With carboxylate, the active center of metal-ion-catalyzed hydrolysis may involve the four forms shown in Scheme 3 (18). The first two methods are difunctional, and the metal ion frequently forms a stable intermediate by coordination to the carboxyl oxygen, which can neutralize the charge of carboxyl oxygen and assist departure of the leaving group (NP^-). The last two methods are the direct attack of metal-bound water or OH^- on the carboxyl carbon and cause the release of NP^-. In our systems, it is reasonable for the metal complexes to attack the carboxyl group by methods (*a*) and (*b*) (Scheme 3). If this occurs, there will exist a pre-equilibrium step (K) before the nucleophilic attack, and as a consequence, the k_{obs} will not increase linearly with the increase of the concentration of metal complexes, but will instead experience a hyperbola (eq. [7]).

$$[7] \qquad k_{obs} = k_{com}[3Zn:L]^T/(1/K' + [3Zn:L]^T)$$

However, this is in contrast to the results shown in Fig. 3, owing to the concentrations of the catalysts (these vary in the range of 0.5~2 × 10^{-3} mol·dm^{-3}). This range of concentrations is hardly enough to test for saturation. When the hy-

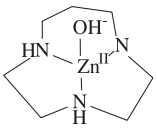
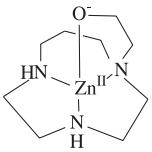
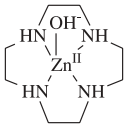
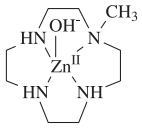
drolysis reactions were made under the condition that [NA] = 0.5×10^{-3} mol·dm^{-3} and [3Zn:L1] = 2~4 × 10^{-2} mol·dm^{-3} at pH 7.61, the reciprocal of the observed rate constant, $(k_{obs})^{-1}$, increased linearly with $[3Zn:L1]^{-1}$. The k_{obs} values were found to be 0.0034, 0.0042, 0.0050, 0.0055, and 0.0067 mol^{-1}·dm^3·s^{-1} in the catalyst concentrations of 0.02, 0.025, 0.03, 0.035, and 0.04 mol·dm^{-3}, respectively. From a plot of $(k_{obs})^{-1}$ vs. $[3Zn:L1]^{-1}$, we obtained k_{com} = 0.229 mol^{-1}·dm^3·s^{-1} and K'= 0.74 dm^3·mol^{-1}. The value of k_{com} is almost the same as that obtained from hydrolysis in the lower catalyst concentrations (Table 3, 0.235 mol^{-1}·dm^3·s^{-1}). The results suggest that the catalyzed hydrolysis of NA occurs through the mechanisms (*a*) and (*b*), shown in Scheme 3, for the monohydroxyl and neutral complexes, respectively. During the formation of the nucleophile:NA complexes, the Zn(II) ion attains an increased opportunity to form a coordination bond with the carboxyl oxygen atom (Scheme 2, complexes **1** and **1′**). This pre-coordination between the Zn(II) ion and carboxyl group will decrease the negative electron density on carboxyl oxygen and will then weaken the repulsion between the hydroxide and carboxyl oxygen. For the nucleophile:NA complex, coordination bonding should constrain the acetate tightly and thus facilitate the expulsion of the leaving group.

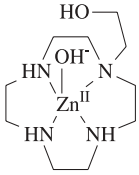
On the other hand, the enhancement of the hydrolysis rate, observed for solutions containing 1:1 Zn(II) to L ratio, was not significant. In the 1:1 metal:ligand system, the Zn(II)-coordinated water is difficult to deprotonate to give the monohydroxide species (14) at neutral pH. The major complexes in neutral pH are ZnLH and ZnL (14), which have no or low catalytic activity at the pH range 6.5–8.2. For example, the k_{com} is 0.0012 and 0.334 mol^{-1}·dm^3·s^{-1} for the hydrolysis of NA catalyzed by 1:1 and 3:1 ZnL1 complexes at pH 8.2, respectively. The latter is about 278-fold greater than the former. The second-order rate constant of NA hydrolysis catalyzed by ZnL1 is only 0.021 mol^{-1}·dm^3·s^{-1}, which is also lower than that of Zn_3L1–OH, 0.34 mol^{-1}·dm^3·s^{-1}. Since the available site for coordination in ZnL1 is presumably fully occupied by amino groups, the formation of Zn(II)–OH$^-$ is difficult (pK_a = 9.6). Furthermore, a possible increase in the coordination number of zinc may radically change the conformation of the complex, thus making it difficult for the nucleophile to interact with the substrate. So, the Zn(II)-bound water molecule or hydroxyl can only take paths (*d*) or (*c*) (shown in Scheme 3) to attack the carboxyl group of the NA ester, respectively.

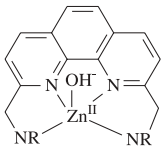












The pK_a of the Zn(II)-bound water plays an important role in the catalytic activity of these model complexes. As obtained from potentiometric titrations, the pK_a values for the process of $Zn_3L \rightarrow Zn_3LH_{-1}(Zn_3L–OH)$ are 7.47, 7.25, 7.52, and 7.38 for the four ligands, respectively. It was observed that the four pK_a values are almost identical, taking into account the calculation errors of the stability constants (Table 1). Thus, it is not reasonable to discuss the effects of the various substituents on the terminal nitrogen atoms (namely, Me, Et, *n*-Pr, and *n*-Bu for L1, L2, L3, and L4, respectively); these effects may include provision of space hindrance for the nucleophilic attack and a decrease the hydrophobicity of the active center of the complexes (Table 4). In general, the increasing size of the substituents will significantly hinder the interaction of the NA ester with metal complexes, resulting in a decrease in the metal–complex catalytic ability. On the other hand, the increased hydrophilicity of the metal center facilitates the stabilization of the NA ester. However, one should keep in mind that much lower pK_a values mean deprotonation at low pH and thus decrease the nucleophilicity of the coordinated nucleophiles, while a too bulky group can restrict the interaction of subject and metal catalysis. This subtle relationship is very important in the design of hydrolytic enzyme model complexes.

Comparison with the other systems

It was observed that all the axial deprotonated complexes Zn_3L–OH serve as good nucleophiles in the catalysis of NA hydrolysis. This observation was made by comparison of

rates and by establishing the mechanism of other model complexes.

The Brönsted equation (eq. [8]) is usually used to compare the efficiency of different catalysts with different pK_a values.

$$[8] \qquad \log k_{NA} = C + \beta pK_a$$

where C is a constant and β is the Brönsted constant. On a plot of logk_{NA} vs. the pK_a values of various complexes, macrocyclic Zn(II) complexes **1**, **3**, and **4** (6) and Zn(II) complexes of linear phenanthroline-bridged polyamines **7**, **8**, and **9** (17) were found in the same line (Fig. 6). The following values were obtained: C = 7.34, Brönsted constant β = 8.80, and R = 0.98. The complexes **2** and **5** are above the line, owing to alkoxide, the more efficient nucleophile (Table 5). At the same time, the methyl-substituted phenanthroline-bridged polyamine **6** (Me) is also above the line, whereas its analogous complexes **10** and **11** are below the line because of the steric effects of the terminal *i*-Pr and *t*-Bu substituents on nucleophilic attack. It is interesting that all the four [3Zn:L] complexes are above the line; this is attributed to the following factors: (*i*) the low pK_a of Zn(II)-coordinated water facilitating the formation of nucleophile Zn(II)–OH^- at neutral pH; (*ii*) less steric effect than that in the 1:1 Zn–L system; and (*iii*) the formation of the coordination bond involving the carboxyl oxygen of NA and the Zn(II) ion, which grasps the CH_3COO^- group tightly and facilitates the release of NP^- to form the complex **2** or **2′** (Scheme 2).

Fig. 6. Comparison of the second-rate constants of NA hydrolysis catalyzed by [3Zn:L] complexes with other models. The numbers of the complexes are listed in Table 5.

Previous studies have reported the importance of multinuclear metal complexation for di- and triphosphates, which are relevant to the role of metal ions in biological phosphoryl transfer, as in the case of *Escherichia coli* alkaline phosphatase, where the active site of the enzyme contains a triplet of metal ions but only two are involved in the active center (18, 19). It is worth noting that it is not clear whether the real catalytic center of our models involve two or three metal ions, since the carboxyl group has only one site — carboxyl oxygen — for interaction with metal ions or others, restricting further investigation.

In summary, in the present paper we focus on the hydrolysis of a simple carboxylic monoester, 4-nitrophenyl acetate (NA), catalyzed by the Zn(II) complexes of tripods L1–L4 in a 3:1 metal:ligand ratio. The OH^- coordinates Zn(II) complexes of tripods that effectively catalyze the hydrolysis of 4-nitrophenyl acetate (NA). However, the pK_a values of our models are near to the physiological pH and, therefore, may have much practical use in mimicking enzyme behaviour, without taking into account the effect of the 10% CH_3CN–H_2O mixed solution on the pK_a values of the Zn_3L–H_2O complexes. To obtain further rate enhancements, one can vary the coordination number or change the microenvironment around the metal center from hydrophilic to hydrophobic. Work in this area is underway.

Conformational behaviour in *S*-methyl halothioacetates through NMR, FT-IR, and theoretical calculations

Ernani A. Basso, Barbara C. Fiorin, Cláudio F. Tormena, and Roberto Rittner

Abstract: This work presents an investigation of the conformational behaviour of *S*-methyl chlorothioacetate (MCTA), *S*-methyl bromothioacetate (MBTA), and *S*-methyl iodothioacetate (MITA) through NMR and IR spectroscopies and through theoretical calculations that apply DFT/B3LYP theory. The DFT calculations showed two stable rotamers in the vapour phase, *gauche* and *trans,* for all the compounds. The coupling constants, $^1J_{CH}$, were obtained from NMR spectroscopy; these were used in the solvation theory to calculate the vapour-phase energy difference, the coupling constants for each rotamer, the solution energy difference, and the rotamer population for each solvent. These data showed that for MCTA, the most stable rotamer is *trans*; however, for MBTA and MITA, the most stable rotamer is *gauche*, both in the vapour phase and in solution. The changes in rotamer stability are because of the preference in stereoelectronic interactions; in the MCTA case the interaction is mainly electrostatic, while for MBTA and MITA, it is because of the interaction between $n_{Br,I} \rightarrow \pi^*_{CO}$.

Key words: *S*-methyl halothioacetates, conformational analysis, theoretical calculations, NMR, solvation theory.

Résumé : Ce travail a été réalisé pour étudier le comportement conformationnel du chlorothioacétate de *S*-méthyle (CTAM), du bromothioacétate de *S*-méthyle (BTAM) et de l'iodothioacétate de *S*-méthyle (ITAM) par spectroscopies RMN et IR et par des calculs théoriques en se basant sur la théorie DFT/B3LYP. Les calculs DFT mettent en évidence, pour tous les composés, qu'il existe deux rotamères stables en phase vapeur, *gauche* et *trans*. Sur la base de la RMN, on a déterminé les constantes de couplage $^1J_{CH}$ qui ont été utilisées dans la théorie de la solvatation pour calculer la différence d'énergie libre en phase vapeur, les constantes de couplage de chaque rotamère, la différence d'énergie en solution et la population de chaque rotamère dans chaque solvant. Ces données montrent que dans le cas du CTAM, le rotamère le plus stable est le *trans* alors que pour les BTAM et ITAM le rotamère le plus stable est le *gauche*, tant en phase vapeur qu'en solution. Les changements dans la stabilité des rotamères sont dus à des préférences dans les interactions stéréoélectroniques qui, dans le cas du CTAM, sont principalement de nature électrostatique alors que, pour les BTAM et ITAM, elles sont principalement dues à l'interaction $n_{Br,I} \rightarrow \pi^*_{CO}$.

Mots clés : halothioacétates de *S*-méthyle, analyse conformationnelle, calculs théoriques, RMN, théorie de la solvatation.

[Traduit par la Rédaction]

Introduction

Geometric structure has a significant influence on the chemical, physical, and biological properties of a molecule (1). The geometrical parameter that is most important in establishing conformational properties is the torsional angle (dihedral angle) (1–5).

It is well known that fluorinated compounds are widely used in biochemistry, medicinal chemistry, and pharmacology (6). The substitution of hydrogen or hydroxyl by fluorine in pharmacologically active organic molecules can have an intense effect on their activity (7). This replacement causes a minor change in the functionality of the steric effect, unlike the significant effects it causes on the chemical properties, as well as on the stereoelectronic properties, which results in specific overall conformational change of the fluorinated nucleosides (6).

Fluorine substitution in the position α to a carbonyl group of small aliphatic compounds, as well as in α-fluoroaldehydes (8), α-fluoroketones (4–5), α-fluoroesters (2, 9), and α-fluoroamides (3, 10), gives only two conformers, *cis* and *trans*, except for fluoroamides, where the conformational equilibrium is between *cis* and *gauche* (3, 10).

An earlier study concerning the conformational behaviour of some *S*-ethyl-α-heterosubstituted molecules pointed out the existence of the *cis* and *gauche* rotamers (11). This study

also concluded that the *gauche* rotamer predominates over the *cis* one for fluorine, chlorine, and bromine derivatives, while for iodine, only the *gauche* rotamer was assigned (11).

Theoretical calculations

The ab initio calculations were performed using the Gaussian 98 (12) program. The potential energy surfaces were obtained at the B3LYP/6-311+g(d,p) level. The geometries were optimized with the B3LYP method, using the 6-311++g(3df,3pd) basis set for carbon, hydrogen, oxygen, chlorine, and bromine atoms, with zero-point energy correction (ZPE). Since the sulphur atom has a more complicated electronic structure, a specific basis set (18s14p10d) developed for this atom has been applied (13). For the iodine atom, a special basis sets (9s9p4d) (14) was applied for the valence electrons and a pseudo-potential LAN2DZ was used for core electrons. The optimized geometries and energies of all the rotamers are given in Table 1.

Solvation theory

The solvation theory has been fully described elsewhere (2–5, 10, 15), and thus, only a brief description is given here. The solvation energy of any molecule in state A is the difference between the energy in the vapour phase (E_A^V) and in any solvent (E_A^S) within relative permittivity ε. This is given in terms of dipolar (k_A) and quadrupolar (q_A) reaction field terms in addition to a direct dipole–dipole term, which takes into account the breakdown of the Onsager reaction-field theory in very polar media (15). The input for the program is simply the dipole and quadrupole moments plus the solute radius and refractive index, the latter two calculated by the program. In state B, a similar equation is obtained, differing only in the values of dipole and quadrupole terms. The subtraction of the two equations ($E_A^S - E_B^S$) gives ΔE^S, the energy difference in any solvent within a relative permittivity, in terms of ΔE^V together with calculable parameters. An accurate value of the solvent dependence from a variety of conformational equilibria is obtained (2–5, 10).

It should be noted that the calculated energies correspond to the potential energy differences, while the experimental results refer to free energies (ΔG). However, the entropy value in the system is negligible, and thus, $\Delta G = \Delta E$. The calculations were performed by the MODELS program (15), using the geometries from Gaussian 98 (12) as input. The dipole and quadrupole moments of the molecules were calculated directly from their partial atomic charges, which were obtained from the CHARGE routine (16).

Experimental

The solvents were obtained commercially, stored over molecular sieves, and used without further purification.

^{1}H and ^{13}C NMR spectra were obtained on a Varian Mercury plus BB spectrometer operating at 300.059 MHz for proton and 75.457 MHz for carbon NMR. Spectra were of 0.65 mol L^{-1} solutions in a probe temperature of ca. 25 °C. Typical conditions for proton spectra were 48 transients,

spectral width 3000 Hz with 32 k data points, and zero filled 128 k to reach a digital resolution of 0.04 Hz. Proton-coupled carbon spectra (gated decoupling) were obtained with 3000 transients, 2 s pulse delay, spectral width 15 000 Hz with 64 k data points, and zero filled 256 k for 0.1 Hz digital resolution. The spectra were all first-order, and the coupling constants and chemical shifts taken directly from them are shown in Tables 2–4.

The carbonyl stretching bands, both in the fundamental (1850–1600 cm^{-1}) and in the first overtone regions (3650–3300 cm^{-1}), were recorded in a Bomem FT-IR MB-100 spectrometer, from 0.03 mol L^{-1} solutions for all compounds studied, in solvents of varying polarity, using 0.5 mm sodium chloride matched cells for the fundamental region and 1.00 cm quartz matched cells for the overtone region. Deconvolution analyses were performed through the GRAMS program.

_S_-Methyl chloro- and bromothioacetate (17)

To a three-neck flask, equipped with magnetic stirrer and N_2 atmosphere, was added anhydrous THF (150 mL). The flask was cooled down to –60 °C with an $N_{2(l)}$–ethanol bath, and to this was added 5.0 mL of methanethiol (collected at –60 °C and dried over anhydrous magnesium sulphate), 5.1 mL (62.5 mmol) of pyridine, and 5.0 mL (62.5 mmol) of chloroacetyl chloride or 5.4 mL (62.5 mmol) of bromoacetyl chloride. The reaction mixture was stirred at –25 °C for 3 h and then poured into water (200 mL). The organic layer was separated, and the aqueous layer was extracted with ether (3 × 30 mL). The organic extracts were combined, washed with a 3% HCl solution (8 × 12 mL), and dried over anhydrous sodium sulphate. The solvent was evaporated under reduced pressure. The product obtained was distilled through a Vigreux column, yielding 4.6 g (bp 53–55 °C at 12 mmHg (1 mmHg = 133.322 Pa); 57%) of the *S*-methyl chloro-

thioacetate and 5.6 g (bp 63–64 °C at 7 mmHg; 51%) of the *S*-methyl bromothioacetate.

S-Methyl iodothioacetate (18)

Potassium iodide (15.28 g, 92 mmol) and acetone (10 mL) were placed into a 50 mL three-neck flask, which was equipped with magnetic stirrer, reflux condenser, and addition funnel. Soon after, *S*-methyl chlorothioacetate was added dropwise under stirring at room temperature. After the addition, the reaction mixture was stirred for 4 h. It was then filtered through a Büchner funnel; the solid was then washed with acetone, and the solution was concentrated under reduced pressure. The product was distilled through a Vigreux column, yielding pure *S*-methyl iodothioacetate (bp 79 °C at 6 mmHg; 9.30 g; 56%).

Results

The potential-energy surfaces were obtained, through DFT calculations, for MCTA and MBTA (see Fig. 1). Figures 1*a* and 1*b* show the *trans* and *gauche* rotamers (Fig. 2) as the most stable forms for all compounds. The geometries for the *gauche* and *trans* rotamers for each compound were optimized at special basis sets (see theoretical calculation section). The *trans* forms for MCTA, MBTA, and MITA were identified through the dihedral angles (X–C–C=O) of 180.0°, 180.0°, and 179.9°, respectively. The dihedral angles for the *gauche* rotamers were 78.8° for MCTA, 82.7° for MBTA, and 81.6° for MITA, as can be observed in Fig. 1 and Table 1.

In the case of MCTA, the *trans* rotamer is the most stable form in the vapour phase ($\Delta E_{gauche-trans}$ = 1.05 kcal mol^{-1}); for MBTA, the energy difference in the vapour phase is almost zero, but for MITA, the *gauche* form is more stable ($\Delta E_{trans-gauche}$ = 1.39 kcal mol^{-1}). This distinct behaviour is because of the different interactions. In chlorine derivatives, the electrostatic interaction between a chlorine atom and sulphur, in the *trans* form, is predominant in the vapour phase. On the other hand, for bromine and iodine derivatives, the electronic interaction between $n_{Br,I} \rightarrow \pi^*_{CO}$ is dominant in the *gauche* form (Fig. 3).

The ^{13}C NMR spectra of MCTA, MBTA, and MITA were recorded in solvents of varying polarity, and the coupling constant, $^1J_{CH}$, of the methylene carbon exhibited a dependence on the solvent (Tables 2–4).

Although the use of $^4J_{HF}$, $^1J_{CF}$, and $^2J_{CF}$ couplings in conformational investigations is well established (2–5), this is not the case for the $^1J_{CH}$ couplings measured in this work. Thus, it is of the first necessity to determine how much the observed variation in the couplings is because of changes in the conformer populations and how much is because of an intrinsic solvent dependence. Comparing the observed changes in $^1J_{CH}$ for methylene carbon (Tables 2–4) with those of the methyl group, in which all (methyl group) conformers are identical, the $^1J_{CH}$ couplings for methylene groups in MCTA, MBTA, and MITA are essentially independent from the solvent; thus, the noticed changes for these

Table 5. The individual coupling constants calculated and the energy differences between the rotamers in the vapour phase (ΔE^V).

Compound	Rotamer	$^1J_{CH}$ (Hz)	ΔE^V (kcal mol^{-1})
MCTA	*trans*	142.5	1.00
	gauche	176.0	
MBTA	*trans*	127.9	0.10
	gauche	162.4	
MITA	*trans*	113.7	0.65
	gauche	157.2	

couplings, in the methylene groups, may be reasonably attributed to changes in the conformer populations.

The $^1J_{CH}$ coupling constants were used to perform the solvation calculations, as shown in eq. [1], in which n is the molar fraction of the rotamer. Through this methodology, we compute the energy difference between the rotamers (ΔE^V), the individual coupling constants ($^1J_{CH(trans)}$ and $^1J_{CH(gauche)}$), the calculated coupling constants, and the population of the rotamers.

$$J_{obsd} = n_{gauche}J_{gauche} + n_{trans}J_{trans}$$

$$n_{trans} + n_{gauche} = 1$$

$$n_{trans}/n_{gauche} = (1/2)\exp^{(-\Delta E/RT)}$$

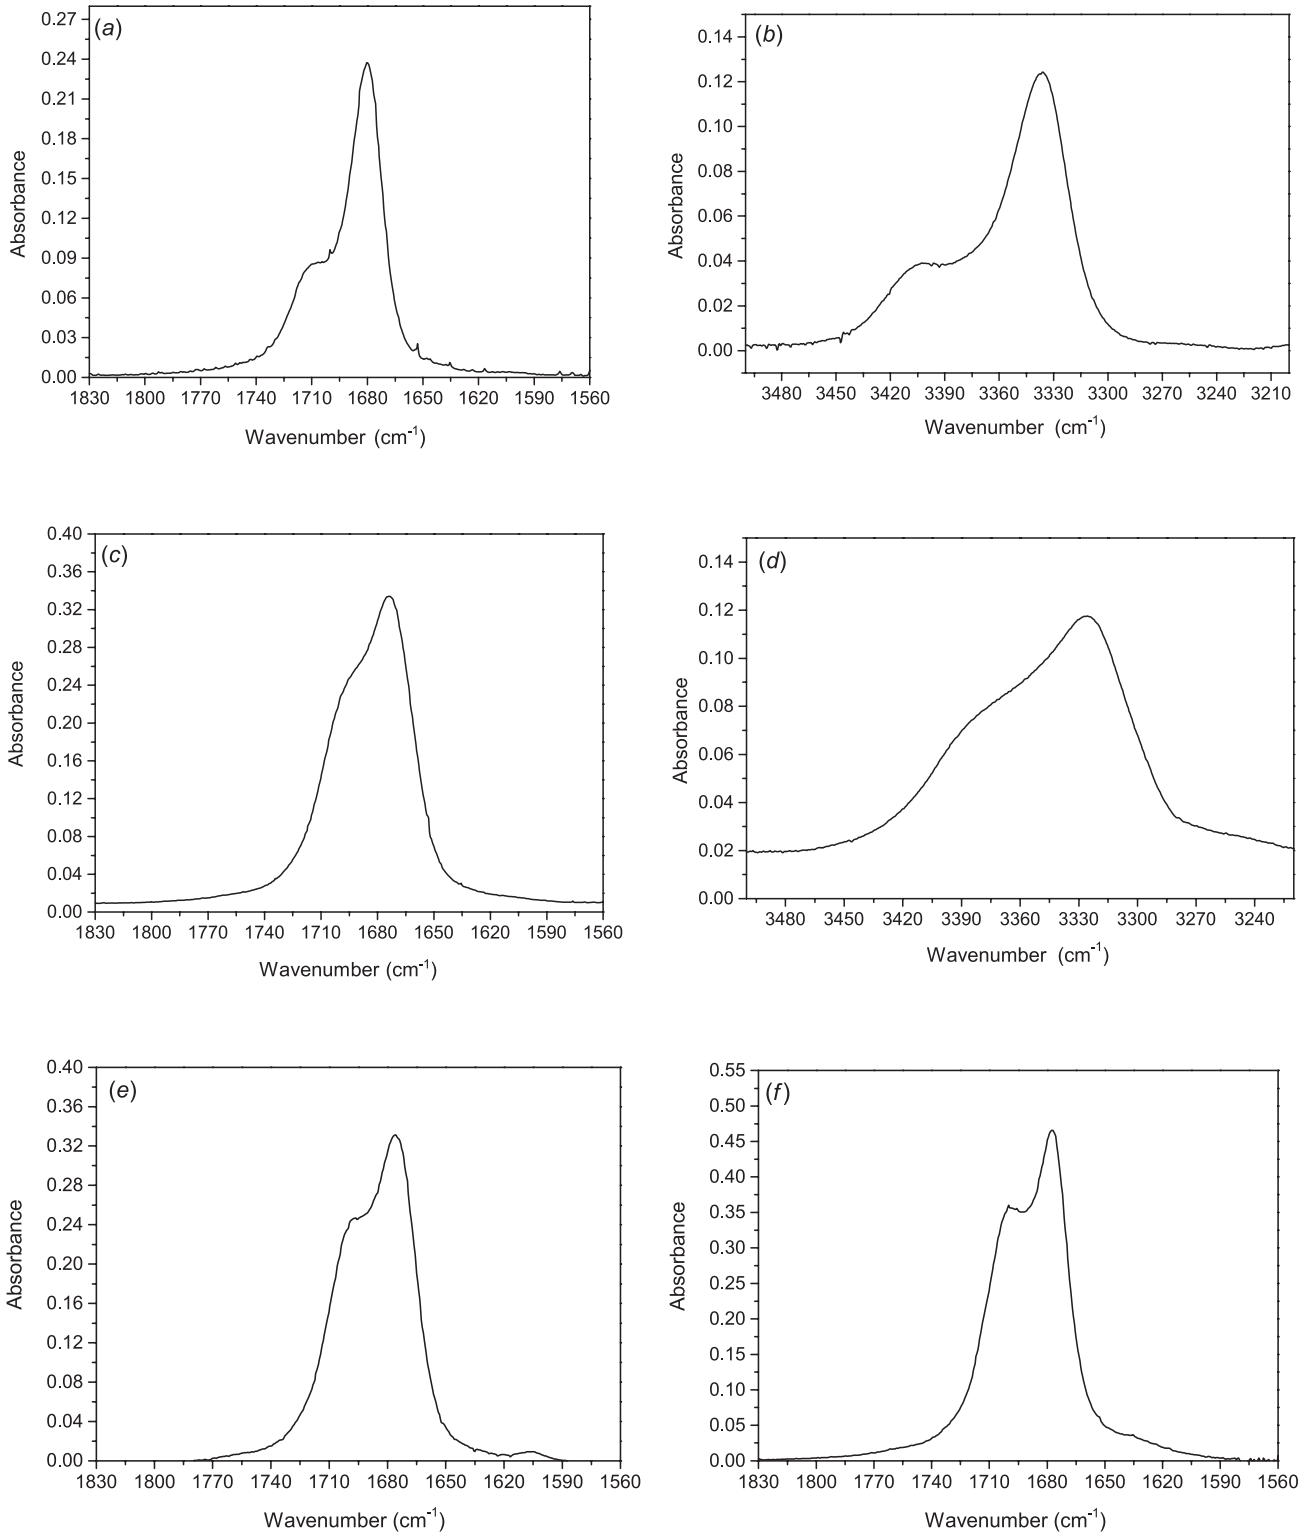
[1] $$\Delta E = E_{gauche} - E_{trans}$$

For the compounds MBTA and MITA, the ΔE value is given by $\Delta E = E_{trans} - E_{gauche}$; using this equation, the results are always positive. The energy differences between the rotamers in the vapour phase (ΔE^V) and the individual calculated coupling constants ($^1J_{CH(trans)}$ and $^1J_{CH(gauche)}$) are shown in Table 5. The energy differences between the rotamers in solution, the calculated coupling constants ($^1J_{CH(calcd)}$), and the rotamer population are shown in Table 6.

The IR spectra, using solvents of varying polarity, corroborate with the NMR data and show the carbonyl absorption as a double band for MCTA (Fig. 4). Through deconvolution analysis, it was possible to observe two resolved bands, which confirms the presence of the two rotamers. The same behaviour was observed for MBTA (Fig. 5) and for MCTA as well, except in the carbon tetrachloride solution where three bands were observed, both in the fundamental and the first overtone regions (Figs. 5*a* and 5*b*).

For MITA (Fig. 6), the IR spectra of the carbonyl absorption band appears as a single sharp band (except for the overtone region); however, the carbonyl band deconvolution showed two peaks (Fig. 7).

Discussion



In this work, the DFT calculations allow us to observe (for MCTA, MBTA, and MITA) the presence of two rotamers, *gauche* and *trans* (Fig. 2), unlike in a previous study (11), in which it was concluded that the rotational isomerism for these compounds was between the *cis* and *gauche* forms. For MCTA, the *trans* rotamer predominates over the *gauche* form in the vapour phase, while for MBTA and MITA, the *gauche* rotamer is the most stable form. This behaviour can be explained by considering that in MCTA,

there is a strong Coulomb attraction between the positive charge on the sulphur atom (0.8026) and the negative charge on the chlorine atom (–0.2591). However, for the bromine and iodine derivatives, this attraction could be neglected because the bromine and iodine charges are –0.0816 and 0.608, respectively, giving support for the *gauche* rotamer preference. In addition, it should be expected that this behaviour could be related to the steric repulsion between the

larger bromine and (or) iodine and sulphur atoms. The *gauche* rotamer stability in MBTA and MITA could also be due to attractive interaction between $n_{Br,I} \rightarrow \pi^*_{CO}$ (Fig. 3).

From the NMR data, it was observed that the coupling constant $^1J_{CH}$ shows dependence on solvent polarity, owing to the changes in rotamer population. The $^1J_{CH}$ for MCTA varied from 152.2 Hz in CCl_4 to 154.2 Hz in DMSO, producing a change in *trans* rotamer population from 72% to 66%, respectively. This result indicates that the most polar rotamer (*gauche*) is more favoured in polar solvents, but the *trans* form is the most stable overall in all the solvents employed. For MBTA and MITA, the *gauche* rotamer is the most stable one, and the $^1J_{CH}$ values varied from 153.1 and 152.0 Hz in CCl_4 to 155.1 and 153.1 Hz in DMSO, respec-

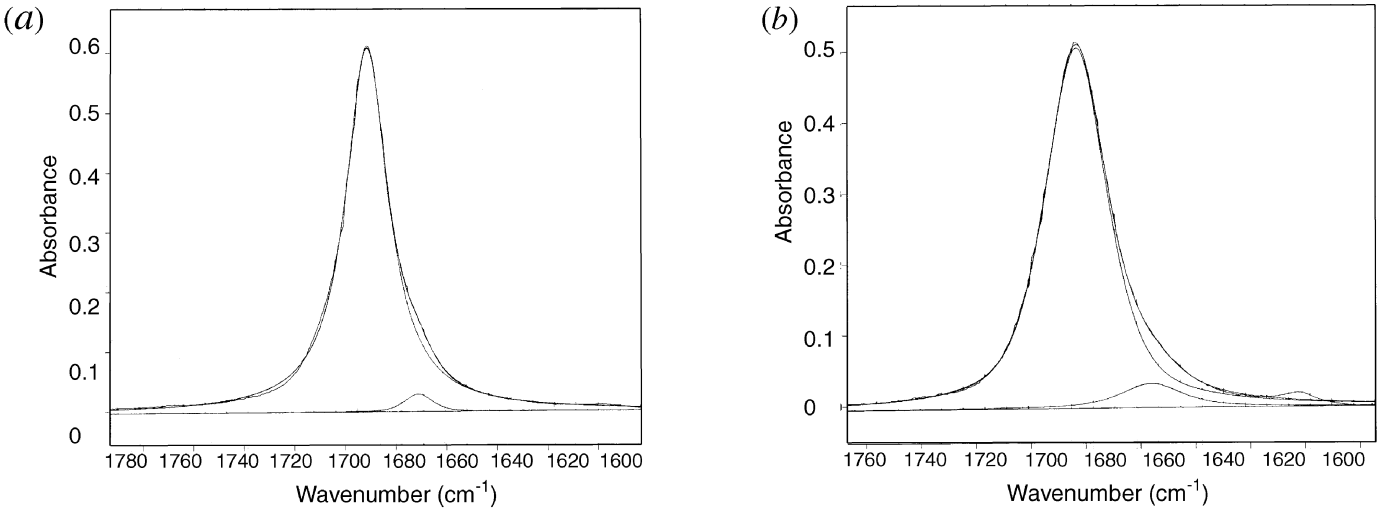
Fig. 6. The carbonyl absorption band in the IR spectrum of MITA in (*a*) CCl_4, (*b*) CCl_4 in the first overtone, (*c*) $CHCl_3$, (*d*) $CHCl_3$ in the first overtone, (*e*) CH_2Cl_2, and (*f*) CH_3CN.



tively. The proportion of *gauche* rotamer for MBTA and MITA increased from 72% and 87% in CCl_4 to 78% and 91% in DMSO, respectively. All these data are compiled in Table 6. These results clearly show the preference for the *trans* rotamer for MCTA and the *gauche* form for MBTA and MITA. The rotational isomerism is affected by the solvent; as the solvent polarity increases, the population of the rotamer with the higher dipole moment also increases (Table 6).

The solvation theory, together with the NMR experiments, yields an excellent methodology for conformational analysis of these compounds. The FT-IR experiments for the three

Fig. 7. The carbonyl band deconvolution of MITA in (*a*) CCl_4 and (*b*) $CHCl_3$.

compounds showed one peak for each rotamer in the fundamental and the first overtone regions. After spectra deconvolution, the two bands were clearly observed. For MBTA in carbon tetrachloride solution, we observed a third band at a higher frequency. This third absorption is weak and may be the result of an overtone or combination frequency in Fermi resonance with the carbonyl stretching vibration. Studies explaining this behavior have not yet been done. Through theoretical calculations (Table 1), we have attributed the carbonyl bands for each rotamer of MCTA, MBTA, and MITA. In all compounds, the *trans* rotamer band absorbs in a lower frequency than the *gauche* one.

Neat reaction microwave technology for the synthesis of *N*-substituted-1,4-dihydropyridines

Mazaahir Kidwai and Richa Mohan

Abstract: Hantzsch synthesis of *N*-substituted-1,4-dihydropyridines (1,4-DHP) was carried out using an environmentally benign procedure. Neat reactants were subjected to microwave irradiation (MWI) to give the required products in excellent yield. Appreciable results were not obtained when conventional synthesis using neat reactants was carried out. The good yield and rate enhancement observed in the case of microwave irradiation is attributed to the uniform heating effect of microwaves.

Key words: 1,4-dihydropyridines (1,4-DHP), microwave irradiation (MWI), neat reaction, solid support.

Résumé : On a réalisé une synthèse de Hantzsch de 1,4-dihydropyridines (1,4-DHP) *N*-substituées en faisant appel à une méthode environnementalement bénigne. On a soumis les réactifs sans solvants à une irradiation par des microondes (IMO) qui a conduit à la formation des produits requis avec d'excellents rendements. On n'a pas obtenu de bons résultats lorsqu'on a effectué la synthèse conventionnelle avec des réactifs sans solvant. On attribue les excellents rendements et l'augmentation de la vitesse de la réaction observée avec une irradiation par des microondes à l'effet de chauffage uniforme des microondes.

Mots clés : 1,4-dihydropyridines (1,4-DHP), irradiation par des microondes (IMO), réaction sans solvant, support solide.

[Traduit par la Rédaction]

Introduction

Research on the 1,4-dihydropyridine (1,4-DHP) moiety is of current interest because of its recognition as a core structure in calcium antagonists (1). In the case of structure–activity relationships, the effect of substitution on the 1,4-DHP ring has been thoroughly studied (2). However, most of the studies have been devoted to the Hantzsch synthesis of *N*-unsubstituted dihydropyridines (3, 4), since the classical routes (5), yielding *N*-alkyl or *N*-aryl 1,4-DHP products, suffer from negative results (6) or very poor yields (7). Modified synthetic methodologies (8) for the above compounds reportedly provide improved yields but use expensive reagents and require longer reaction times. The drive for clean technology in the chemical industry requires a level of innovation. Thus, the eco-friendly goal of making organic compounds without using solvents has come several steps closer in recent years (9). With the development of microwave-assisted solid-phase synthesis (10), it has now become easier to perform reactions without solvents, as these high-yield protocols offer the benefits of enhanced reaction rates, greater selectivity, and experimental ease of manipulation (11).

In this communication, synthesis of *N*-substituted-1,4-DHP was carried out under conventional heating by refluxing 1 mol of aldehydes 1a–b, 2 mol of ethylacetoacetate, and 1 mol of amines 2a–d in acetic acid for several hours (Scheme 1). The products were obtained in low yield (Table 1), while the same reaction over acidic alumina[2] using microwave irradiation gave the desired products in good yield within a few minutes. The microwave reaction was also carried out over neutral alumina,[3] wherein appreciable yields were observed within the same reaction time. Although the microwave-assisted solid-support synthesis is a solventless technique, it requires the use of an appreciable amount of solvent at the pre- and post-reaction stages.

In our endeavour to develop an environmentally benign synthesis that eliminates the use of solvent, and in continuation to our earlier work on the neat Hantzsch synthesis (13) of 1,4-DHP, an attempt was made to synthesize *N*-substituted-1,4-DHP under neat reaction conditions. As a test case, 2 mol of ethylacetoacetate and 1 mol each of benzaldehyde and aniline were subjected to microwave irradiation. On completion of reaction, as monitored by TLC, the reaction mixture was cooled at 5 °C for 24 h, and the sticky solid obtained was titurated with a few drops of methanol to give the required product in excellent yield. The positive results obtained in the above case prompted us to synthesize some novel *N*-substituted-1,4-DHP using heterocyclic amines. The products were obtained in less time than with solid support and conventional methodology. A slight improvement in yield was also observed on moving from solid support to

neat reaction methodology (Table 1). The neat reaction was also carried out under conventional heating, keeping similar reaction conditions. Conventional neat synthesis took more time for completion and gave the products in moderate yield and, in certain cases, lead to charring.

Thus, we have developed an easier, practically convenient, and environmentally benign synthesis of bioactive *N*-substituted-1,4-DHP that proceeds under much milder reaction conditions than conventional means. Eliminating organic solvents in chemical synthesis is an important drive towards clean chemical technology. Although solventless reactions are more appropriate for small-scale production, these results may stimulate interest among researchers involved in the industrial scale-up of reactions.

Experimental section

Melting points were determined on a Thomas Hoover melting point apparatus and are uncorrected. IR spectra were recorded on a PerkinElmer FT-IR-1710 spectrophotometer. ^{1}H NMR spectra were recorded on an FT-NMR Hitachi R-600 (60 MHz) instrument using TMS as the internal reference. Microwave irradiation was carried out in a Kenstar microwave oven, Model No. OM9925E (2450 MHz, 800 W). Monitoring of the reaction was done through TLC, using silica-gel-coated Al plates (Merck). The reaction temperature was measured using an AZ minigun type non-contact IR thermometer (Model No. 8868).

General procedure for the synthesis of *N*-substituted diethyl 1,4-dihydro-2,6-dimethyl-4-furyl/phenyl-3,5-pyridinedicarboxylate (3a–h)

Solution phase (conventional)

A mixture of aldehyde 1a–b (0.01 mol), primary amine 2a–d (0.01 mol), and ethylacetoacetate (0.02 mol) in 30 mL acetic acid was refluxed for a specified time. On completion of the reaction, as monitored by TLC examination, the reaction mixture was cooled for 24 h; the solid obtained was filtered, washed with cold MeOH, dried, and recrystallized from ethanol.

Solid support (microwave)

To the solution of aldehyde 1a–b (0.01 mol), primary amine 2a–d (0.01 mol), and ethylacetoacetate (0.02 mol) in ethanol (15 mL), solid support (20 g) was added. The reaction mixture was dried in air, kept in an alumina bath, and subjected to MWI for a specified time (Table 1). On completion of the reaction, as examined by TLC (at an interval of 30 s), the product was extracted in ethanol (3 × 15 mL). Re-

© 2003 NRC Canada

covering the solvent under reduced pressure gave the required product, which was recrystallized from ethanol.

Neat synthesis (microwave)

A mixture of 0.01 mol of aldehyde 1a–b, 0.01 mol of primary amine 2a–d, and 0.02 mol of ethyl acetoacetate was taken in an Erlenmeyer flask and subjected to MWI. The progress of the reaction was monitored by TLC at an interval of 30 s. On completion of the reaction, the reaction mixture was cooled and titurated with a few drops of methanol, and the product was recrystallized from aqueous methanol.

Kinetics and mechanism of the oxidation of L-α-amino-*n*-butyric acid in moderately concentrated sulfuric acid medium

Homayoon Bahrami and Mansour Zahedi

Abstract: The reaction kinetics of L-α-amino-*n*-butyric acid oxidation by permanganate ion have been investigated in moderately strong acid medium using a spectrophotometric technique. In all cases studied an autocatalytic effect, due to Mn^{+2} ions formed as a reaction product, was observed. Both catalytic and noncatalytic processes were determined to be first order with respect to the permanganate ion and the amino acid. The overall rate equation for this process may be written as:

$$-d[MnO_4^-]/dt = k'_1[MnO_4^-] + k'_2[MnO_4^-]\cdot[Mn^{+2}]$$

where k'_1 and k'_2 are pseudo-order rate constants for the noncatalytic and catalytic reactions, respectively. The influence of some factors such as temperature and reactant concentration on the rate constants has been studied, and the activation parameters have been calculated. Reaction mechanisms satisfying observations for both catalytic and noncatalytic routes have been presented.

Key words: L-α-amino-*n*-butyric acid, permanganate oxidation, concentrated acidic medium, autocatalysis, free radical intermediates.

Résumé : Faisant appel à une technique spectrophotométrique, on a étudié la cinétique de la réaction d'oxydation de l'acide L-α-aminobutyrique par l'ion permanganate dans un milieu acide relativement fort. Dans tous les cas étudiés, on a observé un effet autocatalytique par les ions Mn^{+2} qui se forment comme produit de la réaction. On a déterminé que les processus tant catalytique que non-catalytique sont tous les deux du premier ordre par rapport à l'ion permanganate et à l'acide aminé. L'équation globale de vitesse pour le processus est de la forme:

$$-d[MnO_4^-]/dt = k'_1[MnO_4^-] + k'_2[MnO_4^-]\cdot[Mn^{+2}]$$

dans laquelle k'_1 et k'_2 sont les constantes de vitesse du premier ordre des réactions respectivement non-catalytique et catalytique. On a étudié l'influence de quelques facteurs, tels que la température et la concentration, sur les constantes de vitesse étudiées et on a calculé les paramètres d'activation. On propose des mécanismes réactionnels pour les voies catalytique et non catalytique qui satisfont les résultats obtenus.

Mots clés : acide L-α-aminobutyrique, oxydation avec du permanganate, milieu acide concentré, autocatalyse, intermédiaires radicalaires.

Introduction

Owing to the biological importance of amino acids, the kinetics and mechanistic study of their oxidation has received considerable attention. The permanganate oxidation process of amino acids in strong acid media (1–14), in neutral and weak basic solutions (15–23), and in weak acid media (24–29) has been investigated. The occurrence of autocatalysis effects in weak acid media, neutral aqueous solution, and weak basic media has been extensive (15–29), whereas no rigorous evidence of such an effect has been reported in strong acid media. There have been just two reports (10, 14) of a "double-stage" process vaguely attributed to possible autocatalysis, with no thorough information as far as the autocatalysis effect is concerned.

In autocatalytic pathways in which Mn^{+2} ions have been determined to be responsible for the effect, a mechanism with no free radicals involved has been suggested (28, 29). In the present paper, distinct evidence of the autocatalytic influence of Mn^{+2} for the permanganate oxidation of L-α-amino-*n*-butyric acid in strong acid medium has been presented, and a free radical mechanism has been proposed.

Experimental

All the reagents were from Merck or Sigma. The solutions were prepared with triply distilled and deionized water. The

Fig. 1. Spectral changes in the oxidation of L-α-amino-*n*-butyric acid by permanganate ion. [$KMnO_4$] = 4×10^{-4} mol dm^{-3}, [L-abu] = 0.1 mol dm^{-3}, [H_2SO_4] = 3.16 mol dm^{-3}, T = 318 K. Scanning time intervals = 6 min.

permanganate solutions were prepared and tested by the Vogle method (30). The kinetic progress of the reaction was followed by measuring the absorbance of the permanganate ions at 525 nm with a thermostated (Shimadzu TB-85 ± 0.1 K) Shimadzu (2100 Model) UV–vis spectrophotometer within the temperature range 25–45 °C. For the permanganate molar absorption coefficient at 525 nm and in strong acid solution, a value of 2.26×10^3 dm^3 mol^{-1} cm^{-1} was obtained.

In all the kinetic measurements, the amino acid was used in excess (250-fold) relative to permanganate, to insure pseudo-first-order kinetics (28, 29).

Results

Stoichiometry and product analysis

By employing spot tests (31, 32), the final reaction products were detected as ammonium ions and the corresponding aldehyde. For carbon dioxide detection, the standard Vogle method (33) was employed. As well, it is well known (4, 12, 34) that in the reduction process of permanganate ions in strong acid media (as long as the reducing species is in excess), Mn^{+2} ions are the final product.

Our reaction was performed in an excess of amino acid, and we used the procedure outlined below to study the stoichiometry of the reaction; the following equation is proposed as the reaction stoichiometry:

$$[1]\quad 2MnO_4^- + 5CH_3\text{-}CH_2\text{-}CH(NH_3)^+COO^- + 11H^+ \rightarrow 5CH_3\text{-}CH_2\text{-}CHO + 5NH_4^+ + 5CO_2 + 2Mn^{+2} + 3H_2O$$

Procedure

Equal concentrations of known amounts of permanganate and amino acid were mixed and kept at 45 °C temperature for 1 h. For the permanganate concentration determination, a known amount of reaction mixture was quenched by a standard iron(II) solution. The unreacted iron was subsequently titrated by a standard cerium(IV) solution. Aldehyde concentration was determined by a calorimetric procedure using chromotropic acid. We came to the final conclusion that 1 mol of permanganate generates 2.5 mol of aldehyde, as is indicated by the balanced equation, eq. [1] (1, 2, 8).

Rate equation

Figure 1 illustrates the permanganate absorption vs. wavelength curves obtained at 6 min intervals as the reaction proceeded. From previous studies (15–23), Mn(IV) ions absorb in the region 400–650 nm. Figure 1 shows the lack of spectral changes from 400–650 nm, which means that MnO_2 is not a reaction product. Furthermore, since no rise and fall in absorption is observed at 418 nm, it is concluded that Mn(IV) ions do not intervene as possible oxidizing agents unless they are short lived.

The absorbance–time plots are illustrated in Fig. 2. In all the experiments performed, curves with a sigmoid profile (Fig. 2*a*) were obtained. This characteristic suggests the existence of an autocatalytic mechanism. To demonstrate that Mn^{+2} is the species responsible for the autocatalytic effect, kinetic runs were carried out in the presence of the $MnSO_4$ species at the beginning of the reaction. As the initial concentration of Mn^{+2} ions increased, a notable increase in the reaction rate was seen (Fig. 2*b*). Further increases of initial Mn^{+2} concentration and maintaining the Mn^{+2} concentration equal to the permanganate ion concentration led to a complete disappearance of the sigmoid form (Fig. 2*c*). Taking the Mn^{+2} effect on the reaction rate into account, the following rate equation has been proposed:

$$[2]\quad d[MnO_4^-]/dt = k'_1[MnO_4^-] + k'_2[MnO_4^-]\cdot[Mn^{+2}]$$

where k'_1 and k'_2 are pseudo-order rate constants for the noncatalytic and catalytic processes, respectively. The amino acid concentration, which is always kept in large excess, and the constant acid concentration in each experiment are included in these pseudo-order rate constants.

The integrated form of this equation gives:

$$[3]\quad \ln[(k'_1/k'_2 + x)/(a - x)] = (k'_1 + k'_2a)t - \ln(k'_2a/k'_1)$$

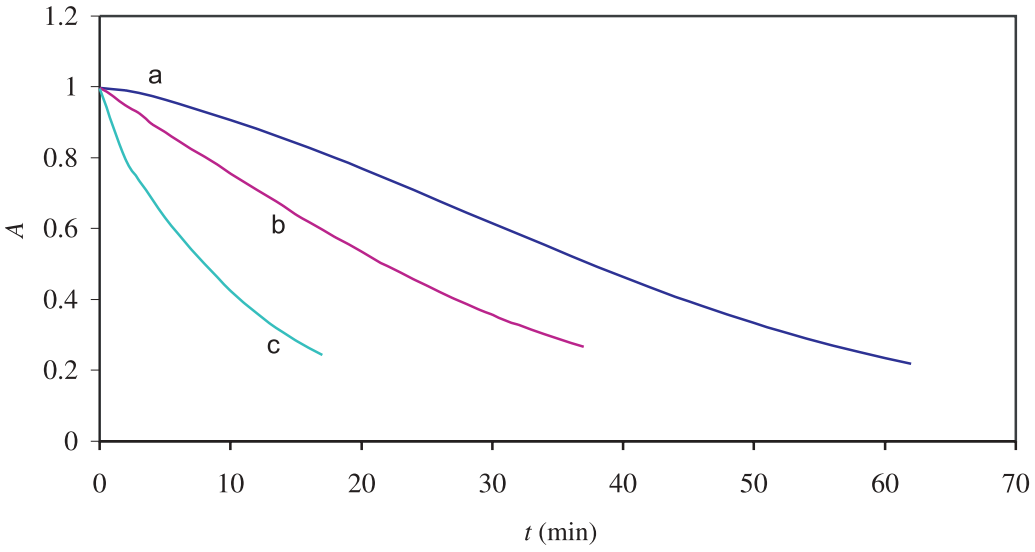
Fig. 2. Effect of the added initial concentration of ions on the absorbance time plots. [$KMnO_4$] = 4×10^{-4} mol dm^{-3}, [L-abu] = 0.1 mol dm^{-3}, [H_2SO_4] = 3.16 mol dm^{-3}, T = 313 K. (*a*) [Mn^{+2}] = 0 mol dm^{-3}; (*b*) [Mn^{+2}] = 2×10^{-4} mol dm^{-3}; (*c*) [Mn^{+2}] = 4×10^{-4} mol dm^{-3}.



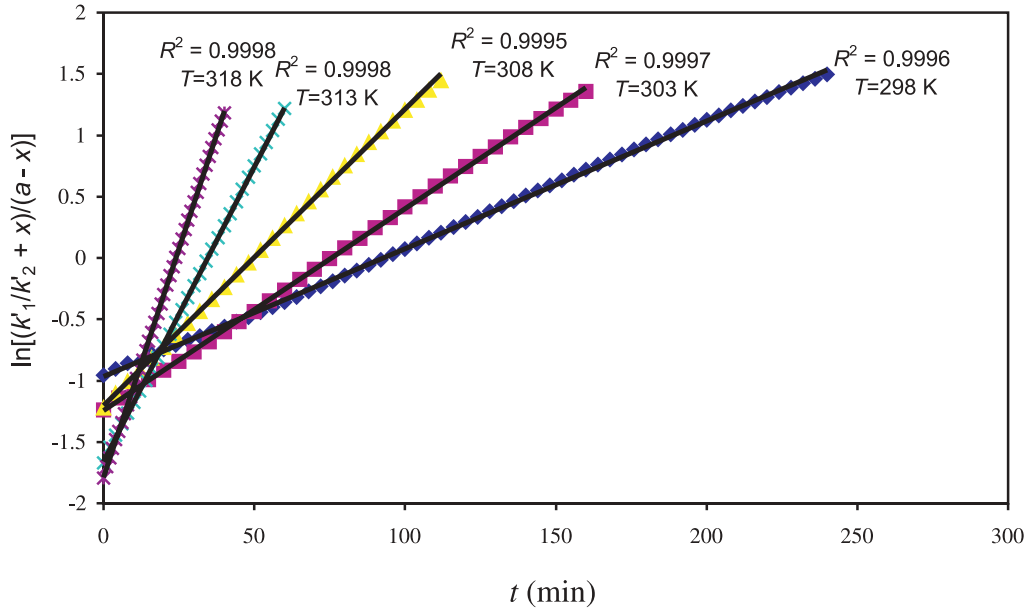


Fig. 3. Integrated rate-law plots for the oxidation of L-α-amino-*n*-butyric acid by potassium permanganate at various temperatures. [$KMnO_4$] = 4×10^{-4} mol dm^{-3}, [L-abu] = 0.1 mol dm^{-3}, [H_2SO_4] = 3.16 mol dm^{-3}.

where a represents the initial concentration of permanganate and x the amount of permanganate ion consumed up to time t.

For the correct determination of pseudo-constants k'_1 and k'_2, the following procedure has been employed. Because the reaction is slow and the initial Mn^{+2} concentration is sufficiently low, initial guesses of k'_1 values have been obtained by fitting the initial portion of the rate data to a first-order rate equation and assuming no catalytic effect in the early stages of the reaction. Moreover, our kinetic run in the presence of manganese sulfate(II) with a concentration equal to that of the permanganate ion satisfies the following rate equation:

$$[4] \qquad \ln[a(b + x)/b(a - x)] = k'_2 (a + b)t$$

where b refers to the initial concentration of manganese sulfate(II). The calculated rate constants under this condition have provided a reasonable initial guess for k'_2. Having previously determined preliminary values of k'_1 and k'_2, eq. [3] has then been used for the simultaneous determination of the kinetic data of the reaction by taking advantage of iterative methods (18, 24–29). Figure 3 demonstrates the results of the fitting process of rate data at various temperatures and under the same conditions.

Table 1 gives the final values for k'_1 and k'_2 at various temperatures. Almost perfect fits to the curves in Fig. 3 (R^2 values of 0.9995–0.9998) not only corroborate the validity of the applied kinetic method but also confirm the autocatalytic effect of the Mn^{+2} species.

Dependence of the kinetic parameters

Dependence of reaction rate on [amino acid], [MnO_4^-], and [Mn^{2+}]

The pseudo-order rate constants obtained at various amino acid concentrations are summarized in Table 2. Figure 4 shows these results. The plots of $1/k_1'$ and $1/k_2'$ against 1/[L-abu] (L-abu = L-α-amino-*n*-butyric acid) (not shown) gave straight lines that both pass through the origin. These observations confirm first order with respect to the amino acid for both the noncatalytic and catalytic pathways (12).

To investigate the effect of permanganate concentration on the reaction rate, its concentration was varied from 4 × 10^{-4} to 6 × 10^{-4} mol dm^{-3} at 313 K, which caused k_1' and k_2' values to be decreased by 14% and 31%, respectively.

Table 3 summarizes the data that have been obtained for k_2' with increasing Mn^{+2} ion concentration. From these results it is evident that when Mn^{+2} concentration is raised, k_2' values decrease. This observation, and the fact that the very slow reaction of Mn^{+2} with MnO_4^- (35, 36) switches to a fast reaction when the amino acid is present, suggest that in the process of permanganate consumption some intermediate complex has probably been formed between Mn^{+2} and the amino acid (24–29).

Table 3. Effect of Mn(II) on k_2' at 313 K; [L-abu] = 0.1 mol dm^{-3}; [H_2SO_4] = 3.16 mol dm^{-3}; [$KMnO_4$] = 4 × 10^{-4} mol dm^{-3}.

[Mn(II)]	0	0.0002	0.0004	0.0006
k_2' (dm^3 mol^{-1} s^{-1})	1.43	1.41	1.34	1.19

Dependence of reaction rate on sulfuric acid concentration

The effect of [H^+] has been investigated by means of a series of experiments carried out at various sulfuric acid concentrations. As Fig. 5 indicates, k_1' increases when the acid concentration is raised, whereas k_2' initially decreases and then shows a sharp increase. The region of 3–4 mol dm^{-3} sulfuric acid shows the least variation for k_2'. Thus, this concentration region was determined to be the most appropriate region for the rest of our kinetic studies.

Determination of activation parameters

As a further justification of the method that has been applied to determine the pseudo-order rate constants k_1' and k_2' at various temperatures, calculated values of these parameters have been evaluated by the Eyring equation. Figure 6 demonstrates the agreement of both k_1' and k_2' with the Eyring equation. The thermodynamic activation parameters obtained, energy, enthalpy, and entropy, are reported in Table 4.

Acrylonitrile addition

The presence of free radicals as intermediates was con-

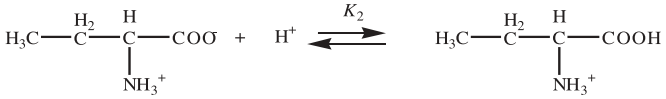
firmed by addition of acrylonitrile, which led to polymerization, both in the presence and in the absence of manganese sulfate(II).

Discussion

In agreement with the experimental results that have been presented and taking into account the previous literature references, two separate mechanisms for the catalyzed and uncatalyzed pathways are proposed to describe the reaction pathway. Since the existence of intermediate free radicals was confirmed, their involvement in the reaction mechanism has also been considered.

Reaction mechanism for the uncatalyzed process

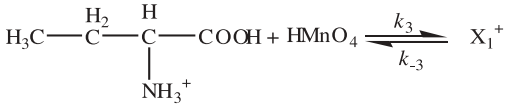


All the experiments were performed in strong acid media. With the evidence presented pointing to no involvement of other manganese oxidation states, Mn(VII) is the most probable reactive species. Reaction rate enhancement observed by increasing acid concentration suggests the formation of a more powerful oxidant, namely permanganic acid, by the following equilibrium:

[5] $$MnO_4^- + H^+ \underset{}{\overset{K_1}{\rightleftharpoons}} HMnO_4$$

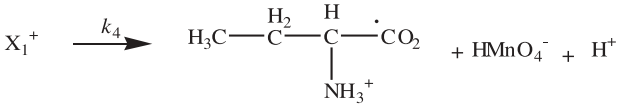
© 2004 NRC Canada

At the high acid concentration used, protonation of the zwitterionic form of amino acid gives



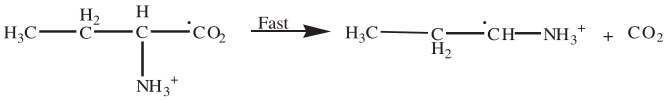
[6]

A mechanism consistent with the observed kinetic data includes the following steps.



In agreement with the experimental results, the formation of an addition complex between the permanganic acid and the cationic form of the amino acid is proposed (11, 12, 28).

[7]



This complex may rupture according to the following equation:

[8]

Based on the radical involvement in the reaction mechanism, the iminium cation (24–29) is possibly formed via three steps

[9]

[10]

[11]

By hydrolysis of the iminium cation, the corresponding aldehyde is obtained (28)

[12]

Knowing the fact that the species Mn(V) is very unstable in strong acidic media, it will be converted into Mn(II) and Mn(VII) by means of a rapid disproportionation.

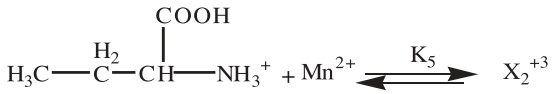
[13] $5HMnO_4^{2-} + 11H^+ \rightarrow 3MnO_4^- + 2Mn^{2+} + 3H_2O$

Multiplying eqs. [5], [6], [7], [8], [9], [10], [11], and [12] by a factor of five and then summing them with eq. [13] results in the overall reaction with the stiochiometry satisfied. In agreement with the above scheme, assuming a steady state approximation for X_1^+, the rate equation obtained for the uncatalyzed process is

[14] $-d[Mn(VII)]/dt = k_1'[MnO_4^-]$

[15] $$k_1' = \frac{\alpha_0[H^+]^2[\text{L-abu}]_t}{\beta_0(1+\beta_1[H^+]+\beta_2[H^+]^2)+\alpha_1[H^+]^2[MnO_4]}$$

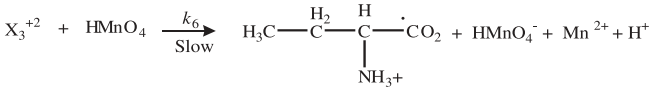
where $[\text{L-abu}]_t$ represents the total concentration of amino acid; [Mn(VII)] represents the total concentration of permanganate; and where



$$\alpha_0 = K_1K_2k_3k_4$$
$$\alpha_1 = K_1K_2k_3$$
$$\beta_0 = k_{-3} + k_4$$
$$\beta_1 = K_1 + K_2$$
$$\beta_2 = K_1K_2$$

The rate law obtained above corresponds to that mechanism explaining the observed experimental behavior: the first-order reaction with respect to both permanganate and amino acid and the change in k_1', the uncatalyzed pseudo-order rate constant, when the permanganate concentration varies.

