Measurement of the autoionization lifetime of the superexcited atomic sulfur S($3s^2 3p^3(^2D^o)4d$) state using tunable vacuum ultraviolet (VUV) radiation[1]

Jianhua Huang, Dadong Xu, Alexei Stuchebrukhov, and William M. Jackson

Abstract: A new method is described that combines a tunable coherent vacuum ultraviolet (VUV) radiation source and an ion velocity imaging apparatus to study the autoionization of superexcited sulfur atoms. The photolysis of CS_2 at 193 nm is used to produce metastable sulfur atoms in the $^1D_2$ state. The S($^1D_2$) atom is then directly excited to the neutral superexcited state $3s^2 3p^3(^2D^o)4d$ ($^1D_2^o$) at 11.317 eV with a tunable VUV photon at ~121.896 nm. This excited state then undergoes autoionization into the first ionization continuum state of $S^+(^4S_{3/2}^o) + e^-$, which is not directly accessible from the S($^1D_2$) state through optical transition. By monitoring the S^+ signal in the time-of-flight mass spectrometer while scanning the excitation wavelength, the line profile of the $3s^2 3p^3 4d\ ^1D_2^o \leftarrow 3s^2 3p^4\ ^1D_2$ transition is recorded and found to have a full width at half maximum (FWHM) of 0.9 cm^{-1}. This has been used to determine an autoionization lifetime of the neutral superexcited $3s^2 3p^3 4d\ ^1D_2^o$ state of 5.9 ps. The accurate measurement of the autoionization lifetime provides a benchmark for testing fundamental theoretical models of processes occurring in excited states of atoms.

Key words: autoionization, atomic sulfur, vacuum ultraviolet (VUV), full width at half maximum (FWHM).

Résumé : On décrit une nouvelle méthode qui combine une source cohérente et réglable de rayonnement ultraviolet du vide avec un appareil d'imagerie de la vitesse des ions pour étudier l'autoionisation d'atomes de soufre surexcités. On a utilisé la photolyse du CS_2 à 193 nm pour produire des atomes de soufre métastables dans l'état $^1D_2$. L'atome S($^1D_2$) est alors directement excité à l'état surexcité neutre $3s^2 3p^3(^2D^o)4d$ ($^1D_2^o$), à 11,317 V, à l'aide d'un photon VUV réglable à ~121,896 nm. Cet état excité subit alors une autoionisation dans le premier état d'ionisation continue du $S^+(^4S_{3/2}^o) + e^-$ qui n'est pas directement accessible à partir de l'état S($^1D_2$) par le biais d'une transition optique. En suivant le signal du S^+ dans un spectromètre de masse à temps d'envol alors qu'on balaye la longueur d'onde d'excitation, on a enregistré le profil de la raie de la transition $3s^2 3p^3 4d\ ^1D_2^o \leftarrow 3s^2 3p^4\ ^1D_2$ et on a trouvé que la largeur totale à demi-hauteur maximale (« FWHM ») est de 0,9 cm^{-1}. Cette valeur a été utilisée pour déterminer que le temps de vie de l'autoionisation de l'état surexcité neutre $3s^2 3p^3 4d(^1D_2^o)$ est de 5,9 ps. La mesure précise du temps de vie d'autoionisation fournit une référence pour évaluer les modèles théoriques fondamentaux des processus se produisant dans les états excités d'atomes.

Mots clés : autoionisation, soufre atomique, ultraviolet du vide, largeur totale à demi-hauteur maximale.

[Traduit par la Rédaction]

Introduction

The study of the photoionization of sulfur is of great interest because of its applications in astrophysics. Spectroscopic measurements indicate that sulfur and oxygen dominate the torus plasma of the Jupiter satellite Io (1, 2). Furthermore, the study of the photoabsorption spectrum of sulfur is interesting because it is an open-shell heavy atom where spin–orbit coupling can be large and correlation effects in determining the properties of the excited state can be important. The electronic configuration of atomic sulfur is $1s^2 2s^2 2p^6 3s^2 3p^4$, which gives rise to the $^3P_{2,1,0}$, $^1D_2$, and $^1S_0$ terms. The ground state is the $^3P_2$ state. The photoionization of ground-state sulfur ($^3P_2$) has been extensively studied in the past. The absolute values of the cross sections were reported by Tondello (3) for photon energies from the ionization threshold at 119.67 to 90 nm using the flash pyrolysis method. Sarma and Joshi (4) did the same work but made more detailed analysis in the region between 109 and 100 nm. Berkowitz and co-workers (5) observed the photoionization spectrum of sulfur in the region between the first ionization threshold and 92.5 nm. They assigned many of the autoionization states that converge on the $^4S^o$, $^2D^o$, $^2P^o$ states of the S^+ ion originating from the ground state of sulfur ($^3P_2$). They also showed that the autoionization features of the $3p^3(^2D^o)nd\ ^3D^o$ levels are broad, while those of the $3p^3(^2D^o)nd\ ^3S^o, ^3P^o$ levels are narrow. However, surprisingly, we failed to find previous measurements of the lifetimes

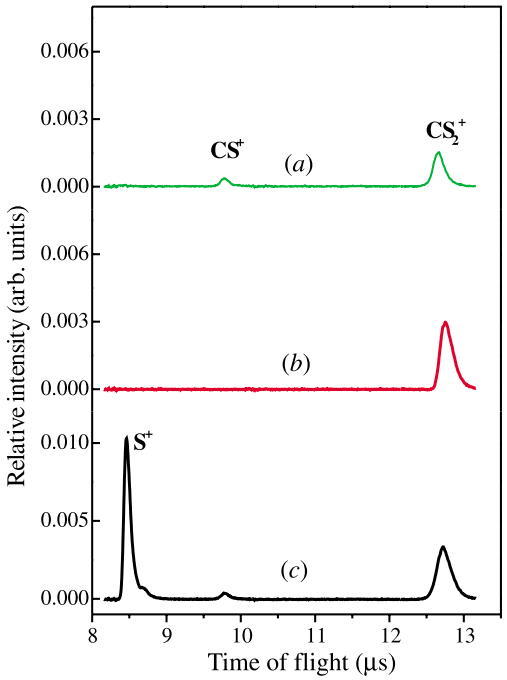
from these line widths for atomic sulfur. For atomic oxygen, with the similar electronic configuration $1s^2 2s^2 2p^4$, Smith and co-workers (6, 7) measured the autoionizing lifetimes originating from the ^{3}P state by a variety of techniques including Rabi oscillation. All of their measurements were based on multiphoton ionization of atomic oxygen (6, 7). Some lifetime measurements of weakly autoionizing states in O I in the region of 75–125 nm were also done by observing the decay rate of emitted photons (8). Fewer studies have been carried out on the superexcited singlet states of oxygen atoms compared to the triplet states, most likely because of the difficulty of producing a high density of atoms in the lower singlet state, from which optical excitation originates. We will show that this limitation can be overcome by using laser photolysis of the proper precursor for the metastable atom in a pulsed molecular beam along with a tunable coherent vacuum ultraviolet (VUV) source to excite the atom to the autoionization state. Strong signals can be obtained for the autoionizing state because the lasers cross the molecular beam at the point in both space and time at which the atom density is at a maximum, as well as because of the high sensitivity of the ion velocity imaging system.

The photodissociation dynamics of CS_2 at 193 nm has been extensively studied (9–14). It is well known that the photolysis of CS_2 gives rise to sulfur atoms in both the ground ($^3P_{2,1,0}$) and excited ($^1D_2$) states. The S($^1D_2$) in the beam is then excited using a single VUV photon at 121.896 nm (10.17 eV) to the $3s^2 3p^3(^2D^o)4d\ ^1D_2^o$ neutral state at 11.317 eV, which is above the first ionization threshold of the sulfur atom. This superexcited state then undergoes autoionization into the first ionization continuum of $S^+(^4S_{3/2}) + e^-$, with its threshold at 10.36 eV. The energy of the photon (10.17 eV) is not high enough to ionize the ground state S($^3P_2$). The relevant energy level diagram of the sulfur atom and ion is shown in Fig. 1. The $3s^2 3p^3(^2D^o)4d\ ^1D_2^o \leftarrow 3s^2 3p^4\ ^1D_2$ transition line profile is then recorded by monitoring the S^+ signal in the time-of-flight mass spectrometer (TOF-MS), while scanning the excitation wavelength.

Experimental

The measurements were performed using an ion velocity imaging apparatus, which has been described in detail elsewhere (15). It consists of three stainless steel chambers that are all pumped with separate turbo-molecular pumps. The first chamber is the molecular beam source chamber, which houses a piezoelectric pulsed valve with a nozzle having a diameter of 0.25 mm. The molecular beam is skimmed twice before it interacts with the laser beams. The second chamber is the reaction chamber where the skimmed molecular beam crosses the laser beams. During the experiments, the typical pressure in this chamber was 4×10^{-5} Pa. The laser beams enter the reaction chamber in a direction that is perpendicular to the molecular beam and intercept the molecular beam in the center of the ion optics of the TOF-MS. The ion optics of the TOF-MS consists of three plates, a repeller, an accelerator, and a ground plate, the last of which is the entrance to the flight tube for the mass spectrometer. High voltages with the appropriate ratio for ion velocity imaging are applied to the repeller and accelerator to focus the ions into the flight tube that is perpendicular to the plane defined by the laser and the molecular beams. The typical voltage ratio in our experiment was 1500 V/1042 V. To avoid any field effects on the line width measurement, the voltages on the ion optics were applied 300 ns after the arrival of the VUV light in the ionization region. The pressure in the flight tube during an experiment was about 8×10^{-7} Pa. This is low enough so that the ion cloud can fly for 62 cm without a collision in a field-free region before it strikes the detector. The detector assembly consists of two microchannel plates and a fast P47 phosphor screen. A CCD camera and a photomultiplier tube are mounted behind the screen to collect images and TOF spectra, respectively.

Fig. 1. Energy level diagram of the sulfur atom and ion.



The CS_2 molecular beam is crossed with a 193 nm laser beam, which is produced by a GAM laser (EX5). The S($^1D_2$) atom is ionized by a coherent VUV radiation beam that is obtained by frequency tripling. A Scanmate 2 (or FL2002) dye laser operating with the Pyridine 2 dye is pumped by the 532 nm output of an Nd:YAG laser (Spectra-Physics, Pro-230–30). The wavelength of the dye laser is calibrated by a wavelength meter (COHERENT WaveMaster^{TM}). The dye laser output is frequency doubled in an Inrad auto-track unit, which keeps the intensity of the UV output the same while the wavelength is scanned. The UV beam is separated from its fundamental with a prism and is focused with a quartz lens into a gas cell, which contains Kr gas that is used for generating the VUV radiation. The focal length of the quartz lens is 15 cm, and the UV light is focused about 6.5 cm in front of a LiF lens with a 6.5 cm focal length at the VUV wavelength so that the VUV light is nearly collimated through the reaction chamber.

Results

Figure 2 shows a series of mass spectra that were obtained under different excitation conditions. A pure CS_2 beam with 50 torr (1 torr = 133.322 Pa) backing pressure was used for

Fig. 2. Time-of-flight mass spectra of CS_2: (*a*) beam + 193 nm light; (*b*) beam + 121.896 nm light; (*c*) beam + 193 nm light + 121.896 nm light (121.896 nm light arrives 20 ns later relative to 193 nm light).

these experiments. The timing for the pulse valve opening was carefully adjusted so that no clusters were observed in the TOF spectra. Figure 2*a* shows that CS_2^+ and CS^+ ions are produced by multiphoton ionization even though the 193 nm laser fluence is very low (~1 mJ/cm^2) (16). This is because the single and multiphoton absorption cross sections of CS_2 are very large. Figure 2*b* is the TOF spectrum taken when only the VUV light at 121.896 nm (10.17 eV) was present. The CS_2^+ signal is the result of single-photon ionization of the CS_2 molecule whose ionization energy is 10.07 eV. Figure 2*c* shows the TOF mass spectrum when both lasers were present. The 121.896 nm light is delayed 20 ns with respect to the 193 nm laser. A strong S^+ signal is now seen in the TOF mass spectrum as expected. The S^+ ion comes from the VUV ionization of the S($^1D_2$) atom that is produced by the photodissociation of CS_2 at 193 nm. The S^+ ion signal disappears when the Kr gas is evacuated from the VUV cell.

The S^+ ion signal as a function of ionization wavelength was recorded using a Stanford Research Boxcar Averager (SR 250). Figure 3 shows the line profiles obtained when the wavelength of the ionization laser was scanned through the $3s^23p^3(^2D^o)4d\ ^1D_2^o \leftarrow 3s^23p^4\ ^1D_2$ transition using different gas pressures in the four-wave mixing cell with Scanmate 2 and FL2002 dye lasers. Different conversion efficiencies occur at these different pressures for frequency tripling that result in different VUV intensities. The absolute intensities at different Kr pressures vary by more than one order of magnitude. Figure 3 shows that the line profile does not change as the Kr pressure changes, which indicates that it is free from power broadening. The FWHM is a little different for the two dye lasers because of the different bandwidths of the lasers. The natural line width can be determined from these scans by assuming the dye lasers have Gaussian profiles, which have to be convoluted with the expected Lorentzian profile to produce the measured line shape. Figure 4 shows the fits obtained for the experimental line profiles using this convolution. The FWHM of the Lorentzian profiles obtained by these convolutions was 0.90 cm^{-1} for scans using both Scanmate 2 and FL2002 dye lasers. Different Gaussian bandwidths of 0.5 and 0.9 cm^{-1} have to be used in the convolution for the measurements using the Scanmate 2 and FL2002 dye lasers, respectively. The fits are excellent, and they yield a FWHM of 0.90 ± 0.05 cm^{-1} for the natural line width in both cases, which corresponds to an autoionization lifetime of 5.90 ± 0.31 ps. The bandwidths of the fundamentals of the two dye lasers are 0.09 and 0.16 cm^{-1} for the Scanmate 2 and the FL2002, respectively. The VUV bandwidths obtained by tripling the doubling output of the dye lasers should be at most 6 times those for the fundamentals, which turn out to be 0.54 and 0.96 cm^{-1}, respectively. However, during the fitting it was found that the width of the Gaussian function for the FL2002 could be chosen between 0.9 and 1.2 cm^{-1} to obtain a reasonable fit, with 0.9 cm^{-1} producing the best fit. Similarly, the width of the Gaussian function for the Scanmate 2 could be chosen between 0.4 and 0.6 cm^{-1}, with 0.5 cm^{-1} producing the best fit. The identical results for the natural line width from measurements using different dye lasers indicate the results are reliable.

Discussion

When an electron combines with the $3s^23p^3$ ion-core states of the sulfur atom, Rydberg series are formed whose energies converge to the associated $^4S^o$, $^2D^o$, or $^2P^o$ ion states. The $^4S^o$ core forms a series of triplet and quintet S, P Rydberg states, while $^2D^o$ forms singlet and triplet P, D, F Rydberg states, and $^2P^o$ forms singlet and triplet S, P, D Rydberg states. Photoabsorption and photoionization spectra of sulfur have been studied extensively in this region (3–5). Berkowitz and co-workers (5) reported the photoionization spectrum of sulfur in detail between the first ionization threshold and 92.5 nm. They assigned many of the autoionization states that converge to the $^4S^o$, $^2D^o$, $^2P^o$ states of the S^+ ion originating from the ground state of sulfur ($^3P_2$) (5).

Even though there have been many studies on the photoionization of sulfur atoms and the autoionization levels for these sulfur atoms have been previously assigned, to our knowledge no autoionization lifetime measurements have been reported. On the other hand, there are measurements on the autoionization lifetimes for atomic oxygen. The O ($^2D^o$)$3p\ ^1P_1$ and $^1F_3$ levels were first observed in the emission studies by Edlen and Sven (17) and by Eriksson and Isberg (18). The transitions involving the $^1P_1$ level were broadened by approximately 0.2 cm^{-1} with an autoionization lifetime of 3×10^{-11} s to the $^4S^o_{3/2}$ continuum; the transitions involving the $^1F_3$ level were sharper, and hence the lifetimes were longer (18). Instances of forbidden autoionization in atomic oxygen have been discussed by Huffman et al. (19) and Dehmer and co-workers (20–22) for Rydberg states excited from the ^3P, $^1D_2$, and $^1S_0$ lower states. Recently, Pratt et al. (23) reported the autoionization of O ($^2D^o$)$3p\ ^1P_1$ and

$^1F_3$ levels excited from the O($^1D_2$) state by two-photon absorption. They evaluated the autoionization lifetimes of the $^1P_1$ and $^1F_3$ levels and found that they were longer than 3×10^{-10} and 5.8×10^{-10} s, respectively. Smith and co-workers (6, 7) have done a considerable amount of work on the autoionizing states of atomic oxygen. They measured the autoionization lifetimes for the ($^2D^o$)3p ^{1,3}P and ($^2D^o$)3p ^{3}D, ^{3}F states by measuring the Rabi oscillations that were induced when the atoms were excited from the $^3P_2$ ground state by the multiphoton process. The autoionization lifetimes are on the order of 10^{-10} s for all the states except the ($^2D^o$)3p ^{3}P state, which has a 6-fs lifetime (7). More recently, single-photon ionization of atomic singlet oxygen O ($^1D_2$) was investigated by Flesch et al. (24). The photoionization efficiency spectrum was recorded between the onset of the first ($^4S^o$) and the second ($^2D^o$) ionization thresholds. However, no lifetimes were reported in this paper.

Within the *LS* coupling approximation, direct photoionization to the $^4S^o + e^-$ state between the first and the second ionization threshold (to ($^2D^o$)) is optically forbidden from the singlet states of the atom, since it violates the spin conservation rule. Thus, the only way these states can be ionized is via autoionization to $^4S^o$ as a result of spin–orbit, spin–spin, or other possible weaker interactions that couple atomic states with different spins (25–27). As discussed above, the lifetimes of the singlet states for atomic oxygen were found to be of the order of 10^{-10} s. In the current measurements for singlet atomic sulfur $^1D_2^o$, the lifetime was determined as 5.9 ps. This much faster autoionization rate for sulfur $^1D_2^o$ compared with singlet oxygen atoms can be understood in terms of spin–orbit and spin–spin interactions. The mass of the sulfur atom is much greater than that of the oxygen atom; one would therefore expect that spin–orbit interaction in the heavier sulfur atom would be much stronger than in the oxygen atom. This is seen in the spin–orbit splittings that are observed in the $^3P_{2,1,0}$ ground state of the sulfur atom, which are 396 and 177 cm^{-1} for $^3P_1$–$^3P_2$ and $^3P_0$–$^3P_1$, respectively, whereas they are only 158 and 69 cm^{-1} for the oxygen atom (28). The spin–spin interaction can also play an important role in the autoionization process. In the highly excited states, mixing between states with different spin is expected because of spin–spin interaction. The existence of state mixing between the very rapidly ionizing triplet state and the singlet state could promote the autoionizing rate of the singlet state.

The rate of autoionization, and the corresponding lifetime, can be estimated by the Golden Rule formula,

$$[1] \qquad k = \frac{2\pi}{\hbar}\left|V_{if}\right|^2 \rho_f$$

where V_{if} is the transition matrix element and ρ_f is the density of the final states. The zeroth-order initial and final states are described in a SCF Breit–Pauli approximation (29) by neglecting spin–spin and spin–orbit interactions. In the initial state $3s^2 3p^3(^2D^o)4d$ ($^1D_2^o$), prepared by single-photon excitation, one electron occupies a 4d orbital, and the rest form an ionic core, whose electronic configuration, $3s^2 3p^3(^2D^o)$, corresponds to an excited state of the S^+ ion. In the absence of spin–spin and spin–orbit interactions, the excited state is stable, with one 4d electron moving in a Coulomb field of the ionic core. The additional interaction between this electron and the core results in their energy exchange, a process in which the 4d electron is excited to an unbound state with kinetic energy sufficient to escape the Coulomb cage of the core, while the ionic core itself relaxes to its ground state of $^4S_{3/2}$. In the latter process, one of the electrons in the doubly occupied p orbital of the $3s^2 3p^3(^2D^o)$ configuration is transferred to an empty p orbital, simultaneously changing its spin, so that in the final state of the core all three electrons occupy three different p orbitals and have parallel spins, yielding $3s^2 3p^3$ $S^+(^4S^o_{3/2})$. Owing to the exchange effects, the same final state can be obtained by a transfer of the 4d electron to an empty orbital of the 3p shell, while one of the paired electrons from the 3p shell of the core is promoted to an unbound state and ejected from the atom. However, the contributions of the exchange effects in the latter type of interactions are typically small (29). The exact evaluation of the rate of the described process requires rather sophisticated computational work as, e.g., in ref. 30. However even a rough estimate described in the *Appendix* gives FWHM values in the range 10–40 cm^{-1}, which is about an order of magnitude higher than the experimental measurements.

Conclusion

For the first time, we are able to record the $3s^2 3p^3 4d$ $^1D_2^o \leftarrow 3s^2 3p^4$ $^1D_2$ transition line width of atomic sulfur using single VUV photon excitation by monitoring the S^+ signal in a TOF-MS while scanning the excitation wavelength. The deconvolution of the measured excitation line shape with the finite laser bandwidth yields a natural line width (FWHM) of 0.90 ± 0.05 cm^{-1}, from which the autoionization lifetime of the neutral superexcited state $3s^2 3p^3 4d$ $^1D_2^o$ is found to be 5.90 ± 0.30 ps. These results show that this is a general method to measure the lifetimes of atomic autoionization states with strong spin–orbit and spin–spin interactions.

Appendix A

Here, we estimate the order of magnitude of the autoionization rate of the process described in the text, using experimental data for typical spin–orbit interactions in sulfur. The rate is given by the Golden Rule formula,

$$[A1] \quad k = \frac{2\pi}{\hbar}\left|V_{\mathrm{if}}\right|^2 \rho_{\mathrm{f}}$$

where V_{if} is the transition matrix element, and ρ_{f} is the density of the final states. The final states result from the ionized electron moving in the field of the ionic core. The number of such states is given by the usual expression:

$$[A2] \quad \mathrm{d}n = V\frac{\mathrm{d}\vec{p}}{(2\pi\hbar)^3}$$

where V is the volume of the system, and $\vec{p}$ is the momentum of the ejected electron. Integration over all directions gives the density of states,

$$[A3] \quad \rho = V\frac{m}{\pi^2\hbar^3}\sqrt{\frac{mE}{2}}$$

where E is the kinetic energy of the ejected electron ($E(^1\mathrm{D}^{\mathrm{o}}_2)$ – IP; about 1 eV). The exit state of the ejected electron should be described by a wave function of an electron moving in the field of the ionic core. For a rough estimate, however, we will take

$$[A4] \quad \left|\vec{p}\right\rangle = \frac{1}{\sqrt{V}}\exp\left(\frac{i\vec{p}\vec{r}}{\hbar}\right)$$

For an estimate of the matrix element, we can then write

$$[A5] \quad V_{\mathrm{if}} = \left\langle \varphi^{\downarrow}_{3px}(1)\,\varphi^{\uparrow}_{4d}(2)\left|\hat{V}(1,2)\right|\varphi^{\uparrow}_{3pz}(1)\vec{p}(2)\right\rangle \approx \overline{V}_{12}\frac{a_{4d}^{3/2}}{\sqrt{V}}$$

where a_{4d} is the radius of the 4*d* orbital, and $\overline{V}_{12}$ is the average spin–spin and spin–orbit interactions between the 4*d* electron and electrons of the 3*p* shell of the core. The exchange effects should not change the order of magnitude of the above estimate. Here, we neglect factor $2\sqrt{2}/\pi$, which is on the order of unity. Thus, for the rate we roughly have

$$[A6] \quad k \approx \frac{\overline{V}_{12}^2}{2\hbar}\frac{a_{4d}^2 m}{\hbar^2}\frac{a_{4d}\sqrt{mE}}{\hbar}$$

The last term in the above expression is roughly the angular momentum of the ejected electron; since the kinetic energy of the electron is about 1 eV, the last term gives a factor close to 4. The second term is the inverse kinetic energy of the 4*d* electron, the order of magnitude of which is also 1 eV. A typical value of spin–orbit interaction in the sulfur atom can be estimated from the splittings of the $^3\mathrm{P}_2$–$^3\mathrm{P}_1$ (396 cm^{-1}) and $^3\mathrm{P}_1$–$^3\mathrm{P}_0$ (177 cm^{-1}) energy levels of the ground state (A1). For $\overline{V}_{12}$ = 200 cm^{-1}, the FWHM is estimated to be 10 cm^{-1}; for $\overline{V}_{12}$ = 400 cm^{-1}, FWHM = 40 cm^{-1}. Given the crude nature of the estimate, it is not surprising that the estimation is an order of magnitude higher than the observed value. Note that the term $\overline{V}_{12}$ in eq. [A5] should be the interaction between the 4*d* Rydberg electron and the 3*p* core electrons. Considering the large diameter of the Rydberg orbital, the interaction $\overline{V}_{12}$ should be much weaker than that in the ground state S(^{3}P). Using the measured line width of 0.9 cm^{-1}, we can estimate $\overline{V}_{12}$ to be 60 cm^{-1}.

Transition state dynamics and a QM/MM model for the $Cl^- + C_2H_5Cl$ S_N2 reaction[1]

Lipeng Sun, Eunkyung Chang, Kihyung Song, and William L. Hase

Abstract: A MP2/6-31G* direct dynamics simulation is used to study the dynamics of the central barrier $[Cl\text{-}C_2H_5\text{-}Cl]^-$ for the $Cl^- + C_2H_5$ S_N2 reaction. The majority of the trajectories move off the central barrier to form the Cl^-–C_2H_5Cl complex and appear to undergo efficient IVR as assumed by RRKM theory. However, some of the trajectories move directly to products without forming the complex, a non-RRKM result. A hydrogen atom link-atom QM/MM model is described for studying the dynamics of $[X\text{-}CH_2R\text{-}Y]^-$ central barriers with the -R substituent. The model is used to calculate vibrational frequencies for the $[Cl\text{-}C_2H_5\text{-}Cl]^-$ central barrier.

Key words: S_N2 reaction dynamics, RRKM theory, QM/MM model, central barrier dynamics, direct dynamics classical trajectories.

Résumé : On utilise une simulation dynamique directe MP2/6-31G* pour étudier la dynamique de la barrière centrale $[Cl\text{-}C_2H_5\text{-}Cl]^-$ de la réaction S_N2 $Cl^- + C_2H_5$. La majorité des trajectoires se déplacent à partir de la barrière centrale pour former le complexe $Cl^$–C_2H_5Cl et elles semblent subir un « IVR » efficace, tel que suggéré par la théorie « RRKM ». Toutefois, certaines de ces trajectoires se déplacent directement vers les produits sans former de complexe, ce qui est un résultat qui ne correspond pas à la théorie de RRKM. On décrit un modèle QM/MM d'atome d'hydrogène agissant comme atome liant pour étudier la dynamique de $[X\text{-}CH_2R\text{-}Y]^-$ comportant un substituant -R. On a utilisé le modèle pour calculer les fréquences vibrationnelles de la barrière centrale de $[Cl\text{-}C_2H_5\text{-}Cl]^-$.

Mots clés : dynamique d'une réaction S_N2, théorie de RRKM, modèle QM/MM, dynamique de la barrière centrale, trajectoires classiques.

Introduction

Bimolecular nucleophilic substitution (S_N2) reactions of the type

[1] $$X^- + CH_3Y \rightarrow XCH_3 + Y^-$$

are of central importance in gas-phase ion chemistry (1–4) and organic reaction mechanisms (5). Extensive investigations, both computational–theoretical (6–19) and experimental (20–32), have been carried out to understand the energies and dynamics of these reactions. Given the prominence of statistical theories in chemical reaction dynamics and kinetics (33), it was natural to use these theories to model S_N2 reaction rates (1). However, recent detailed examinations of S_N2 reactions of the type in eq. [1] have discovered a range of important nonstatistical attributes (7, 8, 11–18, 27–32) arising from weak couplings between the X^--CH_3Y intermolecular and CH_3Y intramolecular modes. Trajectories calculated for the $Cl^- + CH_3Cl$ and $Cl^- + CH_3Br$ S_N2 reactions become trapped in the central barrier region of the potential energy surface, with concomitant recrossing of the barrier (8, 11, 15). The former suggests that vibrational states prepared in the central barrier region may be sufficiently long-lived to resolve their spectra (34), while the latter indicates that crossing the central barrier may not be the rate-controlling step, as assumed by statistical theories for many S_N2 reactions (1, 10).

In a previous classical trajectory study (15) of the $Cl^- + CH_3Cl$ reaction, 10 trajectories were calculated by sampling 300 K Boltzmann distributions at the $[Cl\text{-}CH_3\text{-}Cl]^-$ central barrier for the reaction coordinate, the 11 orthogonal normal modes of vibration, and the three external rotational degrees of freedom. The Born–Oppenheimer direct dynamics method (35) was used to calculate the trajectories, with the potential energy and its gradient obtained directly from the MP2/6-31G* level of theory. Each of the 10 trajectories initiated at the central barrier was integrated for 3 ps in both forward and backward directions off the barrier. The RRKM statistical theory of chemical kinetics (36) assumes the trajectories move off the barrier and form a Cl^-–CH_3Cl com-

plex with an average lifetime (τ) equal to the anharmonic RRKM value of 4 ps. For the integration time (t) of 3 ps, RRKM predicts that 50% (i.e., $\exp(-t/\tau)$) of these complexes should form Cl^- + CH_3Cl products. In contrast to this prediction, not one of the twenty 3 ps forward and backward trajectories off the central barrier formed products. Instead, five of the 10 trajectories initiated at the central barrier started in one Cl^-–CH_3Cl complex and ended in another, while the remaining five trajectories started and ended in the same complex. Many of the trajectories exhibited a regular type motion, with well-defined frequencies and extensive recrossings of the central barrier. The barrier recrossing dynamics observed for these direct dynamics trajectories is very similar to that found for trajectories calculated on an analytic potential energy function fit to HF/6-31G* calculations (11).

A total of 29 central barrier crossings occurred for the 10 direct dynamics trajectories, a result much different than the predictions of the RRKM and transition state (TST) theories. Because of the higher potential energy at the central barrier in comparison to that for the products (i.e., ~3 kcal/mol) (37) and the much tighter transition state at the central barrier compared to that for dissociation, RRKM theory predicts that the Cl^-–CH_3Cl complex preferentially dissociates to Cl^- + CH_3Cl with negligible recrossing of the central barrier. Thus, crossing the central barrier is predicted to be the rate-controlling step of the S_N2 reaction, as assumed by TST.

In the first part of this article, the $[Cl\text{-}C_2H_5\text{-}Cl]^-$ central barrier dynamics of the Cl^- + C_2H_5Cl S_N2 reaction was studied for comparison with the above $[Cl\text{-}CH_3\text{-}Cl]^-$ central barrier dynamics. MP2/6-31G* direct dynamics was also used for this study. It is of interest to determine the effect of replacing one of the structureless H-atoms in $[Cl\text{-}CH_3\text{-}Cl]^-$ with a $-CH_3$ group. This changes the symmetry of the system, which influences the dynamics. In addition, the $-CH_3$ group may serve as an energy bath during the course of the reaction, which may also affect the reaction dynamics. This study of the $[Cl\text{-}C_2H_5\text{-}Cl]^-$ central barrier dynamics will lead to a deeper understanding of the effect of a -R side chain on the dynamics of Cl^- + CH_2RCl S_N2 reactions. It is noteworthy that Brauman and co-workers (38) found that the kinetics for the Cl^- + $ClCH_2CN$ S_N2 reaction, with the -CN substituent, agrees with the RRKM theory.

Direct dynamics simulations often require a prohibitive amount of computer time as the number of atoms in the chemical reaction increases (35). An approach to treat such large systems by direct dynamics is to represent the atoms most intimately involved in the chemical reaction by a quantum mechanical (QM) electronic structure theory and the remaining atoms by a molecular mechanical (MM) analytic potential energy function. This QM/MM model (39) may be used to replace one or more of the H-atoms of the CH_3Y reactant in eq. [1] with -R substituents, by using the MM component of the model to represent the potential energy of the substituents. In this manner, a direct dynamics simulation may be used to study how a S_N2 reaction's central barrier dynamics is affected by the number and type of substituents on the CH_3Y reactant. In the second part of this paper, a link-atom QM/MM model is presented and its application to the Cl^- + C_2H_5Cl S_N2 reaction, with $-CH_3$ represented by a MM potential, is described.

Transition state dynamics for the Cl^- + C_2H_5Cl reaction

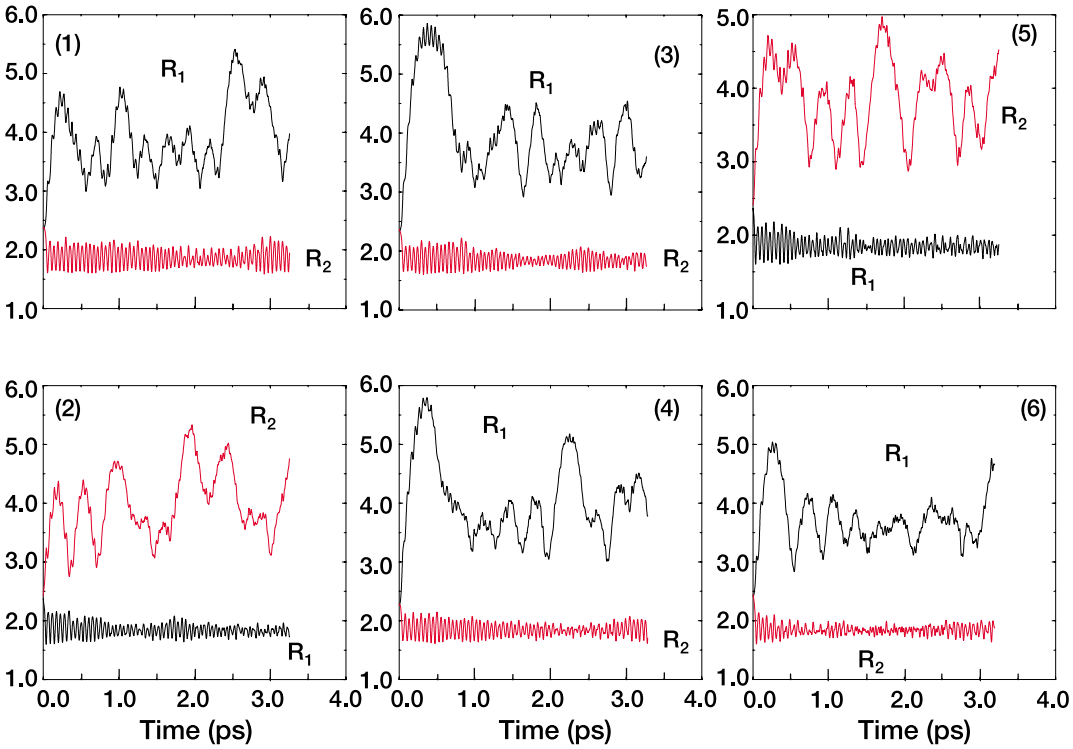
Computational procedure

Electronic structure theory

The MP2/6-31G* level of theory was used to calculate the direct dynamics trajectories. In previous work (40, 41), MP2/6-31G* and other ab initio theories (e.g., MP2, MP3, and MP4 with 6-311+G(2d) and 6-31+G* basis sets) (40) were compared for the Cl^- + $C_2H_5Cl^-$ reaction. The MP2/6-31G* geometries and energies for stationary points on the potential energy surface are in good agreement with experiment and the higher-level ab initio calculations (40). Though MP2/6-31G* has not been compared with CCSD(T)/large basis set calculations for the Cl^- + C_2H_5Cl reaction, they have been compared for Cl^- + CH_3Cl (15). For the latter reaction, the MP2/6-31G* classical potential energy barrier of 4.54 kcal/mol is in good agreement with the CCSD(T) value of 3.16 kcal/mol (37). For this reaction, MP2/6-31G* also gave a structure and vibrational frequencies for the $[Cl\text{-}CH_3\text{-}Cl]^-$ central barrier (15) in excellent agreement with the CCSD(T) values (37) (i.e., the Cl—C bond lengths of the two theories agree to within 0.005 Å and the symmetric Cl-C and C-H stretch frequencies differ by only 6 and 65 cm^{-1}, respectively).

The MP2/6-31G* classical barrier for the Cl^- + C_2H_5Cl reaction is 8.39 kcal/mol (i.e., 3.85 kcal/mol higher than the Cl^- + CH_3Cl barrier). The MP2, MP3, and MP4 theories with the 6-311+G(2d) basis set gave 3.0–3.4 kcal/mol for this barrier difference (40). Though there are no definitive values for the Cl^- + CH_3Cl and Cl^- + C_2H_5Cl barrier heights, experimental values in the range of 1.1–3.4 kcal/mol have been reported (23, 24, 42) for the difference in the barrier heights for the similar reactions Cl^- + CH_3Br and Cl^- + C_2H_5Br. The MP2/6-31G* value for the Cl^- + $C_2H_5Cl \rightarrow Cl^-\text{-}C_2H_5Cl$ complexation energy is 12.3 kcal/mol, very similar to the 11.0 kcal/mol value for Cl^- + CH_3Cl. The MP2, MP3, and MP4 theories with the 6-311+G(2d) basis set (40) give 11.5–11.8 kcal/mol for the Cl^- + C_2H_5Cl complexation energy.

At the MP2/6-31G* level of theory, the Cl^- + $C_2H_5Cl^-$ central barrier has an asymmetric structure (40) with C—Cl bonds that have slightly different lengths of 2.342 and 2.369 Å. One of the C—H bonds of the $-CH_3$ group eclipses one of the C—Cl bonds. However, apparently there is no strong preference for a specific internal rotation orientation of the $-CH_3$ group. Rotating the $-CH_3$ group by 30° so that the central barrier has a plane of symmetry, which includes the two carbon atoms, the two hydrogens on the reacting carbon, and one hydrogen on $-CH_3$, forms a second-order saddle point only 0.11 kcal/mol higher in energy (40).



The conclusion reached from the above comparisons between MP2/6-31G* and other electronic structure theories and experiment, for the Cl^- + $C_2H_5Cl^-$ reaction and related S_N2 reactions, is that MP2/6-31G* theory gives a good representation of the Cl^- + $C_2H_5Cl^-$ potential energy surface and is a practical approach for performing a direct dynamics simulation of the $[Cl\text{-}C_2H_5\text{-}Cl]^-$ central barrier dynamics.

Trajectory initial conditions and calculations

The direct dynamics $[Cl\text{-}C_2H_5\text{-}Cl]^-$ barrier excitation tra-

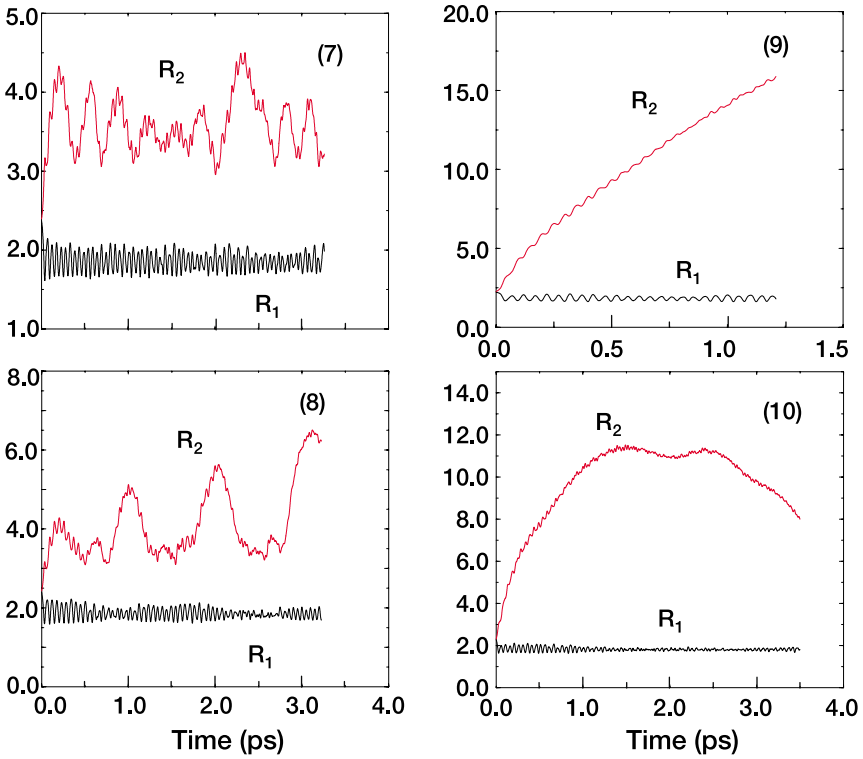
Fig. 1. The two C—Cl bond lengths (R_1 and R_2) in Å vs. time (ps) for six of the [Cl-C_2H_5-Cl]$^-$ barrier excitation trajectories.

jectories were calculated by interfacing (43) the VENUS96 (44) chemical dynamics and GAUSSIAN98 (45) electronic structure programs. Hessian updating (46) and an efficient predictor–corrector algorithm (47) were used to numerically integrate the classical equations of motion. Energy conservation at the end of the integration varied from 0.03–0.17 kcal/mol, out of a total energy of 45–48 kcal/mol.

Quasiclassical sampling (48), which includes zero-point energy, was used to select initial conditions for 68 trajectories from the 300 K Boltzmann energy distributions at the central barrier for the reaction coordinate, the 11 orthogonal normal modes of vibration, and the three external rotation degrees of freedom. The sign (i.e., positive or negative) of the reaction coordinate momentum was chosen randomly so that initially the trajectory could move towards either Cl^-–C_2H_5Cl potential energy well. The trajectories were integrated for 3.2–3.4 ps or until the Cl^- + C_2H_5Cl separation reached 16 Å for a dissociation event. It required about 140 CPU-hours to integrate a trajectory for 3.2 ps on a Pentium IV/1.9 GHz single processor.

Direct dynamics results

Plots of the Cl—Cl bond lengths vs. time for the first 10 [Cl-C_2H_5-Cl]$^-$ barrier excitation trajectories, which were calculated, are given in Figs. 1 and 2. Eight of the trajectories became immediately trapped in the ion-dipole well of the Cl^-–C_2H_5Cl complex as they moved off the central barrier. One of the trajectories directly dissociates to products, within 1.2 ps, without being trapped in the ion-dipole potential energy well. For another trajectory, the Cl^- ion leaves C_2H_5Cl and reaches a center of mass separation of 12 Å and then returns to the potential energy well.



The dynamics illustrated in Figs. 1 and 2 are representative of those for the complete batch of 68 trajectories. Sixty-two of the trajectories moved off the barrier and became immediately trapped in one of the Cl^-–C_2H_5Cl complexes. One of these trajectories dissociated with a lifetime of 3.3 ps and two had large Cl^- + C_2H_5Cl center-of-mass separations of 14.5 and 15.3 Å when they were terminated. As discussed above, another trajectory became trapped in a Cl^-–C_2H_5Cl complex and did not dissociate, but initially moved directly towards products, attaining a center-of-mass separation of 12 Å. Three trajectories directly formed products with lifetimes of 1.2 ps or less, without forming a Cl^-–C_2H_5Cl complex. Two trajectories had a single barrier recrossing and remained trapped in a Cl^-–C_2H_5Cl complex. For one of these, the center-of-mass separation between the reaction products was 11.8 Å when the trajectory was terminated.

The [Cl-C_2H_5-Cl]$^-$ barrier excitation trajectories do not exhibit the regular type motion observed for the [Cl-CH_3-Cl]$^-$ system. The former trajectories do not remain locked in a nonstatistical motion giving rise to extensive recrossings of the central barrier. For the 62 trajectories that leave the central barrier and immediately form the Cl^-–C_2H_5Cl complex, the intermolecular Cl^--C and intramolecular Cl-C stretch modes undergo irregular motion as a result of energy transfer to and from these modes. Such efficient energy transfer is consistent with the RRKM theory of unimolecular dynamics, which assumes the vibrational states of the energized species are populated in a statistical way (36).

Though the Cl^-–C_2H_5Cl complexes exhibit statistical type behavior, strong evidence remains for a nonstatistical component in the Cl^- + C_2H_5Cl S_N2 reaction. Four of the 68 trajectories are inconsistent with the RRKM model of unimolecular kinetics, which assumes the Cl^-–C_2H_5Cl complex should be formed as the trajectory moves off the central barrier as a result of strong coupling between the reaction coordinate motion and the system's other degrees of freedom.

© 2004 NRC Canada

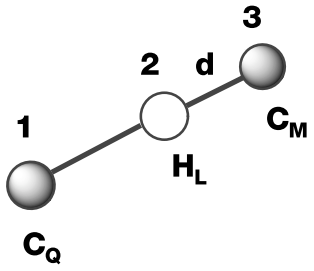
Fig. 2. Same as for Fig. 1, but for the remaining four trajectories.

For these four trajectories, this initial coupling is weak. Three trajectories go directly to products without forming a complex, as depicted by trajectory (9) in Fig. 2. Though another trajectory, i.e., number (10) in Fig. 2, returns to the ion-dipole complex, initially a sufficient amount of translational energy remains in the Cl^--C stretch motion to extend this bond to about 12 Å. The implication from these trajectories is that for the 300 K temperature considered here a fraction of the $Cl^- + C_2H_5Cl$ reaction will occur with trajectories moving directly from the $[Cl\text{-}C_2H_5Cl]^-$ central barrier to $Cl^- + C_2H_5Cl^-$ products without becoming trapped in the exit channel $Cl^–C_2H_5Cl$ ion-dipole complex. This fraction is expected to increase as the temperature or energy of the reactive system is increased (2, 4). In addition, two trajectories recross the high central barrier, a result inconsistent with both RRKM and TST (15).

A link-atom QM/MM model for S_N2 reactions

A QM/MM model for a chemical reaction or molecule partitions the system into one part whose potential energy is represented by a quantum mechanical (QM) electronic structure theory and the remainder by a molecular mechanical (MM) analytic potential energy function (39). Often the QM/MM boundary cuts through one or more chemical bonds. To illustrate, one might construct a QM/MM model for *n*-hexane (C_6H_{14}) with the C_2H_5· moiety represented by QM and C_4H_9· by MM. The QM/MM boundary is a C—C bond and it is necessary to saturate the valency of C_2H_5·. One way to accomplish this is to use the "link-atom" method (49–51), in which an unphysical atom is added to the boundary QM atom. Typically a hydrogen atom is chosen as the link atom since the broken bond is usually a σ bond (e.g., a C—C bond). The link atom is invisible to the MM atoms, since there are no interactions between the link and MM atoms. MM potentials are used to connect the QM and MM atoms at the boundary. For the above C_2H_5· and C_4H_9· QM and MM components, a stretching potential is added to connect the two C atoms, and bending and torsional analytic functions are used to represent the angular and internal rotational potentials at the QM/MM boundary.

In this work, an H atom link-atom model is described for a QM/MM boundary at a C—C bond. This C—C bond is constrained to lie along the C—H bond of the link atom, with the C—C bond length constrained to equal the length of this C—H bond plus a constant additional length. As a result of the similarity between both stretching and bending force constants for C—C and C—H bonds (52), only small forces must be added, or minor scaling of the force constants performed, (53) to obtain accurate vibrational frequencies for the complete QM/MM system.



Details of the model

The link-atom model described here for a QM/MM boundary that cuts through a C—C covalent single bond is depicted in Fig. 3. To avoid introducing additional degrees of freedom, the link hydrogen atom H_L was constrained on the C—C bond. The distance between H_L and the MM carbon C_M was kept fixed. Therefore, the motion of H_L and C_M was synchronized. The relationship between the force on H_L and C_M were derived and shown in the next section.

Let $\vec{r}_1$, $\vec{r}_2$, $\vec{r}_3$ denote the positions of the QM carbon C_Q, H_L, and C_M, respectively. The C_Q—H_L and H_L—C_M bonds

© 2004 NRC Canada

Fig. 3. A H-atom link-atom model for a QM/MM boundary that cuts through a C—C bond.

are then $\vec{r}_{12} = \vec{r}_2 - \vec{r}_1$ and $\vec{r}_{23} = \vec{r}_3 - \vec{r}_2 = \vec{d}$. Their components on the x-axis are

$$[2] \quad x_3 - x_2 = d\ \sin\theta\ \cos\phi$$

$$[3] \quad x_2 - x_1 = r_{12}\ \sin\theta\ \cos\phi$$

where θ and ϕ are the polar angles that determine the orientation of C_Q-H_L-C_M. The first- and second-order time derivatives of eqs. [2] and [3] are

$$[4] \quad \dot{x}_3 - \dot{x}_2 = d(\cos\theta\cos\phi\dot{\theta} - \sin\phi\sin\theta\dot{\phi})$$

$$[5] \quad \ddot{x}_3 - \ddot{x}_2 = d[\cos\theta\cos\phi\ddot{\theta} - \sin\phi\sin\theta\ddot{\phi} - \sin\theta\cos\phi(\dot{\theta}^2 + \dot{\phi}^2) - 2\sin\phi\cos\theta\dot{\theta}\dot{\phi}]$$

$$[6] \quad \dot{x}_2 - \dot{x}_1 = r_{12}\sin\theta\cos\phi + r_{12}(\cos\theta\cos\phi\dot{\theta} - \sin\phi\sin\theta\dot{\phi})$$

$$[7] \quad \ddot{x}_3 - \ddot{x}_2 = r_{12}[\cos\theta\cos\phi\ddot{\theta} - \sin\phi\sin\theta\ddot{\phi} - \sin\theta\cos\phi(\dot{\theta}^2 + \dot{\phi}^2) - 2\sin\phi\cos\theta\dot{\theta}\dot{\phi}] + \ddot{r}_{12}\sin\theta\cos\theta + \cos\theta(\sin\phi + \cos\phi)\dot{r}_{12}\dot{\theta}_{12} - \sin\theta(\sin\phi + \cos\phi)\dot{r}_{12}\dot{\phi}$$

Combining eqs. [4]–[7] one obtains

$$[8] \quad \ddot{x}_2 - \ddot{x}_1 = \ddot{r}_{12}\sin\theta\cos\phi + \cos\theta(\sin\phi + \cos\phi)\dot{r}_{12}\dot{\theta} - \sin\theta(\sin\phi + \cos\phi)\dot{r}\dot{\phi} + \frac{r_{12}}{d}(\ddot{x}_3 - \ddot{x}_2)$$

from which the x-component of the force on C_M can be obtained as

$$[9] \quad -\frac{\partial V}{\partial x_3} = \frac{(d + r_{12})}{r_{12}}\frac{m}{M}\left(-\frac{\partial V}{\partial x_2}\right) - \frac{d}{r_{12}}\left(\frac{\partial V}{\partial x_1}\right) + \frac{d}{r_{12}}m\,(\ddot{r}_{12}\sin\theta\cos\phi + 2\cos\phi\cos\theta\dot{r}\dot{\theta} + 2\sin\theta\sin\phi\dot{r}\dot{\phi})$$

where the m and M are the atomic masses of carbon and hydrogen. Similarly, the force component of C_M on the y-axis and z-axis can be derived, i.e.,

$$[10] \quad -\frac{\partial V}{\partial y_3} = \frac{(d + r_{12})}{r_{12}}\frac{m}{M}\left(-\frac{\partial V}{\partial y_2}\right) - \frac{d}{r_{12}}\left(\frac{\partial V}{\partial y_1}\right) + \frac{d}{r_{12}}m\,(\ddot{r}_{12}\sin\theta\sin\phi + 2\sin\phi\cos\theta\dot{r}\dot{\theta} + 2\sin\theta\cos\phi\dot{r}_{12}\dot{\phi})$$

$$[11] \quad -\frac{\partial V}{\partial z_3} = \frac{(d + r_{12})}{r_{12}}\frac{m}{M}\left(-\frac{\partial V}{\partial z_2}\right) - \frac{d}{r_{12}}\left(\frac{\partial V}{\partial z_1}\right) + \frac{d}{r_{12}}m\,(\ddot{r}_{12}\cos\theta - 2\sin\theta\dot{r}_{12}\dot{\theta})$$

In most cases the classical trajectory is integrated in a Cartesian coordinate system. Therefore, the internal coordinates variables in eqs. [9]–[11] must be transformed into Cartesian coordinates. The transformations of $\vec{r}_1$, $\vec{r}_2$, $\vec{r}_3$ are straightforward. Transformation of their first derivatives is written as

$$[12] \quad \begin{pmatrix} \dot{x}_2 - \dot{x}_1 \\ \dot{y}_2 - \dot{y}_1 \\ \dot{z}_2 - \dot{z}_1 \end{pmatrix} = \begin{pmatrix} \sin\theta\cos\phi & \cos\theta\cos\phi & -\sin\phi \\ \sin\theta\sin\phi & \cos\theta\sin\phi & \cos\phi \\ \cos\theta & \sin\theta & 0 \end{pmatrix} \begin{pmatrix} \dot{r}_{12} \\ r_{12}\dot{\theta} \\ r\sin\theta\,\dot{\phi} \end{pmatrix}$$

Since the 3 × 3 matrix is unitary, the transformation is just the interchange of the off-diagonal elements. Therefore, $\dot{r}$, $\dot{\theta}$, $\dot{\phi}$ are derived directly. Once the forces for C_Q and H_L are calculated from the QM potential, the force on C_M is determined from eqs. [9]–[12].

In the QM/MM classical direct dynamics calculation, the quantum mechanical program calculates the QM part, which includes the H_L atom. The forces on H_L and C_Q are then transformed to C_M according to eqs. [9]–[12]. Together with the force for the MM part, the trajectory is integrated for one step for every atom in the system except the H_L atom to find the new coordinates and momenta. The position of H_L is then updated by $|\vec{r}_{C_M} - \vec{d}|$. A new QM and MM force calculation with an update of H_L is then carried out for the next integration step. Such a procedure repeats until the trajectory reaches one of its stopping criteria.

Tests and (or) applications of the model

Collinear three-atom model

With the H_L and C_M distances fixed, holding the atoms collinear is equivalent to making the C_Q-H_L-C_M bending and H_L-C_M stretch forces very high (i.e., making these vibrations stiff). It is straightforward to show that, if the H_L-C_M distance is fixed, the vibrational frequency for the collinear system is

$$[13] \quad \nu = \frac{1}{2\pi}\sqrt{\frac{k_1}{\mu}}$$

© 2004 NRC Canada

$$\mu = \frac{(M+m)m}{M+2m}$$

where m is the mass of the carbon atoms and M is that of H_L. Equation [13] means that C_M and H_L behave as a single atom with mass $M + m$.

To show that eq. [13] is also the result for the stiff model, first assume that the C_Q-H_L interaction can be described by a harmonic oscillator with a force constant k_1. Similarly, the H_L-C_M potential is given by a harmonic oscillator with force constant k_2. The potential can be written as

$$[14] \quad V = \frac{1}{2}k_1(x_2 - x_1)^2 + \frac{1}{2}k_2(x_3 - x_2)^2$$

where x_1, x_2, and x_3 are the deviations of C_Q, H_L, and C_M from their equilibrium positions. Following the standard procedure for a normal mode analysis, the force constant matrix is constructed as

$$[15] \quad \begin{vmatrix} \frac{k_1}{m} - \lambda & -\frac{k_1}{\sqrt{mM}} & 0 \\ -\frac{k_1}{\sqrt{mM}} & \frac{k_1+k_2}{M} - \lambda & -\frac{k_2}{\sqrt{mM}} \\ 0 & -\frac{k_2}{\sqrt{mM}} & \frac{k_2}{m} - \lambda \end{vmatrix} = 0$$

Diagonalization of the above equation involves solving

$$[16] \quad \lambda^2 - (k_1 - k_2)\left(\frac{1}{m} + \frac{1}{M}\right)\lambda + \left(\frac{2k_1k_2}{Mm} + \frac{k_1k_2}{m^2}\right) = 0$$

When $k_2 \to \infty$, which is the stiff model, eq. [16] becomes

$$[17] \quad \lambda^2 - \left[k_1\left(\frac{1}{m} + \frac{1}{M+m}\right) + k_2\left(\frac{1}{m} + \frac{1}{M}\right)\right]\lambda + \left(\frac{2k_1k_2}{Mm} + \frac{k_1k_2}{m^2}\right) = 0$$

Therefore, $\lambda_1 = k_1/\mu_1$, where $\mu_1 = (M+m)m/(M+2m)$, $\lambda_2 = k_2/\mu_2$, and $\mu_2 = 1/M + 1/m$. The eigenvalue λ_1 gives the same frequency as eq. [13].

[Cl-C_2H_5-Cl]$^-$ central barrier

It is of interest to test the QM/MM model described here by using the [Cl-C_2H_5-Cl]$^-$ central barrier as an example. If the model correctly describes the properties of [Cl-C_2H_5-Cl]$^-$, it is expected that it can be used to study how adding -R substituents to the [Cl-CH_3-Cl]$^-$ system affects the S_N2 reaction dynamics. For [Cl-C_2H_5-Cl]$^-$ the -CH_3 group is -R.

This QM/MM model was used to calculate vibrational frequencies for the [Cl-C_2H_5-Cl]$^-$ central barrier. Force constants for the [Cl-CH_3-Cl]$^-$ QM part of the model were calculated at the MP2/6-31G* level of theory. The -CH_3 MM force field consists of three C_M-H stretches and three H-C_M-H bends. Three C_Q-C_M-H bends are added for the QM/MM boundary. The -CH_3 torsion is treated as a free rotor (see previous discussion) and nondiagonal force constants were neglected in the MM force field. The MM force constants are the same as the MP2/6-31G* values for the [Cl-C_2H_5-Cl]$^-$ central barrier. The C_Q-C_M stretching and H-C_Q-C_M bending force constants associated with the C_Q-C_M interaction are the same as those for the C_Q-H_L interaction.

Table 1. Vibrational frequencies (cm^{-1}) for the [Cl-C_2H_5-Cl]$^-$ central barrier.

[a]MP2/6-31G* frequencies for the [Cl-C_2H_5-Cl]$^-$ stationary point.
[b]QM/MM model with the MM force constants obtained from the ab initio calculation in footnote *a*.
[c]The same QM/MM model with the MM force constants increased to get better overall agreement with the ab initio calculated frequencies.
[d]The same QM component and MM force field as used in footnote *c*, except the C_Q-H_L-C_M bending and H_L-C_M force constants are set to 15.0 mdyn Å/rad^2 and 50.0 mdyn/Å, respectively.

Since the QM part of the model is [Cl-CH_3-Cl]$^-$, the Cl—C bond lengths and Cl-C-Cl angle for the [Cl-C_2H_5-Cl]$^-$ central barrier are the values for [Cl-CH_3-Cl]$^-$. The latter has a symmetric structure with bond lengths of 2.307 Å and the Cl-C-Cl angle is 180°. The structure of [Cl-C_2H_5-Cl]$^-$ is slightly asymmetric with Cl—C bond lengths of 2.342 and 2.369 Å and a Cl-C-Cl angle of 165.3°.

The ab initio and QM/MM vibrational frequencies for the [Cl-C_2H_5-Cl]$^-$ central barrier are compared in Table 1. The first two colums in the table are the ab initio frequencies and the QM/MM frequencies with the force constants described previously. There is overall good agreement between the two sets of frequencies, with the difference usually much less than 10%. However, the difference is much larger for some of the frequencies in the 200–300 and 1100–1500 cm^{-1} ranges. There are two sources for this difference. As described below, there are differences between the force field for [Cl-CH_3-Cl]$^-$ and the force field for the Cl-CH_2-Cl component of [Cl-C_2H_5-Cl]$^-$, particularly for the low-frequency vibrations. Second, because the MM force constants are only taken from the diagonal elements of the ab initio force constant matrix for [Cl-C_2H_5-Cl]$^-$, inaccuracies in the frequencies may also result from neglecting the nondiagonal elements.

The third column in Table 1 illustrates the effect of making minor adjustments to the MM force field by increasing the H-C_M-H and C_Q-C_M-H bending force constants by scaling factors in the range of 1.17–1.23. Comparing columns

© 2004 NRC Canada

1–3 in the table shows that increasing the MM force constants results in much better agreement between the ab initio and QM/MM frequencies in the 1440–1600 cm^{-1} range. As expected, the low vibrational frequencies, which are for motions involving the Cl-atoms, are independent of these changes in the MM force field. The factor of 1.41 difference between the 326.5 and 231.4 frequencies is the largest difference between the ab initio and QM/MM vibrational frequencies. This mode is analogous to the CH_3 out-of-plane bend for the $[Cl\text{-}CH_3\text{-}Cl]^-$ central barrier and apparently it is not well described by the Cl-C-H and Cl-C-Cl force constants of the $[Cl\text{-}CH_3\text{-}Cl]^-$ QM component of the QM/MM model. These force constants could be scaled to bring the ab initio and QM/MM frequencies for this mode into better agreement.

The fourth column in Table 1 illustrates the effect of replacing the QM/MM link-atom model with a constrained collinear $C_Q\text{-}H_L\text{-}C_M$ geometry and a fixed H_L-C distance by a force field with large $C_Q\text{-}H_L\text{-}C_M$ and $H_L\text{-}C_M$ bending and stretching force constants of 15.0 mdyn-Å/rad^2 and 50.0 mdyn/Å, respectively. If larger force constants were used, calculating the force constant matrix from the gradient of the potential by finite difference becomes numerically unstable. However, even with these force constants, the comparison between the third and fourth columns of Table 1 shows excellent agreement between the QM/MM link-atom and equivalent stiff-force constant model. If it were possible to calculate analytic second derivatives of the potential from VENUS (i.e., they are not programmed), it would be possible to show by numerical means that the two approaches are equivalent.

Summary

The 300 K central barrier dynamics for $[Cl\text{-}C_2H_5\text{-}Cl]^-$ is strikingly different than that for $[Cl\text{-}CH_3\text{-}Cl]^-$. Trajectories initiated at the central barrier for the latter system show extensive recrossings of the central barrier and no dissociation to the Cl^- + CH_3Cl products on a 3 ps timescale. In contrast, RRKM theory predicts no recrossing and approximately 50% dissociation. For the $[Cl\text{-}C_2H_5\text{-}Cl]^-$ system, the majority of the 68 trajectories calculated form Cl^-–C_2H_5Cl complexes, which appear to undergo efficient IVR. Only two barrier recrossings occur. However, some trajectories leave the barrier and go directly to Cl^- + C_2H_5 products without first becoming trapped in the Cl^-–C_2H_5Cl complex, an important non-RRKM property. Recrossing the high central barrier is also a non-RRKM result.

The origin of the remarkable difference in the $[Cl\text{-}CH_3\text{-}Cl]^-$ and $[Cl\text{-}C_2H_5\text{-}Cl]^-$ intramolecular and unimolecular dynamics is unclear and needs to be probed in detail in future studies. Previous studies (54–58) have shown that the presence of a -CH_3 rotor, as is the case for $[Cl\text{-}C_2H_5\text{-}Cl]^-$, often enhances IVR because of coupling between the rotor and the molecule's low frequency vibrations. This may explain why central barrier recrossing is unimportant for the $[Cl\text{-}C_2H_5\text{-}Cl]^-$ system and why this system tends to form a complex as it moves off the central barrier. However, this coupling with the rotor does not keep some of the $[Cl\text{-}C_2H_5\text{-}Cl]^-$ trajectories from dissociating directly without forming a complex.

A QM/MM link-atom model is described for studying the central barrier dynamics of S_N2 reactions. In the model, the C_Q—C_M bond of the QM/MM boundary is constrained to lie along the C_Q—H_L bond of the hydrogen link atom, with the $H_L\text{-}C_M$ separation held fixed so that $C_Q\text{-}C_M$ distance represents that for a C—C bond. Because of the similarity in stretching and bending force constants for C-C and C-H interactions, bending and stretching force constants for $C_Q\text{-}H_L$ are good models for those of $C_Q\text{-}C_M$. Better agreement may be obtained with only minor scaling of the $C_Q\text{-}H_L$ forces.

This QM/MM model is used to calculate vibrational frequencies for the $[Cl\text{-}C_2H_5\text{-}Cl]^-$ central barrier, with a QM/MM boundary at the C—C bond. Excellent agreement is found between the QM/MM and ab initio frequencies except for one mode that involves Cl-C-C bending, which is not well-described by the $[Cl\text{-}CH_3\text{-}Cl]^-$ QM component of the model. This problem may be rectified by scaling this bending force constant or using the larger QM/MM model $[Cl\text{-}CH_2(CH_2)_nCH_3\text{-}Cl]^-$ with the QM/MM boundary at the CH_2—$(CH_2)_nCH_3$ bond. With this model, one could investigate the change in the central barrier dynamics as the $-(CH_2)_nCH_3$ chain length is increased. RRKM theory predicts a significant increase in the lifetime of the Cl^-–$ClCH_2(CH_2)_nCH_3$ complex as the chain length is increased and it will be of interest to study the actual dynamics by direct dynamics simulations with this QM/MM model.

Methods for calculating vibrational energy levels[1]

Tucker Carrington, Jr.

Abstract: This article reviews new methods for computing vibrational energy levels of small polyatomic molecules. The principal impediment to the calculation of energy levels is the size of the required basis set. If one uses a product basis the Hamiltonian matrix for a four-atom molecule is too large to store in core memory. We discuss iterative methods that enable one to use a product basis to compute energy levels (and spectra) without storing a Hamiltonian matrix. Despite the advantages of iterative methods it is not possible, using product basis functions, to calculate vibrational spectra of molecules with more than four atoms. A very recent method combining contracted basis functions and the Lanczos algorithm with which vibrational energy levels of methane have been computed is described. New ideas, based on exploiting preconditioning, for reducing the number of matrix-vector products required to converge energy levels of interest are also summarized.

Key words: vibrational energy levels, kinetic energy operators, Lanczos algorithm, contracted basis functions, preconditioning.

Résumé: Dans ce travail, on passe en revue de nouvelles méthodes de calculs des niveaux d'énergie vibrationnelle de petites molécules polyatomiques. Le principal obstacle au calcul des niveaux d'énergie est la taille requise de l'ensemble de base. Si on utilise une base produite, la matrice de l'hamiltonien pour une molécule contenant quatre atomes est trop grosse pour être placée dans la mémoire active. On discute de méthodes itératives qui permettent d'utiliser une base produite pour calculer les niveaux d'énergie (et les spectres) sans garder une matrice d'hamiltonien en mémoire. Malgré les avantages des méthodes itératives, il n'est pas possible, en utilisant fonctions de base produites, de calculer les spectres vibrationnels de molécules contenant plus de quatre atomes. On décrit une méthode très récente, combinant des fonctions de base contractées et l'algorithme de Lanczos, à l'aide de laquelle il a été possible de calculer les niveaux d'énergie du spectre vibrationnel du méthane. On résume aussi de nouvelles idées, basées sur l'exploitation du préconditionnement, pour réduire le nombre de produits matrice–vecteur nécessaire pour faire converger les niveaux d'énergie qui présentent de l'intérêt.

Mots clés : niveaux d'énergie vibrationnelle, opérateurs d'énergie cinétique, algorithme de Lanczos, fonctions de base contractées, préconditionnement.

1. Introduction

The methods of spectroscopic analysis thoroughly and carefully presented in Herzberg's books enable one to understand spectra of semi-rigid molecules (1, 2). Using these methods one can disentangle the spectrum of a molecule to extract, for example, its equilibrium geometry and information about its Born–Oppenheimer potential. Standard methods of spectroscopic analysis are based on the use of normal coordinates (to describe the shape of the molecule), Eckart axes (to describe its orientation), and perturbation theory (to calculate energy levels) (3). When vibrations are of small amplitude, normal coordinates are appropriate and perturbation theory converges well. Normal coordinates and standard perturbative methods are, however, not suitable if vibrations are of large amplitude. To analyse in detail the spectra of molecules for which large amplitude motion is important, one must choose geometrically defined curvilinear coordinates to describe the shape of the molecule, derive a kinetic energy operator (KEO) in terms of the curvilinear coordinates, and calculate transition energies and intensities from eigenvalues and eigenvectors of a matrix that represents the Hamiltonian operator in a basis (5–10). This numerical approach is difficult for three reasons: (*i*) for the potential energy $\hat{V}$, one must calculate electronic energies at a large number of points and either fit a functional form to them or employ an interpolation scheme; (*ii*) for the kinetic energy T, one must derive an operator in advantageous coordinates; (*iii*) to determine energy levels and wavefunctions, one must choose basis functions, construct a matrix representation of the Hamiltonian operator, and compute eigenvalues and eigenvectors of the (typically) very large matrix **H**. New methods are being developed in all of these areas. In this article we focus on (*ii*) and (*iii*).

New methods for the calculation of energy levels and wavefunctions have evolved with the ability of quantum chemists to calculate reasonably accurate potential energy surfaces and the ability of experimentalists to measure highly resolved rovi-

brational spectra of small polyatomic molecules. A method for calculating energy levels (and intensities) is the link between the potential surface and the spectrum. If a potential energy surface is known, one can analyse experimental spectra and sometimes predict unobserved spectral features. Alternatively, knowing the spectrum and having a method to calculate spectra, one can learn a lot about a molecule's potential energy surface. Potential energy surfaces are extremely important in chemistry. They determine not only spectra but also everything from properties of clusters to reaction dynamics. Because there is no direct, general approach for determining potentials of polyatomic molecules from experimental spectroscopic information, the best way to test and refine a potential is to calculate its spectrum and to adjust the potential to minimize the difference between the calculated and observed spectra.

In this article I shall discuss the calculation of vibrational spectra. To calculate rovibrational energy levels, one must choose not only internal coordinates, to describe the shape of the molecule, but also define a molecule-fixed axis system (that rotates with the molecule). The Hamiltonian matrix is also larger than for the vibrational ($J = 0$) case (one must calculate eigenvalues of matrices approximately $JN_v \times JN_v$, where N_v is the size of the vibrational basis).

2. Deriving the kinetic energy operator

If motions of large amplitude have an important effect on the spectrum, it is frequently best not to use normal coordinates but instead to use geometrically defined internal coordinates that describe the shape of the molecule. Geometrically defined internal coordinates have the advantage that even if motion is of large amplitude, each point in configuration space is described by only one set of coordinate values. Of the $3N$ coordinates required to specify the configuration of the N nuclei of an N-atom molecule, $3N - 6$ coordinates describe its shape. What criteria should one consider when choosing vibrational (shape) coordinates? (*i*) Vibrational coordinates (and their domains) must be chosen so that there is a one-to-one correspondence between a geometry of the molecule and a set of coordinate values. If two sets of coordinate values describe the same molecular geometry, the coordinates are not acceptable. It is also essential that a single set of coordinate values not correspond to more than one molecular geometry. (*ii*) Because basis functions are usually chosen as functions of the coordinates in terms of which the kinetic energy operator is written, choosing coordinates influences the quality of the basis functions. It is advantageous to choose coordinates to minimize coupling and therefore facilitate choosing good basis functions. If the basis functions are good, the size of the matrix required to converge the energy levels of interest will be smaller. (*iii*) Coordinates should also be chosen to allow one to take advantage of symmetry. (*iv*) It is often helpful to choose coordinates to simplify the kinetic energy operator. (*v*) If potential integrals are evaluated by Gauss quadrature (11), the number of points required to converge the integrals depends on the degree of the polynomial of largest degree in a polynomial expansion of the potential (even if the potential is not explicitly expanded) and it is, therefore, good to choose coordinates so that the potential, when expanded in terms of polynomials of the coordinates, converges quickly.

Most methods of deriving KEOs follow one of two routes: (*i*) obtain the classical kinetic energy expression and then quantize it (usually using the procedure of Podolsky (12)), or (*ii*) use the chain rule to transform a known quantum mechanical KEO (usually the space-fixed Cartesian KEO) to derive a new KEO. Chapuisat and co-workers (13–18) have advocated the first route. Sutcliffe and Tennyson and co-workers (19–23) and Handy (24) were early proponents of the second route. In recent articles, Mladenović (25, 26) has also used the chain rule route. Lukka (27) has greatly simplified the derivation of KEOs in bond coordinates by suggesting the use of infinitesimal rotation angles. In recent years, several groups have noticed that it is easy to write a compact rovibrational KEO in terms of angular momenta operators for $N - 1$ vectors, which specify the shape and orientation of a molecule in the centre of mass frame. Chapuisat and Iung (16) were perhaps the first to adopt this sort of approach, which was also used recently in refs. 17, 18, 25, and 26.

2.1. Kinetic energy operators from vectors

For any set of $N - 1$ vectors, the KEO has the general form

$$[1] \qquad K = \frac{-1}{2} \sum_{i,j=1}^{N-1} \frac{1}{\mu_{ij}} \nabla(\vec{t}_i) \nabla(\vec{t}_j)$$

This general form is discussed and expressions for μ_{ij} are given in refs. 20 and 25. Note that in ref. 25, $\frac{1}{\mu_{ij}}$ is denoted by F_{ij}.

If $\frac{1}{\mu_{ij}} = 0$ when $i \neq j$, then there are no cross terms in the previous equation, and one says that the vectors are orthogonal. There are different ways of choosing the $\vec{t}_i$ so that they are orthogonal. To obtain a useful KEO from eq. [1], it is necessary to transform it to write the KEO in terms of orientational and shape coordinates. The orientational coordinates are usually the Euler angles that specify the orientation of a molecule-fixed axis system with respect to a space-fixed axis system. The shape coordinates are any coordinates derived from the $N - 1$ $\vec{t}_i$ vectors that describe the shape of the molecule. Chapuisat and Iung (16) pointed out that if one uses coordinates they denoted polyspherical coordinates and chooses the molecule-fixed z axis so that it is parallel to one of the $\vec{t}_i$ vectors it is possible to derive, from eq. [1], a general and rather simple KEO for an N-atom molecule. Polyspherical coordinates are the lengths of the $N - 1$ $\vec{t}_i$ vectors, $N-2$ angles between pairs of $\vec{t}_i$ vectors, and $N-3$ dihedral angles between two vectors around a third. Chapuisat and Iung (16) defined the molecule-fixed frame so that the molecule-fixed z axis is along $\vec{t}_1$ and the molecule-fixed xz plane is the plane defined by $\vec{t}_1$ and $\vec{t}_2$. Using this molecule-fixed frame and $N - 2$ polar polyspherical angles that are the angles between $\vec{t}_1$ and the other $\vec{t}_j$ ($j = 2, 3, \cdots, N-1$) and $N-3$ dihedral polyspherical angles that are the dihedral angles between the planes $(\vec{t}_1\ \vec{t}_2)$ and $(\vec{t}_1\ \vec{t}_j)$, they derived a general and compact KEO by first obtaining a classical kinetic energy expression and then quantizing it. They and their co-workers derived KEOs both for orthogonal (17) and non-orthogonal vectors (18). Recently, Mladenović (25, 26) obtained a compact KEO in terms of the same set of polyspherical coordinates and in the same molecule-fixed axis system. She obtains a general and useful KEO from the chain rule: she does not proceed via a classical expression. Bramley and Carrington (28) transformed the KEO of eq. [1], for four-atom molecules, using the chain rule to obtain a $J = 0$ KEO in terms of polyspherical coordinates. They demonstrated

© 2004 NRC Canada

that one obtains the same four-atom KEO regardless of the set of orthogonal (Jacobi, Radau, hybrid Radau–Jacobi, orthogonal satellite) vectors from which the polyspherical coordinates are defined.

An important advantage of the KEO in polyspherical coordinates and in a molecule-fixed frame whose z axis is along one of the $N-1$ vectors from which the polyspherical coordinates are defined is its generality: one can write a general KEO for a molecule with N atoms. A disadvantage of a polyspherical vector-embedded KEO is its lack of flexibility. If one uses the polyspherical vector-embedded KEO, one must place the molecule-fixed z axis along one of the $\vec{t}_i$ vectors and one must choose as vibrational coordinates polyspherical coordinates obtained from the $N-1$ $\vec{t}_i$ vectors.

If the $\vec{t}_j (j = 3, \cdots, N-1)$ vectors are orthogonal to the two embedding vectors, then a useful (and more flexible) molecule-fixed KEO can be derived from the KEO of eq. [1] as follows (29). (*i*) Rewrite it as

$$[2] \qquad K = -\frac{1}{2\mu_1}\frac{\partial^2}{\partial \vec{t}_1^{\,2}} - \frac{1}{2\mu_2}\frac{\partial^2}{\partial \vec{t}_2^{\,2}} - \frac{1}{\mu_{12}}\frac{\partial}{\partial \vec{t}_1}\frac{\partial}{\partial \vec{t}_2} - \frac{1}{2}\sum_{i,j=3}^{N-1}\frac{1}{\mu_{ij}}\frac{\partial}{\partial \vec{t}_i}\frac{\partial}{\partial \vec{t}_j}$$

(*ii*) From the first three terms in eq. [2], derive a rovibrational KEO for a triatomic-like system in terms of vibrational coordinates q_1, q_2, and q_3 and in (*any*) molecule-fixed frame attached to the two embedding vectors $\vec{t}_1$ and $\vec{t}_2$. (*iii*) Substitute $\vec{J} - \vec{l}$ for $\vec{J}$ in the triatomic-like KEO. This yields

$$[3] \qquad K = K_{\text{tri}}(q_1, q_2, q_3, \vec{J} - \vec{l}) - \frac{1}{2}\sum_{i,j=3}^{N-1}\frac{1}{\mu_{ij}}\frac{\partial}{\partial \vec{z}_i}\frac{\partial}{\partial \vec{z}_j}$$

where the $\vec{z}_i$ are Cartesian coordinates in the molecule-fixed frame. (*iv*) Transform from the z_{ia} coordinates to some non-Cartesian coordinates that describe the length and orientation of the $N-3$ $\vec{z}_j$ vectors with respect to the molecule-fixed frame attached to $\vec{t}_1$ and $\vec{t}_2$. Here, $\vec{l}$ is the total angular momenta of the non-embedding vectors in the molecule-fixed frame. This recipe enables one to obtain a KEO for an N-atom molecule from the KEOs of smaller molecules. This procedure works only because the $\vec{t}_j (j = 3, \cdots, N-1)$ vectors are orthogonal to the two embedding vectors (29).

This KEO is simple and general despite the fact that we do not require that the z axis be placed along one of the $\vec{t}_i$ vectors. This is important because either to reduce rovibrational coupling or to facilitate exploiting symmetry it is sometimes better not to have the z axis along a $\vec{t}_i$ vector.

3. Basis functions

To define a matrix representation of the Hamiltonian (composed of the KEO and the potential energy surface), one must choose basis functions.

3.1. Product basis functions

A product basis is a basis each of whose functions is a product of functions of a single coordinate. If each of the single coordinate functions is labelled by a single index, the basis is a direct product basis and each function may be written

$$[4] \qquad \Phi_{i_1,i_2,\cdots,i_f} = \phi_{i_1}(q_1)\phi_{i_2}(q_2)\cdots\phi_{i_f}(q_f)$$

where f is the number of vibrational degrees of freedom. Direct product basis sets are simple to work with because if the Hamiltonian is factorizable, i.e., if it can be written in the form

$$[5] \qquad \hat{H} = \sum_{l=1}^{g}\prod_{k=1}^{f}\hat{h}^{(k,l)}(q_k)$$

as a sum of g terms each with f factors (for a single term at most two of the factors involve derivative operators), then matrix elements of each term can be written as products of matrix elements of the factors. If one chooses basis functions of the form $\phi_{i_k}(z_k) = h_{i_k}^{-1/2}[w(z_k)]^{1/2}p_{i_k}(z_k)$ where $p_{i_k}(z_k)$ is a classical polynomial, $w(z_k)$ is the corresponding weight function, $z_k = f(q_k)$, and h_{i_k} is a normalization factor, then matrix elements of the kinetic energy factors are usually known in closed form. Matrix elements of potential factors can be computed by evaluating one-dimensional quadratures. To perform the quadrature it is actually not necessary that the potential be factorizable, or even known, as a function of the coordinates in terms of which the kinetic energy operator and the basis functions are written (30). Direct product basis sets have the advantage of simplicity, but to calculate highly excited states of triatomic molecules, or more than a few levels for four-atom molecules, one requires an enormous number of direct product basis functions and it becomes impossible to use conventional diagonalization methods to calculate eigenvalues. As a crude rule of thumb, one requires about 10 basis functions per degree of freedom, and hence about 10^f product-basis functions to calculate vibrational energy levels and wavefunctions of a molecule with f vibrational degrees of freedom. For a triatomic molecule, the product-basis Hamiltonian matrix is only about $1\,000 \times 1\,000$, but for a four-atom molecule the product-basis Hamiltonian matrix is about $1\,000\,000 \times 1\,000\,000$, which cannot be stored in the main memory of any computer.

3.2. Single coordinate basis functions

If the $\phi_{i_k}(q_k)$ functions are of the form $h_{i_k}^{-1/2}[w(f(q_k))]^{1/2} \times p_{i_k}(f(q_k))$ and potential integrals are evaluated with the Gauss quadrature scheme appropriate for the $p_{i_k}(f(q_k))$ polynomials with as many points as there are $\phi_{i_k}(q_k)$ functions, one obtains what is called the finite basis representation (FBR) (31). Instead, it is often advantageous to choose the $\phi_{i_k}(q_k)$ functions to be discrete variable representation (DVR) (31,32) functions. DVR functions are (orthogonal) finite basis approximations to Dirac delta functions. DVR functions are linear combinations of functions of the form $h_{i_k}^{-1/2}[w(f(q_k))]^{1/2}p_{i_k}(f(q_k))$ chosen so that DVR and FBR matrices are unitarily equivalent and so that the DVR matrix for $f(q_k)$ is diagonal. DVR functions are usually obtained by diagonalizing the FBR matrix, which represents $f(q_k)$. DVRs are useful because potential and multiplicative operators in the kinetic energy operator are diagonal in the DVR and hence easy to construct (no integrals are computed) and use.

Whether or not one uses DVR functions, one begins by choosing polynomial basis functions. When choosing polynomials

© 2004 NRC Canada

for the single coordinate functions of q_k, one must consider the domain of the coordinate and the behaviour of wavefunctions near limiting values of the coordinates. For an angle coordinate θ, which assumes values between 0 and $+\pi$, one might choose Legendre or Jacobi polynomials of $\cos(\theta)$ (31). For a stretch coordinate r, which assumes values between 0 and ∞, it is best to take Laguerre polynomials of $Ke^{-a(r-r_e)}$, where K and a are defined in ref. 33, and r_e is the equilibrium value of r. It is possible to choose the parameters of the Laguerre basis so that N_e basis functions exactly span the space spanned by N_e solutions of a Morse oscillator (see ref. 33).

It is of course possible to use single coordinate functions that are not of the form $h_{i_k}^{-1/2}[w(f(q_k))]^{1/2}p_{i_k}(f(q_k))$, either directly or to construct DVR functions. DVR functions obtained by diagonalizing a function of the coordinate operator in a basis of selected eigenfunctions of a one-dimensional Hamiltonian whose potential is derived from the f-dimensional potential are called potential optimized discrete variable (PO–DVR) functions (33, 34).

3.3. Contracted basis functions

Product basis functions would be good basis functions if coupling were unimportant, but because coupling is important the number of product basis functions required to converge even a modest number of energy levels of a four-atom molecule is enormous. Contracted basis functions represent wavefunctions more compactly. They are chosen to reduce the number of basis functions required to obtain converged energy levels. It has been clearly demonstrated that contracted basis functions are powerful tools for computing vibrational energy levels (32,35). Contracted basis functions are usually obtained by diagonalizing reduced-dimension Hamiltonian matrices. There are at least two ways to define effective reduced-dimension Hamiltonian matrices: (*i*) one diagonalizes blocks of the full Hamiltonian matrix in a product basis representation; (*ii*) one diagonalizes matrices that represent the Hamiltonian with one or more coordinates fixed. The first route leads to nondirect product basis functions (32, 36–42). The second route leads to basis functions that are direct products of functions of different coordinates or groups of coordinates (35,43). An example should make this clearer. For a triatomic molecule, a contraction scheme of type 1 is obtained by diagonalizing (stretch) blocks $\langle\alpha(\theta)|\hat{H}(\theta, r_1, r_2)|\alpha(\theta)\rangle$ to get eigenfunctions $\phi_n^\alpha(r_1, r_2)$, where $\alpha(\theta)$ is a DVR bend function, $\hat{H}(\theta, r_1, r_2)$ is the full Hamiltonian operator, and θ, r_1, r_2 are the bend and stretch coordinates. The contracted basis functions are then $\alpha(\theta)\phi_n^\alpha(r_1, r_2)$. A contraction scheme of type 2 is obtained by combining the eigenfunctions of $H(\theta_e, r_1, r_2)$, denoted $\psi(r_1, r_2)$, and eigenfunctions of $H(\theta, r_1^e, r_2^e)$, denoted $\chi(\theta)$. The contracted basis functions are $\psi(r_1, r_2)\chi(\theta)$, and r_1^e, r_2^e, and θ_e are selected specific values of r_1, r_2, and θ. Often, equilibrium values will be good choices. Regardless of the route one takes, only some of the eigenvectors of the reduced-dimension Hamiltonian matrices are retained: such methods are sometimes called diagonalization–truncation–recoupling methods (31,44).

The type 1 approach has been used extensively by Bačić, Bowman, Light, Tennyson, and their co-workers (31,32,36,38, 39, 44). Luckhaus (42) and Mladenović (40, 41) have recently used type 1 contractions in 6D calculations. Both these authors use contracted basis functions with a direct eigensolver (Householder transformations). The type 2 approach was pioneered by Carter and Handy (35) and Bramley and Handy (43) and has been used with a direct eigensolver to compute rovibrational energy levels of four-atom molecules, e.g., C_2H_2 (45), H_2O_2 (46), and NH_3 (vibration only) (47).

4. Eigensolvers

4.1. Direct methods

If the Hamiltonian matrix is not too large, its eigenvalues and eigenvectors can be determined easily using a standard implementation of Householder's algorithm (11). To use the Householder algorithm, one must store the matrix whose eigenvalues are desired (i.e., N^2 numbers), where N is the size of the matrix, and the cost of the calculation scales as N^3. If N is larger than about 10 000, it is difficult to store the Hamiltonian matrix and its diagonalization becomes very costly. The disadvantages of the Householder algorithm become debilitating if one wishes to calculate rovibrational energy levels of a triatomic molecule or vibrational energy levels of a molecule with more than three atoms. Even to calculate high-lying vibrational energy levels of a triatomic molecule, it is difficult to use the Householder algorithm if a simple product basis set is used.

4.2. Iterative methods

The unfavourable scaling of the Householder algorithm has prompted the investigation and development of iterative methods for calculating spectra (28, 48–60). An iterative method requires only the computation of matrix-vector products. The matrix is not modified or stored (61). Hamiltonian matrix-vector products can be computed without storing the Hamiltonian matrix and without even calculating its matrix elements (28,62,63).

The most popular iterative methods employed to calculate energy levels, or energy levels and wavefunctions, are variants of either the Lanczos algorithm (61, 64) or the filter diagonalization method (53,56–58). In the Lanczos method, eigenvalues of an $N \times N$ symmetric matrix H are calculated by diagonalizing an associated $M \times M$ tridiagonal matrix T_M, which is generated recursively, having dimension M after M iterations. To obtain T_M one must compute M matrix-vector products. If M is large enough, among the eigenvalues of T_M there will be eigenvalues of the original matrix H (64). There are several refined versions of the Lanczos algorithm designed to accelerate the convergence of selected eigenvalues (65–67). These methods facilitate the calculation of low-lying energy levels and allow calculation of eigenvectors without redoing matrix-vector products, but they require considerably more storage than a straightforward Lanczos method. The goal of the filter diagonalization method is to calculate energy levels and wavefunctions in a selected (not necessarily low-lying) spectral window. One builds a matrix representation of the Hamiltonian using basis vectors $\mathbf{z_n} = f(\mathbf{H}, n)\mathbf{v}$, $n = 1, 2, \cdots L$, where $\mathbf{v}$ is a starting vector and $f(\mathbf{H}, n)$ is chosen so that the filtered basis vectors have only very small overlaps with eigenvectors of $\mathbf{H}$ whose eigenvalues are outside the window in which one wishes to calculate eigenvalues (53). $\mathbf{v}$ and $\mathbf{H}$ are representations in some original basis of a starting ket, and the Hamiltonian operator is scaled so that its eigenvalues are between -1 and $+1$.

© 2004 NRC Canada

In the filtered basis, one solves a generalized eigenvalue problem to obtain energy levels (and possibly wavefunctions). If the size of the original basis is large, storing the $\mathbf{z_n}$ vectors requires much more memory than would be needed to calculate eigenvalues using the Lanczos algorithm. Wall and Neuhauser (56) pointed out that if Hamiltonian and overlap matrix elements are calculated directly, eigenvalues of the Hamiltonian may be computed without computing (and storing) the $\mathbf{z_n}$ vectors. Using this low-storage approach to filter diagonalization, one is able to calculate energy levels using as little memory as one requires using a Lanczos approach. The Cullum and Willoughby (C&W) Lanczos approach and the filter diagonalization method extract energy levels from the same Krylov space. Both may be viewed as methods for dealing with numerical error introduced as the space is generated. Formally, the space spanned by the Lanczos vectors is larger than (and includes) the space spanned by the filtered $\mathbf{z_n}$ vectors.

Both low-storage filter diagonalization methods and the C&W Lanczos method (64) yield eigenvalues. To obtain eigenvectors from a Lanczos calculation, one must either recalculate or store the Lanczos vectors. To obtain eigenvectors from a low-storage filter diagonalization method calculation, one must recalculate the matrix-vector products used to compute the Hamiltonian and overlap matrix elements. If one wishes to calculate only energy levels and not wavefunctions, the C&W Lanczos method appears to be superior to low-storage filter diagonalization methods: the C&W method requires fewer matrix-vector products and it is simpler to implement (68). In its original form (which involved storing the $\mathbf{z_n}$), filter diagonalization had the advantage that it enabled one to obtain eigenvectors (69).

5. Using iterative methods with a product basis set

An important advantage of a product basis is its inherent structure. If one uses a direct linear algebra method to compute eigenvalues, this structure is not exploited. If instead one uses an iterative method, one can exploit the structure to reduce the cost of calculating matrix-vector products.

If the basis is a product basis, then it is always possible to evaluate matrix-vector products so that their cost scales as n^{f+1}, where n is a representative number of basis functions for a single degree of freedom, and f is the number of degrees of freedom. If H is factorizable (KEOs are almost always factorizable and potentials sometimes are), then it may be written as

$$[6] \qquad H = \sum_{l=1}^{g} \prod_{k=1}^{f} \hat{h}^{(k,l)}(q_k)$$

and a matrix-vector product $\mathbf{Hu} = \mathbf{u}'$ is evaluated most efficiently by doing sums sequentially

$$[7] \qquad \sum_{l=1}^{g} \sum_{i_1} h^{(1,l)}_{i'_1,i_1} \sum_{i_2} h^{(2,l)}_{i'_2,i_2} \cdots \sum_{i_f} h^{(f,l)}_{i'_f,i_f} u_{i_1,i_2,\cdots,i_f} = u'_{i'_1,i'_2,\cdots,i'_f}$$

where $h^{(k,l)}_{i'_k,i_k}$ is an element of the $n \times n$ matrix representation of the factor $\hat{h}^{(k,l)}(q_k)$ (an operator for a single coordinate) (28, 62, 63). Note that for notational simplicity we have assumed that there are n basis functions for each degree of freedom but that this is not necessary. If the lth term has c_l nondiagonal $\mathbf{h}^{(k,l)}$ matrices, the number of multiplications required to evaluate the matrix-vector product for that term is $c_l n^{f+1}$ (28). The total number of operations required for a direct-product Lanczos calculation is $Mn^{f+1}\sum_l c_l$.

What happens if the potential (or a term in the KEO) is not factorizable? In this case, it is still possible to do matrix-vector products at a cost that scales as n^{f+1}, *if a direct product quadrature grid is used*. For example, the quadrature approximation for the integral

$$[8] \qquad V_{n'm',nm} = \int \mathrm{d}q_1\, \mathrm{d}q_2\, f_{n'}(q_1) g_{m'}(q_2) V(q_1, q_2) f_n(q_1) g_m(q_2)$$

is

$$[9] \qquad \sum_{\alpha}\sum_{\beta} \sqrt{\frac{\omega_\alpha}{w((q_1)_\alpha)}}\sqrt{\frac{\omega_\beta}{w((q_2)_\beta)}} f_{n'}((q_1)_\alpha) g_{m'}((q_2)_\beta) \times V((q_1)_\alpha, (q_2)_\beta) f_n((q_1)_\alpha) g_m((q_2)_\beta) \times \sqrt{\frac{\omega_\alpha}{w((q_1)_\alpha)}}\sqrt{\frac{\omega_\beta}{w((q_2)_\beta)}}$$

where $(q_1)_\alpha$ and $(q_2)_\beta$ are quadrature points for the q_1 and q_2 coordinates, ω_α and ω_β are the corresponding quadrature weights, and $w(q_1)$ and $w(q_2)$ are the corresponding weight functions. In terms of $\mathbf{T}$ matrices with elements

$$[10] \qquad \left({}^{[q_1]}T\right)_{n',\alpha} = f_n((q_1)_\alpha)\sqrt{\frac{\omega_\alpha}{w((q_1)_\alpha)}}$$

$$[11] \qquad \left({}^{[q_2]}T\right)_{n',\beta} = f_n((q_2)_\beta)\sqrt{\frac{\omega_\beta}{w((q_2)_\beta)}}$$

the potential integral is

$$[12] \qquad V_{n'm',nm} \approx \sum_{\alpha}\sum_{\beta} \left({}^{[q_1]}T\right)_{n',\alpha} {}^{[q_2]}T_{m',\beta} \times V((q_1)_\alpha, (q_2)_\beta) \left({}^{[q_1]}T^\dagger\right)_{\alpha,n} \left({}^{[q_2]}T^\dagger\right)_{\beta,m}$$

The matrix-vector product can now be written

$$[13] \qquad \sum_{\alpha} \left({}^{[q_1]}T\right)_{n',\alpha} \sum_{\beta} {}^{[q_2]}T_{m',\beta} V((q_1)_\alpha, (q_2)_\beta) \times \sum_{m} \left({}^{[q_2]}T^\dagger\right)_{\beta,m} \sum_{n} \left({}^{[q_1]}T^\dagger\right)_{\alpha,n} u_{nm} = u'_{n'm'}$$

and the n^{f+1} scaling is evident.

The favourable n^{f+1} scaling relation is not due to the sparsity of the Hamiltonian matrix nor to the sparsity of the $\mathbf{h}^{(k,l)}$ matrices, it is not due to the absence of mixed second-order

© 2004 NRC Canada

differential operators, and it is not due to choosing special single coordinate functions from which to build the product basis functions. (Note that it is sometimes advantageous to choose the single coordinate functions so that the $\mathbf{h}^{(k,l)}$ matrices are sparse to further accelerate the matrix-vector product (70). The n^{f+1} scaling relation is a result of using a product basis. Note that if one evaluates matrix-vector products by doing sums sequentially, one never actually calculates matrix elements of the Hamiltonian (not even "on the fly"): one uses matrix elements of the factors of the terms of the Hamiltonian to build up the Hamiltonian matrix-vector product.

For some problems it is advantageous to use a nondirect product basis. We use the term nondirect product function to mean a function that is a product of functions of a single coordinate, but for which at least one of the single coordinate functions is labelled not only by the index for its coordinate but also by the index for another coordinate, i.e., there is a shared index. The most familiar example of a nondirect product basis function is a spherical harmonic ($Y_{lm} = \Theta_l^m(\theta)\Phi_m(\phi)$); m is the shared index. Convergence of the Lanczos algorithm is poorer if the spectral range (the difference between the largest and the smallest eigenvalues) of the matrix is large. For many molecules, this problem is not really debilitating but it is exacerbated by any important singularities in the kinetic energy operator (71, 72). An important singularity is one for which the wavefunctions one wishes to calculate have significant amplitude at points in configuration space at which the kinetic energy operator is infinite. To deal with important singularities, it is useful to use nondirect product basis functions to reduce the spectral range of the Hamiltonian matrix.

Singularities occur whenever one coordinate takes a limiting value and another becomes undefined. If a singularity is important, optimal basis functions are nondirect product functions, which are eigenfunctions of part of the Hamiltonian, which includes the kinetic energy term(s) with the singularity. To evaluate the matrix-vector product efficiently for basis functions that have the form $f_n^m(q_1)g_m(q_2)$ (m is the shared index and the singularity occurs when q_1 takes a limiting value and q_2 becomes undefined), one uses equations very similar to those given previously. The nondirect product basis functions will usually be eigenfunctions either of part of the kinetic energy operator or of the sum of part of the kinetic energy operator and part of the potential, and therefore the only nontrivial matrix-vector product will be for the potential or for part of the potential. One may always attain n^{f+1} scaling by choosing the same set of q_1 quadrature points for all values of m (73). In this case, the integral

$$[14]\quad V_{n'm',nm} = \int \mathrm{d}q_1\,\mathrm{d}q_2\, f_{n'}^{m'}(q_1)g_{m'}(q_2)V(q_1,q_2)f_n^m(q_1)g_m(q_2)$$

is

$$[15]\quad \sum_\alpha\sum_\beta \sqrt{\frac{\omega_\alpha}{w((q_1)_\alpha)}}\sqrt{\frac{\omega_\beta}{w((q_2)_\beta)}} f_{n'}^{m'}((q_1)_\alpha)g_{m'}((q_2)_\beta) \times V((q_1)_\alpha,(q_2)_\beta) f_n^m((q_1)_\alpha)g_m((q_2)_\beta) \times \sqrt{\frac{\omega_\alpha}{w((q_1)_\alpha)}}\sqrt{\frac{\omega_\beta}{w((q_2)_\beta)}}$$

In terms of $\mathbf{T}$ matrices

$$[16]\quad V_{n'm',nm} \approx \sum_\alpha\sum_\beta \left({}^{[q_1]}T^{m'}\right)_{n',\alpha} {}^{[q_2]}T_{m',\beta} \times V\left((q_1)_\alpha,(q_2)_\beta\right)\left({}^{[q_1]}T^{m\dagger}\right)_{\alpha,n}\left({}^{[q_2]}T^{\dagger}\right)_{\beta,m}$$

As the notation implies, there is a different ${}^{[q_1]}T^m$ for each value of m (because there is a different set of q_1 functions for each m). The matrix-vector product can now be written

$$[17]\quad \sum_\alpha \left({}^{[q_1]}T^{m'}\right)_{n',\alpha}\sum_\beta {}^{[q_2]}T_{m',\beta}V\left((q_1)_\alpha,(q_2)_\beta\right) \times\sum_m\left({}^{[q_2]}T^{\dagger}\right)_{\beta,m}\sum_n\left({}^{[q_1]}T^{m\dagger}\right)_{\alpha,n}u_{nm} = u'_{n'm'}$$

The n^{f+1} scaling is evident. It has been exploited in many calculations (71, 74–76).

6. Exploiting symmetry with an iterative method

Molecular symmetry is useful because symmetry labels enable one to understand spectra (selection rules) and because symmetry facilitates computing spectra (77). If basis functions can be chosen so that they transform like irreducible representations, then the size of the matrices one must diagonalize to compute a spectrum can be reduced. Matrix elements between basis functions that transform like different irreducible representations are zero. Such basis functions are called symmetry-adapted basis functions. If they are ordered properly, the Hamiltonian matrix in the symmetry-adapted basis is block diagonal. If one wishes to use a direct method to compute the spectrum, it is immediately obvious that having a block diagonal matrix is a significant advantage. To diagonalize a block diagonal matrix, one requires both less memory and less CPU time. Consequently, it is always advantageous when using a direct method to exploit symmetry. Symmetry-adapted basis functions may be more complicated than simpler basis functions but the advantage of reducing the size of the matrix is extremely important.

It is natural to think that one should also exploit symmetry when using an iterative method to compute a spectrum. It is reasonable to expect that doing so should enable one to reduce the size of the vectors (decrease the memory required) and speed up the evaluation of matrix-vector products (reduce the CPU time). However, there is a problem. The cost of an iterative calculation is a product of the number of matrix-vector products required to converge the energy levels of interest and the cost of a single matrix-vector product. In the previous section it was stressed that matrix-vector products are simple and surprisingly inexpensive if one uses a product basis. If, instead of using a product basis, one uses a symmetry-adapted basis, both the simplicity and the favourable n^{f+1} scaling relation are, in general, sacrificed. This is a significant loss. As discussed by Bramley and Carrington (28), symmetry-adapted basis functions can be used efficiently if a symmetry operation affects only one coordinate. However, symmetry-adapted basis functions for a

© 2004 NRC Canada

symmetry operation that mixes or exchanges coordinates are linear combinations of the original product basis functions, and the corresponding matrix-vector product is difficult to evaluate efficiently. In this section, a symmetry-adapted Lanczos (SAL) method is described with which one can use a product basis to calculate energy levels of different symmetries separately, but from one set of matrix-vector products (78, 79).

6.1. Symmetry-adapted Lanczos method

The conventional Lanczos iteration is based on a simple three-term recurrence relation (61)

$$[18] \qquad \beta_{i+1}\mathbf{v}_{i+1} = \mathbf{H}\mathbf{v}_i - \alpha_i\mathbf{v}_i - \beta_i\mathbf{v}_{i-1}$$

with $\beta_1 = 0$.

In exact arithmetic, the Lanczos vectors ($\mathbf{v_i}$) calculated using eq. [18] are orthogonal and the Hamiltonian matrix in the basis of the Lanczos vectors is tridiagonal. The β_i and α_i are elements of the tridiagonal matrix. If one requires more than a small number of iterations, the orthogonality of the Lanczos vectors is lost due to the finite precision of computer arithmetic. However, it is still possible, using a scheme suggested by Cullum and Willoughby (64), to extract accurate eigenvalues from the tridiagonal matrix .

In the symmetry-adapted Lanczos method, the Lanczos vectors $\mathbf{v}_i^{(m)}$ and the $\alpha_i^{(m)}$ and $\beta_i^{(m)}$ coefficients are calculated for all irreducible representations m from a single set of matrix-vector products. Each set of Lanczos vectors is computed from the usual three-term recurrence relation

$$[19] \qquad \beta_{i+1}^{(m)}\mathbf{v}_{i+1}^{(m)} = \mathbf{H}\mathbf{v}_i^{(m)} - \alpha_i^{(m)}\mathbf{v}_i^{(m)} - \beta_i^{(m)}\mathbf{v}_{i-1}^{(m)}$$

but rather than applying H to symmetry-adapted Lanczos vectors to compute the first term on the right-hand-side (RHS) of this equation, we use projection operators.

Each projection operator is defined

$$[20] \qquad \hat{P}_{ii}^{(m)} = \frac{d_m}{h}\sum_R D_{ii}^{(m)}(R)\hat{R}$$

where m labels an irreducible representation, i labels a basis function (ϕ_i^m) that transforms like irreducible representation m (irreducible representations may be degenerate), $\hat{R}$ is a symmetry operation in the group, h is the order of the group, d_m is the dimension of irreducible representation m, and $D_{ii}^{(m)}(R)$ is the ith diagonal element of the matrix representation of $\hat{R}$ in the ϕ_i^m basis. To calculate energy levels, $\hat{P}_{ii}^{(m)}$ is only required for one i and we shall write $\hat{P}_{ii}^{(m)}$ as $\hat{P}^{(m)}$. If an irreducible representation is multidimensional, an index i is implied. The projection operator $\hat{P}^{(m)}$ projects the mth symmetry component from a general vector with N symmetry components without changing the amplitude and sign of the component. For example,

$$[21] \qquad \hat{P}^{(m)}\sum_{n=1}^{N}\mathbf{v}^{(n)} = \mathbf{v}^{(m)}$$

Projection operators commute with the Hamiltonian, i.e.,

$$[22] \qquad \hat{P}^{(m)}H - H\hat{P}^{(m)} = 0$$

Combining eq. [21] with eq. [22], it is clear that

$$[23] \qquad \mathbf{H}\mathbf{v}^{(m)} = \hat{P}^{(m)}\left[\mathbf{H}\sum_{n=1}^{N}\mathbf{v}^{(n)}\right]$$

Therefore, rather than computing $\mathbf{H}\mathbf{v}^{(m)}$ in eq. [19] directly, one can obtain it from eq. [23]. At each iteration, one applies $\mathbf{H}$ to the sum of the Lanczos vectors computed at the previous iteration. Note that in this fashion $\mathbf{H}\mathbf{v}_i^{(m)}$ is obtained for all m from one set of matrix-vector products.

It has been observed that in some cases, after computing $\beta_{i+1}^{(m)}\mathbf{v}_{i+1}^{(m)}$, it is necessary to purify it by applying the projection operator to it; i.e., $\beta_{i+1}^{(m)}\mathbf{v}_{i+1}^{(m)}$ is replaced by $\hat{P}^{(m)}\beta_{i+1}^{(m)}\mathbf{v}_{i+1}^{(m)}$. This purification step is not always required (78).

Using the Lanczos algorithm to calculate separately energy levels in all N irreducible representations by using symmetry-adapted starting vectors would require a factor of N more matrix-vector products. It is noted that the SAL method can be used to calculate energy levels in any number of symmetry species. One might wish to calculate energy levels of some but not all of the symmetries.

The most efficient way to implement the symmetry-adapted Lanczos algorithm entails storing Lanczos vectors for each irreducible representation. To reduce the storage requirement, one must necessarily apply projection operators more frequently. Here, I discuss two schemes for using the SAL method (75). The first requires storing six vectors and applying the projection operators twice per iteration. The second requires storing only five vectors, but one needs three applications of the projection operators per iteration.

The first scheme is shown in Table 1, where K is the number of Lanczos iterations and M is the number of irreducible representations. The starting vector $\mathbf{v}_1 = \sum_{m=1}^{M}\mathbf{v}_1^{(m)}$ is a sum of unit vectors of different symmetries. With this scheme, one needs to store (in addition to vectors required to compute the matrix-vector product) six vectors: $\mathbf{v}_{k-1}$, $\mathbf{v}_k$, $\tilde{\mathbf{v}}_k$, $\mathbf{t}_1$, $\mathbf{t}_2$, and one scratch vector to do the projection in step (7) (note that $\mathbf{v}_k$, $\mathbf{v}_{k+1}$ at steps (11) and (12) occupy the memory previously used to store $\mathbf{v}_{k-1}$, $\mathbf{v}_k$), and do two projections per iteration. Note that the vector is purified at step (7) (78). We find that this purification is necessary (if there are multidimensional irreducible representations) to avoid computing erroneous eigenvalues. At the end of step (10), $\mathbf{t_2}$ is equal to the sum of the kth Lanczos vectors for the M irreducible representations. Note that at step (6) it would be possible to compute

$$[24] \qquad \alpha_k^{(m)} = \mathbf{t}_1^t\hat{P}^{(m)}\mathbf{v}_k$$

but this projection is not necessary because $\mathbf{t}_1$ is of symmetry m.

It is possible to reduce the number of vectors that one must store by one, at the expense of increasing by one the number of applications, per iteration, of the projection operators (75). Because more applications of projection operators are required, this scheme is more expensive, but if the basis size is large, it might be necessary to reduce the number of stored vectors from six to five to calculate energy levels. In the first scheme, to calculate $(\tilde{\mathbf{v}}_k - \beta_k^{(m)}\mathbf{v}_{k-1})$ at step (5), it is necessary to have both $\tilde{\mathbf{v}}_k$ and $\mathbf{v}_{k-1}$. To reduce storage requirements one could store the

(8)	$\beta_{k+1}^{(m)} = \|\mathbf{t}_1\|$
(9)	$\mathbf{t}_2 \Leftarrow \mathbf{t}_2 + \mathbf{t}_1/\beta_{k+1}^{(m)}$
(10)	END DO
(11)	$\mathbf{v}_k = \mathbf{v}_{k-1}$
(12)	$\mathbf{v}_{k+1} = \mathbf{t}_2$
(13)	END DO

Table 2. Implementation of the SAL using 5 vectors and 3 projections.

(0)	Start with $\beta_1^{(m)} = 1$, initial vectors $\mathbf{v}_1 = \sum_{m=1}^{M} \mathbf{v}_1^{(m)}$ and $\mathbf{w}_0 = 0$,
(1)	DO k=1, K
(2)	$\mathbf{w}_{k-1} \Leftarrow \mathbf{H}\mathbf{v}_k - \mathbf{w}_{k-1}$
(3)	$\mathbf{t}_2 = 0$
(4)	DO m=1, M
(5)	$\mathbf{t}_1 = \hat{P}^{(m)}\mathbf{w}_{k-1}$
(6)	$\alpha_k^{(m)} = \mathbf{t}_1^t\mathbf{v}_k$
(7)	$\mathbf{t}_1 \Leftarrow \hat{P}^{(m)}(\mathbf{t}_1 - \alpha_k^{(m)}\mathbf{v}_k)$
(8)	$\beta_{k+1}^{(m)} = \|\mathbf{t}_1\|$
(9)	$\mathbf{t}_2 \Leftarrow \mathbf{t}_2 + \mathbf{t}_1/\beta_{k+1}^{(m)}$
(10)	END DO
(11)	$\mathbf{t}_1 = 0$
(12)	DO m=1, M
(13)	$\mathbf{t}_1 \Leftarrow \mathbf{t}_1 + \beta_{k+1}^{(m)}\hat{P}^{(m)}\mathbf{v}_k$
(14)	END DO
(15)	$\mathbf{w}_k = \mathbf{t}_1$
(16)	$\mathbf{v}_{k+1} = \mathbf{t}_2$
(17)	END DO

combination, $(\tilde{\mathbf{v}}_k - \mathbf{w}_{k-1})$, where $\mathbf{w}_{k-1} = \sum_{m=1}^{M} \beta_k^{(m)}\mathbf{v}_{k-1}^{(m)}$, with $\mathbf{v}_{k-1}^{(m)} = \hat{P}^{(m)}\mathbf{v}_{k-1}$. Then $\mathbf{t}_1 = \hat{P}^{(m)}(\tilde{\mathbf{v}}_k - \mathbf{w}_{k-1})$ because $\hat{P}^{(m)}\mathbf{w}_{k-1} = \beta_k^{(m)}\mathbf{v}_{k-1}^{(m)} = \hat{P}^{(m)}\beta_k^{(m)}\mathbf{v}_{k-1}$. Note that if one stores only the combination $(\tilde{\mathbf{v}}_k - \mathbf{w}_{k-1})$, the vector $\mathbf{w}_{k-1}$ must be computed (at the cost of an additional projection) at the end of the kth iteration. The second scheme is shown in Table 2. Using this scheme, one needs to store five vectors: $\mathbf{w}_{k-1}, \mathbf{v}_k, \mathbf{t}_1$, $\mathbf{t}_2$, and one scratch vector to do the projections at lines (7) and (13) (note $\mathbf{w}_k$, $\mathbf{v}_{k+1}$ at steps (15) and (16) occupy the memory previously used to store $\mathbf{w}_{k-1}$, $\mathbf{v}_k$) and three projections. Note that, as in the first scheme, $\mathbf{v_k}$ is the sum of the kth Lanczos vectors for the M irreducible representations.

If one is interested only in a single symmetry species, one can use the conventional Lanczos algorithm with a starting vector that transforms like the irreducible representation of interest. However, to avoid converging energy levels of other symmetries, it is necessary to apply the corresponding projection operator $\hat{P}^{(m)}$ to the vector $\beta_{i+1}\mathbf{v}_{i+1}$ at each iteration. This is certainly better than using the method of ref. 80 to distinguish between correct-symmetry and wrong-symmetry energy levels.

The symmetry-adapted Lanczos method enables one to calculate energy levels of different symmetries from a single set of matrix-vector products. It has been used in several calculations (75,81). The SAL method has two important advantages: (*i*) using it one obtains symmetry-labelled energy levels; (*ii*) it significantly reduces the number of matrix-vector products required to achieve convergence. The number of matrix-vector products is reduced because convergence is not hampered by near degeneracies if the nearly degenerate levels occur in different symmetry blocks. The reduction is more important the higher the symmetry of the molecule.

© 2004 NRC Canada

7. The preconditioned, inexact spectral transform method

Using the C&W Lanczos approach, it is easiest to calculate low-lying energy levels. The simple C&W Lanczos method is effective and useful but it has two deficiencies: (*i*) it is necessary to evaluate many matrix-vector products to compute high-lying energy levels; (*ii*) it is not possible to calculate both energy levels and wavefunctions simultaneously without storing a large number of vectors, each with as many components as the number of basis functions required to converge the energy levels of interest. The preconditioned inexact spectral transform (PIST) method overcomes both of these disadvantages (82, 83).

One way to use the Lanczos algorithm to calculate both eigenvalues and eigenvectors without being obliged to store a large number of vectors is to use a spectral transform (84–87). Rather than using the Lanczos algorithm on $\mathbf{H}$, one uses it on $F(\mathbf{H})$, where $F(\mathbf{H})$ is chosen so that the desired eigenvalues of $\mathbf{H}$ correspond to widely separated eigenvalues of $F(\mathbf{H})$. Because widely separated eigenvalues converge quickly, this means that the desired eigenvalues of $\mathbf{H}$ are obtained after only a small number of iterations. If the number of iterations is small, the number of Lanczos vectors that must be stored to permit calculation of eigenvectors is also small. However, computing matrix-vector products with $F(\mathbf{H})$ is, in general, costly.

A very natural spectral transform function (84,87) is $F(\mathbf{H}) = (E\mathbf{I} - \mathbf{H})^{-1}$. Eigenvalues of $F(\mathbf{H})$, which correspond to eigenvalues of $\mathbf{H}$ close to the shift E, are widely spaced and converge quickly. Many authors have used $F(\mathbf{H}) = (E\mathbf{I} - \mathbf{H})^{-1}$ to accelerate the convergence of eigenvalues of $\mathbf{H}$ close to E (87). It is costly to compute $F(\mathbf{H})\ \mathbf{v}$, where $\mathbf{v}$ is a vector, accurately. One way to do so is to expand $F(\mathbf{H})$ in a Chebyshev series. Many terms are required to obtain an accurate estimate of $F(\mathbf{H})\ \mathbf{v}$. Another way to obtain $\mathbf{w} = F(\mathbf{H})\ \mathbf{v}$ is to solve the system of linear equations $(E\mathbf{I} - \mathbf{H})\mathbf{w} = \mathbf{v}$ for $\mathbf{w}$. To do so one could choose an iterative linear equation solver such as MINRES, CGS, or QMR (88). Again, many iterations (many matrix-vector products) are required to obtain an accurate $\mathbf{w}$. With a spectral transform method, which uses a linear equation solver to compute $\mathbf{w} = F(\mathbf{H})\ \mathbf{v}$, the total number of matrix-vector products required is the product of the number of matrix-vector products performed to solve the system of linear equations and the number of Lanczos iterations needed to converge the eigenvalues (assuming that at each Lanczos iteration the same number of matrix-vector products are used for solving the linear equations). If the system of linear equations is solved accurately, this product is quite large.

The PIST method uses an inexact preconditioned spectral transform. The Lanczos algorithm is applied to $(E\mathbf{I} - \mathbf{H})^{-1}$, where $\mathbf{H}$ is the matrix representation of the Hamiltonian. Rather than evaluating matrix-vector products with $(E\mathbf{I} - \mathbf{H})^{-1}$ accurately (which is costly), computing exact eigenvalues of $(E\mathbf{I} - \mathbf{H})^{-1}$, and extracting exact eigenvalues of $\mathbf{H}$ from those of $(E\mathbf{I} - \mathbf{H})^{-1}$, we evaluate matrix-vector products with $(E\mathbf{I} - \mathbf{H})^{-1}$ approximately and diagonalize $\mathbf{H}$ in a basis of the approximate Lanczos vectors of $(E\mathbf{I} - \mathbf{H})^{-1}$. We deliberately compute *approximate* Lanczos vectors knowing that we can compensate by diagonalizing $\mathbf{H}$ in a basis composed of them to obtain *exact* energy levels and wavefunctions. It is much less costly to compute approximate than accurate Lanczos vectors. This is a critical advantage of an inexact spectral transform method. The Lanczos vectors computed in this fashion are orthogonalized using an iterated modified Gram–Schmidt algorithm.

Approximate matrix-vector products with $(E\mathbf{I} - \mathbf{H})^{-1}$ are computed by solving systems of linear equations $(E\mathbf{I} - \mathbf{H})\mathbf{w} = \mathbf{v}$ using an iterative linear solver and stopping the linear solver when the residual is smaller than a predefined error. Because the systems of linear equations are solved approximately, a matrix representation of $(E\mathbf{I} - \mathbf{H})^{-1}$ in the basis of the Lanczos vectors would not be formally tridiagonal. A key advantage of using a linear solver to evaluate the $(E\mathbf{I} - \mathbf{H})^{-1}$ matrix-vector products is the fact that it allows us to use preconditioning to (greatly) speed up their computation. Instead of solving $(E\mathbf{I} - \mathbf{H})\mathbf{w} = \mathbf{v}$ directly, we solve the preconditioned system $(\mathbf{P})^{-1}(E\mathbf{I} - \mathbf{H})\mathbf{w} = (\mathbf{P})^{-1}\mathbf{v} = \mathbf{v}'$, where $\mathbf{P}$ is an approximate preconditioner. Preconditioning is extremely important because the number of $\mathbf{A}$ matrix-vector products required to compute the solution of $\mathbf{Ax} = \mathbf{b}$ depends on the distribution of the eigenvalues of $\mathbf{A}$, and the eigenvalue distribution of $(\mathbf{P})^{-1}(E\mathbf{I} - \mathbf{H})$ is more favourable than the eigenvalue distribution of $(E\mathbf{I} - \mathbf{H})$ (88).

The method is straightforward to implement. There are two parameters. The first parameter (ϵ) determines the accuracy with which the linear equations are solved. To solve the equations $(E\mathbf{I} - \mathbf{H})\mathbf{w_i} = \mathbf{v_i}$, we iterate QMR until $\| (E\mathbf{I} - \mathbf{H})\mathbf{w_i} - \mathbf{v_i} \| \leq \epsilon$ (the vector $\mathbf{v_i}$ always has a norm of unity). The second parameter is M_L, the number of vectors in the space used to calculate eigenvalues and eigenvectors. The method works well as long as ϵ is small enough. To calculate bound states we usually use $\epsilon = 10^{-2}$.

7.1. Preconditioning

It is well-known that to solve $\mathbf{Ax}$= $\mathbf{b}$ using an iterative linear solver, it is best to precondition the system of linear equations (61, 88). One simple way to do this is to multiply on the left by $\mathbf{P}^{-1}$ to obtain $\mathbf{P}^{-1}\mathbf{Ax} = \mathbf{P}^{-1}\mathbf{b} = \mathbf{c}$. If $\mathbf{P}$ is chosen so that $\mathbf{P}^{-1}\mathbf{A}$ is close to the identity, the number of matrix-vector products required to solve $\mathbf{P}^{-1}\mathbf{Ax} = \mathbf{c}$ is much smaller than the number required to solve $\mathbf{Ax} = \mathbf{b}$.

An "approximate Hamiltonian preconditioner" (AHP) of the form $\mathbf{P} = (E\mathbf{I} - \mathbf{H_0})$, where H_0 represents some approximation to the true Hamiltonian operator H, often works quite well. A good choice is $H_0 = T + V_0$, where V_0 is a separable sum of effective potentials in each degree of freedom (82).

The separable preconditioner exhibits a drawback inherent to all AHPs — namely, the number of iterations required to solve $(E\mathbf{I} - \mathbf{H})\ \mathbf{x} = \mathbf{b}$ grows quickly as E is increased. This is due to the density of states, which is (generally) greater at higher energies, and which has an adverse effect on the convergence. Therefore, if iterative methods are to be effective for problems for which many basis functions are necessary — the promise of which is a large part of their appeal — it is *vital* to devise a preconditioner that scales favorably with the density of states.

One way to do so is to use the optimized separable basis (OSB) of Poirier with an idea suggested by Wyatt (87). The OSB is obtained from an original product basis by doing block Jacobi rotations (89). The rotation angles are chosen to minimize the Frobenius norm of the off-block diagonal part of the Hamiltonian matrix. Rather than using the block-diagonal part of the matrix as the preconditioner, we incorporate into the preconditioner off-diagonal matrix elements for some of the OSB

© 2004 NRC Canada

functions whose energies are in the vicinity of E (the energy close to which we wish to compute energy levels). The resultant OSB+Wyatt (OSBW) preconditioner is a particularly effective combination, because Wyatt preconditioning is most efficient when the matrix (from which off-diagonal elements are incorporated into the preconditioner) is nearly diagonal. Using the OSBW preconditioner, we were able to compute high-lying vibrational levels of H_2O with orders of magnitude fewer matrix-vector products than are required using the CW Lanczos approach (83).

8. Using contracted basis with the Lanczos method

The efficacy of iterative methods for solving the Schrödinger equation is contingent on the cost of matrix-vector products. If one uses a product basis, matrix-vector products can always be evaluated at a cost that scales as n^{f+1}. The n^{f+1} scaling relation is attained by exploiting the special structure of the product basis and evaluating summations (over basis or quadrature indices) sequentially. Although n^{f+1} is certainly favourable, it is nevertheless clear that as f or n increases, the cost of the matrix-vector product calculation will become prohibitive. In addition, although iterative methods obviate the need to store a Hamiltonian matrix, one does need to store vectors, with as many components as there are basis functions, and eventually, as f (or n) is increased, one finds that the core memory of the computer is not large enough to do so. To mitigate both these problems, it is natural to consider using iterative methods with basis functions, which represent wavefunctions or wavepackets more compactly (so that one will require fewer basis functions than would be needed if product basis functions were used). If fewer basis functions are required, one expects the memory of the calculation to be reduced. It might appear that the cost of each matrix-vector product should also be reduced.

It is not at all obvious that contracted-basis matrix-vector products are less expensive than product-basis matrix-vector products. Recall that the n^{f+1} scaling relation (responsible for the efficiency of the product-basis matrix-vector product) is due to the simplicity of the product basis. In fact, because better basis functions are necessarily more complicated (the structure of the basis is less simple), the corresponding matrix-vector products are, in general, more costly. If one considers only the cost of a single matrix-vector product, it appears that using better basis functions may increase (and not decrease) the computer time required, but in fact using contracted basis functions will, in general, make Lanczos calculations more efficient (90–92). Why? The cost of an iterative calculation depends not only on the cost of the matrix-vector product but also on the number of matrix-vector products required to achieve convergence. Using a better basis reduces the spectral range of the Hamiltonian matrix and uniformizes the gaps between neighbouring large basis-unconverged eigenvalues and thus decreases the number of iterations required to converge the energy levels of interest.

To efficiently evaluate matrix-vector products for a contracted representation, one uses matrices (much like the quadrature **T** matrices) to transform between the contracted representation and a representation in which matrix elements of Hamiltonian terms can be computed easily and inexpensively. The number of labels on the transformation matrices and the number of values each label assumes determine the cost of the matrix-vector products.

There are two major classes of contracted basis functions (cf. sect. 3.3). Contracted functions of type 1 are excellent and might fruitfully be combined with iterative methods. Consider first the type 1 contracted matrix-vector product for a triatomic. In this section, we label with j functions of q_1 and q_2 obtained by diagonalizing a two-dimensional Hamiltonian for each DVR point $(q_3)_\gamma$ for coordinate q_3. If the two-dimensional Hamiltonian is diagonalized in a direct product q_1 q_2 basis and α and β are DVR labels for the q_1 and q_2 DVR basis functions, then the matrix of eigenvectors is the transformation matrix whose elements are $C^{\gamma}_{\alpha\beta,j}$. In a basis of functions labelled by j and γ, the triatomic Hamiltonian (written in Radau, symmetrized Radau, or Jacobi coordinates) matrix elements are

$$[25]\qquad \langle j'\gamma'|\hat{H}|j\gamma\rangle = E^{\gamma}_{j}\delta_{j'j}\delta_{\gamma\gamma'} + \sum_{\alpha\beta} C^{\gamma'}_{\alpha\beta,j'}\mu((q_1)_\alpha,(q_2)_\beta)l_{\gamma'\gamma}C^{\gamma}_{\alpha\beta,j}$$

where μ is an inverse moment of inertia function, and $l_{\gamma'\gamma}$ is a DVR matrix element of an operator proportional to $\frac{\partial^2}{\partial\theta^2} + \cot\theta\frac{\partial}{\partial\theta}$. In this representation, applying the Hamiltonian to a vector implicates only one nontrivial matrix-vector product. When sums are evaluated sequentially, the cost of the matrix-vector product

$$[26]\qquad \sum_{\alpha\beta} C^{\gamma'}_{\alpha\beta,j'}\mu((q_1)_\alpha,(q_2)_\beta)\sum_{\gamma} l_{\gamma'\gamma}\sum_{j} C^{\gamma}_{\alpha\beta,j}v_{\gamma j}$$

scales as $2(n_j n_\alpha n_\beta n_\gamma + n_\gamma^2 n_\alpha n_\beta + n_\alpha n_\beta n_\gamma$ (n_j is the number of eigenfunctions of the two-dimensional Hamiltonians that are retained). If $n_\alpha = n_\beta = n_\gamma = n$ and it were necessary to retain all n^2 eigenvectors (i.e., $n_j = n^2$) of the two-dimensional Hamiltonians, then the cost would scale as n^5 (and in general as n^{2f-1}). This should be compared to the cost of the product-basis matrix-vector product (n^{f+1}). Clearly, if at each stage of the sequential diagonalization procedure it were necessary to retain all the eigenvectors of the reduced dimensional Hamiltonians, the sequential-diagonalization and the product matrices would have the same eigenvalues (same spectral range, same gap structure), and the same number of iterations would be required to converge eigenvalues of interest for both representations, and it would be much more expensive to use the sequential-diagonalization basis. However, the utility of the sequential-diagonalization basis is derived from the truncation and if it is truncated, one reduces *both* the cost of each individual matrix-vector product and the number of iterations required. For the three-dimensional example, if n_j is reduced from n^2 to n (by retaining only n of the n^2 eigenvectors of the two-dimensional Hamiltonians), the cost of each matrix-vector product is reduced from n^5 to n^4. The cost of a product-basis matrix-vector product also scales as n^4 but because the spectral range and (or) gap structure of the sequential-diagonalization basis are much more favourable, the number of required iterations is reduced and the calculation is less costly (91). Although it is not possible to know a priori how effective the sequential-diagonalization procedure will be (how much one will be able to truncate), it seems clear

© 2004 NRC Canada

that for Lanczos calculations of energy levels the sequential-diagonalization – Lanczos method will, for many, but not all, triatomic molecules, be more efficient than the product-basis - Lanczos method (90, 91). For molecules with four or more atoms, the advantages of the sequential-diagonalization basis are even more convincing: as the number of degrees of freedom increases, it becomes more and more important to reduce the size of the product basis and to exclude poor (unimportant) functions from the basis (93).

8.1. Using simply contracted basis with the Lanczos method

Contracted basis functions of the type discussed in the previous section are certainly very efficient. If there is a good separation of timescales (for example, for a triatomic molecule, if the bend is much slower than the stretches), the coupling between blocks labelled by eigenvectors of the reduced-dimension problem is very weak. Nonetheless, the combination of iterative methods with these contracted functions has two important deficiencies: (*i*) matrix-vector products are expensive, and (*ii*) the storage cost is high. This might appear surprising because it seems natural to expect that one should need fewer contracted (than product) basis functions and that therefore a contracted-Lanczos method should be more efficient and require less memory.

The somewhat unexpected disadvantages of contracted-Lanczos methods are due to the way the matrix-vector products are evaluated. To evaluate a matrix-vector product, the vector is transformed to a simple product representation in which it is easy to apply the KEO and the potential and then back transformed to the contracted representation. This inevitably entails storing a vector in the product representation. Thus, despite the fact that the vector in the contracted basis is not large, one must store a large vector to evaluate matrix-vector products. It is the complexity of the contracted functions that makes matrix-vector products costly. Both of these disadvantages can be overcome by using "simply contracted" basis functions (91, 94).

In orthogonal polyspherical coordinates the KEO (for $J = 0$) can be written (15, 17, 25)

$$[27] \qquad H = T_{\text{ben}}(\theta, r) + T_{\text{str}}(r) + V(\theta, r)$$

with

$$[28] \qquad T_{\text{ben}}(\theta, r) = \sum_i G_b^{(i)}(r) T_b^{(i)}(\theta)$$

$$T_{\text{str}}(r) = \sum_i G_s^{(i)} \frac{\partial^2}{\partial r_i^2}$$

where θ represents all of the bend coordinates and r represents all of the stretch coordinates. The functions $G_b^{(i)}(r)$, $G_s^{(i)}$ and the operators $T_b^{(i)}(\theta)$ are known (17, 25).

The contraction schemes we present may be used with either a FBR (e.g., spherical harmonics) or DVR primitive bend basis. On the other hand, our contraction schemes rely on the use of DVR primitive stretch basis functions.

We first construct contracted bend functions from a Hamiltonian obtained by freezing all the stretch coordinates at their equilibrium values and contracted stretch functions from a Hamiltonian obtained by freezing all the bend coordinates at their equilibrium values. Products of the bend contracted functions and stretch contracted functions are our final basis functions.

The reduced-dimension Hamiltonian for the bend contraction is

$$[29] \qquad H^{(b)} = T_{\text{ben}}(\theta, r_e) + V(\theta, r_e)$$

Its wavefunctions are denoted by

$$[30] \qquad X_b(\theta) = \sum_l C_{lb} f_l(\theta)$$

and the energies by E_b. The f_l are primitive FBR or DVR bend basis functions (if there is more than one bend coordinate, l is a composite index), and the number of retained bend wavefunctions is denoted by n_b.

Similarly, the reduced-dimension Hamiltonian for the stretch contraction is

$$[31] \qquad H^{(s)} = T_{\text{str}}(r) + V(\theta_e, r)$$

with the wavefunctions denoted by

$$[32] \qquad Y_s(r) = \sum_\alpha D_{\alpha s} g_\alpha(r)$$

and the energies by E_s. The g_α are primitive DVR stretch basis functions (if there is more than one stretch coordinate, α is a composite index representing a multidimensional DVR function), and the number of retained stretch wavefunctions is denoted by n_s. θ_e and r_e represent equilibrium values of (respectively) all the bend coordinates and all the stretch coordinates. The final basis is a product of the retained stretch and bend eigenfunctions

$$[33] \qquad |bs\rangle = |X_b\rangle |Y_s\rangle$$

To facilitate calculation of its matrix elements in this basis, we write the full Hamiltonian

$$[34] \qquad H = H^{(b)} + H^{(s)} + \Delta T + \Delta V$$

where

$$[35] \qquad \Delta V(r, \theta) = V(r, \theta) - V(r_e, \theta) - V(r, \theta_e)$$

and

$$[36] \qquad \Delta T = \sum_i \Delta G_b^{(i)}(r) T_b^{(i)}(\theta)$$

with

$$[37] \qquad \Delta G^{(i)}(r) = G_b^{(i)}(r) - G_b^{(i)}(r_e)$$

Since $H^{(b)}$ and $H^{(s)}$ are diagonal in the product contracted basis and the diagonal matrix elements are known (they are the eigenvalues of $H^{(b)}$ and $H^{(s)}$), one only needs to calculate matrix elements of ΔT and ΔV in the product contracted basis. If it were possible to store the Hamiltonian matrix in the product contracted basis $|bs\rangle$, a direct linear algebra method could be used to compute the energy levels. If this is not possible, one *must* use an iterative method and evaluate matrix-vector products.

8.1.1. Matrix-vector products for ΔT

In the orthogonal vector formalism, the kinetic matrix elements are simple. Because there are no momentum cross terms coupling bend and stretch coordinates, we only have to deal with the coupling term of eq. [36].

This term is diagonal in the stretch PODVR basis (note that there are no derivatives with respect to stretch coordinates in eq. [36]). Due to the product structure of eq. [36], it is best to store the bend and stretch matrices separately. The matrix-vector product for ΔT can be performed sequentially without summing over n_b bend functions and n_s stretch functions simultaneously. Note that it not necessary to store any vectors in the primitive basis.

Specifically, the ΔT matrix-vector product can be calculated

$$[38] \qquad u'_{b's'} = \sum_{i,s} \langle s'|\Delta G_b^{(i)}|s\rangle \sum_b \langle b'|T_b^{(i)}|b\rangle u_{bs}$$

The $\Delta G_b^{(i)}$ and $T_b^{(i)}$ matrices are both small and are stored. The $\Delta G^{(i)}$ matrix elements are computed from

$$[39] \qquad \langle s'|\Delta G_b^{(i)}|s\rangle = \sum_\alpha D_{\alpha s'} \Delta G_b^{(i)}(r_\alpha) D_{\alpha s}$$

The $T_b^{(i)}$ matrix elements are computed from

$$[40] \qquad \langle b'|T_b^{(i)}|b\rangle = \sum_{l,l'} C_{l'b'} \langle f_l|T_b^{(i)}|f_{l'}\rangle C_{lb}$$

Because $\Delta G_b^{(i)}$ is diagonal in the DVR basis it is inexpensive to calculate matrix elements of it. Regardless of whether DVR or FBR primitive basis functions are used, matrix elements of $T_b^{(i)}$ are inexpensive to compute because each of the $T_b^{(i)}$ operators is factorizable and involves at most derivatives with respect to two coordinates. Assuming that $n_b > n_s$ (which almost always holds), the memory cost of the ΔT matrix-vector product is n_b^2 and the CPU cost is $n_b^2 n_s$ (if n_s were greater than n_b, then the memory and CPU costs would be n_s^2 and $n_s^2 n_b$). The memory and CPU costs of the ΔV matrix-vector product are much higher (94).

8.1.2. Matrix-vector products for ΔV

In this subsection, I present a method for calculating the ΔV matrix-vector product (94). If one uses an FBR primitive bend basis, a matrix element of ΔV in the product contracted basis is

$$[41] \qquad \begin{aligned} &\langle b's'|\Delta V(\theta, r)|bs\rangle \\ &\quad = \sum_{\substack{l'l \\ \alpha}} C_{l'b'} C_{lb} D_{\alpha s'} D_{\alpha s} \langle l'\alpha|\Delta V(\theta, r)|l\alpha\rangle \\ &\quad = \sum_{\substack{l'l \\ \alpha\beta}} C_{l'b'} C_{lb} D_{\alpha s'} D_{\alpha s} T_{l'\beta} T_{l\beta} \Delta V_{\beta\alpha} \end{aligned}$$

where

$$[42] \qquad \begin{aligned} T_{l\beta} &= \sqrt{w_\beta} f_l(\theta_\beta) \\ \Delta V_{\beta\alpha} &= \Delta V(\theta_\beta, r_\alpha) \end{aligned}$$

(θ_β, w_β) are quadrature points and weights for the angles. Note that if there is more than one bend coordinate, l and β are composite indices, and if there is more than one stretch coordinate, α is a composite index. It is sometimes advantageous to rewrite eq. [41] as

$$[43] \qquad \langle b's'|\Delta V(\theta, r)|bs\rangle = \sum_{\alpha\beta} \tilde{C}_{\beta' b'} \tilde{C}_{\beta b} D_{\alpha s'} D_{\alpha s} \Delta V_{\beta\alpha}$$

where

$$[44] \qquad \tilde{C}_{\beta b} = \sum_l C_{lb} T_{l\beta}$$

Note that the columns of $\mathbf{C}$ are the eigenvectors of $H^{(b)}$ in the FBR basis, and the columns of $\tilde{\mathbf{C}}$ are the eigenvectors of $H^{(b)}$ in the DVR basis. If the primitive bend basis is a DVR basis, a ΔV matrix element is also given by eq. [43] but with $\tilde{C}_{\beta b}$ replaced by $C_{\beta b}$.

One obvious way to evaluate the ΔV matrix-vector product is by doing sums sequentially (90–93),

$$[45] \qquad \begin{aligned} u'_{b's'} &= \sum_{bs} \langle b's'|\Delta V(\theta, r)|bs\rangle u_{bs} \\ &= \sum_\alpha D_{\alpha s'} \sum_\beta \tilde{C}_{\beta b'} \Delta V_{\beta\alpha} \sum_s D_{\alpha s} \sum_b \tilde{C}_{\beta b} u_{bs} \end{aligned}$$

This approach has two important disadvantages: (*i*) one needs to store at least one (more vectors are required to exploit symmetry using the symmetry-adapted Lanczos algorithm (78, 79)) very large vector (with as many components as there are quadrature points) and a potential vector $\Delta V_{\beta\alpha}$; (*ii*) the matrix-vector product is costly because the $\mathbf{D}$ and $\tilde{\boldsymbol{C}}$ matrices cannot be factorized. In this subsection, we discuss a method for overcoming these problems.

A potential matrix element in the product contracted basis is rewritten

$$[46] \qquad \begin{aligned} \langle b's'|\Delta V(\theta, r)|bs\rangle &= \sum_{\alpha\beta} \tilde{C}_{\beta' b'} \tilde{C}_{\beta b} D_{\alpha s'} D_{\alpha s} \Delta V_{\beta\alpha} \\ &= \sum_\alpha F_{b'b,\alpha} D_{\alpha s'} D_{\alpha s} \end{aligned}$$

where we have introduced a $\mathbf{F}$ matrix defined by

$$[47] \qquad F_{b'b,\alpha} = \sum_\beta \tilde{C}_{\beta b'} \tilde{C}_{\beta b} \Delta V_{\beta\alpha}$$

To use our method, one calculates and stores all the $F_{b'b,\alpha}$. One then does the ΔV matrix-vector product

$$[48] \qquad u'_{b's'} = \sum_{bs} \langle b's'|\Delta V|bs\rangle u_{bs}$$

This is most efficiently done in three steps:

$$[49] \qquad \begin{aligned} u^{(1)}_{b\alpha} &= \sum_s D_{\alpha s} u_{bs} \\ u^{(2)}_{b'\alpha} &= \sum_b F_{b'b\alpha} u^{(1)}_{b\alpha} \\ u'_{b's'} &= \sum_\alpha D_{\alpha s'} u^{(2)}_{b'\alpha} \end{aligned}$$

© 2004 NRC Canada

The CPU cost of the matrix-vector product in eq. [49] is $n_\alpha(n_b^2 + 2n_b n_s)$. Assuming $n_b > n_s$, the CPU cost scales as $n_\alpha n_b^2$. Each matrix-vector product is therefore very cheap. The cost is comparable to, or less than, the cost of a product-basis matrix-vector product $f n_{1d}^{f+1}$ (it is actually *much* less for many examples), where n_{1d} is the number of basis functions and quadrature points for each coordinate. Because n_b is much smaller than n_β, it is also more efficient to evaluate the matrix-vector product with eq. [49] than with eq. [45] (for which the cost of the most expensive matrix-vector product scales as $n_\alpha n_\beta n_b$). Of course, this comparison is not really fair: to estimate the total CPU cost of the calculation, one needs to also include the cost of calculating **F**. The **F** matrix is computed prior to and not during the Lanczos recursion. Calculating **F** can be costly. If one evaluates eq. [47] as it is written, the cost of computing the matrix scales as $n_\alpha n_b^2 n_\beta$. In practice, we use Level 3 BLAS for each α in eq. [47] by storing $\tilde{C}\Delta V$ first. This speeds up the calculation of **F** by about a factor of five for H_2O_2 (94).

Does the cost of calculating **F** make this method expensive? It is true that the cost of calculating **F** is formally a factor of n_β larger than the cost of a single contracted matrix-vector product (eq. [49]). However, if one wishes to calculate more than a few energy levels, the *number* of matrix-vector products required to converge the energy levels is also large, and because the cost of the matrix-vector product of eq. [49] is much less than the cost of a standard product matrix-vector product, the contracted product method is more efficient than the product method.

On a parallel computer one could *easily* reduce the total time by parallelizing the calculation of **F**. The calculation of **F** can be trivially parallelized as one can allocate the stretch DVR (α) points to different computers or processors and allow each to calculate a block of **F** for the allocated α points. The full **F** is then assembled from these blocks.

Now we estimate the memory one needs to use this method. Once **F** has been calculated, the simplest way to use eq. [49] to calculate matrix-vector products requires storing **F** and **D**. To store **F**, one must store $n_\alpha n_b^2/2$ numbers (**F** is symmetric). To store **D**, one must store $n_\beta n_s$ numbers. The memory cost is therefore dominated by the cost of storing **F** and scales as $n_\alpha n_b^2/2$. It clearly makes sense to exploit all of the memory available, but if it is not possible to store $n_\alpha n_b^2/2$ numbers, the method can nonetheless be used by storing **F** on disk and reading blocks of **F** labeled by α sequentially from the disk into memory as the ΔV matrix-vector product is computed. This is feasible as it costs only seconds to read gigabytes of data on modern desktop workstations.

The method of this section is not only quicker than a product/iterative method; it also enables one to bypass the memory bottleneck. The most costly quantities to store (**F**, **D**) are all used for one α at a time and can therefore be read one α at a time from disk. Note in addition that because **C** and $\tilde{\mathbf{C}}$ are discarded *before* matrix-vector products are evaluated, one can use an extremely large bend basis to converge the contracted bend functions without increasing the memory cost of the calculation (the CPU cost of the calculation of **F** does increase moderately). In contrast, if one uses the standard approach (eq. [45]), increasing the size of the bending basis increases both the CPU and the memory cost dramatically.

9. Conclusion

Significant progress has been made in the development of iterative methods for computing rovibrational spectra. The CPU and memory costs of a direct calculation scale as N^3 and N^2. It is very clear that no matter how much effort is put into reducing N, both N^3 and N^2 will make it impossible to use direct methods to solve many difficult and interesting problems. Iterative methods enable one to calculate a spectrum without storing a $N \times N$ Hamiltonian matrix. Instead, it is only necessary to store vectors with N components. There is no question that this makes feasible calculations with much larger basis sets. Nonetheless, for a molecule with five atoms it is not possible, if one uses a product basis set, to store even vectors. In this article I have discussed new ideas for overcoming this problem.

The cost of an iterative calculation scales as MC_{mv}, where M is the number of matrix-vector products needed to converge the energy levels of interest, and C_{mv} is the cost of a single matrix-vector product. If M is very large, then even if C_{mv} is modest the cost of an iterative calculation of a spectrum can be excessive. In this article I have reviewed new ideas for reducing M.

The simple fact that iterative methods enable one to calculate a spectrum without storing (or even calculating!) a Hamiltonian matrix immediately suggests that they should be methods of choice. So far, however, it has not been demonstrated that iterative methods enable one to solve more difficult problems. The success of iterative methods has been limited because they are almost always used with simple product basis functions. There is a good reason for this: product basis functions make it very easy to do matrix-vector products. In this article I have argued that iterative methods will reveal their true power only when they are used in conjunction with contracted basis functions. Contracted-basis matrix-vector products are necessarily more complicated but if one uses simply-contracted functions, obtained by dividing coordinates into groups, the cost of the matrix-vector products can be reduced by storing an intermediate matrix (**F**). Once **F** has been computed, the size of the primitive bend basis becomes irrelevant. With the method discussed in this article, it is not necessary to transform from the contracted basis to the primitive basis to do matrix-vector products. If the contracted basis is used as suggested in this article, the memory cost of a calculation can be reduced significantly. The CPU cost is also reduced. It is reduced both because the cost of the matrix-vector products is reduced and because the number of matrix-vector products required to converge energy levels is reduced.

The CPU cost of an iterative calculation can be reduced not only by reducing the cost of a single matrix-vector product but also by reducing their number. The PIST method discussed in this article enables one to exploit preconditioning to do so. Preconditioning has been used for many years to speed up the solution of systems of linear equations. A great deal has been learned about how to build good preconditioners. It is less obvious how to use preconditioning to accelerate the calculation of eigenvalues. PIST offers a good way of doing this.

The key to finding a good preconditioner is finding a good zeroth-order Hamiltonian. For many molecules the sum of the reduced-dimension bend Hamiltonian and the reduced-dimension stretch Hamiltonian would be a very good zeroth-order Hamiltonian. The eigenfunctions of this zeroth-order

© 2004 NRC Canada

Hamiltonian are just the contracted basis functions we have discussed using. The combination of these two ideas should be very effective.

Fermi resonance and conformation in glycolaldehyde particles[1]

Martin Jetzki, David Luckhaus, and Ruth Signorell

Abstract: The infrared spectra of gas-phase glycolaldehyde and small glycolaldehyde particles both exhibit a split carbonyl band around 1730 cm^{-1}. Ab initio calculations show that this splitting can be traced back to a Fermi resonance involving the C=O-stretching band and the first overtone of the C–C-stretching band. The analysis of this resonance leads to detailed information about the conformation of glycolaldehyde in the particles. The results can be summarized as follows. (*i*) In the particles, monomers with OCCO dihedral angles of 0° and CCOH dihedral angles around 50° are strongly preferred. (*ii*) The intramolecular hydrogen bond observed in the gas phase is partly replaced by intermolecular hydrogen bonds. (*iii*) The calculated infrared spectrum and the results from the Fermi resonance analysis are in good agreement with the formation of long chains of monomeric glycolaldehyde. This is in contrast to the solid bulk, which consists of chemically bound dimers.

Key words: Fermi resonance, conformation, glycolaldehyde particles, hydroxyacetone particles, Fourier transform infrared spectroscopy.

Résumé : Les spectres infrarouge du glycolaldéhyde en phase gazeuse et de petites particules de glycolaldéhyde présentent tous les deux une bande carbonyle dédoublée autour de 1730 cm^{-1}. Des calculs ab initio montrent que ce dédoublement provient d'une résonance de Fermi impliquant la bande d'élongation C=O et la première harmonique de la bande d'élongation C–C. L'analyse de cette résonance fournit de l'information détaillée au sujet de la conformation du glycolaldéhyde dans les particules. Les résultats peuvent être résumés de la façon suivante: (*i*) dans les particules, il existe une préférence marquée pour le OCCO avec un angle dièdre de 0° et le CCOH avec un angle dièdre d'environ 50°; (*ii*) la liaison intramoléculaire observée en phase gazeuse est en partie remplacée par des liaisons hydrogènes intermoléculaires; (*iii*) le spectre infrarouge calculé et les résultats de l'analyse de Fermi sont en bon accord avec la formation de longues chaînes de glycolaldéhyde monomère. Ces observations sont en opposition avec celles qui ont été faites à l'état solide dans lequel le glycolaldéhyde existe sous la forme de dimères chimiquement liés.

Mots clés : résonance de Fermi, conformation, particules de glycolaldéhyde, particules d'hydroxyacétone, spectroscopie infrarouge à transformée de Fourier.

[Traduit par la Rédaction]

1. Introduction

The aggregation of gas-phase molecules to oligomers, small particles, or bulk material is often accompanied by conformational changes of the molecules. They are caused by the influence of intermolecular interactions which in general are rather weak. Conformational changes are expected to be particularly pronounced in hydrogen-bonded systems when intramolecular hydrogen bonds compete with the formation of hydrogen-bonded networks.

Broad-band infrared spectroscopy is ideally suited to investigate conformational changes upon aggregation. In the spectra, such changes lead to characteristic shifts of the vibrational frequencies and to changes in the relative intensities. Corresponding characteristic group frequencies often lie in the fingerprint region. The fingerprint region, however, commonly consists of a dense manifold of vibrational transitions, which can complicate the analysis. Anharmonic resonances are particularly sensitive to conformational changes (1–3) and to aggregation processes in hydrogen-bonded systems (4–6). Compared with the characteristic group frequencies in the fingerprint region, they often appear at higher frequencies, where the infrared spectra typically are less dense. This makes the analysis simpler and more clear-cut.

With their multiple hydrogen-bonding valences, sugars are ideal model systems to study molecular aggregation processes. Depending on the experimental conditions, chemical and conformational changes are observed upon aggregation to small particles (7–9). The present work focuses on glycolaldehyde, which is the simplest monosaccharide sugar. Gas-phase glycolaldehyde also plays a role as an intermediate in the gas-phase oxidation of ethylene (10, 11). In such reactions, the formation of nonvolatile compounds, such as glycolaldehyde, can lead to gas-to-aerosol transitions, i.e., to the formation of small particles (11). Recently, interstellar gas-phase glycolaldehyde has been detected, and its formation by grain-surface reactions has

been discussed (12, 13). The understanding of these and related processes requires the knowledge of gas-phase spectra as well as of particle spectra. Very detailed information can be obtained through the analysis of infrared spectra. There exist some infrared spectra for glycolaldehyde in the vapor phase, in matrices, as a melt, and in solution (10, 11, 14–17), but no particle spectrum had been reported until now. A comparison of the available data, however, shows a contradictory assignment of some characteristic features in the spectra.

In the present study, we combine Fourier transform infrared spectroscopic investigations of small glycolaldehyde particles and gas-phase glycolaldehyde with theoretical predictions of the vibrational dynamics. The focus lies on conformational changes upon aggregation. This leads to a consistent explanation of the characteristic features in the infrared spectra, which had previously been the subject of some controversy.

2. Experiment

All infrared spectra were recorded with a Bruker Equinox 55 Fourier transform infrared spectrometer equipped with a Globar light source, a KBr beam splitter, and an HgCdTe detector. The spectral resolution was set to be 1 cm^{-1}. The spectrometer was connected to a long-path cell (White optics; optical path length ~10 m) which can be cooled down to liquid-helium temperature. This so-called collisional cooling cell and its operation are described in detail in refs. 18 and 19.

Glycolaldehyde particles were generated in the collisional cooling cell immediately before their infrared spectra were recorded. In a collisional cooling cell, particles are formed by injecting a warm sample gas into a cold bath gas where, due to the supersaturation of the sample gas, nucleation and condensation take place. In the present investigation, we have used helium as bath gas equilibrated to a temperature of 78 K using liquid nitrogen as cooling agent. To generate particles of nonvolatile substances, such as glycolaldehyde, the cell can be equipped with a heatable sample inlet (9). It consists of a heatable sample gas reservoir and a heatable stainless steel injection lance which is controlled by a magnetic valve and projects into the cold cell. In the reservoir, glycoladehyde gas (CH_2OHCHO) was formed by heating solid 2,5–dihydroxy-1,4–dioxane ($C_4H_8O_4$; Fluka research grade) to 383 K. The purity of the vapour thus obtained was obvious from its IR absorption spectrum. In particular, the vapour does not contain any dimer. The glycolaldehyde gas was then mixed with helium gas ($T = 383$ K) to increase the sample gas pressure to ~400 mbar. To form particles, short pulses of the hot sample gas (glycolaldehyde with helium) were injected into the cold bath gas (pressure: 200 mbar). From Mie scattering calculations for the particle infrared spectra (18, 20), we estimate the mean particle size to lie around 50 nm.

For the gas-phase measurements of glycolaldehyde, the same procedure was performed as described above for the particles. The only difference was the bath gas temperature, which was kept at $T = 298$ K. Under these conditions, the sample gas cools down to room temperature inside the cell. For these cell temperatures, any particle formation can be excluded.

3. Calculations

All quantum chemical calculations were performed with the Gaussian program package (21) at the B3LYP and MP2 levels of theory using different basis sets up to quadruple-ζ quality including polarization and diffuse functions (aug-cc-pVQZ). The density functional theory (DFT) calculations employed integration grids of 75 radial shells with 302 angular points each, pruned to about 7000 grid points per atom. The MP2 calculations included only valence orbitals (frozen core approximation). Equilibrium geometries, electronic energies, and harmonic vibrational wavenumbers were determined for different conformers of glycolaldehyde monomer and for several of its hydrogen-bonded oligomers. Some of the corresponding results are listed in Table 1. In the following the different conformers are labelled according to the OCCO (first letter) and CCOH (second letter) dihedral angles: Z and E indicate values around 0° and 180°, respectively; G stands for a value around 50°.

For the calculation of the Fermi resonance between the C=O-stretching vibration ($\nu_{C=O}$) and the first overtone of the C–C-stretching vibration (ν_{C-C}), we have derived two-dimensional potential energy surfaces in the corresponding reduced normal coordinates q_1 for C=O and q_2 for C–C (see eq. [1]). A major advantage of using normal coordinates lies in the fact that the coupling of the "active" coordinates (C=O and C–C stretching) to all the other vibrations of the molecule is accounted for up to quadratic terms. Moreover, anharmonic couplings occur only in the potential energy (neglecting small vibrational angular momentum terms). For each conformer of glycolaldehyde and for all monomeric units in the oligomers, we have calculated 121 single points with the Gaussian program at different levels of theory. As an example, Fig. 1 shows the corresponding point-wise potential (B3LYP/6-31+G*) for the ZZ conformer of glycolaldehyde monomer (see Fig. 2). The potential energy surfaces were then expanded in power series of the form

$$[1] \qquad V = \sum_{l,m=0}^{6} f_{lm} q_1^l q_2^m \text{ with } q_i = Q_i \sqrt{\frac{\omega_i hc}{\hbar^2}}$$

by fitting the coefficients f_{lm} to the calculated grid points (obviously $f_{10} = f_{01} = f_{11} = 0$). The index $i = 1$ refers to the C=O normal coordinate and $i = 2$ to the C–C normal coordinate, Q_i is the mass-weighted normal coordinate, ω_i is the corresponding harmonic wavenumber, c is the speed of light, and $\hbar$ is Planck's constant divided by 2π. In the reduced normal coordinates q_i and their conjugate momenta $\hat{p}_i = -i\partial/\partial q_i$, the vibrational Hamiltonian for the C=O/C–C Fermi resonance system takes the form

$$[2] \qquad \hat{H} = \hat{H}_1^{(0)} + \hat{H}_2^{(0)} + V_{\text{couple}}$$

with

$$V_{\text{couple}} = \sum_{l,m=1}^{6} f_{lm} q_1^l q_2^m$$

and

$$\hat{H}_i^{(0)} = \hat{H}(\hat{p}_{i\neq k} = 0, q_{i\neq k} = 0)$$

Note: $\Delta\omega = \omega_{C=O} - 2\omega_{C-C}$ and $\Delta\tilde{\nu} = \tilde{\nu}_{C=O} - \tilde{\nu}_{2(C-C)}$.

This expression neglects all vibrational-angular momentum terms and the pseudo-potential, both of which are usually small. V_{couple} is the nonseparable contribution to the potential energy V and $\hat{H}_i^{(0)}$ is the one-dimensional (1-D) separable anharmonic Hamiltonian for the vibrational motion in q_i. $\hat{H}$ is diagonalized in a product basis $|v_1 v_2\rangle = |v_1\rangle|v_2\rangle$ of the 1-D C=O-stretching function $|v_1\rangle$ and the 1-D C–C-stretching function $|v_2\rangle$. The C=O and C–C vibrations fulfill the 1:2 resonance condition almost perfectly. Since the coupling between them is much smaller than the vibrational quanta, the Fermi resonance between the C=O-stretching fundamental and the first C–C-stretching overtone can be reduced to an effective two-level Fermi resonance with the following matrix representation:

$$[3] \qquad \begin{pmatrix} \langle 10|\hat{H}|10\rangle & W \\ W & \langle 02|\hat{H}|02\rangle \end{pmatrix}$$

with the coupling matrix element

$$[4] \qquad W = \langle 10|\hat{H}|02\rangle = \langle 02|\hat{H}|10\rangle$$

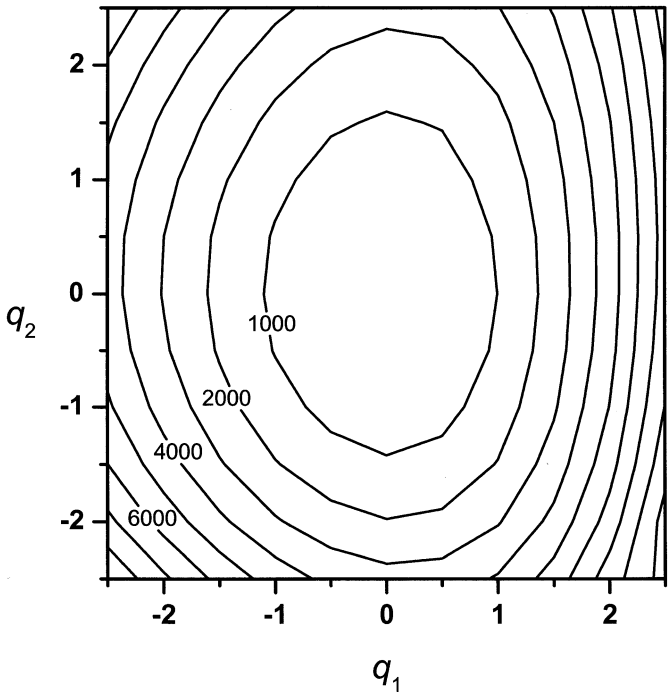
Because typical anharmonicities (Table 1) are comparable to W (Table 2), the product basis has to be built from separable anharmonic wave functions. These were obtained by diagonalizing $\hat{H}_i^{(0)}$ in a basis of harmonic oscillator eigenfunctions:

$$[5] \qquad \hat{H}_i^{(0)}|v_i\rangle = E_{i,v_i}|v_i\rangle$$

The contribution of the leading harmonic basis function to the three lowest eigenfunctions exceeds 95%. Since the C=O/C–C Fermi resonance is dominated by the $q_1 q_2^2$ potential term, the coupling matrix element W can be approximated as

$$[6] \qquad W \approx \frac{1}{2} f_{12}$$

The solution of the Fermi resonance problem leads to the two eigenvalues



$$[7] \qquad E_A > E_B$$

and to the eigenfunctions

$$[8] \qquad \psi_A = a \cdot |10\rangle - b \cdot |02\rangle$$
$$\psi_B = b \cdot |10\rangle + a \cdot |02\rangle$$

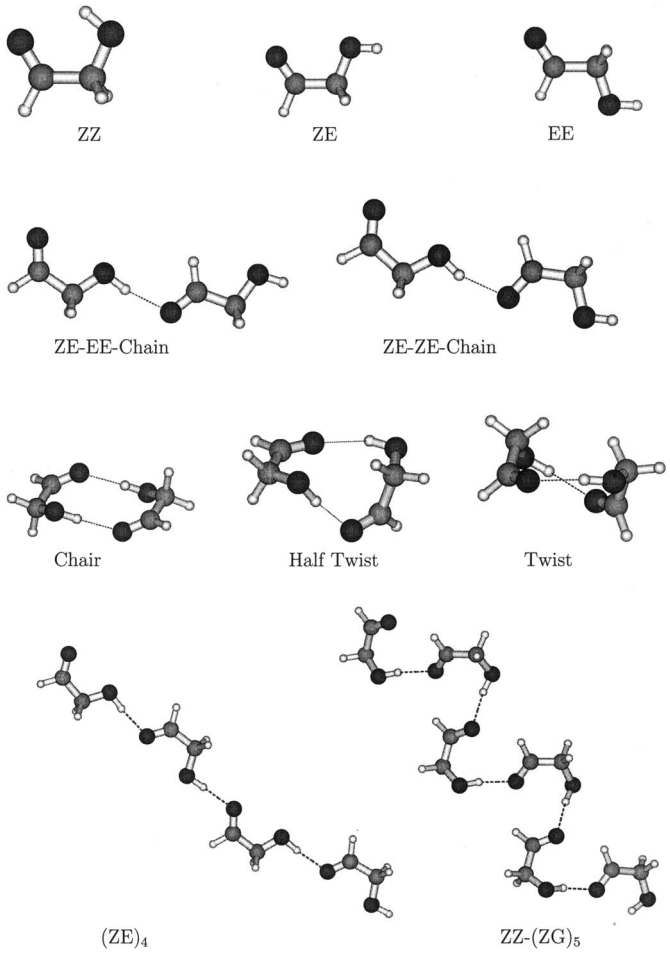
Fig. 1. Two-dimensional potential energy surface V (eq. [1]) in the reduced normal coordinates q_1 (C=O-stretching vibration) and q_2 (C–C-stretching vibration). The contours represent equipotential lines separated by 1000 cm^{-1}.



Assuming that only the C=O-stretching fundamental carries intensity, the relative band strength $\frac{I_A}{I_B}$ is given approximately by:

$$[9] \qquad I = \frac{I_A}{I_B} \approx \frac{a^2}{b^2}$$

The approximations inherent in eqs. [3]–[6] were checked against a numerically exact diagonalization of the full Hamiltonian (eq. [2]). The corresponding eigenvalues agree to within 2 cm^{-1}.

Fig. 2. Equilibrium structures for different conformers (ZZ, ZE, and EE) and small oligomers (chair, half twist, twist, ZE–EE, ZE–ZE, $(ZE)_4$, and ZZ–$(ZG)_5$) of glycolaldehyde. O, C, and H atoms are represented by dark, medium, and light grey spheres, respectively. The different conformers are labelled according to the OCCO (first letter) and CCOH (second letter) dihedral angles. Z and E indicate values around 0° and 180°, respectively. G stands for a value around 50°.

4. Results

Figure 3 shows the gas-phase infrared spectrum of glycolaldehyde (trace *a*) in comparison with the corresponding particle spectrum (trace *b*) between 600 and 3750 cm^{-1}. The comparison of the two spectra provides insight into the conformational changes that accompany the aggregation of the gas-phase monomers to hydrogen-bonded aggregates in the particles. The overall agreement between the gas-phase spectrum and the particle spectrum confirms that the chemical composition does not change upon aggregation even though the solid bulk phase consists of the chemically bound dimer 2,5-dihydroxy-1,4-dioxane (14, 16). This agrees with earlier observations on dihydroxyacetone (9): The proton-catalyzed dimerization of α-hydroxy-carbonyl compounds cannot compete with aggregation under aprotic conditions. Consequently, the main differences between the two spectra arise from the formation of hydrogen bonds in the particles and from conformational changes of the monomers upon aggregation. The most prominent difference between the two spectra appears in the OH-stretching region around 3300 cm^{-1}. Compared with the gas phase, the OH-stretching band of the particles is red shifted and distinctly broader. This observation can clearly be explained by the formation of intermolecular hydrogen bonds in the particles, which are evidently more favorable than the intramolecular one in the gas phase (probably due to cooperative effects). However, the hardly characteristic OH-stretching region of the particle spectrum cannot provide any further information about conformations. More informative with regard to conformation is the region below 2000 cm^{-1} with the following most notable features: (*i*) The band labelled with an asterisk in the gas-phase spectrum has disappeared in the particle spectrum. (*ii*) In both spectra, the C=O-stretching bands around 1750 cm^{-1} are split. The intensity ratio, however, of the higher frequency band to the lower frequency band is smaller in the particle spectrum (2:1) than in the gas-phase spectrum

(5:1). In the following, we demonstrate how these observations can be exploited to extract information about conformational changes upon particle formation.

4.1. Fermi resonance in the gas phase

In agreement with the results of an early microwave investigation (22) and a matrix study (15), our analysis of the gas-phase spectrum (trace *a* in Fig. 3) shows that the hydrogen-bonded ZZ conformer (Fig. 2) is the dominant species in the gas phase at 293 K. Harmonic ab initio calculations of the infrared spectrum of the energetically most favorable ring conformer ZZ agree best with the experimental spectrum. For illustration, Fig. 4 compares the experimental gas-phase spectrum (trace *d*) with the calculated spectrum of the ring conformer ZZ (trace *c*) and with the calculated spectra of the open conformers ZE (trace *b*) and EE (trace *a*). In contrast to all open forms of glycolaldehyde, only the intramolecularly hydrogen-bonded ZZ conformer shows the characteristic absorption band observed at 1276 cm^{-1}, which is labelled by an asterisk in Figs. 3 and 4. This band arises from the excitation of the OH-bending motion in combination with the CH_2-wagging motion of the intramolecularly hydrogen-bonded ring structure. Analogous characteristic absorption bands can be observed in the gas-phase spectra of hydroxyacetone at 1288 cm^{-1} (trace *a* in Fig. 5) and dihydroxyacetone at 1288 cm^{-1} (8,9). As demonstrated previously (8,9), this absorption band is highly characteristic for the intramolecularly hydrogen-bonded ring structures common to the most stable conformers of these molecules.

An assignment of the bands observed in the gas-phase spectrum is given in Table 3 based on the harmonic ab initio calculations. Compared with refs. 10 and 14, some transitions are reassigned here. Our assignment matches the assignment of matrix spectra by Aspiala et al. (15) within the expected wavenumber shifts. From Fig. 4 and Table 3, it is clear that the two rather weak bands at 2709 and 1706 cm^{-1} (Fig. 3*a*) cannot be explained within a harmonic analysis. In principle, three explanations could account for this: The two bands arise from a second less stable conformer or from hot band transitions or from anharmonic resonances. A second minor species would obviously have to be an open conformer, i.e., one without intramolecular hydrogen bonds. Compared with the ZZ conformer, the open conformers show blue shifted OH-stretching bands and blue shifted C=O-stretching bands. The additional C=O band at 1706 cm^{-1}, however, is red shifted and not blue shifted relative to the C=O band of the ZZ conformer, nor is there any indication in Fig. 3 of a blue shifted OH-stretching absorption or any other of the characteristic bands predicted for open forms of glycolaldehyde. The presence of a second conformer in the gas phase can therefore be excluded. The same holds for the alternative explanation of the bands at 2709 and 1706 cm^{-1} in terms of vibrationally hot transitions as there are two observations that clearly contradict it. First, hot bands should also be observable in other regions of the spectrum, which is not the case. Moreover and more importantly, the presence of both transitions in the particle spectrum (Fig. 3*b*) recorded at much lower temperature ($T = 78$ K) contradicts the assignment as hot bands. This leaves anharmonic resonances as the only plausible explanation for the bands at 2709 and 1706 cm^{-1}. This possibility had already been considered in the analysis of the matrix spectra of glycolaldehyde (15). The transition at 2709 cm^{-1} arises from the first in-plane bending overtone of the aldehyde group with its CH-stretching fundamental. Consequently, the bending fundamental would be expected above 1360 cm^{-1}. This value coincides with the CH_2-bending multiplet (1356–1456 cm^{-1}). In this range, four peaks are observed instead of only the three calculated fundamental transitions. This is consistent with a second Fermi resonance between the aldehydic in-plane and out-of-plane bending vibrations (fundamental transition calculated at 721 cm^{-1} with vanishing intensity). Similar resonances have been observed for other aldehydes (23) such as acetaldehyde (24) with typical stretch–bend coupling matrix elements around 50 cm^{-1}. This Fermi resonance is thus not particularly characteristic for glycolaldehyde nor is it particularly sensitive to conformational changes. Although the resonance is still observed in the particles, it is therefore ill suited to extract information about specific conformational changes upon aggregation. More characteristic is the Fermi resonance that causes the splitting of the C=O band. In this case, the C=O-stretching mode couples most probably to the first overtone of the C–C-stretching vibration, which appears at 859 cm^{-1} in the gas-phase spectrum. Because both the C=O and the C–C-stretching vibrations shift only slightly upon aggregation, the splitting is also observed in the particle spectrum in Fig. 3*b*. In systems where the C–C-stretching vibrations move to higher or lower frequencies compared with glycolaldehyde, e.g., in dihydroxyacetone (9) or hydroxyacetone (see Fig. 5), no splitting of the C=O band is observed.

To support this explanation, we have modeled the Fermi resonance between the C=O band and the first overtone of the C–C-stretching band for the ZZ conformer by ab initio calculations, as explained in Sect. 3. Note that the resulting evidence is quite independent from our experimental observations. The harmonic wavenumbers ($\omega_{C=O}$ and $2\omega_{C-C}$) and the anharmonic wavenumbers ($\tilde{\nu}_{C=O}$ and $\tilde{\nu}_{2(C-C)}$) for the uncoupled 1-D problems (eq. [5]) are summarized in Table 1 for different levels of theory. These data reveal anharmonicities less than 1% nearly independent of the methods used. Thus, the resonance defect is largely determined by the harmonic contribution $\Delta\omega$, which differs significantly for different levels of ab initio theory. Table 2 lists values of the coupling matrix element W (eq. [4]), the relative band strength I (eq. [9]), and the calculated transition wavenumbers $\tilde{\nu}_{A,B} = E_{A,B} - E_{1,0} - E_{2,0}$ (eqs. [5] and [7]). For the matrix element W, all levels of theory lead to a similar value of about 20 cm^{-1}. A simple two-level data analysis (see p. 216 in ref. 25) of the doublet at 1754 and 1706 cm^{-1} with an intensity ratio $I_{exptl.} = 5{:}1$ leads to an experimental value of $W_{exptl.} = 18$ cm^{-1} in perfect agreement with our theoretical value. Because the anharmonicities and the coupling matrix element both are stable with respect to the increasing level of theory, the differences in the values of I, $\tilde{\nu}_A$, and $\tilde{\nu}_B$ calculated for the ZZ form with different methods arise almost exclusively from remaining small errors in the harmonic wavenumbers $\omega_{C=O}$ and ω_{C-C} (Table 1), which are to be expected at the levels of theory employed. The intensity ratio I of the doublet (eq. [9]) reacts very sensitively to minor shifts of the vibrational wavenumbers. The B3LYP calculation consistently overestimates the C=O-stretching wavenumber, increasing the resonance defect, and thus weakening the resonance (I becomes too large). The MP2 calculation by contrast predicts the C–C-stretching vibration too high, effectively inverting the

intensity ratio. Notwithstanding these small errors, all values for I consistently indicate a pronounced Fermi resonance for the ZZ conformer. The (expected) deviations in calculated harmonic wavenumbers (and consequently in absolute band positions) do not affect this conclusion. Since the fundamental band centers are known experimentally, the ab initio prediction of anharmonicities and coupling matrix elements proves — independent from the experiment — that the observed splitting in the gas-phase spectrum around 1730 cm^{-1} arises from a Fermi resonance involving the C=O-stretching vibration and the first overtone of the C–C-stretching vibration. In particular, the comparison of B3LYP and MP2 calculations with systemat-

ically increasing basis size clearly shows that the rather modest B3LYP/6-31+G* level of theory is sufficient to derive a realistic model of this characteristic Fermi resonance.

4.2. Conformation in the particles

The analysis of the gas-phase spectrum in the previous section enables us to obtain information on the type of conformers and aggregates in the particles. As mentioned at the beginning of Sect. 4, this is mainly based on two prominent features in the experimental spectra: (*i*) the band at 1276 cm^{-1} in the gas-phase spectrum which is missing in the particle spectrum, and (*ii*) the C=O-stretching doublet observed both in the gas-phase and in the particle spectra.

Observation (*i*) hints at an at least partial breakup of the intramolecular hydrogen bond in the ZZ conformer upon aggregation. As outlined in the previous section, this band is characteristic only for the intramolecularly hydrogen-bonded ring conformer ZZ. The fact that the transition near 1276 cm^{-1} is missing in the particle spectrum therefore indicates that the particles consist of open forms of glycolaldehyde, for example, the ZE or the EE conformer of Fig. 2. The same effect upon aggregation is also found for dihydroxyacetone (9) and hydroxyacetone (Fig. 5). Both molecules form an intramolecular ring in the gas phase that is broken up upon particle formation. With the predominance of open forms in glycolaldehyde particles thus established, we can derive more detailed information about the nature of these conformers from the C=O-stretching doublet. To this end, we first investigate the influence of the conformation on the corresponding Fermi resonance. In a second step, the influence of the aggregation, i.e., the formation of intermolecular hydrogen bonds, on the Fermi resonance is studied.

To account for the effect of conformational changes, we have modeled the Fermi resonance for different conformers via ab initio calculations as explained in Sect. 3. Here, we restrict ourselves to the conformers ZZ, ZE, and EE (Fig. 2) because all important points can be discussed with these three examples. The results from our calculations for these conformers are listed in Tables 1 and 2. For clarity, we only show the results of the B3LYP/6-31+G* calculations for the new conformers; however, in extensive calculations with basis sets up to aug-cc-pVQZ at the B3LYP and at the MP2 level of theory (not shown here), the ZE and EE conformers show the same behavior as described above for the ZZ form: Harmonic wavenumbers vary within expected errors while anharmonicities and coupling matrix elements remain stable. In particular, we note that B3LYP and MP2 calculations yield essentially the same wavenumber shifts upon hydrogen bonding (comparing ZZ vs. ZE) with only weak basis set dependence. Dispersion forces, which cannot be described by local density approximations (such as B3LYP), apparently do not play any major role in this context. The relative band strength I for the EE conformer indicates that the Fermi resonance is negligible for this form. In the ZE conformer, the resonance is stronger than in the EE conformer but weaker than in the ZZ conformer. The data in Tables 1 and 2 clearly reveal the origin of this behavior. The matrix element W has a similar magnitude for all different conformers as do the anharmonicities. Consequently, the difference between the two conformers arises from different harmonic wavenumbers $\omega_{C=O}$ and $2\omega_{C-C}$ (Table 1).

In the most stable ZZ conformer, the intramolecular hydrogen bond weakens the C=O bond, which acquires more single-bond character compared with the free C=O group. At the same time, the C–C bond stiffens as the enolic resonance structure obtains more weight in the hydrogen-bonded form. By the reverse argument, the $\nu_{C=O}/2\nu_{C-C}$ resonance defect increases significantly in the ZE conformer, and the Fermi resonance becomes less pro-

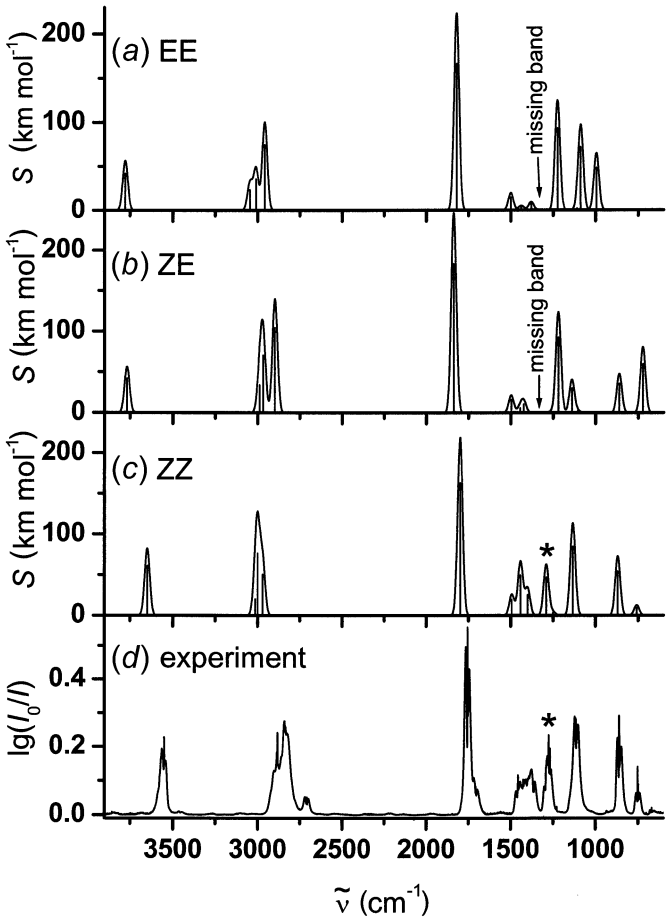
Fig. 4. Theoretical infrared spectra of the (*a*) EE conformer, (*b*) ZE conformer, and (*c*) ZZ conformer of glycolaldehyde calculated at the B3LYP/6-31+G* level. For better comparison with the experimental gas-phase spectrum in trace *d*, the calculated stick spectra are convoluted with a Gaussian band shape of 35 cm^{-1} fwhm. The absolute intensity scale refers to the calculated stick spectra. The integrated absorption intensity S may be converted to integrated absorption cross sections G via $G = S/\tilde{\nu}_0$, where $\tilde{\nu}_0$ is the band centre. $\tilde{\nu}$ is the transition wavenumber.



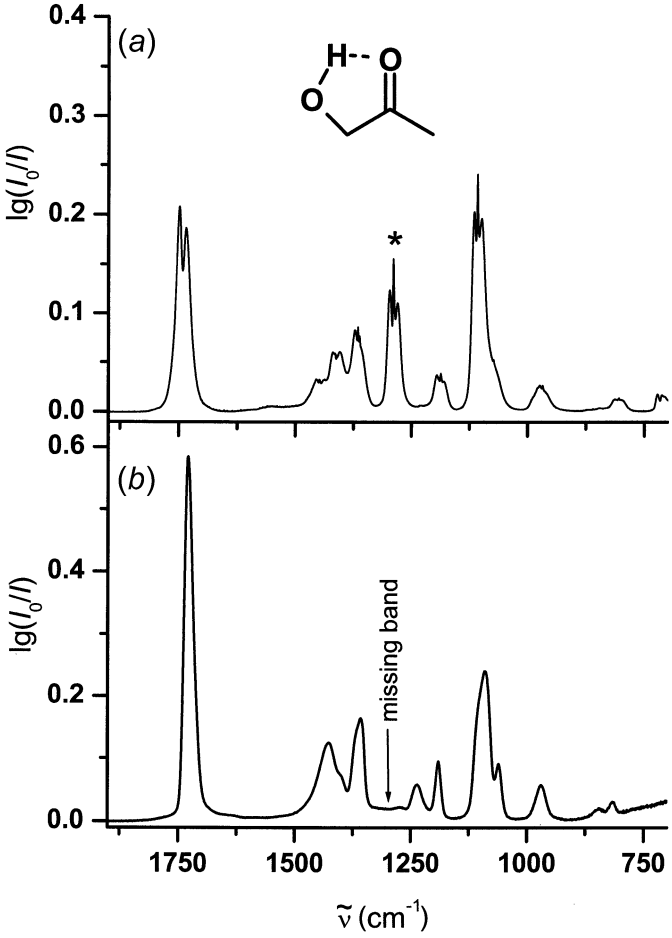


Fig. 5. Experimental infrared spectra of hydroxyacetone ($CH_2OHCOCH_3$). (*a*) Gas-phase spectrum recorded at $T = 293$ K. (*b*) Particle spectrum recorded at $T = 78$ K. The band at 1288 cm^{-1} labelled with an asterisk in the gas-phase spectrum has disappeared in the particle spectrum. $\tilde{\nu}$ is the transition wavenumber.

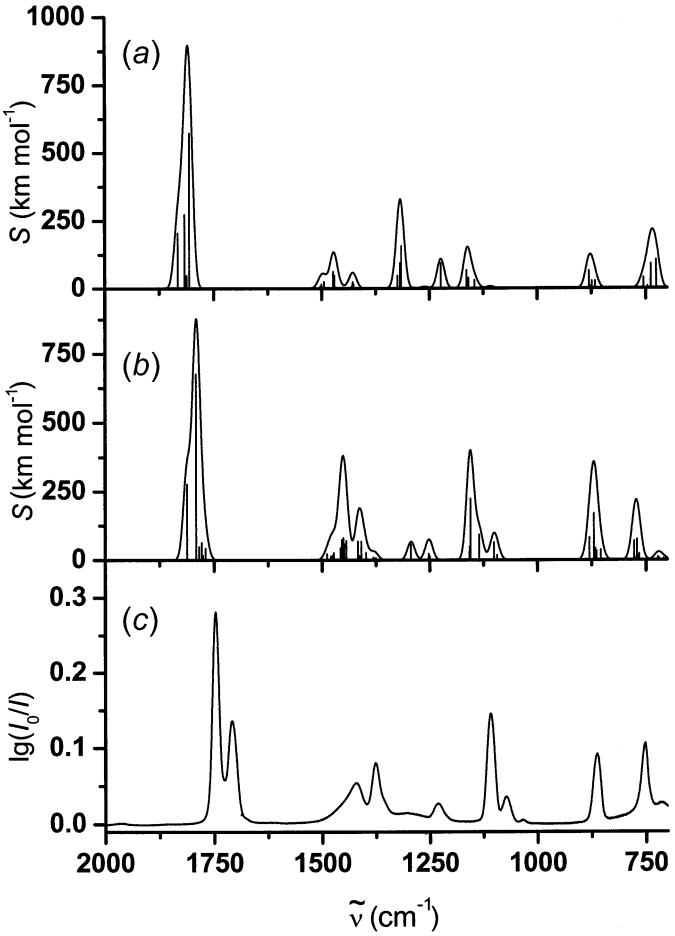

nounced. Beyond the breaking of the intramolecular hydrogen bond, the torsion of the OH group itself hardly influences the Fermi resonance, so that we cannot distinguish between different CCOH dihedral angles.

In contrast to the ZE conformer, the increased value of $\omega_{C=O}$ is only of minor influence in the EE conformer. Here, the main influence arises from the huge increase of ω_{C-C}, which depends very sensitively on the OCCO dihedral angle. For a torsional angle of 180°, this increase is so large that $2\omega_{C-C}$ is no longer in resonance with the C=O-stretching fundamental. The EE conformer can thus be excluded as a major component in glycolaldehyde particles. This is confirmed by calculations for small hydrogen-bonded dimers of glycolaldehyde. The ZE–EE dimer shows an increased C–C transition wavenumber only in its EE moiety. In the ZE unit, this value stays nearly stable (Table 1). Consequently, the Fermi resonance is negligible in the EE moiety but not in the ZE moiety, as indicated in Table 2. In the same way, the value of $2\omega_{C-C}$ explains why the Fermi resonance is important in both subunits of the ZE–ZE dimer and of the "chair" dimer (Z-arrangement of the C=O group and the C–O group). The half twist (only for one unit) and the twist conformer (for both units) show what happens when the relative arrangement of the C=O group and the C–O group lies between an E-arrangement and a Z-arrangement. Tables 1 and 2 show that this arrangement also leads to a strong increase of the C–C transition wavenumber and a negligible Fermi resonance as a consequence. Thus, the strong Fermi resonance observed in the experimental particle spectrum is only compatible with a Z-arrangement of the OCCO dihedral angle in the monomeric subunits.

As a second step, we consider the influence of intermolecular hydrogen bonds on the Fermi resonance with ZE-chains as examples. In the following, we have disregarded basis set superposition effects as our discussion focuses on spectral features rather than the absolute stability of particular oligomers. As mentioned above, due to the missing intramolecular hydrogen bond, the value of $\omega_{C=O}$ is increased in the open forms compared with the ZZ conformer of the gas phase. To explain the stronger Fermi resonance in the particle spectra, the

Fig. 6. (*a*) Theoretical infrared spectrum of the tetramer $(ZE)_4$ of glycolaldehyde calculated at the B3LYP/6-31+G* level. (*b*) The same for the hexamer ZZ–$(ZG)_5$. (*c*) Part of the experimental particle spectrum of glycolaldehyde shown in Fig. 3*b*. For better comparison with the experimental spectrum in trace c, the calculated stick spectra are convoluted with a Gaussian band shape of 20 cm^{-1} fwhm. The absolute intensity scale refers to the calculated stick spectra. $\tilde{\nu}$ is the transition wavenumber.

C=O groups obviously have to act as acceptors of intermolecular hydrogen bonds (as illustrated in Fig. 2), thus restoring $\omega_{C=O}$ roughly to its gas-phase value. This effect is found for the dimers, for the trimer $(ZE)_3$, and for the tetramer $(ZE)_4$ in Table 1. The calculations also show the corresponding slight blue shift of $2\omega_{C-C}$ upon aggregation. It is most interesting to note that the aggregation to longer chains reduces the resonance defect even beyond the gas-phase values. While the end groups mimic the behavior of the dimer, the inner monomer units appear to be subject to cooperative effects that put the Fermi resonance levels closer into resonance. The formation of hydrogen bonds apparently improves the resonance condition $\Delta\omega$ for conformers inside long chains compared to free monomers. This result qualitatively explains the observed stronger Fermi resonance in the experimental particle spectrum.

From the above arguments, long hydrogen-bonded chains of ZE conformers would appear as probable main constituents of glycolaldehyde particles. With the Z conformation of the OCCO dihedral angle, the necessary condition for the $\nu_{C=O}/2\nu_{C-C}$ Fermi resonance is fulfilled. Its increased strength compared with the gas-phase spectrum results from the above-mentioned cooperativity in longer chains. The E conformation of the CCOH dihedral angle explains the absence of the band near 1280 cm^{-1}. The agreement, however, between the calculated harmonic spectrum of the $(ZE)_4$ oligomer (Fig. 6*a*) and the experimental particle spectrum (Fig. 6*c*) is less than satisfactory. The most prominent deviations arise from the intensity distribution in the C–O-stretching region ($\sim$1150 cm^{-1}). In fact, much better qualitative agreement is obtained for the chair-dimer featuring a gauche conformation of OH relative to CC (CCOH $\sim$50°) while the OCCO dihedral angle remains at the required 180°. Although the intramolecular hydrogen bond is not completely broken in this arrangement, it is sufficiently weakened to make the characteristic 1280 cm^{-1} band disappear. In this conformation the glycolaldehyde monomers preferably arrange in "zig-zag" chains enabling the formation of a weak CH$\cdots$O=C hydrogen bond in addition to the strong OH$\cdots$O=C hydrogen bond. As an example, Fig. 2 shows the hexamer ZZ–$(ZG)_5$. The corresponding calculated harmonic absorption spectrum is depicted in Fig. 6*b*. Except for the marked overestimation of the C=O-stretching fundamental wavenumber, the agreement with the experimental particle spectrum is very good. Allowance has obviously to be made for the finite length of the short chains accessible to ab initio calculations. The main boundary effect in the calculated hexamer spectrum is a high-frequency shoulder on the C=O-stretching band due to the one "free" carbonyl group of the chain (the ZG end unit). In longer chains this effect will become negligible. However, the exact length of the hydrogen-bonded chains remains unknown nor can we distinguish between long chains and large rings. Both types of aggregates would lead to very similar spectral features.

5. Summary

The present study shows that Fermi resonances in infrared spectra can be used as a sensitive probe for conformational changes upon aggregation of molecular substances. This is demonstrated here by the example of glycolaldehyde, which shows a split carbonyl band around 1730 cm^{-1} in the gas-phase spectrum as well as in the spectrum of small (size: $\sim$50 nm) glycolaldehyde particles. The gas phase of glycolaldehyde consists of an intramolecularly hydrogen-bonded ring (ZZ conformer). With the help of ab initio calculations, we have shown that the doublet around 1730 cm^{-1} can clearly be traced back to a Fermi resonance involving the C=O-stretching vibration and the first overtone of the C–C-stretching vibration. The corresponding result is in agreement with a simple two-level analysis of the experimental data.

Upon the aggregation to particles, the intramolecular hydrogen bond of the gas-phase ZZ conformer partially breaks and intermolecular hydrogen bonds are formed. Consequently, the aggregates in the particles consist of open conformers of glycolaldehyde monomer. The ab initio calculations reveal a strong dependence of the Fermi resonance on the monomeric conformations. Here, the important factor is the transition wavenumber of the C–C-stretching vibration, whereas the coupling matrix element W and the anharmonicities hardly change at all. In particular, the value of W is apparently characteristic for the particular structural (α-hydroxy-carbonyl) feature, quite

© 2004 NRC Canada

independent of the details of the molecular environment. By contrast, the value of the C–C-stretching wavenumber sensitively determines the relative arrangement of the C=O group and the C–O group. The observed strong Fermi resonance in the particle spectra is only consistent with a Z-arrangement (cis-configuration) of these two groups. Furthermore, the formation of intermolecular hydrogen bonds has an influence on the Fermi resonance. We find that the formation of longer chains improves the resonance condition between the C=O vibration and the C–C vibration. Taken together, these results explain the strong Fermi resonance observed in the particle spectrum, at least qualitatively. The particular value of the OH torsion angle has only negligible effects on the Fermi resonance, but the intensity distribution in the C–O-stretching region suggests an out-of-plane angle of around 50°. This conformation is particularly favorable as it enables the formation of secondary hydrogen bonds between the carbonyl group and the aldehydic C–H group. These results demonstrate how characteristic anharmonic resonances can serve as sensitive probes into structural details of intermolecular arrangements.

The ν_1 and ν_2 vibrational bands of the OCCN radical detected through time-resolved Fourier transform IR emission spectroscopy[1]

William McNavage, William Dailey, and Hai-Lung Dai

Abstract: Through monitoring the IR emission from vibrationally excited radicals generated by exothermic photolysis reactions, the CN stretch (ν_1) and the CO stretch (ν_2) vibrational bands of the cyanooxomethyl radical (OCCN) have been observed for the first time at 2093 cm^{-1} and 1774 cm^{-1}, respectively. The OCCN radical was produced through 193 nm photolysis of methyl cyanoformate ($NCC(O)OCH_3$), carbonyl cyanide (NCC(O)CN), and pivaloyl cyanide ($NCC(O)C(CH_3)_3$). The IR emission spectra were recorded by using nanosecond time-resolved Fourier transform IR emission spectroscopy. Assignments of the spectral peaks were made based on observed time and pressure dependences of IR emission intensities, ab initio calculations, and two-dimensional cross-spectra correlation analysis.

Key words: radical, cyanooxomethyl, OCCN, time-resolved vibrational spectroscopy, FTIR, substituted carbonyl dissociation reactions, two-dimensional cross-spectra correlation analysis

Résumé : En se basant sur une détermination de l'émission IR de radicaux vibrationnellement excités, générés par des réactions de photolyse exothermique, on a pu observer pour la première fois les bandes de vibration d'élongation CN (ν_1) et de vibration d'élongation CO (ν_2) du radical cyanooxométhyle (OCCN), respectivement à 2093 cm^{-1} et 1774 cm^{-1}. On a produit le radical OCCN par une photolyse à 193 nm du cyanoformiate de méthyle, $NCC(O)OCH_3$, du cyanure de carbonyle, NCC(O)CN, et du cyanure de pivaloyle, $NCC(O)C(CH_3)_3$. Les spectres d'émission ont été enregistrés en faisant appel à la spectroscopie d'émission IR à transformation de Fourier, résolue en fonction du temps au niveau de la nanoseconde. On a effectué les attributions des bandes spectrales sur la base des dépendances en fonction du temps et de la pression des intensités d'émission IR, de calculs ab initio et d'une analyse de corrélation interspectre bidimensionnelle.

Mots clés : radical, cyanooxométhyle, OCCN, spectroscopie vibrationnelle résolue en fonction du temps, FTIR, réactions de dissociation de carbonyles substitués, analyse de corrélation interspectre bidimensionnelle.

Introduction

In 1971, Herzberg published one of his seminal books on spectroscopy, *The Spectra and Structure of Simple Free Radicals*. In this book, works appearing as early as 1925 were quoted. Though great advances have been made over the years, the spectroscopy of free radicals remains a challenge for research in many disciplines of science owing to the transient and unstable nature of these species. This is particularly the case for radical vibrational spectroscopy because of the generally weaker intensity of vibrational transitions. For example, understanding and characterizing the vibrational modes of the small but important cyanooxomethyl radical, OCCN, in the electronic ground state has, until this work, remained elusive despite the significant role of this radical in the atmosphere. OCCN is an important dissociation product of many substituted carbonyls (1–10) with the general structure NCC(O)X, a class of carbonyl-containing compounds that are major constituents of urban atmospheric pollution related to motor vehicles (9). None of its vibrational bands, however, have been reported previously.

Prior studies have focused on the dissociation dynamics of symmetrically or asymmetrically substituted carbonyls such as pivaloyl cyanide (X = $C(CH_3)_3$), methyl cyanoformate (X = OCH_3), and acetyl cyanide (X = CH_3) (2, 4–6, 8, 11–13). Molecules of this type fall into the Norrish type I group (14) in organic photochemistry, and their reactions involve an α-bond cleavage upon $^1(n, \pi^*)$ excitation, which can be facilitated through direct optical transition or internal conversion following the $^1(n, 3s)$ excitation to a Rydberg state (8). One of the major interests in studying the dissociation dynamics relates to bond selectivity (4–6, 8, 11, 13) — which of the two α-bond dissociation channels dominates upon electronic excitation and which is the weaker of the two bonds? For example, 193 nm photodissociation of acetyl cyanide ($CH_3C(O)CN$) shows a strong preference for primary CN elimination over CH_3 elimination even though CN elimination involves the rupture of the stronger C—C bond (8). In the case of the dissociation of acetyl chloride

($CH_3C(O)Cl$), there is a preferential cleavage of the C—Cl bond over the C—C bond with nearly identical dissociation energy (13). For most systems, the dissociation process has been understood to be complex and not straightforward.

The only experimental study of the OCCN radical itself has been by Huber and co-workers, who used photofragment translational energy spectroscopy to probe the 193 nm dissociation of various asymmetrically substituted carbonyls that produced OCCN as a common product (4). Even though these experiments were revealing on OCCN production following UV excitation of the precursor molecules, they yielded little structural information on OCCN. In prior theoretical studies, Francisco and Liu performed QCISD level ab initio calculations on the OCCN radical and determined its structure, rotational constants, and vibrational frequencies on the basis of these calculations (15). Results from these calculations are listed in Table 1 and will be discussed later.

In this work, we will report the detection of the first two normal modes of the electronic ground state of the OCCN radical using time-resolved Fourier transform IR emission spectroscopy (TR-FTIRES). In general, vibrational spectroscopy of radicals has been challenging owing to the transient nature of radical species and because they are generally produced in small quantities (16). The TR-FTIRES approach, on the other hand, has proven to be an efficient (sensitive) and versatile technique that can detect IR-active vibrational modes with modest spectral resolution (17–20).

In our approach, UV (193 nm) photodissociation of a carbonyl-containing molecule is first used to generate the OCCN radical. A precursor is chosen for which the photodissociation reaction has a high quantum yield and is highly exothermic so that the OCCN generated has abundant internal excitation to facilitate IR emission through its IR-active modes. TR-FTIRES offers nanosecond time resolution (19) and is thus capable of detecting IR emission from short-lived transient species. Another advantage is that the entire mid-IR region can be investigated in one experiment with temporal information. The gas sample is mixed with a modest pressure of inert gas to promote collisional quenching of the vibrational excitation energy in OCCN so that in emission spectra recorded at longer times, the emission frequencies approach the values of the fundamental transitions. This technique has been successfully applied to the study of the vinyl radical (17, 20), for which the first complete experimental observation of all nine modes was made, and the cyanovinyl radical (18, 20, 21).

In the experiments reported here, the NCC(O)X precursors chosen for OCCN production were carbonyl cyanide (CC; X = CN), pivaloyl cyanide (PC; X = $C(CH_3)_3$), and methyl cyanoformate (MC; X = OCH_3). Their structures are shown in Fig. 1. All three molecules are known to be stable sources of OCCN as evidenced by photofragment translational energy spectroscopy experiments (4). MC is expected to dissociate along the following channels:

$$NCC(O)OCH_3 + h\nu \text{ (193 nm)}$$

$$[1] \quad \rightarrow OCCN + OCH_3 \quad (95 \pm 2\%, \Delta H = -104.2 \text{ kcal/mol})$$

$$[2] \quad \rightarrow OCOCH_3 + CN \quad (5 \pm 2\%, \Delta H = -115.4 \text{ kcal/mol})$$

Dissociation of PC was found to proceed along the following channels:

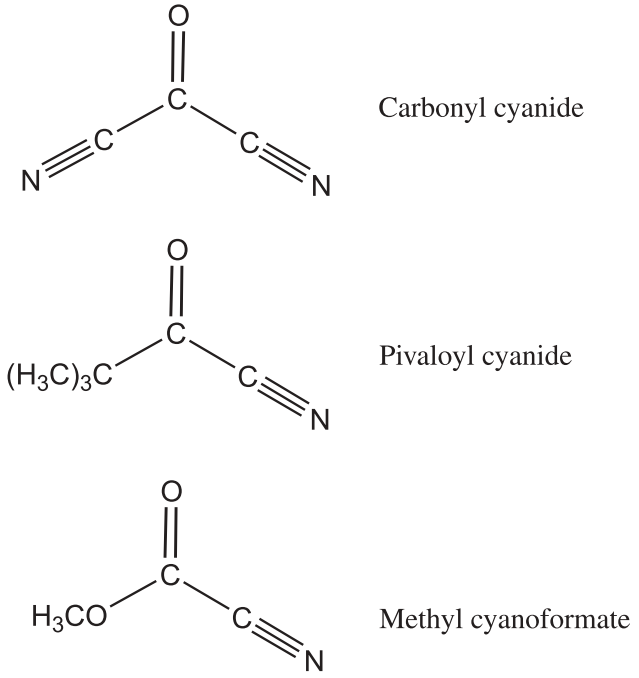
$$NCC(O)C(CH_3)_3 + h\nu \text{ (193 nm)}$$

$$[3] \quad \rightarrow OCCN + C(CH_3)_3 \quad (83 \pm 10\%, \Delta H = -80.3 \text{ kcal/mol})$$

$$[4] \quad \rightarrow OCC(CH_3)_3 + CN \quad (17 \pm 10\%, \Delta H = -101.1 \text{ kcal/mol})$$

Finally, CC was found to dissociate along both a radical elimination pathway and a molecular elimination pathway:

$$NCC(O)CN + h\nu \text{ (193 nm)}$$



$$[5] \quad \rightarrow OCCN + CN \quad (94 \pm 2\%, \Delta H = -98.0 \text{ kcal/mol})$$

$$[6] \quad \rightarrow NCCN + CO \quad (6 \pm 2\%, \Delta H = -102.6 \text{ kcal/mol})$$

In TR-FTIRES, following photodissociation of the precursor molecule, IR emission from all the dissociation products that are vibrationally excited can be observed with time resolution. Information on the time evolution of the intensity and frequency of the emission features is used to assign vibrational modes of emitting species. Also, a newly developed spectral analysis technique, two-dimensional cross-spectra correlation (2DCSC), is used to confirm the assignment. The spectral features identified from the common OCCN product among the spectra from the three precursors are then compared with ab initio calculations to assist in the assignment of vibrational modes. Based on these observations/analyses, we present here the first experimental evi-

dence on the ν_1 CN stretch and ν_2 CO stretch vibrational bands of the OCCN radical.

Experimental

A detailed description of the experimental setup has been given elsewhere (19). Briefly, output from an ArF excimer (λ = 193 nm, 20 Hz, ≤30 mJ/pulse) laser (Lambda Physik, EMG 201 MSC) was lightly focused (fl = 1 m) into a photolysis cell mounted with CaF_2 windows. Pressures inside the cell were typically maintained between 20×10^{-3} and 120×10^{-3} torr (1 torr = 133.322 Pa) of precursor molecules and ~4 torr of Ar bath gas under constant flow conditions and were monitored with a capacitance manometer (MKS Baratron, 0–10 torr). Emission was collected perpendicular to the axis of the photolysis laser beam by a gold mirror Welsh cell arrangement and collimated and focused into the FTIR spectrometer by two KCl lenses that match the *f*/4 focusing characteristics of the spectrometer. The FTIR spectrometer (Bruker IFS-88) was equipped with an interferometer with step-scan capability and a mercury cadmium telluride detector (MCT J15D14, Judson Technologies) with a 500-ns rise time and a spectral range of 8000–720 cm^{-1}. The interferograms were recorded at 50-ns time intervals with averaging over 32–64 laser shots for a total observation window of 20 μs. The interferometric signal was amplified (10×) by a fast amplifier (SRS SR445) before reaching the transient digitizer (Tektronix TDS380) for signal processing. Subsequent Fourier transformation of each time-resolved interferogram yielded a time-resolved spectrum at every 50 ns with a spectral resolution of 12 cm^{-1}.

Carbonyl cyanide was synthesized through a published procedure (22) and purified by vacuum distillation before use. Commercially available methyl cyanoformate (Aldrich, 99%) and pivaloyl cyanide (Fluka, >97%) were used after undergoing several freeze–pump–thaw cycles. FTIR spectra taken after sample preparation showed no detectable impurities. The argon gas from the supplier (Spectra Gas, research grade, 99.9%) was used directly.

Results and analysis

Time-resolved emission spectra in the mid-IR range

As an example of the time-resolved emission spectra obtained for all three precursors, Fig. 2 shows a sampling of the time-resolved emission spectra in the range between 700 and 4000 cm^{-1} taken following the 193 nm dissociation of CC. Data was collected at 50-ns intervals for a total period of 20 μs, with $t = 0$ set at the arrival of the photolysis pulse. The time-resolved spectra should contain emission features from all species that are sufficiently vibrationally excited and have IR-active modes.

Owing to anharmonicities of vibrational modes, the emission features in general are at the lower energy side of the fundamental transition frequencies. In earlier time slices, when the emitting molecules are highly excited, the red shift is more prominent. As collisions occur over time, the IR emission detected at longer times eventually arises from the fundamental transitions as the vibrationally excited molecules cascade down the vibrational manifold.

IR emission spectra from different precursors

Common emission features associated with OCCN are expected in all emission spectra obtained using the three different precursor molecules. Since at longer time slices the IR emission features are closer to the fundamental transitions, we first compare these longer-time (9.8 μs after photolysis pulse) emission spectra from the three precursors as shown in Fig. 3. Each spectrum consists of many vibrational features although only one apparent frequency overlap is observed, slightly below 2100 cm^{-1}. Other frequency overlaps may occur among these spectra but are not immediately apparent.

The center frequencies of emission features were determined by fitting each of these features to a Gaussian line shape. Uncertainties reported were determined as a quarter of the half-width at half-maximum of each line shape. Emission spectra following MC dissociation show features (at longer times) at 1242 ± 11 and 1763 ± 26 cm^{-1} as well as a broad feature between 1829 and 2369 cm^{-1}. The PC precursor spectra show emission features at 950 ± 6 and 1090 ± 7 cm^{-1} and one other feature at 2093 ± 6 cm^{-1}. Finally, the CC precursor emission exhibits four features at 1105 ± 17, 1703 ± 22, 2096 ± 26, and 2199 ± 22 cm^{-1}. Table 2 is a summary of all the IR emission features observed in spectra obtained using these different precursors.

Time dependence of the intensity of IR emission features

In the gas cell in which the experiments were carried out, collisions among precursor molecules, bath molecules, and product molecules from the primary (photolysis) reactions occur. Further, secondary reactions of the photolysis products may be induced, and these may produce vibrationally excited by-products that also give IR emission. To determine whether the observed IR emission features result from pri-

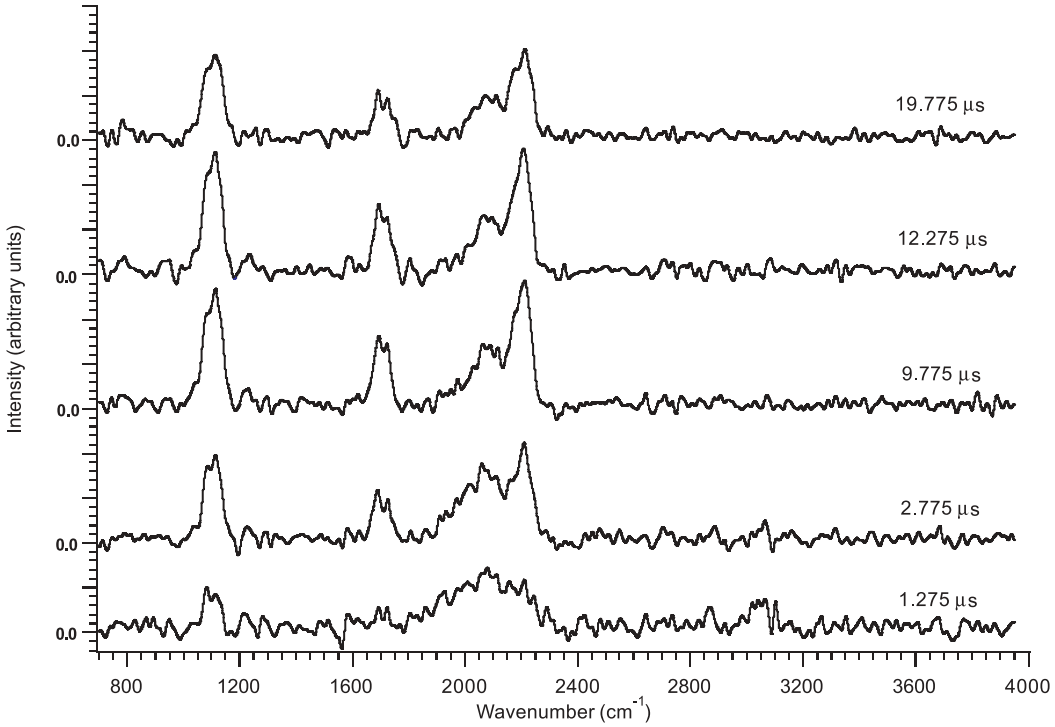

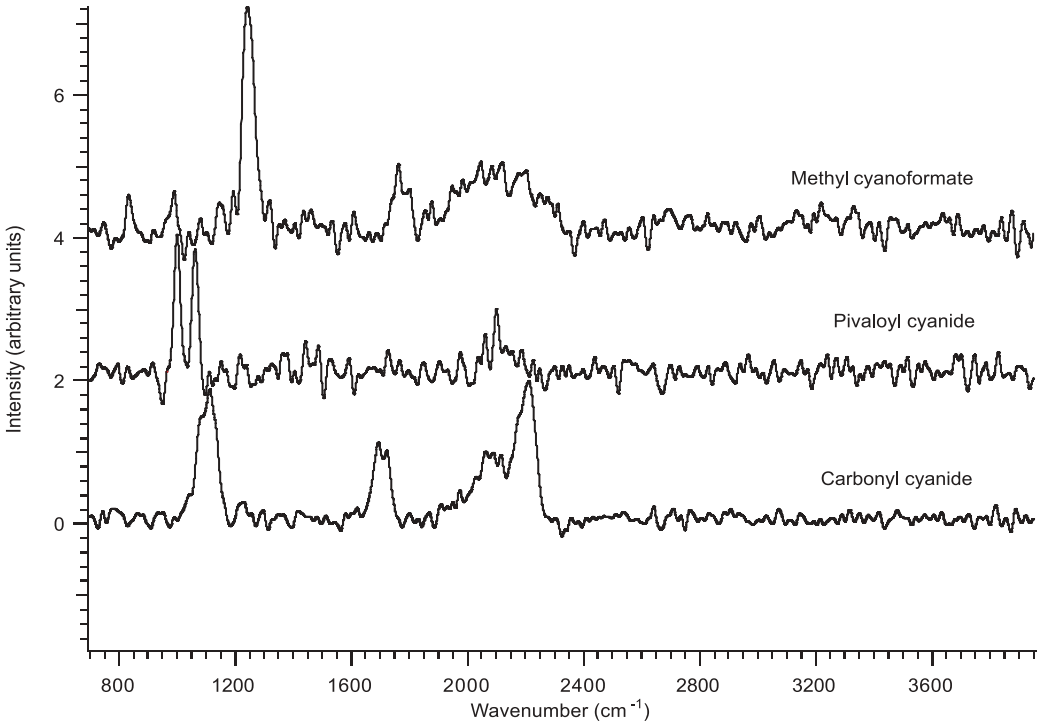

Fig. 3. IR emission spectra following photodissociation of MC, PC, and CC as OCCN precursors. The spectra were taken 9.8 μs after the photolysis pulse, at which time the emitting species are quenched to the lowest excited vibrational level.

mary photodissociation or secondary reactions, the time dependence of the emission intensity was examined for each feature. Figure 4 shows for comparison the intensity of two peaks as a function of time following the photolysis pulse in CC dissociation: one at 2093 cm^{-1} labeled as (*a*) and the other at 2199 cm^{-1} labeled as (*b*). The intensity plotted was integrated over the entire feature under the Gaussian line shape in that particular time-slice spectrum. Two clearly different time dependences are observed. These time dependences can be well fitted to a rise and a decay function (with

[a]P, primary reaction; S, secondary reaction.

