]_2^{2+}$ and 2-mercaptoethanol was carried out (Scheme 4). A formulation of the new complex isolated as in Scheme 4 is supported by its spectroscopic features. It shows in the solid-state a strong, characteristic IR band at ~1090 cm^{-1} (BF_4), a broad band at 3360 cm^{-1}, and a weak band at 3521 cm^{-1}. The latter can be assigned respectively to the H-bonded and free O—H stretching vibrations of coordinated 2-mercaptoethanol. Consistently, in 1,2-dicholoroethane (DCE) solution only a weak band at 3533 cm^{-1} can be observed. No bands are observed in the region 2500–2600 cm^{-1} that can be assigned to the presence of SH ligands. Conductivity measurements (1×10^{-3} M in MeOH) are consistent with the presence of a 1:1 electrolyte (Λ_M 91 Ω^{-1} mol^{-1} cm^2) (15). In contrast to the inequivalence of the two phosphorus donors, the ^{31}P NMR spectrum in CD_3OD at 25°C shows only a sharp singlet at 15.82 ppm with a $^1J_{P\text{-}Pt}$ of 2904 Hz. When the temperature is lowered the signal broadens significantly and, at –70°C, the signal is so broad that it can hardly be distinguished from the base line. These observations may be consistent with the presence of a fast interchange equilibrium between the O and S donors as depicted in Scheme 4 promoted by a revers-

© 2001 NRC Canada

Scheme 4.

ible displacement of the OH moiety by MeOD. Unfortunately, the poor solubility of the new complex in solvents such as dichloromethane and acetone did not allow to confirm this hypothesis in other solvents.

Subsequently, the complex isolated from the previous reaction was dissolved in a large amount of 1,2-dichloroethane (the solvent used for the catalytic reactions) followed by addition of a 10-fold excess of *p*-anisaldehyde. The mixture was allowed to react both at 25°C and at 65°C for 2 h, however, no new product formation was observed by GC analysis. Isolation of the Pt species followed by spectroscopic analysis indicated that its features were identical to those of the starting complex. These observations are apparently in contrast with the observed catalytic effects displayed by $[(dppb)Pt(\mu\text{-}OH)]_2^{2+}$ and seem to indicate that the chelating effect of 2-mercaptoethanol as indicated in Scheme 4 is quite strong and is not reverted by the addition of a moderate excess of a mild ligand such as an aldehyde (or a ketone). However, it can be observed that under catalytic conditions, the carbonyl compound is added before 2-mercaptoethanol and in a much larger excess (1000–10 000 times with respect to the catalyst). In addition, the desiccating agent is present which allows the reaction to proceed at room temperature. These conditions are practically impossible to meet on a stoichiometric basis. In any case, the results reported in the above experiments show that the bridging hydroxy ligand can be promptly opened under catalytic conditions and support the plausibility of Scheme 3 as the activating process.

In conclusion, the platinum complex reported here appears to be a very interesting Lewis acid catalyst for the thioacetalization of a variety of aldehydes and ketones showing productivities that are attractive also for synthetic purposes. The easy modification of this class of complexes with chiral diphosphines seems to open also a viable access to the asymmetric transformation.

Experimental

Apparatus

Infrared spectra were taken on a Nicolet FT-IR Magna 750 and on a Digilab FTS 40 interferometer either in solid (KBr pellets) or in CH_2Cl_2 solution using CaF_2 windows. ^{31}P NMR spectra were recorded on a Bruker AC 200 spectrometer operating in FT mode, using as external reference 85% H_3PO_4. Conductivity measurements were performed on a Radiometer instrument using 1×10^{-3} M solutions in MeOH at 25°C. Gas chromatographic measurements were taken on a Hewlett–Packard 5790A gas chromatograph equipped with a 3390 automatic integrator. GC–MS measurements were performed on a Hewlett–Packard 5971 mass selective detector connected to a Hewlett–Packard 5890 II gas chromatograph. Identification of products was made with GC or GC–MS by comparison with authentic samples.

Materials

Solvents were dried and purified according to standard methods (14). Aldehyde and ketone substrates, 2-mercaptoethanol employed in the thioacetalization reactions and the desiccating agents ($Mg(ClO_4)_2 \cdot 2H_2O$, Na_2SO_4, molecular sieves 3A, $MgSO_4$) were commercial products (purum or puriss quality) used without purification.

The complex $[(dppb)Pt(\mu\text{-}OH)]_2(BF_4)_2$ was prepared according to literature procedures (13).

Thioacetals used as standards for gas chromatography in the individual catalytic reactions were synthesized from the starting aldehyde–ketone (20 mmol) and the stoichiometric amount of 2-mercaptoethanol in 25 mL DCE (1,2-dicholoroethane), to which 0.2 mmol PTSA (*p*-toluenesulfonic acid) were added under N_2 with stirring. The solution containing the acetal was used for qualitative identification in the GC analysis.

Reaction between $[(dppb)Pt(\mu\text{-}OH)]_2(BF_4)_2$ and 2-mercaptoethanol

The complex $[(dppb)Pt(\mu\text{-}OH)]_2(BF_4)_2$ (120 mg, 0.083 mmol) was dissolved in 20 mL of dry N_2 saturated 1,2-dichloroethane. 2-Mercaptoethanol (11.6 μL, 0.166 mmol) was added under N_2 and the solution was stirred for 2 h at room temperature. Addition of 20 mL of Et_2O lead to the precipitation of a white solid, which was filtered, washed with Et_2O, and dried in vacuo. (Yield: 92%). Anal. calcd. for $C_{30}H_{33}BF_4OP_2PtS$: C 45.87, H 4.23; found: C 46.01, H 4.11.

Catalytic reactions

These were carried out in a 25-mL round-bottomed flask equipped with a stopcock for vacuum–N_2 operations and a side-arm fitted with a screw-capped silicone septum to allow sampling. Constant temperature (±0.1°C) was maintained by water circulation through an external jacket connected with a thermostat. For reactions carried out at temperatures >25°C the reaction vessel was equipped with a reflux condenser and heating was ensured by a thermostatted external oil bath. Stirring was performed by a teflon-coated bar driven externally by a magnetic stirrer.

© 2001 NRC Canada

The following general procedure was followed: the required amount of catalyst was placed solid in the reactor which was evacuated and filled with N_2. Nitrogen-saturated solvent was added followed by aldehyde–ketone in the appropriate amount under N_2 flow. After thermostatting at the required temperature for a few min, 2-mercaptoethanol was injected through the septum and time was started.

All reactions were monitored with GC by direct injection of samples taken periodically from the reaction mixtures with a microsyringe. Separation of the products was performed on 25 m capillary columns using a flame ionization detector. Prior quenching of the catalyst using an excess of LiCl showed no differences in randomly selected analyses.

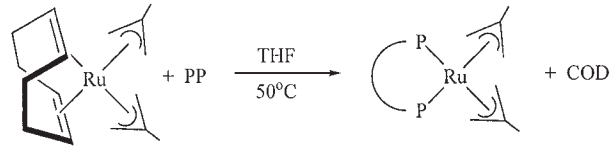
Synthetic and solution calorimetric investigations of chelating phosphine ligands in Ru(allyl)$_2$(PP) complexes (PP = diphosphine)

Dale C. Smith, Jr., Jérémie Cadoret, Laleh Jafarpour, Edwin D. Stevens, and Steven P. Nolan

Abstract: Reaction enthalpies of (COD)Ru(allyl)$_2$ (COD = η^4-1,5-cyclooctadiene; allyl = 2-methylpropenyl) with a series of bidentate phosphines (dppm, dppf, dppe, dppb, dppp, depe, dmpe) have been measured by anaerobic solution calorimetry. The relative stability of the resulting complexes is strongly influenced by the electronic donor properties of the bidentate phosphine ligand. Reactions involving ligands that are better σ donors result in higher enthalpy values and, therefore, more thermodynamically stable complexes. Additionally, the synthesis and characterization of two new ruthenium allyl complexes Ru(allyl)$_2$(dppf) (**3**) and Ru(allyl)$_2$(depe) (**8**) and the X-ray crystal structure of **3** are reported.



Key words: ruthenium, allyl, solution calorimetry, thermodynamics, X-ray structure.

Résumé : Les enthalpies de réaction entre (COD)Ru(allyl)$_2$ (COD = η^4-cycloocta-1,4-diène; allyl = 2-méthylpropényl) et une série de phosphines bidentates (dppm, dppf, dppe, dppb, dppp, depe, dmpe) ont été mesurées par calorimétrie de solution sous des conditions anaérobiques. La stabilité relative des complexes est fortement influencée par les propriétés électroniques du ligand. Les réactions impliquant des ligands ayant un fort caractère σ mènent à des valeurs enthalpiques élevées et des complexes thermodynamiquement plus stables. De plus, la synthèse et la caractérisation de deux nouveaux complexes allyles du ruthénium, Ru(allyl)$_2$(dppf) (**3**) et Ru(allyl)$_2$(depe) (**8**) ainsi qu'une étude par diffraction des rayons X de **3** sont décrites.

Mots clés : ruthénium, allyle, calorimétrie en solution, thermodynamique, diffraction des rayons X.

Introduction

Thermochemical measurements have been applied for some time to the quantitative assessment of metal–ligand interactions in organometallic systems (1). We have previously investigated the steric and electronic contributions present in tertiary phosphine-based organoruthenium systems by means of solution calorimetry (2). The present study extends our earlier thermochemical investigations to the reaction of (COD)Ru(allyl)$_2$ (**1**) with a series of diphosphine ligands [bis(diphenylphosphino)ethane (dppe), bis(diphenylphosphino)propane (dppp), bis(diphenylphosphino)butane (dppb), bis(diphenylphosphino)ferrocene (dppf), bis(dimethylphosphino)ethane (dmpe), and bis(diethylphosphino)ethane (depe)] as shown in the following general reaction:

[1] 

1

PP = dppm, dppf, dppe, dppp, dppb, dmpe, depe

Ruthenium complexes containing allylic ligands have found a wide range of useful applications in organic synthesis. Allylic ruthenium(IV) catalysts have been used for the ring opening polymerization of cyclic olefins (3) and in the allylation of carbon and nitrogen nucleophiles (4). Additionally, allylic ruthenium catalysts can be used in the C–C coupling of alkynes with allyl alcohol (5) and the *anti*-Markovnikov addition of carboxylic acids to terminal alkynes yielding (*Z*)-alk-1-en-1-yl esters (6, 7). The (PP)Ru(allyl)$_2$ complexes have shown to be effective catalyst precursors for the thermal cleavage of nonactivated sp^3 C—H bonds (8) and important catalysts in the formation of *o*-1-(1,3-dienyl) carbamates from the regioselective addition of CO_2 and secondary amines to isopropenylacetylene (9). Ruthenium allyl complexes bearing chiral phosphine lig-

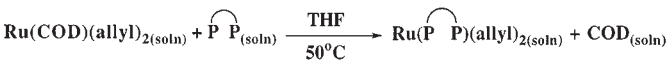
ands have been extensively studied as catalysts precursors in the asymmetric hydrogenation of numerous unsaturated organic substrates (10, 11). In the present contribution we report thermochemical studies on the reaction of (COD)Ru(allyl)$_2$ (**1**) with a wide variety of chelating diphosphines: dppe, dppp, dppb, dppf, dmpe, and depe in tetrahydrofuran (THF) at 50°C. Additionally, we report the synthesis and characterization of two new complexes Ru(allyl)$_2$(dppf) (**3**) and Ru(allyl)$_2$(depe) (**8**), and present the crystal structure of **3**.

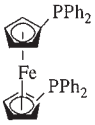
Experimental

General

All manipulations involving organoruthenium complexes were performed under an inert atmosphere of argon, using standard high vacuum or Schlenk techniques, or in a MBraun glove box containing less than 1 ppm oxygen and water. Only materials of high purity as indicated by NMR spectroscopy were used in the calorimetric experiments. Multinuclear NMR spectra were recorded using a Gemini 300 MHz or Varian 400 MHz spectrometer. Calorimetric measurements were performed using a Calvet calorimeter (Setaram C-80), which was periodically calibrated using the TRIS reaction (12) or the enthalpy of solution of KCl in water (13). The calorimeter has been previously described (14, 15). The experimental enthalpies for these two standard reactions compared closely with literature values. Control reactions with diphosphine ligands and Hg showed no reaction or enthalpy contribution.



NMR titrations



Prior to every set of calorimetric experiments involving a new ligand, a precisely measured amount (5.0 ± 0.1 mg) of (COD)Ru(allyl)$_2$ (**1**) was placed in an NMR tube along with THF-d_8 and >1.2 equiv of ligand and placed in a oil bath at 50°C. All ^{31}P NMR spectra were recorded within 1.5 h of mixing, which indicated the reactions were clean and quantitative. These conditions are necessary for accurate and meaningful calorimetric results and were satisfied for all reactions investigated.

Solution calorimetry

In a representative experimental trial, the mixing vessels of the Setaram C-80 calorimeter were cleaned, dried in an oven maintained at 150°C, and then taken into the glove box. A sample of (COD)Ru(allyl)$_2$ (**1**) (15.7 mg, 0.049 mmol) was loaded into the lower vessel, which was closed and sealed with 1.5 mL of mercury. A solution of dmpe (9.0 mg, 0.060 mmol) in THF (4 mL) was added, and the remainder of the cell was assembled, removed from the glove box, and inserted into the calorimeter. The reference vessel was loaded in an identical fashion with the exception that no ruthenium complex was added to the lower vessel. After the calorimeter had reached thermal equilibrium at 50.0 ± 0.2°C (ca. 2 h), it was inverted thereby allowing the reactants to mix. The reaction was considered complete after the calorimeter had once again reached thermal equilibrium (ca. 2 h). Control reactions with Hg and phosphine show no reaction. The enthalpy of ligand substitution (–30.0 ± 0.3 kcal mol^{-1}) listed in Table 1 represents the average of at least three individual calorimetric determinations with all species in solution. The enthalpy of solution of (COD)Ru(allyl)$_2$ (**1**) (+6.2 ± 0.2 kcal mol^{-1}) in THF was determined using identical methodology.

Table 1. Enthalpies of substitution (kcal mol^{-1}) in the reaction.

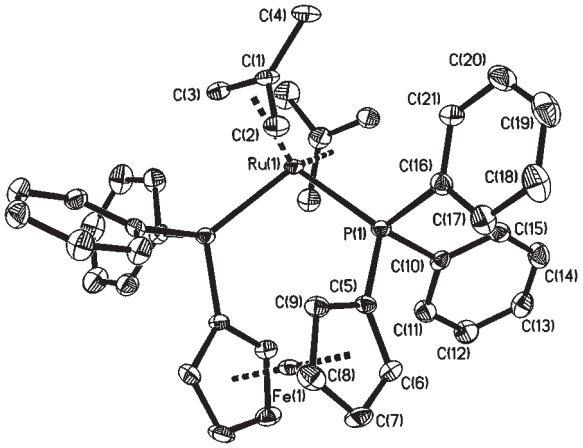
Synthesis of diallyldiphosphineruthenium(II) complexes



Unless otherwise noted, all new complexes were prepared according to the following typical procedure. The bis(phosphine) ligands dppm, dppe, dppp, dppb, dppf, dmpe, and depe were obtained from Strem and used as received. Synthesis of (COD)Ru(allyl)$_2$ (**1**) was conducted according to the method in the literature (16). Experimental synthetic procedures leading to the isolation of the previously unreported complexes are described below.

*Synthesis of (bis(diphenylphosphino)ferrocene)(allyl)$_2$ruthenium (**3**)*

In the glovebox, **1** (102 mg, 0.319 mmol), bis(diphenylphosphino)ferrocene (179 mg, 0.322 mmol), and THF (5 mL) were loaded to a 50 mL Schlenk tube. The tube was removed from the glovebox and interfaced to a Schlenk line. The Schlenk tube was placed in an oil bath at 50°C and vigorously stirred for 18 h. The solvent was removed in vacuum and the resulting residue was triturated with pentane. The orange residue was recrystallized from a CH_2Cl_2–pentane mixture, yielding orange blocks. Yield: 215 mg (88%). ^{1}H NMR (400 MHz, C_6D_6) δ: 0.86 (m, 2H, allylic CH_2), 1.41 (m, 2H, allylic CH_2), 1.49 (m, 2H, allylic CH_2), 2.25 (s, 6H, allylic Me), 2.32 (m, 2H, allylic CH_2), 4.01 (s, 2H, Cp), 4.22 (s, 2H, Cp), 4.26 (s, 2H, Cp), 4.88 (s, 2H, Cp), 6.90–7.50 (m, 20H, Ph). ^{31}P NMR (162 MHz, C_6D_6) δ: 49.84. Anal. calcd. for $C_{42}H_{42}P_2FeRu\cdot H_2O$: C 64.37, H 5.66; found: C 64.06, H 5.26.

Fig. 1. An ORTEP diagram of $Ru(allyl)_2(dppf)$ (**3**). Selected bond lengths: Ru—P, 2.3457(7) Å; Ru—C(1), 2.193(3) Å. Selected bond angles: P(1)-Ru-P(2), 104.18(3)°; C(1)-Ru-P(1), 106.1(2)°; C(1)-Ru-P(2), 116.9(1)°.

*Synthesis of (bis(diethylphosphino)ethane)(allyl)$_2$ruthenium (**8**)*

In a similar manner, **1** (153 mg, 0.479 mmol) and bis(diethylphosphino)ethane (103.5 mg, 0.5018 mmol) were reacted in THF (5 mL); after removing the solvent in vacuum and trituration with pentane, a yellow microcrystalline solid was isolated. Yield: 179 mg (90%). ^{1}H NMR (400 MHz, C_6D_6) δ: 0.81–1.42 (m, 8H, allylic; m, 20H, CH_2CH_3), 1.72 (m, 2H, PCH_2), 1.96 (m, 2H, PCH_2), 2.23 (s, 6H, allylic, Me). ^{31}P NMR (162 MHz, C_6D_6) δ: 64.38. Anal. calcd. for $C_{18}H_{38}P_2Ru$: C 51.78, H 9.17; found: C 51.41, H 8.93.

X-ray crystal structure determination and crystallographic data

A suitable crystal of **3** was mounted on the glass fiber of a goniometer head in a random orientation and placed in the cold stream of N_2 in an automated diffractometer using Mo Kα radiation. The structure of **3** was determined from data collected on a Bruker diffractometer with CCD detection equipped with Mo Kα radiation and a low-temperature apparatus (170 K). The cell dimensions were determined from at least 25 centered reflections, and standard reflections were monitored during data collection. The structure was solved by direct methods using the SHELXS program, and an azimuthal absorption correction was applied. The structure of **3** was refined in a full-matrix least-squares refinement on *F*, using anomalous terms for Ru and P, with all non-hydrogen atoms refined anisotropically. The hydrogen atoms were located from a Fourier difference map and used as the basis of H atom positions in the final structure. The structures have idealized and fixed H atoms, after attempts to refine them proved unsatisfactory. An ORTEP diagram of **3** and selected bond distances and angles are both given in Fig. 1. Positional and equivalent isotropic parameters for all non-hydrogen atoms and torsion angles are given as supplementary materials.[2]

Results and discussion

Organoruthenium synthesis

Two new complexes, $Ru(allyl)_2(dppf)$ (**3**) and $Ru(allyl)_2(depe)$ (**8**), were prepared by reacting $(COD)Ru(allyl)_2$ (**1**) (COD = η^4-1,5-cyclooctadiene; allyl = 2-methylpropenyl) with the appropriate bis(phosphine) ligand in THF at 50°C for 18 h. The colorless solution of **8** slowly turned yellow, whereas the reaction forming **3** remained orange throughout the ligand exchange process. When the solvent was removed, a yellow-orange oil was isolated (in both cases), which was triturated with pentane and filtered to give the resulting microcrystalline complexes in high yields. All complexes are moderately air-stable in the solid state and can be stored over several months under an argon atmosphere. The new complexes were characterized by ^{1}H and ^{31}P NMR and elemental analysis. The ^{31}P NMR spectra of the complexes display a single peak for both **3** and **8**, which is consistent with C_2 symmetrical molecule. The ^{1}H NMR spectra of the complexes are similar to that of other $(PP)Ru(allyl)_2$ complexes (8). Importantly, both complexes possess a five-resonance pattern characteristic of the allyl fragments.

X-ray crystal structure of 3

Crystallization by slow diffusion of a layered CH_2Cl_2–pentane solution leads to the formation of single crystals of **3**. The solid-state structure of **3** was found to crystallize in the monoclinic crystal system (space group *C*2/*c*), and an ORTEP diagram of **3** is presented in Fig. 1.

The central ruthenium atom is coordinated to two phosphorus atoms and two η^3-allyl ligands. The coordination geometry can be considered as a slightly distorted octahedral (outer two carbon atoms of both η^3-allyl ligands and the phosphorus atoms) or as a slightly distorted tetrahedral (coordination center of the η^3-allyl fragments and the phosphorus atoms). Specific details concerning structure determination are given in Table 2, and selected metrical parameters are given in Fig. 1. The Ru—P bond length of **3** is similar to that found in related ruthenium complexes (8, 10*b*, 17). The P-Ru-P angle in **3** (104.18°) is dictated by the six-membered chelate ring, and this angle is very different from the five-membered rings found in both $Ru(allyl)_2(dcpe)$ (85.03°) (8) and $Ru(allyl)_2(CHIRAPHOS)$ (85.0°) (10*b*). The P-Ru-P angle of **3** is very similar to that found for the monodentate complex $Ru(allyl)_2(PPh_3)_2$ (109.9°) (17). The Ru—C bond lengths of the allyl fragment are typical: the short bonds to the outer carbon (1.415(3) and 1.430(5) Å) and longer bonds to the central carbon (1.505(4) Å) of the η^3-allyl fragment.

Solution calorimetry

We have previously observed in organoruthenium phosphine systems (2) that steric, electronic, and structural parameters such as the Tolman's (18) cone angle (θ) and electronic parameter (χ) and metal–ligand bond lengths can be correlated with solution thermochemical data. These relationships can

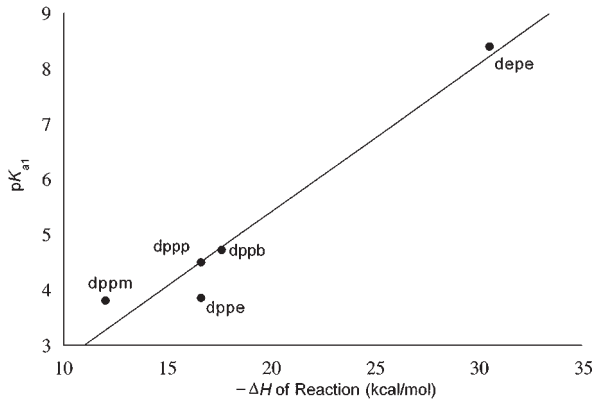
be used to indicate the relative contribution of steric and electronic effects in transition-metal systems. All (PP)Ru(allyl)$_2$ complexes have a central ruthenium atom coordinated by four groups: two methyl(allyl) ligands and the two coordinating phosphorus atoms of a bidentate ligand. In view of the rather unhindered geometry, any variation in the enthalpy of reaction could principally be attributable to the steric and electronic effects provided by the pnictide ligand. The general reaction illustrated in eq. [1] is notably fast (<2 h), clean, and quantitative for the chelating diphosphines, dppe, dppp, dppb, dppf, dmpe, and depe, at 50°C in THF, as determined by ^{1}H and ^{31}P NMR spectroscopy. The enthalpies of ligand substitution measured range from –12.0(2) kcal mol^{-1} for **2** to –30.5(3) kcal mol^{-1} for **8**.[3] The overall order of stability is as follows: dppm < dppf < dppe < dppp < dppb < dmpe < depe. As the Tolman electronic parameter scale predicts, the relative stability of the resulting complexes is strongly influenced by the electronic donor properties of the bidentate phosphine ligand in the absence of any steric factors. Reaction enthalpies involving better σ donor (or more basic) phosphine ligands result in more thermodynamically stable complexes, as shown in Table 1. This trend can be quantitatively illustrated by a plot of enthalpy of substitution versus pK_{a1} (H_2O) (19) of selected bidentate phosphine ligands (20) as illustrated in Fig. 2.[4]

The basicity of the free ligand is defined as the pK_{a1} value for the conjugated acid ($HPR_2P{\sim}PR_2^+$) and can be used to provide a measure of the ligand's ability to donate in a σ fashion to the metal (21) The good correlation between these two parameters (R = 0.974) clearly indicates the enthalpy of substitution to be related to the basicity of the bis(phosphine) ligand, and thus the electronic donating ability of the bis(phosphine).

The present enthalpy data allow for comparison to prior thermochemical studies on the Cp′Ru(PP)Cl (Cp′ either Cp* = η^5-C_5Me_5; or Cp = η^5-C_5H_5) systems (2*g*, *h*). The rel-

Fig. 2. Plot of pK_{a1} vs. –ΔH of substitution (kcal mol^{-1}) for selected bis(phosphine) ligands (pK_{a1} for H_2O (21); slope = 0.27, R = 0.97).



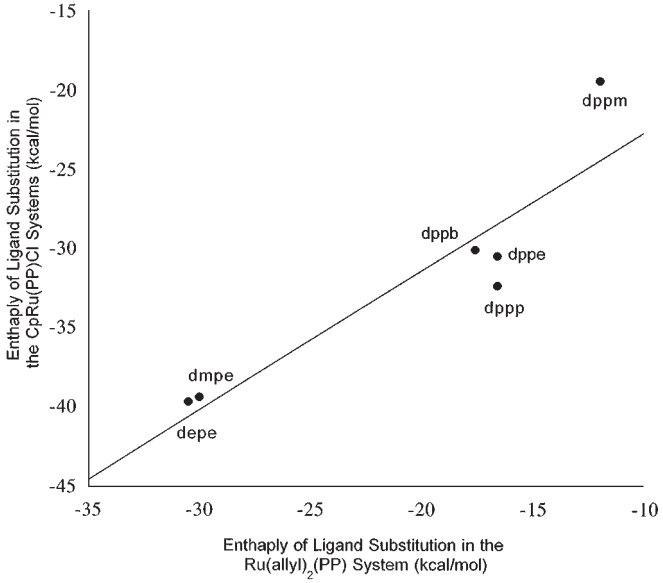


Fig. 3. Comparison between the enthalpies of ligand substitution (kcal mol^{-1}) in the CpRu(PP)Cl andRu(allyl)$_2$ (PP) systems (slope = 0.88, R = 0.91).

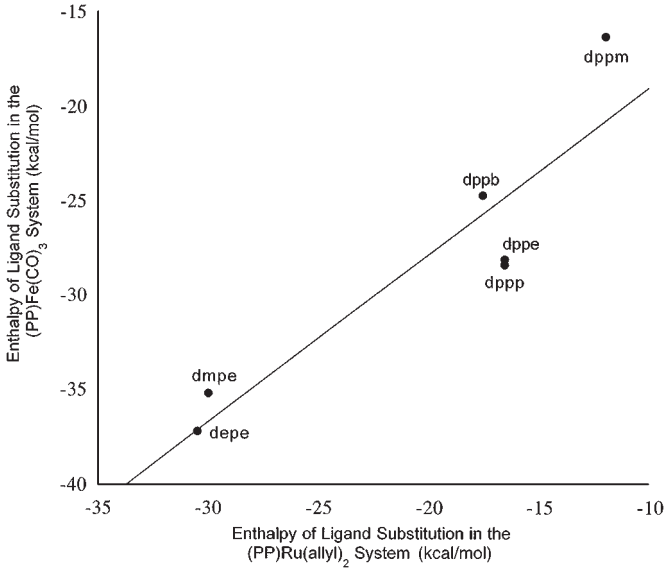

ative order of stability of the resulting complexes for both the Cp*Ru(PP)Cl and CpRu(PP)Cl systems follows a trend similar to that of the (PP)Ru(allyl)$_2$ system. A relationship between ΔH_{rxn} for PP ligand substitution in the CpRu(PP)Cl and (PP)Ru(allyl)$_2$ systems is presented in Fig. 3.[5]

A fair correlation (R = 0.91) is found for this quantitative comparison. A similar relationship is found to exist in the Cp*Ru(PP)Cl system (R = 0.89). The average difference between enthalpies of substitution in (PP)Ru(allyl)$_2$ and Cp*Ru(PP)Cl (2*g*) is found to be worth 8.6 kcal mol^{-1}, favoring the Cp* system. The same comparison with the CpRu(PP)Cl (2*h*) data yields an 11.4 kcal mol^{-1} difference, favoring the Cp system. These differences indicate that the metal center in the Ru(allyl)$_2$ moiety is more electron rich than either of

[3] Reported enthalpies of reaction include enthalpy values for the reaction with all species in solution. No correction is made for solvation enthalpy differences of free ligands which have previously been determined to cancel in neutral organometallic systems (14, 15).
[4] pK_a values for dppf and dmpe are not available.
[5] The enthalpy values for dppf in the CpRu(PP)Cl and (PP)Fe(CO)$_3$ are not available.

Fig. 4. Comparison between the enthalpies of ligand substitution (kcal mol^{-1}) in the $Fe(PP)(CO)_3$ and $Ru(allyl)_2(PP)$ systems (slope = 0.88, R = 0.91).

the Cp′RuCl moieties. The metal center in the $Ru(allyl)_2$ moiety is, therefore, not as good of an electron acceptor as the Cp′RuCl moieties, which leads to lower enthalpies of ligand substitution.

We have also previously observed that the ruthenium system and the $(PP)Fe(CO)_3$ system (22) presented similar trends in terms of thermodynamic stability. As expected, the relative order of stability of the resulting complexes of the $(PP)Ru(allyl)_2$ system is similar to that of the $(PP)Fe(CO)_3$ system. For reactions involving the same PP ligand with either $(bda)Fe(CO)_3$ (bda = benzylideneacetone) or $(COD)Ru(allyl)_2$, a fair correlation (R = 0.91) is found. This linear relationship between ΔH_{rxn} for PP ligand substitution in both the $(PP)Fe(CO)_3$ and $(PP)Ru(allyl)_2$ systems is presented in Fig. 4. The lack of steric hindrance in the iron system and the fairly linear correlation presented in Fig. 4 suggest that the main factors dictating the magnitude of the reaction enthalpies in the $(PP)Ru(allyl)_2$ system are the Lewis acidic character of the metal center and the electronic properties of the diphosphine ligand. The dppm entries in Figs. 3 and 4 appear to deviate the most from linearity. We attribute this deviation to the previously measured ring strain attributable to a metallacyclopropane-like structure. This strain energy, worth some 7–10 kcal mol^{-1} (2*g*, *h*, 22) if independently considered, would lead to enthalpy values significantly closer to those predicted from the linear relations.

Conclusions

The reaction enthalpies for the complex $(COD)Ru(allyl)_2$ with a series of bidentate phosphines have been measured by anaerobic solution calorimetry. The correlation between the $pK_{a1}(H_2O)$ (19) of the bis(phosphines) and the enthalpies of substitution demonstrates that the relative stability of the resulting complexes is influenced by the electronic donor abilities or basicity of the bidentate phosphine ligand. Thus, phosphine ligands that are better σ donors result in more thermodynamically stable $(PP)Ru(allyl)_2$ complexes. The present results are similar to those of prior studies on the Cp′Ru(PP)Cl systems (Cp′ = Cp, Cp^*) (2*g*, *h*) which established the thermodynamic stability of these complexes to be governed by electronic factors of the metal center and electronic properties characteristic of the incoming phosphine ligand.

Addition of bridging-hydrosulfido ligands in diiridium complex to acrylonitrile. Synthesis of diiridium cyanoethylthiolato complexes and $RuIr_2$ sulfido-cyanoethylthiolato cluster

Fusao Takagi, Hidetake Seino, Yasushi Mizobe, and Masanobu Hidai

Abstract: Treatment of [Cp*Ir(μ-SH)$_3$IrCp*]Cl (Cp* = η^5-C_5Me_5) with acrylonitrile and NEt_3 in MeCN or $ClCH_2CH_2Cl$ gave [Cp*Ir(μ-$SCH_2CH_2CN)_3$IrCp*]$^+$, [Cp*Ir(μ-S)(μ-$SCH_2CH_2CN)_2$IrCp*] (**3**), or [Cp*Ir(μ-$SCH_2CH_2CN)_2$(μ-SCH_2CH_2Cl)IrCp*]$^+$, depending upon the conditions employed. From the reaction of **3** with [(Cp*Ru)$_4$(μ-Cl)$_4$], a sulfido-thiolato cluster [Cp*$_3$$RuIr_2$(μ$_3$-S)(μ-$SCH_2CH_2CN)_2$Cl] was obtained.

Key words: diiridium complex, thiolate, sulfide, ruthenium, cluster.

Résumé : Le traitement du [Cp*Ir(μ-SH)$_3$IrCp*]Cl (Cp* = η^5-C_5H_5) avec de l'acrylonitrile et du NEt_3, dans du MeCN ou du $ClCH_2CH_2Cl$, conduit à la formation de [Cp*Ir(μ-$SCH_2CH_2CN)_3$IrCp*]$^+$, [Cp*Ir(μ-S)(μ-$SCH_2CH_2CN)_2$IrCp*] (**3**) ou [Cp*Ir(μ-$SCH_2CH_2CN)_2$(μ-SCH_2CH_2Cl)IrCp*]$^+$ suivant les conditions utilisées. La réaction du composé **3** avec du [(Cp*Ru)$_4$(μ-Cl)$_4$] conduit à la formation d'un agrégat sulfido-thiolato [Cp*$_3$$RuIr_2$(μ$_3$-S)(μ-$SCH_2CH_2CN)_2$Cl].

Mots clés : complexe de diiridium, thiolate, sulfure, ruthénium, agrégat.

[Traduit par la Rédaction]

In contrast to extensive studies on the reactions of transition metal complexes with organic thiols and their derivatives, those with H_2S as well as the reactivities of the hydrosulfido complexes thus formed are still poorly developed (1). Previously we have shown that treatment of chloro-bridged dinuclear complexes [Cp*MCl(μ-Cl)$_2$MCp*Cl] (M = Ir, Rh (2), Ru (3); Cp* = η^5-C_5Me_5) with H_2S results in the formation of hydrosulfido-bridged complexes [Cp*MCl(μ-SH)$_2$MCp*Cl]. Under certain conditions, triply bridged complexes [Cp*MCl(μ-SH)$_3$MCp*Cl]Cl were also available for M = Ir (**1**) and Rh (2). Although various reactions of the former doubly bridged neutral complexes have already been demonstrated (3, 4), the reactivities of the latter cationic complexes are not yet explored. In this paper, we report the addition of the hydrosulfido ligands in **1** to acrylonitrile (AN) in the presence of base to give the cyanoethylthiolato-bridged diiridium complexes, one of which is transformed into a $RuIr_2$ cluster by reaction with a ruthenium complex.

When a mixture of **1** and 4 equiv of AN in MeCN was treated with 4 equiv of NEt_3 at –40°C, an immediate color change from yellow to red was observed. The mixture was warmed to 40°C and stirred continuously for 70 h, affording [Cp*Ir(μ-$SCH_2CH_2CN)_3$IrCp*][PF_6] (**2**)[3] as yellow needles in 36% yield after anion metathesis using [H_4N][PF_6] (Scheme 1). In the absence of NEt_3, addition of the SH ligands to AN did not take place under otherwise similar conditions. If **1** is treated with only 2 equiv of AN and 4 equiv of NEt_3 at –40°C, followed by stirring of the resulting red solution at room temperature for 24 h, the neutral complex [Cp*Ir(μ-S)(μ-$SCH_2CH_2CN)_2$IrCp*] (**3**)[3] is obtained as red prisms in 70% yield (Scheme 1). Complex **3** is the apparent result of insertion of 2 equiv of AN into two S—H bonds

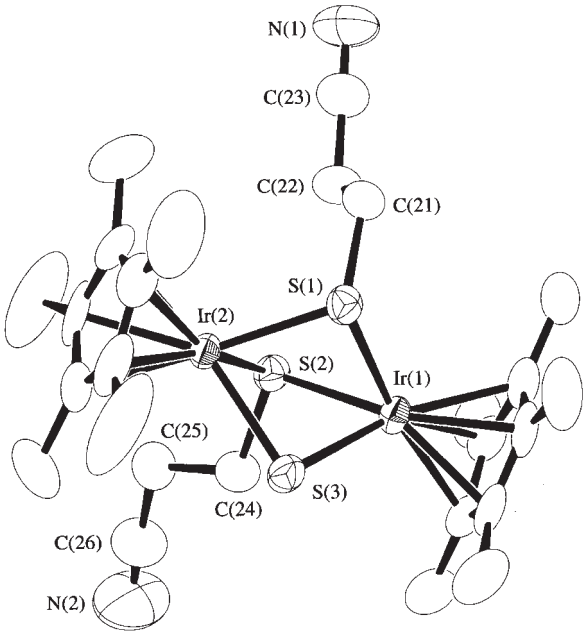

Scheme 1.

and deprotonation of the third thiolato group, and might represent one of the intermediate stages on the route from **1** to **2**.[4] Differences in the reaction conditions required for the isolation of **2** and **3** suggest that incorporation of the third AN is somehow much slower than that of the first or second AN.

Interestingly, when the reaction of **1** with 4 or more equiv of AN in the presence of 4 equiv of NEt_3 was performed in $ClCH_2CH_2Cl$ in place of MeCN, $[Cp^*Ir(\mu\text{-}SCH_2CH_2CN)_2(\mu\text{-}SCH_2CH_2Cl)IrCp^*][PF_6]$ (**4**)[3] was isolated as yellow crystals in 52% yield by treatment with $[H_4N][PF_6]$ (Scheme 1). Formally, two SH ligands in **1** underwent the addition to AN, while the remaining SH group was subjected to electrophilic substitution of the SH proton by the chloroethyl moiety. Addition to the third AN is so slow that the substitution may preferentially proceed at the third bridging sulfur atom. Indeed, it has been confirmed that **3** readily reacts with $ClCH_2CH_2Cl$ to give $[Cp^*Ir(\mu\text{-}SCH_2CH_2CN)_2(\mu\text{-}SCH_2CH_2Cl)IrCp^*]^+$ at room temperature.

Fig. 1. A molecular structure of **3**. Hydrogen atoms are omitted.

The structures of **3** and **4**·$ClCH_2CH_2Cl$ were determined in detail by X-ray crystallography.[5] The ORTEP drawing of **3** is shown in Fig. 1, whose Ir_2S_3 core structure is quite analogous to that in **4**. The Ir···Ir distances at 3.324(1) and 3.330(1) Å in **3** and **4**, respectively, which are elongated only slightly from 3.2954(7) Å of the hydrosulfido-bridged cation in **1**, indicate the absence of any bonding interactions between two Ir atoms. There exist no significant differences between the Ir—$S_{sulfido}$ and Ir—$S_{thiolate}$ bond lengths in **3**, which fall in the range 2.382(2)–2.395(2) Å and are comparable to the Ir—$S_{thiolate}$ bond distances in **4** (2.370(5)–2.399(5) Å).

With respect to the SH ligand, a considerable number of addition reactions toward unsaturated C—C bonds have been known for some time, which include, for example, the reactions of bridging SH ligands in dinuclear complexes such as $[\{Fe(CO)_3\}_2(\mu\text{-}SH)_2]$ (5), $[(Cp^*Rh)_2(\mu\text{-}CH_2)_2(\mu\text{-}SH)]^+$ (6), $[(Cp'Mo)_2(\mu\text{-}S)_2(\mu\text{-}SH)_2]$ (Cp′ = η^5-C_5H_4Me) (7), $[Rh(CO)(\mu\text{-}SH)(\mu\text{-}Ph_2PCH_2PPh_2)_2Mn(CO)_3]^+$ (8), and $[\{(\eta^5\text{-}C_5H_5)_2\}Ti(\mu\text{-}SH)_2Mo(CO)_4]$ (9) with alkynes and (or) alkenes. Nucleophilic substitution of the SH complexes with alkyl halides is also precedented for, e.g., $[(Cp'Mo)_2(\mu\text{:}\eta^2\text{-}$

[4] It has been confirmed that **3** dissolved in MeCN reacts with AN in the presence of $[Et_3NH]Cl$ to give **2**.

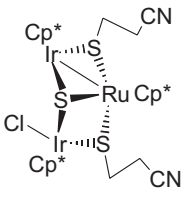
Equation 1.

[1] **3** + 1 4[$(Cp^*Ru)_4(\mu_3\text{-}Cl)_4$] $\xrightarrow{THF}$ **5**



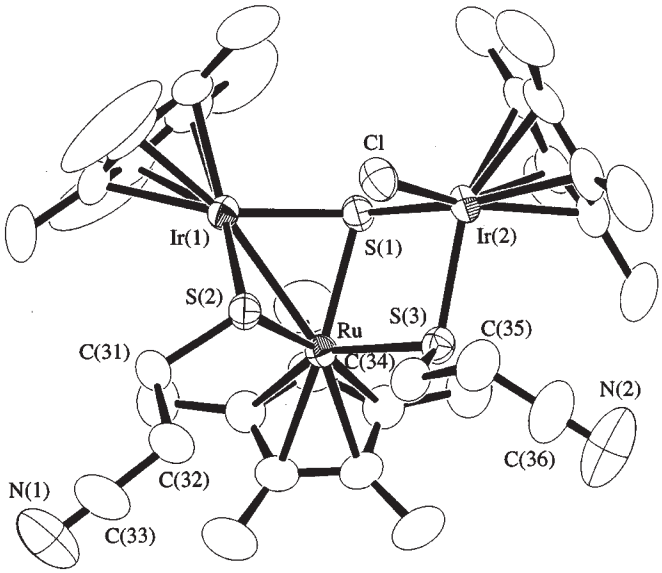


Fig. 2. A molecular structure of **5**. Hydrogen atoms are omitted.

S_2CH_2)(μ-SMe)(μ-SH)] (10) and [{$IrH(PPh_3)_2$}$_2$(μ-H)(μ-$SH)_2$]$^+$ (11).

Recent studies in this group have focused on the syntheses of mixed-metal sulfido clusters containing noble metals, which have revealed that the dinuclear complexes containing sulfido bridge(s) can serve as good precursors to such clusters (12). As expected, treatment of **3** with 0.25 molar equiv of [$(Cp^*Ru)_4(\mu_3\text{-}Cl)_4$] in THF at room temperature afforded a trinuclear bimetallic cluster [$Cp^*_3RuIr_2(\mu_3\text{-}S)(\mu\text{-}SCH_2CH_2CN)_2Cl$] (**5**)[3] in 70% yield (eq. [1]). Complex **5**, obtained as black needles, was also characterized by X-ray analysis.[5] As shown in Fig. 2, **5** has a sulfido-capped $RuIr_2$ core, which is further bridged by two cyanoethylthiolato ligands at each Ru—Ir edge. For the $RuIr_2$ triangle, there exists only one metal—metal single bond, thus satisfying the 18-e count for all metals. Thus, the Ru—Ir(1) distance at 2.8362(5) Å is consistent with the presence of a Ru—Ir single bond, while the separation of the Ru atom from Ir(2), having a terminal Cl ligand (3.6922(6) Å), as well as that between two Ir atoms (4.1529(3) Å), are apparently indicative of the absence of any bonding interaction.

Further studies are now in progress to clarify the reactivities of **1** towards more diversified unsaturated C—C bonds and also to synthesize a series of bimetallic clusters from **3**.

We are grateful to the Ministry of Education, Science, Sports, and Culture of Japan for financial support.

(*para*-Diphenylphosphino)benzenesulfonic acid and its ruthenium(II) complexes: an old water soluble phosphine ligand in a new perspective

Gábor Papp, József Kovács, Attila Cs. Bényei, Gábor Laurenczy, Levente Nádasdi, and Ferenc Joó

Abstract: Chloro- and hydrido-complexes of ruthenium(II) with potassium (4-diphenylphosphino)benzenesulfonate (pTPPMS) were prepared and their properties were compared with those of the related complexes of (3-diphenylphosphino)benzenesulfonates. An X-ray crystal structure determination revealed that the *para*-sulfonated ligand has a Tolman cone angle slightly smaller than that of PPh_3. It was established by pH-potentiometric measurements and by ^1H and ^{31}P NMR studies that the distribution of the hydride derivatives $[RuClH(pTPPMS)_3]$ and $[RuH_2(pTPPMS)_{3,4}]$ is strongly pH-dependent. Hydrogenation of *trans*-cinnamaldehyde in aqueous–organic mixtures is catalyzed by $[RuCl_2(pTPPMS)_4]$ and is also strongly influenced by the pH of the aqueous phase due to the pH-dependent formation of the above hydrides. In acidic solutions (pH < 2) an exclusive C=C reduction takes place, while in alkaline solutions (pH > 6) a selective C=O hydrogenation was observed.

Key words: ruthenium, water soluble, hydrogenation, hydrides, sulfonated phosphines, biphasic.

Résumé : On a préparé les complexes chloro- et hydrido de ruthénium(II) avec le (4-diphénylphosphino)benzènesulfonate de potassium (pTPPMS) et on a comparé leurs propriétés avec celles des complexes apparentés des (3-diphénylphosphino)benzènesulfonates. Une détermination de structure par diffraction des rayons X a permis de mettre en évidence que le ligand *para*-sulfoné présente un cône de Tolman qui est légèrement inférieur à celui du PPh_3. Des mesures potentiométriques de pH et des études de RMN du ^1H et du ^{31}P ont permit de déterminer que la distribution des dérivés hydrures $[RuClH(pTPPMS)_3]$ et $[RuH_2(pTPPMS)_{3,4}]$ dépend beaucoup du pH. L'hydrogénation du *trans*-cinnamaldéhyde, dans des mélanges eau/solvant organique, est catalysée par le $[RuCl_2(pTPPMS)_4]$ et qu'elle est fortement influencée par le pH de la phase aqueuse en raison de la formation des hydrures mentionnés plus haut qui est influencée par le pH. En solutions acides (pH < 2), on observe exclusivement la réduction de la liaison C=C alors qu'en solutions alcalines (pH > 6), on observe une hydrogénation sélective de C=O.

Mots clés : ruthénium, soluble dans l'eau, hydrogénation, hydrures, phosphines sulfonées, à deux phases.

[Traduit par la Rédaction]

Introduction

Aqueous organometallic chemistry and catalysis has attracted a great deal of interest recently mostly as a consequence of the relatively easy and cheap regeneration of the catalysts and isolation of products in aqueous–organic biphasic systems (1–3). Although by far not exclusive, water soluble tertiary phosphines are the most important ligands in this field; the best known example being 3,3′,3″-phosphinetriylbenzenesulfonic acid (Na^+ or K^+ salts) (TPPTS) or more precisely, mTPPTS (4, 5). The simplest way of preparation of sulfonated arylphosphines is the sulfonation of the parent triarylphosphine by fuming sulfuric acid. In fact, the first water soluble phosphine ligand (3-diphenylphosphino)benzenesulfonic acid (mTPPMS) (as a Na^+ or K^+ salt), introduced into coordination chemistry by Ahrland et al. (6), was prepared this way as early as 1958. As a result of the protonation of phosphorus in fuming sulfuric acid these compounds contain the $-SO_3$ moiety in the *meta* position to the P donor atom. Based on a large body of experimental findings in coordination chemistry (7) and in organometallic catalysis (1–3, 8, 9) it could be concluded that such a modification of triarylphosphines did not lead to spectacular changes in complexation properties of these ligands despite

the somewhat diminished electron density on phosphorus and the obvious increase in size. Nevertheless, a few distinct changes have been noticed. For example, although $[RuCl_2(PPh_3)_3]$, $[RuCl_2(PPh_3)_4]$, and $[\{RuCl_2(PPh_3)_2\}_2]$ are all known in solid form (10, 11), with the *meta*-monosulfonated triphenylphosphine only $[\{RuCl_2(mTPPMS)_2\}_2]$ could be isolated (12, 13). Furthermore, the water soluble analog of the easily isolable $[RhH(PPh_3)_4]$, i.e., $[RhH(mTPPMS)_4]$ could not be prepared at all (14). There are only a few X-ray crystal structures of complexes with sulfonated arylphosphines available (15–17) that would allow comparison of ligands having the sulfonate substituent in different positions; no systematic study was devoted to this question. Both (4-diphenylphosphino) benzenesulfonates (pTPPMS) (18) and 4,4′,4″-phosphinetriylbenzenesulfonates (pTPPTS) (19, 20) have already been described in the literature. The *para*-monosulfonated triphenylphosphine, pTPPMS was first prepared by Schindlbauer (18) in 1965, but since then only one study (21) concerned its use in catalysis. Ruthenium(II)–phosphine complexes play an important role in catalysis (22) and the dissociation equilibria and reactivity of $[RuCl_2(PPh_3)_3]$ was thoroughly studied in this context (23, 24). Therefore, it seemed of interest to us to prepare ruthenium(II) complexes of pTPPMS and compare them to the well known Ru(II) complexes of mTPPMS. Herein, we report the results of our structural and catalytic studies.

Experimental

All manipulations were done under an argon or nitrogen atmosphere. All solvents were purified by distillation and carefully deaerated before use. Doubly distilled water was used throughout.

Chlorodiphenylphosphine, triphenylphosphine, chlorosulfonic acid, and fluorobenzene were obtained from Aldrich. Fuming sulfuric acid (30% SO_3) was supplied by Merck. $RuCl_3$ (aq) was a loan from Johnson Matthey. D_2O (99.9%) was purchased from Cambridge Isotope Laboratories. H_2, N_2, and Ar were acquired from Carbagas-CH or from Messer (Hungary). *trans*-Cinnamaldehyde (Aldrich) was distilled at reduced pressure before use. All other reagents were obtained from Aldrich and used without further purification.

Infrared spectra were recorded on a PerkinElmer Paragon 1000 PC FT-IR spectrometer on KBr discs. ^1H and proton decoupled ^{31}P NMR measurements were run on Bruker AC 200, AM 360, DRX 400, and DRX 600 NMR spectrometers and are referenced to 3-(trimethylsilyl)-1-propanesulfonic acid sodium salt (TSPSA, Fluka) and 85% phosphoric acid, respectively. The spectra were fitted with WIN-NMR, GNMR 4.0, and NMRICMA/MATLAB programs using a PC. Conditions of the pH-potentiometric measurements are described in detail in refs. 25 and 26, and those of HPLC analysis of the sulfonated phosphines in ref. 13.

The sulfonated phosphines pTPPMS (K^+ salt, monohydrate) (21) and mTPPMS (Na^+ salt) (13), as well as the complexes $[RuCl_2(PPh_3)_3]$ (10), $[\{RuCl_2(mTPPMS)_2\}_2]$ (13), and $[\{Ru(H_2O)_6\}(tosylate)_2]$ (27) were prepared as described in the literature. The purity of pTPPMS was checked by ^{31}P NMR (D_2O, δ = –5.87 ppm, s) and by HPLC (13); both methods revealed a uniform compound with no phosphine oxide present. X-ray quality crystals of the pTPPMS–Cs^+ salt could be obtained by recrystallization of 0.1 mmol of the pTPPMS–K^+ salt from 12 mL of a 0.4 M CsCl solution.

$[RuCl_2(pTPPMS)_4]$ was prepared by an adaptation of the method of Borowski et al. (28) for the preparation of various mTPPMS complexes. To a solution of $[RuCl_2(PPh_3)_3]$ (288 mg, 0.3 mmol) in tetrahydrofuran (THF) (50 mL) was added pTPPMS (570 mg, 1.5 mmol). The resulting clear solution was stirred at room temperature for 24 h during which the THF-insoluble $[RuCl_2(pTPPMS)_4]$ (as a stable tetrahydrate) precipitated as a light brown powder. For several batches the yields were consistently higher than 90%. The ruthenium and phosphorus content was determined on a Spectroflame ICP-AES (λ_{Ru} = 267.876 nm, λ_P = 178.287 nm). Anal. calcd. for $C_{72}H_{64}Cl_2K_4O_{16}P_4S_4Ru$: Ru 5.72, P 7.02, [P]/[Ru] = 4; found: Ru 5.58, P 7.02, [P]/[Ru] = 4.10.

Catalytic hydrogenation of *trans*-cinnamaldehyde (50 μL, 0.4 mmol) was carried out in a thoroughly stirred two-phase liquid mixture comprised of an aqueous phosphate buffer (3.00 mL) of known pH, containing KCl (45 mg), and chlorobenzene (5.00 mL) at 80°C. The reaction was started by the addition of $[RuCl_2(pTPPMS)_4]$ (13.0 mg, 7.4 μmol) together with pTPPMS (12.0 mg, 30 μmol), and the organic layer was analyzed by gas chromatography after 240 min reaction time. GC conditions: Chrom 5; packed column, Carbowax 20M on Chromosorb, 240 cm; injector 220°C, column 200°C, detector (FID) 200°C; carrier Ar.

X-ray crystal structure determination of $Ph_2PC_6H_4$-4-$SO_3Cs\cdot H_2O$

A colourless prism of dimensions of 0.35 × 0.20 × 0.15 mm was mounted on a glass fiber with epoxy cement. Data collection was performed on an Enraf–Nonius MACH3/PC diffractometer in non-profiled ω/2θ scans with θ_{max} = 23.01°. A total of 7775 independent reflections were collected. The structure was solved with the use of direct methods (29) and refined by using SHELXL 97 (30). Hydrogen atoms were treated by a mixture of independent and constrained refinement. Scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 31. Pertinent crystal data are shown in Table 1.

Results and discussion

Preparation and properties of pTPPMS

Potassium (4-diphenylphosphino)benzenesulfonate (pTPPMS) was prepared by the reaction of potassium 4-fluorobenzenesulfonate and $KPPh_2$ in THF as described by Novak and co-workers (21). In some cases we have observed formation of small amounts of the water insoluble 1,4-bis(diphenylphosphino)benzene. In fact, the latter compound was prepared in high yield by Schindlbauer (18) by heating at reflux (160–180°C) 1,4-$ClC_6H_4SO_3Na$ and $KPPh_2$ in β,β′-diethoxy-diethyl ether. Similar to mTPPMS, in aqueous solutions pTPPMS behaves as a surfactant, which may result in solubilization of unsulfonated phosphines (13). Infrared stretching frequencies of the $-SO_3$ group in pTPPMS are very close to those in mTPPMS (13): 1038 and 1042 cm^{-1} (A_1) and 1200 and 1196 cm^{-1} (E), respectively.

We could obtain X-ray quality crystals of the cesium salt of pTPPMS by recrystallization of the K-salt from a CsCl

solution. The structure of the pTPPMS–Cs^+ salt was determined by X-ray diffraction and this gives an opportunity to compare it to a recently published structure (32) of the benzyltriethylammonium salt of mTPPMS. An ORTEP representation is shown in Fig. 1. Each unit cell contains two phosphine molecules and one H_2O molecule. The two molecules consistently have slightly different geometric parameters, however, the difference is within the error of structure determination. Selected interatomic distances and angles are given in Table 2.[3]

As expected, the geometry around the phosphorus atom is trigonal pyramidal, and the average value (for both phosphine moieties in the asymmetric unit) of the three P—C bonds is 183.6 pm and that of the C-P-C angles is 101.9°. These values are insignificantly different from those determined for PPh_3 (182.8 pm and 103.0° (33) and 183.1 pm and 102.8° (34)), and from those obtained in the case of the mono- and tri-sulfonated triphenylphosphines $[N(CH_2C_6H_5)(C_2H_5)_3^+](Ph_2PC_6H_4$-3-$SO_3^-\cdot H_2O]$ (182.6 pm and 102.5° (32)) and $[P(C_6H_4$-4-$SO_3K)_3\cdot KCl\cdot 0.5H_2O]$ (184.3 pm and 103.5° (20)), respectively. The cone angle, as defined by Tolman (35), was determined from these structural data essentially as described by Darensbourg et al. (16, 17). To this end, a virtual H atom was placed at a distance of 228 pm from the phosphorus atom and the cone angle of the *smallest* cone which originates from the coordinates of this hydrogen and circumscribes the whole molecule (without the cation) was computed. For comparison, similar calculations were made using X-ray crystal structural data of other tertiary arylphosphines taken from the Cambridge Structural Database. In the case of *para*-subsituted arylphosphines it is also important to consider the space requirement of the hydrogen atoms in *ortho*-positions of the aryl rings; this was accounted for by using the Bohr radius of H (52.9 pm). Cone angles of several substituted triphenylphosphines and that of PPh_3 are collected in Table 3.

Our calculations resulted in a cone angle of 141.5° for PPh_3, which is in a reasonable agreement with the value of 145° reported by Tolman (35). More interestingly, the cone angles for pTPPMS and pTPPTS are slightly *smaller* (by 4° and 2°, respectively), while for mTPPMS and mTPPTS are considerably *larger* (approximately by 35°) than that of PPh_3. It can be concluded, therefore, that the space requirement of *para*-sulfonated triphenylphosphines is practically the same as that of PPh_3 itself, *meta*-sulfonated triphenylphosphines, however, are much more space-demanding. Furthermore, it is the position and not the number of the -SO_3 substituents

that defines the size of these ligands (at least in terms of their cone angles).

Preparation and reactions of $[RuCl_2(pTPPMS)_4]$ and its catalytic activity in hydrogenation of *trans*-cinnamaldehyde

When a THF solution of $[RuCl_2(PPh_3)_3]$ was reacted with 5 equiv of pTPPMS, metathesis of the phosphine ligands produced the title compound, which is only sparingly soluble in THF, in high yield.

The overall composition of the complex in solid form as $[RuCl_2(pTPPMS)_4]$ was confirmed by determination of its ruthenium–phosphorus content (1:4). This is an interesting difference in comparison with mTPPMS. Ruthenium(II) complexes of (3-diphenylphosphino)benzenesulfonic acid (Na salt) can be prepared either by heating at reflux ethanolic solutions of aq $RuCl_3$ with an excess of mTPPMS, or by phosphine metathesis in THF (13), similar to the procedure described above with pTPPMS. However, in both reactions the product is $[\{RuCl_2(mTPPMS)_2\}_2]$. While one can expect a larger extent of phosphine dissociation, and hence, an increased probability of dimerization at reflux temperature, the exclusive formation of the dimeric mTPPMS derivative in room temperature metathesis reactions is in contrast to the formation of $[RuCl_2(PPh_3)_3]$ in refluxing ethanol and to that of $[RuCl_2(PPh_3)_4]$ in cold methanol (10). On the other hand, the relative stability of the various monomeric and dimeric compounds correlates well with the space requirement of PPh_3, pTPPMS, and mTPPMS as represented by the respective Tolman cone angles. Such a lowering of the number of coordinated phosphine ligands was also observed in the case of $[Pd(mTPPMS)_3]$ (15) and in the failed attempts to prepare $[RhH(mTPPMS)_4]$ (14) (Na^+ or K^+ salts).

Characterization of the new water soluble phosphine complexes by NMR spectroscopy presented considerable difficulties. Unfortunately, in all measurements described below the signals were found to be very broad (50–150 Hz) and were basically uneffected by ^1H decoupling, changes in the temperature between 0–50°C, or by addition of small amounts of MeOD, which were found to be useful in other cases (14). Although the line width of the signals refer to intra- and (or) intermolecular dynamic processes or fast relaxation, insufficient solubility of the compounds in the ususal NMR solvents other than D_2O (alcohols, THF, acetone etc.) precluded measurements in a wide temperature range.

In D_2O solutions of $[RuCl_2(pTPPMS)_4]$ the ^{31}P NMR spectra showed two overlapping unresolved, symmetric resonances at 54.5 and 53.7 ppm in addition to resonances representing some phosphine oxide (36.0 ppm, br s) and some free phosphine (–5.8 ppm, br s). Upon addition of pTPPMS in excess (up to [P]/[Ru] = 15) the signal at 53.7 ppm became dominant at the expense of the signal at 54.5 ppm, which shows the existence of at least two ruthenium complexes in the solution. However, the signals were still unresolved, and therefore, unsuitable for structural characterization. To obtain more information we wanted to study the ^{19}F NMR spectra of related fluoro complexes. Addition of KF to solutions of $[RuCl_2(pTPPMS)_4]$ ($[F^-]/[Ru]$ = 2–10) produced complex spectra, therefore, chloride-free samples were prepared in the reaction of $[Ru(H_2O)_6]^{2+} + 2F^- + 8(pTPPMS)$. The only major ^{31}P NMR signal was observed at 53.2 ppm (broad but symmetric) accompanied by several small peaks at 54.0, 52.0, 45.1, and 39.2 ppm (in addition to free pTPPMS and some of its oxide). ^1H or ^{19}F decoupling did not reveal any structure of the resonances either, as it did not cause any noticable line sharpening (for technical reasons simultaneous decoupling was not possible). The ^{19}F NMR spectrum of the same solution was more informative. Remarkably, it showed no signs of free F^- indicating that the dominant peak in the ^{31}P NMR spectrum should belong to a *difluoro* species. Furthermore, a well resolved triplet of triplets centered at –108.70 ppm was observed with coupling constants $^2J_{P_{trans},F}$ = 8.5 Hz and $^2J_{P_{cis},F}$ = 5.2 Hz. ^{31}P decoupling resulted in partial collapse of the structure of the ^{19}F signal, although with our technical capabilities full collapse to a singlet could not be observed. These data are consistent with the presence of a *cis*-$[RuF_2(pTPPMS)_4]$ complex, and the small values of the coupling constants explain the insensitivity of the ^{31}P NMR signals for fluorine decoupling. Such a species should show two ^{31}P resonances of equal intensity, which we do not observe separately as they may overlap or be hidden underneath the broad envelope at 53.2 ppm. Although one may not extrapolate with certainty the conclusions regarding the fluoro-complex(es) to the case of the chloride-containing species, the similarity of the ^{31}P NMR spectra at high pTPPMS excess allows us to believe that at least some of the ruthenium is present as *cis*-$[RuCl_2(pTPPMS)_4]$. Stabilization of higher phosphine species by hydrogen bonding as in case of sulfonated phosphine complexes relative to the analogous PPh_3 compounds has already been observed and quantitatively established for the phosphine dissociation equilibria of $[Rh(CO)H(mTPPTS)_3]$ vs. $[Rh(CO)H(PPh_3)_3]$ (36).

We have described earlier that $[\{RuCl_2(mTPPMS)_2\}_2]$ is prone to hydrolysis in water (25, 26). This complex activates H_2 via heterolytic fission, and therefore, formation of both $[RuClH(mTPPMS)_3]$ and $[RuH_2(mTPPMS)_4]$ is accompanied by proton production. All these reactions were followed by pH-potentiometry and the resulting ruthenium complexes were identified by ^1H and ^{31}P NMR spectroscopy (25, 26). Similarly, in aqueous solutions at slightly elevated temperatures $[RuCl_2(pTPPMS)_4]$ readily reacts with molecular hydrogen. A combined potentiometric–NMR study of this reaction was undertaken. In short, $[RuCl_2(pTPPMS)_4]$ was dissolved under an inert gas atmosphere (Ar) in a solution of a supporting electrolyte (KCl) and excess pTPPMS at a preset *constant pH*. In case of any hydrolysis the pH was kept constant by delivering KOH solution of known concentration by an autoburette. The volume of the KOH solution consumed is proportional to the extent of hydrolysis at that particular pH. After attaining equilibrium the solution was

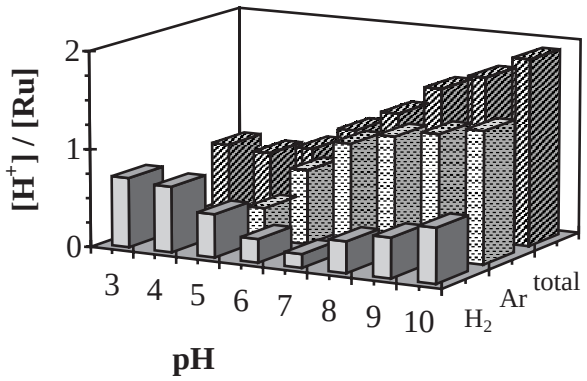
Fig. 2. Proton production upon dissolution (middle set of bars) and further hydrogenation (front set) of solutions of $[RuCl_2(pTPPMS)_4]$ as a function of pH. Total proton production is shown by the back set of bars (220 mg $[RuCl_2(pTPPMS)_4]$, 200 mg pTPPMS, 10 mL 0.2 M KCl, H_2O:D_2O = 9:1, 60°C, 1 bar of Ar or H_2).



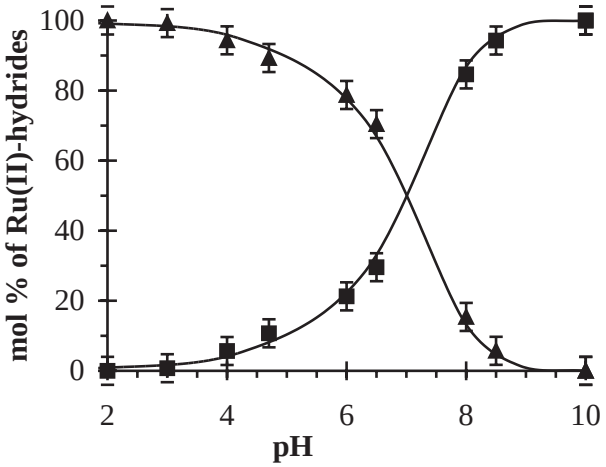


Fig. 3. Distribution of ruthenium into $[RuClH(pTPPMS)_3]$ (▲) and $[RuH_2(pTPPMS)_{3,4}]$ (■) in aqueous solution as a function of pH (220 mg $[RuCl_2(pTPPMS)_4]$, 200 mg pTPPMS, 10 mL 0.2 M KCl, H_2O:D_2O = 9:1, 60°C, 1 bar of Ar or H_2).

placed under hydrogen gas. Formation of any ruthenium hydrides with heterolytic splitting of H_2 was, again, indicated by further KOH consumption until the reaction attained a new equilibrium position at the particular (preset) pH. This way the whole pH-range, amenable to measurements with a glass electrode, was investigated for hydrolysis of and hydride formation from $[RuCl_2(pTPPMS)_4]$ under H_2. The results are shown in Figs. 2 and 3.

It is seen from Fig. 2 that below pH 5 there is no or negligible proton production upon dissolution of $[RuCl_2(pTPPMS)_4]$. However, hydrogenation of the same solutions results in the formation of 1 mol of H^+ for 1 mol of Ru. During this reaction the colour of the solution turns deep cherry red. The ^1H and ^{31}P NMR spectra of these solutions were recorded (90% H_2O – 10% D_2O, 50°C). ^1H NMR δ: –17.9 (q, $^2J_{P,H}$ = 24.9 Hz). ^{31}P NMR δ: 58.7 (br s). These data are consistent with the formation of $[RuHCl(pTPPMS)_3]$; similar $[RuHCl(P)_3]$ complexes have already been reported with PPh_3 (37), mTPPMS (25, 26), and mTPPTS ligands (38, 39).

In basic solutions significant proton production is observed upon dissolution of $[RuCl_2(pTPPMS)_4]$ with excess pTPPMS under argon indicating extensive hydrolysis. Bubbling hydrogen through these solutions resulted in further proton production (Fig. 2) giving $[H^+]_{total}/[Ru]$ = 2 at pH 10. Above pH 9 the hydrogenated solutions are bright yellow. ^{31}P NMR spectra of these yellow solutions recorded at 81.01 and 161.94 MHz (90% H_2O – 10% D_2O, 50°C) showed broad singlets at δ = 41.5, 52.0, and 54.6 ppm in a ratio of 2:2:1, respectively. However, at 242.94 MHz the signal at 41.5 ppm split into two resonances of equal intensity at 41.39 and 41.57 ppm. The only ^1H NMR signal was observed at –10.3 ppm (br td or pseudo q) with the coupling constants $^2J_{P_a,H}$ = 34.4 Hz and $^2J_{P_b,H}$ = 35.0 Hz. Selective ^{31}P decoupling at 41.5 ppm caused this signal to collapse into a triplet while irradiation at 52.0 ppm resulted in a doublet in the hydride region. According to the results of the pH-static hydrogenation (2 mol H^+ is produced for 1 mol Ru) the hydride species present should be *dihydride(s)*, so any monohydride which otherwise would fit the NMR data can be disregarded. Consequently, one pair of the ^{31}P NMR signals, one of those at 41.39 and 41.57 ppm together with the resonance at 52.0 (intensity ratio 1:2) is assigned to trisphosphine species, i.e., we suggest that part of the ruthenium(II) is present as the trigonal bipyramidal *cis*-$[RuH_2(pTPPMS)_3]$ and (or) the structurally close octahedral *trans*-$[RuH_2(H_2O)(pTPPMS)_3]$ (analogous to $[RuH_2(PPh_3)_3(THF)]$ (40)). Such complexes have been identified as the catalytically active species in transfer hydrogenation experiments (42, 44).

Based on literature reports (40–43), *exclusive* formation of trisphosphine complexes is unlikely in the presence of excess phosphine such as pTPPMS used in our experiments ($[P]_{total}/[Ru]$ = 8). In agreement with the above, the two other ^{31}P NMR signals at around 41.5 and 54.6 ppm (intensity ratio 1:1) may belong to *cis*-$[RuH_2(pTPPMS)_4]$. In two earlier studies the analogous *cis*-$[RuH_2(TPPTS)_4]$ was found to have ^{31}P chemical shifts at δ = 42.4 (br s) and 55.0 (br s) (38) and at δ = 41.9 and 53.9 ppm (39). The same authors observed the hydride signal of *cis*-$[RuH_2(TPPTS)_4]$ at δ = –10.6 ppm ("pseudo-quartet," $^2J_{P,H}$ = 33 Hz) (38) and at δ = –10.5 ppm ("four intense merging lines," $^2J_{P,H}$ = 35 Hz) (39). In our case the putative *cis*-$[RuH_2(pTPPMS)_4]$ species is also expected to show a pseudo-quartet in ^1H NMR around δ = –10.3 ppm which may coincide with the signal(s) of the above *trans*-$[RuH_2(H_2O)(pTPPMS)_3]$ or *cis*-$[RuH_2(pTPPMS)_3]$ complexes. Selective ^{31}P decoupling of either P_a or P_b of *cis*-$[RuH_2(pTPPMS)_4]$ should result in collapse of the pseudo-quartet to a triplet, however, this may be obscured by the changes in the ^1H NMR spectra of the trisphosphine hydride complexes. The presence of both kinds of dihydrides is further supported by the simulation of the hydride resonance. The experimental spectrum could not be fitted properly with either *trans*-$[RuH_2(H_2O)P_3]$ or *cis*-$[RuH_2P_3]$ alone, however, an acceptable fit was obtained by considering a mixture of the trisphosphine complexes with *cis*-$[RuH_2(pTPPMS)_4]$ around 1:1 ratio. These simulations gave coupling constants for the td part of the spectrum as $^2J_{P_a,H}$ = 33 Hz and $^2J_{P_b,H}$ = 39 Hz (compared to 34.4 and 35.0 Hz, respectively, from the ^{31}P NMR spectrum) and for the supposed pseudo-quartet as $^2J_{P,H}$ = 44 Hz, its center being shifted by 11 Hz from the center of the td signal. Based on these considerations we conclude

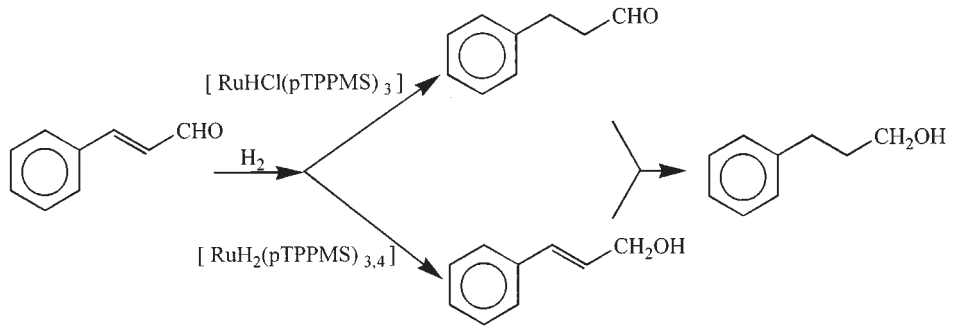
Fig. 4. Hydrogenation of *trans*-cinnamaldehyde.



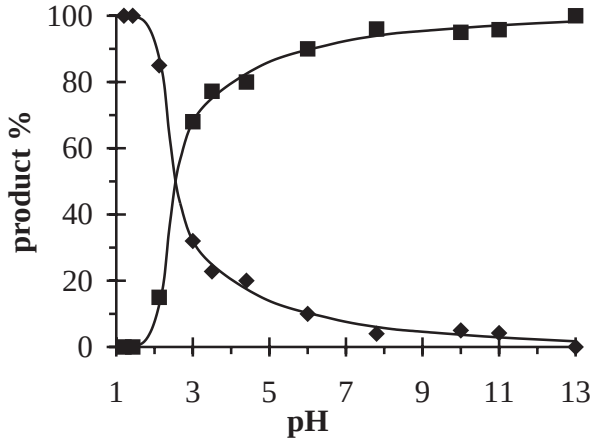


Fig. 5. Selectivity of the hydrogenation of *trans*-cinnamaldehyde to saturated aldehyde (◆) and unsaturated alcohol (■) catalyzed by $[RuCl_2(pTPPMS)_4]$ as a function of pH. For conditions see *Experimental*.

that in our solutions prepared from $[RuCl_2(pTPPMS)_4]$ with excess pTPPMS under hydrogen at high pH (>9) ruthenium is present in form of a mixture of tris- and tetrakisphosphine dihydrides, $[RuH_2X(pTPPMS)_3]$ (X = nothing or H_2O) and *cis*-$[RuH_2(pTPPMS)_4]$; for a general description of the ruthenium hydrides in such solutions in the following we use $[RuH_2(pTPPMS)_{3,4}]$.

In the intermediate pH range (5 < pH < 9) both mono- and dihydrides are present and their concentration distribution was calculated from the integrated intensities of the respective hydride ^1H NMR signals. Under these conditions a small amount of a third complex was also detected (90% H_2O – 10% D_2O, 50°C). ^1H NMR δ: –8.7 (td, $^2J_{P,H}$ = 37.7 Hz, $^2J_{P,H}$ = 7.9 Hz). ^{31}P NMR δ: 51.4 (br s). These data are very close to those of $[\{RuClH(mTPPMS)_2\}_2]$ identified earlier by Sánchez-Delgado et al. (45) (^1H NMR δ: –8.7 (td, $^2J_{P,H}$ = 38 Hz, $J_{H,H}$ = 9 Hz). ^{31}P NMR δ: 52.11 (AB q, $J_{A,B}$ = 38 Hz)) and suggest the presence of $[\{RuClH(pTPPMS)_2\}_2]$. No signs of other hydrides, such as e.g., the analogs of $[RuClH(PPh_3)_3]_2$ (46) and $[(PPh_3)_2(H)Ru(\mu\text{-}H)(\mu\text{-}Cl)RuH(PPh_3)_2]^-$ (47) were seen by NMR spectroscopy in solutions of any pH.

As expected, both the ^1H and ^{31}P NMR data of the Ru-pTPPMS complexes are very close to the corresponding parameters of $[RuHCl(mTPPMS)_3]$ and $[RuH_2(mTPPMS)_4]$, since in these hydrides the steric requirements of the phosphine ligands seem to play no important role. However, the higher stability of the corresponding pTPPMS complexes manifests itself in the onset of the formation of $[RuH_2(pTPPMS)_{3,4}]$ at somewhat lower pH, than for $[RuH_2(mTPPMS)_4]$. Under strictly comparable conditions there is only a negligible fraction of Ru(II) in the form of $[RuH_2(mTPPMS)_4]$ at pH 6 (25, 26), while $[RuH_2(pTPPMS)_{3,4}]$ represents about 20% of all ruthenium at this pH and $[RuH_2(pTPPMS)_{3,4}]$ can be detected in a small relative concentration already at pH ≈ 2 (Fig. 3). This has important consequences in catalysis.

Selective reduction of an aldehyde or ketone function in the presence of an olefinic C=C bond is a challenge in catalysis and ruthenium phosphine complexes are among the best catalysts of such processes (25, 38, 44, 48). Hydrogenation of *trans*-cinnamaldehyde (Fig. 4) is actively catalyzed by the hydrido-complexes formed from $[RuCl_2(pTPPMS)_4]$. Depending on the pH, overall turnover frequencies up to 13 h^{-1} were determined under the conditions specified in *Experimental* (complete conversion of cinnamaldehyde). However, the selectivity of the reaction was a striking function of the pH (Fig. 5). In acidic solutions, around and below pH 2 slow hydrogenation of *trans*-cinnamaldehyde yields the saturated aldehyde, 3-phenylpropanal (C=C reduction). An increase in the pH of the aqueous phase results in a sharp increase in the overall rate and more importantly in the selectivity of hydrogenation in favour of the unsaturated alcohol, 3-phenyl-2-propenol (C=O reduction), which represents about 80% of all products already at pH 4. Although this change in selectivity does not strictly parallel the concentration distribution of $[RuClH(pTPPMS)_3]$ and $[RuH_2(pTPPMS)_{3,4}]$ as a function of the pH, it can be easily rationalized by assuming a higher specific rate of C=O reduction catalyzed by $[RuH_2(pTPPMS)_{3,4}]$ than that of C=C reduction catalyzed by $[RuClH(pTPPMS)_3]$. In comparison to catalysis of hydrogenation of *trans*-cinnamaldehyde by $[RuHCl(mTPPMS)_3]$ and $[RuH_2(mTPPMS)_4]$, the basic characteristics are very similar except that the change in the selectivity happens in a lower pH range with complexes of pTPPMS (pH 2–4 compared to 4.5–6.5 with mTPPMS). This may be a useful feature of catalysis by $[RuCl_2(pTPPMS)_{3,4}]$ in cases where lower pH is beneficial, such as the hydrogenation of bicarbonates (49, 50) under CO_2 pressure. The mechanism of the reaction is thought to be similar to that of the hydrogenation of unsaturated aldehydes with $[\{RuCl_2(mTPPMS)_2\}_2]$ + mTPPMS (25, 26), however, elucidation of a detailed picture requires further measurements.

Conclusions

In this study we have shown that the (4-diphenylphosphino)benzenesulfonate anion pTPPMS has approximately the same Tolman cone angle (determined by X-ray diffraction as its Cs^+ salt) as PPh_3. Consequently, the steric requirements for its coordination are considerably smaller than those of the closest analog, the (3-diphenylphosphino)benzenesulfonate anion, mTPPMS. NMR data of the two phosphines and their Ru(II)-complexes showed the ligand electronic properties to be very similar. Due to its smaller size (cone angle) pTPPMS forms more stable tetrakisphosphino–Ru(II) complexes, such as $[RuCl_2P_4]$ and $[RuH_2P_4]$ than mTPPMS; this is manifested in the distribution of the hydride complexes and the resulting selectivity of hydrogenation of *trans*-cinnamaldehyde as a function of pH.

Synthesis and structural features of complexes $[(P^{\frown}P)_2Rh][hfacac]$ containing hexafluoroacetylacetonate as a noncoordinating anion

Roland Fornika, Christian Six, Helmar Görls, Magnus Kessler, Carl Krüger, and Walter Leitner

Abstract: The synthesis and characterization of complexes $[(P^{\frown}P)_2Rh][hfacac]$ ($P^{\frown}P$ = chelating bidentate phosphine ligand $R_2P(CH_2)_nPR_2$ (**2a**–**g**), hfacac = hexafluoroacetylacetonate anion) (**4**) is reported. The molecular structures of **4a** (R = Ph, *n* = 1) and **4f** (R = Cy, *n* = 2) in the solid state were determined by single-crystal X-ray diffraction. The complexes crystallize in the monoclinic space groups *C*2/*c* (No. 15) and $P2_1/n$ (No. 14), respectively. No coordinative interaction between the rhodium center of the cation $[(P^{\frown}P)_2Rh]^+$ (**4a**$^+$, **4f**$^+$) and the hfacac anion is evident in either cases. In the crystal structure of **4a**, hydrogen bonds between the oxygen atoms of the hfacac anion and methylene protons of the CH_2 bridges of the phosphine ligand lead to highly symmetric chains of regularly alternating cations and anions. The coordination geometry around the rhodium center in **4a**$^+$ is ideally square-planar, whereas **4f**$^+$ is significantly distorted towards a tetrahedron with an angle between the two P_2Rh moieties of 18.6°. The cation **4b**$^+$ (R = Cy, *n* = 1) was investigated in form of the tetrafluoroborate salt for comparison. The compound $[\{Cy_2P(CH_2)PCy_2\}_2Rh][BF_4]$ crystallizes as a THF solvate (**4b′**) in the triclinic space group $P\bar{1}$ (No. 2) containing ideally square-planar $[(P^{\frown}P)_2Rh]^+$ cations.

Key words: rhodium, chelating ligands, coordination modes, 1,3-diketonates, phosphorus ligands.

Résumé : On a effectué la synthèse et la caractérisation de complexes $[(P^{\frown}P)_2Ph][hfacac]$ (**4**) ($P^{\frown}P$ = ligand phosphine chélatant bidentate $R_2P(CH_2)_nPR_2$, **2a**–**g**, hfacac = anion hexafluoroacétylacétonate). On a déterminé les structures moléculaires de **4a** (R = Ph, *n* = 1) et **4f** (R = Cy, *n* = 2) à l'état solide par diffraction des rayons X par des cristaux uniques. Les complexes cristallisent respectivement dans les groupes d'espace monocliniques *C*2/*c* (No. 15) et $P2_1/n$ (No. 14). Dans chacun de ces cas, on n'observe aucune interaction de coordination entre le centre rhodium du cation $[(P^{\frown}P)_2Rh]^+$ (**4a**$^+$, **4f**$^+$) et l'anion hfacac. Dans la structure cristalline du produit **4a**, des liaisons hydrogènes entre les atomes d'oxygène de l'anion hfacac et les protons méthyléniques des ponts CH_2 du ligand phosphine conduisent à des chaînes fortement symétriques comportant une alternance régulière de cations et d'anions. La géométrie de coordination autour du centre rhodium de **4a**$^+$ se présente comme un plan carré idéal alors que dans le cas du **4f**$^+$ on observe une déformation importante vers un tétraèdre avec un angle de 18,6° entre les deux portions de P_2Rh. Pour fins de comparaison, on a étudié le cation **4b**$^+$ (R = Cy, *n* = 1) sous la forme de sel de tétrafluoroborate. Les cristaux du composé $[\{Cy_2P(CH_2)PCy_2\}_2Rh][BF_4]$ qui est solvaté par le THF (**4b′**) sont tricliniques, groupe d'espace $P\bar{1}$ (No. 2) et ils comportent des cations $[(P^{\frown}P)_2Rh]^+$ qui sont dans un plan carré idéal.

Mots clés : rhodium, ligands chélatant, modes de coordination, 1,3-dicétonates, ligands phosphorés.

[Traduit par la Rédaction]

Introduction

1,3-Diketonates are frequently used as ligands in coordination chemistry (1). Metal complexes containing the acetylacetonate ligand (acac), and its trifluoro (tfacac) and hexafluoro (hfacac) analogues have found widespread applications. Such compounds are intensively studied in cancer chemotherapy (2), for metal extraction (3), as precursors for CVD applications (4), and as catalyst precursors (for example rhodium(I) 1,3-diketonates are frequently used as precur-

Scheme 1.

sors for olefin hydroformylation, see ref. 5*a*) to name just some of the most prominent fields of their uses.[2] We have utilized neutral complexes of type $[(P_2)Rh(hfacac)]$ (P_2 = phosphine ligand of general formula $R_2P\text{-}X\text{-}PR_2$) as model compounds to study the intrinsic influence of chelating phosphine ligands on catalytic active rhodium centers (6, 7*a*, and for a related discussion concerning complexes of the nickel triad see ref. 7*b*).

The classical coordination mode for 1,3-diketonates is the κ^2O,O′ bonding, which is favored by the generally strong M—O bond energy and the chelate effect of the planar six membered ring (1). Although less ubiquitous, the unidentate coordination modes κO (for an example see ref. 8) and κC (for a recent application of Ir(III)-acac complexes in benzene alkylation see ref. 5*b*, for other examples see ref. 9*a*, 9*b*) are also well-documented in the literature. A number of bridging coordination modes are known for acac-type anions, some of which have been described for the first time quite recently (5*b*, 10). However, there are very few cases of structurally characterized compounds with noncoordinating 1,3-diketonate anions in transition-metal chemistry (only one example could be localized in the Cambridge structure database, see ref. 11). For simple alkali and ammonium salts of acac-type anions, see ref. 12. Here, we report results on the synthesis and structure of complexes $[(P^{\frown}P)_2Rh][hfacac]$ ($P^{\frown}P$ = chelating bidentate phosphine ligand $R_2P(CH_2)_nPR_2$) (**4**), which consist of discrete anions and cations in solution and in the solid state. Structural features of the four coordinated d^8 cations $[(P^{\frown}P)_2Rh]^+$ ($\mathbf{4}^+$) related to the tendency of their formation are also discussed.

Results and discussion

Complexes $[(P^{\frown}P)_2Rh][hfacac]$ (**4a**–**g**) are readily synthesized in almost quantitative yield by treating either neutral complexes $[(P^{\frown}P)Rh(hfacac)]$ (**1a**–**g)** or [(cod)Rh(hfacac)] (cod = 1,5-cyclooctadiene) (**3**) with the $P^{\frown}P$-ligands **2a**–**g** in the appropriate stoichiometry (Scheme 1) (13, 14). The apparent simple cod substitution from **3** (15*a*, *b*; for a classical contribution to ligand exchange in complexes $[L_2Rh(acac)]$ see ref. 15*c*) has been shown to involve rather subtle ligand exchange equilibria (for recent examples see ref. 6*b*). The same is true for the addition of the second phosphine ligand to **1**; if **1g** is reacted with **2d**, only small amounts of the expected unsymmetrical [(**2d**)Rh(**2g**)][hfacac] are detected in solution by ^{31}P NMR, the main components being homoleptic complexes **4d** and **4g**. Similar observations have been made for acac-type rhodium complexes with monodentate phosphine ligands (14*d*) and upon addition of a second chelating phosphine to $[(P_2)Rh(L_2)]^+$ cations (L_2 = norbornadiene, cod) (16).

Table 1. Selected NMR data of complexes $[(R_2P(CH_2)_nPR_2)_2Rh]$-[hfacac)] (**4a**–**g**) and $[(Cy_2PCH_2PCy_2)_2Rh][BF_4]$ (**4b′**).

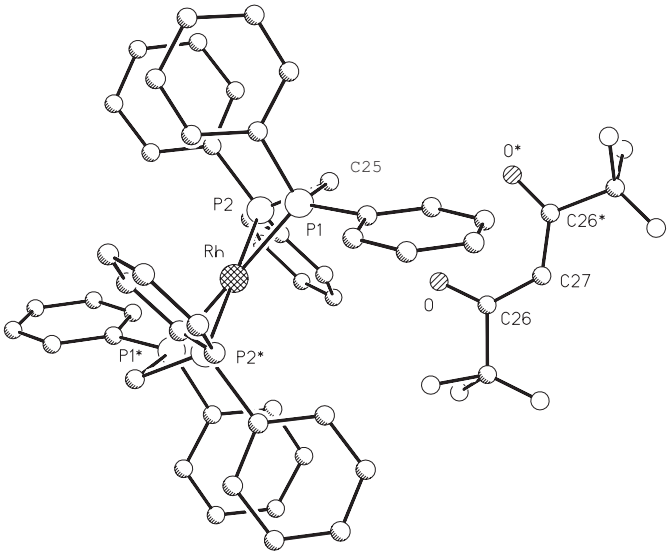
[a]Resonances of the hfacac anion only.
[b]n.d., not determined.



The influence of the ligand structure on the incorporation of a second chelating phosphine at the rhodium center to form $\mathbf{4}^+$ is reflected in the rate of reaction of **1** with a second equivalent of the corresponding phosphine ligand. The incorporation of the second ligand occurs almost immediately in the case of ligands **2a**–**d**, but requires approximately 3 h for the cyclohexyl analogue **2f**, as estimated from the colour change from dark red-brown to bright orange of the reaction solution. Notably, no reaction at all is observed with ligands $R_2P(CH_2)_4PR_2$ (R = Ph (**2h**), R = Cy (**2i**)) even upon prolonged heating, although the cation $[(\mathbf{2h})_2Rh]^+$ is a stable compound and has been obtained via cod substitution from $[\{(cod)Rh(\mu\text{-}Cl)\}_2]$ (17). It is interesting to note that the decreasing tendency of formation of $\mathbf{4}^+$ from **1** correlates with the increase of steric repulsion and thus the tetrahedral distortion within the $[(P^{\frown}P)_2Rh]^+$ cations (vide infra).

Selected NMR-spectroscopic data of complexes **4a**–**g** are listed in Table 1 together with the value for $[(\mathbf{2b})_2Rh][BF_4]$ (**4b′**). The tetrafluoroborate complex was isolated in the form of the crystalline THF solvate **4b′**·2THF as a by-product from the reaction of $[(cod)_2Rh][BF_4]$ with 1 equiv of **2b** at room temperature. The ^{31}P NMR spectroscopic data of the double substituted cation $\mathbf{4b}^+$ are independent from the counterion within experimental limits. The same holds for all other cations listed in Table 1 for which literature data are available. This observation strongly supports the formulation of compounds **4** as ionic complexes containing free cations $[(P^{\frown}P)_2Rh]^+$ ($\mathbf{4}^+$). It has been suggested, however, that coordination of hfacac to the unsaturated 16e$^-$ metal

centers could not be ruled out completely in solution and especially in the solid state on basis of NMR data (14*d*). Table 1 reveals indeed very small variations in the ^{1}H and ^{19}F NMR shifts of the hfacac anion, which might be indicative for some ion pairing in solutions of **4**.[3,4] The X-ray crystal structure analyses of complexes **4a** and **4f**, however, demonstrate unambiguously that there are no coordinative interactions between the hfacac anion and the rhodium centers of these compounds in the solid state.

Solid state structures

Yellow to orange crystals suitable for X-ray diffraction were obtained by slow cooling of warm solutions of **4a** and **4f** in acetone or THF to room temperature. The crystallographic data of both complexes are summarized in the *Experimental* section. No coordinative interaction between the hfacac moiety and the rhodium center is observed in the solid-state structure of **4a** (Fig. 1), although five coordinated derivatives of the cation $\mathbf{4a}^{+}$ are well known and can adopt either trigonal bipyramidal (18) or square pyramidal (19*d*) arrangements.

The cation $\mathbf{4a}^{+}$ has a centro-symmetric structure with the transition metal at the center of inversion. The coordination geometry at rhodium is ideally planar with a P-Rh-P bite angle of 70.8°. The four-membered chelate rings are puckered with an intersecting angle between the P-Rh-P and the P-C-P planes of 30.3°. The two pseudo-axial phenyl rings are oriented nearly parallel to each other. This contrasts the edge-to-face arrangement commonly encountered for phenyl rings in chelating phosphines. It appears from this structure and from published data (for structurally characterized examples with two molecules **2a** at rhodium see ref. 19) that the four-membered ring in the [(**2a**)Rh] moiety preferably adopts one of two different stable conformations in the solid state; one is characterized by a wider P-Rh-P angle (71.8–72.8°), less puckering (15–20°), and edge-to-face orientated phenyl rings. The other one, which includes the present example, is characterized by a bite angle of 70 to 71°, a puckering of 30°, and a parallel orientation of two of the phenyl groups.

The number of structurally characterized free 1,3-diketonate anions in transition-metal complexes is remarkably small (11), and no example involving the hfacac ligand could be retrieved in the Cambridge database. The free hfacac anion in **4a** has the symmetrical and entirely planar skeleton expected for a delocalized heteroatom-*p*-system and also observed in the simple salts [M][acac] (for simple alkali and ammonium salts of acac-type anions see ref. 12). Interestingly, a hydrogen bond between one of the fairly acidic (19*b*; for a discussion of dppm as hydrogen bond donor see ref. 19*e*) methylene protons of coordinated **2a** and one of the oxygen atoms of hfacac is indicated by a short distance of 3.394 Å between C(25) and O. This interaction leads to highly symmetrical indefinite chains of alternating cations and anions in the crystal structure without any coordinative interaction between the metal center and the hfacac anion (Fig. 2).

The molecular structure of **4f** is represented together with selected bond distances and angles in Fig. 3. As with **4a**, discrete cations and anions are present in the crystal lattice of complex **4f**. The structural data of the hfacac anion are very similar to those obtained for **4a**, but no short interatomic distances are observed between any of the hydrogen atoms of the cation and the anion. In contrast to planar $\mathbf{4a}^{+}$, the cation $\mathbf{4f}^{+}$ is significantly distorted towards a tetrahedral arrangement with a dihedral angle of $\theta = 18.6°$. Similar distortions have been observed for this cation with typical noncoordinating anions.[5]

In general, the amount of tetrahedral distortion in cations $[(P^{\frown}P)_2Rh]^{+}$ can be rationalized as a compromise between the preferred square planar arrangement of a d^8 transition-metal center and the steric repulsion of the four PR_2 groups[6] (17). This is nicely reflected within the series of cations containing two adjacent five-membered rings, where the amount of distortion increases steadily with R = Me (0°, $\mathbf{4d}^{+}$) (20), R = Ph (3.6–8.8°, $\mathbf{4c}^{+}$) (21), and R = Cy (18.6°, $\mathbf{4f}^{+}$). Ideal planar arrangements are only possible when 1,3-interactions between adjacent PR_2 groups of two different chelates are negligible. These interactions will be minimized with ligands featuring small R groups but also by small P-Rh-P bite

[3] Alternatively, the variations may partly arise from temperature and concentration effects, at least in the case of the fluorine resonances.
[4] The ligand exchange reactions observed in the P_2–Rh–hfacac system are likely to proceed via associative mechanisms (15), which may involve short lived intermediates or transition states of type $[(P_2)_2Rh(\kappa O\text{-hfacac})]$ or $[(P_2)(L_2)Rh(\kappa O\text{-hfacac})]$.

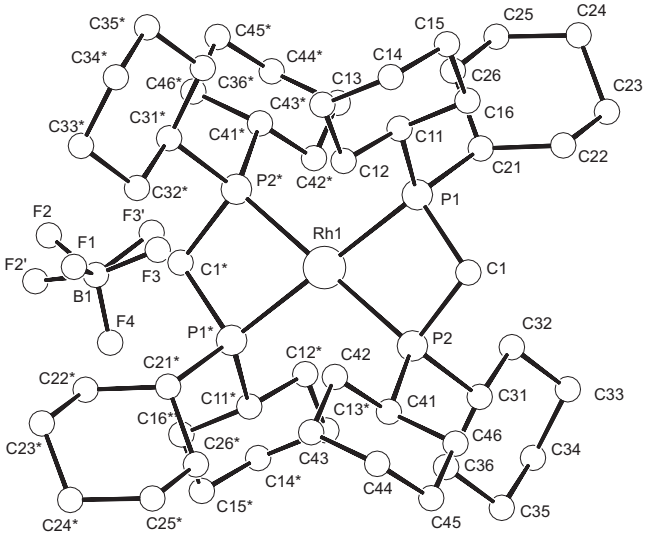
Heavy atoms are represented as spheres and hydrogen atoms have been omitted for clarity. Selected bond distances (Å) and angles (°): Rh—P(1), 2.332(2); Rh—P(2), 2.332(2); Rh—P(3), 2.328(2); Rh—P(4), 2.343(2); P(1)—C(1), 1.844(6); P(2)—C(2), 1.854(7); P(3)—C(3), 1.842(6); P(4)—C(4), 1.846(6) Å; C(1)—C(2), 1.497(8); C(3)—C(4), 1.503(6); O(1)—C(53), 1.208(12); O(2)—C(55), 1.234(8); C(53)—C(54), 1.385(9); C(54)—C(55), 1.373(9) Å; P(1)-Rh-P(2), 84.03(6); P(3)-Rh-P(4), 82.71(6); P(1)-Rh-P(4), 98.61(6); P(2)-Rh-P(3), 97.34(6); P(1)-Rh-P(3), 168.43(7); P(2)-Rh-P(4), 166.65(6); Rh-P(1)-C(1), 109.2(2); Rh-P(2)-C(2), 108.9(2); Rh-P(3)-C(3), 109.2(2); Rh-P(4)-C(4), 108.8(2); C(53)-C(54)-C(55), 124.4(7)°.

angles within the chelate. In this context, it appeared interesting to investigate the solid state structure of the cation $[\{Cy_2P(CH_2)PCy_2\}_2Rh]^+$ (**4b**$^+$) containing bulky cyclohexyl groups embedded in two adjacent four-membered chelate rings.

As depicted in Fig. 4, the cation **4b**$^+$ has a C_2-symmetric molecular structure in the crystal lattice of compound **4b′**. The P-Rh-P angle and the P—Rh distance are with 72.4° and 2.32 Å, slightly larger than the corresponding values in **4a**$^+$. The four-membered chelates in **4b**$^+$ appear to be essentially planar, in contrast to the strongly puckered rings observed in **4a**$^+$. However, the large thermal ellipsoids of the bridging methylene carbon in **4b**$^+$ may indicate some statistical disorder at this position. Most significantly, the ideally square planar coordination geometry at rhodium indicates that the small P-Rh-P angle is sufficient to prevent severe steric interaction between the PCy_2 groups of the individual chelates.

Conclusion

Complexes $[(P^{\frown}P)_2Rh][hfacac]$ (**4**) can be readily synthesized according to the reaction sequences shown in Scheme 1. The crystallographic and spectroscopic data show that the compounds exist as discrete cations and anions in solution and in the solid state without any direct evidence for coordinative interaction between the rhodium center and the hfacac anion. The cations $[(P^{\frown}P)_2Rh]^+$ have ideally planar coordination geometries when both phosphines form four-membered chelate rings as in **4a**$^+$ and **4b**$^+$, regardless of the size of the R group at phosphorus. In contrast, the cation **4f**$^+$ containing a five-membered chelate ligand with cyclohexyl groups at phosphorus shows considerable tetrahedral distortion (θ = 18.6°). The hfacac anion has the symmetrical structure expected for the delocalized 1,3-diketonate anion and can form hydrogen bridges to acidic sites of the complex cations in the solid state.



Experimental

General

The starting complexes [(cod)Rh(hfacac)] (**3**) (6) and $[Rh(cod)_2][BF_4]$ (22) were prepared as described in the literature. The bidentate phosphines **2a**–**g** were commercial products (Aldrich or Strem) and used as received. All reactions involving air- or moisture-sensitive materials were performed under argon using standard Schlenk techniques. Glassware was either oven-dried for at least 24 h or flame-dried under vacuum before use. Solvents were dried and deoxygenated by standard methods and freshly distilled prior to use.

Hydrogen atoms and THF solvent molecule have been omitted for clarity. Selected bond distances (Å) and angles (°): Rh(1)—P(1), 2.324(1); Rh(1)—P(2), 2.315(1); P(1)—C(1), 1.852(3); P(2)—C(1), 1.847(3) Å; P(2)-Rh(1)-P(1), 72.4(1); P(1)*-Rh(1)-P(2), 107.6(1); P(2)-C(1)-P(1), 95.7(1); C(1)-P(1)-Rh(1), 95.3(1); C(1)-P(2)-Rh(1), 95.7(1)°.

Crystallographic data collection and processing

For all structures, data were collected on an Enraf–Nonius CAD4 diffractometer in the ω–2θ scan mode using graphite monochromated Mo Kα radiation. Unit cell parameters were determined from least-squares refinement of setting angles for 25 reflections. Data were corrected for Lorentz and polarization effects (23*a*). There was no correction for crystal decay. No absorption correction was applied. The structures were solved by direct methods (SHELXS (23*b*)) refined by full-matrix least-squares techniques against F_o^2 (SHELXL-97) (23*c*). The hydrogen atoms of the molecules were included at calculated positions with fixed thermal parameters. All non-hydrogen atoms were refined anisotropically (27*c*). XP (SIEMENS Analytical X-ray Instruments Inc.) was used for structure representations.[7]

NMR spectroscopy

Spectra were recorded on a Bruker AC 200 or AM 200 spectrometer operating at 200.13, 50.29, 188.15, or 81.00 MHz for ^1H, ^{13}C, ^{19}F, and ^{31}P NMR, respectively. Chemical shifts are given in ppm downfield from TMS (^1H and ^{13}C NMR), 85% H_3PO_4 (^{31}P NMR), and $CFCl_3$ (^{19}F NMR) as external standards. The solvent resonances were used as secondary standards if possible.

Further analytic methods

FAB-MS were obtained using a Finnigan MAT SSQ 710 spectrometer and DMBA as a matrix. Elemental analyses were performed on a LECO CHNS 932 analyzer at the laboratory of organic chemistry of the Friedrich-Schiller-Universität, Jena, Germany.

General procedures for the preparation of complexes $[(\mathbf{2a–g})_2Rh][hfacac]$ (4a–g)

Method A

[(**2a**–**g**)Rh(hfacac)] (**1a**–**g**) (ca. 200 mg) and 1 equiv amount of the corresponding phosphine **2a**–**g** were separately dissolved in THF (5 and 10 mL, respectively) at room temperature. The phosphine solution was added dropwise to the stirred solution of the rhodium complex using a cannula. The completeness of the reaction was indicated by a colour change from red-brown to yellow-orange. Within a few minutes an orange precipitate was formed. The supernatant was removed using a cannula and the solid dried 4 h under vacuum. The crude products were recrystallized from acetone or THF (ca. 5–15 mL) to give **4a**–**g** in >90% yield.

Method B

[(cod)Rh(hfacac)] (3) (150 mg, 0.36 mmol) and 2 equiv of the desired phosphine **2a**–**g** were separately dissolved in THF (15 mL) at room temperature. The phosphine solution was added dropwise to the stirred solution of the rhodium complex using a cannula. After addition was complete, stirring was continued until the colour of the reaction mixture had changed to yellow-orange. Work-up and isolation was identical as described for method A.

A relationship between the catalytic carbonylation of (*N*-arenesulfonyl)imides and iodonium ylides

Gábor Besenyei, András Neszmélyi, Sándor Holly, László I. Simándi, and László Párkányi

Abstract: Reactivities of various sulfonamide derivatives of general formula $ArSO_2N{=}XPh_n$ (X = I; n = 1; X = S, Se, n = 2; X = P, As, n = 3) in catalytic carbonylations have been explained by structural properties of the substrates. Based on crystallographic data reported in the literature, it has been concluded that the two-step catalytic oxidative carbonylation of sulfonylimides proceeds only when the N=X double bond is strongly polarized. The structural requirement observed within the sulfonamide derivatives has been found to be applicable for iodonium ylides. Catalytic carbonylation of the phenyliodonium methylide (**3a**) prepared from dimedone (5,5-dimethyl-1,3-cyclohexanedione) and (diacetoxyiodo)benzene, resulted in a new spirobenzofuranone derivative (**5a**) which was characterized by X-ray single crystal diffraction, $^1J_{C,C}$ coupling constants, ^{13}C-T_1 relaxation times, as well as by IR and Raman spectroscopic methods. Crystals of **5a** are monoclinic, space group $P2_1/c$, a = 7.187(1), b = 21.129(1), and c = 10.636(1) Å, β = 92.81(1)°, V = 1613.2(3) Å^3, and Z = 4. A ketene intermediate has been postulated in the catalytic carbonylation of the iodonium ylide. A survey of databases has revealed that the triacyl dihydrofuranone moiety in **5a** constitutes a new structural unit.

Key words: oxidative carbonylation, palladium catalyst, iodonium ylides, spirobenzofuranone.

Résumé : Les réactivités de divers dérivés du sulfonamide, de formule générale $ArSO_2N{=}XPh_n$ (X = I, n = 1; X = S, Se, n = 2; X = P, As, n = 3), dans des réactions de carbonylations catalytiques sont expliquées par des propriétés structurales des substrats. En se basant sur des données cristallographiques rapportées dans la littérature, on a conclu que la réaction de carbonylation oxydante, catalysée et en deux étapes, de sulfonylimides ne se produit que lorsque la double liaison N=X est fortement polarisée. On a trouvé que les conditions structurales observées dans les dérivés sulfonamides s'appliquent aussi aux ylures d'iodonium. La carbonylation catalytique du méthylure de phényliodonium (**3a**) préparé à partir de la dimédone (5,5-diméthylcyclohexane-1,3-dione) et de (diacétoxyiodo)benzène, conduit à la formation d'un nouveau dérivé spirobenzofuranone (**5a**) qui a été caractérisé par diffraction des rayons X sur un cristal unique, par les constantes de couplage $^1J_{C,C}$, les temps de relaxation ^{13}C-T_1 ainsi que par spectroscopies IR et Raman. Les cristaux de **5a** sont monoclinique, groupe d'espace $P2_1/c$ avec a = 7,187(1), b = 21,129(1) et c = 10,636(1) Å, β = 92,81°, V = 1613,2(3) Å^3 et Z = 4. On suggère l'existence d'un intermédiaire cétène lors de la carbonylation catalytique de l'ylure d'iodonium. Une revue des bases de données indique que la partie triacyldihydrofuranone du composé **5a** correspond à une nouvelle unité structurale.

Mots clés : carbonylation oxydante, catalyseur de palladium, ylures d'iodonium, spirobenzofuranone.

[Traduit par la Rédaction]

Introduction

The practical importance of organic isocyanates and their derivatives like urethanes and ureas has attracted continuous interest in catalytic carbonylation at nitrogen atoms (1, 2). Reductive carbonylation of aromatic nitro and nitroso compounds and oxidative carbonylation of aromatic amines are the most representative cases of these catalytic transformations.

During our search for phosgene-free methods for the preparation of arenesulfonyl isocyanates, we have discovered three new reactions leading to the formation of these target molecules (3–5). The catalytic transformation of *N*-chloroarenesulfonamidates (**1**) and (*N*-arenesulfonyl)imides (**2**) are shown by eqs. [1] and [2].

$$[1]\quad \underset{\mathbf{1}}{[ArSO_2NCl]M} + CO \xrightarrow[25^\circ C,\ 5\text{–}30\ bar]{\text{Pd–complex}} ARSO_2NCO + MCl$$

$$M = Na^+,\ K^+$$

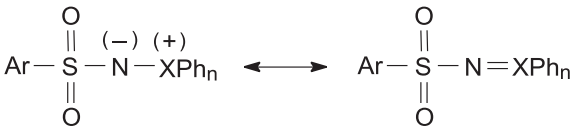
[2] $$\underset{\mathbf{2}}{ArSO_2N{=}XPh_n} + CO \xrightarrow[25\text{–}50^\circ C,\ 30\ bar]{Pd\text{–}complex} ArSO_2NCO + Ph_nX$$

2a X = I, $n = 1$; **2b** X = Se, $n = 2$

Although the products are isocyanates, resembling those of the catalytic carbonylation of nitro arenes, rxns. [1] and [2] cannot be described as reductive carbonylations. As substrates **1** and **2** are prepared via oxidative reactions, these transformations of sulfonamide derivatives have been classified as two-step oxidative carbonylations and constitute a new class of catalytic reactions taking place at nitrogen atoms.

To check if other sulfonylimides have a tendency to undergo the reaction described by eq. [2], we prepared several known imidocompounds of general formula $4\text{-}CH_3C_6H_4SO_2N{=}XPh_n$ (**2c** X = S, $n = 2$; **2d** X = P, $n = 3$; **2e** X = As, $n = 3$) and subjected them to catalytic carbonylation. No CO consumption could be detected, however, under reaction conditions successfully applied earlier for the catalytic transformation of *N*-chloroarenesulfonamidates, [(*N*-arenesulfonyl)imino]phenyliodinanes, and imido selenium compounds.



It seemed to us of interest to find an explanation for why compounds possessing seemingly close structural features behave differently under the same reaction conditions. To elucidate this problem, we examined various structural and chemical properties of the substrates. As the reaction takes place via the cleavage of nitrogen-heteroatom bonds, special attention was paid to data characterizing the bonding properties within the SO_2NX fragments.

Results and discussion

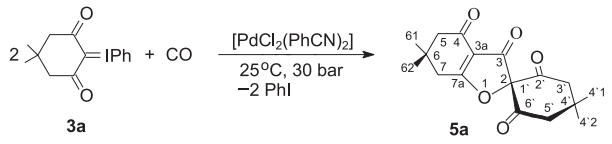
As a result of the long-standing interest toward the sulfonamide derivatives used here as model compounds, crystallographic data are available for the typical representatives of these substrates, providing us with the necessary structural information to discuss a structure–reactivity relationship. A compilation of selected crystallographic data is shown in Table 1.

The phosphorus—nitrogen bond length of **2d** (1.579(4) Å) is much shorter than a P—N single bond (1.77(2) Å), therefore a bond order of 2 is most probable in the (*N*-*p*-toluenesulfonyl)iminotriphenylphosphorane (6). A comparison of the experimentally determined arsine—nitrogen distance in **2e** (1.755(3) Å) with the As—N single bond length of ca. 1.87 Å makes feasible a similar conclusion (7). Based on a systematic study of sulfur—nitrogen bonds, the S(IV)—N bond order in **2c** can be estimated to be ca. 1.5 (d = 1.628(7) Å) (8, 9).

On the contrary, available structural data for the [(*N*-arenesulfonyl)imino]phenyliodinanes ($ArSO_2N{=}IPh$) and the theoretical calculations as well, have suggested little evidence for the iodine-nitrogen multiple bonding (10–12). Single crystal diffraction studies have revealed the strongly polarized nature of the I=N bonds, which brings about secondary interactions between the amide nitrogen, sulfonyl oxygen, and iodine atoms. In $4\text{-}CH_3C_6H_4SO_2N{=}IPh$ (**2a**, Ar = $4\text{-}CH_3C_6H_4$), the I—N bond length is 2.039(2) Å (12), which together with other iodine—nitrogen covalent bonds found in this series of imidocompounds (1.997(8)–2.027(3) Å) (10, 11), compares well with the value of 1.99 Å calculated for a single bond (12). Although the nitrogen—selenium bond length in **2b** (Ar = $4\text{-}CH_3C_6H_4$) falls somewhat out of the range observed for a selenium—nitrogen single bond (1.824(6)–1.846(4) Å), the experimentally determined value of 1.787(6) Å is still much greater than that predicted for a selenium nitrogen double bond (1.64 Å) (13). X-ray diffraction studies may indicate a further loss of Se—N multiple bonding in $C_6H_5SO_2N{=}SePh_2$ (1.82(1) Å) (14). These observations suggest that resonance structure **A** makes a major contribution to the distribution of valence electrons in **2a** and **2b,** while formula **B** is thought to be a good approximation for the structural description of **2c–e**. The N—Cl bond length in the sodium *N*-chloro-*p*-toluenesulfonamidate **1** (1.750(2) Å) was found to be equal to the mean N—Cl distance in NCl_3 and was described as a single bond (15).

A **B**

Apart from the crystallographic data, the other structural parameter considered was the position of the $\nu_{as}SO_2$ band in the IR spectra of the substrates (recorded in KBr pellets) because the wave number of this absorption can vary considerably depending on the nature of the bonds surrounding the sulfonyl group. The extent of these shifts, however, does not have a predictive power by itself with respect to the reactivity of a given imide. The $\nu_{as}SO_2$ for the inert phosphorane **2d** and for the highly reactive [(*N*-*p*-toluenesulfonyl)imino]-phenyliodinane were equally found to appear at 1266 cm^{-1}.



This overview of the available structural data clearly shows that the same structural formulas may hide completely

different structural properties within the SO_2NX system and a bond order of close to unity is a precondition of the carbonylation reaction. It seems plausible to assume that it is the strength of the SO_2N—X bond that is reflected by the reactivity of the substrates, and strongly polarized, consequently weaker, double bonds make the imide more reactive. The polarization of the N—X bond is not important just for weakening the bond but certainly facilitates the initial interaction with the catalyst.[2] Different reactivities of *N*-sulfonylimides in copper-catalyzed aziridination of olefins have also been observed by Evans et al. (16) by demonstrating that **2a** (Ar = *p*-tolyl) resulted in the highest yield, while the imido sulfur compound $PhMeS{=}NSO_2Ph$ gave no reaction in copper-catalyzed aziridination of olefins.

All these observations may be viewed as indirect evidence for the intermediacy of palladium–nitrene complexes that may emerge in the catalytic *N*-carbonylation of sulfonamide derivatives.

[(*N*-arenesulfonyl)imino]phenyliodinanes and phenyliodonium methylides of general formulas $ArSO_2N{=}IPh$ and $E^1E^2C{=}IPh$ (E represents electron-withdrawing groups like RC(O), RSO_2, R_FSO_2), respectively, have been mentioned as nitrogen and carbon analogues of iodosylbenzene (PhIO) and have been postulated as sources of arylsulfonylnitrene (16) and diacylcarbene species (17). Considerations regarding the structural properties of iodonium ylides (18) and available crystallographic data for them (19) have turned our attention toward the structural similarities of **2a** and iodonium ylides and have made the latter promising candidates as substrates for two-step oxidative carbonylations.

[3] 

Iodonium ylides were first described in the pioneering works of Neiland and co–workers (20), and their chemical and physical properties have been extensively studied (18, 21). However, to our knowledge, catalytic carbonylation of phenyliodonium methylides has not been described.

As expected, catalytic carbonylation of the iodonium ylide **3a** prepared from 5,5-dimethyl-1,3-cyclohexanedione and (diacetoxyiodo)benzene was accompanied by CO consumption, but the IR spectrum of the final reaction mixture did not reveal any absorption that could have been explained by the formation of ketene **4**. Based on X-ray crystallographic data as well as on NMR and IR-Raman studies, structure **5a** was ascribed to the product. The carbonyl group in position 3 clearly indicates that the isolated compound is a product of catalytic carbonylation.

A survey of various databases has shown (22) that compound **5a** has not been synthesized earlier although benzofuranones and their derivatives have been the subject of extensive research for decades. Moreover, a recent search of the CA on-line registry file has revealed that the central triacyl dihydrofuranone ring as well (shown as formula **6**) is a structural element that has not been observed in any cyclic or open-chain molecule ("A" represents a hydrogen atom, any organic moiety, or forms a ring with other units defined as "A"). Therefore, catalytic carbonylation of iodonium ylides can be viewed as a promising method to prepare formerly unknown heterocyclic compounds.

Based on two-dimensional routine ^1H and ^{13}C NMR methods (including HMQC) it was not feasible to conclusively establish the connectivity of the carbon atoms. Determination of the $^1J_{C,C}$ coupling constants and T_1 relaxation times for all carbon atoms and the assignment of the ν(C=C) band both in IR and Raman spectra together with Raman depolarization measurements have unequivocally proved, however, that the product is a hexahydrobenzofuranone derivative.

The results of spectroscopic studies carried out on bulk samples are in agreement with the results of crystallographic studies on a single crystal. NMR data are collected in Table 2. Crystallographic data, data collection parameters, and selected bond lengths and angles are summarized in Tables 3 and 4. A molecular diagram of **5a** is shown in Fig. 1.

Apart from the large difference between the angles C(3)-C(3a)-C(4) (130.8°) and C(7)-C(7a)-O(1) (118.3°), compound **5a** is quite regular from a structural point of view. The atoms in the hexahydrobenzofuranone ring are coplanar with the exception of the C(6) atom that bends above the plane by 0.6 Å and this feature turns this portion of the molecule into an envelope conformation. The cyclohexanedione moiety adopts a chair conformation with the two carbonyl groups pointing toward the side of the O(1) atom.

The relaxation times for methylene and methyl carbon atoms (see Fig. 2) result in average values of 0.58 s and 3.2 s, respectively. The averaging of carbon chemical shifts in the saturated rings reflect conformational transitions (envelope–envelope transitions probably). In addition, the methyl substituents have a nearly complete rotational freedom (methyl relaxation times are approximately nine times longer than expected for a rigid methyl carbon). From these observations and the individual T_1 values of the protonated carbons along the skeleton we may deduce that the microdynamics of the molecule in solution corresponds to that of a virtual rigid body.

We feel noteworthy that the NMR and IR-Raman spectroscopic data supported by crystallographic investigations reported here for **5a** may be of help in recognizing similar structural units.

We suppose that **5a** is formed via the intermediate ketene **4**, which is thought to be the primary product of the reaction. The postulated formation of **4** is in agreement with previous reports on the intermediacy of diketocarbene species generated from **3a**. Compound **5a** seems to be a product of the interaction of **4** with the unreacted starting substrate **3a**. The feasibility of a thermal reaction of diphenylketene with **3a** has been demonstrated (23) and was found to produce heterocycles formally composed of the ketene and the alicyclic fragment of the iodonium ylide. Compound **5a** is, however, structurally different from those described as major products of the interaction of **3a** with diphenylketene. It seems reasonable to postulate that the presence of a

[2] This point was raised by one of the reviewers.

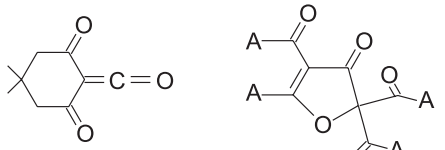
palladium catalyst induces a reaction path different from that followed in the thermal interaction.



Further support for the intermediacy of **4** was obtained when carbonylation of **3a** was accomplished in the presence of 2-amino-4-methyl-6-methylthiotriazine. The solid material isolated upon carbonylation could be identified as amide **7**. It is believed that **7** is formed by trapping the primarily formed ketene **4** by the aminotriazine reactant to give an *N*-substituted-1,3-cyclohexanedione-2-carboxamide derivative, which is rearranged into its enol form.

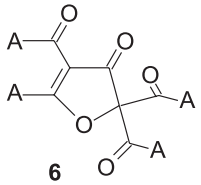

Fig. 1. Molecular structure of the spirobenzofuranone derivative **5a**. Atomic displacement parameters represent 50% probabilities.

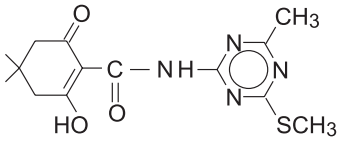

Our preliminary experiments with phenyliodonium methylide **3b,** synthesized from dibenzoylmethane and (diacetoxyiodo)benzene, have demonstrated that the catalytic reaction is accompanied by a pressure drop indicating the incorporation of carbon monoxide from the gas phase. The isolated product has proved to contain two major components, one of them having a molecular mass of 472.1311 amu (±5 ppm). The expected product (**5b**), formally composed of two dibenzoyl methanide moieties and one molecule of carbon monoxide, corresponds to the formula $C_{31}H_{20}O_5$ (theoretical molecular mass: 472.1311 amu).

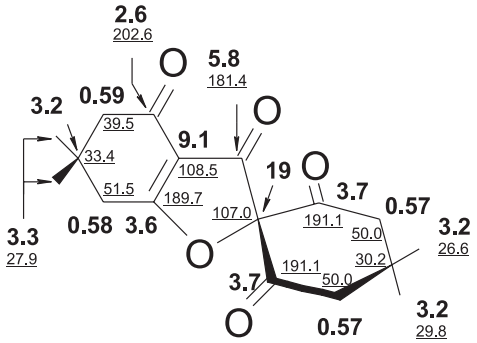
6

7

This strongly suggests that rxn. [3] takes place with **3b** as well but a combination of crystallographic and nonroutine spectroscopic methods should be applied to obtain unquestionable proof for the connectivity of the quaternary carbon atoms. Further studies on catalytic carbonylation of iodonium ylides are in progress in our laboratory.



3b **5b**

Experimental

Iodonium ylides **3a** and **b** were prepared according to described procedures (24). Catalytic carbonylations were carried out in a pressure vessel (Parr Model 4712) with a total volume of 45 mL. NMR spectra were recorded on Bruker DRX-500 and Varian Unity Inova (400 MHz) spectrometers. IR spectroscopic investigations were carried out on a Magna 750 (Nicolet) fourier-transform spectrometer equipped with a DTGS detector at a resolution of 4 cm^{-1}. Raman shifts were measured in the range of 4000–100 cm^{-1} on a Nicolet System 950 FT Raman spectrometer using Nd:YAG laser. Mass spectroscopic analyses were performed on a VG ZAB-2SEQ instrument.

Fig. 2. NMR relaxation times (T_1, s) of the carbon atoms of **5a** measured at 125 MHz and room temperature in 0.2 M $CDCl_3$ solution. Underlined numbers represent the ^{13}C NMR chemical shifts in ppm.

X-ray diffraction studies

Intensity data were collected on an Enraf–Nonius CAD4 diffractometer (graphite monochromator, Cu Kα radiation, λ = 1.54180 Å) at 293(2) K using ω–2θ scans. An experimental (ψ-scan) absorption correction (25) was applied to the data (the min and max transmission factors were 0.896 and 0.998, respectively). The structure was solved by direct methods (26) (and subsequent difference syntheses). The structure was refined on F^2 (27). Hydrogen atomic positions were calculated from assumed geometries. Hydrogen atoms were included in structure factor calculations but they were not refined. The isotropic displacement parameters of the hydrogen atoms were approximated from the U_{eq} value of the atom they were bonded to. Data collection and refinement data are shown in Table 3.

Carbonylation of iodonium ylide 3a

1.84 g (5.4 mmol) of ylide **3a** and 0.1 g of $[PdCl_2(PhCN)_2]$ were charged in a pressure vessel equipped with a glass lining and 10 mL of dried (stored over activated 3 Å molecular sieve) CH_2Cl_2 was added. The reactor was flushed and pressurized to 32 bar with CO. The reaction mixture was stirred at 20°C until the pressure drop ceased. Evaporation of the solvent and precipitation with ethanol resulted in a grayish powder (414 mg), which was redissolved in dichloromethane, filtered through a Celite™ layer and precipitated again with EtOH. Yield: 355 mg (43%). Anal. calcd. for $C_{17}H_{20}O_5$: C 67.09, H 6.62; found: C 67.11, H 6.52.

Physical data of compound 5a

EI-MS (70 eV) *m/z* (%) (MF = $C_{17}H_{20}O_5$, molecular ion = 304.1448): 304 (M^+, 38), 289 (55), 276 (11), 261 (15), 207 (15), 193 (64), 83 (100). IR (cm^{-1}) (17 mg of **5a** in 1 mL of

CH_2Cl_2, KBr cell, d = 0.016 cm): 1757 (vw) and 1732 (vs) (ν_sCO and ν_{as}CO of 2′ and 6′ carbonyls), 1717 (s) and 1676 (m) (νCO of carbonyl groups at positions 3 and 4), 1592 (νC=C). Raman-IR (measured on the same solution, cm^{-1}): 1755 (s) (ρ = 0.19) and 1733 (m) (ρ = 0.72) (ν_sCO and ν_{as}CO of 2′ and 6′ carbonyls), 1719 (m) (ρ = 0.47) and 1677 (s) (ρ = 0.60) (νCO of carbonyl groups at 3 and 4), 1594 (s) (ρ = 0.22) (νC=C); (ρ denotes the depolarization ratio). NMR data are shown in Table 2.

Carbonylation of iodonium ylide 3a in the presence of 2-amino-4-methyl-6-methylthiotriazine

2.02 g (5.9 mmol) of iodonium ylide **3a** and 0.95 g (6.0 mmol) of 2-amino-4-methyl-6-methylthiotriazine were carbonylated overnight in 10 mL of CH_2Cl_2 in the presence of 96 mg of $[PdCl_2(PhCN)_2]$. The solvent was distilled off under vacuum and the oily residue was treated with diethyl ether. The white precipitate proved to be an analytically pure compound (0.74 g, 39%). Based on MS, NMR, and IR data the product was formulated as *N*-(4-methyl-6-methylthio-triazin-2-yl)-5,5-dimethyl-1,3-cyclohexanedione-2-carboxamide (**7**) observed in its enol form in solution, as shown by NMR spectra. Anal. calcd. for $C_{14}H_{18}N_4O_3S$: C 52.16, H 5.63, N 17.38, S 9.96; found: C 52.45, H 5.87, N 17.46, S 9.85.

Physical data of compound 7

EI-MS (70 eV) m/*z* (%): 322 (M^+, 86), 307 (4), 294 (4), 266 (22), 251 (18), 183 (25), 156 (100), 110 (27). IR (KBr, cm^{-1}): 3500–2800 (O*H*, N*H*, C*H*), 1661, 1624, 1579, 1526, 1479, 1423, 1387, 1276. ^{1}H NMR ($CDCl_3$) δ: 1.12 (6H, s), 2.44 (2H, s), 2.57 (6H, s, methyl and S-methyl protons on the triazine ring), 2.59 (2H, s), 12.33 (1H, N*H*), 16.77 (1H, O*H*). ^{13}C NMR ($CDCl_3$) δ: 197.3, 194.5, 183.5, 176.4, 170.0, 161.7, 103.2, 51.2, 45.2, 30.9, 28.0 (2C), 25.7, 13.4 (S*C*H_3).

Conclusions

A survey of available structural data on (*N*-arenesulfonyl)imides and the outcome of carbonylation experiments with them and with iodonium ylides have shown that: (*i*) the feasibility of two-step catalytic oxidative carbonylation is not restricted to sulfonamide derivatives; and (*ii*) the occurrence of transformation of this kind is associated with structural properties of the substrates rather than with the presence of special functional groups. We may conclude as well that other ylides like $(ArSO_2)_2C{=}IPh$ or $(R_FSO_2)_2C{=}IPh$ (where R_F represents a perfluoroalkyl group), may also prove suitable starting materials for catalytic carbonylation. The catalytic transformation of iodonium ylides described here is expected to open a new route for the preparation of heterocyclic compounds.

Acknowledgements

The authors are indebted to Dr. Pál Kolonits, Department of Organic Chemistry, Technical University, Budapest for taking the nonroutine NMR spectra and for his invaluable help in their interpretation. This work was supported by the Hungarian Research Fund (OTKA Grants T 25 870 and T 25 967).