Reaction mechanism for the catalyzed process



Addition of Mn^{+2} ions led to an increase in the reaction rate, while the evidence presented also suggests that an adduct might be formed between Mn^{+2} and the protonated L-α-amino-*n*-butyric acid in a fast step before it is oxidized by permanganic acid in a slow step (15, 16).

[16]

As the rate determining step, slow attack of permanganic acid on complexes has been proposed (28–29)

[17]

The remaining steps, leading to the final products, resemble those presented for the uncatalyzed pathway above. Again, multiplying eqs. [5], [6], [7], [16], [17], [9], [10], [11], and [12] by a factor of five and summing them up with eq. [12] results in the overall reaction with the correct stoichiometry. Assuming a steady-state approximation for the X_2^{3+} complex in the above mechanism, the following rate equation (28) is derived:

[18] $-d[Mn(VII)]/dt = k_2'[Mn^{2+}][MnO_4^-]$

© 2004 NRC Canada

$$[19] \quad k'_2 = \frac{\beta_0\delta_0[\text{L-abu}]_t[H^+]^2}{\beta_0(1+\beta_1[H^+]+\beta_2[H^+]^2)+\alpha_1[H^+][MnO_4^-]+\beta_0\delta_1[H^+][Mn^{+2}]+\beta_0\delta_2[H^+]^{2+}[Mn^{+2}]}$$

where the notation employed in eq. [14] is conserved, and in addition

$$\delta_0 = K_1K_2K_5k_6$$

$$\delta_1 = K_2K_5$$

$$\delta_2 = K_1K_2K_5$$

This rate law, along with the one proposed for the uncatalyzed process, is in accord with all experimental results presented in this article; namely, first-order dependence on Mn^{+2} ions, permanganate ions, and the amino acid and inverse dependence of k'_2 on permanganate and Mn^{+2} ion concentrations, as shown in the k'_2 expression.

Owing to the complexity of the proposed mechanism, evaluation of the values of the rate constants corresponding to the reaction rate-determining steps for both processes has not been possible. Thus, the activation parameters reported are associated with reaction pseudo-rate constants k'_1 and k'_2, and these values cannot be attributed to any particular reaction step.

Conclusions

The kinetics of the permanganate oxidation process of L-α-amino-*n*-butyric acid in strong acid media was investigated using a spectrophotometric technique. Addition of manganese sulfate(II) to the reaction mixture raised the reaction rate. The sigmoid profile observed for permanganate absorption variation at 525 nm vs. time was completely transformed to a linear one under conditions of $[KMnO_4] = [Mn(II)]$. In the presence of manganese sulfate(II), by increasing the amino acid concentration, the reaction rate was increased. Thus, we report the first conclusive evidence of an autocatalytic oxidation process of an amino acid in strong acid media in which Mn^{+2} species are responsible for the effect. The pseudo-order rate constants obtained for both the catalytic and noncatalytic pathways when the amino acid was in excess obeyed the Eyring relation. The presence of free radicals was confirmed, and mechanisms satisfying experimental observations for both catalytic and noncatalytic pathways were presented.

A new family of N_xO_y pyridine-containing macrocycles: Synthesis and characterization of their Y(III), Ln(III), Zn(II), and Cd(II) coordination compounds

Carlos Lodeiro, Rufina Bastida, Emilia Bértolo, and Adolfo Rodríguez

Abstract: Reaction between 2,6-bis(2-formylphenoxymethyl)pyridine and *N*,*N*-bis(3-aminopropyl)methylamine or tris(2-aminoethyl)amine has been used as the starting point for the synthesis of seven oxa-aza macrocyclic ligands, five of them never reported previously. They all feature different pendant arms, which provide a wide range of coordination possibilities. The Schiff base macrocycles L^1 and L^4 and their reduced ligands L^2 and L^5 are derived from 2,6-bis(2-formylphenoxymethyl)pyridine and tris(2-aminoethyl)amine or *N*,*N*-bis(3-aminopropyl)methylamine, respectively. The reaction of L^1 with salicylaldehyde forms L^3, which features an imine bond in the pendant arm. The ligand L^5 has been the precursor for the pendant-armed L^6 and L^7, by alkylation of the free NH groups with methyl-imidazole or methyl-indole. By a template or a nontemplate approach, we have synthesized different mono- and dinuclear complexes with Y(III), Ln(III), Zn(II), and Cd(II) cations. Both the free macrocyclic ligands and their corresponding metal complexes have been characterized by microanalysis, IR, UV–vis, ^{1}H and ^{13}C NMR spectroscopy, FAB mass spectrometry, MS electrospray, and conductivity measurements.

Key words: Schiff-base macrocycle, template synthesis, macrocyclic ligand complexes, lanthanide(III) complexes.

Résumé : On a utilisé la réaction de la 2,6-bis(2-formylphénoxyméthyl)pyridine avec la *N*,*N*-bis(3-aminopropyl)méthylamine ou la tris(2-aminoéthyl)amine comme point de départ pour la synthèse de sept ligands oxa-aza macrocycliques, dont cinq n'avaient pas été rapportés antérieurement. Ils comportent tous des bras pendants différents qui peuvent donner lieu à des possibilités différentes de coordination. Les macrocycles à base de bases de Schiff, L^1 et L^4, ainsi que leurs ligands réduits, L^2 et L^5, sont dérivés respectivement de la 2,6-bis(2-formylphénoxyméthyl)pyridine et de la tris(2-aminoéthyl)amine ou de la *N*,*N*-bis(3-aminopropyl)méthylamine. La réaction du ligand L^1 avec le salicylaldéhyde conduit à la formation du ligand L^3 qui comporte une liaison imine dans le bras pendant. Le ligand L^5 est le précurseur des ligands L^6 et L^7 à bras pendant par l'alkylation des groupes NH libres à l'aide de méthyl-imidazole ou de méthyl-indole. Utilisant des approches avec ou sans gabarit, on a réalisé la synthèse de différents complexes mono- et dinucléaires comportant dans cations Y(III), Ln(III), Zn(II) et Cd(II). On a caractérisé les ligands macrocycliques libres ainsi que leurs complexes métalliques correspondants par microanalyse, spectroscopies IR, UV–vis et RMN du ^{1}H et du ^{13}C, par spectrométrie de masse par bombardement avec des atomes rapides (FAB) ou par ionisation par électronébulisation.

Mots clés : base de Schiff macrocyclique, synthèse à l'aide de gabarit, complexes de ligands macrocycliques, complexes de lanthanide(III).

[Traduit par la Rédaction]

Introduction

Pyridine-containing macrocycles have always attracted considerable interest because of their versatility. They can be used as building blocks that lead to more complicated structures, including systems with more than one cavity, three-dimensional cages, and ligands with additional functional groups attached to the macrocyclic skeleton (1–7). Some macrocycles involving *N*-methyl-pyridine, *N*-methyl-indole, or *N*-methyl-imidazole have been prepared and their coordination ability towards divalent and trivalent metal anions evaluated (8–11).

The synthesis of new receptors with pendant arms that have aromatic or aliphatic units is a fascinating area of research because of the importance of these receptors both in basic and applied chemistry. A subject of special interest is

the design of homo- or hetero-binuclear complexes for biomedical applications that require covalent attachment of the macrocycle system to a recognition site (12–16). Cytotoxic studies of transition metal ion concentrations (i.e., copper(II), zinc(II), and cadmium(II)) have also been carried out using macrocyclic ligands with pendant arms (17, 18). Lanthanide(III) ions have been employed as effective template agents (19, 20) in the synthesis of large macrocycles with pyridine head units.

In the present work, we describe the synthesis and characterization of a new group of oxa-aza macrocyclic ligands containing a pyridine head and phenyl lateral units (see Fig. 1). The heptadentate Schiff base macrocycle L^1 and its corresponding reduced ligand L^2 are derived from the reaction between 2,6-bis(2-formylphenoxymethyl)pyridine (**I**) and tris(2-aminoethyl)amine. Both macrocycles have a flexible amine pendant arm, with potential to form new macrocyclic ligands by condensation with different carbonylic species. Very recently we have reported a related compound of ligand L^1 (21). In those cases the stability of the complexes was increased by coordination of the flexible amine pendant arm to the metal ions. In this work, we present the reaction of L^1 with salicylaldehyde to form L^3, which features an imine bond. The Schiff base ligand L^4 has been obtained by reaction between 2,6-bis(2-formylphenoxymethyl)pyridine and *N*,*N*-bis(3-aminopropyl)methylamine and subsequently reduced to obtain L^5. The ligand L^5 has been the precursor for the pendant-armed macrocycles L^6 and L^7 by alkylation reaction of the NH groups with methylimidazole or methyl-indole. This thus covalently introduces a biological substrate in the macrocycle skeleton. We have studied the coordination capability of the macrocyclic ligands towards different metallic ions. We report the synthesis of the corresponding homodinuclear or mononuclear Y(III), Ln(III), Zn(II), and Cd(II) complexes, using nitrate or perchlorate as the counter ions. Both a direct route and a template approach have been used as required.

Experimental section

Methods

Elemental analyses were performed by the University of Santiago de Compostela Microanalytical Service in Carlo Erba 1108 and Leco CNHS-932 microanalysers. Infrared spectra were recorded as KBr discs or in CsCl windows, using a Mattson Cygnus 100 spectrophotometer. Proton and carbon NMR spectra were recorded using a Bruker WM-300. Positive ion FAB mass spectra were recorded on a Kratos MS50TC spectrometer, using 3-nitrobenzyl alcohol (MNBA), glycerol, or 2-hydroxyethyl disulfide matrixes. Electrospray mass spectra were recorded using acetonitrile and acetic acid mixture as solvent. Melting points were carried out using a BÜCHI melting point apparatus. Conductivity measurements were carried out in 10^{-3} mol dm^{-3} acetonitrile or DMF solutions at 25 °C using a WTW LF-3 conductivimeter. The electronic absorption spectra of some complexes and ligands (MeCN solutions) were measured in the 220–850 nm range using a PerkinElmer Lambda 6 spectrophotometer, and the fluorescence emission spectra of the Eu(III), Tb(III), and Zn(II) complexes were measured on a SPEX F111 Fluorolog spectrofluorometer.

Chemicals and starting materials

2,6-Bis(2-formylphenoxymethyl)pyridine was prepared according to the method reported by Fenton and co-workers (22). *N*,*N*-bis(3-aminopropyl)methylamine and tris(2-aminoethyl)amine, Y(III), Ln(III), Zn(II), and Cd(II) metal nitrates and perchlorates were commercial products from Alfa and Aldrich and were used without further purification. Salicylaldehyde was a commercial product from Carlo Erba. 5-Chloromethyl-4-methylimidazole hydrochloride and 3-chloromethylindole were synthesized according to the literature method (23). Solvents were of reagent grade and were purified by the usual methods. The synthesis of the free imine macrocyclic ligands L^1 and L^4 has been reported in a previous paper (24). Caution: Perchlorate salts are potentially explosive.

Synthesis of the reduced macrocycles L^2 and L^5

The two ligands were prepared by a modification of the method reported in refs. 22 and 25. The corresponding aliphatic polyamine (4.0 mmol) in warm solvent (100 cm^3) was slowly added to a solution of 2,6-bis(2-formylphenoxymethyl)pyridine (4.0 mmol) and $Ba(ClO_4)_2{\cdot}xH_2O$ (4.0 mmol) in warm solvent (300 cm^3). The reaction mixture was refluxed for 6 h, allowed to cool down, and then put in an ice bath. Solid $NaBH_4$ (55.0 mmol) was added carefully in solid incremental amounts, with stirring. After the effervescence stopped, a white precipitate was removed by filtration. The filtrate was reduced to dryness by rotary evaporation, and chloroform (150 cm^3) was added; the resulting solution was then stirred for ca. 72 h. A grey precipitate was removed by filtration; the filtrate was then dried over anhydrous sodium sulphate, and subsequently the sodium sulphate was removed by filtration. The filtrate was concentrated to ca. 10–15 cm^3 and diethyl ether was added, producing the product, which was filtrated (L^2) or decanted (L^5) and dried in vacuo.

FAB-MS (positive-ion) *m*/*z* (%): 461 ([L^5 + H]$^+$, 100), 921 ([2 + 2]$^+$, 10). Anal. calcd. for $C_{28}H_{36}N_4O_2\cdot 3H_2O$ (%): C 65.35, H 9.05, N 10.90; found: C 65.65, H 9.20, N 10.60.

The ligand is air stable and soluble in acetonitrile, absolute ethanol, chloroform, dimethylformamide, and dimethylsulfoxide. It is moderately soluble in dichloromethane and benzene and is insoluble in diethyl ether, petroleum ether, *n*-hexane, and water.

Synthesis of the scorpionand macrocycle L[3]

A fresh solution of L^1 (yellow oil) in absolute ethanol (75 cm^3) was refluxed during 30 min; an ethanolic solution of salicylaldehyde (1.02 mmol) was then added dropwise. The resulting solution, with an intense yellow colour, was refluxed with magnetic stirring for ca. 4 h. After cooling over ice, it was filtered off and reduced to dryness by rotary evaporation. The intense yellow oil obtained was dried under vacuum for 2 h.

Synthesis of the di-pendant-armed macrocycles L[6] and L[7]

Four millimoles of freshly prepared 5-chloromethyl-4-methylimidazole hydrochloride or 3-chloromethylindole were mixed with triethylamine in 50 cm^3 of dry acetonitrile under a nitrogen atmosphere. The mixture was refluxed during 1 h. After the effervescence disappeared, 2 mmol of L^5 dissolved in 50 cm^3 of dry acetonitrile was slowly added. The reaction was then kept at 50 °C in a silicone bath during 5 days, with vigorous stirring and under the nitrogen atmosphere. After 5 days, the solution was filtered, and the filtrate was reduced to dryness. The crude product was then dissolved in water–chloroform and extracted with 3 × 25 cm^3 of $CHCl_3$. The organic phase was washed twice with 2 × 40 cm^3 of water and dried with anhydrous Na_2SO_4. The solution was then filtered and reduced to give an oil.

L[6]

Orange-yellow oil. Yield 26%. [a]Required values are given in parentheses.

(25 cm^3) was added dropwise; magnetic stirring and heating was maintained during the addition. The solution was refluxed for 3 to 4 h, allowed to cool to room temperature, and then concentrated to ca. 15 cm^3. The complexes precipitated directly or after addition of diethyl ether (15 cm^3); they were filtered off and dried in vacuo. Microanalytical data are given in Tables 1 and 2. The complexes are air stable and soluble in acetone, dimethylformamide, methanol, acetonitrile, and dichloromethane. They are moderately soluble in chloroform and insoluble in water and absolute ethanol.

Direct synthesis between L^2, L^3, L^5, L^6, and L^7 and divalent and trivalent metal ions: General procedure for $[ML][X]_n$ (X = ClO_4^- or NO_3^-)

The appropriate metal salt $MX_n \cdot xH_2O$ (Y(III), Ln(III), Zn(II), or Cd(II) and X = NO_3^- or ClO_4^-) (0.50 mmol) was dissolved in methanol (for L^2, L^3, L^5, and L^7) or absolute ethanol (for L^6) (20 cm^3) and added to a solution of the ligand (0.50 mmol) in methanol (L^2, L^3, and L^5) or chloroform (L^6 and L^7) (50 cm^3). The mixture was stirred during 24–72 h at room temperature and cooled. When a precipitate did not developed immediately, the solution was partially concentrated under vacuum to give a solid, although in some cases the precipitation was aided by addition of some diethyl ether (ca. 5–10 cm^3). The products were filtered off, washed with cold absolute ethanol or methanol, and dried in vacuo.

Microanalytical data are given in Tables 1, 2, and 3. The complexes are air stable and are soluble in acetone, methanol, acetonitrile, and dichloromethane. They are moderately soluble in dimethylformamide and insoluble in chloroform, water, and absolute ethanol.

Results and discussion

Synthesis of the free ligands

We have previously reported that direct reaction between (**I**) with aliphatic or aromatic amines in the absence of template agents is a valid method to obtain Schiff-base and oxa-aza macrocyclic ligands (2, 19, 24). We now present seven macrocyclic ligands derived from this dicarbonyl precursor and two aliphatic diamines (mentioned in the starting material section) and the study of the complexation capacity of these ligands with a range of trivalent and divalent metal ions. Ligands L^1 and L^4 were obtained by reaction of (**I**) with both aliphatic diamines. These two macrocycles have already been reported in a previous paper (24).

Using L^1 and L^4 as the starting point, we have prepared five new macrocyclic ligands with different donor atom arrays (see Fig. 1). L^2 was synthesized by reduction of L^1, formed in situ using barium perchlorate, with sodium borohydride. In a similar way, L^5 was obtained from L^4. The pendant-armed macrocycle L^3 was obtained by a Schiff-base reaction between L^2 and salicylaldehyde, with formation of an iminic bond in the pendant arm. The ligands L^6 and L^7 were obtained by reaction of L^5 with 5-chloromethyl-4-methylimidazole hydrochloride and 3-chloromethylindole, respectively, following the method described in the experimental section.

We have found that the template approach is more effective for the preparation of L^2 and L^5, with yields of 64% and 58%, respectively. In previous papers, we have reported the effectiveness of a direct approach in the synthesis of large macrocycles, in which the presence of aromatic groups in

both organic precursors helps to minimize the formation of acyclic structures (19, 20). However, when the direct route was used to prepare L^2 and L^5, the aliphatic nature of the amine precursors seemed to increase the formation of undesired acyclic compounds, and low yields were obtained for both macrocycles. A template approach was thus chosen, and we have found that the use of barium(II) as the template agent increased the yields of the two macrocycles.

The FAB mass spectra for L^2, L^3, and L^5, as well as the electrospray mass spectra for L^6 and L^7, show the highest molecular weight peaks at *m*/*z* 462 (L^2), 566 (L^3), 461 (L^5), 650 (L^6), and 720 (L^7), corresponding to ($[L + H]^+$). The IR spectra feature the secondary amine N–H stretching band at ca. 3200–3292 cm^{-1} (in L^2, L^3, and L^5) or $\delta(NH)_{pyrrolic}$ at ca. 3330–3400 cm^{-1} (in L^6 and L^7). The spectra for L^2 and L^5 do not show bands in the 1620–1640 cm^{-1} region, where imine stretches are expected. The spectrum for L^3 features a band at ca. 1630 cm^{-1}, owing to the imine group present in the pendant arm. For L^7 it is possible to observe a band at ca. 3266 cm^{-1}, attributable to δ(NH) of the indole group.

The ^1H NMR spectra in CD_3CN (for L^2 and L^3) and in $CDCl_3$ (for L^5, L^6, and L^7) confirm the integrity of the ligands in solution. The ^{13}C NMR spectra for L^2, L^5, L^6, and L^7 feature 27, 28, 38, and 46 signals, respectively, one for each C in the macrocyclic skeleton. This suggests that both the reduction of the imine bonds and the presence of the pendant arms lead to an increase in the ligand flexibility and unsymmetrical behaviour of the ligands. UV–vis spectra in acetonitrile were recorded for L^2, L^3, and L^5. The broad absorption bands observed at 269 nm for L^2, at 257 and 317 nm for L^3, and at 266 nm for L^5 can be attributed to the π–π* transitions of the pyridine and phenyl groups.

Metal complexes: Microanalytical and molar conductivity data

Yttrium and lanthanide trivalent metal ions and divalent zinc and cadmium have been used to explore the coordination behaviour of this new family of oxa-aza macrocycles. Condensation between 2,6-bis(2-formylphenoxymethyl)pyridine and tris(2-aminoethyl)amine (L^1) or *N*,*N*-bis(3-aminopropyl)methylamine (L^4) in the presence of the corresponding hydrated metal salt, in a 1:1:1 molar ratio, leads to the formation of mononuclear complexes formulated as $[LaL^1](ClO_4)_3 \cdot 10H_2O$, $[ZnL^1](ClO_4)_2 \cdot 4H_2O$, and $[ML^4](X)_n \cdot xH_2O$ (M = Y(III), Ce(III), Nd(III), Eu(III), Ho(III), Er(III), Lu(III), and Cd(II); X = NO_3^- or ClO_4^-) and dinuclear complexes formulated as $[Cd_2L^1](ClO_4)_4 \cdot 5H_2O$ and $[M_2L^4](X)_n \cdot xH_2O$ (M = La(III); X = NO_3^- and M = Zn(II); X = ClO_4^-). Microanalytical data for these complexes are shown in Table 1 (L^1) and Table 2 (L^4).

Only complexes with trivalent metal ions have been obtained with L^2, with the formula $[ML^2](X)_3 \cdot xH_2O$ (M = Y(III), La(III), Ce(III), Sm(III), Gd(III), and Er(III); X = ClO_4^- or NO_3^-). Reaction between L^5 and Y(III), La(III), Gd(III), Eu(III), Tb(III), Zn(II), and Cd(II) leads to the formation of mononuclear complexes, formulated as $[ML^5](X)_n \cdot xH_2O$ (M = La(III), Eu(III), Gd(III), Tb(III), and Zn(II); X = ClO_4^- or NO_3^-), as well as the dinuclear complexes $[M_2L^5](X)_n \cdot xH_2O$ (M = Y(III); X = NO_3^- and M = Cd(II); X = ClO_4^-). Microanalytical data for these complexes are shown in Table 1 (L^2) and Table 2 (L^5). The syntheses were also attempted with the perchlorates of Zn(II) and Cd(II) for L^2, as well as the nitrates of La(III) and the perchlorates of Ce(III) and Eu(III) for L^5; however, with these metals only species with unsatisfactory analytical data were obtained.

A direct method has been successfully used to synthesize complexes with L^3. Reaction of freshly prepared L^3 in the presence of the corresponding metal salt yielded mononuclear complexes of formula $[ML^3](X)_3 \cdot xH_2O$ (M = La(III) and Sm(III); X = ClO_4^-; M = Eu(III) and Tb(III); X = NO_3^-) (see Table 1) and the dinuclear complexes $[Pr_2L^3](ClO_4)_6 \cdot 5H_2O$ and $[Zn_2L^3](ClO_4)_4 \cdot 4H_2O$. Under the experimental conditions employed, it has been impossible to isolate the expected metal complexes with the nitrates of Y(III) and La(III) and with the perchlorate of Cd(II).

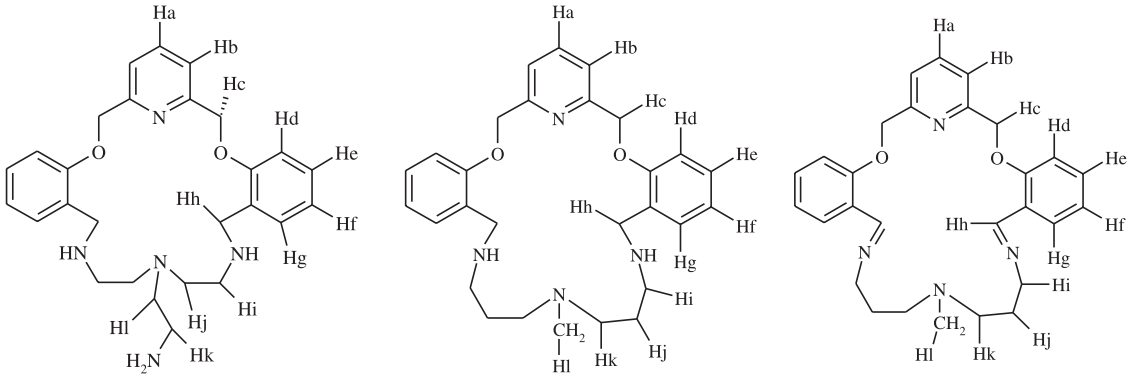
The reaction between equimolar amounts of freshly prepared L^6 and L^7 and the perchlorates of La(III) and Zn(II), as well as the nitrates of Y(III) and Gd(III), gave analytically pure products of formula $[LaL^6](ClO_4)_3 \cdot 7H_2O$, $[M_2L^6](NO_3)_6 \cdot xH_2O$ (M = Y(III) and Gd(III)), and $[M_2L^7](ClO_4)_n \cdot H_2O$ (M = La(III) and Zn(II)). The presence of extra donor atoms in the pendant arms leads to the formation of binuclear species with the majority of the metal ions employed. The syntheses were also attempted using the perchlorate of Cd(II) and the nitrates of Eu(III) and Tb(III), but only a mixture of unreacted metal salt and free ligand were recovered.

In the absence of crystal structures, which are decisive in the elucidation of the coordinative environment of the metal ions in these molecules, it is difficult to give an appropriate explanation for the formation, depending on the ligand and the metal ion, of di- or mononuclear complexes. Reaction with Cd(II) and Zn(II) yields dinuclear complexes in most cases, probably because of the small size of both ions when compared with the lanthanide(III) cations. It is also noteworthy that the increase in the flexibility and complexity of the ligands, from L^1 to L^3 and from L^4 to L^6 or L^7, does not appear to affect especially the formation of the corresponding complexes.

Molar conductivity data, measured at room temperature using DMF or acetonitrile solutions, show the ionic nature of all complexes in these solvents. The values are in accordance with those expected for 1:1 or 1:2 electrolytes (for complexes with L^1, L^2, L^3, L^4, and L^5) or for 1:2 or 1:3 electrolytes (L^6 and L^7 complexes) (26). The value for the complex $[Pr_2L^3](ClO_4)_6 \cdot 5H_2O$, measured in acetonitrile, falls between the ranges reported for 1:2 and 1:3 electrolytes. Data for the different complexes are given in Tables 1, 2, and 3. Molar conductivities were measured again 1 week after sample preparation for the complexes containing L^2, L^5, and L^6; a significant increase in the values was observed in some complexes, suggesting the displacement of counter ions from the coordination sphere by solvent molecules (26).

Metal complexes: FAB and electrospray mass spectra

All mass spectra feature peaks attributable to the corresponding macrocyclic ligand, confirming the stability of the seven macrocycles in their metal complexes. Moreover, the spectra show peaks at higher molecular weights, which in some cases have also been assigned. The spectra for the complexes with L^1 contain peaks attributable to $[ML^1]^+$ (M = La(III) and Cd(II)) and $[ZnL^1(ClO_4)]^+$. For the complexes with L^2, the spectra show peaks assignable to the fragments $[ML^2(ClO_4)]^+$ (M = La(III) and Ce(III)), and $[L^2(ClO_4)]^+$ and $[LaL^2(NO_3)]^+$ are present. In the case of the L^3 complexes, peaks assignable to the fragments $[ML^3(ClO_4)]^+$ (M = La(III), Pr(III), Sm(III) and Zn(II)), $[ML^3(NO_3)]^+$ (M = Eu(III)), and $[ML^3]^+$ (M = Eu(III) and Sm(III)) can be observed.



The spectrum of the dinuclear nitrate La(III) complex with L^4 contains peaks corresponding to the fragments $[La_2L^4(NO_3)_3]^+$ and $[LaL^4(H_2O)]^+$. The mononuclear Ce(III), La(III), and Nd(III) complexes exhibit peaks due to the species $[ML^4(ClO_4)_2]^+$ (M = La(III) and Ce(III)) and $[NdL^4(NO_3)]^+$, confirming the presence of the metal ions in the complexes. Peaks attributable to the fragment $[L^4(ClO_4)]^+$ are also present in the spectra of the complexes with Ce(III) and Cd(II). For the complexes with L^5, the mass spectra feature peaks assignable to the fragments $[ML^5(NO_3)_2]^+$ (M = Y(III), Eu(III), and Tb(III)), $[ML^5(ClO_4)]^+$ (M = La(III), Gd(III), Zn(II), and Cd(II)), and $[ML^5]^+$ (M = Y(III) and Zn(II)). The FAB mass spectra for the L^6 complexes show peaks assignable to the fragments $[ML^6]^+$ and $[L^6(NO_3)_2]^+$, while for the L^7 complexes, peaks corresponding to the fragments $[LaL^7]^+$ and $[ZnL^7(H_2O)]^+$ can be observed.

Infrared spectra

The IR spectra for the complexes with L^1, L^2, L^4, and L^5 confirm the cyclic nature of the ligands in their metal complexes. The spectra for the complexes with L^1 and L^4 show a band at ca. 1639–1660 cm^{-1}, attributable to the imine groups, and no bands due to ν(C=O) vibrations. In the Cd(II) complex with L^1, a band at ca. 3227 cm^{-1}, attributable to

Fig. 2. ^{1}H NMR data (300 MHz) for $[LaL^2](ClO_4)_3\cdot 9H_2O$ (in CD_3CN), $[LaL^5](ClO_4)_3\cdot 6H_2O$ (in $CDCl_3$), and $[La_2L^4](NO_3)_6$ (in DMSO-d_6).

L^2 **L^5** **L^4**

$\nu(NH_2)$, is also observed (27). The spectra exhibit medium to strong bands at ca. 1603–1597 and 1458 cm^{-1}, as expected for the $\nu(C{=}C)_{ar}$ and $\nu(C{=}N)_{py}$ ring vibrations (28). The $\nu(C{=}N)_{py}$ band, as well as those corresponding to the imine groups, are generally shifted to higher wave numbers when compared with those of the free ligands, suggesting coordination via nitrogen atoms (29, 30). The IR spectral results for the complexes with L^3 confirm that the imine group is present in the pendant arm of the ligand, showing an intense band at ca. 1630–1650 cm^{-1} that is attributable to $\nu(C{=}N)$ and no bands due to $\nu(C{=}O)$ and $\nu(NH_2)$ groups (27). The bands attributable to $\nu(NH)$ in the complexes of L^2, L^3, and L^5 cannot be observed because of the existence of a broad band at ca. 3380–3520 cm^{-1}, assignable to the stretching and bending modes of water (31). For the complexes with L^2 and L^5, the absence of bands at ca. 1620–1660 cm^{-1} in the spectra confirms the reduction of the iminic groups.

The IR spectra of the complexes with L^6 and L^7 also contain absorption bands characteristic of the ligand frameworks. The sharp absorption band occurring in the region 3340–3060 cm^{-1} is attributable to $\nu(NH)$ of the indole or imidazole groups. For the complexes of L^6, the band at ca. 1648 cm^{-1} can be assigned to the $\delta(NH)$ of the imidazole groups. Bands at ca. 1602 and 1458 cm^{-1}, corresponding to the aromatic ring vibrations, are also present. These bands are shifted to lower energy when compared with their position in the spectra of the free ligands, probably because of coordination to the metal ion.

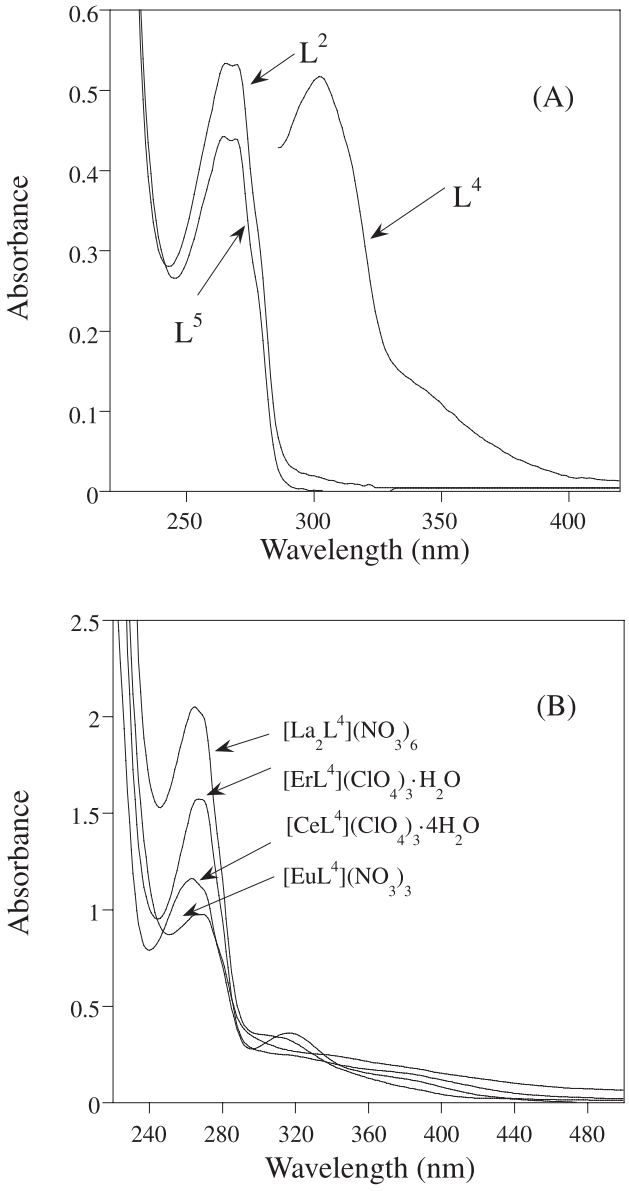
The absorptions of the counter-ions provide some useful structural information. The IR spectra for all nitrate complexes show bands at ca. 1448–1460 (ν_5), 1300 (ν_1), and 1030 (ν_2) cm^{-1}, suggesting the existence of coordinated nitrate groups, as well as a band at ca. 1384 cm^{-1}, attributable to the presence of ionic NO_3^- (32, 33). Although the spectra do not allow a clear-cut difference between mono- and bidentate chelating nitrates, the separation between ν_5 and ν_1 (ca. 160 cm^{-1}) suggests the presence of nitrate groups acting as bidentate (34, 35). Regarding the perchlorate complexes, bands attributable to the asymmetric Cl–O stretching mode at ca. 1088 cm^{-1} (ν_3) and the asymmetric Cl–O bending mode (ν_4) at ca. 625 cm^{-1} can be observed. The highest energy band consists in three well-resolved maxima at ca. 1121, 1115, and 1088 cm^{-1}; the ν_4 band also shows splitting with maxima at ca. 636 and 626 cm^{-1} (36). The splitting of these bands is indicative of coordination of at least one perchlorate anion to the metal.

NMR spectra

The ^{1}H NMR spectra of some diamagnetic complexes with Y(III), La(III), and Zn(II) were recorded immediately after dissolution in CD_3CN, DMSO-d_6, or CD_3OD at room temperature. The spectra of the complexes $[LaL^1](ClO_4)_3\cdot 10H_2O$ and $[ZnL^1](ClO_4)_2\cdot 4H_2O$ (in CD_3CN) are complicated, showing more signals than expected. This may be indicative of the following: (*i*) the co-existence of additional processes in solution such as dimerization; (*ii*) the existence of demetallation processes in solution or geometric changes; and (or) (*iii*) the hydrolysis of the iminic groups. We ran the spectra at the following different temperatures: 298.15, 313.15, and 323.15 K. In all cases the number of signals never decreased notably, suggesting slow intersystem changes. The complexes $[LaL^2](ClO_4)_3\cdot 9H_2O$ and $[La_2L^4](NO_3)_6$ (in DMSO-d_6) and $[LaL^5](ClO_4)_3\cdot 6H_2O$ (in CD_3CN) gave the expected simple spectra, indicating the integrity of the complexes in those solvents (see Fig. 2, Table 4).

The spectra of the complexes $[LaL^3](ClO_4)_3\cdot 5H_2O$, $[YL^4](NO_3)_3\cdot 5H_2O$, $[Zn_2L^4](ClO_4)_4\cdot 2H_2O$, and $[LaL^4](ClO_4)_3\cdot 4H_2O$ (in CD_3CN) are complicated and show more signals than expected (complex and free ligand signals), which may be indicative of the existence of demetallation processes in solution or dimerization reactions in the dinuclear complexes. Nevertheless, clear peaks at δ 9.20, 8.60, 9.00, and 9.20 ppm, corresponding to the imine protons in the ligands, are present. The ^{1}H NMR spectra of $[Y_2L^6](NO_3)_6\cdot 5H_2O$ and $[LaL^6](ClO_4)_3\cdot 7H_2O$ (in DMSO-d_6) are also complicated, maybe because of the nonsymmetric topology of the ligand. Nevertheless, clear peaks at δ 7.8 and 8.8 ppm, corresponding to the aromatic imidazol protons of the pendant arms, as well as the signals attributable to aromatic rings of the macrocycle (37), confirm the integrity of the ligand L^6 in both metal complexes.

Electronic absorption spectra



The electronic spectra for L^2, L^3, L^4, and L^5, as well as some of their corresponding metal complexes, were recorded at room

temperature in acetonitrile solutions. The spectra for the reduced ligands L^2 and L^5 present one band at ca. 269–266 nm (ε ≈ 5344 and 3595 $mol^{-1}\cdot L\cdot cm^{-1}$, respectively). The Schiff base ligands L^3 and L^4 exhibits two bands, at ca. 257 nm (ε ≈ 12 444 $mol^{-1}\cdot L\cdot cm^{-1}$) and ca. 317 nm (ε ≈ 2921 $mol^{-1}\cdot L\cdot cm^{-1}$) for L^3 and at ca. 303 nm (ε ≈ 16 066 $mol^{-1}\cdot L\cdot cm^{-1}$) and ca. 351 nm (ε ≈ 5930 $mol^{-1}\cdot L\cdot cm^{-1}$) for L^4. In all cases, these bands are associated with the π–π* and *n*–π* electronic transitions in the chromophores — pyridine and phenyl rings — that are present in the macrocyclic skeletons (38).

The UV–vis spectra for some Y(III), Ln(III), and Zn(II) nitrate and perchlorate complexes of L^2 and L^4 exhibit two or three absorption bands in the regions 262–270, 315–325, and 370–385 nm. The shift in the absorption maxima that is observed when it is compared with those of the free macrocycles may be due to the presence of the metal in the species and could be attributable to the π–π* and *n*–π* transitions of the coordinated macrocycles. In some cases, the intensity of the absorption bands changed slightly when the spectra were recorded after 1 and 2 weeks, suggesting the displacement of some coordinated anions or water molecules by acetonitrile molecules. The spectral data for the complexes are given in Table 5, and the electronic spectra for the free ligands L^2, L^4, and L^5 and some ML^4 metal complexes are shown in Fig. 3.

Fluorescence emission spectra

Room-temperature emission spectra were registered using 10^{-5}–10^{-6} mol L^{-1} acetonitrile solutions for the Eu(III), Tb(III), and Zn(II) complexes with L^3, L^4, and L^5. Unfortunately, no emission could be detected in these complexes, probably because of (*i*) the presence of water molecules in the complexes; (*ii*) the presence of free uncoordinated amines with the lone-pair unoccupied; and (*iii*) the coexistence of nonradiative mechanisms that quenched the emission, in a similar way to those reported for other macrocycle ligands derived from similar aliphatic or aromatic precursor (2, 19, 24, 39).

Conclusions

Seven [1+1] oxa-aza macrocyclic ligands, five of them new, have been prepared using 2,6-bis(2-formylphenoxymethyl)pyridine as the precursor. Treatment of the previously reported Schiff-base macrocycles L^1 and L^4 with $NaBH_4$, in the presence of Ba(II) as a template agent, gave the corresponding reduced macrocycles L^2 and L^5. The more sophisticated ligands L^3, L^6, and L^7, provided with pendant arms, have been synthesized by condensation or alkylation reactions with the amine groups present in L^2 and L^5. Complexes with these seven ligands have been prepared by template reaction or direct methods, using the nitrates and (or) perchlorates of Y(III), Ln(III), Cd(II), or Zn(II) ions.

The complexes are mono- or dinuclear, depending on the macrocyclic ligand and (or) metal salt employed. Although

Note: [Complex] = 10^{-4}–10^{-6} mol L^{-1}; *sh* = shoulder.

it is not possible to establish any clear link between the formation of mono- or dinuclear species and the size of the cation employed, it is worth mentioning that reaction with Cd(II) and Zn(II) generally generates the dinuclear complex, suggesting that the macrocyclic cavity in L^1, L^3, L^4, and L^5 is large enough to accommodate two of these metal cations. The complexes obtained with L^6 and L^7, provided with two lateral pendant arms, are always dinuclear except in one case, suggesting that the increase in the number of donor atoms present in the macrocyclic skeleton facilitates the formation of dinuclear compounds and showing the ability of these two macrocycles to host two metal ions.

1,2-Bis-(1-{3-pyridyl-}3-methyltriazen-3-yl)ethane: Synthesis and X-ray crystal structure

Keith Vaughan, Elizabeth Turner, and Hilary Jenkins

Abstract: 3-Aminopyridine is diazotized in the conventional manner and the diazonium salt coupled with *N*,*N*′-dimethylethylenediamine to afford the title compound (**1**), which is a potential antitumour agent. The compound has been characterized by spectroscopic methods. The ^{1}H NMR spectrum shows evidence of rotational conformerism, from the observation of broadening of the N-methyl signals in the room-temperature spectrum. Low-temperature NMR spectra (down to 223 K) show the presence of three distinct rotamers. The crystal structure of 1,2-bis-(1-{3-pyridyl-}3-methyltriazen-3-yl)ethane (**1**) has been determined by single crystal X-ray diffraction analysis. The bis-triazene (**1**) exists as the "staggered" conformation in the solid state, with an "*anti–anti*" configuration around the N—N bond of the triazene units. The crystal structure of **1** is compared with the closely related bis-triazene **2** and also compared with the simple mono-triazene **3**. Crystal data for **1**, $C_{14}H_{18}N_8$: orthorhombic, space group *Pbca*, a = 11.2550(8) Å, b = 8.8507(6) Å, c = 15.0069(10) Å, β = 90°, and V = 1494.91(18) Å^3, for Z = 4.

Key words: triazene, bis-triazene, pyridine, X-ray, VT NMR, diazonium coupling.

Résumé : On a réalisé la diazotation de la 3-aminopyridine de la façon conventionnelle et on a procédé au couplage du sel de diazonium avec le *N*,*N*′-diméthyléthylènediamine pour obtenir le produit mentionné dans le titre (**1**), un agent antitumoral potentiel. Le composé a été caractérisé par des méthodes spectroscopiques. L'élargissement des signaux du groupe N-méthyle dans le spectre RMN du ^{1}H à la température ambiante suggère l'existence de conformères rotationnels. Le spectre RMN à des températures allant jusqu'à 223 K met en évidence la présence de trois rotamères distincts. La structure cristalline du 1,2-bis-(1-{3-pyridyl-}-3-méthyltriazén-3-yl)éthane (**1**) a été déterminée par diffraction des rayons X sur un cristal unique. Dans l'état solide, le bis-(triazène) existe dans une conformation décalée dans laquelle on observe une configuration « *anti–anti* » autour de la liaison N—N des unités triazènes. On a comparé la structure cristalline du composé **1** avec celle du bis-triazène **2** qui lui est très apparentée ainsi qu'avec celle du monotriazène simple **3**. Les données cristallographiques pour **1**, $C_{14}H_{18}N_8$, sont: orthorhombique; groupe d'espace *Pbca*, a = 11,2550(8) Å, b = 8,8507(6) Å et c = 15,0069(10) Å, β = 90°, V = 1494,91(18) Å^3 et Z = 4.

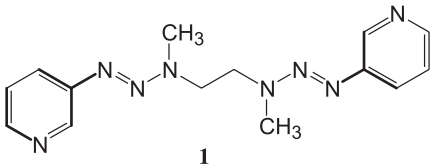
Mots clés : triazène, bis-triazène, pyridine, rayons X, RMN à température variable, couplage de diazonium.

[Traduit par la Rédaction]

Introduction

In a previous study, a series of 1,2-bis-(1-aryl-3-alkyltriazen-3-yl)ethanes, e.g., **2**, was synthesized by diazonium coupling with *N*,*N*′-dimethylethylenediamine (1). Subsequently, two compounds in this series were characterized by X-ray crystallography (2), and the bis-triazene structure was confirmed. Heterocyclic modification to the benzene ring in these compounds may be seen as a way to evoke more enhanced antitumour activity. In this paper we report the first example of a bis-(pyridyltriazen-3-yl)ethane, compound **1**, with a complete X-ray crystal structure and a comparison of the structure with that of the bis-aryl triazenylethane, **2**, and of the 3,3-dimethyltriazene, **3** (3). The solution of the crystal structure of **1** is the first reported example of a 1-heteroaryl-3,3-dialkyltriazene crystal structure.

Synthesis



3-Aminopyridine (0.948 g, 0.010 mol) was dissolved in 2 mol L^{-1} hydrochloric acid (15 mL), and the solution was cooled to 0 °C. The cold solution was diazotized with aqueous sodium nitrite (0.827 g, 0.012 mol in 6.0 mL water) and then stirred in the cold for 0.5 h. The diazonium salt was treated gradually with a cold solution of *N*,*N*′-dimethylethylenediamine (0.450 g) in water (5.0 mL). The mixture was stirred cold for a further 0.5 h, and the solution was then basified with saturated sodium bicarbonate solution to pH 8. The solid precipitate was removed by vacuum filtration and dried to give the crude bis-triazene (1.062 g, 35% yield), which recrystallized from toluene to afford the crystal for X-ray study. mp 130–132 °C. ^{1}H NMR ($CDCl_3$) δ: 3.30 (6H, broad, N-Me), 4.14 (4H, s, N-CH_2), 7.26–8.41 (8H, m, aro-

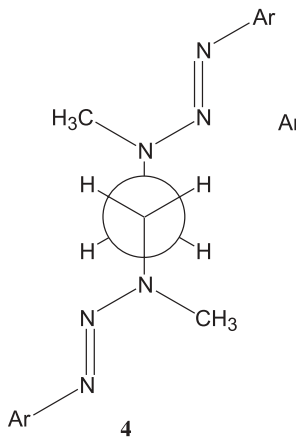
matic). ^{13}C NMR ($CDCl_3$) δ: 34.72 (N-Me), 53.59 (N-CH_2), 123.72, 125.77, 142.80, and 146.09 (aromatic). Calcd. for $C_{14}H_{18}N_8$ (%): C 56.4, H 6.0, N 37.6; found: C 56.4, H 6.0, N 37.2.

Crystallography



All X-ray diffraction data were collected on a Siemens SMART/CCD diffractometer equipped with an LT-II low temperature device.[2] Diffracted data were corrected for absorption corrections using the SADABS program (4). SHELXTL (5) was used for the structure solution, and refinement was based on F^2. All the nonhydrogen atoms were refined anisotropically. Hydrogen atoms were fixed in calculated positions and refined isotropically on the basis of corresponding C atoms (U(H) = 1.2 Ueq(C)). Structure refinement parameters for **1** are given in Table 1. Atomic coordinates and equivalent isotropic displacement parameters for **1** are provided in Table 2. Bond lengths and bond angles for compound **1** are given in Table 3.

Results and discussion

An ORTEP perspective view of the 1,2-bis-(1-{3-pyridyl-}3-methyltriazen-3-yl)ethane (**1**) is shown in Fig. 1. In the solid state, **1** adopts the "staggered" conformation with respect to the orientation around the C—C bond of the ethane unit and also has the *trans* configuration around each of the N=N azo groups in the triazene moieties. These geometries are pre-

dictable, but the orientation of the triazene units around the N—N single bonds is more interesting. With respect to the orientation around the N—N bonds (N(3)—N(4) in Fig. 1), bis-triazene **1** adopts the "*syn–syn*" rotamer, as opposed to the "*anti–anti*" rotamer. (In this context, the terms *syn* and *anti* refer to the configuration of the C(7) methyl carbon and the N(2) nitrogen with respect to the N(3)—N(4) bond.) A Newman projection of this preferred structure is shown in structure **4**.

The comparable perspective of compound **2**, taken from the X-ray structure in ref. 2, looks like the Newman projection in structure **5**. The orientation around the C—C bond of the ethane unit is similarly staggered, but the triazene units adopt the "*anti–anti*" rotamer with respect to the N—N bond. Taken from the other perspective of the rotameric equilibrium shown below, it can be seen that the bis-pyridyltriazenylethane (1) prefers the "*syn–syn*" rotamer (**1B**), whereas the bisaryltriazenylethane (2) prefers the "*anti–anti*" rotamer (**1A**) (Scheme 1).

Previous NMR studies (1) of bis-triazenes of type **2** were very successful in elucidating the equilibrium behaviour in solution. The variable temperature NMR (VT NMR) spectra of the title compound **1** in $CDCl_3$ solution have been recorded down to 223 K (see Fig. 2), and it is apparent that there are three distinct species of this molecule in solution. The broad signal of the methylene protons at 4.14 parts per million (ppm) resolves into two signals of unequal intensity at 223 K, but the clearest picture comes from the separation of the N-methyl signal at 3.30 ppm. In the low-temperature spectrum, the three species visible are as follows: (*a*) the most abundant "*anti–anti*" species **1A**, with equivalent methyl signals at 3.10 ppm; (*b*) the least abundant "*syn–syn*" species **1B**, also with equivalent methyl signals at 3.43 ppm; and (*c*) the "*syn–anti*" species **1C**, with nonequivalent methyl signals at 3.16 and 3.40 ppm. These assignments are based on a comparison with the previously reported (1) NMR spectra of the benzenoid analogues of **1** and on the intuitive assumption that the *anti*-configuration is the most stable. From the relative intensities of the signals in the low-temperature NMR spectrum, the relative amounts of the three rotamers in the mixture at 223 K is 86% **1A**, 2% **1B**, and 12% **1C**. In this context, the terms "*syn*" and "*anti*" refer to the orientation of the CH_3 and Ar-N groups around the N3—N4 bond.

Table 3. Bond lengths (Å) and angles (°) for **1**.

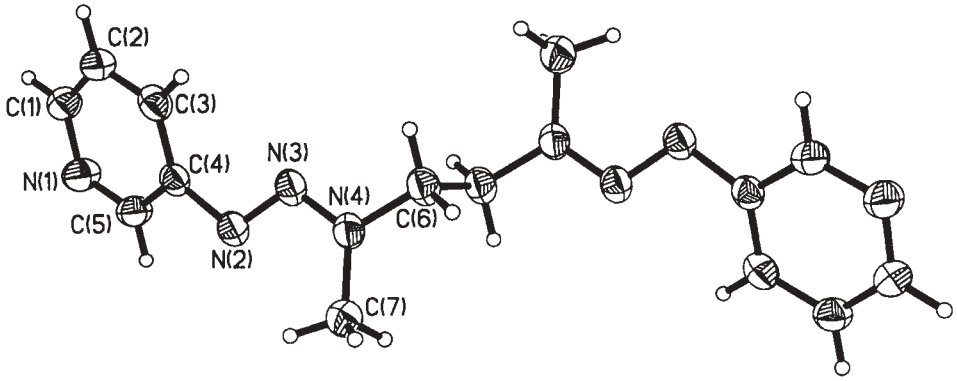
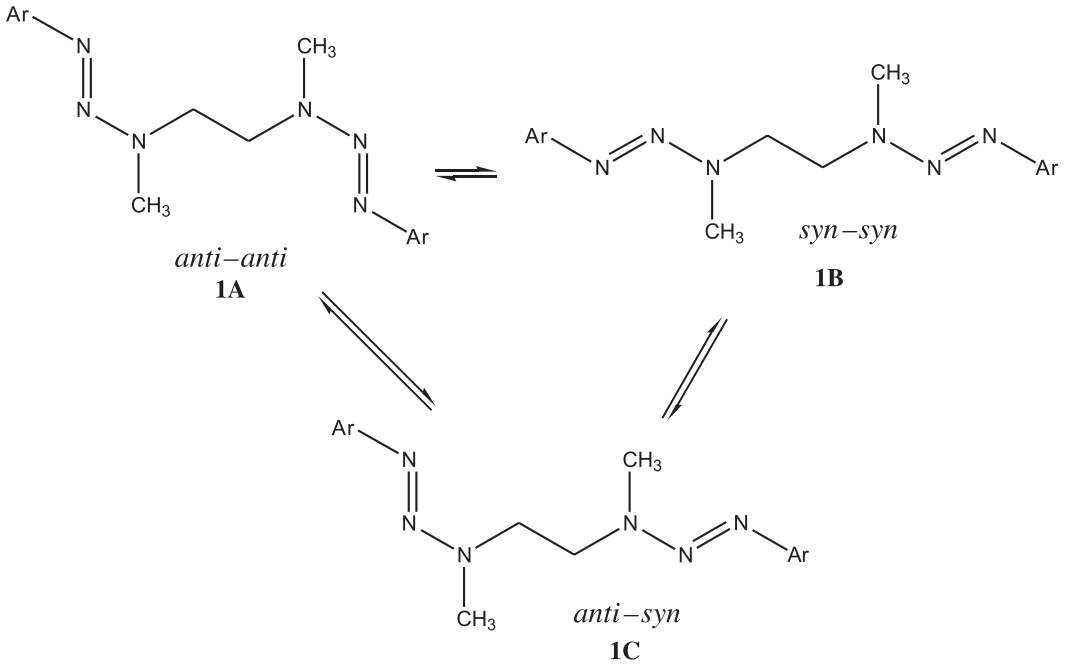
C(2)—C(3)	1.384(4)
C(3)—C(4)	1.389(4)
C(4)—C(5)	1.386(4)
C(6)—C(6)#1	1.528(6)
Bond angles (°)	
C(5)-N(1)-C(1)	116.7(2)
N(3)-N(2)-C(4)	111.0(2)
N(2)-N(3)-N(4)	113.9(2)
N(3)-N(4)-C(7)	122.2(2)
N(3)-N(4)-C(6)	115.2(2)
C(7)-N(4)-C(6)	121.9(2)
N(1)-C(1)-C(2)	123.6(3)
C(1)-C(2)-C(3)	119.2(3)
C(2)-C(3)-C(4)	118.5(3)
C(5)-C(4)-C(3)	117.8(3)
C(5)-C(4)-N(2)	116.6(2)
C(3)-C(4)-N(2)	125.5(2)
N(1)-C(5)-C(4)	124.2(3)
N(4)-C(6)-C(6)#1	111.8(3)



The bond lengths in structure **1** are comparable with previously reported (2, 3) results with similar triazenes. Table 4 shows a comparison of key bond lengths and bond angles for compounds **1**, **2**, and **3**. (It should be noted that the atom notations, e.g., N(2), N(3), N(4), etc., are the notations used in this structure for compound **1**; the atom notations used in refs. 2 and 3 may not be the same, but the bond lengths and angles listed in Table 4 have been cross-checked with meticulous attention to ensure that the analogous bonds are being compared.) The comparison of bond lengths in the three structures is remarkably close. The N=N azo linkages of the triazene moiety is observed at ca. 1.28 Å, whereas the N—N single bond of the triazene is consistently longer at ca. 1.32 Å but not as long as expected for an isolated N—N single bond, ca. 1.43 Å. This shortening of the N3—N4 bond in the triazene moiety is consistent with the resonance shown in Scheme 2, which gives the N3—N4 bond some double bond character.

The N-methyl bond length in the three structures is consistent at ca. 1.45 Å, as is the N2—aryl bond length at ca. 1.42 Å. The bond length of the C—C bond of the ethane spacer in **1** and **2** is very close at ca. 1.53 Å.



Bond angles in structure **1** indicate some distortion, arising from different interactions of N2 and N3 with neighbouring groups. Repulsion between the lone pair on N2 with the C7 methyl group causes the bond angle N3-N4-C7 to open up to 122.2°, with the concomitant compression of the

Scheme 1.

Scheme 2.

N3-N4-C6 bond angle to 115.2°. Similarly, steric crowding between N3 and the hydrogen attached at C3 causes the bond angle C3-C4-N2 to open up to 125.5°, with compression of C5-C4-N2 to 116.6°. The bond angle N4-C6-C6′ is found to be 111.8°, indicating slight distortion from tetrahedral geometry around C6.

The bond angle comparison of the three structures **1**, **2**, and **3** shows much similarity but also some real divergence. The major divergence in bond angles occurs in compounds **1** and **2** with respect to the bond angles around N4. The N-N-Me bond angle in structure **1** is 122.2(2)° compared with 115.9(3)° in structure **2**; the order of the N-N-CH_2 bond angles in **1** and **2** is predictably in the reverse order, 115.2(2)° in **1** compared with 123.4(3)° in **2**. The C-N-C angle at N4 is very close, 121.9(2)° vs. 120.6(3)°. This striking variation in bond angle appears to be consistent with the conformational preference of the two compounds described earlier. The crystal structure of **1** shows that this compound adopts the "*syn–syn*" structure (rotamer **1B**), which leads to repulsion between N(2) and C(7) (Fig. 1). This repulsion causes the bond angle N(3)-N(4)-C(7) to open up to 122.2(2)°, with a corresponding compression of the bond angle N(3)-N(4)-

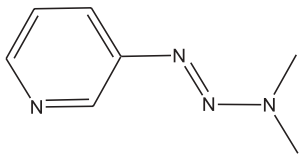
C(6) to 115.2(2)°. Compound **2** adopts the "*anti–anti*" structure (rotamer **2B**), leading to compression of the N(3)-N(4)-C(7) bond to 115.9(3)°.



The comparison of bond lengths and bond angles in Table 4 shows that the presence of the heteroatom in the pyridyl ring has virtually no direct effect on the molecular parameters. However, there is one striking effect of the heteroatom, and that is the orientation of the triazene moiety with respect to the orientation of the pyridyl ring, as illustrated by structures **6** and **7**. The preferred structure of **1** in the solid state is that represented by **6**, i.e., with the triazene moiety angled away from the pyridyl nitrogen. There does not appear to be

© 2004 NRC Canada

any reason for this preference intrinsic to the molecule itself, and the reason for this preference may be something to do with the packing of molecules within the crystal.

6

7

A packing diagram of the crystal structure of **1** is shown in Fig. 3. There is no immediate indication of π-stacking between pyridyl rings of adjacent molecules. If anything, the plane of the pyridyl ring of one molecule is almost perpendicular to that of its neighbour. However, there is a close interaction between the pyridyl ring and the triazene nitrogen atoms of a neighbouring molecule. As shown in the packing diagram (Fig. 3), the structure is arranged to allow the lone pairs to face the partially positive 2- and 6-positions of the neighbouring pyridyl ring. The centre of the pyridine ring to N2 distance is the closest point of interaction at 4.060 Å; the next closest is N3 to the centre of pyridine at 4.587 Å.

The synthesis of two novel neutral receptors and their anion binding properties

Zhen-Ya Zeng, Yong-Bing He, Lan-Hua Wei, Jin-Long Wu, Yan-Yan Huang, and Ling-Zhi Meng

Abstract: Two new neutral receptors (**1** and **2**) containing thiourea and amide groups were synthesized by simple steps in good yields. The binding properties of **1** and **2** with anions were examined by UV–vis, fluorescence, and ^{1}H NMR spectroscopy. Receptor **1** had a better AcO^-: $H_2PO_4^-$ selectivity in comparison with that for receptor **2**. The association constants of **1**·AcO^-, **2**·AcO^-, and **2**·$H_2PO_4^-$ were higher in comparison with those of other anions (Cl^-, Br^-, I^-, *p*-NO_2PhO^-, and *p*-$NO_2PhOPO_3^{2-}$). In particular, a clear color change was observed, from pale yellow to red-brown, upon addition of AcO^- to the solution of **1** in DMSO. The UV–vis and fluorescence data indicate that a 1:1 stoichiometry complex is formed between compound **1** or **2** and anions through hydrogen-bonding interactions.

Key words: neutral receptors, anion recognition, synthesis, hydrogen bonds.

Résumé : On a synthétisé les deux nouveaux récepteurs neutres (**1** et **2**) contenant des groupes thiourée et amide par des réactions simples et avec de bons rendements. On a évalué les propriétés de fixation des anions des composés **1** et **2** par le biais de leurs spectres UV–vis, de fluorescence et RMN du ^{1}H. Par rapport au récepteur **2**, le récepteur **1** présente une meilleure sélectivité AcO^-:$H_2PO_4^-$. Les constantes d'association des anions **1**·AcO^-, **2**·AcO^- et **2**·$H_2PO_4^-$ sont plus élevées que celles pour les autres anions (Cl^-, Br^-, I^-, *p*-NO_2PhO^- et *p*-$NO_2PhOPO_3^{2-}$). On a observé en particulier un changement remarquable de couleur de jaune pale à brun rouge lors de l'addition de AcO^- à une solution du composé **1** dans le DMSO. Les données de spectroscopie UV–vis et de fluorescence indiquent qu'il y a formation d'un complexe de stoechiométrie 1:1 entre les composés **1** ou **2** et les anions par le biais d'interactions de liaisons hydrogènes.

Mots clés : récepteurs neutres, reconnaissance d'anion, synthèse, liaisons hydrogènes.