Fig. 4. Time dependence of integrated intensity of emission features, using CC as precursor, at 2093 cm^{-1} (*a*) and 2199 cm^{-1} (*b*). Each point of the intensity time profile is separated by 50 ns.

rate constants k_r and k_d), with an instrument response function (k_{Det}) convoluted in, according to:

$$[7] \qquad I = A_0(\exp(-k_d t) - \exp(-k_r t))(1 - \exp(-k_{Det} t))$$

For trace (*a*), the rise can be characterized by a time constant << 500 ns, well below the rise time of the MCT detector. This feature at 2093 cm^{-1} can therefore be attributed to a product from the primary photolysis reaction. In comparison, trace (*b*) was found to have a rise time on the order of 3 μs and is more likely to result from a secondary reaction. Similar analyses of other CC dissociation features at 1105 and 1703 cm^{-1} also show rise times on the order of 3 μs, suggesting they too are from secondary reaction products.

The time dependence of the intensities of emission features in spectra from precursors PC and MC was also analyzed. In PC dissociation, the features at 950 and 1090 cm^{-1} result from secondary reactions while the feature at 2093 cm^{-1} has a time evolution consistent with a primary dissociation product. In MC dissociation, features at 1242 and 1763 cm^{-1} were observed to have very long rise times, indicating that they are from secondary reactions. The very broad feature between 1829 and 2369 cm^{-1} showed a rise time in between those assignable to primary and to second-

© 2004 NRC Canada

ary reactions. As this feature does not show a distinctly assignable time evolution and may contain emission features from several species, it cannot wholly be attributed to either a secondary or a primary reaction product. The feature at 2093 cm^{-1} once again can be assigned to a primary dissociation product.

In all precursor dissociation reactions, every emission feature except that at 2093 cm^{-1} shows a dramatic pressure dependence induced by varying precursor concentration in its rise time. This further confirms the assignment of the emission feature at 2093 cm^{-1} to the primary photodissociation reaction.

Discussion

Based on the time dependence of the intensities of the emission features and the overlap among the emission spectra from the three different precursors, the feature at 2093 cm^{-1} is assigned to the OCCN radical. Comparisons with theoretical calculations (15) suggest that this feature is the ν_1 CN stretch of OCCN. Application of the two-dimensional cross-spectra correlation analysis (see below) revealed that there is another emission feature that is common to spectra from all three precursors at 1774 cm^{-1}. This feature can be assigned to the ν_2 CO stretching mode of OCCN.

Comparison with ab initio calculations

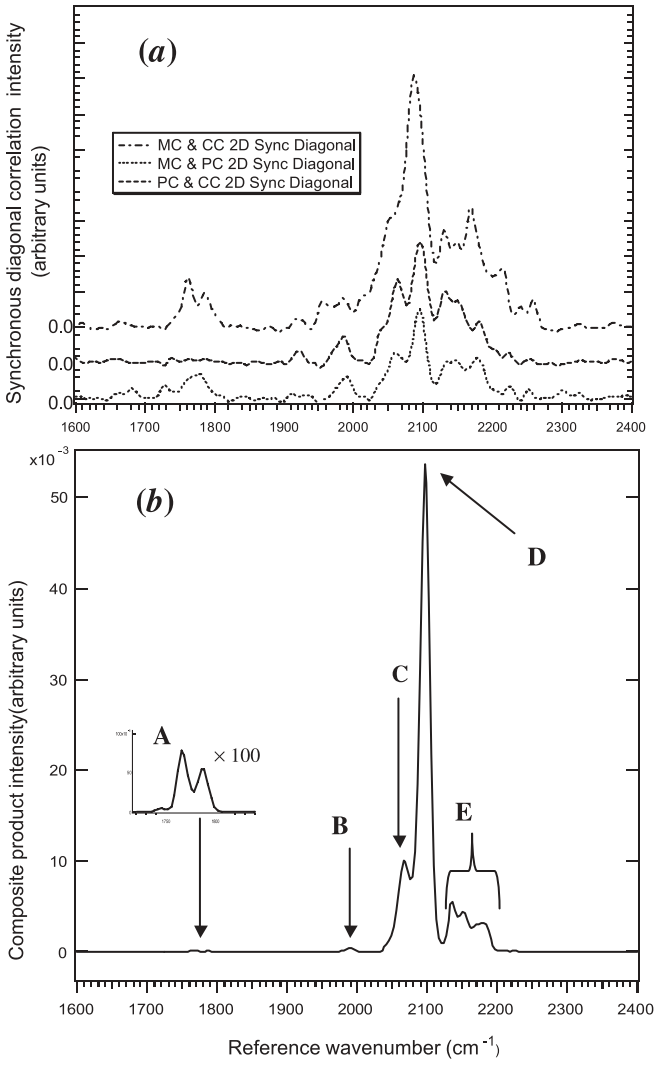
Francisco and Liu performed ab initio calculations on the OCCN radical and its corresponding cation (15). These calculations were performed at the QCISD/6-31G(d) level. The calculations show that the radical is a bent molecule with C_s symmetry, and the predictions of its vibrational modes are shown in Table 1. Three of the six vibrational modes are stretching vibrations, two are low-frequency bending motions, and the sixth mode is a torsional motion around the C—C bond. According to the calculations, the CN stretch harmonic frequency is predicted at 2293 cm^{-1}. Comparison with the experimentally observed fundamental frequency of this mode at 2093 cm^{-1} indicates a correction factor of 0.91 to the ab initio value. This is a reasonable correction considering that the fundamental frequencies are usually somewhat smaller than the corresponding harmonic frequencies. Similar correction factors have been observed for the vibrational modes of the cyanovinyl radical that were calculated using the same method/basis set (21). Using a similar correction factor of 0.91, the frequency of the CO stretch can be scaled from the calculated 1939 cm^{-1} to 1765 cm^{-1}. The emission feature that we observed at 1774 cm^{-1} matches the scaled frequency within the uncertainty of the band.

The ab initio calculations predict the CN stretch to be the mode with the strongest emission intensity, with the CO stretch being the next strongest. After converting absorption intensities to emission intensities, the calculation indicates that emission from the CN stretch is 16 times stronger than that from the CO stretch. The weak intensity in the 1770 cm^{-1} region of the spectra in Fig. 3 is consistent with the ν_2 CO stretch being present but very weak.

Two-dimensional cross-spectra correlation analysis

The common features in the emission spectra obtained using different precursors can be quantitatively identified by two-dimensional correlation analysis of the spectra. This analysis is particularly useful for identifying weak features that are common to all the spectra. The particular algorithm we have developed for analyzing the emission spectra is an application of Noda's generalized two-dimensional correlation spectroscopy (23), which is commonly used for revealing correlation among the spectral features within the same spectra. However, our algorithm, which we denote as two-dimensional cross-spectra correlation analysis (2DCSC), is aimed at revealing the correlation between spectral features of two *different* spectra. The details of the theoretical modeling and analysis procedure as well as the detailed application to the OCCN emission spectra will be reported elsewhere.[3] A brief description of 2DCSC and the results on OCCN are presented here.

In correlation spectroscopy, a perturbation is introduced into the system to induce a dynamic response in the spectral features. The principle that spectral features associated with the same group of atoms or the same molecule should have the same response to the perturbation is the basis for generalized two-dimensional correlation analysis (23). The same idea holds true for 2DCSC. Here the collisions between the emitting molecules and the ambient molecules (in excess amount) over time serve as the perturbation, and the time-resolved emission intensity contains the dynamic information that can be used for correlation analysis.



2DCSC analysis can be applied to any two sets of time-resolved spectra obtained from the OCCN precursor dissociation reactions. Following photolysis, all three precursors generate OCCN radicals with similar internal excitation energies. The excited radicals, in all three cases, experience a similar collisional perturbation as a function of time. As a result, the time dependence of the intensity of the same spectral feature from OCCN, though in different spectra, ought to be similar. Under correlation analysis, this same feature from any two spectra would show positive correlation. In each correlation analysis, the features common to OCCN should therefore be revealed due to the similar dynamic response of internally excited OCCN to collision quenching. Even in the cases where the internal excitation of the OCCN radicals generated from the two different precursors is not identical, the ones with higher energy will be quenched and will eventually reach the same energy as the ones resulting from the other precursor. Thus, the time dependence of the intensity in the time period leading to the emission at the fundamental transition frequency will be identical and suitable for correlation analysis.

In the 2DCSC procedure, first a dynamic spectrum is constructed based on the time dependence of the intensity in the frequency spectrum. The intensity as a function of time at each frequency is then Fourier analyzed. Multiplication of the Fourier-transformed functions at each pair of frequencies allows the construction of a correlation map. There are two portions of the correlation map: real and imaginary. The real portion of the map is referred to as the synchronous map and highlights the similarity in evolution of the intensity of spec-

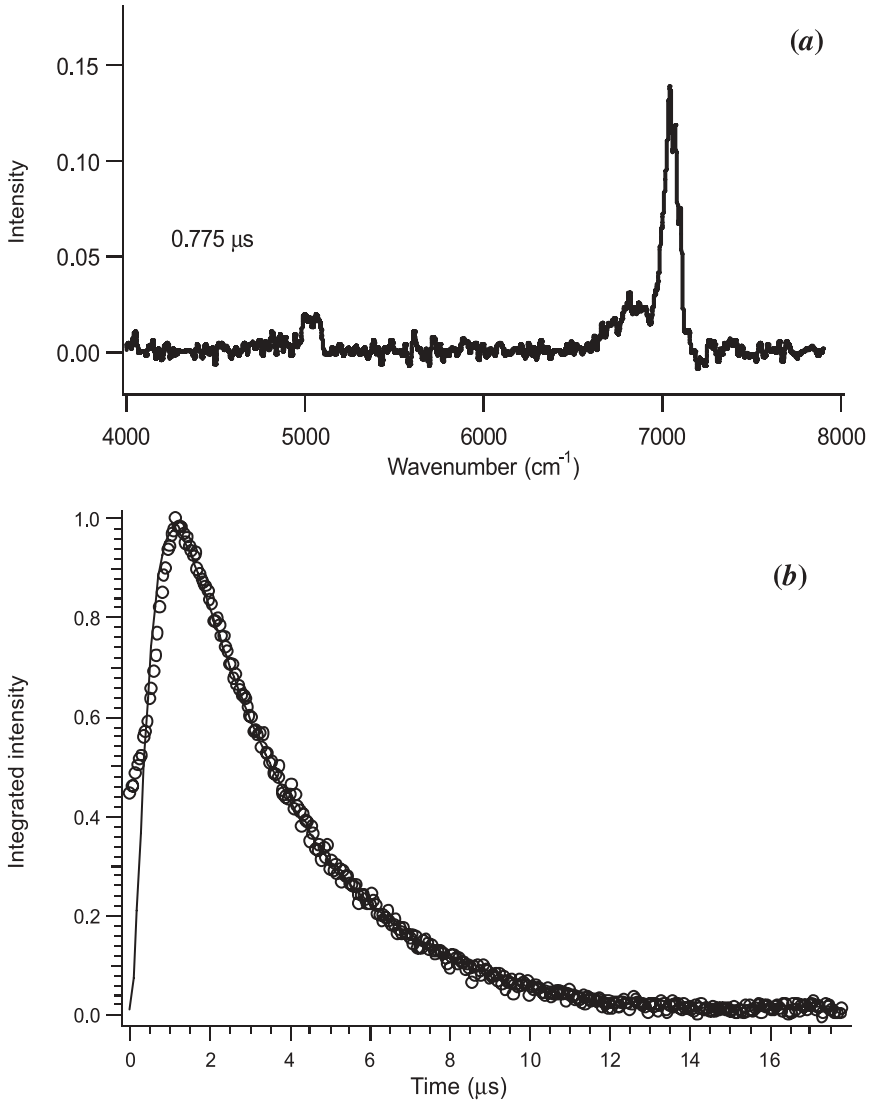
Fig. 5. (*a*) Extracted diagonal elements from each pair of synchronous correlation spectra. (*b*) Composite product of extracted diagonal elements shown in (*a*). Five clearly identifiable features A through E are assigned (see text).

tral features. The imaginary portion is the asynchronous map and shows how dissimilar the two features are.

The synchronous map's diagonal displays activity at the same frequency in the two spectra. If the two spectra contain the same spectral feature, i.e., the same time-dependent intensity at the same frequency, there is a positive correlation at that frequency. Three sets of 2DCSC results are obtained between MC/PC, MC/CC, and CC/PC, and the correlation spectrum along the diagonal for each pair of spectra is shown in Fig. 5*a*. A corresponding zero in the asynchronous map should confirm a positive correlation in the synchronous map. Both indications from the synchronous and asynchronous correlations identify the set of spectral features that are common to each pair of spectra. Furthermore, the product of all three synchronous correlation functions along the diagonal, shown in Fig. 5*b*, can be used to represent the overall correlation among all three spectra.

From this analysis, it is evident that the correlation activity at 2093 cm^{-1}, shown as feature D in Fig. 5*b*, is overwhelming. There are other prominent features present as well. Of these features, the one below 1800 cm^{-1}, labeled as A, falls near the predicted position of the CO stretch based on the scaled ab initio frequency. The relative intensity values of this mode and the strongest CN stretch are also in qualitative agreement with the one order of magnitude intensity ratio predicted from ab initio calculations (Table 1).

The features in Fig. 5*b* other than the two assigned to OCCN can be assigned to common dissociation products after photolysis reactions of the three precursors. For example, feature E may be due to the antisymmetric CN stretch of NCCN that is a by-product produced from the combination of two CN radicals or, in the case of precursor CC, from dissociation along its minor pathway. Energetics determined from photofragment translational energy spectroscopy (4) indicates that some of the OCCN produced in our experiments would have had enough energy to spontaneously dissociate to form CN + CO. If this were the case, the stretch of the CN radical may appear at the position of peak C, with the stretch of the CO overlapping with that of NCCN at the position of feature E. Finally, NCCN's less stable but energetically accessible isomer CNNC has a strong antisymmetric stretching mode below 2000 cm^{-1} that may account for the peak labeled B.



Products from secondary reactions

Table 2 summarizes all IR features directly observed in all spectra presented here. The emission features from secondary reactions in the MC and CC spectra can all be assigned. Emission at 1242 and 1763 cm^{-1} in MC experiments can be assigned to the ν_7 C=O stretch and ν_4 C-O-C antisymmetric stretch, respectively, of vibrationally excited MC (24). Emission at 1105, 1703, and 2199 cm^{-1} in the CC spectra corresponds to the $2\nu_7$ overtone, ν_2 C=O stretch, and ν_9 antisymmetric CN stretch, respectively, of vibrationally excited CC (1). On the other hand, the broad secondary emission feature observed in PC experiments remains currently unassigned.

The dissociation quantum yield following photoexcitation at 193 nm is unity for all three precursors. Vibrationally excited precursor molecules do not result from photoexcitation directly. Rather, vibrationally excited MC and CC can be related to the electronically excited CN generated directly from precursor photodissociation. Figure 6*a* shows the emission spectrum in the region from 4000 to 8000 cm^{-1} acquired 0.775 μs following the dissociation of CC. The strongest feature at 7046 cm^{-1} can be assigned to the CN $A(v' = 0) \rightarrow X(v'' = 1)$ transition (25), and the ones at 6834, 6606, and 5028 cm^{-1} correspond to the CN $A(v' = 1) \rightarrow X(v'' = 2)$, $A(v' = 2) \rightarrow X(v'' = 3)$, and $A(v' = 0) \rightarrow X(v'' = 2)$ transitions, respectively. Figure 6*b* shows the integrated intensity of the 7046 cm^{-1} feature over time. The time dependence can be fitted to a single exponential decay with a lifetime of 3.0 μs. This decay time constant appears to correlate with the rise times of the mid-IR secondary emission features in CC spectra that are assignable to emission from vibrationally excited CC. Similarly, electronically excited CN(A) is also observed in MC dissociation, and its decay also corresponds to the slow rise of the secondary features in the mid-IR emission spectrum that are assignable to vibrationally excited MC. The correlation between the loss of

Fig. 6. (*a*) The near-IR emission spectrum 0.775 μs after photodissociation of carbonyl cyanide. (*b*) Time dependence of the integrated intensity of the strongest CN emission feature in (*a*), the A(v′ = 0) → X(v′′ = 1) transition at 7046 cm^{-1}.

electronically excited CN and the formation of vibrationally excited precursor molecules may arise through the following proposed mechanism. The electronically excited CN may react with the carbonyl group of the precursor molecules, causing the elimination of a CN radical. This bimolecular reaction does not lead to the destruction of the precursor molecules but does result in vibrational excitation in the precursor molecules as product.

Summary

This work presents the first experimental report of the observation of the vibrational modes of the OCCN radical. The vibrational modes of OCCN have been detected through the IR emission from vibrationally excited OCCN produced in 193 nm photodissociation of a substituted carbonyl molecule as precursor. Three different precursors, carbonyl cyanide, pivaloyl cyanide, and methyl cyanoformate, have been used, and the IR emission spectra as a function of time following photodissociaiton have been recorded by the nanosecond time-resolved Fourier transform emission spectroscopy technique.

The CN stretch (ν_2) at 2093 cm^{-1} is the mode with the strongest transition intensity and can be readily identified in the emission spectra from all three precursors. The CO stretch (ν_1) at 1774 cm^{-1} is more than one order of magnitude weaker and not as apparent as the strongest mode in the emission spectra but can be identified after a two-dimensional cross-spectra correlation analysis of the spectra. Ab initio calculation results confirm the reasonableness of the assignment of the two modes with respect to both frequency and relative intensity.

Infrared photodissociation spectroscopy of $Si^+(CO_2)_n$ and $Si^+(CO_2)_nAr$ complexes — Evidence for unanticipated intracluster reactions[1]

J.B. Jaeger, T.D. Jaeger, N.R. Brinkmann, H.F. Schaefer, and M.A. Duncan

Abstract: $Si^+(CO_2)_n$ and $Si^+(CO_2)_nAr$ ion–molecule complexes were produced by laser vaporization in a pulsed supersonic expansion. The ions were mass-selected in a reflectron time-of-flight spectrometer and studied with infrared photodissociation spectroscopy near the asymmetric stretch vibration of CO_2. $Si^+(CO_2)_n$ clusters fragment by the loss of CO_2 whereas $Si^+(CO_2)_nAr$ complexes fragment by the loss of argon. All clusters have resonances near the CO_2 asymmetric stretch, but with shifts in frequency that are size dependent. The patterns seen in the small clusters are consistent with electrostatic bonding, while the larger systems provide evidence for an intracluster reaction forming oxide-carbonyl species. Density functional theory was employed to examine the structures of these clusters, and their calculated vibrational frequencies were compared to the measured values. Ligand assembly in $Si^+(CO_2)_n$ complexes is dominated by the presence of the occupied 3*p* valence orbital of the silicon cation.

Key words: ion–molecule complexes, infrared spectroscopy, photodissociation, density functional theory.

Résumé : Les complexes ion-molécule $Si^+(CO_2)_n$ et $Si^+(CO_2)_nAr$ ont été produits par une vaporisation au laser dans une expansion supersonique pulsée. Les ions ont été sélectionnés en fonction de leur masse dans un spectromètre à temps d'envol à réflectron et on les a étudiés par spectroscopie de photodissociation infrarouge près de la vibration d'élongation asymétrique du CO_2. Les agrégats de $Si^+(CO_2)_n$ se fragmentent par la perte de CO_2 alors que les complexes $Si^+(CO_2)_nAr$ se fragmentent par une perte d'argon. Tous les agrégats présentent des résonances près de l'élongation asymétrique du CO_2; toutefois, elles présentent des déplacements dans la fréquence qui dépendent de leur taille. Les patrons observés dans les petits agrégats sont en accord avec une liaison électrostatique alors que pour ceux des systèmes plus gros il y a des indications à l'effet qu'il pourrait y avoir une réaction intra-agrégat qui conduirait à la formation d'espèces oxyde-carbonyle. On a utilisé la théorie de la densité fonctionnelle pour étudier les structures de ces agrégats et on a comparé les valeurs calculées pour les fréquences vibrationnelles avec les valeurs mesurées. L'assemblage du ligand $Si^+(CO_2)_n$ est dominé par la présence de l'orbitale de valence 3*p* occupée du cation silicium.

Mots clés : complexes ion–molécule, spectroscopie infrarouge, photodissociation, théorie de la densité fonctionnelle.

[Traduit par la Rédaction]

Introduction

Silicon cations occur in the Earth's atmosphere following meteor ablation (1, 2), in both diffuse and dense interstellar clouds (3, 4), and in stellar atmospheres (5). Silicon ions and neutrals play a critical role in chemical-vapor deposition (CVD) of silicon and in the plasma etching of semiconductor surfaces (6). For these reasons and others, silicon ions have been explored extensively in gas-phase ion chemistry and mass spectrometry (7–12). Reaction pathways for silicon anions and cations have been investigated with a number of small molecules, and ion–molecule complexes have been studied with collision-induced dissociation experiments to explore bonding energetics. However, there is essentially no spectroscopy of small silicon ion–molecule complexes to investigate their structures. In this study, we report infrared (IR) photodissociation spectroscopy of small silicon cation complexes with carbon dioxide, e.g., $Si^+(CO_2)_n$, for $n = 1$–10. These experiments are supplemented by density functional theory (DFT) predictions of the structures and vibrations of these complexes.

The chemical reactions, rate constants, and branching ratios of ground-state silicon ions with numerous small molecules have been investigated by several mass spectrometry research groups (7–11). Armentrout and co-workers have used guided ion-beam mass spectrometry and threshold collision-induced dissociation to determine the bonding energetics of silicon cations with several small organics (8).

Dunbar and co-workers used laser vaporization to make silicon ions in a Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometer and reacted these ions with polycyclic aromatic hydrocarbons (PAHs) (11). Radiative association kinetics were employed to study dissociation energies in these complexes. In many of the previous mass spectrometry studies, silicon ions were produced from organosilicon precursors, and the production of bare Si^+ ions was relatively inefficient. The laser vaporization method employed by Dunbar and co-workers, and also used in the present work, provides a clean source of Si^+ without hydrocarbon by-products. Velegrakis and co-workers investigated the Si^+–Ar_n clusters produced by laser vaporization in a supersonic expansion (12).

Our research group has previously investigated the spectroscopy of ion–molecule complexes of the third-row elements magnesium (13–16) and aluminum (16, 17), and the structural trends in these species have been compared with those of transition-metal-cation complexes (16, 18, 19). These species have also been investigated using theory (15, 17, 20). The combined results from theory and experiment have revealed an interesting trend in the structures of multiligand complexes. While ligands tend to cluster symmetrically around transition-metal ions, clustering around Mg^+ and Al^+ is notably asymmetric. This behavior arises because the valence electron(s) in these ions resides in the 3*s* orbital, which has high polarizability (15, 17, 20). Electrostatic bonding via charge–dipole (e.g., M^+–OH_2 complexes) or charge–quadrupole (e.g., M^+–OCO complexes) interactions leads to polarization of the 3*s* electrons, which causes electron density to localize spatially opposite the first ligand. Subsequent ligands tend to bind away from this electron density and more on the same side as the first ligand, leading eventually to a metal ion located in the surface of a molecular cluster rather than at its core. Silicon cations have the same 3*s* orbital occupation found for Mg^+ and Al^+, but with an additional single electron in the 3*p* orbital. It is therefore interesting to investigate the structures of $Si^+(L)_n$ complexes via spectroscopy and theory. Although Mg^+ has a convenient atomic resonance line that provides a chromophore for electronic spectroscopy of its complexes (14), Al^+ and Si^+ do not have low-lying atomic resonances. We therefore investigate these complexes using IR spectroscopy, taking advantage of the IR photodissociation methodology.

Previous experiments in our lab have studied the IR photodissociation spectroscopy of a number of metal-cation complexes with small molecules (15–19, 21–23). Of these, carbon dioxide complexes are convenient for study because of the energetics of the charge–quadrupole electrostatic interaction, which is strong enough to allow efficient complex formation yet weak enough to allow efficient photodissociation. The convenient IR transition associated with the asymmetric stretch vibration (2349 cm^{-1}) falls within the tuning range of our infrared laser system. The IR spectroscopy of $M^+(CO_2)_n$ complexes has previously been studied for M = Fe (18), Ni (19), Co (23), V (23), Mg (15), and Al (17). These IR studies were complemented by earlier work on electronic spectroscopy of the monoligand complexes Mg^+–CO_2 (13), Ca^+–CO_2 (24), Ni^+–CO_2 (25), and Co^+–CO_2 (25). These studies, and corresponding theoretical investigations (15, 17, 20), showed that M^+–OCO binding occurs in an overall linear configuration for the monoligand complexes as a result of the charge–quadrupole interaction. Multiligand complexes bind with each ligand in a similar linear configuration with respect to the metal. The metal coordination number for the $Ni^+(CO_2)_n$ system (four) corresponded to the known value for stable inorganic complexes (19), while no clear coordination was evident for Mg^+ and Al^+ because of the asymmetric clustering (15, 17). In the present study, we find that IR photodissociation spectroscopy does allow measurement of the vibrational spectra of $Si^+(CO_2)_n$ complexes, providing information about their structures. Except for a recent study of $SiOH^+$–Ar_n clusters (26), there appears to be no other IR spectroscopy on silicon ion complexes. Additionally, these measurements reveal unanticipated evidence for intracluster reactions between Si^+ and CO_2.

Experimental

$Si^+(CO_2)_n$ and $Si^+(CO_2)_nAr$ clusters were produced by laser vaporization in a pulsed nozzle cluster source and mass-analyzed in a reflectron time-of-flight mass spectrometer, as has been described previously (13–19). The third harmonic (355 nm) of a Spectra-Physics Nd:YAG laser (Quanta Ray INDI 30) was used to vaporize a rotating and translating silicon rod (ESPI, 99.999% purity). Ionized clusters of $Si^+(CO_2)_n$ and $Si^+(CO_2)_nAr$ were produced in an expansion of pure CO_2, or a few percent of CO_2 seeded in argon, using a Series 9 valve (General Valve, Brookshire, Texas) operated at 10 Hz with a backing pressure of 40 psi. The expansion was skimmed from the source chamber into the differentially pumped mass spectrometer chamber, where the ions were pulse extracted into a reflectron time-of-flight spectrometer. Ions of interest were mass-selected by pulsed deflection plates before they entered the reflectron. In the turning region of the reflectron, selected ions were photodissociated by the infrared output of an optical parametric oscillator/amplifier (OPO/OPA). Photodissociation is enhanced on resonance with vibrations of the ligand, which may be shifted in frequency from those associated with the free molecule due to interactions with the cation. The parent and fragment ions were mass-analyzed in a second flight tube and detected using an electron multiplier tube and a digital oscilloscope (LeCroy Waverunner LT-342). Data was transferred to a PC via an IEEE-488 interface. Infrared resonance-enhanced photodissociation (IR-REPD) spectra were recorded by monitoring the fragment ion intensity as a function of the infrared wavelength.

An IR OPO/OPA laser (Laser Vision, Bellevue, Wash.) pumped by a Continuum 9010 Nd:YAG laser was used to photodissociate the clusters. This system has two 532-nm-pumped KTP crystals in the grating tuned oscillator section and four KTA crystals in the amplifier section. The idler output from the oscillator is combined with residual 1064 nm in the amplifier, and difference frequency generation here provides the tunable near-IR output from 2.2 to 4.9 μm (4500 to 2050 cm^{-1}). The OPO/OPA was tuned near the ν_3 asymmetric stretch of CO_2, where the pulse energies range from 1 to 3 mJ/pulse, with an approximate linewidth of 0.3 cm^{-1}. Typically, spectra were obtained with a 1 cm^{-1} scan step and averaged over 50 laser shots per step.

Density functional theory quantum-mechanical computations were performed on $Si^+(CO_2)_n$, where $n = 1$ and 2, using the Gaussian94 program package (27). Calculations on the $n = 3$ complex were done using Gaussian03 (28). Two gradient-corrected functionals, denoted B3LYP and BP86, were used to compute the geometries, energies, and harmonic vibrational frequencies. Energies were converged to at least 10^{-6} hartrees (1 hartree (Ha) = 27.211 eV) in the self-consistent field procedures, although the absolute accuracy may be somewhat lower owing to numerical integration procedures. The B3LYP functional is a hybrid Hartree–Fock and density functional theory (HF/DFT) method using Becke's three-parameter exchange functional (B3) (29) with the Lee, Yang, and Parr (LYP) correlation functional (30). The BP86 functional uses Becke's 1988 exchange functional (B) (31) and the 1986 correlation correction of Perdew (P86) (32).

A double-ζ basis set with polarization functions, denoted DZP, was employed. This basis was constructed from the Huzinaga–Dunning–Hay (33, 34) set of contracted double-ζ Gaussian functions. Added to this was one set of five d-type polarization functions for each Si, C, and O atom ($\alpha_d(Si) = 0.550$, $\alpha_d(C) = 0.750$, and $\alpha_d(O) = 0.850$). The final contraction scheme for this basis is Si(12s8p1d/6s4p1d) and C,O(9s5p1d/4s2p1d). Geometries were optimized for each molecular species with each functional using analytic gradient techniques. Residual Cartesian gradients were less than 1.5×10^{-5} hartree/bohr (1 bohr = 5.292×10^{-11} m). Stationary points found in optimizations were confirmed as minima by computing the harmonic vibrational frequencies using analytic second derivatives with each functional. Harmonic vibrations were scaled by calculating the asymmetric stretch of CO_2 at the same level of theory and calculating a correction factor needed to bring this mode into agreement with the known experimental value (2349 cm^{-1}). This same factor was then applied to scale the vibrations in the silicon cation complexes that are derived from the CO_2 asymmetric stretch.

Results and discussion

Figure 1 shows the mass spectrum observed for the cation complexes following laser vaporization of silicon in an expansion of pure CO_2. As indicated, a variety of cluster masses are formed. The major mass peaks correspond to ions of the form $Si^+(CO_2)_n$. A series of minor peaks is also observed at intermediate masses that correspond to either $SiO^+(CO_2)_n$ or $(CO_2)_n^+$ complexes. We are not able to assign these peaks without uncertainty, because there is a mass coincidence at 44 amu between SiO and CO_2. However, in our previous studies of other metal–CO_2 complexes under similar conditions, we did not see pure CO_2 cluster ions. Therefore, $SiO^+(CO_2)_n$ is the most likely assignment for these masses. This indicates that silicon ions are somewhat more reactive in the plasma than the main-group metals Mg and Al that we have studied previously. In similar experiments with CO_2, essentially no oxide masses were observed for those systems (15, 17). Velegrakis and co-workers observed a magic number of $n = 4$ for Si^+Ar_n complexes (12). However, there is no evidence for any magic number in the present distribution.

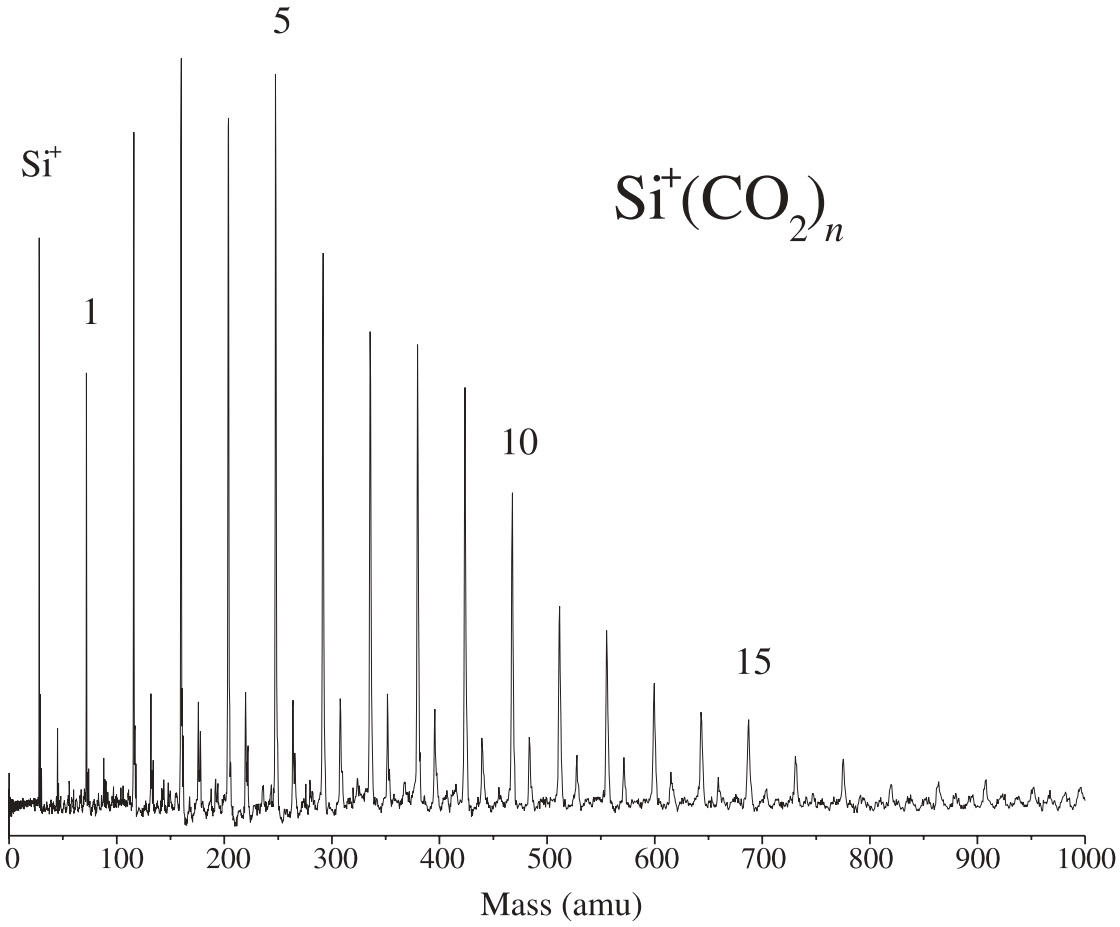

Figure 2 shows the photodissociation mass spectra of various $Si^+(CO_2)_n$ complexes that were mass-selected and excited with the IR laser in the vicinity of the CO_2 asymmetric stretch vibration near 2350 cm^{-1}. As indicated, these complexes dissociate by eliminating one or more intact CO_2 molecules. There is no evidence for the loss of CO or O masses that might occur if these clusters reacted to make oxides within these clusters. If these moieties are present, they are apparently more strongly attached to the cation than the CO_2 molecules that we see as leaving groups. It is apparent in this data that larger clusters dissociate by losing more CO_2 molecules on average than smaller ones do. This is understandable, because the average ligand binding energy to a central cation often decreases as the number of ligands increases. Additionally, it is likely in larger clusters that not all ligands are bound directly to the cation. Conditions in these supersonic expansions are cold enough so that van der Waals clusters can form, and previous studies have shown that large clusters have outer ligands bound by ligand–ligand interactions rather than ligand–metal interactions. Such outer ligands are bound more weakly to the cluster, and they dissociate more easily, explaining in a general way the more extensive fragmentation of larger complexes. The inner ligands that are attached directly to the metal are expected to be more strongly bound. Consistent with this, we find very weak photodissociation signals for the $n = 1$ and $n = 2$ complexes. Complexes for which $n > 2$ dissociate much more easily (see below). In previous studies on transition-metal ions (19, 23), we have seen a sharp final cluster size from the elimination of weakly bonded exterior ligands. The remaining ligands define the coordination sphere of the cation. However, there is no evidence in these dissociation channels for a common termination point, again indicating no strongly preferred coordination number.

As previous studies have shown, more information can be obtained through the wavelength dependence of these fragmentation processes, which reveals the vibrational frequencies of these clusters. The three vibrations of CO_2 are well known ($\nu_1 = 1333$ cm^{-1}, $\nu_2 = 667$ cm^{-1}, $\nu_3 = 2349$ cm^{-1}) (35). In the free molecule, the bend (ν_2) and asymmetric stretch (ν_3) are IR-active, while the symmetric stretch (ν_1) is not. However, regardless of what the structure is, all of these modes are IR-active in cation complexes because of the reduced symmetry. The tuning range of our IR laser system allows us to study only the asymmetric stretch or possible overtone and combination bands that would occur at higher frequencies. Figure 3 shows the wavelength dependence of the photodissociation yield for the $Si^+(CO_2)_n$ complexes for $n = 1$–4 in the vicinity of the asymmetric stretch of CO_2, whose position is indicated by the vertical dashed line. As shown, only a very weak photodissociation signal is detected for the $n = 1$ cluster. The signal is slightly more evident for $n = 2$, with a broad, noisy region of signal and a superimposed peak near the free-CO_2 resonance. Both the $n = 3$ and the $n = 4$ cluster have more clearly defined vibrational resonances that occur at or just to the blue from the free-CO_2 frequency.

The general characteristics of these spectra are understandable based on our previous studies of various metal-cation complexes with CO_2. First of all, the occurrence of a resonance-enhanced absorption near the frequency of the

Fig. 1. The mass distribution of $Si^+(CO_2)_n$ clusters produced by laser vaporization. Although there is a mass coincidence between CO_2 and SiO^+, the intermediate masses are most likely $SiO^+(CO_2)_n$ complexes.

free-CO_2 vibration, together with the observation of intact CO_2 as the elimination product, confirms that these complexes are cation–molecule complexes rather than the products of insertion chemistry. The dissociation yield is low for the smallest complexes, and it increases with additional ligands, as we have seen in essentially all other $M^+(CO_2)_n$ systems. This is likely a result of the stronger binding in the smaller complexes, which makes dissociation more difficult. In the systems we have studied previously (Mg^+, Al^+, Fe^+, and Ni^+), the cation binding energies to CO_2 were measured via collision-induced dissociation experiments. Unfortunately, such data is not available for $Si^+(CO_2)_n$ clusters. However, in the previously studied systems, the low dissociation yield in the smaller clusters came about because the binding energies were greater than the one-photon excitation energy. As we discussed, two-photon photodissociation is possible for these systems, but it is less efficient than one-photon dissociation. The latter process can occur for larger complexes that have weaker bonding, consistent with the improved dissociation yield seen here. If the most stable geometries of the small clusters are strongly bound, these structures will not dissociate efficiently, producing either no signal at all or a region of weak, broad signal from a small amount of multiphoton dissociation. However, isomeric clusters having less stable geometries may be present in minor amounts, and these species may have an advantage in dissociation because of their weaker bonding. Thus, spectra for the smallest clusters may have misleading resonances that are not characteristic of the most stable structures. We have used tagging experiments (see below) to investigate this possibility further.

Another issue discussed previously is the comparison of the CO_2 asymmetric stretch resonance in the cation complexes to this frequency in the free CO_2 molecule. In nearly all of the small complexes studied previously, the asymmetric stretch in the small complexes was shifted 10–80 cm^{-1} to the blue from the free-CO_2 frequency. This blue shift was attributed to increased repulsion on the inner wall of the vibrational potential arising from the presence of the metal ion bound in a linear M^+–OCO configuration. The magnitude of the blue shift was correlated with the binding energy of the clusters; stronger binding was associated with a greater blue shift. A similar effect was found for all cluster sizes that contained different numbers of so-called "core" ligands attached to the metal cation. This effect was also predicted with excellent accuracy by DFT for the $M^+(CO_2)_n$ (n = 1–3) complexes of Mg^+ (15) and Al^+ (17). In larger complexes that contained CO_2 ligands not attached to the cation, the same kind of blue-shifted bands occurred and there was an additional resonance with no blue shift. The latter comes from the so-called "surface" ligands, for which the asymmetric stretch vibration is found at almost exactly the free-

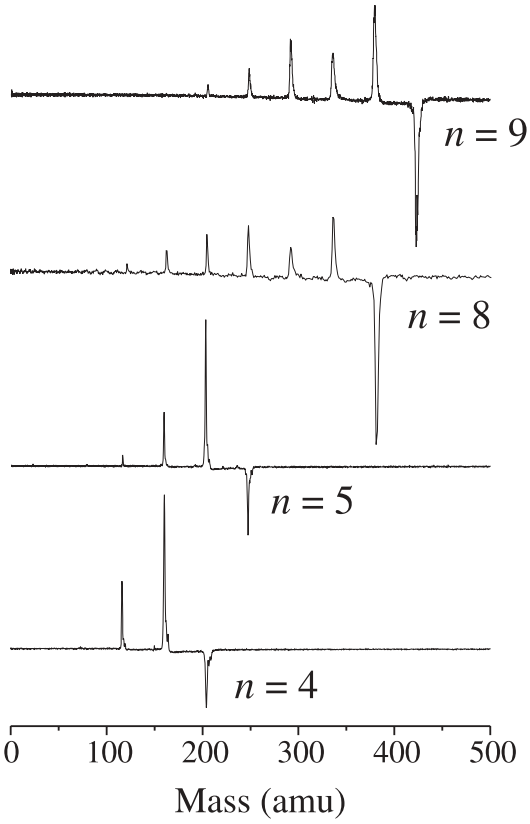
Fig. 2. The photodissociation mass spectra of mass-selected $Si^+(CO_2)_n$ complexes, for n = 4, 5, 8, and 9. The spectra are recorded with a difference method (dissociation laser off–on). The negative peaks indicate the depletion of the selected parent ion, and the positive peaks indicate the fragments. All complexes dissociate by the loss of one or more intact CO_2 molecules.



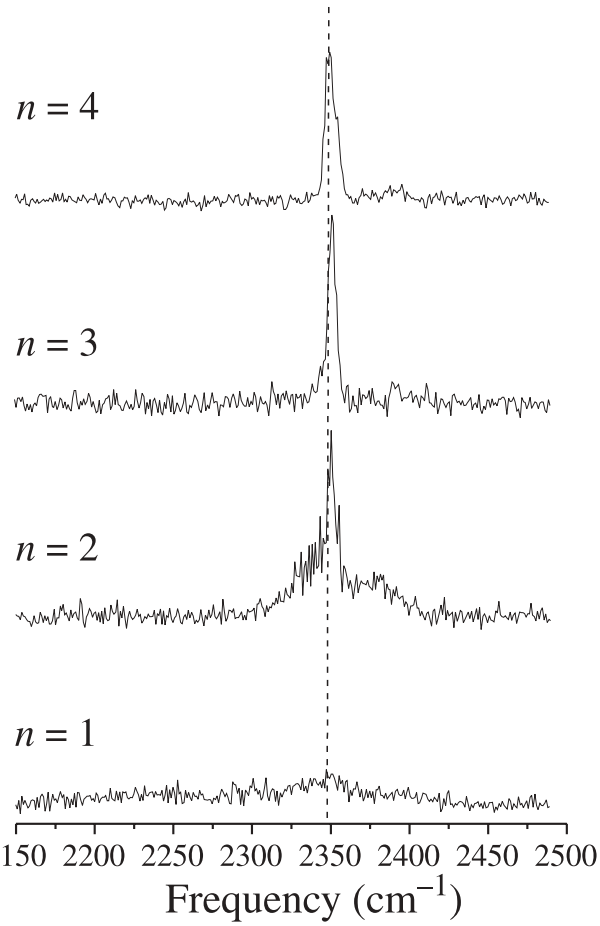


Fig. 3. The wavelength-dependent photodissociation spectra of mass-selected complexes. The vertical dashed line indicates the absorption frequency for the asymmetric stretch (ν_3) of the isolated CO_2 molecule (2349 cm^{-1}). The n = 1 complex has essentially no photodissociation; the n = 2 complex has a weak resonance and the n = 3 and n = 4 complexes have stronger signals, all occurring near the free-CO_2 band.

CO_2 frequency. A similar frequency for this vibration occurs in pure molecular clusters of CO_2 that do not contain any metal (36–41). We also noted in the previous work that any isomeric cluster that has CO_2 not bound in a linear configuration with the cation could also have a resonance near the free-CO_2 value. In the present systems, we see essentially no dissociation signal for the n = 1 complex, but the signals that we do see for the n = 2–4 complexes exhibit only a slight blue shift from the free-CO_2 frequency. These spectra are therefore quite different from those of the small $M^+(CO_2)_n$ complexes. It is not clear whether these spectra indicate clusters with very weakly bound CO_2 or clusters with some new dynamics regarding the CO_2 resonances.

To provide further insight into the structure and bonding in these small $Si^+(CO_2)_n$ complexes, we have performed DFT calculations of their structures, bonding energies, and vibrational frequencies. The results of calculations on the n = 1, n = 2, and n = 3 complexes are given in Tables 1 and 2 and Fig. 4. Stable minima are found for all three complexes, as indicated in the tables. Real frequencies are found for all vibrations except in the case of the n = 3 complex, where some of the lower frequency vibrations have small imaginary values (indicated in italics). The lowest energy structures are shown in Fig. 4. In all of these structures, the CO_2 ligands bind in a linear (or near-linear) configuration with the Si^+ ion. There is no evidence for structures with bent CO_2 molecules or side-bonded CO_2 molecules.

As indicated in Table 1 and shown in Fig. 4*a*, the n = 1 complex has its lowest energy structure with CO_2 bonded in a linear configuration with respect to the Si^+ ion and perpendicular to the p orbital. This leads to an overall ground state of $^2\Pi$ symmetry. Another electronic state of $^2\Sigma^+$ symmetry is derived from the same ground-state Si^+ ion but with the p orbital pointing at the ligand. This configuration is repulsive at all separations of metal and CO_2. We have seen similar binding trends in the excited states of Mg^+ and Ca^+ complexes that correlate to the atomic ^2P asymptote (13, 24). In several systems that we studied, including binding to rare-gas atoms, nitrogen, and CO_2, the $p\pi$ binding configuration always led to much stronger binding than the $p\sigma$ configuration, as seen here. The $p\pi$ configuration exposes the negatively charged oxygen end of the CO_2 ligand to the more positive region of the cation along the nodal plane of the p orbital, and it reduces the strong repulsion that is present between the p orbital and the negative charge on the ligand in the $p\sigma$ configuration. We have also investigated the small com-

Note: Zero-point vibrationally corrected values are listed in parentheses. The D_e values discussed in the text are for the process $Si^+(CO_2)_n \rightarrow Si^+(CO_2)_{n-1} + CO_2$ and therefore represent differences between binding energies for the n and $n - 1$ clusters. Likewise, the D_e values for the $OSi^+(CO)(CO_2)$ cluster are for removal of the CO_2 whereas those for $OSi^+(CO)$ are for loss of CO.

*The C_{2h} structure for the $n = 2$ complex was not a minimum with the B3LYP functional.

plexes that might result from insertion chemistry, e.g., $OSi^+(CO)(CO_2)_{n-1}$, and these results are also contained in Tables 1 and 2.

Surprisingly, the binding energy (D_0) of the $n = 1$ complex (22.9 kcal/mol (1 kcal = 4.184 kJ)) here is much greater than those we have calculated previously for the $Mg^+(CO_2)$ (D_0 = 15.4 kcal/mol) (15) and $Al^+(CO_2)$ (D_0 = 12.4 kcal/mol) (17) complexes. Apparently, the increased nuclear charge on the Si^+ ion increases the attractive charge–quadrupole interaction, and there is no additional screening of this nuclear charge from the extra valence electron because of the favorable $p\pi$ binding configuration. The binding energy here for the $p\pi$ configuration can be compared to that which we found for the *excited* state of $Mg^+(CO_2)$ (D_0' = 32.0 kcal/mol) (13), which has a similar $p\pi$ bonding configuration.

The $n = 2$ complex is calculated to have a bent structure. Both CO_2 ligands are oriented end-on with respect to Si^+ and perpendicular with respect to the p orbital as shown for the $n = 1$ complex. However, they are bent with respect to each other in a C_{2v} structure rather than being on opposite sides of the cation. The O-Si^+-O angle is calculated to be 82°. This bent orientation is presumably due to the same polarization effect involving the 3*s* orbital that we saw before for $Mg^+(CO_2)_n$ and $Al^+(CO_2)_n$ complexes (15, 17). The axes of the two CO_2 molecules are tilted away from each other with an angle slightly greater than the O-Si^+-O angle, as we have seen previously for $Mg^+(CO_2)_2$ and $Al^+(CO_2)_2$ complexes (15, 17). Apparently, this configuration enhances the interaction of the cation with the lone-pair electrons on the adjacent oxygen atoms. The $n = 3$ complex continues the $p\pi$ orientation for each Si^+–OCO interaction but ends up with a calculated D_{3h} structure with the three ligands distributed equally around the waist of the p orbital. The binding energy (with respect to the loss of the outer ligand) is 13.9 kcal/mol for the $n = 2$ species, which is significantly less than the binding energy for the $n = 1$ species. For the $n = 3$ species, the binding energy is only 3.6 kcal/mol, which represents another dramatic decrease.

Such a strong decrease in binding energy with the number of CO_2 ligands was not seen previously for the corresponding Mg^+ and Al^+ complexes. Table 3 shows a comparison of the binding energies versus cluster size for the small Mg^+, Al^+, and Si^+ complexes. All the complexes exhibit the pattern of decreasing binding energy with cluster size, but the $n = 1 \rightarrow n = 2$ and $n = 2 \rightarrow n = 3$ decreases are, respectively, 27% and 25% for Mg^+ and 35% and 23% for Al^+, while the corresponding values for Si^+ are 40% and 74%. The greatest drop is the $n = 2 \rightarrow n = 3$ decrease for Si^+, owing to the particularly low binding energy for the $n = 3$ complex. Consistent with this, we see a significant increase in the photodissociation yield between the $n = 2$ and $n = 3$ complexes. If the binding energy of the $n = 3$ complex is close to the calculated value (3.6 kcal/mol = 1260 cm^{-1}), it can be dissociated with a single photon at 2350 cm^{-1}, which explains the increased dissociation yield that we observe. Thus, the low dissociation energy calculated for $n = 3$ is consistent with experiment, as were the calculated dissociation energies for the Mg^+ and Al^+ complexes, suggesting that the more rapid decrease in binding energy occurs only for the Si^+ complexes. The key difference in electronic structure between Si^+ and the Mg^+ and Al^+ ions studied previously is the occupation of the 3*p* orbital. In the Mg^+ and Al^+ complexes, bent structures resulted from the highly polarizable 3*s* orbital, as discussed above. However, at least three CO_2 ligands could bind on the same side of the cation before additional ligands were forced to bind on the negative side of the distorted orbital or in the second sphere. The most noticeable decrease in binding energy occurred after $n = 3$ for these complexes. For Si^+, the 3*p* orbital provides an additional steric constraint on ligand assembly. Two CO_2 molecules can be accommodated in a bent structure, but this orbital blocks same-side binding of a third CO_2 molecule. Thus, for the $n = 3$ complex, the third ligand is forced into a site opposite the first two ligands, causing all three to interact less favorably with the 3*s* orbital.

To obtain further information about the small $Si^+(CO_2)_n$ complexes, we have also studied their photodissociation spectroscopy using the technique of "rare-gas tagging" (15–18, 42–46) with argon. In previous studies on other metal–CO_2 complexes, we have found that a complex tagged with argon has essentially the same spectrum as one with the same number of ligands without argon, except that the dissociation yield is greater and the lines in the spectrum are

sharper. Dissociation in these experiments leads to loss of argon rather than CO_2, because the former is more weakly bound. The rare gas in these experiments acts essentially as a spectator that enhances the dissociation spectroscopy. The "spectator" character of the added rare gas is only expected to be valid if there is a large difference in the binding energy for the rare gas versus the other ligand. Because the spectra of the small $Si^+(CO_2)_n$ complexes (particularly for $n = 1$ and $n = 2$) without tagging are difficult to obtain and do not have clear sharp bands, we made a mixed expansion gas containing argon and carbon dioxide to produce mixed clusters of the form $Si^+(CO_2)_nAr$. As in the systems previously studied via this approach, we found that photodissociation of $Si^+(CO_2)_nAr$ leads to elimination of argon.

The IR spectra measured in this way for the $Si^+(CO_2)_nAr$ ($n = 1$–3) complexes are shown in Fig. 5. The argon tagging does indeed improve the dissociation yield for all the small clusters. We now see sharp resonant structure for the $n = 1$ and $n = 2$ complexes, whereas without the argon these complexes were extremely difficult to dissociate and the band structure in the IR spectra was broad. For comparison to these spectra, vibrational bands calculated for the neat clusters are shown as solid vertical bars in the figure. The harmonic vibrations from the DFT/B3LYP calculations are scaled to obtain these predicted vibrational bands, as described above. The correction factor needed to bring the calculated asymmetric stretch for the free CO_2 molecule into agreement with the experimental value is –90 cm^{-1}. This factor is applied to all the bands related to the asymmetric stretch for the complexes here. Table 2 shows all the vibrational bands calculated for these complexes and the scaled asymmetric stretch frequencies are compared to the experimental values. As shown in Fig. 5, the vibrational bands computed for these small complexes are all predicted to be found at higher frequencies than the asymmetric stretch in free CO_2 (indicated with the dashed vertical line). Similar blue shifts for corresponding complex vibrations were predicted and measured in the spectra of $Mg^+(CO_2)_n$ (15) and $Al^+(CO_2)_n$ (17) complexes. In those previous experiments, DFT calculations at about the same level as here gave al-

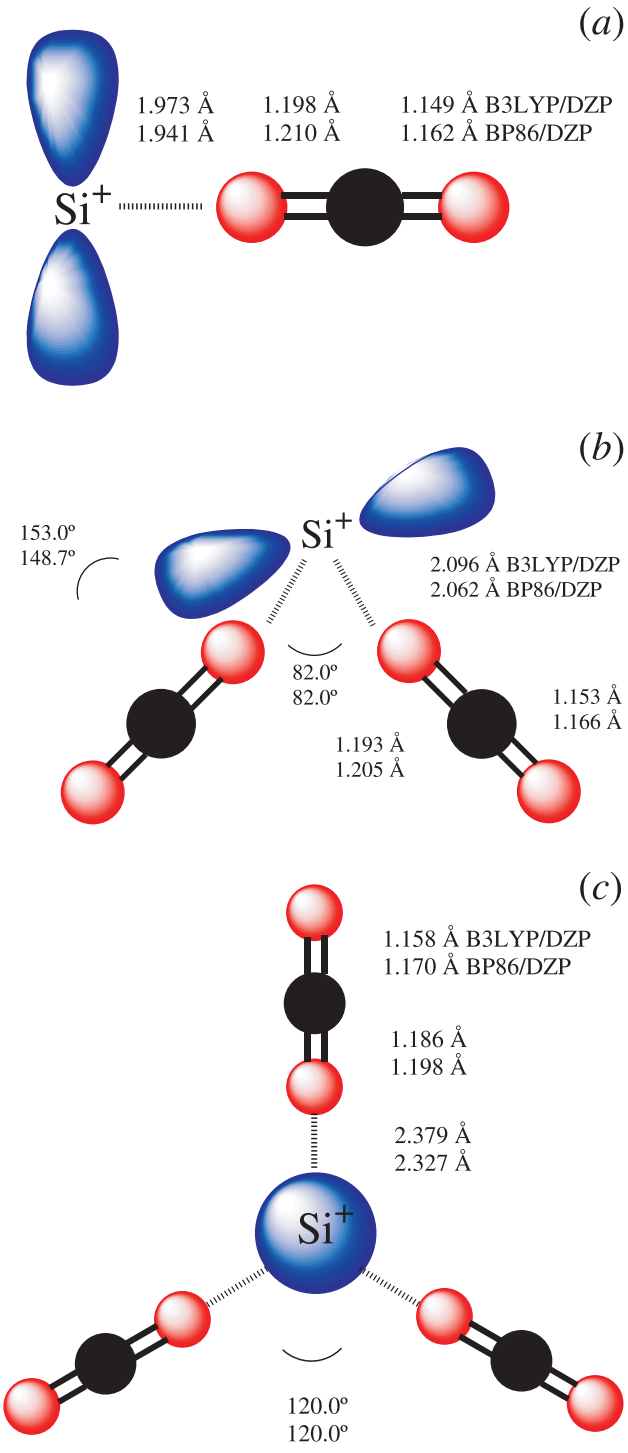
Fig. 4. The calculated structures for the $Si^+(CO_2)_n$ complexes: (*a*) $n = 1$; (*b*) $n = 2$; (*c*) $n = 3$. The ground state of the $n = 1$ complex is $^2\Pi$, with the CO_2 molecule binding in a linear configuration perpendicular to the *p* orbital of Si^+. The $n = 2$ complex has C_{2v} symmetry, with the two CO_2 molecules binding perpendicular to the *p* orbital in a bent configuration with respect to each other. The $n = 3$ complex has D_{3h} symmetry (view shown from above the *p* orbital), with all three CO_2 molecules binding around the waist of the *p* orbital. In all cases, the CO_2 molecules are distorted slightly, with the C=O bond nearest the cation elongated.



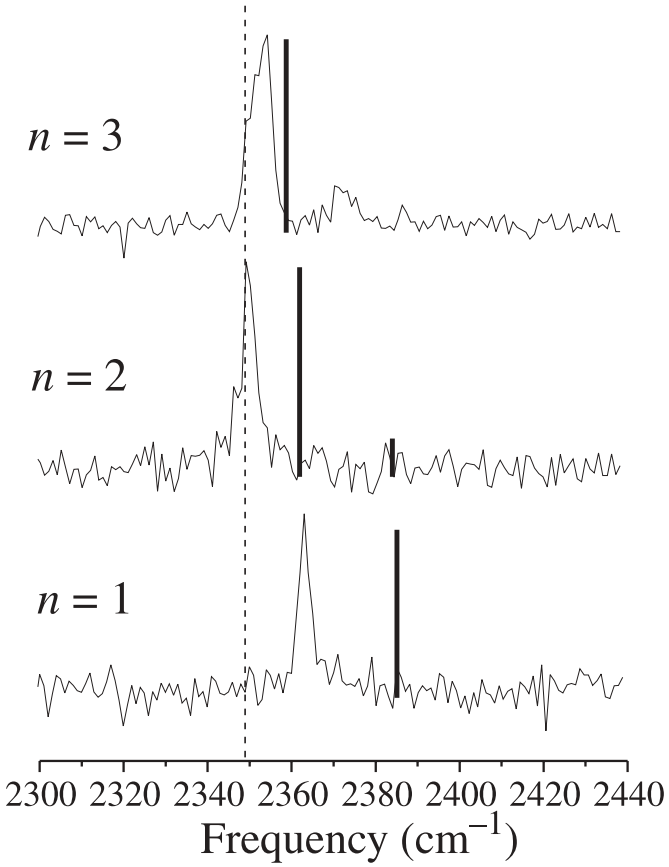


Table 3. A comparison of the calculated binding energies for the last ligand (i.e., $M^+(CO_2)_n \rightarrow M^+(CO_2)_{n-1}$) for magnesium, aluminum, and silicon complexes.

	D_e (kcal/mol)		
M^+	$n = 1$	$n = 2$	$n = 3$
Mg^+	15.8	11.6	8.7
Al^+	12.4	8.1	6.2
Si^+	23.3	13.9	3.6

Fig. 5. The IR photodissociation spectra of the $Si^+(CO_2)_n$ ($n = 1$–3) complexes when they are tagged with argon and the spectrum is detected in the argon elimination channel.The vertical dashed line indicates the free-CO_2 band, while the vertical bars indicate the (scaled) predictions of theory for the $Si^+(CO_2)_n$ complexes.

most perfect agreement (within 1–2 cm^{-1}) with the experimental vibrational bands. In the present experiments, however, there is some disparity between the predictions of DFT and the experimentally observed bands. For $n = 1$, for example, DFT predicts a strongly bound complex and a rather large blue shift of about 37 cm^{-1} from the free-CO_2 vibration. In the argon-tagged $n = 1$ complex, we measured a shift to the blue, but it is only about 14 cm^{-1}. The $n = 2$ complex is predicted to have two bands at 2362 and 2384 cm^{-1}, whereas we measured only one at 2350 cm^{-1}. The 2384 cm^{-1} band is predicted to have a much smaller intensity, and so we might miss it in our experiment, but the

© 2004 NRC Canada

one band we observe is essentially unshifted from the free-molecule vibration. The $n = 3$ complex is predicted to have D_{3h} symmetry, which leads to one doubly degenerate IR-active mode expected at 2359 cm^{-1}. In this case we observe one strong band close to this position, but another unexpected band is observed as a weak feature at about 2371 cm^{-1}. So, with respect to band positions, and even the number of bands observed, theory and experiment do not agree very well for these small complexes.

This disparity between theory and experiment is puzzling, especially in light of the excellent agreement seen before for Mg^+–CO_2 and Al^+–CO_2 complexes. It is clear that either theory has some special problem with Si^+ that it does not have with Mg^+ and Al^+ in predicting vibrations or the argon-tagged complexes here are somehow different from those studied for Mg^+ and Al^+ complexes regarding the relative inertness of the tagging. It is not clear why there should be any special problem with theory for this system. The strange pattern of calculated dissociation energies seen above, however, suggests that adding an additional ligand to these complexes has a dramatic effect in lowering the binding energies. Although argon is not expected to bind as strongly as CO_2, it may bind strongly enough to have a non-negligible effect on the spectroscopy of these complexes, thus explaining in part the mediocre agreement between theory and the tagged spectra.

The possible effect of the argon can be seen by closer inspection of the spectra and the theoretical predictions of the spectra. The $n = 1$ complex, for example, has a tagged spectrum with one band that is not shifted to the blue as much as theory predicts. However, if we consider the tagged $n = 1$ complex as actually having two ligands, we can compare it to the spectrum predicted for the $n = 2$ complex. It is perhaps no accident that the strongest band predicted for n = 2 matches the band observed for $n = 1$ almost perfectly. We can use the same logic to consider the tagged spectrum for $n = 2$, where again the blue shift is less than expected. The calculations predict a similarly small blue shift for $n = 3$. In the $n = 3$ complex, we have an extra weak band near 2371 cm^{-1}, which is close to the frequency predicted for the ν_1 vibration (2378 cm^{-1}). However, this mode is not IR-active for a cluster with D_{3h} symmetry. On the other hand, if the argon acts as a fourth ligand, we might have a square-planar arrangement around the Si^+, and then the three CO_2 ligands would be in a less symmetric configuration. This reduced symmetry would give some weak activity to the ν_1 vibration (2378 cm^{-1}) predicted to be forbidden for the $n = 3$ D_{3h} complex without tagging. In a qualitative way then, the presence of argon as a real perturbation on the system instead of as a spectator can explain the disparity between theory and experiment in these spectra. This suggests that measuring the "real" unperturbed spectra of the small complexes here may be very difficult with any tagging method. To see if this proposal holds up under closer scrutiny, we would need to calculate explicitly the spectra for complexes with and without argon.

Another clear possibility for the spectra of these small multiligand clusters (i.e., $n = 2, 3$) is the presence of minor isomers with one CO_2 molecule not attached to the cation, i.e., bound a bound externally only to CO_2. The binding energy of CO_2 in a free dimer is substantial (about 500 cm^{-1}) (47), and the induction of charge on one ligand caused by the silicon cation would enhance this kind of binding in these complexes. In our previous calculations on aluminum and magnesium complexes with CO_2, we investigated such configurations and found stable minima for them. We have not done these calculations here for silicon complexes owing to difficulties in getting the multiligand complexes to converge. However, as we have indicated above and discussed elsewhere, if such external CO_2 molecules are present, they would have resonances near the free-CO_2 value. We suspect this to be the case for the $n = 2$ complex, which has its main absorption near this value. The $n = 3$ complex has a main band shifted to the blue, but its shape is asymmetric and there is evidence for a shoulder overlapping the free-CO_2 band. The steeply decreasing binding energy seen in the calculations for the $n = 2$ and $n = 3$ complexes when the ligands are attached to the cation makes it reasonable that isomers with externally bound CO_2 might also be present at some concentration in the molecular beam.

Figure 6 shows the spectra measured for complexes in the $n = 4$–6 size range without argon tagging. For $n = 4$, the spectrum exhibits a single peak positioned mostly on the free-CO_2 resonance, but with a noticeable shoulder in the neighborhood of the core peak seen for the tagged $n = 3$ cluster. The simplest explanation for this spectrum is that this complex is basically an $n = 3$ species but with one external CO_2 ligand, giving this spectrum intensity near the free-CO_2 resonance. Interesting new features arise in the spectra for $n = 5$ and $n = 6$. We have similar strong resonances near the free-CO_2 position, just as in the $n = 4$ spectrum, but there is a noticeable new peak further to the blue (near 2370 cm^{-1}) for both of these clusters. This peak occurs at about the same position as the weak peak in the spectrum of the argon-tagged $n = 3$ complex, but it appears to be due to a new kind of chromophore. It has significant intensity beginning at $n = 5$ and growing in at $n = 6$. In the spectra of the larger clusters ($n = 7$–10), shown in Fig. 7, this peak continues to grow, eventually becoming the most intense in the spectrum. In addition to this blue-shifted peak, there is a much weaker peak near 2290 cm^{-1}. This peak is weak, but reproducible, in both the $n = 5$ and $n = 6$ spectra, but it is not present in the spectra of the larger clusters where the 2370 cm^{-1} band is more evident.

An interpretation of these new bands is possible by comparison to our previous studies of other metal ion–CO_2 clusters. In most of the systems we have studied, $M^+(CO_2)_n$ clusters have only resonances associated with the core ligands and those on the surface of the cluster. The core ligand bands occur about 10–30 cm^{-1} to the blue of the free-CO_2 band, with the biggest shift occurring for the smallest clusters and smaller shifts seen as cluster size increases. The surface bands appear near the free-CO_2 band, and this splits slightly into a doublet in the spectra of the larger clusters. In the present clusters, only the $n = 1$ complex has a significant blue shift associated with core ligands. The new blue-shifted band and the weak red-shifted band appear suddenly and only for larger clusters. This suggests that these features are not associated with any gradual solvation process in the clusters. While we have seen only progressive solvation in most of our previous studies on metal ion–CO_2 complexes(15–18), there have been two examples (Ni^+ and V^+)

(23 and unpublished results) in which there was a sudden appearance of similar blue-shifted bands. In both cases, we have interpreted these bands to arise from an intracluster reaction, in which the metal ion reacts with one CO_2 to form an oxide-carbonyl species, i.e., $OM^+(CO)(CO_2)_{n-1}$. Such a reaction would not be detected based on mass spectrometry alone. A similar reaction makes sense here and provides a convenient explanation for the new IR bands seen.

To further investigate such an intracluster reaction, we have done DFT calculations on the $OSi^+(CO)$ and $OSi^+(CO)(CO_2)$ ions to investigate their properties. As shown in Table 1, the covalent bonding interactions of the oxide and the carbonyl are not favorable compared to the cation–CO_2 bonding, and the oxide-carbonyl species is much less stable for the n = 1 complex. However, the diatomic oxide has partial ionic character (e.g., Si^{2+}, O^-) as well as a significant dipole moment. In the larger clusters, binding of other CO_2 molecules to such a core ion would perhaps be stronger than binding to a singly charged silicon cation, especially considering the problems noted above for clustering about Si^+. CO_2 molecules bound strongly to a (Si^{2+}, O^-) core ion would get a stronger blue shift in their spectrum than those bound more weakly to Si^+. This can explain the 2370 cm^{-1} peak observed in the spectra of the larger clusters. Consistent with this, our calculations for the $OSi^+(CO)(CO_2)$ insertion complex find an asymmetric stretch for the CO_2 at 2363 cm^{-1}. Additionally, the DFT calculations find a much greater oscillator strength for this CO_2 mode in the oxide-carbonyl complex than that in the Si^+ complexes, consistent with the increasing prominence of the 2370 cm^{-1} band in larger clusters. The 2290 cm^{-1} band, which is red-shifted from the free-CO_2 band, can be assigned to the carbonyl stretch in such an oxide-carbonyl core ion. A similar peak has been seen in matrix isolation spectroscopy of neutral OSi(CO) complexes, and DFT calculations on the neutral predicted the carbonyl stretch band near 2260 cm^{-1} (48). Likewise, our DFT calculations here predict a carbonyl stretch (scaled) near 2217 cm^{-1} in the monomer complex and 2193 cm^{-1} in the dimer, which might easily shift to higher frequencies in the larger clusters. The IR intensity of this carbonyl band is extremely weak here, and this band is only seen for the n = 5 and n = 6 clusters. In our previous studies on the Ni^+ and V^+ complexes, only the blue-shifted band was observed and there was no evidence for the carbonyl band (23 and unpublished results). Apparently, in all of these various clusters with oxide-carbonyl moieties believed to be present, the carbonyl stretch does not have a strong oscillator strength. Consistent with these observations, our calculations find a

© 2004 NRC Canada

particularly low value for the IR intensity of the carbonyl stretch compared to the CO_2 asymmetric stretch. Overall then, the suggested intracluster reaction producing an oxide-carbonyl species is consistent with the vibrational spectrum observed.

The formation of $SiO^+(CO_2)_n$ clusters was noted above in the mass distribution produced from the cluster source. However, the formation of the intracluster oxide-carbonyl species here is apparently not driven by the plasma chemistry, because it is not found in the small clusters. The occurrence of a reaction product only in larger clusters is possible via a solvation-induced reaction mechanism. The new covalent Si^+—O and Si^+—CO bonds may be present at all cluster sizes, but our calculations for the $n = 1$ and $n = 2$ complexes indicate that these are not as favorable as the Si^+–OCO electrostatic interactions. However, if the reaction product (SiO^+) can be solvated more easily than the reactant species (Si^+), then the energetics of solvation will eventually stabilize the oxide-carbonyl complexes more beyond some critical cluster size. In this case, the calculated binding energy of the first CO_2 molecule to Si^+ is significant, but there is a dramatic decrease in the binding energy of subsequent molecules to this atomic ion, as discussed above. SiO^+, however, would have more ionic character and a dipole moment, as noted above, facilitating its solvation. If there is indeed some transfer of charge from silicon to oxygen, then the steric hindrance for ligand binding caused by the 3*p* orbital of Si^+ will be reduced for SiO^+. Therefore, the lowest-energy structures for the small clusters could be the simple electrostatic complexes with Si^+, as found in our DFT calculations. The larger clusters, whose structures are less accessible with theory, may be more stable in the oxide-carbonyl geometries because of the more efficient solvation of these species. This picture makes sense for these silicon-ion clusters in the same way that it does for the transition-metal-cation systems of nickel and vanadium.

Conclusions

Weakly bound $Si^+(CO_2)_n$ complexes have been studied with IR photodissociation spectroscopy near the asymmetric stretch vibration in CO_2. The smallest complexes studied ($n = 1, 2$) do not dissociate efficiently, but as the size of the complex increases, the dissociation proceeds by the loss of intact CO_2 molecules. Mixed clusters of the form $Si^+(CO_2)_nAr$ dissociate by the loss of argon. Both the pure CO_2 and argon-tagged complexes have vibrational resonances near the frequency of the asymmetric stretch vibration in CO_2, indicating that there are weakly bound ligands present. Density functional theory was employed to investigate the structures of these complexes and their vibrational spectra. The dissociation energy for the $n = 1$ complex is quite high, but the binding energy for subsequent ligands drops steeply. This decline is interpreted to arise because of the difficulty in assembling multiple ligands around the 3*p* orbital. The agreement between theory and experiment on vibrational resonances is much less satisfactory than it was for the previously studied $Mg^+(CO_2)_n$ and $Al^+(CO_2)_n$ complexes. This is likely because the argon used to tag these clusters is not legitimate as an inert spectator atom, as it was in the earlier systems. The acute sensitivity of the binding energy in these complexes amplifies the effect of each added atom, and therefore argon induces significant perturbations on the spectra.

In complexes with five or more CO_2 ligands, new vibrational bands are measured that are assigned to an intracluster reaction producing an oxide-carbonyl species. This reaction is apparently induced because of the differential solvation interactions of the bare silicon cation versus the diatomic SiO^+ species. The latter is more effectively solvated because of its partial ionic character and its dipole moment. The differential binding is also presumably enhanced because of the severely ineffective binding of the bare silicon cation to additional ligands, as discussed above.

If the weak electrostatic binding seen here is indeed associated with the presence of an occupied valence *p* orbital, then this would imply very weak electrostatic interactions for similar cations or those with greater occupation in similar *p* orbitals. For example, we could predict weak binding for ligands to ions such as P^+ or S^+ in the third row. Ion–molecule complexes have not been studied extensively for these cations, but it would be interesting to examine these systems to follow the trend suggested. Larger ions, such as those in the fourth row, would necessarily have *d* orbitals populated before the *p* orbitals, and so such simple predictions are not likely to apply to their binding.

The antisymmetric stretching fundamental band of free MgD_2[1]

Alireza Shayesteh, Dominique R.T. Appadoo, Iouli Gordon, and Peter F. Bernath

Abstract: The gaseous MgD_2 molecule has been synthesized for the first time in an electrical discharge inside a high-temperature furnace. The high-resolution infrared emission spectrum of MgD_2 was recorded with a Fourier transform spectrometer, and the antisymmetric stretching mode (ν_3) was detected near 1176.5 cm^{-1}. The ν_3 band was rotationally analyzed, and the r_0 Mg—D bond distance was determined to be 1.700 874(8) Å.

Key words: gaseous MgD_2, vibration–rotation emission spectrum, Mg-D bond distance.

Résumé : Faisant appel à une décharge électrique dans une fournaise à haute température, on a synthétisé pour la première fois une molécule de MgD_2 gazeuse. On en a enregistré le spectre d'émission infrarouge à haute résolution à l'aide d'un spectrophotomètre à transformée de Fourier et on a détecté le mode d'élongation antisymétrique (ν_3) près de 1176,5 cm^{-1}. On a analysé la bande ν_3 d'un point de vue rotationnel et on a déterminé que la longueur r_0 de la liaison Mg—D est égale à 1,700 874(8) Å.

Mots clés : MgD_2 gazeux, spectre d'émission vibration-rotation, longueur de la liaison Mg-D.

[Traduit par la Rédaction]

Introduction

We recently published a paper on the discovery of MgH_2 in the gas phase and the analysis of its vibration–rotation emission spectrum (1). The MgH_2 molecule is a favorite target for ab initio methods (2–6) because it is a closed-shell system with only a few electrons. The previous studies on the reaction of the magnesium atom with molecular hydrogen and the properties of solid MgH_2 were discussed in our earlier paper (1). Although the ground-state reaction

$$Mg\ (^1S)\ (g) + H_2\ (g) \rightarrow MgH_2\ (g)$$

was predicted to be slightly endoergic (2, 3), we were able to produce gaseous MgH_2 in our furnace-discharge emission source.

The previous experimental work on MgD_2 is limited to matrix isolation experiments. McCaffrey et al. (7) recorded the infrared spectra of MgH_2, MgHD, and MgD_2 in krypton and xenon matrices at 12 K. They found the antisymmetric stretching frequency (ν_3) of MgD_2 at 1153 and 1144 cm^{-1} in krypton and xenon matrices, respectively, while the bending modes (ν_2) were observed at 309 and 300 cm^{-1}. Tague and Andrews (8) recorded the infrared spectra of MgH_2 and MgD_2 in an argon matrix at 10 K, and they detected the antisymmetric stretching mode of MgD_2 at 1163.2 cm^{-1}.

We have produced gaseous MgD_2 in a discharge source, and the analysis of its vibration–rotation emission spectrum is reported in this paper.

Experiment and results

The high-resolution vibration–rotation spectrum of MgD_2 was recorded with a Bruker IFS 120 HR Fourier transform spectrometer. An emission source that combines a high-temperature furnace with an electrical discharge was used to generate gaseous MgD_2. Except for some minor changes, the same experimental setup was used as described in the earlier paper on MgH_2 (1). About 50 g of magnesium (cut from a rod) was placed in the central part of an alumina tube and was heated to 600 °C to produce approximately 1 torr of magnesium vapor (1 torr = 133.322 Pa). Although we used a mixture of argon and hydrogen in our MgH_2 experiment (1), it was found later that pure hydrogen yields a stronger signal. About 1 torr of pure deuterium flowed slowly through the cell. The tube was sealed with BaF_2 windows, and a BaF_2 lens was used to focus the emission from the tube onto the entrance aperture of the spectrometer. A KBr beamsplitter was used, and the spectrum was recorded with a liquid-nitrogen-cooled HgCdTe (MCT) detector at an instrumental resolution of 0.01 cm^{-1}. The detector response, the BaF_2 lens, and a 1700 cm^{-1} longwave pass filter limited the spectral region to 800–1700 cm^{-1}. In order to improve the

Fig. 1. An expanded view of the spectrum showing the relative intensities of MgD_2 lines, compared to the lines from MgD.

signal-to-noise ratio, about 1200 scans were co-added during 18 h of integration.

The spectrum contained blackbody emission from the hot tube, plus atomic and molecular emission lines, and absorption lines from atmospheric water vapor. The strongest emission lines in the spectrum are from the ^{24}MgD $v = 1 \rightarrow 0$ band and from atomic lines. Four hot bands of ^{24}MgD ($v = 2 \rightarrow 1$ to $v = 5 \rightarrow 4$) were also found and rotationally analyzed (9). The natural abundances of the magnesium isotopes ^{24}Mg,^{25}Mg, and ^{26}Mg are 79:10:11, and for the minor isotopomers, ^{25}MgD and ^{26}MgD, only the $v = 1 \rightarrow 0$ to $v = 4 \rightarrow 3$ bands were detected. In addition to these bands, a series of very weak lines, which was assigned to the ν_3 antisymmetric stretching fundamental band of $^{24}MgD_2$, was observed to higher wavenumbers. An expanded view of the spectrum showing the relative intensities of the MgD and MgD_2 lines is given in Fig. 1. The signal-to-noise ratio for the MgD_2 lines was much smaller than that for the MgH_2 lines (1) for several reasons:

- The intrinsic band strength for ν_3 of MgD_2 was calculated by Tague and Andrews (8) to be about 2 times smaller than that of MgH_2.
- The Einstein A coefficient for spontaneous emission is proportional to $\tilde{\nu}^3$. The band origin of MgH_2 is at 1588.7 cm^{-1}, while the band origin of MgD_2 is at 1176.5 cm^{-1}. This difference makes the Einstein A coefficient of MgD_2 about 2.5 times smaller than that of MgH_2.
- For technical reasons, the quality of spectra generally decreases at lower wavenumbers. In this case, for example, the 1700 cm^{-1} longwave pass filter that was used for MgD_2 is made of germanium, and it has a transmittance of ~50% in the 1200 cm^{-1} spectral region. The 2200 cm^{-1} longwave pass filter used for MgH_2 is made of CaF_2, and it has a transmittance of ~90% in the 1600 cm^{-1} spectral region.

Analysis and discussion

The line positions were determined using the program WSpectra written by M. Carleer (Université Libre de Bruxelles). The spectrum was calibrated using several atomic lines common to both the MgH_2 and MgD_2 spectra, while the MgH_2 spectrum was calibrated using impurity CO lines. The absolute accuracy of calibrated MgD_2 lines is better than 0.002 cm^{-1}. The assignment of the bands was facilitated by the use of a color Loomis–Wood program.

The antisymmetric stretching vibrational mode of MgD_2 (linear) has σ_u symmetry, and the observed vibration–rotation band ($001 \rightarrow 000$) is a Σ_u^+–Σ_g^+ transition having only P and R branches. A list of line positions and assignments is presented in Table 1. For the MgD_2 molecule with $D_{\infty h}$ symmetry, the adjacent rotational lines have a 2:1 intensity ratio ($(I + 1)/I$) due to the ortho–para nuclear spin statistical weights associated with the $I = 1$ deuterium nuclei. In this particular band (Σ_u^+–Σ_g^+), the lines with even J'' should be twice as intense as odd-J'' lines, because deuterium nuclei are bosons. The signal-to-noise ratio for MgD_2 lines was small and the 2:1 intensity ratio was not clearly observed, but the even-J'' lines were stronger than the odd-J'' lines. A few lines near the band origin were missing (i.e., too weak to be observed), and this made the absolute rotational numbering difficult. The absolute rotational assignment was made based on three criteria:

Note: The numbers in parentheses (in units of 10^{-4} cm^{-1}) are the observed minus calculated line positions computed with the constants of Table 2.

- The rotational lines with even J'' should be stronger than odd-J'' lines.
- The r_0 value of MgD_2, which is determined from B_0, should be close to the r_0 value of MgH_2.
- The band origin should be relatively close to the matrix isolation values (7, 8) when small matrix shifts are taken into account.

Three different rotational numberings were attempted, and only one rotational assignment (Table 1) satisfies all of the conditions listed above.

The rotational lines were fitted to the customary energy level expression:

$$[1] \qquad E(v_1, v_2, v_3, J) = G(v_1, v_2, v_3) + BJ(J+1) - DJ^2(J+1)^2$$

using our least-squares fitting program, and the constants of Table 2 were determined. We determined the Mg—D bond distance (r_0) for $v = 0$ to be 1.700 874(8) Å (1 Å = 0.1 nm), using the atomic mass of 2.014 101 779 amu (10) for deuterium.

In our earlier paper on MgH_2 (1), we found the r_0 Mg—H bond distance to be 1.703 327(3) Å. The average Mg—D bond distance is expected to be slightly smaller than the Mg—H bond distance at the zero-point level because the potential energy surface is anharmonic. The vibrational frequencies of MgD_2 are smaller than those of MgH_2, so the MgD_2 zero-point level lies deeper in the anharmonic potential surface.

The ν_3 band origins of MgH_2 and MgD_2 observed or calculated in different studies are compared in Table 3. The argon matrix shift (8) for MgH_2 is –16.8 cm^{-1}, which is –1.06% in relation to the gas-phase band origin. Similarly, the shift for MgD_2 is –13.3 cm^{-1} or –1.13% in relation to the observed ν_3 band origin. The relative shifts for the MgH_2 and MgD_2 band origins in krypton and xenon matrices (7) are also very similar. This consistency in the relative matrix shifts for MgH_2 and MgD_2 supports our absolute rotational assignment.

Table 2. Spectroscopic constants (in cm^{-1}) of $^{24}MgD_2$.

v_1 v_2 v_3	G_v	B_v	10^6 D_v
000	0.0	1.446 575(14)	9.5872(92)
001	1176.502 82(51)	1.433 237(14)	9.5221(94)

Note: All uncertainties are 1σ.

Summary

The gaseous MgD_2 molecule was produced for the first time and was identified via its infrared emission spectrum. The antisymmetric stretching fundamental band 001 → 000 was observed and rotationally analyzed to yield spectroscopic constants. MgD_2 has a linear structure with an r_0 Mg—D bond distance of 1.700 874(8) Å.

Vibrational spectra and electron–vibration interactions of the naphthalene radical anion — Experimental and theoretical study[1]

Hajime Torii, Yuko Ueno, Akira Sakamoto, and Mitsuo Tasumi

Abstract: Vibrational analysis is carried out for the radical anions of naphthalene-h_8 and -d_8. Their infrared (IR) spectra are observed in tetrahydrofuran by using a cell designed for IR measurements of unstable species. The vibrational force field and the IR intensities are calculated by the ab initio molecular orbital and density functional methods at various theoretical levels. As found in the cases of the radical cations of many polycyclic aromatic hydrocarbons (PAHs), a few strong IR bands with intensities of the order of 10^2 km mol^{-1} are observed in the 1700–900 cm^{-1} region. These observed spectral features are well reproduced by the calculations at the CASSCF (complete active space self-consistent field) and B3LYP (Becke's three-parameter hybrid method using the Lee–Yang–Parr correlation functional) levels. The calculation at the B3LYP level gives a better fit between the observed and calculated absolute IR intensities. Normal modes and the origin of the strong IR intensities characteristic of the radical anions are discussed in terms of molecular symmetry coordinates and the dipole derivatives based on these coordinates. It is found that the IR intensities of the b_{2u} modes below 2000 cm^{-1} are dominated by the contribution from one molecular symmetry coordinate, in which the C—C bonds in one ring stretch while those in the other ring shrink. The mechanism that gives rise to the strong IR intensity for this vibration is discussed by examining the changes in the electronic structure induced by this vibration.

Key words: vibrational spectra, electron–vibration interaction, naphthalene, radical anion.

Résumé : On a effectué des analyses vibrationnelles sur des anions radicaux du naphtalène-h_8 et naphtalène-d_8. On a observé leurs spectres infrarouge (IR) dans le tétrahydrofurane à l'aide d'une cellule construite pour des mesures IR d'espèces instables. On a calculé le champ de force vibrationnelle et les intensités IR par la méthode ab initio des orbitales moléculaires et par la méthode de la densité fonctionnelle, à divers niveaux théoriques. Tel qu'il a été observé dans les cas des cations radicaux de plusieurs hydrocarbures aromatiques polycycliques (PAH), on a observé quelques bandes IR fortes dans la région de 1700–900 cm^{-1}, avec des intensités de l'ordre de 10^2 km mol^{-1}. Ces caractéristiques spectrales observées sont très bien reproduites par les calculs aux niveaux CASSCF (champ autocohérent de l'espace actif complet) et B3LYP (méthode hybride de Becke à trois paramètres utilisant la corrélation fonctionnelle de Lee–Yang–Parr). Les calculs au niveau B3LYP conduisent à une meilleure corrélation entre les intensités IR absolues observées et calculées. Les modes normaux et l'origine des fortes intensités IR caractéristiques des anions radicaux sont discutés en fonction des coordonnées de symétrie moléculaire et des dérivées des moments dipolaires basées sur ces coordonnées. On a trouvé que les intensités IR des modes b_{2u} en-dessous de 2000 cm^{-1} sont dominées par la contribution d'une coordonnée de symétrie moléculaire dans laquelle les liaisons C—C d'un cycle s'allongent alors que celles de l'autre deviennent plus courtes. Pour discuter du mécanisme qui donne lieu à la forte intensité IR de cette vibration, on examine les changements dans la structure électronique induite par cette vibration.

Mots clés : spectre vibrationnel, interaction électron–vibration, naphtalène, anion radical.

Introduction

The radical cations of polycyclic aromatic hydrocarbons (PAHs) are known to exhibit distinctive features in their infrared (IR) spectra (1–16); the IR intensities of some bands of these species in the fingerprint region (1700–900 cm^{-1}), which arise from the C-C stretching and C-H in-plane bending modes, are stronger by one or two orders of magnitude than those of the corresponding neutral species. In our previous study (17), the mechanism that gives rise to the IR intensities of these bands has been examined theoretically. It has been shown that these IR intensities are induced by charge fluxes generated by specific vibrational modes that are determined by the electronic structure of the molecule.

Strong electron–vibration interaction is responsible for the generation of the charge fluxes. This situation is closely related to that encountered in previous studies (18–26) on charged polyenes and related molecules, in which some bands in the fingerprint region have strong IR intensities. In those cases, the strong IR intensities are induced by charge fluxes generated by the vibrations along the bond-alternation coordinate.

In the subsequent studies by one of the present authors (HT) (27–29), the nature of the electron–vibration interaction that is responsible for the generation of charge fluxes (or dipole derivatives) in charged conjugated π-electron systems has been analyzed theoretically by using a model Hamiltonian. It has been shown that the dipole derivatives for the C-C stretches of these species are mainly generated by a mixing of a few one-electron excited electronic configurations. The changes in the electronic structure occurring upon the mixing of those configurations, as well as the signs and the magnitudes of the dipole derivatives generated by the mixing, support the concept of long-range and short-range charge fluxes introduced in ref. 17. The small IR intensities of the C-C stretches of neutral species are explained by the cancellation of the contributions of various one-electron excited configurations, which results from the pairing theorem (30) that holds for the molecular orbitals of the model Hamiltonian for alternant hydrocarbons.

Although only the cationic and neutral species have been treated in the model Hamiltonian approach described above, it is expected that the concept obtained there also holds for the anionic species because of the pairing theorem. To examine the extent of such generality, it is interesting to analyze the IR spectra of anionic species and compare the results with those obtained for the cationic species. One problem that arises at this point is that there are only a small number of anionic conjugated π-electron systems for which reliable IR spectra have been measured. This is partly because radical anions are very sensitive to molecular oxygen and water, and partly because many radical anions are intrinsically unstable toward electron detachment in the isolated state. For example, IR spectra have been measured for the cationic species (in the matrix-isolated condition) of many PAHs (2–11), including linear polyacenes ranging from naphthalene to pentacene, and other PAHs such as perylene and coronene, but to the best of our knowledge, the IR spectra of only a few anionic counterparts have been measured (6, 31, 32).

In the present study, the IR spectra of the radical anions of naphthalene-h_8 and -d_8 in tetrahydrofuran (THF) are measured by using a cell designed for measuring the IR spectra of unstable species in solution. The absolute IR intensity of each observed band is determined. The observed IR spectra are compared with those obtained from ab initio molecular orbital (MO) and density functional (DFT) calculations carried out at various theoretical levels for an isolated species of the radical anions. The radical anions in solution are of course not isolated, but vibrational spectra are not affected greatly by solvent molecules unless strong intermolecular interactions such as hydrogen bonding exist. It is, therefore, reasonable to expect that the results of calculation for a single molecule would be useful for analysing the spectra observed in solution. It is shown that the main features of the observed IR spectra are best reproduced by the DFT calculation at the B3LYP (Becke's three-parameter hybrid method (33) using the Lee–Yang–Parr correlation functional (34)) level. By using the vibrational force field and the dipole derivatives calculated at this theoretical level, a detailed analysis of the observed spectra is carried out. As in the case of the cationic counterpart (17), IR intensities are particularly large for some specific modes determined by the electronic structure. The mechanism that gives rise to large dipole derivatives for such vibrations is discussed.

Experimental procedure

As described in the *Introduction*, measurements of reliable IR spectra of radical anions in solution need a special technique for keeping the anions intact during the measurement. In the present study, we used CaF_2 cavity cells (Spectra Tech and Pier Optics) and a vacuum-tight holder (Spectra Tech) modified for this purpose. By using the modified vacuum-tight holder, we can connect the CaF_2 cavity cell for IR measurements through a glass joint and a Teflon O-ring to a completely sealed glass apparatus for preparation of radical anions in solution. The optical pathlength was set at 0.3 mm for measurements in the 3200–1200 cm^{-1} region and at 0.1 mm for the 1200–900 cm^{-1} region.

Tetrahydrofuran (THF) was used as a solvent for IR measurements: THF-d_8 in the 3200–2400 and 1700–1200 cm^{-1} regions, and THF-h_8 in the 2400–2000 and 1200–900 cm^{-1} regions. THF-h_8 and THF-d_8 were degassed and dehydrated by distillation in vacuum several times and were stored in vacuum in contact with a sodium mirror. Reduction of naphthalene-h_8 and -d_8 was performed by bringing their degassed and anhydrous THF solution into contact with a sodium mirror in a completely sealed glass apparatus. The concentrations of the sample solutions were determined by measuring electronic absorption spectra and using the absorption coefficients reported in previous studies (35–37) as a reference. The concentrations were 2.9×10^{-2} mol dm^{-3} for the naphthalene-h_8 radical anion in THF-d_8 (used for the measurements in the 3200–1200 cm^{-1} region), 1.3×10^{-1} mol dm^{-3} for the naphthalene-h_8 radical anion in THF-h_8 (1200–900 cm^{-1}), 2.5×10^{-2} mol dm^{-3} for the naphthalene-d_8 radical anion in THF-h_8 (2400–2000 cm^{-1}), and 2.4×10^{-2} mol dm^{-3} for the naphthalene-d_8 radical anion in THF-d_8 (1700–1200 cm^{-1}).

IR spectra were observed at room temperature on a JEOL JIR-5500 Fourier-transform IR spectrophotometer equipped with a mercury–cadmium–telluride (MCT) detector (3200–1200 cm^{-1}) or a triglycine sulfate (TGS) detector (1200–900 cm^{-1}). Spectral resolution was 4 cm^{-1}. Solvent bands were subtracted from the spectra measured in solution. Electronic absorption spectra were measured on a Hitachi U-3500 spectrophotometer.

Computational procedure

Ab initio MO calculations of the structure, vibrational force field, and dipole derivatives of the naphthalene radical anion were carried out at the unrestricted Hartree–Fock (UHF), restricted open-shell Hartree–Fock (ROHF), unrestricted second-order Møller–Plesset perturbation (UMP2), and complete active space self-consistent field (CASSCF) levels in combination with the 6-31G* basis set. CASSCF calculations, 11 electrons were included in the active space consisting of 10 valence π orbitals. DFT calculations at the B3LYP level were also performed in combination with the 6-311G* basis set. To support the discussion on the mechanism that gives rise to strong IR intensities of some normal modes, structural parameters were calculated also for the two Jahn–Teller distorted structures of the benzene radical anion as well as neutral benzene and naphthalene at the CASSCF and B3LYP levels. We used the HONDO 8 program (38) for the calculations at the CASSCF level and the Gaussian 92 and 94 programs (39, 40) for the calculations at the other levels. All these calculations were carried out on IBM SP2 computers at the Computer Center of the Institute for Molecular Science, Okazaki, Japan.

For the vibrational analysis of the naphthalene radical anion, two sets of intramolecular coordinates were needed: local coordinates and molecular symmetry coordinates. The in-plane local coordinates R_1–R_{39} were defined as shown in Table 1, with the numbering of atoms shown in Fig. 1. By using these coordinates, the molecular symmetry coordinates for the IR-active b_{2u} and b_{1u} symmetry species of the D_{2h} point group (S_{18}–S_{33}) were defined as given in Table 2. The latter set of coordinates was used to represent the vibrational force field and the dipole derivatives in the vibrational analysis. Two points are noteworthy in relation to the definition of coordinates. (*i*) No hydrogen atoms are involved in the definition of the C-C-C bending local coordinates (R_{20}–R_{31}) to define the corresponding molecular symmetry coordinates

in a systematic way. (*ii*) The redundancies intrinsic to the ring systems (called the ring redundancies) (41) are removed in the definition of the molecular symmetry coordinates as shown in Table 2, so that the vibrational pattern represented by each coordinate is easily understandable.

All the calculations related to the vibrational analysis were carried out on a Hitachi M5800/320 computer at the Computer Center of the University of Tokyo.

Results and discussion

(A) Observed spectra

The observed IR spectrum of the naphthalene-h_8 radical anion in THF is shown in Fig. 2*a*. The vibrational wavenumbers and the absolute IR intensities of the observed bands are shown on the right side of Table 3.

In Fig. 2*a*, a few strong IR bands are seen in the 1700–900 cm^{-1} region. The absolute IR intensities of the strongest bands are on the order of 10^2 km mol^{-1}, which are one to two orders of magnitude larger than those of the corresponding bands of the neutral species. This situation is similar to the cases of the PAH radical cations. It is, therefore, expected that the strong IR intensities of these bands arise from the same mechanism as those of the PAH radical cations (17). The discussion on this point is described in section D. In contrast to the cases of the PAH radical cations, however, the IR intensities of the C-H stretching bands of the naphthalene radical anion are very strong. This result suggests that the atomic charges on the hydrogen atoms are significantly different between the cationic and anionic species. The Mulliken atomic charges of the hydrogen atoms obtained by the calculations at the B3LYP/6-311G* level are indeed different between the two species (~0.27 *e* in the cationic species and ~0.11 *e* in the anionic species).

Because of the existence of strong solvent bands, all the IR bands in the 1300–900 cm^{-1} region may not be observed

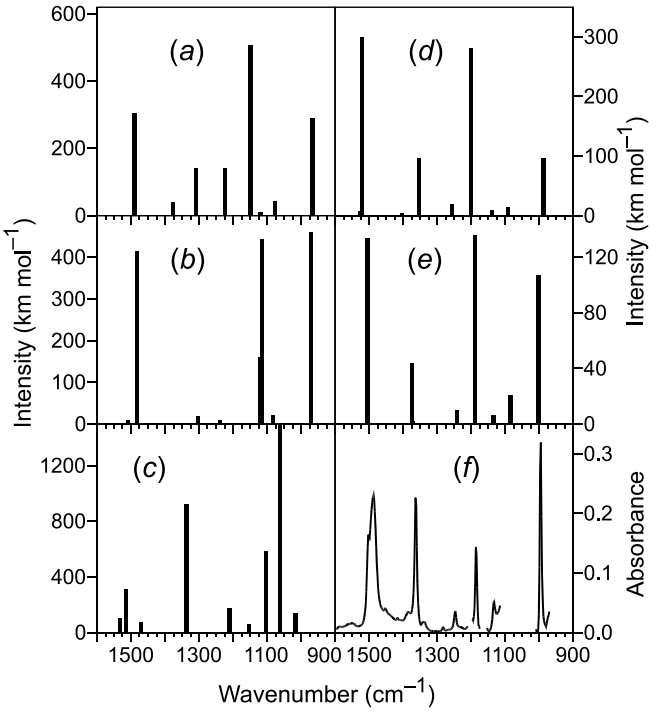
even after the subtraction of the solvent bands. For the same reason, two solvents were used in the present study: THF-d_8 for the measurement in the 3200–1200 cm^{-1} region and THF-h_8 in the 1200–900 cm^{-1} region. The 1246 cm^{-1} band is observed both in THF-h_8 and in THF-d_8. The absolute IR intensities of this band measured in the two solvents are in good agreement with each other. As shown in section B, it is expected from the calculation at the B3LYP level that there is an IR band at ~1085 cm^{-1} for the naphthalene-h_8 radical anion. We could not find an appropriate solvent to observe this band. The absolute IR intensity of the 1186 cm^{-1} band may not be accurate because of the overlap of a solvent band. The weak IR bands observed in the whole wavenumber region may be due to the solvent or to overtones and combinations.



The IR spectrum of the naphthalene-h_8 radical anion was reported in 1965 by Kachkurova (31). In that study, many bands of the neutral species were observed, and the solvent (THF) bands were not subtracted. The observation of many bands of the neutral species in ref. 31 indicates that a great amount of the neutral species remained in the sample, probably because of incomplete sealing of the measurement system used in ref. 31. In the present study, the solvent bands could be subtracted to a satisfactory degree thanks to the high performance of the FT-IR spectrophotometer used. For these reasons, the IR bands at 1502, 1246, and 1133 cm^{-1} observed in the present study were not detected in ref. 31. The absolute intensities of the IR bands of the radical anion (determined for the first time in the present study) are one to two orders of magnitude larger than those of the corresponding bands of the neutral. The IR spectrum of the naphthalene-h_8 radical anion was also observed in 1973 by Dodson and Graham (42). In their spectrum, the IR bands at 1502, 1361, 1246, and 1133 cm^{-1} were not observed. As a consequence, other weak bands arising (probably) from overtones and combinations or from some impurities were erroneously assigned to fundamental modes of the radical anion.

The observed IR spectrum of the naphthalene-d_8 radical anion in THF is shown in Fig. 2*b*. The absolute IR intensities of the observed bands are shown on the right side of Table 4. In this case also, a few strong IR bands are observed in the 1700–1200 cm^{-1} region, and the absolute IR intensities of the strongest bands are on the order of 10^2 km mol^{-1}. The spectral pattern in the 1700–1200 cm^{-1} region observed for the d_8 species is substantially different from that observed for the h_8 species, because the C-C stretches are mixed with the C-H bends more strongly in the h_8 species than with the C-D bends in the d_8 species. The spectral pattern in the C-D stretching (2400–2000 cm^{-1}) region is different from that in the C-H stretching (3200–2800 cm^{-1}) region of the h_8 species, probably because of the difference in the coupling with overtones and combinations.

(B) Calculated spectra

The vibrational wavenumbers and the IR intensities of the naphthalene-h_8 radical anion calculated at various theoretical levels are shown in Table 3. The calculated wavenumbers are uniformly scaled by using a single scale factor at each theoretical level. The scale factors (given in the footnote of Table 3) are determined from the comparison between the observed (43) and calculated wavenumbers of the in-plane

Fig. 3. IR spectra of the naphthalene-h_8 radical anion in the 1600–900 cm^{-1} region calculated at the (*a*) UHF/6-31G*, (*b*) ROHF/6-31G*, (*c*) UMP2/6-31G*, (*d*) CASSCF/6-31G*, and (*e*) B3LYP/6-311G* levels, in comparison with (*f*) the spectrum observed in THF.

modes in the region below 2000 cm^{-1} (except those involving the Kekulé vibration) of four isotopic species of neutral benzene (C_6H_6, C_6D_6, $^{13}C_6H_6$, and $^{13}C_6D_6$). The observed and calculated IR spectra in the 1600–900 cm^{-1} region are shown in Fig. 3 for ease of comparison.

It is evident from Table 3 and Fig. 3 that the observed IR spectrum is reproduced reasonably well only by the calculations at the CASSCF and B3LYP levels (shown in Fig. 3*d* and 3*e*, respectively). Comparison between the observed and calculated absolute IR intensities suggests that the calculation at the B3LYP level gives a better result. It is, therefore, concluded that the vibrational force field and the dipole derivatives calculated at the B3LYP level are sufficiently reliable. These quantities are used in the subsequent vibrational analysis described in sections C and D.

The IR spectra calculated at the three other theoretical levels are substantially different from the observed spectrum. At the ROHF level, the relative IR intensities of the bands in the 1400–1200 cm^{-1} region are too small as shown in Fig. 3*b*, and the vibrational wavenumbers of the ν_{21} and ν_{22} modes are too low as shown in Table 3. At the UHF level also, the vibrational wavenumber of ν_{21} is too low. These discrepancies are considered to arise from the neglect of electron correlation in the calculations at the ROHF and UHF levels. At the ROHF level, the contribution of molecular symmetry coordinate S_{19}, which corresponds to the vibration along the bond-alternation coordinate and is similar to the Kekulé vibration, to ν_{21} and ν_{22} is 50% and 38%, respectively, in terms of potential energy distribution (PED). The corresponding values in the UHF calculation are 58% and

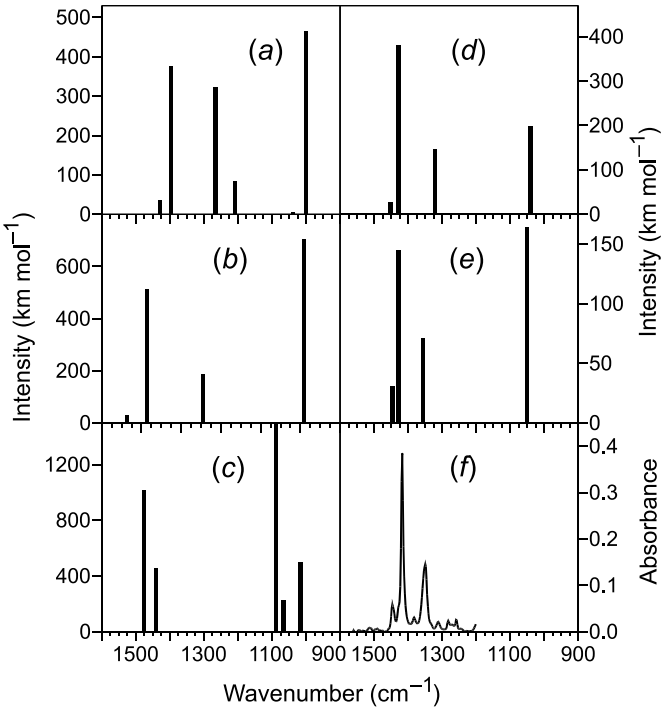
32%. As in the case of neutral benzene (44–46), the calculated diagonal force constant for S_{19} is considered to be too low at the HF level. Another source of the discrepancies in the calculation at the UHF level may be the spin contamination of the electronic wave function. The $\langle s^2 \rangle$ value obtained from the present UHF calculation is 0.8589, which is noticeably larger than the ideal value of 0.75. At the UMP2 level, the discrepancies between the observed and calculated results are more serious. As shown in Table 3, the calculated IR intensities of many b_{1u} modes are extraordinarily large, and the calculated wavenumber of ν_{28} appears to be strange. These discrepancies are considered to arise (at least partly) from the spin contamination of the electronic wave function, since the calculated $\langle s^2 \rangle$ value is as large as 0.8600. In contrast, in the calculation at the B3LYP level, the calculated $\langle s^2 \rangle$ value is 0.7603, which is close to the ideal value of 0.75, and the effect of electron correlation is also taken into account. The good agreement between the observed and calculated spectra obtained at the B3LYP level is therefore reasonable.[3]

The vibrational wavenumbers and the IR intensities of the naphthalene-d_8 radical anion calculated at the five theoretical levels are shown in Table 4. The calculated and observed IR spectra in the 1600–900 cm^{-1} region are compared in Fig. 4. In this case also, good agreement with the observed spectral pattern is obtained by the calculations at the CASSCF and B3LYP levels, and the latter calculation yields a better result with regard to the absolute IR intensities. At the UHF and ROHF levels, the discrepancies between the observed and calculated wavenumbers of ν_{21} are more noticeable for the d_8 species than for the h_8 species. This result is reasonable by considering that the PEDs of S_{19} in ν_{21} calculated at these two levels are 92% and 96%, respectively, for the d_8 species, which are significantly larger than the values calculated for the h_8 species (58% and 50%, respectively).



(C) Characterization of normal modes

The normal modes of the naphthalene-h_8 and -d_8 radical anions are discussed here in terms of the molecular symmetry coordinates (S_j) defined in Table 2. In the same way as in the vibrational analysis in refs. 24 and 26, the origin of the IR intensity of each normal mode (Q_m) is examined by calculating $\partial \boldsymbol{\mu}/\partial S_j \times \partial S_j/\partial Q_m$. The direction of the dipole derivative vector is determined by the symmetry species to which S_j and Q_m belong. As shown in Fig. 1, it is in the x direction for the b_{3u} (out-of-plane, IR-active) modes, y for the b_{2u} (in-plane, IR-active) modes, and z for the b_{1u} (in-plane, IR-active) modes.

The results obtained for the b_{1u} and b_{2u} modes of the naphthalene-h_8 radical anion are shown in Table 5. It is evident from the calculated PEDs that the C-C stretches and the C-H bends are strongly mixed with each other in the normal modes in the 1600–900 cm^{-1} region (ν_{20}–ν_{24} and ν_{27}–ν_{30}). Because of the large contributions of the off-diagonal force constants to the vibrational potential energy, the sum of the PEDs exceeds 100% to a great extent for some normal modes (e.g., the ν_{21} mode).

The strong IR bands observed at 1486 and 995 cm^{-1} correspond to the ν_{20} and ν_{24} modes, respectively. In terms of PED, the former mainly derives from S_{25} (C-H bend) and S_{20} (C-C stretch), and the latter from S_{18} and S_{20} (C-C stretches). The calculated IR intensity of ν_{22} is also strong. This mode arises from S_{18} (C-C stretch) as well as S_{24} and S_{25} (C-H bends). From these results, it may seem as if the IR intensities of these three modes originate from both the C-C stretches and the C-H bends. However, as shown by the values of $\partial \mu_y/\partial S_j \times \partial S_j/\partial Q_m$ in Table 5, they are determined primarily by the contributions from S_{18}. The value of $\partial \mu_y/\partial S_{18} \times \partial S_{18}/\partial Q_m$ exceeds 1.0 D $Å^{-1}$ $amu^{-1/2}$ only in the ν_{20}, ν_{22}, and ν_{24} modes, and the other normal modes below 2000 cm^{-1} have medium to weak IR intensities. The dominance of the contribution of S_{18} to the IR intensities arises from the magnitude of $\partial \mu_y/\partial S_{18}$, the absolute value of which exceeds 7.0 D $Å^{-1}$ in both the CASSCF/6-31G* and B3LYP/6-311G* calculations and is significantly larger than the absolute value of any other $\partial \boldsymbol{\mu}/\partial S_j$ listed in Table 6.

Fig. 4. IR spectra of the naphthalene-d_8 radical anion in the 1600–900 cm^{-1} region calculated at the (*a*) UHF/6-31G*, (*b*) ROHF/6-31G*, (*c*) UMP2/6-31G*, (*d*) CASSCF/6-31G*, and (*e*) B3LYP/6-311G* levels, in comparison with (*f*) the spectrum observed in THF.

For the coordinates belonging to the b_{1u} symmetry species, the magnitude of $\partial \mu_z/\partial S_{26}$ is the largest (3.355 D $Å^{-1}$). However, because this value is not particularly larger than those for the other b_{1u} coordinates, the contributions from the vibrations along many coordinates should be taken into account to understand the IR intensities of the b_{1u} modes.

The values of $\partial \boldsymbol{\mu}/\partial S_j \times \partial S_j/\partial Q_m$ and the PEDs calculated for the b_{1u} and b_{2u} modes of the naphthalene-d_8 radical anion are shown in Table 7. Since the C-D bends are intrinsically lower in wavenumber than the C-H bends, the vibrations along the C-D bends (S_{24}, S_{25}, S_{32}, and S_{33}) contribute

[3] The $\langle s^2 \rangle$ value calculated at the ROHF and CASSCF levels is 0.75 by definition.

mainly to the modes below 1100 cm^{-1} rather than to the modes in the 1600–1100 cm^{-1} region. The C-C stretches are therefore mixed to a minor extent with the C-D bends in the d_8 species.

The strong IR band observed at 1418 cm^{-1} corresponds to ν_{20}. The calculated IR intensity of ν_{22} is also strong, although the IR spectrum could not be measured in the wavenumber region where the IR band corresponding to this mode is expected to be observed. The value of $\partial\mu_y/\partial S_{18} \times \partial S_{18}/\partial Q_m$ exceeds 1.0 D $Å^{-1}$ $amu^{-1/2}$ only for these two modes. The IR intensities of the b_{2u} modes below 2000 cm^{-1} are dominated by the contribution from S_{18}. By contrast, the contributions from the vibrations along many coordinates are important to analyze the IR intensities of the b_{1u} modes. The situation found for the d_8 species is thus similar to that for the h_8 species.

Note: Calculated at the B3LYP/6-311G* level.
[a] $\partial\mu_y/\partial S_j \times \partial S_j/\partial Q_m$ for the b_{2u} modes and $\partial\mu_z/\partial S_j \times \partial S_j/\partial Q_m$ for the b_{1u} modes are given.

It is clear from these results that the significant enhancement of the IR intensities in the 1600–900 cm^{-1} region observed for the naphthalene radical anion as compared with the neutral species is primarily due to the large dipole derivative induced by the vibration along S_{18}, as found in ref. 17 for the cationic species.

(D) Mechanism that gives rise to strong IR intensities

To discuss the mechanism that gives rise to such a large dipole derivative, we first examine the relation between the molecular structural parameters and the electronic wave function of the radical anions of benzene and naphthalene, paying attention to the form of the singly occupied molecular orbital (SOMO).

The calculated structural parameters of these anions and their neutral species are shown in Table 8. The numbering of atoms and the Cartesian coordinate system defined for naphthalene (Fig. 1) are also used for benzene. The structural parameters calculated at the CASSCF and B3LYP levels are in good agreement with each other.

Because of the Jahn–Teller effect, two structures (A and B) with D_{2h} symmetry are considered for the benzene radical anion. In structure A, the C_1—C_2 and C_2—C_3 bonds are longer and shorter, respectively, than those of the neutral species. By contrast, the C_2—C_3 bond of structure B is longer than that of the neutral, while the C_1—C_2 bond length remains almost the same. These structural changes are reasonably explained by the SOMOs of the anionic species, which are shown in Fig. 5*a*. In structure A, the SOMO is antibonding and bonding, respectively, for the C_1—C_2 and C_2—C_3 bonds. Therefore, when neutral benzene is reduced to this form of the anion, the C_1—C_2 bond becomes longer and the C_2—C_3 bond shorter. In structure B, the SOMO is antibonding for the C_2—C_3 bond and nonbonding for the C_1—C_2 bond. Therefore, the C_2—C_3 bond becomes longer and the C_1—C_2 bond length remains almost the same when benzene is reduced to this form of the anion.

The SOMO of the naphthalene radical anion is shown on the upper left part of Fig. 5*b*. It is antibonding and bonding, respectively, for the C_1—C_2 and C_2—C_3 bonds, and nonbonding for both the C_9—C_1 and C_9—C_{10} bonds. By the same reasoning as employed for the benzene radical anion, it is expected that the C_1—C_2 and C_2—C_3 bonds become longer and shorter, respectively, when naphthalene is reduced to the radical anion, while the C_9—C_1 and C_9—C_{10} bond lengths remain almost the same. As shown in Table 8, the changes in the C_9—C_1, C_1—C_2, and C_2—C_3 bond lengths match this expectation. By contrast, the C_9—C_{10} bond of the radical anion is calculated to be longer than that of the neutral. At present, we have no reasonable explanation for this change of bond length.

It is clear from Fig. 5*b* that the electronic structure of each ring in the naphthalene radical anion is similar to that of structure A of the benzene radical anion. The coefficients of the SOMO on the C_9 and C_{10} atoms are zero because the contributions from the two rings cancel each other. In the subsequent analysis of the origin of IR intensities, structure A of the benzene radical anion is regarded as the building block for the naphthalene radical anion.

The vibrational pattern of S_{18} is schematically shown on the upper right part of Fig. 5*b*. It is noticed that one of the rings vibrates in the direction of the structural change from neutral benzene to its radical anion (structure A), and the other ring vibrates in the opposite phase. As a result, the former becomes more anionic and the latter less anionic by this

Fig. 5. (*a*) Singly occupied molecular orbitals (SOMOs) of the benzene radical anion (structures A and B). (*b*) Decomposition of the SOMO and the vibrational pattern of S_{18} of the naphthalene radical anion into those of two benzene rings and scheme of the charge flux induced by the vibration along S_{18}.

vibration. In other words, as shown on the lower left part of Fig. 5*b*, a partial negative charge is transferred from the latter ring to the former by this vibration. Of course, the charge goes back and forth as the vibration proceeds. This mechanism of generating large dipole derivatives, called "long-range charge flux" in our previous study (17), is considered to be important also for other PAH radical ions. The result that the total IR intensities calculated for the radical cations of polyacenes are approximately proportional to the square of the number of rings (17) supports this mechanism.

To see more closely the change in the electronic structure induced by the vibration along S_{18}, the form of the SOMO (more specifically, the singly occupied natural orbital derived from the CASSCF calculation) is examined for the naphthalene radical anion displaced along S_{18}. Since the 6-31G* basis set used in the calculation is of split-valence type, there are two contracted basis functions for valence π orbitals on each carbon atom. As shown in Table 2, the C_9—C_1, C_1—C_2, C_3—C_4, and C_4—C_{10} bonds stretch while the C_{10}—C_5, C_5—C_6, C_7—C_8, and C_8—C_9 bonds shrink by the displacement in the positive direction along S_{18}. Because these eight C—C bonds are involved in S_{18}, the displacement of 1 Å along S_{18} means that each bond stretches or shrinks by $1/\sqrt{8}$ Å.

The result is shown in Table 9. The coefficients of the singly occupied natural orbital on the C_1 and C_2 atoms (and the other two equivalent atoms on the same ring) increase by the displacement in the positive direction along S_{18}, while those on the C_5 and C_6 atoms decrease. This result indicates that the electron–vibration interaction involving the vibration along S_{18} is strong, and the motion of the unpaired electron between the two rings is induced by this vibration.

The change in the electronic structure induced by the vibration along S_{18} may be examined also by using the model Hamiltonian approach developed in refs. 27 and 28. In this approach, dipole derivatives of individual C-C stretches ($\partial\mu_k/\partial R_l$) are represented in atomic units as

$$[1] \qquad \frac{\partial \mu_k}{\partial R_l} = -0.07 \sum_s f_{k,s} P_{ij,s}$$

where

$$[2] \qquad f_{k,s} = \frac{\partial}{\partial E_k} \langle \nu_s \mid g(\boldsymbol{E}) \rangle$$

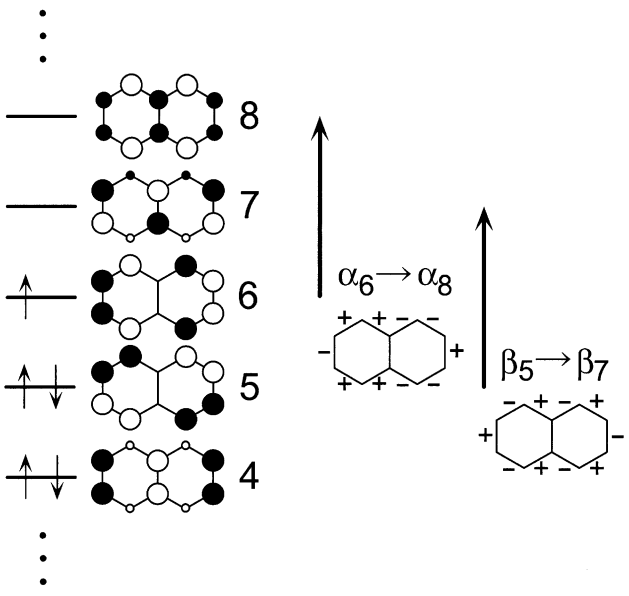
is the electric-field-induced mixing of one-electron excited electronic configurations $|\nu_s\rangle$ (numbered by s) into the ground electronic state $|g(\boldsymbol{E})\rangle$, and

$$[3] \qquad P_{ij,s} = \langle g_0 \mid \sum_{\sigma} (a_{i\sigma}^{\dagger} a_{j\sigma} + a_{j\sigma}^{\dagger} a_{i\sigma}) \mid \nu_s \rangle$$

is an element of the one-particle transition density matrix (47) between $|g_0\rangle$ ($\equiv |g(\boldsymbol{E} = 0)\rangle$) and $|\nu_s\rangle$. In the last equation, $a_{i\sigma}^{\dagger}$ is the creation operator of a π electron of spin σ at the ith carbon atom, and $a_{i\sigma}$ is the corresponding annihilation operator. It is assumed that the lth C—C bond connects the ith and jth carbon atoms.



The configurations ($|\nu_s\rangle$) that are important for generating the IR intensity of the b_{2u} modes are shown in Fig. 6. By the mixing of the $\alpha_6 \rightarrow \alpha_8$ configuration (where the α electron on the 6th orbital is excited to the 8th orbital), the dipole derivatives of individual C-C stretches ($\partial\mu_y/\partial R_l$) are generated with the signs as shown just below the "$\alpha_6 \rightarrow \alpha_8$" label in Fig. 6. From the comparison with the definition of S_{18} shown in Table 2, it is seen that the large dipole derivative in the $-y$ direction is induced for S_{18} by this mixing. It is also seen that the dipole derivative in the $-y$ direction is induced for S_{19} by the mixing of the $\beta_5 \rightarrow \beta_7$ configuration. As discussed in the *Introduction*, the contributions of many one-electron excited configurations cancel each other in the neutral species. Because of the existence of an electron on the 6th orbital in the naphthalene radical anion, we have the contribution of the $\alpha_6 \rightarrow \alpha_8$ configuration. For the same reason, the contribution of the $\beta_5 \rightarrow \beta_7$ configuration is not canceled by that of the $\alpha_4 \rightarrow \alpha_6$ configuration. The IR intensity enhancement observed for the naphthalene radical anion (as well as for the cationic species (27–29)) as compared with the neutral species is thus reasonably explained by the difference in their electronic structures.

From the forms of the 6th and 8th orbitals shown in Fig. 6, it is also clear that the electronic populations on the C_1 through C_4 atoms decrease, while those on the C_5 through C_8 atoms increase by the mixing of the $\alpha_6 \rightarrow \alpha_8$ configuration. This result is fully consistent with that obtained from the CASSCF calculation show in Table 9.

Concluding remarks

The purposes of the present study were to observe the IR spectra of the naphthalene-h_8 and -d_8 radical anions and to elucidate the mechanism that gives rise to the spectral features characteristic of these species. It has been shown from the comparison of the observed spectra with those calculated at the B3LYP level that the strong IR bands observed in the 1600–900 cm^{-1} region with intensities of the order of 10^2 km mol^{-1} originate from the normal modes of b_{2u} symmetry. The IR intensities of these bands are primarily determined by the contribution from the one molecular symmetry coordinate, which is denoted as S_{18} in the present study, because the dipole derivative calculated for this coordinate is substantially larger than those for the other coordinates. From detailed examination of the change in the electronic structure induced by the vibration along this coordinate, it is shown that this vibration generates a large charge flux between the two rings of the naphthalene radical anion. Strong electron–vibration interaction is responsible for this mechanism.

Fig. 6. The forms of orbitals 4–8, the occupation of α and β electrons in these orbitals, the electronic excitations involved in the configurations that are important for generating the IR intensity of the b_{2u} modes, and the signs of the dipole derivatives generated by the mixing of these configurations calculated for the naphthalene radical anion.

Conjugated π-electron systems in general are known to have interesting electronic and vibrational properties. It is expected that electron–vibration interactions are important to understand the molecular aspects of the functions of some conjugated π-electron systems related to those properties, such as electric conductivity and nonlinear optical susceptibilities.

Conformational stability, infrared and Raman spectra, and vibrational assignment of ethyl bromogermane[1]

James R. Durig, Chunhua Pan, Witold Witkowski, and Gamil A. Guirgis

Abstract: The infrared spectra (3200–30 cm^{-1}) of ethyl bromogermane, $CH_3CH_2GeH_2Br$, in the gaseous phase and of amorphous and annealed solid samples as well as the Raman spectrum (3200–100 cm^{-1}) of the liquid have been recorded. Variable-temperature (–105 to –150 °C) studies of the infrared spectra of a sample dissolved in liquid krypton have been carried out. From these data, the enthalpy difference between the gauche and trans conformers has been determined to be 158 ± 16 cm^{-1} (1.89 ± 0.20 kJ/mol), with the gauche conformer being the more stable form. This result is consistent with the prediction from ab initio calculations at both the Hartree–Fock level and with full electron correlation by the perturbation method to second order. It is estimated that at ambient temperature 81 ± 2% of the sample is in the gauche form. A relatively complete vibrational assignment is proposed for both the gauche and trans conformers based on infrared band contours, relative intensities, depolarization values, and group frequencies which is supported by normal coordinate calculations utilizing the force constants from the ab initio MP2/6-31G(d) calculations. The optimized geometries and conformational stabilities have also been obtained from ab initio calculations utilizing several different basis sets with full electron correlation by the perturbation method up to MP2/6-311+G(2d,2p). Additionally, the potential functions governing the conformation interchange have been estimated from ab initio MP2/6-31G(d) and density functional theory calculations by the B3LYP method, with barriers to conformational interchange of 560, 924, and 852 cm^{-1} from MP2/6-31G(d) and 418, 771, and 606 cm^{-1} from B3LYP/6-31G(d) calculations for the trans to gauche, gauche to gauche, and gauche to trans conformers, respectively. The results are discussed and compared to some corresponding quantities for several related molecules.

Key words: conformational stability, Raman spectra, infrared spectra; ab initio calculations, ethyl bromogermane.

Résumé : On a déterminé les spectres infrarouge (3200 à 30 cm^{-1}) de l'éthylbromogermane, $CH_3CH_2GeH_2Br$, en phase gazeuse et ceux d'échantillons solides amorphes et recuits ainsi que les spectres Raman (3200 à 100 cm^{-1}) en phase liquide. On a effectué des études à température variable (–105 à –150 °C) des spectres infrarouge des échantillons dissous dans le krypton liquide. Sur la base de ces données, on a déterminé que la différence d'enthalpie entre les conformères gauche et trans est de 158 ± 16 cm^{-1} (1,89 ± 0,20 kJ/mol) et que le conformère gauche est le plus stable, ce qui est en accord avec la prédiction faite sur la base de calculs ab initio, tant au niveau de Hartree–Fock qu'avec la corrélation électronique complète faisant appel à la méthode de perturbation du deuxième ordre. À la température ambiante, il a été évalué que 81 ± 2 % de l'échantillon est sous la forme gauche. Sur la base des contours des bandes infrarouges, des intensités relatives, des valeurs de dépolarisation et des fréquences de groupe qui est supportée par des calculs de coordonnées normales à l'aide de constantes de force obtenues par des calculs ab initio MP2/6-31G(d), on propose une attribution vibrationnelle relativement complète pour les conformères tant gauche que trans. On a aussi obtenu les géométries optimisées et les stabilités conformationnelles à partir de calculs ab initio utilisant plusieurs ensembles de base différents, avec une corrélation électronique complète à l'aide de la méthode de perturbation jusqu'au niveau MP2/6-311+G(2d,2p). En se basant sur des calculs ab initio MP2/6-31G(d) et des calculs selon la théorie de la densité fonctionnelle (TDF) à l'aide de la méthode B3LYP, on a aussi évalué les fonctions de potentiel gouvernant l'échange de conformation. Les barrières à l'échange conformationnel sont respectivement de 560, 924 et 852 cm^{-1} par la méthode MP2/6-31G(d) et de 418, 771 et 606 cm^{-1} par la méthode B3LYP/6-31G(d) pour les échanges de conformère trans à gauche, de gauche à gauche et de gauche à trans. On discute des résultats et on les compare à des valeurs correspondantes obtenues pour plusieurs autres molécules.

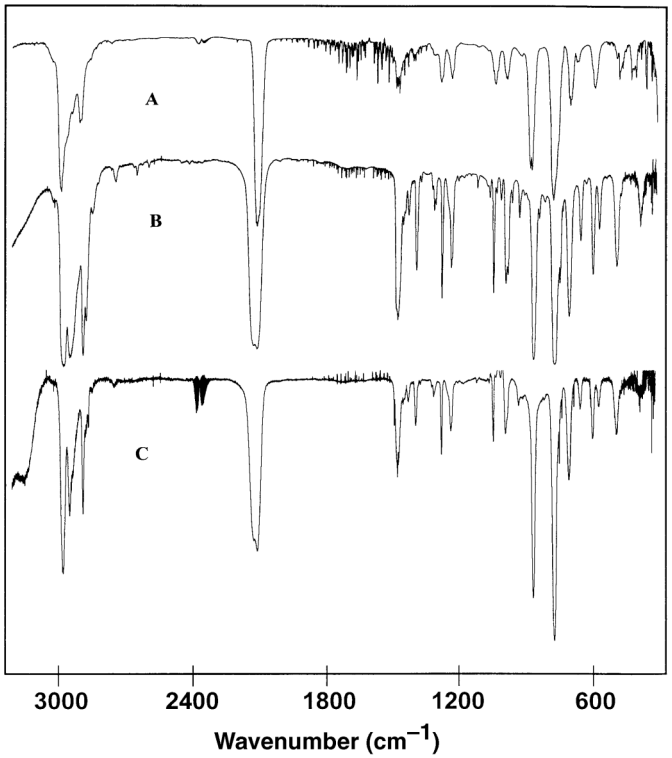
Introduction

To investigate the conformational stability of a series of YCH_2CH_2X, YCH_2SiH_2X, and YCH_2GeH_2X molecules, where Y is a halogen or methyl group and X is F, Cl, Br, or CH_3, we have carried out a number of vibrational spectroscopic and theoretical studies on the 1,2-disubstituted ethane and 1,2-disubstituted methylsilane molecules. For YCH_2CH_2X, when Y is a methyl group and X is F (1), Cl (2), or Br (2), the enthalpy differences between the trans and gauche conformers, obtained from rare-gas solutions, are 104 ± 6, 52 ± 3, and 72 ± 7 cm^{-1} (1 cm^{-1} = 11.963 J/mol), respectively, with the gauche conformer being the more stable form. However, for molecules in which Y and X are both either halogens (except when they are both F atoms (3)) or methyl groups, such as 1,2-dichloroethane (4), 1,2-fluorochloroethane (4), 1,2-fluorobromoethane (5), and *n*-butane (6), the trans conformers were determined to be the more stable forms. Enthalpy differences of 318 ± 25, 17 ± 8, 109 ± 9, and 221 ± 21 cm^{-1} between the trans and gauche conformers were determined in krypton solutions for 1,2-dichloroethane, 1,2-fluorochloroethane, 1,2-fluorobromoethane, and *n*-butane, respectively. However, the 1,2-difluoroethane molecule has the gauche conformer as the more stable rotamer (3) with an enthalpy difference of 283 ± 47 cm^{-1}.

Similar studies of conformational stabilities have been carried out for the corresponding silicon-containing compounds, YCH_2SiH_2X. When Y is a methyl group and X is F (7), Cl (8), or Br (9), the most stable conformer is also the gauche form, with enthalpy differences between the trans and gauche conformers of 54 ± 16, 78 ± 11, and 140 ± 22 cm^{-1}, respectively, again determined in rare-gas solutions. For molecules in which both Y and X are halogens, such as chloromethyl silyl chloride (10), $ClCH_2SiH_2Cl$, and chloromethyl silyl bromide (11), $ClCH_2SiH_2Br$, the trans conformer is found to be more stable by 177 ± 35 and 216 ± 22 cm^{-1}, respectively. However, when both Y and X are methyl groups, there is a large difference in conformational stability between YCH_2CH_2X and YCH_2SiH_2X since *n*-butane ($CH_3CH_2CH_2CH_3$) has the trans conformer as the more stable rotamer with a large enthalpy difference of 221 ± 21 cm^{-1} (6) whereas the trans and gauche forms of ethyl methylsilane ($CH_3CH_2SiH_2CH_3$) were initially reported (12) to have nearly the same energy. In our recent temperature-dependent infrared study of ethyl methylsilane in krypton solution (13), we found the trans conformer to be only 20 ± 5 cm^{-1} more stable than the gauche form.

As a continuation of these conformational stability studies, we have now turned our attention to the corresponding germanium compounds for comparison with the carbon and (or) silicon analogues. There is very little conformational data available for these compounds, although ethyl methylgermane, $CH_3CH_2GeH_2CH_3$, has been predicted to have the gauche form as the more stable rotamer (14). Also, we have recently carried out conformational stability studies of ethyl chlorogermane, $CH_3CH_2GeH_2Cl$, from temperature-dependent Fourier transform infrared (FT-IR) spectra of krypton solutions and determined an enthalpy difference of 143 ± 30 cm^{-1} with the gauche conformer the more stable form (15). Because ethyl bromogermane, $CH_3CH_2GeH_2Br$, is an interesting molecule in this series of studies, we have initiated investigations of the temperature dependence of its vibrational spectra. Additionally, we carried out ab initio calculations utilizing the 6-31G(d) basis set at the restricted Hartree–Fock (RHF) and (or) with full electron correlation by the perturbation method (16) to second order (MP2) as well as density functional theory (DFT) calculations by the B3LYP method to determine the optimized structural parameters, harmonic force constants, vibrational wavenumbers, infrared intensities, Raman activities, and conformational stabilities. We also calculated the structural parameters and conformational stabilities utilizing the larger 6-311+G(d,p) and 6-311+G(2d,2p) basis sets at the MP2 level. The results of these vibrational spectroscopic and theoretical studies are reported herein.

Experimental



The sample of ethyl bromogermane was prepared by a two-step reaction. In the first step, ethyl trichlorogermane (Aldrich Chemical Co., Milwaukee, WI) was reacted with lithium aluminum hydride in dry *n*-butyl ether at room temperature. In the second step, the purified sample of ethyl germane was brominated with equivalent amounts of boron tribromide at 0 °C for 20 h. The ethyl bromogermane was first purified by trap-to-trap distillation. Further purification was performed with a low-temperature, low-pressure fractionating column. The purity was checked by recording the mass spectrum and the mid-infrared spectrum of the gas. The sample was stored under vacuum at low temperature.

The mid-infrared spectra of gaseous, amorphous, and annealed solid ethyl bromogermane were recorded with a Perkin-Elmer model 2000 Fourier transform spectrometer equipped with a Ge/CsI beamsplitter and DTGS detector. Atmospheric water vapor was removed from the spectrometer housing by purging with dry nitrogen. The spectrum of the gas was obtained with the sample contained in a 10-cm cell fitted with CsI windows. The spectra of the solids were obtained by depositing the sample onto a CsI substrate held at the temperature of boiling liquid nitrogen, housed in a vacuum cell fitted with CsI windows. The sample was condensed as an amorphous or glassy solid and repeatedly annealed until no further changes were observed in the spectrum (Fig. 1).

The mid-IR spectra of ethyl bromogermane dissolved in liquid krypton (Fig. 2) as a function of temperature were recorded on a Bruker model IFS 66 Fourier transform spectrometer equipped with a globar source, a Ge/KBr beamsplitter, and a DTGS detector. In all cases, 100 interferograms were collected at 1.0 cm^{-1} resolution, averaged, and trans-

formed with a boxcar truncation function. A specially designed cryostat cell was used to obtain the spectral data. It consists of a copper cell with a path length of 4 cm, with wedged silicon windows sealed to the cell with indium gaskets. This cell was cooled with boiling liquid nitrogen, and the temperature was monitored with a Pt thermoresistor. The complete cell was connected to a pressure manifold, allowing the filling and evacuation of the cell. After the cell had cooled to the desired temperature, a small amount of the compound was condensed into the cell. Next, the pressure manifold and the cell were pressurized with the noble gas, which immediately began condensing in the cell, allowing the compound to dissolve.

The Raman spectrum of liquid ethyl bromogermane from 3200 to 100 cm^{-1} (Fig. 3) was recorded on a Spex model 1403 spectrophotometer equipped with a Spectra-Physics model 164 argon-ion laser operating on the 514.5-nm line. Laser power at the sample ranged from 0.4 to 1 W depending on the physical state of the sample, and a bandpass of 3 cm^{-1} was utilized. The spectrum of the liquid was obtained from the sample sealed in a glass capillary with a spherical bulb on the end (17). The reported frequencies are expected to be accurate to ±2 cm^{-1}.

The far-infrared spectra of gaseous and amorphous and annealed solid samples (Fig. 4) were recorded on the Perkin-Elmer 2000 spectrometer described above. A grid beamsplitter and a cryostat cell with polyethylene windows were used to record the spectrum of the solid sample, which was deposited on a silicon substrate at 77 K and subjected to multiple annealings to obtain a good polycrystalline solid. For the spectrum of the gas, the sample was contained in a 10-cm cell equipped with polyethylene windows. The spec-

Fig. 2. tra were recorded at a spectral resolution of 1.0 cm^{-1}. Typically, 256 scans were used for both the sample and reference data to give a satisfactory signal-to-noise ratio. The interferograms were averaged and then transformed with a boxcar truncation function. All observed infrared and Raman bands assigned as fundamentals are listed in Table 1.

Quantum-chemical calculations

LCAO-MO-SCF calculations were performed by using the Gaussian 98 program (18) with the Gaussian-type basis functions. The energy minima with respect to the nuclear coordinates were obtained by the simultaneous relaxation of all the geometric parameters using the gradient method of Pulay (19). DFT calculations utilizing the B3LYP method were also carried out up to the 6-311+G(2d,2p) basis set. The results of these ab initio calculations are listed in Table 2. All calculations except MP2 (full) and DFT calculations with the 6-31+G(d) basis set, both of which gave the trans conformer as the more stable form, predicted the gauche conformer to be more stable. From either MP2 (full) or DFT calculations with large basis sets such as 6-311G(d) or even larger ones, the conformational energy differences vary little, from 112 to 182 cm^{-1} and from 40 to 56 cm^{-1}, respectively, with the basis sets from 6-311G(d) up to 6-311+G(2d,2p). In addition, structural parameters were ob-

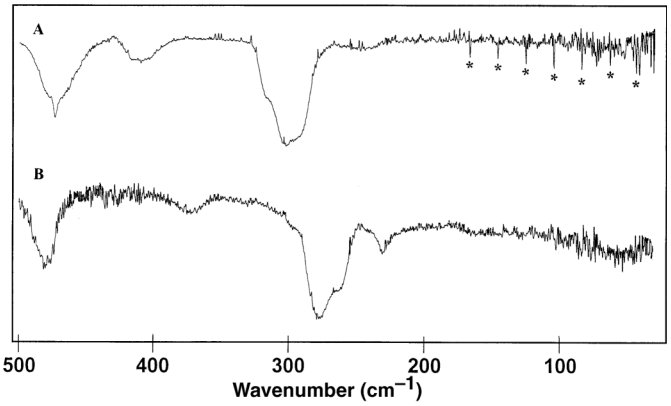

Fig. 3. (A) Raman spectrum of liquid ethyl bromogermane; (B) simulated Raman spectrum of the gauche and trans conformer mixture with ΔH = 158 cm^{-1}; (C) calculated Raman spectrum for the pure gauche conformer; and (D) calculated Raman spectrum for the pure trans conformer.

tained from restricted Hartree–Fock (RHF) calculations with the 6-31G(d) basis set as well as with full electron correlation with Møller–Plesset perturbation at the second order (MP2) with the 6-31G(d), 6-311+G(d,p), and 6-311+G(2d,2p) basis sets. The results of these calculations are listed in Table 3.

For the normal coordinate analysis, the force field in Cartesian coordinates was obtained with the Gaussian 98 program (18) from the MP2/6-31G(d) calculations. The complete set of internal coordinates is shown in Fig. 5, which was used to form the symmetry coordinates listed in Table 4. The **B**-matrix elements were used to convert the ab initio force field in Cartesian coordinates to the force field in the desired internal coordinates (20). The resulting force fields for the *t*rans and gauche conformers are available from the authors. These force fields were used in a mass-weighted Cartesian coordinate calculation to reproduce the ab initio vibrational frequencies and to determine the potential energy distributions (P.E.D.), which are given in Table 1. The diagonal and off-diagonal elements of the force field in internal coordinates were then assigned scaling factors of 0.88 for the CH stretches and 0.9 for the CH bends and heavy-atom stretches; the other coordinates were not scaled. The geometric average was used for the off-diagonal elements. The calculation was repeated to obtain the fixed-scale force field and scaled vibrational frequencies.

Fig. 4. Far-infrared spectra (30 to 500 cm^{-1}) of ethyl bromogermane: (A) gas; (B) annealed solid. Bands marked with an asterisk are due to HCl impurity.

The theoretical Raman (Fig. 3) and infrared spectra (Fig. 2) have been calculated using the scaled wavenumbers, Raman scattering activities, and infrared intensities determined from the MP2/6-31G(d) ab initio calculations. The Raman scattering cross sections, $\partial\sigma_j/\partial\Omega$, which are proportional to the Raman intensities, can be calculated from the scattering activities and the predicted wavenumber for each normal mode (21–24). To obtain the polarized Raman scattering cross sections, the polarizabilities are incorporated into S_j by $S_j[(1 - \rho_j)/(1 + \rho_j)]$, where ρ_j is the depolarization ratio of the *j*th normal mode. The Raman scattering cross sections and calculated frequencies were used, together with a Lorentzian function, to obtain the calculated spectrum. The predicted Raman spectra of the gauche and trans conformers are shown in Figs. 3C and 3D, respectively. Figure 3B is a simulated spectrum of the mixture of the two conformers for the determined ΔH of 158 cm^{-1} (see *Conformational stability* section) with the gauche conformer the more stable rotamer. This spectrum should be compared to the experimental Raman spectrum (Fig. 3A) of the liquid. The calculated spectrum has some differences from the experimental spectrum, especially in the relative intensities of the bands in the low-frequency region. Nevertheless, it provides support for the assignment of the observed bands to the indicated fundamentals to the correct conformers.

Infrared intensities were calculated based on the dipole moment derivatives with respect to the Cartesian coordinates. The derivatives were taken from the ab initio calculations (MP2/6-31G(d)) transformed to normal coordinates by

$$[1] \qquad \left(\frac{\partial \mu_u}{\partial Q_i}\right) = \sum_j \left(\frac{\partial \mu_u}{\partial X_j}\right) L_{ij}$$

where Q_i is the *i*th normal coordinate, X_j is the *j*th Cartesian displacement coordinate, and the L_{ij} are the elements of the transformation matrix between the Cartesian displacement coordinates and normal coordinates.

The predicted infrared spectra of the gauche and trans conformers are shown in Figs. 2C and 2D, respectively, and Fig. 2B is the simulated spectrum of the mixture of the two conformers. The calculated spectrum is in good agreement with the experimental spectrum of the sample dissolved in

krypton (Fig. 2A) with the major differences being in the intensity of the bands located at 976, 743, and 691 cm^{-1}.

Results

Vibrational assignment

The nearly complete vibrational assignment for the gauche conformer and partial assignment for the trans conformer of ethyl bromogermane are listed in Table 1. These assignments are based on the frequencies obtained from the ab initio calculations along with relative intensities and Raman activities. The previous assignment for ethyl chlorogermane (15) was also used in this study since most of the predicted wavenumbers for the fundamentals of ethyl bromogermane and ethyl chlorogermane are nearly the same, particularly for the CH_3 and CH_2 group frequencies. Therefore, only the assignment of the bands that have significantly different frequencies from the corresponding ones of the chloride will be discussed.

In the "fingerprint" region (Fig. 6), six predicted wavenumbers for the gauche conformer (1038, 981, 956, 885, 778, and 700 cm^{-1}) differ significantly from the correspond-

ing predicted ones for the trans conformer (1025, 991, 958, 888, 765, and 749 cm^{-1}), such that these differences should be easily identified in the experimental spectra. The 1050–1000 cm^{-1} portion of the spectrum of the sample in liquid krypton solution (Fig. 7) clearly shows that the band at 1030 cm^{-1} arises from the gauche conformer and that the 1017 cm^{-1} band arises from the trans form. In the region from 800 to 700 cm^{-1}, only three bands located at 773, 762, and 743 cm^{-1} were observed, matching the predicted ones at 778(g), 765(t), and 749(t) cm^{-1}, where g and t in the parentheses indicate the gauche and the trans conformer, respectively. The band at 691 cm^{-1} can undoubtedly be assigned to the predicted band at 700 cm^{-1} from the gauche conformer since this band is so isolated from other bands in the spectrum. For the region from 1000 to 800 cm^{-1}, since the predicted wavenumbers for both conformers are very close and since about 90% of the sample is in the gauche form in the liquid krypton solution (at about –125 °C), the bands observed at 976, 967, and 862 cm^{-1} are only assigned to the predicted frequencies at 981, 956, and 885 cm^{-1} arising from the gauche conformer. The bands below 650 cm^{-1} in the infrared spectrum of the krypton solution are difficult to assign because of the poor signal-to-noise ratio and some decomposition of the sample. However, the infrared spectrum of the amorphous solid and the Raman spectrum of the liquid (Fig. 8) give very clear indication that the bands in the spectrum of the amorphous solid at 641 and 585 cm^{-1} must arise from the gauche conformer and the band of 617 cm^{-1} from the trans form. Also, the bands at 479 and 461 cm^{-1} can confidently be assigned to the GeH_2 rocking (ν_{22}) fundamental from the gauche and trans conformers, respectively.

The assignments for all of the fundamentals in the low-frequency region (below 400 cm^{-1}) cannot be made since the bands for some of these modes have too low intensities to be

[b]Tes energy is relative to Tss and Ges energy is relative to Gss to obtain barriers to methyl rotation for the trans and gauche conformers, respectively.

observed. However, the GeBr stretch (ν_{23}), CH_3 torsion (ν_{24}), and CCGe bend (ν_{25}) can confidently be assigned for both conformers from the infrared spectrum of the gaseous sample or the Raman spectrum of the liquid. The large shift to lower frequency of the GeBr stretch in the condensed phases is similar to what is observed for two similar chlorides (15, 25). The CGeBr bend for the gauche conformer is observed at about 130 cm^{-1} in the Raman spectrum of the liquid, but the corresponding band for the trans conformer was not observed nor were those for the asymmetric torsion for either conformer. However, it is expected that the predicted values for these three modes should be relatively close to the frequencies for these modes.

Conformational stability

Although only a few bands disappeared from the infrared spectrum of the amorphous solid of ethyl bromogermane with annealings (Fig. 9), there was still evidence for the presence of a second conformer in the fluid phases. For example, the bands at 733, 617, and 462 cm^{-1} in the spectrum of the amorphous solid (Fig. 9A), which are assigned to the trans conformer, disappeared in the spectrum of the annealed solid (Fig. 9B). The observed band at 965 cm^{-1} in the spectrum of the amorphous solid (Fig. 9A) is predicted at 958 cm^{-1} for both the trans and gauche conformers, whereas the predicted infrared intensity of this mode is 6.6 km/mol for the trans form, compared with a much smaller value of 2.5 km/mol for the gauche form. Therefore, its intensity decreases significantly in the spectrum of the annealed solid.

From ab initio predicted wavenumbers, several conformer pairs at 1036(g)/1024(t), 752(g)/728(t), 680(g)/739(t), 631(g)/604(t), 592(g)/606(t), and 452(g)/425(t) cm^{-1} can be easily identified. However, many of these bands in the infrared spectrum of the krypton solution are overlapped and some are too weak to obtain accurate intensity measurements so they cannot be used for the conformational stability determinations. The exceptions are the fundamentals at 1030, 1017, 773, 743, and 691 cm^{-1}, which are sufficiently separated from other bands in the spectrum of the krypton solution and also have reasonable intensities that can be confidently used for the determination of the enthalpy difference between the two conformers.

Variable-temperature studies of the krypton solution were carried out to determine the enthalpy difference between the conformers of ethyl bromogermane. Infrared spectral data were collected at 10 different temperatures in the range from –105 to –150 °C. The peak areas of the 1030 cm^{-1} band arising from the gauche rotamer and the 1017 cm^{-1} band arising from the trans form (Fig. 7) were used for the intensity determinations, and the data for this conformer pair (Table 5) were fit to the equation $-\ln K = (\Delta H/RT) - (\Delta S/R)$, where K is the intensity ratio (I_g/I_t) times a constant, ΔS is the entropy change, and it is assumed that ΔH is not a function of temperature over the relatively small temperature range. The slope of the line obtained from a least-squares fit yielded a ΔH value for this conformer pair of 129 ± 8 cm^{-1} with the gauche conformer the more stable form. Additionally, it is very obvious from the spectra in Fig. 7 that as the temperature decreases, the intensity of the 1030 cm^{-1} band assigned to the gauche conformer increases relative to that of the band at 1017 cm^{-1} assigned to the trans form, showing conclusively that the gauche conformer is the more stable rotamer. Similar studies were also carried out for the two other conformer pairs at 773(g)/743(t) and 691(g)/743(t) cm^{-1}, which yielded ΔH values of 224 ± 10 and 118 ± 10 cm^{-1}, respectively, with again the gauche conformer the more stable form. The statistical average of the three ΔH values is 158 ± 11 cm^{-1} (1.89 ± 0.14 kJ/mol).

The above uncertainty value is the statistical uncertainty and does not take into account any underlying overtone or

combination bands. Therefore, a more realistic uncertainty is 10%, which gives a value of 158 ± 16 cm^{-1} (1.89 ± 0.20 kJ/mol) for the enthalpy difference, with the gauche rotamer the more stable form. Thus, at ambient temperature, it is estimated that 81 ± 2% of the sample is in the gauche form.

Discussion

The experimentally determined enthalpy difference between the gauche and trans conformers of ethyl bromogermane is in excellent agreement with the predicted values obtained from the ab initio calculations with full electron correlation at the MP2 level, even with the relatively small 6-31G(d) basis set. In fact, there is only a small change in the predicted energy difference between the conformers in going from the 6-31G(d) basis set to the 6-311+G(2d,2p) basis set (82 vs. 187 functions). Although the experimental ΔH value seems low compared to the relative intensity of the fundamentals for the trans conformer, the ab initio predicted value indicates that the actual value should be within the experimentally indicated error limits.

The asymmetric torsional potential has been predicted from the ab initio calculations. Beginning at the minimum

for the trans conformer at zero, a potential function was initially determined by first calculating the energy every 30° with optimization of the structural parameters at each point from the MP2/6-31G(d) calculations. Both the minima and the maxima were determined with optimization, and the resulting potential function is shown as a dashed line in Fig. 10. With this basis set, the energy difference is 188 cm^{-1} between the more stable gauche conformer and the trans form. The torsional potential is represented as a Fourier cosine series in the internal angle (ϕ):

$$[2] \qquad V(\phi) = \sum_{i=1}^{6} (V_i/2)(1 - \cos i\phi)$$

The values for the potential terms V_1~V_4 and V_6 are presented in Table 6; the V_5 term is negligible. For this potential, the dihedral angle, CCGeBr, is 61.3°, and the gauche-to-gauche barrier of 924 cm^{-1} is much larger than the trans-to-gauche barrier of 560 cm^{-1} (Fig. 10). The potential function was also obtained from DFT calculations by the B3LYP method with the same basis set. Because the energy difference between the two conformers is much larger (292 cm^{-1}) in this case, the V_1 term is very small (–11 cm^{-1}) and the V_3 term is also much smaller (595 cm^{-1}) than the value obtained for the first potential. Also, the gauche-to-gauche barrier is predicted to be 771 cm^{-1} with a similarly smaller trans-to-gauche barrier of 418 cm^{-1}. This potential is also shown in Fig. 10 (solid line), and it is expected to be closer to the actual one since the predicted energy difference from the B3LYP calculations is closer to the experimentally determined ΔH value than that from the MP2 calculations.

Table 4. Symmetry coordinates for ethyl bromogermane.

Description	Symmetry coordinate
CH_3 antisymmetric stretch	$S_1 = r_9 - r_{10}$
CH_3 antisymmetric stretch	$S_2 = 2r_8 - r_9 - r_{10}$
CH_2 antisymmetric stretch	$S_3 = r_6 - r_7$
CH_2 symmetric stretch	$S_4 = r_6 + r_7$
CH_3 symmetric stretch	$S_5 = r_8 + r_9 + r_{10}$
GeH_2 antisymmetric stretch	$S_6 = r_4 - r_5$
GeH_2 symmetric stretch	$S_7 = r_4 + r_5$
CH_3 antisymmetric deformation	$S_8 = \alpha_1 - \alpha_3$
CH_3 antisymmetric deformation	$S_9 = 2\alpha_2 - \alpha_1 - \alpha_3$
CH_2 deformation	$S_{10} = 4\gamma - \phi_1 - \phi_2 - \delta_2 - \delta_1$
CH_3 symmetric deformation	$S_{11} = \alpha_1 + \alpha_2 + \alpha_3 - \varepsilon_1 - \varepsilon_2 - \varepsilon_3$
CH_2 wag	$S_{12} = \phi_1 + \phi_2 - \delta_1 - \delta_2$
CH_2 twist	$S_{13} = \phi_1 - \phi_2 - \delta_2 + \delta_1$
CC stretch	$S_{14} = R$
CH_3 rock	$S_{15} = \varepsilon_3 - \varepsilon_2$
CH_3 rock	$S_16 = 2\,\varepsilon_1 - \varepsilon_2 - \varepsilon_3$
GeH_2 deformation	$S_{17} = 4\beta - \varphi_1 - \varphi_2 - \eta_2 - \eta_1$
GeH_2 wag	$S_{18} = \varphi_1 + \varphi_2 - \eta_2 - \eta_1$
CH_2 rock	$S_{19} = \phi_1 - \phi_2 + \delta_2 - \delta_1$
GeH_2 twist	$S_{20} = \varphi_1 - \varphi_2 - \eta_2 + \eta_1$
CGe stretch	$S_{21} = Q$
GeH_2 rock	$S_{22} = \varphi_1 - \varphi_2 + \eta_2 - \eta_1$
GeBr stretch	$S_{23} = P$
CH_3 torsion	$S_{24} = \tau_1$
CCGe bend	$S_{25} = \omega_1$
CGeBr bend	$S_{26} = \omega_2$
Antisymmetric torsion	$S_{27} = \tau_2$

Note: Symmetry coordinates are not normalized. The symmetry coordinates S_1, S_3, S_6, S_8, S_{13}, S_{15}, S_{19}, S_{20}, S_{22}, S_{24}, and S_{27} are A′′ modes for the trans conformer.

The barrier to methyl rotation has been predicted from MP2(full)/6-31G(d) and B3LYP/6-31G(d) calculations for both conformers, and the values from the MP2 calculations are about 100 cm^{-1} higher than those from the B3LYP results. Also, there is only a minor difference between the barriers for the two conformers, with the one of 1204 cm^{-1} for the gauche rotamer from the MP2 calculations being 13 cm^{-1} higher than that for the trans form from the same calculations whereas the B3LYP predictions indicate that the barrier for the gauche conformer is 6 cm^{-1} lower than that for the trans form (Table 2). The torsional mode was observed at 262 cm^{-1} in the infrared spectrum of the solid for the gauche form, but the P.E.D. indicates that this mode is only 42% torsion with contributions of 31% from the Ge–Br stretch and 16% from the CCGe bend. Thus, the barrier of 1412 cm^{-1} predicted from this frequency is considerably higher than the predicted value from the MP2 calculation, which is probably closer to the actual value.

The mixing of the symmetry coordinates for the gauche conformer is not as extensive as one might expect for a molecule with no symmetry. The heavy mass of the germanium

atom reduces significantly the mixing of the Ge–H bends with the C–H bends of the ethyl moiety except for the CH_2 rock and GeH_2 wag, which are heavily mixed. The mixing is even slightly less for the trans conformer, with more mixing of the CH_2 and CH_3 bending modes, which is probably due to the symmetry plane.

There is little difference in the ab initio predicted structural parameters for the two conformers. The only significant bond distance difference is that for the Ge—Br bond, which is predicted to be ~0.003 Å shorter for the trans conformer compared to the corresponding distance in the gauche form. The significant angle differences for the heavy atoms are those for the BrGeC angle, which is predicted to be 1.1° larger for the trans conformer, and the CCGe angle, which is predicted to be 1.3° smaller for the trans conformer compared to the corresponding angles for the gauche rotamer. These changes then result in the H_5GeC_2 angle being predicted to be 1.1° larger in the gauche conformer than the corresponding angle for the trans form. These angle differences then cause several of the force constants to have

significantly different values. For example, the force constants for the deformations of the CGeBr, CCGe, $CGeH_6$, CCH_8, $BrGeH_5$, and $BrGeH_6$ angles are larger by 26.2, 19.0, 1.8, 2.4, 2.2, and 6.1%, respectively, for the gauche conformer compared to those for the trans rotamer, whereas the force constants for the deformations of the $CGeH_5$ and HGeH angles are larger by 3.5 and 2.2%, respectively, for the trans conformer. These differences produce some notable differences in the predicted frequencies for the normal modes associated with the motions involving the corresponding atom displacements.

Using two scaling factors of 0.88 for the CH stretches and 0.90 for the CH bends and heavy-atom stretches, the wavenumbers for the fundamentals predicted from the MP2/6-

gauche dihedral angle $\tau(C_1C_2Ge_3Br_4)$	62.7°	61.3°

31G(d) calculations are in good agreement with the observed values. The average error in the frequency predictions for the normal modes is 13.3 cm^{-1} for the gauche conformer, which represents an average 1.0% error. Thus, these two scaling factors are sufficient to predict the wavenumbers for the observed fundamentals for this type of organogermane molecule, and these predictions then can be used for making vibrational assignments and identifying the correct modes for two different conformers.

The structural parameters obtained from the MP2/6-311+G(d,p) calculations predict the r_0 values for hydrocarbons with a bromine atom very well (26), as do those for many silanes (27–30). Therefore, it is expected that the predicted bond distances from the MP2/6-311+G(d,p) calculations for ethyl bromogermane should be within 0.005 Å of the actual values, except for the Ge–Br distance, which is expected to be predicted too long, as well as possibly the Ge–H distance. For example, the ab initio MP2/6-311+G(d,p) predictions for Si–H distances are too long by 0.007 Å compared to values obtained for this distance from isolated Si–H stretching frequencies (31). Similarly, the predicted angles are expected to be within one-half of a degree of the actual angles, with the exception of the gauche dihedral angle.

To evaluate how well the ab initio MP2/6-311+G(d,p) calculations predict the Ge–H and Ge–Br distances, we carried out structural calculations for some organogermanes for which these parameters are known. For example, the Ge–H distance of germane, GeH_4, was calculated, and the predicted value of 1.517 Å is smaller by 0.008 Å than the experimentally determined value (32) of 1.5251 ± 0.0005 Å (Table 7). As a check, similar calculations were also carried out for methyl germane, CH_3GeH_3 (15). This molecule is a symmetric top, and the initial structural parameters obtained from a microwave study (33) have larger error limits than indicated based on the distances obtained (34) from the frequencies of the "isolated" C–H and Ge–H stretching vibrations. In the latter study (34), the authors pointed out the problem with the parameters previously proposed for methyl germane, particularly the r_s parameter of 1.083 Å for the C–H distance, which was the preferred value (33). The ab initio predictions (15) from the MP2/6-311+G(d,p) calculations agreed reasonably well with the new proposed parameters (34). The predicted Ge–H distance is too short by 0.006 Å and the two angles are too small by 0.3°, but the predicted Ge–C distance of 1.949 Å is the same as the experimental value (34) of 1.949(1) Å. However, a similar prediction for this parameter (Ge–C distance) for ethyl germane (15) gave a value of 1.955 Å compared to an experimental value of 1.959(5) Å, which may indicate that the predicted value is a little short.

Therefore, we have carried out a determination of the adjusted r_0 parameters for methyl bromogermane, CH_3GeH_2Br, using a new program that we developed in this laboratory (35) by combining the previously reported microwave data

of the values of the rotational constants for several isotopomers (36) and the ab initio predicted parameters. This A&M program fits the rotational constants, with the structural parameters remaining close to the ab initio values. To reduce the number of independent variables, the structural parameters are separated into sets according to their type. Each set uses only one independent parameter in the optimization, and all structural parameters in one set are adjusted by the same adjustment factor. The differences between similar parameters in one set are adjusted by the same adjustment factor. The differences between similar parameters from the ab initio calculations are retained in the final results. Bond lengths in the same set keep their relative ratio in distances, and bond angles and torsional angles in the same set keep their differences in degrees. This assumption is based on the fact that errors from ab initio calculations are systematic.

Among the structural parameters for methyl bromogermane, the major questionable ones are the C–H distances of 1.100 ± 0.012 Å (C–H_s) and 1.097 ± 0.030 Å (C–H_a), which have extremely large uncertainties, and possibly the Ge–C distance of 1.933(2) Å, which seems a little short compared to this distance in methyl germane and ethyl germane (15). We have utilized the rotational constants (36) for the six isotopomers, which include ^{70}Ge, ^{72}Ge, and ^{74}Ge, ^{12}C, and ^{79}Br and ^{81}Br, along with the predicted parameters from the ab initio MP2/6-311+G(d,p) calculation. The fit of 21 of these rotational constants by the adjustment of the ab initio parameters is shown in Table 8, with all of the *B* and *C* rotational constants fit to less than one-tenth of a megahertz. There was a very large uncertainty for the *A* rotational constants (average uncertainty of 3.8 MHz) since only a-type transitions were assigned and their observed frequencies are not very dependent on the *A* rotational constant. Nevertheless, the differences between the experimental and predicted values are well within the expected uncertainties of these constants. The adjusted r_0 parameters, which are listed in Table 7, have C–H distances with normal values of 1.091 (in-plane) and 1.093 Å (out-of-plane) and a Ge–H distance of 1.520 Å. The Ge–Br distance is only slightly smaller than the previously reported value (36). We believe the C–H and Ge–H distances should not be in error by more than 0.002 and 0.003 Å, respectively, and the heavy-atom distances by 0.003 Å, with estimated error limits on the angles of 0.5°.

We have evaluated the ab initio predicted value for the Ge–Br distance using the germyl bromide molecule, for which the distances have been reported (37). From this calculation, the Ge–Br distance is predicted too long by 0.015 Å, and the Ge–H distance too short by 0.008 Å. All of these data indicated that the ab initio MP2/6-311+G(d,p) predictions for the Ge–H bond distances should be slightly too

short (0.005 Å) for this bond whereas the Ge–Br distances will be significantly longer (0.015 Å) than the actual distance.

We have predicted the r_0 structural parameters for ethyl bromogermane by decreasing the Ge–Br distance by 0.015 Å from the predicted value from the MP2/6-311+G(d,p) calculations. The Ge–H distances are increased by 0.004 Å whereas the remaining parameters are the same as the predicted values. Therefore, a microwave study of ethyl bromogermane would be of interest to determine the Ge–Br bond distance as well as the other structural parameters to evaluate the quality of the MP2/6-311+G(d,p) ab initio predictions for this organobromogermane molecule. Since at ambient temperature 19 ± 2% of the sample is predicted to be the trans conformer, it should be possible to assign the microwave spectra for both conformers.

Temporal evolution of an ultrathin, noncrystalline ice deposit at crystallization near 160 K studied by FT-IR reflection–absorption spectroscopy[1]

S. Mitlin and K.T. Leung

Abstract: The temporal evolution of the OH stretching modes of a noncrystalline ice deposit upon annealing followed by crystallization near 160 K has been investigated by FT-IR reflection–absorption spectroscopy. Using the earlier theoretical results from Whalley (E. Whalley. Can. J. Chem. **55**, 3429 (1977)) and from Buch and Devlin (V. Buch and J.P. Devlin. J. Chem. Phys. **110**, 3437 (1999)), the most prominent changes in these modes have been characterized for the first time. A dynamical picture of the structural transformation during crystallization has been developed, and it supports the observation that crystallization proceeds directly from a noncrystalline to a crystalline state without any long-lived intermediate state structurally different from its noncrystalline predecessor.

Key words: crystallization, noncrystalline ice, FT-IR reflection–absorption spectroscopy, temporary evolution.

Résumé : Faisant appel à la spectroscopie de réflexion–absorption infrarouge à transformée de Fourier, on a étudié l'évolution en fonction du temps des modes d'élongation OH d'un dépôt de glace non cristalline soumise à un réchauffement puis à une cristallisation près de 160 K. Utilisant des résultats théoriques antérieurs de Whalley (E. Whalley. Can. J. Chem. **55**, 3429 (1977)) et d'autres de Buch et Devlin (V. Buch et J.P. Devlin. J. Chem. Phys. **110**, 3437 (1999)), on a pu caractériser les changements les plus importants dans ces modes pour la première fois. On a développé une image dynamique de la transformation de structure au cours de la cristallisation et elle est en accord avec l'observation que la cristallisation procède directement d'un état non cristallin à un état cristallin sans l'intermédiaire d'un état de longue durée qui serait différent d'un point de vue structural de son prédécesseur non cristallin.

Mots clés : cristallisation, glace non cristalline, spectroscopie de réflexion–absorption infrarouge à transformée de Fourier, évolution en fonction du temps.

[Traduit par la Rédaction]

Introduction

At cryogenic temperature, water medium exhibits both crystalline form, such as cubic Ic and hexagonal Ih arrangements, and noncrystalline (nc) form. For the nc-ice form, a number of distinct polyamorphs can be generally classified according to their density: the high-density amorph (HDA) with density $\rho > 1.1$ g cm^{-3} and the low-density amorph (LDA) with $\rho \sim 0.94$ g cm^{-3} (1–4). Physico-chemical properties of these two types of polyamorphs are known to be quite different, which suggests qualitative differences in the packing arrangements in their intrinsic local structures and in the arrangements of the network of hydrogen bonds (5). Using elastic neutron diffraction, Finney et al. (5) found structural similarities between the LDA and hexagonal ice and between HDA and liquid water. Furthermore, the observable bulk and surface properties of a particular nc-ice sample appear to depend critically on the preparation method and the post-growth history, as expected for the metastable states that are structurally unrelaxed. In particular, the inelastic neutron scattering measurements by Kolesnikov et al. (6) confirmed the dependence of the local structure of the LDA ice on the preparation method. Computer simulations (7–10) revealed that the LDA could exhibit a fractal structure with a large variation in the local density. However, the characteristic size of the intrinsic "building block" (or molecular cluster) of the fractal structure remains unknown.

The morphology of the nc-ice medium has also been found to depend on the preparation technique. In particular, by varying the direction of the incident (water) molecular beam, Stevenson at al. (11) observed a systematic change in the morphology of the vapour-deposited LDA ice films, which could accommodate nitrogen as much as 2700 m^2 g^{-1} at 22 K and 640 m^2 g^{-1} at 77 K, if prepared at glancing incidence. Large uptakes of argon and methane by the LDA ice films have also been reported recently by Dohlanek et al. (12), which similarly suggests the presence of a fractal, grassy-like structure for the low-temperature vapour-deposit, in agreement with the earlier studies of Mayer and Pletzer (13) and Laufer et al. (14) that support a morphologically porous medium for the LDA. As expected for fractal behaviour, the LDA appears to exhibit recurrent features on different length scales, from ~10 Å for a typical cluster size in the

hydrogen-bonding network (8) to larger though yet-to-be-determined nanopores (13, 15), and to much larger mesoscopic features (14).

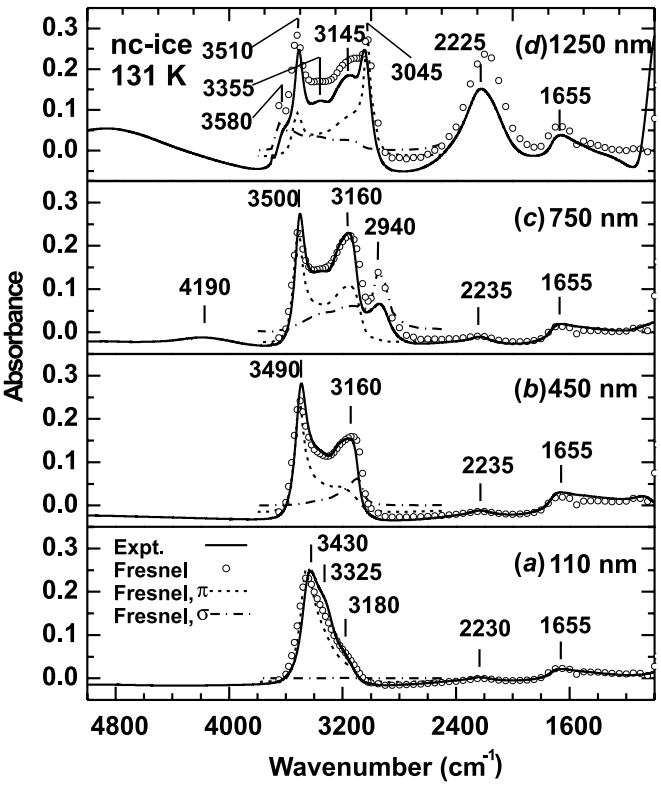
Crystallization of a LDA medium has been found to occur abruptly at a rapid rate over a narrow temperature range above 150 K (16). At a lower temperature, crystallization is too slow to be observed at a laboratory timescale, in spite of the metastable nature of nc ice with respect to its crystalline polymorphs. However, internal motions in these nc-ice structures have clearly been discernible below 130 K. In particular, on annealing thick LDA ice films vapour-deposited at 77 K, Hallbruker et al. (17) observed a rapid reduction in the surface area from several hundreds to 40 $m^2\ g^{-1}$ at 113 K, which was interpreted as the result of the collapse of micropores accompanied by significant exothermic effects. By hyperquenching the micrometer-sized water droplets at 140 K, Kohl et al. (16) were able to obtain LDA samples that exhibit no exothermic effects upon a small anneal, which leads us to suggest that just above the expected glass-to-liquid transition temperature, the hyperquenched nc-ice samples become substantially more homogeneous though remain primarily noncrystalline. By measuring the time dependence of the OH dangling-bond signal of vapour-deposited nc-ice films by FT-IR reflection–absorption spectroscopy (FT-IR–RAS), Zondlo et al. (18) showed that the collapse of the micropores occurs rapidly on a timescale of 10^3–10^4 s at a temperature as low as 105 K, indicative of plausible structural relaxation. By measuring the isotope intermixing, Smith and Kay (19) and Smith et al. (20) found the self-diffusion coefficient ($1 \times 10^{-16} - 1 \times 10^{-13}\ cm^2\ s^{-1}$) in the temperature range of 146–155 K for nc-ice films to be substantially larger than that of crystalline films. Furthermore, they also determined the apparent Arrhenius activation energy for diffusion in a crystalline film to be 14 kcal mol^{-1} and that in an amorphous film to be as high as 41 kcal mol^{-1}. These observations led them to favour the existence of supercooled liquid domains in the temperature range of 145–155 K, which lies between the onset of plausible glass-to-liquid transition in the LDA (135 K) (17) and the onset of crystallization (160 K). Thermal desorption studies by Dohnalek et al. (21, 22) revealed the difference in the desorption spectra of N_2 from the surfaces of nc- and crystalline-ice films and the dependence of the desorption spectra on the annealing history of the pore-less nc-ice films, both of which have been used to follow the crystallization kinetics. The crystallization of thin (15–150 bilayers) nc-ice films deposited on Pt (111) and on smooth crystalline ice films was found to be consistent with bulk nucleation and three-dimensional growth of the crystalline phase, except for very thin amorphous deposits on the crystalline-ice film that was found to crystallize by a two-dimensional substrate-induced growth mechanism. These studies appear to be in accord with the direct transformation of solid amorph to ice crystallites without the formation of an intermediate liquid-like amorphous state (22). In an earlier calorimetric work, MacFarlane and Angell (23) argued that the glass-to-liquid transition in nc ice should be above the crystallization onset at 160 K, because given the very large nucleation rate for water, the driving force towards crystallization (being proportional to the difference between the homogeneous nucleation temperature and the glass-to-liquid transition temperature) should be sufficiently large. In more recent studies, Velikov et al. (24) further argued that the glass-to-liquid transition should be above the onset of crystallization and have estimated the former transition temperature to be 165 K.

To date, there has been no direct spectral evidence for the presence of the glass-to-liquid transition before the onset of crystallization, although it is possible that no spectral difference in the OH stretching modes exist between the glass amorphous and liquid-like amorphous states. The present work examines the spectral evolution of the relevant OH stretching modes before and during crystallization of an nc-ice film by using FT-IR–RAS, with the goal to not only assign these spectral features with the vibrational modes in nc and polycrystalline (pc) ice films, but also correlate the spectral changes to the structural evolution.

Experimental details

The details of the experimental setup and procedures have been described elsewhere (25). Briefly, the FT-IR–RAS experiments were conducted in an ultrahigh vacuum (UHV) chamber evacuated to a base pressure better than 3×10^{-9} torr (1 torr = 133.322 4 Pa). Ice films were grown by water vapour deposition on an optically flat polycrystalline copper disk mounted on a four-motion manipulator. The copper substrate could be cooled to 120 K or annealed to a preset temperature (up to 400 K) by a resistance heater attached to the backside of the substrate. The substrate temperature was monitored by two K-type thermocouples separately fastened to the front surface of the copper disk, with the accuracy of the temperature measurement of ±1 K. Deposition of the ice films was performed by backfilling of the UHV chamber with vapours of H_2O (Millipore) or of D_2O (Isotech) with a small fraction of HDO by a variable leak valve. The liquid water samples were thoroughly degassed by several freeze–pump–thaw cycles prior to use. The deposition pressure was measured by an uncalibrated ionization gauge and held at 1×10^{-6} torr (1 torr = 133.322 4 Pa) unless stated otherwise.

The IR beam from a FT-IR spectrometer (Bruker Equinox 55) was directed to the target surface at ~83° from the surface normal by two external mirrors. The specularly reflected light was collected by another external focusing mirror positioned on the opposite side of chamber, and focused onto a mercury–cadmium–telluride detector. The entire optical path was purged with dry N_2 gas. Spectral data are represented in units of absorbance defined as $A = -\log(R/R_0)$, where R/R_0 is the ratio of reflectances with and without the ice film. In an attempt to elucidate the nature of the observed spectral changes with increasing film thickness, the Fresnel method applied to a triple-layer (vacuum–ice–metal) stratified medium (18, 26, 27) was used to simulate the FT-IR–RA spectra using optical constants for pc and nc ice available in the literature (28, 29). Details of our computational procedure have been given in our earlier work (25).



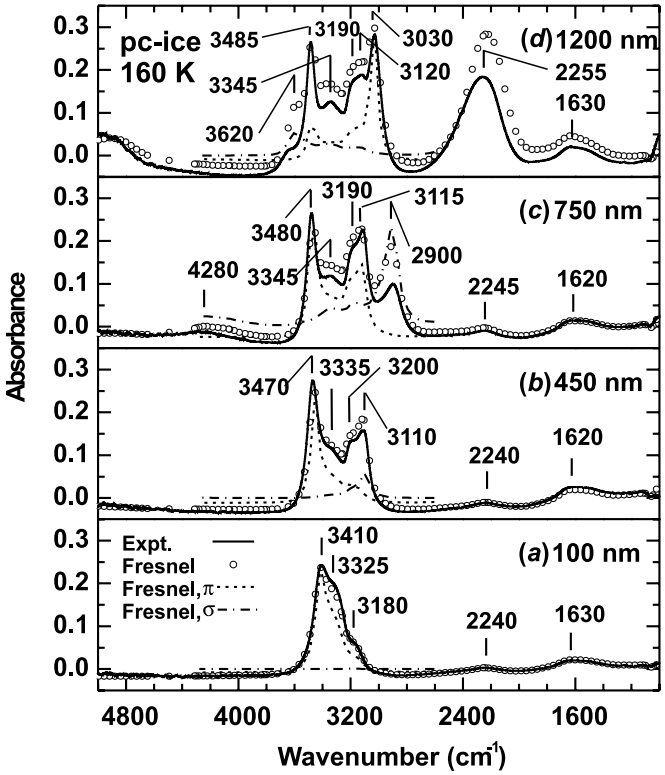
Results and discussion

The growth of pc- and nc-ice films by vapour deposition has been studied by FT-IR–RAS over a range of film thick-

© 2004 NRC Canada

ness from 10 to 1500 nm. In accord with earlier results (18, 25, 30), there are two established optical effects associated with the reflection–absorption of IR light in a stratified ice medium: (*i*) blue shift and profile deformation of the OH stretch (the strongest RA band in the ice spectrum) with respect to that obtained in the transmission mode, and (*ii*) optical interference in the smooth films. There is generally good agreement between the experimental spectra and the simulated Fresnel spectra of ice films for a wide range of thickness from 50 to 1500 nm. However, there are other possible spectral effects associated with the particle size and shape of the ice medium and with scattering from a rough film–vacuum interface, which are more difficult to characterize. These effects could become dominant in the present cases of interest, i.e., the early stage of deposition and during annealing and crystallization. The spectral effects associated with the size and shape of the constituent particles in the absorbing medium were investigated theoretically for finite-sized ionic crystals by Englman and Ruppin (31) and experimentally demonstrated for KCl films and crystals by Martin (32). Later, Buch and Devlin (33) provided a spectral simulation of the crystalline ice in the forms of a sphere and a slab, and illustrated that the OH stretching band strongly depends on not only the polarization of the light but also the shape of the absorbing medium. Following the theoretical treatment of Buch and Devlin (33) and the earlier spectral assignment of the OH stretch features by Whalley (34), we provide a detailed interpretation of the experimentally observed RA features of the OH band at the early stage of pc-ice formation and during crystallization of an ultrathin nc-ice deposit.

Fig. 1. Comparison of experimental FT-IR–RA spectra of noncrystalline (nc) ice films obtained by vapour deposition at 131 K for (*a*) 3.5 min, (*b*) 20.5 min, (*c*) 33.5 min at 1×10^{-6} torr, and (*d*) 11 min at 5×10^{-6} torr (1 torr = 133.322 4 Pa) with the corresponding Fresnel spectra for non-polarized light and their σ- and π-polarized components (arbitrarily normalized) involving 110, 450, 750, and 1200 nm thick films, respectively.



FT-IR–RA spectral features of the noncrystalline and polycrystalline ice in the Fresnel regime (for over 50 nm thick films)

Figure 1 shows typical spectra of nc-ice films obtained by water vapour deposition at 1×10^{-6} torr (1 torr = 133.322 4 Pa) with the copper substrate held at 131 K as a function of film thickness. The features near 1655 and 2230 cm^{-1} (Fig. 1*a*) can be assigned as the OH bending band (ν_2) with contribution from the first overtone ($2\nu_R$) of the hindered rotational lattice mode (ν_R), and as the combination band ($\nu_2 + \nu_R$) of the OH bending and hindered rotation modes, respectively, (35, 36, 37). These features remain essentially in the same peak positions with increasing film thickness. Furthermore, three relatively "stationary" (ν_1, ν_3) OH stretch features at 3490–3510 cm^{-1} (band maximum), 3355 cm^{-1}, and 3160–3145 cm^{-1} can be resolved for film thickness greater than 450 nm (Figs. 1*b*–1*d*). For film thickness below 250 nm, the shape of the (ν_1, ν_3) OH stretching band is predominantly determined by reflection–absorption of the π-polarized component of the incident light (Fig. 1*a*), with negligible contribution from the σ-polarized component. For film thickness greater than 250 nm, the σ-polarized component is generally found to strengthen with the emergence of an interference feature traveling from 3160 cm^{-1} at 450 nm (Fig. 1*b*) to 2940 cm^{-1} at 750 nm (Fig. 1*c*) and to 2225 cm^{-1} at 1250 nm (Fig. 1*d*). Another σ-polarized interference feature near 4190 cm^{-1} for film thickness of 750 nm (Fig. 1*c*) is also seen to travel to 3580 cm^{-1} for the 1250 nm thick film (Fig. 1*d*). It is evident that the π-polarized component also contributes prominently to the three aforementioned stationary OH stretch features over the film thickness range covered in Fig. 1. The movement of the main π-polarized feature (near 3430 cm^{-1} for the 110 nm thick film in Fig. 1*a*) to a higher frequency with increasing film thickness gives rise to the observed blue shift of the band maximum. This shift is therefore related to the physics of reflection–absorption of IR light and not to any possible structural change in the nc-ice network as a result of an increase in the film thickness. For thicker films, the π-polarized interference feature observed at 3160 cm^{-1} for the 750 nm thick film (Fig. 1*c*) is also found to travel to a lower frequency with increasing film thickness, e.g., 3045 cm^{-1} for the 1250 nm thick film (Fig. 1*d*).

Figure 2 demonstrates typical spectral evolution of pc-ice films obtained by water vapour deposition at 1×10^{-6} torr (1 torr = 133.322 4 Pa) with the substrate held at 160 K as a function of film thickness. Evidently, three major absorption features related to the vibrational modes of the water molecules in the pc-ice film are also observed: the OH stretching band (ν_1, ν_3) at 3410 cm^{-1}, the first overtone ($2\nu_R$) of the hindered rotational lattice mode ($\nu_R \approx 850$ cm^{-1} (35, 36)) at 1630 cm^{-1} with higher-frequency contribution from the OH bending band (ν_2), and the ($\nu_2 + \nu_R$) combination band and (or) the $3\nu_R$ second overtone at 2240 cm^{-1} (Fig. 2*a*) (36, 37). There is also generally good accord between the experimen-

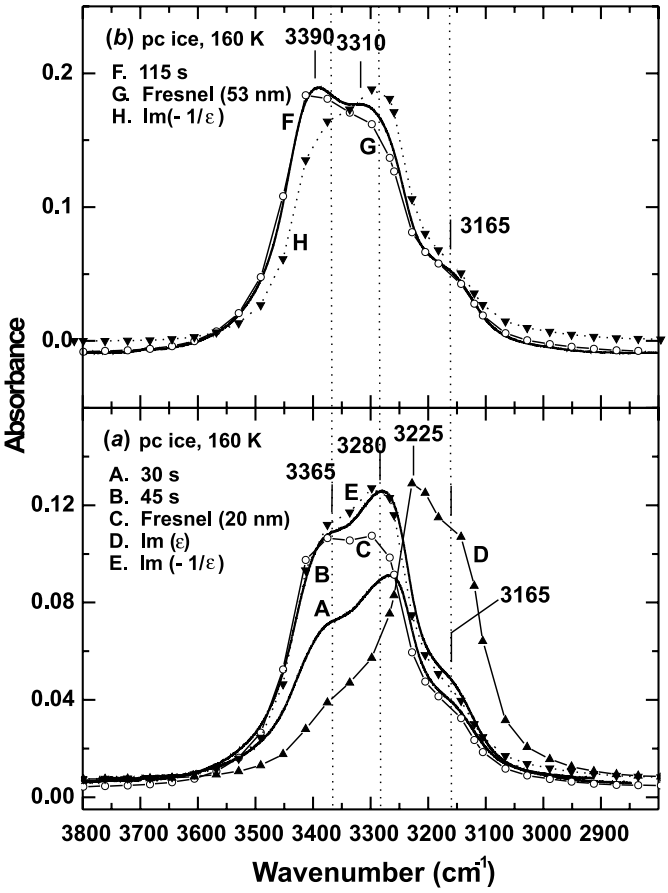
Fig. 2. Comparison of experimental FT-IR–RA spectra of polycrystalline (pc) ice films obtained by vapour deposition at 160 K and 1 × 10^{-6} torr (1 torr = 133.322 4 Pa) for (*a*) 3.5 min, (*b*) 20 min, (*c*) 33.5 min, and (*d*) 52.5 min with the corresponding Fresnel spectra for non-polarized light and their σ- and π-polarized components (arbitrarily normalized) involving 100, 450, 750, and 1200 nm thick films, respectively.

tal spectrum and the corresponding Fresnel spectrum of a pc-ice film for all the film thicknesses depicted in Fig. 2. As with nc-ice films, the residual, non-vibration-related spectral features of the thicker (>100 nm) pc-ice films can be attributed to the σ- and π-polarized IR interference patterns, which are well approximated by the σ- and π-components of the corresponding Fresnel spectra. In particular, the low-frequency shoulder of the σ-polarized profile is seen to travel from 3110 cm^{-1} for the 450 nm thick film (Fig. 2*b*) to 2900 cm^{-1} for the 750 nm thick film (Fig. 2*c*), which evidently contributes to the corresponding features at 3110 and 2900 cm^{-1} in the respective experimental spectra. Further increase in the film thickness to 1200 nm causes the σ-polarized feature to move towards the lower frequency, giving rise to the strong enhancement of the spectral intensity at 2255 cm^{-1} (Fig. 2*d*). Furthermore, a second σ-polarized feature near 4280 cm^{-1} appearing in the spectrum for the 750 nm thick film (Fig. 2*c*) is also found to migrate to 3620 cm^{-1} for the 1200 nm thick film (Fig. 2*d*). Similar interference peak movement is also evident for the π-polarized feature at 3115 cm^{-1} for the 750 nm thick film (Fig. 2*c*), which travels to 3030 cm^{-1} as the film thickness is increased to 1200 nm (Fig. 2*d*). The evolution of the underlying σ- and π-polarized Fresnel contributions to the overall spectrum of pc ice with increasing film thickness (Fig. 2) is therefore similar to that found for the nc ice (Fig. 1). The observed movements of the destructive interference peaks generally reflect the quality of film uniformity obtainable for pc ice by vapour deposition.

Spectral characterization of the OH (OD) stretch manifold of an ultrathin (<50 nm) polycrystalline ice deposit



By using proton-ordered and disordered Ic and Ih ice models, Buch and Devlin (33) made use of four oscillating dipoles tetrahedrally arranged around a central O atom as the basis to calculate the OH stretching band. They attributed the central peak of the OH stretching band at 3220 cm^{-1} to the zero wave-vector modes of two transversal (TO) branches and a longitudinal (LO) branch (which corresponds to two dipoles moving "in" with the other two diploes moving "out" in a way that correlates with the asymmetric stretching character of the ν_3 molecular mode of an isolated water molecule). The asymmetric ν_3 character of the OH central peak is in agreement with the spectral assignment made by Whalley (34). The shoulder located at the lower-frequency side of the central peak appears to originate from the transversal modes strongly perturbed by intramolecular interactions and was therefore attributed to the in-phase ν_1 TO branch by Buch and Devlin (33), again in accord with Whalley's earlier assignment (34). The state with the lowest OH stretch frequency corresponds to the globally in-phase ν_1 vibration, which dominates in the Raman spectra obtained with parallel polarization (38). In the higher-frequency region of the OH stretching band, an intermediate branch (i.e., one that exhibits no systematic variation in the angle between the dipole moment of the lattice and the wave-vector) and nonzero wave-vector modes of the aforementioned longitudinal branch were found (33). Originated from the higher-frequency out-of-phase ν_1 vibration of the four dipoles surrounding the O atom, the intermediate branch was characterized by a small dipole moment near the center of the Brillouin zone, in marked contrast to the longitudinal modes (with origin from the ν_3 molecular vibration), which carry a significant dipole moment over the entire Brillouin zone (33).

Buch and Devlin (33) further demonstrated that the OH stretch absorption band can be strongly affected by the shape of the ice medium and by the polarization of the electric field. In particular, in the case of an ice slab, the modes of the higher-frequency intermediate and longitudinal branches are stimulated with surface-perpendicular polarization, while the lower-frequency transversal modes of the ν_1 branch are preferentially excited with surface-parallel polarization. The dependence of the absorption spectra on the shape is caused by the long-range dipole–dipole interaction, which was found to include a shape-dependent component associated with the surface polarization charge (39). The oscillating surface charge creates an electric field inside the sample that changes the energy gap between the ground and excited vibrational levels (39), and consequently the corresponding vibrational frequencies become shape-dependent. However, the shape-dependent effect predicted by the model was found to be considerably stronger than that observed experimentally (33). This discrepancy was attributed to a limitation on the spatial extent of the vibrational excited states imposed by the imperfections in the pc-ice medium.

© 2004 NRC Canada

The Buch–Devlin simulation of IR absorption by an ice slab for the surface-perpendicular polarization (33) could be directly compared with the experimental RA spectra of ultrathin ice films on a metal surface at grazing-angle illumination with π-polarized or nonpolarized light. Upon reflection on a highly conductive metal, the σ-polarized component of the incident electric field is almost completely eliminated near its surface and only the π-polarized component of the electric field remains, which provides the physical justification for comparing the experimental RA spectra with the simulated spectrum for excitation of an ice slab by just the (surface-perpendicular) π polarization. In particular, the Buch–Devlin model (33) predicts that the absorption spectra of the ice slab for the surface-perpendicular polarization are primarily originated from excitation of the intermediate and ν_3 LO branches, of which the former is of a higher frequency. Figure 3 compares our experimental RA spectra of the OH stretching band obtained for ultrathin pc-ice deposits (with an estimated thickness below 50 nm) with the corresponding Fresnel spectra and with the Berreman and transmission profiles (40) (arbitrarily normalized to the band maxima of the respective experimental spectra). The Berreman profile corresponds to the energy loss function defined as $\mathrm{Im}(-\varepsilon^{-1}) = \varepsilon''/(\varepsilon'^2 + \varepsilon''^2)$, where the dielectric function $\varepsilon = \varepsilon' - i\varepsilon''$ (with its real ε' and imaginary ε'' parts), while the transmission profile is given by $\mathrm{Im}(\varepsilon)$ (i.e., ε''). The Fresnel spectra and both of these profiles are generated based on the spectral data reported by Toon et al. (28). Evidently, the spectra for pc-ice deposited at 160 K and 1×10^{-6} torr (1 torr = 133.322 4 Pa) for 30 and 45 s (curves A and B, Fig. 3*a*) are in good accord in shape with the Buch–Devlin spectrum for the ice slab (see Fig. 3*c* in ref. 33), supporting the assignment of the higher-frequency shoulder at 3365 cm^{-1} to the intermediate branch and of the 3280-cm^{-1} feature to the ν_3 LO band. The band maximum for the 3280 cm^{-1} peak is also found to be in good agreement with that of the ν_3 LO band (3299 cm^{-1}) predicted by Whalley (34). Furthermore, the 45 s spectrum (curve B, Fig. 3*a*) closely follows the energy loss function as represented by the Berreman profile (curve E, Fig. 3*a*), which again indicates that the blue shift of the central OH stretch peak with respect to the transmission profile (curve D, Fig. 3*a*) is due to stimulation of the longitudinal modes of the ν_3 branch. The apparent enhancement of the higher-frequency part of the OH stretch with the corresponding weakening of the lower-frequency part could be associated with the blue shift of the most intense ν_3 branch alone and not to the actual changes in their own respective intensities. As expected for thicker deposits, the 115 s RA spectrum shown in Fig. 3*b* (curve F) evidently begins to deviate from the Berreman profile (curve H, Fig. 3*b*) and converge to the Fresnel spectrum (curve G, Fig. 3*b*), indicating the onset of the formation of a stratified ice film with smooth interfaces. The continual blue shift of the OH stretch and the apparent changes in the relative intensities of the band components (band shape deformation) with increasing thickness are likely caused by optical effects in the film on a metal substrate (41). Accordingly, at the initial stage of pc-ice film formation the ice deposit exists in the form of crystallites, which causes the experimental spectra to deviate from the Fresnel model. This is illustrated by the differences between the 30 and 45 s spectra (both with a common shape, curves A and B in Fig. 3*a*) and the corresponding Fresnel spectrum. In this case, the frequency position of a band associated with the ν_3 LO modes becomes dependent upon the particle shapes of the crystallites (31, 32, 38, 39).

Fig. 3. Comparison of the OH stretching band of the experimental FT-IR–RA spectra of early-stage polycrystalline (pc) ice deposits obtained by vapour deposition at 160 K and 1×10^{-6} torr (1 torr = 133.322 4 Pa) for 30 s (A), 45 s (B), and 115 s (F) with the Fresnel spectra of 20 nm (C) and 53 nm (G) thick pc-ice films and the Berreman (E, H) and transmission profiles (D), all arbitrarily normalized.

Temporal evolution of the OH (OD) stretch manifold during crystallization of an ultrathin, noncrystalline ice deposit

Because nc ice is considered metastable with respect to the crystalline ice form, annealing of an nc-ice deposit could promote crystallization to occur at a detectable rate above an appropriate temperature. Indeed, rapid changes in the OH stretch region are found at 153–163 K in the present work, in good accord with the earlier observations made by using different techniques (16, 17, 23). In particular, Fig. 4 shows the temporal evolution of the OH stretching band at 155 K for 30 min and at 163 K for 6 min for an nc-ice film deposited at 124 K and 1×10^{-6} torr (1 torr = 133.322 4 Pa) for 240 s. In Fig. 5, we compare selected experimental profiles in Fig. 4 with the appropriate calculated spectra. While no significant temporal spectral changes are found at 155 K

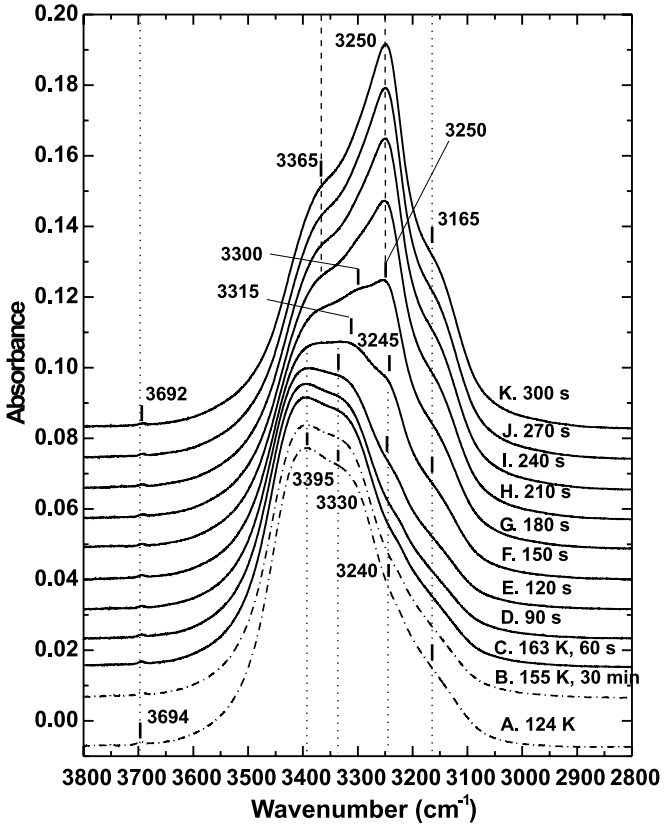
Fig. 4. Evolution of the OH stretching band of the experimental FT-IR–RA spectra for an early-stage, noncrystalline ice deposit obtained by vapour deposition at 124 K and 1×10^{-6} torr (1 torr = 133.322 4 Pa) for 240 s (A), followed by annealing to 155 K for 30 min (B), and to 163 K for 60 s (C), 90 s (D), 120 s (E), 150 s (F), 180 s (G), 210 s (H), 240 s (I), 270 s (J), and 300 s (K).



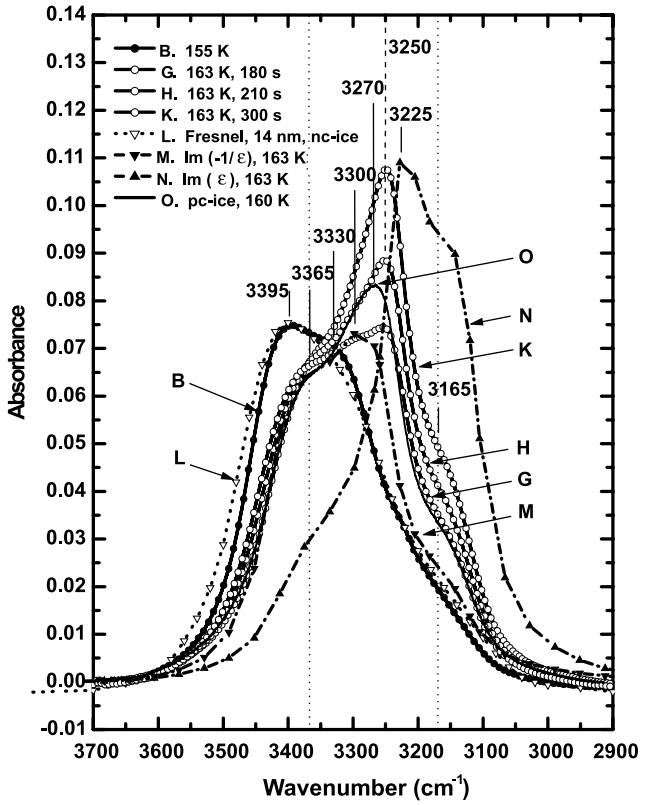


Fig. 5. Comparison of the OH stretching band of the experimental FT-IR–RA spectra of an early-stage, noncrystalline (nc) ice deposit obtained by vapour deposition at 124 K and 1×10^{-6} torr (1 torr = 133.322 4 Pa) for 240 s followed by annealing to 155 K for 30 min (B) and to 163 K for 180 s (G), 210 s (H), and 300 s (K) with that of a polycrystalline (pc) ice deposit obtained by vapour deposition at 160 K and 1×10^{-6} torr (1 torr = 133.322 4 Pa) for 30 s (O), and with the Fresnel spectrum of a 14 nm thick nc-ice film (L) and the Berreman (M) and transmission profiles for the pc ice (N), all arbitrarily normalized.

(curve B, Fig. 4) relative to the as-deposited nc-ice spectrum at 124 K (curve A, Fig. 4), rapid dramatic changes in the shape of the OH stretching band are observed at 163 K (curves C–K, Fig. 4). By analogy with the assignment for pc ice, the weak peak at 3694 cm^{-1} can be attributed to the OH dangling bonds, while the features at 3395, 3330, and 3165 cm^{-1} likely correspond to the out-of-phase ν_1 intermediate modes, the ν_3 LO branch, and the in-phase ν_1 branch, respectively. As shown in Fig. 5, the OH stretch profiles for the nc-ice film as-deposited at 124 K and upon annealing to 155 K (curve B, Fig. 5) are well approximated by the Fresnel spectrum for a 14 nm thick nc-ice film (curve L, Fig. 5), indicating the preservation of the smooth stratified film even upon annealing at 155 K for 30 min. On the other hand, discernible spectral changes near 3245 cm^{-1} are found upon annealing at 163 K for just 2 min (curves C–E, Fig. 4). This feature develops into a strong, well-defined peak at 3250 cm^{-1} upon further annealing at the same temperature for 3 more min (curves F–K, Fig. 4). In contrast, the dangling-bond feature at 3694 cm^{-1} remains essentially unchanged except for the minor red shift during this anneal.

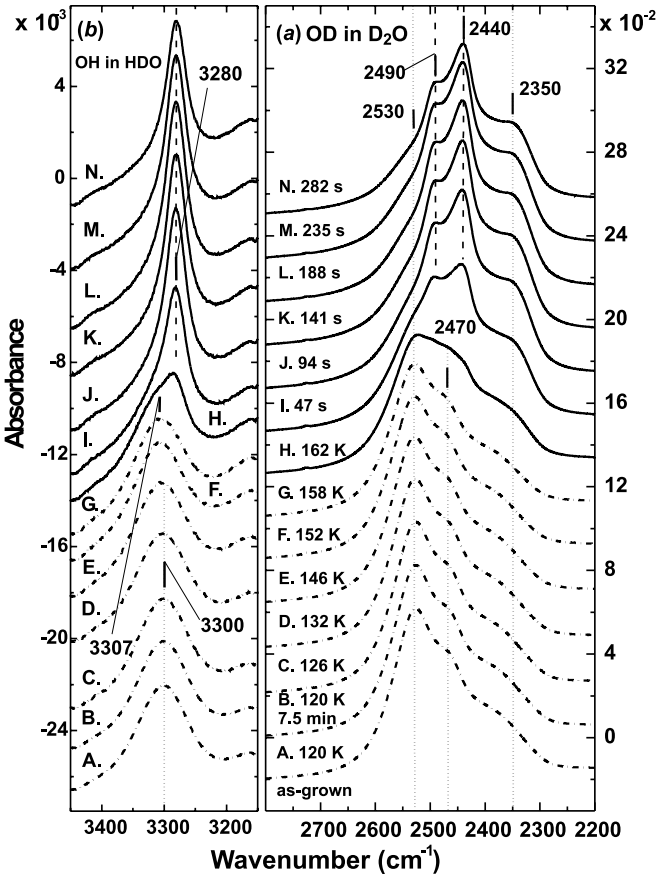

Figure 5 also compares selected spectra obtained during the 163 K anneal with the RA spectrum of the 30 s pc-ice film deposited at 160 K discussed earlier in Fig. 3, and with the Berreman and transmission profiles for pc-ice films. Evidently, the major differences between the OH stretch profiles of the annealed nc-ice film (curves G, H, and K, Fig. 5) and that of the as-grown 30 s pc-ice film (curve O, Fig. 5) are the location and relative intensity of the ν_3 LO manifold (at 3250 vs. 3270 cm^{-1}). According to the theoretical study by Wojcik et al. (42), the emergence of a prominent ν_3 LO band during annealing in the present work can be used as evidence of a rapid increase in the density of excited vibrational states in this narrow frequency region, which in turn indicates the onset of a crystallization process. The intensity increase of the overall OH stretching band during the anneal (curves G, H, and K, Fig. 5) is also consistent with the general chemical principle that crystallization leads to strengthening of the hydrogen bonds in the ice medium (43). Furthermore, the peak maximum of the observed ν_3 band (3250 cm^{-1}) is found to be in between those of the Berreman profile (3300 cm^{-1}, curve M, Fig. 5) and the transmission profile (3225 cm^{-1}, curve N, Fig. 5). (It should be noted that the Berreman profile and the transmission profile are arbitrarily normalized to the experimental spectra shown as curve G and curve K, respectively.) The intermediate peak

© 2004 NRC Canada

location is due to the presence of surface modes in the crystallites, as discussed by Englman and Ruppin (31) and Martin (32). Moreover, the formation and growth of the crystallites introduce tension into the film and could lead to cracking in a sufficiently thin film.

Figure 6 shows the temporal evolution of the OH and OD stretching modes of deuterated nc ice as deposited at 120 K and 1.5×10^{-6} torr (1 torr = 133.322 4 Pa) for 9 min and during annealing to 162 K. Evidently, no discernible change is observed in the OD stretching mode upon annealing from 120 to 162 K (curves A–H, Fig. 6*a*). Furthermore, the temporal evolution in the OD stretch features at 162 K for nearly 5 min (curves H–N, Fig. 6*a*) is found to be remarkably similar to that of the OH stretch observed earlier in the undeuterated nc-ice sample (Figs. 4 and 5), which again indicates the onset of rapid crystallization at this temperature. (Figure 6*a* also shows only minor changes in the dangling-bond signal of the OD surface groups at 2727 cm^{-1} during crystallization). Moreover, the uncoupled OH stretching mode of HOD in the deuterated ice sample exhibits a red shift from 3300 cm^{-1} at 120 K (curve A, Fig. 6*b*) to 3280 cm^{-1} at 162 K (curve N, Fig. 6*b*) with concomitant narrowing of the peak, which is also consistent with the crystallization process. The changes in this vibrational mode are in excellent agreement with the transmission spectra for thick amorphous and polycrystalline ice samples obtained by Bergren et al. (44). Between 120 K (curve A, Fig. 6*b*) and the crystallization onset at 162 K (curve H, Fig. 6*b*), there is a small but discernible blue shift of 7 cm^{-1} accompanied with peak broadening in this structure-sensitive mode, which could be argued as spectral evidence for further disordering of this nc-ice deposit immediately before crystallization. This spectral change might also be associated with an endothermic peak in the calorimetric upscan of an nc-ice medium often appearing just before the crystallization onset, which has been attributed to a glass-to-liquid transition in the earlier studies (16, 17) because frequency shifts for the structure-sensitive modes (including, e.g., the aforementioned modes) are expected in the case of a supercooled liquid state. In particular, Jenniskens et al. (45) used this approach to interpret their FT-IR–RAS data for the transition of nc ice to pc ice. Smith and Kay (19) and Smith et al. (20) also attributed the significant enhancement in the self-diffusivity of nc ice over this temperature range to a glass-to-liquid transition. However, the observed blue shift for this nc-ice feature is also in remarkably good agreement with the blue shift of the corresponding feature for pc-ice solids upon annealing (from 3275.2 cm^{-1} at 120 K to 3280.5 cm^{-1} at 150 K) observed by Sivakumar et al. (46) using Raman spectroscopy. Indeed, we also observed a corresponding red shift in the OH stretch feature in the crystallized ice (curve N, Fig. 6*b*) upon recooling from 162 to 120 K (not shown). The blue shift in the isolated OH stretch observed for nc ice upon annealing in the present work is therefore most likely just the natural consequence of thermal expansion of the ice medium. We favour the latter, simpler explanation over the former explanation invoking the glass-to-liquid transition because such an equilibrium thermodynamic effect is expected to occur regardless of the existence of the glass-to-liquid transition. Together with the early spectroscopic studies on ice crystallization by Hardin and Harvey (36) and

Fig. 6. Evolution of (*a*) the OD stretching band (for D_2O) and (*b*) the OH stretching band (for HDO) of the experimental FT-IR–RA spectra for an early-stage noncrystalline ice deposit obtained by vapour deposition at 120 K and 1.5×10^{-6} torr (1 torr = 133.322 4 Pa) for 9 min (A), followed by annealing to 120 K for 7.5 min (B) and to 132 K (C), 146 K (E), 152 K (F), 158 K (G), and 162 K (H) for 47 s (I), 94 s (J), 141 s (K), 188 s (L), 235 s (M), and 282 s (N).

Hagen et al. (47), the present data therefore provides no conclusive spectroscopic evidence for the existence of a distinct glass-to-liquid transition in nc ice in the 120–163 K range. Although any difference in the rates of relaxation processes is expected to manifest in the shape and width of the OH stretch band, we cannot rule out the possibility that the local structures of the water glass and supercooled liquid states happen to be almost identical, in which case the intermolecular interactions in both media are so close to each other that no spectral differences in the OH (OD) stretching region could be resolved. In a separate experiment, we also obtained FT-IR–RA spectra for an organic guest species, acetone or acetaldehyde, codeposited with water to form a noncrystalline guest–ice matrix at 130 K (48). The temporal evolution of the spectral features of the embedded guest species upon annealing followed by crystallization of the ice at 165 K shows only steady escape of the guest species from the matrix. While spectral differences between the adsorption (absorption) states of the guest species in the nc- and pc-ice samples were clearly resolved, no signature of the intermediate states in the guest-supercooled liquid water matrix in the 130–165 K temperature region could be observed

© 2004 NRC Canada

(48). Similar spectral observations of a steady escape and the absence of any frequency shift for dimethyl ether in a dimethyl ether – water matrix at 130–160 K have also been reported recently by Schriver-Mazzuoli et al. (49), although the spectral changes for dimethyl ether have been found at 120–130 K and attributed to clathrate–hydrate formation (49). These results further support our above observation of direct transition from nc ice to pc ice (i.e., without an intermediate glass-to-liquid transition). Furthermore, the results on crystallization kinetics of thin compact nc ice films by Dohnalek et al. (22) are also consistent with the direct solid-to-solid phase transformation.

It should be noted that for thicker ice deposits, for example those above 100 nm thick shown in Figs. 1 and 2, the temporal evolution of the main peak in the OH or OD stretch manifold upon annealing followed by crystallization is found to be less pronounced, likely due to the optical effects of the film–metal medium as discussed earlier by La Spisa et al. (50).

Concerning the state of surfaces at nc-ice and pc-ice films investigated in the present and early studies (25), it should be noted that the amount of OH dangling bonds as estimated by the intensity of the corresponding spectral feature at 3694 cm^{-1} (Fig. 4) on the as-grown thin (and compact) nc-ice films is similar to that on the pc-ice films prepared by crystallization of nc-ice films or by direct deposition. However, our FT-IR–RAS data on acetone adsorption (48, 51) appear to indicate a dynamical difference in the surface states of the adsorbate on nc- and pc-ice films. This difference is clearly related not only to the "snap-shot" structure of the surface but also to the stability and dynamics of the surface and near-surface regions of nc- and pc-ice films as discussed by Buch et al. (52).

Concluding remarks

The temporal evolution of the OH (and OD) stretch manifold(s) in the (deuterated) nc-ice deposits upon annealing followed by crystallization has been investigated by using FT-IR–RAS at grazing-angle incidence. We provide a microscopic interpretation of the spectral data using the theoretical results of Buch and Devlin (33) and Whalley's assignment (34). For the ultrathin nc-ice deposits, crystallization near 160 K has been demonstrated for the first time to be marked spectroscopically by an abrupt enhancement along with a concomitant red shift in the longitudinal branch of the ν_3 OH (OD) stretching mode at 3250 (2440) cm^{-1}. These observations are consistent with strengthening of the hydrogen bonds in the molecular water network and with increased ordering of an ice medium during crystallization. Furthermore, the spectral dynamics of the OH and OD stretch manifolds and of the isolated OH stretching mode in a deuterated ice matrix near 160 K observed in the present work indicate that rapid crystallization proceeds directly from a noncrystalline to a crystalline state, i.e., without any long-lived intermediate state that involves a hydrogen-bonded network structurally different from that of nc ice at a lower temperature (120 K). While the present interpretation of the OH spectral dynamics does not favour the existence of a glass-to-liquid transition during crystallization, we cannot rule out the existence of a supercooled-liquid state that happens to have a nearly identical local structure to glass. Further studies possibly involving non-spectroscopic data would be of great interest to resolve this intricate fundamental issue about ice.

Chemical adsorption of salicylate on silver — A systematic approach to the interpretation of surface-enhanced vibrational spectra[1]

P.J.G. Goulet and R.F. Aroca

Abstract: In this work, surface-enhanced vibrational spectroscopy and normal vibrational spectroscopy as well as density functional theory (DFT) computational methods have been employed to investigate the nature of the chemical adsorption and orientation of the surface species generated from salicylic acid at silver surfaces. The structure of salicylic acid and its IR and Raman spectra are determined at the B3LYP/6-311+G(d,p) level of theory. These results are used in the assignment of the vibrational spectra. Surface-enhanced Raman scattering (SERS) spectra obtained from silver island films thinly coated with salicylic acid confirm chemical adsorption on the Ag nanostructures. To probe the nature of this surface complex, the optimized geometries and IR and Raman spectra of two model salicylate–silver complexes (Ag1 and Ag2) were calculated at the B3LYP/Lanl2DZ level of theory. It was found that good agreement exists between experimentally observed SERS spectra and the simulated SERS spectra of a complex with the salicylate monoanion bound to a Ag^+ ion through its carboxylate group (Ag1). The carboxylate silver salt of salicylic acid (essentially the Ag1 complex) was also prepared, and its IR and Raman spectra were recorded for comparison with the surface-enhanced vibrational spectra. These results, along with the application of surface selection rules, suggest that salicylic acid is deprotonated at silver surfaces, interacting through its carboxylate group alone, and is preferentially in a tilted head-on orientation.