Mono- and bis-(acetylacetonato) complexes of arene–ruthenium(II) and arene–osmium(II): variation of the binding mode of η^1-acetylacetonate with the nature of the arene

Martin A. Bennett, Thomas R.B. Mitchell, Mark R. Stevens, and Anthony C. Willis

Abstract: The mono(acetylacetonato) complexes [MCl(*O*,*O*′-acac)(η^6-arene)] (M = Ru, Os, arene = C_6H_6, 1,3,5-$C_6H_3Me_3$, C_6Me_6; M = Os, arene = 1,2-$C_6H_4Me_2$, 1,2,3-$C_6H_3Me_3$), which are formed from [MCl_2(η^6-arene)]$_2$ and thallium or sodium acetylacetonate, react with thallium acetylacetonate to give bis(acetylacetonato) complexes [M(*O*,*O*′-acac)(η^1-acac)(η^6-arene)]. The η^1-acac ligand is bound through the γ-carbon atom for M = Ru, Os, arene = C_6H_6; M = Os, arene = 1,2-$C_6H_4Me_2$, 1,2,3-$C_6H_3Me_3$ and through a keto-oxygen atom for M = Ru, Os, arene = 1,3,5-$C_6H_3Me_3$, C_6Me_6, the difference being attributed to a combination of steric and electronic effects. Cationic ruthenium(II) derivatives [Ru(L)(*O*,*O*′-acac)(η^6-arene)]$^+$ (arene = C_6H_6, 1,3,5-$C_6H_3Me_3$, C_6Me_6; L = DMSO, MeCN, py, PPh_3) and [Ru(CO)(*O*,*O*′-acac)(η^6-arene)]$^+$ (arene = 1,3,5-$C_6H_3Me_3$,C_6Me_6), and neutral osmium(II) η^1-acetato derivatives [Os(η^1-OAc)(*O*,*O*′-acac)(η^6-arene)] (arene = C_6H_6, 1,2-$C_6H_4Me_2$, 1,2,3-$C_6H_3Me_3$, 1,3,5-$C_6H_3Me_3$, C_6Me_6) are also described. The molecular structures of the following complexes have been determined by X-ray crystallography: [Os(*O*,*O*′-acac)(η^1-*C*-acac)(η^6-1,2-$C_6H_4Me_2$)], triclinic, space group $P\bar{1}$ (No. 2), a = 9.922(2), b = 9.974(2), and c = 11.001(2) Å, α = 68.33(1), β = 64.18(1), and γ = 62.38(1)°, V = 849.0(3) Å^3, Z = 2; [Os(*O*,*O*′-acac)(η^1-*O*-acac)(η^6-1,3,5-$C_6H_3Me_3$)], monoclinic, space group $C2/c$ (No. 15), a = 16.032(4), b = 11.989(3), and c = 21.562(7) Å, β = 108.91(2)°, V = 3921(2) Å, Z = 8; [Os(η^1-OAc)(*O*,*O*′-acac)(η^6-C_6H_6)], triclinic, space group $P\bar{1}$ (No. 2), a = 8.368(4), b = 8.402(4), and c = 11.008(4) Å, α = 71.68(3), β = 69.35(3), and γ = 69.77(3)°, V = 663.0(6) Å^3, Z = 2.

Key words: arene–ruthenium, arene–osmium, acetylacetone, crystal structures.

Résumé : Les complexes mono(acétylacétonato) [MCl(*O*,*O*′-acac)(η^6-arène)] (M = Ru, Os, arène = C_6H_6, 1,3,5-$C_6H_3Me_3$, C_6Me_6; M = Os, arène = 1,2-$C_6H_4Me_2$, 1,2,3-$C_6H_3Me_3$), qui se forment par réaction de [MCl_2(η^6-arène)]$_2$ avec l'acétylacétonate de thallium ou de sodium, réagissent avec l'acétylacétonate de thallium pour donner des complexes bis(acétylacétonato) [M(*O*,*O*′-acac)(η^1-acac)(η^6-arène)]. Le ligand η^1 est lié par le carbone γ dans les cas où M = Ru, Os, arène = C_6H_6; M = Os, arène = 1,2-$C_6H_4Me_2$, 1,2,3-$C_6H_3Me_3$ et par l'atome d'oxygène de la cétone lorsque M = Ru, Os, arène = 1,3,5-$C_6H_3Me_3$, C_6Me_6; on attribue les différences à une combinaison d'effets stériques et électroniques. On décrit aussi les dérivés cationiques du ruthénium [Ru(L)(*O*,*O*′-acac)(η^6-arène)]$^+$ (arène = C_6H_6, 1,3,5-$C_6H_3Me_3$, C_6Me_6; L = DMSO; MeCN; py, PPh_3) et [Ru(CO)(*O*,*O*′-acac)(η^6-arène)]$^+$ (arène = 1,3,5-$C_6H_3Me_3$, C_6Me_6) et les dérivés neutres η^1-acétato de l'osmium(II) [Os(η^1-OAc)(*O*,*O*′-acac)(η^6-arène)] (arène = C_6H_6, 1,2-$C_6H_4Me_2$, 1,2,3-$C_6H_3Me_3$, 1,3,5-$C_6H_3Me_3$, C_6Me_6). Les structures moléculaires des complexes suivants ont été déterminées par diffraction des rayons X: [Os(*O*,*O*′-acac)(η^1-*C*-acac)(η^6-1,2-$C_6H_4Me_2$)], triclinique, groupe d'espace $P\bar{1}$ (No. 2), avec a = 9,922(2), b = 9,974(2) et c = 11,001(2) Å, α = 68,33(1), β = 64,18(1) et γ = 62,38(1)°, V = 849,0(3) Å^3 et Z = 2; [Os(*O*,*O*′-acac)(η^1-*O*-acac)(η^6-1,3,5-$C_6H_3Me_3$)], monoclinique, groupe d'espace $C2/c$ (No. 15), avec a = 16,032(4), b = 11,989(3) et c = 21,562(7) Å, β = 108,91(2), V = 3921(2) Å^3 et Z = 8; [Os(η^1-OAc)(*O*,*O*′-acac)(η^6-C_6H_6)], triclinique, groupe d'espace $P\bar{1}$ (No. 2), avec a = 8,368(4), b = 8,402(4) et c = 11,008(4) Å, α = 71,68(3), β = 69,35(3) et γ = 69,77(3)°, V = 663,0(6) Å^3 et Z = 2.

Mots clés : arène–ruthénium, arène–osmium, acétylacétone, structures cristallines.

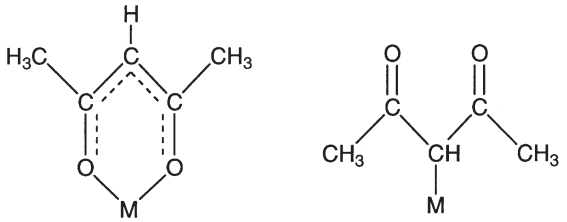
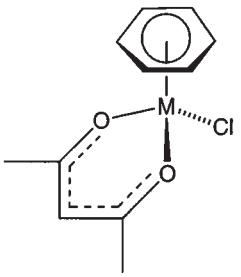
Introduction

Although the acac anion $(CH_3COCHCOCH_3)^-$ (see *List of abbreviations*),[2] and the mono-anions of other β-dicarbonyl compounds, usually behave as bidentate chelate *O*,*O*′-donors to transition metal ions, the more electronegative elements towards the end of the 4*d*- and 5*d*-series, especially Hg(II), Au(I), Au(III), Pt(II), Pd(II), Pt(IV), and Ir(III), display a pronounced tendency to bind to the γ-carbon atom of acetylacetonate ion (Fig. 1) (1–3). There are fewer examples of this behaviour in the coordination chemistry of rhodium, ruthenium, and osmium, which form stable chelate complexes such as [M(*O*,*O*′-acac)$_3$]. Starting from the η^5-pentamethylcyclopentadienyl complexes $[MCl_2(\eta^5\text{-}C_5Me_5)]_2$ (M = Rh, Ir), Maitlis et al. (4) have prepared [MCl(*O*,*O*′-acac)(η^5-C_5Me_5)], [Ir(*O*,*O*′-acac)(η^1-*C*-acac)(η^5-C_5Me_5)], and $[Rh_2(\mu\text{-}O,O',C\text{-acac})_2(\eta^5\text{-}C_5Me_5)_2]Y_2$ (Y = BF_4, PF_6) (**1**); in **1** each acac anion is bound as an *O*,*O*′-bidentate ligand to one rhodium atom and as a γ-*C*-donor to the other. Some

1, Y = BF_4, PF_6



analogous compounds are known in the isoelectronic η^6-*p*-cymene–ruthenium(II) and –osmium(II) systems. The complexes [MCl(*O*,*O*′-acac)(η^6-cym)] have been obtained by reaction of $[MCl_2(\eta^6\text{-cym})]_2$ with acetylacetone and base (5, 6), and [Os(*O*,*O*′-acac)(η^1-*C*-acac) (η^6-cym)] is formed by treatment of the *tert*-butylimido compound [Os(N-*t*-Bu) (η^6-cym)] with acetylacetone (6). We report here the preparation and structural characterization of a wider range of (η^6-arene)ruthenium(II) and (η^6-arene)osmium(II) acetylacetonato complexes, and show that the mode of binding of a second acetylacetonate anion to the [M(*O*,*O*′-acac)(η^6-arene)] moiety depends on the nature of the arene.



Results and discussion

Mono(acetylacetonato) complexes

Chloro(acetylacetonato) complexes of arene–ruthenium(II) or arene–osmium(II) of general formula [MCl(acac)(η^6-arene)] (M = Ru, Os; arene = C_6H_6, 1,3,5-$C_6H_3Me_3$, C_6Me_6; M = Os, arene = 1,2-$C_6H_4Me_2$, 1,2,3-$C_6H_3Me_3$) have been prepared in yields of 60–80% by reaction of 1 mol of the dichloride dimers $[MCl_2(\eta^6\text{-arene})]_2$ with 2 mol of thallium acetylacetonate or sodium acetylacetonate in dichloromethane or dichloromethane–methanol at room temperature. The ruthenium compounds can also be obtained, in generally lower yield, by heating $[RuCl_2(\eta^6\text{-arene})]_2$ with acetylacetone in DMF in the presence of anhyd Na_2CO_3 for 2–10 min at 100°C; longer periods or higher temperatures cause the formation of $[Ru(acac)_3]$. The complexes are orange or yellow, air-stable, microcrystalline solids that are very soluble in chloroform, dichloromethane, or methanol and are poorly soluble in benzene or ether. Molecular weight determinations in dichloromethane confirm that the ruthenium compounds are monomeric. Selected spectroscopic data are collected in Tables 1 and 2. In addition to the expected resonances in the region of δ 5 arising from the protons of the complexed arene, the ^{1}H NMR spectra show a 1H singlet at δ 4.9–5.1 and a 6H singlet at δ ca. 1.9 due to the γ-proton and the methyl protons of the acac group, respectively. The IR spectra show a pair of strong bands at ca. 1570 and 1510 cm^{-1}, which are assignable to coupled ν(C=O) + ν(C=C) modes of the bidentate *O*,*O*′-acetylacetonate (1–3, 7). Thus, the data are in agreement with the half-sandwich formulation **2**, similar to that proposed for the *p*-cymene–ruthenium and –osmium analogues (5, 6).

M = Os; arene = 1,2-$C_6H_4Me_2$, 1,2,3-$C_6H_3Me_3$

2

In a similar manner, we have also made the corresponding hexafluoroacetylacetonato complexes [RuCl(η^6-arene)(*O*,*O*′-hfacac)] (arene = C_6H_6, 1,3,5-$C_6H_3Me_3$,C_6Me_6), whose

[a]ν(C=O), ν(C=C) of acac (KBr, cm^{-1}); bands are very strong except where indicated; nm = not measured.

IR spectra show strong ν(C=O), ν(C=C) bands in the region of 1630–1550 cm^{-1} typical of bidentate *O*,*O*′-coordination of hfacac (7–9). The far-IR spectra of the [RuCl(acac)(η^6-arene)] and [RuCl(hfacac)(η^6-arene)] complexes contain a medium-intensity band at ca. 280 cm^{-1} that may be assigned to ν(RuCl).

Treatment of the [RuCl(*O*,*O*′-acac)(η^6-arene)] complexes with $AgBF_4$ or $AgPF_6$ in an acetone solution containing neutral ligands (L = dimethylsulfoxide (DMSO), acetonitrile, pyridine (py), triphenylphosphine) generates cationic complexes [Ru(L)(*O*,*O*′-acac)(η^6-arene)]$^+$, which can be isolated in good yield as their BF_4 or PF_6 salts. The IR spectra all show the characteristic pair of bands at ca. 1570 and 1510 cm^{-1} due to bidentate, O-bonded acac. The spectroscopic data (Table 1) are consistent with the half-sandwich structure **3**. In the solid state, the IR spectra of the DMSO complexes

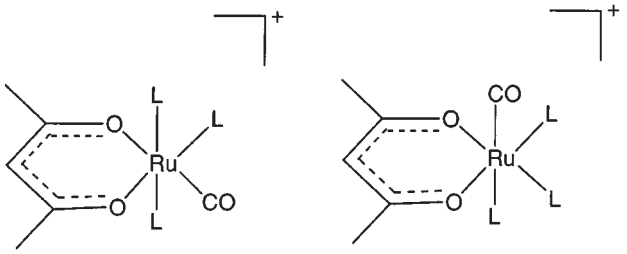
contain a band at ca. 1120 cm^{-1}, which is assigned to ν(S=O) of S-bonded DMSO (10*a*). The region 950–1100 cm^{-1} where ν(S=O) of O-bonded DMSO is expected to appear is masked by an intense ν(BF) absorption of the BF_4 anion, but the spectrum of [Ru(DMSO)(*O*,*O*′-acac)(η^6-C_6H_6)]PF_6 showed no band attributable to ν(S=O) of O-bonded DMSO. However, the IR spectrum of [Ru(DMSO)(*O*,*O*′-acac)(η^6-C_6H_6)]PF_6 in CD_2Cl_2 contains a strong band at 1055 cm^{-1} due to free DMSO, in addition to the band at 1112 cm^{-1} due to S-coordinated DMSO, showing that this ligand is readily lost from the coordination sphere. The ^{1}H NMR spectra of the DMSO complexes in CD_2Cl_2 show a 6H singlet at δ 2.6 due to *Me*$_2$SO, the chemical shift being similar to that of free DMSO (δ 2.53), and addition of DMSO to the solution shifts the resonance towards that of free DMSO; hence, there is rapid exchange on the NMR timescale between free and coordinated DMSO. This conclusion was confirmed by adding DMSO-d_6 (6 mol) to [Ru(*O*,*O*′-acac) (DMSO)(η^6-C_6H_6)] in CH_2Cl_2; the ^{1}H NMR spectrum of the recovered complex showed the presence of only about one-sixth of the original DMSO methyl protons. Since the observations imply the existence of the coordinatively unsaturated or solvent-stabilized species [Ru(*O*,*O*′-acac)(η^6-arene)]$^+$, we treated the [RuCl(*O*,*O*′-acac)(η^6-arene)] complexes with $AgBF_4$ or $AgPF_6$ in acetone. Silver chloride is precipitated, and yellow solutions are formed that presumably contain [Ru(acetone)(*O*,*O*′-acac)(η^6-arene)]$^+$. Addition of ether precipitates yellow powders that are insoluble in chloroform, dichloromethane, or methanol and do not redissolve in acetone. They do dissolve in acetonitrile or DMSO-d_6 to generate solutions of the appropriate cations [Ru(L)(*O*,*O*′-acac)(η^6-arene)]$^+$ (L = MeCN, DMSO-d_6), as shown by ^{1}H NMR spectroscopy. Elemental analyses of the yellow solids were not completely satisfactory, but the presence of a strong ν(C=O) band at 1620 cm^{-1} in the IR spectra suggests that the complexes are the (η^6-arene)ruthenium(II) analogues (**4**) of the binuclear Rh(η^5-C_5Me_5) complex **1**, containing bridging *O*,*O*′,*C*-acac groups.



4

Cationic carbonyl complexes [Ru(CO)(*O*,*O*′-acac)(η^6-arene)]$^+$ (arene = 1,3,5-$C_6H_3Me_3$, C_6Me_6) can be isolated as their BF_4

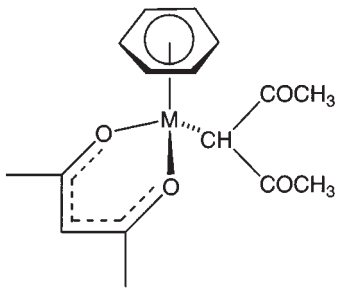
salts by bubbling CO through the yellow solutions containing [Ru(acetone)(*O*,*O*′-acac)(η^6-arene)]$^+$. The mesitylene complex is unstable in chloroform over a period of hours and decomposes slowly in air. The IR spectra show an intense ν(CO) band at ca. 2030–2050 cm^{-1}. Attempts to prepare ethylene analogues were unsuccessful. Under the same conditions, CO displaces benzene from solutions of [Ru(L)(*O*,*O*′-acac)(η^6-C_6H_6)]BF_4 (L = Me_2CO, MeCN) to give an intractable brown oil. Addition of ether to an acetonitrile solution gave a low yield of a pale yellow crystalline salt formulated as [Ru(*O*,*O*′-acac)(CO)$(MeCN)_3$]BF_4 on the basis of spectroscopic data. In addition to the usual resonances of coordinated acac there are two singlets in a 2:1 ratio in the ^{1}H NMR spectrum at δ ca. 2.5 corresponding to the methyl protons of coordinated acetonitrile. The IR spectrum contains a pair of weak bands in the region of 2300 cm^{-1} arising from ν(CN) of coordinated acetonitrile, a strong ν(CO) band at 1982 cm^{-1}, and the usual pair of *O*,*O*′-acac bands at ca. 1570 and 1510 cm^{-1}. These data are consistent with either of the octahedral structures **5a** or **5b** in which the acetonitrile ligands adopt a *mer* or *fac* arrangement about ruthenium, respectively.



5a **5b**

Chloride ion can also be abstracted from the osmium complexes [OsCl(*O*,*O*′-acac)(η^6-arene)], which react with silver acetate to give the acetato complexes [Os(η^1-OAc)(*O*,*O*′-acac)(η^6-arene)]. Their IR spectra (Table 2) show, in addition to the usual *O*,*O*′-acac bands at ca. 1580 and 1520 cm^{-1}, a strong ν(C=O) absorption at ca. 1630 cm^{-1} characteristic of either monodentate or asymmetric bidentate acetate (10b); the ^{1}H NMR spectra show the expected 3H singlet at δ ca. 1.9. The structure of the η^6-benzene complex has been confirmed by X-ray crystallography (see below).

Bis(acetylacetonato) complexes

The [RuCl(*O*,*O*′-acac)(η^6-arene)] complexes react with an equimolar quantity of Tl(acac) in methanol at –20°C to give orange-red (benzene) or yellow (mesitylene, hexamethylbenzene) microcrystalline solids of formula [Ru$(acac)_2$(η^6-arene)]. Attempts to prepare analogous bis(hfacac) complexes were unsuccessful. The benzene complex decomposes both as a solid and in solution, and satisfactory elemental analyses could not be obtained. The mesitylene and hexamethylbenzene complexes are stable for short periods in the solid state at room temperature, but they also decompose in solution at room temperature over periods ranging from minutes in chloroform to several days in methanol. The corresponding thermally more stable osmium compounds [Os$(acac)_2$(η^6-arene)] (arene = C_6H_6, 1,2-$C_6H_4Me_2$, 1,2,3-$C_6H_3Me_3$, 1,3,5-$C_6H_3Me_3$, C_6Me_6) are obtained similarly from [OsCl(*O*,*O*′-acac)(η^6-arene)], and the benzene compound can also be isolated from the reaction of [$OsCl_2$(η^6-C_6H_6)]$_2$ with Tl(acac) in a 1:4 mol ratio in methanol. At a late stage of the study, during attempts to grow single crystals of [Os$(acac)_2$(η^6-C_6H_6)], we realized that the η^1-acetato complexes [Os(η^1-O_2CMe)(*O*,*O*′-acac)(η^6-arene)] are formed as byproducts in these reactions; these complexes have been prepared independently and have been fully characterized (see above). We have not established whether the byproducts arose from adventitious thallium acetate impurity in the sample of Tl(acac), or more likely, from a catalyzed process similar to the known base-promoted decomposition of acetylacetonate ion to acetate ion (11). In most cases the less soluble acetato complexes could be separated from the bis(acetylacetonato) complexes by fractional crystallization.

The key spectroscopic data for the [M$(acac)_2$(η^6-arene)] complexes are collected in Table 3. For the ruthenium compound [Ru$(acac)_2$(η^6-C_6H_6)], and for the osmium compounds [Os$(acac)_2$(η^6-arene)] (arene = C_6H_6, 1,2-$C_6H_4Me_2$, 1,2,3-$C_6H_3Me_3$), these data indicate a structure (**6**) in which one acac group is still bidentate (*O*,*O*′) while the other is bound as a monodentate ligand through the γ-carbon atom.

M = Ru, Os; arene = C_6H_6
M = Os; arene = 1,2-$C_6H_4Me_2$, 1,2,3-$C_6H_3Me_3$

6

Thus, the solid state and solution IR spectra show two pairs of strong bands in the ν(C=O), ν(C=C) region, one due to *O*,*O*′-acac at ca. 1580 and 1520 cm^{-1}, the other at 1650–1680 and 1620 cm^{-1} assignable to $CH(COMe)_2$ (7). Correspondingly, the ^{1}H NMR spectra contain a singlet acac methyl resonance at δ 1.9–2.3 (6H) and a γ-CH resonance at δ 4.3–4.7 assignable to C-bonded acac, in addition to a methyl resonance at δ ca. 1.8 (6H) and a γ-CH resonance at ca. δ 5.2 due to *O*,*O*′-acac. In contrast, although the ^{1}H NMR spectra of [M$(acac)_2$(η^6-arene)] (M = Ru, Os; arene = 1,3,5-$C_6H_3Me_3$, C_6Me_6) contain resonances typical of *O*,*O*′-acac, the η^1- acac group in each case gives rise to two methyl singlets at δ ca. 2.5 and 3.0, and a γ-CH singlet at δ ca. 5.0, consistent with binding through a keto-oxygen atom (structure **7**). The IR spectra show two pairs of strong bands in the ν(C=O), ν(C=C) region, one due to *O*,*O*′-acac at ca. 1580 and 1520 cm^{-1}, the other at ca. 1620 and 1500 cm^{-1}. The bands in the second pair clearly differ from those due to η^1-C-bonded acac and are similar to those reported for the structurally characterized compound [Rh(η^1-*O*-acac)(CO){P(*i*Pr)$_3$}$_2$] (1613 (w), 1515 (m) cm^{-1})) (12). However, the bands reported for *trans*-[Pt(η^1-*O*-acac)$_2$(PEt_3)$_2$] and

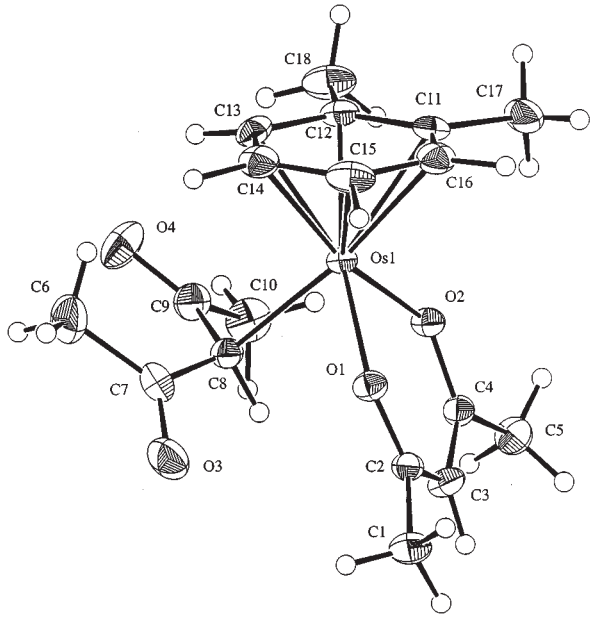
trans-[Pt(η^1-*O*-acac)$_2$($C_5H_{10}NH)_2$] appear at somewhat different frequencies, namely 1650 (s) and 1605 (m) cm^{-1} (13) and 1621 (vs) and 1583 (w) cm^{-1} (14), respectively, so that conclusions based on IR data must be treated with caution. Nevertheless, the proposed structures have been confirmed by single crystal X-ray diffraction studies (see below).



Although the ^{1}H NMR spectrum of [Ru(acac)$_2$(η^6-C_6Me_6)] in coordinating solvents such as acetone and acetonitrile is similar to that in $CDCl_3$ or CD_2Cl_2, the behaviour in methanol is different and suggestive of selective protonation of the acac ligands. At 28°C in methanol-d_4 there is one broad resonance at δ ca. 1.97 arising from the methyl protons of both acac ligands; the methine protons exchange rapidly with residual protons in the solvent and appear as a singlet at δ 4.77 (2H). It should be noted that the methine proton of [RuCl(acac)(η^6-C_6Me_6)] undergoes a similar but slower process at room temperature, complete exchange requiring ca. 100 h. At 7°C the ^{1}H NMR spectrum of [Ru(acac)$_2$(η^6-C_6Me_6)] in methanol-d_4 contains two broad methyl singlets of approximately equal intensity at δ 1.93 and ca. 2.01, the latter being partly obscured by the C_6Me_6 singlet. At this temperature, protonation of the monodentate ligand and subsequent rapid exchange between coordinated and uncoordinated acetylacetone averages the methyl environments of the enolate ligand, whereas at 28°C this process is rapid for both acac ligands. Only at –3°C in methanol-d_4 do the expected three acac methyl singlets appear.

The acac methyl protons of [Ru(acac)$_2$(η^6-C_6Me_6)] exchange completely with CH_3OD over a period of 3 days at room temperature, and the IR spectrum of the resulting deuterated complex shows characteristic shifts of the ν(C=O), ν(C=C) bands to ca. 1560 and 1480 cm^{-1} (15). A plausible intermediate in this process is **8**, which contains

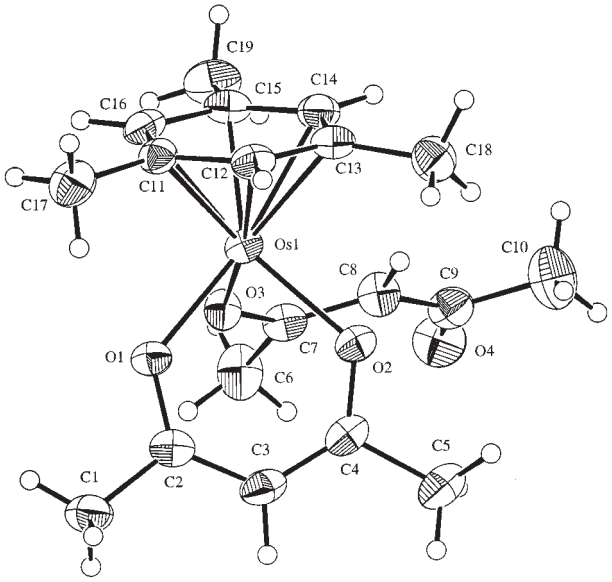
Fig. 2. Molecular structure of [Os(*O*,*O*′-acac)(η^1-*C*-acac)(η^6-1,2-$C_6H_4Me_2$)] with selected atom labeling. Thermal ellipsoids in the ORTEP plot show 30% probability levels.

η^3-acetylacetonate dianion derived by deprotonation of the intermediate [Ru(*O*,*O*′-acac) (solvent)(η^6-C_6Me_6)]$^+$. Examples of this mode of coordination are known for palladium(II) (16) and platinum(II) (17).



Structures determined by X-ray crystallography

The molecular structures of [Os(*O*,*O*′-acac)(η^1-*C*-acac)(η^6-1,2-$C_6H_4Me_2$)], [Os(*O*,*O*′-acac)(η^1-*O*-acac)(η^6-1,3,5-$C_6H_3Me_3$)], and [Os(η^1-OAc)(*O*,*O*′-acac)(η^6-C_6H_6)] are shown in Figs. 2–4, respectively, with atom labeling. They confirm the conclusions drawn above on the basis of spectroscopic data. Selected bond lengths and angles of these three compounds are listed in Tables 4–6, respectively.

All three compounds contain an almost planar η^6-arene ring attached to an osmium atom that is coordinated trigonally by a bidentate *O*,*O*′-bonded acac and a monodentate ligand. In the first compound, the η^1-acac group is bound through carbon atom C(8), the Os(1)–C(8) vector approximately eclipsing one of the Os–C(arene) vectors (Os(1)–C(13)). The orientation of the η^6-arene ring places its two methyl groups well away from the $COCH_3$ substituents of the η^1-acac group. The C=O groups of η^1-acac adopt a mutually *anti*-orientation, and their bond lengths are as expected (1.221(5), 1.235(5) Å). The Os(1)—C(8) bond length (2.233(4) Å) is slightly but significantly greater than the limited number of reported Os(II)—CH_3 and Os(II)—C sp^3 distances, which fall in the range of 2.17–2.21 Å (18–21). In the second compound, the η^1-acac group is bound through one of the keto-oxygen atoms, i.e., it acts as a η^1-enolate; the Os—O vectors of the trigonal array almost eclipse the methyl-bearing carbon atoms of the η^6-arene ring. The Os—O(η^1-acac) distance (2.099(5) Å) is just significantly greater than the Os—O (*O*,*O*′-acac) distances (2.078(5), 2.072(5) Å). The geometry and metrical parameters of the enolate fragment are similar to those observed in the acetylacetonato derivatives *trans*-[Rh(η^1-*O*-acac)(CO)L_2] (L = P(*i*Pr)$_3$, PCy_3) (12, 22),

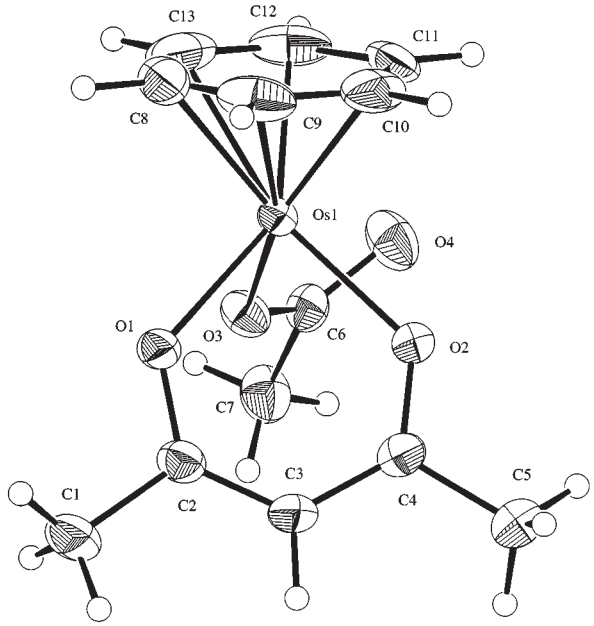
Fig. 3. Molecular structure of [Os(*O,O′*-acac)(η^1-*O*-acac)(η^6-1,3,5-$C_6H_3Me_3$)] with selected atom labeling. Thermal ellipsoids in the ORTEP plot show 30% probability levels.



[$Cr(CO)_5${$PPh(\eta^1$-*O*-acac$)_2$}] (23), and [$Mn(\eta^5$-$C_5H_5)(CO)_2${$PPh_2(\eta^1$-*O*-acac)}] (24), and in the trifluoroacetylacetonato complex [Pd(*O,O′*-tfac)(η^1-*O*-tfac){P(*o*-tolyl)$_3$}] (25); the enolate group is almost planar, the Os-O and $COCH_3$ groups are mutually *trans* about the C—C bond, and the C=C and C=O groups are mutually *cis*. As expected, the C—O bond length of the bound enolate (1.301(9) Å) is greater than that of the uncoordinated C=O group (1.23(1) Å). The structure of [Os(η^1-OAc)(*O,O′*-acac)(η^6-C_6H_6)] confirms that the acetato group is monodentate, the Os—O bond length (2.077(3) Å) being similar to those to the *O,O′*-acac unit (2.074(3), 2.064(3) Å). In contrast to the two structures discussed above, the Os—O vectors of the trigonal array do not eclipse the arene carbon atoms.

Experimental

General procedures

All experiments were performed under an inert atmosphere with use of Schlenk techniques, and all solvents were dried and degassed by standard methods before use. ^{1}H NMR spectra were measured on Varian HA-100 or Jeol MH-100 spectrometers at 100 MHz or on Varian Gemini 300-BB or VXR-300 spectrometers at 300 MHz. Chemical shifts (δ) are in ppm referenced to residual proton signals of the solvent; coupling constants (*J*) are in Hz. IR spectra in the range 4000–400 cm^{-1} were recorded as KBr discs or Nujol™ mulls, or as CH_2Cl_2 solutions in 0.1 mm pathlength cells, on PerkinElmer PE 457 or 683 spectrometers. IR spectra in the range 450–150 cm^{-1} were measured as polythene discs on a PerkinElmer FT-1800 instrument. Electron impact (EI) mass spectra at 70 eV were measured on AEI–MS 902 or VG Micromass 7070 F spectrometers. ^{1}H NMR and selected IR data are collected in Tables 1–3; elemental analyses, which were carried out in-house, are listed in Tables 7 and 8.

Fig. 4. Molecular structure of [Os(*O,O′*-acac)(η^1-O_2CMe)(η^6-C_6H_6)] with selected atom labeling. Thermal ellipsoids in the ORTEP plot show 30% probability levels.

Starting materials

Hydrated ruthenium chloride and osmium tetraoxide were obtained from Johnson Matthey, U.K. The acetylacetonates of sodium and thallium were prepared by literature procedures (34, 35). Most of the [$MCl_2(\eta^6$-arene)]$_2$ complexes were made by reaction of the appropriate cyclohexa-1,3-diene or cyclohexa-1,4-diene with hydrated $RuCl_3$ or Na_2OsCl_6 in refluxing ethanol (27–29). The previously unknown compound [$OsCl_2$ (η^6-1,2,3-$C_6H_3Me_3$)]$_2$ was made in this way as orange microcrystals in 67% yield from Na_2OsCl_6 and a mixture of dihydro-isomers obtained by Li–NH_3 reduction of the arene. Anal. calcd. for $C_9H_{12}Cl_2Os$: C 28.35, H 3.2; found: C 27.8, H 2.8. The hexamethylbenzene complexes [$MCl_2(\eta^6$-$C_6Me_6)]_2$ were prepared by fusion of the corresponding *p*-cymene complexes with an excess of hexamethylbenzene (19, 30, 31). Since cyclohexa-1,3-diene undergoes extensive polymerization on heating with osmium chlorides, we prepared [$OsI_2(\eta^6$-$C_6H_6)]_2$ (32), converted it into the bis(acetate) by treatment with AgOAc for 2 days, and treated the bis(acetate) with conc. HCl to give [$OsCl_2(\eta^2$-$C_6H_6)]_2$ (33).

Preparations

*[RuCl(*O,O′*-acac)(η^6-arene)]*

(*i*) A mixture of [$RuCl_2(\eta^6$-$C_6H_6)]_2$ (200 mg, 0.40 mmol) and Tl(acac) (244 mg, 0.80 mmol) suspended in dichloromethane (15 mL) was stirred for 2 h and then filtered through Celite™ to remove the precipitated TlCl. The orange crystalline product [RuCl(*O,O′*-acac)(η^6-C_6H_6)], which formed on cooling the filtrate, was separated by filtration, washed with ether, and dried in vacuo. The yield was 165 mg (66%). Similarly prepared from [$RuCl_2(\eta^6$-1,3,5-$C_6H_3Me_3)]_2$ or [$RuCl_2(\eta^6$-$C_6Me_6)]_2$ and Tl(acac) with periods of stirring of 2 h and 10 min, respectively, were

[RuCl(*O,O′*-acac)(η^6-1,3,5-$C_6H_3Me_3$)] (81%) and [RuCl(*O,O′*-acac)(η^6-C_6Me_6)] (82%).

(*ii*) A suspension of [$RuCl_2$(η^6-C_6H_6)]$_2$ (200 mg, 0.40 mmol) and Na(acac) (99 mg, 0.81 mmol) in dichloromethane–methanol (1:1) (15 mL) was stirred for 2 h at room temperature. The solution was evaporated to dryness under reduced pressure. The residue was extracted with dichloromethane and the solution was filtered. Addition of ether to the filtrate and cooling gave orange crystals of the product, which were separated by filtration, washed with ether, and dried in vacuo. The yield was 150 mg (60%). The complexes [RuCl(*O,O′*-acac)(η^6-arene)] (arene = 1,3,5-$C_6H_3Me_3$, C_6Me_6) were prepared similarly, with periods of stirring of 2 h and 15 min, respectively, in yields of 60 and 85%, respectively.

(*iii*) A mixture of [$RuCl_2$(η^6-C_6H_6)]$_2$ (200 mg, 0.40 mmol) and an excess of anhyd Na_2CO_3 (1 g) was suspended in DMF (5 mL) and stirred for 10 min at 100°C. The solution was filtered and methanol was added to the filtrate. The orange crystals that separated on cooling were washed with ether and dried in vacuo. The yield was 65 mg (26%).

Similarly prepared were [RuCl(*O,O′*-acac)(η^6-1,3,5-$C_6H_3Me_3$)] (63%) and [RuCl(*O,O′*-acac)(η^6-C_6Me_6)] (29%), the mixture being heated for only 2 min in the latter case.

*[RuCl(*O,O′*-hfacac)(η^6-arene)]*

(*i*) A solution of Tl(hfacac) (197 mg, 0.48 mmol) in dichloromethane (20 mL) was cooled to 0°C and treated with [$RuCl_2$(η^6-C_6H_6)]$_2$ (200 mg, 0.40 mmol). The suspension was stirred for 1 min and filtered at 0°C. Addition of ether to the filtrate gave [RuCl(*O,O′*-hfacac)(η^6-C_6H_6)] as an orange crystalline solid, which was separated by filtration, washed with ether, and dried in vacuo. The yield was 135 mg (67%). The complex [RuCl(*O,O′*-hfacac)(η^6-1,3,5-$C_6H_3Me_3$)] was

prepared similarly from [RuCl(η^6-1,3,5-$C_6H_3Me_3$)]$_2$ and Tl(hfacac).

(*ii*) A solution of [$RuCl_2$(η^6-C_6Me_6)]$_2$ (150 mg, 0.22 mmol) in dichloromethane (15 mL) was stirred for 1 min with Tl(hfacac) (185mg, 0.45 mmol) at room temperature and then filtered. The filtrate was evaporated to ca. half the volume and ether was added to give [RuCl(*O,O′*-hfacac)(η^6-C_6Me_6)] as a red crystalline solid. The yield was 143 mg (63%).

*[Ru(*O,O′*-acac)(η^6-arene)(L)]BF_4 (L = DMSO, MeCN, py, PPh_3)*

Equimolar quantities of [RuCl(*O,O′*-acac)(η^6-arene)] and $AgBF_4$ were stirred in acetone at room temperature for 5 min. The solution was filtered through Celite™, the filtrate was treated with an equimolar quantity of ligand L, and the solution stirred for 1 h. Evaporation to ca. half the volume and addition of ether gave the products as yellow microcrystalline solids, which could be recrystallized from dichloromethane–ether. Yields were 40–80%. L = DMSO: arene = C_6H_6: IR (KBr, cm^{-1}): 1124 (s) (S=O). ^{1}H NMR ($CDCl_3$) δ: 2.66 (s, *Me*$_2$SO). Arene = 1,3,5-$C_6H_3Me_3$: IR (KBr, cm^{-1}): 1123 (s) (S=O). ^{1}H NMR ($CDCl_3$) δ: 2.64 (s, *Me*$_2$SO). Arene = C_6Me_6: IR (KBr, cm^{-1}): 1124 (s) (S=O). ^{1}H NMR ($CDCl_3$) δ: 2.57 (s, *Me*$_2$SO). L = MeCN: arene = C_6H_6: IR (KBr, cm^{-1}): 2295 (w) (CN). ^{1}H NMR (CD_2Cl_2) δ: 2.32 (s, *Me*CN). Arene = C_6Me_6: IR (KBr, cm^{-1}): 2290 (w) (CN). ^{1}H NMR ($CDCl_3$) δ: 2.42 (s, *Me*CN). L = py: arene = C_6H_6: ^{1}H NMR ($CDCl_3$) δ: 7.44 (m, 2H), 7.84 (m, 1H), 8.47 (m, 2H) (py). Arene = 1,3,5-$C_6H_3Me_3$: ^{1}H NMR ($CDCl_3$) δ: 7.49 (m, 2H), 7.87 (m, 1H), 8.50 (m, 2H) (py). Arene = C_6Me_6: ^{1}H NMR ($CDCl_3$) δ: 7.52 (m, 2H), 7.88 (m, 1H), 8.14 (m, 2H) (py).

*[Ru(*O,O′*-acac)(η^6-arene)(CO]BF_4*

A solution of $AgBF_4$ (55 mg, 0.28 mmol) in acetone (15 mL) was saturated with CO and treated with [RuCl(*O,O′*-acac)(η^6-1,3,5-$C_6H_3Me_3$)] (100 mg, 0.28 mmol). The solution was stirred for 5 min while CO was bubbled into it, then filtered, and evaporated under reduced pressure to ca. 5 mL volume. Addition of ether caused the product, [RuCl(*O,O′*-acac)(η^6-1,3,5-$C_6H_3Me_3$)(CO)]BF_4, to form as a yellow microcrystalline solid, which was separated by filtration, washed with ether, and dried in vacuo. The yield was 50 mg (41%). IR (KBr, cm^{-1}): 2045 (vs) (CO). A similar procedure was used to prepare [RuCl(*O,O′*-acac)(η^6-C_6Me_6)(CO)]BF_4 from [RuCl(*O,O′*-acac)(η^6-C_6Me_6)]. Evaporation to dryness of the filtered acetone solution gave an oil, which was dissolved in the minimum volume of dichloromethane. Addition of ether gave the product as a pale yellow solid in 45% yield. IR (KBr, cm^{-1}): 2026 (vs) (CO).

[Ru(acac)(arene)]$_n$(BF_4)$_n$

To a solution of $AgBF_4$ (64 mg, 0.33 mmol) in acetone (15 mL) was added [RuCl(*O,O′*-acac)(η^6-C_6H_6)] (100 mg, 0.32 mmol). The mixture was stirred for 15 min and filtered. Evaporation of the filtrate to ca. 5 mL volume and addition of ether gave [Ru(acac)(η^6-C_6H_6)]$_n$(BF_4)$_n$ as a pale yellow

powder, which was separated by filtration and washed with ether. The yield was 30 mg (26%). IR (KBr, cm^{-1}): 1620 (vs) (C=O)–(C=C). The mesitylene analogue was prepared similarly in 31% yield. IR (KBr, cm^{-1}): 1620 (vs) (C=O), (C=C).

*[Ru(*O,O′*-acac)(CO)(MeCN)$_3$]BF$_4$*

Carbon monoxide was bubbled into a solution of [Ru(*O,O′*-acac)(η^6-C_6H_6) (MeCN)] BF_4 (100 mg, 0.24 mmol) in acetone (15 mL) for 5 min. The solution was filtered and the filtrate evaporated under reduced pressure to give a brown oil. This was dissolved in acetonitrile and to the filtered solution was added ether dropwise to precipitate [Ru(*O,O′*-acac)(CO)$(MeCN)_3$]BF_4 (20mg, 18%) as a pale yellow solid. IR(KBr, cm^{-1}): 2300 (vw) (CN), 1980 (vs) (CO), 1570 (vs) (C=O), (C=C) of acac. ^{1}H NMR ($CDCl_3$) δ: 2.00 (s, 6H, acac-CH_3), 2.51 (s, 3H), 2.54 (s, 6H, MeCN), 5.31 (s, 1H, acac-γ-C*H*). Anal. calcd. for $C_{12}H_{16}BF_4N_3O_3Ru$: C 32.9, H 3.8, N 9.6; found: C 32.9, H 3.7, N 9.6.

*[OsCl(*O,O′*-acac)(η^6-arene)]*

(*i*) A mixture of [$OsCl_2$(η^6-1,3,5-$C_6H_3Me_3$)]$_2$ (200 mg, 0.26 mmol) and Tl(acac) (160 mg, 0.53 mmol) was stirred in dichloromethane (10 mL) for 2 h at room temperature. The yellow solution was separated from the precipitated TlCl by decantation and filtered through Celite™. The solution was concentrated in vacuo and ether was added. Cooling in dry ice – acetone gave [OsCl(*O,O′*-acac)(η^6-1,3,5-$C_6H_3Me_3$)] as a yellow-brown solid (176 mg, 75%). Evaporation of the supernatant liquid gave more yellow-brown solid, which was shown by ^{1}H NMR spectroscopy to be an approximately 1:1 mixture of [OsCl(*O,O′*-acac)(η^6-1,3,5-$C_6H_3Me_3$)] and the acetato complex [Os(η^1-O_2CMe)(*O,O′*-acac)(η^6-1,3,5-$C_6H_3Me_3$)].

The complexes [OsCl(*O,O′*-acac)(η^6-arene)] (arene = 1,2-$C_6H_4Me_2$, 1,2,3-$C_6H_3Me_3$, and C_6Me_6) were prepared similarly from the corresponding [$OsCl_2$(η^6-arene)]$_2$ complexes in yields of 83, 74, and 73%, respectively.

(*ii*) The benzene complex can be made from [$OsCl_2$(η^6-C_6H_6)]$_2$ and Na(acac) as described for the ruthenium analogue (1(*ii*)) or as follows.

Addition of a few drops of acetyl chloride to a solution of [Os(*O,O′*-acac)(η^1-*C*-arene) (η^6-C_6H_6)](125 mg, 0.27 mmol) (see below) in methanol (4 mL) caused a precipitate to form immediately. The solvent was removed in vacuo and the residue was extracted with dichloromethane. The extract was filtered through Celite™, concentrated under reduced pressure, and cooled to give [OsCl(*O,O′*-acac)(η^6-C_6H_6)] (73 mg, 67%) in two crops.

*[Os(*η^1-O$_2$CMe*)(*O,O′*-acac)(*η^6-arene*)]*

A suspension of [OsCl(*O,O′*-acac)(η^6-C_6H_6)] (48 mg, 0.12 mmol) and silver acetate (21 mg, 0.13 mmol) in benzene (10 mL) was stirred overnight. The yellow solution was separated by decantation from the precipitated AgCl, filtered through Celite™, and evaporated to dryness. The resulting yellow solid [Os(η^1-O_2CMe)(*O,O′*-acac)(η^6-C_6H_6)] (47 mg, 92%) was spectroscopically and analytically pure.

The corresponding complexes containing 1,2-$C_6H_4Me_2$, 1,2,3-$C_6H_3Me_3$, 1,3,5-$C_6H_3Me_3$, and C_6Me_6 were prepared similarly in yields of 71, 95, 59, and 95%, respectively.

*[Ru(acac)$_2$(*η^6-arene*)]*

A mixture of [RuCl(*O,O′*-acac)(η^6-C_6H_6)] (200 mg, 0.64 mmol) and Tl(acac) (190 mg, 0.63 mmol) was stirred in methanol (10 mL) at –20°C for 2 h. The solution was evaporated to dryness, the residue was extracted with ether, and the extract was filtered, the temperature being kept below 0°C at all times. The filtrate was concentrated under reduced pressure to give [Ru(*O,O′*-acac)(η^1-*C*-acac)(η^6-C_6H_6)] as a microcrystalline red solid, which darkened when warmed to room temperature. The yield was 120 mg (51%).

The complexes [Ru(*O,O′*-acac)(η^1-*O*-acac)(η^6-arene)] (arene = 1,3,5-$C_6H_3Me_3$, C_6Me_6) were prepared similarly from [RuCl(*O,O′*-acac)(η^6-arene)] in yields of 40 and 60%, respectively.

[Os(acac)$_2$(η^6-arene)]

(*i*) A mixture of [OsCl$_2$(η^6-C_6H_6)]$_2$ (100 mg, 0.15 mmol) and Tl(acac) (179 mg, 0.59 mmol) in methanol (10 mL) was stirred for 2 h. The solvent was removed under reduced pressure and the residue was extracted with dichloromethane. The extracts were filtered through Celite™ and again evaporated to dryness. The residue was extracted with ether (ca. 20 mL) and the ether solution passed down a short column of Celite™. Concentration and cooling gave two crops (34 mg in total) of a yellow solid containing [Os(*O*,*O*′-acac)(η^1-*C*-acac)(η^6-C_6H_6)] contaminated by the acetato complex [Os(η^1-O_2CMe)(*O*,*O*′-acac)(η^6-C_6H_6)] (ca. 10–15%) as shown by ^{1}H NMR spectroscopy. An X-ray quality crystal of the latter was obtained by evaporation of the ether solution. A crystalline, spectroscopically and analytically pure sample of [Os(*O*,*O*′-acac)(η^1-*C*-acac)(η^6-C_6H_6)] was obtained by diffusion of pentane into a dichloromethane solution.

(*ii*) A mixture of [OsCl(*O*,*O*′-acac)(η^6-1,2-$C_6H_4Me_2$)] (130 mg, 0.30 mmol) and Tl(acac) (95 mg, 0.31 mmol) in methanol (10 mL) was stirred for 2 h giving a yellow solution and a colourless precipitate. The methanol was removed in vacuo and the residue was extracted with ether and filtered through Celite™. Concentration of the filtrate and cooling gave a yellow solid containing mainly [Os(*O*,*O*′-acac)(η^1-*C*-acac)(η^6-1,2-$C_6H_4Me_2$)], as shown by ^{1}H NMR spectroscopy. The yield was 82 mg (55%). Evaporation of the supernatant liquid gave a further 34 mg of less pure product. Yellow-brown X-ray quality crystals of [Os(*O*,*O*′-acac)(η^1-*C*-acac)(η^6-1,2-$C_6H_4Me_2$)] were obtained by diffusion of hexane into a benzene solution of the first solid; these crystals also gave satisfactory microanalytical data. EI-MS (70 eV) *m*/*z* : 496.1 (M$^+$, based on ^{192}Os), 397 ([M – acac]$^+$).

(*iii*) Similarly prepared from OsCl(*O*,*O*′-acac)(η^6-1,2,3-$C_6H_3Me_3$)] (123 mg, 0.28 mmol) and Tl(acac) (85 mg, 0.28 mmol) in methanol, after extraction with dichloromethane (10 mL), was crude [Os(*O*,*O*′-acac)(η^1-*C*-acac)(η^6-1,2,3-$C_6H_3Me_3$)] (127 mg, 89%). Purification was carried out by extraction with ether as described above.

(*iv*) Reaction of [OsCl(*O*,*O*′-acac)(η^6-1,3,5-$C_6H_3Me_3$)] (150 mg, 0.34 mmol) with Tl(acac) (103 mg, 0.34 mmol) in

[a] B_{eq} defined as in Table 10.

methanol (10 mL) and work-up as described for the *o*-xylene preparation gave 150 mg (88%) of crude [Os(*O*,*O′*-acac)(η¹-*O*-acac)(η⁶-1,3,5-$C_6H_3Me_3$)] contaminated with the acetato complex. Yellow X-ray quality crystals of the former were obtained by diffusion of hexane into a benzene solution.

(*v*) Reaction of [OsCl(*O*,*O′*-acac)(η⁶-C_6Me_6)] (94 mg, 0.19 mmol) with Tl(acac) (60 mg, 0.20 mmol) in methanol (10 mL) and work-up as described above gave [Os(*O*,*O′*-acac)(η¹-*O*-acac)(η⁶-C_6Me_6)] (38 mg, 36%), which was ca. 90% pure, although ^{1}H NMR spectroscopy and elemental analyses indicated the presence of some of the acetato complex.

Molecular structure determinations

Crystals of [Os(*O*,*O′*-acac)(η¹-*C*-acac)(η⁶-1,2-$C_6H_4Me_2$)] and [Os(*O*,*O′*-acac)(η¹-*O*-acac)(η⁶-1,3,5-$C_6H_3Me_3$)] suitable for X-ray diffraction studies were obtained by vapour diffusion of hexane into benzene solutions. Crystals of [Os(*O*,*O′*-acac)(η¹-OAc)(η⁶-C_6H_6)] were obtained fortuitously from an ether solution of the crude η¹-*C*-acac complex. The crystal data and parameters for data collection are summarized in Table 9. The structures were solved by heavy atom Patterson methods (36) and expanded by use of Fourier techniques (37). Non-hydrogen atoms were refined anisotropically. Most of the hydrogen atoms were located in the difference electron density maps and the positions used to generate all the hydrogen atoms, assuming idealized geometry. For the *o*-xylene complex, the positional parameters for the hydrogen atoms were refined, the isotropic *B*-values being held fixed and tight restraints being imposed on distances and angles for the methyl groups only. For the mesitylene and benzene complexes, the hydrogen atoms were periodically recalculated but

not refined. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$ with the weights w given by $w = |\sigma^2(F_o)|^{-1}$. The software packages used were Xtal (38) for data reduction and teXsan (39) for structure solution, refinement, and graphics. Neutral atom scattering factors were taken from ref. 40. Anomalous dispersion effects were included in F_{calc} (41); values of $\Delta f'$ and $\Delta f''$ and of mass attenuation coefficients were taken from standard compilations (42, 43). Selected bond distances and angles are given in Tables 4–6, atomic coordinates are listed in Tables 10–12.

Crystal data, complete tables of bond distances and angles, atomic coordinates, anisotropic thermal parameters for the non-hydrogen atoms, non-bonded contacts, and selected least-squares planes have been deposited.[2]

Conclusion

In this work, we have shown that the [M(*O*,*O*′-acac)(η^6-arene)] (M = Ru, Os) fragments are capable of binding a range of ligands containing nitrogen, phosphorus, oxygen, and sulfur donor atoms. The mode of binding of a second acac group depends on the nature of the arene. The fact that the preferred binding mode changes from η^1-*C* to η^1-*O* in going from 1,2,3- to 1,3,5-$C_6H_3Me_3$ suggests that there is a delicate balance, possibly mediated by a steric effect. The more symmetrical arrangement of ring methyl groups could give rise to an unavoidable steric repulsion between them and the $COCH_3$ groups of a η^1-*C*-acac group, thus favouring coordination of the sterically less demanding η^1-*O*- enolate form. However, on this basis alone, it is difficult to see why η^1-*C*-bonding should be favoured for the isoelectronic complexes of rhodium(III) and iridium(III) [M(*O*,*O*′-acac)(η^1-*C*-acac)(η^5-C_5Me_5)] (4), since the estimated average cone angles of Rh^{III}-C_5Me_5 and Ru^{II}-$C_6H_3Me_3$ are likely to be very similar (ca. 188°) (26). Another possibility is that, since the charge separation in an arene–metal bond in the sense (arene)(δ^+)–metal(δ^-) is probably greater than that in its isoelectronic C_5Me_5–metal counterpart, the negative charge on the metal may be better accommodated by the more electronegative oxygen atom of an O-bound enolate.

BINAPS — An axially chiral *P,S*-heterodonor ligand for asymmetric catalysis based on binaphthalene backbone

Serafino Gladiali, Serenella Medici, Giovanna Pirri, Sonia Pulacchini, and Davide Fabbri

Abstract: The chelating *P,S*-heterodonor ligand 2-diphenylphosphanyl-1,1′-binaphthalene-2′-thiol (**11**) (BINAPS), which features a chiral axis as the unique stereogenic element, has been prepared in both racemic and enantiopure form through a multistep reaction sequence using 2,2′-dihydroxy-1,1′-binaphthalene (BINOL) as the starting material. The reaction sequence is completely stereoconservative and (*S*)-**11** is obtained with no loss of enantiopurity from pure (*S*)-BINOL. (*R*)-**11** can be alternatively obtained by resolution of racemic **11** using the chiral (*S*)-benzylaminato Pd(II)-complex **19** as the resolving agent. The *S*-methyl or the *S*-*i*-propyl derivatives **14** have been used as chiral ligands in the Rh(I)-catalyzed asymmetric hydroformylation of styrene and in the hydrogen transfer reduction of acetophenone with modest success (up to 20% ee). In the presence of suitable Pd-complexes the same ligands provide higher ees in the hydrosilylation of styrene (50% ee) and in the allylic alkylation of 1,3-diphenylprop-2-enyl acetate (60% ee).

Key words: heterodonor ligands, binaphthalene derivatives, enantioselective catalysis, transition metal catalysts, allylic alkylation.

Résumé : Utilisant le 2,2′-dihydroxy-1,1′-binaphtalène (BINOL) comme produit de départ d'une synthèse en plusieurs étapes, on a préparé les formes racémiques et énantiopures du ligand chélatant *P,S*-hétérodonneur 2-diphénylphosphanyl-1,1′-binaphtalène-2′-thiol, **11** (BINAPS), qui ne comporte qu'un axe chiral comme seul élément stéréogène. La séquence de réaction est complètement stéréoconservatrice et l'isomère (*S*)-**11** a été obtenu sans perte d'énantiopureté à partir du (*S*)-BINOL pur. On peut aussi obtenir l'isomère (*R*)-**11** en procédant au dédoublement du produit **11** racémique en utilisant le complexe chiral **19** (*S*)-benzylaminato Pd(II) comme agent de résolution. On a utilisé avec des succès mitigés (ee allant jusqu'à 20%) les dérivés *S*-méthyle ou *S*-*i*-propyle, **14**, comme ligands chiraux dans l'hydroformylation asymétrique du styrène catalysée par le Rh(I) et dans la réduction par transfert de proton de l'acétophénone. En présence de complexes de Pd appropriés, les mêmes ligands conduisent des ee beaucoup plus élevés lors de l'hydrosilylation du styrène (ee de 50%) et de l'alkylation allylique de l'acétate de 1,3-diphénylprop-2-ényle (ee de 60%).

Mots clés : ligands hétérodonneurs, dérivés du binaphtalène, catalyse énantiosélective, catalyseurs dérivés de métaux de transition, alkylation allylique.

[Traduit par la Rédaction]

Introduction

The preparation of BINAP **1** reported in 1980 has marked a landmark in asymmetric catalysis and has illustrated the peculiar stereorecognitive properties inherent with the axially chiral 1,1′-binaphthalene framework (1). Since then, a great deal of work has been devoted to the preparation of binaphthalene-templated ligands of related design. These efforts have resulted in the generation of a library of bidentate binaphthyl ligands featuring equal (or diverse) substituents with the same (or different) donors on the 2,2′-positions of the binaphthalene backbone (for a review on C_2-symmetric binaphthyl derivatives see ref. 2).

In the course of the last five years, binaphthyl P,X-heterodonor ligands **2** where the P-donor is flanked by a different heteroatom which aids at the chelate coordination of the ligand to the metal, have increased in their number and variety. After the first term of this family (**2**, X = OMe, MOP) was reported by Uozumi and Hayashi (3) almost one decade ago, a range of derivatives where one of the

diphenylphosphanyl substituent of BINAP is retained while the other is substituted by a group containing a donor different from phosphorus, have been synthesized and used in enantioselective catalysis more or less successfully (for a review on axially chiral bidentate ligands see ref. 4).

Scheme 1.

Several structural modifications of BINAP have been pursued in these investigations and the family of these C_1-symmetry axially chiral inducers now comprises a range of structures where the chelate coordination of the P-donor is supported by a group which contains either oxygen (5), or nitrogen, both sp^2- (6) and sp^3- (7), or sulfur (8), or arsenic (9) as the donor.

There are also some derivatives with two not equivalent phosphorus donors. The oxidation state of the two P-centres may be different, as in the case of the extraordinarily efficient phosphane-phosphite ligand BINAPHOS **3** (10), or identical, as in the case of the heterotopic diphosphines BINAPP′ (**2**, X = PAr_2), quite recently reported by us (11), which feature two not equivalent diarylphosphanyl groups.

We were among the first groups involved in this chemistry and, as the result of our initial efforts, a few years ago we (8) reported in a short communication the synthesis of BINAPS (**2**, X = SR), a heterobidentate version of BINAP, where one alkylthio group takes up the position of one of the two diphenylphosphanyl substituents.

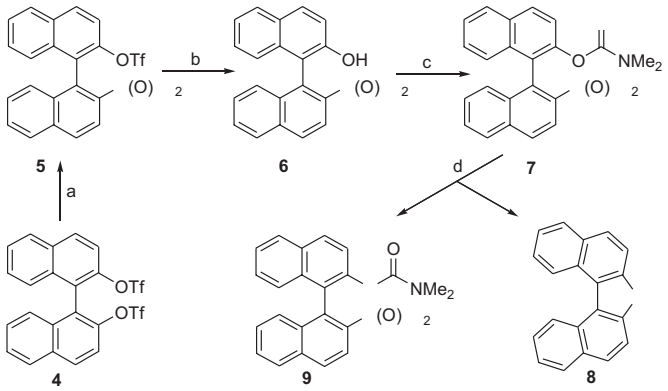
At the time of our preliminary report (1994), there was no significant precedent for the use of chiral *P,S*-heterobidentate ligands in transition-metal-catalyzed asymmetric processes. Thus, BINAPS was the first representative of this class of chiral auxiliaries which had been synthesized for this purpose and exploited with some success in asymmetric catalysis. Since then, however, the use of chiral *P,S*-heterodonor ligands, has attracted increasing interest and several examples of their use in asymmetric catalysis have appeared in the recent literature.

P,S-Chelating derivatives with quite varied chiral skeletal backbones, where the P centre is part of a phosphanyl or a phosphito group, have been exploited more or less successfully by several authors in the asymmetric allylic alkylation–amination with Pd catalysts (12) and in the asymmetric hydrogenation with Rh (13) and Ir (14) complexes. The scope of these ligands in asymmetric catalysis spans also over other enantioselective processes such as the hydrosilylation of ketones (15) and the hydroformylation of styrene (14). The efficiency of chiral *P,S*-ligands to promote the Co-catalyzed Pauson–Khand reaction with quite high stereoselectivity has been very recently demonstrated (16).

In this paper we like to report the details of the chemistry underlying the preparation and resolution of BINAPS **11** and its derivatives **14**, as well as some aspects of its coordination chemistry and some further application of this type of ligands in Rh- and Pd-catalyzed asymmetric reactions

Results and discussion

The preparation of unsymmetrically 2,2′-disubstituted binaphthyl derivatives can be dealt with either by heterocoupling of the appropriate pair of 2-substituted naphthalenes, or by asymmetrization of a suitable C_2-symmetric 2,2′-homodisubstituted binaphthalene. The second route is more practical and, with just one notable exception (6*a*), it has been consistently exploited for the synthesis of C_1-symmetric P,X-binaphthyl derivatives **2** using 1,1′-binaphthalene 2,2′-diol (BINOL) as the starting material.



Accordingly, the synthesis of *S*-alkyl (2′-diphenylphosphanyl-1,1′-binapht)-2-yl sulfides **14** has been accomplished in eight steps starting from BINOL. Dissymmetrization of the substrate is achieved in the second step of the synthetic scheme where the phosphorated substituent is introduced in the form of a diphenylphosphinyl group by Pd-catalyzed displacement of one triflate of **4** following a reported procedure (17). This reaction is remarkable in that only one single triflate undergoes susbtitution. Due to this selectivity it has been exploited by several authors in the preparation of various C_1-symmetry binaphthalene-templated P-donor ligands (5–11).

The key intermediate **9** is obtained by Newmann–Kwart thermo-rearrangement of the thiocarbamate **7** at 260–270°C. In this reaction, the pentahelicenic thiophene **8** is simultaneously formed as a byproduct to a variable extent.

It has been previously pointed out that the selectivity of this reaction is strongly dependent on the quality of the starting material, highly crystalline samples providing better returns in the rearranged carbamate (18). The same result was observed in the rearrangement of **7**. Short reaction times and fast heating of the reactor are crucial factors for obtaining satisfactory yields of **9** in this stage.

It is worth to stress that, in spite of the harsh conditions required and of the capricious nature of this reaction, if properly performed the Newmann–Kwart rearrangement proceeds with retention of the original stereochemistry (19). Actually, we have checked that no loss of enantiomeric pu-

rity occurred in this transformation when enantiopure samples of **7** were used as the starting material (vide infra).

Conversion of **9** into the phosphanyl sulfides **14** has been accomplished through two different but basically equivalent three-step routes. The first involves hydrolysis of the carbamate **9**, alkylation at sulfur, and deoxygenation of the phosphinyl group (Scheme 3, upper part). In the second route deoxygenation precedes hydrolysis (Scheme 3, middle part).

The attempt to prepare the phosphanyl thiol **11** straight from **9** by performing hydrolysis and deoxygenation in a single step by treatment with an excess of $LiAlH_4$ in boiling THF met with a modest success. The product isolated at the end of this reaction consisted of a mixture of hardly separable compounds. One of this did not contain anymore phosphorus and was identified as 1,1′-binaphthyl-2-thiol (**18**). Its formation could proceed through an intramolecular nucleophilic attack of an intermediate thiolate anion to the phosphinyl centre (as in **15**), leading to the cyclic species **16** (Scheme 3, lower part). Ring-opening of **16** should result in the transfer of the phosphinyl group to the sulfur to give the thiol phosphonite **17** which is readily cleaved to the relevant thiol by $LiAlH_4$.

Scheme 3.

The (*S*)-(–)-enantiopure phosphane thiol **11** has been prepared as illustrated above from enantiopure (*S*)-BINOL. Its enantiomeric purity has been checked by NMR on the relevant cyclopalladated complex **20** obtained by reaction with (–)-di-μ-chloro-bis[(*S*)-*N*,*N*-dimethyl(α-methylbenzyl)aminate-2-*C*,*N*]dipalladium(II) ((*S*)-**19)** (20). The presence of only one ^{31}P NMR resonance and of a single set of peaks of the two shown by the same complex prepared from racemic **11** in the ^{1}H NMR demonstrated that the ligand (*S*)-**11** was enantiopure. This proved that the Newmann–Kwart rearrangement has proceeded with complete retention of stereochemistry.

The (+)-(*R*)-enantiomer could be obtained as well by resolution of the racemic compound with the same (*S*)-α-methylbenzylaminato Pd-complex **19** (21). Treatment of racemic **11** with 1 molar equiv of **19** in the presence of triethylamine gave the mononuclear derivatives **20** which could not be separated by chromatography or fractional crystallization (Scheme 4). Upon addition of 1 further equiv of **19**, **20** was converted into the dinuclear-thiolato-bridged species **21** (22) which could be separated by chromatography allowing to isolate the less polar diastereoisomer (R_{ax}, *S*,*S*-configurations) in pure form.

Stirring a dichloromethane solution of this product with an aqueous solution of 1,2-diaminoethane converted the dipalladium complex **21** back into the mononuclear species **20** (R_{ax},*S*-configurations). The enantiopure ligand (*R*)-**11** ($[\alpha]_D^{25}$ + 31.4 (*c* = 1, $CHCl_3$)) could be liberated from this complex by reaction with diphenylphosphinoethane–LiCl in methanol in the presence of methanesulfonic acid. This last step constitutes an improvement of the previously reported procedure which required the sulfur to be previously alkylated for the ligand to be displaced from the complex (22).

Scheme 4.

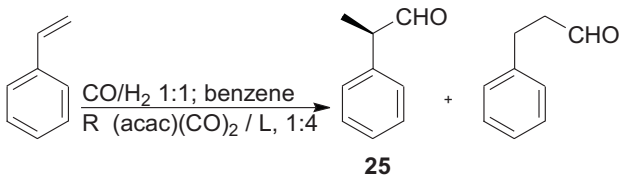
(*R*)-Configured enantiopure sulfides **14** (**14a**, R = Me or **14b**, R = *i*-Pr) have been obtained by *S*-alkylation of (*R*)-**11** obtained from the resolution. They have been as well prepared from (*R*)-BINOL **4** according to the synthetic procedure outlined in Schemes 2 and 3.

The enantomeric purity of (*R*)-**14a** was determined by ^{31}P NMR of the cationic Pd(II) complexes **22** obtained by reaction with **19** in the NMR tube (one single peak detectable at 48.9 ppm) and confirmed by HPLC on chiral phase. Chelate coordination of the ligand is confirmed, inter alia, by the upfield shift of the S-CH$_3$ peak which appears as a singlet at 2.15 δ (2.32 δ in the free ligand). Given that the sulfur becomes sterogenic upon coordination to the metal, the formation of more than one stereoisomer should be possible. These NMR data are in keeping with the presence of one single species in solution. Thus it seems reasonable to

© 2001 NRC Canada

assume that the binding of (*R*)-**14a** to the Pd-centre has proceeded stereoselectively.

Scheme 5.

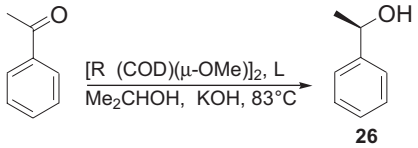


Reaction of the μ-methoxo-bridged dinuclear Rh(I) complex **23** with (*R*)-**14a** in the presence of trimethylsilyl triflate (8) produced the cationic Rh(I)-complex **24**. In this compound, the phosphorus resonance showed the expected downfield shift (36 ppm) appearing as a doublet at 23.03 ppm ($^1J_{P\text{-}Rh}$ = 145.8 Hz). The chelate coordination of the ligand was demonstrated in the ^{1}H NMR by the downfield shift of the *S*-methyl resonance (from 2.32 to 2.59 δ) and by the presence in the ^{13}C NMR of a coupling (J = 10.2 Hz) between the *S*-methyl group and the Rh. Notably, the ^{1}H NMR showed the *S*-methyl peak as a sharp singlet. From these data it seem reasonable to assume that: (*i*) the binding of the Rh to the sulfur centre has occurred with complete stereoselectivity affording only one diastereoisomer; (*ii*) at room temperature inversion of configuration of the *S*-stereocentre, if occurring, is slow on the NMR time scale; (*iii*) at room temperature the complex **24** is locked in a single conformation, where most probably the methyl takes up an equatorial position in the puckered seven-membered ring. All these facts have significant bearings in view of the use of this complex in asymmetric catalysis.

Both the preformed derivative **24** or slightly different Rh(I)-catalysts prepared in situ from enantiopure **14** (R = Me or *i*-Pr) and suitable Rh-complexes have been inspected for their catalytic activity in the asymmetric hydroformylation of styrene and in the H-transfer reduction of acetophenone.

In the hydroformylation at 40°C (Scheme 6) the in situ catalyst obtained from [Rh(acac)(CO)$_2$] and the *i*-Pr sulfide (*R*)-**14b** produced the branched aldehyde (*S*)-**25** with a very high positional selectivity (96% at 100% conversion after 14 h), but with low stereoselectivity (ee 14%). Both the ee and the regioselectivty decreased (10 and 94%, respectively) when the reaction was run in the presence of the same ligand **14b** at higher temperature (60°C for 4 h). A more consistent decrease (only 90% of branched isomer) was observed even at 40°C when the methyl derivative **14a** was used in the place of **14b**. In this case the aldehyde was practically racemic (2% ee).

We are confident that these low ees reflect the real enantioselection of the reaction and are not the consequence of a racemization suffered by the branched aldehyde after its formation, because the extent of the racemization of **25** is negligible under the conditions we have performed the hydroformylation experiments (for a review on asymmetric hydroformylation see ref. 23).



Scheme 6.

Comparable ees (20%) but lower conversions (15–25%) were observed in 1 h when the complex prepared in situ from [Rh(COD)(μ-OMe)]$_2$ and (*R*)-**14** was used as the catalyst in the hydrogen transfer reduction of acetophenone in boiling 2-propanol (Scheme 7). Longer reaction times (12–14 h) led to higher conversions, but the ee decreased (3–5%) due to the concurrent racemization suffered by the chiral carbinol **26** in the presence of base (for a comprehensive overview on H-transfer reduction see ref. 24). The *i*-Pr derivative **14b** was again more efficient of the methyl substituted counterpart **14a**, but the differences were not really impressive (20% vs. 14% ee).

In this same reaction, the Ir(I)-catalyst prepared in situ from [Ir(COD)Cl]$_2$ and (*R*)-**14b** displayed a catalytic activity lower than the Rh(I)-catalyst (6% conversion in 1 h) and provided an even lower ee of (*R*)-**26** (11%).

Scheme 7.

(a) Catalyst p epa ed f om [I (COD)Cl]$_2$.

The phosphanyl sulfide ligands **14** performed better in some Pd-catalyzed asymmetric processes. In the hydrosilylation of styrene, after 40 h at 25°C the (*R*)-*i*-Pr derivative **14b** gave the (*S*)-configured branched derivative in more than 70% conversion and 90% regioselectivity (50% ee) (Scheme 8). The corresponding methyl derivative **14a** was by far less efficient and led to a lower conversion (40% with 82% branched) and a negligible ee (4%).

The use of the methyl derivative **14a** as chiral ligand in the Pd-catalyzed allylic alkylation of 1,3-diphenyl allyl acetate with dimethylmalonate has been explored a few years ago by Kang et al. (25) who scored a remarkably high ee (91%). We have limited our screening to check whether this

range could be maintained or not by changing the alkyl substituent on the sulfur. The reaction was run at room temperature in dichloromethane solution using [Pd(η^3-C_3H_5)Cl]$_2$ as the catalytic precursor in the presence of (*R*)-**14b** as the chiral ligand at a Pd:ligand ratio of 1:2. In these conditions, the (*R*)-configured alkylated product **27** was formed in almost quantitative yield within minutes and showed 60% ee (Scheme 9).

Scheme 9.

Experimental

General procedures

Nuclear magnetic resonance spectra were recorded in $CDCl_3$ on a Varian VXR-300 spectrometer at 300 MHz for ^{1}H, 75 MHz for ^{13}C, and 121.4 for ^{31}P. Chemical shifts are reported in ppm downfield from internal Me_4Si or external H_3PO_4. Gas chromatographic analysis were performed on a 25 m × 0.25 mm capillary column coated with diethyl-*tert*-butylsilyl-β-cyclodextrin using a Hewlett Packard 5890A gas chromatograph equipped with a HP 3396 integrator. Mesitylene (20% w/w to the substrate) was employed as an internal standard. Optical rotations were measured on a PerkinElmer Model 241 polarimeter. Elemental analyses were performed on samples purified by crystallization with a PerkinElmer Analyzer 240B by Mr. A. Canu (Dipartimento di Chimica, Università di Sassari). MS Spectra were recorded with a HP 5988A spectrometer. Melting points were obtained with a Leitz Laborlux S melting point apparatus and are not corrected. Solvents were dried and distilled under nitrogen before use. Commercial reagents (Aldrich) were used as received. Racemic and enantiopure 2-(diphenylphosphinyl)-1,1′-binaphth-2′-ol (**6**) was prepared from BINOL as described in the literature (3).

(*S*)-(+)-2-(Diphenylphosphinyl)-1,1′-binaphth-2′-ol-*N*,*N*-dimethylthiocarbamate ((*S*)-7)

To a solution of (*S*)-(–)-2-(diphenylphosphinyl)-1,1′-binaphth-2′-ol **6** (13.2 g, 28.1 mmol) in DMF (170 mL), cooled at 0°C, NaH (1.6 g, 39.4 mmol) was added and the mixture was stirred at 80°C for 1 h. Then *N*,*N*-dimethylthiocarbamoyl chloride (5.0 g, 39.4 mmol) was added and stirring was continued at 90°C for 3 h. The mixture was cooled to room temperature and poured into water (1 L). The solid thus formed was washed with water, taken up with CH_2Cl_2, and dried (Na_2SO_4). The solvent was removed and the crude product was purified by flash chromatography (ethyl acetate:light petroleum, 6:1) to give 11.3 g (72%) of (*S*)-**7** as a white solid, mp 128 to 129°C (CH_2Cl_2–hexane). $[\alpha]_D^{25}$ = 149 (*c* = 1, $CHCl_3$).EI-MS (*m*/*z*): 557.2 (M^+), 453.0 (100%), 283.9 (48%), 200.9 (27%), 87.9 (53%). ^{1}H NMR δ: 2.98 (s, CH_3, 3H), 3.05 (s, CH_3, 3H), 6.80–8.00 (series of m, Ar, 22H). ^{31}P NMR δ: 27.25. Anal. calcd. for $C_{35}H_{28}NO_2PS$: C 75.39, H 5.06, N 2.51; found: C 75.22, H 5.12, N 2.60.

(*S*)-(–)-2-(Diphenylphosphinyl)-1,1′-binaphthyl-2′-thiol-*N*,*N*-dimethylcarbamate ((*S*)-9)

In a Kugelrohr apparatus (*S*)-(+)-2-(diphenylphosphinyl)-1,1′-binaphth-2′-ol-*N*,*N*-dimethylthiocarbamate **7** (1 g, 1.79 mmol) was heated to 250°C for 9 min. After cooling to room temperature, the brown solid was taken up with CH_2Cl_2, and purified by flash chromatography (light petroleum:acetone, 4:1) to give, after a forerun of the binaphthyl thiophene **8** (0.6 g (60%)) of (*S*)-**9** as a white solid, mp 118 to 129°C (CH_2Cl_2–hexane). $[\alpha]_D^{25}$ = –5.7 (*c* = 1, $CHCl_3$). EI-MS (*m*/*z*): 557.2 (100%, M^+), 284 (58%), 201 (36%). ^{1}H NMR δ: 2.73 (bs, CH_3, 6H), 6.80–8.10 (series of m, Ar, 22H). ^{31}P NMR δ: 28.99. Anal. calcd. for $C_{35}H_{28}NO_2PS$: C 75.39, H 5.06, N 2.51; found: C 75.44, H 5.15, N 2.68.

(*S*)-(–)-2-(Diphenylphosphanyl)-1,1′-binaphthyl-2′-thiol-*N*,*N*-dimethylcarbamate ((*S*)-10)

To a solution of (*S*)-(–)-2-(diphenylphosphinyl)-1,1′-binaphthyl-2′-thiol-*N*,*N*-dimethylcarbamate **9** (1.7 g, 3.04 mmol) and Et_3N (3.6 g, 35.8 mmol) in xylene (50 mL), cooled at 0°C, $HSiCl_3$ (1.21 g, 8.9 mmol) was added. After stirring at 120°C for 6 h, the mixture was cooled to room temperature and ether (50 mL) and a saturated solution of aq $NaHCO_3$ (100 mL) were added. The organic layer was separated and the aqueous phase was extracted with ether. The combined organic phase was dried (Na_2SO_4) and the solvent evaporated. The crude product was purified by flash chromatography ($CHCl_3$), to give 1.32 g (80%) of (*S*)-**10**, mp 178–180°C (CH_2Cl_2–hexane). $[\alpha]_D^{25}$ = –15 (*c* = 0.1, THF). ^{1}H NMR δ: 2.65 (bs, CH_3, 6H), 6.87–8.00 (series of m, Ar, 22H). ^{31}P NMR δ: –14.87. Anal. calcd. for $C_{35}H_{28}NOPS$: C 77.61, H 5.21, N 2.59; found: C 77.84, H 5.38,, 2.61.

(*S*)-(–)-2-(Diphenylphosphanyl)-1,1′-binaphthyl-2′-thiol ((*S*)-11)

To a suspension of $LiAlH_4$ (510 mg, 13.78 mmol) in THF (40 mL), cooled to 0°C, a solution of (*S*)-(–)-2-(diphenylphosphanyl)-1,1′-binaphthyl-2′-thiol-*N*,*N*-dimethylcarbamate **10** (867 mg, 1.6 mmol) in THF (30 mL) was added. After stirring for 5 h at room temperature, the

© 2001 NRC Canada

suspension was cooled to 0°C and water (0.5 mL), then NaOH (0.5 mL, 4 M) and again water (3 × 0.5 mL) were added. The insoluble aluminium salts were separated by centrifugation, and the solvent evaporated to give 730 mg (97%) of (*S*)-**11**, mp 198–200°C (benzene–hexane). $[\alpha]_D^{25}$ = –33.4 (*c* = 0.1, THF). ^{1}H NMR δ: 3.17 (s, SH, 1H), 6.67–7.94 (series of m, Ar, 22H). ^{31}P NMR δ: –13.43. Anal. calcd. for $C_{32}H_{23}PS$: C 81.68, H 4.93; found: C 81.49, H 4.84.

S-Alkyl derivatives of (*S*)-(–)-2-(diphenylphosphanyl)-1,1′-binaphthyl-2′-thiol ((*S*)-14)

To a stirred solution of (*S*)-(–)-2-(diphenylphosphanyl)-1,1′-binaphthyl-2′-thiol **11** (282 mg, 0.6 mmol) in DMF (15 mL) containing *t*-BuOK (84 mg, 0.75 mmol) methyl iodide (or *i*-propyl bromide) (0.62 mmol) was added. The solution turned from red to yellow. Stirring was continued at room temperature for 1 h (16 h in the case of *i*-propyl halide). The solution was diluted with water, neutralized with 3 N HCl, and extracted with CH_2Cl_2. The organic phase was washed with water, dried (Na_2SO_4), and the solvent evaporated. The crude product was purified by flash chromatography using ether–acetone (6:1) as the eluent.

Deoxygenation of (*S*)-13b — preparation of 2-(diphenylphosphanyl)-)-2′-isopropylthio-1,1′-binaphthalene ((*S*)-14b)

To a solution of (*S*)-(2-(diphenylphosphinyl)-2′-isopropylthio-1,1′-binaphthalene **13b** (660 mg, 1.25 mmol) in xylene (10 mL) containing Et_3N (10.5 mL) stirred at 0°C, $HSiCl_3$ (0.85 mL, 6.2 mmol) was added and the mixture was stirred at 120°C for 8 h. After cooling to room temperature, 10% HCl (10 mL) was added and the organic phase was separated. The aqueous layer was extracted with ether (3 × 20 mL), the combined organic phase was dried (Na_2SO_4), and the solvent was evaporated. The residue was purified by flash chromatography, using ethyl acetate:light petroleum (1:1) as the eluent. Compound (*S*)-(–)-**14b** was isolated in 95% yield.

Resolution of (*R*,*S*)-2-(diphenylphosphanyl)-1,1′-binaphthyl-2′-thiol (11)

*[(*S*)-N,N-Dimethyl(α-methylbenzyl)aminate-2-*C,N*][(*R,S*)-2-(diphenylphosphino)-1,1′-binaphthyl-2′-thiolate]palladium(II) (**20**)*

To a solution of (*R*,*S*)-2-(diphenylphosphanyl)-1,1′-binaphthyl-2′-thiol (**11**) (730 mg, 1.46 mmol) in $CHCl_3$ (10 mL) and Et_3N (1 mL), a solution of (–)-di-μ-chloro-bis[(*S*)-*N*,*N*-dimethyl(α-methylbenzyl)aminate-2-*C*,*N*]dipalladium(II) **19** (450 mg, 0.7 mmol) in $CHCl_3$ (7 mL) was added. The mixture turned to a brillant red and was stirred at room temperature 10 min. Then 2% HCl was added to neutralize and the organic phase was separated and washed with water. After drying (Na_2SO_4), the solvent was evaporated to give the (R_a,*S*)- and (S_a,*S*)-complexes **20.** Purification by flash chromatography (*n*-hexane–$CHCl_3$, 1:1) provided **20** as a 1:1 mixture of diastereoisomers in quantitative yield.

(R_a,S)-20: ^{1}H NMR δ: 1.73 (d, *J* = 6.3 Hz, C-CH_3, 3H), 2.84 (d, *J* = 3.6 Hz, N-CH_3, 3H), 2.96 (s, N-CH_3, 3H), 3.51 (m, CH, 1H), 6.13–6.21 (series of m, Ar, 2H), 6.34 (d, *J* = 8.1 H,

^{1}H NMR δ: 0.57 (d, *J* = 6.6 Hz, C-CH_3, 3H), 1.39 (d, *J* = 6.6, C-CH_3, 3H), 2.64 (d, *J* = 3.6 Hz, N-CH_3, 9H), 3.37 (d, *J* = 3.6 Hz, N-CH_3, 3H), 3.51 (m, CH, 1H), 4.85 (m, CH, 1H), 6.01–7.99 (series of m, Ar, 29H), 9.01 (m, Ar, 1H). ^{31}P NMR δ: 41.78.

A solution of (*R*$_a$,*S*,*S*)-**21** (670 mg, 0.66 mmol) in CH_2Cl_2 (5 mL) was vigorously stirred for 15 min at room temperature with a solution of ethylenediamine (110 mg, 1.8 mmol) in water (2.5 mL). The organic phase was separated, washed with water, and dried (Na_2SO_4). The solvent was evaporated and the residue was purified by flash chromatography, using CH_2Cl_2 as the eluent, to give 420 mg (88%) of (*R*$_a$,*S*)-**20**. A solution of this product (0.93 g, 1.3 mmol) in methanol (20 mL) containing LiCl (0.51 g, 12 mmol) and two drops of methansulfonic acid was stirred 10 min at room temperature. Then, bis(diphenylphosphino)ethane (0.51 g, 1.3 mmol) was added and stirring was continued for 2 h, while a precipitate was formed. The solid was filtered and dried to give 610 mg (99%) of (*R*)-(+)-**11**. $[\alpha]_D^{25}$ = +31.4 (*c* = 1, $CHCl_3$).

(+)-(1,5-Cyclooctadiene)[(*R*)-2-(diphenylphosphanyl)-2′-methylthio-1,1′-binaphthalene]rhodium(I) trifluoromethanesulfonate ((*R*)-24)

To a solution of [Rh(μ-OMe)(COD)]$_2$ (400 mg, 0.82 mmol) in CH_2Cl_2 (5 mL), $CF_3SO_3SiMe_3$ (184 mg, 0.82 mmol) was added. The mixture was stirred for 10 min at room temperature, then a solution of (*R*)-(+)-2-(diphenylphosphanyl)-2′-methylthio-1,1′-binaphthalene (422 mg, 0.82 mmol) in CH_2Cl_2 (10 mL) was added. Stirring was continued for 30 min, then the solvent was concentrated and the solid precipitated was filtered and recrystallized from CH_2Cl_2–Et_2O to give 640 mg (91%) of (*R*)-**24**, mp 208 to 209°C. $[\alpha]_D^{25}$ = +118.9 (*c* = 0.5, $CHCl_3$). ^{1}H NMR δ: 1.90 (bs, COD, 2H), 2.35 (bs, COD, 4H), 2.51 (series of m, COD, 2H), 2.54 (s, CH_3, 3H), 4.50 (bs, COD, 2H), 6.10 (d, *J* = 9.9 Hz, Ar, 1H), 6.65 (bs, COD, 2H), 6.85 (m, Ar, 3H), 7.24 (series of m, Ar, 5H), 7.55 (m, Ar, 6H), 7.69 (m, Ar, 2H), 7.95–8.10 (series of m, Ar, 5H). ^{13}C NMR δ (aliphatic carbons only): 16.20 (d, $^2J_{C\text{-}Rh}$ = 10.2 Hz), 29.4 (s), 32.8 (s). ^{31}P NMR δ: 23.03 (d, $^1J_{P\text{-}Rh}$ = 145.8 Hz). Anal. calcd. for $C_{42}H_{37}F_3O_3PS_2Rh$: C 59.76, H 4.41; found: C 58.97, H 4.54.

(+)-[(*S*)-*N*,*N*-Dimethyl(α-methylbenzyl)aminate-2-*C*,*N*][(R)-2-(diphenylphosphanyl)-)-2′-methylthio-1,1′-binaphthalene]palladium(II) ((*R*$_a$,*S*)-22)

To a solution of (–)-di-μ-chloro-bis[(*S*)-*N*,*N*-dimethyl(α-methylbenzyl)aminate-2-*C*,*N*]dipalladium(II) (226 mg, 0.4 mmol) in $CHCl_3$ (5 mL), a solution of (*R*)-(+)-2-(diphenylphosphanyl)-2′-methylthio-1,1′-binaphthalene (*R*)-**14a** (360 mg, 0.8 mmol) in $CHCl_3$ (15 mL) was added. The mixture was stirred for 30 min, then the solvent was evaporated and the residue was washed with ether. The solid obtained was filtered and crystalized from CH_2Cl_2–EtO_2 to give 520 mg (89%) of (*R*$_a$,*S*)-**22**, mp 155–158°C. $[\alpha]_D^{25}$ = +171.4 (*c* = 0.5, $CHCl_3$). ^{1}H NMR δ: 1.61 (d, *J* = 5.4 Hz, CH_3, 3H), 2.15 (s, S-CH_3, 3H), 2.68 (bs, N-CH_3, 3H), 2.95 (bs, N-CH_3, 3H), 3.96 (m, CH, 1H), 5.95 (m, Ar, 1H), 6.15 (m, Ar, 1H), 6.70–7.98 (series of m, Ar, 24H). ^{13}C NMR δ (aliphatic carbons only): 15.69, 17.28, 44.60, 49.55, 73.87. ^{31}P NMR δ: 48.91. Anal. calcd. for $C_{43}H_{39}NPSPdCl$: C 66.67, H 5.07, N 1.81; found: C 66.84, H 5.06, N 1.77.

Hydroformylation of styrene

In a typical experiment, 0.005 mmol of Rh(acac)(CO)$_2$ and 0.02 mmol of **14** (R = *i*-Pr or Me) were dissolved in benzene (6 mL) in a Schlenk tube under argon and styrene (2 mL) was added. The solution was transferred into a 100 mL autoclave and pressurized by CO–H_2 = 1:1 mixture at 60–120 bar. The reaction mixture was agitated by a magnetic stirrer in a thermostatted oil bath at the required temperature. At the end of the reaction, the mixture was cooled to room temperature, vented, and immediately analyzed. Conversions, chemo-, regio-, and enantioselectivities were determined by GC analysis: initial temperature: 60°C, heating rate: 2°C/min; final temperature: 150°C: mesitylene (20% w/w to the substrate) as an internal standard. Retention times (min): branched aldehyde: 21 ((*S*)-isomer), 21.5 ((*R*)-isomer); linear aldehyde (min): 26.7.

H-transfer reduction of acetophenone

A solution of [Rh(COD)(μ-OMe)]$_2$ (3.3 mg, 0.007 mmol) and the ligand **14b** (7 mg, 0.014 mmol) in *i*-Pr-OH (11 mL) containing KOH (0.1 mL, 0.5M in *i*-Pr-OH) was heated to reflux under nitrogen for 1 h. A solution of acetophenone (0.41 mL, 3.5 mmol) in *i*-Pr-OH (11 mL) was then added to the resulting yellow solution and heating was continued while the reaction mixture was monitored by GC. Yield, conversion, and ee were determined by GC analysis at

© 2001 NRC Canada

105°C. Retention times (min): 13.8 ((*R*)-phenylethanol), 14.8 ((*S*)-phenylethanol).

Hydrosilylation of styrene

To a solution of $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ (4.4 mg, 0.012 mmol) and the ligand (R)-**14b** (R = *i*-Pr) (20.5 mg, 0.04 mmol) in benzene (2.5 mL), then styrene (3.9 g, 37 mmol) was added. A solution of $HSiCl_3$ (6.1 g, 45 mmol) in benzene (5 mL) was added dropwise and the reaction was followed via gc after work-up: 0.5 mL of the reaction mixture were treated with MeOH (0.2 mL) and Et_3N (0.4 mL), then diethyl ether (25 mL) was added. The solvent was evaporated, then MeOH and THF (4 mL each) were added, followed by KF (58mg, 1mmol) and $KHCO_3$ (100 mg, 1 mmol), and then H_2O_2 30% (1 mL). The mixture was stirred overnight, then treated with $Na_2S_2O_5$, extracted with diethyl ether, the organic phase dried over Na_2SO_4, and the solvent evaporated. GC Analysis at 105°C showed a 50% ee for (*S*)-phenyl methyl carbinol **26** with 72% conversion and 91% branched selectivity. Retention times (min): 13.8 ((*R*)-phenylethanol), 14.8 ((*S*)-phenylethanol), 14.1 (2-phenylethanol).

Asymmetric allylic alkylation of 1,3-diphenylallyl acetate with dimethyl malonate

A solution of $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ (4.4 mg, 0.012 mmol) and the ligand (R)-**14b** (R = *i*-Pr) (20.5 mg, 0.04 mmol) in CH_2Cl_2 (1 mL) was stirred at room temperature under nitrogen. After 30 min, a solution of 1,3-diphenylprop-2-enyl acetate (100 mg, 0.4 mmol) in CH_2Cl_2 (0.5 mL) was added. A solution of dimethyl malonate (160 mg, 1.2 mmol), *N*,*O*-bis(trimethylsilyl)acetamide (BSA) (244 mg, 1.2 mmol), and potassium acetate (1.2 mg, 0.012 mmol) in CH_2Cl_2 (3.5 mL) was then added and stirring was continued at room temperature until complete conversion was attained. The reaction mixture was diluted with ether (25 mL) and washed with saturated NH_4Cl. The organic phase was dried (Na_2SO_4), concentrated under reduced pressure, and the residue purified by flash chromatography (light petroleum:ether, 3:1) to give dimethyl [(*R*)-1,3-diphenylprop-2-enyl]malonate **27** (60% ee). The enantiomeric purity was determined from the integrals of the methoxy groups of (1,3-diphenylprop-2-enyl)malonate, as split by the chiral shift reagent europium tris[3-(heptafluoropropylhydroxymethylene)-(+)camphorate].

Conclusions

The results obtained in the course of this study show that, unlike the corresponding oxygenated counterpart MOP (3), neutral *P,S*- heterobidenate ligands such as BINAPS derivatives **14** display a sharp propensity to act as chelating ligands towards transition-metal centres in low oxidation state. Unlike the case of the corresponding binaphthyl dithioethers (26), no evidence either of the formation of different stereoisomers or of a fluxional behaviour has been noticed in the NMR for the Pd(II)- and Rh(I)-complexes (**22** and **24**) prepared in this work. Thus, it seems that the presence of a strongly coordinating arm such as the phosphanyl phosphorus aids both at the chelation and at the stabilization of the configurational integrity of the new stereocentre originated upon binding of the *S*-donor.

This reaction apparently affords one single diastereoisomer which, in the case of Rh-complex **24**, is most probably the one with the *S*-methyl group in the equatorial position of a boat-like chelate ring, as we have recently determined for a related complex.[2] Assuming that the same occurs also in catalysis, a matching or a mismatching combination of the chiral elements can be envisaged.

The stereochemistry of the binding is basically determined by the chiral array of the binaphthalene backbone and, to a lower extent, by the steric demand of the alkyl group onto the sulfur atom. When these two effects are cooperative, we have almost no chance to steer the stereochemistry of the binding and can only hope that the final result is coincident with the matching case. If the two effects are contrasting, then the introduction of substituents of different steric demand may be exploited as a tool for controlling to some extent the configuration of the new stereocentre. Further work along this direction is in progress and will be published in due time.

Sulfate as a ligand in ruthenium(II) and (III) ammines

Hildo Antonio dos Santos Silva, Bruce R. McGarvey, Regina Helena de Almeida Santos, Mauro Bertotti, Vânia Mori, and Douglas Wagner Franco

Abstract: The *trans*-$[RuSO_4(NH_3)_4(L)]Cl$ complexes, (L = nicotinamide (nia), L-histidine (L-hist), 4-picoline (4-pic), 4-chloropyridine (4-Clpy), isonicotinamide (isn), pyrazine (pyz), 4-aminopyridine (4-NH_2py), 4-cyanopyridine (4-CNpy), pyridine (py), imidazole (Him), and water (H_2O)), were characterized by elemental analysis cyclic voltammetry, UV–vis, IR, and electron paramagnetic resonance spectroscopies. From the four ν (SO_4^{2-}) observed only ν_3 and ν_4 split in two bands each for the sulfate unidentate coordination. The values of Δ/ξ parameters, extracted from *g* values, allow us to write the following order of increasing π-donation ability: pyz < (py, 4-CNpy, 4-Clpy. 4-pic, isn, nia) < Him < L-hist < 4-NH_2py. The intense absorption in the 317–347 nm ($\varepsilon \sim 2.3–5.6 \times 10^3$ M^{-1} cm^{-1}) region was tentatively assigned to sulfate-to-metal charge transfer (LMCT) and the absorption in the range of 230–270 nm ($\varepsilon \sim 2 – 6 \times 10^3$ M^{-1} cm^{-1}) assigned to an internal (IL) π-π^* transition in the heterocyclic ligands. The rate for the sulfate aquation in *trans*-$[RuSO_4(NH_3)_4L]^0$ complexes was evaluated through chronopotentiometric measurements and are in the 2.6 s^{-1} (chloropyridine) to 20 s^{-1} (pyrazine) range. The SO_4^{2-} is aquated in *trans*-$[Ru^{III}SO_4(NH_3)_4(4\text{-pic})]Cl$ at the specific rate constant of $(1.4 \pm 0.4) \times 10^{-5}$ s^{-1}, which is very much slower than in *trans*-$[Ru^{II}SO_4(NH_3)_4(4\text{-pic})]$ (5.4 s^{-1}). The X-ray crystal structure data show that the Ru—Cl (2.3444(9) Å) and Ru—NH_3 (2.100(2) Å) mean distances in *trans*-$[RuCl(NH_3)_4(4\text{-pic})]Cl_2 \cdot H_2O$ are similar to the ones observed in other tetraammineruthenium(III) complexes.

Key words: ruthenium, sulfate, ammines.

Résumé : Les complexes *trans*-$[RuSO_4(NH_3)_4(L)]Cl$ (L = nicotinamide (nia), L-histidine (L-hist), 4-picoline (4-pic), 4-chloropyridine (4-Clpy), isonicotinamide (isn), pyrazine (pyz), 4-aminopyridine (4-NH_2py), 4-cyanopyridine (4-CNpy), pyridine (py), imidazole (Him) et eau (H_2O)) ont été caractérisés par analyse élémentaire, voltampérométrie cyclique, spectroscopies UV–vis, infrarouge et de résonance paramagnétique électronique. Sur la base des quatre ν (SO_4^{2-}) observées, il n'y a que ν_3 et ν_4 qui se dédoublent pour la coordination unidentate du sulfate. Les valeurs des paramètres Δ/ξ extraites des valeurs de *g* permettent de proposer l'ordre suivant pour la facilité croissante à donner des électrons π: pyz < (py, 4-CNpy, 4-Clpy, 4-pic, isn, nia) < Him < L-hist < 4-NH_2py. L'absorption intense dans la région de 317 à 347 nm (ε d'environ 2,3 à 5,6 × 10^3 M^{-1} cm^{-1}) a été attribuée provisoirement au transfert de charge sulfate à métal (« LMCT ») et l'absorption aux environs de 230–270 nm (ε d'environ 2 à 6 × 10^3 M^{-1} cm^{-1}) est attribuée à une transition π-π* interne (« IL ») dans les ligands hétérocycliques. On a évalué la vitesse d'aquation dans les complexes *trans*-$[RuSO_4(NH_3)_4L]^0$ à l'aide de mesures chronopotentiométriques et sa valeur varie de 2.6 s^{-1} (chloropyridine) à 20 s^{-1} (pyrazine). La constante de vitesse d'aquation du SO_4^{2-} dans le *trans*-$[Ru^{III}SO_4(NH_3)_4(4\text{-pic})]Cl$ est de $(1,4 \pm 0,4) \times 10^{-5}$ s^{-1}, valeur qui est beaucoup inférieure à celle observée dans le *trans*-$[Ru^{II}SO_4(NH_3)_4(4\text{-pic})]$, 5,4 s^{-1}. Les données structurales obtenues par diffraction des rayons X établissent que les distances moyennes Ru—Cl [2,3444(9) Å] et Ru—NH_2 [2,100(2) Å] dans le *trans*-$[RuCl(NH_3)_4(4\text{-pic})]Cl_2 \cdot H_2O$ sont semblables à celles observées dans d'autres complexes tétraammineruthénium(III).

Mots clés : ruthénium, sulfate, ammines.

Introduction

The oxidation of SO_2 to SO_4^{2-}, catalyzed by transition-metal complexes is an important reaction for the environmental control of sulfur dioxide (1, 2). Therefore, the knowledge of the behavior of sulfate as a ligand holds a considerable relevance. The metal center in ruthenium(II)ammines strongly bonds (3) to SO_2, HSO_3^-, and SO_3^{2-}, but has a very low affinity for SO_4^{2-}. Conversely, the Ru(III) center exhibits high affinity for SO_4^{2-}. In addition, sulfate complexes are useful intermediate (3) complexes in the preparation of *trans*-$[Ru^{II}{}_4L_1L_2(NH_3)]^n$ species ($L_1 = L_2$, $L_1 \neq L_2$).

The NH_3 ligands in tetraammineruthenium are innocent ligands and inert regarding substitution reactions (3), therefore making *trans*-$[Ru^{II}L_1L_2(NH_3)_4]^{n+}$ a good model to study the chemical properties of L_1 and L_2 as a function of the metal center oxidation state.

This paper describes the aspects of the electrochemical and spectroscopic properties of 11 ruthenium-sulfate complexes (where L_1 = nicotinamide (nia), pyrazine (pyz), L-histidine (L-hist), imidazole (Him), pyridine (py), 4-cyanopyridine (4-CNpy), 4-chloropyridine (4-Clpy), 4-picoline (4-pic), 4-aminopyridine (4-NH_2py), isonicotinamide (isn), and water (H_2O).

Since the electron paramagnetic resonance spectrum (EPR) of strong field d^5 complexes is very sensitive to the energy gap of t_{2g} orbitals, which are π-bonding in character, it was used to analyze the strength of the ligand–metal π-interaction. The aquation of the sulfate ion in *trans*-$[Ru^{II}SO_4(NH_3)_4(L_1)]^0$ and *trans*-$[Ru^{III}SO_4(NH_3)_4(4\text{-pic})]^+$ species is also reported, as well as the crystal structure analysis of *trans*-$[RuCl(NH_3)_4(4\text{-pic})]Cl_2\cdot H_2O$.

Experimental section

Reagents

All chemicals were reagent grade (Aldrich or Merck). The L = nicotinamide (nia), L-histidine (L-hist), 4-picoline (4-pic), 4-chloropyridine (4-Clpy), isonicotinamide (isn), pyrazine (pyz), 4-aminopyridine (4-NH_2py), 4-cyanopyridine (4-CNpy), pyridine (py), imidazole (Him), and water (H_2O) were used as supplied. The $RuCl_3\cdot nH_2O$ was obtained from Johnson Matthey and also used as supplied. The acetone and ethyl alcohol (Merck), used to precipitate the sulfate complexes were purified just before use according to the literature (4). Doubly distilled water was used throughout the experiment.

All preparation and measurements were carried out under argon using standard techniques (5) for the manipulation of air sensitive compounds.

Synthesis of complexes

The $[RuCl(NH_3)_5]Cl_3$ (6), *trans*-$[Ru(HSO_3)_2(NH_3)_4]$ (7), and *trans*-$[RuCl(NH_3)_4SO_2]Cl$ (8) were prepared as described in the literature.

The *trans*-$[RuSO_4(NH_3)_4L]Cl$ complexes were prepared (9, 10) as follows: 0.100 g of the *trans*-$[RuCl(SO_2)(NH_3)_4]Cl$ was dissolved in a min volume of aq 1.0×10^{-1} mol L^{-1} $NaHCO_3$ (about 3.5 mL), previously argon-degassed. A 10-fold excess of the corresponding L-ligand (except for L-hist) was added and after about 20 min, 1.0 mL of 6 mol L^{-1} HCl and 2.5 mL of 30% H_2O_2 were added to the system, resulting in a faint yellow solution. For L-hist, only twofold ligand excess was used to prevent oil formation. The sulfate complex was precipitated by the addition of acetone (70 mL) and the mixture was kept in the refrigerator for one night (12 h). The solid product was collected by filtration, washed with ethanol or acetone, and kept in vacuum in the dark The overall yield ranged from 83% (L-hist) to 90% (4-pic). All the elemental analyses were consistent with the *trans*-$[RuSO_4(NH_3)_4(L)]Cl$ formulation. According to the hexacoordinate nature of Ru(III), the SO_4^{2-} behaves as a unidentate ligand in these complexes. Elemental analyses for sulfate complexes: Anal. calcd. for L = nia: C 17.0, N 19.9, H 4.3, Ru 23.9; found: C 16.4, N 18.6, H 4.4, Ru, 24.7. Anal. calcd. for L = L-hist: C 14.6, N 19.9, H 5.0, Ru 20.6; found: C 13.8, N 19.0, H 4.9, Ru 20.6. Anal. calcd. for L = 4-pic: C 18.3, N 17.9, H 4.9, Ru 25.7; found: C 18.0, N 17.1, H 4.9, Ru 25.8. Anal. calcd. for L = 4-Clpy: C 13.5, N 16.9, H 4.0, Ru 24.4; found: C 14.0, N 14.7, H 3.1, Ru 22.1. Anal. calcd. for L = isn: C 17.0, N 19.9, H 4.3, Ru 23.9; found: C 16.5, N 19.4, H 4.5, Ru 23.2. Anal. calcd. for L = pyz: C 12.6, N 22.1, H 4.2, Ru 26.5; found: C 12.1, N 22.0, H 4.3, Ru 26.3. Anal. calcd. for L = 4-NH_2py: C 15.2, N 21.3, H 4.6, Ru 25.8; found: C 14.7, N 20.4, H 4.8, Ru 25.4. Anal. calcd. for L = 4-CNpy: C 17.8, N 20.8, H 4.0, Ru 25.2; found: C 17.1, N 20.2, H 4.2, Ru 24.8. Anal. calcd. for L = py: C 15.8, N 18.4, H 4.5, Ru 26.6; found: C 16.0, N 18.2, H 4.5, Ru 26.4. Anal. calcd. for L = Him: C 9.8, N 22.8, H 4.4, Ru 27.4; found: C 9.6, N 22.1, H 4.2, Ru 26.9.

Apparatus and methods

The elemental analyses were carried out at the Instituto de Química at Universidade de São Paulo. The atomic absorption analysis of ruthenium was performed using a Hitachi polarized Zeeman atomic absorption spectrophotometer (model Z-8100) and following Rowston and Ottaway's method (11), modified by Clarke (12).

A Bruker spectrometer model ESP 300E operating in the X-band and coupled to a standard cavity was used to obtain the EPR spectra. All experiments were carried out at liquid nitrogen temperature (77 K) and the samples were both solid powders and frozen solutions in 70% ethylene glycol – 30% water mixture.

The IR spectra were recorded in KBr pellets using a Bomem FT IR spectrometer (model MB-102) in the range of 3000–400 cm^{-1}.

The UV–vis spectra were recorded using a Hitachi U-3501 spectrophotometer. The spectra of the complexes were carried out in aqueous solutions μ = 0.1 mol L^{-1} (CF_3COOH–$NaCF_3COO$) and (pH $\cong$ 3.0) and in a 1.0 cm quartz cell.

Voltammetric measurements were carried out with a Princepton applied research polarographic voltammeter system (model 264) coupled with a IBM compatible microcomputer. The formal reduction potentials ($E_{1/2}$) were measured by cyclic voltammetry using a three electrode cell: (*i*) saturated calomel (SCE) (reference electrode); (*ii*) glassy carbon (working electrode); and (*iii*) platinum (auxiliary electrode). The measurements were carried out in CF_3COOH–$NaCF_3COO$ (pH 2.0, μ = 0.1) and at 4.0 ± 0.2°C. The double potential step chronoamperometry technique was used in

the determination of the aquation rate constant values (13). The calculation was based on work curves described in the literature (14). Current values corresponding to the reduction and oxidation processes of the material generated in the surface of the working electrode were measured at specific times after the potential steps. Chronoamperometric measurements were performed in millimolar solutions of ruthenium complexes in CF_3COOH (pH = 2.0) by using a CV-27 potentiostat (Bioanalytical Systems). In these studies, a glassy carbon electrode (r = 1.5 mm) was used as working electrode and a silver–silver chloride (saturated KCl) and a platinum wire were used as reference and auxiliary electrodes, respectively. The oxygen from solutions was removed by bubbling argon for at least 10 min.

The kinetic measurements of sulfate aquation in *trans*-$[RuSO_4(NH_3)_4(4\text{-pic})]^{2+}$ ions were followed spectrophotometrically at 326 nm (where the sulfate species absorb) and 348 nm (where the chloro species absorbs). The temperature of cells were held constant at 40 ± 0.2°C. The measurements were carried out in HCl 1.0 × 10^{-2} M and μ = 2.0 (NaCl). The plots of log $A_\infty - A_t$ vs. t were linear for at least three half-lives. The $k_SO_4^{2-}$ values calculated from log $A_\infty - A_t$ vs. t plots using the absorbance data measured at 348 and 326 nm are in very good agreement.

The X-ray crystal data were obtained on a CAD4 Enraf–Nonius diffractometer, at the Laboratório de Cristalografia do Departamento de Química e Física Molecular do Instituto de Química de São Carlos.

Crystal structure of *trans*-$[RuCl(NH_3)_4(4\text{-pic})]Cl_2 \cdot H_2O$

Crystals for X-ray diffraction were obtained from acidic solution (0.5 mol L^{-1} HCl) kept at room temperature for a week. A summary of crystal data and refinement conditions are in Table 1. The intensity data were measured at 243 K with graphite monochromatized Mo Kα radiation using the ω-2θ mode, and three standards measured every 7200 s with no significant decay. Unit cell parameters in Table 1 were obtained by least-squares refinement of 25 reflections (θ min = 12.42° and max = 18.39°). The absorption correction was performed by the PSISCAN method (15) (μMo Kα = 15.11 cm^{-1}).

All the calculations were made using WinGX (16). The heavy atom positions were obtained by the Patterson function and the structure was completed using Fourier difference. The refinement was by full-matrix least-squares (17). The hydrogen atoms of the water molecule were found in DF map and not refined, (d (H-O) = 0.900 Å) and the others were located in their ideal positions and not refined, using d (N-H) = 0.940 Å, and d (C-H) = 0.970 Å; with isotropic thermal vibration equal to 1.3 times the isotropic equivalent thermal parameter of the attached atom. All non-hydrogen atoms were refined anisotropically, and the atomic scattering factors were taken from *International Tables for X-ray Crystallography* (18). The final atomic coordinates and the equivalent isotropic temperature factors are shown in Table 2. Anisotropic thermal parameters, a complete list of distance and angles, a complete table of hydrogen bonds, and final structure factors are available as supplementary data.[2]

The Ru, Cl atoms, and the 4-pic group lie on the crystallographic mirror plane, with the CH_3 hydrogen atoms disordered with occupancy factors of 0.5. The oxygen atom of the water molecule lies also in the mirror plane. Figure 1 shows

the compound with the label scheme. Some selected distances and angles are presented in Table 3.

Results and discussion

The EPR portion of the study was undertaken to see if one could get a semiquantitative measure of the π donor ability of a ligand from the EPR g tensor of a Ru(III) ion, to which the ligand was bonded. It is well known that the g tensor of a strong field d^5 is strongly dependent upon the relative energies of the three π bonding t_2 orbitals in which the unpaired electron resides. Ligand field distortions combined with the spin-orbit interaction produce three Kramer's doublet states, which are mixtures of the three t_2 orbitals with different m_s values for the spin. EPR of powders at low temperatures and frozen solutions is capable of measuring the three principal g values associated with the Zeeman splitting of the ground-state doublet by the magnetic field. In powder spectra, the labeling of the principle axes is arbitrary, but it has been shown (19, 20) that much confusion about these systems can be eliminated by defining the z direction to be perpendicular to the orbital whose energy is furthest away from the energy of the two other orbitals. This will become clearer by considering the two energy parameters defined below:

Table 4. EPR g values for *trans*-$[RuSO_4(NH_3)_4L]^+$.

	Frozen solution		Powder	
L	$g_{\|}$	$g_{\perp}$	$g_{\|}$	$g_{\perp}$
Him	1.21	2.60	1.40	2.46
isn	≤0.8	2.59	≤0.8	2.58
nia	≤0.8	2.56	≤0.8	2.58
4-pic	≤0.8	2.61	≤0.8	2.63
4-Clpy	≤0.8	2.57	≤0.8	2.59
4-CNpy	≤0.8[b]	2.80–2.30[b]	≤0.8	2.56
4-NH_2py	?[a]	2.58[a]	1.39	2.56
L-hist	1.24	2.60	?[c]	2.58
py	≤0.8	2.59	≤0.8[d]	2.30[d]
pyz	1.56	2.03	?[d]	2.40[d]

[a] Low solubility, hence weak signal-to-noise.
[b] Multiple signals.
[c] Bad baseline in high field region.
[d] Very broad lines (~2000 gauss) and poor baseline.

$$[1] \qquad \Delta = E\,(d_{xy}) - 0.5[E\,(d_{xz}) + E\,(d_{yz})]$$

$$[2] \qquad V = E\,(d_{xz}) - E\,(d_{yz})$$

V cannot be greater than $2\Delta/3$ in magnitude because that is when we would have to change our designated z axis because $E\,(d_{xy})$ becomes too close to one of the other energy states. This z axis depends only on relative energy spacing and has nothing to do with geometry. This will become clearer below when we find that this z axis in *trans*-$[RuSO_4(NH_3)_4L]^+$ is perpendicular to the L-Ru-SO_4 axis.

The theoretical treatment (19, 20) shows that the three g values depend on three parameters: (Δ/ξ), (V/ξ), and the orbital reduction parameter k. ξ is the one electron spin-orbit parameter, which is approximately 1000 cm^{-1} in Ru(III). The appropriate method of extracting these parameters from the g values is given in two recent reviews (19, 20). There are always two possible solutions, but it is nearly always possible to choose the more likely values by either an unreasonable size for k or Δ/ξ in one of the solutions.

The unpaired electrons in *trans*-$[RuSO_4(NH_3)_4L]^+$ are in *anti*-bonding π-type MOs (molecular orbitals) which are raised in energy proportional to the ability of the ligands that π bond to the given d orbital. As can be seen from Table 4, all complexes studied have $g_x = g_y = g_{\perp}$ and $g_z = g_{\|}$ with $g_{\|} < g_{\perp}$. This means that $V = 0$ and Δ is positive and therefore two of the three t_2 orbitals are degenerate with the third being higher in energy. As will be shown below, this means that the only significant π bonding occurs with the L ligand.

We take the x axis to be the SO_4RuL axis, the y axis perpendicular to both the SO_4RuL axis and the plane of L, and the z axis perpendicular to the SO_4RuL axis and in the plane

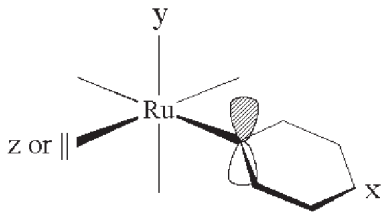
Fig. 2. Cartesian axes orientation.



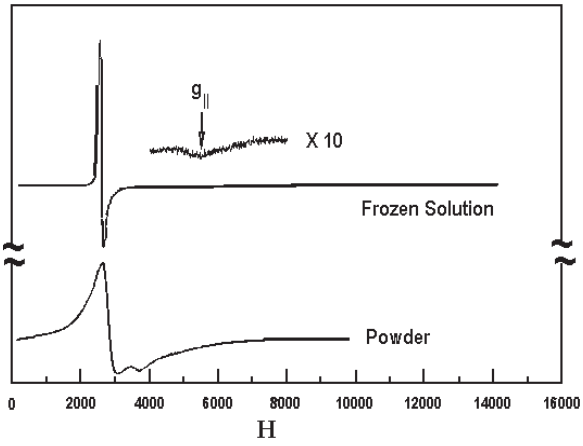


Fig. 3. EPR spectra for *trans*-[$Ru^{III}SO_4(NH_3)_4$(Him)]Cl powder and in a frozen 70% ethylene glycol – 30% H_2O solution. Both spectra were taken at 77 K.

of L. L has only one pair of π electrons to donate, so it interacts only with d_{xy} (see Fig. 2).

Unidentate SO_4^{2-} has two pairs of π electrons, so it interacts with d_{xy} and d_{xz} Using the AOM (atomic orbital method) the energies for the three MOs can be written as:

[3] $$E^*(xy) = \varepsilon_\pi(L) + 2\varepsilon_\pi(NH_3) + \varepsilon_\pi(SO_4)$$

[4] $$E^*(yz) = 2\varepsilon_\pi(NH_3) + \varepsilon_\pi(SO_4)$$

[5] $$E^*(xz) = 4\varepsilon_\pi(NH_3)$$

There are only two ways to produce two degenerate states lower in energy than the third state. One is to make $\varepsilon_\pi(L) = 0$ but this would require us to assume that $\varepsilon_\pi(NH_3) > \varepsilon_\pi(SO_4)$, This is absurd since NH_3 is the only ligand with no π electrons to donate. The second way is assume $\varepsilon_\pi(SO_4) \approx \varepsilon_\pi(NH_3) \approx 0$ and is, therefore, the only reasonable choice. Thus our results show very strongly that the NH_3 and SO_4^{2-} ligands are not π donors with Ru(III) and $\Delta = \varepsilon_\pi(L)$. Also the $g_{||}$ axis is not the SO_4RuL axis as some researchers have assumed. This problem of the location of the $g_{||}$ axis has been discussed more thoroughly in an article (21) on the EPR and NMR of $[Ru^{III}(NH_3)_5(H_2O)]^{3+}$.

We tried to run both the powder and frozen solution spectrum of all the compounds studied. Solution spectra in general give sharper spectra and are to be preferred but in some cases low solubility prevented our obtaining a satisfactory spectrum. We then used an automatic simulation program (B.R. McGarvey, personal communication) to find the best fit between calculated and experimental spectra by adjusting the two *g* values and line widths. Both the powder and frozen solution spectra for L = Him are shown in Fig. 3.

[a]See *Apparatus and methods* section.

These spectra demonstrate some of the problems encountered in this research. The broadness of the powder line makes the determination of $g_{||}$ difficult. The extra bump in the lower portion of the derivative cannot be simulated under any assumptions except as an extra peak. It remains under repeated syntheses but goes away in the solution spectrum. In most of the systems studied, the solid and solution spectra are in reasonable agreement but in this case the solid gives a $g_\perp = 2.46$, which is not what the solution spectrum gives. This is the only compound for which there are *g* values (22) reported in the literature. It was run in the same solution and agrees very well with the values we report. In general we used the solution values wherever possible. The only cases (3) where the $g_\perp$ values differ markedly between the solution and powder samples all had very large line widths (>1000 gauss) in the powder.

In some cases we list a value for $g_{||}$ of < 0.8. In these cases no $g_{||}$ dip could be observed. We have found by simulation that the intensity of such a peak is very difficult to detect for *g* values less than 0.8. In such cases, we have used both a value of 0.9 and 0.0 to estimate a range of values for the parameters.

In Table 5 are given the values of Δ/ξ and *k* that were extracted from these *g* values. We tried to include H_2O as a ligand but the spectra in solution and solid were useless for our purposes. Using the Δ/ξ parameters we find the following order of increasing π donating ability: pyz < (py, 4-CNpy, 4-Clpy. 4-pic, isn, nia) < Him < L-hist < 4-NH_2py. This series is in agreement with the previous one deduced on basis of ν_{NO} data for *trans*-$[Ru(NH_3)_4(L)NO](BF_4)_3$ complexes (23). It is unfortunate that six of these lie in the region $1 > \Delta/\xi > 1.5$ where it was impossible to determine $g_{||}$. One way to get around this would be to obtain Os(III) analogs since its value of ξ (~3000 cm^{-1}) would allow us to determine the $g_{||}$ values. We do have an estimate for the Δ/ξ parameter to be in the region of 1–1.5 from the EPR studies (21) of $[Ru^{III}(NH_3)_5(H_2O)]^{3+}$.

During our attempts to grow *trans*-$[RuSO_4(NH_3)_4$(4-pic)]Cl crystals in HCl medium, we observed the sulfate substitution by the chloride ion yielding as a product *trans*-$[RuCl(NH_3)_4$(4-pic)]$Cl_2 \cdot H_2O$.

The analysis of the crystalline structure of *trans*-$[RuCl(NH_3)_4(4\text{-pic})]Cl_2$ by X-ray diffraction shows that the distances Ru—Cl and Ru—NH_3 (media) are 2.3444(9)and 2.100(2) Å, respectively. These values are similar to the ones found for other ruthenium complexes: Ru—Cl 2.34(1) Å; Ru—NH_3 2.10(1) Å for $[RuCl(NH_3)_5]Cl_2$ (24), Ru—Cl 2.36 Å, Ru—NH_3 2.11(4) Å for *cis*-$[RuCl_2(NH_3)_4]Cl$ (25); and Ru—Cl 2.336(1) Å, Ru—NH_3 2.105(4) Å for *trans*-$[RuCl_2(NH_3)_4]Cl$ (25). The crystal packing shows two short hydrogen bonds between the Cl3 atom and the water molecule using the H1O atom from the water molecule, with *d* (O-Cl) = 3.152(3) Å; and Cl3···H1*n*1-N1 (amine group) with *d* (N-Cl) equal to 3.282(2) Å. The other chlorine atoms hydrogen bond with hydrogen atoms of the amine groups (*d* (N-Cl) 3.362(2), 3.417(2), 3.341(2), 3.421(2) Å), and the oxygen atom of the water is hydrogen bonded to the hydrogen attached to the N2 amine atom with *d* (N-O) = 2.939(3) Å. This hydrogen bond scheme is probably responsible for the high symmetry of the crystal, and shows the importance of the crystallization of water. The Ru coordination geometry in the complex is best described as a slightly distorted octahedron, as shown by the values in Table 3.

The free sulfate ion belongs to the group of high symmetry T_d. Of the four vibrational frequencies only ν_3 and ν_4 are active in the IR. The interaction of SO_4^{2-} with metal ion acts as a perturbation, which decreases the sulfate symmetry. For the *trans*-$[Ru(SO_4)(NH_3)_4(L)]^+$ complex both ν_1 and ν_2 appear with medium and strong intensity, and moreover, ν_3 and ν_4 split into two bands each (see Table 6). These IR data, consistent with the sulfate group in C_{3v} symmetry (26, 27), shows that the sulfate is coordinate to the metal ion as a unidentate ligand.

The most relevant information in the UV–vis spectra of the sulfate complexes are summarized in Table 7. All the assignments are tentative and based on data described in the literature (28). The most significant bands observed were in the 314–347 nm range ($\varepsilon \sim 2.3–5.6 \times 10^3$ M^{-1} cm^{-1}), attributed to the ligand to metal charge transfer (LMTC), and $SO_4^{2-} \rightarrow$ (Ru(III)), in the 230–270 nm range ($\varepsilon \sim 2 – 6 \times 10^3$ M^{-1} cm^{-1}), attributed to the IL π-π^* of the heterocyclic ligand. A value of ~3.0×10^3 cm^{-1} can be calculated for the shift on the LMCT band energy when L changes from pyz to Him (see Table 7).

The $E_{1/2}$ values for the Ru(III)–Ru(II) couple in *trans*-$[RuSO_4(NH_3)_4(L)]^{1+/0}$, *trans*-$[Ru(H_2O)(NH_3)_4(L)]^{3+/2}$, and the specific rate constant data for the sulfate aquation in *trans*-$[RuSO_4(NH_3)_4(L)]$ are shown in Table 8.

Figure 4 shows a typical cyclic voltammogram for the *trans*-$[RuSO_4(NH_3)_4(L)]^{1+/0}$ species. The voltammograms for all sulfate complexes exhibit a general behavior, which can be explained by the following scheme:

[6] $$trans\text{-}[Ru^{III}SO_4(NH_3)_4(L)]^+ + e^- \underset{}{\overset{\text{fast}}{\rightleftharpoons}} trans\text{-}[Ru^{II}SO_4(NH_3)_4(L)]^0$$

[7] $$trans\text{-}[Ru^{II}SO_4(NH_3)_4(L)]^0 + H_2O \xrightarrow{\text{fast}} trans\text{-}[Ru^{II}(NH_3)_4(L)H_2O]^{2+} + SO_4^{2-}$$

[8] $$trans\text{-}[Ru^{II}(NH_3)_4(L)H_2O]^{2+} \underset{}{\overset{\text{fast}}{\rightleftharpoons}} trans\text{-}[Ru^{III}(NH_3)_4(L)H_2O]^{3+} + e^-$$

which suggest an ECE mechanism (14).

At scan rates up to 0.2 V s^{-1} the electrochemical process involving the *trans*-$[Ru^{III}SO_4(NH_3)_4(L)]^{+/0}$ complex ($(E_{1/2})_1$) depicted irreversible behavior due to the fast aquation of the sulfate group from the electrogenerated Ru(II) center. The other redox couple ($(E_{1/2})_2$), which corresponds to the Ru(III)–Ru(II) couple in the aquo species, shows a reversible behavior even at room temperature and scan rate as low as 0.010 V s^{-1}. This assignment was confirmed by addition of the respective aquo compounds to the solution containing the sulfate complex.

At short-time window conditions (scan rate ≥ 0.5 V s^{-1}) and low temperatures (4.0 ± 0.2°C), a good definition for the Ru(III)–Ru(II) couple in the sulfate complexes was obtained, therefore, allowing the $(E_{1/2})_2$ calculation.

The aquation rate constants for the sulfate ion in all these Ru(II) complexes has been estimated through chronoamperometric measurements as being in the range of 2.6 (4-Clpy) to 20 (pyz).

As expected due to the sulfate σ donor ability, the Ru(III)–(II) couple in the *trans*-$[Ru^{III}SO_4(NH_3)_4(L)]^+$ ions is electroactive at more negative potentials than the corresponding aqua species. Since σ bonding is more relevant for Ru(III) than for Ru(II), this shift would reflect the stabilization of Ru(III) relative to Ru(II) due to the $SO_4^{2-} \rightarrow$ Ru(III) interaction.

As observed in Table 8, the $(\Delta E_{1/2})_{1,2}$ for the Ru(III)–Ru(II) redox couple in the sulfate and in the corresponding aqua species, for all the compounds studied, differ by about 0.14 ± 0.02 V. This difference is likely to be more credited to the SO_4^{2-} σ basicity abilities, than to the L ligand σ characteristics.

As mentioned earlier, *trans*-$[RuSO_4(NH_3)_4(4\text{-pic})]^+$ is quantitatively converted into *trans*-$[RuCl(NH_3)_4(4pic)]^+$ in the presence of excess of chloride ion. The sulfate complex has an LMCT band (λ_{max} = 326 nm, ε = 3.2 × 10^3) that is red-shifted by 22 nm when the sulfate is replaced by the chloride ion (see Fig. 5). This red-shift suggests that SO_4^{2-} is a poorer π-donor ligand than Cl^-, which is not surprising in

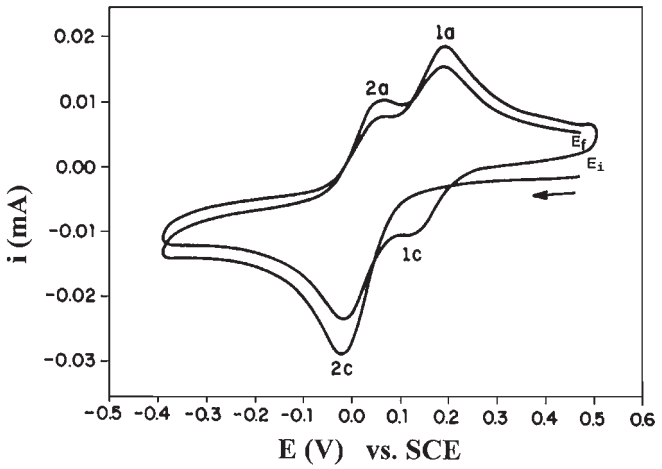
Fig. 4. Consecutive cyclic voltammograms for an aqueous solution of 1.7×10^{-3} M *trans*-$[RuSO_4(NH_3)_4(nic)]^+$, $\mu = 0.10$ (CF_3COOH–$NaCF_3COO$, pH ≅ 2.0, scan rate 0.20 V s^{-1}, E_i 0.50 V and E_f 0.5 V, $t = 4.0 \pm 0.1$°C; 1a, 1c couple corresponds to *trans*-$[Ru(NH_3)_4(H_2O)L]^{3+/2+}$, 2a, 2c couple corresponds to *trans*-$[RuSO_4(NH_3)_4(L)]^{+/0}$.