[Traduit par la Rédaction]

Introduction

The development of anion receptors has attracted increasing interest in supramolecular chemistry, owing to potential applications in clinical diagnosis, environmental monitoring, and biological processes (1). In comparison with the large variety of ligands that have been described for cations (2), the development of selective artificial receptors for anions is still very limited because anions have a wide variety of geometry, comparatively large size, and low charge density. Additionally, anions may be sensitive to pH values for protonation at low pH and to losing their negative charge (3). The basic strategy for the construction of anion-binding receptors is to exploit the receptors that have electrostatic, hydrogen bonding, or Lewis acidic central interactions (4). For the purpose of lessening the dependence on pH values, considerable effort has recently been directed toward the development of synthetic neutral receptors that rely mainly on hydrogen-bonding interactions for anion recognition. These receptors have resulted in successful applications of ion sensors such as ion-selective electrodes (5). For the development of neutral anion receptors, the focus has been on urea or thiourea groups as anion binding sites, because the hydrogen bonding of these functional groups is directional in character and results in relatively strong complexes with biologically important anions such as carbonate, chloride, or phosphate (6).

Although some anion receptors have been reported in the last decades, neutral receptors containing, simultaneously, thiourea and amide binding units have seldom been reported. The cooperative act of two functional groups for the anion could effectively enhance selectivity in the recognition and stability of the complex. In this paper, we report the synthesis and binding properties of two new neutral anion receptors (**1** and **2**) containing thiourea and amide groups. The synthesis route is shown in Scheme 1. The anionic recognition of two compounds has been investigated by UV–vis, fluorescence, and ^{1}H NMR spectroscopy.

Results and discussion

Receptors **1** and **2**, which contain thiourea and amide groups, were synthesized by the reaction of the appropriate isothiocyanate and *N*,*N*′-di(aminoethylene)-2,6-pyridinedicarbonylamine (**3**) in good yields (Scheme 1). Receptor **1** could only dissolve very well in DMSO, as for most thiourea-type compounds, but the synthetic receptor **2** was

Scheme 1.

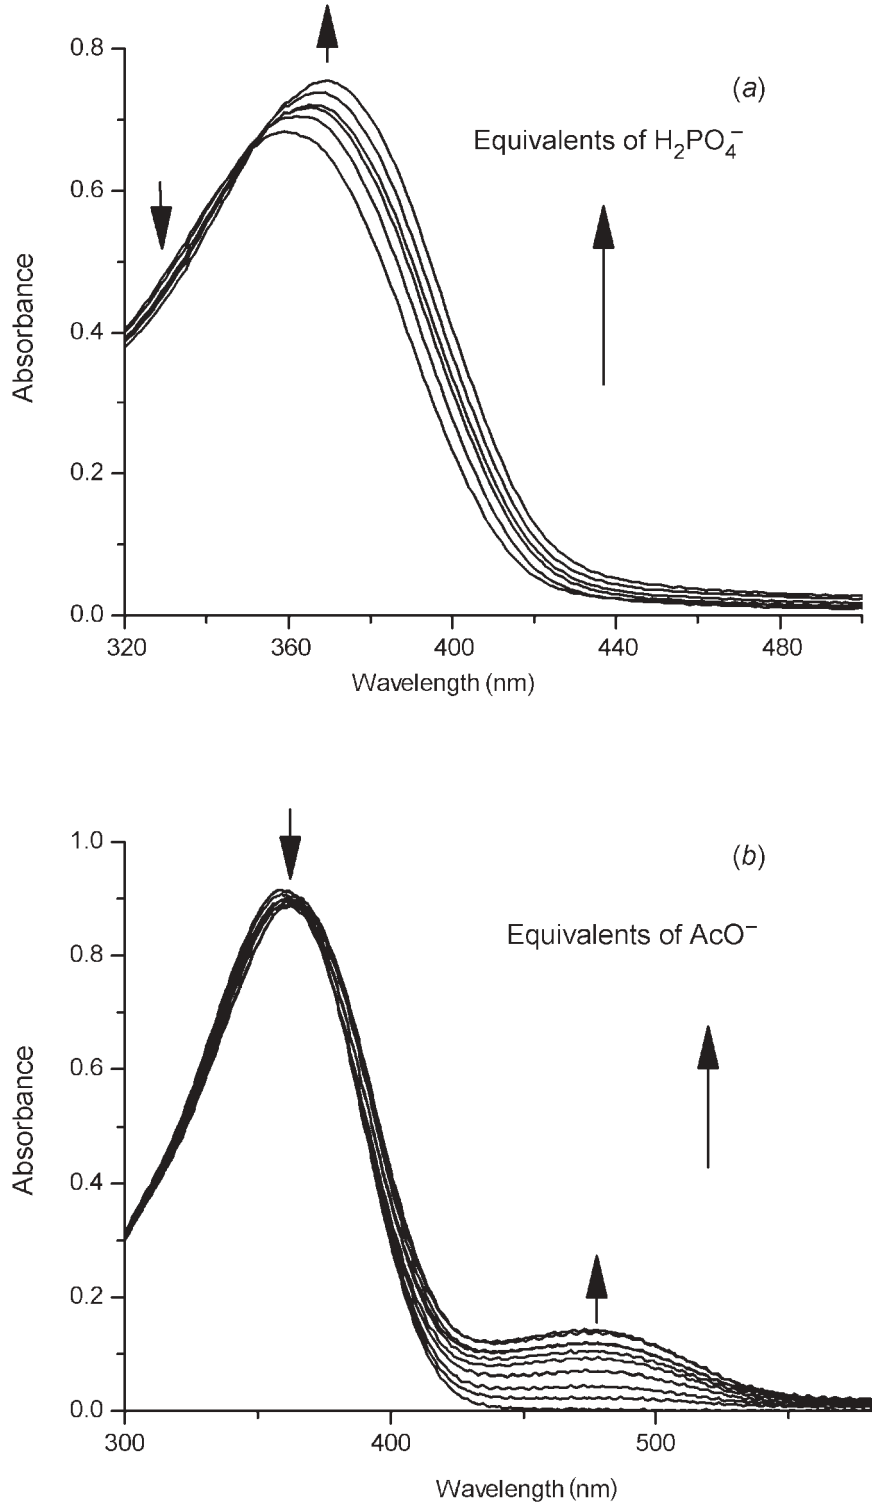
readily dissolved in other organic solvents, such as CH_2Cl_2, $CHCl_3$, acetone, ethanol, methanol, etc.

Absorption and fluorescence spectra

Figure 1*a* shows the absorbance spectra of **1** (2.5×10^{-5} mol L^{-1}) with added dihydrogen phosphate anion in DMSO. Receptor **1** displayed a maximum absorption at 359 nm ($\varepsilon = 2.73 \times 10^4$ (mol $L^{-1})^{-1}$ cm^{-1}), which can be assigned as an intramolecular charge-transfer (CT) absorption band (7). Gradually adding $H_2PO_4^-$ produced a bathochromic shift in the absorption maxima (λ_{max}), from 359 to 370 nm, and a clear isosbestic point appeared at 352 nm. This observation indicated that **1** interacted with $H_2PO_4^-$, and non-linear curve fitting confirmed that **1** and $H_2PO_4^-$ formed a 1:1 complex.

Even after adding 100 equiv. of bromide or iodide anion, the absorption spectra of receptor **1** and **2** did not change at all. When chloride anion was added to a solution of **2**, a decrease of absorbance could be observed, but with receptor **1**, no decrease occured.

Remarkably, significant changes were observed when acetate anion was added to receptor **1** in DMSO. Upon gradually increasing the concentration of AcO^-, a new absorption band appeared with a maximum absorbance wavelength at 474 nm, as shown in Fig. 1*b*, and the color of the solution changed from pale yellow to red-brown, which could be observed by the naked eye. However, no similar color change was observed upon adding AcO^- to receptor **2**. In the supramolecular system, the electronic excitation was mostly accompanied by a charge transfer from the donor nitrogen of the thiourea to the acceptor substituents ($-NO_2$) of the chromophore. Introducing the electron-withdrawing substituents could enhance the acidity of the thiourea moiety, strongly stabilize the excited state, and result in a bathochromic shift in the absorption maxima, to produce a possible effective color change in aprotic media (8). Among all the anions that we studied, this phenomenon appeared only upon adding AcO^- to **1**.



The binding property of **1** with AcO^- was further assessed by a UV–vis spectral titration. Because receptor **1** has many binding sites, a Job plot experiment was carried out to determine the complex ratio. Figure 2*a* illustrates that the absorption of the **1**–AcO^- complex approaches a maximum when the molar fraction of [**1**]/([**1**]+[AcO^-]) is about 0.5 (the total concentration of **1** and AcO^- was 0.1 mmol L^{-1}), meaning that a 1:1 complex of **1** and AcO^- is then formed. The satisfactory result (the correlation coefficient is over 0.99) of the nonlinear curve fitting (absorbance at 474 nm vs. equivalent amounts of anion) confirmed further the 1:1 ratio (Fig. 2*b*) (9).

The fluorescent spectral interactions of receptor **2** with anions were studied by gradual addition of the different substrates to a solution of receptor **2** (5×10^{-6} mol L^{-1}), and the results were analyzed by a non-linear least-squares fitting procedure. Figure 3 shows the changes of fluorescent emission intensity (excitation at 307 nm in $CHCl_3$) on complexation of the reaction of **2** with the AcO^- anion. The fluorescence intensity increased upon addition of AcO^-, with a slight red shift ($\Delta\lambda_{max} \approx 4$ nm) of the emission maximum at 376 nm, which is similar to the anion-induced fluorescence enhancement reported formerly (10). The fluorescence was enhanced with $H_2PO_4^-$ and Cl^-, too. In the absence of an anion, an electron-transfer process between naphthyl and weak electron-withdrawing thiono substituents might result in decreased fluorescence intensity. Upon the addition of anions (AcO^-, $H_2PO_4^-$, and Cl^-), the interaction of the anion with the receptor unit could diminish the PET progress to induce the fluorescence retrieval. Therefore, anion-induced fluorescence enhancement was observed (11). But the fluorescence of receptor **2** was quenched with the addition of 4-nitrophenol anion in $CHCl_3$. The anion-induced signal effects indicated that an efficient interaction happened between the receptor and the anion. In contrast to Cl^-, the fluorescent emission intensity of **2** did not change at all when anions (such as Br^- and I^-) with larger radii and the same spherical geometry were added. When 4-nitrophenylphosphate anion was introduced into a solution of receptor **2** in DMSO, the fluorescence intensity gradually decreased until it was almost completely quenched. The phenomenon was similar to the quenching induced by *p*-NO_2-PhO^-. When host **2** and a guest with a strong electron-withdrawing group (nitro-) interacted, it could be hypothesized that the fluorescence quenching was due to an electron-transfer process. The interaction between receptor **2** and *p*-NO_2-PhO^- (or *p*-$NO_2PhOPO_3^{2-}$) results in the nitro- group and the photoexcited naphthyl fragments being close enough that orbital overlap occurs, leading to efficient electron transfer (12).

Figure 4 shows the resulting fitted curves for the fluorescent emission intensity of receptor **2** at 375 nm when different concentrations of AcO^-, $H_2PO_4^-$, Cl^-, and *p*-NO_2-PhO^-,

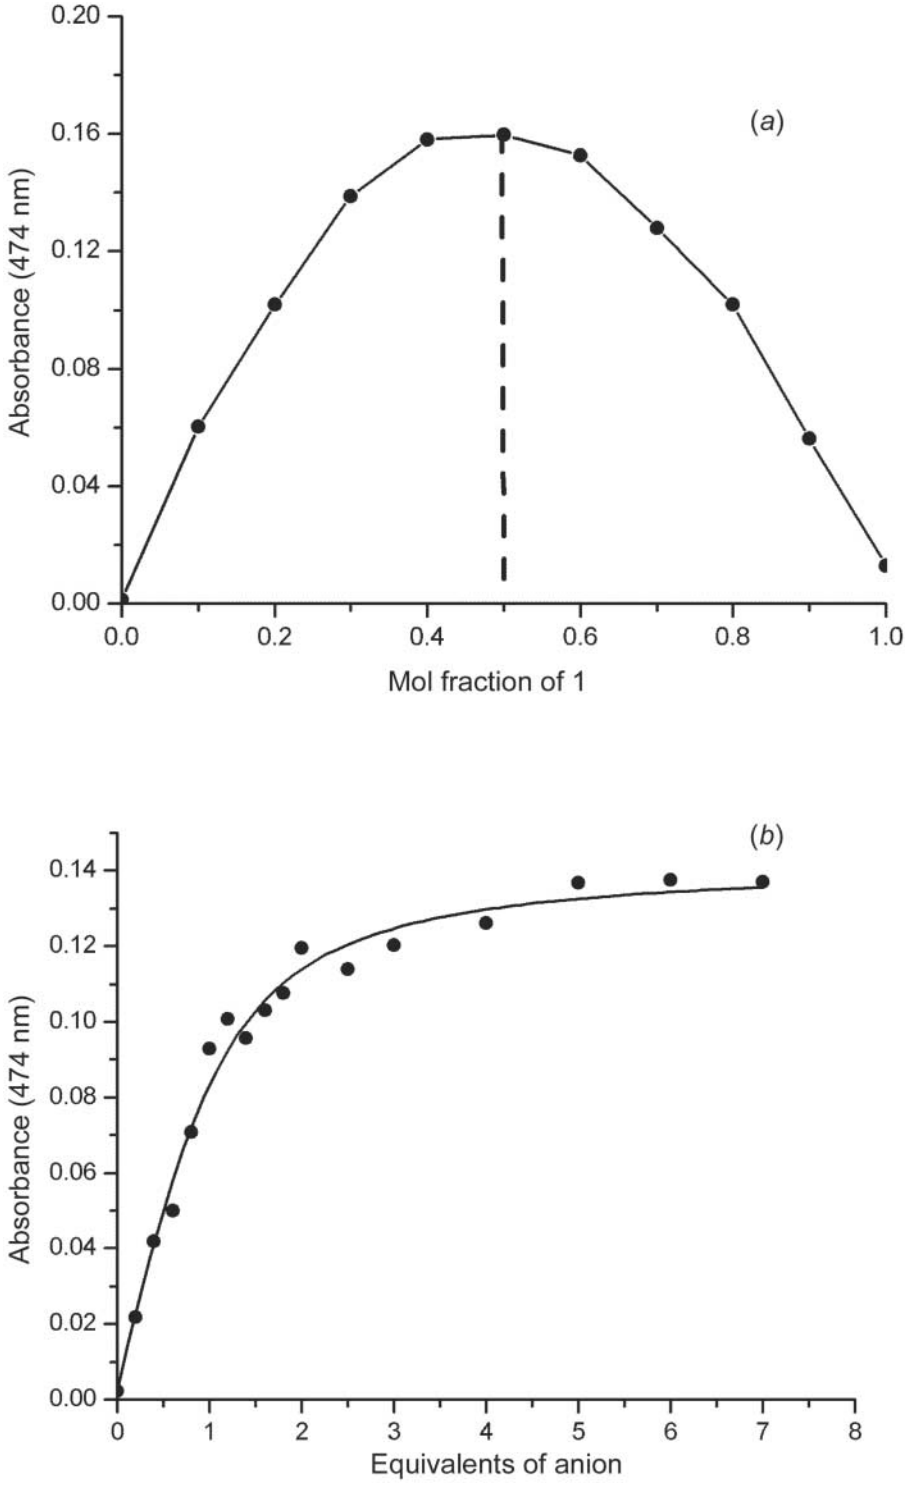
Fig. 1. UV–vis absorption spectra of **1** in DMSO (2.5×10^{-5} mol L^{-1}) upon the addition of various amounts of anions; (*a*) equivalents of Bu_4N^+ ($H_2PO_4^-$): 0, 2, 3, 4, 6, and 20; (*b*) equivalents of Bu_4N^+ (AcO^-): 0, 0.2, 0.4, 0.8, 1, 1.6, 2, 3, 5, and 7.

respectively, were added to the solution of **2** in $CHCl_3$, or at 340 nm when different concentrations of *p*-$NO_2PhOPO_3^{2-}$ were added to the solution of **2** in DMSO. The fitted curves proved the formation of a 1:1 stoichiometry complex (9).



^{1}H NMR study

^{1}H NMR spectroscopy has been widely used to investigate receptor–substrate interactions, and it allows access to the details of the interaction between receptor and substrate.

Addition of anions to compound **1** or **2** caused all NH proton signals of the thiourea or amide groups to shift downfield, and the proton signals of pyridyl, phenyl, and N-CH_2 were changed too. Unfortunately, upon addition of the anions, some NH peaks of the thiourea or amide groups be-

Fig. 2. (*a*) Job plot of **1** and AcO^- at a total concentration of 0.1 mmol L^{-1} in DMSO; (*b*) the plot of the absorbance at 474 nm vs. equivalents of AcO^- in DMSO; [**1**] = 2.5×10^{-5} mol L^{-1}. The solid line is the fitting curve; the correlation coefficient is 0.9930.

came so broad that the peak changes of most receptor–anion systems couldn't be assigned properly. However, the complex of **1** with $H_2PO_4^-$ was assignable within the ^1H NMR spectrum, and the corresponding peak assignments are listed in Table 1. H_a (thiourea, adjacent to phenyl) showed a downfield shift from 10.26 to 12.06 parts per million (ppm); H_b (amide) shifted from 9.54 to 10.15 ppm; and H_c (thiourea, adjacent to methylene) shifted from 8.51 to 9.80 ppm. H_d (pyridyl) showed an upfield shift from 8.14~8.24 to 8.08~8.11 ppm. H_e ($CONCH_2$) at 3.76 ppm and H_f (NCH_2) at 3.61 ppm combined to form a singlet at 3.63 ppm. Compound **1** showed the signal corresponding to H_g (phenyl) as an AA′BB′ system, from 7.17 to 8.17 ppm. After adding $H_2PO_4^-$, H_g shifted to the extent of

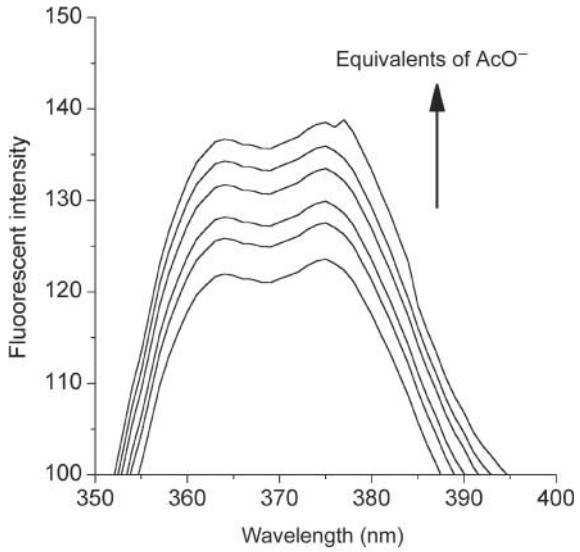

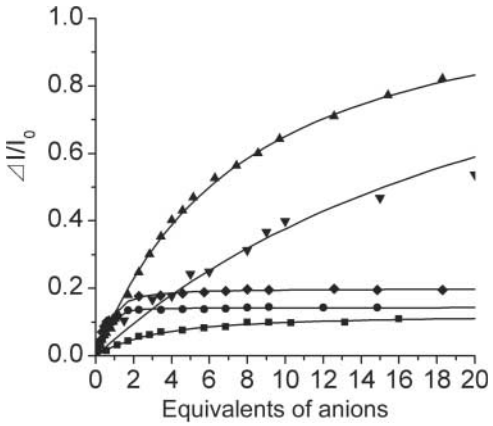

Fig. 4. Plots of fluorescence change vs. equivalents of anions added; [**2**]: 5×10^{-6} mol L^{-1}; the solid lines are the fitting curves (▲, *p*-NO_2-PhO^-; ▼, *p*-$NO_2PhOPO_3^{2-}$; ◆, $H_2PO_4^-$; ●, AcO^-; ■, Cl^-). For *p*-NO_2-PhO^- and *p*-$NO_2PhOPO_3^{2-}$, $\Delta I = I_0 - I$; for the other anions, $\Delta I = I - I_0$. The correlation coefficients are 0.9989, 0.9934, 0.9963, 0.9947, and 0.9958, respectively.

8.00~8.05 ppm. These results illustrate that the connection between receptor **1** and $H_2PO_4^-$ was by multiple hydrogen bonding interactions.

Determination of the association constants (K_{ass}) of the complexes

For a complex of 1:1 stoichiometry, the following relation can be derived easily, as reported formerly (13):

$$X = X_0 + 0.5\ \Delta\varepsilon\ \{c_H + c_G + 1/K_{ass} - [(c_H + c_G + 1/K_{ass})^2 - 4c_Hc_G]^{1/2}\}$$

where X is the absorption or the fluorescence intensity and c_H or c_G is the overall concentration of host or anion guest, correspondingly. The association constants, obtained by a nonlinear least-square analysis of X vs. c_H and c_G, are listed in Table 2. The data showed that both **1** and **2** recognize AcO^- with a high selectively over other anions and also with larger association constants than similar neutral receptors containing only amide groups, as reported formerly (14). This observation confirmed that the cooperative action of the thiourea and amide groups play important roles in bonding to the anion by multiple hydrogen bonding interactions. The interaction between receptor **1** and Cl^-, Br^-, or I^- was too weak to be detected. Receptor **2** bonds with Cl^- in a much weaker fashion than with AcO^- and $H_2PO_4^-$, but it does not bind Br^- or I^- at all. Receptors **1** and **2** bound anions with a similar selectivity, in the order $AcO^- > H_2PO_4^- >$ *p*-$NO_2PhO^- >$ *p*-$NO_2PhOPO_3^{2-}$ and $Cl^- >> Br^-$ and I^-. Receptor **1** had a better AcO^-:$H_2PO_4^-$ selectivity ($K_{ass}(AcO^-)/K_{ass}(H_2PO_4^-) \approx 9.0$~7.8) in comparison with that for receptor **2** ($K_{ass}(AcO^-)/K_{ass}(H_2PO_4^-) \approx 3.6$~3.2). The association constants of **1**·AcO^- ($K_{ass} = (1.3 \pm 0.2) \times 10^5$ (mol $L^{-1})^{-1}$), **2**·AcO^- ($K_{ass} = (3.4 \pm 0.6) \times 10^6$ (mol $L^{-1})^{-1}$), and **2**·$H_2PO_4^-$ ($K_{ass} = (1.0 \pm 0.2) \times 10^6$ (mol $L^{-1})^{-1}$) were higher than those for the other anions (Cl^-, Br^-, I^-, *p*-NO_2PhO^-, and *p*-$NO_2PhOPO_3^{2-}$).

Table 2. Association constants K_{ass} ((mol $L^{-1})^{-1}$) for receptors **1** or **2** with guest anions.

	Receptor **1**	Receptor **2**
Anion	K_{ass} ((mol $L^{-1})^{-1})^a$	K_{ass} ((mol $L^{-1})^{-1})^b$
AcO^- [c]	$(1.3\pm0.2)\times10^5$	$(3.4\pm0.6)\times10^6$
$H_2PO_4^-$ [c]	$(1.6\pm0.1)\times10^4$	$(1.0\pm0.2)\times10^6$
p-NO_2PhO^- [c]	$(1.1\pm0.3)\times10^4$	$(2.8\pm0.1)\times10^4$
p-$NO_2PhOPO_3^{2-}$ [d]	$(5.7\pm0.8)\times10^3$	$(8.1\pm0.7)\times10^3$
Cl^- [c]	[e]	$(8.2\pm0.8)\times10^3$

[a]The data were calculated from UV–vis titration in DMSO.
[b]The data were calculated from fluorescence titration in $CHCl_3$, except for *p*-$NO_2PhOPO_3^{2-}$, which was in DMSO.
[c]Anions were used as the tetrabutylammonium salts.
[d]Anions were used as the disodium salts.
[e]The changes in the spectra were too small to allow for calculation of the associated constants precisely.

Conclusion

The neutral receptors **1** and **2** were synthesized by an easy method in good yields. Both **1** and **2** form 1:1 complexes with anions by multiple hydrogen bonding. Receptor **1** had a better AcO^-:$H_2PO_4^-$ selectivity in comparison with that for receptor **2**. Receptors **1** and **2** bound anions with a similar

© 2004 NRC Canada

selectivity, in the order $AcO^- > H_2PO_4^- > p\text{-}NO_2PhO^- > p\text{-}NO_2PhOPO_3^{2-}$ and $Cl^- >> Br^-$ and I^-. The binding of receptor **1** with AcO^- produced a visible color change, which is promising for its use as an optical chemosensor for the acetate anion.

Experimental section

General methods

Melting points were measured on a Reichert 7905 melting-point apparatus (uncorrected). The infrared spectra were performed on a Nicolet 670 FT-IR spectrophotometer. The mass spectra were recorded on a ZAB-HF-3F spectrometer. Elemental analyses were determined by a PerkinElmer 204B elemental autoanalyzer. ^{1}H NMR spectra were recorded on a Varian Mercury VX-300MHz spectrometer. UV–vis spectra were taken on a TU-1901 spectrometer. Fluorescence spectra were obtained on a Schimadzu RF-5301 spectrometer.

Materials

Methanol was refluxed with magnesium and distilled before use, and CH_2Cl_2 was distilled after refluxing with CaH_2. All other commercially available reagents were used without further purification. The anionic substrates were used as the tetrabutylammonium salts, except $p\text{-}NO_2PhOPO_3^{2-}$, which was used as the disodium salt. Dimethyl 2,6-pyridinedicarboxylate was synthesized according to literature (15).

Synthesis

N,N′-*Di(aminoethylene)-2,6-pyridine-dicarbonylamine (3)*

Under a nitrogen atmosphere, ethylenediamine (4.49 g, 74.49 mmol) and dimethyl 2,6-pyridinedicarboxylate (2 g, 10.2 mmol) were dissolved in dry methanol (150 mL), and the reaction mixture was stirred at room temperature for 2 h. After filtration, the filtrate was collected, and then the solvent and the excess ethylenediamine were removed entirely by evaporation under reduced pressure to give **3** (2.24 g) as a white solid in 83.6% yield, which was used in the next step without further purification. mp 170–172 °C. FT-IR (KBr pellet) (cm^{-1}): 3488, 3405 (ν_{NH}), 1655 (ν_{CONH}). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.87 (t, J = 5.4 Hz, 4H; NCH_2), 3.22 (b, 4H; NH_2, diminished after adding D_2O), 3.51 (t, J = 5.4 Hz, 4H; $CONCH_2$), 8.07~8.19 (m, 3H; PyH), 9.68 (s, 1H; CONH), 10.47 (s, 1H; CONH). Anal. calcd. for $C_{11}H_{17}N_5O_2$: C 52.56, H 6.83, N 27.87; found: C 52.45, H 7.02, N 27.62.

N,N′-*Di(*p-*NO_2-phenylthioureylene-ethylene)-2,6-pyridine-dicarbonylamine (1) (16)*

To a solution of *p*-nitrophenyl isothiocyanate (0.72 g, 4 mmol) in dry CH_2Cl_2 (25 mL), **3** (0.5 g, 2 mmol) in dry CH_2Cl_2 (25 mL) was added slowly at room temperature. After stirring overnight, the precipitate was filtered off, recrystallized from ethanol, washed with petroleum ether, and dried in vacuum to obtain pure **1** (1.11 g) as a pale yellow solid in 90.8% yield. mp 163 to 164 °C. IR (KBr pellet) (cm^{-1}): 1659 (ν_{CONH}), 1538 (ν_{NO2}), 1331 ($\nu_{N\text{-}CS\text{-}N}$), 851, 752 ($\nu_{Ar}$). ^{1}H NMR (300 MHz, DMSO-d_6) δ: 3.61 (s, 4H; NCH_2), 3.76 (s, 4H; $CONCH_2$), 7.77~8.17 (AA′BB′, 8H; ArH), 8.14~8.24 (m, 3H; PyH), 8.51 (s, 2H; NHCS), 9.54 (s, 2H; CONH), 10.26 (s, 2H; ArNHCS). MS (FAB) *m*/*z* (%): 611 (2, $[M]^+$). Anal. calcd. for $C_{25}H_{25}N_9O_6S_2$: C 49.08, H 4.13, N 20.61; found: C 49.15, H 4.22, N 20.44.

N,N′-*Di(1-naphthylthioureylene-ethylene)-2,6-pyridine-dicarbonylamine (2)*

To a solution of naphthylisothiocyanate (0.5 g, 2.7 mmol) in dry CH_2Cl_2 (10 mL), **3** (0.34 g, 1.35 mmol) in dry CH_2Cl_2 (20 mL) was added slowly at room temperature. After stirring overnight, the solvent was removed under reduced pressure to give a yellow oil. The crude product was purified by column chromatography using CH_2Cl_2–CH_3OH (100:1) as eluant on neutral alumina, to obtain **2** (0.73 g) as a white solid in 88.5% yield. mp 117 to 118 °C. FT-IR (KBr pellet) (cm^{-1}): 1664 (ν_{CONH}), 1269 ($\nu_{N\text{-}CS\text{-}N}$), 780, 752 ($\nu_{Ar}$). ^{1}H NMR (300 MHz, DMSO-d_6) δ: 3.61 (s, 4H; NCH_2), 4.30 (s, 4H; $CONCH_2$), 7.24~8.00 (m, 17H; ArH, PyH), 8.14 (s, 2H; NHCS), 8.29 (s, 2H; ArNHCS), 9.23 (s, 2H; CONH). MS (FAB) *m*/*z* (%): 621 (4, $[M]^+$). Anal. calcd. for $C_{33}H_{31}N_7O_2S_2$: C 63.74, H 5.04, N 15.77; found: C 63.68, H 5.09, N 15.61.

Binding studies

The studies on the binding properties of **1** were carried out in DMSO or DMSO-d_6. The studies on the binding properties of **2** were carried out in $CHCl_3$ or $CDCl_3$, except for $p\text{-}NO_2PhOPO_3^{2-}$, which were also in DMSO or DMSO-d_6. UV–vis spectral studies were carried out by addition of anions to a 2.5×10^{-5} mol L^{-1} solution of receptors, except that the receptors were first added to a solution of $p\text{-}NO_2PhOPO_3^{2-}$ or $p\text{-}NO_2PhO^-$ (2.5×10^{-5} mol L^{-1}). The fluorescence titration was performed with a series of 5×10^{-6} mol L^{-1} solutions of receptor **2** containing different amounts of anions (in $CHCl_3$, the excited wavelength was 307 nm, and the excitation and emission slit width were 5 nm and 10 nm, correspondingly, for AcO^-, $H_2PO_4^-$, Cl^-, Br^-, I^-, and $p\text{-}NO_2PhO^-$ anions; in DMSO, the excited wavelength was 293 nm, and the excitation and emission slit width were 5 nm for the $p\text{-}NO_2PhOPO_3^{2-}$ anion). The Job plot study was performed on a total concentration of 0.1 mmol L^{-1}. The ^{1}H NMR study was recorded by adding equivalent amounts of anions to the receptors (1.0×10^{-2} mol L^{-1}).

Concerning the mechanism of the Friedländer quinoline synthesis

Joseph M. Muchowski and Michael L. Maddox

Abstract: Detailed experiments regarding the mechanism of the Friedländer synthesis of quinolines from *o*-aminobenzaldehydes and simple aldehydes or ketones are described. Under the basic or acidic conditions commonly used in this reaction, it is concluded that the first step involves a slow intermolecular aldol condensation of the aldehyde or ketone with the *o*-aminobenzaldehyde. The aldol adduct **5** generated in this manner then undergoes very rapid cyclization to **4**, which subsequently loses water to produce the quinoline derivative **8**. Both **5** and **4** are too short lived to be detectable (TLC), even when deliberately generated by other means. It is also shown that *E*-enones corresponding to **6**, i.e., the aldol dehydration product, are converted into quinolines (e.g., **21a** and **21b** from **17a** and **17b**) under basic or acidic conditions. Such enones are not detected as intermediates in the base-induced Friedländer synthesis, even though certain congeners (**17b**) would be easily observable. Under acidic conditions these enones are too short lived to be detectable. Schiff bases derived from 2-aminobenzaldehyde (**18a**) and aldehydes or ketones can be generated under special conditions, but they show reactivity patterns different from those seen in the usual Friedländer condensations. Thus, the ytterbium-triflate-catalyzed reaction of aldehydes with **18a** at room temperature in toluene generates the *E*-Schiff bases (**33**, R^1 = H), from which isomeric mixtures of tetrahydroquinoline derivatives **26** are formed exclusively. At higher temperatures, the *E*-Schiff bases **33** are isomerized to the *Z*-Schiff bases **34**, from which the 3-substituted quinoline derivatives **24** are formed as the major products under appropriate conditions. Also, the ytterbium-triflate-catalyzed reaction of **18a** with the pyrrolidine enamines of the methyl-*n*-alkylketones **38a**,**b** produces mixtures in which the 2-monosubstituted kinetic products **37b**,**d** predominate over the 2,3-disubstituted thermodynamic products **21c**,**e** by a factor of 4:1 to 5:1. These results are opposite to those observed under the usual basic or acidic Friedländer reactions with methyl-*n*-alkylketones, where the thermodynamic products are usually strongly favored. The unusual kinetic:thermodynamic product ratios observed with **38a**,**b** are ascribed to the generation and rapid cyclization of mixtures of the Schiff bases **35** and **36**, in which the kinetic isomer **35** is highly predominant.

Key words: mechanism, Friedländer synthesis, quinolines, intramolecular aldol reactions, Schiff bases, tetrahydroquinolines, high kinetic:thermodynamic product ratios.

Résumé : On rapporte les détails d'expériences réalisées dans le but d'élucider le mécanisme de la synthèse des quinoléines de Friedländer à partir d'*o*-aminobenzaldéhydes et d'aldéhydes ou des cétones simples. On en déduit que, dans les conditions légèrement acides ou basiques utilisées pour cette réaction, la première étape implique une condensation aldolique intermoléculaire lente de l'aldéhyde ou de la cétone avec l'*o*-aminobenzaldéhyde. L'adduit aldolique ainsi généré, **5**, subit alors une cyclisation très rapide en **4** qui perd subséquemment de l'eau pour conduire au dérivé **8** de la quinoléine. Les temps de vie des intermédiaires **5** et **4** sont tous les deux beaucoup trop courts pour qu'on puisse les détecter (CCM), même lorsqu'on tente de les générer par d'autres méthodes. On a aussi montré que les *E*-énones correspondant à **6**, c'est-à-dire le produit de déshydratation de l'aldol, peuvent être transformées en quinoléines (par exemple, **21a** et **21b** à partir de **17a** et **17b**) dans des conditions acides ou basiques. Ce type d'énone n'est pas détecté comme intermédiaire dans la synthèse de Friedländer induite par les bases même si certains congénères (**17b**) seraient facilement observables. Dans des conditions acides, les temps de vie de ces énones sont trop courts pour qu'on puisse les détecter. Les bases de Schiff du 2-aminobenzaldéhyde (**18a**) avec les aldéhydes ou les cétones peuvent être générées dans des conditions spéciales, mais leurs patrons de réactivité sont différents de ceux observés dans les condensations de Friedländer habituelles. Ainsi, la réaction catalysée par le triflate d'ytterbium des aldéhydes avec **18a**, à la température ambiante et dans le toluène, conduit à la formation de bases de Schiff de stéréochimie *E*- (**33**, R^1 = H) à partir desquelles il se forme uniquement des mélanges isomères de dérivés tétrahydroquinoléines **26**. À des températures plus élevées, les bases de Schiff de stéréochimie *E*- (**33**) s'isomérisent en bases de stéréochimie *Z*- (**34**) à partir desquelles, dans des conditions appropriées, les produits qui se forment d'une façon prépondérante sont des dérivés de la quinoléine substitués en position 3 (**24**). De plus, la réaction catalysée par le triflate d'ytterbium du produit **18a** avec

des énamines formées par réaction de la pyrrolidine sur les méthylalkylcétones **38a,b** conduit à la formation de mélanges dans lesquels les produits cinétiques portant un substituant en position 2 (**37b,d**) prédominent par rapport aux produits thermodynamiques disubstitués en 2,3 (**21c,e**) par un facteur allant de 4:1 à 5:1. Ces résultats sont opposés à ceux observés dans les conditions usuelles des réactions de Friedländer acide ou basique des méthylalkylcétones dans lesquelles les produits thermodynamiques sont généralement fortement favorisés. Les rapports inhabituels de produits cinétiques et thermodynamiques observés avec les produits **38a,b** sont attribués à la génération et à la cyclisation rapide de mélanges des bases de Schiff **35** et **36** dans lesquels l'isomère cinétique **35** est fortement prédominant.

Mots clés : mécanisme, synthèse de Friedländer, quinoléines, réactions aldoliques intramoléculaires, bases de Schiff, tétrahydroquinoléines, rapport élevé des rapports de produits cinétiques et thermodynamiques.

[Traduit par la Rédaction]

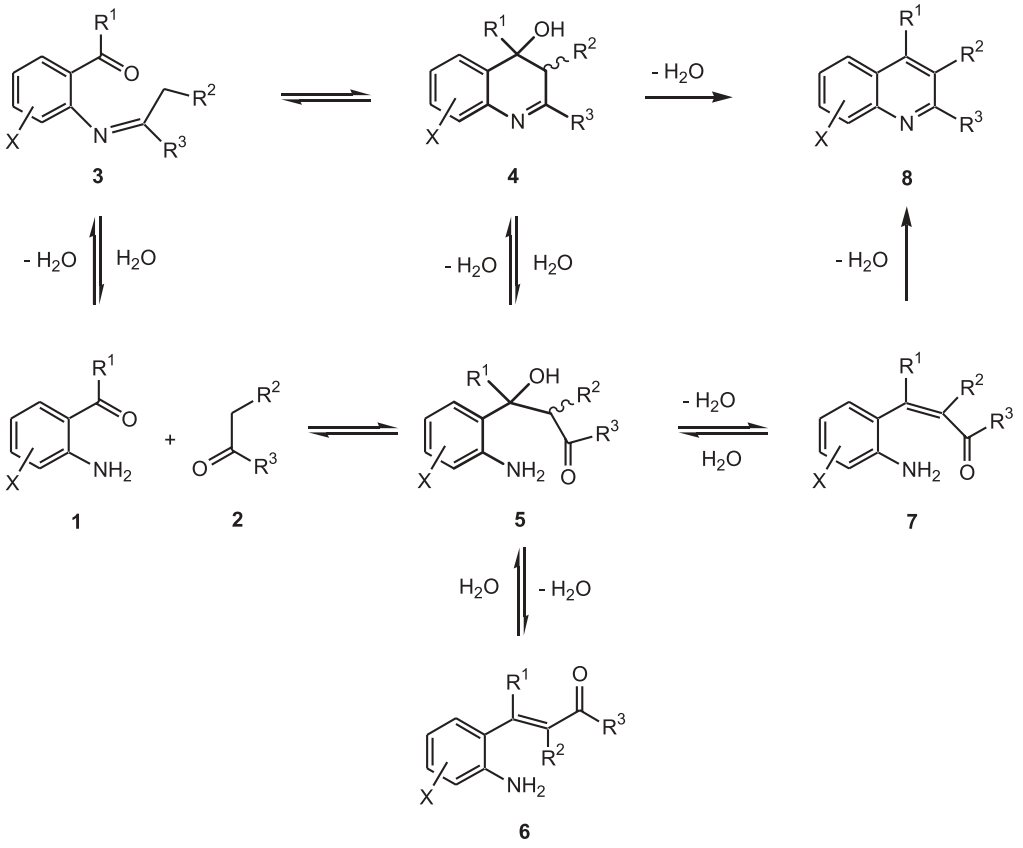
Introduction

The formation of a quinoline derivative by the condensation of an aromatic *o*-aminoaldehyde or *o*-aminoketone with an aldehyde or a ketone containing a methylene group alpha to the carbonyl moiety, under basic or acidic conditions, is known as the Friedländer synthesis (1–5). The development of the heteroatom-directed *o*-metalation of aromatic systems (6), which has provided facile access to a variety of *o*-aminoaldehydes and *o*-aminoketones, has made the Friedländer reaction one of the most reliable of all quinoline syntheses. Basic reaction conditions are particularly efficient for the generation of quinoline derivatives from ketones and *o*-aminoaldehydes, whereas the condensation of ketones with *o*-aminoketones is best effected in acidic media. The most notable advantage of the Friedländer synthesis is that the positions of the substituents in the homocyclic ring are fixed by the structure of the *o*-aminocarbonyl component, and the regiochemistry of the substituents in the heterocyclic ring is predictable because nonsymmetrical ketones usually give rise to the quinoline derived from the thermodynamic enolate as the major or exclusive product.

Although the general features of the Friedländer synthesis are well understood, there is still a considerable degree of uncertainty regarding the mechanistic details of the process. Two distinctly different reaction pathways have been suggested (4, 5) to account for the facts. One involves the rate-determining formation of the Schiff base **3** (Scheme 1), followed by an intramolecular aldol-type condensation to the hydroxyimine **4** and subsequent loss of water therefrom to produce the quinoline **8**. In the other proposal, the rate-limiting step is the generation of the intermolecular aldol intermediate **5**, which proceeds to the quinoline via the above mentioned hydroxyimine **4**.

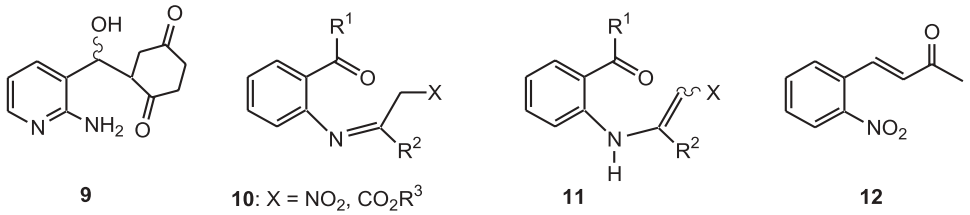
Evidence in support of each mechanistic proposal exists, but that for the intermolecular aldol process is very rare. Thus, a unique example of the isolation of the purported aldol adduct **9** (Scheme 2) in the piperidine-catalyzed, room temperature reaction of 2-aminonicotinaldehyde with 1,4-cyclohexanedione has been described (7). Although an NMR spectrum of **9** could not be obtained, analytical (CHN) and IR data and the nearly quantitative generation of the expected quinoline derivative on mere heating in toluene solution were consistent with the β-ketol structure. On the other hand, Schiff bases **10** bearing a stabilizing substituent in the β-position have been generated in several instances (8–10), although not under the usual Friedländer conditions (see below). These entities, which must exist in the vinylogously stabilized forms **11**, have been cyclized under both basic (8, 10) and acidic (9) conditions. No Schiff base derived from a simple aldehyde or ketone and an aromatic *o*-aminocarbonyl compound has ever been isolated.

Given the weight of the evidence cited above, the Friedländer synthesis is usually considered to occur via an intermediate Schiff base. The intermolecular aldol mechanism has also been considered improbable because of the expected facile formation of the conjugated unsaturated carbonyl compound **6** of *E*-geometry and the unlikely conversion of this species into the quinoline (via the *Z*-stereoisomer **7**) (5). Nevertheless, recently devised versions of the Friedländer synthesis show that neither **5** nor **6** can a priori be discounted as intermediates (11–14). Indeed, in a generally overlooked 1883 publication, Drewsen (15) reported that the nitroenone **12** was converted into 2-methylquinoline with stannous chloride in hydrochloric acid medium, although neither the exact conditions nor the yield were reported!



The putative generation of aldol intermediates corresponding to **5** (11, 12) and the isolation of enones (14) and the enals related to **6** (R^1, R^3 = H) (11) as *N*-acylated congeners, as well as the conversion of these species and **12** into quinolines, encouraged us to take another look at the mechanism(s) of the Friedländer synthesis. Herein are described our attempts to generate each of the intermediates shown in Scheme 1 and to establish the presence or absence thereof under conditions typically used in this synthesis.

Results and discussions



The starting materials required for this study were prepared as shown in Scheme 3. Thus, the sodium-hydroxide-promoted condensation of the aldehydes **13** with acetone or 2-butanone under conditions similar to or slightly modified from those of Baeyer and Drewsen (16) gave the β-ketols **14** as the major products. These were accompanied by minor amounts of the kinetic product **15**, from 2-butanone and **13a**, and the enone **16c**, from **13b** and acetone. The nitroenones **16a** and **16b**, obtained from the β-ketols **14a** and **14b** by dehydration with hot acetic anhydride, were converted into the amines **17a** and **17b** by reduction with iron powder and ammonium chloride in a two-phase system at room temperature (17, 18). The very unstable enal **17c** was prepared by this technique as well. This mild, chemospecific reducing system is also the preferred one for preparing 2-aminobenzaldehydes

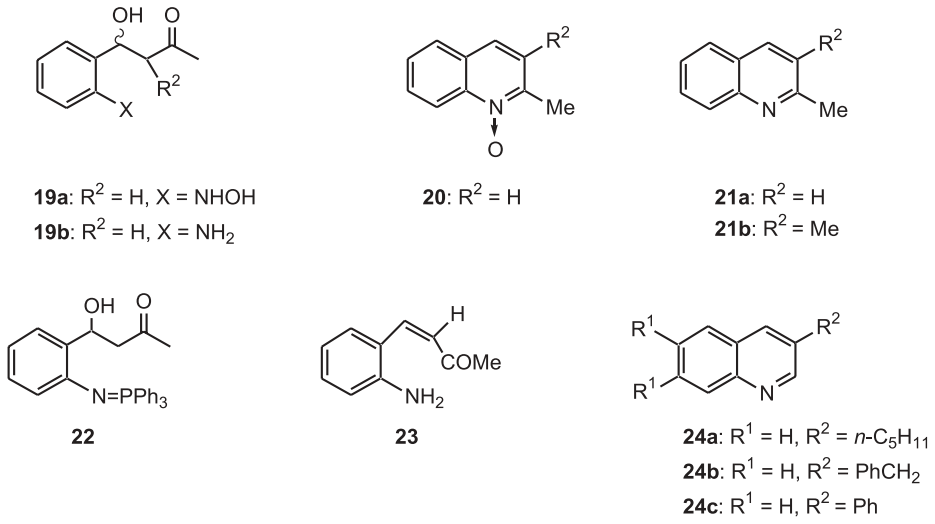
(**18**) from 2-nitrobenzaldehydes (**13a** and **13c**). Indeed, for the synthesis of 2-aminobenzaldehyde itself, it is far superior in terms of yield (86%–93%) and ease of workup than is the commonly used method (19) or its recent modification (20).

The generation of an aldol intermediate analogous to **5** (Scheme 1) was examined first. Reduction of the β-ketol **14a** with the iron – ammonium chloride system gave 2-methylquinoline-*N*-oxide (**20**, Scheme 4, Table 1) in 76% yield and a trace of 2-methylquinoline (**21a**). The *N*-oxide **20** is obviously produced by the cyclization of the very nucleophilic intermediate hydroxylamine **19a**. The nearly exclusive generation of **20** under these conditions is expected, since during the reduction of the nitro compounds **13a**, **16a**, and **16b** at least, the rapid formation of the intermediate hydroxylamines and the much slower appearance of the amines is easily seen by thin layer chromatography (TLC). In contrast, catalytic reduction of **14a** over Pd–C catalyst at atmospheric pressure gave a 4:1 mixture favoring the *N*-oxide. Somewhat similar results have been reported for the catalytic reduction of certain Baylis–Hillman (21) products derived from 2-nitrobenzaldehyde (13). Reduction of the azido compound **14c**, where the amine **19b** must be an intermediate, using the iron – ammonium chloride method gave **21a** exclusively in high yield. No intermediates were detectable by TLC in these reductions; therefore, the lifetime of both the aldol intermediate **19b** and the cyclization product **4** (Scheme 1) enroute to the quinoline must be quite short. This assumption was verified for the latter intermediate by reaction of the azido compound **14c** with triphenylphosphine. No intermediate, not even the iminophosphorane **22**, was detectable by TLC during the course of the reaction, even at room temperature.



The *E*-enones **17a,b** were next studied as potential intermediates in the Friedländer synthesis. Under thermodynamic conditions, the base-catalyzed aldol condensation is reversible in all steps (22). For this reason, as well as because of

Scheme 3. Synthesis of the starting materials.

Scheme 4.

microscopic reversibility (23), it should be possible to convert the *E*-enones into the corresponding quinolines, possibly via the *Z*-enones **7** (see also ref. 24) under basic conditions. Indeed, when dissolved in aqueous ethanol containing 20 mol% sodium hydroxide, **17a** was cleanly converted into 2-methylquinoline (**21a**) after ca. 1 day at room temperature (Table 1). The reaction of 2-aminobenzaldehyde with excess acetone under very similar conditions produced **21a** more slowly but just as efficiently. These are the conditions described by Friedländer himself (2)! Even the aldehyde **17c** is very slowly transformed into quinoline with less than an equivalent of base at ambient temperature (entry 7). In contrast, the enone **17b** is stable under these conditions, but it is converted efficiently into 2,3-dimethylquinoline (**21b**) at reflux temperature using 3.3 equiv. of base. Excess sodium hydroxide is also required for the generation of **21b** from 2-aminobenzaldehyde and 2-butanone, but the reaction proceeds at room temperature (entry 9). It is noteworthy that the enone **17b** was not detectable during the course of the latter reaction, even though it would easily have been observable by TLC (intense yellow color on silica gel plates) had it been formed. Thus, although such enones clearly are viable intermediates, it is unlikely that they play a significant role in the alkali-induced version of the Friedländer quinolone synthesis. Hsaio et al. (14) have recently shown that the Horner–Emmons reaction of 2-aminonicotinaldehyde and β-ketophosphonates generated the expected naphthyridines via the *E*-enones, but they did not examine the corresponding Friedländer synthesis for these intermediates.

The question of a Schiff base intermediate **3** in the alkali-hydroxide-mediated version of the Friedländer synthesis can now be addressed with confidence. Under neutral conditions, 2-aminobenzaldehyde (**18a**) is remarkably resistant to reaction with ketones or aldehydes. For example, it can be recov-

ered unaltered after many hours at reflux temperature in acetone solution. Likewise, toluene solutions of **18a**, containing various aldehydes in excess, are stable at room temperature for long periods of time. Given the diminished reactivity of **18a** and its congeners toward aldehydes and ketones and the aqueous- and (or) alcohol-based media in which the alkaline hydroxide-mediated condensations are usually effected, a Schiff base intermediate in this version of the Friedländer synthesis is quite improbable.

The formation of quinoline derivatives from *N*-acylated congeners of **17c** in acidic media (11) and the relatively facile acid-induced isomerization of *Z*-enones to *E*-enones (24–28) augured well for the acid-promoted generation of quinolines from **17a-c**. The free enal **17c** was, however, rapidly destroyed, even under the mildly acidic conditions previously used (11) to cyclize the *N*-BOC congeners of **17c** (entry 10). By contrast, enones **17a**,**b** were converted into the quinolines **21a,b** in over 80% yields with 1.5 mol L^{-1} hydrochloric acid in 50% aqueous dioxane after only 1 h at reflux temperature. An attempt to prepare **21a** from 2-aminobenzaldehyde and acetone under these conditions resulted in the destruction of the starting materials. Quinoline **21a** was nevertheless slowly formed from these reactants, although only in 26% yield, when the reaction was carried out in acetic acid solution containing a catalytic amount of sulfuric acid (29) at reflux temperature. 2-Methylquinoline (**21a**) was also produced (35% yield) from the enone **17a** upon heating in the same reaction medium for 2 h. Although such enones could well be intermediates under those often-used acidic conditions, their short half-lives ensure that they would not be readily detectable, at least by TLC.

It was tacitly assumed that *Z*-enones were involved as tenuous intermediates in the conversion of the *E*-enones **17a,b** into the quinolines **21a,b**. Corroborative evidence that the *Z*-enones must indeed be very short lived was obtained by photolysis of **17a** in ethanolic solution. 2-Methylquinoline was produced as the sole product, but the presumed intermediate *Z*-enone **23** was undetectable by TLC.

Up to this point no convincing evidence for an intermediate Schiff base had been found under conditions commonly used in the Friedländer synthesis. It seemed reasonable, therefore, to attempt to generate such species from aldehydes and 2-aminobenzaldehyde (**18a**) under more classical conditions. Heating solutions of **18a** and 1.2 equiv. of *n*-heptanal, 3-phenylpropionaldehyde, or phenylacetaldehye, freshly generated from the corresponding bisulfite adducts, in toluene containing a catalytic amount (5 mol%) of *p*-toluenesulfonic acid monohydrate with separation of water, gave modest yields of 3-substituted quinolines **24a-c** (Table 2). These quinolines were formed extremely slowly, or not at all, at room temperature. The quinolines were also obtained under similar conditions and in comparable yields using ytterbium triflate (10 mol%) as the catalyst, except that the reaction periods were greatly reduced, and water separation was not necessary (Table 2, entries 2, 4, 6). In every case, independent of the catalyst used, TLC examination showed that several much less polar, yellow-colored, neutral substances were also formed, none of which was a Schiff base. *n*-Heptanal gave rise to one such material in relatively good yield (25%–43%, ytterbium triflate catalyst) as an oil with a mass spectral molecular weight of 416. This corresponds to the condensation of two molecules of heptanal and two molecules of **18a** with the loss of three molecules of water ($C_{28}H_{30}N_2O$). The IR spectrum showed absorptions at 3334, 2733, and 1659 cm^{-1}, consistent with the presence of aldehyde and NH groups strongly bonded to each other, and this was supported by the ^1H NMR spectrum (DMSO-d_6), with peaks at δ 9.80 and 8.91, respectively. In addition to

other absorptions, the NMR spectrum possessed peaks for eight aromatic hydrogens and three methylene groups at δ 2.78, 2.98, and 5.04 (coupled to the NH by 6.2 Hz). Four of the aromatic hydrogens had a splitting pattern identical to and chemical shifts (δ 6.68 (t), 6.90 (d), 7.35 (dt), 7.58 (dd)) similar to those found in 2-aminobenzaldehyde (20). The chemical shifts of the remaining aromatic hydrogens (δ 7.43 (t), 7.63 (d), 7.78 (d), 8.05 (s)) were essentially identical to those reported for H-6, H-7, H-5, and H-4, respectively, of quinoline (30), and the multiplicities were concordant with those expected for a 2,3,8-trisubstituted derivative. This substitution pattern was strongly supported by a ROESY experiment, which showed that the δ 2.78 methylene group was vicinal to the hydrogen at δ 8.05, that the two upfield methylene groups were also vicinal, and that the low field (δ 5.04) methylene moiety was vicinal to the δ 7.63 hydrogen. The above information is fully accommodated by the quinoline derivative with structure **25a** (Scheme 5). In particular, the unusual chemical shift of the methylene group at C-8 stems from the strong deshielding effect of the peri lone electron pair of the quinoline nitrogen atom. The formation of this compound clearly requires the involvement of one or more Schiff base intermediates.

When the above reaction was attempted with propanal under similar conditions (sealed vessel), only a miniscule amount (ca. 1.5%) of **25b** was formed (crystalline). The major product in this complex reaction mixture was a structurally different yellow-colored oily substance (see below). A reaction with acetaldehyde (4 equiv.) at reflux temperature gave a complex mixture containing no major product and no trace of a material with an *Rf* expected for **25c**. It was assumed that the failure to generate significant amounts of **25b,c** was connected with the volatility of the aldehydes; therefore, the reactions were carried out at room temperature. After 2 to 3 days, acetaldehyde (4 equiv.) gave a major, new, yellow-colored oil (ca. 65% yield), but no quinoline. This material had a mass spectral molecular weight of 294, i.e., derived from the condensation of two molecules of acetaldehyde with two molecules of **18a** minus two molecules of water ($C_{18}H_{18}N_2O_2$). The NMR spectrum of this apparently homogeneous material (TLC) indicated, however, that it was a 4:1 mixture of isomers. The major component showed signals for two aldehyde moieties (δ 9.86 and 9.81), two NH groups (δ 8.67 and 8.40), seven aromatic hydrogens, multiplets corresponding to four mutually coupled aliphatic protons (δ 4.86, 3.38, 2.31, and 1.71), and a methyl group attached to a secondary carbon atom. The hydrogens at δ 4.86 and 3.83 were also coupled to the low-field NH and the methyl group, respectively. Deuteration of the NH hydrogens and decoupling of the methyl group permitted measurement of all the aliphatic hydrogen coupling constants (Table 3) and assignment of the *cis* 2,4-disubstituted tetrahydroquinoline structure **26a** to this substance, with the methyl and aniline moieties occupying equatorial sites in a half-chair system. Full decoupling studies were not carried out on the minor component, but the data in Table 3 indicate that it is the *trans* stereoisomer **26b** with the anilino group axial. When propanal was used in the room temperature reaction, a not-readily-separable 54:34:12 mixture of stereoisomers was obtained in about 50% yield. The high-temperature reaction

Scheme 5.

mentioned above gave mainly the major isomer, and the NMR spectral data in Table 3 establish that this is the 2,3,4-trisubstituted tetrahydroquinoline **26c**, analogous to **26a** but with a C-3 axial methyl group. The isomers of intermediate and least abundance have structures **26d** and **26e**, with the 2,3,4-substituents arranged a,e,e and a,a,e. In addition to the three tetrahydroquinolines, the acyclic dialdehyde **27** was isolated as a single isomer in ca. 40% yield. The room-temperature reaction of 2-aminobenzaldehyde and phenylacetaldehyde was not studied in detail, but a very insoluble, surprisingly high-melting (236 °C) yellow solid could be isolated in ca. 15% yield. The NMR spectral data (Table 3) unequivocally show that this is the all-equatorial isomer **26f**.

The formation of tetrahydroquinolines from anilines and aliphatic aldehydes has been known for some time (31, 32) and proceeds via an intermediate Schiff base dimer **28**, which sometimes can be isolated (e.g., for X = H, R = Et, Ar = Ph (31)). The dimer cyclization is acid catalyzed, high yielding, and takes place at room temperature. It is apparent that the dialdehyde **27** is the hydrolysis product of the intermediate enroute to the tetrahydroquinolines **26**. It is also worth noting that the tetrahydroquinolines and the dihydroquinoline described below are well-recognized intermediates in the Doebner–Miller quinoline synthesis (see ref. 5, pp. 102–104).

The high-temperature ytterbium-triflate-promoted reaction of phenylacetaldehyde with 2-aminobenzaldehyde gave, in addition to 3-phenylquinoline, a complicated neutral mixture from which a crystalline, yellow-colored, structurally unique monoaldehyde could be isolated (13%–29%). That this substance was the 1,2-dihydroquinoline **29** was evident from its NMR spectrum, which showed, among other signals, absorptions for an aldehyde hydrogen, an NH moiety, an olefinic hydrogen (singlet), a methine hydrogen, and a benzylic methylene group at δ 9.77, 8.38, 6.61, 5.03, and 2.82, respectively. The methine hydrogen was coupled to both the NH (J = 2.6 Hz) and the methylene hydrogens (J = 6.0 Hz).

Solutions of **29** underwent slow aerial oxidation to the corresponding quinoline **30**, which was obtained much more efficiently by oxidation with Fremy's salt (33). The aldehyde hydrogen of the latter compound is found at δ 11.46, nearly δ 2 downfield from that observed for **29**. The remarkably low-field position of this proton must be a consequence of an aldehyde conformation in which the hydrogen and oxygen are close to and remote from the lone pair of the quinoline nitrogen atom, which is a conformation that the aldehyde must adopt to avoid an unfavorable dipole–dipole interaction. The hydrogen of a series of quinoline-8-carboxaldehydes has been reported to resonate at δ 11.3–11.5 without comment (34).

The isolation of the dihydroquinoline **29** was of considerable significance, because it suggested a plausible mechanism for the formation of the quinoline containing dimers **25**. Specifically, fragmentation of the tetrahydroquinoline dimers **26** to 2-aminobenzaldehyde and the 1,2-dihydroquinoline **31**, followed by Schiff base formation from these fragments, would generate **32**, which could lead to **25** by an intramolecular redox process (Scheme 6). In fact, a boiling solution of the isomeric tetrahydroquinolines **26c**, **26d**, and **26e** in toluene containing 10 mol% of ytterbium triflate was slowly (15–21 h) converted into a mixture from which the previously described quinoline dimer **25b** could be isolated in ca. 25% yield. The tetrahydroquinoline mixture derived from acetaldehyde (**26a** and **26b**) was converted even more rapidly (4 h) and more efficiently (>45% yield) into the 2-methyl analog **25c**.