Key words: chemisorption, salicylic acid, silver, density functional theory, surface-enhanced Raman scattering, reflection–absorption IR spectroscopy, surface-enhanced IR absorption.

Résumé : Dans ce travail, on a utilisé la spectroscopie vibrationnelle exaltée de surface, la spectroscopie vibrationnelle normale ainsi que des méthodes de calculs de la théorie de la densité fonctionnelle (TDF) pour étudier la nature de l'adsorption chimique et l'orientation des espèces en surface générées à partir de l'acide salicylique sur des surfaces d'argent. La structure de l'acide salicylique et ses spectres infrarouge et Raman ont été déterminés au niveau B3LYP/6-311+G(d,p) de la théorie. On a utilisé ces résultats dans l'attribution des spectres vibrationnels. Les spectres de diffusion Raman exaltée de surface (« SERS ») obtenus pour des films d'îles d'argent légèrement recouverts d'acide salicylique confirment l'adsorption chimique sur la nanostructure d'argent. Afin de pouvoir étudier la nature de ce complexe en surface, on a calculé les géométries optimisées et les spectres infrarouge et Raman de deux modèles de complexes de salicylate d'argent (Ag1 et Ag2) au niveau B3LYP/Lan12DZ de la théorie. On a trouvé qu'il existe un bon accord entre les spectres SERS observés expérimentalement et les spectres SERS simulés d'un complexe dans lequel le monoanion salicylate est lié à un ion Ag^+ par le biais de son groupe carboxylate (Ag1). On a aussi préparé le sel d'argent du carboxylate de l'acide salicylique (essentiellement un complexe Ag1) et, pour fins de comparaison avec le spectre vibrationnel exalté de surface, on en a aussi enregistré ses spectres infrarouge et Raman. Ces résultats, en relation avec l'application des règles de sélection de surface, suggèrent que l'acide salicylique est déprotoné au niveau des surfaces d'argent, qu'il interagit uniquement par le biais de son groupe carboxylate et qu'il est préférentiellement dans une orientation face à face décalée.

Mots clés : chimisorption, acide salicylique, argent, théorie de la densité fonctionnelle, diffusion Raman exaltée de surface, spectroscopie infrarouge de réflexion–absorption, absorption infrarouge exaltée de surface.

[Traduit par la Rédaction]

Introduction

In the late 1970s, the phenomenon of surface-enhanced Raman scattering (SERS) was discovered (1–3). Since then, research into and employing surface-enhanced spectroscopies has exploded with activity (4–6). SERS is primarily due to the enhancement of Raman scattering cross sections of analytes as a result of their interaction with the strong

electromagnetic fields at or near the surface of appropriate enhancing metal nanostructures. The total enhancement of Raman intensities observed in SERS may span several orders of magnitude, up to ~10^{14}, and will depend critically on the architecture of the enhancing nanoparticles or surfaces used (7–9). Typically, SERS measurements are carried out on island films, electrochemically roughened electrodes, and colloidal metal particles of coinage metals such as Ag, Au, and Cu. These nanostructures support dipole particle plasmon resonance (DPPR) in the visible and thus are readily accessible to several excitation laser lines commonly used in Raman measurements (10).

Surface-enhanced Raman scattering and surface-enhanced IR absorption (SEIRA) occur near the surface of metal nanostructures that polarize the electric field of incident light, and, consequently, it is necessary to account for the orientation of adsorbates in the interpretation of experimental spectra. This is similar to the situation that exists for IR and Raman spectra of molecules adsorbed on reflecting flat metal surfaces. Greenler (11) demonstrated that the light at these surfaces is highly polarized, and at appropriate angles of incidence the p-polarized (parallel to the plane of incidence) component of the electromagnetic wave is three orders of magnitude larger than the s-component. Since the component perpendicular to the surface (P) dominates, we expect to see only those vibrational modes whose polarizability derivatives (Raman) or dipole moment derivatives (IR) align well with the field. This leads to the concept of surface selection rules (12), where the vibrational intensities predicted depend upon the contribution of the normal and tangential components of the local electric field near the surface. To the knowledge of the light polarization at the surface, one must also add the very important distinction between physically adsorbed and chemically adsorbed molecules for the interpretation of surface and surface-enhanced vibrational spectroscopy (SEVS). Physisorbed molecules show weak interactions with surfaces and, because of this, are often oriented randomly, loosely maintaining their native symmetry. This, in effect, makes the interpretation of the SEVS spectra of randomly oriented physisorbed molecules relatively simple, as the molecular selection rules do not change, and a comparison can be made directly to reference Raman scattering and IR absorption spectra. In the cases of chemical adsorption or physical adsorption with preferential orientation, however, a new complexity is introduced that can make the interpretation of SEVS spectra very challenging.

Chemisorption is a strong interaction of an analyte with a surface at energies comparable to those of chemical bonds. This results in the formation of surface complexes and therefore leads to striking changes in Raman and IR spectra. In addition to the changes in symmetry and structure that result from strong chemisorption, we will also have the additional factor of a preferred molecular orientation at the surface. A preferred orientation, whether involving chemisorption or physisorption, introduces the necessity for the above-mentioned surface selection rules, as the electric field (polarized perpendicular to the surface) will not interact strongly with those modes that are tangential to the electromagnetic field-enhancing surface. The phenomenon of chemisorption can thus be a very complicating factor for the assignment of SERS and SEIRA spectra, and so presents a perfect opportunity for the strengths of theoretical computational methods to be employed. Notably, if the electronic absorption of the surface complex happens to be in resonance with the exciting laser line, the observed spectrum will be that of resonance Raman scattering, a case that is not considered here for this salicylate complex.

Theoretical methods, such as those available in Gaussian 98 (13), have been recently employed in the study of the chemical adsorption of two different molecules on Ag (14, 15). In these studies the authors calculated the optimized geometries and Raman spectra of analyte–Ag complexes using density functional theory (DFT) methods and compared them to experimental SERS spectra. In both reports, fairly good agreement was found for simulated (computed) and experimental SERS spectra, and as theoretical modeling of chemical systems continues to improve and become more computationally affordable, it is expected that this will become a very useful and common method for predicting and assigning SERS spectra. In this work, strategies similar to those mentioned above have been employed in the study of a molecular system that has not before been submitted to a full theoretical treatment (16) and for which the chemisorption on Ag does not appear to be fully understood. This system is that of salicylic acid (2-hydroxybenzoic acid) and its deprotonated monoanion and dianion forms.

Salicylic acid is a molecule that is of interest to science for several reasons, and perhaps the most important of these is its application in commercial drugs, including its use in the synthesis of drugs such as aspirin (acetylsalicylic acid) (17). However, another significant point of interest about this system is that the salicylate ion is a very important metal-binding agent in nature (18). Several vibrational studies of salicylic acid and its ions have been reported in the literature (16) including a few that have employed SERS (17, 19–21). These reports show inconsistencies with regard to the question of the adsorption of the molecule on Ag. In one report, it is claimed that salicylic acid interacts with the colloidal Ag surface through both its carboxylate and phenolate groups (17), while in other reports adsorption is concluded to occur only through the carboxylate group (19, 20), or in a "tilted side-on orientation", where the C=O stretch was incorrectly assigned (21). Additionally, one recently reported SERS spectrum shows large discrepancies with previous work (19). Much of the confusion that seems to exist in the literature is likely due to the difficulty of accurately assigning peaks in the SERS spectra of this chemisorbed molecule. This is due to the reasons that have been mentioned earlier, but also to the fact that salicylic acid has a very crowded Raman spectrum with many closely spaced bands and shows strong photodegradation at relatively low laser powers. Thus, in an attempt to simplify the assignment of bands in the SERS spectra of this molecule, and to shed light on the question of how it chemically adsorbs to Ag, we have employed DFT techniques to compute optimized geometries and vibrational spectra for salicylic acid and two silver–salicylate complexes.

DFT methods have recently become very widely used and popular owing to their accuracy and low computational cost. These methods minimize an energy functional rather than handling a wave function for each of the electrons in an

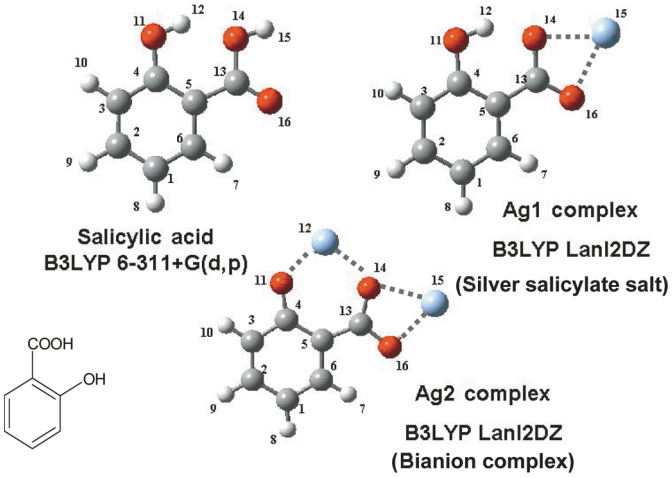
© 2004 NRC Canada

N-electron system, and because of this simplification they are of much lower computational cost than other correlational techniques. In this study, Becke's three-parameter functional (22) including the correlational functional of Lee et al. (23) (B3LYP) has been employed for all reported results. This functional has been shown to perform very well in the calculation of vibrational spectra. However, the accuracy of the results for the two different Ag complexes may be expected to be lacking because of the limited size of the Lanl2DZ (24, 25) basis set that was used. Lanl2DZ was employed, despite its small size, as it is one of the only basis sets available for silver that is also available for second-row elements (15).

Extracting from the spectra the molecular orientation of the surface species on Ag nanostructures and smooth Ag surfaces was an important goal of this work and was done with the hope of gaining a more complete understanding of the molecule–surface interaction. The molecular orientation at the surface was determined by detailed examination of spectra obtained from SERS, SEIRA (26), and reflection–absorption IR spectroscopy (RAIRS) (27) measurements. In RAIRS, the standing electric field at the reflecting metal surface is polarized parallel to the surface normal, and thereby, only those modes that have dipole moment changes perpendicular to the surface will demonstrate appreciable relative intensity in the absorption spectrum. SEIRA experiments, on the other hand, are performed on roughened surfaces having nanoscale features randomly oriented, and so determination of molecular orientation can sometimes be challenging. SEIRA enhancement factors (EF) are modest compared to those of SERS (EF of SEIRA are commonly less than 10^2), and SEIRA spectra may have contributions from molecules more distant from the surface, and thus reflect the effect of random orientation above the first layer for films lacking epitaxy. Conversely, SERS shows a very strong first-layer effect (28). This means that the SERS spectra of oriented chemisorbed species will generally be dominated by those molecules in the first layer on the surface and therefore will reflect their orientation. Notably, however, in the case of a SERS experiment where molecules are adsorbed in the interstitial volumes between multiple particles, where electromagnetic enhancements are known to be highest, spectra may seem to indicate a random orientation.

In summary, in this work, the structures and vibrational spectra of salicylic acid and two silver–salicylate complexes are calculated using DFT methods. By employing an analysis of the calculated polarizability derivative tensor and dipole moment derivatives for each normal mode, with respect to light polarization and a given fixed molecular orientation, we utilize a systematic approach for the interpretation of experimental Raman, SERS, IR, RAIRS, and SEIRA spectra. In addition, the experimental IR and Raman spectra of prepared silver salicylate are presented for comparison with the surface-enhanced vibrational spectra. Insight is provided into the chemical adsorption and the specificity of the interaction of molecular groups on Ag nanostructures. The selection of the vibrational techniques of Raman, IR, SERS, RAIRS, and SEIRA for this work is in recognition of the fact that they represent a complete set of complementary data required for a meaningful interpretation of a molecular system and its interaction with a particular metal surface.

Experimental



Analytical-grade salicylic acid, sodium salicylate, and silver nitrate were obtained from Sigma Aldrich and used without further purification. The complex of silver salicylate was prepared according to the methods described by Alvarez-Ros et al. (17). Raman and attenuated total reflection (ATR) IR spectra of the pure salicylic acid solid were obtained directly from the powder. Raman measurements on silver salicylate were also obtained directly from powder, while IR spectra were recorded from the powder dispersed in KBr pellets. To prepare SERS and SEIRA samples, vacuum evaporated 10 nm (mass thickness) Ag island films were dipped into 10^{-3} and 10^{-4} mol/L solutions of salicylic acid in spectrophotometric-grade acetone. These Ag island films were previously prepared by vacuum evaporation at a pressure of about 10^{-7} torr (1 torr = 133.322 Pa) and a temperature of +200 °C (maintained for 1 h after evaporation), where mass thickness was monitored with a quartz crystal balance. The slides were allowed to remain several minutes in the salicylic acid solution before removal and drying. All Raman spectra were collected with a Renishaw research Ramanscope 2000 or a Renishaw inVia Raman microscope, both equipped with Peltier-cooled CCD detectors (–70 °C) and Leica microscopes. The spectrographs use 1800 g/mm gratings with additional bandpass filter optics. Excitation lines of 488, 514, and 633 nm were used, and did not reveal any significant differences. All IR absorption measurements were recorded with a Bruker Equinox 55 FT-IR spectrometer, employing a nitrogen-cooled MCT detector. Each spectrum was measured with 1024 scans and 4 cm^{-1} resolution. ATR measurements of salicylic acid powder were obtained using an ATR accessory from Pike Technologies. SEIRA measurements on a Ge substrate were collected in transmission mode using the IRscope II microscope from Bruker. Finally, RAIRS spectra were collected from a thin salicylic acid film on a 100 nm mass thickness Ag mirror with the Harrick Auto Seagull variable-angle reflectance accessory. Reported RAIRS measurements were made with p-polarized light at an angle of incidence of 80° to the surface normal.

Computational methods

All reported calculations were performed using the Gaussian 98 (revision A.3) suite of programs (13) and employed Becke's three-parameter functional including the correlational functional of Lee et al. (23) (B3LYP). To calculate an optimized structure and vibrational spectra for salicylic acid, the 6-311+G(d,p) basis set was employed using tight convergence criteria. This basis set was deemed to be a reasonable compromise between accuracy and computational expense for this molecule. The optimized structures and vibrational spectra of the two Ag–salicylic acid complexes were computed using the Lanl2DZ basis set (24, 25), also employing tight convergence criteria. GaussView for Windows was used to view all computed results, and an in-house program (VibWidth) was used to artificially apply a 5 cm^{-1} bandwidth to all peaks in the presented calculated Raman and IR spectra. Raman frequencies were not scaled, as scaling factors are not available for the basis sets used in this study. It is expected, however, that an appropriate scaling

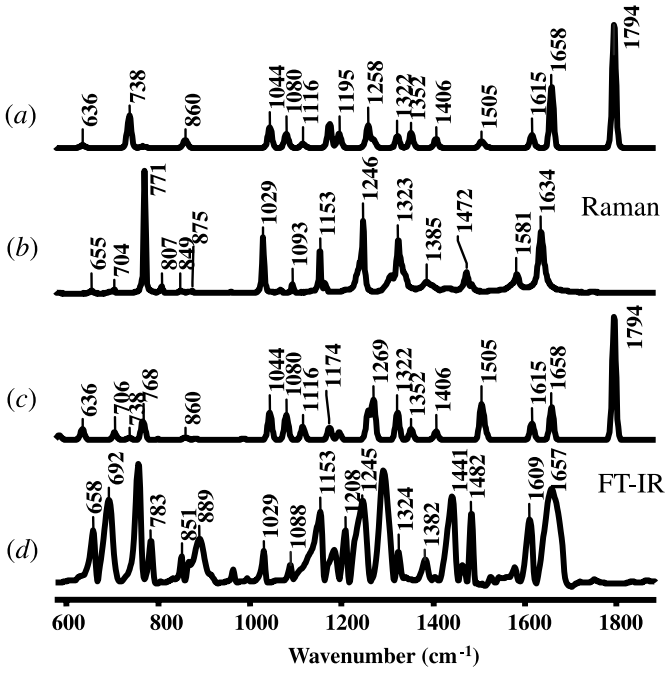
Fig. 1. Optimized structures of salicylic acid and the Ag1 (molecular plane is *xy*) and Ag2 complexes. Also shown is the molecular structure of salicylic acid.

factor for the 6-311+G(d,p) basis set would be close to unity for the B3LYP functional. As a general rule, neglecting scaling results in an overestimation of harmonic frequencies (29), and so this must be considered when reviewing the results for the two calculated silver complexes. In calculations of the Ag1 complex, the molecule was fixed in the *x–y* plane to simplify the application of surface selection rules in the spectral interpretation.

Results and discussion



The optimized geometries of salicylic acid, a salicylate monoanion – Ag^+ complex (Ag1), and a salicylate dianion – $2Ag^+$ complex (Ag2) are shown in Fig. 1. Salicylic acid was calculated at the B3LYP/6-311+G(d,p) level of theory, while the two silver complexes were calculated at the B3LYP/Lanl2DZ level of theory. All three of these structures belong to the C_s symmetry point group and have 42 vibrational degrees of freedom, or normal vibrational modes. A summary of pertinent structural parameters for the three optimized geometries is presented in Table 1, where all bond and angle numbering refers to those numbers assigned in Fig. 1. Upon close examination of these results, it can be seen that the substitution of Ag atoms for H atoms causes drastic changes in the structural parameters of these molecules. These changes are largely concentrated on the carboxyl and hydroxyl groups of these structures and have very little impact on the aromatic ring parameters, especially at parts distant from the affected groups of the molecule.

The experimental Raman and FT-IR (ATR) spectra of bulk salicylic acid powder are directly compared in Fig. 2 with those calculated at the B3LYP/6-311+G(d,p) level of theory. To supplement these spectra, Table 2 shows the calculated and observed IR and Raman frequencies, calculated symmetries, IR intensities, Raman activities, and assignments for the fundamental vibrational modes of salicylic acid. It can be seen from these results that acceptable agreement exists between the calculated and experimentally observed Raman spectra at this level of theory. As well, it should be noted that these spectra also agree very well with results previ-

ously reported in the literature (17, 19, 20). However, there are some differences between the two, and they can be explained as being a result of condensed-phase effects. The calculated spectrum reported is for a noninteracting gas-phase system, whereas the experimental results presented are for a solid powder. This difference is known to account for very significant changes in relative vibrational intensities and can produce spectra that appear to be quite dissimilar (15). This is certainly not surprising, as salicylic acid is known to form both inter- and intramolecular hydrogen bonds in condensed phases. Indeed, this effect is even more pronounced in the IR absorption spectra where strong hydrogen bonding in the condensed phase clearly leads to differences between the calculated IR and FT-IR ATR spectra of salicylic acid.

The most striking example of this condensed-phase effect is the C=O stretch, which is calculated at 1794 cm^{-1} as an intense band but is not observed in the experimental Raman spectrum (Fig. 2). The disappearance of this band is likely the result of C=O participation in intermolecular interactions

Fig. 3. Comparison of (*a*) the Raman spectrum of silver salicylate salt (obtained from powder at 633 nm excitation), (*b*) the B3LYP/Lanl2DZ calculated Ag1 Raman spectrum (random orientation), (*c*) the experimental SERS spectrum, (*d*) the B3LYP/Lanl2DZ calculated Raman spectrum for the Ag1 complex with head-on orientation (only *xx* and *xy* polarizability derivative components used to calculate Raman activity), (*e*) the B3LYP/Lanl2DZ calculated Raman spectrum for the Ag1 complex with face-on orientation (only *xz* and *yz* polarizability derivative components used to calculate Raman activity), and (*f*) the B3LYP/Lanl2DZ calculated Ag2 Raman spectrum (random orientation).

in the condensed phase. It is, however, observed in the experimental IR spectrum as a broad peak showing a maximum at 1657 cm^{-1}. This is in agreement with the vibrational spectra recorded for salicylic acid in aqueous solution, where the C=O stretching was observed in both the Raman and IR at 1660 cm^{-1} (16). Dissolving the salicylic acid in organic solvents shows that this IR band wanders to higher wavenumbers, indicating less association via C=O interactions. A pair of bands at 1580 and 1609 cm^{-1} in the IR spectrum are assigned to C=C stretching vibrations of the aromatic ring. In the Raman spectrum, similar bands are seen at 1581 and 1634 cm^{-1}, as confirmed by the literature (17). The computed spectra clearly show that there are only two ring stretching vibrations in this region, the 1581 and 1609 cm^{-1} bands observed in the IR spectrum. The 1634 cm^{-1} band in the Raman spectrum cannot be assigned to the C=O stretching, since this vibration is clearly observed at 1657 cm^{-1} in the IR spectrum. Therefore, we must conclude that the 1634 cm^{-1} vibration observed in the Raman spectrum is a result of dimers or higher order aggregates formed in the condensed phase.

A direct comparison of several key Raman spectra for this system is presented in Fig. 3 for the region below 1700 cm^{-1}. The spectra are supported by Table 3, which contains the calculated frequencies, symmetries, Raman activities, IR intensities, and assignments for the fundamental vibrational modes of the Ag1 complex, along with the corresponding experimental frequencies for the silver salicylate salt, SERS, and SEIRA samples. The Raman spectrum of the prepared silver salicylate monoanion salt and the SERS spectrum obtained from 10 nm Ag island films coated with thin films of salicylic acid agree well with those previously reported in the literature (17, 19, 20). However, they show some differences with one another, because of the effect of hydrogen bonding that occurs for the salt sample, as well the fact that the spectrum of the salt represents a random spatial distribution, whereas the SERS spectrum is primarily derived from an oriented first layer. Results obtained using different excitation laser energies for these samples did not reveal meaningful changes in the obtained spectra.

When the obtained SERS results are compared with the Raman spectrum of the powder salicylic acid, it becomes immediately clear that the molecule has been altered due to association with the silver nanostructured surface. It is evident that salicylic acid is in fact chemisorbed on the Ag islands, forming a surface complex. This surface complex adopts a preferred orientation at the surface, and it is these two effects that are responsible for the changes in the observed spectral properties. However, it is not immediately clear from these results what the structure of the surface complex is, or what its orientation on the surface is, but there are many valuable pieces of information contained in the spectra.

The first of these pieces of information is the presence of very strong Ag-O bands in the low wavenumber region of the SERS spectrum. These bands appear to be strengthened

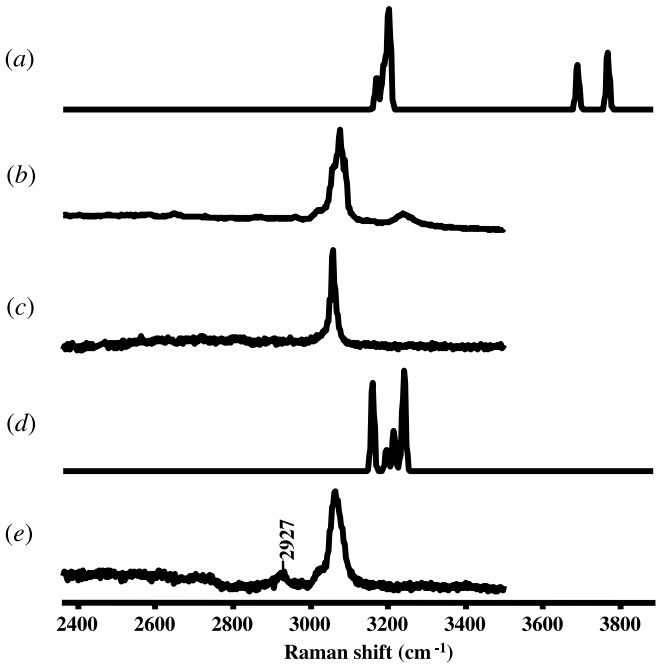
Note: Also shown are the corresponding experimental Raman and IR frequencies for the Ag salt, SERS, and SEIRA samples.

relative to the usual Ag-O peaks that are nearly always found in the spectra of Ag island films (resulting from an ever-present silver oxide layer). The presence of these Ag-O stretching bands provides very strong evidence for the formation of a surface complex (chemisorption). Further strength is provided to this hypothesis by several key spectral changes in the SERS relative to the Raman spectra of salicylic acid. Among these changes are shifts in vibrations resulting from both the carboxyl and hydroxyl groups of the molecule. For example, a clear upshift of the ring stretching + COO scissoring from 771 to 809 cm^{-1} takes place (attributed to deprotonation producing the monoanion (16)), while downshifts in several bands with considerable phenolic O-H contribution, in particular, those found at 451 and 3239 cm^{-1} in the Raman (seen at 407 and 2927 cm^{-1} in the SERS) are observed upon adsorption of the molecule on Ag. Shifts in

© 2004 NRC Canada



bands associated with the carboxylate group suggest that adsorption is occurring through it, while the presence of several downshifted O-H related modes indicates that the molecule is not reacting with the metal through its hydroxyl group, but rather is experiencing drastic changes in the strength of its hydrogen bonds as a result of the adsorption. This is made particularly clear by the unmistakable presence of the O-H stretching band (2927 cm^{-1}) that has shifted below the C-H stretches in the SERS spectrum, as shown in Fig. 4 (and predicted by theoretical results). Moreover, several other bands involving contributions from the O-H group are clear in the SERS spectrum (Table 3). These bands provide direct evidence that salicylic acid is not chemically adsorbed through its hydroxyl group. However, from experimental results alone, where peak assignments are unreliable, this problem remains difficult to solve, as evidenced by unclear and conflicting reports on this matter in the literature. Therefore, attempts have been made to clarify this problem through the use of DFT computational methods.

As mentioned earlier, the structure and vibrational (IR and Raman) spectra of two different Ag–salicylate complexes (Ag1 and Ag2) were calculated at the B3LYP/Lanl2DZ level of theory to determine if one would agree strongly with experimentally observed SERS spectra, and therefore clarify how the chemisorption of this molecule occurs on Ag. (Notably, an interaction of the metal with the π system of the ring was ruled out as a possibility based on early experimental results.) The Raman results derived from these calculations are shown in Fig. 3, where the calculated spectra of these two complexes (Ag1 and Ag2) are compared to the experimentally observed silver salicylate salt and SERS spectra. Tables 3 and 4, which show the calculated frequencies, symmetries, Raman activities, IR intensities, and assignments for the fundamental vibrational modes of Ag1 and Ag2, respectively, support these spectra.

It can be seen in Fig. 3 that both model complexes seem to approximate the SERS spectrum of the surface species to some extent. However, there are once again some very clear signs that will allow us to eliminate one of these possibilities. The calculated Raman spectrum of the Ag2 complex, as expected, does not account for the presence of O-H vibrational bands in the experimental SERS spectrum as that of the Ag1 complex does. The O-H stretching (2927 cm^{-1}), in particular, in the SERS spectrum confirms that the phenolate has not been formed. As shown in Fig. 4, this band demonstrates nearly identical band shape and relative intensity to the O-H stretching band in the experimental Raman spectrum of salicylic acid. As well, it cannot be reasonably assigned to a combination band, as there are no two fundamentals in the SERS spectrum whose frequencies can be summed to arrive close to 2927 cm^{-1}. Thus, given this quite clear assignment, we can conclude with a great deal of certainty that the Ag2 complex does not approximate the chemical adsorption of the salicylate surface complex on Ag.

The calculated Raman spectrum of the Ag1 complex, on the other hand, shows good agreement with the experimental SERS spectrum, especially considering the previously discussed complications created by condensed-phase and field polarization effects. Not only does the Ag1 complex calculation account for the presence of the O-H bands in the SERS spectrum, but it also predicts successfully the shifting of

Fig. 4. Comparison of Raman spectra above 2400 cm^{-1} for (*a*) B3LYP/6-311+G(d,p) calculated salicylic acid, (*b*) salicylic acid powder (experimental), (*c*) silver salicylate salt (experimental), (*d*) B3LYP/Lanl2DZ calculated Ag1 complex, and (*e*) SERS (experimental).

these bands. As shown in Table 3, the Ag1 complex has its O-H stretching mode shifted below the C-H stretches as was also observed in the experimental SERS spectra. In light of this theoretical result, there can be little doubt about the assignment of the O-H stretch in the experimental SERS spectrum. Moreover, the calculated spectrum of the Ag1 complex shows generally good agreement with the entire experimental SERS spectrum in terms of band frequencies and relative intensities. Thus, based on the results presented here, and the results found in the literature, it can be concluded that the chemical adsorption of this analyte on Ag occurs only through its carboxylate group. In fact, the calculated Raman spectrum of the Ag1 complex approximates the experimental SERS spectrum far better than it does the silver salicylate salt Raman spectrum. This may seem unexpected, but it simply demonstrates, once again, the importance of intermolecular interactions in this system. The prepared salt complex experiences strong hydrogen bonding, while the salicylate ions at the surface of the Ag nanoparticles are much more isolated from one another. In fact, for example, the Raman spectrum of the silver salicylate salt does not have an apparent O-H stretching band, as the Ag1 and SERS spectra do.

Having a clear notion about the chemical adsorption of salicylate on silver, the next logical problem becomes that of the molecular orientation at the surface. In a previous study (15), SERS surface selection rules were applied to a different adsorbate by orienting the calculated surface complex and then plotting a simulated SERS spectrum by only including those modes of symmetry with polarizability derivative tensor components parallel to the electromagnetic field at the surface. In this way, the surface selection rules were accounted for by the theoretical methods, and good agree-

ment between the calculated and experimental results was obtained. To produce simulated spectra that account for surface selection rules, we must calculate Raman activities of each mode using only the polarizability derivative tensor components that align with the electromagnetic field at the surface. In this study, the Ag1 salicylate–silver complex, having C_s symmetry, shows modes of only two symmetries (A′ and A″). (The Ag2 complex was not considered in determining the molecular orientation of the surface species, as its calculated spectrum showed poor agreement with the experimental SERS results.) Thus, knowing that salicylic acid is adsorbed through its carboxylate group, we arrive at two test cases for orientation: the molecule standing (head-on) or lying flat on the surface (face-on). In calculations of the Ag1 complex, the molecule was fixed in the *x–y* plane. Consequently, for the case of the molecule lying flat on the surface, the *x–y* plane of the molecular system is parallel to the tangential components of the field, and we can simply calculate the Raman activity of each mode using only the *xz* and *yz* components of the polarizability derivative tensor. This effectively means that we are plotting only the A″, or out-of-plane, modes for the molecule. If, however, the molecule is standing head-on to the surface, then the perpendicular component of the polarized surface field will be parallel to

Fig. 5. Comparison of (*a*) B3LYP/Lanl2DZ calculated IR spectrum for the Ag1 complex, (*b*) IR absorption spectrum of silver salicylate salt (KBr pellet), (*c*) reflection–absorption IR spectrum (RAIRS), and (*d*) surface-enhanced IR absorption spectrum.

the plane of the molecular system, and the Raman activity of each mode can be calculated using only the *xx* and *xy* components of the polarizability derivative tensor (assuming the molecule is standing with its *x*-axis parallel to the surface normal). In this way, we are accounting for all in-plane vibrations that have polarizability derivative components parallel to the surface electromagnetic field. Polarizability derivative tensor components are readily obtained from quantum chemical calculations performed with software packages such as Gaussian 98 (13), and Raman activities can be calculated from the invariants of the derived polarizability tensor (30).

The two cases mentioned above have been tested in this work, and the results are shown in Fig. 3. Upon close examination, it can be seen that the spectrum representing head-on orientation, as expected, is clearly in closer agreement with the experimental SERS spectrum than the spectrum representing face-on orientation. This is unambiguous evidence suggesting that the molecule is not lying flat on the surface. However, it appears that experimental SERS results are likely best approximated by the Ag1 spectrum (average of spatial directions), and from this we can conclude that the molecule is slightly tilted at the surface.

In attempts at obtaining corroborating evidence about the orientation of salicylate chemically adsorbed at silver surfaces, RAIRS and SEIRA measurements were made and used in conjunction with theoretical results for the Ag1 complex. These results are summarized in Fig. 5, which also includes the IR absorption spectrum of silver salicylate dispersed in a KBr pellet. It can be seen that the RAIRS and SEIRA results show agreement with one another and with results for salicylic acid powder (spectrum in Fig. 1), while the silver salt spectrum is quite dissimilar. This can be explained as being the result of strong intermolecular attractions that salicylic acid and the salt complex both exhibit, as confirmed by the observation of several broad IR bands (more than average full width at half-maximum) in the spectra. Due to very modest enhancements in the IR (SEIRA and RAIRS), and thus a weak first-layer effect, even moderate surface concentrations bring about the spectrum of the bulk material. This is in contrast with what is observed in SERS measurements, where first-layer effects are dominant.

However, let us follow the relative intensities of two bands: the strong in-plane vibration at 1655 cm^{-1}, characteristic of the carboxylate moiety, and the out-of-plane C-H bending vibration observed at 757 cm^{-1} in the SEIRA spectrum. Assuming a predominant perpendicular polarization at the silver nanostructures, the intensity ratio for the two bands (I_{1655}/I_{757}), may be used as an indicator for the molecular orientation of the adsorbate at or near the surface. The reference ratio, for a random distribution, is in this case the spectrum of the salicylic acid powder. The ratio will show a maximum for a head-on orientation, and a minimum for flat or face-on (molecular plane parallel to the surface) orientation. The latter is a direct application of the surface selection rules. It can be seen that the ratio increases in the SEIRA spectra, confirming a preferential orientation in favor of the head-on model for the adsorbate. Since the relative intensity of the 757 cm^{-1} mode is diminished, but still clearly observed, it must be concluded that, on average, the molecule demonstrates a predominant tilted head-on orientation at the surface.

Conclusions

In this report, DFT methods were employed to investigate the nature of the chemical adsorption of salicylic acid on silver surfaces. The structure of salicylic acid, along with its IR and Raman spectra, was determined at the B3LYP/6-311+G(d,p) level of theory. These results were then used in the assignment of vibrational spectra and generally showed good agreement with those obtained experimentally, accounting, of course, for condensed-phase effects. SERS spectra obtained from silver island films thinly coated with salicylic acid showed good agreement with results previously reported in the literature for colloidal solutions. To determine the structure and orientation of the surface complex of salicylate formed at Ag surfaces, the optimized geometries and Raman spectra of two model salicylate–silver complexes (Ag1, Ag2) were calculated at the B3LYP/Lanl2DZ level of theory. Experimental vibrational spectra were obtained for a silver salicylate salt for comparison with SERS results. It was found that experimentally observed SERS spectra and simulated SERS spectra of a salicylate complex chemisorbed through its carboxylate group (Ag1) show good agreement with one another. It is concluded that salicylate chemically adsorbs only through its carboxylate group. Conclusive evidence for a tilted head-on orientation of the salicylic acid complex on the surface was obtained from calculations of simulated SERS spectra that account for po-

The Br—O bond in halogen oxides — Empirical force constants and electronic characteristics[1]

Rafael Escribano, Ismael K. Ortega, Rafael G. Mosteo, and Pedro C. Gómez

Abstract: A number of bromine oxides and mixed chlorine–bromine oxides for which spectroscopic information is available have been chosen to investigate the nature and characteristics of the Br—O bond. The study consists of the empirical determination of stretching force constants for these bonds from observed vibrational spectroscopic data and the analysis of the topological characteristics of the bonds via ab initio calculations. The latter have been performed at the MP2 level with a 6-311+G(2df) basis set, to provide a uniform and systematic framework for comparing these species. Three types of Br—O bonds have been found, with different characteristics of strength and electron density. The results are compared with those recently found for the Cl—O bond in chlorine oxides.

Key words: bromine oxides, bond electronic structure.

Résumé : On a choisi un certain nombre d'oxydes de brome et de chlore, ainsi que d'oxydes mixtes de brome et de chlore au sujet desquels on disposait d'information spectroscopique dans le but d'étudier la nature des liaisons chimiques Br—O. L'étude a consisté à déterminer la constante de force d'élongation (« stretching ») à partir des données de spectroscopie vibrationnelle ainsi qu'à étudier les caractéristiques topologiques de la densité de ces liens qui ont été obtenues à partir de calculs ab initio. Pour ces calculs, on a choisi la méthodologie MP2/6-311+G(2df) qui comporte un niveau uniforme de la théorie pour toutes les espèces étudiées. On a trouvé trois classes de liens Br—O qui présentent des différences en ce qui concerne la force du lien ainsi que la densité électronique et on a fait une comparaison avec des résultats publiés antérieurement pour le lien Cl—O.

Mots clés : oxydes de brome, structure électronique de liaison.

[Traduit par la Rédaction]

Introduction

In a recent investigation (1), the electronic structure of the Cl—O bond was studied, taking as subject of research a number of chlorine oxides for which vibrational spectroscopic data were available. It was found that Cl and O can form three types of markedly different bonds, which were characterized by their force constants, obtained from the analysis of the experimental data, and by their electronic density distribution, studied by ab initio methods based on the atoms in molecules (AIM) analysis (2). A similar investigation is presented here for the Br—O bond in bromine oxides and mixed bromine–chlorine oxides.

The halogen oxides, especially those with Cl and Br, have received considerable attention in recent years, since they are involved in atmospheric processes and play a leading role in ozone depletion reactions (3–9). Much more is known of chlorine oxides (1, and refs. cited therein), but there are also a number of papers on the compounds formed by oxygen and bromine with different stoichiometries, as well as on chlorine–bromine oxides. We restrict the scope of this investigation to molecules whose vibrational or rovibrational spectrum has been reported in the literature and leave aside other species of undoubted interest for which only theoretical predictions are available, and which have never been detected experimentally. The list of molecules under study is given in Table 1.

Most of the published spectroscopic information concerns the simplest and more stable species, namely, BrO, OBrO, and BrOBr, which have mainly been observed in matrices, but, when available, gas-phase values for the vibrational frequencies were selected as data for force field refinements. BrO has been extensively studied, both in the gas phase and in matrices (see ref. 10 and refs. cited therein; see also ref. 11 for works prior to 1996). The most recent data on the geometry of OBrO comes from the microwave experiment

of Müller et al. (12), who also determined the empirical force field of this species, whereas the vibrational frequencies have been measured in works on FT-IR (13), visible (14), and matrix (15) spectroscopy, including data on several isotopic derivatives. Müller and Cohen (16) also determined the geometry and force field of BrOBr, for which frequencies were recorded in the gas phase (13) and in matrices (17–19) or were estimated for isotopic derivatives by correcting matrix values or from rotational spectra measurements (16). We have not found in the literature any empirical determination of the geometry for the rest of the oxides studied here, with the exception of some X-ray measurements for $BrOBrO_3$ that will be discussed below, as this molecule deserves special attention. Some vibrational frequencies have been reported for the remaining molecules, although a complete spectrum has not been recorded for any of them. The appropriate references are indicated, together with other data, in the *Results* section.

High-quality ab initio calculations have been previously published for specific bromine or mixed oxides (20–28), at different degrees of theory. On the other hand, the aim of this contribution, from the computational point of view, is to present a uniform and systematic description of these species, calculated at a reasonably high level. This has been chosen as an MP2/6-311+G(2df) combination of method and basis set. We used the refined geometrical structure given in the literature as input for our force field or ab initio calculations, when experimentally derived information on the geometry of the molecules was not available.

We present in the next section a brief description of the

© 2004 NRC Canada

tools and methods used in this work. In the following one, we describe the results, with special emphasis on specific molecules, and we present the main conclusions in the final section of the paper.

Methodology

We have followed the same procedure as in ref. 1, where a detailed description was given of the methods used in this work. In brief, the force field refinement was done in two steps. In the first, the observed frequencies for each individual molecule and its isotopomers were taken as data for a standard fitting to determine the stretching force constants of the bonds involved in the corresponding vibrational mode. In a few cases, a bending force constant or a stretch–stretch interaction constant was also refined. We followed the usual Wilson's GF method (29) using computer programs written by us (30). The results are commented on below. In the second step, we used the so-called group force constants or characteristic force constants method (31), which enables the refinement of a set of force constant parameters common to a series of molecules that contain a common group of atoms. The molecules may have the same number or different numbers of atoms and various symmetries. The refinement yields, in this case, the average values of the force constants for the common bonds in the series of molecules. The observed frequencies are not necessarily reproduced perfectly, but the refined force constants provide a good representation for the forces between the atoms present in the common groups. In our case, we have fitted seven different force constants, corresponding to three markedly different types of Br—O and Cl—O bonds.

For the topological analysis, we have used Bader's AIM analysis (2) as implemented in the Gaussian 98 (G98) set of programs (32). First, we carried out a structure optimization for each molecule at the MP2 level of theory with a 6-311+G(2df) basis, which proved to be a good compromise between use of computational resources and quality of results. Some tests at the CCSD(T) level of theory failed to converge for some of the more difficult radicals, like BrO_3 or BrOO. In the case of the ground-state doublet radicals like OBrO or BrOO, UMP2 rather than MP2 calculations were carried out in this work. These UMP2 calculations often suffer from spin contamination, i.e., mixing of higher spin states (in the present case, quadruplets, sextuplets, etc.), which can be partially removed by means of appropriate projection operators. The amount of spin contamination is normally evaluated by means of the expectation value of the total spin angular momentum, $\langle \mathbf{S}^2 \rangle$, corresponding to the appropriate wave function. For the radicals studied here with only one unpaired electron, $\langle \mathbf{S}^2 \rangle$ should be 3/4, but initial values obtained for the UHF wave function were 0.790 for OBrO and 0.770 for BrOO. This implies a moderate spin contamination that is further diminished after annihilation of the contribution of the next higher state, yielding $\langle \mathbf{S}^2 \rangle$ values of 0.762 and 0.757 for OBrO and BrOO, respectively. The relative agreement with the predicted value is thus within 2%, and therefore the effect of spin contamination on relative energies, equilibrium geometries, and electron density is not likely to be relevant. As for its effect on the calculated harmonic frequencies, the spin contamination for these molecules has already been studied in a previous paper (33) and found to be small as well.

For the optimized geometry of each molecule, we studied several topological properties of the total electron density ρ, which characterize the bonds in the molecule. These properties are the bond critical point of the electron density and its distance to the bonded atoms (r_{bcp}), the density (ρ_{bcp}) and the Laplacian of the density ($\nabla^2\rho_{bcp}$) at the critical point, and the ellipticity of the critical point (ε). In most cases, the critical points are saddle points at which two curvatures of the electron density (λ_1, λ_2) are negative and one is positive. When two atoms are bonded, the electron density reaches a minimum along the bond line precisely at r_{bcp}, whereas this point is a maximum in the perpendicular plane. If we choose λ_2 to be the smallest (absolute value) eigenvalue, the ellipticity of the bond is defined as $\varepsilon = (\lambda_1/\lambda_2) - 1$. It provides an indication about the extent to which the density is accumulated in a plane containing the bond line. Thus, if a particular bond has cylindrical symmetry, it would display equal λ_1 and λ_2 values and the ellipticity would be zero; on the other hand, if some density is accumulated in a perpendicular plane to the bond line, ε would have a nonzero value and would inform about the extent of such concentration. As the λ_2 value diminishes, the bond is thought to become less stable, leading to the point of instability and rupture when it approaches zero. The Laplacian of the density, $\nabla^2\rho(r)$, tells us how the charge is distributed, so that in the regions where $\nabla^2\rho < 0$ the charge is locally concentrated, whereas in the regions where $\nabla^2\rho > 0$ charge depletion is found.

For reference purposes only, we may quote some typical values of the electron density at the bond critical point ρ_{bcp} taken from ref. 34 for the C—C bond: 0.24 au for ethane, 0.36 au for the double bond in ethylene, and 0.45 au for the triple bond in ethyne. In the molecules we study here, values range from 0.06 to 0.28 au.

We have estimated the average values of these magnitudes for the different types of bonds and evaluated their usefulness for describing the bonds. We have also calculated the covalent bond orders for the Br—O and Cl—O bonds under study, based on partitioning of the number of electrons within the topological theory of AIM implemented in the G98 package, as discussed in refs. 35–37. This method does not imply any empirical fitting to specific types of bonds.

Results

We present in Table 1 a summary of the data collected for the set of molecules under study. Where available, we indicate experimental bond lengths and observed vibrational frequencies. We also include previously calculated empirical force constants, which come from ref. 12 for BrO and OBrO and from ref. 16 for BrOBr. Together with these data, we display the results obtained in the present work, both for optimized geometry from our ab initio calculations and for refined wavenumbers and force constants from the individual refinements of each molecule and its isotopomers. These individual refinements are carried out in a standard way (38). When the frequency of a specific normal mode has not been observed, the corresponding force constant is not refined and

a blank is left in the appropriate entry of the table (see, e.g., BrOO and ClBrO). The complete set of data included vibrational frequencies from the following isotopic species: bromine-79 and bromine-81 isotopomers for $Br^{16}O$ (39); 16–79–16, 16–81–16, 18–79–18, and 18–81–18 for OBrO (14, 15); 79–79–16, 79–79–18, 81–81–16, and 81–81–18 for BrBrO (17, 40); 79–16–79, 79–18–79, 79–16–81, and 79–18–81 for BrOBr (13, 16, 18, 19); 16–16, 16–18, and 18–18 for ^{79}BrOO (15); 79–16, 81–16, 79–18, and 81–18 for ^{35}ClBrO (41); 35–16, 35–18, and 37–16 for ^{79}BrClO (41); chlorine-35 and chlorine-37 isotopes for $^{79}Br^{16}OCl^{16}O$ (42); bromine-79 and bromine-81 isotopes for $^{35}Cl^{16}OBr^{16}O$ (42); and the more abundant isotopic species only for BrO_3 (11), $BrOBrO_3$ (43), ClOBr (27), and $BrClO_2$ (42). Only frequencies for the parent molecules are reported in Table 1, values for the minor isotopomers being reproduced with a similar quality in the force field analysis. The last column of Table 1 indicates our labelling of the type of bond formed between the oxygen atom and the halogen, Br or Cl, according to the value of the refined force constant of the corresponding bond stretching.

Based upon these results, we performed a joint fit using the stretching frequencies of all halogen oxides as input to refine a reduced set of stretching force constants. The best estimates of the refined force constants are given in Table 2, with an indication of the molecule in which the appropriate bond is found. For the Cl—O bond, the corresponding refined values reported in the chlorine oxides paper (1) are also listed for comparison.

Table 3 collects the results of the topological analysis performed on these molecules, and Table 4 presents the average values of the electronic density characteristics for the types of bonds found, to facilitate the forthcoming discussion.

From the analysis of the preceding data, we have found three different types of Br—O bonds, similar to the findings for the Cl—O bond. The stronger type of bond, termed type I, occurs in molecules in which the bromine atom is linked to two or more oxygen atoms that are located at the end of the molecule, and it is thus denominated "central". Type II corresponds to weaker bonds, found in molecules with bromine atoms at end positions, called "external". A type III bond is formed when a very weak link occurs between a bromine atom and an otherwise stable molecule, as in BrOO, and we term it simply "weak". The same characteristics apply for the Cl—O bonds present in the mixed oxides studied here, as well as in the Cl_xO_y species studied previously (1).

The frequencies where the Br—O bond stretching modes appear in the spectrum give a straightforward indication of the type of bond, with values around 800 cm^{-1} for the central type and 500 cm^{-1} for the external type. Accordingly, the corresponding force constants have typical values for a strong or for a moderate single bond of 5×10^2 or 2.5×10^2 N m^{-1}, respectively. The strength of the binding is also reflected in the bond length, which varies between values of 1.6 and 1.9 Å (1 Å = 0.1 nm) for central and external bonds, respectively, whereas it is much longer (2.3 Å) for the weak bond in BrOO. Similarly, the covalent bond order has decreasing values in the series, indicating a fairly strong single bond (bond order of 1.7) in the first case, a standard single bond (bond order of 1.1) in the second, and a very weak binding (bond order of 0.6) in the third. There are some special cases that will be discussed in more detail below.

The analysis of the topological characteristics of these bonds presents some interesting results, which are more manifest when one looks at the average values of the electron distribution properties. Table 4 lists the mean values of the electron density at the bond critical point, the Laplacian of the density distribution, and the ellipticity of the bond. These values are calculated for each type of bond from the results given in Table 3 for the corresponding specific bond in the molecules listed in the footnotes to Table 4. We have also included the standard deviation about each mean value. Thus, when comparing the ellipticity mean values of the Br—O bonds, we can see that they increase as the bond gets weaker, indicating a less cylindrical symmetry of the bond, but the uncertainties are very large, overlapping consecutive mean values. The use of this quantity as an indicator of the bond type seems therefore inadvisable. A similar result is found for the Laplacian of the density. Increasing positive values are found as the bonds get weaker, indicating increas-

ing withdrawal from the maximum of charge concentration, where $\nabla^2\rho$ should be negative for a strong bond. However, again the standard deviations about the mean values are larger than the differences between the mean values characteristic of each type of bonds. On the other hand, the electron density at the bond critical point offers a good indication of the bond type. The mean value of ρ decreases substantially from central to external to weak bonds, and the standard deviations about the mean values are relatively small.

In view of these results, the chemical nature of these bonds can be envisaged in the following way. A central type Br—O bond, as found in the BrO_3 molecule, is formed by both the oxygen atom and the bromine atom contributing two electrons each, giving rise to a kind of π-type bonding, comparatively shorter and with higher density in the plane perpendicular to the bond. The typical value of the covalent bond order, 1.6 to 1.8, is consistent with this description. On the other hand, in an external bond, as in BrOBr, the oxygen and bromine atoms contribute one electron each, resulting in a σ-type bond, longer, more cylindrical, and with lower density. The O atom in this case would accommodate its electrons in sp^3 hybrid orbitals, with two pairs of nonbonding electrons. Correspondingly, a covalent bond order close to 1 is calculated for this type of bond. Finally, the weak type of bond is mainly of electrostatic nature; the covalent bond order of ~0.6 reflects that there is still some electron sharing between bromine and oxygen atoms.

It is interesting to see that these topological properties have very similar values for Cl—O bonds, both in pure chlorine oxides and in the mixed species studied here. The substitution of a Cl atom by a Br atom does not alter in any appreciable amount the charge density or the Laplacian of the density of any other Cl—O bonds contained in the molecule. For example, ρ and $\nabla^2\rho$ for the external Cl—O bond in ClO*ClO* and BrO*ClO* are calculated as 0.312 and –0.426 au (ClOClO; ref. 1) and 0.310 and –0.494 au (BrOClO). The computed values for Cl_xO_y species of ref. 1 were obtained with the same basis set as in this work, namely, 6-311+G(2df), although in ref. 1 a density functional method (B3LYP) was used. Thus, it seems that the basis set is more a determinant than the method of calculation in the evaluation of these electronic properties.

It is also illustrative to make a comparison of the charac-

Note: bcp, bond critical point.

teristics of Br—O bonds with those of Cl—O bonds. Table 5 lists both typical values for the properties already discussed for Br—O bonds and the corresponding ones for Cl—O bonds, taken from the results of the present work and of ref. 1. For Cl—O, the same three types of bonds are found, as discussed in ref. 1 and reflected in the table, with characteristics that show the same trends as for Br—O. When comparing Cl—O and Br—O bonds, the higher force constants and larger bond orders of the former with respect to the latter indicate that Cl—O bonds are on average 10% stronger than Br—O bonds of a similar type. The different masses and sizes of the chlorine and bromine atoms account also for the corresponding shorter bond lengths and higher stretching frequencies. The electron densities at bond critical points are also systematically larger for Cl—O bonds, by a factor of 1.1 or 1.2. On the other hand, the Laplacian of the density, which we discarded as a poor indicator for Br—O bonds, was found to change drastically from one type of Cl—O bond to the next. Thus, for central Cl—O bonds, the Laplacian is large and negative, indicating a clear maximum of density distribution at the critical point. This value is close to 0 for the external type of Cl—O bonds and becomes large and positive for the weaker bonds. The absence of negative values for the Laplacian of the density of all Br—O bonds shows the relative weakness of these bonds.

Some special cases

The first molecule under study, bromine oxide (BrO), has special characteristics, as was true for ClO in the Cl_xO_y series (1). All the indicators that we have derived to ascribe the bond to a certain type have values that are between those of a central and those of an external bond, although closer to the former. Thus, this specific Br—O bond shares the properties of both types: the oxygen atom is located at one end of the molecule, which would make this bond of the central type, but the Br atom is also at an end, which would make the bond external. It seems that the existence of an external O atom is the more relevant to impress character to the bond. A rather similar situation is found for the BrBrO molecule, where the Br—O bond shows characteristics intermediate between those of central and external bonds, but again closer to those corresponding to the definition of a central bond adopted in this work.

We thought it interesting to present here a more detailed study of $BrOBrO_3$. The only reference to the geometry of this molecule that we have found comes from X-ray data (43), providing a tentative structure where both bonds of the Br–O–Br bridge have the same length (1.862 Å), and those of the BrO_3 end group are also identical but shorter (1.605 Å). A value of 110° is reported for the angle of the Br–O–Br bridge, but nothing is stated about the other angles of the molecule. The same authors (43) report a Raman spectrum at 77 K, from which the bands in the 500–600 cm^{-1} region are assigned to vibrations of the Br–O–Br bridge. With this information, we carried out ab initio refinements of the geometry, starting at different initial structures and working at a lower level of theory, until we found good convergence for the highest level of calculations performed in this work. The corresponding geometry is represented in Fig. 1, where the electronic density is depicted by contour regions of different shading, and bond critical points are marked by open triangles. Bond lengths for this structure are indicated in Table 1, with values of 115.5° for the angle of the bridge, 97.6° for the in-plane adjacent BrOBr angle, and 115.9° (twice) and 114.1° for the three OBrO angles of the BrO_3 end group, whose symmetry is therefore not exactly threefold. With the optimized structure and by comparison

with other bromine oxides, we performed various normal mode analyses until we reached an acceptable interpretation of the vibrational spectrum reported in ref. 43. The corresponding force constants and calculated wavenumbers are also given in Table 1. It is interesting to see that where the first two bonds are of type II, clearly weaker than those of the BrO_3 end group (type I), they are also significantly different from each other, as illustrated by their stretching force constants and as shown by the lower electron density at the bond critical point of the first Br—O bond with respect to that of the adjacent O—Br. It seems that the first Br—O bond is weakened by having part of its electron density transferred to the second. Surprisingly, the covalent bond order values of these two bonds are reversed from the expected trend, the first weaker bond having a larger bond order than the stronger second O—Br bond, although the values are not widely different. We cannot find an explanation for these abnormal bond order values. The BrO_3 end group behaves in accordance with other central Br—O bonds in the series, as far as all indicators are concerned.

Figure 2 depicts the ClOBrO molecule, with the OBrO group in the plane of the figure and the Cl atom below the plane. Here again we have two markedly different Br—O bonds. Although the Br atom is in a central position, only the last Br—O bond is of the central type I, whereas the presence of the Cl atom at the other end draws electron density from the central O—Br bond to the external Cl—O bond, both of which thus have type II or external characteristics. The different distribution of electron density for the two Br—O bonds is clearly shown in the figure.

Conclusions

This work characterizes three different types of Br—O bonds in bromine oxides, which roughly correspond to bonds where the Br atom occupies a central or apex position in the first and stronger case, occupies an external position in the second, or is loosely linked to a stable structure in the third and weaker type. These three bond types exhibit quite different values for bond lengths, stretching frequencies, force constants, and electron densities at the bond critical point. These types of bonds parallel those previously described for Cl—O in chlorine oxides, the Br—O bonds being on average 10%–15% weaker than the corresponding Cl—O bonds of the same type. The scant spectroscopic information available for the bromine oxides would make further experimental work on these species highly recommendable.

Torsional isomers in methylated aminoethanols — A jet–FT-IR study[1]

Yaqian Liu, Corey A. Rice, and Martin A. Suhm

Abstract: Jet–FT-IR spectra of aminoethanol (AE), *N*-methylaminoethanol (MAE), and *N*,*N*-dimethylaminoethanol (DMAE) are presented and compared to gas-phase and matrix isolation IR, microwave, and quantum chemical data. The intramolecular O-H··N hydrogen bond gives rise to characteristically shifted O-H stretching bands and torsional difference bands in the monomer spectra. It stabilizes one out of 14 diastereomeric monomer conformations of AE and DMAE and two out of 27 diastereomeric MAE conformations. The latter two correspond to torsional or *N*-inversional isomers, the interconversion of which is hindered by the intramolecular hydrogen bond. Their energy difference is found to be <1.2 kJ/mol. The intermolecular aggregation patterns of the three aminoethanols are quite distinct and non-monotonic, as suggested by their O-H stretching fingerprints.

Key words: aminoethanol, IR spectroscopy, conformation, hydrogen bond, supersonic jet.

Résumé : On a déterminé les spectres FT-IR à jet de l'aminoéthanol (AE), du *N*-méthylaminoéthanol (MAE) et du *N*,*N*-diméthylaminoéthanol (DMAE) et on les compare aux données relatives aux spectres IR en phase gazeuse et isolement matriciel, aux spectres de microondes ainsi qu'aux données obtenues par calculs quantiques. Dans les spectres des monomères, la liaison hydrogène O-H··N donne lieu à des bandes d'élongation O-H qui sont déplacées d'une façon caractéristique et des bandes de différence de torsion. Elle stabilise une seule des quatorze conformations monomères diastéréomères du AE et du DMAE et deux des vingt-sept conformations diastéréomères du MAE. Ces deux dernières correspondent aux isomères de torsion ou d'inversion autour de l'azote, l'interconversion qui subit un empêchement en raison de la liaison intramoléculaire. On a trouvé que leur différence d'énergie est de <1,2 kJ/mol. Les patrons d'agrégation intermoléculaire des trois aminoéthanols sont très différents et ne sont pas monotoniques, tel que suggéré par leurs profils caractéristiques dans la région des bandes d'élongation O-H.

Mots clés : aminoéthanol, spectroscopie IR, conformation, liaison hydrogène, jet supersonique.

[Traduit par la Rédaction]

Introduction

Hydroxy and amino groups rank among the most important hydrogen-bond building blocks in nature. If they are separated by a backbone of two sp^3 carbon atoms, an interesting interplay between intra- and intermolecular hydrogen bonding is possible. The resulting simplest prototype, 2-aminoethanol (AE) — an 11-atomic molecule with a single reference (1) in Herzberg's compilation of *Molecular Spectra and Molecular Structure* (2) — has three torsional degrees of freedom, which allow for rich conformational isomerism. This conformational isomerism in AE has been the subject of a number of experimental and theoretical investigations (3, 4). Despite the large number of conformers, microwave (MW) and millimeter-wave studies (5–7) have shown the most stable enantiomeric pair (g′Gg′ and gG′g) to be the dominant species in the gas phase. Here, the notation employed by Radom et al. (8) is applied: G denotes a gauche (≈60°) N-C-C-O torsional angle, whereas g′ refers to an opposite gauche (≈−60°) conformation of the C-C-O-H and C-C-NLp (Lp stands for the N-atom lone pair) dihedral angles. The stability of this pair of conformers is attributed to the formation of an intramolecular hydrogen bond of O-H··N type (see Fig. 1). This finding is also supported by the gas-phase IR spectrum of AE, which shows a dominant absorption centred at 3570 cm^{-1} (9). The same was found for *N*,*N*-dimethylaminoethanol (DMAE, see Fig. 1), which features a somewhat stronger hydrogen bond because of the electron-donating properties of the methyl groups (10). Obviously, all other conformers are energetically less favourable, although some of them can be trapped by rapid cooling in a rare gas matrix (9). Vibrational spectroscopy provides an appropriate tool for the investigation of such conformational isomerism, as the exact frequency of the strong O-H stretching transition depends sensitively on the hydrogen-bond environment. To characterize the low-temperature conformations of isolated AE and DMAE, we have undertaken a ragout-jet–FT-IR (11, 12) investigation. The ragout-jet–FT-IR technique, while originally designed for the study of hydrogen-bonded clusters, can also be used to investigate hydrogen-bonded monomer conformations of moderately volatile compounds. With this technique, we went on to in-

Fig. 1. MP2/6-311++G(2d,2p) g′Gg′ structures of aminoethanols. For MAE, an additional prefix is needed to describe the chirality at the N-atom: *t*- and *g*- refer to trans and gauche positions of the methyl group with respect to the CH_2OH group. The gauche conformation is predicted to be 0.5 kJ/mol above the trans conformation at this level, including zero-point energy contributions.

vestigate the effect of replacing only one amino hydrogen by a methyl group in *N*-methylaminoethanol (MAE, see Fig. 1) (13). This single methyl group introduces a labile chiral centre at the nitrogen, which gives rise to additional diastereoisomerism. At room temperature, two MAE diastereomers, as depicted in Fig. 1, were observed by MW spectroscopy (14). A ground-state energy difference of 1.9 kJ/mol was determined from relative intensity measurements. The question is then: will these two MAE diastereomers relax to a single one in a free jet expansion, as in the case of AE and DMAE, or will they persist even at low temperatures?

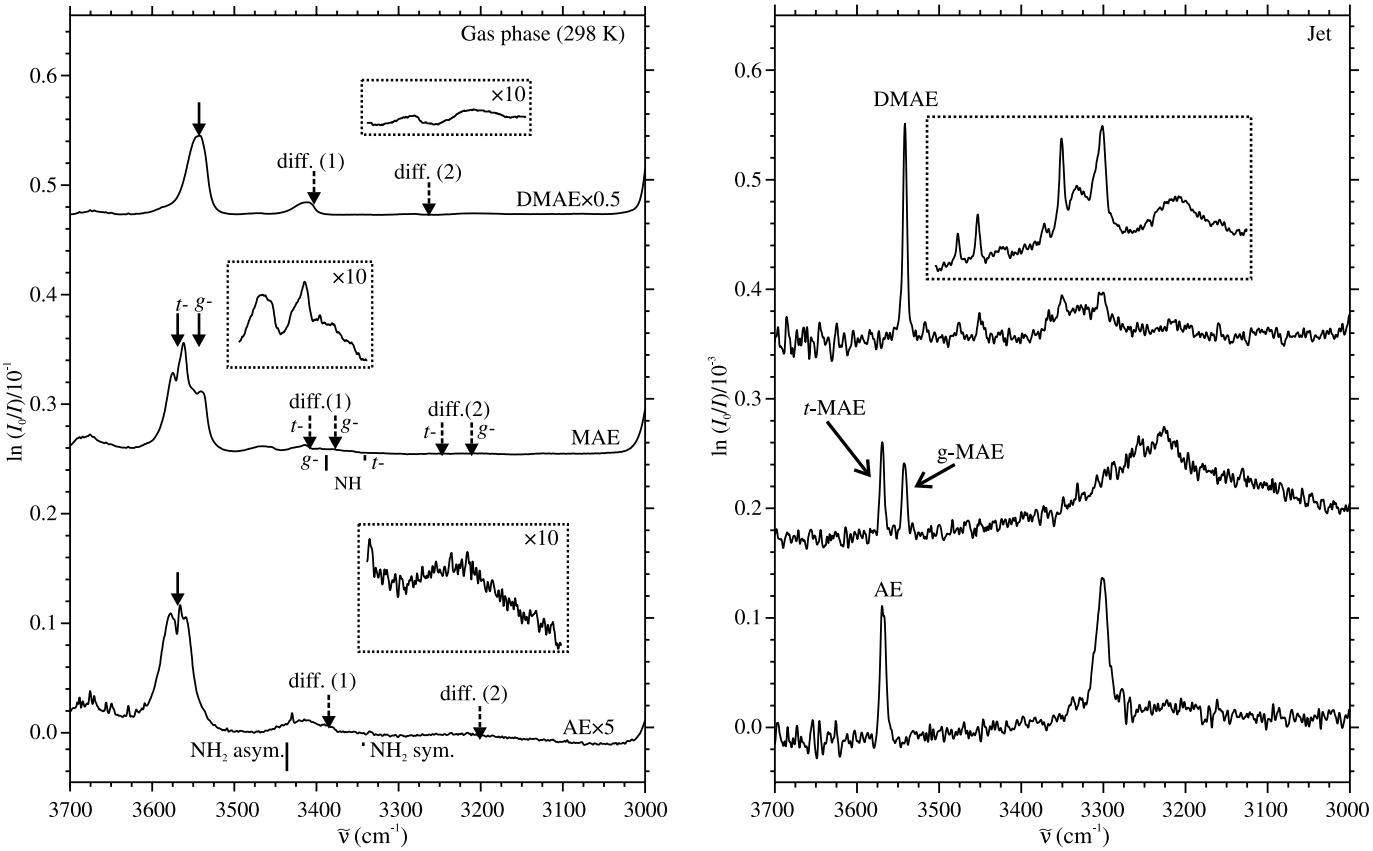
Methods

The IR spectra in the O-H stretching region of the three aminoethanols were recorded with our ragout-jet–FT-IR cluster spectrometer. The setup and operating principles of the spectrometer are given in detail elsewhere (11). Briefly, a commercial Bruker IFS 66v/S rapid-scan FT-IR spectrometer probes a pulsed supersonic expansion into a 15-m^3 vacuum chamber. The expansion is generated by a 12 cm long and 0.5 mm wide pulsed slit nozzle (modified General Valve Series 97). The size of the vacuum chamber allows for the use of long and intense gas pulses, during which entire FT-IR spectra are recorded. At 2 cm^{-1} spectral resolution, a typical gas pulse extends over 140 ms. After a pulse, the buffer volume is pumped for about 30 s at 2000 m^3/h, to prevent the buildup of excessive background gas pressure. Therefore, the actual scan time is quite short, but the idle time is more than two orders of magnitude higher. The low duty cycle is at the heart of the success of this technique (11). A 65-L sample reservoir keeps the stagnation pressure within 10% during a gas pulse.

The three aminoethanols (AE (>99%), Aldrich; MAE (99.8%), Acros; DMAE (>99.5%), Aldrich) were dried over molecular sieves and injected into a saturator. Helium (>99.996%, Messer) was passed through the saturator before entering the sample reservoir. The temperature of the saturator was varied to optimize the monomer absorptions. The optimal temperatures were 20 °C for AE and MAE, and 0 °C for DMAE. The estimated concentration in the gas mixture is 0.005%. An InSb detector with appropriate optical components was used. Representative room temperature, gas-phase and ragout-jet–FT-IR spectra of the three compounds are collected in Fig. 2.

The conformational isomerism of the aminoethanols was also investigated by quantum chemical calculations at double-harmonic level using the Gaussian 98 (15) electronic structure package.

Results and discussion



Geometry optimizations for all 14 spectroscopically distinguishable conformers were not repeated for AE, because of the large number of existing data (3, 4, 8). Geometry optimization followed by harmonic frequency calculation was restricted to the most stable g′Gg′ conformer and the open-chain gTt conformer, at HF, B3LYP, and MP2 levels of theory, with the 6-31+G* basis set. The relative energies are in line with previous data (3, 4).

For DMAE, all 14 energetically distinct conformers were optimized. The relative energies, harmonic O-H stretching wavenumbers, and band strengths are given in Table 1. The HF values are in reasonable agreement with a previous study by Ohno et al. (16). Calculations at all levels predict the g′Gg′ conformer as the most stable conformer. All other conformers are at least 8–14 kJ/mol higher in energy. The energy difference between the g′Gg′ conformer and the open-chain gTt conformer may be used as a rough approximation to the intramolecular H-bond stabilization energy. For the 6-31+G* basis set, it amounts to 8.8, 12.8, and 15.7 kJ/mol at the HF, B3LYP, and MP2 levels, respectively, for DMAE. These values are slightly larger than those for AE (8.0 kJ/mol at the HF level, 12.3 kJ/mol at the B3LYP level, and 13.8 kJ/mol at the MP2 level), consistent with a relatively stronger intramolecular hydrogen bond. This is confirmed by the O-H stretching wavenumber red shift in the g′Gg′ conformer compared to that of the gTt conformer. The values are 123/104 cm^{-1} (DMAE/AE) at the MP2/6-31+G* level. The intramolecular hydrogen bond is also reflected by an increased IR band strength for the g′Gg′ conformer (see Table 1). For the remaining conformers, different relative orders of stability are predicted at different levels. The same phenomenon was previously observed (3, 16).

The 27 conformers of MAE were also optimized at the HF, B3LYP, and MP2 levels with the 6-31+G* basis set. The obtained results are given in Table 2. The HF values are consistent with the study by Ohno et al. (17). As in the case of AE and DMAE, the g′Gg′ conformations are predicted to be the most stable isomers. The introduction of an additional chiral centre at the N atom by single methyl substitution gives rise to two distinct g′Gg′conformers, namely, *t*-g′Gg′ where the methyl group is located trans (~180°) with respect to the CH_2OH group, and *g*-g′Gg′ where the methyl group is

Fig. 2. Gas-phase spectra (left, including some enlarged sections) and ragout-jet–FT-IR spectra (right) in the O-H stretching region of aminoethanols. The gas-phase spectra correspond to a scan time of 19.2 s, while the jet spectra correspond to scan times of 37, 48, and 29 s for AE, MAE, and DMAE, respectively. Experimental conditions are p = 1.0 bar (1 bar = 100 kPa), T = 20 °C for AE; p = 0.8 bar, T = 20 °C for MAE; and p = 1.0 bar, T = 0 °C for DMAE. Dashed arrows mark harmonic MP2/6-311++G(2d,2p) predictions of O-H stretching/O-C-C-N torsion difference bands originating from the first and second excited O-C-C-N torsional states, shifted from the experimental O-H stretching bands (solid arrow). Predicted N-H stretching modes are shown as vertical bars below the corresponding spectrum, shifted in the same manner. The lengths of the bars correspond to relative intensities, but are amplified 10-fold.

gauche (~60°) with respect to the CH_2OH group (see Fig. 1). In this notation, we conserve the underlying AE nomenclature for comparison purposes. At the HF level, the gauche conformer is 2.6 kJ/mol higher in energy than the trans conformer. The energy difference reduces to 1.6 kJ/mol at the B3LYP level, and further to 0.9 kJ/mol at the MP2 level. Relative to the corresponding gTt conformer, the intramolecular O-H··N bond stabilizes *t*-MAE by 7.9, 11.6, and 14.1 kJ/mol and *g*-MAE by 8.6, 12.9, 15.3 kJ/mol at HF, B3LYP, and MP2 levels, respectively. The predicted O-H stretching wavenumber red shifts are 99/122 cm^{-1} for *t*-/*g*-MAE at the MP2/6-31+G* level.

MP2 geometry optimizations and harmonic frequency calculations were extended to larger basis sets, namely, 6-311++G** and 6-311++G(2d,2p), for the most stable g′Gg′ conformers of the three aminoethanols. The predicted equilibrium rotational constants are in good agreement (1 ± 1%) with MW data (5, 10, 14). Calculated O-H stretching harmonic wavenumbers together with IR intensities are given in Table 3. One might expect that the O-H stretching frequencies of the two MAE conformations should fall in between those of AE and DMAE, because of the intermediate inductive methyl influence. In fact, *t*-MAE is predicted by the MP2/6-311++G(2d,2p) calculations to absorb very close to AE, whereas the *g*-MAE absorption falls rather close to the DMAE absorption (see Table 3). It appears that the O-H stretching frequencies correlate with the N-substituent at the gauche position relative to the CH_2OH group. The N-H stretching intensities are predicted to be at least an order of magnitude weaker than the O-H stretching fundamentals. With these quantum chemical predictions, it is rather straightforward to interpret the recorded ragout-jet–FT-IR spectra of the three aminoethanols, which are shown in Fig. 2.

For AE, a single narrow monomer absorption centred at 3569 cm^{-1} is observed, corresponding to the broad absorption band centred at 3570 cm^{-1} in the room-temperature, gas-phase spectrum. This is assigned to the O-H stretching mode of the g′Gg′conformer. Its average number density in the jet is estimated to be 10^{13} cm^{-3}, using the predicted band strength at the MP2/6–311++G(2d,2p) level. The obtained O-H stretching frequency is in agreement with a previously reported gas-phase value of 3570 cm^{-1} (3, 18), an Ar matrix isolation value of 3555 cm^{-1} (9), and a value of 3526 cm^{-1} in C_2Cl_4 solution (19). In the gas-phase spectrum, a weak broad absorption feature is observed to higher frequencies, near 3680 cm^{-1}. The occurrence of this peak was attributed to the O-H stretching absorption of other conformers such as gGt, tGt, and gGg (3). No significant monomer absorption is

located in the jet spectrum in that region, consistent with a relative energy of 6.6 kJ/mol (4) for the second most stable gGt conformer, even if we assume that the conformational equilibrium is frozen at room temperature. It would require a significantly better signal-to-noise ratio in this difficult spectral region to see such high-lying conformers. Towards lower frequencies, an additional weak, broad feature centred around 3410 cm^{-1} with a sharp peak at 3430 cm^{-1} appears in the room-temperature, gas-phase spectrum. The sharp peak was previously assigned to the asymmetric NH_2 stretch of the g′Gg′conformer (9). This assignment is consistent with the MP2/6-311++G(2d,2p) prediction, as denoted by the ver-

Note: The equilibrium energy differences ($\Delta E_e = E_{e,g\text{-conformer}} - E_{e,t\text{-conformer}}$, in kJ/mol), the zero-point corrected values (ΔE_0), and the Gibbs free-energy differences ($\Delta G^\circ_{298.15}$, in kJ/mol) between the two MAE conformers are also given.

[a]From ref. 13.

tical bar labelled as NH_2 asym. (Fig. 2). Position and height of this bar are determined by the calculated relative wavenumber and intensity with respect to the experimental O-H stretching fundamental (solid arrow, Fig. 2). For better visibility, a factor of 10 is applied to calculated NH stretching intensities. The symmetric NH_2 stretching intensity is predicted to be an order of magnitude weaker than the asymmetric NH_2 stretch, and it might correspond to the very weak feature at 3335 cm^{-1}. Neither of the NH_2 bands is observed in the jet spectrum because of their low intensities. This is consistent with a detection limit of 10^{13} cm^{-3} based on the predicted band strength for the asymmetric NH_2 stretching mode (9 km/mol at the MP2/6-311++G(2d,2p) level) at our noise level. The broad band near 3410 cm^{-1} was previously not assigned (9). It disappears in the jet spectrum, which points to a hot-band origin. Among the low-frequency modes of AE (τ_{OCCN} = 184 cm^{-1}, τ_{NH_2} = 263 cm^{-1}, δ_{CCN} = 328 cm^{-1} at MP2/6-311++G(2d,2p) level), the O-C-C-N torsional motion can give rise to a difference band $\nu_{OH} - \tau_{OCCN}$ in this region, in particular as it modulates the H-bond distance. Its harmonic prediction relative to the experimental ν_{OH} band centre is shown by a dashed arrow (diff. (1), see Fig. 2) and agrees reasonably well with the broad feature. The $\nu_{OH} - 2\tau_{OCCN}$ difference band is also predicted (diff. (2)) close to a weak and broad absorption in the spectrum (magnified 10-fold in the insert).

The jet spectrum of DMAE is rather similar to that of AE (Fig. 2). A single monomer absorption band at 3542 cm^{-1} is observed and assigned to the O-H stretch of the g′Gg′ conformer. It corresponds to the broad absorption band centred at 3543 cm^{-1} in the room-temperature, gas-phase spectrum. It is in line with the values obtained in dilute C_2Cl_4 solutions (3506 cm^{-1} in ref. 19 and 3510 cm^{-1} in ref. 20) and the Ar matrix isolation value (3498 cm^{-1}, ref. 16). It is red shifted by 27 cm^{-1} relative to AE, because of a slightly stronger intramolecular H-bond. Similar to AE, the ν_{OH} jet band centre is labelled by a solid arrow in the gas-phase spectrum. Predicted band centres of $\nu_{OH} - \tau_{OCCN}$ and $\nu_{OH} - 2\tau_{OCCN}$ with τ_{OCCN} = 140 cm^{-1} at the MP2/6-311++G(2d,2p) level are also shown by dashed arrows. The $\nu_{OH} - \tau_{OCCN}$ prediction (diff. (1)) agrees rather well with the absorption band around 3410 cm^{-1}, 132 cm^{-1} to the red relative to the O-H stretching fundamental. There is also an absorption near $\nu_{OH} + \tau_{OCCN}$, but it falls in a range where water absorptions and excited conformers make an analysis difficult.

Two O-H absorption bands are observed in the MAE jet expansion. One almost coincides with the AE absorption and is assigned to the *t*-g′Gg′ conformer. The other one is at nearly the same position as in DMAE. It is assigned to the gauche conformer (see Table 3 and Fig. 2). For comparison, the O-H stretching wavenumbers are 3515 cm^{-1} in C_2Cl_4 (only one value was reported) (19) and 3485, 3516, and 3555 cm^{-1} in an Ar matrix (not definitely assigned, ref. 17). The presence of more than one conformation is also apparent in the room-temperature, gas-phase spectrum (Fig. 2). As in the spectra of AE and DMAE, $\nu_{OH} - \tau_{OCCN}$ and $\nu_{OH} - 2\tau_{OCCN}$ predictions relative to the experimental ν_{OH} bands are shown using dashed arrows (τ_{OCCN} = 161/166 cm^{-1} for *t*-/*g*-MAE at the MP2/6-311++G(2d,2p) level). This leaves a peak around 3470 cm^{-1} unexplained. It corresponds nicely to other torsional difference bands involving the N-CH_3 group, predicted at 3465 (*t*-) and 3466 cm^{-1} (*g*-). The predicted NH stretching fundamentals are again shown as vertical bars with appropriate relative intensities (Fig. 2).

It is instructive to discuss the *t*- and *g*-MAE O-H stretching intensities in the jet spectrum. On the basis of the MP2/6-311++G(2d,2p) energy difference (ΔE_e = 0.09 kJ/mol in favour of *t*-MAE, see Table 3) and band strength ratio (nearly 1:1), the experimental intensity ratio of 1:0.84 would be consistent with thermal equilibrium frozen at ~40 K. This is somewhat low, considering the various conceivable isomerization paths, which all involve substantial heavy-atom motion. Likely, the lowest paths do not involve *N*-inversions, but rather g–g′, G′–G torsions. However, this requires closer investigation. Inclusion of zero-point energy raises the energy difference to 0.5 kJ/mol and brings the effective isomerization temperature to ~240 K, a more plausible value for a jet expansion under kinetic control. Actually, the more appropriate quantity in the IR experiment would be ΔG°_T, which is 0.3 kJ/mol at 298.15 K at the MP2/6-311++G(2d,2p) level, i.e., quite similar to the energy difference. Interestingly, there is an experimental value for the energy difference between the conformers based on MW spectroscopy (14), which is substantially higher (1.9 ± 0.4 kJ/mol). This value appears to be inconsistent with our observed jet band intensities, even if equilibrium is frozen already at room temperature. Even if we allow for a 10% error in the calculated *t*-/*g*-band strength ratio and another 10% difference in the partition functions of the two isomers, we get an upper limit for ΔE of about 1.2 kJ/mol. This is

© 2004 NRC Canada

also consistent with our large basis set MP2 calculations, but higher level electronic structure calculations including an analysis of interconversion pathways would be desirable to confirm this finding. On the experimental side, further MW investigations on this delicate conformational equilibrium would be valuable. One might also consider a higher resolution IR study.

In the jet spectra of the aminoethanols (Fig. 2), bands due to aggregates appear to lower frequencies. A single absorption band around 3300 cm^{-1} is observed for AE, possibly corresponding to the IR-active O-H stretch of the most stable cyclic dimer with two intermolecular O-H··N bonds (4). Quite in contrast, a very broad absorption band is observed for MAE, with a peak position near 3225 cm^{-1}. This is in line with a broad band around 3220 cm^{-1} observed in the Ar matrix, assigned to the intermolecular O-H stretching band. The increased width of the cluster band relative to that of AE may be due to a larger number of isomers or to a preference for larger clusters. Rather than restoring the simplicity of AE, the cluster absorptions of DMAE are more complex. They involve several groups of sharp and broad bands over a wide frequency range. This is illustrated by a spectrum at higher concentration, shown as an insert in Fig. 2. The broad bands at lower frequencies might be due to intermolecular O-H stretching modes, while intramolecularly hydrogen-bonded O-H stretches could give rise to the sharp bands. Intramolecular O-H··N bonds should be more persistent in DMAE because of the enhanced strength. Also, N-H vibrations may come into play for intermolecular hydrogen bonds (4). A more detailed discussion of these variations in clustering tendency will be given elsewhere.

We finally note that our accurate ragout-jet–FT-IR aminoethanol monomer band centres can be useful for the interpretation of IR hole burning spectra of clusters involving an aromatic chromophore and an aminoethanol. In those experiments, the corresponding aminoethanol O-H stretch can only be observed in the complex (21, 22). Estimates of the shifts so far had to rely on relatively broad room-temperature, gas-phase band profiles or matrix isolation values.

Conclusions

The intramolecular O-H··N hydrogen bond in symmetrically substituted aminoethanols stabilizes a single pair of enantiomeric conformations (g′Gg′ and gG′g) over all other 25 conceivable structures, so that no significant isomerism is observed in supersonic jet expansions. By breaking the symmetry at the amino group via single methyl substitution, the O-H stretching band splits into two. The two components almost coincide with the band centres of the doubly and the non-methylated aminoethanol. It is shown that these two bands are due to conformations that differ in their relative chirality at the N atom and that their energy difference is probably less than 1.2 kJ/mol, somewhat in contrast to previous MW evidence. In the future, it will be interesting to carry out jet isomerization experiments between *t*- and *g*-MAE, including also Ar coating (23). It will be challenging to analyse in detail the clustering behaviour of these compounds, which clearly shows a non-monotonic trend with increasing *N*-methylation. *N*-Methylaminoethanol may be viewed as an extremely simplified cartoon of the torsional isomerization and intra- versus intermolecular hydrogen-bond competition, which is so vital in protein folding. Even in this simple example, there remains a lot to be explored.

An intercomparison of measured pressure-broadening and pressure-shifting parameters of water vapor[1]

Robert R. Gamache and Jean-Michel Hartmann

Abstract: The present work is an intercomparison of experimental results on the pressure broadening and pressure shifting of water vapor absorption lines. The work focuses on application to the Earth's atmosphere; hence measurements of nitrogen, oxygen, air, and H_2O as the buffer, or perturbing gas, were considered. The literature was searched and over 100 papers found. The data, measured half-widths, their temperature dependence, and the line shifts, were taken and databases created for each perturbing gas. The databases were reordered, grouping data for rovibrational transitions, and intercomparisons of the measurements made. Trends in the data, relationships between the data sets, and dependences on temperature and quantum numbers were investigated. The data were averaged and an estimated uncertainty determined. The averaged data sets are evaluated with respect to the need of the spectroscopic and remote sensing communities. Based on these studies, recommendations for new measurements are made.

Key words: water vapor, half-widths, line shifts, temperature dependence of half-width.

Résumé : Dans le présent travail, on présente une intercomparaison de résultats expérimentaux relatifs à l'élargissement et au déplacement des raies d'absorption dus à la pression. Le travail est principalement orienté vers l'application à la chimie de l'atmosphère de la terre et, en conséquence, des mesures d'azote, d'oxygène, d'air et d'eau comme tampon ou comme gaz provoquant une perturbation. On a fait un relevé de la littérature dans laquelle on a trouvé plus de cent études. Les données relevées pour les demi-largeurs mesurées, leur dépendance sur la température et les déplacements des raies ont été insérées dans des bases de données créées pour chacun des gaz provoquant une perturbation. Ces bases de données ont été réorganisées en regroupant les données pour les transitions rovibrationnelles et on a effectué une intercomparaison des mesures. On a étudié les tendances observées dans les données, les relations entre les ensembles de données et leur dépendance sur la température et les nombres quantiques. On a établi les moyennes des données et on a évalué les incertitudes. On a évalué les ensembles de données pour lesquels les moyennes avaient été établies par rapport à la nécessité des communautés spectroscopiques et de détection à distance. Sur la base de ces études, on fait des recommandations relativement aux nouvelles mesures qui devraient être faites.

Mots clés : vapeur d'eau, demi-largeur, déplacement de raies, dépendance de la demi-largeur sur la température.

[Traduit par la Rédaction]

Introduction

Some 10 years ago the current authors, with L. Rosenmann, published a critical survey (1) of measured half-widths of water vapor perturbed by H_2O, N_2, O_2, air, CO_2, and Ar. There were four goals identified in that work: (1) to use the available data to draw conclusions concerning the influence of vibration, relations between half-widths and their temperature dependence, ratios between broadening by different collision partners, etc.; (2) to extract different broadening values for selected transitions in which one may be very confident by comparing measurements from different authors. Such accurate etalon lines should be of great use to experimentalists as tests of their measurement procedures, for remote sensing, and comparisons with theoretical models.; (3) to propose measurements that are crucially missing to complete the selected set in regard to the requirements of applications and testing of theoretical models; and (4) to make a first test of theoretical results. A literature search at the time revealed a large number of papers concerning measured half-widths of water vapor (2–84). These data gave 1091, 194, 941, and 942 half-widths for N_2-, O_2-, air-, and self-broadening and roughly 500 temperature dependence measurements. Unfortunately, the disagreement among the data was much larger than the experimental uncertainty, making it difficult to address the goals of the work. Goal 1 was addressed as well as could be done at the time with the available data; goal 2 yielded a very small number of transitions for which the confidence in the half-width was high;

we were able to address goal 3 based on the measurements at the time, whereas goal 4 was not possible.

Over the past 10 years there have been a number of measurements of pressure-broadened half-widths and pressure-induced line shifts of water vapor transitions (85–112)[3]. The data sets have grown to 7683, 598, 14 067, and 10 596 measurements of N_2-, O_2-, air-, and self-broadened half-widths and 7097, 461, 8754, and 1543 measurements of N_2-, O_2-, air-, and self-induced line shifts. Using these databases of half-widths and line shifts, the goals of the previous survey are readdressed and the current state-of-the-art of measuring line broadening and shifting is considered.

In the terrestrial atmosphere, water is the principal absorber of longwave radiation, responsible for some 80% of "greenhouse" warming of the Earth's surface (113), and is present in significant amounts in most media. Many water vapor transitions are used or must be accounted for in remote sensing applications. These applications require the calculation of spectra resulting from the interaction of molecular gases with radiation. The data needed for the computation of the spectra consist mainly of the line parameters for each line in the spectrum: the vacuum line position, the line intensity of the molecule–radiation interaction, the lower state energy, the pressure-broadened half-width, and the pressure-induced line shift. For most applications the temperature dependence of these parameters must also be known. The parameters are found in spectral databases such as HITRAN (114), GEISA (115), or the JPL catalogue (116). Some of these catalogues contain collisional-broadening information based on the Voigt or Van Vleck – Weisskopf profile model. Often it is necessary to account for deviations from this model, such as line mixing as in H_2O Raman Q-branch spectra (117–119), finite duration of collision effects in the far wings of the lines (120) of H_2O atmospheric continua (121–123) and high-pressure spectra (124), collisional narrowing effects (2–3), and effects from velocity-changing collisions (125–129).

Currently, the largest source of uncertainty in determining molecular profiles is the pressure-broadening coefficient (130). The effect of errors in the half-width on retrieved profiles has been systematically investigated (131, 132)[4] with the conclusion that inaccurate collision-broadened half-width values and the temperature dependence of the half-width lead to significant errors in retrieved profiles. Traub and Chance[4], using a balloon-borne far-IR FTS during the Balloon Intercomparison Campaign (BIC-2), showed that the estimated uncertainty of 10% rms in the broadening coefficient was by far the dominant error source in H_2O and O_3 profiles at nearly all altitudes. Smith and Gordley (131) and Chu et al. (132) have shown that the magnitude of the error is dependent on altitude and differs with the molecular species in question and depends on the particular transitions under consideration. Chu et al. (132) have also shown that the uncertainty in the temperature dependence of the half-width leads to errors in the retrieved mixing ratios.

The half-widths are also the dominant source of uncertainty in calculation of radiance. Kivel et al. (133) have demonstrated that a 30% increase in the air-broadened half-width of CO_2 leads to a 5% increase in the predicted radiant energy at ~710 cm^{-1}. Smith and Gordley (131) have commented that this change in calculated radiance would correspond to an increase in retrieved temperature on the order of 3 K. In regard to the radiative effects of trace gases, a WMO report on atmospheric ozone (134) cites the lack of data for the half-width and its temperature dependence as a major source of uncertainty in the line-by-line calculations.

The spectroscopic community (130, 135, 136)[5] has determined that for accurate retrievals the half-width and its temperature dependence should be known with an uncertainty of *3%* for strong lines and *10%* for weak lines. The effect of the line shift on reducing data from remote sensing measurements is now known to be significant (137, 138)[6].

This work presents an intercomparison of the measured half-widths and line shifts of water vapor important for terrestrial applications. The goals set forth in the previous survey (1) can be better addressed by the addition of the newer data, and the line shift may now be considered. A survey of the experimental results is presented in the next section and is followed by the analysis of the data including the dependence of the collision-induced parameters on vibration, rotation, temperature, and broadening partner. Intercomparisons of the data are also discussed in the latter section. In the final section, conclusions and recommendations are made.

The experimental results

This work considers the collision-broadened half-widths and pressure-induced line shifts of water vapor for terrestrial applications. A search of the literature was made for half-widths and line shifts of H_2O perturbed by N_2, O_2, air, and H_2O. The result was 112 papers spanning seven decades. Twenty-four have been published since the work of ref. 1. They have increased the half-width data sets by factors of 6.5, 2.0, 7.3, and 10.4 for N_2-, O_2-, air-, and self-broadening. Most of the line shift data are from studies more recent than the study of ref. 1. These data have been organized into databases for each perturbing gas with the half-widths corrected, when necessary, to 296 K by the usual power law model. Table 1 presents a summary of the data. Presented are the number of measurements of the half-width and line shift for a particular broadening gas as a function of vibrational band. The ranges of the data are presented in Table 2; however, to understand this better, some of the newer data must be discussed.

Several of the more recent studies have produced large data sets. Reference 88 reported 5423 N_2-broadened half-widths of water vapor, ref. 89 reported 4168 air-broadened half-widths, and refs. 106 and 107 reported over 6000 half-widths and line shifts for air as the perturbing gas and over 8000 self-broadened half-widths. The analysis of the spectra was automated to produce such large data sets. The codes

that were implemented do not ensure that every spectral line is correct. The assignments for the lines, many of which were very weak transitions, came from ab initio predictions. This fact coupled with transcription errors has led to a small number of transitions with incorrect rotational quantum numbers or a number of transitions with identical rovibrational quantum numbers in the data of ref. 89. One of the current authors (RRG) has corresponded with the authors about these problems.

The data from refs. 88, 106, and 107 have problems that arise from the automated reduction algorithms. For example, in ref. 88, N_2-broadened half-widths as large as 1.65 cm^{-1} atm^{-1} and as small as 0.00099 cm^{-1} atm^{-1} (1 std atm = 101.325 kPa) are reported, values that are much too large and small, respectively. The current authors have been collaborating with the authors of these works. It appears that the spurious values arise for very weak transitions or noise in the spectrum. In the intercomparisons for transitions with reasonable strength (a qualitative guide might be transitions with more than ~5% absorption in the spectra), their data agree well with the data from other groups. We have provided to them an algorithm to identify line shape data that are potentially in error. While they are currently reanalyzing their data, the data used in this intercomparison are from the published work.

Given these facts, when we discuss the range of the data we have not included the data from refs. 88, 106, and 107. However, we have included their data in the intercomparisons since the data that appears to be in question is generally for very weak transitions, which have not been measured by other groups. Hence, there are no intercomparisons of the questionable data. The ranges of the data for the different perturbing molecules are presented in Table 2. These data indicate that the half-widths change by a factor of 39, 15, 44, and 8 from low- to high-J lines for N_2-, O_2-, air-, and self-broadening, respectively. The maximum values of J (K_a) for the data are 20 (11), 16 (10), 19 (11), and 20 (11) for N_2-, O_2-, air-, and self-broadening, respectively. A complete list of J_{max}, J_{min}, $K_{a,max}$, and $K_{a,min}$ for each vibrational band studied can be obtained at faculty.uml.edu/RobertGamache.

There have been a number of investigations into the dependence of the half-width on vibration. Mandin et al. (10, 27), in studies in the 8500–9300 and 9500 – 11 500 cm^{-1} regions, took ratios of their measured half-widths to those of the HITRAN database (114). From this study, Mandin et al. concluded that there was a small (±3%) vibrational dependence of the half-width. Grossman and Browell (5) reported a 5% difference between transitions in the $3\nu_1 + \nu_3$ and $2\nu_1 + 2\nu_2 + \nu_3$ bands, with the $3\nu_1 + \nu_3$ lines having the larger broadening values. This study compared average broadening values, not J-dependent half-widths. In a 1996 study by Brown and Plymate (139) on H_2O broadened by hydrogen, the ratios of half-widths for the same set of rotational quantum numbers were formed for the rotation and ν_1 bands divided by the ν_2 band (51 and 63 pairs of transitions, respectively). The ratios of the rotation to the ν_2 band range from 0.92 to 1.1 and those of the ν_1 to ν_2 band range from 0.98 to 1.19 for the transitions studied. For rotational/ν_2 transitions, the rms ratio is 1.016 (±2.6%), and it is 1.08 (±4%) for ν_1/ν_2 transitions. Brown and Plymate concluded that these differences are too large to be caused by experimental error and that there is a vibrational dependence in the half-width.

Zou and Varanasi (85), in a 2002 study, investigated the vibrational dependence of self- and air-broadening of water vapor in the 950–2100 and 3000–4050 cm^{-1} regions. They considered ratios of the half-widths for the same rotational transition for the $2\nu_2$ and the ν_2 bands, the ν_1 and the ν_2 bands, and the $2\nu_2$ and the ν_1 bands for both self- and air-broadening. From the analysis of the self-broadening data, they concluded that the half-widths in the $2\nu_2$ band are smaller than their counterparts in the ν_2 band by about 10%. The differences in the ratios for the ν_1 and the ν_2 bands and for the $2\nu_2$ and the ν_1 bands contained too much scatter to state conclusively if there was a definite vibrational dependence. Their analysis of the air-broadening data indicated that the half-widths in the ν_1 band are larger than the correspond-

© 2004 NRC Canada

ing half-widths in the ν_2 band by about 5%. This is in rough agreement with the work of Brown and Plymate (139). There were too few ratios for the $2\nu_2$ and the ν_2 bands and the $2\nu_2$ and the ν_1 bands to draw any solid conclusions about the vibrational dependence of the half-widths.

The vibrational dependence of the half-widths of water vapor was addressed in a survey paper (1) and several workshops (130, 135)[5]. It was estimated that, in general, the effect of the vibrational states of the transition was smaller than experimental uncertainties and could change the half-width by ~3%–5%.

A recent theoretical work (140) on the vibrational dependence of the half-widths of water vapor lines found that the half-widths of certain transitions (doublet transitions where $K_c = J$ or $J - 1$) exhibit a strong vibrational dependence. The difference in the half-widths can be up to a factor of 6 for high-J transitions for bands involving 4 quanta of stretch modes. Using the database of measured half-widths, the authors were able to confirm their prediction with experimental data. They were also able to determine the mechanism leading to the vibrational dependence of these half-widths. Given this fact, the intercomparisons made here will not consider identical rotational transitions of different vibrational bands; i.e., the vibrational dependence will be neglected. This greatly reduces the number of transitions that can be compared, but it is necessary. Hence, intercomparisons between measurements made by different groups will be made for transitions with the same quantum numbers: $v_1'v_2'v_3'J'K_a'K_c' \leftarrow v_1''v_2''v_3''J''K_a''K_c''$.

The temperature dependence of the half-width in the databases assumes the usual power law model

$$[1] \qquad \gamma(T) = \gamma(T_0)\left[\frac{T_0}{T}\right]^n$$

where n is the temperature exponent. Measurements (141)[7] and predictions from theory (140) show that for N_2-broadening of water vapor, the temperature exponents range from about 0.8 to –0.3. This is a recent finding. The databases that were created here allow for negative temperature exponents.

Each record of each database contains the wavenumber of the transition, the upper and lower state vibrational quantum numbers ($v_1'v_2'v_3'$ $v_1''v_2''v_3''$), the upper and lower rotational quantum numbers ($J'K_a'K_c'$ $J''K_a''K_c''$), the half-width in units of 10^{-3} cm^{-1} atm^{-1} (1 std atm = 101.325 kPa), the uncertainty in the half-width (same units), the temperature dependence of the half-width and its uncertainty, the line shift in units of 10^{-3} cm^{-1} atm^{-1} (1 std atm = 101.325 kPa), the uncertainty in the line shift (same units), the temperature dependence of the line shift and its uncertainty, an isotopologue code (HITRAN values), and a reference number. While fields in the database have been reserved for the temperature dependence of the line shift, these fields are currently not used. The reference number in the databases refers to a bibliography file that one can download with the database files. These files are available at faculty.uml.edu/Robert_Gamache.

An intercomparison of the collision-induced parameters

Using the database files, codes were written to sort the data into groups for particular rovibrational transitions. All transitions for which only a single measurement was made are eliminated and the resulting data are plotted and intercomparisons made. This procedure results in groups of 2, 3, 4, …, 8 points depending on the number of measurements made for a particular rovibrational transition. For a number of rovibrational transitions, different isotopologues were measured. Intercomparisons were not made between different isotopologues. This procedure yields 499, 19, 3514, and 440 rovibrational transitions for which intercomparisons could be made for N_2-, O_2-, air-, and self-broadening, respectively.

The data for each rovibrational transition are taken and average values of the parameters and their uncertainty produced. Because the uncertainties reported in the literature are not consistent, i.e., some report 1σ of the fit to the data as the uncertainty, others report 2σ or 3σ, others give an overall percentage error for the uncertainty, and in some instances the uncertainty is not reported, it is not possible to use an elaborate scheme to construct the uncertainty. Here, the average value of the half-width was determined as the simple arithmetic average. When five or more points were compared, the uncertainty assigned was twice the standard deviation; otherwise, the uncertainty assigned was the maximum difference between the average and the individual half-width values for the transition or the maximum uncertainty of the measured points, whichever was the greater value. For intercomparisons of two points, the separation of the two data points was considered and compared with the reported uncertainty of the data. This approach yielded a conservative estimate of the accuracy of the data. A similar scheme was used for the line shifts; however, there were far fewer intercomparisons.

Table 3 lists the number of intercomparisons of half-widths made as a function of the number of points in the group, the number of the intercomparisons for which the estimated uncertainty is less than or equal to 3%, 5%, and 10%, the number with estimated uncertainty greater than 10%, and the maximum estimated uncertainty. Table 4 lists the number of comparisons of line shifts made as a function of the number of points in the group, the number of the intercomparisons for which the estimated uncertainty is less than or equal to 5%, 10%, and 20%, and the number with estimated uncertainty greater than 20%. Note that for the line shift there are intercomparisons only for N_2- and air-broadening of water vapor.

Before commenting on the statistics, it should be noted that most of the intercomparisons are for pairs of points, from 80% for air-broadening to 93% for self-broadening. Certainly, at the same level of agreement, more confidence is gained as the number of points compared increases. Unfortunately, the number of intercomparisons with n greater than 3 is small: 6%, 10%, 2%, and 0.9% for N_2-, O_2-, air-, and self-broadening, respectively.

[a]Number of intercomparisons.

For N_2-broadening, there are no three-point or greater intercomparisons with an estimated uncertainty less than or equal to 3%, and among the pair intercomparisons, only 11% meet this criterion. A look at Table 3 shows that most of the estimated uncertainties are in the range greater than 5% to less than or equal to 10%, with a fair number greater than 10%. One rovibrational transition, the $3_{12} \leftarrow 2_{20}$ transition of the rotational band or 183 GHz line, was studied by seven groups, and here the estimated uncertainty is greater than 10%. These data are shown in Fig. 1. This plot is typical of the intercomparisons. Often the data are separated by more than the uncertainty assigned to the data. This fact certainly leads to questions about the uncertainties reported in the literature. For the line shifts, there are only intercomparisons of pairs of points. Often in the plots, the error bars do not overlap (see Fig. 2). Table 4 shows the distribution of the estimated uncertainties. Some 14% of the intercomparisons have agreement to better than 5%.

For O_2-broadening of water vapor, there are only 19 intercomparisons, mostly pairs of data. The estimated uncertainties are mostly greater than 10%. Figure 3 shows the only six-point intercomparison for this database. The estimated uncertainty for this line is 6.2%. There are no shift measurements for intercomparison.

The largest data set is for air-broadening of H_2O, which allows 3514 intercomparisons to be made. Unfortunately, only 81 of the intercomparisons have more than three data points. Of these intercomparisons, none meet the 3% uncertainty criterion of the spectroscopic community. Most of the error estimates are in the 5%–10% range or above 10%. There are two transitions for which seven measurements have been made and one transition for which eight measurements have been made (183 GHz transition). These transi-

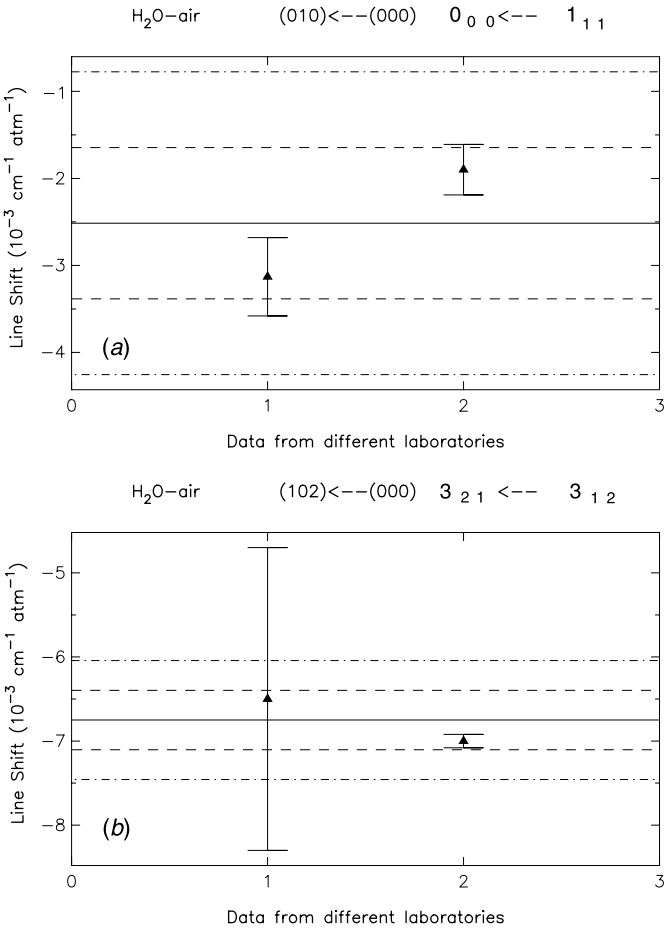
Fig. 1. Measured half-widths (cm^{-1} atm^{-1}, 1 std atm = 101.325 kPa) for nitrogen-broadening of the 183 GHz line of water vapor with reported uncertainties. The solid line is the average half-width, and the dashed lines are 1 and 2 standard deviations.



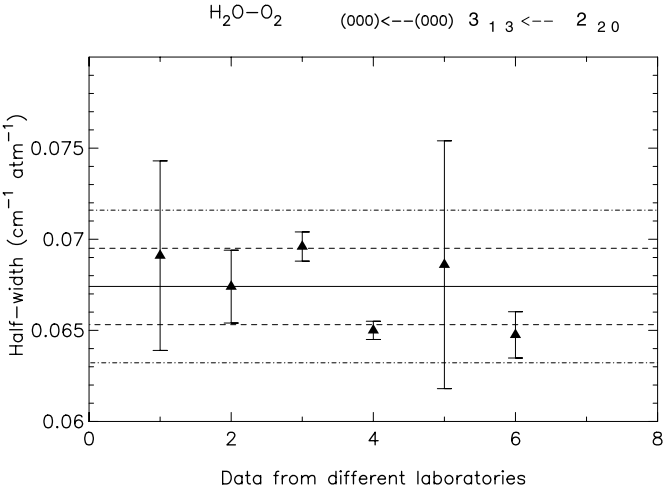
tions have 26%, 8%, and 18% estimated uncertainty, respectively. Figures 4*a* and 4*b* show the two transitions for which there are seven measurements for intercomparison. The first of these (Fig. 4*a*) is typical of many of the air-broadening plots with the error bars of the data points not overlapping. While the error bars do overlap in Fig. 4*b*, the overall 2σ uncertainty is almost 3 times that needed for remote sensing. The intercomparisons for the line shifts only occur as pairs of measurements. As shown in Table 4, these data are heavily skewed toward the 10%–20% and >20% uncertainty ranges. There are 21 intercomparisons with an estimated uncertainty of less than 5%.

The data set for self-broadening of H_2O is also large, some 10 596 measurements. From this data set, it is possible to make 440 intercomparisons of half-widths. There are no intercomparisons of the line shifts. Only four intercomparisons are possible for more than three data points: three four-point intercomparisons and one five-point intercomparison. The estimated uncertainty for these intercomparisons is greater than 10%. The five-point intercomparison for the $3_{1\,3} \leftarrow 2_{2\,0}$ transition of the rotational band is shown in Fig. 5, demonstrating the spread in the measurements. The intercomparison of pairs of points contstitutes 92% of the self-broadening intercomparisons, of which 61% have estimated uncertainties greater than 10%.

Data trends

For the purpose of developing a database of spectral parameters or in running radiative transfer codes, trends in the half-width data have been exploited. One method was to compile an average half-width as a function of the rotational quantum number J'' (or a combination such as $(J' + J'')/2$) and use these values when measurement or calculation was not available for a transition. In Fig. 6, the measured air-broadened half-widths for the ν_2 band are plotted vs. $(J' + J'')/2$. For many of the columns of points the half-width changes by a factor of 6, and hence an algorithm based on averages as a function of J is prone to large error.

Fig. 2. (*a*) Measured line shifts (cm^{-1} atm^{-1}, 1 std atm = 101.325 kPa) for air-broadening of the $0_{0\,0} \leftarrow 1_{1\,1}$ transition in the ν_2 band of water vapor with reported uncertainties. The solid line is the average line shift, and the dashed lines are 1 and 2 standard deviations. (*b*) Measured line shifts (cm^{-1} atm^{-1}, 1 std atm = 101.325 kPa) for air-broadening of the $3_{2\,1} \leftarrow 3_{1\,2}$ transition in the $\nu_1 + 2\nu_3$ band of water vapor with reported uncertainties. The solid line is the average line shift, and the dashed lines are 1 and 2 standard deviations. Note that the data of ref. 106 are included.



Polynomial expressions have been used to fit half-width data for a particular band (142–145). These are typically of the form

$$[2] \qquad \gamma = a + bJ'' + cJ''^2 + dK_a''$$

where a, b, c, and d are fitting constants. In ref. 145, J'' was replaced by $(J'' + J')/2$, and K_a'' was replaced by $(K_a'' + K_a')/2$. The application of eq. [2] to asymmetric rotors has been mostly to heavy species such as ozone. References 142 and 143 consider pressure-broadened half-widths of ozone where the values change by about a factor of 2 from the maximum to the minimum. While there is no physics in the polynomial fit, it sometimes gives a reasonable representation of the half-widths. In refs. 144 and 145, the application is to CO_2- and H_2-broadening of water vapor, a light asym-

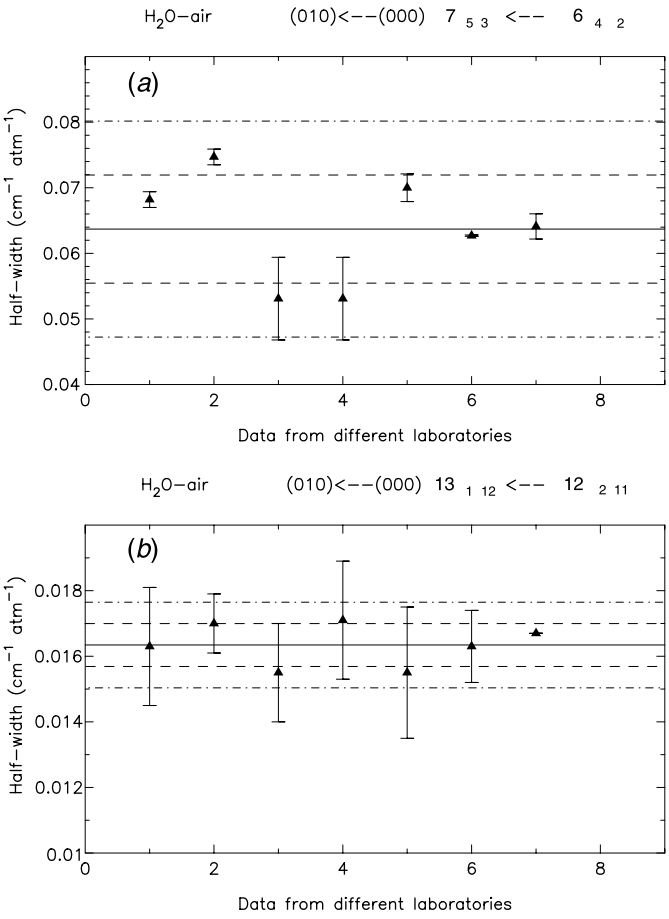
Fig. 3. Measured half-widths (cm^{-1} atm^{-1}, 1 std atm = 101.325 kPa) for oxygen-broadening of the $3_{1\,3} \leftarrow 2_{2\,0}$ transition in the rotation band of water vapor with reported uncertainties. The solid line is the average half-width, and the dashed lines are 1 and 2 standard deviations.



metric rotor. Here, the half-widths change by factors of 15 and 3, respectively. In both of these studies, the authors found that the polynomial expression gave only slightly better results than averaging as a function of $(J'' + J')/2$. This is due to both the range of the half-widths being large and to the energy structure of H_2O (energy gap) and the effect on the half-width. The minimum to maximum half-widths observed in the databases studied here change by factors of 39, 15, 44, and 7 for N_2-, O_2-, air-, and self-broadening, respectively. Hence, it is not expected that polynomial fits of the type in eq. [2] will give reasonable results.

More recently, Wagner et al. (146) used the polynomial fit applied to particular K_a sub-bands of ozone, which are similar to the spectrum of a diatomic molecule. Note, this requires a separate set of coefficients for each sub-band considered. Wagner et al. (146) found that a third-order polynomial gave reasonable results. For water vapor this approach may be possible. To test this, the P and R B-type transitions of the ν_2 band for particular values of K_a'' were extracted from the air-broadening database and plotted vs. J'' and are given in Fig. 7 for $K_a'' = 2$ and 5. Although there is spread due to measurements from different groups in Fig. 7*a* ($K_a'' = 2$), there are clear trends that could be fit with a polynomial. However, a similar plot (Fig. 7*b*) for $K_a'' = 5$ does not demonstrate any clear trend that could be represented by a polynomial. The plots for many other K_a'' values were similar to Fig. 7*b*, from which it can be concluded that this type of polynomial fit should not be applied to water vapor.

Brown and Plymate (139) made plots for a subset of transitions chosen such that $K_a + K_c - J = 0$ for both the upper and the lower state or $K_a + K_c - J = 1$ for both the upper and the lower state and plotted these values vs. $J_m + 0.1(J_m - K_{am})$, where J_m and K_{am} are the larger of the values of J and K_a of the rotational transition quantum numbers. Figures 8*a* and 8*b* are plots for $K_{am} = 2$ and 5. The trends are more evident than those of previous plots; however, at $K_{am} = 5$, it is not clear that a polynomial fit will give a good representation of the data.

Fig. 4. (*a*) Measured half-widths (cm^{-1} atm^{-1}, 1 std atm = 101.325 kPa) for air-broadening of the $7_{5\,3} \leftarrow 6_{4\,2}$ transition in the ν_2 band of water vapor with reported uncertainties. The solid line is the average half-width, and the dashed lines are 1 and 2 standard deviations. (*b*) Measured half-widths (cm^{-1} atm^{-1}, 1 std atm = 101.325 kPa) for air-broadening of the $13_{1\,12} \leftarrow 12_{2\,11}$ transition in the ν_2 band of water vapor with reported uncertainties. The solid line is the average half-width, and the dashed lines are 1 and 2 standard deviations.

One additional method used to estimate the half-width for a particular transition broadened by a gas for which there is no data is by scaling the half-width for a different broadening gas by an average ratio of the half-widths obtained from other transitions (5, 145). To test the soundness of this approach, the databases for N_2-, O_2-, air-, and self-broadening were taken and for each gas the average half-width for each rovibrational transition was determined. Next, the ratios of self-, O_2-, and air-broadening to N_2-broadening were taken for each rovibrational transition for which data was available. The three sets of ratios have similar structure. In Fig. 9, the ratios are plotted vs. J'' of the transition for air-broadening divided by N_2-broadening. The solid line is the average ratio. It is clear that an algorithm to estimate half-widths for one perturbing gas from the data of another per-

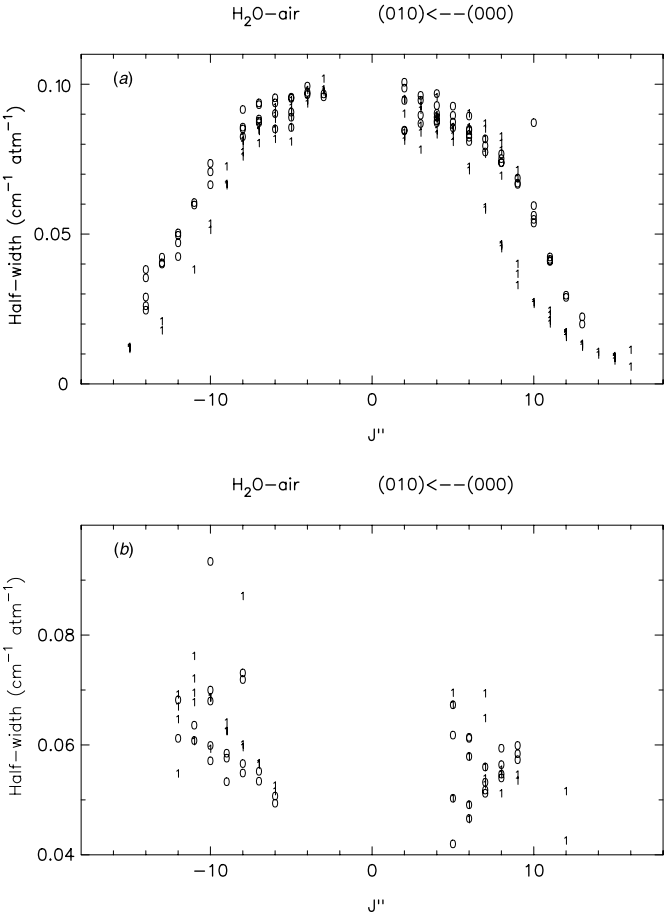
turbing gas from the average ratio will result in data with very large uncertainties.



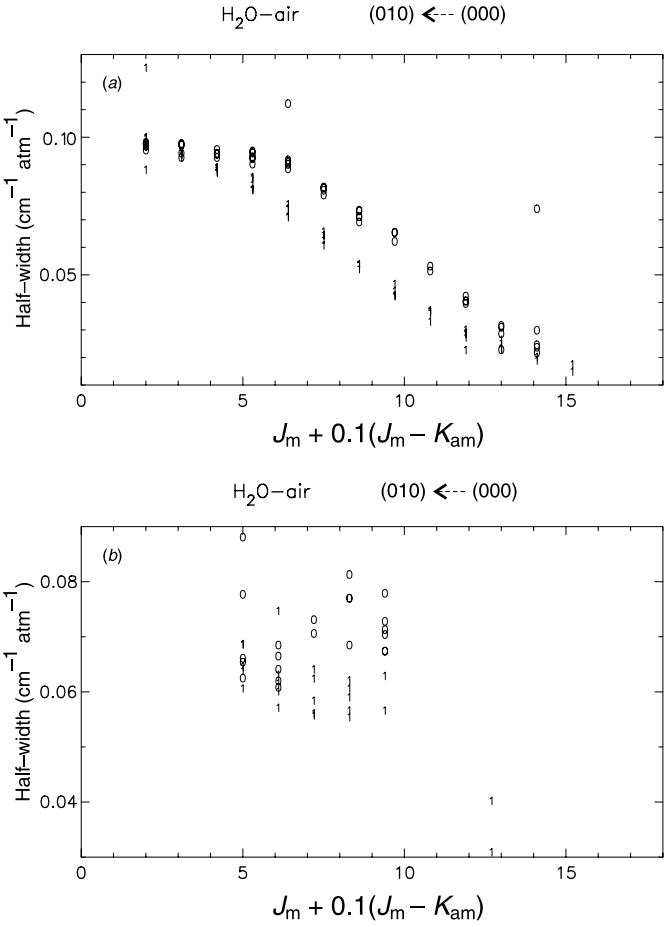
The line shift is a quantity that is dependent on the vibrational states of the transition. As discussed by Gamache and Hartmann (140), the dominant term in the potential is the vibrational dependence of the polarizability, part of the vibrational dephasing term. The expression is given by

$$[3] \quad \alpha = \alpha_0 + 0.29n_{\nu_1} + 0.07n_{\nu_2} + 0.28n_{\nu_3}$$

$$\alpha \approx \alpha_0 + 0.29(n_{\nu_1} + 0.25n_{\nu_2} + n_{\nu_3})$$

where n_{ν_1}, n_{ν_2}, and n_{ν_3} are the number of ν_1, ν_2, and ν_3 quanta exchanged in the transition. The database of measurements for air-broadening was reordered and grouped on rotational quantum numbers. The line shift data were plotted vs. the

Fig. 7. (*a*) Air-broadened half-widths (cm^{-1} atm^{-1}, 1 std atm = 101.325 kPa) of P and R B-type transitions of the ν_2 band for $K_a'' = 2$ vs. J''. Symbols (0 or 1) correspond to values of $K_a'' + K_c'' - J''$. (*b*) Air-broadened half-widths (cm^{-1} atm^{-1}, 1 std atm = 101.325 kPa) of P and R B-type transitions of the ν_2 band for $K_a'' = 5$ vs. J''. Symbols (0 or 1) correspond to values of $K_a'' + K_c'' - J''$.



number of vibrational quanta defined as $(n_{\nu_1} + 0.25n_{\nu_2} + n_{\nu_3})$. Figure 10 is a plot of the line shift for the $4_{14} \leftarrow 3_{03}$ rotational transition vs. the number of vibrational quanta; the straight line is a fit of the data, showing the linear dependence of the line shift on the number of vibrational quanta exchanged in the transition. The problem is more complicated in that there is also a dependence on the other terms in the potential, leading to different slopes and intercepts for each rotational transition. This fact limits the use of eq. [3] for making predictions of the line shift.

Gamache and Hartmann (140) reported a strong vibrational dependence of the half-width for certain types of transitions. Readers are referred to that paper for full details. The basic notion is that rotational states of water vapor that have large energy gaps to other collisionally connected states demonstrate large vibrational dependence of the half-width. Those states with a small energy gap to other states appear independent of the vibrational states. The states showing the large energy gaps are for high J and $K_c = J$ or $J - 1$, e.g., $15_{0\,15}$. Figures 11*a* and 11*b* show the half-width vs. the num-

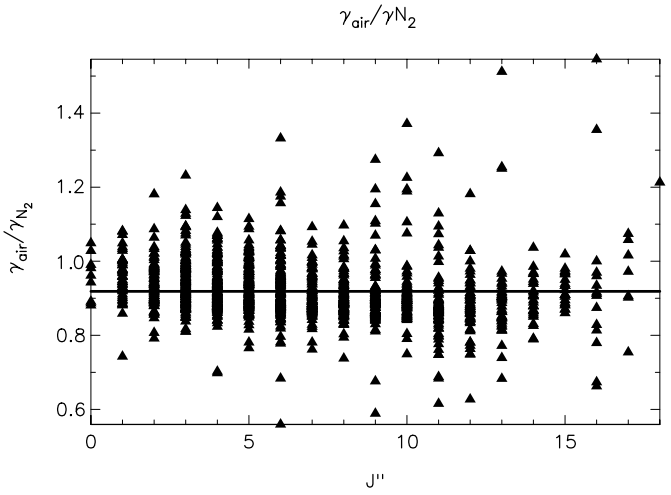
Fig. 8. (*a*) Air-broadened half-widths (cm^{-1} atm^{-1}, 1 std atm = 101.325 kPa) of transitions with $K_a + K_c - J = 0$ or $K_a + K_c - J = 1$ for both the upper and lower states vs. $J_m + 0.1(J_m - K_{am})$, where J_m and K_{am} are the larger of the values of J and K_a of the rotational transition quantum numbers and $K_{am} = 2$. Symbols (0 or 1) correspond to values of $K_a'' + K_c'' - J''$. (*b*) Air-broadened half-widths (cm^{-1} atm^{-1}, 1 std atm = 101.325 kPa) of transitions with $K_a + K_c - J = 0$ or $K_a + K_c - J = 1$ for both the upper and lower states vs. $J_m + 0.1(J_m - K_{am})$, where J_m and K_{am} are the larger of the values of J and K_a of the rotational transition quantum numbers and $K_{am} = 5$. Symbols (0 or 1) correspond to values of $K_a'' + K_c'' - J''$.

ber of vibrational quanta for the $3_{1\,3} \leftarrow 2_{1\,2}$ and the $9_{1\,9} \leftarrow 8_{1\,8}$ rotational transition, respectively. For the first of these transitions, the energy gaps to other states are small and the half-width is only weakly dependent on the vibrational states involved in the transition (Fig. 11*a*). For the second transition, the energy gap is becoming large and the figure shows the half-width increasing by almost a factor of 3 in agreement with the theoretical calculations of ref. 140. As the rotational quantum numbers increase, the energy gaps increase as well, and by $\sim J'' \sim 16$, the half-widths are dominated by the vibrational dephasing terms.

It is still too early to discuss trends in the temperature dependence of the half-width. Measurements are available for 76, 12, 341, and 213 transitions for N_2-, O_2-, air-, and self-broadening of H_2O. While a number of plots were made, the data are too sparse to identify trends at this time.

Fig. 9. Ratio of air-broadened half-widths to nitrogen-broadened half-widths for identical rovibrational transitions vs. J'' of the transition. The solid line is the average ratio.



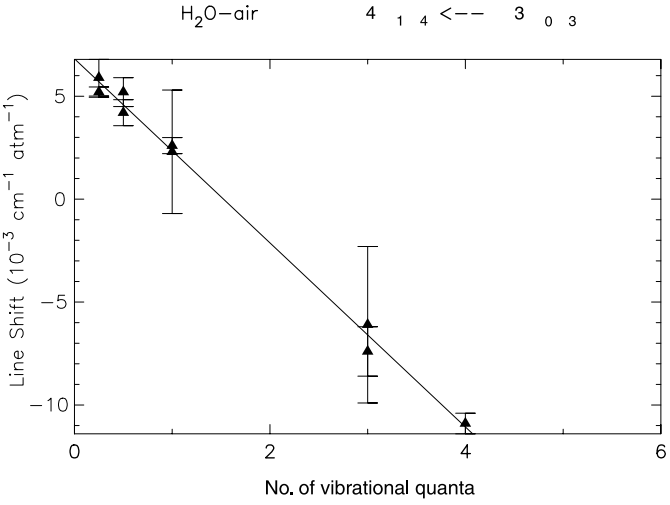


Fig. 10. Measured line shifts (10^{-3} cm^{-1} atm^{-1}, 1 std atm = 101.325 kPa) with reported uncertainties for air-broadening of the $4_{1\,4} \leftarrow 3_{0\,3}$ transition vs. the number of vibrational quanta ($n_{\nu_1} + 0.25n_{\nu_2} + n_{\nu_3}$), where n_{ν_1}, n_{ν_2}, and n_{ν_3} are the number of ν_1, ν_2, and ν_3 quanta exchanged in the transition. The solid line is a least-squares fit of the data to eq. [3].

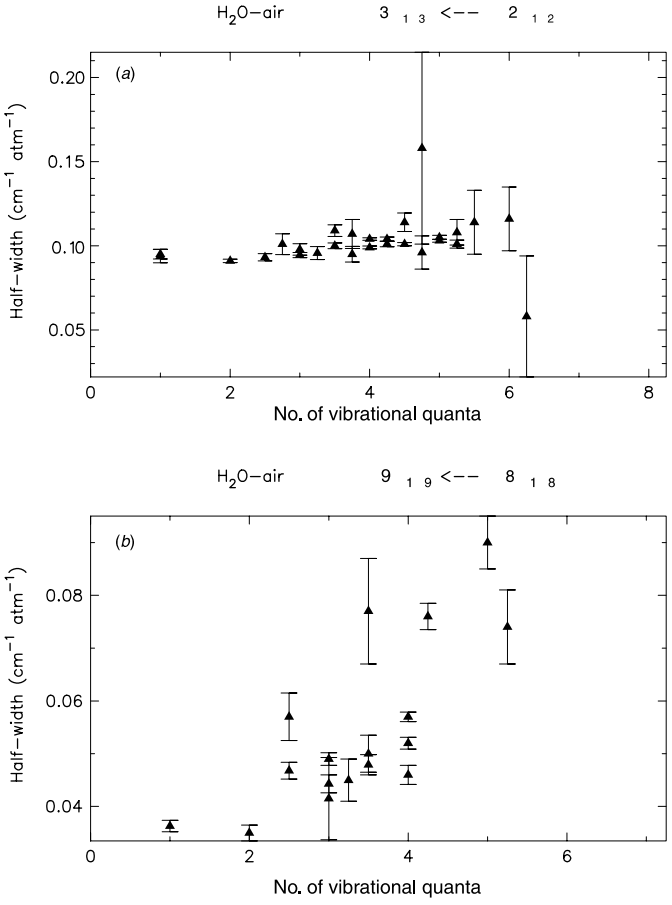

Conclusions and recommendations

We may now consider the four goals stated at the start of this paper. Since the previous study, the data sets for pressure-broadened half-widths have increased by factors of 7, 3, 14, and 10 for N_2-, O_2-, air-, and self-broadening, respectively. The line shift data, which was almost nonexistent in 1994, has grown considerably so that trends are now evident in the data. The influence of vibration, rotational quantum states, and relationships between broadening by different collision partners can be addressed. While there are many more measurements than in 1994, more work needs to be done on the relations between half-widths and their temperature dependence. Overall, there have been big improvements

Fig. 11. (*a*) Measured half-widths (cm^{-1} atm^{-1}, 1 std atm = 101.325 kPa) with reported uncertainties for air-broadening of the $3_{1\,3} \leftarrow 2_{1\,2}$ transition vs. the number of vibrational quanta ($n_{\nu_1} + 0.25n_{\nu_2} + n_{\nu_3}$), where n_{ν_1}, n_{ν_2}, and n_{ν_3} are the number of ν_1, ν_2, and ν_3 quanta exchanged in the transition. Note that the data of refs. 88, 106, and 107 are included. (*b*) Measured half-widths (cm^{-1} atm^{-1}, 1 std atm = 101.325 kPa) with reported uncertainties for air-broadening of the $9_{1\,9} \leftarrow 8_{1\,8}$ transition vs. the number of vibrational quanta ($n_{\nu_1} + 0.25n_{\nu_2} + n_{\nu_3}$), where n_{ν_1}, n_{ν_2}, and n_{ν_3} are the number of ν_1, ν_2, and ν_3 quanta exchanged in the transition. Note that the data of refs. 88, 106, and 107 are included.

in the state of the knowledge since the last study of this kind.

Goal 2, which was to extract different broadening values for selected transitions in which one may be very confident by comparing measurements from different authors, is still far from being realized. A review of Tables 3 and 4 indicated that far too few of the intercomparisons meet the uncertainty criterion set forth by the spectroscopic and remote sensing communities. Of the nearly 4500 intercomparisons made, only 3.6% meet this criterion and these are mostly intercomparisons of pairs. Files of the averaged half-widths and line shifts with the associated estimated uncertainty have been produced and are available with the database files.

The third goal was to propose measurements that are needed to augment the databases. The results of the intercomparisons have identified certain weaknesses in the databases. In particular, the data set on water vapor in collision with oxygen is much smaller than any of the other databases and none of the intercomparisons meet the 3% uncertainty criterion. One advantage of the H_2O–O_2 system is that it can be studied directly via theoretical calculations, unlike the H_2O–air system, allowing comparisons with measurement to be made.

In a study of isotopologues of water vapor (147), it was observed that a relatively small change in the atom–atom parameters of D based on new H_2 and D_2 parameters (148) using conventional combination rules (149) resulted in noticeable changes in the calculated half-widths of HDO and D_2O. These results gave much better agreement with experimental values. There are a number of different methods that have been proposed to determine heteronuclear potential parameters from homonuclear parameters (150 and refs. therein, 151, 152). Thus, the resulting parameters have an uncertainty that depends on the method chosen to go from the homonuclear to the heteronuclear parameters. Differences are on the order of 15% and 5% for the σ and ε parameters. The results in ref. 147 show that such changes in the atom–atom parameters are significant. To refine the intermolecular potential, accurate measurements of O_2-broadening of water vapor are needed. This can best be accomplished with mid- to high-*J* rotational lines of the rotation or ν_2 band.

For the other perturbing gases of this study, additional measurements need to be made. However, the emphasis should be on the accuracy of the measurement rather than the number of transitions measured. Given the results of ref. 140, measurements of the doublet transitions ($K_c = J$ or $J + 1$) would be interesting. Also, half-width and line shift measurements of mid- to high-*J* rotational lines for a number of vibrational bands would be useful for the adjustment of the intermolecular potential.

Measurements of the temperature dependence of the half-width and the line shift need to be made. Currently, there are far too few measurements of the temperature dependence of the half-width to identify trends. There is also some evidence that the temperature dependence model (eq. [1]) may not be valid over large temperature ranges (153) or for certain transitions (141).

Goal 4, a first test of theoretical results, cannot be fully accomplished until goal 3 is better addressed.

While the number of half-width and line shift measurements of water vapor broadened by nitrogen, oxygen, air, and water vapor has increased substantially since the survey paper of 1994, there is still a need for more measurements of high accuracy. The results of the intercomparisons show that the current databases of measured parameters do not demonstrate good agreement with each other, certainly not of the quality needed to meet the needs of remote sensing. Trends in line shift parameters are now becoming evident, but more measurements are needed. The study of the temperature dependence of the half-width needs more measurements to identify trends, and the study of temperature dependence of the line shift is still in its infancy. There is much to be learned for both properties.

From the point of view of the theory, measurements are needed for nitrogen-, oxygen-, and self-broadening. In particular, measurements for high-*J* lines of bands such as the rotation band and ν_2 and the doublet transitions for high vi-

© 2004 NRC Canada

brational bands would be useful for adjusting the interaction potential. Temperature dependence of the half-width and line shift for these transitions would also be useful, given the results of refs. 140 and 141.

The Canadian Light Source — History and scientific prospects[1,2]

G.M. Bancroft

Abstract: The Canadian Light Source (CLS) in Saskatoon has been under construction for the last 4 years, and will be producing a number of very intense beams of far-IR, IR, soft and hard X-rays in 2004 for use by several hundred Canadian scientists in chemistry, surface and material science, and a host of other scientific disciplines. The CLS will dramatically enhance the Canadian spectroscopic tradition that Gerhard Herzberg help create. I begin this article (from my 2002 CIC Montreal Medal lecture) with an overview of the history of SR in Canada, beginning in 1972 with the first Canadian synchrotron workshop organized at the University of Western Ontario by Bill McGowan, and attended by Dr. Herzberg. The CLS facility is then described, along with the properties of the first and second set of beamlines to be built at the CLS. These SR beams, in the IR and X-ray regions from the third generation CSL ring, will be competitive in brightness and intensity with the best beamlines in the world for most applications. Finally, some of the present Canadian SR research at foreign SR sources is described across the entire SR spectrum. All known spectroscopic and diffraction experiments are dramatically enhanced with SR; and SR opens up new areas of spectroscopy, microscopy, and spectromicroscopy that cannot be studied with any other source of radiation.

Key words: synchrotron light, X-rays, infrared, spectroscopy.

Résumé : La construction du Centre canadien de rayonnement synchrotron (CCRS) de Saskatoon a débuté il y a quatre ans et, à partir de 2004, celui-ci sera en mesure de produire des faisceaux très intenses de rayonnements IR et IR lointain, de rayons X de basses et de hautes énergies qu'utiliseront plusieurs centaines de scientifiques canadiens oeuvrant dans le domaine de la chimie des matériaux et des surfaces ainsi que dans plusieurs autres disciplines. Le CCRS augmentera d'une façon dramatique la tradition spectroscopique canadienne que Gerhard Herzberg a su créer. Je débute cet article (tiré de la conférence que j'ai présentée lors de la remise de la Médaille de Montréal de l'Institut de chimie du Canada qui m'a été faite en 2002) en passant en revue l'histoire du rayonnement synchrotron (RS) au Canada, en commençant en 1972, avec la première table ronde canadienne sur le synchrotron qui a été organisée à l'Université de Western Ontario par Bill McGowan et à laquelle a participé le Dr. Herzberg. Je passe ensuite à une description du CCRS et des propriétés des deux premiers ensembles de lignes de faisceaux à être construites au centre. Pour la plupart des applications, la brillance et l'intensité des faisceaux de RS des régions de l'IR et des rayons X obtenus à partir de l'anneau de troisième génération du CCRS pourront supporter la compétition de celles des meilleurs faisceaux du monde. Enfin, je décris les travaux de recherches actuels de RS effectués par des canadiens, sur l'ensemble des domaines du RS, sur des sources étrangères de RS. Toutes les expériences connues de spectroscopie et de diffraction sont améliorées par le RS et le RS ouvre de nouveaux horizons de la spectroscopie, de la microscopie et de la spectromicroscopie qui ne peuvent pas être étudiés par toute autre source de rayonnement.

Mots clés : rayonnement synchrotron, rayons X, infrarouge, spectroscopie.

[Traduit par la Rédaction]

Introduction

The Canadian Light Source (CLS), the Canadian national synchrotron facility, has been under construction on the University of Saskatchewan campus in Saskatoon since 1999. The construction has proceeded very smoothly, and in early February 2004 when the final corrections were done on this article, over 25 mA of a well-characterized electron beam have been stored in the storage ring (with a lifetime of an hour), and synchrotron radiation has been observed. The facility is on-budget and a few beamlines are due to start working in mid-2004 — only a few months behind schedule.

This is probably the largest scientific facility in Canada to be constructed in the last 30 years, both because of its size and $173M capital budget; and it should have a dramatic impact on Canadian science (both academic and industrial) in the next 30 years. Beginning in early 2004, a number of very intense and bright monochromatic beams of IR, soft and hard X-ray radiation will be available for several hundred Canadian researchers in chemistry, physics, geology, materi-

 doi: 10.1139/V04-027 © 2004 NRC Canada

als science, surface science, soils science, and many areas of engineering and biochemistry. Medical imaging and radiation therapy will probably be added to that list in the near future. The CLS will also be very important to industries in a wide variety of sectors spanning the pharmaceutical, biotechnology, mining, environmental, materials and coatings, petrochemical, and micromachining.

In October 1972, Gerhard Herzberg and several of his close NRC spectroscopic colleagues (along with the Director of the Madison, Wisconsin Tantalus SR facility, Ed Rowe) attended the first Canadian workshop organized by Bill McGowan on the uses of synchrotron radiation (SR) at the University of Western Ontario. At that early time, the most important uses of SR appeared to be in the far-UV, soft and hard X-ray regions. Mostly because Dr. Herzberg's outstanding spectroscopic research used much lower photon energies in the microwave and IR, he never became involved directly in the Canadian synchrotron effort. He would now probably be somewhat surprised, and I think delighted, to notice the rapid development of the synchrotron beams at the CLS and the heavy involvement of some of his NRC spectroscopic colleagues in the development of strong research efforts at the CLS in the far- and mid-IR regions as well as in the "traditional" higher energy areas. Indeed, the CLS will certainly greatly enhance the great Canadian spectroscopic tradition that Dr. Herzberg helped create.

Most of the material in this current article was presented as the Montreal Medal Lecture at the June 2002 Vancouver CSC. The above mentioned 1972 workshop was the beginning of my 30 year odyssey to develop Canadian SR capabilities in the US and then in Canada. Because the Montreal Medal "is presented as a mark of distinction for significant leadership in, or for an outstanding contribution to, the profession of chemistry or chemical engineering in Canada", in the first part of this article, I will devote a significant part of this article to the long and somewhat tortuous historical development of SR in Canada. Second, I will describe the CLS facility and the progress towards operation, along with comments on the CLS vision and opportunities. Third, I will describe the seven so-called Phase 1 beamlines, and also comment on the seven Phase 2 beamlines that are hopefully funded by the Canada Foundation for Innovation (CFI) in February 2004. Finally, to give readers a flavour of the kind of research that will be carried out on the Phase 1 beamlines, I will describe some of the Canadian research currently being performed at foreign synchrotrons in the IR, soft, and hard X-ray regions.

History of SR in Canada

The construction of the CLS has involved intense effort by many, many dedicated Canadian scientists over the last 30 years, and I have perused many of my old documents to try to give credit to the major players in this effort. Certainly, Bill McGowan was the initiator of the Canadian SR effort beginning with the above workshop that Herzberg attended in 1972. As the first Director of the Centre for Chemical Physics (CCP) at the University of Western Ontario, Dr. McGowan pushed extremely hard for a Canadian synchrotron in the period 1972–1977. For example, he applied in July 1973 to NRC for a feasibility study for a Canadian SR source. As there were NO known Canadian users at the time (very limited SR work at Stanford, Tantalus, Cornell, and several European sites had only begun about 1969), that request (and many later requests, see below) was rejected. In January 1975, Dr. McGowan hosted a CCP SR workshop to consider a design from Roger Servranckx of the University of Saskatchewan for a Canadian low-energy synchrotron, and Dr. McGowan suggested a possible site for the synchrotron at the University of Western Ontario to the UWO senior administration. This 1975 meeting initiated a long collegial interaction of UWO scientists with the high-energy electron accelerator group from the University of Saskatchewan (the Saskatchewan Accelerator Laboratory (SAL)) which began with the hiring of Leon Katz in the Physics Department in 1947, the construction of a 300 MeV linac in 1962, the construction of a 300 MeV beam stretcher in 1985 directed by Henry Kaplan, and the push for the Canadian Light Source spearheaded by Dennis Skopik in 1995. This group developed state-of-the-art expertise in design and construction of electron accelerators (critical to the construction of the CLS), and operated a very successful high-energy nuclear physics program until the late 1990s.

Dr. McGowan then submitted in September 1975 a very large proposal, entitled "A National Laboratory for SR Studies" to Paul Redhead, the Director of the Physics Division at NRC. Paul Redhead chaired an ad-hoc NRC committee on SR, and that committee met in June, August, and October 1976. The chemists on that committee were Camille Sandorfy, Chris Brion, and myself. Several Canadian scientists began using SR in this period. For example, Daryl Crozier from Simon Fraser began high-energy EXAFS studies at the Stanford Synchrotron Radiation facility (SSRL) in the fall of 1974, and I began SR studies at Tantalus in March 1975 as a result of the contact with Ed Rowe that resulted from the 1972 meeting. Meanwhile, Bill McGowan organized the first very large international SR workshop at Laval University in June 1976. There were 55 attendees at this workshop, with just 11 Canadian scientists. A 624 page report on the many uses of SR was submitted to Paul Redhead's ad-hoc committee. There was still very little Canadian involvement at this time, but it was obvious even then to nearly all the committee members that SR research was going to be very important for Canadian science, and Canada should be a major player in SR research along with all the other G7 countries that already had SR facilities (1, 2). However, because there were still very few Canadian users, and Canada does not take any "risks", this proposal was turned down.

With a cordial invitation from Ed Rowe, excellent scientific support from Ed Rowe and Charlie Pruett from Tantalus, great administrative and financial support from Dean John Bancroft, President George Connell, and the UWO Second Century Fund, I spearheaded (co-applicants were Bill McGowan and Bill Ware, both from UWO) an application to NRC in October1977 for the Canadian Synchrotron Radiation Facility (CSRF) to construct a Canadian soft X-ray beamline and three endstations at the existing Tantalus and newly designed Aladdin SR sources outside Madison, Wisconsin. In July 1978, the newly-created NSERC awarded $320 000 capital for the beamline and two end-stations (photoelectron spectroscopy and X-ray microscopy of cells). NRC

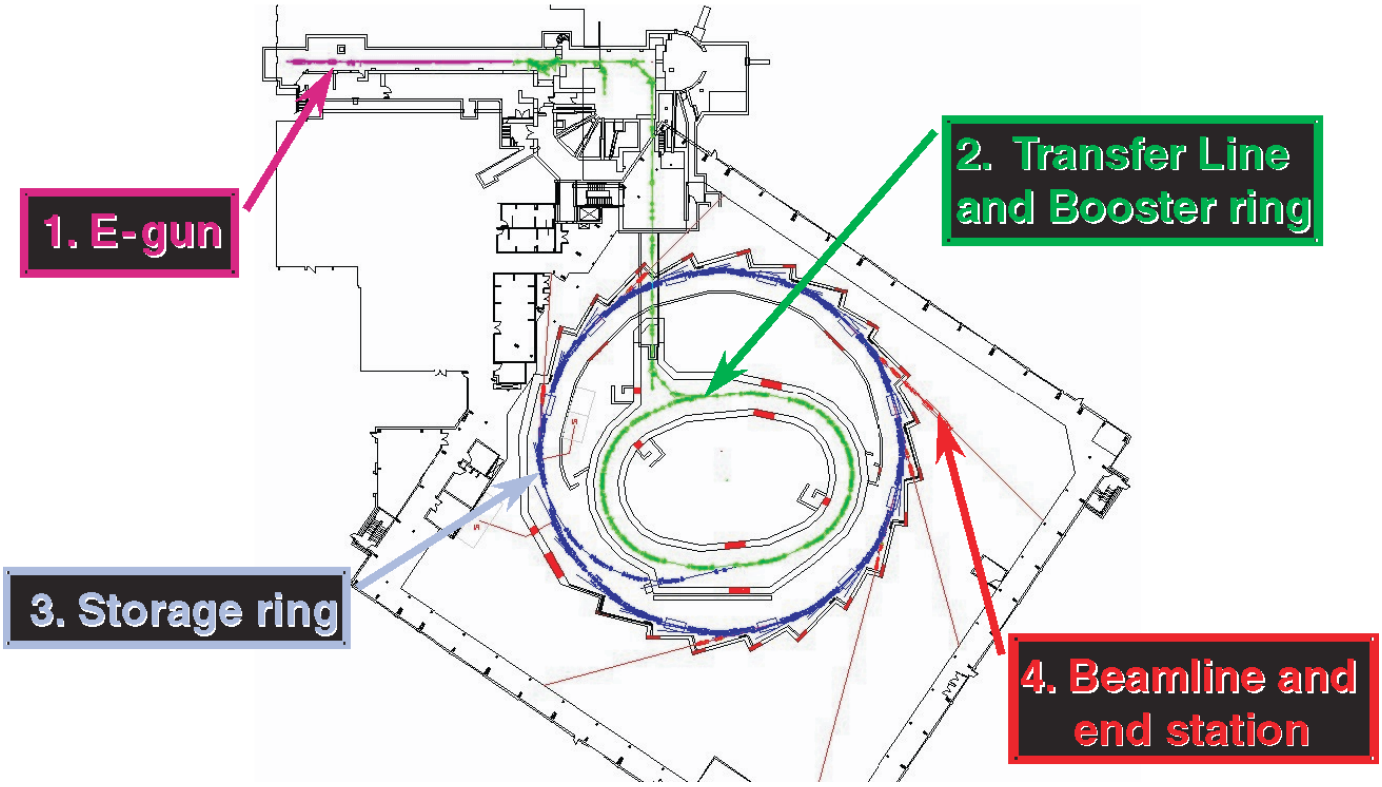
was to own, staff, and manage the facility (and NRC appointed Norman Sherman as the NRC manager for close to two decades), I was appointed the Scientific Director for CSRF (and I continued until 1999), and NRC allotted $5000 annually to own, operate, and maintain the equipment!! This inappropriate small amount created enormous problems for me and for the development of CSRF. Fortunately, UWO (with John Bancroft, George Connell, and Howard Baldwin being enormously helpful) scraped together enough funding, mainly to hire Kim Tan in January 1980 for most of 5 years as the CSRF Operations Manager in Madison. Kim Tan worked closely with Baker Manufacturing outside Madison (with excellent cooperation and collaboration with the monochromator designers Charlie Pruett, Fred Brown, and Niel Lien) in assembling the soft X-ray "Grasshopper" monochromator, and in 1 year the monochromator was successfully tested on Tantalus, the first publication appeared in 1982 (3), and the beamline plus XPS was working routinely by January 1983 (4). The first significant NSERC infrastructure funding ($32 000) was obtained in April 1984, along with an increasing amount of $16 000 from NRC.

CSRF expanded in 1990, with the construction of a higher energy soft X-ray beamline (the double crystal monochromator (DCM) beamline) in the late 1980s, funded by the Ontario Centre for Materials Research (OCMR), and designed and constructed mainly by Bing Xing Yang and T.K. Sham (5, 6). Funding for a third beamline (the spherical grating beamline (SGM)) was obtained from NSERC in 1995; and this beamline,constructed by Brian Yates, began working in 1998 (7). It is important to emphasize that all three beamlines have been working routinely at CSRF. The SGM beamline is being shipped to the Canadian Light Source as I write. As well as Sherman, Sham, Tan, and myself, Ron Cavell and Adam Hitchcock were very helpful over many years on the CSRF management committee, and in providing scientific expertise and equipment at CSRF. Over 400 publications have been generated by many Canadian scientists, and CSRF (T.K. Sham has been the Scientific Director since 1999) has had one of the highest NSERC MFA grants in Canada (e.g., $300 000 in the last few years).

The next big push for a Canadian synchrotron began in 1990. Many countries were designing and building third-generation SR sources with much smaller and brighter beams of radiation that could be used very effectively for protein crystallography, a field that has grown exponentially in the last 10 years. Bruce Bigham from AECL initiated the Canadian Institute for Synchrotron Radiation (CISR), which became very important in coordinating the Canadian SR effort. The first Directors of CISR included myself as President, along with Bruce Bigham, and Daryl Crozier. Cavell, Hitchcock, Sham, and Skopik became prominent. Initially, there was interest from AECL and TRIUMF to design and build the ring, but the Saskatchewan Accelerator Laboratory (with Dennis Skopik as Director, and Les Dalin and Roger Servrankx as the main designers), became prominent in pushing the design of the Canadian SR facility. In October 1991, a proposal from CISR was presented to NSERC for study funds to finalize a Canadian design, and this was turned down. In the early- and mid-1990s, CISR supported several Canadian initiatives at US synchrotrons; Mark Sutton and Daryl Crozier at the APS; Adam Hitchcock at the ALS; and Alice Vrielink and Eastern Canadian protein crystallographers at Brookhaven. NSERC and the President of NSERC, Peter Morand, became very supportive of a Canadian synchrotron, and an NSERC Committee on Materials Research Facilities (Chaired by John Strom-Olsen of McGill) recommended a Canadian SR source in 1994, but of course there was no NSERC money for such a proposal of about $100M. In 1994 to 1995, NSERC sponsored three workshops to better define the machine design and the possible beamlines; and in August 1995, NSERC set up a committee chaired by Alex McAuley of the University of Victoria to assist CISR to select between two bids for the Canadian SR source — the Western Canadian bid from the University of Saskatchewan (headed by Dennis Skopik) and the Eastern Canadian bid (headed by me) from the University of Western Ontario. Both of these bids took over 6 months to put together, and were over 500 pages long each. Dennis Skopik and his University of Saskatchewan (U. Sask.) colleagues (including the President George Ivany, and the Vice-President Dennis Johnson) did a magnificent job on behalf of all Canadian scientists in raising both financial and political support for their bid (a VERY difficult thing to do for such a huge facility at any University!!); and in June 1996, the NSERC committee recommended that a Canadian SR facility should be built, and that it should be built at the University of Saskatchewan. A joint U. Sask./UWO proposal was finalized and submitted to NSERC in September 1996.



But where was the funding coming from? Even in early 1996, the NSERC President Peter Morand wrote to us stating that he could not see this facility funded in the next 5 years! How quickly things can turn around, as the federal government began to run surpluses in 1997; and in June 1997, the federal government announced the creation of the Canada Foundation for Innovation with $800M to fund large University and hospital projects, including national projects such as the Canadian Light Source. Some pundits claim that the CFI was set up in large part to provide a mechanism for funding the CLS. In May 1998, Dennis Skopik and the University of Saskatchewan submitted the CLS proposal to the CFI for $71.3M (40% of the total of $178M) after raising many tens of $Ms from the University, City of Saskatoon, Sask Power, NRC, the province, and Western Economic Diversification to cover a large fraction of the remaining about $100M — a Herculean effort by the Saskatoon team over 3 years. And indeed, on 31 March 1999, the CFI announced that they would fund $56.4M towards a $141M project. The University of Saskatchewan team had raised $65.6M of the remaining $84.5M, as well as having promises of operating funding of $8.6M a year. See my CISR President's report at www.cisr.ca/reports/pres_rep_199906.html for a more complete account. As the 31 March 1999 press announcement from Saskatoon said: "The CLS represents an unprecedented level of collaboration among governments, Universities, and Industry in Canada". In addition to the U. Sask., 18 Canadian universities endorsed the CLS project on behalf of the over 300 users of SR in Canada.

The CLS Facility and Progress

The Canadian Light Source Inc. is a separate, nonprofit company wholly owned by the University of Saskatchewan.

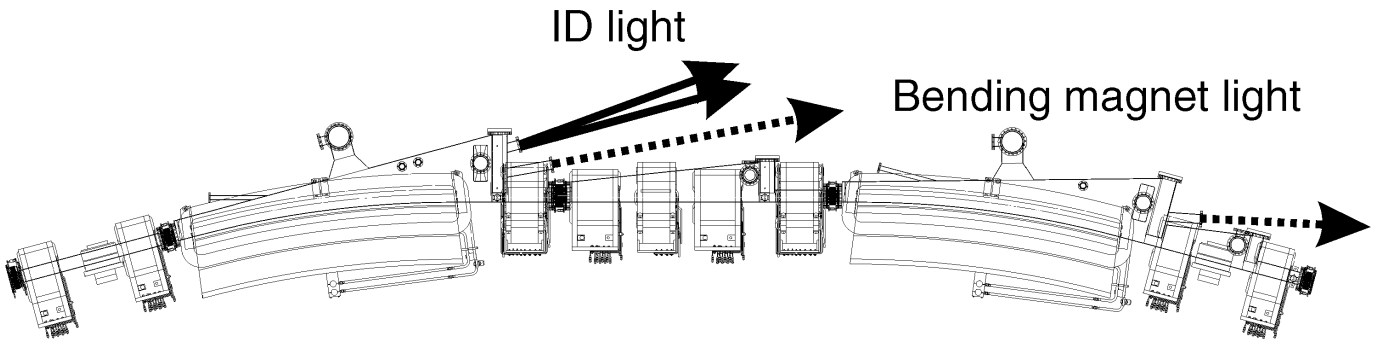
© 2004 NRC Canada

Fig. 1. Floor plan of the Canadian Light Source showing the main components of the facility.

Partly because of timely strategic planning by the University of Saskatchewan in 1998 and 1999, and the hiring of UMA as project manager, CLS progress in the last 4 years has been quite remarkable. First, the immense new building (3) (84 m by 83 m and 20 m high at the center) was completed on schedule in early 2001. Second, all of the new $141M to complete the initial project (including seven beamlines) was identified from 14 different partners, and the project is on budget, and is only a few months behind schedule. Third, over 60 talented employees have been hired to complement the fine core of 25 employees remaining from the Saskatchewan Accelerator Laboratory (SAL). Fourth, a large number of academics from across Canada have coordinated with the CLS to design and build the initial seven beamlines to be operating in 2004. Fifth, a significant amount of industrial business has already been identified (mainly with mining companies), and an impressive marketing and communication effort is well advanced at the CLS and the University of Saskatchewan. Indeed, the CLS vision statement includes a significant industrial mandate: "To advance Canadian scientific and industrial capabilities by operating the CLS facility as the national research and development center of excellence".

The CLS facility has four major components, as shown in Figs. 1 and 2: (1) a 250 MeV linac; (2) a full-energy (2.9 GeV electron energy) booster synchrotron; (3) the storage ring; and (4) a number of beamlines optimized for use in the IR or X-ray regions. Electrons are emitted from a hot metal filament (top left) and accelerated in a high vacuum to 250 MeV by the refurbished original SAL linac (magenta). The 250 MeV electrons are then transferred to the booster ring (green), where the electron energy is increased to 2900 MeV (2.9 GeV). These very high-energy electrons are then transferred to the storage ring (blue) where the electrons circulate for several hours. The 2.9 GeV storage ring (170 m in circumference, and designed by Les Dallin and SAL staff), has a very compact design, and 12-fold symmetry with 24 bending magnets in 12 cells (Fig. 3) to bend the electrons around the whole storage ring. Figure 2 (bottom) illustrates some of the thick concrete shielding that encases the storage ring (represented by black double lines in Fig. 1). The synchrotron light (SL) beams emerge through a rectangular hole in the short side of the concrete saw-tooth (see the lower right part of Fig. 2 for one of these).

One of the 12 equivalent cells of the CLS is illustrated in Fig. 3. Each cell has two large bending magnets, along with six quadrupole and three sextupole magnets for focusing the electron beam, and correcting the orbit of the electron beam, respectively. Twelve straight sections (each 5.2 m long) separate each cell. Three of these will be used for injection and supply of radio frequency (RF) power to the electron beam, and the other 9 straight sections can be used for linear arrays of dipole magnets (so-called insertion devices) — either undulators or wigglers that alternately bend the electrons back and forth many times (8, 9).



Bending of these high-energy electrons — either by the bending magnets or the insertion devices — results in emission of up to 35 beams of synchrotron light (see the four beams, one from each of two insertion devices in a single straight section and one from each bending magnet, from the one cell in Fig. 3). These beams have several remarkable properties (8, 9) (Fig. 4). First, all of the bending magnet

Fig. 2. The CLS experimental hall (84 m × 83 m), taken in early 2002. Note the sawtooth concrete shielding that encases the storage ring. The SL beam emerges from the rectangular hole in the concrete shielding on the lower right. Note also the ceiling crane on the top.

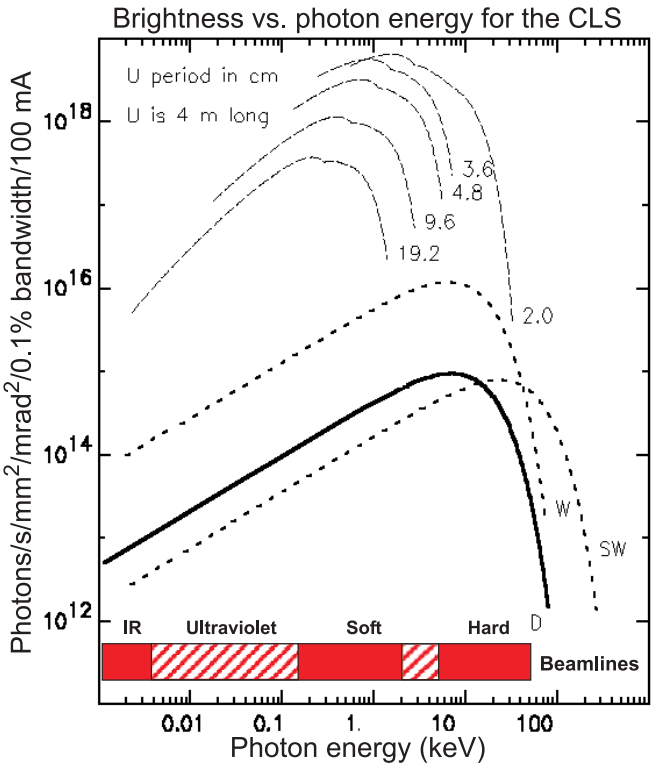

Fig. 3. One storage ring cell of the CLS. The long two magnets are the dipoles, and the short nine magnets are the quadrupoles and hextapoles. Bold solid lines show the SR from the insertion device (from the straight section off scale on the left), dotted lines show SR from the two bending magnets.

beams and some of the insertion device beams of synchrotron light (SL) contain the whole upper two-thirds of the electromagnetic spectrum — the far-IR, IR, visible, UV, to the soft and hard X-ray region. Notice the much higher brightness curves for the undulator (U) and wiggler (W) beams compared to the bending magnet beam in thick black. Also notice that the superconducting wiggler (SW) extends the SR "spectrum" to much higher X-ray energies — even above 50 keV. Second, the intensity of all of these beams is orders of magnitude greater than laboratory sources. Third, the beam sizes are very small, much less than 1 mm^2. For example the bending magnet "point" source, on this third generation ring will be about 0.3 mm (horizontal) × 0.1 mm (vertical); and the beam size increases very slowly with distance — the beam has a small divergence of about 200 μrad (horizontal) × 20 μrad (vertical). This gives a vertical beam size 10 m from the ring of only 0.2 mm, with a horizontal beam size substantially larger depending on the how much beam is accepted horizontally. The very high intensities, combined with the very small size results in a beam bright-

Fig. 4. Plot of the SR brightness vs. photon energy from different magnets on the CLS storage ring (from the bottom curves up): solid line at the bottom (D) from a bending magnet; W, from a wiggler; SW, from a superconducting wiggler as in the XAFS beamline; top five curves (U), for different undulators.

ness or brilliance that can be millions of times greater than any laboratory source of X-rays. Beamlines are constructed to optimize the performance in specific energy regions (for example, the CLS will have IR beamlines, soft X-ray beamlines, and hard X-ray beamlines) with monochromators to vary the energy within that region, and mirrors to focus the slightly diverging beam to the sample, so that the same sub-mm^2 beam size is obtained at the sample to be analyzed. The next section will describe these beamlines in more detail.

It is important to emphasize that the CLS is a so-called "third" generation ring with the above very small beam sizes. There are seven other third generation rings working in the world at present, with two in the US. The CLS should be competitive for most experiments with the best in the world, and will have comparable performance with the other two in North America.

What is the progress on the electron accelerators at the end of October 2003? The 1962 linac from the Saskatchewan Accelerator Laboratory was refurbished almost completely in 2002, and is now generating 250 MeV beams ready to be transferred to the booster ring. Danfysik delivered the booster ring in late 2001, and it exceeded specifications in the fall of 2002. The major storage ring components are now completely assembled, and at the time of writing (October 2003) a few milliamps of electrons have been stored for milliseconds (over 5000 turns) in the storage ring. It is expected that tens of milliamps of beam will be stored in the outer ring by the end of this year. (indeed, 25 mA have been stored as of early February 2004). All of the seven initial beamlines were designed by early 2002, and nearly all beamline components have now been ordered. It is expected that most of the seven beamlines will be working by mid-2004.

The beamlines

The seven beamlines in Table 1 have been approved for construction by several CLS committees after scientific recommendation by the CLS International Facility Advisory Committee (FAC) based on the scientific excellence of the proposals. In addition to these seven, a facility diagnostic beamline (Table 1, top) will be built to monitor the performance of the storage ring. All of these proposals are cooperative efforts between the CLS and Canadian scientific groups. For example, over 150 scientists (mostly academics) from all across Canada are involved in the initial seven beamlines. These academics provide the performance requirements of the beamlines to the CLS (included in the beamline proposal that they write, with assistance from CLS scientists as required) and liaise with CLS beamline scientists who coordinate the design, construction, and operation of the beamlines.

The initial seven beamlines (two IR lines, three soft X-ray lines (the variable line spacing plane grating monochromator beamline (VLS PGM), the spherical grating monochromator beamline (SGM), and the spectromicroscopy beamline (SM)), and the two hard X-ray lines (protein crystallography at the first beamline of the Canadian Macromolecular Crystallography Facility (CMCF), and the micro-XAFS beamline) utilize the full useful spectral range offered by the CLS (see the energy range for each beamline on the right-hand side of Table 1). The far-IR beamline will enable IR measurements from 1.2×10^{-3} eV (10 cm^{-1}) to 0.5 eV (4000 cm^{-1}), the soft X-ray lines will yield energies between 5 eV and 2000 eV, and the hard X-ray lines give photon energies between 4 keV and 30 keV. The academic project leaders are listed first below the name of the beamline, and the CLS beamline scientists are given next in brackets.

Applications to the May 2003 CFI competition were made for the seven "Phase 2" beamlines listed in Table 2, plus an XPS end station for the Phase 1 SGM beamline. These eight applications came from three universities — the University of Saskatchewan, the University of Western Ontario, and the University of British Columbia, and the project leaders are listed in Table 2. These beamlines concentrate on the hard X-ray part of the spectrum with diffraction, microprobe, and medical imaging being prominent. In addition, two soft X-ray beamlines were applied for. The soft X-ray DCM is a replacement for the CSRF DCM mentioned above. The CFI will announce the results of the competition in March 2004.

The most important device for all beamlines is the monochromator that converts the polychromatic SL beam (Fig. 4) into a variable energy monochromatic beam: a double crystal for the hard X-ray region, a grating for the soft X-ray region, and a laboratory interferometer for the IR region. For the hard X-ray micro-XAFS line (Fig. 5*a*) after some filtering and focusing, the SL beam impinges on the first crystal of an identical, and parallel, crystal pair (labeled DCM). The first crystal diffracts the incident polychromatic beam onto

Note that the microprobe focus and XAFS focus in (*a*) are in the same place and are shown separately only for clarity. In the SGM case (*b*), the two foci are at different physical locations for two different end stations. (1 atm = 101.325 kPa; 1 bar = 100 kPa).

the second crystal where a second diffraction occurs. If the two crystals are held so they are parallel and have the correct relative position, then a "monochromatic" beam will emerge from the second crystal. The energy of that beam is determined by the angle of incidence on the first crystal. If the motion of the two crystals (rotation and translation as

© 2004 NRC Canada

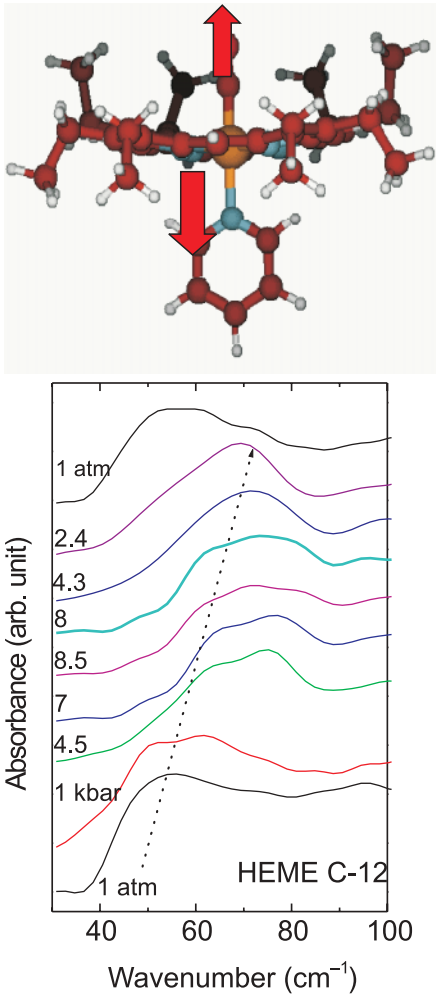
appropriate) is coordinated, the outgoing beam will be parallel to the incoming beam with a fixed offset. The wavelength (λ) of the diffracted X-rays is given by Bragg's law (for first order, set $n = 1$):

$$[1] \qquad n\lambda = 2d \sin \theta$$

where $2d$ is the spacing of the lattice planes in the crystal, θ is the angle of incidence onto the two crystals, and n is the order of the refraction.

For soft X-ray energies lower than about 1.5 keV (e.g., the VLS PGM and the SGM), larger d spacings are essential for the larger wavelengths; in this case, the array of scattering centers is conveniently achieved by ruling a grating according to some well-defined equation. Such "grating monochromators" provide the same function as the parallel crystals used for hard X-rays but are normally used in a single grating configuration. Additional optics are used to keep the monochromatic beam in the right spot; commonly a grating monochromator consists of a grating and at least one more X-ray optical device together with a means to provide coordinated motion of some of the devices (Fig. 5*b*). The polychromatic beam strikes a reflecting surface with a periodic array of lines (the SGM in Fig. 5*b*), usually at a glancing angle. Diffraction of different wavelengths (λ) is given by the well-known equation (set $n = 1$ for first order):

$$[2] \qquad n\lambda = 2d(\sin \alpha + \sin \beta)$$



where d is the distance between two adjacent grating lines, n is the order of the diffraction, and α and β are the incidence and diffraction angles measured perpendicular to the grating surface.

In typical implementations at the CLS, mirrors of various surface figures are used to collimate and focus the photon beam both before and after the monochromator (see the mirrors labeled in Figs. 5*a* and 5*b*). Performance of the beamlines at CLS will be competitive with the best in the world. For example, the SGM beamline will yield a beam size of 0.05 mm (vertical) × 0.1 mm (horizontal), a photon flux of 10^{12} photons/s into that area, and give an energy resolution of 10 000 (e.g., a line width of 0.1 eV at 1000 eV). The SGM is presently working well at CSRF, giving about the same excellent resolution, but with a larger beam size, and only 10^8 photons/s (7). The micro-XAFS and SM will also give a great combination of small beam sizes (down to 50 nm for SM and 2 μ for XAFS) along with very high intensity with special optics. The design of the micro-XAFS line was optimized for spectroscopy; that of the SM line was chosen to preserve brilliance and maximize flexibility in delivering highly customized beams into each of two different endstations (PEEM and STXM). In the IR and far-IR, the small parallel SL beam can deliver far more IR photons through a small aperture in a commercial spectrometer than can a thermal source like a globar normally used in IR spectrometers. This results in better spectral resolution, and much better spatial resolution (3–5 μ resolution compared to the 30 μ available with a laboratory source).

Canadian science

In this section, I will illustrate the power of SR for research in all regions of the SR spectrum, beginning with recent Canadian research at foreign synchrotrons in the far-IR, working up in energy with Canadian examples from the IR, soft X-ray, and finally hard X-ray regions.

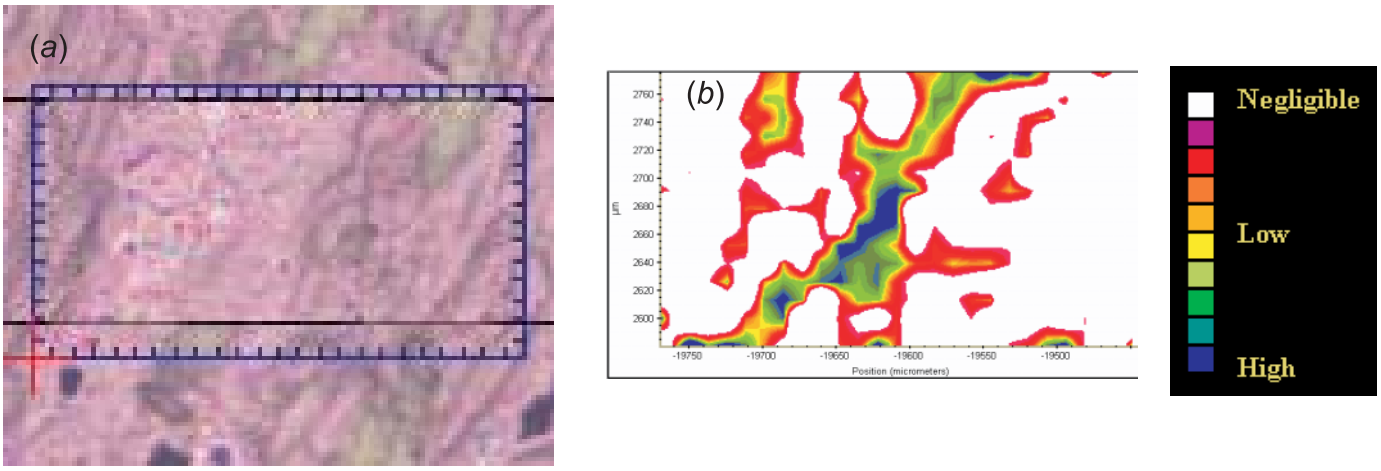


Fig. 6. Far-IR spectra of the model heme compound COFe(OEP)Py (carboxy-octaethyl-ironporphyrinpyridine) (10). The model structure is shown at the top.

The very small, intense, synchrotron beam is absolutely essential for high-pressure experiments from the far-IR (10) to the hard X-ray (11) in which the gaskets in diamond–anvil cells yield experimental apertures of a few hundred μm for absorption experiments. NRC scientists from the Institute for Microstructural Sciences have been especially active in this area. These researchers have been able to obtain the far-IR spectra of model heme compounds (COFe(OEP)Py) (Fig. 6) as a function of pressure. The peak at about 53 cm^{-1} (top spectrum at 1 atm, 1 std. atm = 101.325 kPa) shifts markedly to about 70 cm^{-1} within 0.24 GPa and then more slowly up to 0.85 GPa. The pressure dependency of the peak was completely reversible as the pressure was decreased to 1 atm (1 std. atm = 101.325 kPa) (bottom spectrum). Other higher frequency peaks had a complex structure, including several peaks within a broad absorption feature. Density functional calculations showed that the low-frequency peak was due to the fundamental excitation of the "doming" vibrational mode in which the iron atom moves out of the

Fig. 7. FT-IR imaging of collagen in damaged hamster heart tissue. Newly formed scar tissue is detected as collagen in areas of necrosis (12).

porphyrin plane while the periphyry of the ring moves in the opposite direction (Fig. 6, top). The calculations indicated that this peak should have a large pressure dependence as observed. This "doming" mode is thought to determine the reactivity of oxygen with this type of molecule in biological systems (10). The pressure dependence and the calculations were essential for the first definitive assignment of these very low-frequency vibrations.

The mid-IR of the SR spectrum has been used in the last 10 years in many different scientific areas (see for example the web sites: http://nslsweb.nsls.bnl.gov/infrared and http://infrared.als.lbl.gov/).

Biomedical uses of IR from SR have been the focus of the group at the University of Manitoba. In one study (12), the IR spectroscopy and microscopy of damaged hamster heart tissue was investigated. The high brightness of the IR from SR enabled rapid aquisition of data from a 10 μm × 10 μm area of an 8 μm thick tissue section. The IR spectra in such a small volume yield information on the major chemical components including collogen, lipid, DNA, and noncollagen tissue proteins. The IR absorption spectrum of collagen, which is a major indication of cardiac dysfunction after cardiomyopathy, is well known. Using the intensities of the major IR bands of collagen and the computer-controlled mapping stage, the distribution of collagen can readily be obtained in the damaged hearts (Fig. 7*b*) across an area of about 200 μm vertical × 300 μm horizontal and at about 10 μm resolution. The highest collagen content, and greatest tissue damage is shown in the blue–green region.

Most of the studies in the soft X-ray region look at the excitation of core level electrons, using photoabsorption, photoelectron, Auger, and resonance Auger techniques. The narrow core level edges that can be studied in the soft X-ray region are: the 1*s* (so-called K edges) of the light elements from Li to Ar, the 2*p* (so-called L edges) of the elements from Na to Zn, and the 3*d* (so-called M edges) of many of the heavier elements. The new PGM and SGM Phase 1 beamlines will be ideal sources from 5 eV to 1900 eV to cover all the core levels as well as valence bands at low energy.

In our high-resolution SR gas phase studies in the early 1990s, we were able to resolve ligand field and vibrational effects on core level X-ray photoelectron spectra (XPS) of molecules (13). In recent studies at about 50 meV total resolution (Fig. 8*a*) we have been able to resolve both the ligand field and vibrational splitting on the Br 3*d* level that splits the $3d_{3/2}$ and $3d_{5/2}$ levels into a doublet and triplet, respectively (14). The vibrational profile on the left hand side of each of the five peaks is also evident. Using a commercial XPS source with the best resolution of 0.35 eV, none of these splittings could be observed. The observation of this splitting was essential to interpret the very complex Br 3*d* photoabsorption spectrum in Fig. 8*b*, which show transitions from the five ligand field split states to the Br 5*s*, 6*s*, and *np* (n = 5–9) Rydberg orbitals (15). The ligand field splitting was also necessary to interpret the very complex $3d^{-1}$ ▶ $4p_{\pi}^{-2}$ normal Auger spectrum (Fig. 9*a*), which had been recorded a decade earlier with an electron source at similar resolution (16). The splitting of the three Auger final states, $^1\Sigma^+$, $^1\Delta$, and $^3\Sigma^-$, by the five ligand split 3*d* states is shown at the bottom Fig. 9. The intense vibrational structure on each state is shown beneath the experimental results at the top the figure. Having interpreted the XPS, absorption, and Auger spectrum, the real challenge is to record and interpret the resonant Auger spectra, where the Br 3*d* electron is resonantly excited to the Rydberg orbitals found in Fig. 8*b* — i.e., the 5*s*, 6*s*, or *np* Rydberg orbitals, and the Br atom decays via the Auger process with the Rydberg electron as a "spectator". An example of these spectra is given in Fig. 9*b*, where we show the resonant Auger spectrum of a $3d_{5/2}^{-1}5p_{\pi}$ resonance taken at a photon energy of 74.53 eV (17). The interpretation of these spectra depend on the accurate interpretation of the photoelectron, absorption, and Auger spectra. In these spectra, the inherent line width of about 90 meV does not contribute to the observed line width, and total line widths of 30 meV are observed in this very complex spectrum. The splitting of the normal Auger states (about 1.2 eV) is preserved in this spectrum (see top of horizontal bars), and a kind of angular "shake-up" occurs to give an overlapping $3d^{-1}4d_{\pi}$ resonance Auger spectrum. In contrast to the normal Auger spectra, no spin-orbit splitting, ligand field splitting, or vibrational splitting is observed in this spectrum. The higher energy resonant Auger (e.g., 7*p*, 8*p*, etc.) are enormously complex; but recent analysis shows that

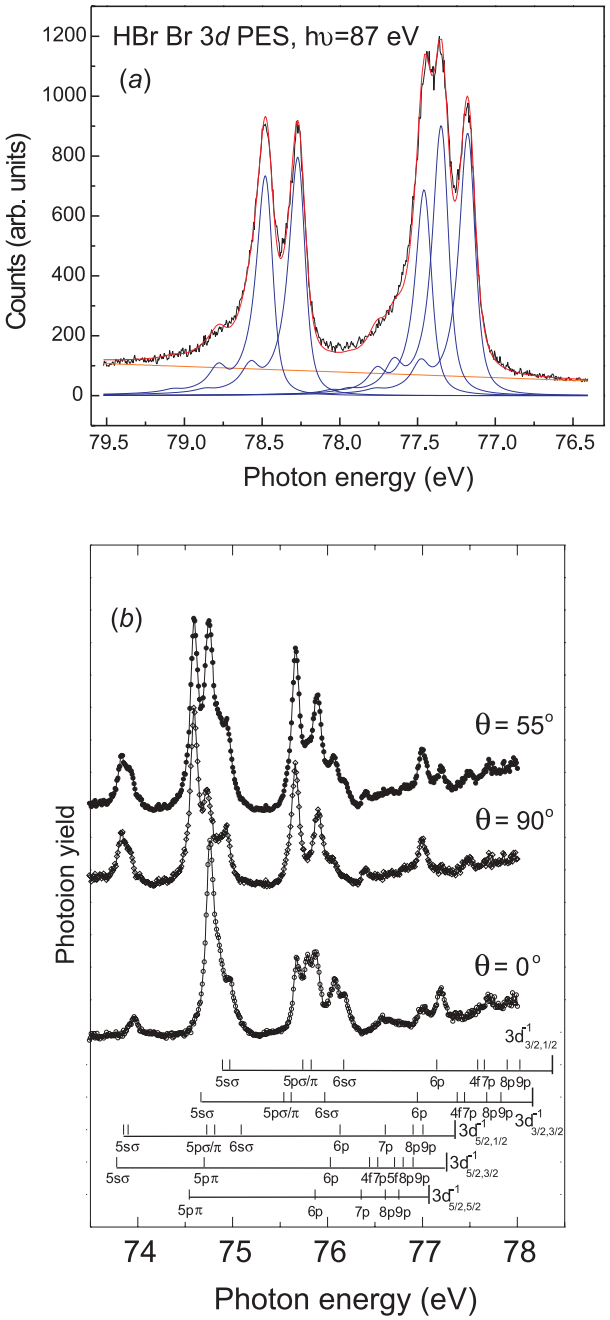
Fig. 8. (*a*) High-resolution photoelectron spectrum of the Br 3*d* level in HBr taken at 50 meV total resolution (14). (*b*) High-resolution Br 3*d* photoabsorption spectrum of HBr taken at different angles (15).



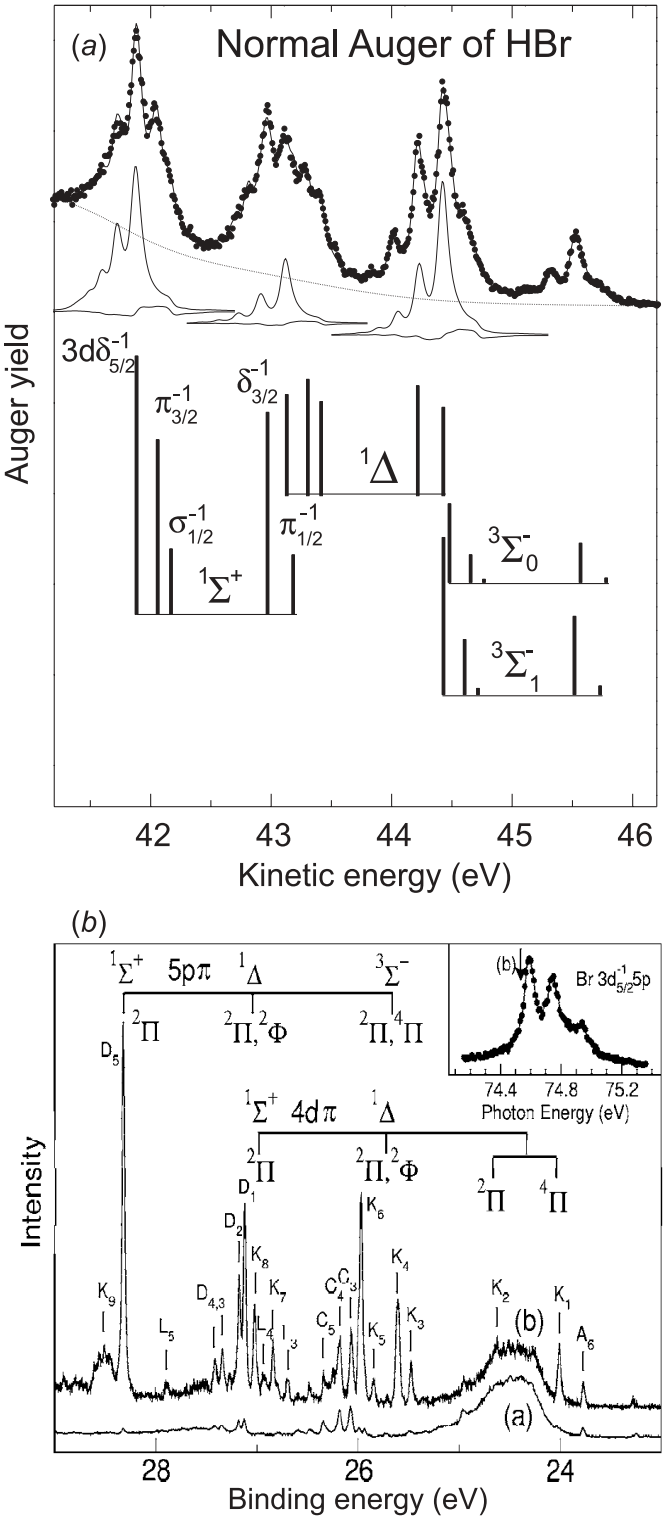


Fig. 9. (*a*) The normal Auger MVV spectrum showing the vibrational envelopes (top) and the ligand field states (bottom) required to fit the spectrum (bold solid line through the spectrum) (16). (*b*) The resonance Auger spectrum after the resonance excitation of a $3d_{5/2}$ electron to the $5p_{\pi}$ Rydberg orbital (17).

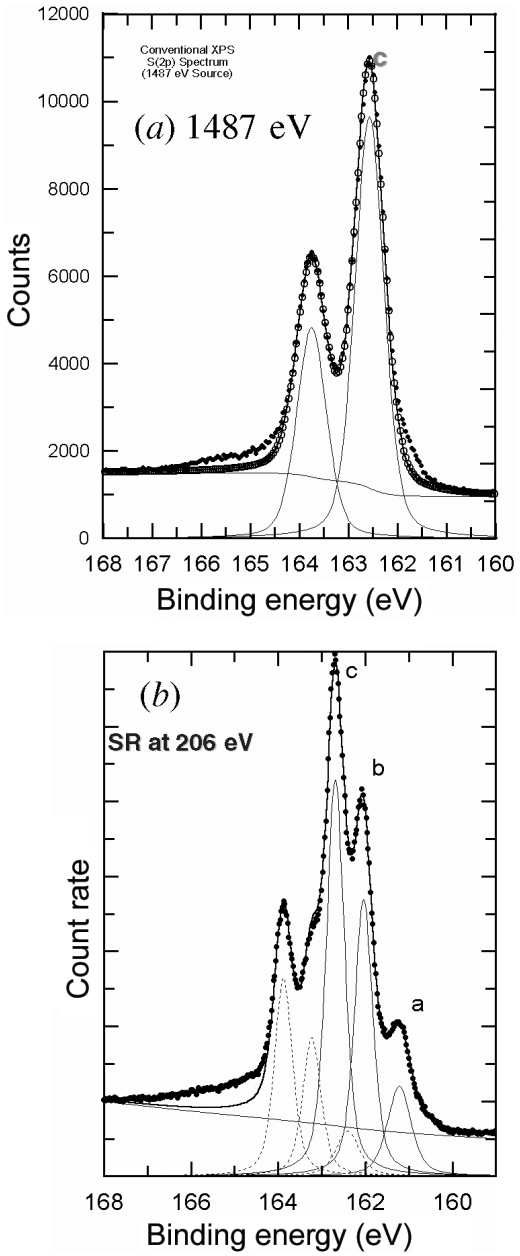

they can be interpreted using very extensive shake-up phenomena (17).

SR also greatly enhances XPS spectra of solids (Fig. 10). A S 2*p* XPS spectrum of pyrite FeS_2 taken with a conventional XPS source is shown in Fig. 10*a*. The normal S 2*p* spin-orbit doublet is immediately obvious, with hints of shoulders on the left and right hand sides of the two peaks. When this spectrum is taken with SR at 206 eV (Fig. 10*b*), the spectrum is dramatically changed due to the great surface enhancement at about 50 eV above threshold. The hint of a shoulder at about 162 eV in Fig. 10*a* turns into two intense peaks b and a in Fig. 10*b* due to a surface disulphide (b) and a surface monosulphide (a) (18). Also the peak

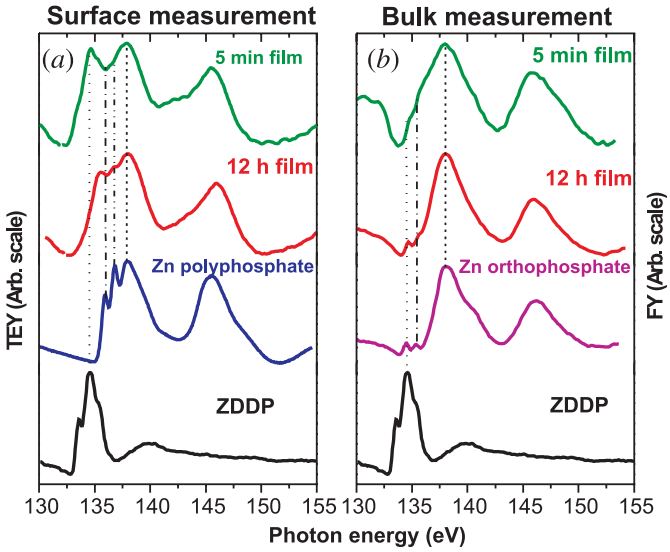

Fig. 10. The S 2*p* XPS spectra of FeS_2 taken: (*a*) with a conventional monochromatic laboratory Al K_α XPS source at 1487 eV; and (*b*) with a high-resolution SR source at 206 eV (18, 19).

widths in Fig. 10*b* are appreciably narrower than in Fig. 10*a*. The surface sensitivity of about two monolayers in Fig. 10*b* make it possible to study the oxidation and reactions of mineral surfaces in great detail (e.g., 18, 19).

X-ray absorption spectra (XAS) in both the soft and hard X-ray regions are extremely useful for obtaining chemical information on the widest variety of samples — gases, liquids, and amorphous and crystalline solids. These spectra (both the near-edge XANES and extended fine structure (EXAFS) can be obtained usually in five modes: absorption, total electron yield (TEY), fluorescence yield (FY), Auger or resonance Auger yield (AY), or optical luminescence yield (PY). Often, more than one of these modes can be obtained simultaneously on the same sample. The AY, TEY,

Fig. 11. The P L-edge XANES spectra of model compounds (bottom two spectra) and tribofilms from ZDDP (top two spectra) taken simultaneously in TEY mode (*a*, left) and FY mode (*b*, right) (20–22).

and FY modes give spectra that are very similar to the straight absorption spectra (the same peaks, but different intensities), but the sampling depths are very different. The AY technique monitors high energy Auger electrons with sampling depths of about 50 Å, so this technique is always fairly surface-sensitive. The TEY technique, often obtained by monitoring the sample current, monitors very low-energy electrons (less than 2 eV), and the sampling depth can be over 1000 Å. For example, the TEY sampling depth in Si for 100 eV photons and electrons at the Si L edge has been shown to be only about 50 Å, while the sampling depth for the Si K edge at 1800 eV is 700 Å (20).

Some of the power of the XANES technique for studying surfaces and materials is illustrated in Fig. 11 (21–23). The phosphate results described below should also be useful for studying environmental phosphate samples. All engine oil contains additives, so-called antiwear agents, anti-oxidants, detergents, and dispersants. The usual antiwear agent is zinc dialkyldithiophosphate (so-called ZDDPs), and this compound decomposes on hot metal surfaces in engines to give very thin "antiwear" films. The chemistry of antiwear films have been studied for many years using conventional surface techniques such as XPS; and XPS showed that the major component of the film was phosphate from decomposition of the ZDDP. The P L-edge and K-edge XANES using TEY and FY detection combined are ideally suited to give details of the chemistry and microchemistry of these films because the analysis depths of these techniques (about 50 Å for TEY and 700 Å for FY at the L-edge) match the thicknesses of these inhomogeneous films (about 1000 Å on average).

Figure 11 gives the P L-edge spectra on about 5 mm^2 samples of ZDDP, two Zn phosphate standards (Zn orthophosphate ($Zn_3(PO_4)_2$) and a Zn polyphosphate with bridging oxygens (formally $Zn(PO_3)_2$)), and two antiwear films produced by rubbing a steel cylindrical pin against a flat piece of steel in hot oil containing ZDDP. This rubbing

(Chemical map derived from pixel-by-pixel fit of reference spectra to image sequence).

occurs in a commercial Plint machine to simulate conditions in an engine. TEY spectra (Fig. T11*a*) and FY spectra (Fig. 11*b*) were obtained simultaneously from the two films and ZDDP, with separate TEY and FY spectra taken of the Zn orthophosphate and Zn polyphosphate, respectively, as standards (bottom two spectra in both Figs. 11*a* and 11*b*). Note that the ZDDP gives a triplet peak structure centered around about 135 eV in both TEY and FY modes. The two phosphate model compounds both give a major, rather broad peak in TEY and FY at about 138 eV, with a narrow doublet at lower energy. Somewhat surprisingly, the intensity of this doublet is VERY different for the two phosphates — orthophosphate gives a very small doublet at about 135 eV, while the polyphosphate gives an intense doublet at about 137 eV. Indeed, the intensity of this doublet increases more or less linearly with an increase in chain length of the phosphate. TEY analysis of the film after 5 min of rubbing (top left) shows the presence of undecomposed ZDDP and phosphate; whereas FY analysis of the same film (top right) shows only phosphate, showing that the ZDDP is only present at the surface of the film. The spectra of the 12 h film are more interesting. The TEY analysis gives a spectrum which is very similar to the spectrum of the model Zn polyphosphate spectrum with the intense doublet at about 137 eV in both cases. In contrast, the FY spectrum of the 12 h film is very similar to the spectrum of the Zn orthophosphate with a very weak doublet at about 135 eV. Obviously, the surface of the 12 h film (the first 50 Å) contains mostly polyphosphate, with the bulk of the 1000 Å film being mostly orthophosphate. From this and other information, a mechanism of formation has been suggested (21–23).

The PY technique has been pioneered by T.K. Sham, and is very useful for investigating the source of luminescence in light-emitting compounds such as porous Si or metal-containing polymers, which may be very useful in the future for optoelectronics applications (24, 25). In the initial study, the photoluminescence intensity was studied on a slightly oxidized porous Si. The Si K-edge XANES in the TEY mode of this sample is seen in the upper right insert in Fig. 12. The relatively weak absorption at about 1840 eV generates a very intense luminescent signal at 690 nm; whereas, the strong SiO_2 signal about 1848 eV generates a very weak luminescent signal. The source of the luminescence must be the porous Si itself rather than the oxide; and this result is consistent with the so-called quantum confinement model in the porous Si. The energy of this luminescence peak position varies with the conditions of electrochemical preparation and the history of the sample (24).

Considering sample size, most measurements have been done on a few mm^2 of sample. However, recently, photoelectron emission microscopy (PEEM) (26) and scanning transmission X-ray microscopy (STXM) (27), with resolutions of

less than 1000 Å, have obtained very novel results on spatially inhomogeneous samples, and both of these techniques will be optimized on a Phase I beamline at the CLS. In PEEM, X-ray absorption spectroscopy and electron microscopy (as in scanning electron microscopy (SEM)) are combined. As for TEY measurements, electron yield from the sample is monitored. XANES can be obtained on very small areas (much less than 1 μm^2); and when the X-ray energy is tuned to a given absorption edge, a microscopic image is obtained for a given chemical species that is absorbing the X-rays.

Using PEEM, it is possible to examine the above antiwear films in much more detail. Very recent results (28), show that the chemistry of these films can be obtained at the 0.5 μm level. The images all show a very patchy film with pads of varying sizes from ~1 μm to ~10 μm. Spectra show that the polyphosphate chain length was smaller on the small pads than on the large pads.

STXM is another powerful spectromicroscopy technique that requires the high brightness of SR. The SR beam is focused with a zone plate to about 20 nm, and the sample is scanned across the stationary SR beam very precisely. On a polymer sample such as seen in Fig. 13, the different polymer components have very different C 1*s* XANES. By sitting on characteristic peaks for each polymer, an image is built up of each component in the polymer, and the amount of each component in a polymer or polymer spheres (29) can be quantified. This technique is now being used as a tool to

© 2004 NRC Canada

Fig. 17. Elemental microscopy of a tailings sample (33) (left), with the As K-edge XANES spectra from 5 μ spots as indicated on the right.

study the biointeractions of proteins on polymers that might be used as medical implants (30). In Fig. 13, the interaction of a protein fibrinogen (Fb) with the polymer shows: the protein Fb in monolayer amounts (blue) can be detected associated with the styrene acrylonitrile (SAN, red), and Fb is not associated with the PIPA (green) or matrix (black).

The hard X-ray uses of SR are even more numerous than the soft X-ray uses, but I only have time to mention the two major areas of hard X-ray research — diffraction and EXAFS. First, the very small intense SR beams are essential for obtaining atomic resolution on very small crystals of proteins and other large molecules. Indeed all 52 protein crystallography groups in Canada go to foreign synchrotrons to obtain their final data. It is anticipated that smaller molecule diffraction will have a separate phase II beamline. In Fig. 14, the structure of an incredibly small crystal from a powder (5 μm × 5 μm × 5 μm) of $Nb_5Pd_4As_4$ is shown (31). The data was obtained at the second generation Daresbury SR source.

EXAFS is the technique of choice to obtain chemical information on noncrystalline samples. The CLS has initiated a strong research initiative with Canadian mining companies to characterize the chemistry of As (and other heavy metal toxins) in amorphous mine wastes. The toxicity of the As depends on its chemistry (for example, As(III) is generally much more toxic than As(V)), and the mobility of the As species in the tailings pond is dependent on the As chemistry (for example, $FeAsO_4$ is more stable than adsorbed As on FeOOH). The As K-edge XANES in Fig. 15 shows that the As oxidation state can be readily distinguished, and the amount of each As oxidation state in tailings samples can be obtained using these model spectra (32). The As K-edge EXAFS in Fig. 16 shows that the nature of the AsO_4^{3-} can be obtained from the EXAFS. For example, the peak at 2.5–2.8 Å due to As–Fe scattering is very sensitive to the nature of the AsO_4^{3-}. The two mine waste samples (dark blue and light blue) have very different spectra than either crystalline or amorphous $FeAsO_4$ (black and green, respectively). In particular the intensities of the black and red spectra are much larger than for the two tailings samples. The tailings spectra are much more similar to that of adsorbed AsO_4^{3-} on FeOOH, and detailed modeling of these spectra has indicated that the predominant species is arsenate bonded to the FeOOH in a bidentate mode.

In the hard X-ray region it is possible to focus the beam down to 1 μm or so, and then microscopy and spectromicroscopy is possible as in the soft X-ray region. Figure 17 shows the element distribution in a tailings sample at about 5 μm spot size (33). It is obvious that the high concentrations of As are associated with high concentrations of Fe and Ni (the yellow green regions) and not associated with

© 2004 NRC Canada

Ca. EXAFS can be obtained from those small yellow regions, and they show that the As is a combination of the two oxidation states (As(-I) and As(V)).

Acknowledgements

This project has required the great effort of at least 200 people in the last 10 years, and I am extremely grateful to all of them. I am hopefully representing many of them in this article. In my 1999 CISR President's report (www.cisr.ca/reports/pres_rep_199906.html) I have acknowledged the many people who were critical in getting the project off the ground. The CLS staff have done a great job in the last 5 years to bring the initial project very close to completion (see the CLS web site: www.lightsource.ca).

I am very grateful to my colleagues (see the text) for providing me with an example of their exciting recent results. Kim Tan deserves a special thank you, for his critical role in making the CSRF in Madison such a successful and productive facility in the last 20+ years. Many thanks to all of my 16 post-graduate students and 18 post-docs who traveled from London, Ontario to CSRF outside Madison, Wisconsin for the last 20 years to obtain their results. They all were productive in a very high-pressure environment. Thanks to all of them, and also to the CSRF staff and my senior colleagues. A number of my former students and post-docs are now working at the CLS in Saskatoon. I am particularly grateful in the last few years to Masoud Kasrai and Wayne Nesbitt for helping supervise joint students and post-docs. It is still exciting to be producing state-of-the-art research, and this would not have been possible without their fine cooperation.

Intrachannel vibronic coupling in molecular photoionization[1]

G.J. Rathbone, E.D. Poliakoff, John D. Bozek, and R.R. Lucchese

Abstract: We discuss the excitation of forbidden vibrational transitions accompanying photoionization of linear triatomic molecules. Excitation of a single quantum of the antisymmetric stretching vibration is observed for molecules with inversion symmetry, as is the bending mode. Photoelectron spectra of the $N_2O^+(A^2\Pi)$, $CO_2^+(C^2\Sigma_g^+)$, and $CS_2^+(B^2\Sigma_u^+)$ states obtained over a range of ionization energies exhibit contrasting behavior for the relative intensities of the forbidden vibrations. These energy-dependent vibrational branching ratios are shown to result from an intrachannel vibronic coupling mechanism. Moreover, this intrachannel coupling can be further divided into two cases, one in which the photoionization cross section is sensitive to geometry changes, and a second case in which it is not. These different cases can be distinguished by comparing the experimental and theoretical results for all three molecules.

Key words: photoelectron spectroscopy, vibronic coupling, photoionization.

PACS Nos.: 33.60.Cv, 33.20.Ni, 33.20.Wr, 33.80.Eh

Résumé : On discute de l'excitation des transitions vibrationnelles défendues qui accompagnent la photoionisation de molécules triatomiques linéaires. Pour les molécules avec inversion de symétrie, on observe l'excitation d'un seul quantum de vibration d'élongation antisymétrique, tel qu'observé dans le mode de déformation angulaire. Les spectres photoélectroniques des états indiqués du $N_2O^+(A^2\Pi)$, du CO_2^+ $(C^2\Sigma_g^+)$ et du $CS_2^+(B^2\Sigma_u^+)$, obtenus sur une large plage d'énergies d'ionisation, présentent des comportements différents pour les intensités relatives des vibrations défendues. On montre que ces rapports de branchements vibrationnels qui dépendent de l'énergie résultent d'un mécanisme de couplage vibronique entre canaux. De plus, ce couplage entre canaux peut se diviser dans deux cas, dont l'un dans lequel la section droite de photoionisation est sensible aux changements de géométrie alors que dans l'autre il ne l'est pas. On peut faire la distinction entre ces différents cas en comparant les résultats expérimentaux et théoriques pour les trois molécules.

Mots clés : spectroscopie photoélectronique, couplage vibronique, photoionisation.

Introduction

Among Herzberg's many accomplishments are his explanations of forbidden transitions, and a prominent example is the phenomenon of Herzberg–Teller coupling, which bears his name. In this paper, we discuss recent results that focus on a closely related topic — the excitation of forbidden vibrations in molecular photoionization. A photoionization process is an electronic transition where the final state electronic wave function includes a continuum photoelectron. As for all electronic transitions, the excitation of a single quantum in a non-totally symmetric vibrational mode is forbidden within the Franck–Condon approximation. While they are forbidden, such vibrations have been observed frequently in photoelectron spectra (1–5), where their occurrence has traditionally been attributed to interchannel vibronic coupling (6–8), and are examples of one type of Herzberg–Teller coupling (7, 9–11). To interpret photoelectron spectra that exhibit such features correctly, it is necessary to understand the mechanism by which such transitions occur. For selected linear triatomic targets, we have performed high-resolution photoelectron spectroscopy and Schwinger variational calculations (12–14) to elucidate the underlying physics of these forbidden transitions. In previous studies, the explanation for these transitions had not been well-established because the photoelectron spectra were limited to fixed photoionization energies. By studying the relative intensities of these transitions as a function of incident photon energy — and combining such experimental data with physically realistic theoretical treatments of the continuum

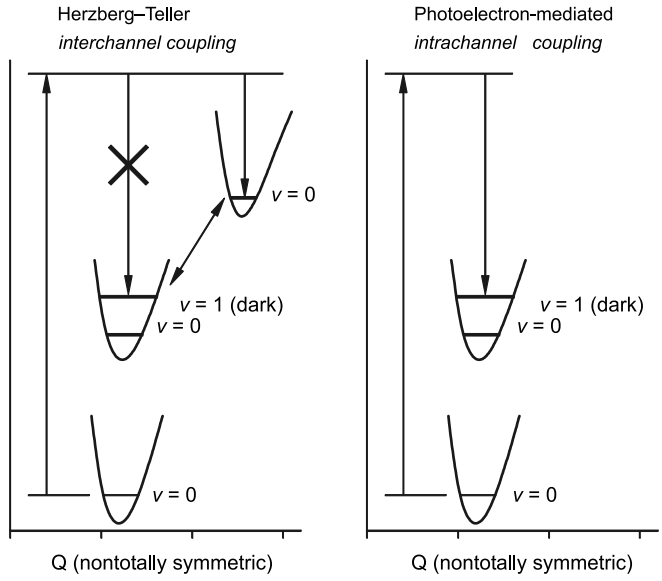
photoelectron — it is possible to discern new and unanticipated phenomena for polyatomic photoionization. In particular, we will demonstrate the importance of *intrachannel* vibronic coupling, or photoelectron-mediated coupling, in polyatomic photoionization processes. For our purposes, we define a channel to be the ion–electron complex at a fixed molecular geometry. Thus, interchannel coupling involves more than a single ion core electronic state, while intrachannel coupling necessarily does not.



We present photoelectron spectra of the $CO_2^+(C^2\Sigma_g^+)$, $CS_2^+(B^2\Sigma_u^+)$, and $N_2O^+(A^2\Sigma^+)$ states. In all cases, the spectra are vibrationally resolved and are acquired as a function of photon energy, which is equivalent to tuning the photoelectron energy. By examining the results for these three similar systems, it is possible to categorize the mechanisms responsible for the forbidden transitions; moreover, these results give us additional insights into non-Franck–Condon effects, which arise for polyatomic systems generally (15–17), and the mode-specificity that is frequently characteristic of such data (16–19).

The strategy of the current study is straightforward. Studies that tune the photoelectron energy can clarify the mechanism of forbidden vibrational transitions because they assess whether the continuum electron has a role in such phenomena. To demonstrate this, it is instructive to consider the normal description of why such forbidden photoelectron features are observed — namely, interchannel coupling, which is represented schematically in the left frame of Fig. 1. Assume that the initial state is a Σ electronic state of the neutral molecule (e.g., $CO_2(X^1\Sigma_g^+)$) and that an ionic state is created with Σ electronic symmetry and a single quantum of bending excitation (e.g., $CO_2^+(C^2\Sigma_g^+)$, $v^+ = (010)$). Traditionally, such observations have been rationalized by assuming that there is a violation of the Born–Oppenheimer approximation and that there is mixing between electronic channels. In other words, the transition is occurring because the Born–Oppenheimer breakdown leads to intensity borrowing between electronic channels, i.e., *interchannel* coupling. Note that the argument listed above does not involve the photoelectron, only the residual ion core.

We have tested this argument that the excitation of the forbidden vibronic level occurs via intensity borrowing because there is a simple experiment one can perform (7). Namely, the ionization properties of the forbidden transition (cross section, asymmetry parameter) should mimic the results for the electronic channel that is donating the oscillator strength. For the CO_2 example, the $CO_2^+(C^2\Sigma_g^+, v^+ = (010))$ level has a total vibronic symmetry of Π_u, i.e., the direct product of Σ_g (electronic) $\otimes$ Π_u (vibrational). So, the only state of the same total symmetry that might donate oscillator strength in this CO_2 example is the $CO_2^+(A^2\Pi_u)$ state. In fact, our previous work has demonstrated that the oscillator strength for the forbidden transition does not have the same energy dependence as the allowed level from which it is borrowing its oscillator strength. In two previous investigations (20, 21), we have shown that this prediction is not followed even qualitatively in the case of some forbidden photoelectron features.

There is an alternative explanation for the existence of these forbidden vibrations involving intrachannel coupling,

Fig. 1. Cartoon comparison of interchannel coupling, as compared with the intrachannel mechanism described in the text.

and it appears that it might be common for the observation of these forbidden transitions in molecular photoelectron spectra. In a previous communication (22), we showed that an intrachannel mechanism — resonantly amplified vibronic symmetry breaking — was responsible for excitation of the symmetry-forbidden bending vibration, $v^+ = (010)$, in $4\sigma_g^{-1}$ photoionization of CO_2. In this intrachannel formulation, it is the photoelectron that is responsible for the symmetry breaking, not the ionic core, as sketched schematically in Fig. 1. In this paper, we describe how the continuum electron induces the symmetry breaking alluded to in the right frame in Fig. 1. Most importantly, we show that these intrachannel phenomena can exhibit two qualitatively distinct phenomena and that these differing mechanisms have significant implications for vacuum UV (VUV) spectroscopy, in general.

Experimental

The experiments were carried out at beam line 10.0.1 at the Advanced Light Source (ALS), and details of the beam line and the high-resolution photoelectron spectrometer are described elsewhere (23). The VUV radiation was generated by an undulator insertion device, and the beam line was equipped with a spherical grating monochromator. The measurements reported here used the 380 line/mm grating for $20 \leq h\nu \leq 50$ eV and 925 line/mm grating for $50 \leq h\nu \leq 110$ eV. The excitation bandwidth in these studies was maintained at 10 meV, which was essential for obtaining vibrationally resolved electron spectra over a wide range of photon energies. The sample pressure in the interaction region (gas cell) was $\sim 5 \times 10^{-3}$ torr, dropping rapidly to 5×10^{-6} torr (1 torr = 133.322 Pa) in the bulk of the spectrometer. Spectra were acquired at several different pressures to ensure that data were not influenced by secondary scattering processes (3). The photoelectron spectrometer was a hemispherical electron energy analyzer (Scienta model SES-200), and the pass energy for these measurements was 2 eV. Slit widths between 0.4 and 0.6 mm were used and were selected

© 2004 NRC Canada

to achieve both good electron energy resolution and adequate counting rates. At 25 eV, for example, the electron analyzer resolution was adjusted to be 7 meV and the overall photoelectron energy resolution was ~12 meV, which was consistent with the values for the photon and photoelectron energy bandwidths. All data were obtained at the magic angle of 54.7°, so the observed intensities are proportional to partial cross sections.

Background: photoelectron-mediated vibronic symmetry breaking

The calculations for all of the systems studied use methods that have been reported previously (22, 24). Before discussing the details of the procedure, this section provides a qualitative overview of the approach to delineate the differences between the photoelectron-mediated intrachannel mechanisms that are relevant in the current study and the interchannel picture, which has been invoked in the past.

The partial cross section for creation of the final vibrational level (f) of the ionic state depends on the magnitudes of the dipole amplitudes $f^{(f\leftarrow i)}(\hat{k},\hat{n})$, where $\hat{k}$ is the direction of emission of the photoelectron and $\hat{n}$ is the polarization vector of the incident radiation. For simplicity, consider the case of a nondegenerate vibrational mode, although a degenerate degree of freedom (such as triatomic bending) can be shown to be equivalent to the description given here. In general, the dipole amplitude can be expressed in the following form, assuming that the wave function is separable into electronic and vibrational components.

$$[1]\qquad f^{(f\leftarrow i)}(\hat{k},\hat{n}) = \left\langle \chi^{(i)}_{v_i}(q)\middle| f(\hat{k},\hat{n},q)\middle|\chi^{(f)}_{v_f}(q)\right\rangle_q$$

Here, $f(\hat{k},\hat{n},q)$ is an electronic dipole amplitude, which depends parametrically on q (the normal coordinate of interest), and no restriction is placed on its symmetry classification. If one does *not* invoke the Franck–Condon approximation, then there is a possibility of single quantum excitations of nonsymmetric modes. This can be seen by expanding the electronic dipole amplitude $f(\hat{k},\hat{n},q)$, as a Taylor series about the vibrational coordinate q to first order, and the result is

$$[2]\qquad f(\hat{k},\hat{n},q) = F_0(\hat{k},\hat{n}) + F_1(\hat{k},\hat{n})q + \ldots$$

where

$$F_0(\hat{k},\hat{n}) = f(\hat{k},\hat{n})_{q=0}$$

$$F_1(\hat{k},\hat{n}) = \left[\frac{\partial f(\hat{k},\hat{n},q)}{\partial q}\right]_{q=0}$$

Substituting eq. [2] into eq. [1] leads to

$$[3]\qquad f^{(f\leftarrow i)}(\hat{k},\hat{n}) = F_0(\hat{k},\hat{n})\left\langle \chi^{(i)}_{v_i}(q)\middle|\chi^{(f)}_{v_f}(q)\right\rangle_q + F_1(\hat{k},\hat{n})\left\langle \chi^{(i)}_{v_i}(q)\middle|q\middle|\chi^{(f)}_{v_f}(q)\right\rangle_q + \ldots$$

The first term leads to the usual Franck–Condon selection rules: allowed transitions have $v_i + v_f = 2n$ (assuming no change in equilibrium structure upon ionization). The second term will lead to transitions where $v_i + v_f = 2n + 1$. However, it contributes to the dipole amplitude only if $F_1(\hat{k},\hat{n})$ is nonzero — in other words, single-quantum excitation occurs in a non-totally symmetric normal mode only if the electronic dipole amplitudes vary with changes in that normal coordinate.