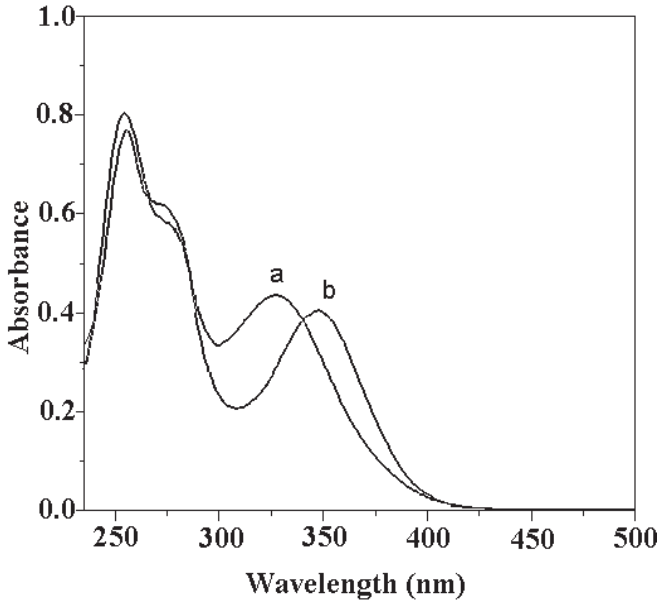


Fig. 5. Electronic spectra for conversion of aqueous 1.5×10^{-3} M *trans*-$[RuSO_4(NH_3)_4(4\text{-pic})]^+$ into *trans*-$[RuCl(NH_3)_4(4pic)]^{2+}$, $t = 40 \pm 0.2$°C, HCl 1.0×10^{-2} M, and $\mu = 2.0$ (NaCl). (*a*) Initial; (*b*) final.

[9] $$trans\text{-}[RuSO_4(NH_3)_4(L)]^+ + H_2O \xrightarrow[\text{slow}]{k\text{-}SO_4^{2-}} trans\text{-}[Ru(NH_3)_4(L)H_2O]^{3+} + SO_4^{2-}$$

[10] $$trans\text{-}[Ru(NH_3)_4(L)H_2O]^{3+} + Cl^- \underset{\text{fast}}{\rightleftharpoons} trans\text{-}[RuCl(NH_3)_4(L)]^{2+} + H_2O$$

view of the EPR results, which show that the SO_4^{2-} is ineffective as a π donor.

The aquation of the SO_4^{2-} in the *trans*-$[RuSO_4(NH_3)_4(4\text{-pic})]^+$ was studied using Cl^- as the auxiliary ligand, assuming eqs. [9] and [10] give the mechanism for the replacement reaction.

The value of $k_SO_4^{2-}$ calculated from measurements at chloride concentrations of 0.5, 1.0, and 2.0 M (40.0 ± 0.10°C) is $(1.4 \pm 0.4) \times 10^{-5}$ s^{-1}. Despite the difference in temperature, the $k_SO_4^{2-}$ data for the two 4-picoline complexes show that sulfate is aquated in Ru(III) complex ions at least 105 times slower than in *trans*-$[RuSO_4(NH_3)_4(4\text{-pic})]^0$ species.

It is also interesting to point out that, SO_4^{2-} dissociation from *trans*-$[RuSO_4(NH_3)_4(4\text{-pic})]^0$, (5.4 s^{-1}) is about the same as the Cl^- (29) aquation from $[RuCl(NH_3)_5]^+$ (6.3 s^{-1}), probably reflecting the difference in the anionic charge.

Efforts to grow a sulfate complex crystal and to perform a quantum mechanical calculation to explain the sulfate and sulfur dioxide complexes' spectra are in progress and will be reported upon in the future.

Conclusion

The EPR spectrum analysis of a strong d^5 field metal complex allows the extraction of valuable information about the nature of the π interactions with aromatic ligands. The values of Δ/ξ parameters, extracted from *g* values, allow the following order of π increasing donation ability to be written: pyz < (py, 4-CNpy, 4-Clpy, 4-pic, isn, nia) < Him < L-hist < 4-NH_2py.

The vibrational modes (ν_1, ν_2, ν_3, ν_4) of SO_4^{2-} in which ν_3 and ν_4 each split into two, were observed in the IR spectra of the sulfate complexes, confirming the unidentate coordination of SO_4^{2-}.

A variation of one order of magnitude in the aquation rates of sulfate in *trans*-$[RuSO_4(NH_3)_4(L)]^+$ was observed suggesting the following order of L *trans-effect*: pyz > 4-NHz py ~ Him ~ isn ~ L-hist > 4-pic ~ nia ~ 4-CNpy ~ py > 4.

As inferred from the sulfate aquation in *trans*-$[RuSO_4(NH_3)_4(4\text{-pic})]^+$ and *trans*-$[RuSO_4(NH_3)_4(4\text{-pic})]^0$, the increase of one unit charge in the metal center oxidation state leads to a decrease on the SO_4^{2-} rate of at least 300 times.

Comparing the ($E_{1/2}$) values for the Ru(III)–Ru(II) couple in the aqua and in the sulfate species, it was possible to observe a $(\Delta E_{1/2})_{1,2}$ value of 0.14 ± 0.02 V ($\Delta G° \sim -3.2$ kcal mol^{-1} (1 kcal = 4184 J)), which should be credited to the SO_4^{2-} presence in the coordination sphere.

Amide directed hydrocarboxylation of *N*-allylacetamide catalyzed by the aqueous Pd – tppts – Brønsted acid system (tppts = $P(C_6H_4$-*m*-$SO_3Na)_3$)[1]

Göran Verspui, Gábor Besenyei, and Roger A. Sheldon

Abstract: The Pd – tppts – HOTs (tppts = $P(C_6H_4$-*m*-$SO_3Na)_3$, HOTs = *p*-toluenesulfonic acid) catalyzed hydrocarboxylation of *N*-allylacetamide in an aqueous medium afforded 4-acetamidobutyric acid and 3-acetamido-2-methylpropanoic acid under mild conditions, with a high regioselectivity towards the linear isomer. During the hydrocarboxylation an acid catalyzed hydrolysis of the amide moieties of both the substrate and the products took place, as well as the formation of acetamide and propanal, presumably via a Pd-catalyzed allylic substitution reaction of *N*-allylacetamide. The hydrolysis reaction was suppressed by lowering the amount of Brønsted acid cocatalyst (HOTs) or by employing a weaker Brønsted acid such as propanoic acid. The allylic substitution reaction was minimized by increasing the CO pressure but unfortunately this caused a decrease in the regioselectivity. A sudden inhibition took place after ca. 70% conversion, presumably caused by one of the side products. By increasing the tppts concentration to 13.1 mmol L^{-1} (20 equiv per Pd) the inhibition was circumvented and a quantitative conversion of *N*-allylacetamide was achieved.

Key words: aqueous media, olefins, palladium, hydrocarboxylation, *N*-allylacetamide.

Résumé : Le complexe Pd – tppts – HOTs (tppts = $P(C_6H_4$-*m*-$SO_3Na)_3$, HOTs = acide *p*-toluènesulfonique) catalyse l'hydrocarboxylation du *N*-allylacétamide, en solution aqueuse et dans des conditions douces, pour conduire à la formation des acides 4-acétamidobutyrique et 3-acétyl-2-méthylpropanoïque, avec une régiosélectivité élevée en faveur de l'isomère linéaire. Au cours de la réaction d'hydrocarboxylation, il se produit une hydrolyse acidocatalysée des portions amides tant du substrat que du produit ainsi que la formation d'acétamide et de propanal, probablement par le biais d'une réaction de substitution allylique du *N*-allylacétamide, catalysée par le Pd. La réaction d'hydrolyse peut être supprimée en abaissant la quantité de l'acide de Brønsted utilisé comme cocatalyseur (HOTs) ou en utilisant un acide de Brønsted plus faible, tel que l'acide propanoïque. On peut minimiser la réaction de substitution allylique en augmentant la pression de CO; toutefois, ceci provoque une diminution de la régiosélectivité. Après environ 70% de conversion, il se produit une inhibition soudaine de la réaction qui est probablement causée par l'un des produits secondaires. En augmentant la concentration de tppts jusqu'à une valeur de 13,1 mmol L^{-1} (20 équivalents par Pd), on peut prévenir l'inhibition et obtenir une conversion quantitative du *N*-allylacétamide.

Mots clés : milieu aqueux, oléfines, palladium, hydrocarboxylation, *N*-allylacétamide.

[Traduit par la Rédaction]

Introduction

Organometallic catalysis in aqueous media currently attracts much attention due to the advantages of using the safe, environmentally friendly and economically attractive process solvent: water (1). Recently, we and others have developed a novel aqueous biphasic system for the hydrocarboxylation of olefins (2). In the presence of a Brønsted acid cocatalyst consisting of weakly coordinating anions, the Pd–tppts catalyst efficiently converts partly water-soluble olefins, such as ethene, propene, or isobutene, into their corresponding hydrocarboxylation products: propionic acid, *n*- and isobutyric acid and 3-methylbutyric acid, respectively. Unfortunately, when higher olefins were applied, e.g., 1-octene, due to phase transfer limitations, the reaction rate decreased dramatically, accompanied by the decomposition of the catalyst.

We have also shown that a hetero-atom substituted olefin, *N*-allylacetamide, was smoothly converted into 4-acetamidobutanal and 3-acetamido-2-methylpropanal by a Rh–tppts catalyzed hydroformylation reaction in water (3). In comparison with the conventional Rh–PPh_3 catalyst in an

organic solvent, e.g., toluene or THF, the reaction in water proceeded considerably faster and in a higher selectivity towards the aldehydes. The rapid hydroformylation of *N*-allylacetamide in water suggested that the Pd–tppts catalyzed hydrocarboxylation reaction of this water-soluble olefin, affording 4-acetamidobutyric acid and 3-acetamido-2-methylpropanoic acid (Scheme 1), might proceed smoothly in a neat aqueous medium as well. The de-acetylated derivative of the linear product, γ-aminobutyric acid (GABA), is a well-known neurotransmitter with interesting pharmacological properties.

The hydrocarboxylation and alkoxycarbonylation of amide-functionalized olefins have been sporadically reported. Becker et al. (4) described the $PdCl_2(PPh_3)_2$ catalyzed methoxycarbonylation of *N*-vinylphtalimide in 2-butanone. After a 21 h reaction time at 70°C and 100 bar CO pressure, in the presence of 1% catalyst, 48% of the olefin was converted into the methylester of 2-phthalimidopropanoic acid. Ojima and Zhang (5) reported the methoxycarbonylation of *N*-allylbenzamide in the presence of $PdCl_2(PPh_3)_2$ in benzene at 80°C and a CO pressure of 100 bar. The products methyl-4-benzamidobutanoate and methyl-3-methyl-3-benzamidopropanoate were obtained in 18% and 71% yield, respectively. Magnus and Slater (6) studied the $Co_2(CO)_8$ catalyzed carbonylation of *N*-allylacetamide in ethylacetate, in the presence of 1 equiv of water. Under forcing conditions (140–160°C), a mixture of 2-acetamidobutyric acid and 2-acetamido-2-methylpropanoic acid was obtained in a 3.8:1 ratio. The formation of the linear hydrocarboxylation product 4-acetamidobutyric acid was not observed. When a combination of Co and Rh carbonyl precursors was used, the selectivity increased towards 2-acetamidobutyric acid.

In this paper we report on the hydrocarboxylation of *N*-allylacetamide in water catalyzed by the Pd – tppts – Brønsted acid system. The high water-solubility of *N*-allylacetamide enabled us to study this reaction in a single phase aqueous medium, i.e., in the absence of phase transfer limitations.

Results and discussion

In the hydrocarboxylation experiments we started with a freshly prepared catalyst solution by codissolving $PdCl_2$ and 10 equiv of tppts in water. We previously observed by NMR that under these conditions a cationic $[PdCl(tppts)_3]^+$ intermediate is formed, which is rapidly reduced to $[Pd(tppts)_3]$ in the presence of CO (7). We assume that this reduction is complete before the autoclave has reached the reaction temperature (within 8 min). We have also established by multinuclear NMR experiments, that $[Pd(tppts)_3]$ is protonated by the acid cocatalyst to afford the cationic $[PdH(tppts)_3]^+$, which reacts with ethene and CO to give a relatively stable Pd–acyl intermediate (8). The rate determining hydrolysis of the Pd—acyl bond affords propanoic acid and the Pd–hydride which returns to the catalytic cycle. Since we did not observe any induction period in our hydrocarboxylation reactions, we assume that the generation of the active catalyst is complete when the reaction temperature was reached.

When the hydrocarboxylation of *N*-allylacetamide was carried out under similar reaction conditions to those which we previously applied for ethene and propene (110°C, 50 bar) (2*a*), severe catalyst decomposition took place. In contrast, at a reaction temperature below 80°C the catalyst remained

intact and converted *N*-allylacetamide into 4-acetamidobutyric acid and 3-acetamido-2-methylpropanoic acid (Table 1). During the reaction some acetic acid was formed via an acid-catalyzed hydrolysis of the amide moieties in *N*-allylacetamide and both carboxylic acid products. Decreasing the amount of HOTs to 0.50 mmol led to a slower hydrolysis (1.3% after 24 h reaction time (Table 2, Experiment 2/1)) with only a small compromise in the initial hydrocarboxylation rate. The hydrolysis reaction was also suppressed by using a much weaker Brønsted acid cocatalyst (we chose propionic acid for analysis reasons).

In addition to hydrocarboxylation and hydrolysis products we also observed the formation of acetamide, propanal, and traces of allylalcohol. The formation of these side products continues at room temperature, in the absence of CO, which necessitated immediate analysis of the samples (within 5 min) as soon as they were withdrawn from the reaction mixture. The formation of acetamide and propanal could be suppressed to some extent by increasing the CO pressure, but unfortunately, this also resulted in a considerably lower regioselectivity (1:b = 4 at 50 bar CO, Experiment 1/6). We suggest that a Pd-catalyzed allylic substitution reaction of *N*-allylacetamide takes place, affording acetamide and allylalcohol, of which the latter is isomerized to propanal (Scheme 2). In basic media, such an allylic hydrolysis reaction occurs readily at room temperature (9). The reaction apparently also proceeds under our mildly acidic conditions. Alternatively, *N*-allylacetamide might undergo an isomerization reaction to 1-acetamidopropene, followed by a fast acid-catalyzed hydrolysis, which would also afford acetamide and propanal. However, the absence of 1-acetamidopropene in the reaction mixtures and the high stability of the related enamide, *N*-methyl-*N*-vinylacetamide, under representative reaction conditions are not consistent with the latter explanation and, thus, would favour the allylic substitution mechanism.

The much higher regioselectivity towards the linear carboxylic acid in the hydrocarboxylation of *N*-allylacetamide, compared to propene (1:b = 1.3–1.6, irrespective of the conditions applied) suggests that the amide moiety has a directing effect. During the insertion of the C=C bond into the Pd—hydride bond, at which stage the regioselectivity is determined, the amide might coordinate to the palladium. We envisage two possible mechanisms that explain the higher selectivity to the linear isomer compared to the hydrocarboxylation of the nonfunctionalized olefin

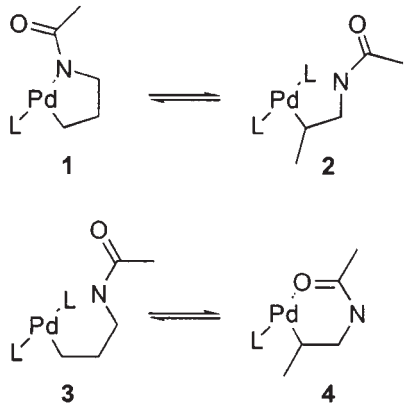
Scheme 2. Possible mechanisms for the formation of propanal and acetamide.

propene (Scheme 3): (*i*) coordination takes place via the nitrogen which favours the formation of the anti-Markovnikov addition product (1) while there is not a large difference in reactivity of both Pd–alkyl intermediates (**1** and **2**) towards CO; (*ii*) coordination takes place via the oxygen; Markovnikov addition of Pd-H to *N*-allylacetamide affords the six-membered chelate (**4**), which is more stable but less reactive towards CO compared to the anti-Markovnikov addition product (**3**).



The experiments in Tables 1 and 2 reveal that the 1:b ratio decreases at higher pressures, indicating that the amide moiety competes with CO for coordination to the palladium. The rate of hydrocarboxylation is, however, independent of the pressure, which suggests that the first mechanism is operative, since a higher reactivity at higher pressures would be expected if inhibition is due to the formation of a putative stable intermediate such as **4**.

In all experiments reported in Tables 1 and 2, conducted at 60°C, the reaction rates remained constant up to ca. 70% conversion, after which inhibition was observed. Although the catalyst decomposes at temperatures >80°C, at 60°C we did not observe a black precipitate, indicating that this sudden decrease in reaction rate is not due to decomposition of the catalyst. Neither the Brønsted acid concentration, the type of Brønsted acid, the pressure, nor temperature had a significant effect on the inhibition. Addition of extra *N*-allylacetamide at t = 24 h also gave no further reaction, which rules out a possible need for a threshold substrate concentration. Only by increasing the concentration of the ligand to 13.1 mmol L^{-1} (20 equiv per Pd) were we able to achieve full conversion. In the absence of tppts the catalyst decomposed, while when 5 equiv of phosphine were added, the reaction was already inhibited after 24% conversion. Addition of more tppts as a solid to the latter reaction mixture (Experiment 3/1) led to an almost quantitative conversion.

As previously shown by a number of groups, tppts reacts with unsaturated compounds, such as acrylic acid esters, unsaturated alcohols and aldehydes, in the presence of an acid, to afford phosphonium salts (10). However, under our reaction conditions (60°C, [tppts] = 6.5 mmol L^{-1}, [*N*-allylacetamide] = 0.13 mol L^{-1}, [HOTs] = 6.5 mmol L^{-1}) the tppts ligand remained unchanged; no formation of phosphonium salts from tppts, *N*-allylacetamide, and HOTs or phosphine oxide was observed by ^{31}P NMR spectrometry. We assume that the observed inhibition of the hydrocarboxylation is caused by the coordination of byproducts that can only be displaced by an excess of tppts.

By adding 4-acetamidobutyric acid and 3-acetamido-2-methylpropanoic acid to the reaction mixture at the beginning of the experiment, we again observed an inhibition after ca. 70% conversion, just as in the case of the previously described experiments. We conclude that not the hydrocarboxylation products, but one (or more) of the side products formed in the competing hydrolysis and allylic substitution reaction, are responsible for the lower reaction rate. Further studies should reveal the identity of the actual inhibitor.

Scheme 3. Possible intermediates in the hydrocarboxylation of *N*-allylacetamide.

Finally, we observed that during the hydrocarboxylation reaction the 1:b ratio decreases with time. Since the rate of hydrolysis of both carboxylic acid products is similar, the decrease in regioselectivity must be due to changes in the coordination sphere of the palladium. We suggest that a coordinating compound can alter the coordination sphere in such a manner that the amide substituent of allylacetamide can no longer fulfil its directing effect during the insertion of the C=C bond into the Pd—hydride bond (Scheme 2). This phenomenon is also the subject of further investigations.

Experimental details

All manipulations were done under an nitrogen atmosphere. Tppts (11), *N*-allylacetamide (12), *N*-acetyl-4-aminobutyric acid, and *N*-acetyl-3-amino-2-methylpropanoic acid (13) were prepared according to previously described procedures. All other chemicals are commercially available. HPLC analyses were done using a Phenomenex organic acid collumn using a solution of 0.01 M trifluoroacetic acid in water as eluent.

Hydrocarboxylation reactions

Tppts and $PdCl_2$ were codissolved in water and the resulting bright yellow solution was transferred into a 300 mL Hasteloy C Parr autoclave that contains an aqueous solution of the Brønsted acid, the substrate, and *n*-BuOH (standard). The autoclave was closed, the nitrogen atmosphere was replaced by CO, and the autoclave was heated. When the contents reached reaction temperature (t = 0) samples were taken at regular time intervals (t = 0. 2, 4, 6, 8, and 24 h). The samples were analyzed by HPLC immediately (within 5 min). The products were identified by LC–MS and by comparing the ^{1}H and ^{13}C NMR spectra and the retention times with those of the authentic samples.

© 2001 NRC Canada

Conclusions

In comparison with the Rh–tppts catalyzed hydroformylation, the Pd–tppts catalyzed hydrocarboxylation of *N*-allylacetamide in water proceeds considerably less facile. Nevertheless, in comparison with related Pd chemistry in organic media, the results obtained are encouraging. The hydrocarboxylation of *N*-allylacetamide proceeds with a high regioselectivity towards 4-acetamidobutyric acid under mild reaction conditions, but the reaction is complicated by the hydrolysis of amide moieties in the substrate and the products, a competing allylic substitution reaction and a sudden inhibition, caused by side products. Amide hydrolysis was suppressed by optimization of the concentration of the Brønsted acid cocatalyst and the formation of acetamide and propanal was minimized by increasing the CO pressure. Unfortunately a higher CO pressure led to a lower regioselectivity. The inhibition could be circumvented by increasing the concentration of the ligand.

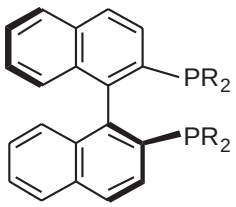
Binap and MeO-Biphep complexes of Ru(II). Dicationic ligands as 6e donors. Unexpected cyclometallation in connection with P—C bond breaking

Carolien J. den Reijer, Pascal Dotta, Paul S. Pregosin, and Alberto Albinati

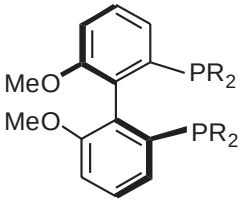
Abstract: A series of cationic and dicationic Ru-arene complexes with Binap (**1a**) and MeO-Biphep (**1b**) have been prepared. ^{13}C NMR studies are shown to be useful in connection with recognising the 6e-bonding mode of **1a** and **1b** in the dications [Ru(**1a** or **1b)**(η^6-arene)]$(SbF_6)_2$ (**8**, **9**). Reaction of **8**, **9** with: (*a*) $(Bu_4N)(Ph_3SiF_2)$ leads to a cyclometallated product which arises via P—C bond breaking and P—F bond making; (*b*) methanol provides a straightforward synthesis of the corresponding hydrides. ^{13}C NMR *p*-cymene chemical shifts are reported.

Key words: P—C bond cleavage, 6e donors, cyclometallation, hydrides, ^{13}C NMR.



Résumé : On a préparé une série de complexes cationiques et dicationiques Ru-arène avec du Binap (**1a**) et MeO-Biphep (**1b**). Des études de RMN du ^{13}C se sont avérées utiles pour reconnaître le mode de liaison à 6-e de **1a** et **1b** dans les dications [Ru(**1a** ou **1b**)(η^6-arène)]$(SbF_6)_2$ (**8**, **9**). Les réactions des composés **8** et **9** avec : (*a*) du $(Bu_4N)(Ph_3SiF_2)$ conduisent à la formation des produits cyclométallés qui découlent de la scission d'une liaison P—C et de la formation d'une liaison P—F; (*b*) du méthanol conduisent à une synthèse directe des hydrures correspondants. On rapporte les déplacements chimiques du *p*-cymène en RMN du ^{13}C.

Mots clés : scission du liaison P—C, donneurs à 6-e, cyclométallation, hydrures, RMN du ^{13}C.



[Traduit par la Rédaction]

Introduction

The atropisomeric chelating bidentate phosphines Binap (**1a**) and MeO-Biphep (**1b**) have enjoyed substantial success in enantioselective homogenous catalysis (1, 2).

1a, R = Ph

1b, R = Ph, **1c** R = *i*-Pr

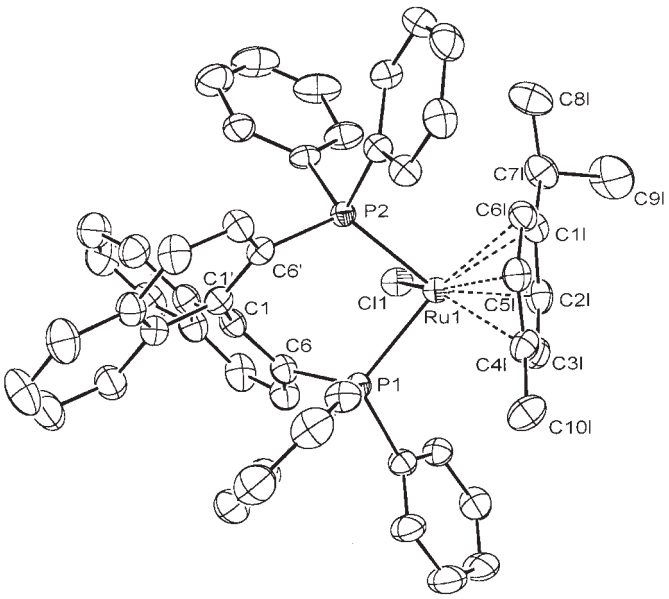
5. We report here preparative and spectroscopic studies on new dicationic η^6-arene Ru-complexes which extend our understanding of this 6e-bonding mode.



Results and discussion

The new Ru-complexes were prepared as described in Scheme 1. This chemistry starts from the cationic chloro-Ru-derivatives [RuCl(**1a** or **1b**)(η^6-arene)]Cl (**6** or **7**, respectively), which can be prepared from [$RuCl_2(\eta^6$-arene)]$_2$ (7) and the appropriate bidentate phosphine (see experimental part).

X-ray structure of 6a·1.5CH_2Cl_2

The solid-state structure of the Binap *p*-cymene analogue (**6a**) has been determined via X-ray diffraction and a view of the cation is shown in Fig. 1. The immediate coordination sphere consists of the two P-donors, the chloride, and the six carbon atoms of the η^6 p-cymene arene ligand. The six Ru-C(arene) separations fall in the range 2.258(5)–2.315(5) Å

Fig. 1. An ORTEP view of the structure of the cation of **6a**, (ellipsoids at 50% probability). The η^6-complexation is indicated by dotted lines.

and are all fairly routine (8–11). The two Ru—P distances (Ru—P(1), 2.345(1) Å and Ru—P(2), 2.380(1) Å) are somewhat long but not unusual (12). Both the Ru—Cl bond

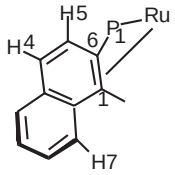
length (2.394(1) Å) and the P(1)-Ru-P(2) angle (89.51(4)°) are normal.

A list of selected bond lengths and bond angles is given in Table 1. The structure of the cation $[RuCl(Binap)(benzene)]^+$ has been reported previously (13). Taken together, the X-ray data show a classical "piano stool" structure with relatively little distortion.



Recognition of 8 and 9

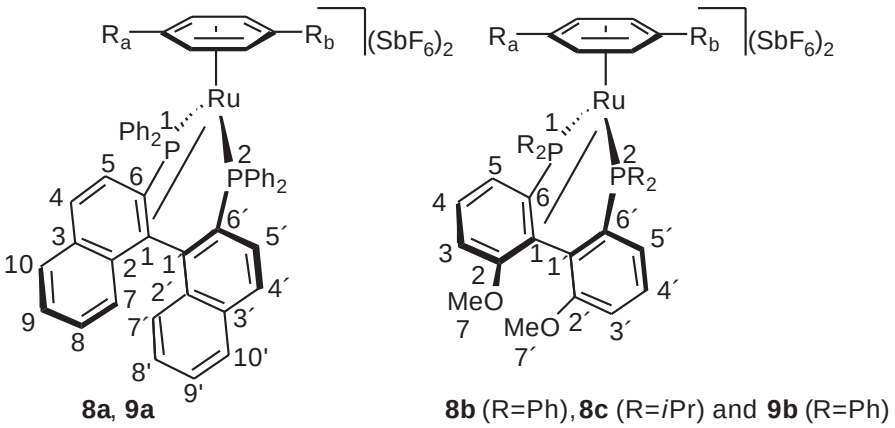
Treatment of **6**, **7** with 2 equiv of $AgSbF_6$ for prolonged periods affords the compounds **8** and **9**, as *p*-cymene and benzene derivatives, respectively, in which the chelating ligands act as 6e-donors.

8c (using ligand **1c**)

The Binap derivatives **8a** and **9a** as well the MeO-Biphep complex (**8c**) containing *i*-Pr groups on the MeO-Biphep phosphorus donors, could be isolated and afforded satisfactory analytical data. MeO-Biphep analogues **8b** and **9b**, exist in solution together with an aquo-complex. This latter assignment is based on the observation that addition of water to a solution of **9b** and the presumed aquo-species, results in a marked increase in the concentration of this second species, at the expense of **9b**. Proof of the coordination mode for **8** and **9** stems from the low frequency ^{13}C NMR coordination chemical shifts for C1 and C6 of the complexed biaryl double bond (see Table 2 and Fig. 2). The chemical shifts of C1 and C6 were determined via their three bond long-range couplings to H4, H5, and H7.

(Fragment of **9a** showing the protons used for the correlation)

The chemical shifts of the corresponding C1′ and C6′-carbons (in the second biaryl ring) fall at ca. 135–140 ppm so that the $\Delta\delta$ values for the two coordinated carbons (C1 and C6) are ca. 30–40 ppm for C1 and ca. 60–70 ppm for C6. It is tempting to use the observed relatively low-frequency ^{31}P NMR resonance of P1 (see Table 2) as an indication of this bonding mode. This chemical shift empiricism (3, 4, 6), also noted early on by James and co-workers (14), but not explored, is not always a reliable indicator since cyclometallated Ru-complexes can show similar ^{31}P NMR chemical shifts (15, 16).



It is interesting that the observed ^{31}P frequencies for complexed **1a** vs. **1b**, do not depend markedly on the structure of the bidentate phosphine, however the ^{13}C chemical shifts values for C1 and C6 in these dications do vary as a function of the chelate (see Table 2).

P—C bond cleavage

We (6) previously reported that P—C bond splitting together with carbon protonation resulted from reaction of $Ru(OAc)_2$(**1a** or **1b**) with wet HBF_4 under relatively mild conditions (see eq. [1]). The product contains a complexed

diphenyl-fluoro-phosphine ligand with the BF_4^- anion functioning as the source of the fluoride. Complex **5** is an intermediate in this reaction. We know of only one related reaction (17) in which a P—C bond is so easily cleaved to form a fluorophosphine. It seemed of interest to attempt the preparation of a Ru-F species via an independent route, as the fluoride is transferred initially to the metal and only later to the P-atom. To this end we allowed $(Bu_4N)(Ph_3SiF_2)$ (18), a soluble fluoride source, to react with the Binap dications **8a** and **9a**. As shown in Scheme 1 the products are the cyclometallated fluorophosphine derivatives **10** and **11**. Obviously the complexed P-donor is sufficiently electrophilic to accept the fluoride anion with resulting cleavage of the P—C bond. In **10** and **11** the Ru(II) coordinates the (formally) negative charged carbon, whereas in the chemistry of eq. [1], where wet HBF_4 was used, one observes protonation. Compounds **10** and **11** were identified by ^{1}H, ^{13}C, ^{19}F and ^{31}P NMR spectroscopy. The $PFPh_2$ ligand is readily identified via its large $^1J(^{31}P, ^{19}F)$ value (936 Hz (**10**), 951 Hz (**11**)) and its high frequency ^{31}P NMR chemical shift (181.7 ppm (**10**), 180.4 ppm (**11**)) (19). The cyclometallated carbons are observed at 147.0 and 145.6 ppm for **10** and **11**, respectively. Figure 3 shows the ^{19}F and ^{31}P NMR spectra of the cation of compound **11**.

Fig. 2. ^{13}C-^{1}H long-range correlation for **9a** showing cross-peaks for the two olefinic carbons with the three Binap backbone protons.

Hydride synthesis from 8

The dications **8a**, **b** react smoothly on stirring in MeOH as solvent at room temperature to afford the hydride complexes [RuH(*p*-cymene)(**1a** or **1b**)]SbF_6 (**12a**, **b**). No base is necessary and the yields are good. This straightforward ap-

proach to hydride synthesis provides a useful alternative to synthetic routes involving molecular hydrogen or boron or aluminium hydrides. The ^1H NMR spectra for **12a**, **b** show the hydride resonances as a doublet of doublets at δ = –9.79 and δ = –10.10 for **12a** and **12b**, respectively. The *p*-cymene ^{13}C NMR resonances are shifted to lower frequency and fall in the region δ = 91.5–116.8, with the four CH-carbons of the *p*-cymene appearing in the narrow range 91.5–98.3 ppm. Interestingly, the MeO-Biphep complex (**8b**) reacts to afford product ca. 10 times faster than the Binap analogue (**8a**). We have made similar qualitative observations with respect to relative kinetics in other reactions, as well, i.e., MeO-Biphep is generally faster than Binap in our Ru-chemistry. There are relatively few well-characterised Ru-H complexes of **1a** and **1b** (20, 21).

^{13}C NMR data for the *p*-cymene ligand

The carbon-13 chemical shifts for the complexed arenes in e.g., **6**–**12** are readily determined in that they fall in a convenient region (ca. 70–110 ppm). Having noticed that this NMR parameter varies somewhat for the η^2-olefin of **8**, **9** we

Scheme 2. ^{13}CH-chemical shifts (ppm) for selected arene complexes. The averages of the chemical shifts, i.e., the sum divided by four, are written in bold (ppm).

considered it interesting to compare the ^{13}C NMR η^6 *p*-cymene characteristics in several Binap and MeO-Biphep compounds. To this end we prepared the dicationic nitrile and isonitrile complexes (**13**–**15** and **16**, **17**, respectively), and show examples in Scheme 2 (and the remaining data in the experimental part). It is interesting that the four CH=*p*-cymene ^{13}C NMR signals are well separated suggesting asymmetric bonding for this arene. It is equally interesting that these ^{13}C NMR chemical shifts in **6** and **14** do not vary very much, either as a function of charge on the complex or as a function of the chelate ligand. Moreover, the averages of the four δ CH= values (98.5 for **6a**, 98.3 for **6b**, 99.8 for **14a**, and 99.7 ppm for **14b**) are quite close. Thus, it appears that the total charge on the molecule, i.e., monocationic for the chloride complexes and dicationic for the acrylonitrile complexes, is of secondary importance in this connection. The nature of the donor is the more important factor as shown by the averages for **16a** (104.1) and **16b** (103.8), i.e., ca. 4–5 ppm larger than the previous averages. This suggests that the isocyanoacetate ligand is a better π-acceptor ligand than either the cloride or the acrylonitrile. In Table 3 we show averages for the four cymene CH= signals for a larger data set. The olefin and isonitrile π-acceptor ligands result in higher frequency positions whereas the hydride, due to its stronger σ-donor character, affords a lower frequency result. For the Binap series, we have carried out a similar analysis using all six carbons of the *p*-cymene. Inclusion of the two fully substituted carbon chemical shifts moves the averaged results to higher frequency by ca. 5–6 ppm, but does not change any of the conclusions.

Conclusions

The biaryl phosphine ligands **1a** and **1b** readily complex an adjacent biaryl double bond. This co-ordination introduces some strain in the molecule so that reaction with a fluoride source readily leads to P—C bond cleavage and the formation of a cyclometallated complex. The complexes **8a** and **8b** react easily with MeOH to give the respective hydride complexes **12a** and **12b** in good yield. Interestingly, the *p*-cymene ^{13}C NMR chemical shifts do not depend on the formal positive charge on the cation, but rather the nature of the donor ligands.[2]

Experimental section

Crystallography

Air stable, orange crystals of compound **6a** were obtained via slow diffusion of diethyl ether into a solution of **6a** in dichloromethane.

For the data collection, a prismatic single crystal was mounted on a Bruker SMART CCD diffractometer. The space group was determined from the systematic absences, while the cell constants were refined, at the end of the data collection with the data reduction software SAINT (22). The collected intensities were corrected for Lorentz and polarization factors (22) and empirically for absorption using the SADABS program (23). Selected crystallographic and other relevant data collection and refinement parameters are listed in Table 4.

The standard deviations on intensities were calculated in term of statistics alone, while those on F^2_o were calculated as shown in Table 4. The structure was solved by direct and Fourier methods and refined by full-matrix least-squares (24), minimizing the function $(\Sigma w(F_o^2 - (1/k)F_c^2)^2)$ and using anisotropic displacement parameters for all atoms. Toward the end of the refinement a disordered solvent (CH_2Cl_2) molecule was located in a difference Fourier map and successfully refined, allowing two orientations for the Cl atoms (with occupancy factors of 0.75 and 0.25, respectively). After refinement, a second CH_2Cl_2 molecule was located in the difference Fourier map but refined satisfactorily (with isotropic temperature factors) only with partial occupancy of the site (0.5). No extinction correction was deemed necessary. Upon convergence (max parameter shift $\Delta p/\sigma < 0.3$) the final difference Fourier map showed no significant peaks.

The contribution of the hydrogen atoms, in their calculated position (C—H = 0.95 Å, B(H) = 1.5 × $B(C_{bonded})$ Å^2), was included in the refinement using a riding model; the hydrogen atoms bonded to the disordered solvent molecules were not included.

All calculations were carried out by using the PC version of the SHELX-97 programs (22). The scattering factors used, corrected for the real and imaginary parts of the anomalous dispersion, were taken from the literature (25).

General

All manipulations were carried out under argon atmosphere. Methanol was distilled from magnesium. Diethyl ether was distilled from sodium-benzophenone ketyl. Dichloromethane and pentane were distilled from CaH_2. Hexane and toluene were distilled from sodium. $[Ru(benzene)Cl_2]_2$ (**7a**) (7), [Ru(Binap)(benzene)Cl]Cl (13) as well as tetrabutylammonium difluorotriphenylsilicate ($(Bu_4N)(F_2SiPh_3)$) (18) were prepared according to the literature. $[Ru(p\text{-cymene})Cl_2]_2$ is commercially available at Aldrich, and was purified before use. Rac-2,2′-bis(diphenylphosphino)-1,1′-binaphthyl (Binap) was purchased from Strem Chemicals. *S*-(6,6′-Dimethoxybiphenyl-2,2′-diyl)bis(diphenylphosphine) (*S*-MeO-Biphep) and *R*-*i*-Pr-MeO-Biphep were provided by

F. Hoffmann-La Roche AG. All the other chemicals were commercial products used as received. NMR Spectra were measured on a Bruker AVANCE 400 MHz spectrometer. Chemical shifts are given in ppm, coupling constants in Hz.

Synthesis of [RuCl(Binap)(*p*-cymene)]Cl (6a)

$[Ru(p\text{-cymene})Cl_2]_2$ (60.9 mg, 0.10 mmol) and Binap (130.0 mg, 0.21 mmol) were dissolved in 3 mL methanol and then stirred for 15 h at room temperature. The solution was then heated for 8 h at 40°C. The reaction mixture was filtered through Celite and then the solvent was evaporated in vacuo. The resulting orange powder was washed with 2 × 3 mL Et_2O and 1 × 2 mL pentane and then dried in vacuo. Color: orange. Yield: 62.2 mg (67%). FAB-MS calcd. M^+: 892.6; found: M^+-*p*-cymene: 758.5; M^+-Cl: 857.6. ^{1}H NMR (298 K, CD_2Cl_2): 1.03 (d, $^3J_{HH}$ = 6.8, CH(CH_3)$_2$), 1.37 (d, $^3J_{HH}$ = 6.8, CH(CH_3)$_2$), 1.99 (s, CH_3), 3.08 (m, CH(CH$_3$)$_2$), 4.41 (d, $^3J_{HH}$ = 3.7, cyH), 4.42 (d, $^3J_{HH}$ = 6.8, cyH), 6.00 (d, $^3J_{HH}$ = 6.8, cyH), 6.50 (d, $^3J_{HH}$ = 3.7, cyH). ^{13}C NMR (298 K, CD_2Cl_2): 19.4 (*C*H$_3$), 21.8 (CH(*C*H$_3$)$_2$), 23.2 (CH(*C*H$_3$)$_2$), 30.6 (*C*H(CH$_3$)$_2$), 86.8 (cy), 97.1 (cy), 103.9 (cy), 106.0 (cy), 110.8 (cy), 113.6 (cy). ^{31}P NMR (298 K, CD_2Cl_2): 41.5 (d, $^2J_{PP}$ = 63), 26.7 (d, $^2J_{PP}$ = 63). Anal. calcd. for $C_{54}H_{46}P_2Cl_2Ru\cdot 0.5CH_2Cl_2$ (928.1): C 67.39, H 4.88; found: C 66.67, H 5.67.

Synthesis of [RuCl(*S*-MeO-Biphep)(*p*-cymene)]Cl (6b)

$[Ru(p\text{-cymene})Cl_2]_2$ (151.7 mg, 0.25. mmol) and *S*-MeO-Biphep (292.3 mg, 0.50. mmol) were dissolved in 3 mL methanol and then stirred for 3 h at room temperature. Then the orange solution was filtered through Celite. The solvent was evaporated in vacuo to afford the orange product. Color: orange. Yield: 410.1 mg (93%). Anal. calcd. for $C_{48}H_{42}O_2P_2Cl_2Ru\cdot 3MeOH$ (884.78): C 62.42, H 5.49; found: C 62.44, H 5.51. FAB-MS calcd. M^+: 849.4; found: M^+-Cl-*p*-cymene: 679.7. ^{1}H NMR (298 K, CD_2Cl_2): 1.04 (d, $^3J_{HH}$ = 6.9, CH(CH_3)$_2$), 1.39 (d, $^3J_{HH}$ = 6.9, CH(CH_3)$_2$), 1.99 (s, CH_3), 3.09 (m, CH(CH$_3$)$_2$), 3.38 (s, OCH_3), 3.45 (s, OCH_3), 4.38 (d, $^3J_{HH}$ = 7.0, cyH), 4.52 (br d, $^3J_{HH}$ = 6.2, cyH), 5.97 (d, $^3J_{HH}$ = 7.0, cyH), 6.52 (d, $^3J_{HH}$ = 6.2, cyH). ^{13}C NMR (298 K, CD_2Cl_2): 19.2 (*C*H$_3$), 21.6 (CH(*C*H$_3$)$_2$), 23.0 (CH(*C*H$_3$)$_2$), 30.4 (*C*H(CH$_3$)$_2$), 55.3 (O*C*H$_3$), 55.5 (O*C*H$_3$), 86.0 (cy), 97.5 (cy), 103.9 (cy), 105.2 (cy). ^{31}P NMR (298 K, CD_2Cl_2): 41.5 (d, $^2J_{PP}$ = 63), 28.3 (d, $^2J_{PP}$ = 63).

Synthesis of [RuCl(*R*-*i*-Pr-MeO-Biphep)(*p*-cymene)]Cl (6c)

$[Ru(p\text{-cymene})Cl_2]_2$ (65.3 mg, 0.11 mmol) and R-*i*-Pr-MeO-Biphep (95.5 mg, 0.22 mmol) were dissolved in 2 mL methanol and then stirred for 3 h at room temperature. Then the orange solution was filtered through Celite and the solvent was evaporated in vacuo to afford an orange powder. The product was then washed with 3 × 1 mL Et_2O and dried in vacuo. Color: orange. Yield: 130.2 mg (79%). HR-MALDI-MS calcd. M^+: 717.3; found: M^+-*i*-Pr: 701.2; M^+-*p*-cymene: 583.1; M^+-*p*-cymene-Cl: 545.2. ^{1}H NMR (298 K, CD_2Cl_2) : 0.78–1.85 (overlapping *i*-Pr protons and *p*-cymene Me-protons), 2.71 (m, CH(CH$_3$)$_2$), 3.75 (s, OCH$_3$), 3.78 (s, OCH$_3$), 5.60 (br d, cyH), 6.06 (d, $^3J_{HH}$ = 5.8, cyH), 6.68 (br d, cyH), 7.00, 7.16, 7.40, 7.62, 7.72 (overlapping cyH and MeO-biphep backbone protons). ^{31}P1H NMR (298 K, CD_2Cl_2): 41.6 (d, $^2J_{PP}$ = 46), 34.4 (d, $^2J_{PP}$ = 46). Anal. calcd. for $C_{36}H_{54}O_2P_2Cl_2Ru\cdot 2MeOH$ (752.74): C 55.88, H 7.59; found: C 55.88, H 7.56.

Synthesis of [RuCl(*S*-MeO-Biphep)(benzene)]Cl (7b)

$[Ru(benzene)Cl_2]_2$ (122.0 mg, 0.24 mmol) and *S*-MeO-Biphep (286.8 mg, 0.49 mmol) were dissolved in 6 mL of a 2:1 mixture of methanol and toluene. Stirring at room temperature for 3 h was followed by the filtration through Celite. The solvents were evaporated in vacuo and then the yellow powder was washed with 3 × 1 mL Et_2O and dried in vacuo. Color: yellow. Yield: 367.8 mg (90%). FAB-MS calcd. M^+: 832.8; found M^+-benzene: 718.9; M^+ -benzene -Cl: 684.0. ^{1}H NMR (298 K, CD_2Cl_2): 3.46 (s, OCH_3), 3.57 (s, OCH_3), 5.76 (s, C_6H_6), 6.50, 6.82, 6.76, 6.96, 7.17, 7.24 (all 6 MeO-Biphep backbone). ^{13}C NMR (298 K, CD_2Cl_2): 55.5 (O*C*H$_3$), 55.6 (O*C*H$_3$), 97.4 (*C*$_6$H$_6$), 113.0, 113.2, 125.1, 126.0, 126.6, 127.2, 127.5, 129.1, 129.6, 130.9, 158.0, 159.0 (all 12 MeO-Biphep backbone). ^{31}P NMR (298 K, CD_2Cl_2): 39.1 (d, $^2J_{PP}$ = 64), 32.3 (d, $^2J_{PP}$ = 64). Anal. calcd. for $C_{44}H_{38}O_2P_2Cl_2Ru$ (832.75): C 63.47, H 4.60; found: C 63.04, H 5.22.

Synthesis of 8a–9b

The reactions are quantitative, however due to the small scales, losses occurred in the work-up.

Synthesis of [Ru(Binap)(*p*-cymene)][SbF_6]$_2$ (8a)

[RuCl(Binap)(*p*-cymene)]Cl (**6a**) (185.0 mg, 0.20 mmol) and $AgSbF_6$ (137.0 mg, 0.40 mmol) were dissolved in 6 mL dichloromethane. The resulting suspension was stirred for 24 h at 40°C. Then the precipitate of AgCl was filtered and the solvent was removed in vacuo to afford the product. Color: red. Yield: 216.2 mg (87%). ^{1}H NMR (253 K, CD_2Cl_2): 0.00 (d, CH(CH_3)$_2$), 0.02 (m, CH(CH$_3$)$_2$), 0.71 (d, CH(CH_3)$_2$), 1.78 (s, CH_3), 4.55 (d, cyH), 5.59 (d, cyH), 5.79 (d, cyH), 6.27 (d, cyH), 5.56 (H7′), 7.22 (H10′), 7.34 (H5′), 7.44 (H9′), 7.54 (H7′), 7.57 (H4′), 7.59 (H8′), 7.60 (H8), 7.77 (H9), 8.31 (H10), 8.56 (H5), 8.66 (H4). ^{13}C NMR (253 K, CD_2Cl_2): 17.4 (*C*H$_3$), 18.3 (CH(*C*H$_3$)$_2$), 24.1 (CH(*C*H$_3$)$_2$), 29.2 (*C*H(CH$_3$)$_2$), 67.5 (C6), 92.0 (cy), 98.0 (C1), 104.0 (cy), 104.0 (cy), 107.6 (cy), 114.0 (cy), 124.7 (C5′), 125.1 (C7′), 125.4 (C5), 126.0 (cy), 128.6 (C7), 128.8 (C8′), 129.7 (C9′), 129.8 (C10′), 130.2 (C3), 131.6 (C10), 131.7 (C6′), 133.0 (C8), 133.2 (C2′), 133.8 (C4′), 134.0 (C9), 135.5 (C3′), 138.3 (C4), 142.0 (C2), 145.3 (C1′). ^{31}P NMR (253 K, CD_2Cl_2): 68.7 (d, $^2J_{PP}$ = 44), 3.3 (d, $^2J_{PP}$ = 44). Anal. calcd. for $C_{54}H_{46}F_{12}P_2RuSb_2\cdot H_2O$ (1242.6): C 48.13, H 3.59; found: C 48.10, H 3.85. FAB-MS calcd. M^{2+}: 857.9; found: M^{2+} + SbF_6: 1092.6; M^{2+} + SbF_6-*p*-cymene: 958.6; M^{2+}: 857.9; M^{2+}-*p*-cymene 721.2.

Synthesis of [Ru(*S*-MeO-Biphep)(*p*-cymene)][SbF_6]$_2$ (8b)

[RuCl(*S*-MeO-Biphep)(p-cymene)]Cl (**6b**) (58.6 mg, 0.07 mmol) and $AgSbF_6$ (41.6 mg, 0.12 mmol) were dissolved in 1 mL dichloromethane and the resulting suspension was refluxed overnight. Then the precipitate of AgCl was filtered through Celite and the solvent was removed in vacuo to afford the product. Color: red. Yield: 68.2 mg (76%). FAB-MS calcd. M^{2+}: 818.0; found: M^{2+}: 818.9; M^{2+}-*p*-cymene: 683.0. ^{1}H NMR (243 K, CD_2Cl_2): 0.47 (d, CH(CH_3)$_2$), 1.01 (d, CH(CH_3)$_2$), 1.77 (m, CH(CH$_3$)$_2$), 2.16 (s, CH_3), 3.58 (s, OCH_3), 3.92 (s, OCH_3), 4.29, (d, cyH),

Reaction of [Ru(Binap)(*p*-cymene)][SbF_6]$_2$ (8a) with (Bu_4N)(F_2SiPh_3) (10)

[Ru(Binap)(*p*-cymene)][SbF_6]$_2$ (**8a**) (18.8 mg, 0.014 mmol) was dissolved in 1 mL CD_2Cl_2 in an NMR tube. The resulting red solution was cooled to –78°C before (Bu_4N)(F_2SiPh_3) (7.9 mg, 0.014 mmol), under a continous Ar flow, was added. The color of the solution changed from red to yellow. A ^{31}P NMR spectrum of the cooled solution, measured immediately, showed complete conversion of the starting Ru-compound to a single new Ru-complex, **10**. The solution was allowed to come to room temperature and the complex **10** was characterised by NMR spectroscopic methods. Then the solvent was evaporated in vacuo and washed 3 × 3 mL Et_2O. The yellow powder was dried in vacuo. FAB-MS calcd. M^+: 877.0; found: M^+: 877.3; M^+ -*p*-cymene: 743.3. ^{1}H NMR (298 K, CD_2Cl_2): 0.13 (d, $^3J_{HH}$ = 6.9, CH(CH_3)$_2$), 1.03 (d, $^3J_{HH}$ = 6.9, CH(CH_3)$_2$), 1.67 (s, CH_3), 2.56 (m, CH(CH_3)$_2$), 5.56 (br d, $^3J_{HH}$ = 6.5, cyH), 5.71 (d, $^3J_{H7',H8'}$ = 8.8, H7′), 5.84 (br d, $^3J_{HH}$ = 6.7, cyH), 6.09 (br d, $^3J_{HH}$ = 6.5, cyH), 6.12 (br d, $^3J_{HH}$ = 6.9, cyH), 6.67 (ddd, $^3J_{H7',H8'}$ = 8.8, $^3J_{H8',H9'}$ = 7.8, $^3J_{H8',H10'}$ = 1.2, H8′), 6.33 (d, $^3J_{H7,H8}$ = 8.6, H7), 6.79 (H8), 7.19 (H9), 7.30 (H5′), 7.32 (H4′), 7.33 (H9′), 7.48 (H4), 7.70 (H10), 7.76 (br d, $^3J_{H8',H9'}$ = 8.3, H10′), 8.39 (d, $^3J_{H4,H5}$ = 8.4, H5). ^{13}C NMR (298 K, CD_2Cl_2): 17.4 (CH_3), 20.1 (CH(CH_3)$_2$), 23.8 (CH(CH_3)$_2$), 31.0 (CH(CH_3)$_2$), 99.4 (cy), 102.0 (cy), 102.3 (cy), 103.8 (cy), 114.1 (cy), 125.0 (C5′), 124.2 (C9), 124.9 (C8), 125.9 (C7), 129.3 (C8′), 127.3 (C7′), 127.2 (C10), 126.2 (C10′), 128.0 (C9′), 127.6 (C4′), 131.9 (C3), 132.3 (cy), 133.3 (C2′), 134.3 (C2), 134.8 (C3′), 140.3 (C1), 144.1 (C5), 147.0 (C6), 147.7 (C6′), 140.3 (C1′). ^{31}P NMR (298 K, CD_2Cl_2): 181.7 (dd, $^1J_{PF}$ = 936, $^2J_{PP}$ = 50), 50.9 (dd, $^2J_{PP}$ = 50, $^3J_{PF}$ = 13). ^{19}F NMR (298 K, CD_2Cl_2): –139.1 (dd, $^1J_{PF}$ = 936, $^3J_{PF}$ = 13).

Reaction of [Ru(Binap)(benzene)][SbF_6]$_2$ (9a) with (Bu_4N)(F_2SiPh_3) (11)

[Ru(Binap)(benzene)][SbF_6]$_2$ (**9a**) (33.5 mg, 0.03 mmol) was dissolved in 1 mL CD_2Cl_2 in an NMR tube. The resulting red solution was cooled to –78°C before (Bu_4N)(F_2SiPh_3) (13.9 mg, 0.03 mmol), under a continous Ar flow, was added. The color of the solution changed immediately from red to yellow. A ^{31}P NMR spectrum of the cooled solution, measured immediately, showed complete conversion of the starting Ru-compound to a single new Ru-complex (**11**). The solution was allowed to come to room temperature and the complex **11** was characterised by NMR spectroscopic methods. ^{1}H NMR (298 K, CD_2Cl_2): 5.68 (br d, $^3J_{H7',H8'}$ = 8.8, $^3J_{H7',H9'}$ = 1.1, H7′), 6.56 (ddd, $^3J_{H7,H8}$ =

In an attempt to separate the metal complex **11** from (Bu_4N)(SbF_6) and $FSiPh_3$, a second reaction was carried on a 2.5-fold larger scale following the same procedure described previously but using dichloromethane at room temperature. After 5 min the solvent was evaporated in vacuo. The resulting yellow powder was washed with 3 × 1 mL Et_2O. Slow diffusion of Et_2O into a dichloromethane solution resulted in two crystalline materials (i.e., yellow and white crystals). X-ray diffraction measurements on the yellow crystals failed to give a structure. An attempt was made to separate the two species on basis of the color of the crystals. However, this solid did not afford satisfactory microanalytic data. The isolated yellow product is stable under Ar and affords the same ^{31}P, ^{19}F, and ^{1}H NMR characteristics described above. However, in solution it decomposes over a short period of time. FAB-MS calcd. M^+: 820.9; found M^+: 820.2; M^+ -benzene: 742.8; M^+ -PPh_2F: 614.0.

Synthesis of [RuH(Binap)(*p*-cymene)]SbF_6 (12a)

[Ru(Binap)(*p*-cymene)][(SbF_6)$_2$] (**8a**) (74.4 mg, 0.06 mmol) was dissolved in 2 mL methanol. The resulting orange solution was then stirred at room temperature. After 15 min the yellow product began to precipitate. The suspension was stirred for another 2 h after which the orange solution was removed using a syringe. The remaining powder was washed 2 × 1 mL methanol. The resulting yellow product was dried in vacuo. Color: yellow. Yield: 48.4 mg (71%). FAB-MS calcd. M^+: 858.5; found M^+: 858.4; M^+ -*p*-cymene: 722.8. ^{1}H NMR (298 K, CD_2Cl_2): –9.79 (q, $^2J_{PH}$ = 29.2, $^2J_{PH}$ = 40.6, RuH), 0.93 (d, $^3J_{HH}$ = 6.6, CH(CH_3)$_2$), 1.23 (d, $^3J_{HH}$ = 6.6, CH(CH_3)$_2$), 2.10 (s, CH_3), 2.41 (m, CH(CH_3)$_2$), 3.84 (d, $^3J_{HH}$ = 5.8, cyH), 4.08 (d, $^3J_{HH}$ = 5.8, cyH), 5.71 (d, $^3J_{HH}$ = 5.8, cyH), 5.97 (d, $^3J_{HH}$ = 5.8, cyH). ^{13}C NMR (298 K, CD_2Cl_2): 20.5 (*C*H_3), 23.4 (CH(*C*H_3)$_2$), 23.8 (CH(*C*H_3)$_2$), 32.3 (*C*H(CH_3)$_2$), 91.7 (cy), 96.5 (cy), 97.3 (cy), 98.3 (cy), 113.0 (cy), 116.8 (cy). ^{31}P NMR (298 K, CD_2Cl_2): 52.8 (d, $^2J_{PP}$ = 47), 52.0 (d, $^2J_{PP}$ = 47). Anal. calcd. for $C_{54}H_{47}F_{12}P_2RuSb_2\cdot H_2O$ (1132.8): C 58.28, H 4.40; found: C 57.92, H 4.80.

Synthesis of [RuH(*S*-MeO-Biphep)(*p*-cymene)]SbF_6 (12b)

[Ru(*S*-MeO-Biphep)(*p*-cymene)]Cl (**6b**) (156.3 mg, 0.18 mmol) and $AgSbF_6$ (120.4 mg, 0.35 mmol) were dissolved in 1 mL dichloromethane. The resulting suspension was refluxed overnight. The precipitate of AgCl was filtered using Celite and the solvent was evaporated in vacuo; 5 mL methanol was added to the remaining powder. The color changed from red to yellow. A ^{31}P NMR spectrum of the sample recorded within 5 min, showed complete conversion. The solution was concentrated to 1 mL methanol during which time the yellow product precipitated. After 1 h the orange solution was removed by use of a syringe and then the remaining powder was washed with 2 × 3 mL methanol. The yellow product was dried in vacuo. Color: yellow. Yield: 158.2 mg (83%). FAB-MS calcd. M^+: 818.0; found: M^+ + SbF_6: 1053.3; M^+ + SbF_6-*p*-cymene: 902.2; M^+: 817.4; M^+-*p*-cymene-H: 683.0. ^{1}H NMR (298 K, CD_2Cl_2): –10.10 (q, $^2J_{PH}$ = 31.6, $^2J_{PH}$ = 39.7, RuH), 0.92 (d, $^3J_{HH}$ = 7.0, CH(CH_3)$_2$), 1.26 (d, $^3J_{HH}$ = 7.0, CH(CH_3)$_2$), 2.12 (s, CH_3), 2.44 (m, 1CH(CH_3)$_2$), 3.19 (s, OCH_3), 3.26 (s, OCH_3), 3.74 (d, $^3J_{HH}$ = 6.6, cyH), 4.05 (d, $^3J_{HH}$ = 6.6, cyH), 5.74 (d, $^3J_{HH}$ = 6.6, cyH), 6.00 (d, $^3J_{HH}$ = 6.6, cyH), 6.27, 6.30, 7.03. 7.07, 7.12, 7.40 (all 6 MeO-Biphep backbone). ^{13}C NMR (298 K, CD_2Cl_2): 20.4 (*C*H_3), 23.2 (CH(*C*H_3)$_2$), 23.5 (CH(*C*H_3)$_2$), 32.2 (*C*H(CH_3)$_2$), 54.6 (O*C*H_3), 54.7 (O*C*H_3), 91.5 (cy), 96.3 (cy), 97.5 (cy), 97.8 (cy), 110.6 (MeO-Biphep backbone), 111.2 (MeO-Biphep backbone), 112.4 (cy), 115.7 (cy), 119.2, 121.0, 125.7, 127.0, 134.2, 137.2, 157.0, 157.3 (all 8 MeO-Biphep backbone). ^{31}P NMR (298 K, CD_2Cl_2): 51.0 (d, $^2J_{PP}$ = 46), 50.4 (d, $^2J_{PP}$ = 46). Synthesis of [Ru(CNCH$_2$CO$_2$Et)(Binap)(*p*-cymene)][SbF$_6$]$_2$ (16a)

Ethyl isocyanoacetate (4.5 μL, 0.04 mmol) was added to a solution of [Ru(Binap)(*p*-cymene)][SbF$_6$]$_2$ (**8a**) (50.3 mg, 0.04 mmol) in 1 mL dichloromethane. An immediate color change from orange to yellow occurred. ^{31}P NMR recorded within 5 min after adding the isocyanoacetate, showed complete conversion of the starting material to the product. The solvent was evaporated in vacuo and then the remaining powder was washed with 2 × 3 mL Et$_2$O. The yellow product was dried in vacuo. Color: yellow. FAB-MS calcd. M^{2+}: 971.1; found: M^{2+} + SbF$_6$: 1207.9; M^{2+}-*p*-cymene: 836.9. ^{1}H NMR (298 K, CD_2Cl_2): 0.94 (d, $^3J_{HH}$ = 6.8, CH(C*H*$_3$)$_2$), 1.37 (d, $^3J_{HH}$ = 6.8, CH(C*H*$_3$)$_2$), 1.42 (t, CNCH$_2$CO$_2$CH$_2$C*H*$_3$), 1.95 (s, C*H*$_3$), 3.23 (d, $^2J_{HH}$ = 19, CNC*H*$_2$CO$_2$CH$_2$CH$_3$), 3.37 (m, C*H*(CH$_3$)$_2$), 4.24 (d, $^2J_{HH}$ = 19, CNC*H*$_2$CO$_2$CH$_2$CH$_3$), 4.41 (m, CNCH$_2$CO$_2$C*H*$_2$CH$_3$), 4.75 (d, $^3J_{HH}$ = 6.0, cyH), 4.77 (d, $^3J_{HH}$ = 6.6, cyH), 6.80 (d, $^3J_{HH}$ = 6.6, cyH), 7.15 (d, $^3J_{HH}$ = 6.0, cyH). ^{13}C NMR (298 K, CD_2Cl_2): 14.1 (CNCH$_2$CO$_2$CH$_2$*C*H$_3$), 19.6 (*C*H$_3$), 20.5 (CH(*C*H$_3$)$_2$), 24.4 (CH(*C*H$_3$)$_2$), 31.2 (*C*H(CH$_3$)$_2$), 47.3 (CN*C*H$_2$CO$_2$CH$_2$CH$_3$), 64.3 (CNCH$_2$*C*O$_2$CH$_2$CH$_3$), 98.6 (cy), 102.7 (cy), 103.7 (cy), 111.2 (cy), 123.2 (cy), 125.7 (cy), 142.8 (*C*NCH$_2$CO$_2$CH$_2$CH$_3$), 163.7 (CNCH$_2$*C*O$_2$CH$_2$CH$_3$). ^{31}P NMR (298 K, CD_2Cl_2): 46.0 (d, $^2J_{PP}$ = 40), 29.8 (d, $^2J_{PP}$ = 40). A temperature-controlled reversible ionic liquid – water two phase – single phase protocol for hydrogenation catalysis

Paul J. Dyson, David J. Ellis, and Thomas Welton

Abstract: An ionic liquid – water system that undergoes a reversible two phase – single phase transformation dependent upon temperature has been used as a novel medium for the transition-metal-catalyzed hydrogenation of a water soluble substrate. At room temperature, the ionic liquid 1-octyl-3-methylimidizolium tetrafluoroborate, containing $[Rh(\eta^4\text{-}C_7H_8)(PPh_3)_2][BF_4]$ catalyst, forms a separate layer to water containing 2-butyne-1,4-diol. In a stirred autoclave the mixture was pressurized with hydrogen to 60 atm (1 atm = 101.325 kPa) and heated to 80°C giving a homogeneous single phase solution. On cooling to room temperature, two phases reform, with the ionic liquid phase containing the catalyst and the aqueous phase containing a mixture of 2-butene-1,4-diol and butane-1,4-diol products that can be simply removed without catalyst contamination.

Key words: ionic liquids, biphasic catalysis, hydrogenation, rhodium.

Résumé : Un système liquide ionique – eau soumis à une transformation réversible de deux à une phase suivant la température est utilisé comme nouveau milieu pour l'hydrogénation, catalysée par des métaux de transition, de substrats solubles dans l'eau. À la température ambiante, le liquide ionique tétrafluoroborate de 1-méthyl-3-méthylimidizolinium contenant le catalyseur $[Rh(\eta^4\text{-}C_7H_8)(PPh_3)_2][BF_4]$ forme une couche séparée de l'eau qui contient du but-2-yne-1,4-diol. Dans un autoclave sous agitation, le mélange est soumis à une pression d'hydrogène de 60 atm (1 atm = 101.325 kPa) et chauffé à 80°C pour donner une solution homogène comportant une seule phase. Par refroidissement à la température ambiante, les deux phases se reforment avec la phase du liquide ionique qui contient le catalyseur et la phase aqueuse qui contient un mélange de but-2-ène-1,4-diol et de but-2-yne-1,4-diol qui peut être enlevé sans contamination par le catalyseur.

Mots clés : liquides ioniques, catalyse biphasique, hydrogénation, rhodium.

[Traduit par la Rédaction]

Introduction

Room temperature ionic liquids are emerging as excellent alternatives to organic solvents in homogeneous and biphasic processes and several excellent reviews are available (1). For example, liquids composed of various imidazolium cations with aluminium chloride based anions have replaced organic solvents in Friedel–Crafts reactions (2) and in polyethylene cracking (3) (both being catalyzed by aluminium chloride). More inert ionic liquids, also composed of imidazolium cations, but with counter anions such as tetrafluoroborate or hexafluorophosphate, have been used as catalyst supports in biphasic processes for a wide range of reactions as outlined in the reviews cited in ref. 1. Specific examples include hydrogenation (4) and hydroformylation, (5) Heck, (6) Trost–Tsuji (7), and Sukuzi (8) coupling reactions, the Diels–Alder reaction (9), alkylation (10), and polymerization (11) reactions.

While comparisons between ionic liquid – biphasic systems and others such as water and fluorous biphasic systems have been widely discussed from an environmental perspective, detailed assessment of the influence of the solvent regime on the catalyst has not been widely made (1). One of the most impressive aspects of some ionic liquids is that the liquid is essentially non-nucleophilic and as a consequence extends the lifetime of supported catalysts giving higher turnover numbers, clearly demonstrated for the hydroformylation of methyl-3-pentenoate using rhodium-based catalysts supported in the ionic liquid 1-butyl-3-methylimidazolium hexafluorophosphate (5*b*). When the reaction is carried out in organic solvents such as dichloromethane and toluene deactivation of the catalysts takes place rapidly, whereas in the reactions conducted in the ionic liquid, the catalyst remains active for considerably longer periods with turnover numbers typically 600% greater. This feature is especially important since concerns have been expressed that homogeneous catalysts tend to have short lifetimes and therefore there is little point in trying to recover them.

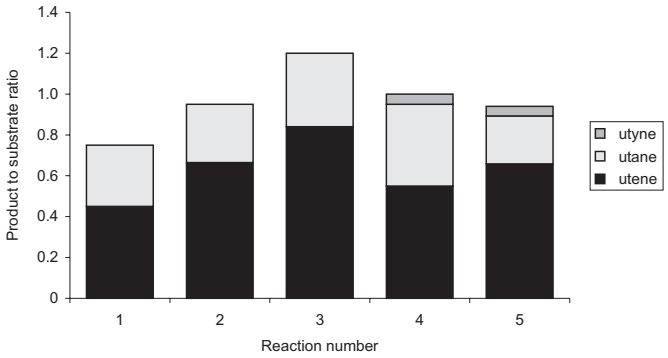
Chart 1.

Scheme 1.



In this paper we describe an ionic liquid – water biphasic system employing a cationic rhodium catalyst that has been applied to the hydrogenation of a water soluble substrate. At higher temperatures, the ionic liquid and water form a single phase allowing truly homogeneous catalysis to be carried out, whereas at lower temperatures the ionic liquid and water form two phases allowing easy separation of the product in the aqueous phase from the catalyst supported in the ionic liquid. As far as we are aware this represents the first example of an ionic liquid to be employed in such a process although a related process has been used in fluorous phase – organic systems (12).

Results and discussion

The ionic liquids 1-butyl-3-methylimidizolium tetrafluoroborate ([bmim][BF_4]), 1-hexyl-3-methylimidizolium tetrafluoroborate ([hmim][BF_4]), and 1-octyl-3-methylimidizolium tetrafluoroborate ([omim][BF_4]) (see Chart 1) reported previously (13) have been shown to exhibit pH dependent reversible partitioning with water (14). These liquids also exhibit temperature-dependent reversible-phase separation with water. The temperature at which the [omim][BF_4] ionic liquid and water form a homogeneous system (established by measuring w/w) is 80°C which is ideally suited to chemical reactions. At room temperature (20°C) the [omim][BF_4] ionic liquid contains 12% water (w/w). This provides a potential method of conducting homogeneously catalyzed reactions at 80°C with the combined advantages of biphasic separation at 20°C (or below).

The solubility of numerous catalysts in the ionic liquid – water systems has been examined. To effectively dissolve a catalyst into an ionic liquid the catalyst must be a salt (recently a new cobaltacenium-based diphosphine ligand was specifically made with this in mind) (5*c*). To induce water solubility hydrophilic groups must be present and a wide range of water soluble phosphine ligand have been developed over the years (15). One of the most widely used hydrophilic groups is sulphate, and for example, P(C_6H_4-*m*-$SO_3Na)_3$ has been extensively employed in biphasic aqueous – organic catalysis (for recent examples see ref. 16) with very little contamination of the catalyst observed in the organic phase after reaction. We have found that complexes containing P(C_6H_4-*m*-$SO_3Na)_3$ ligands are also reasonably soluble in ionic liquids but they are clearly unsuitable for the ionic liquid – aqueous regime described herein due to preferential solubility in water. Since the triphenylphosphine complex [Rh(η^4-C_7H_8)($PPh_3)_2$][BF_4] is a hydrophobic salt, with high solubility in [omim][BF_4] and other ionic liquids (4*a*), it is ideally suited to the [omim][BF_4]–water system. Furthermore, cationic rhodium(I) compounds of formula [Rh(diene)$P_2]^+$ (where P_2 represents two monophosphines or a single diphosphine) have been used extensively as hydrogenation catalysts (17) and show excellent activity and have even been used in ionic liquid – organic biphasic hydrogenations (18). The P(C_6H_4-*m*-$SO_3Na)_3$ derivative has been used in aqueous – organic biphasic catalysis (19).

Fig. 1. Graphic representation of the relative components obtained from a consecutive series of hydrogenations of 2-butyne-1,4-diol (10 g of substrate was introduced into each batch).

Based on the above criteria [Rh(η^4-C_7H_8)($PPh_3)_2$][BF_4] was used to catalyze the hydrogenation of maleic acid and 2-butyne-1,4-diol in [omim][BF_4]–water at 80°C. The succinic acid product obtained quantitatively from the hydrogenation of maleic acid was not significantly more water soluble than ionic liquid soluble and presented separation problems that offer no advantage over other methodologies (20). In contrast, the hydrogenation of 2-butyne-1,4-diol afforded preferentially water soluble 2-butene-1,4-diol and butane-1,4-diol products (see Scheme 1) that were easily separated from the ionic liquid – catalyst phase after cooling the reaction mixture to room temperature. The results obtained from a series of consecutive batch hydrogenation reactions of 2-butyne-1,4-diol are presented graphically in Fig. 1.

Over the series of five reactions the catalyst decomposes slightly, as evidenced by the formation of a black precipitate and slight decoloration of the ionic liquid phase. The presence of a black precipitate often indicates the active catalyst species is colloidal, however, tests using mercury as a selective poison proved this not to be the case. Figure 1 shows that over the five batch reactions the conversion not only remains high, but also the recovery of the products remains high.

The initial relatively low recovery level of the product, stems from the fact that 2-butyne-1,4-diol and the hydrogenation products (as well as water) show some degree of solubility in the [omim][BF_4] ionic liquid. Once the ionic liquid

© 2001 NRC Canada

solution becomes saturated with these compounds higher recovery is observed.

Experimental

The ionic liquids 1-butyl-3-methylimidizolium tetrafluoroborate, 1-hexyl-3-methylimidizolium tetrafluoroborate, and 1-octyl-3-methylimidizolium tetrafluoroborate (13) and the catalyst $[Rh(\eta^4\text{-}C_7H_8)(PPh_3)_2][BF]_4$ (21) were prepared according to the literature methods. 2-Butyne-1,4-diol was purchased from Aldrich and used without further purification; water was distilled before use.

Hydrogenations were carried in a Parr stainless steel autoclave (300 mL) fitted with a PTFE liner. The catalyst was dissolved in ionic liquid and added directly to the autoclave. The autoclave was then sealed and purged with nitrogen. The reaction substrate was then dissolved in water and added through the liquid inlet port via a syringe. The autoclave was then purged thoroughly with hydrogen gas (99.9995% purity) and the pressure was then set at room temperature to 60 atm (1 atm = 101.325 kPa). The autoclave was then heated to 10°C and stirred for 2 h. Once the desired time period had elapsed, heating and stirring was stopped. The autoclave was allowed to cool and the pressure released. Substrate and catalyst layers were separated in a separating funnel.

The products were identified by ^{1}H NMR spectroscopy on a JEOL JNM-EX270 FT-NMR instrument and quantified gas chromatographic analysis using a Varian gas chromatograph with a capillary carbowax column (30 m) using injection, oven and detector temperatures 10–30°C above the boiling points of the substrate–product being studied. Such conditions typically gave good separations within 10 min although *cis* and *trans* isomers of the 2-butene-1,4-diol could not be resolved.

Concluding remarks

We have demonstrated the use of a temperature-controlled reversible ionic liquid – water partitioning system for the catalytic hydrogenation of 2-butyne-1,4-diol. However, the process still requires some optimization as it operates under fairly harsh conditions (cf. the hydrogenation of cyclohexene with a related rhodium(I) catalyst in a similar ionic liquid occurs at 10 atm (1 atm = 101.325 kPa) H_2 compared to 60 atm (1 atm = 101.325 kPa) H_2 used here) and some catalyst decomposition takes place. Furthermore, since the amount of water in the ionic liquid at lower temperatures remains relatively high (and visa versa) some contamination of the aqueous product phase with the catalyst or catalyst decomposition products is observed. However, it is likely that this problem could be largely overcome by selection of an alternative ionic liquid. In fact, by simply using the PF_6^- anion in place of BF_4^- in the ionic liquid the solubility with water drops considerably. Despite these problems the ease of catalyst–substrate separation combined with the isolation of product largely uncontaminated by the catalyst does indicate that this type of method could become highly desirable for certain processes. For example, the synthesis of pharmaceuticals, many of which are water soluble, using this approach, could help to overcome product contamination by toxic metal residues.

Transmetalation reactions with nitrogen-containing "pincer"-class ligands on platinum(II) centers

Martin Albrecht, Stuart L. James, Nora Veldman, Anthony L. Spek, and Gerard van Koten

Abstract: The transmetalation reaction of the aryllithium compound $[Li(NCN)]_2$ (NCN is the monoanionic "pincer" ligand $[C_6H_3(CH_2NMe_2)_2\text{-}2,6]^-$) with the cyclometalated arylplatinum complex [PtCl(NCN)] afforded the bisaryl platinum(II) complex $[Pt(NCN)_2]$ (**3**) containing one η^3-*N,C,N*-terdentate and the other η^1-*C*-monodentate-bonded pincer ligand. Spectroscopic analyses on **3** suggest that η^3 to η^1 interconversion of the ligand binding mode (or vice versa) is inhibited. Two independent X-ray structure determinations on crystals of **3** revealed the existence of a rare polymorph containing one and three crystallographically independent molecules, respectively, in the unit cell. A similar transmetalation reaction with lithium and platinum complexes containing heteroleptic $NCN^{RR'}$ ligands ($NCN^{RR'}$ is $[C_6H_3(CH_2NRR')\text{-}2,6]^-$ with R = R′ = Me or R = Me, R′ = Et) pointed to the formation of a heterodinuclear cationic bisaryl platinum lithium species as an intermediate of a preequilibrium to the final transmetalation products, involving, rapid transcyclometalation (TCM) reactions. These TCM reactions comprise the exchange of the monoanionic $NCN^{RR'}$ ligands between the platinum(II) and lithium centers. A consequence of the latter properties is that the strong Pt—N bonds in [PtX(NCN)] complexes are considerably weakened by the presence of Li^+ cations.

Key words: transmetalation, transcyclometalation (TCM), platinum, bisaryl complex, polymorphism.

Résumé : La réaction de transmétallation du composé aryllithium $[Li(NCN)]_2$ (NCN = ligand « en pince » monoanionique $[C_6H_3(CH_2NMe_2)_2\text{-}2,6]^-$) avec le complexe d'arylplatine cyclométallé [PtCl(NCN)] conduit à la formation du complexe bisaryle de platine(II) $[Pt(NCN)_2]$ (**3**) qui contient un ligand η^3-*N,C,N*-terdentate et l'autre ligand en forme de pince lié de façon η^1-*C*-monodentate. Les analyses spectroscopiques de **3** suggèrent qu'il y a une inhibition à l'interconversion η^3 à η^1 (ou vice versa) du mode de fixation du ligand. Deux déterminations indépendantes de la structure des cristaux de **3** par diffraction des rayons X révèlent l'existence d'une polymorphie rare dans laquelle chacune des formes comprend respectivement une et trois molécules cristallographiquement indépendantes par maille. Une réaction de transmétallation semblable avec des complexes de lithium et de platine contenant les ligands hétéroleptiques $NCN^{RR'}$ ($NCN^{RR'}$ = $[C_6H_3(CH_2NRR')\text{-}2,6]^-$ avec R = R′ = Me ou R = Me, R′ = Et) suggère qu'il y a formation d'une espèce bisaryle de platine et de lithium hétérodinucléaire cationique comme intermédiaire d'un prééquilibre vers les produits finaux de transmétallation et qu'il implique des réactions rapides de transcyclométallation (TCM). Ces réactions de TCM incluent l'échange des ligands monoanioniques $NCN^{RR'}$ entre les centres de platine(II) et de lithium. En conséquence de ces propriétés, les fortes liaisons Pt—N présentes dans les complexes de [PtX(NCN)] sont de beaucoup affaiblies par la présence des cations Li^+.

Mots clés : transmétallation, transcyclométallation (TCM), platine, complexe bisaryle, polymorphie.

Introduction

The reversible formation of an intermediate metal-to-carbon bond is a crucial step in many catalytic cycles (1). In particular, making and breaking of C_{aryl}—M σ-bonds is of great significance, e.g., in C_{aryl}—C_R cross coupling reactions (Heck: R = alkene; Sonogashira: R = alkyne; Suzuki:

Scheme 2. TCM reaction of [PtCl(NCN)] with PCHP to give [PtCl(PCP)] and NCHN (12*d*).

R = aryl) and in C_{aryl}—E bond activation processes (E = carbon or heteroatom) (for examples of cross coupling see ref. 2*a*; for examples of bond activation see ref. 2*b*). Intramolecular stabilization of this C—M bond by heteroatom coordination, i.e., formation of metallacycles, has been demonstrated to be an efficient methodology for stabilizing the metal-to-carbon bond. As a consequence, the rate of (catalytic) processes is often considerably reduced, which provides insight into mechanistic details and thus important information for efficient catalyst design (3, 4). Other applications of transition metal complexes containing C_{aryl} σ–bonding chelates include the engineering and processing of materials properties, e.g., for gas storage (5) and sensoring purposes (6).

Up to now, cyclometalated complexes containing C—M σ-bonds have been accessible predominantly via two different methods: (*i*) transmetalation of (main group) organometallics (C-Mg, C-Li, C-Sn) with a suitable metal precursors (7); or (*ii*) direct cyclometalation via C—E bond activation (E = e.g., C, Si, halide) (8). Recently, transcyclometalation (TCM) reactions have been introduced as a new methodology for the generation of cyclometalated transition-metal complexes. In close relation to (organic) transesterification reactions (9), TCM reactions consist of the substitution of one (monoanionic) cyclometalated ligand by another one (Scheme 1). In some cases, this has the advantage of being a cleaner reaction than direct cyclometalation. Previous examples, though at that time not recognized as TCM reactions, include a variety of ligand systems, which were predominantly activated with palladium complexes (10). More recently, the TCM reaction of a terdentate coordinated NCN-type pincer-ligand (11) by another bis(*ortho*)-chelating PCP pincer-ligand has been described to occur on a ruthenium(II) (i.e., M in Scheme 1 is $RuCl(PPh_3)$) and a platinum(II) (Scheme 2) metal center, respectively, (12). As a primary conclusion of these studies (12*a*), the higher bond strength of the M—P bond compared to the analogous M—N bond is anticipated to be the driving force. Indeed, the selective and quantitative replacement of the amines by phosphorus donors has been demonstrated to initiate the TCM process. In this report we present evidence that also cyclometalated aryllithium and platinum compounds can undergo TCM reactions. This leads even for η^3-coordinated NCN ligands to the formation of mixtures of cyclometalated compounds.

Results and discussion

Initial attempts to transcyclometalate aryl ligands of the type $NC(H)N^{RR'}$ ($NCN^{RR'}$ denotes the monoanionic bis(*ortho*)-substituted aryl ligand $[C_6H_3(CH_2NRR')_2\text{-}2,6]^-$) with either the neutral cyclometalated complex $[PtCl(NCN^{Me_2})]$ (**2**), or its cationic analogue $[Pt(NCN^{Me_2})(H_2O)](BF_4)$ (13) gave no detectable reaction. Obviously, the Pt—N bond in [PtCl(NCN)] cannot be displaced by an amino group of the $NCHN^{RR'}$ ligand, and consequently, a TCM process is prevented since in these reactions ligand substitution has been identified as an initial step. Hence, half an equivalent of the dimeric aryllithium species $[Li(NCN^{Me_2})]_2$ (**1-Li**) (14) was reacted with the arylplatinum(II) complex **2** in polar solvents and at elevated temperatures (THF, reflux temperature). This afforded the bisaryl platinum(II) complex $[Pt(\eta^3\text{–}NCN^{Me_2})(\eta^1\text{–}C\text{–}NCN^{Me_2})]$ (**3**) in 60% yield (Scheme 3). This complex contains two differently bonded pincer ligands, one monodentate η^1-*C* and the other terdentate η^3-*N*,*C*,*N* coordinating. This compound may be envisaged as an intermediate in the full substitution of one NCN ligand by another in the TCM reaction, cf. the isolation of $[Pt(\eta^3\text{–}P,C,P\text{–PCP})(\eta^1\text{–}C\text{–NCN})]$ in the TCM reaction of **1** with PCHP (Scheme 2). This is further underlined by the reactivity of **3** towards aq HCl, which results in rapid Pt—C bond cleavage of the η^1-coordinated ligand and formation of the starting materials **2** and **1** as the diprotonated chloride salt (Scheme 3). Remarkably, these conditions affect neither the Pt—N nor the Pt—C bonds of the η^3-*N*,*C*,*N* chelating ligand, and are a good indication for the excellent stability of the [Pt(NCN)] unit. This is also in concert with the fact that **2** does react with the bis-phosphinoarene PCHP but not with the bis-aminoarene NCHN.

Unambiguous confirmation of the connectivity pattern in **3** was accomplished by detailed X-ray structure analyses of single crystals, which were grown by slow evaporation of a saturated Et_2O solution.

Solid-state structure of 3

The molecular structure of **3**, measured at room temperature, is shown in Fig. 1 and reveals a platinum(II) center that is ligated by a terdentate, η^3-*N*,*C*,*N*-bound, and a mono-

© 2001 NRC Canada

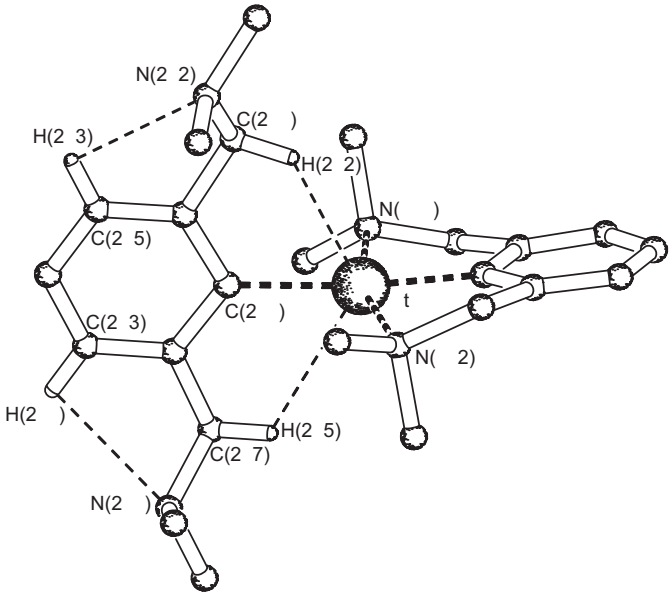
dentate, η^1-*C*-bound, NCN pincer ligand, resulting in a *trans* positioning of the two aryl groups across the metal square plane. The puckered five-membered chelate ring conformations, bond lengths, and bond angles of the [Pt(η^3-NCN^{Me_2})] moiety are normal for square planar platinum(II) complexes containing this ligand (Table 1) (13, 15). As a consequence of the different denticity of the ligands, the metal-to-carbon σ-bond of platinum to the monodentate bonded NCN ligand is considerably longer (Pt—C(201) 2.126(5) Å) than the one to the terdentate coordinating NCN ligand (Pt—C(101) 1.963(6) Å). Moreover, the aromatic ring of the η^1-*C*-bonded ligand system is considerably distorted (the internal angle at C_{ipso} is 114.3(5)° for the η^1-*C*-NCN, and 121.4(5)° for the η3-*N*,*C*,*N*-bonded ligand), which is presumably a consequence of the steric crowding around the platinum nucleus. The noncoordinating tertiary amines are directed away from the metal center.

Two different structural motifs have been identified, for the orientation of the CH_2NMe_2 groups with respect to the arylplatinum unit. The first comprises short interatomic C-H···N contacts between the aryl protons H(201) and H(203) and the nitrogen atoms of the η^1-coordinated NCN ligand (C_{aryl}-H···N 2.627 and 2.679 Å, respectively; see Fig. 2 and Table 2). The second motif has the benzylic protons H(205) and H(212) of the η^1-coordinating pincer ligand positioned near the virtual *z* axis of the platinum center (Pt···H 2.803 and 2.704 Å, respectively). The filled d_z2 orbitals in such d^8 metal centers, particularly in bisaryl platinum(II) complexes, have been established to be important frontier orbitals. As a consequence, the observed C-H···Pt arrangement provides additional stabilization to this particular CH_2NMe_2 conformer (12*a*, 16).

Surprisingly, a second crystal structure determination, which was performed at 150 K, revealed a polymorph (17). While the overall connectivity was the same as established for the first X-ray analysis, distinctly different intramolecular orientations for the CH_2NMe_2 substituents were identified for the crystal structures. Representative sections of the two polymorphous crystal structures (**I** and **II**) are shown in Fig. 3. Form **I** (data collected at room temperature, Fig. 3*a*) contains one molecule per asymmetric unit, in which the two free amine arms are both positioned on the same side of the aryl ring to which they are connected, i.e., they have a *cisoid* arrangement. The asymmetric unit in the polymorph **II** (150 K), however, contains three independent molecules, two of which have the *cisoid* conformation as observed in **I**, while the third (molecule 3, Fig. 3*b*) has the free amine groups positioned on opposite sides of the aryl ring (*transoid*). It is noteworthy that no phase transition was observed on cooling of crystal **I** to 150 K.

Structural aspects of 3 in solution



As a result of the ligand arrangement at the platinum center (viz. two metal-bound aryl units and two noncoordinating *tert*-amine moieties), complex **3** displays good solubility in apolar solvents (e.g., in Et_2O and pentane) which is unusual for related platinum-halide species such as **2** (13). In the ^{1}H NMR spectrum (C_6D_6 solution), two distinct signals for the

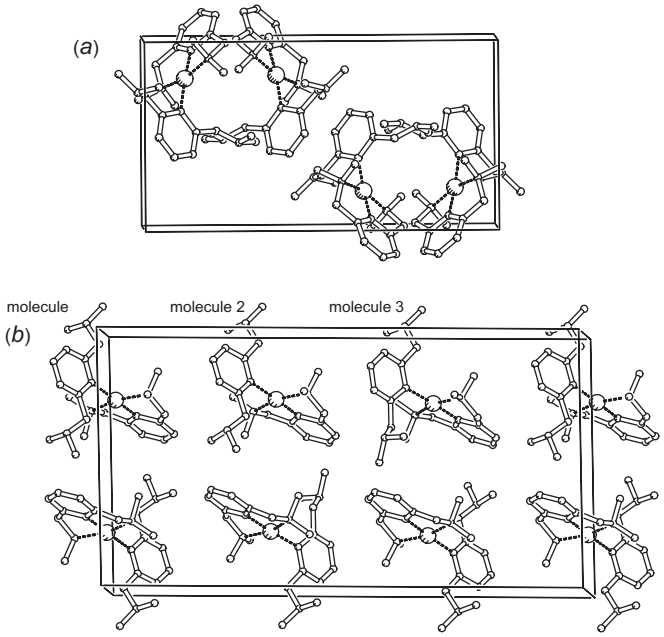
Fig. 2. Short intramolecular contacts of the noncoordinating *ortho*-substituents from the η^1-coordinating pincer ligand.

NMe_2 groups are observed, which are located at 2.41 and 2.58 ppm, respectively. The resonance at 2.41 ppm is typical for noncoordinating amine methyl groups, but is shifted to higher frequency when compared to free ligand (δ_H (NMe_2) = 2.21 ppm in **1**). In contrast, the signal at 2.58 ppm displays a coupling pattern ($^3J_{HPt}$ = 42 Hz) which is diagnostic for nitrogen coordination to the metal center, even though these nuclei seem to be considerably shielded when compared to related groups, in **2** and analogues where the chloride in **2** is replaced by another halide or a *para*-tolyl ligand, cf. δ_H (NMe_2) = 2.95–3.18 (13*a*). Similar features are also observed for the resonances at 4.38 and 3.57 ppm, which, on the basis of either the absence or presence of ^{195}Pt coupling ($^3J_{HPt}$ = 47.0 Hz),

Table 2. Short intramolecular distances (Å) and angles (deg) in **3**.



Donor–acceptor system	Distances (Å)		Angles (deg)
D-H···A	H···A	D···A	D-H···A
C(207)-H(205)···Pt	2.803	3.391(6)	119.8
C(210)-H(212)···Pt	2.704	3.324(6)	122.2
C(203)-H(201)···N(201)	2.627	2.914(9)	98.5
C(205)-H(203)···N(202)	2.679	2.960(9)	98.3

were assigned to the $ArCH_2N$ protons of the η^1-*C* and the η^3-*N,C,N*-coordinating pincer systems, respectively, (12*a*, 13). The low field shift of the noncoordinating CH_2N protons is remarkable and points to additional deshielding of these nuclei. Such effects may originate from weak intramolecular interactions (e.g., hydrogen bonding) with the nucleophilic platinum(II) center (Fig. 2) (12*a*, 18). The properties of the platinum(II) center as hydrogen bond acceptor have recently been applied for the fabrication of organometallic proton sponges (12*a*, 19). Further confirmation of the structure of **3** was obtained from ^{13}C NMR spectroscopy. In particular, the two signals at 172.6 and 182.2 ppm are characteristic for Pt(NCN) type complexes containing an aryl anion in mutual *trans*-position to the metal-bound pincer-carbon N*C*N (13). As expected, two sets of benzylic carbons (at 68.4 and 80.8 ppm) and nitrogen-bound methyl carbons (at 45.9 and 54.7 ppm) were observed, which belong to the monodentate coordinating and to the chelating ligand, respectively. The symmetric structure in solution, indicated by ^{1}H and ^{13}C NMR spectra, is consistent with a purely *transoid* arrangement of the free arms, or fast exchange between *transoid* and *cisoid* forms on the NMR time scale.

Variable temperature NMR experiments were carried out to probe in particular whether dynamic processes could be feasible involving a fluxional switch between η^3- and η^1-bonding of each of the pincer ligands. At low temperature (–80°C, CD_2Cl_2) the signals due to the free amine arms broaden. Although this may be due to the onset of freezing

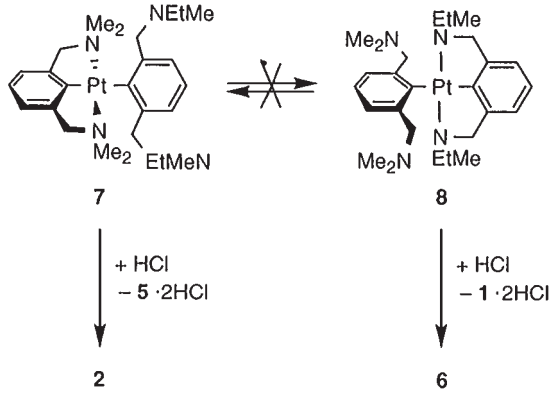

Fig. 3. Polymorphism in crystalline **3**: (*a*) crystal structure of crystal **I**, which is characterized by one single independent molecule of **3**. Note that the noncoordinating nitrogens are in *cisoid* configuration with respect to the bisecting aryl plane of the η^1-bound ligand; (*b*) the second polymorph, crystal **II**, contains three independent molecules of **3** in the unit cell. Molecule 1 and 2 display a similar *cisoid* confirmation as identified for crystal **I**, whereas molecule 3 contains the non-coordinating amines in a *transoid* position.

out of a *cisoid–transoid* equilibrium, temperatures low enough to resolve the interconverting species could not be attained. Fluxional processes involving coordination of the free amine groups with associated decoordination of the bonded amine groups could also occur at higher temperatures. However, neither ^{1}H NMR spectra in toluene-d_8 solution at 110°C nor spin saturation transfer experiments revealed any evidence for a dynamic behavior of **3** on the NMR time scale. These results show that even *intra*molecular substitution of coordinated amines by free amine sites is not occurring (vide infra).

The presence of noncoordinating tertiary amines in **3** was further established by derivatization with MeI, which gave the bis-ammonium salt [Pt(η^3-NCN^{Me_2})(η^1-NCN^{Me_3})](I)$_2$ (**4**) (Scheme 3). Interestingly, no arenium species was formed, as might be expected on basis of previous results related to the reaction of NCN platinum(II) aryl complexes with MeI (20). Two different explanations may rationalize these observations: Either the bulk of the noncoordinating CH_2NMe_2 groups of the η^1-monodentate bound pincer ligand efficiently reduce the accessibility of the platinum center or alternatively, oxidative addition of MeI may take place to form an intermediate platinum(IV) species (4*a*, 21), followed by irreversible trapping of the platinum-bound methyl group by the noncoordinated amine groups, and formation of a cationic ammonium structure as **4**. The accumulation of positive charges and (or) steric crowding in close proximity to the metal center apparently prevents the reaction of **4** with another equivalent of MeI. The methyl groups of the terdentate pincer ligand in **4** are chemically inequivalent (viz. two singlet resonances with ^{195}Pt couplings in the ^{1}H NMR spectrum at δ_H = 2.69 and 2.74, respectively). Also, the benzylic protons of the η^3-bonded ligand in **4** became diastereotopic as shown by the AB-type pattern with δ_A at 3.83 ppm and δ_B at 5.03 ppm, respectively. These observations suggest a reduced symmetry in **4**, which may be due to a frozen wagging of the methylene CH_2 groups of the five-membered metallacycles. In solution, puckering effects are usually fast and cannot be slowed down significantly by cooling (22). However, the steric constraints of the bulky ammonium groups on the η^1-bonded ligand may reduce the fluxionality of the metallacycles considerably. This is corroborated by the anticipated relative position of the aryl planes of the η^1-bonded and η^3-bonded pincer ligands, which are most likely significantly tilted from an ideal perpendicular orientation, cf. the solid-state structure of related bis-ammonium complexes (12*a*).

Scheme 4. Selective acid-mediated cleavage of the unsupported Pt—C bond.

Bisaryl platinum(II) complexes containing heteroleptic pincer ligands

It must be noted that during the formation of **3**, a TCM type reaction could be operative, which is undetectable as it is degenerative in the products. To distinguish a transmetalation reaction, i.e., Li–Pt exchange on NCN, from an eventually competitive TCM type process, a chemical modification in one ligand framework was introduced. Ideally, such a modification should allow to distinguish between the different amine donors but not cause significantly different coordination properties. Therefore, the prochiral pincer ligand precursor NCHN^{EtMe} (**5**) containing one methyl and one ethyl group bound to each nitrogen donor, was used as a marker.[4] Lithiation and subsequent transmetalation of this ligand readily afforded the corresponding platinum complex [PtCl(NCN^{EtMe})] (**6**) (23).

[4] It has been shown previously that replacement of all methyl groups by ethyl substituents severely disturbes nitrogen coordination and reduces the accessibility of the metal center rigorously. As a consequence, the platinum center in complexes such as [PtX(NCN^{Et_2})] is not available anymore for, e.g., SO_2 (23) or I_2 (4*b*) coordination. Moreover, X-ray structure analyses revealed that the puckering of the metallacycle in, e.g., [PtI(NCN^{Et_2})] is considerably smaller than in the corresponding NCN^{Me_2} complexes (23).

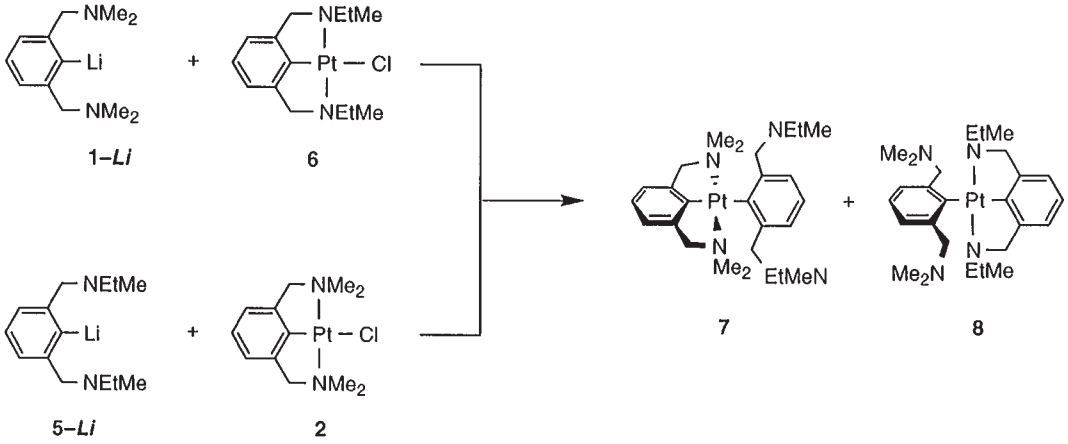
Scheme 5. Heteroleptic bisaryl platinum(II) complex formation by using modified pincer ligands containing ethyl-labeled amino groups.



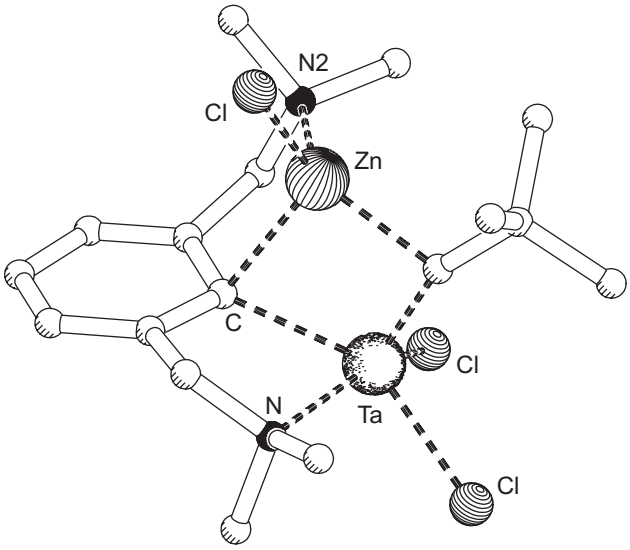


Fig. 4. Snapshot of the transmetalation reaction between tantalum and zinc on a pincer ligand. Note the structural analogy of this complex with intermediate **A** as proposed for the transcyclometalation between platinum and lithium (see Scheme 6).

Reaction of **6** with **1-Li** is anticipated to give selectively the bisaryl complex **8** containing the NEtMe groups coordinated to the platinum center, provided the reaction is a straightforward transmetalation reaction involving substitution of the Li^+ cation in **1-Li** by $[Pt(NCN^{EtMe})]^+$ (Scheme 5). Analogously, the product of a transmetalation of **5-Li** with **2** would afford complex **7** as the exclusive product. On the contrary, an eventually operative TCM reaction would be indicated in these cross-experiments by the concomitant presence of both complexes **7** and **8**, since this process involves (repetitive) formation and cleavage of metallacycles with reformation of the corresponding $[Li(NCN^{RR'})]$ compounds.

Analysis of the product mixtures obtained from the cross-experiments (performed under experimental conditions that were analogous to those applied for the formation of **3**) pointed to the presence of both **7** and **8**. The NMR spectra of the product mixtures of both reactions were complicated (24). However, they were remarkably consistent, irrespective of whether the ethyl-labeled nitrogen donors were in the lithium species or in the cyclometalated starting material. The high field region of the ^1H NMR spectra is diagnostic: the signals at δ_H = 2.69 and 2.10 are indicative for platinum-bound and noncoordinated NMe_2 groups, respectively. Furthermore, two sets of resonances were observed for the nitrogen-bound ethyl substitutents. The set at lower field (δ_H = 2.64 (q) and 1.16 (t)) is located at frequencies similar to those observed for nonmetalated **5**, whereas the set at higher field (δ_H = 2.33 (m) and 0.99 (t)) showed the expected pattern for nitrogen coordination to platinum (24), with characteristic coupling constants of the methylene NCH_2 protons to the platinum center ($^3J_{HPt}$ = 78 Hz). A product ratio between **7** and **8** of 3:5 was estimated based on the signals due to the NCH_2CH_3 methyl groups. Interestingly, this ratio is nearly constant and independent of the chosen starting materials, i.e., the cycloplatinated starting materials **2** or **6**. This implies an equilibrium situation which precedes the ultimate formation of the transmetalation products.

Product analyses using variable temperature ^1H NMR lead to similar results as obtained for **3**. In the measured temperature range (–80 to +100°C, toluene-d_8 solution), no significant line-broadening was observed. More importantly, the product ratio between **7** and **8** remained constant, implying a high kinetic barrier for the transition of **7** to **8** and vice versa (Scheme 4). These results exclude a potential equilibrium situation *after* the transmetalation sequence.

When the complexes **3**, or **7** and **8** were treated with an excess of aq HCl, rapid fission of the unsupported Pt—C bond was observed, thus giving the cyclometalated platinum chloride complexes **2** and **6**, respectively, along with the protonated pincer ligands **1**·2HCl and **5**·2HCl (Scheme 4). Since the non-chelating Pt—C bond is cleaved selectively (the Pt—C bond in complex **2** was stable towards HCl at 60°C for several hours), quantification of the product ratio between **2** and **6** provides an a posteriori method for the determination of the ratio between **7** and **8**.

Mechanistic consequences for TCM reactions with $[Li(NCN^{RR'})]$ complexes

Related transmetalation studies have emphasized the relevance of bimetallic intermediates comprising an aryl carbanion bridging to two (different) metal centers through 3*c*—2*e* or 3*c*—4*e* bonding (Fig. 4) (25). A similar

intermediate (A) is likely to be involved in the transmetalation of **1-Li** or **5-Li** by the cyclometalated platinum(II) complexes **6** and **2**, respectively, (Scheme 6). Due to the low stability of such complexes, it is expected that intermediate **A** equilibriates rapidly with the starting materials. Notably, it is not possible to deduce the precursors, i.e., **2** and **5-Li** or **6** and **1-Li**, from complex **A** and formation of either of these two sets of starting materials occurs on nucleophilic attack of Cl^- on the platinum center. This interconversion of **2** and **5-Li** to **6** and **1-Li** and vice versa corresponds to a transcyclometalation (TCM) reaction between the platinum and lithium centers. Alternative attack of the Cl^- nucleophile on the lithium center in intermediate **A** induces the formation of LiCl and the respective bisaryl platinum(II) product, which is probably an irreversible reaction sequence. Apparently, the equilibrium situation of the TCM reaction with complex **A** as an intermediate must be reached rapidly. This is an interesting further reaction trajectory for a TCM process and contrasts to earlier established reactions where one starting material was metal-free. The relatively low selectivity of this TCM reaction (Scheme 6) in terms of product distribution (nearly equal yields of **7** and **8**) is most likely a direct consequence of the only small differences in the bond strength of the platinum center to either N^{Me_2} or N^{EtMe} type amines. Similar arguments account for the Li—N^{Me_2} and Li—N^{EtMe} bond strengths. According to

© 2001 NRC Canada

spectroscopic analyses (NMR signal integration), there is a slight preference for initial Li—N^{EtMe} bond cleavage rather than Li—N^{Me_2} fission, since the major product of the transmetalation is complex **8** having metallacycles containing N^{EtMe} type amines. The low product selectivity contrasts with previously reported TCM processes, which involved amine and phosphines donors on the pincer ligands (Scheme 2). In those systems, exclusive formation of [PtCl(PCP)] and NCHN resulted from a more pronounced donor-metal bond strength difference, since the Pt—P bond is significantly more stable than the corresponding M—N bond.

Experimental

Reactions involving organolithium derivatives were carried out using standard Schlenk techniques under an inert atmosphere of dry, oxygen-free nitrogen. Hexane, Et_2O, and THF were distilled from Na–benzophenone, CH_2Cl_2 from CaH_2 prior to use. All ^1H and ^{13}C NMR spectra were recorded on a Bruker AC300 or a Varian Inova 300 spectrometer, operating at 300 and 75 MHz, respectively. Spectra were obtained at 25°C, unless stated otherwise, and are referenced to external TMS (δ = 0.00 ppm, *J* in Hz). Elemental analyses were obtained from Kolbe, Mikroanalytisches Laboratorium (Mülheim, Germany).

The ligand precursors $NC(H)N^{Me_2}$ (**1**), $NC(H)N^{EtMe}$ (**5**), and the platinum complexes [PtCl(NCN^{Me_2})] (**2**) and [PtCl(NCN^{EtMe})] (**6**), were prepared according to described procedures (13, 15, 23).

[Pt(η³-NCN^{Me2})(η¹-NCN^{Me2})] (3)

To a pentane solution of **1** (0.25 g, 1.3 mmol in 4 mL) was added *n*-BuLi (1.5 M hexane solution, 0.87 mL, 1.3 mmol) at –80°C. The reaction mixture was allowed to warm to room temperature over 14 h. All volatiles were then removed in vacuo and the residue was redissolved in THF. To this solution was added the platinum complex **2** (0.50 g, 1.2 mmol) and the mixture was heated to reflux temperature for 4 h. After cooling to room temperature, the solvents were removed and the residue was extracted with Et_2O (3 × 20 mL). The combined ether layers were concentrated to 5 mL and pentane was overlayered, which caused slow crystallization of the product. Yield: 0.41 g (60%). ^1H NMR (C_6D_6) δ: 7.70 (d, 2H, $^3J_{HH}$ = 7.0, Ar*H*), 7.40 (t, 1H, $^3J_{HH}$ = 7.0, Ar*H*), 7.17 (t, 1H, $^3J_{HH}$ = 8.0, Ar*H*), 6.93 (d, 2H, $^3J_{HH}$ = 8.0, Ar*H*), 4.38 (s, 4H, CH_2N), 3.57 (s, $^3J_{HPt}$ = 47, 4H, CH_2NPt), 2.58 (s, $^3J_{HPt}$ = 42, 12H, $PtNCH_3$), 2.41 (s, 12H, NCH_3). ^{13}C NMR (C_6D_6) δ: 182.2 (C_{ipso}, $^1J_{HPt}$ not resolved), 172.6 (C_{ipso}, $^1J_{HPt}$ not resolved), 147.4, 145.1, 127.4, 122.7, 122.3, 119.0 (all Ar*C*), 80.8 (CH_2NPt), 68.4 (CH_2N), 54.7 ($PtNCH_3$), 45.9 (NCH_3). Anal. calcd. for $C_{24}H_{38}N_4Pt$ (587.66): C 49.90, H 6.63, N 9.70; found: C 50.07, H 6.90, N 9.59.

[Pt(η³-NCN^{Me3})(η¹-NCN^{Me3})]$(I)_2$ (4)

To a stirred solution of **3** (0.50 g, 0.87 mmol) in CH_2Cl_2 (5 mL) was added a solution of MeI (0.28 g, 2.0 mmol) in CH_2Cl_2 (2 mL) and the mixture stirred for 3 h. The volatiles were removed to leave **4** as an off-white solid (0.72 g, 97%). Analytically pure **4** was obtained by recrystallization from H_2O–acetone. ^1H NMR (D_2O, 200 MHz) δ: 7.41 (d, 4H, $^3J_{HH}$ = 7.3, Ar*H*), 7.27 (t, 2H, $^3J_{HH}$ = 7.3, Ar*H*), 5.04 (d, 2H, $^3J_{HH}$ = 13.2 Hz, $^3J_{HPt}$ not observed, C*H*$HNMe_2$), 4.84 (d, 2H, $^3J_{HH}$ = 11.6, C*H*$HNMe_3$), 4.52 (d, 2H, $^3J_{HH}$ = 11.6, C*H*$HNMe_3$), 3.83 (d, 2H, $^3J_{HH}$ = 13.4, $^3J_{HPt}$ not observed, CH*H*NMe_2), 3.24 (s, 18H, NMe_3), 2.75 (s, 6H, $^3J_{HPt}$ = ca. 40, NCH_3Me), 2.73 (s, 6H, $^3J_{HPt}$ = 36.2, $NMeCH_3$). ^{13}C NMR (D_2O) δ: 175.8 (C_{ipso}), 149.2, 132.8, 130.5, 123.6, 123.5 (all Ar*C*), 78.9 (CH_2NPt), 74.9 (CH_2N), 56.1 ($PtNCH_3Me$), 52.9 (NMe_3), 51.7 ($PtNMeCH_3$). Anal. calcd. for $C_{26}H_{44}I_2N_4Pt \cdot H_2O$ (879.57): C 35.50, H 5.27, N 6.37; found: C 35.50, H 5.42, N 6.21.

[Pt(η³-NCN^{Me2})(η¹-NCN^{EtMe})] (7) and [Pt(η³-NCN^{EtMe})(η¹-NCN^{Me2})] (8)

These complexes have been prepared following a similar protocol as for **3**. The products were obtained as mixtures, which precipitated as off-white powders from pentane–Et_2O systems. All attempts to separate the products were unsuccessful.

Method A

From **1** (0.17 g, 0.89 mmol) in pentane (4 mL), *n*-BuLi (1.5 M in hexane, 0.60 mL, 0.9 mmol), and **6** (0.37 g, 0.82 mmol). Yield: 0.22 g (44%).

Method B

From **5** (0.26 g, 1.2 mmol) in pentane (6 mL), *n*-BuLi (1.5 M in hexane, 0.8 mL, 1.2 mmol), and **2** (0.46 g, 1.1 mmol). Yield: 0.35 mg (53%).

^1H NMR (C_6D_6) δ: 7.83 (d, $^3J_{HH}$ = 7.4, Ar*H*), 7.55 (s, Ar*H*), 7.43 (t, $^3J_{HH}$ = 7.4, Ar*H*), 7.31–7.19 (m, Ar*H*), 7.04 (t, $^3J_{HH}$ = 7.5, Ar*H*), 6.93 (d, $^3J_{HH}$ = 7.4, Ar*H*), 6.64 (d, $^3J_{HH}$ = 7.5, Ar*H*), 4.47 (s, CH_2N (**8**)), 3.57 (s, $^3J_{HPt}$ = 43.7, CH_2NPt (**7**)), 3.40 (s, CH_2N (**7**)), 3.29 (s, $^3J_{HPt}$ = 30.3, CH_2NPt (**8**)), 2.69 (s, $^3J_{HPt}$ = 38.0, $PtNCH_3$ (**8**)), 2.64 (q, $^3J_{HH}$ = 7.1, NCH_2CH_3 (**7**)), 2.58 (s, $^3J_{HPt}$ = 43.6, $PtNCH_3$ (**7**)), 2.41 (s, NCH_3 (**8**)), 2.33 (q, $^3J_{HH}$ = 7.1, $^3J_{HPt}$ = 78.0, $PtNCH_2CH_3$ (**8**)), 2.10 (s, NCH_3 (**7**)), 1.16 (t, $^3J_{HH}$ = 7.1, 2.25H, NCH_2CH_3 (**7**)), 0.99 (t, 3.75H, $^3J_{HH}$ = 7.1, $PtNCH_2CH_3$ (**8**)). ^{13}C NMR (C_6D_6) δ: 181.6 (C_{ipso}), 172.7 (C_{ipso}), 147.5, 145.1, 143.8, 140.2, 130.0, 127.4, 126.9, 122.9, 122.6, 122.5, 119.2, 119.0 (all Ar*C*), 80.9 ($^2J_{CPt}$ = 28.0, CH_2NPt (**8**)), 77.7 ($^2J_{CPt}$ = 65.0, CH_2NPt (**7**)), 66.8 (CH_2N (**7**)), 62.6 (CH_2N (**8**)), 54.8 ($^2J_{CPt}$ not resolved, $PtNCH_3$ (**8**)), 54.0 ($^2J_{CPt}$ = 15.3, $PtNCH_3$ (**7**)), 52.0 (NCH_2CH_3 (**7**)), 51.6 ($PtNCH_2CH_3$ (**8**)), 42.0 (NCH_3 (**7**)), 41.6 (NCH_3 (**8**)), 13.5 (NCH_2CH_3 (**7**)), 12.8 ($PtNCH_2CH_3$ (**8**)).

Reaction with HCl

A solution of the bisarylplatinum complex **3**, or **7** and **8** in CH_2Cl_2 was saturated with freshly prepared anhyd HCl. Stirring was maintained for 1 h and all volatiles removed in vacuo. Identification of the products (^1H NMR) was performed by comparison with authentic samples of **2** and **6**, respectively.

Structure determination and refinement of 3

Intensities were measured on an Enraf–Nonius CAD4-T diffractometer with rotating anode (Mo Kα, λ = 0.71073 Å). Crystal data and details on data collection and refinement

© 2001 NRC Canada

are collected in Table 3.[5] The structures were solved with Patterson methods (DIRDIF-92 (26)) and refined against F^2 of all reflections (SHELXL-93 (27)). Non-hydrogen atoms were refined freely with anisotropic displacement parameters, hydrogen atoms were introduced at calculated positions and refined riding on their carrier atoms. Weights were optimized in the final refinement cycles. Neutral atomic scattering factors and anomalous dispersion corrections were taken from the *International Tables of Crystallography*. All calculations, graphical illustrations, and checking for higher symmetry were performed with the PLATON package (28).

Conclusions

The use of labeled NCN pincer ligands suggested that the transmetalation of [Li(NCN)] with cyclometalated [PtCl(NCN)] precursors is preceded by a comparatively fast and reversible TCM process between lithiated and platinated metallacycles. Such a TCM reaction does not involve C—H bond activation and therefore follows a distinctly different reaction coordinate than previously analyzed TCM processes. Importantly, in this case the product distribution is most likely determined by steric preferences rather than metal-to-heteroatom bond strength arguments as established previously. A cationic heterodinuclear bisaryl platinum lithium species has been suggested as a key intermediate. Attack of chloride on the platinum center of this intermediate induces a TCM reaction, whereas attack on lithium completes the transmetalation trajectory with formation of the corresponding bisaryl platinum(II) complex and LiCl. Investigations towards the stabilization and characterization of the proposed intermediate of this novel TCM process are currently in progress.

Hydrogenation of carbon dioxide catalyzed by ruthenium trimethylphosphine complexes — Effect of gas pressure and additives on rate in the liquid phase

Colin A. Thomas, R. Jason Bonilla, Yong Huang, and Philip G. Jessop

Abstract: Kinetic and mechanistic studies of CO_2 hydrogenation were performed in liquid triethylamine and at subcritical CO_2 pressures to avoid complications from phase behaviour that are observed under supercritical conditions. Kinetic measurements of the hydrogenation of CO_2 to formic acid, catalyzed by $RuCl(O_2CMe)(PMe_3)_4$, support a CO_2 insertion mechanism. The reaction is first-order in both H_2 and CO_2 under most conditions. The rate is strongly dependent on the choice of additive, with methanol giving the greatest rates. Because only trace amounts of methanol are needed, the effect of the additive is believed to involve direct interactions with the catalyst rather than changes in the physical properties of the reaction medium. The optimized rates exceed 3500 h^{-1}. Addition of an inert gas affects the rate of the reaction, probably via the phenomenon of gas expansion of the liquid phase.

Key words: carbon dioxide, homogeneous catalysis, hydrogenation, formic acid, expanded liquids.

Résumé : On a réalisé des mesures de cinétique et de mécanisme d'hydrogénation du CO_2 en opérant dans la triéthylamine liquide et à des pressions sous critiques de CO_2 pour éviter les complications résultant du comportement de la phase observées dans des conditions supercritiques. Les mesures cinétiques d'hydrogénation du CO_2 dans l'acide formique, catalysée par le $RuCl(O_2CMe)(PMe_3)_4$, supportent le mécanisme impliquant une insertion de CO_2. Dans la plupart des conditions, la réaction est du premier ordre en H_2 ainsi que CO_2. La vitesse dépend grandement du choix d'additif; le méthanol est celui qui donne les vitesses les plus élevées. En raison du fait que des traces de méthanol sont suffisantes, on croit que l'effet de l'additif implique des interactions directes avec le catalyseur plutôt que des changements dans les propriétés physiques du milieu réactionnel. Les vitesses optimisées dépassent 3500 h^{-1}. L'addition d'un gaz inerte affecte la vitesse de la réaction, probablement en raison du phénomène de l'expansion du gaz dans la phase liquide.

Mots clés : bioxyde de carbone, catalyse homogène, hydrogénation, acide formique, expansion des liquides.

[Traduit par la Rédaction]

Introduction

Carbon dioxide is a renewable and inexpensive C_1 carbon source, but the lack of very efficient methods for its reduction has restricted its utility to only a few industrial processes (1–3). In the past few years, there have been a number of studies of homogeneously catalyzed CO_2 hydrogenation to formic acid (eq. [1]) with ever-increasing rates of reaction (4–14). Principal among the breakthroughs have been the development of improved catalysts (primarily Rh and Ru phosphine complexes) and identification of optimal solvents (such as DMSO and supercritical carbon dioxide). Previous studies by one of us (9–11, 15) showed that ruthenium trimethylphosphine complexes, particularly $RuH_2(PMe_3)_4$, were highly active for the hydrogenation of supercritical CO_2. Under such conditions the rate was very high, but was unfortunately a strong function of phase behaviour. All attempts at determining the chemical rate dependence on the concentration of reagents or the partial pressures of the gases were frustrated by the occurrence of phase changes, which altered the rate and therefore obscured the kinetic information. To circumvent this problem, we have reopened the investigation and decided to concentrate on determining the factors that control the rate of the reaction *in liquid triethylamine*. The goals of this study are to determine the mechanism of the reaction, to find the reasons for the rapid rate, to explore the role of additives such as methanol, and to optimize the liquid phase reaction. This note describes our early findings.

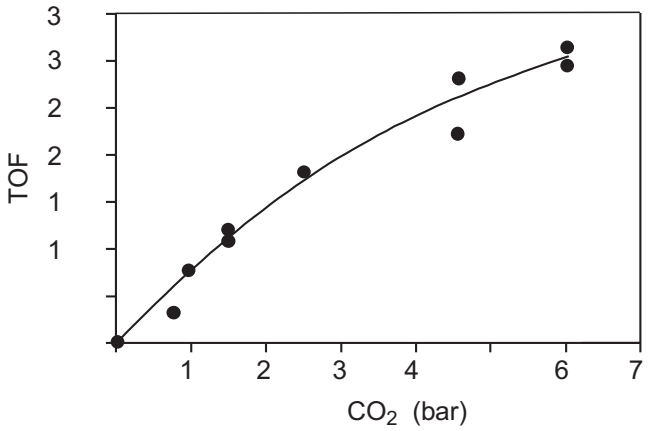
Fig. 1. The dependence of the rate of CO_2 hydrogenation on the pressure of CO_2. Conditions: 50°C, 0.5 h reaction time, 31 mL vessel, 40 bar H_2, 2.5 mmol MeOH, 3.6 mmol NEt_3, 3.0 μmol $RuCl(O_2CMe)(PMe_3)_4$.



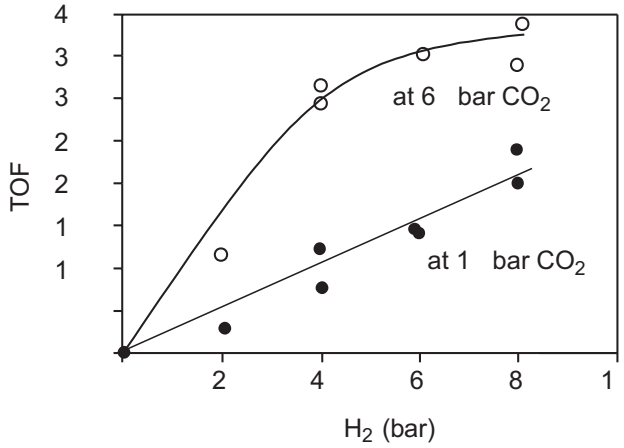


Fig. 2. The dependence of the rate of CO_2 hydrogenation on the pressure of H_2 at 10 and 60 bar CO_2. Conditions: 50°C, 0.5 h reaction time, 31 mL vessel, 2.5 mmol MeOH, 3.6 mmol NEt_3, 3.0 μmol $RuCl(O_2CMe)(PMe_3)_4$.

Results and discussion

The reaction system consists of CO_2 and H_2 gases, liquid triethylamine, an additive, and a catalyst precursor. Although the earlier studies focused on the $RuH_2(PMe_3)_4$ catalyst precursor, we now prefer the related complex $RuCl(O_2CMe)(PMe_3)_4$ because it is equally active (11), more stable, and far easier to prepare. The triethylamine serves as a base, which stabilizes the formic acid product as a 2:1 adduct (eq. [1]). Although additives, usually water in the earlier studies, are known to accelerate the reaction in the supercritical phase, the reason for this is not clear. In the present study, methanol was chosen as the additive, although a number of other additives were tested (vide infra). The rate is reported as the turnover frequency (TOF), meaning the number of turnovers per hour, where turnover number (TON) is mol of formic acid per mol of catalyst. The yield is reported as the formic acid to triethylamine molar ratio (acid to amine ratio, AAR), where the highest possible AAR is 2.0 (based upon eq. [1]) and the highest practically attainable AAR is 1.8.

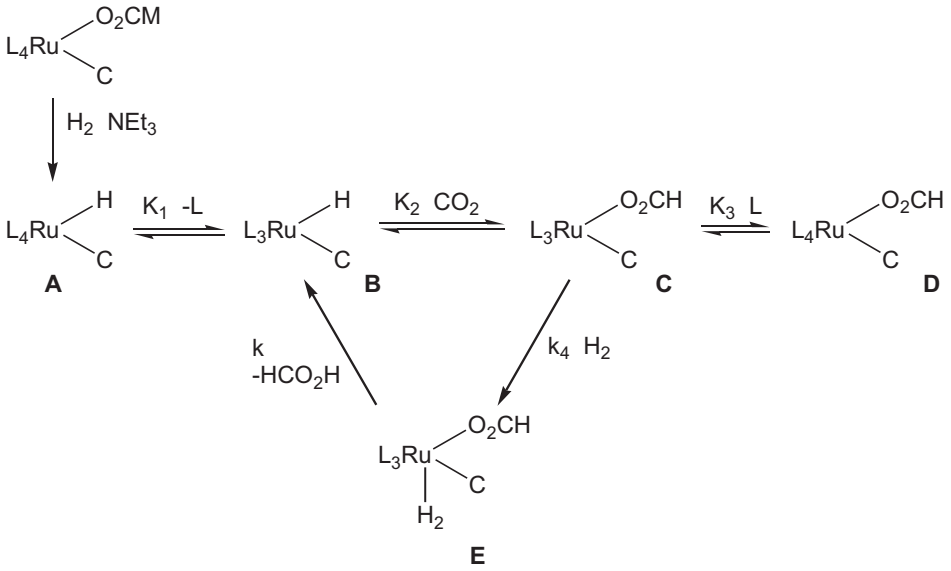
Pressure dependence of rate

We have now found that the rate of the reaction is a function of the CO_2 and the H_2 pressures. At lower pressures of CO_2, the rate is first-order with respect to CO_2, while the order declines somewhat at higher pressure (Fig. 1). The rate dependence on H_2 pressure was measured at two pressures of CO_2 (Fig. 2). At 10 bar of CO_2, the rate is first-order with respect to H_2, while at 60 bar of CO_2 the rate shows saturation kinetics with respect to H_2 (i.e., it is first-order at low H_2 pressure and lower order at higher pressure).

Of the several mechanisms that have been observed in homogeneously catalyzed CO_2 hydrogenation (12, 14), only one (Scheme 1, L = PMe_3) is consistent with a first-order H_2 dependence, a decreasing order dependence on CO_2, and the previously observed (11) CO_2 insertion into the Ru—H bond in $Ru(H)_2(PMe_3)_4$. The first step is the presumed conversion of the acetate group (and possibly also the chloride group) of the catalyst precursor to a hydride ligand; this is considered likely because there are no reasonable mechanisms for CO_2 hydrogenation which do not involve a hydride ligand (12, 14). The mechanism continues with CO_2 insertion into the Ru—H bond, a step which may be preceded by phosphine dissociation. The insertion of CO_2 into the Ru—H bond of $Ru(H)_2(PMe_3)_4$, giving $RuH(O_2CH)(PMe_3)_4$, has been directly observed in an in situ NMR experiment (11). A similar reaction has been observed with $RuH_2(PPh_3)_3$ (16). The hydrogenolysis of the ruthenium formate, giving formic acid, presumably proceeds via a molecular hydrogen complex $RuCl(O_2CH)(H_2)(PMe_3)_3$, a classical dihydride $RuCl(O_2CH)(H)_2(PMe_3)_3$, or by concerted hydrogenolysis with unbound H_2. Of these options, the molecular hydrogen complex should be thermodynamically preferred over the dihydride (11) based upon ligand additivity calculations (17).