Why are the Schiff bases derived from aliphatic aldehydes and 2-aminobenzaldehyde converted exclusively into tetrahydroquinolines at room temperature and only give the expected 3-substituted quinolines at higher temperature? The answer must certainly be associated with the geometry of the Schiff base. At ambient temperature, the thermodynamically more stable *E*-isomer **33** (Scheme 7) must be generated essentially exclusively. This geometry cannot, however, lead to the 3-substituted quinoline; therefore, intermolecular aldolization to the Schiff base dimers followed by cyclization to the tetrahydroquinoline derivatives takes place. At higher temperature the *E*-isomer exists in equilibrium

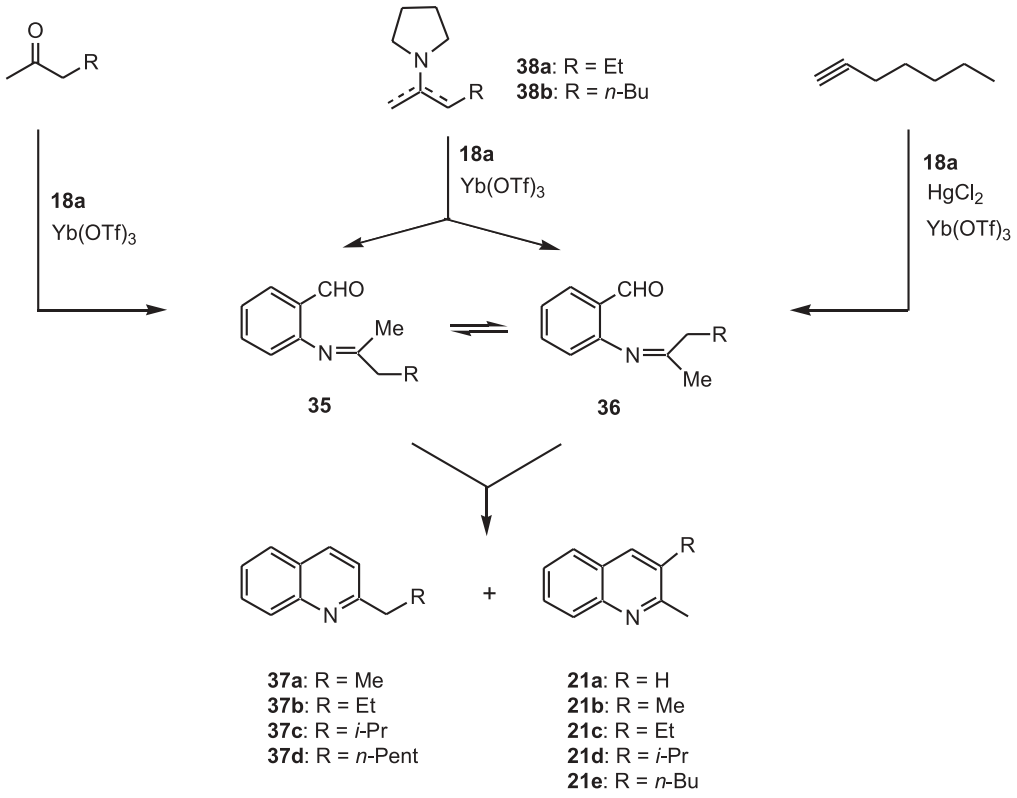

Scheme 6. Generation of quinolines **25** from tetrahydroquinolines **26**.

Scheme 7. Aldehyde Schiff base cyclization.

Scheme 8. Ketone Schiff base cyclization.

with *Z*-isomers **34**, which by an intramolecular aldolization can now produce the 3-alkylquinoline. The conversion of the tetrahydroquinoline derivatives **26** into the dimeric quinoline derivatives **25** must also involve higher energy processes, and thus, the temperature must be raised for this transformation to occur at a useful rate as well.

There are two important consequences of the above results. Firstly, given that the *Z*-Schiff base is a high-temperature intermediate, it should be possible to devise conditions that would favor its formation and thus increase the 3-alkylquinoline yield. Indeed, addition of a solution of the 2-aminobenzaldehydes **18a** or **18b** and a slight excess of *n*-heptanal or phenylacetaldehyde in toluene to a boiling suspension of ytterbium triflate in toluene over a 3 to 4 h period gave the expected 3-substituted quinolines in 40%–80% yields (Scheme 7 and Table 2, entries 7–10). Secondly, if Schiff bases of unsymmetrical ketones (e.g., methyl alkyl ketones) could be generated, and if *E–Z* equilibration did occur (e.g., **35** with **36**, Scheme 8), then mixtures of two quinolines (**21** and **37**) should be formed, and the 2-

© 2004 NRC Canada

substituted quinoline **37** might well predominate. This would be quite different from what occurs under the usual basic or acidic conditions of the Friedländer synthesis (see above). Schiff bases unfortunately do not form from ketones and 2-aminobenzaldehyde under the conditions described above for aldehydes. It was found, however, that heating a solution of **18a** in 2-butanone containing catalytic ytterbium triflate at 95 °C resulted in the very slow (>2 days) consumption of the aldehyde. Removal of the excess 2-butanone, followed by heating the residue in toluene at reflux temperature for 7 h, gave a 1.7:1 mixture of 2,3-dimethylquinoline (**21b**) and 2-ethylquinoline (**37a**, Scheme 8) in over 90% yield (Table 2, entry 11). In contrast, under alkaline conditions, 2,3-dimethylquinoline was the only product obtained (Table 1, entry 9). When 2-pentanone was used in the above reactions, 2-*n*-propylquinoline (**37b**) predominated over 2-methyl-3-ethylquinoline (**21c**) by a factor of 1.2 for ytterbium triflate, whereas the latter quinoline was the major product in the sodium-hydroxide-mediated reaction (**21c**:**37b** = 3.3:1, Table 2, entries 12 and 13). Hawes and Gorecki (35) also observed a slight predominance (factor of 1.1) of the kinetic over the thermodynamic product in the piperidine-catalyzed reaction of 4-aminonicotinaldehyde with neat 2-butanone. These results suggested that the kinetic product might be favored to an even greater extent for 4-methyl-2-pentanone, and a 15.3:1 **37c**:**21d** ratio supported this prediction. It was astonishing to find, however, that essentially the same product ratio (15.6:1) was observed for the sodium-hydroxide-promoted reaction, in which a Schiff base intermediate is unlikely based on the data described herein. Since the enolization of 4-methyl-2-pentanone occurs rapidly at both sites (deuteration complete in <5 min in perdeuteriomethanol containing a catalytic amount of the sodium derivative), it is probable that the highly selective formation of **37c** in the alkali-mediated condensation results from steric inhibition of aldolization at the methylene site. It is significant that analogous results have been reported for β-methyl substituted ketones both under acidic (36) and basic (37) conditions. Except for the case of 4-methyl-2-pentanone, the alterations in product ratios toward the kinetic one, although significant, are not so large that they are convincingly diagnostic of Schiff base intermediates. Since anhydrous conditions were not maintained in these reactions, it is quite possible that substantial amounts of the quinoline were formed by intermolecular aldol processes in both the piperidine- (35) and the ytterbium-triflate-catalyzed reactions. The facile acid-catalyzed transamination of enamines and Schiff bases (38–40) and the well-known water sensitivity of the latter prompted an examination of the reactivity of the pyrrolidine enamines of 2-pentanone (**38a**) and 2-heptanone (**38b**) towards 2-aminobenzaldehyde (Scheme 8). For example, a solution of **18a** in anhydrous toluene containing 2.4 equiv. of the enamine **38a** (1 equiv. of **38a** to ensure anhydrous conditions) and catalytic ytterbium triflate was rapidly and efficiently converted into a mixture of the expected quinolines **21c** and **37b**, both at reflux (<1 h) and room (4 h) temperature. The kinetic product **37b** was favored by a factor of ca. 5 in both cases (Table 2, entries 16 and 17). The kinetic product was also highly favored for the reaction of **18a** with the enamine **38b** at room temperature (**37d**:**21e** = 4:1). These are reasonable results if both the generation of the Schiff bases (mainly **35**) and the cyclization thereof to the quinolines are very fast processes.

Lastly, the room-temperature hydroarylamination of 1-heptyne with **18a** in the presence of an equimolar amount of mercuric chloride (41) and catalytic ytterbium triflate gave a mixture of **37d** and **21e** (4:1) in low, but reproducible yield (4%). In this case, the quinolines must be generated via Schiff base intermediates. The 4:1 kinetic:thermodynamic product ratio was identical to that observed for **38b** and strongly supports Schiff base intermediates in the enamine based reactions.

When this study was completed, Dormer et al. (37) reported that the kinetic product was dramatically favored when the methyl alkyl ketone was added slowly to a hot ethanolic solution of the 2-aminoarylaldehyde, a slight excess of various secondary amines, and a catalytic amount of sulfuric acid. Kinetic:thermodynamic product ratios as high as 24 were observed when the secondary amine was 1,3,3-trimethyl-6-azabicyclo[3.2.1]octane (TABO). The authors did not offer an explanation of these remarkable results. It is our contention that the reaction conditions reported by these investigators are precisely those that should result in the rapid formation and cyclization of the kinetic Schiff base, which arises by the fast transamination of an intermediate enamine.

In conclusion, the results described herein show that the generation of quinolines from simple aldehydes and 2-aminobenzaldehydes under the typically used acidic or basic conditions of the Friedländer synthesis takes place by a process in which an intermolecular aldol condensation is the first step. It is highly probable that the same mechanism is involved when 2-aminoarylketones are used to prepare quinolines. When Schiff bases are deliberately generated from aldehydes at room temperature, the kinetically formed *E*-isomer is diverted to nonFriedländer products. 3-Substituted quinolines are formed only at higher temperatures, which effect isomerization of the *E*-Schiff base to the *Z*-isomer, which then undergoes intramolecular aldolization to the heterocyclic aromatic product. When Schiff bases are generated from methyl alkyl ketones, the kinetically favored, less-hindered *Z*-Schiff base is formed preferentially and rapidly cyclizes to the 2-alkylquinoline derivative. Thus, the hallmark of such cyclizations is a high kinetic:thermodynamic product ratio, a result completely opposite to that observed when the usual acidic or basic reaction conditions are employed in the Friedländer quinoline synthesis. This result has obvious synthetic consequences, which have been convincingly demonstrated in the recently described study of Dormer et al. (37).

Experimental

General

The melting points are uncorrected. The NMR spectra (300 and 600 MHz) were recorded in deuteriochloroform unless indicated otherwise, and the chemical shifts are reported in parts per million (ppm) (δ) with internal tetramethylsilane as zero. The IR spectra were measured as dispersions in KBr for solids and as films for liquids. The UV spectra were taken in methanol solution. Reactions were followed by TLC on silica gel plates unless otherwise indi-

© 2004 NRC Canada

cated. Column chromatographic separations were effected using 230–400 mesh silica gel. The columns were packed dry, successively layered with the crude reaction mixture (absorbed onto silica gel) and a small amount of sand, and then eluted with the appropriate solvent system. The mixtures absorbed on silica gel were prepared by dissolving the reaction mixture in dichloromethane, adding this solution to silica gel, and then removing the solvent in vacuo.

The terms "worked up in the usual manner", "the usual workup", etc., signify that the extract was dried over anhydrous sodium sulfate, and the solvent was then removed in vacuo.

4-Hydroxy-4-(2-azidophenyl)-2-butanone (14c) and 4-(2-azidophenyl)-(3*E*)-buten-2-one (16c)

Aqueous sodium hydroxide (0.25 mol L^{-1}, 0.6 mL) was added dropwise at 15 °C to a stirred solution of 2-azidobenzaldehyde (**13b** (42)) (294 mg, 2 mmol) dissolved in a mixture of acetone (2.6 mL), water (2 mL), and ethanol (2 mL). One half hour after the addition was completed, the reaction mixture was poured into aqueous sodium chloride and extracted with dichloromethane. The extract was washed with water and then worked up as usual to give an oil (401 mg), which was taken up in a small amount of dichloromethane and added to silica gel (2 g), and the mixture was evaporated to dryness in vacuo. This material was layered onto a dry packed column (3.5 × 8.5 cm) of silica gel (40 g) covered with sand and eluted with hexane – ethyl acetate ((70:30), 20 mL fractions (F)). F 2–4 contained the enone **16c** (34 mg, 9.1%), and F 6–10 contained the β-ketol **14c** (324 mg, 78.9%), both of which were crystalline.

After crystallization from cyclohexane and drying in vacuo at 23 °C for 5 h with protection from light, the β-ketol **14c** had mp 69 to 70 °C. ^{1}H NMR δ: 2.20 (s, 3H), 2.72 (dd, 1H, *J* = 9.5, 17.6 Hz), 2.91 (dd, 1H, *J* = 2.7, 17.6 Hz), 3.47 (d, 1H, *J* = 3.1 Hz, exchanged with D_2O), 5.34 (m, 1H), 7.13 (dd, 1H, *J* = 1.0, 8.0 Hz), 7.17 (td, 1H, *J* = 1.1, 7.7 Hz), 7.32 (td, 1H, *J* = 1.7, 7.7 Hz), 7.54 (dd, 1H, *J* = 1.6, 7.7 Hz). ^{13}C NMR δ: 30.62, 50.45, 65.31, 117.87, 125.18, 128.65, 133.83, 136.05, 209.22. Anal. calcd. for $C_{10}H_{11}N_3O_2$: C 58.94, H 5.40, N 20.48; found: C 58.85, H 5.40, N 20.60.

After crystallization from cyclohexane and drying in vacuo (17 h), the enone **16c** had mp 107 to 108 °C. ^{1}H NMR δ: 2.39 (s, 3H), 6.70 (d, 1H, *J* = 16.5 Hz), 7.15 (d, 1H, *J* = 7.8 Hz), 7.20 (td, 1H, *J* = 1.0, 8.1 Hz), 7.43 (td, 1H, *J* = 1.5, 8.5 Hz), 7.6 (dd, 1H, *J* = 1.5, 7.8 Hz). ^{13}C NMR δ: 27.20, 118.82, 125.05, 126.11, 127.90, 128.71, 131.54, 137.62, 139.32, 198.57. Anal. calcd. for $C_{10}H_9N_3O$: C 64.16, H 4.85, N 22.45; found: C 64.54, H 4.89, N 22.33.

4-(2-Nitrophenyl)-3-methyl-(3*E*)-buten-2-one (16b)

Sodium hydroxide (0.25 mol L^{-1}) was added dropwise at 15 °C to a stirred solution of 2-nitrobenzaldehyde (**13a**, 3.022 g, 20 mmol) in a mixture of 2-butanone (32 mL, 25.7 g), ethanol (12 mL), and water (20 mL), until the solution was weakly alkaline (ca. 15 mL). After 1 h the solution was diluted with water, and the mixture was extracted with ether, washed with saturated NaCl solution, and then processed as usual to give a mixture of the β-ketols **14b** and **15** (4.42 g). This mixture was dissolved in acetic anhydride (10 mL); sodium acetate (1.64 g, 20 mmol) was added, and the mixture was heated at reflux temperature for 1 h. Water was added cautiously to the hot solution to decompose the excess acetic anhydride, and when the vigorous reaction was over, the mixture was poured into ice-water and extracted with dichloromethane. The extract was washed successively with 10 wt % sodium carbonate solution and water and then worked up as usual. The crude product (4.07 g) was absorbed onto silica gel (20 g), loaded onto a dry packed column (6 × 28 cm) of silica gel (380 g), and eluted with hexane – ethyl acetate (70:30, 50 mL fractions). F 13–16 contained the desired crystalline enone **16b** (2.66 g, 65.6%). Subsequent fractions contained a mixture of **16b** and 5-(2-nitrophenyl)-(4*E*)-penten-3-one. An analytical specimen of the desired enone was obtained by crystallization from hexane and had mp 59 to 60 °C after drying in vacuo (4 h). ^{1}H NMR δ: 1.83 (d, 3H, *J* = 1.4 Hz), 2.50 (s, 3H), 7.39 (d, 1H, *J* = 7.8 Hz), 7.54 (td, 1H, *J* = 1.2, 7.8 Hz), 7.69 (td, 1H, *J* = 1.2, 7.5 Hz), 7.81 (bs, 1H), 8.18 (dd, 1H, *J* = 1.3, 8.2 Hz). ^{13}C NMR δ: 13.25, 26.26, 125.38, 129.58, 131.68, 132.30, 133.83, 136.64, 139.22, 147.88, 200.14. Anal. calcd. for $C_{11}H_{11}NO_3$: C 64.38, H 5.40, N 6.83; found: C 64.52, H 5.33, N 6.95.

Reduction of nitro compounds with iron powder and ammonium chloride

The following is a typical reduction. A mixture of the nitro compound (10 mmol) dissolved in ethyl acetate (100 mL), water (60 mL), iron powder (2.1 g, 37.5 mmol (Fisher Scientific, electrolytic, <100 mesh; iron powder from other suppliers, e.g., Malinckrodt, gave similar results, but the reductions were slower.)), and ammonium chloride (3.34 g, 62.5 mmol) was stirred vigorously at room temperature for the time period shown below. The mixture was filtered through Celite, and the inorganic residue was washed well with ethyl acetate. The ethyl acetate phase was separated and combined with an ethyl acetate extract of the aqueous phase; the extract was washed with saturated NaCl solution and then worked up as usual. The crude product was then purified by column chromatography on silica gel as described below.

4-(2-Aminophenyl)-(3*E*)-buten-2-one (17a)

Reaction time, 17 h. A 4 mmol scale reaction product (absorbed on silica gel, 3 g) was purified by column (3.5 × 14 cm) chromatography on silica gel (67 g, 25 mL fractions). The product (0.516 g, 80.0%), present in F 3–5, was obtained as a yellow oil. ^{1}H NMR δ: 2.36 (s, 3H), 4.01 (bs, 2H), 6.53 (d, 1H, *J* = 16.0 Hz), 6.71 (dd, 1H, *J* = 1.3, 8.3 Hz), 6.77 (td, 1H, *J* = 1.0, 7.3 Hz), 7.18 (td, 1H, *J* = 1.5, 7.3 Hz), 7.39 (dd, 1H, *J* = 1.5, 8.0 Hz), 7.68 (d, 1H, *J* = 16.0 Hz). ^{13}C NMR δ: 28.47, 117.30, 119.48, 120.29, 127.16, 128.57, 131.96, 139.06, 146.32, 198.63. A sample of this material was converted into the pivalamide (59.9%) by the technique described below for **17b**. A sample on solution in hot toluene and dilution with an equal volume of hexane gave material with mp 119 to 120 °C (lit. (43) value mp 117 to 118 °C).

4-(2-Aminophenyl)-3-methyl-(3*E*)-buten-2-one (17b)

Reaction time, 20 h. The crude product from an 8.38 mmol reaction was absorbed onto silica gel (8 g) and

© 2004 NRC Canada

purified on a column (4 × 23 cm) of silica gel (152 g) using hexane – ethyl acetate (65:35, 50 mL fractions). The product was contained in F 10–15 as an oil (1.266 g, 83.8%). IR (film) (cm^{-1}): 3452, 3366, 3244, 1659, 1623. ^{1}H NMR δ: 1.95 (d, 1H, J = 1.4 Hz), 2.46 (s, 3H), 3.74 (bs, 2H), 6.74 (dd, 1H, J = 0.9, 8.0 Hz), 6.80 (dt, 1H, J = 1.0, 7.5 Hz), 7.12 (dd, 1H, J = 1.6, 7.6 Hz), 7.17 (dd, 1H, J = 1.5, 7.7 Hz), 7.45 (bs, 1H). ^{13}C NMR δ: 13.64, 26.38, 116.20, 118.77, 121.84, 130.02, 130.11, 136.19, 144.70, 200.55.

The pivalamide of this compound was prepared as follows. Trimethylacetyl chloride (0.25 mL, 245 mg, 2.03 mmol) was added all at once to a stirred solution of the above amino compound (269 mg, 1.49 mmol) in toluene (30 mL) containing triethylamine (0.3 mL, 218 mg, 2.15 mmol) and 4-dimethylaminopyridine (18 mg) at 0 °C. The cooling bath was removed, and the mixture was stirred at room temperature for 18 h. The mixture was washed successively with water, 1 mol L^{-1} HCl, 10 wt % sodium carbonate, and saturated NaCl solution. After the usual workup, the brown solid was taken up in hot toluene (3 mL) and diluted with hexane (9 mL) to give the pivalamide (127 mg, mp 111 to 112 °C). A second crop (31 mg, mp 110–111.5 °C, total yield, 158 mg, 40.9%) of product was obtained from the mother liquor. Recrystallization of the first crop gave the analytical specimen, which had mp 111.5–112 °C, after drying in vacuo (9 h at 40 °C). Anal. calcd. for $C_{16}H_{21}NO_2$: C 74.10, H 8.16, N 5.40; found: C 74.33, H 8.10, N 5.57.

2′-Aminocinnamaldehyde (17c)

Reaction time, 4 h. After washing the ethyl acetate solution of the crude product with saturated NaCl solution and drying over sodium sulfate, the solvent was removed in vacuo at room temperature or below and the amino compound (100% yield) was immediately dissolved in toluene. Toluene solutions of this material, which contains a trace of quinoline (TLC), can be kept for a few days without significant decomposition when stored at 5 °C with protection from light.

2-Aminobenzaldehyde (18a)

Reaction time, 5 h. The crude product from a 20 mmol reaction was purified by normal column (4.2 × 18 cm) chromatography on silica gel (125 g), using hexane – ethyl acetate (70:30, 50 mL fractions). F 5–8 contained the product (2.08–2.25 g, 86%–93%), which crystallized spontaneously and usually had mp 37 to 38 °C (lit. (19) value mp 38 to 39 °C) after drying in vacuo. It is indefinitely stable when stored at 5 °C.

2-Amino-4,5-dimethoxybenzaldehyde (18b)

Reaction time, 20 h. The crude product from a 10 mmol reaction was purified by normal column (3.5 × 19.5 cm) chromatography on silica gel (100 g) using hexane – ethyl acetate (1:1, 50 mL fractions). F 7–13 contained the product (1.395 g, 77%), which had mp 82–84 °C (lit.(44) value mp 86 °C) after drying in vacuo. ^{1}H NMR δ: 3.85 (s, 3H), 3.89 (s, 3H), 6.12 (s, 1H), 6.88 (s, 1H), 9.69 (d, 1H, J = 0.4 Hz). ^{13}C NMR δ: 56.36, 56.92, 98.82, 111.75, 116.43, 141.42, 147.67, 156.56, 191.78.

Preparation of 2-methylquinoline-*N*-oxide (20) and 2-methylquinoline (21a) from the β-ketol 14a

Iron – ammonium chloride reduction

This reduction was effected in the manner described above on a 1 mmol scale. Evaporation of the ethyl acetate phase in vacuo gave 92 mg of a crystalline solid. The aqueous phase was brought to pH 9 with solid sodium carbonate, then saturated with sodium chloride and extracted with ethyl acetate. The extract was processed as usual to give a further 42 mg of solid. The solid material was identical to authentic **20** (yield 75.6%) and contained only a trace of **21a** by TLC.

Catalytic reduction

A solution of **14a** (418 mg, 2 mmol) in ethanol (30 mL), containing 10% Pd–C (40 mg), was hydrogenated at room temperature and atmospheric pressure. After 25 min, hydrogen absorption (89% of theory) ceased, the mixture was filtered through Celite, and the solvent was removed in vacuo to give a residue (321 mg), which by ^{1}H NMR was an 80:20 mixture of **20** and **21a**. Crystallization from hot water gave the monohydrate of **20** (222 mg, 62.6%), which had mp 72.5–74 °C (lit. (45) value mp 77 to 78 °C).

Preparation of 2-methylquinoline (21a) from the azido compound 14c

Iron – ammonium chloride reduction

This reduction was carried out using the same reagent and solvent ratios as described above for the nitro compound reductions. Reaction time, 22 h. The ethyl acetate phase, containing **21a**, was extracted with 1 mol L^{-1} HCl; the acid extract was brought to pH 9 with solid sodium carbonate; the mixture was extracted with ethyl acetate, and the extract was washed with saturated NaCl solution. After the usual workup, the crude base (138 mg from a 1 mmol reaction) was converted into the picrate (317 mg, 85.1%) with picric acid (240 mg) in hot ethanol (10 mL). The picrate was identical to an authentic specimen by mmp, and the free base recovered therefrom was identical by NMR spectroscopy to authentic material.

Triphenylphosphine

A solution of the azido compound **14c** (61.5 mg, 0.3 mmol) in toluene (10 mL), containing triphenylphosphine (79 mg, 0.3 mmol), was stirred at room temperature. By 1 h, **21a** and triphenylphosphine oxide were clearly visible by TLC (20:80 ethyl acetate – hexane, UV), but no other new spots were present. After 2 h, the solution was heated at reflux temperature for 2 h; it was extracted with 1 mol L^{-1} HCl, and the acid extract was worked up exactly as described for the iron – ammonium chloride reduction. Crude **21a** (41 mg) was converted into the picrate (81.7 mg, 73.3%) with picric acid (70 mg) in hot ethanol (4 mL).

Preparation of the quinolines by isomerization of 17a-c

With sodium hydroxide

2-Methylquinoline (21a)

A solution of **17a** (100 mg, 0.62 mmol) in ethanol (3 mL), water (1 mL), and 1 mol L^{-1} NaOH (0.1 mL) was stirred at room temperature for 22 h. Water was added, and the mix-

© 2004 NRC Canada

ture was extracted with ethyl acetate; the extract was washed with saturated NaCl solution and worked up in the usual way. The crude base (96 mg) was converted into the picrate (192 mg, 83.4%) in the usual way.

Quinoline

A solution of the freshly prepared enal **17c** (147 mg, 1 mmol) in ethanol (6 mL), water (2 mL), and 1 mol L^{-1} NaOH (0.1 mL) was left at room temperature. Additional NaOH was added at 22 h (1 mol L^{-1}, 0.2 mL) and at 47 h (2.5 mol L^{-1}, 0.2 mL). After 75 h the ethanol was removed in vacuo, and the residue was made acidic with 1 mol L^{-1} HCl and washed with ethyl acetate. The acidic phase was then worked up, as described for the preparation of **21a** from **14c** above. The crude base was converted into quinoline picrate (224 mg, 62.5%).

2,3-Dimethylquinoline (21b)

A solution of the enone **17b** (120 mg, 0.67 mmol) in ethanol (3 mL), water (1 mL), and 1 mol L^{-1} NaOH (2.2 mL) was heated at reflux temperature for 16 h. The reaction mixture was worked up as described above for the preparation of **21a**. The crude base was converted into the picrate (213 mg, 82.8%). A sample of the picrate was stirred with excess 1 mol L^{-1} NaOH and toluene. The toluene phase was separated, washed with saturated NaCl solution, and worked up in the usual way to give 2,3-dimethylquinoline, mp 67–68.5 °C (lit. (46) value mp 68.2–69 °C).

Acid-mediated isomerization

2-Methylquinoline (21a): 1.5 mol L^{-1} HCl

A solution of **17a** (100 mg, 0.62 mmol) in dioxan (3 mL) and 3 mol L^{-1} HCl (3 mL) was heated at reflux temperature for 1 h. The cooled solution was diluted with water and made basic with solid sodium carbonate. The mixture was extracted with ethyl acetate; the extract was washed with saturated NaCl solution and worked up in the usual way to give the crude base (86 mg), from which was obtained the picrate (189 mg, 81.8%).

2-Methylquinoline (21b): Catalytic sulfuric acid in acetic acid

To a solution of the enone **17a** (315 mg, 1.95 mmol) in acetic acid (8 mL) was added a 0.18 mol L^{-1} solution of sulfuric acid in acetic acid (2 mL), and the blood-red reaction mixture was heated at reflux temperature for 2.25 h. Toluene was added, and the mixture was evaporated to a small volume in vacuo. The residue was diluted with water, made basic with sodium carbonate, and extracted with ethyl acetate. The extract was washed with 1 mol L^{-1} HCl, and the acid phase was made basic with solid sodium carbonate and extracted with ethyl acetate. The extract was washed with saturated NaCl solution and worked up as usual to give an oil (219 mg), which was absorbed onto silica gel (2.2 g) and purified by column (2.2 × 12 cm) chromatography on silica gel (23 g) using hexane – ethyl acetate (65:35, 10 mL fractions). F 6–9 contained the product (168 mg), which was converted into the picrate (251 mg, 34.6%).

2,3-Dimethylquinoline (21b): 1.5 mol L^{-1} HCl

The enone **17b** was converted into **21b** exactly as described above to give the picrate in 86.7% yield.

Preparation of the quinolines from 2-aminobenzaldehyde (18a) and ketones

Sodium-hydroxide-mediated condensations

2-Methylquinoline (21a)

A solution of **18a** (121 mg, 1 mmol) in ethanol (4 mL), water (4 mL), acetone (0.6 mL, 0.475 g, 8 mmol), and 1 mol L^{-1} NaOH (0.2 mL) was left at room temperature for 47 h. The reaction mixture was worked up exactly as described for the preparation of **21a** from **17a** under alkaline conditions to give the picrate (298 mg, 80.0%).

2,3-Dimethylquinoline (21b)

A solution of **18a** (121 mg, 1 mmol) in ethanol (6 mL) and 1 mol L^{-1} NaOH (3.5 mL) containing 2-butanone (108 mg, 1.5 mmol) was left at room temperature for 12 h and then worked up as described above for **17a**. The crystalline base was converted into the picrate (296 mg, 76.6%).

Acid-mediated condensation

2-Methylquinoline (21a)

To a solution of **18a** (61 mg, 0.5 mmol) and acetone (87 mg, 1.5 mmol) in acetic acid (4.5 mL) was added a 0.18 mol L^{-1} solution of sulfuric acid in acetic acid (0.5 mL), and the solution was heated at reflux temperature for 18 h. The reaction mixture was worked up exactly as described for the sulfuric-acid-catalyzed isomerization of **17a**. The crude product (43 mg) was absorbed onto silica gel (1 g) and purified by column (1.8 × 5.5 cm) chromatography on silica gel (9 g) using hexane – ethyl acetate (60:40, 10 mL fractions). F 2–4 contained the product (20 mg), which was converted into the picrate (49 mg, 26.2%).

2-Methylquinoline (21a) by photolysis of 17a

A solution of the enone **17a** (20 mg, 0.124 mmol) in ethanol (4 mL) in a pyrex test tube was placed next to a Pen-Ray Model PS-1 pencil light, and both were enveloped in aluminum foil. The solution was irradiated until TLC showed that **17a** was absent (24 h); the solvent was removed in vacuo, and the crude base was converted into the picrate (34.4 mg, 74.6%).

Preparation of 3-substituted quinolines 24a-c from 18a and aldehydes

p-Toluenesulfonic acid catalyst

A solution of **18a** (121 mg, 1 mmol) and the appropriate aldehyde (1.2 mmol, freshly liberated from the bisulfite adduct) in toluene (50 mL) containing *p*-toluenesulfonic acid monohydrate (10 mg) was heated at reflux temperature with separation of water in a Dean–Stark apparatus until **18a** was no longer present by TLC (see Table 2). The base was extracted into 1 mol L^{-1} HCl; the extract was made basic with solid sodium carbonate and extracted with ethyl acetate. After the usual processing the crude base was converted into the known picrate (See Table 2 for yields). The bases, liberated from the picrates, were also fully characterized by NMR spectroscopy.

© 2004 NRC Canada

Ytterbium triflate as catalyst

Normal conditions

A solution of **18a** (121 mg, 1 mmol) and the appropriate aldehyde (1.2–1.4 mmol, freshly liberated from the bisulfite adduct) in toluene (10 mL) containing suspended ytterbium triflate (62 mg, 0.1 mmol) was stirred at reflux temperature (argon atmosphere) for 4 h. The cooled mixture was vigorously stirred with 10 wt % sodium carbonate solution for 15 min, and the toluene phase was separated. The bases were extracted into 1 mol L^{-1} HCl and processed as described above. See Table 2 for picrate yields. When the product was 3-phenylquinoline, HCl extraction often caused the insoluble salt to crystallize and form an emulsion. In this case, it was necessary to alternatively extract with HCl and water, until all of the salt had been removed.

*Modified conditions: Preparation of quinolines **24a** and **24c-e***

A solution of **18a** or **18b** (2 mmol) and the aldehyde (2.4–2.5 mmol) in toluene (15 mL) was added dropwise (argon atmosphere) to a stirred suspension of ytterbium triflate (124 mg, 0.2 mmol) in toluene (15 mL) at reflux temperature over the time period indicated in Table 2 in parentheses. Heating at reflux temperature was then continued until the total elapsed time indicated in Table 2. The cooled mixture was vigorously stirred with 10 wt % sodium carbonate solution for 15 min, and the toluene phase was separated. The subsequent workup depended on the specific compound. For **24a** and **24c**, the bases were extracted with 1 mol L^{-1} HCl and liberated with sodium carbonate as described above. The yield of **24a** corresponds to that of the picrate, whereas that of **24c** refers to the free base. See below for **24d** and **24e**.

3-*n*-Pentyl-6,7-dimethoxyquinoline (24d)

The acid extract was made basic in the usual way and extracted with ethyl acetate. The extract was washed with saturated NaCl solution and then processed as usual to give the crude crystalline base (277 mg). This material was absorbed onto silica gel (1.5 g) and subjected to column (3.5 × 11.5 cm) chromatographic purification on silica gel (55.5 g) using 1:1 hexane – ethyl acetate (25 mL fractions). F 10–13 contained the solid product (217 mg, 41.8%). After two crystallizations from hexane and drying in vacuo for 24 h, it had mp 63.5–65 °C. ^{1}H NMR δ: 0.90 (t, 3H, J = 7.0 Hz), 1.29–1.40 (m, 4H), 1.65–1.75 (m, 2H), 2.74 (t, 2H, J = 7.6 Hz), 4.01 (s, 3H), 4.02 (s, 3H), 7.00 (s, 1H) 7.40 (s, 1H), 7.71 (d, 1H, J = 2.1 Hz), 8.57 (d, 1H, J = 2.1 Hz). ^{13}C NMR δ: 14.01, 22.51, 31.01, 31.37, 33.06, 56.00, 56.06, 104.78, 107.81, 123.72, 132.73, 133.68, 143.61, 149.58, 149.79, 151.71. Anal. calcd. for $C_{16}H_{21}NO_2$: C 74.10, H 8.16, N 5.40; found: C 74.25, H 8.16, N 5.56.

3-Phenyl-6,7-dimethoxyquinoline (24e)

The toluene solution containing the reaction mixture was not extracted with acid. Instead, after washing with saturated NaCl solution and the usual workup, the crude product from a 1 mmol reaction was absorbed onto silica gel (1.5 g) and subjected to column (2.2 × 20 cm) chromatographic purification on silica gel (35.5 g) using 1:1 hexane – ethyl acetate (20 mL fractions). F 9–18 contained the product (208 mg, 78.4%), the ^{1}H NMR spectrum of which was identical to that reported (47).

2-*n*-Hexyl-3-*n*-pentyl-8-(2-formyl)anilinomethylquinoline (25a)

A 2 mmol reaction was carried out as described in the section Normal conditions above, except that the acid extraction to remove **24a** was not carried out. The toluene solution of the product mixture was washed with saturated NaCl solution and then worked up as usual to give an oil (439 mg), which was absorbed onto silica gel (2.2 g) and subjected to column (3.5 × 17 cm) chromatography on silica gel (88 g) using hexane – ethyl acetate (90:10, 25 mL fractions). F 5–7 contained **25a** (104–179 mg, 25%–43%) as a yellow oil. IR: see Discussion section. UV (nm): 385 (ε 6520), 319.5 (ε 4620), 306.5 (ε 4330), 261.5 (ε 10 100), 229 (ε 57 700), 213 (ε 59 600). ^{1}H NMR: see Discussion section. ^{13}C NMR (CD_2Cl_2) δ: 14.58, 14.69, 23.34, 23.48, 28.93, 29.25, 30.20, 32.58, 32.71, 33.00, 36.12, 43.39, 112.23, 115.47, 119.49, 125.88, 126.85, 127.00, 127.92, 135.32, 136.27, 136.45, 137.31, 162.00, 194.50. MS m/z (%): 417 ([M + H]$^+$, 56), 312 (65), 296 (100), 212 (28), 198 (31), 171 (27). HR-FAB$^+$-MS m/z calcd. for $[C_{28}H_{36}N_2O]H^+$: 417.2897; found: 417.2895.

2-Ethyl-3-methyl-8-(2-formyl)anilinomethylquinoline (25b)

A mixture of the isomeric tetrahydroquinolines **26d-e** (227 mg, 0.704 mmol, see below for synthesis) in toluene (25 mL) containing suspended ytterbium triflate (48 mg, 0.077 mmol) was stirred at reflux temperature under argon for 22 h. The reaction mixture was stirred with sodium carbonate for 15 min, and then the toluene phase was processed as described above to give a solid residue (206 mg), which was absorbed onto silica gel (1.0 g) and purified by column (3.5 × 14 cm) chromatography on silica gel (69 g) using hexane – ethyl acetate (85:15, 20 mL fractions). F 3–5 contained the product (76 mg), and F 7 contained the product admixed with a slightly more polar material (8 mg). The major fraction on crystallization from cyclohexane gave the crystalline product in two crops, mp 145–147 °C (47 mg) and mp 144–146 °C (2 mg). The minor fraction gave an additional 2 mg of product, mp 144.5–145 °C, from cyclohexane. Total yields, 51 mg (23.8%). Recrystallization from cyclohexane gave an analytical specimen that had mp 147–148.5 °C after drying in vacuo (45 °C, 16 h). IR (KBr) (cm^{-1}): 3434, 3334, 2750, 1656. UV (nm): 386 (ε 6250), 318.5 (ε 3750), 304.5 (ε 3530), 263 (ε 9370), 228 (ε 51 600), 211 (ε 55 500). ^{1}H NMR (CD_2Cl_2) δ: 1.45 (t, 3H, J = 7.4 Hz), 2.48 (d, 3H, J = 0.9 Hz), 3.02 (q, 2H, J = 7.4 Hz), 5.16 (bs, 2H), 6.65 (td, 1H, J = 0.9, 6.7 Hz), 6.83 (d, 1H, J = 8.5 Hz), 7.30 (td, 1H, J = 1.7, 7.8 Hz), 7.37 (d, 1H, J = 7.1 Hz), 7.47 (dd, 1H, J = 1.7, 7.8 Hz), 7.57 (dd, 1H, J = <1, >6 Hz), 7.65 (dd, 1H, J = <1, 8.3 Hz), 7.85 (bs, 1H), 8.98 (bs, 1H, exchanged with D_2O), 9.83 (d, 1H, J = 0.6 Hz). ^{13}C NMR δ: 12.29, 19.40, 29.55, 43.22, 125.67, 126.39, 126.51, 127.59, 130.03, 135.82, 136.06, 137.02, 144.86, 151.47, 162.36, 194.25. Anal. calcd. for $C_{20}H_{20}N_2O$: C 78.92, H 6.62, N 9.20; found: C 79.25, H 6.58, N 9.35.

2-Methyl-8-(2-formyl)anilinomethylquinoline (25c)

A solution of a mixture of **26a** and **26b** (203 mg, 0.69 mmol, see below for synthesis) in toluene (20 mL) containing suspended ytterbium triflate (86 mg) was stirred at reflux temperature (argon atmosphere) for 4 h and then

© 2004 NRC Canada

worked up as described for **25b**. The crude product (177 mg) was absorbed onto silica gel (1 g) and subjected to column (3.5 × 11.5 cm) chromatographic purification on silica gel (54 g) using hexane – ethyl acetate (85:15, 20 mL fractions). F 5–10 contained the product (121 mg), which was crystallized from cyclohexane to give the desired material in two crops, mp 95–95.5 °C (85 mg) and mp 94.5–95 °C (10 mg). Thus the yield of **25c** was 95 mg (46.5%). Recrystallization of a sample from cyclohexane gave the analytical specimen, which had mp 94.5–95.5 °C after drying in vacuo (9.5 h). IR (KBr) (cm^{-1}): 3480 (bw), 3350, 2738, 1666. UV (nm): 383 (ε 6850), 317 (ε 3530), 304 (ε 3500), 267 (ε 9980), 224 (ε 52 900), 208 (ε 51 900), 206.5 (ε 52 500). ^{1}H NMR δ: 2.78 (s, 3H), 5.17 (d, 2H, *J* = 5.9 Hz), 6.65 (td, 1H, *J* = 0.8, 7.4 Hz), 6.76 (d, 1H, *J* = 8.5 Hz), 7.29 (td, 1H, *J* = 1.6, 8.6 Hz), 7.38 (t, 3H, *J* = 7.6 Hz), 7.47 (dd, 1H, *J* = 1.6, 7.7 Hz), 7.61 (dd, 1H, *J* = 1.0, 7.1 Hz), 7.66 (d, 1H, *J* = 8.1 Hz), 8.02 (d, 1H, *J* = 8.4 Hz), 9.02 (bs, 1H, exchanged with D_2O), 9.87 (s, 1H). ^{13}C NMR δ: 25.93, 43.21, 111.99, 115.19, 119.08, 122.37, 125.71, 126.82, 127.14, 127.42, 135.95, 136.09, 137.03, 146.30, 151.41, 158.68, 194.32. Anal. calcd. for $C_{18}H_{16}N_2O$: C 78.23, H 5.84, N 10.14; found C 78.50, H 5.89, N 10.22.

Synthesis of the tetrahydroquinolines 26

A solution of **18a** (242 mg, 2 mmol) and the appropriate aldehyde (8 mmol) in toluene (20 mL) containing suspended ytterbium triflate (124 mg, 0.2 mmol) was stirred at room temperature under argon for the time period indicated below. The reaction mixture was then vigorously stirred with excess 10 wt % sodium carbonate solution for 15 min; the toluene phase was separated, washed with saturated NaCl solution, and worked up as usual. The bases were purified as described below.

cis- And *trans*-2-methyl-4-(2-formyl)anilino-1,2,3,4-tetrahydroquinoline-8-carboxaldehydes 26a and 26b

The crude product from a 2 mmol reaction was absorbed onto silica gel (1.5 g) and purified by column (3.5 × 12.5 cm) chromatography on silica gel (63.5 g) using hexane – ethyl acetate (80:20, 25 mL fractions). F 4–7 contained the product as a TLC homogeneous oil (191–210 mg, 65%–72%), which by ^{1}H NMR spectroscopy was a 4:1 mixture of **26a** and **26b**. IR (film) (cm^{-1}): 3317, 2744, 1653. UV (nm): 388 (ε 12 000), 262.5 (ε 11 400) 237 (ε 33 800). ^{1}H NMR: see Table 3. ^{13}C NMR (*e*,*e*-isomer **26a**) δ: 22.51, 36.34, 46.93, 49.57, 111.39, 115.05, 115.84, 117.59, 118.99, 123.35, 132.40, 135.84, 136.48, 137.41, 147.93, 150.75, 193.96, 194.53. MS *m*/*z* (%): 294 (27), 279 (28), 174 (100). HR-FAB$^+$-MS *m*/*z* calcd. for $C_{18}H_{18}N_2O_2$: 294.1368; found: 294.1362.

2-Ethyl-3-methyl-4-(2-formyl)anilino-1,2,3,4-tetrahydroquinoline-8-carboxaldehydes (26c-e) and 2-methyl-3-(2-formyl)anilinopentanal (27)

A reaction effected in the usual manner was complete in 2 days. The mixture from a 2 mmol reaction was absorbed onto silica gel (2 g) and purified by column (4 × 21.5 cm) chromatography on silica gel (143 g) using hexane – ethyl acetate (85:15, 50 mL fractions). F 5–7 contained **26c-e** (135 mg); F 8,9 contained a 1:1 mixture of **26c-e** and **27**; and F 10–12 contained pure **27** (50 mg), all as oils. See Table 3 for the ^{1}H NMR spectra of **26c-e**. The aldehyde **27** was a single isomer. ^{1}H NMR (CD_2Cl_2) δ: 0.96 (t, 3H, *J* = 7.4 Hz), 1.19 (d, 3H, *J* = 7.2 Hz), 1.65 (m, 2H), 2.68 (m, 1H, *J* = 1.2, 4.6, 7.2 Hz), 3.96 (m, 1H), 6.69 (td, 1H, *J* = 0.9, 7.4 Hz), 6.79 (d, 1H, *J* = 8.6 Hz), 7.39 (td, 1H, *J* = 1.7, 7.9 Hz), 7.47 (dd, 1H, *J* = 1.7, 7.7 Hz), 8.41 (bd, 1H, *J* = 9.7 Hz, exchanged with D_2O), 9.69 (d, 1H, *J* = 1.2 Hz), 9.79 (d, 1H, *J* = 0.7 Hz). ^{13}C NMR (CD_2Cl_2) δ: 9.07, 11.05, 26.55, 50.01, 53.94, 111.51, 115.47, 119.01, 136.19, 137.30, 150.90, 194.46, 203.92. MS *m*/*z* (%): 219 (87), 190 (20), 161 (44), 162 (100), 144 (100), 132 (31), 122 (45), 118 (47), 93 (42). HR-FAB$^+$-MS *m*/*z* calcd. for $[C_{13}H_{17}NO_2]H^+$: 220.1337; found: 220.1341.

A reaction effected at 110 °C had a very different product spectrum. Thus, a 2 mmol reaction was carried out in toluene (40 mL) in a pressure bottle for 6 h. Workup as described above gave a mixture, which by TLC (hexane – ethyl acetate (85:15)) showed four major products with *Rf*s 0.88, 0.78, 0.72, and 0.67. The most polar material corresponded to **26c**. The mixture was absorbed onto silica gel (1.5 g) and subjected to column (3.5 × 12 cm) chromatography on silica gel (60 g) using hexane – ethyl acetate (85:15, 25 mL fractions). F 8–10 (112 mg) partially crystallized, and after slurrying with 95:5 hexane – ethyl acetate, crystalline **25b** (8.8 mg, 1.4%), mp 144 to 145 °C, was collected by filtration. F 11–13 (102 mg) contained impure **26c**. F 14,15 (11 mg) was pure **26c**. ^{1}H NMR: see Table 3. ^{13}C NMR (CD_2Cl_2) δ: 6.63, 10.96, 26.46, 54.21, 111.84, 115.36, 116.17, 117.53, 119.66, 122.58, 133.08, 135.78, 136.80, 135.78, 136.80, 137.70, 148.26, 151.17, 194.17, 194.94. MS *m*/*z* (%): 322 (32), 307 (13), 293 (34), 202 (100), 186 (55), 172 (29), 149 (47). HR-EI-MS *m*/*z* calcd. for $C_{20}H_{22}N_2O_2$: 322.1681; found: 322.1667.

trans,*trans*-2-Benzyl-3-phenyl-4-(2-formyl)anilino-1,2,3,4-tetrahydroquinoline-8-carboxaldehyde (26f)

Reaction was carried out in the usual manner, except that the ratio of phenylacetaldehyde to **18a** was 2 and the reaction time was 41 h. Removal of the toluene from a 2 mmol reaction gave a residue, which partially crystallized. The mixture was slurried with toluene; the insoluble solid was collected by filtration and dried to give **26f** (130.5 mg, 14.6%), mp 235–238 °C. A sample was dissolved in hot 1,2-dichloroethane, diluted with four volumes of hexane, and seeded to give material with mp 236–238 °C, after drying in vacuo (75 °C, 6 h). IR (KBr) (cm^{-1}): 3428, 3292, 2751, 2733, 1652. ^{1}H NMR: see Table 3. ^{13}C NMR (CD_2Cl_2) δ: 40.64, 49.56, 55.97, 58.06, 111.71, 115.04, 115.66, 118.07, 118.67, 124.25, 127.25, 127.67, 128.57, 128.79, 129.05, 129.17, 129.38, 129.88, 133.01, 135.77, 136.95, 137.86, 140.14, 146.85, 151.11, 193.68, 194.14. Anal. calcd. for $C_{30}H_{26}N_2O_2$: C 80.69, H 5.87, N 6.27; found: C 80.71, H 5.81, N 6.41.

1,2-Dihydro-2-benzyl-3-phenylquinoline-8-carboxaldehyde (29)

The reaction was carried out as described for the synthesis of **25a** except that the reaction time was 6 h, and the 3-phenylquinoline was removed by extraction with 1 mol L^{-1} HCl. The toluene phase containing **29** was then washed suc-

cessively with 10 wt % sodium carbonate and saturated NaCl solution and then worked up as usual. The crude product from a 2 mmol reaction was absorbed onto silica gel (2 g) and purified by column (4 × 17 cm) chromatography on silica gel (110 g) using hexane – 1,2-dichloroethane (35:65, 25 mL fractions). F 9–13 contained the product (52–115 mg, 13%–29% yield based on phenylacetaldehyde), which was crystalline. After two crystallizations from cyclohexane and drying in vacuo (7 h), it had mp 119.5–121.5 °C. IR (CCl_4) (cm^{-1}): 3313, 2737, 1663. UV (nm): 420.5 (ε 9330), 346.5 (ε 3940), 269 (ε 23 800), 234 (ε 18 600). ^{1}H NMR: see Discussion. ^{13}C NMR (CD_2Cl_2) δ: 43.28, 55.99, 115.99, 118.25, 122.20, 122.67, 125.75, 126.88, 128.36, 128.65, 130.08, 132.61, 135.22, 135.28, 137.66, 138.40, 146.29, 193.44. Anal. calcd. for $C_{23}H_{19}NO$: C 84.89, H 5.89, N 4.30; found: C 84.66, H 5.75, N 4.49.

2-Benzyl-3-phenylquinoline-8-carboxaldehyde (30)

A solution of potassium nitrosodisulfonate (Fremy's salt, 90 mg, 0.335 mmol) in 4 wt % aqueous sodium carbonate (6 mL) was added to a stirred solution of **29** (87 mg, 0.267 mmol) in acetonitrile (9 mL). This caused precipitation of some **29**, but after 1 h a clear solution was obtained. After 6 h, the solution was diluted with a large volume of water and extracted with ethyl acetate. The extract was washed with saturated NaCl solution and then worked up as usual. The crude product was absorbed onto silica gel (0.5 g) and subjected to column (2.2 × 15 cm) chromatographic purification on silica gel (27.5 g) using hexane – 1,2-dichloroethane (35:65, 15 mL fractions). F 4,5 contained the starting material (19 mg), and F 7–21 contained the product (46.5 mg, 66% yield based on starting material consumed). On crystallization from cyclohexane **29** was obtained in two crops, mp 131–132.5 °C (37.5 mg) and mp 126.5–129.5 °C (3.5 mg). Recrystallization of the first crop from cyclohexane gave pure **29**, which had mp 132–132.5 °C after drying in vacuo (6 h). IR (CCl_4) (cm^{-1}): 1692. ^{1}H NMR (CD_2Cl_2) δ: 4.35 (s, 3H), 7.04–7.07 (m, 2H), 7.12–7.20 (m, 3H), 7.31–7.34 (m, 2H), 7.43–7.48 (m, 3H), 7.65 (td, 1H, *J* = 0.7, 7.4 Hz), 8.06 (s, 1H), 8.09 (dd, 1H, *J* = 1.5, 8.1 Hz), 8.26 (dd, 1H, *J* = 1.5, 7.2 Hz), 11.46 (d, 1H, *J* = 0.7 Hz). ^{13}C NMR (CD_2Cl_2) δ: 43.15, 126.32, 126.48, 127.44, 128.28, 128.49, 128.82, 128.88, 129.58, 129.88, 131.69, 134.27, 136.94, 137.19, 139.51, 139.63, 146.84, 160.91, 193.11. Anal. calcd. for $C_{23}H_{17}NO$: C 85.42, H 5.30, N 4.33; found: C 85.62, H 5.28, N 4.50.

Synthesis of quinolines 21 and 37 from 2-aminobenzaldehyde (18a) and methyl alkyl ketones

Neat ketones

A solution of **18a** (121 mg, 1 mmol) in the neat ketone (10 mL) containing ytterbium triflate (62 mg, 0.1 mmol) was placed in an oil bath at 95 °C and stirred in an argon atmosphere for the time given in Table 2, and then the excess ketone was removed in vacuo. Toluene (20 mL) was added to the residue, and the mixture was stirred at reflux temperature in an argon atmosphere for 7 h. After the usual treatment with 10 wt % sodium carbonate solution, the toluene phase was extracted with 1 mol L^{-1} HCl; the extract was made basic with solid sodium carbonate, and the products were extracted into ethyl acetate. The extract was washed with saturated NaCl solution and then worked up as usual.

2,3-Dimethylquinoline (21b) and 2-ethylquinoline (37a)

The crude product was absorbed onto silica gel (1 g) and purified by column (3.5 × 10.5 cm) chromatography on silica gel (49 g) using hexane – ethyl acetate (80:20, 20 mL fractions). F 7–9 contained **37a** (54 mg, 28.2%, converted into the picrate, mp 147–149 °C, lit.(48) value mp 148 °C); F 11–19 contained crystalline **21b** (54 mg, 47.7%), mp 67–78 °C.

2-Methyl-3-ethylquinoline (21c) and 2-n-propylquinoline (37b)

Purified in exactly the same manner as described for **21b** and **37a**. F 2–5 contained **37b** (70 mg, 40.9%, identified by NMR), and F 8–12 contained **21c** (59 mg, 34.5%, mp 69.5–71.5 °C, lit.(49) value mp 74–74.5 °C).

2-Methyl-3-isopropylquinoline (21d) and 2-isobutylquinoline (37c)

Purified as described above. F 3–5 contained **37c** (112 mg, 60.5%, picrate mp 163–166 °C, lit.(50) value mp 163 to 164 °C), and F 8–12 contained **21d** (8 mg, 4.3%). See below for characterization.

From ketones under alkaline conditions

2-Methyl-3-ethylquinoline (21c) and 2-n-propylquinoline (37b)

A solution of **18a** (61 mg, 0.5 mmol) and 2-pentanone (71 mg, 0.82 mmol) in ethanol (3 mL) and 1 mol L^{-1} NaOH (1.75 mL) was left at room temperature for 24 h, diluted with water, and made acidic with 1 mol L^{-1} HCl. The acid solution was extracted with toluene, and then the acid phase was made basic with solid sodium carbonate. The products were extracted with toluene; the extract was washed with saturated NaCl solution and worked up as usual to give the mixture of bases (73 mg, 85.2%), which by ^{1}H NMR was shown to be a 77:23 mixture of **21c** and **37b**.

2-Methyl-3-isopropylquinoline (21d) and 2-isobutylquinoline (37c)

A solution of **18a** (121 mg, 1 mmol) and 4-methyl-2-pentanone (150 mg, 1.5 mmol) in ethanol (6 mL) and 1 mol L^{-1} NaOH (3.5 mL) was heated at reflux temperature under argon for 4 h. The reaction was worked up exactly as described above to give **37c** (144 mg, 77.7%) and **21d** (10 mg, 5.4%). Compound **21d** was an oil. ^{1}H NMR δ: 1.34 (d, 6H, *J* = 6.8 Hz), 2.78 (s, 3H), 3.26 (sept., 1H, *J* = 6.8 Hz), 7.45 (td, 1H, *J* = 1.1, 8.0 Hz), 7.61 (td, 1H, *J* = 1.5, 7.7 Hz), 7.74 (dd, 1H, *J* = 1.2, 81. Hz), 7.92 (s, 1H), 7.99 (d, 1H, *J* = 8.4 Hz). ^{13}C NMR δ: 23.52, 23.54, 29.75, 125.98, 127.49, 127.92, 128.63, 128.86, 131.56, 140.93, 146.51, 158.44. The base was converted into the picrate, mp 216–218 °C decomposition (dec), in hot ethanol. The mp was unchanged on recrystallization and drying in vacuo (60 °C, 14.5 h). Anal. calcd. for $C_{19}H_{18}N_4O_7$: C 55.07, H 4.38, N 13.52; found: C 55.12, H 4.43, N 13.49.

From pyrrolidine enamines 38

A solution of **18a** (121 mg, 1 mmol) and **38a** (51) or **38b** ((52), 2.4 mmol) in anhydrous toluene (10 mL) containing

© 2004 NRC Canada

ytterbium triflate (62 mg, 0.1 mmol) was either left at room temperature or heated at reflux temperature (see Table 2) in an argon atmosphere. HCl (1 mol L^{-1}, 10 mL) was added to the reaction mixture, which was stirred vigorously at room temperature for 15 min. The acidic aqueous phase was worked up as described above to give the crude mixture of bases. This mixture was spiked with hexamethylbenzene (internal standard) and analyzed by ^{1}H NMR.

By arylhydroamination of 1-heptyne

A solution of **18a** (121 mg, 1 mmol), mercuric chloride (472 mg, 1 mmol), and 1-hepytne (0.7 mL, 513 mg, 5.33 mmol) in anhydrous THF (15 mL) was stirred at room temperature for 18 h in an argon atmosphere. Ytterbium triflate (62 mg, 0.1 mmol) was added, and stirring was continued for a total time of 3 days. Even though **18a** was still present by TLC, the solvent was removed in vacuo, water and ethyl acetate were added, and the mixture was filtered through Celite. The organic phase was separated and extracted with 1 mol L^{-1} HCl. The acidic extract was worked up as in the section From pyrrolidine enamines 38 above; the crude mixture was spiked with hexamethylbenzene and analyzed by ^{1}H NMR.

Note added in proof

The Friedländer synthesis of quinolines from *o*-aminoarylketones and ketones also proceeds by a rate-determining aldol mechanism. This is strongly supported by the observation that heating a toluene solution (reflux, 17 h) of 2-hexanone (4 equiv.), *o*-aminoacetophenone (1 equiv.), and pyrrolidine (2 equiv.), containing suspended anhydrous magnesium sulfate (10 equiv., in situ generation of the pyrrolidine enamine of 2-hexanone (53)), and ytterbium triflate (0.1 equiv.), gave a 5.5:1 mixture (ca. 25% yield) of 2-*n*-butyl-4-methylquinoline (kinetic) and 2,4-dimethyl-3-*n*-propylquinoline (thermodynamic). In contrast, effecting the condensation of 2-hexanone and *o*-aminoacetophenone in acetic acid (reflux), containing catalytic sulfuric acid (29), gave a 1:1.7 kinetic to thermodynamic product ratio. Comparable results were obtained starting with 2-butanone and *o*-aminoacetophenone.[2]

Packed-column supercritical fluid chromatography with splitless flame ionization detection

Kevin B. Thurbide and Shawn Gilbert

Abstract: The design and characterization of a flame ionization detector (FID) that is compatible with the high flow rates of packed-column supercritical fluid chromatography (pSFC) is presented. The modified FID uses a large quartz burner (4.0 mm i.d.) in place of the conventional burner (0.4 mm i.d.) and operates a stable flame in the presence of gas flows tested up to nearly 3000 mL/min. This modification allows the full flow of effluent from a pSFC column (i.e., splitless mode) to be directed into the FID. Results demonstrate that the modified FID yields response that is within a factor of 3 to that of a commercial FID. The attributes of the modified detector indicate that this approach could be a reliable and relatively simple means of achieving a splitless pSFC-FID system.

Key words: supercritical fluid chromatography, packed column, splitless, flame ionization detector.

Résumé : On a développé et caractérisé un détecteur à ionisation de flamme (DIF) qui est compatible avec les vitesses élevées d'écoulement d'une colonne à remplissage pour chromatographie fluide supercritique. Le DIF modifié utilise un grand brûleur en quartz (4,0 mm de diamètre intérieur) à la place du brûleur conventionnel (0,4 mm de diamètre intérieur) et il opère une flamme stable en présence d'écoulements de gaz allant jusqu'à environ 3000 mL/min. Cette modification permet de diriger tout l'effluent d'une colonne à remplissage (c'est-à-dire dans le mode sans division) vers le DIF. Les résultats démontrent que le DIF modifié fournit une réponse qui est à l'intérieur d'un facteur de trois par rapport à une DIF commercial. Les attributs du détecteur modifié indiquent que cette approche pourrait être une méthode fiable et relativement simple de développer un système sans division comme détecteur à ionisation de flamme pour chromatographie fluide supercritique avec colonne à remplissage.

Mots clés : chromatographie fluide supercritique, colonne à remplissage, sans division, détecteur à ionisation de flamme.

Introduction

In recent years there has been an increase in the use of packed-column supercritical fluid chromatography (pSFC) as a complimentary separation method to high-performance liquid chromatography (HPLC) and gas chromatography (GC) (1–3). This is attributed to the number of advantages that pSFC can offer, such as improved speed, selectivity, and resolving capability relative to HPLC and compatibility with a broader range of compounds relative to GC (4, 5). Additionally, the most common mobile phase in pSFC, carbon dioxide, provides a more environmentally compatible alternative to the conventional organic solvents used in HPLC (3). One of the greatest advantages offered by carbon dioxide as a mobile phase in pSFC is that it does not respond in the flame ionization detector (FID), which is widely used in GC for its large linear range and sensitive, universal response toward organic compounds (6). In this way, pSFC offers a beneficial means of combining HPLC-type separations with an informative GC detector.