We now apply the above discussion to the specific example of the CS_2 case studied here. Consider a system which has g–u symmetry at the equilibrium geometry and where the vibrational coordinate under consideration (q) is an antisymmetric stretching mode that breaks the g–u symmetry. Then assume that the initial electronic state $\Phi^{(i)}_g(q)$ has g symmetry at the equilibrium, $q = 0$, as indicated by the subscript, and that the final ion state $\Phi^{(f)}_u(q)$ has u symmetry. Now consider the photoionization amplitude for ionization to a continuum of u symmetry $\psi_u(\hat{k},q)$.

$$[4]\qquad f(\hat{k},\hat{n},q) = \left\langle \Phi^{(i)}_g(q)\middle|\hat{n}\cdot\vec{\mu}\middle|\Phi^{(f)}_u(q)\,\psi_u(\hat{k},q)\right\rangle$$

Note that the final electronic state has an overall symmetry of g, i.e., u(ion) ⊗ u(photoelectron) = g(total electronic), so that in this case the photoelectron channel under consideration is forbidden in a symmetric geometry ($q = 0$), i.e.,

$$[5]\qquad \begin{aligned} f(\hat{k},\hat{n},q=0) &= F_0(\hat{k},\hat{n}) \\ &= \left\langle \Phi^{(i)}_g(q=0)\middle|\hat{n}\cdot\vec{\mu}\middle|\Phi^{(f)}_u(q=0)\,\psi_u(\hat{k},q=0)\right\rangle \\ &= 0 \end{aligned}$$

where $\vec{\mu}$ is the dipole operator that has u symmetry. Now all three electronic wave functions will acquire components of the opposite symmetry as the molecule stretches. These changes in the wave functions can be expanded to first order in q to give

$$[6]\qquad \Phi^{(i)}_g(q) = \Phi^{(i)}_g(q=0) + q\bar{\Phi}^{(i)}_u \qquad \text{(initial electronic state)}$$

$$[7]\qquad \Phi^{(f)}_u(q) = \Phi^{(f)}_u(q=0) + q\bar{\Phi}^{(f)}_g \qquad \text{(final ion state)}$$

$$[8]\qquad \psi_u(\hat{k},q) = \psi_u(\hat{k},q=0) + q\bar{\psi}_g(\hat{k}) \qquad \text{(photoelectron)}$$

The first derivative of f is then given by

$$[9]\qquad \begin{aligned} F_1(\hat{k},\hat{n}) = &\left\langle \Phi^{(i)}_g(q=0)\middle|\hat{n}\cdot\vec{\mu}\middle|\Phi^{(f)}_u(q=0)\bar{\psi}_g(\hat{k})\right\rangle \\ &+ \left\langle \Phi^{(i)}_g(q=0)\middle|\hat{n}\cdot\vec{\mu}\middle|\Phi^{(f)}_g\psi_u(\hat{k},q=0)\right\rangle \\ &+ \left\langle \bar{\Phi}^{(i)}_u\middle|\hat{n}\cdot\vec{\mu}\middle|\Phi^{(f)}_u(q=0)\psi_u(\hat{k},q=0)\right\rangle \end{aligned}$$

Thus, the symmetry-breaking coordinate q can induce transitions to a continuum symmetry, which is not allowed at the equilibrium. Also, we see that the symmetry breaking of all three wave functions involved in the transition matrix element can contribute to the value of F_1. If the initial state has vibrational quantum number $v = 0$, then these first-order terms will allow excitation of the $v = 1$ level of the antisymmetric stretching mode of the ion state. Note that if there are resonance features in the "forbidden" continuum,

© 2004 NRC Canada

then the final state vibrational populations that depend on coupling to that continuum will also exhibit resonance features.

To put this result into context, we note that Franck–Condon breakdown in diatomics will occur as a result of the sensitivity of the trapping of the continuum electron to changes in bond length (25, 26). It is well known that this sensitivity results in a relative enhancement of the cross section for weaker vibrational levels in diatomics (25). This leads to an extension for polyatomic systems based on the above discussion, which is general and potentially useful. Specifically, the same effect that amplifies weak transitions in diatomics can be responsible for nonvanishing cross sections in forbidden vibrational transitions for polyatomics.

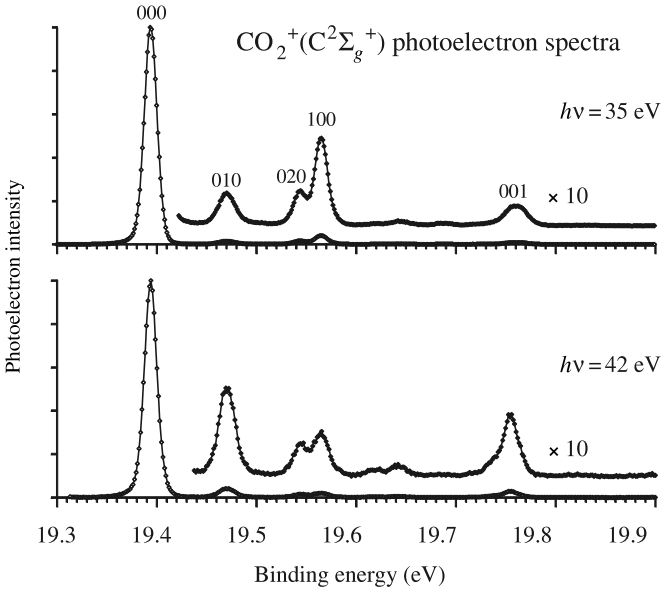
It is useful to consider the implications of this mechanism of symmetry breaking with the more traditional explanation used in photoionization studies, namely, the interchannel type of Herzberg–Teller coupling. First, this formulation described above does not assume any violation of the Born–Oppenheimer approximation, with a concomitant mixing of different electronic channels. In fact, the treatment described above — as described in detail in the following section — is explicitly adiabatic, and therefore *not* an interchannel coupling phenomenon. It is inherently intrachannel in nature, and this actually can serve as a powerful tool, as discussed in the following sections. Moreover, it is a qualitatively distinct effect, in that the interchannel explanation typically applied to photoionization transitions involves only the vibronic mixing in the ion core (10) and does not consider any influence of the continuum electron, while the intrachannel mechanism described above (22, 24) arises solely because of the behavior of the photoelectron. If both interchannel and intrachannel mechanisms are active, a vibrational close-coupling treatment would be needed. In such a treatment, the interchannel coupling would modify the vibronic states and thus would also influence the intrachannel mechanism. Thus, the schematic representation of the competing explanations introduced in Fig. 1 takes on a more explicit meaning. In the case of interchannel coupling, effects involving the ion core induce the forbidden transition. By way of contrast, the intrachannel mechanism has the photoelectron mediating the vibrational coupling; that is why the second frame in Fig. 1 does *not* include any additional potential surfaces. It is the photoelectron that is responsible for the effect. There is an important corollary to this distinction, namely, one can uncover new aspects of continuum electron dynamics as well as VUV molecular spectroscopy by studying such effects.

Theory and computational methods

For vibrationally specific photoionization transitions, we used the adiabatic approximation so that the cross section leading to a specific vibrational state was obtained as an integral over the coordinates of the nuclear motion of the product of the initial and ion-state vibrational wave functions and the dipole matrix element for photoionization obtained within the fixed-nuclei approximation over the range of geometries need to converge the vibrational integral. In calculations on the triatomic systems considered here, we have approximated the vibrational wave functions by harmonic oscillator wave functions.

The fixed nuclei photoionization matrix elements were obtained using the single-channel Schwinger method. For linear geometries, we used either Hartree–Fock wave functions for the initial and ion-target states or configuration interaction wave functions. The scattering equations were then solved using numerical techniques based on single-center expansions of the electronic wave function (12–14). For nonlinear geometries, the bound states were represented by Hartree–Fock wave functions, and the resulting scattering equations were solved using methods we developed for studying electron scattering from nonlinear molecules (27–29).

In addition to the Schwinger variational calculations, we also analyzed the various shape resonances using the adiabatic static model-exchange (ASME) potential, which is a simple local model potential for the electron–molecule interaction. This approach has been previously used to visualize resonant states in electron–molecule scattering (30) and molecular photoionization (27) and has been discussed in detail previously (30, 31).With the ASME potential, the scattering calculations are performed at complex energy allowing for the resonances in the scattering system to be directly determined by locating the poles of the *S* matrix at complex energy. The wave functions at resonance energies can then be analyzed. The position and width of the resonances in the ASME model are usually within a few eV of those found in the Schwinger variational calculation, and thus we can use the resonance wave functions found with the model potential to interpret the resonances found in the full calculation.



Results

The photoelectron spectra for all three molecules studied have been reported previously (1–5, 8,11, 18, 32–36), and the current results agree well with previous investigations. Representative results are shown for the $CO_2^+(C^2\Sigma_g^+)$ state in Fig. 2, and the vibrational structure is very clear. In particular, the v^+ = (010) and (001) levels (i.e., the symmetry forbidden vibrational excitations) are clearly evident. As mentioned earlier, such transitions were observed previously (2–4, 6–8), although the energy dependence for their relative partial cross sections has not been investigated until the work reported here and a few other studies (7, 21, 22, 24, 37). In Fig. 2, data are shown for two different photon energies, and it is apparent that the relative intensities are varying substantially between these two spectra. This is true for both the allowed vibrational transitions as well as for the forbidden ones.

The ratios of intensities for alternative vibrational levels provide branching ratios, and we acquire such data over a dense energy mesh, as shown in Figs. 3–5. Figure 3 shows results for N_2O, and data are presented for the two stretching motions. In N_2O, both stretching vibrations are allowed because there is no inversion symmetry. Note that the branching ratio for the antisymmetric stretch is relatively constant with photon energy, while the branching ratio curve for the symmetric stretch is varying significantly as a function of photon energy for approximately 6 to 7 eV above threshold.

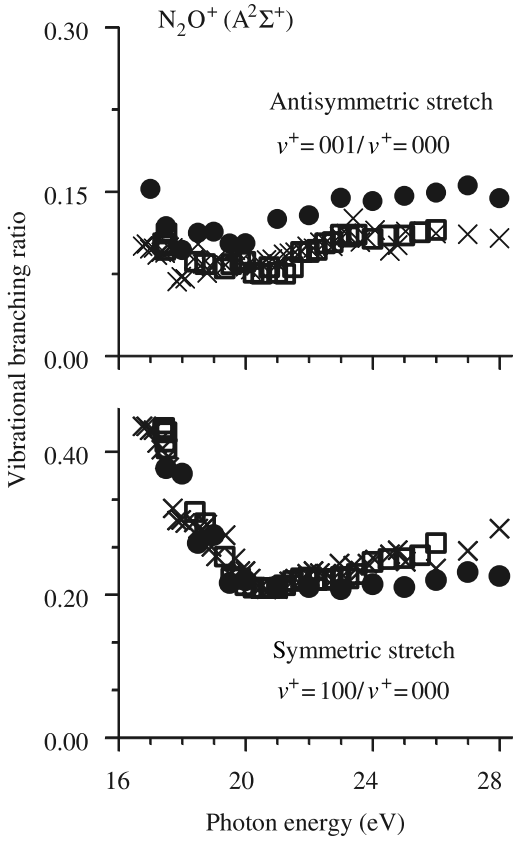
Fig. 2. Photoelectron spectra of the $CO_2^+(C^2\Sigma_g^+)$ state at two selected photon energies. Note the forbidden vibrational excitations (v^+ = (010) and (001)) and the changes in relative intensities for all of the vibrational levels.

Data from two previous investigations are also shown, and the agreement between these data sets is good.

Figure 4 shows theoretical and experimental branching ratio curves for the $CO_2^+(C^2\Sigma_g^+)$ state (21). These data are only for the single quantum excitations; the results for all the other observed vibrational transitions are reported elsewhere (21). Both the antisymmetric stretch and the bending vibration exhibit significant maxima in the region of the $4\sigma_g \rightarrow k\sigma_u$ shape resonance (21, 22, 38–45) at $h\nu \approx 45$ eV. In contrast, the symmetric stretch branching ratio exhibits a pronounced minimum in the same energy range. Comparing the various branching ratio curves, we see that the branching ratios for the forbidden vibrations actually exceed the value for the allowed symmetric stretch vibration at selected energies. This underscores the point that the partial cross section for these forbidden transitions can become significant under certain conditions.



The vibrational branching ratio curves for the $CS_2^+(B^2\Sigma_u^+)$ stretching vibrations are shown in Fig. 5. The data are very striking in their mode-specificity, although the trends are the opposite of what was observed for N_2O. For $CS_2^+(B^2\Sigma_u^+)$, the antisymmetric stretch branching ratio curve exhibits a pronounced maximum, while the symmetric stretch is comparatively constant.

Discussion

Non-Franck–Condon mode-specificity for allowed transitions ($N_2O^+(A_2\Sigma^+)$)

In the following sections, we will show that both the occurrence and the energy dependence of the forbidden vibrational transitions in CO_2 and CS_2 are due to effects of shape resonances. Thus, it is useful to consider more generally how shape resonances induce deviations from Franck–Condon behavior in polyatomic systems. We present results

Fig. 3. Vibrational branching ratios obtained as a function of energy for the stretching modes of N_2O from this study compared with earlier data. Current study (solid circles), ref. 18 (hollow squares), ref. 16 (×).

on non-Franck–Condon effects for N_2O to illustrate the main effects, as they are common to both the molecules with and without inversion symmetry. The basic picture describes the photoionization shape resonance as an above-threshold quasibound state, which results from angular momentum barriers that trap the continuum photoelectron at specific energies. The energy at which trapping occurs is strongly dependent on the shape of the potential experienced by the photoelectron, which in turn depends strongly on the molecular geometry. As a result of the sensitivity of the resonance excitation to changes in geometry, the energy-dependence of the dipole transition amplitudes depends strongly on molecular geometry, implying that deviations from Franck–Condon behavior will occur. While this picture is clearly established for diatomic molecules with a well-characterized connection between bond length and resonance changes (25, 46), polyatomic systems present nuances that have no analog in diatomic systems. In particular, the details of the photoelectron localization for polyatomic systems — as well as the effects it has on alternative molecular motions — are not well understood.

Figure 3 shows the vibrational branching ratios for the $N_2O^+(A^2\Sigma^+)$ state. It is striking that the symmetric stretch ratio is varying significantly near threshold, while the antisymmetric stretch is rather constant. There is a well-characterized shape resonance near threshold (16, 18, 19), and it is responsible for the observed behavior. It is interest-

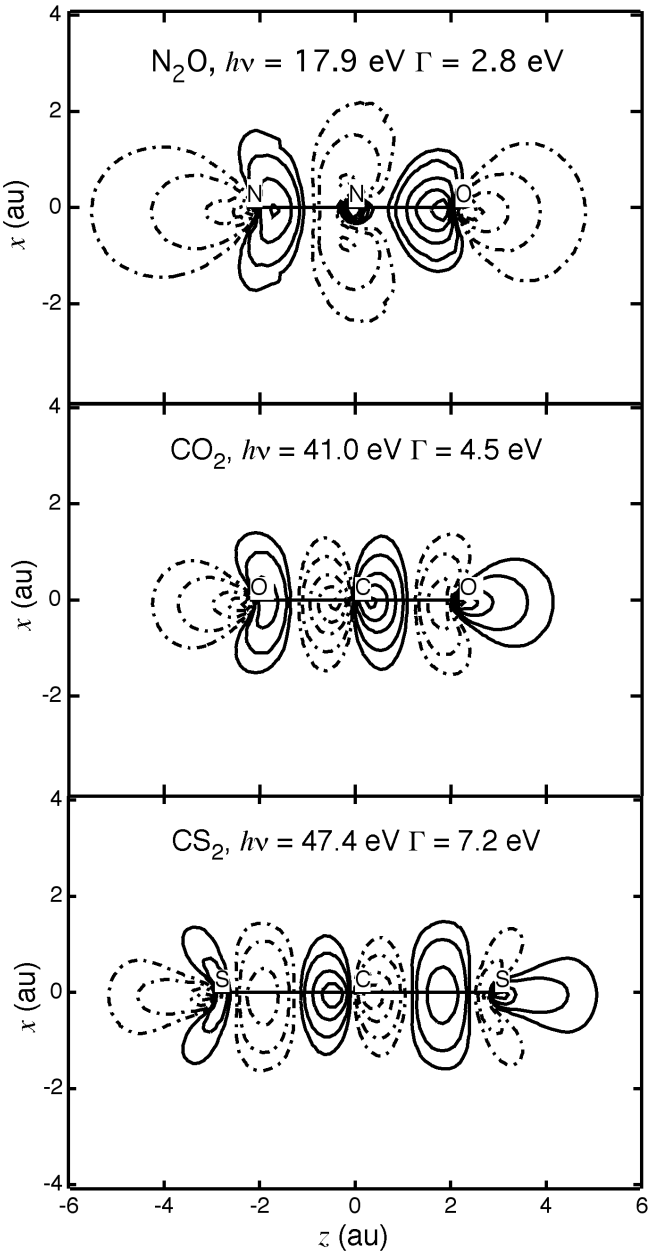
ing to note that the shape resonance is very sensitive to changes in the breathing mode of the ion, but rather insensitive to the antisymmetric stretching vibration. In previous theoretical studies (19), it was suggested that this mode specificity could be rationalized by noting that the shape resonant dynamics were sensitive to the overall size of the molecule, as the end-to-end length of the molecule does not change much for the antisymmetric stretching motion. The contour map for this shape resonant wave function has been calculated for the first time using methods mentioned above (27, 30, 31), and the result is shown in the top panel of Fig. 6. The resonant state clearly has the nature of an antibonding σ orbital constructed from *sp* hybrid orbitals on the outer N and O atoms and an *s* orbital on the central N atom. The nodal structure is characteristic of an $l = 4$ angular momentum shape resonance when analyzed in terms of confocal elliptic coordinates (47). It is clear that the electron is not associated with a specific bond of the molecule, but it is not straightforward to correlate the earlier arguments regarding mode specificity with the picture of the resonant wave function shown in Fig. 6. This remains a topic of continuing investigation.



These N_2O results have bearing on the observation of forbidden transitions, because they show that it is possible, and even likely, that shape resonance behavior might change as the geometry is altered along a normal coordinate, a prerequisite for the photoelectron-mediated vibronic symmetry breaking mechanism described in the earlier discussion on photoelectron-mediated vibronic symmetry breaking. While the N_2O results do not show much sensitivity to the antisymmetric stretch, it is certainly possible that other cases might exhibit sensitivity to non-totally symmetric vibrations. The results shown for CO_2 and CS_2 reinforce this point, and they also demonstrate that there can be considerable diversity in terms of how mode-specific behavior is manifested.

Photoelectron-mediated intrachannel vibronic coupling ($CO_2^+(C^2\Sigma_g^+)$)

The CO_2 results are shown in Fig. 4, and they are strikingly different from those for N_2O. There is an intensively studied shape resonance at ca. 40 eV (21, 22, 38–45), and we have shown previously (22) that this resonance is responsible for the amplification of the bending branching ratio also shown in Fig. 4. Note that the profiles for the experi-

Fig. 6. The real part of the resonant wave function in the $k\sigma$ continua of N_2O, CO_2, and CS_2 computed using the ASME model potential. The solid contours are for positive values of the wave function and the dashed contours are for negative values of the wave function.

mental and theoretical curves match closely for the (010) and (001) levels; the theoretical treatment uses the Chase adiabatic approximation (48) that does *not* include effects of interchannel Herzberg–Teller coupling or the intensity borrowing mechanism alluded to in Fig. 1. This is additional evidence that the sensitivity of the shape resonance to selective changes in molecular geometry is the mechanism by which these forbidden vibrational levels are being excited. Because the electron trapping is sensitive to the geometry changes, it is the electron scattering dynamics that result in the forbidden excitation. This is why we refer to this mechanism as a *photoelectron-mediated vibronic coupling*.

To clarify the details of the transitions — and to lay the groundwork for a comparison with CS_2 — it is useful to consider the electronic and vibrational symmetry considerations. The target state is Σ_g (both electronic and vibrational). The electronic symmetry of the ion state is Σ_g, while the electronic symmetry of the continuum shape resonance is $k\sigma_u$. Thus, the electronic symmetry of the final electronic state (ion plus electron) is also Σ_u. The implication is that the electronic transition is allowed, even for the symmetric equilibrium geometry. We will show how this contrasts with the CS_2 case in the following section. Of course, the vibrational symmetry for the antisymmetric stretch is Σ_u, so the overall vibronic symmetry of the final state is Σ_g. Note that this resonant channel in CO_2 is allowed even in the absence of symmetry-breaking vibrations.

A comparison between the CO_2 and N_2O results is revealing. The main difference is that all three single quantum excitations are clearly sensitive to the shape resonance for CO_2, while the antisymmetric stretch was relatively insensitive to the shape resonance occurring in N_2O. The dip in the branching ratio curve for the symmetric stretch is not well-reproduced by theory. In fact, it is likely that this discrepancy results from a Fermi resonance between the $v^+ = (020)$ and (100) vibrational levels that is not accounted for by the theoretical formulation. The evidence for the influence of a Fermi resonance is described in detail elsewhere (21). The key point for the CO_2 results is that all vibrational levels are affected by the resonance. The fact that the CO_2 and N_2O branching ratio data are qualitatively different drives home the point that the photoelectron scattering dynamics can vary considerably from molecule to molecule; moreover, the comparison also shows that experiments that interrogate the vibrational motion provide a useful means of investigating the photoelectron escape in the anisotropic molecular field. While the results for CO_2 are different from those of N_2O, they are analogous in one important respect. Namely — for both molecules — the variation of the branching ratio with energy is a direct result of the resonance profile with changes in geometry. This is an extension of the effect observed for diatomics (26) described earlier, and we will see that this behavior is qualitatively distinct from what is observed for CS_2.

The contour map for the CO_2^+ $k\sigma_u$ shape resonant photoelectron is shown in the middle panel of Fig. 6. This resonance is also a typical σ^* type resonance composed of *sp* hybrid orbitals on the terminal O atoms and a *p* orbital on the central C atom. The characteristic angular momentum of this state is $l = 5$, which leads to the fairly narrow resonance found in the full calculations. While clearly different from the one shown for N_2O in the top panel, it is not obvious why the response of the resonance to the antisymmetric stretch is qualitatively different from that of N_2O.

A photoelectron-mediated, vibrationally driven resonance ($CS_2^+(B^2\Sigma_u^+)$)

The $CS_2^+(B^2\Sigma_u^+)$ stretching vibration branching ratio curves are shown in Fig. 5. These data appear similar to both the N_2O and the CO_2 results in some respects, i.e., there is an excursion in a branching ratio curve driven by a reso-

© 2004 NRC Canada

nance, and the results are strongly mode-specific. While these characteristics of the CS_2 data are similar to those of the N_2O and CO_2 data, there are fundamental differences, as we will show. In Fig. 6, we also show the resonant state that is responsible for non-Franck–Condon effects seen in the vibrational branching ratios. This state can be described as a linear combination of $d\sigma$ orbitals on the S atoms and a *p* orbital on the central C atom. An analysis of the nodal surfaces of this state suggests that it is trapped behind an $l = 7$ angular momentum barrier, leading to its relatively high energy of $h\nu = 47.4$ eV, which corresponds to a photoelectron energy of 32.8 eV.

The first empirical difference between the CS_2 and N_2O data is that the mode-sensitivity is the opposite in these two cases. For N_2O, the antisymmetric stretch did not influence the shape resonance and the symmetric stretch did; the situation is reversed for CS_2. This result is of central importance, and the explanation for this difference is particularly revealing because it illustrates how the CS_2 results arise from an alternative type of resonant behavior. The peak in the CS_2 results is due to a resonance in the $k\sigma_u$ continuum channel (37), and it appears that this assignment is correct, given the agreement between theory and experiment (cf. Fig. 5). It is significant that the resonant electronic channel responsible for the observed results has σ_u symmetry. To see why, consider the symmetries for the electronic wave functions. The lower state is Σ_g, and the upper electronic state (ion plus electron) is also Σ_g; the ion has Σ_u symmetry, as does the resonant photoelectron, so $\Sigma_u \otimes \Sigma_u = \Sigma_g$. At the equilibrium geometry, this *gerade–gerade* transition is rigorously forbidden. However, the resonance is "activated" when the molecule undergoes the zero-point antisymmetric stretching motion; i.e., the instantaneously broken symmetry allows the molecule to be excited to this resonance, *provided that the overall vibronic symmetry selection rules are obeyed*. In this instance, the implication is that the total vibronic symmetry must be *ungerade*, which can be accomplished by exciting an odd number of quanta in the antisymmetric stretching vibration (or alternatively the bending mode, as well).

There is an important facet that is not apparent from the figures. For N_2O and CO_2, the non-Franck–Condon effects occur because the resonant trapping of the electron depends strongly on the molecular geometry; i.e., the profile for the cross section calculated as a function of energy depends on the molecular geometry. In fact, for the calculations used to generate the theoretical N_2O (49) and CO_2 (21) branching ratio curves, the resonance shifted and broadened as the geometry was altered, as was originally described for diatomics by Wallace and co-workers (25). However, the calculations show that the resonance profile does *not* change for CS_2; i.e., the profile of the resonance is insensitive to changes in the geometry. The resonant contribution to the cross-section curve is turning on and off as the distortion from equilibrium geometry occurs during a non-totally symmetric vibrational motion. The magnitude of the $k\sigma_u$ resonant cross section (at all energies) is zero at the equilibrium geometry and increases in the region of the symmetry-forbidden resonance as the molecule is distorted from its equilibrium geometry.

There is a very close connection between this CS_2 result and the traditional Herzberg–Teller effect in bound–bound electronic transitions. To illustrate the similarities and highlight the differences, consider the famous case of the $\tilde{A}^1B_{2u} - \tilde{X}^1A_{1g}$ band system of benzene (50). Like the CS_2 case, this electronic transition is forbidden at the equilibrium geometry. This electronic transition only occurs when $\Delta\nu_6 = 1$; ν_6 has e_{2g} symmetry, and the direct product corresponding to the total vibronic symmetry of the excited state is $B_{2u} \otimes E_{2g} \supset E_{1u}$, which is connected to the A_{1g} ground state of benzene via dipole transitions. The similarities with the CS_2 case are clear. For CS_2, the shape resonant $k\sigma_u$ final state is inaccessible at the equilibrium geometry and is excited only when a non-totally symmetric vibration is also accessed. On the other hand, the explanation for the benzene example is that there is a breakdown of the Born–Oppenheimer approximation and that this induces mixing between the target vibrational state and other nearby vibronic levels of the same total symmetry. The CS_2 case is fundamentally different in that the effect occurs without any violation of the Born–Oppenheimer approximation. There is no intensity-borrowing that is invoked to explain the results. Indeed, the theoretical treatment that reproduces the experimental result faithfully is performed explicitly within an adiabatic framework.

Implications for other ionization processes

It is likely that these effects will be manifested in many ways, some of which are not immediately apparent. First, analogous effects can arise for linear systems that do not have Σ electronic symmetry. For linear molecules, this suggests that some observations of bending vibrational excitation attributed to Renner–Teller coupling might be due — wholly or in part — to intrachannel analogs of the effects described above for CO_2 and CS_2. It also implies that analogous effects might occur for nonlinear systems, where excited vibrations have been attributed to Jahn–Teller coupling (51, 52). Second, these effects can occur near threshold, not just at 20 eV above threshold. Third, the intrachannel effects described in these systems do not imply that the interchannel, Herzberg–Teller mechanism is not responsible for some of the previous observations of forbidden vibrational excitation in photoelectron spectroscopy. In this same vein, the two mechanisms are not mutually exclusive and can, in fact, be occurring simultaneously in a single vibronic channel; i.e., some enhancement of a forbidden vibration might be the result of intensity borrowing via interchannel coupling that involves only the ionic core, and additional enhancement results from effects of the continuum electron. Finally, it is clear that in cases where the intrachannel mechanism is operative, it is possible to learn how the photoelectron dynamics respond to changes in molecular geometry, even for those modes that are nominally forbidden. Thus, this effect opens up the possibility of studying even more complex molecular systems, which naturally have a larger number of vibrational degrees of freedom.

Quantitative oscillator strengths for ionic fragmentation of C 1*s* and O 1*s* excited CO[1]

A.C.O. Guerra, J.B. Maciel, C.C. Turci, R.C. Bilodeau, and A.P. Hitchcock

Abstract: Ionic photofragmentation of carbon monoxide following carbon 1*s* and oxygen 1*s* excitation has been measured quantitatively with tuned synchrotron light and time-of-flight mass spectrometry using a Wiley–McLaren apparatus modified with an additional ion lens for improved quantitative performance. The sensitivity of the apparatus to kinetic energy and angular distribution effects has been characterized for selected lens settings through ion trajectory simulations and experimental measurements. Three distinct modes of the added lens have been identified (focus, defocus, and maximum). The focus mode has the least sensitivity to details of the angular and ion kinetic energy distribution and, therefore, is the best mode for measuring quantitative partial ion and ion-pair yields. The defocus mode has the most sensitivity to angular and kinetic energy distributions and, therefore, is the mode that provides the most information about the kinematics of photofragmentation. Branching ratios for ion and ion-pair production in all positive ion fragmentation channels were recorded from 280 to 330 eV (C 1*s*) and from 520 to 570 eV (O 1*s*) in the "focus" mode. Quantitative oscillator strengths were derived by combining these branching ratios with absolute total ion yield spectra. The results are compared to literature values.

Key words: CO, time-of-flight mass spectrometry, inner-shell excitation, quantitative oscillator strengths, cross sections.

Résumé : On a mesuré quantitativement le photofragmentation ionique du monoxyde de carbone qui suit les excitations 1*s* du carbone et 1*s* de l'oxygène à l'aide d'un rayonnement synchrotron et un spectromètre de masse à temps d'envol utilisant un appareil Wiley–McLaren modifié par l'addition d'une lentille ionique afin d'en améliorer la performance quantitative. Utilisant des simulations de trajectoires ioniques et des mesures expérimentales, on a caractérisé la sensibilité de l'appareil à l'énergie cinétique et aux effets de distribution angulaire pour divers ajustements choisis des lentilles. On a identifié trois modes distincts de lentilles ajoutées (focalisation, défocalisation et maximum). Le mode de focalisation est le moins sensible aux détails de la distribution de l'énergie angulaire et cinétique des ions et est donc le meilleur mode pour la mesure quantitative des rendements ioniques partiels et de paires d'ions. Le mode de défocalisation est le plus sensible aux distributions de l'énergie angulaire et cinétique et est donc le mode qui fournit le plus d'information concernant la cinématique de la photofragmentation. Les rapports de bifurcation dans la production de l'ion et de la paire d'ions dans les voies de fragmentation de tous les ions positifs ont été enregistrés de 280 à 330 eV (C 1*s*) et de 520 à 570 eV (O 1*s*) dans le mode de « focalisation ». On a dérivé les forces quantitatives de l'oscillateur en combinant ces rapports de bifurcation au spectre de rendement ionique total absolu. On compare les résultats aux valeurs rapportées dans la littérature.

Mots clés : CO, spectrométrie de masse en temps de vol, excitation de la couche interne, forces quantitatives de l'oscillateur, sections droites.

Introduction

Inner-shell excitation and associated decay spectroscopies are site-specific probes of electronic and geometrical structure and photoionization dynamics. Auger decay of inner-shell excited and ionized states is an efficient source of multiply charged ions. The fragmentation of these species, studied by photoelectron – photoion – photoion coincidence (PEPIPICO) and photoion–photoion coincidence (PIPICO) spectroscopy (also called charge separation mass spectrometry), gives insight into bonding and electronic structure. In triatomic and larger polyatomic molecules, the dependence

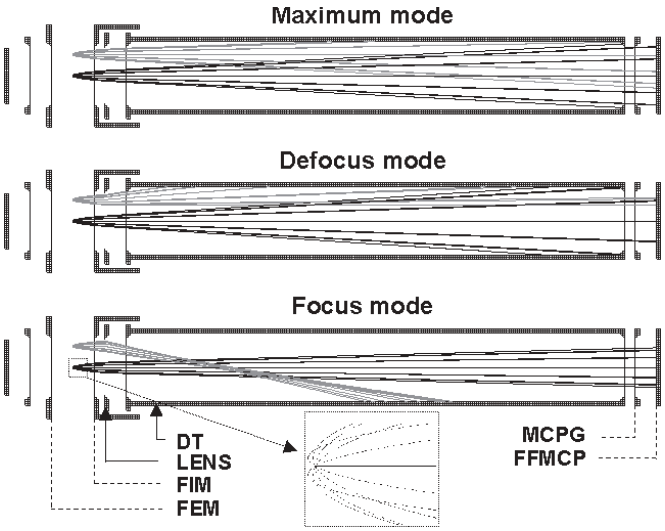
of the fragmentation process on the X-ray energy can reveal cases of site- and (or) state-selective fragmentation. The identification of potential candidates for selective X-ray photochemistry is an ongoing goal of our research program. To identify selectivity in fragmentation processes, quantitative yields are required, and thus it is important to understand the relationship between measured signals and the true partial photoionization cross sections (1). Some previous claims of selectivity in core level ionic fragmentation have been found to be, at least in part, an artefact of strong selectivity of the instrumentation to kinetic energy release distribution (KER or KERD) or angular distributions, combined with simultaneous changes of these factors among different core excited or ionized states (2).

To improve its quantitative performance, we have recently modified our Wiley–McLaren (3) time-of-flight (TOF) mass spectrometer to incorporate an ion-focussing lens (4). Here, we have used SIMION^{TM} trajectory simulations (5) and experimental measurements of CO to investigate the sensitivity of the modified apparatus to kinetic energy and ion angle distributions. We have found the additional ion lens has produced an instrument with three distinct modes — maximum signal rate (maximum mode), minimum selectivity to angle and kinetic energy distributions (focus mode), and maximum selectivity to ion angle and kinetic energy distributions (defocus mode). The focus mode of our apparatus is shown to provide the most representative partial ion and ion-pair yields — i.e., those with the least distortions associated with varying kinetic energy or angular distributions, as judged by absence of structure in the ion and ion-pair yields for high kinetic energy ions. Photoelectron–photoion coincidence (PEPICO) and PIPICO measurements of the ionic fragmentation following C 1*s* and O 1*s* excitation and ionization of CO are used to demonstrate these modes. The CO molecule was chosen because its electronic spectroscopy and core level photofragmentation have been studied extensively, and because there have been several previous studies of the core level photofragmentation yields claiming quantitative results (6, 7). Photoionization mass spectroscopy (6–15), photoelectron spectroscopy (16, 17), electron–ion coincidence spectroscopy (18, 19), and electron energy loss spectroscopy (20–24) measurements on CO were performed. The results are compared to an early time-of-flight photoionization mass spectrometry study, in which a very short extraction pulse was used to improve quantitative collection (6), and to (e,e + ion) coincidence measurements (7) simulating photoionization, which are generally accepted to produce branching ratios free from kinetic energy distortion. We discuss our results relative to a wider range of partial ion yield results on CO (6, 7–11, 25).

Experimental

The experiments were performed using two different beamlines at the Synchrotron Radiation Center (SRC), University of Wisconsin at Madison. One was a modest resolution grasshopper monochromator (Mark II) equipped with a 1200 lines/mm grating. The other was the high-resolution spherical grating monochromator (SGM) of the Canadian Synchrotron Radiation Facility (CSRF). The X-ray beam

Fig. 1. Schematic diagram of the experimental TOF apparatus. Drift tube (DT), first electron mesh (FEM), first ion mesh (FIM), multichannel plate grid (MCPG, prevents ion feedback), microchannel plate (MCP), front electrode of the MCP (FFMCP), electron pre-amplifier, amplifier, discriminator (e-PAD), ion pre-amplifier, amplifier, discriminator (i-PAD), time-to-digital converter (TDC), personal computer (PC).



cross section in the ionization region was 2 × 1 mm in each case. For C 1*s* measurements, a 100 nm thin film of Ti was placed in the beam path to reduce second-order radiation by 70%. The sample was introduced into the experimental chamber as an effusive jet through a high-aspect-ratio stainless steel needle oriented perpendicular to both the time-of-flight (TOF) axis and the monochromatized photon beam. There was very little variation in gas density over the volume of the X-ray beam in the interaction region, as evidenced by negligible variation in signal strengths or spectral shapes as the position of the tip of the needle was varied over large ranges. Thus, signal is generated all along the X-ray beam path as it traverses the interaction region defined by the 25 mm mesh-covered openings into the electron detector and ion TOF drift tube. The sample pressure was maintained at ~6×10^{-6} torr (1 torr = 133.322 Pa) during data acquisition. The base pressure was ~2×10^{-8} torr so that residual gas signals contributed negligibly.

The TOF apparatus, prior to modification for addition of the ion lens, along with the PEPICO, PIPICO, and PEPIPICO modes, has been described earlier (1). Figure 1 shows a schematic diagram of the modified TOF apparatus, along with the electronic setup. It consists of a Wiley–McLaren type space charge focusing instrument (3) in which an electric field of up to 1050 V/cm (2000 V over 19 mm) was used to extract the parent and fragment ions. An additional lens (4) was installed between the drift tube (DT) and the ion extraction grid (FIM). The lens was designed to focus the fragment ions on a microchannel plate (MCP) detector.

Electrons and ions produced from photoionization were detected by two microchannel plate detectors (MCP), positioned directly opposite in relation to the TOF axis. Signals from the two MCP detectors were amplified and fed into LeCroy 688AL amplifier/discriminators. Coincidence detection was performed using an Ortec picosecond time analyzer (pTA) operated in a list mode, in which the arrival times of start (electron) and one or more stop (ion) signals were stored in a local memory and periodically downloaded to a microcomputer for further processing to generate the PEPICO, PIPICO, and other visualizations.

Fig. 2. C^+ ion trajectories computed by SIMION^{TM}, showing the existence of three modes of lens operation. Ions (20 eV) were started from the centre of the ionization region with initial ejection angles covering the full 360° (see insert figure at the bottom). One set of trajectories was started on the TOF axis and a second was started close to the edge of the entrance aperture into the drift tube. Potentials for the simulation: DT (–3800 V), FEM (+1000 V), FIM (–1000 V), MCPG (–3900 V), FFMCP (–3800 V), lens (–800 V for focus mode, –2200 V for maximum ion signal mode, and –3000 V for defocus mode).

Results and discussion

Characterization of the lens

Figure 2 shows the SIMION^{TM} simulations using potentials identified empirically for the instrument. The simulations are for the three different lens modes and an extraction field of 1050 V/cm (2000 V over 19 mm). The geometric parameters used in the simulation are listed in Table 1. For this geometry, the simulation flight times agree quite well with the measured times, indicating that the SIMION^{TM} model closely approximates the actual apparatus. The existence of the three modes was deduced from the SIMION^{TM} simulations, although the optimum lens voltages (summarized in Table 2) were found experimentally by determining optimal performance of each type — maximum ion signal for maximum mode; minimum kinetic energy discrimination, as evidenced by absence of the dip in the PIPICO signals, for "focus" mode; and maximum kinetic energy discrimination, as evidenced by the deepest dip in the PIPICO signals, for "defocus" mode. The PEPICO and PIPICO signals at 305 eV, for a 1050 V/cm extraction field and these three lens conditions, are compared in Fig. 3. The trajectories displayed in Fig. 2 are those of a positive ion with 20 eV kinetic energy, emitted at two points along the photon trajectory, one at the centre of the ionization region, the other 10 mm from the centre of the DT. The DT inner diameter is 25 mm, and thus the 10 mm off-centre starting point is still 2.5 mm away from the edge of the opening in the DT. Since the SIMION^{TM} geometry is a close approximation to the actual geometry, any edge effects not included in the simulation are expected to be minimal. From each of these points, a set of ion trajectories are plotted using take-off angles covering the full 360° (see insert to Fig. 2).

Table 1. Geometric parameters used in the SIMION^{TM} simulations.

Geometric feature	Dimension in simulation (mm)
FEM–FIM gap	19.0
FIM lens and DT thickness	1.0
FIM (grid) – lens (front surface)	5.0
Lens (front surface) to DT (grid)	10.0
DT grid-to-grid	232.0

In the *focus* mode (V_{lens} = –800 V for V_{DT} = –3800 V), a convergent potential is used in which the ions emitted at any angle from a single spot are transported to the detector without loss, for all kinetic energies up to 20 eV. Of the three modes, this one provides the least kinetic energy or angular discrimination, and thus it should be the best for measuring representative partial ion yields, which can form the basis for quantitative partial ion yields. In the *defocus* mode (V_{lens} = –3000 V for V_{DT} = –3800 V), a divergent potential is used in which the ions emitted along the TOF axis from a wide range of lateral positions along the X-ray beam are transported to the detector. Ions starting with large off-axis angles tend to hit the walls. This mode provides the most information about on-axis kinetic energy distributions since the system has a narrow acceptance angle (approximately ±30°). In the *maximum* mode, ions emitted all along the photon path are focused to the detector. The simulation shows that, for many positions along the photon path, an approximately ±60° acceptance angle is achieved at an extraction field of 1050 V/cm. Note that although, relative to the defocus mode, poorer kinetic energy distribution information results from the larger acceptance angle, the angle is better defined (all positions on the X-ray beam axis have the same angular distribution sampled), resulting in significantly larger signals (about 3 to 4 times more than in the focus or defocus modes).

PEPICO and PIPICO signals from CO in the three lens modes

Figure 3 shows the PEPICO and PIPICO signals for CO ionized at 305 eV, the peak of the excitation to the quasi-bound (C $1s^{-1}$, σ*) state, also called the σ* shape resonance. The extraction field was 1050 V/cm and the lens voltages for the three modes are those for which the SIMION^{TM} calculations were performed. The first stop signal (from single and the faster ion produced in dissociative double ionization) and the second stop signal (from the slower ion of dissociative double ionization) have been summed in each case. The peak shapes of high kinetic energy species (C^{++}, O^{++}, C^+, O^+), and especially the PIPICO signals that correspond mostly to highly energetic ions, show significant changes between the focus and defocus modes. For example, $I(C^+)/I(O^+) > 1$ for the focus mode but $I(C^+)/I(O^+) < 1$ for the defocus mode (I(x) = intensity of ion x). These changes are consistent with loss of fast C^+ ions, and thus much higher KER sensitivity in the defocus mode but very little KER or angular selectivity in the focus mode. The maximum mode gives a significantly higher signal in both PEPICO and

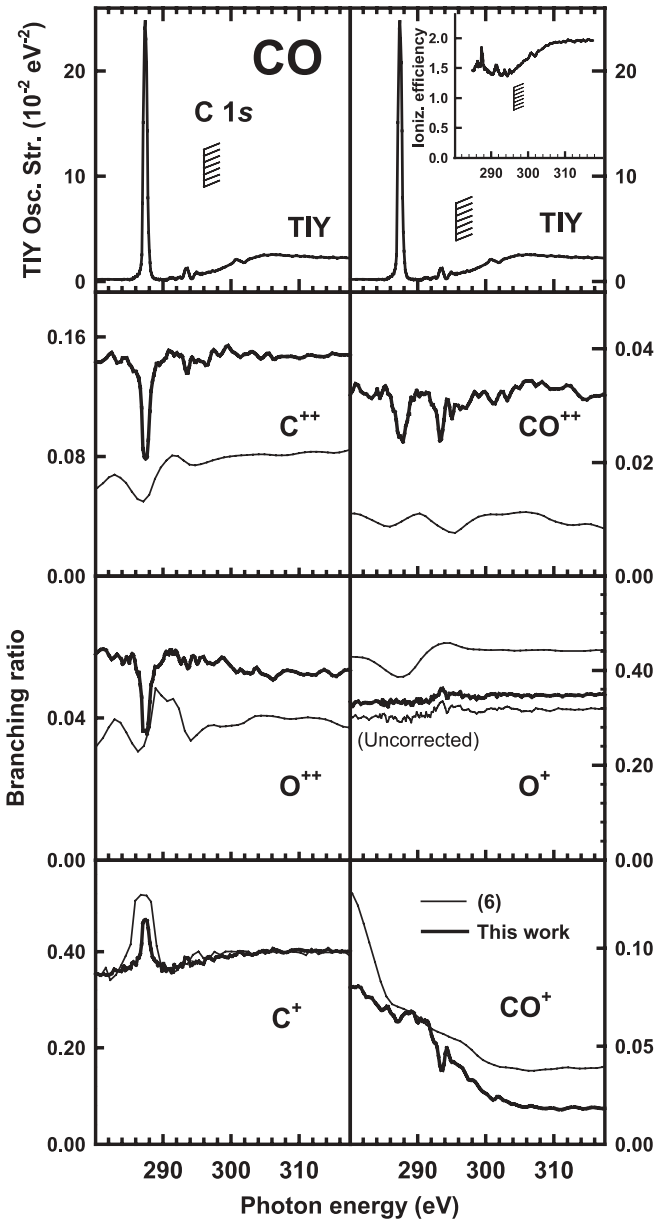
[a] V_d is the applied lens voltage used for defocus mode.
[b] V_f is the applied lens voltage used for focus mode.
[c] V_m is the applied lens voltage used for maximum mode.

Fig. 3. PEPICO (upper) and PIPICO (lower) spectra for C 1*s* ionized CO at 305 eV, measured with the lens set for focus, defocus, and maximum modes, as indicated in the legend. For clarity, the ordinates of the curves have been shifted with respect to each other. The intensities are in correct proportions.

PIPICO and has a KER discrimination somewhere in between the focus and defocus modes. Since the kinetic energy release distribution (KERD) is spread over more time at weak extraction fields and is thus easier to sample, it is often favorable to use the low extraction field to explore kinetic energy distributions and polarization-dependent ion yields. We stress the extremely flat-topped character of the (C^+, O^+) PIPICO signals in the focus mode. This is an unambiguous indication of the absence of angular discrimination and strongly supports our claim that this mode provides relative ion yields that are proportional to the quantitative ion yields.

Experimental conditions with these three limiting behaviors could be found for a wide range of different extraction fields, indicating they are a fundamental aspect of the ion optics. Table 2 lists the voltages and lens ratios for the three modes at the various extraction fields explored. We chose to use an extraction field of 1050 V/cm to maximize the yield. Even below 200 V/cm extraction field, it is possible to see the characteristic changes in the TOF or PIPICO shapes seen in Fig. 3 as a function of lens voltages, indicating there are distinct modes, even under weak extraction field conditions. Within experimental error, the lens ratios V_d/V_f and V_d/V_m are independent of extraction fields (V_d, V_f, and V_m are the optimal lens voltages in defocus, focus, and maximum modes, respectively). This observation suggests to us that our experimental procedure used to define the optimal lens voltages is valid and that the conditions we are identifying in this manner are general properties of the lens, and not specific to a narrow range of extraction fields.



At 305 eV photon energy, the CO^+ yield is very small since this species only arises from the weak underlying valence shell ionization or from the even weaker fluorescence decay of the C 1*s* core hole. In fact, there is also a small contribution from CO^+ produced by low-energy UV stray light. Since virtually all of the 1*s* ion states decay by Auger, a final charge state of at least 2+ must exist. Although there is a small yield of CO^{++}, most of the CO^{++} states undergo symmetric dissociative double ionization producing C^+ and O^+, as explained by the "Coulomb explosion" model (26). The C^+ and O^+ signals from core ionization are very similar and dominate the spectra. These signals arise mainly from (C^+, O^+) ion-pair production (6). The yields of C^{++} and O^{++} are likely associated with asymmetric dissociation, although some also arise from the weak triple ionization processes producing (C^{++}, O^+) or (O^{++}, C^+) ion pairs detected in the PIPICO and PEPICO measurements.

Photoion branching ratios

The branching ratio (BR) is the ratio of the yield of a specific ion to the total ion yield. Figure 4 shows the C 1*s* photoion branching ratios between 280 and 320 eV measured in the focus mode, as compared to literature values (6). The branching ratio data shown in Fig. 4 are the average from two sets of measurements. The curves for each ion were derived from the peak areas in the PEPICO spectra measured at a series of energies, with high extraction fields and the focus mode of the lens. After subtraction of the background of accidental coincidences, the first stop and second stop signals were summed to generate the branching

Fig. 4. Branching ratios for positive ion production from CO in the C 1*s* region derived from PEPICO mass spectra recorded with a Mark II grasshopper monochromator, as compared to literature values (6), which were digitized. The top of each column displays the total ion yield (TIY) spectra measured simultaneously and placed on an absolute scale, taking into account the estimated ionization efficiency of 2 in the C 1*s* continuum. The inset figure in the upper right panel is the estimated ionization efficiency. The O^+ curve marked uncorrected is prior to addition of 20% of the C^+ signal (followed by renormalization of all branching ratios to sum to unity). This correction compensates the fraction of the O^+ signal lost because of masking by first arrival of a C^+ signal. (A similar correction was applied in ref. 6.)

ratio. However, because the efficiency of ion detection is low (estimated to be 20%), this procedure does not account for the large loss of the O^+ signal from the "masking" of that species by the C^+ species for the (C^+, O^+) ion-pair process, which dominates the decay of C 1*s* ionized states. To compensate for the loss of the O^+ signal, 20% of the signal from

Fig. 5. Branching ratios for positive ion production from CO in the O 1*s* region derived from PEPICO mass spectra recorded with the spherical grating monochromator, as compared to literature values (6). The top of each column displays the total ion yield (TIY) spectrum, with the oscillator strength scale set from published oscillator strength data (24, 27), taking into account the estimated ionization efficiency of 2 in this energy region. The O^+ curve marked uncorrected is prior to the addition of 20% of the C^+ signal (see caption to Fig. 4 for further details).

the C^+ yield was added to the O^+ yield and the branching ratios recomputed. Figure 4 plots both the uncorrected and corrected O^+ branching yield spectra. Figure 5 shows the measured O 1*s* photoion branching ratios, derived from a sequence of PEPICO spectra measured in the 525–570 eV range with high extraction fields and the focus mode of the lens. As with the C 1*s* region, the O^+ signal was augmented by 20% of the C^+ signal to compensate for loss of the O^+ from the dominant (C^+, O^+) ion-pair process.

[a]Branching ratio at peak energy.
[b]The cited uncertainties are based on local statistical fluctuations in the data and do not reflect uncertainties associated with systematic errors.

The general shapes of the branching ratios are similar to those reported earlier, but there are differences in the quantitative yields. In particular, relative to ref. 6, in this work the yield of all doubly charged ion species is larger by 50%–100%, while that of the C^+ and O^+ singly charged species is about 20% smaller. This suggests that the earlier measurements underestimated the lower kinetic energy ion species. Note that the structure in the π^* region is much broader in the literature branching ratios (6) simply because of the poorer energy resolution of the earlier measurements (2.5 eV (6) vs. 0.6 eV fwhm (full width at half-maximum) in C 1*s*; 5 eV (6) vs. 1.5 eV fwhm in O 1*s*).

Figures 4 and 5 each include the total ion yield spectrum at the top of each column to help in the location of the states. This signal was measured simultaneously with the photoionization yields. For the O 1*s* spectrum, a small signal from impurity O_2 was subtracted (the O_2 π^* signal at 530.8 eV was about 3% of the CO π^* signal). Both C 1*s* and O 1*s* signals are set on an absolute oscillator strength scale by matching to earlier absorption oscillator strengths (6, 7, 24, 27), with a correction for the ionization efficiency, which is taken to be two above the C 1*s* ionization potential (6).

The inner-shell spectroscopy of CO has been described previously (6, 24) and is not controversial. Briefly, for the C 1*s* spectrum, the first strong peak at 287.4 eV is due to the C 1$s \rightarrow 2\pi^*$ transition. The weak structures at 292.4 and 293.4 eV correspond to C 1$s \rightarrow 3s$ and C 1$s \rightarrow 3p$ Rydberg excitations, respectively. The 294.8 eV feature is assigned as the overlap of 4*s* and 3*d* Rydberg transitions. The C 1*s* ionization potential (IP) is 296.1 eV (10). The feature in the near continuum at 300.7 eV is assigned to double excitation, while the broad structure at 305 eV is the σ^* shape resonance. The O 1*s* spectral features are assigned similarly: 534.1 eV (O 1$s \rightarrow 2\pi^*$), 539.1 eV (O 1$s \rightarrow 3s$), 540.4 eV (O 1$s \rightarrow 3p$), 541.7 eV (O 1$s \rightarrow 4s$, 3*d*), 542.4 eV (IP) (10), and 550.6 eV (shape resonance).

The C 1*s* branching ratio spectra can generally be divided into five regions: that below the onset of C 1*s* excitation (<287 eV), the C 1*s* discrete region (287–296 eV), the region just above the C 1*s* ionization threshold (296–300 eV), the near continuum (300–320 eV), and the continuum above the shake-off threshold (>320 eV). In contrast to the essentially constant ion branching ratios in the core ionization continua, at the π^* resonance there are large increases in the C^+ yield and significant decreases in the C^{++} and O^{++} yields. Similar observations can be made about the O 1*s* branching ratios, although the pre-O1*s*-edge signal is characteristic of C 1*s* ionization, rather than valence ionization, as in the pre-C 1*s*-edge signal, and thus the change from below to above the O 1*s* IP is smaller.

The C 1*s* branching ratios are also compared to results from a dipole regime electron–ion (e,e + ion) experiment (7) (Table 3). We found considerable disagreement, which was unexpected, since such measurements are generally considered quantitative. The CO (e,e + ion) study was one of the very first performed with that apparatus. It would be interesting to see the results of a modern (e,e + ion) measurement of CO.

Table 3 presents branching ratios at selected energies derived from the quantitative focus mode, in comparison to literature values (6, 7). The $I(C^+)/I(O^+)$ ratio for the C 1s π^* state is 1.39, very similar to the 1.33 value from ref. 6, but 34% lower than that from ref. 7. The $I(C^+)/I(O^+)$ ratio for the O 1s π^* state is 1.12, as compared to 1.30 from ref. 6. As noted in ref. 6, these similar ratios in the C 1*s* and O 1*s* regions indicate that the site of the core hole in CO has relatively little influence on the final ion distribution for this molecule. The largest factor determining variation in the fragmentation pattern is discrete vs. continuum excitation, associated with essentially complete double ionization above the C 1*s* IP, but only partial double ionization below the IP.

Partial ion and ion-pair yields for CO

C 1s partial ion yields

Figure 6 presents the quantitative partial ion yield (PIY) spectra of C 1*s* excited – ionized CO from 280 to 320 eV, derived by taking the product of the branching ratio and the absolute total ion yield signal. The partial ion yield spectra of C^{++}, O^{++}, and CO^{++} have enhanced continuum signals relative to the total ion yield (TIY). As found earlier (6), the C^{++} and O^{++} signals show a further rise at ~320 eV (not shown) corresponding to the onset of shake-off (simultaneous core and valence ionization) (6). The CO^+ signal has negligible signal in the C 1*s* continuum since the only channel that can give rise to CO^+ is fluorescence decay of the core hole, which has an extremely low probability. Note there is a very weak residual CO^+ signal, amounting to less than 2% of the total signal, which is most likely from low-

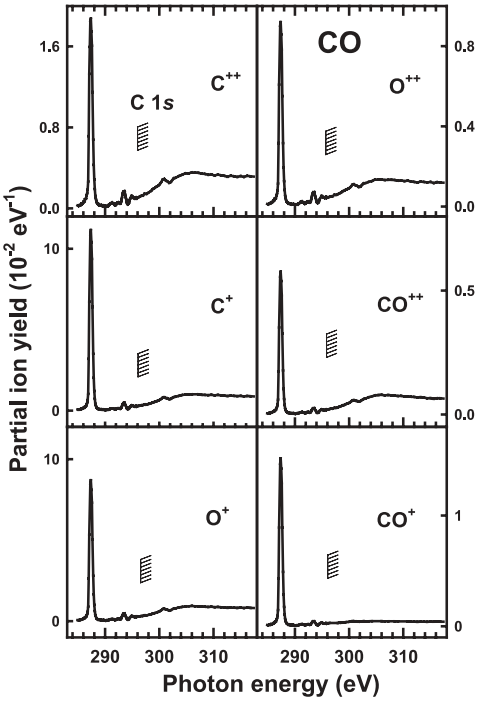
Fig. 6. Quantitative partial ion yield (PIY) oscillator strength spectra of all positive ions produced from CO in the 280–320 eV region recorded in the focus mode.



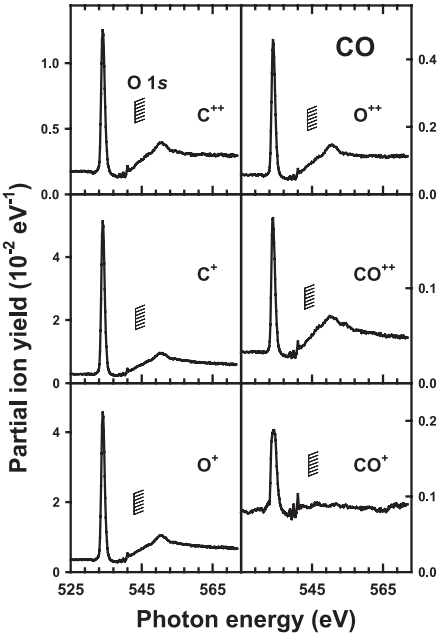


Fig. 7. Quantitative partial ion yield (PIY) oscillator strength spectra of all positive ions produced from CO in the 525–570 eV region recorded in the focus mode.

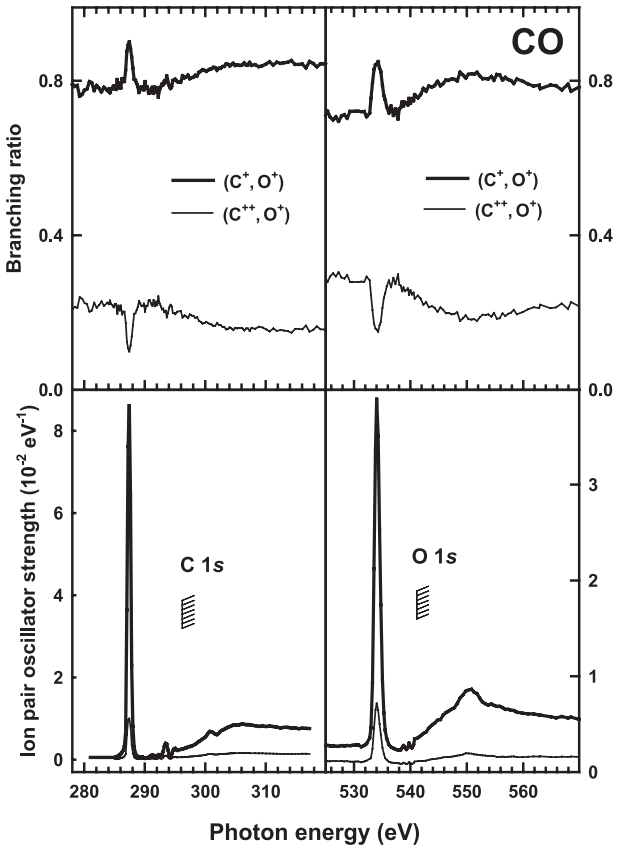
energy UV stray light. The relative strength of the C $1s \rightarrow 2\pi^*$ peak varies for the different ion products, indicating changes in the branching ratio for ionic fragmentation as discussed in the previous section and listed in Table 3.



O 1s partial ion yields

Figure 7 presents the quantitative PIY spectra of O 1*s* excited – ionized CO from 525 to 570 eV, derived by taking the product of the branching ratio and the absolute TIY signal. As with the C 1*s* partial ion yields, the yields of the doubly charged products are increased in the O 1*s* continuum, although the effect is less dramatic since the underlying signal arises mostly from C 1*s* ionization, where already the double ionization dominates. The CO^+ parent ion signal shows a constant contribution from underlying valence ionization, with additional yield at the O $1s \rightarrow \pi^*$ transition and relatively more at the O $1s \rightarrow$ Rydberg transitions, but no signal in the O 1*s* continuum.

C 1s and O 1s ion-pair yields

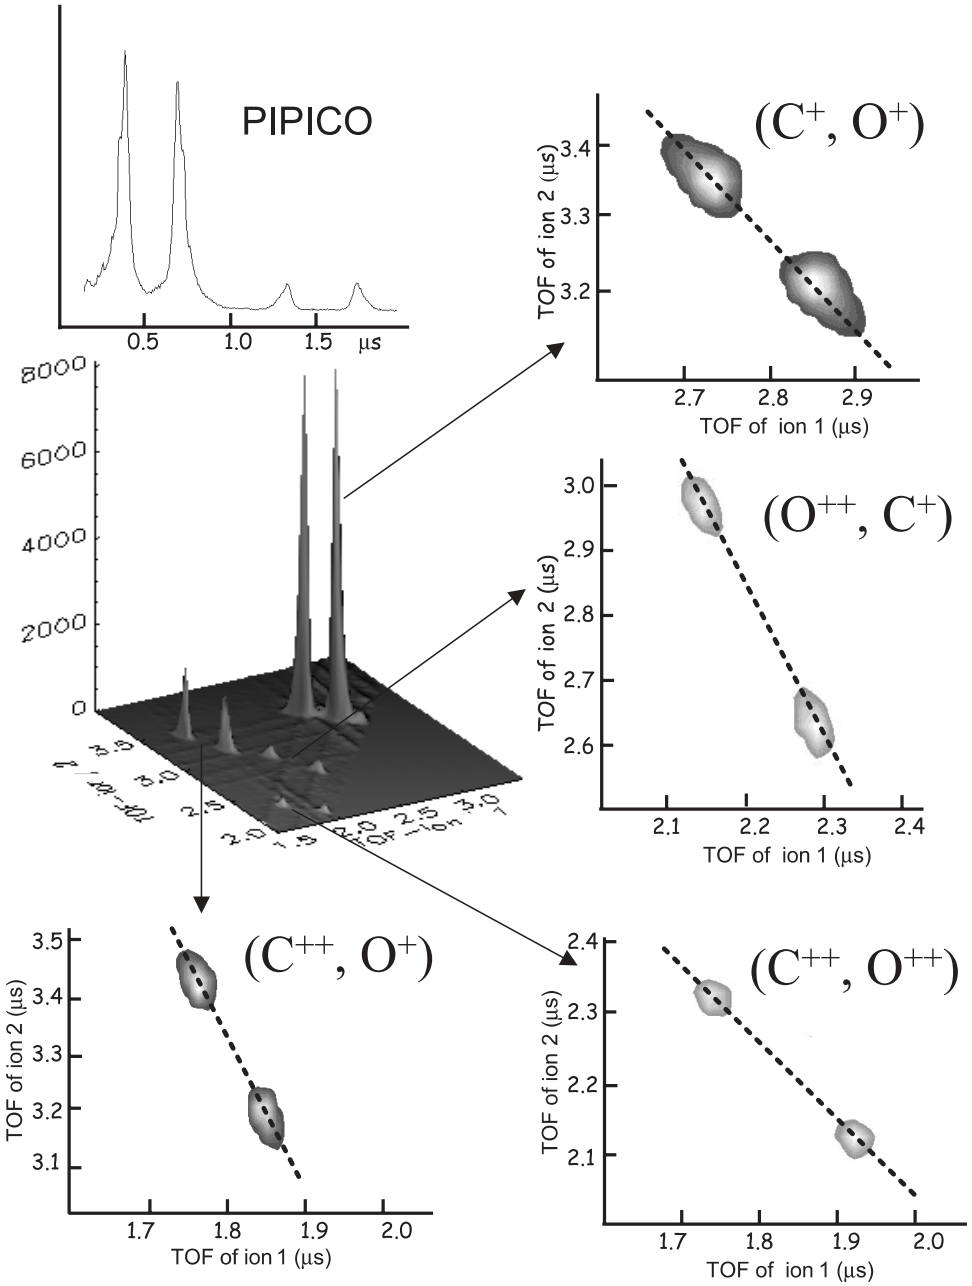


Figure 8 plots the branching ratios and the PIY spectra for the (C^+, O^+) and (C^{++}, O^+) ion pairs in the C 1*s* and O 1*s* regions derived from PIPICO data. The (C^+, O^+) ion-pair signal dominates the C 1*s* and O 1*s* continua. From the sum of the C^+ and O^+ branching ratios, we estimate that the ion-pair signal is 80% of the total ion signal. Since the TIY counts each ion separately, the derived total ion-pair yield (80% of the continuum TIY) was further divided by two to derive the oscillator strength for only ion-pair production. Thus, the absolute oscillator strength for producing the individual ion pairs was obtained by multiplying the ion-pair branching ratio times the TIY signal scaled by 0.40. (C^+, O^+) pair production is the strongest pair process in both core ionization

Fig. 8. Branching ratios (upper) and oscillator strength spectra (lower) for production of (C^+, O^+) and (C^{++}, O^+) ion pairs from CO in the C 1*s* and O 1*s* regions, derived from PIPICO spectra recorded with a high extraction field (1050 V/cm) and in the focus mode.

continua. The dissociative triple ionization channel that produces the (C^{++}, O^{+}) pair constitutes ~10% of the total ion-pair signal, while the (O^{++}, C^{+}) signal, which is almost invisible in PIPICO but readily visible in PEPIPICO, is only a few percent of the ion-pair signal.

PEPIPICO

The PEPIPICO spectrum measured at 305 eV (C $1s \rightarrow \sigma^*$ resonance maximum) under weak extraction field conditions and with the lens operated in defocus mode, using the voltages displayed in the first row of Table 2, is presented in Fig. 9 in comparison to the PIPICO spectrum recorded at the same time. The defocus mode with a weak extraction field is the best condition for examining kinematics of ionic fragmentation since these conditions provide the largest sensitivity to kinetic energy and angular distributions. Figure 9 illustrates clearly the advantage of PEPIPICO relative to PIPICO. A total of four distinct ion-pair signals are clearly observed by PEPIPICO, whereas only two distinct signals are detected in the PIPICO signal recorded simultaneously. The (O^{++}, C^{+}) signal is clearly observed in PEPIPICO, whereas it is masked by the much stronger (C^{+}, O^{+}) signal in PIPICO. The very weak (C^{++}, O^{++}) signal from quadruple ionization is also clearly detected. Figure 9 also illustrates the power of the defocus mode to reveal details of the kinetic energy release distributions. The differences in the slope of the major axis of the coincidence signal are trivially related to the changes in the charge state of the ions in-

© 2004 NRC Canada

volved (1), since the events are pair dissociations in which all particles are detected. The separation of the two peaks along the major axis is related to the average kinetic energy release, which is significantly larger for 2+/1+ than for 1+/1+ and larger again for 2+/2+ charge separation. Detailed analysis of the full line shape (1) provides quantitative kinematic information, which can be compared to computed potential energy surfaces of CO^{++} (6).

Summary

Three different operation modes of a newly installed ion lens were found, corresponding to conditions predicted from SIMION™ simulations. The focus mode was found to produce yields that have minimal kinetic energy or angular discrimination and thus are likely to correspond to the true quantitative yields. The photoion branching ratios for C 1*s* and O 1*s* excited and ionized CO were measured in the focus mode and converted to absolute partial ion yield oscillator strengths. When compared with an early literature result (6), claimed to be quantitative, we find significant differences in the individual ion yields. While we believe the present system operated in the focus mode provides more quantitative ion yields than the method used in the earlier study, beamline-specific factors such as interference from stray light or residual second-order radiation may still have distorted the results presented in this work. Comparison to other independent photoionization or (e,e + ion) coincidence measurements with mass spectrometers optimized for quantitative results is required to properly establish the accuracy of these results. We encourage other researchers to provide such results. In the meanwhile, we will continue to use our apparatus in the focus mode to study the photon energy dependence of molecular photofragmentation in our ongoing search for X-ray selective photochemistry.

Threshold photoelectron spectroscopy of benzene up to 26.5 eV[1]

Andrew J. Yencha, Richard I. Hall, Lorenzo Avaldi, Grant Dawber, Andrew G. McConkey, Michael A. MacDonald, and George C. King

Abstract: The threshold photoelectron spectrum of benzene has been recorded up to 26.5 eV photon energy under high-resolution conditions using synchrotron radiation and employing the penetrating-field threshold electron collection method. By means of a direct comparative study with a recent HeI photoelectron spectrum of benzene of equally high resolution, numerous autoionization effects are observed in the formation of the ionic band systems of benzene in the outer valence ionization region in the threshold photoelectron spectrum. The Rydberg states responsible for these effects are identified. Autoionization does not appear to play a role in the formation of the two lowest-energy, inner-valence bands of $C_6H_6^+$.

Key words: threshold photoelectron spectroscopy, photoelectron spectroscopy, benzene, ionization, autoionization, Rydberg states.

Résumé : On a enregistré le spectre de seuil photoélectronique du benzène jusqu'à une énergie photonique de 26,5 eV, dans des conditions de haute résolution, utilisant un rayonnement synchrotron et la méthode du champ pénétrant pour la collection des électrons de seuil. Faisant appel à une étude comparative directe avec un spectre photoélectronique HeI récent du benzène d'une résolution aussi haute, on a pu observer divers effets d'autoionisation dans la formation des systèmes de bandes ioniques du benzène dans la région d'ionisation de valence externe du spectre de seuil photoélectronique. On a identifié les états de Rydberg responsables de ces effets. L'autoionisation ne semble pas jouer un rôle dans la formation des deux bandes de valence interne de plus faible énergie du $C_6H_6^+$.

Mots clés : spectroscopie de seuil photoélectronique, spectroscopie photoélectronique, benzène, ionisation, autoionisation, états de Rydberg.

[Traduit par la Rédaction]

Introduction

The electronic structure of benzene has been of great interest to both experimentalists and theoreticians for more than seven decades due to its being the simplest example of a large class of polyatomic aromatic molecules. In fact, there are 24 separate entries in the subject index on this molecule in the 1966 seminal book on the electronic spectra and electronic structure of polyatomic molecules by Gerhard Herzberg (1). On the other hand, only a single entry is given in the book for the cation of benzene. Thus, most of our knowledge about the electronic structure of the benzene cation has occurred since and largely because of the advent of photoelectron spectroscopy (PES) in the 1960s. The first report of the PE spectrum of benzene was given by Akopian et al. (2) in 1961 using a variable-wavelength light source, but it has been reported on numerous times since. In the early days of PES, there was considerable controversy over the assignment of the low-lying ionization bands of benzene, primarily over the ordering of the three lowest-energy bands (3). The controversy stems from the assignment given by El-Sayed et al. (4) that the second ionization potential (IP) at 11.489 eV was due to the $1a_{2u}$ (π) orbital. This controversy has now long been settled with the ordering of the first three IPs of benzene being generally accepted to be $1e_{2g}$ (π) (ground state), $3e_{2g}$ (σ), $1a_{2u}$ (π). The most recent and, to date, the most extensive study of benzene by PES was that by Baltzer et al. (5) in 1997 using both synchrotron and HeI radiation. In spite of all the activity over the years on the PES of benzene, it is surprising that no report on the threshold photoelectron spectroscopy (TPES) of benzene has yet appeared to our knowledge. Since TPES provides a different

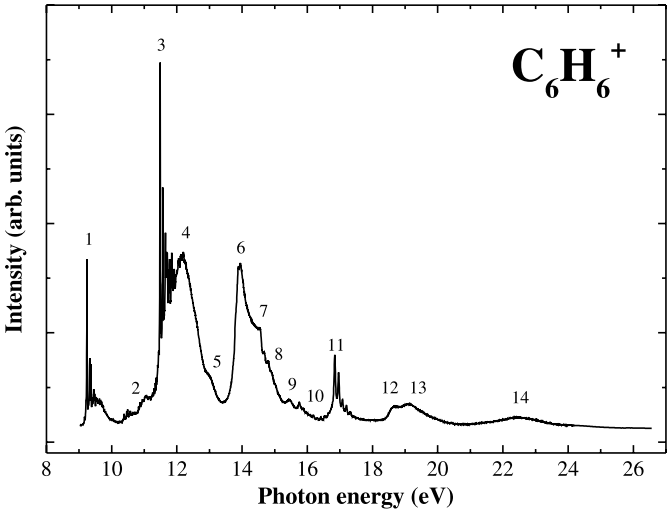
perspective of photoionization, it is of interest to see what we can learn about the formation of the cationic states of benzene by recording and analyzing the TPE spectrum of benzene at a resolution comparable to that of the highest resolution PE spectrum of benzene yet obtained. The object of this report is then to compare and contrast the TPE spectrum of benzene with the HeI PE spectrum of benzene. As such, we will not dwell on the details of the vibrational and electronic-state analysis of the HeI PE spectrum (5) but generally accept it.

Experimental

The TPE spectrum of benzene reported here was obtained on beamline 3.2 of the Synchrotron Radiation Source (SRS) of the Daresbury Laboratory. Details of the experimental procedure for taking TPE spectra have been given previously (6, 7), so only a brief description will be given here. Synchrotron radiation emanating from the electron storage ring of the SRS was dispersed using the 5 m McPherson monochromator of the station prior to entering the experimental apparatus. Near-zero-kinetic-energy electrons (<20 meV, although ~95% were within 3 meV of zero) were detected as a function of the scanning photon energy using a penetrating-field energy analyzer (8, 9) tuned to accept primarily threshold electrons using the argon ion doublet lines, $^2P_{3/2}$ and $^2P_{1/2}$. An effusive beam of benzene gas entered the ionization region of the apparatus through a platinum/iridium needle of 0.8 mm bore mutually perpendicular to the photon beam (1 mm diameter) and the entrance aperture (5 mm) of the analyzer and positioned ~3 mm above the photon beam. The temperature of the main chamber of the apparatus was maintained at ~100 °C to minimize local patch fields because of contact potential variations.



The TPE spectrum of benzene presented here was obtained by joining together spectra recorded in four energy regions: 9.0–14.0, 13.9–19.0, 18.9–24.1, and 24.0–26.5 eV, respectively. The first three of these regions were recorded in 5 meV steps, while the last region was recorded in 20 meV steps. These spectra were independently corrected for the variation in the photon flux as a function of energy and the decay of the synchrotron current with time. Normalization of the individual spectra in the overlapping regions resulted in the complete TPE spectrum of benzene over the photon energy range 9.0–26.5 eV. This spectrum was energy calibrated by measuring the TPE spectra of Xe in the presence of benzene over the $5p^{-1}$ (13.436 eV) and $5s^{-1}$ (23.397 eV) ionization peaks. These spectra also enabled a determination of the resolution of the benzene spectrum that was found to range smoothly from ~6 meV at 9 eV photon energy to ~19 meV at 26.5 eV photon energy. The pressure of benzene in the apparatus was of the order of 2×10^{-5} to 3×10^{-5} mbar (1 bar = 100 kPa). Benzene was supplied by the Aldrich Chemical Co. (Milwaukee, Wis.) and used directly.

Results and discussion

General considerations

Benzene is a planar molecule of D_{6h} symmetry containing 30 valence electrons whose orbital configuration is generally accepted to be (10):

Fig. 1. The full TPE spectrum of benzene up to 26.5 eV photon energy. The band features shown are identified in Table 1 as discussed in the text.

$$(2a_{1g})^2(2e_{1u})^4(2e_{2g})^4(3a_{1g})^2(2b_{1u})^2(1b_{2u})^2(3e_{1u})^4$$
$$(1a_{2u})^2(3e_{2g})^4(1e_{1g})^4$$

where $1a_{2u}$ and $1e_{1g}$ are pure π orbitals — all others being σ orbitals. On the basis of the independent-particle approximation for ionization, removal of an electron from each of these orbitals is expected to produce 10 single-hole states. However, it has been shown theoretically that electron correlation effects are important in the photoionization of benzene, even in the removal of outer valence electrons (11). In fact, an additional outer valence satellite state was predicted (11) and a band later confirmed in the Penning ionization electron spectrum of benzene (12), even though this band had eluded detection in any HeI or HeII PE spectrum of benzene. In addition, one might anticipate because of the high symmetry of the benzene molecule that the Jahn–Teller effect (1) would be important in describing the vibronic bands of $C_6H_6^+$ of *E*-symmetry in the PE spectrum of benzene. This would manifest itself in the observation of Jahn–Teller active modes of vibration of e_{2g} symmetry in the vibronic structure of states of *E*-symmetry as well as the possibility of splitting of the electronic state into two components (13). Hence, the details of the ionization of benzene are expected to be far more complicated than would at first appear. These aspects have been thoroughly considered and discussed in the most recent PE study of benzene (5) and will not be considered further here.

The TPE spectrum of benzene

The full TPE spectrum of benzene over the photon energy range 9.0–26.5 eV is shown in Fig. 1. Many individual features can be identified in this figure and are labeled 1–14. The identities of these features are given in Table 1 based on the discussion in the text. How this spectrum compares with the conventional HeI PE spectrum of benzene (5) can be seen in Fig. 2. The high-resolution HeI PE spectrum shown here displays the seven well-known band systems of $C_6H_6^+$ lying below 18 eV binding energy. The labeling of these sys-

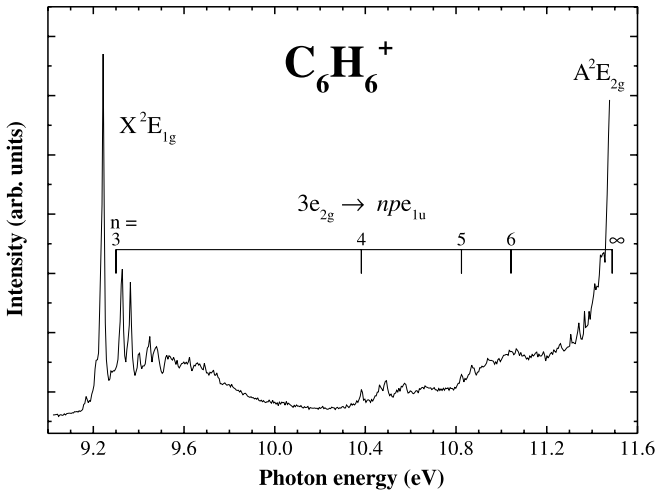
Table 1. Identification of the band features in the TPE spectrum of benzene shown in Fig. 1 resulting in the populating of different states of $C_6H_6^+$ by the autoionization of Rydberg states formed through various Rydberg transitions.

Feature number	$C_6H_6^+$ state	Rydberg transition
1	X^2E_{1g}	$(3e_{2g} \rightarrow 3pe_{1u})$
2	X^2E_{1g}	$3e_{2g} \rightarrow npe_{1u}$, n = 4–6
3	A^2E_{2g}	$(3e_{1u} \rightarrow 3da_{1g})$
4	A^2E_{2g}/B^2A_{2u}	$(3e_{1u} \rightarrow 3de_{2g})$
5	B^2A_{2u}	$1b_{2u} \rightarrow 3de_{2g}$
6	C^2E_{1u}	$2b_{1u} \rightarrow 3de_{2g}$
7	C^2E_{1u}	$2b_{1u} \rightarrow 4de_{2g}$
8	D^2B_{2u}	$3a_{1g} \rightarrow 3pe_{1u}$
9	E^2B_{1u}	$(3a_{1g} \rightarrow 3pa_{2u})$
10	E^2B_{1u}	$3a_{1g} \rightarrow npe_{1u}$, n = 4–6
11	F^2A_{1g}	$(2e_{2g} \rightarrow 3pe_{1u})$
12	G^2E_{2g}	
13	G^2E_{2g}	
14	H^2E_{1u}	



Note: Transitions in parentheses are postulated (see text).

Fig. 2. Comparison between the TPE spectrum (upper panel) and the HeI PE spectrum (lower panel) of benzene (5), reproduced with permission, below a binding energy of 19 eV.

tems follows the orbital ordering used in ref. 5. Upon inspection of these two spectra (TPE vs. HeI PE), one is immediately struck by the dramatic changes in relative intensities in features within one spectrum as compared with the other. For example, the X^2E_{1g} and F^2A_{1g} bands in the PE spectrum are the dominant two systems (most intense peak heights), while the corresponding features in the TPE spectrum appear much suppressed compared with the central part of the spectrum. Upon closer inspection, one finds considerable "filling-in" in the Franck–Condon (FC) gap regions in the TPE spectrum, especially noticeable between the X^2E_{1g} and A^2E_{2g} bands and between the B^2A_{2u} and C^2E_{1u} bands. In addition, in the binding energy region encompassing the C^2E_{1u}, D^2B_{2u}, and E^2B_{1u} bands in the PE spectrum, the TPE

Fig. 3. A portion of the TPE spectrum of benzene covering the X^2E_{1g} band of $C_6H_6^+$ showing an identified Rydberg series contributing to the formation of this band (see text). The energy resolution in this part of the TPE spectrum is 6–8 meV.

spectrum is dramatically different. We shall now examine the various regions of the TPE spectrum in detail.

TPE spectrum in the 9.0–11.5 eV photon energy region

This expanded region of the TPE spectrum is presented in Fig. 3. It shows considerable filling-in between the X^2E_{1g} and A^2E_{2g} band systems as noted previously with some sharp features evident between about 10.4 and 11.4 eV. In addition, the breadth of the X^2E_{1g} band system appears larger than in the PE spectrum (see Fig. 2) with a long high-energy tail merging with sharp features beginning at about 10.4 eV. We attribute all these differences between the TPE and PE spectra to the autoionization of Rydberg states of benzene converging on the A^2E_{2g} cationic state as identified in Fig. 3 as the series $(3e_{2g} \rightarrow npe_{1u}$, for n = 3–6). This Rydberg series has been identified previously in the absorption spectrum (4, 14) and in the electron impact energy loss spectrum (15) as interpreted by Jonsson and Lindholm (16). Autoionizing structure in this energy range has also been observed in the ion yield spectrum of benzene (17). The position of the n = 3 member of this series was set at 9.3 eV in Fig. 3 as given by Jonsson and Lindholm (16), while the other members shown are experimental positions from this work. The sharp peaks between 11.3 and 11.4 eV are possibly due to hot-band structure associated with the A^2E_{2g} band of $C_6H_6^+$ due to the elevated temperature (100 °C) of the benzene used in obtaining the TPE spectrum. Similar hot-band effects are to be found in other band systems in the TPE spectrum but will not be dwelled upon.

TPE spectrum in the 11.4–13.4 eV photon energy region

The TPE spectrum in this expanded photon energy region is shown in Fig. 4. This binding energy region encompasses the overlapping A^2E_{2g} and B^2A_{2u} band systems of $C_6H_6^+$. There are a number of features in the TPE spectrum that differ from the PE spectrum (see Fig. 2): (*i*) the sharp vibrational structure of the A^2E_{2g} band differs qualitatively, i.e., the relative intensities of peaks are different; (*ii*) the peak

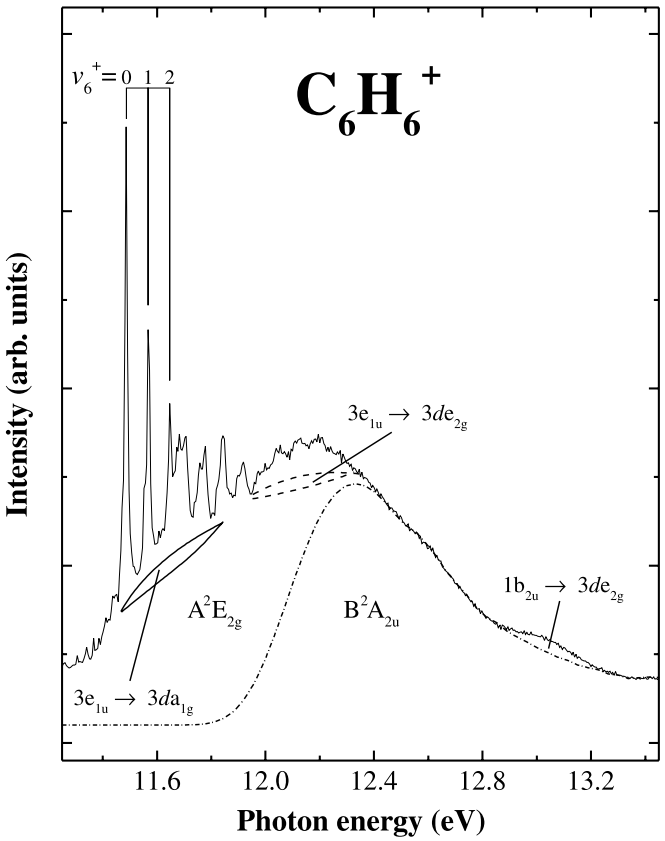
Fig. 4. A portion of the TPE spectrum of benzene covering the A^2E_{2g} and B^2A_{2u} bands of $C_6H_6^+$ showing the influence of three Rydberg transitions contributing to the formation of these bands (see text). The energy resolution in this part of the TPE spectrum is 8–10 meV.



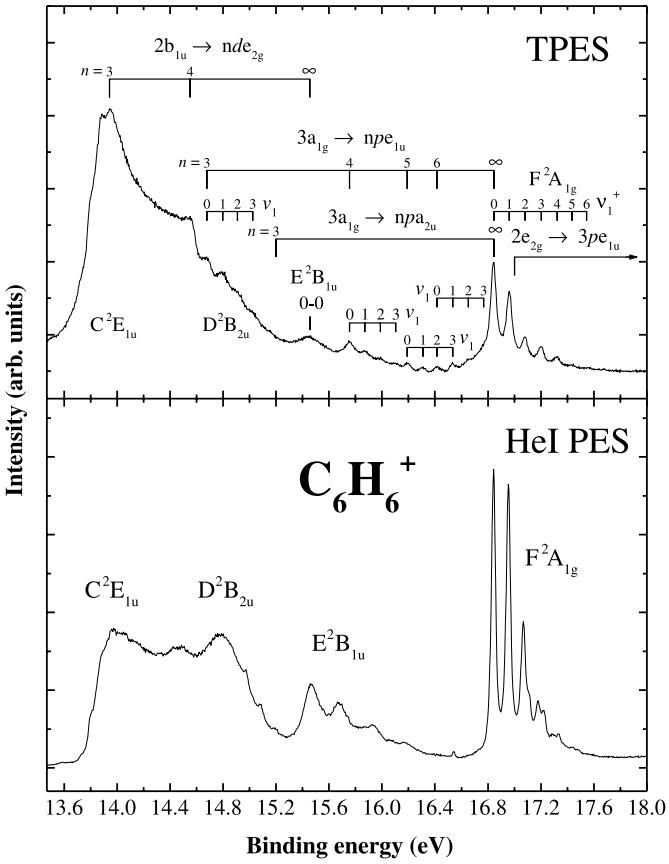


Fig. 5. Comparison between the TPE spectrum (upper panel) and the HeI PE spectrum (lower panel) of benzene (5), reproduced with permission, covering the C^2E_{1u}, D^2B_{2u}, E^2B_{1u}, and F^2A_{1g} bands of $C_6H_6^+$ in the 13.5–18.0 eV binding energy region. In the TPE spectrum numerous Rydberg transitions are identified as contributing to the formation of these bands (see text). The energy resolution in this part of the TPE spectrum is 10–13 meV.

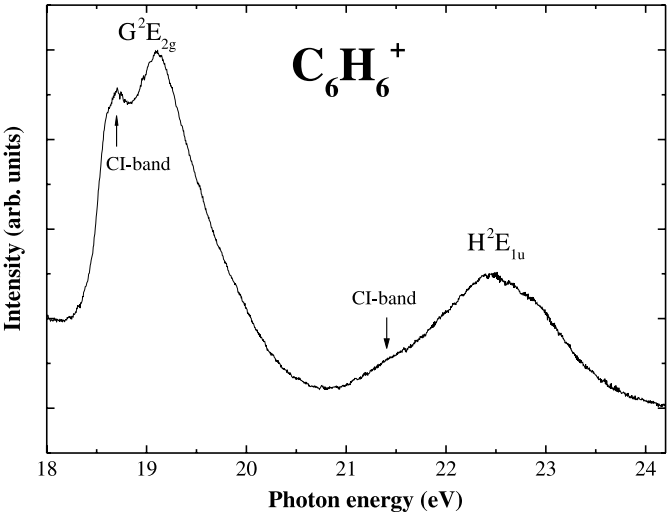
maximum in the broad-band region following the sharp structure of the A^2E_{2g} band representing the vertical energy position of the B^2A_{2u} band in the PE spectrum at 12.3 eV (5) is not at all evident in the TPE spectrum; (*iii*) there appears to be a broad band on the high-energy tail of the B^2A_{2u} band in the TPE spectrum not seen in the PE spectrum (see Fig. 2). We attribute all of these effects in the TPE spectrum to autoionization of Rydberg states lying in this energy region. To interpret these observations, we have schematically drawn in Fig. 4 (dot–dashed curve) the expected vibronic band shape of the B^2A_{2u} system based on the calculated ionization profile (Fig. 4*a* in ref. 18) and positioned the band maximum at the measured vertical ionization potential of 12.3 eV (5). Based on the interpretation by Jonsson and Lindholm (16) of the electron impact energy loss spectrum of benzene by Lassettre et al. (15), we identify the Rydberg states in Fig. 4 as follows. Autoionization of the Rydberg state $3da_{1g}$ ($\leftarrow 3e_{1u}$) predicted to lie at 11.6 eV (16) would account for the vibrational intensity variations in the A^2E_{2g} band as noted above in point (*i*). The location of this state is schematically shown as the solid curves in Fig. 4. The rising of the broad vibrational band features following the sharp vibrational peaks of the A^2E_{2g} band is ascribed to the $3de_{2g}$ ($\leftarrow 3e_{1u}$) Rydberg state predicted to lie at 12.2 eV (16) and would account for point (*ii*) above. The location of this state is schematically shown as the dashed curves in Fig. 4.

The broad-band feature noted in point (*iii*) above is assigned to the $3de_{2g}$ ($\leftarrow 1b_{2u}$) Rydberg state identified to lie at 13.1 eV (16). A broad feature at ~13.0 eV in the absorption spectrum of benzene was assigned to the $5sa_{1g}$ ($\leftarrow 3e_{1u}$) Rydberg state. We favor the former assignment simply because of the lower principal quantum number of the Rydberg state.

TPE spectrum in the 13.6–18.0 eV photon energy region

The TPE spectrum in this photon energy region is shown in the upper panel of Fig. 5. It covers the binding energy range encompassing the C^2E_{1u}, D^2B_{2u}, E^2B_{1u}, and F^2A_{1g} PE bands of $C_6H_6^+$ as identified in the lower panel of Fig. 5. This portion of the TPE spectrum is by far the most different from the PE spectrum. Only the F^2A_{1g} band is fully recognizable by comparison with the PE spectrum, but even in this case, there are some differences to be noted (see the following). The shapes of the C^2E_{1u} and D^2B_{2u} vibronic bands in the TPE spectrum are dramatically altered in comparison with the PE spectrum. The three broad-peak maxima of the overlapping C^2E_{1u} and D^2B_{2u} bands of the PE spectrum *do not* have *any* correspondence in the TPE spectrum, although



© 2004 NRC Canada

the weak vibrational structure on the low-energy side of the C^2E_{1u} band does appear in both spectra. The dominant features in the C^2E_{1u}/D^2B_{2u} bands region in the TPE spectrum of benzene are ascribed to the autoionization of three overlapping Rydberg states as shown in the upper panel of Fig. 5. This is based on the interpretation given by Jonsson and Lindholm (16) of the electron impact energy loss spectrum of benzene of Lassettre et al. (15). The first two Rydberg states, ($3de_{2g}$ and $4de_{2g}$) converging on the E^2B_{1u} ionic state, primarily populate the C^2E_{1u} state of $C_6H_6^+$, while the third Rydberg state ($3pe_{1u}$), converging on the F^2A_{1g} ionic state, primarily populates the D^2B_{2u} state of $C_6H_6^+$ based on the energy location of the Rydberg states in relationship to the ionic states of benzene (see lower panel of Fig. 2). The electronic band structure due to the latter exhibits four vibrational peaks of the dominant ν_1 mode familiar in the F^2A_{1g} ionic band of benzene as shown in the upper panel of Fig. 5. In addition, three other members of the $3a_{1g} \rightarrow npe_{1u}$ Rydberg series, for n = 4–6, display the same four vibrational bands of the ν_1 mode. The only feature in the TPE spectrum of benzene that can be assigned to the E^2B_{1u} ionic band is the 0–0 vibration at 15.46 eV as identified in the upper panel of Fig. 5. We postulate that this feature is, in fact, produced by autoionization of a Rydberg state lying in this energy region based on the extensive Rydberg-state activity in this photon energy range. The likely Rydberg state would be the $3pa_{2u}$ ($\leftarrow 3a_{1g}$) state converging on the F^2A_{1g} ionic state of benzene identified to lie at 15.2 eV (16) in the electron impact energy loss spectrum of Lassettre et al. (15). Finally, the F^2A_{1g} band in the TPE spectrum, although generally similar to the same band in the PE spectrum (see Fig. 5), does show broader vibrational peaks, a different vibrational distribution, and a longer progression in ν_1. These suggest that autoionization plays some role in the formation of the F^2A_{1g} band in the TPE spectrum. A likely Rydberg-state candidate would be the $3pe_{1u}$ ($\leftarrow 2e_{2g}$) state converging on the G^2E_{2g} ionic state of benzene (see Fig. 1 and the following) predicted to lie at 17.0 eV (16). No evidence is found in the TPE spectrum of benzene shown in Fig. 5 for the shake-up band ($(1e_{1g})^{-2}(1e_{2u})^1$, $^2A_{2u}$) found to appear at 16.2 eV in the Penning ionization electron spectrum of benzene (12) and confirmed theoretically (18) as well as being detected, most likely, in the $\Theta = 0°$ photoelectron spectrum of benzene using synchrotron radiation of energy 38 eV (5).

TPE spectrum in the 18.0–24.2 eV photon energy region

In this photon energy region, ionization of benzene is mainly attributed to the inner-valence orbitals $2e_{2g}$ and $2e_{1u}$ giving rise to the main lines and several satellites (19). The TPE spectrum given in Fig. 6 clearly shows two broad bands with peak maxima at 19.09 and 22.45 eV associated with ionization from these orbitals with subsidiary bands at 18.71 and ~21.4 eV identified as configuration interaction (CI) bands in the HeII PE spectrum of benzene (20). In general, the overall appearance of the TPE spectrum in this photon energy region is quite similar to that of the HeII PE spectrum of benzene (20) except for the CI feature at ~21.4 eV, which appears somewhat weaker in the TPE spectrum. Thus, autoionization does not appear to play a significant role in the formation of these bands in the TPE spectrum.

Fig. 6. A portion of the TPE spectrum of benzene covering the G^2E_{2g} and H^2E_{1u} bands of $C_6H_6^+$ with associated configuration interaction (CI) bands. The energy resolution in this part of the TPE spectrum is 13–17 meV.

Summary

The complete TPE spectrum of benzene up to 26.5 eV photon energy is presented for the first time at a resolution ranging smoothly from ~6 meV at 9 eV photon energy to ~19 meV at 26.5 eV photon energy. Analysis of the TPE spectrum by comparison with the HeI PE spectrum reveals dramatic differences in the appearance of the observed bands of $C_6H_6^+$ in the outer valence ionization region (9–18 eV). These differences are attributed in the TPE spectrum to the autoionization of Rydberg states found across the entire photon energy region. These Rydberg states appear to be major contributors to the TPE spectrum. In the inner-valence ionization region studied (18–26.5 eV), the TPE spectrum is similar in appearance to the HeII PE spectrum of benzene (20), suggesting that autoionization is not an important factor in the formation of the band systems of $C_6H_6^+$ in this binding energy region. This study demonstrates how TPE spectroscopy affords a different perspective of the photoionization of molecules as compared with conventional PE spectroscopy.

Acknowledgements

The authors thank the CLRC Daresbury Laboratory for providing beam time and facilities for carrying out this study. The authors are most grateful to Professor Leif Karlsson for providing the high-resolution photoelectron spectrum of benzene in digital form used in this paper. Financial support for this research from the Engineering and Physical Sciences Research Council (UK) (EPSRC) is acknowledged.

Zero electron kinetic energy photoelectron and threshold photoionization spectroscopy of M-X$(CH_3)_3$ (M = Ga, In; X = P, As)[1]

Shenggang Li, Gretchen K. Rothschopf, Bradford R. Sohnlein, Jason F. Fuller, and Dong-Sheng Yang

Abstract: This paper presents pulsed-field ionization, zero electron kinetic energy (ZEKE) photoelectron and threshold photoionization spectra of M-X$(CH_3)_3$ (M = Ga, In; X = P, As). The ZEKE spectra exhibit well-resolved vibrational structures. A comparison with B3LYP calculations shows that the spectrum of In-P$(CH_3)_3$ arises from the $^1A_1 \leftarrow {}^2E$ transition and the spectra of Ga-P$(CH_3)_3$ and Ga-As$(CH_3)_3$ arise from transitions of a Jahn–Teller distorted doublet state to the $^1A_1$ state. The intensities of the $^1A_1$–^2E transition in the indium species are described with the Franck–Condon approximation, while the transitions in the gallium complexes are more complicated due to the dynamic Jahn–Teller effect. The adiabatic ionization potentials of Ga-P$(CH_3)_3$, In-P$(CH_3)_3$, and Ga-As$(CH_3)_3$ are 39 635, 38 930, and 40 322 cm^{-1}, respectively, and the ionization threshold of In-As$(CH_3)_3$ is ~39 550 cm^{-1}. The metal–ligand stretching frequencies are 143, 116, and 125 cm^{-1} for Ga^+-P, In^+-P, and Ga^+-As, respectively, and 96 cm^{-1} for In-P. The intermolecular bending frequencies are 71, 65, and 42 cm^{-1} for Ga^+-P-C, In^+-P-C, and Ga^+-As-C, respectively, and 47 cm^{-1} for In-P-C. In addition, ligand-based vibrational frequencies are determined for the CH_3 wag, PC_3 and AsC_3 umbrella, and P-C stretching vibrations.

Key words: ZEKE photoelectron, photoionization, DFT, gallium–phosphine, gallium–arsine, indium–phosphine, indium–arsine.

Résumé : Dans ce travail, on décrit les spectres photoélectroniques d'énergie cinétique électronique nulle (« ZEKE »), à ionisation par champ pulsé, ainsi que les spectres de seuil de photoionisation des composés M-X$(CH_3)_3$ (M = Ga, In; X = P, As). Les spectres ZEKE présentent des structures vibrationnelles bien définies. Une comparaison avec les calculs B3YLP permet de montrer que le spectre de In-P$(CH_3)_3$ découle de la transition $^1A_1 \leftarrow {}^2E$ alors que les spectres de Ga-P$(CH_3)_3$ et Ga-As$(CH_3)_3$ découlent de transitions d'un état doublet déformé de Jahn–Teller vers un état $^1A_1$. Les intensités de la transition $^1A_1$–^2E dans l'espèce contenant de l'indium peuvent être décrites par l'approximation de Franck–Condon alors que les transitions dans les complexes du gallium sont plus compliquées en raison de l'effet Jahn–Teller dynamique. Les potentiels d'ionisation adiabatique des complexes Ga-P$(CH_3)_3$, In-P$(CH_3)_3$ et Ga-As$(CH_3)_3$ sont respectivement 39 635, 38 930 et 40 322 cm^{-1}; le seuil d'ionisation du complexe In-As$(CH_3)_3$ est ~39 550 cm^{-1}. Les fréquences d'élongation métal–ligand sont de 143, 116 et 125 cm^{-1} pour Ga^+-P, In^+-P et Ga^+-As et 96 cm^{-1} pour In-P. Les fréquences de déformation angulaire intermoléculaires sont de 71, 65 et 42 cm^{-1} pour Ga^+-P-C, In^+-P-C et Ga^+-As-C et 47 cm^{-1} pour In-P-C. De plus, on a déterminé les fréquences vibrationnelles basées sur le ligand pour le balancement du CH_3, pour les parapluies PC_3 et AsC_3 et pour les vibrations d'élongation P-C.

Mots clés : photoélectron d'énergie cinétique électronique nulle, photoionisation, « DFT », gallium–phosphine, gallium–arsine, indium–phosphine, indium–arsine.

Introduction

The importance of group 13–15 compounds has stimulated great interest in characterizing compounds formed by reactions of the group 13 metal atoms with the group 15-containing molecules. A majority of these studies have focused on the metal complexes of nitrogen-bearing molecules. Experimental investigations have included matrix isolation IR spectra of reaction products of M (M = Al, Ga, In) with NH_3 (1–3) and N_2 (4, 5), photoionization efficiencies of M-NH_3 (6, 7) and Al-$(N_2)_x$ (x = 1–14) (8), resonant two-photon photoionization of Al-ND_3 (9) and In-N_2 (10), pulsed-field ionization, zero electron kinetic energy photoelectron (ZEKE) of M-$NH_{3-n}(CH_3)_n$ (n = 0–3) (11–17), laser fluorescence of Al-N_2 (18, 19) and Ga-N_2 (20), laser-induced plasma of Al^+-N_2 (21), electrostatic multipole field of Al-NH_3 (22), and electron paramagnetic resonance of Al-$(NH_3)_{2,4}$ (23). Computationally, ab initio and density functional theory (DFT) calculations were performed on Al-NH_3 (24–27), Al^+-NH_3 (28–31), and Al-N_2 (32). However, there have been relatively few studies on group 13 metal complexes with phosphorus- and arsenic-containing molecules.

These have involved matrix isolation IR absorption of MPH_3, $HMPH_2$, and H_2MPH (33), photoionization and ZEKE photoelectron of M-XH_3 (34) and Al-$X(CH_3)_3$ (X = P, As) (35), and ab initio calculations of Al-PH_3 (25, 36).

Previously, we reported ZEKE studies of the group 13 metal complexes with ammonia and methylamine ligands (11–17) and aluminum complexes with phosphine and arsine ligands (35). From the vibrationally resolved ZEKE spectra, we were able to determine adiabatic ionization potentials (AIPs), metal–ligand and ligand-based vibrational frequencies, low-lying electronic states, and molecular conformations of these complexes. In this paper, we present the first photoionization and ZEKE photoelectron study of the Ga- and In-$X(CH_3)_3$ (X = P, As) complexes. The vibrationally resolved ZEKE spectra reveal a strong Jahn–Teller distortion in Ga-$P(CH_3)_3$ and Ga-$As(CH_3)_3$, but no significant effect in In-$P(CH_3)_3$. The ZEKE spectra of the gallium and indium complexes will be discussed in combination with DFT calculations and compared with other group 13–15 complexes.

Experimental and computational details

The ZEKE apparatus has been described in a previous publication (12). Briefly, it consists of a Smalley-type laser ablation molecular beam source (37) and a Wiley–McLaren type of time-of-flight mass spectrometer (38). The molecular beam source is housed in a cubic chamber that is pumped by a 2200 L s^{-1} oil-diffusion pump (BOC Edwards). The spectrometer is placed in a six-way cross chamber evacuated by two 400 L s^{-1} turbomolecular pumps (Seiko Seiki) and is isolated from the Earth's magnetic field by a cylindrical, double-walled μ-metal shield. The spectrometer is used to detect both ions and electrons.

Metal complexes were produced by reactions of metal atoms with trimethylphosphine (99%, Aldrich) or trimethylarsine (99%, Strem). The metal atoms were produced by pulsed-laser vaporization of a pure metal rod (Al, 99.999%, Aldrich) or an alloy target (GaSb, 99.99%, Aldrich). The target was rotated and translated by a motor-driven mechanism and vaporized with the second-harmonic output of a Nd:YAG laser (2 mJ, 532 nm, Quanta-Ray GCR-3). $P(CH_3)_3$ or $As(CH_3)_3$ vapor at 0 and 25 °C, respectively, was mixed with helium (UHP, Scott-Gross) or argon (UHP, Scott-Gross) at a stagnation pressure range of 40~60 psi and delivered to the vaporization region by a piezoelectric pulsed valve (39). The mixture pulses were synchronized with the vaporization laser pulses to optimize the metal–ligand reactions.

Masses of the products formed in the molecular beams were determined by photoionization time-of-flight (TOF) mass spectrometry. Approximate ionization potentials of Ga-$P(CH_3)_3$, In-$P(CH_3)_3$, Ga-$As(CH_3)_3$, and In-$As(CH_3)_3$ were located by threshold photoionization measurements in the TOF mass operation mode. Prior to ZEKE experiments, intensities of ionized metal complexes were maximized by optimizing the timing and power of the ablation and ionization lasers, the temperature and concentration of the reactants, and the backing pressure of the carrier gas. The ZEKE measurements were carried out by photoexcitation of the molecules to high-lying Rydberg states, followed by pulsed-electric-field ionization. The second-harmonic output of a dye laser (Lumonics HD-500), pumped by a XeCl excimer laser (Lumonics PM-884), was used as photoionization and photoexcitation sources. A delay pulse generator (Stanford SR 445) was used to provide electric pulses (1.2 V cm^{-1}, 100 ns) for field ionization. The ZEKE electron signal was capacitively decoupled from a dual microchannel plate anode (Galileo), amplified by a preamplifier (Stanford SR445), averaged by a gated integrator (Stanford SR250), and collected and stored in a computer. A small dc field (0.08 V cm^{-1}) was applied to help remove prompt electrons from direct photoionization. A field dependence study was not performed due to the limited size of the ZEKE signal. Laser wavelengths were calibrated against vanadium or titanium atomic transitions in the frequency range of each individual spectrum. Attempts to record ZEKE spectra for In-$As(CH_3)_3$ were not successful. This may indicate that the lifetime of the ZEKE Rydberg states in this molecule is shorter than the microsecond timescale used in our measurements.

To aid in the ZEKE spectral interpretation, geometries, harmonic vibrational frequencies, and dissociation energies of the neutral and ionized complexes were calculated using the hybrid DFT B3LYP method implemented in the Gaussian 98 program package (40). The 6-311+G(d,p) basis was used for all atoms except for indium, for which the Los Alamos ECP plus DZ basis (Lanl2DZ) was employed. Multidimensional Franck–Condon (FC) factors were computed using the equilibrium geometries and normal modes of the neutral and ionized molecules. In these calculations, the Duschinsky effect (41) was considered to account for normal mode differences in the neutral and ionic species. Details of the FC calculations were previously described (42, 43). Spectral broadening was simulated by giving each line a Lorenztian line shape with the linewidths of experimental ZEKE spectra. Boltzmann factors were used to simulate spectra at finite temperatures.

Results and discussion

Computation

Table 1 lists the electronic energies and major equilibrium bond lengths and angles of low-lying electronic states of M^+/M-$X(CH_3)_3$ (M = Ga, In; X = P, As) from the B3LYP calculations. Bond lengths and angles involving hydrogen atoms are not included as they are insensitive to metal coordination. The ground state of M-$X(CH_3)_3$ is predicted to be $^2A''$ in the C_s point group. This doublet state is formed by the interaction of a $p\pi$ orbital of the metal atom with the lone-pair orbital of the ligand. The metal $p\pi$ electron is oriented to be perpendicular to the M-X internuclear axis to minimize the electron repulsion with the electron lone pair of the ligand. In this configuration, the ligand donates the electron lone pair to the empty metal $p\sigma$ orbital, and the metal $p\pi$ orbital interacts with one or more ligand orbitals of appropriate symmetry. Since the metal $p\pi$ orbital lies much higher in energy than filled ligand orbitals, the highest occupied molecular orbital (HOMO) formed by the interaction largely consists of the metal character, as shown in Fig. 1. The mixing of the ligand orbital with the metal $p\pi$ orbital will depend on the relative energies of the interacting orbitals. Because there are two possible perpendicular orientations of the $p\pi$ orbital, the HOMO is expected to be doubly

Note: The basis for the indium atom is Lanl2DZ.

degenerate under C_{3v} symmetry. However, a partially filled degenerate orbital is liable to the Jahn–Teller distortion, leading to a lower molecular symmetry by the removal of the orbital degeneracy. This is exactly what is predicted by the B3LYP calculations. The extent of the distortion is evident from the two sets of nonequivalent M-X-C angles, which differ by as much as 17°. Interestingly, the distortion for the ligand framework is very small, as the C-X-C angles are different by less than 1°. Furthermore, the M-X-C angle differences are slightly larger in the Ga complexes than in the corresponding In analogues, while the distortions in both the Ga and In species are smaller than those in the Al complexes (35).

The prediction seems to be reasonable, so far as it goes. However, it does not explain the ZEKE spectrum of In-P$(CH_3)_3$ (see the section titled In-P$(CH_3)_3$ in *ZEKE spectra*). As a further effort, we have also carried out the B3LYP calculations for this species by enforcing the C_{3v} point group. In this symmetry, the ground state is predicted to be ^2E. Compared to the $^2A''$ state in C_s symmetry, the doubly

Fig. 1. The HOMO of the $^2A''$ state of In-P$(CH_3)_3$ showing a predominant In $p\pi$ character with some ligand contributions.

degenerate state is ~70 cm^{-1} higher in energy, the In—P bond length is ~0.03 Å longer, and the In-P-C angle is ~2° larger than the average of the In-P-C angles. The ^2E state also shows an imaginary frequency, indicating that this state may not be a minimum at the potential energy surface. The imaginary frequency was calculated to be 1019i cm^{-1} with the default convergence defined in Gaussian 98 (40). With a tighter convergence criterion (e.g., cutoff values of 1.5×10^{-5} au for forces and 6×10^{-5} au for step sizes) and a finer grid (e.g., 99 radial shells, each with 590 angular points), the frequency was reduced to 193i cm^{-1}. However, it will be clear from the section on *ZEKE spectra* that spectral simulations from the C_{3v} structure yield far better agreement with the experimental spectra than the simulation from the C_s structure.

Ionization of the M-X$(CH_3)_3$ complexes leads to an $^1A_1$ ground electronic state in C_{3v} symmetry. The ionized species possesses a higher symmetry because the orbital degeneracy is lost by the removal of the metal *p*-based electron. The three M^+-X-C angles in the ion are the same size, with a value equivalent to the average of the corresponding M-X-C angles of the neutral molecule. The Ga-P/As bond lengths increase by 0.024 and 0.001 Å, while the In-P/As bond lengths shrink by 0.021 and 0.056 Å, respectively. It seems to be surprising that ionization leads to elongation of the Ga-P/As bonds, as their bond energies increase by as much as four times from the neutral $^2A''$ state to the ion $^1A_1$ state. Moreover, the metal–ligand distances of the Ga/In-N$(CH_3)_3$ complexes decrease by 0.17/0.25 Å upon ionization (15, 17). However, it has been known in inorganic chemistry that phosphine as well as arsine ligands can function not only as σ donors, but also as π acceptors because of the availability of relatively low energy empty orbitals. On the other hand, the amine ligand can only act as a σ donor since it has no low energy empty orbitals available for such a π interaction (44, 45). Thus, the metal atom may donate its pπ electron to an appropriate empty π orbital of the phosphine or arsine in the neutral complex. Such back-donation is lost upon the removal of the metal $p\pi$ electron. This means that the short-range interaction due to the π-orbital overlap between the metal and ligand is reduced in the ion, resulting in a possible increase of the metal–ligand bond length. On the other hand, ionization results in an additional long-range, charge–dipole interaction, strengthening the metal–ligand bonding. Of course, the degree of the variation in the bond length depends on the strength of the orbital overlap interaction. The predicted changes in the bond distances indicate that the π-back-donation to the phosphine ligand is slightly stronger than that to the arsine ligand. Previously, DFT calculations predicted an increase of the Al-P/As distances from the neutral to the ionized Al-P(CH_3) and -As(CH_3) complexes (35).

Table 1 also lists the harmonic vibrational frequencies of the Ga and In complexes, which will be compared with the ZEKE measurements.

Photoionization spectra

Figure 2 presents the photoionization efficiency (PIE) spectra of M-X$(CH_3)_3$ (M = Ga, In; X = P, As) seeded in helium and the PIE spectrum of In-P$(CH_3)_3$ in argon. Photoionization wavelengths in these spectra are corrected by +110 cm^{-1}, an energy shift induced by a dc field of 315 V cm^{-1} applied in the ionization region of the TOF spectrometer. The energy correction is given by $\Delta E = 6.1 F_{dc}^{1/2}$, where ΔE is in units of cm^{-1} and F_{dc} is the dc extraction field in units of V cm^{-1} (46). There is an onset of the ion signal in each of the PIE spectra, which corresponds to the ionization threshold of the complex. To estimate the threshold, a line through the onset is drawn to intersect with the baseline. Using this method, the ionization thresholds from the spectra with the helium carrier are estimated to be 39 650 (100), 40 300 (100), 38 850 (150), and 39 550 (100) cm^{-1} for Ga-P$(CH_3)_3$, Ga-As$(CH_3)_3$, In-P$(CH_3)_3$, and In-As$(CH_3)_3$, respectively.

Although the thresholds obtained from the PIE measurements are only approximate, they are very useful for the search of the ZEKE signal. Moreover, the accuracy of the PIE measurements may be significantly improved by using a heavier carrier gas. This is because heavier carriers are often more efficient in cooling the internal degrees of freedom of molecular systems, reducing the number of hot transitions from the neutral molecule. To show the carrier effect, Fig. 2*c* compares the PIE spectra of In-P$(CH_3)_3$ in helium and argon. Clearly, the ionization onset with argon is much sharper than the onset with helium, and the threshold is more accurately measured to be 38 930 (20) cm^{-1}. The carrier effect has also been observed in other complexes (17, 47, 48).

Above the ionization threshold, there appear to be some spectral features superimposed on the rising ion signal (Figs. 2*a* and 2*b*). In the PIE spectrum of In-P$(CH_3)_3$ seeded in argon, some step-like structures exist, which may be associated with transitions to higher vibrational levels of the ion state. However, definitive assignments of these structures are difficult because autoionization often obscures the observation of true threshold ion signals.

ZEKE spectra

In-P$(CH_3)_3$

Figures 3*a* and 3*b* present the ZEKE spectra of In-P$(CH_3)_3$ seeded in helium and argon carriers. The linewidth (the full width at half-maximum) of the spectrum with helium is ~8 cm^{-1}, and it is reduced to ~5 cm^{-1} with argon. Two observations can be made from the spectra. First, the spectrum in helium shows more transitions compared with that in argon. By comparing the two spectra, hot transitions

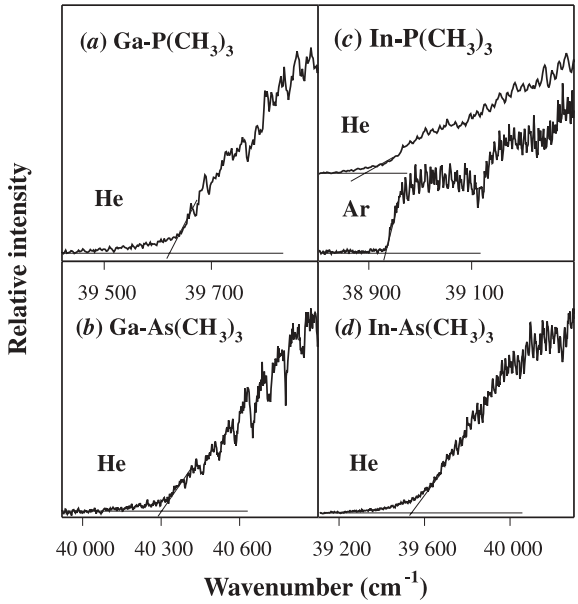
Fig. 2. PIE spectra of: (*a*) Ga-P(CH_3)$_3$, (*b*) Ga-As(CH_3)$_3$, (*c*) In-P(CH_3)$_3$, and (*d*) In-As(CH_3)$_3$ with the helium carrier gas. The spectrum of In-P(CH_3)$_3$ with an argon carrier gas is also shown in (*c*).



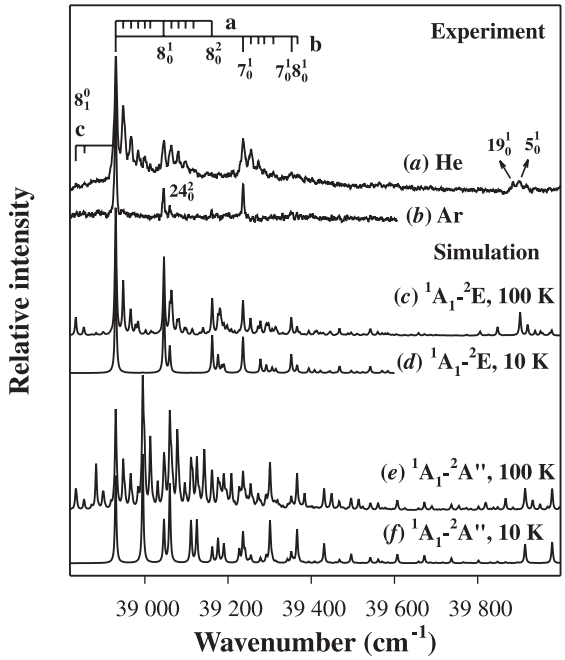


Fig. 3. ZEKE spectra and simulations of In-P(CH_3)$_3$: (*a*, *b*) The experimental spectra with helium and argon carrier gases, (*c*, *d*) the simulations from the $^1A_1 \leftarrow {}^2E$ transition at 100 and 10 K, and (*e*, *f*) the simulations from the $^1A_1 \leftarrow {}^2A''$ transition at 100 and 10 K.

can be quickly identified. Second, the spectra exhibit relatively short progressions, indicating that the change in the molecular structure is small upon ionization.

Figures 3*c* and 3*d* show the simulations from the $^1A_1 \leftarrow {}^2E$ transition, and Figs. 3*e* and 3*f* display the simulations from the $^1A_1 \leftarrow {}^2A''$ transition. In these simulations, the theoretical energy of the 0–0 transition is referenced to the experimental value for simplicity. Simulations for both transitions were carried out at various temperatures to estimate the vibrational temperatures of the complex in the argon and helium beams. In general, vibrational temperatures are dependent on frequencies of normal modes, since different modes are expected to cool with different efficiencies. In supersonic beams, however, transitions from vibrationally excited levels of the neutral molecule are limited to the smallest frequency mode(s). Thus, simulations at finite temperatures often reproduce hot transitions in ZEKE spectra (12–17, 35, 47, 48). It is clear that the $^1A_1 \leftarrow {}^2E$ simulations at 10 and 100 K match well to the experimental spectra with the argon and helium carriers, respectively. In contrast, the $^1A_1 \leftarrow {}^2A''$ simulations have little similarity with the experimental spectra. The comparison between the simulated and measured spectra suggests that the neutral complex is in the ^2E ground state, rather than the Jahn–Teller distorted $^2A''$ state. This is contrary to the B3LYP calculations, which predict that the ^2E state is ~70 cm^{-1} higher in energy than the $^2A''$ state. One should keep in mind, however, that the relativistic effect is not included in the B3LYP method. Such an effect is expected to yield a sizeable spin–orbit splitting for an indium-containing molecule. For the atomic indium, the splitting between the two *J* levels of the ground ^2P state is 2212 cm^{-1} (49). The splitting is expected to be reduced by complex formation because of the recoupling of the angular momentum in a molecular framework. The reduction is estimated to be a factor of one-third in a strong-field approximation (50), resulting in a splitting of about 1500 cm^{-1} in an In complex. Thus, if the spin–orbit effect were included in the B3LYP calculations, the lower spin component ($^2E_{1/2}$) would be below the $^2A''$ state.

The spectral assignment is trivial with the excellent agreement between the $^1A_1 \leftarrow {}^2E$ simulations and experimental spectra and is listed in Table 2 and labeled in Fig. 3 as well. The ν_8 mode is identified as the In-P stretching (a_1), with a ν_8^+ frequency of 116 cm^{-1} in the cation and a ν_8'' frequency of 96 cm^{-1} in the neutral molecule. The ν_{24} mode is the In-P-C bending vibration that has an ion frequency (ν_{24}^+) of 65 cm^{-1} and a neutral frequency (ν_{24}'') of 47 cm^{-1}. In addition to the metal–ligand stretching and bending vibrations, two CH_3 wag vibrations (ν_5^+/ν_{19}^+) and a PC_3 umbrella vibration (ν_7^+) in the ionized complex are also identified from these spectra. The CH_3 wag frequencies are measured to be 972 cm^{-1} for ν_5^+ and 956 cm^{-1} for ν_{19}^+. The PC_3 umbrella frequency is determined to be 306 cm^{-1}. No hot transitions were observed from the excited levels of these relatively high frequency modes.

Ga-P(CH_3)$_3$

The ZEKE spectra of Ga-P(CH_3)$_3$ are presented in Fig. 4. The top trace was recorded with argon and the bottom one was obtained with helium. As in the case of the indium complex, argon shows more efficient cooling than helium. Furthermore, the spectrum of Ga-P(CH_3)$_3$ in argon exhibits many more transitions than the spectrum of In-P(CH_3)$_3$ (Figs. 3*b* and 4*a*). At this point, we may also compare Ga-P(CH_3)$_3$ with previously studied Al-P(CH_3)$_3$ (35). The ZEKE spectrum of Al-P(CH_3)$_3$ is dominated by the Al^+-P-C degenerate bending progression and its combination with the

[a] 24_a (14 cm^{-1}) and 24_b (112 cm^{-1}) are two sublevels of 24_1, split by the linear Jahn–Teller effect.

PC_3 umbrella vibration. The spectrum has been identified from the $^1A_1 \leftarrow {}^2A''$ transition. In contrast, the In-P$(CH_3)_3$ spectrum exhibits a predominant In^+-P stretching progression combined with the PC_3 vibration and is described by the $^1A_1 \leftarrow {}^2E$ transition. This indicates that the Jahn–Teller distortion is reduced from Al to In. This is not surprising because the spin–orbit coupling increases with increasing atomic number and competes with the Jahn–Teller effect in lifting orbital degeneracies. With this in mind, we expect the degrees of the Jahn–Teller distortion and spin–orbit splitting in Ga-P$(CH_3)_3$ to be between those in Al- and In-P$(CH_3)_3$. Indeed, the ZEKE spectrum of Ga-P$(CH_3)_3$ shows significant activities from both the Ga^+-P stretching and Ga^+-P-C bending vibrations. Due to the dynamic Jahn–Teller effect, the observed intensities in the spectrum of Ga-P$(CH_3)_3$ cannot be satisfactorily described with the FC approximation.

Fig. 4. ZEKE spectra of Ga-P$(CH_3)_3$ with (*a*) argon and (*b*) helium carrier gases.

However, cold transitions from the vibrationless level of the neutral state to excited vibrational levels of the ionic $^1A_1$ state can be easily identified by comparing them to the theoretical predictions and to the vibrations in the In-P$(CH_3)_3$ complex.

The spectrum recorded with the argon beam displays short progressions with 71, 143, and 313 cm^{-1} intervals as well as their combinations. In addition, the spectrum exhibits three peaks located at 660, 954, and 968 cm^{-1} to the blue of the band origin (39 635 cm^{-1}). The 71 and 143 cm^{-1} intervals are in good agreement with the predicted Ga^+-P-C bending (ν_{24}^+, e) and Ga^+-P stretching (ν_8^+, a_1) fundamentals of 76 and 132 cm^{-1}. Thus, these two progressions are assigned to the 8_0^n and 24_0^n transitions. Because the ν_{24}^+ frequency is about one-half of the ν_8^+ frequency, the 8_0^n progression may also contain the contribution from the 24_0^n transitions. The observation of the 24_0^n transitions is the result of the vibronic coupling.

From the spectrum of In-P$(CH_3)_3$, we identified two CH_3 wags (972/956 cm^{-1}) and a PC_3 umbrella (306 cm^{-1}) vibration. Since these are ligand-based vibrations, their frequencies are expected to be similar in both In-P$(CH_3)_3$ and Ga-P$(CH_3)_3$. By comparison, the 968 and 954 cm^{-1} peaks in the spectrum of Ga-$(CH_3)_3$ are assigned to the two CH_3 wag modes, and the 313 cm^{-1} interval to the PC_3 umbrella motion. The weak peak at 660 cm^{-1} to the blue of the band origin is also expected to be from a ligand-based vibration. On the basis of the B3LYP prediction, this peak can only be assigned to the P-C stretching (ν_6^+, a_1) in the ion, which has a theoretical frequency of 640 cm^{-1}. There are a few unlabeled peaks in Fig. 4*a*, which are identified as hot transitions by comparing with the spectrum in helium. The analysis of these hot transitions is discussed in the following.

The helium spectrum of Ga-P$(CH_3)_3$ (Fig. 4*b*) shows increased intensities for the hot transitions observed in argon and additional peaks that are not observed in the argon spectrum. To the red of the band origin, a hot transition (labeled a) appears at 41 cm^{-1}. To the blue of the band origin, hot transitions (labeled b–f) lie 57 cm^{-1} above each of the 8_0^n, $7_0^1 8_0^n$, $7_0^2 8_0^n$, $8_0^n 19_0^1$, and $5_0^1 8_0^n$ peaks. Assigning these hot transitions requires at least two neutral frequencies to be involved. Two possible assignments are presented below. In the first scenario, the peak at 41 cm^{-1} below the 0–0 transition is attributed to $8_1^1 24_1^0$ and the peaks at 57 cm^{-1} above various ion vibrations are assigned to the transitions from the first excited level of ν_{24}'' (e.g., $8_0^1 24_1^0$ for the first peak). This assignment yields a ν_{24}'' frequency of 86 cm^{-1} and a ν_8'' frequency of 98 cm^{-1}, which are in fair agreement with the calculated values of 68 and 112 cm^{-1}, respectively. Although the frequency comparison between the theory and experiment is not unacceptable, this assignment has difficulty explaining why the transitions from the first excited level of ν_{24}'' remain in the cooler argon spectrum. In the case of In-P$(CH_3)_3$, ν_{24}'' has a frequency of 47 cm^{-1} and ν_8'' has a frequency of 96 cm^{-1}, and the transitions associated with these two modes disappear by changing the carrier from helium to argon. If the ν_{24}'' mode of Ga-P$(CH_3)_3$ has a frequency of 86 cm^{-1}, then the transitions associated with 24_1 should also disappear from the argon spectrum. However, this is not the case although the transition intensities are reduced. Therefore, we propose another assignment for these hot transitions. The second scenario assumes that the 24_1 level is split into two sublevels by the linear Jahn–Teller effect (51). The relative energies of these two levels with respect to the vibrationless level are assumed to be $\omega_e \pm 2D\omega_e$, where ω_e is the harmonic frequency of ν_{24}'' and D is a small, linear Jahn–Teller coefficient. With this assumption, the peak at 41 cm^{-1} to the red of the band origin can be assigned to the higher energy sublevel of 24_1, which is labeled as 24_b in Fig. 4*b* and Table 2. The peaks at 57 cm^{-1} above various cold transitions are attributed to the transitions associated with the lower energy sublevel of 24_1, which is labeled as 24_a. On the basis of this assignment, the 24_a and 24_b sublevels are located at 14 and 112 cm^{-1} above the vibrationless level of the neutral ground state. This gives a 24_1 frequency of 63 cm^{-1} prior to Jahn–Teller splitting and a linear Jahn–Teller coefficient of 0.39. Now the ν_{24}'' frequency of 63 cm^{-1} is in excellent agreement with the calculated value of 68 cm^{-1}. Although the D value is relatively large, it is not unusual. A linear Jahn–Teller coefficient as large as 0.45 has been reported for the ^2E state of OCF_3 (52). Furthermore, the very small frequency of 24_a much better explains the observation of the weak peaks in the argon spectrum.

Ga-As$(CH_3)_3$

The ZEKE spectrum of Ga-As$(CH_3)_3$ with helium is shown in Fig. 5. Attempts to record a ZEKE spectrum in argon were not successful due to the limited size of the signal. In coordination with the B3LYP calculations, we identified short 7_0^n and 8_0^n progressions and their combinations as well as a 24_1^0 transition and its combinations with ν_7^+ and ν_8^+. The vibrational frequencies of the ν_7^+, ν_8^+, and ν_{24}^+ modes are determined to be 228, 125, and 42 cm^{-1}, respectively. The measured ν_7^+ and ν_8^+ frequencies match well to the cal-

culated values of 223 and 120 cm^{-1}, while the agreement for ν_{24}^+ is not as good.

Table 3 summarizes the vibrational frequencies from the ZEKE measurements and the B3LYP calculations. It can be seen that the agreement between the experiment and theory is excellent for most vibrational modes, but the predicted values are in larger error for some of the very low frequency modes.

Adiabatic ionization potentials and bond dissociation energies

Table 4 lists the AIPs and dissociation energies of the gallium and indium complexes reported in this work and those of other similar molecular systems for comparison. The AIPs were obtained from the ZEKE measurements and B3LYP calculations, and the dissociation energies were calculated with the B3LYP methods. The theoretical AIPs are a few hundreds of wavenumbers from the experimental values for the aluminum and gallium complexes and are about a thousand wavenumbers smaller for the indium systems. The larger errors for the heavy metal systems likely arise from the use of the pseudopotential Lanl2DZ basis set. Although the accuracy of the calculated dissociation energies cannot be evaluated directly, the differences between the ion and neutral dissociation energies can be compared with the experimental AIP shifts from the bare metal atoms to the complexes [AIP(M) – AIP(ML) = $D_0^+(M^+L) - D_0(ML)$, where M = Al, Ga, In; L = X$(CH_3)_3$; X = N, P, As]. Differences

© 2004 NRC Canada

between the experimental Δ(AIP) and the theoretical Δ(D_0^+ – D_0) are about 1 kcal mol^{-1} for the aluminum and gallium complexes and around 2 kcal mol^{-1} for the indium species.

A number of trends in the AIPs and bond energies can be drawn from Table 4. First, the AIPs of the metal atoms are reduced upon ligand coordination, and the reduction is substantially larger for Al/Ga-N(CH_3)$_3$ than for other systems. The AIP reduction correlates with the increase of the bond energy from the neutral to the ionized complex. This binding enhancement is the result of the removal of an antibonding electron in the neutral and the addition of a charge–dipole interaction. Second, the bond dissociation energies of the neutral complexes follow the order P(CH_3)$_3$ > N(CH_3)$_3$ > As(CH_3)$_3$ for a given metal and Al > Ga > In for a given ligand. Interestingly, the ion bond energies do not follow the same trends as those of the neutral complexes. For a given metal ion, the bond energies are in the order N(CH_3)$_3$ > P(CH_3)$_3$ > As(CH_3)$_3$. For the nitrogen ligand, the order is Al^+ > Ga^+ > In^+; for the phosphine and arsine ligands, it is Al^+ ~ Ga^+ > In^+. To explain these bonding trends, both short- and long-range forces must be considered to include orbital, σ/π dative, charge–dipole, dipole – induced-dipole, and polarization interactions. A quantitative analysis of each interaction is in progress and will be reported in the future.

Conclusions

The analysis of the vibrationally resolved ZEKE spectra shows that the spectrum of In-P(CH_3) arises from the $^1A_1$–^2E transition and the spectra of Ga-P(CH_3)$_3$ and Ga-As(CH_3)$_3$ are due to the transitions from the Jahn–Teller distorted doublet state to the $^1A_1$ state. The spectrum of the indium complex can be treated with the FC approximation, while the spectra of the gallium systems cannot be so described because of significant vibronic couplings. The adiabatic ionization energies of the metal complexes are substantially lower than those of the bare metal atoms, and the metal–arsine complexes have slightly higher ionization energies than the corresponding phosphine systems. The metal–phosphine binding is significantly stronger than the metal–arsine binding, in both the neutral and ionized complexes. In comparison with the ZEKE measurements, the B3LYP calculations yield excellent frequencies for most vibrational modes, but the agreement is less desirable for some of the low frequency modes. The calculated ionization energies are in better agreement for the gallium systems than for the indium species.

A vacuum ultraviolet laser single-photon zero kinetic energy photoelectron spectroscopic study of the $\tilde{X}^2E_{3/2}$ ground electronic state of CH_3Br^+ [1]

Y.J. Shi, S. Wang, Z.J. Jakubek, and B. Simard

Abstract: The vacuum ultraviolet laser single-photon zero kinetic energy (ZEKE) photoelectron spectrum of the $\tilde{X}^2E_{3/2}$ ground electronic state of the methyl bromide cation is reported. The spectrum is dominated by the origin band 0_0^0 of the transition $\tilde{X}^2E_{3/2} \leftarrow \tilde{X}^1A_1$. In addition, the 2_0^1 band and the 3_1^1 hot band are observed. All observed bands show similar rotational contours. Simulation of the rotational contour of the origin band yields the first ionization energy of methyl bromide (85 031.2 ± 1.0 cm^{-1}) and the rotational constants of the cation in its ground electronic state.

Key words: methyl bromide, vacuum ultraviolet laser, single-photon excitation, zero kinetic energy photoelectron spectroscopy.

Résumé : Faisant appel à un laser ultraviolet du vide, on a déterminé le spectre photoélectronique d'énergie cinétique électronique nulle (« ZEKE »), à excitation photonique unique, de l'état électronique fondamental $\tilde{X}^2E_{3/2}$ du cation bromure de méthyle. Le spectre est dominé par la bande d'origine, 0_0^0, de la transition $\tilde{X}^2E_{3/2} \leftarrow \tilde{X}^1A_1$. On a de plus observé la bande 2_0^1 et la bande chaude 3_1^1. Toutes les bandes observées présentent des contours rotationnels semblables. La simulation du contour rotationnel de la bande d'origine permet d'obtenir l'énergie de première ionisation du bromure de méthyle (85 031,2 ± 1,0 cm^{-1}) et les constantes de rotation du cation dans son état électronique fondamental.

Mots clés : bromure de méthyle, laser ultraviolet du vide, excitation photonique unique, spectroscopie photoélectronique d'énergie cinétique électronique nulle.

Introduction

Methyl bromide has recently received considerable interest from atmospheric and environmental scientists owing to its role as the most abundant atmospheric source of bromine in the gas phase (1–4), which is found to be extremely efficient, nearly 40 times more than chlorine, in removing ozone in the stratosphere (5, 6). Atmospheric CH_3Br comes essentially from natural and anthropogenic sources (2). The major process of the destruction of CH_3Br in the atmosphere involves its reaction with the hydroxyl radical. Investigation of the role that methyl bromide plays in atmospheric chemistry has stimulated many laboratory studies of the physicochemical and spectroscopic properties of methyl bromide in the last several decades.

The molecular structure and the thermodynamic and spectroscopic properties of neutral CH_3Br have been extensively investigated in the past (7–11). However, less is known about the methyl bromide cation. The lowest ionization energy (IE = 85 020 cm^{-1}) of CH_3Br was first obtained by Price from an analysis of the Rydberg series observed in the vacuum ultraviolet (VUV) absorption spectrum (12). Two other VUV absorption studies of the same molecule in the mid-1970s yielded the lowest IE of 85 020 cm^{-1} (13) and 85 012 cm^{-1} (14). The photoelectron spectra in the outer valence region of methyl bromide have been reported by several research groups (15–20). In these studies, the ionization energies of the ground electronic state and several excited electronic states of CH_3Br^+ were obtained. The vibrational frequencies of the totally symmetric ν_2 and ν_3 modes, as well as the degenerate ν_4 and ν_6 modes in the cationic ground electronic states, were also determined. However, these studies suffered from the major deficiency of conventional photoelectron spectroscopy, namely its poor resolution, typically no better than 10 meV. This problem was overcome with the development of zero kinetic energy (ZEKE) photoelectron spectroscopy in the 1980s (21, 22). ZEKE spectroscopy offers a significantly higher spectral resolution and has become a method of choice for high-resolution spectroscopy of molecular ions. Song et al. (23) reported the pulsed-field ionization photoelectron (PFI–PE) spectra of CH_3Br^+ using a VUV synchrotron radiation. They obtained the lowest IE value of 10.5427 ± 0.0010 eV (85 032.6 ± 8.0 cm^{-1}), with a resolution of 1 meV. Very recently, Urban and Bondybey (24) reported the threshold photoelectron spectra (ZEKE) of CH_3Br^+ using one-color,

two- and three-photon excitations. The lowest IE was determined to be 85 024.6 ± 4.0 cm^{-1}; the frequencies of the six vibrational modes of the ground electronic state of CH_3Br^+ were also obtained. However, none of the observed features in the previous studies showed resolved rotational structures or rotational contours.

In this work, the high-resolution ZEKE photoelectron spectrum of CH_3Br^+ was recorded using single-photon VUV excitation, in which the coherent VUV laser radiation was generated by a two-photon resonance-enhanced four-wave mixing process in Hg vapor. By carefully optimizing the ZEKE detection scheme, we obtained a spectral resolution in the range 1.0–1.2 cm^{-1}, which was mainly determined by the line widths of the lasers used. The resolution was insufficient to fully resolve the rotational structures of the bands, but it allowed for the observation of the rotational contours of the origin band and some excited vibrational bands of the ground electronic state of CH_3Br^+. Simulation of the rotational contours of the origin band resulted in the determination of the adiabatic ionization energy and the rotational constants for the ground electronic state of CH_3Br^+.

Experimental

The ZEKE photoelectron spectrum of the CH_3Br^+ ion was obtained using a home-built, versatile high-resolution ZEKE/MATI (mass analyzed threshold ionization) spectrometer. Details of the apparatus have been described elsewhere (25). Only the new features relevant to the present work are discussed here. Two Nd:YAG pumped dye lasers were used to generate tunable, coherent, and monochromatic VUV light by two-photon resonance-enhanced four-wave mixing in Hg vapor (26, 27). The red beam of the first dye laser (ν_1) was frequency doubled in a KDP crystal to be two-photon resonant with the Hg $6s7s$ ($^1S_0$) $\leftarrow$ $6s^2$ ($^1S_0$) transition at 63 928.243 cm^{-1} (28). The second dye laser (ν_2) was scanned between 20 960 and 22 420 cm^{-1} to produce VUV light tunable between 84 890 and 86 350 cm^{-1}. The wavenumber of this visible beam (ν_2) was calibrated using a Fizeau wavelength meter (New Focus, 7711) with a factory-specified precision of 0.4 cm^{-1}. The maximum error in the ionization potential, including the maximum calibration error of 0.4 cm^{-1}, was estimated to be 1.0 cm^{-1}. Both visible beams (ν_1 and ν_2) have a line width of 0.15 cm^{-1}. Hg vapor was produced in a heated Pyrex cell equipped with a water-cooling jacket on each end to prevent condensation of Hg vapor on both the quartz entrance window and the LiF (lithium fluoride) exit window. Krypton gas (≤5 torr; 1 torr = 133.322 Pa) was added to the Hg vapor to satisfy the phase-matching condition. The Hg cell was mounted on the front end of the vacuum chamber housing a linear time-of-flight (TOF) mass spectrometer.

The VUV light was directed into the ionization chamber to cross a skimmed molecular beam of the CH_3Br–He mixture located between the E_2 and E_3 grids of the TOF mass spectrometer. It should be noted that the ion optics of the TOF mass spectrometer is composed of four parallel copper mesh grids, labeled from bottom to top as E_1, E_2, E_3, and E_4. The CH_3Br–He mixture was prepared by diluting 300 torr of CH_3Br in ultrahigh purity helium to a total pressure of 4 atm (1 atm = 101.325 kPa). The sample was subsequently introduced into the vacuum chamber in a supersonic jet expansion through a nozzle of a pulsed piezoelectric valve. The arrival of the VUV light was synchronized to the valve opening using a digital delay generator (Stanford Research Systems, DG 535).

In the ZEKE experiment, the methyl bromide molecule was excited in a VUV single-photon process to high-n* Rydberg states converging to an eigenstate of the methyl bromide cation. After a 30-ns delay with respect to the firing of the excitation laser, the first pulsed electric field (discrimination) of 333 mV/cm (duration = 600 ns) was created between the E_2 and E_3 electrodes by applying a negative voltage to the E_3 grid. The second pulsed field (ionization) of 667 mV/cm was created between the E_2 and E_3 electrodes by applying a negative voltage on the E_2 grid 830 ns after the laser excitation. The third pulsed electric field (acceleration) between E_3 and E_4 with an amplitude of 28 V/cm and a duration of 20 ns was generated by applying a short positive voltage pulse to the E_4 grid 51 ns after the start of the ionization pulse. The E_1 grid was grounded in the ZEKE experiment. The electrons, generated either by direct photoionization or by pulsed-field ionization, were extracted into a 40-cm-long field-free flight tube of the TOF mass spectrometer and detected by a Z-stack microchannel plate (MCP) detector. The previously described ZEKE detection scheme resulted in the spectral resolution of 1.0–1.2 cm^{-1}.

We also tried to detect the zero kinetic energy ions using MATI techniques. In our MATI experiment, both E_1 and E_4 grids were grounded. Constant positive voltages of 1548 V and 1550 V were applied to both E_2 and E_3 grids, respectively. The resulting 667 mV/cm constant field was used to separate the prompt ions created by direct photoionization from the highly excited neutral molecules remaining at the center. A pulsed field of 217 V/cm between E_2 and E_3 electrodes was triggered 3.53 μs after the laser excitation by applying a high positive voltage to the E_2 grids. This delayed pulsed field produced the MATI ions and also served to extract and accelerate the MATI and prompt ions. The two groups of ions arrived at the detector at different times. By gating at the signals on the MATI ion group, the MATI spectrum was obtained.

Results

The most prominent features in the TOF mass spectrum of the CH_3Br–He mixture recorded following one-photon excitation–ionization at 86 310 cm^{-1} are the methyl bromide parent-ion peaks corresponding to the two isotopomers, $CH_3{}^{79}Br^+$ and $CH_3{}^{81}Br^+$. The methyl fragment ion peak is just discernable above the noise, which is not surprising since soft ionization can be easily achieved with single-photon VUV ionization. It should be noted that a very high mass resolution ($m/\Delta m \approx 450$) was obtained, bearing in mind that the VUV light is not focused and the flight tube of the TOF mass spectrometer is only 40 cm long. The reason behind this is that a delayed pulsed extraction field rather than a constant field was used. For ion detection, a constant high voltage of 1550 V was applied to both E_2 and E_3 grids. A pulsed field of 217 V/cm between the E_2 and E_3 grids was triggered 3.53 μs after the excitation laser by applying a high positive voltage to the E_2 grid. The photoionization effi-

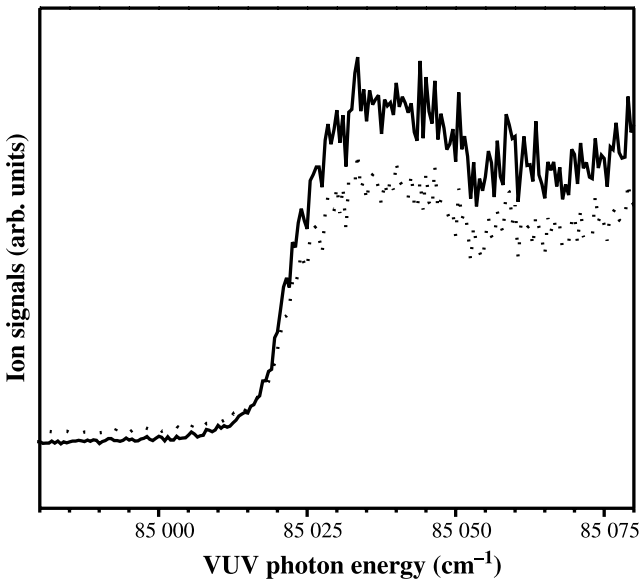
Fig. 1. Photoionization efficiency curves of $CH_3{}^{79}Br$ (solid line) and $CH_3{}^{81}Br$ (dotted line).



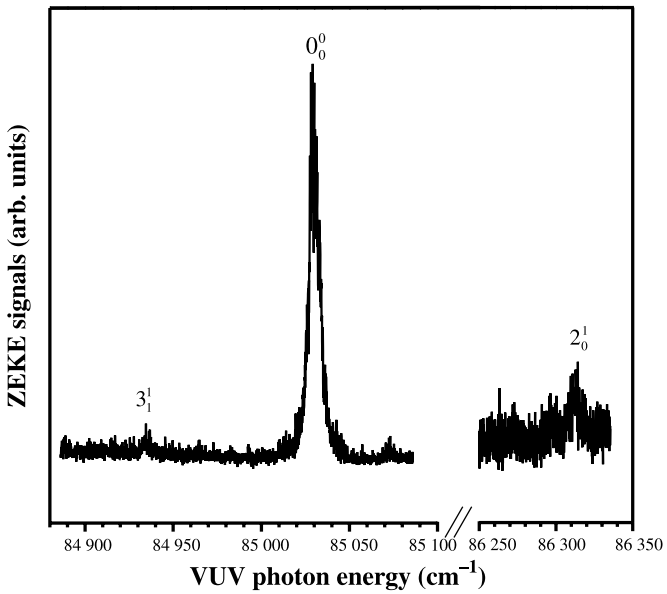


Fig. 2. The ZEKE photoelectron spectrum of CH_3Br^+ in its $\tilde{X}^2E_{3/2}$ ground electronic state.

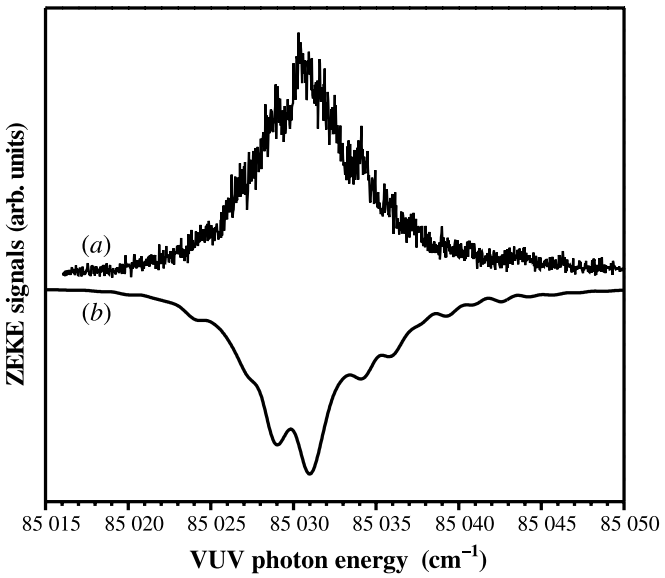
ciency curves of the two isotopomers of methyl bromide show a mid-rise at ~85 022 cm^{-1}, as is seen in Fig. 1.

An overview scan of the transitions to the lowest vibrational levels of the $\tilde{X}^2E_{3/2}$ electronic ground state of the methyl bromide cation recorded using the ZEKE scheme described previously is shown in Fig. 2. No feature has been observed in the gap between the disconnected lines. The intensities of the features in the two separate parts of the spectrum are not directly comparable. We did not attempt to normalize the spectrum since the ZEKE signal intensity is not expected to be proportional to the laser intensity (29). The dominating feature in the ZEKE spectrum is assigned as the origin band (0_0^0) of the $\tilde{X}^2E_{3/2} \leftarrow \tilde{X}^1A_1$ transition. The weak peak at the higher energy side of the origin band remains unassigned. Vibrational features observed in the spectrum are labeled by both the upper and the lower vibrational level using the symbol i_m^n, where i indicates a vibrational mode, as in ν_i, n is the number of quanta of the ν_i mode excited in the upper electronic state, and m is the number of quanta of the ν_i mode in the lower electronic state. Excitation of one quantum of the symmetric CH_3 bending vibration, ν_2 (a_1 symmetry), is observed at 1281 cm^{-1} above the 0_0^0 band. The peak observed 94 cm^{-1} below the origin is assigned as the 3_1^1 hot band, based on the ν_3 vibrational frequency in the $\tilde{X}^2E_{3/2}$ cationic ground state determined in the multiphoton ZEKE photoelectron spectroscopic study (24). The origin band and the 2_0^1 band were previously observed in the low-resolution HeI photoelectron spectrum (19) and the one-color multiphoton ZEKE spectrum (24). However, the better resolution (1.0–1.2 cm^{-1}) of our ZEKE detection scheme allows for the observation of the rotational contours of the three vibrational bands but is insufficient to fully resolve the rotational structures of these bands. It is found that the origin band and the other two vibrational bands in Fig. 2 show similar rotational contours. Figure 3*a* shows the rotational contour of the origin band.

The one-photon VUV spectrum was also recorded using the MATI detection scheme described in the *Experimental* section. Weak MATI ions were observed at a shorter flight time as compared with the prompt ions. The MATI spectrum of the origin band appeared as a broad feature with unresolved rotational structures because of poorer resolution of the MATI scheme as compared with the ZEKE detection scheme, but it confirmed the attribution of the ZEKE signal to the CH_3Br.



Discussion

The ground electronic state of methyl bromide has C_{3v} symmetry and a $1a_1{}^2 2a_1{}^2 1e^4 3a_1{}^2 2e^4$ electronic configuration yielding the total symmetry of A_1. The highest occupied molecular orbital (2e) has the predominant character of the halogen lone pairs. The lowest (ground) electronic state of the cation is ^2E formed by the removal of a nonbonding 2e electron. The degenerate ^2E electronic state is subject to vibronic coupling of the Jahn–Teller type and spin–orbit coupling. For methyl bromide, the latter is found to be significant in the outermost, lone-pair orbital. Therefore, the ^2E ground state is split into two spin–orbit components ($^2E_{3/2}$ and $^2E_{1/2}$), with the $^2E_{3/2}$ component lying lower in energy. The strongest feature observed in Fig. 2 is attributed to the origin band of the lower spin–orbit component of the degenerate ^2E ground ionic state $\tilde{X}^2E_{3/2}$, based on the comparison with previous photoelectron (19) and ZEKE (23, 24) spectroscopic studies. The fact that this band dominates the ZEKE photoelectron spectrum indicates that the geometry of the $\tilde{X}^2E_{3/2}$ ground ionic state is nearly the same as that of neutral CH_3Br in its ground electronic state. This is consistent with the electron being ejected from the nonbonding halogen lone-pair orbit upon ionization.

Neutral CH_3Br in its $\tilde{X}^1A_1$ vibronic ground state is a prolate ($A'' = 5.08$ cm^{-1}, $B'' = C'' = 0.31916$ cm^{-1} (8)) symmetric top molecule possessing C_{3v} symmetry. As was discussed earlier, the dominating appearance of the origin band in the obtained ZEKE spectrum suggests that the CH_3Br cat-

Fig. 3. The ZEKE photoelectron spectrum of the origin band of the ground electronic state of the CH_3Br^+ cation, showing the rotational contour from (*a*) experiment and (*b*) simulation (inverted). The energy scale has been corrected for the shifts owing to electric fields. The *A*, *B*, and *C* constants of the neutral ground state used in the simulation are from ref. 8.

ion is also of C_{3v} symmetry in its $\tilde{X}^2E_{3/2}$ state. The highest occupied molecular orbital of CH_3Br in its $\tilde{X}^1A_1$ ground state is a doubly occupied 2e orbital, which is predominantly nonbonding localized on the Br atom with some C—H bonding character (20). The 2e orbital is, therefore, essentially composed of the Br 4*p* atomic orbitals with minor contributions from the carbon 2*p* and the hydrogen 1*s* orbitals (17). For atomic-like, one-photon transition, $\Delta l = \pm 1$. Therefore, the Rydberg states excited by one photon from the 2e orbital are most probably predominantly of *ns* ($l = 0$) and *nd* ($l = 2$) characters, with some weak *np* ($l = 1$) characters. However, the absorption spectroscopic studies (9, 12) showed that the high Rydberg states converging to the first ionization potential of CH_3Br are predominantly of *s* with some *p* character.

It can be easily shown that only perpendicular transitions are allowed to *s* Rydberg states. For the *p* and *d* Rydberg states, both perpendicular and parallel transitions are possible, but their contributions to the ZEKE states of the ground electronic state of CH_3Br^+ are small compared with the *s* Rydberg states. The general rotational selection rules for a perpendicular band are:

$$[1] \qquad \Delta J' = J' - J'' = 0, \pm 1; \qquad \Delta K = K' - K'' = \pm 1$$

where *J* and *K* are the total angular momentum and its projection on the symmetry axis quantum numbers, respectively. The "′" ("″") superscript indicates the upper (lower) state. In a ZEKE state ($n \geq 100$), the Rydberg electron is asymptotically decoupled from the ion core, and we can write

$$[2] \qquad \mathbf{J}' = \mathbf{J}^+ + \mathbf{l} + \mathbf{s}$$

where vector $\mathbf{J}^+$ is the total angular momentum of the cation core, while vectors **l** and **s** are the orbital and the spin angular momenta of the Rydberg electron, respectively. Taking the experimental evidence into account and using eq. [2], the rotational selection rules can be expressed in terms of $\Delta J^+ = J^+ - J''$ as follows:

$$[3] \qquad \Delta J^+ = J^+ - J'' = -3/2, -1/2, +1/2, +3/2 \text{ for } l = 0$$

$$[4] \qquad \Delta J^+ = J^+ - J'' = -5/2, -3/2, -1/2, +1/2, +3/2, +5/2 \text{ for } l = 1$$

The spin–orbit splitting of the ^2E state of CH_3Br^+ is as large as 2541 cm^{-1} (315 meV) (12), and the Hund case (*c*) coupling scheme applies. In this case, the projection of the total angular momentum quantum number *J* along the principal symmetry axis of a symmetric rotor is equal to (30)

$$[5] \qquad P = \sum_i l_i + K + \Sigma$$

where l_i is the projection of the vibrational angular momentum on the principal symmetry axis for degenerate vibration ν_i, while Σ and *K* are the projections of the spin and the angular momentum without spin on the principal symmetry axis, respectively. For the origin band of the $\tilde{X}^2E_{3/2} \leftarrow \tilde{X}^1A_1$ transition in CH_3Br, $\sum_i l_i = 0$ and $\Sigma = 1/2$. Therefore, we can write

$$[6] \qquad P^+ = K^+ + 1/2$$

for the $\tilde{X}^2E_{3/2}$ state of CH_3Br^+. Now, the rotational selection rules in eq. [1] can be expressed in terms of $\Delta K^+ = P^+ - K''$ as

$$[7] \qquad \Delta K^+ = +3/2, -1/2$$

As described previously, the origin band and two vibrational bands of the $\tilde{X}^2E_{3/2} \leftarrow \tilde{X}^1A_1$ transition show similar rotational contours. As the rotational structure of the origin band is unresolved in our spectra, to determine the ionization energy and estimate the rotational constants of the CH_3Br^+ ion, we have simulated the profile of the origin band and compared it with the observed spectrum. The rotational Hamiltonian of a symmetric rotor can be written as

$$[8] \qquad \mathbf{H} = B[\mathbf{R_x}^2 + \mathbf{R_y}^2] + A\mathbf{R_z}^2$$

where *A* and *B* are rotational constants, and **R** ($\mathbf{R_x}$, $\mathbf{R_y}$, $\mathbf{R_z}$) is the operator of molecular rotation. The **R** operator can be written in terms of molecular angular momenta as

$$[9] \qquad \mathbf{R} = \mathbf{J} - \mathbf{L} - \mathbf{S}$$

where **J**, **L**, and **S** are the total, orbital, and spin angular momenta of a molecule, respectively. Substituting eq. [9] into eq. [8] and evaluating diagonal matrix elements of a symmetric rotor, we obtain

$$[10] \qquad T = B[J(J+1) - P^2] + A(P - \Omega)^2 + B[L(L+1) + S(S+1) + 2(\Omega - \Sigma)\Sigma - \Omega^2]$$

where *J* and *P* are the total angular momentum and its projection on the principal symmetry axis quantum numbers, *S* and Σ are the spin and its projection on the principal symmetry axis quantum numbers, *L* is the expectation value of the orbital angular momentum, and Ω is the expectation value of

© 2004 NRC Canada

the projection of the electronic angular momentum (orbital and spin) on the principal axis. The last term in eq. [10] reduces to zero for the ground state of the neutral CH_3Br molecule $\tilde{X}^1A_1$, and the diagonal matrix elements can be written as

$$[11] \quad T'' = B''[J''(J'' + 1) - K''^2] + AK''^2$$

where we substitute $P'' = K''$. For the ground state of the CH_3Br^+ ion ($\tilde{X}^2E_{3/2}$), the last term of eq. [10] cannot be evaluated explicitly because L and Ω are not good quantum numbers. By substituting $L = 1$, $S = 1/2$, $\Sigma = 1/2$, and $\Omega = 3/2$, we estimate that this term is expected to be small, approximately equal to $3/2B$, constant for a given vibronic state. Consequently, we constrain this term in the simulation at the value of $3/2B$. Thus, we write the diagonal matrix elements of the Hamiltonian of the $\tilde{X}^2E_{3/2}$ state as

$$[12] \quad T^+ = B^+[J^+(J^+ + 1) - (P^+)^2] + A^+(P^+ - \Omega)^2 + 3/2B$$

The rotational constants of the ground state of the neutral molecule have been constrained at the values $A'' = 5.08$ cm^{-1} and $B'' = 0.31916$ cm^{-1} taken from ref. 8. The ionization energy (IE), the rotational constants of the CH_3Br^+ ion ground state (A^+ and B^+), and the expectation value of the electronic angular momentum projection (Ω^+) were varied to reproduce the observed spectrum. Only excitations to s ($l = 0$, weight 1.0) and p ($l = 1$, weight 0.2) Rydberg states from $K'' = 0$ and $K'' = 1$ levels were included in the simulation. Rotational lines satisfying the $\Delta J^+ = J^+ - J'' = -1.5, \ldots, +1.5$ (for s Rydberg states) and $\Delta J^+ = -2.5, \ldots, +2.5$ (for p Rydberg states) selection rules were included, with the extreme branches of one-half the intensity of the main branches. The width of the rotational lines was set equal to 1.0 cm^{-1}. The rotational temperature of the ground state of the neutral molecule was optimized at $T = 6.0(5)$ K. The ionization energy (IE), the rotational constants of the ground state of the CH_3Br^+ ion (A^+ and B^+), and the expectation value of the electronic angular momentum projection (Ω), were fitted to be equal to 85 031.2(1.0) cm^{-1}, 4.75(5) cm^{-1}, 0.32(1) cm^{-1}, and 1.48(2), respectively. The simulated spectrum is shown in Fig. 3*b* (lower trace).

The adiabatic ionization energy of CH_3Br of 85 031.2 ± 1.0 cm^{-1} obtained in this work is in very good agreement with the values recently obtained from the ZEKE spectroscopic studies using VUV synchrotron radiation (85 032.6 ± 8.0 cm^{-1}) (23). It also agrees very well with the value of 85 035 ± 50 cm^{-1} obtained by Karlsson et al. (19) in their HeI photoelectron spectroscopic study.

The A^+ rotational constant value of 4.75 cm^{-1} is 0.33 cm^{-1} smaller than that of the neutral ground state ($A = 5.08$ cm^{-1}), which indicates that the three H atoms move away from the *a* rotational axis upon ionization. This is consistent with the lowering from 1305 cm^{-1} in $\tilde{X}^1A_1$ to 1281 cm^{-1} in $\tilde{X}^2E_{3/2}$ in the wavenumber of the vibrational mode (ν_2, CH_3 symmetric bend) (8). This wavenumber lowering in ν_2 upon excitation should also translate into an increase in the rotational constant B^+; however, it is found from the simulation of the rotational profile of the origin band that B^+ (0.32 cm^{-1}) does not change from its neutral ground state value ($B'' = 0.31916$ cm^{-1}). The 3_1^1 band is observed 94 cm^{-1} below the origin band (see Fig. 2), indicating that the wavenumber of the ν_3 vibrational mode (the C-Br stretch) in the cationic ground state is lowered by 94 cm^{-1} compared with that in the neutral ground state. This suggests that the C—Br bond is elongated upon ionization, which in turn should cause a decrease in the B^+ rotational constant. Consequently, we attribute the little change in the B value upon excitation to a canceling of the opposing effect caused by the decrease in ν_2 and ν_3.

Conclusions

The VUV single-photon ZEKE photoelectron spectrum of CH_3Br^+ in its $\tilde{X}^2E_{3/2}$ ground electronic state has been recorded. The dominating feature in the spectrum is the origin band 0_0^0 of the transition $\tilde{X}^2E_{3/2} \leftarrow \tilde{X}^1A_1$. The excitation of the totally symmetric vibrational mode (ν_2) is observed. The 3_1^1 hot band is also present. The rotational contours of three vibrational bands have been observed. Simulation of the rotational contour of the origin band has yielded the improved value of the first adiabatic ionization energy (85 031.2 ± 1.0 cm^{-1}) and the rotational constants of CH_3Br^+ in its $\tilde{X}^2E_{3/2}$ ground state.

Temperature- and pressure-dependent luminescence spectroscopy on the *trans*-$[ReO_2(pyridine)_4]^+$ complex — Analysis of vibronic structure, luminescence energies, and bonding characteristics[1]

John K. Grey, Ian S. Butler, and Christian Reber

Abstract: Resolved vibronic structure in electronic spectra provides a detailed view into how molecular structure changes after absorption or emission of a photon. We report temperature- and pressure-dependent luminescence spectra of *trans*-$[ReO_2(pyridine)_4]I$. Low-temperature spectra reveal long vibronic progressions in the totally symmetric O=Re=O (907 cm^{-1}) and Re-pyridine (211 cm^{-1}) stretching modes, indicating large structural displacements along these normal coordinates. The luminescence band maximum is at ca. 15 500 cm^{-1}. Room-temperature spectra are somewhat less-resolved; however, intervals closely matching the O=Re=O frequency (~870 cm^{-1}) persist at higher temperatures. The variable pressure spectra exhibit distinct changes in the vibronic patterns, and luminescence energies decrease by 16 ± 2 cm^{-1}/kbar (1 bar = 100 kPa). Low-temperature spectra are modeled using two-dimensional potential energy surfaces to represent the initial and final electronic states, from which the quantitative normal coordinate offsets can be determined. We then adapt this model to the room-temperature, pressure-dependent data where it is possible to determine how the offsets and other important spectroscopic parameters vary with the pressure-induced changes of the molecular structure.

Key words: trans-$[ReO_2(pyridine)_4]I$, low-temperature luminescence spectroscopy, high-pressure luminescence spectroscopy, vibronic structure, emitting state distortions.

Résumé : La structure vibronique résolue des spectres électroniques nous permet d'obtenir de l'information détaillée concernant les changements de la structure moléculaire suite à l'absorption ou l'émission d'un photon. Nous présentons et analysons les spectres de luminescence du *trans*-$[ReO_2(pyridine)_4]I$ en fonction de la température et de la pression. Les progressions vibroniques observées impliquent les modes de vibration totalement symétriques O=Re=O et Re-pyridine avec des fréquences Raman de 907 cm^{-1} et de 211 cm^{-1} et indiquent d'importants déplacements le long de ces coordonnées normales. Le maximum de la bande de luminescence est à approximativement 15 500 cm^{-1}. Les spectres de luminescence à la température ambiante montrent une résolution inférieure, mais suffisante pour distinguer des intervalles de 870 cm^{-1} se rapprochant de la fréquence de vibration O=Re=O. Les spectres à pression variable montrent des changements dans la structure vibronique ainsi qu'une décroissance des énergies de luminescence de 16 ± 2 cm^{-1}/kbar (1 bar = 100 kPa). Les spectres expérimentaux à basse température sont comparés à des spectres calculés selon un modèle impliquant des surfaces d'énergie potentielle bidimensionnelles. Ces surfaces représentent les états électroniques initial et final et permettent de déterminer quantitativement les écarts le long des coordonnées normales. Ce modèle est ensuite adapté aux données à température ambiante et à pression variable, de façon à déterminer la nature des déplacements et des variations des paramètres spectroscopiques amenés par les changements dans la structure moléculaire induits par la pression.

Mots clés : *trans*-$[ReO_2(pyridine)_4]I$, spectroscopie de luminescence à basse temperature et à haute pression, structure vibronique, distorsions structurales à l'état excité.

Introduction

Transition metal complexes with metal–oxygen multiple bonds have received much attention for uses in oxygen atom transfer catalysis and as photochemical sensitizers (1–4). The electronic structures of many second- and third-row metal–oxo complexes have been well studied both spectroscopically and theoretically since the seminal work of Winkler and Gray (5, 6). We present and analyze temperature- and pressure-dependent luminescence spectra of the *trans*-[ReO_2(pyridine)$_4$]I compound that show well-resolved vibronic structure, even at room temperature, and provide an in-depth view into how the molecular geometry changes in the emitting state. Perhaps the most relevant application of *trans*-dioxo complexes to the results presented in the following is their use as luminescent probes to determine the influence of host–guest interactions in layered materials (7), where a *trans*-[ReO_2(pyridine)$_4$]$^+$ complex was intercalated into hectorite lattices and changes in the resolved vibronic structure and luminescence energies determined from low-temperature luminescence spectra were used to understand the nature of interaction between the host lattice and the guest luminophore. These host–guest interactions represent what has become known as a "chemical pressure" and here we use a *trans*-dioxo rhenium(V) complex to study the effect of external pressure on the resolved luminescence spectrum. Pressure-dependent emitting state normal coordinate offsets, luminescence band maxima energies, and energies of the electronic origin transition are determined quantitatively based on a model developed from the low-temperature luminescence spectrum.

The six-coordinate [Xe $5d^2$] *trans*-dioxo class of complexes usually are described in idealized D_{4h} point group symmetry and show well-resolved vibronic structure in their low-temperature electronic spectra (6). Long progressions in high frequency (900–1000 cm^{-1}) metal–oxo stretching modes are often observed, indicating a large structural change along metal–oxo coordinates in the emitting state, and the offset of the ground and emitting state potential energy minima can be determined from the intensity distribution of the resolved vibronic progressions. The high vibrational frequencies of the metal–oxo modes are due to the strength of the formal M=O double bonds. This feature makes such complexes amenable to room-temperature spectroscopic studies because of the low thermal population of higher vibrational levels allowing vibronic structure to persist even at relatively high temperatures. By applying high external pressures to single crystals of these systems, it is possible to determine the change in the metal–oxo normal coordinate offset as a function of pressure through the changes in vibronic patterns. We have previously used the resolved structure in a O=Re=O totally symmetric stretching mode to study the influence of pressure on coupling interactions between the ground- and excited-electronic-state potential energy surfaces in a series of *trans*-[ReO_2(*N*,*N*,*N*′,*N*′-ethylenediamine)$_2$]$^+$ complexes (8, 9). The ethylenediamine ligands effectively "clamp" to the metal center, thus resisting changes in molecular geometry because of changes in intermolecular packing forces with increasing pressure, whereas the pyridine ligands of the title compound are expected to be more susceptible to pressure-induced changes in molecular geometry. Furthermore, the luminescence properties of the title complex show a strong dependence on the environment whereby the luminescence energy and intensity distribution of vibronic progressions change noticeably upon changing counter-ions.

The ground- and excited-state electronic structures of d^2 *trans*-dioxo complexes are well-known and have been parameterized in terms of ligand-field strength and interelectronic repulsion (10). For these and other six-coordinate tetragonal complexes, the five *d*-orbitals are split in the following fashion in increasing energy: $d_{xy}(b_{2g})$, d_{xz}, $d_{yz}(e_g)$, $d_{x^2-y^2}(b_{1g})$, $d_{z^2}(a_{1g})$. The ground electronic state in the title complex is both spin and orbitally nondegenerate ($^1A_{1g}$) in D_{4h} symmetry because of the pairing of the two *d* electrons in the d_{xy} orbital (HOMO). The energy of this state depends on the two-electron parameter (K_{xy}), which is defined as $3B + C$, where *B* and *C* are the Racah parameters describing interelectronic repulsion. Promotion of one electron to the e_g orbitals (LUMO) leads to both ^1E_g and ^3E_g excited states separated by $2K_{xy}$ with the triplet state at lower energy. Due to strong spin–orbit coupling effects intrinsic to third-row transition metal atoms, the ^3E_g state is split into several components and luminescence occurs from the lowest energy spin–orbit components. The energy of the LUMO depends on the difference in π overlap between the oxo and ancillary ligands to the metal *d* orbitals, which is defined by the ligand-field parameter Δ_π. In *trans*-dioxo complexes with anisotropic π-donating ligands, such as the pyridine ligands in the title compound, Δ_π is represented as $2e_\pi(O) + 2e_\pi(ligand) - 4e_\pi(ligand)$, where e_π is the angular-overlap parameter describing π overlap between the metal e_g and b_{2g} orbitals with ligand orbitals of π-symmetry that accounts for contributions both parallel and perpendicular to the ML_4 equatorial plane (10). The pyridine ligands are oriented perpendicular to the equatorial plane where the lone unhybridized *p*-orbital on the nitrogen atom has the maximum π interaction with the metal center, causing $e_\pi \approx 0$ and Δ_π then becomes $2e_\pi(O) - 4e_{\pi\perp}(ligand)$ (10). Because the energy difference between the ground and emitting states depends on both ligand-field effects arising from metal–ligand bond lengths and interelectronic repulsion parameters, one of the goals of this work is to rationalize the pressure-dependent change in luminescence energies in terms of K_{xy} and Δ_π and compare to previous studies of *trans*-dioxo complexes.

We calculate the well-resolved 5 K luminescence spectrum of the title complex using harmonic potential energy surfaces with the ground and emitting states displaced along the O=Re=O and Re-N(pyridine) symmetric stretching modes. The two-dimensional model can then be adapted to calculate room-temperature pressure-dependent luminescence spectra using potential energy surfaces displaced along a single effective coordinate with predominant O=Re=O stretching character. The pressure-induced changes of the most important parameters are compared to those reported for complexes with less π-bonding characteristics (8, 9, 11). The title complex demonstrates the quantitative transferability of parameters obtained from low-temperature spectra to less resolved room temperature spectra.

Experimental

Synthesis and spectroscopy

trans-[ReO_2(py)$_4$]I was synthesized following literature

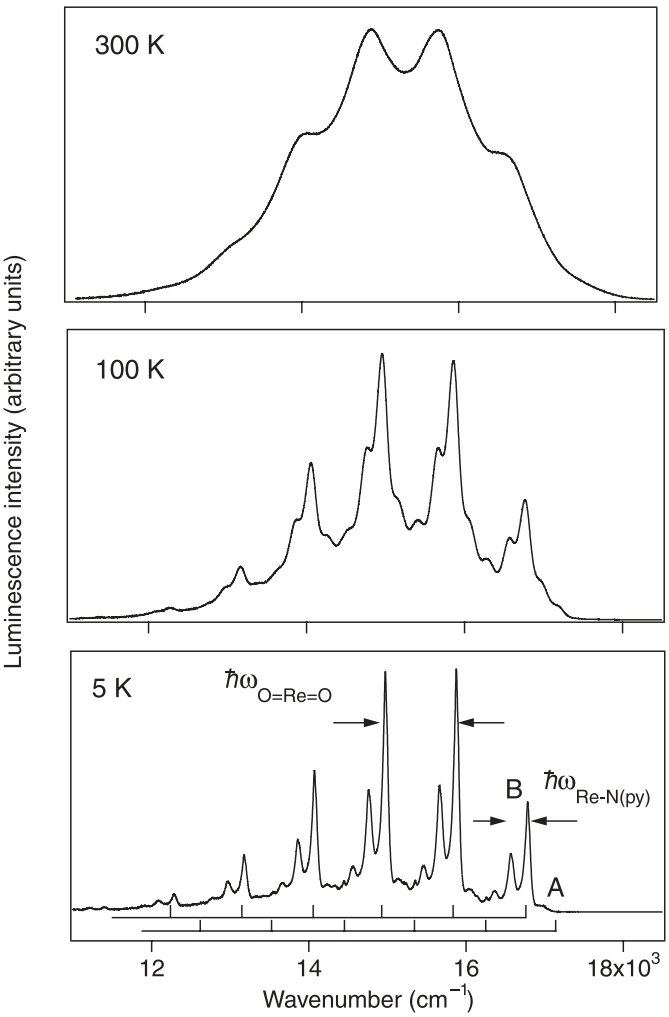
methods (12) and all starting materials were used as received. Luminescence and Raman spectra were recorded as a function of temperature and pressure on a microscope spectrometer described previously (8, 9). Crystalline samples were placed in a liquid helium cryostat (Janis ST 500) and temperature was controlled between 300 and 5 K. Variable pressure experiments were carried out by placing samples in a gasketed diamond-anvil cell (DAC). All spectra were unpolarized and corrected for spectrometer response. Absorption measurements were performed on a Varian CARY 5E spectrometer. For the absorption spectra, the *trans*-$[ReO_2(py)_4]I$ compound was dissolved in water and the solution was allowed to evaporate slowly on quartz plates, which produced a thin layer of microcrystals on the surface.



Spectroscopic results

Variable temperature luminescence spectroscopy

Figure 1 shows the luminescence spectra of *trans*-$[ReO_2(py)_4]I$ at 5 K (bottom panel), 100 K (middle panel), and 300 K (top panel). All spectra measured over the indicated temperature range show resolved vibronic structure in the high-frequency O=Re=O totally symmetric stretching mode, with an average progression interval of 905 cm^{-1}. This mode is observed in the 300 K Raman spectrum at 907 cm^{-1}. At temperatures lower than 150 K, progressions in the lower frequency (211 cm^{-1}) Re-N(pyridine) totally symmetric stretching mode are visible on the lower energy side of the main (O=Re=O) progression. In the 5 K spectrum shown in Fig. 1, up to seven quanta of the O=Re=O mode can be observed, indicating a large change in emitting-state rhenium–oxo bond length compared to the ground-state equilibrium configuration. At 300 K the vibronic structure in the luminescence spectrum becomes less resolved and the observed high frequency progression interval decreases to an average 870 cm^{-1}.

The highest energy discernible maximum of the 5 K spectrum appears at approximately 17 200 cm^{-1} and overlaps with the lowest energy absorption onset, shown in Fig. 2. The luminescence spectrum consists of two bands, the first (labeled **A** in Fig. 1) originates from the highest energy peak and the more intense band (labeled **B** in Fig. 1) begins at 314 cm^{-1} lower in energy. The beginning of each cluster of lower frequency Re-N(py) progressions is indicated by tick marks for both bands **A** and **B** for the 5 K spectrum in Fig. 1 and the clusters of vibronic transitions are exact replicas, i.e., they have the same relative intensity distributions across the entire luminescence spectrum. All energy positions of individual vibronic peaks and frequency intervals are listed in Table 1 for the dominant vibronic band (**B**). It is also interesting to note the decrease in the O=Re=O frequency toward the lower energy side of the spectrum by approximately 4 cm^{-1} for each subsequent quantum of the O=Re=O mode, which becomes 21 cm^{-1} lower at the highest quantum of this mode. Comparison with the 5 K luminescence spectrum of the tetraphenylborate $(BPh_4)^-$ salt of this complex reveals a similar trend where this interval decreased by 10 cm^{-1} between the second and third quanta followed by an anomalous large increase between the third and fourth quanta by 30 cm^{-1} (6). This apparent anharmonicity was also observed

Fig. 1. Luminescence spectra of single crystals of *trans*-$[ReO_2(pyridine)_4]I$ at three temperatures: 300 K (top panel), 100 K (middle panel), and 5 K (bottom panel). Frequency intervals of the two resolved progressions are indicated by arrows. The tick marks below the 5 K spectrum mark the main progressions for the two band systems, labeled **A** and **B**, that comprise the total spectrum.

in theoretical calculations on the *trans*-$[ReO_2(ethylenediamine)_2]^+$ complex where it was revealed that the ground electronic state potential energy surface was anharmonic along the O=Re=O coordinate (13).

Figure 2 shows the effect of temperature on the intensity distribution between the two bands (**A** and **B**). As temperature increases, the intensity of band system **A** increases, whereas band system **B** shows a slight decrease. The higher energy bands (**A**) of the BPh_4^- salt also demonstrate similar temperature-dependent characteristics as those observed in Fig. 2 and were assigned as transitions from a second luminescent state slightly higher in energy (6). This assignment was consistent with temperature-dependent luminescence lifetimes where the higher energy state becomes thermally populated at higher temperatures and leads to a decrease in the lifetime from 68 μs (5–70 K) to 32 μs at room temperature (6). The temperature-dependent features in Fig. 2 are in agreement with this assignment, further supported by the

Fig. 3. (*a*) Selected pressure-dependent single-crystal luminescence spectra of *trans*-[ReO_2(pyridine)$_4$]I recorded at room temperature (ca. 300 K). Individual pressures are in descending order: 4 kbar (top trace), 13 kbar, 21 kbar, 29 kbar, 37 kbar, and 42 kbar (bottom trace) (1 bar = 100 kPa). (*b*) High-pressure luminescence spectra with additional features indicated by arrows.

different bandwidths for transitions labeled as **A** and **B**, indicating transitions originating from different components of the ^3E_g excited state.

Variable pressure luminescence spectroscopy

Figure 3 shows the effect of pressure on the luminescence spectrum of the title complex. The dominant progression interval in the room-temperature spectra is 870 cm^{-1}, almost 40 cm^{-1} less than the observed O=Re=O vibrational frequency in the Raman spectrum. As pressure increases, the luminescence intensities show steady decreases, an effect that is often observed and most likely due to efficient energy transfer to deep traps at high pressure. In addition, the intensity distribution within the resolved progression change with increasing pressure, which can be observed by comparing the second and third members of the 4 kbar spectrum in Fig. 3*a* and the 42 kbar spectrum in Fig. 3*b*. The energy of the luminescence band maximum (E_{max}) shows a visible decrease with increasing pressure that can be seen qualitatively by following a particular vibronic peak. Luminescence spectra at the highest working pressures (37–42 kbar) also reveal additional features not observed in the lower pressure spectra and indicated in Fig. 3*b* by arrows. Pressure-dependent

© 2004 NRC Canada

Raman spectra of the title compound show smooth shifts of the O=Re=O stretching mode to higher frequencies by 0.53 cm^{-1}/kbar. This value is similar to the pressure-induced shifts determined for various *trans*-dioxo rhenium(V) complexes with substituted imidazole ligands, which range from 0.55 to 0.69 cm^{-1}/kbar, and larger than those found in complexes with ethylenediamine ligands (0.37–0.42 cm^{-1}/kbar) (11).

Discussion

The title complex has exact D_{4h} point group symmetry for the *trans*-ReO_2N_4 fragment and we use the labels from this symmetry group to describe the electronic states and relevant vibrational modes. The removal of electron density in the x,y plane to the π* LUMO orbital results in large changes in metal–ligand bond lengths along the Re-N(py) and O=Re=O coordinates, therefore these modes are expected to have the largest displacements between ground- and emitting-state potential minima. Only one emitting state is considered in the model for both temperature- and pressure-dependent luminescence spectra where the most intense luminescence band (**B**) is analyzed.

Analysis of the temperature-dependent vibronic structure

The detailed spectroscopic features shown in Figs. 1 and 2 provide a means to analyze the rich vibronic structure and characterize the ground- and emitting-state potential energy surfaces. We use two-dimensional harmonic potential surfaces with the ground and emitting states displaced along the totally symmetric O=Re=O and Re-N(pyridine) stretching modes. The luminescence spectrum is calculated using the time-dependent theory of luminescence spectroscopy, an approach that has been described in detail before (14–16). Briefly, a wave packet is created on the final potential energy surface (ground state) upon emission of a photon from a molecule in the emitting state at $t = 0$. The shape of the luminescence spectrum is given by eq. [1]

$$[1] \qquad I_{\mathrm{lum}}(\omega) = C\omega^3 \int_{-\infty}^{+\infty} e^{i\omega t} \left\langle \phi \middle| \phi(t) \right\rangle \mathrm{d}t$$

where $I_{\mathrm{lum}}(\omega)$ is the luminescence intensity at the frequency ω, C is a constant scaling factor, and $\langle\phi|\phi(t)\rangle$ is the autocorrelation function. Its absolute value can be visualized as the overlap of the initial wavepacket ($\phi = \phi(t = 0)$) with the time-dependent wavepacket ($\phi(t)$). The autocorrelation is calculated from a closed-form analytical equation obtained by making several assumptions: (*i*) the vibrational frequencies (ω) in the ground and excited states are identical and both states are represented by harmonic potential energy surfaces, (*ii*) there is no mixing of normal coordinates, and (*iii*) the transition dipole moment is constant. The autocorrelation for the *k*th mode is then given by eq. [2]

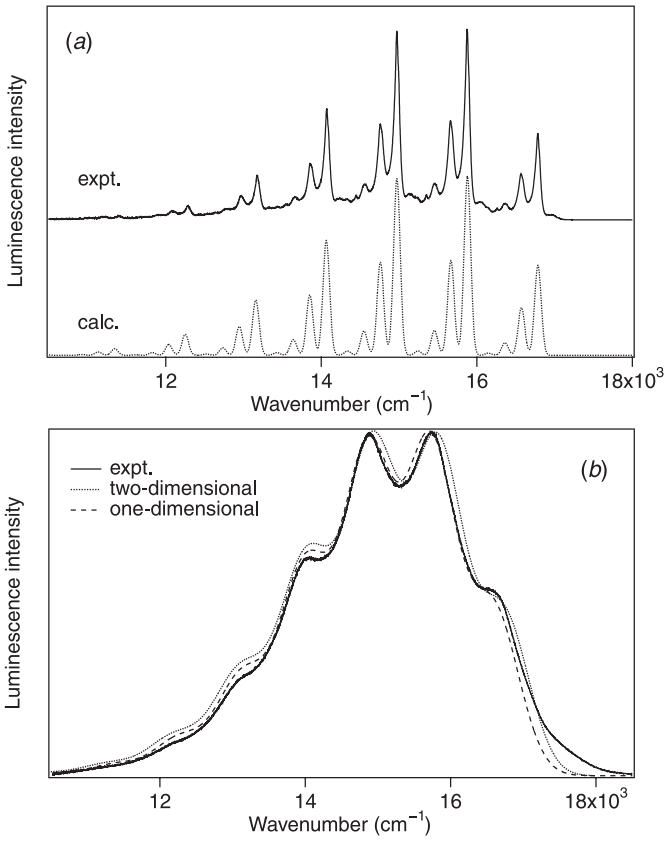
$$[2] \qquad \left\langle \phi_k \middle| \phi_k(t) \right\rangle = \exp\left[-\frac{\Delta_k^2}{2}(1 - \exp(-i\omega_k t)) - \frac{i\omega_k t}{2} \right]$$

for harmonic ground- and emitting-state potential energy surfaces with minima displaced by Δ_k in dimensionless units.[3] For multiple displaced modes, the total autocorrelation is the product of autocorrelations for each individual mode

$$[3] \qquad \left\langle \phi \middle| \phi(t) \right\rangle = \prod_k \left\langle \phi_k \middle| \phi_k(t) \right\rangle \exp\left(\frac{-iE_{00}t}{\hbar} - \Gamma^2 t^2 \right)$$

where E_{00} is the energy of the electronic origin, and Γ is a Gaussian damping factor that determines the width of individual vibronic transitions, both in cm^{-1} units. After calculating the total overlap, the result is Fourier transformed (eq. [1]) to give the spectrum. The uncoupled coordinates for the ground state are a good assumption because clusters of vibronic transitions observed across the entire luminescence band are "replicas" of each other. This feature arises from Lissajous motion of the wave packet along the two displaced normal coordinates, as was superbly illustrated by Herzberg for two orthogonal harmonic oscillators with different force constants, k_x and k_y, leading to a complicated pattern resulting from the superposition of the individual motions (17, 18). The appearance of replicas in the vibronic structure of electronic spectra is due to these uncoupled individual motions, justifying the use of harmonic potential energy surfaces and eq. [3] to describe the wave packet motion on the final (ground) state potential energy surface. Two other salts of the *trans*-$[ReO_2(py)_4]^+$ complex also show such replicas (6), however, the I^- salt studied here shows the best resolution of vibronic structure where there are two distinct progression-forming modes and details of the vibronic patterns can be carefully scrutinized.

Figure 4*a* compares the experimental luminescence spectrum at 5 K to the spectrum calculated with eq. [1]. The energy (E_{00}) of the origin transition for the calculation was set to the first resolved peak in progression **B** at 16 786 cm^{-1}. All parameters used in this calculation are shown in Table 2. Literature values for the emitting-state bond length changes for individual Re=O and Re-N(py) bonds were found to be 0.07 and 0.03 Å, respectively, for the BPh_4^- salt (6). The offset along the Re-N coordinate is negative due to the removal of electron density from the x,y plane, thus decreasing these bonds and resulting in a negative emitting state offset along this coordinate (19). In the model used here, only the absolute values can be determined since harmonic potential energy surfaces are used. From the calculated 5 K luminescence spectra, we determine values of 0.074 and 0.022 Å for the Re=O and Re-N(pyridine) bond length



[3] The conversion of the emitting-state offset for a particular mode from dimensionless units to Å is given by

$$\Delta Q_k = \sqrt{\frac{N_A \hbar}{4\pi^2 c \hbar \omega_k M}}\, 10^8 \Delta_k$$

where N_A is Avogadro's number, $\hbar$ is Planck's constant in erg s (1 erg = 0.1 μJ), c is the speed of light in cm s^{-1}, $\hbar\omega_k$ is the frequency of the vibration in cm^{-1}, and M is the mass of the mode in g mol^{-1}.

Fig. 4. (*a*) Experimental (solid trace, 5 K) and calculated (dotted trace) luminescence spectra using two-dimensional harmonic potential energy surfaces and parameters from Table 2. (*b*) Comparison of the 300 K luminescence spectrum with the broadened two-dimensional calculated spectrum (dotted trace) and best-fit one-dimensional effective mode model (dashed trace).

changes based on the normal coordinate offsets in Table 2,[4] values similar to those calculated for the BPh_4^- salt indicating that different counter-ions do not lead to large changes in emitting-state distortions along the same normal coordinates. For other *trans*-$[ReO_2]^+$ complexes with aromatic nitrogen-donor ligands, such as substituted imidazoles, the emitting-state distortions along the Re=O bond lengths are in a similar range to those given above, between 0.07 and 0.09 Å, whereas some Re-N(ligand) distortions are much larger (19, 20).

Previous luminescence measurements and analyses of near-IR emitting *trans*-$[ReO_2]^+$ complexes revealed coupling between normal coordinates in the ground electronic state based on the nonreplica clusters of vibronic bands (20, 21). The coupling is induced by avoided crossings between the ground and excited states of the same symmetry (13). This effect is also mediated by the magnitude of the normal coordinate offset for each displaced vibrational mode. In lower energy emitting systems with large emitting state normal coordinate displacements, the coupling effect is much stronger and leads to noticeably anharmonic luminescence bandshapes. However, the title complex luminesces at higher energy and the emitting-state distortion along the Re-N(py) stretching mode is much less than in other *trans*-dioxo rhenium(V) complexes, thus making the coupling effect comparatively smaller since the avoided crossings between same-symmetry states occur farther away from the Franck–Condon region of the luminescence transition. These trends explain why there is no spectroscopic manifestation of coupling interactions between the ground and excited states in the title complex, which further justifies the use of harmonic potential energy surfaces with uncoupled coordinates to describe the ground electronic state.

Table 2. Parameter values used to calculate the spectra in Fig. 4.

Parameter	5 K	300 K
E_{00}	16 786	16 570
$\hbar\omega_{O=Re=O}$ (cm^{-1})	907	870
$\hbar\omega_{Re-N}$ (cm^{-1})	212	
$\Delta Q_{O=Re=O}$ (Å)	0.105	0.106
ΔQ_{Re-N} (Å)	0.045	
Γ (cm^{-1})	30	250

Luminescence spectra of *trans*-dioxo complexes of rhenium (V) with substituted ethylenediamine ligands measured at room temperature display partially resolved vibronic structure in the O=Re=O totally symmetric stretching mode (9). Analyses of these bandshapes were achieved with one-dimensional potential surfaces because of the lack of resolution in the lower frequency Re–ligand modes at higher temperatures. Figure 4*b* shows the 300 K spectrum with a calculated spectrum using the same parameter values in Table 2 for the 5 K spectrum (Fig. 4*a*, bottom trace), but with the damping factor (Γ) increased to 250 cm^{-1}. The agreement is very good between the experimental spectrum at 300 K and the broadened two-dimensional calculated spectrum; however, for the pressure-dependent spectra measured at 300 K, the lack of resolved structure in the Re-N(py) lower frequency mode forbids the use of a two-dimensional model to determine changes in emitting-state offsets.

The room-temperature spectra can also be calculated with a model based on effective one-dimensional potential energy surfaces, which is necessary to extract the normal coordinate offsets as a function of pressure. To fit the 300 K spectrum with the one-dimensional model, a lower vibrational frequency of 870 cm^{-1}, a value close to the O=Re=O frequency of 907 cm^{-1}, but not observed in the ground-state Raman spectrum of the title compound is used. Figure 4*b* shows the best-fit two-dimensional calculated spectrum (5 K) broadened to achieve the same resolution as the spectrum measured at 300 K compared to the best-fit calculated spectrum obtained from the one-dimensional effective coordinate model. The agreement between calculated spectra from these two models is very good and the values for the $\Delta Q_{O=Re=O}$ parameter do not vary significantly, indicating that the O=Re=O mode is the dominant contribution to the effective

[4] The conversion of the emitting-state distortion (ΔQ (Å)) to individual bond-length distortions is: for O=Re=O, $1/\sqrt{2}\,\Delta Q_{O=Re=O} = \Delta r_{Re=O}$, and for Re-N(pyridine), $1/2\,\Delta Q_{Re-N} = \Delta r_{Re-N}$, assuming that these coordinates are the sole contributors to the normal modes.

coordinate, and confirming that the offsets ΔQ obtained from the one-dimensional model can be reliably interpreted as Re=O bond length changes. We use the effective coordinate model to determine pressure-induced changes in 300 K luminescence spectra.

Effect of pressure on the luminescence spectrum at room temperature

The majority of previous pressure-dependent spectroscopic studies involving transition metal complexes have focused largely on octahedral systems where the pressure-induced decrease in metal–ligand bond lengths leads to increases in $10Dq$ (22–25). Because changes in both π (t_{2g}) and σ (e_g) bonding contribute to this ligand-field parameter and spectra are usually devoid of resolved vibronic structure, analyses are usually restricted to qualitative energy level diagrams whereby states (orbitals) shift in energy relative to one another. In the idealized D_{4h} point group symmetry of the title complex, the t_{2g} level splits into the b_{2g} (HOMO) and e_g (LUMO) levels and we only consider this orbital energy difference that depends on Δ_π. The energy difference between the $^1A_{1g}$ ground state and the ^3E_g emitting state is then $\Delta_\pi - 3K_{xy}$. As an external pressure is applied to the title compound, the energy of the luminescence transition will change according to the variation of both parameters. It has been found in pressure-dependent spectroscopic studies involving doped transition metal ions (i.e., Cr^{3+} in ruby) and molecular coordination compounds that the Racah parameters decrease with increasing pressure resulting in an increase of covalency (22–26). In the title compound, this expected decrease of K_{xy} leads to a blue shift of the spectrum if the value of Δ_π does not change appreciably. However, the experimental pressure-dependent spectra shown in Fig. 3 reveal a substantial red shift with increasing pressure, which implies a strong decrease of Δ_π with pressure. The dominance of this parameter is apparent in its definition where the π contribution from the pyridine ligand ($e_{\pi\perp}$) has a large influence on Δ_π. Because it is easier to compress metal–ligand single bonds (Re-N) than double bonds (Re=O), an increasing pressure corresponds to a large increase of $e_{\pi\perp}$ but only a small increase of e_π(O), leading to a large decrease of Δ_π if no changes in the orientation of the pyridine ligands occur. This significant decrease of Δ_π as a function of pressure is a manifestation of strong π bonding between the metal center and ancillary ligands. This is confirmed by a comparison with systems having similar luminescence energies as the title compound, but smaller π interactions from the ancillary ligands, such as *trans*-[ReO_2(*N*,*N*,*N*′,*N*′-tetramethylethylenediamine)$_2$]Cl (9). In this compound, the luminescence band maximum shows a much smaller pressure-dependent red shift that indicates a smaller variation of Δ_π in complexes with ancillary ligands that do not form strong metal–ligand π bonds.

In the pressure-dependent luminescence spectra reported in Fig. 3, the partially resolved vibronic structure provides an opportunity to study the effect of pressure on the Re=O bond length differences from the changes in vibronic patterns and energies of the luminescence origin and band maximum. These important spectroscopic parameters are extracted by fitting a calculated spectrum to the experimental spectrum at each measured pressure using the effective coordinate one-dimensional harmonic potential energy surface model described in the previous section. The energy of the electronic origin transition at each pressure was assumed to be the first resolved shoulder observed in the luminescence bands. This assumption is necessary due to thermal broadening of the vibronic bands and, at ambient pressure, leads to an energy that is lower than the 5 K value by approximately 200 cm^{-1}. Figure 5 shows the comparison between calculated and experimental spectra at selected pressures. The agreement between the calculated spectra and the pressure-dependent luminescence bands is excellent and the parameters used to calculate the spectra are summarized in Table 3. At the highest pressures, starting from 37 kbar (Fig. 3*b*) there is additional intensity to the blue side of the first vibronic transition. This feature closely corresponds to the position of the less-intense band system (**A**) observed in the temperature-dependent luminescence spectra. This band could gain intensity if the two emitting states have different pressure dependence, thus leading to an increased population of **A** at the expense of **B**. Another possibility for the appearance of this feature arises from a pressure-induced increase of inhomogeneity throughout the lattice, creating a luminophore slightly different in structure than that found in ambient pressure spectra. Because the pyridine ligands are oriented perpendicular to the ML_4 plane, a pressure-induced change in crystal-packing forces could favor a structure where the pyridine ligand twists around the Re—N single bond axes. This change in orientation of the pyridine ligand would then alter its contribution to Δ_π and the magnitude of red shift would be expected to decrease at higher pressures. We cannot rule out any of these possibilities in rationalizing the pressure-dependent luminescence properties of the title compound based on the spectra in Fig. 3.

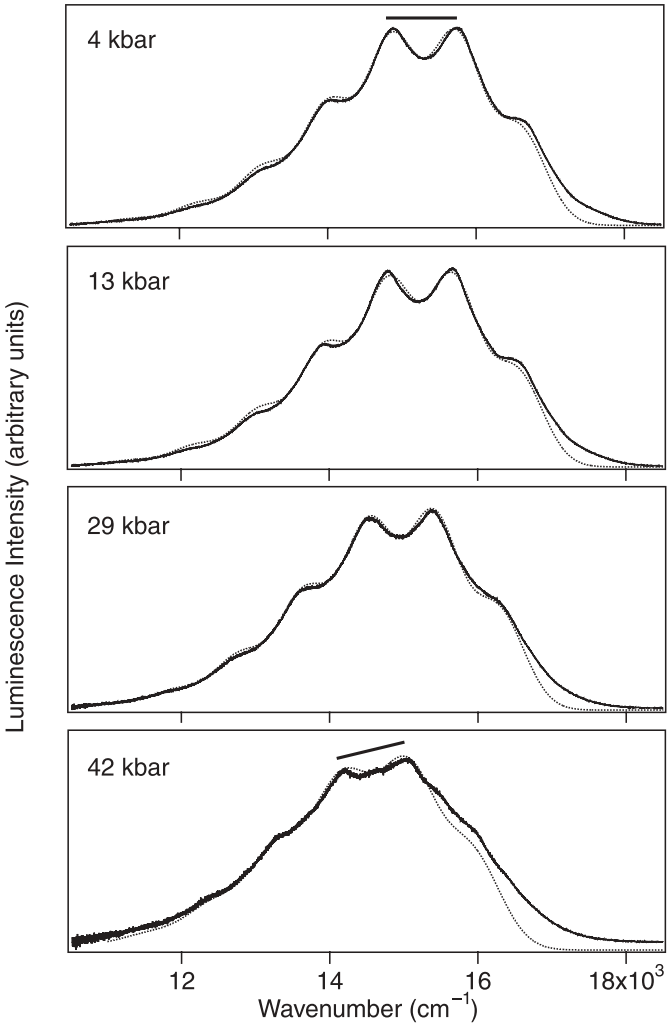
Fig. 5. Selected pressure-dependent luminescence spectra with the calculated spectra shown as dotted traces calculated using parameter values from Table 3. The slanted lines shown in the top and bottom panels are included as a guide for the eye to illustrate the change in intensity distribution for the resolved vibronic progression.



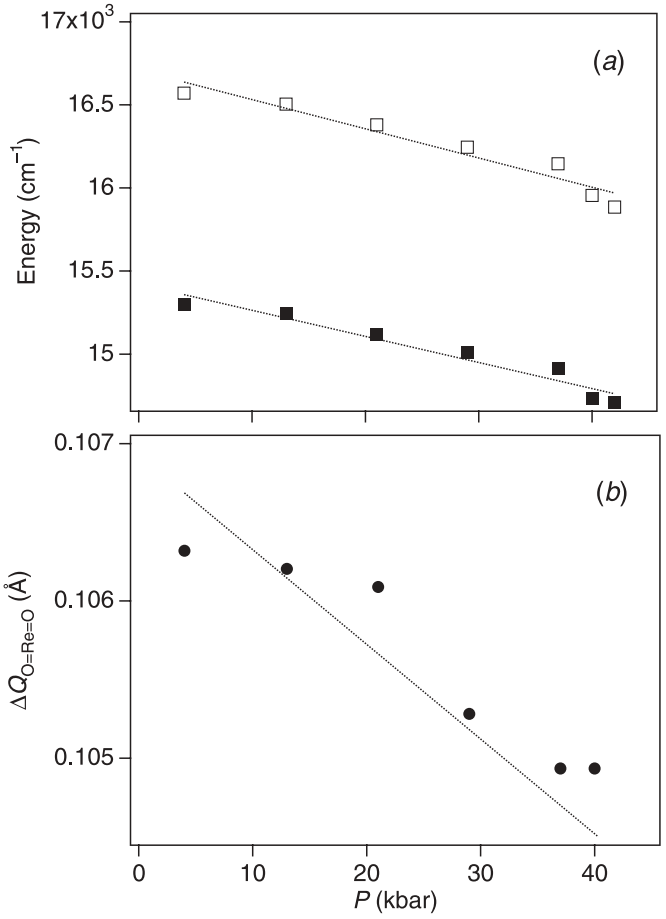


Fig. 6. (*a*) Pressure dependence of the origin transition (E_{00}) (open squares) and the energy of the luminescence band maximum (E_{max}) (solid squares). (*b*) Pressure dependence of the normal coordinate offset ($\Delta Q_{O=Re=O}$) from the one-dimensional model.

In typical pressure-dependent studies, the energy of the band maximum is the only spectroscopic parameter reported quantitatively. Because most pressure-dependent electronic spectra of transition metal complexes are devoid of any resolved vibronic structure, the unresolved bands (absorption or luminescence) are fitted with Gaussian functions from which the energy of the band maxima can be determined and qualitative energy level diagrams can be used to rationalize pressure-induced shifts in energy. In contrast, our spectra with resolved vibronic structure allow us to determine not only the shift of the band maximum, but also the pressure-induced shift of the normal coordinate offset ($\Delta Q_{O=Re=O}$) and the energy of the electronic origin (E_{00}) quantities obtained from the fit of calculated spectra to the experimental results. The quantitative calculated spectra in Fig. 5 can be phenomenologically broadened (by increasing Γ) to give an unresolved band whose overall maximum (E_{max}) is easily determined. This procedure is necessary due to the fact that individual vibronic maxima are not suitable to describe how the overall band maximum changes with pressure. Figure 6 shows the effect of pressure on the parameters used in the calculation of the room-temperature, pressure-dependent luminescence spectra.

Figure 6*a* demonstrates that E_{00} and E_{max} have very similar pressure-dependent behavior, which justifies the choice of harmonic potential energy surfaces to describe the ground electronic state and our rationalization in the changes in luminescence energies in terms of purely electronic parameters, Δ_π and K_{xy}. This is in contrast to the trends observed in the substituted ethylenediamine complexes, where E_{00} and E_{max} have a markedly different response to increasing pressure because of avoided crossings between the ground state and excited states of the same symmetry (9).

Figure 6*b* illustrates the effect of pressure on the normal coordinate offset ($\Delta Q_{O=Re=O}$) determined from the one-dimensional calculated spectra. All normal coordinate offsets decrease as a function of pressure because of the reduced sample volume; however, the extent to which they vary depends on the influence of intermolecular packing forces on the intramolecular properties, such as metal–ligand bond lengths and angles. The pressure-induced decrease of

© 2004 NRC Canada

$\Delta Q_{O=Re=O}$ was found to be -6×10^{-5} Å/kbar, much smaller than determined for substituted ethylenediamine complexes of rhenium(V), where this decrease is on the order of -1×10^{-4} Å/kbar (9). This previous study showed that as luminescence energies increase, bandshapes become more harmonic and the decrease of $\Delta Q_{O=Re=O}$ became smaller, and the title complex confirms this trend.

In contrast, the pressure-induced red shift of the luminescence band maximum is much larger (16 ± 2 cm^{-1}/kbar) than determined for *trans*-dioxo rhenium(V) complexes with substituted ethylenediamine ligands, with red shifts of less than 10 cm^{-1}/kbar (9). We attribute this large red shift to the ancillary pyridine ligands that form strong π bonds with the metal center, illustrating that both interactions between electronic states (9) and the detailed nature of the metal–ligand bonds can be probed via the observed pressure effects on the luminescence spectra of *trans*-dioxo complexes.

Conclusion

The *trans*-[ReO_2(pyridine)$_4$]I luminophore is an excellent system to study the effect of an external perturbation on the resolved vibronic luminescence spectrum at room temperature because of the sensitivity of its luminescence properties to the crystalline environment. We find that the luminescence energies of complexes with monodentate ligands that have strong π-bonding interactions with the metal center, such as pyridine, are more susceptible to changes in the crystalline environment whereas *trans*-[ReO_2]$^+$ complexes with chelating and weakly π interacting ligands tend to show smaller variations. The analysis of less-resolved room-temperature spectra with one-dimensional potential energy surfaces reveals the effects of pressure on the spectroscopic parameters defining the ground and emitting states. These subtle aspects of metal–ligand bonding can be quantitatively derived from the temperature- and pressure-dependent luminescence spectra of related *trans*-dioxo complexes.

The dependence of thymine and thymidine Raman spectra on solvent[1]

L. Beyere, P. Arboleda, V. Monga, and G.R. Loppnow

Abstract: Recent work has focused on developing Raman spectroscopy as a noninvasive probe of DNA interactions with solvents, intercalants, proteins, and other ligands. Here, we report the Raman spectra of thymine in eight solvents and thymidine in nine solvents obtained with visible excitation. Raman spectra under acidic, neutral, and basic conditions were also obtained of both thymine and thymidine. Changes in both the frequencies and intensities of several of the vibrational bands in the 800–1800 cm^{-1} region are observed. No evidence of deprotonation in the different solvents is observed for either thymine or thymidine. Correlations of the observed frequency shifts of specific vibrational modes with characteristic properties of the solvent for both thymine and thymidine show a significant correlation with acceptor and donor numbers, measures of the hydrogen-bonding ability of the solvent, in both thymine and thymidine. These results are interpreted in terms of hydrogen-bonding interactions between the N-H protons of the thymine base and lone pairs of electrons on the solvent molecules and between the solvent hydrogens and lone pairs on C=O sites. The solvent-dependent intensity in vibrational bands of thymine between 1500 and 1800 cm^{-1} indicates a strong interaction between thymine and solvent at the C=O and N-H sites that leads to separation of the C=O stretches from the C=C stretch. The intensity variations with solvent were much smaller for thymidine than for thymine, perhaps as a result of replacing the N_1 proton by the sugar. These results suggest that Raman spectroscopy is uniquely sensitive to specific interactions of thymine and thymidine with their environment.

Key words: Raman spectroscopy, thymine, thymidine, solvent effects, hydrogen bonding.

Résumé : Un récent travail a été orienté vers le développement de la spectroscopie Raman comme sonde non invasive des interactions de l'ADN avec des solvants, des intercalants, des protéines et d'autres ligands. Dans ce travail, on a mesuré les spectres Raman de la thymine dans huit solvants et de la thymidine dans neuf solvants, obtenus à l'aide d'une excitation visible. On a aussi déterminé les spectres Raman de la thymine et de la thymidine dans des milieux acide, neutre et basique. On a observé des changements tant dans les fréquences que dans les intensités de plusieurs bandes vibrationnelles dans la région de 800 à 1800 cm^{-1}. On n'a observé aucun donnée pouvant laisser croire qu'il se produit une déprotonation de la thymine ou de la thymidine dans les différents solvants. Des corrélations entre les propriétés caractéristiques des solvants et les déplacements de fréquence observés pour des modes vibrationnels spécifiques tant de la thymine que de la thymidine présentent une corrélation significative avec les nombres de donneur et d'accepteur, des mesures du pouvoir d'un solvant à former des liaisons hydrogènes tant avec la thymine qu'avec la thymidine. On interprète ces résultats en fonction d'interactions de liaisons hydrogènes entre les protons N-H de la base, la thymine, et les paires d'électrons libres des molécules de solvant et entre les hydrogènes du solvant et les paires libres des sites C=O. L'intensité qui varie en fonction du solvant des bandes vibrationnelles de la thymine entre 1500 et 1800 cm^{-1} est un reflet d'une interaction forte entre la thymine et le solvant au niveau des sites C=O et N-H qui conduit à une séparation des bandes d'élongation C=O par rapport à la bande d'élongation C=C. Les variations d'intensité en fonction du solvant sont beaucoup plus faibles dans le cas de la thymidine que dans celui de la thymine et ceci est peut-être le résultat du remplacement du proton en N_1 par un sucre. Ces résultats suggèrent que la spectroscopie Raman comporte une sensibilité unique aux interactions spécifiques de la thymine et de la thymidine dans leur environnement.

Mots clés : spectroscopie Raman, thymine, thymidine, effets de solvant, liaison hydrogène.