If one assumes that the CO_2 insertion and the phosphine dissociation reactions of Scheme 1 are fully reversible and rapid and that the reaction of H_2 with the formate complex is the slow step in the catalytic cycle, then one can predict the following rate law (L = PMe_3, $[Ru_{tot}]$ = initial concentration of the catalyst precursor (for derivation see *Appendix*)):

$$[2] \quad \frac{d\,HCO_2H}{dt} = \frac{k_4K_2\,H_2\;CO_2\;Ru_{tot}}{\left(\frac{L}{K_1} + 1 + K_2\,CO_2 + K_2K_3\,CO_2\;L\right)}$$



which simplifies, at very low [L], to:

$$[3] \quad \frac{d\,HCO_2H}{dt} = \frac{k_4K_2\,H_2\;CO_2\;Ru_{tot}}{1 + K_2\,CO_2}$$

This rate law predicts that the rate will be first-order with respect to $[H_2]$ and will show saturation kinetics with respect to $[CO_2]$, as observed (here we are assuming that the concentrations of the gases in the liquid phase are proportional to their pressures in the gas phase). This rate law does not, however, explain the decline in the order with respect to H_2 at high H_2 and CO_2 pressures. A satisfactory explanation for that observation has not yet been found. The rate law also does not explain why, in the earlier studies, a small excess of

Scheme 1.

PMe_3 failed to slow down the reaction (11). Our further studies will explore these questions.

Musashi and Sakaki (18) have completed ab initio calculations for the reaction catalyzed by $RuH_2(PH_3)_4$. While this is not exactly the same as the catalyst used in the present study, it can be considered to be roughly analogous to species A in Scheme 1. They found that for the CO_2 insertion step, the path with phosphine dissociation was more energetically demanding (30.5 kcal mol^{-1} relative to $RuH_2(PH_3)_4$) than the path without phosphine dissociation (26.7 kcal mol^{-1}). However, for the hydrogenolysis step, the path with phosphine dissociation (i.e., via $RuH(O_2CH)(\eta^2\text{-}H_2)(PH_3)_3$) was less energetically demanding than the path without phosphine dissociation (reductive elimination of HCO_2H). Most importantly, they found that the hydrogenolysis takes place via a six-membered ring transition state (structure F below), not the four-membered ring that was anticipated (structure G). With or without phosphine dissociation, they predicted that the rate-determining step would be the CO_2 insertion, which would result in the reaction being first order in CO_2 and zero-order in H_2. The contradiction with the experimentally observed results could be the slight difference in the catalyst or the fact that the liquid phase conditions have a low H_2 concentration, which could cause the hydrogenolysis to become rate limiting.

Kinetic studies of CO_2 hydrogenation by other homogeneous catalysts have been reported. The first such study used $PdCl_2$ as the catalyst under rather extreme conditions (240°C) in aqueous KOH solution (19). The rate was zero-order with respect to CO_2 pressure and exhibited saturation kinetics with respect to H_2. The mechanism was proposed to be hydrogenation of HCO_3^- anion, with rate-limiting binding of that ion to the active catalyst. Taquikhan et al. (20) observed that the reaction catalyzed by $K[Ru(EDTA\text{-}H)Cl]\cdot 2H_2O$ in water was first-order in both H_2 and CO_2 (EDTA-H refers to deprotonated EDTA). They proposed a mechanism involving abnormal CO_2 insertion into a Ru—H bond, giving a metallocarboxylic acid; such a step has no confirmed literature precedent (12). Tsai and Nicholas (5) found that the reaction catalyzed by $[Rh(NBD)(PMe_2Ph)_3]BF_4$ was also first-order in both H_2 and CO_2. Their proposed mechanism involved H_2 oxidative addition to $[Rh(solvent)(PMe_2Ph)_3]^+$, CO_2 insertion, and reductive elimination of HCO_2H. Such a reductive elimination pathway, although feasible for Rh, is likely to be energetically unfavourable for Ru (18). Leitner's group (6–8, 13, 21–25) has extensively studied Rh catalysts for this reaction in a variety of solvents. Their kinetic study using Rh(hfacac)(dppp) (where hfacac = hexafluoroacetylacetonate and dppp = 1,3-bis(diphenylphosphino)propane) in DMSO–NEt_3 showed that the reaction is nearly first-order in CO_2 and has saturation kinetics with respect to H_2 pressure (25). With assistance from ab initio calculations, they proposed a mechanism of initial hydrogenolysis of the catalyst precursor to give the active catalyst RhH(dppp), followed by CO_2 insertion (giving $Rh(O_2CH)$(dppp)), H_2 coordination (giving $Rh(O_2CH)(H_2)$(dppp)), and then hydrogenolysis. The rate-limiting step was proposed to be the product-eliminating hydrogenolysis. The Leitner mechanism is the closest of those described in the literature to the mechanism proposed in Scheme 1; it is therefore noteworthy that H_2 saturation kinetics were observed in both Leitner's system and our own.

Gas expansion of the liquid phase

At high pressures of CO_2 (above ca. 40 bar), the phenomenon of gas expansion of liquids takes place. In this phenomenon, a gas (either CO_2 or another gas commonly used

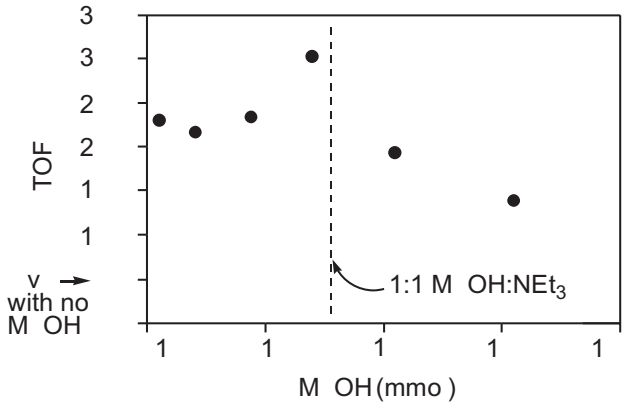
© 2001 NRC Canada

Table 1. Effect of added inert gas on the rate of hydrogenation of CO_2 in the liquid phase.[a]

Added gas (bar)	AAR	TON	TOF (h^{-1})
None	0.32	390	770
Ethane (40)	0.072	79	160
Fluoroform (40)	0.40	455	910
Fluoroform (50)	0.40	450	900

[a]Conditions: 50°C, 0.5 h reaction time, 31 mL vessel, 40 bar H_2, 10 bar CO_2, 2.5 mmol MeOH, 3.6 mmol NEt_3, 3.0 μmol $RuCl(O_2CMe)(PMe_3)_4$.

as a SCF) dissolves in a liquid to such an extent that the liquid phase increases substantially in volume (26). The increase in volume, which can be over 10-fold, is accompanied by many changes in the physical properties of the liquid phase, including its dielectric constant (27), viscosity (28), diffusion rates (29), and its ability to dissolve hydrogen (30). Therefore, the higher pressures of CO_2 in the present study could result not only in the expected increase in [CO_2] in the liquid phase, but also in many other changes, any of which could affect the rate of the reaction in the liquid phase. We speculated in an earlier paper that this may play a role in the reaction (11), but evidence of this was not obtained.



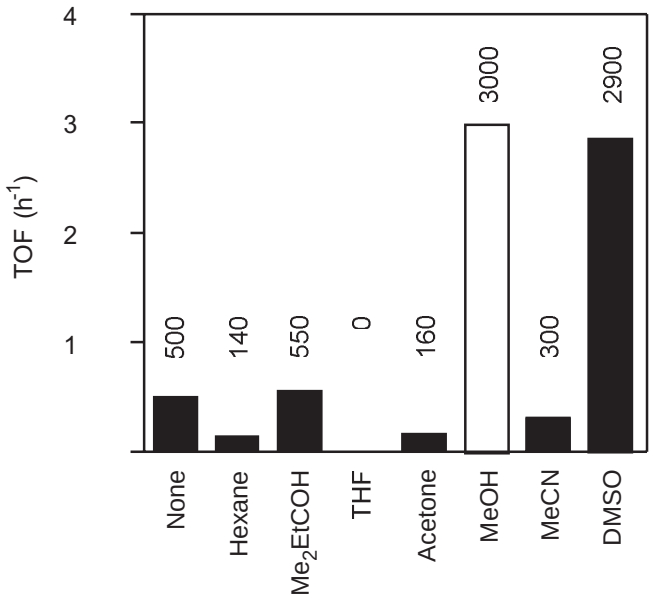
We have now evaluated the effect of this phenomenon by using inert gases (i.e., other than CO_2) to expand the liquid phase. Adding an inert gas in addition to the CO_2 and H_2 indeed changes the rate of the reaction. With H_2 and CO_2 pressures roughly constant, adding 40 bar of ethane (T_c = 32°C, P_c = 49 bar) causes the rate to drop greatly, but adding 40 or 50 bar of fluoroform (CHF_3, T_c = 26°C, P_c = 48 bar) causes the rate to rise slightly (demonstrated with multiple experiments, typical results shown in Table 1). Because ethane and fluoroform are very similar in their critical parameters but differ primarily in their dipole moments, one could speculate that the contrasting rates with these two gases are a result of their differing polarity; ethane renders the liquid phase less polar, while fluoroform does not. A similar decrease in rate is observed if liquid hexane is added instead of ethane, further evidence that a low polarity reaction medium is detrimental to the rate.

The role of the additive

The role of the methanol additive has not been satisfactorily explained, and [MeOH] is not shown in the above mechanism or rate law. To further explore this question, we determined the dependence of the rate of reaction on the concentration of methanol (Fig. 3). The rate in the absence of any added methanol was 500 h^{-1}. Poor reproducibility is encountered at very low [MeOH], but it can be clearly seen that rate is improved by the addition of methanol. With the addition of any amount of methanol from 0.124 to 1 mmol (41–333 equiv of methanol per Ru atom) the rate was approximately 2300 h^{-1}, a significant increase over that without methanol. The observation that only a trace of alcohol or water is required to increase the rate of CO_2 hydrogenation has been observed previously for other catalysts such as $Pd(dpppe)_2$ (4) and $[Rh(NBD)(PMe_2Ph)_3]BF_4$ (5).

Possible roles for the methanol additive are: (*i*) to raise the dielectric constant of the liquid phase; (*ii*) to bind to and therefore stabilize the 16 e complexes in the mechanism (18); (*iii*) to bind to the $RuHCl(PMe_3)_3$ intermediate and facilitate CO_2 insertion through secondary interactions (5); (*iv*) to provide a proton source during the preheating time to facilitate the conversion of the catalyst precursor to the active catalyst; or (*v*) to help solubilize the complex in the triethylamine. The fact that only trace amounts of methanol were needed to enhance the rate suggests that it is not a true solvent effect. The amount of methanol (3 mol% in NEt_3) was too small to have any significant effect on the dielectric constant or other physical properties of the liquid phase, or on the ability of the triethylamine to dissolve the catalyst. At these very small amounts, the only likely role of the additive is to interact with the catalyst in some manner.

Fig. 3. The dependence of the rate of CO_2 hydrogenation on the amount of MeOH additive. Conditions: 50°C, 0.5 h reaction time, 31 mL vessel, 60 bar CO_2, 40 bar H_2, 3.6 mmol NEt_3, 3.0 μmol $RuCl(O_2CMe)(PMe_3)_4$.



Increasing the amount of methanol to approximately a 1:1 mol ratio with the triethylamine causes a further increase in the rate to 3100 h^{-1}. An even greater amount of methanol causes a decline in the rate, which suggests that bulk methanol is a poor solvent, relative to triethylamine containing trace methanol, in which to perform these hydrogenations. This parallels the earlier observation (11) that bulk methanol as a solvent is inferior to supercritical CO_2 with methanol and triethylamine dissolved therein.

The result of a comparison of different additives (Fig. 4) shows that the identity and not so much the amount of the additive affects the reaction rate most significantly. The most effective additive, methanol, is protic, polar, sterically unencumbered, and mildly coordinating. The use of a sterically bulky alcohol, *t*-amyl alcohol instead of methanol, causes the rate to drop significantly. This supports the notion that binding of the alcohol to the metal centre is necessary, although the low dielectric constant of *t*-amyl alcohol (5.78 (31)) may also have contributed to the low rate. Aprotic polar additives had mixed results. DMSO nearly duplicated the high rate seen with methanol, while MeCN and acetone were ineffective. Carefully dried DMSO gave the same result as undried DMSO. Aprotic solvents that are less polar and coordinating (e.g., THF and hexane) caused the rate to decrease relative to the rate without an additive. We have been unable to discern a trend in these results; although, the two most effective additives both have high dielectric constants. Similarly polar solvents such as MeCN are ineffective. The rate does not correlate with the coordinating ability of the additive; MeCN and DMSO are known to be able to

Fig. 4. The rate of CO_2 hydrogenation in the presence of various additives, presented in order of increasing dielectric constant. Conditions: 50°C, 0.5 h reaction time, 31 mL vessel, 60 bar CO_2, 40 bar H_2, 3.6 mmol NEt_3, 2.6 mmol additive, 3.0 μmol $RuCl(O_2CMe)(PMe_3)_4$.

coordinate to vacant sites on Ru complexes, but only one of these additives accelerates the reaction. The rate also does not correlate with the miscibility of the additive with triethylamine; methanol is miscible and DMSO is not. Further investigation of the role of the additive is underway.

Experimental

Safety warning

Operators of high-pressure equipment such as that required for these experiments should take proper precautions, including but not limited to the use of blast shields and pressure relief mechanisms, to minimize the risk of personal injury.

General

All liquid reagents and solvents were degassed before use. The gases H_2 (99.99% purity, Praxair) and C_2H_6 (99.995% purity, Nellcor Puritan Bennett) were used as received, but CHF_3 (99.995% purity, AGA), and CO_2 gas (99.9999% purity, SFC/SFE grade product of Air Products) were passed through an oxygen trap before use. Liquid additives, deuterated solvents, and triethylamine were degassed by freeze–vacuum–thaw cycles and then stored under nitrogen. $RuCl(O_2CMe)(PMe_3)_4$ was prepared as described in the literature (32). Acetone was dried with $MgSO_4$ and then freshly activated molecular sieves — in addition to being degassed. Similarly treated DMSO gave the same result as DMSO that had not been dried.

The high-pressure equipment, similar to that published previously (11), consists of stainless steel 31 mL reaction vessels, a Jasco PU-980 HPLC pump fitted with a liquid CO_2 reservoir cooled by an Isotemp 1016S coolant circulator, and a constant-temperature water bath, underneath which is a magnetic stir plate known to be able to couple to a stir bar inside the reaction vessels. The vessels are equipped with burst disks (345 bar) and a pressure transducer.

CO_2 hydrogenation method

Standard reaction conditions are described below. Parameters were varied accordingly from those conditions. Reaction time was measured from the introduction of CO_2 to the time that the vessel was placed in the cooling bath; this leads to a minor ambiguity in the actual reaction stopping time (<2 min).

Triethylamine (3.6 mmol), methanol (2.5 mmol), a stir bar, and the catalyst precursor $RuCl(O_2CMe)(PMe_3)_4$ (3 μmol) were introduced into a pressure vessel in a nitrogen filled glove box and the vessel was sealed. Upon removal from the glove box, the vessel was flushed with 15 bar H_2 three times after which 95% of the final pressure of H_2 was added to the vessel. The vessel was placed into a 50°C water bath and stirring was begun. The vessel was allowed to equilibrate to this temperature for 1 h. Further H_2 was added until the required pressure of 40 bar was attained, and CO_2 was added as rapidly as possible to a total pressure of 100 bar (CO_2 pressure was assumed to be the difference between the total pressure and the H_2 pressure). After 30 min reaction time, the vessel was half submerged in an ice water bath. Once the pressure ceased to decline (typically after 10 min), the vessel was placed in a dry ice–acetone bath. After the pressure in the vessel dropped below the original pressure of H_2, the pressure was slowly vented. The vessel was then allowed to return to room temperature venting the CO_2 as it sublimed. 250 μL (2.35 mmol) of toluene was added to the vessel contents as an internal reference. A sample of the vessel contents was dissolved in CD_3OD and analysed by ^1H NMR spectroscopy (300 MHz). The following parameters were determined from the integration: the formic acid to triethylamine molar ratio (acid to amine ratio, AAR), the yield of formic acid, the turnover number, and the turnover frequency.

Experiments with other gases in addition to CO_2 and H_2 had the gases added in the following order: H_2, CO_2, and then the extra gas.

Conclusions

This liquid phase study shows that meaningful kinetic data can be obtained without the interference of phase changes when subcritical CO_2 pressures are used. The results are consistent with the CO_2 insertion mechanism. One can optimize the reaction by adjusting the gas partial pressures to obtain rates of reaction over 3500 h^{-1}, even without

© 2001 NRC Canada

resorting to supercritical pressures. If these results can be extrapolated to the hydrogenation of supercritical CO_2, then one can conclude that the rapid rate that was observed in earlier studies in the supercritical phase was a direct result of *both* the high CO_2 and the high H_2 concentrations.

Appendix

The rate law was derived from the mechanism in Scheme 1 by making the following assumptions: (*i*) that k_5 is faster than k_4; (*ii*) that all the catalyst precursor was converted to the hydrido or formato complexes shown in the scheme; and (*iii*) that K_1, K_2, and K_3 are able to maintain equilibrium.

$$[4] \qquad \text{rat} = \frac{d\,HCO_2H}{dt} = k\,E = k_4\,H_2\,C$$

Define $[Ru_{tot}] = [A] + [B] + [C] + [D]$
From the equilibrium equations.

$$[5] \qquad B = \frac{C}{K_2\,CO_2} \qquad D = K_3\,C\,L \qquad A = \frac{B\,L}{K_1} = \frac{C\,L}{K_1K_2\,CO_2}$$

$$Ru_{tot} = \frac{C\,L}{K_1K_2\,CO_2} + \frac{C}{K_2\,CO_2} + C + K_3\,C\,L$$

Solve for [C] and plug into eq. [4]:

$$[6] \qquad \frac{d\,HCO_2H}{dt} = \frac{k_4\,H_2\,Ru_{tot}}{\left(\frac{L}{K_1K_2\,CO_2} + \frac{1}{K_2\,CO_2} + 1 + K_3\,L\right)}$$

Simplify by multiplying top and bottom by $K_2[CO_2]$:

$$[7] \qquad \frac{d\,HCO_2H}{dt} = \frac{k_4K_2\,H_2\,CO_2\,Ru_{tot}}{\left(\frac{L}{K_1} + 1 + K_2\,CO_2 + K_2K_3\,L\,CO_2\right)}$$

Asymmetric hydroformylation of styrene catalyzed by platinum complexes of chiral diphosphites with atropisomeric terminal moieties

J. Bakos, S. Cserépi-Szűcs, Á. Gömöry, C. Hegedüs, L. Markó, and Á. Szöllősy

Abstract: To study the nature of steric and electronic effects of diphosphites, a novel diphosphite was synthesized and tested with regard of its catalytic performance in the hydroformylation of styrene catalyzed by platinum complexes. The novel ligand **3** was prepared by the reaction of enantiomerically pure pentane-2,4-diol with (*S*)-2-chloro-5,5′,6,6′,7,7′,8,8′-octahydro-dinaphtho[2,1-*d*:1′,2′-*f*][1,3,2]dioxaphosphepine based on H_8-BINOL (H_8-BINOL = 5,5′,6,6′,7,7′,8,8′-octahydro-1,1′-bi-2-naphthol). For a comparative study, the BINOL (1,1′-bi-2-naphthol) based analogue **4** of **3** has also been synthesized. The highest chemoselectivity to aldehyde (71%) and regioselectivity to branched aldehyde (85%) with an enantiomer excess (ee) of 86% was obtained with the platinum(II)–$SnCl_2$ catalytic system associated with (2*S*,4*S*)-bis(*S*)-**3**.

Key words: asymmetric hydroformylation, chirality, homogeneous catalysis, P ligands, platinum.

Résumé : Dans le but d'étudier la nature des effets stériques et électroniques des diphosphites, on a synthétisé un nouveau diphosphite et on a évalué sa performance catalytique dans l'hydroformylation du styrène catalysée par des complexes de platine. On a préparé le nouveau ligand **3** par réaction du pentane-2,4-diol énantiomériquement pur avec de la (*S*)-2-chloro-5,5′,6,6′,7,7′,8,8′-octahydrodinaphto[2,1-*d*:1′,2′-*f*][1,3,2]dioxaphosphépine préparé à partir de H_8-BINOL (H_8-BINOL = 5,5′,6,6′,7,7′,8,8′-octahydro-1,1′-binapht-2-ol). Pour fins d'études comparatives, on a aussi synthétisé l'analogue **4** du composé **3**, préparé à partir du BINOL (1,1′-binapht-2-ol). Les niveaux les plus élevés de chimiosélectivité pour conduire à l'aldéhyde (71%) et de régiosélectivité pour conduire à l'aldéhyde ramifié (85%) avec un ee de 86% ont été obtenus avec un système platine(II)-$SnCl_2$ associé au (2*S*,4*S*)-bis(*S*)-**3**.

Mots clés : hydroformylation asymétrique, chiralité, catalyse homogène, ligands phosphorés, platine.

[Traduit par la Rédaction]

Introduction

Homogeneously catalyzed asymmetric hydroformylation represents a rapidly growing field because of its industrial potential and academic challenge. Applying this synthetic method aldehydes of great value can be obtained, which are attractive building blocks in organic synthesis (1). High activity and stability of the catalyst, high enantiomeric excess (ee), and an almost exclusive chemoselectivity to aldehydes and regioselectivity to branched aldehydes are required for an efficient catalytic system. These challenges prompted us to continue our research in the field of asymmetric hydroformylation by matching the structure of the ligand (for recent reviews, see ref. 2).

Although the investigation of the phosphine-modified rhodium (3) and platinum (4) systems is still overwhelming, the importance of applying phosphite (5) and phosphine-phosphite (6) modified systems is increasing. For example, rhodum complexes of the chiral phosphinephosphite ligand, (*R*)-2-(diphenylphosphino)-1,1′-binaphthalene-2′-yl-(*S*)-1,1′-binaphthalene-2,2′-diyl phosphite ((*R*,*S*)-BINAPHOS) catalyze asymmetric hydroformylation of styrene with an outstanding level of regio- and enantio-control (94% ee, iso:normal = 88:12). The catalyst system was also effective for a variety of other alkenes.

Surprisingly, however, there have been only a few reports on the application of bisphosphite-Pt(II)–$SnCl_2$ complexes in asymmetric hydroformylation (7). We have already reported that in the asymmetric hydroformylation of styrene by Pt-complexes containing chiral diphosphites with terminal atropisomeric substituents, the handiness of the product is dictated by the configuration of the stereogenic carbons of

the chiral backbone (7). Thus, for example, by using (2*S*,4*S*)-bis[((*S*)-dinaphtho[2,1-*d*:1′,2′-*f*][1,3,2]dioxaphosphepin-2-yl)oxy]pentane **4** (matched structure) as the ligand remarkably high catalytic activity and enantioselectivity (91% ee in CH_2Cl_2 at 17°C) were achieved, however, the hydrogenation activity of this heterobimetallic Pt–Sn catalytic system was still rather high (7*a*). In contrast to this, the use of the diastereomeric pair of **4**, (2*R*,4*R*)-bis(*S*) (mismatched constellation), leads to the opposite prevailing configuration of the product with a considerably lower asymmetric induction.

We have established that phosphites with enhanced π-acceptor ability give higher hydrogenation activity. The best chemoselectivity for hydroformylation was achieved when bisphosphites, based on the pentanediol backbone associated with dioxaphosphorinane terminal units, were used in the hydroformylation of styrene catalyzed by platinum complexes (7*b*). Based on these findings, we set up our hypothesis that retaining the appropriate structure of **4** and decreasing the π-acceptor ability of the terminal groups could improve chemoselectivity and regioselectivity and simultaneously retain high enantioselectivity. With this consideration in mind, we synthesized a new diphosphite **3** and the previously described diphosphite **4** (7*a*).

This paper describes the preparation and the catalytic properties of the chiral bisphosphites **3** and **4** in asymmetric hydroformylation of styrene. Both diphosphites **3** and **4** bear two methyl groups on the backbone and two atropisomeric 1,1′-bitetralin or 1,1′-binaphthyl frameworks on the phosphorus atoms.

Experimental

General

All reaction were carried out in oven-dried glasswork using Schlenk techniques under an atmosphere of argon. Benzene and toluene were distilled from sodium–benzophenone. Triethylamine and dichloromethane were distilled from CaH_2 and stored under an atmosphere of argon. Infrared (IR) spectra were recorded on a Specord IR-75A spectrometer. ^{31}P (202.45 MHz), ^{13}C (125.77 MHz), and ^{1}H (500.13 MHz) NMR spectra were obtained on a Bruker DRX-500 or on Varian Unity 300 spectrometer (121 MHz for ^{31}P, 75.4 MHz for ^{13}C, and 300.15 MHz for ^{1}H). Optical rotations were measured on Schmidt Haensch 21245. Gas chromatographic analyses were run on a Hewlett–Packard 5830A gas chromatograph (SPB-1 30 m column, film thickness 0.1 μm, carrier gas 2 mL min^{-1}). Mass spectrometric measurements were performed using a PE SCIEX API 2000 triple quadrupole instrument. Electrospray ionization (ES) was used and positive ions were detected. Samples were dissolved in acetonitrile. LiI was added to the solution to obtain abundant adduct ion with the molecule, because protonoted molecular ions were observed only in very low abundance.

Mass spectrum of (*S*)-**2** was obtained using a VG ZAB2-SEQ instrument with electron impact ionization (EI). Electron energy was 70 eV. The sample was introduced via a direct inlet system.

Materials and methods

Enantiomerically pure pentane-2,4-diol was synthesized by asymmetric hydrogenation of 2,4-pentanedione over Raney nickel catalyst modified with the corresponding enantiomer of tartaric acid and NaBr (TA-NaBr-MRNi) (8). 2,2′-Dihydroxy-1,1′-binaphthyl (BINOL) was obtained from Merck–Schuchardt. 2,2′-Dihydroxy-5,5′,6,6′,7,7′,8,8′-octahydro-1,1′-binaphthyl (H_8-BINOL) was prepared according to the literature procedure (9).

Catalytic experiments

In a typical experiment, $Pt(PhCN)_2Cl_2$ (0.0125 mmol), ligand (0.014 mmol), $SnCl_2$ (0.0125 mmol), CH_2Cl_2 (2 mL), and then styrene (25 mmol) (for a substrate:catalyst mol ratio of 5000:1, 62.5 mmol of styrene was used) and decane (5 mmol) (as an internal standard) were placed into a Schlenk-tube under argon. A stainless-steel autoclave (20 mL) was filled with this solution and then purged with syn gas ($CO:H_2$ (1:1)) and pressurized to the appropriate initial pressure with this gas mixture. At the end of the reaction the autoclave was cooled and depressurized. The reaction mixture was directly vacuum distilled to remove the catalyst. The reaction mixture and the distilled products were analyzed by gas chromatography. The enantiomeric excess of the aldehyde was determined by GC analysis of the distilled product (Hewlett–Packard HP 4890 gas chromatograph, split–splitless injector, β-DEX 225, 30 m, internal diameter 0.25 mm, film thickness 0.25 μm, carrier gas: 100 kPa nitrogen, FID detector; the retention times of the enantiomers are 30.5 min (*R*), 32.1 min (*S*)). The configuration of the prevailing enantiomer in the product was determined by the sign of optical rotation of the corresponding aldehyde. Conversions and composition of the reaction mixture (**5**:**6**:**7**, branched:linear:hydrogenated) were determined by GC (SPB-1) using decane as an internal standard.

Preparation of (*S*)-2-chloro-5,5′,6,6′,7,7′,8,8′-octahydro-1,1′-dinaphtho[2,1-*d*:1′,2′-*f*][1,3,2]dioxaphosphepine ((*S*)-2)

(*S*)-H_8-BINOL **1** (4.2 g, 14 28 mmol) was dried azeotropically with toluene (3 × 20 mL), and then the solvent was evaporated. The residue was dissolved in dry THF (50 mL) and added slowly (30 min) to a solution of PCl_3 (1.6 mL, 18.6 mmol) and Et_3N (4.4 mL, 31.4 mmol) in THF (20 mL) at 0°C. The reaction mixture was stirred overnight at room temperature. The formed amine salts were removed by filtration. Evaporation to dryness gave the pale yellow phosphorochloridite, which was washed with ether (2 × 30 mL) to give the product as a white solid (4.92 g, 95.9%). This product was used without any further purification. mp 109–111°C, $[\alpha]_D^{20}$ = +391.52° (*c* = 1.18, CH_2Cl_2). EI-MS *m*/*z*: 358 (M^+). ^{1}H NMR ($CDCl_3$, 300.15 MHz) δ: 1.48–1.64 (m, 2H, CH_2), 1.70–1.85 (m, 6H, CH_2), 2.26 (dt, *J* = 16.6, 6.4 Hz, 2H, CH_2), 2.58–2.70 (m, 2H, CH_2), 2.76–2.88 (m, 4H, CH_2), 6.91 and 7.01 (d, *J* = 8.3 Hz, 2H, H_3, $H_{3'}$), 7.09 (d, *J* = 8.3 Hz, 2H, H_4, $H_{4'}$). ^{13}C NMR ($CDCl_3$, 75.42 MHz) δ: 23.00 (s, CH_2), 23.06 (s, CH_2), 23.15 (s, CH_2), 23.24 (s, CH_2), 28.5 (s, CH_2), 29.8 (s, CH_2), 29.9 (s, CH_2), 119.42 (d, $J_{P,C}$ = 15.1 Hz), 119.42 (d, $J_{P,C}$ = 18.1 Hz), 128.3 (d, $J_{P,C}$ = 3.0 Hz), 129.8 (d, $J_{P,C}$ = 5.0 Hz), 129.9 (s), 130.5 (s), 135.7 (d, $J_{P,C}$ = 2.0 Hz), 136.7 (d, $J_{P,C}$ = 2.0 Hz) 139.5 (d, $J_{P,C}$ = 2.0 Hz), 145.9 (d, $J_{P,C}$ = 5.0 Hz) 147.4 (d,

$J_{P,C}$ = 3.0 Hz). $^{31}P\{^1H\}$ NMR ($CDCl_3$, 121.42 MHz) δ: 171.5 (s).

Preparation of (2*S*,4*S*)-2,4-bis[(*S*)-5,5′,6,6′,7,7′,8,8′-octahydro-dinaphtho[2,1-*d*:1′,2′-*f*][1,3,2]dioxaphosphepin-2-yloxy]-pentane ((2*S*,4*S*)-bis(*S*)-3)

To a solution of **2** (2.00 g, 5.57 mmol) and Et_3N (2.25 mL, 16.0 mmol) in toluene (20 mL) was added slowly a solution of optically pure (*S*,*S*)-pentane-2,4-diol (281.0 mg, 2.7 mmol, azeotropically dried with toluene, 3 × 3 mL) in toluene (25 mL) at 0°C. The reaction mixture was stirred for 30 min at 0°C and then at room temperature overnight. The formed hydrochloride salt was removed by filtration. Evaporation to dryness gave a pale yellow foam, which was washed with ether (2 × 30 mL) to give the product as a white solid (1.92 g, 95.0%). mp 158–160°C, $[\alpha]_D^{20}$ = +269.23° (*c* = 1.04, CH_2Cl_2). EI-MS *m*/*z*: 755 ($[M + Li]^+$). ^1H NMR ($CDCl_3$, 500.13 MHz) δ: 1.38 (d, *J* = 6.3 Hz, 6H, CH_3), 1.56–1.65 (m, 4H, CH_2), 1.76 (m, 2H, CH_2), 1.79–1.86 (m, 12H, CH_2), 2.29–2.36 (m, 4H, CH_2), 2.66–2.74 (m, 4H, CH_2), 2.77–2.89 (m, 8H, CH_2), 4.65 (m, 2H, CH) 6.88 (d, *J* = 8.2 Hz, 2H, CH), 7.05 (d, *J* = 8.2 Hz, 2H, CH) 7.06 (d, *J* = 8.2 Hz, 2H, CH), 7.09 (d, *J* = 8.2 Hz, 2H, CH). ^{13}C NMR ($CDCl_3$, 125.75 MHz) δ: 22.91 (s), 22.95 (s), 23.10 (s), 23.16 (s), 23.76 (s), 28.21 (s), 29.61 (s), 29.65 (s), 46.60 (m, CH_2), 69.00 (t, $J_{P,C}$ = 12.1 Hz, CH), 119.20 (s), 119.60 (s), 125.70 (s), 128.50 (s), 128.60 (s), 129.3 (s), 129.40 (s), 129.70 (s), 129.90 (s), 131.20 (s), 134.10 (s), 134.90 (s), 137.50 (s), 137.90 (s), 138.60 (s), 146.40 (s) 146.90 (s). $^{31}P\{^1H\}$ NMR ($CDCl_3$, 202.45 MHz) δ: 146.2 (s).

(*S*)-2-chloro-dinaphhtho[2,1-*d*:1′,2′-*f*][1,3,2]dioxaphosphepine

This compound was prepared according to the literature procedure (10). mp 113–115°C, $[\alpha]_D^{20}$ = +709.25° (*c* = 1.135, CH_2Cl_2).

(2*S*,4*S*)-2,4-bis[(*S*)-dinaphtho[2,1-d:1′,2′-*f*][1,3,2]dioxaphosphepin-2-yloxy]-pentane ((2*S*,4*S*)-bis(*S*)-4)

To a solution of (*S*)-2-chloro-dinaphhtho[2,1-*d*:1′,2′-*f*][1,3,2]-dioxaphosphepine (5.3 g, 15.11 mmol) and Et_3N (6.3 mL, 16.0 mmol) in toluene (10 mL) was added slowly a solution of optically pure (*S*,*S*)-pentane-2,4-diol (0.755 g, 7.25 mmol, azeotropically dried with toluene, 3 × 8 mL) in toluene (30 mL) at 0°C. The reaction mixture was stirred for 30 min at 0°C and then at room temperature overnight. The formed hydrochloride salt was removed by filtration. Evaporation to dryness gave a pale yellow residue, which was washed with ether (2 × 20 mL) to give the product as a white solid (5.2 g, 97.9%). mp 100–102°C, $[\alpha]_D^{20}$ = +509.43° (*c* = 1.06, CH_2Cl_2). EI-MS *m*/*z*: 739 ($[M + Li]^+$). ^1H NMR ($CDCl_3$, 500.13 MHz) δ: 1.43 (d, *J* = 6.3 Hz, 6H, CH_3), 1.78 (m, 2H, CH_2), 4.80 (m, 2H, CH), 7.19–7.34 (m, 4H, CH), 7.41–7.50 (m, 10H, CH), 7.60 (d, *J* = 8.8 Hz, 2H, CH), 7.94–8.01 (m, 8H, CH). ^{13}C NMR ($CDCl_3$, 125.75 MHz) δ: 23.85 (s, CH_3), 46.50 (m, CH_2), 69.71 (t, $J_{P,C}$ = 10.9 Hz, CH), 122.30 (s), 122.40 (s), 123.40 (s), 124.80 (s), 125.20 (s), 125.3 (s), 125.70 (s), 126.50 (s), 126.60 (s), 127.50 (d, $J_{P,C}$ = 3.6 Hz), 128.70 (s), 128.80 (s), 129.40 (s), 130.10 (s), 130.70 (s), 131.60 (s), 132.00 (s), 133.10 (s), 133.30 (s), 148.00 (s) 148.30 ppm (s). $^{31}P\{^1H\}$ NMR ($CDCl_3$, 202.45 MHz) δ: 153.5 (s).

Results and discussion

H_8-BINOL **1** can be readily derived from BINOL using the protocol of Cram et al. (9). The reaction of racemic H_8-BINOL with PCl_3 in the presence of triethylamine in THF gave phosphorochloridite, (*S*,*R*)-2-chloro-5,5′,6,6′,7,7′,8,8′-octahydro-dinaphtho[2,1-*d*:1′,2′-*f*][1,3,2]dioxaphosphepine ((*S*,*R*)-**2**). The $^{31}P\{^1H\}$ NMR spectrum of the compound showed one absorption at 171.5 ppm, which is in the region expected for a chlorodioxaphosphepine. It is noteworthy that there is a substantial upfield ^{31}P chemical shift relative to the BINOL-based chlorophosphepine (179.0 vs. 171.5 ppm, Δδ = 7.5 ppm) (10). A similar upfield shift was observed when the chemical shift of phosphorochloridite based on 2,2′-bisphenol was compared to the value of that based on 2,2′-bisphenol bearing bulky *tert*-butyl substituents at the *ortho* and *para* positions (180.2 vs. 172.1 ppm) (5*b*).

Two equivalents of the racemic chloro-compound (*S*,*R*)-**2** were reacted with optically pure (2*S*,4*S*)-pentane-2,4-diol in the presence of triethylamine to give a diastereomeric mixture of **3** (Scheme 1). In the $^{31}P\{^1H\}$ NMR spectrum of the product at ambient temperature, six lines are observed with relative intensities and splittings consistent with the expected three diastereomers. An obvious explanation is that a pair of doublets arises from the diastereomer, (2*S*,4*S*)-(*S*,*R*) = (2*S*,4*S*)-(*R*,*S*). The absolute configuration of the diastereomers is given in a shorthand notation as (2*S*,4*S*)-(*R*,*S*), (2*S*,4*S*)-bis(*R*), and (2*S*,4*S*)-bis(*S*). Where (2*S*,4*S*) refer to the absolute configurations of carbon atoms C(2) and C(4) in the pentane-2,4-diol backbone, and (*R*) or (*S*) refer to the configuration of the axial chirality. The 2D homonuclear ^{31}P COSY NMR spectrum of the product confirms the existence of coupling ($^6J_{P,P}$ = 8.8 Hz) between the P atoms (δ 140.9 and 145.7 ppm) six bonds apart (11). Two singlets (δ 146.2 for (2*S*,4*S*)-bis(*S*)-**3** and 141.1 for (2*S*,4*S*)-bis(*R*)-**3**) are attributed to the presence of the other two diastereomers. This was supported by the NMR spectrum of the optically pure diastereomer, (2*S*,4*S*)-bis(*S*)-**3** obtained from (*S*)-**2** and (2*S*,4*S*)-pentane-2,4-diol. In this case the other diastereomers were not detected by $^{31}P\{^1H\}$ NMR, implying that diastereomer **3** was obtained in optically pure form.

The "like" (*S*,*S*,*S*) diastereomers of **3** and **4** give ^{31}P resonances at 146.2 and 153.6 ppm, respectively. The "unlike" (*S*,*S*,*R*) diastereomers of **3** and **4** give signals at 141.1 and 147.1 ppm, respectively. In both cases there are substantial upfield shifts relative to the BINOL based bisphosphite (146.2 to 153.6 ppm, Δδ = 7.4 ppm and 141.6 to 147.1 ppm, Δδ = 6.0 ppm), which might be primarily due to the change of the electronic character of the phosphorus, rather than to an increase of strain of the partially hydrogenated dioxaphosphepine ring.

Phosphites **3** and **4** form phosphite–platinum complexes. For example, treatment of **4** with $PtCl_2(PhCN)_2$ in CD_2Cl_2 resulted in displacement of PhCN by the ligand. The $^{31}P\{^1H\}$ NMR spectrum of $PtCl_2$[(2*S*,4*S*)-bis(*S*)-**4**] consists of a singlet supplemented with *J* ^{195}Pt–^{31}P satellites (δ = 87.5, $J_{Pt,P}$ = 5672 Hz). The phosphorus resonance is 66.1 ppm upfield from that of the free ligand (153.6 ppm). From the magnitude of the coordination shift and the coupling constant ($J_{Pt,P}$) a *cis* P-Pt-P disposition in a square pla-

nar arrangement can be confidently assigned (7). Both diphosphites form eight-membered chelate rings upon coordination of the Pt metal center, and afford only the *cis* complexes without any oligomeric species. Oligomeric platinum complexes of diphospholes, dibenzophospholes, and bisnaphthophospholes have been reported with *trans* P-Pt-P arrangement (4*d* and *e*).

Catalysts were prepared in situ from $PtCl_2(PhCN)_2$ and 1.12 equiv. of ligand in dichloromethane using a 6.25 mM solution of platinum–diphosphite catalyst. It is noteworthy that, in contrast to rhodium systems modified with phosphines or phosphinephosphites, there is no need for an excess of phosphite ligand in the platinum system. Anhydrous $SnCl_2$ was used as a co-catalyst. Addition of $SnCl_2$ is essential for catalytic activity (12). Catalytic reactions were carried out under classical conditions to give a mixture of the branched 2-phenylpropanal **5**, the normal 3-phenylpropanal aldehyde regioisomers **6**, and the hydrogenated ethylbenzene product **7**. Some representative results are given in Table 1.

[1] 

Several studies (2) have shown that regio- and enantioselectivity of platinum-catalyzed asymmetric hydroformylation can be very sensitive to the nature of the solvent. Dichloromethane and toluene, having medium polarity, give the highest reaction rate and the best enantioselectivity and therefore were chosen as the routine solvents. It is interesting to note that the chemoselectivity and the activity of the catalysts are significantly lower in toluene than in dichloromethane. For example, although the highest ee of 94% was obtained at a conversion of 27% in toluene (Table 1, run 5) the enantioselectivity is not constant in time, i.e., after 20 h (run 6) at a conversion of 83% the ee is 88%.

The data show that the in situ platinum catalyst is most effective for hydroformylation of styrene when the reaction is performed at room temperature. As usual, on lowering the temperature enantioselectivity improves at the expense of reaction rate (Table 1, runs 1–4 compared to runs 10–12). At higher temperature the activity of the catalyst increases from 83 to 1200 mol mol^{-1} h^{-1} (runs 4–1, TOF in mol aldehydes

© 2001 NRC Canada

(mol Pt)$^{-1}$ h^{-1} determined at the reaction time indicated in Table 1). In dichloromethane the highest enantioselectivity is obtained (91%, *R*) when ligand **4** is used, but in case of ligand **3** the enantioselectivity is only slightly lower (86%). At the same time, chemoselectivity to hydroformylation (71%) and regioselectivity to branched aldehyde (85%) of the catalyst improved substantially (run 4). Thus, an important feature of this diphosphite system in combination with platinum is the relatively high regioselectivity of the reaction. The branched isomer forms with these ligands in a significantly higher amount than with the usual mono- and ditertiary phosphines (4*e*).

Regioselectivity of the reaction depends largely on the reaction temperature in case of **3**; with decreasing temperature regioselectivity to branched aldehyde increases markedly. This can be explained by the enhanced rate of isomerization of the initially formed Pt-*i*-alkyl complex to the thermodynamically more stable *n*-alkyl complex, which leads to a higher percentage of *n*-aldehyde. It is interesting to note that the regioselectivity is less dependent on temperature in the case of ligand **4.**

We have shown recently that with the platinum phosphite systems the *relative* configuration of the stereogenic elements in the backbone and in the terminal units play crucial roles in the degree of enantioselectivities and the sense of enantioface discrimination. In the case of styrene, the latter is mainly determined by the configuration of the backbone of the ligand. Accordingly, both ligands used in this study gave (*R*)-2-phenylpropanal as the prevailing enantiomer. It is not surprising because **3** and **4** can be considered "like" sytems (2*S*,4*S*)-bis(*S*) and the relative spatial arrangement around the stereogenic elements of the backbone is the same.

When **3,** a partially hydrogenated analogue of **4**, was used as the bisphosphite ligand for the catalyst precursor, the branched:linear ratio of hydroformylation products was found to increase from ~1.5 to 5.7 (i.e., 85:15).

Enhancing the electron-donating ability of the ligand resulted in an increase of chemoselectivity to hydroformylation from 53% with **4** (run 7) to 68% with **3** (run 2) at 60°C. The regioselectivity to branched aldehyde were 59 and 70%, respectively. The increase of the branched:linear ratio with increasing phosphite basicity (ligand **3** vs. ligand **4**) probably results from the different behaviour of branched and linear platinum alkyls toward β-hydrogen elimination. The linear alkyls, the anti-Markovnikov products of the insertion of styrene into the Pt–H bond, are mainly converted to linear aldehyde, while the branched alkyls partially regenerate styrene through enhanced β-hydrogen elimination. Selective β-hydrogen elimination from the branched alkyl metal intermediate was already observed by Lazzaroni et al. (13) for rhodium systems. In our case increasing electrophilicity of the platinum center may result in higher reactivity of the branched alkyl platinum species toward β-hydrogen elimination (14).

Recently, RajanBabu and Ayers (15) studied the electronic effect of the ligands on the enantioselectivity of hydroformylation of vinylarenes using rhodium diphosphinites and found that the introduction of electron-withdrawing aryl groups on the phosphorus increased the enantioselectivity of the catalyst. The mechanistic aspects of the electronic effects on rhodium diphosphine catalyzed hydroformylation were investigated by Casey et al. (16) and van Leeuwen et al. (17).

Similarly, Ir(I)- and Ru(II)-complexes of H_8-BINAP served as more effective catalyst precursors for asymmetric hydrogenation of some substrates, than did the analogous complexes of BINAP (18). Furthermore, the Pd(II) complex of (*R*,*S*)-H_8-BINAPHOS is a more active catalyst compared to that of (*R*,*S*)-BINAPHOS for alternating copolymerization of propene with carbon monoxide. A completely isotactic copolymer was obtained in high optical purity with (*R*,*S*)-H_8-BINAPHOS (19). It is noteworthy that in [Rh{(*S*)-H_8-BINAP}(COD)]ClO_4 the dihedral angle between the two phenyl rings of the bitetralin moiety (18*a*) is markedly larger (80.3°) than that between the two naphthalene rings in [Rh{(*R*)-BINAP}(NBD)]ClO_4 (74.4°) (20). Recently, we have reported the X-ray structure of the complex [$PtCl_2$(2,2′-bis[(4*R*,6*R*)-4,6-dimethyl-1,3,2-dioxaphosphorinan-2-yloxy]-1,1′-binaphtyl)] and that of the free ligand (7*c*). It is interesting to note that the dihedral angle defined by the planes of the naphthyl rings is 77.6° in the complex and 103.0° in the free ligand, while in the free ligand of the octahydro analogue it is 98.2° (7*d*). The dihedral angles in these structures suggest that ligands having H_8-BINOL based backbone possess a quite different axial flexibility, however, in our case the seven-membered dioxaphosphepine ring restricts this flexibility. Unfortunately, suitable crystals of the free ligand **3** or its platinum complex for X-ray analysis could not be obtained.

Conclusion

As an the extension of our study on asymmetric hydroformylation, we reported herein a comparative study of the catalytic performance of bisphoshites **3** and **4**. Chiral bisphosphites with C_2 symmetry afforded highly active platinum catalysts for asymmetric hydroformylation of styrene. High enantioselectivities (86–91%) have been obtained with the platinum(II)–$SnCl_2$ catalytic system containing ligands **3** and **4.** Retaining the favorable structure of ligand **4** but increasing the electron density in the terminal group significantly improved the catalytic performance, i.e., higher regioselectivity to branched aldehyde (85%) and lower hydrogenation activity were achieved with almost unchanged enantioselectivity. Although the chemoselectivity of the process could be improved, the level is still modest. The observed changes of activity, chemoselectivity, and regioselectivity may have their origin in electronic effects, but steric factors like the bite angle of the ligands cannot be excluded.

Acknowledgments

Financial support from Hungarian National Science Foundation (OTKA T 032 004) is gratefully acknowledged. We are grateful to Mr. Béla Édes for skillful assistance in the synthetic and catalytic experiments.

Chiral metallocenes: the synthesis and X-ray crystal structures of $TiCl_2(\eta^5{:}\eta^5\text{-}C_5Me_4SiMe_2C_5H_3R^*)$ (R^* = menthyl or neomenthyl) and related compounds

Paul Beagley, Philip Davies, Harry Adams, and Colin White

Abstract: The syntheses of the chiral ansa-metallocene complexes $TiCl_2(\eta^5{:}\eta^5\text{-}C_5Me_4SiMe_2C_5H_3R^*)$ (R^* = menthyl (**4a**) or neomenthyl (**4b**)) are reported; initially **4a** was obtained as a 3:1 mixture of (*R*:*S*) diastereoisomers, which differ only in which face of the asymmetrically substituted cyclopentadienyl ring is bonded to the titanium (chiral descriptor shown). The major diastereomer $\mathbf{4a}_{\boldsymbol{R}}$ was crystallized out optically pure from the initial reaction mixture, whereas the $\mathbf{4a}_{\boldsymbol{S}}$ diastereoisomer was isolated after isomerizing a racemic mixture of **4a** to a 1:3 mixture of (*R*:*S*) diastereoisomers using UV irradiation. The corresponding neomenthyl complex **4b** was obtained as a 1.3:1 mixture of diastereoisomers that could not be separated. The optically pure $\mathbf{4a}_{\boldsymbol{R}}$ was converted stereoselectively into the corresponding (*R*)-$TiMe_2(\eta^5{:}\eta^5\text{-}C_5Me_4SiMe_2C_5H_3R^*)$ (R^* = menthyl). Syntheses of the related indenyl ligand system $C_5Me_4SiMe_2C_9H_7$ (**3**) is reported but complexation to titanium proved to be problematic although $ZrCl_2(\eta^5{:}\eta^5\text{-}C_5Me_4SiMe_2C_9H_6)$ (**6**) was isolated. The crystal structures of both $\mathbf{4a}_{\boldsymbol{R}}$ and $\mathbf{4a}_{\boldsymbol{S}}$ are reported and compared. Crystals of $\mathbf{4a}_{\boldsymbol{R}}$ are orthorhombic, a = 27.857(11), b = 9.985(5), and c = 9.596(4) Å, Z = 4, space group $P2_12_121$ (D_2^4, No. 19), and those of $\mathbf{4a}_{\boldsymbol{S}}$ are monoclinic, a = 8.5810(10), b = 38.679(4), and c = 8.5842(10) Å, β = 113.001(2)°, Z = 4, space group $P2_1$ (C_2^2, No. 4). The structures were solved by the Patterson method and $\mathbf{4a}_{\boldsymbol{R}}$ was refined by blocked-cascade least-squares procedures to R = 0.0628 (R_ω = 0.0503) for 902 reflections with $|F|/\sigma(|F|) \geq 3.0$, whereas $\mathbf{4a}_{\boldsymbol{S}}$ was refined by full-matrix least-squares procedures to R = 0.0646 (wR_2 = 0.1829) for 5734 reflections with $|F|/\sigma(|F|) \geq 4.0$. Both diastereomers of **4a** catalyze hydrosilylation of ketones, but as expected from a comparison of the two crystal structures, the $\mathbf{4a}_{\boldsymbol{R}}$ isomer is the more stereoselective catalyst, i.e., hydrosilylation of acetophenone followed by hydrolysis gives 82% enantiomeric excess (ee) of (*S*)-PhCH(Me)OH with $\mathbf{4a}_{\boldsymbol{R}}$ whereas only 16% ee of (*R*)-PhCH(Me)OH with $\mathbf{4a}_{\boldsymbol{S}}$.

Key words: titanium, metallocene, chiral, structure, catalyst.

Résumé : On a réalisé la synthèse des complexes ansa-métallocènes chiraux $TiCl_2(\eta^5{:}\eta^5\text{-}C_5Me_4SiMe_2C_5H_3R^*)$ (R^* = menthyle **(4a)**; R^* = néomenthyle (**4b**)). Originalement **4a** a été obtenu sous la forme d'un mélange 3:1 des diastéréomères (*R*) et (*S*) qui ne diffèrent que par quelle face du noyau cyclopentadiényle substitué de façon asymétrique est liée au titane (on explicite le descripteur chiral). Le diastéréomère principal, $\mathbf{4a}_{\boldsymbol{R}}$ a été retiré optiquement pur par cristallisation du mélange réactionnel initial; le diastéréomère $\mathbf{4a}_{\boldsymbol{S}}$ n'a été isolé qu'après avoir isomérisé un mélange racémique de **4a** en un mélange 1:3 des diastéréomères (*R*) et (*S*) par irradiation UV. Le complexe néomenthylique correspondant **4b** a été obtenu sous la forme d'un mélange 1:4:1 de diastéréomères qui n'a pas pu être séparé. Le produit $\mathbf{4a}_{\boldsymbol{R}}$ a été optiquement pur a été transformé stéréosélectivement en (*R*)-$TiMe_2(\eta^5{:}\eta^5\text{-}C_5Me_4SiMe_2C_5H_3R^*)$ (R^* = menthyle) correspondant. On rapporte aussi la synthèse du système de ligand indényle apparenté $C_5Me_4SiMe_2C_9H_7$ (**3**), mais sa complexation avec le titane s'est avérée être problématique même si on a pu isoler le $ZrCl_2(\eta^5{:}\eta^5\text{-}C_5Me_4SiMe_2C_9H_6)$ (**6**). On a déterminé les structures cristallines des composés $\mathbf{4a}_{\boldsymbol{R}}$ et $\mathbf{4a}_{\boldsymbol{S}}$ et on en a fait une comparaison. Les cristaux de $\mathbf{4a}_{\boldsymbol{R}}$ sont orthorhombiques, groupe d'espace $P2_12_12_1$ (D_2^4, No. 19), avec a = 27,857(11), b = 9,985(5) et c = 9,596(4) Å et Z = 4 alors que ceux de $\mathbf{4a}_{\boldsymbol{S}}$ sont monocliniques, groupe d'espace $P2_1$ (C_2^2, No. 4), avec a = 8,5810(10), b = 38,679(4) et c = 8,5842(10) Å, β = 113,001(2)° et Z = 4. Les structures ont été résolues par la méthode de Patterson et celle de $\mathbf{4a}_{\boldsymbol{R}}$ a été affinée par des méthodes de moindres carrés à cascade bloquée jusqu'à des valeurs de R = 0,0628 (R_ω = 0,0503) pour 902 réflexions avec $|F|/\sigma|F| \geq 3,0$ alors que celle de $\mathbf{4a}_{\boldsymbol{S}}$ a été affinée par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de R = 0,0646 (wR_2 = 0,1829) pour 5734 réflexions avec $|F|/\sigma|F| \geq 4,0$. Les deux diastéréomères de **4a** catalyzent l'hydrosilylation des cétones mais, comme on peut s'y attendre sur la base d'une comparaison des deux structures cristallines, l'isomères $\mathbf{4a}_{\boldsymbol{R}}$ est plus stéréosélectif; par exemple l'hydrosilylation de l'acétophénone, suivie d'une hydrolyse, conduit à un mélange avec 82% d'ee du (*S*)-PhCH(Me)OH avec $\mathbf{4a}_{\boldsymbol{R}}$ alors que l'on n'obtient que 16% d'ee de (*R*)-PhCH(Me)OH avec $\mathbf{4a}_{\boldsymbol{S}}$.

[Traduit par la Rédaction]

Introduction

Chiral metallocenes have attracted considerable attention in the last decade (1) fueled by their spectacular successes in catalyzing stereoselectively a wide range of organic transformations (2), including the stereospecific polymerization of α-olefins (3). We were particularly impressed by the report of Marks and co-workers (4) that lanthanide complexes, containing a chiral ansa-bis(cyclopentadienyl)[2] ligand (**1**), cata-

1 (R* = menthyl or neomenthyl)

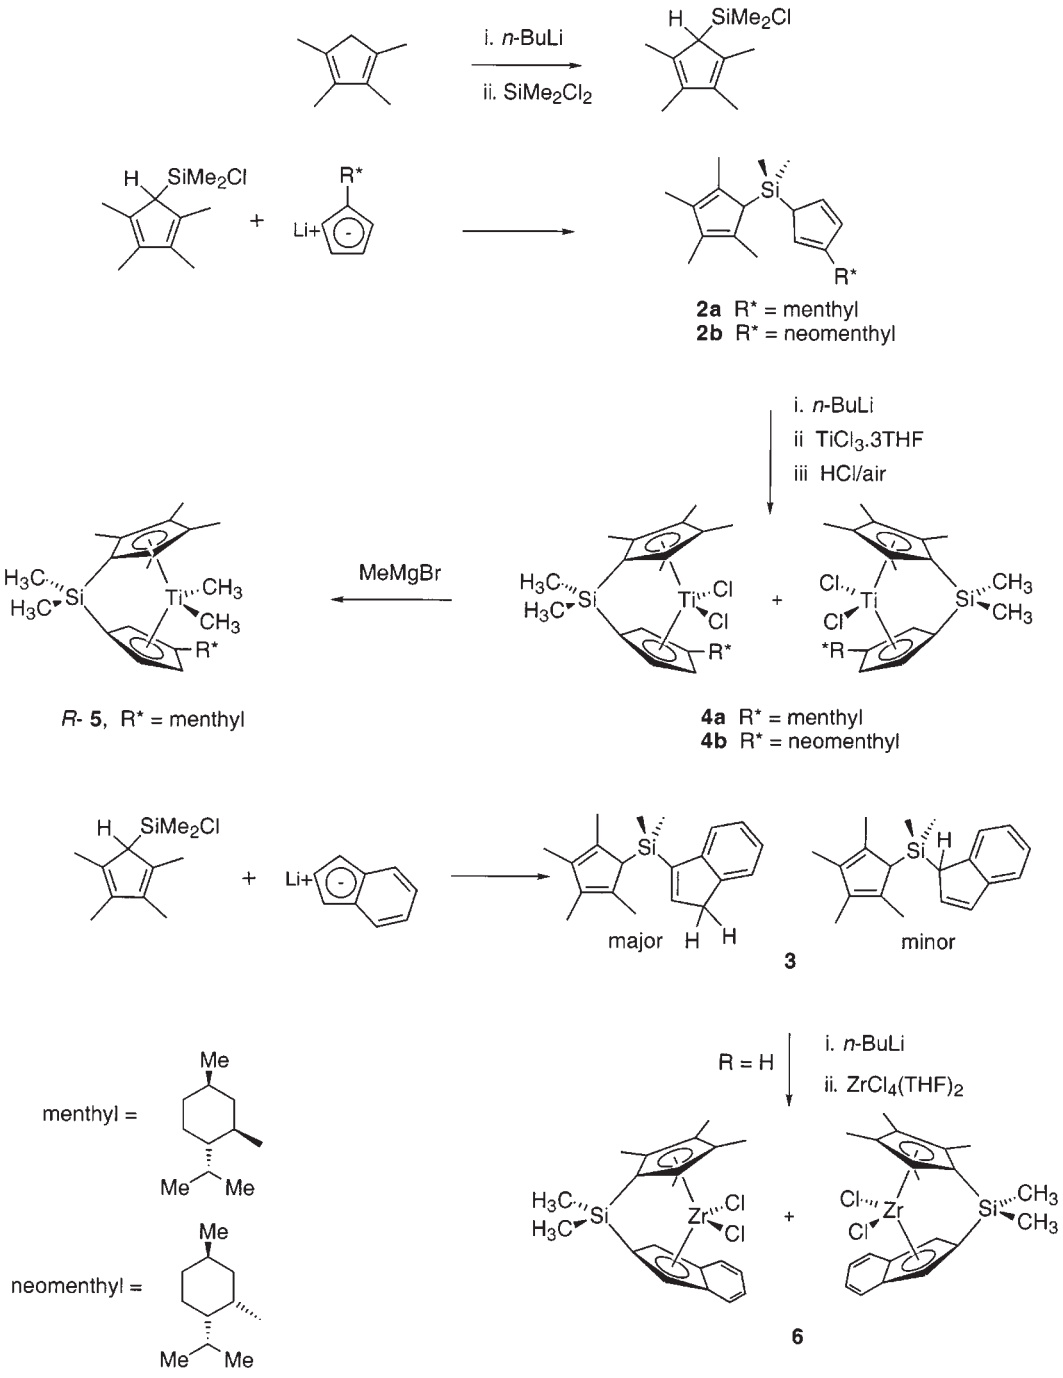
lyzed the hydrogenation of nonfunctionalized alkenes in up to 96% enantiomeric excess (ee). To put this in context, the best result that we know of for the hydrogenation of a nonfunctionalized alkene using a rhodium(I)–chiral bis(phosphine) catalyst is 48% ee (5), and results of 0–20% ee are typical even with well-known phosphines such as Diop (6) and Binap (7). Organolanthanide complexes are, however, notoriously moisture-sensitive, and synthesizing and handling them requires special techniques. We, therefore, wondered if the chiral ansa-bis(cyclopentadienyl) ligand developed by Marks and co-workers (4), and related ligands, could be complexed to less moisture-sensitive transition metals and still give impressive results in enantioselective synthesis. We report herein our studies involving the syntheses of the corresponding titanium complexes. Our choice of titanium was influenced by the fact that two other research groups had reported impressive results for the hydrogenation of nonfunctionalized alkenes using titanocene systems, but with C_2-symmetric chiral ligands (8). We should also point out that, after the start of this work, hydrogenation of nonfunctionalized alkenes with ee's of up to 98% were reported using an iridium – chiral phosphanodihydrooxazole system (9) and also using a cationic zirconocene catalyst (10).

Results and discussion

Ligand syntheses

The ansa-cyclopentadiene ligands consisting of a 2,3,4,5-tetramethylcyclopentadienyl ring linked via a dimethylsilyl bridge to a menthyl- (**2a)** or neomenthyl- (**2b**) cyclopentadienyl moiety were synthesized by a modification of the procedure reported by Marks and co-workers (4) (Scheme 1). In our experience, the key to successful synthesis of these ligands is to use freshly prepared 1-(chlorodimethylsilyl)-2,3,4,5-tetramethylcyclopentadiene; if this is not possible then this reagent should be distilled immediately before use. The corresponding indenyl analogue (**3**) was synthesized using similar procedures (Scheme 1).

Metal complexes



Complexation of ligands **2a** and **2b** to titanium was carried out as shown in Scheme 1. The dilithium salt of the appropriate ligand precursor was formed via double deprotonation with two equiv of *n*-butyllithium in THF and was then reacted in situ with one equiv of $TiCl_3 \cdot 3THF$ in refluxing THF for 12 h. The resulting Ti(III) complex was then oxidized to the desired Ti(IV) complex by stirring with concentrated hydrochloric acid, open to the air, and worked up, followed by removal of solvent to give the crude products **4a** and **4b** as red solids. The ligands **2a** and **2b** are chiral by virtue of the menthyl or neomenthyl substituent, but in addition, the two faces of the asymmetrically substituted cyclopentadiene ring are different and, therefore, complexation to titanium introduces an element of planar chirality into the system. Hence, the titanium complexes **4a** and **4b** are obtained as a mixture of diastereoisomers. This is readily apparent from the ^{1}H NMR spectra; the asymmetry of the complex renders all four methyl groups on the tetramethyl-substituted cyclopentadienyl ring chemically inequivalent and the four methyl signals corresponding to each diastereoisomer are readily assigned from their relative intensity. Thus, the diastereoisomeric ratio can be easily measured via integration of a major and its corresponding minor peak. In this way the diastereoisomeric ratios were found to be 3.0:1 for **4a** and 1.3:1 for **4b**, i.e., 75 and 57% diastereoselectivities, respectively. In contrast, Marks and co-workers (4) found that both these ligands complexed to lanthanides with much higher diastereoselection (>80%) under similar reaction conditions. In both cases ligand complexation takes place to the metal in the +3 oxidation state, and we had expected that complexation to the smaller titanium atom would have led to an increase in the diastereoselection compared to that observed for the lanthanides. We can only presume that as a result of solvent coordination the lanthanides are more sterically congested and hence more stereo-differentiating.

In the case of the menthyl derivative **4a**, which was formed in a diastereomeric ratio of 3:1, cooling a hexane solution to –60°C resulted in the selective crystallization of the major isomer, presumed to be the kinetically favoured isomer. By X-ray crystallography (see below) we were able to show that this was the $\mathbf{4a}_{\boldsymbol{R}}$ diastereomer where the *R* chiral descriptor refers to the planar chirality of the asymmetric cyclopentadienyl ring. There are several reports of photo-induced racemate–meso interconversions of group IV ansa-metallocene dichlorides, which it is generally agreed, proceed via photolytic homolytic cleavage of a Ti-(η^5-cyclopentadienyl) bond, rotation of the cyclopentadienyl radical about the linking-Cp bond, and recombination of the Ti(III) centre with the opposite face of the cyclopentadienyl

[2] Prefix ansa Latin for bent handle, attached at both ends.

Scheme 1.

ligand (11). We were, therefore, interested to see the effect of photolysis upon these chiral titanium complexes. Photolyzing the mother liquor left from the recrystallization of the $\mathbf{4a}_{R}$ diastereomer, which now consisted of an approximately equal mixture of diastereomers, with UV radiation at –30°C slowly led to a change in this isomeric ratio with preferential formation of the most thermodynamically stable product, i.e., the $\mathbf{4a}_{S}$ diastereomer, which was initially the minor isomer. Thus, after irradiating for 1 week, the solution contained a 1:3 ratio of $\mathbf{4a}_{R}$:$\mathbf{4a}_{S}$, and upon cooling to –60°C the $\mathbf{4a}_{S}$ diastereomer selectively crystallized out. Hence, both diastereomers could be obtained and the crystal structures of both were determined.

In contrast, the separation of the two diastereoisomers of the neomenthyl complex **4b** by recrystallization was not possible because of the high solubility of both diastereoisomers in hydrocarbon solvents. For example, no crystals were formed even after cooling a hot, saturated hexane solution of **4b** to –30°C for a number of days. Attempts to significantly increase the diastereomeric ratio by UV irradiation were also unsuccessful. Thus, the initial diastereomeric ratio of 1.3:1 changed to only 1:1.4 after UV irradiation for 1 week at

© 2001 NRC Canada

–30°C. Further irradiation had no effect upon this ratio. Crystallization from pentane was attempted, but no single diastereoisomer was isolated by this method.

The use of silanized silica as a stationary phase in liquid chromatography has proved successful for the purification of ansa-bis(η^5-cyclopentadienyl)dichlorotitanium complexes (12). Therefore, silica gel was modified via treatment with chlorotrimethylsilane (see *Experimental*), and the resulting silanized silica gel was used as a stationary phase for the attempted separation of the two diastereoisomers of **4b**. Unfortunately, no separation of the two diastereoisomers occurred, although there were no visible signs of decomposition either. Attempts to separate the diastereoisomers by converting the dichloride complex into a less soluble derivative by reaction with either 1,2-benzenedimethanol or (*R*)-(–)-acetylmandelic acid failed to yield stable characterizable products.

From the diastereoselectivity observed in the initial formation of the titanium complexes it is clear that the difference in free energy between the two menthyl diastereomers is greater than the difference in free energy between the two neomenthyl diastereomers. The initial diastereomeric ratio is determined by kinetic control but under UV irradiation the diastereomers are in equilibrium and the ratio is determined by their relative thermodynamic stabilities. Hence, it is possible to estimate the difference in free energy between the two diastereoisomers of the menthyl substituted complex (**4a**$_R$ and **4a**$_S$) at –30°C as 2.2 kJ mol^{-1} and that of the neomenthyl diastereomers as 0.7 kJ mol^{-1}.

The NMR spectra of the titanium complexes **4a** and **4b** are worthy of comment; the three cyclopentadienyl protons are grouped together in a similar manner in both diastereoisomers of both catalysts with one proton exhibiting a greater degree of deshielding than the other two protons adjacent to the silicon bridge. This proton sits directly over one of the chloride ligands, and the magnetic anisotropy of the halogen atom has been ascribed as the origin of the low-field shift of such protons (13).

The optically pure dichloro-complex **4a**$_R$ was reacted with methylmagnesium bromide to give the corresponding (*R*)-$TiMe_2(\eta^5{:}\eta^5\text{-}C_5Me_4SiMe_2C_5H_3R^*)$ (R^* = menthyl) (**5**$_R$). We were surprised and disappointed to find that this compound was rather unstable, like the corresponding $Ti(C_5H_5)_2Me_2$ (14), as compared to the more robust $Ti\{(C_5H_4)_2SiMe_2\}Me_2$ (15). Similarly, although synthesis of the related indenyl ligand system $C_5HMe_4SiMe_2C_9H_7$ (**3**) proved to be relatively straightforward, complexation of this ligand was not. The reaction of $TiCl_3{\cdot}3THF$ with the dilithium salt of **3** using similar reaction conditions as those successfully used for the syntheses of the titanium complexes **4a** and **4b** repeatedly failed to yield $TiCl_2(\eta^5{:}\eta^5\text{-}C_5Me_4SiMe_2C_9H_7)$. Titanium indenyl complexes are notoriously difficult to synthesize or are unstable and, therefore, these are often prepared and reduced in situ to the corresponding more stable tetrahydroindenyl titanium complexes using hydrogen in the presence of a PtO_2 catalyst (12*a*, 16); unfortunately, even this strategy failed to yield a stable complex. More successful was the synthesis of the corresponding zirconium indenyl complex $ZrCl_2(\eta^5{:}\eta^5\text{-}C_5Me_4SiMe_2C_9H_6)$ (**6**), although this too proved to be unstable in solution.

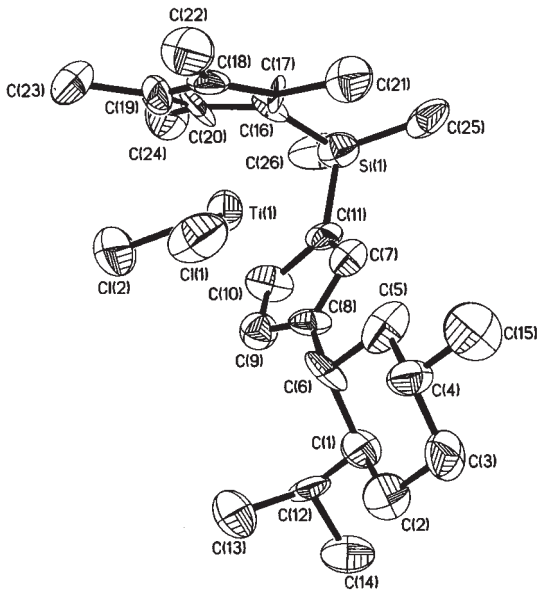

Fig. 1. Molecular structure of $TiCl_2\{\eta^5{:}\eta^5\text{-}C_5Me_4SiMe_2C_5H_3(menthyl)\}$, (*R*)-diastereoisomer **4a**$_R$. Hydrogen atoms are omitted for clarity.

Comparison of the X-ray crystal structures of the diastereoisomers 4a$_R$ and 4a$_S$

Crystallographic data are presented in Table 1 and atomic cooordinates are listed in Table 2.[3] The crystal stucture of the menthyl complex with *R* planar chirality (**4a**$_R$) is shown in Fig. 1; the corresponding diastereoisomer with *S* planar chirality crystallized as two independent molecules per unit cell and these are shown as **4a**$_S$ and **4a**$_{S'}$ in Figs. 2*a* and *b*, respectively. As expected, the bond distances in all the diastereoisomers are essentially similar taking into account that the face of the menthyl-Cp is reversed on going from **4a**$_R$ to **4a**$_S$ and **4a**$_{S'}$ (Table 3). In all the structures each cyclopentadienyl ring is asymmetrically pentahapto bonded to the titanium (Ti—C in the range 2.35–2.59 Å), with the greater asymmetry for the menthylated ring in which the menthylated carbon C(8) is always more distant from the titanium than any other ring carbon. All these Ti—C distances are within the range reported for similar titanium complexes (17). In each complex both five-membered rings are planar with the four methyl groups of the tetramethylcyclopentadienyl ring bent away from the titanium by up to 0.24 Å from the mean plane of the cyclopentadienyl ring. A consequence of the short bridging unit and the bulky menthyl substituent is that the angle between the planes of the two Cp rings (i.e., the bite angle) is relatively large at 58.0 and 59.2° for **4a**$_R$ and **4a**$_S$, respectively, (Table 4) compared to

other ansa-dichlorotitanocenes; for example, $[TiCl_2\{(\eta^5{:}\eta^5\text{-}C_5H_4)_2SiMe_2\}]$ has a bite angle of 56.2° (17a).

The Cl(1)-Ti-C(11) and Cl(1)-Ti-C(16) bond angles are 131(4) and 131.1(3)°, respectively, for **4a$_R$**, whereas the coresponding angles for **4a$_S$** are 124.1(2) and 123.11(19)°, showing the different relative orientations of the ligands about the titanium. However, the differences between the two diastereoisomers are best viewed by comparison of the space-filling models (Fig. 3). With the bulky C_5Me_5 ligand occupying the top face of the complex it can be seen that the bottom face of **4a$_R$** is more sterically crowded because the *i*-Pr group of the menthyl substituent points across this face, whereas in **4a$_S$** the menthyl group is orientated such that the *i*-Pr group points away from this face. This steric crowding presumably accounts for the smaller Cl-Ti-Cl bond angle of 95.3(2)° found in **4a$_R$** compared to that of 97.75(8)° found in **4a$_S$**. If the structures of the diastereoisomers are similar in solution this would imply that the diastereoisomer **4a$_R$**

[a] U_{eq} is defined as one third of the trace of the orthogonalized U_{ij} tensor.

should be a more stereoselective catalyst. Preliminary results from hydrosilylation experiments (Table 5) are in keeping with this statement (18).

Experimental

All reactions of moisture sensitive reagents were performed under nitrogen. THF was heated under reflux over sodium benzophenone ketyl and distilled under nitrogen. Hexane, toluene, and diethyl ether were heated under reflux over sodium and freshly distilled under nitrogen prior to use.

Menthyltosylate [(1*R*, 2*S*, 5*R*)-(–)-2-isopropyl-5-methylcyclohexyl tosylate] and neomenthyltosylate [(1*S*, 2*S*, 5*R*)-(+)-2-isopropyl-5-methylcyclohexyl tosylate] were prepared by modifications of the literature procedures (19, 20) as we have previously described (21). (+)-Neomenthyl tosylate is thermally unstable, therefore, it is best stored at –10°C.

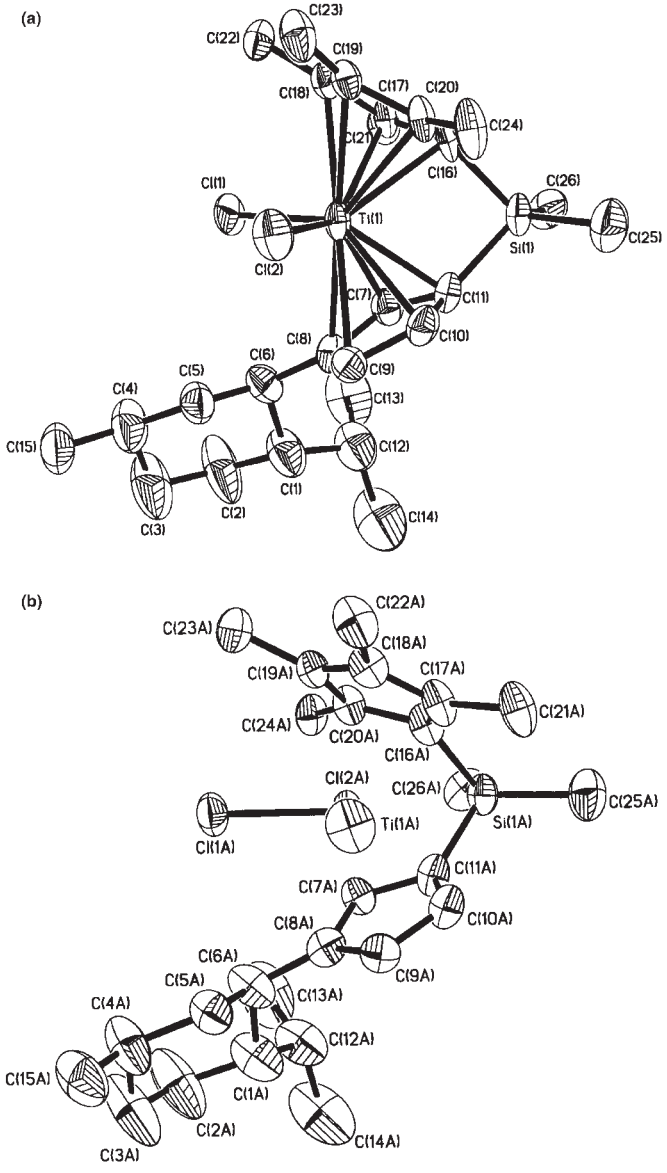
Trichlorotris(tetrahydrofuran)titanium was synthesized by the procedure reported by Manzer (22).

Preparation of silanized silica gel

Dichloromethane (1500 cm^3) was added to silica gel (150 g) and the resulting slurry rapidly stirred by an overhead stirrer. Chlorotrimethylsilane (150 cm^3) was added and the slurry stirred for a further 1 h. The slurry was washed with saturated sodium hydrogencarbonate solution (100 cm^3) and then with water until the washings were neutral. The resulting silanized silica gel was washed with acetone and dried in an oven at 100°C overnight.

Menthylcyclopentadiene



This was prepared by the following modification of the literature procedure (23). NaH (9.6 g, 0.4 mol, i.e., 19.2 g 50% dispersion) was washed with hexane, and freshly distilled THF (150 cm^3) was added. Freshly cracked cyclopentadiene (26 g, 0.4 mol) in THF (50 cm^3) was added slowly over a 2 h period and the mixture stirred until the bubbling stopped and the NaH was consumed (approximately 30 min). The resulting pale red solution of sodium cyclopentadienide was added to a solution of (1*S*, 2*S*, 5*R*)-5-methyl-2-(2-propyl)-cyclohexyl tosylate (63.4 g, 0.2 mol) in THF (200 cm^3) at 0°C via cannula. This mixture was heated under reflux for 6 h producing a sodium tosylate precipitate. Then the mixture was cooled, filtered, and the solvent removed in vacuo. The brown viscous residue was redissolved in diethyl ether and washed with water (5 × 100 cm^3). After drying the organic layer over Na_2SO_4, the solvent was

removed in vacuo to yield a brown oil which was distilled[4] to yield the product as a colourless liquid ($bp_{0.1}$ 70°C, 23.84 g, 58%). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.71 (d, $^3J_{H,H}$ = 6 Hz, 3H, CH_3), 0.84 (d, $^3J_{H,H}$ = 6 Hz, 3H, CH_3), 0.88 (d, $^3J_{H,H}$ = 6 Hz, 3H, CH_3), 0.95–1.84 (m, 9H, CH_2's and CH's), 2.31–2.48 (m, 1H, CH), 2.83–2.98 (m, 2H, allylic), 5.97–6.54 (m, 3H, vinylic). 95% pure by GC.

Preparation of neomenthylcyclopentadiene

An analagous procedure to that employed for the preparation of menthylcyclopentadiene but using menthyltosylate yielded the title product as a colourless liquid ($bp_{0.01}$ 70°C, 42%, 95% pure by GC). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.79–0.90 (m, 9H, CH_3), 0.90–1.86 (m, 9H, CH_2's and CH's), 2.90–3.12 (m, 3H, CH and allylic), 6.08–6.58 (m, 3H, vinylic).

Preparation of 1,2,3,4-tetramethylcyclopentadiene

The synthesis was based on the method reported by Marks and co-workers (4). 2,3,4,5-Tetramethylcyclopent-2-enone (24) (18.8 g, 0.13 mol) in diethyl ether (50 cm^3) was added over 1 h to a suspension of lithium aluminium hydride (2.5 g, 0.07 mol) in diethyl ether (200 cm^3) and the mixture was stirred for 2 h. Aqueous hydrochloric acid (1.0 M, 300 cm^3) was added slowly and the mixture stirred for 16 h in air. The organic layer was separated and the aqueous layer washed with diethyl ether (3 × 100 cm^3). Both organic layers were combined, washed with a saturated sodium carbonate solution (2 × 50 cm^3), and dried over Na_2SO_4. Removal of the solvent in vacuo gave a yellow liquid that was distilled to produce the title product as colourless liquid (30–35°C, 0.5 mm Hg, 6.59 g, 37%). (EI) GC–MS *m*/*z* (%): 122 (M^+, 60). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 1.80 (br s, 6H, $2CH_3$), 1.95 (br s, 6H, $2CH_3$), 2.75 (br s, 2H, $C_5Me_4H_2$).

Preparation of 1-(chlorodimethylsilyl)-2,3,4,5-tetramethylcyclopentadiene

The literature procedure (4) was modified as follows. 1,2,3,4-Tetramethylcyclopentadiene (6 g, 0.05 mol) was dissolved in dry petroleum ether (bp 40–60°C) and a solution of *n*-butyllithium (2.5 M, 20 cm^3, 0.05 mol) was added at 0°C over 1 h. The mixture was stirred for 15 h at room temp to produce a milky white suspension which was thinned by the addition of THF (45 cm^3). A solution of dichlorodimethylsilane (9.7 g, 0.075 mol) in THF (30 cm^3) was added at 0°C over 1 h and the mixture stirred for 15 h. The yellow solution was filtered under nitrogen through Celite previously dried at 100°C under vacuum to remove the lithium chloride precipitate. The solvent was removed in vacuo to give the crude product as a yellow-brown oil which was distilled to give the title product as a yellow-green liquid; $bp_{0.1}$ 60–65°C (lit. $bp_{0.1}$ 56–60°C), 7.05 g (67%). EI-MS *m*/*z* (%): 214 (M^+, 60), 121 ([M – $SiMe_2Cl$]$^+$), 97, 106 ([M – $SiMe_2Cl$ –Me]$^+$), 100). IR (neat) cm^{-1}: 2961s, 2916s, 2861s, 1445m, 1380m, 1258s, 1058br, 844s, 811br, 656m. ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.30 (s, 6H, 2Si-CH_3), 1.9 (s, 6H, $2CH_3$), 2.06 (s, 6H, $2CH_3$) 3.06 (br s, 1H, Cp-H).

Preparation of 1-(2,3,4,5)-tetramethylcyclopentadiene)-1′-(3′(-1*R*, 2*S*, 5*R*)-5-methyl-2-(2-propyl)-cyclohexylcyclopentadiene)dimethylsilane (2a)

The synthesis was based on the procedure reported by Marks and co-workers (4). A solution of lithium menthylcyclopentadienide was prepared by adding a solution of *n*-butyllithium (2.5 M, 5.6 cm^3, 0.014 mol) to a solution of (1*R*, 2*S*, 5*R*)-5-methyl-2-(2-propyl)-cyclohexylcyclopentadiene (2.81 g, 0.014 mol) in THF (50 cm^3) at 0°C and stirring the mixture for 30 min at room temp. The solution was then transferred via cannula at room temp to a solution of freshly distilled 1-(chlorodimethylsilyl)-2,3,4,5-tetramethylcyclopentadiene (3.8 g, 0.018 mol) in THF (25 cm^3). The

[4]The vacuum distillation must be performed at high vacuum since the product decomposes at higher temperatures and this is probably the main reason for the low yields. A two stage distillation and washing the condenser after the CpH–$(CpH)_2$ is distilled at 30°C is also recommended to ensure no CpH contaminates the product.

© 2001 NRC Canada

mixture was heated under reflux for 12 h, cooled to room temp, and filtered to remove the lithium chloride formed. Solvent was removed in vacuo to yield a brown residue which was redissolved in diethyl ether, washed with water (3×10 cm^3), dried over Na_2SO_4,and the solvent removed in vacuo to yield a yellow-brown oil. Excess 1-(chlorodimethylsilyl)-2,3,4,5-tetramethylcyclopentadiene was removed by distillation (heating to 80°C, 0.01 mm Hg) to yield the isomers of the desired menthyl product **2a** as a brown residue. Yield 3.55 g (67%). EI-MS *m*/*z* (%): 382 (M^+, 10), 261 ([M – TMCp]$^+$, 31), 204 ([M – TMCpSiMe$_2$]$^+$, 100). ^{1}H NMR (250 MHz, $CDCl_3$) δ:–0.35–0.10 (m, 6H, Si-CH_3), 0.62 (d, $^3J_{H,H}$ = 6 Hz, 3H, CH_3), 0.75 (d, $^3J_{H,H}$ = 6 Hz, 3H, CH_3), 0.80 (d, $^3J_{H,H}$ = 6 Hz, 3H, CH_3), 0.85–1.60 (m, 9H, CH_2's), 1.60–1.75 (m, 6H, Cp-CH_3), 1.78 (s, 3H, Cp-CH_3), 1.90 (s, 3H, Cp-CH_3), 2.29 (m, 1H, menthyl CH), 2.61–3.21 (m, 2H, allylic), 5.8–6.60 (m, 3H, Cp-H). ^{13}C NMR (63 MHz, $CDCl_3$) δ: 151.9, 150.4, 145.5, 136.1, 133.5 (Cp tertiary), 143.0, 142.0, 133.9, 138.5, 131.1, 131.0, 130.4, 127.3, 126.8, 126.6 (Cp quaternary), 47.4, 46.6, 41.9, 33.0, 27.9, 27.7, 22.6, 21.6, 15.3, 14.7, 14.2, 11.3, 11.1 (CH_3's and CH's), 43.7, 35.4, 24.5, (CH_2's), 1.0, –4.0 (Si-CH_3).

Preparation of 1-(2,3,4,5-tetramethylcyclopentadienyl)-1′-(3′-(1*S*, 2*S*, 5*R*)-5-methyl-2-(2-propylcyclohexyl-cyclopentadienyl)dimethylsilane (2b)

An analogous procedure to that employed for the preparation of 1-(2,3,4,5-tetramethylcyclopentadienyl)-1′-[3′-menthylcyclopentadienyl]dimethylsilane but employing neomenthylcyclopentadiene yielded the desired neomenthyl product **2b** as a yellow oil (70%) found to be 91% pure by GC. (EI) GC–MS *m*/*z* (%): 382 (M^+, 12), 261 ([M – TMCp]$^+$, 78), 179 ([M – nmCp]$^+$, 100). ^{1}H NMR (250 MHz, $CDCl_3$) δ:–0.05–0.33 (m, 6H, Si-CH_3), 0.90–1.11 (m, 9H, neomenthyl CH_3), 1.07–1.85 (m, 9H, CH_2's and CH's), 1.85–2.20 (m, 12H, Cp-CH_3's), 3.00–3.40 (m, 3H, allylic, neomenthyl CH), 6.15 (br s, 1H, olefinic), 6.36–6.48 (m, 1H, olefinic), 6.61–6.72 (m, 1H, olefinic). ^{13}C NMR (63 MHz, $CDCl_3$) δ: 156.5, 147.7, 147.3, 142.6, 136.1, 135.2, 133.2, 132.4, 129.0, 119.7 (Cp's), 48.0, 47.9, 37.8, 37.7 (CH's), 42.4, 35.8, 26.1 (neomenthyl CH_2's), 30.2, 26.5, 22.8, 21.4, 21.3, 14.7, 11.3 (CH_3's), 1.1, –2.6 ($SiMe_2$).

Synthesis of (*R*/*S*)-dichloro[1-(η^5-3′-(1*R*, 2*S*, 5*R*)-5-methyl-2-(2-propyl)cyclohexyl-cyclopentadienyl)-1′-(η^5-2,3,4,5-tetramethylcyclopentadienyl)dimethylsilane]titanium (4a$_{R/S}$)

1-(2,3,4,5-Tetramethylcyclopentadiene)-1′-[3′-menthylcyclopentadiene]dimethylsilane (3.02 g, 7.9 mmol) was dissolved in THF (45 cm^3). A solution of *n*-butyllithium (2.5 M, 6.3 cm^3, 15.8 mmol) in hexanes was added at 0°C and the mixture stirred at room temp for 30 min. The solution was cooled to –78°C and $TiCl_3$·3THF (2.9 g, 7.9 mmol) was added rapidly against a stream of nitrogen and the mixture was allowed to warm to room temp before heating under reflux for 6 h. After cooling to room temp, chloroform (45 cm^3) and concentrated aqueous hydrochloric acid (1 M, 30 cm^3) were added and the mixture stirred at room temp in air for 30 min. The organic layer was separated, dried, and the solvent removed in vacuo to yield a red viscous oil which was shown by ^{1}H NMR to be a 3:1 mixture of *R*:*S*.

Isolation of (*R*)-dichloro[1-(η^5-3′-(1*R*, 2*S*, 5*R*)-5-methyl-2-(2-propyl)cyclohexyl-cyclopentadienyl)-1′-(η^5-2,3,4,5-tetramethylcyclopentadienyl)dimethylsilane]titanium (4a$_R$)

The above oil was dissolved in the minimium of boiling hexane and crystallized at –30°C, to yield the title product as red crystals. Yield 0.75g (19%), mp 162–164°C. [α]^{20} (*c* 0.032, DCM): –62.5° (589 nm), –103.1° (578 nm), and –256.3° (549 nm). EI-MS *m*/*z* (%): 498 (M^+, 10%), 463 ([M – Cl]$^+$, 100). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.66 (m, 3H, CH_3), 0.76 (m, 3H, CH_3), 0.79 (m, 3H, CH_3), 0.82 (m, 3H, CH_3), 0.83 (m, 3H, CH_3), 0.88–1.76 (m, 9H, CH's, CH_2's), 1.84 (s, 3H, Cp-CH_3), 1.87 (s, 3H, Cp-CH_3), 2.00 (s, 3H, Cp-CH_3), 2.10 (s, 3H, Cp-CH_3), 2.69–2.81 (m, 1H, CH), 5.37 (t, $^4J_{H,H}$ = 3 Hz, 1H, Cp-H), 5.67 (t, $^3J_{H,H}$ = $^4J_{H,H}$ = 3 Hz, 1H, Cp-H), 6.50 (t, $^3J_{H,H}$ $^4J_{H,H}$ = 3 Hz, 1H, Cp-H). ^{13}C NMR (63 MHz, $CDCl_3$) δ: 155.2, 145.7, 139.1, 137.4, 128.7, 103.4, 96.8 (Cp quarterary), 126.7, 122.6, 114.3 (C1, C3, C4), 48.6 (C12), 41.7, 41.2 (C6, C7), 35.2, 32.3 (C10, C8), 27.0 (C13), 24.8 (C11) 22.8, 21.8, 16.7, 16.3, 16.2, 13.8, 12.8 (TMCp CH_3's and menthyl CH_3's), 0.36, –1.5 ($SiMe_2$). Anal calcd. for $C_{26}H_{40}Cl_2SiTi$: C 62.5, H 8.1, Cl 14.2; found: C 62.4, H 8.1, Cl 14.1.

Isolation of (*S*)-dichloro[1-(η^5-3′-(1*R*, 2*S*, 5*R*)-5-methyl-2-(2-propyl)cyclohexyl-cyclopentadienyl)-1′-(η^5-2,3,4,5-tetramethylcyclopentadienyl)dimethylsilane]titanium (4a$_S$)

A 1:1 diastereomeric mixture (2 g) of (*R*)- and (*S*)-dichloro{1-[η^5-3′-(menthylcyclopentadienyl)-1′-[η^5-2,3,4,5-tetramethylcyclopentadienyl)dimethylsilane]}titanium was dissolved in toluene (200 cm^3), cooled to –30°C, and irradiated with UV light using a Hanovair medium pressure 125 W lamp. After 7 d the solvent was removed in vacuo and the mixture filtered through a silanized silica column, eluting with 4% diethyl ether in pet ether (40–60 °C), resulting in a viscous red oil (1.1 g) which was shown by ^{1}H NMR spectroscopy to contain a *S*:*R* ratio of 3:1. The red oil was dissolved in boiling pentane and cooled to –30°C; the title compound crystallized as red-brown microcrystals which were collected by suction filtration (520 mg, 26%). FAB-MS m/z (%): 498 (M^+, 24), 463 ([M – Cl]$^+$, 100). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.70 (s, 3H, CH_3), 0.72 (m, 3H, CH_3), 0.81 (m, 3H, CH_3), 0.83 (m, 3H, CH_3), 0.86 (m, 3H, CH_3), 0.85–1.60 (m, 8H, CH's, CH_2's), 1.69 (s, 3H, Cp-CH_3), 1.83 (s, 3H, Cp-CH_3), 2.05 (s, 3H, Cp-CH_3), 2.13 (s, 3H, Cp-CH_3), 2.25–2.88 (m, 1H, CH), 2.65–2.78 (m, 1H, CH), 5.05 (t, $^4J_{H,H}$ = $^4J_{H,H}$ = 3 Hz, 1H, Cp-H), 5.47 (t, $^3J_{H,H}$ = $^4J_{H,H}$ = 3 Hz, 1H, Cp-H), 6.81 (t, $^3J_{H,H}$ = $^4J_{H,H}$ = 3 Hz, 1H, Cp-H). ^{13}C NMR (63 MHz, $CDCl_3$) δ: 148.3, 145.3, 141.6, 132.7, 127.8, 101.8, 96.5 (Cp quaternary), 134.9, 117.7, 115.0 (C1, C3, C4), 50.1 (C12), 41.8, 40.3 (C6, C7), 35.6 (C10), 32.7 (C8), 27.3 (C13), 24.9 (C11), 22.8, 21.7, 16.3, 15.7 (TMCp CH_3's and menthyl CH_3's), 0.0, 1.0 ($SiMe_2$). Anal. calcd. for $C_{26}H_{40}Cl_2SiTi$: C 62.5, H 8.1, Cl 14.2; found: C 62.8, H 8.3, Cl 14.3.

Preparation of (*R*/*S*)-dichloro[1-(η^5-2,3,4,5-tetramethyl-cyclopentadienyl)-1′-(η^5-3′-(1*S*, 2*S*, 5*R*)-5-methyl-2-(2-propyl)-cyclohexylcyclopentadienyl)dimethylsilane]titanium (4b$_{R/S}$)

1-(2,3,4,5-Tetramethylcyclopentadienyl)-1′-[3′-neomenthyl-cyclopentadienyl]dimethylsilane (3.07 g, 8 mmol) was dissolved in THF (45 cm^3). A solution of *n*-butyllithium (2.5 M,

© 2001 NRC Canada

6.4 cm^3, 16 mmol) in hexanes was added at 0°C via syringe and the mixture stirred at room temp for 30 min. The solution was cooled to –78 °C and $TiCl_3$·3THF (3.1 g, 8 mmol) was added rapidly against a stream of nitrogen; the mixture was maintained at –78°C for 5 h then allowed to warm to room temp and heated under reflux for a further 6 h. After cooling to room temp, chloroform (45 cm^3), together with concentrated aqueous hydrochloric acid (30 cm^3), was added and the mixture stirred at room temp in air for 30 min. The organic layer was separated, dried over Na_2SO_4, and the solvent removed in vacuo to yield a red, viscous oil. This was chromatographed on a silanized silica column eluting with hexane to remove organic residues and then a 4% diethyl ether – hexane mixture to elute a red band. Removal of solvent in vacuo yielded the title product (2.74 g, 68%), which was found to consist of a 1.3:1 mixture of (*R*) and (*S*) diastereoisomers, mp 122–130°C. $[\alpha]^{20}$ (*c* 0.026, CH_2Cl_2): +7.6° (589 nm), +30.8° (546 nm), and –61.5° (378 nm). FAB-MS *m*/*z* (%): 499 ($[M + 1]^+$, 20), 463 ($[M – Cl]^+$ 100). ^1H NMR (250 MHz, $CDCl_3$) δ: 0.05 (s, 6H, Si-CH_3), 0.79–0.96 (m, 9H, neomenthyl CH_3's), 0.96–1.72 (m, 9H, neomenthyl CH's, CH_2's), 1.77 (s, CH_3 (minor)), 1.79 (s, CH_3 (major)), 1.87 (s, CH_3 (major)), 1.93 (s, CH_3 (minor)), 2.09 (s, CH_3 (minor)), 2.12 (s, CH_3 (major)), 2.13 (s, CH_3 (major)), 2.18 (s, CH_3 (minor)), 3.50–3.60 (m, CH (minor)), 3.63–3.71 (m, CH (major)), 5.20–5.29 (m, 1H, Cp-H), 5.53–5.61 (m, 1H, Cp-H), 6.85–7.01 (m, 1H, Cp-H). ^{13}C NMR (63 MHz, $CDCl_3$) δ: 150.1, 146.4, 144.9, 144.0, 142.0, 141.6, 134.0, 132.0, 129.8, 128.9, 102.5, 102.1, 97.5, 97.1 (Cp quaternary), 137.0, 132.1, 119.1, 118.0, 116.5, 115.7 (Cp tertiary), 51.1, 49.6, 37.9, 37.2, 29.4, 29.1, 28.7, 28.0, 22.8, 22.6, 22.3, 21.9, 20.8, 16.3, 16.2, 16.0, 13.8, 13.7, 13.6, 13.3, 13.2, 1.0 (CH's, CH_3's), 40.2, 38.8, 35.8, 35.7, 26.0, 25.0 (neomenthyl CH_2's), 0.4, –0.3, –0.7, –1.0 (Si-CH_3's). Anal. calcd. for $C_{26}H_{40}Cl_2SiTi$: C 62.5, H 8.1; found: C 61.2, H 8.2.

Synthesis of (*R*)-dimethyl[1-(η^5-3′-(–)-menthylcyclopentadienyl)-1′-(η^5-2,3,4,5-tetramethylcyclopentadienyl)dimethylsilane]titanium (5)

Methylmagnesium bromide (0.76 cm^3, 2.4 mmol, 3M in diethyl ether) was added to a red solution of $\mathbf{4a}_{R}$ in diethyl ether (15 cm^3) and the mixture stirred overnight in the dark. The diethyl ether was removed in vacuo from the resulting yellow solution and the product extracted by washing the residue with hexane (5 × 1 cm^3). The solvent was removed in vacuo. No further purification was attempted since previous attempts to crystallize the product or purify on a silanized silica column had failed. The product was stored under $Ar_{(g)}$ in a lightshielded flask at –30°C. FAB-MS *m*/*z*: 459 ($[M + 1]^+$), 429 ($[M + 1 – 2CH_3]^+$). ^1H NMR (250 MHz, C_6D_6) δ: –0.29 (s, 3H, Ti-CH_3), –0.19 (s, 3H, Ti-CH_3), 0.02 (s, 3H, Si-CH_3), 0.28, (s, 3H, Si-CH_3), 0.75 (d, *J* = 7 Hz, 3H, Me), 0.81 (d, *J* = 7 Hz, 3H, Me), 0.92 (d, *J* = 7 Hz, 3H, Me), 0.7–1.65 (m, 8H, menthyl-CH's, CH_2's), 1.49 (s, 3H, TMCp CH_3), 1.59 (s, 3H, TMCp CH_3), 1.75 (s, 3H, TMCp CH_3), 2.11 (s, 3H, TMCp CH_3), 2.40 (m, 1H, menthyl CH), 2.70 (m, 1H, menthyl CH), 4.94 (t, $^4J_{H,H}$ = 2 Hz, $^4J_{H,H}$ = 2 Hz, 1H), 5.47 (t, $^3J_{H,H}$ = 2 Hz, $^4J_{H,H}$ = 2 Hz,1H), 6.93 (t, $^3J_{H,H}$ = 2 Hz, $^4J_{H,H}$ = 2 Hz, 1H). ^{13}C NMR (63 MHz, C_6D_6) δ: 143.3, 132.3, 129.9, 128.5, 122.7, 99.7, 94.3 (quarternary Cp), 122.3, 119.8, 111.3 (C1, C3, C4), 50.7, 47.5 (Ti-CH_3), 41.6, 35.6, 25.2 (neomenthyl CH_2's), 47.9, 41.2, 33.0, 27.5, 23.0, 22.0, 16.3, 15.6, 15.4, 12.2, 12.1 (CH's, CH_3's), 1.35, –1.9 (Si-CH_3).

Synthesis of 1-indenyl-1′-(2,3,4,5-tetramethylcyclopentadienyl)dimethylsilane (3)

Freshly distilled indene (48°C, 0.5 mm Hg, 4.3 cm^3, 37 mmol) was dissolved in THF (100 cm^3), cooled to 0°C, and then *n*-butyllithiium (2.5 M, 14.8 cm^3, 37 mmol) in hexanes was added over 30 min. The resulting orange-red solution was stirred at room temp for 2 h. 1-(Chlorodimethylsilyl)-2,3,4,5-tetramethyl-cyclopentadiene (10.0 g, 46 mmol) was dissolved in THF (75 cm^3) and the indenide solution transferred to this solution via cannula. The reaction mixture was heated to reflux for 18 h. The suspension was cooled to room temp and transferred via cannula through Celite, under nitrogen, to remove lithium chloride. The solvent was removed in vacuo from the filtrate yielding a red-brown oil which was redissolved in diethyl ether and washed with water (3 × 20 cm^3). The organic layer was dried over Na_2SO_4, filtered, and the solvent removed in vacuo to give an oil, which was heated to 80°C under 0.01 mm Hg to remove excess starting material and to leave the title product as an orange oil (7.29 g, 67.0%; 98% pure by GC). Attempts to separate isomers by recrystallization from pentane at –30°C were unsuccessful. Similarly, chromatography on alumina, eluting with pentane, failed to separate the isomers but did yield a yellow oil. (EI) GC–MS *m*/*z* (%): major, 294 (M^+, 33), 179 ($[M – indenyl]^+$, 44), 173 ($[M – TMCp]^+$, 100); minor, 294 (M^+, 52), 179 ($[M – indenyl]^+$, 49), 173 ($[M – TMCp]^+$, 100). ^1H NMR (250 MHz, $CDCl_3$) δ: –0.61, –0.21, –0.05 (s, 12H, 2SiCH_3 (major), 2SiCH_3 (minor)), 1.59 (s, 6H, 2Cp″CH_3 (major)), 1.71 (s, 6H, 2Cp″CH_3 (major)), 1.82 (s, 6H, 2Cp″CH_3 (minor)), 1.89 (s, 6H, 2Cp″CH_3 (minor)), 2.86 (br s, 2H, Cp″ipso-CH (major)), 3.05 (br s, 1H, Cp″ ipso-CH (minor)), 3.26 (d, *J* = 3 Hz, 2H, indenyl CH_2 (minor)), 3.45 (d, *J* = 3 Hz, 1H, indenyl SiCH (major)), 6.39 (dd, *J* = 11, 3 Hz, 2H, indenyl olefinic CH (major)), 6.49 (t, *J* = 3 Hz, 1H, indenyl olefinic CH (minor)), 6.69–6.75 (m, 2H, indenyl olefinic CH (major)), 6.95–7.15 (m, 6H, 2 × indenyl CH (major) and 2 × indenyl CH (minor)), 7.12–7.39 (m, 6H, 2 × indenyl CH (major) and 2 × indenyl CH (minor)). ^{13}C NMR (32.44 MHz, $CDCl_3$) δ: –5.9, -5.1, –3.7 ($SiCH_3$), 11.1, 11.3 (Cp″CH_3 (major)), 14.7, 14.8 (Cp″CH_3 (minor)), 40.8 (indenyl CH_2 (minor)), 44.4 (indenyl ipso-C (major)), 54.2 (Cp″ ipso-C (minor)), 54.6, (Cp″ ipso-C (major)), 120.8 (indenyl CH (major)), 122.2 (indenyl CH (minor)), 122.9 (indenyl CH (major)), 124.4 (indenyl CH (minor)), 123.7 (indenyl CH (major)), 126.0 (indenyl CH (minor)), 124.8 (indenyl CH (major)), 128.8 (indenyl CH (minor)), 129.1 (indenyl olefinic CH (major)), 135.7 (olefinic indenyl CH (major)), 144.3 (indenyl ipso-C (minor)), 144.4 (olefinic indenyl CH (minor)), 133.1, 135.1, 136.4, 136.5 (Cp″), 144.5, 144.9, 148.0 (indenyl).

Synthesis of dichloro[(η^5-1-indenyl)-1′-(η^5-2,3,4,5-tetramethylcyclopentadienyl)dimethyl silane]zirconium (6)

1-Indenyl-1′-(2,3,4,5-tetramethylcyclopentadienyl)dimethylsilane (1.01 g, 3.45 mmol) was dissolved in THF (10.0 cm^3) and the solution cooled to –78°C. *n*-Butyllithium (2.3 M,

© 2001 NRC Canada

3.00 cm^3, 6.89 mmol) in hexanes was slowly added and the reaction mixture stirred at –78°C for 10 min, then at room temp for a further 1 h, giving a dark red solution. Tetrachloro-bis(tetrahydrofuran)zirconium (1.30 g, 3.45 mmol), was dissolved in THF (25 cm^3), cooled to 0°C, and transferred via cannula onto the dianion solution at 0°C. The reaction mixture was stirred at room temp for 20 h giving a yellow suspension in an orange solution. The reaction was heated to 40°C for 72 h causing the mixture to become increasingly yellow. The mixture was filtered and washed with toluene yielding a bright yellow solid (1.41 g, 90.0% crude). Solutions were prepared immediately prior to running NMR spectra since the solid was unstable in solution. FAB-MS m/z (%): 455 (M^+, 5), 419 ($[M - Cl]^+$, 14), 247 (24), 173 (80). ^1H NMR (400 MHz, $CDCl_3$) δ: 0.95, 1.15 (s, 6H, $2SiCH_3$), 1.89, 1.93, 1.45, 1.47 (s, 12H, $4Cp''CH_3$), 5.98, 7.24 (d, J = 3 Hz, 2H, indenyl), 7.06, 7.33, 7.50, 7.70 (m, 4H, indenyl).

Catalytic studies

Hydrosilylations were carried out by adding *n*-BuLi in toluene (1 cm^3, 0.08 M) to the titanium complex (20 mg, 0.04 mmol) at room temp. After stirring the mixture rapidly for 5 min., phenylsilane (108 μL, 0.88 mmol) was added followed 5 min later by the ketone (0.8 mmol). The mixture was then placed in a thermostatic bath and the reaction monitored by GC. The product alcohols were obtained by adding acetone and 0.1 M HCl to the mixture; after bubbling had ceased, excess HCl was neutralized with a saturated solution of $NaHCO_3$ and the product extracted into diethyl ether and run through a short plug of anhydrous $MgSO_4$. Enantiomeric excess was determined using chiral GC using a β-Dex support.

Acknowledgments

We thank the EPSRC for postgraduate studentships (to P.D. and P.B) and I.C.I. Specialties for financial support. Advice and constant encouragement from David J. Milner (I.C.I.) is gratefully acknowledged.

New pathways of site selective aromatic alkylation of palladium complexes: fragmentation to arenes vs. ring closure to hexahydromethano-fluorenes or -phenanthrenes

Marta Catellani, Federica Cugini, and Domenico Tiefenthaler

Abstract: Dimeric arylbicycloheptylpalladium halide complexes of type **1** undergo selective alkylation at the aromatic site by reaction with allyl, styryl, and benzyl bromides (RBr) via hexahydromethanopalladafluorenes (**2**). Ring closure of the resulting palladium complex (**7**) on sp^2 and sp^3 C–H bonds of a suitable R group then occurs with formation of hexahydromethanophenanthrene or hexahydromethanofluorene derivatives. Alternatively, substituted arenes derived from bicycloheptene deinsertion are formed. In some cases the latter can be obtained in substantial amounts when methyl isonicotinate is used as ligand.

Key words: alkylations, C–H activation, palladium, palladacycles.

Résumé : Les complexes dimères halogénure d'arylbicycloheptylpalladium de type **1** subissent des réactions d'alkylation sélective du site aromatique par réaction avec les bromures d'allyle, de styryle et de benzyle, RBr, via les hexahydrométhanopalladafluorènes, **2**. La réaction de fermeture de cycle du complexe de palladium **7** qui en résulte, par réaction avec les liaisons C–H sp^2 et sp^3 d'un groupe R approprié, se produisent alors avec formation de dérivés hexahydrométhanophénanthrène ou hexahydrométanoflurorène. Des arènes substitués dérivant d'une désinsertion du bicycloheptène peuvent aussi se former. Dans quelques cas, ces derniers peuvent être obtenus en assez grandes quantités en présence d'isonicotinate de méthyle comme ligand.

Mots clés : alkylations, activation C–H, palladium, palladacycles.

[Traduit par la Rédaction]

Introduction

Organic syntheses involving selective activation and functionalization of aromatic and aliphatic C–H bonds by means of transition metal complexes are important goals of chemistry (1– 4). To this end metallacycles have been proved to be particularly useful providing an easy route to direct C–H activation (5), in addition to many useful synthetic applications (6–9). Selective aromatic dialkylation of hexahydromethanopalladafluorenes (**2**) with aliphatic iodides and bromides with consequent expulsion of the cycloaliphatic moiety (bicycloheptene) has been obtained in our laboratory (10). Catalytic processes based on this method have been reported (11–14). The starting palladacycle **2**, resulting from aromatic C–H activation (15), can be readily formed in situ from the phenylbicycloheptylpalladium chloride precursor **1** (16–19) (Scheme 1, L = solvent or added ligand).

To get further insight into this chemistry we varied the type of organic halide used, passing to allyl, vinyl, and benzyl halides. We, thus, could discover new types of alkylation followed by ring closure involving attack of palladium–carbon bonds on sp^2 and sp^3 C–H bonds. The present paper offers an outlook on the observed behaviour.

Results and discussion

Experiments were performed with dimeric arylbicycloheptylpalladium chloride complexes and different organic bromides, which react much better than the corresponding chlorides, in the presence of potassium carbonate in dimethylacetamide (DMA). We shall consider the results in the following sequence: allyl bromide, styryl bromide, and benzyl bromide. Aromatic arylation with aryl iodides has been the subject of previous papers (20–22).

Allyl bromide was caused to react with the phenylbicycloheptylpalladium chloride dimer **1**, or with its aryl analogues, dissolved in DMA at room temperature in the presence of potassium carbonate, using a fivefold excess of allyl bromide, which was found beneficial to obtain complete conversion of the starting palladium complex. While the migration of two allyl groups occurred as expected (Scheme 1, R = $CH_2CH{=}CH_2$), the resulting palladium-bonded intermediate

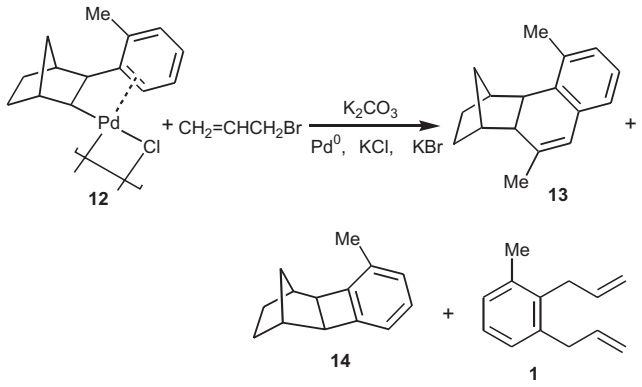


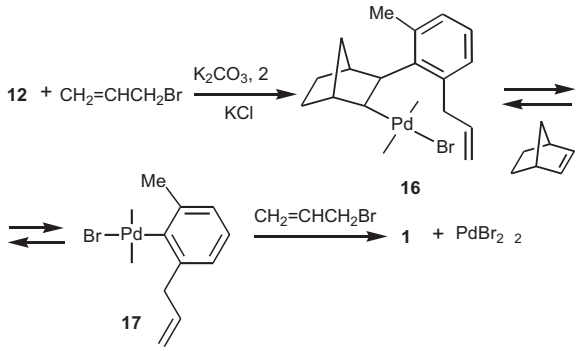
Scheme 1.

Scheme 2.

Scheme 3.

7 (R = $CH_2CH{=}CH_2$) underwent ring closure to hexahydromethanophenanthrene **9** in 62% yield (Scheme 2). It is worth noting that the entire process not only is stereoselective, leading to an *exo* C–C bond with the bicycloheptyl group, but also is regioselective, with the methyl group being placed near the bicycloheptyl site as ascertained by NMR spectra.

An allyl derivative of hexahydromethanobiphenylene **10**, resulting from reductive elimination of complex **5** (R = $CH_2CH{=}CH_2$), was formed in 26% yield as a by-product.



Under these conditions the previously observed deinsertion reaction of bicycloheptene from complex **7** to **8** (Scheme 1) did not take place because of the faster ring closure, probably involving previous coordination of the allyl double bond (23, 24). It is worth noting that the ring closure on the allylic double bond did not occur at the stage of the first allylation product **4** (R = $CH_2CH{=}CH_2$), when the formation of the benzocyclobutene derivative **10** was preferred, but only after the introduction of the second allyl group, when the only alternative would have been bicycloheptene deinsertion.

We also carried out the same reaction in the presence of nitrogen ligands. Pyridine and methyl isonicotinate (10:1 and 5:1 molar ratio to palladium, respectively) gave results similar to those of the previously reported reaction, however, a lower conversion (82%) was observed with the latter ligand. The addition of phenanthroline (1:1 molar ratio to palladium) blocked the reaction at the initial stage and phenylnorbornane was recovered almost quantitatively after treatment with sodium borohydride. Neocuproin (2,9-dimethyl-1,10-phenanthroline; 1:1 molar ratio to palladium), which is more dissociable than phenanthroline, allowed the reaction to proceed to the first allylation of the aromatic ring (complex **4**, R = $CH_2CH{=}CH_2$) to afford the organic product *exo*-2-[2′-(prop-2-enyl)phenyl]bicyclo[2.2.1]heptane (**11**) (92%) after addition of sodium borohydride as the reducing agent.

2-Methylphenylbicycloheptylpalladium chloride dimer **12** was then used as the starting complex in place of **1** under the standard conditions previously reported. The reaction (Scheme 3) gave products **13** (61%) and **14** (11%) (25), corresponding to analogous compounds **9** and **10**, respectively,

Scheme 4.

of Scheme 2. This time, however, a third product (**15**, 7%), was present.

Apparently compound **15** is formed via bicycloheptene deinsertion from complex **16** followed by coupling of the resulting species **17** with another molecule of allyl bromide (Scheme 4).

The fact that the presence of a methyl and an allyl group in the *ortho* positions leads to deinsertion only to a very small extent is probably due to stabilization of the complex by coordination of the allyl double bond (23, 24). The yield of **15** depends on the ability of the ligands to prevent coordination of the allyl group, as shown in Table 1.

While phenanthroline completely blocked the reaction, as with complex **1**, neocuproin gave only 51% conversion with yields for **13**, **14**, and **15** of 35, 9, and 5%, respectively. Monodentate ligands gave better results; pyridine (10:1 molar ratio to palladium) increased the yields to 41, 23, and 16%, respectively, while methyl isonicotinate (5:1 molar ratio to palladium) gave the best yield of product **15** (34%), resulting from deinsertion and coupling with an allyl group, along with **13** and **14** in 28 and 9% yield, respectively. The combined effect of the *ortho* methyl group and of the ligand thus allows deinsertion to be obtained to a substantial extent.

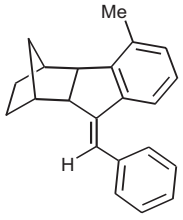
To get more information on the steric effect caused by the *ortho* methyl group, complexes **18**, **21**, and **24** were caused to react with allyl bromide under the same conditions adopted for **12**. As shown in Scheme 5 only **24** gave the deinsertion product.

Complex **18** gave compounds **19** and **20** (25) in 78 and 11% yield, respectively, and complex **21** gave **22**, **23**, and **20** (25) in 52, 35, and 11% yield, respectively.

It is worth noting that, contrary to what occurred in the case of compound **9** (Scheme 2), compound **19** was formed by ring closure on the allyl group in the absence of a second allyl substituent on the *ortho* position. This is probably due to the steric hindrance exerted by the *meta* methyl group to allylation in the second *ortho* position. While addition of methyl isonicotinate as the ligand to complexes **18** and **21** did not lead to significant amounts of products resulting from bicycloheptene deinsertion, complex **24** in the presence of methyl isonicotinate as the ligand (5:1 molar ratio to palladium) gave compounds **25**, **26**, and **27** (25) in 35, 31, and 15% yield, respectively. The yield of compound **26** (31%) compares well with the yield for compound **15** (34%) (derived from complex **12)** under the same conditions. In the absence of additional ligands compounds **25**, **26**, and **27** were obtained in 68, 9, and 13% yield, respectively.

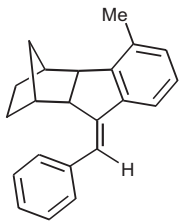
Table 1. Ligand effect on the reaction of 2-methylphenylbicycloheptylpalladium chloride dimer (**12**) with allyl bromide.

Ligand	Yield of compound (%)		
	13	**14**	**15**
—	61	11	7
Phenanthroline[a]	n.a.	n.a.	n.a.
Neocuproin	35	9	5
Pyridine	41	23	16
Methyl isonicotinate	28	9	34



[a]n.a., not applicable.

These results offer further evidence that methyl isonicotinate competes with the allyl group for coordination to palladium, thus causing bicycloheptene deinsertion to occur to a substantial extent.



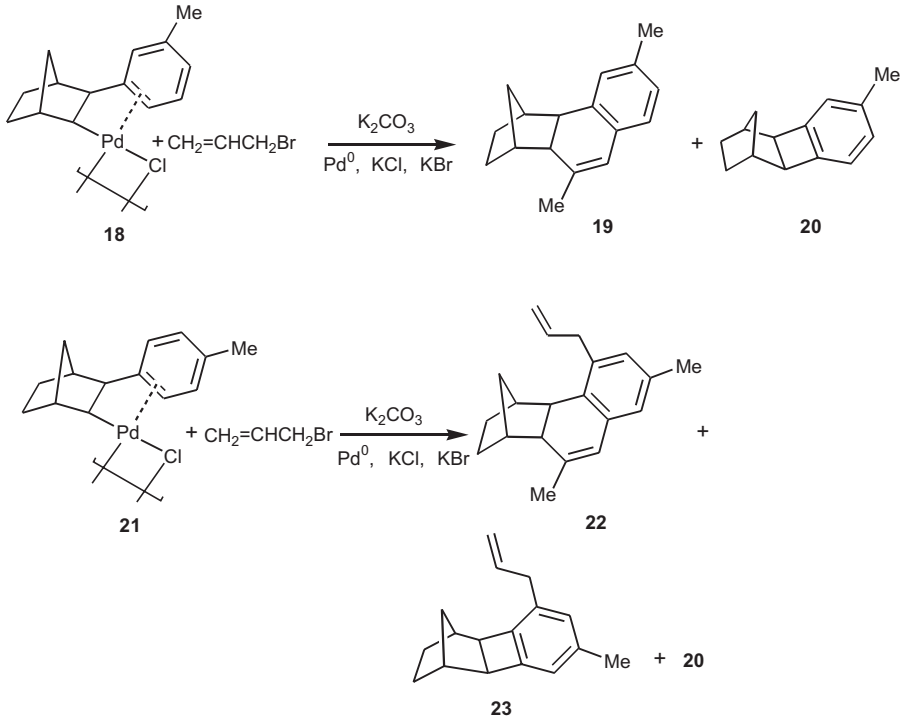
Styryl bromide

Under the conditions adopted for the previous reactions *E*-styryl bromide reacted with complex **1** to give the hexahydromethanofluorene derivatives **30a** (*Z*, 64%) and **30b** (*E*, 21%). The reaction is likely to proceed, as shown in Scheme 6, through oxidative addition of styryl bromide to give the palladium(IV) species **28** (for general overview of palladium(IV) intermediates, see ref. 26), followed by styryl migration on the metallacycle aryl site (**29**). At this point ring closure to the *syn* and *anti* phenylmethylenehexahydromethanofluorene derivatives **30a** and **30b** occurred according to (Scheme 6).

The situation did not change using complex **12**, instead of **1**, and methyl isonicotinate as the ligand. The corresponding *Z*- and *E*-5-methyl-9-phenylmethylenehexahydromethanofluorenes **31a** and **31b** were obtained in 74 and 24% yield, respectively. Apparently double bond coordination predominates over the steric and ligand effects.

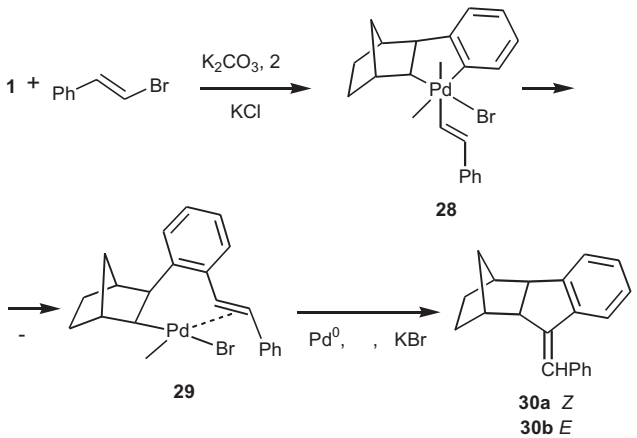
31a

31b



Benzyl bromide

Benzyl bromide had been previously shown to react with complex **1** to give the aromatic dibenzylated product resulting from bicycloheptene deinsertion in the same way shown in the general Scheme 1 (10).



Starting from the *ortho* methyl-substituted complex **12**, however, an unexpected behaviour was observed. The complex underwent activation of the methyl group with ring closure to a hexahydromethanofluorene derivative; compounds **34a** and **34b** were obtained both in 77% yield using benzyl bromide and 4-methylbenzyl bromide, respectively (Scheme 7).

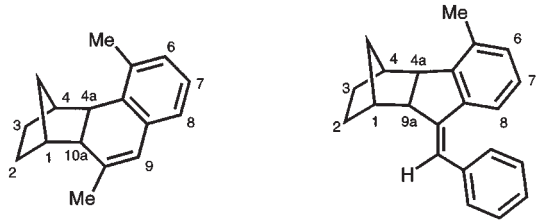
Scheme 8.



The reaction proceeds through the palladium(IV) complex **32** and the bicycloheptyl palladium species **33**. Complexes of this type (**32** and **33**) had been isolated with phenanthroline as the ligand (26–28). Ring closure between two sp^3 carbons, thus, appears to be preferred not only to bicycloheptene deinsertion and but also to ring closure on the benzylic CH_2. Catalytic reactions of this type have been derived from this observation (29). An agostic interaction of CH_3 with palladium might be at the origin of this behaviour (30). Bicycloheptene deinsertion has also occurred in small amount as evident by the isolation of the corresponding products **36a** and **36b** (14 and 10% yield, respectively) obtained after carbonylation in methanol (Scheme 8).

The situation changes completely in the presence of methyl isonicotinate as the ligand (fivefold excess with respect to palladium). This time complexes **33** (R = H, CH_3) undergo deinsertion almost quantitatively. The resulting arylpalladium complexes **35** (R = H, CH_3) were treated in situ with CO and methanol at room temperature and atmospheric pressure. Compounds **36a** and **36b** were obtained in 97 and 95% yield, respectively. The reaction of benzyl halides with complex **12**, thus offers the possibility to obtain deinsertion products (diphenylmethane derivatives) in the presence of methyl isonicotinate as the ligand or cyclization products (hexahydromethanofluorene derivatives) in its absence.

Ring size, regiochemistry, and stereochemistry of compounds 9, 13, 19, 22, 25, 30a, 30b, 31a, and 31b

The regiochemistry of the products was established from the NOESY spectra. For the hexahydromethanophenanthrene derivatives (**9**, **13**, **19**, **22**, **25**) the strong dipolar interaction of the methyl protons on C10 with both H10a and H1 clearly indicates that the methyl group is placed in the proximity of the bicycloheptyl unit. Accordingly, the vinyl proton on C9 shows an NOE effect with the facing aromatic proton on the adjacent C8. Although the NMR data were in agreement with the proposed phenanthrene structure, they could not, however, unambiguously proved it, as they were also compatible with fluorene systems such as in compounds **30a** and **31a**. The fluorene system was ruled out by carrying out a long range C–H correlation HMBC experiment. As expected for the phenanthrene structure, the vinyl proton of compound **13** shows correlations to CH_3C=, C10a, C8, C4b ($^3J_{^{13}C,^1H}$), and 8a ($^2J_{^{13}C,^1H}$) and the methyl protons on C10 correlate to C9, C10a ($^3J_{^{13}C,^1H}$), and C10 ($^2J_{^{13}C,^1H}$). For compounds **30a** and **31a** the strong NOE interactions between the vinyl proton and both H9a and H1 complement the correlation signal of the aromatic *ortho* protons of the styryl unit with H8, thus indicating that the phenyl ring of the styryl group is situated in the proximity of the aromatic side. The fluorene structure of **30a** and **31a** is, thus, confirmed since the formation of a six-membered ring would have placed the phenyl ring of the styryl unit adjacent to the bicycloheptyl moiety. Moreover, vicinal couplings ($^3J_{^1H,^1H}$) on the order of 7 to 8 Hz have been usually observed for the two *endo* protons (H4a and H9a) on the bicycloheptyl unit involved in a five-membered ring, while larger coupling constants, on the order of 10 Hz, have been encountered in six-membered rings for the corresponding H4a and H10a *endo* protons (31). The cross peaks present in the NOESY spectra of compounds **30b** and **31b** are in agreement with the assigned *E*-stereochemistry; moreover yield of these compounds increases with increased reaction times as a result of the *Z* to *E* isomerization process.

Experimental

General

Reagents were obtained from commercial sources and were used without further purification. Starting complexes were prepared using the procedure reported for the unsubstituted parent compound (16). Their structural characterization will be the subject of a forthcoming paper.[2] DMA was distilled under reduced pressure and stored under an atmosphere of dinitrogen over 4 Å molecular sieves. Reactions were carried out under dinitrogen using conventional Schlenk techniques. Column chromatography was performed on silica gel (Merck silica 70–230 mesh) using hexane or a mixture of hexane – ethyl acetate as the eluent. TLC analyses were carried out on precoated plates (Merck silica gel 60). GLC analyses were run with a Carlo Erba HRGC 5300 instrument equipped with a 30 m long capillary column (SE-30 as the stationary phase). Mass spectra (EI) were acquired with Finnigan MAT SSQ 710 spectrometer operating at 70 eV and are reported as *m/z* (relative intensity). Infrared spectra were run on a Nicolet 5PC FT-IR instrument and are reported in wave numbers (cm^{-1}). Melting points were determined by the capillary method on an electrothermal apparatus and are uncorrected. Elemental analyses were performed by using a Carlo Erba EA1108 elemental analyzer. Unless indicated otherwise, ^1H and ^{13}C NMR spectra were recorded in $CDCl_3$ at 20°C using the solvent as internal standard on a Bruker AC 300 operating at 300.1 and 75.4 MHz, respectively. The HMBC experiments were run on a Bruker AMX 400 using the program INVBTP supplied by Bruker. ^{13}C

spectra were collected using TD = 16 or 64K; in the latter case two decimal figures were given. One or more asterisks (*) indicate interchangeable assignments.