Most commercial versions of the FID are compatible with conventional GC column flow rates on the order of 10–50 mL/min (7). Accordingly, since supercritical carbon dioxide expands about 500 times upon decompression, the FID can fully accept the typical microlitre per minute column flow rates used with capillary column supercritical fluid chromatography (8). However, pSFC commonly uses flow rates around 2 mL/min, similar to HPLC, which translates into about 1000 mL/min of carbon dioxide gas entering the FID burner. Such a large gas flow causes the flame to extinguish, and thus the FID can only be used in pSFC if the flow is split (usually after leaving the separation column), allowing only a portion of the effluent and analyte to enter the FID (9). While such methods allow a stable flame to be operated, a frequent concern reported for split-flow pSFC-FID interfaces is a variable split ratio that can lead to a nonuniform response factor (10). Still, this approach is common, and a successful split-flow interface adapted to operate with modern pSFC-FID instrumentation has been reported (7). In this method, the column flow was split twice before entering the FID, which provided a good detection limit of 50 pg for a mixture of *n*-alkanes. However, system plugging was reported to occur when injected amounts of sample exceeded 10 ng, which significantly limits the range of sample concentrations that can be directly investigated by the method.

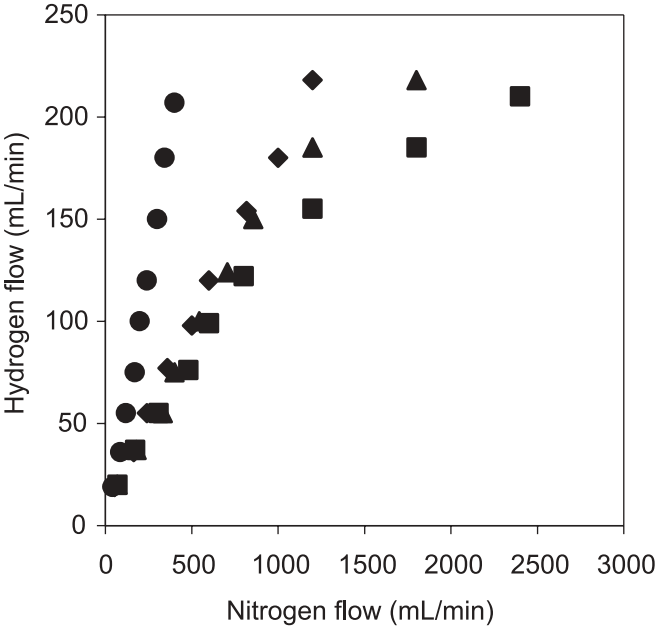
Further, the use of an additional post-column solvent flow was advised to prevent plugging of the pressure regulation valve, which increases solvent usage relative to a pure carbon dioxide mobile phase. Thus, an FID method that has the ability to operate and maintain good detector performance in the presence of the full flow of column effluent in pSFC (i.e., splitless mode) is desirable.

This paper describes the design and characterization of an FID that has been modified to operate with pSFC in the splitless mode. Through systematically increasing the burner diameter, the FID can maintain a stable flame for flow rates of several liters per minute and yield comparable sensitivity with that of a conventional FID.



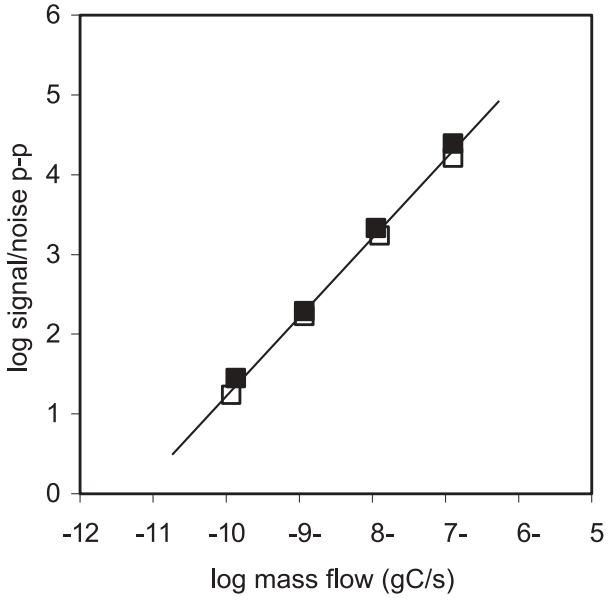
Experimental

The pSFC system was a Gilson series SF3 (Gilson, Villiers-le-Bel, France), which is comprised of a dual reciprocating pump – solvent delivery system (model 308 and 306), a column oven (model 831), a back pressure regulator (model 821), and a UV–vis variable wavelength detector (model 151). The separation column used was a 250 mm × 4.6 mm i.d. Econosil CN column packed with 5 µm diameter particles (Alltech, Deerfield, Ill., U.S.A.). The GC-FID system used for adaptation to the pSFC instrument was a Shimadzu model GC-9A (Shimadzu, Kyoto, Japan). Instrument-grade carbon dioxide and high-purity hydrogen, air, helium, and nitrogen were obtained from Praxair (Praxair, Calgary, Alta., Canada). Anthracene (99%) and octadecane (99%) were used as obtained from Aldrich (Aldrich, Oakville, Ont., Canada).

The FID is connected to the pSFC instrument directly downstream from the back pressure regulator, similar to a splitless interface described for an evaporative light-scattering detector (7). With the original outlet tubing removed, a 5 foot (1 foot = 0.3048 m) length of 1/16″ × 0.01″ (1″ = 25.4 mm) i.d. stainless steel tubing (Alltech) is instead used to guide the effluent from the back pressure regulator into the GC oven through a side port. Using a stainless steel zero dead volume union (Alltech), this tubing is connected to a 40 cm length of 0.10 mm i.d. deactivated, fused-silica restrictor tubing (Alltech), which extends into the detector base of the GC. The original Shimadzu FID burner was replaced by a length of quartz tubing (80 mm × 4.0 mm i.d. × 1 mm wall thickness), the last 25 mm of which tapers to 3.0 mm i.d. at the bottom to fit the threaded burner nut. The optimal restrictor position was 85 mm below the tip of the burner situated just below its base inside the stainless steel insert leading to the GC oven. The optimal position of the polarizer electrode was 2 mm below the tip of the burner, and the optimal separation between the polarizer and the collector electrode was found to be 25 mm. Optimal conditions for this transfer line were obtained when the GC oven was maintained at 250 °C and the FID was maintained at 350 °C.

Experiments in the conventional GC-FID mode employed an EC-5 ((5% phenyl)–95% methylpolysiloxane) megabore separation column (30 m × 0.53 mm i.d.; 1.00 µm thickness; Alltech). Typically, 8 mL/min of helium was used as the carrier gas and 30 mL/min of hydrogen and 400 mL/min of air provided optimum FID response. For GC-FID experiments using a 4.0 mm i.d. burner, the optimum hydrogen flow was 100 mL/min, and the optimum air flow was 1500 mL/min. Alternatively, ambient air could be entrained at the base of the detector housing with no change in the performance of the FID. For pSFC-FID experiments using a 4.0 mm i.d. burner, the optimum hydrogen flow was 340 mL/min, and all other conditions were the same. Also for this burner, a 300 mL/min flow of nitrogen added to the hydrogen flow was frequently found to improve the FID response by a factor of about 8. All other variations are outlined in the text.

Fig. 1. Stability of the FID flame at various gas flows using burners of 0.4 mm (●), 2.0 mm (◆), 3.0 mm (▲), and 4.0 mm (■) i.d. Each point on the graph represents the maximum amount of nitrogen flow that could be added to a given flow of hydrogen before the flame would extinguish.



Results and discussion

Initial experiments were performed to evaluate how the flame stability is affected by varying the FID burner diameter and the gas flow directed through it. Figure 1 displays the results of flame stability tests conducted with the original FID burner (0.4 mm i.d.) and others tested up to an inside diameter of 4.0 mm. Nitrogen and hydrogen were used to estimate the maximum gas flow through the burner that the FID flame could withstand. Each point on the graph represents the amount of nitrogen required to extinguish the flame for a given flow of hydrogen. As can be seen in the figure, for a constant hydrogen flow, the corresponding amount of nitrogen that can be introduced into the FID flame increases with burner diameter. Also, for each burner, this parameter increases with an increase in the hydrogen flow. As an example, at 210 mL/min of hydrogen flow, the flame of the original burner can withstand up to about 400 mL/min of nitrogen, while, when using the 4.0 mm i.d. burner, about 2400 mL/min of nitrogen can be introduced into the FID before the flame extinguishes. This considerable difference in capacity is reasoned in terms of the linear

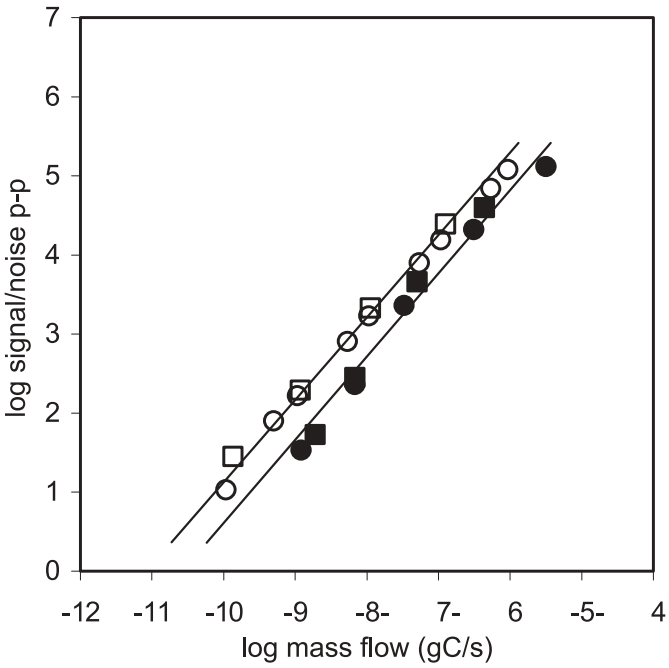
Fig. 2. GC-FID response toward anthracene, using the original low-flow 0.4 mm i.d. burner (■) and the modified high-flow 4.0 mm i.d. burner (□). See Experimental section for conditions.

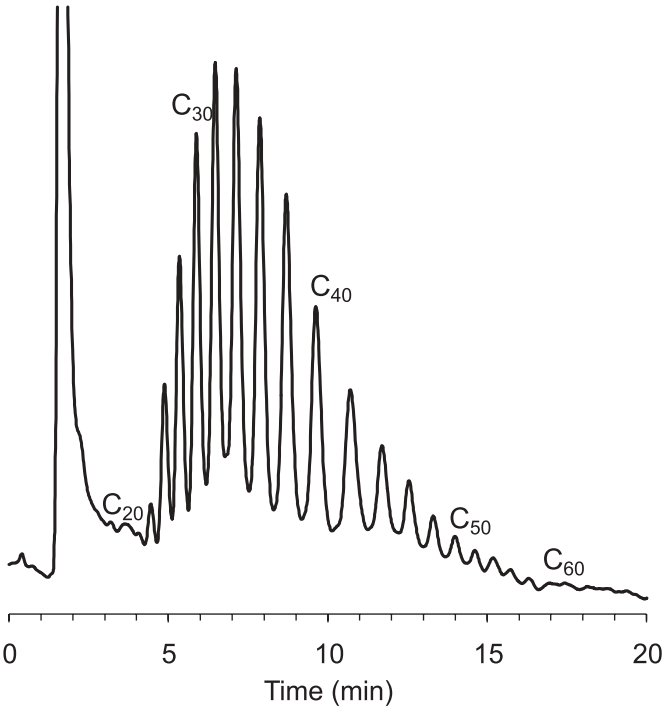


gas velocity travelling through the burner. For instance, the optimum gas flows of the original GC-FID instrument (i.e., 30 mL/min hydrogen and 8 mL/min helium) correspond to a linear gas velocity of about 500 cm/s through the burner. Using 210 mL/min of hydrogen and 400 mL/min of nitrogen, this value increases to about 8000 cm/s. By comparison, the maximum gas flow tested with the 4.0 mm i.d. burner (i.e., 210 mL/min hydrogen and 2400 mL/min nitrogen) corresponds to a linear gas velocity of about 360 cm/s through the burner. Thus, by reducing the linear gas velocity directed into the FID flame front, a stable flame can be maintained with larger gas flows, using burners with larger internal diameters.

To investigate the effect of using a larger flame in the FID on its response characteristics, experiments were conducted that compared the optimum FID performance of the original detector to that obtained using a larger burner. Figure 2 shows the results of calibrating anthracene in the GC mode using both the original FID burner and the 4.0 mm i.d. burner, each under optimized conditions. The figure clearly demonstrates that the response is practically identical between the two burners, and thus no deterioration in detector performance due to the usage of a larger burner in the FID is observed. The burner provided stable operation for several hours, with no change in performance, which correlates with visual observations of the larger flame that indicate it burns very smoothly with little turbulence compared with larger flows in the original burner.

Experiments were subsequently performed in the pSFC-FID mode using direct, splitless introduction of the decompressed carbon dioxide column flow into the modified detector. Several restrictor positions with respect to the burner tip were investigated. It was found that if the restrictor was too close to the flame front, then detector noise would increase. Increasing their separation improved this noise level; however, because of the large inner diameter of the burner and

Fig. 3. GC-FID response toward octadecane (○) and anthracene (□), using the original low-flow 0.4 mm i.d. burner, and the pSFC-FID response toward octadecane (●) and anthracene (■), using the modified high-flow 4.0 mm i.d. burner. The pSFC column pressure (isobaric) is 8.5 MPa for octadecane and 12 MPa for anthracene. The pSFC column flow rate is 1.0 mL/min. The pSFC oven temperature is 40 °C. All other conditions as outlined in the Experimental section.



the relative cooling of the restrictor tip upon decompression, the restrictor would occasionally plug temporarily as solvent peaks eluted and froze. The optimum position for the restrictor was ultimately determined to be at the base of the burner, at a distance of about 85 mm from the flame front, where it was in contact with and resided inside the heated stainless steel enclosure leading to the GC column oven. Under these conditions, the flame response was very stable for extended periods of usage, and the restrictor no longer plugged in the presence of solvent peaks.

Using the 4.0 mm i.d. burner, the pSFC-FID flame remained stable toward increasing column flow rates of carbon dioxide tested up to 3.7 mL/min. This column flow rate translated into a decompressed flow of about 2200 mL/min of carbon dioxide gas entering the detector. Including the additional hydrogen and nitrogen flow through the burner under optimum pSFC-FID conditions, this amounts to nearly 3 L/min of gas flow being directed through the FID flame, which remained stable and did not extinguish. To investigate how the pSFC-FID system compares with the original GC-FID system in terms of response, two test analytes, anthracene and octadecane, were calibrated in each system under optimum conditions, and the results are shown in Fig. 3. As observed, the original GC-FID system yields a detection limit (i.e., signal/noise peak to peak equal to 2) of about 13 pg C/s, and a linear response over at least 5 orders of magnitude tested up to analyte mass flows of about 1 µg

© 2004 NRC Canada

Fig. 4. pSFC-FID chromatogram of a 10 μg sample of paraffin wax. Injection solvent is carbon disulfide. The pSFC oven temperature is 120 °C. Column flow rate is 1.5 mL/min. Pressure program is 20 MPa until 10 min, then increasing at 1 MPa/min for 5 min. All other conditions as outlined in the Experimental section.

C/s. These values are typical of those expected from a conventional FID and confirm that similar response is obtained from anthracene and octadecane in terms of carbon flow. By comparison, the pSFC-FID response, which is also similar between the two test analytes, yields a detection limit around 40 pg C/s. This compares quite well, differing within a factor of about 3 from the detection limit provided by the original GC-FID system. Additionally, the pSFC-FID system also provided linear response over the range investigated, which was tested up to analyte mass flows of about 3 μg C/s. Thus, the splitless pSFC-FID system is stable toward typical pSFC column flow rates and yields response that is similar to a conventional GC-FID system and similar to or better than other pSFC-FID systems operated in the split mode (7, 9). In daily operation, the splitless interface was routinely subjected to 10–100 μg quantities of test analyte, and plugging was not found to be a significant problem. Under regular usage, the restrictor tubing was usually replaced every 3 to 4 weeks.

Unlike earlier instruments, modern pSFC units independently control column pressure and flow (11). As such, a stable column flow and FID baseline can be maintained during changes in column pressure. The splitless pSFC-FID system was investigated at pressures up to 40 MPa (the maximum operating pressure of the instrument), and no adverse affects on the FID response or flame stability were observed. To illustrate this and demonstrate the pSFC-FID system response, Fig. 4 displays the separation of a 10 μg sample of paraffin wax using a basic pressure program. As shown, paraffins up to C_{60} are separated using a moderate pressure gradient up to 25 MPa and a typical column flow rate of 1.5 mL/min of carbon dioxide with no major changes in the detector baseline. The results of these experiments indicate that this approach may also be useful for coupling pSFC to other low-pressure, flame-based detection methods.

Syntheses, crystal structures, and magnetism of one-dimensional complexes generated from copper(II) and carbamyldicyanomethanide bridging ligand

Jing-Min Shi, Qing-Yun Liu, Wen Xu, Lin Meng, Peng Cheng, Bin Zhao, and Wen-Tao Yu

Abstract: Two one-dimensional chain complexes, $\{[Cu(cda)_2H_2O]\cdot H_2O\}_n$ (**1**) and $\{[Cu(cda)(H_2O)_2]\cdot(ClO_4)\cdot 3H_2O\}_n$ (**2**) (cda = carbamyldicyanomethanide anion) have been synthesized and their crystal structures determined by X-ray crystallography. The copper(II) ions in **1** are bridged by two $\mu_{1,5}$-cda bridging ligands, whereas in **2** the copper(II) ions are connected by a single $\mu_{1,5}$-cda ligand. Complex **1** is red while **2** is green. Variable-temperature magnetic susceptibility data indicate that there is a very weak antiferromagnetic interaction between the bridged copper(II) ions in both **1** and **2**.

Key words: synthesis, crystal structure, copper complex, polynitrile ligand, magnetism.

Résumé : On a synthétisé deux complexes en chaînes unidimensionnelles, $\{[Cu(cda)_2H_2O]\cdot H_2O\}_n$ (**1**) et $\{[Cu(cda)(H_2O)_2]\cdot(ClO_4)\cdot 3H_2O\}_n$ (**2**) (cda = anion carbamyldicyanométhanure) et on a déterminé leurs structures cristallines par diffraction des rayons X. Les ions cuivre(II) du composé **1** sont pontés par des ligands doublement pontants $\mu_{1,5}$-cda alors que les ions cuivre(II) du composé **2** sont reliés par une seule unité $\mu_{1,5}$-cda. La couleur du composé **1** est rouge alors que celle du composé **2** semble verte. L'analyse magnétique basée sur des données de susceptibilité magnétique à température variable indique qu'il existe une très faible interaction antiferromagnétique entre les ions de cuivre(II) pontés des composés **1** et **2**.

Mots clés : synthèse, structure cristalline, complexe du cuivre, ligand polynitrile, magnétisme.

[Traduit par la Rédaction]

Introduction

Recently, the field of molecular magnetism has attracted considerable attention, and major advances have been made in both the theoretical description and the application of molecular-based magnetic materials (1–4). Polynitrile compounds such as tricyanomethanide (5–7), dicyanamide (8–15), 7,7,8,8-tetracyanoquinodimethane (16–21), 1,2,4,5-tetracyanobenzene (22, 23), and tetracyanoethene (24–28) display versatile bridging modes, and many coordination compounds have been constructed from such polynitriles and metal ions, some of which exhibit distinctive magnetic properties (24). Although some complexes with the carbamyldicyanomethanide anion (cda) as ligand have been synthesized and their crystal structures determined by X-ray crystallography (29–32), no reports on the magnetic properties of cda-bridged complexes have been published. Here we report the crystal structures and the magnetic properties of the titled complexes $\{[Cu(cda)_2H_2O]\cdot H_2O\}_n$ (**1**) and $\{[Cu(cda)(H_2O)_2]\cdot(ClO_4)\cdot 3H_2O\}_n$ (**2**).

Experimental

Materials

Sodium carbamyldicyanomethanide (Na(cda)) was prepared according to a procedure reported in the literature (33). All other chemicals were analytical grade and used without further purification.

Physical measurements

IR spectra were recorded with a Shimadzu Corporation 408 IR spectrometer using KBr discs.The main bands (cm^{-1}) for **1** appear at 3250 (br, vs), 2225 (vs), 2175 (vs), 1630 (vs), 1565 (vs), and 1425 (vs) and for **2** at 2250 (vs), 2200 (vs), 1645 (vs), 1580 (vs), 1410 (vs), and 1100 (br, vs). C, H, and N elemental analyses were carried out on a PerkinElmer

2400 elemental analyzer, and Cu content was measured on a Hitachi model Z-8000 atom absorption spectrophotometer. Thermogravimetric analysis was performed on a PerkinElmer TGA-7 thermogravimetric analyzer under flowing argon at a heating rate of 10 °C/min. The variable-temperature magnetic susceptibility of powder samples (0.10039 g for **1** and 0.06472 g for **2**) was measured under an applied magnetic field of 10 kOe in the approximate range 5–300 K with a SQUID magnetometer, and all the experimental data were corrected for the diamagnetic susceptibility of the samples by using Pascal constants.

X-ray crystallography

The determination of the crystal structures was carried out on a Bruker Smart-1000 CCD diffractometer using graphite-monochromated Mo Kα radiation (0.71073 Å). Data reduction and structure refinement were performed using the SHELXL-97 program system.[2] Crystal structure and data collection and refinement parameters are listed in Table 1. Selected bond lengths and angles are listed in Table 2, and the hydrogen bond lengths and angles are listed in Table 3.

Synthesis of $\{[Cu(cda)_2H_2O]\cdot H_2O\}_n$ (1)

Hydrated copper perchlorate (0.5521 g, 1.49 mmol) and Na(cda) (0.3506 g, 2.67 mmol) were each dissolved in 45 cm^3 H_2O, respectively. When the two solutions were mixed together, a yellowish green color appeared immediately. A well-formed deep-red single crystal suitable for X-ray determination was obtained after the mixed solution was kept at room temperature for about two weeks. Yield: 0.3794 g, 90%. Anal. calcd. for $C_8H_8CuN_6O_4$: C 30.43, H 2.55, N 26.62, Cu 20.13; found: C 30.12, H 2.41, N 24.26, Cu 20.52.

Synthesis of $\{[Cu(cda)(H_2O)_2]\cdot(ClO_4)\cdot 3H_2O\}_n$ (2)

Method 1

$Cu(ClO_4)_2\cdot 6H_2O$ (0.7256 g, 1.96 mmol) and Na(cda) (0.2510 g, 1.91 mmol) were each dissolved in ca. 80 cm^3 of H_2O, respectively, and the two solutions were mixed together. The resulting solution turned green when solid Na(cda) (4.9640 g, 0.0379 mol) was added in batches. Green single crystals were obtained after the green solution was kept at room temperature for ca. half a year. Anal. calcd. for $C_4H_{12}ClCuN_3O_{10}$: C 13.30, H 3.35, N 11.64, Cu 17.59; found: C 13.56, H 3.68, N 12.04, Cu 17.24.

Method 2

Hydrated copper perchlorate (0.6227 g, 1.68 mmol), Na(cda) (0.2224 g, 1.70 mmol), and $NaClO_4\cdot H_2O$ (4.0 g,

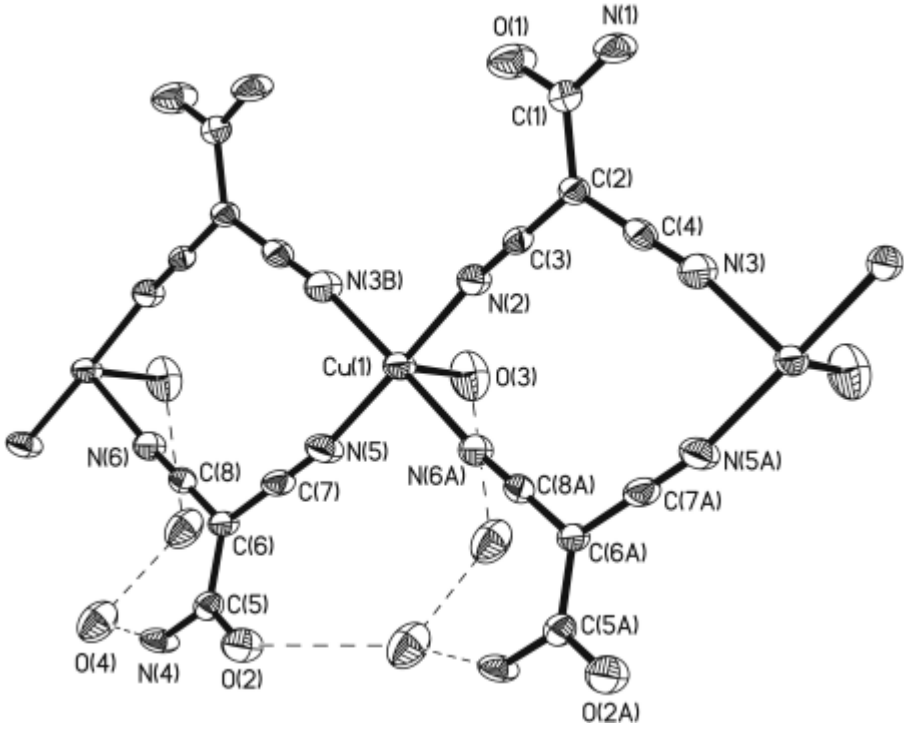
0.028 mol) were each dissolved in 10 cm^3 H_2O, respectively. When the three solutions were mixed together, a light-green color appeared immediately. When the mixed solution was kept at room temperature for about two weeks, a small amount of green single crystals and a large amount of red single crystals were obtained. The IR spectrum and elemental analysis indicated that the green single crystals were identical to those obtained by method 1.

Results and discussion

IR spectrum of $\{[Cu(cda)_2H_2O]\cdot H_2O\}_n$ (1)

In comparison with the bands of Na(cda), the characteristic -C≡N bands of compound **1** have shifted from 2160 and 2200 cm^{-1} to 2175 and 2225 cm^{-1}, respectively. The sharp peaks at 3220, 3320, and 3455 cm^{-1}, assigned to $\nu(NH_2)$, appear as a broad band between 3150 and 3350 cm^{-1}. The intense bands of the -$CONH_2$ group at 1440, 1560, and 1660 cm^{-1} are shifted to 1425, 1565, and 1630 cm^{-1} and are also broadened in the spectrum of complex **1**.

IR spectrum of $\{[Cu(cda)(H_2O)_2]\cdot(ClO_4)\cdot 3H_2O\}_n$ (2)



The characteristic -C≡N bands appear at 2250 and 2200 cm^{-1}. The strong and broad bands at 1645, 1580, and 1410 cm^{-1} may be attributed to ν(C=O), and the strong band near 1100 cm^{-1} may be assigned to the perchlorate ion.

Thermal stability of $\{[Cu(cda)_2H_2O]\cdot H_2O\}_n$ (1) and $\{[Cu(cda)(H_2O)_2]\cdot(ClO_4)\cdot 3H_2O\}_n$ (2)

The results of thermogravimetric analysis indicate that **1**

Fig. 1. The coordination and 1D chain diagram of **1** with the atom numbering scheme.

began to decompose distinctly at ca. 163 °C, and before 188 °C all the coordinated and uncoordinated H_2O had been lost, whereas **2** began to decompose distinctly at ca. 96 °C, and at ca. 209 °C all the coordinated and uncoordinated H_2O had been lost.

Crystal structure of $\{[Cu(cda)_2H_2O]\cdot H_2O\}_n$ (1)

Figure 1 shows the coordination diagram with the atom numbering scheme. In the crystal, each Cu(II) ion is coordinated to four $\mu_{1,5}$-cda ligands and capped by one H_2O ligand, and each $\mu_{1,5}$-cda ligand is coordinated to two copper(II) cations via two nitrile-nitrogen atoms. The Cu(1), N(2), N(5), N(3B), and N(6A) atoms lie in a plane, designated plane 1, such that a square-pyramidal polyhedron is formed around Cu(1), with O(3) located at the apex of the pyramid. Among copper(II) complexes with polynitriles as ligands, tetrahedral (22), square-planar (7), and octahedral coordination polyhedrons (6, 9–10, 14) have been observed, but no square-pyramidal polyhedron has been reported previously. The N(2), C(3), C(2), C(1), O(1), C(4), and N(3) atoms are located in a plane, designated plane 2, while the N(6A), C(8A), C(6A), C(5A), O(2A), C(7A), and N(5A) atoms lie in another plane, designated plane 3. The angles between planes 1 and 2, planes 1 and 3, and planes 2 and 3 are 13.2°, 18.6°, and 21.7°, respectively. The coordination mode of cda in this crystal is identical with that reported for a one-dimensional zinc(II) chain (31). Figure 2 shows the hydrogen bonding and also reveals that the two adjacent chains extensively interdigitate to form a parallelepiped block and that the blocks stack in a parallel fashion to form a three-dimensional structure.

Crystal structure of $\{[Cu(cda)(H_2O)_2]\cdot(ClO_4)\cdot 3H_2O\}_n$ (2)

Figure 3 shows the coordination diagram with the atom numbering scheme and the structure of the zigzag one-dimensional chain. In the crystal, the Cu(1) ion is coordinated by the O(2), O(2C), N(2), and N(2C) atoms, and the five atoms lie in a plane, which is designated plane 4. The bond lengths pertaining to the Cu(I) ion and the associated angles indicate that the coordination environment of the Cu(1) ion is slightly distorted from a square. The coordination geometry of the Cu(2) ion is almost identical with that of the Cu(1) ion, with the N(3), O(3), Cu(2), O(3B), and N(3B) atoms lying in a plane, designated plane 5. Obviously, the coordination geometry of **2** is different from that of **1**, and thus the splitting energy of the *d* orbitals in **1** and **2** is different, which leads to the difference in color. The N(2), C(3), C(2), C(1), O(1), C(4), and N(3) atoms of the cda bridging ligand are situated in another plane, designated plane 6. The angles between planes 4 and 6, planes 5 and 6, and planes 4 and 5 are 112.5°, 149.5°, and 59.0°, respectively. The bridging mode of cda is identical with that in **1**, but the neighboring Cu(II) ions are bridged by only a single $\mu_{1,5}$-cda bridging ligand. Figure 4 displays the unit cell and the locations of the chains, uncoordinated H_2O molecules, and the perchlorate counter anion in the crystal, as well as the hydrogen bonding between the cda anions, coordinated H_2O molecules, uncoordinated H_2O molecules, and the perchlorate ion.

Magnetic properties

The variable-temperature magnetic susceptibility data showed a small change of μ_{eff} from 300 to 50 K for the two complexes, and at 5 K the values of μ_{eff} are 1.64 and 1.81 for **1** and **2**, respectively. These values are close to the spin-only value for copper(II) and indicate that there is only very weak magnetic coupling between the bridged Cu(II) ions. To determine the extent of the magnetic coupling in **1** and **2**, the

Fig. 2. Unit cell of **1** and the location of the 1D chains viewed from the *a* axis.

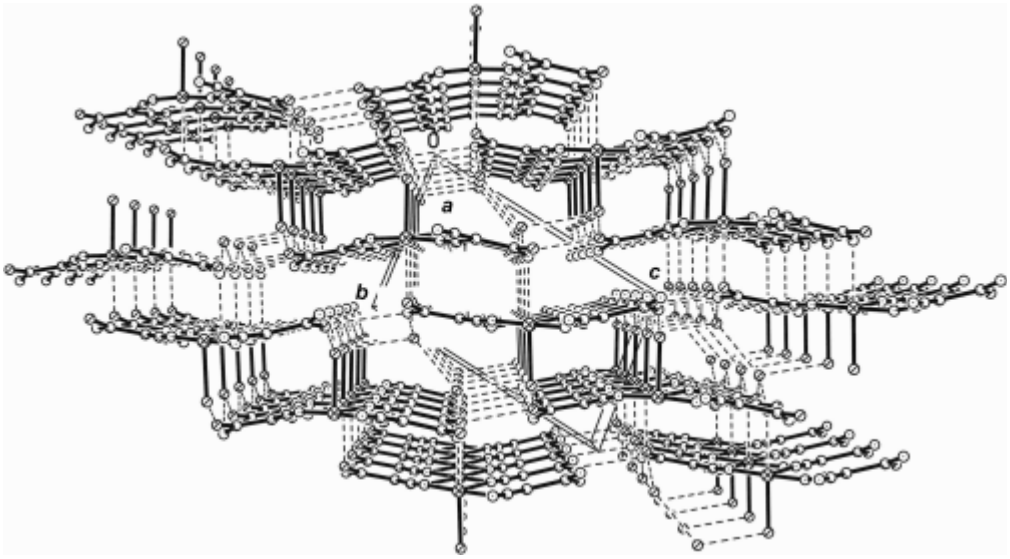

Fig. 3. The coordination and 1D chain diagram of **2** with the atom-numbering scheme.

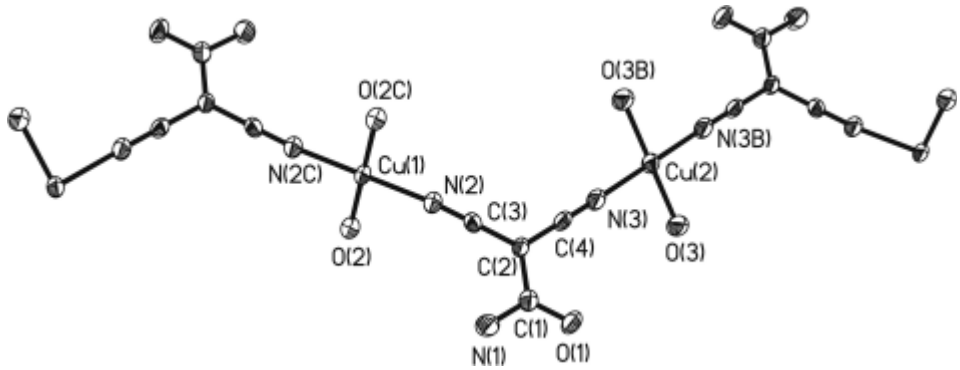

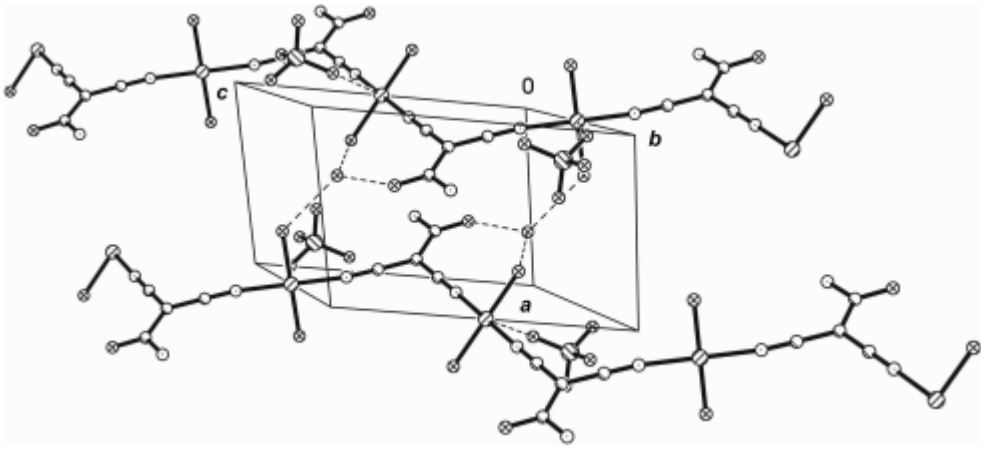

Fig. 4. Unit cell of **2** and the locations of the 1D chains, uncoordinated H_2O molecules, and the perchlorate counter ion.

following formula for the magnetic susceptibility of one-dimensional Cu(II) chain complexes (34) was used:

$$\chi_m = [Ng^2\beta^2/k(T - \theta)][0.2500 + 0.18297(J/kT)^2][1 + 1.5467(J/kT) + 3.4443(J/kT)^3]^{-1}$$

In the above equation, the symbols of J, θ, N, g, β, k, and T represent the magnetic coupling of intrachain, the magnetic coupling of interchains, the Avogadro constant, the lander g factor, Bohr magneton, the Boltzmann constant, and the absolute temperature, respectively. The plots of χ_m vs. T and $\chi_m T$ vs. T for **1** and **2** are shown in Figs. 5 and 6, respectively, and the formula fits the experimental data well. The

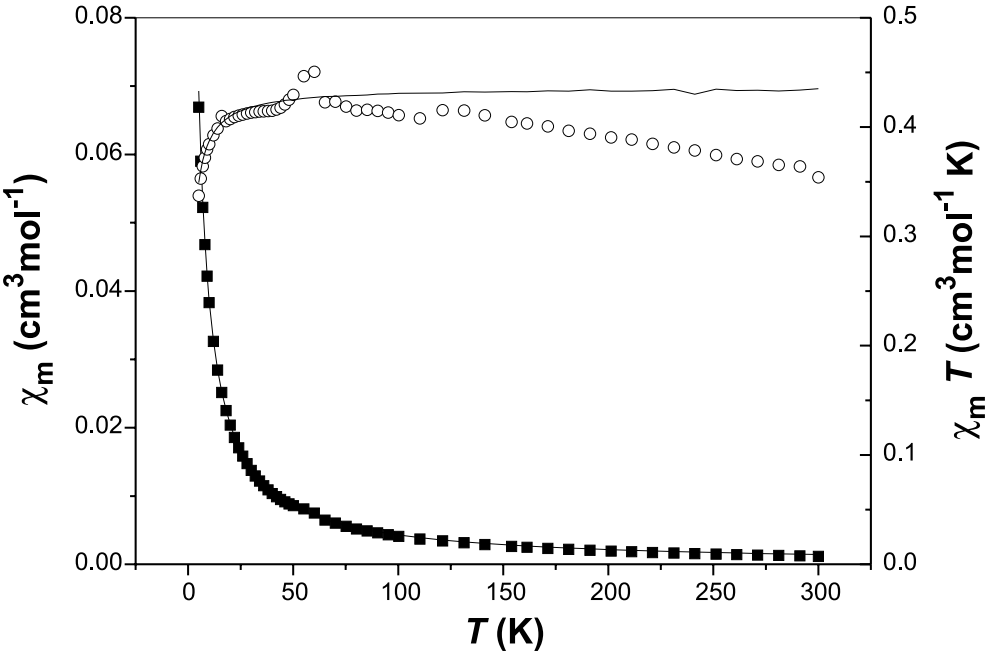
Fig. 5. Plots of temperature dependence of χ_M and $\chi_m T$ for **1**; (■) experimental data of χ_M; (○) experimental data of $\chi_m T$; (—) calcd. curve.



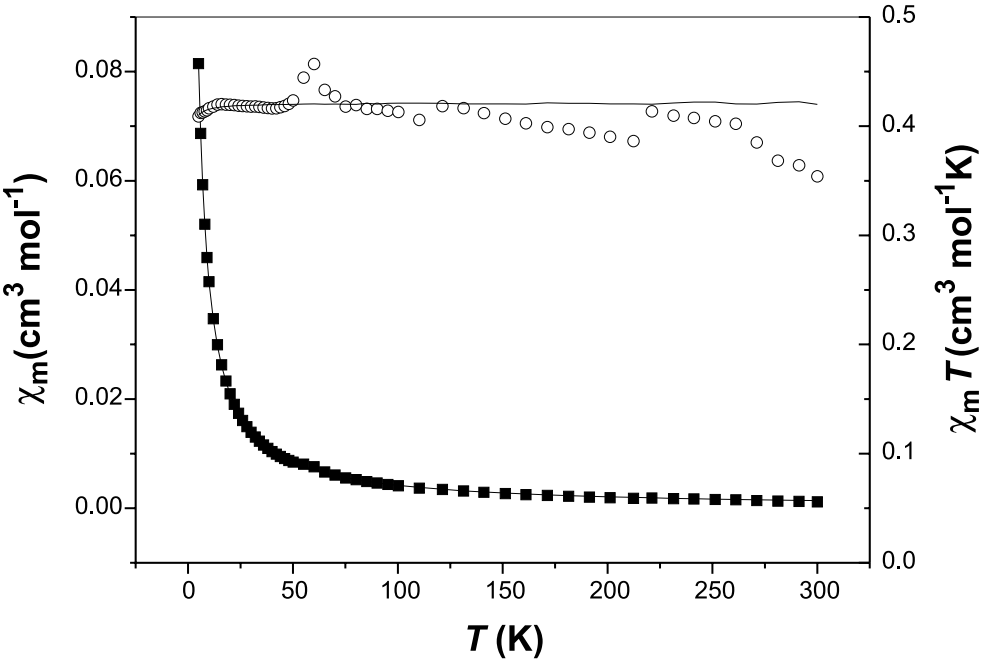


Fig. 6. Plots of temperature dependence of χ_M and $\chi_m T$ for **2**; (■) experimental data of χ_M; (○) experimental data of $\chi_m T$; (—) calcd. curve.

best-fit parameters are $J = -0.584$ cm^{-1}, $\theta = -0.003$ cm^{-1}, g = 2.16, and $F = [\Sigma(\chi_m)_{obsd} - \Sigma(\chi_m)_{calcd}]^2/\Sigma(\chi_m)^2_{obsd} = 1.41 \times 10^{-5}$ for **1**, and $J = -0.059$ cm^{-1}, $\theta = -0.006$ cm^{-1}, g = 2.12, and $F = 1.49 \times 10^{-6}$ for **2**. The very small J and θ values indicate that in both **1** and **2** there is a very weak antiferromagnetic interaction between the bridged Cu(II) ions and a very weak antiferromagnetic coupling in the interchains. The similar $\mu_{1,5}$-dicyanamide (dca)-bridged one-dimensional Cu(II) and one-dimensional Mn(II) complexes also exhibit very weak magnetic couplings (8, 9), and MO calculations confirm that the $\mu_{1,5}$-dicyanamide ligand is a very poor superexchange mediator (35). By comparing the bridging ligand cda to dca, with respect to its structure and coordination mode and the magnetic behavior of the complexes, it may be concluded that cda is also a very poor superexchange mediator. The difference in magnetic coupling between **1** and **2** may originate from coplanarity within their structures. Generally, in multiatom-bridged complexes the

© 2004 NRC Canada

magnetic interaction is propagated by a delocalized π orbital of the bridging ligand, and the coplanarity between the plane consisting of magnetic orbital atoms and the plane of bridging ligand atoms is one of the major factors that affect magnetic interaction (36). The higher the coplanarity is, the stronger the overlap of magnetic orbitals and hence the stronger the magnetic interaction. In **1** the angles between planes 1 and 2 and between planes 1 and 3 are 13.2° and 18.6°, respectively, whereas in **2** the angles between planes 4 and 6 and between planes 5 and 6 are 112.5° and 149.5°, respectively. Thus, planes 4 and 6 are almost perpendicular to each other and this severely limits electron delocalization, such that the magnetic coupling in **2** is weaker than in **1**.

Ionic liquids derived from trialkylsulfonium bromides: Physicochemical properties and potential applications

Li Xiao and Keith E. Johnson

Abstract: Several new ionic liquids were prepared from trialkylsulfonium bromides and $AlCl_3$ or HCl. They include both Lewis basic and acidic combinations of Et_3SBr with $AlCl_3$, which are liquid at ambient temperatures. Density, molarity, conductivity, NMR, infrared, and electrochemical data are presented. The sulfonium cations are not hydrogen bonding, are unattacked by hydride, provide NMR windows in the aromatic regions, and offer different solubility prospects from ionic liquids derived from aromatic cations.

Key words: ionic liquids, triethylsulfonium, haloaluminates, halohydrogenates, molarities, NMR, voltammetry, hydride.

Résumé : On a préparé plusieurs nouveaux liquides ioniques à partir des bromures de trialkylsulfonium et $AlCl_3$ ou HCl; ils incluent des combinaisons de Lewis tant basiques qu'acides de Et_3SBr avec $AlCl_3$, liquides à la température ambiante. On rapporte les données relatives à leur densité, molarité, conductivité, RMN, infrarouge et à leur propriétés électrochimiques. Les cations sulfonium ne forment pas de liaisons hydrogènes, ne sont pas attaqués par les hydrures, fournissent une fenêtre dans les régions aromatiques de la RMN et offrent des possibilités de solubilité différentes de celles associés aux liquides ioniques obtenus à partir de cations aromatiques.

Mots clés : liquides ioniques, triéthylsulfonium, haloaluminates, halohydrogénates, molarités, RMN, voltampérométrie, hydrure.

[Traduit par la Rédaction]

Introduction

There has been a steady increase in work on ambient-temperature ionic liquids since 1980. The early driving force for this was the development of an aluminum battery, so systems with wide electrochemical windows and involving chloroaluminates received much attention (1). Since $AlCl_3$ is well known for catalyzing Friedel–Crafts and other organic reactions (2), ionic liquids, as catalytic solvents, became a topic of research (3, 4). By now the variety of ionic liquids prepared is large, and electrochemical properties may be less significant than viscosities (5), NMR windows, and recovery and disposal limitations.

Although alkylammonium and alkylphosphonium salts have a long history, the favorite liquid semi-organic salts have become those of *N*,*N*′-dialkylimidazolium ions, especially 1-ethyl-3-methyl-1*H*-imidazolium ($[emim]^+$) (1) and now 1-butyl-3-methyl-1*H*-imidazolium ($[bmim]^+$) (6). *N*-Butylpryidinium salts also received attention, since some have low melting points (7), while simple pyridinium salts have been used for ether cleavage (8), although at higher temperature. In a study of the superacidity of liquids derived from an organic halide together with $AlCl_3$ or $AlBr_3$ plus HCl or HBr (9), we took advantage of the simple NMR spectrum of the salt $(CH_3)_3SBr$. However, ambient temperature liquidity does not extend to Lewis-basic compositions for these systems. We have synthesized, therefore, several asymmetric tri-alkylsulfonium bromides and their combinations with $AlCl_3$. The physiochemical characteristics of these liquids are reported with particular emphasis on the Et_3S–$AlCl_3$ system, which has a wider liquid composition range at ambient temperatures. We also discuss some halohydrogenate salts and the potential uses of these new liquids.[3]

Experimental

Materials

All manipulations involving aluminum chloride, semi-organic salts, and the ionic liquids derived therefrom were performed in a glovebox (Mbraun Labmaster 100) under an atmosphere of dry nitrogen. Aluminum chloride (Fluka AG,

Received 30 July 2003. Published on the NRC Research Press Web site at http://canjchem.nrc.ca on 4 March 2004.

[3]The organic bromides are easier to prepare than the chlorides, while AlC_3 and HCl are more readily available and somewhat easier to handle than $AlBr_3$ and HBr. While the physiochemical details would change for all-chloride or all-bromide systems and the cross-halogen ion equilibria would be eliminated, the primary conclusions regarding the sulfonium salts would be expected to hold for such systems, also.

 doi: 10.1139/V04-004 © 2004 NRC Canada

puriss) was purified by double vacuum sublimation, and trimethylsulfonium bromide was recrystallized twice with anhydrous ethanol (9) and vacuum dried at ~40 °C for 2 days. HCl gas (Mattheson) was electronic grade and ethene-free. Organic solvents were freshly distilled before use.

Ethyldimethylsulfonium bromide ($EtMe_2SBr$), diethylmethylsulfonium bromide (Et_2MeSBr), and triethylsulfonium bromide (Et_3SBr) were synthesized according to Saunders, Jr. and co-workers' method (10), with acetonitrile as the solvent and an alkyl halide : dialkyl sulfide ratio of 2. For Et_3SBr specifically, a yield of 25% was obtained after refluxing for 3 days; crystals were washed with ethanol and vacuum dried at 40 °C. The method of Islam and Leffek (11), employing excess sulfide, was unsuccessful.

1-Butyl-3-methyl-1*H*-imidazolium chloride (bmim Cl) was prepared under atmospheric pressure, as described by Rogers and co-workers (12). The yield was 90%.

Triethylsulfonium tetrafluoroborate and hexafluorophosphate were prepared by procedures akin to those for the $bmim^+$ salts, but since they had melting points close to 80 °C, they were not studied further.

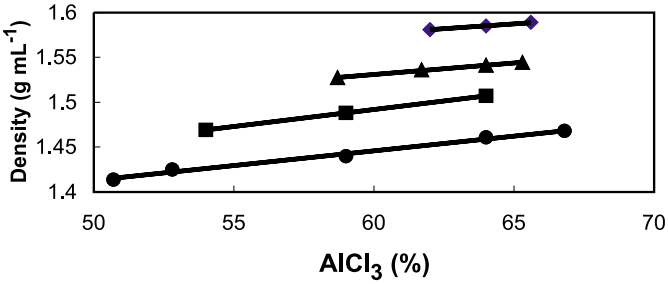
Chloroaluminate ionic liquids were prepared by adding the required amount of $AlCl_3$ *slowly* with stirring to the solid organic salt so that a colorless or pale yellow liquid formed.

To reduce the proton level in such a liquid from the estimated 20 mmol L^{-1} level to <1 mmol L^{-1}, either $AlEtCl_2$ or CaH_2 was added in a roughly equivalent amount; any small excess of $AlEtCl_2$ does not affect the Lewis acidity.

Halohydrogenate(I) liquids were obtained by introducing HCl gas slowly through a needle valve into a preweighed, sealed vial containing solid organic salt. The added HCl was determined gravimetrically or by titration.

Physical measurements

Melting points were obtained with an Electrothermal 1A9100 series Digital Melting Point Apparatus. Densities of liquids were measured at 25 °C in the glovebox with 2 mL or 5 mL flasks calibrated with twice-distilled water. Viscosities were measured with a Cannon-Fenske viscometer 150 (constant of 0.04591 at 40 °C, 0.04570 at 100 °C). It was calibrated by the overlapping technique with aqueous glycerol solutions. Measurements were made in a thermostated paraffin oil bath in the glovebox, taking 10 min for equilibration and at least 120 s of flow time. Conductances were measured with a YSI Model 31 Conductivity Bridge (Yellow Spring Instrument Co.), using a commercial (1.0 cm^{-1} cell constant) or home-made cell (5.28 cm^{-1} cell constant) and 0.1 daL aqueous KCl at 25 °C as calibrant.



Fourier transform infrared (FTIR) spectra were obtained with a PerkinElmer instrument (range 400–2500 cm^{-1}) and KBr salt plates. Provided the plates were dry and the ionic liquid was placed between them in the glovebox, the film was sufficiently air stable.

NMR spectra were obtained with a Bruker AC-200 MHz spectrometer, using DMSO-d_6, D_2O, $CDCl_3$, and CD_3COCD_3 as locking solvents; they were sealed into capillaries and inserted into the 5 mm NMR tubes, which were loaded with ionic liquid samples and capped in the glovebox prior to measurements.

Table 1. Bromide content of trialykylsulfonium bromides.

Salt	Theoretical Br (%)	Experimental Br (%)	Deviation (%)
Me_2EtSBr	46.70	46.78	0.17
Et_2MeSBr	43.16	43.18	0.05
Et_3SBr	40.13	40.18	0.12

Fig. 1. Ambient temperature density of trialkylsulfonium ionic liquids at different compositions (25 °C): ◆ $AlCl_3$–Me_3SBr (R^2 = 0.9905); ▲ $AlCl_3$–Me_2EtSBr (R^2 = 1.000); ■ $AlCl_3$–Et_2MeSBr (R^2 = 0.9935); ● $AlCl_3$–Et_3SBr (R^2 = 0.9959).

Cyclic voltammetry was carried out with a BAS 100W system. A diamond-polished Pt working electrode, a Pt counter-electrode, and an Al – acidic chloroaluminate reference electrode were employed.

Results and discussion

Salt purity

The experimental (12) and theoretical bromide contents of the 3 trialkylsulfonium bromides synthesized are shown in Table 1.

Density

Figure 1 shows the density of trialkylsulfonium chloroaluminate ionic liquids at 25 °C at different $AlCl_3$ contents. The range of composition for which the systems are liquid at 25 °C increases with the total number of carbon atoms, reaching 23 mole % $AlCl_3$ for $AlCl_3$–Et_3SBr. An approximate phase diagram for $AlCl_3$–Et_3SBr shows a minimum at (46% $AlCl_3$, 10 °C) and a maximum at (50% $AlCl_3$, 40 °C) such that while a basic liquid is obtainable at 25 °C, a neutral one is a jelly. As the number of C atoms increases at constant $AlCl_3$ mole %, the density decreases linearly (R^2 = 0.9974), a trend noted for other ionic liquid groups (13). When the densities of several 64% $AlCl_3$ ionic liquids are compared, it is apparent that the trend is not a function of cation size but rather a question of packing (15), as follows: bmim Cl (1.3229 g L^{-1}) (5) < emim Cl (1.3747 g L^{-1}) (1) < Et_3SBr (1.4607 g L^{-1}) < PyHCl (1.4759 g L^{-1}) < Me_3SBr (1.5849 g L^{-1}) (9).

Molarities

Although it has been customary to express the acidity of haloaluminate ionic liquids in terms of the AlX_3 mole fraction, the molarity of the various species present in the system is determined by the density and average molecular

Note: $X_{AlX_4^-}$ represents the mole fraction of anion $AlCl_4^-$ or $AlCl_3Br^-$ and other halide-exchange species (when the organic salt is a bromide). Similarly, $M_{AlX_4^-}$ represents the molarity of the anion species, $AlCl_4^-$ or $AlCl_3Br^-$.
[a]Temperature of 50 °C.
[b]Temperature of 30 °C.

weight. Further, the ratio of the acid $Al_2X_7^-$ to the neutral AlX_4^- increases dramatically as the AlX_3 mole fraction approaches 2/3. Both of these effects are demonstrated by the data of Table 2.

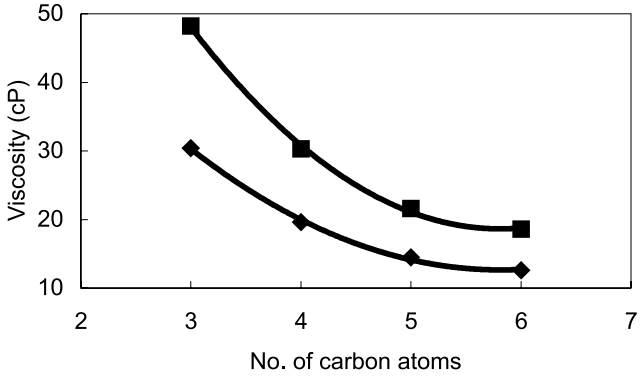
Viscosity

The viscosities of the trialkylsulfonium haloaluminates (Table 3) decrease with the size of the sulfonium group (Fig. 2). The activation energy for viscous flow obtained from absolute viscosity – temperature plots is much smaller for $AlCl_3$–Et_3SBr (7.86 kJ mol^{-1}) than for AlC_3–Me_3SBr (12.75 kJ mol^{-1}), and for both sulfonium systems it is less than for $AlCl_3$–emimCl (19 kJ mol^{-1}). This is consistent with the denser packing of the Me_3SBr system and the presence of limited H bonding in the emim system (the H bonding in the acidic system is, however, much less than when free Cl^- is present).

Conductivity

The specific conductivities of 46% $AlCl_3$–Et_3SBr and 64% $AlCl_3$–Et_3SBr are 1.14 and 0.845 $mm^2\ s^{-1}\ cm^{-1}$ respectively. These values are of the same order as seen in $AlCl_3$–emimCl systems (1), but in the imidazolium systems the conductivity is higher for the acidic than the basic liquids, a situation readily ascribed to strong H bonding between Cl^- and $emim^+$ in basic liquids and no H bonding by Et_3S^+.

NMR spectra



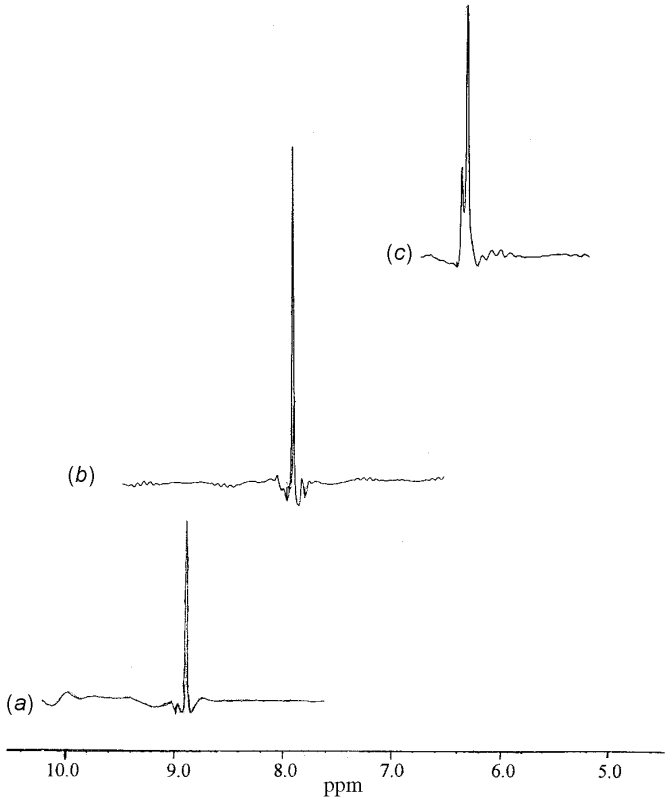
$R_1R_2R_3SBr$–$AlCl_3$ systems

The 64% $AlCl_3$–$R_1R_2R_3SBr$ systems show the anticipated ^1H NMR spectra ($R_1 = R_2 = R_3 = Me$ (8), $\delta = 0.9$ ppm; $R_1 = R_2 = R_3 = Et$, $\delta = 0.50$, 2.25 ppm; $R_1 = R_2 = Me$, $R_3 = Et$, $\delta = 0.4$, 2.15 ppm; $R_1 = Me$, $R_2 = R_3 = Et$, $\delta = 0.5$, 2.3 ppm). In contrast to the emimCl–$AlCl_3$ system (18), the chemical shift changes little with composition ($\delta = 0.55$, 2.35 for 51% $AlCl_3$).

Table 3. Trialkylsulfonium haloaluminate viscosities with 64% $AlCl_3$ at 25 °C.

Sulfonium salt	Salt mp (°C)	Kinematic viscosity ($mm^2\ s^{-1}$)	Absolute viscosity (Pa s)
Me_3SBr	193	30.4	0.0482
$EtMe_2SBr$	153	19.6	0.0302
Et_2MeSBr	83	14.4	0.0216
Et_3SBr	167	12.6	0.0185

Fig. 2. Relationship between absolute viscosity (cP (1 P = 0.1 Pa s)) and the number of carbon atoms in 64% $AlCl_3$–trialkyl sulfonium bromide ionic liquids: ■ absolute viscosity (cP) ($R^2 = 0.9988$ for polynomial relationship); ◆ kinematic viscosity (cSt (1 St = 100 $mm^2\ s^{-1}$) ($R^2 = 0.9984$ for polynomial relationship).



Et_3SBr–HCl and bmimCl–HCl systems

In the halohydrogenate(I) systems, the anionic species present change from X^- through HX_2^- to $H_2X_3^-$ and even $H_3X_4^-$ as the HX ratio is increased. For emimCl–HCl (19), the chemical shift of the acidic proton ranges from 13.5 ppm at 37 mole % HCl to 10.0 ppm at 60%, while for PyHCl–

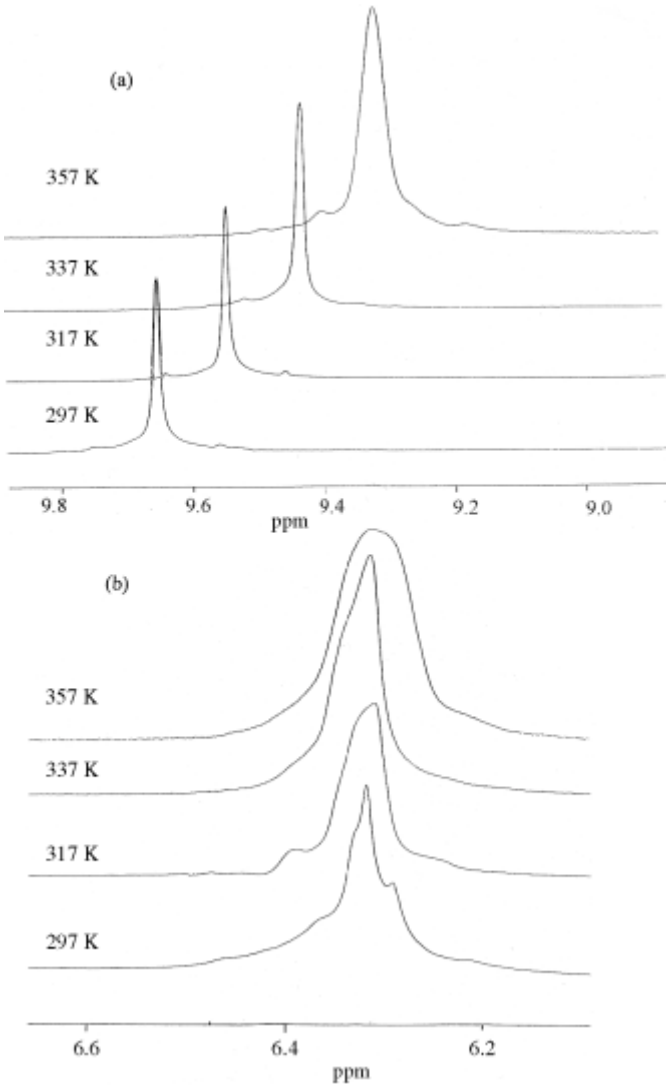
Fig. 3. ^{1}H NMR spectra, at 24 °C, of Et_3SBr–HCl with (*a*) 52%, (*b*) 54%, (*c*) 68% HCl.