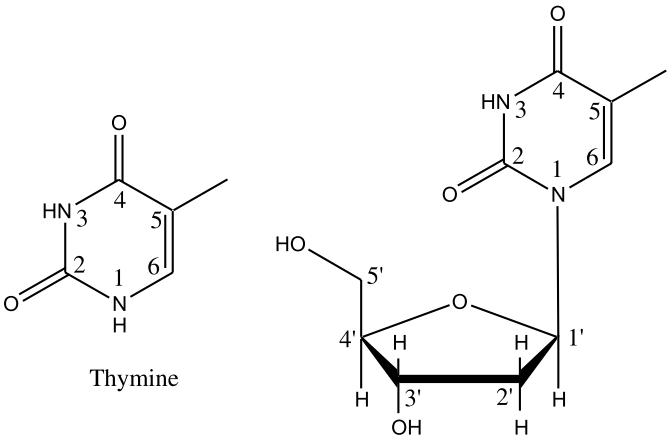
Introduction



Thymidine (1-[2′-deoxy-β-ribofuranosyl]-5-methyluracil) is one of the four nucleoside constituents of DNA and consists of 2′-deoxyribose attached to the pyrimidine base thymine (2,4-dioxo-5-methylpyrimidine) (Scheme 1). The pyrimidine nucleosides are more photochemically active than their purine counterparts, with thymidine and its derivatives being the most photochemically active (1). Of the pyrimidine bases, thymine is particularly prone to damage by UV light, forming a variety of photoproducts such as cyclobutane photodimers, 6–4 photoproducts, spore photoproducts, and photohydrates (2, 3). Many aspects of the photophysical, photochemical, and photobiological properties of DNA and related compounds have been intensively studied (4–8), resulting in a large body of information on the various structural features of the photoproducts (9). However, most methods for detecting and quantifying DNA photodamage and repair, such as chromatography, gel electrophoresis, and immunological approaches (8, 10–12), are invasive and destructive. The ultimate aim of this work is to probe DNA structure and interactions using Raman spectroscopy, a noninvasive method.

Vibrational spectroscopy is a powerful probe of structure and interactions. For example, infrared (IR) absorption spectroscopy has been used to assign the IR-allowed vibrational modes of uracil and thymine (13–16). Raman vibrational spectroscopy, the inelastic scattering of light (17, 18), has been applied to DNA by a number of groups, in an effort to understand its structure and dynamics (16, 19–28). Raman spectroscopic studies of thymidine-containing molecules have also been performed, leading to the preliminary assignment of thymidine vibrational Raman bands (29–32). Advantage has been taken of the more selective and sensitive method of UV-resonance Raman spectroscopy to probe nucleic acids, their constituents, and related molecules (21, 24, 25). However, these studies have focused on the structure of nucleic acids, and few studies have explored the applicability of using Raman spectroscopy to probe nucleic acid interactions with different chemical environments and other molecules. The solvent dependence of the UV Raman spectrum of only adenine among the nucleobases has been reported (26). Recently, Raman spectroscopy with excitation at 532 nm has shown that thymines are particularly sensitive to the binding of HU protein to the minor groove of DNA (27).

Since thymine and thymidine both have proton-accepting and -donating sites, spectral changes are expected to result from their interaction with proton-acceptor and acceptor–donor solvents (33). Raman spectroscopy has been used recently to explore the dependence of the Raman spectra of ethyl 4-(dimethylamino)benzoate (DMABEE) (34) and of sunscreens (35) on solvent.

In this paper, we explore the Raman frequency shifts of thymine and thymidine as a function of solvent environment. Guided by an experimental assignment of the normal modes in thymine (28) and by solvent parameter scales, we attempt to elucidate the specific interaction sites of solvent molecules with thymine and thymidine in the condensed phase. Several of the observed thymine modes exhibit frequency shifts as a function of solvent parameters. Interestingly, the magnitude of the shifts in a particular solvent is different for different modes, suggesting that Raman spectroscopy is a structurally specific probe of solvent–thymine interactions. In addition, intensity changes in thymine C=O stretch-containing modes indicate particularly strong interactions with solvent. These results provide an important foundation for analyzing the spectra of nucleic acids in different chemical environments, which will eventually lead to developing Raman spectroscopy as a better probe of DNA interactions with other nucleic acids, proteins, and smaller molecules such as drugs and intercalants.

Scheme 1.

Experimental

Thymine and thymidine (99%) were obtained from the Sigma Chemical Company (St. Louis, Missouri) and used as received. Acetic acid (glacial), benzyl alcohol, *N*,*N*-dimethylformamide, ethanol, ethylene glycol, formamide, formic acid (88%), pyridine, trifluoroacetic acid, and water (deionized, 18 MΩ) were reagent grade or better from freshly opened bottles and were used without further purification. The important solvent parameters are collected in Table 1.

Room-temperature Raman spectra were obtained of freshly prepared solutions of thymine and thymidine in various solvents. Due to the differences in solubility of thymine and thymidine in the various solvents used, the concentration varied from a high range of 0.5–4 mol L^{-1} for the acidic solvents to a low range of 1–20 mmol L^{-1} in the other solvents (the highest concentration was 4 mol L^{-1} for thymidine in formic acid and the lowest concentration was ~1 mmol L^{-1} for thymine in pyridine), as determined from the UV–vis absorption measurements of the saturated solutions using ε = 10 200 L mol^{-1} cm^{-1} at 260 nm. Raman spectra were excited by 250 mW of 457.9 nm light from an Ar^+ ion laser (Coherent, Santa Clara, California) spherically focused on a 5 mm diameter (o.d.) spinning NMR tube in a 135° backscattering geometry (34, 36, 37) containing approximately 300 μL of the solution. Multichannel detection of the resulting Raman scattering was accomplished with a liquid-nitrogen-cooled, charged-coupled device (CCD) detector (Princeton Instruments, Trenton, New Jersey) coupled to the first half of a double monochromator (Spex, Metuchen, New Jersey).

Spectral slit widths were 5–7 cm^{-1} and typical spectral acquisition times were 1 h. UV–vis absorption spectra of the samples were measured using a diode array spectrophotometer (Hewlett-Packard, Sunnyvale, California) before and after irradiation. In addition, NMR spectra of thymine and thymidine in the perdeuterated forms of the solvents used here showed no perturbations from the NMR spectra of thymine and thymidine in D_2O. A solvent spectrum was subtracted from the spectrum of each solution, and the resulting spectrum was frequency calibrated by measuring the Raman scattering of solvents with known frequencies (acetone, benzene, carbon tetrachloride, and chloroform). The reported frequencies are accurate to ±1.5 cm^{-1}. The baselines were leveled by subtraction of multiple joined line segments. Raman spectra of freshly prepared saturated solutions of thymine in acid (0.31 mol L^{-1}, H_2O, pH ~ 3) and base (0.60 mol L^{-1}, H_2O, pH ~ 11) were also obtained under similar conditions.

Results

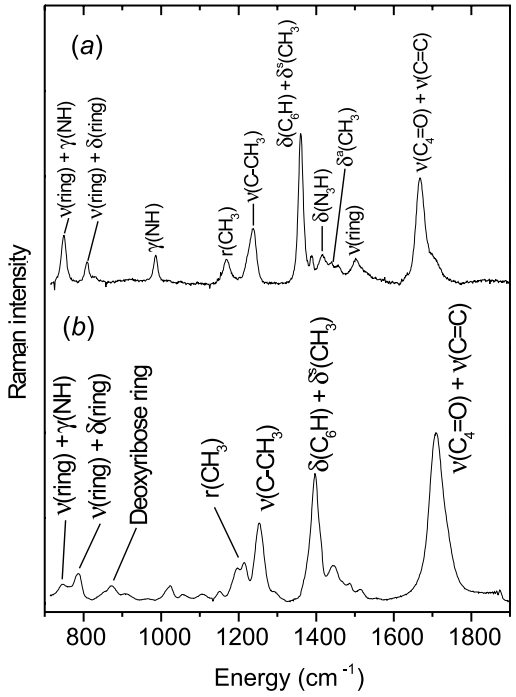

Figure 1 shows the Raman spectrum and vibrational assignments of thymine and thymidine in water for the 700–1800 cm^{-1} region. The Raman spectra of thymine and thymidine obtained in this work agree with previously reported Raman spectra (29–32). No significant bands due to thymine or thymidine are observed at frequencies above 1800 cm^{-1}. Very weak bands are observed below 700 cm^{-1}, too weak to determine accurate frequencies. Therefore, only the vibrational bands within the 700–1800 cm^{-1} region were considered. The vibrational assignments of thymine were determined earlier from an extensive isotopic labeling study (28). For thymidine, modes assigned to the 2′-deoxyribose sugar ring only and vibrations due to coupling of the base and sugar ring are based on Raman studies of thymidine (29–32), while the assignment of the 740, 787, 1180, 1235, 1372, and 1660 cm^{-1} modes to the thymine base are from an extensive isotopic labeling study of Zhang et al. (28).

For thymine, the 700–800 cm^{-1} region is dominated by bands assigned to ring-breathing modes of the thymine base, while more localized vibrations are observed from 800 to 1800 cm^{-1} (30). Several bands are observed in this latter region of the spectrum, arising mainly from ring stretches, as well as stretches, bends, wags, and rocks of the exocyclic groups (28). Because the vibrations in this region of the spectrum arise from all of the groups of the molecule, particularly the NH and CO groups that are expected to interact strongly with solvent, this "fingerprint" region should allow a determination of the interaction sites with solvent.

For thymidine, modes in the 800–1200 cm^{-1} region are thought to be localized on the 2′-deoxyribose sugar ring, while in the 1200–1600 cm^{-1} region we expect modes resulting from the coupling of the vibrational coordinates of the thymine base and the sugar ring (29–32). It is evident from the spectra in Fig. 1 that the Raman modes due to the sugar ring are very weak, the most intense peaks being those due to coupled vibrations of the base and sugar, and those due to the base only, with the mode assigned to the C=C and C=O double bond stretches of the base being the most intense. In fact, many of the same vibrations are observed in the Raman spectra of both thymine and thymidine, although they are

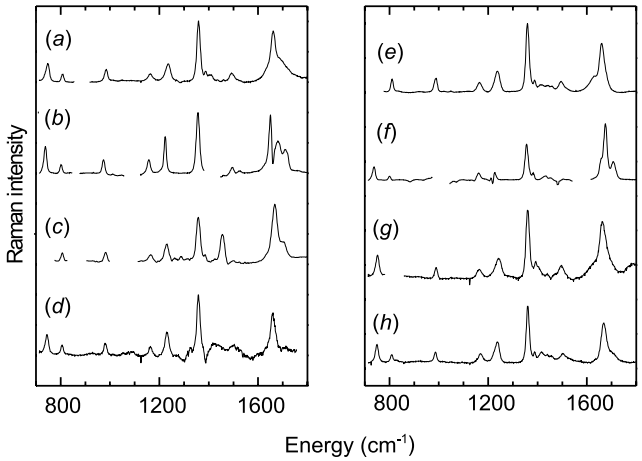
Fig. 1. Raman spectra of (*a*) thymine and (*b*) thymidine in water excited at 457.9 nm. The spectra are the sum of 3–9 scans, and a Raman spectrum of water has been subtracted. The vibrational assignments for thymine (28) and thymidine (28–32) are shown above the bands: ν stretch; δ in-plane bend; γ out-of-plane bend (wag); r rock. The superscripts "a" and "s" stand for asymmetric and symmetric, respectively.

shifted slightly to higher frequency in thymidine. This result suggests that the most intense modes arise from vibrations of the base with slight perturbations to the frequency by the sugar attached to N_1 instead of a proton. Thus, the intense modes at 1235, 1415, and 1690 cm^{-1} are assigned to the methyl stretch, $C_6H + CH_3$ deformation, and $C_4=O + C=C$ stretch of the thymine base, respectively.

To determine the sensitivity of Raman spectroscopy to specific solvent–solute interactions, and to identify the molecular sites of interaction with thymine, the Raman spectra of thymine dissolved in eight solvents and thymidine dissolved in nine solvents with a wide range of properties were obtained. Since thymine and thymidine each have multiple proton-accepting and proton-donating sites, their vibrations are expected to be sensitive to solvent interaction. The Raman spectra of the thymine and thymidine solutions are presented in Figs. 2 and 3. Table 1 lists the major fundamental and derived parameters of the solvents used. Good-quality spectra were obtained in all cases. In some solvents, Raman scattering from the solvent interfered with the precise determination of the data in some regions of the spectrum. These regions have been blanked out in Figs. 2 and 3. Examination of Figs. 2 and 3 shows that the general pattern of the Raman spectrum is the same in all of the different solvents. To ensure that no reaction was occurring between thymine and the solvent, UV-absorption and NMR spectra were taken of the thymine and thymidine solutions before and after irradiation in the Raman excitation laser beam. The absorption spectra of thymine and thymidine were similar, with

Fig. 2. Raman spectra of thymine in (*a*) glacial acetic acid, (*b*) *N*,*N*-dimethylformamide, (*c*) ethylene glycol, (*d*) formamide, (*e*) formic acid, (*f*) pyridine, (*g*) trifluoroacetic acid, and (*h*) water. Solvent spectra have been subtracted from each spectrum. The portions of each spectrum where no data are reported have been blanked out owing to strong solvent interference in those regions.



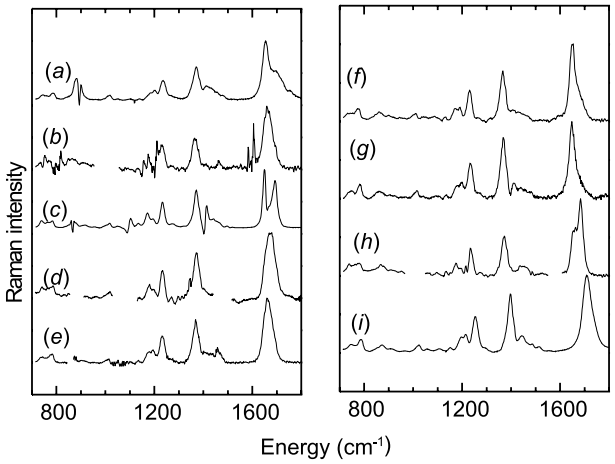


Fig. 3. Raman spectra of thymidine in (*a*) glacial acetic acid, (*b*) benzyl alcohol, (*c*) *N*,*N*-dimethylformamide, (*d*) ethanol, (*e*) ethylene glycol, (*f*) formamide, (*g*) formic acid, (*h*) pyridine, and (*i*) water. Solvent spectra have been subtracted from each spectrum. The portions of each spectrum where no data are reported have been blanked out owing to strong solvent interference in those regions.

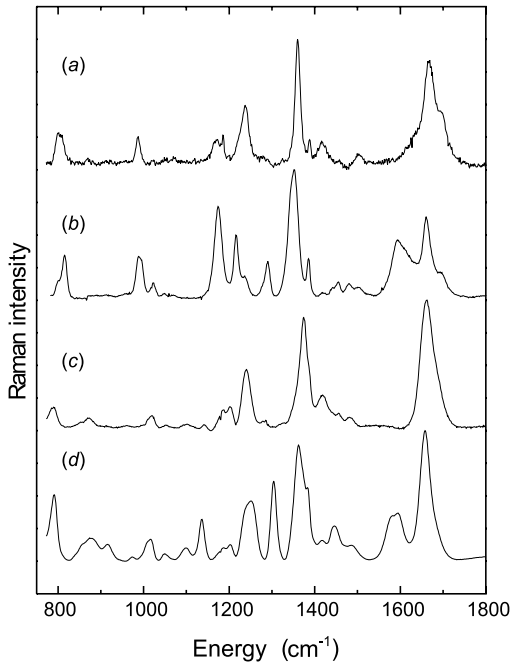
only slight absorption maxima shifts, in all of the solvents studied. Except for slight changes in coupling constants, expected from the different hydrogen-bonding properties of the solvents, no changes were seen in any ^1H NMR spectrum of fresh solutions or of solutions left sitting for 3–5 days. All of these observations suggest that there is no reaction between thymine or thymidine and any of the solvents used.

Although no major changes in the absorption or Raman spectra of thymine were observed in any solvent, there are obvious frequency shifts and relative intensity changes in the Raman spectra as a function of the solvent environment. The frequencies of the bands at ca. 740, 980, 1230, 1360, 1390,



© 2004 NRC Canada

and 1500 cm^{-1} all vary with the solvent (Fig. 2). In addition to these frequency shifts, striking changes in relative intensity also appear as a function of solvent. The most dramatic of these intensity changes occur in the 1600–1800 cm^{-1} region. In some solvents, such as acetic acid, water, trifluoroacetic acid, and formamide, a single peak is observed at ca. 1680 cm^{-1}. However, in other solvents, one or more additional peaks are seen in this region. For example, the band at 1680 cm^{-1} exhibits a high-frequency shoulder in ethylene glycol and pyridine, a low-frequency shoulder in formic acid and pyridine, and two or more peaks at higher frequency in *N*,*N*-DMF. The presence of a solvent peak at 1660 cm^{-1} in *N*,*N*-DMF (Fig. 2*c*) raises a doubt as to the assignment of these two new peaks to thymine in this solvent. However, in the subtraction, the three most intense solvent peaks at 865, 1406, and 1439 cm^{-1} were well subtracted and any contribution from the less intense 1660 cm^{-1} peak should have been completely removed. Hence, we assign the three peaks to actual thymine peaks, not to solvent subtraction artifacts. In addition to these dramatic changes, smaller changes in relative intensity also occur between the 1680 and 1360 cm^{-1} peaks in many of the solvents, in the 1230 cm^{-1} peak in *N*,*N*-DMF, and in the 1460 cm^{-1} peak in ethylene glycol.

For thymidine, similar spectral features are also observed in all the solvents (Fig. 3). Although there are no obvious major changes in the Raman spectra, some frequency shifts and slight intensity changes are observed. The frequencies of the bands at ca. 740, 787, 1140, 1180, 1450, and 1690 cm^{-1} all shift significantly with the solvent, while slight shifts occur for the modes at 867, 1100, and 1200 cm^{-1}. Some slight intensity changes are also evident, especially in the 1600–1800 cm^{-1} region. Two peaks appear in *N*,*N*-DMF, while a single peak appears around 1660 cm^{-1} in all the other solvents. As was observed for thymine, the presence of a solvent peak at 1660 cm^{-1} in *N*,*N*-DMF (Fig. 3*c*) raises a doubt as to the assignment of the two peaks in this region to thymidine. However, in the subtraction, the three most intense solvent peaks at 865, 1406, and 1439 cm^{-1} were well subtracted, and any contribution from the less intense 1660 cm^{-1} peak should have been completely removed. Hence, we assign the two peaks to thymidine, and not to solvent subtraction artifacts. In pyridine, a low-frequency shoulder is seen, while for acetic acid a high-frequency shoulder is observed. However, there is very little change in the relative intensities of the 1660 cm^{-1} peak to the 1240 and (or) the 1450 cm^{-1} peak.

Since the most logical interaction of solvent with thymine or thymidine would be a hydrogen-bonding interaction, because of the extensive number of sites on thymine where hydrogen bonding can occur, Raman spectra were also obtained of thymine and thymidine at low and high pH. These spectra in the 800–1800 cm^{-1} region are presented in Fig. 4. The Raman spectra of thymine at neutral and acidic pH (pH ~ 3) were essentially identical, so only the spectrum at neutral pH is shown. This was similarly true for thymidine. However, significant differences between the Raman spectra at neutral and basic pH are observed for both thymine and thymidine. In the pH range 2–11, thymine is neutral in the acidic region and negatively charged in the alkaline region (38). Therefore, at the pH used in this study (pH ~ 11), thymine exists mostly as the monovalent anion, since the N_3 pK_a of thymine is 10.0 (38). The Raman spectrum at pH ~ 11 therefore represents a weighted mixture of the spectra for the monovalent anion and neutral. The largest differences between the neutral and basic thymine Raman spectra are the presence of two strong new bands at 1290 and 1593 cm^{-1} and an increase in intensity of the band at 1160 cm^{-1} in the high-pH spectrum. Thus, the presence of the two new bands can be used as a diagnostic for the deprotonation of thymine in the solvents used in this study. Since none of the spectra in Fig. 2 show bands at either 1290 or 1593 cm^{-1}, no deprotonation of thymine occurs in any of the solvents tested.

Fig. 4. Raman spectra of thymine in (*a*) neutral and (*b*) basic aqueous solution, and thymidine in (*c*) neutral and (*d*) basic aqueous solution. The Raman spectra of thymine and thymidine in acidic solution were indistinguishable from those in neutral solution. A solvent spectrum has been subtracted from each spectrum.

A comparison of the neutral and base spectra of thymidine (Figs. 4*c* and 4*d*) to those of thymine shows great similarities. This is expected, since thymine is the main contributor to the Raman spectrum of thymidine. For thymidine, three new strong bands are seen at 1136, 1303, and 1594 cm^{-1} in the basic spectrum, which are not present in the neutral spectrum. A number of bands also experience relative intensity changes such as the bands at 1100 and 1450 cm^{-1}. Because thymidine can be deprotonated–protonated at the N_3-H site, which has a pK_a of 9.93 (38, 39), thymidine exists mostly as the monovalent anion at the pH ~ 11 used for this study. Thus, the presence of these three new bands in the basic pH spectrum can be used as a diagnostic for the deprotonation of the thymidine in the other solvents used for this study. Since the 1136, 1303, and 1594 cm^{-1} bands are not observed in any of the spectra in Fig. 3, we conclude that no deprotonation of thymidine occurred in any of the solvents used for the study.

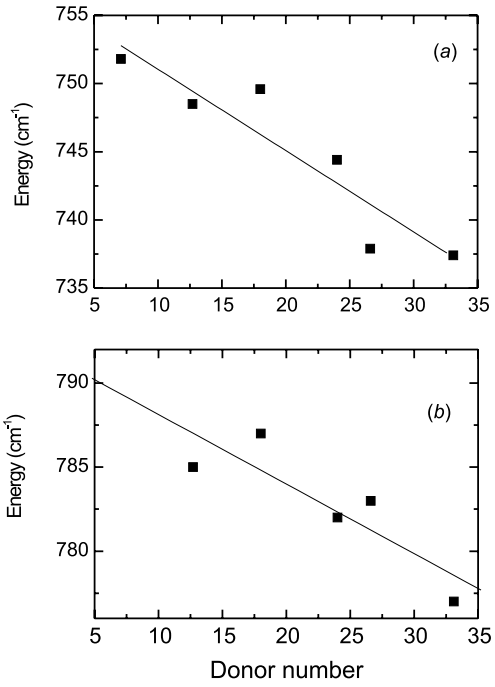
Discussion

Frequency changes with solvent

To understand the significant changes in the Raman spectra of thymine and thymidine observed in Figs. 2 and 3 as a function of environment, correlations were obtained between the observed Raman frequencies and the solvent properties (Table 1) expected to be important in solvent–solute interactions, such as polarity, polarizability, and hydrogen bonding. Tables of all the resulting correlation coefficients are given in the supplementary information.[3] From these results, it is clear that only two solvent properties are well-correlated with the observed frequency shift in thymine, acceptor number (AN) and donor number (DN), generally thought to be measures of hydrogen-bonding ability of the solvent with solute. No correlations greater than 0.75 were obtained between any of the "nonspecific" solvent properties, such as polarity (ε, *K*) and polarizability (*n*, *L*), or mixed terms (ε_p, *KL*), and the vibrational frequency of any thymine mode, except between the 1500 cm^{-1} mode and ε, a measure of solvent polarity. The acceptor numbers are derived from ^{31}P NMR chemical shifts of triethylphosphine oxide (Et_3PO) (40):

$$[1] \qquad AN = 100\delta_{corr}/\delta_{corr}(Et_3PO{\cdot}SbCl_5) = (2.348)\delta_{corr}$$

where δ_{corr} ($Et_3PO{\cdot}SbCl_5$) = 42.59 ppm and acceptor numbers range from 0 (hexane) to 100 ($SbCl_5$). Donor numbers are obtained directly from calorimetric measurements with $SbCl_5$ and are defined as the molar enthalpy value for the reaction of the donor (D) with $SbCl_5$ as a reference acceptor in 10^{-3} mol L^{-1} solution of dichloroethane (40):



$$[2] \qquad D + SbCl_5 = D{\cdot}SbCl_5 \ (-\Delta H_{D\cdot SbCl_5} \equiv DN)$$

Donor numbers can also be inferred indirectly from ^{23}Na NMR chemical shifts of $NaClO_4$ (40).

Correlation coefficients of 0.83 or greater are observed for the 740, 980, 1230, 1360, and 1390 cm^{-1} modes with both solvent donor and acceptor numbers for thymine. This clear correlation with acceptor and donor numbers indicates the interaction between thymine and solvent is a *specific* interaction, nominally involving hydrogen bonding. The correlation between the 740 cm^{-1} mode frequency for thymine and donor number is shown in Fig. 5*a*. Figure 5*b* shows the correlation between the 740 cm^{-1} mode frequency of thymidine and donor number.

The nature of the vibrations affected by the hydrogen-bonding properties of the solvent can be used to determine the sites of interaction between thymine and solvent. The modes at 740, 980, and 1390 cm^{-1} all contain contributions from NH bending vibrations, either in-plane or out-of-plane (Fig. 1). The sensitivity of these NH vibrations to the hydrogen-bonding ability of the solvent is expected and indicates solvent donation of a pair of electrons involved in a hydrogen bond at the hydrogens on the N_1 and (or) N_3 nitrogens. The mode at 1230 cm^{-1} is the isolated C_5-$C_\alpha H_3$ stretch and correlates very well with solvent hydrogen-bonding strength. It is difficult to imagine why this should be so. This result may indicate that this C-C stretching internal coordinate is also mixed with N-H internal coordinates. Significant hydrogen-bonding correlation is also observed for the 1360 cm^{-1} mode, which has been assigned to $\delta(C_6H) + \delta(C_\alpha H_3)$. This could be due to the influence of the π electrons from the $C_5{=}C_6$ bond, although the $C_5{=}C_6$ stretch itself does not appear to be sensitive to solvent hydrogen bonding.

Fig. 5. Correlations of the Raman frequency with donor number, a measure of hydrogen bonding ability of the solvent, for (*a*) thymine (r = –0.93) and (*b*) thymidine (r = –0.86). The correlations presented here have some of the largest correlation coefficients of all of the solvent parameters tested.

As observed in Fig. 3, there are some significant frequency shifts in the Raman spectra of thymidine with solvent. As with thymine, correlations (supplementary information)[3] were obtained between the observed Raman frequencies and solvent properties to understand the molecular origin of these shifts. Again, only a few solvent properties correlate well with the observed frequency shifts. The modes at 740, 787, 1450, and 1690 cm^{-1} all correlate very well with the acceptor and (or) donor numbers. These modes are due to vibrations of the thymine base only or to coupling of the base and sugar ring. However, none of the sugar ring modes correlates well with the solvent property of hydrogen bonding, although the 1180 cm^{-1} mode correlates well with acceptor number (r = –0.87). This results suggests that the proton-accepting and (or) -donating sites of the molecule localized on the thymine base are more solvent-sensitive than those on the sugar ring. There is also significant correlation between several thymidine modes and nonspecific solvent properties such as the 787, 1100, 1200, and 1690 cm^{-1} modes with polarizability (*n*, *L*, Π), 1180 and 1450 cm^{-1}

[3] Supplementary data may be purchased from the Directory of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada (http://www/nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically).

modes with dipolarity (π^*/π^*II), and 1140 cm^{-1} mode with polarity (Θ).

Therefore, unlike in thymine where good correlation is only observed between certain modes and the specific solvent property of hydrogen bonding, good correlation of the observed frequency shifts with a few nonspecific solvent properties, such as polarity and polarizability, exists for thymidine. Here, we are only considering the dynamic, or AC, component of the polarizability in the high-frequency optical range. We attribute this correlation difference with nonspecific solvent properties between thymine and thymidine as being due to the larger size of the thymidine molecule compared with the smaller thymine molecule. The somewhat surprising fact that the modes most sensitive to polarizability are those localized on the thymine moiety may be more related to the absence of intense sugar modes in the Raman spectra excited here in the visible than to any inherent insensitivity of the sugar modes to solvent. Resonance Raman spectra at wavelengths below 200 nm or near-IR excited Raman spectra may be more sensitive to the sugar modes and reveal the solvent dependence, if any, of these modes.

While it is difficult to explain all these varied correlations of several modes with numerous and diverse solvent properties, it is clear that the modes that correlate very well with acceptor and donor numbers, i.e., the 740, 787, 1180, 1450, and 1690 cm^{-1} modes, are due mainly to the N_3-H and C=O sites or contain contributions from these sites. These results are similar to those obtained for thymine, where all the modes with N-H contributions showed good correlation with acceptor and donor numbers. This clear correlation suggests that the major interaction between thymidine and solvent is a specific interaction involving hydrogen bonding.

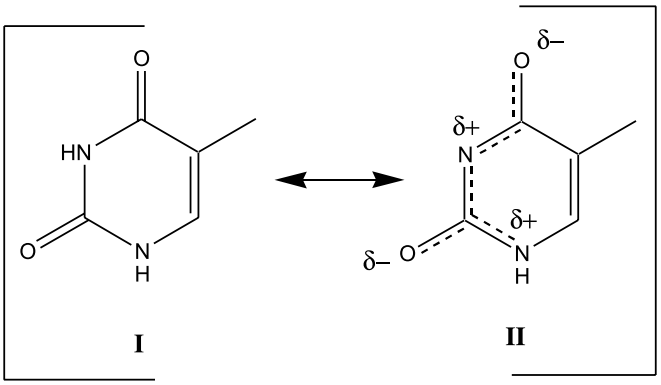
Intensity changes with solvent

Similar arguments can be used to understand the relative intensity changes in the 1600–1800 cm^{-1} region. The two CO stretches $\nu(C_2{=}O)$ and $\nu(C_4{=}O)$ as well as the $\nu(C_5{=}C_6)$ bands are all expected in this region. The most intense peak in this region around 1680 cm^{-1} in all the spectra in Figs. 2 and 3 has been assigned to $\nu(C_4{=}O)$ coupled with $\nu(C_5{=}C_6)$ from an extensive isotopic labeling experiment (28). Spiro and co-workers (21, 41) reported from UV-resonance Raman experiments on thymine and its derivatives that, at longer excitation wavelengths (240–266 nm), a single broad band appears around 1665 cm^{-1}. However, with shorter wavelength excitation (218, 200 nm), a narrower band is observed at 1648 cm^{-1}, with a shoulder at 1700 cm^{-1}. They interpreted the results to show that the $\nu(C_5{=}C_6)$ and $\nu(C_4{=}O)$ were coupled or degenerate in water solutions to give a single peak at 1665 cm^{-1} and the $\nu(C_2{=}O)$ vibration gave the band at 1700 cm^{-1}. This is an indication that the $\nu(C_4{=}O)$ is part of the composite band at 1665 cm^{-1}, in agreement with our assignment of the mode around 1680 cm^{-1} in our spectra to accidentally degenerate $\nu(C_4{=}O)$ and $\nu(C_5{=}C_6)$ (33). While these assignments may imply that the peaks are due to localized internal coordinates, in reality, they should be regarded as due to normal modes with different contributions from each internal coordinate, with, say, the $\nu(C_5{=}C_6)$ contribution being dominant for the 1680 cm^{-1} peak. Also, the lack of correlation between the mode at 1680 cm^{-1} and any property of the solvent supports a previous assignment of this mode in the Raman spectrum primarily to the C=C vibration, which should be relatively insensitive to solvent polarity, polarizability, and (or) hydrogen bonding. This result suggests that the C=O contribution to this band's intensity is minimal, as the C=O stretch is expected to be solvent sensitive. This assignment is confirmed by spectral intensity changes in this region.

There are three possible explanations for the spectral intensity changes observed in the 1600–1800 cm^{-1} region: symmetry breaking of the vibrational bands due to strong solvent–solute interactions, interaction at the C=O sites only, and (or) interaction with both the N-H and C=O sites. Johnson and Myers (42, 43) observed in resonance Raman experiments for the photodissociation of I_3^- that, in addition to the allowed symmetric stretch band seen in all the solvents, the symmetry-forbidden asymmetric stretch was also observed in ethanol, the most polar solvent used. This was attributed to solvent-induced symmetry breaking of the "chromophore", effectively lowering its symmetry and giving some allowed character to the nominally forbidden bands. However, in our results, a doublet appears in the less or non-polar solvents such as *N*,*N*-DMF and pyridine, while a single peak is seen in the more polar, hydrogen-bonding solvents of water, formamide, and trifluoroacetic acid. Therefore, the intensity changes observed in our spectra cannot be due to solvent-induced symmetry breaking, as they are inconsistent with increased symmetry breaking as the solvent polarity increases.

The second possible cause for these intensity changes is interaction of the solvent with the C=O sites alone of thymine. UV-resonance Raman (UVRR) experiments on nucleobase derivatives in several solvents (33) have shown that, for uracil, the $\nu(C_5{=}C_6)$ appears at 1620–1630 cm^{-1} in all the solvents, with little or no frequency shift with solvent. The $\nu(C_4{=}O)$ band at 1673 cm^{-1} in water was seen to shift to higher frequency, however, as the polarity of the solvents decreased, an indication of a stronger C=O bond and a weaker hydrogen bonding of the solvent at the C=O sites. For thymine, only one band is observed at 1600–1800 cm^{-1} in the polar solvents water and methanol, around 1665 cm^{-1} in the UVRR spectrum, assigned to overlap of the $\nu(C_4{=}O)$ and $\nu(C_5{=}C_6)$. Because the $\nu(C_5{=}C_6)$ is shifted to higher frequency in thymine compared with uracil (22), due to the electron-donating effect of the C_5-$C_\alpha H_3$ group, it overlaps with the $\nu(C_4{=}O)$ in the polar solvents, giving rise to a single peak. The $\nu(C_2{=}O)$ has a weak Raman signal, which only has intensity at excitation wavelengths of 218 nm and below. However, in non-hydrogen-bonded solvents such as 1,4-dioxane and chloroform, doublets are seen with the $\nu(C_5{=}C_6)$ well-separated from the $\nu(C_4{=}O)$. Because of weaker or no hydrogen bonding at the C=O sites in these low-polarity or non-polar solvents, the $\nu(C_4{=}O)$ vibration shows up well-separated and at higher frequency than the unshifted $\nu(C_5{=}C_6)$. Although these results were obtained in UVRR experiments, we observe similar spectral features in the 1600–1800 cm^{-1} region in our Raman data. Therefore, the single peak observed in the polar solvents of water, trifluoroacetic acid, formamide, and formic acid in the 1600–1800 cm^{-1} region (Fig. 2) is due to interaction of the solvent with the C=O sites, lowering the $\nu(C_4{=}O)$ and making it

© 2004 NRC Canada



overlap with the $\nu(C_5{=}C_6)$. The doublets in pyridine and *N*,*N*-DMF, which have low H-bonding capability as shown by their lower acceptor numbers (Table 1), result from separation of the $\nu(C_5{=}C_6)$ from the $\nu(C_4{=}O)$, which appears at a higher frequency owing to less or no interaction in these solvents. However, interaction solely at the $C_4{=}O$ bond does not explain the frequency shifts and sensitivity of the N-H modes with the solvent. From the comparison of the spectra in Fig. 2 to the base spectrum of thymine in Fig. 4*b*, we conclude that thymine is not deprotonated in any of the solvents. Depending on the polarity of the solvent and the extent of the interaction mainly at the N_3-H site, the electronic structure of thymine may resemble a zwitterionic or neutral thymine in solution (Fig. 6). Increased interaction at the C=O sites would be expected to stabilize the zwitterionic structure in Fig. 6. Since the N-H bends are not directly affected, it is unclear how this interaction could explain the sensitivity of the N-H deformations and wags to the solvent. The dramatic intensity changes cannot therefore be completely explained only by H-bonding with solvent at the C=O sites.

The only other possible explanation for the intensity changes observed is a strong interaction of solvent with the C=O and N-H sites of thymine. This explanation can best be understood by considering the resonance structures of thymine. In polar solvents, the zwitterionic structure (Fig. 6) is expected to dominate, lowering the $\nu(C_4{=}O)$ band and making it overlap with the $\nu(C_5{=}C_6)$. This gives rise to a single peak in these solvents. However, in the less or non-polar solvents, because of little or no electron-pair donation to the N_3-H site, the neutral resonance structure of thymine (Fig. 6) dominates, giving rise to a higher frequency $\nu(C_4{=}O)$ band, which is well-separated from the $\nu(C_5{=}C_6)$, and a doublet is observed in these solvents. Again, this interaction only accounts for the intensity changes in the 1600–1800 cm^{-1} region and does not explain the changes in the N-H modes as a function of solvent observed in our results. As suggested by Zhang et al. (28), the peaks in the 1600–1800 cm^{-1} region may not be due to localized internal coordinates or overlapping bands but may be due to mixed and (or) coupled vibrational modes. It is, therefore, also possible that the spectral changes observed are due to solvent "turning on" intensity in weak and (or) forbidden modes, such as the $\nu(C_2{=}O)$. However, since this band has a weak Raman signal and is only strongly enhanced at shorter excitation wavelengths, the contribution of this effect is minimal.

We, therefore, conclude that the intensity changes observed in thymine are not due to solvent-induced symmetry breaking but are rather a result of the interaction of solvent with thymine at both the C=O and N-H sites. This leads to a weakening of the $\nu(C_4{=}O)$ frequency in the polar solvents, resulting in an overlap with the $\nu(C_5{=}C_6)$ and giving rise to a single peak. However, the interaction of solvent with thymine at these sites also results in the frequency shifts and good correlation of the N-H modes with solvent as shown by the sensitivity of the N-H modes to acceptor and donor numbers.

Some intensity changes in the Raman spectra of thymidine as a function of solvent are observed mainly in the 1600–1800 cm^{-1} region. As in the case of thymine, a peak appears around 1660 cm^{-1} in all the spectra in Fig. 3, assigned to the $\nu(C_4{=}O)$ coupled with the $\nu(C_5{=}C_6)$ (21, 25, 29). Again, we note that these assignments do not refer to localized internal coordinates but to normal modes with different contributions from each internal coordinate. Hence, the contribution of the $\nu(C_5{=}C_6)$ internal coordinate is dominant for the 1660 cm^{-1} mode, with the $\nu(C_4{=}O)$ contribution to the intensity of this band being minimal as shown by the lack of correlation of this band with any solvent property, and the $\nu(C_2{=}O)$ contribution being negligible, since it has a weak Raman signal, which only has intensity at excitation wavelengths of 218 nm and below. While a single peak is observed in the more polar and (or) hydrogen-bonding solvents such as water, formamide, formic acid, and the alcoholic solvents, a doublet appears in the less or non-polar solvents pyridine and *N*,*N*-DMF. However, it is not clear why a doublet appears in acetic acid, a very polar solvent. Acetic acid is known to associate in solution, forming dimers and to a smaller extent higher polymers (44–47). The dimerization is due to the formation of hydrogen bonds between two or more monomers of acetic acid. In fact, IR spectra have been reported (46, 47) for acetic acid solutions in carbon tetrachloride where absorption bands for monomers and dimers were observed. Hence, dimer formation by acetic acid may make it interact to a lesser extent with thymidine, as is the case for the non-polar solvents, resulting in the doublet and (or) higher shoulder peak. As in the case of thymine, based on UVRR experiments on nucleobase derivatives in several solvents (33), these intensity changes are due partly to the interaction of solvent with thymidine at the C=O sites. This interaction weakens the C=O bond strength, leading to a lowering of the $\nu(C_4{=}O)$ frequency in the polar solvents that causes it to overlap with the $\nu(C_5{=}C_6)$, giving rise to a single peak. In the less polar solvents, due to less or no interaction of solvent with thymidine, the $\nu(C_4{=}O)$ appears at a higher frequency, well-separated from the $\nu(C_5{=}C_6)$, and gives rise to a doublet in these solvents. However, interaction of solvent solely at the $(C_4{=}O)$ site cannot explain the dramatic intensity changes observed, nor does it account for the sensitivity of the N_3-H modes to solvent. A comparison of the spectra in Fig. 3 to the base spectrum in Fig. 4*d* shows that thymidine is not deprotonated in any of the solvents. Again, as in thymine, depending on the polarity of the solvent, there is electron pair donation to the proton at the N_3 site, leading to a change in the balance of resonance structures between a zwitterionic and a neutral thymine spe-

Fig. 6. Neutral and zwitterionic resonance structures of thymine.

cies in solution (Fig. 6). Increased interaction at the C=O sites would be expected to stabilize the zwitterionic structure, weakening the (C_4=O) bond strength, making the $\nu(C_4=O)$ appear at a lower frequency and thus overlapping with the $\nu(C_5=C_6)$ in the polar solvents. These observed intensity changes can only be explained by interaction of solvent with thymidine at both the C=O and N_3-H sites. Since the zwitterionic species is a better representation of thymine in the more polar solvents, the $\nu(C_4=O)$ stretch, with its weaker (C_4=O) bond, appears at a lower frequency and overlaps with the $\nu(C_5=C_6)$ stretch. Hence, a single peak is observed in these solvents. However, in the less polar solvents, owing to less or no interaction of solvent with thymidine, the neutral species predominates. Therefore, the $\nu(C_4=O)$ stretch, with its stronger bond, appears at higher frequency, well-separated from the $\nu(C_5=C_6)$ stretch. We, therefore, conclude that the interaction of thymidine with solvent results in frequency shifts and slight intensity changes. The major interaction is at the proton-accepting and -donating sites of the thymine base, i.e., at both the N_3-H and C=O sites, with little or no apparent interaction with the proton-accepting and -donating sites of the sugar ring.

Conclusion

In this paper, the Raman spectra of thymine in eight solvents and thymidine in nine solvents were obtained with visible excitation. Spectra of both thymine and thymidine under acidic, neutral, and basic conditions were also obtained. Correlations of the observed frequency shifts of specific vibrational modes with characteristic properties of the solvent for both thymine and thymidine show that a significant hydrogen-bonding interaction occurs between the N-H protons of the thymine base and lone pairs of electrons on the solvent molecules and between the solvent hydrogens and lone pairs on C=O sites. The solvent-dependent intensity of vibrational bands of thymine between 1500 and 1800 cm^{-1} indicates a strong interaction between thymine and solvent at the C=O and N-H sites that leads to separation of the C=O stretches from the C=C stretch. The intensity variations with solvent were much smaller for thymidine than for thymine, perhaps as a result of replacing the N_1 proton by the sugar. These results suggest that Raman spectroscopy is uniquely sensitive to specific interactions of thymine and thymidine with their environment and that it may be a useful technique in probing DNA binding of intercalants, proteins, and other substances.

A computational study of a cyano-bridged dinuclear ruthenium complex containing the non-innocent methylpyrazinium ligand[1]

A.B.P. Lever

Abstract: The properties of a series of complexes *trans*-[LRu(NH_3)$_4$-NC-Ru(NH_3)$_4$(methylpyrazinium)]$^{n+}$ where L is an anion (Cl^-, F^-, CN^-, OH^-) or neutral ligand (CO, H_2O, pyridine, CH_3NO_2) were analyzed using density functional theory. The objective was to probe the change in electronic coupling between the two ruthenium atoms and between ruthenium and the non-innocent methylpyrazinium ligand as L is varied. Molecular orbital coefficients and optical spectra were derived. The electronic interactions involved are seen to be quite sensitive to the charge on the ruthenium to which the ligand L is attached as L is varied. Exchange (*K*) and Coulomb (*J*) energies are also calculated, using the INDO/S model, for the various metal-to-ligand charge-transfer transitions. *K* correlates well with the energy and intensity of the transitions and specifically with the variation in delocalization induced by variation of L.

Key words: DFT, ruthenium, non-innocent ligand, methylpyrazinium, ZINDO.

Résumé : Faisant appel à la théorie de la densité fonctionnelle, on a analysé les propriétés d'une série de complexes *trans*-[LRu(NH_3)$_4$-NC-Ru(NH_3)$_4$(méthylpyrazinium)]$^{n+}$ dans lesquels L est un anion (Cl^-, F^-, CN^-, OH^-) ou un ligand neutre (CO, H_2O, pyridine, CH_3NO_2). L'objectif était d'étudier le changement dans le couplage électronique entre les deux atomes de ruthénium ainsi qu'entre le ruthénium et le ligand méthylpyrazinium qui n'est pas innocent en fonction d'une variation de L. On en a dérivé les coefficients d'orbitales moléculaires et les spectres optiques. On a observé que lors des variations de L, les interactions électroniques impliquées sont très influencées par la charge portée par le ruthénium sur lequel le ligand L est attaché. Faisant appel au modèle INDO/S, on a aussi calculé les énergies d'échange (*K*) et de Coulomb (*J*) pour diverses transitions de transfert de charge du métal au ligand. Il existe une bonne corrélation entre les valeurs de *K* et l'énergie et l'intensité des transitions et, plus spécifiquement, avec la variation dans la délocalisation induite par une variation de L.

Mots clés : théorie de la densité fonctionnelle, ruthénium, ligand non innocent, méthylpyrazinium, ZINDO.

[Traduit par la Rédaction]

Introduction

We have been interested in developing methods to describe the electronic coupling in ruthenium complexes of π-accepting ligands, especially so-called non-innocent ligands (1–14). For the most part, these studies have involved mononuclear ruthenium species except for a couple of recent studies (5, 12). We are now concerned with exploring how information might be electronically transmitted along a chain by modifying the terminus L of the species *trans*-[LRu^{II}(NH_3)$_4$-NC-Ru^{II}(NH_3)$_4$(Mpz+)]$^{n+}$ (**I**) (Mpz+ = methylpyrazinium; L = Cl^-, OH^-, CN^-, F^-, CH_3CN, CO, pyridine, CH_3NO_2, H_2O; *n* = 4 or 3 depending on whether L is neutral or mononegative). Both density functional theory (DFT) (15–17) and the semiempirical INDO/S in its Zerner manifestation (ZINDO) (18–22) have been employed in our studies.

The bonding between ruthenium(II) and the methylpyrazinium ligand has long been a subject of interest (14, 23–29). Two relevant crystal structures have been reported. In the species [Ru^{II}(NH_3)$_5$(Mpz+)]I_3, the Ru—N(Mpz) bond distance is reported (14) to be as short as 195 pm, supposedly as a consequence of strong π-back-donation. On the other hand, in the species *trans*-RuCl(pdma)(phen)(Mpz+)]$^{2+}$ (pdma = 1,2-phenylenebis(dimethylarsine), phen = 1,10-phenanthroline) the distance is 202 pm (30).

The title dinuclear complexes are, as yet, experimentally unknown. Yet, the predictive capabilities of both the INDO/S and DFT methods have been shown (1–13, 31–39, 39–47) to be sufficiently precise that the overall properties of these species can be deduced without proceeding to the laboratory. Previously, we demonstrated that a good to excellent agreement can be achieved between the experimental optical spectra of ruthenium(II) complexes and those predicted by time-dependent density functional response theory (TD-DFRT) or INDO/S. Certainly, the future of chemistry will involve computation followed by the laboratory synthesis only of specifically desired species. The geometries of the complexes were all optimized using DFT.

The discussion that follows deals specifically with these complexes in the gas phase, i.e., there is no solvent, and further, the counter anions are not considered. In the solid state, the counter anions will most likely occupy positions hydrogen bonding to the NH_3 hydrogen atoms, and this will influence the electronic characteristics through modification of the charge on the ruthenium atoms. The study probes how modification of the electron density at one end of the molecule is recognized by a corresponding change at the other end. The application might be to molecular wires where an electrochemical perturbation at one end is recognized by a response at the other end.

Computational details

The DFT calculations employed in this article were carried out with the Gaussian 98 program (48). Becke's three-parameter hybrid functional (49) with the LYP correlation functional (50) (B3LYP) and an effective core potential basis set LanL2DZ (51–54) were used. The self-consistent field (SCF) convergence criterion was a change of less than 10^{-8} hartree (1 hartree = 27.211 eV) in the total energy. Harmonic frequency calculations were performed to establish the nature of the critical points (minimum or transition state). The energies and intensities of the lowest 40 singlet–singlet electronic transitions were calculated with TD-DFRT (15–17, 55–61). The profiles of the absorption spectra of the complexes were calculated using the SWizard program (62). The half-bandwidths of all electronic transitions ($\Delta_{1/2}$) were assumed to be 3000 cm^{-1} (a typical half-bandwidth value for the complexes under consideration). The atomic orbital compositions of the molecular orbitals (MOs) were calculated using Mulliken population analysis (MPA) and the AOMix program (63).

Coulomb J and exchange K values were derived for the specific electronic excitations responsible for the optical spectra using the SIG-JK program (64) and DFT-optimized structures. This program computes these values for the electron excitations involved in the transitions, prior to configurational interaction. However, the computational basis for this calculation is the Hartree–Fock semiempirical INDO/S model as implemented by Zerner and co-workers (ZINDO/S) (18–22). We have demonstrated, in a comparative study, that for species of the type discussed here, both methods give very similar results (9). Recently, it has been concluded that the Kohn–Sham MOs generated by the DFT model are equivalent in meaning to the Hartree–Fock MOs, generated, for example, by ZINDO/S (65–69). To confirm that the ZINDO/S calculations do give essentially the same interpretation as the DFT for the specific complexes under study, we report in the following a comparison of MOs generated by each model (Fig. 1).

Results and discussion

Optimized geometries

Geometries were optimized using DFT as described in *Computational details*. Table 1 displays some of the relevant data for key bond distances.

The average Ru—N(NH_3) bond distances are effectively independent of ligand L, but the distances around the local ruthenium atom (Ru_L) are marginally but systematically longer than those around the remote Ru atom (Ru_R). These distances lie within, but at the longer end of, the range observed previously for Ru(II)—N(NH_3) distances (70–80). Both the Ru—N(MPz+) and Ru—CN distances are clearly and significantly dependent on L, with both decreasing with the electron richness of the metal as the ligand donicity increases. Anionic ligands yield much shorter distances than strongly π-acidic ligands such as CO and CH_3NO_2. The predicted Ru—N(Mpz+) distances are longer than those seen in the two crystal structures. A parallel DFT study of the mononuclear $[LRu(NH_3)_4(Mpz+)]^{n+}$ species[2] reveals that the Ru—N(Mpz+) distance is very sensitive to the net electron density on the Ru atom, becoming substantially shorter with increasing electron richness on Ru. Gas-phase calculated Ru—N(Mpz+) distances are likely to be longer than the solid-state observed distances because of the effect of the counter anions in donating charge to the metal centre through hydrogen bonding in the latter case.

The ammine ligands on each metal atom lie in an almost eclipsed configuration. A cross check of the total binding energy for L = OH^- as an example (using ZINDO/S and Hyperchem) showed that the optimized DFT structure deviating slightly from an eclipsed configuration was indeed more stable than either the totally eclipsed or totally staggered configurations. This is likely true for all the species.

Electronic coupling

We are concerned with how information input at the remote ruthenium (Ru_R) by variation of L influences the Ru_R–Ru_L electronic coupling and how the perturbation is "felt" by the local ruthenium (Ru_L) bound to the methylpyrazinium ligand. The methylpyrazinium ligand is a strong π-acceptor ligand with non-innocent character (81). We can expect that the "back donation" to that ligand will be sensitive to the donicity or electron richness of the local ruthenium atom. There are a number of computational methods to probe this. We can evaluate the $d\pi$ metal contribution to the LUMO from the local or remote Ru centre and mixing of filled $d\pi$ orbitals of Mpz with Ru $d\pi$, and also evaluate the coupling between the remote and local ruthenium atoms as a function of symmetry, $d\sigma$, $d\pi$, or $d\delta$. Further, the metal-to-ligand charge-transfer (MLCT) energies can be calculated and the exchange-energy contributions to these excitations evaluated.

The data in Table 2 can be summarized from the viewpoint of symmetry as follows. The $d\delta$-symmetry orbitals (with respect to the metal–metal axis) are more than 90% localized on one metal (see Fig. 1). Orbitals that have $d\pi$ symmetry with respect to the MPz+ plane invariably also have π-MPz+ or π*-Mpz+ character; usually both Ru atoms are involved to a greater or lesser degree. The two Ru localized orbitals having $d\sigma$ symmetry with respect to the MPz+ plane (see Fig. 1) are coupled via an in-MPz+-plane π orbital on the cyanide bridge. They contain little or no MPz+ character. With these aforementioned attributes, it is fairly easy to identify the symmetries of the metal-localized

orbitals listed in Table 2. In certain cases (especially L = H_2O), the lack of axial symmetry causes a small degree of mixing between the $d\sigma$ and $d\pi$ orbitals, generating two MOs that are canted with respect to the MPz+ plane. This has an effect on the electronic spectrum as discussed in the following.

Local–remote ruthenium coupling

While both ruthenium atoms contain a tetraammine ligand set, the presence of the strongly Lewis acidic methylpyrazinium ligand at the local end and an anion at the remote end causes a rather substantial difference in mean energies and reduces the interaction between the two ruthenium cen-

tres. The mean energies of the *d* shells on the remote and local ruthenium centres can be compared by considering the average energies of the easily recognizable "t_{2g}" sets in Table 2. Thus, the *d* orbitals of Ru_R are the frontier filled orbitals and lie $\Delta eV > 1.6$ eV above the mean energy of the *d* orbitals of Ru_L. The difference is significantly smaller when neutral ligands are bound to Ru_R. In the case of L = CO, the difference decreases to 0.43 eV. The value of ΔeV shows a definite linear trend with the value of the ligand electrochemical parameter for ligand L ($E_L(L)$) (82).

Thus, as a consequence, for anionic L the MOs are essentially localized on each ruthenium atom with little interaction between the two ruthenium atoms. With neutral ligands, as ΔeV decreases, mixing between the ruthenium centres (via σ and π pathways) increases but remains small for all species except L = CO, where mixing involving remote and local ruthenium $d\pi$ and $d\sigma$ orbitals is extensive.

The HOMO in all cases (except L = CO) is localized on Ru_R, and for L = anion, it has a substantial contribution from π^*-Mpz+. This arises because the HOMO–LUMO gap is significantly smaller for the anionic ligands than for the neutral ligands and the frontier $d\pi$ orbital on Ru_R lies close in energy to the LUMO on Mpz+. With L = neutral, the HOMO is still $d\pi$ and localized on Ru_R but has very little contribution from π^*-Mpz+. For L = CO, it is the HOMO-2 that is $d\pi$ with 5% contribution from π^*-Mpz+. This is larger than the contributions observed with the other neutral L but much smaller than with anionic L.

Fig. 2. Molecular orbital coefficients expressed in a bar graph for: L = CH_3NO_2 (upper), L = F (middle), and L = CO (lower). The HOMO–LUMO gap is noted as a white intermission, and all orbitals below this gap are filled (DFT).

For all species, except L = CH_3NO_2, which has an intervening π* orbital on CH_3NO_2, the LUMO and LUMO + 1 are π* orbitals localized on Mpz+. The LUMO has the correct symmetry to interact with metal *d*π, while the LUMO + 1 does not and is essentially entirely localized on Mpz+. For the neutral L species, it is not surprising that only the local Ru_L *d*π orbital will back-donate to this π*-LUMO on Mpz+; there is very little contribution from Ru_R *d*π. However, because of the smaller HOMO–LUMO gap, there is a greater contribution of the remote Ru_R *d*π back-bonding to π*-LUMO for the anionic ligands. Indeed, back-bonding from the remote ruthenium is comparable to, or even greater than, that from the local ruthenium. The magnitude of the Ru_L π-back-bonding at 10%–15% is significantly greater than observed in ruthenium(II) bipyridine complexes (ca. 5%) (3).

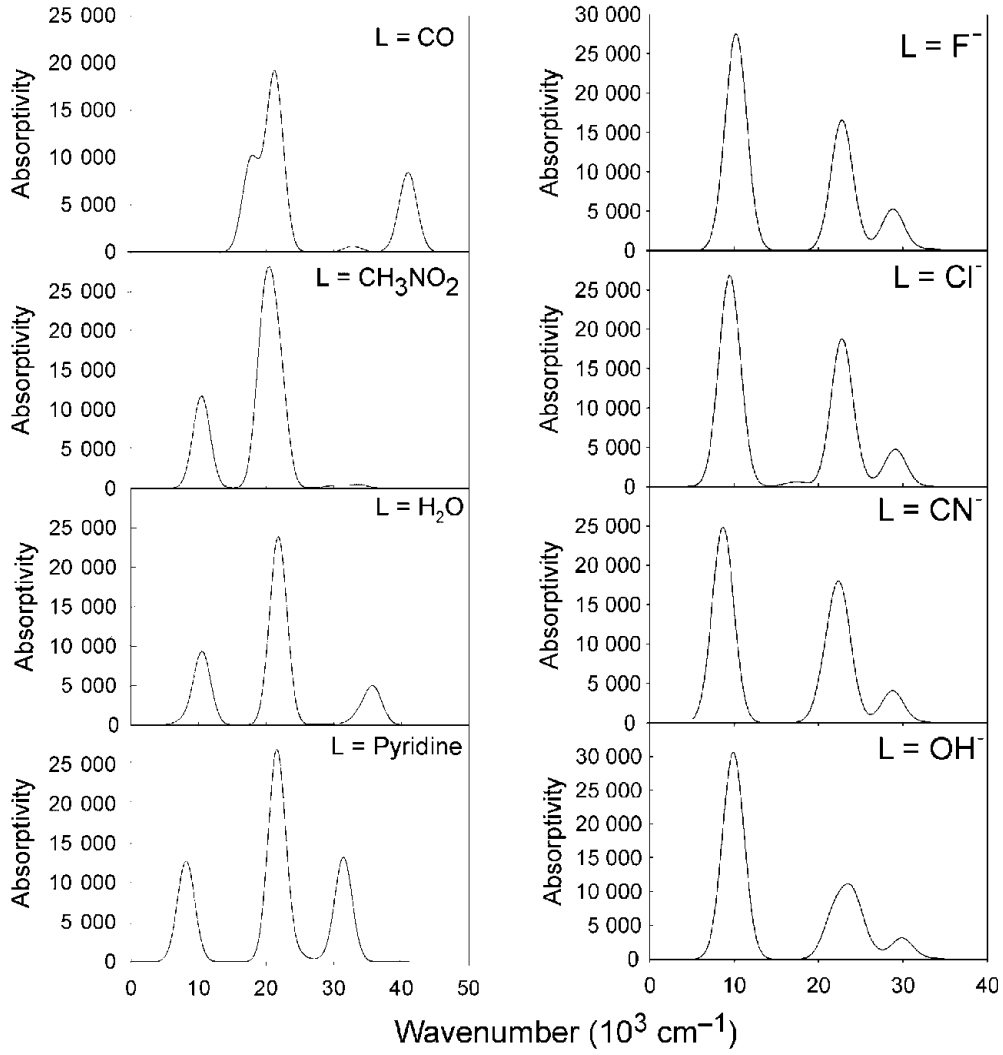
21.8 (0.09)	88 → 92 L(75%)
24.0 (0.12)	85 → 92 L(81%)

Note: Assignments are based on MO numbering in Table 2. L = LUMO, H = HOMO.

The HOMO (HOMO-2 for L = CO) and LUMO can be described as a pair of in- and out-of-phase coupled (Ru_R) *d*π ± *d*π (Ru_L) orbitals, the bonding combination, of course, being the HOMO.

There is a further pair of deeper-lying in- and out-of-phase coupled Ru_R(*d*π) – Ru_L(*d*π) MOs with nonzero contributions from a π-symmetry Mpz+ orbital but which have a much larger contribution from the local Ru_L *d*π orbital. For clarity, we identify the HOMO orbital as ***dπ***-*d*π-Mpz and the deeper orbitals as *d*π-***dπ***-Mpz (1, 2), where the bolded orbital is the dominant orbital in the order Ru_R-Ru_L-Mpz+. We also note that a frontier π orbital on L, especially L = CN^-, Cl^-, or OH^-, is coupled with these *d*π-*d*π-Mpz+ orbitals. As we describe in the following section, transitions from these three orbitals to the LUMO provide the principal features of the visible-region electronic spectra.



Examples of MO data are displayed in Fig. 2 as bar graphs, which provide a convenient visual display of the extent of mixing between the various components.

Gas-phase optical spectra

The predicted gas-phase optical spectra are presented in Table 3 and illustrated in Fig. 3. They all involve essentially

© 2004 NRC Canada

Fig. 3. TD-DFRT predicted optical spectra for the neutral L species as identified (left) and the anionic L species as identified (right).

the same assignments, but with quite markedly different predicted intensities. There are two principal features common to all the species. These are the first pair of bands shown in Fig. 3, where it is evident that they are not fully resolved for L = CO. For L = neutral (Fig. 3, left-hand panel), the first band is weaker than the second. The same pair is identified for L = anion (Fig. 3, right-hand panel), but now the first transition is the more intense.

The lowest-energy, nonzero-intensity transition is the ***dπ***-*d*π-Mpz → LUMO (usually HOMO → LUMO) excitation lying in the range 7700 – 10 500 cm^{-1} for all except L = CO, where it lies at 17 800 cm^{-1}. This has a significant intensity for anionic L but less so for the neutral L. This can be understood readily from Table 2 as follows. For the neutral ligands, the LUMO is almost totally localized on π*-Mpz+ with only a very small contribution from *d*π Ru_R, while the donor orbital is mostly *d*π Ru_R with very little contribution from π*-Mpz+; thus, the overlap between the ground and the excited state is small and hence the intensity is small (83, 84). For anionic L, on the other hand, the LUMO has substantial *d*π Ru_R character and the donor orbital has substantial π*-MPz+ character; hence, overlap is greater and this is reflected in the greater intensity (83).

The second common feature, which is usually a composite of two closely lying excitations, lies in the range 19 900 – 24 000 cm^{-1}, appearing near 21 500 – 21 800 cm^{-1} for all the L = neutral and at 22 700 – 24 000 cm^{-1} for the L = anion species. This second feature arises through excitations from the deeper-lying pair of *d*π-coupled orbitals, localized primarily on the local Ru_L, again to the LUMO. This feature is moderately intense for all L because these donor orbitals always have substantial π-MPz+ character and we are generally observing the overlap of two transitions, the higher-energy component of which is the more intense. These transitions are all most simply described as MLCT transitions to the LUMO of the Mpz+ ligand. However, both metal ions are usually involved, to a greater or lesser extent. To ascertain the dominant contribution, i.e., local or remote Ru to Mpz+ MLCT, one needs to compare the details of the assignment in Table 3 with the MO composition in Table 2.

In the examples where *d*σ–*d*π mixing occurs yielding canted orbitals, transitions from each of these to the LUMO is predicted, yielding thereby an extra transition, though one is generally much weaker than the other (e.g., L = H_2O).

Some species have additional moderately intense transitions associated with the group L. For example, with L = Py,

Note: MOs are ordered sequentially with respect to the DFT calculation. The ZINDO/S MOs are ordered to match the corresponding DFT orbitals. L = LUMO, H = HOMO.

the band at 24 500 cm^{-1} (100 → 108) is mostly an interligand Py → Mpz+ ligand-to-ligand charge transfer (LLCT), while the most intense transition in the visible region for L = CH_3NO_2, at 19 900 cm^{-1}, is mostly $Ru_R \rightarrow \pi^*$ CH_3NO_2 MLCT. For L = anion, there is an additional band near 30 000 cm^{-1}, which is a composite transition involving excitations both to the LUMO and to higher virtual orbitals. These are not germane to this study and are not discussed further.

The question of overlap is addressed again immediately below in terms of the exchange contributions involved in these transitions.

Exchange (*K*) and Coulombic (*J*) integral contributions

It has been previously demonstrated (3, 7, 10, 26, 70, 85, 86) that evaluation of the *J* and *K* integrals, especially *K*, involved in the electronic excitations, can provide additional insight into the delocalization extant in the complex. As noted in the previous section, this calculation utilizes the ZINDO/S calculated data; it is, therefore, relevant to ensure that the INDO/S calculation essentially reproduces the DFT calculations. Table 4 describes the ZINDO/S computed electronic coupling for one neutral and one anionic ligand species for comparison with the DFT data. The MO numbering system differs for the two models and, since some MOs have very similar energies, the ordering of the MOs is not exactly the same in the two calculations. Nevertheless, one can readily identify corresponding orbitals between the two models by their σ, δ, or π symmetry and their composition. Figure 1 illustrates that the ZINDO/S MOs are closely similar to the DFT Kohn–Sham orbitals.

Table 5 collects the *J* and *K* values derived for the dominant electronic excitations listed in Table 3. The value of *K* is inversely and exponentially proportional (84, 86–88) to the distance travelled by the electron in the excitation. Thus, if the electron formally leaves an orbital 100% localized on the metal to arrive at one 100% localized on the ligand, then the formal distance travelled might be supposed to approximate to the distance between the metal centre and ligand centre. However, if the initial orbital involves delocalization over metal and ligand and the terminating ligand orbital is also delocalized over the same metal and ligand orbitals,

Table 5. Coulomb and exchange integral values.

Ligand (L)	Transition	*J* (10^3 cm^{-1})	*K* (10^3 cm^{-1})
CH_3NO_2	102 H → 103 L	15.4	0.43
	102 H → 104	31.3	2.93
	98 → 103 L	28.1	2.81
Pyridine	107 H → 108 L	14.35	0.35
	102 → 108 L	25.8	2.63
	100 → 108 L	13.7	0.49
H_2O	91 H → 92 L	15.9	0.3
	90 → 92 L	15.9	0.3
	87 → 92 L	27.7	2.7
CO	91 → 94 L	20.3	1.18
	89 → 94 L	21.0	1.26
CN^-	93 H → 94 L	16.0	2.28
	89 → 94 L	16.9	1.45
	86 → 94 L	26.5	3.59
F^-	91 H → 92 L	19.7	4.18
	87 → 92 L	30.6	5.0
Cl^-	90 H → 91 L	18.3	2.8
	87 → 91 L	14.9	0.8
	84 → 91 L	28.7	4.4
OH^-	91 H → 92 L	20.6	5.5
	88 → 92 L	28.2	4.4
	85 → 92 L	17.0	1.0

Note: Assignment of transitions is based on MO numbering in Table 2 (see Table 3). L = LUMO, H = HOMO.

then we may suppose that the time-average distance the electron jumps will be much smaller than in the localized case. This description has been shown to be accurate experimentally via measurement of the Stark effect in related species (89).

Transitions between similarly delocalized MOs are indicated by a much larger value of K than in the case of the localized excitation. Thus, the lowest energy transition displays higher values for K (2280–5500 cm^{-1}) for L = anions, where both the donor and acceptor orbitals contain substantial contributions from the same ligand π^* and same metal $d\pi$ orbital and smaller values for L = neutral ligands (300–1180 cm^{-1}), where such delocalization is smaller. For the second major transition, where delocalization is greater for both neutral and anionic L, we observe the range 1260–2810 cm^{-1} for neutral L and 3590–5000 cm^{-1} for anionic L. As expected, there is a general trend whereby the higher values of K are associated with the more intense transitions. Moreover, the grouping of the second pair of transitions appearing at slightly higher energy for L = anion than for L = neutral is due to the higher value of K, whose magnitude contributes directly to the transition energy (83, 86). The variation in J generally follows the same patterns, becoming larger along with K when delocalization causes significant overlap between ground and excited state, but there are a few exceptions. For some useful comparative J and K values, see Table 4 of ref. 7.

Comparison with experimental data

For further confirmation that the methodologies discussed in this report are valid, we calculate optical data for a cyano-bridged dinuclear ruthenium(II) species (**II**) reported by Bignozzi et al. (90, 91) and Endicott et al. (92). Species **II** ($[(NH_3)_5Ru^{II}\text{-}NC\text{-}Ru^{II}(CN)(bpy)_2]^{4+}$) contains a ruthenium bound by two 2,2′-bipyridine (bpy) groups and a cyanide residue linked, in a cis conformation, via a bridging cyanide to a $[Ru(NH_3)_5]^{2+}$ fragment.

This is actually quite an interesting system. The two bpy groups are inequivalent since one is trans to a negatively charged cyano group and the other to the positively charged $[Ru(NH_3)_5\text{-}NC]^+$ residue. The π^* LUMO is localized essentially entirely (94%, INDO/S; 94% DFT) on the former, while the π^* LUMO + 1, lying ca. 0.35 eV above the LUMO (INDO/S), is almost entirely localized (95%, INDO/S; 93% DFT) on the latter.

For convenience, we define a molecular plane on the pentaamminoruthenium centre (designated as Ru_t) to contain the terminal cyano group on the bpy-bound ruthenium centre (designated Ru_c) and three NH_3 groups including the terminal one. The $d(t_{2g})$ orbitals on Ru_t can be identified as σ, π, or δ with respect to this plane, in a similar fashion to the arguments above. The HOMO is predominantly $d\sigma(Ru_c)$, the HOMO-1 is $d\delta(Ru_c)$, and the HOMO-2 is $d\pi((56\%)Ru_c\text{–}(25\%)Ru_t)$ (DFT). Thus, the HOMO-2 is quite extensively mixed and phased so that the two Ru $d\pi$ orbitals are in a bonding phase with one another but separated by an antibonding interaction with the bridging cyano group.

The visible absorption spectrum of this species (shown in Fig. 1 of ref. 90) exhibits an intense MLCT band centred at 21 600 cm^{-1} (ε = 6400 L mol^{-1} cm^{-1}) (in DMF) with well-defined shoulders at 19 300 and 16 000 cm^{-1}. The intense band is calculated to be a composite of two transitions, HOMO-2 $\rightarrow$ LUMO (50%) and HOMO $\rightarrow$ LUMO + 1 (30%), and so is mostly from the heavily mixed $d\pi$ orbital on both Ru centres to the π^* localized on the bpy trans to the terminal pentaammino group. Its calculated energy and intensity (22 600 cm^{-1}, f = 0.14 (ε = 7500 L mol^{-1} cm^{-1}),[3] INDO/S) are in excellent agreement with the experimental data. The calculation predicts several weaker and lower-energy transitions to explain the experimental shoulder, the two more intense of these being 20 900 cm^{-1} (f = 0.03) HOMO $\rightarrow$ LUMO (77%) and 22 200 cm^{-1} (f = 0.009) HOMO – 1 $\rightarrow$ LUMO + 1 (66%) (INDO/S). These are both MLCT transitions involving predominantly the central bpy-bound ruthenium atom in contrast to an earlier assignment (91) that assigned them as MLCT involving the terminal Ru. Overall, the agreement between theory and experiment is excellent, in terms of energy, intensity, and the number of observed bands. This short analysis provides additional support for the validity of the analyses of the experimentally unknown species discussed herein.

Summary

This analysis has demonstrated the significant but often subtle effects of changing the terminal ligand on the electronic structure of these molecules. The changes can readily be mapped via the application of density functional theory and lead to a firmer understanding of the factors that determine electronic interactions between the metal centres. The variations in the predicted optical spectra follow from careful analysis of the MO coefficients. Exchange integral values are seen to correlate well with the degree of delocalization and with both the energy and intensity of the electronic transitions. The extent of π-back-donation to the non-innocent methylpyrazinium ligand can evidently be tuned over quite a wide range, involving either or both metal centres, leading to exquisite control not only of electronic structure but also of geometry from the viewpoint of bond distances.

Taxol interaction with DNA and RNA — Stability and structural features[1]

A. Ahmed Ouameur, H. Malonga, J.F. Neault, S. Diamantoglou, and H.A. Tajmir-Riahi

Abstract: Taxol (paclitaxel) is an anticancer drug that interacts with microtubule proteins in a manner that catalyzes their formation from tubulin and stabilizes the resulting structures. However, in the human lung tumor cell, the concentration of paclitaxel is highest in the nucleus. Therefore, it was of interest to examine the interaction of taxol with DNA and RNA in aqueous solution at physiological pH. Capillary electrophoresis and Fourier transform infrared (FTIR) difference spectroscopic methods were used to characterize the nature of drug–DNA and drug–RNA interactions and to determine the taxol binding site, the binding constant, the sequence selectivity, the helix stability, and the biopolymer secondary structure in the taxol–polynucleotide complexes in vitro. The FTIR spectroscopic studies were conducted with taxol/polynucleotide (phosphate) ratios of 1/80, 1/40, 1/20, 1/10, 1/4, and 1/2 with a final DNA(P) or RNA(P) concentration of 12.5 mmol/L, and capillary electrophoresis was performed after incubation of taxol with polynucleotides at ratios of 1/200 to 1/12 with a final polynucleotide concentration of 1.25 mmol/L. Taxol was shown to bind to DNA and RNA at G–C, A–T, or A–U bases and the backbone PO_2 group. Two types of binding were observed for taxol–DNA with $K_1 = 1.3 \times 10^4$ L mol^{-1} and $K_2 = 3.5 \times 10^3$ L mol^{-1}, whereas taxol–RNA complexes showed one type of binding with $K = 1.3 \times 10^4$ L mol^{-1}. The taxol–polynucleotide complexation is associated with a partial helix stabilization and no major alterations of B-DNA or A-RNA structure.

Key words: DNA, RNA, taxol, binding site, binding constant, conformation, helix stability, electrophoresis, FTIR spectroscopy.

Résumé : Le taxol est un médicament anticancéreux qui interagit avec les protéines microtubulaires d'une façon qui catalyse leur formation à partir de la tubuline et qui stabilise les structures qui en résultent. Toutefois, il a été démontré que les concentrations de taxol dans la cellule d'une tumeur d'un poumon humain sont plus élevées dans le noyau. Il y avait donc un intérêt à examiner l'interaction entre le taxol et l'ADN et l'ARN en solution aqueuse, au pH physiologique. On a utilisé l'électrophorèse capillaire et des méthodes de spectroscopie infrarouge à transformée de Fourier (FTIR) pour caractériser la nature des interactions médicament–ADN et médicament–ARN et pour déterminer le site de fixation du taxol, la constante d'association, la sélectivité séquentielle, la stabilité de l'hélice et la structure secondaire du biopolymère dans les complexes taxol–acides nucléiques. On a effectué ces études avec des rapports (r) de taxol/polynucléotides (phosphate) de 1/80, 1/40, 1/20, 1/10, 1/4 et 1/2, avec une concentration finale d'ADN(P) ou d'ARN(P) de 12,5 mmol/L pour l'infrarouge et de 1/200 à 1/12, avec une concentration finale de polynucléotides de 1,25 mmol/L pour l'électrophorèse capillaire. L'analyse structurale a montré que le taxol se fixe avec l'ADN et l'ARN au niveau des bases G–C, A–T ou A–U et aux groupements phosphates (PO_2). Deux types de liaison ont été observés pour les complexes taxol–ADN, avec $K_1 = 1{,}3 \times 10^4$ L mol^{-1} et $K_2 = 3{,}5 \times 10^3$ L mol^{-1}, alors que les complexes taxol–ARN ne comportent qu'un seul type de liaison, avec $K = 1{,}3 \times 10^4$ L mol^{-1}. Les interactions taxol–polynucléotides stabilisent partiellement la structure secondaire des acides nucléiques, qui restent dans leur conformation naturelle (conformation B pour l'ADN et A pour l'ARN).

Mots clés : ADN ARN, taxol, site de fixation, constante d'association, conformation, stabilité de l'hélice, électrophorèse, spectroscopie infrarouge à transformée de Fourier.

Introduction

Taxol (paclitaxel) is an anticancer drug with the structure shown in Scheme 1. It interacts with microtubule proteins in a manner that catalyzes the formation of microtubules from tubulin and stabilizes the resulting structures (1). Its antitumor activity is based on increasing the stability of microtubules and preventing mitosis (2–4). In the cell, this

Scheme 1.

Taxol

phenomenon leads to an altered morphology, with microtubules forming stable bundles and the cell being unable to assemble a normal mitotic spindle (5). In cells treated with taxol, the transition between interphase and mitosis is normally arrested and the cells die. The elucidation of this unique mechanism of action during the late 1970s and 1980s promoted the development of taxol as an anticancer drug. Taxol has shown unusual efficacy as a clinical agent for the treatment of breast, ovarian, skin, lung, head, and neck cancers (6). In 1993, taxol was approved by the U.S. Food and Drug Administration for use in the treatment of breast and ovarian cancers.

In recent years, to further elucidate the mechanism of action of taxol's antitumor activity, the structures of several taxol–protein and taxol–lipid complexes have been investigated (7, 8). On the other hand, it has been demonstrated that the presence of nucleotide strongly affects the taxol–tubulin complexation (9). It has also been demonstrated in the human lung tumor cell that paclitaxel is concentrated (twofold) in the nucleus (10). Recently, it was reported that paclitaxel exhibits major interaction with poly(dA–dT), inducing partial helical stability of the oligonucleotides, but not with poly(dG–dC) (11).[3] This prompted us to examine the interaction of taxol with DNA and RNA in vitro.

We report the results of capillary electrophoresis and FTIR difference spectroscopic studies on the interaction of taxol with calf-thymus DNA and yeast RNA in aqueous solution at physiological pH. Taxol/polynucleotide molar ratios of 1/80 to 1/2, with a final polynucleotide (phosphate) concentration of 12.5 mmol/L, and of 1/200 to 1/12, with a final polynucleotide (phosphate) concentration of 1.25 mmol/L, were employed for the FTIR spectroscopic studies and for capillary electrophoresis, respectively. Structural analyses regarding the drug binding site, the binding constant, sequence preference, helix stability, and nucleic acid conformation are reported here. The structural evidence presented provides major information on taxol–polynucleotide complexation and helps to elucidate the nature of this biologically important complex formation in vitro and in vivo.

Materials and methods

Materials

Highly polymerized type I calf-thymus DNA sodium salt (7% Na content) and Baker's yeast RNA sodium salt were purchased from Sigma Chemical Co. and used without further purification. To check the protein content of DNA and RNA solutions, the absorbance bands at 260 and 280 nm were used. The A_{260} / A_{280} ratio was 1.80 for DNA and 2.1 for RNA, showing that the DNA and RNA samples were sufficiently free from protein (12). Taxol was obtained from Biolyse Pharmacopée (Port-Daniel, QC) and recrystallized from methanol. Other chemicals were of reagent grade and were used without further purification.

Preparation of stock solutions

Sodium-DNA or sodium-RNA was dissolved to 1% *w*/*v* (25 mmol polynucleotide (phosphate)/L) in an aqueous solution containing 0.1 mol NaCl/L and 1 mmol sodium cacodylate/L (pH 7.30) at 5 °C for 24 h with occasional stirring to ensure the formation of a homogeneous solution. The appropriate amount of taxol (0.3–25 mmol/L) was dissolved in a 20/80 methanol–water mixture. (Taxol is not soluble in H_2O or D_2O but is soluble in this methanol–water mixture.) The drug solution was then added dropwise to the DNA or the RNA solution to attain desired taxol/DNA(P) and taxol/RNA(P) molar ratios of 1/80, 1/40, 1/20, 1/10, 1/4, and 1/2 at a final DNA or RNA concentration of 0.5% *w*/*v* (12.5 mmol polynucleotide (phosphate)/L) for infrared measurements. For capillary electrophoresis, the taxol/polynucleotide ratios were 1/200 to 1/12 with a final DNA or RNA concentration of 1.25 mmol polynucleotide (phosphate)/L. The pH of the solutions was adjusted to 6.5–7.5, using NaOH solution.

FTIR spectra

Infrared spectra were recorded on a Bomem DA3–0.02 FTIR spectrometer equipped with a liquid-nitrogen-cooled HgCdTe (MCT) detector and a KBr beam splitter. The spectra of the taxol/polynucleotide solutions were acquired using a cell assembled with AgBr windows. Spectra were collected after 2 h incubation of taxol with the polynucleotide solution and were measured in triplicate (three individual samples of the same polynucleotide and taxol concentrations). For each spectrum, 100–500 scans were collected at a resolution of 2 to 4 cm^{-1}. The water subtraction was carried out using an NaCl (0.1 mol/L) solution at pH 6.5–7.5 as a reference (13). A good water subtraction was considered to be achieved when there was a flat baseline around 2200 cm^{-1}, where the water combination mode is located. This method yields a rough estimate of the subtraction scaling factor, but it removes the spectral features of water in a satisfactory way (13). Owing to the insolubility of taxol in aqueous solution, we did not perform the same experiments in D_2O solution. The difference spectra [(polynucleotide solution + taxol solution) – (polynucleotide solution)] were obtained using a

sharp DNA band at 968 cm^{-1} and an RNA band at 861 cm^{-1} as internal references. These bands, which are due to sugar C–C and C–O stretching vibrations, exhibit no spectral changes (shifting or intensity variations) upon taxol–polynucleotide complexation, and they were cancelled out upon spectral subtraction (Fig. 1). The intensity ratios of bands due to several DNA or RNA in-plane vibrations related to A–T, A–U, and G–C base pairs[4] and the PO_2 stretching vibrations were measured with respect to the reference band at 968 (DNA) or 861 cm^{-1} (RNA) as a function of taxol concentration with an error of ±3%.

Capillary electrophoresis

A P/ACE System MDQ (Beckman) with a photodiode array detector was used to study taxol–polynucleotide complexation. An uncoated fused-silica capillary of 75 µm i.d. and 50 cm effective length was used. The capillary was initially conditioned by washing with an NaOH (1 mol/L) solution for 30 min, followed by a 15-min wash with a more dilute (0.1 mol/L) NaOH solution. It was then extensively rinsed with deionized water and running buffer before use. Samples were injected using a voltage injection at 10 kV for 5 s. Electrophoresis was carried out at a voltage of 25 kV for 10 min using normal polarity. All runs were carried out at 25 °C. A stock solution of taxol (2 mmol/L) was prepared in 20% methanol. The capillary inlet and outlet vials were replenished after every five runs. The taxol binding experiments were performed on a sample buffer containing 15 mmol Tris-HCl/L, pH 7.2 (with 4 mmol NaCl/L and 20% methanol) using constant concentrations of DNA or RNA and various concentrations of taxol. The taxol solution (20% methanol) was added to the DNA or RNA solution to attain desired drug/polynucleotide (phosphate) molar ratios of 1/200 to 1/12. Each sample was allowed to equilibrate for 30 min and subjected to two separate runs. The electropherograms were monitored at 260 nm for taxol–DNA and taxol–RNA complexes and were collected and analyzed with the Beckman P/ACE Windows controller software.

Data analysis

The binding constants for taxol–DNA and taxol–RNA adducts can be determined by capillary electrophoresis, using Scatchard analysis (14, 15). The extent of saturation (R_f) of the polynucleotide was determined from the change of the peak heights of the polynucleotide in the presence of various concentrations of taxol by the following equation:

$$[1] \qquad R_f = \frac{h - h_0}{h_s - h_0}$$

where h is the peak height of DNA or RNA measured for any added taxol concentration, while h_0 and h_s correspond to the peak heights of free and drug-saturated DNA or RNA, respectively.

The binding constant K_b, given by

$$[2] \qquad K_b = \frac{[\text{taxol–polynucleotide adduct}]}{[\text{polynucleotide}][\text{taxol}]}$$

was determined by fitting the experimental values of R_f and taxol concentration to the equation

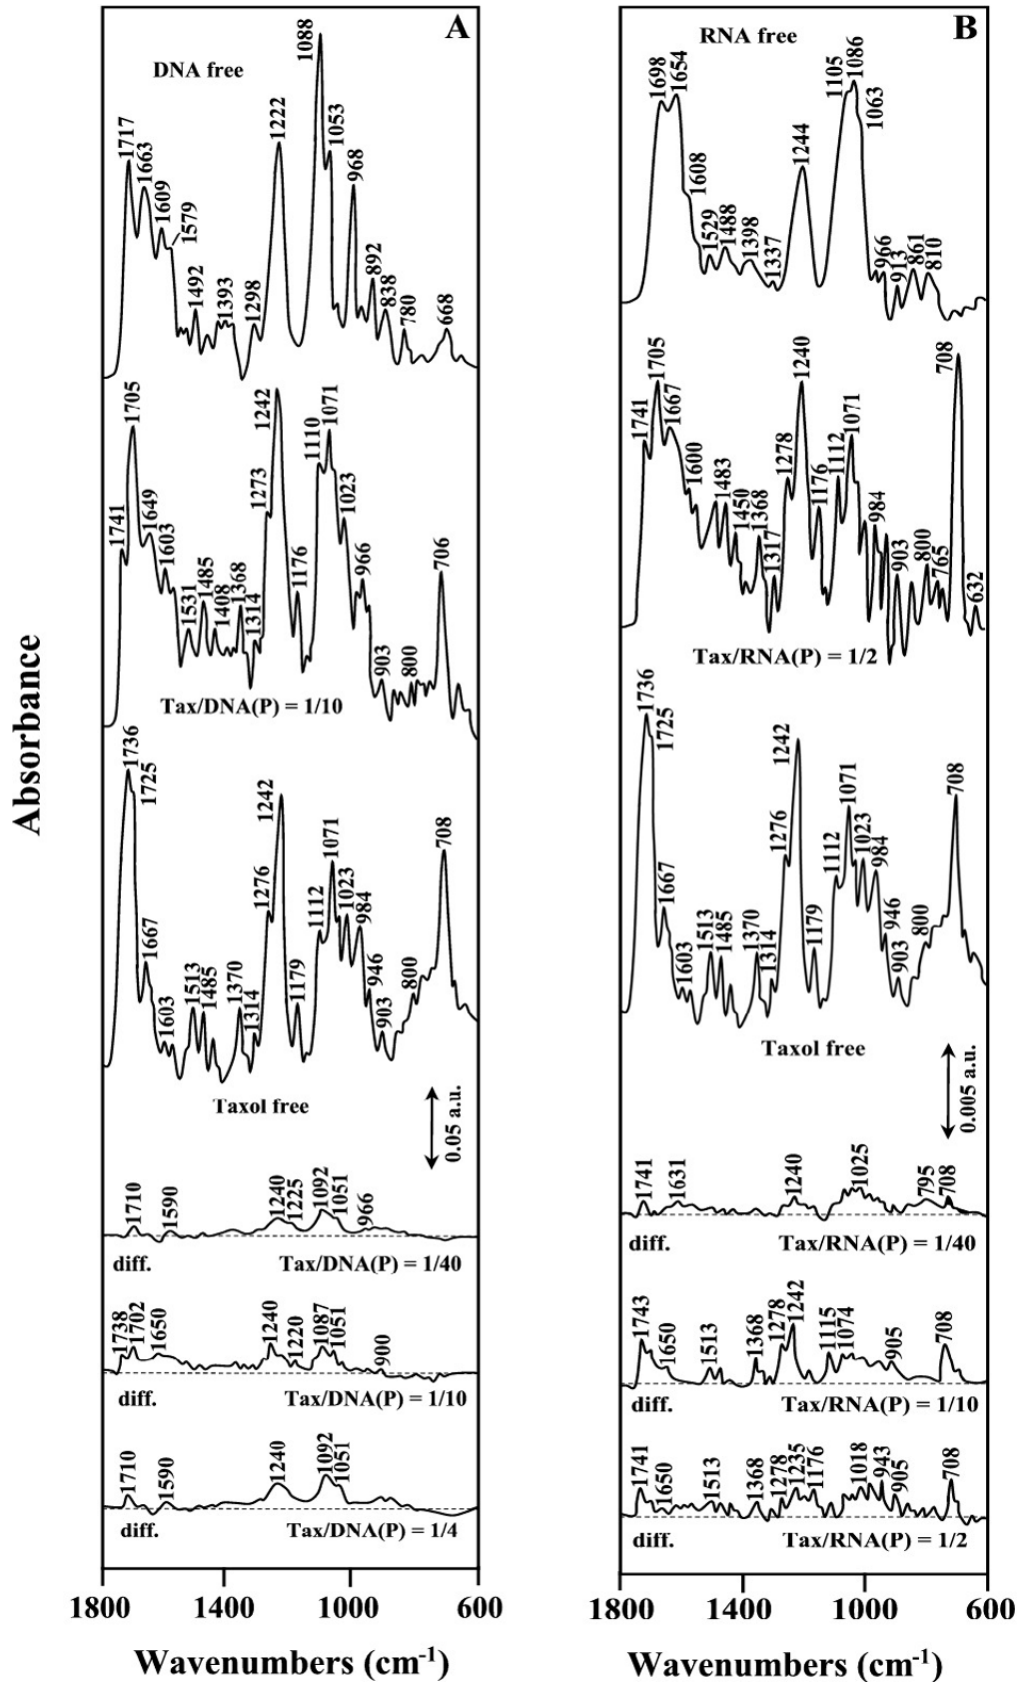
$$[3] \qquad R_f = \frac{K_b[\text{taxol}]}{1 + K_b[\text{taxol}]}$$

Rearrangement of this equation gives a convenient form for Scatchard analysis:

$$[4] \qquad \frac{R_f}{[\text{taxol}]} = K_b - K_b R_f$$

Results and discussion

Taxol–DNA complexes



At a low taxol concentration (taxol/DNA ratio r = 1/80), no major drug–DNA interaction occurred, as indicated by the minor decrease in the intensity of several DNA bands related to the G–C, A–T, and backbone phosphate vibrational modes in the presence of taxol, such as the bands at 1717 (G), 1663 (T), 1609 (A), 1529 (C), 1492 (C), and 1222 cm^{-1} (asymmetric PO_2 stretching vibration) (16–25) (Fig. 2A). As drug content increased (r = 1/40 to 1/20), major increases in the intensities of the bands at 1717 (G) and 1222 cm^{-1} (phosphate) were observed (Fig. 2A). These results are supported by the difference spectra presented in Fig. 1A. The positive features at 1710 and 1225 cm^{-1} in the difference spectra of the taxol–DNA complexes (Fig. 1A, r = 1/40) have been attributed to drug interaction with the guanine-N7 reactive site and backbone PO_2 group. At r = 1/10, the interaction continues with the guanine bases and the PO_2 group, as well as with the thymine-O2 atom. Evidence for this comes from the further increase in the intensities of the bands at 1717 (G), 1663 (T), and 1222 cm^{-1} (phosphate) (Fig. 2A). These intensity changes were associated with positive features at 1702, 1650, and 1220 cm^{-1} in the difference spectra of the taxol–DNA complexes (Fig. 1A, r = 1/10). These spectral changes are due to taxol interaction with the guanine-N7 and thymine-O2 reactive sites and PO_2 groups, respectively. The other positive features centered at 1738, 1248, 1240, 1087, and 1092 cm^{-1} in the difference spectra of the drug–DNA complexes arise from the vibrational modes of taxol (26) and are not due to DNA vibrations (Fig. 1A). In the spectra of taxol–DNA complexes (Fig. 1A, r = 1/10), several other bands at 1741, 1707, 1603, 1485, 1368, 1273, 1242, 1176, 1110, 1071, 1023, and 706 cm^{-1} are also related to the taxol vibrational frequencies (26). The band at 1492 cm^{-1} (mainly cytosine) showed no spectral changes upon drug interaction, which is indicative of no participation of cytosine bases in taxol–DNA complexation (Fig. 2A).

At high taxol concentration (r > 1/10), a partial stabilization of the DNA helix occurs, which is associated with minor decreases in the intensities of the bands at 1717 and 1222 cm^{-1} and a minor increase in the intensity of the band at 1663 cm^{-1} (Fig. 2A). Similar infrared spectral changes were observed for DNA vibrations in cases in which metal–cation interaction induced helical stability (27–29). Recent calorimetric titration of several synthetic DNAs by

Fig. 2. Intensity ratio variations for several DNA and RNA in-plane vibrations as a function of taxol concentration. (A) Intensity ratios for the DNA bands at 1717 (G, T), 1663 (T), 1609 (A), 1492 (C, G), and 1222 cm^{-1} (PO_2 stretch), referenced to the DNA band at 968 cm^{-1}; (B) intensity ratios for the RNA bands at 1698 (G, U), 1654 (U), 1608 (A), 1488 (C, G), and 1244 cm^{-1} (PO_2 stretch), referenced to the RNA band at 861 cm^{-1}.

pacilitaxel also showed major increases in helical stability for poly(dA–dT) oligonucleotides (11).

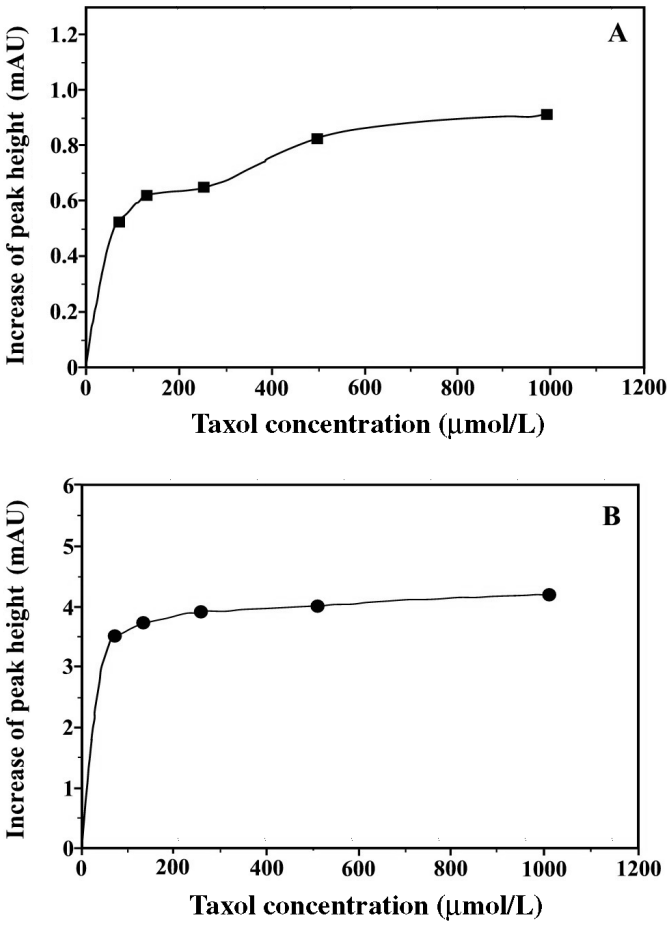
Taxol–RNA complexes

No major taxol–RNA interaction occurred at low drug concentration (r = 1/80), as indicated by the minor decrease in intensity of bands due to RNA in-plane vibrations at 1698 (mainly G), 1654 (mainly U), 1608 (A), 1488 (mainly C), and 1244 cm^{-1} (asymmetric PO_2 stretch) (17–25) in the presence of taxol (Fig. 2B). As drug concentration increased (r = 1/40 and 1/20), major increases in the intensities of the bands at 1698, 1654, 1608, and 1244 cm^{-1} were observed (Fig. 2B). These intensity changes arise from major drug interaction with the guanine, uracil, and, to a lesser extent, adenine bases, as well as the backbone phosphate groups. However, the cytosine band at 1488 cm^{-1} exhibited no major spectral changes, which is indicative of no drug–cytosine interaction (Fig. 2B). Several positive features centered at 1741, 1743, 1631, 1513, 1368, 1278, 1235–1242, 1175, 1115, 1074, 1025, 1018, 905, and 708 cm^{-1} in the difference spectra of the taxol–RNA complexes arise from taxol vibrational frequencies (26) and are not due to the RNA vibrations (Fig. 1B).

Effects of complexation on taxol vibrational modes

Additional evidence regarding taxol–DNA and taxol–RNA complexation comes from the major shifts of the taxol vibrational bands. A strong band at 1736 cm^{-1} related to the drug's exocyclic carbonyl C=O stretching vibration (26) is shifted to 1741 cm^{-1} in the spectra of taxol–polynucleotide complexes (Figs. 1A and 1B; r = 1/10 and 1/2, respectively). Similarly, a shoulder band at 1725 cm^{-1} due to taxol ring carbonyl vibrations (26) is shifted to 1705 cm^{-1} upon DNA and RNA complexation. A band with medium intensity at 1667 cm^{-1}, related to the free taxol OH bending and C–N stretching vibrations (26), is also shifted toward lower frequency in the spectra of drug–DNA and drug–RNA complexes (Figs. 1A and 1B). The observed spectral changes are indicative of taxol–polynucleotide complexation through taxol's polar groups and alterations of its H-bonding network. The rearrangement of the drug's H-bonding network to a drug – nucleic acid H-bonding system may stabilize taxol–DNA and taxol–RNA adduct formation.

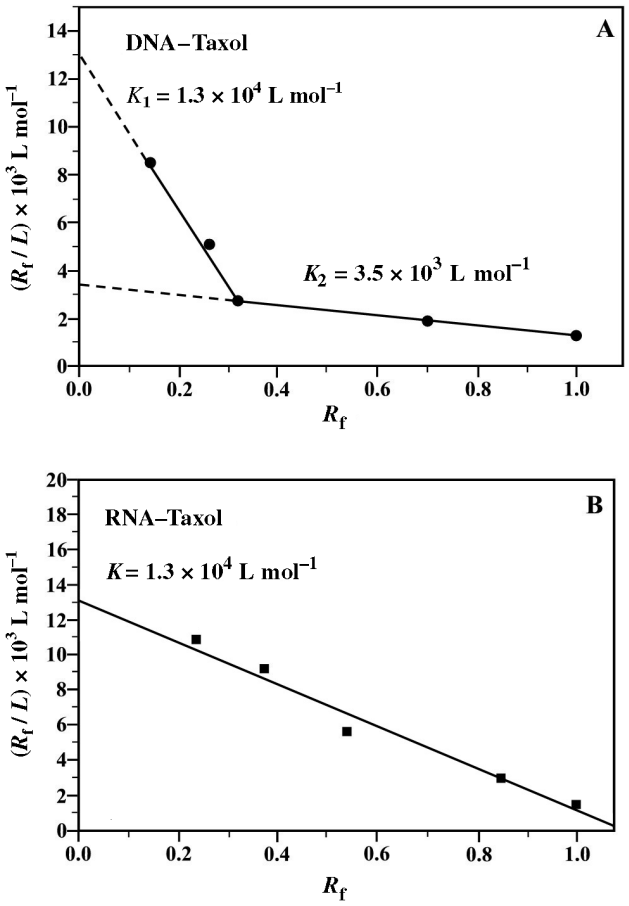
DNA and RNA conformations



The infrared spectra also provided evidence that taxol–polynucleotide interaction leads to no major biopolymer conformational changes, with DNA maintaining the B-family structure and RNA maintaing the A-conformation. No major shifts of the B-DNA marker bands (22, 25, 29) at 1717 (G), 1222 (PO_2), and 836 cm^{-1} (phosphodiester) occurred in our experiments (Fig. 1A). Similarly, the marker bands for A-form RNA were observed at 1698 (G), 1244 (PO_2), and 861 and 810 cm^{-1} (phosphodiester modes) (Fig. 1B). When the B to A transition occurs, the DNA marker bands are shifted to 1710–1700, 1225–1240, and 825–800 cm^{-1}, respectively, and a new band appears at about 870–860 cm^{-1} (22, 25, 29). In the B to Z conformational transition, the sugar–phosphate band at 836 cm^{-1} appears at 800–780 cm^{-1}, and the guanine band is displaced to 1690 cm^{-1}, while the phosphate band shifts to 1216 cm^{-1} (22, 25, 29). Since no such spectral changes occurred in our experiment, DNA remained in the B-conformation upon interaction with taxol. Similarly, the RNA remained in the A-conformation in the taxol–RNA complexes, since there was no major shifting of the A-form RNA marker bands at 810 (phosphodiester mode), 1244 (PO_2 stretch), and 1698 cm^{-1} (mainly guanine carbonyl stretch) (22, 25, 29) upon drug complexation (Fig. 1B).

Stability of taxol–DNA and taxol–RNA adducts

The binding of the taxol–DNA and taxol–RNA complexes was also studied by capillary electrophoresis. Mixtures containing various concentrations of taxol and either DNA or RNA with molar ratios of 1/200 to 1/12 were prepared and subjected to electrophoresis, using an uncoated silica capillary of 75 μm i.d. (50 cm effective length) at 25 kV. The electropherogram was monitored at 260 nm for DNA and RNA in the run buffer (15 mmol Tris-HCl/L, pH 7.2, 4 mmol NaCl/L) at 25 °C. The peak heights of taxol–DNA and taxol–RNA adducts gradually increased as the taxol concentration increased and nearly reached a plateau at a



© 2004 NRC Canada

Fig. 3. Plots of increase of peak heights (in milliabsorbance units (mAU)) of taxol–polynucleotide complexes from capillary electrophoresis following incubation of a constant concentration of DNA (A) or RNA (B) (1.25 mmol phosphate/L) with various concentrations of taxol. Incubations were carried out in the run buffer (15 mmol Tris-HCl/L, pH 7.2, 4 mmol NaCl/L) at 25 °C for 30 min prior to capillary electrophoresis. The increase in peak height of the taxol–DNA and taxol–RNA complexes at 260 nm was determined by subtracting the peak height of the free DNA or RNA from that of each taxol–polynucleotide adduct.

taxol concentration of 1 mmol/L (Fig. 3). Based on these results, binding constants of the drug–DNA complexes were determined by Scatchard analysis as described in *Materials and methods*. As shown by the saturation curves in Fig. 3, the slope for the taxol–DNA complexes is biphasic (Fig. 3A), suggesting the presence of low-affinity and high-affinity binding sites for the drug–DNA complexes, whereas the slope for the taxol–RNA complexes is monophasic with one binding site (Fig. 3B). Scatchard analysis of the data for the taxol–DNA adducts showed high- and low-affinity sites with binding constants of $K_1 = 1.3 \times 10^4$ L mol^{-1} and $K_2 = 3.5 \times 10^3$ L mol^{-1}, respectively (Fig. 4A). Similar Scatchard analysis for the taxol–RNA complexes showed one binding site with $K = 1.3 \times 10^4$ L mol^{-1} (Fig. 4B). These results suggest that taxol binds at two distinct binding sites on DNA and at one binding site on RNA. Furthermore, it may be

Fig. 4. Scatchard plots for taxol–DNA (A) and taxol–RNA complexes (B). L = [taxol].

speculated that the stronger interaction is due to binding to G–C bases, while the weaker is due to binding to A–T bases.

Concluding remarks

Our capillary electrophoresis and spectroscopic results on DNA and RNA complexes with taxol showed that (*a*) taxol binds to the major and minor grooves of DNA with apparent binding constants of $K_1 = 1.3 \times 10^4$ L mol^{-1} and $K_2 = 3.5 \times 10^3$ L mol^{-1}; (*b*) taxol binds to RNA via G–C and A–U bases with $K = 1.3 \times 10^4$ L mol^{-1}; and (*c*) taxol–polynucleotide complexation results in a partial helix stabilization with no alterations of the B-DNA or A-RNA structure.

TRIBUTE / HOMMAGE

This issue of the *Canadian Journal of Chemistry* is dedicated to the memory of one of Canada's greatest scientists: Gerhard Herzberg. There have been many special journal issues honoring Herzberg, or "GH" as all his scientific colleagues called him. Nevertheless, the timing of this particular one is significant. GH was born 100 years ago this year, in Hamburg, Germany, on 25 December 1904. He passed away five years ago on 3 March 1999 at the age of 94, and in the time since his passing we have entered the 21st century. It therefore seems appropriate to take a "scientific snapshot" of what is happening in the field of high-resolution molecular spectroscopy. By doing so, we are able not only to acknowledge the tremendous advances that have been made but also to illustrate the debt the community owes to Herzberg and his profound contributions to the field.

The first anecdote in Boris Stoicheff's wonderful biography *Gerhard Herzberg: An Illustrious Life in Science* refers to a humorous statement Herzberg made when reminded that he shared a very famous birthday, coming as it did on Christmas Day: "Yes, with Sir Isaac Newton". Of course, his connection to Newton runs deeper than that of a mere chronological coincidence. In 1666, Newton was the first to observe a spectrum obtained from a prism, and for many laypeople that achievement is their main knowledge of spectroscopy, even if the word spectroscopy itself is not part of their vocabulary. It can be said that Herzberg's accomplishments link not only scientifically back through history to Newton but, even five years after his passing, continue to be relevant today. The reason for this is that GH's career spanned both the birth of quantum mechanics and the development of the laser. His work, insight, and influence, therefore, set the agenda for generations of spectroscopists.

Although GH was a scientific icon even during his lifetime, those who were privileged to work with him knew him to be a true gentleman, always accessible, deeply inquisitive, and caring. In the voluminous amount of correspondences with authors and referees from all around the globe that was exchanged during the past year in putting this issue together, numerous references were made to Herzberg's style and wisdom. It is clear that GH continues to be a tremendously positive influence.

Many people consider Herzberg to be a physicist; perhaps even GH did. Furthermore, his association with the astronomy community has also been nothing short of profound. Yet, it is probably fairest to say that the field of molecular spectroscopy rests very happily at the interface of physics, astronomy, and chemistry. For one thing, GH did win the Nobel Prize in Chemistry, and today many chemists from around the world are carrying out some of the most innovative and creative spectroscopy. For this reason, we are grateful to the Editorial Board of the *Canadian Journal of Chemistry* for recognizing GH's extraordinary contributions to the chemistry community in Canada and beyond, and for allowing these papers to be published in this venue. We are particularly grateful for the help provided by Judy Murdoch in the Editorial Office.

The quality of the papers in this issue is extremely high. Knowing that Herzberg's standards were the highest possible, we believe he would approve of the progress the spectroscopy community continues to make in building upon his legacy.

Rob Lipson and Benoit Simard

Le présent numéro de la *Revue canadienne de chimie* est dédié à la mémoire d'un des plus éminents scientifiques du Canada : Gerhard Herzberg. Certes, ce n'est pas la première fois qu'une revue honore Herzberg, ou « GH » comme l'appelaient affectueusement ses collègues. Cette année marque toutefois ce qui aurait été le 100e anniversaire de naissance de GH, qui est né à Hambourg, en Allemagne, le 25 décembre 1904, et marque également le 5e anniversaire de sa mort, à 94 ans, le 3 mars 1999. Nous avons donc cru probant, à la lumière des précédentes et en ce début de siècle, de « faire le portrait » du domaine de la spectroscopie moléculaire à haute résolution, dans son incarnation contemporaine. Par ce geste, nous levons le voile sur les avancées déterminantes dans ce secteur tout en rendant hommage aux inestimables contributions d'Herzberg à notre collectivité.

La première anecdote relatée par Boris Stoicheff dans sa fascinante biographie de GH intitulée *Gerhard Herzberg: An Illustrious Life in Science* atteste de l'humour fin d'Herzberg, qui, lorsqu'on lui rappelait qu'il partageait son anniversaire (le 25 décembre) avec un personnage d'exception, rétorquait volontiers : « Effectivement, avec Sir Isaac Newton! » La date de son anniversaire n'était toutefois pas le seul point en commun que GH avait avec Newton. Ainsi, en 1666, Newton a fait la première observation du spectre produit par un prisme. Pour plusieurs, cet événement constitue leur seul niveau d'intimité avec la spectroscopie, même s'ils ne connaissent peut-être même pas ce mot. Autant la science passée a influé sur les réalisations d'Herzberg, autant ses réalisations ont influé sur l'avenir de la science. En effet, pendant sa carrière, GH aura vu éclore la mécanique quantique et le laser. Ses travaux, ses réflexions et son influence sur ces découvertes marquantes aiguillent encore aujourd'hui le travail des spectroscopistes.

Bien que GH ait connu la gloire pendant sa carrière, ceux et celles qui ont eu la chance de le côtoyer admiraient son caractère charmant, affable, curieux et sensible. À maintes reprises, dans la vaste correspondance échangée pendant l'année de préparation du présent numéro honorifique, auteurs et arbitres du monde entier ont loué la finesse et la sagesse d'Herzberg. Même sur le plan humain, GH continue d'inspirer.

Plusieurs affirment qu'Herzberg était un physicien, ce à quoi GH ne s'objecterait probablement pas, et une étroite association avec la collectivité de l'astronomie ne saurait lui être contestée. Nous ne croyons pas nous tromper, cependant, en affirmant que la spectroscopie moléculaire se situe véritablement à l'intersection de trois disciplines : la physique, l'astronomie et la chimie. Après tout, GH a été lauréat de prix Nobel de chimie et nombreux chimistes du monde entier sont au premier rang des chercheurs et des innovateurs dans le domaine de la spectroscopie. Nous désirons remercier le Comité de rédaction de la *Revue canadienne de chimie* de reconnaître les exceptionnelles contributions de GH à la collectivité des chimistes du Canada et du monde entier en nous permettant de publier les articles qui suivent sous la bannière de la *Revue*. Nous sommes particulièrement reconnaissants de l'aide que nous a portée Judy Murdoch, du Comité de rédaction.

Les articles qui suivent ont de l'étoffe. Sachant qu'Herzberg jurait par la rigueur, nous croyons qu'il conviendrait, avec nous, que les progrès faits par ses successeurs demeurent nettement dans son sillage.

GERHARD HERZBERG PC CC[1]

25 December 1904 — 3 March 1999

Elected FRS 1951

BY BORIS P. STOICHEFF OC FRS

Department of Physics, University of Toronto, Toronto, Ontario, Canada M5S 1A7

Gerhard Herzberg, Nobel Laureate in Chemistry, had broad interests and achieved supreme accomplishments in physics, chemistry and astrophysics. The high points in his research were many. In physics they were the work on atomic hydrogen and helium, and evaluations of energy levels and constants of molecular hydrogen and its isotopes. His determinations of many molecular structures and discoveries of spectra of the free radicals CH_2 and CH_3, and of the Rydberg molecule H_3, were each outstanding contributions in chemistry. In astrophysics, his reproduction in the laboratory of the spectrum of CH^+, proving its presence in the interstellar medium, and of spectra of C_3 and H_2O^+ and their presence in comets, his observation of the quadrupole spectrum of H_2 and his discovery of hydrogen in the atmospheres of the planets opened up new applications of spectroscopy for our knowledge of the universe. His classic volumes on molecular spectra and molecular structures remain as encyclopaedias of molecular knowledge for all time. And his famous laboratory, the 'Temple of spectroscopy', served as a home for hundreds of scientists around the world, and helped to bring Canadian science to international prominence.

FAMILY AND EDUCATION, 1904–24

Gerhard Herzberg was born on 25 December 1904 in Osdorf, Pinneberg, a northwestern suburb of Hamburg, Germany. He was the younger son of Albin and Ella Herzberg, his brother Walter having been born in January of the same year. Gerhard was christened Gerhard Heinrich Friedrich Otto Julius on 9 July 1905, in the Lutheran St Gertrudkirche. This was a middle-class family; Albin Herzberg worked as the assistant manager of a small company that manufactured electrical products. The Herzberg genealogy has been traced back to 1573 through records of two Lutheran churches in the town of Langensalza (now Bad Langensalza) where 11 generations of Herzberg families had lived for almost 400 years. Albin was born

© 2003 The Royal Society

there on 12 April 1872, in a family of five sisters and two brothers. His father, Franz Otto, and mother, Anna Sophia Christina (*née* Kürsten), were both born in Langensalza, where Franz Otto spent his life as a merchant. Albin was not a healthy youth: he suffered from dropsy, and became a vegetarian for the good of his health. He and Ella Biber were married in November 1902, Ella at 17 years of age and Albin 13 years her senior. Ella was born in Hamburg to Henrietta Maria and Rudolf Albert Biber, a master glazier.

Albin Herzberg was anxious that his two sons should have the best education possible and more advanced than was the custom in the Herzberg or Biber families. With Ella's interest in music, a piano was purchased and Walter began his serious study of the piano in what was to become his profession, while Gerhard took up the violin.

Just before Gerhard's graduation from the Vorschule, his father died in February 1915 at 43 years of age, leaving a young widow and the boys aged 10 and 11. On the advice of his teachers, Gerhard enrolled in the Realgymnasium of the Johanneum, and thanks to his excellent Vorschule record, he won a scholarship for his nine years at the Johanneum. He immersed himself in science studies and developed a particular love for astronomy. This led to his building a telescope and to his lasting fascination with the heavens. Along with his favourite subjects of mathematics, physics and chemistry, he studied Latin, French, Spanish and English, as well as the works of Goethe, Schiller, Kant and others. Gerhard formed a close friendship with Hans-Werner Döring and Alfred Schulz during the gymnasium years, and the three maintained lifelong relationships, while continuing their studies and professions in different cities.

What especially caught Gerhard's attention in science was a stimulating course in modern atomic physics during special classes, held at 7 o'clock each morning. Lectures on Bohr's model of the atom with spectacular demonstrations of the emission and absorption of light, and the spectra of different gases, entranced the young Gerhard. He was intrigued to learn that light was produced when electrons in atoms jumped from higher orbits to lower ones. These results remained embedded in his mind.

At Easter in 1924, Gerhard graduated with the 'Abitur', the prerequisite for entry into university, and, being one of the best students in his graduating class, he began to think about university. Astronomy was at the top of his list, but he became discouraged when the Director of the Hamburg Observatory thought it unwise unless he had private means of support. Gerhard then considered the more practical possibility of enrolling in a new programme of engineering physics recently introduced in several universities, and chose the Technische Hochschule in Darmstadt (now the Darmstadt University of Technology). By good fortune he was awarded a scholarship by the Stinnes Company, a huge corporation, which had worldwide holdings in mines, shipbuilding, paper mills and foundries.

Early career, 1924–35

Darmstadt, Göttingen and Bristol, 1924–30

All of Herzberg's undergraduate and graduate studies took place in Darmstadt. Although his original idea was to devote himself to engineering physics, he changed his mind and concentrated on basic research in physics. He came under the influence of Professor Hans Rau, whom Herzberg cherished as an exceptional mentor. Along with his heavy duties as Director of the Physics Institute and then as Rector, Rau supervised the research of several students, yet he did not add his name to their publications. As an undergraduate, Herzberg followed the current

literature, and saw in a new issue of *Annalen der Physik* Schrödinger's first paper 'Quantization as an eigenvalue problem'. This aroused his interest because he had just taken a course in partial differential equations and had learned about eigenvalues and eigenfunctions. He gave a talk about the paper in the Physics Colloquium; subsequently, Rau sent him to Freiburg, where Schrödinger was lecturing, and he had the thrilling experience of meeting Schrödinger. In 1927, Herzberg was granted the Dipl.Ing., and received the Müller–Alewyn–Plakette Medal as the best student. His first research resulted in one of the most complete spectra of the Balmer series of hydrogen to the ionization limit. This work was part of his first three papers, including a brief note on spectra of H_2, a subject to which he returned on many occasions in the next 50 years. He also mentioned the possibility of H_3, a radical he was to observe in 1979. In 1928 he was awarded the Dr.Ing., his thesis being on the afterglow of nitrogen and the spectra of N_2 and the ion N_2^+. This intriguing investigation decided him to pursue molecular spectroscopy as his life's work.

He then spent a very profitable postdoctoral year in Göttingen working on theoretical problems in the group of Max Born (FRS 1939), and on an experimental study of the far ultraviolet absorption spectra of methyl halides in the institute of James Franck (ForMemRS 1964). In Göttingen he met many of the giants of mathematics and science, including the younger members E.P. Wigner (ForMemRS 1970), F. Hund, W.H. Heitler (FRS 1948), L.W. Nordheim, V.F. Weisskopf, M. Goeppert, M.L.H. Delbrück (ForMemRS 1967), among others, all destined to become founders of twentieth-century science. While in Göttingen, Herzberg met Luise Oettinger, a physics student in Franck's group, and they married in December 1929. It was also in Göttingen that his acclaimed series of texts on atomic and molecular spectra and structures had their origin: students had asked him to give introductory lectures on atomic and molecular spectra because they had difficulty following discussions in the colloquia. G. Scheibe, a visiting professor from Erlangen, then suggested that he publish the lectures in a book. What began as an introductory volume of about 160 pages eventually blossomed into six volumes of more than 3200 pages, written over four decades.

Herzberg's research made use of several theoretical concepts. He showed that according to the correlation rules just enunciated by Wigner and E. Witmer, the dissociation energy of O_2 was wrong because the excited state could not arise from normal atoms. An important work with Heitler has all but been forgotten over the years. On examining the N_2 rotational Raman spectrum observed by F. Rasetti, they recognized that the even-numbered lines being stronger than the odd-numbered lines meant that nitrogen nuclei obeyed Bose rather than Fermi statistics, contrary to the theory of that time. Although this result was the first indication that electrons are not present in nuclei, Heitler and Herzberg explained the discrepancy by suggesting that electrons in the nucleus lose their spin and thus their influence on statistics of nuclei. This result was clarified three years later with the discovery of the neutron by J. (later Sir James) Chadwick FRS. Herzberg also became interested in Hund's theory of molecular orbitals and produced a paper on bonding and antibonding electrons. This caught the attention of J.E. (later Sir John) Lennard-Jones (FRS 1933) of the University of Bristol, who was visiting Göttingen, and he offered Herzberg a research fellowship in Bristol.

In Bristol, a grating spectrograph was built with the assistance of H.W.B. Skinner (FRS 1942), and spectra of P_2, CP, N_2, C_2H_2 and CH_2O were investigated, some with the help of Luise. Herzberg found a striking case of predissociation in the spectrum of P_2: he observed a breaking-off of rotational structure in two successive vibrational levels and was able to determine the dissociation energy of P_2. Beginning with this study, he became well versed in the concept of

predissociation and wrote a review on this topic. He attended his first of many Faraday Society conferences, visited universities in London and became acquainted with many English scientists. At that time, he completed the procedure of *Habilitation* and was given a position as *Privatdozent* in Darmstadt, to build a spectroscopy laboratory, after his year in Bristol.

Privatdozent in Darmstadt, 1930–35

Back in Darmstadt in 1930, Herzberg built two grating spectrographs, one of 3 m length for the visible and infrared regions, for which he obtained an excellent grating from R.W. Wood ForMemRS, and a 2 m vacuum instrument for the far ultraviolet. He was an invited speaker at many conferences, one being the prestigious 'Week of Physics' on spectra of polyatomic molecules, organized by Peter Debye (ForMemRS 1933) in Leipzig. The other speakers were R. Mecke, F. Rasetti, G. Placzek, H. Sponer, V. Henri and R. de L. Kronig. There he met Werner Heisenberg (ForMemRS 1955), Michael Polanyi (FRS 1944) and Edward Teller for the first time. With Hund present, Herzberg decided to present his ideas on bonding and antibonding electrons. Discussions with Teller led to a two-year collaboration on the vibrational structure of electronic transitions in polyatomic molecules. The main result was that in allowed electronic transitions, totally symmetric vibrations are predominantly excited, whereas transitions with changes in non-totally symmetric vibrations are weak. In 1931, Herzberg became an assistant to Rau, with responsibilities to supervise students. He launched an ambitious research programme with students, postdoctoral fellows from the USA, China and Sweden, a senior assistant from Germany, and Luise.

By photographing the solar spectrum to 12 900 Å, the forbidden $^1\Delta_g$–$^3\Sigma_g$ (magnetic dipole) bands of O_2 were found. New ultraviolet spectra of O_2 were observed at low resolution, consisting of a progression of single Q branches ($^3\Sigma_u^+$–$^3\Sigma_g^-$ transitions, $\Delta K = 0$), now known as the 'Herzberg bands'. Other diatomic molecules investigated were PN, CP, HCl and BeO (which Luise had started in Bristol, completed at high resolution in Darmstadt, and submitted for her PhD thesis to the University of Frankfurt in 1933). Spectra of the polyatomic molecules CO_2, H_2O, HCN, C_2H_2 and CH_3CCH were obtained in the photographic infrared, and of C_2H_2, H_2CO and B_2H_6 in the ultraviolet. Fluorescence spectra of H_2CO confirmed the selection rules proposed by Herzberg and Teller.

Herzberg's laboratory quickly became known internationally and attracted many visitors, including R.S. Mulliken (ForMemRS 1967) and F.A. Jenkins from the USA. With the discovery of deuterium by H.C. Urey (ForMemRS 1947) in 1932, Herzberg recognized its importance for studies of molecular structure. When John W.T. Spinks, from the University of Saskatchewan in Saskatoon, Canada, spent a year with Herzberg, they succeeded in concentrating a spoonful of heavy water by electrolysis, sufficient to make samples of deuterated HCl, HCN, H_2O, C_2H_2 and CH_3CCH, and obtained their spectra.

With the Nazis in power in 1933, life became difficult for the Herzbergs because Luise was of Jewish descent. A year later, Herzberg was informed that his appointment would not be renewed, and he realized he would have to leave Germany. He sought the assistance of the emergency committees in London and Zurich, and found that positions in all six continents were scarce because of the Depression, and those that had been available were filled by refugees. Finally, through the efforts of Spinks, back in Canada, he was offered a guest professorship for two years at the University of Saskatchewan, funded by the Carnegie Corporation. He accepted and arrived there in September 1935. Just before leaving Germany, Herzberg submitted the manuscript of *Atomspektren und Atomstruktur* for publication.

Research professor, University of Saskatchewan, 1935–45

The University of Saskatchewan was one of the most unlikely universities to which someone of Herzberg's stature might have gone. It had a faculty of about 100, 5 in physics, a student enrolment of 2000, and was situated in a city with a population of about 45 000, in the middle of the Canadian prairies, hundreds of miles away from any major city. The university lacked equipment for spectroscopic research, and funds for apparatus or additional staff were almost non-existent.

Within two weeks of his arrival, Herzberg was teaching two courses, one in elementary mechanics to undergraduates and the other in atomic and molecular spectroscopy to students in the Master's degree programme, the highest degree given at the university. To his pleasant surprise, he found the standards at the university to be remarkably high, with top-quality, hard-working students. Among the students in his first graduate class were William G. Schneider (FRS 1962), who was destined to serve as President of the National Research Council in Ottawa from 1967 to 1980, and Henry Taube (ForMemRS 1988), who joined Stanford University and received the 1983 Nobel Prize in Chemistry for his work on electron transfer reactions. Within three months, the Head of the Physics Department and the President could hardly believe their good fortune in having acquired Herzberg. He was given a permanent faculty appointment as Research Professor, and he and Luise decided to make Canada their home and to start a family. Paul Albin was born in 1936 and Agnes Margaret two years later.

An early task was to read the galley proofs of *Atomspektren und Atomstruktur*, which was published in 1936. An English version, *Atomic spectra and atomic structure*, was translated with the help of Spinks, and appeared in 1937. Herzberg then completed *Spectra of diatomic molecules*, the first of three volumes in the series *Molecular spectra and molecular structure*, published in German and in English in 1939, before World War II erupted.

An important result for molecular structure was Herzberg's discovery in 1937 that the length of the C–C single bond was dependent on the number of adjacent atoms. When spectra of methylacetylene (CH_3CCH and CH_3CCD) taken in Darmstadt were analysed, the C–C bond length was found to be 1.460 Å, considerably shorter than the 1.543 Å accepted for ethane, much to the surprise of Linus Pauling (ForMemRS 1948), who accepted this result only after his colleague R.M. Badger confirmed it by electron diffraction. In C_2H_6 the C–C bond is surrounded by three single bonds on each side, and in methylacetylene by three single bonds on one side and a triple bond on the other. Herzberg was to continue such studies for the remaining C–C and C=C bonds.

He was regularly invited to attend conferences in Canada and the USA. A small meeting on interstellar molecules, organized by Otto Struve (FRS 1954), Director of the Yerkes Observatory, in 1941 was attended by Mulliken, Teller and H. Beutler, from the Chicago campus, and P. Swings, Herzberg, and staff of the Observatory. The purpose was to discuss a series of lines near 4000 Å, observed in absorption spectra of distant stars by T. Dunham and W.S. Adams (ForMemRS 1950) at Mount Wilson Observatory. One of the lines had been identified as being due to CH; however, four other lines posed a problem. Swings thought they might belong to an ionized molecule like C_2^+, CH^+, CN^+, NH^+ or NO^+, and Mulliken suggested the free radical CH_2. Herzberg and Teller favoured CH^+: they surmised it would have an electronic band near 4000 Å because of the similarity of CH^+ to iso-electronic BH, whose spectrum was in this wavelength region.

Herzberg attempted to reproduce these unidentified lines in the laboratory. He had been

awarded $1500 by the American Philosophical Society to build a 6 m grating spectrograph, which was now ready. He also had a good student, Alex E. Douglas (FRS 1970), who was later instrumental in assisting Herzberg in establishing the Spectroscopy Laboratory in Ottawa. A discharge in helium with a trace of benzene produced a molecular spectrum in the 4000 Å region. Closer examination showed that three R(0) lines, the only lines expected to occur at the extremely cold temperatures of space, were exactly at the positions of the unidentified interstellar lines. Further experiments convinced Herzberg and Douglas that the spectrum was due to the ion CH^+. This was the first molecular ion to be identified in the interstellar medium. (Later, Douglas found that the fourth line was also an R(0) line of a CH^+ band.)

Herzberg's work on the free radical CH_2 began on receiving a letter and spectrum from Swings: 'We observed in a comet a group of features around 4050 Å, and we can't understand what they are'. Herzberg, who was then writing *Infrared and Raman spectra of polyatomic molecules*, thought the spectrum looked like a perpendicular band of a nearly symmetrical top molecule, and had the idea that it might be due to CH_2. He reproduced the spectrum with an interrupted discharge in CH_4 and assumed that it was due to CH_2, but did not rule out CH_3 or CH_4. This result on the comet bands and the identification of CH^+ in interstellar space quickly established Herzberg's reputation among astronomers. Even so, about seven years later, his identification of the 4050 Å group with CH_2 was shown to be wrong; this induced him to search for the spectrum of CH_2 until he discovered it two decades later. He and Douglas later showed the 4050 Å group to be due to C_3.

In 1942, Herzberg presented his idea of *l*-type doubling. He showed that infrared spectra of C_2H_2, CO_2, and HCN exhibited a splitting of Π vibrational levels into two components, the double degeneracy being removed by the interaction of rotation and vibration. His simple theoretical treatment caused some controversy, but was later accepted to be correct. During his 10 years in Saskatchewan, Herzberg supervised the research of 10 students who received their Master's degrees with studies of B_2, C_2, S_2, CH, CN, CO, NO, BCl, B_2H_6 and active nitrogen. After the war he learned that two of his students, J.G. Fox and R.B. Sutton, had worked on the atomic bomb project at Los Alamos, New Mexico.

Although technically 'an enemy alien', Herzberg was invited to investigate spectra of explosives. He signed an Oath of Secrecy and attended classified meetings on explosives in the USA with G.B. Kistiakowski, H. Eyring, G. Gamow and B. Crawford Jr, among others. As Herzberg was to say later, the explosives work was challenging and interesting scientifically, but it did not help to end the war.

On completing *Infrared and Raman spectra of polyatomic molecules*, Herzberg began taking singing lessons for relaxation. His resonant bass-baritone voice was suited to lieder by Schubert and Brahms and some arias by Mozart and Verdi, which he especially enjoyed.

Professor of Spectroscopy, Yerkes Observatory, 1945–48

Just before the end of World War II, Herzberg was surprised to receive a letter from Otto Struve inquiring whether he would be interested in joining the Yerkes Observatory of The University of Chicago to set up a spectroscopy laboratory. This was an opportunity to work with the major astronomers in the world and to concentrate on molecules of astrophysical interest. He accepted a position as an associate professor, then as Professor of Spectroscopy, arrived in Williams Bay in September 1945, and spent three productive years there. His col-

leagues at Yerkes were Otto Struve, G.P. Kuiper, W.A. Hiltner, W.W. Morgan and Subrahmanyan Chandrasekhar FRS, all distinguished astronomers. He also had the opportunity to continue his association with Mulliken, Beutler, Teller and Franck at the Chicago campus. Herzberg valued highly his close and lasting friendship with Chandra (Chandrasekhar).

To emulate planetary atmospheres, Herzberg built a cell 22 m long, running under the ceiling, through almost the whole length of the observatory basement. This iron pipe was fitted with concave mirrors, which could be aligned for multiple traversals of the cell to provide an extremely long absorbing path. This made possible the study of absorption spectra of diatomic and polyatomic molecules of astrophysical interest, and others for determination of their structures. Spectra of O_2, CO, NO, CO_2, N_2O, C_2H_2, CH_4, CHF_3, CH_3I and CH_3CF_3 were investigated with the assistance of Luise, Harold J. Bernstein from the National Research Council in Ottawa, S.P. Sinha from Patna University in India, and two graduate students, R. Narahari Rao and John G. Phillips.

The observation of the quadrupole spectrum of hydrogen turned out to be Herzberg's major achievement at Yerkes Observatory. He had predicted 10 years earlier that large amounts of H_2 in planetary atmospheres would make up for the weak quadrupole spectrum and was determined to find this spectrum of hydrogen in laboratory experiments. For the 3–0 band in the 8000–8600 Å region he used a path length of 5370 m and a gas pressure of nine atmospheres, and observed four lines in their predicted positions. Another four lines of the 2–0 band were found in the region 11 300–12 400 Å. As expected, all eight lines were extremely sharp. Twelve years later, the H_2 quadrupole spectrum was observed in the atmospheres of Jupiter and Uranus. Later still, its emission spectrum was observed in the Orion nebula and in planetary ionospheres, and superluminous galaxies.

In spite of the many research activities and a light teaching load, Herzberg missed the daily contact with humanists, chemists, and physicists that he had enjoyed in Saskatoon. He and Luise realized they were homesick for Canada, and let friends know they were eager to return. John Spinks mentioned their hopes to C.J. Mackenzie FRS, President of the National Research Council of Canada (NRC) in Ottawa, and E.W.R. (Ned) Steacie (FRS 1948), Director of the Division of Chemistry, and they quickly set into motion the means for enticing Herzberg to join the NRC. He was invited to establish a major spectroscopy laboratory for basic research, with an appointment to the new and highest non-administrative position of Principal Research Officer. This was an opportunity not to be missed, and one in which he would realize his full potential. He accepted in July 1947 for arrival a year later, when he felt he would have adequately discharged his obligations to Yerkes Observatory.

A HALF-CENTURY AT THE NATIONAL RESEARCH COUNCIL, OTTAWA, 1948–94

The NRC had its beginnings in 1916 as an Advisory Council appointed by the Government to promote and undertake scientific and industrial research for national development. It enjoyed arm's-length treatment from the Government and became a major scientific resource for the Armed Services during World War II, winning strong support for increased research activity in peacetime. Under these favourable conditions, Herzberg was given complete freedom in research, and substantial space and funds for staff and equipment. The availability of devices and techniques developed during the war, such as radar, sensitive detectors for infrared radiation, and photomultipliers for the visible and ultraviolet regions, made this an ideal time at

which to develop a spectroscopy laboratory. Herzberg rose to the challenge and established a major laboratory that quickly won acclaim for its many accomplishments in atomic and molecular spectroscopy.

A month after his arrival in Ottawa, Herzberg was informed that R.W. Boyle, Director of the Division of Physics, would retire in October, and was urged to take the position. Because his main interest in joining the NRC was research and not administration, he finally accepted when L.E. Howlett agreed to be the Assistant Director, to lead the applied research groups and to take care of the day-to-day administration of the Division of Physics. Herzberg served as Director from 1949 to 1955, when the Division of Physics was split into the Division of Pure Physics and the Division of Applied Physics. Howlett took over the latter and Herzberg directed the former until his retirement from administrative duties at age 65 in 1969. As Herzberg often noted to visitors, 'I am the Director but I don't direct': he provided the physics groups with the best facilities possible for scientists to work on problems of their own choosing, and encouraged them to include postdoctoral fellows in their programmes and to invite leading scientists from around the world to visit, give lectures and collaborate in research. He also initiated research in several new areas, including low-temperature and solid state physics under the leadership of the dynamic D.K.C. MacDonald (FRS 1960), theoretical physics under Ta-You Wu, and laser and plasma physics headed by S.A. Ramsden.

The enlightened leadership provided by Herzberg in physics, and by Steacie as Director of the Division of Chemistry (and then as President of the NRC from 1952 to 1962), was instrumental in bringing world recognition of the NRC. While continuing an active research programme and attending scientific conferences usually as a keynote speaker, Herzberg served on many international committees looking after problems in notation, standards and related matters in spectroscopy, and kept in constant touch with colleagues all over the world. In the midst of these many activities, Herzberg always found time to make the way a little easier for fellow scientists, young and old, by writing letters of encouragement, making recommendations about jobs and advancements, and nominating deserving candidates for awards. Such unselfish interest in other people's careers was unique.

As Canadian politicians jumped on the 'world bandwagon' of the 1960s, for development of coherent national science policies to help in solving social and economic problems, and criticized the NRC and its presidents past and present, the usually mild-mannered Herzberg ventured out of his laboratory to speak in the defence of science. He argued vigorously for the freedom of choice for scientists and against the encroaching bureaucratic control of science and technology. His pleas for freedom were not confined to scientists and the NRC, but embraced human rights, and he persistently appealed on behalf of unjustly detained dissidents worldwide, even participating in demonstrations in front of the Soviet Embassy in Ottawa on several occasions.

Herzberg received numerous awards, the most prestigious being the Faraday and Royal Medals, and in 1971 the Nobel Prize in Chemistry. The death of Luise five months before the announcement of the Nobel Prize was a severe blow. She had admirably managed a busy household, yet had the energy to work and publish papers with Gerhard, and provide figures and tables of molecular data for his texts. Since the 1950s she had performed independent research on solar spectra and photochemical processes in the upper atmosphere at the Dominion Observatory and then the Radio Physics Laboratory. With her death, Canada lost one of its few accomplished women physicists.

Among the many honours that Herzberg received from his adopted country, he was especially

pleased to receive his first honorary degree from the University of Saskatchewan, to be appointed a Companion of the Order of Canada (CC) in 1968 and a Member of the Queen's Privy Council for Canada in 1992, in recognition of his outstanding contributions to Canada. As a Privy Councillor, his title was The Honourable Gerhard Herzberg PC.

At a conference on 'Free radical spectroscopy', held in honour of Herzberg's 65th birthday, the NRC's President W.G. Schneider announced that Herzberg would be appointed Distinguished Research Scientist and would continue his research at the NRC. This occasion was the first in a series of birthday conference celebrations, held every five years in Canada, the one in 1994 being the last that Herzberg was able to attend. On his 70th birthday in 1974, the creation of the Herzberg Institute of Astrophysics (HIA) was announced by Schneider. In March 1972, Herzberg married Monika Tenthoff, the niece of his gymnasium friend Alfred Schulz.

Herzberg continued with his research activities, completed *Electronic spectra of polyatomic molecules*, the last of his trilogy on *Molecular spectra and molecular structure*, and published *The spectra and structures of simple free radicals*, based on his George Fisher Baker Lectures at Cornell University. Extensive tables of data on electronic states and constants of over 900 diatomic molecules and ions were published in 1979 with K.P. Huber in *Constants of diatomic molecules*. After a few mild heart attacks in the 1970s, Herzberg began to reduce his travels but maintained an active research agenda. He also found the energy to publish revised editions of all three volumes of *Molecular spectra and molecular structures* in 1989–91. As he approached his 90th birthday, his health and failing eyesight prevented him from maintaining an active eight-hour workday, and he proposed to retire. A ceremonial retirement tribute took place at the NRC on 13 December 1994, his official retirement date being 31 December.

The Spectroscopy Laboratory

Herzberg was fortunate in being able to recruit Alex Douglas as his principal assistant in the development of the Spectroscopy Laboratory. Thus began the fruitful collaboration, lasting for 33 years, which Herzberg often emphasized: 'Douglas made a towering contribution to the laboratory'. They planned to achieve the highest resolution possible, with access from the longest to the shortest wavelengths for the study of atomic and molecular spectra. Four grating instruments were designed and built to cover the visible, infrared and far ultraviolet regions: a 7 m spectrograph for 2000–12 000 Å; an infrared spectrometer beyond 12 000 Å, equipped with sensitive detectors; and 3 m and later 10 m instruments for the vacuum ultraviolet below 2000 Å.

Others in the founding staff included Donald A. Ramsay (FRS 1978), who initially helped Herzberg in developing the flash-photolysis technique, Hin Lew, whose interests were in atomic and molecular beams, and Cecil C. Costain, who established the microwave laboratory. In time, each had the assistance of an expert technician and two postdoctoral fellows, and given the means for inviting visiting scientists, and encouragement to attend conferences to report on research. Also, on average about six postdoctoral fellows (PDFs) participated each year. By 1975, over 130 PDFs from the best laboratories around the world had spent up to two years in the Spectroscopy Laboratory, and more than 100 visiting scientists had worked there for periods of four months or more. Over the years a small number of PDFs were offered permanent appointments: I was the first of the lucky ones, followed by John W.C. Johns, Takeshi Oka (FRS 1984), Klaus P. Huber and A. Robert W. McKellar, mainly involved in experimen-

tal work, and theorists Jon T. Hougen, Philip R. Bunker and James K.G. Watson (FRS 1987), among others.

Scientific life in the Spectroscopy Laboratory was intense, with excellent equipment and facilities at hand, and much exciting research was done. Herzberg gave guidance to the group by his own inimitable example of working long hours, six days a week. Neither he nor Douglas directed our research, and each PDF was free to collaborate with a staff member or to work independently. There were weekly group meetings, seminars and colloquia by distinguished visitors, and daily afternoon tea, with all members taking part in discussions on science, and sometimes on hockey or cricket. In the lively environment created by Herzberg and Douglas it is easy to understand that, in the words of the Nobel citation, 'A noted English chemist has said that the only institutions which have previously played such a role were the Cavendish Laboratory in Cambridge and Bohr's institute in Copenhagen'.

Scientific research

Within a few years the Spectroscopy Laboratory was in full swing, with numerous investigations on a variety of topics. The spin and magnetic moments of nuclei were measured, and the interaction between nuclear and electronic motions was studied; spectra of many diatomic and polyatomic molecules, ions and free radicals were obtained, many for the first time; and a variety of forbidden transitions were investigated. These studies were important for elucidating ground and excited states and structures and for developing and confirming atomic and molecular theory, and were often significant for astrophysics.

Herzberg's own interests and experiments in molecular spectroscopy continued on a broad front, and he also became involved with some problems in atomic spectroscopy and structures. The first experiment carried out in the new laboratory was the determination of the spin and statistics of the ^{3}He nucleus. Herzberg and Douglas established the value $\frac{1}{2}$ for the spin and Fermi statistics from the 3:1 intensity alternation of odd to even rotational lines in the spectrum of $^3He_2$, in agreement with theory. Herzberg began a lengthy programme of accurate measurements of absolute wavelengths for spectra of D, He and He^+ in the vacuum ultraviolet to test theoretical predictions for Lamb shifts. For the 1S level of deuterium he obtained the value 0.264 cm^{-1}, in agreement with the theoretical value 0.2726 cm^{-1}. Experimental values for the ground states of ^{3}He and ^{4}He were also in general agreement with theory (to ± 0.05 cm^{-1}). Measurements were also made for excited states of He, He^+ and Li^+. Because some of these determinations were dependent on theoretical values of specific energy levels and ionization potentials, which turned out to be less reliable than assumed, Herzberg became involved with Chandra, in lengthy computations of He, Li^+ and O^{6+}, using variational methods.

From his earliest work with hydrogen, Herzberg realized that experimental data on H_2 and its isotopes would be of fundamental importance for astrophysics and for testing quantum theory. He began a concerted study of hydrogen spectra and reported the results in over 40 publications. Because HD has a dipole moment, although small, he had suggested in 1938 that its spectrum could be used to detect deuterium in planetary and stellar atmospheres. In 1950 he observed the 3–0 and 4–0 bands, and later the 1–0 band in the infrared. Two decades later, HD was detected in a spectrum of Jupiter.

In 1949 Kuiper found broad features in spectra of Uranus and Neptune, and asked Herzberg whether he had any idea of their origin. A feature at 8270 Å agreed closely with a line of the 3–0 spectrum of H_2 but was clearly not a quadrupole line because these are extremely sharp. He surmised that it could be caused by pressure-induced absorption (an effect discovered at

the University of Toronto a year earlier), and began experiments with H_2 at high gas pressure in a long absorbing path cooled to liquid nitrogen temperature. He observed a broad 3–0 band, in agreement with the spectra of Uranus and Neptune, and established for the first time the presence of hydrogen in extraterrestrial atmospheres.

The improved techniques in high-resolution spectroscopy at the NRC provided precise values of energy levels of the ground and excited states of hydrogen and its isotopes. To test quantum theory, comparisons of experimental and *ab initio* values were made of rotational and vibrational energy levels, dissociation energies and ionization potentials. From spectra with the 10 m ultraviolet spectrograph, Herzberg and colleagues obtained precise values for the dissociation energy and ionization potential, in good agreement with theoretical values. He continued the investigations of electronic spectra of hydrogen and its isotopes into the 1990s and obtained improved ionization potentials, as well as detailed data of high orbital angular momentum states for H_2 and D_2. Many of these investigations were performed with the assistance of PDFs and visiting scientists.

Along with the above studies, Herzberg concentrated his efforts on obtaining the spectra of short-lived free radicals, particularly methylene (CH_2) and methyl (CH_3). Although these building blocks of organic molecules had long been postulated as intermediates in chemical reactions, Herzberg argued that he wanted to observe their spectra before he could feel entirely convinced of their presence in chemical reactions, flames, explosions or discharges. His pursuit of this question after his first involvement with CH_2, 17 years earlier, culminated in what undoubtedly became one of his most notable and satisfying achievements.

With the help of his superb technician Jack Shoosmith, Herzberg explored several different experimental approaches, chose the technique of flash photolysis and succeeded in obtaining spectra of CH_3 from the parent molecules $Hg(CH_3)_2$, and $(CH_3)_2CO$ in 1956. Proof that these were spectra of CH_3 was established by using partly deuterated samples, which produced four slightly shifted bands arising from the isotopic species CH_3, CH_2D, CHD_2 and CD_3. Two years later, a spectrum of CH_2 was found in the extreme ultraviolet region at 1415 Å by using the parent molecule CH_2N_2. Further experiments with deuterated compounds showed three slightly shifted bands (due to CH_2, CHD and CD_2), proving that the radical had two H atoms. The spectrum with $^{13}CH_2N_2$ established the presence of a single carbon atom. Analyses of the spectra led to a nonlinear symmetrical structure with C–H distances of 1.071 Å and an H–C–H angle of 140°. The discovery of the spectra of CH_2 and CH_3 was undoubtedly the criterion leading to the award of the Nobel Prize in Chemistry in 1971, with the citation 'for contributions to the knowledge of electronic structure and geometry of molecules, particularly free radicals'. Four decades later, CH_2 was detected in the interstellar medium, and CH_3 in the atmospheres of Saturn and Neptune and the interstellar medium.

Spectra of over 30 free radicals were discovered and studied by Herzberg, Ramsay and other members of the laboratory during the 1950s and 1960s. Their use of flash photolysis coupled with the superb spectrographs built at the NRC changed in a dramatic manner the field of free radicals from unobservable chemical intermediates to well-known molecules, and provided new molecules for study. Investigations with a variety of sources, resulted in the excitation of spectra of many molecular ions, C_2^+, CO_2^+, N_2O^+, $C_4H_2^+$ and H_2S^+, and in the discovery of the first discrete spectrum of a gaseous negative molecular ion, C_2^-.

With its studies of spectra of free radicals and molecular ions, and Herzberg's interests in molecular astrophysics, the Spectroscopy Laboratory was an integral part of the HIA. The

study of molecular ions provided an important confirmation of early ideas that comets consisted mainly of ices, including water (H_2O). Because the water molecule does not exhibit an emission spectrum, various groups had attempted in vain to obtain the laboratory spectrum of H_2O^+ to compare with spectra of comets. At Herzberg's suggestion, Hin Lew succeeded in obtaining a rich and complex emission spectrum in the visible region, just as astronomers were awaiting the reappearance of Comet Kohoutek. When spectra of the tail of the comet were sent to Herzberg by colleagues in Italy and Israel, he and Lew immediately identified parts of the spectrum to be identical with the laboratory spectrum of H_2O^+, thus proving that Comet Kohoutek was partly composed of ice.

Herzberg believed that because of the great stability of H_3^+ and the simple reaction forming it from collisions of H_2 and H_2^+, H_3^+ must be present in interstellar space, where hydrogen is by far the most abundant element. Meanwhile, others predicted that it was the starting point for the creation of most of the molecules found in interstellar space. A friendly competition in the search for this elusive species developed at the HIA, with Takeshi Oka looking for an absorption spectrum and Herzberg an emission spectrum, expected to occur near 2522 cm^{-1}.

Herzberg also kept up a search in the visible region and found a spectrum at 5600 Å with broad lines for hydrogen and sharper lines for deuterium. He concentrated on the deuterium spectrum but deduced that it was due to neither D_2 nor D_3^+ but to D_3, a molecule stable in its excited states. The structure was an equilateral triangle, as predicted for D_3^+ (H_3^+), but with the third electron in an orbit far from the protons, and he called it a 'Rydberg molecule'. He also examined spectra of the diatomic Rydberg molecules HeH^+, $HeNe^+$, $HeAr^+$, KrH, KrD, XeH, XeD, ArH and ArD, keeping in mind the possibility that they could be detected in space and might be the cause of the diffuse interstellar bands.

Meanwhile, Oka searched for the absorption spectrum of H_3^+, using laser techniques, and after four years of concentrated effort he succeeded in detecting its infrared spectrum in 1980. This was a fundamental discovery for interstellar spectroscopy and chemistry. Another important achievement of the HIA was the detection of spectra of the long-carbon-chain molecules HC_5N, HC_7N and HC_9N in the interstellar medium. This work was initiated by Harry (later Sir Harold) Kroto (FRS 1990), a former PDF at NRC and a Nobel laureate in chemistry (1996), and was carried out by him together with Oka and colleagues with the HIA radio telescope.

THE LAST YEARS, 1995–99

As expected, Herzberg continued to work in his office daily, mainly carrying on his voluminous correspondence and reading technical papers. He persisted in his search for the rare molecular species or chemical processes that could give rise to the ubiquitous diffuse interstellar bands: 'It is one of my aims to solve that problem before I quit'. But this was not to be. A fall down a short flight of stairs at home prevented him from spending more than a few hours each day at the office. After a severe heart attack in 1996, his health noticeably failed. He ceased working in his office and was often in hospital for tests lasting a day or more. With the progressing effects of Parkinson's disease, increasing medication and loss of appetite, he weakened rapidly and was confined to his home, where Monika cared for him faithfully in the last three years of his life. He died at home on 3 March 1999.

At a Memorial Tribute held on 11 May 1999 in the Auditorium of the National Research

Council, President Arthur Carty announced the creation of the Herzberg Memorial Prize and Fellowship, open to applicants in Canada and around the world to work at the NRC for up to a year. In November 2000 the Federal Government also launched the country's premier research award, the annual Gerhard Herzberg, Canada Gold Medal for Science and Engineering with a $1 million research award over five years. Such awards to applaud and encourage outstanding research would have pleased Herzberg immensely. His office, Room 2057 in the NRC Laboratories at 100 Sussex Drive, was renovated and named The Gerhard Herzberg Reading Room, as a lasting tribute to this gentle and peaceful man, one of Canada's most renowned scientists.

Honours and awards

Fellowships, medals and special lectures

1927	Mueller–Alewyn–Plakette Medal, Darmstadt
1939	Fellow, Royal Society of Canada
1950	Médaille de l'Université de Liège
1951	Fellow, The Royal Society of London
1953	Henry Marshall Tory Medal, Royal Society of Canada
1954	Honorary Fellow, Indian Academy of Sciences
	Joy Kissen Mookerjee Gold Medal, Indian Assoc. for the Cultivation of Science
1957	Gold Medal for Achievement in Physics, Canadian Association of Physicists
	Honorary Fellow, National Academy of Sciences, India
1959	Medal of the Society for Applied Spectroscopy
1959–60	Chair Francqui, Université de Liège
1960	Médaille de l'Université de Liège
	Médaille de l'Université de Bruxelles
	Corresponding Member, Société Royale des Sciences de Liège
	Bakerian Lecture, The Royal Society of London
1962	Spectroscopy Award, Spectroscopy Society of Pittsburgh
1963	Twelfth Spiers Memorial Lecture, Faraday Society
1964	Frederic Ives Medal, Optical Society of America
	Honorary Member, Hungarian Academy of Sciences
	Academician, Pontifical Academy of Sciences
1965	Foreign Honorary Member, American Academy of Arts and Sciences
1966–67	President, The Royal Society of Canada
1968	Honorary Fellow, Optical Society of America
	Honorary Fellow, Chemical Society of London (now Royal Society of Chemistry)
	Foreign Associate, National Academy of Sciences, Washington
	Companion of the Order of Canada
	George Fisher Baker Non-Resident Lecturer in Chemistry, Cornell University
1969	Willard Gibbs Medal, American Chemical Society
	Gold Medal, Professional Institute of the Public Service of Canada
	Honorary Member, Society for Applied Spectroscopy
1970	Faraday Medal, Chemical Society of London
	Honorary Member, Royal Irish Academy

1970	Honorary Fellow, Chemical Institute of Canada
	Honorary Member, Spectroscopy Society of Canada
1971	Royal Medal, The Royal Society of London
	Linus Pauling Medal, American Chemical Society
	Nobel Prize in Chemistry, Swedish Royal Academy of Sciences
1972	Foreign Member, American Philosophical Society
	Chemical Institute of Canada Medal
1973–80	Chancellor, Carleton University
1973	Member, International Academy of Quantum Molecular Science
	Honorary Fellow, Indian Chemical Society
1974	Madison Marshall Award, American Chemical Society (North Alabama Section)
	Foreign Fellow, Indian National Science Academy
	Honorary Member, La Asociacion de Quimicos Farmaceuticos de Colombia
	Foreign Associate, Royal Academy of Belgium
1976	ACS Centennial Foreign Fellow, American Chemical Society
	Honorary Member, Japan Academy
1978	Honorary Member, Chemical Society of Japan
	Honorary Member, Real Sociedad Espanola de Fisica y Quimica
1980	Member, European Academy of Arts, Sciences and Humanities
1981	Foreign Member (Physics), Royal Swedish Academy of Sciences
1985	Earle K. Plyler Prize, American Physical Society
1986	Korrespondierendes Mitglied Bayerische Akademie der Wissenschaften
1987	Jan Marcus Marci Memorial Medal, Czechoslovak Spectroscopy Society
	Minor planet 3316–1984 CN1 officially named ‘Herzberg’
1990	Ohio Engineering Hall of Fame, Dayton
1992	Member of the Queen’s Privy Council for Canada

Honorary degrees

1953	LLD, University of Saskatchewan
1954	DSc, McMaster University, Hamilton
1956	DSc, National University of Ireland, Dublin
1958	LLD, University of Toronto
1960	LLD, Dalhousie University
	DSc, Oxford University
1961	LLD, University of Alberta
1964	DSc, University of British Columbia
1965	DSc, Queen’s University, Kingston
1966	DSc, University of New Brunswick
	Fil.Hed.-Dr., University of Stockholm
1967	DSc, University of Chicago
	DSc, Carleton University, Ottawa
1968	Dr.rer.nat., University of Göttingen
	DSc, Memorial University, Newfoundland
1969	DSc, York University, Toronto
1970	DSc, University of Windsor
1971	DSc, Royal Military College of Canada

1972	DSc, Drexel University, Philadelphia
	LLD, St. Francis Xavier University
	DSc, University of Montreal
	LLD, Simon Fraser University
	DSc, Université de Sherbrooke
	DSc, Cambridge University
	DSc, McGill University, Montreal
1973	DSc, University of Manitoba
1974	Dr.rer.nat., University of Hamburg
1975	DSc, University of Bristol
	DSc, Andhra University
1976	DSc, Osmania University
	DSc, University of Delhi
	DPhil, Weizmann Institute of Science
	DSc, University of Western Ontario
1979	DSc, Laval University
1983	Dr.phil.nat., University of Frankfurt
1984	PhD, University of Toledo
1991	DSc, St. Mary's University

Acknowledgements

In this memoir I have drawn on my knowledge of Gerhard Herzberg, whom I had known for almost five decades as a mentor and friend, and whose life and achievements I have described in more detail in *Gerhard Herzberg: an illustrious life in science*, published by the NRC Press in 2002. I am particularly appreciative of the assistance of Mrs Monika Herzberg, and Paul and Agnes Herzberg, as well as colleagues of the Spectroscopy Laboratory, who provided much material and advice in preparation of the biography.

The frontispiece photograph was taken in 1967, and is reproduced by courtesy of the Public Relations Office of the National Research Council of Canada.

Bibliography

A full bibliography appears on the accompanying microfiche, a photocopy of which is available from The Royal Society's Library at cost.

AWARD LECTURE / CONFÉRENCE D'HONNEUR

The 2003 CSC Pure or Applied Inorganic Chemistry Award Lecture
Adventures in stable radical chemistry

Robin G. Hicks

Abstract: Stable radicals are of intense fundamental interest because they challenge conventional bonding paradigms, and they find a wide range of uses ranging from organic and polymer synthesis to biological and medicinal applications to materials science. Yet the directed synthesis and study of stable radicals for either fundamental or applied purposes are rarely pursued strategies. This Award Lecture describes my research group's efforts in exploratory and targeted research focusing on stable radical design.

Key words: stable radicals, verdazyls, molecular magnetism.

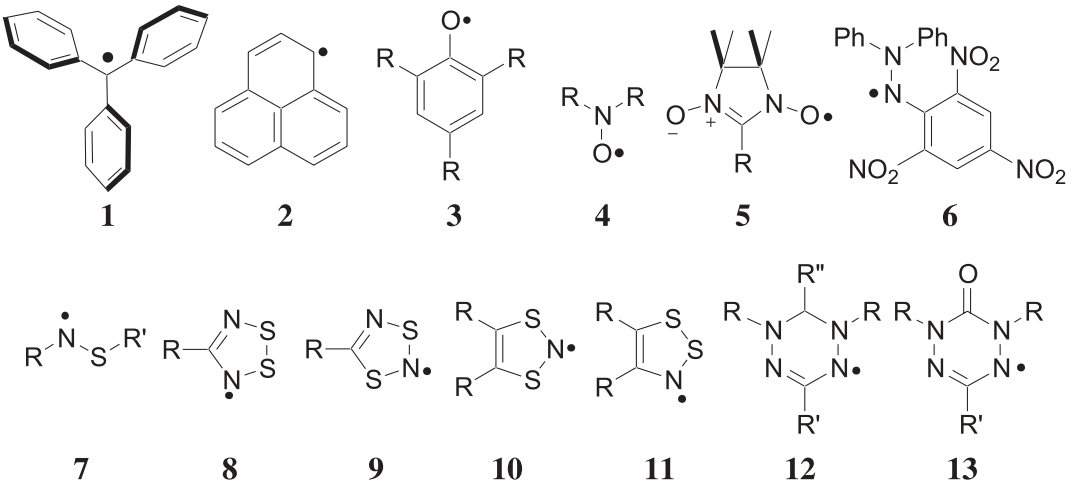
Résumé : Les radicaux stables présentent un intérêt fondamental intense en raison de leur défi aux paradigmes conventionnels des liaisons et on leur connaît beaucoup d'applications en sciences biologiques, médicinales et celles des matériaux en plus de les utiliser en synthèse organique et celle des polymères. Toutefois, il y a rarement de travaux orientés directement à la synthèse et à l'étude de radicaux stables pour des fins fondamentales ou appliquées. Dans cette présentation, on décrit les recherches exploratoires et orientées effectués dans mon groupe pour le développement de radicaux stables.

Mots clés : radicaux stables, verdazyles, magnétisme moléculaire.

[Traduit par la Rédaction]

Introduction

One of the fundamental tenets of molecular structure and bonding is that closed-shell electronic configurations are stable. The corollary to this principle is that species with unpaired electrons — *radicals* — are transient or reactive intermediates. However, there are examples of open-shell compounds that do not exhibit the high reactivity normally associated with radicals (dimerization, autoxidation, H· or R· abstraction, etc.). These relatively inert species, generally referred to as *stable radicals*,[1] stand out as molecules of exceptional structure and properties.



Gomberg's discovery of the triphenylmethyl radical **1** (2) marked the dawn of stable radical chemistry. Triarylmethyl derivatives remain the best known class of stable radicals based on hydrocarbons — although only heavily substituted derivatives are isolable (3). Other stable organic radicals include phenalenyl radicals **2** (4) and substituted phenoxyl radicals **3** (5), though like the triarylmethyls these also require bulky substituents for stability. Most of the general families of stable radicals are based on catenated *inorganic elements*

[1]The terms stable and persistent have long been used loosely with respect to radicals, and indeed both are subjective terms. In general, persistence is a kinetic phenomenon related to lifetime whereas stability implies thermodynamic stability under a certain set of conditions. From a practical perspective, "stable" radicals are arbitrarily defined here as those that persist for many days in solution and can be isolated and (or) stored as radicals without appreciable decomposition. For a more detailed account of the use of these terms, see ref. 1.

 doi: 10.1139/V04-064 © 2004 NRC Canada

such as nitrogen, oxygen, and sulfur. This is exemplified by small molecules such as NO, NO_2, and O_2. By far the most familiar stable organomain group[2] radicals are the nitroxides **4** and the closely related nitronyl nitroxides **5** (6). The *N*,*N*-diphenyl-*N′*-picrylhydrazyl (DPPH) radical **6** is well known, although hydrazyls as a class are not very long-lived (7). Other established stable radicals include a multitude of sulfur–nitrogen-based species **7–11** (8) and verdazyls **12** and **13** (9). In addition to these, new individual examples continue to be discovered (10), many of which appear to warrant publication largely on the basis that they are stable radicals (11). This lends support to the notion that, despite their existence for over a century, to this day the chemical community views stable radicals as highly unusual and intriguing species.

But stable radicals offer much more than pure novelty. From a fundamental perspective, they challenge conventional thinking about molecular electronic structure. Gomberg's triphenylmethyl was the first example of a molecule with trivalent carbon, a bonding arrangement thought at the time to be nonexistent. Recent examples of molecules possessing features such as "one-electron bonds" (12) or so-called "singlet diradicals" (13) offer further evidence that we can and should continue to look to open-shell molecules in order to improve our understanding of structure and bonding. Stable radicals are also central to a diverse array of applications:

1. The incorporation of stable radicals into chemical and particularly biological systems facilitates structural, mechanistic, and dynamic investigations using electron paramagnetic resonance (EPR) spectroscopic methods. Of particular importance are techniques such as spin labeling (14), spin trapping (15), and EPR imaging (16).
2. There is tremendous interest in the electronic and magnetic properties of stable radical-based materials as part of the general pursuit of new generations of functional molecular-based materials (17). These efforts stem from the simple fact that many interesting and technologically relevant charge transport and magnetic properties require unpaired electrons.
3. The chemical biology of stable radicals is well established. Small-molecule radicals such as dioxygen, superoxide, and nitric oxide, as well as tyrosyl radicals (18), are known to play crucial roles arising from their reactions with reactive free radicals and metals.
4. Most "stable" radicals in fact do possess some chemical reactivity, but of a much more controlled nature than is normally associated with radicals. A variety of synthetically useful reactions have been developed based on the "persistent radical effect" (PRE) (19), i.e., the selective cross-coupling reactions of stable and reactive radicals. A particularly exciting synthetic application of the PRE is the development of "living" free-radical polymerization processes (20). In addition to PRE-based chemistry, stable radicals exhibit a rich redox chemistry that has led to their development as practical oxidizing agents (21) and as *anti*oxidants too (22).

Personal motivations

My own fascination with stable radicals began during my graduate school days at the University of Guelph. My doctoral research, carried out under the supervision of Rich Oakley, focused on the solid-state packing and charge transport properties of heterocyclic sulfur–nitrogen and selenium–nitrogen radicals (23). I maintained a fleeting interest in radical ions (24) (through electrochemistry) and neutral radicals (25) while acquiring expertise in synthetic organic chemistry and electrochemistry during my postdoctoral stint with Fred Wudl at the University of California-Santa Barbara. As I developed ideas for what would become my own research program, I was certainly mindful of the general (unwritten) rule that assistant professors avoid repeating previous doctoral or postdoctoral research (26). But this gen-

[2] Most of the common stable radicals (in addition to a great many other compounds based on *p*-block elements) combine carbon with other elements and, as such, are not readily categorized as either "organic" or "inorganic" molecules. In fact, one of our early synthetic publications on verdazyl radicals was rejected by an inorganic journal without review on the grounds that the molecules were not inorganic enough! Although "heteroatom chemistry" has been employed to describe compounds of this sort, I think that the term "organomain group" better captures the dichotomous nature of these molecules, as do the corresponding ingrained terms "organometallic" or "organotransition metal" for compounds containing metallic and organic fragments.

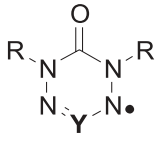
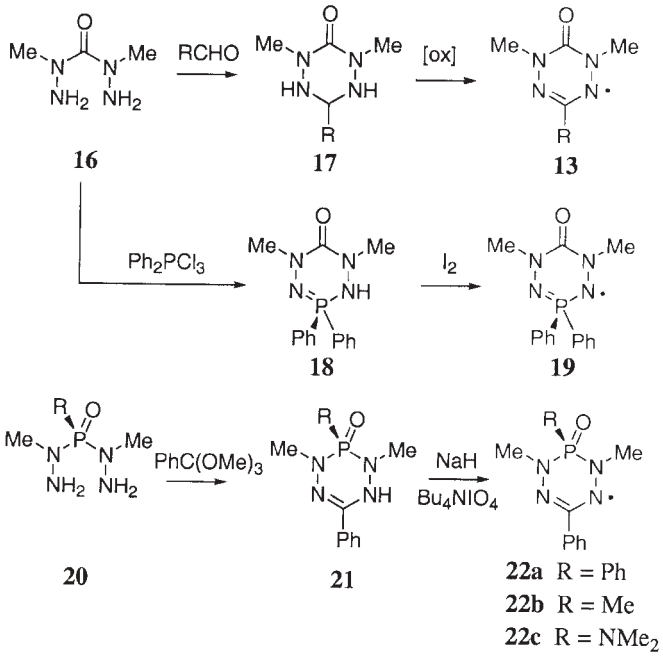
eral field seemed to me to be wide open with possibilities. Fundamentally, almost all new examples of stable radicals appear to be serendipitous discoveries. In the many applied forums described above, the stable radicals that are employed are usually the most readily available ones, typically nitroxide derivatives **4** or **5**. In many of these areas, there is still much room for improvement in the efficacy of the radicals that are used. It seemed to me that the collective shortcomings in these and other areas originated from the fact that few researchers were *actively* pursuing the *design* of stable radicals with a view to understanding, or "tuning", their properties (e.g., spin distributions, redox properties, and reactivity, to name a few). There appeared to be many areas ripe for discovery that would allow me to build on my expertise and take stable radical chemistry into new directions, with the long-term goal of a rational stable radical science, including a deeper understanding of why stable radicals are stable and the development of structure–property relationships in selected targeted areas.



Expanding the verdazyl family

Many stable radicals rely on the steric bulk of substituents for their stability. This strategy of stabilizing reactive fragments has long been practiced by inorganic chemists, but it turns out to be the wrong strategy for radical stabilization if one is interested in ultimately *doing* anything with the resulting radicals: Virtually all of the "applications" described above require that the radical (in addition to being stable) must be able to interact — chemically, magnetically, etc. — with other substrates. Too much steric protection can inhibit or prohibit these interactions. So the challenge from a molecular design perspective was to find new templates for radical stability while relying as little as possible on steric stabilization.

Rather than try to create new radicals from scratch, I opted to start with an established architecture that was amenable to modification. In this respect, verdazyl radicals **12** and **13** represented appealing systems. Although they were discovered over 40 years ago (27) and are generally quite stable, almost the entire body of work on these radicals focused on synthesis and spectroscopic analyses. I viewed verdazyls as templates that could be converted (on paper) to

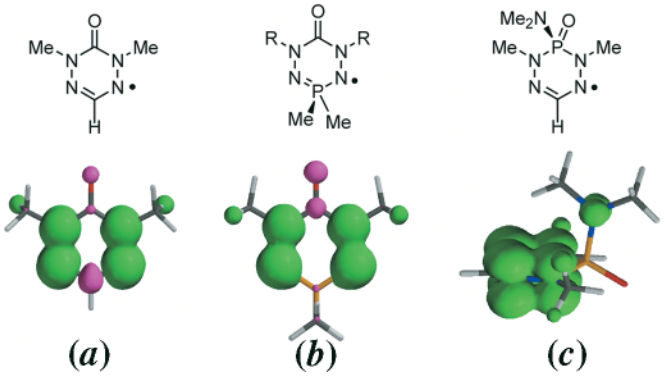


14

15

new radicals by skeletal atom substitution. Given that the stability of verdazyls is due in large part to the nitrogen-rich ring, it seemed prudent to start out with the relatively modest goal of making new radicals in which the ring carbon atoms were replaced by other elements, hence their general moniker "heteroverdazyls", generically depicted as **14** and **15**. I hoped that this would give us a fighting chance of obtaining something stable, and also provide a handy reference point (the "parent" verdazyl) for comparisons of electronic

Scheme 1.



structure. Phosphorus stood out as an ideal element to start with, as the introduction of another spin-active nucleus (^{31}P: I = 1/2, 100% abundance) would give us a direct handle on the electronic structure of the radicals through EPR spectroscopy. There were, in fact, already a few reports on these sorts of "phosphaverdazyls", but the characterization was far from complete (28).

The synthesis of the phosphaverdazyls built on established routes to the parent verdazyl ring **13** (Scheme 1). The latter are made by condensations of dimethyl carbohydrazide **16** with aldehydes to give tetrazanes **17**, followed by oxidation to give radicals **13** (9*b*, 29). We found that **16** could be condensed with Ph_2PCl_3 to give the 3-phosphatetrazine **18** and then oxidized with iodine to give the 3-phosphaverdazyl **19**. Phosphorus could also be introduced into the 6-position of the verdazyl via analogous chemistry. Derivatives of **20**, the phosphorus analogues of bis-hydrazide **16**, were originally synthesized by Majoral et al. (30). Reactions of **20** with aldehydes were problematic, so we turned to orthoesters $RC(OMe)_3$, which gave the desired 6-phosphatetrazines **21.** Subsequent oxidations with periodate gave the 6-phosphaverdazyl radicals **22a**-**c** (31).

The stability of the phosphaverdazyl radicals was unfortunately not quite as high as that of their carbon counterparts. They survive for several days in solution or in the solid state and are essentially insensitive to oxygen or water, but they slowly decompose to give mixtures of products (mainly the corresponding precursor phosphatetrazines). This has made it a challenge to obtain X-ray crystallographic data for these radicals. However, we were able to gain insights into their molecular and electronic structures through a combination of EPR spectroscopy and density functional theory (DFT) calculations. The calculated spin densities of three radicals that are simpler models of verdazyls and phosphaverdazyl radicals are shown in Fig. 1. All three share the common feature of having the majority of their spin on the four heterocyclic

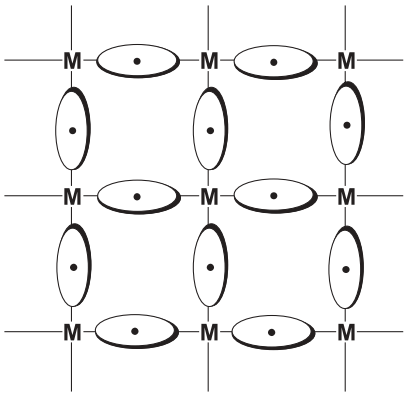
Fig. 1. Molecular structure and calculated spin densities of model compounds for (*a*) a 6-oxoverdazyl radical, (*b*) a 3-phosphaverdazyl radical, and (*c*) the dimethylamino-substituted 6-phosphaverdazyl radical. Positive spin density is green and negative spin density is pink.

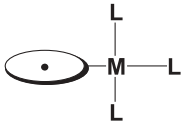
nitrogen atoms. In this regard, the electronic structures of the phosphaverdazyls are qualitatively similar to that of the parent radical. However, closer inspection reveals subtle but important differences between the phosphorus-based radicals and the parent verdazyl. We were quite surprised, for example, to find that in the 3-phosphaverdazyls **19** there is essentially *no* spin on the phosphorus atom (Fig. 1*b*), whereas the carbon analogue **13** is known to have appreciable *negative* spin density on the corresponding carbon atom (Fig. 1*a*). These differences can be understood through a combination of spin polarization effects coupled with the specific nature of each radical's singly occupied molecular orbital (SOMO) (31*b*). The 6-phosphaverdazyls, exemplified by **22a–c**, turn out to be more complex, as the ring conformation (planar vs. bent) and the spin density at phosphorus turn out to be exquisitely sensitive to the substituents on the phosphorus. In one example, **22c**, the orientation of the dimethylamino group in its minimum-energy conformation permits through-space overlap between the exocyclic nitrogen and the π-SOMO of the verdazyl moiety (Fig. 1*c*). Calculations and EPR spectra corroborated one another and established *spiroconjugation* as a new form of spin delocalization in radicals that is distinct from the common π-conjugated delocalization in π radicals.

Intrigued by the novel spiroconjugation spin propagation mechanism in **22c**, we designed a phosphaverdazyl radical (**23**) in which this phenomenon might be enhanced. The phosphorus atom in this structure is in a spiro*cyclic* environment, simultaneously part of both the phosphaverdazyl ring and a phosphazene heterocycle. The synthesis of this compound conveniently built on our established "bis-hydrazide" route for 6-phosphaverdazyls **22** and the known substitution chemistry patterns of the dichlorocyclotriphosphazene starting material. Analyses of the EPR spectrum of the radical, which required additional experiments based on the ENDOR double-resonance technique, indeed indicated that spin density was being transferred from the verdazyl ring onto the phosphazene ring, presumably by a spiroconjugation-type mechanism (32). This is an intriguing result because it is an extremely rare example of spin injection into a PN backbone. Phosphazene rings and polymers are among the most well-known and robust inorganic systems, but they are poor electronic conductors despite the presence of a formally π-conjugated framework. The behavior of ompound **23** suggests that phosphazenes may be able to transmit *spin* — and spin *communication* — in verdazyl/phosphazene materials. Work is underway to explore these possibilities in model systems related to **23** but in which multiple verdazyl radicals are linked to the central phosphazene ring in a spirocyclic manner.



23

Verdazyl coordination chemistry



One intensively pursued facet of stable radical chemistry concerns their magnetic properties. One of the holy grails of the field of "molecular magnetism" is the realization of bulk magnetic materials based in whole or in part on nonmetal building blocks. A promising strategy in pursuit of this goals involves combining paramagnetic metal ions and stable radicals. The ideal architecture, depicted schematically in **24**, is a coordination network in which the bridging ligands are radicals. The presence of spin on the ligands as well as the metals is an improvement in design over conventional coordination networks containing conventional (diamagnetic) ligands. Paralleling the effort to make high critical temperature (high-T_C) magnets has been the development of the fundamental coordination chemistry of stable radicals. Discrete complexes of the type depicted in **25** can yield insights into how metal- and radical-based spins interact and can, in principle, guide the way towards magnetically functional network solids.

Not surprisingly, metal–radical complex chemistry has been dominated by nitroxides (33). Although these radicals have the requisite stability, they are weak Lewis bases and consequently require Lewis acidic metal ions for effective binding. More problematic is the fact that the structure of the nitroxide–metal interaction is quite flexible: Nitroxides bind to metals through the oxygen atom and the N-O-M bond angle takes on a range of values from linear to strongly bent. This variation in structure is difficult to control and renders the magnetic interactions between radical and metal — which depend crucially on structure — unpredictable. This makes it difficult to carry out meaningful structure–

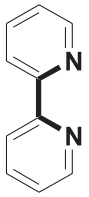
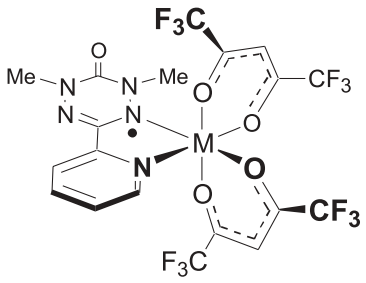
24



25

property correlations or to *design* structures like **24** that have the "best" magnetic properties.

When I arrived at the University of Victoria in 1996, there was not a single report in the literature of a transition-metal complex of a verdazyl radical. We decided to attempt to control the mode of coordination by preparing chelating verdazyls by using substituents with donor atoms. The prototype ligand for this approach is the 3-(2-pyridyl) derivative **26**: It possesses a diimine-type environment closely structurally related to the ubiquitous 2,2'-bipyridine **27**. The use of this simple chelating ligand would facilitate the preparation of discrete complexes; our strategy was to develop the fundamental coordination chemistry of verdazyls and then use information gleaned from these first-generation studies to eventually push toward extended networks (i.e., **24**).

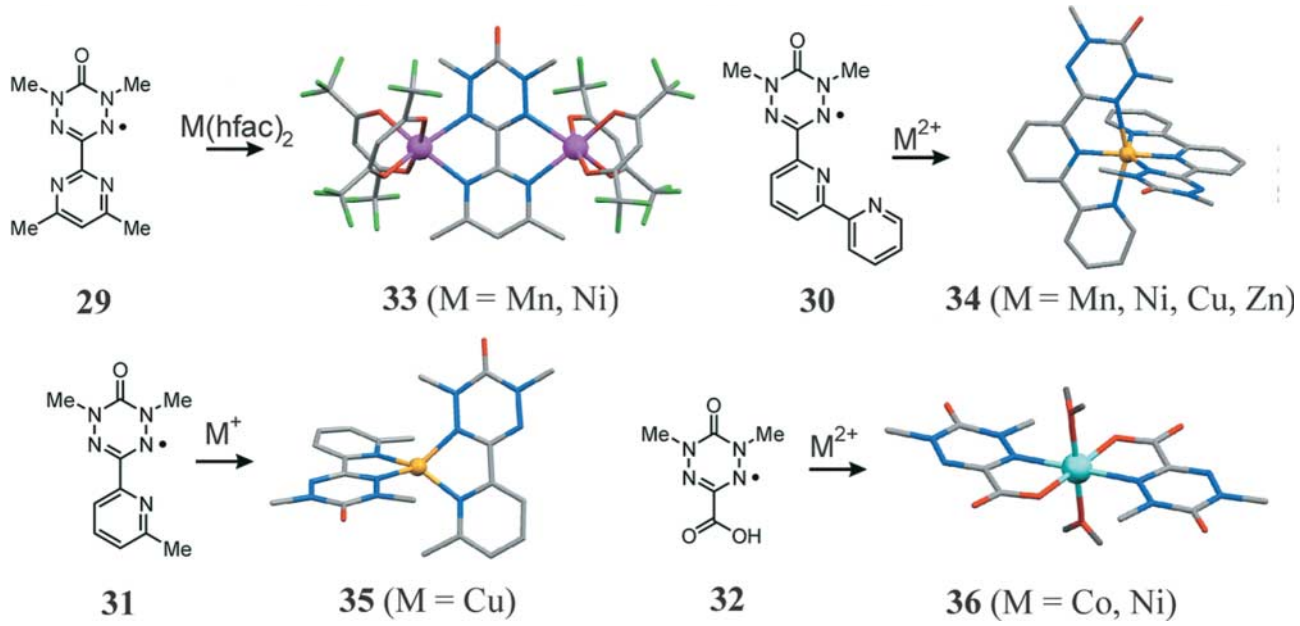


26

27

Our first breakthrough came with complexes based on manganese and nickel with hexafloruo-β-diketonate ancillary ligands (34). Although X-ray structures proved elusive, all of our data were consistent with the expected structure **28**, consisting of pseudo-octahedral metal ions and radical ligand **26** in a chelating binding mode. Importantly, UV–visible spectra confirmed that the radicals remained genuine radicals when coordinated; no electron transfer chemistry with the metals had occurred. Magnetic susceptibility data indicated that the metal–verdazyl magnetic exchange interactions are metal dependent. The manganese complex exhibited moderate antiferromagnetic coupling between the $S = 5/2$ Mn(II) center and the $S = 1/2$ radical, with an exchange interaction energy (J) of –45 cm^{-1}, which is a typical value for a metal–radical complex. In sharp contrast, the exchange interaction between the $S = 1$ Ni(II) ion and the $S = 1/2$ radical was very strongly ferromagnetic, with a value of at least +200 cm^{-1}. This was one of the largest ferromagnetic metal–radical interactions ever observed. The large magnitude of J (a measure of the strength of the interaction) can be rationalized based on the large amount of spin density at the verdazyl N atom directly bound to the metal, while the sign of J (which indicates whether the interaction is ferromagnetic or antiferromagnetic) is determined by straightforward orbital symmetry considerations (34). These were the first examples of verdazyl complexes showing metal–radical exchange interactions (some verdazyl complexes of diamagnetic Cu(I) were reported in 1997 (35)), and the nickel–verdazyl exchange, in particular, represented a major development: Strong ferromagnetic metal–radical interactions are precisely the kind needed in order to realize high-T_C magnetic ordering in structures like **24**.

28 (M = Mn, Ni)



We have since prepared several chelating verdazyl-based ligands that present different binding topologies to metal ions (Fig. 2) (36). The chelate effect makes the verdazyls better ligands and also constrains the geometry of the metal–radical binding, which leads to consistent (metal-dependent) magnetic exchange interactions. Thus, *all* of the Ni(II) verdazyl complexes we have prepared to date exhibit strong ferromagnetic coupling, whereas the Mn(II) complexes are moderately antiferromagnetic. To be sure, there are other factors (e.g., ancillary ligands, metal–verdazyl bond lengths, inter-radical exchange in bis-ligand complexes) that influence the magnetic properties, but to a first approximation the magnetic interactions between verdazyls and metals are predictable. Examples of verdazyls with at least two binding sites are now in hand (e.g., **29** and **32** in Fig. 2), and we have begun to explore their coordination chemistry (36*b*, 36*d*). These ligands are also building blocks for extended structures akin to **24**, which, based on the magnetochemistry of the discrete complexes, are excellent candidates for high-T_C magnets. Future work in our group will also involve verdazyl coordination chemistry of these radicals with a wider range of metals.

Supramolecular chemistry of radicals

The verdazyl radical ligands described above can usually be made, handled, and purified using "normal" procedures. However, our early efforts to purify the pyridine derivative **26** were frustrated by this radical's gradual decomposition in solution or in the solid state. However, we found that by switching from ferricyanide to *p*-benzoquinone as the oxidizing agent in the synthesis of the radical, **26** cocrystallized in a 1:1 stoichiometry with hydroquinone, the by-product of the reaction. These crystals can be stored indefinitely without decomposition of the radical. The hydroquinone can be

© 2004 NRC Canada

Fig. 2. Verdazyl ligands **29**–**32** and X-ray structures of corresponding metal complexes **33**–**36**.

readily separated from the radical by chromatography, thereby affording solutions of pure radical that can then be used for subsequent chemistry. This fortuitous development certainly facilitated the verdazyl coordination chemistry described above. In addition, the structure and magnetic properties of the radical:hydroquinone material turn out to have significant implications for the magnetochemistry of molecular systems.

The crystal structure contains π stacks of **26** assembled in a head-over-tail manner, with each verdazyl ring sandwiched between two pyridines and vice versa (Fig. 3*a*) (37). The mean interplanar separation between molecules within the stacks is close to the normal van der Waals distance for π stacks of ~3.4 Å (1 Å = 0.1 nm). Rows of these stacks fill the *ac* plane and are separated from one another by layers of hydroquinone. There is an extensive two-dimensional hydrogen-bond network involving the hydroxyl groups and the pyridine nitrogen atoms (Fig. 3*b*) perpendicular to the π stacking axis.

Analysis of the variable-temperature magnetic susceptibility data indicated fairly strong antiferromagnetic interactions, and the data could be fit to a model in which one-dimensional chains of spins couple antiferromagnetically to one another. The exchange interaction obtained from the best fit to the data is $J = -56$ cm^{-1}. This is by no means a record, but it is fairly strong for an intermolecular radical interaction. In general, the observation of strong exchange in molecular solids is always ascribed to close intermolecular contacts (within van der Waals distances) between radicals, *in particular between atoms that bear a significant portion of the radical's spin density*. EPR and computational work had established that the spin density in **26** is essentially confined to the four nitrogen atoms of the verdazyl ring. But there are no intermolecular N–N contacts under 4 Å in this structure! The antiparallel nature of the π stacks prevents the verdazyl π systems from overlapping directly with one another, and there are no interstack N–N contacts to speak of. As such, this system is unique in that its magnetic properties run counter to current paradigms about the requirements for strong intermolecular exchange.

To rationalize these observations, we proposed a mechanism of exchange within the π stacks that invokes the pyridine substituents. The pyridine moiety possesses an empty orbital with the same symmetry properties as the radical SOMO. Interactions between two SOMOs via direct (albeit weak) orbital overlap mediated by the pyridine π* orbital could permit through-space (or *supramolecular) superexchange* (Fig. 4*a*). Conceptually, this mechanism is closely related to the superexchange mechanism for metal–metal antiferromagnetic coupling in transition-metal oxides (Fig. 4*b*). However, two key differences in our system are that the orbitals involved are molecular, not atomic, and the interactions are through-space because the molecules are not covalently attached.

One of the biggest challenges in the development of purely organic magnetic materials is that the relationships between molecular packing in the solid state and intermolecular exchange are not well understood (38). The magnetic properties of verdazyl **26**, and our proposed mechanism to explain them, offer a partial explanation as to why structure–magnetism correlations have been so tricky to delineate: Although it is undoubtedly true that close approach between radicals can lead to strong magnetic interactions, through-space magnetic exchange does not *require* spin centers to be as close together as once thought. Although the magnetism of molecular crystals or the radicals themselves was not initially a focus of my research program, the results described here have motivated us to study intermolecular exchange in verdazyls more actively. Structural and magnetic characterization of other radicals is underway, as are efforts to build model systems designed to probe more deeply the intimate mechanism of supramolecular superexchange.

Summary

The work described herein began with what seemed to be

straightforward ideas for modifying or building on a well-established stable radical system in a number of different ways. The long-term goals of these pursuits were, and continue to be, to bring rational design and the development of structure–property relationships – themes that lie at the very heart of inorganic chemistry – to stable radical chemistry. There are a number of challenges specific to carrying out research on stable radicals (the inability to obtain conventional NMR spectra of open-shell molecules being just one practical obstacle!), and we have certainly encountered our share of these problems along the way. However, overall our progress over the past several years has shown that verdazyl radical chemistry and magnetochemistry are proving to be rich and fruitful areas of study. Our recent successes have emboldened us to pursue new radical architectures that depart more dramatically from the verdazyl template. As progress in basic science is made, we anticipate making significant inroads in selected applications of stable radical science.

Acknowledgements

I thank the CSC Division of Inorganic Chemistry for sponsoring the Award for Pure or Applied Inorganic Chemistry and, in particular, for creating an award that recognizes early career achievement. The work described herein was supported initially by generous startup funds from the University of Victoria and has been sustained through grants from the Natural Sciences and Engineering Research Council of Canada (NSERC), the Petroleum Research Fund, and the Department of National Defense.

This article summarizes "my" research efforts at the University of Victoria over the past several years. Of course, the achievements described herein would not have been possible without the efforts of, and assistance from, many people. The Chemistry Department at the University of Victoria has provided me with a tremendously supportive and stimulating environment, and I offer the faculty and staff there my sincere gratitude; in particular, I thank my colleagues Tom Fyles, Cornelia Bohne, Terry Gough, Peter Wan, and Penny Codding for their guidance and enthusiasm. I have also benefited enormously from a number of fruitful collaborations. First and foremost among these is Laurie Thompson (Memorial University), who for the past six years has provided me with a wealth of magnetic data and has been a willing and patient tutor to a group that had essentially no experience in magnetochemistry at the outset. I also thank my other collaborators for their expertise in X-ray crystallography (Tosha Barclay, North Harris College; John F. Richardson, Louisville), computational chemistry (Lars Ohrstrom, Chalmers Institute of Technlogy, Sweden), and ENDOR spectroscopy (Andrew Ichimura, San Francisco State).

Lastly, and most importantly, I tip my hat to the past and present members of my research group. Although space did not permit a full discussion in this article of all aspects of my program, the contributions of all of my co-workers are deeply appreciated. This includes postdocs (Richard Hooper, Mhamed Chahma, Rajsapan Jain, Khayrul Kabir, and Peter Otieno), graduate students (Greg Patenaude, Martin Lemaire, Matt Nodwell, Bryan Koivisto, Dan Myles, Steve McKinnon, Joe Gilroy, and Sharon Caldwell), and a group of undergraduate researchers too long to list here but whose contributions were, are, and will continue to be crucial.

Revisiting lipid – general anesthetic interactions (I): Thinned domain formation in supported planar bilayers induced by halothane and ethanol

Zoya V. Leonenko and David T. Cramb

Abstract: A long-standing question in anesthesia is that of the molecular mechanism. Do anesthetics target proteins or change membrane properties or both? We used temperature-dependent magnetic A/C mode atomic force microscopy (AFM) to study interaction of the volatile anesthetics halothane and ethanol with model membranes made from supported planar bilayers (SPBs) of 1,2-dioleoyl-*sn*-3-glycero-3-phosphocholine (DOPC), dioleoyltrimethylammonium propane (DOTAP), or 1,2-dipalmitoyl-*sn*-3-glycero-3-phosphocholine (DPPC). We found that the incorporation of halothane or ethanol induces structural changes in the bilayer. These compounds cause thickness reduction in L_α bilayers (either globally or in domains) and the formation of domains with reduced thickness in L_β phase bilayers. We propose that an anesthetic-induced increased area per lipid drives local chain disorder, thus promoting local phase change. The characteristics of SPBs with halothane or ethanol incorporated were compared with characteristics of the L_α and L_β phases of anesthetic-free SPBs.

Key words: atomic force microscopy, anesthesia, lipid bilayer domains, phase transition

Résumé : Le mécanisme moléculaire de l'anesthésie n'a toujours pas été résolu. On se demande encore est-ce que les produits anesthésiques s'attaquent aux protéines ou s'ils changent les propriétés des membranes ou agissent-ils sur les deux fronts. On a fait appel à la microscopie de forces atomiques (MFA) en mode A/C magnétique et dépendante de la température pour étudier l'interaction d'anesthésiques volatiles, tels l'halothane et l'éthanol, avec des membranes modèles faites à partir de bicouches planaires supportées (BPS) de 1,2-dioléoyl-*sn*-3-glycéro-3-phosphocholine (DOPC), de dioléoyltriméthylammonium propane (DOTAP) ou de 1,2-dipalmitoyl-*sn*-3-glycéro-3-phosphocholine (DPPC). On a observé que l'incorporation d'halothane ou d'éthanol induit des changements structuraux dans la bicouche. Ces composés provoquent une réduction de l'épaisseur des bicouches L_α (globalement ou dans les domaines) accompagnée de la formation de domaines comportant des épaisseurs réduites dans les bicouches de la phase L_β. On suggère qu'une surface par lipide accrue, induite par l'anesthésique, provoque un désordre de chaîne local qui induit un changement de phase local. On a comparé les caractéristiques des BPS dans lesquelles on a incorporé de l'halothane ou de l'éthanol avec les caractéristiques des phases L_α et L_β de BPS ne contenant pas d'anesthésique.

Mots clés : microscopie de forces atomiques, anesthésie, domaines de bicouches lipidiques, transition de phase.

Introduction

The phenomenon of domain formation in model membranes is of great interest, as membrane structural changes define changes in membrane functional properties. This may also be true for anesthesia. Indeed, there have been paradigm shifts in the molecular theory of anesthetic action over the past century. The correlation found by Meyer and Overton (1, 2) between anesthetic potency and lipid solubility suggested that alteration of the lipid membrane structure was key to anesthetic efficiency. As membrane protein studies became possible at the molecular level, attention shifted to the direct action of anesthetics on ligand-gated ion channels (3, 4). More recently, it has been suggested that volatile anesthetics indirectly affect membrane protein by altering the lateral pressure within bilayers (5). Also, a multiple-sites-of-action hypothesis has been forwarded in which general anesthetics may bind to many protein and lipid sites with relatively low affinity (1–10 mmol/L) (6). Despite considerable study, the exact molecular effect of volatile anesthetics on membranes is only beginning to emerge. It has been demonstrated that volatile anesthetics can induce a change in lipid packing in membranes (7–9). For example, several experimental and theoretical studies were devoted to investigation of changes in membrane properties due to the incorporation of alcohols. For example, Holte and Gawrish (10) found that ethanol partitions near the lipid–water interface close to the lipid glycerol backbone and upper segments of lipid hydrocarbon chains and increases the degree of motional disorder in lipid chains. The implication is that a contributing factor in the physiological effect of ethanol results from the mole-

cules dissolving in specific lipid hydrophobic sites, which significantly modifies membrane structure and may lead to bilayer thinning. Thinned bilayers could contain both interdigitated lipids (interpenetration of hydrocarbon chains of the upper leaflet to the lower leaflet of the bilayer, resulting in disappearance of the bilayer midplane) and lipids with vastly increased tilt angles. It has been reported that bilayer thinning occurs when the local concentration of the species in the bilayer is higher than a threshold value (11). Bilayer thickness changes may have a strong effect on the function of membrane-associated proteins because of a mismatch of the protein–lipid hydrophobic interaction region. Changes in lipid packing in the presence of ethanol have been examined by X-ray diffraction, and they have been suggested in fluorescence spectroscopic studies (12, 13). Interdigitated domains caused by ethanol were proposed by Mou et al. (14) to explain the thinned dipalmitoylphosphatidylcholine (DPPC) bilayer they observed using atomic force microscopy (AFM). Recently, AFM studies by McClain and Breen (15) suggest that 2-propanol-induced DPPC bilayer thinning is strictly due to interdigitation.

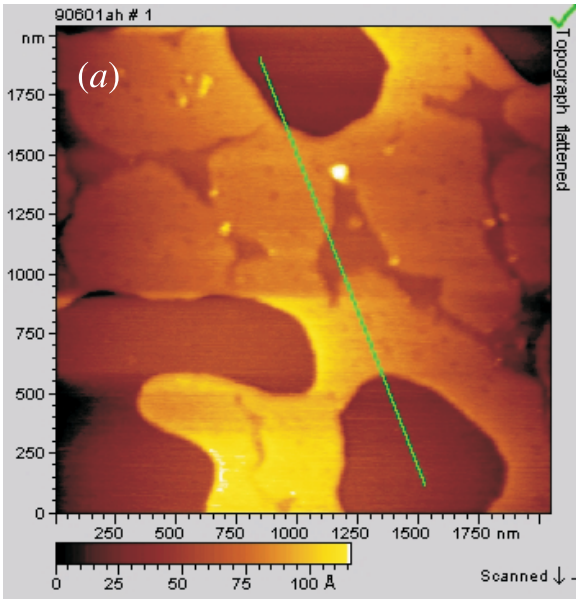
Halothane is a clinical anesthetic that has received increasing attention as a model molecule for fundamental studies on anesthetic action. Molecular dynamics simulations (16) of halothane in a DPPC bilayer revealed that halothane self-associates and also is distributed nonuniformly across the membrane interior. This resulted in significant modifications of the lipid bilayer, including thinning. A decrease in lipid wobble and an increase in tail defects of the lipid system were also observed.

A temperature-dependent AFM study may provide valuable information about the effect of anesthetics on the thinned-bilayer formation by monitoring the effect of anesthetics on the chain-melting phase transition. Very recently, three temperature-dependent AFM studies involving bilayers have been reported (17–19). In these papers, increases in temperature were used to induce L_β–L_α phase changes in the supported planar bilayers (SPBs). In our studies of DNA – cationic bilayer interactions as a function of temperature, we have shown that topology can be accurately measured using magnetic A/C (MAC) mode AFM to temperatures as high as 70 °C in a liquid sample cell (19). Temperature-dependent AFM allows a novel examination of halothane-induced changes in lipid bilayer properties and permits powerful re-examination of some previous results (14) for anesthetic – DPPC bilayer interactions, because the characteristics of both the gel- and the liquid-phase SPB can be measured on the same sample in the presence and absence of anesthetic.

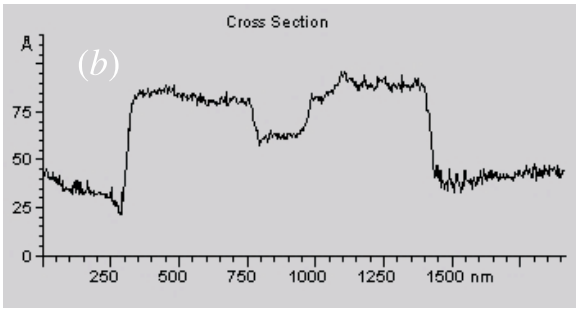
In the present work, we have concentrated our efforts on studying the incorporation of ethanol and halothane into SPBs. We employed MAC mode AFM to study anesthetic-induced changes in supported phospholipid bilayers of dioleoylphosphatidylcholine (DOPC), DPPC, or dioleoyltrimethylammonium propane (DOTAP). The goal of this study was to extend the knowledge that exists in the literature for ethanol and to examine the incorporation of halothane into a bilayer. We were also able to measure the bilayer properties as a function of temperature and to induce the L_β–L_α phase transition in DPPC, and we used a temperature increase to irreversibly drive ethanol out of the SPBs. In the following companion paper (20), the results of our AFM studies for halothane are compared with those obtained using spectroscopic techniques.

Materials and methods

Dioleoylphosphatidylcholine (DOPC, lyophilized or in chloroform solution), dioleoyltrimethylammonium propane (DOTAP, chloroform solution), and dipalmitoylphosphatidylcholine (DPPC) were obtained from Avanti Polar Lipids Inc. (Alabaster, Ala.) and were used without further purification. Tris–EDTA (TE) buffer, pH 7.6, and distilled, ultrapure water were used in the generation of all vesicles. Freshly cleaved ASTMV-2 quality, scratch-free ruby mica (Asheville-Schoonmaker Mica Co., Newport News, Va.) was used throughout this study as a substrate. In some cases, mica was modified by addition of a dilute solution of 3-aminopropyltriethoxysilane (APTES) using standard procedures (21).



All vesicles were prepared using the "dry" method as previously reported (22). An appropriate aliquot of phospholipid chloroform solution was measured into a small vessel, and the chloroform was removed using a stream of dry nitrogen. The dry phospholipid was then resuspended in buffer to its final concentration and stirred for 30 min. The solution was sonicated (Branson 1200; Branson Ultrasonics, Danbury, Conn.) at room temperature for 10-min periods. Between each 10-min period, there was a 15-min "rest" interval where the solution was placed in an ice bath and then stirred at room temperature. For this method, the solutions were cycled an average of 10 times or until they were observed to clear.



Supported planar bilayers were prepared for AFM imaging by the method of vesicle fusion (22, 23). Aliquots of liposome solution were deposited on modified or unmodified freshly cleaved mica. After a controlled period of time, the mica was gently rinsed with ultrapure water, and the surface was imaged under water in the liquid cell, at room temperature and at various higher temperatures.

Addition of ethanol and halothane was performed in two ways: (*i*) by addition of pure anesthetic into the vesicle solution with an incubation time of 1.5 h and (*ii*) by addition of an ethanol/water mixture (50% by volume) or pure liquid halothane into the AFM liquid cell with the established supported bilayer and incubation for the same period of time. A time of 1.5 h was shown by fluorescence experiments to be optimal for halothane distribution between buffer and membrane (20).

We employed MAC mode AFM, where a magnetically coated probe oscillates near its resonant frequency driven by an alternating magnetic field. This technique has proven to be advantageous for measuring supported planar bilayers in liquid media (22, 24, 25). All images were taken using a Pico SPM microscope with AFMS-165 scanner (Molecular Imaging Inc., Phoenix, Ariz.). Magnetically coated type I Maclevers® (Molecular Imaging Inc.) were used for MAC mode imaging. Their specifications include a length of 85 μm, a force constant of 0.06–0.1 N/m, a resonant frequency of 20–40 kHz in water, and a tip radius of curvature quoted as less than 10 nm. The standard MAC mode fluid cell (Molecular Imaging Inc.) was used throughout. The scanning speed was 1–2 lines per second. The height scale

An EtOH–water mixture (50:50 by volume) was added to a supported DPPC bilayer, incubated for 1.5 h, and then rinsed with pure water prior to the AFM measurements. The scale bar in panel (*c*) is 500 nm long.

was calibrated using colloidal gold spheres of 5 nm and 14 nm in diameter (26). For elevated-temperature experiments, the AFM Temperature Controller and Hot Mac Mode Stage from Molecular Imaging Inc. were used. Heating and cooling were performed at ΔT = 1 °C/min, with the possibility to hold at any given temperature. The mean value(s) of the bilayer thickness was calculated using between 50 and 70 measurements over several scanned regions, where appropriate. The standard deviation is quoted at the 99% confidence level.

Results and discussion

DPPC

The changes in a L_β DPPC bilayer structure as a function of incorporation of halothane and ethanol were examined and compared with the effect of temperature. The reason for using ethanol was to compare our data, obtained by MAC mode AFM, with the results of previous studies (14, 15). There are several studies in the literature that have examined incorporation of ethanol and other alcohols into phospholipid bilayers using various methods, including fluorescence (27) and AFM (14, 15). It has been suggested that a high concentration of ethanol in a lipid-containing aqueous solution can induce transformation of a lipid bilayer from (L_β) gel phase to the fully interdigitated ($L_{\beta I}$) phase of monounsaturated phosphatidylcholine (PC) lipids, which alters the L_β–L_α melting transition temperature of the phospholipid bilayer (28). In our study, ethanol was added to a supported DPPC bilayer on mica. After 1.5 h, the cell was then rinsed and imaged in water. In the absence of ethanol, we measured the thickness of a pure supported DPPC bilayer on mica as 5.5 nm, from natural defects, which is in good agreement with the value of 5.7 nm reported earlier (14). We observed the formation of thin domains in the presence of ethanol (Fig. 1). The thickness of the higher domains was 5.6 nm, and that of the lower domains was 3.6 nm (Table 1). The difference in thickness of the two domains was 2.0 nm, compared with 1.9 nm previously reported (14). The ethanol/SPB system remained stable at room temperature for up to 2 days. Changing the relative concentration of ethanol only changed the extent of thin domains, but not their thickness. The stability of the thin domains suggests that ethanol remains preferentially in the bilayer at room temperature. When the bilayer was heated to 50 °C (i.e., above the melting transition point, T_m = 41 °C) while imaging was performed and then slowly cooled back to room temperature, the lower domains disappeared and the original bilayer thickness was restored. This reversibility of the ethanol effect is in agreement with data of Mou et al. (14), although the latter authors were not able to simultaneously image and scan temperature. These findings suggest that ethanol repartitions into water when DPPC is at elevated temperature and that this repartitioning depends on the phase of the bilayer. Recently, we investigated the temperature dependence of a pure DPPC SPB (data not shown). As the tempera-

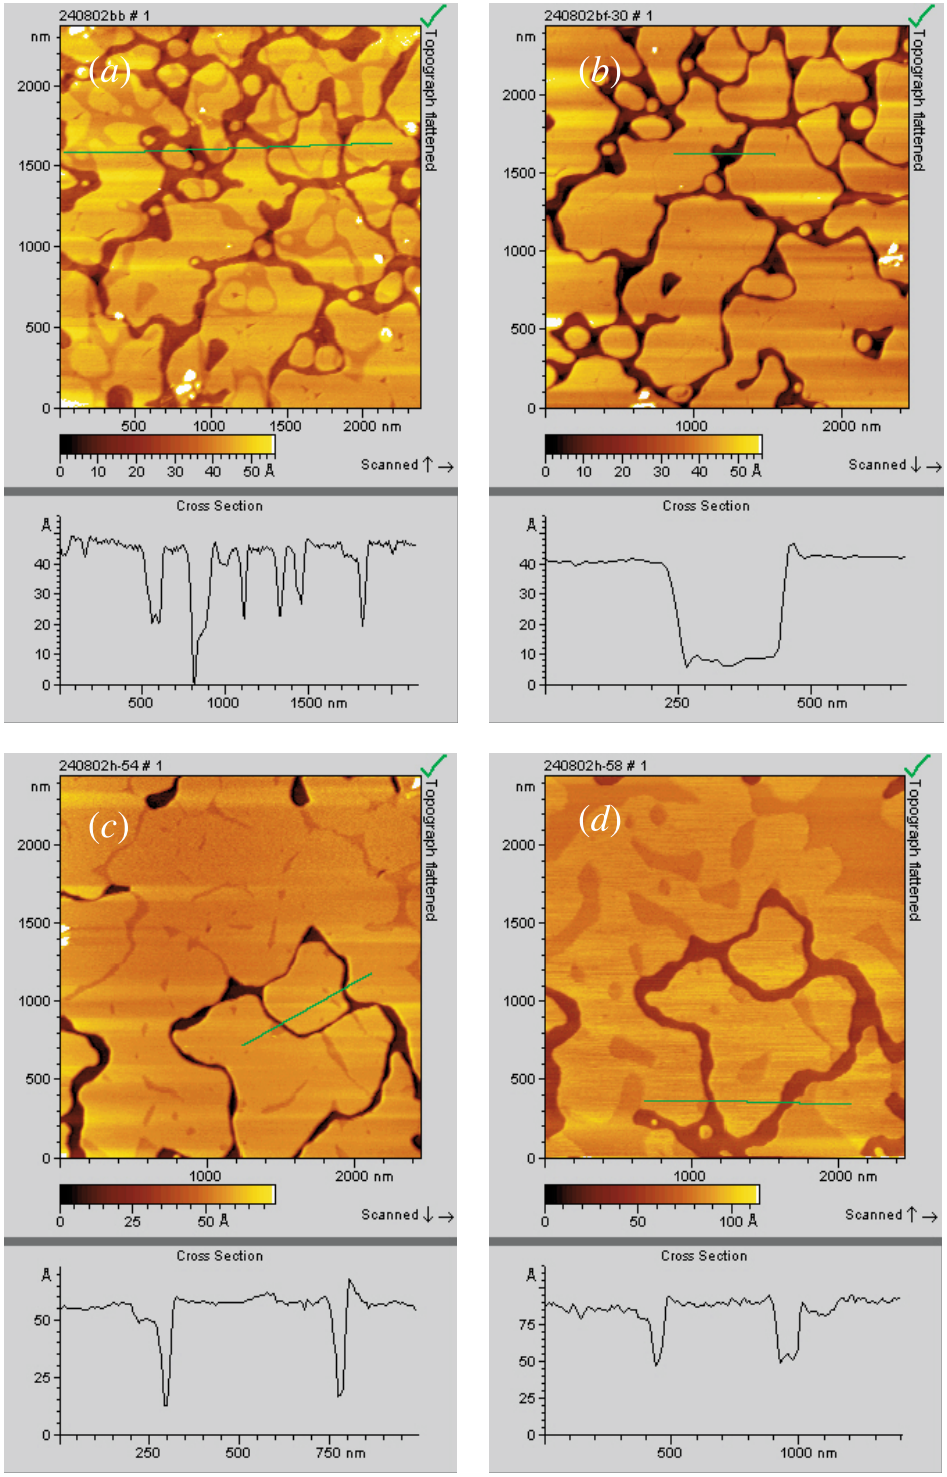
Table 1. Dependence of thickness (nm) of supported planar bilayers (SPBs) on the incorporation of halothane and ethanol.

SPB[a]	Thickness of pure lipid bilayer	Thickness after addition of ethanol		Thickness after addition of halothane	
		$C_{EtOH\ in\ water}$ = 75 mmol/L	$C_{EtOH\ in\ water}$ = 1.4 mol/L	MR = 3.6:1	MR = 7.3:1
DOTAP	3.7 ± 0.2		3.6 ± 0.2		3.5 ± 0.2
					2.9 ± 0.2
DOPC	5.4 ± 0.1	5.3 ± 0.3	3.5 ± 0.2	5.0 ± 0.5	3.6 ± 0.2
		3.5 ± 0.2		3.6 ± 0.3	
DPPC	5.5 ± 0.1		5.6 ± 0.2	5.5 ± 0.1	5.5 ± 0.1
			3.6 ± 0.3		3.5 ± 0.1

Note: MR is the ratio of the number of moles of halothane in the membrane to the number of moles of lipids.
[a]DOTAP, dioleoyltrimethylammonium propane; DOPC, dioleoylphosphatidylcholine; DPPC, dipalmitoylphosphatidylcholine.

Fig. 2. Topography images and cross sections showing the effects of incorporation of halothane into a DPPC bilayer. (*a*) Pure DPPC bilayer; (*b*) DPPC with halothane, at an estimated molar ratio of halothane in the membrane to lipid of 3.4:1; (*c*) DPPC with halothane, molar ratio = 14.6:1. In these experiments, halothane was added into the vesicle solution prior to SPB formation.



ture approached the L_β–L_α phase transition, thinned domains appeared. The heights of the domains were exactly the same as those induced by ethanol, described above. When holding at a temperature of 50 °C, the lower domains coalesced and grew in extent. There is every reason to believe that these thinner domains represent a DPPC SPB in its L_α state. The value of 3.6 nm for L_α DPPC thickness is in the range previously determined using X-ray scattering ($X_{head\text{-}to\text{-}head}$ = 3.6–4.0 nm) (29). A similar range was also calculated by Feller et al. (30) by molecular dynamics simulation. Interestingly, the simulation illustrated that the DPPC lipid chains in the L_α phase displayed both some interdigitation and significant tilting. However, there was no indication of the completely interdigitated $L_{\beta I}$ phase, where methyl end groups would be exposed to water.