General procedure for the reaction of arylnorbornylpalladium chloride dimer with allyl, styryl, and benzyl bromides

The palladium complex and potassium carbonate were introduced under dinitrogen into a 25 mL Schlenk-type flask. The appropriate ligand, if any, and the desired organic halide, separately dissolved in DMA, were then added and the resulting solution stirred at room temperature for 4–24 h. After addition of methanol (0.5–1 mL), dinitrogen was replaced by CO at atmospheric pressure and stirring was continued for 6 h until palladium black was formed. Alternatively, the reaction mixture was quenched by treatment with $NaBH_4$ in slight excess. The mixture was diluted with CH_2Cl_2 and extracted three times with a 5% solution of H_2SO_4. The combined organic layer was washed with water and dried over anhyd Na_2SO_4. The solvent was evaporated and the products were isolated by column chromatography using hexane or a mixture of hexane–EtOAc as the eluent. Yields, based on monomeric arylnorbornylpalladium chloride, were determined by GC. Conversions were obtained from the corresponding arylnorbornane formed by decomposition with $NaBH_4$ and were determined by GC. Compounds **14**, **20**, and **27** were previously reported (25).

*Reaction of **1** with allyl bromide*

Following the general procedure dimeric complex **1** (76 mg, 0.12 mmol), allyl bromide (145 mg, 1.20 mmol), and K_2CO_3 (100 mg, 0.72 mmol) in DMA (12 mL) were converted to yield **9** (37 mg, 62%) and **10** (13 mg, 26%). An isomer of **9** (ca. 3%) was also detected by GC–MS but not further characterized. Conversion of **1** was complete in 4 h. Similar results were obtained using pyridine or methyl isonicotinate as the ligand (10:1 and 5:1 molar ratio to palladium, respectively) in 4 and 8 h. Reaction with phenanthroline (43 mg, 0.24 mmol) for 24 h gave *exo*-2-phenylbicyclo[2.2.1]heptane (39 mg, 95%) (32) as the only product after treatment with $NaBH_4$, while using neocuproin (50 mg, 0.24 mmol) for 24 h gave 2-[2′-(prop-2-enyl)phenyl]bicyclo[2.2.1]heptane (**11**, 47 mg, 92%).

*Reaction of **12** with allyl bromide*

Following the general procedure dimeric complex **12** (79 mg, 0.12 mmol), allyl bromide (145 mg, 1.20 mmol), and K_2CO_3 (100 mg, 0.72 mmol) in DMA (12 mL) were converted to yield **13** (33 mg, 61%), **14** (5 mg, 11%) (25), and **15** (3 mg, 7%). Conversion of **12** was complete in 4 h. In the presence of phenanthroline as the ligand (43 mg, 0.24 mmol) for 24 h only *exo*-2-(2′-methyl)phenylbicyclo[2.2.1]heptane (43 mg, 96%) (33) was obtained after treatment with $NaBH_4$. Reaction with neocuproin (50 mg, 0.24 mmol) for 24 h gave 2-(2′-methyl)phenylbicyclo[2.2.1]heptane (22 mg, 49%) (33) together with **13** (19 mg, 35%), **14** (4 mg, 9%), and **15** (2 mg, 5%), while using pyridine (190 mg, 2.4 mmol) for 4 h gave **13** (22 mg, 41%), **14** (10 mg, 23%), and **15** (7 mg, 16%). Methyl isonicotinate (166 mg, 1.2 mmol) for 8 h led to **13** (15 mg, 28%), **14** (4 mg, 9%), and **15** (14 mg, 34%).

Conclusions

In conclusion, we have shown that alkylation of palladacycles with allyl, styryl, and benzyl halides undergoes new pathways when the position *ortho* to the aryl-bicycloheptyl bond is or becomes occupied. Cyclization occurs either directly as in the case of the styryl group or after a second group (allyl, benzyl) has occupied the other *ortho* position. In all cases cyclization is regio and stereoselective. Ligands can interfere in the cyclization process leading to C–C cleavage between the aryl and bicycloheptyl groups with liberation of bicycloheptene.

Acknowledgments

Financial support was provided by Ministero dell'Università e della Ricerca Scientifica e Tecnologica (MURST, Roma) and Consiglio Nazionale delle Ricerche (CNR, Roma). We thank Prof. B.E. Mann (University of Sheffield) for carrying out and discussing some key NMR experiments. Mass and NMR facilities were provided by the Centro Interfacoltà di Misure of the University of Parma.

Structural studies of $PdCl_2L_2$ complexes with fluorinated phosphines, phosphites, and phosphinites as precursors of benzyl bromide carbonylation catalysts, and and X-ray crystal structure of *cis*-$PdCl_2[PPh_2(OEt)]_2$

Anna M. Trzeciak, Hubert Bartosz-Bechowski, Zbigniew Ciunik, Katarzyna Niesyty, and Józef J. Ziółkowski

Abstract: $PdCl_2L_2$-type complexes with phosphines (L = $PPh_x(C_6F_5)_{3-x}$ (x = 0–3)), phosphites (L = $P(OMe)_3$, $P(OPh)_3$, $P(OEt)_3$), and phosphinites (L = $PPh_2(OC_6F_5)$, PPh_2(O-3,5-$F_2C_6H_3$), $PPh_2(OEt)$, PPh_2(O-*n*-Bu), PPh_2(O-*t*-Bu)) were synthesized and characterized by UV–vis and ^{31}P NMR methods. $PdCl_2L_2$ complexes with less sterically demanding phosphines ($\Theta < 140°$) exist as *cis* isomers, which is confirmed by the X-ray structure of *cis*-$PdCl_2[PPh_2(OEt)]_2$. These complexes react with CO in the presence of NEt_3 forming $Pd(CO)_xL_y$ ($x + y = 4$) type carbonyls characterized by IR spectra. All $PdCl_2L_2$ complexes studied are active as precursors of benzyl bromide carbonylation catalysts at 40°C and 1 atm CO; however, the activity of the *cis* isomers is higher than that of the *trans* isomers. The highest yields of the carbonylation product, phenylacetic acid methyl ester, were obtained using *cis*-$PdCl_2[P(OMe)_3]_2$ (92%), *cis*-$PdCl_2[P(OPh)_3]_2$ (89%), and *cis*-$PdCl_2[PPh_2$(O-*n*-Bu)$]_2$ (78%) as catalyst precursors.

Key words: palladium complexes, fluorinated phosphines, benzyl bromide carbonylation.

Résumé : On a synthétisé des complexes de type $PdCl_2L_2$ comprenant des phosphines L = $PPh_x(C_6F_5)_{3-x}$ (x = 0–3), des phosphites L = $P(OMe)_3$, $P(OPh)_3$ et $P(OEt)_3$ et des phosphinites L = $PPh_2(OC_6F_5)$, PPh_2(O-3,5-$F_2C_6H_5$), $PPh_2(OEt)$, $PPh_2(OBu)$ et PPh_2(O-*t*-Bu) et on les a caractérisés par spectroscopie UV–vis et par RMN du ^{31}P. Les complexes $PdCl_2L_2$ comportant des phosphines stériquement moins encombrées ($\theta < 140°$) existent sous la forme d'isomères *cis*; cette situation a été confirmée par diffraction des rayons du *cis*-$PdCl_2[PPh_2(OEt)]_2$. Ces complexes réagissent avec le CO en présence de NEt_3 pour former des complexes carbonylés de type $Pd(CO)_xL_y$ ($x + y = 4$) qui ont été caractérisés par spectroscopie IR. À 40°C et 1 atm de CO, tous les complexes de type $PdCl_2L_2$ sont actifs comme précurseurs de catalyseurs pour la carbonylation du bromure de benzyle; toutefois, l'activité des isomères *cis* est supérieure à celle des isomères *trans*. Les rendements les plus élevés en produit de carbonylation, le phénylacétate de méthyle, ont été obtenus avec les *cis*-$PdCl_2[P(OMe)_3]_2$ (92%), *cis*-$PdCl_2[P(OPh)_3]_2$ (89%) et *cis*-$PdCl_2[P(OBu)_3]_2$ (78%) comme précurseurs de catalyseur.

Mots clés : complexes de palladium, phosphines fluorées, carbonylation du bromure de benzyle.

Introduction

The electronic and steric properties of fluorine-containing phosphorus ligands are quite different from those of their nonfluorinated analogues. The σ-electron-withdrawing character of fluorine reduces the basicity of the ligand, as has been demonstrated for *trans*-$MCl(CO)(PR_3)_2$ (M = Rh, Ir) by an increase of the ν(CO) frequency in the following series of PR_3 ligands: $PPh_3 < PPh_2(C_6F_5) < P(C_6F_5)_3$ (1). However, when only two fluorines are present in the phenyl ring of the phosphine coordinated in complexes of the same type ($PPh_x(2,6\text{-}F_2C_6H_3)_{3-x}$, x = 0–2), the ν(CO) remains constant and close to the value observed for $MCl(CO)(PPh_3)_2$ (1). On the basis of ligand displacement studies of $PtCl_2(PR_3)_2$ complexes, phosphorus ligands have been ordered according to their ligand exchange ability, which increases in the following order: $P(C_6F_5)_3 < PPh(C_6F_5)_2 < P(2,6\text{-}F_2C_6H_3)_3 < PPh_2(C_6F_5) < PPh_3$ (2). Rhodium and platinum complexes with fluorinated phosphines, diphosphines, phosphonites, and phosphinites have been studied (3–5). Examples of *ortho*-C–F bond activation in rhodium and iridium complexes with fluorinated diphosphines have been reported (6, 7).

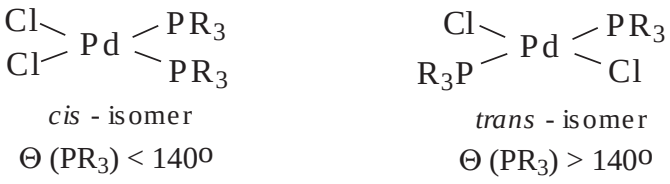
[a]Cone angle. References are given in parentheses.
[b]Calculated from the equation $\theta = 2/3\ \Sigma\theta_i/2$ (8).
[c]Not isolated.

The presence of fluorines in the phosphine phenyl ring, especially in *ortho*-positions, dramatically changes the steric properties of the ligand causing an increase of the cone angle (Θ), e.g., from 145° for PPh_3 to 184° for $P(C_6F_5)_3$ (8).

Long chain alkyl fluorinated phosphines, such as $P(CH_2CH_2(CF_2)_5CF_3)_3$, are successfully applied for catalytic processes in highly fluorinated solvents (9, 10).

Looking for good modifying ligands for palladium carbonylation catalysts, we selected fluorinated phosphorus ligands such as phosphines of the form $PPh_x(C_6F_5)_{3-x}$ (x = 0–2) and phosphinites of the form $PPh_2(OC_6F_5)$ and PPh_2(O-3,5-$F_2C_6H_3$) for systematic studies of the electronic and steric effects of ligands on the structural and catalytic properties of $PdCl_2L_2$-type palladium complexes.



It was particularly interesting to test complexes with ligands that are bulky and simultaneously have a strong acceptor character (low basicity). Recently, we found a new Pd(0)–triphenylphosphite complex formation reaction when $PdCl_2[P(OPh)_3]_2$ was treated with NEt_3 (11). Although triphenylphosphite is a stronger π-acceptor, it has relatively small cone angle (Θ = 128°), and the question arises how the same reaction with NEt_3 would proceed in the case of more bulky fluorinated phosphines. To supplement the series of complexes under study and to be able to draw more general conclusions, we prepared palladium complexes with nonfluorinated phosphites ($P(OPh)_3$, $P(OMe)_3$, $P(OEt)_3$) and phosphinites (PPh_2(OEt), PPh_2(O-*n*-Bu), PPh_2(O-*t*-Bu)) for comparison.

Results and discussion

$PdCl_2L_2$-type complexes

The palladium complexes that we used for spectroscopic and catalytic studies were prepared by substitution of cyclooctadiene (cod) in $PdCl_2$(cod) with a suitable phosphorus ligand. All complexes were isolated and characterized by spectroscopic and analytical methods (Table 1, and see *Experimental*).

Scheme 1.

Square planar complexes of the $PdCl_2L_2$ type can exist as two isomers, *cis* and *trans* (14). Some of the compounds listed in Table 1, namely $PdCl_2L_2$ (L = PPh_3, $P(C_6F_5)_3$, $P(OPh)_3$, PCy_3) had been characterized earlier by X-ray crystallography (14–18), and the presence of *trans*-isomers was confirmed for complexes with bulky ligands, e.g., *trans*-$PdCl_2(PPh_3)_2$ (15), *trans*-$PdCl_2[P(C_6F_5)_3]_2$ (14), and *trans*-$PdCl_2(PCy_3)_2$ (17). The phosphites and phosphinites, on the other hand, preferentially formed *cis*-isomers (14), as was recently confirmed by the structure of *cis*-$PdCl_2[P(OPh)_3]_2$ (8) and the structure of *cis*-$PdCl_2[PPh_2(OEt)]_2$ in this paper. On the basis of the literature data (14–18), we assigned *cis* or *trans* geometry for all complexes under study (Table 1) according to the general rule shown in Scheme 1. The only doubtful structure is that of $PdCl_2[PPh_2(OC_6F_5)]_2$, which decomposes during recrystallization thereby making it impossible to determine the structure via X-ray crystallography. The cone angle of the $PPh_2(OC_6F_5)$ ligand, calculated from the molecular structure of the platinum complex (3), is 145°, and by analogy with *trans*-$PdCl_2(PPh_3)_2$ (Θ for PPh_3 = 145°), we proposed a *trans* geometry for $PdCl_2[PPh_2(OC_6F_5)]_2$.

It is important to note that the presence of only one ^{31}P NMR signal in the spectrum of each of the palladium complexes suggested the presence of only one isomer in solution.

UV–vis spectra

Spectroscopic data for the $PdCl_2L_2$ complexes are presented in Table 1. All of the complexes display one elec-

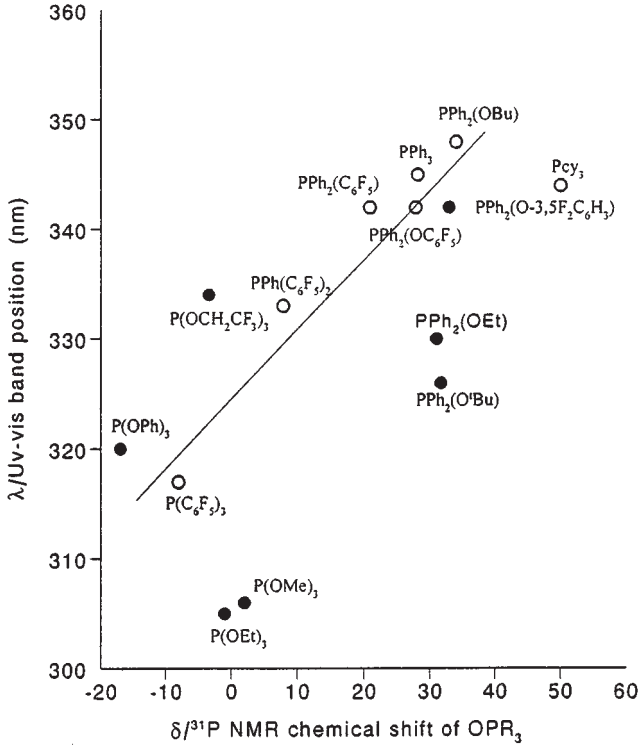

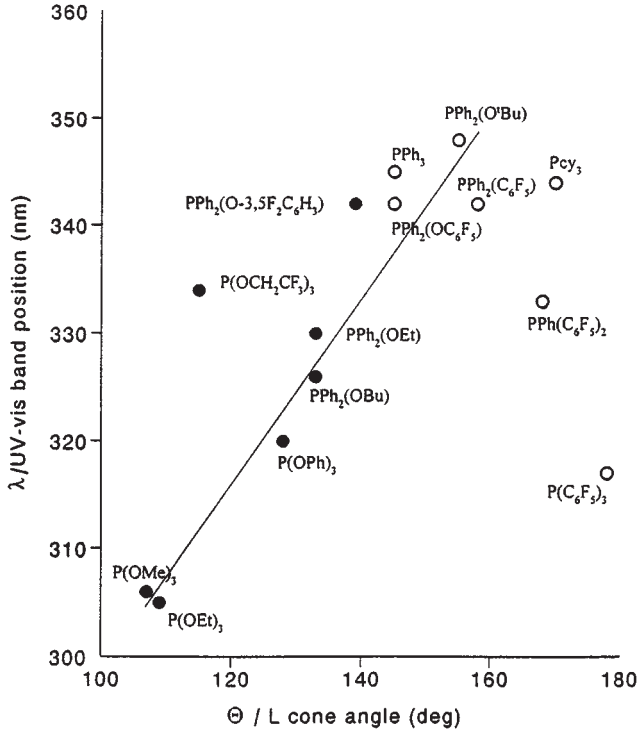

Fig. 2. Correlation between the UV–vis band position (λ, nm) of $PdCl_2L_2$ complexes in $CHCl_3$ and the cone angles (θ) of respective phosphines (L) **1** PPh_2(O-*t*-Bu), **2** PPh_3, **3** PCy_3, **4** $PPh_2(C_6F_5)$, **5** $PPh_2(OC_6F_5)$, **6** PPh_2(O-3,5-$F_2C_6H_3$), **7** $P(OCH_2CF_3)_3$, **8** $PPh(C_6F_5)_2$, **9** PPh_2(OEt), **10** PPh_2(O-*n*-Bu), **11** $P(OPh)_3$, **12** $P(C_6F_5)_3$, **13** $P(OMe)_3$, **14** $P(OEt)_3$. *cis*-$PdCl_2L_2$ (●), *trans*-$PdCl_2L_2$ (○).

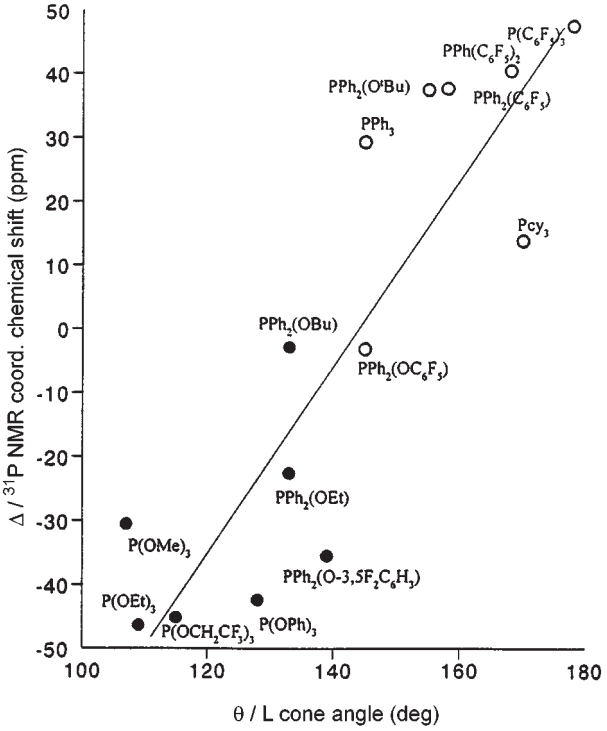
tronic transition (λ) in the 300–350 nm region of the UV–vis spectrum, as similarly reported for other palladium(II) complexes with phosphorus ligands (12). In the group of complexes studied, the band is shifted from 348 nm for $PdCl_2[PPh_2$(O-*t*-Bu)$]_3$ to 305 nm for $PdCl_2[PPh_2(OEt)]_2$, showing a dependence on the type of phosphorus ligand coordinated to palladium. The influence of the phosphorus ligand on the spectroscopic properties of metal complexes can be discussed in terms of two types of effects; electronic and steric, which could not be separated and considered as totally independent effects. In the group of palladium complexes under study, we can however, discuss the domination of electronic or steric influence of the ligand on the spectroscopic properties of the compound.

To characterize the influence of the electronic properties of the phosphorus ligand coordinated to palladium on the UV–vis spectrum of the complex, we plotted the relationship between the band position (λ) and the ^{31}P NMR chemical shift of phosphine oxides (δ_{OPR_3}) (13) (Fig. 1).

The selection of this parameter was based on Derenesceyi's demonstration (13) that the carbonyl stretching frequency (ν(CO)) of $Ni(CO)_3PR_3$, being the measure of the electronic properties of PR_3, is linearly correlated with the ^{31}P NMR chemical shift of OPR_3 (δ). The linear correlation is fairly good only for *trans*-$PdCl_2L_2$ with fluorinated phosphines (L = $PPh_x(C_6F_5)_{3-x}$ (x = 0–3)) (Fig. 1).

Another correlation, between the UV–vis band position (λ) and the phosphine cone angle (Θ), was plotted because of the estimation of the influence of the steric effect of the ligand on the spectroscopic properties of palladium complexes (Fig. 2). This correlation is also not satisfactory as it still shows some deviations from linearity. However, it allows one to conclude that the band position in the spectra of $PdCl_2L_2$ complexes are dependent on both the electronic and steric properties of ligand L.



^{31}P NMR spectra

The chemical shift of the ^{31}P NMR signal, being strongly dependent on the kind of phosphorus ligand, is not very informative (Table 1). However, the coordination chemical shift (Δ), defined as the difference in the ^{31}P NMR chemical shift between coordinated and free phosphine ($\Delta = \delta_{coord.} - \delta_L$), can be used to compare structurally similar complexes with different phosphorus ligands (8). The coordination chemical shift can also be used for the estimation of bond strength, as was demonstrated for $PtCl_2L_2$ complexes with fluorinated phosphines (2).

We found that the coordination chemical shift (Δ) of complexes under study increases with increase of phosphine cone angle (Θ) (Fig. 3), as was similarly reported for $RhCl(CO)(PR_3)_2$ complexes (8). The lowest (negative) values of Δ were found for complexes with less bulky phosphorus ligands (Θ < 140°), existing as *cis*-isomers. The coordination of these ligands to palladium causes an upfield shift of

Fig. 3. Correlation between the ^{31}P NMR coordination chemical shift ($\Delta = \delta_{coord.} - \delta_L$) of $PdCl_2L_2$ complexes in $CHCl_3$ and the cone angles (θ) of the phosphorus ligand (L). **1** PPh_2(O-*t*-Bu), **2** PPh_3, **3** PCy_3, **4** $PPh_2(C_6F_5)$, **5** $PPh_2(OC_6F_5)$, **6** PPh_2(O-3,5-$F_2C_6H_3$), **7** $P(OCH_2CF_3)_3$, **8** $PPh(C_6F_5)_2$, **9** PPh_2(OEt), **10** PPh_2(O-*n*-Bu), **11** $P(OPh)_3$, **12** $P(C_6F_5)_3$, **13** $P(OMe)_3$, **14** $P(OEt)_3$. *cis*-$PdCl_2L_2$ (●), *trans*-$PdCl_2L_2$ (○).

the ^{31}P NMR signal as compared with the free ligand and as a consequence leads to a negative coordination shift. The highest (positive) values of Δ were noted for *trans*-complexes with bulky ligands ($\Theta > 140°$). Changes in coordination chemical shift (Δ) were explained by changes in SPS angles (angles between substituents on trivalent phosphorus upon coordination of phosphine to metal) (8).

Attempts to correlate both the ^{31}P NMR parameters; the coordination chemical shift (Δ) and the chemical shift of phosphine oxides (δ), failed.

Reactions of $PdCl_2L_2$ complexes with CO and NEt_3

A $PdCl_2L_2$ complex used as a carbonylation reaction catalyst precursor should first undergo reduction to a palladium(0) complex. We recently found that $PdCl_2[P(OPh)_3]_2$ is reduced to a Pd(0) species by NEt_3, even in aprotic solvents such as CH_2Cl_2 or C_6H_6 (11) (eq. [1]).

$$[1]\quad PdCl_2[P(OPh)_3]_2 + nNEt_3 \rightarrow Pd[(P(OPh)_3]_4 + Pd[P(OPh)_3]_x[(NEt_3)]_{4-x}$$

$x = 1–3$

The $PdCl_2(PPh_3)_2$ complex under similar conditions exhibits different reactivity, forming a carbomethoxy complex (eq. [2]) (19):

$$[2]\quad PdCl_2(PPh_3)_2 + CO + NEt_3 + MeOH \rightarrow PdCl(C(O)OMe)(PPh_3)_2 + HNEt_3Cl$$

Table 2. ν(CO) frequencies observed for $Pd(CO)_xL_y$ ($x + y = 4$) complexes in KBr.

L	ν(CO) (cm^{-1})
PPh_2(OEt)	1816 (m), 1876 (vs), 1896 (s), 1916 (vs)
PPh_2(OBu)	1809 (m), 1846 (s), 1876 (vs), 1896 (vs), 1942 (m)
$P(OCH_2CF_3)_3$	1876 (vs), 1920 (m)
$P(OPh)_3$	1810 (m), 1849 (m), 1876 (s), 1893 (s), 1926 (m)
$P(OMe)_3$	1822 (m), 1883 (vs), 1903 (vs), 1916 (vs)

When a tertiary amine was replaced by a secondary one, a mixture of Pd(0) carbonyls, $Pd(CO)_x(PPh_3)_y$ ($x + y = 4$), was identified in the reaction product (eq. [3]) (19):

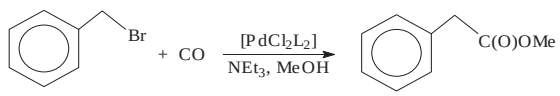
$$[3]\quad PdCl_2(PPh_3)_2 + CO + HNR^1R^2 + MeOH \rightarrow Pd(CO)(PPh_3)_3 + Pd_3(CO)_3(PPh_3)_4 + H_2NR^1R^2Cl$$

The $PdCl_2L_2$ complexes react with CO in the presence of NEt_3, giving products depending on the phosphorus ligand used.

Palladium complexes with fluorinated phosphines ($PPh_x(C_6F_5)_{3-x}$ ($x = 0–2$)) treated with CO (1 atm) in methanol containing an excess of NEt_3 ([NEt_3]:[Pd] = 5) did not give any new products, even after 24 h. In contrast, complexes with less bulky phosphines react with CO forming the respective palladium carbonyls in about 20 min (eq. [4]). The carbonyls were identified by IR spectra and showed ν(CO) bands of terminally bonded CO-ligands at ca. 1900 cm^{-1} (Table 2).

$$[4]\quad PdCl_2L_2 + CO + NEt_3 + MeOH \rightarrow Pd(CO)_x(L)_y + HNEt_3Cl$$

$L = PPh_2$(OEt), PPh_2(O-*n*-Bu), $P(OPh)_3$, $P(OCH_2CF_3)_3$, $P(OMe)_3$

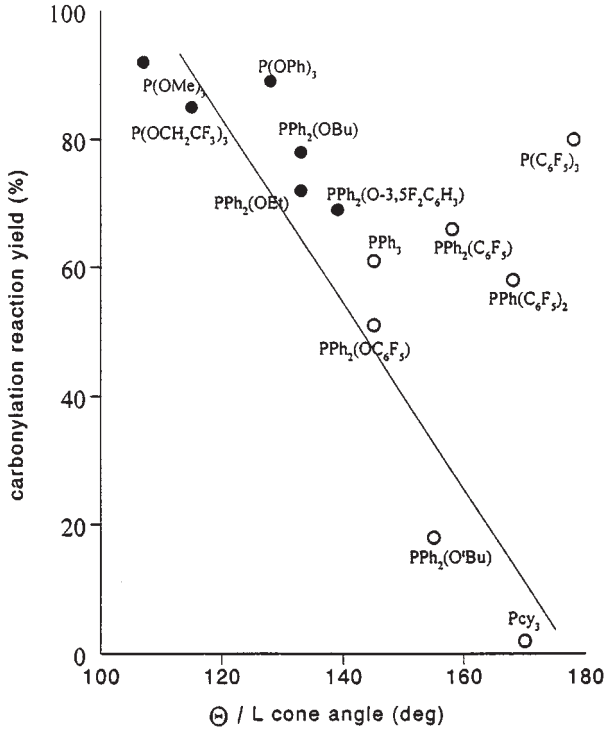


$x + y = 4$

It is worth mentioning that carbomethoxy complexes were not identified during rxn. [3] nor in its final product.

It is reasonable to propose that NEt_3 acts as a reducing agent with respect to all complexes mentioned in rxn. [4], and the presence of methanol is not necessary, as palladium carbonyls were also obtained in reactions of $PdCl_2[P(OPh)_3]_2$ or $PdCl_2[PPh_2(O\text{-}n\text{-}Bu)]_2$ with CO and NEt_3 in CH_2Cl_2 as a solvent.

Catalytic activity of $PdCl_2L_2$ complexes in benzyl bromide carbonylation



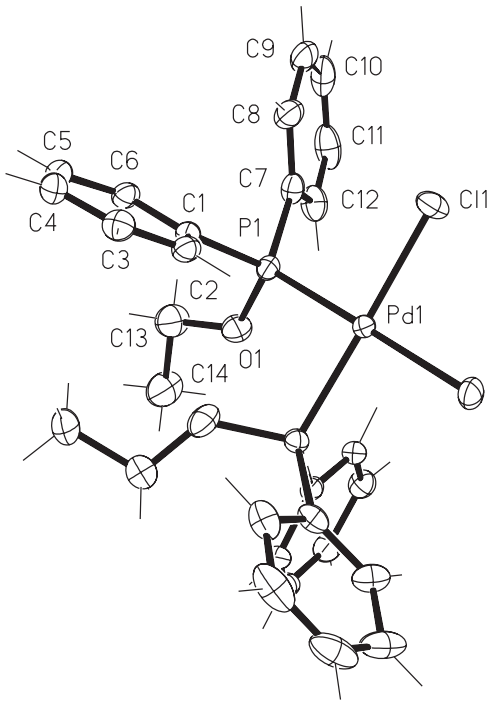
A test of the catalytic activity of $PdCl_2L_2$ complexes in the carbonylation of benzyl bromide to phenylacetic acid methyl ester was performed under standard conditions of 40°C and 1 atm of CO in MeOH (eq. [5]).

[5] 

The results are summarized in Fig. 4 in the form of a correlation between the yield of phenylacetic acid methyl ester and the cone angle of the phosphorus ligand (Θ). It can be

© 2001 NRC Canada

Fig. 4. Dependence of the benzyl bromide carbonylation reaction yield on the cone angle (θ) of phosphorus ligand (L) coordinated in $PDCl_2L_2$ complex. **1** PPh_2(O-*t*-Bu), **2** PPh_3, **3** PCy_3, **4** $PPh_2(C_6F_5)$, **5** $PPh_2(OC_6F_5)$, **6** PPh_2(O-3,5-$F_2C_6H_3$), **7** $P(OCH_2CF_3)_3$, **8** $PPh(C_6F_5)_2$, **9** PPh_2(OEt), **10** PPh_2(O-*n*-Bu), **11** $P(OPh)_3$, **12** $P(C_6F_5)_3$, **13** $P(OMe)_3$, **14** $P(OEt)_3$. *cis*-$PdCl_2L_2$ (●), *trans*-$PdCl_2L_2$ (○).



concluded that palladium complexes with less crowded phosphorus ligands ($P(OMe)_3$, $P(OPh)_3$, PPh_2(O-*n*-Bu)) exhibit higher catalytic activity, producing ca. 90% of the phenylacetic acid methyl ester. This is in agreement with the observation that these complexes undergo easier reduction to palladium(0) species when treated with CO and NEt_3 (eq. [4]). Therefore, the higher catalytic activity can be explained by the higher concentration of the active form of the catalyst, a Pd(0) complex, which activates benzyl bromide by an oxidative addition reaction. It is interesting to note that palladium complexes with fluorinated phosphines ($PPh_x(C_6F_5)_{3-x}$, x = 1 or 2) exhibit higher catalytic activity than expected on the basis of the correlation presented in Fig. 4. In these cases, the electronic effect of phosphine seems to be dominating over the steric effect.

The formation of black palladium metal at the end of some carbonylation reactions was observed, i.e., in reactions with *cis*-$PdCl_2[P(OCH_2CF_3)_3]_2$ and *cis*-$PdCl_2[P(OPh)_3]_2$. However, the good yields of carbonylation products in these reactions show that the benzyl bromide carbonylation reaction is faster than palladium reduction. It was found earlier (20) that palladium black is not catalytically active.

X-ray crystal structure of *cis*-$PdCl_2[PPh_2(OEt)]_2$

The molecular structure of the *cis*-$PdCl_2[PPh_2(OEt)]_2$ complex is shown in Fig. 5, and selected bond distances and angles are given in Table 3. The complex is of square-planar

Fig. 5. Molecular structure of *cis*-$PdCl_2[PPh_2(OEt)]_2$ (**9**).

geometry with P-Pd-Cl angles of 178.54(3) and 89.40(3)°, respectively.

The Pd—P distance (2.2474(8) Å) in *cis*-$PdCl_2[PPh_2(OEt)]_2$ is significantly shorter than corresponding Pd—P distances in *trans*-$PdCl_2L_2$ complexes with L = PPh_3 (15), $P(C_6F_5)_3$ (16), PCy_3 (17). In the series of these complexes, a gradual shortening of Pd—P distances is observed as ligand's (L) basicity decreases from 2.3628(9) Å in *trans*-$PdCl_2(PCy_3)_2$ (17) to 2.3051(12) Å in *trans*-$PdCl_2[P(C_6F_5)_3]_2$ (16). The basicity of PPh_2(OEt) is expected to be intermediate between that of PPh_3 and $P(C_6F_5)_3$, and therefore, the order of decreasing basicity is as follows: $PCy_3 > PPh_3 > PPh_2(OEt) > P(C_6F_5)_3$. Thus, the Pd—P bond in *cis*-$PdCl_2[PPh_2(OEt)]_2$ should be longer compared to that in *trans*-$PdCl_2[P(C_6F_5)_3]_2$, which was not observed. On the other hand, the Pd—P bond in complex *cis*-$PdCl_2[PPh_2(OEt)]_2$ is only slightly longer than that in *cis*-$PdCl_2(P(OPh)_3)_2$ (2.2299(11) and 2.2314(12) Å, respectively) (18), because of the higher basicity of the PPh_2(OEt) ligand compared with that of $P(OPh)_3$. The observed shortening of the Pd—P distance in the *cis*-$PdCl_2[PPh_2(OEt)]_2$ and other *cis*-$PdCl_2L_2$ complexes with respect to *trans*-$PdCl_2L_2$ complexes is consistent with the stronger *trans* influence of a phosphorus ligand than that of a chloride ligand. The Pd—Cl bond length in *cis*-$PdCl_2[PPh_2(OEt)]_2$ (2.3430(8) Å) is similar to those found in *cis*-$PdCl_2(P(OPh)_3)_2$ (2.3273(11) and 2.3354(11) Å) (18) and *cis*-$PdCl_2[PPh_2(OMe)]_2$ (2.349(8) and 2.358(6) Å) (21). In the *trans*-$PdCl_2L_2$ complexes mentioned above the respective distances are ca. 0.04 Å longer. The conformation of PPh_2(OEt) ligand is slightly different from that of PPh_2(OEt), which is illustrated by smaller Pd-P-O angles, 118.6(7) and 115.5(6)° in *cis*-$PdCl_2[PPh_2(OMe)]_2$ (21) and 108.19(10)° in *cis*-$PdCl_2[PPh_2(OEt)]_2$.

Experimental

General

All syntheses were conducted under dry dinitrogen using the Schlenk technique. Ethyl ether and THF were dried prior the use by distilling over sodium. Methanol was distilled over Mg, triethylamine was dried over KOH and distilled. C_6H_6 and CH_2Cl_2 have been purified according to the standard methods (22). Compounds $C_6H_5CH_2Br$, $PClPh_2$, and PCl_2Ph were purchased from Aldrich and used without purification. $P(C_6F_5)_3$ was purchased from Strem Chemicals. $PdCl_2(cod)$ was obtained according to the literature method (23).

NMR spectra were recorded with Bruker 300 spectrometer and chemical shifts are given vs. TMS (^1H) and vs. 85% H_3PO_4 (^{31}P). Abbreviations used in multiplicities are: singlet (s), doublet (d), triplet (t), quartet (q), and virtual quartet (vq). IR spectra were measured with FT-IR Nicolet Impact 400 instrument. UV–vis spectra were measured with an HP 4852 Diode Array spectrophotometer. GC–MS analyses were carried out with HP 5890 II linked to an HP 5971 A mass detector.

Ligand syntheses

*Syntheses of fluorophenyl phosphines (**2**)*

Diphenyl pentafluorophenyl phosphine ($PPh_2(C_6F_5)$): Bromopentafluorobenzene (2.46 g, 10 mM) was added to a suspension of activated magnesium (0.3 g, 1.2 equiv) in freshly distilled THF (100 mL). The reaction mixture was stirred and heated under reflux until almost all magnesium reacted (~40 min). The reaction mixture was cooled to –30°C and distilled chlorodiphenyl phosphine (1.8 mL, 2.21 g, 10 mM) was added. The cooling bath was removed and the whole mixture was stirred overnight.

The THF was removed on rotary evaporator and the remaining oil was dissolved in methanol (30 mL) and evaporated (3 times). The oil was extracted with dry ethyl ether (3 times), the extracts were collected, and evaporated. The residue was extracted with hot petroleum ether (PE) (bp 40–60°C), the extracts were treated with charcoal, and evaporated. The crude phosphine (1.9 g, 54%) was recrystalized from PE–methanol to give 1.2 g (37.5%) of white crystals. mp 57–60°C (lit. mp (2) 65–68°C). GC–MS: single peak. MS *m*/*z*: 352. ^1H NMR ($CDCl_3$) δ: 7.35–7.45 (m). ^{31}P NMR ($CDCl_3$) δ: –24.9.

Phenyl di(pentafluorophenyl)phosphine ($PPh(C_6F_5)_2$): The compound was obtained in analogous manner as given above starting from bromopentafluorobenzene (20 mM) and dichlorophenylphosphine (1.38 mL, 1.82 g, 10 mM). The attempted crystallization failed so the phosphine was purified chromatographically on basic alumina with ethyl acetate – hexane (1:1 v/v) as the eluent. The obtained red oil was frozen at –10°C. A small sample of the waxy substance was dissolved in dry methanol and allowed to evaporate slowly. A few reddish crystals obtained were then used to initialize crystallization of the remaining wax. The reddish crystals were recrystallized from methanol (2 times) giving the 2.1 g of the white phosphine (38%). mp 68°C, (lit. (2) mp 68–70°C) GS–MS-MS *m*/*z*: 442. ^{31}P NMR ($CDCl_3$) δ: –46.4.

Syntheses of phosphinous esters and their palladium complexes ($PdCl_2L_2$)

Our attempts to synthesize pentafluorophenyl esters of (di)phenyl phosphinous acid by the literature method (applied for the synthesis of 2,6-difluorophenyldiphenyl phosphinite) (3) using pentafluorophenol, triethyl amine, and chlorodiphenyl phosphine failed. Based on NMR analysis (data not shown) we suppose that because of its acidic properties pentafluorophenol forms an adduct with the amine rather then reacting with chlorophosphine. Increasing the ratio of phenol and amine to chlorophosphine led to inhomogeneous mixture, which was very difficult to separate and purify. An additional problem of very fast hydrolysis of esters by atmospheric humidity was also observed. We, therefore, decided to use a less convenient indirect way based on the application of sodium methanolate for generation of appropriate phenolate, which in turn reacts with stoichiometric amounts of chlorodiphenyl phosphine in ethyl ether.

Preparation of sodium salts of phenols $Na(OC_6F_5)$ and $Na(O\text{-}3,5\text{-}F_2C_6H_3)$: Metallic sodium was reacted with dry methanol. When all the metal was dissolved, a stochiometric amount of appropriate phenol was added, mixed, and then the methanol was removed on rotary evaporator. To the white product was added dry ethyl ether, mixed, evaporated (3 times), and dried in vacuo.

*Preparation of pentafluorophenyl diphenylphosphinite and $PdCl_2[PPh_2(OC_6F_5)]_2$ (**5**)*: Dry sodium pentafluorophenolate (0.486 g, 2.3 mM) was dissolved in a Schlenk flask in dry ethyl ether and cooled. A solution of of chlorodiphenyl-

phosphine (0.42 mL, 0.52 g, 2.3 mM) in ethyl ether (10 mL) of was added at once. The formation of sodium chloride occurred immediately. The mixture was stirred overnight. The NaCl was filtered off and solid $PdCl_2$(cod) (0.5 equiv) was added to the filtrate. The mixture was stirred 30 min and the yellow product was filtrated off and dried. ^{1}H NMR ($CDCl_3$) δ: 7.22 (t), 7.36 (t), 7.55 (q, Ph). Anal. calcd. for $C_{36}H_{20}Cl_2F_{10}O_2P_2Pd$: C 47.3, H 2.2; found: C 47.5, H 2.6.

Preparation of (3,5-difluorophenyl) diphenylphosphinite and $PdCl_2[PPh_2(O\text{-}3,5\text{-}F_2C_6H_3)]_2$ ***(6)***: Dry sodium 3,5-difluorophenolate (0.746 g, 5.2 mM) was allowed to react at 0°C with chlorodiphenyl phosphine (0.66 mL, 0.86 g, 3.9 mM) for 2 days. The insoluble salts were filtered off and the solution was used immediately to prepare the palladium complex (**6**) by the method given for (**5**). Yield: 78%. ^{1}H NMR ($CDCl_3$) δ: 6.1 (dd, $J_{H,F}$ = 8 Hz, $J_{H,H}$ = 2.0 Hz), 6.5 (dt, 3,5-$F_2C_6H_3$), 7.38 (t), 7.51 (vt), 7.75 (vq, Ph). Anal. calcd. for $C_{36}H_{26}Cl_2F_4O_2P_2Pd$: C 53.7, H 3.3; found: C 52.7, H 3.3.

Preparation of tert-*butyl diphenylphosphinite and* $PdCl_2[PPh_2(O\text{-t-}Bu)]_2$ ***(1)***: PPh_2(O-*t*-Bu) was prepared by reacting potassium *tert*-butanolate (0.634 g, 5.2 mM) with chlorodiphenyl phosphine (0.70 mL, 0.86 g, 3.9 mM) for 2 days. To the filtrated ether solution was added $PdCl_2$(cod) (0.5 equiv), and the complex (**1**) was isolated after 10 h of stirring of the mixture as a dark yellow powder (yield 85%). ^{1}H NMR ($CDCl_3$) δ: 0.2 (CH_3), 7.22 (t), 7.34 (d), 7.54 (q, Ph). Anal. calcd. for $C_{32}H_{48}Cl_2O_2P_2Pd$: C 54.6, H 6.9; found: C 54.7, H 6.3.

Preparation of ethyl diphenylphosphinite and $PdCl_2[PPh_2(OEt)]_2$ ***(9)***: PPh_2(OEt) was synthesized analogously to the butyl analog using sodium ethanolate (0.316 g, 4.6 mM) and chlorodiphenyl phosphine (0.83 mL, 1.03 g) in ether (30 mL) for 3 days. The addition of $PdCl_2$(cod) (0.5 equiv) and stirring of the mixture for 30 min allowed the formation of complex (**9**) with 90% yield. The crystals for X-ray studies were obtained by recrystallization of the yellow powder from CH_2Cl_2–EtOH. ^{1}H NMR ($CDCl_3$) δ: 0.96 (t, $J_{H,H}$ = 7 Hz, CH_3), 3.67 (q, CH_2), 7.38 (m), 7.48 (m), 7.76 (m, Ph). Anal. calcd. for $C_{28}H_{30}Cl_2O_2P_2Pd$: C 52.7, H 4.7; found: C 52.1, H 4.4.

Other syntheses

The other $PdCl_2L_2$ complexes have been obtained in reaction of $PdCl_2$(cod) with 2 mol equiv of phosphorus ligands in C_6H_6, CH_2Cl_2, or $(C_2H_5)_2O$. Depending on the solubility they have been isolated as precipitates or after solvent evaporation. In all cases the products have been washed by ethyl ether and dried in vacuo. The preparation and spectroscopic data of $PdCl_2[PPh_2(O\text{-}n\text{-}Bu)]_2$ (**10**) and $PdCl_2[P(OPh)_3]_2$ (**11**) are reported in ref. 11.

$PdCl_2[PPh_2(C_6F_5)]_2$ ***(4)***: ^{1}H NMR ($CDCl_3$) δ: 7.42 (t), 7.51 (t), 7.86 (q, Ph). Anal. calcd. for $C_{36}H_{20}Cl_2F_{10}P_2Pd$: C 49.0, H 2.3; found: C 49.9, H 3.0.

$PdCl_2[PPh(C_6F_5)_2]_2$ ***(8)***: ^{1}H NMR ($CDCl_3$) δ: 7.40 (t), 7.48 (t), 7.83 (q, Ph). Anal. calcd. for $C_{36}H_{10}Cl_2F_{20}P_2Pd$: C 40.7, H 1.0; found: C 40.7, H 1.0.

$PdCl_2[PCy_3]_2$ ***(3)***: ^{1}H NMR ($CDCl_3$) δ: 1.24 (s), 1.68 (m), 1.95 (d), 2.49 (m, CH_2). Anal. calcd. for $C_{36}H_{66}Cl_2P_2Pd$: C 58.6, H 9.0; found: C 58.0, H 8.5.

$PdCl_2[P(OCH_2CF_3)_3]_2$ ***(7)***: Anal. calcd. for $C_{12}H_{12}Cl_2F_{18}O_6P_2Pd$: C 17.3, H 1.5; found: C 17.1, H 1.2.

$PdCl_2[P(OMe)_3]_2$ ***(13)***: Compound **13** was obtained in reaction of $PdCl_2$(cod) with a fourfold excess of $P(OPh)_3$ in MeOH (yield 50%). ^{1}H NMR ($CDCl_3$) δ: 1.2 (s, CH_3). Anal. calcd. for $C_6H_{18}Cl_2O_6P_2Pd$: C 16.3 H 4.1; found: C 16.9, H 4.3.

Reactions of $PdCl_2L_2$ complexes with CO and NEt_3

In the typical experiment, MeOH (1 mL) and NEt_3 (ca. 0.01 mL) were added consecutively under dinitrogen to the palladium complex (0.05 g). The Schlenk tube was filled twice with CO and the solution was stirred under CO atmosphere for 30 min. The resulting precipitate of palladium carbonyl complex was filtrated off, dried, and analyzed by IR. The products decompose in the presence of air in ca. 30 min.

Carbonylation reaction of benzyl bromide

To the thermostated glass reactor (40°C), was added under a N_2 atmosphere MeOH (1.5 mL), NEt_3 (1.5 mL), and benzyl bromide (0.5 mL), the mixture was stirred for 1 min and then the catalyst (2.45×10^{-5} mol) in small teflon vessel was added. The reactor was connected with the CO-container (1 atm), flushed twice with CO, and left for 2 h with magnetic stirring. After that time, the reaction mixture was treated with HCl up to pH ca. 7. The reaction products were extracted with ethyl ether (1 mL) and analyzed by GC–MS.

X-ray crystallography

X-ray crystal data, together with refinement details, are given in Table 4. All measurements of crystal were performed on a Kuma KM4CCD κ-axis diffractometer with graphite-monochromated Mo Kα radiation. The crystal was positioned at 65 mm from the KM4CCD camera, and 612 frames were measured at 0.75° intervals with a counting time of 20 s. The data were corrected for Lorentz and polarization effects. No absorption correction was applied. Data reduction and analysis were carried out with the Kuma Diffraction (Wroclaw) programs. The structure was solved by direct methods (program SHELXS 97 (24)) and refined by the full-matrix least-squares method on all F^2 data using the SHELXL 97 (25) programs. Nonhydrogen atoms were refined with anisotropic thermal parameters; hydrogen atoms were included from geometry of molecules and Δρ maps but were not refined.

Conclusions

The attempts to correlate the spectroscopic (UV–vis, ^{31}P NMR) data of $PdCl_2L_2$ complexes with the steric and electronic parameters of phosphorus ligands (L) show a dominating influence of the steric over the electronic effect. Correlations between ^{31}P NMR coordination chemical shifts (Δ) and the cone angles (Θ) of L on the other are not perfect, but strong enough to show the tendency and directions

of changes. The most important conclusion of the reported studies is the finding that the catalytic activity of $PdCl_2L_2$ complexes in the carbonylation of benzyl bromide also depends mainly on the steric properties of L and thus on the *cis–trans* geometry of the starting complex. Complexes with less sterically hindered ligands (phosphites, phosphinites) having *cis* structure are more active than those with bulky ligands (Θ > 140°, e.g., PCy_3, PPh_2(O-*t*-Bu)). An exception should, however, be noted for complexes with bulky fluorinated phosphines ($PPh_x(C_6F_5)_{3-x}$, x = 0–2), which are *trans*-isomers that exhibit unexpectedly high catalytic activity.

The fluxionality and crystal structures of $[Fe_3(CO)_{10}L_2]$ (L_2 = dppm, $(Ph_2P)_2NH$, $\{(EtO)_2P\}_2O$) and $[Fe_3(CO)_9(dppm)\{P(OMe)_3\}]$

Harry Adams, Sylvana C.M. Agustinho, Krystyna Chomka, Brian E. Mann, Stephen Smith, Clare Squires, and Sharon E. Spey

Abstract: The crystal structures of $[Fe_3(CO)_{10}L_2]$ (L_2 = dppm, $(Ph_2P)_2NH$, $\{(EtO)_2P\}_2O$) and $[Fe_3(CO)_9(dppm)\{P(OMe)_3\}]$ (dppm = $(Ph_2P)_2CH_2$) have been determined. $[Fe_3(CO)_{10}L_2]$ (L_2 = dppm, $(Ph_2P)_2NH$, $\{(EtO)_2P\}_2O$) adopt a stereochemistry in the crystal with the bidentate ligand across an unbridged Fe–Fe edge, resulting in one phosphorus ligand being unusually in the axial position. In contrast, $[Fe_3(CO)_9(dppm)\{P(OMe)_3\}]$ adopts a stereochemistry in the crystal with the bidentate ligand across the bridged Fe–Fe edge. The structures of the $[Fe_3(CO)_{10}L_2]$ (L_2 = dppm, $(Ph_2P)_2NH$, $\{(EtO)_2P\}_2O$) support the Mann concerted bridge – opening bridge – closing mechanism of carbonyl fluxionality rather than the Johnson libration mechanism. The fluxionality of the compounds in the ^{13}C NMR spectra is explained by a combination of the concerted bridge – opening bridge – closing, merry-go-round, and trigonal twist mechanisms, and $\Delta G^{\ddagger}$ values were determined.

Key words: iron carbonyls, crystal structures, ^{13}C NMR spectroscopy, fluxionality, mechanisms.

Résumé : On a déterminé les structures cristallines des complexes $[Fe_3(CO)_{10}L_2]$ (L_2 = dppm, $(Ph_2P)_2NH$, $\{(EtO)_2P\}_2O$) et $[Fe_3(CO)_9(dppm)[P(OMe)_3]$. Dans le cristal, le $[Fe(CO)_{10}L_2$ (L_2 = dppm, $(Ph_2P)_2NH$, $[(EtO)_2P]_2O$) adopte une stéréochimie comportant un ligand bidentate à travers une arête non pontée Fe–Fe; il en résulte qu'un ligand phosphoré se trouve de façon inhabituelle en position axiale. Par ailleurs, à l'état cristallin, le $[Fe_3(CO)_9(dppm)\{P(OMe)_3\}]$ adopte une stéréochimie avec un ligand bidentate à travers une arête Fe–Fe pontée. Les structures des complexes $[Fe_3(CO)_{10}L_2]$ (L_2 = dppm, $(Ph_2P)_2NH$, $\{(EtO)_2P\}_2O$) sont en accord le mécanisme d'ouverture et fermeture concertées de pont de Mann pour la fluxion du carbonyle plutôt que le mécanisme de libration de Johnson. La fluxion des composés dans les spectres RMN du ^{13}C est expliquée par les mécanismes d'ouverture et de fermeture concertées de pont et de carrousel et par des mécanismes trigonaux déformés et on a déterminé les valeurs de $\Delta G^{\ddagger}$.

Mots clés : fer-carbonyle, structures cristallines, spectroscopie RMN du ^{13}C, fluxion, mécanismes.

[Traduit par la Rédaction]

Introduction

$[Fe_3(CO)_{12}]$ is highly fluxional, and even at –150°C a singlet is observed in the ^{13}C NMR spectrum (1). Cotton and Hunter (1) proposed that the fluxionality is a result of the merry-go-round mechanism, see Scheme 1. In 1976, Johnson (2) proposed a mechanism going via a $[Fe_3(CO)_{10}(\mu_3\text{-}CO)_2]$ intermediate and (or) transition state **1** as a result of rotation of the $Fe(CO)_4$ moieties. To slow down the fluxionality of $[Fe_3(CO)_{12}]$ on the NMR timescale, it is necessary to introduce ligands that do not readily move between iron atoms, and hence, block dynamic pathways.

There have been a number of papers reporting dynamic NMR investigation of $[Fe_3(CO)_{12}]$ derivatives. In 1981, Johnson and co-workers (3) examined the ^{13}C NMR spectrum of $[Fe_3(CO)_{11}\{P(OR)_3\}]$ and concluded that at –90°C it shows CO signals in an intensity ratio of 6:4:1. They explained the fluxionality on the basis of an icosahedron $\rightleftharpoons$ cube octahedron $\rightleftharpoons$ icosahedron rearrangement. Subsequently Farrar and Lunniss (4) synthesized a number of di- and trisubstituted $[Fe_3(CO)_{12}]$ derivatives. Unfortunately, their interpretation of the fluxionality was flawed as it required the activation energy of the merry-go-round mechanism to vary wildly between similar derivatives.

In 1989, the fluxionality of $[Fe_3(CO)_{12-n}\{P(OMe)_3\}_n]$ was reexamined (5). It was found that at –101°C, the intensity of the carbonyl signals of $[Fe_3(CO)_{11}\{P(OMe)_3\}]$ are 5:5:1, not 6:4:1 as previously reported (3). As a result, a new mechanism for the fluxionality of $[Fe_3(CO)_{12}]$ and its derivatives was proposed (5). The mechanism involves the rotation of the Fe_3 triangle around the S_{10} axis of the carbonyl icosahedron defined by carbonyls C(6)O and C(10)O, see

Scheme 1.

Scheme 2.

Scheme 2.[3] As the carbonyl bridge opens on one Fe–Fe edge, another closes on a second Fe–Fe edge, and hence, this mechanism is described as the concerted bridge – opening bridge – closing mechanism. The halfway stage of this carbonyl exchange has been observed in the crystal structure of $[Fe_3(CO)_{10}\{1,2\text{-}(Me_2As)_2C_6H_4\}]$ (6). This mechanism, when applied to $[Fe_3(CO)_{11}\{P(OMe)_3\}]$, causes the exchange of carbonyls C(1)O, C(2)O, C(7)O, C(11)O, and C(12)O as one set of five carbonyls, and C(3)O, C(4)O, C(5)O, C(8)O, and C(9)O as the second set of five carbonyls, leaving C(6)O as the unique carbonyl.

Subsequently Johnson and Bott (7) revised the Johnson mechanism, and showed how rotations of the $Fe(CO)_4$ groups about the axis going through the iron and the opposite edge of the Fe_3 triangle, called librations, could lead to the same exchange.

An investigation involving $[Fe_3(CO)_{10}(CN\text{-}t\text{-}Bu)\{P(OMe)_3\}]$ confirmed that the rotation of the two groups of five carbonyls is concerted (8).

To differentiate between the two mechanisms, an analysis of X-ray crystal structures was performed (9). A Bürgi–Dunitz analysis (10) was applied to then known crystal structures and a web movie was produced.[4]

The Johnson libration mechanism and the Mann concerted bridge – opening bridge – closing mechanism differ in the pathway followed by the iron triangle during fluxional pathway. However, the difference is best seen in terms of the location of the carbonyls with respect to the iron triangle. In the Johnson libration mechanism all the equatorial carbonyls (C(5)O, C(6)O, C(7)O, C(10)O) move out of the plane defined by the iron triangle. In the Mann concerted bridge – opening bridge – closing mechanism, C(5)O and C(7)O move out of the plane defined by the iron triangle, while C(6)O and C(10)O remain in the plane. The crystal structure of $[Fe_3(CO)_{10}\{1,2\text{-}(Me_2As)_2C_6H_4\}]$ (6) represents the half way stage for the exchange. The structure lies almost exactly on the ideal pathway predicted by the Mann concerted bridge – opening bridge – closing mechanism with the line joining C(6)O and C(10)O lying only 2.6° from the plane of the iron triangle. Although Johnson (11) published a rebuttal of the Mann concerted bridge – opening bridge – closing mechanism, he failed to address this key point. Johnson also claimed priority, but his mechanism is different going via **1**, which does not lie on the pathway mapped out by the Bürgi–Dunitz analysis (9).

The majority of crystal structures of $[Fe_3(CO)_{12}]$ and its derivatives have structures that are close to that found in $[Fe_3(CO)_{12}]$ and shed little light on the differences between the two mechanisms. In view of the distortion produced by $1,2\text{-}(Me_2As)_2C_6H_4$, a number of compounds containing bidentate ligands have been synthesized. $[Fe_3(CO)_{10}(dppe)]$ showed only minor distortions from the $[Fe_3(CO)_{12}]$ structure with the ligand bridging the $Fe(\mu\text{-}CO)_2Fe$ edge of the iron triangle (12, 13). To increase the distortions, ligands with a smaller bite angle were examined, and it is this that is reported in this paper.

Experimental

$[Fe_3(CO)_{12}]$ was synthesized according to the literature (14). $Me_3NO{\cdot}2H_2O$, $Ph_2PCH_2PPh_2$ ($Ph_2PCH_2PPh_2$ = dppm), $(EtO)_2POP(OEt)_2$, and $P(OMe)_3$ were purchased from Aldrich. $Ph_2PNHPPh_2$ was purchased from Strem Chemicals, Inc. $Me_3NO{\cdot}2H_2O$ was dehydrated by Dean–Stark distillation using toluene.

Synthesis of $[Fe_3(CO)_{10}L_2]$ (L_2 = dppm, $Ph_2PNHPPh_2$, $(EtO)_2POP(OEt)_2$)

$[Fe_3(CO)_{12}]$ (0.5 g, 0.992 mmol) was placed in a nitrogen purged three-neck round-bottom flask and dissolved in

[3] There is an identical axis through C(5)O and C(7)O.
[4] To observe movie go to http://www.shef.ac.uk/misc/personal/ch1bem/Fe3-carbonyl12A.html.

© 2001 NRC Canada

CH_2Cl_2 (150 cm^3). The flask was cooled to –78°C in a solid CO_2–acetone bath. The phosphorus ligand (0.992 mmol) was slowly added to the flask with stirring, followed by Me_3NO (0.15 g, 2.0 mmol). The flask was left in the solid CO_2–acetone bath and allowed to warm to room temperature. The reaction was then monitored by TLC; all the $[Fe_3(CO)_{12}]$ had been consumed in 4 h at room temperature. The solvent was removed and the product purified by chromatography on a 30 cm silica gel column, eluting with hexane–CH_2Cl_2 (3:1). The dark green compounds were recrystallized from acetonitrile.

$[Fe_3(CO)_{10}(dppm)]$

Yield: 47%. MS *m/z*: 832. IR (CH_2Cl_2) (cm^{-1}): 2114, 2048, 2008. ^{13}C NMR (–105°C) δ: 229.9, 225.5, 218.6, 205.9, 131.5 (t, $N_{P,C}$ = 48 Hz), 130.5 (*ortho*), 129.8 (*para*), 127.7 (*meta*), 47.8, ($J_{P,C}$ = 19 Hz, CH_2). ^{31}P NMR (CD_2Cl_2) δ: 47.

$[Fe_3(CO)_{10}(Ph_2PNHPPh_2)]$

Yield: 25%. Crystallographic data for $[Fe_3(CO)_{10}(dppm)]\cdot 1.5NCCH_3$

Crystal data for $C_{76}H_{53}Fe_6N_3O_{20}P_4$: MW = 1787.19, crystallizes from acetonitrile as black blocks, crystal dimensions 0.10 × 0.02 × 0.02 mm^3. Triclinic, space group $P\bar{1}$, *a* = 11.3686(13), *b* = 17.2410(19), and *c* = 20.148(2) Å, α = 82.753(2), β = 83.366(2), and γ = 72.853(2)°, *U* = 3730.6(7) $Å^3$, *Z* = 2, D_c = 1.591 Mg m^{-3}, Mo Kα radiation (λ = 0.71073 Å), μ (Mo Kα) = 1.297 mm^{-1}, *F*(000) = 1812.

Data collected were measured on a Bruker Smart CCD area detector with Oxford Cryosystems low temperature system. Cell parameters were refined from the setting angles of 64 reflections (θ range 1.02 < 23.35°).

Reflections were measured from a hemisphere of data collected of frames each covering 0.3 degrees in omega. Of the 16769 reflections measured, all of which were corrected for Lorentz and polarization effects and for absorption by semi empirical methods based on symmetry-equivalent and repeated reflections (minimum and maximum transmission coefficients 0.8812 and 0.9745), 6546 independent reflections exceeded the significance level $|F|/\sigma(|F|) > 4.0$. The structure was solved by direct methods and refined by full-matrix least-squares methods on F^2. Hydrogen atoms were placed geometrically and refined with a riding model (including torsional freedom for methyl groups) and with U_{iso} constrained to be $1.2U_{eq}$ (1.5 for methyl groups) of the carrier atom. Refinement converged at a final *R* = 0.0598 (wR_2 = 0.2215, for all 10688 data, 984 parameters, mean and maximum δ/σ: 0.000, 0.001) with allowance for the thermal anisotropy of all non-hydrogen atoms. Minimum and maximum final electron density –0.834 and 1.540 e $Å^{-3}$.

A weighting scheme $w = 1/[\sigma^2(F_o^2) + (0.1390P)^2 + 0.00P]$ where $P = (F_o^2 + 2F_c^2)/3$ was used in the latter stages of refinement. Complex scattering factors were taken from the program package SHELXTL (15) as implemented on the Viglen Pentium computer.

Crystallographic data for $[Fe_3(CO)_{10}(Ph_2PNHPPh_2)]\cdot 0.5CH_2Cl_2$

Crystal data for $C_{34.5}H_{22}ClNO_{10}P_2Fe_3$: MW = 875.47, crystallizes from deuterated dichloromethane as dark green blocks, crystal dimensions 0.38 × 0.25 × 0.12 mm^3. Monoclinic, space group *C*2/*c*, *a* = 22.223(15), *b* = 20.984(17), and *c* = 16.229(15) Å, β = 106.46(6)°, *U* = 7258(10) $Å^3$, *Z* = 8, D_c = 1.602 Mg m^{-3}, Mo Kα radiation (λ = 0.71073 Å), μ (Mo Kα) = 1.402 mm^{-1}, *F*(000) = 3528.

Three-dimensional, room temperature X-ray crystal data were collected in the range 2.72 < 2θ < 50.20° on a Siemens P4 diffractometer by the omega scan method. Of the 7266 reflections measured, all of which were corrected for Lorentz and polarization effects, and for absorption by semi-empirical methods based on symmetry-equivalent and repeated reflections (minimum and maximum transmission coefficients 0.6178 and 0.8498), 3620 independent reflections exceeded the significance level $|F|/\sigma(|F|) > 4.0$. The structure was solved by direct methods and refined by full-matrix least-squares methods on F^2. Hydrogen atoms were placed geometrically and refined with a riding model and with U_{iso} constrained to be $1.2U_{eq}$ of the carrier atom. Refinement converged at a final *R* = 0.0908 (wR_2 = 0.2657 for all 6338 data, 465 parameters, mean and maximum δ/σ: 0.000, 0.000) with allowance for the thermal anisotropy of all non-hydrogen atoms. Minimum and maximum final electron density –0.709 and 1.402e $Å^{-3}$ (the latter 1.28 Å from Fe(1)). A weighting scheme $w = 1/[\sigma^2(F_o^2) + (0.1456P)^2 + 0.00P]$ where $P = (F_o^2 + 2F_o^2)/3$ was used in the latter stages of refinement. Complex scattering factors were taken from the program package SHELXTL (15) as implemented on the Viglen Pentium computer.

Crystallographic data for $[Fe_3(CO)_{10}\{(EtO)_2POP(OEt)_2\}]$

Crystal data for $C_{18}H_{20}Fe_3O_{15}P_2$: MW = 705.83, crystallizes from pet ether as black blocks, crystal dimensions 0.20 × 0.10 × 0.06 mm. Monoclinic, space group $P2_1/n$ (a non-standard setting of $P2_1/c$ C_h, No. 14), *a* = 9.175(5), *b* = 18.294(11), and *c* = 16.584(10) Å, β = 104.489(13)°, *U* =

2695(3) Å^3, Z = 4, D_c = 1.740 Mg m^{-3}, Mo Kα radiation (λ = 0.71073 Å), μ (Mo Kα) = 1.781 mm^{-1}, F(000) = 1424.

Data collected were measured on a Bruker Smart CCD area detector with Oxford Cryosystems low temperature system. Cell parameters were refined from the setting angles of 23 reflections (θ range 1.69 < 28.47°).

Reflections were measured from a hemisphere of data collected of frames each covering 0.3 degrees in omega. Of the 17546 reflections measured, all of which were corrected for Lorentz and polarization effects and for absorption by semi empirical methods based on symmetry-equivalent and repeated reflections (minimum and maximum transmission coefficients 0.7172 and 0.9007) 2572 independent reflections exceeded the significance level $|F|/\sigma(|F|) > 4.0$. The structure was solved by direct methods and refined by full-matrix least-squares methods on F^2. Hydrogen atoms were placed geometrically and refined with a riding model (including torsional freedom for methyl groups) and with U_{iso} constrained to be $1.2U_{eq}$ (1.5 for methyl groups) of the carrier atom. Refinement converged at a final R = 0.0766 (wR_2 = 0.2053 for all 6439 data, 343 parameters, mean and maximum δ/σ: 0.000, 0.000) with allowance for the thermal anisotropy of all non-hydrogen atoms. Minimum and maximum final electron density –0.762 and 0.890e Å^{-3}.

A weighting scheme $w = 1/[\sigma^2(F_o^2) + (0.0824P)^2 + 0.00P]$ where $P = (F_o^2 + F_c^2)/3$ was used in the latter stages of refinement. Complex scattering factors were taken from the program package SHELXTL (15) as implemented on the Viglen Pentium computer.

Crystallographic data for $[Fe_3(CO)_9(dppm)\{P(OMe)_3\}]\cdot 0.618NCCH_3\cdot 0.382CH_3CH_2OH$

Crystal data for $C_{39}H_{35.14}N_{0.62}O_{12.38}P_3Fe_3$ ($C_{37}H_{31}Fe_3O_{12}P_3$ and two disordered solvents – acetonitrile and ethanol): MW = 971.04, crystallizes from acetonitrile – pet. ether as black plates, crystal dimensions 0.26 × 0.15 × 0.02 mm^3. Monoclinic, space group $P2_1/n$ (a non-standard setting of $P2_1/c$ C_{2h}^5, No. 14), a = 11.1541(16), b = 10.3350(14), and c = 35.384(5) Å, β = 91.678(3)°, U = 4077.3(10) Å^3, Z = 4, D_c = 1.582 Mg m^{-3}, Mo Kα radiation (λ = 0.71073 Å), μ (Mo Kα) = 1.235 mm^{-1}, F(000) = 1982.

Data collected were measured on a Bruker Smart CCD area detector with Oxford Cryosystems low temperature system. Cell parameters were refined from the setting angles of 98 reflections (θ range 1.15 to 28.33°).

Reflections were measured from a hemisphere of data collected of frames each covering 0.3 degrees in omega. Of the 23908 reflections measured, all of which were corrected for Lorentz and polarization effects and for absorption by semi empirical methods based on symmetry-equivalent and repeated reflections (minimum and maximum transmission coefficients 0.7396 and 0.9757) 4145 independent reflections exceeded the significance level $|F|/\sigma(|F|) > 4.0$. The structure was solved by direct methods and refined by full-matrix least-squares methods on F^2. Hydrogen atoms were placed geometrically and refined with a riding model (including torsional freedom for methyl groups) and with U_{iso} constrained to be $1.2U_{eq}$ (1.5 for methyl groups) of the carrier atom. Refinement converged at a final R = 0.0648 (wR_2 = 0.1180 for all 9780 data, 522 parameters, mean and maximum δ/σ: 0.000, 0.000) with allowance for the thermal anisotropy of all non-hydrogen atoms with the exception of the solvent molecules. Minimum and maximum final electron density –0.613 and 1.004 e Å^{-3}. Two solvents of crystallization were found to be disordered and refined as 61.8% acetonitrile and 38.2% ethanol. A weighting scheme $w = 1/[\sigma^2(F_o^2) + (0.0225P)^2 + 0.00P]$ where $P = (F_o^2 + 2F_c^2)/3$ was used in the latter stages of refinement. Complex scattering factors were taken from the program package SHELXTL (15) as implemented on the Viglen Pentium computer.

NMR Investigations

NMR spectra were recorded on a Bruker AMX400 NMR spectrometer in CD_2Cl_2. Temperatures were calibrated using a Comark electronic thermometer, placing a thermocouple in an NMR tube containing ethanol and placing this tube in the probe. EXSY spectra were determined qualitatively using the Bruker pulse sequence "NOESYTP" which had been modified to include ^{1}H composite pulse decoupling.

$\Delta G^{\ddagger}$ values were obtained from line widths. In most cases the simple equation, $k = \pi\Delta\nu$ was used below coalescence, where Δν is the line broadening due to exchange. This was estimated from the spectrum. In the case of rotation about the C(7)O–P(1) axis in $[Fe_3(CO)_{10}\{(EtO)_2POP(OEt)_2]$, only a broad signal was obtained for C(1)O, C(3)O, C(4)O, and C(12)O at –106°C. It was assumed that in the absence of rotation about the C(7)O–P(1) axis they would give two signals of equal intensity separated by 15 ppm. The equation given below was used to determine the rate.

$$[1] \qquad k = \frac{\pi(\nu_A - \nu_B)^2}{2\Delta\nu}$$

Results and discussion

Crystallographic sudies

The crystal structures of $[Fe_3(CO)_{10}L_2]$ (L_2 = dppm, $(Ph_2P)_2NH$, $\{(EtO)_2P\}_2O$)

The crystal structures of $[Fe_3(CO)_{10}L_2]$ (L_2 = dppm, $(Ph_2P)_2NH$, $\{(EtO)_2P\}_2O$) are all similar and are shown in Figs. 1–4. Crystal intensity data, and collection and structural refinement information are summarized in Table 1. Positional parameters and isotropic thermal parameters are given for the four compounds in Tables 2–5. Key distances and angles are given in Table 6.

The phosphorus ligand substitutes an equatorial carbonyl on Fe(1) and an axial carbonyl on Fe(3). This contrasts with the structure of $[Fe_3(CO)_{10}(dppe)]$ where the ligand bridges the Fe(μ-CO)$_2$Fe edge of the iron triangle. For monodentate phosphorus ligands there is a strong preference for them to go into an equatorial position (12), and this is the first example where a phosphorus group goes into an axial position. As a result the structure distorts towards a geometry where this phosphorus is equatorial. This can be seen in a view down the C(6)O–C(10)O axis, see Fig. 5, where P(2) is markedly out of the plane of the Fe_3 triangle. The group of five ligands at the front of the projection, C(1)O, C(2)O, C(7)O, C(11)O, and P(1), have rotated clockwise from the position found in $[Fe_3(CO)_{12}]$. As a result of this rotation, carbonyls C(1)O and C(2)O have become semi-bridging.

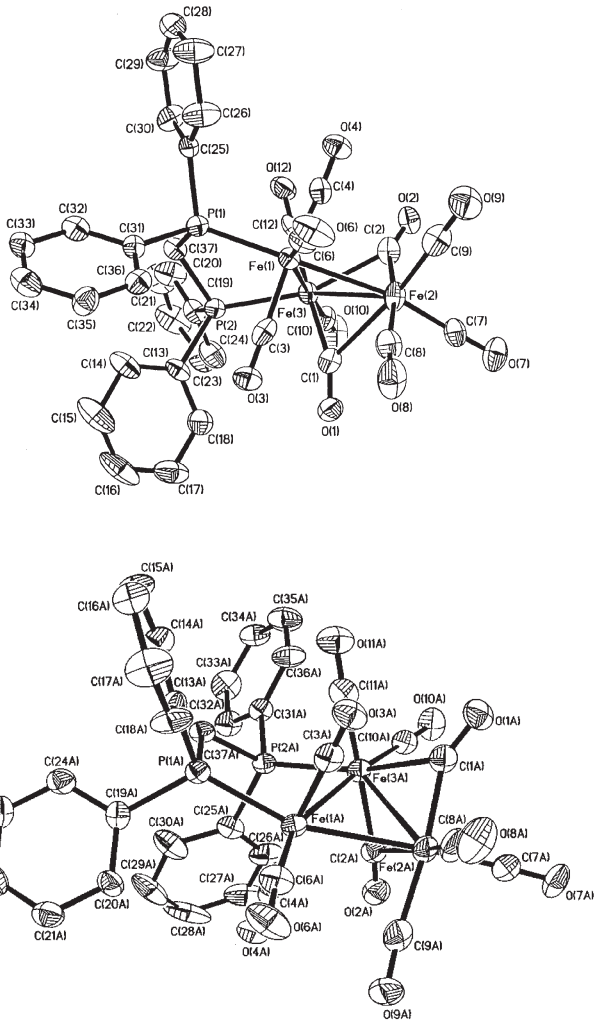

Fig. 2. The molecular structure of $[Fe_3(CO)_{10}(Ph_2PNHPPh_2)]$ as an ORTEP diagram showing the numbering system.

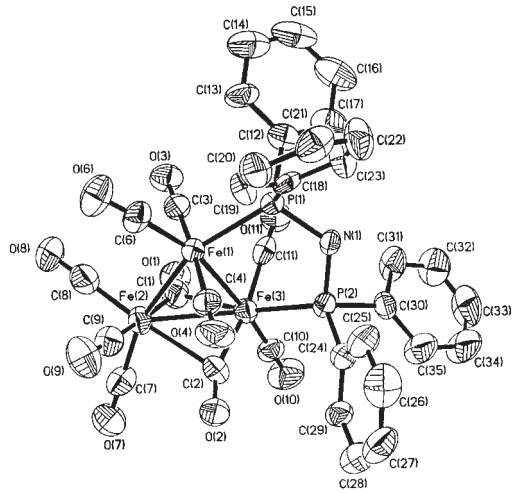

Fig. 3. The molecular structure of $[Fe_3(CO)_{10}\{(EtO)_2POPO(OEt)_2\}]$ as an ORTEP diagram showing the numbering system.

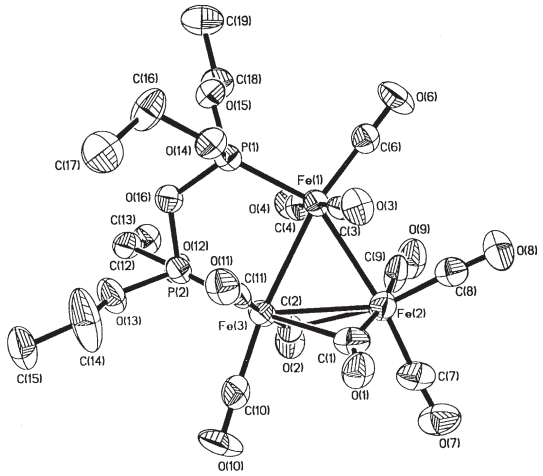

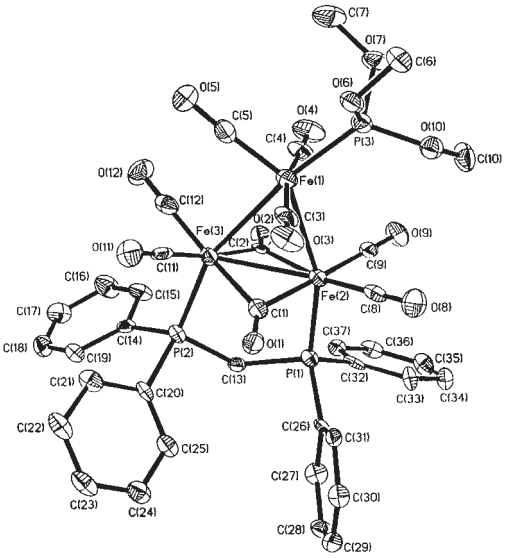

Fig. 4. The molecular structure of $[Fe_3(CO)_9(dppm)\{P(OMe)_3\}]$ as an ORTEP diagram showing the numbering system.

There has been a smaller clockwise rotation for C(3)O, P(1), C(4)O, C(9)O, and C(8)O.

In view of the strong tendency of phosphorus ligands to go into equatorial positions, it might be expected that the chelating ligands would prefer to coordinate in the positions occupied by C(5)O and C(6)O, or C(7)O and C(10)O. The only example of a similar bidentate ligand coordinating to a single iron in $[Fe_3(CO)_{12}]$ derivatives is $[Fe_3(CO)_{10}\{1,2\text{-}(Me_2As)_2C_6H_4\}]$ (6). It is possible that such a derivative is formed for $[Fe_3(CO)_{10}L_2]$ (L_2 = dppm, $(Ph_2P)_2NH$, $\{(EtO)_2P\}_2O$), but the compounds decompose. This leaves coordination in the positions of C(7)O and C(10)O. This geometry is adopted by $[Fe_3(CO)_{10}\{(Ph_2PC_5H_4\text{-}\eta^5)_2Fe\}]$ (16), $[Fe_3(CO)_{10}(dppe)]$ (13), and $[Fe_3(CO)_{10}\{1,2\text{-}(Me_2As)_2\text{-}$perfluorocyclobut-1-ene$\}]$ (17). For these compounds, the P···P–As···As distances are 4.797, 3.867, and 4.079–4.083 Å, respectively. This is a long distance for the ligands dppm, $(Ph_2P)_2NH$, and $\{(EtO)_2P\}_2O$ to bridge. The distance can be

reduced by bridging between the positions occupied by C(5)O and C(12)O. In the case of $[Fe_3(CO)_{12}]$ at 100 K (18), the C(7)O···C(10)O carbon—carbon distance is 3.948 Å, while the C(5)O···C(12)O carbon—carbon distance is 3.480 Å. The distance is reduced further by decreasing the torsion angle from 46.9° for C(5)-Fe(1)-Fe(3)-C(12) found in $[Fe_3(CO)_{12}]$ at 100 K (18), to between 29.5 and 32.5° for P(1)-Fe(1)-Fe(3)-P(2). The P···P distances are L_2 = dppm (3.067(2), 3.053(2) Å), $Ph_2PNHPPh_2$ (2.978(4) Å), and $(EtO)_2POP(OEt)_2$ (2.836(3) Å).

The crystal structure of $[Fe_3(CO)_9(dppm)\{P(OMe)_3\}]$

The crystal structure of $[Fe_3(CO)_9(dppm)\{P(OMe)_3\}]$ is shown in Fig. 4, and key distances and angles are given in Table 1. In contrast with $[Fe_3(CO)_{10}L_2]$ (L_2 = dppm, $(Ph_2P)_2NH$, $\{(EtO)_2P\}_2O$) it is the Fe(μ-CO)$_2$Fe edge that is bridged by the dppm ligand. It would be wrong to attribute this change of geometry to the $P(OMe)_3$ ligand as it will be shown later by ^{13}C NMR spectroscopy that both geometries are present in solution. Hence, the geometry observed in the crystal structure is more a function of crystal packing than of intramolecular factors.

Comparison of the concerted bridge – opening bridge – closing and the libration mechanisms

The molecules $[Fe_3(CO)_{10}L_2]$ (L_2 = dppm, $(Ph_2P)_2NH$, $\{(EtO)_2P\}_2O$) provide excellent examples to compare the concerted bridge – opening bridge – closing and the libration mechanisms. The L_2 ligand bridges between the C(5)O and C(12)O coordination sites. The P···P distance is rather short and this will cause a torque to try to rotate the iron triangle within the icosahedron of ligands. If the

libration mechanism is the lowest energy pathway, then the ligands P(1), C(6)O, C(7)O, and C(10)O will all be out of the plane of the iron triangle. If the concerted bridge – opening bridge – closing mechanism is the lowest energy pathway, then P(1) and C(7)O are permitted to move out of the plane of the iron triangle, but C(6)O and C(10)O should remain in it. Examination of the data in Table 7 shows that C(6)O and C(10)O do remain in the plane of the iron triangle, while P(1) and C(7)O move substantially out of the plane. This is strong evidence for the concerted bridge – opening bridge – closing mechanism over the libration mechanism.

Although it has been shown that the two groups, each composed of five ligands, rotate about the S_{10} axis of the

icosahedron concertedly (7), the crystal structures of $[Fe_3(CO)_{10}L_2]$ (L_2 = dppm, $(Ph_2P)_2NH$, $\{(EtO)_2P\}_2O$) show that it is possible to distort the icosahedron by slightly rotating one set of five ligands with respect to the other. This can be seen qualitatively in Fig. 5, where the L_2 ligand closes the angle between the two sets of ligands, C(1)O, C(11)O, P2, C(2)O, and C(7)O with C(3)O, P(1), C(4)O, C(9)O, and C(8)O. This can be seen most easily by comparing the projected angle between P(1)-Fe(1)-Fe(3)-P(2) with the angles between P(1)-Fe(1)-Fe(2)-C(11) and C(4)-Fe(1)-Fe(2)-P(2). The distortion is localized to that side of the icosahedron and is barely apparent around C(7). This can be verified by comparing the projected angles between C(8)-Fe(2)-C(7) and C(7)-Fe(2)-C(9) in Fig. 5.

NMR spectra and fluxionality

For $[Fe_3(CO)_{10}L_2]$ (L_2 = dppm, $(Ph_2P)_2NH$, $\{(EtO)_2P\}_2O$) the ^{13}C carbonyl NMR spectrum in CD_2Cl_2 consists of a singlet at approximately δ 223. On cooling to ca. –40°C two new signals appear at approximately δ 206 and 230 giving intensity ratios of 2:6:2, respectively. These two signals are not observed at room temperature as they are exchanging at an intermediate rate of exchange, and hence, give a signal too broad to observe. Because at room temperature the signal at δ 223 is broadened, presumably by exchange with these two signals, it is possible that all three signals are exchanging by a single dynamic process. Pairwise exchange between the signals at approximately δ 206 and 230 was demonstrated using exchange spectroscopy (EXSY), see Fig. 6. It will be shown later that these signals are due to C(2)O–C(8)O and C(7)O–C(9)O, and the free energies of activation were derived for this pairwise exchange for all three compounds, see Table 8.

A similar exchange is observed between C(2)O–C(8)O and C(9)O in $\{Fe_3(CO)_9(dppm)\{P(OMe)_3\}]$, and the activation energy for this is also given in Table 8.

On further cooling of $[Fe_3(CO)_{10}(dppm)]$, the ^{13}C NMR signal at ca. δ 223 broadened and split into two signals at δ 225.4 and 218.6, in a 2:4 ratio (Fig. 7). In the case of $[Fe_3(CO)_{10}\{(EtO)_2POP(OEt)_2\}]$, the ^{13}C NMR signal at δ 223 split into two very broad signals at δ 223 and 206, in a 4:2 intensity ratio (Fig. 8). In the case of $[Fe_3(CO)_{10}(Ph_2PNHPPh_2)]$, the low temperature limit was not achieved and the central signal of intensity 6 produced a broad hump, as seen in Fig. 9.

The variable temperature behaviour of the ^{13}C NMR spectra of $[Fe_3(CO)_{10}L_2]$ (L_2 = dppm, $(Ph_2P)_2NH$, $\{(EtO)_2P\}_2O$) proved difficult to explain until the low temperature ^{13}C NMR spectrum of $[Fe_3(CO)_9(dppm)\{P(OMe)_3\}]$ was recorded. The presence of the $P(OMe)_3$ ligand acted as a block, and the low temperature ^{13}C NMR spectrum consisted

[a]Two independent molecules in each unit cell. Note that the two molecules are mirror images of each other to the first approximation. This results in reversal of bond lengths involving C(1)O and C(2)O.

Fig. 5. A projection of the crystal structure of $[Fe_3(CO)_{10}(dppm)]$ looking along the S_{10} axis from C(6)O to C(10)O.

of five signals with an intensity ratio of 2:2:2:2:1, see Fig. 10.

Previous work has shown that only two dynamic processes need to be considered at ca. –100°C (5). In $[Fe_3(CO)_{12}]$ and its derivatives, the concerted bridge – opening bridge – closing mechanism is very fast unless blocked by a ligand, and $\Delta G^{\ddagger}$ is less than 16 kJ mol^{-1}. In general, the merry-go-round mechanism is just stopped at –100°C with $\Delta G^{\ddagger}$ around 40 kJ mol^{-1}. However, with the dppm, $Ph_2PNHPPh_2$, and $(EtO)_2POP(OEt)_2$ ligands used in this paper, the ligands are trying to open the Fe(μ-CO)$_2$Fe bridge as shown by the asymmetric nature of the bridge, and the barrier for the merry-go-round mechanism could be lowered.

There are two types of the concerted bridge – opening bridge – closing mechanism possible in these complexes. The rotation may occur about the C(6)O–C(10)O axis, see Scheme 3, or about the C(7)O–P(1) axis, see Scheme 4.

Rotation about the C(6)O–C(10)O axis in Scheme 3 has the effect of exchanging the role of the two phosphorus atoms and making the carbonyl ligands pairwise exchange. There is no apparent reason for this dynamic process to be of much higher energy than in $[Fe_3(CO)_{12}]$ and is expected to be fast on the NMR timescale at –100°C. Substitution of C(7)O by $P(OMe)_3$ in $[Fe_3(CO)_9(dppm)\{P(OMe)_3\}]$ will result in the blockage of this pathway, as there is a substantial barrier to the phosphorus ligands going into the axial position.

The ease of rotation about the C(7)O–P(1) axis will depend on the accessibility of the isomer with the chelating phosphorus ligand along the Fe(μ-CO)$_2$Fe edge. This should

be accessible for $[Fe_3(CO)_{10}(dppm)]$ as this bonding arrangement is found in the crystal structure of $[Fe_3(CO)_9(dppm)\{P(OMe)_3\}]$. However, as the P···P distance shortens on going to $[Fe_3(CO)_{10}(Ph_2PNHPPh_2)]$ and $[Fe_3(CO)_{10}\{(EtO)_2POP(OEt)_2\}]$, the barrier to this pathway should increase. As C(7)O lies on the axis of rotation, substitution by $P(OMe)_3$ should not block the pathway based on this rotation, but it will block the pathway based on rotation about the C(9)O–P(2) given in Scheme 4.

The effect of the merry-go-round mechanism is given in Scheme 5. At ca. –40°C, the ^{13}C carbonyl spectrum of $[Fe_3(CO)_{10}L_2]$ (L_2 = dppm, $(Ph_2P)_2NH$, $\{(EtO)_2P\}_2O$) consists of a 2:6:2 set of signals. No single mechanism produces six exchanging carbonyls, nor does a combination of two mechanisms. To achieve this pattern all three mechanisms shown in Schemes 3–5 have to be combined. This produces the exchanging sets of carbonyls: C(2)O and C(8)O; C(1)O, C(3)O, C(4)O, C(6)O, C(10)O, and C(12)O; C(7)O and C(9)O.

On cooling to around –105°C, the carbonyl ^{13}C NMR signals split to give a 2:2:4:2 pattern for $[Fe_3(CO)_{10}(dppm)]$ and a 2:4:2:2 pattern for $[Fe_3(CO)_{10}\{(EtO)_2POP(OEt)_2\}]$. The behaviour is markedly different for the two compounds with the new signal of intensity 2 being at δ 225.6 for $[Fe_3(CO)_{10}(dppm)]$ and δ 206 for $[Fe_3(CO)_{10}\{(EtO)_2POP(OEt)_2]$. The behaviour is substantially different and suggests for one the mechanism in Scheme 4 is freezing out, while for the other it is the mechanism in Scheme 5 that is freezing out. Combining the mechanisms in Schemes 3 and 4 produces

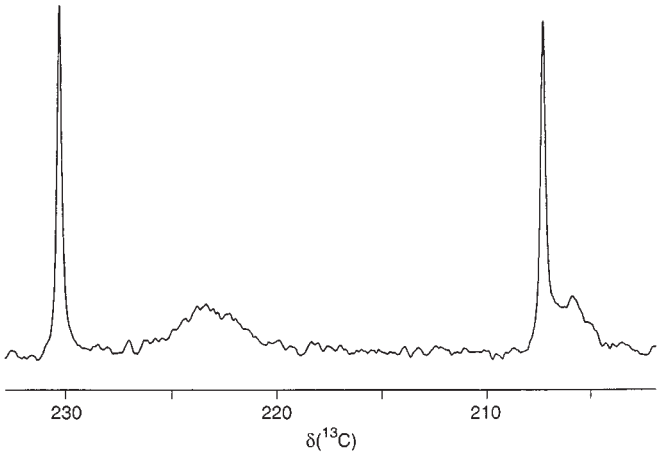
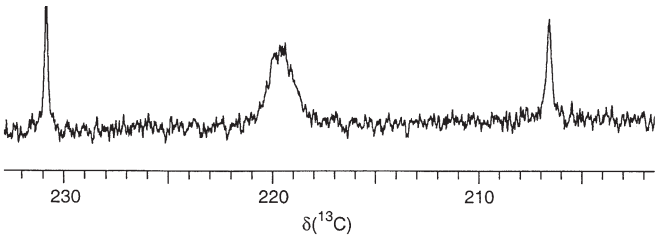
Fig. 8. A partial 100.62 MHz ^{13}C NMR spectrum of $[Fe_3(CO)_{10}\{(EtO)_2POP(OEt)_2\}]$ in CD_2Cl_2 at –106°C.





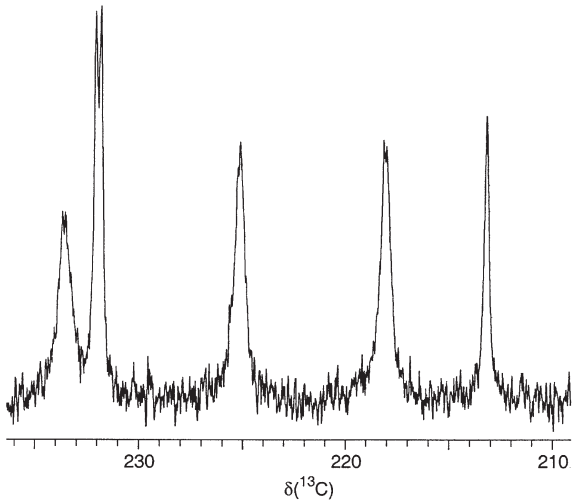


Fig. 9. A partial 100.62 MHz ^{13}C NMR spectrum of $[Fe_3(CO)_{10}(Ph_2PNHPPh_2)]$ in CD_2Cl_2 at –105°C.

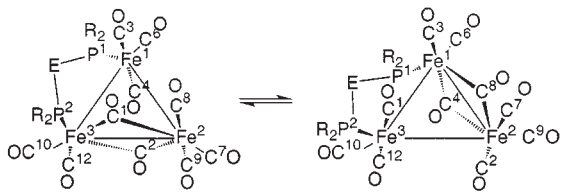

four sets of exchanging carbonyls: C(2)O and C(8)O; C(3)O and C(12)O; C(1)O, C(4)O, C(6)O, and C(10)O; C(7)O and C(9)O. Combining the mechanisms in Schemes 3 and 5 produces the exchanging sets of carbonyls: C(2)O and C(8)O; C(1)O, C(3)O, C(4)O, and C(12)O; C(6)O and C(10)O; C(7)O and C(9)O. This analysis works very well for $[Fe_3(CO)_{10}\{(EtO)_2POP(OEt)_2]$ with the mechanism in Scheme 4 freezing out. Figure 11 shows the estimated chemical shifts for the carbonyls at the various positions of $[Fe_3(CO)_{12}]$. This can be used to estimate the ^{13}C chemical shifts for the carbonyls of $[Fe_3(CO)_{10}\{(EtO)_2POP(OEt)_2]$ assuming that the fluxional mechanisms are according to Schemes 3 and 5. The calculated shifts (δ) based on Fig. 11 are as follows: 233.5 for C(2)O, C(8)O; 227.8 for C(1)O, C(3)O, C(4)O, C(12)O; 207 for C(6)O, C(10)O; and 209 for C(7)O, C(9)O, which are in tolerable agreement with the observed shifts (Table 9). A perfect agreement would not be expected as the effects of substitution and distortion from an ideal geometry would produce deviations from the predicted values.

When this approach is applied to $[Fe_3(CO)_{10}(dppm)]$ with the mechanism in Scheme 5 frozen out, there is a problem. The predicted chemical shifts (δ), based on the crystal structure, for the four sets of exchanging carbonyls are: 233.5 for C(2)O, C(8)O; 218.5 for C(3)O, C(12)O; 222 for C(1)O, C(4)O, C(6)O, C(10)O; and 209 for C(7)O, C(9)O. The agreement is very poor for C(3)O and C(12)O. However, as the crystal structure of $[Fe_3(CO)_9(dppm)\{P(OMe)_3\}]$ shows that the geometry with the chelate ligand across the Fe(μ-$CO)_2$Fe edge is accessible the chemical shifts would be very different. It follows from the position of the ligands in

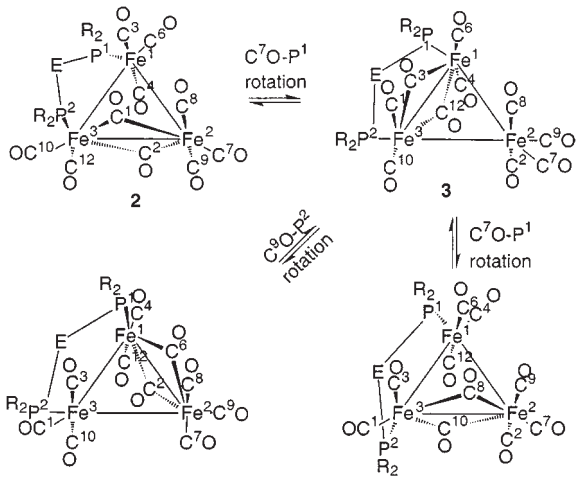

Fig. 10. A partial 100.62 MHz ^{13}C NMR spectrum of $[Fe_3(CO)_9(dppm)\{P(OMe)_3\}]$ in CD_2Cl_2 at –97°C.

Scheme 3.

Scheme 4.

Scheme 3, that if this geometry was exclusively present, the chemical shifts would be δ: 222 C(2)O, C(8)O; 252 C(3)O, C(12)O; 215 C(1)O, C(4)O, C(6)O, C(10)O; and 203 C(7)O, C(9)O. Hence, to account for the observed shifts, it is necessary to conclude that isomers **2** and **3** are present in solution in a ratio of approximately 3:1.

The low temperature ^{13}C NMR spectrum of $[Fe_3(CO)_9(dppm)\{P(OMe)_3\}]$ is shown in Fig. 10. By analogy with $[Fe_3(CO)_{10}(dppm)]$, only the mechanism in Scheme 4 should be operating as the presence of the $P(OMe)_3$ blocks the mechanism shown in Scheme 3. This leads to the following exchange: C(1)O ⇌ C(10)O, C(4)O ⇌ C(6)O, C(3)O ⇌ C(12)O, C(2)O ⇌ C(8)O, C(6)O ⇌ C(10)O,

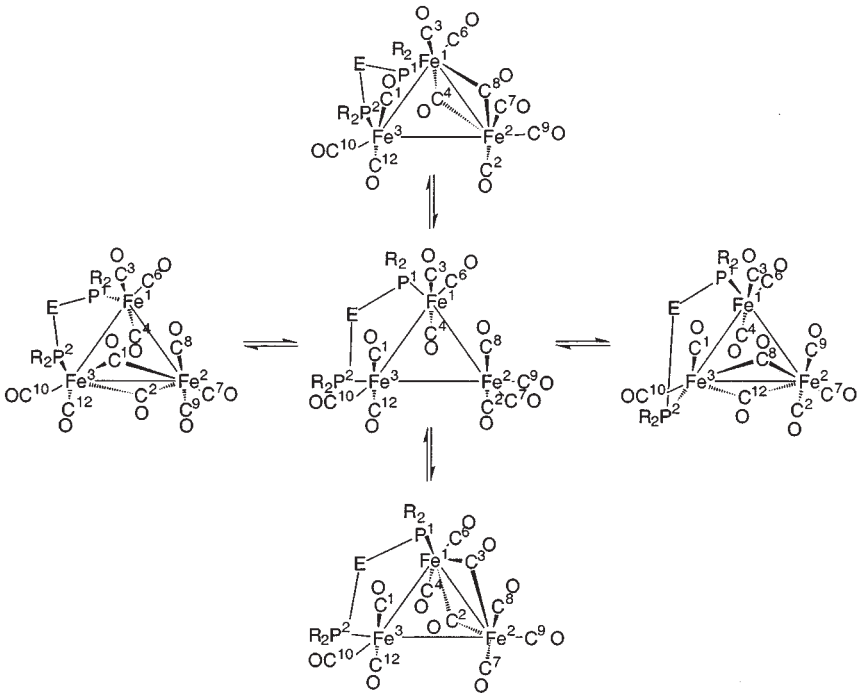
Scheme 5.



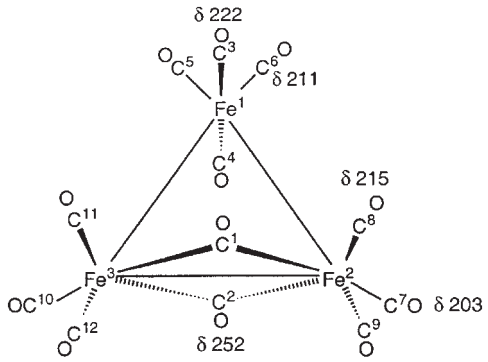


Fig. 11. Estimated ^{13}C NMR chemical shifts for carbonyls on $[Fe_3(CO)_{12}]$ based on the reported chemical shifts for $[Fe_3(CO)_{12-n}\{P(OMe)_3\}_n]$, n = 2, 3.

and C(9)O is left unaffected. If the structure in solution is **2**, then the predicted chemical shifts are δ: 227.5 C(1)O, C(10)O; 216.5 C(4)O, C(6)O; 218.5 C(3)O, C(12)O; 233.5 C(2)O, C(8)O; and 215 C(9)O. If the structure in solution is **3**, then the predicted chemical shifts are δ: 215 C(1)O, C(10)O; 215 C(4)O, C(6)O; 252 C(3)O, C(12)O; 222 C(2)O, C(8)O; 211 C(7)O and C(9)O. Comparison of these shifts with the spectrum and the observation of $J_{P,C}$ on the signal at δ 232 makes the probable assignments δ: 225 C(1)O, C(10)O; 218 C(4)O, C(6)O; 233 C(3)O, C(12)O; 232 C(2)O, C(8)O; 213 C(9)O. The ^{13}C chemical shifts suggest that **2** is the major isomer in solution despite the crystal structure being **3**.

The concerted bridge – opening bridge – closing mechanism

Usually the concerted bridge – opening bridge – closing mechanism is extremely facile and cannot be stopped. The only previous example of it being stopped is $[Fe_3(CO)_{11}(CNCF_3)]$ and related complexes, where the $CNCF_3$ is tightly held into a μ_2-bridging position (19). In the cases of the $[Fe_3(CO)_{10}L_2]$ (L_2 = dppm, $Ph_2PNHPPh_2$, $(EtO)_2POP(OEt)_2$) complexes, rotation about the S_{10} axis through C(6)O and C(10)O is fast on the NMR time scale even at –105°C. However, the barrier to rotation about the S_{10} axis through C(7)O and P(1) is increased because of the strain produced by the chelating ligand in **3**. The formation of a carbonyl bridge on the same edge as the chelate is bonding increases the ideal separation of the two phosphorus atoms. The barrier increases from <24 kJ mol^{-1} in $[Fe_3(CO)_{10}(dppm)]$ to 33 ± 2.0 kJ mol^{-1} in $[Fe_3(CO)_{10}\{(EtO)_2POP(OEt)_2\}]$ correlating with the P···P distance decreasing from 3.053(2)–3.067(2) to 2.836(3) Å.

The merry-go-round mechanism

The strain produced by the chelate ring has a tendency to open the Fe(μ-CO)$_2$Fe bridge. As the strain increases from $[Fe_3(CO)_{10}(dppm)]$ to $[Fe_3(CO)_{10}\{(EtO)_2POP(OEt)_2\}]$, the Fe(μ-CO)$_2$Fe bridge opens more easily and $\Delta G^{\ddagger}$ drops from 33.7 ± 1.0 to ca. 26 kJ mol^{-1}. The clearest demonstration of the merry-go-round mechanism occurs with $[Fe_3(CO)_{10}(dppm)\{P(OMe)_3\}]$, where an EXSY NMR spectrum clearly shows C(1)O, C(4)O exchanging with C(3)O, C(12)O and C(6)O, C(12)O as would be expected when the merry-go-round mechanism is applied to isomer **3**, see Fig. 12. No direct exchange is detected between the signals due to C(3)O, C(12)O and C(6)O, C(12)O. The exchange mechanism in Scheme 5 does not produce this exchange, and the merry-go-round mechanism has to operate around the edge Fe(1)–Fe(3), see Scheme 6.

For both the concerted bridge – opening bridge – closing and merry-go-round mechanism, $\Delta G^{\ddagger}$ for $[Fe_3(CO)_{10}(Ph_2PNHPPh_2)]$ is expected to be between the

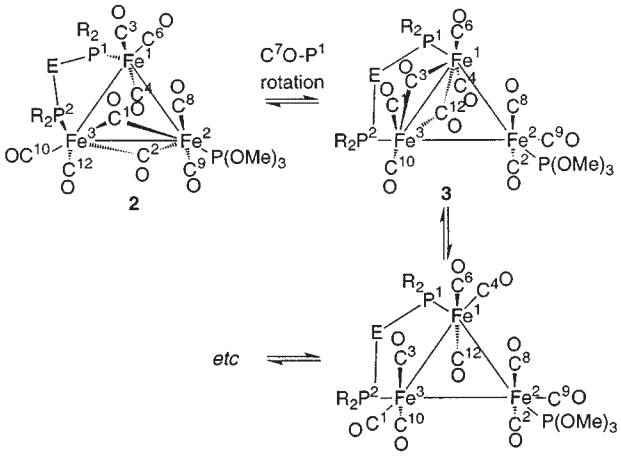
$[Fe_3(CO)_{10}\{(EtO)_2POP(OEt)_2\}]$	224[a]	229.8	224[a]	206	206.6
$[Fe_3(CO)_{10}(Ph_2PCH_2PPh_2)\{P(OMe)_3\}]$	233.7	231.9 (24)	225.1	218.1	213.2

[a]Averaged.

Fig. 12. A partial 100.62 MHz ^{13}C EXSY NMR spectrum of $[Fe_3(CO)_{10}(dppm)\{P(OMe)_3\}]$ in CD_2Cl_2 at –96°C with a mixing delay of 0.002 s.



values determined for $[Fe_3(CO)_{10}(dppm)]$ and $[Fe_3(CO)_{10}\{(EtO)_2POP(OEt)_2\}]$. Hence, both values are expected to be less than 30 kJ mol^{-1}. As a result, neither mechanism is frozen out at –105°C and the resulting signal is broad. No value could be determined for $\Delta G^{\ddagger}$ as it is unknown if one or both mechanisms are freezing out.

Trigonal twist mechanism

All four complexes reported here show exchange between C(2)O, C(8)O and C(7)O, C(9)O, or just C(9)O in the case of $[Fe_3(CO)_{10}(dppm)\{P(OMe)_3\}]$. At the onset of the exchange, the exchange is localized to C(2)O, C(8)O and C(7)O, C(9)O for $[Fe_3(CO)_{10}L_2]$ (L_2 = dppm, $Ph_2PNHPPh_2$, $(EtO)_2POP(OEt)_2$), although this is not known for $[Fe_3(CO)_{10}(dppm)\{P(OMe)_3\}]$. The most likely mechanism to fit this exchange is the trigonal twist mechanism. It appears to have been facilitated in these compounds as in $[Fe_3(CO)_{11}\{P(OMe)_3\}]$ it is believed to occur with $\Delta G^{\ddagger}$ = 62 kJ mol^{-1} and in $[Fe_3(CO)_{10}\{P(OMe)_3\}2]$ with $\Delta G^{\ddagger}$ = 60 kJ mol^{-1}. It would, therefore, appear that substitution of the carbonyls facilitates the dynamic process.

Scheme 6.

Conclusions

The distortions observed in the crystal structures induced in the structure of $[Fe_3(CO)_{12}]$ by substitution with the small bite-angle ligands ($Ph_2PCH2PPh_2$, $Ph_2PNHPPh_2$, $(EtO)_2POP(OEt)_2$) follow from the predictions of the Mann concerted bridge – opening bridge – closing mechanism rather than the Johnson libration mechanism.

The dynamic processes observed in the ^{13}C NMR spectra can be fully explained using either the Mann concerted bridge – opening bridge – closing mechanism or the Johnson libration mechanism, the merry-go-round mechanism, and the trigonal twist mechanism.

The changes in $\Delta G^{\ddagger}$ from those previously observed with monodentate ligands are predictable as a consequence of using small bite-angle ligands.

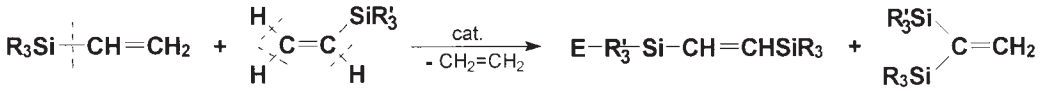
Functionalization vs. degradation of 1,4-polybutadiene by ruthenium complex catalyzed reaction with vinylsilanes

Bogdan Marciniec, Ewa Małecka, Jacek Guliński, Monika Grundwald-Wyspiańska, and Mariusz Lewandowski

Abstract: Polybutadiene (**I**) containing 91% of 1,4-(*cis–trans*) units and 9% of 1,2-units in the presence of vinyltriethoxysilane (**II**) and ruthenium catalysts $RuCl_2(PPh_3)_3$ (**III**), $RuHCl(CO)(PPh_3)_3$ (**IV**), and $[RuCl_2(CO)_3]_2$ (**V**) at 100–130°C undergoes functionalization and (or) partial degradation as an effect of competitive silylative coupling of =C-H and cross-metathesis of **I** with **II**. Significant degradation of **I** occurs at lower temperatures (100–110°C) (particularly when the process is carried out in air), but exclusive functionalization of **I** is observed at higher temperature (120–130°C) regardless of the atmosphere (air or argon) used.

Key words: functionalization, degradation, polybutadiene, ruthenium complexes.



Résumé : Le polybutadiène (**I**) contenant 91% d'unités 1,4-(*cis–trans*) et 9% d'unités 1,2 mis en présence de vinyltriéthoxysilane (**II**) et des catalyseurs de ruthénium $RuCl_2(PPh_3)_3$ (**III**), $RuHCl(CO)(PPh_3)_3$ (**IV**) ou $[RuCl_2(CO)_3]_2$ (**V**), à 100–130°C, subit une fonctionnalisation et (ou) une dégradation partielle qui résultent d'un couplage silylisant de =C-H qui est en compétition avec une réaction de métathèse croisée de **I** avec **II**. À des températures plus faibles (100–110°C) (particulièrement lorsqu'on effectue la réaction en présence d'air), on observe une dégradation importante du composé **I**; toutefois, à des températures plus élevées (120–130°C), on n'observe que la fonctionnalisation du composé **I** quelle que soit la nature de l'atmosphère (air ou argon).

Mots clés : fonctionnalisation, dégradation, polybutadiène, complexes du ruthénium.

Introduction

Cross-metathesis of unsaturated polymers with olefins has been widely studied to follow their degradation and to determine their cross linked structure (1). The degradation of 1,4-polybutadiene by hex-2-ene (2), hex-3-ene (3, 4), as well as ethylene (5), occurs mostly in the presence of tungsten and molybdenum carbenes. Recently Grubbs ruthenium-carbenes have been used as degradation agents (6). Silicon-containing olefins, mainly allylsilanes, have been applied by Marmo and Wagener (7, 8) in metathetical (ADMET) degradation of 1,4-polybutadiene in the presence of a Schrock molybdenum catalyst to yield perfectly difunctional (f = 2.0) telechelic polybutadiene oligomers. Vinyl-substituted silanes are not active in ADMET depolymerization (M and W catalysts) (9, 10), however, they can be used for the reduction of the molar mass of polymers (11). Our recent study has shown that polybutadiene (**I**) containing 91% of 1,4-(*cis–trans*) units and 9% of 1,2-units in the presence of vinyltriethoxysilane and ruthenium carbenes undergoes partial degradation and functionalization (12).

On the other hand, olefins react readily via silylative coupling with vinylsilanes (*trans*-silylation) in the presence of ruthenium complexes containing or initially forming Ru—H and (or) Ru—Si bonds (13–16). Evidence has been found confirming nonmetathetical conversion of the olefins with vinylsilanes in the presence of such catalysts (14–16). Instead of the cleavage of the C=C bonds in olefin metathesis the process occurs via silylation of olefins by vinylsilanes (i.e., cleavage of vinyl C—H in the olefins and Si—C_{vinyl} bonds) according to eq. [1] (15):

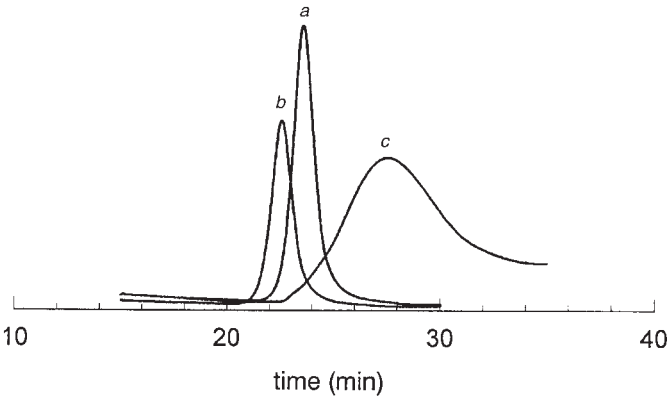
[c]M_w/M_n.

The vinyl group in 1,2-polybutadiene in the presence of various ruthenium complexes at elevated temperature undergoes facile silylation, which leads a new type of modification of unsaturated polymers (17).

In view of the catalytic activity of ruthenium–carbenes in degradation of 1,4-polybutadiene by vinylsilanes and effective catalysis by Ru–H and Ru–Si complexes for functionalization of 1,2-units of polybutadiene, a study was undertaken to show the suitability of vinyltriethoxysilane (**II**), not for depolymerization of 1,4-polybutadiene (**I**), but for its modification to synthesize silyl-substituted polymers.

Experimental



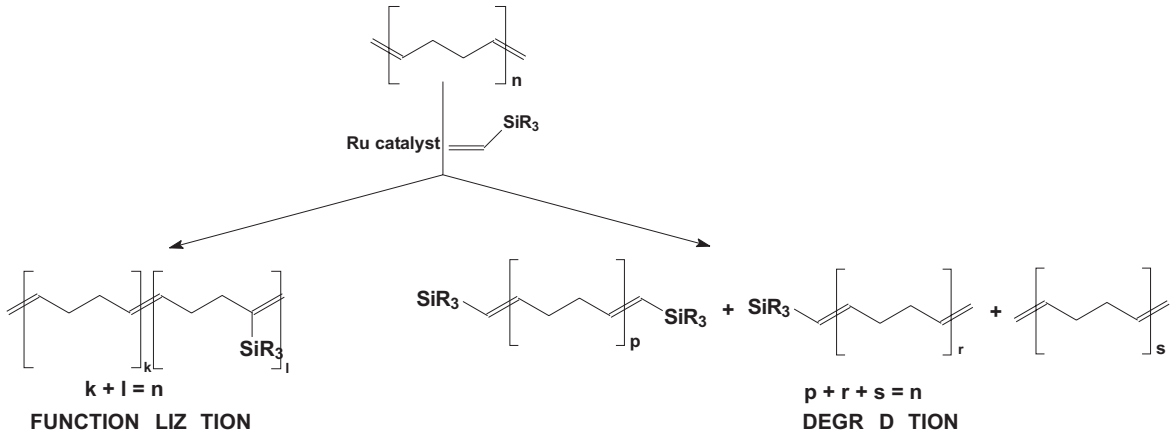
Materials

Polybutadiene (M_n = 400 000) (**I**) containing 91% of 1,4-(*cis–trans*) units and 9% of 1,2-units, was purchased from Polysciences, Inc. and used without additional purification. Vinyltriethoxysilane (**II**), purchased from Fluka, was distilled prior to use. $RuCl_2(PPh_3)_3$ (**III**) (18) and $RuHCl(CO)(PPh_3)_3$ (**IV**) (19) were prepared by standard procedures. $[RuCl_2(CO)_3]_2$ (**V**) was purchased from Strem Chemicals, Inc.

Functionalization and (or) degradation reactions

Reactions were carried out under dry air or under argon in a glass reactor equipped with a condenser and a heater or in sealed glass ampules. In a typical reaction, 1,4-polybutadiene (1.00 g, 0.001 mol), chlorobenzene (24 g), vinyltriethoxysilane (0.32 cm^3), and a catalyst (7.4×10^{-6} mol) were placed in the reaction system and heated for 24 h at the required temperature (100–130°C). Reaction mixtures were analyzed by gel permeation chromatography (GPC) and NMR techniques. GPC results are presented in Tables 1 and 2 and Fig. 1. Spectroscopic analyses (NMR) were performed both for the reaction mixtures and the isolated products. For example, for the reaction mixture of **I** with **II** in the presence of $RuCl_2(PPh_3)_3$ (dry air, 100°C) the following signals (ppm) were observed: 0.96 (t), 1.19 (t), 1.21 (t), 2.10 (s), 3.34 (t), 3.80 (t), 3.92 (t), 5.48 (s), 6.00 (m) (signals originating from solvent were omitted for clarity). Polymeric products were precipitated from the solution with methanol, filtered, washed with methanol, and dried under vacuum. IR and NMR spectra of the isolated polymer were also obtained.

Fig. 1. GPC spectra of initial 1,4-polybutadiene (**I**) and after undergoing functionalization and degradation with vinyltriethoxysilane in the presence of catalyst $RuCl_2(PPh_3)$: (*a*) initial polymer; (*b*) under argon, 130°C; (*c*) under dry air, 100°C.



Equipment and analytical measurements

^1H and ^{13}C NMR spectra were recorded on a Varian XL300 spectrometer. GPC data were collected using a Gilson HPLC system with 2 × 250 × 10 mm, Jordi-Gel DVB

Scheme 1.

Column: 500 and 100 Å, using polystyrene standards (mobile phase, THF; flow rate, 1.2 mL min^{-1}; ambient temperature). The ratio (**F**:**D**) of GPC peak area coming from functionalized polybutadiene (higher M_n) to the area of GPC peak originating from degraded polybutadiene (lower M_n) were calculated for reaction products. IR spectra (film or KBr pellet) were recorded using a FT-Bruker JFS-113V instrument.

Results and discussion

Polybutadiene (**I**) was used as the substrate in its reaction with vinyltriethoxysilane (**II**) to synthesize polymers or oligomers containing alkoxy-substituted silyl groups, i.e., polymeric coupling agents (20). $RuCl_2(PPh_3)_3$ (**III**), $RuHCl(CO)(PPh_3)_3$ (**IV**), and $[RuCl_2(CO)_3]_2$ (**V**) were used as catalysts. All three Ru-complexes catalyze the cross-disproportionation (silylative coupling) of olefins with vinylsilanes according to eq. [1]. Oligomers obtained as a result of this reaction are the products of metathetical degradation (**D**) (cleavage of the C=C bond in the chain, followed by silylation of the newly formed $CH{=}CH_2$ unit). On the other hand, polymers of the molecular weight higher than the initial polybutadiene (**I**) are products of functionalization (silylation) (**F**) of starting **I**.

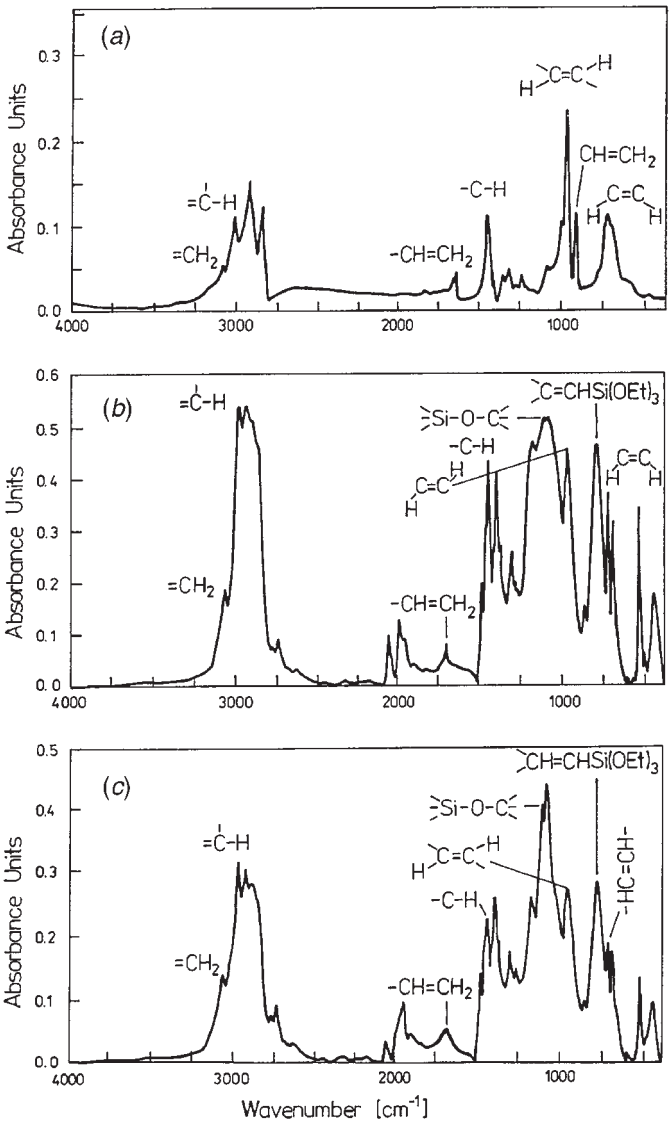
All experiments of **I** and any catalyst performed at different conditions (argon or oxygen) in the absence of vinyltriethoxysilane showed no changes (evidenced by IR, NMR, and GPC analysis) in the starting polybutadiene. No oxidation of polybutadiene, resulting in the formation of OH groups, is observed.

Scheme 1 illustrates both reactions (functionalization and degradation) occurring under the above specified conditions, but omits for clarity the reactions of the 1,2-units (present in 9% in **I**). To follow the effect of vinylsilane on the process, GPC was used to measure the functionalization and degradation of **I**. The GPC chromatograms of the initial 1,4-polybutadiene (*a*) and the same compound after heating with vinyltriethoxysilane in the presence of $RuCl_2(PPh_3)_3$ in argon (130°C) (*b*) and in air (100°C) (*c*), are presented in Fig. 1.

If the reaction occurs under oxygen-free conditions predominantly at higher temperature (i.e., 130°C) exclusive functionalization over degradation is observed (Table 1). On the basis of the results of GPC analysis (Fig. 1*b*) it is possible to distinguish the modified 1,4-polybutadiene from the degraded oligomers, and simultaneously to determine the degree of functionalization of **I** by vinyltriethoxysilane (**II**). The latter effect is observed to increase with increasing temperature to the optimum of 130°C.

$RuCl_2(PPh_3)_3$ is well-known as an effective unicomponent catalyst for the ring-opening metathesis polymerization (ROMP) of norbornene. The rate of the reaction increases as much as 100-fold when O_2 is bubbled through the reactor (21).

Our experiments carried out with catalysts **III**–**V** (see Table 2 and Fig. 1*c*) indicate that significant degradation of **I** via metathetical cleavage of C=C bonds, when compared to the functionalization of =C—H bonds, is taking place, but only at lower temperatures (100–110°C). At higher temperatures (120–130°C), even if the process occurs in the air, the functionalization of **I** is exclusively observed.



^1H and ^{13}C NMR spectrometry experiments as well as FT-IR studies of **I** heated with vinyltriethoxysilane were performed to find the possible evidence for functionalization, i.e., silylation or activation, of the =C—H bond of HC=CH units and (or) vinyl groups.

The ^1H NMR spectra of all the reaction products mixtures show not only resonances close to 6.00, 3.80, and 1.19 ppm (characteristic of the starting vinylsilane (22)), but also new signals (at about 3.40 and 1.00 ppm) attributed to ethoxy substituted silyl groups located in silylated unsaturated oligomers (polymers). Such signals, of different intensities, can be detected in the spectra of all systems, and they are convincing evidence for both functionalization and degradation of 1,4-polybutadiene (**I**) accompanied by the incorporation of triethoxysilyl groups into oligomer chain. The spectra of the isolated polymeric products are similar, however, in the air-free conditions with $RuCl_2(PPh_3)_3$ as the catalyst (i.e., when functionalization is most prevalent) the intensities of OCH_2CH_3 signals (3.34 and 0.96 ppm) are more than 10-fold higher than those observed for the dry-air reaction products (i.e., when degradation predominates) in relation to the CH_2 signals of polybutadiene network.

The IR spectrum (Fig. 2*a*) of 1,4-polybutadiene (**I**), shows a strong absorption at 964 cm^{-1} characterizing deformation vibrations of *trans* =C—H bonds (23). The spectrum recorded after the reaction of **I** with vinyltriethoxysilane (**II**) in argon ($RuCl_2(PPh_3)_3$ as the catalyst) (Fig. 2*b*) reveals the

Fig. 2. FT-IR spectra of: (*a*) initial 1,4-polybutadiene (**I**) and functionalized and (or) degraded with vinyltriethoxysilane; (*b*) $RuCl_2(PPh_3)_3$, argon, 120°C, 48 h; (*c*) $RuCl_2(PPh_3)_3$, dry air, 100°C, 48 h.

presence of new bands at 1078 and 1102 cm^{-1} attributable to the Si—O-C vibration in $CH=CHSi(OEt)_3$ and (or) in $CH=C[Si(OEt)_3]_2$, which proves the occurrence of the silylation of C—H bonds with vinyltriethoxysilane. Moreover, the spectra show the appearance of a new band at 789 cm^{-1} presumably characterizing deformation vibrations of $CH=CHSi(OEt)_3$ and (or) $CH=C[Si(OEt)_3]_2$. Simultaneously, a decrease in the intensity of the bands at 723 cm^{-1}, which are due to *cis*-CH=CH deformation, and the lack of changes in the absorption band assigned to *trans*-HC=CH vibration are observed. Figure 2*c* reflects the same effect, since it corresponds to the mixture of the functionalized and degraded oligomers when **I** is heated with vinylsilane in the presence of $RuCl_2(PPh_3)_3$ in air (100°C).

Thus, FT-IR analysis may be valuable proof for activation of C—H in the chain (to get $CH=C[Si(OEt)_3]_2$ fragments) and simultaneously in the terminal vinyl groups of the degradated oligomers and pendant groups of 1,2-polybutadiene units (to yield $CH=CHSi(OEt)_3$ fragments). The former effect can be accounted for by activation of *cis*-HC=CH units in the silylation of (**I**) by vinylsilanes, while the latter by a well-known process of silylation of most vinylic olefins with vinylsilanes (13).

All the results on the silylative coupling (the functionalization) vs. cross-metathesis (the degradation) of vinyltriethoxysilane with 1,4-polybutadiene are strongly supported in detail by previous examination of the reaction of the vinylsilanes with alkenes catalyzed by Ru–H and Ru–Si containing complexes (16, 24) or ruthenium carbenes (24–26).

Synthesis and coordination studies of new aminoalcohol functionalized tertiary phosphines

Sean E. Durran, Martin B. Smith, Alexandra M.Z. Slawin, Thomas Gelbrich, Michael B. Hursthouse, and Mark E. Light

Abstract: The synthesis of two new aminoalcohol functionalized tertiary phosphines *o*-$Ph_2PCH_2N(H)C_6H_4(OH)$ (**I**) and *o*-$Ph_2PCH_2N(H)C_6H_4(CH_2OH)$ (**II**) are reported. Oxidation with aqueous H_2O_2 gave the corresponding phosphine oxides *o*-$Ph_2P(O)CH_2N(H)C_6H_4(OH)$ (**III**) and *o*-$Ph_2P(O)CH_2N(H)C_6H_4(CH_2OH)$ (**IV**) (^{31}P NMR evidence only). The ligating ability of **I**, **II** and, in several cases, the known ligand 2,3-$Ph_2PCH_2N(H)C_5H_3N(OH)$ (**V**), was investigated with a range of late transition-metal precursors. Accordingly, reaction of 2 equiv of **I** (or **II**) with [MCl_2(cod)] (M = Pd or Pt, cod = cycloocta-1,5-diene) gave the corresponding dichloro metal(II) complexes [MCl_2(**I**)$_2$] (M = Pd **1**; M = Pt **2**) and [MCl_2(**II**)$_2$] (M = Pd **3**; M = Pt **4**) in which **I** (and **II**) *P*-coordinate. Solution NMR studies reveal that **2** and **4** are exclusively *cis* whereas **1** and **3** are present as a mixture of *cis* and (or) *trans* isomers [4.7:1 (for **1**); 2.2:1 (for **3**)]. Reaction of 2 equiv of **II** with [$Pt(CH_3)_2$(cod)] gave the neutral complex [$Pt(CH_3)_2$(**II**)$_2$] (**5**) whose X-ray structure confirmed a *cis* disposition of "hybrid" ligands. In contrast, reaction of **I** with [$Pt(CH_3)_2$(cod)] gave initially [$Pt(CH_3)_2$(**I**)$_2$] (**6**) which, upon standing, afforded several products possibly reflecting an increased acidity of the phenolic groups of ligated **I**. Chloro bridge cleavage reactions of [{Ru(μ-Cl)Cl(*p*-cymene)}$_2$] or [{Rh(μ-Cl)Cl{$C_5(CH_3)_5$}}$_2$] with **I** (or **II**) proceeds smoothly and gave the mononuclear complexes [$RuCl_2$(*p*-cymene)**I**] (**7**), [$RuCl_2$(*p*-cymene)**II**] (**8**), [$RhCl_2${$C_5(CH_3)_5$}**I**] (**9**), and [$RhCl_2${$C_5(CH_3)_5$}**II**] (**10**) in good yield. X-ray crystallography confirms both ruthenium complexes bear *P*-coordinated **I** (or **II**) ligands. Molecules of **7** are linked into linear chains via O-H···Cl_{coord} intermolecular hydrogen bonding, a feature absent in the closely related compound **8**. Reaction of [AuCl(tht)] (tht = tetrahydrothiophene) with 1 equiv of **I** (or **II**) gave the corresponding gold(I) complexes [AuCl(**I**)] (**11**) and [AuCl(**II**)] (**12**). Bridge cleavage of the cyclometallated palladium(II) dimers [{Pd(μ-Cl)(C~N)}$_2$] [C~N = *C*,*N*-$C_6H_4CH_2N(CH_3)_2$, *C*,*N*-$C_{10}H_6N(CH_3)_2$, *C*,*N*-$C_6H_4N{=}NC_6H_5$] with **V** (or **I**) gave the neutral complexes [PdCl(C~N)**V**] (**13**–**15**) (or [PdCl($C_9H_{12}N$)**I**] (**16**)), respectively. Chloride abstraction from **13** (or **15**) with Ag[BF_4] gave the cationic complexes [Pd(C~N)**V**][BF_4] (**17**) (or **18**) in which **V** *P*,$N_{pyridyl}$-chelates to the palladium(II) metal centre. The X-ray structures of **13** and **18** have been determined and confirm the expected coordination environments. An array of intra- and intermolecular H-bonding contacts are also observed. All compounds have been characterized by a combination of spectroscopic and analytical studies.