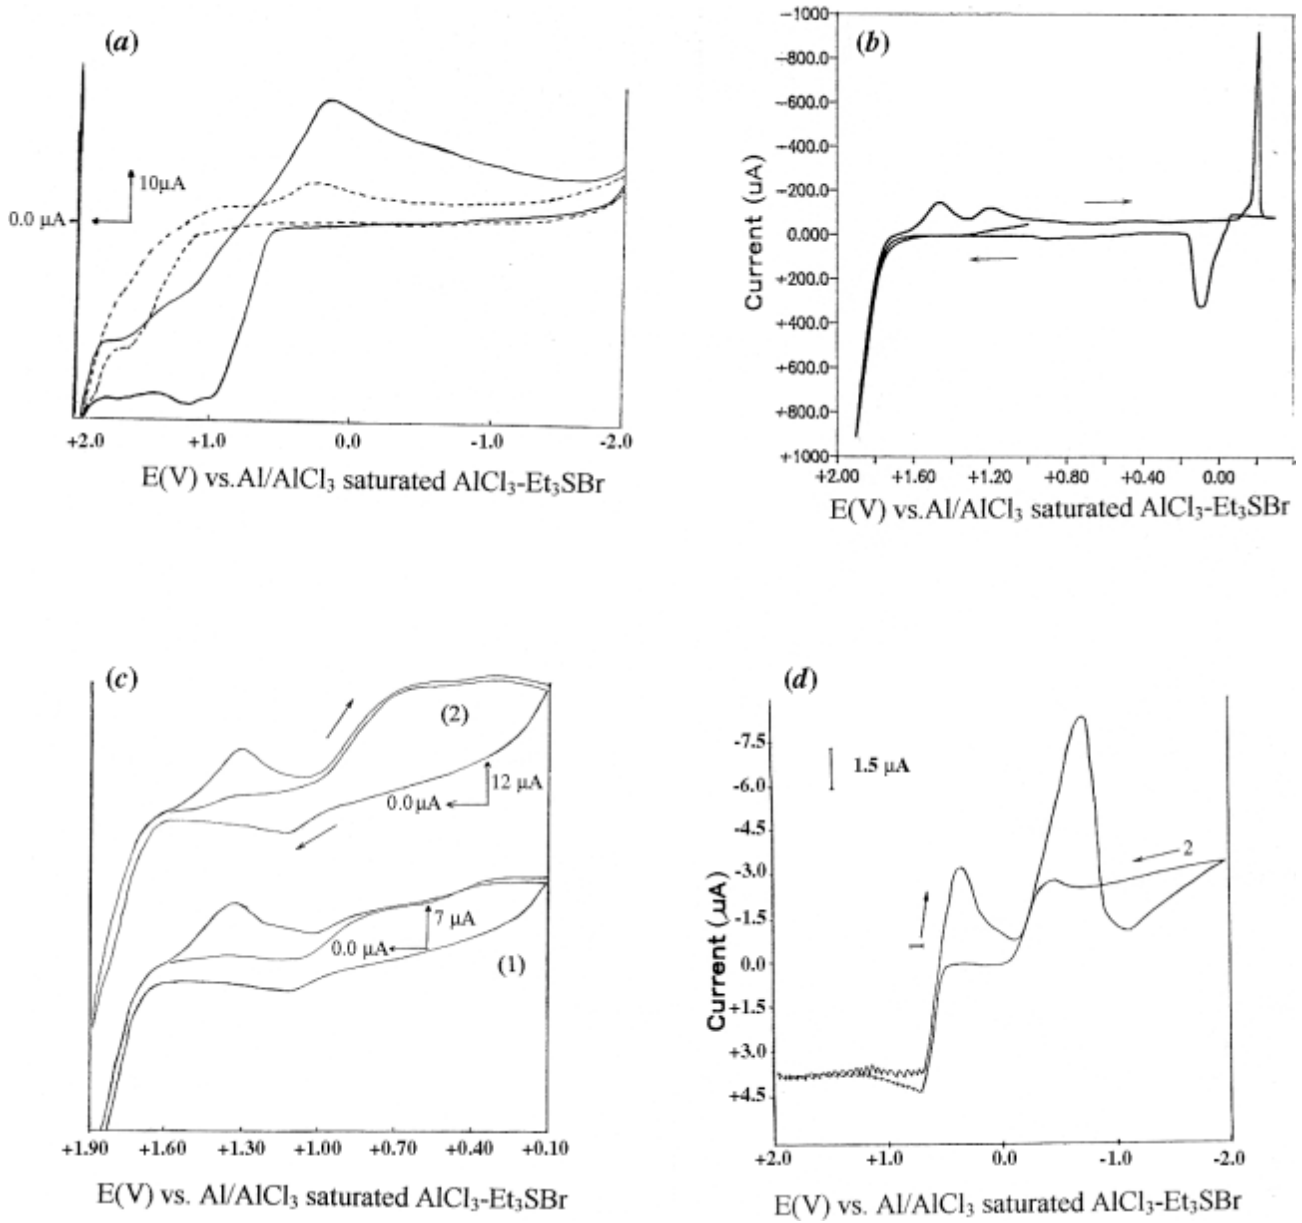
HCl (20), a shift from 13.3 ppm at 58% HCl to 3.0 ppm at 95% HCl was observed. In these systems, exchange gives rise to a single signal. In Et_3SBr–HCl, where halide exchange scrambles the halides X to all combinations of Cl and Br, we find the acidic proton shift moves from 8.85 ppm at 52% HCl to 6.30 ppm at 68% HCl. At the higher HCl composition, the signal splits at 24 °C (Fig. 3). This splitting is still discernible at 64 °C, and the peak at 84 °C is broad (Fig. 4*b*). For HCl:bmimCl, however, cooling to –6 °C is required to see any splitting; the signal at 84 °C is somewhat broad; and there is a shift upfield with temperature (Fig. 4*a*). At a constant HCl mole fraction of 0.58, the acidic proton signal for the series HCl:emimCl, HCl:bmimCl, and HCl:Et_3SBr moved from 10.7 to 9.97 to 7.85 ppm. Several effects are in play here, as follows: (*a*) the signal splitting at lower temperatures is due to the slowing down of exchange between protons in the different anions, and this is necessarily greater for bromide-containing species; (*b*) stronger H bonding in all-chloride anions (HCl_2^-, HCl_3^-, etc.) will lead to a downfield signal vs. that of the anions containing bromide; (*c*) further H bonding to $bmim^+$ by HCl_2^- would decrease with temperature and create the upfield shift not seen with the Et_3S^+ system.

Cyclic voltammetry

Et_3SBr–$AlCl_3$

The electrochemical window of a basic (46% $AlCl_3$) liquid is approximately 4 V, ranging from the reduction of Et_3S^+ to the oxidation of Br^- and $AlCl_3Br^-$. The protic impurity reduction and oxidation peaks were decreased by the addition of $EtAlCl_2$ (Fig. 5*a*). For an acidic (64% $AlCl_3$) system the window is closer to 2 V with the formation of Al metal being the limiting cathode reaction, as confirmed by the stripping peak at +0.1 V (Fig. 5*b*). Protic impurity peaks in this system were also decreased by $EtAlCl_2$ addition. When HCl was deliberately added to the (Lewis) acidic liquid, a composite peak developed in the 0.3–0.8 V region (Fig. 5*c*); this resembles the behavior of emimCl–$AlCl_3$–HCl (19), where the adducts $Al_2Cl_7{\cdot}HCl^-$ and $AlCl_4{\cdot}HCl^-$ show distinct reduction peaks ~0.7 V apart. The voltammograms also show the reduction (at 1.4 V) of anodically generated halogen.

Fig. 4. Variable temperature ^{1}H NMR spectra of (*a*) 60.5% HCl–bmimCl and (*b*) 68% HCl–Et_3SBr.



Et_3SBr–HCl

The cyclic voltammogram of 68% HCl–Et_3SBr shows well-separated reduction peaks at +0.3 V and –0.7 V (Fig. 5*d*). Since HCl_2^- and $H_2Cl_3^-$ reductions in an all-chloride system are separated by only 0.2 V, it appears that the expected $H_2Cl_2Br^-$ species disproportionates considerably to HBr_2^- (E_p +0.3 V) and $H_2Cl_3^-$ (E_p –0.7 V).

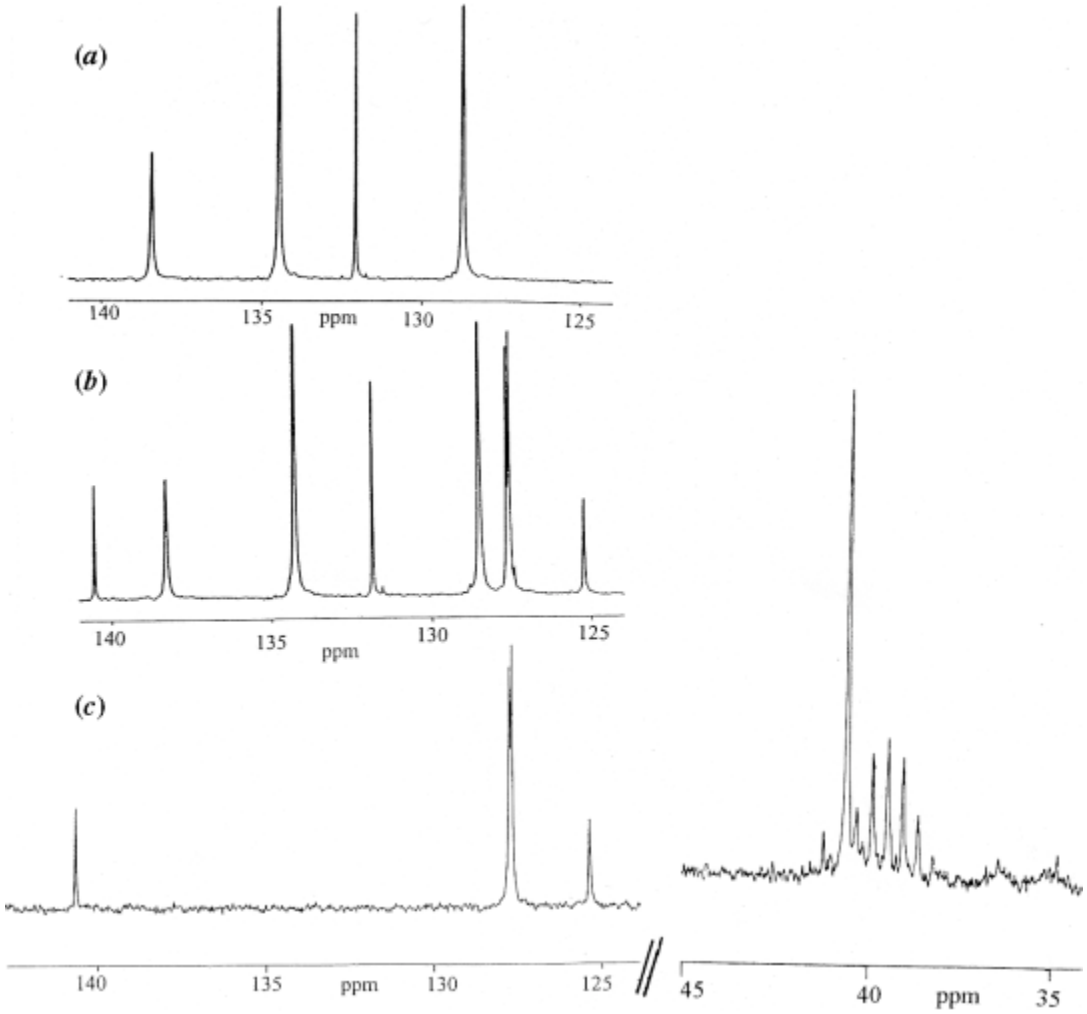
FTIR spectra

Table 4 shows the infrared spectrum of 52% HCl–Et_3SBr. The broad peak at 2060–1500 cm^{-1} can be assigned to the $HClBr^-$ and $H_2Cl_2Br^-$ species. This compares with the assignment of the 2200–1600 cm^{-1} absorption of HCl–emimCl (19) to the higher polymers $H_2Cl_3^-$ and $H_3Cl_4^-$. The broad band at 2200–1500 cm^{-1} in the HBr–Me_3SBr system (17) is probably due to $H_2Br_3^-$, not HBr.

Potential applications



Hydride reactions

Under Lewis-basic conditions the hydrogen at the C-2 position of 1,3-disubstituted imidazolium salts reacts with hydride ions to produce hydrogen and carbenes, which can be used as a source of different salts or can form complexes with metals such as palladium (22, 23). Under Lewis-acidic conditions hydride does not attack the C-2 position of the imidazolium salts but rather the heptahaloaluminate, to form AlX_3H^- and substituted alanes (24).

CaH_2 is sparingly soluble in basic $AlCl_3$–Et_3SBr but does not react with either Et_3S^+ or $AlCl_3Br^-$. However, it reacts with the acidic $AlCl_3$–Et_3SBr, as shown by the IR band at 1904 cm^{-1} (Table 5). The IR and ^{13}C NMR spectra of benzophenone in this solvent were recorded (Tables 5 and 6), and their changes upon the addition of CaH_2 were found to be as follows: in the IR spectrum the Al-H band develops and the 1654 and 997 cm^{-1} bands are lost, while the five solute singlets in the ^{13}C NMR spectrum (Fig. 6*a*), including that due to C=O at 207.1 ppm (not shown), are replaced by five different singlets (Fig. 6*c*). The new peak at 40.6 ppm can be identified as arising from $–CHO^-$ (it is readily distinguish-

able from a weak DMSO locking solvent multiplet centred at 39.9 ppm) when compared with recent ^1C NMR spectra of liquid alkoxides (25). The addition of HCl to the product gives an IR spectrum with an O-H stretch at 3304 cm^{-1} and no Al-H band, consistent with the formation of the benzhydrol.

An aliphatic cation

Chemistry using ionic liquids at any temperature has tended to emphasize the anion of the salt. We have pointed out elsewhere (26) that the role of the cation is often much more than that of a spectator species. Sulfonium salts provide an aliphatic alternative to the aromatic imidazolium and pyridinium salts with different solubility prospects when complex reaction mixtures such as heavy oil – ionic liquid are considered (27). They also provide different NMR windows, are compatible with hydrides, and give different reduction products from imidazolium salts (not carbenes). The chirality of asymmetric sulfonium salts has long been known, and the possibility of developing a chiral solvent is intriguing.

Chemical transformations of *cis*-$W(CO)_4(C_5H_5N)_2$ in the ring-opening metathesis polymerization of norbornene

L. Bencze, N. Bíró, B. Szabó-Ravasz, and L. Mihichuk

Abstract: The six-coordinate W^0 complex *cis*-$W(CO)_4(C_5H_5N)_2$ has been found to be active in the in situ formation of a carbene species from norbornene, which generates a typical ring-opening metathesis product (ROMP). A proposed mechanism of initiation suggests that the reaction involves a 2,3-hydrogen shift in the coordinated norbornene ($\eta^2 \rightarrow \eta^1$). The initiating carbenoid group is identified from the products of the spontaneous carbene–CO coupling and Wittig reactions test. Formation of $W(CO)_3(\eta^6\text{-}C_6H_5CH_3)$ when toluene is the solvent, followed by reaction with the carbene, is blamed for catalyst deactivation.

Key words: bis-pyridine-tetracarbonyl-tungsten, ROMP, olefin metathesis, norbornene.

Résumé : On a trouvé que le complexe hexacoordiné du W^0, *cis*-$W(CO)_4(C_5H_5N)_2$, est actif dans la formation in situ d'une espèce carbénique dérivée du norbornène qui conduit à un produit résultant d'une ouverture typique de cycle avec métathèse. Un mécanisme d'initiation proposé suggère que la réaction implique un déplacement 2,3 d'hydrogène dans le norbornène pentacoordiné ($\eta^2 \rightarrow \eta^1$). Le groupe carbénoïde qui provoque l'initiation est identifié à partir des produits qui résultent d'un couplage spontané carbène–CO et de tests de réactions de Wittig. La formation de $W(CO)_3(\eta^6\text{-}C_6H_5CH_3)$, quand on utilize du toluène comme solvant et qu'on effectue ensuite la réaction avec le carbène, est attribuée à une désactivation du catalyseur.

Mots clés : bis-pyridine-tétracarbonyl-tungstène, produit d'ouverture de cycle avec métathèse, métathèse d'oléfine, norbornène.

[Traduit par la Rédaction]

Introduction

Olefin metathesis is of great value in organic and polymer synthesis. The reactions do not occur spontaneously, but all require the presence of a transition-metal carbene complex (*well defined catalyst*) or a *catalyst system* containing a transition-metal complex (precursor) in conjunction with a second compound, generally an organo main-group metal compound (co-catalyst), and sometimes a third compound (promoter) (1).

The transition-metal carbenes formed in these systems trigger the transalkylidenation (i.e., metathesis) of olefins (2, 3). Catalyst systems having neither a preformed metallocarbene nor an organometallic hydrocarbon group in any component represent a relatively minor class of metathesis initiators (4, 5).

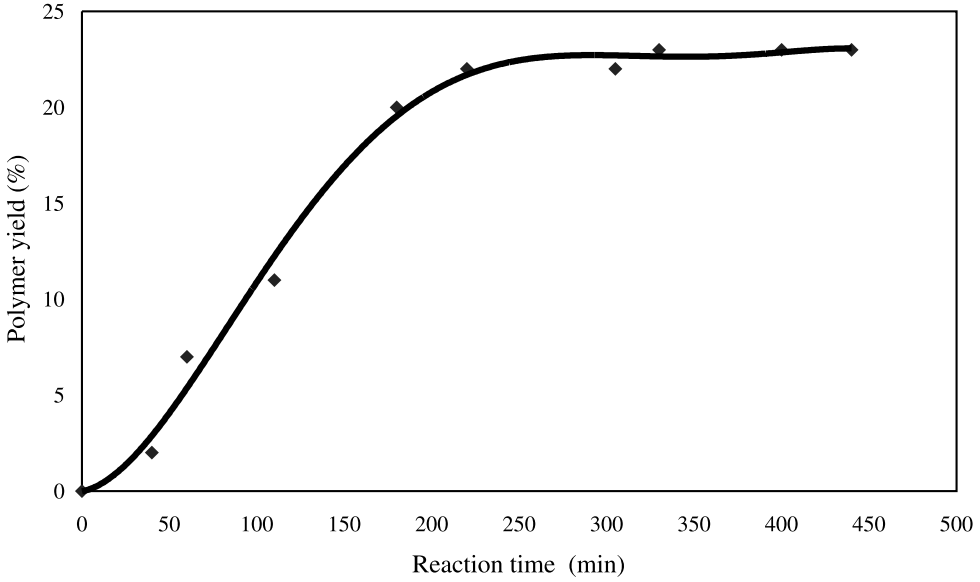
We wish to report here the catalytic properties of *cis*-$W(CO)_4(C_5H_5N)_2$ (**1**) in the ring-opening metathesis polymerization (ROMP) of norbornene (NBE). This is the first six-coordinate W^0 noncarbenoid unimolecular catalyst that does not require a co-catalyst, a carrier, or light for activation. The aim of this work is to study the initiation reactions of a system in which the catalyst precursor contains the minimum number of ligands whose reactions might interfere with an olefin → carbene transformation and which involves no side reactions other than metathesis.



Experimental

cis-$W(CO)_4(C_5H_5N)_2$ (**1**) was prepared according to literature methods (6), with CO evolution being monitored until complete conversion of $W(CO)_6$ and formation of only the tetracarbonyl complex, as seen by infrared analysis. All experiments were conducted using standard Schlenk techniques under deoxygenated argon. Toluene was distilled from sodium and benzophenone, and NBE (Aldrich) was distilled from sodium before use. Tungsten hexacarbonyl (Aldrich) was used without further purification.

ROMP experiments were carried out in a reaction mixture composed of toluene (10 mL), olefin (0.52 mol/dm^3), and *cis*-$W(CO)_4(C_5H_5N)_2$ (4.4 mmol/dm^3). The reaction mixture was immersed in an oil bath heated to 116 °C and was stirred by a magnetic stirrer.

 doi: 10.1139/V04-007 © 2004 NRC Canada

Fig. 1. Norbornene polymer yield vs. reaction time. Each point represents the average of three experimental runs.

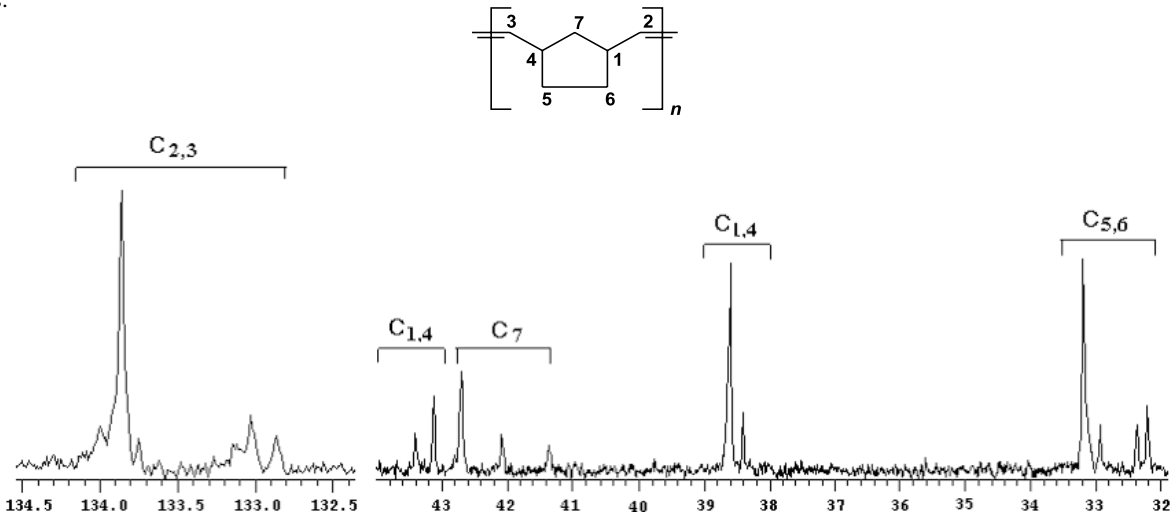
The NBE reaction mixture changed in time, from yellow to orange, to brown-orange, and then to a transparent golden brown color, with a gradual increase of viscosity. The reaction was quenched by the addition of ethanol (20 mL). The precipitated polymer was washed with ethanol, dried, and analyzed by $^{13}C\{^1H\}$ NMR spectroscopy. The spectra of the polymers were recorded in $CDCl_3$ solution at 125 MHz, using a GE GN Omega 500 spectrometer. The assignments of $^{13}C\{^1H\}$ NMR shifts were based on previous analysis, and the microstructural details of the polymers were calculated from the NMR integrals (7–10). GC–MS analyses were carried out on a Shimadzu QP5000, 70 eV instrument equipped with a 10 m × 0.20 mm HPI column at a flow rate of 2 mL/min. The identification of products from GC–MS analyses was carried out using an existing mass spectral library database. IR spectra were obtained using a SPECORD M80 spectrophotometer in CH_2Cl_2 solution, using KBr (0.065 mm) cells.

Results and discussion

The rate of polymer formation is rather slow, but nearly the same throughout the active period. The catalyst is poisoned or inactivated in some fashion within approximately 220 min. The maximum yield for the polymer is 25%, attainable after 220 min of reaction, as seen in Fig. 1.

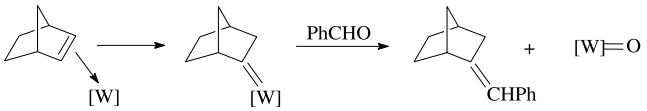
The solubility of the polymer in $CDCl_3$ is satisfactory for NMR examination, but it is not free from some swollen gel. The $^{13}C\{^1H\}$ NMR analysis indicates a typical ROMP product of NBE. The assignments of $^{13}C\{^1H\}$ NMR shifts, based on previous analysis (7–10), were made as shown in Fig. 2, where a comparison of line intensity illustrates the high *cis* content (σ_c = 0.75–0.80) of the polymer. The distribution of the *cis* and *trans* double bonds in all cases is blocky ($r_c \cdot r_t$ ~ 9–14), consistent with the high *cis*- content of the polymers, as previously found (9–11).

The addition of benzaldehyde to the NBE–*cis*$W(CO)_4(C_5H_5N)_2$ system, followed by heating to 116 °C, inhibits the ROMP and leads to 2-benzylidenenorbornane (*m*/*z* (%): 184 (25, $[M]^+$), 155 (27), 130 (100), 115 (38), 77 (25)), the product of a Wittig-type carbene – aldehyde reaction, as illustrated in Scheme 1.



To elucidate the mechanism of carbene initiation, a GC–MS analysis was carried out on the low-molecular-weight fraction of the ethanol-quenched solution. The major products identified and mass spectral data are listed in Table 1. The first two entries (**5** and **6** in Scheme 2) are also consistent with a norbornylidene–carbene–ketene pathway, as found earlier for an NBE–$W(CO)_3Cl_2(AsPh_3)_2$ system, with the ketone being the major product formed (4*c*).

IR analysis of the quenched solution shows $W(CO)_5(C_5H_5N)$ (**2**) and $W(CO)_3$ (η^6-$C_6H_5CH_3$) (3) (besides traces of **1**) as the only complex-carbonyl-containing products identified by comparison of the ν_{CO} bands with literature values (6, 12) (Fig. 3). The GC–MS analysis of the quenched solution also provides evidence for the presence of the $W(CO)^3$ (η^6-$C_6H_5CH_3$) complex by a comparison of its mass spectrum with that of an authentic sample. The presence of the toluene-derived product, which was the second major product, seemed to be perplexing in a metathesis catalyst system; however, a separate experiment showed that it also forms from *cis*-$W(CO)_4(C_5H_5N)_2$ in refluxing toluene after a few hours, the result of a transformation pathway.



The transformation of the catalyst precursor is commenced by the loss of a pyridine ligand followed by the competition of CO, NBE, and toluene for the vacant coordination site (Scheme 2). The basis for this deduction is provided by the fact that $W(CO)_5(C_5H_5N)$ is the only product obtained when the above reaction is carried out *in the presence of CO*. The presence, in increasing quantity, of the penta- (**2**) and tricarbonyl (**3**) species at the beginning and by the end of the reaction helps to rule out their involvement as precursors in the formation of the active carbene species. Their presence does not maintain the catalytic activity. Owing to the rapid disappearance of *cis*-$W(CO)_4(C_5H_5N)_2$ and the quantity of the trapped primary alkylidene groups, it is

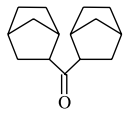
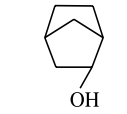
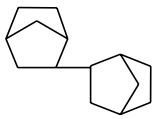
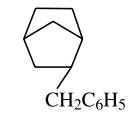
Fig. 2. Assignments of the ^{13}C NMR chemical shifts, illustrating the high *cis* content of the NBE polymer. Carbon signals are labeled as follows:

Scheme 1.









easily envisaged that the tetracarbonyl species is the precursor of the initiating carbene, and the latter forms soon after the reaction commences.

Thus, it appears that *cis*-$W(CO)_4(C_5H_5N)_2$ initiates the reaction at 116 °C through loss of one pyridine ligand followed by formation of a π-complex with NBE and rearrangement by a 2,3-hydrogen shift (4) to give the initiating carbene. Loss of the other pyridine ligand is followed by coordination of another NBE ligand in a π fashion, generating a metallacyclobutane intermediate (3), which then forms the coordinatively unsaturated ROMP propagator. The slow accumulation and the high molecular weight of the polymer product indicates that the primary carbene complex is relatively stable (13) and that the initiation is slow. Having no low-molecular-weight polymer fraction formed, living polymerization is assumed with little termination. The $^{13}C\{^1H\}$ NMR analysis of the polymer is indicative of only the repeating unit, as illustrated in the caption for Fig. 2, with no spectral lines associated with end groups, thereby suggesting no low-molecular-weight fraction.

The catalyst deactivation, leading to an approximate 25% polymer yield, is intriguing. The last entry in Table 1 is not a product derived from a norbornylidene–carbene–ketene pathway, as illustrated in Scheme 2, but may be indicative of an additional pathway involving the initiating carbene complex and the $W(CO)_3(\eta^6\text{-}C_6H_5CH_3)$ complex, leading to deactivation of the catalyst and the 25% maximum polymer yield. To gain further insight concerning this aspect, we are actively pursuing a detailed computational study of this reaction at the DFT level using the Gaussian 98 series of programs (14). It is interesting that although the olefin metathesis reaction is one of the most studied in organometallic chemistry, there have been few reports dealing with the modeling of this reaction and the ROMP reaction using quantum chemistry

tools (15–17). A future publication will deal with these computational results, as well as attempts to isolate the initiating carbene complex and an extension of these studies with the related norbornadiene substrate.

Conclusions

cis-$W(CO)_4(C_5H_5N)_2$ was found to be active in the in situ formation of a metathesis active carbene species from NBE substrate. The reactions follow the course of a 2,3-hydrogen shift in the coordinated olefin, and the initiating carbene could be identified from the products of the carbene–CO

The recognition and catalytic hydrolysis of ATP by protonated phenanthroline-bridged polyamine and (or) Ca(II), Mg(II), Zn(II), and La(III) ions

Yan-He Guo, Qing-Chun Ge, Hai Lin, Hua-Kuan Lin, and Shou-Rong Zhu

Abstract: The supramolecular interactions of 2,9-di(((2′-phenylamino)ethyleneamino)methyl)-1,10-phenanthroline (L) and (or) metal ions (M = Ca^{2+}, Mg^{2+}, Zn^{2+}, or La^{3+}) with nucleotides were investigated. Furthermore, the hydrolysis of ATP catalyzed by a protonated ligand and (or) a metal ion (M = Ca^{2+}, Mg^{2+}, Zn^{2+}, or La^{3+}) was studied at pH 7.6 using ^{31}P NMR spectra. Kinetics studies show that at pH 7.6 the protonated ligand, with a rate constant of 2.9×10^{-4} min^{-1}, does not significantly promote ATP hydrolysis. However, in the presence of Ca^{2+}, Mg^{2+}, Zn^{2+}, or La^{3+} ions, L can accelerate the hydrolysis of ATP, with corresponding rate constants of 5.73, 1.48, 6.76, and 31.7×10^{-3} min^{-1}, respectively, which are about 29-, 7.5-, 34-, and 159-fold faster than the hydrolysis rate of free ATP. By comparison with M–ATP (M = Ca^{2+}, Mg^{2+}, and La^{3+}) systems, the rates of M–L–ATP were also promoted. This has been achieved through the effective recognition of ATP and the availability of a good intramolecular nucleophile, i.e., a free amino nitrogen atom of L. Compared with the Zn^{2+}–ATP system, the decrease in the rate of the Zn^{2+}–L–ATP system at pH 7.6 may be attributed to the competition between the mixed ligands in binding Zn^{2+}. Similar to L–ATP, the hydrolysis reactions in the Zn^{2+}–L–ATP or M–L–ATP (M = Ca^{2+}, Mg^{2+}, and La^{3+}) systems occur through an addition–elimination type mechanism, in which phosphoramidate intermediates were observed at 2.88 and 4.06 parts per million (ppm) in the L–ATP and Mg^{2+}–L–ATP systems, respectively. Here, metal ions add control or regulation to the hydrolysis reaction.

Key words: recognition, ATP hydrolysis, metal ions, phenanthroline-bridged polyamine.

Résumé : On a étudié les interactions supramoléculaires de la 2,9-di((2′-phénylamino)éthylèneamino)méthyl-1,10-phénanthroline (L) et/ou de l'ion métallique (M = Ca^{2+}, Mg^{2+}, Zn^{2+} ou La^{3+}) avec des nucléotides. De plus, utilisant la spectroscopie RMN du ^{31}P, on a étudié l'hydrolyse de l'ATP, catalysée par un ligand protoné et/ou un ion métallique (M = Ca^{2+}, Mg^{2+}, Zn^{2+} ou La^{3+}), à un pH de 7,6. Les études cinétiques montrent que, à un pH de 7,6, le ligand protoné, avec une constante de vitesse de $2,9 \times 10^{-4}$ min^{-1}, n'active pas l'hydrolyse de l'ATP de façon significative. Toutefois, en présence des ions Ca^{2+}, Mg^{2+}, Zn^{2+} ou La^{3+}, le ligand L peut accélérer l'hydrolyse de l'ATP, avec des constantes de 5,73, 1,48, 6,76 et $31,7 \times 10^{-3}$ min^{-1} respectivement, soit 29, 7,5, 34 et 159 fois plus rapides que la vitesse d'hydrolyse de l'ATP libre. Par comparaison avec les systèmes M–ATP (M = Ca^{2+}, Mg^{2+}, Zn^{2+} ou La^{3+}), les vitesses d'hydrolyse sont aussi augmentées. Ce résultat a été obtenu par une reconnaissance effective de l'ATP et la disponibilité d'un bon nucléophile intramoléculaire, c'est-à-dire l'atome d'azote libre de l'amino du ligand L. Comparé au système Zn^{2+}–ATP, la diminution de la constante de vitesse dans le système Zn^{2+}–L–ATP, à un pH de 7,6, doit être attribuée à une compétition entre les ligands mixtes dans la fixation du Zn^{2+}. Semblable à celle observée dans le système L–ATP, la réaction d'hydrolyse dans les systèmes Zn^{2+}–L–ATP ou M–L–ATP (M = Ca^{2+}, Mg^{2+} ou La^{3+}) se produit par un mécanisme de type addition–élimination dans lequel les intermédiaires phosphoramidates sont observés à 2,88 et 4,06 ppm respectivement dans les systèmes L–ATP et Mg^{2+}–L–ATP. Dans ces cas, l'ion métallique contrôle ou régularise la réaction d'hydrolyse.

Mots clés : reconnaissance, hydrolyse de l'ATP, ions métalliques, polyamine pontée de la phénanthroline.

Introduction

The enzyme-catalytic transfers of nucleotidyl or phosphoryl groups of adenosine 5′-triphosphate (ATP) depend on the presence of divalent metal ions, which either play structural roles or may be one of the catalytic cofactors (1–7). In kinetic studies of ATP hydrolysis, the emphasis has been placed on the effect of transition metal ions, al-

Scheme 1. Synthesis of L and structures of ATP and ADP.

though magnesium(II) and calcium(II) are reported as having the most biological significance (8). For example, studies of the binding interaction between highly biologically active Zn^{2+} and nucleotides have aroused intensive interest (9, 10), since the role zinc(II) plays in the active site of zinc-dependent enzymes can be conventionally studied with model zinc complexes (11). On the other hand, La(III) and its complexes, although not used directly by this type of enzyme for ATP hydrolysis, are by far the most efficient in promoting the hydrolysis of phosphate esters with good (12) or poor leaving groups (13).

Polyaza ligands in their protonated forms can bind to nucleotides strongly and selectively via electrostatic interactions, as well as by hydrogen bonding between the cationic binding sites (ammonium groups) of the receptor and the negatively charged polyphosphate groups of the substrates (14–17). On the other hand, recognition of the nucleobase residue may be achieved either by stacking with the nucleoside of nucleotides or by sites capable of forming complementary hydrogen-bonding patterns (15). It has been reported that polyammonium can promote the rate of ATP hydrolysis via an addition–elimination type mechanism, with the formation of a phosphoramidate intermediate (14–18).

Since metal ions influence the processes of recognition and nucleophilic attack of nucleotides, it is believed that metal ions with different properties — namely "hard" or "soft" metal ions — will exhibit unlike actions and differences in efficiency when assisting with ATP hydrolysis that is catalyzed by protonated polyaza receptors (19–21). In this paper, a multifunctional receptor L, containing phenanthroline and polyamines, has been used to achieve high molecular recognition and reaction selectivity in the dephosphorylation of ATP. The fact that ATP hydrolysis depends on the features of the Lewis acid (metal ions) provides insight into the supramolecular interactions between the receptor and the nucleotides and the catalytic hydrolysis of the physiologically important anions.

Experimental

Materials

All the experimental techniques and the standard IR, element analysis, and NMR equipment were the same as described previously (22). The compound 2,9-dicarboxaldehydro-1,10- phenanthroline (Phen) was synthesized according to the reported method (23), and *N*-phenylethylenediamine and sodium salts of ATP, ADP, and AMP were purchased from Aldrich Co. The synthesis of L is shown in Scheme 1.

Synthesis of 2,9-di(((*N*′-phenylamino)ethylene-amino)methylene)-1,10-phenanthroline (L)

To a suspension of 2,9-dicarboxaldehydro-1,10-phenanthroline (23) (0.8 g, 3.75 mmol) in anhydrous alcohol (50 cm^3), a solution of *N*′-phenylaminoethylenediamine hydrobromide (1.55 g, 8.0 mmol) and triethylamine (0.6 mL, 16 mmol) in 50 cm^3 alcohol was added slowly, and then the mixture was stirred under N_2 at 25 °C for 12 h. After filtration of the reaction mixture, $NaBH_4$ (0.15 g, 4.2 mmol) was added in small quantities, and the solution was stirred for another 12 h. The solvent was removed under reduced pressure, and NH_4OAC (4 g) in 20 cm^3 water was added to the white residue. The aqueous mixture was then extracted with chloroform (4 × 80 cm^3). The organic fractions were combined, washed with distilled water (3 × 30 cm^3), and then dried over $MgSO_4$. The solution was filtered, and the chloroform was removed on a rotary evaporator to give a yellow oil. The oil was dissolved in alcohol, and then concentrated HCl was added. The white-yellow precipitate formed was collected and dried on P_2O_5; 1.5 g was obtained, a yield of 42.64%. ^{1}H NMR (D_2O) δ: 6.51 (m, 6H, *m*-phenyl), 6.88 (m, 4H, *o*, *p*-phenyl), 3.49–3.58 (m, 8H, $NHCH_2CH_2NH$), 4.75 (s, 4H, Phen-CH_2), 7.86 (d, 2H Phen $H_{3,8}$), 7.98 (s, 2H, Phen $H_{5,6}$), 8.54 (d, 2H, Phen $H_{4,7}$). IR (KBr pellet): 3422 (ν_{N-H}); 693, 747 (Phen); 862, 1455, 1603 (Ar). Elemental analysis

Measurements

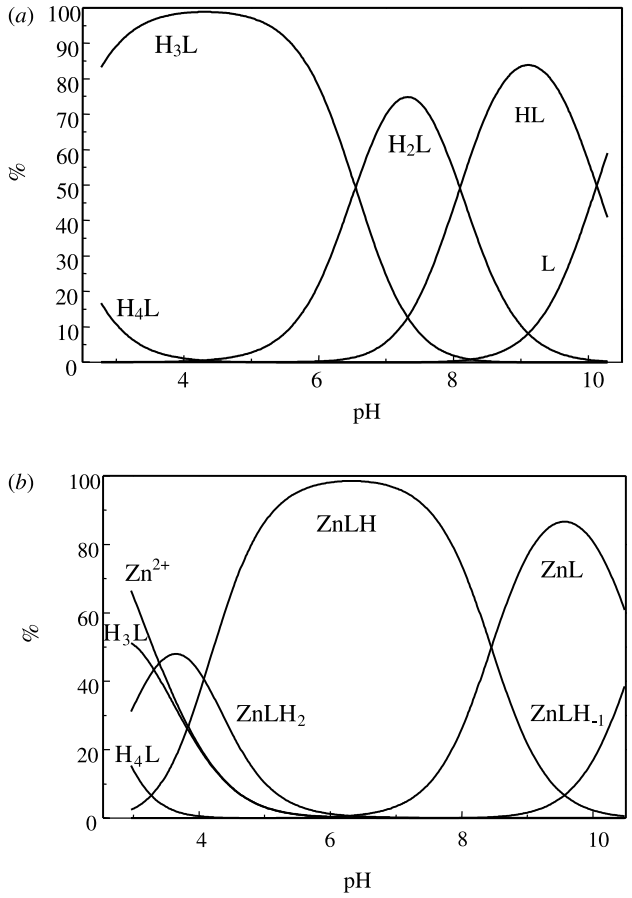
The potentiometric titrations (22), ^1H and ^{31}P NMR experiments, and the kinetic studies (^{31}P NMR spectra) were the same as those described previously (14).

Results and discussion

Protonation and metal complexes

The ligand L consists of a hexa-aza ligand with a Phen moiety and four amino groups. But potentiometric pH titration indicated that the ligand L has only four stepwise protonation constants, i.e., 10.16, 8.09, 6.64, and 2.50, respectively. The species distribution curves of the protonation of L are shown in Fig. 1*a*. Because of the electron repulsion of the already protonated ammonium ion(s) and the weaker basicity of 2,9-dimethyl-1,10-Phen compared with that of secondary amino groups (that is, $pK^{H}_{CH_3-Phen}$ = 5.85 vs. pK^{H}_{amine} = 9–11 (24)), the two nitrogen atoms of Phen are not involved in the protonation. This was proven by the ^1H NMR titration of L as a function of pH, which showed that the ^1H signals of Phen shift significantly only at pH < 2. Thus, the first two protonation steps involve the two benzylic N2 atoms, while the last two steps belong to the two terminal N1 atoms, since N1 is directly linked by an aromatic phenyl substituent.

[1] $\quad L + lH^+ = H_lL^{l+}$



The ligands L that contain Phen and polyamines are good donors for Zn^{2+}. The stability constants of the species $ZnLH_2$, ZnLH, ZnL, and $ZnLH_{-1}$, formed in the Zn^{2+}–L system according to the equilibrium found in eq. [2], are listed in Table 1. Notwithstanding the existence of the strong donors of Phen and the four amino nitrogen atoms, the ligand cannot stabilize Zn^{2+} and three protons simultaneously because of the electrostatic repulsion effect. As is seen from Fig. 1*b*, species $ZnLH_2$, ZnLH, and ZnL (charge omitted for clarity) reach the maximum concentration at pH ca. 3.7, 6.2, and 9.6, respectively. The complex $ZnLH_2$ is formed at pH 2.7, and the structure has Phen and two terminal N1 atoms coordinated to Zn^{2+}, while the two benzylic N2 atoms are protonated. It is interesting to note that the complex ZnLH exists in a wide pH range (3–10) and is at almost 100% concentration at pH around 7, the physiological pH. The mono-hydroxyl compound $ZnLH_{-1}$ begins to form at pH 8.0 and becomes an important species at pH > 10; it is formed by deprotonation of the Zn(II)-bound water molecule. Although the highly charged species $ZnLH_3^{5+}$ was not involved in the calculations because of the pH range studied (2.5~10.5), we do accept the hypothesis of its existence in strongly acidic solution, and we make the assumption that the pK_a of the equation $ZnLH_3 = ZnLH_2 + H^+$ is 2.5.

[2] $\quad Zn^{2+} + L + mH^+ = ZnLH_m^{m+2}$

Protonated ligands interact with nucleotides

Protonated L forms five supramolecular complexes, $LNuH_m$ (Nu = ATP, ADP; m = 2, 3, 4, 5, and 6), with ATP or ADP in aqueous solution. The binding strength of protonated ligands with nucleotides, i.e., the log$K$ value of the equilibrium found in eq. [3], are listed in Table 1. The equilibrium in eq. [3] is obtained from eqs. [4], [5], and [5′], which represent the overall stability constants of molar complexes and the protonation constants of Nu, respectively. The protonation constants of Nu and the stability constants of their metal complexes were cited directly from the literature (25).

[3] $\quad H_lL^{l+} + H_nNu^{n-4\ (or\ 3)} = LNuH_{l+n}^{l+n-4\ (or\ 3)}$

[4] $\quad (l + n)H^+ + L + Nu^{-4\ (or\ 3)} = LNuH_{l+n}^{l+n-4\ (or\ 3)}$

[5] $\quad nH^{n+} + Nu^{-4\ (or\ 3)} = H_nNu^{n-4\ (or\ 3)}$

[5′] $\quad lH^+ + L = H_lL^+$

As seen from Fig. 2*a*, the supramolecular complexes form in the pH range in which the amine is protonated, while the nucleic acids are at least partly deprotonated. It is observed that the species $LATPH_3$ dominates at pH ca. 8, while $LATPH_6$, $LATPH_5$, $LATPH_4$, and $LATPH_2$ reach their maximum concentration at pH ca. 3, 5, 6.5, and 10, respectively.

The protonated ligands interact with the anion substrates via electrostatic interactions, as well as via hydrogen bonds formed between the polyammonium ions and the negatively charged oxygen atoms of the nucleotides. As shown in Table 1, the increasing degree of protonation of the ligand increases the binding strength between the supramolecular

+	+	Zn(II)	0.15	1.51	0.79
+	+	La(III)	–0.17	2.34	–0.08

Note: Metal ions: 0.01 mol·dm^{-3} Ca^{2+} (Mg^{2+}, Zn^{2+}, and La^{3+}) at pH 7.6 and at 25 °C. δATP: P_α, –15.54 ppm; P_β, –26.44 ppm, and P_γ, –11.92 ppm.

counterparts, owing to the increasing ability of the receptor to participate in Coulombic interactions and form H-bonds with the bound nucleotides. Because logK_1 (6.50 and 6.36 for ATP and ADP, respectively) (25) of the nucleotides is close to the third stepwise protonation constant of L (6.64) or higher than the last protonation constant of L (2.5), the highly protonated species formed at low pH might involve protonated HNu and H_2Nu (Nu = ATP and ADP). However, partial neutralization of the nucleotide will weaken the electrostatic interaction and decrease the number of H-bonds and then the binding strength. The orders of concentration $[H_3L][HATP] < [H_3L][ATP]$ and $[H_4L][H_2ATP] < [H_4L][HATP]$ are consistent with this result.

On the other hand, Table 2 shows that at pH 7.6, the ^{31}P NMR signals of P_β (0.32 ppm) and P_γ (1.42 ppm) shift downfield, whereas the P_α signal remains almost unchanged. This indicates that only the P_γ and P_β phosphorus centers are involved in the complexation. Moreover, the presence of Phen can indicate marked π-stacking interactions with the nucleoside of nucleotides, which has been proven by ^1H NMR spectra, as all the chemical resonances of $Phen_{3,8}$,

M–ATP systems (M = Zn^{2+}, Mg^{2+}, Ca^{2+}, and La^{3+})

Previously, studies have revealed that Zn^{2+}, Mg^{2+}, and Ca^{2+} can form 1:1 complexes with ATP in the 1:1 metal–ATP stoichiometry (26). Both the Ca^{2+} and Mg^{2+} complexes of ATP could be a mixture of α–β–γ tridentate and β–γ bidentate (ATP is mainly β–γ bidentate), whereas in the Zn^{2+}–ATP system, ATP uses only β and γ-phosphate to coordinate to Zn(II). With regard to the La^{3+}–ATP system, La(III) and ATP favor forming $La(ATP)_2$, and ATP is α–β–γ tridentate (27).

^{1}H NMR experiments indicated that the divalent metal ions Ca^{2+}, Mg^{2+}, Zn^{2+}, and Cd^{2+} can promote stacking of the purine bases (4). On the other hand, the hard metal ions have no tendency to interact with the N-7 of purine, while Zn^{2+} exhibits association with the N-7 of the adenosine ring (26). As shown in Table 2, ^{31}P NMR studies indicate a common trend for the binary metal–ATP systems, i.e., large downfield shifts for P_β (2.47–2.85 ppm) and P_γ (0.92–0.87 ppm) and small downfield shifts for P_α (0.33–0.43 ppm). The La^{3+} ion is an exception with a relatively small upfield shift for P_γ (–0.39 ppm) and a small downfield shift for P_α (0.38 ppm) (27).

The facilitation of ATP hydrolysis by Zn^{2+} was previously studied (26). The reaction occurs via a dimer, namely, $[Zn_2ATP]_2(OH^-)$. One Zn(II) ion coordinates to α- and β-phosphates, while another Zn^{2+} ion binds to the γ-phosphate of the ATP, with a large tendency to form a nucleophilic hydroxide complex. The other coordination side, involving two Zn^{2+} ions and one ATP molecule, is used only to stabilize the transition state of $[Zn_2ATP]_2(OH^-)$. At the same time, direct Zn(II)–N-7(purine) interaction occurs while the purine rings of different ATP molecules stack with each other. Because Mg^{2+} lacks metal ion – N-7 interaction and has a low tendency to form a nucleophilic Mg^{2+}–OH^- species at neutral pH (28), Mg^{2+} alone has a lower ability to accelerate ATP hydrolysis (4.5×10^{-4} min^{-1}) at neutral pH, whereas Ca^{2+} has a much higher catalytic rate constant (2.12×10^{-3} min^{-1}) because of the stronger affinity of Ca^{2+} (compared with that of Mg^{2+}) for the phosphate oxygens of ATP.

Recognition in the Zn(II)–L–ATP system

The interactions of Zn^{2+}–L complexes with nucleotides were determined by pH titrations and ^{31}P and ^{1}H NMR spectra. The binding strengths of the metal complexes with nucleotides, according to the equilibrium found in eq. [6], are listed in Table 1. The equilibrium in eq. [6] were obtained from eqs. [7], [2], and [5]. The species distribution curves are shown in Fig. 2*b*.

$$[6] \quad ZnLH_m^{m+2} + H_nNu^{n-4\ (or\ 3)} = ZnLNuH_{m+n}^{m+n-2\ (or\ 1)}$$

$$[7] \quad Zn^{2+} + L + (m+n)H^+ + Nu^{-4\ (or\ 3)} = ZnLNuH_{m+n}^{m+n-2\ (or\ 1)}$$

As is seen from Fig. 2*b*, there are five ternary species, from ZnLATPH to $ZnLATPH_5$, in the Zn^{2+}–L–ATP system. The increase in the binding strength of the Zn^{2+}–L–ATP system when compared with the L–ATP system should be attributed to the presence of noncovalent intramolecular interactions (29, 30). In the first approach, there are ion-pairing and H-bonding interactions between the polyammonium of L and the negatively charged phosphate chain of ATP; these were determined by comparison of the shifts of the ^{31}P signals of ATP before and after the addition of the metal ion to the L–ATP system. As shown in Table 2, the ^{31}P signals of α, β, and γ-phosphate of ATP in Zn^{2+}–L–ATP are upfield shifted by 0.15, 1.51, and 0.79 ppm, respectively, in comparison with those of free ATP, whereas the shifts of ATP in the Zn^{2+}–ATP system are 0.35, 2.79, and 0.92 ppm for α, β, and γ-phosphates, respectively. The results indicate that the mixed ligands compete to bind Zn^{2+} to some extent at neutral pH. On the other hand, all the signals of H-2, H-8, and H-1′ of ATP, as well as those of H-3,8, H-5,6, and H-4,7 of Phen in the Zn^{2+}–L–ATP system shift upfield, which indicates that the Phen has π-stacking interactions with the nucleobase residue of the substrate (Table 3). It is surprising that the Zn–L complexes mainly affect the chemical shifts of H-5,6 rather than the H-3,8 and H-4,7 of Phen; this is probably due to the fact that H-5,6 faces the nucleobase residue directly.

Taking into account the degree of protonation of the nucleotide and polyamine, it should be assumed that the species $ZnLATPH_3$ (which exists in the 4–8 pH range and binds

© 2004 NRC Canada

90% of the metal at pH ca. 5.5 (Fig. 2*b*)) can be considered a mixture of $[ZnLH_3][ATP]$ and $[ZnLH_2][HATP]$, since pK^{H}_{HATP} = 6.50 (25) is almost equal to $pK^{H}_{LH_3}$ = 6.64. For the same reason, the mixtures $[ZnLH_2][ATP]$ and [ZnLH][ATP] are reasonable assumptions for species $ZnLATPH_2$ and ZnLATPH, respectively. Because $pK^{H}_{H_2ATP}$ = 4.20 (25) and $pK^{H}_{LH_4}$ = 2.50, complex $ZnLATPH_4$ prefers the composition of $[ZnLH_2][H_2ATP]$. Because it is not easier for the nucleotide to be tri-protonated (pK_a < 1.7) (25) and because the ligand L can possibly bear one Zn^{2+} and three protons under the assisting coordination of the nucleotide, $[ZnLH_3][H_2ATP]$ is favorable for complex $ZnLATPH_5$. In a word, beside the coordination, ion-pairing, and H-bonding (^{31}P NMR) staking interactions (^{1}H NMR), there possibly exists cation–π-system, hydrophobic–hydrophilic, and even van der Waals interactions in the Zn^{2+}–L–ATP ternary system. These features are similar to those that occur in biosystems.

Supramolecular interactions in Ca(II), Mg(II), and La(III)–L–ATP systems

Since hard metal ions prefer oxygen atoms rather than nitrogen atoms, the competition between the mixed ligands disappears or decreases to some extent in the M–L–ATP systems (M = Ca^{2+}, Mg^{2+}, La^{3+}). Both the ^{31}P and ^{1}H NMR data indicate that Ca^{2+}, Mg^{2+}, and La^{3+} are strongly bound to the nucleotide ATP but not to L. As shown in Table 2, in the $Mg^{2+}(Ca^{2+})$–L–ATP system, the ^{31}P chemical shifts of α, β, and γ-phosphate of ATP are similar to those of the corresponding metal–ATP system. The La^{3+}–L–ATP system is an exception, with the upfield shift of P_α (–0.17 ppm) and P_γ (–0.08 ppm) (27). On the other hand, all the ^{1}H signals of the M–L–ATP systems (M = hard ions) upfield shift compared with those of free ATP and L, indicating that the nucleobase residue of ATP undergoes stacking interactions with the Phen moiety of L.

Owing to their high affinity for oxygen atoms, hard ions have the ability to "structure" ATP and facilitate the location of ATP in the polyammonium chain. The electron-withdrawing effect of positively charged metal ions bound to the substrate increases the susceptibility of the P_γ center and enhances its activity toward nucleophilic attack. If the recognition process occurs in such a sterically controlled way, the metal ion becomes a "messenger" between the receptor and the substrate.

ATP hydrolysis catalyzed by protonated L

Protonated L binds ATP strongly in the pH range of 3–10 (Fig. 1*b*). According to the binding strength of anions with the protonated ligands shown in Table 1, the catalytic conversion of ATP→ADP is reasonable. The product of this reaction, ADP, binds less strongly to protonated L than ATP does because of the shorter phosphate backbone of ADP, which has fewer oxygen atoms and, hence, weaker electrostatic interactions, as well as fewer hydrogen bonds.

The kinetics of ATP hydrolysis catalyzed by a protonated ligand as a function of time was studied at 70 °C using ^{31}P NMR spectra. Analysis of the ^{31}P NMR data shows that protonated L can accelerate the hydrolysis rate of ATP, with the observed rate constant $k_{obs} = 17.4 \times 10^{-3}$ min^{-1} at pH 2.5. But k_{obs} dropped acutely to a rate of 4.0×10^{-3} min^{-1} when the pH value was adjusted to 5.0. With an increase of pH, the k_{obs} decreased rapidly to small values of 2.9×10^{-4} min^{-1} and 3.1×10^{-5} min^{-1} at pH 7.6 and pH 10.1, respectively.

As shown in Scheme 2, the catalytic hydrolysis reaction involves an initial formation of the supramolecular complex (k_1), followed by intramolecular (by amine) or intermolecular nucleophilic attack (by water) of P_γ, leading to the formation of a phosphoramidate intermediate (k_2) and the release of ADP from the phosphorous center (k_3). Finally, the PO_3^{2-} of the intermediate captures a water molecule and gives HPO_4^{2-}, and the catalyst is regenerated and ready for another cycle. The ^{31}P signal observed at 2.55 ppm during the hydrolysis process of ATP should be considered a phosphoramidate intermediate. The same type of intermediate formed by phosphorylation of the amino nitrogen of the receptor has been found at 3–22 ppm (14–18). It is worth noting that the standard of ^{31}P signal in our studies was upfield shifted by 5.63 ppm in comparison with the reported values (14–18), so the ^{31}P shifts of the intermediate should be 8.18 ppm compared with other observations. For an efficient catalytic hydrolysis of ATP, strong binding of the substrate by the catalyst is required. The binding of ATP by protonated L has the following dual effects on the rate acceleration: neutralization of negative charge of the substrate and an increase in susceptibility of the phosphorus center.

ATP hydrolysis catalyzed by M–L complexes

The ^{31}P titration shows that the hydrolysis reactions in M–L–ATP systems favor 1:1:1 stoichiometry, which was demonstrated by the titration of [L–ATP] as a function of, for example, $[Zn^{2+}]$ (Fig. 3). The La^{3+}–L–ATP system also prefers a 1:1:1 stoichiometry in the control of 1:1:1 La^{3+}:L:ATP. As shown in Table 4, the ternary systems of Ca^{2+}, Mg^{2+}, Zn^{2+}, and La^{3+} possess the following rates: 5.73, 1.48, 6.76 and 31.7 × 10^{-3} min^{-1}, respectively, which are about 29-fold, 7.5-fold, 34-fold, and 159-fold as fast as the rate of free ATP (2×10^{-4} min^{-1}), respectively. By comparison with the rate of L–ATP (2.9×10^{-4} min^{-1}), the acceleration ratio is ca. 20-, 5-, 23-, and 109-fold, respectively. However, compared with M–ATP, the rate of the $La^{3+}(Ca^{2+}$, $Mg^{2+})$–L–ATP system is accelerated, while the Zn^{2+} ternary system is retarded.

The mechanisms proposed for the ATP hydrolysis catalyzed by L in the presence of Zn^{2+} and Mg^{2+} (or Ca^{2+} or La^{3+}) are shown in Scheme 3. Similar to Scheme 2, the first step is the formation of a supramolecular complex with a stability constant of K (k_1/k_{-1}). In the Zn^{2+}–L–ATP system, the coordination competition between L and ATP decreases the susceptibility of the P_γ group toward electrophilic attack, compared with that of the Zn^{2+}–ATP system. On the other hand, in the ternary system of Ca^{2+} (Mg^{2+} or La^{3+}), the "structuring" ATP, bound to hard metal ions, is more favored by the polyammonium chain.

Subsequently, the second step involves a nucleophilic attack on P_γ of ATP, the formation of an intermediate, and the release of ADP. In the $ZnLATPH_2$ complex, L coordinates with Zn^{2+} by one (or two) N1 atoms and (or) Phen (at pH > 7, the Zn^{2+}–Phen pair begins to dissociate), while two protonated N2 atoms interact with the phosphates of ATP via electrostatic and H-bonding interactions. Since it is difficult for the second N1 of L to bind Zn^{2+}, in view of its low ba-

Scheme 3. Proposed mechanisms for the catalytic hydrolysis of ATP in the (*a*) Zn^{2+}–L–ATP; (*b*) Mg^{2+} (Ca^{2+}, La^{3+})–L–ATP systems.

sicity (pK_a = 2.5), it is reasonable for the free nitrogen atom to be an efficient nucleophile at neutral pH. Because Mg^{2+}, Ca^{2+}, and La^{3+} prefer phosphate oxygen atoms rather than the secondary amino nitrogen atoms of L, attack by uncharged amino groups is possible for these metal-ion-containing systems. It is worth noting that the ^{31}P signal of the phosphorylated intermediates (14–18) found at 2.88 and 4.06 ppm (should be added 5.63 ppm compared with other studies) in the hydrolysis process of ATP in the L–ATP and Mg^{2+}–L–ATP systems were not observed in the Ca^{2+}(Zn^{2+}, La^{3+})–L–ATP system, since the appearance of the phosporamidate intermediate is relative to several factors, such as pH, time, the concentration of ATP, and so on. Owing to the higher affinity of hard ions for the nucleotide, the release of ADP from the reaction center could be initially caused by a strong coordination of the metal ion to the negatively charged β- and γ-phosphates, leading to a release of metal–ADP in the M–L–ATP (M = hard metal ion) systems. With regard to the Zn^{2+}–L–ATP system, the products are the Zn–L complex and free ADP. The final step (k_4) of the mechanism at neutral pH is the breakdown of the intermediate, involving the capture of a water molecule by PO_3^{2-}, the release of HPO_4^{2-}, and the regeneration of the catalyst.