We have also examined the incorporation of halothane into a DPPC bilayer to compare the effects of ethanol and halothane. The halothane was added into the vesicle solution or into the liquid cell with a preformed supported bilayer. In Fig. 2 we illustrate the effects of incorporating halothane into vesicles prior to SPB formation. In the presence of halothane, we observed similar domain formation in a DPPC bilayer to that induced by ethanol. The thickness of the higher and lower domains was measured as 5.5 and 3.5 nm, respectively, giving the same difference of 2.0 nm as we observed in the case of ethanol (Table 1). The surface coverage of the thin domains was 2–3% at lower halothane concentrations (Fig. 2*b*) and comparable to that naturally formed in pure DPPC SPBs (1–2%). At higher halothane content, we observed a considerable amount of lower domain surface coverage (25–50%, Fig. 2*c*). We were able to image the surface during slow heating of the bilayer above the melting transition point (T_m = 41 °C). Heating the system to 42 °C did not induce considerable changes in the domain structure. After 1 h of scanning at 42 °C, lower domains in the bilayer were still present. A further increase in temperature to 50 °C

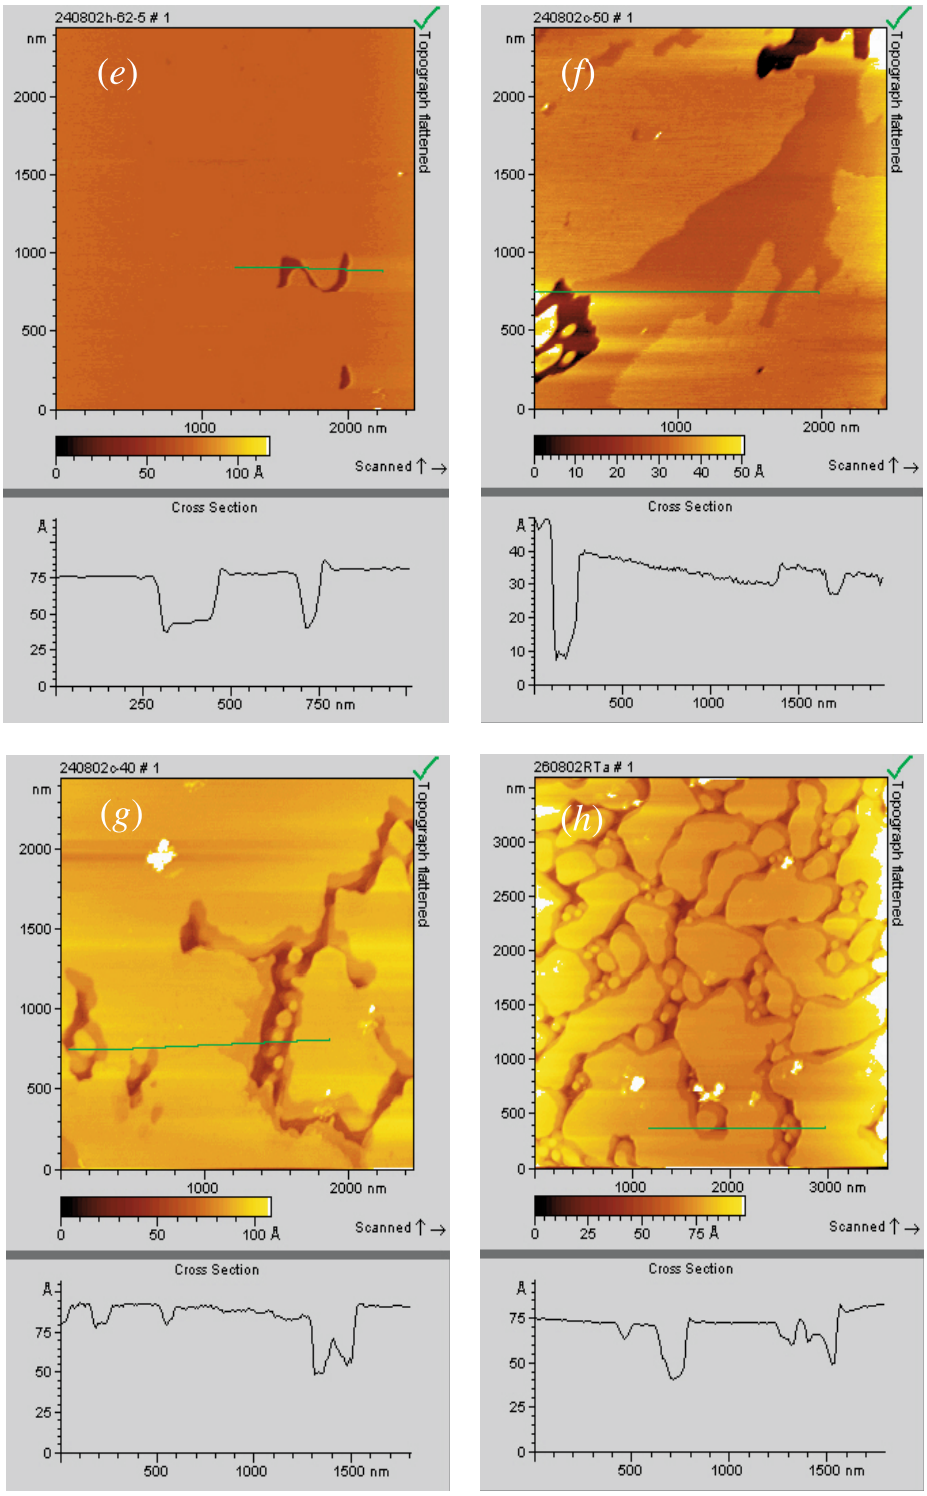
Fig. 3. Topography images and cross sections of supported DPPC bilayer with halothane recorded as a function of temperature and time. Halothane was added into the liquid cell containing a supported DPPC bilayer covered with 1 mL of water; no rinsing was performed for this sample. Halothane remained in the water and the sample was scanned during heating. (*a*) Room temperature; (*b*) 30-min scanning at room temperature; (*c*) heated to 50 °C; (*d*) heated to 58 °C; (*e*) heated to 62 °C; (*f*) cooled to 55 °C; (*g*) cooled to 50 °C; (*h*) cooled to room temperature. The estimated molar ratio of halothane in the membrane to lipid was 3.4:1.



demonstrated that the remaining thicker domains melted at a higher temperature than the pure DPPC free-standing bilayer and the phase transition was broad. This is consistent with the melting of a pure DPPC SPB (data not shown).

In the alternate preparation, halothane was added into the liquid cell containing the supported DPPC bilayer covered with 1 mL of water. After the addition of halothane, no rinsing was performed. In Fig. 3, we follow the SPB containing

Fig. 3 (*concluded*).

halothane as a function of temperature and time. In this case we observed a very interesting transition of the bilayer containing halothane at room temperature during the first 30 min of scanning. Domains (thickness of higher domains was 4.5 ± 0.2 nm) initially present (Fig. 3*a)* disappeared and the bilayer became generally thin (3.3 ± 0.3 nm, Fig. 3*b*). Because the bilayer was supported on mica, we consider that halothane first causes structural changes in the upper leaflet, and scanning at room temperature might induce equilibration of halothane between the two leaflets. After this thinner bilayer is formed, the system is stable during scanning at room temperature and becomes thinner yet at a temperature higher than that of the L_β–L_α transition for a pure DPPC bilayer. Further thinning was observed to start at 50 °C and was complete at 62 °C (Figs. 3*c*–*e*). After the system was cooled back to room temperature (Figs. 3*f*–*h*), bilayer thick-

© 2004 NRC Canada

ness was 3.9 ± 0.2 nm, which is lower than that of pure L_β DPPC bilayer. The initial thickness of pure DPPC without halothane was restored during a similar cooling process (data not shown). The molar ratio of the amount of halothane in the membrane to that of lipid was estimated as $n_{Hal}/n_L = 3.4$ at room temperature and has been shown to increase by a factor of 4 above the chain-melting transition temperature (31). The amount of halothane in the bilayer was estimated using the partition coefficient of halothane in DPPC provided by Simon et al. (31). This increase in halothane partitioning during heating is probably responsible for a saturation of the bilayer with halothane and stabilization of thinned domains when the system was cooled back to room temperature.

The persistence of thinner domains and the complete thinning of the bilayer show that interaction of halothane with the lipids is very strong and increases at elevated temperature. These results are consistent with those reported in the companion paper (20) as well as with those obtained by Simon et al. (31) and by Hill (32).

When compared with ethanol, halothane shows different behavior during heating. Whereas ethanol leaves the bilayer, thus restoring its initial thickness, halothane partitioning increases with temperature, leading to more extensive domain formation. The reason for this difference in behavior likely originates from the higher hydrophobicity of halothane and its lower solubility in water (17 mmol/L) (20) compared with that of ethanol. Ethanol can escape during heating when the mobility of phospholipids and ethanol is high, whereas for solubility reasons halothane remains in the bilayer.

The transitions observed upon heating the bilayer with and without halothane were compared. For a pure DPPC bilayer, we observed a broad main transition between 42 °C and 52 °C and further change between 52 °C and 60 °C; upon cooling back to room temperature, a transition between 35 °C and 36 °C occurred. When the bilayer with halothane incorporated was heated, the lower temperature transition was not observed, and only one transition at 52–60 °C occurred. The presence of halothane likely changes structural properties of the bilayer in such a way that the other transitions observed for a pure bilayer are not possible. The transition below T_m likely involves reorganization of water molecules at the interface. In the presence of halothane, water molecules are exchanged for halothane molecules, which eliminates the low-temperature transition.

The inhomogeneous domain formation observed with both ethanol and halothane incorporation is presumably due to a cooperative mechanism of anesthetic penetration and partitioning into the bilayer. This mechanism may include localized dehydration of headgroups by disruption of the coordinated hydration shell. The existence of such a hydration shell has been suggested by molecular dynamics simulations (33). Additionally, the initial rupture of the hydration shell may promote inhomogeneous anesthetic incorporation into the bilayer at the exposed location. After water shell rupture, further incorporation of anesthetic into the bilayer increases the headgroup area and motional disorder in lipid chains and leads to formation of the thinned state. The possible role of water in the mechanism of anesthesia was emphasized in previous studies (33, 34). Ueda and co-workers (34, 35) have obtained evidence, through proton NMR measurements and FTIR spectroscopy, for the release of bound interfacial water by inhalation anesthetics in a water-in-oil emulsion. This suggested that some anesthetics compete with water for binding sites. Both ethanol and halothane are able to form hydrogen bonds. Halothane contains a so-called acidic hydrogen, which is considered to be involved in a "hydrogen bond breaking effect". It has been shown that anesthetics with "acidic hydrogen" and therefore with high "hydrogen bond breaking" ability have higher anesthetic potency than halogenated molecules containing no acidic hydrogen (36). An NMR study (10) has shown that ethanol incorporates into the lipid–water interface near the lipid glycerol backbone and upper segments of lipid hydrocarbon chains and increases the degree of motional disorder in the lipid chains, which promotes formation of a thinned bilayer.

Molecular dynamics simulations (16) indicate that halothane induces lateral expansion and contraction of the L_α DPPC bilayer. Koubi et al. (16) reported a thickness reduction of 8 Å (from 42 to 34 Å; 1 Å = 0.1 nm) and an increase in area per lipid of 16% (from 63.6 to 72.0 $Å^2$). We observed a thickness reduction from 5.5 to 3.5 nm (2.0 nm) in the L_β DPPC bilayer due to incorporation of halothane. We also have observed a thinning of a pure DPPC bilayer to 3.6 nm upon heating above 42 °C. Thus, incorporation of halothane produces a similar thinning effect as heating the bilayer above the chain melting transition temperature. The difference in an L_α DPPC SPB with and without halothane is small (0.1 nm) compared with that predicted (0.8 nm (16)). This might reflect the differences between supported planar bilayers and free-standing bilayers.

The fact that very similar DPPC bilayer changes are observed for both ethanol and halothane incorporation suggests a common mechanism. Moreover, because the formation of thin bilayer domains surrounded by thick domains is analogous to what we observe for a DPPC SPB near the L_β–L_α phase transition temperature, it is likely that ethanol and halothane induce something similar to a local phase change in the SPB. The mechanism may include initially smaller L_α-like domains coalescing into larger thin domains. The stability of these domains for periods of days would be due to a cage effect by the surrounding thicker and less mobile L_β regions. Fluorescence results from our companion paper (20) also suggest that increased disorder of the lipid packing and penetration of water near the headgroup region of DPPC small unilamellar vesicles is induced by the incorporation of halothane.

DOPC

To gain insight into how the lipid phase might affect the interaction of ethanol and halothane with SPBs, we used DOPC. DOPC exists in a fluid phase (L_α) at room temperature and serves as a fluid-phase analog of the DPPC bilayer. A pure DOPC SPB (Fig. 4*a*) has a thickness of 5.4 nm, as we reported earlier (22). In the presence of ethanol (Fig. 4*b*) or halothane (Fig. 4*c*) at a molar ratio of 7.2:1, the DOPC SPB transforms to a uniform thickness of 3.5 and 3.6 nm, respectively (Table 1). We assume that the higher lipid disorder of a DOPC bilayer results in much less cooperativity in

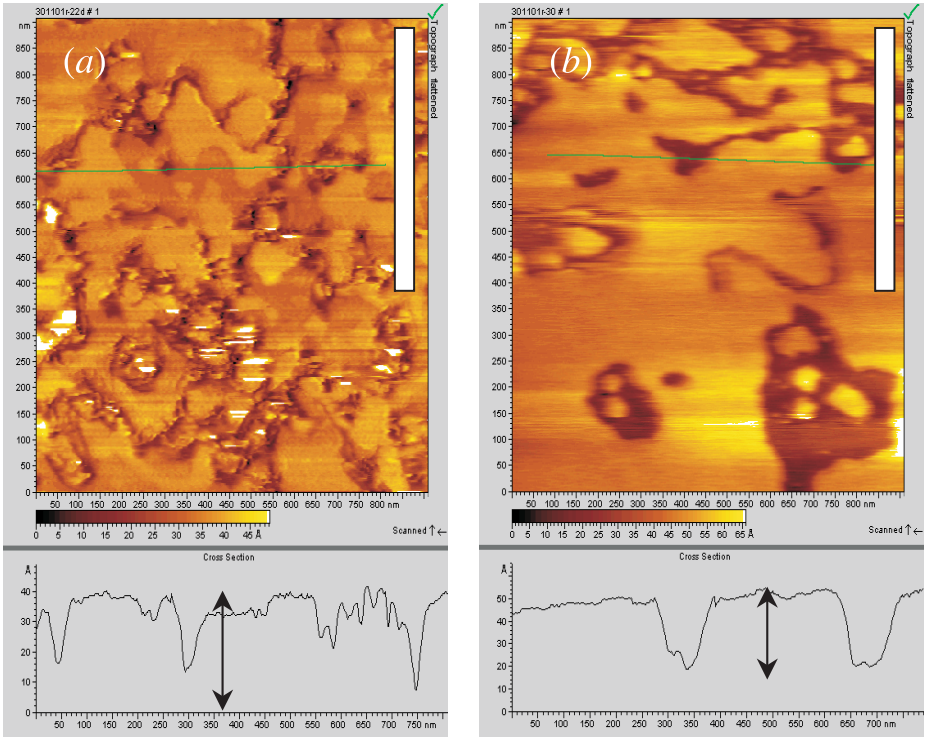
the incorporation of anesthetic at these higher molar ratios, and thus no domains are formed.

Interestingly, at a lower concentration of halothane (molar ratio = 3.6:1), domain formation was observed (Fig. 5*a*). These domains were 5.0 and 3.6 nm thick (Table 1), and the domain shape and size changed during 40 min of scanning (Fig. 5*b*). The fact that DOPC domains were not well resolved and more dynamic compared to DPPC bilayer may be explained by higher mobility of anesthetic in DOPC bilayer than in DPPC L_β bilayer. Thinned DOPC domains were observed in the presence of ethanol as well (Fig. 6*a*).

Although the ethanol-induced domains were more stable at room temperature than those induced by halothane, they started to disappear at 35 °C as the sample was heated and simultaneously imaged. We found that heating the DOPC bilayer with ethanol incorporated and then cooling it back to room temperature revealed changes in SPB surface coverage (Figs. 6*a*–*c*) and bilayer thickness. Initially, we observed a bilayer with domains of 5.5 and 3.5 nm. Upon heating and slow cooling, the bilayer was restored to 5.3 nm. This implies that the release of ethanol from DPPC is largely due to elevated temperature rather than the lipid phase, since the ethanol–DOPC system is stable at room temperature but releases ethanol at elevated temperature.



For an SPB with anesthetic incorporated, changes in surface coverage as a function of temperature can be used to provide insight into the amount of lateral expansion the SPB undergoes during incorporation. For the ethanol-containing bilayer, surface coverage increased by 42.3% (compared to the surface coverage at room temperature) upon heating to 43 °C (observed after 50 min of scanning at 43 °C). After

Fig. 8. Topography images and cross sections of a dioleoyltrimethylammonium propane (DOTAP) bilayer with halothane, at an estimated molar ratio of halothane in the membrane to lipid of 7.3:1. (*a*) At room temperature; (*b*) at 30 °C, 30-min scanning. An aqueous solution of halothane (41 mmol/L) was added into the vesicle solution prior to SPB formation. The scale bars in all panels are 500 nm long. The arrows in all cross sections represent 4.0 nm in height.

the bilayer was slowly cooled back to room temperature, the surface coverage was decreased by 6.2% compared to the initial value before heating. The increase in surface area at 43 °C (with a concomitant decrease in thickness to 3.6 nm) indicates an increase in lipid disorder. Restoring of the bilayer full thickness and a decrease of surface area indicate ethanol escape and formation of the L_α DOPC bilayer. For our conditions, we estimate that incorporation of ethanol produces a 10% increase in DOPC area per lipid compared to that of a pure DOPC bilayer at room temperature. This estimation has been made on the basis of surface changes we observed and known DOPC area per lipid in pure DOPC bilayer without ethanol (A_{DOPC} = 64 Å^2) (37). The increase in DOPC area per lipid can be compared to that of an L_α DPPC bilayer (16%) in the presence of halothane at high concentrations (16) and to that of DPPC in the presence of 2-propanol (15) (57.8% — from 52 Å^2 to 90 Å^2). The smaller increase in the case of DOPC can be explained by taking into account the liquid phase of DOPC bilayer, which is more disordered compared to gel-phase DPPC bilayer, and also to differences in the volume of incorporated molecules.

At a higher concentration of ethanol (3 mol/L) in the vesicle incubation solution, we observed formation of small disk-shaped aggregates and clusters of these aggregates upon exposure of the solution to a mica surface (Fig. 7). No bilayers were observed for this preparation. The height of the circular aggregates was in the range 10–15 nm. We assume that these aggregates could be flattened vesicles, which were stabilized by the partitioning of more ethanol molecules in the upper leaflet. This seems to make vesicles more susceptible to a pre-fusion type of aggregation but resistant to rupture upon adsorption to the mica surface. Mou et al. (14) mentioned previously the existence of such small globular structures in the presence of high concentrations of ethanol.

DOTAP

To help elucidate the influence of the headgroup on the anesthetic-induced changes in SPB structure, we performed analogous experiments using DOTAP. DOTAP is L_α at room temperature, and its headgroup carries a positive charge at neutral pH. A pure DOTAP supported bilayer was described in our earlier publication (18). Halothane was incorporated into the DOTAP bilayer via incubation in the vesicle solution at a 7.3:1 molar ratio of halothane to lipid. An AFM image of the resulting SPB is presented in Fig. 8. Although a DOTAP SPB is already very thin, we again observed formation of thinner domains. The thickness of the higher domain was 3.5 nm and that of the lower domain was 2.9 nm (Table 1). The difference in thickness of the two domains was 0.5–0.6 nm. This difference is close to that calculated (0.4 nm) by Koubi et al. (16) for halothane in L_α DPPC using molecular dynamics. We assume that high lateral mobility of lipid in a DOTAP bilayer, which exists in L_α phase at room temperature, explains the higher mobility of the domains that we observed (Fig. 8).

Conclusions

We have demonstrated by AFM that the thinned domains in DOPC, DPPC, and DOTAP supported planar bilayers in-

© 2004 NRC Canada

duced by halothane and ethanol are similar, regardless of whether the headgroup is the zwitterionic PC or the cationic TAP. This is consistent with the molecular dynamics simulations of Koubi et al. (16) for halothane in the L_α phase of DPPC, where halothane was observed to partition preferentially on the lipid side of the headgroup region. A room temperature DPPC bilayer showed stable domains when either ethanol or halothane was present in the bilayer. Upon heating above the phase transition temperature, ethanol was released whereas halothane was retained. This indicates that the effects we observe are solely due to anesthetic within the bilayer and not an effect of anesthetic content in aqueous solution. In a fluid-phase DOPC bilayer, inhomogeneous, dynamic domains were formed at a ratio of incorporated anesthetic to lipid of less than 7:1. DOPC SPBs completely thinned when this ratio was 7.3:1. The fact that domain formation was almost universally observed implies that anesthetic-induced bilayer thinning is a cooperative process. For gel-phase bilayers, it seems that volatile anesthetics induce a localized phase transformation to L_α, whereas for lipids already in L_α, even thinner domains are generated. Heating of the DPPC bilayer with halothane showed that halothane affects the transition in the bilayer. For the anesthetics studied here, the mechanism likely involves partitioning of the anesthetic preferentially near the headgroups. This is in agreement with the findings of the following companion paper and with previous theoretical and experimental studies. The fact that thinning seems to be universal means that this effect cannot be ignored when considering the physiological mechanism of anesthesia, since membrane thinning may affect the function of some membrane-associated proteins.

Revisiting lipid – general anesthetic interactions (II): Halothane location and changes in lipid bilayer microenvironment monitored by fluorescence

Anna Carnini, Heather A. Phillips, Leanne G. Shamrakov, and David T. Cramb

Abstract: A universal mechanism for the action of general anesthetics (GA) is not yet available. In this study, we investigated the interaction between halothane and 1,2-dipalmitoyl-*sn*-3-glycero-3-phosphocholine (DPPC) and 1,2-dioleoyl-*sn*-3-glycero-3-phosphocholine (DOPC) bilayers labeled with Laurdan, Prodan, and NBD-C_6-PC as the reporter probes using steady-state fluorescence spectroscopy. We have evidence that halothane is located on the acyl chain side, near the headgroup region of the bilayer. Additionally, we find that halothane may be inhomogeneously distributed within DOPC and DPPC bilayers. We also show data that indicate halothane increases the free volume available to fluorescent probes. Differential scanning calorimetry and UV scanning calorimetry experiments were implemented to further observe the effects of halothane addition to the DPPC lipid bilayer. A significant shift of the phase-transition temperature of the DPPC system was observed. Our findings suggest that general anesthetic – lipid bilayer interactions may play a significant role in the overall mechanism of anesthetic action, and these effects should not be ignored when interactions between membrane proteins and anesthetics are considered.

Key words: liposomes, anesthesia, fluorescence, phase transition, phospholipid bilayers.

Résumé : On ne connaît pas encore de mécanisme universel d'action pour l'action des anesthésiques généraux (AG). Dans cette étude, faisant appel à la spectroscopie de fluorescence en état stationnaire, on a étudié l'interaction de l'halothane et de bicouches de 1,2-dipalmitoyl-*sn*-3-glycéro-3-phosphocholine (DPPC) et de 1,2-dioléoyl-*sn*-3-glycéro-3-phosphocholine (DOPC) marquées avec du Laurdan, du Prodan et du NBD-C_6-PC comme sondes. On a obtenu des résultats qui suggèrent que l'halothane se situe sur la chaîne acyle latérale, près de la région du groupe de tête de la bicouche. De plus, on a trouvé que l'halothane n'est peut être pas distribué de façon homogène dans les bicouches de DOPC ou de DPPC. On présente aussi des données qui suggèrent que l'halothane augmente le volume libre pour les sondes fluorescentes. Des expériences d'analyse calorimétrique différentielle et de calorimétrie à balayage UV ont été réalisées pour mieux observer les effets de l'addition de l'halothane à la bicouche de lipide DPPC. On a observé un déplacement notable de la température de transition du système DPPC. Nos observations suggèrent que les interactions entre une bicouche de lipide et un anesthésique général peuvent jouer un rôle significatif dans le mécanisme global de l'action anesthésique et que ces effets ne devraient pas être ignorés lorsqu'on considère les interactions entre la protéine de la membrane et les anesthésiques.

Mots clés : liposomes, anesthésie, fluorescence, transition de phase, bicouches de phospholipides.

[Traduit par la Rédaction]

Introduction

There is a lack of a detailed universal mechanism for general anesthetics (GA). Historically, a strong correlation between oil solubility of general anesthetics and their anesthetic potency was noted at the beginning of the twentieth century (Overton–Meyer correlation) (1, 2). As a result, it was speculated that anesthetics exerted their action by affecting unidentified fatty components of cells. Only later, with a greater understanding of membrane structure and composition, was it hypothesized that general anesthetics targeted the lipid matrix of cell membranes (3). In recent years, a protein-mediated mechanism of general anesthesia has been favored over the lipid-mediated mechanism. Extensive work has been carried out to establish the interaction of general anesthetics with water-soluble proteins as well as with integral membrane proteins (4, 5). A specific class of proteins, ligand-gated ion channels, was found to be an important target of volatile anesthetics (5). Existing models for the mechanism of action of GA include a GA–lipid mediated mechanism, a GA – ion-channel mediated mechanism, and lipid lateral pressure (6). Consistent with a variety of putative mechanisms, volatile anesthetics have a wide range of structures. Small anesthetics such as xenon, organic solvents, steroids, arabinosides, and pyrimidines can induce general anesthesia if present at high enough concentration. It may thus be naive to think that there is a single mechanism

for all general anesthetics, and many factors may be operating synchronously. That is, even if general anesthetics directly affect ion channels, they may also alter membrane characteristics. We therefore need a simple, understandable model to help separate the variables.

Halothane has been prevalent in studies of the effects of volatile anesthetics on model membranes, and several techniques have been applied to the study of its anesthetic mechanism. These include X-ray diffraction, NMR, fluorescence, differential scanning calorimetry (DSC) (7), atomic force microscopy (AFM) (8), and, more recently, molecular dynamics (9–12). Previous work using X-ray diffraction showed that bilayers manifested an increased disorder upon halothane incorporation while maintaining constant membrane thickness (13). Our AFM work (8) suggests that there is change in local structure in the bilayer upon halothane incorporation, resulting from an inhomogeneous distribution of anesthetic in the bilayer. However, AFM cannot provide information about the depth distribution of halothane molecules in the bilayer.

The amphiphilic nature of anesthetics, including halothane, suggests that these molecules would reside mainly at the hydrophobic–hydrophilic interface in model systems such as phospholipid vesicles or micelles. NMR (^{19}F, ^{1}H) and nuclear Overhauser effect (NOE) studies of halothane in sodium dodecyl sulfate (SDS) micelles revealed that halothane molecules reside mostly at the water–micelle interface region (14). At low halothane:SDS ratios, the anesthetic interacted mainly with protons closer to the water–micelle interface; at higher halothane:SDS ratios, the anesthetic interacted with protons that are farther away from the hydrophilic interface. Halothane did not interact with the core of the micelle, even at high concentration (15). Kaneshina et al. (16) and Yoshida et al. (17) demonstrated by ^{19}F and ^{1}H NMR that volatile anesthetics remain at the surface of SDS micelles without losing contact with water. Additionally, NMR studies of halothane, enflurane, and isoflurane distribution in palmitoyloleoylphosphatidylcholine (POPC) bilayers suggested that these anesthetics locate primarily in the interfacial region of the bilayer (18). Other work by Tang and Xu (19) has shown that anesthetics 1-chloro-1,2,2-trifluorocyclobutane and isoflurane locate preferentially in the headgroup region, whereas nonanesthetics locate deeper in the bilayer.

Molecular dynamics simulations (10) of halothane in a DPPC bilayer revealed that halothane self-associates and is also distributed nonuniformly across the membrane interior. This resulted in significant modifications of the lipid bilayer. Because of its nonzero electric dipole moment, this anesthetic was found to reside in a region of the bilayer most accessible to water (i.e., preferentially in the upper portion of the acyl chain). A decrease in lipid wobble and an increase in tail defects of the lipid system were also observed.

To further our understanding of the localization of general anesthetics in a membrane system, we have used fluorescence spectroscopy, temperature-scanned UV–vis spectrophotometry, and DSC on small unilamellar vesicles (SUVs) as a method to examine the location of halothane in model membranes and examine localized lipid order/organization changes. In the present work, we studied the interaction between halothane and 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC) and 1,2-dioleoyl-*sn*-3-glycero-3-phosphocholine (DOPC) bilayers labeled with Laurdan, Prodan, and NBD-C_6-PC as the reporter probes. Laurdan (20–22) has been previously used to detect lipid phase changes from gel (L_β) to liquid crystalline (L_α). We have chosen to study single lipid systems to understand the fundamental nature of halothane distribution and to directly compare our results with those of others and of our AFM study in the companion paper (8).

Materials

DPPC and DOPC were purchased from Avanti Polar Lipids (Alabaster, Ala.) and were used with no further purification. 2-Bromo-2-chloro-1,1,1-trifluoroethane (halothane) 99% (0.01% thymol) was obtained from Sigma (St. Louis, Mo.). 2-Dimethylaminonaphthalene (Prodan), 6-dodecanoyl-2-dimethylaminonaphthalene (Laurdan), and 2-(6-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino)hexanoyl-1-hexadecanoyl-*sn*-glycero-3-phosphocholine (NBD-C_6-PC) were obtained from Molecular Probes (Eugene, Ore.). All lipids, anesthetics, and fluorescent labels were used without further purification. Ultrapure water was used in the preparation of buffer and aqueous solutions using a Mega Pure System ACS by Corning.

Saturated aqueous solutions of halothane were made at room temperature using ultrapure water. The halothane concentration of this saturated solution was 17.5 mmol/L (23). All stock solutions were prepared at room temperature.

Methodology

Preparation of small unilamellar vesicles and large unilamellar vesicles

Solutions of DPPC and DOPC unilamellar vesicles were prepared using a chloroform stock solution (2.5 mg/mL). An appropriate aliquot of the chloroform stock was transferred to a 10-mL volumetric flask to give a final lipid concentration of 0.1 mmol/L (0.25 mg/mL). Chloroform was driven off using nitrogen gas until a lipid film was visible in the flask. The resulting lipid film was resuspended in phosphate buffer (0.01 mol/L, pH 7.0). Unilamellar vesicles were formed by sonication in a sonicator bath from Laboratory Supplies Co. (Hicksvile, N.Y.) followed by extrusion with a miniextruder from Avanti Polar Lipids. DOPC vesicles were extruded after a 10-min sonication–stirring cycle for a total sonication time of 30 min. The DOPC and DPPC unilamellar vesicles were determined to be 100 and 43 nm in diameter, respectively, using a Dyne Pro (Protein Solutions, Piscataway, N.J.) light scattering particle sizer.

Vesicle labeling

DPPC and DOPC vesicles were labeled with fluorescent probes following the procedure outlined by Gratton and coworkers (21). Stocks of fluorescent probes (Laurdan, Prodan, and NBD-C_6-PC) were prepared in chloroform, and appropriate aliquots were added to the lipid fraction in chloroform to obtain a probe:lipid ratio of 1:100 (lipid and dye concentrations of 10^{-4} and 10^{-6} mol/L, respectively). The lipid/dye mixtures were dried under nitrogen gas and then resuspended in buffer.

Note: a.u., arbitrary units.

Loading of halothane into vesicle solution

Halothane was used in its pure liquid form or as a saturated aqueous solution (17.5 mmol/L). The anesthetics were either delivered to the fluorescence cuvette using an Eppendorf pipette or a gas-tight syringe as required. To avoid loss of anesthetic, the cuvette was immediately stoppered, sealed with Parafilm, and neither shaken nor stirred. Solutions were not shaken prior to collecting fluorescence spectra.

Preparation of aqueous micelle solutions

For fluorescence quenching experiments, stock solutions of SDS micelles (80 mmol/L) were prepared. Micelles were labeled with Laurdan using the dry preparation method to give a 1:1 Laurdan:micelles molar ratio. Solutions were allowed to stir for 1.5 h prior to use. Aliquots of pure anesthetics were added to 3-mL aliquots of stock SDS solution to obtain anesthetics concentration in the range of 0.1-20 mmol/L. Solutions were allowed to equilibrate with anesthetics for 2 h prior to recording of their fluorescence spectra.

Collection of emission and excitation spectra

All steady-state fluorescence spectra were collected using a Varian Eclipse fluorimeter (Varian, Palo Alto, Calif.) equipped with a Peltier cryobath. Emission and excitation spectra were collected approximately every 10 min after the addition of halothane. Spectra were collected until no further change in the fluorescence emission intensity occurred. Laurdan and Prodan were excited at 360 nm, and NBD-C_6-PC was excited at 460 nm.

Calorimetry

UV temperature-scanning experiments (22) were carried out using a Varian UV–vis spectrophotometer equipped with a Peltier temperature control unit. Unlabeled DPPC liposome samples were allowed to equilibrate at 25 °C for 10 min prior to beginning the heating/cooling cycle. Heating/cooling cycles were carried out from 25 °C to 45 °C and from 45 °C to 20 °C. Samples were let rest for 10 min at 45 °C prior to starting the cooling cycle. The temperature was scanned at 0.5 °C/min. DPPC liposome samples were prepared in the same manner as for the fluorescence experiments following the procedure outlined above.

Thermograms were collected using a MicroCal (Northampton, Mass.) calorimeter. The data was analyzed using Microcal Origin. The temperature was scanned from 20 °C to 45 °C and back at a rate of 0.5 °C/min. Samples were allowed to equilibrate for 10 min prior to scanning the temperature. The DPPC lipid concentration used was 1 mmol/L (2.5 mg/mL). Vesicles were prepared by sonication and by extrusion through a 50-nm polycarbonate membrane using a miniextruder from Avanti Polar Lipids.

Results

The interaction of the volatile anesthetic halothane with DPPC and DOPC single unilamellar and multilamellar vesicles was investigated by following changes in fluorescent emission of the probes Laurdan, Prodan, and NBD-C_6–PC over time. Studies of anesthetics incorporation were carried out at temperatures below and above the phase transition temperature (T_m) of DPPC (41 °C). This allowed for the investigation of the interaction of the drugs with the bilayer in both its gel and its liquid-crystalline phase. DOPC single unilamellar vesicles were used to study lipid bilayer – volatile anesthetic interactions in a room temperature liquid-crystalline-phase lipid environment. To quantify the degree to which the emission spectra of Laurdan in DPPC and DOPC in SUVs and multilamellar vesicles (MLVs) were altered in the presence of halothane, they were modeled using a sum of two Gaussian functions. The results of these fits are presented collectively in Table 1.

Incorporation of halothane in DPPC MLVs below the L_β–L_α transition temperature

Pure halothane was pipetted into a quartz cuvette containing the vesicle solution and allowed to mix without stirring to give a final concentration of 17.5 mmol/L This is the saturation concentration of halothane in a pure aqueous solution. Stirring or shaking was avoided to minimize volatilization of the anesthetic. Emission and excitation spectra were collected approximately every 10 min after the addition of halothane. Spectra were collected until no further change in the fluorescence intensity occurred. Figure 1*a* shows the intensity changes observed during incorporation of halothane in DPPC MLVs at 20 °C. As halothane was loaded into the vesicles, there was a decrease in Laurdan emission until an equilibrium state was reached 2 h after injecting the drug. This amount of time was required for purely diffusive mixing. Shaking and stirring of the sample was avoided so as to minimize volatilization of halothane. Figure 1*a* also shows

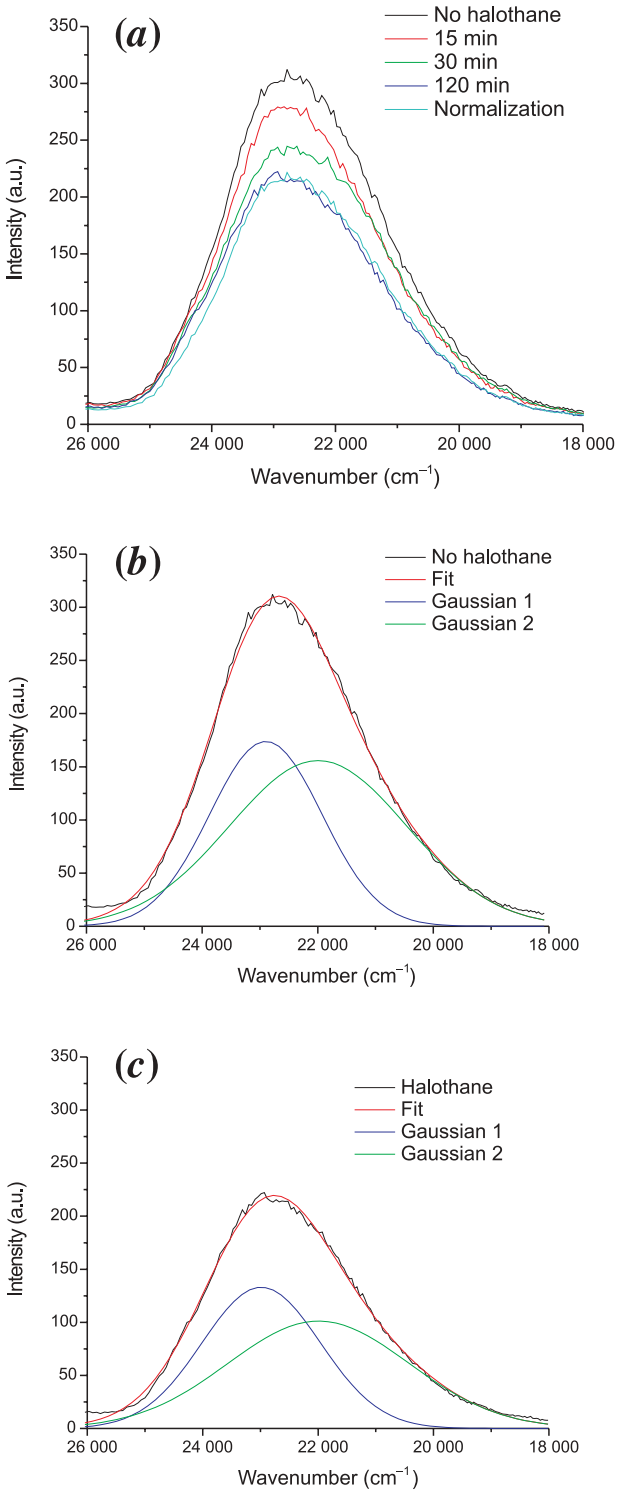
Fig. 1. (*a*) Incorporation of halothane in DPPC MLVs labeled with Laurdan at room temperature (gel phase). Equilibrium is reached after 2 h from drug injection, as indicated by no further change in Laurdan emission intensity. (*b*) Two-Gaussian deconvolution of the Laurdan spectrum without halothane. (*c*) Two-Gaussian deconvolution of the Laurdan spectrum with halothane. The dye:lipid ratio was 1:100.



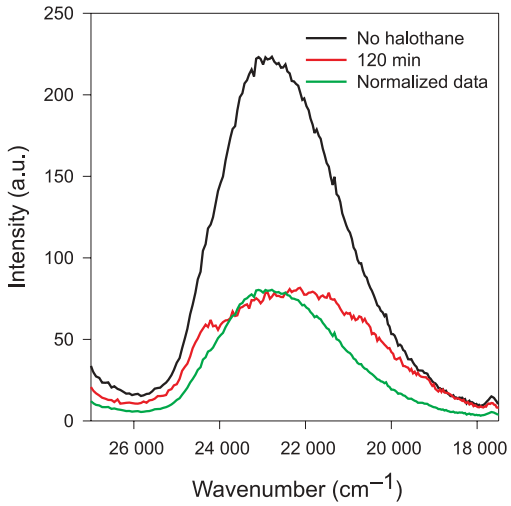


Fig. 2. Incorporation of halothane in DPPC MLVs above the phase transition temperature followed by Laurdan fluorescence. No shift in the λ_{max} of emission occurs. Slight broadening of the Laurdan emission peak occurs upon the incorporation of halothane. The dye:lipid ratio was 1:100.

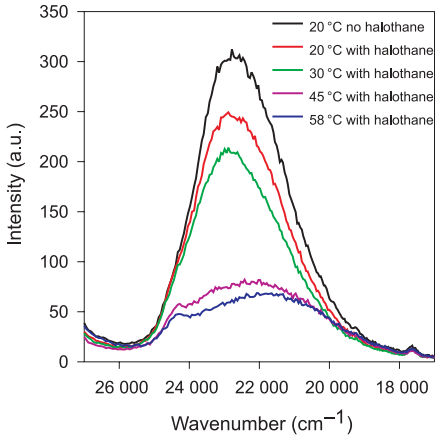
an emission spectrum of Laurdan with no drug present that has been normalized to the trace collected after 2 h from injection time. No significant shift in the emission wavelength of the probe is observed between these two traces, suggesting no change in the probe environment upon incorporation of halothane. Figures 1*b* and 1*c* depict deconvolutions of the spectra in Fig. 1*a* using the sum of two Gaussian functions. The use of two Gaussian functions suggests that Laurdan finds itself in two environments of differing polarity. The lineshape parameters determined for these deconvolutions are given in Table 1.

The gel to liquid-crystalline phase (L_β–L_α) transition in DPPC MLVs can be monitored using Laurdan (20–22). The vesicle solution was heated in stages above the phase transition temperature of DPPC (T_m = 41 °C). As the bilayer becomes more fluid, the fluorescence λ_{max} shifts to the red, indicating that the probe environment becomes more polar owing to more water molecules percolating into the upper region of the bilayer. Since we observe only a slight red-shifting with added anesthetic, the anesthetic-related loss of fluorescence intensity may be due to direct quenching. This will be addressed further in the Discussion section



At a "clinical" (i.e., very low) concentration of 280 µmol/L, halothane shows no significant effect on the Laurdan emission. This indicates that at these concentrations Laurdan may not report on any localized changes in bilayer properties.

Incorporation of halothane at elevated temperatures in nonextruded DPPC vesicles

Halothane was incubated with DPPC liposomes at 42 °C. Although this temperature is above the chain melting temperature, it is clear from Fig. 2 that the vesicle system has not completely transformed to L_α. We therefore consider that there was a mixture of L_β and L_α in the liposomes. Again, we found that Laurdan fluorescence decreased as halothane was incorporated in the vesicles and that 2 h was

Fig. 3. Study of the effect of temperature on halothane incorporated in DPPC MLVs labeled with Laurdan. The drug was not fully expelled from the vesicles despite heating the sample up to 58 °C. The concentrations of halothane and lipid were 17.5 and 0.1 mmol/L, respectively. The dye:lipid ratio was 1:100.

required for this preparation to reach equilibrium. Incorporation of halothane caused a broadening of the main Laurdan fluorescence peak; no shift of the λ_{max} was observed (Fig. 2). The spectra were fitted using a sum of two Gaussian functions. The fit produced one major peak at 435 nm (22 993 cm^{-1}) and a second smaller peak at 464 nm (21 562 cm^{-1}). The peak at 435 nm was quenched 55% by halothane. The redder contribution to the spectrum at 464 nm was quenched by 92%.

After equilibrium was reached, the sample was cooled to 20 °C and then reheated. During reheating, spectra were collected at different temperatures (Fig. 3) to study the effect of temperature cycling on halothane partitioning in the vesicles. Halothane was not entirely expelled from the bilayer even when the vesicle solution was heated above the boiling point of halothane (50.2 °C) for up to 30 min.

Incorporation of halothane in DPPC SUVs above the phase transition temperature

For incorporation of halothane in DPPC (L_α) SUVs, just less than 2 h was required to reach an equilibrium point as indicated by no further change in Laurdan fluorescence intensity. The λ_{max} of emission was at 468 nm. This value is much redder than in the case of nonextruded DPPC vesicles (λ_{max} = 439 nm), and thus we can assume that our sample was in the L_α phase. Fitting to the data revealed again that two peaks contributed to the overall Laurdan spectrum: one major peak at 456 nm (21 930 cm^{-1}) and a smaller redder peak at 477 nm (20 964 cm^{-1}). Upon halothane incorporation, the predominant peak at 456 nm was quenched considerably (65%), whereas the second, red peak was only quenched by 11%, and a 6-nm blue shift occurred (Fig. 4); no broadening of the spectrum was observed.

Direct quenching of probes by halothane SDS micelles

Since the SUV and MLV work indicates that direct quenching of the fluorescent probe may take place, we were motivated to investigate the direct interactions of fluorescent probes with volatile anesthetics. An easy method to ensure

Fig. 4. Incorporation of halothane in DPPC SUVs above the phase transition temperature followed by changes in Laurdan intensity of emission. Equilibrium was reached after 100 min from drug injection. The concentrations of halothane and lipid were 10 and 0.1 mmol/L, respectively. The dye:lipid ratio was 1:100.

that probe and anesthetic are in close proximity is to solubilize them both using micelles. The relative concentrations can then be arranged such that each micelle contains one probe and one anesthetic molecule on average, given Poisson occupation statistics.

Halothane was incorporated in Laurdan-labeled SDS micelles. The range of concentrations of halothane used was between 0.1 and 10 mmol/L. Laurdan in SDS shows its fluorescence λ_{max} at 450 nm with a red shoulder at 510 nm (Fig. 5). This is suggestive of a bimodal distribution of Laurdan within the micelle environment. The blue peak would likely represent a dimerized probe, and the red peak probe near the micelle–water interface. Inspection of the

Fig. 6. (*a*) Effect of heat on the emission spectrum of NBD-C_6-PC in DPPC MLVs (no halothane). Temperature increase leads to an increase of NBD-C_6-PC emission intensity. (*b*) Effect of halothane incorporation in DPPC MLVs vesicles on NBD-C_6-PC fluorescence intensity of emission at room temperature. As halothane partitions in the vesicles, NBD-C_6-PC emission intensity increases. Halothane and lipid concentrations were 17.5 and 0.1 mmol/L, respectively. The dye:lipid ratio was 1:100.

spectra versus halothane concentration added showed that the intensity across the entire spectrum is reduced, but the red peak is quenched to a greater degree. This confirms that direct quenching of Laurdan by halothane is possible.

Do anesthetic–bilayer interactions induce local phase changes?

It is known that the incorporation of molecules in a lipid bilayer can induce structural changes in membranes that may reflect changes in lipid phase (25, 26). Laurdan is, in principle, sensitive to L_β–L_α phase transitions, as has been shown for DPPC; however, because the anesthetic may quench the fluorescent probe located exactly in those microdomains with nearby anesthetic, its ability to report on the local phase of the bilayer may be compromised. Thus, it was not possible to use the generalized polarization fluorescence technique (21) in the present work. Alternatively, NBD-C_6-PC is a highly effective fluorescent probe for monitoring changes in membrane lipid packing. An increase in lipid disorganization and interlipid free space is accompanied by an increase in the fluorescence emission intensity, possibly due to a reduction in self-quenching (27) as the vesicle expands. To confirm this, a solution of DPPC vesicles labeled with NBD-C_6-PC was heated from 20 to 45 °C above the DPPC phase transition temperature (Fig. 6*a*) at three different probe concentrations (0.5, 1, and 2 mol% in DPPC). As the vesicles underwent a chain-melting transition, the fluorescence emission of the NBD-C_6-PC probe increased, without any substantial excitation or emission spectral shifts. This same trend was observed upon the incorporation of halothane in the NBD-C_6-PC-labeled vesicles at room temperature (Fig. 6*b*). This suggests that halothane incorporation increases the DPPC lipid bilayer disorder and the free volumes within the bilayer.

Calorimetry

A calorimetric analysis was undertaken to assess the halothane-induced changes in melting temperature of DPPC. Temperature-scanning UV spectrophotometry was used to follow phase transition events of unlabeled DPPC MLV suspensions in the absence and presence of halothane. The change in absorbance with temperature was followed at 250 nm, which has been shown to be sensitive to changes in lipid packing. Heating was carried out from 25 °C to 45 °C followed by a cooling cycle from 45 °C to 25 °C. The heating cycles showed a broad drop in absorbance between 34 °C and 36 °C followed by a second sharp decrease in absorbance between 41 °C and 44 °C (Fig. 7*a*). Cooling cycles showed this process to be reversible (cooling scan not shown). To better visualize the changes in absorbance associated with the phase transition of DPPC vesicles, the first derivative with respect to temperature was taken and plotted against the temperature (Fig. 7*b*). The first derivative for the heating cycle showed a major peak at 42.0 °C, corresponding to the main phase transition of the DPPC system from gel to liquid-crystalline phase (L_β to L_α). The second peak at 35 °C is due to the pretransition of DPPC MLVs (gel to gel ripple phase).

Samples incubated with halothane were subjected to the same heating/cooling cycle as described above. The incorporation of halothane in the liposome solution caused the shape of the absorbance curve to change. The broad drop in absorbance at 35.0 °C was no longer detectable, and the sharper loss of absorbance, observed between 41°C and 44 °C in the absence of halothane, occurred at the lower temperature range of 33–35.5 °C. Again, to better visualize the changes in absorbance associated with the phase transition of DPPC vesicles, the first derivative was taken and plotted against the temperature (Fig. 7*b*). The first derivative shows only one sharp peak at 34 °C. This suggests that incorporation of halothane in the DPPC solution caused a significant lowering of the phase transition temperature from 42.0 °C to 34.0 °C. Samples that were subjected to the heating/cooling cycle twice produced the same results as the samples exposed to only one heating/cooling cycle.

To verify the temperature-scanning spectrophotometric results, the same sample conditions were examined using differential scanning microcalorimetry. The resulting ther-

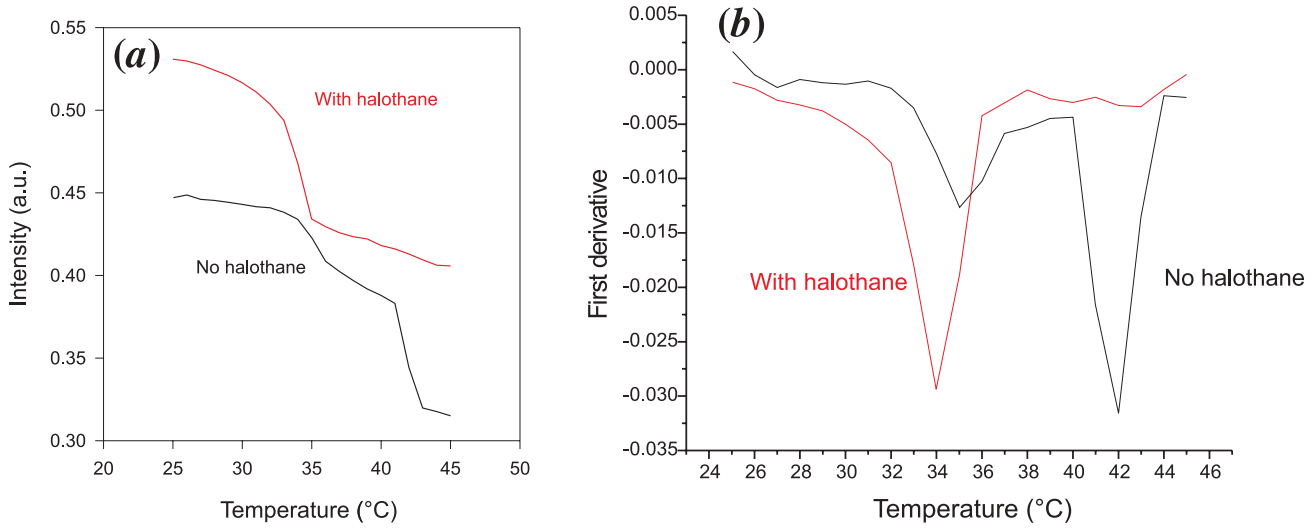
The phase transition temperature in the absence of halothane was 42 °C, and it decreased to 34 °C in the presence of the drug. Halothane and lipid concentrations were 17.5 and 0.1 mmol/L, respectively. The vesicles were unlabeled.



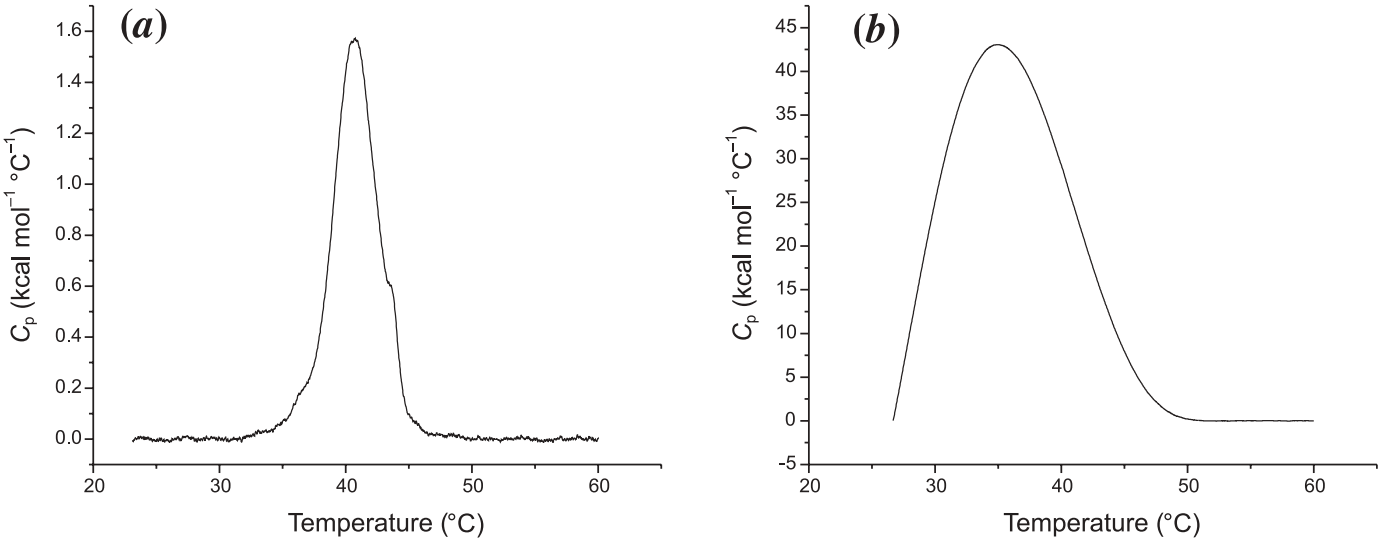


Fig. 8. (*a*) Thermogram for a solution of extruded DPPC vesicles, showing the main phase transition T_m at 41 °C. (*b*) Thermogram for a solution of extruded DPPC vesicles loaded with halothane (17.5 mmol/L), showing a shift in the T_m to 35 °C. Halothane and lipid concentrations were 17.5 and 1 mmol/L, respectively.

mogram for a sample of pure lipid SUVs, presented in Fig. 8*a*, shows a broad peak typical of SUVs and of large unilamellar vesicles (LUVs), with the main phase transition, T_m, occurring at 40.7 ± 1 °C. Two shoulders are visible in the thermogram at 36.6 ± 1 °C and at 43.5 ± 1 °C, and deconvolution of the thermogram confirmed the existence of these two smaller peaks hidden beneath the main peak. The first one is possibly due to the ripple phase transition, and the second to the presence of multilamellar vesicles.

The thermogram for a sample containing halothane at a concentration of 17.5 mmol/L shows a much broader peak than for the sample containing no halothane (Fig. 8*b*). The center of this broad peak is around 34 °C, consistent with the above shift. The considerable broadening may have resulted from aggregation and possibly fusion of the DPPC SUVs during heat cycling; however, the solution did not appear to become more translucent. The broadening could suggest that halothane is reducing the cooperativity between the lipids during phase transition. Interestingly, this does not occur in the absence of halothane.

Incorporation of halothane in extruded DOPC unilamellar vesicles

Because most bilayers found in mammalian cells exist in the liquid-crystalline phase (L_α) at physiological temperature, it is important to examine the effect of volatile anesthetics on a system appropriate to this. DOPC liposomes represent such a system. A sample of DOPC vesicles labeled with Laurdan (Fig. 9*a*) shows a 490 nm emission peak characteristic of a liquid-crystalline-phase bilayer. A significant

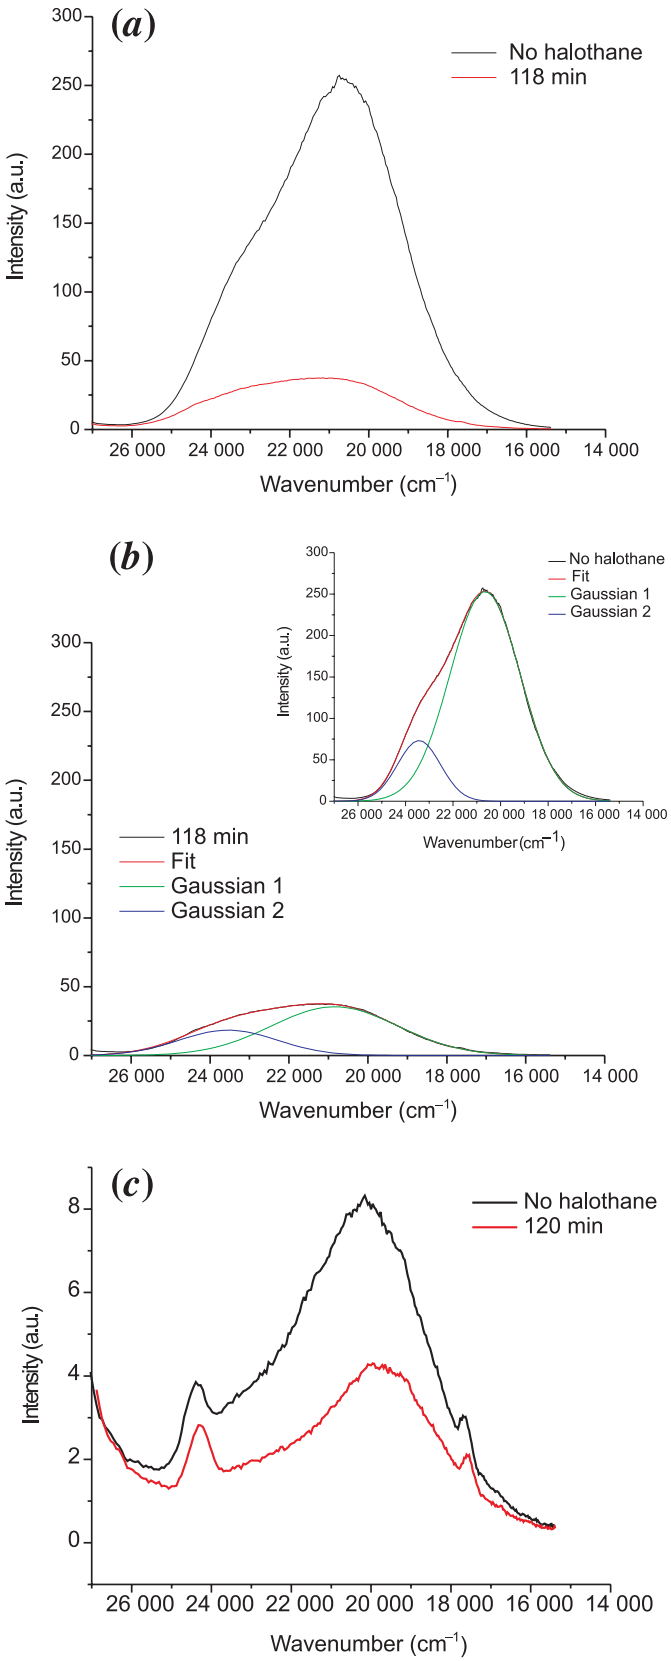

Fig. 9. (*a*) Incorporation of halothane in DOPC SUVs followed by Laurdan fluorescence. Equilibrium was reached after 2 h from adding halothane. (*b*) Deconvolution of the data by fitting Gaussian functions, showing that the red shoulder of the Laurdan spectrum is preferentially quenched by halothane. The insert shows the Gaussian fits obtained for a sample containing no halothane. The concentrations of halothane and lipid were 17.5 and 0.1 mmol/L, respectively. The dye:lipid ratio was 1:100. (*c*) Incorporation of halothane into DOPC SUVs followed by Prodan fluorescence. Equilibrium was again reached after 2 h from adding halothane.

shoulder is visible to the blue of this peak at ~440 nm. This blue peak is indicative of a more nonpolar probe environment and (or) of probe aggregation. This peak was found to be dependent on the dye concentration (data not shown). The incorporation of halothane in DOPC unilamellar vesicles was followed over time. Two hours was required to reach an equilibrium point for halothane incorporation (Fig. 9*a*), after which no further change in fluorescence intensity was observed. The spectra were fitted using a sum of two Gaussian functions (Fig. 9*b*). Both peaks were quenched by halothane, 86% of the red peak (484 nm, 20 651 cm^{-1}) and 75% of the blue peak (426 nm, 23 432 cm^{-1}). It is also notable that the quenched spectrum is slightly broader near the band center (Fig. 9*a*), and when this spectrum was normalized to the initial intensity, it appeared to have broadened significantly. However, as in the case of DPPC, total loss of fluorescence was never achieved.

Extruded DOPC unilamellar vesicles were also labeled with Prodan, which reports on conditions near the headgroup–water interface. In Fig. 9*c*, the same 490 nm peak, indicative of a L_α bilayer, is observed. However, in contrast to the spectrum of Laurdan, no significant peak is found at 440 nm. Upon incorporation of halothane into the vesicles, the spectrum loses intensity, although not as significantly as in the case of Laurdan, and there seems to be a slight (5 nm) red shift of the spectrum.

Incorporation of halothane in DOPC MLVs

The interaction of halothane with Laurdan-labeled DOPC was studied to investigate the drug partitioning in a multicompartment system. As in the case of extruded DOPC vesicles, nonextruded DOPC samples showed a 490 nm emission peak characteristic of a liquid-crystalline-phase bilayer and a significant blue shoulder at ~440 nm. The red peak of Laurdan was quenched by 68% of its original intensity, whereas the 440 nm peak was quenched by 47% (data not shown).

Discussion

Location of volatile anesthetics in bilayers

In this paper, Prodan and Laurdan were used to help elucidate halothane location in the DPPC and DOPC bilayers. Prodan monitors the headgroup region; Laurdan monitors the region immediately below the headgroup. We found that the fluorescence of both Prodan and Laurdan was quenched by halothane for DPPC (L_α and L_β) and for DOPC (L_α) liposomes. The reduction in Laurdan and Prodan fluorescence

© 2004 NRC Canada

intensity is likely due to direct quenching by halothane via the Br heavy-atom effect. This hypothesis is corroborated by our SDS micelle studies, where similar quenching was observed when the micelles were occupied by a single probe molecule and a single halothane molecule. Additionally, some change in fluorescence yield would be expected in DPPC from the induction of lipid melting by halothane. It has been demonstrated that the strongest effect of DPPC melting on Laurdan is a spectral shifting to the red, rather than general loss of intensity (21). The degree of quenching observed upon halothane incorporation both into DPPC and into DOPC cannot be explained solely by alteration in the bilayer structure. Taken together, these results suggest that a fraction of halothane is near the headgroup region.

Since Prodan and Laurdan report on different regions near the bilayer–water interface, a heterogeneous distribution of anesthetic in the bilayer should result in differential quenching of these probes. This is indeed observed for DOPC vesicles. Laurdan experiences a greater loss in fluorescence intensity as anesthetic partitions into the liposomes than does Prodan. Moreover, the reddest feature (490 nm) of Laurdan fluorescence in DOPC is quenched to a greater extent than the blue feature (440 nm). The differential quenching of Laurdan over Prodan by halothane is very suggestive that a significant fraction of these anesthetics take up positions just below the headgroups of DOPC.

For both Prodan and Laurdan, there is minimal spectral shifting as a function of anesthetic incorporation. This is somewhat counterintuitive, since both these probes should report localized induction of more L_α-like domains. However, since changes in the L_α domains are observed using AFM (8), it is possible that the anesthetics quench exactly those probes that are proximal to the bilayer region undergoing change.

It is informative to compare the behaviour of the system above and below T_m for DPPC. The fluorescence spectrum of Laurdan is already broad for L_α DPPC (SUVs at 42 °C), and incorporation of halothane only serves to quench the fluorescence, but not to broaden it further. Furthermore, the quenching of Laurdan is greater when DPPC is at elevated temperatures. This is consistent with the study of Simon et al. (28), in which the partition coefficient of halothane in L_α DPPC was observed to increase by a factor of 4 compared with that in L_β. The slight shift (5–10 nm) of the unquenched probe is in a sensible direction for L_α DPPC and DOPC (i.e., to the red). The fact that there is incomplete quenching, even at levels at which the liposomes appear to be saturated with halothane, indicates that the anesthetic is distributed within the bilayer at several locations.

The present study, nevertheless, indicates that a significant fraction of the membrane-bound halothane is located near the headgroup region of DPPC and DOPC bilayers. This appears to be independent of whether the system examined is unilamellar or multilamellar. Moreover, preferential quenching of Laurdan located near the surface of SDS micelles suggests that halothane also partitions near the water–surfactant interface in micelles. These findings are consistent with the NMR work of Yoshino et al. (14). NMR spectroscopy has also been used to examine the location of halothane in lipid bilayers (29). The apparent disagreement on halothane location (water side of headgroups versus lipid side of headgroups) was reconciled by molecular dynamics simulation (10), which concluded that the distribution of halothane in a DPPC bilayer is concentration dependent and nonuniform. In the present study, experiments were performed in the high concentration regime, i.e., greater than 50 mol%. In this regime, halothane has consistently been suggested to partition largely just under the headgroups on the acyl chain side, in agreement with our results. Additionally, NMR studies (18, 19) have revealed that other volatile anesthetics locate in this region of the bilayer, whereas nonanesthetics partition deeper into the hydrophobic region.

We found that the red peak of Laurdan is quenched to a greater degree in DOPC than in L_α DPPC SUVs (86% vs. 65%, respectively). This peak is due to probe molecules that are more exposed to water, and the difference in quenching may simply reflect the relative partition coefficients of halothane in these two systems, given that L_α DPPC is at elevated temperature (50 °C). Future studies will help reveal any correlation between halothane location and unsaturation in the lipid tails. The challenge of future studies will be to find a fluorescent probe that reliably reports on the inner core of the bilayer.

We recognize that DOPC SUV aggregation and fusion may take place in the presence of higher concentration anesthetic. Our companion paper (8) indicates that this has happened for DOPC SUVs in ethanol solution (3 mol ethanol/L). Thus, aggregation/fusion is also possible for DOPC SUVs in a solution containing 17 mmol halothane/L. However, we do not believe that this significantly influences our fluorescence data. Fusion to form LUVs should not affect the local environment of Laurdan. Moreover, the minor differences observed in the fluorescence behaviour of Laurdan-labeled MLVs compared with SUVs suggest that the quenching of fluorescence does not result from MLV formation via fusion.

Anesthetic-induced phase changes

In the companion paper to this (8), we observed by AFM that incorporation of anesthetics into supported planar bilayers induced domain formation. These domains were thinner and may have been more disordered than the original bilayer. This is suggestive that volatile anesthetics induce local chain-melting phase changes (L_β–L_α) in DPPC and transformation to an increasingly disordered liquid-crystalline phase in DOPC. In the present study, we further investigated this possibility using fluorescence and temperature-scanned UV–vis spectroscopies and DSC.

We acknowledge that the concentrations of anesthetic used in this study are high compared with those in clinical applications. However, this does not obviate the impact of the current results. As shown in our companion paper (8), halothane loads heterogeneously into bilayers, and therefore it is possible that there are regions of high local concentration within physiological bilayers even at much lower aqueous concentrations. Our examination of simple, single lipid bilayers is the first step toward examining bilayers of increasing complexity.

Traditionally, the definition of the lipid chain-melting phase transition is that the individual phospholipid molecules become more mobile or that their lateral diffusion co-

© 2004 NRC Canada

efficients increase significantly. Commensurate with this would be an increase in transverse displacement within the bilayer. The main driving force for melting is that lipid tails acquire gauche defects, which push individual lipid molecules apart. The net effect is often an increase in headgroup spacing. At first glance, it is not unreasonable to expect the same result from the incorporation of anesthetic molecules into a bilayer. Therefore, for halothane/DPPC, one would expect that a significant accumulation of anesthetic just below the headgroup would push the lipid molecules apart. This would lead to more space available for the tails, and again an increase in gauche defects and (or) greater lipid tilting may occur. Indeed, this has been observed in molecular dynamics simulations (10) and inferred from NMR studies (29). In our companion paper (8), we suggest that this increase in interlipid spacing leads to a localized thinning of the bilayer. In the following discussion, we will explore the evidence from the present study for halothane induction of increased interlipid spacing.

By examining the dependence of the fluorescence of NBD-C_6-PC (1 mol%) on the temperature of DPPC SUVs, we have demonstrated that fluorescence yield increases as the bilayer undergoes chain melting (Fig. 6*a*). Probe concentration dependences suggest that this is primarily due to dequenching (i.e., a reduction in self-association) since no change in the 325 nm vs. 470 nm peaks in the excitation spectra was observed. This is in slight contrast to the observations of Alakoskela and Kinnunen (30), who observed changes in $I_{325\ nm}/I_{470\ nm}$ for NBD-C_{12}-PC at 3 mol% in a DPPC liposome as a function of temperature. However, our results agree with the findings of Krull and co-workers (27, 31), who performed extensive studies on NBD self-quenching in monolayers and vesicles for a wide range of concentrations.

Similar to the increase in fluorescence observed when heating DPPC, an increase in fluorescence yield was observed as halothane was added to room temperature DPPC SUVs. Again, we infer that since the excitation intensity ratio, $I_{325\ nm}/I_{470\ nm}$, was constant over the fluorescence increase, the increase results from a dequenching due to changes in membrane lipid packing, i.e., an increase in the space available to the probe molecules. It would also appear that NBD-C_6-PC may be relatively insensitive to changes in local polarity induced by the incorporation of volatile anesthetics into bilayers because no spectral shifting was observed.

Changes in the lipid packing/order in bilayers at the nanometer length scale should be accompanied by changes in the phase transition temperature (T_m) for the system (32). A straightforward way to measure T_m for low-concentration SUVs is by measuring absorbance changes at 250 nm (33). For halothane in DPPC, we observed a lowering of T_m from 42 °C to 34 °C. DSC studies on unlabeled nonextruded DPPC samples (1 mmol lipid/L) supported this finding. In the DSC experiment, the T_m was shifted from 42 °C to 34 °C (Fig. 8).

Lipids that constitute a DPPC bilayer in the gel phase are tightly packed together in an orderly fashion. The partitioning of a solute in a bilayer will change the thermotropic behaviour of the liposomes. We and others (10) suggest that the incorporation of halothane in the bilayer leads to the disruption of the ordered gel-phase packing. As the disorder in the packing increases, so does the entropy of the system, and consequently the phase transition occurs at a lower temperature.

The presence of multiple peaks constituting the main peak in the DSC plot indicates that the DPPC vesicle suspension was perhaps a heterogeneous system. Vesicles of different sizes may have been present in solution. The feature at the highest temperature may be due to larger multilamellar vesicles.

Addition of halothane caused the T_m to shift to a lower temperature. This is consistent with the idea that small molecules like ethanol and 1-butanol (32) or halothane (29) inserting a lipid bilayer will decrease the lipid bilayer ordered packing and thus reduce the temperature at which the phase transition occurs. It is notable that the value obtained for the T_m of halothane/DPPC by DSC (34 ± 1 °C) agrees with the value obtained by temperature-scanning UV spectrophotometry (34 ± 1 °C). Janes et al. (34) have shown that the change in transition temperature has a linear dependence on the mole fraction of hexanol in a dimyristoylphosphatidylcholine (DMPC) bilayer. The authors argue that the incorporation of anesthetics into a bilayer is the equivalent of local thermal heating and cooling, which disrupts the domain structure.

We investigated the effect of subjecting a sample to more than one heating/cooling cycle. Interestingly, there was no indication of halothane being expelled from the vesicles despite the fact that samples were heated above the halothane boiling point (data not shown). This result is consistent with our findings from fluorescence and AFM data.

Since phase transitions in DPPC can be detected using Laurdan (21), halothane-induced packing changes localized within SUVs and MLVs should also be detectable. Using Laurdan, T_m is reported by a red shift in the fluorescence maximum owing to an increase in H_2O penetration into the bilayer and concomitant increase in polarity. Recall in Fig. 1 we observed quenching of Laurdan. In Fig. 1, the Laurdan fluorescence spectrum in DPPC is typical of the L_β phase, with a maximum at 450 nm. Although quenching is observed, no significant spectral broadening can be seen, suggesting that the domains that may undergo complete melting are exactly those where Laurdan is quenched. This is consistent with observations by Merlo and Yager on the effect of isoflurane on Laurdan fluorescence in DPPC (20).

Near the transition temperature of DPPC, an interesting effect is observed (Fig. 4). As halothane partitions into the liposomes, the intensity of the fluorescence spectrum decreases and the spectrum broadens. Thus, there seems to be a small but general increase in the polarity of unquenched Laurdan, consistent with a further departure of the liposome from pure gel phase.

The changes in lipid order suggested by our work are in harmony with the NMR-based results of North and Cafiso (35) and Baber et al. (18), where a decrease in chain order parameter was observed in the presence of volatile anesthetic. The interpretation of our fluorescence and calorimetric data agrees with the molecular dynamics study of Koubi et al. (10), where increased DPPC lipid chain disorder was also observed in the presence of high-concentration (50 mol%) halothane. Moreover, other microcalorimetry

© 2004 NRC Canada

studies have shown that volatile anesthetics lower the lipid chain-melting temperature (7).

Conclusions

In the present work, we studied the interaction between halothane and DPPC and DOPC bilayers labeled with Laurdan, Prodan, and NBD-C_6-PC as the reporter probes. Our results indicate that halothane is located on the acyl chain side, near the headgroup region of the bilayer. Additionally, we find that halothane may be inhomogeneously distributed within DOPC and DPPC bilayers, and this is consistent with what others have observed (10, 12). We also show data that indicate halothane increases the free volume available to fluorescent probes. An increase in lipid disorder is also indicated by DSC and UV scanning calorimetry experiments. The halothane-induced increase in lipid bilayer disorder is reflected in a shift of the phase transition temperature (T_m) to lower temperatures. Our findings suggest that even if anesthesia results from a protein-mediated mechanism, general anesthetic – lipid bilayer interactions cannot be ignored and may play a significant role in the overall mechanism of anesthetic action. For example, the anesthetics may bind to a hydrophobic region of ion channels via the cell membrane. Additionally, if the proteins affected in anesthesia are located in lipid rafts, the changes in lipid packing induced by anesthetics may be an important mechanistic factor.

Electrochemical behaviour of 1-{[(3-halophenyl)-imino]methyl}-2-naphthol Schiff bases on graphite electrodes

Kamran Polat, Mustafa Uçar, M. Levent Aksu, and Hüseyin Ünver

Abstract: An electrochemical study of the reduction of 1-{[(3-halophenyl)imino]methyl}-2-naphthol compounds on graphite electrodes was carried out. All the compounds were dissolved in a 1:4 (volume fraction) mixture of tetrahydrofuran (THF) and methanol. $NaClO_4$ (0.1 mol L^{-1}) was used as the supporting electrolyte. Cyclic voltammetry, chronoamperometry, constant-potential coulometry (bulk electrolysis), and constant-potential preparative electrolysis were employed. The cyclic voltammetric data revealed that the reduction on graphite was irreversible and followed an EC mechanism. The diffusion coefficients and the number of electrons transferred were determined using the chronoamperometric Cottrell slope and the ultramicro electrode steady-state current. The number of electrons was also determined by bulk electrolysis. The products of the electroreduction were synthesized in milligram quantities by the use of constant-potential preparative electrolysis. These products were purified and characterized by spectroscopic methods. Based on these findings, a mechanism for the electroreduction process is proposed.

Key words: electrochemical reduction, hydroxynaphthylideneaniline Schiff bases, cyclic voltammetry, ultramicro electrode.

Résumé : On a effectué une étude électrochimique de la réduction de 1-{[3-halophényl)imino]méthyl}-2-naphtols sur des électrodes de graphite. On a dissous tous les composés dans des mélanges 1:4 (v/v) de tétrahydrofurane (THF) et de méthanol. Du $NaClO_4$ 0,1 mol L^{-1} a été utilisé comme électrolyte de support et on a fait appel aux techniques des voltampérométrie cyclique, de chronoampérométrie, de coulométrie à potentiel constant (électrolyse globale) et d'électrolyse préparative à potentiel constant. Les données de voltampérométrie cyclique révèlent que la réduction sur le graphite est irréversible et qu'elle suit un mécanisme EC. On a déterminé les coefficients de diffusion et le nombre d'électrons transférés à l'aide de la pente chronoampérométrique de Cottrell et du courant d'état stationnaire d'une ultramicro électrode. On a aussi déterminé le nombre d'électrons par le biais de l'électrolyse globale. On a synthétisé les produits d'électroréduction en quantités de l'ordre du milligramme en faisant appel à des électrolyses préparatives à potentiel constant. Ces produits ont été purifiés et caractérisés par des méthodes spectroscopiques. Sur la base de ces observations, on propose un mécanisme pour le processus d'électroréduction.

Mots clés : réduction électrochimique, bases de Schiff de l'hydroxynaphtylidèneaniline, voltampérométrie cyclique, ultramicro électrode.

Introduction

Schiff bases are used extensively as ligands in coordination chemistry (1, 2). Some Schiff bases have thermochromic and photochromic properties in the solid state (3, 4). They are also used as model systems in studies of biological macromolecules and catalytic reactions (5, 6).

Aromatic Schiff bases containing a hydroxy group in the *ortho* position may have two tautomeric forms, namely phenol-imine and keto-amine structures (7). The existence of the tautomers has been documented with X-ray crystallography and UV spectroscopy (8–10). Dudek and Holm (10) observed these tautomers in hydroxynaphthylideneaniline-type compounds. UV and ^{1}H NMR studies carried out on Schiff bases derived from 2-hydroxy-1-naphthaldehyde and some aliphatic and aromatic amines revealed that the keto-amine structure is predominant in polar solvents, and the phenol-imine form is predominant in apolar solvents (11, 12).

The electrochemistry of Schiff bases in aqueous media has been studied in detail (13–16). It was observed that the reduction takes place with a transfer of two electrons and two protons, thereby converting >C=N– to –HCNH–. Two reduction waves are reported to accompany this reduction. The first reduction wave shows a strong dependence on the pH of the media, whereas the second wave was more or less independent of pH (14–16). The reaction is further complicated by the hydrolysis of the azomethine group, which

 doi: 10.1139/V04-021 © 2004 NRC Canada

yields the constituent amine and carbonyl compound (14, 15). This complication is avoided by carrying out the reaction in nonaqueous media. However, studies using aprotic media, such as dimethylformamide and acetonitrile, are few in number and lack detail (17–21).

Scott and Jura (17) proposed the electroreduction process illustrated in Scheme 1, based on their study of the electrochemistry of Schiff bases in DMF. Kononenko et al. (18), on the other hand, concluded that the first reduction wave is an irreversible, two-electron process. Andrieux and Saevant (19) studied the reduction of several imines in DMF and acetonitrile and concluded that, depending on the solvent employed, there is either an irreversible two-electron reduction leading to a saturated amine or, again, an irreversible process, consisting of one-electron steps, which results in dimerization. The first reduction step is assumed to involve an immonium cation derived from the attachment of a proton to the nitrogen atom of the >C=N– group. Dimerization has been considered to be the only cause of irreversibility when explaining the behaviour of benzaldehyde anil in linear-sweep voltammetry (19). The radical formed by protonation of the anion radical produced initially is able to dimerize or to be reduced at the electrode more easily than the imine itself. This second trend is stronger than the first one. However, dimerization was observed, at least partially, in a less acidic medium in DMF (19). Fry and Reed (20) also indicated that the reduction of several imines takes place through an irreversible two-electron transfer.

N-(Benzylidene)-2-aminopyrimidine has been found to be reduced by two electrons at pH 9.8–13.0, ending in *N*-(benzyl)-2-aminopyrimidine. The protonation precedes the electronation in the reduction process, and from voltammetric findings, the whole process is found to be diffusion-controlled and irreversible, and no dimeric product is formed (21).

In our previous work, 1-{[(3-halophenyl)imino]methyl}-2-naphthol Schiff bases were synthesized, and their structures and keto–enol tautomerism in protic and aprotic media were elucidated by the use of spectroscopic methods (22). The present study is concerned with the examination of the electrochemical behaviour of the synthesized Schiff bases using cyclic voltammetric, chronoamperometric, and coulometric methods. The studies in the literature lack detail. In addition, the electroreduction products are studied by spectroscopic methods, to determine the detailed electrochemical mechanism.

Experimental

Apparatus

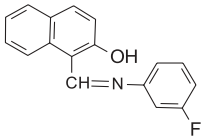
Melting points (uncorrected) were determined on a Gallenkamp melting point apparatus. Infrared spectra (KBr discs) were recorded with a Mattson 1000 FTIR spectrophotometer. UV–vis spectra were measured with a Perkin-Elmer Lambda 2 Series recording spectrophotometer. Mass spectra were obtained using an Agilent GC–MSD and Micromass Platform 2 mass spectrometer operated at 70 eV ionizing potential. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker DPX 400-MHz FT-NMR spectrometer, operating at a proton frequency of 400.5 MHz and a carbon frequency of 100.7 MHz, using $CDCl_3$ as the solvent and tetramethylsilane (TMS) as the internal standard.

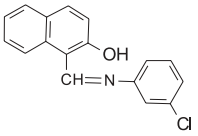
Bulk electrolysis (BE), chronoamperometry (CA), and cyclic voltammetry on ultramicro electrodes were carried out on a BAS100B Electrochemical Analyser equipped with a BAS100B Cell Stand and with a BAS100W.EXE data processing program. Cyclic voltammograms on graphite electrodes were recorded on an EG&G Princeton Applied Research Model 362 Scanning Potantiostat with scan rates between 5 and 500 mV s^{-1}. The *iR* drop was compensated. Constant-potential preparative electrolyses (CPE) were obtained on a PGZ 301 Dynamic-EIS Voltammetry (Radiometer Analytical Co.) system equipped with VoltaLab 4.0+ PC Software.

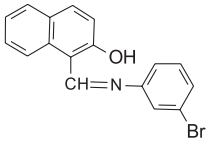
All experiments except the CPE experiments were carried out in an undivided conventional three-electrode cell with a working electrode and a platinum-wire auxiliary electrode. An Ag–$AgNO_3$ (0.01 mol L^{-1}) – CH_3CN electrode, connected to the solution by a Luggin capillary, was employed as the reference electrode. No correction for the junction potential was made. The working electrode for the electrochemical experiments (except for cyclic voltammetry on the ultramicro electrode and CPE) was a 3 mm diameter (0.071 cm^2) graphite disc (spectroscopic grade). Cyclic voltammograms on an ultramicro electrode were recorded with a 10 μm diameter platinum disc (Cypress Systems) and the CPE was performed with a 7 mm diameter (0.3848 cm^2) graphite electrode. The working electrodes were polished with 0.05 μm and 1 μm Al_2O_3 (Buehler). All measurements were run under a blanket of nitrogen. To remove the dissolved oxygen, the solutions were purged at room temperature with nitrogen saturated with the solvent for ca. 15 min prior to each experiment.

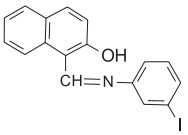
The number of electrons was calculated from the amount of charge passed and the equivalent amount of the reduced BE product. Electrolysis was continued until the current dropped to about 1% of its initial value.

To ascertain the feasibility of an electrochemical synthesis of Schiff bases, different solvents and supporting electrolytes were tested, such as DMSO–Bu_4NF_4, $NaClO_4$; DMF–Et_4NBr, $NaClO_4$; CH_3CN–Bu_4NF_4 or $NaClO_4$. Solutions containing 20% (volume fraction) methanol in THF and Bu_4NBF_4 or Et_4NBr were also examined, but none gave a reduction peak in the potential range studied. For this reason, the solvent and supporting electrolyte (SSE) were chosen as a solution of THF containing 20% (volume fraction) methanol and 0.1 mol L^{-1} $NaClO_4$, which gave the best results in the appropriate potential range.









The structures of the compounds obtained by electrochemical reduction were elucidated by IR, UV–vis, ^{13}C NMR, ^{1}H NMR, and GC–MS techniques.

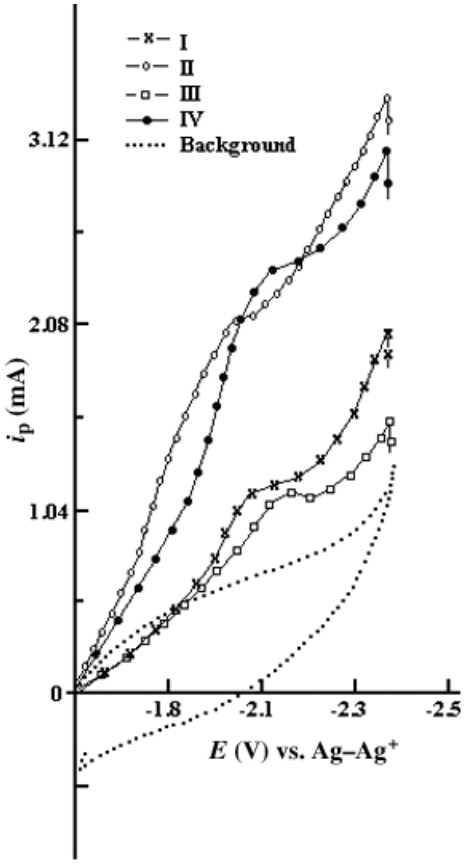
Table 1. Chemical structure and melting points of the Schiff bases investigated.

Compound	Name	Structure	Melting point (°C)
I	1-{[(3-Fluorophenyl)imino]methyl}-2-naphthol		113
II	1-{[(3-Chlorophenyl)imino]methyl}-2-naphthol		115
III	1-{[(3-Bromophenyl)imino]methyl}-2-naphthol		140
IV	1-{[(3-Iodophenyl)imino]methyl}-2-naphthol		163

Note: All the structures given here are based on the assumption that the compounds are in the phenol-imine form.

Merck and purified as described in the literature (23). Sodium perchlorate ($NaClO_4$) was from Aldrich and was used without further purification. 1-{[(3-Halophenyl)imino]methyl}-2-naphthols were prepared according to the method described elsewhere (22). These compounds are listed in Table 1. The melting points relate to a reversible, true melting process. No decomposition was noticed.

Results and discussion



Characterization of the electrode reaction

The cyclic voltammograms of the compounds **I–IV** are shown in Fig. 1. The plotted curves represent the initial scans with a freshly cleaned graphite electrode. As evident on the voltammograms, there is only one reduction peak observed in the –2.0 to – 2.2 V potential range. Also, the anodic half cycle does not have any peak, indicating that the electroreduction is irreversible.

The electrochemical data extracted from the cyclic voltammograms are summarized in Table 2. The reduction potentials shift towards more negative values as the scan rate is increased. Because of this shift, there were no reduction peaks recorded, even at moderate scan rates such as 200 and 500 mV s^{-1}. Even for compound **IV**, with the most positive reduction potential, there was no peak observed at scan rates above 50 mV s^{-1}.

The peak current (i_p) and the current function ($i_p/v^{1/2}C$, where C is the bulk concentration) values were plotted against the scan rate in order to apply the Nicholson–Shain criteria, to elucidate the reaction mechanism (24). The plots obtained are given in Figs. 2 and 3. The plots in Fig. 2 are clearly straight lines, while in Fig. 3 the corresponding plots are concave curves whose slopes decrease towards higher scan rates. Figure 4 is a plot of current against concentration. Both Fig. 2 and Fig. 4 gave linear plots for all the com-

pounds investigated. The Nicholson–Shain criteria state that the linear change of the current with scan rate is an indication that the reaction is diffusion-controlled (24).

The fact that the current function decreases exponentially towards the higher scan rates is an indication that the electron transfer is followed by a chemical reaction. In the absence of chemical complications, this graph would be expected to be a nearly horizontal line. $E_{p,c} - E_{p,c/2}$ values were found to be 45–120 mV, in good agreement with those given in the literature for EC systems (24, 25). All these points suggest that the overall reaction is irreversible and follows an EC mechanism (25).

As shown in Fig. 1 and Table 2, the order of reduction of the compounds is **IV** > **I** > **II** > **III**, which reflects the de-

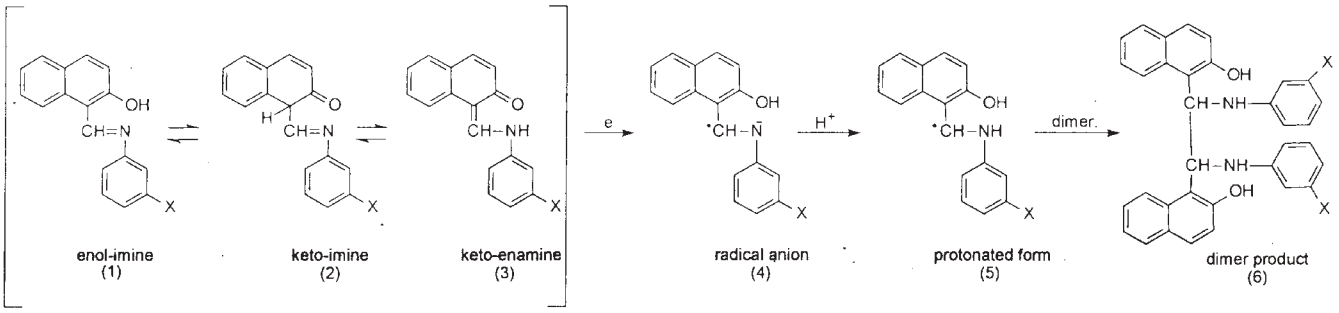
Scheme 2. The electrochemical reduction reaction mechanism.



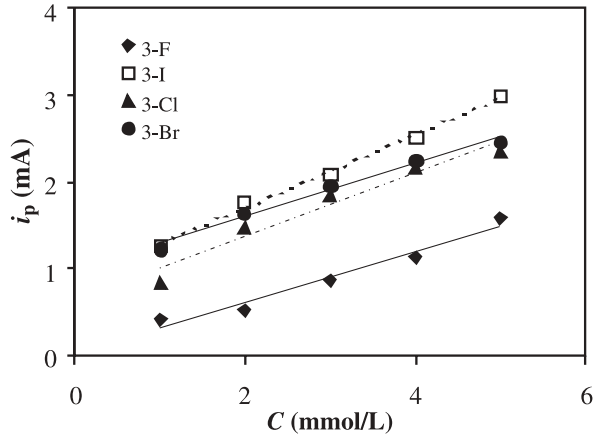


Fig. 4. The change, with concentration, of the current for compounds **I–IV** in solutions containing 20% (volume fraction) methanol in THF (0.1 mol L^{-1} $NaClO_4$) at a scan rate of 50 mV s^{-1} on a 3 mm diameter graphite electrode.

crease in the basicity of the iminic nitrogen, according to Scheme 2, as keto-imine (**2**) → keto-enamine (**3**) → radical anion (**4**) → protonated form (**5**). Such a sequence would be related to shifts in the reduction potentials caused by changes in the halogen-substituted Ar groups attached to the iminic nitrogen. The electron-withdrawing group on the aniline ring facilitates the reduction of the compound. However, it decreases the electron density at the N atom and makes proton transfer from the solvent more difficult. In Schiff bases, the phenyl ring is twisted, and the substituents are not fully conjugated with the rest of the molecule. Therefore, the tautomeric ratio does not depend, in general, on the electron action (donor or acceptor) of the substituents. Thus, the tautomeric process is localized on the naphthylmethylidene moiety. These results are in good agreement with the literature for similar compounds, except for compound **IV** (16).

Determination of the number of electrons transferred and the diffusion coefficients

First, we used both cyclic voltammetry at an ultramicro electrode (26–28) and chronoamperometry at the electrode to determine the number of electrons transferred (n) and the diffusion coefficent (D) simultaneously, for compounds **I–IV**. Equations [1] and [2] give the slope (S_{cott}) of the chronoamperometric i vs. $t^{-1/2}$ plot and the limiting steady-state current (i_{ss}) at an ultramicro electrode, respectively.

$$[1] \qquad S_{cott} = \frac{nFACD^{1/2}}{\pi^{1/2}}$$

$$[2] \qquad i_{ss} = 4nFCDr$$

When the last two equations are combined the number of electrons transferred (n) is given by the expression

$$[3] \qquad n = \frac{4\pi r S_{cott}^2}{A^2 F C i_{ss}}$$

Here, r is the radius of the ultramicro electrode, A is the area of the microelectrode, and all other symbols have their usual meaning (27). In the chronoamperometric experiments, the potential was stepped up from a value where there was no Faradaic current (about –100 mV) to a potential of –2300 mV, which is about 100 mV more cathodic than the first reduction peak for all the compounds investigated. The electrochemically active area of the 3 mm graphite electrode was determined from the slope of the chronoamperometric i vs. $t^{-1/2}$ plot, which was obtained with 5 mmol L^{-1} solutions of ferrocene in 0.1 mol L^{-1} $NaClO_4$–THF (containing 20% methanol) and was found to be 0.80 ± 0.015 cm^2. The value of D for ferrocene used in calculating this area was 4.8(± 0.1) × 10^{-6} cm^2 s^{-1} (29) and was obtained from the limiting current of the voltammograms by assuming the true geometric area of a 10 μm diameter Pt ultramicrodisc electrode as the electroactive area and by employing eq. [2]. The value of n of the ferrocene–ferrocenium couple was taken to be 1. The experimental values of n and D for all compounds are shown in Table 3.

Bulk electrolysis was performed at each peak potential (Fig. 1) for the compounds **I–IV**. The results obtained are shown in Table 3.

Controlled-potential preparative electrolyses and mechanism of the electrode reaction

Controlled-potential preparative electrolysis was carried out in a divided cell. The catholyte was 40 mL of solution containing 28 mmol of compounds **I–IV**. A Pt foil electrode was used as the anode. The anolyte was 20 mL of an SSE solution. The results are illustrated in Table 4.

The reduction products of CPE gave no absorption bands (λ_{max}) above 372 nm, indicating the disappearance of the azomethine group (>CH=N–). After the electrolysis process, the mixture was evaporated to dryness in a rotary evaporator. The solid residue was triturated with diethyl ether several times, and the ether-soluble portion was crystallized from this solvent after drying over K_2CO_3 powder (mp compound

[b]Calculated from the Cottrell slope (eq. [1]).
[c]Calculated from bulk electrolysis.
[d]Calculated from eq. [3].

Table 4. Controlled-potential preparative electrolysis results for the compounds **I**–**IV**.

Compound	Electrolysis products (10^{-3} mol)	t (min)	Potential (mV)	Q/C (F mol^{-1})	Product yield (%)	Current efficiency (%)
I	9.5	51.7	–2200	1785	33.9	66.1
II	9.2	50.0	–2250	1814	32.9	67.2
III	11	51.1	–2300	1640	39.3	60.7
IV	10	57.7	–2150	1736	35.7	64.3

I, 130–133 °C; compound **II**, 74–76 °C; compound **III**, 60–63 °C; and compound **IV**, 66–68 °C).

As a typical example, the following assignments have been made from the IR spectrum of compound **I** after the electrolysis process: peaks (cm^{-1}) at 3474 (OH), 3437 (NH), 3072–3046 (CH arom.), 2920–2859 (CH aliphatic), 1578 (C=C arom.), 1437 (C-N), 1334–1089 (C-O). The IR spectra in the case of compounds **II**–**IV** are similar except for the expected differences in the fingerprint region.

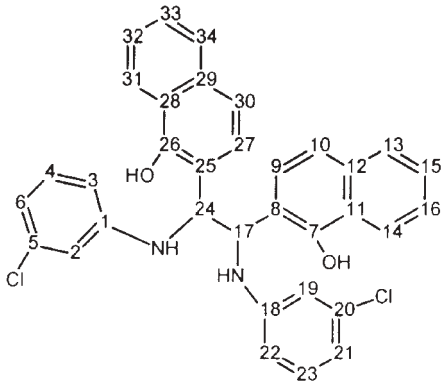
In addition, the broad band in the 3100–3000 cm^{-1} region, characteristic of intramolecular hydrogen bonding, and the bands between 1700 and 1600 cm^{-1}, due to C=N and C=O stretching (22), were found to disappear after CPE.

Principal mass spectral peaks observed after CPE were as follows:

Compound I

MS (EI+, 6.124 × 10^4) *m*/*z* (%): 531.5 ([M – 1(H)$^+$], 9.2), 533.5 ([M + 1]$^+$, 6.7), 437 ([M – 1(H)$^+$ – C_6H_5F], 4.76), 266 ([M – 1(H)$^+$ – $C_{17}H_{13}NOF^+$], 100), 264 ([$C_{17}H_{13}NOF$ – 2H]$^+$, 41.1), 95 ([C_6H_4F]$^+$, 88.9).

Compound II



MS (EI+, 5.73 × 10^4) *m*/*z* (%): 565.55 ([M]$^{+\bullet}$, 2.4), 281 ([$C_{17}H_{12}NOCl$]$^{+\bullet}$, 60), 110.85 ([C_6H_4Cl]$^+$, 100).

FAB+ (ZabSpec) *m*/*z* (%): 580.49 ([M – 1]$^{+\bullet}$, 10.7), 579.4 ([M – 2]$^{+\bullet}$, 19.0), 341.1 ([M – C_6H_4Cl – H]$^+$, 100), 342.13 ([M – C_6H_4Cl]$^+$, 19.67).

Compound III

MS (EI+, 5.57 × 10^3) *m*/*z* (%): 652 ([M + 4]$^{+\bullet}$, 1.2), 655.50 ([M + 2]$^{+\bullet}$, 0.8), 326.01 ([M + 2]$^{+\bullet}$ – [$C_{17}H_{13}NOBr^+$], 55), 324.01 ([$C_{17}H_{13}NOBr$ – 2H]$^+$, 100), 170.52 ([C_6H_5NBr]$^+$, 3.17), 154.61 ([C_6H_4Br]$^+$, 2.93).

Scheme 3. The molecular structure for 2,2′-{1,2-bis[(3-chlorophenyl)amino]ethane-1,2-diyl}di(1-naphthol).

Compound IV

MS (EI+, 1.18 × 10^4) *m*/*z* (%): 748.35 ([M]$^{+\bullet}$, 0.62), 218.83 ([C_6H_5NHI]$^+$, 100), 126.53 ([I]$^+$, 50.81), 372.06 ([M$^{+\bullet}$ – $C_{17}H_{13}NOI$ – 1]$^+$, 30.04), 373.66 ([M$^{+\bullet}$ – $C_{17}H_{13}NOI$]$^+$, 15.73).

The molecular-ion peaks corresponding to the dimerized product (depicted in Scheme 3 for compound **II**) are observed in the MS spectra of all compounds. Also, the base peaks indicate that the fragmentation in compounds **I** and **III** was symmetrical.

Further evidence for the identity of the reduction products of compounds **I**–**IV** was provided by ^{13}C NMR and ^{1}H NMR data. As an example, ^{13}C NMR data obtained for compound **II** after CPE are given below.

^{13}C NMR (proton decoupled, ppm) δ: 148.16 (C1, C18), 109.48 (C2, C19), 115.69 (C3, C22), 129.82 (C4, C23), 133.49 (C5, C20), 119.43 (C6, C21), 156.95 (C7, C26), 120.86 (C8, C25), 127.98 (C9, C27), 121.77 (C10, C30),

© 2004 NRC Canada

135.77 (C11, C28), 137.10 (C12, C29), 126.86 (C13, C34), 116.65 (C14, C31), 128.60 (C15, C33), 124.17 (C16, C32), 56.82 (C17, C24).

DEPT (45, 90, 135) (ppm) δ: 109.48 (C2, C19), 115.69 (C3, C22), 129.82 (C4, C23), 119.43 (C6, C21), 127.98 (C9, C27), 121.77 (C10, C30), 126.86 (C13, C34), 116.65 (C14, C31), 128.60 (C15, C33), 124.17 (C16, C32), 56.82 (C17, C24).

The ^{13}C NMR DEPT results show that there are 11 methine protons ((DEPT-90 and DEPT-45) and no methylene protons (DEPT-135) and no methyl protons (DEPT-45 and DEPT-135)) in the structure. Moreover, the observation of 17 signals in the proton-decoupled spectrum shows that the structure is a symmetrical dimer.

The ^{1}H NMR data for compound **II** after electrolysis are as follows:

^{1}H NMR δ (ppm): 12.4 (s, Ar-O*H* proton), 8.5–6.5 (m, arom. protons), 3.0–4.0 (m, aliph. –C*H* protons), 2.2 (hump, -N*H* proton).

The fact of the disappearance of the characteristic peaks located at δ 9.2 (C=N-H) and δ 15.2 (OH–NH) in the original ^{1}H NMR spectra (22) of the compounds is another verification of the dimer formation.

The fact that the CPE product of compounds **I**–**IV** appears to take one electron per molecule to yield the final product suggests the formation of a protonated radical intermediate, followed by dimerization to yield the final product (Scheme 2, structure **6**). Indeed, the spectroscopic evidence on CPE of compounds **I**–**IV** supports the formation of these kinds of products.

Conclusions

The conclusions drawn from the electrochemical and spectroscopic data are the following:

The cyclic voltammetric investigation of the compounds on graphite electrodes indicates an irreversible reduction peak with a diffusion-controlled EC mechanism for all of the compounds investigated.

Cyclic voltammetry on ultramicro disc electrodes and the chronoamperometric and coulometric studies indicate $n = 1$ for each compound investigated.

The CPE data shows that the dimerized products are very stable. They were isolated and characterized spectroscopically.

It has been demonstrated that the dimeric product of electrolyses can be synthesized on a laboratory scale by the electrochemical reduction in a solution of THF containing 20% methanol, using sodium perchlorate as the supporting electrolyte. The stereochemical investigation of this dimeric product may be interesting and could be a subject of another study.

Is acyl migration to the aglycon avoidable in 2-acyl assisted glycosylation reactions?[1]

Attila Bérces, Dennis M. Whitfield, Tomoo Nukada, Iwona do Santos Z., Agnes Obuchowska, and Jiri J. Krepinsky

Abstract: This report unequivocally separates orthoester formation from acyl transfer for the first time and indicates possible routes to eliminate 2-*O*-acyl transfer during glycosylation reactions. Experimental evidence is shown that acyl transfer from 2-*O*-acyl-3,4,6-tri-*O*-benzyl-D-galactopyranose-derived glycosyl donors decreases in the order formyl > acetyl > pivaloyl. The 2-*O*-benzoyl derivatives are more variable, in some cases transferring easily, and in others not at all. Density functional theory (DFT) calculations of the structure and energetics of dioxolenium ion and related intermediates suggest that a proton transfer pathway from the nucleophile to O-2 provides an explanation for the observed trends. These DFT calculations of the proton transfer pathway support a mechanism in which a relay molecule is involved. Further DFT calculations used a constraint based on linear combinations of six bond lengths to establish the sequence of bond breaking and bond forming. The calculated anomeric carbon to former carbonyl oxygen bond that breaks during acyl transfer is the longest in the formyl case and shortest in those that exhibit little or no acyl transfer. Rotation about the aromatic to carbonyl Ph—C(=O) bond is different from the alkyl series. Analysis of this proposed TS led to the postulate that 2,6-substitution may hinder rotation even more. Thus, the 2,6-dimethylbenzoyl analogue was synthesized and it does not transfer directly or by rearrangement of its readily formed orthoester. DFT calculations suggested that 2,6-dimethoxybenzoyl should also not transfer easily. Experimentally, this proved to be the case and this new 2-*O*-acyl protecting group cleaves at 50 °C with a 1 mol/L solution of LiOH in methanol. Thus, a calculated transition state has led to a prototype of a protecting group that solves a major problem in oligosaccharide synthesis.

Key words: glycosylation, carbohydrates, quantum chemistry, reaction mechanism, neighboring-group effects.

Résumé : Dans ce travail, on sépare sans équivoque et pour la première fois la formation d'orthoester des transferts d'acyles et on suggère des voies possibles pour éliminer le transfert de 2-*O*-acyle lors des réactions de glycosylation. On présente des données expérimentales montrant que le transfert d'acyle de donneurs glycosyles dérivés du 2-*O*-acyl-3,4,6-tri-*O*-benzyl-D-galactopyranose diminue dans l'ordre formyle > acétyle > pivaloyle. Les dérivés 2-*O*-benzoyles sont plus variables; dans certains cas, le transfert se fait facilement alors que dans d'autres il ne se fait pas du tout. Des calculs basés sur la théorie de la densité fonctionnelle (THF) de la structure et des énergies de l'ion dioxolénium et d'intermédiaires apparentés suggèrent qu'un transfert de proton du nucléophile vers O-2 s'avère la meilleure explication pour les tendances observées. Ces calculs de THF de la voie de transfert de proton appuient un mécanisme dans lequel une molécule relais serait impliquée. Des calculs supplémentaires de THF ont été réalisés en appliquant une contrainte basée sur des combinaisons linéaires de six longueurs de liaisons pour déterminer la séquence de bris et de formation de la liaison. La longueur calculée pour la liaison entre le carbone anomérique et l'oxygène du carbonyle antérieur qui se brise au cours du transfert d'acyle est la plus longue dans le cas du formyle et elle est la plus courte dans les cas de ceux qui ne donnent que peu ou pas de transfert d'acyle. La rotation autour de la liaison aromatique vers le carbonyle de Ph—C(=O) est différente de celle observée dans la série alkyle. L'analyse de cet état de transition proposé conduit au postulat que la substitution en 2 et 6 peut empêcher la rotation encore plus. On a donc réalisé la synthèse de l'analogue 2,6-diméthoxybenzoyle et on a observé qu'il n'y a pas de transfert direct ou par le biais d'un réarrangement de la part de cet orthoester facilement formé. Des calculs de TDF suggèrent que le 2,6-diméthoxybenzoyle ne devrait pas donner lieu à des transferts. D'un point de vue expérimental, cette prédiction s'est avérée juste et ce nouveau groupe protecteur 2-*O*-acyle peut être clivé à 50 °C, avec du 1 mol/L LiOH dans du méthanol. Ainsi, un état

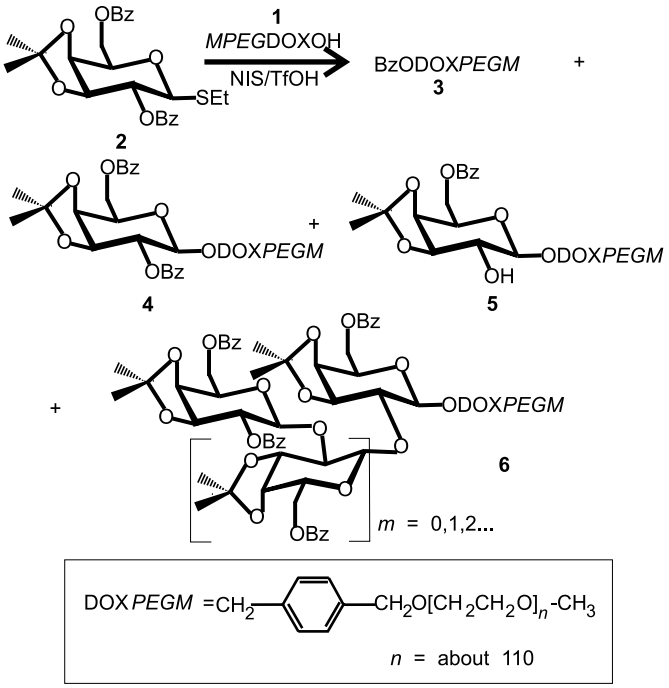
Introduction

Many biologically active molecules contain sugar molecules with acetal or ketal linkages. The study of the diastereomeric complexities of joining two sugar molecules together to form such linkages is an active area of research. Most linkages are formed by glycosylation reactions between an activated electrophilic glycosyl donor and a weakly nucleophilic alcoholic acceptor. This necessity to use highly reactive donors makes these reactions prone to side reactions. Minimizing side reactions and achieving stereochemical control are the two main objectives of research into glycosylation reaction mechanisms (1).

The commonest approach to stereochemical control of glycosylation reactions is to use neighboring group participation, typically of an ester at C-2 of a hexopyranosyl donor. After activation by a promoter in the absence of nucleophiles such species form dioxolenium ions by nucleophilic attack of the ester carbonyl oxygen (O-7) on C-1 (2). It has been shown theoretically that such cations have a LUMO predominantly situated on the former carbonyl carbon (C-7) and therefore C-7 should be the site of nucleophilic attack. In the presence of nucleophiles, calculations suggest that stable intermediates that have long C-7—O_{nuc} bonds are formed (3). After shortening of this bond, hydroxylic proton transfer and pyranose ring conformational change stable orthoesters can be formed. A common side reaction long associated with orthoester formation is acyl transfer. This unwanted side reaction is the transfer of the O-2 acyl protecting group (4) to the nucleophilic acceptor to form a new ester linkage and a free OH group at O-2 of the sugar (5). This side reaction is the focus of this study.

Acyl transfer from the glycosyl donor to the sugar acceptor has been noted numerous times over many years (6). This side reaction has been observed with many different glycosyl donors (7) under many different glycosylation reaction conditions. Besides the acylated acceptor alcohols, glycosides often of both anomers with a 2-OH group, for example **5**, are frequently formed as well (8). For "conventional" solution-phase chemistry this side reaction is only a problem of yield and adds extra complexity to the reaction mixture to be purified. For solidphase methodologies, where the acceptor is bound to the polymeric support, it is particularly troublesome (9). If the acyl group is used as the cleavable group then two or more hydroxyl species instead of one will be available for the subsequent glycosylation. If the acyl group is not the cleavable protecting group then the acyl transfer itself essentially caps the polymer bound acceptor and it is the formation of polymer bound donor derived glycosides with free OH groups that can undergo further glycosylation, which is the problem.

Such a reaction was observed between the linker-polymer combination MPEG-DOXOH (**1**) and the donor ethyl 2,6-di-*O*-benzoyl-3,4-*O*-isopropylidene-1-thio-β-D-galactopyranoside (**2**) under a wide variety of reaction conditions. Donor **2** was designed to allow for subsequent branching at O-3 and O-4. Among the reaction products were: **3** the result of benzoyl transfer to the nucleophile, **4** the expected product, **5** a 2-OH glycoside, and **6** β(1 → 2)-linked oligomers that accounted for up to half the polymer bound products (see Scheme 1 (10)). Previously (1 → 2)-linked disaccharides have been isolated as side products in glycosylation reactions that also exhibited acyl transfer (11). Also, some groups have independently developed protocols to preparatively prepare (1 → 2)-linked disaccharides based on this reaction type (12). Since preparative polymer-supported chemistry requires very high yields with no side products, we adopted a program to develop strategies towards the elimination of the acyl transfer side reaction.



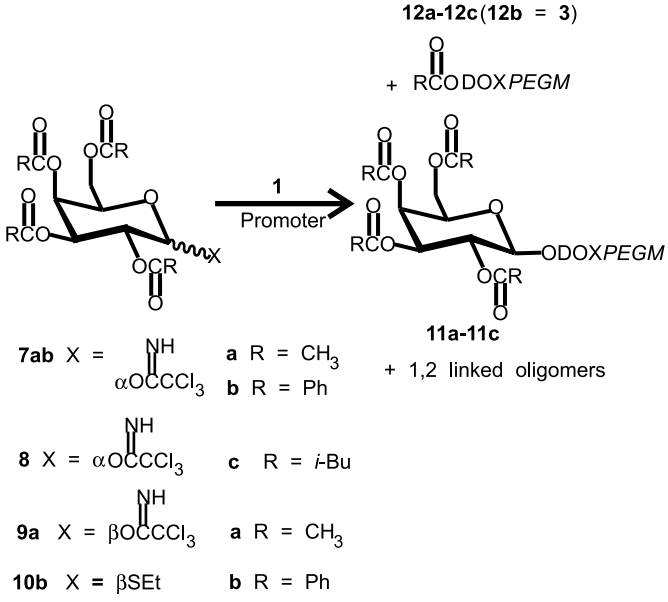
It has long been known that increasing the steric bulk about the acyl substituent minimizes acyl transfer. For example, the suppression of acyl transfer during the preparation of multigram quantitities of glucosylated sapogenins was achieved by switching from peracetyl- to perbenzoyl-substituted donors (13). Another group has shown the utility of isobutyryl to minimize acyl transfer with glucuronyl donors (14). Several groups have used pivaloyl esters to suppress acyl transfer (15). Most of these reports discuss the use of pivaloyl in terms of suppressing orthoester formation and do not discuss acyl transfer (16). Similarly, the mesitoyl (2,4,6-trimethylbenzoyl) group has also been used to suppress orthoester formation (17). Orthoesters can be rearranged to glycosides by acid catalysis (18) but acyl transfer is frequently observed in this reaction (19). As we will show below, the propensity to form orthoesters and the propensity to give acyl transfer are not directly related (20).

Results and discussion

Few studies have attempted to systematically study the effect of the acyl group on acyl transfer. We had previously studied a series of 2,3,4,6-tetra-*O*-acyl-substituted galactopyranosyl trichloroacetimidate donors (**7ab** and **8**), and shown that the order of acyl transfer was benzoyl (**12b**) << isobutyryl (**12c**) ≈ acetyl (**12a**) (8). This study also showed that trifluoromethanesulfonic anhydride as promoter with the peracetate **7a** (21) led to 1,2 linked-oligomers, whereas using silver or copper(II) triflate as promoter eliminated the 1,2-oligomers but not acetate transfer (see Scheme 2). We now show that the powerful promoter triethylsilyltriflate also leads to acetate transfer in a ratio of 40:60 (glycoside **11a** to acetate transfer **12a**) for the α-trichloroacetimidate **7a** and 33:67 for the β-trichloroacetimidate **9a**. Changing to the perbenzoyl trichloroacetimidate **9b** improves the ratio to 93:7 (see *Experimental*). This matches the previously reported result with the perbenzoyl 1-thio-galactoside donor

© 2004 NRC Canada

Scheme 1. Acyl transfer side reaction during a polymer-supported glycosylation reaction. Even after extensive optimization desired glycoside **4** could only be formed in <40% yield (10).



10b, where a ratio of 93:7 (**11b**:**12b**) was also found (10). We interpret these results to indicate that one or more intermediates are formed in such glycosylation reactions that eventually lead to acyl transfer or glycosylation (cf. **D** and **E** in Scheme 3).

Returning to 3,4-*O*-isopropylidene galactose derivatives, we showed that even pivaloyl esters transfer to form MPEG-DOXOPiv although 1,2-oligomer formation was suppressed.

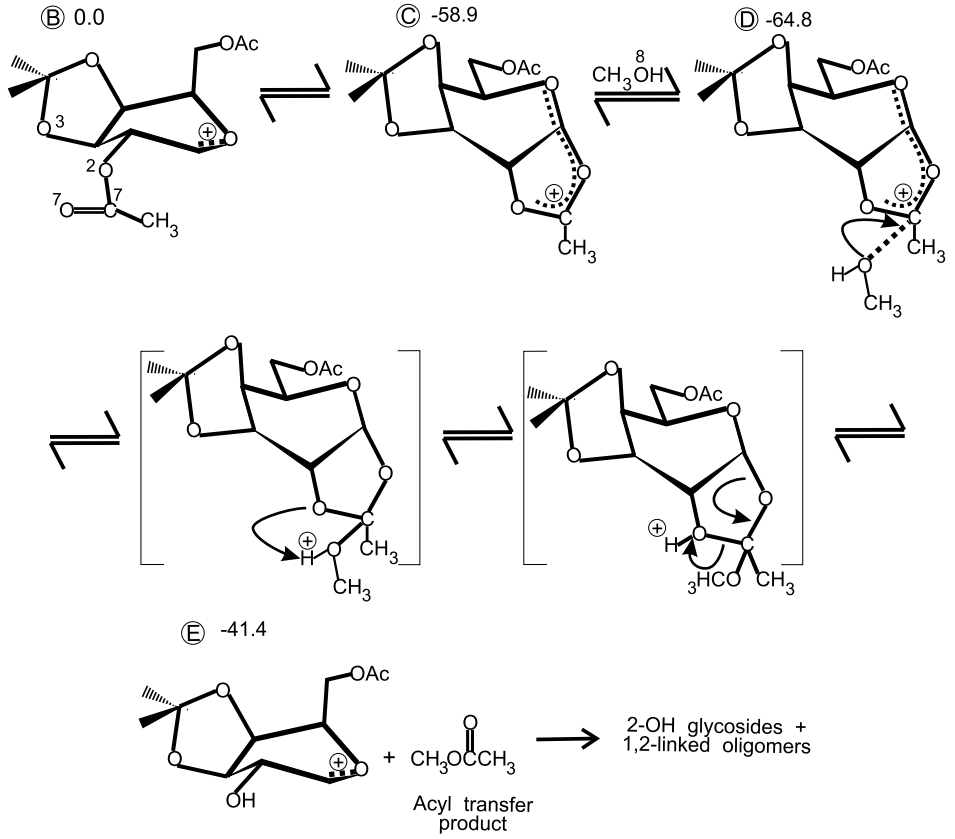
Following a literature precedent (22), increasing the steric bulk about the alcohol acceptor by forming the α-methyl benzyl derivative MPEG-MDOXOH was undertaken for the preparation of synthetically useful amounts of MPEG-MDOXyl glycosides. Two other factors, namely operating at the highest possible concentration of TfOH and the highest possible temperature that did not lead to decomposition reactions, were also necessary to suppress acyl transfer. These last two observations can be interpreted to indicate that acyl transfer gives the apparent kinetic product and glycosylation the apparent thermodynamic product (10). The importance of the acid concentration also suggests that proton transfer is integral to the mechanism as previously proposed (11*a*).

Given the high propensity to undergo acyl transfer of the 3,4-isopropylidene galactose derivatives, we undertook to study the mechanism of acyl transfer with the 2,6-di-*O*-acetyl-3,4-*O*-isopropylidene-D-galactopyranosyl cations. The structures and energetics of the following intermediates were calculated using density functional theory (DFT) with a continuum solvent correction (see Scheme 3). The "parent" cat-

Scheme 2. Effect of acyl groups on acyl transfer with galactose donors (8, 10).

ion **B** is derived by ionization of donor **A**. Monocyclic **B** after ring inversion can cyclize to the bicyclic dioxolenium ion **C** associated with neighboring group participation with a calculated barrier of 34 kJ mol^{-1} (23). This ion has a vacant *p*-like orbital centered on the former carbonyl carbon (C-7) (3). This reacts with methanol to form an ion–dipole complex **D** with a C-7—O-8 (O-8 from MeOH) bond length of 2.81 Å. After considerable search, a pathway involving proton transfer to O-2 from **D** spontaneously led to acyl transfer and the 2-OH ion **E**.[4] Ion **E** is presumably the precursor to 2-OH glycosides and 1,2-oligomer formation but its reactivity has not been studied further.

To further study the acyl transfer pathway, we decided to study the effect of acyl substituents. For this purpose, a series of 2-*O*-acyl 3,4,6-tri-*O*-benzyl-D-galactopyranosyl donors (**13a**–**13e**), where the acyl groups are formyl, acetyl, benzoyl, pivaloyl, and levulinoyl, were prepared and reacted with **1** (see *Supplementary material*[5] and *Experimental*. The ease of acyl transfer during the preparation of glycosides **14a**–**14e** followed the order formyl > acetyl > levulinoyl >> benzoyl = pivaloyl in the amounts 56%, 5%, 2%, and 0% (cf. **15a**-**15e**, see Scheme 4). This compares to the 3,4-isopropylidene donors where benzoyl transfers more than pivaloyl with the same acceptor suggesting that the more reactive 3,4,6-tri-*O*-benzyl donors suppress acyl transfer (24).



To study the acyl group effect theoretically we calculated the intermediates **B**, **C**, **D**, and **E′** for the series 2-*O*-acyl 3,4-*O*-isopropylidene-6-*O*-acetyl-D-galactopyranosyl cation plus MeOH where the acyl is formyl, acetyl, benzoyl, and pivaloyl (see Table 1). Note as shown below, **E′** in this series is an ion–dipole complex of the ion **E** and the appropriate acyl methyl ester. The pyranose ring in all **C** and **D**s is in the

[4] In the original report of ref. 3 other ion–dipole complexes resulting from the methanol approach to the anomeric center of **C**, to the β-face of **B**, and the α-face of **B**, respectively, as well as a plausible intermediate with a tetrahedral carbon were considered.

Scheme 3. Previously proposed mechanism for acyl transfer via proton transfer to O-2. Intermediates **B**–**E** derived by the ionization of donor **A** (10).

Scheme 4. 2-*O*-Acyl-substituted galactose donors used to assess the substituent effect on acyl transfer.

$B_{2,5}$ conformation and in all **B**s is in an ^2S_O conformation. Figure 1 shows partial ball and stick representations of the structures of the **D** complexes. It is readily apparent that the C-1—O-7 bond length is the longest for the formyl derivative among the series formyl (1.810 Å), acetyl (1.640 Å), and pivaloyl (1.618 Å). These trends fit the observation of acyl transfer diminishing in the series formyl > acetyl > pivaloyl (see Figs. 1*a*–1*c*). The benzoyl **D** has the shortest calculated C-1—O7 bond length (1.607 Å) but is quite close to pivaloyl (cf. Figs. 1*d* and 1*c*). These results suggest some π-resonance contribution, which is not unexpected given the similarity to a substituted benzyl cation. Similarly, the benzoyl complex **D** is the most stable relative to isolated **B** and MeOH as shown in Table 1.

From our previous calculations we know that proton transfer triggers the acyl transfer and for this reason, the proton transfer is probably the rate-determining step (10). We first studied the direct transfer of the H-(O-8) to O-2 using constrained linear transit calculations explained in *Computational details*. We found that the direct proton transfer involves a 170 kJ mol^{-1} barrier, which is clearly too high and this mechanism is therefore unrealistic. For a proton transfer to take place with a reasonably low energy barrier, the donor, the acceptor, and the proton should ideally be situated on a straight line. In contrast, the angle between the H—O-8 bond and the H—O-2 hydrogen bond is 78° in the formyl case. Consequently, the proton transfer does not take place directly but likely involves a relay molecule. We note that these reactions normally take place in aprotic solvent but a small amount of water or other proton relay molecules cannot be ruled out. The counteranions or leaving-group derived entities as well as added bases and molecular sieves etc. are all possible relay molecules. To keep the model as simple as possible we considered a second methanol to be involved as

Scheme 5. The constraint based on r_1r_6 used for the mechanism calculation (see eq. [2]).

a relay molecule in the proton transfer. Similar relay molecules have been used in theoretical studies of the mutarotation reaction (25).

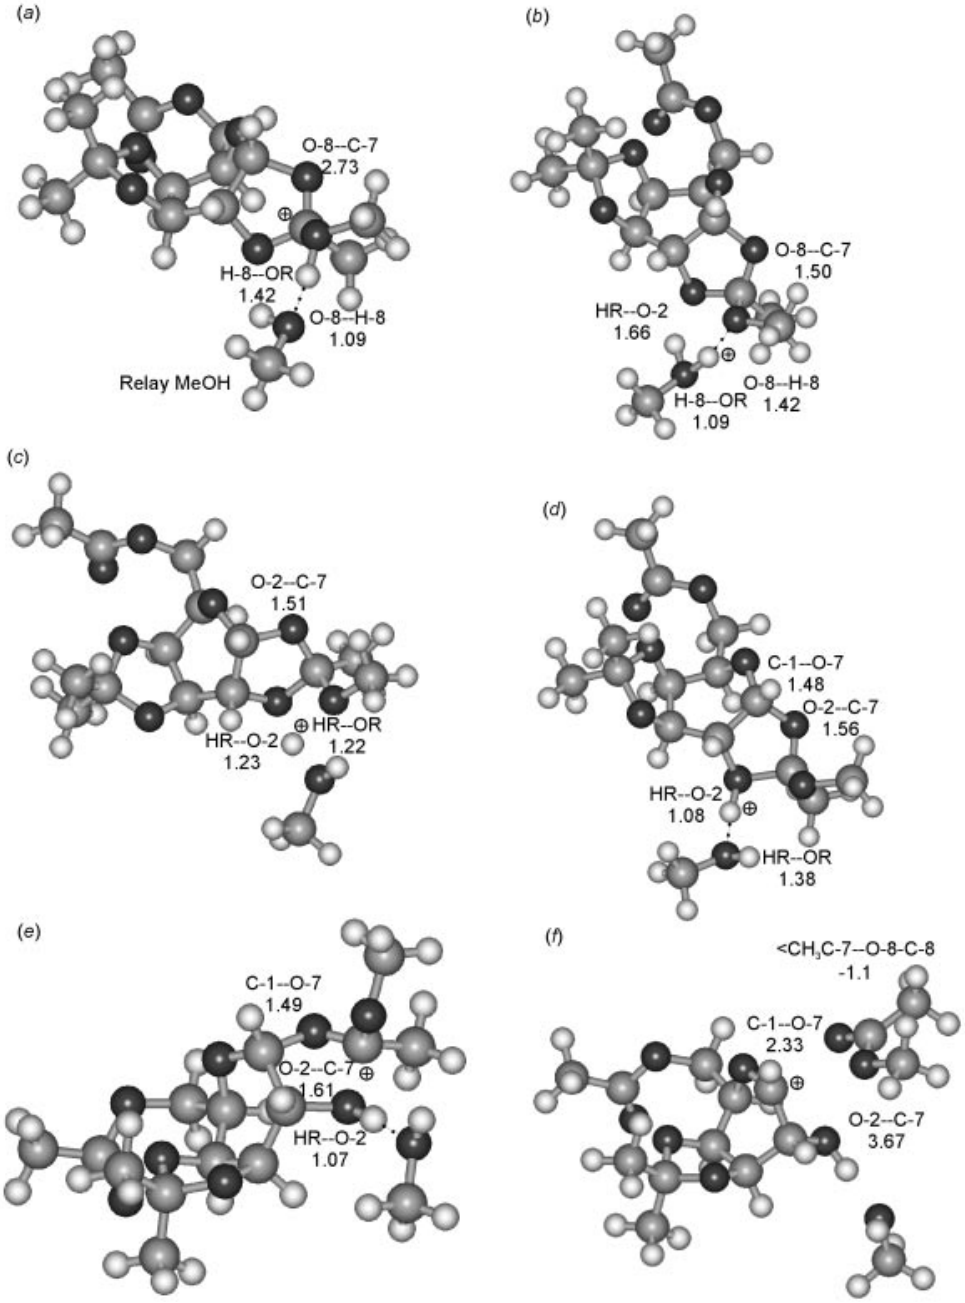
To understand the mechanism of acyl transfer we carried out calculations mapping the reaction path leading from **F** to **G** as shown in Scheme 5. General methods of reaction path following usually consider elementary reaction steps. The application of these methods becomes intractable for multistep reactions such as acyl transfer. Consequently, we customized our approach to this reaction to gain insight into the mechanism. We carried out linear transit calculations using a constraint that ensures that the reactant and the product states correspond to **F** and **G**.

This reaction involves the formation and breaking of seven bonds as well as hybridization changes such as C-1 going from sp^2 in **F** to sp^3 in neutral products. Two hydrogen bonds become covalent bonds and two covalent bonds involving hydrogen break to become hydrogen bonds. In addition, the formation of the O-8—C-7 bond and the breaking of O-2—C-7 and O-7—C-1 are key features in the mechanism. Since the O-7—C-1 bond breaking is the consequence of the rest of the rearrangements, we do not have to consider this bond as part of our linear transit constraints. To consider the breaking and formation of six separate bonds individually requires assessing the $6 \times 5 \times 4 \times 3 \times 2 = 720$ possible sequences of events. For this reason, we have to define a constraint that brings the reactants to product state without predefining the sequence of events. We shall explain how this can be carried out on a simpler example and extend the results to acyl transfer. Lets consider the transfer of H—(O-R) to O-2. There are two bonds involved in this transfer: the forming H—O-2 bond and the breaking H—(O-R) bond. A simple constraint

$$[1] \qquad Q = \mathrm{R[H—(O\text{-}R)]} - \mathrm{R[H—(O\text{-}2)]}$$

where R[H—(O-R)] and R[H—(O-2)] are the H—(O-R) and H—(O-2) bond lengths, respectively, can be used to study this mechanism. At the reactant state, the value of Q is negative while it is positive in the product state. To study this reaction by quantum mechanical methods, we can carry out constrained geometry optimization at varying values of Q representing the progress of the reaction. This procedure is called linear transit. The application of Q as a constraint has some distinct advantages compared to using either the forming or the breaking bond distance as constraint alone. Most importantly, this constraint does not specify the sequence of events, whether the bond breaking or the formation takes place first or if the two steps are synchronized. In addition, it is straightforward to extend this constraint to the case described in Scheme 5. For the exploration of the reaction path from **F** to **G** we used the following definition of the constraint:

$$[2] \qquad Q = r_1 - r_2 + r_3 - r_4 + r_5 - r_6$$



where r_1 through r_6 are defined in Scheme 5. In our calculations, we varied Q stepwise from a negative value to a positive one in 50–60 steps. At each value of the constraint the geometry was optimized subject to the constraint. Consequently, going from one value to the next of Q in the reaction path, the bond that changes its length is always whichever bond involves the least increase in the energy. These calculations enable one to find out the sequence of events without any assumption. However, this constraint has its own limitations. If the mechanism is stepwise, after the first proton transfer the broken bond involving the transferred hydrogen becomes the softest coordinate. Consequently, the lowest energy path involving the increase of Q is the increase of the distance of the broken bond, which may be irrelevant to the mechanism. For this reason, in a clearly stepwise reaction, once the first step is explored Q may be modified to the exploration of the next step to exclude the coordinates irrelevant for the rest of the reaction.

In addition, in the definition of Q we assumed that all conformational changes are the consequence of the formation and breaking of the bonds. As we found in the calculations, the products often involve different conformations from the reactants. To explore the importance of conformational change in the mechanism in a quantitative manner is a subject for future research. Even with its limitations, these calculations gave some significant insight into the reaction mechanism. It is remarkable that out of the 720 theoretically possible reaction mechanisms, all studied reactions follow essentially the same steps with four different protecting groups (see Fig. 2*a*–2*f* for the acetyl example). The potential energy surface involves an initial barrier followed by a high energy intermediate in a plateau region (see Fig. 3). The plateau is followed by a second barrier, which is higher than the first barrier except for the pivaloyl case.

The mechanism starts with the shortening of the O-8—C-7 bond length, which markedly increases the acidity of the nucleophilic hydroxlic proton. This charge movement presumably triggers transfer of this hydroxylic proton from O-8 to the relay molecule (see Fig. 2*b*) followed immediately by the transfer of the proton from the relay molecule to O-2. The first barrier (TS1) on all calculated potential surfaces corresponds to the second proton transfer step to O-2 (see Fig. 4). The first proton transfer causes the formation of a shoulder on the potential surface but no barrier can be associated with it. The intermediate is not clearly defined due to the shallow nature of the plateau region. The second barrier (TS2) involves the breaking of the O-2—C-7 bond and charge transfer to C-7 associated with the change of sp^3 to sp^2 hybridization of C-7. Subsequently the C-1—O-7 bond breaks to give **G**. This mechanism resembles the intuitive proposal of Bochkov et al. (26) except that their model has

an equivalent to **E′** with a covalent O-7—C-1 bond and no proton relay.

The first barrier is between 30 and 78 kJ mol^{-1}, the formyl being the lowest and the benzoyl the highest. The second barrier is between 40 and 92 kJ mol^{-1}, the pivaloyl being the lowest and the benzoyl the highest. The second barrier appears as a sharp peak in all potential surfaces except the pivaloyl (see Fig. 3). We found that the lack of the large peak at the second barrier in the case of the pivaloyl is due to a qualitatively different pathway. The difference is best understood by considering the difference in the conformation of the final ester product. Methyl pivalate is found in the preferred trans conformation, while all other esters were found in the undesirable cis conformation at the end of the reaction path (see Figs. 2*f* and 5). The steric repulsion of the bulky pivaloyl group prevented the rotation of the methyl group towards the cis orientation. For all other systems, the rotation of the methyl group is easier towards the cis position at the beginning of the reaction. Consequently, we consider the large second barrier an artifact of the conformational orientation. This clearly points to the need to improve the reaction path following method by enabling the

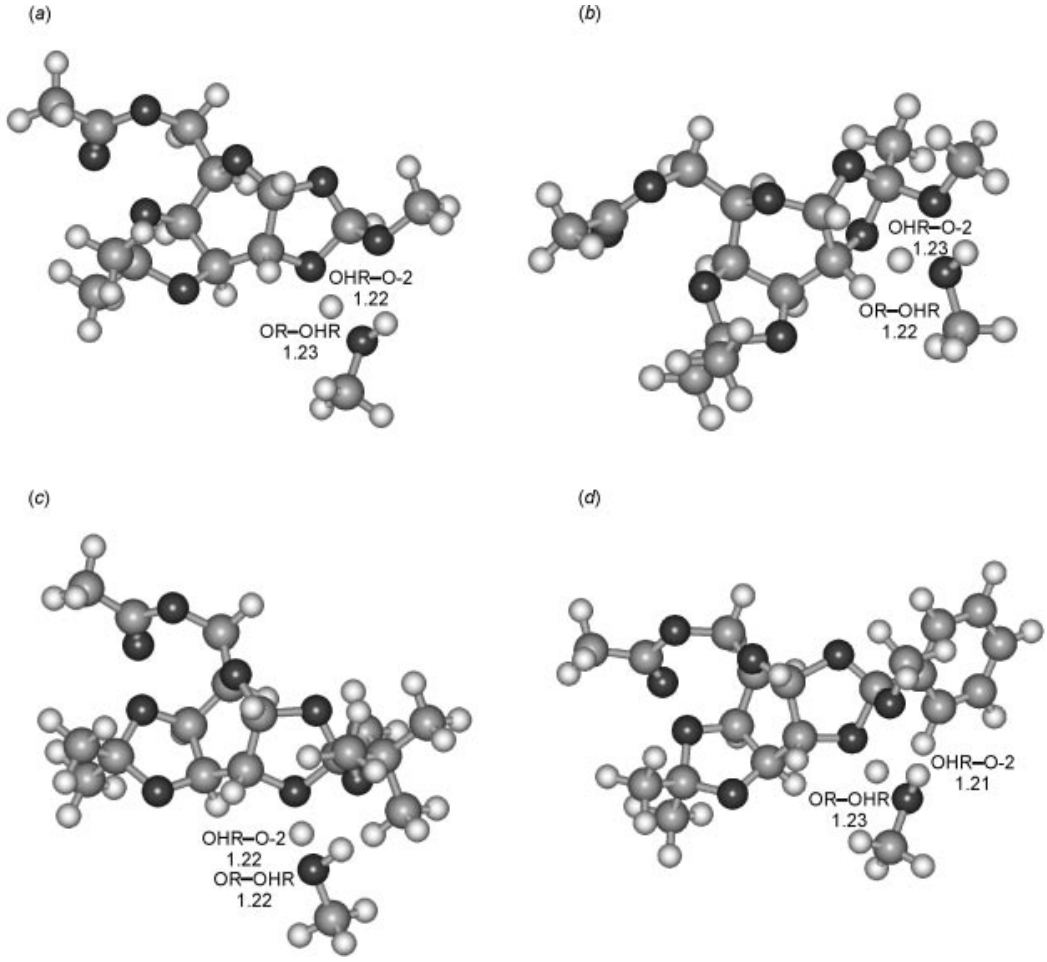
Fig. 3. Bond lengths (r_1–r_6) used for the constrained acyl transfer reaction plus C-1—O-7 and the relative energy vs. the constraint step. The acyl group is pivaloyl.

involvement of conformational as well as bond distance coordinates in the constraints. Such a development is for future studies.

Taking all these finding into consideration, the rate-determining barrier is the first barrier on the calculated reaction surface associated with proton transfer to O-2. The height of this barrier is 30, 40, 40, and 78 kJ mol^{-1} for formyl, acetyl, pivaloyl, and benzoyl, respectively. Some contribution from the undesirable conformation can be attributed to the first barrier in all cases except the pivaloyl. The largest difference between the cis and trans product was found in the case of benzoyl ester, which is 33.5 kJ mol^{-1}, while it is 10.7 and 18.3 in the case of formyl and acetyl (see Table 1). Considering the relative magnitudes of these undesirable contributions, our calculated barriers are consistent with the experimentally found order of propensity to acyl transfer.



From these four trajectories we can draw some important conclusions. The conformational reorganization is driven by the change in the hybridization of C-7, which goes from sp^3 to sp^2, and consequently from tetrahedral to a planar conformation. In addition to the conformational change leading to either cis or trans in the final ester product, the protecting groups also play a role in determining the conformation around the C-7—O-7 bond, which is crucial in the reaction mechanism (see Fig. 5). In this regard, the benzoyl stands out as different from the rest and especially different from pivaloyl. The flat benzoyl group can accommodate a conformation helping the C-7—O-2 bond breaking by simply rotating around the C-7—phenyl bond.

The above analysis suggested to us that in the benzoyl case 2,6-disubstitution may inhibit this rotation and hence acyl transfer. The DFT-calculated intermediates **B**–**E′** are shown in Table 1 and Fig. 1*e*. Like the parent benzoyl, the 2,6-dimethylbenzoyl **D** is predicted to be stable with a short C-1—O-7 bond length. Thus, we synthesized the 2,6-dimethylbenzoic acid analogue in the 3,4-isopropylidene series and tested its reactivity (see *Experimental* and Scheme 6). This derivative **17** synthesized from known diol **16** (27) exhibited no acyl transfer giving an almost quantitative yield of glycoside **18**. The structure of **18** was confirmed by cleaving from the polymer to give **19** (28). Furthermore, if less triflic acid was added (0.7 equiv. vs. 1.4 equiv.) then a mixture of orthoester **20** and **18** was obtained. The orthoester **20** in the mixture could be smoothly isomerized to **18** with more triflic acid without acyl transfer. To the best of our knowledge this is the first experimental result that uncouples orthoester formation and acyl transfer.

Orthoesters (29) have been previously suggested to be intermediates to glycosides and acyl transfers (30). The acid-catalyzed isomerization of **20** to **18** without acyl transfer strongly supports a mechanism for acyl transfer that does not involve neutral orthoesters. Note that our **D** ion–dipole complexes have long C-7—O-8 bond lengths (see Figs. 1*a*–1*f*), and must undergo three major changes to become neutral orthoesters: the O-8—C-7 bond must shorten, the pyranose ring conformation must change, and the alcoholic proton must be transferred. DFT calculations (not shown) of this process suggest that proton transfer is the last of these three steps. This uncoupling of orthoester formation and acyl

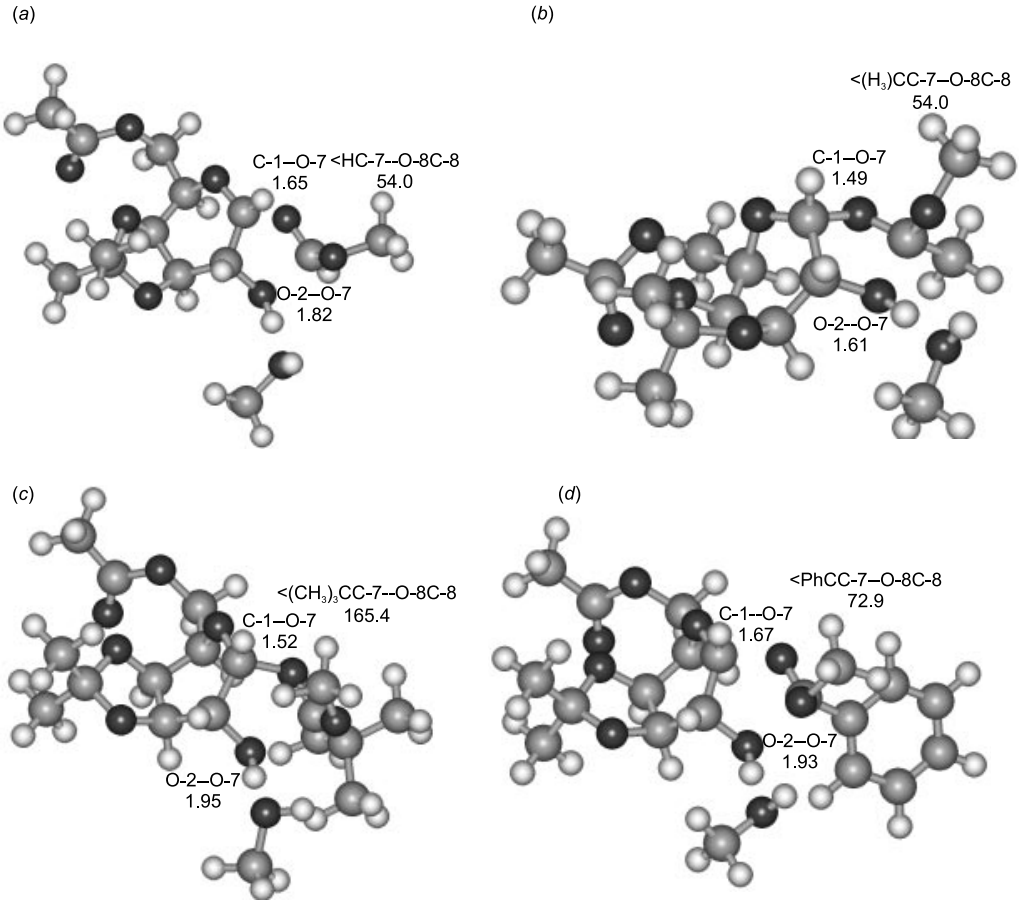
Fig. 4. Ball and stick representations of putative TS1: (*a*) formyl, (*b*) acetyl, (*c*) pivaloyl, (*d*) benzoyl.

transfer is in agreement with the ease of formation of pivaloyl orthoester (31) but their reluctance to undergo acyl transfer. What the mechanism is for proceeding from **D** to glycosides is not known (32). This is a subject of current research for us (33).



Our previous results had shown that even benzoate is difficult to cleave from polymer-supported Gal C-2 (10) and it is well-known that 2,6-dimethylbenzoyl esters are difficult to hydrolyse (34). Therefore, it was not surprising that under a variety of vigorous conditions (for example $LiAlH_4$ at reflux in THF, 1 mol/L KOHaq at 50 °C, etc.), we could not cleave the 2,6-dimethylbenzoate group from **18** without decomposition or recovery of intact **18**. Eventually we discovered that 1 mol/L LiOH in methanol at 70 °C for 48–60 h did cleave this group (see Scheme 7). This led us back to the results in Figs. 1*e* and 1*d* where the C-1—O-7 bond length (1.584 Å) in complex **D** of the 2,6-dimethylbenzoate is shorter than in **D** of the benzoate (1.607 Å). This suggested to us that the difference in this bond length may be at least in part a π-electronic effect. Therefore, we calculated the parameters for the more electron-donating 2,6-dimethoxybenzoate analogue, and the C-1—O-7 bond length (1.557 Å) is even shorter (see Fig. 1*f*). Subsequently, we synthesized this analogue **21** from **16** and reacted it with **1** (see Scheme 7). The reaction proceeded smoothly to give glycoside **22** contaminated with only a small amount of acyl transfer product **23** (**22**:**23**, 92%:8%). We had also envisaged that the 2,6-dimethoxy analogue would cleave easier than the 2,6-dimethyl one due to the possibility of chelation to the methoxy oxygens. The 2,6-dimethoxybenzoyl group is smoothly cleaved with 1 mol/L LiOH in methanol at 50 °C for 16 h to diol **24**. To improve the ease of removal, we are examining 2,6-dimethoxy-4-X-benzoyl esters, where X is an electron-withdrawing group. Thus, we have progressed from a calculated TS to a prototype of a protecting group that minimizes acyl transfer. Since the 3,4-isopropylidene galactose donors are the most prone to acyl transfer among those that we have studied, this new protecting group should be a general solution to acyl transfer.

Conclusions

Computational evidence is presented that ion–dipole complexes like **D** are formed under glycosylation reaction conditions. A pathway from **D** that most likely involves a proton relay from the nucleophile's proton to O-2 of the electrophilic sugar with accompanying formation of the O-8—O-7 bond, O-2—C-7 bond rupture, and finally O-7—C-1 bond breaking leads to an ion–dipole complex of a 2-OH glycosyl cation and the ester by-product **E′**. This order of bond forming and bond breaking was determined by computations using a complex constraint (see Scheme 5). In the model, the

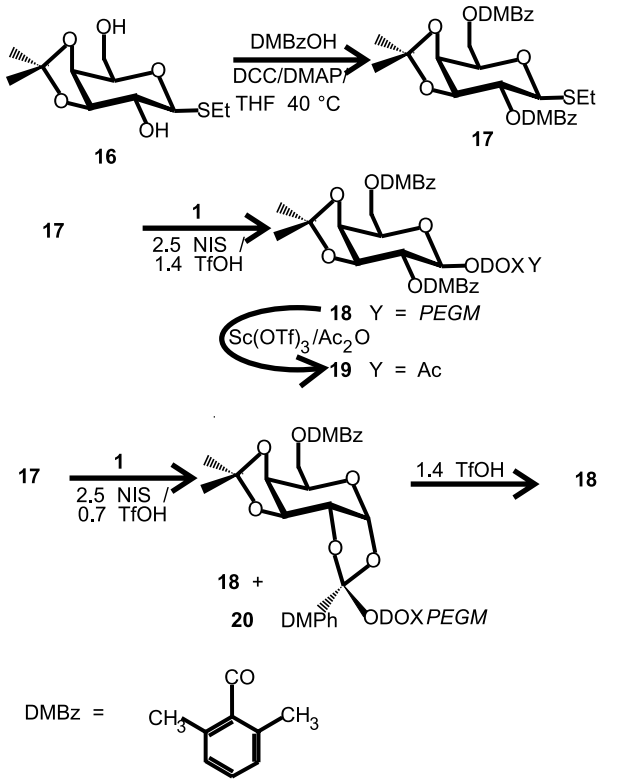
Fig. 5. Ball and stick representations of putative TS2: (*a*) formyl, (*b*) acetyl, (*c*) pivaloyl, (*d*) benzoyl.

ester is formed in the unfavorable cis conformation except the pivaloyl, which perhaps explains the strong sensitivity to steric bulk of the acyl transfer side reaction. The O-7—C-1 bond in the **D** complexes is the longest in the formyl case and the shortest in the pivaloyl case along the series formyl, acetyl, pivaloyl. It is even shorter in the benzoyl case even though benzoyl still transfers in some cases suggesting an electronic component besides a steric component to this side reaction. The steric effect led us to use the 2,6-dimethyl- and 2,6-dimethoxybenzoyl groups as neighboring groups, which eliminate or greatly minimize acyl transfer especially compared to benzoate where >50% of the reaction products were 1,2-linked oligomers under the same reaction conditions. The 2,6-dimethoxybenzoyl is easier to remove and its use is under investigation in other oligosaccharide syntheses. Orthoester formation with the 2,6-dimethylbenzoyl protecting group is facile but its rearrangement to glycoside is not accompanied by acyl transfer. Although these two side reactions are probably related, this result clearly shows that the two reactions are distinct. This separation of reaction mechanisms strongly suggests that acyl transfer can be eliminated by the judicious choice of protecting groups and reaction conditions like the ones described here.



Methods

All starting materials were dried overnight in vacuo at 10^{-3} mmHg (1 mmHg = 133.322 4 Pa). All reactions were done under argon. The progress of the reactions was monitored by thin layer chromatography (TLC) on silica gel. The TLC results were visualized under UV light (254 nm) and by spraying with 50% sulphuric acid in methanol and heating at 200 °C. The ^{1}H and ^{13}C NMR spectra were recorded in deuteriochloroform solution at 500.1 MHz and 125.8 MHz, respectively, with Varian Unity Plus spectrometers. For polymer-bound samples, the *MPEG* methylenes were saturated and quantitation was made by comparing integrals to the terminal methyl of the MPEG. Assignments were made by comparison to the spectra of building blocks and cleaved compounds. ^{1}H NMR spectra in $CDCl_3$ were referenced to residual $CHCl_3$ at 7.26 ppm, and ^{13}C NMR spectra to the central peak of $CDCl_3$ at 77.0 ppm. Assignments were made by standard ^{1}H^{-1}H-COSY and ^{13}C-^{1}H-COSY experiments. The mass spectral analysis was done on a forward mass spectrometer. Fast atom bombardment (FAB) MS was performed using xenon atom at 6 kV as the source. Thioglycerol or a mixture of glycerol and thioglycerol was used as FAB matrix. Typically, 10–15 full-range, low-resolution MS scans were averaged to yield a low-resolution mass spectrum. For high-resolution MS, the electric sector was scanned over the range of interest. Typically, polyethylene glycol or polypropylene glycol was used as an internal mass standard and between 75 and 150 scans were averaged. Some MS were done by ion spray with a PerkinElmer/Sciex API triple quadrupole mass spectrometer.

were obtained by acylating the polymer i.e., either formyl, acetyl, or benzoyl. The ^{1}H NMR spectrum of MPEGDOX-*O*-formyl shows that the CHO-O-CH_2-C_6H_4-CH_2-$(OCH_2CH_2)_nOCH_3$ peak is shifted to 5.19 ppm from 4.68 ppm in MPEGDOXOH. This same peak appears at 5.09, 5.05, 5.10, 5.35, and 5.34 ppm in the acetylated (**12a**), pivaloylated (**15d**), levulinoylated (**15e**), benzoylated (**3**), and 2,6-dimethoxybenzoylated (**23**), MPEGDOXOH, respectively.

Computational details

The Amsterdam density functional (ADF) calculations use the methods described in ref. 3 and include a continuum dielectric solvent term. The basis set used was a double ζ basis set with a single polarization function. The conformational description based on the IUPAC nomenclature is described in detail in ref. 35. A fully working version of the program is available at http://www.sao.nrc.ca/ibs/6ring.html.

To enable the exploration of the reaction pathways we incorporated some changes in the ADF program. ADF enables the user to follow the reaction pathway by slowly varying a constrained coordinate from the value representative of the reactant state to the product state with geometry optimization subject to this constraint at given values of the constraint. This procedure is called a linear transit calculation. The original implementation of linear transit allows only individual internal coordinates such as bond length, bending angles, and torsion angles to be defined as a constraint. However, it is not possible to define linear combinations of individual internal coordinates, which is desirable for complicated reaction profiles such as acyl transfer. To facilitate the exploration we extended the definition of constraint by implementing a general constraint of the following form:

$$Q = l_1{*}q_1 + l_2{*}q_2 \ \ldots \ + l_nq_n$$

where q can be any bond length, bending angle, or torsion angle.

The coordinates are kept constant in the geometry optimization by simply projecting out the contribution of the Cartesian forces to the force on the constrained coordinate followed by a Cartesian geometry optimization step. After the Cartesian optimization step, the constraints are exactly imposed by an iterative correction of the coordinates (36).

MPEGDOXOH (**1**) was synthesized according to ref. 37. The synthesis of donors **13a**–**13e** is described in the *Supplementary material*.[5]

MPEGDOXyl 2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranoside 11a (38)

Experiment I (using α-imidate)

A solution of TESOTf in CH_2Cl_2 (2.0 µL, 8.8 µmol) was added to a solution of 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl trichloroacetimidate (39) (**8a**) (27 mg, 55 µmol) and **1** (57 mg, 27 µmol) in dry CH_2Cl_2 (2 mL) at room temperature. After 1 h of stirring, TLC (hexanes : ethyl acetate, 2:1, 2% diisopropylethylamine (DIPEA)) indicated complete disappearance of the starting imidate. The reaction was stopped 3 h after the addition of TESOTf by addition of

© 2004 NRC Canada

$NaHCO_3$ (and stirring for ~10 min), filtered, and the volume was reduced to ~0.5 mL. Dry *tert*-butylmethylether (TBME) (30 mL) was then added and the polymer was precipitated at 4 °C overnight. The polymer (64 mg) was then isolated by filtration. The ^{1}H NMR spectrum indicates that 40% yield of the β-glycosylated product **11a** and 63% yield of acyl transfer product **12a** were obtained. ^{1}H NMR (ppm) δ: 5.39 (dd, 1H, $J_{3,4}$ = 3.4 Hz, $J_{4,5}$ = 1.0 Hz, H-4), 5.27 (dd, 1H, $J_{1,2}$ = 8.1 Hz, $J_{2,3}$ = 10.5 Hz, H-2), 4.98 (dd, 1H, H-3), 4.51 (d, 1H, H-1), 4.21 (dd, 1H, $J_{5,6}$ = 6.4 Hz, $J_{6,6'}$ = 11.3 Hz, H-6), 4.16 (dd, 1H, $J_{5,6'}$ = 6.8 Hz, H-6′), 3.89 (m, 1H, H-5), 2.16 (s, 3H, CH_3CO), 2.07 (s, 3H, CH_3COO), 2.02 (s, 3H, CH_3CO), 1.98 (s, 3H, CH_3CO).

Experiment II (using β-imidate)

TESOTf (3.9 μL, 17 μmol) was added to a solution of 2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl trichloroacetimidate **9a** (43 mg, 87 μmol) and **1** (92 mg, 43 μmol) and were reacted as above to yield 33% of the β-glycosylated product **11a** and 67% of acyl transfer product **12a**.

MPEGDOXyl 2,3,4,6-tetra-*O*-benzoyl-β-D-galactopyranoside (11b)

2,3,4,6-Tetra-*O*-benzoyl-β-D-galactopyranosyl trichloroacetimidate (39) (**10b**) (40 mg, 54 μmol) and **1** (57 mg, 27 μmol) were reacted as for **11a** to yield 93% of the β-glycosylated product **11b** and 7% of acyl transfer product **3**. ^{1}H NMR (ppm) δ: 8.10 (d, 2H, J = 7.5 Hz, Bz_o), 8.05 (d, 2H, J = 7.5 Hz, Bz_o), 7.92 (d, 2H, J = 7.7 Hz, Bz_p), 7.78 (d, 2H, J = 7.7 Hz, Bz_p), 5.98 (d, 1H, $J_{3,4}$ = 3.0 Hz, H-4), 5.86 (dd, 1H, $J_{1,2}$ = 8.1 Hz, $J_{2,3}$ = 10.1 Hz, H-2), 5.54 (dd, 1H, H-3), 4.29 (m, 1H, H-5).

MPEGDOXyl 3,4,6-tri-*O*-benzyl-2-*O*-formyl-β-D-galactopyranoside (14a)

TESOTf (12 μL, 53 μmol) was added to a solution of compound **13a** (0.169 g, 0.271 μmol) and **1** (0.275 g, 0.130 μmol) in dry CH_2Cl_2 (3 mL). After 3 h of stirring at room temperature, TLC (hexanes : ethyl acetate, 3:1) indicated absence of the imidate. The reaction was stopped by the addition of 2 drops of DIPEA and the volume was reduced to ~0.5 mL. Dry TBME (50 mL) was added and the polymer was allowed to precipitate at 4 °C overnight. The polymer (0.278 g) was then isolated by filtration. The ^{1}H NMR spectrum indicated that ~25% yield of the β-glycosylated product **14a**, ~4% yield of the orthoester, and 56% yield of acyl transfer product **15a** were obtained. **14a**: ^{1}H NMR (ppm) δ: 8.14 (s, 1H, HCOO), 5.10 (dd, 1H, $J_{1,2}$ = 8.3 Hz, $J_{2,3}$ = 9.0 Hz, H-2), 3.96 (d, 1H, $J_{3,4}$ = 2.4 Hz, H-4).

MPEGDOXyl 2-*O*-acetyl-3,4,6-tri-*O*-benzyl-β-D-galactopyranoside (14b)

Compound **13b** (27 mg, 42 μmol) was treated as for **14a**. The ^{1}H NMR spectrum indicated that 64% yield of the β-glycosylated product **14b**, 13% yield of the orthoester, and 5% yield of acyl transfer product **15b** were obtained. **14b**: ^{1}H NMR (ppm) δ: 7.36–7.22 (m, aromatic), 5.43 (dd, 1H, $J_{1,2}$ = 7.9 Hz, $J_{2,3}$ = 10.0 Hz, H-2), 4.37 (d, 1H, H-1), 3.94 (m, 1H, H-4), 1.99 (s, 3H, CH_3CO).

MPEGDOXyl 2-*O*-benzoyl-3,4,6-tri-*O*-benzyl-β-D-galactopyranoside (14c)

Compound **13c** (47 mg, 67 μmol) was treated as for **14a**. The ^{1}H NMR spectrum indicated that 66% yield of the β-glycosylated product **14c**, 11% yield of the orthoester, and no detectable acyl transfer product were obtained. **14c**: ^{1}H NMR (ppm) δ: 7.98–7.96 (m, 2H, Bz_o), 7.59 (m, 1H, Bz_o), 7.47–7.43 (m, 2H, Bz_p), 5.71 (dd, 1H, $J_{2,1}$ = 8.0 Hz, $J_{2,3}$ = 9.8 Hz, H-2), 4.00 (m, 1H, H-4). Orthoester: 5.25 (d, 1H, H-1).

MPEGDOXyl 3,4,6-tri-*O*-benzyl-2-*O*-pivaloyl-β-D-galactopyranoside (14d)

Compound **13d** (17 mg, 25 μmol) was treated as for **14a**. The ^{1}H NMR spectrum indicated that 47% yield of the β-glycosylated product **14d**, 14% yield of the orthoester, and no detectable acyl transfer product were obtained. **14d**: ^{1}H NMR (ppm) δ: 5.49 (dd, 1H, $J_{2,1}$ = 7.9 Hz, $J_{2,3}$ = 10.0 Hz, H-2), 4.42 (d, 1H, H-1), 3.94 (m, 1H, H-4).

MPEGDOXyl 3,4,6-tri-*O*-benzyl-2-*O*-levulinoyl-β-D-galactopyranoside (14e)

Compound **13e** (23 mg, 33 μmol) was treated as for **14a**. The ^{1}H NMR spectrum indicated that 49% yield of the β-glycosylated product **14e**, 7% yield of the orthoester, and 2% yield of acyl transfer product **15e** were obtained. **14e**: ^{1}H NMR (ppm) δ: 5.42 (dd, 1H, $J_{2,1}$ = 7.9 Hz, $J_{2,3}$ = 10.0 Hz, H-2), 3.93 (m, 1H, H-4), 2.71–2.66 (m, 2H, CH_2 Lev), 2.53–2.49 (m, 2H, CH_2 Lev).

Ethyl 2,6-di-*O*-(2,6-dimethylbenzoyl)-3,4-*O*-isopropylidene-1-thio-β-D-galactopyranoside (17)

2,6-Diol (27, 40) (**16**) (1.5 g, 5.71 mmol) was dissolved in THF (30 mL) and 2,6-dimethylbenzoic acid (3.43 g, 4 equiv.), dicyclohexylcarbodiimide (5.3 g, 4.5 equiv.), and DMAP (50 mg) were added. After stirring at room temperature (RT) for 1 day, the mixture was heated to 40 °C and the temperature maintained for 1 week. Each day, further aliquots of DCC (0.5 equiv.) and DMAP (50 mg) were added until the starting material disappeared. After filtration and concentration, the residue was purified by MPLC eluting with hexanes : ethyl acetate : dichloromethane (8:1:1) to yield slightly impure material, which was recrystallized from ethanol:water about 1:1 to form colorless needles of **17** (750 mg, 25%); mp 159 to 160 °C. $[\alpha]_D$ = 35.5 (*c* 0.84, $CHCl_3$). ^{1}H NMR (ppm) δ: 7.22 (m, 2H, Bz), 7.06 (m, 4H, Bz), 5.37 (brt, 1H, H-2), 4.65 (m, 2H, H-6ab), 4.45 (d, 1H, $J_{1,2}$ = 10.3 Hz, H-1), 4.31 (m, 2H, H-3, H-4), 4.17 (t, 1H, $J_{4,5+5,6}$ = 12.2 Hz, H-5), 2.78 (m, 2H, CH_3CH_2S), 2.43, 2.37 (2s, 12H, $ArCH_3$), 1.66, 1.39 (2s, 6H, $O_2C(CH_3)_2$), 1.28 (t, 3H, J = 7.3 Hz, CH_3CH_2S). ^{13}C NMR (ppm) δ: 169.6, 168.6 (2*C*OAr), 135.3, 135.1 ($2Bz_{ip}$), 133.4 ($2Bz_o$), 129.5, 129.4 ($2Bz_p$), 127.5, 127.5 ($2Bz_m$), 110.8 ($O_2C(CH_3)_2$), 82.2 (C-1),

MPEGDOXyl 2,6-di-*O*-(2,6-dimethylbenzoyl)-3,4-*O*-isopropylidene-β-D-galactopyranoside (18)

Method 1

Donor **17** (77 mg, 0.15 mmol), **1** (512 mg, 0.1 mmol), and activated 4 Å molecular sieves (about 300 mg) were dried together overnight at high vacuum. Dichloromethane (3 mL) was added and the mixture cooled in an ice–salt bath. After stirring for 0.5 h, NIS (112 mg, 0.5 mmol) was added followed by TfOH (12 μL, 0.14 mmol). After stirring for 30 min, the reaction was quenched with DIPEA (50 μL) and the polymer precipitated with TBME (40 mL). The solid was recovered by filtration and after rinsing with TBME was reprecipitated from absolute ethanol (25 mL). The resulting solid was collected by filtration and after washing with cold ethanol and diethyl ether was taken up in CH_2Cl_2, filtered, and evaporated to yield **18** (490 mg, 88%). Partial ^{1}H NMR (ppm) δ: 7.31 (m, 4H, Ar*H*-DOX), 7.24 (t, 1H, *J* = 7.8 Hz, Bz_p), 7.20 (t, 1H, *J* = 7.8 Hz, Bz_p), 7.08 (d, 2H, *J* = 7.8 Hz, Bz_m), 7.03 (d, 2H, *J* = 7.8 Hz, Bz_m), 5.37 (brt, 1H, H-2), 4.95 (d, 1H, *J* = 11.7 Hz, C*H*HC$_6$H$_4$-DOX), 4.70 (m, 1H, H-6a), 4.65 (m, 1H, H-6b), 4.58 (d, 1H, *J* = 11.7 Hz, CH*H*C$_6$H$_4$-DOX), 4.56 (s, 2H, CH_2C$_6$H$_4$-DOX), 4.54 (d, 1H, $J_{1,2}$ = 7.8 Hz, H-1), 4.29 (m, 2H, H-3, H-4), 4.17 (t, 1H, $J_{4,5+5,6}$ = 9.8 Hz, H-5), 2.39, 2.29 (2s, 12H, ArCH_3), 1.68, 1.40 (2s, 6H, $O_2C(CH_3)_2$).

Method 2

Orthoester **20** was treated as for **18** above except no NIS, extra donor, or **1** were added.

6-*O*-(2,6-Dimethylbenzoyl)-3,4-*O*-isopropylidene-β-D-galactopyranosyl-1,2-*O*-MPEGDOXyl-*ortho*-(2,6-dimethylbenzoate) (20)

Orthoester **20** was prepared as for **18** except 0.7 equiv. of TfOH was used. Partial ^{1}H NMR (ppm) δ: 5.80 (d, 1H, $J_{1,2}$ = 4.9 Hz, H-1), 4.38 (m, 1H, H-2), 1.68, 1.40 (2s, 6H, $O_2C(CH_3)_2$).

[4-*O*-Acetoxymethyl]benzyl 2,6-di-*O*-(2,6-dimethylbenzoyl)-3,4-*O*-isopropylidene(-β-D-galactopyranoside (19)

Compound **18** (480 mg, 0.087 mmol) was dissolved in CH_2Cl_2 (2.0 mL) and Ac_2O (2.0 mL) under an atmosphere of argon at RT. To this solution was added $Sc(OTf)_3$ (25 mg, 0.02 mmol) and the stirring continued for 4 h. After cooling with an ice bath, the polymer was precipitated with TBME (60 mL) and collected by filtration. The filtrate was evaporated. The solid was reprecipitated from ethanol (40 mL) and collected by filtration. The filtrate was combined with the residue from TBME and evaporated. The residue was purified by preparative TLC eluting with hexanes : ethyl acetate (80:20) to yield a viscous oil **19** (12 mg, 22% assuming 100% yields for all polymer steps including linker attachment). $[\alpha]_D$ –75.0 (*c*, 0.06, $CHCl_3$). ^{1}H NMR (ppm) δ: 7.27 (q_{AB}, 4H, *J* = 8.1 Hz, Ar*H*-DOX), 7.22 (t, 1H, *J* = 7.3 Hz, *J* = 8.0 Hz, Bz_p), 7.18 (t, 1H, *J* = 7.3, *J* = 8.0 Hz, Bz_p), 7.06 (d, 2H, *J* = 8.0 Hz, Bz_m), 7.01 (d, 2H, *J* = 7.3 Hz, Bz_m), 5.39 (brt, 1H, H-2), 5.08 (s, 2H, CH_2C$_6$H$_4$-DOX), 4.94 (d, 1H, *J* = 11.7 Hz, C*H*HC$_6$H$_4$-DOX), 4.67 (m, 2H, H-6ab), 4.57 (d, 1H, *J* = 11.7 Hz, CH*H*C$_6$H$_4$-DOX), 4.52 (d, 1H, $J_{1,2}$ = 8.8 Hz, H-1), 4.28 (m, 2H, H-3, H-4), 4.15 (t, 1H, $J_{4,5+5,6}$ = 10.2 Hz, H-5), 2.36, 2.26 (2s, 12H, ArCH_3), 2.11 (s, 3H, COCH_3), 1.66, 1.38 (2s, 6H, $O_2C(CH_3)_2$). ^{13}C NMR (ppm) δ: 170.8 (*C*OCH$_3$), 169.6, 168.4 (2*C*OAr), 136.7, 135.5 ($2CH_2$-*C*Ar-DOX), 135.0, 135.1 ($2Bz_{ip}$), 133.6, 133.3 ($2Bz_o$), 129.6, 129.3 ($2Bz_p$), 128.2, 128.1 (*C*HAr-DOX), 127.6, 127.4 ($2Bz_m$), 110.9 ($O_2C(CH_3)_2$), 99.0 (C-1), 77.2 (C-3), 73.8 (C-4), 73.0 (C-2), 71.1 (C-5), 70.1 (CH_2C$_6$H$_4$), 66.0 (CH_2C$_6$H$_4$-DOX), 64.1 (C-6), 27.7, 26.6, ($2O_2C(CH_3)_2$), 21.0 (CO*C*H$_3$), 19.8, 19.6 ($2ArCH_3$). FAB-MS: +ve 669 (M + Na^+), 467 (M – DOX^+), 133 (DiMeBz$^+$). HR-MS calcd. for $C_{37}H_{42}O_{10}Na$: 669.2676; found: 669.2715.

Ethyl 2,6-di-*O*-(2,6-dimethoxylbenzoyl)-3,4-*O*-isopropylidene-1-thio-β-D-galactopyranoside (21)

Diester **21** was made from diol **16** as for **17** (750 mg, 25%). $[\alpha]_D$ = 18.2 (*c* 0.2, $CHCl_3$). ^{1}H NMR (ppm) δ: 7.27 (m, 2H, Bz), 6.53 (m, 4H, Bz), 5.34 (brt, 1H, *J* = 6 Hz, H-2), 4.73 (d, 1H, $J_{1,2}$ = 7.0 Hz, H-1), 4.57 (m, 2H, H-6ab), 4.41 (brt, 1H, *J* = 5.7 Hz, H-3), 4.31 (brd, 1H, $J_{3,4}$ = 4.5 Hz, H-4), 4.14 (t, 1H, $J_{4,5+5,6}$ = 12.2 Hz, H-5), 3.80, 3.76 (2s, 12H, ArOCH_3), 2.76 (m, 2H, CH_3CH_2S), 1.61, 1.39 (2s, 6H, $O_2C(CH_3)_2$), 1.27 (t, 3H, *J* = 7.3 Hz, CH_3CH_2S). ^{13}C NMR (ppm) δ:, 166.2, 164.7 (2*C*OAr), 157.6, 157.2 ($2Bz_o$), 131.3, 131.0 ($2Bz_p$), 112.8, 112.2 ($2Bz_{ip}$), 110.5 ($O_2C(CH_3)_2$), 103.9, 103.8 ($2Bz_m$), 82.6 (C-1), 75.6 (C-3), 73.2 (C-5), 72.8 (C-4), 72.3 (C-2), 64.0 (C-6), 56.0, 55.9 ($2ArOCH_3$), 27.8, 26.6 ($2O_2C(CH_3)_2$), 23.7 (CH_3CH_2S), 14.8 (CH_3CH_2S). FAB- MS calcd. for $C_{29}H_{36}O_{11}S$: 592; found *m/z*: 615.2 (M + Na^+), 531.2 (M – SEt^+), 165 (DiMeOBz$^+$). HR-MS calcd. for $C_{29}H_{36}O_{11}S$: 592.2115; found: 592.2128.

MPEGDOXyl 2,6-di-*O*-(2,6-dimethoxylbenzoyl-3,4-*O*-isopropylidene-β-D-galactopyranoside (22)

Donor **21** was reacted with **1** as for **18** to yield **22** and **23**. **22**: partial ^{1}H NMR (ppm) δ: 7.32 (m, 2H, Bz), 7.30 (d, 2H, *J* = 8.1 Hz, Ar*H*-DOX), 7.22 (d, 2H, *J* = 8.1 Hz, Ar*H*-DOX), 6.54 (m, 4H, Bz), 5.27 (brt, 1H, *J* = 6.1 Hz, H-2), 4.93 (d, 1H, *J* = 12.0 Hz, C*H*H-DOX), 4.38 (brt, 1H, H-3), 4.30 (dd, 1H, $J_{3,4}$ = 5.8 Hz, $J_{4,5}$ = 1.9 Hz, H-4), 4.11 (brt, 1H, *J* = 4.4 Hz, H-5), 1.60, 1.36 (2s, 6H, $O_2C(CH_3)_2$).

MPEGDOXyl 3,4-*O*-isopropylidene-β-D-galactopyranoside (24)

Diester **22** (98 mg, 0.017 mmol) was dissolved in 1 mol/L LiOH in methanol (2 mL) and heated at 50 °C for 16 h un-

Studies on the two-photon absorption properties of trigonal dehydrobenzo[18]annulenes

Xin Zhou, Ai-Min Ren, Ji-Kang Feng, and Xiao-Juan Liu

Abstract: The one-photon and two-photon absorption properties of donor–acceptor substituted dehydrobenzo[18]annulenes were determined by using density functional theory and ZINDO methods. The macrocycle containing C_{2v} symmetry exhibited the largest TPA cross-section value of 3376×10^{-50} cm^4 s/photon. The calculated results indicate that the TPA response in the whole molecule comes from the contribution of that in the every side in the trigon. It is notable that the magnitudes of the transition dipole moment from the virtual intermediate state to the TPA final state and the dipole moment difference between the ground state and the virtual intermediate state play important roles in increasing the TPA cross-section value. This series of molecules can circumvent the trade-off between efficiency and transparency, and they provide a promising direction for the further development of novel two-dimensional molecules with such properties.

Key words: two-photon absorption, ZINDO, sum-over-states, dehydrobenzo[18] annulenes, transparency.

Résumé : Faisant appel à la théorie de la densité fonctionnelle ainsi qu'à des méthodes ZINDO, on a déterminé les propriétés d'absorption monophotonique et biphotonique de déhydrobenzo[18]annulènes substitués, des donneurs–accepteurs. Le macrocycle comportant une symétrie C_{2v} exhibe la valeur la plus élevée de section droite de « TPA », 3376×10^{-50} cm^4 s/photon. Les résultats calculés indiquent que la réponse de TPA dans une molécule complète provient de la contribution de ce qu'on retrouve dans l'aire trigonale. Il est à noter que les amplitudes de la transition du moment dipolaire de l'état intermédiaire virtuel à l'état final de TPA ainsi que la différence de moment dipolaire entre l'état fondamental et l'état intermédiaire virtuel jouent des rôles importants dans l'augmentation de la valeur de la section droite de la TPA. Les molécules de cette série permettent de contourner le compromis entre l'efficacité et la transparence et elles s'avèrent être une direction de choix pour le développement ultérieur de nouvelles molécules bidimensionnelles ayant de telles propriétés.

Mots clés : absorption biphotonique, ZINDO, somme sur l'ensemble des états, déhydrobenzo[18]annulènes, transparence.

[Traduit par la Rédaction]

Introduction

Organic molecular two-photon absorption (TPA) has attracted increasing attention because of a variety of applications in many areas such as three-dimensional microfabrication (1–3), ultra-high-density optical data storage (4), biological imaging (5), the controlled release of biologically relevant species (6), immunoassays (7), and photodynamic cancer therapy (8). For these applications, the magnitude of the TPA cross section is crucially important. To prepare organic material with large TPA cross sections, researchers are examining various design strategies. Numerous compounds including donor–bridge–acceptor (D–π–A) dipoles (9, 10), donor–bridge–donor (D–π–D) quadrupoles (11–13), octupoles (14–16), multibranched compounds (17–19), and dendrimers (20, 21) have been synthesized and their structure–property relationships established. The studied results indicate that increasing donor and acceptor strength, extending the conjugated length and the molecular dimensionality, and changing the character of the conjugated bridge are in favor of enhancing the magnitude of the molecular TPA cross section. Recently, many groups paid attention to the nonlinear optical (NLO) properties of the octupolar molecules. Compared with the typical NLO chromophores, which are one-dimensional, conjugated π-systems with donor (D) and acceptor (A) moieties as terminal substituents, the transparency as well as efficiency of adequately tailored octupolar molecules are expected in different instances to significantly improve. The octupolar systems without permanent dipole moments would be less prone to reorientational relaxation, which is the detrimental factor for the dipolar molecules favoring undesired antiparallel pairing.

Here, we will study a series of novel two-dimensional molecules — dehydrobenzo [18]annulenes, which have been shown to be useful precursors for a variety of carbon-rich polymeric systems such as ladder polymers (22), molecular tubes (23), and novel allotropes of carbon (24, 25). Haley

and co-workers (26, 27) developed a straightforward synthetic scheme to easily tune the substitution pattern of the dehydrobenzo[18]annulene chromophore for maximum NLO behavior. In addition, the macrocycle is locked into a planar conformation, which increases the overall π conjugation, and thus should result in better NLO efficiency. In this paper, we theoretically investigated the one-photon absorption (OPA) and TPA properties of dehydrobenzo[18]annulenes, and analyzed the micromechanism of the increase in the molecular TPA cross-section value.

Theoretical methodology

The TPA process corresponds to simultaneous absorption of two photons. The TPA efficiency of an organic molecule, at optical frequency $\omega/2\pi$, can be characterized by the TPA cross-section $\delta(\omega)$. It can be directly related to the imaginary part of the second hyperpolarizability $\gamma(-\omega; \omega, \omega, -\omega)$ by (11):

$$[1] \qquad \delta(\omega) = \frac{8\pi^2\hbar\omega^2}{n^2c^2} L^4 Im\, \gamma(-\omega;\omega,\omega,-\omega)$$

where $\hbar$ is Planck's constant divided by 2π, n is the refractive index of medium, c is the speed of light, and L is a local field factor (equal to 1 for vacuum).

The sum-over-states (SOS) expression to evaluate the components of the second hyperpolarizability γ_{ijkl} can be induced out using perturbation theory and density matrix method. By considering a power expansion of the energy with respect to the applied field, the γ_{ijkl} Cartesian components are given by (28, 29):

$$[2] \qquad \gamma_{ijkl}(-\omega_\sigma;\omega_1,\omega_2,\omega_3) = \frac{4\pi^3}{3h^3} P(i,j,k,l;-\omega_\sigma;\omega_1,\omega_2,\omega_3)$$
$$\left[\sum_{m\neq o}\sum_{n\neq o}\sum_{p\neq o} \frac{\langle o|\mu_i|m\rangle\langle m|\bar{\mu}_j|n\rangle\langle n|\bar{\mu}_k|p\rangle\langle p|\mu_l|o\rangle}{(\omega_{mo}-\omega_\sigma-i\Gamma_{mo})(\omega_{no}-\omega_2-\omega_3-i\Gamma_{no})(\omega_{po}-\omega_3-i\Gamma_{po})} \right.$$
$$\left. - \sum_{m\neq o}\sum_{n\neq o} \frac{\langle o|\mu_i|m\rangle\langle m|\mu_j|o\rangle\langle o|\mu_k|n\rangle\langle n|\mu_l|o\rangle}{(\omega_{mo}-\omega_\sigma-i\Gamma_{mo})(\omega_{no}-\omega_3-i\Gamma_{no})(\omega_{no}+\omega_2-i\Gamma_{no})} \right]$$

where P(i,j,k,l; $-\omega_\sigma$ ω_1, ω_2, ω_3) is a permutation operator defined in such a way that for any permutation of (i,j,k,l), an equivalent permutation of ($-\omega_\sigma$; ω_1, ω_2, ω_3) is made simultaneously; $\omega_\sigma = \omega_1 + \omega_2 + \omega_3$ is the polarization response frequency; ω_1, ω_2, ω_3 indicate the frequencies of the perturbing radiation fields (considering the degenerate TPA, $\omega_1 = \omega_2 = \omega$ and $\omega_3 = -\omega$); i, j, k, and l correspond to the molecular axes x, y, and z; m, n, and p denote excited states, and o, the ground state; μ_j is the j(= x, y, z)th component of the dipole operator; ($\langle m|\vec{\mu}_j|n\rangle = \langle m|\mu_j|n\rangle - \langle o|\mu_j|o\rangle$); $(h/2\pi)\omega_{mo}$ is the transition energy between the m and o states and Γ_{mo} is the damping factor of excited state m. Considering the higher the excited state is and the shorter its lifetime is, the Γ_{mo} is expressed as follows (29):

$$[3] \qquad \Gamma_{mo} = 0.08 \times \frac{\omega_{mo}}{\omega_{1o}}$$

To compare the calculated $\delta(\omega)$ value with the experimental value measured in solution, the orientationally averaged (isotropic) value of γ is evaluated, which is defined as

$$[4] \qquad \langle\gamma\rangle = \frac{1}{15}\sum_{i,j}(\gamma_{iijj} + \gamma_{ijij} + \gamma_{ijji}) \qquad i,j = x,y,z$$

Whereafter, $\langle\gamma\rangle$ is taken into eq. [1], and then the TPA cross section $\delta(\omega)$ is obtained.

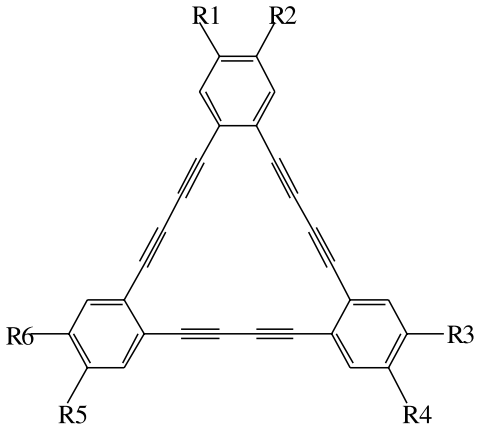
Generally, the position and relative strength of the two-photon resonance are predicted using the following simplified form of the SOS expression (30):

$$[5] \qquad \delta \propto \frac{M_{0k}^2 (M_{kn}^2 + \Delta\mu_k^2)}{(E_{0k} - E_{0n}/2)^2\Gamma}$$

where M_{ij} is the transition dipole moment from the state i to j; E_{ij} is the corresponding excitation energy, the subscripts 0, k, and n refer to the ground state S_0, the intermediate state S_k, and the TPA final state S_n, respectively; $\Delta\mu_k$ is the dipole moment difference between S_0 and S_k, which is neglected in molecules having central symmetry. So for molecules with a center of inversion symmetry, eq. [5] becomes the following formula (11):

$$[6] \qquad \delta \propto \frac{M_{0k}^2 M_{kn}^2}{(E_{0k} - E_{0n}/2)^2\Gamma}$$

In principle, any kind of self-consistent field molecular orbital procedure combined with configuration interaction can be used to calculate the physical values in the above expression. In the present paper, the B3LYP/6-31g method was firstly used to calculate molecular equilibrium geometry. Then, the property of the electronic excited state was obtained by 196 single-electron excitation and 54 double-electron excitation configuration interactions using the ZINDO program. Furthermore, UV–vis (ground-state, one-photon absorption) spectra, which were needed to predict TPA, were provided. Then according to eqs. [1]–[4], the second hyperpolarizability (γ) and TPA cross section $\delta(\omega)$ were calculated.



Results and discussions

Geometry optimization and electronic structure

The molecular structures were chosen according to Fig. 1

D6	NO_2	H	OMe	OMe	H	NO_2
D7	NO_2	H	$N(Me)_2$	$N(Me)_2$	H	NO_2

with systematic donor–acceptor substitutions — in terms of donor dimethylamino ($N(Me)_2$) and oxymethyl (OMe), and acceptor nitro (NO_2) groups — on a hydrocarbon backbone. The basic building block is dehydrobenzo[18]annulene denoted by D1, which is nonsubstituted with R_i = H and possesses D_{3h} point group symmetry. When R1 and R2 are replaced by NO_2 and $N(Me)_2$, respectively, the D2 is formed, whose symmetry is reduced into C_s.

In the same way, because of the unsymmetric substituent of one pair of the donor–acceptor, the molecules D3 and D4 have C_s point group symmetry. The intention of designing D2, D3, and D4 was to study the effect of the different positions of donor or acceptor on the OPA and TPA properties. As far as the D5 compound is concerned, unsymmetric substitutions of two pairs of the donor–acceptor allow the molecule to retain C_s symmetry. To investigate the contribution of the increase of the donor strength to the OPA and TPA properties, we designed the chromophores D6 and D7, whose point group symmetry becomes C_{2v} owing to symmetric positions of two $N(Me)_2$ or OMe and two NO_2 groups. We select some bond lengths and bond angles of molecule D4 and the experimental results are given in parentheses (shown in Fig. 2). In the theoretical calculations, butyl groups in the experiment were replaced by methyl groups. The optimized geometries show that the macrocycle in all molecules are locked into a planar conformation, which is in accordance with the experimental result and are in favor of the intramolecular charge transfer.

One-photon absorption

Table 1 collects the calculated and experimental (given in parentheses) wavelengths ($\lambda^{(1)}$), oscillator strengths (f), and the nature of the transition for the maximum OPA of every compound. From Table 1, one can see that the results we calculated are in good agreement with the experimental values. The substitution of one pair of donor–acceptor in D2 makes $\lambda_{max}^{(1)}$ red-shifted by 2.4 nm on the basis of that of D1 (354.4 nm). The enhanced effects of the donor–acceptor groups in D3 and D4 result in a longer OPA maximal wavelength than that for D2 by 10–12 nm. The reason that $\lambda_{max}^{(1)}$ of D4 is longer than that of D3 is the more efficient conjugated pathway. The $\lambda_{max}^{(1)}$ value increases with the change of the substituent in the order $N(Me)_2$ (in D7) > OMe (in D6). The reason for this result is that $N(Me)_2$ group has a stronger electron-donating ability than the OMe group. As shown in Fig. 1, there are two pairs of the same donor–acceptor substitutions in both D5 and D7. However, the $\lambda_{max}^{(1)}$ displayed in Table 1 is red-shifted by 25 nm from D5 to D7, which is possibly owing to the fact that molecule D7 has a higher point group symmetry (C_{2v}) than D5 (C_s), and then is in favor of the symmetric electron transfer.

Two-photon absorption

Table 2 summarizes the position of the maximal TPA ($\lambda_{max}^{(2)}$) and the nature of the transition. According to eqs. [1]–[4], we compiled a program to calculate the third-order optical susceptibility $\langle\gamma\rangle$ abbreviated as γ, and the TPA cross section $\delta(\omega)$. Using the program, we calculated the real and imaginary part of γ as well as the δ_{max} value, which are also listed in Table 2. To examine the accuracy of the calculation method, we chose stilbene (molecule A in Tables 1 and 2) and 4,4-bis(dimethyl-amino)stilbene (molecule B in Tables 1 and 2) as comparison samples and the corresponding experimental values are given in parentheses. We can see from Tables 1 and 2 that the results we calculated are in good agreement with the experimental values.

The absorption of light by matter is a consequence of the interaction of an electromagnetic field with optically induced electric dipoles in a molecule. For the molecule that has central symmetry, a change in the parity between the initial and final states (wave functions) is required for every photon involved in the transition for electric dipole transitions. Thus, the selection rule for TPA is different from that of OPA. One change of parity is required for a one-photon transition, while two-photon transitions must have initial and final states with the same parity. In this work, all of the studied compounds have no center of inversion symmetry, so every state is of mixed parity and transition between all electronic states involving any numbers of photons are allowed. We studied the TPA spectra for all compounds by considering the 25 lowest excited states one point by one point, and at the same time obtained the maximum TPA cross section δ_{max} and the position of TPA maximum $\lambda_{max}^{(2)}$. We take the molecule D1 as an example to depict its TPA spectrum (shown in Fig. 3).

It is well-known that the simplified form of the SOS expression – three-state approximation can be used to predict the position and relative strength of the two-photon resonance (11). In this paper, there is no central symmetry in the investigated compounds, and hence eq. [5] should be applicable to this series of molecules. According to the results in Tables 2 and 3, the relationship between the maximum TPA cross section (δ_{max}) of every compound and $M_{0k}^2(M_{kn}^2 + \Delta\mu_k^2)/(E_{0k} - E_{0n}/2)^2\Gamma$ is depicted in Fig. 4. As can be seen,

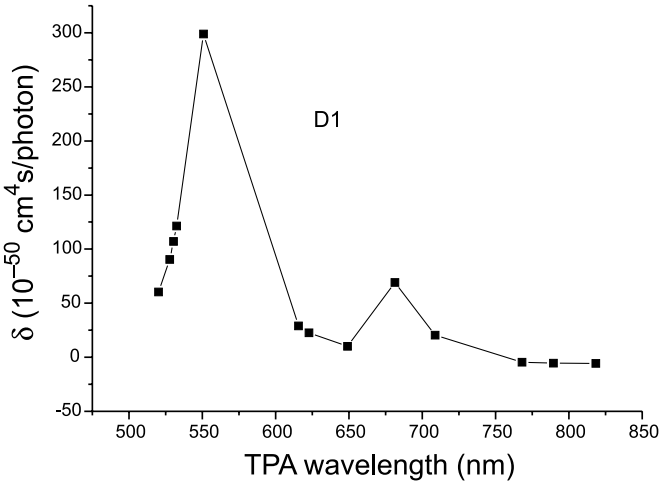

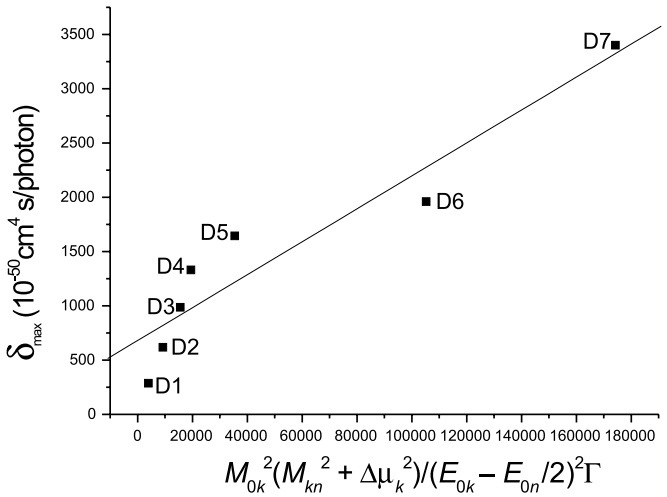

Fig. 4. Plot of δ_{max} vs. $M_{0k}^2(M_{kn}^2+\Delta\mu_k^2)/(E_{0k} - E_{0n}/2)^2\Gamma$.

the calculated points are distributed on average on the two sides of the line, which indicated the basal applicability of three-state approximation in this class of molecules. It is notable that the increasing magnitude of M_{kn}^2 and $\Delta\mu_k^2$ plays the most significant role in the enhanced TPA cross-section value from D1–D7.

To examine further the reliability of the applied method to calculate the nonlinear optical properties, we choose 4-amino-4 -nitro-diphenylacetylene as the comparison sample. We calculated its transition dipole moment M_{ge} and state dipole moment difference $\Delta\mu$. The calculated M_{ge} is equal to 8.49, which is close to the calculated result 8.62 and the experimental value 6.16 in the literature (32). The $\Delta\mu$ value is 13.62, which is larger than the experimental value 9.5 but almost equal to the calculated result 13.54 in the literature (32). From Table 3, the TPA maximum wavelength for all molecules is in the range from 540 to 610 nm, in which there is no linear absorption and so a TPA process may occur. Except for D2 with the higher-lying TPA final state, the $\lambda_{max}^{(2)}$ of the donor–acceptor substituted compounds is redshifted in comparison to that for the nonsubstituted molecule D1. As far as one pair of donor–acceptor substituted molecules are concerned, with the enhancement in the efficiency of conjugation, the $\lambda_{max}^{(2)}$ value increases in the order of D4 (605.6 nm) > D3 (600 nm) > D2 (541.8 nm). In terms of chromphores with two-pairs of donor- acceptor, because of the more symmetric substituents (C_{2v}) in D6 and D7 than that in D5 (C_s), the $\lambda_{max}^{(2)}$ is bathochromic more than 20 nm. From D6 to D7, there is a slight shift (2.4 nm) of the peak position of the TPA to a longer wavelength upon increasing the donor strength.

In general, an octupolar system should exhibit the character of the basic trigonal C_3 group included in all-trigonal groups such as C_{3h}, D_3, and D_{3h}. In this paper, only the molecule D1 possesses D_{3h} point group symmetry, but the other molecules have reduced symmetry (C_{2v} or C_s) because of substitutions of donor and acceptor and become the distorted octupolar compounds. The TPA response in octupolar compounds is highly sensitive to the actual interactions among the individual molecular branches. Then, in these distorted octupolar systems, what does result in the increase of maximum TPA cross-section δ_{max}?

As shown in Table 2, the octupolar system D1 presents the smallest TPA cross section — 298.9×10^{-50} cm^4 s/photon — since there is no outside force driving the electron transfer. As both functional groups on D2 are positioned on a single benzene ring ortho to each other, most of the electron transfer is localized in the six-membered ring. The increased quantities of electron transfer make the δ_{max} value of D2 (632.1×10^{-50} cm^4 s/photon) larger than that of D1. In the case of D3, because the effect of the donor–acceptor groups through the delocalization pathway is better than that in D2, the maximum TPA cross section is added to 979.4×10^{-50} cm^4 s/photon. The donor–acceptor substitution locates a conjugated pathway in D4 compared with the cross- conjugated pathway in D3, which makes for the electron transfer in the molecular plane. As a result, D4 exhibits a larger TPA cross-section value of 1325×10^{-50} cm^4 s/photon. To probe into the origin of the TPA response in molecule D4, we calculated the TPA cross section of the linear donor–acceptor chromophore 4-nitro-4 -dimethylaimno-diphenyldiacetylene, denoted by P. The computed δ_{max} for molecule P is up to

© 2004 NRC Canada

1338×10^{-50} cm^4 s/photon, which is almost equal to the δ_{max} for D4. The above result suggests that the TPA response in molecule D4 mostly comes from that in the side connected by donor and acceptor in the trigonal molecule. The magnitude of the TPA cross section of the molecule D5 is 1623×10^{-50} cm^4 s/photon, which is the sum of that of D2 and D3. The obtained TPA cross section increases from 1934×10^{-50} cm^4 s/photon of D6 to 3376×10^{-50} cm^4 s/photon of D7 as the electron-donating ability of substituents enhances. Examining the data in Table 3, one can find that the δ_{max} for molecule D7 (3376×10^{-50} cm^4 s/photon) is more than twice as that for D4 (1325×10^{-50} cm^4 s/photon). The result illuminates that the symmetric substitutions of donors and acceptors in molecule D7 are propitious to the electron transfer and cooperative enhancement in TPA response of the individual side.

Theoretical calculations and experimental observations indicate that the enhanced nonlinear optical properties of organic molecules quite often are hampered by an optical transparency problem. It causes the bathochromic shift of the π-π^* absorption band, and thus the requirement of high transparency to visible light will not be met. The calculation shows that the maximum TPA cross section of D7 is enhanced by one order of magnitude on the basis of that of D1, while the $\lambda^{(1)}_{max}$ has red-shifted by 30 nm. Gompper et al. (33) pointed out that the maximum wavelength ($\lambda^{(1)}_{max}$) of the electronic spectra of the chromophore molecules of the nonlinear optical materials ought to be shorter than 415 nm so that the transparency can be guaranteed. From the calculated electronic spectra listed in Table 1, it can be seen that $\lambda^{(1)}_{max}$ of all molecules is lower than 385 nm (i.e., the third-order susceptibility and the TPA cross section increase without lowering the transparency).

Conclusion

The linear and nonlinear optical properties for various dehydrobenzo[18]annulenes were systematically investigated. Overall, the effects of increasing donor strength and the efficiency of the conjugation on the OPA and TPA properties were studied in detail. The results indicate that macrocycle D7 with the stronger donors ($N(Me)_2$) and higher point group symmetry (C_{2v}) exhibits the largest TPA cross-section value. For this series of chromphores, the three-state approximation is still applicable to predict the changing trend of the TPA cross section. It is notable that the calculated TPA cross-section value for the molecule D7 is 15-fold larger than that of the famous TPA material — 4,4 -bis(di-*n*-butylamino)-*E*-stilbene (11). In general, dehydrobenzo[18]annulenes with the high transparency and the larger TPA response are worth being investigated further.

A one-pot synthesis and X-ray crystallographic and computational analyses of methyl-2,4-dimethoxysalicylate — a potential anti-tumour agent

Hossein A. Dabbagh, Nader Noroozi-Pesyan, Brian O. Patrick, and Brian R. James

Abstract: The thermal decarboxylation of 2-methoxycarbonyl-5-(4′-nitrophen-oxy)tetrazole (**1a**) with the electron-rich, aromatic compounds (anisole, *N*,*N*-dimethylaniline, 1,4-dimethoxybenzene, and 1,3,5-trimethoxybenzene), neat or in polar solvents (DMSO, DMF, and CH_3CN), is investigated. The solid phase thermal decomposition of a mixture of **1a**, 1,3,5-trimethoxybenzene, and a Lewis acid ($AlCl_3$) produces methyl-2,4-dimethoxysalicylate (**8**) in good yield, instead of the expected 2,4,6-trimethoxybenzoic acid. The X-ray structure of **8** shows intramolecular hydrogen bonds between the carbonyl oxygen and hydrogens of Me and OH groups. A measured pK_a value of 6.8 compares well with a value of 6.4 estimated using the [C=O···H···O] hydrogen bond distances.

Key words: anti–tumor, novel synthesis, X-ray structure, hydrogen bonds, computational analysis.

Résumé : On a étudié la décarboxylation thermique du 2-méthoxycarbonyl-5-(4′-nitrophényl)tétrazole (**1a**) en présence de composés aromatiques riches en électrons (anisole, *N*,*N*-diméthylaniline, 1,4-diméthoxybenzène et 1,3,5-triméthoxybenzène) à l'état pur ou dans des solvants polaires (DMSO, DMF et CH_3CN). La décomposition thermique en phase solide d'un mélange de **1a**, de 1,3,5-triméthoxybenzène et d'un acide de Lewis ($AlCl_3$) conduit à la formation du 2,4-diméthoxysalicylate de méthyle (**8**) avec un bon rendement au lieu de l'acide 2,4,6-triméthoxybenzoïque attendu. La structure du composé **8** telle que déterminée par diffraction des rayons X montre la présence de liaisons hydrogènes intramoléculaires entre l'oxygène du carbonyle et les atomes d'hydrogène des groupes méthyle et hydroxyle. La valeur mesurée de 6,8 pour le pK_a se compare bien avec la valeur de 6,4 évaluée sur la base des longueurs des liaisons hydrogènes [C=O···H···O].

Mots clés : antitumoral, synthèse nouvelle, structure par diffraction des rayons X, liaisons hydrogènes, analyse conformationnelle.

[Traduit par la Rédaction]

Introduction

Trimethoxybenzoic acid derivatives are important because of their pharmaceutical and biological activities (1), and industrial applications (2). A recent patent reported that a wide range of benzoic acid derivatives have good anti-tumour properties, their activity being related to novel synergistic compositions that selectively control tumour tissue (3); the mixtures contain at least two of the following benzoic acid derivatives: 2-OH, 2-O_2CMe, 2,4-$(OMe)_2$, 2,4,6-$(OMe)_3$, 2-OH-4-NH_2. Other derivatives of dimethoxybenzoic acid have also received considerable attention (4).

Numerous methods have been reported for the synthesis of hydroxybenzoic acids and their methoxy derivatives (e.g., 2,3-$(OH)_2$ (5), 2,4-$(OH)_2$ (6), 2,5-$(OH)_2$ (7), 2,6-$(OH)_2$ (8), 3,4-$(OH)_2$ (9), 2,3,4-$(OH)_3$ (10), 2,3,5-$(OH)_3$ (11), 2,3,6-$(OH)_3$ (12), 2,4,5-$(OH)_3$ (13), and 2,4,6-$(OH)_3$ (14)). 2,4,6-Trimethoxybenzoic acid has been synthesized by methylation of 2,4,6-trihydroxyphenyl allyl ether using Me_2SO_4, followed by oxidation using $KMnO_4$ (15), or from phloroglucinol (16) or β-resorcinol (17). The best known derivative of benzoic acid is the most often recommended drug aspirin (acetylsalicylic acid), which is an analgesic, effective in relieving headaches, and has anti-inflammatory and other beneficial properties (18).

One of our groups recently reported the equilibria, kinetics, and mechanism for the isomerization of 2-methoxycarbonyl-5-(*p*-X-phenoxy)tetrazoles (X = H, Me, NHCOMe, Cl, Br, and NO_2; **1** → **2** (Scheme 1, pathways *a* and *b*)) (19, 20), and also their thermal decarboxylation to form in high yield 5-(aryloxy)tetrazoles (**3**, **4** (Scheme 1, pathways *c* and

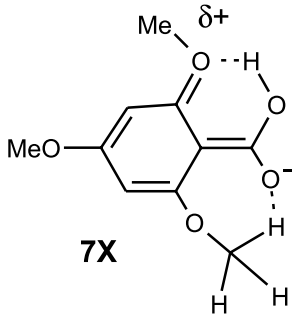
d)) (21), when CO_2 is released at temperatures below the melting points of the precursor methoxycarbonyl derivatives.

In the work reported here, we attempted to utilize **1** as a potential carboxylation and (or) alkylation agent (Scheme 1, pathways *e* and *f*) for electron-rich aromatic compounds such as *N*,*N*-dimethylaniline, anisole, 1,4-dimethoxybenzene, and 1,3,5-trimethoxybenzene (Schemes 1 and 2), the plan being to trap any released (free) alkyl or acyl groups during the reaction. However, we unexpectedly synthesized methyl-2,4-dimethoxysalicylate by a method that might aid in the synthesis of new compounds or compounds previously difficult to prepare. The new findings also shed more light on the mechanism of isomerization, decarboxylation, alkylation, and (or) acylation of 2-alkloxycarbonyl-5-aryloxytetrazoles.



Results and discussion

The thermal decomposition of **1a**–**1e** in polar aprotic solvents (DMSO, DMF, and MeCN) gives **3a**–**3e** and **4a**–**4e** in high yield (21). In the present study, the reaction of **1a**–**1e** in the presence of the electron-rich aromatic compounds mentioned above was investigated both in polar aprotic solvents and solvent-free conditions. There was no trace of the carboxylation or alkylation of the electron-rich aromatic ring (Scheme 2). With 1,3,5-trimethoxybenzene (the most electron-rich aromatic ring) under solvent-free conditions, a low yield product was obtained (<2%), while in the presence of a Lewis acid ($AlCl_3$), the yield was increased to 30%. There were no akylation (**6A**–**6C**) or carboxylation (**7A**–**7C**) products (see Scheme 1) detected from reactions with the

Scheme 2. Formation of **8**.

other electron-rich reagents. We initially thought that the 30% product was 2,4,6-trimethoxybenzoic acid (**7D**) (Scheme 1). This was based on ^{1}H NMR (90 MHz) in DMSO-d_6: δ 3.63 (br s, 3H), 3.66 (s, 6H), and 6.0 (br s, 2H), and MS data that showed a parent M^+ peak at 212. However, the melting point (96–98 °C) did not match the value of 158 °C (decomp.) given for **7D** in the *Lancaster Chemicals* catalogue. Further examination by ^{1}H NMR (300 MHz) in $CDCl_3$ revealed a well-resolved spectrum (δ 3.73 (s, 3H), 3.74 (s, 3H), 3.83 (s, 3H), 5.89 (d, 1H, J = 8 Hz), 6.02 (d, 1H, J = 8.3 Hz), 11.91 (s, 1H)), while the corresponding ^{13}C NMR spectrum showed 10 signals (see Experimental). The NMR data show the presence of three inequivalent OMe groups and two inequivalent aromatic protons. We considered as a possibility the H-bonded structure **7X**, but an X-ray structure revealed that the product was, in fact, methyl-2,4-dimethoxysalicylate (**8**, Fig. 1; see Table 1 for crystal and structure refinement data), which accounts for the NMR data; formally, this has been formed from the "expected **7D**" by the interchange of a Me group (of a 2- or 6-OMe) with the carboxylic acid proton. The co-products isolated with **8** are 1- and 2-Me-5-aroyltetrazole (**4a** and **3a**, respectively) and the tetrazole **5**.

Of note, the structure of 2,4,6-trimethoxybenzoic acid (**7D**) has not been determined, although the structure of an inclusion compound of this acid with 2′,6′-dimethoxyflavone (in which the carboxylic acid proton is H-bonded to the flavone carbonyl) reveals a nonplanar benzoic acid component, the carboxylic acid moiety being ~66° out of the plane of the rest of the acid molecule (4*c*).

The carbon–oxygen framework of the molecular structure of **8** is essentially planar; bond lengths and angles are summarized in Table 2, while a structural diagram is shown also in Scheme 3. Planarity is maintained by a strong intramolecular H-bonding interaction between the carbonyl oxygen and phenolic H atom (H(1)···O(1) = 1.68(4) Å; O(5)-H(1) = 1.00(4) Å), and a much weaker intramolecular H-bond of distance 2.535 Å between Me hydrogens (H(8)) and the

Scheme 3. Structure of **8**. Corresponding structures calculated by ab initio, AM1, and PM3 methods are available as Supplementary material.[2]

C=O double bond (in what we label a "bisected" conformation with C_s symmetry (Figs. 2*a* and 2*b*, and Scheme 4)). The orientations of the *o*-OMe and ester-OMe are such to minimize steric interactions. The structure of **8** was also calculated by semiempirical ab-initio, PM3, and AM1 methods, and data for bond lengths and angles, and the torsion angles match well the experimental ones (Tables S1–S3)[2], while the corresponding calculated H(1)···O(1) bond lengths were 1.57, 1.78, and 1.97 Å, respectively, and the calculated O(5)-H(1) values were 1.00, 0.980, 0.970 Å, respectively. The ab initio value for the weaker H-bonding interaction

Scheme 4. Diagrams showing the favored so-called bisected (left) and eclipsed (right) conformations of **8**.

was 2.574 Å. The ab initio calculation also revealed a 1.40 kcal (1 cal = 4.1868 J) higher energy, eclipsed conformation with C_1 symmetry (Figs. 2*c* and 2*d*, Scheme 4, Table 3) with an H(8)-carbonyl bond length of 2.14 Å.

The proposed mechanism for the formation of **8** is outlined in Scheme 5. The Lewis acid activates the carbonyl group of the tetrazole **1a** and initiates a nucleophilic aromatic substitution reaction with 1,3,5-trimethoxybenzene to form a resonance-stabilized intermediate (**9** ↔ **10**) and the tetrazolide anion (**B**:); this then reacts with the Me group of the 2-OMe of **10** (via a bimolecular nucleophilic substitution process) to produce intermediate **11** that isomerizes to **8**, a strongly resonance-stabilized compound (Scheme 6). That methyl-4-hydroxy-2,6-dimethoxy benzoate is not formed is a good indication that intermediate **10** is involved. Compound **8** is not sensitive to air, moisture, or heat, and could be converted easily to other useful derivatives such as 2-hydroxy-4,6-dimethoxybenzoic acid, methyl-2,4,6-trimethoxybenzoate, and 1,3,5-trimethoxybenzoic acid. The mechanism accounts nicely for the observed methyltetrazole co-products **3a** and **4a**, while **5** is a hydrolysis product (see Scheme 1). Corre-

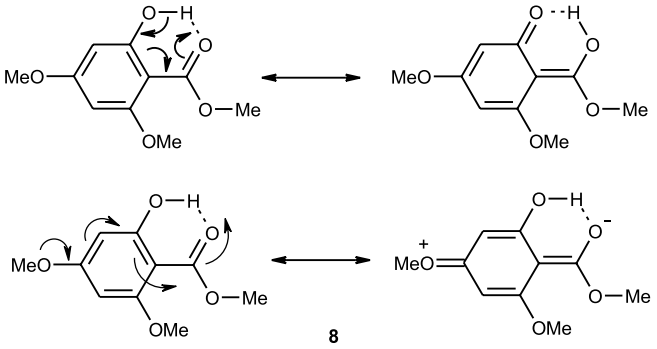
sponding reactions with the tetrazoles **1b–1e** (containing weaker electron-donor substituents in the Ar′ moiety, Scheme 1) generate, respectively, the tetrazoles **3b–3e**, **4b–4e**, **5b–5e** and CO_2, but no **8**.

Comparison of the strength of the H-bond in **8** with those in the 2′-6′-dimethoxyflavone-carboxylic acid derivatives reported by Wallet and co-workers (4) allows for the determination of the pK_a of the flavone acid compounds (Fig. 3).

© 2004 NRC Canada

Scheme 6. Resonance forms for **8**.



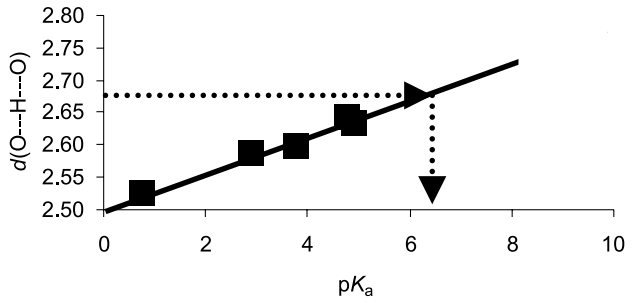


Fig. 3. Correlation of H-bond distances in 2′,6′-dimethoxyflavone-carboxylic acid adducts (O···H···O) with increasing pK_a values of trichloroacetic, chloroacetic, formic, acetic, and propionic acids (4*a*, 4*b*). Estimation of the pK_a value for **8** (···▸**).**

They used this method when the experimental pK_a determination was impractical. The estimated pK_a value for **8** is equal to ~6.4; an experimental value of 6.8 is in the range 6.5–7 determined for similar derivatives of **8** with anti-tumour properties (3).

Experimental

The key ^{1}H NMR and ^{13}C NMR data were recorded on a Bruker AV 300 (300 MHz) instrument, and the FT-IR spectra were obtained on a Shimadzu IR-470. MS data were measured on a GC–MS Fission Trio 1000 instrument (70 eV). Melting points (mp) (uncorrected) were taken on a Gallenkamp apparatus. The computational analyses were performed using HyperChem pro 6.0, with the ab initio, AM1, and PM3 calculations optimized using Polak–Ribiere or Fletcher–Reeves algorithms.

X-ray crystallographic analysis of 8

Data (see Table 1) were collected on a Rigaku/ADSC CCD instrument in 0.50° oscillations with 90.0 s exposures (with graphite-monochromated Mo-Kα radiation, 0.710 69 Å). A sweep of data was done using φ oscillations from 0.0 to 190.0° at χ = –90° and a second sweep was performed using ω oscillations between –17.0 and 23.0° at χ = –90.0°. The crystal-to-detector distance was 38.82 mm, with a detector swing angle of –5.5°. Data were corrected for Lorentz and polarization effects. Computing of data collection, cell refinement, and data reduction (see Table 1) were done using the d*TREK program (22*a*), and the structure was solved by direct methods (SIR97) (22*b*). All calculations were performed using the teXsan crystallographic software package (22*c*).

Synthesis of aryloxytetrazoles

2-Methoxycarbonyl-5-aryloxytetrazoles (aryl = 4-nitrophenyl (**1a**), 4-methylphenyl (**1b**), 4-methoxyphenyl (**1c**), 2,6-dimethylphenyl (**1d**), 2,6-dimethoxyphenyl (**1e**)) were synthesized by reported methods (21).[3]

Synthesis of methyl-2,4-dimethoxysalicylate (8)

Compound **1a** (3.8 mmol), 1,3,5-trimethoxy-benzene (3.8 mmol). and 1.5 mol equiv. of $AlCl_3$ were mixed and ground to a homogeneous powder, and heated at 100 °C for 20 min; the TLC spot for the trimethoxybenzene gradually disappeared. The mixture was then transferred to a separating funnel using 10 mL CH_2Cl_2, 10 mL H_2O, and 5 mL HCl (5%), and the organic phase was washed several times with brine. The orange organic phase was dried over $CaCl_2$ and the solvent evaporated off. The residue was passed through a silica gel column and elution with cyclohexane:ethyl acetate (95:5) gave **8** (30% yield, mp. 96–98 °C), **4a** (30% yield), **3a** (15% yield), and tetrazole **5** (25%). This procedure was repeated with tetrazoles **1b**–**1e**; the product tetrazoles **3b**–**3e** and **4b**–**4e** were detected, but there was no trace of **8**. The ^{1}H NMR and IR data for the **3b**–**4e** and **4b**–**4e** have been reported (19–21). For **8**: FT-IR (KBr, cm^{-1}): 3200–3600 (s), 2925 (m), 2800 (w), 1642 (s), 1615 (s), 1440 (m), 1380 (s), 1273 (s), 1250 (s), 1165 (s), 1119 (s), 1051 (m), 944 (w), 828 (m), 460 (s). ^{1}H NMR ($CDCl_3$): δ 3.73 (s, 3H, *p*-CH_3O), 3.74 (s, 3H, *o*-CH_3O), 3.83 (s, 3H, CH_3OCO), 5.89 (d, 1H^3, J = 8.0 Hz), 6.02 (d, 1H^5, J = 8.3 Hz), 11.91 (s, 1H, OH). ^{13}C NMR ($CDCl_3$): δ 53.48, 56.81, 57.43, 92.92, 94.88, 98.00, 163.56, 166.74, 167.22, 173.00. MS (70 eV): 212 (M^+, 40), 211.1 (72), 180.5 (92), 178.9 (100), 152.2 (36), 137.2 (40). A crystal of **8** was grown over 2 days at room temperature from a cyclohexane:CH_2Cl_2 (~4:1) solution of the compound.