Key words: phosphines, crystal structures, alcohols, precious metals.

Résumé : On a réalisé la synthèse de deux nouvelles phosphines tertiaires fonctionnalisées par un aminoalcool, *o*-$Ph_2PCH_2N(H)C_6H_4(OH)$ (**I**) et *o*-$Ph_2PCH_2N(H)C_6H_4(CH_2OH)$ (**II**). Leur oxydation par du peroxyde d'hydrogène aqueux conduit aux oxydes de phosphines correspondantes, *o*-$Ph_2P(O)CH_2N(H)C_6H_4(OH)$ (**III**) et *o*-$Ph_2P(O)CH_2N(H)C_6H_4(CH_2OH)$ (**IV**) (uniquement démontré par RMN du ^{31}P). On a étudié l'habilité des composés **1** et **2** et, dans plusieurs cas, du ligand bien connu 2,3-$Ph_2PCH_2N(H)C_5H_3N(OH)$ (**V**), d'agir comme coordinats pour une variété des précurseurs contenant des métaux de transition lourds. En conséquence, la réaction de deux équiv de **I** (ou **II**) avec du [MCl_2(cod)] (M = Pd ou Pt, cod = cycloocta-1,5-diène) conduit à la formation de complexes dichlorométalliques [MCl_2(**I**)$_2$] (M = Pd **1**; M = Pt **2**) et [MCl_2(**II**)$_2$] (M = Pd **3**; M = Pt **4**) dans lesquels les phosphines **I** (et **II**) sont coordinées au phosphore. Des études de RMN en solution révèlent que les composés **2** et **4** existent exclusivement sous la forme *cis* alors que les composés **1** et **3** existent sous la forme de mélanges d'isomères *cis*/*trans* [4,7:1 pour **1** et 2,2:1 pour **3**]. La réaction de deux équiv de **II** avec le [$Pt(CH_3)_2$(cod)] conduit à la formation du complexe neutre [$Pt(CH_3)_2$(**II**)], **5**, dont la structure telle que déterminée par diffraction des rayons X confirme la présence d'une disposition *cis* des ligands hybrides. Par opposition, la réaction de **I** avec le [$Pt(CH_3)_2$(cod)] conduit initialement à la formation de [$Pt(CH_3)_2$(**I**)$_2$], **6**, qui laissé à lui-même conduit à la formation

de plusieurs produits et ceci est vraisemblablement un reflet d'une augmentation de l'acidité des groupes phénoliques de la phosphine (**I**) qui est liée. Les réactions de clivage du pont chloro du [{Ru(μ-Cl)Cl(*p*-cymène)}$_2$] ou du [{Rh(μ-Cl)Cl{C$_5$(CH$_3$)$_5$}}$_2$] avec **I** (ou **II**) se produisent facilement et conduisent à la formation de complexes mononucléaires [RuCl$_2$(*p*-cymène)**I**], **7**, [RuCl$_2$(*p*-cymène)**II**], **8**, [RhCl$_2$l{C$_5$(CH$_3$)$_5$}**I**], **9**, et [RhCl$_2$l{C$_5$(CH$_3$)$_5$}**II**], **10** avec de bons rendements. La diffraction des rayons X permet de confirmer que les deux complexes du ruthénium comportent des ligands **I** (ou **II**) qui sont coordinés au phosphore. Les molécules de **7** forment des chaînes linéaires par le biais d'une liaison hydrogène intermoléculaire, O–H···Cl$_{coord}$, une caractéristique qui est absente dans le composé **8** qui lui est fortement apparenté. La réaction de [AuCl(tht)] (tht = tétrahydrothiophène) avec un équivalent de **I** (ou **II**) conduit à la formation des complexes d'or correspondants [AuCl(**I**)], **11**, et [AuCl(**II**)], **12**. Le clivage du pont des dimères cyclométallés du palladium [{Pd(μ-Cl)(C~N)}$_2$] [C~N = *C*,*N*-C$_6$H$_4$CH$_2$N(CH$_3$)$_2$, *C*,*N*-C$_{10}$H$_6$N(CH$_3$)$_2$ et *C*,*N*-C$_6$H$_4$N=NC$_6$H$_5$] à l'aide des phosphines **V**
(ou **I**) conduit respectivement à la formation des complexes neutres [PdCl(C~N)**V**], **13–15**, ou [PdCl(C$_9$H$_{12}$N)**I**], **16**. L'enlèvement du chlorure à partir des composés **13** (ou **15**) à l'aide de Ag[BF$_4$] conduit à la formation des complexes cationiques [Pd(C~N)**V**][BF$_4$], **17** (ou **18**) dans lesquels le *P*,*N*-$_{pyridyl}$ de la phosphine **V** se chélate au centre métallique du palladium(II). Les structures des composés **13** et **18** ont été déterminées par diffraction des rayons X et elles confirment les environnements attendus par la coordination. On a aussi observé un arrangement de contacts par liaisons hydrogènes intra- et intermoléculaires. Tous les composés ont été caractérisés par une combinaison d'études analytiques et spectroscopiques.

Mots clés : phosphines, structures cristallines, alcools, métaux précieux.

[Traduit par la Rédaction]

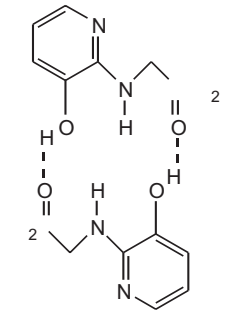
Introduction

Tertiary phosphines continue to engage a quintessential role in the development of many avenues of coordination and organometallic chemistry and in catalysis. The ability to modify a ligand structure, in a precise and controlled fashion, explains the recent significant advances made in catalytic selectivity and activity, facile catalyst separation and enhanced enantiomeric excesses in asymmetric transformations.

Recent impressive progressions in the synthesis and chemistry of new functionalized tertiary phosphines have been made, one notable class are the so-called "hemilabile" ligands (1). Alcohol functionalized tertiary phosphines (2–10) which, in addition to a mismatch of "soft" and "hard" donor centres, have several attractive attributes: (*i*) reactive site(s) for further functionalization. The ligand Ph$_2$PCH$_2$OH is an excellent precursor for tertiary phosphines containing macrocycle (11), β-cyclodextrin (12), chitosan (13), or even dendrimer (14) backbones. Recently, we (15) prepared a hydroxy-functionalized pyridylphosphine while Faraone and co-workers (16) described the synthesis and catalytic applications of new mixed phosphine-phosphonite ligands, in both cases using Ph$_2$PCH$_2$OH as a convenient starting material; (*ii*) the hard oxygen donor can further be utilized in forming heterobimetallic complexes, e.g., Ph$_2$PCH$_2$OH can function as a uninegative *P*,*O*-bridging ligand (17); (*iii*) the presence of several hydroxy groups can render transition-metal complexes water soluble. The groups of Pringle (18,19), Katti (20), and more recently Fukuoka (21) made extensive use of this unique property in various coordination, catalytic, and biomedical studies.

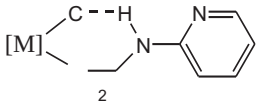
As part of an ongoing programme, we reported (15) the synthesis and characterization of a new alcohol functionalized, potentially terdendate, pyridylphosphine and demonstrated its suitability for further functional group inclusion. Herein we describe the synthesis of two new "hybrid" ligands and demonstrate their coordination capabilities with selected precious metal precursors. To the best of our knowledge, there are very few reports (22–24) of hydroxy-functionalized tertiary phosphines in which the connectivity between disparate P and O donors bears an additional nitrogen donor atom, itself potentially capable of metal complexation. One interesting aspect we wished to probe further is what hydrogen bonding motifs would be expected upon coordination and accordingly, subtle variations in the ligand structures described here enable such a comparison to be tested. Previously we noted that Ph$_2$PCH$_2$N(H)C$_5$H$_3$N(X) (X = H, OH) can adopt a range of H-bonding motifs (e.g., **A**–**D**) (15) and in this work, two new network arrangements (**E** and **F**) are presented.

Experimental



Chemicals

All reactions were performed under nitrogen unless otherwise stated. The starting materials [MCl$_2$(cod)] (M = Pd, Pt) (25, 26), [Pt(CH$_3$)$_2$(cod)] (27), [{Ru(μ-Cl)Cl(*p*-cymene)}$_2$] (28), [{Rh(μ-Cl)Cl{C$_5$(CH$_3$)$_5$}}$_2$] (29), [AuCl(tht)] (30), and [{Pd(C~N)(μ-Cl)}$_2$] (C~N = C$_9$H$_{12}$N, C$_{12}$H$_{12}$N, C$_{12}$H$_9$N$_2$) (31) were prepared according to previous reported procedures. The ligands Ph$_2$PCH$_2$OH (32) and Ph$_2$PCH$_2$N(H)C$_5$H$_3$N(OH) (15) were synthesized according to known literature methods. The compounds *o*-H$_2$NC$_6$H$_4$(OH) and *o*-H$_2$NC$_6$H$_4$(CH$_2$OH) were purchased from Aldrich Chemical Co. and used directly without further purification.



Physical techniques and methods

Infrared spectra were recorded as KBr pellets in the range 4000–220 cm^{-1} on a PerkinElmer System 2000 Fourier transform spectrometer. ^{1}H NMR spectra (250 MHz) were recorded on a Bruker AC250 FT spectrometer with chemical shifts (δ) in ppm to high frequency of SiMe$_4$ and coupling constants (*J*) in Hz. ^{31}P NMR spectra (36.2 MHz) were recorded on a JEOL FX90Q spectrometer with chemical shifts (δ) in ppm to high frequency of 85% H$_3$PO$_4$ and coupling constants (*J*) in Hz. All spectra were measured in CDCl$_3$ unless otherwise stated. Elemental analyses (PerkinElmer 2400

Ligand syntheses

*o-$Ph_2PCH_2N(H)C_6H_4(CH_2OH)$ (**II**)*

To a solution of *o*-$H_2NC_6H_4(CH_2OH)$ (0.286 g, 2.32 mmol) in CH_3OH (5 mL) was added a solution of Ph_2PCH_2OH (0.501 g, 2.23 mmol) in CH_3OH (3 mL). After stirring the solution for 30 min, toluene (13 mL) was added and the solution heated at ca. 65°C for 18 h. The solution was evaporated to dryness under reduced pressure and triturated with several portions of petroleum ether (bp 40–60°C). The solid was collected by suction filtration and dried in vacuo. (yield 0.36 g, 48%). A similar method was used for the synthesis of *o*-$Ph_2PCH_2N(H)C_6H_4(OH)$ (**I**) (53%) from *o*-$H_2NC_6H_4(OH)$.

*NMR reaction of aq H_2O_2 with (**II**)*

To a $CDCl_3$ (0.5 mL) solution of *o*-$Ph_2PCH_2N(H)C_6H_4(CH_2OH)$ (0.020 g, 0.067 mmol) was added H_2O_2 (30% w/w, 0.1 mL) and a ^{31}P NMR spectrum recorded. Only *o*-$Ph_2P(O)CH_2N(H)C_6H_4(CH_2OH)$ **IV** was formed as inferred by a new ^{31}P NMR resonance of characteristic downfield shift (δ (P) 30.9 ppm). In a similar manner we observed the formation of *o*-$Ph_2P(O)CH_2N(H)C_6H_4(OH)$ (**III**).

Complexes

*[$PtCl_2${*o*-$Ph_2PCH_2N(H)C_6H_4(CH_2OH)$}$_2$] (**4**)*

To a CH_2Cl_2 (10 mL) solution of [$PtCl_2$(cod)] (0.050 g, 0.134 mmol) was added *o*-$Ph_2PCH_2N(H)C_6H_4(CH_2OH)$ (0.089 g, 0.277 mmol). The solution turned immediately deep yellow and progressively faded to pale yellow. After ca. 15 min, solid **4** deposits from solution and was collected by suction filtration and dried in vacuo (yield 0.094 g, 74%).

Using a similar procedure the following complexes were prepared: [$PdCl_2${*o*-$Ph_2PCH_2N(H)C_6H_4(OH)$}$_2$] (**1**) (93%), [$PtCl_2${*o*-$Ph_2PCH_2N(H)C_6H_4(OH)$}$_2$] (**2**) (72%), and [$PdCl_2${*o*-$Ph_2PCH_2N(H)C_6H_4(CH_2OH)$}$_2$] (**3**) (68%).

*[$Pt(CH_3)_2${*o*-$Ph_2PCH_2N(H)C_6H_4(CH_2OH)$}$_2$] (**5**)*

To the solids [$Pt(CH_3)_2$(cod)] (0.025 g, 0.075 mmol) and **II** (0.048 g, 0.149 mmol) was added toluene (ca. 1 mL) and the solution left to stand. After ca. 12 d crystalline **5** was isolated from solution (yield 0.038 g, 58%).

*[$RuCl_2$(*p*-cymene){*o*-$Ph_2PCH_2N(H)C_6H_4(OH)$}] (**7**)*

To the solids [{Ru(μ-Cl)Cl(*p*-cymene)}$_2$] (0.100 g, 0.163 mmol) and *o*-$Ph_2PCH_2N(H)C_6H_4(OH)$ (0.100 g, 0.326 mmol) was added CH_2Cl_2 (20 mL) and the deep red solution stirred for 15 min. The solvent was reduced in volume to ca. 1 to 2 mL under reduced pressure and diethyl ether (5 mL) added. The solid was isolated by suction filtration and additional crops isolated from the filtrate (yield 0.181 g, 91%). Using a similar procedure the following compounds were prepared: [$RuCl_2$(*p*-cymene){*o*-$Ph_2PCH_2N(H)C_6H_4(CH_2OH)$}] (**8**) (78%), [$RhCl_2${$C_5(CH_3)_5$}{*o*-$Ph_2PCH_2N(H)C_6H_4(OH)$}] (**9**) (90%), and [$RhCl_2${$C_5(CH_3)_5$}{*o*-$Ph_2PCH_2N(H)C_6H_4(CH_2OH)$}] (**10**) (63%).

*[AuCl{*o*-$Ph_2PCH_2N(H)C_6H_4(OH)$}] (**11**)*

To a CH_2Cl_2 (ca. 5 mL) solution of [AuCl(tht)] (0.030 g, 0.094 mmol)) was added *o*-$Ph_2PCH_2N(H)C_6H_4(OH)$ (0.029 g, 0.094 mmol) and stirred for ca. 15 min. The volume was concentrated in vacuo to ~1 mL and petroleum ether (bp 60–80°C, 20 mL) added. The solid was collected by suction filtration and dried in vacuo (yield 0.035 g, 70%). In a similar manner [AuCl{*o*-$Ph_2PCH_2N(H)C_6H_4(CH_2OH)$}] (**12**) was prepared (74%).

*[PdCl($C_{12}H_{12}N$){$Ph_2PCH_2N(H)C_5H_3N(OH)$}] (**14**)*

To a CH_2Cl_2 (15 mL) solution of [{Pd($C_{12}H_{12}N$)(μ-Cl)}$_2$] (0.099 g, 0.159 mmol) was added $Ph_2PCH_2N(H)C_5H_3N(OH)$

© 2001 NRC Canada

(0.100 g, 0.324 mmol) as a solid. After stirring for ca. 1 h, **14** was filtered under reduced pressure and dried in vacuo (yield 0.160 g, 81%). Using a similar procedure the following complexes were prepared: [$PdCl(C_9H_{12}N)\{Ph_2PCH_2N(H)C_5H_3N(OH)\}$] (**13**) (94%), [$PdCl(C_{12}H_9N_2)\{Ph_2PCH_2N(H)C_5H_3N(OH)\}$] (**15**) (91%), and [$PdCl(C_9H_{12}N)\{o\text{-}Ph_2PCH_2N(H)C_6H_4(OH)\}$] (**16**) (86%).

*[$Pd(C_{12}H_9N_2)\{Ph_2PCH_2N(H)C_5H_3N(OH)$-*P,N*$\}][BF_4$] (**18**)*

To a CH_2Cl_2 (30 mL) suspension of $Ag[BF_4]$ (0.040 g, 0.206 mmol) was added [$PdCl(C_{12}H_9N_2)\{Ph_2PCH_2N(H)C_5H_3N(OH)\}$] (0.100 g, 0.158 mmol) and stirred, in the dark, for ca. 2 h. The AgCl was removed by filtration through a small Celite plug and reduced in vacuo to ca. 1 to 2 mL. Addition of diethyl ether (25 mL) gave **18** which was collected by suction filtration and dried in vacuo (yield 0.086 g, 80%). In a similar manner [$Pd(C_9H_{12}N)\{Ph_2PCH_2N(H)C_5H_3N(OH)$*P,N*$\}][BF_4$] (**17**) (93%) was prepared.

X-ray Crystallography

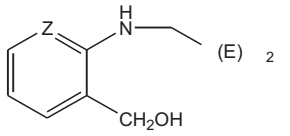
Crystals of **5** were grown by allowing a toluene solution of [$Pt(CH_3)_2$(cod)] and 2 equiv of **II** to stand for ca. 12 days. For **7** and **8** suitable crystals for X-ray crystallography were grown by slow diffusion of either Et_2O (for **7**) or petroleum ether (bp 60–80°C) (for **8**) into $CDCl_3$ solutions over several days. Suitable crystals of **13** were grown by slow diffusion of Et_2O into a $CDCl_3$–CH_3OH solution over 7 days whereas for **18**, X-ray quality crystals were obtained by allowing $CDCl_3$ solutions to stand for several days.

The crystal structures of compounds **7**, **8**, and **13** were obtained using a Rigaku AFC7S serial diffractometer with graphite-monochromated Mo Kα radiation (λ = 0.71069 Å) and ω scans. Details of the crystal data collection and refinement are given in Table 1. Intensities were collected by ω scans over a single quadrant of reciprocal space. All data were corrected for Lorentz polarization and long-term intensity fluctuations. Absorption effects were corrected on the basis of multiple equivalent reflections or by empirical methods (33). Structures were solved by direct methods and refined by full-matrix least-squares against *F* (teXsan) (34) for data with $I > 2\sigma(I)$. The weighting scheme used was as previously reported (35). Refinements converged to residuals given in Table 1. All calculations were made with programs of the teXsan systems.

Data were collected (for **5** and **18**) using a Nonius κ CCD area detector diffractometer mounted at the window of a rotating molybdenum anode. Ω scans were employed such that 95% of the unique data were recorded at least once. Data collection and processing were carried out using the programs COLLECT (36), DENZO (37), and maXus (38) and an empirical absorption correction was applied using SORTAV (39, 40). The structures were solved via direct methods (41) and refined by full-matrix least-squares (41) on F^2. Non-hydrogen atoms were refined anisotropically and hydrogen atoms were treated using a riding model.

Crystallographic data (excluding structure factors) have also been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC 148 356 (**5**), 149 218 (**7**), 149 219 (**8**), 149 220 (**13**), and 148 357 (**18**) and can be obtained, free of charge, on request from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, U.K. (Fax: 44-1223-336033 or e-mail: deposit@ccdc.cam.ac.uk).

Results and discussion



Ligand syntheses

Reaction of Ph_2PCH_2OH (32) with commercially available aminoalcohols *o*-$H_2NC_6H_4(OH)$ and *o*-$H_2NC_6H_4(CH_2OH)$ in toluene–methanol at ca. 65°C for 18 h, gave after workup, the new hybrid ligands *o*-$Ph_2PCH_2N(H)C_6H_4(OH)$ (**I**) and *o*-$Ph_2PCH_2N(H)C_6H_4(CH_2OH)$ (**II**), respectively, in reasonable yields. A similar procedure was used recently for the preparation of the pyridyl analogue $Ph_2PCH_2N(H)C_5H_3N(OH)$ (**V**) (15). The ^{31}P NMR spectra of **I** and **II** both displayed single ^{31}P NMR resonances at ca. δ (P) –18 ppm, some 8 ppm upfield of that observed for Ph_2PCH_2OH (δ (P) –9.9 ppm). One feature noted upon monitoring the stability of these ligands, when $CDCl_3$ solutions are allowed to stand, is the formation of a second new phosphorus species. Thus for **I**, after ca. 3 h, a new species at δ (P) –25.6 ppm was observed and confidently assigned as the diphosphine *o*-$(Ph_2PCH_2)_2NC_6H_4(OH)$. Independently *o*-$(Ph_2PCH_2)_2NC_6H_4(OH)$ can be prepared by reaction of *o*-$H_2NC_6H_4(OH)$ with 2 equiv of Ph_2PCH_2OH under similar conditions.[2] Other supporting data for **I** and **II** are given in Tables 2 and 3.

Oxidation of **I** (or **II**) with aq H_2O_2 proceeds smoothly affording (as confirmed by ^{31}P NMR spectroscopy, Table 3) the corresponding tertiary phosphine oxides *o*-$Ph_2P(O)CH_2N(H)C_6H_4(OH)$ (**III**) and *o*-$Ph_2P(O)CH_2N(H)C_6H_4(CH_2OH)$ (**IV**).

Z = CH, E = lone pair **I**

Z = CH, E = O **IV**

Palladium(II) and platinum(II) chemistry

Reaction of 2 equiv of either **I** (or **II**) with [MCl_2(cod)] (cod = cycloocta-1,5-diene) gave the corresponding metal(II) complexes [$PdCl_2$(**I**)$_2$] (**1**), [$PtCl_2$(**I**)$_2$] (**2**), [$PdCl_2$(**II**)$_2$] (**3**), and [$PdCl_2$(**II**)$_2$] (**4**). Previously, we (15) showed that reaction of 2 equiv of **V** with [$PtCl_2$(cod)] gave the bis *P*,$N_{pyridyl}$-chelate complex [$Pt\{Ph_2PCH_2N(H)C_5H_3N(OH)$-*P,N*$\}_2]Cl_2$. The platinum(II) complexes **2** and **4** in solution have a *cis* configuration as inferred by large ^1J (Pt-P) coupling constants (3678 Hz for **2**, 3660 Hz for **4**) whereas **1** and **3** are present as a mixture of both *cis* and (or) *trans* isomers (4.7:1 (for **1**); 2.2:1 (for **3**)). For comparison the spectral data of

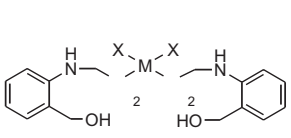
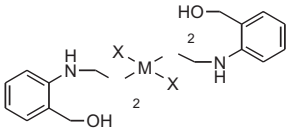
[a]Calculated values in parentheses.
[b]Contains 1 mol toluene as solvate.
[c]Contains 0.25 mol CH_2Cl_2 as solvate.



1–**4** are similar to $[MCl_2\{Ph_2PCH_2OH\}_2]$ (δ (P) 7.3 ppm, ^1J (Pt-P) 3687 Hz, M = Pt (42); δ (P) 27.8 and 13.7 ppm, M = Pd (recorded in CH_2Cl_2–C_6D_6)). Further support comes from the IR spectra (KBr disc) of **2** and **4** which display two ν_{PtCl} bands (Table 3). Apparently in the solid-state only the *cis* isomer is observed for the palladium(II) complexes **1** and **3**.



X = Cl, M = Pd **1a**

X = Cl, M = Pd **3a**
X = Cl, M = Pt **4**
X = CH_3, M = Pt **5**

X = Cl, M = Pd **3b**

Reaction of 2 equiv of **II** with $[Pt(CH_3)_2(cod)]$ in toluene gave a white solid which analyzed, by microanalysis, as $[Pt(CH_3)_2(\mathbf{II})_2]$·toluene (**5**·toluene). The ^{31}P NMR spectrum showed a single ^{31}P NMR resonance at δ (P) 17.2 ppm, with a considerably reduced ^1J (Pt-P) of 1830 Hz and in keeping with **II** *trans* to a methyl group (43). The Pt-CH_3 signals appear in the ^{1}H NMR spectrum as phosphorus coupled multiplets with ^{195}Pt satellites (J (Pt-H) = 68.4 Hz). In contrast, reaction of 2 equiv of **I** with $[Pt(CH_3)_2(cod)]$ in $CDCl_3$ gave initially **6** which, upon standing at ambient temperature for 20 h, gave a new major species tentatively assigned as *trans*-$[Pt(CH_3)Cl(\mathbf{I})_2]$ (δ (P) 21.4 ppm, ^1J (Pt-P) 3106 Hz). After ca. 5 days the intensity of this species diminishes and a new, as yet unidentified compound at δ (P) 22.9 ppm (^1J(Pt-P) 4469 Hz) is the major species present. Clearly, either the acidity of the phenolic group of *P*-coordinated **I** or residual traces of HCl (in $CDCl_3$) may account for methane elimination observed here. No attempts to identify methane formation were pursued. Further reactivity studies are underway and will be reported in due course.

Fig. 1. Crystal structure of **5** (solvent omitted for clarity). Thermal ellipsoids set at 50% probability level.

The X-ray structure of **5** (Fig. 1, Table 4) shows the expected near square-planar geometry (C(21)-Pt(1)-C(21′) 83.2(2)°, C(21)-Pt(1)-P(1) 86.84(15)°, C(21′)-Pt(1)-P(1′) 92.26(18)°, P(1)-Pt(1)-P(1′) 98.05(5)°) and comprises two aminoalcohol functionalized tertiary phosphines and two methyl ligands arranged in a *cis* configuration. The Pt—P and Pt—C bond distances are comparable with those recently reported (43) for $[Pt(CH_3)_2(PR_3)_2]$ complexes. Hydrogen bonds involving both hydroxy groups of each molecule result in a tetrameric $(OH)_4$ eight-membered ring that contain two intramolecular O(1)-H···O(1̇) (O(1)···O(1̇) 2.69 Å, H···O(1̇) 2.00 Å; O(1)-H···O(1′) 150°) and two intermolecular O(1′)-H···O(1̈) (where i = –x, –y, –z + 1; O(1′)···O(1̈) 2.76 Å, H···O(1̈) 1.95 Å; O(1′)-H···O(1̈) 169°] interactions (Fig. 2). The two hydrogen bonded molecules in each dimer are related by inversion symmetry. Additional short intramolecular N(1)···O(1) and N(1̇)···O(1̇) contacts, both in the range of 2.87 Å, show less favourable N-H···O angles (113 and 128°), so we conclude they are probably the result of steric restrictions rather than hydrogen bonds.

[w] Other resonance at δ (H): 6.47 (*J* (P-H) 16.3 Hz, NH). OH not observed.

Ruthenium(II), rhodium(III), and gold(I) chemistry

Reaction of **I** (or **II**) with [{Ru(μ-Cl)Cl(*p*-cymene)}$_2$] in CH_2Cl_2 at ambient temperature gave the mononuclear ruthenium complexes [$RuCl_2$(*p*-cymene)**I**] (**7**) and [$RuCl_2$(*p*-cymene)**II**] (**8**). The ^{31}P NMR spectra show, in both cases, a single phosphorus resonance at δ (P) 23.9 (for **7**) and 22.2 (for **8**) ppm [cf. 16.3 ppm for [$RuCl_2$(*p*-cymene)(Ph_2PCH_2OH)] (**G**)]. Upon inspection of the coordination chemical shifts (Δ_{coord}) (Δ_{coord} = 42.7 (for **7**), 40.7 (for **8**), 25.3 (for **G**)) we observe a larger Δ_{coord} for complexes bearing **I** and **II**. Other spectroscopic and microanalytical data (Tables 2 and 3) confirm the constitution of **7** and **8**. The X-ray structures of both ruthenium compounds have been determined (Figs. 3 and 4, Table 5). Both molecules display similar overall structures — pseudo-octahedral geometries at ruthenium comprising an η^6-*p*-cymene, two chlorides and one phosphorus bound ligand completing the metal coordination sphere. The Ru—Cl and Ru—P distances in **7** and **8** are similar (44), broadly as expected, and furthermore in the case of **8** comparable to those values for [$RuCl_2$(*p*-

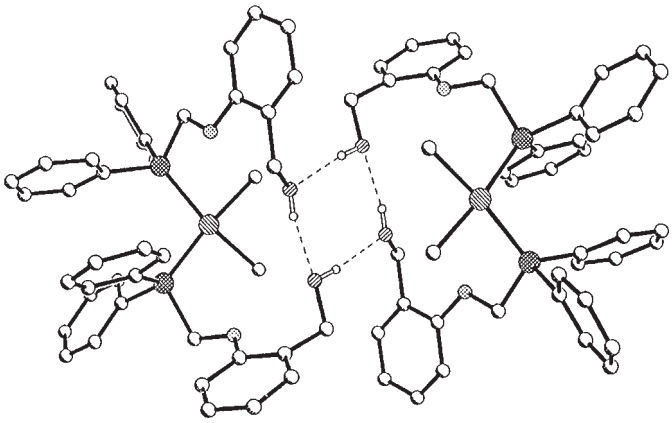
Fig. 2. Hydrogen bond interactions in **5**.



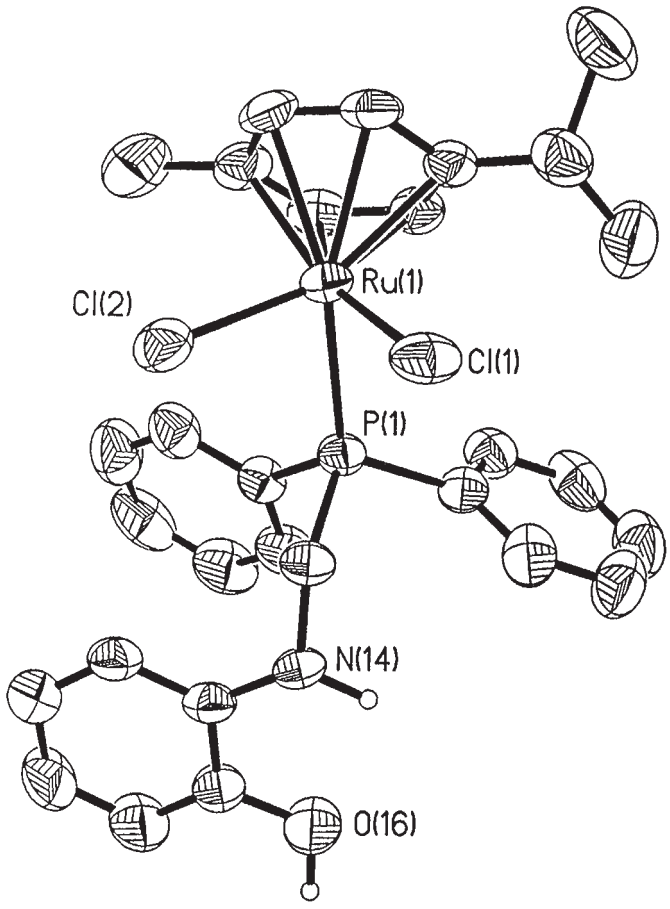


Fig. 3. Crystal structure of **7**. Thermal ellipsoids set at 50% probability level.

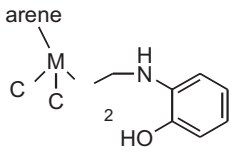

cymene){*o*-$Ph_2PCH_2CH_2C_6H_4(CH_2OH)$}] (5). In **7**, molecules are linked into one-dimensional chains through O-H···Cl_{coord} intermolecular hydrogen bonds (O(16)···Cl(1) 3.10 Å, H(16o)···Cl(1) 2.11 Å; O(16)-H(16o)···Cl(1) 162°). Short intramolecular N···O contacts (N(14)···O(16) 2.62 Å, H(14n)···O(16) 2.23 Å; N(14)-H(14n)···O(16) 100° for **7**; O(16)···N(14) 2.88 Å, H(16o)···N(14) 2.17 Å; O(16)-H(16o)···N(14) 128° and O(46)···N(44) 2.87 Å, H(46o)···N(44) 2.25 Å; O(46)-H(46o)···N(44) 143° for **8**) are also present which again are probably a consequence of steric limitations. The related complex [RuCl(*p*-cymene){$Ph_2PCH_2N(H)C_5H_3N(OH)$-*P*,*N*}]Cl exists in the solid-state (15) as a dimer pair through simultaneous N-H···Cl_{anion} and O-H···Cl_{anion} hydrogen bonding (**D**).

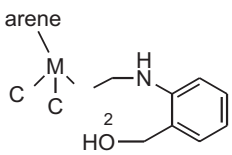

Table 4. Selected bond distances (Å) and angles (°) for compound **5**.

Bond distances (Å)	**5**
Pt(1)—C(21)	2.095(5)
Pt(1)—C(21′)	2.116(5)
Pt(1)—P(1)	2.2849(13)
Pt(1)—P(1′)	2.2817(14)
Bond angles (°)	
C(21)-Pt(1)-C(21′)	83.2(2)
C(21)-Pt(1)-P(1)	86.84(15)
C(21′)-Pt(1)-P(1′)	92.26(18)
P(1)-Pt(1)-P(1′)	98.05(5)
C(21′)-Pt(1)-P(1)	168.67(17)
C(21′)-Pt(1)-P(1′)	174.05(15)

We also studied the reaction of **I** (and **II**) with the rhodium(III) precursor [{Rh(μ-Cl)Cl{$C_5(CH_3)_5$}}$_2$]. Chloro bridge cleavage of [{Rh(μ-Cl)Cl{$C_5(CH_3)_5$}}$_2$] with **I** (and **II**) in dichloromethane gave the rhodium(III) complexes [$RhCl_2${$C_5(CH_3)_5$}**I**] (**9**) and [$RhCl_2${$C_5(CH_3)_5$}**I**] (**10**). The ^{31}P and ^{1}H NMR data are consistent with the proposed structures (Table 3). Hence δ (P) and ^{1}J (Rh-P) for **9** (28.8 ppm, 141 Hz) and **10** (26.4 ppm, 145 Hz) are similar as expected. In the ^{1}H NMR spectra clear, well-resolved doublets at ca. 1.40 ppm (*J* (P-H) 3.5 Hz) confirm the presence of η^5-ligated $C_5(CH_3)_5$ ligands. The gold(I) complexes **11** and **12** were prepared from [AuCl(tht)] and 1 equiv of either **I** (or **II**).

Cyclometallated palladium(II) chemistry

Treatment of the cyclometallated palladium(II) dimers [{Pd(C~N)(μ-Cl)}$_2$] [C~N = $C_9H_{12}N$, $C_{12}H_{12}N$, $C_{12}H_9N_2$] with 2 equiv of **V** gave the mononuclear complexes [PdCl(C~N)**V**] ($C_9H_{12}N$ (**13**), $C_{12}H_{12}N$ (**14**), $C_{12}H_9N_2$ (**15**)) in high yields (>80%) (Scheme 1). The ^{31}P NMR spectra (Table 3) of **13**–**15** show single ^{31}P NMR resonance at δ (P) 34.5 (**13**), 38.6 (**14**), and 33.7 ppm (**15**) indicating similar structures. We also prepared the related complex [PdCl(C~N)**I**] **16** (C~N = $C_9H_{12}N$) whose ^{31}P NMR reveals a singlet at δ (P) 34.2 ppm indicating that pyridyl or phenyl group inclusion has a marginal influence on δ (P). The trans N-Pd-P geometry was inferred from the magnitude of the *J* (P-H) couplings observed in the ^{1}H NMR spectra (Table 3) which correspond well with related compounds and by X-ray crystallography. The X-ray structure of **13** (Fig. 5,

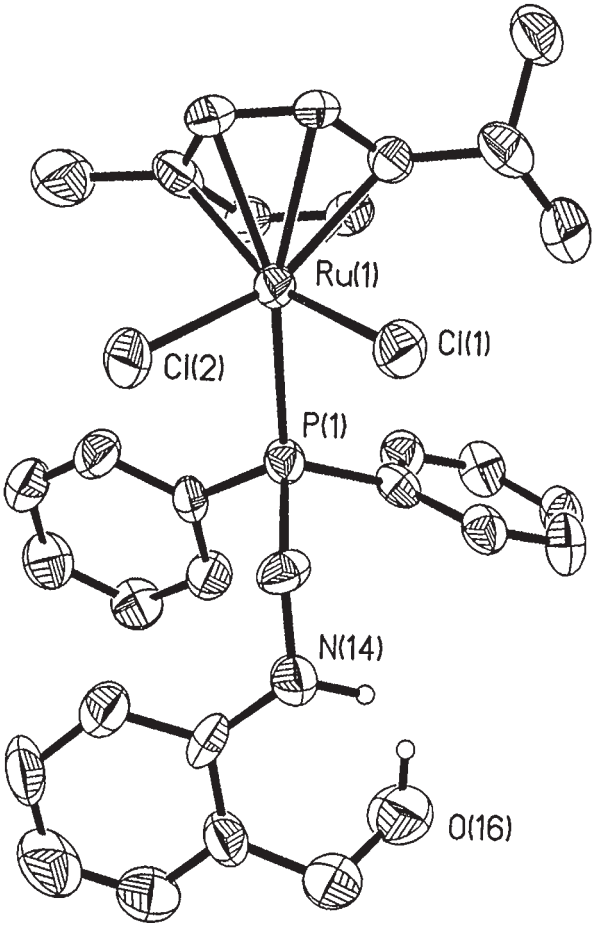

Fig. 5. Crystal structure of **13** (solvent omitted for clarity). Thermal ellipsoids set at 50% probability level.

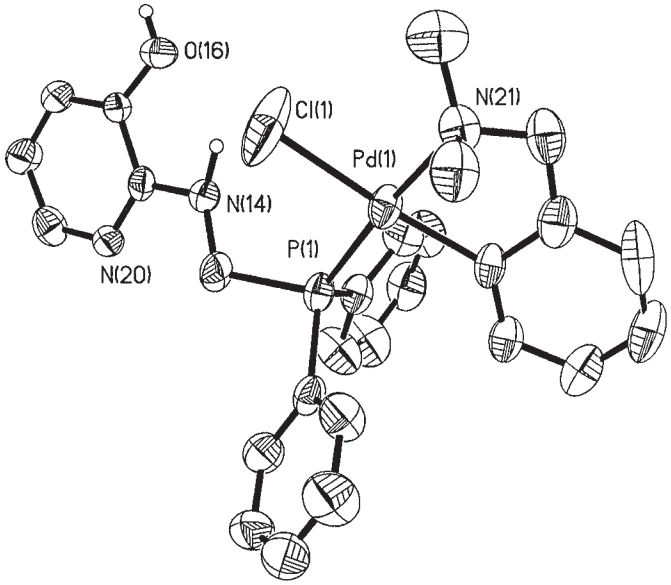

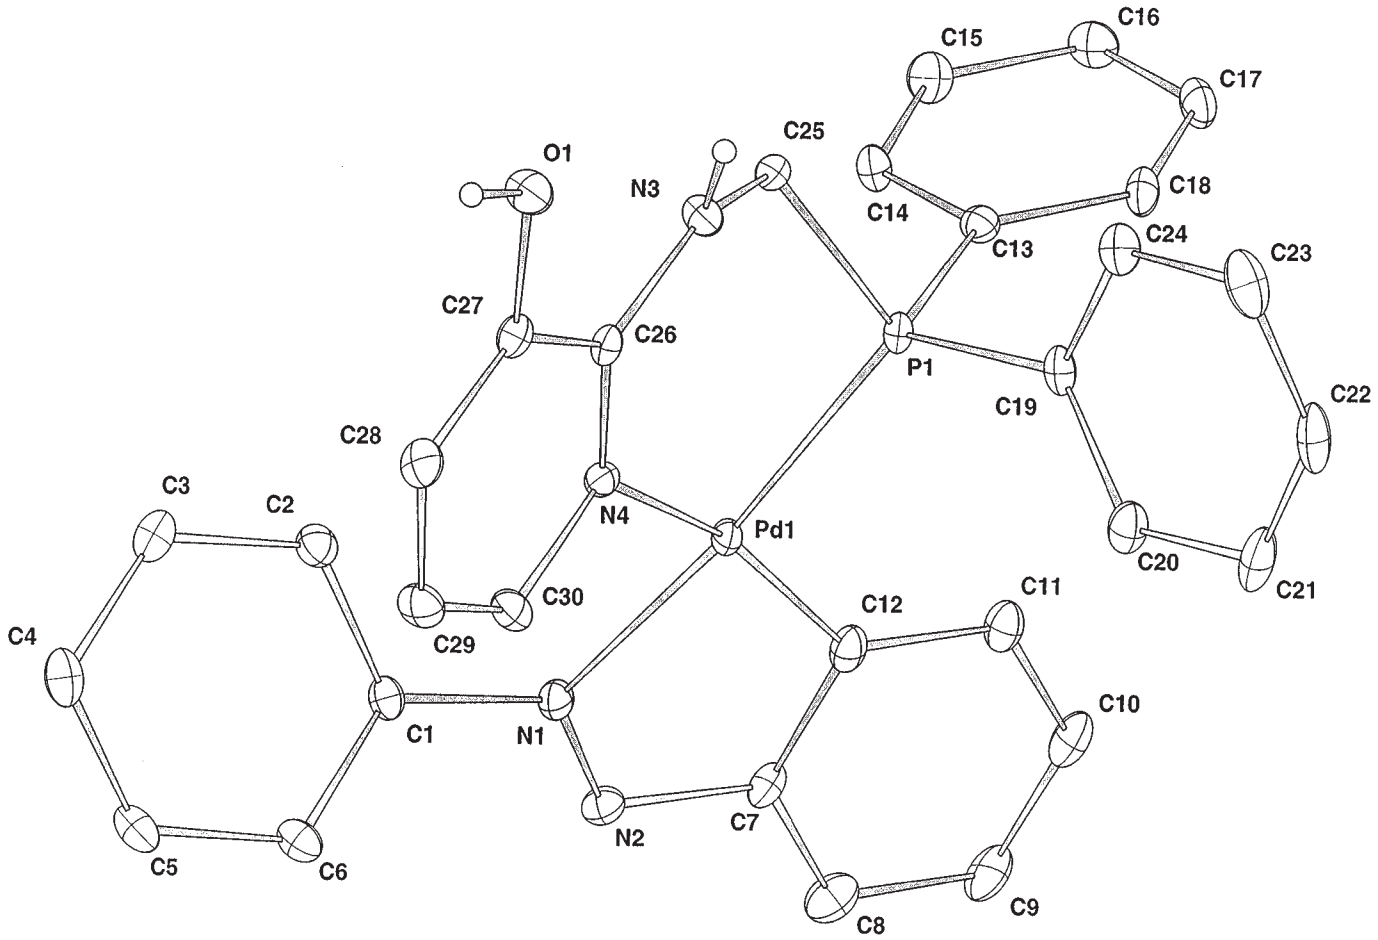

Table 6) shows a near square-planar geometry around the palladium(II) centre (N(21)-Pd(1)-C(25) 83.0(3)°, Cl(1)-Pd(1)-N(21) 90.2(2)°, P(1)-Pd(1)-C(25) 92.9(3)°, and Cl(1)-Pd(1)-P(1) 93.7(1)°) and comprises a chelating cyclometallated $C_9H_{12}N$, a chloride, and a *P*-bound **V** ligand. The P donor is *trans* to the dimethylamino group of the cyclometallated ligand. The Pd—C, Pd—N, Pd—P, and Pd—Cl distances are all broadly as anticipated (45). Molecules are arranged into linear chains through O-H···$N_{pyridyl}$ intermolecular H-bonding (O(16)···N(20A) 2.64 Å, H(16o)···N(20A) 1.82 Å; O(16)-H(16o)···N(20A) 179°). There is also an intramolecular N···O contact (N(14)···O(16) 2.64 Å, H(14n)···O(16) 2.09 Å; N(14)-H(14n)···O(16) 114°) but like **5**, **7**, and **8** is probably not a legitimate H-bond.

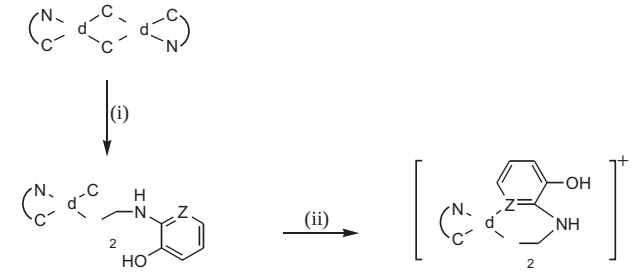

Unlike complexes of **I** (or **II**) for which no further coordination studies were probed, reaction of **13** or **15** with $Ag[BF_4]$ in dichloromethane gave the *P,N*-chelate complexes $[Pd(C\sim N)\{Ph_2PCH_2N(H)C_5H_3N(OH)\}][BF_4]$ (C~N = $C_9H_{12}N$ (**17**); $C_{12}H_9N_2$ (**18**)). Slight upfield shifts were

observed in the ^{31}P NMR spectra while the IR spectra showed small (typically ca. 10–15 cm^{-1}) downfield shifts in $\nu_{C=N(pyridyl)}$ (Table 3). The X-ray structure of **18** (Fig. 6, Table 7) confirms *P*,*N*-co-ordination of **V** with the pyridyl nitrogen *trans* to the orthometallated carbon. The Pd—N bond lengths (Pd(1)-N(1) 2.098(3) Å (N *trans* to P) and Pd(1)-N(4) 2.176(3) Å (N *trans* to C)) differ and reflect the higher *trans*-influence of the aryl ligand compared to the tertiary phosphine. The tetrafluoroborate and water molecules are alternately linked via hydrogen bonds to form single chains running along the 2_1 screw axis (Fig. 7 shows these hydrogen bonded chains viewed along the *a* axis, only the core of the palladium complex is drawn). This involves both protons on the water (H1W and H2W) and two of the tetrafluoroborate fluorines (F2 and F3). The hydrogen bonds formed are: O2-H1W···F2^{ii} where *ii* = $-x + 1$, $y + 0.5$, $-z$ (O2···F2^{ii} 2.72 Å, H1W···F2^{ii} 2.14 Å; O2-H1W···F2^{ii} 168°) and O2-H2W···F3 (O2···F3 2.82 Å, H2W···F3 2.09 Å; O2-H2W···F3 165°). The palladium complex is connected, in a branch like manner, to these chains by a single hydrogen

Highly efficient and stable catalyst for peroxynitrite decomposition

Yurii V. Geletii, Alan J. Bailey, Jennifer J. Cowan, Ira A. Weinstock, and Craig L. Hill

Abstract: The new cobalt substituted-polyoxometalate $K_7[CoAlW_{11}O_{39}]\cdot 15H_2O$ and the simple $CoCl_2\cdot 6H_2O$ salt are efficient catalysts for peroxynitrite decomposition. These compounds also catalyze the oxidation of ascorbic acid and the nitration of phenol by peroxynitrite.

Key words: peroxynitrite, polyoxometalates, antioxidant.

Résumé : Le nouveau polyoxométalate substitué du cobalt, $K_7[CoAlW_{11}O_{39}]\cdot 15H_2O$ ainsi que le simple sel $CoCl_2\cdot 6H_2O$ sont des catalyseurs efficaces pour la décomposition du peroxynitrite. Ces composés catalysent aussi l'oxydation de l'acide ascorbique et la nitration du phénol par le peroxynitrite.

Mots clés : peroxynitrite, polyoxométalates, antioxydant.

[Traduit par la Rédaction]

Introduction

The recent interest in peroxynitrite[1], a compound known for many years (1), was inspired by Beckman et al. (2), who suggested it was formed in vivo from NO and $O_2^{\bullet -}$. Under physiological conditions, $ONOO^-$ is partially protonated to HOONO (pK_a = 6.8), which rapidly ($k \sim 1\ s^{-1}$, pH = 7.0, 25°C) decomposes to highly reactive radical species in a unimolecular reaction (1–4). Peroxynitrite also reacts with many compounds in bimolecular reactions, and it is a powerful oxidant with substantial toxicity (1–4). There is accumulating evidence for peroxynitrite formation in vivo, which naturally has led to a search for compounds that can intercept this powerful oxidant and destroy it safely. The discovery of a fast peroxynitrite reaction with myeloperoxidase ($6.2 \times 10^6\ M^{-1}\ s^{-1}$ at pH = 7.2) (5) inspired studies of peroxynitrite reactions with synthetic, water-soluble Fe- and Mn-porphyrin complexes (6–11). Reactions of peroxynitrite with combinations of these metalloporphyrins and antioxidants were found to be even more rapid. Recently, several nonheme catalysts for peroxynitrite decomposition were reported (9, 12, 13); however, they appeared to be unstable and less active.

Here we report that a simple cobalt salt, $CoCl_2\cdot 6H_2O$, and the Co-substituted polyoxometalate, $K_7[Co^{II}AlW_{11}O_{39}]\cdot 15H_2O$, catalytically decompose peroxynitrite at neutral pH (6.5–7.4) with high turnover numbers. Their activity is comparable to MnTMPyP, where TMPyP is the dianion of tetrakis(*N*-methyl-4′-pyridyl) porphyrin. All species also catalyze ascorbic acid oxidation and phenolic nitration by peroxynitrite.

Results and discussion

Peroxynitrite decay in the absence and in the presence of representative catalysts is exponential and follows the rate law in eq. [1].

$$[1] \qquad -d[ONOO^-]/dt = k_{obs}[ONOO^-] = k_o[ONOO^-] + k_{cat}[ONOO^-][cat]$$

When k_{obs} values are plotted as a function of catalyst concentrations ([cat]) straight lines are obtained. The *y*-intercepts provide k_o and the slopes of each line provide k_{cat}. The data are summarized in Table 1. The following compounds were evaluated and found to be minimally active ($k_{cat} < 1 \times 10^3\ M^{-1}\ s^{-1}$): $CuCl_2\cdot 2H_2O$, $FeCl_2\cdot 4H_2O$, $K_9[AlW_{11}O_{39}]\cdot 13H_2O$, $Na_5[AlW_{12}O_{40}]\cdot 13H_2O$, $K_7[V^{IV}AlW_{11}O_{40}]\cdot 8H_2O$, and $K_5[Co^{III}W_{12}O_{40}]\cdot 13H_2O$ (the reproducible value for the uncatalyzed rate constant, $k_o = 0.35 \pm 0.03\ s^{-1}$ at pH 7.4).

The stabilities of the three most active catalysts, $CoCl_2$, $K_7[Co^{II}AlW_{11}O_{39}]$, and MnTMPyP, were evaluated by comparing their activities, indicated by experimental k_{obs} values, before and after reaction with large excesses of peroxynitrite (for concentrations see Table 2). The resistance of each catalyst to irreversible decomposition was estimated by $n = [NaOONO]_d/\Delta[cat]$, where $[NaOONO]_d$ is the total amount of peroxynitrite decomposed and $\Delta[cat]$ is the amount of the catalytic activity lost in the catalytic reaction. The latter term

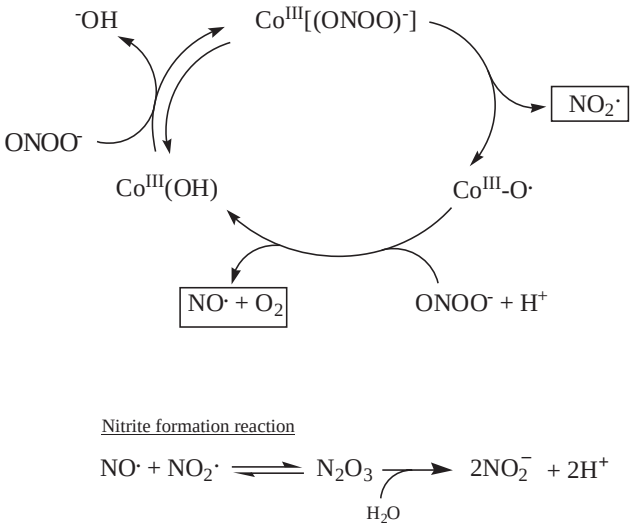
Table 1. The rate constants (k_{cat}) of representative compounds used to catalyze peroxynitrite decomposition at 25°C.

Catalyst	k_{cat} (1×10^{-4}) (M^{-1} s^{-1})
MnTMPyP	2.1 ± 0.2
$CoCl_2$	3.0 ± 0.3
$K_7[CoAlW_{11}O_{39}]$	1.9 ± 0.15

Note: For all experiments the pH = 7.0 ± 0.05, 75 mM phosphate buffer, $[ONOO^-]_o$ = 300–400 μM, $[cat]_o$ = 0–40 μM (0–14 μM for MnTMPyP).

was calculated as $\Delta[cat] = [cat]_o(k^\circ_{obs} - k'_{obs})/(k^\circ_{obs} - k_o)$, where $[cat]_o$ is the initial concentration of the catalyst, k_{obs} is the decomposition rate in the presence of the catalyst that has been pretreated with a large excess of peroxynitrite, and k°_{obs} and k_o are the decomposition rates in the presence and the absence of the catalyst, respectively.[3] The results, presented in Table 2, show that both $K_7[Co^{II}AlW_{11}O_{39}]$ and MnTMPyP are substantially more stable than Co^{2+} (as $CoCl_2$).

The self-decomposition of peroxynitrite at neutral pH is known to form nitrate and nitrite, and the formation of nitrite is accompanied by dioxygen evolution in a 2:1 ratio (14). The addition of $K_7[Co^{II}AlW_{11}O_{39}]$ increases the yield of nitrite (from 11 to 23% based on peroxynitrite, if 20 μM of $K_7[Co^{II}AlW_{11}O_{39}]$ is added at pH 7.4).



Since $CoCl_2$ is more active than $K_7[Co^{II}AlW_{11}O_{39}]$, the activity of the latter could be attributed to Co^{2+} ions formed via dissociation of $K_7[Co^{II}AlW_{11}O_{39}]$ (eq. [2]). However, the activity of a mixture of $CoCl_2$ and $K_7[Co^{II}AlW_{11}O_{39}]$ was the same as the sum of the activities of each of the individual components, suggesting that $K_7[Co^{II}AlW_{11}O_{39}]$ itself is also an active catalyst.

$$[2] \qquad [Co^{II/III}AlW_{11}O_{39}]^{7-/6-} \rightleftharpoons Co^{2+/3+} + [AlW_{11}O_{39}]^{9-}$$

Treatment of the starting $K_7[Co^{II}AlW_{11}O_{39}]$ with peroxynitrite results in its immediate oxidation to $K_6[Co^{III}AlW_{11}O_{39}]$ (λ_{max} shifts from 560 to 680 nm). The mechanism in Scheme 1 (proposed mechanism of peroxynitrite decomposition catalyzed by $K_7[Co^{II}AlW_{11}O_{39}]$, where Co^{II} represents $[Co^{II}AlW_{11}O_{39}]^{7-}$) is consistent with all the above data and is based on that proposed for catalysis of peroxynitrite decomposition by Fe-porphyrins (7, 11) and sulfito-bound Co(III) (*cis*-$[Co(NH_3)_4(SO_3)_2]^-$) (12).[4] The rate-limiting step is likely to be a homolysis of the O—O bond in a Co^{III} peroxonitrito intermediate to form Co^{III}-$O^\bullet$ and $NO_2^\bullet$. Previously, a Co(III) peroxynitrito complex has been isolated and characterized (15). The reaction is thought to occur by an outer-sphere mechanism. However, since the lability of Co(III) increases when its geometry is perturbed from rigorous O_h symmetry (16), as is the case in $K_7[Co^{II}AlW_{11}O_{39}]$, an inner-sphere mechanism cannot definitely be ruled out. Further investigations are ongoing.

The addition of ascorbic acid significantly increases the rate of peroxynitrite consumption in reactions catalyzed by $K_7[Co^{II}AlW_{11}O_{39}]$, i.e., the observed second-order rate constant (k_{cat}, eq. [1]), increases from 1.9×10^4 to 12.7×10^4 M^{-1} s^{-1} in the presence of 7.4 mM ascorbic acid at pH 7.4. However, the rate of $K_6[Co^{III}AlW_{11}O_{39}]$ reduction by ascorbic acid is too slow to account for the observed increase in the total rate of peroxynitrite decomposition. Therefore, ascorbic acid is likely to reduce the $Co^{III}[(OONO)^-]$ intermediate complex, thus accelerating the total rate.

Scheme 1.

The nitration of phenols by peroxynitrite has long been known (17), and Beckman et al. (18) were the first, to our knowledge, to report a catalytic version of this process. To assess phenol nitration activity by the Co systems, the yield and the rate of 3-nitro-4-hydroxyphenylacetic acid (3-NO_2-4-HPA) from the nitration of 4-hydroxyphenylacetic acid (4-HPA) were quantified. The yield of 3-NO_2-4-HPA, and the rate of its formation, both increase with increasing $K_7[Co^{II}AlW_{11}O_{39}]$ concentration. Based on the initial peroxynitrite concentration, the 3-NO_2-4-HPA yield was 7% in the absence of a catalyst and 40% in the presence of 82 μM of $K_7[CoAlW_{11}O_{39}]$ (pH 7.4, [4-HPA] = 6.0 mM, $[NaOONO]_o$ = 1.1 mM). However, unlike in the catalyzed oxidation of ascorbic acid by peroxynitrite, the observed second-order rate constant (k_{cat}, eq. [1]) does not increase with 4-HPA concentration. The mechanism of nitration may involve a fast reduction of Co^{III}-$O^\bullet$ by the phenolic species; subsequent coupling of the resulting phenoxy radical and $NO_2^\bullet$ gives nitrophenol. Mn- and Fe-porphyrins active in peroxynitrite decomposition have also been found to catalyze the nitration of phenols (6, 8–11, 19) likely through the coupling of phenoxy and $NO_2^\bullet$ radicals (19).

Experimental

MnTMPyP (ICN Biomedicals Inc.) was standardized in aqueous solution using $\varepsilon_{462} = 1 \times 10^5$ M^{-1} cm^{-1} (20). Peroxynitrite was synthesized from H_2O_2 and nitrite in a simple flow reactor (21, 22) and its concentration was deter-

[3] $k'_{obs} = k_o + k_{cat}[cat]$, see eq. [1].
[4] The reaction decelerates at $[OH^-]$ = 0.4 M, $[NaOONO]_o$:[cat] ~ 10–15, as a result of catalyst decomposition.

Table 2. The observed reaction rate constants before (k°_{obs}) and after (k'_{obs}) reaction of the catalyst with a large excess of peroxynitrite, and n values.

Catalyst	k°_{obs} (s^{-1}) [a]	k'_{obs} (s^{-1}) [a]	$(k^{\circ}_{obs} - k'_{obs})/(k^{\circ}_{obs} - k_o)$ [b]	n [c]
$CoCl_2$	1.85 ± 0.07	1.33 ± 0.07	0.3	~3×10^3
$K_7[CoAlW_{11}O_{39}]$	1.33 ± 0.05	1.30 ± 0.05	<0.03	>3×10^4
MnTMPyP	1.10 ± 0.04	1.09 ± 0.04	<0.03	>3×10^4

Note: All experiments carried out at 25°C. Pretreatment conditions: $[NaOONO]_o$ = 24 mM, $[cat]_o$ = 25 μM, pH 6.8, 0.15 M phosphate buffer.

[a] $[NaOONO]_o$ = 0.4 mM, $[cat]_o$ = 15 μM, pH 7.4, 0.11 M phosphate buffer.

[b] $k_o = 0.35 \pm 0.03\ s^{-1}$.

[c] $n = [NaOONO]_d/\Delta[cat]$; see text for details.

mined by UV–vis spectroscopy, $\varepsilon_{302} = 1.7 \times 10^3\ M^{-1}\ cm^{-1}$ (23).

The new transition-metal-substituted POM (α-$K_7[CoAlW_{11}O_{39}]\cdot 15H_2O$) was prepared by metallation of the lacunary complex α-$K_9[AlW_{11}O_{39}]\cdot 15H_2O$ (24) by $Co(NO_3)_2\cdot 6H_2O$. A 10 g portion of $K_9[AlW_{11}O_{39}]$ (3.05 mmol) was stirred in water (100 mL), and a solution of $Co(NO_3)_2\cdot 6H_2O$ (0.88 g, 3.05 mmol, in 10 mL water) was added dropwise to the slurry via a pipette. The reaction mixture was stirred in a hot water bath (70–80°C) until the solution became clear. The resulting solution was dark pink (pH 6.2), and after cooling to room temperature, a red powder deposited. The product was recrystallized from a minimum of warm (60°C) water.[5]

Kinetic experiments were studied using a SF-61 stop flow instrument (Hi-Tech Scientific, U.K.). A buffer solution with the reactants and peroxynitrite diluted in aqueous NaOH were mixed and the absorbance at 302 nm was measured. The first-order reaction rate constants were determined using standard software (KISS 5.1 for Macintosh computer). The yields of nitrite and 3-NO_2-4-HPA were determined after a small amount of highly concentrated (~0.6 M) peroxynitrite solution was mixed with a buffer solution containing all other ingredients. Yields of nitrite were determined as previously described (25) and 3-NO_2-4-HPA was quantified from its absorbance at 430 nm after adjusting the pH to 10–11 (18).

Hetero trinuclear oxo-bridged complexes of ruthenium porphyrin and iron phthalocyanine

Fabio Zobi and Dennis V. Stynes

Abstract: New diamagnetic hetero bi- and trinuclear oxo-bridged metal complexes of formula (L)(Pc)Fe-O-Ru(TPP′)(O) and (L)(Pc)Fe-O-Ru(TPP′)-O-Fe(Pc)(L) have been prepared from Ru(TPP′)$(O)_2$ and Fe(Pc)$(L)_2$ (TPP′ = tetrakis(4-methoxyphenyl)porphyrinate, Pc = phthalocyanate ion, L = monodentate ligand). The trinuclear complex binds a variety of ligands (4,4′-bipy, 4-MePy, $P(OEt)_3$, pip, NH_3, 1-MeIm, $P(Me)_2Ph$) *trans* to the oxo-bridge. ^{1}H NMR spectra are characterized by large ring current shifts (rcs) due to the TPP′ and Pc ions. The complexes show an unusually weak Pc Q band in their visible spectra at 700 nm and two CT bands in the near-IR region from 1000 to 1500 nm, which are sensitive to the *trans* ligand. The trinuclear complex can be reversibly oxidized to the +1 and +2 ions, formally Fe(IV)-O-Ru(IV)-O-Fe(III) and Fe(IV)-O-Ru(IV)-O-Fe(IV) at 0.4 and 0.76 V. The +1 ion is chemically obtained by reaction of the neutral species with $(Cp)_2Fe^+$ for L = 4-MePy and this reaction is reversed upon addition of L′ = $P(Me)_2Ph$. Reductive cleavage by hydroquinone, phosphines and phosphites are the slowest of all RuTPP[$O(FeN_4)$]$_2$ systems studied to date ($t_{1/2}$ = 8 h at 40°C).

Key words: ruthenium, iron, porphyrin, phthalocyanine, oxo.

Résumé : En faisant réagir du Ru(TPP′)$(O)_2$ et du Fe(Pc)$(L)_2$ (TPP′ = tétrakis(4-méthoxyphényl)porphyrinate, Pc = ion phtalocyanate, L = ligand monodentate), on a préparé de nouveaux complexes métalliques diamagnétiques, hétéro-bi et -trinucléaires, à ponts oxo, de formules (L)(Pc)Fe-O-Ru(TPP′)(O) et (L)(Pc)Fe-O-Ru(TPP′)-O-Fe(Pc)(L). Le complexe trinucléaire se fixe à une variété de ligands (4,4′-bipy, 4-MePy, $P(OEt)_3$, pip, NH_3, 1-MeIm, $P(Me)_2Ph$), de façon *trans* par rapport au pont oxo. Les spectres de RMN du ^{1}H sont caractérisés par d'importants déplacements de courant de cycle causés par les ions TPP′ et Pc. Dans leurs spectres dans le visible, ces complexes comportent une bande Q anormalement faible pour le Pc, à 700 nm, et deux bandes CT dans la région du proche infrarouge, entre 1000 et 1500 nm, qui sont sensibles au ligand *trans*. À des valeurs de 0,4 et 0,76 V suivant le cas, le complexe trinucléaire peut être oxydé de façon réversible vers les ions +1 et +2 qui sont formellement le Fe(IV)-O-Ru(IV)-O-Fe(III) et le Fe(IV)-O-Ru(IV)-O-Fe(IV). On peut obtenir l'ion +1 de façon chimique par réaction de l'espèce neutre avec $(Cp)_2Fe^+$, pour L = 4-MePy, et cette réaction est renversée par l'addition de L′ = $P(Me)_2Ph$. De tous les clivages réducteurs par l'hydroquinone, les phosphines et les phosphites observés à date avec des systèmes RuTPP[$O(FeN_4)$]$_2$, ce sont les plus lents ($t_{1/2}$ = 8 h, à 40°C).

Mots clés : ruthénium, fer, porphyrine, phtalocyanine, oxo.

[Traduit par la Rédaction]

Introduction

The study of oxo-bridged multinuclear metal complexes has continued to attract interest both for their biological relevance (1) and as the most common example of single atom bridged systems (2). Oxo-bridged metal complexes have been prepared by hydrolytic processes (3), by one-electron redox reactions in which a high valent metal-oxo compound is reacted with a lower valent metal complex (4), and by autoxidation (5). We and others have employed a $Ru^{VI}(O)_2$ porphyrin as a route to μ-oxo trinuclear species (6, 7) In this study we extend this reaction to a new class of oxo-bridged heterotrinuclear complexes containing the iron phthalocyanine (FePc) moiety.

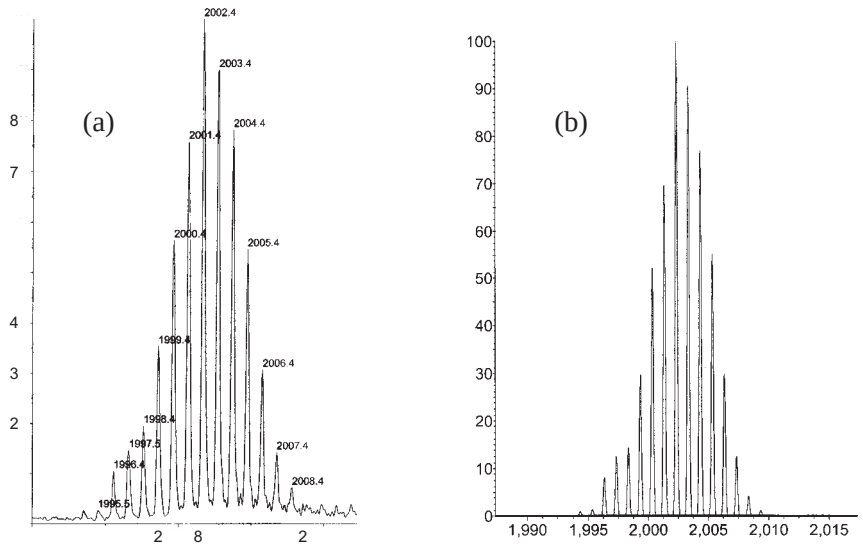
Experimental

Materials



Common ligands were obtained from standard sources and were used as received. Solvents were distilled and kept over molecular sieves (3 Å). $CDCl_3$ was dried over activated molecular sieves (3 Å) and freed of acid by filtering through vacuum dried $Al(OH)_3$. Tetrakis(4-methoxyphenyl) porphyrin (H_2TPP′), Ru(TPP′)(CO)(C_2H_5OH), and Ru(TPP′)$(O)_2$ were prepared by literature methods (8–10).

Physical measurements

Visible spectra were recorded on a HP-8451 Diode array UV–vis spectrometer in 1 cm glass cuvettes thermostated at 25°C. ^{1}H NMR spectra were obtained on a Bruker ARX 400 MHz spectrometer at 300 K using $CDCl_3$ as the solvent

 DOI: 10.1139/cjc-79-5/6-795 © 2001 NRC Canada

Fig. 1. Experimental (*a*) and simulated (*b*) MS spectra of **2**. Shown is the isotopic distribution of the peak at *m*/*z* 2002, assigned to the $[(Pc)FeO]_2Ru(TPP')$ skeleton.

with TMS as an internal standard. Near-IR spectra were recorded on a Cary 2400 UV–vis – near-IR spectrometer at 25°C. Electrochemical data were collected with a computer-controlled Electroanalytical Cypress System model CS-1090. Cyclic voltammetry experiments were performed under a nitrogen atmosphere in a CH_2Cl_2 solution containing 0.1 M $(TBA)PF_6$ and ~5 × 10^{-3} M complex at −42°C. A platinum disk sealed in glass was used as a working electrode. Graphite was used as a counter electrode and AgCl/Ag was used as the reference electrode. Ferrocene was used as an internal reference (Fc+/Fc = 0.46 V in CH_2Cl_2 vs. SCE). Mass spectra were collected with a Perseptive Biosystems MALDI spectrometer, model Voyager-DE STR operating in the positive-ion mode.

Fe(Pc)(L)$_2$ (L = 4-MePy, 1-MeIm)

Fe(Pc) (Pc = phthalocyanate ion) (Aldrich) (1 g, 1.76 mmol) was dissolved in a $CHCl_3$ solution (25 mL) containing 4-MePy (5 mL, 51.4 mmol). After stirring the solution for 10 h at room temperature a purple crystalline precipitate was collected by filtration through paper. The product was then washed with hexane and dried in vacuo. Yield: 579 mg, 44%. $Fe(Pc)(1\text{-MeIm})_2$ was prepared by a similar procedure. Yield: 697 mg, 54%.

[(1-MeIm)Fe(Pc)O]Ru(TPP′)(O) (1)

Freshly made $Ru(TPP')(O)_2$ (5 mg, 5.8 × 10^{-3} mmol) and $Fe(Pc)(1\text{-MeIm})_2$ (10 mg, 1.36 × 10^{-2} mmol) were dissolved in a N_2 purged $CDCl_3$ solution (5 mL) and the reaction followed by NMR. When all $Ru(TPP')(O)_2$ had reacted (indicated by the disappearance of the H_β peak at 9.11 ppm) the reaction was quenched by slowly adding hexane (10 mL). The ppt was filtered through paper and dried in vacuo. Yield: 6.9 mg, 80%. The complex was very reactive and it formed an insoluble precipitate both in solution (within minutes) and in the solid state even when stored in vacuo at –20°C.

[(4-MePy)Fe(Pc)O]$_2$Ru(TPP′) (2)

Freshly made $Ru(TPP')(O)_2$ (100 mg, 0.116 mmol) and $Fe(Pc)(4\text{-MePy})_2$ (200 mg, 0.265 mmol) were mixed as solids and dissolved in a CH_2Cl_2–$CHCl_3$ solution (3:1, 18 mL). After 40 min hexane (50 mL) was slowly added depositing 223 mg of a black crude precipitate. The product was found to be contaminated by unreacted $Fe(Pc)(4\text{-MePy})_2$ and $[Ru(TPP')(OH)]_2O$, which were subsequently removed by recrystallizing the complex from a hexane–$CHCl_3$ solution. Yield: 199 mg, 79%. MALDI-MS ($CHCl_3$) *m*/*z*: 2188 ($[M]^+$). Other relevant peaks are at 2002 ($[(PcFeO)_2Ru(TPP')]^+$) (Fig. 1), 1418 ($[(Pc)FeORu(TPP')]^+$), 850 ($[Ru(TPP')(O)]^+$), 662 ($[Fe(Pc)(4\text{-MePy})]^+$), 569 ($[Fe(Pc)]^+$). Anal. calcd for $C_{124}H_{82}N_{22}O_6Fe_2Ru$: C 68.04, H 3.78, N 14.08; found: C 68.39, H 3.76, N 13.91. This complex is sensitive to trace acid normally present in $CDCl_3$, therefore, its ^1H NMR spectrum must be taken in acid free solvents. Various ligated derivatives of **2** were generated in situ in a NMR tube by addition of excess ligand L (L = 4,4′-bipy, pip, NH_3, 1-MeIm, $P(CH_3)_2Ph$) to the 4-MePy-ligated derivative in a chloroform solution. Solid samples were obtained in quantitative yields by precipitation with hexane (typically 1–3 mg).

Kinetic measurements

Neat phosphines, phosphites, or a dichloromethane solution of hydroquinone were injected via syringe into a thermostated (40°C) $CHCl_3$ solution of the complex (1 × 10^{-5} M) and the subsequent reaction followed by visible spectroscopy. Pseudo-first-order rate constants were obtained by monitoring the growth of the Soret band of the $Ru(TPP')L_2$ complex. Spectra were typically scanned between 380 and 820 nm under anaerobic conditions.

Results and discussion

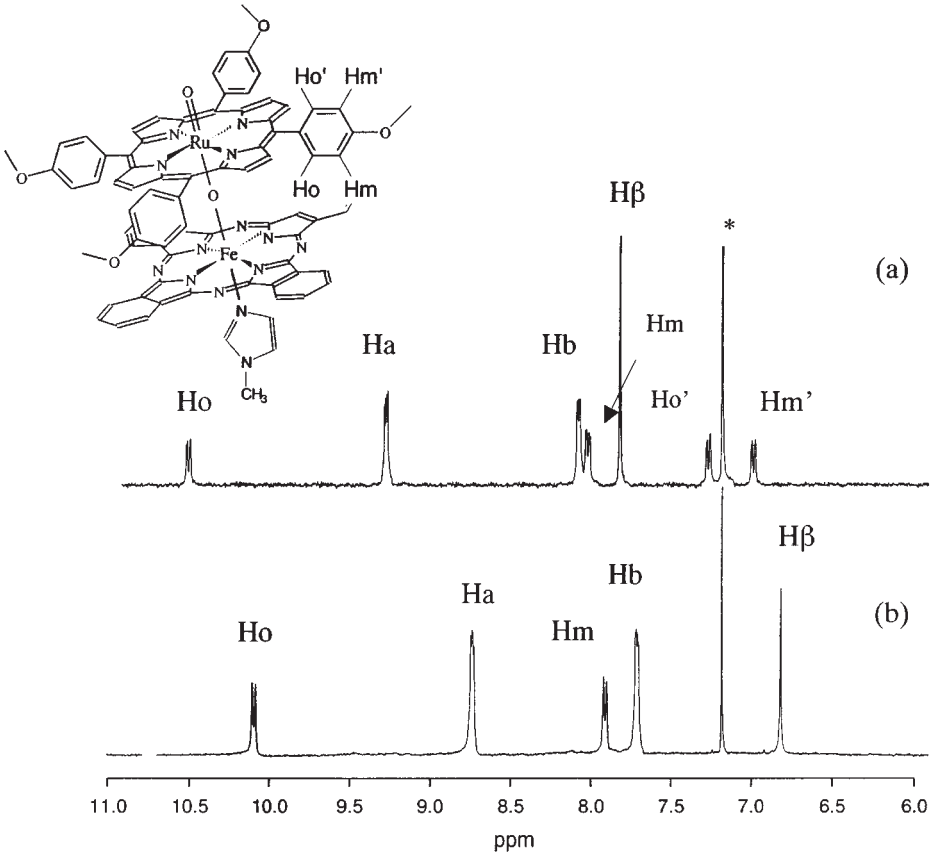
Synthesis

Formation of **2**, the trinuclear complex, proceeds through the initial formation of a reactive binuclear species **1** (Fig. 2). Both steps involve an inner-sphere oxidation of the Fe^{II} metal center by the dioxo Ru-porphyrin. Attempts to isolate the 4-MePy derivative of **1** proved unsuccessful as **1**-(4-MePy) is extremely reactive.

The 1-MeIm derivative was isolated but survives only long enough to obtain an NMR and observe its reactions with reductants. Oxidation of the Fe^{II} metal center by $Ru(TPP')(O)_2$ requires a vacant coordination site on Fe(Pc). Ligand dissociation in $Fe(Pc)(1\text{-MeIm})_2$ is about 50 times slower than $Fe(Pc)(4\text{-MePy})_2$ (11) and this allows for a better control over the reaction. Slow dissociation of 1-MeIm in the binuclear complex may also retard polymerization of **1**. While **1**-(4-MePy) is generated in situ by reacting $Ru(TPP')(O)_2$ with $Fe(Pc)(4\text{-MePy})_2$ in a 1:1 ratio, an excess of $Fe(Pc)(1\text{-MeIm})_2$ was used in the slower formation of **1**-(1-MeIm) to avoid formation of the $[Ru(TPP')(OH)]_2O$ dimer.

The binuclear complex is formally Fe^{IV}-O-Ru^{IV} and is the first example of a Ru porphyrin complex containing both a terminal and a bridging oxo ligand. The presence of the reactive terminal oxygen is inferred from the observation that the binuclear species reacts with a second Fe(Pc) unit to form the trinuclear compound and undergoes rapid reactions on mixing with hydroquinone, DMSO, or dimethylphenylphosphine. The oxidation products quinone, $DMSO_2$, and dimethylphenylphosphine oxide, respectively, were identified in the NMR spectrum.

^{1}H NMR spectra



Both **1** and **2** are diamagnetic as expected for linear species with axial d_π^4 and d_π^8 configurations (6). ^{1}H NMR provides definitive characterization of the different ligated bi- and trinuclear μ-oxo species. All spectra are characterized by large ring current shifts (rcs) due to the TPP′ and Pc ions. Observed shifts are consistent with rcs calculations carried out on the basis of Abraham 12-loop model (12). An eclipsed conformation of the macrocycles is most consistent with the NMR data as this places the porphyrin H_β protons directly over the benzopyrrole rings. A staggered conformation would lead to prohibited contacts with the TPP′ phenyls (Fig. 3). An eclipsed structure is rare for X-bridged dimers and trimers (X = C, N, O). The only other known examples are $[(THF)(TPP)Fe\text{-}N\text{-}Fe(Pc)(H_2O)](I_5)$ (13), $[(Pc)Al]_2O$ (14), and $[Fe(OEP)]_2O$ (15). Complex **2** is the first example of a fully eclipsed macrocyclic trinuclear.[2]

^{1}H NMR spectra of the bi- and trinuclear complexes are shown in Figs. 4*a* and *b*, respectively. The binuclear species is identified on the basis of differentiated TPP′ phenyls protons. Phenyl protons directed toward the Fe(Pc) face project into the deshielding region of the Pc ring and experience a downfield shift, while those directed to the open face (denoted $H_{o'}$ and $H_{m'}$ in Fig. 4*a*) experience a small upfield shift. In the centrosymmetric trinuclear species a single set of ortho and meta phenyl resonances is observed (H_o and H_m in Fig. 4*b*). The porphyrin H_β protons are shifted upfield (rela-

[2] The $[Mo_3O_4(TPP)_3]^+$ ion shows partial eclipse of two Mo(TPP) moieties (16).

tive to Ru(TPP′)(O)$_2$) in both **1** and **2**. Axial ligand resonances are also shifted upfield as a result of the cumulative effect of Pc and TPP′ rcs. Hydrogen atoms at the *ortho* position in 4-MePy, for example, suffer a 8.5 ppm upfield shift in **1** and over 9 ppm upfield shift in **2** when compared to the free ligand. Spectral data are collected in Table 1.

Electronic spectra

The visible spectrum of **2** is given in Fig. 5. It shows a typical porphyrin Soret band at 410 nm in contrast to a red-shifted Soret band at about 435 nm in DMG and DPG trinuclears (6). A weak bathochromic shifted phthalocyanine Q band at about 700 nm is present in the visible spectrum of **2**. An unusually weak Pc Q band is also reported for the μ-nitrido (TPP)Mn-N-Fe(Pc) (17) and the μ-oxo (TPP)Cr-O-Fe(Pc) (18) complexes. This feature may be characteristic of X-bridged metal atoms containing face-to-face Pc and porphyrin rings. Additionally, two low energy charge transfer bands (CT1 and CT2) appear in the near-IR region at 1050 and 1330 nm (see Fig. 6 and Table 2).

The CT bands show significant shifts as a function of the axial ligand suggesting that MO's with substantial iron character are involved. The two bands are tentatively assigned to an oxo-to-metal (CT1) and to an intervalence metal-to-metal charge transfer (CT2). A similar assignment was made in DMG based systems (6). The lower oxidation potential of **2** translates in a smaller HOMO–LUMO gap and less energy is required for this transition. Consequently CT2 in **2** shifts 500 nm and is well-resolved in the IR. The same is true for CT1 (see Tables 3 and 4). Both CT bands undergo a bathochromic shift with increasing π-acceptor strength and (or) increasing basicity of the axial ligand. A typical change is shown in Fig. 6.

Ligation

The Fe(Pc) based heterotrinuclear complexes are substantially more stable in solution than borylated dioxime and paramagnetic heme or Fe(Schiff base)-derived Fe-O-Ru-O-Fe systems (6, 7). Ligand displacement at the Fe^{III} center can be followed at room temperature by both NMR and near-IR spectroscopy. 4-MePy in **2** is easily displaced by stonger σ-donors such as NH_3 and 1-MeIm, by π-acid ligands including P(Me)$_2$Ph, and by ligands capable of promoting chain elongation like 4,4′-bipy (eq. [1]). These substitution reactions are over on mixing at ambient temperature but are in the slow exchange limit in the ^{1}H NMR.

[1] $$[(4\text{-MePy})Fe(Pc)O]_2Ru(TPP') + 2L' \rightarrow [(L')Fe(Pc)O]_2Ru(TPP') + 2(4\text{-MePy})$$

The relative binding strength of the different ligands was obtained from spectrochemical titrations in the near-IR and follows the order:

$$4,4'\text{-bipy} < 4\text{-MePy} \sim P(OEt)_3 < pip < NH_3 < 1\text{-MeIm} < P(CH_3)_2Ph$$

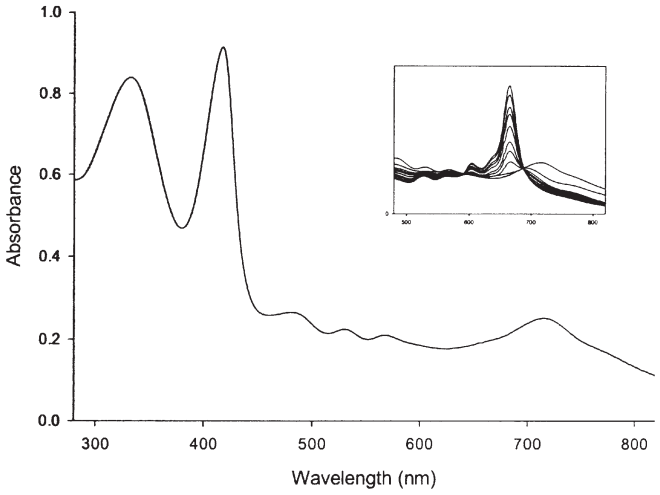
[a] **3** = [Fe((DMG)BF$_2$)$_2$O]$_2$Ru(TPP′), ref. 6.

Fig. 5. Visible spectrum of **2** in $CHCl_3$. Insert shows the growth of the Pc Q band during the reductive cleavage of the oxo-bridge.



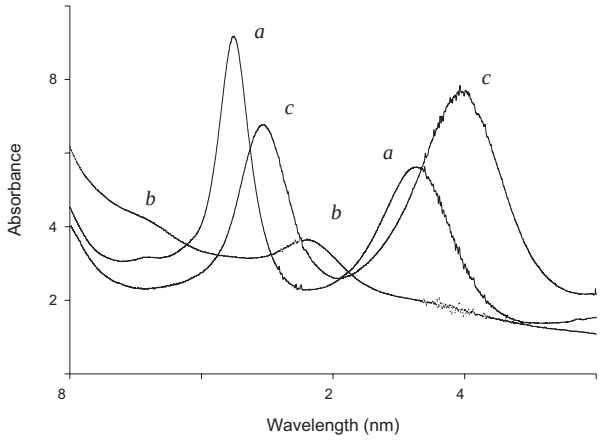


Fig. 6. Spectral changes in the near-IR region during the oxidation and subsequent reduction of **2**. (*a*) **2**-(4-MePy)$_2$; (*b*) [**2**-(4-MePy)$_2$]$^+$, obtained upon addition of 1 equiv. of [(η^5-Cp)$_2$Fe](PF$_6$); and (*c*) **2**-[(PMe$_2$Ph)]$_2$ obtained by addition of neat P(Me)$_2$Ph to the +1 ion.

Shifts in the near-IR as a function of axial ligand are similar to those previously described for Fe(DMG) systems (6).

Electrochemistry and redox reactions

Cyclic voltammetry experiments were carried out for **2** in CH_2Cl_2 containing 0.1 M (TBA)PF$_6$. Four reversible one-electron oxidation waves are observed for the 4-MePy adduct at –42°C and these occur at $E_{1/2}$ = 0.4, 0.76, 1.04, and 1.32 V (Fig. 7). The two lower oxidation waves are assigned to successive Fe$^{III/IV}$ oxidations in agreement with what previously reported for (PcFe)$_2$O (19). The third and fourth waves (1.04 and 1.32 V) are tentatively ascribed to successive oxidations of the Pc rings (20). Complex **2** shows a lower oxidation potential than the borylated dioxime-derived heterotrinuclear of Vernik (6) (Table 3).

The complex may be chemically oxidized to the +1 cation by using [(η^5-Cp)$_2$Fe](PF$_6$) ($E_{1/2}$ = 0.46 V in CH_2Cl_2). This chemical oxidation is reversible upon changing the axial ligand to P(CH$_3$)$_2$Ph. Figure 6 shows the change in the near-IR spectrum caused by the oxidation and subsequent reduction of the 4-MePy derivative. No reduction wave for **2** was detected up to –2.0 V. In related systems reduction normally results in irreversible oxo-bridge cleavage as electrons are added to antibonding orbitals (21).

Kinetics of reductive cleavage of oxo-bridge

The trinuclear complex undergoes slow reductive cleavage of the oxo-bridge with hydroquinones (H_2Q), phosphines, or phosphites. The kinetics of the reactions were studied at 40°C under anaerobic conditions and all changes were monitored by visible spectroscopy. Products were identified on the basis of distinctive visible–IR and ^{1}H NMR spectra and

[3] **2**-$(L)_2$ + 4L + $2H_2Q \rightarrow 2Fe(Pc)(L)_2$ + $Ru(TPP')(L)_2$ + 2Q (where L = 4-MePy)

The rate constant for the reduction of **2** (7×10^{-6} s^{-1}) was found to be independent of the concentration or nature of the reductant used and it is at least four orders of magnitude slower than that of μ-oxo borylated dioxime systems (6) (see Table 4). The reaction proceeds cleanly (isosbestic point at 688 nm) with no binuclear or other intermediates detected. Mechanism A in Fig. 8 is proposed in which the rate determining step is the dissociation of a Fe(Pc) unit to generate a binuclear species, which is subsequently reduced to the monomeric $Ru^{II}(TPP')$ and $Fe^{II}(Pc)$ complexes. In contrast, mechanism B was proposed in DMG systems where reduction was found to show an inverse first-order dependence on the axial ligand concentration implying a loss of one ligand prior to the rate determining μ-oxo cleavage (6, 22). A folding back of the pentacoordinate FeN_4 fragment in a bent geometry permits direct attack at the oxo site in these systems. Mechanism B may be much more difficult in FePc-based trinuclears as the Pc ring lacks the flexibility of the DMG macrocycles. Thus, only a [L] independent dissociative path is observed in the FePc systems.

Acknowledgments

Financial support from NSERC (Canada) is gratefully acknowledged. The authors are also thankful to Christos Alexiou for his assistance in CV data collection, and Gianni Manno of the Department of Mathematics at the King's College, London, U.K. for his suggestions regarding rcs calculations.

Derivatization of polyoxotungstates in aqueous solution. Exploration of the kinetic stability of cobalt(II)- and cobalt(III) derivatives of lacunary anions with pyridine and pyridine-type ligands

Joseph L. Samonte and Michael T. Pope

Abstract: Four complexes of cobalt(II) with lacunary polyoxotungstate ligands, α-$[PW_{11}O_{39}Co(H_2O)]^{5-}$, α-$[SiW_{11}O_{39}Co(H_2O)]^{6-}$, α_1-, and α_2-$[P_2W_{17}O_{61}Co(H_2O)]^{8-}$ have been examined as potential precursors to substitutionally inert derivatized polytungstates that are stable in aqueous solution at near neutral pH. Replacement of the terminal water ligand by pyridine is readily achieved and the rates of exchange between bound and free pyridine were determined from NMR line widths at temperatures between 24 and 48°C. Oxidation to the aquacobalt(III) and pyridinecobalt(III) polytungstates occurs at potentials between +0.64 V (for α_1-$P_2W_{17}O_{61}Co(py)]^{8-}$) and +1.00 V (for α_2-$[P_2W_{17}O_{61}Co(H_2O)]^{8-}$). The cobalt(III) complexes (with the exception of α-$[PW_{11}O_{39}Co(H_2O)]^{4-}$ which undergoes slow reduction by the solvent) were prepared by controlled potential electrolysis and by oxidation with potassium perdisulfate. The rates of pyridine substitution on the aquacobalt(III) complexes were determined and follow the sequence α_1-$[P_2W_{17}O_{61}Co(H_2O)]^{7-}$ (~0.5 M^{-1} s^{-1}) » α_2-$[P_2W_{17}O_{61}Co(H_2O)]^{7-}$ ~ α-$[SiW_{11}O_{39}Co(H_2O)]^{5-}$. Cesium salts of α_1-$[P_2W_{17}O_{61}Co^{III}(L)]^{7-}$ (L = pyrazine, 4,4′-bipyridine, isonicotinic acid, and the ethyl ester of isonicotinoylglycylglycine) and the "dumbbell" 2:1 complex with bridging 4,4′-bipyridine were isolated and characterized by cyclic voltammetry and ^{1}H NMR spectroscopy.

Key words: lacunary polyoxotungstates, cobalt, ligand substitution, kinetics, redox.

Résumé : On a étudié la possibilité d'utiliser quatre complexes de cobalt(II) avec des ligands polyoxotungtate lacunaires, α-$[PW_{11}O_{39}Co(H_2O)]^{5-}$, α-$[SiW_{11}O_{39}Co(H_2O)]^{6-}$, α_1 et α_2-$[P_2W_{17}O_{61}Co(H_2O)]^{8-}$, comme précurseurs potentiels à des dérivés de polytungstates, inertes vis-à-vis de la substitution, qui sont stables en solution aqueuse à de pH proches de la neutralité. On peut facilement effectuer le remplacement de la molécule d'eau agissant comme ligand terminal par une pyridine et les vitesses d'échange entre la pyridine liée et libre ont été déterminées par les largeurs des raies RMN à des températures entre 24 et 48°C. L'oxydation des polytungstates d'aquacobalt(III) et de pyridinecobalt(III) se produit à des potentiels allant de +0,64 V (pour le α_1-$[P_2W_{17}O_{61}Co(py)]^{8-}$) à 1,00 V (pour le α_2-$[P_2W_{17}O_{61}Co(H_2O)]^{8-}$). Les complexes de Co(III) (à l'exception du α-$[PW_{11}O_{39}Co(H_2O)]^{4-}$ qui subit une réduction lente par le solvant) ont été préparés par une électrolyse à potentiel contrôlé et par oxydation à l'aide de perdisulfate de potassium. On a déterminé les vitesses de substitution de la pyridine sur les complexes aquacobalt(III) qui sont dans la séquence suivante: α_1-$[P_2W_{17}O_{61}Co(H_2O)]^{7-}$ (environ 0,5 M^{-1} s^{-1}) » α_2-$[P_2W_{17}O_{61}Co(H_2O)]^{7-}$ ~ α-$[SiW_{11}O_{39}Co(H_2O)]^{5-}$. On a aussi isolé les sels de césium de α_1-$[P_2W_{17}O_{61}CO^{III}(L)]^{7-}$ (L = pyrazine, 4,4′-bipyridine, acide isonicotinique, isonicotinoylglycylglycinate d'éthyle) et le complexe 2:1 en forme d' « haltère » et on les a caractérisés par voltampérométrie cyclique et par spectroscopie RMN du ^{1}H.

Mots clés : polyoxotungstates lacunaires, cobalt, substitution du ligand, cinétique, redox.

[Traduit par la Rédaction]

Introduction

The current interest and research activity in the chemistry of polyoxometalates (1) is driven to a large extent by applications of these complexes in catalysis (2), and in recent years by their biological activity (3). Long known (and used) as electron-dense electron microscope stains ("phosphotungstic acid") polyoxometalates have recently been used for structural crystallographic investigation of very large biomolecules (4). We have been exploring ways of functionalizing the surfaces of large polytungstate anions for several reasons. In the biological context these species could be targeted towards specific sites on the surfaces of proteins for imaging and crystallographic purposes. Appropriately derivatized

polyanions known to have antitumoral and antiviral activity in vitro might also be rendered membrane-permeable, thereby opening up pharmaceutical applications. The present investigation explores the possibility of using "substitution-inert" cobalt(III) to attach appropriate ligands to polytungstate anions in aqueous media at near neutral pH.

The first examples of polyoxoanions that contained transition-metal cations *in place of* a W^{VI} or Mo^{VI} atom were recognized by Baker et al. (5) and by numerous subsequent investigators (6) in the 1960s. In 1970, Baker and Figgis (7) pointed out that a *substituted* polyanion should be regarded as a coordination complex of the transition-metal cation with pentadentate polyoxometalate and (in most cases) monodentate aqua ligand. Since the terminal water molecule was susceptible to replacement by other ligands, the complexes were predicted to have an important role in catalysis (7). This prediction has been borne out by work from several groups within the past 10–15 years (2). There have been many qualitative observations of ligand substitution processes, including isolation of adducts, (1*a*, 8) but, to our knowledge, only two publications address the thermodynamic or kinetic parameters associated with these processes. Weakley (8) has reported conditional formation constants, *K*, for $[XW_{11}O_{39}Co^{II}(OH_2)]^{n-}$ + L ⇔ $[XW_{11}O_{39}Co^{II}(L)]^{n-}$ (X = B, P, As; L = pyridine, 3-cyano-, 2-methyl-, 4-methyl-pyridines, NCS^-, thiourea). In aqueous solution (no pH or ionic medium specified) *K*s range from 1.0 to 255 M^{-1} at 20°C. For the Co^{III} anion $[BW_{11}O_{39}Co(OH_2)]^{6-}$ the *K*s are somewhat larger (e.g., 16.0 M^{-1} for L = 2-methylpyridine vs. 1.0 M^{-1} for the corresponding Co^{II} derivative). More recently Finke and coworkers (9) have measured the nonaqueous equilibria, α_2-$[P_2W_{17}O_{61}Mn^{III}(solvent)]^{7-}$ + L ⇔ α_2-$[P_2W_{17}O_{61}Mn^{III}(L)]^{7-}$. In dichloromethane solution, *K*s range from 4100 ± 1700 M^{-1} (L = pyridine) to 6 ± 3 M^{-1} (L = triphenylphosphine). Kinetic data appear to be limited to Weakley's observation (8) that the second-order rate constant for substitution of water by pyridine on the Co^{III} complex $[BW_{11}O_{39}Co(OH_2)]^{6-}$ is ~0.1 M^{-1} s^{-1} at 20°C.

Results and discussion

The four lacunary tungstate anions, α-$[PW_{11}O_{39}]^{7-}$, α–$[SiW_{11}O_{39}]^{8-}$, α_1-$[P_2W_{17}O_{61}]^{10-}$, and α_2-$[P_2W_{17}O_{61}]^{10-}$ were converted to the red aquacobalt(II) derivatives, $[PW_{11}O_{39}Co(H_2O)]^{5-}$, etc., as described in the *Experimental section*. Cyclic voltammograms of these complexes revealed, in addition to reversible two-electron tungsten reduction waves at negative potentials, a quasireversible feature at positive potentials corresponding to the oxidation of cobalt(II) to cobalt(III) (see Fig. 1 (upper) for example).

The yellow cobalt(III) complexes, $[PW_{11}O_{39}Co(H_2O)]^{4-}$ etc., were obtained by controlled potential electrolysis or by oxidation with potassium perdisulfate. Solution features of the Co(II) and Co(III) derivatives are summarized in Table 1.

Addition of pyridine to solutions of the Co(II) complexes caused an intensification of the red color and the introduction of an additional redox feature at positive potentials corresponding to the Co(II/III) couple of the pyridine complex (see Fig. 1 (lower)).

^{1}H NMR spectra of solutions containing mixtures of the polyoxometalates and pyridine show signals from both free and coordinated pyridine, as has been observed by So and co-workers (10) for analogous polytungstate systems. Chemical shifts for the coordinated pyridine are given in Table 2.

The chemical shifts for the free pyridine in these solutions were constant within ±0.04 ppm. Consequently, it was possible to estimate the rate of exchange between free and coordinated pyridine from measurement of the line width of the α-proton signal of free pyridine using the equation appropriate for the slow exchange limit, i.e. $\frac{1}{T_2} = \frac{1}{t_2} + \frac{1}{\tau}$

where T_2' and T_2 are the transverse relaxation times for the proton in the presence and absence of the Co(II)-polyoxometalate respectively, and τ is the coordination lifetime of the free pyridine. Figure 2 illustrates the free pyridine signals in a solution containing a 1:1 molar mixture of α_2-$[P_2W_{17}O_{61}Co(H_2O)]^{8-}$ and pyridine at different temperatures.

Calculated rates for the four polyoxometalates are summarized in Table 3 and activation parameters in Table 4.

These data illustrate a clear distinction between isostructural anions of different charge and between the two isomers of $[P_2W_{17}O_{61}Co(H_2O)]^{8-}$. However, it is not possible with the present limited data set to establish whether the compensation effects (11) exhibited by the activation parameters are real or artifactual.[2]

Electrolytic oxidation of the pyridine-containing solutions yielded green solutions from which the pyridine complexes

[2] The slope of a plot of $\Delta H^{\ddagger}$ vs. $\Delta S^{\ddagger}$ (*Deposited material*) is not significantly different from the mean temperature of the experiments.

$[PW_{11}O_{39}Co(py)]^{4-}$, etc., were isolated as cesium salts. Spectroscopic features of the pyridine complexes are summarized in Table 5.

It was observed that the same Co(III) – pyridine complexes could be prepared by treatment of the Co(III) – aqua complexes by pyridine and warming the solution to 60°C for a few minutes. This observation led to an examination of the rate of pyridine substitution on the Co(III) – aqua complexes.

Fig. 2. ^1H NMR spectra of uncomplexed pyridine in a solution containing a 1:1 mixture of pyridine and α_2-$[P_2W_{17}O_{61}Co(H_2O)]^{8-}$ recorded at different temperatures. As indicated in the text, the signals for coordinated pyridine appeared at –8.8, +21.8, and +112.8 ppm at 24°C.

Preliminary spectrophotometric measurements established that: (*i*) $[PW_{11}O_{39}Co^{III}(H_2O)]^{4-}$ underwent slow reduction by the solvent to the Co(II) derivative in aqueous solution, but that the other three complexes were redox-stable for at least 4 h; and (*ii*) the Co(III) – pyridine derivatives (with the exception of $[PW_{11}O_{39}Co(py)]^{4-}$ as just noted) did not undergo aquation in aqueous solution over a period of 4 days. Kinetic measurements were therefore made on solutions of the three stable aqua-complexes under pseudo-first-order conditions (60-fold excess of pyridine) by following absorbance changes at 626–654 nm. The plots were linear over at least

two half-lives (see *Deposited material*), and the derived rate constants are shown in Table 6.

With the exception of Weakley's result for $[BW_{11}O_{39}Co(H_2O)]^{7-}$ (8) noted above, these kinetic data are the first to have been reported regarding ligand substitution at a transition-metal center in a polyoxometalate. The rates are high for octahedral Co(III) substitution. Expressed as a second-order rate constant, k for α_1-$[P_2W_{17}O_{61}Co(H_2O)]^{7-}$ + py $\rightarrow$ α_1-$[P_2W_{17}O_{61}Co(py)]^{7-}$ + H_2O is ~0.5 M^{-1} s^{-1}. Although not reaching the astonishingly high rates for substitution on aquacobalamin (e.g., 2.3×10^3 M^{-1} s^{-1} for SCN^-) (12), the rates are two to six orders of magnitude greater than those involving classical Werner complexes (e.g., SCN^- on $[Co(NH_3)_5H_2O]^{3+}$, 1.3×10^{-6} M^{-1} s^{-1}) (13), and underscore the analogy that has been drawn between macrocyclic and lacunary polyoxometalate ligands (14). That substitution on the α_1-isomer of $[P_2W_{17}O_{61}Co(H_2O)]^{7-}$ is two orders of magnitude faster than on the α_2-isomer and the Keggin-derived anion is tentatively attributed to the more congested environment of the cobalt center (Fig. 3) that would favor a presumed pentacoordinate intermediate.

Based on the stability of the Co(III) – pyridine derivatives in aqueous solution, examples of complexes with other pyridine-type ligands were prepared using α_1-$[P_2W_{17}O_{61}Co^{II}(H_2O)]^{8-}$ as the starting material. It was possible to isolate products with pyrazine, 4,4′-bipyridine, isonicotinic acid, and isonicotinoylglycylglycylethyl ester. In each case, the complexes were isolated as cesium salts and characterized by cyclic voltammetry, electronic and NMR spectroscopy (see Table 7 and Fig. 4).

Although pyrazine and 4,4′-bipyridine are potentially capable of acting as bridging ligands, only in the case of the latter ligand were both 1:1 and 2:1 (dumbbell) complexes prepared. Earlier work (15) has shown that dumbbell complexes of Keggin derivatives can be detected, and it is possible that our inability to observe such complexes with α_1-$[P_2W_{17}O_{61}]^{10-}$ is a result of steric interactions between the bulky ligands.

Fig. 3. Polyhedral and space-filling representations of the structures of (upper) α_1- and (lower) α_2-$[P_2W_{17}O_{61}]^{10-}$. Oxygen atoms forming five-sixths of the coordination environment of the cobalt ions in $[P_2W_{17}O_{61}Co(H_2O)]^{n-}$ are indicated as gray spheres.

Experimental

Synthesis of Complexes

Salts of the lacunary anions, $K_7[\alpha$-$PW_{11}O_{39}]\cdot 13H_2O$, $K_8[\alpha$-$SiW_{11}O_{39}]\cdot 13H_2O$, $K_9[\alpha_1$-$LiP_2W_{17}O_{61}]\cdot 20H_2O$, and $K_{10}[\alpha_2$-$P_2W_{17}O_{61}]\cdot 20H_2O$ were prepared according to literature methods, and characterized by cyclic voltammetry, ^{31}P NMR, and IR spectroscopy (16).

The Co(II) derivatives were prepared following a modification of the method of Weakley and Malik (17). Five g (ca. 1 to 2 mmol) of the appropriate lacunary salt was dissolved in 500 mL 1.0 M lithium acetate buffer (pH 4.7). In a separate container, 0.25 g (10 mmol) cobalt(II) acetate tetrahydrate was dissolved in 10 mL of the same buffer solution. As the cobalt acetate solution was stirred into the heteropolyanion solution the mixture

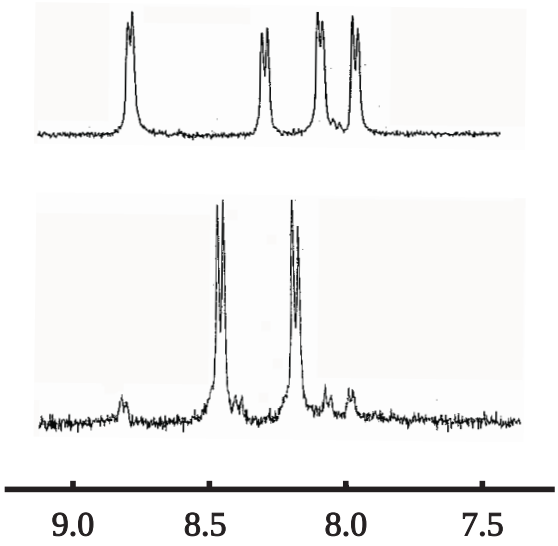
[c]Ethyl ester of isonicotinoylglycylglycine.
[d]Spectra also show signals from methylene groups of glycine residues and the ethyl group.



turned intensely red. The product was precipitated by adding saturated KCl solution, and was filtered off, and recrystallized from hot water. Yields: 92–94%. For characterization, see Table 1. TGA revealed the level of hydration corresponding to $K_5[PW_{11}O_{39}Co(H_2O)]\cdot 10H_2O$, $K_6[SiW_{11}O_{39}Co(H_2O)]\cdot 16H_2O$, α_1-$K_8[P_2W_{17}O_{61}Co(H_2O)]\cdot 19H_2O$, and α_2-$K_8[P_2W_{17}O_{61}Co(H_2O)]\cdot 18H_2O$.

The yellow Co(III) complexes were prepared either by oxidation with potassium perdisulfate (e.g., 100 mg polyoxometalate in 10 mL water with 160 mg $K_2S_2O_8$ heated to 90°C for 10 m) or by controlled potential electrolysis (see below). The oxidized anions were isolated as cesium salts by the addition of CsCl. For characterization, see Table 1. ^{31}P NMR α_1-$[P_2W_{17}O_{61}Co(H_2O)]^{7-}$ (ppm): –4.2, –13.2; α_2-$[P_2W_{17}O_{61}Co(H_2O)]^{7-}$ (ppm): –7.8, –13.1.

The Co(III) – pyridine complexes were prepared as follows: 300 mg $K_5[[PW_{11}O_{39}Co(H_2O)](aq)$ (ca. 0.1 mmol) dissolved in 50 mL 1.0 M lithium acetate buffer was treated with 80 μL (1.0 mmol) pyridine. The resulting solution was electrolyzed at a potential of 1.20 V and the product isolated in 60% yield by addition of CsCl. The other derivatives were prepared analogously: α-$[SiW_{11}O_{39}Co(py)]^{5-}$ (300 mg, 80 μL pyridine, guanidinium salt, 50% yield); α_1-$[P_2W_{17}O_{61}Co(py)]^{7-}$ (500 mg, 25 μL pyridine, cesium salt, 90% yield); α_2-$[P_2W_{17}O_{61}Co(py)]^{7-}$ (500 mg, 25μL pyridine, cesium salt, 90% yield). For characterization, see Table 5.

The cesium salts of the pyrazine, 4,4′-bipyridine, isonicotinic acid, and isonicotinoylglycylglycyl ethyl ester (ingge) derivatives of α_1-$[P_2W_{17}O\}61Co^{III}]^{7-}$ were prepared and isolated using the above-described method for the pyridine derivative, and the following quantities of $K_8[P_2W_{17}O_{61}Co(H_2O)]\cdot 19H_2O$ and ligand respectively: 500 mg (~100 mmol) and 25 mg (320 mmol) pyrazine; yield: 62%; 250 mg (~50 mmol) and 8 mg (50 mmol) 4,4′-bipyridine; yield: 60%; 500 mg and 37 mg (300 mmol) isonicotinic acid; yield: 72%; 500 mg and 83 mg (~300 mmol) ingge; yield: 77%. The 2:1 complex with 4,4′-bipyridine was prepared by mixing 1.00 g $K_8[P_2W_{17}O_{61}Co(H_2O)]$ (~200 mmol) with 4 mg (25 mmol) bipyridine in 50 mL lithium acetate buffer (pH 4.7). After electrolysis and precipitation with CsCl, the solid was slurried with 10 mL water and treated with solid $LiClO_4$. The resulting $KClO_4$ was removed by centrifugation and the centrifugate applied to a column of Sephadex G50. Upon elution with water two bands were separated; a faster-moving red band (unreacted polyoxometalate ligand, reduced to the Co(II) state) and a green fraction that was collected and characterized by absorption spectroscopy (λ_{max} 650 nm) and cyclic voltammetry (E_{pc} +0.43 V). The product was isolated as the cesium salt, which yielded the 4-line ^{1}H NMR spectrum shown in Fig. 4.

Fig. 4. ^{1}H NMR spectra of solutions of cesium salts of (upper) 1:1 and (lower) 2:1 complexes of α_1-$[P_2W_{17}O_{61}Co^{III}]^{7-}$ with 4,4′-bipyridine. Signals indicating the presence of about 10% of the 1:1 complex are also seen in the lower spectrum.

Instrumental

NMR spectra were recorded on a Bruker AM-300 instrument at a field of 7.05 T (300.10 MHZ for ^{1}H; 121.496 MHZ for ^{31}P). Chemical shifts are reported with respect to internal sodium 3-(trimethylsilyl)-1-propane sulfonate (^{1}H NMR) and external 85% phosphoric acid (^{31}P NMR). Variable temperature measurements were calibrated using external ethylene glycol as a temperature standard. Line widths were determined using a standard Lorentzian line-fitting program. Infrared and UV–vis spectra were recorded on MIDAC FT IR (KBr pellets) and Hewlett–Packard 8541A diode array instruments, respectively. Cyclic voltammetry was recorded using a BAS-100A electroanalyzer with a glassy carbon working electrode, platinum wire counter electrode, and Ag–AgCl reference electrode. All potentials are reported with respect to Ag–AgCl (+0.22 V vs. NHE). Scan rate: 100 mV s^{-1}. Controlled potential electrolyses were carried out using a Brinkmann/Wenking TS1

© 2001 NRC Canada

potentiostat and a Koslow Scientific Model 841 coulometer. The working electrode was graphite cloth (National Electrical Carbon Corporation) and the counter and reference electrodes were as for the voltammetry. The degree of hydration of the polyoxometalate salts was determined using a TA 2050 thermogravimetric analyzer.

Rate measurements

Pyridine exchange rates on the Co(II) complexes were made in 0.1 M sodium acetate buffer (pH 5.6). Five μL (60 μmol) of pyridine, previously deoxygenated by a 5-m stream of N_2 was injected into 10 mL of deoxygenated buffer to make a 6.0 mM solution of pyridine. Twelve μmol of the polyoxometalate salts (37–58 mg) were weighed into 2-mL volumetric flasks and dissolved in the pyridine-buffer solution. The resulting solutions contained 1:1 molar ratios of polyoxometalate and pyridine. One solution was also made up to contain no polyoxometalate. NMR spectra were recorded in triplicate at temperatures of 24, 30, 34, 41, and 48°C, using an external sample of ethylene glycol to calibrate the probe temperature. Sample tubes were equilibrated for 5 m at each temperature before data collection. Values of T_2 and T_2' as defined above were determined from the line widths using a Lorenztian line-fitting program.

The rates of pyridine substitution on the Co(III) derivatives were determined as follows:

Millimolar solutions of the potassium salts of the Co(II) derivatives of $[SiW_{11}O_{39}]^{8-}$ and both isomers of $[P_2W_{17}O_{61}]^{10-}$ in 0.1 M sodium acetate buffer, pH 4.7 (total ionic strength 1.0 M with sodium perchlorate) were electrolytically oxidized at 1.20 V as described above. One mL of the oxidized solution (containing 1.0 μmol polyoxometalate) was pipetted into a 1.0-cm quartz cell thermostated at 30°C. After 5 min, 5 μL pyridine (60 μmol) was introduced into the cell and the absorbance at 626 nm (Si anion), 654 nm (α_1-isomer), or 634 nm (α_2-isomer) was recorded as a function of time. Each kinetic run was carried out in triplicate. First-order plots (ln $[(A - A_\infty)/(A_0 - A_\infty)]$ vs. time, where A_0 is the initial absorbance (aqua complex) and A_∞ is the final absorbance (pyridine complex) were linear over at least two half-lives (*Deposited material*). Preliminary experiments to determine the stability of the Co(III) derivatives towards reduction by the solvent showed no change in the absorption spectra over a period of 4 days at 30°C. Under the same conditions solutions of $[PW_{11}O_{39}Co^{III}(H_2O)]^{4-}$ showed significant reduction to the Co(II) analogue within 1 h. The instability of this complex towards reduction by solvent has been noted before (16*a*).

Conclusions

Redox and ligand substitution processes involving cobalt derivatives of four lacunary polyoxotungstate anions have been investigated. As anticipated, the rates of exchange between free and coordinated pyridine on the cobalt(II) complexes, determined by NMR line-broadening, are moderately rapid (*k*s 10–260 s^{-1} at 30°C). The rates of substitution of pyridine on aquacobalt(III) derivatives of the polytungstates are also surprisingly fast and approach those of macrocyclic species such as the cobalamins. Substitution on the α_1-isomer (C_1 symmetry) of $[P_2W_{17}O_{61}Co(H_2O)]^{7-}$ is two orders of magnitude faster than on the α_2-isomer (C_s symmetry). Such lability may limit the value of cobalt(III) as a linker for the derivatization of polyoxometalates. Nevertheless binuclear dumbbell polytungstates linked by 4,4′-bipyridine, and anions incorporating the dipeptide glycylglycine moiety can be formed and characterized in aqueous solution, offering hope for further biochemical derivatization of polytungstates by this route.

A DFT study of Zr–S rotational barriers of $(\eta^5\text{-}C_5H_5)_2Zr(Cl)(SR)$; the origin of an inverse steric effect

P.K. Das, Susan Stanislav Alguindigue, and Michael T. Ashby

Abstract: We have previously reported the experimental rotational barriers about the M–S bonds of $16e^-$ bent metallocene monothiolates $(\eta^5\text{-}C_5H_5)_2Zr(Cl)(SR)$ (R = CH_3, CH_2CH_3, $CH(CH_3)_2$, $C(CH_3)_3$] (**1a**–**d**): 32, 33, 35, and 26 kJ mol^{-1}, respectively. The ground-state orientation about the Zr–S bonds of **1** that maximizes S($p\pi$) → M($d\pi$) bonding (Cl-Zr-S-R ≈ 90°) also maximizes Cp ↔ R (Cp = $\eta^5\text{-}C_5H_5$) steric interaction, whereas the rotational transition-state orientation (Cl-Zr-S-R ≈ 0°) is one that minimizes S($p\pi$) → M($d\pi$) bonding and maximizes Cl ↔ R steric interaction. Deviation from a ground-state orientation that is ideal for S($p\pi$) → M($d\pi$) bonding might be expected as the size of the R-group and Cp ↔ R steric interaction increases. The present study employs hybrid density function computational methods to reproduce the experimental rotational barriers. The computational rotational barriers decrease in the order **1a** (R = CH_3) > **1b** (R = CH_2CH_3) > **1c** (R = $CH(CH_3)_2$) at low temperature. However, opposing enthalpic factors reverse this trend at higher temperatures. The aberrant trend (unexpectedly low rotational barrier) that is observed for the **1d** (R = $C(CH_3)_3$) derivative is due to dominant ground-state steric (enthalpic) effects. We conclude the thiolate ligand of **1d** is misdirected in the ground-state with respect to the other thiolate derivatives.

Key words: misdirected ligands, metallocene, thiolate, structure, bonding, dynamics.

Résumé : On a rapporté antérieurement que les barrières expérimentales à la rotation autour des liaisons M–S des monothiolates de métallocènes repliés, à 16 électrons, $(\eta^5\text{-}C_5H_5)_2Zr(Cl)(SR)$ (R = CH_3, CH_2CH_3, $CH(CH_3)_2$, $C(CH_3)_3$) (**1a–d**) sont respectivement de 32, 33, 35 et 26 kJ mol^{-1}. L'orientation à l'état fondamental des liaisons Zr–S de **1** qui maximise la liaison S($p\pi$) → M($d\pi$) (Cl-Zr-S-R ≈ 90°) maximise aussi l'interaction stérique Cp ↔ R (Cp = $\eta^5\text{-}C_5H_5$) alors que l'orientation rotationnelle de l'état de transition (Cl-Zr-S-R ≈ 0°) en est un qui minimise la liaison S($p\pi$) → M($d\pi$) et qui maximise l'interaction stérique Cp ↔ R. Lorsque la taille du groupe R et que l'interaction sétrique Cp ↔ R augmentent, on peut s'attendre à une déviation par rapport à l'orientation de l'état fondamental qui est idéale pour une liaison S($p\pi$) → M($d\pi$). Dans le présent travail, on a fait appel à des méthodes de calcul de la fonction de densité hybride pour reproduire les barrières rotationnelles expérimentales. Les barrières rotationnelles calculées à basse température diminuent dans l'ordre **1a** (R = CH_3) < **1b** (R = CH_2CH_3) < **1c** (R = $CH(CH_3)_2$). Toutefois, des facteurs enthalpiques inverses provoquent une inversion de cette tendance à températures plus élevées. La tendance aberrante (barrière rotationnelle particulièrement basse) observée pour le dérivé **1d** (R = $C(CH_3)_3$) résulte d'effets stériques (enthalpiques) prédominants dans l'état fondamental. On en conclut que, dans l'état fondamental, le ligand thiolate du composé **1d** n'est pas bien orienté par rapport aux autres dérivés thiolates.

Mots clés : ligands mal orientés, métallocène, thiolate, structure, liaison, dynamique.

[Traduit par la Rédaction]

Introduction

Thiolate ligands are capable of stabilizing coordinatively unsaturated main-group and transition metal moieties via π-donation of the chalcogenide lone pair (1, 2). Since thiolates may be viewed as single-sided π-donors, rotational orientations about the M–S bonds of thiolate ligands are significant when the π-acceptor orbitals of the metal are not symmetric with respect to the M–S bonds (3). Asymmetrical M($d\pi$)–S($p\pi$) bonding is evident in the preferred rotational orientations of bent metallocene complexes of the type $(\eta^5\text{-}C_5H_5)_2MX_2$. The electronic structures of such bent metallocene complexes have been modeled using Extended Hückel (4), Fenske–Hall (5), and ab initio (6) methods and they have been experimentally investigated by single-crystal electron paramagnetic resonance spectroscopy (7, 8) and gas-phase photoelectron spectroscopy (9). The results of these studies indicate that the M *d*-orbital, that is π to X and spatially

localized in the plane containing the MX_2 moiety, is the lowest unoccupied molecular orbitals (LUMO) of the d^1 derivatives, the singly occupied molecular orbital (SOMO) of the d^0 derivatives, and the highest occupied molecular orbitals (HOMO) of the d^2 derivatives.

Accordingly, the rotational orientations of the thiolate ligands of bent metallocenes $(\eta^5\text{-}C_5H_5)_2M(X)(SR)$ observed in the solid-state reflect the electron configuration of M (1). Thus, when the metal has a d^0 electron count an "*endo*" conformation (X-M-S-R angle of ca. 90°) is observed, when the metal has a d^2 electron count an "*exo*" conformation (X-M-S-R angle of ca. 180°) is observed, and when the metal has a d^1 electron count both "*endo*" and "*exo*" conformations are observed (for crystal structures of d^0 and d^2 derivatives see the citations in ref. 11). For the d^1 cases, the conformations are presumably dictated by subtle intramolecular steric and electronic effects (vide infra) and possibly intermolecular crystal packing effects (10).

endo *exo*

We have previously reported that the thiolate ligands of the d^0 bent metallocene thiolate complexes $(\eta^5\text{-}C_5H_5)_2Zr(Cl)(SR)$ (R = CH_3, CH_2CH_3, $CH(CH_3)_2$, $C(CH_3)_3$) (**1a**–**d**) exhibit rotational orientations in solution that favor M($d\pi$)–S($p\pi$) bonding, and we described the first experimental energy barriers associated with rotation about M–S bonds (11). Surprisingly, the rotational barriers do not appear to depend entirely upon the strength of the M($d\pi$)–S($p\pi$) bonding interaction, but rather they also apparently depend *inversely* on the steric size of the thiolate ligand (cf. R = CH_3, CH_2CH_3, $CH(CH_3)_2$ vs. R = $C(CH_3)_3$). Thus, rotational barriers about the Zr–S bond actually decrease if the R-group becomes significantly large. As explained previously (11), this trend might be attributed to either enthalpic or entropic effects. Unfortunately, it was not possible in our earlier study to measure the rates of rotation about the Zr–S bonds of **1** as a function of temperature. Consequently, we did not discern the significance of entropy. Furthermore, the issue of whether the apparent inverse steric dependency of the rotational barriers is due to a ground-state (GS) or transition-state (TS) phenomenon was not resolved. The computational results that are reported herein resolve the ambiguities that remained following our previous experimental study of the rotational barriers about Zr–S bonds of $(\eta^5\text{-}C_5H_5)_2Zr(Cl)(SR)$ complexes.

Methods and basis sets

The ab initio electronic structure computations were performed primarily using density functional theory (DFT) as implemented in GAUSSIAN 94 and 98 (12, 13). For **1a**–**d**, the B3LYP method (14) (Table 1, method A) based on Becke's 3-parameter hybrid exchange functionals (15) and Lee–Yang–Parr correlation functionals (16, 17) was used. Energetics, geometries, and analytical second derivatives were calculated at the B3LYP level with the following basis sets (18–24): LANL2DZ-ECP for Zr, Cl, and S; 3–21G for C and H atoms of the cyclopentadienyl (Cp) ligands; LANL2DZ for the remaining atoms. Optimized ground-state (GS) and transition-state (TS) geometries were obtained using nonredundant internal coordinates and starting Hessians calculated at the restricted Hartree-Fock (RHF) level. Analytical second derivatives were calculated to verify stationary points on the potential energy surface using the criteria of zero and one imaginary frequency for GS's and TS's, respectively. The analytical second derivatives were also used to calculate the real frequencies (using a scale factor of 1.0) that were subsequently used in the harmonic approximation of various thermodynamic properties: free energies ($\Delta G^{\ddagger}$), enthalpies ($\Delta H^{\ddagger}$), entropies ($\Delta S^{\ddagger}$), and zero-point energies (ZPE).

The role of the basis sets was tested for **1a** and **1d** by repeating the aforementioned calculations with a 6–31G basis set in place of the 3–21G basis set (Table 1, method B). The effect of the DFT functional was investigated by replacing the B3LYP method of A with the BLYP functional (i.e., Becke 88 exchange (25) and Lee–Yang–Parr correlation (16, 17)) with the same basis sets in method A (Table 1, method C). In both methods B and C, the geometries were fully optimized. To check the sensitivity of the computed energies with respect to correlation methodology, single-point calculations using second-order Moller–Plesset (26–31) perturbation theory (MP2) were performed on **1a** and **1d** using the optimized geometries that were obtained from method A (Table 1, method D).

Results

The GS minima and TS optimized structures for **1a**–**d** that were obtained using method A are shown in Figs. 1–4, respectively. Some relevant metric data for the computed structures are compiled in Table 2. Some of these metric data for **1a**–**d** are compared with the corresponding data that were determined by single-crystal X-ray crystallography for the analogous series of dithiolate complexes $(\eta^5\text{-}C_5H_5)_2Zr(SR)_2$ (R = CH_3, CH_2CH_3, $CH(CH_3)_2$, $C(CH_3)_3$) (**2a**–**d**) in Table 3. Tables 4 summarizes the computed rotational barriers at 0 K for **1a**–**d** using various methods. The previously reported experimental rotational energies and the temperature-corrected computed energies are compared in Table 5. For **1a** and **1d**, intrinsic rotational profiles were computed by constraining the Cl-Zr-S-C torsion angles at various values and optimizing the remainder of the molecules. The energy profile thus

obtained for **1a** is given in Fig. 5. Details concerning the SCF energies, ZPE's, vibrational frequencies and intensities, and thermodynamic quantities are available as supplementary material.[2]

Discussion

Rotational barriers are determined by the difference between the energies of the GS and rotational TS structures. It is conceivable that the aberrant barrier that is observed experimentally is attributable to destabilization of the GS or stabilization of the TS of **1d**. For example, the lower rotational barriers that are associated with borates as compared to thioborates R_2BZR (Z = O, S) is attributed to stabilization of the TS of the former (32). In addition to stationary-state

effects, entropic factors may be important in determining the difference in rotational barriers that are observed for **1** as a function of the R-group. We will first discuss GS vs. TS effects and the possible role of ligand misdirection. We will then describe the possible influence of entropy on the rotational barriers. Thus, by outlining the ambiguities that are associated with employing the available experimental data to discern the origin of the inverse steric effect associated with rotation about the Zr–S bonds of **1**, we will set the stage for resolution of these issues using the DFT method.

We have previously measured the rotational barriers about the Zr–S bonds of **1a**–**d** experimentally using variable-temperature nuclear magnetic resonance (11). These experiments were undertaken because of our interest in ligand misdirection (11, 33–37) and our expectation that larger R-groups would disfavor rotational orientations about the Zr–S bonds

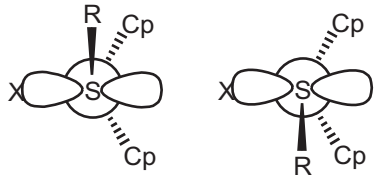
Note: Cp and Cp′ are the centroids of the two cyclopentadienyl rings. C_5 and C_5' are the least-squares planes that contain the cyclopentadienyl rings.