Thus, the broad range of the dephosphorylation rates, including retardation or acceleration (compared with M–ATP), depends on the metal ions. The metal ions play different roles in all the steps of the hydrolysis process in the Zn^{2+}–L–ATP system and M–L–ATP (M = Mg^{2+}, Ca^{2+}, and La^{3+}) systems, involving recognition of the substrate, nucleophilic attack of P_γ, stabilization of the negatively charged leaving group, and regeneration of the catalyst.

Table 4 shows that all the rate constants of the ternary systems are higher than those of L–ATP. This is because of the increased activity of the P-O-P group of the substrate, caused by the electron-withdrawing effect of metal ions towards the phosphate oxygens. However, the coordination of L to Zn^{2+} makes the positive charge density of Zn^{2+} shift to L, and it then decreases the power of attraction of the Zn^{2+} ion towards phosphates; thus the slower hydrolysis rate of ATP, compared with that of Zn^{2+}–ATP. On the other hand, the rate enhancements in Ca^{2+}, Mg^{2+}, and La^{3+} ternary systems, compared with the corresponding M–ATP systems, are attributed to the fact that metal ions "structure" ATP for a better recognition by the receptor. Owing to the neutralization of the negative charge of the intermediate oxygen atoms, the presence of Ca^{2+}, Mg^{2+}, or La^{3+} may be expected to increase the ability of ADP to release from the center of the intermediate. Moreover, the highest rate of La(III)–L–ATP might account for the tri-positive charge of La^{3+}, which favors the strongest electrostatic and acidic catalysis.

© 2004 NRC Canada

Conclusions

This paper reports the supramolecular interactions of nucleotides with Phen (phenanthroline) bridged polyamine and (or) metal ions (M = Zn^{2+}, Mg^{2+}, Ca^{2+}, and La^{3+}). Furthermore, the catalytic hydrolysis of ATP by L and (or) metal ions was also investigated. The results of ATP hydrolysis with different messengers, i.e., "critical" or "hard" metal ions, demonstrate the following two factors: (*i*) A highly facilitated reaction is connected with a very sensitive and delicate recognition; (*ii*) Metal ions play different roles in the process of the reaction mechanisms. Since the ternary complexes are viewed as the weak inter- or intramolecular interactions formed during biological self-assembly, they are "true" catalysts for ATP hydrolysis. To achieve more active molecular catalysts, ligands containing more amino groups or ligands bearing multi-ions are potentially useful (31).

Syntheses of novel modified acyclic purine and pyrimidine nucleosides as potential substrates of herpes simplex virus type-1 thymidine kinase for monitoring gene expression

Michaela Grote, Steffi Noll, Bernhard Noll, Bernd Johannsen, and Werner Kraus

Abstract: Suicide gene therapy with the herpes simplex virus type-1 thymidine kinase gene (HSV-1 tk) is considered to be a promising approach to the treatment of cancer. Making use of the lower specificity of the viral enzyme compared to human thymidine kinase, the therapy involves the administration of antiviral agents (e.g., ganciclovir) as prodrugs to induce enzymatic cell death in those cells that express the transferred gene. ^{18}F-labelled derivatives have been described for monitoring location, duration, and magnitude of the viral kinase enzyme activity by positron emission tomography (PET). Since an optimal radiotracer has not been developed, novel substances were synthesized for monitoring gene expression. A group of 13 nucleoside analogues were synthesized, among them N^1-methyl-9-[(1,3-dihydroxy-2-propoxy)methyl]guanine (**5**) and N^1-methyl-9-[(4-hydroxy)-3-hydroxymethylbutyl]guanine (**7**) as methyl analogues of ganciclovir and penciclovir and their related fluoro compounds (**6**, **8**). Further novel derivatives include N^6-methyl-9-[(1,3-dihydroxy-2-propoxy)methyl]-, N^6-methyl-9-[(4-hydroxy)-3-hydroxymethylbutyl]adenine (**9**, **10**), as well as the uracil derivatives 5-hydroxy-1-[(1,3-dihydroxy-2-propoxy)methyl]uracil (**11**), 6-methyl-1-[(1,3-dihydroxy-2-propoxy)-methyl]uracil (**12**), and its 3-fluoro-derivative (**13**).

Key words: fluorinated nucleoside analogues, gene therapy, PET, thymidine kinase.

Résumé : La thérapie à l'aide de gènes suicidaires dérivés du gène kinase de la thymidine du virus de type-1 de l'herpès simplex (HSV-1 tk) est considérée comme une approche intéressante au traitement du cancer. En utilisant une spécificité plus faible de l'enzyme viral par comparaison à celle de la kinase de la thymidine humaine, la thérapie implique l'administration d'agents antiviraux (par exemple le ganciclovir) comme prodrogues pouvant induire la mort de cellules enzymatiques dans les cellules qui expriment le gène transféré. Des dérivés marqués au ^{18}F ont été décrits pour la surveillance continue de la location, de la durée et du degré d'activité de l'enzyme kinase virale par tomographie à émission de positron (« PET »). Considérant qu'un marqueur isotopique optimal n'a pas encore été développé, de nouvelles substances ont été synthétisées pour la surveillance continue de l'expression génétique. On a synthétisé un groupe de 13 analogues de nucléosides, dont la N^1-méthyl-9-[(1,3-dihydroxy-2-propoxy)méthyl]guanine (**5**) et la N^1-méthyl-9-[(4-hydroxy)-3-hydroxyméthylbutyl]guanine (**7**) comme analogues méthylés du ganciclovir et du penciclovir et les composés fluorés apparentés (**6** et **8**). On a aussi synthétisé d'autres dérivés nouveaux, dont les N^6-méthyl-9-[(1,3-dihydroxy-2-propoxy)méthyl]- et N^6-9-[(4-hydroxy)-3-hydroxyméthylbutyl]adénine (**9** et **10**) ainsi que les dérivés uraciles 5-hydroxy-1-[(1,3-dihydroxy-2-propoxy)méthyl]uracile (**11**), 6-méthyl-1-[(1,3-dihydroxy-2-propoxy)méthyl]uracile (**12**) ainsi que son dérivé 3-fluoro (**13**).

Mots clés : analogues fluorés du nucléoside, thérapie génétique, « PET », kinase de la thymidine.

[Traduit par la Rédaction]

Introduction

Recently, transfer of genes for therapy has become more of reality for the treatment of human malignancies (1). One of the promising approaches is suicide gene therapy with the herpes simplex virus type-1 thymidine kinase gene (HSV-1 tk) (2, 3). This approach, which is also referred to as virus-directed enzyme–prodrug therapy (VDEPT) (4) involves gene delivery into replicating tumor cells, and after sufficient expression of the enzyme herpes simplex virus type-1

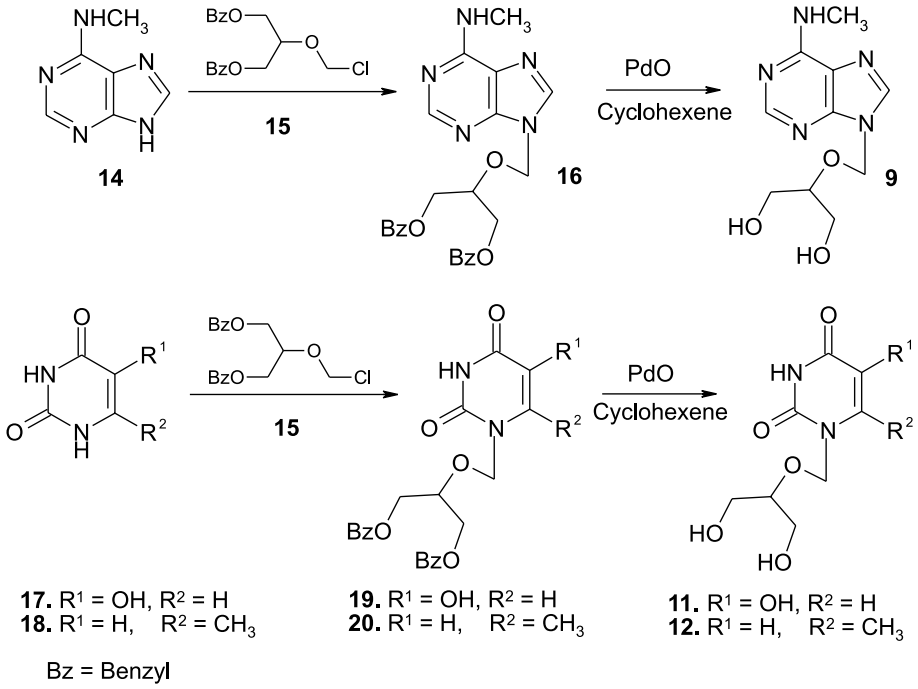
F*: fluorine-18 or fluorine-19

thymidine kinase (HSV-1 TK), treatment with a prodrug, which is converted to a cell-toxic product by the viral enzyme.

Unlike the highly substrate-specific human TK, the viral enzyme (HSV-1 TK) accepts a diversity of pyrimidine- and purine-based nucleoside analogues, converting them into monophosphates. Subsequent phosphorylation by human (host) kinases leads to triphosphates that inhibit DNA polymerase and induce cell death. Inadequate site specific transfection and gene expression are some of the issues in gene therapy (5). Positron emission tomography (PET), a clinically valuable diagnostic modality for a noninvasive visualization of tissue functions in vivo, offers a possibility to monitor location and magnitude of gene expression, thereby helping to optimize protocols of gene and prodrug administration in humans. Fluorine-18, with a half-life of 110 min, is the most common isotope used for PET. Several nucleoside analogues labeled with ^{18}F for monitoring suicide gene therapy mediated by HSV-1 tk have been synthesized. They are usually derivatives of acyclonucleosides, which are selective anti-herpes agents, among them 9-[(3-[^{18}F]-fluoro-1-hydroxy-2-propoxy)methyl]guanine ([^{18}F]FHPG) **2**, derived from ganciclovir (GCV) **1**, and 9-[4-[^{18}F]-fluoro-3-hydroxymethylbutyl]guanine ([^{18}F]FHBG) **4**, derived from penciclovir **3** (6–11). Phosphorylation of these radioactive-labeled nucleoside analogues by virus-encoded thymidine kinase leads to metabolites trapped within the infected tumor cells, and the ensuing accumulation of radioactivity allows monitoring of the enzyme activity with PET (12).

In the search for improved PET radiotracers for gene therapy monitoring, we have synthesized and characterized a series of novel acyclic nucleosides.

Here we report on the synthesis of acyclic analogues of guanine (**5**–**8**) and adenine (**9**, **10**), as well as the related pyrimidines (**11**–**13**) (Fig. 1).



Guanine-based nucleoside analogues offer several possibilities to be labeled with ^{18}F, e.g., on the 8-position of the purine ring (13) or by replacement of a hydroxyl group in the side chain by fluorine (6, 10). Our strategy to replace fluorine for hydroxyl involves protection of one of the hydroxyl groups of the acyclic chain and, in the case of guanine derivatives, also the protection of the amino group in the 2-position, followed by introduction of a leaving group for the fluorination.

Chemistry

Many methods for the preparation of acyclic nucleoside analogues have been described. In most cases they involve synthesis of a suitably protected side chain, followed by coupling to the nucleobase and subsequent deprotection. For example, Martin et al. (14) started from epichlorohydrin to obtain GCV via condensation of 2-*O*-(acetoxymethyl)-1,3-di-*O*-benzylglycerol with N^2-9-diacetylguanine. We used 1,3-dichloro-2-propanol, sodium hydride, and benzyl alcohol to produce 1,3-dibenzyloxy-2-propanol, which was added to 1,2-dichloroethane followed by paraformaldehyde and hydrogen chloride gas, to obtain 1,3-dibenzyloxy-2-chloromethoxypropane (**15**) (15, 16). N^6-Methyladenine **14** was coupled to **15** in dry dimethyl formamide with triethyl amine. Compound **14** may react with **15** either at the 7-position or the 9-position of the purine ring, but additional heating of the reaction mixture afforded only **16**. Treatment with palladium oxide in cyclohexene removed the benzyl protection groups, yielding N^6-methyl-9-[(1,3-dihydroxy-2-propoxy)methyl]adenine (**9**) (15, 16). The structure of **9** was assigned by its ^1H NMR spectra as the 9-isomer. It was found that the chemical shifts resulting from the $H_2C(1')$ (5.64 ppm) and HC(8) (8.23 ppm) were in good agreement with the almost similar compound 9-[(2-hydroxyethoxy)methyl]adenine (5.67 and 8.27 ppm) (17); also the NH shift of **9** amounted to 7.73 ppm, which was also analogous to 9-[(2-hydroxyethoxy)methyl]adenine (~7.3 ppm), taking into account that the downfield shift is caused by a methyl group. Because our substance showed a weak downfield shift, we synthesized the 9-substituted guanine derivative. In contrast, the corresponding signals of 7-[(2-hydroxyethoxy)methyl]adenine showed a strong downfield

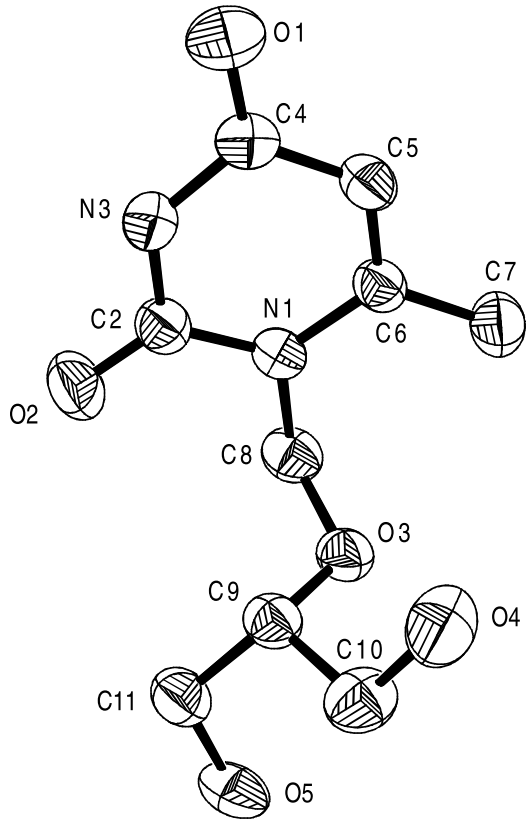
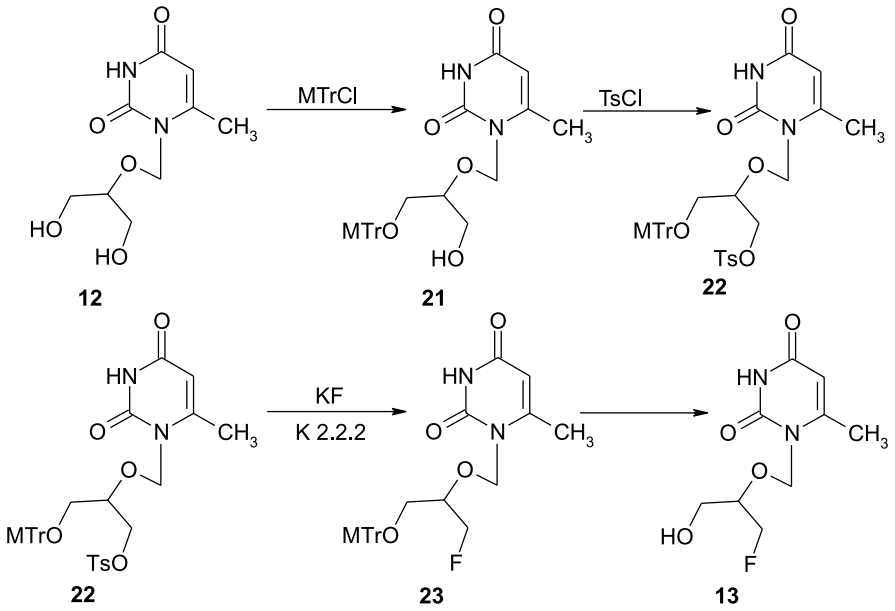
shift ($H_2C(1')$ = 5.79 ppm, HC(8) = 8.60 ppm, NH_2 = 9.2 ppm resp. 10.0 ppm) (17).



Nucleoside analogues can also be prepared by a coupling reaction of an activated base at the halogenated side chain (18). The pyrimidine derivatives were synthesized by direct condensation of the appropriate persilylated base with the chloromethyl ether **15** and tetra-*n*-butylammonium iodide as the catalyst to produce 5-hydroxy-1-[(1,3-dibenzyloxy-2-propoxy)methyl]uracil (**19**) and 6-methyl-1-[(1,3-dibenzyloxy-2-propoxy)methyl]uracil (**20**), respectively. Removal of the benzyl protection groups with palladium oxide resulted in 5-hydroxy-1-[(1,3-dihydroxy-2-propoxy)methyl]uracil (**11**) and 6-methyl-1-[(1,3-dihydroxy-2-propoxy)methyl]uracil) (**12**) (Scheme 1).

The molecular structure of **12** (Fig. 2) obtained by X-ray analysis proved that the acyclic chain has been coupled with the N^1-position of the pyrimidine ring.

The precursor 6-methyl-1-[[1-(*p*-anisyldiphenylmethoxy)-3-(*p*-toluenesulfonyloxy)-2-propoxy]methyl]uracil (**22**) was obtained from **12** by treatment with *p*-anisylchloro-diphenylmethane in dimethyl formamide and with traces of dimethylamino pyridine to produce 6-methyl-1-[[1-(*p*-anisyldiphenylmethoxy)-3-hydroxy-2-propoxy]methyl]uracil (**21**) in 47% yield, followed by tosylation with tosyl chloride in anhydrous pyridine (63%). Fluorination with potassium fluoride and Kryptofix® 2.2.2 in acetonitrile at 120 °C, afforded 6-methyl-1-[[1-(*p*-anisyldiphenylmethoxy)-3-fluoro-2-propoxy]methyl]uracil (**23**) in a yield of 23%. Finally, the protection group was removed, to give 63% of the fluorinated compound 6-methyl-1-[(3-fluoro-1-hydroxy-2-propoxy)methyl]uracil (**13**) (Scheme 2).



The carba-analogue of GCV (18, 19), penciclovir **3** can be prepared by several procedures. There are three steps, including the synthesis of a suitable side chain, coupling to a purine derivative that is able to undergo highly regioselective alkylation at the N-9 position, and transformation of the resulting alkylated purine derivative into the target compound. Some of the reported alkylating agents that

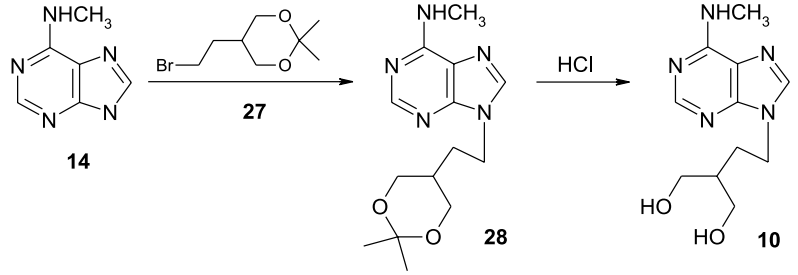
Scheme 2. Protection, tosylation, and subsequent fluorination of **12** to obtain **13**.

Scheme 3. Synthesis of N^6-methyl-9-[(4-hydroxy)-3-hydroxymethylbutyl]adenine (**10**).



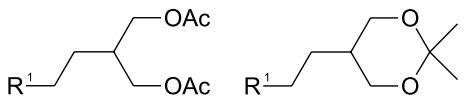


Fig. 3. Several alkylation agents used for the preparation of penciclovir.

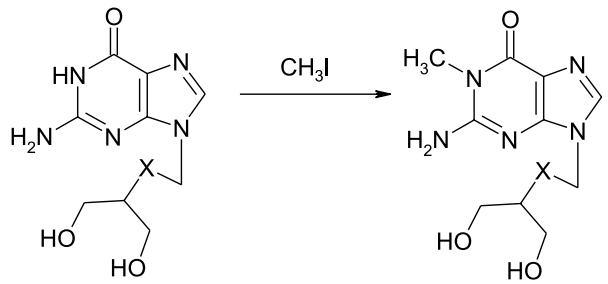
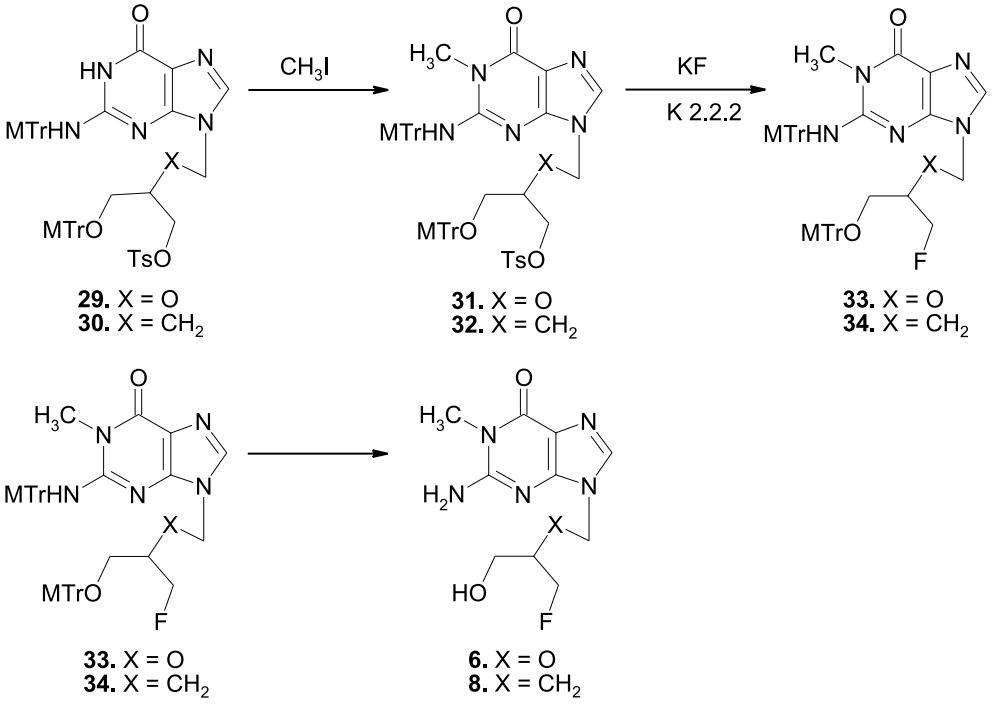


have been used are for instance, 4-acetoxy-3-acetoxymethyl-1-iodobutane (**24**) (20, 21), 4-acetoxy-3-(acetoxymethyl)butanol (**25**) (22), and 2,2-dimethyl-5-(2-*p*-toluenesulfonyloxyethyl)-1,3-dioxane (**26**) (23) (Fig. 3).

We used 5-(2-bromoethyl)-2,2-dimethyl-1,3-dioxane (**27**) to synthesize both penciclovir **3** (21, 24) and N^6-methyl-9-[(4-hydroxy)-3-hydroxymethylbutyl]adenine (**10**), using hydrochloric acid under refluxing conditions for deprotection (Scheme 3). The UV spectra of **10** and **9** were similar and suggested that it was the N-9 isomer.

We decided to modify the substrate properties of GCV and penciclovir by introducing a methyl group and therefore changing the lipophilicity of the molecule (Scheme 4). As



Scheme 4. Methylation of ganciclovir and penciclovir.

described for acyclovir (25, 26), introduction of a methyl group resulted in the alteration of the antiviral activities. The desired products **5** and **7** were obtained from GCV **1** and penciclovir **3** by treatment with methyl iodide in dimethyl formamide followed by extensive preparative column chromatography.

Scheme 5. Methylation, followed by fluorination and splitting off of the protection groups to obtain **6** and **8**.

To obtain N^1-methylated guanine derivatives **6** and **8**, we started from N^2-(*p*-anisyldiphenylmethyl)-9-[[1-(*p*-anisyldiphenylmethoxy)-3-(*p*-toluenesulfonyloxy)-2-prop-oxy]methyl]-guanine (**29**) or N^2-(*p*-anisyldiphenylmethyl)-9-[(4-(*p*-toluenesulfonyloxy))-3-*p*-anisyldiphenylmethoxy-methyl-butyl]guanine (**30**), prepared by modified literature procedures (6, 27). After reaction with methyl iodide yielding 44% of **31** and 29% of **32**, fluorination followed. After fluorination, the removal of the methoxytrityl group was carried out. Details of both sysnthesis steps were described above (Scheme 5).

All synthesized substances were characterized by elemental analysis and ^{1}H NMR spectroscopy, and derivatives containing fluorine were also determined by ^{19}F NMR. The UV spectra of the compounds **3**, **5**, **7**, and **9**–**13** are listed in Table 1.

Radiochemistry

To obtain [^{18}F]-labeled tracers the reaction conditions must consider the half-life of fluorine-18 (110 min). We synthesized the established [^{18}F]FHPG (**2**) and [^{18}F]FHBG (**4**) (6–11), as well as the new tracers [^{18}F]FMHPG (**6**) (N^1-methyl-9-[(3-[^{18}F]-fluoro-1-hydroxy-2-propoxy)methyl]guanine), [^{18}F]FMHBG (**8**) (N^1-methyl-9-(4-[^{18}F]-fluoro-3-hydroxymethyl-butyl)guanine), and [^{18}F]FMHPU (**13**) (6-methyl-1-[(3-[^{18}F]-fluoro-1-hydroxy-2-propoxy)methyl]-uracil. The tosylated and methoxytritylated precursors (**22**, **29**–**32**) were radiolabeled with a K[^{18}F]F/Kryptofix® 2.2.2 complex in acetonitrile, followed by splitting off the protection groups under acidic conditions. The labeled products were purified by HPLC. The synthesis time amounted to 90–110 min, the radiochemical purity was >98%, and an average specific activity of 19 GBq/μmol were determined.

Experimental

Instrumentation and reagents

^{1}H NMR spectra were obtained on a Varian Inova-400 (400 MHz) instrument with DMSO-d_6 as an internal standard. The chemical shifts are given as δ in ppm, the coupling constants as *J* in Hz. Fluorine ^{19}F NMR spectra were obtained on a Varian Inova-400 (376 MHz) with $CFCl_3$ as the internal standard. Elemental analyses were carried out with a LECO CHNS 932 elemental analyzer. Melting points were determined on a BOËTIUS melting point apparatus and are uncorrected. UV spectra were recorded on a Specord UV–vis S10 instrument (Zeiss) in aqueous solution.

The X-ray data were collected at room temperature (293 K) on a SMART-CCD diffractometer (Siemens), using graphite-monochromatized Mo-K_α radiation (λ = 0.71073 Å). A summary of the crystallographic data is given in Table 2. The structure was solved by direct methods. All hydrogen atoms were located by a difference Fourier synthesis and refined freely. Empirical absorption corrections were

made using ψ scans. Most of the calculations were carried out in the SHELXTL system with some local modifications.

Position parameters and relevant bond lengths and angles are contained in Tables 3 and 4. Atomic positional and thermal parameters, full lists of bond lengths and angles, and F_o/F_c values have been deposited as supplementary material.[2]

Chromatographic purification was performed using either Silica gel 60 (Merck) or RP-18 material (LiChroprep™). Furthermore, a MPLC (middle pressure liquid chromatography) system (Knauer) with two columns (silica gel: Eurosil Baselect, 25 mm × 200 mm, from Merck; RP-18 material, 30 × 480, from Kronlab) was used with pressures ranging from 2 to 5 bar (1 bar = 100 kPa). HPLC analysis was performed on a system using a PerkinElmer LC binary pump 250, UV detector (absorbance detector model 759A, Applied Biosystems) operating at 254 nm, and a radioactivity detector using a semipreparative C-18-column (Eurospher, Knauer, 8 mm × 250 mm) and an analytical C-18-column (Eurospher, Knauer, 5 mm × 250 mm).

Solvents and reagents were purchased from the following commercial sources and used without further purification: Sigma, Fluka, Lancaster, Aldrich, and Merck.

Ganciclovir **1** was obtained by neutralization of the sodium salt (Cymeven™) with 0.1 mol L^{-1} HCl and recrystallization from water; penciclovir **3** was synthesized according to a method of Harnden et al. (21). The precursors **29** and **30** were synthesized in modified procedures (10, 27).

Syntheses of potential substrate and fluorinated reference compounds

N^1-Methyl-9-[(1,3-dihydroxy-2-propoxy)methyl]guanine (5)

Ganciclovir (**1**, 214 mg, 0.838 mmol) and tetrabutylammonium hydroxide solution (1 mol L^{-1}, 0.88 mL, 0.88 mmol) were dissolved in 20 mL of dry DMF at room temperature. To this solution methyl iodide (120 µL, 1.93 mmol) in 1.2 mL DMF was slowly added and the mixture was stirred for an additional 45 min. The solvent was evaporated in vacuum and the crude product was purified by MPLC (RP-18, acetonitrile–water (1:9, v/v)) to afford **5** (136 mg, 61%), mp 198–200 °C. ^{1}H NMR (DMSO-d_6) δ: 7.79 (s, 1H, 8-CH), 7.04 (s, 2H, -NH_2), 5.43 (s, 2H, -H_2C(1′)), 4.58 (t, 2H, *J* = 5.4 Hz, -OH), 3.53–3.50 (m, 1H, -CH-O-), 3.44–3.38 (m, 2H, -CH_2-), 3.32 (s, 3H, -NCH_3), 3.29–3.24 (m, 2H, -CH_2-). Anal. calcd. for $C_{10}H_{15}N_5O_4$: C 44.61, H 5.62, N 26.01; found: C 44.35, H 5.58, N 25.92.

phenylmethyl)-3-fluoro-2-propoxy]-methyl]guanine (**33**, 50 mg, 0.061 mmol) was heated under reflux in 5 mL methanol and 5 mL acetic acid (80%) for 4.5 h. The solvent was evaporated and the residue purified by MPLC (RP-18, acetonitrile–water (1:9, v/v)) to give **6** (13 mg, 78%), mp 216–219 °C. ^{1}H NMR (DMSO-d_6) δ: 7.81 (s, 1H, 8-CH), 7.08 (s, 2H, -NH_2), 5.43 (s, 2H, -H_2C(1′)), 4.89 (s, 1H, -OH), 4.54–4.27 (m, 2H, -CH_2-F), 3.85–3.77 (m, 1H, -CH-O-), 3.32 (m_c, 2H, -CH_2-), 3.30 (s, 3H, -NCH_3). ^{19}F NMR (DMSO-d_6) δ: –231.0. Anal. calcd. for $C_{10}H_{14}N_5O_3F$: C 44.28, H 5.20, N 25.82; found: C 44.17, H 5.34, N 25.70.

N^1-Methyl-9-[(4-hydroxy)-3-hydroxymethylbutyl]guanine (7)

Penciclovir (**3**, 231 mg, 0.841 mmol) and tetrabutylammonium hydroxide solution (1 mol L^{-1}, 0.88 mL, 0.88 mmol) were dissolved in 20 mL of dry DMF. A solution of methyl iodide (120 μL, 1.92 mmol) in 1.2 mL DMF was added under vigorous stirring at room temperature. After 2 h, the solvent was evaporated and the residue purified by MPLC (RP-18, acetonitrile–water (1:9, v/v)) to obtain **7** (48 mg, 21%), mp 221–227 °C. ^{1}H NMR (DMSO-d_6) δ: 7.68 (s, 1H, 8-CH), 6.97 (s, 2H, -NH_2), 4.42 (t, 2H, J = 5.2 Hz, -OH), 3.98 (t, 2H, J = 7.4 Hz, -H_2C(1′)), 3.44–3.38 (m, 4H, -CH_2(OH)), 3.29 (s, 3H, N-CH_3), 1.69 (m_c, 2H, -H_2C(2′)), 1.45–1.40 (m, 1H, -CH(3′)). Anal. calcd. for $C_{11}H_{17}N_5O_3$: C 49.43, H 6.41, N 26.20; found: C 49.35, H 6.30, N 26.12.

N^1-Methyl-9-[(4-fluoro)-3-hydroxymethylbutyl]guanine (8) (FMHBG)

N^1-Methyl-N^2-(*p*-anisyldiphenylmethyl)-9-[(4-fluoro)-3-*p*-anisyldiphenylmethoxy-methyl-butyl]guanine (**34**, 58 mg, 0.072 mmol) was heated under reflux with 5 mL methanol and 5 mL acetic acid (80%) for 4 h. The solvents were evaporated and the residue purified by MPLC (RP-18, acetonitrile–water (2:8, v/v)) to give **8** (17 mg, 88%), mp 135–138 °C. ^{1}H NMR (DMSO-d_6) δ: 7.70 (s, 1H, 8-CH), 6.98 (s, 2H, -NH_2), 4.68 (s, 1H, -OH), 4.55–4.34 (m, 2H, -CH_2-F), 4.01 (t, 2H, J = 7.2 Hz, -H_2C(1′)), 3.39 (d, 2H, J = 6.4 Hz, -CH_2(OH)), 3.29 (s, 3H, N^1CH_3), 1.78–1.67 (m, 2H, -H_2C(2′)), 1.65–1.61 (m, 1H, -HC(3′)). ^{19}F NMR (DMSO-d_6) δ: –227.4. Anal. calcd. for $C_{11}H_{16}N_5O_2F$: C 49.06, H 5.99, N 26.01; found: 49.01, H 5.78, N 25.88.

N^6-Methyl-9-[(1,3-dihydroxy-2-propoxy)methyl]adenine (9)

Freshly activated palladium oxide (495 mg) and 10 mL cyclohexene were added to a solution of N^6-methyl-9-[(1,3-dibenzyloxy-2-propoxy)methyl]adenine (**16**, 1.0 g, 2.3 mmol) in 20 mL ethanol and refluxed for 30 h. After that, the reaction mixture was filtered and the solvent evaporated. The residue was washed first with chloroform, then with diethyl ether and dried. The crude product was redissolved in hot water, ethanol was added, and the substance was allowed to precipitate when cooling down to give **9** (365 mg, 63%), mp 160 °C. ^{1}H NMR (DMSO-d_6) δ: 8.23 (s, 2H, 2-CH, 8-CH), 7.73 (s, 1H, -NH), 5.64 (s, 2H, -H_2C(1′)), 3.59 (t, 2H, J = 5.5 Hz, -OH), 3.59 (m_c, 1H, -CH-O), 3.44–3.38 (m, 2H, -CH_2(OH)), 3.31–2.94 (m, 2H, -CH_2(OH)), 2.94 (s, 3H, NCH_3). Anal. calcd. for $C_{10}H_{15}N_5O_3$: C 47.43, H 5.97, N 27.65; found: C 47.37, H 5.86, N 27.52.

N^6-Methyl-9-[(4-hydroxy)-3-hydroxymethylbutyl]adenine (10)

N^6-Methyl-9-[(2,2-dimethyl-1,3-dioxane-5-yl)ethyl]purine (**28**, 80 mg, 0.27 mmol) was dissolved in 1.5 mL methanol and 1.5 mL HCl (2 mol L^{-1}) and refluxed for 3 h. After cooling, the solvent was reduced and the precipitate filtered off. Crystallization from water gave **10** (23 mg, 34%), mp 134–136 °C. ^{1}H NMR (DMSO-d_6) δ: 8.22 (s, 1H, 8-CH), 8.14 (s, 1H, 2-CH), 7.73 (s, 1H, -NH-), 4.44 (s, 2H, -OH), 4.20 (t, 2H, J = 7.4 Hz, -H_2C(1′)), 3.39 (m_c, 4H, -CH_2(OH)), 2.94 (s, 3H, NCH_3), 1.78 (m_c, 2H, -H_2C(2′)), 1.44–1.40 (m, 1H, -HC(3′)). Anal. calcd. for $C_{11}H_{17}N_5O_2$: C 52.58, H 6.82, N 27.87; found: C 52.43, H 6.73, N 27.72.

5-Hydroxy-1-[(1,3-dihydroxy-2-propoxy)methyl]uracil (11)

5-Hydroxy-1-[(1,3-dibenzyloxy-2-propoxy)methyl]uracil (**19**, 412 mg, 1.0 mmol) was refluxed with 6 mL of ethanol, 2.4 mL of cyclohexene, and freshly activated palladium ox-

© 2004 NRC Canada

ide (170 mg, 1.40 mmol) for 17 h. The catalyst was filtered off and washed with ethanol and water. The solutions were collected and the solvents were removed. The residue was purified by crystallization from ethanol to give **11** (111 mg, 48%), mp 147 to 148 °C. ^{1}H NMR (DMSO-d_6) δ: 11.43 (s, 1H, -NH), 8.68 (s, 1H, 6-CH), 7.14 (s, 1H, -OH), 5.09 (s, 2H, -H_2C(1′)), 4.60 (s, 2H, -OH), 3.49 (m, 1H, -CH-), 3.45–3.29 (m, 4H, -CH_2(OH)). Anal. calcd. for $C_8H_{12}N_2O_6$: C 41.38, H 5.21, N 12.06; found: C 41.27, H 5.09, N 11.91.

6-Methyl-1-[(1,3-dihydroxy-2-propoxy)methyl]uracil (12)

6-Methyl-1-[(1,3-dibenzyloxy-2-propoxy)methyl]uracil (**20**, 6.17 g, 15 mmol) was dissolved in 64 mL ethanol and treated with freshly activated palladium oxide (2.0 g, 16.3 mmol), 20 mL cyclohexene, and stirred for 18 h at room temperature. Afterwards the mixture was refluxed for 90 min and the catalyst was filtered. Precipitation of the product proceeded when cooling and recrystallization from ethanol gave 2.4 g (70%) of **12**, mp 147–150 °C. ^{1}H NMR (DMSO-d_6) δ: 11.20 (s, 1H, -NH), 5.50 (s, 1H, 5-CH), 5.23 (s, 2H, -H_2C(1′)), 4.61 (t, 2H, J = 5.6 Hz, -OH), 3.51–3.47 (m, 1H, -CH-O), 3.45–3.39 (m, 2H, -CH_2(OH)), 3.35–3.30 (m, 2H, -CH_2(OH)), 2.29 (s, 3H, -CH_3). Anal. calcd. for $C_9H_{14}N_2O_5$: C 46.95, H 6.13, N 12.17; found: 46.77, H 6.09, N 12.07.

6-Methyl-1-[(3-fluoro-1-hydroxy-2-propoxy)methyl]uracil (13) (FMHPU)

6-Methyl-1-[[1-(*p*-anisyldiphenylmethoxy)-3-fluoro-2-propoxy]methyl]uracil (**23**, 55.0 mg, 0.109 mmol) was dissolved in 5 mL of ethanol and 5 mL of 80% acetic acid and refluxed for 1 h. The solvent was evaporated and the residue was dissolved in ethanol. Final purification was carried out with MPLC (RP-18, acetonitrile–water (1:4, v/v)) affording **13** (16.0 mg, 63%), mp 118–120 °C. ^{1}H NMR (DMSO-d_6) δ: 11.24 (s, 1H, -NH), 5.52 (s, 1H, 5-CH), 5.34 (d, 1H, J = 11.0 Hz, -H_2C(1′)), 5.30 (d, 1H, J = 11.0 Hz, -H_2C(1′)), 4.88 (s, 1H, -OH), 4.58–4.29 (m, 2H, -CH_2-F), 3.78 (m_c, 1H, -CH-O-), 3.41 (d, 2H, J = 5.6, -CH_2(OH)), 2.27 (s, 3H, 6-CH_3). ^{19}F NMR (DMSO-d_6) δ: –232.0. Anal. calcd. for $C_9H_{13}N_2O_4F$: C 46.55, H 5.65, N 12.06; found: C 46.42, H 5.59, N 12.02.

N^6-Methyl-9-[(1,3-dibenzyloxy-2-propoxy)methyl]adenine (16)

Triethylamine (3.8 mL) was added to N^6-methyladenine (**14**, 3.7 g, 24.8 mmol) dissolved in 20 mL of dry DMF under stirring. After addition of 1,3-dibenzyloxy-2-chloromethoxypropane (**15**, 8.0 g, 25.0 mmol) in 12.5 mL DMF, the solution was stirred for 1 h at room temperature and then heated for 3 h to 90 °C. The reaction mixture was cooled down and the precipitated triethylammonium chloride was removed. The solvent was evaporated and the residue purified by MPLC (RP-18, methanol–water (8:2, v/v)), yielding **16** (3.4 g, 31%), mp 91 °C. ^{1}H NMR (DMSO-d_6) δ: 8.25 (s, 2H, 2-CH, 8-CH), 7.75 (s, 1H, -NH), 7.31–7.16 (m, 10H, -CH(arom)), 5.66 (s, 2H, -H_2C(1′)), 4.37 (s, 4H, -CH_2(Bz)), 4.09 (m, 1H, -CH-O), 3.45–3.39 (m, 4H, -CH_2-(OBz)), 2.95 (s, 3H, NCH_3). Anal. calcd. for $C_{24}H_{27}N_5O_3$: C 66.50, H 6.28, N 16.15; found: C 66.25, H 6.08, N 16.06.

5-Hydroxy-1-[(1,3-dibenzyloxy-2-propoxy)methyl]uracil (19)

Isobarbituric acid (**17**, 384 mg, 3.0 mmol) was suspended in 17 mL of hexamethyldisilazane. Ammonium sulfate (225 mg, 1.70 mmol) was added and the mixture refluxed for 70 min. The solvent was evaporated and the residue suspended in 8 mL of dichloromethane, then tetra-*n*-butylammonium iodide (12.0 mg, 0.03 mmol) and 1,3-dibenzyloxy-2-chloro-methoxypropane (**15**, 1.44 g, 4.5 mmol) were added and the reaction mixture was refluxed for 90 min. After cooling, the solution was treated with 4 mL of methanol and 1 mL of water. The solvent was distilled off, the residue solved in CH_2Cl_2, washed with satd. NaCl solution and water. The organic layer was separated, dried, and the solvent was evaporated. The purification of the reaction product occurred by MPLC (silica gel, dichloromethane–methanol (25:1, v/v)) resulting in 853 mg (69%) of a yellowish viscous liquid of **19**. ^{1}H NMR (DMSO-d_6) δ: 11.47 (s, 1H, -NH), 8.72 (s, 1H, 6-CH), 7.32–7.22 (m, 10H, -CH(arom)), 7.17 (s, 1H, -OH), 5.14 (s, 2H, -H_2C(1′)), 4.45 (s, 4H, -CH_2(Bz)), 3.96 (m, 1H, -CH-O), 3.51–3.42 (m, 4H, -CH_2-(OBz)). Anal. calcd. for $C_{22}H_{24}N_2O_6$: C 64.07, H 5.87, N 6.79; found: C 63.81, H 5.92, N 6.66.

6-Methyl-1-[(1,3-dibenzyloxy-2-propoxy)methyl]uracil (20)

6-Methyluracil (**18**, 378 mg, 3.0 mmol) was refluxed with ammonium sulfate (150 mg, 1.14 mmol) and 11 mL of hexamethyldisilazane. The solvent was removed and the residue was dried. After dissolving the substance in CH_2Cl_2, it was treated with tetra-*n*-butylammonium iodide (12 mg, 0.03 mmol). 1,3-Dibenzyloxy-2-chloromethoxypropane (**15**, 1.44 g, 4.5 mmol) was added, followed by refluxing for 70 min. The reaction mixture was cooled, 1 mL of water and 4 mL of methanol were added and after stirring for 2 min, the solvent was removed. The residue was solved in CH_2Cl_2 and washed with satd. NaCl solution and water. The organic layer was separated, dried, and the solvent was removed. The reaction product was purified by column chromatography (silica gel, dichloromethane–methanol (25:1, v/v)) to afford **20** as yellow oil (426 mg, 35%). ^{1}H NMR (DMSO-d_6) δ: 11.24 (s, 1H, -NH), 7.34–7.25 (m, 10H, -CH(arom)), 5.49 (s, 1H, 5-CH), 5.34 (s, 2H, -H_2C(1′)), 4.45 (s, 4H, -CH_2(Bz)), 3.95–3.93 (m, 1H, -CH-O), 3.49–3.43 (m, 4H, -CH_2-(OBz)), 2.25 (s, 3H, -CH_3). Anal. calcd. for $C_{23}H_{26}N_2O_5$: C 67.30, H 6.38, N 6.82; found: C 66.98, H 6.34, N 6.51.

*6-Methyl-1-[[1-(*p*-anisyldiphenylmethoxy)-3-hydroxy-2-propoxy]methyl]uracil (21)*

6-Methyl-1-[(1,3-dihydroxy-2-propoxy)methyl]uracil (**12**, 460 mg, 2.00 mmol), *p*-anisylchloro-diphenylmethane (672 mg, 2.18 mmol), triethylethylamine (418 µL, 3.00 mmol), and DMAP (2.9 mg) in 7 mL DMF were stirred for 2 h at 50 °C. After removing the DMF, the residue was dissolved in ethyl acetate, washed with $NaHCO_3$ solution and water. The combined organic layers were dried, the solvent removed, and the crude product purified by chromatography (silica gel, dichloromethane–methanol (25:1, v/v)) to give **21** (468 mg, 47%), mp 83 °C. ^{1}H NMR (DMSO-d_6) δ:11.31 (s, 1H, -NH), 7.36–6.86 (m, 14H, CH(arom)), 5.56 (s, 1H, 5-CH), 5.50 (d, 1H, J = 12.3 Hz, -H_2C(1′)), 5.30 (d, 1H, J = 12.3 Hz, -H_2C(1′)), 4.71 (t, 1H, J = 5.5 Hz, -OH),

General syntheses of the [^{18}F]-fluorinated compounds 2, 4, 6, 8, and 13

A solution of 0.5 mL of Kryptofix® 2.2.2 (45 mM), 20 µL potassium carbonate (1 mol L^{-1}), and aqueous [^{18}F]fluoride solution (0.5–1.0 mL, 0.5–5.0 GBq) was azeotropically evaporated with acetonitrile (3 mL) at 100 °C; 2 to 3 mg of the appropriate precursors **22**, **29**–**32** solved in dry acetonitrile (300 mg) were added to the dry K[^{18}F]F/Kryptofix® 2.2.2 complex. The reaction mixture was heated at 160 °C for 20 min. After cooling down to room temperature, the mixture was passed through a LiChrolut Si (500 mg) cartridge. ^{18}F-labelled compounds were eluted with 2 mL of dichloromethane–methanol (85:15). Methanolic hydrochloric acid (150 µL, 0.85 mol L^{-1}) was added to the eluate, the vial sealed and heated for 3 min at 120 °C, then the solvent was removed under a stream of nitrogen. A sodium hydroxide solution (400 µL, 0.2 mol L^{-1}) was added to the residue. The mixture was given to a LiChrolut RP-18 (200 mg) cartridge, the crude product eluted with 500 µL of a water–ethanol mixture (9:1) and subsequent purified by HPLC as described in Table 5 at a flow of 5 mL min^{-1}. The radiochemical purity and the identity of each probe with the reference standards was identified by analytical HPLC.

Synthesis, IR, and multinuclear NMR spectroscopic studies of complexes of the type *cis*- and *trans*-Pt(amine)$_2$(NO$_3$)$_2$

Fernande D. Rochon and Viorel Buculei

Abstract: Compounds of the types *cis*- and *trans*-Pt(amine)$_2$NO$_3$)$_2$ have been synthesized and characterized by IR and multinuclear (^{195}Pt, ^{13}C, and ^{1}H) NMR spectroscopies. The nitrato IR bands were compared for the two isomers. The ^{195}Pt NMR resonances of the trans complexes were observed at lower fields (avg. –1570 ppm for primary amines) than the cis analogues (avg. –1698 ppm) for an average $\Delta\delta$ value of 124 ppm. The complexes containing a secondary amine were observed at about the same field for the cis isomers (avg. –1682 ppm) and surprisingly at much higher fields for the trans compounds (avg. –1638 ppm). In ^{1}H NMR, the coupling constants $^{2}J(^{195}\text{Pt-}^{1}\text{HN})$ are larger for the cis isomers (avg. 67 Hz) than for the trans compounds (avg. 58 Hz). The $^{3}J(^{195}\text{Pt-}^{1}\text{H})$ are also larger for the cis complexes (avg. 40 vs. 33 Hz). In ^{13}C NMR, the coupling constants are also geometry dependent. The $^{3}J(^{195}\text{Pt-}^{13}\text{C})$ are larger for the cis isomers (avg. 37 Hz) than for the *trans* compounds (avg. 28 Hz). The $^{2}J(^{195}\text{Pt-}^{13}\text{C})$ are much smaller (avg. 18 Hz for the cis complexes and 16 Hz for the trans isomers).

Key words: platinum, amine, nitrato, NMR, IR.

Résumé : Des composés de types *cis*- et *trans*-Pt(amine)$_2$(NO$_3$)$_2$ ont été synthétisés et caractérisés par spectroscopies infrarouge et de résonance magnétique multinucléaire (^{195}Pt, ^{13}C et ^{1}H). Les vibrations des ligands nitrato ont été comparées dans les deux isomères. Les signaux en RMN du ^{195}Pt ont montré des résonances à plus hauts champs pour les composés cis (moy. –1698 ppm pour les amines primaires) que pour les analogues trans (moy. –1570 ppm). La valeur moyenne de $\Delta\delta$ est 124 ppm. Les complexes contenant des amines secondaires ont été observés à environ le même champ pour les isomères cis (moy. –1682 ppm) et à plus haut champ pour les composés trans (moy. –1638 ppm). En RMN du ^{1}H, les constantes de couplage $^{2}J(^{195}\text{Pt-}^{1}\text{HN})$ sont plus grandes pour les isomères cis (moy. 67 Hz) que pour les composés trans (moy. 58 Hz). Les couplages $^{3}J(^{195}\text{Pt-}^{1}\text{H})$ sont aussi plus importants pour les complexes cis (moy. 40 vs. 33 Hz). En RMN du ^{13}C, les constantes de couplage dépendent aussi de la géométrie. Les valeurs $^{3}J(^{195}\text{Pt-}^{13}\text{C})$ sont plus grandes pour les isomèrs cis (moy. 37 Hz) que pour les composés trans (moy. 28 Hz). Les constantes $^{2}J(^{195}\text{Pt-}^{13}\text{C})$ sont beaucoup plus petites (moy. 18 Hz pour les complexes cis et 16 Hz pour les isomères trans).

Mots clés : platine, amine, nitrato, IR, RMN.

Introduction

The antitumor compound *cisplatin* (*cis*-Pt(NH$_3$)$_2$Cl$_2$) is the most widely used anticancer drug today. Its mechanism of action involves its hydrolysis inside the cells, where the pH is neutral and the chloride ion concentration is low. In these conditions, *cis*-Pt(NH$_3$)$_2$Cl$_2$ becomes aquated, producing different ionic species that can bind to DNA (1) leading to the eventual destruction of the cell. One of these species is the diaqua complex *cis*-[Pt(NH$_3$)$_2$(OH$_2$)$_2$]$^{2+}$, which, because of the neutral pH inside the cells, will exist predominantly in the form *cis*-[Pt(NH$_3$)$_2$(OH)(OH$_2$)]$^{+}$ (2). The latter species has been shown in laboratories to produce different oligomeric species, which have been characterized by ^{195}Pt NMR (3–5) and by crystallographic methods (6–10). Some of these species are toxic and could be partially responsible for the toxicity of cisplatin in humans. Therefore, it is important to study the hydrolysis reactions of a complex before its development as an anticancer drug.

Platinum complexes with amines are potent antitumor agents. Some compounds have shown much better antitumor properties than *cis*-Pt(NH$_3$)$_2$Cl$_2$, but several are too insoluble to become useful drugs.

Our research group has undertaken a systematic study of complexes of the types *cis*- and *trans*-Pt(amine)$_2$I$_2$. The compounds have been studied by various spectroscopic techniques and by crystallography (11). We have characterized these products to study their hydrolysis reactions. However, the solubility of these complexes in water is very low. Substitution of the halides by nitrato ligands leads to a much greater solubility in water. A method for the synthesis of Pt(amine)$_2$(NO$_3$)$_2$ has been published for a few amines (12), but the complexes were characterized only by elemental analysis, IR spectroscopy, and by ^{1}H NMR.

Several complexes of the types *cis*- and *trans*-$Pt(amine)_2(NO_3)_2$ have now been synthesized in our laboratories and the compounds were studied by IR and multinuclear NMR (^{195}Pt, ^1H, and ^{13}C) spectroscopies. The study of the hydrolysis and aquation reactions of these cis and trans dinitrato compounds is underway and the results will be published in a subsequent paper.

Experimental

Potassium tetrachloroplatinate(II) was purchased from Johnson Matthey and was recrystallized in water before use. The amine ligands were obtained from Aldrich, while silver nitrate was purchased from Anachemia. Deuterated acetone was acquired from CDN Isotopes.

The IR spectra were recorded between 4000 and 270 cm^{-1} as KBr pellets, on a PerkinElmer 783 grating spectrometer. The decomposition points were measured on a Fisher-Johns instrument. The NMR spectra were measured on a Varian Gemini 300BB in acetone. The fields were 300.075, 75.460, and 64.395 MHz for ^1H, ^{13}C, and ^{195}Pt, respectively. The acetone peaks were used as an internal standard for ^1H NMR (2.04 ppm) and ^{13}C NMR (29.8 ppm). For the ^{195}Pt spectra, $K_2[PtCl_4]$ (in D_2O with KCl, adjusted at –1628 ppm from $K_2[PtCl_6]$ whose δ(Pt) = 0 ppm) was the external standard.

Synthesis

The complexes $Pt(amine)_2I_2$ were synthesized as recently published (11). The dinitrato complexes were prepared according to a modified version of a published method described for other ligands (12). The complexes $Pt(amine)_2I_2$ (0.5 mmol) were dissolved in a minimum quantity of acetone (8 mL). A slight excess of $AgNO_3$ was added and the mixture was stirred in the dark and at lower temperature (5 °C) until a colorless solution (with a yellow precipitate) was obtained. The precipitate was filtered out and the solution was evaporated to dryness. The white residue was dissolved in 5 mL of acetone and filtered again to remove the last traces of AgI and $AgNO_3$. Diethyl ether was added and the mixture was cooled several hours until precipitation was complete. The precipitate was filtered, washed with diethylether, and dried under vacuum.

The notation of Nakamoto (13) was used for the IR assignments of the nitrato ligands.

Results and discussion

The dinitrato complexes were prepared by the reaction of the diiodo complexes with a slight excess (10%) of silver nitrate in acetone similar to a published method (12).

$$Pt(amine)_2I_2 + 2AgNO_3 \rightarrow Pt(amine)_2(NO_3)_2 + 2AgI\downarrow$$

The diiodo complexes dissolved in acetone resulting in a yellow solution. Silver nitrate is only slightly soluble in acetone. The reaction was performed in the dark and at a lower temperature in ice, to reduce decomposition. The published method (12), which was used for other ligands, required 5–20 min of stirring time. The reaction time for our ligands varied between a few hours to 2 days depending on the amine. After filtration and the purification process, the white dinitrato complexes were isolated and characterized. The cis or trans geometry was retained during the reaction. The cis and trans compounds with amine = methylamine ($MeNH_2$), ethylamine ($EtNH_2$), *n*-propylamine (*n*-$PrNH_2$), *n*-butylamine (*n*-$BuNH_2$), *iso*-propylamine (*i*-$PrNH_2$), *iso*-butylamine (*i*-$BuNH_2$), *sec*-butylamine (*sec*-$BuNH_2$), dimethylamine (Me_2NH), and trans compounds with *tert*-butylamine (*t*-$BuNH_2$) and diethylamine (Et_2NH) were synthesized.

The use of a slight excess of silver nitrate increased the yields. When the reactions were performed at room temperature, oily compounds were obtained and the products decomposed quite rapidly. The yields were also very low. Most dinitrato complexes are stable when kept in the dark and at lower temperature. Even in these conditions, a few compounds decomposed fairly rapidly to a black material. The complex *cis*-Pt(*i*-$BuNH_2)_2(NO_3)_2$ decomposed after a few hours. All the IR and NMR spectra were measured on fresh samples. The compound *trans*-$Pt(Et_2NH)_2(NO_3)_2$ was not pure, since two series of signals were observed in NMR (^1H, ^{13}C, and ^{195}Pt) spectroscopy. The second compound was assumed to be the cis analogue, since the starting material *trans*-$Pt(Et_2NH)_2I_2$ contained some cis isomers as described in a previous paper (11).

IR spectroscopy

The IR spectra of the complexes were recorded and are listed in the *Experimental* section. The notation of Nakamoto (13) was used for the bands involving the nitrato ligands.

The symmetry of the free nitrate ion is D_{3h}, with a bond order of 1 1/3. However, in the monodentate-coordinated nitrato ligand, the N—O(Pt) bond order is close to 1. The π electronic density is then delocalized on only two N—O bonds resulting in a bond order of 1 1/2 for the two bonds. The approximate symmetry of coordinated NO_3^- is C_{2v}. The reduction in the N—O(Pt) bond order is clearly observed by comparing the stretching band ν_1 (13) in free NO_3^- (1049 cm^{-1}) with the one observed in CH_3ONO_2 (854 cm^{-1}), a purely covalent compound (14). It has been suggested that the position of the ν_1 band gives important information on the covalent character of the Pt—O bond (15). Because of the reduction in symmetry of the coordinated nitrato ligand, some of the vibration modes, which were degenerate in the free ion, will be split. This is the case for the ν_3 stretching mode in D_{3h} (E), which will separate into the ν_2 (A_1) and ν_4 (B_2) stretching modes in C_{2v} symmetry (13). The energy difference between the two latter modes ($\Delta = \nu_4 - \nu_2$) should also give additional information on the covalent character of the Pt—O bond (14, 15). For ionic nitrate Δ is 0 cm^{-1}, while it is 385 cm^{-1} in CH_3ONO_2.

The values of Δ as well as the energy difference ($\Delta\nu_1$) between the ν_1 band for free nitrate and the coordinated nitrato ligands are shown in Table 1. The average value $\Delta(\nu_4 - \nu_2)$ is 243 cm^{-1} in the *cis* complexes and 246 cm^{-1} in the trans isomers. The difference is not significant. We have calculated this $\Delta(\nu_4 - \nu_2)$ value for a few dinitrato complexes reported in the literature. These values for *cis*-$PtA_2(NO_3)_2$ are 230 cm^{-1} for A = NH_3 (16), 227 cm^{-1} for NH_2CH_3 (12), 214 cm^{-1} for $NH_2(C_6H_{11})$ (12), 226 cm^{-1} for 4-hydroxymethylpyridine (12), and 238 cm^{-1} for $NH_2(CH_2Ph)$ (12), and 245 cm^{-1} for A_2 = bipy and 240 cm^{-1} for phen (14). These results are close to our values. In a study on *cis*- and *trans*-$Pt(Ypy)_2NO_3)_2$, (Ypy = pyridine derivative) the average value for $\Delta(\nu_4 - \nu_2)$ was found to be higher in the

trans compounds (264 cm^{-1}) than in the cis isomers (233 cm^{-1}) (17).

The position of ν_1 for our compounds is also not very different in the two geometries (avg. $\Delta\upsilon_1$ 89 cm^{-1} for cis and 84 cm^{-1} for trans). For the compounds *cis*- and *trans*-$Pt(Ypy)_2NO_3)_2$, the ν_1 band was found to be less energetic in the trans complexes (avg. $\Delta\upsilon_1$ = 120 vs. 90 cm^{-1} for the cis isomers), suggesting a more covalent character for the Pt—O bonds in the trans geometry (17). Our results on the amine system seem to indicate that the covalency of the Pt—O bonds in the cis and trans compounds are not very different.

The stretching energy of a more covalent bond should increase and these results can be compared with the energies of the ν(Pt-O) vibrations. The skeletal symmetry around the platinum atom is C_{2v} for the cis complexes and D_{2h} for the trans isomers. Two ν(Pt-O) bands are expected for the cis compounds and one for the trans complexes, according to group theory. Our assignment of the υ(Pt-O) bonds was made according to some published works (17–19). These bands are shown in Table 2 along with the results published in the literature. Some of the published work on the cis complexes have shown two ν(Pt-O) absorption bands, while others have shown only one. We have observed only one band for both isomers. The position of the band is not very different for the different isomers, although it appears slightly larger for the trans compounds (avg. 346 vs. 333 cm^{-1}). These results seem to agree with our conclusion reached above from the study of the nitrato ν_1 band and $\Delta(\nu_4 - \nu_2)$ values. There seems to be no important difference between the two isomers. These ν(Pt-O) vibrations are not very energetic and are close to the ν(Pt-Cl) vibrations. They are difficult to assign with certainty, since they are quite weak. It is also possible that they are not pure and might couple with other vibrations.