Fluorine chemistry — Wittig based synthesis of volatile organofluorine compounds

Pinaki S. Bhadury, Sapna Singh, Mamta Sharma, Meehir Palit, and Devendra K. Jaiswal

Abstract: A simple and practical method has been developed for the synthesis and characterization of several interesting classes of volatile organofluorine compounds from fluorophosphonium salts via their in situ generated corresponding ylides. The fluorinated phosphonium ylides react with hexafluoroacetone in DMF to generate perfluoroisobutylene, whereas in the presence of bromine or iodine containing electrophiles, tetrafluoroethylene, perfluoro-2-butene, perfluorocyclobutane, and 1*H*-heptafluoropropane are obtained.

Key words: difluoromethylene phosphonium ylides, perfluoroisobutylene, tetrafluoroethylene, perfluorocyclobutane, 1*H*-heptafluoropropane.

Résumé : On a développé une méthode simple et pratique pour synthétiser et caractériser plusieurs classes intéressantes de composés organofluorés volatils à partir de sels de fluorophosphonium, par le biais des ylures correspondants générés in situ. Les ylures de phosphonium fluorés réagissent avec l'hexafluoroacétone, dans le DMF, pour générer le perfluoroisobutylène alors que, en présence d'électrophiles contenant du brome ou de l'iode, on obtient le tétrafluoroéthylène, le perfluorobut-2-ène et le 1*H*-heptafluoropropane.

Mots clés : ylures de difluorométhylènephosphonium, perfluoroisobutylène, tétrafluoroéthylène, perfluorocyclobutane, 1*H*-heptafluoropropane.

[Traduit par la Rédaction]

Introduction

Fluorinated phosphonium salts can be generated by the reaction of tertiary phosphines and halogenated fluoroalkanes (1, 2). Metal dehalogenation of these quaternary phosphonium salts in dimethylformamide (DMF) generates in situ difluoromethylene phosphonium ylides which, on reaction with electrophilic carbonyl compounds, e.g., activated ketones and aldehydes, provide a practical route to terminal 1,1-difluoroolefins (3, 4). In the absence of suitable electrophilic substrates, the ylide decomposes into difluorocarbene ($:CF_2$) and in DMF can act as a source of fluoride ion or a combination of fluoride ion and proton (3–5). This property has been utilized by us to obtain several classes of organofluorine compounds, e.g., chlorofluorocarbon (CFC) substitutes (3), the HF addition product of fluoroolefins (6), *O*-(chlorodifluoroacylated) alcohols from fluorinated alcohols (7), and chlorohydrins from epoxides (8). Based on these results, a novel and practical procedure has been developed for the synthesis and characterization of several other interesting classes of volatile organofluorine compounds from fluorophosphonium salts and their in situ generated corresponding ylides. The compounds selected in our studies include perfluoroisobutylene, a Schedule 2 chemical under the Chemical Weapons Convention (9). We have also investigated the fate of the nucleophilic ylide in the presence of electrophiles containing positive iodine or bromine. The study has resulted in the synthesis of several synthetically and (or) industrially useful organofluorine compounds such as tetrafluoroethylene (TFE), perfluoro-2-butene (*E* and *Z*), perfluorocyclobutane, and 1*H*-heptafluoropropane (HFC-227ca). The synthesis and characterization, based on ^{1}H NMR (wherever applicable) and ^{19}F NMR and mass spectral studies, of the above-named organofluorine compounds are described in this communication.

Results and discussion

Perfluoroolefins are an important group of organofluorine compounds amongst which perfluoroisobutylene (1,1,1,3,3-pentafluoro-2-(trifluoromethyl)propene), commonly known as PFIB, has been used as a test compound for the determination of the protective properties of activated carbon in filters owing to its extreme respiratory toxicity and alleged mask-breaking properties (10, 11). Perfluoro-2-butene is an important isomer of PFIB, whereas perfluorocyclobutane has been reported as the immediate precursor of PFIB through thermal degradation (12). TFE finds several industrial appli-

cations and has been employed as the starting monomer for the manufacture of numerous classes of commercially important organic fluoropolymers, including Teflon, Neoflon, and Viton (13). HFC-227ca can be employed as a potential CFC replacement under the Montreal Protocol (14). We have studied reactions for the preparation of the above-mentioned organofluorine compounds, for which simple and practical synthetic procedures were not readily available.

Highly volatile fluorinated olefins such as PFIB, TFE, and perfluoro-2-butene (*E* and *Z*) are, in general, known to be produced by high-temperature disproportionation of perfluorinated hydrocarbons and polymers (12, 15). While pyrolysis of fluorocarbons usually leads to complex mixtures, other methods reported require high temperature and use of corrosive materials (13). Therefore, alternate synthetic procedures to synthesize these fluoroolefins would be highly useful. In this context, the reactions of fluorinated phosphonium ylides generated in situ from quaternary salts in DMF with appropriate substrates have been investigated. Thus, difluoromethylene triphenylphosphonium ylide reacts with hexafluoroacetone (sesquihydrate) in a Wittig reaction to generate PFIB. Other compounds produced are tetrafluoroethylene from 1-bromo-2-iodotetrafluoroethane, tetrafluoroethylene and perfluorocyclobutane from 1-iodononafluorobutane, perfluoro-2-butene from 2-iodononafluorobutane, and HFC-227ca from 1-iodoperfluoropropane. We have also studied the formation of TFE from the quaternary phosphonium salt generated by the reaction of triphenylphosphine and 1-bromo-2-iodotetrafluoroethane. The syntheses of these highly volatile organofluorine compounds employing different reagent systems are summarized in Table 1. The compounds have been characterized by ^{1}H NMR, ^{19}F NMR, and mass spectral data, shown in Table 2, which were consistent with their structure and reported literature values (10, 13, 16).

The in situ ylide formation reaction in DMF has been carried out for the conversion of carbonyl compounds into the corresponding terminal 1,1-difluoroolefins. We have employed this reaction to convert several activated aromatic ketones and aldehydes into olefins (3). The Wittig reaction has now been successfully extended to yield yet another highly volatile aliphatic difluoroolefin, PFIB, a highly toxic Schedule 2 chemical.

Facile conversion of hexafluoroacetone (sesquihydrate) into PFIB has been achieved when the ketone is subjected to a Wittig reaction with difluoromethylene triphenylphosphonium ylide. The reaction is based on zinc metal dehalogenation of in situ generated (bromodifluoromethyl)triphenylphosphonium bromide salt (**I**, Scheme 1) in DMF (3). The salt was formed when an equimolar amount of dibromodifluoromethane was added all at once to a well-stirred solution of triphenylphosphine at room temperature in dry DMF. This was followed by the addition of 0.5 mol of hexafluoroacetone (sesquihydrate) to the salt solution at room temperature. Then 1 mol of zinc powder was added slowly into the reaction mixture. Within 1 to 2 min an exothermic reaction ensued due to the formation of organozinc bromide (**II**) in equilibrium with difluoromethylene triphenylphosphonium ylide (**III**). The PFIB generated was collected in a trap cooled by a liquid-nitrogen/methanol mixture. It should be noted that an initially attempted synthesis of PFIB via a Wittig reaction of the in situ generated ylide with hexafluoroacetone gas did not produce any significant amount of PFIB. This may presumably be due to the fact that anhydrous hexafluoroacetone (bp –26 °C), a low-boiling gaseous substance at ambient temperature, would have very low contact time with the reagents and may have escaped from the reaction mixture. A reported procedure in which hexafluoroacetone (sesquihydrate) was successfully used in place of anhydrous hexafluoroacetone in catalytic epoxidation of alkenes (17) led us to employ the sesquihydrate instead of hexafluoroacetone gas for generation of PFIB. This also meets the requirement that substrate be present before the addition of the zinc metal to the phosphonium salt. Although the sesquihydrate predominantly exists as a diol, presumably the equilibrium between thediol and the ketonic form is shifted towards the right in the aprotic solvent DMF. This enables the ylide to consume the ketone to yield PFIB at a rapid rate (Scheme 1). The synthetic route provides a convenient and safe method for the generation and isolation of the highly toxic compound PFIB.

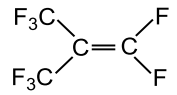
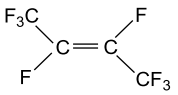
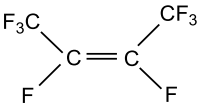
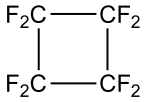
$Ph_3P/CF_2Br_2/Zn$	$CF_3CF_2CF_2CF_2I$	$CF_2=CF_2$, 
$Ph_3P/CF_2Br_2/Zn$	$CF_3CF_2CFICF_3$	$CF_3CF=CFCF_3$
$Ph_3P/CF_2Br_2/Zn$	$CF_3CF_2CF_2I$	$CF_3CF_2CF_2H$









Note: GC yields are 84–96% based on starting compound; isolated yields are given in Experimental section.

For the synthesis of TFE, the substrate 1-bromo-2-iodotetrafluoroethane was added to a room temperature solution of the salt $[Ph_3P^+–CF_2Br]Br^–$, which had been generated in situ by the reaction of Ph_3P and CF_2Br_2 in DMF. This was followed by the addition of zinc metal, resulting in a highly exothermic reaction due to the formation of an organozinc halide/fluoromethylene ylide system. The nucleophilic ylide under the reaction conditions presumably abstracts the more labile positive iodine from the substrate to give a carbanion (**IV**, Scheme 2). Subsequent elimination of bromide ion from the adjacent carbon atom forms TFE. Alternatively, TFE could also be generated from the quaternary phosphonium salt $[Ph_3P^+–CF_2–CF_2Br]I^–$ (**V**, Scheme 2) obtained in situ by the reaction of Ph_3P and CF_2BrCF_2I. The organozinc halide **VI**, obtained after the addition of zinc metal, collapses spontaneously to yield TFE by the elimination of a molecule of Ph_3P from the carbon atom adjacent to the carbanion center (Scheme 2).

Similarly, when 1-iodononafluorobutane was added into a solution of the salt $[Ph_3P^+–CF_2Br]Br^–$ followed by zinc metal, a mixture of volatile products consisting of TFE and perfluorocyclobutane was generated. As the result of the nucleophilic attack of the ylide on the positive iodine of the substrate, the carbanion (**VII**, Scheme 3) is first generated. Fragmentation and fluoride ion elimination from the terminal carbon atom of the conjugated system lead to the formation of TFE. The nucleophilic attack by this carbanion on

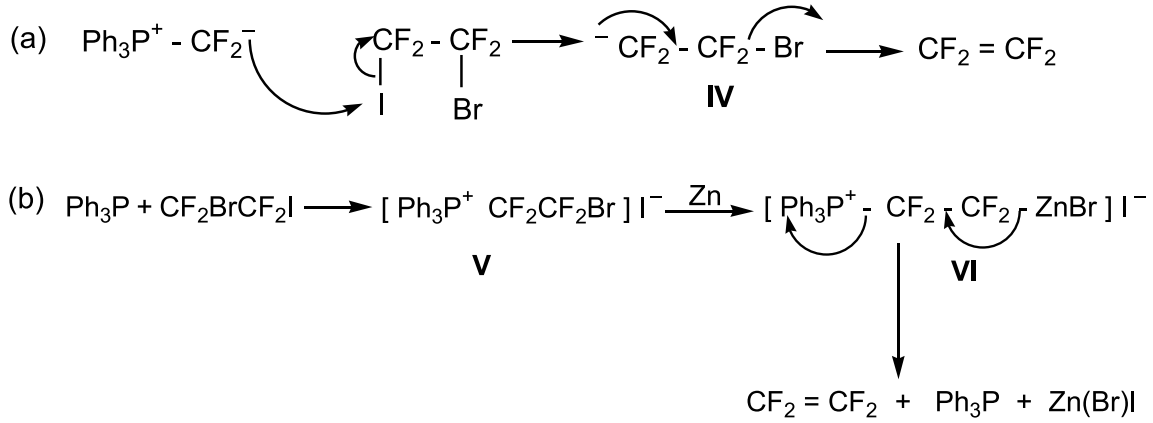
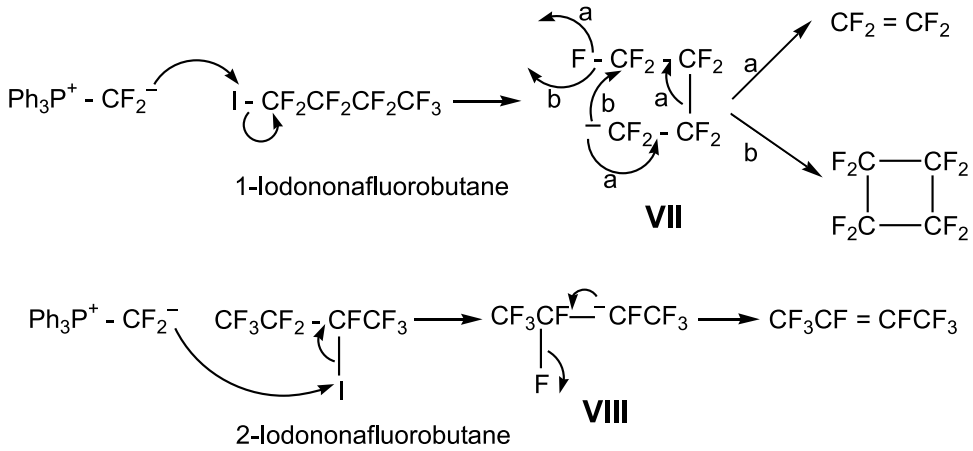
Scheme 1. Formation of perfluoroisobutylene (PFIB) from zinc dehalogenation of fluorinated phosphonium salt.



the terminal carbon atom in an S_Ni fashion can lead to the formation of perfluorocyclobutane. Fluoride ion elimination from the adjacent carbon atom generating terminal fluoroolefin (perfluoro-1-butene) seems unlikely in favor of the more stable cyclic saturated product (1). On the other hand, when the difluoromethylene triphenylphosphonium ylide was reacted with 2-iodononafluorobutane, perfluoro-2-butene (predominantly the *Z* isomer) was obtained. Here again, elimination of F^- from the carbanion (**VIII**) occurred to favor a stable internal olefin over a terminal isomer, as shown in Scheme 3.

When the ylide reaction was carried out with 1-iodoperfluoropropane, neither a perfluoroolefin nor a cyclic product was obtained. This is probably due to the fact that an S_Ni substitution would not produce a stable perfluorocycloalkane, and F^- elimination from the carbanion (**IX**, Scheme 4) would have resulted in a less stable terminal fluoroolefin, hexafluoropropene. The intermediate carbanion, therefore, instead abstracts a proton from the solvent to form a hydrofluorocarbon, 1*H*-heptafluoropropane (Scheme 4). As observed earlier (3, 6–8), the solvent DMF can provide a proton in the presence of :CF_2, which in turn is generated by the decomposition of excess ylide under the reaction conditions.



It should be noted further that control experiments involving the substrates (e.g., hexafluoroacetone (sesquihydrate), 1-bromo-2-iodotetrafluoroethane, 1-iodononafluorobutane, 2-iodononafluorobutane, and 1-iodoperfluoropropane) and CF_2Br_2 and Zn in the absence of Ph_3P did not lead to the formation of products. This shows that generation of the nucleophilic ylide Ph_3P^+–CF_2^- (**III**) is necessary either for a Wittig reaction (Scheme 1) or for the abstraction of positive iodine (Schemes 2*a*, 3, and 4) from the substrate. This observation rules out any possibility of participation by Zn in the reaction by the activation of dibromodifluoromethane. When CF_2BrCF_2I is used in place of CF_2Br_2, no ylide formation takes place, and quite understandably the inter-

Scheme 4. Formation of 1*H*-heptafluoropropane.

mediate organozinc halide (**VI**) collapses into CF_2=CF_2 (Scheme 2*b*).

It is thus observed that the above study has resulted in the synthesis of several useful organofluorine compounds. The reactions are facile and the products are generated in high yield under mild reaction conditions.

Conclusion

A facile synthesis of several interesting classes of volatile organofluorine compounds has been developed. The method essentially utilizes the Wittig based reaction of fluorophosphonium ylides generated in situ from their corresponding quaternary phosphonium salts in DMF with different substrates. Thus, facile conversion of hexafluoroacetone (sesquihydrate) into PFIB has been achieved. This synthetic route provides a convenient and safe method for the generation and isolation of the highly toxic PFIB. Other compounds prepared by this method are TFE from 1-bromo-2-iodotetrafluoroethane, perfluoro-2-butene from 2-iodononafluorobutane, TFE and perfluorocyclobutane from 1-iodononafluorobutane, and HFC-227ca from 1-iodoperfluoropropane. The procedure is simple and convenient, does not involve high-temperature reaction conditions, and is devoid of any significant side products.

Experimental

The volatile organofluorine compounds generated can be safely stored in 1- and 2-L capacity Tedlar® bags (3) procured from Supelco (Bellefonte, Pa.). Their analysis was effected either by gas-phase injection after drawing the sample

© 2004 NRC Canada

through the septum for mass spectrometry or by bubbling the gas into a NMR tube in deuterated solvent at low temperature. Reactions were monitored by gas chromatography – mass spectrometry (GC–MS), and the mass spectra were recorded on a TSQ 7000 mass spectrometer (Finnigan MAT) using a Varian 3400 GC inlet with a BP-5 column (30 m × 2.5 mm (i.d.) × 0.25 μm (film thickness)) with a temperature program of 30 °C (2 min), 120 °C at 5 °C/min, 200 °C at 200 °C/min, and 200 °C (5 min) using helium as the carrier gas at a flow rate of 1.2 mL/min. The injector temperature was 150 °C, and the transfer line was heated to 200 °C. Electron-impact ionization mass spectrometry (EI-MS) was performed at 70 eV with an ion source temperature of 150 °C and an emission current of 400 mA. Chemical-ionization mass spectrometry (CI-MS) experiments were performed using methane as a reagent gas at a pressure of 4 torr (1 torr = 133.322 Pa), a source temperature of 150 °C, and an emission current of 300 mA. The NMR spectra of fluoroolefins and fluorocarbons were recorded on a Bruker Avance DPX 400 spectrometer in acetone-d_6 solution using TMS and $CFCl_3$ as internal references for ^1H and ^{19}F NMR, respectively (3).

PFIB shows respiratory toxicity and alleged mask-breaking properties (11, 18). It is recommended that precautions taken in handling volatile toxic compounds should strictly be followed during its synthesis and handling.

Perfluoroisobutylene

Triphenylphosphine (25.2 g, 0.096 mol) was dissolved in 80 mL of dry DMF and placed in a three-necked 250-mL round-bottom flask, containing a stirring bar, at room temperature under positive nitrogen pressure. The middle neck of the flask was connected directly to a distillation device, downstream of the nitrogen flow, whose end was connected to a receiver cooled by a mixture of liquid nitrogen and methanol. Nitrogen gas was bubbled into the stirred mixture for 2 h, after which time dibromodifluoromethane (20.15 g, 0.096 mol) was added all at once and a mildly exothermic reaction occurred. The formation of (bromodifluoromethyl)triphenylphosphonium bromide salt was almost instantaneous. Then the substrate 1,1,1,3,3,3-hexafluoroacetone (sesquihydrate) (9.26 g, 0.048 mol) was added all at once into the reaction mixture at room temperature through the third neck of the flask. This was followed by slow addition of zinc powder (6.28 g, 0.096 mol) through a solid addition tube. As soon as the zinc powder addition started, an exothermic reaction began. The reaction mixture first assumed a green color; then all the zinc went into solution turning the reaction mixture colorless, and immediately after the excess zinc settled to the bottom of the flask, the reaction mixture became orange–yellow. The heat of reaction was sufficient to distill PFIB. The conversion of hexafluoroacetone (sesquihydrate) to PFIB was high under these experimental conditions as indicated by GC analysis. The product was collected in DMF at –30 to –40 °C at a purity > 98.0%.

Tetrafluoroethylene

From in situ generated ylide

Triphenylphosphine (12.6 g, 0.048 mol) was dissolved in 35 mL of dry DMF and placed in a three-necked 250-mL round-bottom flask, containing a stirring bar and equipped with a dry nitrogen inlet, at room temperature. The middle neck of the flask was connected to a condenser fitted with a $CaCl_2$ guard tube. Dibromodifluoromethane (10.08 g, 0.048 mol) was added all at once to the well-stirred solution, and a mildly exothermic reaction occurred. After stirring the mixture for another 30 min, 1-bromo-2-iodotetrafluoroethane (7.36 g, 0.024 mol) was added at room temperature. Nitrogen flow was stopped and the guard tube was replaced at this stage by an evacuated and preweighed Tedlar® bag by connecting the end of its valve stem to tubing (3/16 in. i.d.) fitted to an adapter. To open the valve, the tubing was pushed onto the stem to the appropriate overlap distance. Zinc powder (3.14 g, 0.048 mol) was then slowly added to the reaction mixture through a solid addition tube, and almost immediately a violent exothermic reaction occurred. Gaseous product could be seen evolving, and TFE gas was collected in the Tedlar® bag attached to the reaction system as described in our earlier work (3). The course of the reaction was followed by withdrawing the sample and subjecting it to GC–MS analysis. The isolated yield of TFE was 1.6 g (67%).

From quaternary phosphonium salt

In this procedure, instead of CF_2Br_2, 1-bromo-2-iodotetrafluoroethane (14.7 g, 0.048 mol) was added to a well-stirred solution of triphenylphosphine (12.6 g, 0.048 mol) dissolved in 35 mL of dry DMF. A mildly exothermic reaction occurred due to the formation of an in situ quaternary phosphonium salt. Zinc powder (3.14 g, 0.048 mol) was added through a solid addition tube. A highly exothermic reaction took place, and the volatile C_2F_4 was collected in a Tedlar® bag. Yield 3.07 g (64%).

Perfluoro-2-butene

Perfluoro-2-butene was prepared by the same procedure as described for the TFE by ylide method using the substrate 2-iodononafluorobutane (8.3 g, 0.024 mol). Yield 2.68 g (56%).

Perfluorocyclobutane along with tetrafluoroethylene

The volatile products $CF_2{=}CF_2$ and perfluorocyclobutane were generated by the same procedure as above but using the substrate 1-iodononafluorobutane (8.3 g, 0.024 mol) and were collected in a Tedlar® bag. GC yield 96% (ratio of perfluorocyclobutane:C_2F_4 = 51:49 by GC).

1*H*-Heptafluoropropane

For the synthesis of this hydrofluorocarbon, the substrate 1-iodoperfluoropropane (7.1 g, 0.024 mol) was added to the in situ generated quaternary phosphonium salt obtained by the reaction of Ph_3P and CF_2Br_2 in DMF. The gaseous product ($CF_3CF_2CF_2H$) generated after the addition of Zn metal was collected in a Tedlar® bag. Yield 2.57 g (63%).

Green preparation of quinoline derivatives through $FeCl_3 \cdot 6H_2O$ catalyzed Friedlander reaction in ionic liquids

Jianji Wang, Xuesen Fan, Xinying Zhang, and Lijun Han

Abstract: The preparation of substituted quinoline derivatives through a Friedlander condensation reaction utilizing the ionic liquid [bmim][BF_4] as the reaction medium and iron chloride hexahydrate ($FeCl_3 \cdot 6H_2O$) as a catalyst is described. The advantages in using this method include its environmental friendliness, simple operating process in both mild and neutral reaction conditions, and good yields.

Key words: ionic liquid, Friedlander reaction, quinoline derivatives, green chemistry.

Résumé : On décrit l'utilisation du [bmim][BF_4], un liquide ionique, comme milieu réactionnel et de l'hexahydrate du chlorure de fer ($FeCl_3 \cdot 6H_2O$) comme catalyseur pour la préparation de dérivés de quinoléines substituées par la réaction de condensation de Friedlander. Cette méthode présente l'avantage d'être bénigne pour l'environnement, d'impliquer un processus d'opération simple, de se faire dans des conditions douces et neutres et de donner de bons rendements.

Mots clés : liquide ionique, réaction de Friedlander, dérivés de la quinoléine, chimie verte.

[Traduit par la Rédaction]

Introduction

For many years, the synthesis of quinoline and its derivatives has been of considerable interest in organic and medicinal chemistry since a large number of natural products and drugs contain this heterocyclic nucleus (1). While versatile methods for the synthesis of the quinoline ring system have been developed (2), many of them suffer from harsh reaction conditions, poor yields, and (or) the use of expensive catalysts. Thus, simple, general, and efficient procedures for the synthesis of this important heterocycle are still in demand.

As one of the most frequently used pathways to prepare quinoline derivatives, Friedlander synthesis involves a condensation of 2-aminobenzaldehyde with an aldehyde, ketone, or polyfunctional carbonyl compound having a reactive α-methylene group (3). This classical process is usually carried out either by refluxing an aqueous or alcoholic solution of the reactants in the presence of a base or by heating a mixture of substrates at temperatures ranging from 150 to 220 °C in the absence of solvent and catalyst to produce the corresponding 2- and 3-substituted quinolines in moderate yields. Unfortunately, attempts to extend this method to the preparation of 4-substituted quinolines from 2-aminoaryl ketones appear to have met with very limited success. Subsequent studies showed that problems resulting from the classical Friedlander procedure can be overcome by using acid catalysis. For example, it has been reported that drops of concentrated sulfuric acid or 6 mol/L hydrochloric acid can be used as efficient catalysts in the Friedlander condensation procedure (4). With this method, various structurally varied substrates, including 2-aminobenzophenone, can give the corresponding quinolines in moderate to high yields. However, this method still has some drawbacks, notably use of very strong acids as the catalyst, use of excessive glacial acetic acid as the solvent, or even requiring the use of a metal bath that can maintain a reaction temperature as high as 200 °C, thus making this method unsuitable for scale up in an environmentally benign and economical way.

Room temperature ionic liquids based on the 1,3-dialkylimidazolium cation are attracting increasing interest as alternative reaction media. The desirable advantages of ionic liquids, include their lack of vapor pressure, wide liquid range, and thermal stability, have made them exceptional reaction media as well as environmentally benign solvents in organic synthesis (5). In line with our research program of using ionic liquids as novel reaction media in organic reactions (6), we wish to report here a novel and efficient procedure for the preparation of quinolines through a Friedlander reaction catalyzed by $FeCl_3 \cdot 6H_2O$ in an ionic liquid (Scheme 1).

Results and discussion

We set out to examine the Friedlander reaction in one of the most widely used ionic liquids, 1-butyl-3-methylimidazolium tetrafluoroborate ([bmim][BF_4]), using

2-aminobenzophenone (Scheme 2, **1a**) and acetophenone (**2a**) as the starting materials.

Firstly, the mixture of **1a** (1 mmol) and **2a** (1mmol) in 1 mL of [bmim][BF_4] was stirred at room temperature for 10 h, but no reaction took place as indicated by TLC (Table 1, entry 1). Then, the mixture was heated at 100 °C. To our delight, the desired condensation reaction eventually took place but in a rather sluggish way. In fact, after being stirred at 100 °C for more than 10 h, the mixture produced the corresponding quinoline product in less than 10% yield (Table 1, entry 2). This means that while the ionic liquid [bmim][BF_4] itself possesses some catalytic activity for this condensation process, the activity is too low to give the product in a reasonable yield. Bearing in mind that $FeCl_3{\cdot}6H_2O$ has been successfully used as an environmentally benign and efficient Lewis acid catalyst for promoting several kinds of reactions (7), we then added catalytic amounts of $FeCl_3{\cdot}6H_2O$ to the reaction mixture. Fortunately, the expected product was obtained with a much improved yield (Table 1, entry 3). Further studies showed that the yield could be increased to as high as 75% within 6 h when 0.5 mmol of $FeCl_3{\cdot}6H_2O$ was used (Table 1, entry 6). However, any excess use of $FeCl_3{\cdot}6H_2O$ beyond this amount did not show any further increase in yield.

As for the possible mechanism of this catalytic reaction, we believe that the Lewis acidity of Fe(III) ion in $FeCl_3{\cdot}6H_2O$ has played an important role in the promotion of this condensation process. In order to clarify the role of Fe(III) ion and the hydration water of $FeCl_3{\cdot}6H_2O$, anhydrous $FeCl_3$ was also tried as the catalyst for this reaction, and it gave similar results compared with $FeCl_3{\cdot}6H_2O$ (Table 1, entry 7). At this stage, it may be safe to say that it is the Fe(III) ion rather than Fe(III) ion together with the hydration water in $FeCl_3{\cdot}6H_2O$ that acts as the real catalyst in this condensation process. Of the two Fe(III) salts used, although anhydrous $FeCl_3$ exhibited a similar catalytic activity for this reaction when compared with $FeCl_3{\cdot}6H_2O$, the latter is preferred because of its higher solubility in ionic liquid, ease in handling, and lower price.

In addition, the use of several conventional organic solvents, specifically toluene, tetrahydrofuran (THF), ethyl acetate (EtOAc), and ethanol, in this catalytic process were also studied for the sake of comparison with [bmim][BF_4]. The results are also shown in Table 1. It has been shown that of the five solvents used, [bmim][BF_4] gave the highest yield for the desired product under similar reaction conditions. Thus, the use of [bmim][BF_4] as the reaction medium not only avoids the disadvantages of conventional organic solvents, such as volatility, inflammability, and potential pollution hazards, but it also results in greatly enhanced reactivity.

Based on the above results, this process was then extended to other structurally varied substrates to investigate its scope and generality. The results collected are listed in Table 2. It can be seen that under similar conditions, a wide range of ketones containing a reactive α-methylene group can undergo easy condensation with 2-aminobenzophenones to give substituted quinolines with fast reaction times and in reasonably high yields. It is worthwhile noting that both aliphatic and aromatic-aliphatic ketones gave corresponding quinoline products in almost equally fair yields. With unsymmetrical ketone substrates of the type CH_3COCH_2R, from which two different modes of cyclization are theoretically possible, condensation occurred predominantly at the more highly substituted alpha position and thus only one product was obtained (Table 2, entry 13). In addition, higher

yields were obtained using 4-nitroacetophone (Table 2, entries 3 and 11), showing that the yields of quinolines are to some extent affected by the nature of the substituents attached to the aromatic ring of the ketone.

Our attention was then directed toward the possibility of recycling the reaction media since recovery and reuse of the catalyst and solvent are highly preferable for a greener process. At completion, the reaction mixture was diluted with water and extracted with diethyl ether to obtain the desired product. Meanwhile, due to its much higher solubility in water and ionic liquid than in diethyl ether, Fe(III) ion was left and immobilized in [bmim][BF_4]. After removal of water under reduced pressure, [bmim][BF_4] together with the catalyst could be recovered almost quantitatively. Then, their reusability was investigated by using 2-aminobenzophenone and acetophenone as model substrates. It was observed that even in the sixth recycle, reuse of the ionic liquid and the catalyst recovered from the fifth recycle still gave the corresponding product in fairly good yield (Table 3, Recycle no. 6).

In conclusion, [bmim][BF_4] was proved to be a useful and alternative reaction medium, and $FeCl_3 \cdot 6H_2O$ was found to be an efficient catalyst for the preparation of quinolines. The simple experimental and product isolation procedures, combined with ease of recovery and reuse of the catalyst and the reaction media, are expected to contribute to the development of greener and waste free chemical processes for the preparation of quinolines with biological activity. Further studies to develop other new uses for ionic liquid in the preparation of heterocyclic compounds are now in progress in our laboratory.

Experimental

Melting points were measured using a Kofler micro melting point apparatus and were uncorrected. IR spectra were recorded for KBr pellets on a Bruker Vector 22 spectrometer with absorptions given in cm^{-1}. ^1H NMR spectra were obtained with a Bruker AC 400 spectrometer using $CDCl_3$ as the solvent. Chemical shifts (δ) were expressed in ppm downfield from an internal tetramethylsilane standard and coupling constants (*J*) were given in Hz. Mass spectra were recorded on a HP-5989B mass spectrometer. Elemental analyses were performed on an EA-1110 (CE Instruments) instrument.

[a]Reaction conditions: reaction time 6 h at 100 °C.

The ionic liquid [bmim][BF_4] was prepared and purified according to a literature procedure (8). All other reagents were reagent grade and were used without further purification.

General procedure for the preparation of quinoline derivatives

2-Aminobenzophenone (**1**, 1 mmol), ketone (**2**, 1 mmol) and $FeCl_3 \cdot 6H_2O$ (0.5 mmol) were added to a 10-mL round-bottom flask containing 1 mL of [bmim][BF_4]. The mixture was then stirred at 100 °C for a certain period of time to ensure complete reaction (monitored by TLC). At completion, the reaction mixture was diluted with water (5 mL) and ex-

© 2004 NRC Canada

tracted with ethyl ether (3 × 10 mL). After drying, the combined ether layers were concentrated under reduced pressure and the resulting residue was charged on a silica gel column and eluted with a mixture of ethyl acetate/*n*-hexane (1:8) to obtain product **3**. All products were fully characterized by IR, ^{1}H NMR, MS, and elemental analysis. The aqueous solution of ionic liquid and catalyst was concentrated at reduced pressure to recover the ionic liquid and catalyst for subsequent reuse.

TMAH-pyrolysis – gas chromatography – mass spectrometry analysis of residual lignin changes in softwood kraft pulp during oxygen delignification

Shiyu Fu and Lucian A. Lucia

Abstract: The residual lignins from pulps and effluent lignins from oxygen delignification effluents were characterized using pyrolysis – gas chromatography – mass spectrometry in the presence of tetramethylammonium hydroxide. The results indicated that oxidation under alkali oxygen conditions can induce fragmentation in lignin and produce more acid groups, but the lignin maintains most of its C_6–C_3 units. Oxygen delignification also led to a decrease in diphenyl structures in the residual lignin and an enrichment in concentration of lignin carbohydrate complex structures.

Key words: residual lignin, pyrolysis, oxygen delignification.

Résumé : Faisant appel à la spectrométrie de masse couplée à la chromatographie en phase gazeuse avec pyrolyse en présence d'hydroxyde de tétraméthylammonium, on a caractérisé les lignines résiduelles de pulpes et d'effluents de lignines provenant de la délignification des effluents. Les résultats indiquent que l'oxydation dans des conditions impliquant de l'oxygène en milieu alcalin peut induire une fragmentation de la lignine et conduire à une production accrue de groupes acides, mais que la lignine maintient la plupart de ses unités C_6–C_3. La délignification à l'oxygène conduit aussi à une diminution des structures diphényles dans la lignine résiduelle et à une augmentation dans la concentration des structures « LCC ».

Mots clés : lignine résiduelle, pyrolyse, délignification à l'oxygène.

Introduction

Tetramethylammonium hydroxide (TMAH) thermochemolysis or pyrolysis in the presence of TMAH was developed by Challinor (1, 2) and has gained wide acceptance as a powerful means to characterize lignin (3–6). Online TMAH thermochemolysis programs are characterized by selective cleavage of β-aryl ether linkages, while online permethylated products indicate that the structural attributes of the β-aryl ether substructures have been retained (3). Filly found that the base-catalyzed reactions caused by TMAH thermochemolysis occurred mainly where propyl-aryl ether linkages were adjacent to hydroxyl groups on the alkyl side chain (7). This suggested that phenylpropane units linked by C—C bonds or without an adjacent hydroxyl group were not released as thermochemolysis products. The functional groups in raw lignin samples are, therefore, retained in the products of thermochemolysis.

Oxygen delignification has been recognized as an efficient method to remove the bulk of the residual lignin from pulps and is widely used in mills prior to bleaching. However, the degree of lignin removal for a single oxygen stage is about 50%; further delignification would lead to excessive damage of cellulose and result in a decrease in the pulp viscosity and a loss in pulp strength (8). Residual lignin in kraft pulp is a three-dimensional polymer linked by condensed bonds and some ether linkages between dihydrophenyl propionic diphenylmethane and stilbene units, most of which are not readily hydrolysable. The structure of residual lignin in kraft pulps is significantly different from that of lignin in wood and even from lignin dissolved in black liquors from kraft cooking. During kraft pulping, aryl ethers are depleted, condensed bonds are enriched, and new links to polysaccharides are formed. Heretofore, several methods have been used in the characterization of lignin in pulping and bleaching processes: NMR (9–11), nitrobenzene oxidation, manganate oxidation (12), and the derivatization followed by reductive cleavage (DFRC) method (13, 14).

To provide a greater understanding of the structural changes occurring in kraft pulp residual lignin during the oxygen delignification process, a mill softwood kraft pulp was oxygen delignified in three stages (O-O-O), as illustrated in Fig. 1. Residual lignins were extracted from the original and delignified pulps, as were the effluent lignins from oxygen delignified liquors and all were analyzed as appropriate by the following methods: the crystallinity of the

Fig. 1. Flow diagram for the three stages in oxygen delignification and lignin isolation.

pulps, an elemental analysis of the chemical changes, NMR spectra, and the low molecular weight compounds were analyzed as in a previous report (15). This report will evaluate the molecular characterization of residual lignins from pulps and effluent lignins from oxygen delignification effluents using pyrolysis – gas chromatography – mass spectrometry (pyrolysis–GC–MS) in the presence of TMAH and will estimate the structural changes in lignin during the oxygen delignification process.

Experimental

Pulp and residual lignin preparations

Softwood kraft pulp with oxygen pretreatment from a North American paper mill was delignified with oxygen-alkaline in stages according to the following program. The oxygen delignification in each stage was done using the following conditions (final concentrations given): sodium hydroxide 2.5%, magnesium sulfate 1.5%, phenol 0.5%, consistency of pulp 12%, reaction in two phases; the first phase was under an oxygen pressure of 135 psi at 193°F (89.4 °C) for 30 min while the second phase was at 80 psi at 210°F (98.9 °C) for 60 min.

The residual lignins in the pulps were extracted with 0.1 mol/ L HCl in aqueous dioxane according to the method described by Chakar (9). The remaining lignin in the effluent after oxygen-alkaline delignification was precipitated by adding HCl until the final pH was 2.3. It was then washed with 0.002 mol/L HCl and freeze dried for thermochemolysis analysis.

Pyrolysis

Approximately 0.4 mg of the lignin sample was dissolved in 10 μL of 1 mol/L TMAH solution. The resulting lignin mixture solution was homogenously distributed on the glass fiber which had previously been inserted into a pyrolysis tube. The tube was then loaded into the pyrolysis probe (CDS Pyroprobe 1000, Chemical Data System Oxford, Pa.) and was preheated in the pyrolysis chamber at 150 °C for 10 min under purged helium gas. The lignin sample was degraded at a 360 °C pyrolysis temperature for 10 s and the pyrolysis products were immediately methylated because of the presence of 1 mol/L TMAH.

GC–MS analysis

The methylated lignin degradation products were separated and analyzed with a HP 5890 Series II gas chromatograph coupled to a HP 5971A mass selective detector. The gas chromatograph was equipped with a DB-1 column with dimensions of 15 m × 0.25 mm × 0.25 μm. The initial temperature was set at 50 °C for 1 min, and the oven temperature was then increased at a rate of 10 °C/min until a maximum temperature of 280 °C was achieved. Final time at the maximum temperature was 1 min. The solvent delay was set to 2 min. The compounds identified by GC–MS with major fragments are shown in Table 1.

Results and discussion

Analysis of pyrolysis products

The TMAH-pyrolysis method causes cleavage of β-aryl ether bonds in lignin samples followed by online methylation of degraded polyhydroxy products. The characteristics of these products can indicate the identity of lignin subunits in pulp, and can let us know the reason why residual lignins in pulp are stagnant during the oxygen alkali process and why more than 20% of residual lignins can not be removed even after three stages of delignification. The compounds identified from the pyrolysis of the lignin samples are illustrated in Fig. 2. Table 1 lists the retention times and major fragments of the corresponding components.

The isolated lignins were thermochemolysed in the presence of TMAH at 360 °C, and the main products were aromatics that contain the 3,4-dimethoxylphenyl group (veratryl units), i.e., methylated guaiacyl units (shown in Fig. 2). The major products include veratric aldehyde and acid, veratryl units with two or three carbon side chains, together with several phenols. Phenol from the identified compounds, which did not exist in the residual lignin from the original pulp, mainly originates from the residuals of the reaction system because phenol was used as an additive. The appearance of compounds **2, 4, 5, 6, 7,** and **13** (see Table 1 for a complete listing of identified compounds) was also attributed to impurities introduced during the oxygen delignification process. Compound **2** was formed through the cleavage of C_{α}—$C_{aromatic}$ bonds during thermochemolysis (16).

The glycerol backbone of the phenylpropane unit in lignins contains asymmetric carbons, which yield both a threo and an erythro form. Compounds **24** and **25** are the two diasteriomeric derivatives shown in the pyrogram through a β-O-4 ether cleavage, which is maintained as the glycerol hydroxyl group, while the other moiety of the ether linkage is lost as oxygen; therefore compound **10** was probably formed during pyrolysis. The aryl glycol compounds, **16**–**21** and **26**–**29** constituted most of the rest of the products. Compounds **17** and **19**, **20** and **21**, and, **28** and **29** were stereoisomeric pairs with identical mass spectra. Because the C_{γ}–C_{β} side chain cleavage took place during the kraft pulping process, the residual lignins of the pulp possessed two carbon side chains; therefore, a few of these products came from pyrolysis. Compounds **14**, **17**,**19**, and **22** had two carbon

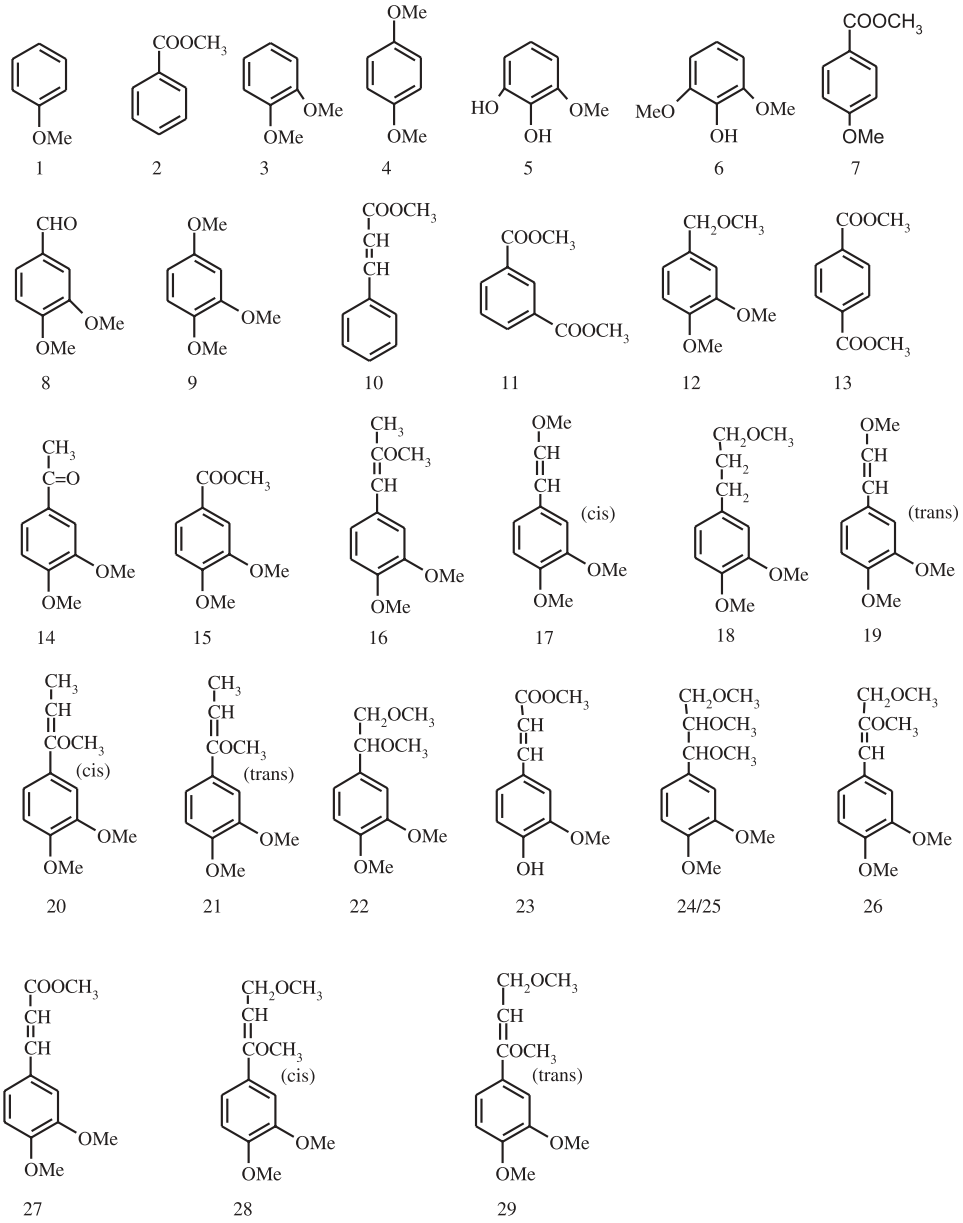
side chains. Dihydrogen conifer alcohol (17) and γ-carboxylic acid (18) are formed from the disproportionation reaction of coniferyl alcohol. The β-ether aryl-alkyl linkage units with α-hydroxyl groups form α-methoxyl veratryl propenyl products, such as compounds **20**, **21**, **28**, and **29**. The formation of compounds **16**, **17**, **19**, and **26** does not all come from α-ether aryl-alkyl linkage units, which were eliminated during the kraft pulping process, but from the enol ether structures. The chemistry of the pyrolysis of lignins in the presence of TMAH is very much akin to the chemistry of pulping. In non-phenolic lignin units, β-ether linkages are cleaved with the assistance of ionized neighboring hydroxyl groups (19). During pyrolysis, the oxidative reaction leads to 1,3-benzene dicarboxylic acid formation from the β-5 linkage of diphenyl methane structural units.

Quantitative analysis of products from pyrolysis



The operational conditions selected for the pyrolysis process appeared to be feasible for the study of residual lignin structures. Coupled with quantitative analysis, the procedure should be able to reveal the change of aryl ether linkages in lignin macromolecules during the different stages of oxygen delignification (shown in Table 2). The relative amount of products observed from lignin sample RL-B was different from the others because of contamination and therefore will not be discussed.

Vanillin, in our experiment, is responsible for 9% in the pyrograms of residual lignin from the original pulp and 7% from oxygen delignified pulp. Choi et al. (20) obtained 1.4%–2.3% vanillin in the pyrograms of residual lignin from spruce pulp. These differences in the pyrograms of residual lignin are most likely due to temperature differences in pyrolysis. It is found that the ratios of carboxylic acid to aldehyde are much different for residual lignins from the original pulp compared with the oxygen delignified pulp and effluent lignin compared with the oxygen delignified effluents (shown in Table 2). The carboxylic acid group from the residual lignin of the original pulp was less than that in residual lignin of oxygen delignified pulp and effluent lignin, which can be explained by the oxidation of lignin during oxygen delignification. Though oxidation of the side chains took place during pyrolysis (19) it is actually limited under a helium atmosphere. These results are consistent with our previous results from NMR determination (15).

In whole spruce milled wood lignin, 1-(3,4-dimethoxylphenyl)-1,2,3-trimethoxypropane constituted about 20% of all products for pyrolysis (19), but only about 4% was in our residual lignins from kraft pulp, oxygen delignified pulp, and effluent lignins. However, different pyrolysis conditions give rise to different product profiles. Pyrolysis at 600 °C in the presence of TMAH gave products including two carbon side chains containing 3,4 dimethoxybenzenes (3), whose reaction is similar to kraft pulping in inducing cleavage of the side chains in alkali. Pyrolysis at low temperatures of 310–360 °C does not cause cleavage of the phenylpropane side chains; the one carbon and two carbon

Fig. 2. Structure of compounds identified in pyrolysis of lignin samples.

side chain compounds arise mainly from the lignin samples used for pyrolysis. The C_3 side chain dimethoxybenzene units are responsible for about 34% of all products from thermochemolysis of lignin preparations, which indicates that residual lignins or effluent lignins dissolved from oxygen delignification still contain complete benzyl propane units.

Oxidation under alkali oxygen conditions can fragment lignin and produce more acid groups but the lignin can retain most of its C_6–C_3 units. The ratio of C_1 and C_2 side chain compounds to C_3 side chain compounds (shown in Table 2) demonstrates that residual lignin either from original pulp or from oxygen delignified pulps contained not many more short side chains than effluent lignins. The rationale is probable because of the loss of low molecular weight compounds from residual lignins during oxygen delignification.

The dicarboxylic acid that arises from diphenyl methane structures decreased after oxygen delignification which indicates that the diphenyl methane structures formed during the kraft process can be partly removed by oxygen delignification. Lai (21) demonstrated, using model compounds, that diphenyl methane structures subjected to oxidation under alkali oxygen conditions, led to a decrease in diphenyl methane structures in the residual lignin of oxygen delignified pulp.

Actually, it was found that the products in pyrograms of residual lignin from the 1st to the 3rd stage of oxygen delignified pulps were not much different in C_6–C_3 compounds except for 3,4-dimethoxy benzaldehyde and 3,4-dimethoxy benzoic acid methyl ester, which showed that oxidation of residual lignin in kraft pulp occurs through a peeling process. After each oxygen delignification step, the retained lignin is similar to the original residual lignin. The way to improve delignification in an alkali oxygen process would be to improve the active oxidative agents (22) and in-

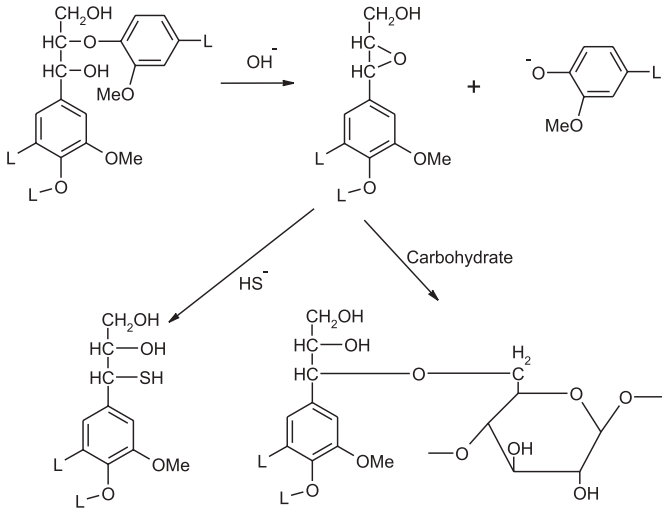
Note: Quantitative estimation of the identified compounds was made based on the response factors of 1,2,3-trimethoxy benzene, vanillin, vanillic acid, and 1-(3,4-dimethoxyphenyl)ethanone. The response factors for peak area to the compounds weight were similar. The values of relative abundance were calculated according to the weight from quantitative estimation. The heading notation in this table is explained in Fig. 1.



crease the penetrability of the reactive agent into the lignin matrix of the pulp fibers.

The possibility of lignin carbohydrate complexes (LCC)

The chemical linkages between lignin and sugars, known as lignin carbohydrate complexes (LCC) exist in native wood or are formed during the pulping process. The structural research on residual lignins in kraft pulp by Chen (18) suggested that LCC in pulp are difficult to oxidize by alkali oxygen delignification, which is one of the main reasons why residual lignin in pulps is difficult to completely remove by oxygen alkali. Gierer and Wannstrom proposed the formation of an ether linkage between a sugar moiety and a non-phenolic or phenolic lignin structure (see Fig. 3) using model compounds in kraft pulping (17, 23).

Hardell and Nilvebrant (19) have claimed that the glucose unit in model compound ***I***, which has the structure of linkage bonding lignin and carbohydrate, a model of LCC, would form 1,2,4-trihydroxy benzene under pyrolysis temperatures of 360 °C as indicated in Fig 4. When lignocellulosic materials were used, a typical pyrolysis temperature of 650 °C was required to cleave the glycosidic bonds to give this 1,2,4-trihydroxy benzene (19). However, the amount of

Fig. 4. Possible mechanism leading to the formation of 1,2,4-trimethoxy benzene (19).

pyrolysis temperatures provides evidence for the existence of LCC in lignin samples.

The amount of 1,2,4-trihydroxy benzene in the pyrograms increased for the oxygen delignified lignin. This indicated that LCC might be enriched during the delignification process. This finding was in agreement with the proposal that the presence of LCC during oxygen delignification may constitute a barrier to delignification since LCC strongly resist degradation even under alkaline oxygen conditions.

Conclusions

Pyrolysis of lignin under 360 °C in the presence of TMAH led to cleavage in lignin aryl ether linkages and generated methyl derivatives. The results of pyrolysis indicated that oxidation under alkali oxygen conditions can fragment lignin and generate more acid groups, but lignin can retain most of its C_6–C_3 units. The step-wise degradation of lignin generated low molecular weight compounds and caused the dissolution of effluent lignin during oxygen delignification. Oxygen delignification led to a decrease in diphenyl structures in residual lignin, whereas the identification of 1,2,4-trihydroxy benzene may serve to indicate the presence of LCC in lignin. LCC also appear to be enriched during the oxygen delignification process.

Acknowledgement

The authors thank Dr. Rallming Yang for his pyrolysis–GC–MS analyses and gratefully acknowledge the United States Department of Energy for financial support (Contract DE-FC07–02ID14261), the member companies of the Institute of Paper Science and Technology, and the Georgia Institute of Technology for the use of their facilities. Voltammetric behavior and quantification of the anti-leukemia drug imatinib in bulk form, pharmaceutical formulation, and human serum at a mercury electrode

E. Hammam, H.S. El-Desoky, A. Tawfik, and M.M. Ghoneim

Abstract: Imatinib (Gleevec™, ST1571) exemplifies the successful development of a rationally designed molecularly targeted therapy for treatment of a specific cancer. It is a highly promising new drug for the treatment of chronic myelogenous leukemia in blast crisis, in the accelerated or chronic phase after interferon failure or intolerance. The electrochemical behavior of imatinib was studied in Britton–Robinson (B–R) buffers of pH 2 to 11 by means of cyclic voltammetry at a hanging mercury drop electrode. The voltammograms showed a single 2-electron irreversible cathodic peak, which may be attributed to reduction of the C=O double bond of the imatinib molecule. Imatinib exhibited a strong adsorption onto the electrode surface especially in B–R buffers of pH 6 and 7. The adsorptive response of the drug was optimized with respect to the pH of the electrolysis medium, accumulation variables, and instrumental parameters using a square-wave stripping voltammetry technique. A fully validated, simple, sensitive, precise, and selective square-wave adsorptive cathodic stripping voltammetric procedure is described for trace determination of imatinib. The limits of detection (LOD) and quantitation (LOQ) of the bulk imatinib, following preconcentration for 150 s onto the hanging mercury drop electrode, were found to be 2.6×10^{-10} and 8.7×10^{-10} mol/L, respectively. The proposed procedure was successfully applied for quantitation of imatinib in pharmaceutical formulation (Glivec®) and spiked human serum, without the necessity for sample pretreatment or time-consuming extraction or evaporation steps prior to analysis of the drug. LOD and LOQ of 4.6×10^{-10} and 1.5×10^{-9} mol/L, respectively, were achieved after 120 s of preconcentration of the drug spiked in human serum.

Key words: imatinib, Gleevec™, Glivec®, ST1571, cyclic voltammetry, square-wave stripping voltammetry, electrochemical behavior, quantification, pharmaceutical formulation, human serum.

Résumé : L'imatinib (Gleevec™, ST1571) est un exemple du développement avec succès d'une thérapie orientée d'une façon moléculaire du traitement d'un cancer spécifique mis au point d'une façon rationnelle. Il s'agit d'un nouveau médicament très prometteur pour le traitement de la leucémie myélogéneuse chronique en phase de crise, en phase accélérée ou en phase chronique, après l'échec d'un traitement ou une intolérance à l'interféron. On a étudié le comportement électrochimique de l'imatinib dans des tampons de Britton–Robinson, à des pH allant de 2 à 11, en faisant appel à la voltampérométrie cyclique à électrode avec goutte de mercure suspendue. Les voltampérogrammes présentent une seule vague cathodique irréversible à deux électrons qui peut être attribuée à la réduction de la double liaison C=O de la molécule d'imatinib. L'imatinib présente un fort caractère absorbant sur la surface de l'électrode, particulièrement dans le tampon de Britton–Robinson de pH 6 et 7. La réponse absorbante du médicament a été optimisée par rapport au pH du milieu électrolytique, des variables d'accumulation et des paramètres expérimentaux en faisant appel à la voltampérométrie à vague carrée. On décrit une méthode sélective, précise, sensible, simple et validée de voltampérométrie cathodique d'absorption à vague carrée pouvant être utilisée pour la détermination de traces d'imatinib. On a déterminé que les limites de détection (LDD) et de quantification (LDQ) du médicament global, suivant une préconcentration de 150 s sur l'électrode à goutte pendante de mercure, sont respectivement de $2{,}6 \times 10^{-10}$ et de $8{,}7 \times 10^{-10}$ mol/L. La méthode proposée a été appliquée avec succès à la quantification de l'imatinib dans la formulation pharmaceutique (Glivec®) et dans du sérum humain additionné d'imatinib, sans devoir soumettre les échantillons, avant l'analyse du médicament, à des prétraitements, de longues étapes d'extraction ou d'évaporation. Les valeurs obtenues pour les limites de détection et de quantification de sérum humain additionné du médicament, à la suite d'une préconcentration de 120 s, sont respectivement de $4{,}6 \times 10^{-10}$ et de $1{,}5 \times 10^{-10}$ mol/L.

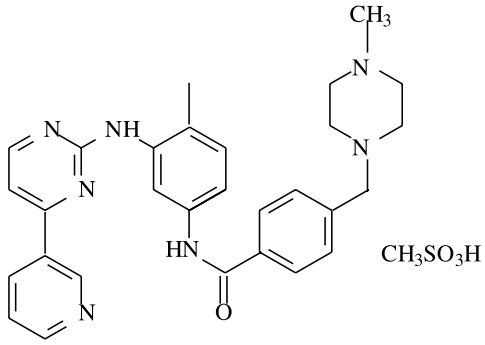
[Traduit par la Rédaction]

Introduction

Imatinib mesylate (Scheme 1), also known as Gleevec™, Glivec® or ST1571, (4-[(4-methyl-1-piperazinyl) methyl]-*N*-[4-methyl-3-[[4-(3-pyridinyl)-2-pyrimidinyl] aminophenyl] benzamide methanesulfonate), is a protein-tyrosine kinase inhibitor that potently inhibits the Abelson (Abl) tyrosine kinase in vitro (1–3) and in vivo (4–8).



The drug selectively inhibits proliferation and induces apoptosis in Bcr-Abl positive cell lines as well as in fresh leukemia cells from Philadelphia chromosome positive chronic myelogeous leukemia (CML) and acute lymphoblastic leukemia (ALL) patients. In colony transformation assays using ex vivo peripheral blood and bone marrow samples, the drug shows selective inhibition of Bcr-Abl positive colonies from CML patients. In vivo, imatinib shows anti-tumor activity as a single agent in animal models using Bcr-Abl positive tumor cells. In addition, the drug is a potent inhibitor of the receptor tyrosine kinases for platelet-derived growth factor (PDGF) and stem cell factor (SCF), c-kit, and inhibits PDGF- and SCF-mediated cellular events. Imatinib has been shown to inhibit the growth of glioblastoma cells injected into the brains of nude mice, suggesting that this agent could have potential as a therapy for this currently incurable disease. Imatinib is used for the treatment of patients with CML in blast crisis, accelerated phase, or in chronic phase after failure of interferon-alpha therapy.

To date, six assays for the determination of imatinib in plasma including liquid chromatography tandem mass spectrometry (LC–MS–MS) (9, 10), liquid chromatography electro spray ionization mass spectrometry (11), isocratic reverse-phase liquid chromatography UV spectrometry (12), isocratic high-performance liquid chromatography tandem mass spectrometry (13), and capillary zone electrophoresis (14), have been published. While most of these assays provided the sensitivity and speed that were necessary for quantitation of imatinib in different samples, all necessitate sample pretreatment or time-consuming separation steps prior to analysis of the drug. Besides, most of the chromatographic methods use LC–MS–MS technology, which is expensive and not widely available.

In our opinion, the clinical and pharmacological studies of imatinib still require more facile, sensitive, simple, and low cost analytical methods for its determination in different samples. The remarkable sensitivity, broad scope, and low cost of stripping voltammetric analysis have led to its application in several analytical problems (15).

We describe here, for the first time, the electrochemical behavior of imatinib in Britton–Robinson (B–R) buffers of pH 2 to 11 at a hanging mercury drop electrode. In addition, a simple fully-validated, low cost square-wave adsorptive cathodic stripping voltammetric procedure for quantitation of imatinib in bulk, pharmaceutical formulation, and spiked in human serum is described. The procedure does not require sample pretreatment or time-consuming extraction or evaporation steps prior to analysis of the drug.

Scheme 1.

Experimental

Apparatus and software

The voltammetric measurements were carried out using the PAR (Princeton Applied Research, Princeton, N.J.) Electrochemical Analyzer Models 394 and 263A, interfaced with a personal computer loaded with the software package 270/250 (PAR). The electrode assembly (303A-PAR) and a micro-electrolysis cell incorporating a three electrode configuration system consisting of a hanging mercury drop electrode (HMDE) as a working electrode (area: 0.026 cm^2), an Ag/AgCl (saturated KCl) reference electrode, and a platinum wire auxiliary electrode were used in this study. The solution was stirred in the electrochemical cell, using a magnetic stirrer (305-PAR) and a stirring bar, to provide convective transport during the preconcentration step. All measurements were automated and controlled through the programming capacity of the apparatus.

A Mettler balance (Toledo–AB104, Switzerland) was used for weighing the solid materials. An Orion SA 720 pH-meter with combined glass and saturated calomel electrodes was used for the pH measurements. The de-ionized water was supplied from a Purite–Still Plus de-ionizer connected to an AquaMatic (Hamilton Laboratory Glass Ltd., Kent, UK) double-distillation water system.

Reagents and solutions

Bulk drug solutions

Standard stock solutions (10^{-3}–10^{-5} mol/L) of imatinib (Novartis, East Hanover, N.J.) were prepared in methanol (Merck) and were then stored in the dark at 4 °C. Working solutions were obtained by appropriate dilution of the standard stock solution with methanol, then kept in the dark immediately after preparation.

Glivec® solutions

The drug content of five capsules of Glivec® (Novartis Pharm. AG, Basle, Switzerland, labeled as containing 100 mg/capsule) were weighed and then ground to a homogeneous fine powder in a mortar. A portion of the powder equivalent to 50–100 mg of imatinib was accurately weighed

© 2004 NRC Canada

and transferred to a 100-mL calibrated flask, then made up to volume with methanol. The content of the flask was sonicated for at least 10 min to effect complete dissolution. The solution was next filtered through a 0.45-μm Millipore filter (Gelman, Germany) and then kept in the dark at 4 °C. The drug solutions were stable and their concentrations did not change with time.

Imatinib spiked in human serum

Serum samples collected from healthy volunteers were stored frozen until assay. An aliquot of the standard stock solution of imatinib was fortified with serum sample. A 100-μL aliquot of this solution was diluted to 1.0 mL with methanol (to precipitate the proteins originally present in the blood sample) in a small centrifuge tube. The precipitated proteins were removed by centrifugation for 5 min at 14 000 rpm. The clear supernatant layer was filtered through a 0.45-μm Millipore filter to produce protein-free spiked human serum solution, which was then stored in the dark at 4 °C.

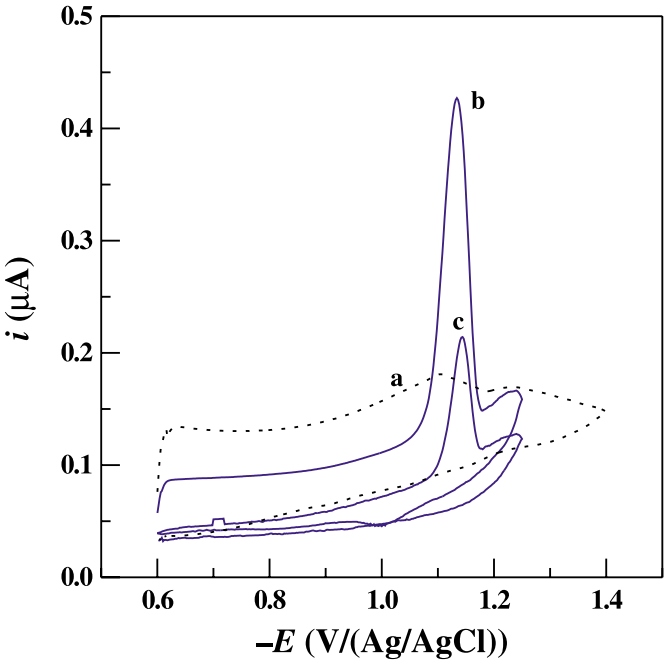
Supporting electrolyte

B–R buffers of pH 2 to 11 were prepared by mixing equal volumes of 0.04 mol/L acetic, 0.04 mol/L boric, and 0.04 mol/L orthophosphoric acids (16) to serve as supporting electrolytes. The pH of the solution was adjusted with an appropriate amount of 0.2 mol/L sodium hydroxide solution.

All chemicals were analytical reagent grade and were used without further purification.

General analytical procedure

For stripping voltammetric measurements, an aliquot of the analyte solution was transferred quantitatively into a 10-mL calibrated flask and made up to volume with B–R buffer of the appropriate pH value. The solution was transferred into a dark electrolysis cell, then deoxygenated with pure nitrogen for 10 min. A selected accumulation potential was applied to the working electrode for a selected time period while the solution was stirred. At the end of the accumulation period the stirrer was stopped and a 5 s time period was allowed for the solution to become quiescent. Then the voltammograms were recorded by scanning the potential toward the negative direction using the square-wave waveform and the peak heights were measured. All data were obtained at room temperature.



To study the reproducibility, accuracy, and precision of the proposed procedure in determining the drug in bulk, capsule, and human serum samples, recovery experiments were carried out using both the calibration curve and standard addition methods.

Results and discussion

Cyclic voltammetry

The cyclic voltammograms for 1×10^{-4} mol/L imatinib at the HMDE in B–R buffers of pH 2–11 exhibited a single 2-electron irreversible cathodic peak over the whole pH range. The peak current (i_p) was practically pH-independent. This peak may be attributed to reduction of the C=O double bond of the reactant molecule. The peak potential shifted to more negative values with increasing pH, indicating the involvement of protons in the electrode reaction and the proton-transfer reaction preceding the electrode process proper (17). Accordingly, the general sequence of the reduction process of imatinib is: proton, electron, proton, electron (H^+, e, H^+, e) (17). The irreversible nature of the cathodic reaction of imatinib at the HMDE was confirmed from the shift of peak potential (E_p) to more negative values upon increasing the scan rate (ν).

Fig. 1. Cyclic voltammograms for 5×10^{-7} mol/L imatinib: (*a*) without preconcentration for an accumulation time (t_{acc}) of 0 s, (*b*) following preconcentration for t_{acc} = 30 s at an accumulation potential (E_{acc}) = –0.6 V, and (*c*) the repetitive cycle at the same mercury drop; scan rate ν = 100 mV/s.

The adsorptive character of imatinib onto the HMDE was identified from the study of cyclic voltammograms for 5×10^{-7} mol/L imatinib in a B–R buffer of pH 6 (Fig. 1) without preconcentration (curve a) and following preconcentration for 30 s (curve b) at –0.6 V. In a repetitive cycle at the same mercury drop (curve c), the peak height significantly decreased, which may be attributed to desorption of the drug species from the mercury electrode surface. This behavior indicates the adsorption of imatinib onto the HMDE during the preconcentration step. The interfacial adsorptive character of imatinib onto the mercury electrode surface in B–R buffers of pH 2–11 was also identified from plots of log i_p (after preconcentration of the drug for 30 s) against log ν, at different pH values; straight lines were obtained. The slope values of 0.85–0.96 were obtained for the pH values of 6 and 7 and agree well with the theoretical value of 1.0 which is expected for an ideal reaction of surface species (18). The result confirms again the adsorptive character of imatinib onto the HMDE surface during the preconcentration step, especially in B–R buffers of pH 6 and 7.

The electrode surface coverage

The electrode surface coverage, Γ_o (the amount of reactant adsorbed onto the working electrode surface), was calculated from the total charge (Q_{total}) consumed by the surface pro-

© 2004 NRC Canada

cess, which was estimated by integration of the area under the peak of the cyclic voltammogram of 5×10^{-7} mol/L imatinib in a B–R buffer of pH 6, corrected for the residual current (19). The surface coverage Γ_o (mol cm^{-2}) was calculated according to the equation $\Gamma_o = Q/nFA$, where n is the number of electrons consumed in the reduction process (n = 2), F is Faraday's constant (96 487 C), and A is the electrode surface area (0.026 cm^2). On dividing the number of coulombs transferred, 0.91 μC, by the conversion factor (nFA), a Γ_o value of 1.8×10^{-10} mol cm^{-2} was obtained, and each adsorbed imatinib molecule therefore occupies an area of 0.93 nm^2.

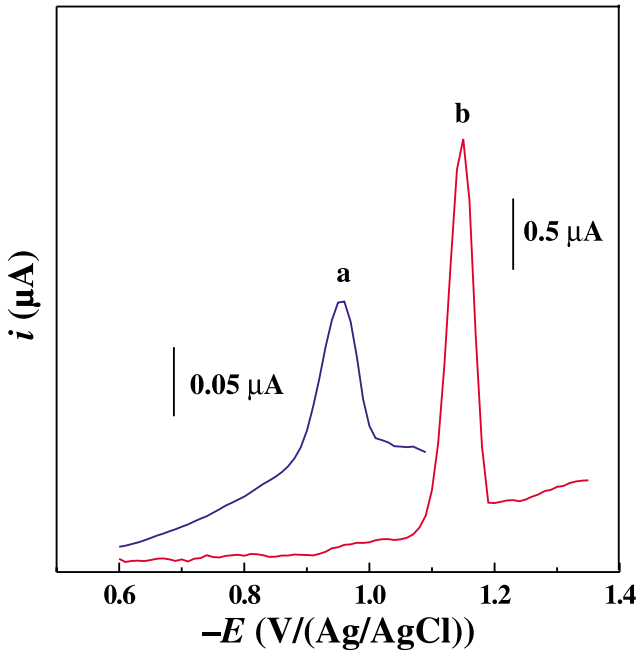
A value for Γ_o was also estimated from chronocoulometry experiments for 10 mL of B–R buffer of pH 6 alone (blank) and in the presence of 1×10^{-5} mol/L imatinib. The Q_{total} versus square root of time ($t^{1/2}$) plots were obtained for the blank alone and in the presence of imatinib after its preconcentration for 30 s onto the HMDE. The amount of reactant adsorbed onto the mercury electrode surface in mol cm^{-2} was estimated by applying the following relation (20)

$$Q_{total} = Q_{diff} + Q_{ads} + Q_{dl}$$

$$Q_{total} = \int_0^t i\mathrm{d}t = \frac{2nFACD^{1/2}t^{1/2}}{\pi^{1/2}} + nFA\Gamma + Q_{dl}$$

where Q_{total} is the total charge, Q_{diff} is the charge required to reduce the reactant species in solution at a diffusion-controlled rate, Q_{ads} is defined below, Q_{dl} is the double layer charge (blank), C is the concentration (mol/L) of the reactant, and D is the diffusion coefficient (cm^2 s^{-1}) of the reactant species. The plot of the Q_{total} vs. $t^{1/2}$ has an intercept equal to ($nFA\Gamma_o + Q_{dl}$). Since Q_{dl} was measured in a separate experiment for the supporting electrolyte alone (blank), the contribution of the adsorbed species of the drug was determined and then the Γ_o was estimated.

$$Q_{dl} = 2.7920\ t^{1/2} + 0.0546 \text{ (blank)}$$



$$Q_{total} = 2.1825\ t^{1/2} + 0.8586 \text{ (imatinib)}$$

The difference between the intercepts of Q_{total} and Q_{dl} is the amount of charge required to reduce the adsorbed reactant species (Q_{ads}). Thus the Γ_o was found to equal 1.6×10^{-10} mol cm^{-2}, and each adsorbed imatinib molecule therefore occupies an area of 1.1 nm^2, which agrees well with the value obtained from cyclic voltammetry measurements. The diffusion coefficient ($D°$) of imatinib in a B–R buffer of pH 6 was also estimated from the slope of the Q_{total} vs. $t^{1/2}$ plot and found to equal 1.49×10^{-7} cm^2 s^{-1}.

Adsorptive stripping voltammetry

In order to develop a voltammetric methodology for determination of the drug, comparative voltammograms for 5×10^{-8} mol/L imatinib in a B–R buffer of pH 6 following preconcentration for 60 s at –0.6 V (vs. Ag/AgCl/KCl$_s$) were recorded applying: (*a*) differential-pulse (pulse-height a = 25 mV and ν = 10 mV/s) and (*b*) square-wave (scan increment ΔE = 10 mV, frequency f = 120 Hz, and a = 25 mV) waveforms. The square-wave peak signal (i_p = 2.5 μA and peak potential E_p = –1.14 V) was more developed compared to that of the differential pulse (i_p = 0.14 μA and E_p = –0.95 V) waveform (Fig. 2). Thus, the square-wave waveform was preferred for the present study, since the cathodic peak was sharper and its current more developed even for low concentrations of the drug.

Fig. 2. Adsorptive cathodic stripping voltammograms for 6×10^{-8} mol/L imatinib in a Britton–Robinson (B–R) buffer of pH 6 using: (*a*) Differential-pulse (pulse-height a = 25 mV and ν = 10 mV/s) and (*b*) square-wave (pulse-height a = 25 mV, frequency f = 120 Hz, and scan increment ΔE = 10 mV) waveforms; t_{acc} = 90 s, E_{acc} = –0.6 V, stirring rate = 400 rpm, and rest period = 5 s.

Operational parameters of square-wave procedure

Effect of pH

In general, the pH of the electrolysis medium is one of the variables that commonly and strongly influences the shape of voltammograms. Thus, it was important to investigate the effects of pH on the electrochemical behavior of imatinib. The square-wave adsorptive cathodic stripping (SWAdCS) voltammograms recorded for 1×10^{-7} mol/L imatinib in B–R buffers of pH 2–11, following preconcentration of the drug for 30 s onto the HMDE, exhibited a single irreversible peak over the whole pH range (Fig. 3). A more developed peak current was obtained in B–R buffers of pH 6 and 7.

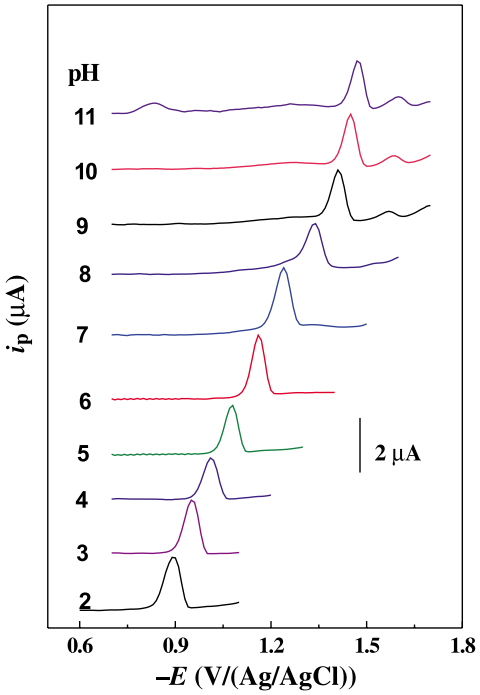
Effect of accumulation time and potential

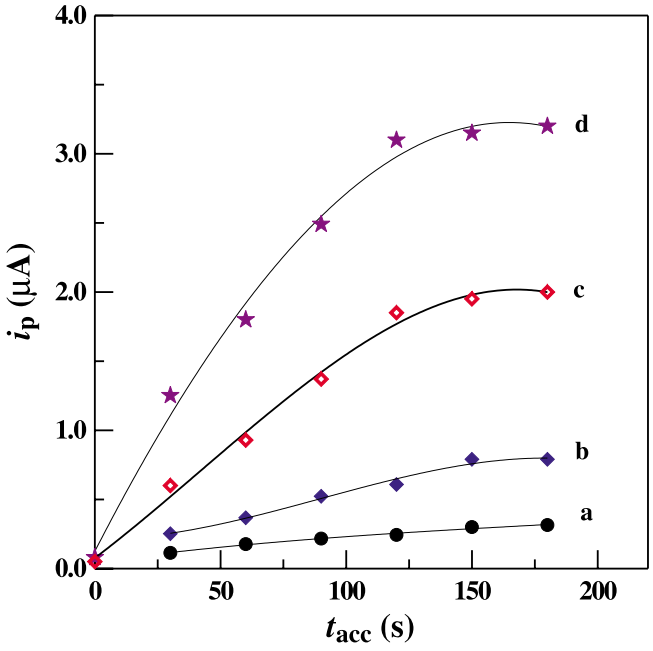
The effect of accumulation time (t_{acc}) on the peak current at a selected potential was studied. Four concentrations of bulk imatinib (3×10^{-9}, 7×10^{-9}, 2×10^{-8}, and 6×10^{-8} mol/L) were analyzed in a B–R buffer of pH 6 at different accumulation time periods, while the accumulation potential was kept constant at –0.6 V. As shown in Fig. 4, the response was linear up to about 150 or 120 s for imatinib concentrations lower or higher than 2×10^{-8} mol/L, respectively.

To determine the optimal accumulation potential, the potential range of 0 to –1.1 V was examined for 7×10^{-8} mol/L imatinib in B–R buffer of pH 6, following pre-

© 2004 NRC Canada

Fig. 3. Square-wave adsorptive cathodic stripping (SWAdCS) voltammograms for 1×10^{-7} mol/L imatinib in B–R buffers of different pH values 2–11; t_{acc} = 30 s, E_{acc} = –0.6 V, f = 120 Hz, ΔE = 10 mV, and a = 25 mV. Other operational parameters are as described in the caption of Fig. 2.





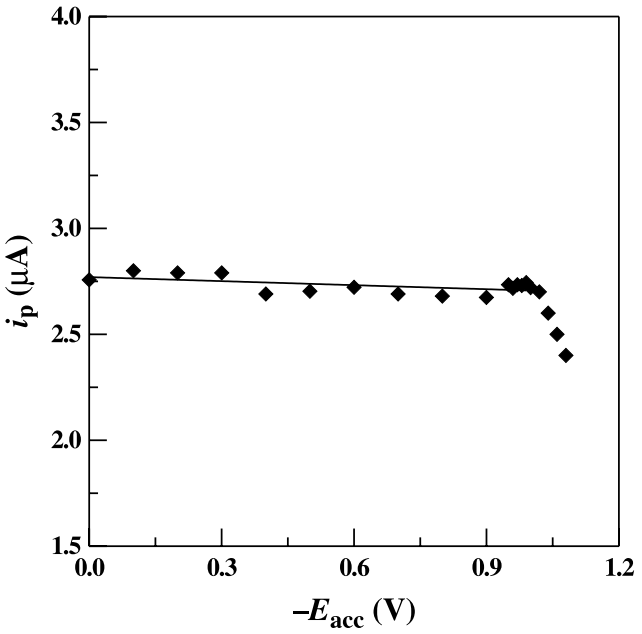


Fig. 4. Effect of t_{acc} on SWAdCS voltammetric peak current at different concentrations of imatinib: (*a*) 3×10^{-9}, (*b*) 7×10^{-9}, (*c*) 2×10^{-8}, and (*d*) 6×10^{-8} mol/L in a B–R buffer of pH 6; E_{acc} = –0.6 V. Other operational parameters are as described in the caption of Fig. 2.

concentration for 90 s. The accumulation potential had no obvious effect on the peak height over the range 0 to – 0.9 V (Fig. 5).

Fig. 5. Effect of E_{acc} on SWAdCS voltammetric peak current for 7×10^{-8} mol/L imatinib in a B–R buffer of pH 6; t_{acc} = 90 s. Other operational parameters are as described in the caption of Fig. 2.

The optimum instrumental conditions were identified from a study of the variation in peak current, for 5×10^{-8} mol/L imatinib in a B–R buffer of pH 6, with frequency, scan increment, and pulse-amplitude. A more developed peak current was achieved with high frequencies of the order 120 Hz. Higher peak current was also obtained by increasing the pulse-amplitude up to 25 mV and the scan increment up to 10 mV without loss of resolution, i.e., the peak half-width remains almost constant. According to the foregoing results, the following parameters were chosen as the optimal operational conditions for the proposed stripping procedure: an accumulation potential (E_{acc}) = –0.6 V, t_{acc} = 120–150 s, frequency (f) = 120 Hz, pulse amplitude = 25 mV, and scan increment 10 mV using a B–R buffer of pH 6 as the supporting electrolyte.

Validation of the analytical procedure

The SWAdCS voltammograms of different concentrations of bulk imatinib standard solutions following preconcentration onto the HMDE for different time periods (30–150 s) were recorded five times for each concentration under the optimized operational conditions of the proposed procedure. The corresponding calibration graphs were linear over the concentration ranges reported in Table 1. The limits of detection (LOD) and quantitation (LOQ) were calculated (Table 1) using the following equations: LOD = 3 s/m and LOQ = 10 s/m, respectively (21), where s is the standard deviation of the blank and m is the slope of the calibration curve.

The selectivity (22) of the optimized procedure for assays of imatinib was identified by studying the effect of various substances that often accompany the drug in various pharmaceutical preparations. An attractive feature of an analytical procedure is its relative freedom from interference by the usual occupants such as cellulose, magnesium searate, glu-

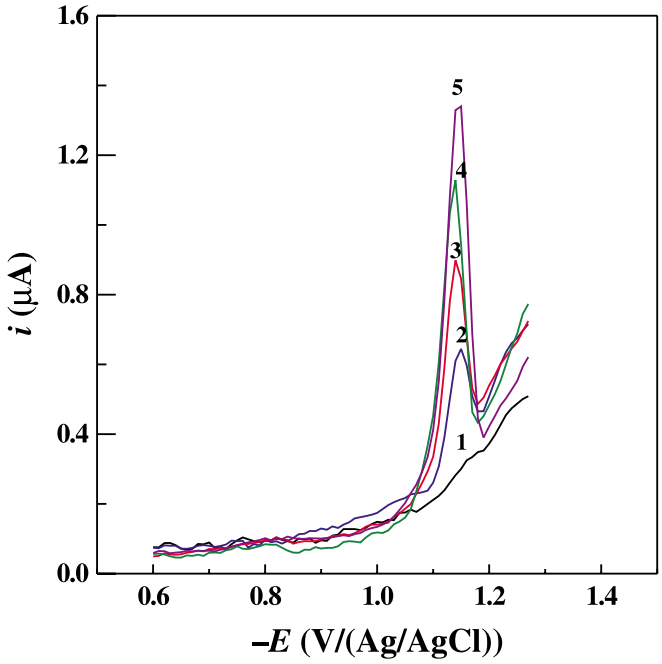
cose, lactose, dextrose, and starch. Samples containing 5×10^{-8} mol/L bulk imatinib and different concentrations of the occupants under evaluation were analyzed by means of the proposed procedure. The obtained mean percentage recoveries (%R) and relative standard deviations (%RSD), based on three replicate measurements, (98.5 ± 1.6 – 100.1 ± 1, respectively) showed that there was no significant interference from occupants. Thus the procedure was able to assay imatinib in the presence of occupants and it can, therefore, be considered selective.

The proposed procedure analysis accuracy (22) was evaluated by calculating any systemic error involved. The estimated mean percentage recoveries of imatinib (97.8 ± 1.2 – 98.6 ± 1.5) indicated the high accuracy of the proposed analysis procedure.

The intra-day and inter-day precision (22) of the method was determined by analyzing different concentrations of imatinib for three times in one day and for five days over a period of one week. The intra-day and inter-day coefficients of variation of imatinib recovery (1.1–1.5) indicated good repeatability confirming the high precision of the proposed procedure.



The robustness (22) of the proposed analysis procedure was also examined by evaluating the influence of small variations in some of the most important procedural conditions including pH, preconcentration time period, and preconcentration potential. The mean percentage recoveries obtained (97.7 ± 1.2 – 98.5 ± 1.3) were not significantly affected within the operational parameter variation range studied, and consequently the proposed analysis procedure was reliable for assay of imatinib and it can be deemed robust.

Application

Assay of imatinib in capsules

The proposed procedure was successfully applied for direct assay of imatinib in its pharmaceutical formulation (Glivec® capsules) without the necessity for sample pretreatment or any time-consuming extraction or evaporation steps prior to analysis of the drug The %R obtained using the standard addition method (Table 2) and the corresponding %RSD verified the accuracy of the proposed procedure for assay of the drug in capsules.

erages of five replicate measurements, at different concentrations of imatinib spiked in human serum using the standard addition method (Table 3).

Conclusion

The electrochemical behavior of imatinib in B–R buffers of pH 2–11 at a HMDE was studied for the first time. The drug was found to exhibit strong adsorption onto the electrode surface over the pH values 6 and 7. A SWAdCS voltammetric procedure for quantification of imatinib in bulk form, pharmaceutical formulation, and spiked in human serum was described. The developed procedure was facile, fast, sensitive, selective, and inexpensive; as well it did not require sample pretreatment or any time-consuming extraction or evaporation steps prior to analysis of the drug. The procedure could possibly be adopted for use in clinical and quality control laboratories.

Identification of glycerophospholipids in rapeseed, olive, almond, and sunflower oils by LC–MS and LC–MS–MS

Sadok Boukhchina, Khaled Sebai, Ammar Cherif, Habib Kallel, and Paul M. Mayer

Abstract: HPLC employing a thermostatted Lichrospher 100 diol column was used to separate mixtures of glycerophospholipids of rapeseed, olive, almond, and sunflower oils. Elution was performed with a binary gradient of two mixed solvents A: hexane – isopropanol – acetic acid – triethylamine (82:17:1.0:0.08 v/v/v/v) and B: isopropanol – water – acetic acid – triethylamine (85:14:1.0:0.08 v/v/v/v). The LC effluent was directly introduced into the mass spectrometer through an electrospray capillary. Information about the fatty acid composition of each glycerophospholipid class was given by tandem mass spectrometry (MS–MS). These techniques permitted a rapid separation and identification of complex mixtures of glycerophospholipids. The relative abundance of each lipid class in each oil was also determined. The resulting glycerophospholipid signature may provide an efficient means of identifying oil origin and possible adulteration.

Key words: glycerophospholipids, vegetable oils, tandem mass spectrometry, LC–MS.

Résumé : Faisant appel à la chromatographie liquide à haute performance et une colonne de diol Lichrospher 100 maintenue à température constante, on a séparé les mélanges de glycérophospholipides d'huiles de colza, d'olive, d'amande et de tournesol. On a effectué l'élution à l'aide de gradients binaires de deux solvants mixtes, A: hexane – isopropanol – acide acétique – triéthylamine (82:17:1,0:0,08 v/v/v/v) et B: isopropanol – eau – acide acétique – triéthylamine (85:14:1,0:0,08 v/v/v/v). Les effluents des chromatographies liquides ont été introduits directement dans un spectromètre de masse par le biais d'un capillaire à électronébulisation. On a obtenu l'information relative à la composition en acide gras de chaque classe de glycérophospholipide à partir d'un tandem de spectrométrie de masse (SM/SM). Ces techniques ont permis d'effectuer une séparation et une identification rapides de mélanges complexes de glycérophospholipides. On a aussi déterminé l'abondance relative de chaque classe de lipide dans chacune des huiles. Les signatures de glycérophospholipides résultantes pourraient fournir une méthode efficace d'identifier l'origine d'une huile et éventuellement de déterminer s'il y a eu adultération.

Mots clés : glycérophospholipides, huiles végétales, spectrométrie de masse en tandem, chromatographie liquide – spectrométrie de masse.

[Traduit par la Rédaction]

Introduction

Glycerophospholipids constitute a principal class of membrane lipids. They are comprised of a glycerol backbone in which two alcohol substituents have been replaced with fatty acid side chains and the third has been phosphorylated. They play a role in both the physical structure of the cell membrane and in the various phenomena linked to the functioning of these membranes such as selective permeability, active transportation, and electrical conductivity.

The various classes of glycerophospholipids are derived from phosphatidate (diacylglycerol-3-phosphate) which itself is not usually a prominent membrane phospholipid but is involved in their biosynthesis. The phosphate group of the phosphatidate is esterified by the hydroxyl group of various alcohols such as ethanolamine, choline, inositol and glycerol (Fig. 1). This variety makes their separation and analysis with classical techniques difficult.

The conventional method for analysing glycerophospholipids required a preliminary separation by thin layer chromatography (TLC) (1) followed by enzymatic hydrolysis to permit their separation and detection by gas chromatography (GC) (2). To enhance the resolution of the often complex mixtures of lipids, high performance liquid chromatography (HPLC) has largely supplanted TLC (3–6). A combination of HPLC and GC methods has been proposed to resolve the complex mixtures of potato tuber and tobacco leaf glycerophospholipids into the various molecular species present in each lipid class (7). Liquid chromatography – mass spectrometry (LC–MS) employing a thermospray interface has

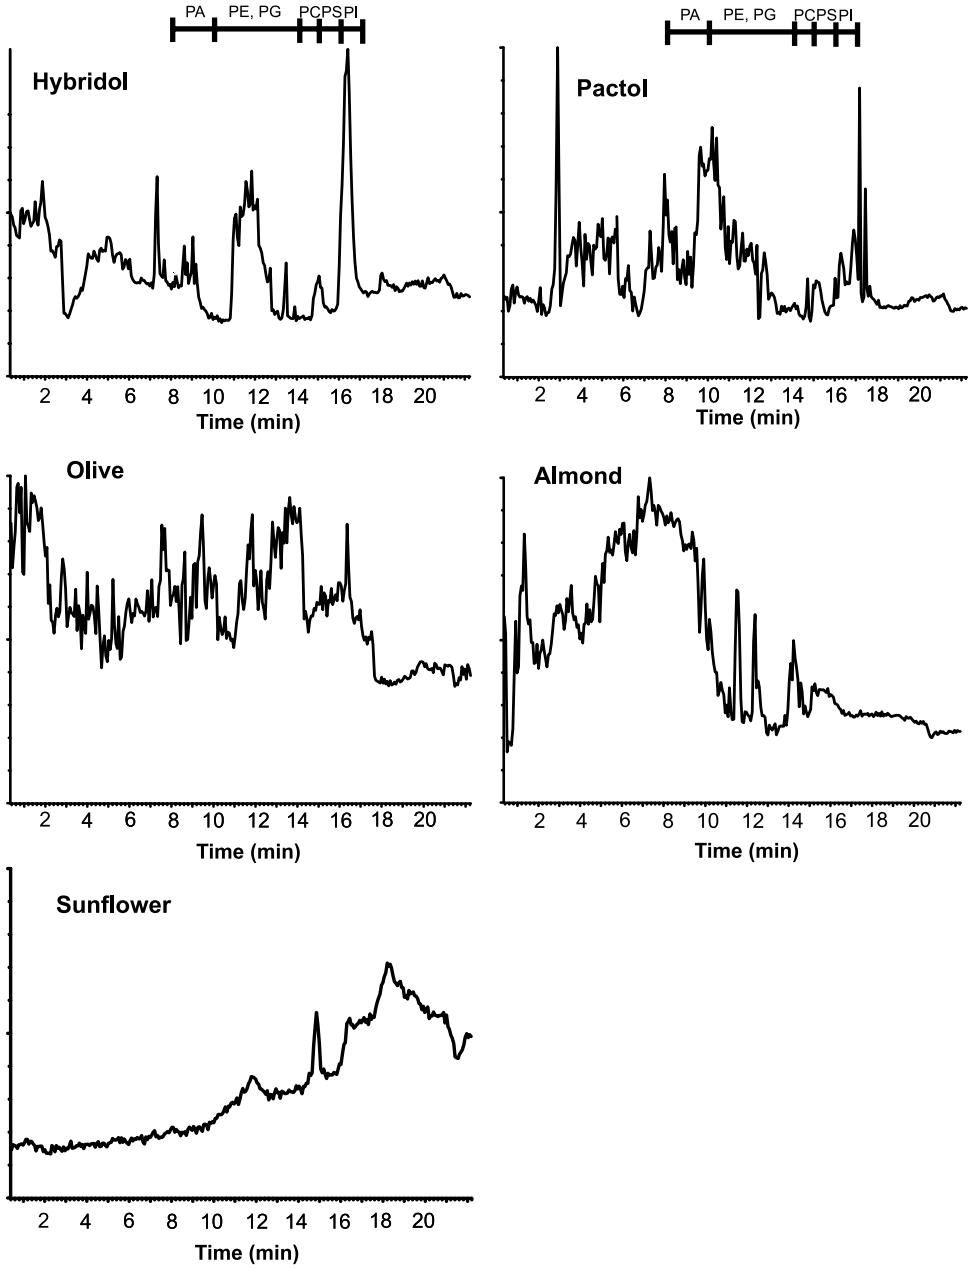
[a]No glycerophosphatidylserines were observed in the oil samples reported here.

Fig. 1. Chemical structures of glycerophospholipid classes: phosphatidic acid (PA), phosphatidylglycerol (PG), phosphatidylethanolamine (PE), phosphatidylcholine (PC), phosphatidylserine (PS), phosphatidylinositol (PI). Fatty acid groups R1 and R2 vary within each class and are typically denoted according to carbon chain length and number of double bonds (e.g., C18:1 denotes a fatty acid chain of length 18 carbons (including the carbonyl carbon) containing one double bond).

been used to determine the molecular species of several components of the lipid classes (8) but the procedure still required that the fatty acids be analysed by GC. Off-line coupling of HPLC separation with fast-atom bombardment (FAB) mass spectrometry has also been used in the analysis of phospholipids in peanuts (9). There have been considerable efforts in the last few years to identify glycerophospholipids by electrospray-tandem mass spectrometry (10) and all have focussed on the analysis of positive lipid ions (either protonated lipids or ones complexed by a metal ion). The tandem mass spectra obtained in positive ion mode, however, are quite complex and requiring extensive interpretation (10). Recently, a sensitive method has been described for the separation and identification of glycerophospholipids derived from fungi and pollen in air samples by negative ion LC–MS and tandem mass spectrometry (MS–MS) (11). The tandem mass spectra obtained for negatively charged lipids are very simple and typically contain only peaks due to the fatty acid side chains, thus allowing their identification.

In the present study, we have employed LC–MS and LC–MS–MS as a rapid separation and identification tool for the complex mixtures of glycerophospholipids found in five vegetable oils: the oils from two forms of rapeseeds (Hybridol and Pactol), olives, almonds, and sunflowers. Tandem mass spectrometry is used to aid in the identification of lipid class and fatty acid composition. The information provides a unique glycerophospholipid signature for each kind of oil, which may be used to improve purity tests for these oils that face frequent adulteration.



Experimental procedures

Olive oil was commercially obtained (Almoubaraka). Rapeseeds (*Brassica napus* L.) of the variety Pactol and Hybridol, almonds and sunflower seeds were provided by the Institut de Recherches Agronomiques de Tunis. Total lipids were extracted by a modified Bligh and Dyer method (12). The seeds were put in boiling water for 5 min to inactivate the phospholipases and were then finely crushed with a mortar and pestle. Lipids were extracted with a mixture of chloroform and methanol (1:1, v/v). Fixing water was added at the end of the extraction to eliminate nonlipid components. The extract was centrifuged at 3000 rpm for 15 min. The final chloroform extract was evaporated using a rotary evaporator at 35 °C and finally dried under a stream of nitrogen. The extracted was stored at –10 °C.

The LC-MS and LC-MS–MS procedures employed in this study have been discussed previously (11). Briefly, liquid chromatography was performed on an HP 1050 Ti series gradient pump having a 10 µL sample loop. A Lichrospher 100 diol column (250 mm × 4.6 mm, 5 µm particle size; Merck, Germany) was used to separate phospholipids according to class (see Table 1). The binary solvent gradient consisted of solvent mixture A: hexane – isopropanol – acetic acid – triethylamine (82:17:1.0:0.08 v/v/v/v) and mix-

Fig. 2. Total ion chromatograms for Hybridol, Pactol, olive, almond, and sunflower oil extracts. Superimposed on the top two chromatograms are the retention time windows for each glycerophospholipid class.

ture B: isopropanol – water – acetic acid – triethylamine (85:14:1.0:0.08 v/v/v/v). The gradient was started at 5% mixture B and its percentage was increased linearly to 80% over 25 min. This composition was maintained for 1 min before being returned to 5% B over 10 min and maintained at 5% for another 4 min (40 min total run time). The flow rate of 1 mL/min through the column was subsequently split to 100 µL/min using a micro-splitter valve (Upchurch Scientific, Oak Harbor, Wash.) before being introduced to the electrospray ionization source of the mass spectrometer.

Glycerophospholipids were detected with a Quattro-LC (Waters) electrospray ionization triple-quadrupole mass spectrometer (operating in negative ion mode) employing the MassLynx (ver. 3.5) control and processing software. The 100 µL/min flow of eluent was passed through the electrospray capillary, which was held at –3.8 kV. The source block temperature was 80 °C and the cone voltage was set at –70 V. N_2 drying gas was passed coaxially to the capillary with a flow rate of approximately 100 L/h. Tandem mass spectra were obtained by introducing argon collision gas into the central, RF-only hexapole to a recorded pressure of 2×10^{-4} mbar (1 bar = 100 kPa). Precursor ions were selected with unit mass resolution by the first quadrupole (Q1) and collision-induced dissociation (CID) mass spectra were obtained by scanning the last quadrupole (Q3) with slightly less than unit mass resolution.

Results and discussion

The total ion chromatograms for the five oils are shown in

© 2004 NRC Canada

Fig. 3. Mass spectra corresponding to each lipid class in the chromatogram of Pactol oil. Each spectrum is an average over the corresponding retention time window for that class.

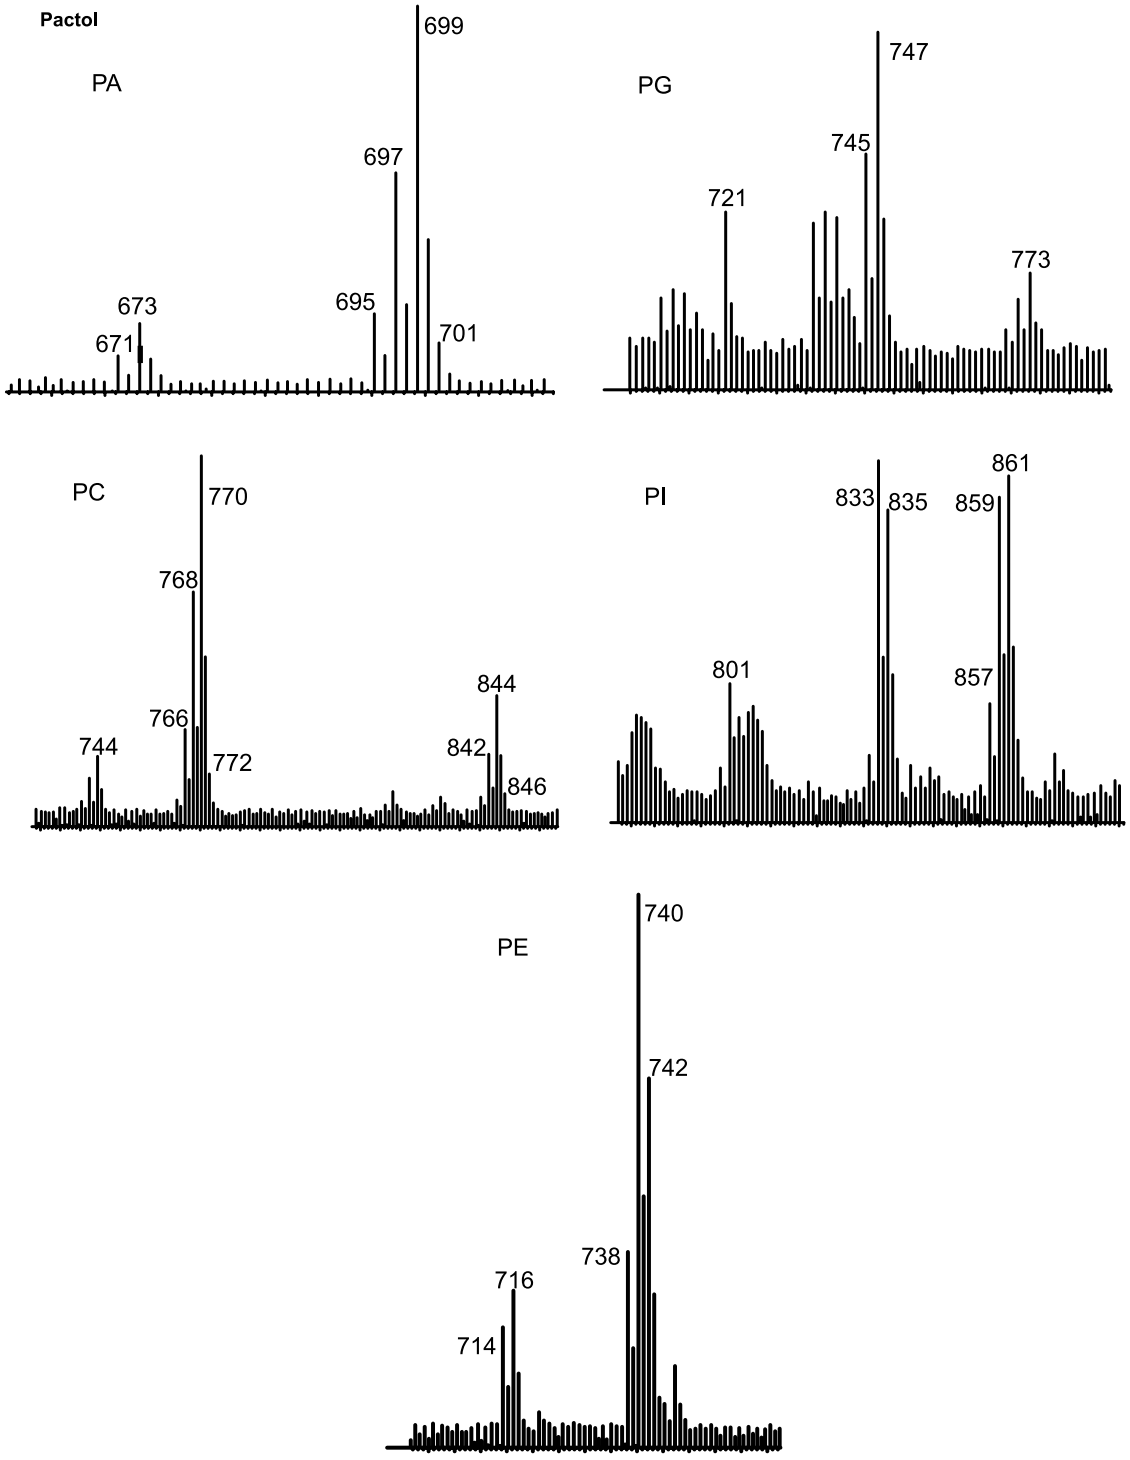

Fig. 2. Glycerophospholipid class identification was confirmed by summing the mass of each R group (Fig. 1) identified by MS–MS with that of the glycerol backbone (41 Da) and phosphoric acid (95 Da). The remaining mass is due to the polar head group. This was done once for the Pactol oil extract and the resulting retention time ranges used in the analyses of the other oils. No glycerophosphatidylserines were observed in the oil samples reported here. Figure 3 shows the averaged mass spectrum for each class of glycerophospholipid in Pactol. An example of the MS–MS data is shown in Fig. 4 for *m*/*z* 768, a PC class glycerophospholipid. Due to the small amounts of glycerophospholipids present in each sample, MS–MS identification of the R groups for all phospholipids in each oil could not be achieved. Those glycerophospholipids in Pactol oil that could be identified with respect to their fatty acid chains are summarized in Ta-

[a]Fatty acids for which peaks were not observed in the tandem mass spectrum, but whose presence was inferred from the molecular weight, are denoted with an asterisk.

ble 2. Fatty acid chains of C18 are predominant in the oils, which is consistent with the results from previous studies of a wide range of plant material (7–9, 11). One exception in Table 2 is for *m*/*z* 747, a PG class lipid that has both C18 and C16 side chains. This combination has also been observed by Demandre et al. (7) in potato tuber and tobacco leaf samples and by Womiloju et al. (11) in extracts from fungal spores.

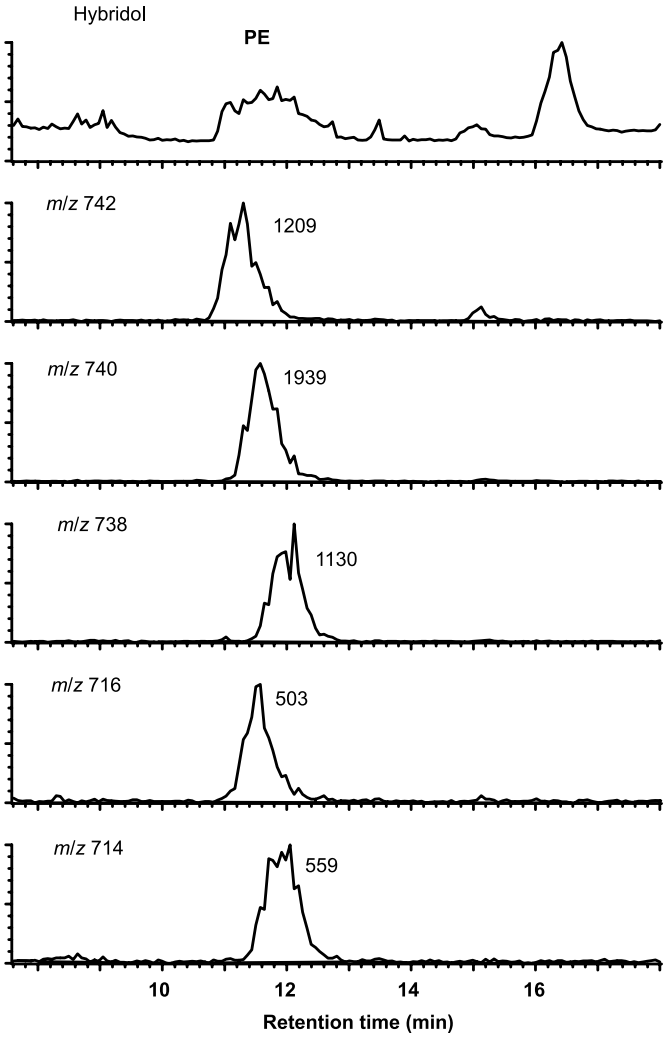

Table 3. Relative abundance of each glycerophospholipid class in each vegetable oil.

	Relative abundance (%)				
Oil	PA	PG	PE	PC	PI
Olive	12	63	9	5	11
Almond	0	2	45	45	8
Sunflower	0	11	34	46	8
Hybridol	1	0	38	6	55
Pactol	25	30	2	19	24

Relative abundances of each individual glycerophospholipid in each class were determined from the area of the ion chromatogram corresponding to the detected ion for that particular lipid (see Table 1). An example is shown in Fig. 5

Fig. 5. Selected ion chromatograms for individual glycerophosphatidylethanolamine lipids in Hybridol oil. Integrated peak areas are listed for each chromatogram (arbitrary units).

for the glycerophosphatidylethanolamines (PE) in Hybridol oil. The results for each oil are summarized in Table 3. Without a suitable internal standard, it was not possible to compare the absolute amounts of glycerophospholipids among oils, but provided that the extraction efficiencies were similar, the rapeseed oils had significantly more lipid content than olive, almond, or sunflower oils. Olive oil is characterized by a unique signature being comprised principally of PG class glycerophospholipids. It is the only oil that exhibits a single dominant class of lipids and is the only nonseed derived oil in this study. Almond and sunflower oils are poor in PG lipids, the profiles for both exhibiting primarily PE and PC class glycerophospholipids. Indeed, it would be difficult to distinguish these two oils based solely on their lipid profiles. Interestingly, rapeseed oils derived from the two varieties of seeds dealt with here, Pactol and Hybridol, display quite unique lipid abundances. Hybridol oil contains mainly PE and PI class lipids, while Pactol is more evenly distributed, except for a notable absence of PE class lipids.

Conclusions

The described LC–MS and MS–MS methods for the separation and identification of glycerophospholipids in vegetable oils (two types of rapeseed plus olive, almond, and sunflower) are simple and rapid alternatives to previous approaches that require chemical fictionalisation of the lipids and multiple-technique analyses. HPLC allows speed and reproducible separations of the main glycerophospholipid classes. Information about the fatty acid composition of each glycerophospholipid class was given by tandem mass spectrometry without the need to further chemically modify the phospholipids.

Each vegetable oil was found to have a characteristic glycerophospholipid composition, including significant differences between two rapeseed oils, which may be useful in the identification of the oil source in commercial applications.

An ab initio study of the potential energy surfaces for the collision between a Cs atom and an I_2 molecule

Xiaomin Sun, Dacheng Feng, Zhengting Cai, and Wensheng Bian

Abstract: For the Cs + I_2 collision system, a systematic theoretical study is first reported using the ab initio method. Three of eight possible channels are considered. The nonadiabatic coupling between the covalent state and the ionic one is calculated from different angles, especially the T-shape collision. The complete ion-pair formation potential energy surfaces of the T-shape collision in two electronic states (ionic $^2B_2$ state and covalent $^2A_1$ state) and the reactive surface of the linear collision are constructed at the QCISD(T)/SDD level. The main features of potential energy surfaces, such as the minimum energy reaction path, the crossing radius (R_c), and energy minimum geometries, are analyzed. The cross section of this titled system is calculated based on the harpoon mechanism and compared with the available experimental data and those obtained for the M + I_2 (M = Li, Na) systems.

Key words: ab initio two-state potential energy surfaces, nonadiabatic coupling, ion-pair formation, cross section.

Résumé : Faisant appel à une méthode ab initio, on a réalisé la première étude théorique systématique du système de collision Cs + I_2. On a considéré trois des huit canaux possibles. Le couplage non adiabatique entre l'état covalent et l'état ionique a été calculé pour divers angles, particulièrement pour la collision en forme de T. Opérant au niveau QCISD(T)/SDD, on a construit l'ensemble des surfaces d'énergie potentielle conduisant à la formation de la paire d'ions de la collision en forme de T dans les deux états électroniques (état ionique $^2B_2$ et l'état covalent $^2A_1$) ainsi que la surface réactive de la collision linéaire. On a analysé les caractéristiques principales des surfaces d'énergies potentielles, telles que la voie réactionnelle d'énergie minimale, le rayon de croisement (R_c) et les géométries minimales d'énergie. La section droite du système mentionné dans le titre a été calculée sur la base du mécanisme du harpon et on l'a comparée avec les données expérimentales ainsi que celles obtenues pour les systèmes M + I_2 (M = Li, Na).

Mots clés : surfaces d'énergie potentielle à deux états ab initio, couplage non adiabatique, formation de paires d'ions, section droite.

[Traduit par la Rédaction]

Introduction

Potential energy surface (PES) is the key to the research of molecular reaction dynamics, and the main features of a PES could directly influence the energy distribution, the ratio of the products, the role that the translational and internal energy plays in a reaction, and so on. Theoretically, as long as the whole fine PES of a reaction system is provided, the foundation is laid for solving the Schrödinger equation of its nuclear motion. Thus, constructing a reliable PES is of great importance to the study of basic chemical dynamics.

The collision between an alkali metal atom M (M = Li, Na, K, Rb, Cs) and a halogen molecule X_2 (X = F, Cl, Br, I) has been widely investigated by a variety of techniques in the last 30 years, from which valuable information for collision-induced reaction dynamics can be obtained. For example, the crossed molecular beam (CMB) was adopted to provide considerable experimental data (1–3). For these collision systems, the main processes involved are as follows:

[1] $M + X_2 \rightarrow M + X_2$

[2] $\rightarrow M + X + X$

[3] $\rightarrow M^+ + X_2^-$

[4] $\rightarrow M^+ + X^- + X$

[5] $\rightarrow M^+X + X^-$

[6] $\rightarrow M^+ + X + X + e$

[7] $\rightarrow M^+X + X + e$

[8] $\rightarrow MX + X$

where rxn. [1] represents the nonreactive collision including elastic and inelastic collisions, rxn. [2] is the process of collisionally induced dissociation, and rxns. [3] to [7] involve the electron transfer and ion-pair formation. Among them, rxn. [4] includes the dissociation one, rxn. [5] consists

of an association reaction, rxn. [6] is a Penning ionization, and rxn. [7] is a Penning ionization with an association reaction. Reaction [8] is a reactive collision. These eight channels are applicable to the Na + I_2 system (4). Research for these systems has been performed at a highly systematic level. There are comprehensive CMB studies and calculations of the classical trajectory (5, 6) and the quantum reaction scattering theory (7–9). Those calculations were performed on the semiempirical PESs (10). Various mechanisms and calculated models were proposed to interpret experimental phenomena. Among them, the most famous theory was the harpoon mechanism proposed by Polanyi (11) and Magee (12) and developed by Herschbach (13).

For the titled system, previous research results are mainly as follows: In 1971, Edelstein and Davidovits (14) obtained the reaction cross section of alkali metal atoms with an I_2 molecule by direct measurement of the Cs atom decay rates. In 1974, Tang et al. (15) used CMB to study the ionizing collision of energetic Cs atoms with I_2, and the cross section for formation of Cs^+, the intensity ratio I^-/I_2^-, and the electron affinity of the I_2 molecule were reported. In 1975, Anderson and Herschbach (16) performed the calculation of the orbiting scattering inversion from elastic collisions of reactive molecules; Gislason and Grobe Sachs (17) examined the reaction of a Cs atom with an I_2 molecule via an electron jump using the multiple-crossing formalism and obtained the reactive cross section from the already known properties of the Cs atom and the I_2 molecule. Howard and Andrews (18) measured the Raman spectra of cesium atom – iodine matrix reaction products and the resonance Raman spectrum of the iodine molecular anion I_2^-. In 1976, Andrews (19) found a strong 254/286 nm doublet absorption in the $Cs^+I_2^-$ spectrum. In 1977, Aten et al. (10, 20) measured the energy dependence of the differential cross section for ion-pair formation in the Cs + I_2 collision and proposed a semiempirical PES. Later, they carried out the calculation of trajectory surface hopping (TSH) (21). In 1999, Ma et al. (7–9) performed the quantum-scattering dynamics calculations using the extended linear combination of arrangement channels – scattering wavefunction (LCAC–SW) method (7) on Aten–Langting–Los PESs (10).

To the best of our knowledge, no ab initio PES for the Cs + I_2 collision system has been reported up to now. In the present paper, the quantum chemical study was performed for the Cs + I_2 collision system. Three channels (Cs + I_2, Cs^+ + I_2^-, and CsI + I) were mainly considered among the eight possible ones. The collision between the ionic state and covalent state was investigated from various angles with the equilibrium distance of the I_2 molecule fixed. The results indicated that the energy minimum geometry on each PES appears at θ = 90° and was called the T-shape configuration. The complete ab initio PESs of two electronic states (ionic $^2B_2$ state and covalent $^2A_1$ state) for the T-shape collision and the $^2\Sigma$ state for collinear collision were constructed at the QCISD(T) (22) level. Minimum energy reaction paths (MEPs) on each PES and the crossing curve of the two-state PESs were abstracted. Based on the crossing curve, the crossing radius (R_c) between the ionic and covalent states was determined, and the fine electronic structure on the crossing point was computed. The energy minimum geometry on each PES was optimized. The cross sections obtained in terms of the harpoon mechanism were compared with the available data of the title system and those of the M + I_2 (M = Li, Na) systems.

Fig. 1. Reaction coordinates (P represents the center of the I_2 molecule).

Calculation methods

Geometry optimization and the scanning of PESs were performed at the QCISD(T) level, and at the same time, the natural bond orbital (NBO) population was analyzed at the QCISD level. For the Cs and I atoms, a SDD (23) basis set (an effective core potential basis set), including the relativistic effect, was applied.

The Jacobi coordinate is illustrated in Fig. 1 where R is the distance from the Cs atom to the center of the I_2 molecule, r_1 is the I_2 bond distance, and θ is the angle between vectors $\boldsymbol{R}$ and $\boldsymbol{r_1}$. In the process of scanning PES, r_1 was fixed at the equilibrium distance, while θ and R were changing, and then the PES dependent of angle θ was obtained. With a similar method, the PES independent of angle θ (angle θ fixed) could also be obtained. It should be noted that the energy unit in the contours of the PES was a hartree. All the work was completed with the Gaussian 98 packet (24).

Results and discussion

Potential energy surfaces

The PESs dependent of angle θ in the ionic and covalent states are shown in Figs. 2 and 3. During scanning of the PESs, r_1 was fixed at 0.2922 nm (obtained at the QCISD(T)/SDD level), while R with a step-length of 0.01 nm and with the θ angle at 5° was changing. It should be noted that, for an atom plus a diatomic molecule, the total electronic wavefunction depends not only on the electronic species of M and X_2 (or M^+ and X_2^-), but also on the angle θ (17). For example, ground-state Cs (^2S_g) plus ground-state I_2 ($^1\Sigma_g$) combines to generate a $^2A_1$ state in C_{2v} symmetry (θ = 90°), while a $^2\Sigma$ state in $C_{\infty v}$ symmetry (θ = 0°or 180°) and a $^2A'$ state in C_s symmetry (0° < θ < 90°or 90° < θ < 180°) are also generated. By comparison, ground-state Cs^+ (^1S_g) and ground-state I_2^- ($^2\Sigma_u$) yield $^2B_2$, $^2\Sigma$, and $^2A'$ states for the same symmetries. From the PES, it is clearly seen that a potential well appears as R decreases at each θ value in Fig. 2. As θ increases, the depth of the potential well becomes deeper. When θ = 90°, the deepest potential well comes into being, which illustrates the existence of a long-lived geometry. A similar case emerges on the covalent PES in Fig. 3. From the above analysis, the long-lived geometry is formed

under the T-shape collision, and the electron is evenly distributed on two I atoms in the process of ion-pair formation. Hence, the T-shape collision is a very important case in the study of ion-pair formation.

The T-shape collision has C_{2v} symmetry with two electronic states (the ionic $^2B_2$ state and the covalent $^2A_1$ state). The PESs of the T-shape collision were calculated during scanning using r_1 at 0.01 nm in step-length, and R at 0.02 nm in step-length. Figures 4 and 5 show the contour of the whole two-state PESs.

Figure 4 shows the $^2A_1$ state PES of the T-shape structure with C_{2v} symmetry (the covalent state). The entrance point, which is also the exit point of a reaction path, at r_1 = 0.29 nm, R = 1.0 nm, is close to the reactant Cs + I_2 (or the product Cs + I_2), which corresponds to the elastic and inelastic collisions. Its energy is –42.27180 au, and the net charge is 0.00 for both Cs and I atoms. When the Cs atom gradually approaches and then departs from the I_2 molecule, the energy passes a small and shallow well that corresponds to the van der Waals intermediate A, then climbs up quickly, and finally returns back along the reaction path. This phenomenon is vividly demonstrated through the U-type curve on the equal-counter potential plot. It is worth mentioning that the net charge on each atom is almost zero for the $^2A_1$ state PES.

In Fig. 5, the point with r_1 = 0.34 nm and R = 1.0 nm for the $^2B_2$ state PES is close to the ion-pair species $Cs^+ + I_2^-$ and is located at the entrance to the reaction path. The total energy of the system is –42.28962 au. The electronic charge on Cs and on each I atom is +0.9995 and –0.49975, respectively. There is no potential barrier from the entrance to the long-lived geometry B and then to the exit. The potential energy first decreases and then increases smoothly along the reaction path.

Fig. 6. The main features of the collision PESs for the Cs + I_2 system. (*a*) The MEP on the $^2A_1$ state PES, (*b*) the MEP on the $^2B_2$ state PES, (*c*) the crossing curves between the two-state PESs at the crossing radius R_c, and (*d*) the MEP on the $^2\Sigma$ state PES.

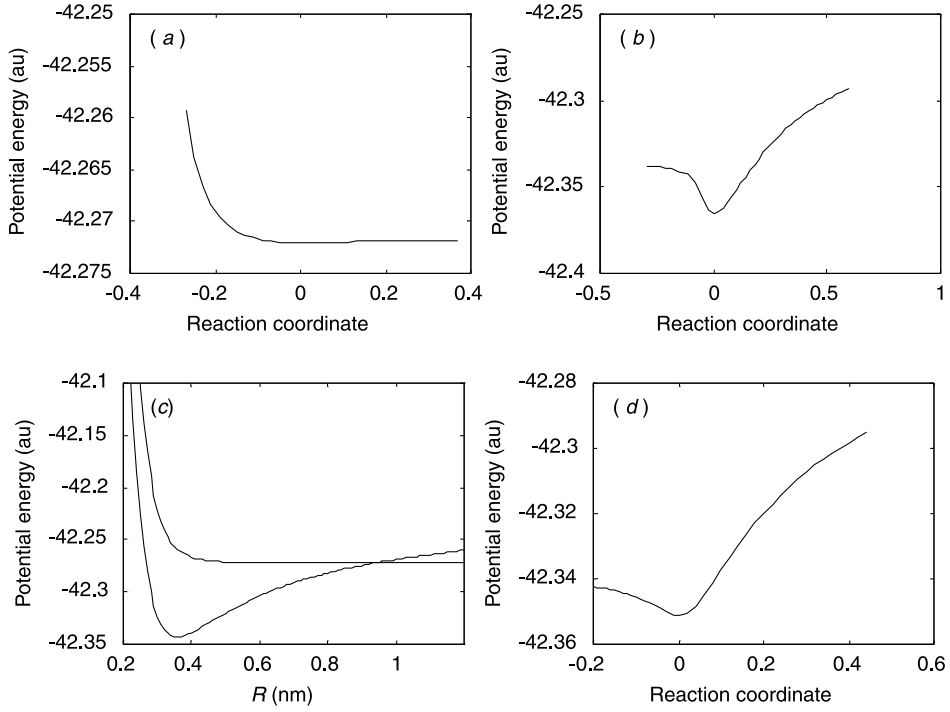

Figure 6 shows the main characteristics of the PESs. Curve (*a*) is the MEP on the $^2A_1$ state PES for the T-shape configuration, and curve (*b*) is the counterpart of (*a*) for the $^2B_2$ state PES. The crossing curve between the two-state PESs is represented by curve (*c*), where R_c is obtained step-by-step, and the value is 0.9427 nm, and at this point the system energy is –42.27188 au. The charge population analysis calculated at the QCISD level illustrates that about 99.9% of the electron transfers from the Cs atom to the I_2 molecule at the cross point. The process is very fast (even within several fs) according to the Cai study (25, 26). Curve (*d*) is the MEP on the $^2\Sigma$ state PES for the linear configuration.

From Figs. 4–6, the whole ion-pair formation process (the reaction path) can be described as follows: while the Cs atom is approaching the I_2 molecule along the $^2A_1$ state PES, the potential energy first mildly decreases. At about R_c = 0.9427 nm, the $^2A_1$ state PES crosses with the $^2B_2$ state PES where there are two alternative paths. Path one is moving continuously on the $^2A_1$ state PES and reaches the bottom of the potential well where van der Waals complex A is formed, and then the potential energy increases gradually and stably. The other path jumps to the $^2B_2$ state PES and electron transfer occurs, so Cs^+ and I_2^- are formed. Under the effect of the strong Coulomb force between Cs^+ and I_2^-, the potential energy drops sharply as Cs^+ continues to approach the I_2^- molecule anion and reaches the bottom of the second well. At that moment the strong polar geometry B appears. After Cs^+ departs from I_2^-, the ionizing collision is completed. Clearly, there are two interaction paths leading to ionization (10). The first interaction path is called covalent scattering. In this case, the first crossing is passed adiabatically and the second diabatically; the transition to the ionic state takes place at the second crossing. The larger part of the trajectory is located on the covalent potential surface. The second interaction path is called ionic scattering. Here, the first crossing is passed diabatically and the second adiabatically; the transition to the ionic state occurs at the first crossing. It should be noted that the ionizing process is different from that described for the M + $I_2 \rightarrow M^+ + I_2^-$ (M = Li, Na) system (4, 27, 28). In the latter, the van der Waals collision complex forms first and then crosses between the covalent and ionic state PES so that double-potential-well structure will be found, though one is very shallow. The result is similar to the Marcus electronic transfer theory (29, 30). The ionization potential of the Cs atom is smaller than that of the Li and Na atoms, thus the electron can be transferred easily, even at a larger R_c.

Under the collinear collision, the system has the $C_{\infty v}$ symmetry and the electronic state belongs to the $^2\Sigma$ state. In the process of scanning the reactive PES for Cs + $I_2 \rightarrow$ CsI + I, angle θ is fixed at 0°, while r_1 and r_2 are changing with the step-length at 0.01 and 0.02 nm, respectively. The PES is shown in Fig. 7, where an unstable geometry (configuration C) is found. The detailed structure is listed in Table 1.

This type of contour in Fig. 7 is referred to as a downhill attractive PES without barrier and Fig. 6*d* demonstrates the MEP on the collinear PES. The reaction is a topic exothermic one. Its reaction energy is released along the reaction path and is converted into vibrational energy of the newly formed CsI molecule. A similar case is found in the CMB experiment. It is widely accepted that the reaction M + $I_2 \rightarrow$ MI + I is a direct reactive collision via a stripping mechanism. But in collinear collision, they may mainly follow the rebound mechanism. In fact, it is difficult to retain the collinear collision, and the collinear configuration shows its in-

Fig. 7. The contour of the collinear reactive collision PES with $C_{\infty v}$ symmetry and the $^2\Sigma$ electronic state.

stability. So the reaction occurs easily via the stripping mechanism as long as the collinear geometry has a tiny variation (i.e., in the case of θ ≠ 0° or 180°).

The intensity contour maps for the atom–molecule CMB experiment show a symmetry about θ = 90°, which reflects the existence of a long-lived collision complex. The existence of a deep potential valley along the reaction path suggests the long-lived configuration is formed such that the collision pairs may be combined together long enough. The above two cases verify each other. In the experiment, whether the collision complex is measured or not is determined by the relationship among the collision time, the lifetime, and the rotational cycle of the collision complex; while in the ab inito method, the detailed geometry structure can be calculated. Of course, it was performed on the static PES.

Optimized geometry structures

The optimized results of all geometry structures including the eight channels are illustrated in Table 1, where the numeral ladder method is used to optimize the reactant, minimum configuration, and the product; meanwhile, the vibration analysis and zero-energy correction are also carried out on them. Configurations A, B, and C are the minimum energy ones for $^2A_1$, $^2B_2$, and $^2\Sigma$ state PESs, respectively.

Configuration A is a van der Waals complex in the very smooth and shallow potential valley of the $^2A_1$ state PES, whose frequencies are 5.0563 (A_1) cm^{-1}, 5.9021 (B_2) cm^{-1}, and 156.6694 (A_1) cm^{-1}. From the NBO population analysis on the QCISD level, it is known that the net charge on each atom is nearly zero. Similarly, configuration B is a long-lived complex in the deep potential valley of the $^2B_2$ state PES whose frequencies are 52.6047 (B_2) cm^{-1}, 69.2449 (A_1) cm^{-1}, and 96.6696 (A_1) cm^{-1}. The population analysis illustrates that this complex is a strong polar intermediate (the net charge on Cs and each I is +0.9147 and –0.4573, respectively).

As for configuration C, it lies at the potential valley of the $^2\Sigma$ state PES. It is interesting that configuration C has two virtual frequencies and another two frequencies are real. The concrete values are –6.6188(∏) cm^{-1}, –6.5563(∏) cm^{-1}, 55.8811(∑) cm^{-1}, and 101.6466(∑) cm^{-1}, respectively. The detailed interpretation is the same as that of the Na + I_2 system (31).

Cross section of ion-pair formation

According to the harpoon mechanism, the reaction occurs as a result of the electron transfer from the alkali atom to the halogen molecule. The rapid transfer or jump of the electron occurs in the region of crossing between the covalent M-X_2 and the ionic M^+-X_2^- potential energy curves. Coulomb attraction dominates the interaction in this region since the ion pair is formed and the internuclear distance is relatively large. The harpoon model yields a straightforward expression for the reaction cross section, and it is assumed that once colliding particles have reached the crossing point (R_c), the electron jump occurs and then the reaction proceeds to completion. Therefore, the reaction cross section for the collision of M with X_2 is simply πR_c^2. The longer R_c is, the larger the cross section will be. R_c for the Cs + I_2 ion-pair formation system is 0.943 nm. When the same process is applied to the M + $I_2 \rightarrow M^+ + I_2^-$ (M = Li, Na) system, R_c is 0.439 and 0.493 nm, respectively. The comparison of the cross sections for different systems and experimental groups is listed in Table 2. The ionization potential of the Cs atom

Note: For *a*, the data is quoted in ref. 14; for b, the data is quoted in ref. 16; for *c* the data is quoted in ref. 17; for *d*, the data is calculated using the following empirical equation:

$$\Delta E_0 = I(\mathrm{M}) - \mathrm{EA}(\mathrm{X}_2)_{\mathrm{eV}}$$

$$R_c = \frac{e^2}{\Delta E_0} = \frac{14.35}{\Delta E_0}, \sigma = \pi R_c^2$$

where the electron affinity (EA) of the I_2 molecule is 2.55 eV and the ionization potentials (I) of the Li, Na, and Cs atoms are 5.3317, 5.1391, and 3.8939 eV, respectively.

is 3.544 eV obtained with the ab initio method, while the experimental value is 3.8939 eV (32). The electron affinity of the I_2 molecule in this work is 2.585 eV, whereas the experimental value varies from one experiment group to another with those values being $2.50^{+0.2}_{-0.1}$ eV (33), 2.55 ± 0.55 eV (34), 2.6 + 0.1 eV (35), 2.58 + 0.1 eV (36), and 2.42 + 0.2 eV (37). From Table 2, it is clear that the R_c and the cross section are getting larger and larger from Li to the Cs atom. The results are in accord qualitatively with those of the previous studies.

Conclusions

The two-state PESs of the ion-pair formation process for the $Cs + I_2 \rightarrow Cs^+ + I_2^-$ system were constructed for the first time at the QCISD(T)/SDD level. In scanning the PESs, the T-shape ion-pair formation and the linear reactive collision are mainly considered. In the former, the charge is evenly distributed on two I atoms, which is identical with the assumption in the Aten–Lanting–Los PES (10). The two-state PESs crosses and the crossing radius (R_c) is 0.9427 nm. Our calculation reveals that the ion-pair formation process is electronically nonadiabatic. The energy minimum geometry on each PES is given. According to the harpoon mechanism, the reaction cross section is calculated. The variation trend from Li, Na to the Cs atom is similar to those of previous studies.

Micellar properties of zwitterionic surfactant – alkoxyethanol mixed micelles

Maria K. Mullally and D. Gerrard Marangoni

Abstract: The micelle formation process for a zwitterionic surfactant, *N*-dodecyl-*N*,*N*-dimethyl-3-ammonio-1-propanesulfonate (ZW3-12), has been investigated in a series of mixed solvents consisting of different concentrations of ethoxylated alcohols and polymers. The critical micelle concentrations (cmc values) of the aggregates were determined by fluorescence spectroscopy, and the surfactant aggregation numbers were obtained from luminescence probing experiments. The cmc values for ZW3-12 changed very little in the presence of increasing amounts of poly(ethyleneoxide) (PEO) in the mixed solvent. In the case of the ethoxylated alcohol – ZW3-12 systems, the cmc values and aggregation numbers decreased systematically with increasing alcohol concentration. However, the cmc values of the mixed micelles showed little dependence on the number of ethylene oxide (EO) groups at constant alcohol concentration. These results are compared with the well-studied sodium dodecylsulfate – ethoxylated alcohol, and dodecyltrimethylammonium bromide – ethoxylated alcohol mixed micellar systems and to SDS–PEO systems and are discussed in terms of the contribution of the EO groups to the hydrophobic interactions.

Key words: zwitterionic surfactant, alcohols, mixed micelles, luminescence probing.

Résumé : On a étudié le processus de formation de micelle pour un agent de surface zwitterionique, le *N*-dodécyl-*N*,*N*-diméthyl-3-ammonio-1-propanesulfonate (ZW3-12), dans une série de solvants mixtes formés de concentrations diverses d'alcools éthoxylés et de polymères. On a déterminé les concentrations micellaires critiques (valeurs des cmc) en faisant appel à la spectroscopie de fluorescence et on a obtenu les nombres d'agrégation de l'agent de surface à partir d'expériences de luminescence exploratoire. Les valeurs de cmc pour le ZW3-12 varient très peu en présence de quantités croissantes de poly(oxyde d'éthylène) (POE), dans le solvant mixte. Dans le cas des systèmes alcool éthoxylé – ZW3-12, les valeurs des cmc et les nombres d'agrégation diminuent d'une façon systématique avec une augmentation de la concentration d'alcool. Toutefois, les valeurs des cmc ne dépendent que faiblement sur le nombre de groupes d'oxyde d'éthylène (OE), à des concentrations constantes d'alcool. Ces résultats se comparent bien avec les systèmes micellaires mixtes bien étudiés dodécylsulfate de sodium – alcool éthoxylé et bromure de dodécyltriméthylammonium – alcool éthoxylé et aux systèmes SDS–POE et on les discute en fonction de la contribution des groupes OE aux interactions hydrophobes.

Mots clés : agent de surface zwitterionique, alcool, micelles mixtes, luminescence exploratoire.

Introduction

Zwitterionic surfactants are, to date, generally much less studied than other classes of surfactants. However, they are widely used in industry (1), and the interest in these surfactants as well as the amount of research into their fundamental micellar and solution properties is increasing. Their main applications are based on such properties as mildness to the skin and eyes (which is related to their low cmc values and the nonionic nature of the headgroups), excellent water solubility, broad isoelectric ranges, and resistance to hard water. They are also resistant to degradation by oxidizing and reducing agents, exhibit low toxicity, and are highly compatible with most of the main commercial surfactants and detergent additives.

When an alcohol with a sufficiently long chain is in solution with a surfactant, it is generally accepted that mixed micelles — incorporating both surfactant monomers and alcohol molecules — form (1–8). That is, the alcohol may solubilize preferentially in a micelle interior, rather than in the aqueous phase, facilitating mixed micelle formation. The interaction of alcohols with surfactants is widely studied, but has been mostly focused on mixtures of *n*-alkanols with ionic and nonionic surfactants (5). A number of papers have examined the mixed micelle formation process for typical anionic and cationic surfactants with a variety of alcohols and alkanediols (3, 6, 7).

Ethoxylated alcohols represent an interesting family of cosurfactants that may be considered as lower members of the alcohol ethoxylate, nonionic surfactant family. In the case of the nonionic surfactants, the ethoxylate (EO) group ($-CH_2CH_2O-$) is considered to be hydrophilic, whereas for the lower members of this family, the EO groups have been clearly shown to contribute to hydrophobic effects and to a

decrease in the Gibbs transfer energy of the alcohol from the aqueous phase to the micellar phase. The interactions between ethoxylated alcohols and the anionic surfactant sodium dodecylsulfate (SDS) and the cationic surfactant dodecyltrimethylammonium bromide (DTAB) have been examined by a number of authors and were found to be as follows (4, 7, 9–14). For SDS, critical micelle concentrations (cmc values) and surfactant aggregation number (N_s) values decreased as the number of EO groups was increased, suggesting that the EO group has a contribution to hydrophobic effects, whereas for DTAB, the cmc and N_s values did not vary with increasing numbers of EO groups at constant alcohol concentration. This suggested that the EO groups do not contribute to the hydrophobic interactions in mixed micelle formation for the cationic surfactants studied. In the case of the volumetric and other thermodynamic properties of carboxylate surfactants mixed with ethoxylated alcohols, the properties of the mixed micelles changed in a fashion consistent with the EO group contributing to the hydrophobic interactions (10, 11).

Surfactant–polymer mixtures are of widespread use in biochemical, pharmaceutical, paint, and cosmetic industries (15, 16). In the presence of certain polymers, surfactant molecules associate with the polymers to form polymer–surfactant aggregates at surfactant concentrations below the cmc value. In such cases, a plot of a surfactant physicochemical property, such as surface tension or fluorescence, vs. surfactant concentration exhibits two breaks. The first break is taken to be the concentration above which interaction between the two molecules begins and is called the critical aggregation concentration (CAC). At this concentration, the surfactant begins to adsorb on the polymer chain forming aggregates. Once the polymer is saturated with surfactant, free surfactant monomers form micelles and the second break in the curve is the cmc value. At concentrations above the cmc value, polymer-bound surfactant aggregates coexist in solution with free micelles. Intuitively, aggregation formation or binding between oppositely charged polyelectrolytes and surfactants can be rationalized in terms of the strong electrostatic forces. However, nonionic, water-soluble polymers and ionic surfactants are the most studied polymer–surfactant systems and the interaction between these polymers and surfactants is strong. Some of the explanations of this phenomenon that have been proposed are (15, 16): (*a*) the reduction of the hydrocarbon–water contact area of the alkyl chains of the surfactant; (*b*) an ion-dipole interaction between the surfactant head group and the polymer; and (*c*) a hydrophobic interaction between the polymer and the surfactant hydrocarbon chains.

For zwitterionic surfactants, there have been very few studies concerning interactions with polymer additives. Ribera and Velazquez (17) have studied the interactions of ZW3-12 (which they called DPS) in solution with poly(vinylpyrrolidone) (PVP), polyacrylic acid sodium salt (PAC), and poly(sodium 4-styrenesulfonate) (PSS). The only polymer that showed any significant interaction was PSS. PVP and PAC exhibited virtually no interaction with ZW3-12. The authors used surface tension measurements and determined the cmc values in the presence and absence of polymers. However, no explanation was offered for the observed interactions (or lack thereof).

This paper presents the micellar properties of the zwittergent ZW3-12 (cmc and N_s values) in aqueous solutions of *n*-butanol (C_4E_0), ethylene glycol mono-*n*-butyl ether (C_4E_1), diethylene glycol mono-*n*-butyl ether (C_4E_2), and triethylene glycol mono-*n*-butyl ether (C_4E_3), and also in a mixture with 35 000 g/mol poly(ethyleneoxide) (PEO). Both the cmc and the N_s values have been determined using luminescence probing techniques. The results are compared with the well-studied mixed micelles composed of ethoxylated alcohols and SDS and DTAB to examine whether or not the hydrophobic effects of the EO groups are evident in the zwitterionic surfactant micelles.

Experimental

Materials

ZW3-12 was received from Calbiochem and was used without further purification. C_4E_0, C_4E_1, and C_4E_2 were spectrophotometric grade solvents from Aldrich and were used as received. C_4E_3 was obtained from Tokyo Kasei and used without purification.

PEO with an average molecular weight of 35 000 g/mol was a 99% pure Fluka product and was used as received. Pyrene was received from Aldrich and purified by successive sublimations. Safranine T was a Tokyo Kasei product and was used without further purification. The quencher, cetylpyridinium chloride monohydrate (CPC), was also obtained from Aldrich and it was purified by repeated recrystallization from an acetone–ethanol mixture.

All solutions were prepared with deionized, conductance grade water from a Millipore ion-exchange system and all experiments were performed at room temperature.

Methods

Cmc value determination by fluorescence spectroscopy

Solutions of the surfactant (ZW3-12) and alcohols were prepared in volumetric flasks using the appropriate mass of surfactant and alcohol in deionized water. All surfactant and alcohol concentrations are expressed in molarity units, where the molarity is defined as the number of moles of surfactant per litre of mixed solvent. A stock solution of the fluorescence probe, safranine T, was prepared by dissolving the probe in water and this stock solution was used in the preparation of the surfactant solutions. Sample preparation was done by combining the appropriate volumes of the surfactant–alcohol–probe solution with the alcohol–probe solution so that the alcohol and probe concentrations were constant and the surfactant concentrations ranged above and below its cmc value. The surfactant–PEO solutions were prepared in the same way as the surfactant–alcohol solutions with the exception that the polymer concentrations are expressed as the weight percent of the polymer per volume of solution.

Fluorescence spectra were measured using the Aminco-Bowman Series 2 luminescence spectrometer. Slit widths were set at 2.0 nm and the excitation wavelength was set to 532 nm, scanning the emission from 550 to 625 nm. The cmc values of the surfactant–alcohol and surfactant–polymer systems were obtained from the break in the plot of

© 2004 NRC Canada

maximum fluorescence emission intensity against surfactant concentration.

Luminescence probing experiments

All the solutions for the luminescence probing experiments were made up on a molar basis. A small amount of a 0.025 mol L^{-1} pyrene–ethanol solution was placed in a beaker, and the ethanol was allowed to evaporate overnight, leaving a thin film of pyrene on the bottom of the beaker. A solution of 20 mmol L^{-1} surfactant with the desired concentration of alcohol was placed in the beaker and the solution was stirred vigorously for a minimum of 3 to 4 h to ensure complete solubilization of the pyrene by the micelles. A portion of the solution (≈half) was then used to make a solution of approximately 1.00×10^{-4} mol L^{-1} CPC. This quencher solution was stirred for 3 to 4 h to fully dissolve the CPC in the micelles. Solutions were prepared with varying amounts of quencher so that the concentration of quencher was between 0 and approximately 1.00×10^{-4} mol L^{-1}. Steady-state pyrene fluorescence emission spectra were recorded using an Aminco-Bowman Series 2 luminescence spectrometer with an excitation wavelength of 338 nm, and scanning the emission from 350 to 500 nm. The heights of the first (I_1) and third (I_3) emission peaks were recorded directly from the spectra. The intensities of the first emission peak (at 373 nm) were used in the plot of $\ln(I_0/I)$ vs. quencher concentration to determine the aggregation numbers for the mixed micellar systems.

Results and discussion

Cmc values for ZW3-12 – ethoxylated alcohol mixed micelles

A sample curve of the fluorescence intensity of the safranine T probe vs. the concentration of ZW3-12 is given in Fig. 1. The cmc values were obtained from the breaks in the plots of maximum fluorescence emission intensity vs. total surfactant concentration ($C_{surf,t}$). These values are presented in Table 1 and plotted in Figs. 2 and 3 as a function of total concentration for each of the ethoxylated alcohols investigated. The cmc value for ZW3-12 without added alcohol is 2.74 mmol L^{-1} ± 0.10 mmol L^{-1}, which is somewhat lower than the literature value (1, 17). This is consistent, however, with cmc values from spectroscopic methods being somewhat lower than cmc values obtained via other methods (e.g., surface tension, viscosities, and densities) (19).

From Figs. 2 and 3, it is seen that, in all cases, the cmc values decrease as the total concentration of added alcohol increases. This trend is consistent with the well-known decrease in the cmc values for several types of ionic and nonionic surfactants mixed with alcohols possessing at least a four-carbon chain (1, 3–9), and it is consistent with the formation of mixed micelles containing surfactant and alcohol molecules. The cmc values decrease because, though the favourable increase in entropy upon micellization is lowered, mixed micelle formation means alcohol molecules replace some surfactant monomers and so micelles can be formed at lower surfactant concentrations. The higher alcohol concentration at which the cmc value begins to increase often correlates with the concentration at which the number of alcohol molecules and the number of surfactant monomers in the mixed micelle are roughly equivalent.

It is also useful to look at the rates of cmc value decrease (the dcmc/dC_a values) for each one of the alcohols. From the slopes of the linear portions of the cmc value graphs in Figs. 2 and 3, the dcmc/dC_a values are –5.7 mmol L^{-1}/mol L^{-1} for C_4E_0, –4.9 mmol L^{-1}/mol L^{-1} for C_4E_1, –5.2 mmol L^{-1}/mol L^{-1} for C_4E_2, and –4.3 mmol L^{-1}/mol L^{-1} for C_4E_3. It is clear from Figs. 2 and 3 and the calculated dcmc/dC_a values that the formation of the mixed micelles between the zwittergent and the ethoxylated alcohols is insensitive to the number of EO groups in the alcohol at similar alcohol concentrations. This can be compared with the data of Marangoni and Kwak (4) and Marangoni et al. (9) for the

systems SDS–C_4E_n and DTAB–C_4E_n. In their study of ethoxylated alcohols with anionic and cationic micelles, it was clear that in the case of the cmc values of SDS – ethoxylated alcohol mixed micelles, at a constant alcohol concentration, the cmc values are observed to decrease in the direction of increasing number of alcohol ethoxylate groups. For the DTAB–C_4E_n series, these authors found that the cmc values are rather insensitive to the number of EO groups in the alcohol at constant alcohol concentration. In addition, the degree of solubilization of the ethoxylated alcohol (p-values) in the micellar phase was determined by NMR paramagnetic relaxation enhancement experiments. The p-values for the SDS micelles increased with an increase in the number of EO groups, suggesting that ethoxylated alcohols have a greater preference to be solubilized in the micellar interior with an increasing number of alcohol ethoxylate groups. In the case of DTAB – ethoxylated alcohols, the p-values were essentially constant for $C_4E_0 \rightarrow C_4E_3$. The authors proposed that the EO groups not only enhance micelle formation by a reduction of headgroup repulsion, they also drive micelle formation by a contribution to hydrophobic effects in the anionic surfactant systems, whereas they have little effect in the case of the cationic surfactants. As with the cationic surfactant – ethoxylated alcohol systems, Figs. 2 and 3 show that the rate of decrease of the cmc value is relatively insensitive to the number of EO groups in the alcohol. Thus, the ZW3-12 – ethoxylated alcohol systems are more comparable to the DTAB system because the increasing number of EO groups does not cause a drastic decrease in the cmc value of the mixed micelles at constant alcohol concentration. This suggests that EO groups in the alcohols do not contribute significantly to the hydrophobic effects or to the screening of electrostatic interactions when mixed micelles are formed. However, the magnitude of these interactions in a zwitterionic surfactant is not well known, as we have not yet measured the partition coefficients for ethoxylated alcohols in the ZW3-12, nor is there a reasonable picture of the charge distribution in the headgroups of these zwitterionic surfactants.

Cmc values for the ZW3-12–PEO system

Cmc values for the ZW3-12–PEO system were also obtained by fluorescence spectroscopy. All the fluorescence plots exhibited one break, indicating that no ZW3-12–PEO aggregates form in this system. The two main postulates for explaining the lack of interaction of cationic micelles with polymers have to do with the size of the headgroup and the polymer's hydration shell (13–16). In the first case, cationic surfactants are considered to have larger headgroups than anionic ones that reduce the access of the polymer to the micelles. In the second case, systematic alteration of the kind and size of headgroups in anionic surfactants has shown that interaction between ionic surfactants and polymers can depend on the polymer's hydration shell (the hydrogen-bonded water molecules that surround it). For surfactants, the amount of hydration of cationic head groups is much less than that for anionic ones. Thus, with anionic surfactant micelles, the polymer can associate with the water molecules that hydrate the headgroups and its ether oxygens can remain hydrogen bonded. This would occur less with a cationic surfactant micelle, and would thus contribute to the weaker interactions for these surfactants. Overall, the fluorescence data show no interaction with PEO and so ZW3-12 seems to mimic a cationic surfactant more than an anionic one.

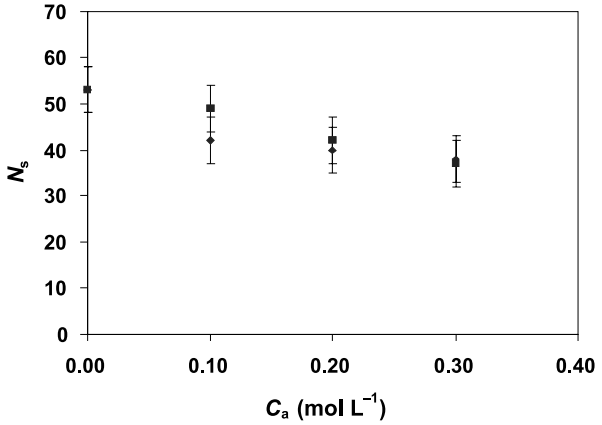

Table 2. Cmc values (±0.1 mmol L^{-1}) for ZW3-12–PEO systems as a function of the total weight percent of added PEO.

Total wt% of added PEO-35 000	Cmc value (mmol L^{-1})
0.00	2.74
0.05	2.79
0.15	2.86
0.20	2.83
0.25	2.89
0.30	2.96

Cmc values for the ZW3-12–PEO system are presented in Table 2 and are plotted in Fig. 4 as a function of the total added weight percent of PEO. We observe a slight increase in the cmc value as the weight percent of added PEO increases. This suggests that PEO acts as a net structure breaker in the system. That is, PEO breaks up the structure "icebergs" of water that form around the hydrocarbon chains

© 2004 NRC Canada

Fig. 5. N_s values (±5) for ZW3-12–C_4E_0 (■) and ZW3-12–C_4E_1 (◆) mixed micelles as a function of C_a.

of the surfactant monomers. This means that the entropy increase upon micellization is decreased and so a higher concentration of surfactant is required before micelles form. The increase in the cmc value confirms the lack of interaction between ZW3-12 and the polymer. This is because if surfactant–polymer aggregates were formed or if there were partitioning of the PEO inside the micelle, the cmc value would be expected to decrease as it did with the addition of the ethoxylated alcohols at low concentrations. It should be noted that higher molecular weight PEOs may have an interaction with the zwittergents, as it has been shown in the literature that anionic surfactants are known to interact more strongly with higher weight PEOs. Indeed, Gao et al. (20) have shown by a study of solubilization equilibria that the nature of the interaction between SDS and PEO depends strongly on the molecular weight of the polymer. As well, Weng and Olofsson (13, 14) have shown that the enthalpies of the interaction of PEO with various surfactants are strongly dependent on the polymer molecular weight.

Luminescence probing experiments

N_s values were calculated using the Turro–Yekta equation and the derived relationship:

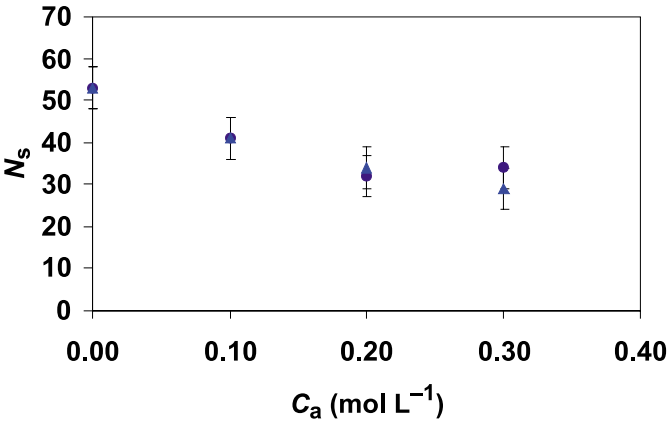
$$[1] \qquad N_s = \frac{C_{surf,t} - cmc}{[M]}$$

where the cmc values are those for the mixed micelles, reported earlier; [M] is the micellar concentration; 1/[M] is the slope of the plot of $\ln(I_0/I)$ vs. quencher concentration (21, 22), and $C_{surf,t}$ is the total surfactant concentration. These N_s values are presented in Table 3 and are plotted in Figs. 5 and 6 as a function of the total alcohol concentration. The N_s value without added alcohol was found to be 53 ± 6, which is considerably lower than the literature value for ZW3-12 (1). However, several trends in the N_s values with increasing additive concentration are noteworthy, particularly keeping in mind the SDS – ethoxylated alcohol and DTAB – ethoxylated alcohol systems mentioned earlier. First, the N_s values decrease as the concentration of added alcohol increases. This is true for all four alcohols and is an expected trend. In a surfactant–alcohol mixture where mixed micelles are formed, N_s is expected to decrease and N_a, the alcohol aggregation number, is expected to increase as more alcohol is incorporated into the micelle. The decrease in the N_s values is due to the changes in the hydrophobic interactions and electrostatic interactions that occur when the alcohol is incorporated into the micelle.

Table 3. Aggregation numbers (±5) of surfactant and alcohol for 20 mmol L^{-1} ZW3-12 – ethoxylated alcohol mixed micelles as a function of the concentration of alcohol.

C_a (mol L^{-1})	C_4E_0	C_4E_1	C_4E_2	C_4E_3
0.00	53	53	53	53
0.10	49	42	41	41
0.20	42	40	32	34
0.30	37	38	34	29

Table 4. I_1/I_3 ratios (±0.01) of surfactant and alcohol for 20 mmol L^{-1} ZW3-12 – ethoxylated alcohol mixed micelles as a function of the concentration of alcohol.



C_a (mol L^{-1})	C_4E_0	C_4E_1	C_4E_2	C_4E_3
0.0	1.55	1.55	1.55	1.55
0.1	1.53	1.54	1.55	1.53
0.2	1.49	1.53	1.52	1.51
0.3	1.47	1.52	1.53	1.49

If we examine the N_s values at a given alcohol concentration in Figs. 5 and 6, a decrease in N_s value is observed when the values for C_4E_0 are compared to those for the three other alcohols, but there are no significant differences noted within the ethoxylated alcohols themselves. This suggests again that the number of EO groups is not contributing to hydrophobic effects in these systems.

The I_1/I_3 ratios provide information on the polarity experienced by pyrene in these mixed micelles; these values are given in Table 4. In all cases, we observe a decrease with increasing concentration of added alcohol for all four alcohols. This suggests that pyrene is experiencing a progressively less polar environment as more alcohol is added to the mixed solvent system. This could be due to alcohol molecules blocking water penetration into the micelle (22). However, this trend is only subtle. Comparing the I_1/I_3 ratios at a given alcohol concentration, it is seen that the ratios are relatively insensitive to changing the alcohol from C_4E_0 to C_4E_3. This suggests that the pyrene experiences essentially the same microenvironment in all the ethoxylated alcohol – zwitterionic surfactant systems studied at the same alcohol concentration. An important point about these I_1/I_3 ratios is that they are comparable to the I_1/I_3 ratios of cationic surfactants such as DTAB, i.e., the ratio for ZW3-12 without added alcohol is 1.55, whereas the I_1/I_3 ratio for DTAB is 1.40, and that of SDS is 1.26 (22). For the ZW3-12 surfactants, a considerable nonpolar environment could be provided by the two methyl groups and the methylene groups of the intercharge arm. On the basis of this, the relatively high I_1/I_3 ratio for ZW3-12 both by itself and in the presence of the ethoxylated alcohols at all concentrations suggests that this affinity of the quaternary ammonium headgroup for pyrene could play a role, despite the nearby presence of an anionic functionality, the sulfonate group. Perhaps the affinity of the quaternary ammonium site could be due to the ob-

© 2004 NRC Canada

Fig. 6. N_s values (±5) for ZW3-12–C_4E_2 (●) and ZW3-12–C_4E_3 (▲) mixed micelles as a function of C_a.

servation that zwitterionic micelles are expected to bind anions electrostatically because the charge density due to the cationic ammonium centres is higher than that at the anionic sulfonate centres (24). In this case, although pyrene is not an anion, it acts as a Lewis base, and a polarization of its π-electron cloud could be caused by protons and positively charged groups. However, the interaction between pyrene and the quaternary ammonium groups is not thought to be strong (25). As well, in a zwitterionic surfactant, the possibility exists that the pyrene is repelled by the anionic sulfonate group.

A consideration that might explain these observations is that the sulfonate group can bend toward the ammonium group and the electrostatic interaction causes the formation of a six-member ring-like structure. The headgroups of these surfactants are already large, but this would make them very bulky. Thus, the longer ethoxylated alcohols might be too large for significant formation of mixed micelles because they are blocked from penetration into the micelle and any additional EO groups would not significantly decrease the cmc values. The bulkiness might also prevent aggregation with the polymer and if the positively and negatively charged centres essentially neutralize one another, the sulfonate group would not be expected to interact strongly with PEO. The subtle decrease of N_s values might also be explained by the idea of a six-member ring. We are currently undertaking NMR 2D-NOESY and ^{13}C chemical shift experiments of these systems to investigate the possibility of inter- and intramolecular correlations that would give us significant insights as to the conformation of the tail and headgroup moieties in the zwitterionic surfactant.

If the alcohols cannot penetrate the micelle very effectively as the micelles become larger, then N_a values would not be expected to increase and N_s values would not decrease significantly, at a constant total aggregation number ($N_a + N_s$). N_a values can be calculated if the partition constants for these alcohols in the zwitterionic surfactant are known; this will be the subject of a future paper.

The I_1/I_3 value might be observed to be large because the pyrene finds a significantly more polar environment in the region created by the ammonium–sulfonate interaction. The presence of alcohols and the ethoxylate groups likely would not alter this environment in any substantive way if they cannot penetrate significantly into the micellar interior. We note that most of these effects can be explained with the idea of a six-member ring-like structure, or some other conformation change that leads to subtle changes in the packing and charge distribution in the headgroup region of the ZW3-12 surfactant micelles. The aforementioned NMR 2D-NOESY and ^{13}C chemical shift experiments are expected to shed light into these areas.

Finally, in considering the results presented here, it is important to note the nature of the EO group in the alcohol. The hydroxyl group is hydrophilic and, as has been demonstrated for other alcohols by NMR 2D-NOESY experiments (26), it would be anchored at the micellar surface when mixed micelles form. The EO group is more complex. The oxygen is capable of hydrogen bonding and so may favour interactions with water in some cases. Indeed, Manabe et al. (3) have described EO as a hydrophilic group, though less so than the OH group. However, the two-carbon chain on the EO group is hydrophobic and may prefer the micellar interior environment if it is accessible. A strict definition of the behaviour of the EO group is difficult here. There may be binding of the alcohol groups and complex interactions with the micellar interior, the headgroup region, and (or) with water molecules at the micellar surface and in the bulk. This therefore limits any predictions of its behaviour. Marangoni and Kwak (4) and Marangoni et al. (9) have viewed the EO group as contributing in a small but significant manner to the hydrophobic effects in mixed micelles with SDS because there the cmc value decreased drastically with more EO groups. Since this is not observed with ZW3-12, it could be surmised that the EO group in this system behaves more as a hydrophilic group. This would be supported by the lack of interaction of ZW3-12 with PEO. With the large number of EO groups, the polymer prefers the bulk water solution, even though it has been shown by both NMR 2D-NOESY experiments (27, 28) and NMR ring-current effects (29) that for some surfactant systems, some of the PEO EO groups are penetrating the micelle palisade layer and are indeed solubilized in the micellar interior. Since the system also exhibits no CAC, interaction of PEO with surfactant monomers also seems unfavourable and may be due to a lack of an interaction between the EO groups and the micellar interior (in effect, the PEO seems to be blocked out of the micellar interior, much like the case of the cationic surfactants). The increase in the cmc value with increasing weight % of PEO also supports these poor interactions between ZW3-12 and PEO.

Conclusions

The interactions of ZW3-12, a zwitterionic surfactant, with ethoxylated alcohols and the polymer PEO were examined by luminescence probing experiments. The cmc values of the ZW3-12 – ethoxylated alcohol systems decreased with increasing added alcohol concentration. However, as the number of EO groups in the alcohol increased, at a constant concentration of added alcohol, the cmc values appeared to be insensitive to the addition of the EO groups to the alcohol. Surfactant aggregation numbers decreased with increasing added alcohol concentration, and again the EO group showed no significant influence on the magnitude of

© 2004 NRC Canada

the N_s value at a constant alcohol concentration. As well, I_1/I_3 values decreased with increasing added alcohol concentration but were relatively high, and again the number of EO groups did not cause significant variation in these ratios. The probe, therefore, consistently experienced a relatively nonpolar environment in these zwitterionic surfactants. Thus, it can be concluded from these measurements that mixed micelles are formed in these systems but the EO groups do not solubilize preferentially in the micellar interior, and hence do not appear to contribute to the hydrophobic effects. For the ZW3-12–PEO system (a polymer–surfactant system), no formation of complexes or penetration of PEO into the micellar interior was observed. By comparing these results to the case of SDS – and DTAB – ethoxylated alcohol mixed micellar systems, the ZW3-12 surfactant appears to behave more like the cationic DTAB surfactant. This suggests that the ammonium functionality of the headgroup defines the behaviour for this surfactant in these systems. Questions remain about the specifics of the interactions observed, especially regarding the sulfonate functionality of the headgroup, and the EO group. These will be the subject of future investigations.

A simple biomimetic protocol for the oxidation of alcohols with sodium hypochlorite in the presence of β-cyclodextrin in water

K. Surendra, N. Srilakshmi Krishnaveni, and K. Rama Rao

Abstract: A simple and efficient protocol, which is inexpensive, convenient, clean, and facile, for oxidation of alcohols to carbonyl compounds has been developed using sodium hypochlorite in the presence of β-cyclodextrin with water as solvent. A series of alcohols were oxidized at room temperature in excellent yields.

Key words: oxidation, alcohols, sodium hypochlorite, KBr, β-cyclodextrin, biomimetic, water.

Résumé : On a mis au point un protocole simple et efficace d'oxydation des alcools en composés carbonylés qui est peu coûteux, pratique, propre, et facile et qui fait appel à l'utilisation d'hypochlorite de sodium en présence de β-cyclodextrine dans l'eau comme solvant. On a oxydé une série d'alcools, à la température ambiante, avec d'excellents rendements.

Mots clés : oxydation, alcools, hypochlorite de sodium, KBr, β-cyclodextrine, biomimétique, eau.

Introduction

Green chemistry is becoming a central issue in both academic and industrial research in the 21st century (1). Industrial chemistry is not sustainable without this approach. Hence, the goal of present-day industrial research is to develop environmentally benign and clean synthetic technologies, thereby minimizing the cost of waste disposal.

Among various reactions of industrial significance, oxidation of alcohols to carbonyl compounds is a pivotal reaction and is essential for the preparation of organic intermediates, fragrances, and food additives (2). Numerous methods have been developed for these oxidations (3–17). All these traditional methods involve the use of stoichiometric amounts of inorganic oxidants, e.g., Cr(VI), which generate copious amounts of waste heavy metals. Moreover, these methods involve the use of hazardous reagents and solvents, and sometimes expensive reagents and transition metal catalysts, which interfere and make the recovery of catalyst cumbersome. In some cases, overoxidation products have also been detected. The use of molecular O_2 for oxidation is often difficult to control and sometimes results in combustion, and the reaction is performed with low conversion to avoid overoxidation.

Among various oxidizing agents, sodium hypochlorite seems to be the most inexpensive with the highest potential for industrial application. The earliest application of NaOCl as a practical synthetic reagent for alcohol oxidation involved its use in a two-phase system with a phase-transfer catalyst (18). More recently, two improved methods for bleach oxidation of alcohols have been developed. One method employs acetic acid as a solvent in a monophasic system (19) while the other uses catalytic amounts of TEMPO in a buffered biphasic medium (20). All these methods involve the use of biphasic systems employing dichloromethane or toluene as the organic phase, a phase-transfer catalyst, and subsequent formation of overoxidation products. It is difficult to find a procedure that is selective, cheap, efficient, and easy to work up.

In a continuation of our work on supramolecular chemistry involving cyclodextrins (21), we have attempted the oxidation of alcohols with sodium hypochlorite in the presence of β-cyclodextrin in water to develop an environmentally viable process. Cyclodextrins, which are cyclic oligosaccharides, exert microenvironmental effects leading to selective reactions. They catalyze reactions by supramolecular catalysis through non-covalent bonding as seen in enzymes. Complexation depends on the size, shape, and hydrophobicity of the guest molecule. Thus, mimicking biochemical selectivity, where orientation of the substrate by complex formation positioning presents only certain regions for favorable attack, will be superior to chemical selectivity, which involves random attack at different regions due to the intrinsic reactivity of the substrate. These attractive features of cyclodextrins in the biomimetic modeling of chemical reactions prompted us to investigate a variety of oxidations us-

ing the substrate β-cyclodextrin complexes with sodium hypochlorite in water. The complexes were formed with β-cyclodextrin since it is easily accessible and the least expensive among the cyclodextrins.

There are reports of utilizing sodium hypochlorite in conjunction with cyclodextrins for certain oxidations such as for the chlorination of anisole at the para position (22), for asymmetric catalytic epoxidation (23), and sulfoxidation (24). To date, no alcohol oxidations to important carbonyl compounds have been carried out with sodium hypochlorite under supramolecular catalysis involving cyclodextrins.

Experimental

Materials

All reactions were carried out in an air atmosphere without any special precautions. Chemicals and solvents were purchased from Fluka and S. D. Fine Chemicals and used as received. ^{1}H NMR spectra were obtained on a Gemini-200 or 300 MHz spectrometer. IR spectra were recorded on a Nicolet Nexus 670 FT-IR spectrometer. Mass spectra were observed on a Micromass VG AutoSpec M spectrometer.

Typical procedure for oxidation

β-Cyclodextrin (1 mmol) was dissolved in water (15 mL) at 60 °C, then substrate (1 mmol) previously dissolved in methanol/acetone (1 mL) was added slowly with stirring and cooled to room temperature. Later, the reaction was cooled in an ice bath and sodium hypochlorite (5 mmol) was added slowly, followed by addition of KBr (1 mmol) and subsequent stirring at room temperature was continued until the reaction had gone to completion (Table 1). It was extracted with ethyl acetate and filtered. The organic layer was dried over anhydrous Na_2SO_4 and the solvent was removed in vacuum to obtain the crude product, which was purified by column chromatography using *n*-hexane : ethyl acetate (95:5) on silica gel.

Results and discussion

The reaction was carried out by the in situ formation of the β-cyclodextrin complex of the alcohol in water followed by addition of sodium hypochlorite and KBr at 0–5 °C and later stirring at room temperature until the reaction went to completion. A variety of alcohols have been oxidized to their corresponding carbonyl compounds in impressive yields using NaOCl–KBr under supramolecular catalysis in water (Scheme 1). This methodology is also compatible in the presence of other functionalities such as methoxy, methylenedioxy, nitro, hydroxy, and alkene double bonds. The yields of oxidation products of primary alcohols are comparatively better than secondary alcohols. Though inclusion complexation takes place in situ during the reaction, the complexes have been isolated and characterized by powder X-ray (25) and ^{1}H NMR studies (26). All the compounds were characterized by MS, ^{1}H NMR, and IR techniques followed by comparison of the collected data to known compounds (27).

The reaction has also been studied in detail for various ratios of β-cyclodextrin and KBr by taking 4-methoxybenzyl alcohol as an example (Table 2). It was observed that optimum yields were obtained when β-cyclodextrin and KBr were taken in equimolar ratios of 1 equiv. each. However, the yields were comparatively less with lower ratios of β-cyclodextrin and KBr. Another point of interest is that the yields were drastically reduced with lower equivalents of KBr in spite of higher ratios of β-cyclodextrin. Thus, it could be seen that KBr plays a major role in these oxidations and its function can be explained as follows.

Scheme 1.

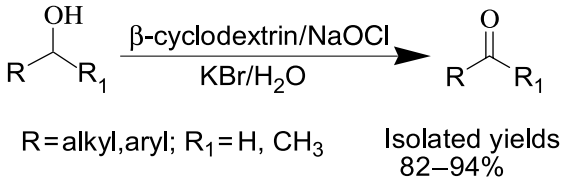

Table 2. Oxidation of 4-methoxybenzyl alcohol using NaOCl–KBr system.

Entry	β-CD [a] (mmol/L)	Hypo[b] (mmol/L)	KBr (mmol/L)	Alcohol (mmol/L)	Yield (%)
1	0.1	5.0	0.1	1.0	30
2	0.1	5.0	1.0	1.0	45
3	1.0	5.0	0.1	1.0	68
4	1.0	5.0	1.0	1.0	94

[a]β-Cyclodextrin.
[b]Sodium hypochlorite.

The oxidation of alcohols in the presence of β-cyclodextrin using sodium hypochlorite and KBr can take place through the initial formation of β-cyclodextrin–hypochlorite as observed by Breslow and co-workers (22) followed by the in situ generation of the more active β-cyclodextrin–hypobromite, which further increases the oxidation yields. This is substantiated by the fact that no oxidation was observed when the alcohol was reacted in the presence of β-cyclodextrin using hydrogen peroxide and KBr.

In conclusion, we have developed an inexpensive, eco-conscious chemical process for the oxidation of alcohols to carbonyl compounds in aqueous medium. This methodology is simple, inexpensive, and can be applied to a variety of substrates with high potential for industrial applications.

ANNOUNCEMENT / COMMUNIQUÉ

May 1929 marked the publication of Volume 1 Number 1 of the *Canadian Journal of Research* by the National Research Council of Canada. An introduction by NRC President H.M. Tory stated that, "While the Journal is intended primarily for the publication of results of work carried out under the auspices of the Council, it will also be open for suitable papers from Canadian research workers not connected with this organization" — little imagining that one day NRC research journals would be open to the world.

NRC Research Press (now part of the NRC Canada Institute for Scientific and Technical Information) is Canada's foremost publisher of scientific and technical information. The Press publishes 15 journals in fields as diverse as genomics, chemistry, zoology, and civil engineering.

A number of Research Press journals trace their origins back to the original volume in 1929 and, testament to growing specialization in the sciences, have undergone many name changes along the way. In recent years, new journals reflecting emerging areas of research have been added to the Research Press stable. The most recent addition is the 2002 launch of the *Journal of Environmental Engineering and Science*.

All Research Press journals are internationally respected, peer-reviewed journals, well rated in terms of impact factor (the number of times papers from specific publications are cited by other authors, divided by the number of scientific papers published, calculated over a two-year period). Research Press journals *Canadian Journal of Fisheries and Aquatic Sciences* and *Biochemistry and Cell Biology* have very high impact factors; in addition, the *Canadian Journal of Fisheries and Aquatic Sciences* and the *Canadian Journal of Forest Research* are listed among the top four publications in their fields.

NRC Research Press journals focus on critical, high-quality research from Canadian universities and industry and from international research centres. In 2003 the Press received 3941 research papers from authors in Canada and around the world, of which 1841 were accepted and published after rigorous peer review by international boards of associate editors and peer reviewers.

Once published, Research Press journals appear in print and on the Web. More than three quarters of the journals' subscriptions are sent to international subscribers such as academic libraries, research centres, and universities. The journals are now available on the Web free of charge to all Canadians through the support of the federal government's Depository Services Program.

Research Press also has developed an extensive program of scientific monographs and conference proceedings. It has recently launched a series of biographies of famous Canadian scientists and engineers, including physicist Gerhard

Mai 1929 a marqué la parution du numéro inaugural du *Canadian Journal of Research* par le Conseil national de recherches du Canada. En préface, le président du CNRC de l'époque, H.M. Tory, observait : « Bien que cette revue se veuille principalement un véhicule de diffusion des résultats de la recherche réalisée sous la bannière du Conseil, on y publiera volontiers des articles méritoires signés par des chercheurs canadiens non affiliés à notre organisme. » Jamais il n'aurait pu présager la place que se tailleraient un jour les revues du CNRC sur la scène mondiale.

Les Presses scientifiques du CNRC (aujourd'hui rattachées à l'Institut canadien de l'information scientifique et technique) constituent le plus important éditeur de publications scientifiques et techniques du pays. Elles publient quinze revues dans des domaines aussi variés que la génomique, la chimie, la zoologie et le génie civil, pour ne nommer que ceux-là.

Plusieurs des revues des Presses scientifiques tirent leur origine du premier numéro du *Journal*, en 1929, et ont revêtu de nouvelles dénominations au fil de la spécialisation de la science. Au cours des dernières années, de nouvelles revues reflétant des secteurs scientifiques naissants sont venues s'ajouter à la gerbe des Presses scientifiques du CNRC. La cadette, qui a vu le jour en 2002, est la *Revue du génie et de la science de l'environnement*.

Toutes les revues des Presses scientifiques sont arbitrées, mondialement respectées et déterminantes par leur facteur d'impact (soit le nombre de fois que des articles d'une publication sont cités par des auteurs externes, divisé par le nombre total d'articles publiés sur une période de deux ans). De fait, les revues des Presses scientifiques *Journal canadien des sciences halieutiques et aquatiques et Biochimie et biologie cellulaire* affichent des facteurs d'impact très élevés; de plus, le *Journal canadien des sciences halieutiques et aquatiques* et la *Revue canadienne de recherche forestière* font partie des quatre publications les plus reconnues dans leur domaine respectif.

Les revues des Presses scientifiques du CNRC ciblent principalement la recherche critique et supérieure réalisée par les universités et l'industrie canadienne de même que par les centres de recherche internationaux. En 2003, les Presses ont reçu 3941 articles en provenance du Canada et de l'étranger, parmi lesquels 1841 ont été publiés après un rigoureux examen par des comités de lecture internationaux composés de directeurs scientifiques associés et d'examinateurs spécialisés.

Toutes les revues des Presses paraissent sous forme imprimée et sur le Web. Plus des trois quarts des abonnements sont destinés à des organismes étrangers, y compris des bibliothèques savantes, des centres de recherche et des universités. Nos revues sur le Web sont maintenant accessibles

Herzberg and inventor George J. Klein. Since 1997, the Press has supported the research and scientific community in Canada by publishing 14 other journals on behalf of Canadian scientific societies such as the Agricultural Institute of Canada and the Mineralogical Association of Canada.

NRC Research Press has moved a long way in the past 75 years, but it cannot slow the pace. *Au contraire*: scientific communication is evolving quickly, and NRC Research Press is evolving with it. The need for speedy publication, new publishing technologies, new delivery formats, and new business models such as open access are the main drivers in scientific publishing today. To meet future needs, the Press is adopting new publishing technologies and standards such as XML, as well as exploiting the functionality of the Internet to launch a new submission and review system called **OSPR**EY. The Press has also allowed the popular search engine Google to "deep index" its Web-based publication, to assist users in gaining fast and precise access to valuable content. Articles will soon be available in full-text HTML on the Web, enabling reference linking and other functionality.

NRC Research Press continues to plan and work toward the future, but it cannot work alone. The Research Press is looking for partners and has recently undertaken joint projects with the Commonwealth Scientific and Industrial Research Organisation in Australia and CABI Publishing in the United Kingdom.

Finally, none of this illustrious 75 years of publishing would have been possible without the commitment and support of the researchers in the scientific community, the editors and reviewers who select and review the research, and the staff of the NRC Research Press who edit and publish it. My personal thanks to all of you, and my sincere wishes for another 75 years of scientific publishing leadership.

Bruce Dancik
Editor-in-Chief
NRC Research Press

à titre gratuit à tous les Canadiens, grâce à l'appui du Programme des services de dépôt du gouvernement du Canada.

Les Presses scientifiques administrent également un enviable programme de publication de monographies scientifiques et de comptes rendus de conférences. Par ailleurs, elles ont récemment donné le coup d'envoi à une collection de biographies de scientifiques et d'ingénieurs canadiens de renom, notamment le physicien Gerhard Herzberg et l'inventeur George J. Klein. Depuis 1997, les Presses ont prêté main-forte à la collectivité canadienne de la recherche et de la science en publiant quatorze autres revues au nom de sociétés scientifiques canadiennes telles que l'Institut agricole du Canada et l'Association minéralogique du Canada.

Les Presses scientifiques du CNRC ont certes fait de grandes enjambées au cours des 75 dernières années, mais elles ne peuvent pas s'endormir sur leurs lauriers. Il est un fait que la communication savante se transforme sans cesse et que les Presses scientifiques se doivent d'emboîter le pas. Ainsi, la publication accélérée, les nouvelles technologies d'édition, les modes de diffusion évolués et les nouveaux modèles commerciaux, notamment le libre accès, sont les tendances les plus influentes sur le secteur de l'édition savante. Conscientes de l'importance d'être « de leur temps », les Presses adoptent de nouvelles technologies et normes de publication, telles que le XML, et exploitent le plein potentiel d'Internet en lançant un nouveau système de soumission et d'examen de manuscrits en direct appelé **OSPR**EY. Les Presses ont également autorisé le moteur de recherche bien connu Google à réaliser un dépouillement approfondi de leurs publications Web, cela afin d'assurer le repérage rapide et efficace d'articles d'intérêt par les utilisateurs. À courte échéance, tous les articles intégraux seront offerts en format HTML sur le Web, ce qui permettra l'hyper-référençage et d'autres fonctions avancées.

Les Presses scientifiques du CNRC continuent à planifier l'avenir et à travailler en ce sens mais savent qu'elles ne peuvent pas s'exécuter en solitaire. Elles restent à l'affût des partenariats et, témoin, ont récemment lancé des coentreprises avec la Commonwealth Scientific and Industrial Research Organisation, en Australie, et CABI Publishing, au Royaume-Uni.

Nos 75 brillantes années d'édition sont étroitement tributaires de l'engagement et de l'appui des chercheurs de la collectivité scientifique, des directeurs scientifiques et examinateurs qui sélectionnent et évaluent les manuscrits, et du personnel des Presses scientifiques du CNRC, qui les pétrissent et les publient. Je tiens à remercier chacun de vous de votre apport et je nous souhaite à tous encore 75 ans d'excellence en édition scientifique.

Gaussian basis sets for low-lying excited states of neutral atoms with $2 \leq Z \leq 36$

M.T. Barreto, A. Canal Neto, and F.E. Jorge

Abstract: The improved generator coordinate Hartree–Fock method is used to generate Gaussian basis sets for low-lying excited states of neutral atoms from He (Z = 2) to Kr (Z = 36). Then, excitation energies and orbital energies of the outermost orbitals of each symmetry are calculated and compared with the corresponding values obtained with numerical Hartree–Fock calculations. Besides this, the basis sets for Be (^{3}P) and F (^{2}P) are contracted by a standard procedure and, then, enriched with polarization functions. From these basis sets, total energies, dissociation energy, and bond length for BeF are calculated and compared with results obtained with other basis sets and with experimental values. The sets for He–Kr are useful in constructing basis sets for molecular calculations.

Key words: improved generator coordinate Hartree–Fock method, Gaussian basis sets, low-lying excited states, neutral atoms.

Résumé : On a utilisé la méthode améliorée de Hartree–Fock avec coordonnée génératrice pour générer des ensembles de base gaussiens pour les états excités de basse énergie des atomes neutres allant de He (Z = 2) à Kr (Z = 36). On a ensuite calculé les énergies d'excitation et les énergies orbitales des orbitales extérieures de chacune des symétries et on les a comparées aux valeurs correspondantes obtenues par des calculs de Hartree–Fock numériques. De plus, on a contracté les ensembles de base pour Be (^{3}P) et F (^{2}P) en faisant appel à une procédure standard suivie par l'enrichissement à l'aide de fonctions de polarisation. À partir de ces ensembles de base, on a calculé les énergies totales et l'énergie de dissociation de BeF ainsi que la longueur de la liaison BeF et on les a comparées aux résultats obtenus avec d'autres ensembles de base et avec les valeurs expérimentales. Les ensembles pour He–Kr sont utiles pour construire des ensembles de base pour faire des calculs moléculaires.

Mots clés : méthode améliorée de Hartree–Fock avec coordonnée génératrice, ensembles de base gaussiens, états excités de basse énergie, atomes neutres.

[Traduit par la Rédaction]

Introduction

Mohallem et al. (1) developed the generator coordinate Hartree–Fock (GCHF) method, which was used with success in the generation of universal basis sets of various atomic systems (2–5).

In 1999, Jorge and de Castro (6) presented the improved GCHF (IGCHF) method and applied it to generate Gaussian basis sets (GBSs) for first-row atoms. In the last 4 years, the IGCHF method has been applied with success to generate accurate GBSs for several atomic and molecular systems (7–10).

It is known that for some atoms (for example: Li, Be, Na, etc.) it is necessary to optimize uncontracted basis sets of some excited states to obtain reasonable descriptions of all valence orbitals, since these orbitals have a crucial importance to the chemical bond description of molecular systems. In this work, the IGCHF method was applied to generate GBSs of low-lying excited states of neutral atoms from He (Z = 2) to Kr (Z = 36). The excitation energies were evaluated and compared with those obtained with a numerical HF (NHF) method (11, 12). Besides this, the orbital energies of the outermost orbitals of each symmetry were also computed. To test the performance of the GBSs generated in this work, the basis sets of Be (^{3}P) and F (^{2}P) were contracted and enriched with polarization functions and, then, used at the restricted open-shell HF (ROHF) and RO Møller–Plesset second-order (ROMP2) levels to calculate energies, bond length, and dissociation energy of the BeF molecule. A comparison with results obtained with other approaches (13, 14) and with experimental values (15, 16) was done.

Improved generator coordinate Hartree–Fock method

The GCHF approach (1) is based on choosing the one-electron functions as a continuous superposition, i.e.,

$$[1] \qquad \Psi_i(1) = \int \phi_i(1,\alpha)\, f_i(\alpha) \mathrm{d}\alpha \qquad i = 1,\ldots,n$$

where ϕ_i are the generator functions, f_i are the weight functions, and α is the generator coordinate. Using eq. [1] to build a Slater determinant for the multielectronic wave functions, and minimizing the total energy (E) with respect to the

 doi: 10.1139/V04-084 © 2004 NRC Canada

f_i, one arrives at the Griffin–Hill–Wheeler–HF (GHWHF) equations (1),

$$[2] \qquad \int [F(\alpha,\beta) - \varepsilon_i S(\alpha,\beta)]\, f_i(\beta)\mathrm{d}\beta = 0 \qquad i = 1,\ldots,n$$

where the ε_i are the HF eigenvalues, and the Fock ($F(\alpha, \beta)$) and overlap ($S(\alpha,\beta)$) kernels were defined by Mohallem et al. (1).

The GHWHF equations were integrated numerically through a technique called integral discretization (ID) (17). This technique was implemented through a relabelling of the generator coordinate space, i.e.,

$$[3] \qquad \Omega = \ln\alpha/A \qquad A > 1$$

where A is a scaling parameter determined numerically. The new generator coordinate space (Ω) was discretized for each s, p, d, and f symmetry in an equally spaced mesh $\{\Omega_i\}$ so that:

$$[4] \qquad \Omega_k = \Omega_{\min} + (k - 1)\Delta\Omega \qquad k = 1,\ldots,N$$

In eq. [4], N is the number of discretization points defining the basis set size, $\Omega_{\min}$ is the initial point, and $\Delta\Omega$ an increment. Thus, the original GCHF method (1) corresponds to the use of only one arithmetic sequence of equally spaced points $\{\Omega_i\}$ to generate single-optimized Gaussian basis sets.

Jorge and de Castro (6) have found a simple modification in the GCHF method that produces improvements in the HF atomic energy values without adding more functions (in our case, Gaussian-type functions (GTFs)); this methodology has been named the IGCHF method. In this new approach, the new generator coordinate space (Ω) was discretized for each s, p, d, and f symmetry in three independent arithmetic sequences,

$$[5] \qquad \Omega_k = \begin{cases} \Omega_{\min} + (k-1)\Delta\Omega & k = 1,\ldots,j \\ \Omega'_{\min} + (k-1)\Delta\Omega' & k = j+1,\ldots,M \\ \Omega''_{\min} + (k-1)\Delta\Omega'' & k = M+1,\ldots,N \end{cases}$$

For a given value of N, the number of parameters now to be optimized for each symmetry when one uses eq. [5] is three times that of the original GCHF method (see eq. [4]). The basis sets generated through eqs. [3] and [5] were called triple-optimized Gaussian basis sets (TOGBSs) (6).

We call attention to the fact that when eq. [5] is used, there is no longer an equally spaced mesh $\{\Omega_i\}$ because now there are three arithmetic sequences to generate the basis function exponents for each symmetry.

Results and discussion

Neutral atoms

The IGCHF method presented in the previous section was employed to generate TOGBSs for low-lying excited states of the neutral atoms from He to Kr. The scaling parameter A (see eq. [3]) utilized in the calculations is equal to 6.0. All calculations were carried out using a modified version of the ATOMSCF program (18). For all excited states studied, the optimization process was repeated until the total energies stabilized within 10 significant figures.

In this work, we considered all states arising from the following electronic configurations:

He ($1s^2$ and $1s^12p^1$), Li and Na (ns^1 and np^1), Be to F and Mg to Cl (ns^2np^m and ns^1np^{m+1}), Ne ($2s^22p^6$ and $2s^22p^53s^1$), Ar ($3s^23p^6$, $3s^23p^54s^1$, and $3s^23p^53d^1$), K ($4s^1$, $4p^1$, and $3d^1$), Ca ($4s^2$, $4s^14p^1$ and $4s^13d^1$), Sc to Cu ($4s^23d^m$ and $4s^13d^{m+1}$), Zn ($4s^2$, $4s^14p^1$, and $4s^14d^1$), Ga to Br ($4s^24p^m$ and $4s^14p^{m+1}$), and Kr ($4s^24p^6$, $4s^24p^55s^1$, and $4s^24p^54d^1$).

Although we have calculated 109 excited states arising from the above configurations, we give information about the ground states (6–8) for completeness here. Tables 1 (He to Ar) and 2 (K to Kr) display the excitation energies [E(excited state) – E(ground state)] of some states and the orbital energies (ε) of the outermost orbitals of each symmetry evaluated with the IGCHF (6) and NHF (11, 12) methods. The ground-state total HF energies are also presented. All values are given in hartrees (1 hartree = 4.3598×10^{-18} J).

From Table 1 one can verify that the total energy errors obtained with the TOGBSs for the atoms from He to Ar are always smaller than 1.3 mhartree. Colpa et al. (19) observed that within the same electronic configuration, the smallest mean electron–nucleus distance is associated with the state of the lowest total energy and maximum multiplicity. One particular example is the case of the ^{1}P and ^{3}P states of Be $2s^12p^1$. As discussed previously by other authors (20–23), the broadness of the $2p$ atomic orbital in Be ^{1}P arises from a repulsive exchange potential among the $2s$ and $2p$ electrons. In both the ^{1}P and ^{3}P states, the $2s$ orbital energies are lower than in the ground state (see Table 1). Thus, one can think that in excited states arising from $2s \rightarrow 2p$ transitions, the ε_{2s} should be lower than in the ground state, but Table 1 shows that this expectation does not hold in many cases. The $3p^53d^1$ ^{3}D and ^{1}D energy levels of Ar are degenerate in the restricted HF theory, since the two configuration state functions share the same energy expression. In general, in the same group of the Periodic Table, the excitation energies of each atom of the first row are larger than the corresponding ones of the second row. Here, it is also important to emphasize that for the atoms from He to Ar the excitation and orbital energies evaluated with the TOGBSs are in good agreement with the corresponding NHF results (11).

For the atoms from K to Kr (see Tables 2), the differences among the corresponding total energies computed with the IGCHF (6) and NHF (12) methods are in the range between 0.36 and 6.88 mhartree. The excitation energy from the $4s$ to $3d$ atomic orbital ($4s^23d^m \rightarrow 4s^13d^{m+1}$) decreases from Sc (0.036 604 6 hartree) to V (0.004 148 3 hartree). For Cr, the $4s^13d^5$ configuration becomes the ground state. For the next atom (Mn), the ground state is the $4s^23d^5$ configuration and the $4s \rightarrow 3d$ transition requires an excitation energy of 0.121 786 hartree. The excitation energy again decreases to 0.046 150 hartree for Ni. Then, for the Cu atom the $4s^13d^{10}$ configuration is the ground state. The symmetry of the ground states obtained with the IGCHF method (6) agrees with the experimental one (24). For the atoms displayed in Table 2, there is excellent agreement among corresponding excitation and orbital energies evaluated with the IGCHF and NHF (12) methods.

[a]Excitation energies and energies of the outermost atomic orbitals obtained with our triple-optimized Gaussian basis sets (TOGBSs).
[b]Excitation energies obtained by Tatewaki et al. (11) with a numerical HF (NHF) method.
[c]Ground state total and orbital energies obtained with the TOGBSs of refs. 6 and 7.
[d]Ground state total energies obtained with an NHF method (11).

oped in three stages: (*i*) generation of extended basis sets in atomic calculations; (*ii*) construction of contracted basis sets using a segmented or general contraction scheme; and (*iii*) addition of supplementary functions of polarization and of diffuse character. The first stage in this work was done by employing the IGCHF method (6). The second stage was implemented by employing the segmented contraction scheme proposed by Dunning (25), instead of the general contraction scheme proposed by Raffenetti (26). The main reason for choosing the segmented contraction scheme is to minimize the time required to calculate the two-electron integrals and energy gradient when using a quantum chemistry code.

For Be (^{3}P) and F (^{2}P), our (18*s*11*p*) and (20*s*11*p*) TOGBSs were contracted to [6s5p] through the contraction schemes 10,2,2,2,1,1/7,1,1,1,1 and 12,2,2,2,1,1/7,1,1,1,1, respectively. The total energies of the selected states are minimized with the ATOMSCF program (18), modified by us to introduce the IGCHF method (6). This program uses the RO SCF procedure. For F, exponents for the inner and valence atomic orbitals were obtained by minimizing the total energy of the atomic ground state and, then, optimized contraction coefficients for the schemes presented above were calculated with the ATOMSCF program (18). For Be, optimization was carried out on the ^{3}P excited state to obtain a reasonable simultaneous description of both valence *s* and *p* orbitals.

To implement the contracted GBSs presented above in molecular calculations, it is necessary to include polarization functions to the basis sets to better describe the energy and other chemical and physical properties. The choice of *d*, *f*, *g*, and *h* polarization functions for Be (^{3}P) and F (^{2}P) was done using the minimum ROMP2 energy criterion in atomic calculations. These calculations were performed with the Gaussian 94 program (27) using pure *d*, *f*, *g*, and *h* functions.

Some comment should be made on the variational use of the second-order perturbation energy. The variational theorem does not apply to this energy, which is not an expectation value of the Hamiltonian. Nevertheless, practical computations have suggested that MP2 energy does approach a limiting value from above as the size of the basis set is increased (28).

In the above procedure, we have not included the full correlation energy correction, but have limited it to the valence atomic orbitals. This approximation is known as frozen core

[b]The total energies were calculated using the experimental nuclear distance (1.361 Å).
[c]The dissociation energies were calculated using the experimental nuclear distance (1.361 Å).

for electron correlation. The reason for making this approximation is that the correlation energy associated with inner shell electrons varies little with chemical environment. Besides this, if this approximation were not used in deriving the basis sets, there would be an undesirable tendency for some of the functions to adjust themselves to give an improved description of inner shell at the expense of valence electron correlation.

Next, we considered *s* and *p* basis sets to be used in correlated calculations, that is, we reoptimized at the ROMP2 level the uncontracted exponents of the valence shell.

To obtain a preliminary assessment of the performance of the molecular basis sets constructed in this work, ROHF and ROMP2 energies (*E*), bond length (*r*), and energy dissociation (D_e) of the BeF open shell (X $^2\Sigma^+$) molecule (see Table 3) are computed and compared with results obtained with other approaches (13, 14) and with experimental values (15, 16). The calculations were performed with the Gaussian 94 program (27).

From Table 3, one can see that the 6-311++G(3df,3pd) basis set (13), the Be(32s17p17d);F(30s15p15d) basis set of primitive GTFs (14), the Be[6s5p4d3f2g1h];F[6s5p4d3f2g1h] basis set generated from the IGCHF method (6), and the Be(32s17p17d17f);F(30s15p15d15f) basis set generated by Kobus et al. (14) have associated errors of 15 723, 1177, 949, and 70 μhartree, respectively. From these results, one can verify that our total HF energy is only worse than the very large atom centered basis set of primitive GTFs of ref. 14. Here, it is important to say that this basis set has three times the number of functions of our set and that the number of two-electron integrals, which consumes a major part of the time needed in a SCF molecular orbital calcula-

© 2004 NRC Canada

tion, increases as N^4. At the MP2 level, the difference between the energies obtained with the correlated wave function of this work and the 6-311++G(3df,3pd) basis set (13) is 47 mhartree. The widely used correlation consistent basis sets of Dunning (29) are atom specific and, to our knowledge, have not been tabulated for the Be atom; thus, this is the reason that calculations with these basis sets were not included in Table 3.

At the HF level, our r and D_e results, when compared with the corresponding experimental values, are, respectively, as good as and better than those evaluated with the 6-311++G(3df,3pd) basis set (see Table 3). At the MP2 level, our r and D_e results are closer to the experimental values than those obtained with the 6-311++G(3df,3pd) basis set, and in good agreement with the corresponding experimental values.

Conclusions

The IGCHF method was employed to generate TOGBSs for low-lying excited states of neutral atoms from He to Kr. From these basis sets, excitation energies and orbital energies of the outermost atomic orbitals were calculated and compared with NHF results (11, 12). For all excited states studied here, the errors obtained with the TOGBSs are always smaller than 6.88 mhartree, and our excitation and orbital energies are in excellent agreement with the corresponding NHF results. Besides this, from the TOGBSs for Be (^{3}P) and F (^{2}P), contracted GBSs plus polarization functions are constructed and, then, used with success to study the electronic structure of the BeF molecule.

In summary, from the results presented in this work and those of refs. 6–8, we believe that the TOGBSs are useful for constructing basis sets for molecules containing any atom of the first, second, or third row of the Periodic Table.

The TOGBSs generated in this work are available as supplementary material.[2]

The titanocene-catalyzed reduction of acetamides to tertiary amines by $PhMeSiH_2$

Kumaravel Selvakumar, Kesamreddy Rangareddy, and John F. Harrod

Abstract: A variety of acetamide derivatives are reduced in excellent yields to tertiary amines by $PhMeSiH_2$ in the presence of Cp_2TiX_2 (X = F or Me) catalysts. The reactions are very clean at 80 °C. At room temperature a secondary reaction, hydrogenolysis of the C(O)—N bond, intervenes and reduces the chemoselectivity. Nevertheless, this chemistry provides a simple methodology for the amide/alkylamine transformation using inexpensive, commercially available reagents.

Key words: amides, reduction, secondary amides, methylphenylsilane, titanocene, catalysis.

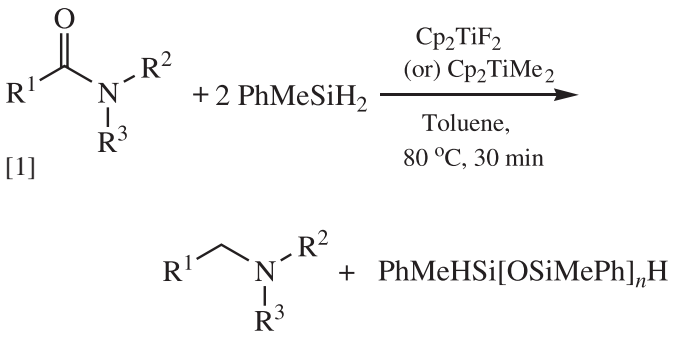
Résumé : Divers dérivés de l'acétamide sont réduits avec d'excellents rendements en amines tertiaires par le $PhMeSiH_2$ en présence de catalyseurs du type Cp_2TiX_2 (X = F ou Me). Les réactions sont très propres à 80 °C. À la température ambiante la chimiosélectivité est réduite par l'intervention d'une réaction secondaire, l'hydrogénolyse de la liaison C(O)—N. Néanmoins, cette chimie fournit une méthodologie simple pour la transformation d'amides en alkylamines faisant appel à des réactifs peu coûteux et commercialement disponibles.

Mots clés : amides, réduction, amides secondaires, méthylphénylsilane, titanocène, catalyse.

[Traduit par la Rédaction]

Introduction

The use of hydrosilation chemistry to achieve the reduction of carbonyl groups has received a great deal of attention (1–5). Many studies of ketone hydrosilation have been directed towards enantioselective synthesis of carbinols, and excellent results have been achieved with both later and early transition metal homogeneous catalysts (6, 7). Facile hydrosilations of esters and lactones have also been reported (8, 9). Among the early transition metal catalysts, titanocene derivatives are the most effective with respect to both rate and selectivity for all of these reactions.



Carboxamides are generally more resistant to reduction than ketones and esters. Nevertheless, the conversion of amides to the corresponding amines is an important transformation in organic synthetic methodology. Catalytic hydrogenation of amides normally requires high pressures and elevated temperatures (10). Consequently, stoichiometric reduction using expensive reactive main group metal hydride complexes is the usual method of choice (11–15).

Literature on the hydrosilation of carboxamides is sparse (16–19). Kuwano et al. (17) and Igarashi and Fuchikami (18) reported efficient reduction of aliphatic amides to amines by catalytic hydrosilation, using late transition metal catalysts. In a preliminary communication (19), we described an unusal titanocene-catalyzed deoxygenation/coupling of aromatic amides to give 1,2-diaminoethanes. Classical hydrosilation products (i.e., those containing either Si—OR or Si—C bonds) have never been observed as products of the reaction of amides under hydrosilation conditions.

In the present paper, we report results for the catalytic reduction of acetamides, under hydrosilation conditions, using titanocene-based catalysts. Although there is still much scope for improving the specificity and yields of catalytic amide reduction reactions, the present work shows that appropriate catalytic hydrosilation conditions can be useful for reduction of tertiary amides to tertiary amines.

Results

The reaction of acetamide derivatives with $PhMeSiH_2$ at moderate temperature in the presence of catalytic amounts of Cp_2TiX_2 (Cp = η-C_5H_5; X = F or Me) takes place as shown in eq. [1].

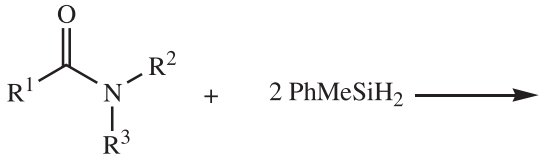
12	*N*,*N*′-Dimethylacrylamide				94 (polymer)

Note: Method A, Cp_2TiF_2 catalyst; method B, Cp_2TiMe_2 catalyst. Yields are given for isolated compounds.

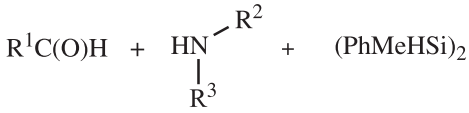
[a]10% secondary amine formed as deacetylated product.

[b]No reaction.



At 80 °C this reaction occurs rapidly and gives excellent yields of the tertiary amine, for a range of substituents R_1, R_2, and R_3. This product results from reduction and deoxygenation of the carbonyl group and contrasts with the coupling, to give vicinal diamines, observed with aromatic amides (19). The present results are very similar to those reported for reactions catalyzed by complexes of Rh (17) and Ru (18). There is, however, a considerable price advantage in using the relatively inexpensive Cp_2TiF_2.

The siloxane product was identified by ^{1}H NMR as a typical mixture of H-terminated oligo(phenylmethylsiloxanes). The resonances occur at 0.2–0.5 ppm (CH_3; broad massif or many singlet and doublet peaks), 4.6–4.8 ppm (Si–H; overlapping quartets), and 6.6–7.5 ppm (Ph; broad massif). The mass spectrum of a crude extract of the siloxane product recorded by chemical ionization mass spectrometry (CI-MS) showed the presence of oligomers of *n* up to a value of ca. 10. The siloxane product was not studied further.



The reaction shows some tolerance for functional groups, as exemplified by entries 5, 7, and 9 in Table 1. Reduction of secondary amides is very slow compared to that of *N*,*N*-disubstituted acetamides. For example, under similar conditions, acetanilide undergoes reduction to give a small amount of *N*-ethylaniline and aniline along with unreacted acetanilide. Incomplete conversion is observed even after 15 h at 80 °C. *N*,*N*-Dimethylacrylamide underwent rapid polymerization under the conditions used in these experiments, probably due to free radical initiation, and there was no evidence for reduction of the amide function.

There is little difference in the performance of Cp_2TiF_2 and Cp_2TiMe_2, but given the long-term stability of the fluoride, its commercial availability (or ease of preparation from the commercially available Cp_2TiCl_2), and its insensitivity to air and humidity, it is the preferred catalyst (20).

At room temperature, reactivity remains high (Table 2), but a side reaction involving hydrogenolysis of the C(O)—N bond (eq. [2]) lowers the efficiency of the reaction in certain

[2]

cases and complicates purification of the tertiary amine product. In some cases, this reaction becomes a major consumer of reactant (Table 2, entries 1, 3, and 7), and in one case (Table 2, entry 10) it is the only reaction observed. In the latter case, if the reaction is carried out in a closed tube, ca. 1 equiv. of acetaldehyde is also detected in solution by ^{1}H NMR. In other cases, where secondary amine is produced in a significant amount, the characteristic quartet of acetaldehyde is also detected in the ^{1}H NMR spectrum.

Catalyst concentration also has a significant influence on the relative contributions of reactions [1] and [2] at room temperature (Table 2, entries 1–6). A similar effect was detected at 80 °C. At a catalyst loading of 10 mol%, the reduction of *N*-benzylacetanilide (Table 1, entry 3) to the tertiary amine occurs with high chemoselectivity. At 5 mol% catalyst concentration, both the rate of reduction and the chemoselectivity are similar to those at 10 mol% catalyst. However, at 2 mol% catalyst concentration, the reaction is slow (1.5 h for complete conversion) and *N*-benzylaniline (24%) is formed along with *N*-ethyl-*N*-benzylaniline (76%).

The reaction mechanism

Kuwano et al. (17) suggested a mechanistic cycle for the Rh(I)-catalyzed reaction [1] involving a series of conventional two-electron oxidative addition/elimination steps, in conjunction with a σ-bond metathesis step. In principle, the mechanism of the titanocene-catalyzed reaction could be analogous to that proposed for Rh. This would require a sequence in which the Ti cycles alternately through Ti(II) and Ti(IV). Although such a two-electron cycle is not unreasonable for titanocene, a cycle involving $Ti^{III}H$ and $Ti^{III}Si$ is, in our opinion, more likely. The facile disproportionation of titanocene(III) to titanocene(II) and titanocene(IV) and vice versa makes the distinction between these two possibilities very difficult to draw, but there is ample evidence that all three oxidation states are chemically available in Cp_2TiMe_2/silane reaction mixtures (21). A tentative set of pathways that explain the observed chemistry is shown in Scheme 1. In this scheme, the silane functions as a source of hydride to generate Ti–H (step **a**) and as a receptor for O) but does not give rise to silylated organic products. Addition of Ti–H across the C=O bond (step **b**) generates the highly functionalized alkoxytitanocene intermediate, **1**. This intermediate then undergoes reactions to the various observed products, whose relative importance depends on the substituents on the substrate, on the catalyst concentration, and on the temperature. The various titanocene derivatives produced in the reactions of Scheme 1 will be recycled by appropriate σ-bond metathesis reactions with $PhMeSiH_2$.

[a]No reaction.

Scheme 1. A $[Cp_2TiH]$-mediated reaction sequence for the reduction, deoxygenation, and coupling of amides in the presence of $PhMeSiH_2$.

A possible mechanism for C—N bond cleavage is shown in Scheme 1. The favoring of the C—N bond cleavage reaction, relative to that of the C—O bond cleavage, at lower catalyst concentrations (Table 2, entries 1–6) could be due to the former involving a rate law that is higher order in catalyst concentration than is the rate law for the latter. Such a situation could arise if the recycling reactions of the titanocene products of reactions **e** and **f** in Scheme 1 are slow enough to contribute to the overall rate. Given the known tendency of titanocene(III) species to form coordination complexes (21–23), intramolecular coordination of the amino group to the Ti is a reasonable possibility. The resulting complex could then decompose in a unimolecular process to give the aldehyde and Cp_2TiNR_2. The latter could then undergo a σ-bond metathesis with Si–H to generate Ti–Si and give the secondary amine product. Finally, Ti–Si can then be converted by a σ-bond metathesis step to Ti–H and the silane dimer.

© 2004 NRC Canada

Buchwald and co-workers (24) have described a synthesis of aldehydes from acetamide derivatives by reaction with $Ti(O\text{-}i\text{-}Pr)_4/Ph_2SiH_2$. In those reactions, the primary product was found to be the enamine, which was then converted to aldehyde by mild acid hydrolysis. With our system, the aldehyde is the direct product in entry 10 of Table 2, and no intermediate vinylamine was detected. In the other reactions where significant amounts of the secondary amine were produced, acetaldehyde was also detected, but not vinylamine. However, the complexity of the reaction products in the latter cases prevented the definitive exclusion of the possible presence of vinylamine.

We attribute the reactivity difference between aromatic amides and acetamide derivatives to the lower stability of the radical intermediate in step **d** when R is an alkyl, rather than an aromatic, substituent. Detailing the mechanisms of these interesting reactions is the subject of continuing studies.

Experimental

Materials

All of the reactant amides were either obtained commercially from Aldrich Chemical Co. or synthesized by standard methods. Cp_2TiF_2 (20) and Cp_2TiMe_2 (25) were prepared according to previously described methods.

A typical procedure for the synthesis of tertiary amines is the following (Table 1, method A). *N*-Methylacetanilide (149 mg, 1 mmol), Cp_2TiF_2 (21 mg, 0.1 mmol), methylphenylsilane (0.28 mL, 2 mmol), and toluene (1 mL) were heated at 80 °C for 30 min in a Schlenk tube. After the reaction mixture had cooled to room temperature, ether (10 mL) was added and the solution was extracted with 1 mol/L HCl solution. Evaporation of the depleted ether solution gave an oily residue, which was shown by ^{1}H NMR to consist of a mixture of oligo(phenyl-methylsiloxanes) and catalyst residues. The acid extract was neutralized with 3 mol/L KOH and extracted with ether. The ether layer was dried with anhydrous $MgSO_4$ and evaporated to give analytically pure *N*-methyl-*N*-ethylaniline. In method B of Table 1, Cp_2TiMe_2 was used instead of Cp_2TiF_2. The identity of all the products listed in Table 1 was determined by comparison of ^{1}H NMR data to literature values and to those of authentic samples.

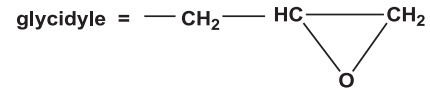
Difluorocarbene induced facile synthesis of chlorohydrins from glycidyl ethers



Sapna Singh, Pinaki S. Bhadury, Mamta Sharma, Meehir Palit, and Devendra K. Jaiswal

Abstract: A novel and unusual approach based on a $ClCF_2COONa$–DMF system has been developed for the synthesis of chlorohydrins via an unexpected mechanism. In a first ever report for the synthesis of chlorohydrins from glycidyl ethers, e.g., CH_2=CH-CH_2-O-Z, CH_3CH_2-O-Z, C_6H_5-O-Z, C_6H_4(*o*-CH_3)-O-Z, CH_2=C(CH_3)C(=O)-O-Z, etc., (where Z = glycidyl), difluorocarbene-induced facile regioselective ring opening of epoxides has generated the compound in high yield (70%–83%).

glycidyl = 

Key words: difluorocarbene, sodium chlorodifluoroacetate, chlorohydrins.