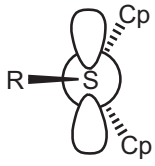
of **1** that favor Zr($d\pi$)–S($p\pi$) bonding. Steric factors (steric conflict between a Cp ligand and the R-group in the GS) and electronic factors (orientation about the Zr–S bond that favors Zr($d\pi$)–S($p\pi$) bonding) are at odds for **1**. Recognizing that the S–C bond will be staggered with respect to the Cp_2ZrX moiety in the conformation of **1** that minimizes Cp ↔ R and X ↔ R steric contact, and the "X" substituent on Zr is far less sterically demanding than the Cp rings, there are two symmetry-related steric-minimized conformations of **1**:



STERIC MINIMA

X Zr S R ~ 55° X Zr S R ~ 55°

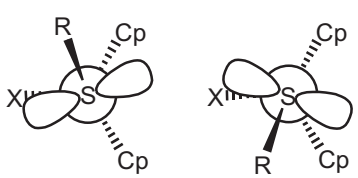
Steric factors alone presumably do not dictate the ground-state conformations about the Zr–S bonds. Electronic minima will arise when Zr–S π-bonding is optimized:



ELECTRONIC MINIMA

X-Zr-S-R ≈ 90° X-Zr-S-R ≈ –90°

Again, assuming that Cp ↔ R contact is more significant than X ↔ R contact, the saddle-point steric maximum would be for X-Zr-S-C = 0° (i.e., the X-Zr-S-C = 180° conformation is assumed to be unpopulated). Similarly, the electronic saddle-point would also be for X-Zr-S-C = 0°, when the π-type thiolate lone pair is orthogonal to the Zr-based $d\pi$ acceptor orbital (the LUMO). Thus, the rotational transition-state reflects both a steric and electronic maximum:



TRANSITION-STATE STRUCTURE

X-Zr-S-R = 0°

However, the ground-state structure represents a compromise between favorable S($p\pi$) → M($d\pi$) electronic interactions and unfavorable Cp ↔ R steric interactions:

GROUND-STATE STRUCTURES

X Zr S R ~ 60° X-Zr-S-R ~ –60°

Note: No ZPE corrections have been applied.

We previously hypothesized that the trend in slightly increasing (rather than decreasing) $\Delta G^{\ddagger}$ for R = CH_3, CH_2CH_3, $CH(CH_3)_2$ is due to either (*i*) an inductive effect, (*ii*) a dominant enthalpic effect that opposes the proposed entropic effect, or (*iii*) a transition-state steric effect (11). We will not repeat the detailed argument we have previously made for possible entropic effects and the literature precedence for such effects; however, we simply point out for the GS conformations of **1a**–**d** three, two, one, and three rotomers are likely, respectively. Accordingly, the decreasing number of populated GS rotomers relative to TS rotomers for **1a**–**c** should give rise to opposing enthalpic and entropic factors, which could account for the trend of slightly increasing barriers of rotation for **1a**–**c**. To assess the significance of entropic factors, it is necessary to measure the rates of rotation as a function of temperature. Unfortunately, because of the very small energies involved and the relatively small differences between the chemical shifts of the conformers, low temperatures were required that limited the temperature range over which variable temperature NMR data could be collected. Furthermore, **1a**–**d** disproportionate in solution to give approximately statistical 2:1:1 mixtures of **1a**–**d**, **2a**–**d**, and $(\eta^5\text{-}C_5H_5)_2Zr(Cl)_2$, respectively. The small temperature range and overlapping spectra conspire to make it difficult to separate enthalpic and entropic contributions to the free-energy of rotation. It is also conceivable that the measured values of $\Delta G^{\ddagger}$ for **1a**–**c** are within experimental error. These errors are difficult to estimate for the experimental method employed (coalescence temperature). The DFT calculations we will describe shortly suggest the entropy issue is in fact moot since the trends in rotational barriers that are observed experimentally for **1** are apparently due to enthalpic factors.

We reason that the origin of the rotational barrier trends might be discerned from trends in the metric data for **1a**–**d**. However, it proved impossible to crystallize these compounds because they scramble their ligands in solution (vide supra). We did manage to crystallize the corresponding series of dithiolate complexes **2a**–**d** and determine their molecular structures by single-crystal X-ray crystallography. However, our comparison of these structures was inconclusive as a result of the experimental errors that are associated with those data, crystal packing effects, and the relatively small effect the R-groups have on the metric data. Since the errors that are associated with the computed metric data are presumably systematic and the calculations were performed in the gas-phase, the DFT stationary-state structures offer considerable insight into the nature of the Zr–S rotational barriers of **1a**–**d**. The GS and TS structures of **1a**–**d** are illustrated in Figs. 1–4. Selected computed interatomic distances and angles for the GS and TS structures of **1a**–**d** are summarized in Table 2. The trends of some of these data are illustrated graphically in Fig. 6.

Importantly, most of the trends that are observed in Fig. 6 for the TS of the *t*-Bu derivative **1d** are regular with respect

Fig. 5. Zr–S conformational coordinate diagram for (η^5-$C_5H_5)_2$Zr(Cl)(SMe) (**1a**) (obtained using method A).

to the other derivatives (e.g., the Zr–S bond length, Zr-S-C bond angle, Cp-Zr-Cp′ angle, Cl-Zr-S-C torsional angle and the C5–C5′ angle). Only the Cl-Zr-S and Cp-Zr-Cp′ – S-Zr-S′ angles exhibit irregular trends. The more obtuse Cl-Zr-S bond angle for the TS of **1d** is expected because of the relative bulk of the R-group and the fact the TS is a steric maximum (vide supra), and it is in the direction of destabilizing Zr–S bonding. The trend that is observed for the Cp-Zr-Cp′ – S-Zr-S′ angles in the TS's of **1a**–**d** is the same trend that is observed in the GS's. In contrast to the trends that are observed for the TS's, many of the metric data for the GS of **1d** exhibit irregular trends (e.g., the Zr–S bond distance, Cl-Zr-S-C torsional angle and Cp-Zr-Cp′ – S-Zr-S′). These data indicate a destabilization of the GS of **1d** with respect to **1a**–**c**.

The influence of adding methyl groups on the total energy of the GS and TS of **1a**–**d** is illustrated in Fig. 7 as ΔE[(R = $CH_{3-(n+1)}Me_{(n+1)}$), (R = $CH_{3-n}Me_n$)] = E[**1**(R = $CH_{3-(n+1)}Me_{(n+1)}$)] – E[**1**(R = $CH_{3-n}Me_n$)]. Two features of Fig. 7 are notable: (*i*) the relative effects on the GS vs. the TS structures for a given comparison of ΔE(GS) vs. ΔE(TS), and (*ii*) the magnitudes of the stabilizations (ΔE) upon adding a methyl group. Figure 7 clearly illustrates that there is relatively little influence of adding methyl groups on the relative total energies of the GS and TS structures of **1a**–**c** (ΔE_{GT} vs. ΔE_{TS} for **1a**–**c**). However, a marked difference in the relative total energies of the GS and TS structures of the *i*-Pr and *t*-Bu derivatives (ΔE_{GS}[*t*-Bu, *i*-Pr] vs. ΔE_{TS}[*t*-Bu, *i*-Pr]) is observed, which we interpret as a larger steric destabilization of the GS of **1d** relative to its TS. The magnitudes of the effect on the total energies upon adding a methyl group are also telling. Dias and co-workers (38) have measured the standard enthalpies of formation for the series $Cp_2Mo(SR)_2$ (R = *n*-Pr, *i*-Pr, *n*-Bu, and *t*-Bu) and other thiolate complexes using reaction-solution calorimetery. Their investigation revealed that increasing the bulkiness of the alkyl group decreases the bond enthalpy (BE) and mean bond dissociation energy (BDE), whereas increasing the length of the alkyl chain increases the M–S BE and BDE. This trend was especially true for R = *t*-Bu. Thus in the absence of steric effects, adding methyl groups is expected to reduce the relative total energies by inductively strengthening the Zr–S bonds. Although such a trend is apparently reflected in the first two columns of Fig. 7, we note the small difference between the first two columns is negligibly small. Indeed, the apparent decreasing energies of the first two columns is reversed for ZPE-corrected room-temperature enthalpies. However, the magnitude of the relative total energies of the third column is substantially less than that of the first two, which we interpret as a counter destabilizing steric effect that partially negates the stabilizing inductive effect of adding a methyl group for **1c** → **1d**. This steric destabilization of **1d** is reflected in the magnitude of ΔE_{GS}[*t*-Bu, *i*-Pr] and ΔE_{TS}[*t*-Bu, *i*-Pr], albeit more so in the difference in GS energies.

Summary

We have previously measured rotational barriers about the M($d\pi$)–S($p\pi$) bonds of **1**. The trends in $\Delta G^{\ddagger}$ indicate that the strength of the M($d\pi$)–S($p\pi$) bonds and the steric interactions of the substituents of (η^5-$C_5H_5)_2$Zr(Cl)(SR) (**1**) both

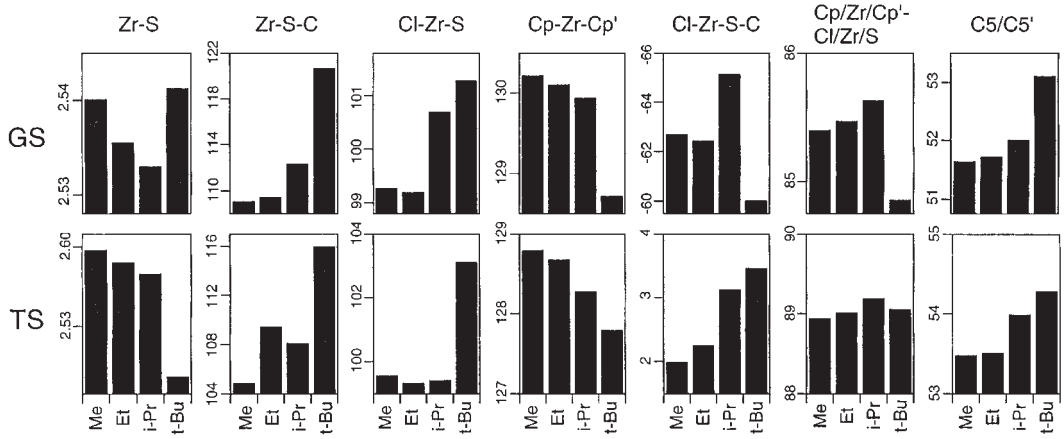
Fig. 6. Graphical representations of selected computed metric data for the ground-state and transition-state structures of $(\eta^5\text{-}C_5H_5)_2Zr(Cl)(SR)$ for R = Me, Et, *i*-Pr, *t*-Bu. See Table 2 for definitions of the abbreviations. Note for the trends in the data for the R = *t*-Bu derivative are regular for the transition-state but irregular for the ground-state.



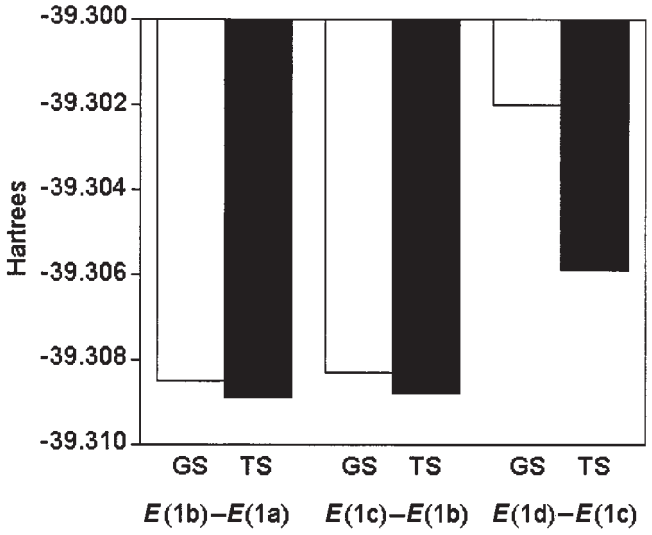


Fig. 7. Effect of adding a methyl group on the total energies of the GS and TS structures of **1a**–**d** (as calculated using method A and without a ZPE correction). Note the larger destabilizing effect on the GS of **1d** compared with its TS and the relative magnitudes of *E*(**1d**) – *E*(**1c**) vs. *E*(**1b**) – *E*(**1a**) and *E*(**1c**) – *E*(**1b**).

play important roles in determining the magnitude of the rotational barriers. For R = CH_3, CH_2CH_3, and $CH(CH_3)_2$, the experimental Zr–S rotational barriers are 32, 33, and 35 kJ mol^{-1}, respectively. However, the 26 kJ mol^{-1} barrier that was measured for R = $C(CH_3)_3$ is considerably less than the other derivatives. Previous studies of bond dissociation enthalpies of metal-thiolates suggest that *tert*-butyl thiolates have unusually weak bonds. This is presumably echoed in rotation about the Zr–S bond of **1**, where partial bond breakage takes place. The DFT calculations reported herein address the ambiguities that existed following the experimental study regarding the origin (enthalpy vs. entropy, electronic vs. steric, and GS vs. TS) of the irregular rotational barrier that was observed for **1d**. The trend of increasing rotational barriers for **1a**–**c** is attributed to inductive effects and overall stronger Zr–S bonds in the GS in the order $CH_3 < CH_2CH_3 < CH(CH_3)_2$. However, unfavorable Cp ↔ R steric contacts cannot be avoided for R = $C(CH_3)_3$. Consequently, the GS of **1d** is destabilized with respect to the other alkyl derivatives of **1**. The lower rotational barrier that was observed for **1d** is attributed to GS thiolate ligand π misdirection and overall weaker Zr(*d*π)–S(*p*π) overlap.

Adsorption of etioporphyrin and Ni-etioporphyrin on a fractal silica

Josephine Mary Hill and Flora T.T. Ng

Abstract: Metal compounds are contaminants in heavy oil and must be removed using hydrodemetallization catalysts. To optimize the structure of hydrodemetallization catalysts it is useful to know the effective size of the metal compounds. To this end, fractal geometry has been used to determine the relationship between monolayer coverage and adsorbate size for silica by adsorbing a series of alcohols at 298 K. It was found that the silica had a fractal dimension of 2.923. Etioporphyrin and Ni-etioporphyrin were then adsorbed on the silica and their effective areas determined based on this fractal dimension. Cross-sectional areas of 4.58 and 14.8 nm^2 were determined for etioporphyrin and Ni-etioporphyrin, respectively. The areas are larger than those determined by X-ray methods and likely reflect the fact that the porphyrins are solvated with solvent (cyclohexane) molecules.

Key words: silica, adsorption, fractal dimension, etioporphyrin, Ni-etioporphyrin

Résumé : Les composés métalliques sont des contaminants des huiles lourdes qui doivent être éliminées par des catalyseurs d'hydrodémétallisation. Pour optimiser la structure des catalyseurs d'hydrodémétallisation, il est utile de connaître la taille effective des composés métalliques. À cette fin, on a fait appel à la géométrie fractale pour déterminer la relation entre la couverture de la monocouche et la taille de l'adsorbat d'une série d'alcools adsorbés à 298 K. On a trouvé que la dimension fractale de la silice est de 2,923. On y a ensuite adsorbé de l'étioporphyrine et de la Ni-éthioporphyrine et les superficies effectives ont été déterminées en se basant sur cette dimension fractale. On a déterminé que les superficies de section droite sont de 4,58 et 14,8 nm^2 respectivement pour l'étioporphyrine et la Ni-éthioporphyrine. Ces superficies sont supérieures à celles déterminées par diffraction des rayons X et elles reflètent probablement le fait que les porphyrines sont solvatées par des molécules de solvant (cyclohexane).

Mots clés : silice, adsorption, dimension fractale, étioporphyrine, Ni-étioporphyrine.

[Traduit par la Rédaction]

Introduction

There remains a high demand for fossil-based hydrocarbons for both energy and petrochemicals (1). At the same time, the world's reserves of crude oil are declining, and as a result, lower quality heavier crudes with more contaminants must be processed. Hydrodesulphurization (HDS) and hydrodemetallization (HDM) are two of the primary processes for upgrading heavy oil (2).

Both sulphur and metal contaminants are a problem in the process stream because they poison the cracking catalysts by depositing on the active sites and blocking pores. In addition, the metals can cause erosion of the furnace linings and turbine blades. Thus, the sulphur and metals are removed using HDS and HDM catalysts, respectively. Heavy oil contains Ni, V, and Fe in porphyrin type structure (Fig. 1), which generally precipitate with the asphaltenes. Ni is present in relatively high concentration and is a more severe poison for fluid catalytic cracking catalysts than V and Fe as a result of its high dehydrogenation activity, which results in coke formation. Therefore, it is particularly important to remove Ni.

Optimization of the HDM catalysts involves a balance between smaller pores for high surface area and larger pores to reduce diffusional resistance and pore-mouth plugging. Knowledge of the effective cross-sectional area of the metal compound, therefore, will help elucidate the optimum catalyst configuration. Various techniques can be used to determine the size of a metal compound. The size or cross-sectional area measured, however, will be technique dependent. That is, the diameter of a compound in dry powder form will be different than the effective area of the same compound fully solvated in solution or adsorbed on a surface. It is the latter effective area that is of interest for optimizing HDM catalysts.

To determine the effective area occupied by an adsorbed molecule, the surface area of the adsorbent must be known. Traditionally the surface area of a catalyst is determined by nitrogen BET adsorption, but this technique has the disadvantage that for a porous material, such as a catalyst support, the accessible area is dependent on the size of the adsorbate (i.e., larger molecules are excluded from smaller pores).

Table 1. Cross-sectional areas (σ) of adsorbates.

Adsorbate	σ (nm^2)
Nitrogen	0.162
Methanol	0.180
Ethanol	0.230
2-Methyl-2-propanol	0.317
2-Methyl-2-butanol	0.350
3-Ethyl-3-pentanol	0.414

Fractal analysis of materials offers a solution to this dilemma (3). For a material that is fractal in nature, the accessible surface area scales with the adsorbate size over a certain range. Given the fractal dimension of a surface and the monolayer coverage of an adsorbate on that surface, the effective cross-sectional area of the adsorbate can be calculated.

In the present study, this approach has been used to determine the effective size of etioporphyrin and Ni-etioporphyrin (Fig. 1) adsorbed on silica. First, the fractal dimension of the silica is determined by adsorbing a series of alcohols of different diameters onto the silica. Then the porphyrins are adsorbed and their cross-sectional areas determined.

Experimental

The two silica samples (Sigma) used for the adsorption studies had average pore diameters of 6 nm (S-2509 Lot 3 1H0 876, particle size range 63–200 μm) and 2.5 nm (S-4133 Lot 1 9F3 506, particle size range 70–140 μm). The alcohols and solvents used for the adsorption, methanol (Fisher Scientific A.C.S. grade), ethanol (absolute), 2-methyl-2-propanol (Aldrich HPLC grade), 2-methyl-2-butanol (Aldrich 99%), 3-ethyl-3-pentanol (Aldrich 98%), toluene (BDH Omnisolve), and cyclohexane (BDH Omnisolve), were dried and stored over 3 Å molecular sieves (BDH). Solutions of the alcohols in toluene were prepared gravimetrically.

Adsorption studies were carried out in test tubes with 1 to 2 g of silica dried at 450 K for 12 h under vacuum. The test tubes were sealed with a septum and purged with nitrogen (Linde Ultra High Purity). Solutions of alcohol in toluene, of known concentration, were then transferred using a cannula into the test tube. The solution and solid were stirred at 298 K for 2 to 3 h to allow equilibrium to be reached, and then a centrifuge was used to separate the solid and liquid phases. A sample of the liquid phase was taken using a gas-tight syringe (Hamilton). This liquid sample was analyzed in a gas chomatograph (PerkinElmer Sigma 3 B) with an FID detector and a 60 m × 0.32 mm diameter column (J&W Scientific DB1). The column temperature was ramped from 423 to 523 K at 15 K min^{-1}, and maintained at 523 K for 5 min. For the analysis of ethanol the temperature program was varied slightly, i.e., the temperature was held at 373 K for 4 min, ramped to 473 K at 15 K min^{-1}, and held at 473 for 2 min.

The adsorption experiments with the porphyrins (Midcentury Chemical Company) were done in a similar manner to those with the alcohols using both cyclohexane and toluene as solvents, but the analysis was done with an UV–vis Spectrophotometer (Varian Cary 219). Porphyrins are intensely coloured and their main absorption bands have very high molar extinction coefficients in the order of 2×10^5 (4). The Soret band around 400 nm is the most intense absorption band in the spectra of porphyrins. Etioporphyrin also has four characteristic bands in the visible region between approximately 500–630 nm (4). In contrast, Ni-etioporphyrin has only two bands in the visible region, around 515 and 555 nm, depending on the solvent (4). The bands in the visible region will be used to determine the solution concentrations of the porphyrins. Calibration curves were prepared for the porphyrins using the UV–vis spectrophotometer, and for the alcohols using the GC.

The nitrogen BET surface area of the silica was determined using a volumetric glass vacuum system with an MKS Baratron capacitance monometer and digital display (MKS 270B). The sample was pretreated for 16 h at 298 K under vacuum and then nitrogen was adsorbed at 77 K.

Determination of fractal dimension

The amount of a probe molecule adsorbed onto a surface can be given by the following relationship (5):

$$[1] \qquad n \propto \sigma^{-D/2}$$

or

$$[2] \qquad n = K\sigma^{-D/2}$$

where n is the monolayer value (mmol g^{-1}), K is a constant, σ is the cross-sectional area of the adsorbate (nm^2), and D is the fractal dimension, where $2 \leq D \leq 3$ for a surface. The fractal dimension (D) of a surface can be determined by adsorption of a series of adsorbates with different cross-sectional areas. Table 1 lists the cross-sectional areas of the probe molecules used for this work (6). The cross-sectional areas of the alcohols were determined by liquid density measurements. It should be noted that some of the areas reported in the literature for alcohols are incorrect because they were

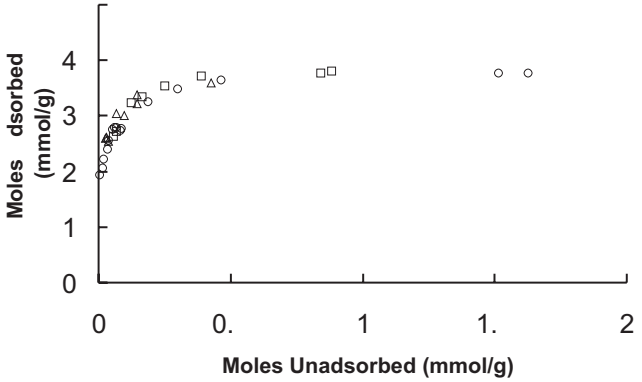
Fig. 2. Effect of drying temperature on the adsorption of ethanol on silica at 298 K: 383 K (Δ); 423 K (○); and 450 K (□).



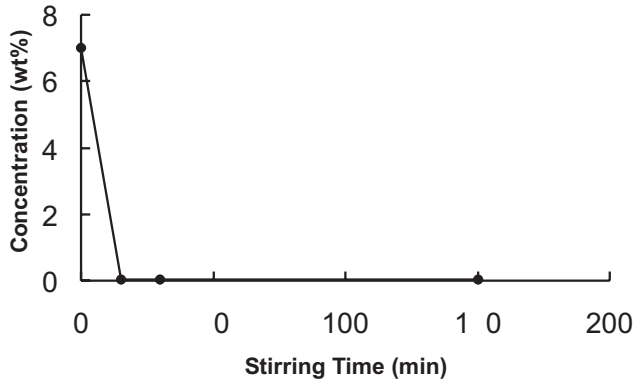


Fig. 3. Change in concentration with time for ethanol adsorbed on silica at 298 K.

determined by adsorption experiments on porous materials using the nitrogen BET surface area. In one study (7), alcohols were adsorbed on a silica that was later determined to have a fractal dimension of 2.94 (3). Monolayer coverages have been assumed for the adsorption of alcohols except for methanol, which was found to have more than a monolayer coverage (7).

The Langmuir Equation in the following form is used to determine the monolayer capacity:

$$[3] \qquad n' = \frac{bnC}{1+bC}$$

where C is the concentration of the adsorbate in the liquid phase at equilibrium, n' is the amount adsorbed, b is a constant, and n is the monolayer coverage. Nonlinear regression was performed using a Levenberg–Marquart algorithm (Sigmaplot 4.10, Jandel Corp.) to relate the amount adsorbed (n'), to the concentration in the liquid (C), and to calculate the monolayer coverage (n). Data from approximately 16 adsorption experiments with different initial concentrations of the alcohols or porphyrins were used to fit the Langmuir equation for each adsorbate.

Results and discussion

Experiments were carried out to establish the effects of drying temperature and mixing time on the uptake of alcohol from solution. The condition of the adsorbent surface was found to be very important in adsorption studies. That is, in the case of silica, the surface must be completely free of physisorbed water. To determine how best to pretreat the silica the adsorption of ethanol was studied on the smaller pore silica at three different temperatures. The results of drying the silica at 383, 423, and 450 K are shown in Fig. 2. The equilibrium absorptions are essentially the same for all three drying temperatures. Removal of surface hydroxyls groups begins at approximately 525 K (8). Thus, a drying temperature of 450 K is sufficient to remove physically adsorbed water but not so high as to remove surface hydroxyl groups. Figure 2 is a representative plot of the adsorption of all of the alcohols (except methanol as will be described below) and suggests that the alcohols adsorb in monolayer coverage on the silica.

Table 2. Monolayer coverages for nitrogen and alcohols on silica.

	Monolayer coverage (mmol g^{-1})[a]	
Adsorbent	Nonlinear regression	Linear regression
Nitrogen	4.84	4.84
Methanol	5.67(0.172)	5.87(0.143)
Ethanol	3.11(0.0585)	2.97(0.0543)
2-Methyl-2-propanol	1.79(0.0268)	1.80(0.0249)
2-Methyl-2-butanol	1.58(0.0663)	1.42(0.0644)
3-Ethyl-3-pentanol	1.14(0.0164)	1.16(0.0153)

[a]Standard error is given in parentheses.

It was also important to establish the length of time for equilibrium to be obtained between the solid and solution. Figure 3 shows the adsorption of ethanol from solution onto silica as a function of time. After 15 min of stirring the solution concentration decreased to 0.025 wt%. On stirring for an additional 135 min the amount adsorbed changed by less than 0.02% indicating the adsorption of ethanol on silica occurred quite rapidly. Solutions of alcohols with different initial concentrations and different weight of silica were stirred for 120 min before analyzing each solution concentration using the GC. This length of time allowed the solution and solid to come to equilibrium and also allowed the solution temperature to return to 298 K after the exothermic process of adsorption. Note that the smaller pore silica was used for these preliminary experiments. Unless otherwise noted all other references to silica refer to silica with an average pore size of 6 nm.

The monolayer coverages of nitrogen and the series of alcohols onto the silica are given in Table 2. All of the residuals from the nonlinear fit were randomly distributed, indicating that there is no bias in the experimental technique. It is apparent from Table 2 that methanol had adsorbed beyond a monolayer on the silica. Not only is the monolayer value higher for methanol than for the smaller molecule nitrogen, but the standard error is more than a factor of two larger for methanol than for any of the other adsorbates. Other studies have shown that methanol forms more than a monolayer when adsorbed on silica (7). Therefore, the data for methanol will not be used in the determination of the fractal dimension.

In Table 2 the results for the linear regression of eq. [3] are also given to illustrate that linear and nonlinear regres-

sion give different results. Statistically it is not as accurate to plot a function of a variable against itself because it alters the error structure inherent in the measurement (9).

The nonlinear fit of eq. [2] is shown in Fig. 4 and is equal to:

$$[4] \qquad n = 0.3425\sigma^{-2.923/2}$$

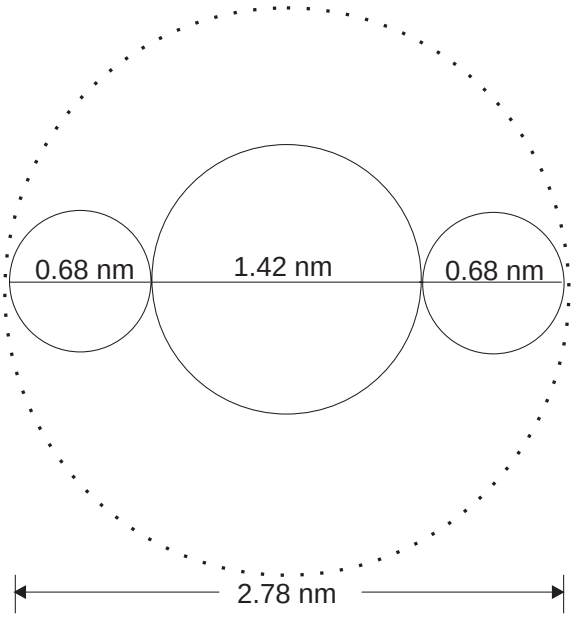
for n in mmol g^{-1} and σ in nm^2. Thus, the resulting fractal dimension for this surface is 2.923 and the preexponential factor is 0.3425 with 95% confidence intervals of ±0.363 and ±0.1014, respectively. The calculated fractal dimension is close to the upper limit of 3.00, which implies that the surface is irregular and that the accessible surface area decreases rapidly as the adsorbate size increases. At the other end of the range, a fractal dimension of 2.00 indicates that the surface is relatively flat and the accessible surface area is independent of adsorbate size. The value obtained herein is in agreement with that obtained by other groups on similar silica gels using the adsorption of alcohols or alkanes (3, 10–12). Rearrangement of eq. [4] into linear form and conversion of units (i.e., σ in $Å^2$) yields a prefactor of 2.46, which is also consistent with that obtained for silicas with an average pore size of 6 nm (11, 12).

Similar to the alcohols, the porphyrins were adsorbed onto the silica, and the monolayer coverages determined (see Table 3). Equilibrium was achieved between the porphyrin solution and the silica within 2 to 3 h, as has been seen previously (13). The adsorption experiments with the porphyrins were difficult because of their limited solubility and smaller adsorption on the silica. As a result, the standard errors for the porphyrins are larger relative to the monolayer coverages than for the alcohols. The residuals from the nonlinear regression, however, show no trends or systematic errors.

Table 4. Calculated cross-sectional areas of the porphyrins.

Adsorbent	σ (nm^2)
Etioporphyrin in cyclohexane	4.58
Etioporphyrin in toluene	101
Ni-etioporphyrin in cyclohexane	14.8

The monolayer coverages are significantly higher for the porphyrins dissolved in cyclohexane than in toluene, consistent with other studies (13, 14). In fact, there was no measurable adsorption of the Ni-etioporphyrin from toluene onto silica. These results suggest that toluene competes for surface sites with the porphyrins. It has been reported that benzene competes with porphyrins for adsorption sites on silica–alumina catalysts (13). Aromatic molecules interact with surfaces through their conjugated rings. Mitchell and Scott (15) determined that nickel porphyrins lie flat on alumina and silica–alumina supports when adsorbed at 298 K, and that the delocalized π-system of the porphyrin ring is an electron donor and the Brønsted and (or) Lewis acid function of the catalyst is the electron acceptor.



Interestingly, the silica in contact with a solution of etioporphyrin in cyclohexane changed colour after several days of aging. Initially the solution and the silica were a red colour, but the silica became green after approximately three days of aging. The silica was washed with toluene and the wash solution was analyzed in the UV–vis spectrophotometer. A new peak around 660 nm appeared in the spectra. This peak is characteristic of protonated porphyrins (15, 16). In the first step of hydrodemetallization, the metalloporphyrin is reversibly hydrogenated to a metal chlorin (2, 17, 18). The metal chlorin (see Fig. 1*c*) subsequently undergoes hydrogenolysis, which results in metal deposition.

Using eq. [4] the cross-sectional areas of the porphyrins have been calculated and are reported in Table 4. The cross-sectional area for Ni-etioporphyrin is calculated to be larger than that for the metal-free porphyrin. A larger cross-sectional area indicates that the addition of a metal centre to the porphyrin increases the interaction between the porphyrin and the solvent. This is supported by the observation that the Ni-etioporphyrin is an order of magnitude more soluble in cyclohexane than the metal-free etioporphyrin. In contrast, the solubilities of the two porphyrins are similar in toluene. The calculated value of 101 nm^2 for etioporphyrin in toluene is obviously too large and is likely a result of the toluene competing for adsorption sites on the silica. Because the etioporphyrin did not exclusively form a monolayer on the surface, the calculated cross-sectional area is too large.

The cross-sectional area for etioporphyrin in cyclohexane was calculated to be 4.58 nm^2 (Table 4). Based on X-ray data the diameter of Ni-etioporphyrin has been estimated to be 1.42 nm (19). Assuming that the porphyrin is circular, this diameter corresponds to a cross-sectional area of 1.58 nm^2 (i.e., $A = \pi r^2$). A value of 1.86 nm^2 has been suggested for the cross-sectional area of vanadyl etioporphyrin (14). These values are for unsolvated molecules. Galiasso and Morales (13) have studied the diffusion of vanadyl porphyrins in catalysts with varying silica–alumina ratios. Their studies showed that the vanadyl porphyrins interacted with the solvent (either cyclohexane, benzene, or thiophene) and

© 2001 NRC Canada

Fig. 5. Schematic drawing of porphyrin molecule with adjacent cyclohexane molecules, showing the effective cross-sectional area of the solvated molecule demarcated by the dashed line. Note that for simplicity only two cyclohexane molecules are shown.

that this interaction increased the hydraulic radius of the molecule while decreasing the diffusivity.

It is likely, therefore, that the cross-sectional areas measured in this study is that of the porphyrins solvated with cyclohexane. The cross-sectional area of Ni-etioporphyrin solvated with cyclohexane can be estimated based on the diameters of these molecules measured by X-ray and liquid density techniques. That is, the cross-sectional area of cyclohexane is 0.363 nm^2 (6) and corresponds to a diameter of 0.68 nm. If the Ni-etioporphyrin is solvated with cyclohexane molecules around the edge as shown in Fig. 5, the effective diameter of the solvated porphyrin is equal to the diameter of the porphyrin (1.42 nm) plus twice the diameter of cyclohexane (2 × 0.68 nm) or 2.78 nm. This diameter corresponds to a cross-sectional area of 6.07 nm^2 and is similar to an estimate of 3.0 nm, corresponding to a cross-sectional area of 7.1 nm^2, for the diameter of a solvated molecule of vanadyl etioporphyrin in cyclohexane (13).

Comparison of the calculated cross-sectional areas of 4.78 and 14.8 nm^2 for etioporphyrin and Ni-etioporphyrin (Table 4) to the estimated values for the cross-sectional areas of solvated metalloporphyrins seem to be reasonable although the cross-sectional area for the Ni-etioporphyrin is quite a bit larger than expected. We have no further data or explanation for this result. It should be noted that we have determined the fractal dimension of the silica using molecules between 0.162 and 0.414 nm^2 and then extrapolated the results to the much larger porphyrins molecules. It is possible that the fractal dimension of the silica is different outside of the range for which it was calculated. Galiasso and Morales (13) also performed HDM reactions and found that the solvated porphyrins were unable to diffuse to the active sites situated in the narrower pores. As a result, the number of accessible active sites was only a small fraction of the total number of active sites. Therefore, the effective area of the porphyrin (i.e., the area of a solvated molecule) is the relevant area for catalyst design.

Traditionally the nitrogen BET surface area is used to characterize catalysts, but using this technique, rather than the fractal dimension of the surface, gives considerably larger cross-sectional areas for the adsorbed molecules. For example, the surface area of the silica calculated using the monolayer coverage of nitrogen (Table 2) and a cross-sectional area for nitrogen of 0.162 nm^2, is 472 $m^2\ g^{-1}$. When this surface area is used to calculate the cross-sectional areas of the porphyrins, based on the uptakes in Table 3, the cross-sectional areas are 21.5 and 119 nm^2 for etiopophyrin and Ni-etioporphyrin, respectively, and much larger than the values calculated from the fractal dimension. This comparison demonstrates the utility of the fractal approach for highly porous supports. The nitrogen BET area does not describe the porous nature of the support or the pore size distribution. Conversely, fractal analysis allows the relationship between adsorbate size and accessible surface area to be determined.

Nonetheless, a few comments should be made about using fractal geometry for characterizing materials. First, it appears that the success of the approach depends on a number of factors, including the material itself as well as the method of determining the fractal dimension. We successfully applied the adsorption of a series of alcohols to determine the fractal dimension of silica with an average pore size of 6 nm. However, when we applied this same technique to silica with an average pore size of 2.5 nm we obtained a fractal dimension of 3.112 ± 0.293, which is slightly above the theoretical limit. Possibly the fractal dimension of the silica changed over the range of adsorbates used. The technique also failed for a γ-alumina support (10 nm average pore size). Unlike the silicas, the monolayer plots for the alumina were very scattered and it was evident immediately that the adsorption of alcohols was not the appropriate technique to use with alumina.

The values used for the cross-sectional areas of the adsorbates are also very important because the fractal dimension is quite sensitive to these values. For instance, if the cross-sectional areas in Table 1 are increased or decreased by 0.01 nm^2, the fractal dimension changes between 2.794 and 3.051, approximately ±10%. In addition, the use of nonlinear regression also makes a difference to the results.

As shown above, the nitrogen BET surface area gives exceedingly large values for the cross-sectional areas of the porphyrins because nitrogen is able to adsorb in pores that are too narrow for the porphyrin. This example illustrates the advantage of determining the fractal dimension of a surface. Although the fractal approach has limitations, and there has been controversy over the fractal nature of silica gels (8), we feel it is a useful technique for characterizing catalyst supports and determining the area occupied by an adsorbed molecule on a surface.

Conclusions

The fractal dimension of silica with an average pore diameter of 6 nm has been determined using nonlinear regression to be 2.923 with a preexponential factor of 0.3425 for the

© 2001 NRC Canada

monolayer coverage in mmol g^{-1} and cross-sectional areas in nm^2. It was found that methanol adsorbed beyond monolayer coverage on silica and so it was not used in the determination of the fractal dimension.

Etioporphyrin and Ni-etioporphyrin dissolved in cyclohexane were adsorbed onto silica and their cross-sectional areas were determined to be 4.58 and 14.8 nm^2, respectively, using fractal analysis. If the porphyrins were dissolved in toluene, monolayer coverage by the porphyrins was not achieved because the solvent competed for surface sites.

Selective dehydrogenation of alcohols and diols catalyzed by a dihydrido iridium PCP pincer complex

David Morales-Morales, Rocío Redón, Zhaohui Wang, Do W. Lee, Cathleen Yung, Kevin Magnuson, and Craig M. Jensen

Abstract: The PCP pincer complex, $IrH_2\{C_6H_3\text{-}2,6\text{-}(\mathbf{CH_2}P\text{-}t\text{-}Bu_2)_2\}$ (**1**) catalyzes the transfer dehydrogenation of primary and secondary alcohols. Dehydrogenation occurs across the C—O bond rather than the C—C bonds and the corresponding aldehydes or ketones are obtained as the sole products arising from the dehydrogenation reactions. Methanol is an exception to this pattern of reactivity and undergoes only stoichiometric dehydrogenation with **1** to give the carbonyl complex, $Ir(CO)\{C_6H_3\text{-}2,6\text{-}(\mathbf{CH_2}P\text{-}t\text{-}Bu_2)_2\}$ (**2**). The products are obtained in nearly quantitative yields when the reactions are carried out in toluene solutions. Under the same conditions, 2,5-hexanediol is converted to the annulated product, 3-methyl-2-cyclopenten-1-one which has been isolated in 91% yield in a preparative scale reaction.

Key words: alcohol, dehydrogenation, ketones, iridium pincer complex, annulation.

Résumé : Le complexe PCP en forme de pince, $IrH_2\{C_6H_3\text{-}2,6\text{-}(\mathbf{CH_2}P\text{-}t\text{-}Bu_2)_2\}$ (**1**) catalyse la réaction de déshydrogénation par transfert des alcools primaires et secondaires. La déshydrogénation se fait à travers la liaison C—O plutôt qu'à travers les liaisons C—C et on n'obtient que les aldéhydes et les cétones comme seuls produits de ces réactions de déshydrogénation. Le méthanol est une exception à ce mode de réactivité et il ne subit qu'une déshydrogénation stoechiométrique avec **1** pour conduire à la formation d'un complexe de carbonyle, $Ir(CO)\{C_6H_3\text{-}2,6\text{-}(\mathbf{CH_2}P\text{-}t\text{-}Bu_2)_2\}$ (**2**). Lorsqu'on effectue les réactions en solution dans le toluène, les produits sont obtenus en rendements pratiquement quantitatifs. Dans les mêmes conditions, l'hexane-2,5-diol est transformé en produit cyclique, la 3-méthylcyclopent-2-én-1-one qui a été isolée avec un rendement de 91% au cours d'une réaction à l'échelle préparative.

Mots clés : alcool; déshydrogénation, cétones, complexe de l'iridium en forme de pince, annellation.

[Traduit par la Rédaction]

Introduction

Ketones and aldehydes are most commonly prepared through the oxidation of alcohols (1). The large scale commercial production of acetone and 2-butanone is accomplished through aerobic dehydrogenation of alcohols using heterogenous catalysts such as copper chromite and silver (2). The high (>250°C) temperatures that are required for these processes, however, limits their application to production of only the simplest ketones. A remarkable homogeneous catalyst for the aerobic oxidation of alcohols has been discovered by James and co-workers (3) that operates at ambient temperature but proceeds at unpractical (1.5 turnovers/day) rates. Stoichiometric methods have been developed for the selective oxidation of alcohols to a variety of sensitive ketones and aldehydes. However, there are increasing environmental concerns about the highly toxic reagents employed in methods such as Moffatt (DMSO, DCC, and phosphoric acid), and Swern (oxalyl chloride) oxidations (1). Alternatively, the conversion of alcohols to ketones and aldehydes can be accomplished under mild conditions through transfer dehydrogenation. Oppenaurer oxidation, in which hydrogen is transferred from an alcohol to a ketone acceptor in the presence of a base (most commonly aluminum *tert*-butoxide in nearly stoichiometric amounts), has been widely employed in organic synthesis (1, 4). Several transition-metal complexes have been shown to catalyze the transfer of hydrogen from alcohols to olefins (5), acetylenes (6), or aldehydes and ketones (7, 8) acceptors. Other complexes have been found to catalyze "acceptor-less" dehydrogenation of alcohols (9, 10). Catalytic hydrogen transfer systems have been utilized in organic synthesis for the reduction of oxo-steriods to hydroxy-steriods (8) and its mircroreverse (10). More recently, enantioselective versions of this reaction have been developed for asymmetric synthesis (8*d–f*).

The iridium PCP pincer complex $IrH_2\{C_6H_3\text{-}2,6\text{-}(CH_2P\text{-}t\text{-}Bu_2)_2\}$ (**1**) has been found to be an efficient and robust catalyst for the transfer dehydrogenation of alkanes (11, 12),

ethers (13), alkyl arenes (13), and amines (14). Thus it was of interest to examine the reactivity of **1** towards alcohols. We have found that **1** catalyzes the selective transfer dehydrogenation of primary and secondary alcohols to aldehydes and ketones in very high yields. We have also found that **1** catalyzes the unusual dehydrogenation and (or) annulation of 2,5-hexanediol to 3-methyl-cyclopenten-1-one. The results of these studies are reported herein.

Experimental

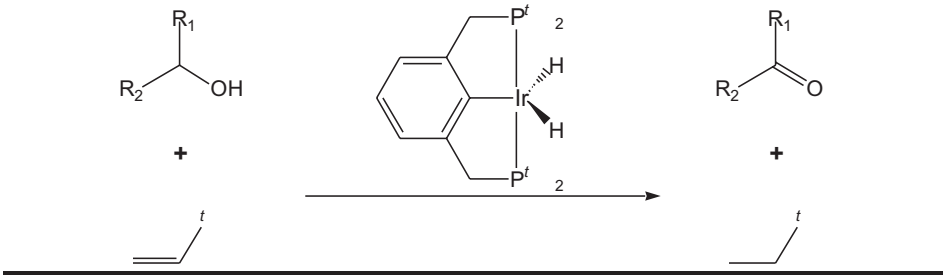
All manipulations were carried out using standard Schlenk and glovebox techniques under purified argon. Solvents were degassed and dried using standard procedures. The alcohols were purchased from Aldrich Chemicals Co. and used without further purification. The complex IrH_2{C_6H_3-2,6-(CH_2P-*t*-Bu_2)$_2$} (**1**) was synthesized by the literature methods (12). The ^{1}H NMR spectra were recorded on a Varian Unity Inova 400 spectrometer. Chemical shifts are reported in ppm down field of TMS using the solvent as internal standard ($CDCl_3$, 7.26 or cyclohexane-d_{12}, 1.38). ^{13}C and ^{31}P NMR spectra were recorded with complete proton decoupling and are reported in ppm down field of TMS with solvent as internal standard ($CDCl_3$, 77.0 or cyclohexane-d_{12}, 26.43) and external 85% H_3PO_4, respectively. Infrared spectra were recorded in a PerkinElmer Paragon FT IR spectrometer as Nujol mulls in NaCl plates. Gas chromatographic analyses were performed with a Hewlett–Packard 5890 instrument with a HP 5980A flame ionization detector and HP-1 capillary column (25.0 m). Gas chromatographic–mass spectral analyses were carried out using a HP 5890 Series II instrument with an 5971A mass selective detector and HP-1 capillary column (25.0 m).

Catalytic reactions

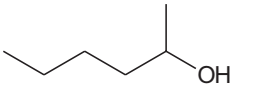
Solutions of the substrates (0.26 mmol), tbe (0.20 mL, 1.53 mmol), and 4 mL of toluene were charged with **1** (22 mg, 0.037 mmol) in sealed Schlenk tubes in a Vacuum Atmospheres glovebox under argon. The tubes were then fully immersed in a constant temperature bath at 200°C for the prescribed reaction times. After this time the tubes are allowed to cool down to room temperature. The products were identified by GC–MS analysis upon comparison to purchased samples of the authentic compounds. Product yields were calculated from the ratio of the integrated intensities of signals produced by the products and those of the toluene solvent after weighting the data by a predetermined relative molar response factor.

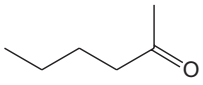
The attempted acceptor-less dehydrogenation reactions were carried out with mesitylene solutions of the substrates (0.26 mmol) and **1** (22 mg, 0.037 mmol) that were refluxed while passing a stream of argon above the condensor. Gas chromatographic analysis of the reaction mixtures following 72 h of rigorous reflux showed no traces of dehydrogenated products.

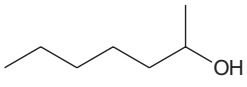
Preparative scale synthesis of 3-methyl-2-cyclopenten-1-one

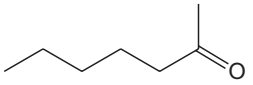


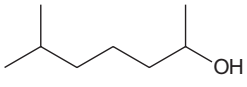
A solution of the 2,5-hexanediol (1.0 mL, 81 mmol), tbe (2.2 mL, 17 mmol), and 4 mL of toluene was charged with **1** (100 mg, 0.17 mmol) in a sealed Schlenk tube in a Vacuum Atmospheres glovebox under argon. The tube was then fully immersed in a constant temperature bath at 200°C for 78 h. After this time, the reaction mixture was cooled to room temperature and concentrated to ~1.4 mL. The product was then separated by column chromatography (Davisil (100–200 mesh silica gel) by eluting first with pentane and then with acetone. The product fraction was collected and concentrated under vacuum. The isolated product (yield: 0.73 mL, 91%) was identified as 3-methyl-2-cyclopenten-1-one by MS and NMR (^{1}H and ^{13}C) analysis upon comparison to an authentic sample. MS (*m*/*z*): $[M]^+$ 96, $[M\text{-}CH_3]^+$ 81. ^{1}H NMR (400.00 MHz, $CDCl_3$) δ: 5.91 (m, 1H, *H*C-2), 2.55 (m, 2H, H_2C-5), 2.38 (m, 2H, H_2C-4), 2.10 (s, 3H, CH_3). ^{13}C NMR (100.60 MHz, $CDCl_3$) δ: 210.15 (s, *C*=O), 178.82 (s, *C*-3), 130.62 (s, *C*-2), 35.66 (s, *C*-5), 32.97 (s, *C*-4), 19.30 (s, *C*H_3).

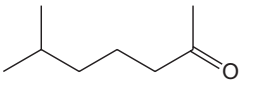


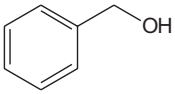


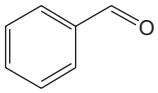


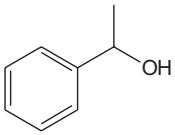


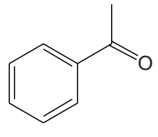


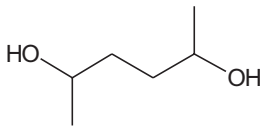


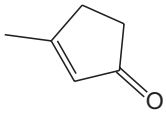












Synthesis of Ir(CO){C_6H_3-2,6-(CH_2P-*t*-Bu_2)$_2$} (2)

A pentane (5 mL) solution of **1** (20 mg, 0.034 mmol) was treated with *tert*-butylethylene (66 μL, 0.51 mmol) under 1 atm (1 atm = 101.325 kPa) of argon at 25°C. After 1 h of reaction, the resulting red-purple solution was treated with degassed methanol (0.1 mL, 5.6 mmol). Removal of the solvent in vacuo yields **2** as a deep yellow-orange solid. Yield: 19 mg, 90%. ^{1}H NMR (400.00 MHz, cyclohexane-d_{12}) δ: 6.93 (d, J_{HH} = 7.3 Hz, 2H, *m*-H), 6.67 (t, J_{HH} = 7.3 Hz, 1H, *p*-H), 3.42 (vt, J_{HH} = 3.0 Hz, 4H, CH_2), 1.28 (vt, J_{PH} =

Molecular structure determination of (2)

Yellow-orange crystals of **2** that were suitable for X-ray diffraction were obtained from slow evaporation of a pentane solution of the complex. Centering and data collection were performed with a Nicolet P3 diffractometer, graphite monochromator (λ = 0.71073 Å, Mo Kα) at room temperature using a crystal that was mounted on a glass fiber with epoxy. The unit cell was determined from the angular

coordinates of 25 reflections with 2θ values between 15 and 30°. The diffractometer autoindexing routine found a monoclinic unit cell, which was confirmed by axial photographs.

Three check reflections, monitored every 100 reflections, showed no significant decay. The data were processed using SHELXTL program package (15), and an absorption correction was applied based upon ψ-scans of five reflections. Since the unit cell is triclinic, the space group *P*2(1)/*n* was assumed. The iridium was located by Patterson methods and the remainder of the structure was easily developed via a few cycles of least-squares refinement and difference Fourier maps. The unit cell was found to contain two symmetry-independent molecules of **2**. Hydrogen atoms were input at calculated positions, and allowed to ride on the atoms to which they are attached. Two group of thermal parameters were refined for hydrogen atoms, one each for methylene and methyl protons. The final cycle of refinement was carried out on all non-zero data using SHELXL-97 (6) and anisotropic thermal parameters for all non-hydrogen atoms. Crystal data and relevant information are summarized in Table 1.

Results

The catalytic activity of **1** was initially screened using solutions consisting of the saturated alcohol, and the hydrogen acceptor, *tert*-butylethylene (tbe). The orange solutions were sealed in tubes under argon and fully immersed in an oil bath at 200°C for 18 h. The solutions became red upon heating and gradually change color to yellow-orange during the reaction period. Gas chromatographic analysis of the reaction mixtures showed the substrates were converted to the corresponding dehydrogenated compounds with greater than 99% selectivity. However, only ≈1% yields were obtained in preliminary experiments with the neat reaction mixture even upon longer reaction times and increased catalyst loadings. This finding was not unanticipated as dehydrogenation reactions catalyzed by **1** have generally been found to be inhibited at low concentrations of the unsaturated products (11–14, 16). Apparently deactivation of the active catalyst through a coordinative interaction with the carbonyl groups prevents the occurrence of the slower process of catalytic dehydrogenation of aliphatic groups. In support of this hypothesis, 2-hexanone was found to be unreactive with **1** under the conditions employed for the dehydrogenation of the alcohols.

To obtain high yields, it was necessary to dilute the reaction mixtures. A similar strategy has been used to achieve high yields in the catalytic dehydrogenation of secondary amines to imines by **1** (14). Table 2 summarizes the results of the dehydrogenation experiments in which toluene solutions of the alcohols, **1**, and tbe were heated for 3 days at 200°C. The products were characterized by GC–MS analysis of the reaction mixtures. Excellent selectivities and yields were uniformly obtained without regio-restriction on the alcohol functionality. No traces of dehydrogenationated products were detected in acceptor-less experiments in which mesitylene solutions of alcohols and **1** were refluxed while passing a stream of argon above the condensor.

The dehydrogenation of 2,5-hexanediol produced an unexpected result. A single product arises upon heating dilute toluene solutions of the diol, **1**, and tbe for 3 days at 200°C. MS and NMR analysis showed the product to be the cyclic ketone, 3-methyl-2-cyclopenten-1-one. This product can be understood to arise upon dehydrogenation across both of the C—O bonds to produce the hexadione followed by an internal aldol reaction and subsequent dehydrogenation as in the final step of a Robinson annulation reaction (17). We are unaware of any previous reports of the catalytic dehydrogenation of diols resulting in the formation of cyclic unsaturated ketones. To probe the possible synthetic utility of this type of reaction, the dehydrogenation of 2,5-hexanediol was carried out on a preparative scale. Starting with 1.00 mL (81 mmol) of the diol, we were able to isolate 0.73 mL (74 mmol, 91% yield) of 3-methyl-2-cyclopenten-1-one upon work-up using silica gel column chromatography.

The pincer complex does not catalyze the dehydrogenation of methanol to formaldehyde but instead undergoes a stoichiometric reaction with methanol to yield the carbonyl compound Ir(CO){C_6H_3-2,6-(CH_2P-*t*-Bu_2)$_2$} (**2**). The presence of the carbonyl ligand of **2** is clearly indicated by the observation of a signal at 198.23 ppm in its ^{13}C NMR spectrum and strong absorption at 1911.8 cm^{-1} in the IR spectrum of the complex. Although carbonyl complexes commonly result upon the reaction of late transition-metal complexes with alcohols (for example see ref. 18; 19) it is surprising to find this partitioning in the reactivity of **1**. A similar dichotomy was previously observed for [Ru_2Cl_3(PMePh_2)$_6$]Cl which reacts with KOH in isopropanol

solution to give [*cis*-$Ru_2Cl_3(PMePh_2)_4$] but yields $RuH_2(CO)(PMePh_2)_3$ when the reaction is carried out in ethanol (19).

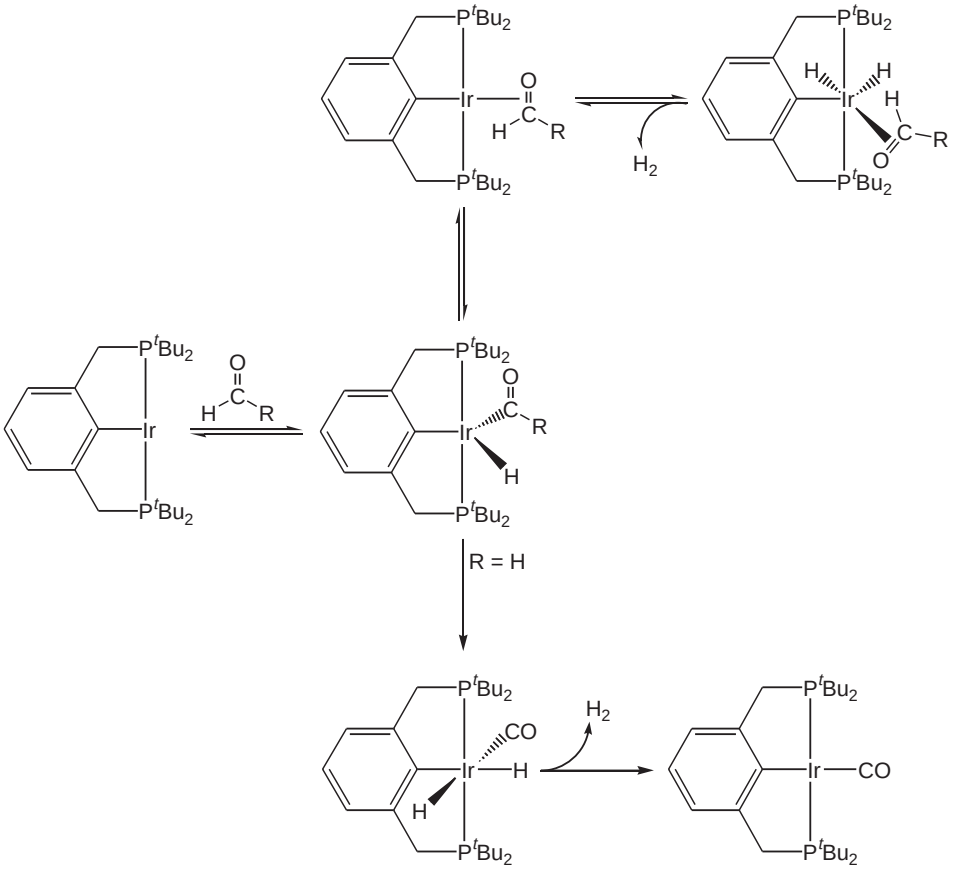
The molecular structure of **2** was determined through a single crystal X-ray diffraction study.[2] The structure consists of two molecules of **2** in the asymmetric unit. A thermal ellipsoid drawing of one of the molecules with atomic number scheme of the obtained structure is presented in Fig. 1. Selected bond angles and distances are listed in Table 3.

A distorted square-planar coordination geometry can be recognized about the iridium consisting of the tridentate PCP pincer and carbonyl ligands. While the vector between the metalated carbon in the aromatic ring and the carbonyl ligand O(1A)-C(25A)-Ir(1) is a nearly ideal 176.800(8)°, the vector between the two phosphorus atoms (P(2A)-Ir(1)-P(1A), 164.510(8)°), is much more distorted due to the geometric constraints imposed upon establishing the chelating interaction of the PCP ligand. The Ir-P and Ir-metalated C distances are comparable to those observed in similar PCP pincer complexes (12, 20, 21).

Scheme 1.

Discussion

A plausible mechanism for the catalytic reaction is depicted in Scheme 1.



Alcohols apparently undergo O-H oxidative addition with the 14-electron complex arising upon dehydrogention of **1** by tbe to give intermediate alkoxy hydride complexes. In support of this hypothesis, the dehydrogenation of **1** in the presence of water produces the analogous hydroxy hydride complex IrH(OH)({C_6H_3-2,6-(CH_2P-*t*-Bu_2)$_2$}, that has been characterized spectroscopically and through a single crystal X-ray structure determination (22). The pincer alkoxide complexes would be expected to undergo the C-H β-elimination reaction that have generally been observed for metal alkoxide complexes (23) to produce η^2-aldehyde or ketone complexes. Dissociation of the dehydrogenated product then regenerates **1** and completes the catalytic sequence.

The alternate reaction pathway observed in the case of methanol can be rationalized in terms of the differing reactives of formyl and acyl complexes. As illustrated in Scheme 2, such intermediates could quite plausibly result from C-H oxidative addition of aldehydes in either: (*i*) an intermolecular process involving the 14-electron intermediate in the catalytic sequence; (*ii*) or an intramolecular process involving a 16-electron η^2-aldehyde species arising upon reductive elimination of H_2 from the 18-electron, η^2-aldehyde, dihydride intermediate in the catalytic sequence. Hydride elimination from a formyl ligand to generate a hydrido carbonyl complex is well known to be much more facile than the corresponding alkyl deinsertion from an acyl

[2] Copies of material on deposit (tables of crystal data, thermal parameters, bond distances, bond angles, and atomic coordinates for Ir(CO){C_6H_3-2,6-(CH_2P-*t*-Bu_2)$_2$}) may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically). Some of this material has also been deposited with the Cambridge Crystallographic Data Centre. Copies of the data can be obtained, free of charge, on application to the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. (Fax: 44-1223-336033 or e-mail: deposit@ccdc.cam.ac.uk).

Scheme 2.

intermediate (24). Thus while all aldehydes are likely to undergo C-H oxidative addition in this catalytic system, subsequent deinsertion to form a carbonyl is competitive with the mircoreverse, reductive elimination of aldehyde only in the case of the formyl intermediate.

Conclusions

In summary, the PCP pincer complex **1** catalyzes the highly selective dehydrogenation of a variety of primary and secondary alcohols to aldehydes and ketones, respectively. The problem of product inhibition of the catalyst is eliminated by carrying out the dehydrogenation reactions in dilute solutions and dehydrogenated products have been uniformly obtained in nearly quantititative yields. The unusual dehydrogenation and (or) annulation of 2,5-hexanediol to 3-methyl-2-cyclopenten-1-one has been carried out on the preparative scale suggesting that the catalytic conversion of diols to cyclic enones could be utilized in organic synthesis.

Synthesis, characterization, and protonation of octaethylporphyrin osmium nitrosyl complexes containing axial thiolate ligands — X-ray structures of an alkyl thionitrite (RSNO) and its (OEP)Os(NO)(SR) addition product

Jonghyuk Lee, Geun-Bae Yi, Douglas R. Powell, Masood A. Khan, and George B. Richter-Addo

Abstract: The (OEP)Os(NO)(SR) compounds (R = Me, Et, *i*-Pr, *t*-Bu) have been prepared in 33–48% isolated yields by the formal *trans*-addition of the precursor alkyl thionitrites (RSNO) across the metal center in (OEP)Os(CO). The nitrosyl thiolate compounds have been characterized by IR, ^{1}H NMR, and UV–vis spectroscopy, and by FAB mass spectrometry. Their IR spectra display bands in the 1751–1755 cm^{-1} (KBr) range, which is indicative of terminal *N*-bound NO ligands in this class of compounds. The thiolate–thiol (OEP)Os(NO)(SCH_2CH_2SH) complex has been prepared in 70% isolated yield from the reaction of (OEP)Os(NO)(O-*i*-C_5H_{11}) with ethane-1,2-dithiol. Nitrosation of the free -SH group in (OEP)Os(NO)(SCH_2CH_2SH) with *t*-BuONO, followed by reaction with (TTP)Ru(CO) gave [(OEP)Os(NO)](μ-SCH_2CH_2S-*S*,*S*′)[Ru(NO)(TTP)] in 70% yield by ^{1}H NMR spectroscopy. The (OEP)Os(NO)($SCR'_2CH_2NHC(O)Me$) compounds have also been prepared either by an alkoxide–thiolate exchange reaction (for R′ = H) or by RSNO addition to (OEP)Os(CO) (for R′ = Me). The solid-state molecular structures of the precursor RSNO thionitrite (for R′ = Me) and the metalloderivative have been determined by single-crystal X-ray crystallography. Protonation of these (OEP)Os(NO)($SCR'_2CH_2NHC(O)Me$) complexes gave the amide-bound [(OEP)Os(NO)($O=C(Me)NHCH_2CR'_2SH$)]BF_4 derivatives. The latter cationic compounds were also obtained by the sequential reaction of (OEP)Os(CO) with nitrosonium tetrafluoroborate, followed by addition of the amide–thiol reagent.

Key words: thionitrite, nitrosothiol, porphyrin, X-ray structure, nitric oxide, osmium.

Résumé : En procédant à une addition formelle *trans* des alkyl thionitrites (RSNO) précurseurs dans le centre métallique du (OEP)Os(CO), il a été possible de préparer les composés (OEP)Os(NO)(SR) (R = Me, Et, *i*-Pr et *t*-Bu), avec des rendements en produits isolés de 33 à 48%. Les composés thiolate de nitrosyle ont été caractérisés par IR, RMN du ^{1}H, spectroscopie UV–vis et spectrométrie de masse « FAB ». Les spectres IR présentent des bandes dans la plage allant de 1751 à 1755 cm^{-1} (KBr) qui, dans cette classe de composés, indiquent la présence de ligands NO terminaux liés par l'azote. Le complexe thiolate–thiol (OEP)Os(NO)(SCH_2CH_2S) a été préparé avec un rendement de 70% en produit isolé en faisant réagir du (OEP)Os(O-*i*-C_5H_{11}) avec de l'éthane-1,2-dithiol. La nitrosation du groupe -SH libre du (OEP)Os(NO)(SCH_2CH_2SH) avec du *t*-BuONO, suivie d'une réaction avec du (TTP)Ru(CO) conduit à la formation de [(OEP)Os(NO)](μ-SCH_2CH_2S-*S*,*S*′)[Ru(NO)(TTP)] avec un rendement de 70% sur la base de la spectroscopie RMN du ^{1}H. Faisant appel à une réaction d'échange alcoolate–thiolate (pour R′ = H) ou à une réaction d'addition de RSNO sur le composé (OEP)Os(CO) pour R′ = Me), il a aussi été possible de préparer les composés [OEP)Os(NO)($SCR'_2CH_2NHC(O)Me$)]. Les structures moléculaires à l'état solide du précurseur thionitrite RSNO (pour R′ = Me) et du dérivé métallique ont été déterminées par diffraction des rayons X sur un cristal unique. La protonation de ces complexes [(OEP)Os(NO)($SCR'_2CH_2NHC(O)Me$)] conduit à la formation des dérivés [(OEP)Os(NO)($O=C(Me)NHCH_2CR'_2SH$)]BF_4 liés par l'amide. On a aussi obtenu ces composés cationiques par la réaction en séquence du (OEP)Os(CO) avec le tétrafluoroborate de nitrosium, suivie par l'addition du réactif amide–thiol.

Mots clés : thionitrite, nitrosothiol, porphyrine, structure par diffraction des rayons X, oxyde nitrique, osmium.

The chemistry of the *S*-nitroso functional group in alkyl thionitrites (RSNO, nitrosothiols) is invariably linked to the biology of nitric oxide, although the exact physiological relationship between RSNO and NO remains to be discerned. For example, thiol groups on proteins can be nitrosated (1–4), and it has been shown that the βCys93 residue of hemoglobin can be nitrosated under some conditions (5–8). The X-ray structure of *S*-nitrosated hemoglobin has also been reported (9).

Nitrosation of thiols to give RSNO has a rather long history, and reviews on the chemistry of RSNOs have been published (10–16). A major breakthrough in the chemistry of RSNO compounds came when Butler and co-workers (17) reported that some trace metals (e.g., copper in buffered solutions) catalyze the decomposition of the *S*-nitroso functional group. We have also shown that metalloporphyrins of the group 8 metals react with RSNO to give formal *trans*-addition products, via initial *S*-coordination of the RSNO molecule (11, 18–22). We are interested in the chemical and spectroscopic properties of the resulting six-coordinate (por)M(NO)(SR) compounds, since these are potential structural models for the NO adducts of cytochrome P450, chloroperoxidase, and NO synthase (23). Prior to the current study, only three osmium (por)M(NO)(SR) derivatives had been reported in the literature, namely (TTP)Os(NO)(S-*i*-C_5H_{11}), (OEP)Os(NO)(S-*i*-C_5H_{11}), and the unstable (OEP)Os(NO)(SPh) (TTP = tetratolylporphyrinato dianion, OEP = octaethylporphyrinato dianion) (19, 21).

In this paper, we report the synthesis and characterization of an extended series of (OEP)Os(NO)(SR) compounds. We also report the single-crystal X-ray structures of an RSNO and (OEP)Os(NO)(SR) pair of compounds. It is surprising that only three crystal structures of organic RSNO compounds had been reported prior to this work, despite the recognized importance of RSNO chemistry. This manuscript contains, to the best of our knowledge, the first RSNO–metal-complex pair to be characterized by spectroscopy or crystallography.

Experimental section

All reactions were performed under an atmosphere of prepurified nitrogen using standard Schlenk glassware and (or) in an Innovative Technology Labmaster 100 dry box. Solutions for spectral studies were also prepared under a nitrogen atmosphere. Solvents were distilled from appropriate drying agents under nitrogen just prior to use: CH_2Cl_2 (CaH_2), hexane (CaH_2), toluene (Na).

Chemicals

(OEP)Os(CO) (24) and (TTP)Ru(CO) (25) were prepared by literature methods. HBF_4 (54 wt% solution in Et_2O), $NOBF_4$, MeOH (99.8%, anhyd), isoamyl nitrite (*i*-$C_5H_{11}ONO$, 97%), *t*-BuONO (96%), ethane-1,2-dithiol ($HSCH_2CH_2SH$, 90+%), methanethiol (CH_3SH, 99.5+%), ethanethiol (C_2H_5SH, 97%), 2-propanethiol ($(CH_3)_2CHSH$, 97+%), 2-methyl-2-propanethiol ($(CH_3)_3CSH$, 99%), and *N*-acetylcysteamine (95%) were purchased from Aldrich Chemical Co. and used as received. The thionitrite $MeC(O)NHCH_2C(Me)_2SNO$ was prepared by a literature procedure (26). Chloroform-*d* (99.8%) was obtained from Cambridge Isotope Laboratories. Elemental analyses were performed by Atlantic Microlab, Norcross, Georgia. The thionitrites (RSNO) were generated in situ from the reaction of *t*-BuONO and their thiol precursors either at low temperature (R = Me) or at room temperature (R = Et, *i*-Pr, *i*-Bu).

Instrumentation

Infrared spectra were recorded on a Bio-Rad FT-155 FT IR spectrometer. Proton NMR spectra were obtained on Varian 400 MHz or 300 MHz spectrometers and the signals referenced to the residual signal of the solvent employed. All coupling constants are in Hz. FAB mass spectra were obtained on a VG-ZAB-E mass spectrometer. UV–vis spectra were recorded on a Hewlett–Packard model 8453 diode array instrument. Wavelengths are reported with ε values or as %-intensities for the samples whose yields were too small for accurate concentration measurements.

Preparation of (OEP)Os(NO)(SR) compounds (R = Me, Et, *i*-Pr, *t*-Bu)

These compounds were synthesized via a formal *trans*-addition of the RSNO across the metal center. The following reaction is representative:

To a stirred CH_2Cl_2 solution (20 mL) of (OEP)Os(CO) (0.080 g, 0.107 mmol) was added a previously prepared green mixture of 2-methy-2-propanethiol and *t*-BuONO (1:1.1 ratio by volume, 1:1 mol ratio, 0.16 mL in 4 mL of CH_2Cl_2, 10 min mixing time). The mixture was stirred for 30 min, during which it turned from pink red to slightly dark red. The solvent was removed in vacuo, the residue was dissolved in a CH_2Cl_2–hexane (1:3, 5 mL) mixture, and filtered through a neutral alumina column (2 × 20 cm) in air. The bright red band was collected, and the filtrate was dried in vacuo for 5 h to give (OEP)Os(NO)(S-*t*-Bu)·$0.9CH_2Cl_2$ (0.041 g, 0.045 mmol, 42% isolated yield). Low-resolution FAB-MS *m*/*z*: 813 $[(OEP)Os(SC(CH_3)_3)]^+$ (13%), 754 $[(OEP)Os(NO)]^+$ (100%), 724 $[(OEP)Os]^+$ (28%). UV–vis (λ, CH_2Cl_2) (nm): 357 (100), 446 (49), 551 (20), 585 (16). IR (CH_2Cl_2, cm^{-1}): υ_{NO} = 1758. IR (KBr, cm^{-1}): υ_{NO} = 1754 s; also 2964 m, 2932 m, 2871 m, 1468 m, 1452 m, 1382 w, 1375 w, 1316 w, 1272 m, 1154 m, 1112 w, 1056 m, 1021 m, 994 m, 963 m, 842 m, 745 m, 737 m, 718 w. ^1H NMR ($CDCl_3$) δ: 10.29 (s, 4H, *meso*-H of OEP), 5.28 (s, CH_2Cl_2), 4.14 (m, 16H, CH_2CH_3 of OEP), 1.96 (t, *J* = 8, 24H, CH_2CH_3 of OEP), –2.19 (s, 9H, $SC(CH_3)_3$). Anal. calcd. for $C_{40}H_{53}N_5O_1S_1Os_1$·$0.9CH_2Cl_2$: C 53.48, H 6.01, N 7.62, Cl 6.95, S 3.49; found: C 53.42, H 5.95, N 7.43, Cl 6.75, S 3.29.

The other (OEP)Os(NO)(SR) compounds were generated similarly. The MeSNO reagent was prepared at low temperature (–78°C) by reacting condensed methanethiol with *t*-BuONO in CH_2Cl_2.

(OEP)Os(NO)(SMe)

Isolated yield: 48%. Low-resolution FAB-MS *m*/*z*: 771 $[(OEP)Os(SCH_3)]^+$ (11%), 754 $[(OEP)Os(NO)]^+$ (100%), 724 $[(OEP)Os]^+$ (20%). UV–vis (λ (ε, mM^{-1} cm^{-1}), 1.64 × 10^{-5} M in CH_2Cl_2) (nm): 354 (53), 439 (28), 551 (12), 585 (9). IR (CH_2Cl_2, cm^{-1}): υ_{NO} = 1759. IR (KBr, cm^{-1}): υ_{NO} = 1755 s; also 2962 m, 2927 m, 2869 m, 1905 w, 1467 m, 1447 m, 1424 w, 1374 m, 1316 w, 1303 w, 1270 m, 1229 w,

(OEP)Os(NO)(S-i-*Pr)*

Isolated yield: 33%. Low-resolution FAB-MS *m*/*z*: 799 [(OEP)Os(SCH(CH$_3$)$_2$)]$^+$ (12%), 754 [(OEP)Os(NO)]$^+$ (100%), 724 [(OEP)Os]$^+$ (29%). UV–vis (λ, CH_2Cl_2) (nm): 354 (100), 441 (53), 551 (21), 585 (16). IR (CH_2Cl_2, cm^{-1}): υ_{NO} = 1754. IR (KBr, cm^{-1}): υ_{NO} = 1751 s; also 2963 m, 2928 m, 2869 m, 1471 m, 1464 m, 1457 m, 1442 w, 1374 w, 1314 w, 1271 m, 1230 w, 1154 m, 1110 w, 1056 m, 1020 m, 993 m, 963 m, 841 m, 746 m, 737 m, 718 w. ^{1}H NMR ($CDCl_3$) δ: 10.30 (s, 4H, *meso*-H of OEP), 4.15 (q, *J* = 8, 16H, C*H*$_2$CH$_3$ of OEP), 1.98 (t, *J* = 8, 24H, CH$_2$C*H*$_3$ of OEP), –1.95 (d, *J* = 7, 6H, SCH(C*H*$_3$)$_2$), –4.03 (m, 1H, SC*H*(CH$_3$)$_2$).

Preparation of (OEP)Os(NO)(SCH$_2$CH$_2$SH)

A mixture of (OEP)Os(NO)(O-*i*-C$_5$H$_{11}$) (0.100 g, 0.119 mmol) (21) and excess HSCH$_2$CH$_2$SH (0.1 mL, 1.073 mmol) in toluene (20 mL) was refluxed under N_2 gas with vigorous stirring for 48 h. Color change of the solution was apparent. The solvent was removed in vacuo, and a ^{1}H NMR spectrum of the residue in $CDCl_3$ showed the presence of the desired thiolate–thiol product and some unreacted thiol. The residue was dissolved in CH_2Cl_2–hexane (2:1, 10 mL), and the solution was transferred to the top of a silica gel column (2 × 20 cm). Elution with a CH_2Cl_2–hexane (2:1) mixture in air yielded a pale red band and a bright red band. The pale red band was discarded and the bright red band was collected by eluting with CH_2Cl_2. The filtrate was dried in vacuo, the residue was dissolved in CH_2Cl_2–hexane (10 mL, 3:1), and slow evaporation of the solvent mixture in air gave (OEP)Os(NO)(SCH$_2$CH$_2$SH)·0.85CH_2Cl_2 (0.076 g, 0.083 mmol, 70% isolated yield). Low-resolution FAB-MS *m*/*z*: 817 [(OEP)Os(SCH$_2$CH$_2$SH)]$^+$ (5%), 754 [(OEP)Os(NO)]$^+$ (100%), 724 [(OEP)Os]$^+$ (24%). UV–vis (λ (ε, mM^{-1} cm^{-1}), 1.31 × 10^{-5} M in CH_2Cl_2) (nm): 354 (75), 443 (39), 551 (15), 585 (11). IR (CH_2Cl_2, cm^{-1}): υ_{NO} = 1764. IR (KBr, cm^{-1}): υ_{NO} = 1756 s; also 2964 m, 2932 m, 2870 m, 1690 w, 1467 m, 1451 m, 1373 m, 1316 w, 1272 m, 1230 w, 1154 m, 1111 w, 1057 m, 1021 m, 994 m, 964 m, 842 m, 746 m, 737 m, 716 w. ^{1}H NMR ($CDCl_3$) δ: 10.35 (s, 4H, *meso*-H of OEP), 5.28 (s, C*H*$_2$Cl$_2$), 4.18 (m, 16H, C*H*$_2$CH$_3$ of OEP), 2.02 (t, *J* = 8, 24H, CH$_2$C*H*$_3$ of OEP), –0.30 (t, *J* = 8, 1H, SCH$_2$CH$_2$S*H*), –1.17 (m, 2H, SCH$_2$C*H*$_2$SH), –2.76 (m, 2H, SC*H*$_2$CH$_2$SH). Anal. calcd. for $C_{38}H_{49}N_5O_1S_2Os_1$·0.85$CH_2Cl_2$: C 50.81, H 5.56, N 7.63, Cl 6.56, S 6.98; found: C 50.67, H 5.46, N 7.46, Cl 6.88, S 7.32.

Preparation of [(OEP)Os(NO)](μ-SCH$_2$CH$_2$S-*S*,*S*′)[Ru(NO)(TTP)]

To a CH_2Cl_2 (20 mL) solution of (OEP)Os(NO)(SCH$_2$CH$_2$SH)·0.85CH_2Cl_2 (0.020 g, 0.022 mmol) was added *t*-BuONO (5 μL, 0.04 mmol), and the reaction mixture was stirred for 10 min. To this solution was added (TTP)Ru(CO) (0.018 g, 0.022 mmol), and the solution was stirred for a further 10 min, during which time its color turned from dark red to brown-purple. The solvent was removed in vacuo, and a ^{1}H NMR spectrum of the residue in $CDCl_3$ showed the formation of a mixture of the desired mixed bimetallic [(OEP)Os(NO)](μ-SCH$_2$CH$_2$S-*S*,*S*′)[Ru(NO)(TTP)] and [(OEP)Os(NO)]$_2$(μ-SCH$_2$CH$_2$S-*S*,*S*′) (a singlet at –6.27 ppm) in a 70:1 ratio (by ^{1}H NMR spectroscopy), together with several unidentified products in 29% yield total. Attempts to obtain spectroscopically pure [(OEP)Os(NO)](μ-SCH$_2$CH$_2$S-*S*,*S*′)[Ru(NO)(TTP)] were unsuccessful, since it is unstable in solution and there is little difference in solubility between this air-sensitive product and its by-products. ^{1}H NMR ($CDCl_3$) δ: 9.81 (s, 4H, *meso*-H of OEP), 8.51 (s, 8H, *pyrrole*–H of TTP), 7.87 (br d, *J* = 7, 4H of TTP), 7.46 (m, 12H of TTP), 3.85 (m, 16H, C*H*$_2$CH$_3$ of OEP), 2.73 (s, 12H, C*H*$_3$ of TTP), 1.71 (t, *J* = 8, 24H, CH$_2$C*H*$_3$ of OEP), –5.92 (app m (see text), 2H, SC*H*$_2$CH$_2$S), –6.01 (app m (see text), 2H, SCH$_2$C*H*$_2$S).

Preparation of (OEP)Os(NO)(SCH$_2$CH$_2$NHC(O)Me)

A mixture of (OEP)Os(NO)(O-*i*-C$_5$H$_{11}$) (0.050 g, 0.059 mmol) (21) and excess HSCH$_2$CH$_2$NHC(O)Me (20 μL, 0.178 mmol) in xylene (20 mL) was refluxed under N_2 gas with vigorous stirring for 48 h. The solvent was removed in vacuo, and an ^{1}H NMR spectrum of the residue in $CDCl_3$ showed the presence of the desired thiolate product and unreacted thiol. The residue was dissolved in a CH_2Cl_2–hexane mixture (1:10, 55 mL), and this solution was kept at –20°C overnight. Precipitation of the solid was enhanced by mixing of the CH_2Cl_2–hexane solution, and the supernatant solution was discarded. The remaining solid product was dried in vacuo, the residue was dissolved in a CH_2Cl_2–hexane (1:1, 5 mL) mixture, and the solution was transferred to the top of a neutral alumina column (1.5 × 15 cm). Elution with hexane in air removed unreacted thiol, and then elution with CH_2Cl_2 yielded a bright red band. This bright red band was collected and taken to dryness in vacuo. The residue was dissolved in a CH_2Cl_2–hexane (2:1, 15 mL) mixture, and slow evaporation of the solvent mixture in air gave (OEP)Os(NO)(SCH$_2$CH$_2$NHC(O)Me) (0.034 g, 0.039 mmol, 66% isolated yield). Low-resolution FAB-MS *m*/*z*: 842 [(OEP)Os(SCH$_2$CH$_2$NHC(O)Me)]$^+$ (3%), 754 [(OEP)Os(NO)]$^+$ (100%), 724 [(OEP)Os]$^+$ (29%). UV–vis (λ (ε, mM^{-1} cm^{-1}), 1.61 × 10^{-5} M in CH_2Cl_2) (nm): 354 (60), 441 (32), 551 (13), 585 (10). IR (CH_2Cl_2, cm^{-1}): υ_{NO} = 1765; υ_{CO} = 1665. IR (KBr, cm^{-1}): υ_{NO} = 1756 s; υ_{CO} = 1642 m br; also 2964 m, 2930 m, 2870 m, 1465 m, 1444 m, 1372 m,

© 2001 NRC Canada

1273 m, 1230 w, 1154 m, 1111 w, 1056 m, 1020 m, 994 m, 963 m, 843 m, 745 m, 736 m, 717 w. ^{1}H NMR ($CDCl_3$) δ: 10.34 (s, 4H, *meso*-H of OEP), 4.16 (m, 16H, C*H*$_2$CH$_3$ of OEP), 2.47 (br, 1H, SCH$_2$CH$_2$N*H*C(O)CH$_3$), 2.00 (t, *J* = 8, 24H, CH$_2$C*H*$_3$ of OEP), 1.10 (s, 3H, SCH$_2$CH$_2$NHC(O)C*H*$_3$), 0.22 (m, 2H, SCH$_2$C*H*$_2$NHC(O)CH$_3$), –2.98 (m, 2H, SC*H*$_2$CH$_2$NHC(O)CH$_3$).

Preparation of (OEP)Os(NO)(SC(Me)$_2$CH$_2$NHC(O)Me)

To a stirred CH_2Cl_2 solution (20 mL) of (OEP)Os(CO) (0.080 g, 0.107 mmol) was added MeC(O)NHCH$_2$C(Me)$_2$SNO (0.019 g, 0.108 mmol). The mixture was stirred for l h, during which it turned from pink red to slightly dark red. The solvent was removed in vacuo, the residue was dissolved in CH_2Cl_2 (10 mL), and the solution was transferred to the top of an alumina column (2 × 20 cm). Elution with CH_2Cl_2 in air yielded a pale brown band and a bright red band. The pale brown band was discarded, and the bright red band was collected and taken to dryness in vacuo. The resulting red product was identified as (OEP)Os(NO)(SC(Me)$_2$CH$_2$NHC(O)Me) (0.021 g, 0.023 mmol, 21% isolated yield). Low-resolution FAB-MS *m*/*z*: 870 [(OEP)Os(SC(Me)$_2$CH$_2$NHC(O)Me)]$^+$ (22%), 754 [(OEP)Os(NO)]$^+$ (100%), 724 [(OEP)Os]$^+$ (22%). UV–vis (λ, CH_2Cl_2) (nm): 357 (100), 443 (48), 552 (20), 585 (17). IR (CH_2Cl_2, cm^{-1}): υ_{NO} = 1773; υ_{CO} = 1681. IR (KBr, cm^{-1}): υ_{NO} = 1764 s; υ_{CO} = 1656 s br; also 2964 m, 2932 m, 2872 w, 1561 m, 1510 m, 1465 m, 1450 m, 1370 m, 1275 m, 1231 w, 1154 m, 1112 w, 1057 m, 1022 m, 995 m, 963 m, 845 m, 749 vs, 717 w. ^{1}H NMR ($CDCl_3$) δ: 10.35 (s, 4H, *meso*-H of OEP), 4.16 (m, 16H, C*H*$_2$CH$_3$ of OEP), 1.98 (t, *J* = 8, 24H, CH$_2$C*H*$_3$ of OEP), 1.52 (br, 1H, SC(CH$_3$)$_2$CH$_2$N*H*C(O)CH$_3$), 1.23 (s, 3H, SC(CH$_3$)$_2$CH$_2$NHC(O)C*H*$_3$), –0.88 (d, *J* = 4, 2H, SC(CH$_3$)$_2$C*H*$_2$NHC(O)CH$_3$), –2.08 (s, 6H, SC(C*H*$_3$)$_2$CH$_2$NHC(O)CH$_3$).

Preparation of disulfide {MeC(O)NHCH$_2$C(Me)$_2$S-}$_2$ (*R′SSR′*)

A MeOH solution of green thionitrite MeC(O)NHCH$_2$C(Me)$_2$SNO (0.010 g, 0.057 mmol) was refluxed with vigorous stirring for 3 h under a nitrogen atmosphere, during which the color of the solution turned colorless. The solvent was dried in air, and a ^{1}H NMR spectrum of the residue in $CDCl_3$ showed the quantitative formation of the disulfide. ^{1}H NMR ($CDCl_3$) δ: 5.80 (br, 2H), 3.30 (d, *J* = 6, 4H), 2.00 (s, 6H), 1.26 (s, 12H). Low-resolution FAB-MS *m*/*z*: 293 [*R′SSR′*+ H]$^+$ (76%), 146 [*R′S*]$^+$ (15%), 114 [*R′*]$^+$ (100%).

This previously unreported disulfide was also prepared from the decomposition of thionitrite MeC(O)NHCH$_2$C(Me)$_2$SNO in a CH_2Cl_2–MeOH solution (1:10) by light. Suitable crystals for X-ray crystallography were grown from a CH_2Cl_2–MeOH (1:10) mixture of the thionitrite precursor that had been left at –10°C under nitrogen for 2 weeks. The X-ray data has been deposited in the *Supplementary material*.

Preparation of [(OEP)Os(NO)(O=C(Me)NHCH$_2$CH$_2$SH)]BF$_4$

To a stirred CH_2Cl_2 solution (15 mL) of (OEP)Os(CO) (0.020 g, 0.027 mmol) was added $NOBF_4$ (0.003 g, 0.026 mmol). The color of the solution changed from pink red to slightly dark red over a 30 min period, and an IR spectrum (CH_2Cl_2) showed the replacement of the 1883 cm^{-1} assigned to the υ_{CO} of (OEP)Os(CO) with a new band at 1833 cm^{-1} assigned to the υ_{NO} of [(OEP)Os(NO)]BF_4. Liquid HSCH$_2$CH$_2$NHC(O)Me (6 μL, 0.053 mmol) was then added to the reaction solution, and the mixture was stirred for 5 h. The solvent was removed in vacuo, and a ^{1}H NMR spectrum of the residue in $CDCl_3$ showed the presence of the desired product and unreacted thiol. The residue was dissolved in CH_2Cl_2–hexane (1:10, 55 mL), and this solution was kept at –20°C for 2 days. Precipitation of the product was enhanced by mixing of the CH_2Cl_2–hexane solution, and the supernatant solution was discarded. The precipitate was washed with hexane (5 × 50 mL), and then dissolved in CH_2Cl_2–hexane (2:1, 6 mL). Slow evaporation of the solution in a dry box gave [(OEP)Os(NO)(O=C(Me)NHCH$_2$CH$_2$SH)] BF_4·CH_2Cl_2 (0.010 g, 0.010 mmol, 38% isolated yield). Low-resolution FAB-MS *m*/*z*: 873 [(OEP)Os(NO)(O=C(Me)NHCH$_2$CH$_2$SH)]$^+$ (11%), 754 [(OEP)Os(NO)]$^+$ (100%), 724 [(OEP)Os]$^+$ (15%). UV–vis (λ, CH_2Cl_2) (nm): 346 (sh, 91), 361 (94), 421 (100), 539 (26), 575 (42). IR (CH_2Cl_2, cm^{-1}): υ_{NO} = 1826; υ_{CO} = 1603. IR (KBr, cm^{-1}): υ_{NO} = 1814 s; υ_{CO} = 1605 m; also 2964 m, 2932 m, 2873 m, 1574 m, 1466 m, 1450 m, 1441 m, 1378 w, 1357 w, 1315 w, 1274 m, 1230 w,1207 w, 1155 m, 1085 s, 1056 s, 1022 s, 996 s, 964 m, 849 m, 745 m, 736 m, 714 w. ^{1}H NMR ($CDCl_3$) δ: 10.54 (s, 4H, *meso*-H of OEP), 5.74 (br, 1H, HSCH$_2$CH$_2$N*H*C(O)CH$_3$), 5.28 (s, C*H*$_2$Cl$_2$), 4.23 (q, *J* = 8, 16H, C*H*$_2$CH$_3$ of OEP), 2.02 (t, *J* = 8, 24H, CH$_2$C*H*$_3$ of OEP), –0.01 (t, *J* = 9, 1H, *H*SCH$_2$CH$_2$NHC(O)CH$_3$), –0.41 and –0.53 (m's, 4H of HSC*H*$_2$C*H*$_2$NHC(O)CH$_3$), –3.04 (s, 3H, HSCH$_2$CH$_2$NHC(O)C*H*$_3$). Protonation of (OEP)Os(NO)(SCH$_2$CH$_2$NHC(O)Me)

To a CH_2Cl_2 (10 mL) solution of (OEP)Os(NO)(SCH$_2$CH$_2$NHC(O)Me) (0.010 g, 0.011 mmol) was added HBF_4·Et_2O (0.9 μL, 0.012 mmol). The mixture was stirred overnight. The solvent was removed in vacuo, and an ^{1}H NMR spectrum of the residue in $CDCl_3$ showed the formation of a mixture of [(OEP)Os(NO)(O=C(Me)NHCH$_2$CH$_2$SH)]BF_4

© 2001 NRC Canada

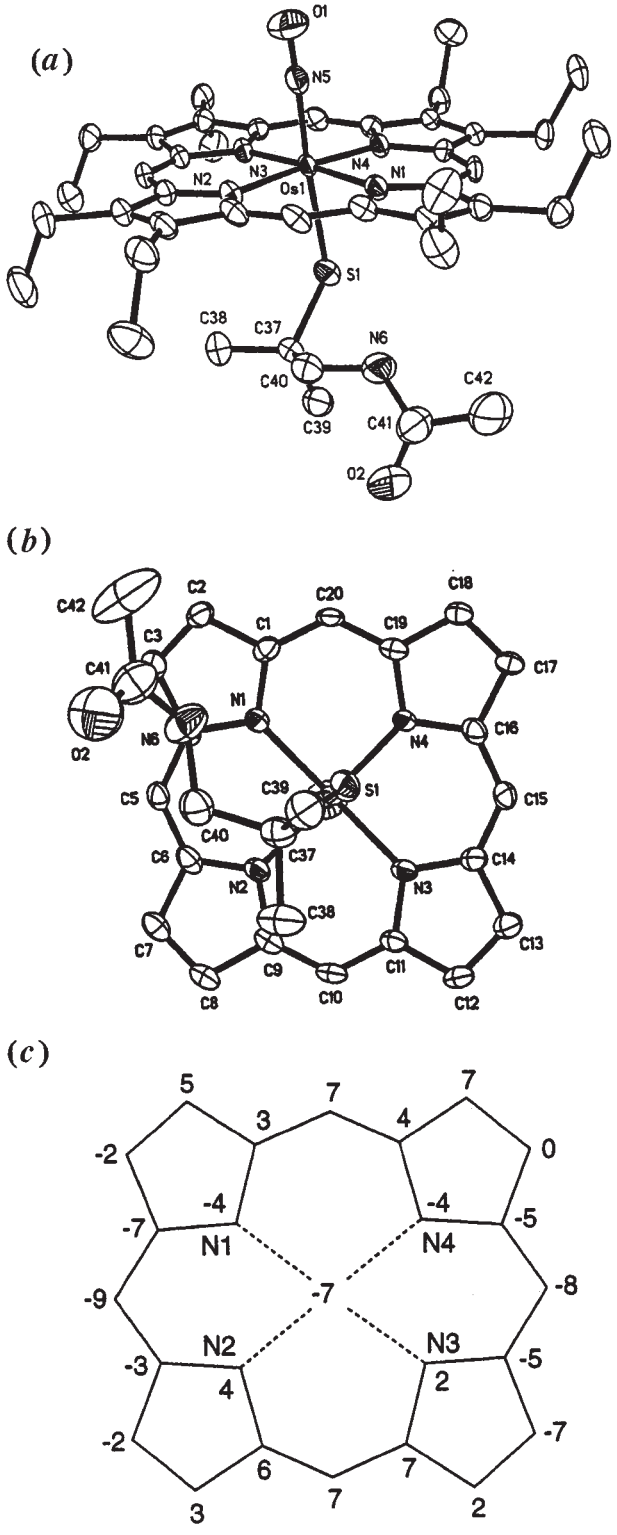
and the known (OEP)Os(NO)F (27) in a 78:15 ratio based on integrations of the *meso*-Hs of their OEP ligands.

Protonation of (OEP)Os(NO)(SC(Me)$_2$CH$_2$NHC(O)Me)

To a CH_2Cl_2 (10 mL) solution of (OEP)Os(NO)-(SC(Me)$_2$CH$_2$NHC(O)Me) (0.010 g, 0.011 mmol) was added $HBF_4 \cdot Et_2O$ (0.9 μL, 0.012 mmol). The reaction was monitored by IR spectroscopy, and the reaction stopped when the IR spectrum in CH_2Cl_2 was almost identical to that of authentic [(OEP)Os(NO)(O=C(Me)NHCH$_2$C(Me)$_2$SH)]BF_4 (ca. 30 min). The solvent was removed in vacuo, and an ^{1}H NMR spectrum of the residue in $CDCl_3$ showed the formation of [(OEP)Os(NO)(O=C(Me)NHCH$_2$C(Me)$_2$SH)]BF_4 in 29% yield (by ^{1}H NMR spectroscopy). The reaction mixture was stirred for a further 2 h, the solvent was removed in vacuo, and a ^{1}H NMR spectrum of the residue in $CDCl_3$ showed the presence of [(OEP)Os(NO)(O=C(Me)-NHCH$_2$C(Me)$_2$SH)]BF_4, and the known (OEP)Os(NO)F in a 56:4 ratio, together with other as yet unidentified products. Further reaction overnight yielded, by ^{1}H NMR spectroscopy, [(OEP)Os(NO)(O=C(Me)NHCH$_2$C(Me)$_2$SH)]BF_4 and (OEP)Os(NO)F in a 67:7 ratio.

Structural determinations by X-ray crystallography

Crystal data were collected using monochromated Mo Kα radiation (λ = 0.71073 Å). Displacement ellipsoids in Figs. 1 and 2 are drawn at the 50% probability level. Details of the crystal data and refinement are given in Table 1 and in the Supporting Information.



(i) (OEP)Os(NO)(SC(Me)$_2$CH$_2$NHC(O)Me)

A suitable crystal was grown from a CH_2Cl_2–hexane solution (5:1) left in air overnight. The data were corrected for Lorentz and polarization effects; and an empirical absorption correction based on ψ scans was applied. The structure was solved by the heavy atom method using the SHELXTL (Bruker) system, and refined by full-matrix least-squares on F^2 using all reflections (SHELXL-93). One of the methyl groups on the porphyrin ring (C24) is disordered at two sites, and both positions (C24a, C24b) were refined with 50% occupancy. Other atoms (C42, O1, and O2) are also slightly disordered as indicated by the large thermal motions of these atoms. The structure was solved and refined in both the noncentric space group $P1$ (no. 1) and the centric space group $P\bar{1}$ (no. 2). Better refinement was obtained in the $P\bar{1}$ space group. Hydrogen atoms were included in the refinement with idealized positions.

(ii) ONSC(Me)$_2$CH$_2$NHC(O)Me

The intensity data were measured as a series of ø oscillation frames each of 0.3° for 30 s per frame. Coverage of unique data was 99.6% complete to 25.00° in θ. Cell parameters were determined from a nonlinear least-squares fit of 3581 peaks in the range $2.63 < \theta < 26.76°$. The first 50 frames were repeated at the end of data collection and yielded 120 peaks showing a variation of 0.17% during the data collection. A total of 4483 data were measured in the range $2.98 < \theta < 27.10°$. A total of 100 parameters were refined against 1832 data to give $wR(F^2) = 0.1257$ and $S = 1.088$ for weights of $w = 1/[\sigma^2(F^2) + (0.0760P)^2 + 0.2300P]$, where $P = [F_o^2 + 2F_c^2]/3$. The final $R(F)$ was 0.0441 for the 1635 observed, $[F > 4\sigma(F)]$, data.

Results and discussion

Synthesis of nitrosyl thiolate complexes

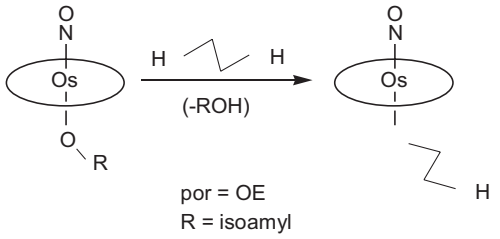
The reaction of the alkyl thionitrites (RSNO: R = Me, Et, *i*-Pr, *t*-Bu) with the (OEP)Os(CO) compound generates, after appropriate work-up, the formal *trans*-addition products (OEP)Os(NO)(SR) in 33–48% isolated yields (eq. [1]).

[1]

The (OEP)Os(NO)(SR) nitrosyl thiolate products are red, moderately air-stable in solution, and can be stored in air in the solid state for at least 1 month with no noticeable decomposition. They are freely soluble in CH_2Cl_2 but only slightly soluble in hexane. These (OEP)Os(NO)(SR) nitrosyl thiolates are of the $\{OsNO\}^6$ formulation according to the Enemark–Feltham notation (28–30), and are expected to have linear Os-NO linkages. Their spectroscopic properties are consistent with their formulation as such. For example, their IR spectra reveal strong bands in the 1754–1759 cm^{-1} (CH_2Cl_2) or 1751–1755 cm^{-1} (KBr) ranges, which are indicative of terminal *N*-bound NO ligands for this class of compounds (23). This range is similar to that seen for related (OEP)Os(NO)(OR) alkoxide compounds (21, 31), but is higher than that seen for the organometallic (OEP)Os(NO)R compounds (1703–1748 cm^{-1}; R = alkyl, aryl) (27). In our previous work with the latter organometallic compounds, we showed that their υ_{NO}s decrease in the order (OEP)Os(NO)Me (1720 cm^{-1}) > (OEP)Os(NO)Et (1710 cm^{-1}) > (OEP)Os(NO)(*i*-Pr) (1703 cm^{-1}) ≈ (OEP)Os(NO)(*t*-Bu) (1703 cm^{-1}), consistent with increased electron donation of the R groups. Interestingly, however, the IR spectra of the alkyl *thiolate* (OEP)Os(NO)(SR) compounds in CH_2Cl_2 show that the υ_{NO}s fall in a very narrow range: (OEP)Os(NO)(SMe) (1759 cm^{-1}) ≈ (OEP)Os(NO)(SEt) (1758 cm^{-1}) ≈ (OEP)Os(NO)(S-*t*-Bu) (1758 cm^{-1}) > (OEP)Os(NO)(S-*i*-Pr) (1754 cm^{-1}). Clearly, the presence of the sulfur atom in these (OEP)Os(NO)(SR) compounds masks the direct interaction of the alkyl groups with the metal center, making a less dramatic variation in Os → NO back donation of electron density.

The ^{1}H NMR spectra of the (OEP)Os(NO)(SR) compounds in $CDCl_3$ reveal that the chemical shifts of the δ_{meso} protons of the OEP macrocycle decrease slightly from the (OEP)Os(NO)(SMe) (10.33 ppm) to the (OEP)Os(NO)(S-*t*-Bu) (10.29 ppm), consistent with a slight *cis*-influence of the

© 2001 NRC Canada



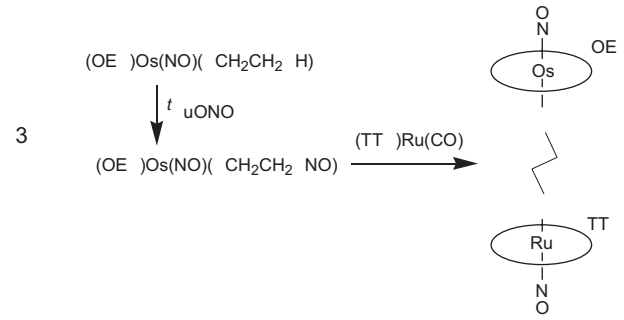
axial thiolate ligands. For comparison, the chemical shifts of the δ_{meso} protons in the related (OEP)Os(NO)(OR) *alkoxide* compounds are at 10.44 ppm (R = Me) or 10.32 ppm (R = Et, *i*-Pr, hexyl, cyclohexyl) (31). Buchler et al. (32) have previously examined similar *cis*-effects of axial ligands in (OEP)Os-containing compounds. The ^{1}H NMR spectra of these (OEP)Os(NO)(SR) compounds in $CDCl_3$ show that all the peaks due to the coordinated thiolate ligands are shifted upfield relative to those of the free thiols, consistent with the influence of the porphyrin ring current. Thus, the α-CH protons appear upfield at ca. –3.12 ppm (for the -SC*H*$_3$ and -SC*H*$_2$CH$_3$ compounds) and at –4.03 ppm for the SC*H*(CH$_3$)$_3$ derivative. Apparently, the presence of the two methyl substituents in the isopropyl group places the α-CH proton in closer proximity to the porphyrin ring current. The β-CH resonances for the thiolate ligands also appear upfield at –1.85 ppm (for SCH$_2$C*H*$_3$), –1.95 ppm (for SCH(C*H*$_3$)$_2$), and –2.19 ppm (for SC(C*H*$_3$)$_3$).

In general, the FAB-MS of the (OEP)Os(NO)(SR) compounds show ion fragments assigned to loss of the NO ligands or loss of the thiols. In the case of (OEP)Os(NO)(SEt), however, the mass spectrum also shows the parent ion at *m*/*z* 815.

Monometallic thiolate–thiol complex

The (OEP)Os(NO)(SCH$_2$CH$_2$SH) thiolate–thiol complex is prepared by an alkoxide–thiolate exchange reaction. Thus, the (OEP)Os(NO)(O-*i*-C$_5$H$_{11}$) alkoxide complex reacts with excess ethane-1,2-dithiol in toluene under refluxing conditions for 48 h to generate the monometallic thiolate–thiol derivative in 70% isolated yield as shown in eq. [2].

2



We note that high temperatures (e.g., refluxing toluene) and long reaction times (ca. 48 h by ^{1}H NMR spectroscopy) are required for this reaction to proceed with high yield. We found that this alkoxide–thiolate exchange method is more efficient in preparing this (OEP)Os(NO)(SCH$_2$CH$_2$SH) complex in high yields compared with the formal *trans*-addition reaction of eq. [1]. Unlike the ruthenium analog reported previously (22), this red (OEP)Os(NO)(SCH$_2$CH$_2$SH) compound is moderately air-stable in solution, showing no signs of decomposition for at least 8 h. It can also be stored in air in the solid state for at least 1 week without noticeable decomposition. This thiolate–thiol complex is freely soluble in CH_2Cl_2 but only slightly soluble in hexane.

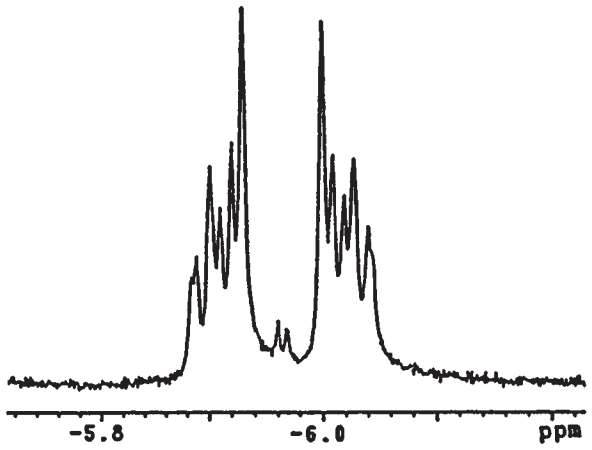
The IR spectrum of this red product (as a KBr pellet) shows a band at 1756 cm^{-1} assigned to υ_{NO}. Its ^{1}H NMR spectrum shows, in addition to the characteristic OEP signals, peaks at –2.76 ppm (SC*H*$_2$CH$_2$SH), –1.17 ppm (SCH$_2$C*H*$_2$SH), and –0.30 ppm (SCH$_2$CH$_2$S*H*) assigned to the coordinated thiolate–thiol ligand. Although the FAB-MS does not show the parent ion, it shows ion fragments at *m*/*z* 817 (loss of the NO ligand) or at *m*/*z* 754 (loss of the thiolate–thiol ligand).

Bimetallic μ-dithiolate complex

Only a handful of bimetallic μ-dithiolate complexes are known (22, 33–40). We previously showed that the free -SH group in (por)Ru(NO)(SCH$_2$CH$_2$SH) can be nitrosated with *t*-BuONO (22). We have employed a similar methodology to prepare the intermediate (OEP)Os(NO)(SCH$_2$CH$_2$SNO) compound, which can then be reacted with (TTP)Ru(CO) to give the heterobimetallic [(OEP)Os(NO)](μ-SCH$_2$CH$_2$S-*S*,*S*′)[Ru(NO)(TTP)] derivative (eq. [3]) in 70% yield by ^{1}H NMR spectroscopy.

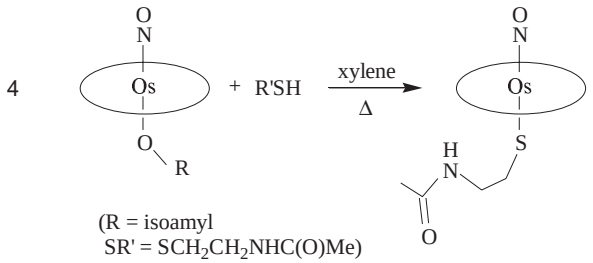
3

We have not yet been able to obtain a spectrocscopically pure sample of this air-sensitive compound. Thus, the ^{1}H NMR spectrum of the product mixture (of eq. [3]) shows, in addition to the signals for two porphyrin macrocycles (TTP and OEP), an AA′BB′ coupling pattern (41) consisting of two sets of peaks centered at ca. –5.92 ppm and –6.01 ppm (Fig. 3) assigned to the μ-SCH$_2$CH$_2$S- protons; spectral simulation gave $J_{AB'} = J_{A'B} = 13.4$ Hz, $J_{AA'} = J_{BB'} = -12.6$ Hz, $J_{AB} = 6$ Hz, $J_{A'B'} = 3.6$ Hz, and $\Delta\upsilon_{AB} = 43$ Hz. Due to the presence of two distinctly different metalloporphyrin moieties in this bimetallic derivative, it is not surprising that the AA′BB′ coupling pattern observed is almost identical to that of the related unsymmetrical [(TPP)Ru(NO)](μ-SCH$_2$CH$_2$S-*S*,*S*′)[Ru(NO)(OEP)] compound published previously (22).



There are several notes of interest regarding the synthesis of [(OEP)Os(NO)](μ-SCH$_2$CH$_2$S-*S*,*S*′)[Ru(NO)(TTP)]. Reaction of the (OEP)Os(NO)(SCH$_2$CH$_2$SH) complex with (TTP)Ru(NO)(OR) did not produce the bimetallic derivative via the expected alkoxide–thiolate exchange reaction. In addition, we have found that the reaction of (OEP)Os(NO)(SCH$_2$CH$_2$SNO) with (TTP)Ru(CO) is more efficient in the formation of the desired bimetallic derivative than the reaction of (TTP)Ru(NO)(SCH$_2$CH$_2$SNO) with (OEP)Os(CO). Indeed, the latter reaction revealed the formation of the known [(TTP)Ru(NO)]$_2$(μ-SCH$_2$CH$_2$S-*S*,*S*′) (δ_{SCH_2} –5.73 ppm) compound (22) as a major product through an as yet unknown mechanism. In any event, the successful reaction of (OEP)Os(NO)(SCH$_2$CH$_2$SNO) with (TTP)Ru(CO) is consistent with our earlier observations that RSNO additions to (por)Ru(CO) were faster and cleaner than the analogous additions to (por)Os(CO) (19).

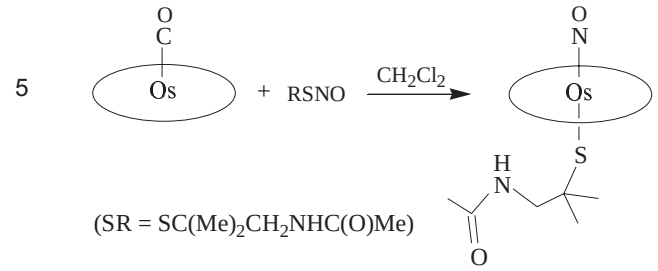
Amide-containing thiolate complexes



Organic thionitrites containing other heteroatoms are biologically relevant (10, 12). Examples of these include *S*-nitroso-*N*-acetyl-penicillamine, *S*-nitrosoglutathione, and *S*-nitrosocysteine. Part of our ongoing research effort is geared towards determining the preferred binding or reaction modes

© 2001 NRC Canada

Fig. 3. Upfield region of the 400 MHz ^{1}H NMR spectrum of [(OEP)Os(NO)](μ-SCH$_2$CH$_2$S-*S*,*S*′)[Ru(NO)(TTP)] in $CDCl_3$.



of such alkyl thionitrites with group 8 metalloporphyrins and heme. Reaction of the amide-containing *N*-acetylcysteamine thiol (containing a primary carbon atom next to sulfur) with (OEP)Os(NO)(O-*i*-C_5H_{11}) in refluxing xylene results in an alkoxide–thiolate exchange reaction to produce the desired (OEP)Os(NO)(SCH$_2$CH$_2$NHC(O)Me) product in 66% isolated yield (eq. [4]).

Relatively high temperatures are required for this reaction to proceed to completion. For example, the use of refluxing toluene (the solvent used in the related synthesis of (OEP)Os(NO)(SCH$_2$CH$_2$SH), vide supra) does not result in the reaction to form the product. Furthermore, the ^{1}H NMR spectrum of the crude product mixture in $CDCl_3$ (after reaction in refluxing xylene) only showed the presence of the desired thiolate complex and unreacted organic thiol, implying a quantitative conversion to the product in the high-temperature reaction.

This red (OEP)Os(NO)(SCH$_2$CH$_2$NHC(O)Me) product is moderately air-stable in solution and is stable in the solid state. It is readily soluble in CH_2Cl_2 and slightly soluble in hexane. Its IR spectrum shows bands at 1756 and 1642 cm^{-1} (KBr) assigned to υ_{NO} and υ_{CO}, respectively. The ^{1}H NMR spectrum of the compound in $CDCl_3$ shows that the chemical shift of the porphyrin *meso*-protons occur at 10.34 ppm, close to that observed for the other (OEP)Os(NO)(SR) complexes described earlier. All the peaks in the ^{1}H NMR spectrum due to the coordinated thiolate ligand are shifted upfield relative to those of the free thiol. For example, the peaks for the OsSC*H*$_2$- protons occur at –2.98 ppm, which is 5.63 ppm upshifted from that of the free thiol ligand (at 2.65 ppm). The FAB-MS of this compound shows ion fragments at *m*/*z* 842 (loss of the NO ligand) or at *m*/*z* 754 (loss of the thiol). We were not able to obtain suitable crystals of the compound for a crystallographic study.

We were successful in synthesizing the analogous (OEP)Os(NO)(SC(Me)$_2$CH$_2$NHC(O)Me) derivative (containing a tertiary carbon next to sulfur) by employing the formal *trans*-addition reaction described earlier in eq. [1]. Thus, reaction of 1 equiv of solid 1-(acetylamino)-2-methylpropane-2-thionitrite to the (OEP)Os(CO) compound results in the generation of the red (OEP)Os(NO)(SC(Me)$_2$CH$_2$NHC(O)Me) in 21% (nonoptimized) isolated yield (eq. [5]).

This red product can be stored in air in the solid state for at least 1 week without noticeable decomposition. Its IR spectrum as a KBr pellet shows bands at 1764 and 1656 cm^{-1} (KBr) assigned to υ_{NO} and υ_{CO}, respectively. The υ_{NO} band is slightly higher than those of the other (OEP)Os(NO)(SR) compounds described in this paper (1751–1756 cm^{-1}), however, it is within the range observed for linear NO ligands in (por)Os(NO)-containing complexes (23). The υ_{CO} of the amide group of the thiolate ligand is close to that of the precursor thionitrite (1655 cm^{-1}). The υ_{NO} and υ_{CO} bands of (OEP)Os(NO)(SC(Me)$_2$CH$_2$NHC(O)Me) are slightly shifted, by 8 cm^{-1} and 14 cm^{-1}, respectively, to higher wavenumbers relative to those of the (OEP)Os(NO)(SCH$_2$-CH$_2$NHC(O)Me) product of eq. [4]. The FAB-MS of this compound shows ion fragments at *m*/*z* 870 (loss of the NO ligand) or at *m*/*z* 754 (loss of the thiol). The ^{1}H NMR spectrum of (OEP)Os(NO)(SC(Me)$_2$CH$_2$NHC(O)Me) is also similar to that of the product of eq. [4], with the notable exception of the presence of the peak at –2.08 ppm due to the -SC(C*H*$_3$)$_2$CH$_2$- protons.

Prior to this study, only one X-ray structural determination of a (por)Os(NO)(SR) complex had been reported in the literature, namely that of (TTP)Os(NO)(S-*i*-C_5H_{11}) (19). We were able to obtain single crystals of the (OEP)Os(NO)(SC(Me)$_2$CH$_2$NHC(O)Me) product suitable for X-ray crystallography. The molecular structure is shown in Fig. 1*a*, and the thiolate orientation and porphyrin atom displacements are shown in Figs. 1*b* and 1*c*, respectively.

Selected bond lengths and angles are listed in Table 2. The Os—N(O) and N—O bond lengths are 1.781(5) and 1.126(6) Å, respectively, and the Os-N-O bond is essentially linear with a bond angle of 176.8(5)°. The Os—N(por) bond lengths range from 2.060(4)–2.068(4) Å, which is within the 2.03–2.068 Å range observed for other structurally characterized Os^{II} porphyrins. The Os atom is displaced by 0.07 Å from the porphyrin plane towards the axial NO ligand, and porphyrin moiety exhibits a *ruffled* distortion (Fig. 1*c*). The axial Os—S distance is 2.415(2) Å, which is longer than the Os—S distances found in the only other structurally characterized osmium alkanethiolate complexes: 2.298(3)–2.323(3) Å

for $Os(SCH_2Ph)_2[(BA)_2en]$ (where $(BA)_2en$ is the bis(benzoylacetone) ethylenediimine dianion) (42), and 2.209(3) Å for (TTP)Os(NO)(S-*i*-C_5H_{11}) (19). The Os-S-C bond angle in (OEP)Os(NO)($SC(Me)_2CH_2NHC(O)Me$) is 121.8(2)°, which is larger than those observed in $Os(SCH_2Ph)_2[(BA)_2en]$ (107.8(4)–102.5(4)°) (42) and (TTP)Os(NO)(S-*i*-C_5H_{11}) (111.8(5)°) (19). The thiolate S—C37 bond essentially eclipses a porphyrin nitrogen, with the C37-S-Os-N2 torsion angle of 10.5(2)° (Fig. 1*b*). The thiolate Os-S-C37 angle is 121.8(2)°, and the corresponding S-C37-C40 angle is 113.8(4)°. The amide NH and C=O groups are in their usually favored *trans* arrangement (43), and the N6-C40-C37-S1 torsion angle is 52.8(6)°. The overall structure is similar to that seen for the ruthenium analogue reported earlier (20).

The molecular structure of the precursor $ONSC(Me)_2CH_2NHC(O)Me$ thionitrite is shown in Fig. 2, and selected bond lengths and angles are collected in Table 3.

Surprisingly, only three other RSNO solid-state structures have been reported in the literature, namely those of *S*-nitroso-*N*-acetylpenicillamine, Ph_3CSNO, and *S*-nitrosocaptopril (44–47). Their selected structural parameters are shown in Table 4, as are those for $ONSC(Me)_2CH_2NHC(O)Me$. The thionitrite functionality of $ONSC(Me)_2CH_2NHC(O)Me$ (Fig. 2) exists in an *anti* orientation, similar to that seen in *S*-nitroso-*N*-acetylpenicillamine and Ph_3CSNO. The N(7)-S(6)-C(5)-C(4) torsion angle is 66.65(12)°, whereas that of S(6)-C(5)-C(4)-N(3) is 54.10(17)°. Examination of the metrical parameters of $ONSC(Me)_2CH_2NHC(O)Me$ and those of its Os derivative (Fig. 1) reveal an expanded bond angle around the sulfur atom in the Os compound (121.8(2)°) relative to that in the free thionitrite (99.44(8)°). Furthermore, the amide C=O bond length of 1.232(2) Å in the free thionitrite is slightly longer than that in the Os derivative (1.196(9) Å), however, this may be a result of the moderate *inter*molecular C=O···HN hydrogen-bonding (48) observed in the crystal structure of the thionitrite (see *Supplementary material*).

Table 3. Selected bond lengths and angles for $ONSC(Me)_2CH_2NHC(O)Me$.

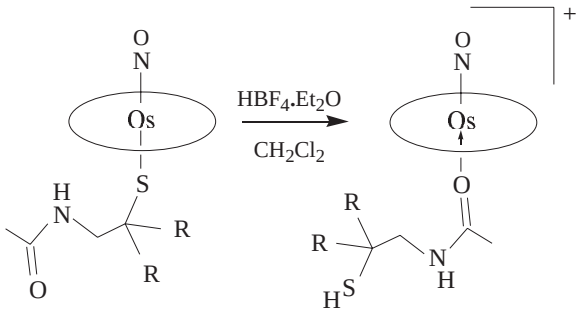
[a]This represents an interaction between adjacent molecules, and is the distance between the amide nitrogen and the carbonyl group of a different molecule.



Protonation reactions

We have recently demonstrated that osmium nitrosyl porphyrins containing alkoxide ligands can be readily protonated to give the corresponding cationic derivatives containing labile alcohol ligands (e.g., eq. [6]) (31).

[6] $$(OEP)Os(NO)(OEt) \xrightarrow{H^+} [(OEP)Os(NO)(HOEt)]^+$$

We were thus interested in extending this protonation chemistry to the related thiolate ligated complexes. In general, protonation of the amide-containing (OEP)Os(NO)($SC(R)_2CH_2NHC(O)Me$) complexes (R = H, CH_3) with tetrafluoroboric acid in CH_2Cl_2 results in the formation of the amide-bound derivative shown in eq. [7].

7

(R = H, Me)

For the case where R = H, the amide-bound $[(OEP)Os(NO)(O=C(Me)NHCH_2CH_2SH)]BF_4$ derivative was obtained in 78% yield (by ^1H NMR spectroscopy). Monitoring this reaction (R = H) by IR and ^1H NMR spectroscopy reveals the simultaneous formation of the (OEP)Os(NO)F compound, the latter presumably from fluoride abstraction from the tetrafluoroborate anion in $[(OEP)Os(NO)]BF_4$. We also obtained the elementally pure amide-bound cationic [(OEP)Os(NO)(O=C(Me)NH-

$CH_2CH_2SH)]BF_4$ product in 38% isolated yield from the sequential reaction of (OEP)Os(CO) with $NOBF_4$ (to produce $[(OEP)Os(NO)]BF_4$), followed by addition of the amide–thiol reagent. This cationic product of eq. [7] (R = H) is air-stable in the solid state. Its IR spectrum shows bands at 1814 and 1605 cm^{-1} (KBr) assigned to υ_{NO} and υ_{CO}, respectively. The υ_{NO} is 58 cm^{-1} higher than that of the neutral thiolate-bound precursor, consistent with less Os → NO back donation in this cationic complex. Furthermore, the shift in υ_{CO} of the coordinated amide–thiol ligand from 1642 cm^{-1} in the neutral precursor to 1605 cm^{-1} in the cationic derivative indicates a reduction in the C=O bond order in the cationic product complex, consistent with *O*-binding of the amide functional group. We have observed a similar IR spectral change in the related protonation reaction of $(OEP)Ru(NO)(SC(Me)_2CH_2NHC(O)Me)$, for which we were able to obtain X-ray crystal structures of both the thiolate-bound starting complex and the amide-bound product (20). The ^1H NMR spectrum of the cationic product of eq. [7] (R = H) shows that the SCH_2- and the amide N*H* peaks are shifted *downfield* from those of the coordinated thiolate in the precursor neutral complex (consistent with a placement of these groups further from the metal center). More striking is the upfield shift of the amide $C(CH_3) = O$ protons, indicative of an amide-bound form of the thiol ligand in the cationic product complex. The FAB-MS of this compound shows ion fragments at *m*/*z* 873 (loss of BF_4) or *m*/*z* 754 (loss of BF_4 and amide–thiol).

When R = CH_3 in eq. [7], the $[(OEP)Os(NO)(O=C(Me)NHCH_2C(Me)_2SH)]BF_4$ product is obtained in 67% yield (by ^1H NMR spectroscopy). The known fluoride (OEP)Os(NO)F compound (27) is the major by-product in this reaction. Not unexpectedly, we were also able to obtain this cationic product (in 46% isolated yield) from the reaction of in situ generated $[(OEP)Os(NO)]BF_4$ with the organic thiol. Similar by-products to those formed in the protonation reaction (eq. [7]) are also observed. This red compound is moderately air-stable in solution, showing signs of decomposition to the known (OEP)Os(NO)F complex in solution over a 1 week period. However, it is air-stable in the solid state. The υ_{NO} of the cationic product (as a KBr pellet) is 52 cm^{-1} higher than that of the neutral precursor. As was the case where R = H, the shift in υ_{CO} of the coordinated ligand from 1656 cm^{-1} in the neutral osmium thiolate precursor to 1594 cm^{-1} in the cationic derivative indicates a lowering of the C=O bond order in this amide-bound form of the thiol ligand in the cationic product complex. The ^1H NMR spectrum of this red compound (in $CDCl_3$) reveals that the $C(CH_3)$=O peak (at –2.98 ppm) is shifted by 4.21 ppm upfield from that of the thiolate precursor, a feature consistent with amide-binding to the metal center. We have not as yet been able to obtain suitable crystals of these cationic complexes for X-ray studies. We have also not been able to isolate or detect the putative thiol-bound $[(OEP)Os(NO)(HSR)]^+$ intermediates. Further studies to obtain stable thiol-bound derivatives are in progress.

Conclusion

In summary, we have prepared a new series of stable nitrosyl thiolate (OEP)Os(NO)(SR) complexes from (*i*) the formal *trans*-addition of thionitrites (RSNO) to the metal center in (OEP)Os(CO); or (*ii*) alkoxide–thiolate exchange reactions using (OEP)Os(NO)(OR) and the appropriate thiol. We have characterized these osmium nitrosyl thiolates by conventional spectroscopic techniques. Two such (OEP)Os(NO)(SR) complexes containing amide groups in the SR moieties have also been prepared. We have characterized, for the first time, a related pair of RSNO and (OEP)Os(NO)(SR) compounds by single-crystal X-ray crystallography. Protonation of the amide-containing thiolate complexes results in a net rearrangement of the protonated amide–thiol ligands to give the amide-bound cationic derivatives.

Pressure effects and solvent dynamics in the electrochemical kinetics of the tris(hexafluoroacetylacetonato)ruthenium(III)/(II) couple in nonaqueous solvents

Jinkui Zhou and Thomas W. Swaddle

Abstract: Rate constants and reactant diffusion coefficients for the $Ru(hfac)_3^{0/-}$ electrode reaction have been measured at 25°C as functions of pressure (0–200 MPa) in acetone, acetonitrile, methanol, and propylene carbonate. In sharp contrast to the negative volumes of activation $\Delta V_{ex}^{\ddagger}$ found for the corresponding bimolecular self-exchange reaction in organic solvents, the volumes of activation $\Delta V_{el}^{\ddagger}$ for the electrode reaction are markedly positive, ranging from 8 to 12 $cm^3\ mol^{-1}$. The volumes of activation $\Delta V_{diff}^{\ddagger}$ for reactant diffusion (which can be equated to the volume of activation $\Delta V_{visc}^{\ddagger}$ for viscous flow) range from 12 to 19 $cm^3\ mol^{-1}$. For the Debye solvents acetonitrile and acetone at least, $\Delta V_{el}^{\ddagger}$ is given within the experimental uncertainty by $\Delta V_{diff}^{\ddagger} + (\Delta V_{ex}^{\ddagger}/2)$. In this relation, the numerical value of $\Delta V_{diff}^{\ddagger}$ represents indirectly the dominant contribution of solvent dynamics (solvent friction) to $\Delta V_{el}^{\ddagger}$, and $\Delta V_{ex}^{\ddagger}/2$ represents the pressure dependence of the free-energy barrier height for the electrode reaction. It is proposed that solvent friction is important in nonaqueous electrode processes but not in the corresponding bimolecular self-exchange reactions because the free-energy activation barrier is twice as high in the latter.

Key words: electrode reaction kinetics, solvent dynamics, electron transfer mechanisms, pressure effects, volume of activation.

Résumé : On a mesuré les constantes de vitesse et les coefficients de diffusion des réactifs pour la réaction à l'électron du $Ru(hfac)_3^{0/-}$, à 25°C, en fonction de la pression (0–200 MPa), dans l'acétone, l'acétonitrile, le méthanol et le carbonate de propylène. En opposition avec les volumes négatifs observés pour les volumes d'activation, $\Delta V_{ex}^{\ddagger}$, de la réaction d'autoéchange bimoléculaire correspondante dans les solvants organiques, les volumes d'activation, $\Delta V_{el}^{\ddagger}$, pour la réaction à l'électrode sont très positifs, allant de 8 à 12 $cm^3\ mol^{-1}$. Les volumes d'activation, $\Delta V_{diff}^{\ddagger}$, pour la diffusion des réactifs (que l'on peut considérer comme égale au volume d'activation, $\Delta V_{visc}^{\ddagger}$, pour l'écoulement visqueux) vont de 12 à 19 $cm^3\ mol^{-1}$. Au moins pour les solvants de Debye, comme l'acétonitrile et l'acétone, $\Delta V_{el}^{\ddagger} = \Delta V_{diff}^{\ddagger} + (\Delta V_{ex}^{\ddagger}/2)$ aux erreurs expérimentales près. Dans cette équation, la valeur numérique de $\Delta V_{diff}^{\ddagger}$ représente indirectement la contribution dominante de la dynamique du solvant (friction du solvant) à $\Delta V_{el}^{\ddagger}$ alors que $\Delta V_{ex}^{\ddagger}/2$ représente la relation entre la pression et la hauteur de la barrière à l'énergie libre pour la réaction à l'électrode. On suggère que la friction du solvant est importante dans les processus non aqueux à l'électrode, mais qu'elle ne l'est pas dans les réactions correspondantes d'autoéchange bimoléculaire en raison du fait que, dans ce dernier cas, la barrière d'activation de l'énergie libre est deux fois plus élevée.

Mots clés : cinétique de la réaction à l'électrode, dynamique du solvant, mécanismes de transfert d'électron, effets de la pression, volume d'activation.

[Traduit par la Rédaction]

Introduction

It has recently been demonstrated (1–4) that, for transition-metal complex couples $ML_x^{z+/(z-1)}$ or $ML_x^{z-/(z+1)-}$ *in aqueous solutions*, a close proportionality exists between the volume of activation $\Delta V_{el}^{\ddagger}$ for the electrode reaction ($= -RT(\partial \ln k_{el}/\partial P)_T$, where k_{el} is the standard electrode reaction rate constant at zero driving force) and the corresponding parameter $\Delta V_{ex}^{\ddagger}$ for the bimolecular self-exchange reaction:

$$[1] \qquad \Delta V_{el}^{\ddagger} = (0.50 \pm 0.02)\Delta V_{ex}^{\ddagger}$$

This empirical observation, which is consistent with the corresponding relationship proposed by Marcus (5) for the free energies of activation

[2] $\Delta G_{el}^{\ddagger} = \Delta G_{ex}^{\ddagger}/2$

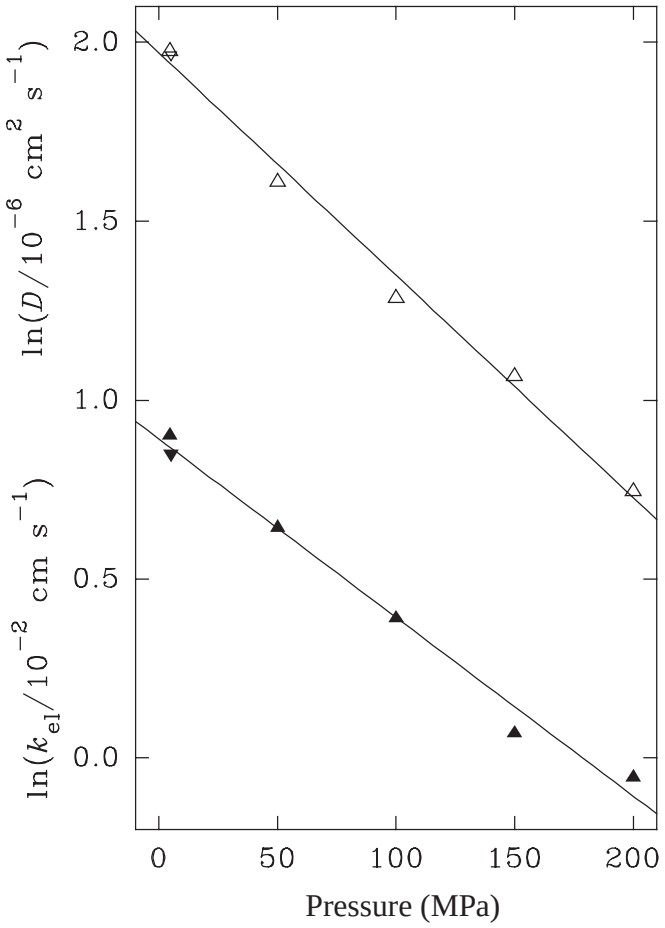
holds with remarkable accuracy for all 15 couples tested to date, regardless of charge type,[2] and we therefore refer to it for convenience as the "50% rule". In the absence of complicating factors such as spin-state preequilibria (6) or catalysis by the counterions (7), $\Delta V_{ex}^{\ddagger}$ can be accounted for quantitatively (8) in terms of transition-state theory (TST) by an extension of Marcus' theory of adiabatic outer-sphere electron transfer reactions (9). The success of these calculations of $\Delta V_{ex}^{\ddagger}$ implies that, for couples in *aqueous* solution at least, $\Delta V_{el}^{\ddagger}$ can be also be accounted for theoretically.

The present paper addresses the question how $\Delta V_{el}^{\ddagger}$ relates to $\Delta V_{ex}^{\ddagger}$ in solvents *other than* water. As a first step in this direction, we recently examined the effects of pressure on the electrode kinetics of the $Co(bpy)_3^{3+/2+}$ couple in nonaqueous solvents as well as water (10)[3]. That choice was prompted by the discovery by Murray and co-workers (11, 12) that the electrode reaction rate constant k_{el} for $Co(bpy)_3^{3+/2+}$ in various organic solvents was proportional to the mean physical diffusion coefficient D of the complex ions and consequently (in accordance with the Stokes–Einstein relation — see below) inversely proportional to the viscosity η of the solvent over some 11 orders of magnitude. A marked viscosity dependence of the rate constant for any reaction that is plainly not diffusion-controlled is generally taken as evidence for control of the reaction rate by solvent dynamics (solvent "friction") (13–18). The relevant parameter is actually the longitudinal relaxation time τ_L of the solvent (19–27), but, for Debye solvents at least (i.e., ones in which dielectric relaxation can be modeled in terms of single spherical molecules rotating in a continuous viscous medium), η is usually proportional to τ_L.

These observations invite complementary variable-pressure kinetic studies, which have the advantage that the relevant nonaqueous solvent properties — notably η, but also the static dielectric constant ε_s and the optical dielectric constant ε_{op} ($\approx n^2$, where n is the refractive index) — can be "tuned" by varying the pressure for any one solvent individually without changing its chemical identity (10, 18). In particular, the assumption of a proportionality between η and τ_L is safer in pressure-tuning of a single solvent than in comparisons between solvents (18). Furthermore, because η is effectively *exponentially dependent* on pressure P over the first few hundred MPa for typical nonaqueous solvents but *almost independent* of P for water at near- or subambient temperatures (10), solvent dynamics in nonaqueous media can be expected to make a strongly positive contribution to $\Delta V_{el}^{\ddagger}$ in nonaqueous solvents but *none at all* in water at near-ambient temperatures. Thus, in organic solvents (but not in water), solvent dynamics, if rate-controlling, will make a large, positive contribution to $\Delta V_{el}^{\ddagger}$ that may overwhelm the moderately negative activation barrier height contribution expected from TST (10). Indeed, if solvent friction leads to a complete breakdown of TST, $\Delta V_{el}^{\ddagger}$ may be governed exclusively by the pressure dependence of τ_L (in effect, of η).

As anticipated, the observed $\Delta V_{el}^{\ddagger}$ values for $Co(bpy)_3^{3+/2+}$ in acetone, acetonitrile, and propylene carbonate turned out to be strongly positive (9–12 $cm^3\ mol^{-1}$, contrast –9 $cm^3\ mol^{-1}$ for water). The negative value of $\Delta V_{el}^{\ddagger}$ for *aqueous* $Co(bpy)_3^{3+/2+}$ is very similar to those found for $Co(en)_3^{3+/2+}$ and $Co(phen)_3^{3+/2+}$ (2) and can be accounted for theoretically (8), but it is not clear whether it implies that solvent friction is absent or simply that the near-independence of η on P for water fails to reveal it; in either case, $\Delta V_{el}^{\ddagger}$ in water can be equated with $\Delta V_{el(TST)}^{\ddagger}$. In any event, the difference in sign between $\Delta V_{el}^{\ddagger}$ in water and in nonaqueous media for the $Co(bpy)_3^{3+/2+}$ electrode reaction is a strong indication of solvent dynamical control of the reaction rate.

There remains, however, the possibility that association of $Co(bpy)_3^{2+}$ and particularly $Co(bpy)_3^{3+}$ with the supporting anions, which is expected to be of minor importance in water but dominant in typical organic solvents, could be responsible for the sharp contrast between the negative $\Delta V_{el}^{\ddagger}$ in water and the strongly positive $\Delta V_{el}^{\ddagger}$ in nonaqueous media. Indeed, the only known cases of positive $\Delta V_{el}^{\ddagger}$ or $\Delta V_{ex}^{\ddagger}$ for outer-sphere electron transfer reactions in water involve strong catalysis of anion–anion electron transfer by the counterions (cations) (3, 7). There is, however, no evidence for a comparable involvement of anions in cation-cation reactions, and furthermore Pyati and Murray (11) argue persuasively against ion pairing as a major contributor to the observed correlations of k_{el} for $Co(bpy)_3^{3+/2+}$ with D and η^{-1}. Nevertheless, the possibility of ion association introduces uncertainties into any analysis of $\Delta V_{el}^{\ddagger}$ data. A further limitation with respect to testing the 50% rule with $Co(bpy)_3^{3+/2+}$ is the absence of directly determined $\Delta V_{ex}^{\ddagger}$ values for this couple in any solvent (8).



We have therefore turned our attention to the effects of pressure on the kinetics of electron transfer of the $Ru^{III}(hfac)_3/Ru^{II}(hfac)_3^-$ couple (28–31)[3] in polar organic solvents at an electrode, since $\Delta V_{ex}^{\ddagger}$ values are available for this couple in four organic solvents (29) and because ion pairing of the supporting electrolyte will not occur with the uncharged complex $Ru^{III}(hfac)_3$ and is expected to be minimal for $Ru^{II}(hfac)_3^-$ (indeed, Weaver and co-workers (32) found that ion pairing had only minor effects on the kinetics of the $Fe(\eta^5\text{-}C_5H_5)_2^{+/0}$ self-exchange in polar nonaqueous solvents). Furthermore, any effects of double-layer structure on electrode kinetics should be minimal for a neutral/low-charge couple (13). Similarly, Bjerrum–Brønsted–Christiansen theory predicts an absence of ionic strength effects on kinetics of reactions involving a zero-charged reactant, and coulombic work contributions to $\Delta V_{ex}^{\ddagger}$ and $\Delta V_{el}^{\ddagger}$ will also be effectively zero (8). Thus, since the contribution of internal reorganization is also expected to be very small (0 to +1 $cm^3\ mol^{-1}$), the theoretical $\Delta V_{ex(TST)}^{\ddagger}$ is given by the solvent reorganizational term $\Delta V_{SR}^{\ddagger}$ within the experimental uncertainty (29, 30). Values of $\Delta V_{ex}^{\ddagger}$ for the $Ru(hfac)_3^{0/-}$ self-

[2] The largest discrepancy in $\Delta V_{el}^{\ddagger}$ as predicted by eq. [1] was 1.7 $cm^3\ mol^{-1}$ for the diaminosarcophaginecobalt(III/II) couple $Co(diamsar)^{3+/2+}$ (6), which was also the only couple for which the measured electrochemical transfer coefficient α (= 0.27) deviated substantially from the ideal value of 0.5. In no other case did the discrepancy in $\Delta V_{el}^{\ddagger}$ exceed 1.0 $cm^3\ mol^{-1}$.

Fig. 1. Pressure dependences of the mean diffusion coefficient D ((△) ascending pressure, (▽) descending pressure) and electrode reaction rate constant k_{el} ((▲) ascending pressure, (▼) descending pressure) at 25.0°C for $Ru(hfac)_3^{0/-}$ ([Ru] = 2.25 mmol L^{-1}) in acetone containing 0.2 mol L^{-1} $[Bu_4N]PF_6$.

exchange reaction in methanol, acetonitrile, and acetone conform well to predictions based on TST (for chloroform, predictions are unrealistic because ε_s is too low) (30). Finally, there are no indications of solvent dynamical effects in this self-exchange reaction (28–31) or any other homogeneous self-exchange reaction for which $\Delta V_{ex}^{\ddagger}$ data are available (33), so that the experimental $\Delta V_{ex}^{\ddagger}$ can be identified with $\Delta V_{ex(TST)}^{\ddagger}$.

We show below that the experimental $\Delta V_{el}^{\ddagger}$ values for $Ru(hfac)_3^{0/-}$ turn out to be strongly positive, in contrast to the $\Delta V_{ex}^{\ddagger}$ values which are all negative (29). Unfortunately, the scope of our study was limited by the poor solubility of $Ru^{III}(hfac)_3$ in many solvents (notably water) and unsatisfactory electrochemical behavior in others (such as *N*,*N*-dimethylformamide). Of the four tractable solvent systems, methanol and propylene carbonate (PC) are non-Debye liquids and consequently pose difficulties in theoretical interpretation (13). Nevertheless, the positive $\Delta V_{el}^{\ddagger}$ observed for all these solvents are consistent with a substantial measure of rate control by solvent dynamics.

Experimental section

Materials

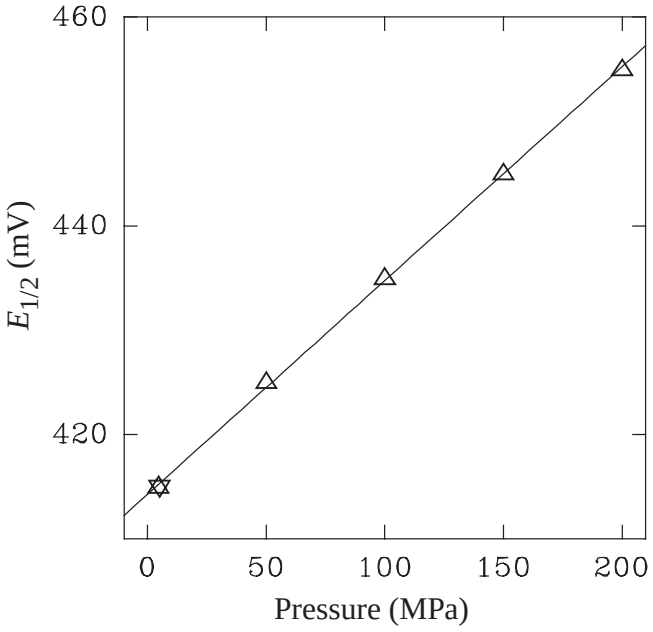
Acetonitrile (BDH, ACS Assured) was distilled three times. Acetone (EM Science, Omnisolv spectroscopic grade) was dried and distilled over $CaSO_4$ twice. Methanol (BDH, ACS Assured) was purified by refluxing over Mg for several hours, and then distilled. These solvents were stored over 4A molecular sieves. Propylene carbonate (Aldrich, Gold Label, sealed under N_2), tris(hexafluoroacetylacetonato)-ruthenium(III) (Strem), and tetrabutylammonium perchlorate and hexafluorophosphate (Fluka, puriss. electrochemical grade) were used as received.

Electrochemical measurements

Cyclic voltammetry (CV) and alternating current voltammetry (ACV) were carried out at 25.0 ± 0.1°C over ~50 MPa intervals, 0–200 MPa, as described previously (1–4, 10) with solutions containing 2.0–3.5 mmol L^{-1} $Ru(hfac)_3$ and 0.2 mol L^{-1} supporting electrolyte.[4] Solution samples were made up under dry N_2, placed in the three-electrode cell within the thermostated pressure vessel, and then purged with solvent-saturated N_2 for at least 40 min before the cell was closed. The working and counter electrodes were of Pt or Au wire (⌀ 0.5 mm). Results with Pt and Au electrodes were similar, but Pt gave better consistency and was used preferentially in the pressure experiments. The reference electrode was a silver rod in contact with a solution of 0.01 mol L^{-1} $AgClO_4$ and 0.2 mol L^{-1} Bu_4NClO_4 in CH_3CN. As the electrode reaction rates were rather low and decreased with rising pressure, the imposed AC frequency f was varied only between 25 and 45 Hz. Since the expression

$$[3] \qquad E_{max} = E_{1/2} + (RT/F) \ln [\alpha/(1 - \alpha)]$$

where E_{max} is the ACV peak potential and $E_{1/2}$ is the half-wave potential from the CVs, showed the transfer coefficient α to be 0.5 in all cases, the simplified relation



$$[4] \qquad \cot \phi = 1 + (D\omega/2)^{1/2}/k_{el}$$

where ϕ is the phase angle (corrected for the uncompensated resistance R_u) and $\omega = 2\pi f$, was used to calculate k_{el} (2, 10). R_u was measured directly at a relatively high frequency (8 kHz) and a potential at least 300 mV removed from $E_{1/2}$ (see *Supplementary information*). As expected for organic solvents, R_u was fairly high and increased markedly with rising pressure, especially for PC,[3] but the R_u values measured directly at each pressure were specifically used in calculating k_{el} as described previously (10). Thus, the k_{el} values and pressure dependence parameters reported here are not artifacts arising from R_u (cf. the concerns expressed by Weaver (19)). The useful range of f, though narrow, was sufficient to establish the linearity of the cot ϕ vs. $\sqrt{f}$ plots and to extract an average value of k_{el} (10). Only those cycles of variable-pressure measurements for which the initial and final low-pressure data agreed within the experimental uncertainty were accepted.

[4] Concentrations specified in this article are temperature- and pressure-independent, expressed as if at 22°C and 0.1 MPa.

Fig. 2. Pressure dependence of the half-wave potential $E_{1/2}$ ((△) ascending pressure, (▽) descending pressure) at 25.0°C for $Ru(hfac)_3^{0/-}$ ([Ru] = 2.25 mmol L^{-1}) in acetone containing 0.2 mol L^{-1} $[Bu_4N]PF_6$.

Results

Figures 1 and 2 show a sample set of pressure dependences of ln D, ln k_{el}, and $E_{1/2}$ for acetone as solvent; full details for all four solvents used are given in the *Supporting information*. The reaction volume ΔV_{cell} for $Ru(hfac)_3^{0/-}$ relative to Ag/Ag^+ ($= -F(\partial E_{1/2}/\partial P)_T$, where F is the faraday), the volume of activation $\Delta V_{diff}^{\ddagger}$ ($= -RT(\partial \ln D/\partial P)_T$) for diffusion of the reactants, and $\Delta V_{el}^{\ddagger}$ all appeared to be pressure-independent for a particular solvent over the experimental range (0–200 MPa) within the experimental uncertainty. Nevertheless, a small secondary dependence on pressure may be concealed (8), so that the values in Table 1 should be regarded as averages valid at 100 MPa, the midpoint of the pressure range. The derived electrochemical parameters are given in Table 1. To obtain optimal ACV measurements, it was necessary to adjust the electrode reaction rates by changing the identity or concentration of the supporting electrolyte between solvents, so that the k_{el} or ΔV_{cell} values given in Table 1 should not be directly compared. Fortunately, the pressure-dependence parameters are expected from past experience (34) to be rather insensitive to the nature or concentration of the supporting electrolyte in polar solvents such as those used in the present study. The lack of freedom of choice of supporting electrolyte precluded testing for ion pairing with the reactants, but in the $Ru(hfac)_3^{0/-}$ couple ion pairing is possible only for the reduced partner, and should be minimal in view of the large size and low charge of this anion (cf. Weaver and co-workers (32)). The values of k_{el} for $Ru(hfac)_3^{0/-}$ at the Pt electrode at atmospheric pressure are rather low, and may be compared with k_{el} = 0.015 cm s^{-1} reported by Weaver et al. (31) for the same couple at an annealed gold electrode in CH_3CN containing 0.1 mol L^{-1} tetraethylammonium perchlorate.

Discussion

A salient feature of the results in Table 1 is the sharp contrast between the moderately negative experimental values of the activation volumes for the $Ru(hfac)_3^{0/-}$ self-exchange reaction ($\Delta V_{ex}^{\ddagger}$ ~ –6 cm^3 mol^{-1}) and the strongly positive values for the electrode reaction ($\Delta V_{el}^{\ddagger}$ ~ +8 to +12 cm^3 mol^{-1}) in the same organic solvents. A rough correlation (but not equality) between $\Delta V_{el}^{\ddagger}$ and the activation volume $\Delta V_{diff}^{\ddagger}$ for the diffusion of the reactants is also clearly evident. We argue below that these facts indicate that the 50% rule (eq. [1]) does in fact hold for the solvents used here, but that its effect is swamped by a strongly positive contribution to $\Delta V_{el}^{\ddagger}$ from solvent dynamics, just as for the $Co(bpy)_3^{3+/2+}$ systems (10, 11, 12) but independently of any ion association effects that may have been present in the latter.

Solvent properties can affect the rate constant k for an electron transfer reaction directly in two principal ways. The first is through a contribution to the activation *barrier height*, represented by free energy of activation $\Delta G^{\ddagger}$ which comprises internal and solvent reorganizational components ($\Delta G_{IR}^{\ddagger}$ and $\Delta G_{SR}^{\ddagger}$, respectively):

$$[5] \qquad k = K_{prec}\kappa\nu_n\exp(-\Delta G^{\ddagger}/RT)$$

Here, κ is the electronic transmission coefficient (κ = 1 for adiabatic electron transfer) and ν_n the nuclear frequency factor, whereas K_{prec} is the equilibrium constant for assembly of a precursor state and effectively includes any coulombic work and medium (Debye–Hückel) terms (9). The second (solvent dynamical) way is through the influence of the *motions* of the solvent molecules on the electron transfer process, which can affect the *barrier crossing frequency* and hence influence k through ν_n. In an early paper, Kramers (35) treated the contribution of solvent dynamics to barrier climbing in the manner of a one-dimensional coupling of the Brownian motion to the reaction coordinate, an approach that has been further developed by others, notably Grote and Hynes (36). An alternative approach, originated by Agmon and Hopfield (37, 38) and developed first by Marcus and Sumi (39, 40) and Nadler and Marcus (41), and later by Basilevsky et al. (42, 43), treats the activation process in terms of a two-dimensional free energy surface with diffusive solvent motions represented along one coordinate and a low-frequency intramolecular vibration of the reactants along the other (21).

Following the Kramers–Grote–Hynes approach for the limiting case of adiabatic electron transfer in Debye liquids with a negligibly small $\Delta G_{IR}^{\ddagger}$ (10–17, 19–27), we have

$$[6] \qquad \nu_n = \tau_L^{-1}(\Delta G_{SR}^{\ddagger}/4\pi RT)^{1/2}$$

(Cases in which $\Delta G_{IR}^{\ddagger}$ is not negligible can be treated with the Sumi–Marcus theory (39, 40), considered below.) If the solvent behaves as a Debye liquid of Debye relaxation time τ_D, and V_M is the effective hard-sphere molar volume of the solvent molecules, τ_L can be obtained (at least approximately) (10–15, 23, 24, 27, 44) from

$$[7] \qquad \tau_L^{-1} = (\varepsilon_s/\varepsilon_{op})\tau_D^{-1} = (\varepsilon_s/\varepsilon_{op})RT/3V_M\eta$$

Here, η is properly the microscopic viscosity, but may be identified with the bulk viscosity of the solvent for our purposes. For a given reaction in different solvents, or (as in this work) in the same solvent over a range of pressure, the

[j]Calculated from eq. [13].

dominant variable is η, and so in the simplest treatment we have

$$[8] \qquad \ln k \propto \ln k_{TST} - \ln \eta$$

From this follows an expression for the volume of activation $\Delta V^{\ddagger}$ for any reaction subject to Kramers–Grote–Hynes solvent dynamics:

$$[9] \qquad \Delta V^{\ddagger} = -RT(\partial \ln k/\partial P)_T = \Delta V_{TST}^{\ddagger} + RT(\partial \ln \eta/\partial P)_T = \Delta V_{TST}^{\ddagger} + \Delta V_{visc}^{\ddagger}$$

Literature values exist for the volume of activation $\Delta V_{visc}^{\ddagger}$ for viscous flow of acetonitrile (45), acetone (46), and methanol (46, 47) but are not entirely appropriate for the pressure range, temperature, and supporting electrolyte concentrations of our experiments. However, the Stokes–Einstein relation

$$[10] \qquad D = k_B T/C\pi a\eta$$

where a is the pressure-independent hydrodynamic radius, D is the mean diffusion coefficient of the reactant, and C is a constant (usually taken to be 6), allows us to substitute the volume of activation $\Delta V_{diff}^{\ddagger}$ for reactant diffusion (= $-RT(\partial \ln D/\partial P)_T$) for $\Delta V_{visc}^{\ddagger}$. Values of $\Delta V_{diff}^{\ddagger}$ are easily and accurately calculable from the variable-pressure CVs routinely obtained as a prerequisite for the ACV measurements (10), and have the advantage that they refer specifically to interactions between $Ru(hfac)_3^{0/-}$ and the solvent and (or) electrolyte of interest. Thus, we have

$$[11] \qquad \Delta V^{\ddagger} = \Delta V_{diff}^{\ddagger} + \Delta V_{TST}^{\ddagger}$$

or, more precisely from eqs. [6]–[10],

$$[12] \qquad \Delta V^{\ddagger} = \Delta V_{diff}^{\ddagger} + \Delta V_{TST}^{\ddagger} + Q$$

where $Q = -RT[(\partial \ln \varepsilon_s/\partial P)_T - 2(\partial \ln n/\partial P)_T + \Delta V_{SR}^{\ddagger}/2\Delta G_{SR}^{\ddagger}]$.

The solvent reorganizational terms $\Delta V_{SR}^{\ddagger}$ and $\Delta G_{SR}^{\ddagger}$ can be calculated as described elsewhere (8). If eqs. [1] and [2] apply, Q will be the same for self-exchange and electrode reactions, but in any case Q typically turns out to be small (Table 1). For the case where $\Delta G_{IR}^{\ddagger}$ is not negligible relative to $\Delta G_{SR}^{\ddagger}$ (we estimate $\Delta G_{IR}^{\ddagger}$ ~ 8.0 kJ mol^{-1} for the $Ru(hfac)_3^{0/-}$ self-exchange, cf. $\Delta G_{SR}^{\ddagger}$ ~ 8.5, 9.2, and 9.3 kJ mol^{-1} in acetone, acetonitrile and methanol respectively at 25°C and 0.1 MPa (31)), Q may be replaced by an analogous parameter Q' obtained by differentiation of eqs. [8.6] and [8.7] of ref. 39 with respect to pressure. It turns out that Q and Q' are the same within the experimental uncertainty — in other words, eq. [12] holds regardless of whether the internal reorganization barrier is negligible.

The strongly positive $\Delta V_{diff}^{\ddagger}$ and negative $\Delta V_{ex}^{\ddagger}$ values of Table 1 show that solvent dynamical effects on the *self-exchange* reaction kinetics are either minor or absent — the latter case is very likely because $\Delta V_{ex}^{\ddagger}$ for the $Ru(hfac)_3^{0/-}$ couple in CH_3CN, $(CH_3)_2CO$, and CH_3OH is accounted for fully by TST (29, 30). By the same token, however, the positive $\Delta V_{el}^{\ddagger}$ values imply that the electrode reaction is strongly influenced by solvent dynamics. Furthermore, for the Debye solvents acetonitrile and acetone at least, eq. [13] holds within the experimental uncertainty:

$$[13] \qquad \Delta V_{el}^{\ddagger} = \Delta V_{diff}^{\ddagger} + 0.5\Delta V_{ex}^{\ddagger} + Q$$

Comparison with eq. [12] indicates that, for the electrode reactions, $\Delta V_{TST}^{\ddagger}$ is given by $0.5\Delta V_{ex}^{\ddagger}$, i.e., that the 50% rule (eq. [1]) does in fact hold for nonaqueous solvents but the barrier-height contribution to $\Delta V_{el}^{\ddagger}$ is swamped by the pressure dependence of solvent friction.

Equation [13] is not expected to apply with methanol as solvent because of substantial hydrogen-bonding, in which case several solvent frequencies may contribute to the effective longitudinal relaxation time τ_L^{eff} leading to a non-Debye response (22, 48). Furthermore, although the Stokes–Einstein relation (eq. [10]) is valid for methanol, increasing the pressure in the range 0–400 MPa causes a shift from near the "sticking" boundary condition (C = 6.0) toward the "slipping" limit (C = 4.0) as pressure breaks up the methanol dimers

© 2001 NRC Canada

(49). This complication is absent in the cases of acetone and acetonitrile (50, 51). Not surprisingly, then, the agreement between the experimental $\Delta V_{el}^{\ddagger}$ and the prediction of eq. [13] for methanol is less close than for acetone and acetonitrile, yet it is better than might be expected, perhaps because of partial cancellation of the complicating factors. Unfortunately, $\Delta V_{ex}^{\ddagger}$ is not available for propylene carbonate, which in any event is a non-Debye solvent (13, 48).

The foregoing Kramers–Grote–Hynes-type treatment assumes that electron transfer in $Ru(hfac)_3^{0/-}$ at the electrode is adiabatic, i.e., that electronic coupling is sufficiently strong that solvent dynamics emerge as the rate-controlling factor. Certainly, the self-exchange reaction is as fast as other couples with low internal reorganization barriers (e.g., $Fe(phen)_3^{3+/2+}$ (33)), and the fact that $\Delta V_{ex}^{\ddagger}$ is accurately accounted for by the adiabatic TST model militates against significant nonadiabaticity which is expected to lead to anomalously negative $\Delta V_{ex}^{\ddagger}$ values (33). The $Ru(hfac)_3^{0/-}$ electrode reaction, however, is relatively slow (e.g., five times slower than the $Co(bpy)_3^{3+/2+}$ electrode reaction in CH_3CN, despite the greater $\Delta G_{IR}^{\ddagger}$ expected for the Co couple), and Weaver et al. (31) have proposed that it may be significantly nonadiabatic, i.e., that the electronic transmission coefficient κ may be substantially smaller than 1. This is unexpected, inasmuch as electrode reactions are ordinarily more fully adiabatic than the corresponding bimolecular self-exchange reactions, and in the case of $Ru(hfac)_3^{0/-}$ the latter appears to be adiabatic in nonaqueous solvents (29, 30). According to the Nadler–Marcus treatment (41) and experimental observations by McGuire and McLendon (52), the dependence of ν_n on τ_L can be more generally expressed as $\nu_n \propto \tau_L^{-\theta}$, where θ ranges from 1 when electron transfer is fully adiabatic and solvent coupling determines ν_n (cf. eq. [7]), to 0 for highly nonadiabatic cases where electronic coupling is completely dominant (21, 23, 24, 41, 52). For Debye solvents, eq. [13] can therefore be rewritten thus:

$$[14] \quad \Delta V_{el}^{\ddagger} = \theta[RT(\partial \ln \eta/\partial P)_T + Q] + \Delta V_{TST}^{\ddagger} = \theta(\Delta V_{diff}^{\ddagger} + Q) + (\Delta V_{ex}^{\ddagger}/2)$$

Here, $\Delta V_{TST}^{\ddagger}$ refers to the nonadiabatic case ($\kappa << 1$). The data of Table 1, however, suggest that $\theta \sim 0.87$–1.0, consistent with a high degree of adiabaticity of the $Ru(hfac)_3^{0/-}$ electrode reaction. Even if the contribution of $\Delta V_{TST}^{\ddagger}$ is simply ignored, $\theta \sim 0.6$–0.8, again suggesting only a small departure from adiabaticity.

If, however, we accept the conclusion of Weaver et al. (31) that the $Ru(hfac)_3^{0/-}$ electrode reaction is significantly nonadiabatic, we can estimate the contribution $\Delta V_{NA}^{\ddagger}$ of nonadiabaticity to $\Delta V_{el}^{\ddagger}$, as the electronic transmission coefficient κ_{el}, which depends on the electrode-reactant separation σ, will then approach 1 more closely as the pressure is increased (i.e., $\Delta V_{NA}^{\ddagger}$ will be *negative*) (53). This presupposes a Sutin model in which electron transfer occurs over a compressible reaction zone of thickness $\delta\sigma$ (nominally ~100 pm) rather than on hard contact (for which $\Delta V_{NA}^{\ddagger}$ would be 0), so that σ is pressure sensitive (54).

$$[15] \quad \kappa_{el} = \kappa_{el}^0 \exp[-\alpha(\sigma - \sigma^0)]$$

$$[16] \quad \Delta V_{NA}^{\ddagger} = -RT(\partial \ln \kappa_{el}/\partial P)_T = -\alpha\beta\sigma RT/3$$

In eqs. [15] and [16], κ_{el}^0 is the value of κ_{el} at the pressure-independent closest approach distance σ^0, β is the isothermal compressibility of the solvent, and the distance scaling factor α may be assumed to be about 16 nm^{-1} (54). For acetonitrile, acetone, and methanol, β is on the order of 6×10^{-10} Pa^{-1} at 25°C and the midrange pressure of 100 MPa (53). Taking the effective radius of $Ru(hfac)_3$ to be ~500 pm (so that $\sigma \sim 500$–600 pm), we find that $\Delta V_{NA}^{\ddagger}$ should not be more negative than about –5 $cm^3\ mol^{-1}$.

Thus, any contribution to $\Delta V_{el}^{\ddagger}$ from nonadiabaticity will be moderate in magnitude and *negative*, whereas our task is to explain why substantially *positive* values of $\Delta V_{el}^{\ddagger}$ are observed in nonaqueous media. In other words, any contribution of nonadiabaticity to $\Delta V_{el}^{\ddagger}$ would be far outweighed by that of solvent dynamics. The conflict between the conclusions of Weaver et al. (31) and the present findings may reflect difficulties inherent in making comparisons of electrochemical kinetics in chemically different solvents, a problem that the pressure-tuning approach circumvents.

Conclusions

An unequivocal result that emerges from the data of Table 1 is that the volumes of activation for the $Ru(hfac)_3^{0/-}$ electrode reaction in organic solvents are *all positive*, whereas for the corresponding parameters for self-exchange reactions are *all negative*. This is traceable to dependence of the electrode reaction rates on the organic solvent viscosities (which increase exponentially with pressure) because no such dichotomy in the direction of pressure effects on electrode and self-exchange reaction rates occurs in water (the viscosity of which is effectively independent of pressure at near-ambient temperatures). The viscosity-related pressure effect on nonaqueous electrode kinetics is attributable to the incursion of solvent friction; no such solvent dynamical influences are discernible in the homogeneous self-exchange reaction.

The numerical values of $\Delta V_{el}^{\ddagger}$ can be adequately accounted for by either the Kramers–Grote–Hynes or the Agmon–Hopfield–Sumi–Marcus approaches, at least for Debye solvents such as acetone and acetonitrile and surprisingly well for the non-Debye solvent methanol. The 50% rule (eq. [1]) appears still to be valid for nonaqueous solvents if the overwhelming solvent dynamical contributions to $\Delta V_{el}^{\ddagger}$ are taken into account.

It remains to be explained why solvent dynamics are manifest in electrode reactions but not self-exchange electron transfer, in nonaqueous systems (10). Equation [2] implies that $\Delta G^{\ddagger}$ for an electrode reaction is just one-half that for the corresponding self-exchange in homogeneous solution. In the case of $Ru(hfac)_3^{0/-}$ in the organic solvents considered here, the electrode reaction will therefore be over 1000-fold faster (on a common pseudo-first-order basis) than the already quite rapid self-exchange reaction on the basis of eq. [2] alone. Consequently, although the activation barrier height is kinetically dominant in bimolecular electron exchange, solvent dynamical control of barrier crossing can emerge in the electrode reaction.

The pressure dependence of rate constants in *aqueous* electron transfer reactions is not diagnostic of solvent friction at near-ambient temperatures because η for water is essentially independent of pressures on the order of 0–

200 MPa (10). It is possible, however, that electrode reactions in water may not be subject to solvent dynamical influences in the manner described above because of the extensive solvent–solvent hydrogen bonding and occurrence of ultrafast relaxation modes that are unique to water (55–57). Indeed, we have noted (10) that there appears to be an unidentified mechanistic difference between the electrode reactions of $Co(bpy)_3^{3+/2+}$ in organic solvents (where solvent friction is evidently dominant) and in water. Unfortunately, experimental comparison of organic and aqueous solutions is not possible for the $Ru(hfac)_3^{0/-}$ electrode reaction because of the insolubility of $Ru^{III}(hfac)_3$ in water.

Kinetic modeling of homogeneous methanol synthesis catalyzed by base-promoted nickel complexes

Devinder Mahajan, Viwat Krisdhasima, and Robert D. Sproull

Abstract: Nickel complexes promoted by alkoxide bases can affect facile conversion of synthesis gas into methanol under thermodynamically favorable temperatures. At 100°C, syngas conversion of 99% with turnover frequency of 66 h^{-1} is reported. The reaction is truly catalytic in Ni as well as in base. A kinetic study of the $Ni(CO)_4$–KOMe catalyst system in 1,2-bis(2-methoxy ethoxy)ethane (triglyme)–MeOH solvent mixture is presented. The kinetic expression includes terms of zero-order in H_2 and first-order in CO with syngas of H_2–CO stoichiometry of ~2:1 and less than first-order in Ni (0.03–0.10 M), ~third-order in base (2.0–4.75 M), and an exponential dependence on methanol concentration (13.0–23.7 M at 2.0 M base; 15.8–22.6 M at 3.0 M base). The activation energy of 42.2 kJ mol^{-1} was estimated from the Arrhenius plot of the data between 374 and 393 K. Gas phase IR spectrum at the end of each run showed an intense signature peak at 2060 cm^{-1} for $Ni(CO)_4$. Process uncertainties to commercialization of this versatile homogenous catalyst system for CO hydrogenation to methanol are discussed.

Key words: homogeneous catalysis, syngas conversion, methanol synthesis, alkoxides, carbonyls of nickel.

Résumé : Des complexes de nickel activés par des bases de type alcoolate peuvent effectuer facilement la conversion du gaz de synthèse en méthanol, dans des conditions de température thermodynamiquement favorables. À 100°C, on observe une conversion à 99% du gaz de synthèse avec une fréquence de renouvellement de 66 h^{-1}. La réaction est vraiment catalytique tant en Ni qu'en base. On présente les résultats d'une étude cinétique du système $Ni(CO)_4$–KOMe dans un mélange de solvant 1,2-bis(2-méthoxyéthoxy)éthane (triglyme)–MeOH. L'expression cinétique comprend des termes d'ordre zéro en H_2 et du premier ordre en CO dans le gaz de synthèse de stoechiométrie H_2–CO d'environ 2:1, d'ordre inférieur à l'unité en Ni (0,03 à 0,10 M), du troisième ordre en base (2,0 à 4,75 M) et une dépendance exponentielle sur la concentration de méthanol (13,0 à 23,7 M à 2,0 M en base; 15,8 à 22,6 M à 3,0 M en base). On a évalué une énergie d'activation de 42,2 kJ mol^{-1} à l'aide d'une courbe d'Arrhenius des données entre 374 et 393 K. Les spectres infrarouges en phase gazeuse des produits à la fin de chaque réaction montrent tous une bande signature intense à 2060 cm^{-1} pour le $Ni(CO)_4$. On discute des incertitudes qui entourent les possibilités de commercialisation de ce système versatile de catalyseur homogène pour l'hydrogénation du CO en méthanol.

Mots clés : catalyse homogène, conversion du gaz de synthèse, synthèse du méthanol, alcoolates, carbonyls de nickel.

[Traduit par la Rédaction]

Introduction

A vast amount of natural gas is stranded in remote locations and economical transport of this clean fuel is highly desirable. Methanol and Fischer–Tropsch (F–T) hydrocarbons are considered shippable liquids that can be produced at remote locations from natural gas-derived synthesis gas (eqs. [1]–[3]) and as such, there is a renewed interest in catalytic synthesis gas conversions (also known as C_1 chemistry).

[1] $CH_4 + O_2\ (H_2O) \rightarrow CO + nH_2\ (n = 2, 3)$

[2] $CO + 2H_2 \rightarrow CH_3OH$

[3] $xCO + yH_2 \rightarrow (\text{-}CH_2\text{-})_n + pCO_2 + qH_2O$

Methanol has particularly attractive attributes as a fuel, an additive in conventional fuels, and a versatile building block in the synthesis of chemicals (1, 2). Methanol is presently manufactured from synthesis gas using supported Cu–ZnO heterogeneous catalyst at 250–300°C and between 5–10 MPa operating pressure (3). Reaction [2] is highly exothermic (ΔH_{298} = –128.6 kJ mol^{-1}) that poses thermodynamic limitations and together with poor process heat control allows <20% per pass gas conversion during the reaction (4). A homogeneous catalyst that affords high reaction rates at low temperatures would offer superior reaction heat management, higher yields per pass, and may afford attractive economics. Efforts have been made to synthesize

oxygenates from synthesis gas using homogeneous systems. The use of transition-metal carbonyls especially those of Ru (5) and Rh (6) for synthesis of methanol, ethanol, other higher alcohols, and ethylene glycol is well documented for synthesis gas conversion but with these systems the overall reaction parameters are not economically attractive.

We previously reported (7) our approach to methanol synthesis from synthesis gas that utilized base-activated nickel tetracarbonyl as a catalyst for operation in homogeneous mode. In a follow-up paper (8), we reported on the kinetics of methanol synthesis catalyzed by the $Ni(CO)_4$–KOMe system in 1,4-dioxane–MeOH solvent mixture. Our further work on this catalyst suggested that 1,4-dioxane–MeOH was not particularly a good solvent mixture for this reaction because the solution homogeneity could not be maintained under a wide range of Ni and base concentrations. In this paper, we report on our work with other solvents for the reaction including a kinetic study in the MeOH–1,2-bis(2-methoxy ethoxy)ethane (triglyme) solvent mixture.

Experimental

Materials

Potassium methoxide (>95% pure) and nickel tetracarbonyl (>99.9% pure) were purchased from Alfa and used as received. Methanol, triglyme, and other solvents were obtained from Aldrich. For the kinetic study, methanol was distilled in 400mL batches with magnesium turnings and iodine under dry argon and triglyme was stored over molecular sieves prior to use. Pure CO, H_2, and syngas (H_2 and CO) mixtures were purchased in aluminum cylinders (to avoid any iron pentacarbonyl impurity) from Scott Specialty Gases.

Apparatus

A stainless steel MagneDrive II Packless Zipperclave 0.5 L reactor manufactured by Autoclave Engineers, Inc. (AE) was modified for this study. The reactor was equipped with a Dispersamax six-blade impeller mounted on a shaft driven by an AE variable speed motor. Ports were provided for loading nickel tetracarbonyl, reactant gases, and sampling vapor and liquid phases. The temperature of the reactor was maintained with a Parr 4831 temperature controller, which controlled an external heating mantle and an internal air-cooling system. The pressure was monitored with a Setra 204 pressure transducer (accuracy to ±1 psig). The transducer and temperature outputs were recorded using an Omega dual pen continuous chart recorder. The unit ratings were as follows: stirrer = 0–2000 rpm, T = 25–350°C, P = 0.1–14 MPa.

Run procedure and analysis

All runs containing nickel tetracarbonyl were performed under a well-ventilated fume hood (Caution: $Ni(CO)_4$ is volatile and extremely toxic!).[2] In a typical kinetic run, a specified amount of $KOCH_3$ was weighed inside a Labconco glove box under N_2 and was brought out in a closed vial. The methanol–triglyme solvent mixture (100mL) was degassed with N_2 and the weighed $KOCH_3$ in the vial was mixed with the degassed solvent mixture to obtain a light yellow homogeneous solution. The solution was poured into the pressure vessel and the vessel was quickly sealed and purged several times with N_2. A known amount of nickel tetracarbonyl was then injected into the base solution through the catalyst injection port and the vessel was immediately pressurized with syngas to about 750 psig. After 10 min, a gas sample was taken to establish the initial gas composition in the vessel. The automatic temperature controller and the stirrer were set at 120°C and 1600 rpm respectively. The stirring speed of 1600 rpm ensured that the reaction was operating out of the mass transfer regime. The vessel contents were then stirred for 15 min at room temperature to monitor initial gas absorption by the solvent and the base. At this time, methanol synthesis was initiated by heating the solution. The temperature and pressure were recorded as a function of time until the reaction became very slow. The reaction was quenched by replacing the heater with an ice water bath. Once the vessel cooled to room temperature, the final pressure and temperature were recorded. Gas and liquid samples were taken for analysis and the final liquid volume was measured. For this study, methanol synthesis was carried out under conditions with respect to nickel, base, and methanol concentrations that allowed collection of several data points during the runs. The data points were collected by analyzing the vapor-phase composition every 2 to 3 min during the run.

Gas samples were analyzed for H_2 and CO using Gow-Mac 550 gas chromatographs in the TCD mode: a molecular sieve column (8′ × 1/8″) with He carrier gas for CO and a molecular sieve column (6′ × 1/8″) with N_2 carrier gas for H_2 with data reproducibility within ±2%. Liquid phase samples (2μl) were analyzed on chromosorb-102 (8′ × 1/8″) column fitted in a PerkinElmer Model 8500 GC in the TCD mode with the data reproducibility within ±5%. All gas chromatographs were connected to HP Model 3390A integrators for peak quantification. A qualitative detection of $Ni(CO)_4$ in the vapor phase was achieved as follows. A 1-cm gas cell with KBr windows was evacuated and filled with the gas sample from the pressure vessel. The IR spectrum of the sample was recorded between 4000 and 400 cm^{-1} on a PerkinElmer Model 1330 IR spectrophotometer. The broad peaks at 2170, 2120 cm^{-1} (free CO), 2060 cm^{-1} ($Ni(CO)_4$), and 1760 cm^{-1} (CH_3O_2CH) were monitored.

For the kinetic study, the Redlich–Kwong equation of state was used to calculate the number of moles of H_2 and CO in the gas phase from the experimental data of syngas consumption vs. time. These data were further processed to yield rate constant values.

Results and discussion

Catalyst performance

It has been shown in an earlier study (8) that the $Ni(CO)_4$–KOMe system is a versatile catalyst to affect methanol synthesis from syngas. Table 1 lists representative runs

[2] Pure Ni is commercially manufactured via the Mond process (9) that involves the intermediacy of $Ni(CO)_4$. $Ni(CO)_4$ is volatile (bp = 43.2°C at 25°C; vapor pressure @ 20°C = 315 mmHg (1 mmHg = 133.322 Pa)) and extremely toxic. The OSHA limit for $Ni(CO)_4$ is set at 1 ppb in air for an 8-h daily exposure.

8	MeOH	5	Methyl (600)	92	1.4
9	Triglyme[e]	5	Methyl (200)	95	2.2

[a]All runs were carried out in 100mL solvent at 100°C under 2.1 MPa syngas (66% H_2:33%CO) per charge in a pressure vessel stirred at 1600 rpm. Typically, the reactor was charged twice in a given run.
[b]THF: tetrahydrofuran; triglyme: 1,2-bis(2-methoxyethoxy)ethane.
[c]Based on the final pressure at the end of the first charge.

that demonstrate the performance of the alkoxide base-activated Ni catalyst for CO hydrogenation. A typical run proceeded as follows. For example in Run 1, on adding tetracarbonyl nickel to a light yellow solution of potassium 2-methyl-2-butoxide in tetrahydrofuran (THF) under argon, a deep red solution resulted. The red solution yielded an active catalyst when heated at 100°C under 2.1 MPa syngas (66% H_2:34% CO). During heating, syngas consumption commenced and within minutes the reactor pressure dropped below 0.2 MPa corresponding to an average gas consumption rate of 1 mmol s^{-1}. Gas chromatographic analysis of the final liquid and gas phases yielded >98% selectivity to methanol with the rest comprising of methyl formate and dimethyl ether as by-products. The total gas consumption during the run was 93%. Such analysis resulted in the data presented in Table 1 for all the runs. Gas phase IR spectrum taken at room temperature at the end of each run showed a sharp and intense signature peak at 2060 cm^{-1} for $Ni(CO)_4$. These data suggest the presence of free $Ni(CO)_4$ during these runs. The IR spectrum of the final solutions from these runs was somewhat complex that are being analyzed. It is known (10, 11) that basic solutions of $Ni(CO)_4$ yield multinuclear Ni species that are in facile equilibrium with $Ni(CO)_4$:

$$[4] \qquad Ni(CO)_4 \underset{CO}{\overset{Base}{\Leftrightarrow}} [Ni_x(CO)_y]^{n-}$$

Metal alkoxides as precursors for electronic and ceramic materials have been extensively studied (12). Alkali metal alkoxides are known to form hydrogen bonded homoconjugate anion. Specific hydrogen bonding is thought to contribute greatly to the solvation of alkoxides in protic solvents (13):

$$[5] \qquad RO^-M_{(s)} + HOR \Leftrightarrow [RO\cdots H\cdots OR] + M^+_{(s)}$$

Methoxides are strongly associated due to reduced steric effect and increased localization of charge compared to higher alkoxides. In the present catalyst system containing KOMe–MeOH, methanol is necessary to dissolve KOMe but the presence of methanol is likely to have a pronounced effect on the reaction rate. The data of Runs 6, 7, and 8 (Table 1) confirm the negative effect of methanol on rate with the slowest rate measured in neat methanol as solvent even at 6.0 M KOMe concentration. Thus in the present system, a suitable balance between methanol and base concentrations is needed to attain high reaction rates while maintaining solution homogeneity during the methanol synthesis reaction.

The screening runs in Table 1 also show that as a general trend, the reaction rate was dependent on Ni (0.01–0.10 M) and base (0.4–6.0 M) concentrations. Furthermore, the rate was affected by the nature of the alkyl group associated with potassium alkoxide. For example, in THF, at fixed Ni and alkoxide concentrations, the rate dependence followed the order: KOMe > KO-2-methyl-2-propyl > KO-2-methyl-2-butyl (Runs 5, 4, 1). KOMe was the preferred alkoxide because irrespective of the starting alkoxide, once MeOH is formed, methoxide is invariably produced via rxn. [6] and exists in equilibrium with the added alkoxide (13):

$$[6] \qquad KOR + MeOH \Leftrightarrow KOMe + ROH$$

It is thus clear that the use of KOMe as the alkoxide base yields the highest rates and avoids the complication of equilibrium [6].

The catalyst was evaluated in several different solvents (Runs 5–9). The reaction rate was solvent dependent and followed the order: 1,4-dioxane ~ THF > triglyme > MeOH. As stated earlier, methanol is necessary as a solvent to solubilize the base via rxns. [5] and [6] but the presence of a cosolvent appears to decrease methoxide association (rxn. [5]) and yield higher rates. Initially, THF was the solvent of choice based on the rate data in Table 1 but its similar boiling point (65°C) limited its use in the downstream separation from product methanol (bp: 65°C). 1, 4-dioxane (bp: 102°C) was then selected and a kinetic study in this solvent was reported (8). But the utility of the MeOH–1, 4-dioxane solvent mixture was limited due to its base solubility constraints. Triglyme boils at a higher temperature (216°C) and the MeOH–triglyme solvent mixture appeared to satisfy several reaction and process criteria. This led us to undertake a kinetic study on the $Ni(CO)_4$–KOMe catalyst system in MeOH–triglyme solvent mixture.

Kinetic study

Methanol synthesis requires syngas with H_2:CO ratio of 2:1 (eq. [2]). Therefore, all runs in this study were con-

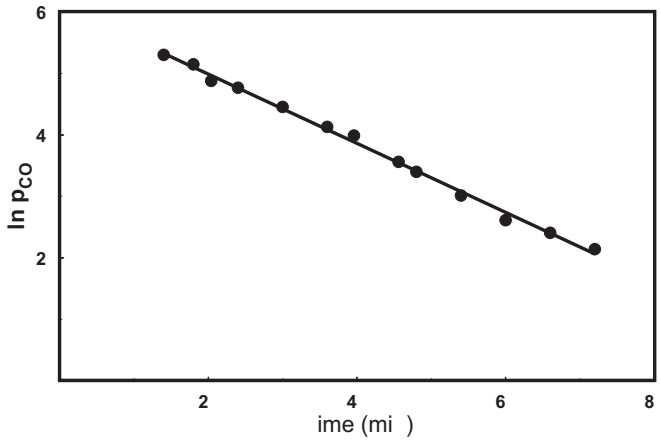
Fig. 1. Typical log plots of CO consumption as a function of time during a typical kinetic run for the $Ni(CO)_4$–KOMe catalyst system. Solvent: 10% triglyme:90% MeOH = 100 mL. [Ni] = 0.05 M, [KOMe] = 3.0 M, T = 110°C. Stirring speed = 1600 rpm. Syngas: 66% H_2:34% CO = 5.0 MPa at 25°C.



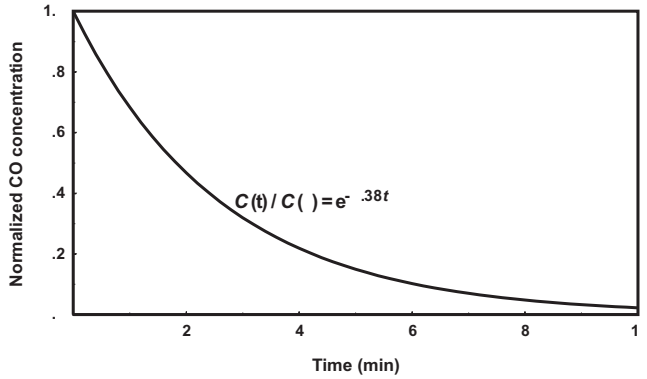


Fig. 2. Normalized CO concentration as a function of time during a typical kinetic run with the $Ni(CO)_4$–KOMe catalyst system. Solvent: 50% triglyme:50% MeOH = 100 mL. [Ni] = 0.05 M, [KOMe] = 3.0 M, T = 110°C. Stirring speed = 1600 rpm.

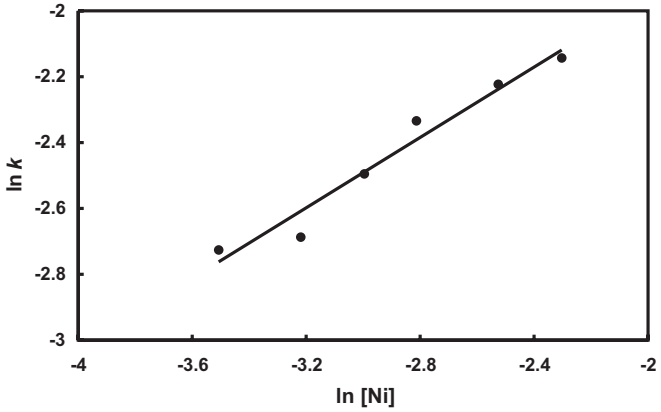


ducted with a constant syngas composition of 66% H_2:34% CO. The data in Table 1 show that under certain conditions, syngas consumption can be fast. For the kinetic runs, the catalyst composition was adjusted to allow enough reaction time for collection of several data points during each run. As shown below, four kinetic parameters were varied to collect the kinetic data on the $Ni(CO)_4$–KOMe system in MeOH–triglyme solvent mixture.

Rate of CO disappearance

The rate constants were calculated from the CO consumption data as follows. First, the Redlich–Kwong equation was used to calculate the individual H_2 and CO values from the experimentally measured values of the total syngas consumption. The time dependent CO values were corrected for solvent vapor pressure and liquid phase CO concentration factors. The variations of CO mol fraction as a function of time data were then used to determine the rate of disappearance of CO. Figure 1 shows one such plot for a run that was charged with 5.0 MPa syngas pressure at room temperature

Fig. 3. Effect of nickel concentration on the observed rate constant. Solvent: triglyme–MeOH = 100 mL. [KOMe] = 4.0 M, [MeOH] = 21.7 M, T = 110°C.

under the following reaction conditions: [Ni] = 0.05 M, [KOMe] = 3.0 M, T = 110°C; solvent: 100 mL triglyme–MeOH (10%:90%). The log of CO partial pressure vs. time plot yielded a straight line suggesting a first-order disappearance of CO:

$$[7] \qquad -dC_{co}/dt = kC_{co}$$

where C_{co} is the liquid-phase CO concentration and k is a first-order rate constant. Such analysis was carried out for all the runs. The data points could be used to construct a normalized CO concentration curves as a function of time during a kinetic run. Such a curve depicting CO consumption vs. time data is shown in Fig. 2 for a run that was carried out at: [Ni] = 0.05 M, [KOMe] = 3.0 M, T = 110°C; solvent: 100 mL triglyme–MeOH (50%:50%).

Effect of Ni concentration

The Ni concentration was varied between 0.03 and 0.10 M at fixed values of 4.0 M KOMe, 21.7 M MeOH, and a constant temperature of 110°C. In this Ni concentration range, the expression simplifies to:

$$[8] \qquad k = k_{Ni}C_{Ni}^{\alpha}$$

where α is the exponent of Ni concentration C_{Ni} and k_{Ni} is a constant. A plot of the experimental data in Fig. 3 shows that log k varied linearly with log C_{Ni}. The slope of this line yielded α of 0.534.

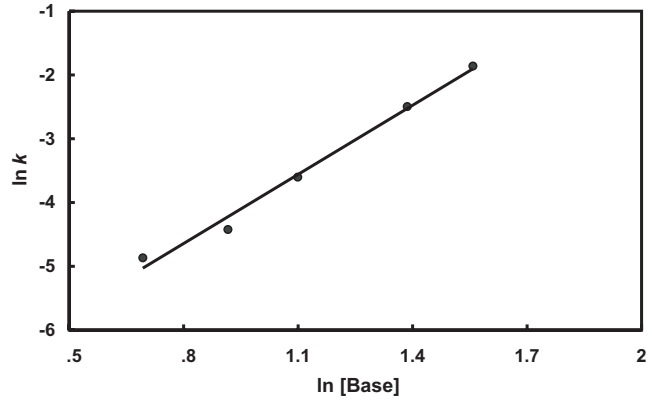
Effect of base concentration

The concentration of KOMe was varied between 2.0 and 4.75 M at fixed values of 0.05 M $Ni(CO)_4$ at a constant temperature of 110°C. Note that in this set, the methanol concentration was adjusted at 23.7, 24.0, 22.6, 21.7, 21.1 M, respectively, at KOMe concentrations of 2.0, 2.5, 3.0, 4.0, 4.75 M. Since the solution volume changes on dissolution of KOMe in the solvent mixture, this correction was necessary to keep the total solution volume constant. In this base concentration range, the rate constant can be modeled as a power function:

$$[9] \qquad k = k_bC_b^{\beta}$$

© 2001 NRC Canada

Fig. 4. Effect of base concentration on the observed rate constant. Solvent: triglyme–MeOH = 100 mL. [Ni] = 0.05 M, [MeOH] = 21.7 M, T = 110°C.



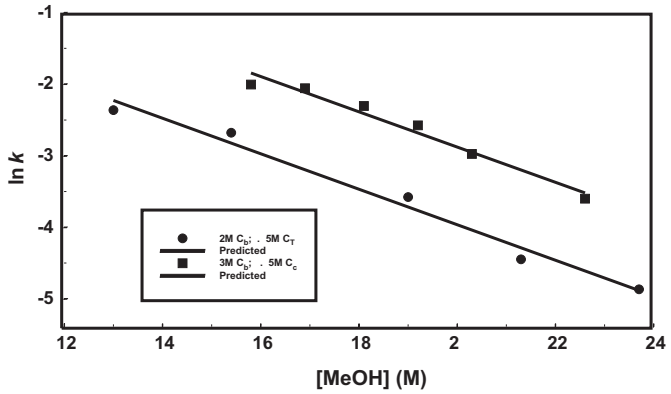


Fig. 5. Effect of methanol concentration on the observed rate constant. Solvent: triglyme–MeOH = 100 mL. [Ni] = 0.05 M, [KOMe] = 2.0, 3.0 M, T = 110°C.

where β is the exponent of base concentration C_b and k_b is a constant. A log–log plot of the experimental data in Fig. 4 shows that log k varied linearly with log C_b. The slope of this line yielded β of 2.89.

Effect of methanol concentration

We discussed earlier that a complex dependence of methanol and methoxide concentrations was noted during the methanol synthesis reaction. We, therefore, collected two sets of data, at 2.0 M and 3.0 M KOMe, in which MeOH concentration was varied. The plots in Fig. 5 show that there is a linear relation between log k and the liquid-phase methanol concentration (C_m). The slopes of the lines for both the both 2.0 M and 3.0 M data sets were the same (–0.248). From these data, the relationship between methanol concentration and the rate constant can be expressed as:

$$[10] \quad k = k_m \exp(-k_i C_m)$$

where k_m and k_i are methanol concentration dependent constants.

Effect of temperature

Rate constants were measured at 374, 383, and 393 K at constant 0.05 M Ni, 4.0 M base, 21.7 M MeOH in triglyme. An Arrhenius plot of the data yielded a straight line as shown in Fig. 6. This plot was used to calculate the frequency factor (A) and the energy of activation (E_{act}) of the reaction.

Fig. 6. An Arrhenius plot of the observed rate constant data at 101, 110, and 120°C. Solvent: triglyme–MeOH = 100 mL. [Ni] = 0.05 M, [KOMe] = 4.0 M, [MeOH] = 21.7 M.

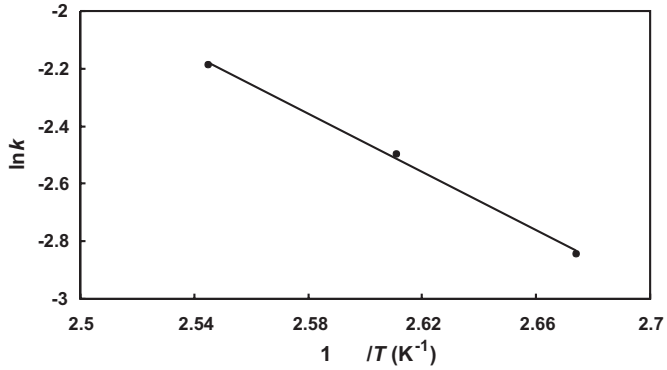

Table 2. Parameters in the kinetic model for methanol synthesis.

Parameter	Experimental	Calculated[a]
k_o	—	1.267×10^6
k_i	0.248	0.256
α	0.534	0.548
β	–2.89	–2.81
E_{act}	42.23	42.22

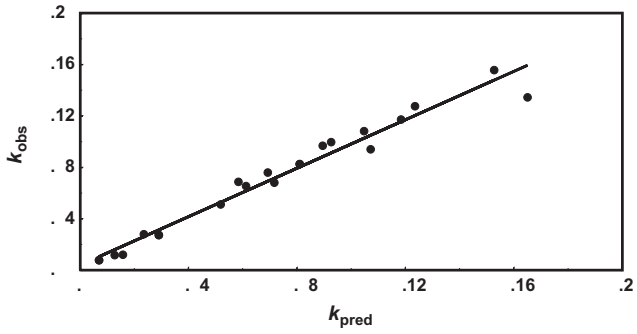
[a]For these values, regression constant (R^2) was 0.98.

$$[11] \quad k = A\exp(E_{act}/RT)$$

E_{act} was calculated by linear regression to be 42.2 kJ mol^{-1}. This value appears low compared to what is expected for a typical chemical reaction (83–126 kJ mol^{-1}). This value is also smaller compared to our previous data (97.6 kJ mol^{-1}) for the Ni–$^{-}$OMe catalyst system in 1,4-dioxane–MeOH solvent mixture (8). Interestingly, the measured E_{act} value is in the range of that measured for carbonylation of methanol to methyl formate (67.7 kJ mol^{-1} between 323 and 343 K) catalyzed by sodium methoxide (13). We are further analyzing the data to explain this discrepancy in the E_{act} values.

Kinetic model

The experimental data in Figs. 3–6 were used to estimate the respective parameters, α, β, k_i, and E_{act}. Next, all of the parameters were determined simultaneously by utilizing all the data points at one time. The proposed model is based on a combination of eqs. [8]–[11] that yields the following expression:



$$[12] \quad k = k_o \exp(-E_{act}/RT) C_{Ni}^{\alpha} C_b^{\beta} \exp(-k_i C_m)$$

A better estimate of the parameters in this model can be calculated by using multiple linear regression of eq. [11] (14). The parameter values from experimental data and the calculated values are given in Table 2. The final expression is then modified to:

$$[13] \quad k = (1.27 \times 10^6)\exp(-10\,084/RT) C_{Ni}^{0.548} C_b^{2.81} \exp(-0.256 C_m)$$

© 2001 NRC Canada

Fig. 7. A comparison of the observed and the predicted rate constants.

In Fig. 7, the observed rate constants (k_{obs}) are compared to the line based on the predicted rate constants (k_{pred}) from eq. [13]. The data are in excellent agreement.

The kinetic expression in eq. [13] includes terms for temperature, nickel, alkoxide base, and methanol concentrations. A less than first-order dependence on nickel may indicate the presence of more than one Ni species that are in equilibrium in solution. An approximate third-order dependence of rate on alkoxide base and a negative exponential methanol term likely result from ion-pairing due to hydrogen bonding in methanol, a protic solvent. Thus, the RO^-–ROH interaction results in slow reaction kinetics that is consistent with the presented data. Further work with different alkoxide bases in combination with various alkali metals in methanol will likely establish the effect of these parameters on thermodynamics and kinetics of the system.

Future direction

The potential use of methanol as a clean fuel including its use as a peak-shaving fuel in the integrated gasification combined cycle (IGCC) power plants is justifying further research in developing a simple and cost-effective methanol synthesis process. A catalyst that yields high reaction rates, high CO conversion, and high methanol selectivity would be applicable to such systems. In this paper, we have presented data to demonstrate that it is possible to develop such a catalyst system that operates in the homogeneous mode. The base activated $Ni(CO)_4$ system, in its present formulation, is not yet commercially attractive for two reasons. These are: (*i*) the presence of toxic $Ni(CO)_4$; and (*ii*) the sensitivity of the catalyst to CO_2 and H_2O. The latter is due to interaction of these molecules with the alkoxide base that yield alkyl carbonate and hydrolysis products respectively:

[14] $^-OMe + CO_2 \rightarrow {}^-OCO_2Me$

[15] $^-OMe + H_2O \rightarrow {}^-OH + MeOH$

Reaction [14] lies far to the right and the equilibrium constant (K_{eq}) for the NaOMe–CO_2 reaction is known to be ~2 × 10^{-8} (15). Both these reactions compete with presumably the initial methanol synthesis step that requires the availability of alkoxide base. This reaction has been studied for other metal carbonyls both with methoxide and hydroxide bases that result in methoxycarbonyl and hydroxycarbonyl adduct formation respectively via rxn. [16]:

[16] $M_x(CO)_y + RO^- \rightarrow M_x(CO)_{y-1}(CO_2R)^-$

(R = H or Me)

Rate constants have been reported for the reaction of $Ru_3(CO)_{12}$, $Ru(CO)_5$, $Fe_3(CO)_{12}$, and $Fe(CO)_5$ with ^-OMe and ^-OH ions at 25°C (16). The Ru carbonyls do yield methanol even in the absence of methoxide though at higher temperatures and pressures (5). A preliminary mechanistic study has appeared in literature for methanol synthesis catalyzed by the $Ni(CO)_4$–NaOMe catalyst system but the rate determining step (RDS) was not identified (17). The rate expression in eq. [13] is empirical and, as such, only limited information can be derived from the presented kinetic data. We are presently establishing a detailed mechanism of the KOMe–Ni catalyst system that will allow us to correlate the observed kinetic dependence and identify the rate-controlling step in methanol synthesis. A detailed study of our catalyst system will be the subject of a forthcoming publication[3] in which we also seek to establish the role of multinuclear Ni species (10, 11) in methanol synthesis.

Equilibrium thermodynamic studies for the formation of 1:1 complexes of CO and ethene with a rhodium(II) porphyrin metallo-radical

Leah Basickes, Andrew G. Bunn, and Bradford B. Wayland

Abstract: Tetra(2,4,6 triisopropropyl phenyl)porphyrinatorhodium(II) ((TTiPP)Rh^{II}·**1**) is a persistent metal-centered radical with the odd electron in the rhodium(II) dz^2 orbital. (TTiPP)Rh^{II}· forms 1:1 complexes with CO and CH_2CH_2 where the porphyrin ligand steric properties inhibit further reactions of the one-electron activated substrates. ^{1}H NMR paramagnetic shifts at a series of temperatures are used in evaluating the thermodynamics for CO complex formation with **1** to form [(TTiPP)Rh^{II}(CO)]·**2** ($\Delta H°$ = –5.5 ± 0.5 kcal mol^{-1}; $\Delta S°$ = –9 ± 1 cal K^{-1} mol^{-1}). Related ^{1}H NMR studies show that the bonding of **1** with ethene is less favorable than CO.

Key words: rhodium porphyrin, carbon monoxide, ethene, thermodynamics, complex formation, metal-centered radical.

Résumé : Le tétra(2,4,6-triisopropylphényl)porphyrinatorhodium(II) ((TTiPP)Rh^{II}·**1**) est un radical persistant centré sur un métal comportant un électron célibataire dans l'orbitale dz^2 du rhodium(II). Le (TTiPP)Rh^{II}· forme des complexes 1:1, avec le CO et le CH_2CH_2, dans lesquels les propriétés stériques du ligand porphyrine empêchent d'autres réactions avec des substrats à un électron activés. On a utilisé les déplacements paramagnétiques en RMN du ^{1}H à une série de températures pour évaluer les facteurs thermodynamiques de la réaction entre CO et **1** pour conduire à la formation du complexe [(TTiPP)Rh^{II}(CO)]·**2** ($\Delta H°$ = –5,5 ± 0,5 kcal mol^{-1}; $\Delta S°$ = –9 ± 1 cal K^{-1} mol^{-1}). D'autres études de RMN du ^{1}H montrent que la liaison entre **1** et l'éthène est moins favorable que celle avec le CO.

Mots clés : porphyrine-rhodium, monoxyde de carbone, éthène, thermodynamique, formation de complexe, radical centré sur un métal.

[Traduit par la Rédaction]

Introduction

Carbon monoxide and ethene are most often activated by binding with Lewis acid metal centers that promote two-electron reactions of nucleophiles at a substrate carbon site. The binding of carbon monoxide and ethene with rhodium(II) porphyrin metal-centered radicals results in complexes that manifest an alternate pattern of reactivity associated with one-electron activated substrates (1–6). Reactions of CO and ethene with rhodium(II) porphyrins that yield substrate bridged (Rh-C(O)-Rh (3, 4), Rh-CH_2CH_2-Rh (7, 8)) and coupled species (Rh-C(O)-C(O)-Rh (1–3), Rh-CH_2CH_2-CH_2CH_2-Rh (5, 6)) illustrate one-electron activated carbon centers in CO and ethene ligands. Direct investigation of complexes with one-electron activated substrates is usually precluded because they are highly reactive transient intermediates. However, steric constraints can be built into the porphyrin ligand which inhibit access to the reactive substrate site and provide persistent complexes containing one-electron activated CO and ethene (2, 5).

Tetra(2,4,6 triisopropyl phenyl)porphyrinatorhodium(II) ((TTiPP)Rh^{II}·) is an example of a metal-centered radical where the structural features sterically preclude Rh^{II}—Rh^{II} bonding and inhibit CO and ethene substrate reactions. This article reports on measurements of equilibrium thermodynamic values for complex formation of (TTiPP)Rh^{II}· with carbon monoxide and ethene.

Results and discussion

(TTiPP)Rh^{II}·**1** is a stable persistent metal-centered radical with a $(d_{xy})^2(d_{xz,yz})^4(d_{z2})^1$ electron configuration as shown by the EPR spectral parameters in toluene glass (90 K) (g_{xx} = g_{yy} = 2.82, g_{zz} = 1.85) (9). ^{1}H NMR chemical shifts for (TTiPP)Rh^{II}· in toluene-d_8 solutions manifest an inverse dependence on temperature (T = 190–330 K) that is characteristic of Curie–Weiss paramagnetism (Fig. 1). There is no evidence from ^{1}H NMR, electronic spectra, or EPR for dimerization of (TTiPP)Rh^{II}· through Rh^{II}—Rh^{II} bonding in toluene solution (190–330 K) or frozen glass (160–90 K). The steric constraints for the TTiPP porphyrin ligand preclude dimerization through Rh^{II}—Rh^{II} bonding which occurs with less sterically demanding porphyrin ligands such as tetraphenyl porphyrin ([(TPP)Rh]$_2$) (10).

The EPR spectrum in toluene glass (90 K) for (TTiPP)Rh^{II}· in contact with ^{13}CO demonstrates the formation of a mono CO complex ([(TTiPP)Rh^{II}(CO)]·) through splitting of each

 DOI: 10.1139/cjc-79-5/6-854 © 2001 NRC Canada

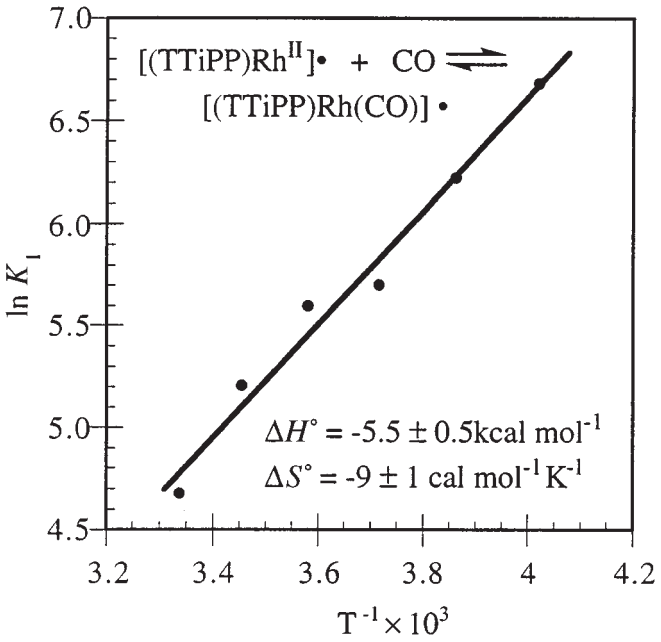

Fig. 1. Temperature dependence for the pyrrole ^{1}H NMR paramagnetic shift (δ (ppm)) for toluene-d_8 solutions of (TTiPP)Rh^{II}· (■), (TTiPP)Rh^{II}· (●) in contact with CH_2CH_2 (0.25 atm (1 atm = 101.325 kPa)), and (TTiPP)Rh^{II}· (▲) in contact with CO (0.855 atm (1 atm = 101.325 kPa)).

of the three *g* value transitions into a doublet by ^{13}C (9). The observed pyrrole ^{1}H NMR paramagnetic shifts for toluene-d_8 solutions of (TTiPP)Rh^{II}·**1** (1.0×10^{-3} M) in contact with carbon monoxide (P_{CO} = 0.855 atm (1 atm = 101.325 kPa)) are plotted vs. the inverse of temperature (T = 180–300 K) in Fig. 1. Sections of linearity are observed in both the higher and lower temperature regimes. The observed pyrrole chemical shifts in the higher temperature linear region coincide with the values for (TTiPP)Rh^{II}· ($\delta_1 = -1.86 + 3334\ T^{-1}$) and the lower temperature linear portion is assigned to the limiting shift values for a mono carbonyl complex ([(TTiPP)Rh^{II}(CO)]·**2** ($\delta_2 = -2.72 + 2376T^{-1}$)). The ratio of the slope of the pyrrole hydrogen paramagnetic shifts vs. T^{-1} plots for [(TTiPP)Rh^{II}(CO)]· to that for (TTiPP)Rh^{II}· equals 0.71 and this value is proportional to the ratio of the electron-pyrrole hydrogen coupling constants A_H (**2**)/A_H (**1**) and related pyrrole hydrogen spin densities (11). This ratio of the porphyrin pyrrole electron-hydrogen coupling constants (0.71) is similar to the ratio of 0.65 for the total rhodium spin density of [(TTiPP)Rh^{II}(CO)]· (0.62) to that of the (TTiPP)Rh^{II}· (0.95) which were estimated from EPR studies (9). In the temperature regime between 270 and 330 K, substantial amounts of both (TTiPP)Rh^{II}· and [(TTiPP)Rh^{II}(CO)]· are present in equilibrium with CO (eq. [1]). The

[1] $$[(TTiPP)Rh^{II}]\cdot + CO \rightleftharpoons [(TTiPP)Rh^{II}(CO)]\cdot$$

Fig. 2. van't Hoff plot for reaction of (TTiPP)Rh^{II}· with CO in toluene-d_8.

observed pyrrole shifts in this temperature range correspond to the mol fraction averaged positions for the (TTiPP)Rh^{II}· and [(TTiPP)Rh^{II}(CO)]· species in limiting fast exchange.

The pyrrole chemical shifts determined for (TTiPP)Rh^{II}·**1** ($\delta_1 = -1.86 + 3334\ T^{-1}$) and [(TTiPP)Rh^{II}(CO)]·**2** ($\delta_2 = -2.72 + 2376\ T^{-1}$) were used in determining the fraction of monocarbonyl complex from the observed mol fraction averaged chemical shifts (δ_{obs} = N(**1**)δ(**1**) + N(**2**)δ(**2**)), N(**2**) = [**2**]/[**1**] + [**2**]). The equilibrium constant expression for rxn. [1] (K_1 = [[(TTiPP)Rh^{II}(CO)]·]/[(TTiPP)Rh^{II}·][CO]) is evaluated using the ratio of mol fractions N(**2**):N(**1**) and the molar concentration of CO at each temperature (T). The plot of ln K_1 vs. T^{-1} (Fig. 2) gives an enthalpy change ($\Delta H_1°$) of –5.5 ± 0.5 kcal mol^{-1} and entropy change ($\Delta S_1°$) of –9 ± 1 cal K^{-1} mol^{-1} for the reaction of (TTiPP)Rh^{II}· with CO to form [(TTiPP)Rh^{II}(CO)]· (eq. [1]). The enthalpy change for complex formation of **1** with CO ($\Delta H_1° = -5.5 \pm 0.5$ kcal mol^{-1}) is very small even when compared to the reaction of CO with a related Rh^{II}—Rh^{II} bonded dimer [(OEP)Rh]$_2$ to form the mono CO adduct [(OEP)Rh]$_2$CO ($\Delta H° = -12$ kcal mol^{-1}) (3).

Reaction of (TTiPP)Rh^{II}· with ethene produces a 1:1 complex [(TTiPP)Rh^{II}(CH_2CH_2)]·**3** that is kinetically *meta*-stable relative to an ethene coupling product (Rh-$(CH_2)_4$-Rh).

[2] $$[(TTiPP)Rh^{II}]\cdot + CH_2CH_2 \rightleftharpoons [(TTiPP)Rh^{II}(CH_2CH_2)]\cdot$$

The g_{zz} transition in the EPR spectrum for the $^{13}C_2H_4$ derivative of **3** (90 K) occurs as a triplet of doublets arising from coupling of two equivalent ^{13}C nuclei on each ^{103}Rh transition which demonstrates that **3** is a 1:1 complex, [(TTiPP)Rh^{II}(CH_2CH_2)]· (5).

^{1}H NMR chemical shifts for the pyrrole hydrogens of (TTiPP)Rh^{II}· in contact with ethene (0.25 atm (1 atm = 101.325 kPa)) in toluene-d_8 over a wide range of tempera-

© 2001 NRC Canada

tures is shown in Fig. 1. At temperatures above 220 K the observed pyrrole ^{1}H NMR shifts are indistinguishable from the values for (TTiPP)$Rh^{II}\cdot$ and only below 200 K is there a clear indication of ethene complex formation with **1** to form **3**. Only a small temperature range is available for the study of **3** forming in toluene solutions and the regime with the limiting shift values and thus complete conversion to **3** was not attained. Qualitatively, the thermodynamics of ethene coordination with **1** are substantially less favorable than CO complexation.

Experimental

The synthesis of (TTiPP) has been described previously (2). All manipulations were performed under argon or by vacuum techniques. Reagents were purchased from Aldrich or Strem. Research grade carbon monoxide and ethene (Matheson) and ^{13}C-labeled carbon monoxide and ethene (Aldrich) were used without further purification. Benzene and toluene solvents used in the EPR and NMR studies were degassed, refluxed over sodium benzophenone, and then degassed again by freeze–pump–thaw cycles.

NMR Studies

Proton NMR spectra were recorded using a Bruker AF500 instrument equipped with a variable temperature FTS Refrigerator unit. NMR samples used toluene-d_8 as the solvent in a sealed NMR tube and low temperatures were obtained by utilizing the boil-off from liquid nitrogen. Temperature calibration was obtained by using methanol or ethylene glycol as an external standard.

Reaction of (TTiPP)$Rh^{II}\cdot$ with CO–CH_2CH_2

In a typical experiment, (TTiPP)$Rh^{II}\cdot$ was generated by photolysis of a benzene solution of (TTiPP)Rh-CH_3 (1×10^{-3} M) in a vacuum adapted NMR tube. Samples of (TTiPP)$Rh^{II}\cdot$ in vacuum adapted NMR tubes were then pressurized with CO (0.86 atm (1 atm = 101.325 kPa)) or ethene (0.25 atm (1 atm = 101.325 kPa)) and sealed. The solubility of CO and ethene in toluene was determined as a funtion of temperature. When measuring the concentration of disolved gas in solution at a temperature T_2, P is the pressure in atm (1 atm = 101.325 kPa) at the laboratory temperature T_1 in K when the gas was added into the tube. ([CO] (12) = $[a + b(T_2)][P][T_1/T_2]$ (a and b are solvent dependent in toluene, $a = 4.405 \times 10^{-3}$ and $b = 1.085 \times 10^{-5}$)); ([CO] (303 K) in toluene = 6.5×10^{-3} M), [ethene] (13) = $-0.4906 + (0.1850T_2)P$. ([ethene] (303 K) in toluene = 3.0×10^{-2} M).

Synthesis, characterization and chemistry of bis-(pentafluorophenyl)boryl ferrocene

Bryon E. Carpenter, Warren E. Piers, Masood Parvez, Glenn P.A. Yap, and Steven J. Rettig

Abstract: Bis-(pentafluorophenyl)boryl ferrocene, **1**, was prepared via borylation of ferrocene with $HB(C_6F_5)_2$ or via a transmetallation reaction involving FcHgCl and $ClB(C_6F_5)_2$ in 87–91% yield. The compound is characterized by a deep maroon colour. A significant intramolecular iron–boron interaction is manifested in the solution spectroscopic (Fe → B charge transfer band at ~230 nm, $\varepsilon = 1.33 \times 10^4$) and solid-state crystallographic data (Fe-B = 2.924 Å) This interaction has an impact on the Lewis acidity of the boron center which, unlike the related compound $B(C_6F_5)_3$, does not strongly bind Lewis bases such as acetone, THF, or acetonitrile. However, an adduct between the stronger base PMe_3 and **1** forms readily and this complex (**2**) was fully characterized. The electron withdrawing $-B(C_6F_5)_2$ group causes **1** to be oxidized at +450 mV relative to ferrocene. Oxidation of **1** with $[NO][BF_4]$, $AgOSO_2CF_3$, or AgC_6F_5 leads to the zwitterionic ferrocenium borates **3-F**, **3-OTf**, and **3-C_6F_5**, respectively. Each of these compounds was characterized spectroscopically and via X-ray crystallography. The properties of these compounds relative to **1** suggest that oxidation of the iron center significantly enhances the Lewis acidity of the boron center. Due to the σ-donating ability of the borate substituents, zwitterions **3** are weaker oxidizing agents than unsubstituted ferrocenium salts.

Key words: organoboranes, ferrocene derivatives, Lewis acids.

Résumé : On a préparé le bis-(pentafluorophénylboryl)ferrocène, **1**, par le biais d'une borylation du ferrocène à l'aide de $HB(C_6F_5)_2$ ou par une réaction de transmétallation impliquant le FcHgCl et le $ClB(C_6F_5)_2$; les rendements varient de 87 à 91%. Le composé est caractérisé par une couleur marron foncé. Il se manifeste une interaction intermoléculaire fer–bore significative tant en spectroscopie en solution (un transfert de bande Fe → B à environ 230 nm, $\varepsilon = 1{,}33 \times 10^4$) que dans les données cristallographiques à l'état solide (Fe-B = 2,924 Å). Cette interaction a une influence sur l'acidité de Lewis du bore qui, contrairement au composé $B(C_6F_5)_3$ apparenté, ne se lie pas fortement aux bases de Lewis telles que l'acétone, le THF ou l'acétonitrile. Toutefois, il se forme facilement un adduit entre le composé **1** et PMe_3, une base plus forte, et on a fait une caractérisation complète de ce complexe, **2**. La présence du groupe électroaffinitaire $B(C_6F_5)_3$ fait que le composé **1** peut s'oxyder à +450 mV par rapport au ferrocène. L'oxydation du composé **1** par $[NO][BF_4]$, $AgOSO_2CF_3$ ou AgC_6F_5 conduit suivant le cas à la formation des borates de ferrocénium zwitterioniques **3-F**, **3-Otf** et **3-C_6F_5**. Chacun de ces composés a été caractérisé par spectroscopie et par diffraction des rayons X. Les propriétés de ces composés, comparées à celles du composé **1**, suggèrent que l'oxydation du fer augmente de beaucoup l'acidité de Lewis du bore. En raison de la possibilité des substituants borates de donner des électrons σ, les zwitterions **3** sont des agents d'oxydation plus faibles que les sels de ferrocénium non substitués.

Mots clés : organoboranes, dérivés ferrocènes, acides de Lewis.

[Traduit par la Rédaction]

Introduction

Substituted ferrocenyl derivatives play an important role in many different areas of chemistry (1). While much activity has focussed on ferrocenes substituted with Lewis base donors as ligands for various transition metal catalysts, ferrocene derivatives with Lewis acid centers bonded to the cyclopentadienyl (Cp) ring have seen fewer applications. Nonetheless, borylated ferrocenes have been studied in some detail, initially due to the fact that they are isoelectronic to stable ferrocenyl carbocations (2), and are synthons for other substituted ferrocenes. Early examples involve mainly dihaloboryl derivatives, prepared by direct borylation of the metallocene with BX_3 (3). In these reactions, the ferrocene Cp rings can be borylated up to four times. These haloboryl derivatives can be further derivatized and used as precursors

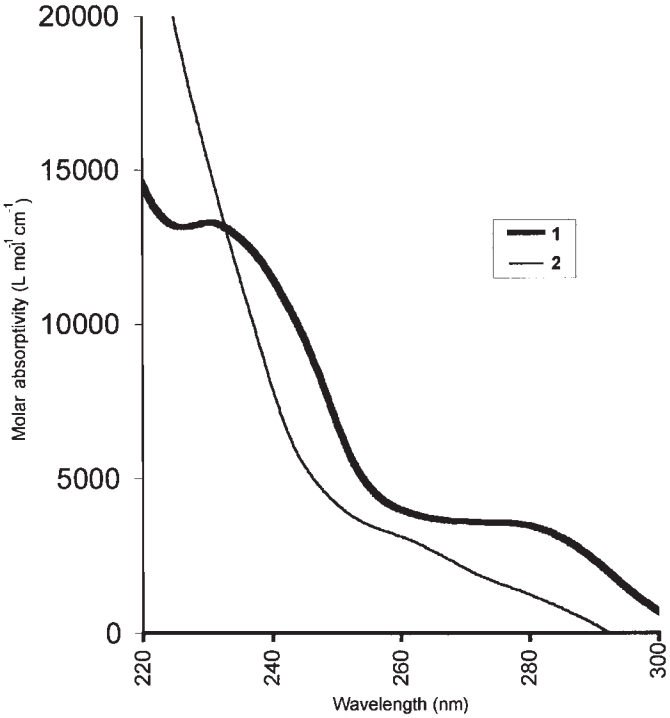
to coordination polymer type materials (4). More recently, a class of *ansa*-ferrocenophanes utilizing a boron atom in the linking bridge have been prepared (5) and subjected to ring-opening polymerization reactions (5*c*).

Our interest in perfluoroaryl substituted boranes (6) led us to develop routes to bis-(pentafluorophenyl)boryl substituted boranes and to explore their properties as Lewis acids. In this paper, we detail the synthesis, properties, and reaction chemistry of the monoborylated ferrocene complex bis-(pentafluorophenyl)boryl ferrocene (**1**).

Results and discussion



Previously, boryl-substituted ferrocenes have been prepared via direct borylation or transmetallation reactions (3). Accordingly, bis-(pentafluorophenyl)borylferrocene (**1**) can be synthesized either via borylation with bis-(pentafluorophenyl)borane, $HB(C_6F_5)_2$, (7) or through reaction of the well-known (chloromercuric)ferrocene, FcHgCl, (8) with bis-(pentafluorophenyl)chloroborane, $ClB(C_6F_5)_2$ (9) (eq. [1]). The former route requires heating for several hours and involves loss of H_2 during the course of the reaction, while the latter reaction occurs at room temperature and produces $HgCl_2$ as the by-product. Both routes are efficient, giving **1** in 87–91% isolated yield.

Boryl ferrocene **1** is a deeply maroon coloured solid which is highly soluble in common aliphatic and aromatic solvents. The UV–vis spectrum of **1** (Fig. 1) exhibits an intense absorption at ~230 nm ($\varepsilon = 1.33 \times 10^4$) likely assignable to an $Fe_{dz2/dx2-y2} \rightarrow B_p$ charge transfer process. Wagner and co-workers (3*j*) have detailed this Fe → B interaction in related dibromoboryl ferrocenes both experimentally and computationally and conclude that the occupied d_{z2} and d_{x2-y2} orbitals on the iron center have appropriate symmetry to interact with the empty *p*-orbital on the boron center, effectively forming a loose intramolecular Lewis acid–Lewis base adduct. A similar phenomenon accounts for the observed stability of ferrocenyl carbocations (2).

The NMR data for **1** also supports the notion that an Fe → B interaction is present in the compound. In perfluoroaryl substituted boranes, the chemical shift of the ^{11}B nucleus in the ^{11}B NMR spectrum is reflective of the coordination number and charge associated with the boron center (10). Neutral, three-coordinate boranes generally resonate in the 65–80 ppm range, neutral, four coordinate centers typically fall into the 5–25 ppm range, while anionic borates appear upfield at –10 to –35 ppm. Similarly, the chemical shift difference between the *meta* and *para* fluorines of the C_6F_5 rings is influenced by the amount of electron density at the boron center (11): as the boron proceeds from neutral, three-coordinate through four-coordinate adducts with Lewis bases, to anionic borates, the *para* fluorines become more shielded as the charge on boron increases, and shift upfield closer to the resonance for the *meta* fluorines. ^{11}B chemical shifts and $\Delta_{m,p}$ values for all the new compounds reported here as well as some comparable compounds are collected in Table 1. Inspection of this data shows that, for **1**, the ^{11}B chemical shift (53 ppm) and the $\Delta_{m,p}$ value (9.2 ppm) is intermediate to the numbers observed for purely neutral, three-coordinate examples and neutral, four-coordinate Lewis base adducts. These observations are consistent with the presence of a weak Fe → B interaction in **1**, which is maintained in nondonating solvents.

Fig. 1. UV–vis spectra of compounds **1** and **2** in 1,2-dichloroethane (concentration ~2×10^{-4} M).

This interaction is also manifested in the solid-state structure of **1**, determined by X-ray crystallography. Compound **1** crystallizes in the $P2_12_12_1$ space group with two crystallographically independent molecules in the asymmetric unit. Figure 2 shows the molecular structure of one of these molecules, along with selected metrical parameters; further details on this structure (and the others reported herein) can be found in the *Supplementary information*.[3] Immediately evident from the view shown is that the $B(C_6F_5)_2$ moiety is

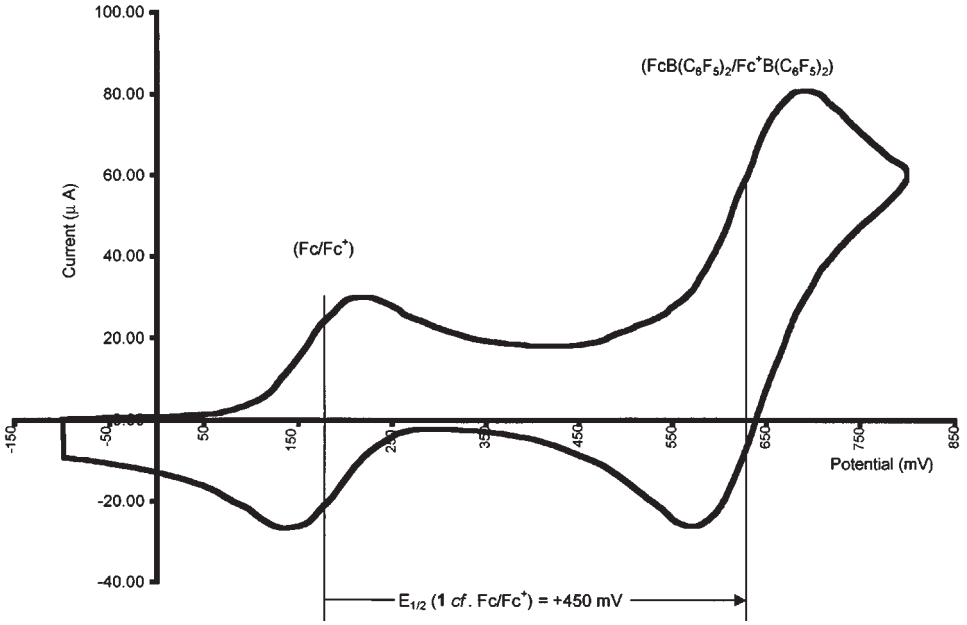
tilted towards the iron center such that the dip angle of the B(1)-C(13) vector out of the plane defined by the five Cp carbons is ~16°. This compares to the values of 17.7° and 18.9° found for the same parameter in crystallographically independent molecules of the related compound $Fc(BBr_2)$ (3*j*). As a consequence of this interaction in **1**, the B(1) center is slightly pyramidalized (the sum of the angles about B(1) is 358.2°) and the Fe(1)—B(1) distance is 2.924 Å. The metrical parameters for the borylated Cp ring suggest a partial contribution from a boratafulvene-like structure (12) akin to **I** is operative for this ligand. Furthermore, the B(1)—C(13) distance of 1.501(4) Å is intermediate between values found for a B(sp^2)-C(sp^2) double bond (e.g., 1.44 Å in $LiCH_2$=$B(mes)_2$ (13)) and that of a B(sp^2)-C(sp^2) single bond (e.g., 1.58 Å in BPh_3 (14)). Thus it appears that, in addition to accepting electron density directly from the iron center, the $B(C_6F_5)_2$ group withdraws π-electron density from the Cp ring as well.



I

The electron-withdrawing capacity of the -$B(C_6F_5)_2$ group is manifested in the electrochemical behaviour of **1**. Cyclic voltammetric measurements were performed against a silver wire quasireference electrode in ≈100 mM solutions of substrate in α,α,α-trifluorotoluene (TFT) with $[NBu_4][B(C_6F_5)_4]$ as the supporting electrolyte (15). Use of the standard $[NBu_4][BF_4]$ electrolyte led to irreversible oxidations, a result of chemical reactions subsequent to oxidation (vide infra). An internal standard of ferrocene was employed; all $E_{1/2}$ values reported (Table 2) are relative to the Fc/Fc^+ couple under these conditions. As can be seen in Fig. 3, **1** exhibits a reversible oxidation wave at +450 mV relative to ferrocene, indicating that it is more difficult to oxidize owing to the electron-withdrawing -$B(C_6F_5)_2$ substituent.

The flow of electron density into the empty boron *p*-orbital dampens the Lewis acidity of **1** in comparison to other perfluoroaryl substituted boranes. For example, while carbonyl functions, (16) ethers and water, (17) isonitriles and nitriles (18) form strong adducts with $B(C_6F_5)_3$, when **1** is treated with oxygen nucleophiles such as acetophenone, acetylferrocene, *N*,*N*-di-iso-propylbenzamide or THF, the equilibrium for adduct formation lies far towards the reactants at room temperature. Treatment of **1** with 1 equiv of water leads to rapid formation of FcH and $HOB(C_6F_5)_2$ (9), indicating that coordination occurs to some extent. Toluene-d_8 solutions of **1** containing a few equiv of acetonitrile, when cooled, change in colour from the deep maroon of **1** to light yellow, indicative of disruption of the Fe → B interaction upon adduct formation. However, the acetonitrile ligand remains labile even at 193 K, as judged by the single resonance for free vs. bound acetonitrile in the sample's ^1H NMR spectrum at this temperature. Use of the Childs' method for assessing Lewis acid strength (19) shows that **1** has a Lewis acid strength of 0.37 ± 0.03 relative to BBr_3 at 1.00. Comparative values for other Lewis acids, for example,

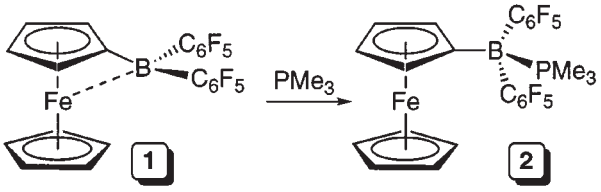

Fig. 3. Representative CV of **1** (1 mM) in α,α,α-trifluorotoluene with $[Bu_4N][B(C_6F_5)_4]$ (100 mM) as supporting electrolyte. Scan rate = 100 mV s^{-1}.

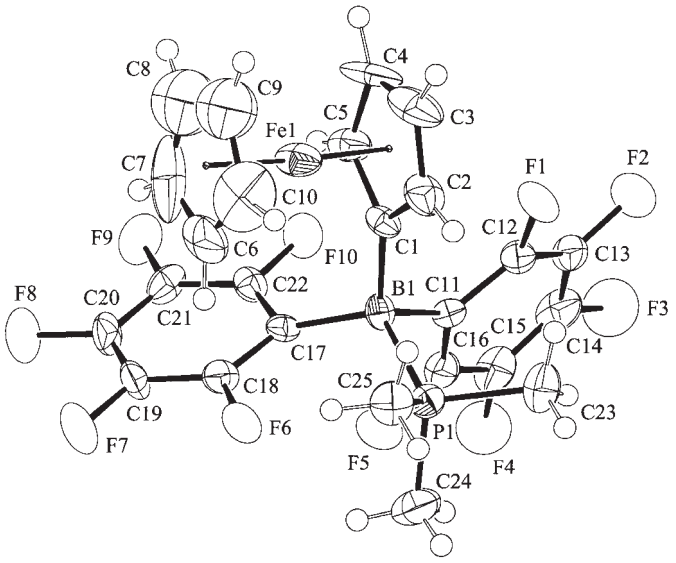
$AlCl_3$ (0.88 ± 0.03), $B(C_6F_5)_3$ (0.77) (20), and $SnCl_4$ (0.56 ± 0.03), show that **1** is a relatively weak Lewis acid by virtue of this Fe → B interaction.

Only strong Lewis bases, such as PMe_3, form adducts irreversibly with **1** (eq. [2]). When maroon solutions of **1** are exposed to PMe_3, an instantaneous colour change to a yellow hue signals formation of adduct **2**. This material was isolated and fully characterized. Notably, the UV–vis spectrum of **2** (Fig. 1) no longer contains a prominent charge transfer band, supporting the assignment of this band for **1** given above. The chemical shift of the ^{11}B nucleus in the NMR spectrum of **2** (–13.5 ppm) is somewhat upfield of the region expected for such four-coordinate adducts but is split into a doublet due to coupling to the ^{31}P nucleus ($J_{B\text{-}P}$ = 46 ± 10 Hz). The $\Delta_{m,p}$ value of 5.6 ppm (Table 1) is consistent with strong coordination of the phosphine to the boron center, although the relatively small value of $J_{B\text{-}P}$ suggests that the phosphine may be labile. The PMe_3 ligated boryl group is now a net electron donator to the Cp ring as judged by the $E_{1/2}$ value of –100 mV (relative to Fc/Fc^+, Table 2) in the cyclic voltammagram of **2**. Since the *p*-orbital on boron is plugged with the phosphine lone pair of electrons, the σ-donating ability of the boryl group now dominates the electronic effect of this group on the Fe(II)–Fe(III) redox couple of the iron center.

[2]



The solid-state structure of **2** was determined by X-ray crystallography, and an ORTEP diagram along with selected metrical data is given in Fig. 4. The B(1)—P(1) distance of 1.992(9) Å is comparable to the 2.046(8) Å and 2.015(3) Å values found for the PH_3 and *t*-$BuPH_2$ adducts, respectively, of $B(C_6F_5)_3$ (21). The now four-coordinate boron atom is tilted out of the Cp plane away from the iron center by 6.4°. As expected, the boratafulvene character of **1** is lost and the B(1)—C(1) distance of 1.61(1) Å is characteristic of a B(sp^3)—C(sp^2) bond.

Given the nature of the Fe → B interaction in **1** and related compounds and its dampening effect on the Lewis acidity of the boron center, it seemed logical to presume that oxidation of the iron center should weaken the Fe → B interaction and concommitantly impart stronger Lewis acidity on the borane. Experiments involving chemical oxidation of **1** appear to bear this out. For example, treatment of **1** with $[NO][BF_4]$, a common oxidizing agent for ferrocene derivatives (22), led to oxidation to a ferrocenium complex as indicated by a change in the solution's colour from maroon to dark green, with visible evolution of NO gas. ^{19}F NMR spectroscopy on the crude product showed that the BF_4 anion was no longer present and that one major $B(C_6F_5)_2$ containing product was present as ≈80% of the mixture. Due to the paramagnetism of this compound, ^1H and ^{11}B NMR spectroscopy provided little useful information; however, the C_6F_5 rings are far enough removed to be relatively unaffected by the paramagnetic iron center. While isolable quantities of pure product were not obtained, analysis of crystals isolated from this product mixture by X-ray crystallography, revealed the fluoroborate zwitterion **3-F** to be this major product (Fig. 5). Evidently, the boron center in the putative ferrocenium intermediate **3** (Scheme 1) is Lewis acidic enough to abstract a fluoride ion from the BF_4 counteranion. Fluoride abstraction by other perfluoroaryl boranes, specifi-

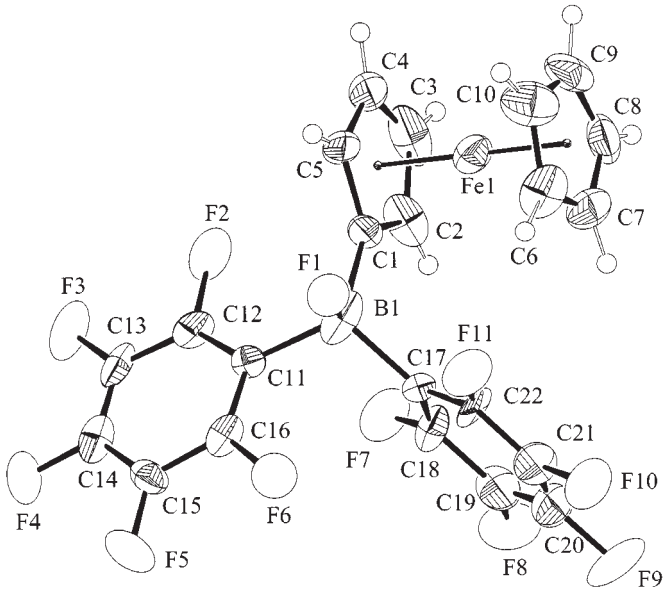
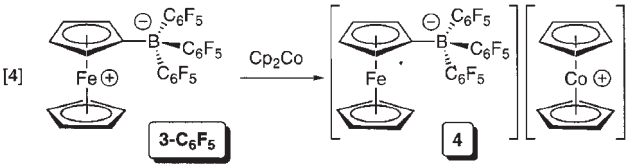
Fig. 4. ORTEP diagram of **2**. Selected bond distances (Å): Fe(1)—C(1) 2.098(7), Fe(1)—C(2) 2.044(8), Fe(1)—C(3) 2.012(9), Fe(1)—C(4) 2.037(8), Fe(1)—C(5) 2.022(8), C(1)—C(2) 1.447(9), C(1)—C(5) 1.424(10), C(2)—C(3) 1.400(12), C(4)—C(5) 1.425(10), C(3)—C(4) 1.401(12), B(1)—C(1) 1.609(11), B(1)—C(11) 1.665(10), B(1)—C(17) 1.637(10), B(1)—P(1) 1.992(9). Selected bond angles (°): P(1)-B(1)-C(1) 109.3(5), P(1)-B(1)-C(11) 102.1(5), P(1)-B(1)-C(17) 116.0(6), C(1)-B(1)-C(11) 110.6(6), C(1)-B(1)-C(17) 109.0(6), C(11)-B(1)-C(17) 109.8(6).



cally $B(C_6F_5)_3$ (23) and the chelating diboryl species 1,2-$C_6F_4[B(C_6F_5)_2]_2$ (24) has also been documented. Significantly, boryl ferrocene **1** does not react with $[NBu_4][BF_4]$, even upon heating. Recall, however, that electrochemical oxidation of **1** in the presence of this electrolyte was irreversible. Taken together, these observations suggest that oxidation of the iron center significantly increases the Lewis acidity of the boron center attached to the Cp ring.

Zwitterion **3-F** crystallizes as two independent molecules with essentially identical metrical parameters, differing only in the orientation of the fluoroborate moiety with respect to the Cp ligand plane. One of the molecules is shown in Fig. 5, along with selected metrical parameters; a picture of the other is given in the deposited material. The borate boron is tetrahedral in geometry and the B(1)—F(1) distance of 1.452(12) Å is typical of these bonding partners.



Two other zwitterionic ferrocenium compounds were prepared in high yield and purity by oxidation of **1** with AgOTf and AgC_6F_5 (25) as shown in eq. [3]. Formation of **3-OTf** was essentially immediate upon dissolution of the reactants

Fig. 5. ORTEP diagram of one molecule of **3-F**. Selected bond distances (Å): C(1)—B(1) 1.626(15), B(1)—F(1) 1.452(12), B(1)—C(11) 1.697(15), B(1)—C(17) 1.651(14). Selected bond angles (°): F(1)-B(1)-C(1) 108.1(11), F(1)-B(1)-C(11) 105.8(9), F(1)-B(1)-C(17) 109.2(8), C(1)-B(1)-C(11) 112.3(8), C(1)-B(1)-C(17) 111.5(10), C(11)-B(1)-C(17) 109.9(10).

in dichloromethane, whereas the reaction leading to **3-C_6F_5** required several hours in toluene solvent. Complex **3-OTf** exhibits a resonance at –89.6 ppm in the ^{19}F NMR spectrum, attributable to the triflate CF_3 group, in addition to those of the C_6F_5 fluorines. The solid-state structure of this compound was determined by X-ray crystallography and an ORTEP diagram and selected metrical data is given in Fig. 6. Again, the quaternized boron center is now directed away (6.0°) from the iron center. The metrical parameters associated with the OTf moiety are similar to other η^1-coordinated trifluoromethanesulfonates (26).

Zwitterion **3-C_6F_5** was also structurally characterized (Fig. 7). Consistent with boron quaternization, the boron atom is 3.59 Å away from the iron center (5.8° tilt). In addition, ^1H, ^{11}B, and ^{19}F NMR spectroscopy were fully consistent with the structure found in the solid state. Furthermore, one-electron reduction using cobaltocene gave a diamagnetic ion pair, $[FcB(C_6F_5)_3][Cp_2Co]$ (**4**, eq. [4]), which was also characterized spectroscopically and via elemental analysis. We were interested in **3-C_6F_5** as a potential activator for metallocene and related olefin polymerization catalyst precursors, since it is known that ferrocenium salts are capable of oxidizing neutral dialkyl metallocenes to the active cationic alkyl catalysts (27). Unfortunately, **3-C_6F_5** is not a strong enough oxidizing agent to remove an electron from Cp_2ZrMe_2. In fact, electrochemical measurements on this

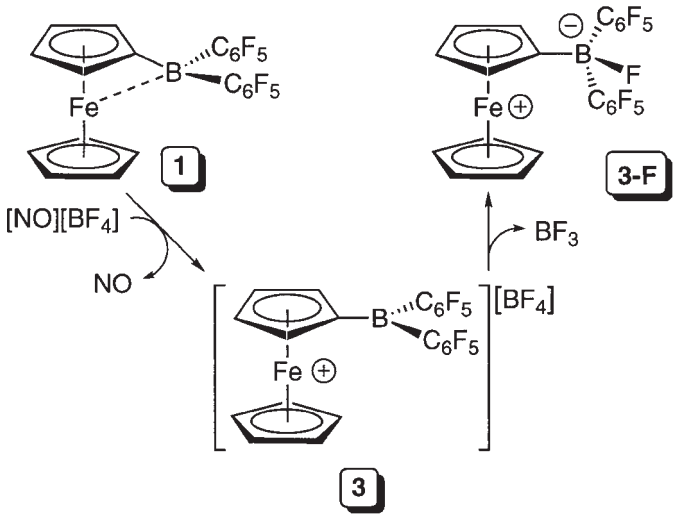

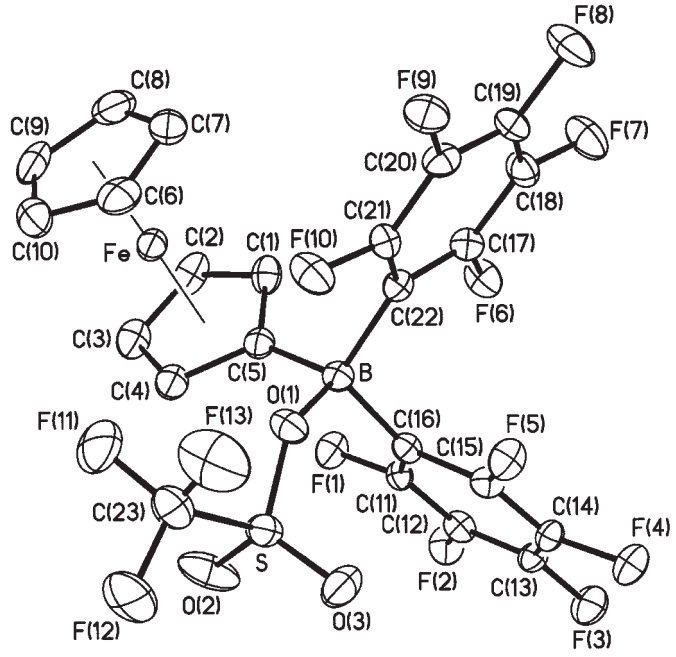

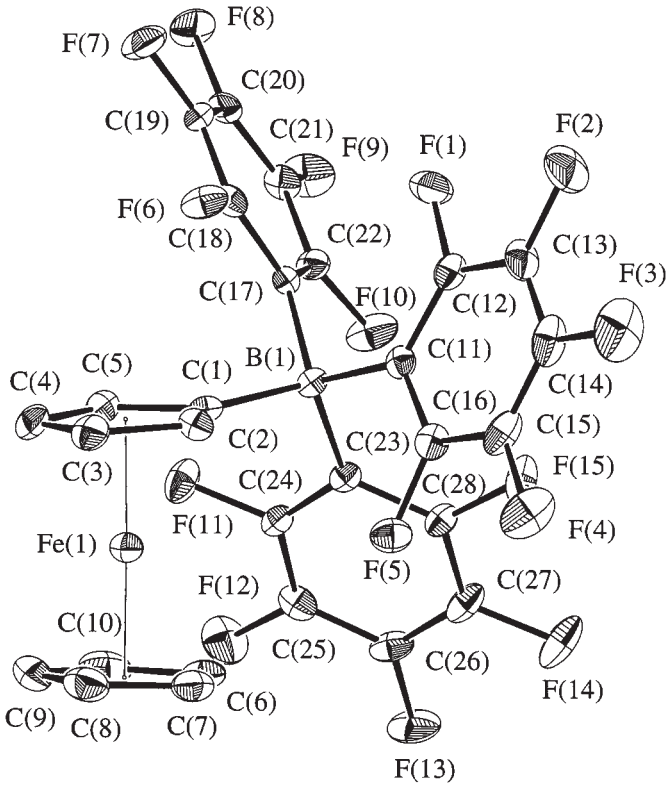

Fig. 6. ORTEP diagram of **3-OTf**. Selected bond distances (Å): B—C(5) 1.601(5), B—C(16) 1.624(5), B—C(22) 1.658(4), B—O(1) 1.575(4), S—O(1) 1.486(2), S—O(2) 1.416(7), S—O(3) 1.392(8), S—C(23) 1.824(6). Selected bond angles (°): O(1)-B-C(5) 107.7(3), O(1)-B-C(16) 109.0(3), O(1)-B-C(22) 104.8(2), C(5)-B-C(16) 112.7(3), C(5)-B-(C(22) 111.7(3), C(16)-B-C(22) 110.5(3).

zwitterion show that its oxidation potential is at –472 mV relative to Fc/Fc^+, indicating that the -$B(C_6F_5)_3$ borate moiety is a very good σ-donor to the Cp ring, stabilizing the Fe(III) center substantially relative to unsubstituted ferrocene. Structurally, there is nothing unusual about this compound; the borate boron is tetrahedral and the B—C bond lengths are normal. Compound **3-C_6F_5** is related to the zwitterion $Fc^+B(Fc)_3$, reported several years ago (28).

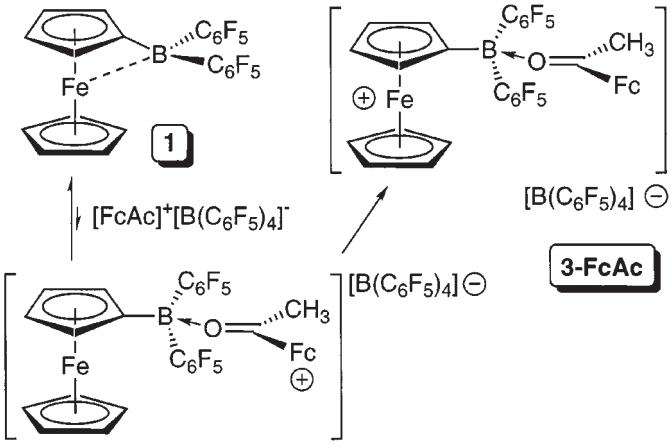

Fig. 7. ORTEP diagram of **3-C_6F_5**. Selected bond distances (Å): Fe(1)—C(1) 2.152(2), Fe(1)—C(2) 2.100(2), Fe(1)—C(3) 2.065(2), Fe(1)—C(4) 2.069(2), Fe(1)—C(5) 2.098(2), C(1)—C(2) 1.433(3), C(1)—C(5) 1.434(3), C(2)—C(3) 1.428(3), C(4)—C(5) 1.414(3), C(3)—C(4) 1.409(3), B(1)—C(1) 1.666(3), B(1)—C(11) 1.648(3), B(1)—C(17) 1.657(3), B(1)—C(23) 1.666(3). Selected bond angles (°): C(1)-B(1)-C(11) 106.0(2), C(1)-B(1)-C(17) 105.7(2), C(1)-B(1)-C(23) 112.0(2), C(11)-B(1)-C(17) 113.2(2), C(11)-B(1)-C(23) 110.9(2), C(17)-B(1)-C(23) 108.9(2).

The observations above infer that the boron center of the putative species **3** is more Lewis acidic than that of neutral borane **1**. Unfortunately, attempts to prepare **3** with a weakly coordinating anion, namely $[B(C_6F_5)_4]^-$ met with failure, although some of the experiments aimed at preparing **3** with this counteranion support the notion that **3** is a stronger Lewis acid than **1**. For example, **1** may be oxidized using the acetylferrocenium reagent $[FcAc]^+[B(C_6F_5)_4]^-$. Acetylferrocenium reagents have been used to oxidize other ferrocene derivatives, since its oxidation potential of +270 mV is higher than most substituted ferrocene derivatives (23). Interestingly, it should not be a strong enough oxidizing agent to oxidize **1**, whose potential is at +450 mV relative to ferrocene, and yet when **1** and $[FcAc]^+[B(C_6F_5)_4]^-$ are mixed together, a rapid redox reaction is observed. Presumably the carbonyl group of the acetyl substituent is able to weakly coordinate the boron center in **1**, converting the electron-withdrawing -$B(C_6F_5)_2$ substituent into an electron-donating (relative to H) -$B(L)(C_6F_5)_2$ group (Scheme 2). Thus, when the acetylferrocenium species coordinates to the boron center in **1**, oxidation is rapid, producing the complex **3-FcAc**. ^1H NMR spectroscopy suggests that the neutral

Scheme 2.

acetylferrocene product of the electron transfer reaction remains coordinated to the boron center. All attempts to remove the acetylferrocene failed; clearly, FcAc is bound much more tightly to the Lewis acid center in **3** compared to that in **1**.

In conclusion, we have prepared bis-(pentafluorophenyl)ferrocenylborane and examined its chemical and electrochemical behaviour. The Lewis acidity of the boron center is attenuated due to a significant Fe → B interaction in the Fe(II) species, but oxidation of the iron center to Fe(III) disrupts this interaction, resulting in a more strongly Lewis acidic boron center.

Experimental section

General

All reactions were carried out under an argon atmosphere either on a double manifold high vacuum line or in an Innovative Technology System One dry box. Standard inert atmosphere, Schlenk, vacuum line, and glove box techniques were used throughout, under purified argon. Nuclear magnetic resonance (NMR) spectra were obtained in d_2-methylene chloride (CD_2Cl_2), d_6-benzene, or d_8-toluene on either Bruker AMX400 (^{1}H NMR, 400.132 MHz, ^{13}C NMR, 100.623 MHz), Bruker AMX300 (^{1}H NMR, 300.138 MHz, ^{11}B NMR, 96.293 MHz, ^{19}F NMR, 282.371 MHz), Varian XL200 (^{13}C NMR, 50.310 MHz, ^{11}B NMR, 64.184 MHz, ^{31}P NMR, 80.988 MHz) or Bruker ACE-200 (^{1}H NMR, 200.134 MHz) spectrometers. ^{1}H and ^{13}C NMR spectra were referenced to tetramethylsilane ($SiMe_4$) via solvent resonances. ^{11}B NMR spectra were externally referenced to borane trifluoride diethyl etherate (δ 0.0 ppm) and ^{19}F NMR spectra were externally referenced to $CFCl_3$ (δ 0.00 ppm) using an external standard of hexafluorobenzene (δ –163.0 ppm) (29). ^{31}P NMR spectra were reference to the external standard H_3PO_4 in deuterium oxide (δ 0.00 ppm). UV–vis spectra were obtained in dry $ClCH_2CH_2Cl$ using a Cary 5E UV–vis and IR spectrometer. The samples were prepared in volumetric flasks (~2.0×10^{-4} M) and transferred to a 1 mm pathlength air-tight cell fused to a Kontes Teflon tap. A background spectrum of the solvent was collected and automatically subtracted from the spectrum collected of the substrate. The molar absorptivity was calculated using Beer's Law. Elemental analyses were performed by Mrs. Dorothy Fox (University of Calgary) on a Control Equipment Corporation 440 elemental analyzer.

Toluene, tetrahydrofuran (THF), and hexanes were purified using the Grubbs purification system (30) and stored in solvent pots over a drying agent. α,α,α-Trifluorotoluene (TFT) was predried over phosphorus pentoxide (P_2O_5) and stored over CaH_2 in a glass bomb. Deuterated solvents were purchased from Cambridge Isotopes Laboratories and dried analogously.

All chemicals were purchased from Aldrich–Sigma unless otherwise stated except tris-(pentafluorophenyl)borane and ferrocene, which were purchased from Boulder Scientific Company. The $B(C_6F_5)_3$ dried as previously described, while ferrocene was purified by sublimation under dynamic vacuum at 55°C. Literature procedures were used to prepare the following reagents: $[n\text{-}Bu_4N]^+[B(C_6F_5)_4]$ (15), ($ClB(C_6F_5)_2$) (9), ($HB(C_6F_5)_2$) (7), ($LiB(C_6F_5)_4\cdot Et_2O$) (31), (AgC_6F_5) (25), (FcHgCl) (8), and $[FcAc]^+[BF_4]^-$ (8).

Preparation of 1

Method A

Ferrocene (1.90 g, 10.2 mmol) and $HB(C_6F_5)_2$ (3.45 g, 9.98 mmol) were dissolved in toluene (60 mL), warmed slowly to 80°C, and stirred for 22.5 h under argon opened to a mercury bubbler. The reaction mixture was cooled and the toluene was removed under vacuum to afford a dark maroon solid. Boryl ferrocene product was extracted from unreacted $HB(C_6F_5)_2$ with hexanes. The hexanes were removed under vacuum to afford a crimson red crystalline solid. Residual ferrocene was removed from the product by sublimation (55°C under full vacuum). Yield of **1**: 4.39 g (8.28 mmol, 91%). X-ray quality crystals were grown from a saturated solution of **1** in dry hexamethyldisiloxane cooled to –35°C. UV (TFT) λ_{max} (nm) (ε): 231 (1.33×10^4). ^{1}H NMR (C_6D_6): 4.51 (t, 2H, J = 1.8 Hz, H_β), 4.03 (s, 5H, C_5H_5), 3.95 (bs, 2H, H_a). ^{13}C NMR (C_6D_6): 145.9 (d, $^1J_{CF}$ = 242 Hz), 141.9 (d, $^1J_{CF}$ = 242 Hz), 137.7 (d, $^1J_{CF}$ = 251 Hz), 115.0 (bs, WHM = 87 Hz, $C_{ipso}(C_6F_5)$), 79.5 (s, WHM = 7.4 Hz, C_β), 77.7 (s, WHM = 8 Hz, C_α), 70.5 (s, WHM = 7.4 Hz, C_5H_5). ^{11}B NMR (C_6D_6): 53.7 (bs, WHM = 650 Hz). ^{19}F NMR (C_6D_6): –129.3 (dd, 4F, F_o), –152.5 (t, 2F, F_p), –161.7 (dt, 4F, F_m). Anal. calcd. for $C_{22}H_9BF_{10}Fe$: C 49.86, H 1.71; found: C 49.69, H 1.90.

Method B

1-(Chloromercuric)ferrocene (2.403 g, 5.32 mmol) and $ClB(C_6F_5)_2$ (1.987 g, 5.23 mmol) were placed into a 100 mL bomb and hexanes (80 mL) added under vacuum transfer conditions. The mixture was warmed to room temperature and stirred for 22 h. The orange chalky suspension changed to a dark maroon solution with a green–grey precipitate. The suspension was cannula-transferred under argon flow into a 100 mL RBF and filtered to extract **1** from the mercuric chloride by-product. The $HgCl_2$ was washed with hexanes until the washings were colourless. The solvent was removed in vacuo to afford the maroon solid **1**. Yield: 2.461 g (4.64 mmol, 87%). The crude product was subjected to sublimation to remove any residual $ClB(C_6F_5)_2$.

Preparation of 2

Compound **1** (394 mg, 0.743 mmol) was dissolved in toluene and the solution degassed by a freeze–pump–thaw routine. At –196°C, an excess of PMe_3 (>15 cmHg in a 115 cm^3 bulb) was condensed into the flask. The reaction was warmed to –78°C during which time the maroon solution changed colour to light yellow. The solvent was removed in vacuo to afford a yellow powder. Yield: 443 mg (0.731 mmol, 98%). A single crystal was grown from a saturated toluene solution. ^{1}H NMR (d_8-toluene): 4.15 (t, 2H, J = 1.80 Hz, H_β), 3.99 (s, 5H, Fe(C_5H_5)), 3.62 (bs, 2H, H_a), 0.47 (d, 9H, $^2J_{PH}$ = 10.7 Hz, P(CH_3)$_3$). ^{13}C NMR (d_8-toluene): 148.1 (*d*, $^1J_{CF}$ = 234 Hz), 139.7 (*d*, $^1J_{CF}$ = 263 Hz, C_p), 137.7 (*d*, $^1J_{CF}$ = 246 Hz), 120.3 (bs, C_{ipso}(C_6F_5)), 80.2 (bs, C_{ipso}(C_5H_4)), 73.7 (*s*, C_α), 69.9 (*s*, C_β), 68.8 (*s*, Fe(C_5H_5)), 9.5 (*d*, $^1J_{CP}$ = 37 Hz, P(CH_3)$_3$). ^{11}B NMR (d_8-toluene): –13.5 (br d, $^1J_{BP}$ = 46 ± 10 Hz). ^{19}F NMR (d_8-toluene): –127.6 (d, 4F, F_o), –157.6 (t,2F, F_p), –163.2 (dt, 4F, F_m). ^{31}P NMR (d_8-toluene): –12.1 (br m, $^1J_{PB}$ = 46 ± 10 Hz).

Preparation of 3-F

Borane **1** (306 mg, 0.577 mmol) and nitrosonium tetrafluoroborate ($NOBF_4$) (65 mg, 0.557 mmol) were dissolved in CH_2Cl_2 (20 mL). The reaction vessel was placed into a 60°C oil bath and stirred for 30 min. The solution was cooled, degassed, and taken into the dry box where it was transferred to a flask fitted with a frit assembly. The solution was concentrated and the slurry sonicated; filtration afforded a dark blue solid. Yield: 250 mg (0.405 mmol, 72%). Crystals were grown by layering hexane on a concentrated solution in CH_2Cl_2 at 25°C. ^{1}H NMR: 33.1 (bs, WHM = 1360 Hz, 2H), 28.0 (bs, WHM = 700 Hz, 5H, Fe(C_5H_5)), 30.1 (bs, WHM = 2150 Hz, 2H). ^{19}F NMR: –157.1 (bs, 4F, F_o), –162.4 (t, 2F, F_p), –166.8 (bs, 4F, F_m); the B-F fluorine was not located.

Preparation of 3-Otf

Silver trifluoromethanesulfonate (245 mg, 0.953 mmol) and **1** (505 mg, 0.953 mmol) were placed into a flask fitted with a frit assembly. CH_2Cl_2 (25 mL) was condensed into the vessel under vacuum transfer conditions. The reaction was warmed to room temperature and stirred for 2 h during which time the solution changed from maroon to navy blue. The reaction mixture was filtered with a grey residue remaining on the frit and the solvent was removed under vacuum to afford 585 mg (0.858 mmol, 90%) of a paramagnetic dark blue solid of high purity by ^{19}F NMR. Crystals were grown at 25°C from a minimum amount of CH_2Cl_2 layered with hexane. UV (TFT) λ_{max} (nm) (ε): 256 (1.42×10^4). ^{1}H NMR: 42.0 (bs, WHM = 2780 Hz), 33.1 (bs, WHM = 2500 Hz), 30.1 (bs, WHM = 1050 Hz). ^{13}C NMR: 142.9 (d, $^1J_{CF}$ = 245 Hz), 137.7 (d, $^1J_{CF}$ = 257 Hz), 133.0 (d, $^1J_{CF}$ = 241 Hz), 92.1 (bs, C_{ipso}). ^{11}B NMR: –4.75 (bs, WHM = 394 Hz). ^{19}F NMR: –89.6 (s, 3F, CF_3), –155.8 (bs, 4F, F_o), –159.6 (s, 2F, F_p), –165.8 (s, 4F, F_m). Anal. calcd. for $C_{23}H_9BF_{13}FeO_3S$: C 40.68, H 1.34; found: C 40.51, H 1.13.

Preparation of 3-C_6F_5