Résumé : On a mis au point une nouvelle approche inhabituelle à la synthèse de chlorohydrines qui est basée sur l'utilization du système $ClCF_2COONa$–DMF et qui implique un mécanisme inattendu. Dans ce travail, on en décrit la première application à la synthèse de chlorohydrines d'éthers glycidylés de la forme CH_2=CH-CH_2-O-Z, CH_3CH_2-O-Z, C_6H_5-O-Z, C_6H_4(*o*-CH_3)-O-Z, CH_2=C(CH_3)C(=O)-O-Z, etc., (dans lesquels Z = glycidyle) qui ont été générés avec des rendements élevés (70%–83%) par le biais d'une ouverture de cycle régiosélective et facile d'époxydes, induite par le difluorocarbène.

glycidyle = 

Mots clés : difluorocarbène, chlorodifluoroacétate de sodium, chlorohydrines.

[Traduit par la Rédaction]

Introduction

Difluorocarbene, a useful synthon (1–3), can be made by thermal decarboxylation of sodium chlorodifluoroacetate. In dimethyl formamide (DMF), this salt can act as a source of hydrogen fluoride (4–7). We showed that this property enabled the esterification of sodium chlorodifluoroacetate by fluoroalcohols (5). Here, we attempted to prepare *O*-(chlorodifluoroacylated) alcohols by treating various epoxides with sodium chlorodifluoroacetate in DMF. However, ring opening occurred to give chlorohydrins. Chlorohydrins are an important class of compounds that have several synthetic and industrial applications, including the manufacture of dye intermediates, pharmaceuticals, pesticides, and plasticizers. Routes to conventional chlorohydrins include hypochlorination, enzymatic methods, or reaction of chromyl chloride with simple aliphatic straight chain alkenes (8–11). The application of these reagents is further limited due to poor yield and the specific nature of the substrate. In this paper, we describe a new way to make them based on the special properties of the sodium chlorodifluoroacetate – DMF system. The difluorocarbene (**:**CF_2) induced regioselective ring opening of epoxides produces chlorohydrins in high yield with the chlorine atom almost exclusively located on the primary and (or) less-hindered carbon atom. This highly facile reaction works particularly well with electron deficient epoxides and has been successfully employed for the first time in the ring opening of glycidyl ethers.

Results and discussion

We have achieved regioselective synthesis of chlorohydrins by the reaction of epoxides and sodium chlorodifluoroacetate in DMF. This highly facile reaction works particularly well with electron deficient epoxides (e.g., glycidyl ethers). Furthermore, the reaction proceeds in DMF only, and no significant product could be detected in other solvents such as diglyme, triglyme, acetonitrile, and dimethyl sulphoxide.

Synthesis of a series of chlorohydrins has been achieved by heating 1 mol of monoepoxides with 2 mol of sodium chlorodifluoroacetate in DMF under a nitrogen atmosphere at a temperature of 150 °C. The compounds synthesized are listed in Table 1. With diepoxide 1,4 butanediol diglycidyl ether, under similar conditions, the reaction required 4 mol of sodium chlorodifluoroacetate. The ring opening occurs at both epoxide centers giving rise to $ClCH_2CH(OH)CH_2O(CH_2)_4OCH_2CH(OH)CH_2Cl$ (**XI**) in 71% yield.

All compounds synthesized have been characterized on the basis of IR spectra, ^{1}H and ^{13}C NMR, and mass spectral data. Purity of the products (>98%) was confirmed by ^{1}H NMR and GC–MS studies. IR showed strong bands in the region 3360–3446 (OH) and 725–752 (C-Cl) cm^{-1}. ^{1}H NMR data were consistent with the assigned structures and chemical shift values were assigned on the basis of observed splitting patterns and shielding and (or) deshielding effects exerted by neighboring groups or atoms (Table 2). This assignment was further confirmed from two-dimensional homo correlation spectroscopy (^{1}H–^{1}H HOMOCOSY) by observing contours indicative of characteristic coupling among all nonequivalent protons. The characteristic pattern of the starting epoxide ring was absent in ^{1}H NMR, confirming the complete ring opening. The integration ratio for all the protons in their respective ^{1}H NMR corresponds to the assigned structures. The representative and distinctive patterns of two magnetically nonequivalent protons of CH_2Cl moiety in product chlorohydrin after ring opening is shown in Fig. 1. Mass spectral data were recorded both in electron ionization (EI) and chemical ionization (CI) modes. The spectra were also obtained on silyl derivatives of chlorohydrins obtained through silylation with *N*,*O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA); these were particularly useful in cases where M^+ was not detectable in the original sample (Table 2). The presence of the chloromethyl moiety in the chlorohydrins is further supported by the fragmentation pattern showing the characteristic loss of CH_2Cl (*m*/*z* 49/51) from the molecular ion in their respective mass spectra. For unequivocal structural assessment of products, ^{13}C NMR data were obtained for all the chlorohydrins and described in Table 3. Physical characteristics (bp and (or) mp) of product chlorohydrins are also given in Table 3. Analytical data for elemental analysis (C and H for **I**–**IV**, **VI**, **VII**, and **XI**) and (C, H, and N for **V**) were found to be in agreement with calculated values.

Fig. 1. Representative ^{1}H NMR pattern of CH_2Cl in the product chlorohydrin.

Formation of difluorocarbene from the present system ($ClCF_2COONa$–DMF) and its participation in several synthetic transformations has been noted by several groups of workers (5, 12, 13). To account for the formation of chlorohydrins, we presume that under the influence of **:**CF_2, obtained by heating $ClCF_2COONa$, the solvent DMF probably generates an active fluoro Vilsmeier–Haack intermediate $[Me_2N–^+CHF]F^-$ (*i*, Scheme 1).

Proof of the formation of this strong Lewis acid intermediate (*i*) has been provided by Burton and Wiemers (4). It is probably that this coordinates with the epoxide oxygen atom. Any possibility of protonation on the β-oxygen (in the alkyl group R) and its subsequent participation in the reaction is ruled out on the ground that in the end, the product alkyl group has been found to remain intact. The S_N2 attack on the primary carbon atom by the chlorodifluoroacetate anion, electrophilically assisted by protonation of epoxide ring (14), generates the intermediates *O*-(chlorodifluoroacylated) alcohols (*ii*) (5). The nucleophilic attack occurs almost exclusively at the less-hindered carbon atom probably due to a

Table 2. ^{1}H NMR and mass spectral data of the chlorohydrins.[a]

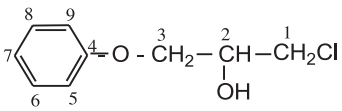
Compound No.	^{1}H NMR δ (ppm), *J* (Hz)	Mass (*m*/*z*) EI (CI)
I	5.86 (1H, m, CH_2=C*H*-CH_2), 5.23, 5.10 (2H, m, CH_2=CH-CH_2), 4.27(1H, bs, OH), 4.0 (2H, td, *J* = 5.2, 1.2, CH-CH_2-O-), 3.88 (1H, m, C*H*-OH), 3.63, 3.61 (2H, m, CH_2Cl), 3.45 (2H, d, *J* = 5.6, O-CH_2-CHOH)	150/152, 109/111, 101, 93/95, 79/81,71, (151/153)
II	7.11 (5H, m, Ar), 4.55 (1H, bs, OH), 4.18 (1H, m, C*H*-OH), 4.06 (2H, d, *J* = 5.6, O-CH_2-CH), 3.79, 3.76 (2H, m, CH_2Cl)	186/188, 137, 109/111, 107, 93/95, 79/81,77, (187/189)
III	6.97 (4H, m, Ar), 4.23 (1H, m,C*H*-OH), 4.08, 4.06 (2H, m, Ar-O-CH_2-), 3.94 (1H, bs, OH), 3.76, 3.78 (2H, m, CH_2Cl), 2.21 (3H, s, CH_3)	200/202, 151, 109/111, 107, 93/95, 79/81,91, (201/203)
IV	6.80 (4H, m, Ar), 4.13 (1H, m, C*H*-OH), 4.0, 3.96 (2H, m, Ar-O-CH_2-), 3.66, 3.64 (2H, m, CH_2Cl), 3.72 (3H,s, OCH_3), 2.88 (1H, bs, OH)	As the silyl derivative: 288/290, 239, 181/183, 165/167, 151/153, 137, 123, 107, 73, (289/291)
V	7.0, 8.2 (4H, 2xd, Ar), 4.29 (1H, m, C*H*-OH), 4.20 (2H, d, *J* = 5.6, Ar-O-CH_2 -), 3.78, 3.76 (2H, m, CH_2Cl), 2.90 (1H, bs, OH)	As the silyl derivative: 303/305, 254, 181/183, 165/167, 152, 151/153, 138, 122, 73, (304/306)
VI	3.65 (1H, m,C*H*-OH), 3.56 (1H, bs, OH), 3.34, 3.32 (2H, m, CH_2Cl), 3.21 (4H, m, CH_2-O-CH_2), 0.82 (3H, t, CH_3CH_2)	138/140, 109/111, 93/95, 89, 79/81, 59, (139/141)
VII	6.03 (2H, m, =CH_2), 4.29 (2H, d, *J* = 5.8, -O-CH_2), 4.13 (1H, m, C*H*-OH), 3.75 (1H, bs, OH), 3.67, 3.65 (2H, m, CH_2Cl), 1.99 (3H, s, CH_3)	As the silyl derivative: 250/252, 235/237, 201, 181/183, 165/167,151/153, 99, 85, 73, 69, (251/253)
X	4.31 (2H, d, *J* = 5.6, CH_2OH), 4.13 (1H, m, CHOH), 3.77, 3.75 (2H, m, CH_2Cl)	As the silyl derivative: 182/184, 165/167, 151/153, 133, 73, (183/185)

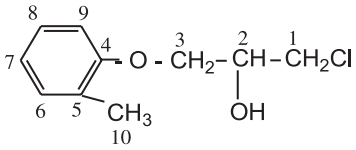
[a]With 1,4 butanediol diglycidyl ether, a diepoxide, the ring opening occurs at both epoxide centers giving rise to $ClCH_2CH(OH)CH_2O(CH_2)_4OCH_2CH(OH)CH_2Cl$ (**XI**). ^{1}H NMR (ppm) δ: 3.92 (2H, m, C*H*OH), 3.57, 3.54 (4H, m, CH_2Cl), 3.48 (8H, m, CH_2-O-CH_2), 2.10 (1H, bs, OH), 1.60 (4H, m, CH_2-CH_2). Mass spectra EI (CI), *m*/*z* as the silyl derivative: 418/420/422, 369/371, 267/269, 253/255, 237/239,116,73 (419/421/423).

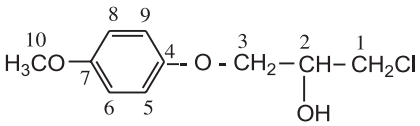
steric factor. However, the ester intermediate is short lived and in the presence of an electron attracting environment decarboxylates readily to generate chlorodifluoromethide ion (CF_2Cl^-), which decomposes to regenerate **:**CF_2 and Cl^- ions. The simultaneous attack of the Cl ion on the primary positive carbon yields the desired chlorohydrins. As with most other S_N2 displacements, the method works well with electron-poor epoxides like alkyl, allyl, and aryl glycidyl ethers and with glycidyl methacrylate and 1,4 butanediol diglycidyl ether, but fails to take place with 1,2-epoxyoctane and butyloxirane. A similar observation was noted earlier when *O*-(chlorodifluoroacylated) alcohols were formed from electron-deficient alcohols using this system (5). With moderately electron-deficient epoxides containing active alcoholic (-OH) functionality (e.g., glycidol), the yield of the desired chlorohydrin (**X**) is poor.

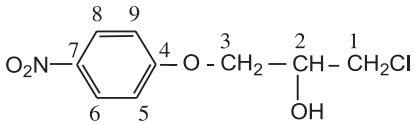
Taking *o*-cresyl glycidyl ether as the model epoxide, the reaction was carried out at different time intervals with sodium chlorodifluoroacetate in DMF. The intermediate *O*-(chlorodifluoroacylated) species (*ii*, Scheme 1) was detected (EI-MS *m*/*z*: 294/296 (M^+), 187/189,108, 85/87) along with the product chlorohydrin (*iii*), after heating the reaction mixture for 0.5 h at 150 °C. On further heating for 1 h, the intermediate disappeared and chlorohydrin was detected as the main product in solution. If the heating was continued further (e.g., after 3 h), the chlorodifluoroacylated derivative of chlorohydrin, (o-CH_3)$C_6H_4OCH_2CH(OCOCF_2Cl)CH_2Cl$, EI-MS *m*/*z*: 312/314/316 (M^+), 205/207/209, 91, δ CF_2 –61.6), similar to our earlier observation with fluoroalcohols (5), started appearing. A similar observation including in situ detection of an *O*-(chlorodifluoroacylated) intermediate was noted with other epoxides. These observations support our proposed mechanism as shown in Scheme 1.

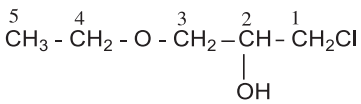
Conclusion

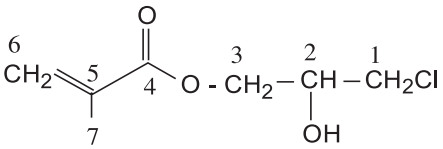


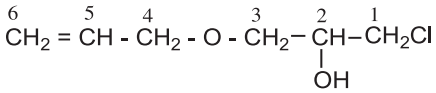


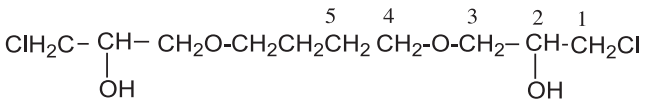












In summary, the $ClCF_2COONa$–DMF mixture works as a facile reagent system for the preparation of chlorohydrins from electron-deficient epoxides. The difluorocarbene (**:**CF_2) induced regioselective ring opening reported for the first time on glycidyl ethers is simple, facile, does not require any prior reagent preparation and is devoid of any appreciable side reaction products. Using a similar system, fluorohydrins, volatile CFC alternatives, and perfluoroolefins have been obtained, which wwill be subsequently communicated.

Experimental

Reactions were monitored by GC–MS and the mass spectra were recorded on a TSQ 7000 mass spectrometer

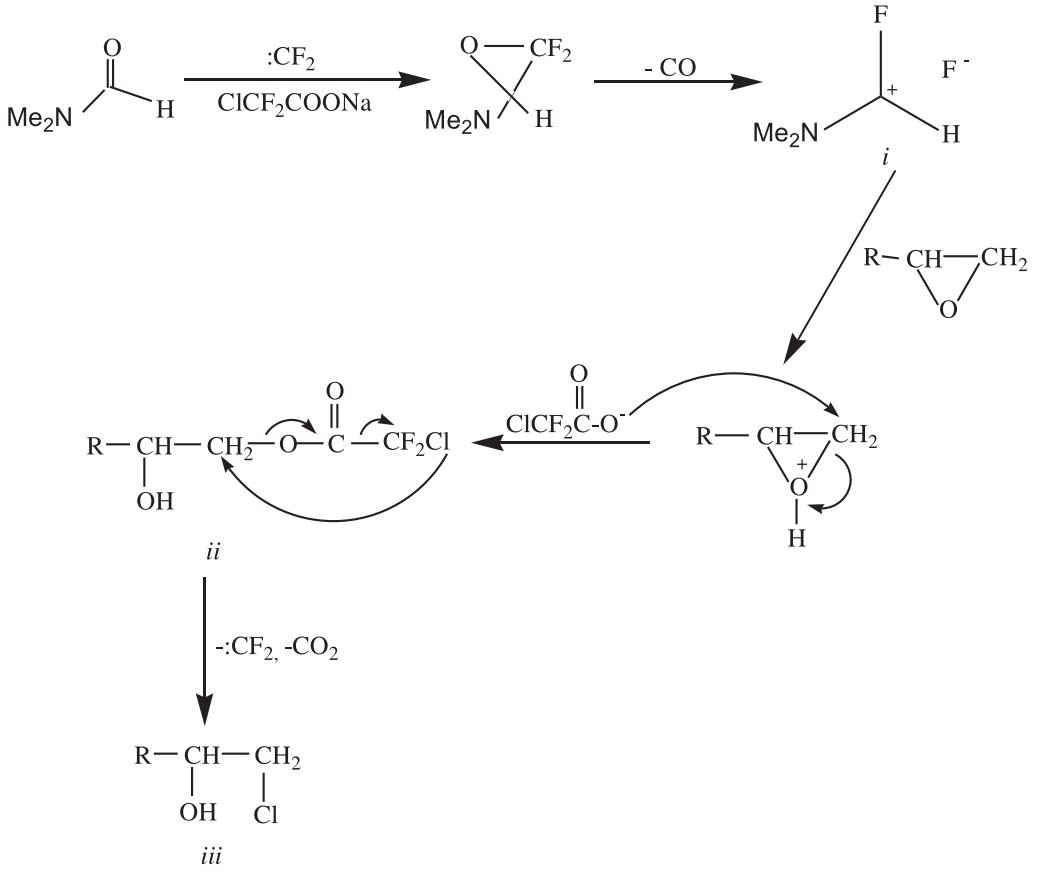
[a]1 mmHg = 133.3224 Pa.



(Finigan MAT, USA) using a Varian 3400 GC inlet with a BP-5 column (30 m × 2.5 mm (i.d.) × 0.25 μm (film thickness) with a temperature program of 50 °C (2 min) – at 10 °C/min – 280 °C (5 min) using helium as carrier gas at a flow rate of 1.2 mL/min. The injector temperature was 250 °C and the transfer line was heated to 280 °C. EI-MS was performed at 70 eV with the ion source temperature 180 °C and an emission current of 400 mA. The CI-MS experiments were performed using methane as a reagent gas at pressure 2500 mtorr (1 torr = 133.3224 Pa), source temperature 200 °C, and emission current 300 mA. The ^{1}H and ^{13}C NMR spectra of the chlorohydrins were recorded on a Bruker Avance DPX-400 spectrometer in $CDCl_3$ solution for all except compound No. **I**, which was run in DMF-d_7, using TMS as the internal reference. ^{19}F NMR of the intermediate *O*-(chlorodifluoroacylated) derivatives was obtained using $CFCl_3$ as the internal standard. The epoxides were obtained commercially and distilled before use. DMF was dried by storing on a 4 Å Linde molecular sieve followed by distillation under vacuum.

Synthesis of chlorohydrins

Sodium salt of chlorodifluoroacetic acid (6.1 g, 0.04 mol for all cases; except for compound No. **XI**, 12.2 g, 0.08 mol) in 50 mL of dry DMF was placed in a 250 mL three-necked flask, containing a stirring bar and a dry nitrogen inlet, at room temperature. Epoxide (0.02 mol) was then added slowly through a dropping funnel to the well-stirred mixture. The temperature of the reaction mixture was raised to 150 °C and was further refluxed for 1 h. The course of the reaction was followed by withdrawing a small aliquot of the reaction mixture and subjecting it to GC–MS analysis. Initially the salt was soluble making a homogeneous solution in DMF. On heating, the reaction mixture turned brown with the deposition of a solid at the bottom of the flask, which in-

Scheme 1. A probable mechanism for the formation of chlorohydrins.

dicated completion of the reaction. The reaction mixture was then filtered and the bulk of DMF was removed by distillation under vacuum. The residue, which still contained some traces of solid, was separated by centrifugation. It was then washed with excess water to remove the remaining DMF and extracted into diethyl ether. The ether layer was dried and then removed by distillation. The chlorohydrins were obtained either by distillation under vacuum (compound Nos. **I–III**, **VI**, **VII**, **X**, and **XI**) or by crystallization from hexane (compound Nos. **IV** and **V**).

Identification of complexes involving toxic heavy metals with amino acid ligands by electrospray ionization mass spectrometry

Neil Burford, Melanie D. Eelman, and Wesley G. LeBlanc

Abstract: Electrospray ionization mass spectra (ESI-MS) of reaction mixtures containing ions of the heavy metals, cadmium, mercury, thallium, lead, and bismuth with each of the naturally occurring amino acids allows for definitive identification of monocationic complexes in the gas phase. Prominent *m*/*z* peaks are assigned to ions of the type $[E(Am) - xH]^+$ (x = 0, 1, 2), $[E(Am)_2 - xH]^+$ (x = 0, 1, 2), $[E_2(Am) - xH]^+$ (x = 1, 2, 3), and (or) $[E_2(Am)_2 - xH]^+$ (x = 1, 3, 5) for all amino acids studied (Am) with all metals studied (E = Cd, Hg, Tl, Pb) except bismuth, which shows complexes with only seven amino acids (Am = His, Thr, Met, Cys, Hcys, Asn, Gln). The results demonstrate the potential application of ESI-MS as a versatile and efficient approach to study toxic heavy metals in biological systems.

Key words: heavy metals, amino acids, electrospray ionization mass spectrometry.

Résumé : La spectrométrie de masse par ionisation avec électronébulisation (SM-IEN) de mélanges réactionnels contenant des ions de métaux lourds, cadmium, mercure, thallium, plomb et bismuth, avec chacun des acides aminés qu'on retrouve dans la nature permet d'identifier d'une façon définitive les complexes monocationiques présents en phase gazeuse. Les pics *m*/*z* prédominants sont attribués aux ions du type $[E(Am) - xH]^+$ (x = 0, 1, 2), $[E(Am)_2 - xH]^+$ (x = 0, 1, 2), $[E_2(Am) - xH]^+$ (x = 1, 2, 3) et (ou) $[E_2(Am)_2 - xH]^+$ (x = 1, 3, 5) pour tous les acides aminés étudiés (Am), avec tous les métaux étudiés (E = Cd, Hg, Tl, Pb) à l'exception du bismuth qui ne donne des complexes qu'avec sept acides aminés (Am = His, Thr, Met, Cys, Hcys, Asn, Gln). Les résultats démontrent que l'application de la SM-IEN est une approche versatile et efficace pour étudier les métaux lourds toxiques dans les systèmes biologiques.

Mots clés : métaux lourds, acides aminés, spectrométrie de masse avec électronébulisation.

[Traduit par la Rédaction]

Introduction

The bioactivity of toxic heavy metals is likely governed by their interaction with biological molecules such as amino acids, peptides, proteins, or enzymes. The existence of specific complexes has been confirmed in a few cases by spectroscopic (1) or X-ray crystallographic studies (2–4), which shed light on potential mechanisms of bioactivity. Nevertheless, a deeper appreciation of heavy metal biochemistry requires a systematic and comprehensive assessment in terms of both the variety of metals and the vast array of biological molecules. To address this challenge, we have used electrospray ionization mass spectrometry (ESI-MS) to examine reaction mixtures containing each of the essential amino acids with ions of the toxic heavy metals (5), cadmium (human minimum lethal dose, MLD = 1 g), mercury (MLD = 0.5 g), thallium (MLD = 0.3 g), and lead (MLD = 10 g). ESI mass spectra show *m*/*z* peaks that are readily assigned to cationic complexes for all amino acid with all toxic heavy metals. In contrast, similar reaction mixtures involving the less-toxic and medicinally relevant (6, 7) heavy metal, bismuth (MLD = 15 g), exhibit complexes with only seven amino acids.

Experimental

All reagents were used as received from Aldrich. Equimolar mixtures (0.5 mmol) of $Cd(NO_3)_2{\cdot}4H_2O$, $Hg(NO_3)_2{\cdot}H_2O$, $Hg_2(NO_3)_2{\cdot}2H_2O$, $TlNO_3$, $Pb(NO_3)_2$, or $Bi(NO_3)_3{\cdot}5H_2O$ with each of 20 common L-amino acids (and DL-homocysteine) in 15 mL distilled water and 15 mL ethanol were stirred overnight (12 h) at room temperature (RT). Reactions involving cysteine or homocysteine were performed under an atmosphere of nitrogen. ESI mass spectra of the suction filtrate from each reaction were obtained using a Finnigan LCQ Duo ion trap mass spectrometer and (or) a Sciex Qtrap quadrupole/ion trap mass spectrometer. Samples were introduced directly into the electrospray source at a flow rate of 1.2 mL/h with a source temperature of 473 K, an applied voltage of 4 kV, and the in-source fragmentation off or a source temperature of 385 K and a declustering potential of 50 V, respectively. Tandem (MS–MS) spectra were obtained by introducing helium as the collision gas and the collision energy was optimized for each sample.

Fig. 1. A positive ion ESI-MS of a reaction mixture containing $Hg(NO_3)_2$ and L-cysteine in 50% ethanol–water. Assignments are supported by MS–MS. The isotopic pattern observed for each peak corresponding to a metal containing cation is shown for the representative peak at *m/z* 442.9.

Results and discussion

Electrospray ionization mass spectrometry (ESI-MS) offers a sensitive and versatile technique to sample low volatility ionic species in the gas phase (8). The absence of high energies that are typically required with electron ionization (EI) and chemical ionization (CI) mass spectrometric techniques facilitates the observation of *m/z* peaks corresponding to molecular ions and minimizes fragmentation. Solutions can be readily sampled providing a convenient approach to study inorganic compounds, including systems containing complexes of metals and metalloids (8–17).

Reaction mixtures containing equimolar combinations of $Cd(NO_3)_2$, $Hg(NO_3)_2$, $Hg_2(NO_3)_2$, $TlNO_3$, $Pb(NO_3)_2$, or $Bi(NO_3)_3$ with each of 21 amino acids in 50% ethanol–water were analysed by positive ion ESI-MS. Most spectra exhibit few prominent *m/z* peaks. Most peaks are readily assigned (Table 1) to monocationic complexes of the metal with one or more amino acids (or conjugate base of the amino acid). Some *m/z* peaks are assigned to cations that contain additional solvent molecules or nitrate units. The observed spectra are essentially independent of reaction mixture stoichiometry (10:1 – 1:10) or reaction time (hours or days).

Characteristic isotopic patterns exhibited by some metals provide valuable "fingerprints" that enable definitive determination of the number of metal ions in the formulae that correspond to an *m/z* peak. A representative ESI-MS is shown in Fig. 1 for $Hg(NO_3)_2$ with L-cysteine. Two prominent peaks with *m/z* values of 443 and 762 are assigned to $[Hg(Cys)_2–H]^+$ and $[Hg_2(Cys)_3–3H]^+$, respectively, assuming retention of the 2+ oxidation state for Hg under these experimental conditions. Each peak exhibits an isotopic pattern consistent with the seven naturally occurring isotopes of Hg, as illustrated for *m/z* 443. Amino acids are given conventional three letter abbreviations.

Table 1 lists formula assignments involving metal and

Note: Amino acids are given traditional three letter abbreviations. Assignments are only given for monocations containing both metal (E) and amino acid (Am) units. Formulae are abbreviated as *n*:*m*–*x* corresponding to the generic formula $[E_n(Am)_m - xH + Y]^+$, where Y = Na, EtOH, H_2O, and (or) NO_3. Assignments for peaks with a relative intensity of greater than 50% are in italics.

[a] Y = Na.
[b] Y = EtOH.
[c] Y = NO_3.
[d] Y = H_2O.

amino acid components for observed *m*/*z* peaks that have been supported by tandem mass spectrometry (MS–MS) experiments. Assignments for peaks with a relative intensity of greater than 50% are italicized. Complexes involving each of the amino acids are observed for lead(II), thallium(I), mercury(II) (except for Hcys), and cadmium(II). Formulae are abbreviated as *n*:*m*–*x*, corresponding to the generic formula $[E_n(Am)_m - xH + Y]^+$, where Y = Na, EtOH, H_2O, and (or) NO_3. Almost all metals are observed to adopt (*n*:*m*–*x*) formulae of 1:1, 1:1–1, or 1:1–2, and most can accommodate two amino acid ligands (*n*:*m*–*x* = 1:2, 1:2–1, or 1:2–2). Formulae that do not involve the loss of a hydrogen atom (e.g., $[Tl(Ala)]^+$) can be considered complexes of the metal with a neutral amino acid ligand, while there are more examples of complexes involving an anionic conjugate base of the amino acid (e.g., $[Pb(Gly -H]^+$). Most numerous are

complexes involving both a neutral amino acid and a conjugate base(s) of the amino acid (e.g., $[Cd(Trp)_2 - H]^+$).

Amino acid rich ($m > n$) complexes are observed in some cases and are most pronounced for arginine with thallium ($m = 5$, $n = 1$) or lead ($m = 6$, $n = 1$). The representative ESI-MS for thallium(I) nitrate with L-arginine in Fig. 2 shows peaks with m/z values corresponding to proton bound clusters of general formula $[Arg_mH]^+$, up to $m = 5$. Of greater or comparable intensity are four peaks that are assigned to the $m = 1$, 2, 3, and 4 series with the general formula $[Tl(Arg)_m]^+$, on the basis of the distinct isotopic pattern corresponding to the presence of a single thallium atom. Metal-rich ($n > m$) complexes are evident for mercury, lead, and thallium (e.g., n:m–x = 2:1–1, 2:1–2, 2:1–3), but clusters of metals and ligands ($n > 1$; $m > 1$; x = 1–6) are more common.

Monocations containing amino acid ligand(s) on mer-

Fig. 2. A positive ion ESI-MS of a reaction mixture containing $TlNO_3$ and L-arginine in 50% ethanol–water. Assignments are supported by MS–MS. The isotopic pattern observed for each peak corresponding to a metal containing cation is shown for the representative peak at *m/z* 379.1.

cury(I) or bismuth(III) are only observed for 16 and seven amino acids, respectively. In the case of reaction mixtures of methionine with $Bi(NO_3)_3$, the charge on two of the observed cations is imposed by complexation with a sodium ion (e.g., $[Bi(Met)_2 - 3H + Na]^+$ and $[Bi_2(Met)_3 - 6H + Na]^+$). The *m/z* peaks corresponding to cations containing bismuth are generally of weak intensity relative to those for other heavy metals, but the assignments have been supported by MS–MS experiments. Bismuth exhibits a particular preference for complexes involving the sulfur-containing amino acids L-methionine, L-cysteine, or DL-homocysteine, consistent with the recognised thiophilicity of bismuth (18).

Conclusions

Complexes of amino acids with toxic heavy metals (Cd, Hg, Tl, Pb) as well as Bi have been definitively identified by ESI-MS. While this study is not comprehensive due to the inability of the technique to detect neutral complexes, this represents a systematic investigation into the chemistry of heavy metal – amino acid complexes and the first identification of most complexes in any phase. ESI-MS is demonstrated as a potentially powerful approach to evaluate and understand coordination chemistry. The gas-phase identification of complexes with peptides, proteins, and other biological molecules is in progress.

Study of acid hydrolysis of bromazepam

Tatjana Damjanović, Gordana Popović, Srđan Verbić, and Lidija Pfendt

Abstract: Quantitative study of an acid hydrolysis of bromazepam, which in acidic solution simultaneously undergoes reversible 4,5-azomethine bond cleavage and protolytic reactions, was performed (t = 25 °C). When an equilibrium is established, four species are simultaneously present in solution. Two approaches, both based on theoretically derived dependence between the absorbance (A) and the solution acidity ($[H_3O^+]$), were used to determine appropriate equilibrium constants. In the first, the least-squares method was used to fit experimentally obtained (A, $[H_3O^+]$) value pairs to a derived function. With values obtained as fitting parameters, the probability distribution for equilibrium constants was calculated with the virtual experiments performed using Monte Carlo simulations. In the second one, spectrophotometric analysis indicated an existence of two distinct pH intervals, both with three dominant species involved. Spectral data were used to calculate equilibrium constants by a linear curve fitting analysis. Values obtained for equilibrium constants from the numerical and the experimental approaches are in good accordance and were used to calculate distribution of all the species as a function of pc_H.

Key words: bromazepam, acid hydrolysis, equilibrium constants.

Résumé : Opérant à 25 °C, on a effectué une étude quantitative de l'hydrolyse acide du bromazépam qui, en solution acide, subit simultanément des réactions protolytique ainsi que de coupure réversible de la liaison 4,5-azométhine. Une fois l'équilibre établit, la solution contient simultanément quatre espèces. Pour la détermination des constantes d'équilibre appropriées, on a utilisé deux approches, toutes deux basées sur la relation théorique entre l'absorbance (A) et l'acidité ($[H_3O^+]$). Dans le premier cas, on a utilisé la méthode des moindres carrés pour ajuster d'une façon expérimentale les paires de valeurs (A, $[H_3O^+]$) avec une fonction dérivée. À l'aide des valeurs obtenues à partir des paramètres d'ajustement, on a calculé la distribution de la probabilité des constantes à l'aide d'expériences virtuelles réalisées à l'aide de simulations de Monte Carlo. Dans le deuxième cas, l'analyse spectroscopique a indiqué l'existence de deux intervalles distincts de pH qui comprenaient toutefois trois espèces dominantes. On a utilisé les données spectrales pour calculer les constantes d'équilibre à l'aide d'une analyse de l'ajustement de la courbe linéaire. Les valeurs pour les constantes d'équilibre à partir des approches numériques et expérimentales sont en bon accord entre elles et on les a utilisées pour calculer la distribution de toutes les espèces en fonction du pc_H.

Mots clés : bromazépam, hydrolyse acide, constantes d'équilibre.

Introduction

Bromazepam (7-bromo-1,3-dihydro-5-(2′-pyridyl)-2*H*-1,4-benzodiazepin-2-one) belongs to the group of 1,4-benzodiazepines, drugs that are widely used in everyday medical practice to treat insomnia, anxiety, panic attacks, muscule spasms, and seizure disorders.

In aqueous solution, 1,4-benzodiazepines undergo acid–base reactions and hydrolytic degradation that cause changes in molecular structure (1–10). Study of these reactions, especially within the physiological pH range, is of great interest, particularly with respect to the study of the metabolism of these drugs, the analysis of the corresponding pharmaceutical preparations, and the pharmaceutical technology in connection with the choice of optimum conditions for the preparation of various dosage forms. The huge number of benzodiazepine analogues provide an excellent opportunity to study the relationship between the structure and chemical reactivity.

As with most of the 1,4-benzodiazepines, bromazepam has two sites potentially susceptible for nucleophilic hydration in acidic solution: the 1,2-amide and the 4,5-azomethine bond. According to newer NMR analysis (11), the 4,5-azomethine bond is the only site of the diazepine ring-opening reaction in the molecule of bromazepam.

The presence of the pyridine moiety in the molecule of bromazepam and the simultaneous occurrence of two processes, simple acid–base and hydrolytic reactions, make the system present in an acidic solution rather complicated. As the complex equilibria present in acidic solution of

bromazepam was not studied yet, the aim of this work was to quantitatively define the multiple equilibria between all the species actually present in the system.

Experimental

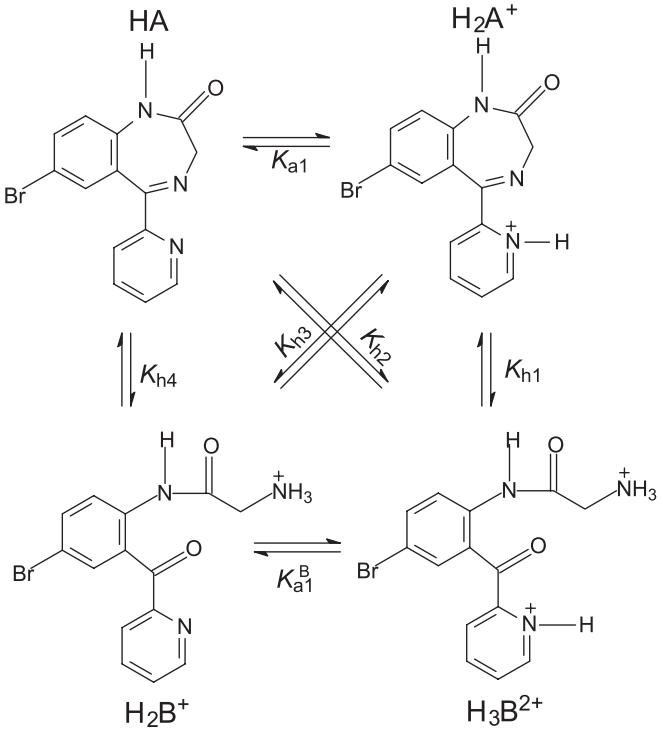
Apparatus and reagents

A GBC 911A Spectrophotometer (GBC Scientific Equipment Pty Ltd.) with 1 cm silica cells was used for spectrophotometric measurements. A PHM240 pH meter (Radiometer) with a combined GK2401B electrode (Radiometer) served for pH value measurements. Titrations were performed with a TTT-60 titrator with an ABU-12 auto burette (Radiometer). Measured pH values (pH > 2) were converted into pc_H according to relation (12): $pc_H = -\log[H_3O^+] = pH - A$. For $I = 0.1$ mol L^{-1} (NaCl) and $t = 25$ °C, the correction factor value was $A = 0.12$. For pH < 2, pc_H values were calculated according to HCl solution concentrations.

Bromazepam (Hoffmann La Roche) was of pharmaceutical purity grade, and other reagents, hydrochloric acid, sodium hydroxide, sodium chloride, sodium acetate, potassium dihydrogenphosphate, sodium hydrogenphosphate dihydrate, and ethanol were of analytical reagent grade (Merck). All solutions were prepared with double distilled water.

HCl and NaOH solutions were potentiometrically standardized. NaOH solution was standardized with potassium hydrogen phthalate. HCl solution was standardized in relation to the standard NaOH solution.

Estimation of the ring-opening reaction reversibility



A stock solution of bromazepam (Bz) was prepared in ethanol ($c_{Bz} = 1.50 \times 10^{-2}$ mol L^{-1}). One mL aliquots of stock solution were transferred into 25 mL volumetric flasks and diluted to volume with HCl solutions of different concentrations (10^{-3}, 10^{-2}, 0.1, and 1 mol L^{-1}). Solutions were thermostated (light protected) for 4 h (until the equilibrium was established) at $t = 25.0 \pm 0.1$ °C (to determine the time needed for equilibrium to establish, time-dependent spectral changes in the absorption spectra of bromazepam were monitored; depending on solution acidity, equilibrium is established in 2–4 h). One mL aliquots of these solutions were rapidly transferred into 25 mL of phosphate buffer ($c = 0.5$ mol L^{-1}, pH 6.8, $c_{Bz} = 2.40 \times 10^{-5}$ mol L^{-1}). The time-dependent ring-closing reaction was spectrophotometrically monitored in the 200–400 nm wavelength range, with the appropriate blanks and the scan speed of 500 nm min^{-1}. For the comparison, a spectrum of bromazepam ($c_{Bz} = 2.40 \times 10^{-5}$ mol L^{-1}) in phosphate buffer (pH 6.8) was also recorded.

Equilibrium constants determination

Equilibrium constants K_{a1}^B, K_{h1}, and K_{h3} (Scheme 1) were determined spectrophotometrically at $t = 25.0 \pm 0.1$ °C.

K_{a1}^B was determined according to the following procedure: bromazepam was dissolved in 1.0 mol L^{-1} HCl ($c_{Bz} = 2.64 \times 10^{-3}$ mol L^{-1}) and hydrolyzed at 25 °C. After equilibration was completed (2 h), this solution served for the preparation of the following solutions (for all of them $c = 5.28 \times 10^{-5}$ mol L^{-1}): (*i*) solution of the H_3B^{2+} form prepared in 1.0 mol L^{-1} HCl, (*ii*) mixture of the H_3B^{2+} and H_2B^+ forms

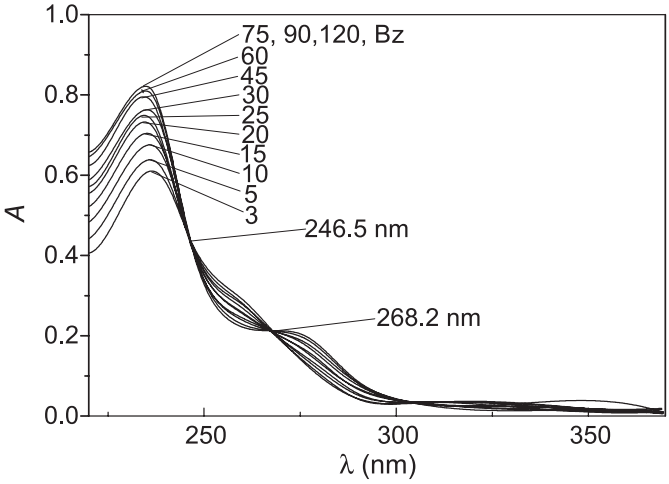
Scheme 1.

prepared in pc_H range 1.2–2.0, (*iii*) and H_2B^+ solution in acetate buffer (pH 4.5). Solutions in the pc_H interval 1.2–2.0 and the solution of the H_2B^+ form were prepared with the fast working procedure to avoid a diazepine ring-closing reaction. The absorption spectra of all solutions were recorded immediately after preparation in the 200–400 nm wavelength range with the scanning speed of 1000 nm/min. For the K_{a1}^B determination measurements were done at 237 nm.

For the K_{h1} and K_{h3} determination, a stock solution of bromazepam was prepared in ethanol ($c_{Bz} = 2.64 \times 10^{-3}$ mol L^{-1}). Aliquots of 1 mL were transferred into 50 mL volumetric flasks and diluted to volume with HCl and NaCl solutions to reach pH in the 1.3–3.8 range and ionic strength $I = 0.1$ mol L^{-1}. These solutions ($c_{Bz} = 5.28 \times 10^{-5}$ mol L^{-1}) were hydrolyzed at 25 °C until complete equilibration was achieved (4 h). UV spectra were recorded in the 200–400 nm wavelength range. Spectra of "pure" bromazepam forms, protonated (H_2A^+) and molecular (HA), were recorded in 1 mol L^{-1} HCl and 0.1 mol L^{-1} NaCl (pH 6.8), respectively. The spectrum of the H_2A^+ form was recorded with a fast working procedure to minimize errors due to the hydrolytic changes in molecular structure. The preparation of the H_3B^{2+} form solution and recording of its spectrum obtaining are described within the K_{a1}^B determination procedure. All spectra were recorded against the corresponding blanks.

The acidity constant of the $-NH_3^+$ in the opened-ring form (K_{a2}^B) was estimated potentiometrically with a fast working procedure. Bromazepam was dissolved in 0.1 mol L^{-1} HCl ($c_{Bz} = 2.00 \times 10^{-3}$ mol L^{-1}) and hydrolyzed for 4 h at 25 °C. To 20 mL aliquots of this solution, a standard solution of NaOH ($c = 1.15$ mol L^{-1}) was rapidly added until pH 8.5–9.5 was reached and solutions were rapidly titrated with 0.02 mL increments of standard HCl solution ($c =$

© 2004 NRC Canada



0.11 mol L^{-1}). Total titration times were 5–7 min. The equilibrium constant K_{a2}^{B} was calculated from the titration curve inflexion point (second derivative equals zero).

Results and discussion

Estimation of the ring-opening reaction reversibility

Bromazepam was hydrolyzed in HCl solutions of different concentrations (10^{-3}, 10^{-2}, 0.1, and 1 mol L^{-1}). When equilibrium was established, the solution pH values were adjusted to 6.8 (phosphate buffer) and the ring-closing reaction spectrophotometrically monitored. As for the comparison, the spectrum of bromazepam kept in phosphate buffer (pH 6.8) was also recorded. In all examined solutions, the final spectrum (after the ring-closing reaction was completed) overlapped with the spectrum of the intact bromazepam form. This draws the conclusion that in neutral solution the diazepine ring was completely restored (i.e., that bromazepam was not degraded with the glycine release). Furthermore, ring-closing time increases (within the time interval of 45–75 min) with the concentration of the HCl solution used for hydrolysis. For example, the ring-closing reaction of the bromazepam hydrolyzed in 1 mol L^{-1} HCl is shown in Fig. 1.

Fig. 1. Time-dependent changes of the absorption spectra of bromazepam during the ring-closing reaction in the phosphate buffer solution (pH 6.8). Previously, bromazepam was hydrolyzed in 1.0 mol L^{-1} HCl solution until equilibrium was established (4 h, $c_{Bz} = 2.40 \times 10^{-5}$ mol L^{-1}). Numbers on the spectra show the time (in min) after the reaction was initiated; Bz–bromazepam solution kept in a phosphate buffer solution.

Equilibrium constants determination

In acidic solution (pH < 6), two processes occur simultaneously, a simple acid–base reaction (fast process) and hydrolysis of the 4,5-azomethine bond (relatively slow process) (11). The simple acid–base reaction was previously studied (13), and it was found that the pyridine nitrogen is protonated in an acidic solution (pK_{a1} 2.83). As the acid–base reactions are much faster processes than the hydrolysis reactions are, with a fast working procedure, K_{a1} was determined independent on hydrolysis. In the alkaline solution, the amide group is deprotonated (pK_{a2} 11.60). If we summarize all the reactions that are occurring in an acidic solution of bromazepam, established equilibrium may be depicted as it is shown in Scheme 1.

In general, equilibrium constants of the processes shown in Scheme 1 are defined as follows:

$$[1] \qquad K_{al} = \frac{[HA][H_3O^+]}{[H_2A^+]}$$

$$[2] \qquad K_{al}^{B} = \frac{[H_2B^+][H_3O^+]}{[H_3B^{2+}]}$$

$$[3] \qquad K_{hl} = \frac{[H_3B^{2+}]}{[H_2A^+][H_3O^+]}$$

$$[4] \qquad K_{h2} = \frac{[H_3B^{2+}]}{[HA][H_3O^+]^2}$$

$$[5] \qquad K_{h3} = \frac{[H_2B^+]}{[H_2A^+]}$$

$$[6] \qquad K_{a4} = \frac{[H_2B^+]}{[HA][H_3O^+]}$$

In solutions with pH < 6, the amino group of the opened-ring form is mostly in its protonated form (its acidity constant (pK_{a2}^{B} 7.6) was determined with fast potentiometric titration as described in the Experimental).

After the equilibrium was established within the solutions of bromazepam in the pH range 0–7, absorption spectra were recorded and analyzed. Determination of the equilibrium constants is based on the fact that the absorbance is an additive value. In acidic solution, the total concentration of bromazepam is given through the mass balance equation:

$$[7] \qquad C = [H_2A^+] + [HA] + [H_3B^{2+}] + [H_2B^+]$$

and the absorbance, for the 1.0 cm cell length, is given by the following equation:

$$[8] \qquad A = \varepsilon_{H_2A^+}[H_2A^+] + \varepsilon_{HA}[HA] + \varepsilon_{H_3B^{2+}}[H_3B^{2+}] + \varepsilon_{H_2B^+}[H_2B^+]$$

where $\varepsilon_{H_2A^+}$, ε_{HA}, $\varepsilon_{H_3B^{2+}}$, and $\varepsilon_{H_2B^+}$ stand for molar absorptivities of the appropriate species. If the total concentration of bromazepam remains constant during all the measurements, combination of the eqs. [1]–[8] gives the following dependence:

$$[9] \qquad A = \frac{A_{H_2A^+}[H_3O^+] + A_{HA}K_{al} + A_{H_3B^{2+}}K_{hl}[H_3O^+]^2 + A_{H_2B^+}K_{h3}[H_3O^+]}{[H_3O^+] + K_{al} + K_{hl}[H_3O^+]^2 + K_{h3}[H_3O^+]}$$

which shows that the absorbance at the chosen wavelength is a nonlinear function of the solution acidity ($[H_3O^+]$) in the pH region in which the hydrolysis occurs (0–6). A_{HA}, $A_{H_2A^+}$, $A_{H_2B^+}$, and $A_{H_3B^{2+}}$ are the absorbances of the appropriate pure forms at the chosen wavelength.

Preliminary values of the equilibrium constants given in eq. [9] were determined by a nonlinear curve-fitting analysis. Two parameters (K_{a1} and A_{HA}) were experimentally obtained and their values introduced into eq. [9] as starting parameters (with no starting parameters nonlinear curve-

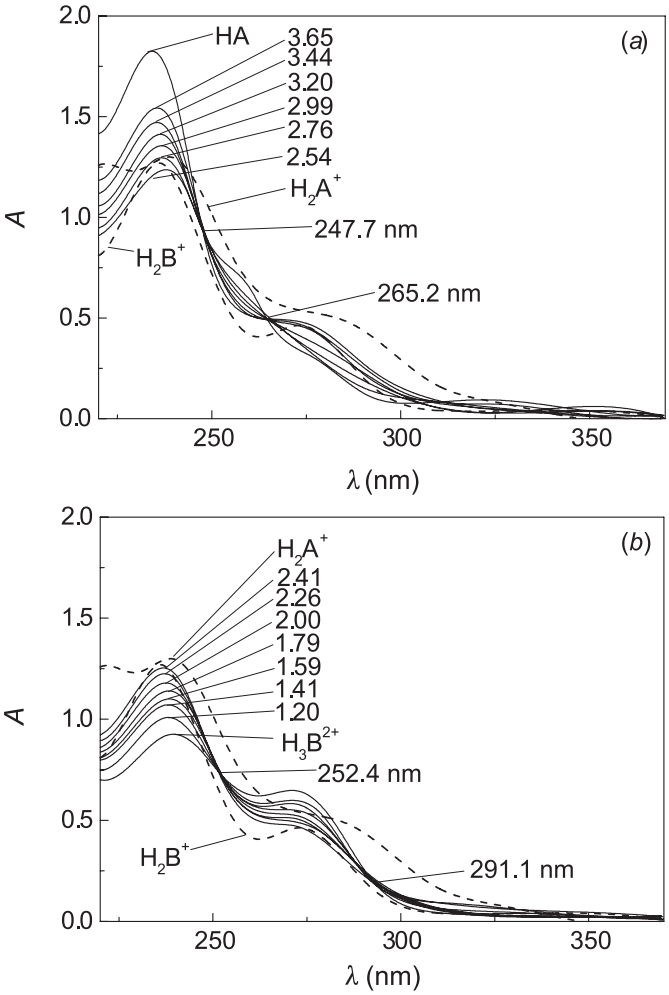
[a]Distribution is considerably asymmetrical, thus the upper and lower interval limits are not equal.

fitting analysis would more likely give a mathematically correct, but for this case meaningless solution). The pK_{a1} value of 2.83 was previously (13) spectrophotometrically determined in the same experimental conditions (I = 0.1 mol L^{-1} (NaCl), t = 25 °C). Absorbance of the molecular form (HA) was relatively easily obtained, because the HA form is actually the only species present in the pH range 6–8, where bromazepam is quite stable. The least-squares method was used to fit the experimentally obtained (A, $[H_3O^+]$) value pairs (λ = 237 nm) to the dependence [9]. For the obtained function [9] parameter values, probability distributions were calculated with the virtual experiments performed using Monte Carlo simulations. Results are shown in Table 1. Equilibrium constants K^B_{a1}, K_{h2}, and K_{h4} were calculated with the K_{a1}, K_{h1}, and K_{h3} values according to relations derived from eqs. [1]–[6]:



$$[10] \quad K_{al} = \frac{K_{h3}}{K_{h4}} = \frac{K_{h1}}{K_{h2}}$$

$$[11] \quad K^B_{al} = \frac{K_{h3}}{K_{h1}}$$

Distribution of the species present in the system, obtained according to calculated equilibrium constants, showed that at pH 0 the diazepine ring is practically completely opened and that H_3B^{2+} form is the dominant species present. Detailed analysis of the spectra obtained after the equilibrium was established in acidic solutions of bromazepam (Fig. 2) showed that two pH regions can be separated. These regions have clearly defined isosbestic points. Spectra of the solutions equilibrated within the pc_H > 2.4 region accompanied with the spectrum of the HA form have isosbestic points at 247.7 and 265.2 nm (Fig. 2*a*), and the spectra of the solutions equilibrated in the pc_H ≤ 2.4 region together with the H_3B^{2+} form have isosbestic points at 252.4 and 291.1 nm (Fig. 2*b*). Absorption spectra of the H_2A^+ and H_2B^+ forms do not pass through any of these isosbestic points. When all these facts are considered, existence of the less complicated systems (Scheme 2) with three species simultaneously present in an equilibrium, can be assumed.

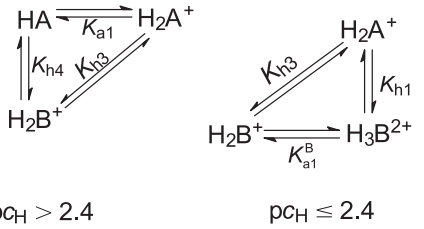
The existence of the isosbestic points in these solutions where three species are present can be explained with the fact that an equilibrium between H_2A^+ and H_2B^+ forms is pH independent (eq. [5]). Their concentrations are pH dependent, but the molar ratio between H_2A^+ and H_2B^+ forms is constant and given through the K_{h3} value. Thus, it can be

Fig. 2. Absorption spectra of bromazepam in solutions of different acidity: (*a*) pc_H > 2.4; (*b*) pc_H ≤ 2.4 after the equilibrium was established. Numbers on the spectra show pc_H values; spectra of the pure forms are marked (c_{Bz} = 5.28 × 10^{-5} mol L^{-1}, pc_H = pH – 0.12).

assumed that when present in the solution, they formally act as one species.

When two separated pH regions are considered, from the following absorbances:

$$[12a] \quad A = \varepsilon_{H_2A^+}[H_2A^+] + \varepsilon_{HA}[HA] + \varepsilon_{H_2B^+}[H_2B^+] \qquad (pc_H > 2.4)$$



$$[12b] \quad A = \varepsilon_{H_2A^+}[H_2A^+] + \varepsilon_{H_3B^{2+}}[H_3B^{2+}] + \varepsilon_{H_2B^+}[H_2B^+] \qquad (pc_H \le 2.4)$$

and eqs. [1]–[6], follows:

$$[13a] \quad A = \frac{A_{H_2A^+}[H_3O^+] + A_{HA}K_{al} + A_{H_2B^+}K_{h3}[H_3O^+]}{[H_3O^+] + K_{al} + K_{h3}[H_3O^+]} \qquad (pc_H > 2.4)$$

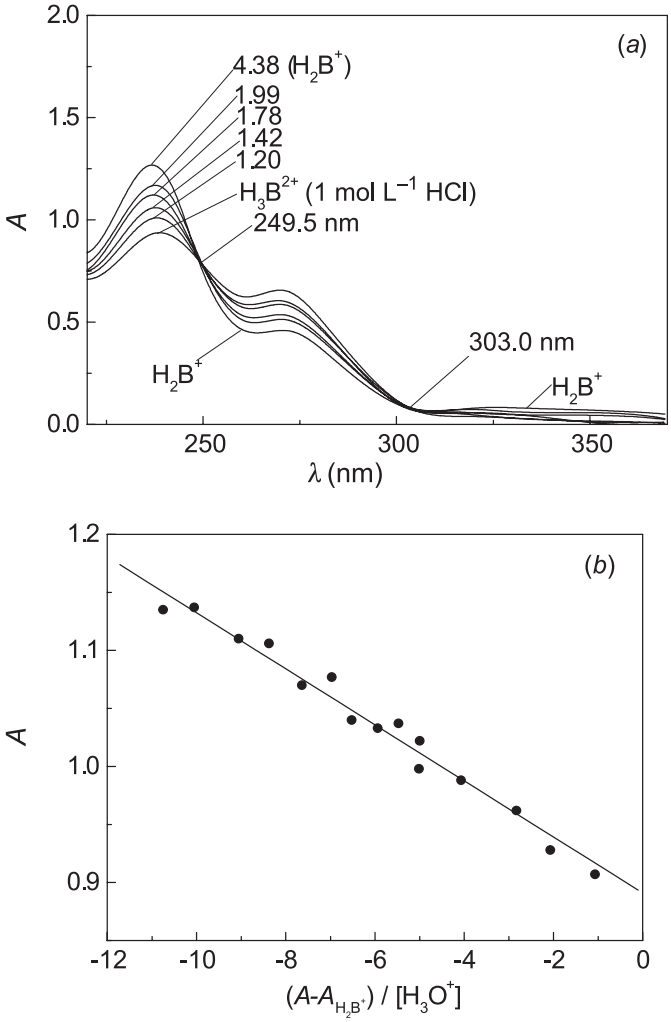
© 2004 NRC Canada

Scheme 2.

$$[13b] \quad A = \frac{A_{H_2A^+} + A_{H_3B^{2+}} K_{h1}[H_3O^+] + A_{H_2B^+} K_{h3}}{1 + K_{h3} + K_{h1}[H_3O^+]} \qquad (pc_H \leq 2.4)$$

With the transformation of the eqs. [13*a*] and [13*b*], the following linear dependences are derived:

$$[14a] \quad \underbrace{A}_{Y} = \frac{A_{H_2A^+} + A_{H_2B^+} K_{h3}}{1 + K_{h3}} + \frac{K_{a1}}{1 + K_{h3}} \underbrace{\frac{1}{[H_3O^+]}(A_{HA} - A)}_{x} \qquad (pc_H > 2.4)$$



$$[14b] \quad \underbrace{A}_{Y} = \frac{A_{H_2A^+} + A_{H_2B^+} K_{h3}}{1 + K_{h3}} + \frac{K_{h1}}{1 + K_{h1} K^B_{a1}} \underbrace{[H_3O^+](A_{H_3B^{2+}} - A)}_{x} \qquad (pc_H \leq 2.4)$$

The set of (A, $[H_3O^+]$) data was used to determine K_{h3} and K_{h1} values according to these linear functions. It can be seen that acidity constants K_{a1} and K^B_{a1} and the spectra of HA and H_3B^{2+} forms are needed for this determination. To determine the value of K^B_{a1}, bromazepam dissolved and equilibrated in 1 mol L^{-1} HCl was used as a stock solution. The K^B_{a1} was spectrophotometrically determined according to the transformation of the classical spectrophotometric equation (14), which gives a linear dependence:

$$[15] \quad A = A_{H_3B^{2+}} - K^B_{a1} \frac{A - A_{H_2B^+}}{[H_3O^+]}$$

where $A_{H_3B^{2+}}$ and $A_{H_2B^+}$ represent absorbances of the appropriate pure opened-ring forms (Scheme 2) and A represents absorbance of their mixture at the specified wavelength (237 nm). The exact procedure is described in the Experimental partsection. Absorption spectra that served for the K^B_{a1} determination are shown in Fig. 3*a*. The K^B_{a1} was calculated by linear regression analysis from the slope of the corresponding line (pK^B_{a1} 1.62) (Fig. 3*b*). Values for $A_{H_3B^{2+}}$ found by linear regression analysis (as the interception with the ordinate, $A_{H_3B^{2+}} = 0.89$) and as the measured value (obtained in 1 mol L^{-1} HCl, $A_{H_3B^{2+}} = 0.91$) are in good accordance. When the K_{a1} and K^B_{a1} values are known, with the set of (A, pc_H) data, A_{HA} and $A_{H_3B^{2+}}$ values measured at 237 nm, and according to eqs. [14*a*] and [14*b*], constants K_{h3} and K_{h1} were calculated by linear regression analysis from the slope of the corresponding lines (Fig. 4). Constants K_{h2} and K_{h4} were calculated according to eq. [10].

Fig. 3. Spectrophotometric determination of K^B_{a1}: (*a*) absorption spectra of bromazepam used for K^B_{a1} determination. Numbers on the spectra show pc_H values; spectra of the pure forms are marked; (*b*) linear dependence given in eq. [15], λ = 237 nm (c = 5.28 × 10^{-5} mol L^{-1}, pc_H = pH – 0.12).

A compendium of all determined equilibrium constants is shown in Table 2. Values of equilibrium constants calculated by Monte Carlo computer simulations and those determined according to linear dependences are in quite good accordance. Thus, it can be concluded that the assumptions made to make the system less complicated and possible for experimental determinations, are correct.

Based on determined equilibrium constants, the distribution of all the species as a function of pc_H is calculated according to equations:

$$[16] \quad X_{H_2A^+} = \frac{1}{10^{pc_H - pK_{a1}} + 1 + 10^{-pK_{h3}} + 10^{-pc_H - pK_{h1}}}$$

$$[17] \quad X_{HA} = \frac{10^{pc_H - pK_{a1}}}{10^{pc_H - pK_{a1}} + 1 + 10^{-pK_{h3}} + 10^{-pc_H - pK_{h1}}}$$

$$[18] \quad X_{H_3B^{2+}} = \frac{10^{pc_H - pK_{h1}}}{10^{pc_H - pK_{a1}} + 1 + 10^{-pK_{h3}} + 10^{-pc_H - pK_{h1}}}$$

Synthesis of the tetranitro derivative of thiacalix[4]arene and its acid–base properties

Xiaojun Hu, Zhongliang Zhu, Tianxiang Shen, Xianfa Shi, Jie Ren, and Qiuhong Sun

Abstract: The tetranitro derivative **3** of thiacalix[4]arene was synthesized and characterized. Its acid–base properties in water solution were studied by UV spectroscopy. The four pK_a values of **3** were determined by target testing factor analysis (TTFA). The pure UV absorption curves and pH distribution curves of five forms of **3** presented in aqueous solution were also calculated by TTFA.

Key words: thiacalixarene, nitro derivative, acid–base properties.

Résumé : On a réalisé la synthèse et caractérisé le dérivé tétranitré **3** du thiacalix[4]arène. On a étudié ses propriétés acide–base, en solution aqueuse, à l'aide de la spectroscopie UV. Les quatre valeurs de pK_a du produit **3** ont été déterminées par « TTFA ». Les courbes d'absorption UV pures et les courbes de distribution de pH des cinq formes du produit **3** présentes en solution aqueuse ont aussi été calculées par TTFA.

Mots clés : thiacalixarène, dérivé nitré, propriétés acide–base.

[Traduit par la Rédaction]

Introduction

The calixarenes, which are typical excellent molecular receptors made up of phenol units linked via methylene bridges, have attracted much attention from chemists all over the world (1). By modification of the upper and lower rims of calixarenes, a variety of derivatives have been synthesized. Recently, thiacalixarenes, a class of new molecular receptors have caught the eyes of chemists. The properties of thiacalixarenes are different from calixarenes due to the substitution of the methylene bridge groups with sulfur atoms. Thiacalixarenes are therefore new types of building blocks and molecular scaffolds for molecular assembly.

A variety of thiacalixarene derivatives have been synthesized after Kumagai et al. (2) reported the facile synthesis of tetra(*p-tert*-butyl)tetrathiacalix[4]arene **1** (Fig. 1). For instance, the derivatives of thiacalix[4]arene with alkyl (3), ether (4), ester (4, 5), carboxylic acid (6), alcohol, and ketone (7) substituents, respectively, on the lower rims have been synthesized. Katagiri et al. (8) used several reaction steps to get a novel derivative in which the phenolic hydroxyls were replaced by amino groups. However, all of these modifications were on the lower rims of thiacalixarenes, with none having been reported on the upper rims to date.

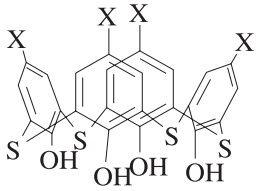
The nitro-substituted derivative **3** of thiacalix[4]arene **2** is a desirable intermediate compound leading to the amino-substituted derivative of thiacalix[4]arene **4**, which in turn is an excellent platform for synthesizing larger molecular building blocks. The nitration of thiacalix[4]arene, however, easily leads to the corresponding sulphoxide or sulphone derivatives of thiacalix[4]arene other than the nitro derivative of thiacalix[4]arene, because the epithio atoms of thiacalix[4]arene would be oxidized during the nitration. Lhoták et al. (9) had tried to prepare the tetranitro derivative of thiacalix[4]arene **3** under various conditions (conc. HNO_3 or 100% HNO_3 – CH_2Cl_2 or acetic acid, 100% HNO_3 – CF_3COOH, $NaNO_3$–CF_3COOH), but all these attempts "lead only to the oxidation of the bridging sulphur atoms".

In this work, the tetranitro derivative of thiacalix[4]arene **3** was successfully synthesized without oxidation of the bridging sulfur, using nitric acid as the nitrating agent in glacial acetic acid as the regulating agent for the acidity. The acid–base properties of **3** were studied by UV spectroscopy and the four pK_a values of **3** as determined by target testing factor analysis (TTFA) (10) are also reported.



Experimental

Materials and methods

All reagents were obtained from commercial sources and were used without further purification. ^{1}H NMR spectra were measured using a Bruker NMR spectrometer (Avance 500 MHz model). Infrared spectra were obtained using a Nicolet FT-IR spectrometer (Nexus 912A0446 model). ESI-MS were measured using an Agilent spectrometer (1100/LC–MSD model). UV–vis were measured using an Agilent spectrometer (8453 model).

Fig. 1. The structural formulas of **1–4**.

Synthesis and characterization of 3

Thiacalix[4]arene **2** (1.25 g, 0.0025 mol) was dissolved in $CHCl_3$ (200mL). Glacial acetic acid (7 mL) and aq.65%~68% HNO_3 (5 mL) were added with stirring, at room temperature. After 30 h, the precipitate was filtered from the reaction mixture and washed with water several times to afford **3** (1.31 g, 76%) as an orange solid.

Characterization: mp > 350 (dec.). IR (KBr) υ (cm^{-1}): 1521 and 1340 (Ar-NO_2), 3313 (Ar-OH), 1240 (C-N). ^1H NMR (DMSO-d_6, 500 Hz) δ: 8.42 ppm (s, Ar-H_β). ESI-MS *m/z* (rel. int.): –674.9 $[M - H]^-$ (100%). EA calcd for $C_{24}H_{12}N_4O_{12}S_4$: C 42.6, H 1.78, N 8.28, S 18.93; found: C 41.6, H 2.06, N 7.79, S 18.59.

The acid–base properties of 3 as determined by UV spectroscopy

The UV absorption spectra were recorded for aqueous solutions containing the tetranitro derivative of thiacalix[4]arene **3** (5×10^{-5}mol L^{-1}) at appropriate pH intervals and I = 0.2 mol L^{-1}.

The determination of four pK_{an} (n = 1–4) values of 3 by TTFA

Assume that spectra collected during a distribution profile can be arranged against measurement time and form a data matrix (**Y**). The size of the matrix is $nt \times w$, where nt denotes the number of measurement times and nw the number of the corresponding wavelengths. The data matrix **Y** is allowed to be decomposed to the pure absorption spectral matrix **S** and the distribution profiles matrix $\mathbf{D}^T$. The relationship can be described by:

$$[1] \qquad \mathbf{Y} = \sum_{i=1}^{nc} s_i \boldsymbol{d}_i^T + \mathbf{E}_1 = \mathbf{S}\mathbf{D}^T + \mathbf{E}_1$$

where nc is the number of the absorbing species, $\boldsymbol{d}_i^T$ (column vector) and $\boldsymbol{s}_i$ (row vector) represent the distribution profile and the absorption spectrum of the ith component, respectively. Superscript T denotes the transpose of a matrix or a vector. $\mathbf{E}_1$ is the residual matrix. Principal component analysis (PCA) is a widely used chemometric technique. By using it, the data matrix **Y** can be decomposed to two orthogonal matrices, a score matrix **T** and a loading matrix $\mathbf{P}^T$. That is,

$$[2] \qquad \mathbf{Y} = \mathbf{T}\mathbf{P}^T + \mathbf{E}_2$$

If the pure absorption spectra of components in the samples are unknown, the concentration distribution of the components can be calculated through a series of acid ionization constants according to the principle of material equilibrium. Denote the samples as H_nL, the corresponding acid ionization constants $K_1K_2...K_{n-1}$. The distribution coefficient model is as follows:

$$[3] \qquad \boldsymbol{d}_i = \frac{[H]^{n-i} \cdot K_1 \cdots K_i}{[H]^n + [H]^{n-1} \cdot K_1 + \cdots + K_1 K_2 \cdots K_{n-1}}$$

Now the question is calculating this distribution coefficient. Concerning the background conditions, we assume some experiential values to the series of K_i, and calculate the corresponding concentration distribution to get the test target $\mathbf{D}_{test}^T(nc \times ns)$. Then according to the following partial least-squares regression equation we get the target transformed matrix:

$$[4] \qquad \mathbf{R} = \mathbf{D}_{test}^T \mathbf{P}$$

Having the target transformed matrix, we get the corresponding pure absorption spectrum matrix $\mathbf{S}_{test}(nc \times ns)$ through the equation $\mathbf{S} = \mathbf{T}\mathbf{R}^{-1}$. The residual matrix $\mathbf{Y}_{res}$ of the original data is:

$$[5] \qquad \mathbf{Y}_{res} = \mathbf{Y} - \mathbf{S}_{test}\mathbf{D}_{test}^T$$

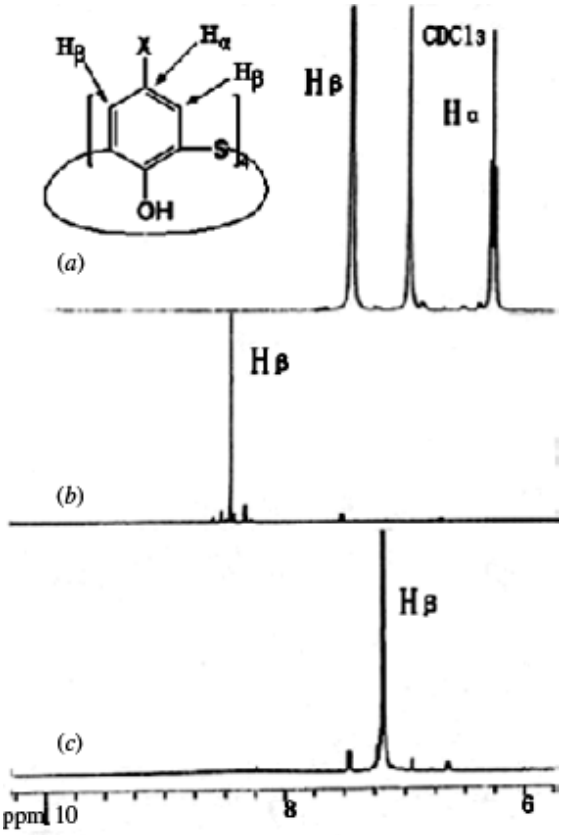
With the sum square of the matrix $\mathbf{Y}_{res}$ as the target function, denoted by SSQ, we can get the minimum value of SSQ after optimization of K_i.

When the value of SSQ is minimum, the corresponding $\mathbf{S}_{test}$ and $\mathbf{D}_{test}^T$ can be seen as the actual spectrum matrix and the concentration distribution matrix, therefore the concentration distribution model can be calculated. We used global search or the NGA algorithm (11) to optimize the parameters.

The key of this method is optimizing the test target through factor analysis, referred to as TTFA (10).

Results and discussion

Synthesis and characterization of 3



The tetranitro derivative **3** of thiacalix[4]arene **2** was synthesized under optimal conditions, which prevented the epithio atoms from being oxidized. Whether the bridging sulphur atoms are oxidized or not is partly dependent on the acidity of solution, therefore, glacial acetic acid was chosen as the regulating regent of acidity, rather than conc. H_2SO_4, which is preferred for the nitration of calixarenes. To ensure full tetranitro-substitution of the thiacalix[4]arene **2**, 65%~68% HNO_3 was used with vigorous stirring. An orange solid **3** slowly separated out after several hours, and after 30 h of reaction it was filtered from the solution. The ESI-MS spectrum of the orange product showed a peak at *m/z* = –674.9 (100%) corresponding to the $(M - 1)^-$ ion of **3**. Figure 2 shows the differences in the ^1H NMR spectra of **2** and **3**: the singlet due to H_β in **3** has been shifted to δ 8.42 ppm (see Fig. 2*b*) due to the electron-withdrawing effect of the nitro groups, while the corresponding signal in **2** shows up as a doublet at δ 7.64 and 7.62 ppm due to the spin coupling (observable in the $CDCl_3$ solvent) (see Fig. 2*a*).

The acid–base properties of 3 as studied by UV spectroscopy

Tetranitro thiacalix[4]arene **3** has strong acidic properties: in aqueous solution, the four hydrogen atoms of the phenolic

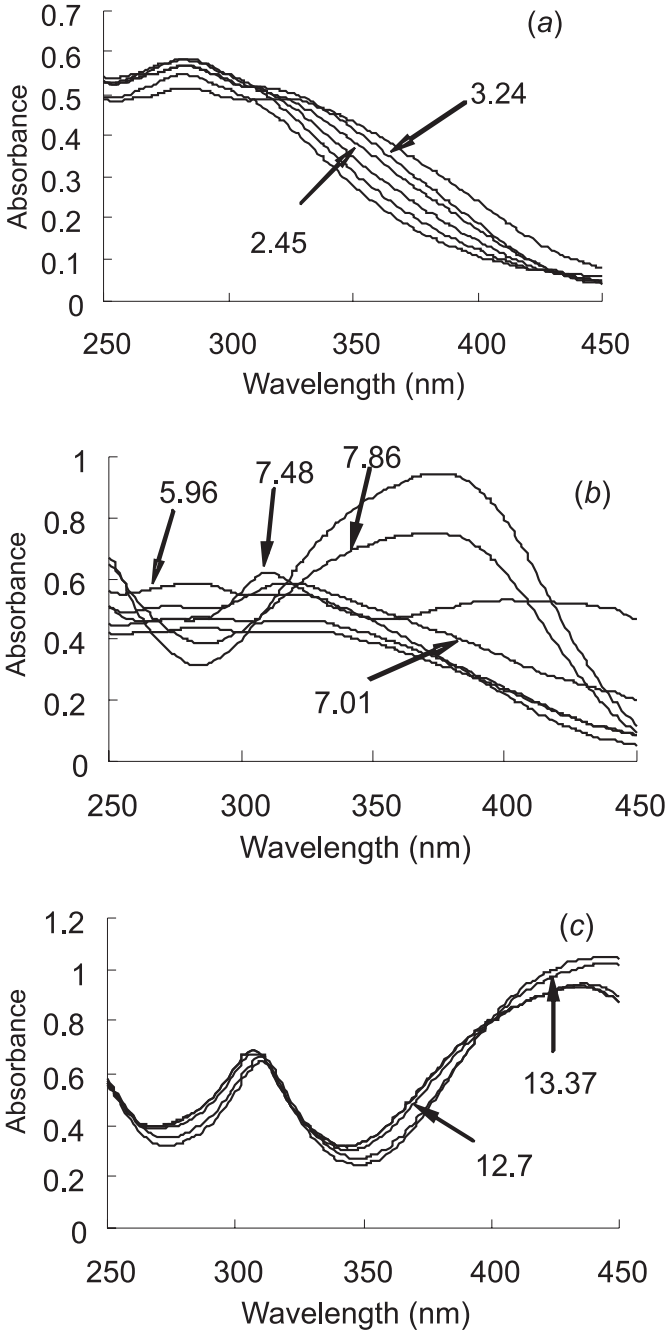
Fig. 2. (*a*) The ^{1}H NMR spectrum of **2** ($CDCl_3$, 500 Hz). (*b*) The ^{1}H NMR spectrum of **3** (DMSO-d_6, 500 Hz). (*c*) The ^{1}H NMR spectrum of **4** (DMSO-d_6, 500 Hz).



hydroxyl groups can be dissociated successively with an increase in the solution pH, and is therefore a tetraprotonic acid, and can be defined as H_4L. H_3L^-, H_2L^{2-}, HL^{3-}, and L^{4-} will correspond to the loss of one, two, three, and four H^+ ions, respectively, from **3**.

Figures 3*a*–3*c* show the UV absorption spectra of **3** in water solution at different pH conditions. As Fig. 3*a* shows, the absorption band around 285 nm increased with an increase in the solution pH from 0.43 to 2.05, and then declined with a further increase in the solution pH. There was an obvious difference in shape of the UV absorption curves, and a shift of the absorption peak observed in the solution pH > 2.45. That is to say, there is an isolated single-step acid dissociation that occurred in the pH region around 2.45. This change can be described by eq. [6]:

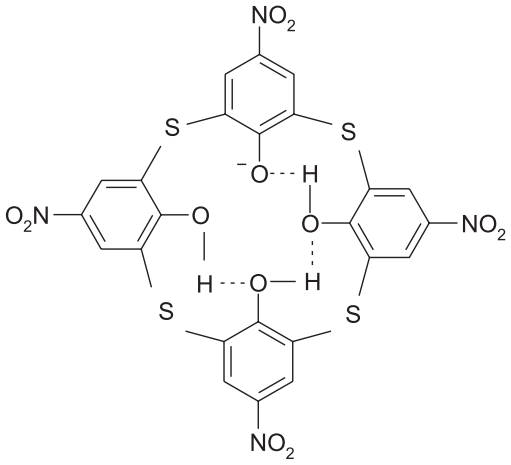
$$[6] \qquad H_4L \overset{K_{a1}}{\rightleftharpoons} H_3L^- + H^+$$

In Fig. 3*b*, an obvious red shift of the absorption peak from pH 5.96 to 7.01 shows that there is a second acid dissociation occurring in this pH region. When the pH value increased from 7.48 to 7.86, there was another acid dissociation of the third phenolic OH group in accordance with the apparent red shift of the absorption peak from 312 to 378 nm. These two acid dissociations can also be depicted by eqs. [7] and [8]:

Fig. 3. (*a*) UV absorbance spectra of **3** at solution pH 0.43, 1.55, 2.05, 2.45, 3.24, and 4.75. (*b*) UV absorbance spectra of **3** at solution pH 5.11, 5.41, 5.96, 7.01, 7.48, 7.86 and 8.73. (*c*) UV absorbance spectra of **3** at solution pH 11.82, 12.11, 12.7, 13.37, 8.98, and 13.62.

$$[7] \qquad H_3L^- \overset{K_{a2}}{\rightleftharpoons} H_2L^{2-} + H^+$$

$$[8] \qquad H_2L^{2-} \overset{K_{a3}}{\rightleftharpoons} HL^{3-} + H^+$$



From pH 12.7 to 13.37 (Fig. 3*c*), the fourth acid dissociation of the phenolic OH group of **3** occurred corresponding to the

isosbestic point at 402 nm. This fourth dissociation can be described by eq. [9]:

$$[9] \qquad HL^{3-} \overset{K_{a_4}}{\rightleftharpoons} L^{4-} + H^+$$

The determination of four pK_{an}(n = 1–4) values of 3 by TTFA

Table 1 shows the four pK_a values of **3** in aqueous solution. The pK_a1 = 2.75 of **3** is far lower than the subsequent pK_a values. This indicates that the first acid dissociation of **3** is far easier than the subsequent acid dissociations. As speculated by several researchers (11), these may be attributed to stabilization of the monophenolate species through the strong intramolecular hydrogen bonding between the phenolate O^- and its flanking OH groups (see Fig. 4). This stabilization effect also makes it possible that the first pK_a of **3** is far lower than the pK_a of *p*-nitrophenol (7.15).

On the other hand, the pure UV absorption curves (Fig. 5) and pH distribution curves (Fig. 6) of the five forms of **3** were also calculated by TTFA.

Conclusion

Tetranitro thiacalix[4]arene **3** was synthesized in good yield and characterized. The acid–base properties of **3** in aqueous solution were studied by UV spectroscopy. Four pK_a values in aqueous solution were determined by TTFA. The pure UV absorption curves and pH distribution curves for five occurring forms of **3** were also calculated by TTFA. The results presented here could be helpful for the further exploration of the complexation properties of thiacalixarene, such as its recognition of metal ions.

Thermodynamic properties of 1,1,1,2-tetrafluoroethane + polyether mixtures up to 60 MPa

M.J.P. Comuñas, C. Boned, A. Baylaucq, E.R. López, and J. Fernández

Abstract: In this work we report several derived thermodynamic properties, the isothermal compressibility (κ_T), the isobaric thermal expansion coefficient (α_p), and the internal pressure (π), and their excess functions (κ_T^E, α_p^E, and π^E) for the refrigerant + lubricant mixtures HFC-134a + triethylene glycol dimethyl ether and HFC-134a + tetraethylene glycol dimethyl ether. These properties have been determined in wide temperature (293.15–373.15 K) and pressure (10–60 MPa) ranges in an effort to better understand the behaviour of these kinds of mixtures and their thermophysical properties as functions of temperature, pressure, and composition. The analysis of the thermodynamic excess properties (negative values for κ_T^E and α_p^E, positive values for π^E) for both systems shows a high degree of interaction between the refrigerant and the synthetic lubricant molecules.

Key words: HFC-134a, high pressure, internal pressure, isobaric thermal expansion coefficient, isothermal compressibility, polyglycol ethers, refrigerant–lubricant mixtures.

Résumé : Dans ce travail nous rapportons plusieurs propriétés thermodynamiques, la compressibilité isotherme (κ_T) l'expansivité isobare (α_p) et la pression interne (π) et aussi leur fonction d'excès (κ_T^E, α_p^E et π^E) pour les systèmes binaires réfrigérant + lubrifiant HFC-134a + triethylene glycol dimethyl éther et HFC-134a + tetraethylene glycol dimethyl éther. Nous avons déterminé ces propriétés dans un large domaine de température (293.15–373.15 K) et de pression (10–60 MPa) avec l'objectif de comprendre le comportement de ces mélanges et des grandeurs d'excès en fonction de la température, de la pression et de la fraction molaire. L'analyse des propriétés d'excès (valeurs négatives de κ_T^E et α_p^E, valeurs positives de π^E) pour les deux mélanges étudiés, met en évidence l'existence d'interactions fortes entre les molécules du réfrigérant et celles du lubrifiant.

Mots clés : HFC-134a, haute pression, pression interne, expansivité isobare, compressibilité isotherme, polyglycol éthers, mélanges réfrigérant–lubrifiant.

Introduction

High-pressure, high-temperature thermodynamic measurements for refrigerant + lubricant mixtures are quite limited and a rapid accumulation of accurate data over wide temperature and pressure ranges is required. A literature review shows several studies concerning the measurement of solubility (1), miscibility (2), viscosity (2, 3), vapour–liquid equilibrium (4), and density (5, 6) of mixtures of selected refrigerants such as HFC-125, HFC-32, HFC-134a, and HFC-410A, and compatible lubricants (polyol esters or polyalkylene glycols) up to the region close to the critical point of the refrigerant. Among these properties, the density and its derived quantities, such as excess volume, are an essential tool to discuss the interactions between the components.

In recent work (5, 6) we have reported experimental densities in the compressed liquid phase for 1,1,1,2-tetrafluoroethane (HFC-134a), triethylene glycol dimethylether (TriEGDME), tetraethylene glycol dimethylether (TEGDME), for six mixtures HFC-134a + TriEGDME (818 experimental points) and for eight mixtures HFC-134a + TEGDME (1017 experimental points) from 293.15 to 373.15 K and at pressures up to 60 MPa. From the experimental results, the volumetric behaviour of HFC-134a + polyether systems has been analysed. In almost all the measurement range, the density of the refrigerant is greater than that of the polyether. Furthermore, the densities of the mixtures display a crossover phenomenon with composition at higher temperatures. The excess volumes for this kind of mixture are strongly negative and asymmetrical towards high refrigerant concentrations, becoming more negative when the temperature increases and

the pressure decreases. The negative values of V_m^E are in agreement with the previous remarks regarding the high degree of interactions in the HFC-134a + polyether (1). Nevertheless, in this case free-volume or packing effects could give an important negative contribution.

The aim of the present work is to determine several thermodynamic properties: the isothermal compressibility (κ_T), the isobaric thermal expansion coefficient (α_p), and the internal pressure (π) for HFC-134a + polyether systems, and to analyze how the pressure and the temperature affect all these thermodynamic properties. We have also determined for these refrigerant + lubricant mixtures the corresponding excess properties κ_T^E, α_p^E, and π^E over wide temperature and pressure ranges. Furthermore, the study of these properties as a function of both pressure and temperature is of fundamental interest because theoreticians need experimental data to apply their models to these chemical species and their mixtures.

Derived properties

For each mol fraction, the density can be satisfactorily represented by the following modified Tait equation

$$[1] \qquad \rho(T, p) = \frac{\rho(T, p_{ref})}{1 - C \ln\left[\dfrac{B(T) + p}{B(T) + p_{ref}}\right]}$$

where $\rho(T, p_{ref})$ is the temperature dependence of the density at the reference pressure (p_{ref} = 10 MPa), for which we have used the following expression

$$[2] \qquad \rho(T, 10\ \text{MPa}) = \rho_0(T) = A_0 + A_1 T + A_2 T^2$$

In eq. [1], the parameter C was assumed to be temperature independent, and for $B(T)$ we have used the polynomial function

$$[3] \qquad B(T) = B_0 + B_1 T + B_2 T^2$$

Taking into account the previous expressions, the final Tait-like equation used for the density correlation at all temperatures and pressures is

$$[4] \qquad \rho(T, p) = \frac{A_0 + A_1 T + A_2 T^2}{1 - C \ln\left(\dfrac{B_0 + B_1 T + B_2 T^2 + p}{B_0 + B_1 T + B_2 T^2 + 10\ \text{MPa}}\right)}$$

The isothermal compressibility is obtained from eq. [4] using the equations

$$[5] \qquad \kappa_T = \left(\frac{1}{\rho}\right)\left(\frac{\partial \rho}{\partial p}\right)_T = \frac{C}{\left\{1 - C \ln\left[\dfrac{B(T) + p}{B(T) + 10\ \text{MPa}}\right]\right\}[B(T) + p]}$$

The isobaric thermal expansion coefficient is determined using the equations

$$[6] \qquad \alpha_p = -\left(\frac{1}{\rho}\right)\left(\frac{\partial \rho}{\partial T}\right)_p = -\frac{1}{\rho}\left[\frac{\rho_0'(T) F(T, p) - \rho_0(T) F'(T, p)}{F(T, p)^2}\right]$$

where $F(T, p)$ is the denominator of the right side of eq. [4] and $F'(T, p)$ is its temperature derivative given by

$$[7] \qquad F'(T, p) = \left[\frac{\partial F(T, p)}{\partial T}\right]_p = CB'(T)\left[\frac{1}{B(T) + 10\ \text{MPa}} - \frac{1}{B(T) + p}\right]$$

$\rho_0'(T) = d\rho_0/dT$ and $B'(T) = dB/dT$ are easily derived from eqs. [2] and [3] obtaining $\rho_0'(T) = A_1 + 2A_2T$ and $B'(T) = B_1 + 2B_2(T)$.

Finally, the internal pressure, is given by

$$[8] \qquad \pi = \left(\frac{\partial U}{\partial V}\right)_T = T\left(\frac{\partial p}{\partial T}\right)_V - p$$

Values of π were obtained from the Tait-like equation, first by expressing p as a function of T and ρ:

$$[9] \qquad p = [B(T) + 10\ \text{MPa}] \exp\left(\frac{\rho - \rho_0}{\rho C}\right) - B(T)$$

and then by performing the analytical differentiation of this expression

$$[10] \qquad \left(\frac{\partial p}{\partial T}\right)_V = B'(T) \exp\left(\frac{\rho - \rho_0}{\rho C}\right) - \frac{1}{\rho C}[B(T) + 10\ \text{MPa}]\rho_0'(T) \exp\left(\frac{\rho - \rho_0}{\rho C}\right) - B'(T)$$

Taking into account eqs. [8] and [10], the expression of the internal pressure can be easily derived.

Excess derived properties

The excess derived properties χ^E can be employed as a measure of the departure from ideal behaviour and are defined as

$$[11] \qquad \chi^E = \chi^{mix} - \chi^{id}$$

where χ^{mix} and χ^{id} stand for the derived property at the same temperature and pressure for the real and the ideal mixtures, respectively. The procedure commonly used in the literature is to calculate χ^{id} as the sum of the mol-fraction weighted contributions of the derived property of the pure components (χ_i)

$$[12] \qquad \chi^{id} = \sum_{i=1}^{N} x_i \chi_i$$

where x_i denotes the mol fraction of the component i in the mixture. However, based on the fundamental thermodynamic definition of the isothermal compressibility and of the isobaric thermal expansion coefficient, it can be shown that

their rigorous expressions for an ideal mixture are obtained by taking into account the volume-fraction weighted contributions of the isothermal compressibility and of the isobaric thermal expansion coefficient (7–13). The volume-fraction ϕ_i is defined by

$$[13] \quad \phi_i = \frac{x_i V_{mi}}{\sum_{j=1}^{N} x_j V_{mj}}$$

where V_{mj} is the molar volume of the pure compound j. Finally, the excess thermal expansion coefficient α_p^E and the excess isothermal compressibility κ_T^E are obtained for a binary system by using the following equations

$$[14] \quad \alpha_p^E = \alpha_p^{mix} - \sum_{i=1}^{2} \frac{x_i V_{mi}}{x_1 V_{ml} + x_2 V_{m2}} \alpha_{pi}$$

$$[15] \quad \kappa_T^E = \kappa_T^{mix} - \sum_{i=1}^{2} \frac{x_i V_{mi}}{x_1 V_{ml} + x_2 V_{m2}} \kappa_{Ti}$$

where α_{pi} and κ_{Ti} are, respectively, the isobaric thermal expansion coefficient and the isothermal compressibility of pure compound i. There are large differences between the excess properties calculated with eqs. [14] and [15] and those evaluated by using the incorrect expression (eq. [12]) for an ideal mixture (14).

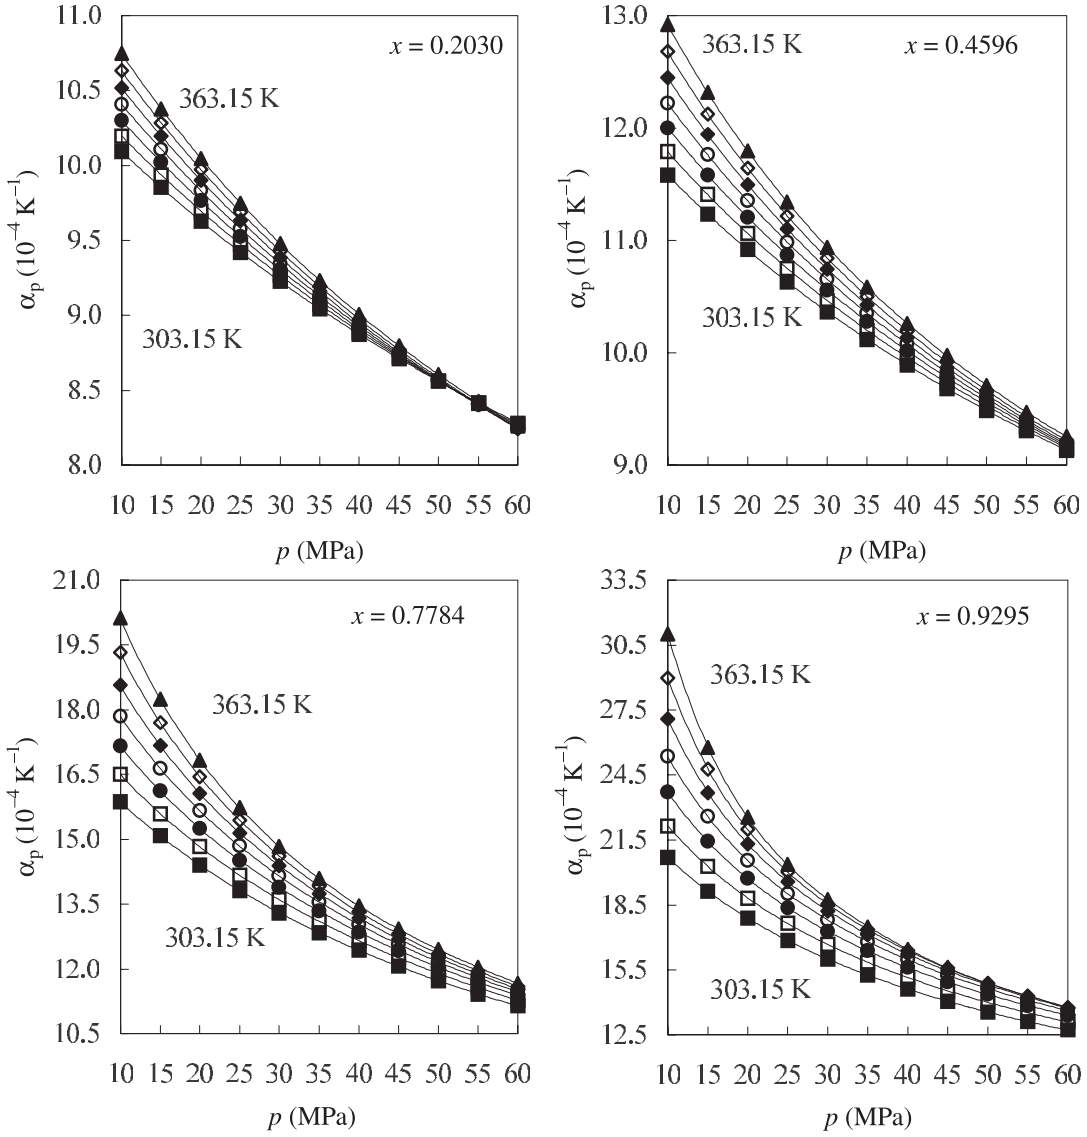
For the excess internal pressure of an ideal mixture, the additivity of this property in the mol fraction scale is often assumed (15, 16). With this assumption, the excess internal pressure can be calculated by using the relation

$$[16] \quad \Delta\pi = \pi^{mix} - \sum_{i=1}^{2} x_i \pi_i$$

However, this expression is not correct because the internal pressure is not an extensive property, and therefore the additivity based on the mol fraction for ideal mixtures is not accomplished. For this reason the quantity calculated from eq. [16] (i.e., $\Delta\pi$) is sometimes (17) called the "deviation internal pressure" or "quasi-excess internal pressure". Recently, Marczak has published a paper (18) concerning the correct expression for the internal pressure of a thermodynamically ideal mixture. Using this expression for the internal pressure of an ideal mixture that includes the "compression fraction", the excess internal pressure for a binary mixture must be obtained using the equation

$$[17] \quad \pi^E = \pi^{mix} - \sum_{i=1}^{2} \frac{x_i V_{mi} \kappa_{Ti}}{x_1 V_{ml} \kappa_{T1} + x_2 V_{m2} \kappa_{T2}} \pi_i$$

In this equation the compression fraction is used instead of the volume fraction that appears in eqs. [14] and [15] for the excess thermal expansion coefficient and the excess isothermal compressibility. It should be pointed out that eq. [17] can be obtained (19) using the expression of the isochoric pressure coefficient $\gamma_V = (\partial p/\partial T)_V$ for an ideal mixture, and taking into account the definition $\pi = T(\partial p/\partial T)_V - p$.



Results

The values of the A_i (i = 0, 1, 2), B_j (j = 0, 1, 2), and C coefficients for the Tait-like density correlation were determined for HFC-134a + TriEGDME and HFC-134a + TEGDME mixtures from our previously reported density data (5, 6) by fitting, at each fixed composition, the $p\rho T$ surface to eq. [4] using a Marquardt–Levenberg type algorithm. In Table 1 the values of these parameters are summarized for the HFC-134a + TriEGDME and HFC-134a + TEGDME systems. For pure HFC-134a, these parameters were reported in our previous paper (5). $B(T)$ increases when the temperature decreases and has a regular mol fraction dependence.

The estimated uncertainties of the isothermal compressibility (κ_T), the isobaric thermal expansion coefficient (α_p), and the internal pressure (π) calculated using eqs. [5]–[10] are $\pm 0.05 \times 10^{-4}$ MPa^{-1}, $\pm 0.02 \times 10^{-3}$ K^{-1}, and 1%, respec-

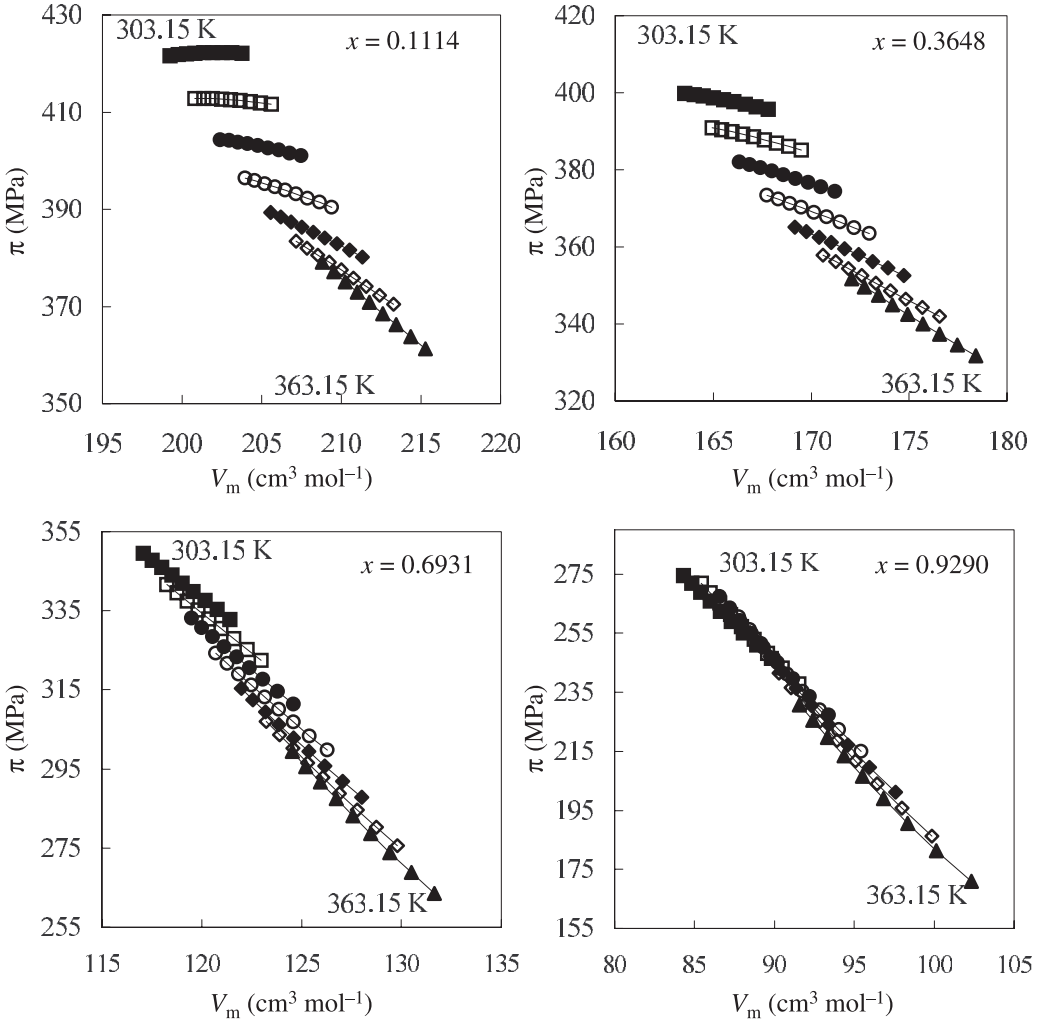
Fig. 1. Temperature and pressure dependence of the isobaric thermal expansion coefficient (α_p) for the *x*HFC-134a + (1 – *x*)TriEGDME mixtures: 303.15 K (■), 313.15 K (□), 323.15 K (●), 333.15 K (○), 343.15 K (◆), 353.15 K (◇), 363.15 K (▲). (—— Polynomial interpolation).



tively, over the entire temperature and pressure ranges. In a previous study (20), isothermal compressibility and isobaric thermal expansivity values have been reported for pure TriEGDME and TEGDME up to 353.15 K and 60 MPa. These values have been calculated from density data measured with the same apparatus and correlated also with the Tait equation, but using as the reference pressure 0.1 MPa instead of 10 MPa used in the present work. We have compared both sets of data for TEGDME obtaining an average absolute deviation of 0.2% for the isothermal compressibility and 0.8% for the isobaric thermal expansivity, along with maximum deviations of 0.4% and 2.5%. For TriEGDME, the previous corresponding deviations are 0.2%, 0.4%, 0.5%, and 0.7%, respectively.

For the isobaric thermal expansion coefficient, it is evident that its pressure dependence is higher for the pure refrigerant than for the pure polyether. For example, at 323.15 K, α_p for TEGDME decreases from 8.8×10^{-4} K^{-1} at 15 MPa to 7.6×10^{-4} K^{-1} at 55 MPa (i.e., a variation of 1.2×10^{-4} K^{-1} in this pressure range), whereas in the same pressure range, the variation of α_p for HFC-134a is 10.6×10^{-4} K^{-1}. Figure 1 shows the dependence of the isobaric thermal expansion coefficient on the temperature and on the pressure at different mol fractions. At fixed temperature and pressure, α_p increases when the refrigerant mol fraction increases. We can also observe in Fig. 1 that there is a crossover point of the isotherms (21–23). At the pressure of the crossing point, α_p is independent of temperature. Increasing the mol fraction of refrigerant increases the crossover pressure. For the *x*HFC-134a + (1 – *x*)TEGDME system at $x = 0$ (pure TEGDME), the crossing point appears near 30 MPa, as we reported in our previous study (20), at $x = 0.2030$ near 50 MPa, and at $x = 0.4596$ near 60 MPa. For higher mol fractions this crossover point is not visible in the pressure range used for the experiments. This intersection point of the isotherms is related to the existence of a minimum in the

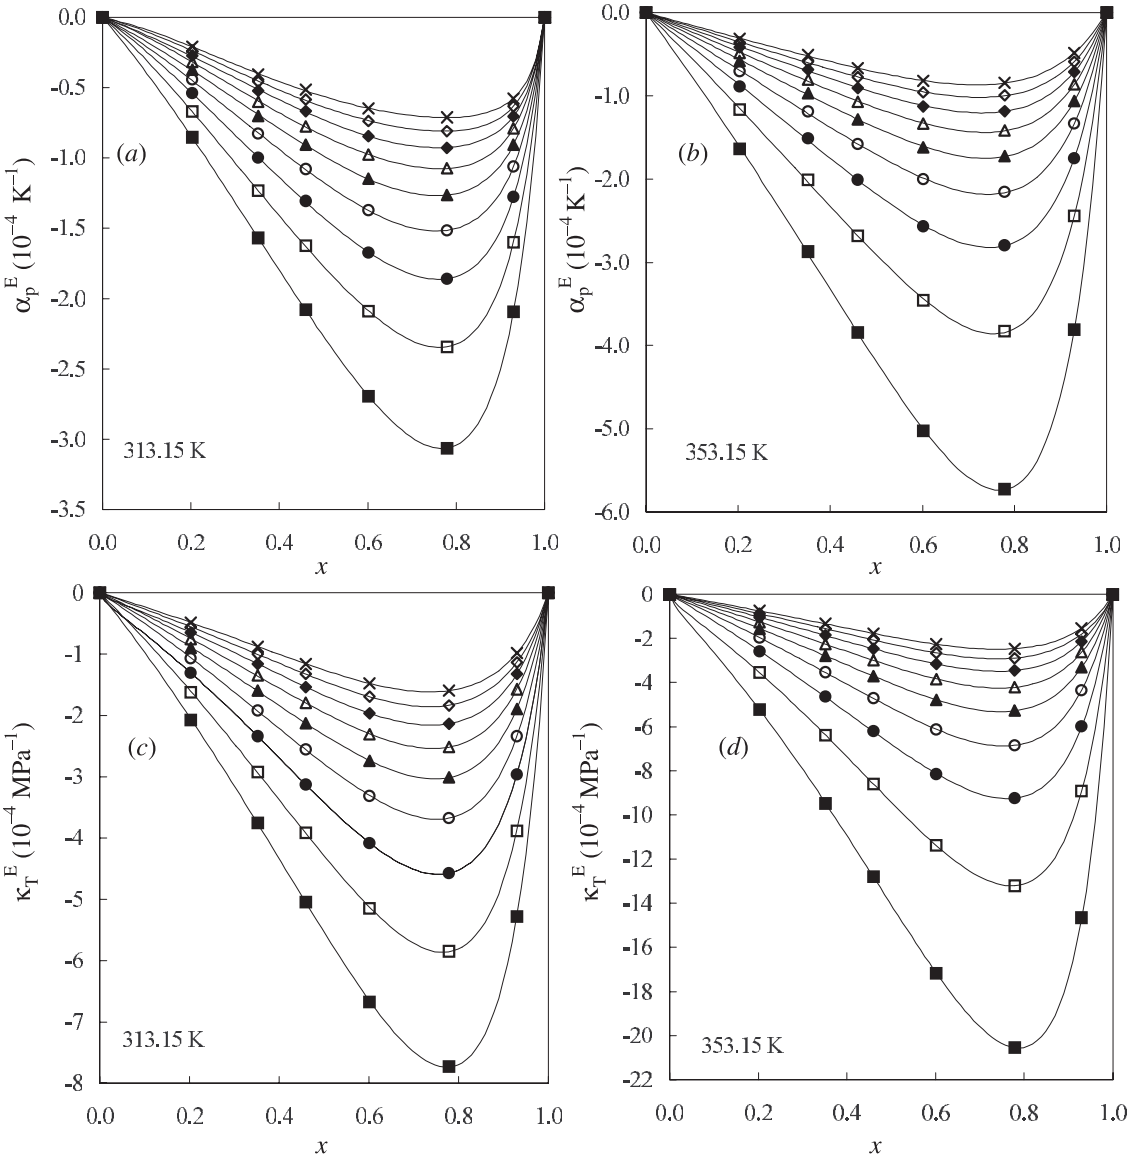
Fig. 2. Internal pressure (π) plotted against the molar volume at different temperatures and pressures for the *x*HFC-134a + (1 – *x*)TEGDME mixtures at several refrigerant mol fractions: 303.15 K (■), 313.15 K (□), 323.15 K (●), 333.15 K (○), 343.15 K (◆), 353.15 K (◇), 363.15 K (▲).

plot of the isobaric heat capacity vs. temperature (21), where $(\partial^2\rho/\partial T^2) = 0$.

The isothermal compressibility for the pure refrigerant is also higher and more pressure dependent (with a variation of 22.7×10^{-4} MPa^{-1} at 323.15 K between 15 and 50 MPa) than that of the polyethers (with a variation of 1.5×10^{-4} MPa^{-1} for TriEGDME and 1.3×10^{-4} MPa^{-1} for TEGDME in the same pressure range). For both mixtures, the variation of α_p and κ_T as a function of the refrigerant mol fraction, at constant temperature and pressure, shows at low concentrations of the refrigerant a small increase, whereas for the higher concentrations a sharp increase can be observed.



In Fig. 2, we have plotted the internal pressure against the molar volume at four refrigerant mol fractions 0.1114, 0.3648, 0.6931, and 0.9290 and at different temperatures for the binary system HFC-134a + TEGDME. When the refrigerant concentration in the mixture increases, the change of the internal pressure with the molar volume tends to the same slope (i.e., the internal pressure could be represented as a unique curve). To the knowledge of the authors no similar behaviour of the internal pressure has been reported.

Concerning the excess thermodynamic properties of liquid mixtures, we must point out that they are useful because their analysis can give information on the intermolecular interactions and of the packing and order effects. The first derivatives (excess molar volumes, enthalpies, and entropies) and the second derivatives (excess isothermal compressibility and thermal expansion coefficients) can provide information on the Gibbs energy of the mixtures.

In Figs. 3*a* and 3*b*, we present the variation of the excess thermal expansion coefficient with the mol fraction, and for nine pressures at two temperatures for the *x*HFC-134a + (1 – *x*)TriEGDME. This excess property is always negative and increases as the pressure rises. The behaviour of the binary mixture *x*HFC-134a + (1 – *x*)TEGDME is similar, but at 343.15 and 363.15 K for the highest pressures, α_p^E reaches small and positive values. Figures 3*c* and 3*d* show that the temperature, pressure, and mol fraction dependences of the excess isothermal compressibility for the binary system containing TriEGDME are similar to those of the excess thermal expansion coefficient. The same observation can be made for the mixture containing the other polyether (TEGDME).

© 2004 NRC Canada

Fig. 3. Variation of α_p^E (*a* and *b*) and κ_T^E (*c* and *d*) with composition and pressure at two different temperatures for the *x*HFC-134a + (1 – *x*)TriEGDME system: 15 MPa (■), 20 MPa (□), 25 MPa (●), 30 MPa (○), 35 MPa (▲), 40 MPa (△), 45 MPa (◆), 50 MPa (◇), 55 MPa (×). (—— Polynomial interpolation).

The excess internal pressure (Figs. 4*a* and 4*b*) contrary to the previously discussed excess properties, is positive as expected, and increases as the temperature increases and as the pressure decreases. This behaviour is similar for the two studied systems. In Figs. 5*a* and 5*b*, we compare the "deviation of the internal pressure" $\Delta\pi$ calculated with eq. [16] with the excess internal pressure π^E calculated by using eq. [17]. Both quantities are positive, but the excess internal pressure is twice as large as the deviation of the internal pressure. The main differences between these quantities are due to the fact that the isothermal compressibilities are much higher for HFC-134a than for the pure polyether. Marczak (18) using the data of Ogawa and Murakami (24) also reported large differences between π^E and $\Delta\pi$ in the methanol + 1-propanol systems at atmospheric pressure and at 298.15 K. The positive values of the excess internal pressure indicate that for these systems the variation of the internal energy during the expansion $((\partial U/\partial V)_T)$ is higher than that of the ideal mixture $((\partial U^{id}/\partial V^{id})_T)$. This could be interpreted by using the fact that new interactions appearing in the mixtures are more sensitive to changes in the intermolecular distance than those existing in the pure compounds (25).

In Fig. 6, we present a comparison between the excess isothermal compressibility, the excess thermal expansion coefficient, and the excess internal pressures for the HFC-134a + TriEGDME and HFC-134a + TEGDME mixtures. The values of α_p^E and κ_T^E are very similar for both binary systems. The values of π^E for the two systems are different; higher π^E values are found for the mixture containing TEGDME. The maxima of the $\pi^E(x)$ curves are located close to the equimolar mixtures, displaying shapes more symmetrical than those for the other excess properties ($\kappa_T^E(x)$ and $\alpha_p^E(x)$).

The results obtained in our previous studies (5, 6) and in

Comparison between the excess internal pressure and the deviations of the internal pressure: (*a*) for the *x*HFC-134a + (1 – *x*)TriEGDME system, and (*b*) for the *x*HFC-134a + (1 – *x*)TEGDME mixture at 313.15 K for two pressures (15 MPa (■, □) and 20 MPa (▲, △)). The filled symbols are calculated by using eq. [17] and the hollow symbols by using eq. [16]. (------; —— Polynomial fitting).

the present work for the two binary systems can be summarized as follows: both highlight negative values for the excess molar volumes ($V_m^E < 0$), for the excess isothermal compressibility ($\kappa_T^E < 0$), as well as for the excess thermal expansion coefficient ($\alpha_p^E < 0$), but positive values for the excess internal pressure ($\pi^E > 0$) in the entire temperature and pressure interval. The negative values of the excess molar volumes indicate that the mixtures are more closely packed that the pure components and can be explained by considering two effects. The first one is the existence of stronger interactions between unlike molecules (TriEGDME or TEGDME with HFC-134a) than between identical molecules. This effect implies a diminution in the volume because the intermolecular distances diminish. The second effect is that the smallest molecules (HFC-134a) occupy the free volume of the largest molecules (TriEGDME or

Fig. 6. Comparison between the excess properties of the *x*HFC-134a + (1 – *x*) polyether system: 15 MPa (□), 25 MPa (○), 35 MPa (△), 45 MPa (◇). The filled symbols are used for the mixture containing TriEGDME and the hollow symbols for the mixture containing TEGDME.

TEGDME). For the HFC-134a + polyether systems, the two contributions can be important, as can be deduced from the results for V_m^E and κ_T^E. Generally, these properties present negative values for systems in which there is hydrogen bonding or important electrostatic interactions between the unlike molecules (26, 27). The dependence of both excess properties with the mol fraction is similar, emphasizing an asymmetrical shape. The excess isothermal compressibility values are also affected by the existence of molecular aggregation due to the molecular interactions. The negative values of these excess properties show that during the mixing process there is a decrease of the volume and an increase of the rigidity (i.e., the mixture is less compressible than the ideal mixture). The negative values of α_p^E show that the mixtures are also less expansible than the ideal mixture, and this idea is compatible with the interpretation of the rigidity increase during the mixing process (28–30). Excess internal pressure and deviations of the internal pressure data are scarce in the literature. We have observed that, frequently, the sign of $\Delta\pi$ is opposite to the sign of the excess volumes (17, 31, 32).

The solubilities of HFC-134a in TriEGDME and in TEGDME have been recently measured (1, 33). These binary systems present negative deviations from Raoult's law ($G^E < 0$) and this also indicates strong interactions between the polyether and the refrigerant molecules. From the VLE data published by Tseregounis and Riley (1), we calculated the NRTL parameters for the HFC-134a + TEGDME mixtures, whereas the NRTL coefficients for the HFC-134a + TriEGDME system were reported by Coronas et al. (33). Taking into account these parameter values, we have estimated the excess enthalpies (H^E) for both systems. The extremely negative H^E values (indicating the exothermic character) of these systems, show again that the formation of new interactions during the mixing process is energetically more important than the rupture of existing interactions.

Our results are in agreement with those reported in refs. 34–36 for the vapour–liquid equilibrium values of several refrigerants + dimethyl ether for which the HFC molecules have active donor protons capable of strong H-bonding with proton acceptors. We must also take into account that in pure HFC-134a and in pure polyethers, strong interactions are also reported by several authors (37). Nevertheless, we can conclude that according to the values presented here and to those reported in refs. 1 and 33–36, the interactions in the mixture of HFC-134a and polyethers are stronger than those for the pure components. This behaviour is in contrast with that for HFC-134a + polyolester oil (POE) systems, which, according to the experimental activity coefficients at infinite dilution, do not present specific interactions between the unlike molecules (38).

Spectroscopic and photophysical properties of carbazole-based triads

Michel Belletête, Mélanie Bédard, Jimmy Bouchard, Mario Leclerc, and Gilles Durocher

Abstract: A study of the spectroscopy and photophysics of four carbazole-based triads, namely, 1,4-bis(*N*-octylcarbazol-2-yl)phenylene (CPC), 2,5-bis(*N*-octylcarbazol-2-yl)thiophene (CTC), 2,7-bis(*N*-octylcarbazol-2-yl)-9,9-dihexylfluorene (CFC), and 2,7-bis(*N*-octylcarbazol-2-yl)-*N*-octylcarbazole (CCC) are reported. From ZINDO/S calculations performed on the optimized ground state geometries (HF/6-31G*), the $S_1 \leftarrow S_0$ and $S_2 \leftarrow S_0$ electronic transitions of CPC, CFC, and CCC are weakly allowed, whereas the $S_3 \leftarrow S_0$ electronic transition is dipole-allowed (*x* axis) and possesses a high value of the oscillator strength. On the other hand, for CTC, the dipole-allowed electronic transition is $S_1 \leftarrow S_0$. For the four derivatives, the dipole-allowed transition corresponds mainly to the promotion of an electron from the HOMO to the LUMO. The first absorption band of each derivative can be assigned to the dipole-allowed transition. The geometry optimization of the excited states has been done with RCIS/6-31G* ab initio calculations. For CPC, CFC, and CCC, S_3 is much more stabilized than S_1 and S_2, causing a crossing of the singlet excited states (S_3 becomes lower in energy than S_1 and S_2). Emission energies from the first relaxed excited states ($S_1 \rightarrow S_0$) have been obtained from ZINDO/S calculations performed on the optimized S_1 geometries (RCIS/6-31G*). It is found that these energies are in very good agreement with those determined from the fluorescence spectra. Going from CPC to CTC, the replacement of a phenylene ring by a thiophene unit induces a red shift in the absorption and fluorescence spectra. This behavior is interpreted in terms of the electron donor properties of the thiophene ring. The increase of the oligomer chain (CFC and CCC compared to CPC) also induces bathochromic shifts in the spectra because of a longer electronic delocalization along the molecular frame. From fluorescence data, it is observed that a more planar conformation is favored in the relaxed excited states. RCIS/6-31G* ab initio calculations performed on the S_1 relaxed excited states confirm this statement. Finally, the photophysical properties of CTC are mainly governed by nonradiative processes (k_{nr}), whereas the variation in the photophysics of CPC, CFC, and CCC mainly involves radiative processes (k_F).

Key words: electronic spectroscopy, fluorescence, photophysics, ab initio calculations, excited states.

Résumé : Une étude de la spectroscopie et de la photophysique de quatre dérivés du carbazole, soit 1,4-bis(*N*-octylcarbazol-2-yl)phenylene (CPC), 2,5-bis(*N*-octylcarbazol-2-yl)thiophene (CTC), 2,7-bis(*N*-octylcarbazol-2-yl)-9,9-dihexylfluorene (CFC), et 2,7-bis(*N*-octylcarbazol-2-yl)-*N*-octylcarbazole (CCC) est reportée. À partir de calculs ZINDO/S effectués sur les géométries à l'état fondamental optimisées (HF/6-31G*), il est démontré que les transitions électroniques $S_1 \leftarrow S_0$ et $S_2 \leftarrow S_0$ du CPC, du CFC et du CCC sont faiblement permises. Par contre, la transition électronique $S_3 \leftarrow S_0$ de ces molécules est fortement permise (axe *x*) et possède une valeur élevée de sa force oscillatrice. D'autre part, pour le CTC, la transition électronique fortement permise est très stabilisée et devient alors la transition $S_1 \leftarrow S_0$. Pour les quatre dérivés, la transition fortement permise correspond principalement à la promotion d'un électron de l'orbitale HOMO vers l'orbitale LUMO. La première bande d'absorption de chaque dérivé peut être assignée à la transition électronique fortement permise. L'optimisation de la géométrie des états excités a été effectuée à l'aide de la méthode RCIS/6-31G*. Pour les molécules CPC, CFC et CCC, il a été démontré que l'état S_3 est beaucoup plus stabilisé que les états S_1 et S_2 causant ainsi un croisement des états singulets excités (S_3 devient moins énergétique que S_1 et S_2). Les énergies d'émission provenant des premiers états excités relaxés ($S_1 \rightarrow S_0$) ont été obtenus à partir de calculs ZINDO/S effectués sur les géométries optimisées des états S_1 (RCIS/6-31G*). Il est démontré que ces énergies sont en très bon accord avec les énergies d'émission expérimentale déterminées à partir des spectres de fluorescence. En passant du CPC au CTC, le remplacement d'un groupe phénylène par un cycle thiophène induit un déplacement bathochrome dans les spectres d'absorption et de fluorescence. Il est suggéré que ce comportement est causé par les propriétés électro-donneur du groupe thiophène. L'augmentation de la longueur de la chaîne de l'oligomère (CFC et CCC comparés à CPC) induit aussi des déplacements bathochromes dans les spectres due à une délocalisation

électronique accrue selon le grand axe moléculaire. À partir des données spectrales de fluorescence, il est observé qu'une conformation plus plane semble atteinte pour les oligomères dans leurs états excités relaxés. Les calculs RCIS/6-31G* effectués sur les états excités relaxés confirment cette observation. Finalement, il est démontré que les propriétés photophysiques du CTC sont principalement gouvernées par des processus non radiatifs (k_{nr}), tandis que la photophysique de CPC, CFC et CCC implique principalement des processus radiatifs (k_F).

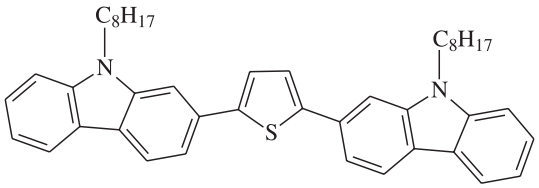
Introduction



Conjugated polymers and oligomers have been investigated intensively in the past few decades because of their great potential for the development of electronic devices such as field-effect transistors (1–3), solar cells (4, 5), and light-emitting diodes (LEDs) (6–10). The advantages of organic electroactive and photoactive materials over inorganic systems are their ease of processing and the tunability of their properties through simple chemical modifications. Recently, the synthesis of various well-defined conjugated oligomers and polymers derived from phenylene, pyrrole, thiophene, and fluorene moieties has been achieved. However, the fabrication of novel materials from conjugated building blocks is still a challenge for future electronic devices.

Recently, novel well-defined 2,7-carbazole-based polymers have been synthesized by Leclerc's research group (11–14). Luminescent materials spanning the entire visible range have been prepared from these polymers (15), which can be useful as LEDs (16, 17). To learn more about the structure–property relationships in this new class of materials, we believe that it is important to study the optical and photophysical properties of the corresponding carbazole oligomers. Therefore, we report herein the spectroscopy and photophysics of four carbazole-based triads: 1,4-bis(*N*-octylcarbazol-2-yl)phenylene (CPC), 2,5-bis(*N*-octylcarbazol-2-yl)thiophene (CTC), 2,7-bis(*N*-octylcarbazol-2-yl)-9,9-dihexylfluorene (CFC), and 2,7-bis(*N*-octylcarbazol-2-yl)-*N*-octylcarbazole (CCC) in solution. The absorption and emission energies of these derivatives are correlated with their electronic transitions computed from ZINDO/S calculations performed on optimized ground state (HF/6-31G*) and first relaxed excited state (RCIS/6-31G*). A good agreement is obtained between the computed electronic transitions and the optical data. Moreover, the photophysical results are discussed in terms of the relative importance of the radiative and nonradiative processes occurring in these materials. The molecular structures of the compounds investigated in this paper are displayed in Fig. 1.

yl)carbazole (12), $Pd(PPh_3)_4$ (18), *N*-octyl-2-(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)carbazole (19), 2-(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)-9,9-dioctylfluorene (20), and 2,7-bis(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)-9,9-dioctylfluorene (21) were synthesized following procedures reported in the literature.

Synthesis and characterization

The carbazole-based triads were synthesized by Suzuki coupling (22).

*1,4-Bis(*N*-octylcarbazol-2-yl)phenylene (CPC)*

Into a 10 mL flask was added 0.617 mmol (250 mg) of *N*-octyl-2-(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)carbazole, 0.339 mmol (80 mg) of 1,4-dibromobenzene, 2.5 mL of toluene, and 1.5 mL of a 2 mol L^{-1} solution of K_2CO_3 in water. The mixture was degassed under argon for 30 min. $Pd(PPh_3)_4$ (0.0123 mmol, 7 mg) was added to the mixture and the whole mixture was refluxed overnight. The whole mixture was extracted three times with chloroform and washed with water. The organic extracts were dried over magnesium sulfate and the solvent was removed under reduced pressure. The crude product was purified by column chromatography using 5% diethyl ether – hexanes as the eluent (R_f = 0.66) to provide 110 mg of a pale brown solid (mp = 172–178 °C) (yield = 51%). ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 8.18 (d, 2H, *J* = 8.1 Hz), 8.14 (d, 2H, *J* = 7.9 Hz), 7.87 (s, 4H), 7.66 (d, 2H, *J* = 1.1 Hz), 7.56 (dd, 2H, *J* = 8.1 and 1.5 Hz), 7.47 (m, 4H), 7.26 (t, 2H, *J* = 7.0 Hz), 4.38 (t, 4H, *J* = 7.0 Hz), 1.93 (qt, 4H, *J* = 7.1 Hz), 1.35 (m, 20H), 0.87 (t, 6H, *J* = 6.7 Hz). ^{13}C NMR (100 MHz, $CDCl_3$, ppm) δ: 144.87, 141.28, 141.09, 132.27, 125.93, 124.21, 122.89, 122.59, 120.94, 120.53, 119.24, 117.43, 108.97, 105.78, 43.30, 32.04, 29.60, 29.41, 29.20, 27.53, 22.84, 14.30. HR-MS calcd. for $C_{46}H_{52}N_2$: 632.4130; found: 632.4138.

*2,5-Bis(*N*-octylcarbazol-2-yl)thiophene (CTC)*

Into a 25 mL flask was added 1.95 mmol (0.22 mL) of 2,5-dibromothiophene, 3.70 mmol (1.5 g) of *N*-octyl-2-(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)carbazole, 5 mL of toluene, and 3 mL of a 2 mol L^{-1} solution of K_2CO_3 in water. The mixture was degassed under argon for 30 min. $Pd(PPh_3)_4$ (42 mg, 0.078 mmol) was added and the mixture was refluxed overnight. The whole mixture was extracted with chloroform three times and washed with water. The organic extracts were dried over magnesium sulfate and the solvent was removed under reduced pressure. The crude product was purified by column chromatography using 5% diethyl ether – hexanes as the eluent (R_f = 0.61) and the product was recrystallized in a minimum of chloroform in hexanes to provide 511 mg of a yellow solid (mp = 181 to 182 °C) (yield = 41%). ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 8.10 (d, 4H, *J* = 8.1 Hz), 7.66 (s, 2H), 7.57 (d, 2H, *J* = 8.1 Hz), 7.46 (m, 6H), 7.25 (t, 2H, *J* = 7.3 Hz), 4.35 (t, 4H, *J* = 7.4 Hz), 1.93 (q, 4H, *J* = 7.5 Hz), 1.36 (m, 20H), 0.87 (t, 6H, *J* = 6.8 Hz). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 144.72, 141.13, 140.93, 132.11, 125.74, 124.01, 122.74, 122.43, 120.74, 120.34, 119.06, 117.27, 108.77, 105.60, 43.10, 31.84, 29.40, 29.20, 28.99, 27.33, 22.63, 14.07. HR-MS calcd. for $C_{44}H_{50}N_2S$: 638.3694; found: 638.3694.

*2,7-Bis(*N*-octylcarbazol-2-yl)-9,9-dihexylfluorene (CFC)*

Into a 5 mL flask was added 0.585 mmol (250 mg) of *N*-octyl-2-trifluoromethanesulfonylcarbazole, 0.278 mmol (163 mg) of 2,7-bis(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)-9,9-dioctylfluorene, 2 mL of THF and 1 mL of 2 mol L^{-1} K_2CO_3 in water. The mixture was degassed for 30 min under argon. $Pd(PPh)_3$ (0.0111 mmol, 6 mg) was added and the whole mixture was refluxed overnight. The mixture was extracted with chloroform three times and washed with water. The organic layer was dried over magnesium sulfate and the solvent was removed under reduced pressure. The crude product was purified by preparative TLC using 5% diethyl ether – hexanes as the eluent (R_f = 0.76). to provide 110 mg of a colorless rubbery solid (T_g = 19 °C) (yield = 44%). ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 8.21 (d, 2H, *J* = 8.1 Hz), 8.17 (d, 2H, *J* = 6.8 Hz), 7.88 (d, 2H, *J* = 7.5 Hz), 7.77 (d, 4H, *J* = 10.0 Hz), 7.69 (s, 2H), 7.60 (d, 2H, *J* = 7.8 Hz), 7.51 (t, 2H, *J* = 7.8 Hz), 7.46 (d, 2H, *J* = 8.1 Hz), 7.29 (t, 2H, *J* = 7.2 Hz), 4.41 (t, 4H, *J* = 6.8 Hz), 2.16 (m, 4H), 1.97 (q, 4H, *J* = 6.5 Hz), 1.39 (m, 20H), 1.17 (m, 12H), 0.90 (t, 10H, *J* = 7.2 Hz), 0.81 (t, 6H, *J* = 7.2 Hz). ^{13}C NMR (100 MHz, $CDCl_3$, ppm) δ: 152.01, 141.39, 141.29, 141.25, 140.18, 139.88, 126.78, 125.83, 122.92, 122.32, 122.28, 120.79, 120.62, 120.21, 119.13, 118.88, 108.96, 107.42, 55.56, 43.34, 40.70, 32.06, 31.74, 29.98, 29.64, 29.47, 29.29, 27.63, 24.14, 22.87, 22.83, 14.33, 14.26. HR-MS calcd. for $C_{40}H_{48}N_2$: 888.6321; found: 888.6339.

*2,7-Bis(*N*-octylcarbazol-2-yl)-*N*-octylcarbazole (CCC)*

Into a 10 mL flask was added 0.702 mmol (300 mg) of *N*-octyl-2-trifluoromethanesulfonylcarbazole, 0.351 mmol (186 mg) of *N*-octyl-2,7-bis(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)carbazole, 2 mL of THF and 1 mL of 2 mol L^{-1} K_2CO_3 in water. The mixture was degassed for 30 min under argon. $Pd(PPh)_3$ (0.0140 mmol, 8 mg) was added and the whole mixture was refluxed overnight. The mixture was extracted with chloroform three times and washed with water. The organic layer was dried over magnesium sulfate and the solvent was removed to dryness. The crude product was solubilized in hot hexanes and filtered to elimimate the catalyst residues. The solution was evaporated and recrystallized in a minimum of hexanes to provide 158 mg of an off-white powder (T_g = 20 °C) (yield = 54%). ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 8.23 (m, 4H), 8.17 (d, 2H, *J* = 8.0 Hz), 7.75 (s, 4H), 7.66 (m, 4H), 7.50 (m, 4H), 7.29 (t, 2H, *J* = 7.6 Hz), 4.48 (t, 2H, *J* = 7.6 Hz), 4.41 (t, 4H, *J* = 6.8 Hz), 1.99 (m, 6H), 1.40 (m, 30H), 0.88 (m, 9H). ^{13}C NMR (100 MHz, $CDCl_3$, ppm) δ: 141.84, 141.28, 141.23, 140.51, 140.48, 125.82, 122.94, 122.22, 122.09, 120.81, 120.80, 120.62, 119.50, 119.30, 119.13, 108.96, 108.01, 107.95, 43.36, 43.39, 32.08, 32.07, 29.69, 29.67, 29.50, 29.47, 27.69, 27.64, 22.87, 14.33, 14.32. Instrumentation

^{1}H and ^{13}C NMR spectra were recorded on a Bruker AMX300 or on a Varian AS400 apparatus in deuterated solvent solutions at 298 K. Differential scanning calorimetry (DSC) analyses were performed on a PerkinElmer (DSC-7)

© 2004 NRC Canada

instrument, calibrated with ultrapure indium, at a scanning rate of 10 °C/min under a nitrogen flow.

Absorption spectra were recorded on a Varian Cary 1 Bio UV–vis spectrophotometer at room temperature using 1 cm quartz cells and solute concentrations of (1–3) × 10^{-5} mol L^{-1}. It has been verified that the Beer–Lambert law is well-respected in the region of the concentrations used. Fluorescence spectra corrected for the emission detection were recorded on a Spex Fluorolog-2 spectrophotometer with a F2T11 special configuration. Excitation and emission band passes used were 2.6 and 1.9 nm, respectively. Each solution was excited near the absorption wavelength maximum using a 1 cm path length quartz cell. Solution concentrations used were (1–3) × 10^{-6} mol L^{-1}, giving absorbances always less than 0.1 to avoid any inner-filter effects. For all molecules, a study of the concentration (*C*) effect has been done on the fluorescence intensity (I_F) and all measurements have been performed in the linear region of the I_F vs. *C* curve. All corrected fluorescence excitation spectra were found to be equivalent to their respective absorption spectra. Quantum yields of fluorescence were determined in argon-saturated solutions of the substrates at 298 K against 9,10-diphenylanthracene in cyclohexane (ϕ_f = 0.90) as a standard (23).

Fluorescence lifetimes were measured on a multiplexed time-correlated single-photon-counting fluorimeter (Edinburgh Instruments, model 299T) at 298 K. Details on the instrument have been published elsewhere (24). The instrument incorporates an all-metal coaxial hydrogen flashlamp. Reconvolution analysis was performed by fitting over all the fluorescence decay including the rising edge. The kinetic interpretation of the goodness-of-fit was assessed using plots of weighted residuals, reduced $\chi 2$ values, and Durbin–Watson (DW) parameters.

Calculation methodology

Ab initio calculations were performed on a Pentium 4 (2.53 Gz) personal computer with 1 Gb RAM using the Gaussian 98W program, version 5.2 (25). The geometries were optimized at the HF level with the 6-31G* basis set. The Berny analytical gradient method was used for the optimizations. The requested HF convergence on the density matrix was 10^{-8} and the threshold values for the maximum force and the maximum displacement were 0.00045 and 0.0018 au, respectively.

The ZINDO/S method including configuration interaction (CI) as employed in the HyperChem package (version 5.01) was used to calculate the singlet–singlet electronic transition energies of the optimized conformers. ZINDO/S is a modified INDO method parameterized to reproduce UV–vis spectroscopic transitions (26, 27). The electron-repulsion integrals were evaluated using the Mataga–Nishimoto formula. All singly excited configurations involving the 20 highest occupied and the 20 lowest unoccupied orbitals (CI = 20/20) were included in the energy calculation. The π-π* overlap weighting factor has been adjusted to 0.548 to reproduce the S_1 origin of fluorene (33 779 cm^{-1}) measured in a supersonic jet (28).

The excited state geometries were optimized with the restricted configuration interaction of singly excited states (RCIS) using 6-31G* basis sets. The optimized excited state geometries have been used as inputs for the ZINDO/S program to obtain the electronic transition energies from the relaxed excited states.

Results and discussion

Optical properties

The absorption and fluorescence spectra of the carbazole-based triads have been recorded in *n*-hexane at room temperature and are shown in Figs. 2–5. Their spectral data are reported in Table 1.

The first absorption band of CPC is centered at 30 800 cm^{-1}. A shoulder is observed around 28 700 cm^{-1} showing that this molecule possesses a certain rigidity in its ground state. In contrast, the fluorescence spectrum of CPC shows two well-resolved vibronic peaks at 26 500 and 25 300 cm^{-1} and a shoulder at around 23 800 cm^{-1}. This indicates that the molecule is more rigid in its first relaxed excited state.

The replacement of the phenyl group by a thiophene ring provokes a large red shift of the absorption and fluorescence bands in CTC. Two effects might be responsible for this be-

havior: (*i*) a decrease in the twisting between thiophene and carbazole rings and (*ii*) a charge transfer interaction due to the electron donor properties of the thiophene ring. To distinguish between these two effects, HF/6-31G* ab initio calculations were performed on both molecules. To reduce the time scale of the calculations, the octyl chain on the nitrogen atom of each carbazole unit was replaced by an ethyl group. The dihedral angles between adjacent rings are summarized in Table 2. One can see that CTC is slightly less twisted than CPC in its ground state. This effect should contribute to the bathochromic shifts observed in the absorption spectrum of CTC. But in our opinion, the experimental shifts are too large to be explained solely by such small conformational changes. To confirm this statement, ZINDO/S calculations were performed for the conformers of CTC having dihedral angles of 45° and 37°, respectively. It was observed that the more planar conformer of CTC contributes to a red shift of about 800 cm^{-1}, whereas the experimental bathochromic shift observed between the absorption maxima of CPC and CTC is about 4000 cm^{-1} (see Table 1). One can then conclude that the presence of the thiophene ring in the CTC chromophore provokes significant charge transfer interactions. This was confirmed from atomic charges obtained from HF and RCIS calculations. Accordingly, the bandwidth of the absorption band of CTC is wider than that of CPC.

Compared to the absorption and fluorescence spectra of CPC, the optical transitions of CFC are red shifted (see Fig. 4 and Table 1). This is due to the increase of the conjugation length. Moreover, one can see in Table 2 that the torsional angles between adjacent rings of both molecules are very close. This indicates that increasing the conjugation length does not improve the molecular planarity of CFC. Accordingly, the absorption and fluorescence bandwidths of CPC and CFC are very similar.

Finally, Table 1 and Fig. 5 show that the absorption and fluorescence band maxima of CCC are very close to those obtained for CFC. Moreover, one can see that the bandwidths of the absorption and fluorescence spectra of both molecules are very similar. Along these lines, Table 2 shows that the dihedral angles and the inter-ring distances of CFC and CCC are very close. It thus seems that that the replacement of a fluorene ring by a carbazole moiety does not significantly affect the molecular structure and the optical properties of carbazole derivatives.

It is also observed that the fluorescence spectra of the four compounds are sharper and more structured compared to their respective absorption spectra (see Figs. 2–5 and Table 1). This suggests that these molecules, in the relaxed S_1 state, are characterized by more rigid conformations of the subunits. This is in agreement with the computed S_1 torsional potentials of carbazole-based dyads showing that the co-planar energy barrier is much reduced for all the derivatives in the S_1 state, whereas the energy barriers at the per-

Table 3. HOMO, LUMO, and HOMO–LUMO energy gaps of carbazole-based triads as obtained from HF/6-31G* ab initio calculations.

Molecule	HOMO (eV)	LUMO (eV)	HOMO–LUMO (eV)
CPC	–7.12	2.37	9.49
CTC	–6.96	2.13	9.09
CFC	–6.93	2.22	9.15
CCC	–6.87	2.25	9.12

pendicular conformations are much larger when the molecules are excited to the S_1 state as compared to those in the ground state (29). Moreover, one can see in Fig. 3 that the 0–1 vibronic peak of the fluorescence spectrum of CTC is more intense than the 0–0 vibronic peak causing a broadening of the emission band. As discussed above, this is probably due to charge transfer interactions caused by the presence of the thiophene ring.

Frontier molecular orbitals

The nature and the energies of the HOMO and LUMO of these carbazole derivatives, which are mainly involved in the first allowed electronic excitation ($S_3 \leftarrow S_0$, see below), were investigated at the HF/6-31G* level. Both molecular orbitals of each derivative are delocalized along the long molecular axis and involve mainly p_z (out-of-plane axis) atomic orbitals. The nature of the molecular orbitals remains unchanged among the oligomers investigated. For each compound, we have found that the HOMO possesses an antibonding character between adjacent rings, which may explain the nonplanarity observed for these derivatives in their ground electronic state. On the other hand, the LUMO of all the derivatives shows a bonding character between adjacent rings. As an example, Fig. 6 shows the contour plots of the HOMO and LUMO of CPC. This implies that the promotion of an electron from the HOMO to the LUMO is indeed improving the molecular planarity of these derivatives as suggested above from the fluorescence spectra.

The energies of the HOMO and LUMO are given in Table 3. Compared to CPC, one can see that the HOMOs of CTC, CFC, and CCC are destabilized whereas their LUMOs are stabilized. Consequently, the HOMO–LUMO energy gaps are smaller for the latter molecules than that of CPC. Among the four carbazole-based triads investigated, the HOMO–LUMO energy gap of CTC is the smallest. This clearly shows that the thiophene ring possesses strong electron donor properties that can be more dominating than the conjugation length of the molecule. Indeed, CFC and CCC possess longer conjugation lengths than CTC but show larger energy gaps.

Electronic excitations

The ZINDO/S semiempirical method was used to obtain the nature and the energy of the first three electronic transitions in the oligomers. Optimized geometries (HF/6-31G*) were used in the calculations. The electronic excitation properties are summarized in Table 4.

The $S_1 \leftarrow S_0$ and $S_2 \leftarrow S_0$ electronic transitions (π-π^*) of CPC are very close in energy and possess oscillator strengths (f) of very small values. On the other hand, the $S_3 \leftarrow S_0$ electronic transition possesses a much larger oscillator strength and is mainly described by the promotion of one electron from the HOMO to the LUMO. ZINDO/S calculations also show that the $S_3 \leftarrow S_0$ electronic transition of CPC is dipole allowed and polarized along the long axis of the molecule (x) (see Table 4). This electronic transition is computed at 31 600 cm^{-1} and should correspond to the first absorption band of this molecule measured at 30 800 cm^{-1} in n-hexane and having a large absorption coefficient (55 900 L mol^{-1} cm^{-1}).

A small energy decrease is computed for the two weakly allowed electronic transitions of CTC compared to those of CPC. On the other hand, the strongly allowed electronic transition of CTC becomes the first electronic transition

[a] X is the long molecular axis.

computed at 28 700 cm^{-1} (see Table 4). This electronic transition is lowered by 2900 cm^{-1} compared to the dipole-allowed transition of CPC ($S_3 \leftarrow S_0$). This indicates the effect of the electron donor properties of the thiophene ring along the x axis of the triad.

The first two electronic transitions of CFC are computed at exactly the same energies as those of CPC. On the other hand, the $S_3 \leftarrow S_0$ electronic transition of CFC is calculated at 30 500 cm^{-1}, which is lower in energy by 1100 cm^{-1} compared to that of CPC. This goes along with the conjugation length, which increases for the former molecule. Finally, Table 4 shows that the electronic transitions of CCC are computed at about the same energy as those of CFC. This shows that the replacement of the fluorene ring by a carbazole unit does not significantly affect the spectroscopy of these carbazole-based triads.

Finally, it is also observed that the excitation energies of the first allowed electronic transition of the four carbazole derivatives follow the relative values of their HOMO–LUMO energy gaps computed in Table 3.

Emission energies

The optimization (relaxation) of the singlet excited states was done using the RCIS/6-31G* method. As observed recently for carbazole-based dyads, a crossing of the excited states occurs such that the first electronic transition becomes dipole allowed, with a high value of its oscillator strength (29).

The RCIS/6-31G* inter-ring distances and the torsional angles (θ) of the molecules in the S_1 (optimized) state are listed in Table 2. For the four derivatives in the S_1 state, it was found that the inter-ring bond lengths are significantly shorter compared to the respective bond lengths computed for the molecules in their ground state (see Table 2). This indicates that, in the S_1 relaxed excited state, these derivatives possess much more quinoidic-like character. In other words, the conjugation along the long axis of the molecule is enhanced in the S_1 state. In these conditions, it is not surprising to observe that each derivative almost reaches coplanarity in the S_1 state.

The RCIS/6-31G*-optimized geometries have been used as input in the ZINDO/S program to obtain the electronic transition energies from the relaxed excited states. For the four carbazole derivatives, a crossing in the relaxed excited states is achieved such that the electronic transition from the first relaxed excited state ($S_1 \leftarrow S_0$) is dipole allowed. Thus, this transition taken at the minimum of the S_1 torsional potentials should correspond to the emission energy of the oligomers. Indeed, the absorption of a photon excites the molecules to a Franck–Condon state, in which they should possess the same torsional angle as the molecules in the S_0 state. After the excitation, the molecules should relax to their most stable geometry before the emission process can occur. The results are compiled in Table 5. As expected, the relative order of the emission energies is the same as that of the corresponding absorption energies. Indeed, the $S_1 \rightarrow S_0$ energy of CPC is the highest among the four carbazole derivatives investigated, whereas the emission transition of CTC is computed at the lowest energy. The energy of the 0–1 fluorescence peaks (near maxima) of the carbazole derivatives are reported in Tables 5. One can see that the fluorescence peaks of the carbazole derivatives are in very good agreement with the computed emission energies.

Molecular photophysics

The fluorescence quantum yields (ϕ_F) and lifetimes (τ_F) as well as the radiative ($k_F = \phi_F/\tau_F$) and nonradiative ($k_{nr} = k_F(1 - \phi_F)/\phi_F$) decay rate constants of all the compounds are reported in Table 6. For all fluorescence decay profiles, a single-exponential fit gives acceptable statistical parameters ($\chi^2 < 1.3$ and DW ≈ 1.7).

Table 6 shows that ϕ_F and τ_F of CTC are smaller than those of CPC giving rise to a much higher value of k_{nr}. For oligothiophenes, it is well-established that the main deactivation pathway of the S_1 state involves an intersystem crossing process (k_{isc}) because of the presence of the heavy sulphur atom (30, 31). The same behavior may also occur here for CTC and might contribute to the deactivation of the fluorescence. An internal conversion process could also contribute to the deactivation of the fluorescence of CTC. How-

CFC	0.66	0.84	7.9	4.0
CCC	0.62	0.88	7.1	4.4

[a]$k_F = \phi_F/\tau_F$ (radiative fluorescence decay rate constant).
[b]$k_{nr} = k_F(1 - \phi_F)/\phi_F$ (nonradiative fluorescence decay rate constant).

ever, we have reported recently that the S_1 torsional potential surfaces of the corresponding dyads (CT and CC) are very similar, suggesting that both molecules possess about the same flexibility in the S_1 excited state (29). Thus, these theoretical results strongly suggest that the internal conversion process does not play an important role in the deactivation pathway of CTC compared with that of CPC. It is also worth noting that the radiative decay constant of CTC is slightly larger than that of CPC. The electron donor properties of the thiophene group may be responsible for this behavior.

On the other hand, Table 6 shows that the fluorescence quantum yields of CFC and CCC are higher than that of CPC. Higher k_F values of CFC and CCC are mainly responsible for this behavior. This is surely due to a longer conjugation length experienced by CFC and CCC as shown by the ε and f values computed in Tables 1 and 4, respectively. Moreover, it is observed that the replacement of a fluorene ring by a carbazole unit does not affect much the photophysical parameters of these carbazole derivatives.

Concluding remarks

The first absorption band of each derivative can be assigned to the calculated electronic transition, which corresponds mainly to the promotion of an electron from the HOMO to the LUMO. The HOMO possesses an antibonding character between neighboring rings, which should contribute to the nonplanarity observed for these derivatives in their ground states. On the other hand, the LUMO shows bonding character between adjacent rings in agreement with more planar S_1 excited states. The overall shape of the absorption and fluorescence spectra suggests that the molecules are more planar in the first relaxed excited state than in the ground state. Ab initio calculations performed on the carbazole derivatives in their ground (HF/6-31G*) and excited states (CIS/6-31G*) confirm this statement.

The replacement of a phenyl group by a thiophene moiety causes a siginificant red shift of the absorption and fluorescence bands, which is mainly due to the electron donor properties of the thiophene ring. The increase of the conjugation length (CFC and CCC) also induces a red shift of the absorption and emission spectra. After relaxation of the excited states (optimization), a crossing of the excited states of the oligomers is achieved such that the first electronic transition of each derivative becomes dipole allowed, with a high value of the oscillator strength. The fluorescence spectrum of each derivative is well reproduced by ZINDO/S semiempirical calculations performed on the optimized S_1 geometries.

The fluorescence quantum yield and lifetime of CTC are smaller than those of CPC giving rise to a higher nonradiative decay rate constant for the former compound. These results are interpreted in terms of an intersystem crossing process (k_{isc}) because of the presence of the heavy sulphur atom. On the other hand, fluorescence quantum yields of CFC and CCC are slightly larger than that of CPC. An increase of the k_F values of CFC and CCC, caused by an increase in the conjugation length, is mainly responsible for this behavior. Moreover, it is observed that the replacement of a fluorene ring by a carbazole moiety does not significantly affect conformational, spectroscopic, and photophysical properties of carbazole-based triads.

Finally, we found a good agreement between theoretical electronic transitions (excitation and emission energies) and experimental spectra (absorption and fluorescence). Thus, we believe that this methodology can be used to design organic light-emitting diodes based on oligo- and polycarbazoles.

A new efficient synthesis of α-methyl-β-ketoesters through an Eschenmoser sulfide reaction

Christian Bellec and Olivier Gaurat

Abstract: Various α-methyl-β-ketoesters were readily synthesized through Eschenmoser condensation of thioamides with a commercially available bromoester. β-Enaminoesters were easily prepared through this sulfide contraction reaction and were hydrolysed to afford the corresponding β-ketoesters in moderate to good yields.

Key words : α-alkylated-β-ketoesters, Eschenmoser, β-enaminoesters.

Résumé : Divers β-cétoesters-α-méthylés sont facilement préparés par condensation d'Eschenmoser de thioamides avec un bromoester commercial. Les β-énaminoesters, facilement préparés par cette réaction d'extrusion de soufre, sont hydrolysés pour conduire aux β-cétoesters correspondants avec des rendements bons à modérés.

Mots clés : β-cétoesters α-alkylés, Eschenmoser, β-énaminoesters.

Introduction

β-Ketoesters are widely recognized as very useful auxiliaries for several organic syntheses. Many synthetic approaches to α-unsubstituted compounds have been reported in the literature over the years (1–3). Conversely, investigations into reactions giving α-alkylated β-ketoesters directly have been more limited. Most often, these latter compounds have been obtained by alkylation of unsubstituted moieties, with the obvious disadvantages associated with this methodology (4, 5).

For some time, we have been interested in the synthesis of β-enaminoesters using the Eschenmoser coupling reaction (6, 7). Such enaminoesters are particularly suitable intermediates for the synthesis of various alkaloids (8, 9). More recently, we became interested in a new application of the efficient Eschenmoser alkylation sulfur contraction reaction for a short and convenient access to α-monoalkylated β-ketoesters that could take its place among other methodologies.

In the literature, various synthetic routes have been exploited for access to α-alkylated β-ketoesters. The direct alkylation method with aliphatic substrates, initially reported by Robinson (1), has been seldom used and leads generally to poor yields (10). Indeed, it is often difficult to avoid a double condensation or an *O*-alkylation process, although some recent modifications of the work-up procedure gave rise to better results (11, 12).

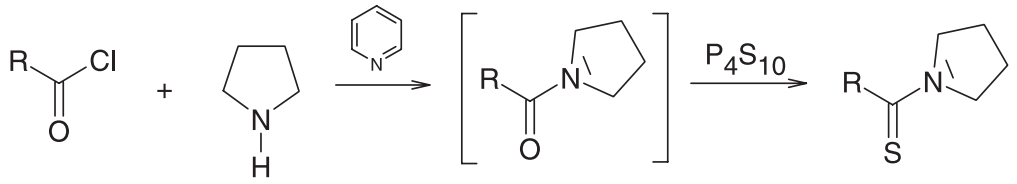
The preparation of β-ketoesters from malonic acid ester precursors has generally been rarely used for monoalkylated compounds (2, 4, 13). Other synthetic approaches, using a modified Reformatsky reaction (14–16), treatment of an acylpyrazole with an organozinc reagent (17), or α-diazo-β-hydroxyester rearrangment (18), have been described but do not have, on the whole, general applicability. Oxidation of β-hydroxyesters has most often been carried out with nonalkylated substrates (19, 20).

We wish to report herein a new methodology that provides direct access to α-substituted β-ketoesters from enaminoesters. These substrates are readily prepared through an Eschenmoser sulfide reaction involving condensation of thioamides with bromoesters and are then hydrolyzed, in a final step, to afford the desired ketoesters with moderate to good yields.

Results and discussion

Synthesis of thioamides

The synthesis of thioamides **2a–2f** was carried out by condensation of acyl chlorides **1a**–**1f** with pyrrolidine in the presence of pyridine. Amide moieties obtained in a first step were not isolated but were directly transformed into thioamides using P_4S_{10} (Scheme 1).



Synthesis of α-substituted β-ketoesters

Various α-substituted β-ketoesters were produced by hydrolysis of the corresponding enaminoesters, which were most often not isolated. The synthesis of these enaminoesters was first carried out by adapting the modified Eschenmoser coupling reaction previously described for thiolactams (6). Thus, a mixture of triethylamine and triphenylphosphine in dry acetonitrile was slowly added to a solution of thioamide **2** and commercially available 2-bromopropionic acid ethylester (**3**) in refluxing CH_3CN (Scheme 2).

The condensation was monitored by gas chromatography. Despite a good rate of thioamide transformation (except in

the case of **2c**, for which no reaction was observed), several by-products were observed in the crude reaction mixture. Besides the α-substituted β-ketoester **5** and the desulfuration product $Ph_3P=S$, the aminoester **6** (Scheme 3), amide **7**, and sulfide **8** ($EtOOC–CH(CH_3)–S–CH(CH_3)–COOEt$) were also detected.

Although the condensation was carried out under a nitrogen atmosphere and despite the use of an anhydrous solvent, some of the thioamide **2** was generally transformed in the reaction mixture to the corresponding amide **7**. Similarly, the presence of lactam as a by-product in the Eschenmoser sulfide contraction of thiolactams with halogenoesters has been reported by some authors (21, 22). The formation of the aminoester **6** could be explained by a nucleophilic substitution of pyrrolidine on the bromoester **3**. Indeed, pyrrolidine was formed in situ by hydrolysis of the enaminoester. Michael and co-workers reported, in a similar manner, the presence of the disulfide **9** in an Eschenmoser reaction with bromoacetophenone (23).

As several by-products were present in the crude reaction mixture, it was difficult to purify the β-ketoester **5** by chromatography on a silica gel column. With various eluents, the yield of the α-substituted β-ketoester was poor to moderate, and some fractions always contained $Ph_3P=S$ and Ph_3P. Therefore, it was necessary to modify the reaction conditions to minimize the formation of by-products in the condensation–extrusion process and to facilitate the elimination of these by-products in the experimental work-up. With Ph_3P as the thiophilic agent, the major difficulty was in eliminating the desulfuration product $Ph_3P=S$. In the case of thiolactam condensation, this problem was resolved by acidic extraction of the cyclic enaminoester with HCl (2 mol/L) (6), but with thioamides, the hydrolysis of the formed enaminoester, leading to the ketoester, was too rapid to permit a satisfactory extraction. So our idea was to mod-

ify the thiophilic reagent. The use of triethylphosphite ($P(OEt)_3$) in CH_3CN and the same work-up as with Ph_3P did not result in a significant modification of the sulfide yield. On the other hand, when the condensation was carried out without solvent (5 mL of CH_3CN being added in the desulfuration step to obtain a concentrated but homogeneous medium), the sulfide yield relative to the enaminoester–ketoester yield was substantially reduced. Unfortunately, the solubility of $(EtO)_3P{=}S$ in water is very low, and the work-up only led to its partial elimination. Hence, another thiophilic agent, $P(NR_2)_3$, was employed. Indeed, tris(alkylamino)phosphines have been reported to be good reagents for the transformation of disulfides to sulfides and for the reduction of thiiranes to olefins (24, 25). The same work-up as with $P(OEt)_3$ was carried out without solvent, but under a nitrogen atmosphere. In the same reaction time, a better transformation rate of the thioamide **2** was observed (Table 1), but, notably, only traces (<1% by gas chromatographic analysis) of the sulfide **8** were detected.

Nevertheless, purification of the β-ketoester on a silica gel column always resulted in some fractions that were contaminated with the desulfuration product $S{=}P(NE_2)_3$, no matter which elution solvent was employed. However, the presence of **8** in very small amounts permitted an appreciable improvement in the extraction yield of the α-substituted β-ketoester **5** in the chromatographic step. Table 2 shows comparative results for the various thiophilic agents employed. For comparison, we have also listed the yields reported in the literature for many different methods and experimental conditions.

Thus, with tris(dimethylamino)phosphine or tris(diethylamino)phosphine as the thiophilic reagent, α-alkylated β-ketoesters were synthesized via an Eschenmoser reaction in moderate to good yields. We have performed several other syntheses using different bromoesters, but no other series has been investigated in a systematic manner. However, even from these limited experiments, this method remains efficient and leads, after extraction, to similar yields to those in Table 2.

Conclusion

We have shown that several α-substituted β-ketoesters can be easily obtained by an efficient direct condensation of bromoesters with thiolactams through the Eschenmoser sulfur extrusion reaction. This strategy represents a quick and convenient route that can take its place among the available methodologies that provide access to these compounds.

Experimental

General procedure for thioamide synthesis

In a mixture of 150 mL of pyridine and about 0.2 mol of pyrrolidine, a slight excess (<1.1 equiv.) of acyl chloride **1** was added dropwise at room temperature. The stirred solution was refluxed for 30 min. After cooling, P_4S_{10} was added and the mixture was heated for 2 h and then poured into 500 mL of 1 mol/L HCl. The mixture was stirred for 1 h and was then extracted three times with 150 mL of dichloromethane (CH_2Cl_2). The combined organic layers were washed successively with 2 × 150 mL of 1 mol/L HCl, 2 × 150 mL of water, and 2 × 100 mL of a saturated solution of sodium hydrogen carbonate ($NaHCO_3$), then dried over magnesium sulfate ($MgSO_4$) and evaporated. The residue was purified by chromatography on a silica gel column.

1-Pyrrolidin-1-yl butan-1-thione (2a)

Condensation of 15.62 g (0.22 mol) of pyrrolidine and 25 g (0.235 mol, 1.07 equiv.) of butanoyl chloride **1a** gave, after chromatography using ethyl acetate (EtOAc)/cyclohexane (1/1), 28.76 g of **2a**. Yield 83%. Oil. ^{1}H NMR: 3.90 and 3.66 (t, J = 7 Hz, 4H), 2.70 (t, J = 7.5 Hz, 2H), 2.10–2.00 (m, 4H), 1.80 (m, 2H), and 1.05 (t, J = 7.5 Hz, 3H). ^{13}C NMR: 200.6, 50.9, 46.1, 26.6, 24.6, 22.5, and 14.1. 1-Thiobenzoyl pyrrolidine (2e)

Condensation of 5.32 g (0.075 mol) of pyrrolidine and 11.24 g (0.08 mol, 1 equiv.) of benzoyl chloride **1e** gave, after chromatography with EtOAc/cyclohexane (1/1), 14 g of a yellow solid **2e**. Yield 97.5%; mp 73 °C. ^{1}H NMR: 7.30–7.20 (m, 5H), 3.90 and 3.39 (2t, J = 7 Hz, 4H), and 2.00–1.90 (m, 4H). ^{13}C NMR: 197.4, 144.3, 129.0, 128.6, 126.0, 54.2, 53.8, 26.8, and 25.0. IR ($CHBr_3$): 1505, 1490, and 1475 cm^{-1}. Anal. calcd. (%) for $C_{11}H_{13}NS$: C 69.09, H 6.85, N 7.33; found: C 68.98, H 6.80, N 7.40.

4-Pyrrolidin-1-yl-4-thioxobutanoic acid methylester (2f)

For the synthesis of the intermediate amide, the following specific procedure was used: 6.39 g (0.09 mol) of pyrrolidine was condensed with 15.05 g (0.1 mol, 1.1 equiv.) of 3-carbomethoxy propanoyl chloride. After reaction, pyridine was evaporated under reduced pressure. Dichloromethane (200 mL) was added. The mixture was washed twice with 100 mL of water. The organic layer was dried (Na_2SO_4) and concentrated to give the crude amide (yield 79%), which was used directly without further purification in the next step. The thionation was achieved with a solution of 13 g (0.07 mol) of amide in 400 mL of dried tetrahydrofuran (THF). Following the addition of 15.5 g of P_4S_{10}, the mixture was heated for 4 h. Using the same work-up as described in the general procedure, 10.9 g of **2f** were obtained after chromatography with EtOAc/cyclohexane (1/2). Yield 60%. Oil. ^{1}H NMR: 3.80 and 3.60 (2t, J = 7 Hz, 4H), 3.63 (s, 3H), 2.90 and 2.80 (2t, J = 6 Hz, 4H), and 2.10–1.90 (m, 4H). ^{13}C NMR: 197.4, 172.6, 53.4, 51.2, 50.1, 36.3, 32.3, 25.8, and 23.7. IR ($CHBr_3$): 1725 and 1480 cm^{-1}. Anal. calcd (%) for $C_9H_{15}NO_2S$: C 53.73, H 7.46, N 6.96; found: C 53.82, H 7.38, N 6.93.

General procedure for an Eschenmoser coupling reaction with Ph_3P as the thiophilic agent

Typically, a mixture of thioamide **2** (6.3 mmol) and bromoester **3** (0.019 mol, 3 equiv.) in 50 mL of acetonitrile (CH_3CN) was heated for 30 min. A solution of 1.26 mmol (2 equiv.) of Ph_3P and 1.26 mmol (2 equiv.) of triethylamine (Et_3N) in CH_3CN (30 mL) was added dropwise. After addition, the mixture was refluxed for 4 h. The solvent was removed in vacuo and the resulting residue was dissolved in CH_2Cl_2 (150 mL). The organic layer was washed with a solution of 1 mol/L HCl (150 mL). The aqueous layers were extracted with CH_2Cl_2 (3 × 75 mL). The combined organic phases were successively washed with saturated $NaHCO_3$ solution (50 mL) and water (50 mL) and were then dried ($MgSO_4$). After evaporation of the solvent, crude β-ketoester **5** was obtained. In some cases, portions of phosphorated by-products were precipitated out in ethanol at –18 °C. Thus, purification of the ketoesters by chromatography on a silica gel column was facilitated.

General procedure for an Eschenmoser coupling reaction with triethylphosphite as the thiophilic agent

A mixture of 5.4 mmol of thioamide **2** and 8.11 mmol of bromoester **3** (1.5 equiv.) was heated at 80 °C for 30–45 min. Then a mixture of triethylamine (8.11 mmol, 1.5 equiv.) and 8.11 mmol (1.5 equiv.) of $P(OEt)_3$ was added. A precipitate of ammonium bromide was formed, and 5 mL of CH_3CN was added. The residue was refluxed until no further change in the ratio of the different compounds was observed by gas chromatography (2–5 h). After addition of CH_3CN (15 mL) and 1 mol/L HCl (1 mL) at room temperature, the resulting mixture was stirred and hydrolysis of the enaminoester was monitored by TLC. The solvent was removed and CH_2Cl_2 (50 mL) was added. The organic layer was washed with a saturated $NaHCO_3$ solution. The aqueous layer was extracted with CH_2Cl_2 (2 × 50 mL). The combined organic layers were dried ($MgSO_4$) and condensed to give crude β-ketoester **5**, which was chromatographed on a silica gel column using various mixtures of EtOAc/cyclohexane as eluant.

General procedure for an Eschenmoser coupling reaction with tris(dimethylamino)phosphine as the thiophilic agent

A mixture of 5 mmol of thioamide **2** and 7.5 mmol (1.5 equiv.) of bromoester **3** was heated at 80 °C for 30–45 min under a nitrogen atmosphere. A mixture of 6 mmol (1.2 equiv.) of Et_3N and 7.5 mmol (1.5 equiv.) of tris(dimethylamino)phosphine was then added, followed by the addition of dry CH_3CN (5 mL). The resulting mixture

© 2004 NRC Canada

was refluxed until no further change in the ratio of the different compounds was observed by gas chromatography. After addition of CH_3CN (10 mL) and 1 mol/L HCl (1 mL) the mixture was stirred for an additional 30 min and the same type of work-up as previously described in the second procedure was achieved. Thus, crude β-ketoester **5** was obtained and then chromatographed as above.

2-Methyl-3-oxo-hexanoic acid ethylester (5a)

Synthesis and characterization of a series of 1-methyl-4-[2-aryl-1-diazenyl]piperazines and a series of ethyl 4-[2-aryl-1-diazenyl]-1-piperazinecarboxylates[1]

Vanessa Renée Little and Keith Vaughan

Abstract: 1-Methylpiperazine was coupled with a series of diazonium salts to afford the 1-methyl-4-[2-aryl-1-diazenyl]piperazines (**2**), a new series of triazenes, which have been characterized by ^{1}H and ^{13}C NMR spectroscopy, IR spectroscopy, and elemental analysis. Assignment of the chemical shifts to specific protons and carbons in the piperazine ring was facilitated by comparison with the chemical shifts in the model compounds piperazine and 1-methylpiperazine and by a HETCOR experiment with the *p*-tolyl derivative (**2i**). A DEPT experiment with 1-methylpiperazine (**6**) was necessary to distinguish the methyl and methylene groups in **6**, and a HETCOR spectrum of **6** enabled the correlation of proton and carbon chemical shifts. Line broadening of the signals from the ring methylene protons is attributed to restricted rotation around the N2–N3 bond of the triazene moiety in **2**. The second series of triazenes, the ethyl 4-[2-phenyl-1-diazenyl]-1-piperazinecarboxylates (**3**), have been prepared by similar diazonium coupling to ethyl 1-piperazinecarboxylate and were similarly characterized. The chemical shifts of the piperazine ring protons are much closer together in series **3** than in series **2**, resulting in distortion of the multiplets for these methylenes. It was noticed that the difference between these chemical shifts in **3** exhibited a linear free energy relationship with the Hammett substituent constants for the substituents in the aryl ring.

Key words: triazene, piperazine, diazonium coupling, NMR, HETCOR, linear free energy relationship.

Résumé : On a procédé au couplage de la 1-méthylpipérazine avec une série de sels de diazonium qui conduit à la formation de 1-méthyl-4-[2-aryl-1-diazényl]pipérazines (**2**), une nouvelle série de triazènes qui a été caractérisée par spectroscopie RMN du ^{1}H et du ^{13}C, par spectroscopie IR ainsi que par analyse élémentaire. L'attribution des déplacements chimiques des protons et des atomes de carbone a été facilitée par une comparaison avec les déplacements chimiques de composés modèles, la pipérazine et la 1-méthylpipérazine, ainsi que par une expérience « HETCOR » avec le dérivé *p*-tolyle (**2i**). Il a fallu faire appel à une expérience de « DEPT » avec la 1-méthylpipérazine (**6**) pour distinguer les groupes méthylènes et le méthyle du composé **6** et un spectre « HETCOR » du composé **6** a permis d'établir une corrélation entre les déplacements chimiques du proton et du carbone. Un élargissement de la raie des signaux des protons méthylène du cycle est attribuée à la rotation empêchée autour de la liaison N2-N3 de la portion triazène du composé **2**. Une deuxième série de triazènes, les 4-[2-phényl-1-diazényl]pipérazine-1-carboxylates d'éthyle, a été préparée par un couplage semblable avec du pipérazine-1-carboxylate d'éthyle et elle a été caractérisée de la même manière. Les déplacements chimiques des protons du cycle pipérazine sont beaucoup plus rapprochés dans la série **3** que dans la série **2**; il en résulte une distorsion dans les multiplets de ces méthylènes. On a noté que la différence entre les déplacements chimiques des composés de la série **3** présente une corrélation d'énergie libre linéaire avec les constantes de substituant de Hammett des substituants du noyau aryle.

Mots clés : triazène, pipérazine, couplage de diazonium, RMN, HETCOR, relation d'énergie libre linéaire.

Introduction

The antitumour activity of 1-aryl-3,3-dimethyltriazenes has been known for many years (1), and at least one member of this family, dacarbazine (5-(3,3-dimethyl-1-triazeno)imidazole-4-carboxamide), is clinically useful in the treatment of malignant melanoma (2). More recently, the pro-drug approach to triazene design led to the discovery of temozolomide, an imidazolotetrazinone, which is a novel broad-spectrum antitumour agent (3). Although temozolomide itself is not an acyclic triazene, its mode of action is thought to involve hydrolysis of the tetrazinone ring to afford a cytotoxic monomethyltriazene. The contemporary chemistry of the antitumour triazenes has been reviewed (4), and the impor-

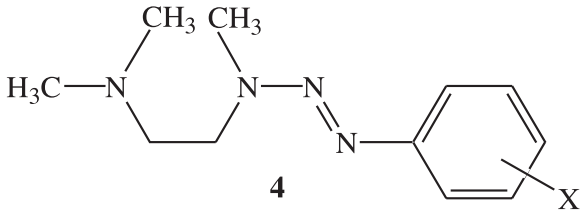
tance of triazenes as a versatile tool in organic synthesis has also been reviewed recently (5).

This paper is the start of a new series that will describe the synthesis of a wide variety of triazenes and bis-triazenes that fit the general classification of 1-aryldiazenyl-(1,*x*)-diazacycloalkanes described by the general structure **1**, where m = 1 or 2 and n = 2, 3, 4, or 5. In some of this series of compounds to be described, the R group will be a second triazenyl group, i.e., **1** will be a bis-triazene, and in others the R group will be a second diazacycloalkane moiety linked to the first by a one-carbon spacer. In this paper, we describe

1

the synthesis and characterization of 1-methyl-4-[(*E*)-2-aryl-1-diazenyl]piperazines (**2**) and a series of ethyl 4-[(*E*)-2-phenyl-1-diazenyl]-1-piperazine carboxylates (**3**). Most of these compounds are new to the triazene family and will serve as excellent model compounds for the characterization

2 R = CH_3
3 R = $CO_2C_2H_5$



of bis-triazenes with the structure **2** (R = aryldiazenyl-) and similar compounds with larger heterocyclic rings.

Triazenes are generally synthesized by diazotization of an aromatic primary amine, followed by coupling of the diazonium salt to a secondary amine to provide the desired triazene in high yield as illustrated in eq. [1]:

[1] $ArN_2^+ + RR'NH \rightarrow ArN{=}NNRR'$

We previously used this approach successfully to synthesize *N,N*-dimethyl-*N*-2-[(*E*)-1-methyl-3-phenyl-2-triazenyl]ethylamines (**4**) by diazonium coupling with *N,N,N′*-trimethylethylenediamine (6); the type **4** triazene is actually the acyclic analogue of the type **2** triazene.

The potential biological activity of *N*-(aryldiazenyl)piperazines has attracted the attention of several previous investigators. Butkus and co-workers investigated a series of aminoazobenzenesulfonic acids for their potential anti-inflammatory activity (7); among this series is the piperazine derivative **2** (X = p-$SO_3^-K^+$). The analogous sulfonamides (**2**, X = p-SO_2NR_2, R = H, Me, or CH_2CH_2Cl) were prepared by Lalezari and Afghahi (8) as potential antitumour agents, but tests for biological activity were not reported. Two of the compounds that were prepared as part of the present study

4

have been reported previously (9), and several *N,N′*-bis-(aryldiazenyl)-piperazines have been reported (7, 10).

Experimental

All reagents were reagent-grade materials purchased from Sigma-Aldrich Canada and were used without further purification. Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. Infrared spectra were obtained using Nujol mulls or KBr discs on a Bruker Vector 22 spectrometer. ^1H and ^{13}C NMR spectra were obtained with either (*i*) Bruker AC250 MHz and 500 MHz spectrometers at the Atlantic Regional Magnetic Resonance Center at Dalhousie University or (*ii*) the Anasazi 60 MHz EFT spectrometer at Saint Mary's University. Chemical shifts were recorded in $CDCl_3$ solutions at 20 °C (unless specified otherwise) and are relative to Me_4Si as the internal standard. Elemental analyses were performed by the Canadian Microanalytical Service Ltd. (Delta, B.C.). High-resolution electron-ionization mass spectral (EI-MS) data were obtained with the CEC 21–110B mass spectrometer at Dalhousie University. The standard deviation of the mass measurement is ±0.0008 amu, which is an average of 3.6 ppm over the mass range of 100–300 amu.

General procedure

1-Methyl-4-[(E)-2-aryl-1-diazenyl]piperazines (2a–2o)

The aromatic primary amine (0.01 mol) was dissolved in 10 mL of 3 mol/L HCl, with the aid of heat if necessary, and the resulting solution was cooled in an ice/salt bath to 0 °C. The solution was diazotized with a solution of sodium nitrite (0.76 g) in water (10 mL), with the temperature maintained below 5 °C, and then stirred for a further 30 min in the cold. The solution was then neutralized with a saturated sodium bicarbonate solution, after which the neat 1-methylpiperazine (1.2 mL, 0.011 mol) was added slowly to the mixture. After stirring for an additional 30 min, the mixture was further neutralized with a saturated sodium carbonate solution and then left to stir until precipitation was deemed to be complete (1–3 h). The solid product was filtered under suction, dried, and recrystallized from an appropriate solvent. In some cases, notably the ones with an ortho substituent in the aryl group, the product was an oil, in which case separation was achieved by extraction into dichloromethane. Physical data of the products (i.e., yield, mp, recrystallization solvent, and IR data) are listed in Table 1. Table 2 is a list of ^1H NMR chemical shift data, with appropriate assignments, and ^{13}C NMR data are listed in Table 3. The elemental analyses of selected compounds in this series are reported in Table 4. High-resolution EI-MS data of selected compounds of type **2** are given in Table 5.

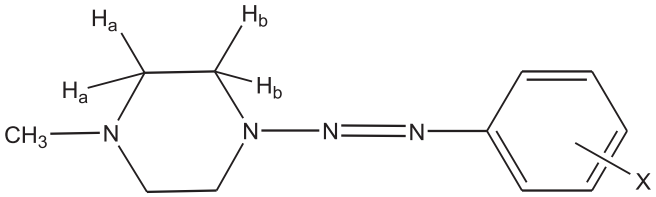
Ethyl 4-[(E)-2-phenyl-1-diazenyl]-1-piperazinecarboxylates (3a–3m)

The general procedure described above for the *N*-methylpiperazines (**2**) was used exactly but with the substitution of ethyl 1-piperazinecarboxylate (1.6 mL) in place of the 1-methylpiperazine. Physical data of the products are listed in Table 6. Table 7 is a list of ^{1}H NMR chemical shift data, with appropriate assignments, and ^{13}C NMR data are listed in Table 8. The elemental analyses of selected compounds in this series are reported in Table 4. High-resolution EI-MS data of selected compounds of type **3** are given in Table 5.

Discussion



The reaction of 1-methylpiperazine with a series of diazonium salts proceeds, as expected, to give mostly excellent yields (60%–87%) of the 1-methyl-4-[2-aryl-1-diazenyl]-piperazines (**2**). Physical data of these triazenes are listed in Table 1. The solid triazenes of this series recrystallize from solvents of low polarity; several of these compounds were isolated as oils, which were found to be spectroscopically pure without further purification. The IR bands listed in Table 1 are all consistent with the particular aryl substituent, including the frequency of the out-of-plane (OOP) bending vibration bands.

The ^{1}H NMR data of the triazenes (**2a–2o**) are shown in Table 2 and are convincing evidence for the identity and purity of the products. The signals from the aromatic protons are consistent with the ortho-, meta-, or para-substitution pattern. The *N*-methyl group resonates at ca. 2.3 ppm as a sharp singlet except in the *p*-sulfonamide (**2g**), which shows an *N*-methyl resonance at 2.70 ppm. The protons of the ring methylene groups appear as two triplets at ca. 2.5–2.6 ppm and ca. 3.8–3.9 ppm, with a coupling constant universally of ca. 5.3 Hz. The lower-field triplet is assigned to the proton labeled H_b on the basis of comparison with model compounds and also from an unequivocal HETCOR NMR experiment with the *p*–tolyl derivative (**2i**) described below. The ^{1}H NMR spectra of triazenes **2c–2g**, **2i,** and **2m** display signals consistent with the protons present in the aryl substituent. A significant amount of line broadening of the methylene proton signals is observed in the spectra of compounds **2g** and **2k**, possibly because of the dynamic equilibrium (see **5A** $\leftrightarrows$ **5B**), which slows down the rotation around N_2–N_3 in the triazene moiety.

The ^{13}C NMR spectra of the triazene series **2** are given in Table 3. Assignment of the chemical shifts in these spectra was helped initially by examination of the ^{13}C NMR spectra of model compounds. Piperazine itself shows one ^{13}C NMR signal at 47.77 ppm; 1–methylpiperazine (**6**) has three signals at 56.6, 46.8, and 46.2 ppm. A DEPT experiment with **6** shows that the 46.8 ppm signal is from the *N*-methyl carbon and that the signals at 46.2 and 56.6 ppm are from methylene groups. Consideration of the 47.77 ppm chemical shift of the carbons in piperazine itself suggests very strongly that

5A **5B**

C_3 in **6** is at 46.2 ppm. Thus, C_2 in **6** is assigned the 56.6 ppm signal.

The ^{1}H NMR spectrum of **6** has the *N*-methyl singlet at 2.22 ppm and triplets at 2.34 and 2.85 ppm. A HETCOR spectrum of **6** confirms that the *N*-methyl carbon at 46.8 ppm correlates with the proton signal at 2.22 ppm. The 56.5 ppm of C_2 correlates with the 2.3 ppm protons and the 46.2 ppm of C_3 correlates with the 2.85 ppm protons. Thus

we conclude that the H_a protons in **6** resonate at 2.3 ppm and the H_b protons at 2.85 ppm, and that the assignment of the 2.5 ppm signal in the spectra of series **2** to the H_a protons is correct.

6

In the assignment of the ^{13}C NMR signals in Table 3, it follows that the *N*-methyl carbon (C_1) be assigned the 46.0 ppm signal and the 54 ppm signal is assigned to the C_2 methylene group in **2**. The signal from the other ring methylene, C_3, at ca. 47 ppm, is considerably broadened due to the dynamic equilibrium **5A** $\leftrightarrows$ **5B**. A HETCOR spectrum of the *p*-tolyl derivative (**2i**) shows that the 21.1 ppm carbon signal correlates with the proton shift at 2.33 ppm in the tolyl methyl group, and the 46.1 ppm carbon signal correlates with the *N*-methyl proton shift at 2.35 ppm. The 54.4 ppm signal of C_2 correlates with the 2.55 proton signal of H_a, leaving the H_b resonance at 3.78 ppm to correlate with the broad 47.2 ppm signal of C_3. The other important information recorded in Table 3 is the presence of the appropriate carbon signals from the substituents in the aromatic rings.

Comparison of the new NMR spectroscopic data of series **2** with the previously published data (6) of the acyclic series **4** is almost perfect. The *N*-methyl group in **2** resonates at

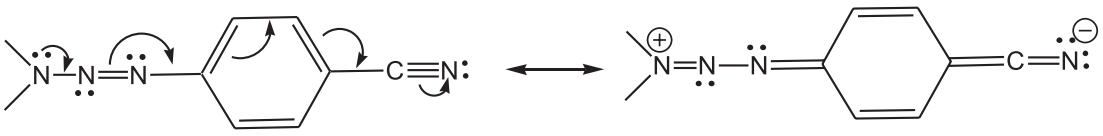
2.33 and 46 ppm, compared with 2.3 and 46 ppm for the analogous *N*-methyl group in **4**. The C_2 methylene in **2** resonates at ca. 2.5–2.6 and 54 ppm compared with 2.6 and 54 ppm for the analogous methylene group in **4**. The proton resonance of the H_b protons attached at C_3 in **2** occurs at ca. 3.8–3.9 ppm, which is exactly the same as the analogous protons in **4**. However, the carbon resonance of C_3 in **2** appearing at 47 ppm is very different from the assigned resonance of 58 ppm for the analogous carbon in **4.** The obvious explanation for this variance is the restricted rotation of the cyclic molecule **2** versus the acyclic equivalent **4**.

Corroboration of the structures of several compounds in series **2** was obtained by high-resolution EI-MS (Table 5). In addition to accurate mass measurement of the molecular ion, the fragmentation patterns give evidence to support the assigned structures. Fragmentation of the N1–N2 bond in the triazene is evident from the universal detection of a strong peak at *m*/*e* 99, corresponding to the *N*-methylpiperazine fragment, and the peak at the mass of the $ArN_2^{\cdot+}$ fragment. Also evident in these spectra is a strong peak from the Ar^+ fragment. Mass spectra of several compounds in series **3** also showed evidence of fragmentation of the N1–N2 bond from the universal presence of a fragment at *m*/*e* 157, which is the mass of the *N*-ethoxycarbonylpiperazine moiety. The $ArN_2^{\cdot+}$ fragment was also clearly evident in these spectra.

Following the complete elucidation of the spectroscopic data of the *N*-methylpiperazine triazene series (**2**), the synthesis of the carbamate series (**3**) was undertaken. Ethyl 1–piperazine carboxylate was coupled in aqueous solution with a series of diazonium salts to afford mostly excellent yields of 4–[2–aryl–1–diazenyl]–1-piperazine carboxylates (**3a–3m**). The physical data for this series of triazenes are given in Table 6. These are mostly solid, crystalline materials that can be recrystallized from hexanes; only compounds **3j** and **3l** were obtained as oils that did not crystallize over time. The carbonyl group of the *N*-ethoxycarbonyl moiety (the carbamate) gives rise to a strong absorption band in the IR spectrum, varying from 1685 to 1715 cm^{-1}. Compounds in this series with two carbonyl bands presented a challenge for the Bruker IR spectrometer to resolve, which it did with compounds **3c**, **3e,** and **3l**, but not with **3d** and **3f**.



The ethyl aryldiazenylpiperazine carboxylates (**3**) were characterized by ^1H and ^{13}C NMR spectroscopy. The ^1H NMR chemical shift assignments are detailed in Table 7. The ethyl group of the *N*-ethoxycarbonyl group shows the typical triplet and quartet at ca. 1.29 and 4.19 ppm, respectively, and the protons of the substituent groups, X, are consistent with expectations, as are the aromatic proton resonances. The resonances of the heterocyclic ring protons are less easily interpreted than those of the *N*-methyl series (**2**) owing to the smaller separation between the chemical shift of the H_a and H_b proton signals and subsequent overlap of the multiplets. On average, the separation between H_a and H_b is only 0.05 ppm (3 Hz), which is less than the apparent coupling constant, J_{ab} (Table 7), which ranges from 3.9 to 9.8 Hz. Thus, the multiplets arising from H_a and H_b are severely distorted when the spectra are recorded at 60 MHz, and in some of the spectra of this series there are as many as

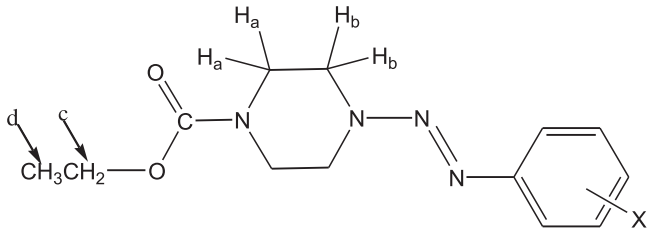
7A **7B**

12 lines in the multiplets. The assignment of the chemical shifts to the protons H_a and H_b has been resolved by analysis of a HETCOR spectrum (see below).



The ^{13}C NMR data of selected compounds in the carbamate series (**3**) are shown in Table 8. The three carbon atoms of the *N*-ethoxycarbonyl group are readily assigned at ca. 14.7 (CH_3), ca. 61.7 (O-CH_2), and ca. 155.2 ppm (carbonyl carbon). The carbon atoms of the piperazine ring occur at ca. 43 and 47 ppm; the 47 ppm signal is significantly broadened in the *p*-cyanophenyl (**3a**) and *p*-nitrophenyl (**3b**) derivatives. This observation is very useful in assigning the 47 ppm signal to C_5; the broadening of the C_5 signal is a direct consequence of the restricted rotation around the N—N bond of the triazene moiety (see **5A** ⇆ **5B**), which is more evident when a strongly electron-withdrawing substituent (CN or NO_2) is present in the para position of the aryl ring. The effect of through-conjugation resonance in the triazene moiety (**7A** ↔ **7B**) is to increase the bond order of the N2—N3 bond.

A ^{13}C NMR study by Axenrod et al. (11) of 1-aryl-3,3-dimethyltriazenes has established a rotational barrier around the N2—N3 bond consistent with some considerable double bond character between N2 and N3 of the triazene. In terms of the secondary orbital interactions within the molecule, overlap of the lone-pair *p*-orbital on N3 with the antibonding π* orbital between N1 and N2 gives rise to a degree of double bond character between N2 and N3.

Further consideration of the assignment of the carbon signals of C_4 and C_5 in the triazene series (**3**) concerns a comparison with the assignments in the *N*-methyl series (**2**),

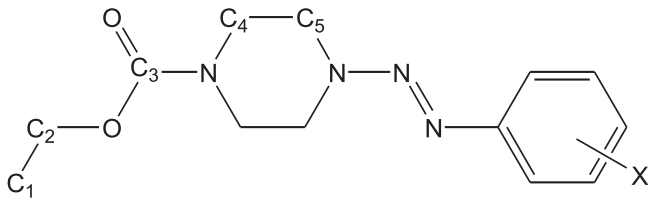
[c]Recorded in DMSO-d_6.
[d]Peaks are too broad to interpret quantitatively.

which shows that the analogous carbon (C_3 in **2**) has a chemical shift (ca. 46.0 ppm) very close to that of C_5 in **3**. However, C_4 in **3** occurs at ca. 43 ppm, which is quite different from C_2 in **2** at ca. 54 ppm. This difference must reflect the different character of the *N*-substituent in each case, i.e., the electron-releasing methyl group in **2** versus the electron-withdrawing ester group in **3**. The ultimate difference lies in the resonance in the carbamate group (**8A** ↔ **8B**).



The assignment of chemical shifts in the carbamate series (**3**) is assisted by a HETCOR spectrum of the *p*-bromophenyl analogue (**3h**). In the HETCOR spectrum, the 14.6 ppm carbon (C_1) correlates with the proton triplet at

Fig. 1. Linear free energy relationship between the proton chemical shifts of H_a and H_b in series **3** and the Hammett constant of the aryl substituent (X).

© 2004 NRC Canada

1.29 ppm, the 61.6 ppm carbon (C_2) correlates with the proton quartet at 4.18 ppm, the 42.9 ppm carbon (C_4) correlates with the proton triplet at 3.70 ppm (H_a), and the 47.0 ppm carbon (C_5) correlates with the proton triplet at 3.73 ppm (H_b). This latter observation is the clearest evidence to assign the chemical shifts of H_a and H_b.

The similarity of the chemical shifts of the piperazine ring protons in the carbamates (**3**) may have implications in the physical organic chemistry of the *N*-substituents. This NMR observation would suggest that the electronic character of the two *N*-sustituents in **3** should be almost identical. The electronic character of the aryldiazenyl group, Ar-N=N–, is not well documented; Isaacs (12) gives a value for the substituent constant (σ_p) of the Ph-N=N group of 0.33, compared with 0.44 for the COOR group. The variation in the chemical shift difference between the H_a and H_b protons in the 60 MHz spectra of the compounds of series **3** has been measured and this difference has been plotted against the Hammett substituent constant (13) of the X substituent in the aryl group of **3** (Fig. 1), showing that there is a linear free energy relationship. It should be noted that the correlation exists for the *difference* in the chemical shift of the H_a and H_b protons, not for the H_b chemical shift itself. The significance of this correlation is not immediately obvious, and an explanation is not easy to formulate. It may indicate that there is a through-space interaction between the lone pairs on the piperazine nitrogen atoms. It certainly suggests that further study of the NMR properties of similar heterocyclic systems may be warranted.

Conclusion

The results reported here provide a comprehensive account of the synthesis and characterization of the *N*-methyl- (**2**) and the *N*-ethoxycarbonyl-*N′*-aryldiazenylpiperazines (**3**), which will provide a valuable resource of data for structure elucidation of related compounds.

Altering molecular weight distributions: Benzyl–phosphinimide titanium complexes as ethylene polymerization catalysts

Emily Hollink, Pingrong Wei, and Douglas W. Stephan

Abstract: The phosphines and corresponding phosphinimines $R_2BnPNSiMe_3$ (R = *t*-Bu, Cy), *p*-$C_6H_4(CH_2PR_2)_2$ (R = *t*-Bu (**1**), Cy (**2**)), and *p*-$C_6H_4(CH_2PR_2NSiMe_3)_2$ (R = *t*-Bu (**3**), Cy (**4**)) were prepared in high yields. Subsequent reaction with Ti precursors afforded $(R_2BnPN)TiCp^*Cl_2$ (Cp* = η-C_5Me_5; R = *t*-Bu (**5**), Cy (**6**)), $(R_2BnPN)TiCpCl_2$ (Cp = η-C_5H_5; R = *t*-Bu (**7**), Cy (**8**)), *p*-$C_6H_4(CH_2PR_2NTiCp^*Cl_2)_2$ (R = *t*-Bu (**9**), Cy (**10**)), and *p*-$C_6H_4(CH_2PR_2NTiCpCl_2)_2$ (R = *t*-Bu (**11**), Cy (**12**)). Methylation of the above complexes gave $(R_2BnPN)TiCp^*Me_2$ (R = *t*-Bu (**13**), Cy (**14**)), $(R_2BnPN)TiCpMe_2$ (R = *t*-Bu (**15**), Cy (**16**)), *p*-$C_6H_4(CH_2PR_2NTiCp^*Me_2)_2$ (R = *t*-Bu (**17**), Cy (**18**)), and *p*-$C_6H_4(CH_2PR_2NTiCpMe_2)_2$ (R = *t*-Bu (**19**), Cy (**20**)). The activity of these species as catalyst precursors in ethylene polymerization catalysis was evaluated using Schlenk line and Buchi reactor techniques using activation by methylaluminoxane (MAO) or $[Ph_3C][B(C_6F_5)_4]$. All these catalysts showed good activities and yield polymers with relatively broad molecular weight distributions. The bimodal polymers derived from catalysts generated using MAO are proposed to result from additional active species, possibly as a result of reaction of MAO with the benzylic fragments. X-ray data are reported for **1**, **4–8**, **10**, **12–14**, **16**, and **18–20**.

Key words: phosphinimides, polymerization, catalysis, polyethylene, titanium, polymer molecular weight distributions.

Résumé : On a préparé les phosphines et les phosphinimines correspondantes $R_2BnPNSMe_3$ (R = *t*-Bu, Cy), *p*-$C_6H_4(CH_2PR_2)_2$ (R = *t*-Bu (**1**), Cy (**2**)), et *p*-$C_6H_4(CH_2PR_2NSiMe_3)_2$ (R = *t*-Bu (**3**), Cy (**4**)) avec d'excellents rendements. Les réactions subséquentes avec des précurseurs de Ti ont conduit à la formation des composés $(R_2BnPN)TiCp^*Cl_2$ (Cp* = η-C_5Me_5; R = *t*-Bu (**5**), Cy (**6**)), $(R_2BnPN)TiCpCl_2$ (Cp = η-C_5H_5; R = *t*-Bu (**7**), Cy (**8**)), *p*-$C_6H_4(CH_2PR_2NTiCp^*Cl_2)_2$ (R = *t*-Bu (**9**), Cy (**10**)), et *p*-$C_6H_4(CH_2PR_2NTiCpCl_2)_2$ (R = *t*-Bu (**11**), Cy (**12**)). Une méthylation subséquente de ces complexes conduit à la formation des composés $(R_2BnPN)TiCp^*Me_2$, (R = *t*-Bu (**13**), Cy (**14**)), $(R_2BnPN)TiCpMe_2$ (R = *t*-Bu (**15**), Cy (**16**)), *p*-$C_6H_4(CH_2PR_2NTiCp^*Me_2)_2$ (R = *t*-Bu (**17**), Cy (**18**)), et *p*-$C_6H_4(CH_2PR_2NTiCpMe_2)_2$ (R = *t*-Bu (**19**), Cy (**20**)). On a évalué l'activité de ces espèces comme précurseurs de catalyseurs pour la polymérisation de l'éthylène à l'aide d'une ligne de Schlenk et un réacteur de Büchi et d'une activation par méthylaluminoxane (MAO) ou du $[Ph_3C][B(C_6F_5)_4]$. Tous ces catalyseurs présentent de bonnes activités et ils conduisent à la formation de polymères ayant des distributions de poids moléculaires relativement larges. Il est suggéré que les polymères à deux modes obtenus à l'aide de catalyseurs résultant d'une génération au MAO pourraient provenir d'espèces actives additionnelles résultant possiblement d'une réaction du MAO avec les fragments benzyliques. On rapporte les données cristallographiques pour les composés **1**, **4–8**, **10**, **12–14**, **16** et **18–20**.

Mots clés : phosphinimides, polymérisation, catalyse, polyéthylène, titane, distributions des poids moléculaires des polymères.

[Traduit par la Rédaction]

Introduction

Many of the developments in early-transition-metal chemistry in recent years have been prompted by attempts to uncover effective new homogeneous olefin polymerization catalysts. A number of studies have described non-metallocene systems based on a variety of novel ancillary ligands (1–3). Among such systems, we have described titanium catalysts that contain bulky phosphinimide ligands. The family of compounds of the form $CpTi(NPR_3)Cl_2$ (Cp = η-C_5H_5) yield active ethylene polymerization catalysts upon activation by methylaluminoxane (MAO) (4–8). Similarly, upon activation by $B(C_6F_5)_3$ or $Ph_3C[B(C_6F_5)_4]$, the species $(t\text{-}Bu_3PN)_2TiMe_2$ provides a remarkably active catalyst, producing polyethylene of narrow polydispersity and relatively high molecular weight (9).

Narrow polydispersities are typically observed for single-site or living polymerization catalysts; however, practical applications often require resins of broader molecular weight distribution for effective processing and manipulation (10, 11). There are a variety of methods employed to alter both the molecular weight and the molecular weight distributions of resins derived from single-site catalysts. These include controlled hydrogenolysis or hydrolysis of the polymeriza-

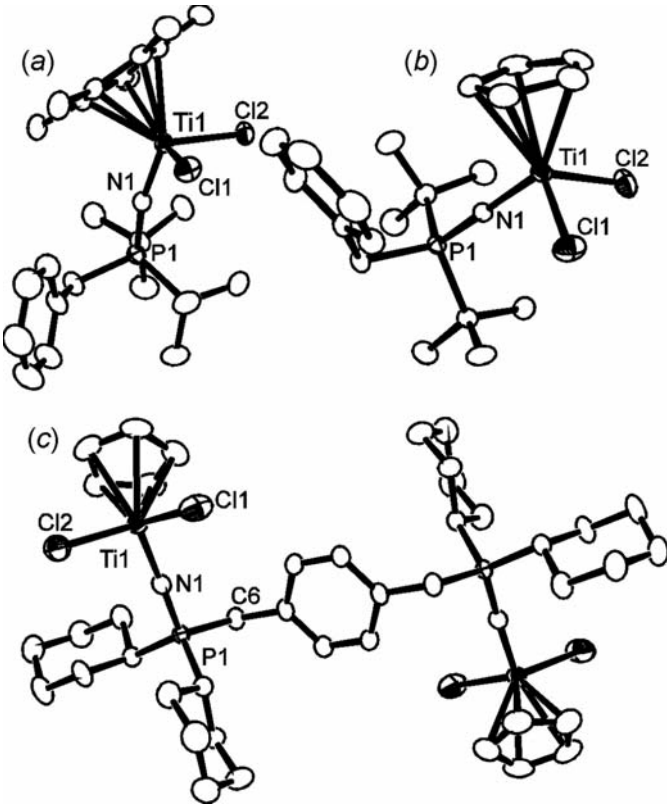
Scheme 1.



tion process (12, 13) or the use of sequential catalyst systems to produce the desired mixture of polymers (14–16). Academic studies and industrial developments continue in this area, with a particular emphasis on bimodal resins (7, 17–28). An alternative approach involves linking single-site catalysts together (16, 29–31), affording differing catalyst sites and thus broader molecular weight distributions (32). Synthetic routes to bimetallic catalyst precursors such as $C_6H_4((Me_3SiN)Zr(NMe_2)_2)_2$ (33), $C_6H_4(OMCpX_2)_2$ (M = Ti, Zr; X = Cl, Me), and $(CH_2PPh_2NCp^*TiX_2)_2$ and 2,6-$(C_5H_3N)(CH_2PPh_2NCp^*TiX_2)_2$ (Cp^* = η-C_5Me_5; X = Cl, Me) (34) have recently appeared, and some of these compounds were tested for their catalytic activity upon activation with MAO. However, very poor catalytic activity was observed, and thus the nature of the resulting polymers has not been explored. In this paper, we describe the facile synthesis of a series of bimetallic phosphinimide-based titanium precatalysts and show that these systems provide effective ethylene polymerization catalysts upon activation by MAO. Moreover, the influence of the nature of the precatalysts on the resulting polymer molecular weight distributions is probed. The implications and ramifications of these data are discussed.

Results and discussion

The phosphines and corresponding phosphinimines $R_2BnPNSiMe_3$ (R = *t*-Bu, Cy) were prepared via a modification of a literature procedure (35). The related diphosphines *p*-$C_6H_4(CH_2PR_2)_2$ (R = *t*-Bu (**1**) or Cy (**2**)) were prepared by a method analogous to that used for the related meta-substituted isomers (36). Thus, treatment of *p*-$C_6H_4(CH_2Br)_2$ with HPR_2 (R = *t*-Bu or Cy) followed by addition of the base NEt_3 afforded **1** and **2** in yields of 88% and 85%, respectively. X-ray data for **1** confirmed the formulation. These phosphines were oxidized in a conventional manner with Me_3SiN_3 to give the species *p*-$C_6H_4(CH_2PR_2NSiMe_3)_2$ (R = *t*-Bu (**3**), Cy (**4**)), also in high yields. Spectroscopic data, as well as X-ray data for compound **4**, were consistent

Fig. 1. ORTEP drawings of (*a*) **5**, (*b*) **8,** and (*c*) **12.** 30% thermal ellipsoids are shown. Hydrogen atoms are omitted for clarity.

with these formulations. The X-ray data revealed that in the solid state, **4** is centrosymmetric with typical P–N and Si–N bond lengths averaging 1.542(2) and 1.663(3) Å, respectively. The P–N–Si angle was found to range from 153.4(1)° to 163.5(1)°, which falls within the range of P–N–Si angles reported in a number of monodentate phosphinimines (37).

Subsequent thermal reaction of the above phosphinimines with 1 or 2 equiv. of Cp^*TiCl_3 or $CpTiCl_3$ resulted in the high-yield formation of $(R_2BnPN)TiCp^*Cl_2$ (R = *t*-Bu (**5**), Cy (**6**)), $(R_2BnPN)TiCpCl_2$ (R = *t*-Bu (**7**), Cy (**8**)), *p*-$C_6H_4(CH_2PR_2NTiCp^*Cl_2)_2$ (R = *t*-Bu (**9**), Cy (**10**)), and *p*-$C_6H_4(CH_2PR_2NTiCpCl_2)_2$ (R = *t*-Bu (**11**) or Cy (**12**)) upon liberation of Me_3SiCl (Scheme 1). While the compounds **9** and **11** were less soluble in benzene than the others, spectroscopic data in all cases were consistent with the formulations. X-ray data (Table 1, Fig. 1) were also acquired for **5–8**, **10,** and **12**. Key metric parameters are tabulated in Table 2. In all cases, the Ti–N distances fall within the range of 1.764(3)–1.786(2) Å. The P–N–Ti angles in these compounds are approximately linear, ranging from 157.1(3)° to 175.2(1)°. These values are similar to those of 155.4(2)° and 165.7(1)° reported for 2,6-$(C_5H_3N)(CH_2PPh_2NTiCp^*Cl_2)_2$ and are typical of titanium complexes of phosphinimide derivatives (5, 37). Variations in the metric parameters among these species are consistent with the steric and electronic differences between the Cp* and Cp ligands.

Methylation of the above complexes proceeded in a facile manner to give $(R_2BnPN)TiCp^*Me_2$ (R = *t*-Bu (**13**), Cy (**14**)), $(R_2BnPN)TiCpMe_2$ (R = *t*-Bu (**15**), Cy (**16**)), *p*-$C_6H_4(CH_2PR_2NTiCp^*Me_2)_2$ (R = *t*-Bu (**17**), Cy (**18**)), and

p-$C_6H_4(CH_2PR_2NTiCpMe_2)_2$ (R = *t*-Bu (**19**), Cy (**20**)) in isolated yields ranging from 46% to 83%. Each of these dimethyl derivatives was characterized spectroscopically. All of these species with the exception of compounds **15** and **17** were also characterized by crystallography (Table 2). In these structures, the Ti–N distances are slightly elongated in comparison to those in the corresponding dichloride derivatives. This is consistent with the increased electron density at the metal center as a result of methylation. The Ti–C bond lengths are typical, ranging from 2.119(7) to 2.228(3) Å. The remaining metric parameters of these compounds are unexceptional.

Olefin polymerization studies

Preliminary evaluation of these compounds as ethylene polymerization catalysts was performed in 50 mL of toluene in a Schlenk flask at 25 °C under 1 atm of ethylene and employing 1000 equiv. of MAO as co-catalyst. These experiments were allowed to run 30 min prior to quenching. The preliminary Schlenk screenings provided an indication of the relative polymerization activity (Table 3), revealing that among the bimetallic systems, precatalyst **19** afforded the best polymerization activity. While the activities were reproducible, the characteristics of the resulting polyethylene (MW and polydipersity index (PDI)) differed from those obtained subsequently, under the more controlled conditions in the Buchi reactor. Such inconsistencies were attributed to the effects of the heat of polymerization within the small volume of the Schlenk flask.

Subsequently, catalysts were tested in a 1-L Buchi reactor equipped with a temperature control bath and a stirring mechanism. The conditions in this case included 500 mL of toluene, 30 °C (±2 °C) and a much lower concentration of precatalyst (50 μmol/L). In initial screening experiments, low pressures of ethylene (1 atm or less) were used; nonetheless, the data was reproducible within acceptable experimental errors. The activities reported (Table 3) are averages of (at least) duplicate runs; however, insufficient saturation of the catalyst with ethylene may have resulted in an underestimation of the activity. Nonetheless, in general, the monometallic catalysts show higher activities, ranging from 200 to 280 g mmol^{-1} h^{-1} atm^{-1}. These activities fall within the range of those reported previously for a series of Ti–phosphinimide complexes (5). These values were significantly higher than those seen for catalysts derived from the previously reported bimetallic systems, where the activities ranged from 20 to 150 g mmol^{-1} h^{-1} atm^{-1}. In particular, these systems stand in contrast to those derived from the related species $(CH_2PPh_2NTiCp^*Cl_2)_2$, which was reported to exhibit extremely low activities for polymerization (34). The cause of such differences is not clear; however, the bimetallic systems are much less soluble than the corresponding monometallic systems. Similarly, this is true for systems incorporating Cp rather than Cp* ligands. It is also noteworthy that in all pairs of analogs, incorporation of the more sterically demanding substituents (Cp* in place of Cp or *t*-Bu in place of Cy) afforded higher catalyst activity. This observation is consistent with the previously suggested notion that steric protection of the phosphinimide N atom enhances activity (4, 38–40).

The monometallic catalysts derived from **5**, **7,** and **13** described herein yield polyethylene of molecular weights ranging from 239 800 to 628 400 g mmol^{-1} h^{-1} atm^{-1} with PDIs of 2.8–3.2 in the Buchi reactor. The corresponding bimetallic catalysts, in contrast, provided PE of molecular weights ranging from 143 300 to 1 416 000 g mmol^{-1} h^{-1} atm^{-1} depending on the precatalyst. These polymers showed broader bimodal molecular weight distributions (Fig. 2). The

separation of the peak molecular weights and the relative intensities of the two modes were catalyst and condition dependent. For example, the polymer derived from the precatalyst **9** (Fig. 2*a*) exhibited a bimodal distribution that was fit with two Gaussian curves of peak molecular weights 98 600 and 447 700 g mmol^{-1}. In contrast, the catalyst derived from **19** (Fig. 2*b*) gave rise to a polymer with clearly separated peaks at 19 700 and 537 000 g mmol^{-1}. These results stand in marked contrast to previous reports regarding compounds of the form $(R_3PN)TiCpCl_2$, which upon activation by MAO, behave as single-site catalysts providing polyethylene of high molecular weight with narrow polydispersities (5).

Related tests done using the monometallic catalyst precursor **5** showed that under 2 atm of constant ethylene pressure (Table 4), polymer with a broaden molecular weight distribution in which a lower molecular weight polymer fraction is similar to that derived from **9** (Fig. 3) was produced. This observation seemed to counter the notion that a bimodal polymer was a direct result of the bimetallic catalysts. Monitoring the polymerizations using **5** and **13** over 10-min intervals revealed the initial appearance of a higher molecular weight fraction that accumulated over time (Fig. 4). This suggests that the active catalyst undergoes some sort of transformation during the course of the polymerization, possibly via reaction of the benzylic protons. It is noteworthy that Bochmann and co-workers have observed metallation of the methylene protons of $(CH_2PPh_2NTiCp^*Cl_2)_2$ (34).

Using similar increased pressure conditions, activation of the bimetallic catalyst precursors **18** and **20** with 1, 2, or

Fig. 2. Observed and two-Gaussian fit of GPC of polyethylene derived from the precatalysts (*a*) **9** and (*b*) **19**.

4 equiv. of $[Ph_3C][B(C_6F_5)_4]$ resulted in the efficient polymerization of ethylene (Table 4). In general, with an increase in the amount of activator from 1 to 2 equiv., polymerization activities also increased. The bulkier Cp* derivative showed 4 times the activity of the Cp analog when 4 equiv. of $[Ph_3C][B(C_6F_5)_4]$ were used, and ca. 60 times the activity when only 1 equiv. of activator was employed. The resulting polymers showed monodisperse GPC traces with PDI values less than 4. This is in contrast to the results obtained when MAO was used as an activator.

In conclusion, MAO or $[Ph_3C][B(C_6F_5)_4]$ activation of the monometallic and bimetallic benzyl-phosphinimide catalysts produced polyethylene with good activities. While all these catalyst systems gave relatively broad molecular weight distributions, catalysts generated using MAO gave bimodal polymers. Given that previous studies have shown that other phosphinimide catalysts give single-site activity, the present observations infer that MAO reacts with the present catalysts, probably at the benzylic fragment, to modify the active species, resulting in two (or more) catalyst sites. While this postulate remains unconfirmed, it is noteworthy that in related systems, Bochmann and co-workers (34) have observed metallation of methylene groups in phosphinimide ligands. While the precise cause remains a subject of investigation, it is clear that modification of the catalyst structure alters the nature of the resulting polymer. We are currently investigating strategies to other modified catalyst systems in an effort to understand the relationship between catalyst structure and polymer properties in more detail.

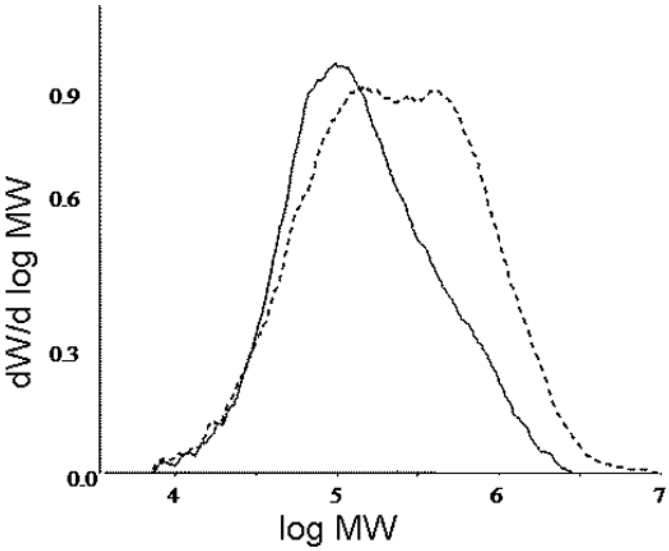

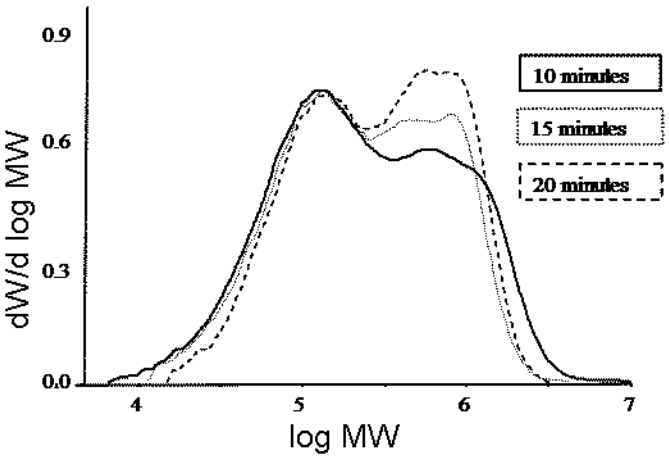

Fig. 4. GPC of polyethylene from catalysts derived from **5** as a function of time.

Experimental

General data

The syntheses were performed under an atmosphere of dry, oxygen-free nitrogen in a Vacuum Atmospheres (Hawthorne, Calif.) inert atmosphere glove box or by standard Schlenk techniques. Proton NMR data were acquired on a Bruker Avance 500-MHz spectrometer, and $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR data on a Bruker Avance 300-MHz spectrometer. Proton and ^{13}C NMR chemical shifts are listed downfield from $SiMe_4$ in parts per million and were referenced to the residual proton or carbon peak of the solvent. Phosphorus-31 NMR data were referenced using an external standard relative to 85% H_3PO_4. All NMR spectra were recorded in C_6D_6 unless otherwise stated. Combustion analyses were performed by Galbraith Laboratories Inc. or in-