The ν(Pt-N) bands were assigned based on some published works (13, 19–22). Two vibration modes are expected for the cis compounds and only one for the trans isomers. Our assignments are shown in Table 3. For most complexes, two bands were observed for the cis complexes while only one was shown by the trans isomers. The energies of these bands are slightly higher than those of the corresponding iodo complexes (11), suggesting that the covalency of the Pt—N bonds are greater in the dinitrato compounds than in the diiodo analogues. The reduced polarizability of the nitrato ligand compared to the iodo ligand could increase the energy of the ν(Pt-N) vibrations. The trans influence of the iodo ligand is larger than the one of the nitrato ligand, which should also increase the energy of the ν(Pt-N) vibrations in the *cis*-dinitrato complexes. The trans compounds with *tert*-butylamine and diethylamine and the *cis-iso*-butylamine compound did not show any band in the ν(Pt-N) region.

^{195}Pt NMR spectroscopy

The ^{195}Pt NMR spectra of the dinitrato complexes were measured in acetone and the chemical shifts are listed in Table 4 as well as the pK_a of the protonated ligands (23) and the proton affinity of the amines (24–27). To determine if the nitrato ligands are partly dissociated in acetone, the conductivity of several cis and trans complexes were measured in acetone. The results have shown that there is no appreciable solvolysis of the compounds. The molar conductivity values varied between 0.03 and 0.06 S cm^2/mol. The corresponding values for several cesium salts were much larger. Therefore, the chemical shifts in Table 4 correspond to those of the dinitrato complexes.

The cis isomers were observed at higher fields than their trans analogues. The complex *trans*-$Pt(Et_2NH)_2(NO_3)_2$ contained a second compound, which we have assigned to the cis isomer, since the starting material *trans*-$Pt(Et_2NH)_2I_2$ was shown to contain some cis compound (11). The signal observed at higher field was assumed to be the cis compound as observed for the other ligands. The difference between the cis and trans isomers is larger for the primary amines (avg. 125 ppm) than for the secondary amines (avg.

44 ppm). Our results are in agreement with those of the NH_3 complexes (28).

Surprisingly, the trans isomers of the complexes containing the secondary amines were observed at higher fields than the compounds containing the primary amines, while the cis compounds were observed at about the same fields. For square-planar complexes, the molecules of solvent can normally approach and weakly bind to the Pt atom on both sides of the coordination plane. For complexes containing more bulky ligands close to the binding site, the molecules of solvent cannot approach the Pt atom easily, resulting in a decrease of the electronic density around the Pt nucleus. This solvent factor is very important for solvents like water that can coordinate to platinum. However, the dinitrato complexes were measured in deuterated acetone, a solvent that could coordinate to Pt, but not as easily as water. Therefore the solvent effect should be considerably reduced. Furthermore, the reduced solvation for crowded ligands is less important in trans compounds, where the two ligands are far from each other.

Nitrato ligands are more bulky than iodo or chloro ligands. Therefore, the presence of the nitrato ligands should have an influence of the solvation of the Pt atom. There are two Pt NMR studies in the literature on dinitrato compounds. The results for the NH_3 (28) complexes are shown in Table 4. NH_3 complexes are usually observed at lower fields than amine complexes. The other published paper is on a series of pyridine complexes (17). In these compounds, the cis compounds were observed between –1485 and –1532 ppm, while the trans isomers were reported between –1402 and –1481 ppm, with Δδ (cis–trans) = –43 to –83 ppm. The compounds with ortho substituents were observed at lower fields than the others, probably because of reduced solvation around the Pt atom, due to a more limited rotation of the pyridine ligand around the Pt—N bond (17). The ortho substituents are mainly located on top of the Pt atom and prevent the approach of the molecules of solvent. Our results on the diamine complexes have shown values of Δδ (cis–trans) from –105 to –140 ppm for the primary amines. The difference is larger than those published for the pyridine complexes (17), but smaller than the one for the NH_3 compounds (28), where it is 179 ppm. Our values for the secondary amines (avg. 44 ppm) are closer to those reported for the pyridine system (17).

*Indicates an impurity in the trans compound (see text).

There seems to be a slight deshielding effect on the Pt atom as the bulkiness on the primary amine is increased. This is probably due to a reduction in the solvation of the metal centre. The difference in chemical shifts is smaller in the cis compounds (30 ppm) than in the trans isomers (68 ppm) for the complexes containing primary amines.

Attempts were made in the literature (29–31) to correlate the ^{195}Pt chemical shifts with the basicity of the amine ligands to study the nature of the Pt–amine bond. Contrary to pyridine, amines cannot accept π electron density from the metal. Therefore, in the formation of the σ(amine → Pt) bond, electron density is transferred from the amine ligand to the platinum nucleus, resulting in a shielding on the ^{195}Pt nucleus and a deshielding effect on the ligands (^{1}H and ^{13}C NMR signals). A weak relation between δ(^{195}Pt) and the basicity of the ligands was reported for complexes of the type *cis*- and *trans*-$Pt(Ypy)_2X_2$ (X = Cl^- or I^-) (29), but the dispersion around the straight line was fairly large. For pyridine derivatives, the ^{195}Pt chemical shifts seem to depend more on the position of the CH_3 substituents then on the basicity of the ligand. To verify the influence of the basicity of the amine on the δ(Pt) values, the latter were plotted vs. the pK_a of the protonated amines. No correlation could be observed for the cis or the trans compounds. The pK_a values were measured in a solvent (water or alcohol) and are influenced by the presence of the substituents on the protonated N atom. The errors on the pK_a values are not negligible, especially for the primary amines where the pK_a values do not vary very much (from 10.62 to 10.78). The proton affinity values of the amines that are measured in the gas phase, might represent better the basicity of the ligands. But these values are not as common as the pK_a values. Figure 1 shows the relation between the δ(Pt) and the published proton affinity of the amines (24–27) for the cis and trans complexes. The ^{195}Pt chemical shift seems to increase slightly as the proton affinity increases. But the difference is small, close to the experimental errors. More data are needed to reach a sound conclusion.

The δ(Pt) does not seem to be very influenced by the basicity of the ligands. Acetone is not an inert solvent for platinum, and solvation around the Pt atom is probably a more

important factor in determining the NMR chemical shifts. The trans complexes with secondary amines have shown resonances at higher fields than those with primary amines, but more complexes with secondary amines are needed before any conclusion can be reached.

^{1}H and ^{13}C NMR spectroscopy

The ^{1}H NMR chemical shifts are listed in Table 5 as well as the published values on Pt(*n*-$PrNH_2)_2(NO_3)_2$ measured in $CDCl_3$ (32). These authors have also measured their compounds in CD_3COCD_3, but only the -NH_2 are reported at 5.2 (cis) and 4.7 (trans) ppm (32). These values agree with ours. There are not many data in the literature on dinitrato amine complexes. The NH and H_1 chemical shifts of the cis compounds are more deshielded than the corresponding values for the trans isomers. These results are in agreement with the δ(Pt), where the cis compounds were observed at higher fields than the corresponding trans isomers. A larger reduction of electron density on the ligand in the cis compounds should be associated with a larger electron density on the platinum atom (δ(Pt) at higher fields). Therefore, the σ bonds seem stronger in the cis compounds than in the trans isomers.

For the chiral ligand, *sec*-butylamine, only one series of signals was observed in the ^{1}H NMR for both isomers. For the compound identified as *trans*-Pt($Et_2NH)_2(NO_3)_2$, two series of signals were observed as in ^{195}Pt NMR. The second series was assigned to the cis isomer as discussed above.

All the NH ^2J(^{195}Pt-^{1}H) coupling constants could be calculated. They are larger in the cis configuration where the average value is 67 Hz compared to 58 Hz (avg.) for the trans isomers. These values were found to be 67 Hz (cis) and 59 Hz (trans) for the corresponding diiodo complexes (11). The ^3J(^{195}Pt-^{1}H) coupling constants also depend on the geometry of the complex. They range between 35 and 47 Hz for the cis complexes and between 32 and 33 Hz for the trans compounds. These values are difficult to measure, since the signals are often multiplets of low intensity. These values agree with those reported for other similar complexes (11, 12, 17, 29, 33). One ^4J(^{195}Pt-$^1H_2$) coupling constant for *trans*-Pt(*t*-$BuNH_2)_2(NO_3)_2$ could be measured (15 Hz).

The ^{13}C NMR chemical shifts as well as the J(^{195}Pt-^{13}C) coupling constants are listed in Table 6. The ^{13}C NMR signals of C_1 and C_2 are more deshielded for the cis complexes than those of the trans analogues. This is consistent with the more upfield ^{195}Pt chemical shifts observed for the cis complexes and with the results obtained in ^{1}H NMR.

The ^2J(^{195}Pt-^{13}C) and ^3J(^{195}Pt-^{13}C) coupling constants are also dependent on the geometry of the compounds. For the

‡See text.

^3J the average value is 37 Hz for the cis complexes and 28 Hz for the trans isomers. The $^2J(^{195}Pt\text{-}^{13}C)$ coupling constants are smaller, probably because of inadequate orientation of the orbitals (30) as reported for other similar compounds. The average values are 18 Hz (cis) and 16 Hz (trans).

For the compound identified as *trans*-$Pt(Et_2NH)_2(NO_3)_2$, two series of signals were observed as in ^{195}Pt and ^1H NMR. The second series was assigned to the cis isomer as discussed above. For the chiral ligand, *sec*-butylamine, only one series of signals was observed in ^{13}C NMR for both isomers. For the diiodo analogues, some spectra with this ligand have shown two series of signals (11).

A new fluorous soluble Lewis acidic borane system

Horace Luong, Melanie D. Eelman, and Mark Stradiotto

Abstract: Treatment of trichlorovinylsilane with 3,3,4,4,5,5,6,6,7,7,8,8,8-tridecafluoro-1-octanol (3 equiv.) in the presence of excess triethylamine produces the fluorous vinylsilane, **1**, which can be isolated in 74% yield as an analytically pure oil. The addition of bis(pentafluorophenyl)borane to **1** produces the fluorous boranes, **2a**–**2b**, as an analytically pure, isomeric mixture of *anti*-Markovnikov and Markovnikov hydroboration products in 38% isolated yield. Compounds **2a**–**2b** are soluble in both arene solvents and perfluoro(methylcyclohexane). Treatment of **2a**–**2b** with excess trimethylphosphine generates a mixture of products, including the Lewis adduct, **3**, which can be isolated as an analytically pure oil in 15% yield. When exposed to either dimethylaminopyridine or piperidine at room temperature, the trimethylphosphine donor in **3** is cleanly displaced, based on in situ ^{31}P NMR studies; under similar conditions, triethylamine does not react with **3**. Addition of either dimethylaminopyridine or piperidine to **2a**–**2b**, followed by purification and subsequent treatment with an excess of either hydrogen chloride or *p*-toluenesulfonic acid, results in cleavage of the Si–O linkages and the regeneration of 3,3,4,4,5,5,6,6,7,7,8,8,8-tridecafluoro-1-octanol.

Key words: fluorous, borane, silane, Lewis acid.

Résumé : La réaction du trichlorovinylsilane avec du 3,3,4,4,5,5,6,6,7,7,8,8,8-tridécafluoroocatan-1-ol (3 équivalents), en présence d'un excès de triéthylamine, conduit à la formation du vinylsilane fluoré **1** qu'on peut isoler avec un rendement de 74 % sous la forme d'une huile analytiquement pure. L'addition de bis(pentafluorophényl)borane au composé **1** fournit les boranes fluorés **2a**–**2b**, analytiquement purs, qui correspondent au mélange d'isomère des produits d'hydroboration *anti*-Markovnikov et Markovnikov et qui sont obtenus avec un rendement de 38 % en produits isolés. Les produits **2a**–**2b** sont solubles tant dans les solvants aromatiques que dans le perfluoro(méthylcyclohexane). Le traitement du mélange des produits **2a**–**2b** à l'aide d'un excès de triméthylphosphine conduit à la formation d'un mélange de produits comportant le produit d'addition de Lewis, **3**, qui peut être isolé sous la forme d'une huile analytiquement pure, avec un rendement de 15 %. Sur la base d'études RMN du ^{31}P in situ, quand on le soumet à la température ambiante à de la diméthylaminopyridine ou à de la pipéridine, le donneur triméthylphosphine présent dans le composé **3** est complètement déplacé; dans des conditions semblables, la triéthylamine ne réagit pas avec le composé **3**. L'addition de diméthylaminopyridine ou de pipéridine au mélange **2a**–**2b**, suivie d'un traitement subséquent avec du chlorure d'hydrogène ou de l'acide *p*-toluènesulfonique conduit à un clivage des liaisons Si–O et à la régénération du 3,3,4,4,5,5,6,6,7,7,8,8,8-tridécafluoroocatan-1-ol.

Mots clés : fluoré, borane, silane, acide de Lewis.

[Traduit par la Rédaction]

Introduction

Since its introduction nearly a decade ago (1), fluorous biphasic catalysis (FBC) has emerged as a powerful and well-established methodology in synthetic chemistry (2). Under the standard FBC protocol, a perfluorocarbon or "fluorous" phase (containing an appropriately phase-labeled catalyst) is used in combination with an organic phase (containing the substrates and products). To sequester the catalytic agent to the fluorous phase, the catalyst must be phase-labeled with numerous perfluoroalkyl sidechains or "fluorous ponytails"; empirical studies indicate that at least 60% fluorine by weight is typically required to achieve *exclusive* fluorous solubility for a given molecule (3).[2] However, the efficient incorporation of such a large number of fluorinated chains into catalyst frameworks poses a considerable synthetic challenge, and virtually all of the FBC systems reported to date employ catalysts that have been permanently modified via covalent attachment of a fluorous phase-label. Though effective in providing a means of catalyst recovery, such an approach is inefficient in that unique labeling strategies must be developed for catalysts possessing different structural attributes.

In an effort to expand the utility and scope of fluorous biphasic techniques, we have recently initiated a research program directed towards the synthesis of new Lewis acidic

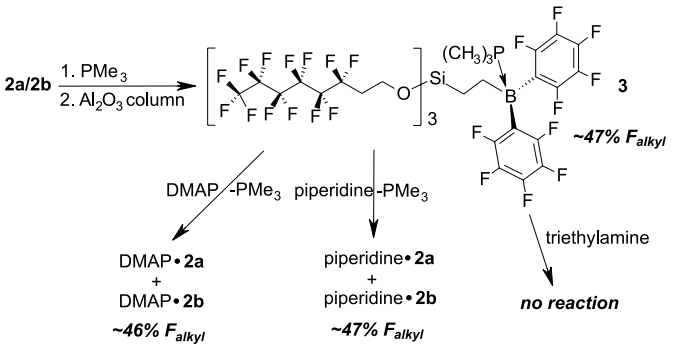
Scheme 1. Hydroboration of the fluorous vinylsilane, **1**, producing **2a**–**2b**.



boranes, possessing chemical properties reminiscent of $B(C_6F_5)_3$, but that are compatible with a fluorous biphasic reaction system (4). In addition to the direct application of fluorous boranes as Lewis acid catalysts for organic transformations (5, 6) or as activators for transition-metal catalyst systems (7), we envision that Lewis acidic fluorous boranes may also function as a hitherto unknown class of fluorous phase-labels that could be reversibly attached to a Lewis basic pendant group (e.g., PR_2) built into the periphery of an appropriately designed transition metal catalyst (8). Herein we report our preliminary synthetic efforts in this area, including the synthesis and coordination chemistry of a new fluorous soluble, boron-centered Lewis acid system that is assembled via hydroboration.

Results and discussion

The synthesis of the target fluorous borane system (**2a**–**2b**) is summarized in Scheme 1 and begins with the dehydrohalogen coupling of 3,3,4,4,5,5,6,6,7,7,8,8,8-tridecafluoro-1-octanol with trichlorovinylsilane to yield the fluorous vinylsilane, **1**, in 74% isolated yield. Subsequent treatment of **1** in benzene with the bis(pentafluorophenyl)borane reagent developed by Piers and co-workers (9*a*) followed by biphasic extraction with perfluoro(methylcyclohexane) allowed for the isolation of an analytically pure mixture of *anti*-Markovnikov and Markovnikov hydroboration products (**2a**:**2b** ≈ 2:1, based on ^{1}H and ^{19}F NMR data) in 38% isolated yield. Examination of the combined benzene extracts revealed the presence of appreciable quantities of impure **2a**–**2b**, indicating that the perfluoroalkyl content (≈50% F_{alkyl} by weight) in this system is insufficient to promote exclusive fluorous solubility under biphasic conditions.

In contrast to the symmetrical nature of the terminal addition product, **2a**, the Markovnikov addition of $HB(C_6F_5)_2$ to **1** produces a stereogenic center that spans the boron and silicon fragments in **2b**. These structural differences are manifested in the observation of a symmetrical ^{1}H NMR resonance attributable to the OCH_2 linkage in **2a**, whereas in **2b** these hydrogen atoms are diastereotopic. The ^{11}B NMR resonance associated with **2a**–**2b** (42 parts per million (ppm)) is shifted to lower frequency relative to other $RB(C_6F_5)_2$ species (9*b*, 9*c*). Although we cannot rule out a dynamic process involving intramolecular coordination of oxygen and (or) fluorine atoms to the boron center, this chemical shift is not consistent with a typical four-coordinate adduct of the type $RB(C_6F_5)_2L$ (9, 10).

Scheme 2. Synthesis and phosphine displacement reactions involving **3**.

Piers and co-workers (9) have demonstrated that the initially formed hydroboration products generated when using $HB(C_6F_5)_2$ are often susceptible to thermal equilibration via retrohydroboration–hydroboration reaction sequences, leading to thermodynamic product mixtures. However, heating a mixture of **2a** and **2b** at 120 °C for several days resulted in no appreciable change in the ratio of these isomers, perhaps indicating that the energetic stability associated with the sterically less-congested isomer, **2a**, is somewhat offset by the stabilizing influence of the β-silyl fragment in **2b** (9*c*).

In an attempt to evaluate the feasibility of employing this new fluorous borane system as a reversibly bound fluorous phase-label (vide supra), the reactivity of **2a**–**2b** with Lewis bases was examined (Scheme 2). Treatment of **2a**–**2b** with excess trimethylphosphine in toluene initially produced a complex reaction mixture, from which the Lewis adduct, **3** (i.e., Me_3P·**2a**; ≈47% F_{alkyl} by weight), was isolated as an analytically pure oil in low yield (15%). Although we have been unable to characterize the side products formed in this reaction, it is conceivable that the addition of trimethylphosphine to **2a**–**2b** promotes retrohydroboration and (or) other unwanted reactions, leading to the degradation of **2a**–**2b** (9*b*).

The ability of nitrogen donors to displace the coordinated trimethylphosphine in **3** was examined. Treatment of **3** with a 30-fold excess of dimethylaminopyridine (DMAP) at room temperature resulted in the slow consumption of **3**, along with the clean production of free trimethylphosphine (^{31}P NMR). The displacement is approximately 30% complete after 6 h, and after 68 h the ^{31}P NMR resonance associated with **3** is no longer discernible. While similar results were obtained with piperidine, no reaction was observed between **3** and triethylamine after 68 h. Attempts to accelerate these displacement reactions by heating produced complex reaction mixtures. In the case of the DMAP and piperidine reactions, the ^{19}F NMR spectral data acquired from samples of the products generated upon completion of the displacement

© 2004 NRC Canada

were similar to those obtained from samples of **2a**–**2b** treated directly with amine. Unfortunately, we have not been able to isolate pure materials from these reactions. However, based on these observations we tentatively assign the displacement products formed upon treatment of either **2a**–**2b** or **3** with amines as a mixture composed primarily of LB·**2a** and LB·**2b** (LB = DMAP or piperidine). Attempts to regenerate **2a**–**2b** via protonolysis of the coordinated amine using an excess of either hydrogen chloride or *p*-toluenesulfonic acid were unsuccessful (11), resulting in the quantitative cleavage of the Si–O linkages, accompanied by the formation of free 3,3,4,4,5,5,6,6,7,7,8,8,8-tridecafluoro-1-octanol.

Summary

A "first-generation" fluorous borane system (**2a**–**2b**) that is comprised of approximately 50% F_{alkyl} by weight has been prepared by the addition of bis(pentafluorophenyl)borane to a new fluorous vinylsilane ponytail derived from commercially available 3,3,4,4,5,5,6,6,7,7,8,8,8-tridecafluoro-1-octanol. The Lewis acidic nature of **2a**–**2b** is evident in their ability to coordinate Lewis bases, which suggests that fluorous boranes of this type may ultimately find use as catalysts and (or) as reversibly bound phase-labels. However, while precise partition coefficients have not been measured, it is evident that **2a**–**2b** are sufficiently soluble in both organic and perfluorocarbon solvents so as to preclude their use within a strict FBC regime. In light of these preliminary results, we have undertaken the study of new and more robust classes of fluorous boranes that exceed 60% F_{alkyl} content by weight, which should exhibit exclusive solubility in fluorous media. Reports on these "second-generation" systems are forthcoming.

Experimental section

General considerations

All manipulations were conducted at room temperature in the absence of oxygen and water under an atmosphere of dinitrogen, either by using standard Schlenk methods or within an Innovative Technologies glove-box apparatus, and employed glassware that was oven dried (130 °C) and evacuated while hot prior to use. Unless otherwise stated, all materials were obtained from Aldrich and were used as received. Celite® was oven dried (130 °C) for 5 days and then evacuated for 24 h prior to use. Alumina (neutral, 150 mesh, activity Brockmann II) was degassed and dehydrated in vacuo for 48 h at temperatures between 200 and 300 °C and subsequently deactivated with 2% deionized water under argon prior to use. Solvents were dried and deoxygenated by refluxing for a minimum of 24 h under a flow of dinitrogen, in the presence of either sodium (for pentane, diethyl ether, and toluene) or potassium (for benzene). Benzophenone was added to the solvent – drying agent mixture to provide visual confirmation (i.e., the observed persistence of the benzophenone ketyl) that an appropriate level of purification had been achieved. The solvents used within the glove box were stored over activated 3 Å molecular sieves. Perfluoro(methylcyclohexane), 3,3,4,4,5,5,6,6,7,7,8,8,8-tridecafluoro-1-octanol, and C_6D_6 were degassed by three freeze-pump-thaw cycles and then dried over 3 Å molecular sieves for 24 h prior to use. Piperidine and $CDCl_3$ were each degassed by three freeze-pump-thaw cycles, dried over CaH_2 for 7 days, and distilled in vacuo. Triethylamine and trichlorovinylsilane were degassed by three freeze-pump-thaw cycles. Tris(pentafluorophenyl)borane, used in the preparation of bis(pentafluorophenyl)borane, was obtained from Boulder Scientific Company and was dried with chlorotrimethylsilane and purified by sublimation at 80 °C under dynamic vacuum; bis(pentafluorophenyl)borane in turn was prepared by using literature methods and was purified by washing with toluene (5 × 1 mL) at –30 °C and then was dried in vacuo for 18 h prior to use (9*b*). Unless otherwise stated, ^{1}H, ^{13}C, ^{19}F, and ^{31}P NMR data were collected at ambient temperature on a Bruker AC-250 spectrometer, at 250.1, 62.9, 235.3, and 101.3 MHz, respectively, while ^{11}B NMR spectra were recorded on an AVANCE 500-MHz NMR spectrometer at 160.5 MHz. Chemical shifts are reported in parts per million downfield of tetramethysilane (for ^{1}H and ^{13}C), BF_3 in diethyl ether (for ^{11}B, with peak width at half height in Hertz following the reported chemical shift), CCl_3F (for ^{19}F), and 85% H_3PO_4 in water (for ^{31}P). In some cases, fewer than expected independent ^{13}C NMR resonances were observed. Elemental analyses were performed by Desert Analytics (Tucson, Ariz.). Atmospheric pressure chemical ionization (APCI) mass spectra were obtained using a Finnigan LCQ Duo ion trap mass spectrometer. Samples were injected directly into the APCI source at a flow rate of 1.2 mL/h using toluene as the solvent with a source temperature of 473 K and collision energy of 0%. MS–MS spectra were obtained for the parent molecular ions using helium as the collision gas, and the collision energy was optimized for each sample.

CH_2=CHSi($OCH_2CH_2C_6F_{13}$)$_3$ (1)

Within a Schlenk flask containing a magnetic stir bar, 3,3,4,4,5,5,6,6,7,7,8,8,8-tridecafluoro-1-octanol (2.86 g, 7.86 mmol) was dissolved in 40 mL of diethyl ether. Triethylamine (2.0 mL, 14.3 mmol) was then added via syringe to the diethyl ether solution; the reaction flask was submersed within an ice bath, and the solution was stirred for 5 min. Trichlorovinylsilane (0.33 mL, 2.61 mmol) was then added dropwise via syringe over 5 min to the diethyl ether solution. Upon completion of the silane addition, the reaction mixture was allowed to warm to room temperature over 3 h while stirring. The solution was subsequently cannula filtered away from the precipitated white solid into a fresh Schlenk reaction flask. This reaction flask was then brought into the glove box, and the solution was filtered through a Pasteur pipette containing a Celite® plug. The resulting colorless solution was dried in vacuo for 24 h to yield **1** as a colorless oil (2.20 g, 1.92 mmol, 74%). ^{1}H NMR ($CDCl_3$) δ 6.26–5.77 (m, 3H, vinyl C*H*s), 4.08 (t, $^{3}J_{HH}$ = 6.6 Hz, 6H, $OCH_2CH_2CF_2$), 2.39 (t of t, $^{3}J_{HH}$ = 6.6 Hz, $^{3}J_{HF}$ = 18.5 Hz, 6H, $OCH_2CH_2CF_2$). $^{13}C\{^{1}H\}$ NMR ($CDCl_3$) δ 139.3 (vinyl *C*H), 126.9 (vinyl *C*H), 122.6–106.3 (m, CF_2s and CF_3), 55.7 ($OCH_2CH_2CF_2$), 33.9 (t, $^{2}J_{CF}$ = 21.2 Hz, $OCH_2CH_2CF_2$). $^{19}F\{^{1}H\}$ NMR (C_6D_6) δ –81.2 (s, CF_3), –113.8 (s, CF_2), –122.1 (s, CF_2), –123.1 (s, CF_2), –124.0 (s, CF_2), –126.5 (s, CF_2). $(C_6F_5)_2BCH_2CH_2Si(OCH_2CH_2C_6F_{13})_3$ (2a) and $(C_6F_5)_2BCH(CH_3)Si(OCH_2CH_2C_6F_{13})_3$ (2b)

To a glass vial containing a stir bar, bis(pentafluorophenyl)borane (0.19 g, 0.55 mmol), and benzene (1 mL) was added a mixture of **1** (0.51 g, 0.45 mmol) in benzene (1 mL). The vial was then sealed with a PFTE-lined cap, and the solution was stirred for 2 h, after which the mixture was allowed to settle, forming a two-phase liquid–liquid system. The upper, benzene layer was then removed by using a Pasteur pipette. The remaining fluorous layer was washed with benzene (3 × 1 mL), and the volatiles in the remaining fluorous layer were removed in vacuo to yield an isomeric mixture of **2a** and **2b** (≈2:1 based on ^{1}H and ^{19}F NMR data) as a clear colorless oil (0.31 g, 0.21 mmol, 38%).

Data for 2a

^{1}H NMR (C_6D_6) δ 3.84 (t, $^3J_{HH}$ = 6.3 Hz, $OCH_2CH_2CF_2$), 2.31–1.82 (m, $OCH_2CH_2CF_2$), 1.66 (t, $^3J_{HH}$ = 7.6 Hz, $SiCH_2$ or BCH_2), 0.70 (t, $^3J_{HH}$ = 7.6 Hz, BCH_2 or $SiCH_2$). ^{19}F{^{1}H} NMR (C_6D_6) δ –82.1 (s, CF_3), –114.9 (s, CF_2), –123.0 (s, CF_2), –124.0 (s, CF_2), –124.8 (s, CF_2), –127.3 (s, CF_2), –133.7 (m, aryl C*F*), –153.4 (m, aryl C*F*), –163.0 (m, aryl C*F*).

Data for 2b

^{1}H NMR (C_6D_6) δ 4.24–3.75 (m, $OCH_2CH_2CF_2$), 2.63 (quart., $^3J_{HH}$ = 6.4 Hz, $CHCH_3$), 2.37–1.86 (m, $OCH_2CH_2CF_2$), 1.15 (d, $^3J_{HH}$ = 6.4 Hz, $CHCH_3$). ^{19}F{^{1}H} NMR (C_6D_6) δ –82.1 (s, CF_3), –114.5 (s, CF_2), –123.0 (s, CF_2), –124.0 (s, CF_2), –124.8 (s, CF_2), –127.3 (s, CF_2), –131.6 (m, aryl C*F*), –149.3 (m, aryl C*F*), –162.3 (m, aryl C*F*).

Data for 2a and 2b

^{13}C{^{1}H} NMR (C_6D_6) δ 150.2–135.1 (m, aryl *C*Fs), 121.1–107.4 (m, *C*F_2s and *C*F_3), 57.8–55.0 (m), 34.2–33.4 (m), 26.5, 15.4 (m), 12.2 (m), 8.1. ^{11}B{^{1}H} NMR (C_6D_6) δ 42 (310). $(CH_3)_3P\cdot(C_6F_5)_2BCH_2CH_2Si(OCH_2CH_2C_6F_{13})_3$ (3)

To a glass vial containing a magnetic stir bar and a freshly prepared sample of **2a**–**2b** (0.15 g, 0.10 mmol) was added excess trimethylphosphine (0.3 mL of a 1.0 mol L^{-1} toluene solution, 0.3 mmol) via syringe. The solution was stirred for 1 h and then dried in vacuo for 2 h to yield a colorless, opaque oil. ^{1}H NMR analysis of this crude oil indicated the formation of a complex reaction mixture. The crude product was then emulsified with pentane (3 mL) and passed through a Pasteur pipette alumina column (5 cm). Perfluoro(methylcyclohexane) (1 mL) was then added to the eluent collected in a fresh glass vial, and the resulting mixture was emulsified by using a Pasteur pipette before sealing the vial with a PFTE-lined cap and storing the vial at –30 °C for 10 min. The upper organic layer was separated from the lower fluorous layer by using a Pasteur pipette. The product-containing fluorous layer was then washed with benzene (3 × 1 mL), and the fluorous solvent and other volatiles in the residual fluorous layer were removed in vacuo to yield **3** as a transparent orange oil (0.061 g, 0.04 mmol, 15%). ^{1}H NMR (C_6D_6) δ 3.87 (t, $^3J_{HH}$ = 6.1 Hz, 6H, $Si(OCH_2CH_2C_6F_{13})_3$), 2.07 (t of t, $^3J_{HH}$ = 6.1 Hz, $^3J_{HF}$ = 18.6 Hz, 6H, $Si(OCH_2CH_2C_6F_{13})_3$), 1.24–1.05 (m, 2H, BCH_2 or $SiCH_2$), 0.63–0.45 (m, 2H, $SiCH_2$ or BCH_2), 0.53 (d, $^2J_{PH}$ = 11.0 Hz, 9H, $P(CH_3)_3$). ^{13}C{^{1}H} NMR (C_6D_6) δ 149.2–134.6 (m, aryl *C*Fs), 119.5–109.1 (m, *C*F_2s and *C*F_3), 55.8 ($OCH_2CH_2CF_2$), 34.0 (t, $^2J_{CF}$ = 21.1 Hz, $OCH_2CH_2CF_2$), 12.3 (m, BCH_2 or $SiCH_2$), 9.1 (d, $^1J_{PC}$ = 37.1 Hz, $P(CH_3)_3$), 6.8 (m, $SiCH_2$ or BCH_2). ^{19}F{^{1}H} NMR (C_6D_6) δ –82.2 (s, CF_3), –114.6 (s, CF_2), –123.0 (s, CF_2), –124.0 (s, CF_2), –124.8 (s, CF_2), –127.3 (s, CF_2), –131.8 (d, $^3J_{FF}$ = 24.0 Hz, CF_{ortho}), –158.1 (t, $^3J_{FF}$ = 20.7 Hz, CF_{para}), –163.9 (m, CF_{meta}). ^{31}P{^{1}H} NMR (C_6D_6) δ –9.6 (m). ^{11}B{^{1}H} NMR (C_6D_6) δ –13.1 (m, 320). APCI-MS *m/z* (*rel* intensity): 1565.7 (23, $[M]^+$). Anal. calcd. for $C_{41}H_{25}B_1O_3F_{49}Si_1P_1$ (%): C 22.25, H 1.61; found: C 22.01, H 1.79.

Treatment of 2a–2b with DMAP

A glass vial containing a magnetic stir bar was charged with **2a**–**2b** (0.35 g, 0.24 mmol) and a solution of DMAP (0.029 g, 0.24 mmol) in benzene (1 mL), followed by stirring for 24 h. Perfluoro(methylcyclohexane) (0.5 mL) was then added to the reaction mixture, and the biphasic mixture was emulsified for 1 min by using a Pasteur pipette. The mixture was then allowed to settle, and the upper benzene layer was removed by using a Pasteur pipette. The remaining fluorous material was again treated with benzene (2 × 0.5 mL) and emulsified, and the organic and fluorous layers were separated. Drying of the residual fluorous layer in vacuo for 6 h yielded a dark yellow oil (0.062 g), which we tentatively assign as a mixture of DMAP·**2a** and DMAP·**2b** (≈2:1 based on ^{1}H and ^{19}F NMR data). Drying of the combined organic extracts in vacuo for 6 h yielded a similar mixture of DMAP·**2a** and DMAP·**2b**, along with a small amount (<10%) of unreacted DMAP (0.134 g). Attempts to separate DMAP·**2a** and DMAP·**2b** by use of column chromatography on alumina were unsuccessful.

Data for DMAP·2a

^{1}H NMR (C_6D_6) δ 7.92 (m, aryl C*H*), 5.55 (m, aryl C*H*), 3.99 (t, $^3J_{HH}$ = 6.3 Hz, $OCH_2CH_2CF_2$), 2.14 (t of t, $^3J_{HH}$ = 6.3 Hz, $^3J_{HF}$ = 18.9 Hz, $OCH_2CH_2CF_2$), 1.87 (s, NCH_3), 1.70 (m, $SiCH_2$ or BCH_2), 0.69 (m, BCH_2 or $SiCH_2$). ^{19}F{^{1}H} NMR (C_6D_6) δ –82.1 (s, CF_3), –114.4 (s, CF_2), –122.9 (s, CF_2), –123.9 (s, CF_2), –124.7 (s, CF_2), –127.2 (s, CF_2), –133.5 (m, aryl C*F*), –159.3 (m, aryl C*F*), –164.6 (m, aryl C*F*).

Data for DMAP·2b

^{1}H NMR (C_6D_6) δ 7.92 (m, aryl C*H*), 5.55 (m, aryl C*H*), 3.85 (m, $OCH_2CH_2CF_2$), 2.03 (m, $OCH_2CH_2CF_2$), 1.93 (s, NCH_3), 1.13 (d, $^3J_{HH}$ = 7.0 Hz, $CHCH_3$). ^{19}F{^{1}H} NMR (C_6D_6) δ –82.1 (s, CF_3), –114.8 (s, CF_2), –122.9 (s, CF_2), –123.9 (s, CF_2), –124.7 (s, CF_2), –127.2 (s, CF_2), –131.9 (m, aryl C*F*), –160.1 (m, aryl C*F*), –165.1 (m, aryl C*F*).

Data for DMAP·2a and DMAP·2b

Treatment of 2a–2b with piperidine

To a Schlenk flask containing a magnetic stir bar, **2a**–**2b** (0.49 g, 0.33 mmol), and hexanes (3 mL) was added piperidine (0.04 mL, 0.40 mmol) dropwise via syringe. The mixture was stirred for 1 h, and then the volatiles were removed in vacuo over 2 h. The Schlenk flask containing the crude product was then sealed and transferred to the glovebox. Within the glovebox, the crude product was treated with perfluoro(methylcyclohexane) (1.5 mL) and toluene (1.5 mL), and the resulting biphasic mixture was transferred to a glass vial, which was sealed with a PFTE-lined cap, manually shaken for 1 min, and then stored at –30 °C for 20 min. The upper toluene layer was separated from the lower fluorous layer by using a Pasteur pipette. The remaining fluorous material was again treated with toluene (3 × 1 mL) and emulsified, and the organic and fluorous layers were separated. Drying of the residual fluorous layer in vacuo for 6 h yielded an orange oil (0.252 g), which we tentatively assign as a mixture of piperidine·**2a** and piperidine·**2b**; drying of the combined organic extracts in vacuo for 6 h yielded a similar mixture of piperidine·**2a** and piperidine·**2b** (0.059 g). Attempts to separate piperidine·**2a** and piperidine·**2b** by use of column chromatography on alumina were unsuccessful and resulted in decomposition.

Data for piperidine·2a and piperidine·2b

^{1}H NMR (C_6D_6) δ 4.39–3.60 (m), 3.36 (m), 3.11 (m), 2.77 (m), 1.84 (m), 1.63–0.21 (m). ^{13}C{^{1}H} NMR (perfluoro(methylcyclohexane), 125 MHz) δ 56.9–56.2 (m), 51.6–49.0 (m), 35.2–33.9 (m), 26.8–26.3 (m), 23.6, 9.8, 7.0–6.7 (m). ^{19}F{^{1}H} NMR (C_6D_6) δ –82.2 (s, CF_3, piperidine·**2a** and piperidine·**2b**), –114.6 (s, CF_2, piperidine·**2a** or piperidine·**2b**), –114.9 (s, CF_2, piperidine·**2b** or piperidine·**2a**), –123.0 (s, CF_2, piperidine·**2a** and piperidine·**2b**), –124.0 (s, CF_2, piperidine·**2a** and piperidine·**2b**), –124.8 (s, CF_2, piperidine·**2a** and piperidine·**2b**), –127.3 (s, CF_2, piperidine·**2a** and piperidine·**2b**), –133.5 (m, aryl C*F*, piperidine·**2a** and piperidine·**2b**), –158.0 (m, aryl C*F*, piperidine·**2a** and piperidine·**2b**), –163.7 (m, aryl C*F* piperidine·**2a** and piperidine·**2b**).

General procedure for displacement reactions involving 3 and nitrogen donors

Within a glass vial, a sample of **3** (≈0.03 g) dissolved in benzene (0.5 mL) was treated with a 30-fold excess of triethylamine, piperidine, or DMAP. The mixture was immediately transferred to a resealable NMR tube by using a Pasteur pipette, and the progress of the displacement reaction was monitored based on ^{19}F and ^{31}P NMR data. Prior to the acquisition of NMR data, the reaction mixture contained within the NMR tube was mixed vigorously for approximately 30 s.

General procedure for the treatment of LB·2a–LB·2b with acid (LB = DMAP or piperidine)

A Schlenk flask containing a magnetic stir bar was charged with either DMAP·**2a**–DMAP·**2b** or piperidine·**2a**–piperidine·**2b** (≈0.01 g, prepared by the addition of **2a**–**2b** to the nitrogen donor as described above), benzene (0.5 mL), and a 20-fold excess of either hydrogen chloride (from a 2.0 mol L^{-1} solution in diethyl ether) or *p*-toluenesulfonic acid. The reaction flask was then sealed, and the mixture was stirred for approximately 1 h, followed by removal of the solvent and other volatile materials in vacuo over 1 h to yield a white solid. This solid was then treated with C_6D_6 (1 mL), and the resulting suspension was filtered through a Pasteur pipette containing a Celite® plug and examined by use of ^{1}H NMR spectroscopic techniques.

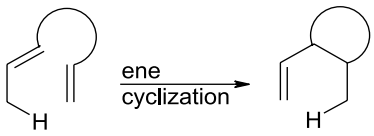
Diastereoselectivity in intramolecular ene cyclisation — A theoretical study

Nityagopal Mondal, Sannyasi Charan Mandal, and Gourab Kanti Das

Abstract: Diastereoselectivity in unactivated and activated ene cyclisation can be predicted using HF/6-31G(d) optimized geometry of the transition states. Relative energies of different conformations of the transition states, calculated using DFT, can be used for the prediction of product ratios. It was found that the dihedral angle around the forming carbon–carbon bond controls the cis–trans diastereoselectivity. A set of three model pericyclic transition structures has been proposed that mimics the activation process of ene cyclisation.

Key words: intramolecular ene reaction, ab initio, DFT.



Résumé : Utilisant une géométrie optimisée au niveau HF/6-31G(d) des états de transition, il est possible de prédire la diastéréosélectivité des cyclisations ènes activées et non activées. Les énergies relatives des diverses conformations des états de transition, calculées à l'aide de la méthode DFT, peuvent être utilisées pour prédire les rapports de produits. On a trouvé que l'angle dièdre autour la liaison carbone–carbone qui se forme contrôle le diastéréosélectivité cis–trans. On propose un ensemble de trois structures de transition péricycliques modèles reflète bien le processus d'activation de la cyclisation ène.

Mots clés : réaction ène intramoléculaire, ab initio, DFT.

[Traduit par la Rédaction]

Introduction

Intramolecular ene cyclisation is a useful tool for the synthesis of five- or six-membered compounds in organic synthesis (1).

The presence of an activating substituent (electron-withdrawing group) in the reactant makes the reaction occur at low temperature (2). Various examples show that the diastereoselectivity depends on the nature of the activating group present in the reactant (3). Proper rationalization of the diastereoselectivity in this reaction is sometimes very difficult.

Theoretical work by Houk and co-workers (3, 4) revealed that the ratio of diastereomeric products in an unactivated ene cyclisation can be predicted nicely with the help of a rigid transition structure. The transition states (TSs) of various ene cyclisations were constructed by connecting a carbon tether to the transition structure of the basic ene reaction (4) in four possible ways (Fig. 1) (3).

The product ratios, obtained by a Boltzmann distribution of the TSs, were found to be in good agreement with the experimentally observed one. However, this approach fails to explain the variation of diastereoselectivity in the cyclisation process when an activating group is present in the reactant. The authors pointed out the fact that the presence of an activating group may deform the basic transition state, which was not considered in the rigid approximation.

Later on, our theoretical study (5) showed that the AM1 semiempirical approximation is, to some extent, capable of predicting the diastereoselectivity in an activated ene cyclisation. It also showed that the TSs obtained from binding modes (*1*), (*2*), and (*3*) (Fig. 1) are sufficient to predict the actual diastereoselectivity, without considering the TSs of the strained mode (*4*). However, the AM1 method is not accurate enough to predict the course of unactivated cyclisation using Houk's rigid model (3).

Meanwhile, another theoretical study (6) on the basic ene reaction revealed that the calculated activation energy, using density functional theory (DFT) on the HF/6-31G(d) optimized geometry, was in good agreement with the experimentally observed one.

In this report, it is shown that single point energies from DFT calculations on the HF/6-31G(d) optimized transition structures in ene cyclisation can be used for the prediction of diastereomeric product ratios in both unactivated and activated cyclisation processes. It is also shown that a small change of a particular dihedral angle in the basic transition structure (effected by a substituent) results in significant change in the diastereoselectivity of the corresponding ene

Fig. 1. Possible binding modes in the transition structure of the basic ene reaction to form the TSs of ene cyclisation.

cyclisation. Finally, some model pericyclic processes are proposed that mimic the variation in geometry of the TS and activation energy of the ene cyclisation.

Computational methods

All TSs were optimized at the HF/6-31G(d) level and single point energies were calculated by B3LYP/6-31G(d) DFT. GAMESS (7) software was used for optimization of the structure and calculation of energies. All structures were characterized by frequency analysis.

Results and discussion

Studies on the TSs of the ene cyclization

The reactions that we have studied are shown in Table 1. The generalized TSs (Fig. 2), produced from the reactants of Table 1, were constructed using binding modes (*1*), (*2*), and (*3*) of Fig. 1.

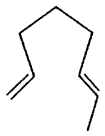
Energies and some relevant dihedral angles of the actual TSs are collected in Table 2. It is evident that TSs obtained from modes (*1*) and (*3*) give cis product while that from mode (*2*) gives trans product (Fig. 2). The product proportions were calculated, using a Boltzmann distribution, on the basis of the relative energies (Table 2) of the corresponding transition states and are shown in Table 1.

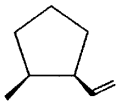
The first five entries in Tables 1 and 2 are the examples of ene cyclisation in unactivated molecules. Isomers (cis and trans) of 1,6-octadiene, its 7-methyl and 3,7-dimethyl derivatives are taken as reactants. Other entries represent the reactants with an activating group. We have inserted an aldehyde (entries 6, 8, 10, and 12) or a carboxylic acid group (entries 7, 9, 11, 13, 14, and 15) as an activating group at the enophile part of the reactant in cis or in trans orientation. The experimental results of the product ratios are shown in those cases where it is available in the literature (entries 1–5, 14, and 15 in Table 1). Although we have not found any actual experimental results in the literature for the reactions of entries 6–13, some similar reactions with similar configurations of reactants have been reported (1*f*, 1*g*). These observations support the fact that the cis product is exclusively formed from a reactant where the ene part is in the cis configuration (as in reactants of entries 10–13) and a mixture of cis and trans products is formed when the ene part in the reactant is in the trans configuration (as in reactants of entries 6–9). We have approximated the carbomethoxy group by the carboxylic group in our theoretical study (in entries 14 and 15).

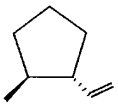
Table 1 shows that only cis products are obtained experimentally in an unactivated reaction (entries 1–5), though theoretical results express the possibility of the formation of trans products in a very low percentage in some situations. The presence of an activating group in the reactant (entries 6–9, 14, 15) promotes cyclisation reactions to produce trans products in higher percentages (in 10–13, the formation of a TS with binding mode (*2*), which is necessary for the formation of a trans product, is not possible). This tendency increases when the activating group is placed in cis orientation in the reactant (entries 7 and 14). Comparison of product ratios in 7 and 14 and 9 and 15 clearly reveals that the presence of an extra methyl group in reactants 14 and 15 leads to the formation of the trans product in higher proportion.

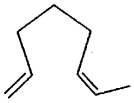
A rough correlation may be observed between the variation of proportion of trans product for different reactants and the variation of the dihedral angle of the corresponding TS in binding mode (*2*) (ϕ) (Fig. 2). Table 2 shows that ϕ of the TS is always smaller in unactivated than in activated cyclisation. In unactivated cases a maximum value of ϕ is 53.6° (entry 1), whereas for activated reactions, the minimum value of the same is 53.9° (entry 6). The reactant, acquiring a maximum ϕ value in the TS (entry 14 in Table 2), also shows formation of a maximum percentage of trans product in a cyclisation reaction (entry 14 in Table 1). Comparison between the entries in 7 and 14 reveals that the presence of an extra methyl group in the ene part of the reactant R = CH_3) also shows a tendency to produce TSs with larger ϕ angles. However, this is not the case in entries 9 and 15.

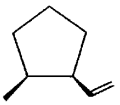
It was pointed out by Houk and co-workers (3) that the formation of the trans product in higher proportion in activated cyclization is due to the deformation of the basic transition structure of the ene reaction, which results from the increased dihedral angle (ϕ) around the forming C—C bond. As ϕ increases the opposite angle (β) decreases (Fig. 1). As a result, the carbon tether in binding mode (*2*) suffers from less strain in the formation of the TS, which ultimately reduces its relative energy. This reduction of relative energy makes the TS more favorable and increases the possibility of the formation of the trans product.

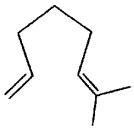


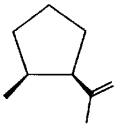


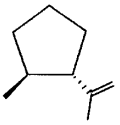












Studies on the TSs of the basic intermolecular ene process

To investigate the role of the dihedral angle in detail, we studied the basic TS with and without some activating groups and without binding any carbon tethers (Fig. 3).

Table 3 shows the dihedral angles ϕ, α, β, and γ for the basic transition structures. The activating groups selected are an aldehyde, a carboxylic acid, and a carbomethoxy group. Dihedral angles shown in parenthesis are for those TSs that contain a methyl group at the 2-position (R = CH_3). Comparison of the dihedral angles of entry 1 (unactivated TS) with others reveals that the presence of an activating substituent at the endo (R_2) or exo (R_1) position always increases ϕ, and consequently, the opposite dihedral angle β decreases. The change of ϕ after the insertion of a Me

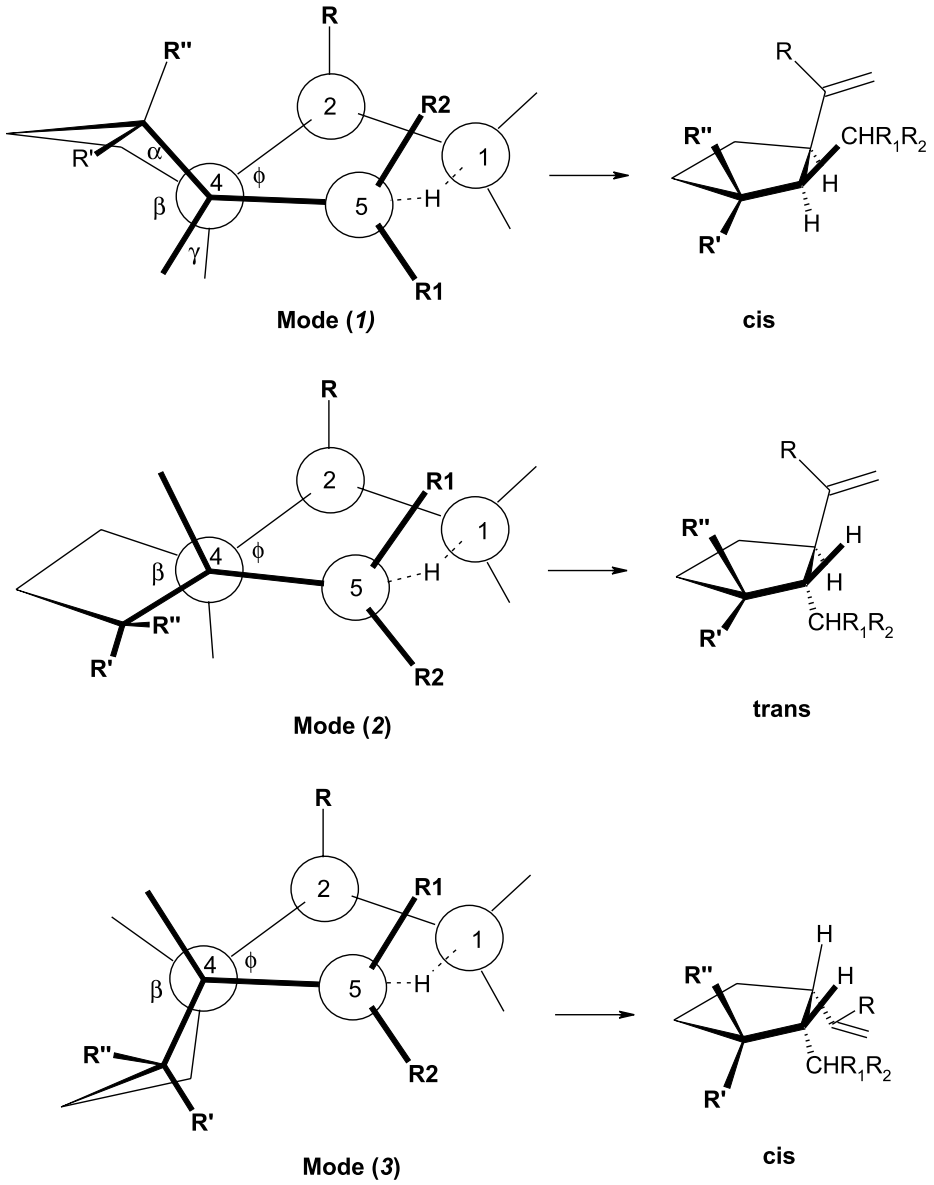

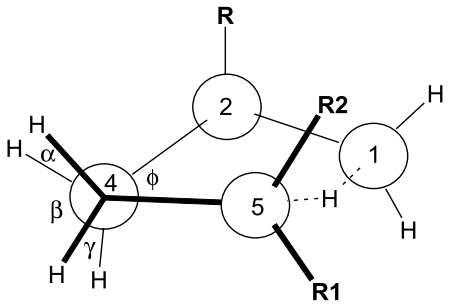

Fig. 3. TS of the basic ene reaction.

substituent at the 2-position of the TS is also interesting. For all activating substituents this change of ϕ value is about +1° to +3° except for entries 5 and 7. The presence of a carboxy (entry 5) or carbomethoxy (entry 7) group at the endo position causes a large increase of ϕ because of the incorporation of a methyl group at the 2-position (7.2° and 7.6° for entries 5 and 7, respectively). This clearly indicates that a strong steric repulsion develops between R and R_2 when R_2 is bulky (Fig. 3). Being a smaller substituent, the aldehyde group is unable to show this effect. We may put forward this idea to explain the formation of a higher proportion of trans products in cyclisation of the cis-carboxyl derivatives in Table 1 (entries 7 and 14). A steric effect between the carbon tether or methyl group (at the 2-position of the TS) and the activating group facilitates the increase in the relative stabilization of the TS of binding mode (*2*) and directs the formation of the product ratio to more of the trans isomer.

Model reactions mimic the activation process

A set of three ene-type pericyclic reactions (Scheme 1) showed a similar increase in the ϕ dihedral angle in their TSs.

[a]R indicates the substituents in Fig. 2 that form the corresponding TS.

Process (A) is the basic ene reaction. Process (B) is basically the mechanism of the oxyene reaction, while process (C) represents the pericyclic pathway of the aldol condensation. Table 4 shows the relevant dihedral angles around the forming C—C bond of the TSs (Fig. 4) of these reactions.

The progressive increase of dihedral angle ϕ and a corresponding decrease in β from reactions (A) to (C), as shown in Table 4, prompted us to use these three reactions as a model system for the activation process of the ene cyclization. As the activation was due to the one or two oxygen atom(s) alone, we may consider that there is no steric effect in these TSs because of a bulky activating group. The next step was to check the product proportions in the cyclisation processes using these three model reactions. As for our previous cases, we constructed the TSs using three binding modes (our results are shown in Tables 5 and 6). Table 5 shows the energies and relevant dihedral angles of the TSs obtained from the reactants shown. We considered

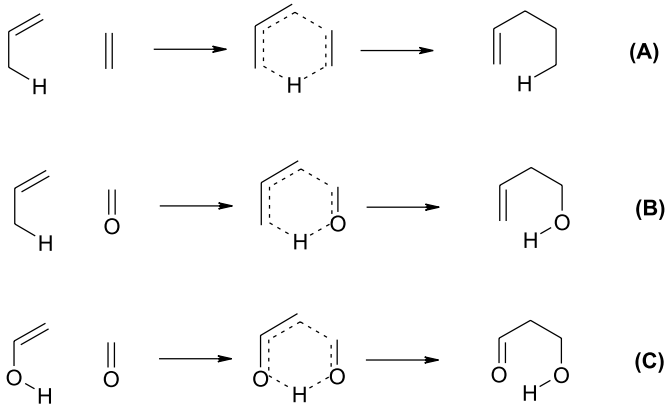

Fig. 4. TS for the model ene reaction.

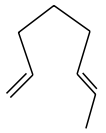
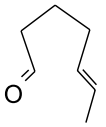
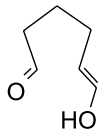
only those reactant configurations that produced both cis and trans isomers. The product ratios (given in Table 6) were calculated at 253 °C (the temperature for activated cyclisation in some entries of Table 1). Reactants and the corresponding TSs in entries 4– 6 of Tables 5 and 6 contain an extra methyl group (R = Me in Fig. 4).

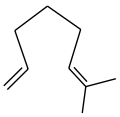
As expected, the proportion of the trans product steadily increases as we move from rxns. 1–3 (Table 6). The presence of a methyl substituent (entries 4–6 in Table 6) enhances this tendency. This suggests that the steric effect of other alkyl (e.g., methyl) substituents also plays a prominent role in determining the product proportions when there is no steric effect of the activating group (the steric effect produced by carbonyl oxygen is considered to be negligible). The dihedral angle, ϕ, (Table 5) also varies in accordance with the ratio of trans products.

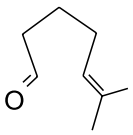
Scheme 1.

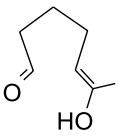












Conclusion

In a nutshell, it may be stated that activated ene cyclisation shows a tendency to produce more trans product than cis. This effect originates from the deformation of the basic transition structure owing to the presence of the activating group. The steric effect of this activating group, along with other substituents, plays a prominent role in controlling the proportion of the diastereomeric products. Proper consideration of the power of activation and bulkiness of substituents can lead a synthetic chemist to design a cyclization reaction that will produce the required diastereomer in high proportion according to his necessity.

Azo-functionalized dendrimers

Kap-Soo Cheon, Peter M. Kazmaier, Sam-Rok Keum, Kuk-Tae Park, and Erwin Buncel

Abstract: We report the synthesis of azo-functionalized Starburst polyamidoamine (PAMAM) dendrimers. The following three systems of azo-functionalized PAMAM dendrimers were prepared by different synthetic routes: (*i*) phenylazo derivatives; (*ii*) naphthalimide azo derivatives; and (*iii*) phthalimide azo derivatives. Model compounds in each system were synthesized for spectroscopic comparison. Confirmation of structure was achieved using a combination of NMR and IR spectroscopy to ascertain the functional sites (i.e., the azo and the cyclic imides), while mass spectrometry and UV–vis spectrophotometry were employed to ascertain the extent of functionalization. Substitution by the azo pendent groups increased the thermal stability of PAMAM dendrimers (TGA weight loss of the naphthalimide azo-functionalized PAMAM dendrimers up to 300 °C, ca. 5%).

Key words: dendrimers, azo compounds, hydrazones, tautomerism, hydrogen bonding.

Résumé : On a réalisé la synthèse de dendrimères polyamidoamine (PAMAM) Starburst fonctionnalisés à l'azote. Faisant appel à diverses voies de synthèse, on a préparé trois systèmes de dendrimères PAMAM fonctionnalisés à l'azote, soit des dérivés phénylazo, des dérivés naphtalimideazo et des dérivés phtalamideazo. On a préparé des composés modèles de chaque système pour comparaison spectroscopique. La confirmation de la structure a été réalisée par une combinaison de spectroscopies RMN et IR qui ont permis de confirmer la présence des sites fonctionnels (par exemple, la fonction azo et les imides cycliques) alors que la spectrométrie de masse et la spectrophotométrie UV–vis a permis de déterminer le degré de fonctionnalisation. La substitution par des groupes azo pendants augmente la stabilité thermique des dendrimères PAMAM (lors de l'analyse thermogravimétrique jusqu'à 300 °C, la perte de poids des dendrimères PAMAM fonctionnalisés à l'azote par le naphtalimide est d'environ 5 %).

Mots clés : dendrimères, composés azo, hydrazones, tautomérie, liaison hydrogène.

[Traduit par la Rédaction]

Introduction

Starburst dendrimers are a new class of highly ordered and branched cascade molecules that have received a great deal of attention (1). Recently, functionalization of dendrimers has shown promising new applications in diverse areas, including materials sciences and life sciences, where applications in medical diagnostics have been proposed (2).

Azo functionalities have been inserted onto dendrimers both as inside linkers and as modifiers of the periphery (3). The resulting molecules have been utilized for their photoswitchable properties and investigated for applications in optical data storage systems, holographic gratings, and drug delivery systems as host molecules (3*e*).

The photoconductive properties of azo compounds were discovered by Rau (4) in 1969, and several years later, the first commercial bisazo pigments (Chlorodiane Blue) for photogenerating pigments in bilayer xerographic devices appeared (5). Azo-functionalized linear polymers have shown promise in the development of electrographic imaging applications, particularly for photoreceptors in xerographic systems (6).

Photoconductivity in organic pigments proceeds primarily by the following two mechanisms: a so-called extrinsic and an intrinsic mechanism (7). The extrinsic mechanism takes advantage of sensitization at the pigment surface; that is to say, a hole-transporting molecule, such as a triarylamine, donates an electron to the exciton generated in the pigment to effect charge separation and hole injection. Surface-functionalized dendrimers have, potentially, a tremendous advantage, since the chromophores are arranged in a thin layer around an inert and impervious core. Thus, if photogeneration takes place in an azo-functionalized dendrimer, the exciton is confined to the surface and is constantly exposed to the hole-transporting sensitizer, and so very rapid and highly efficient hole injection should take place for these systems. We therefore undertook to synthesize a surface-functionalized dendrimer with azo couplers, which are known to have excellent photoimaging properties.

We report the functionalization of ethylenediamine-based Starburst dendrimers using mono-azo moieties. The reac-

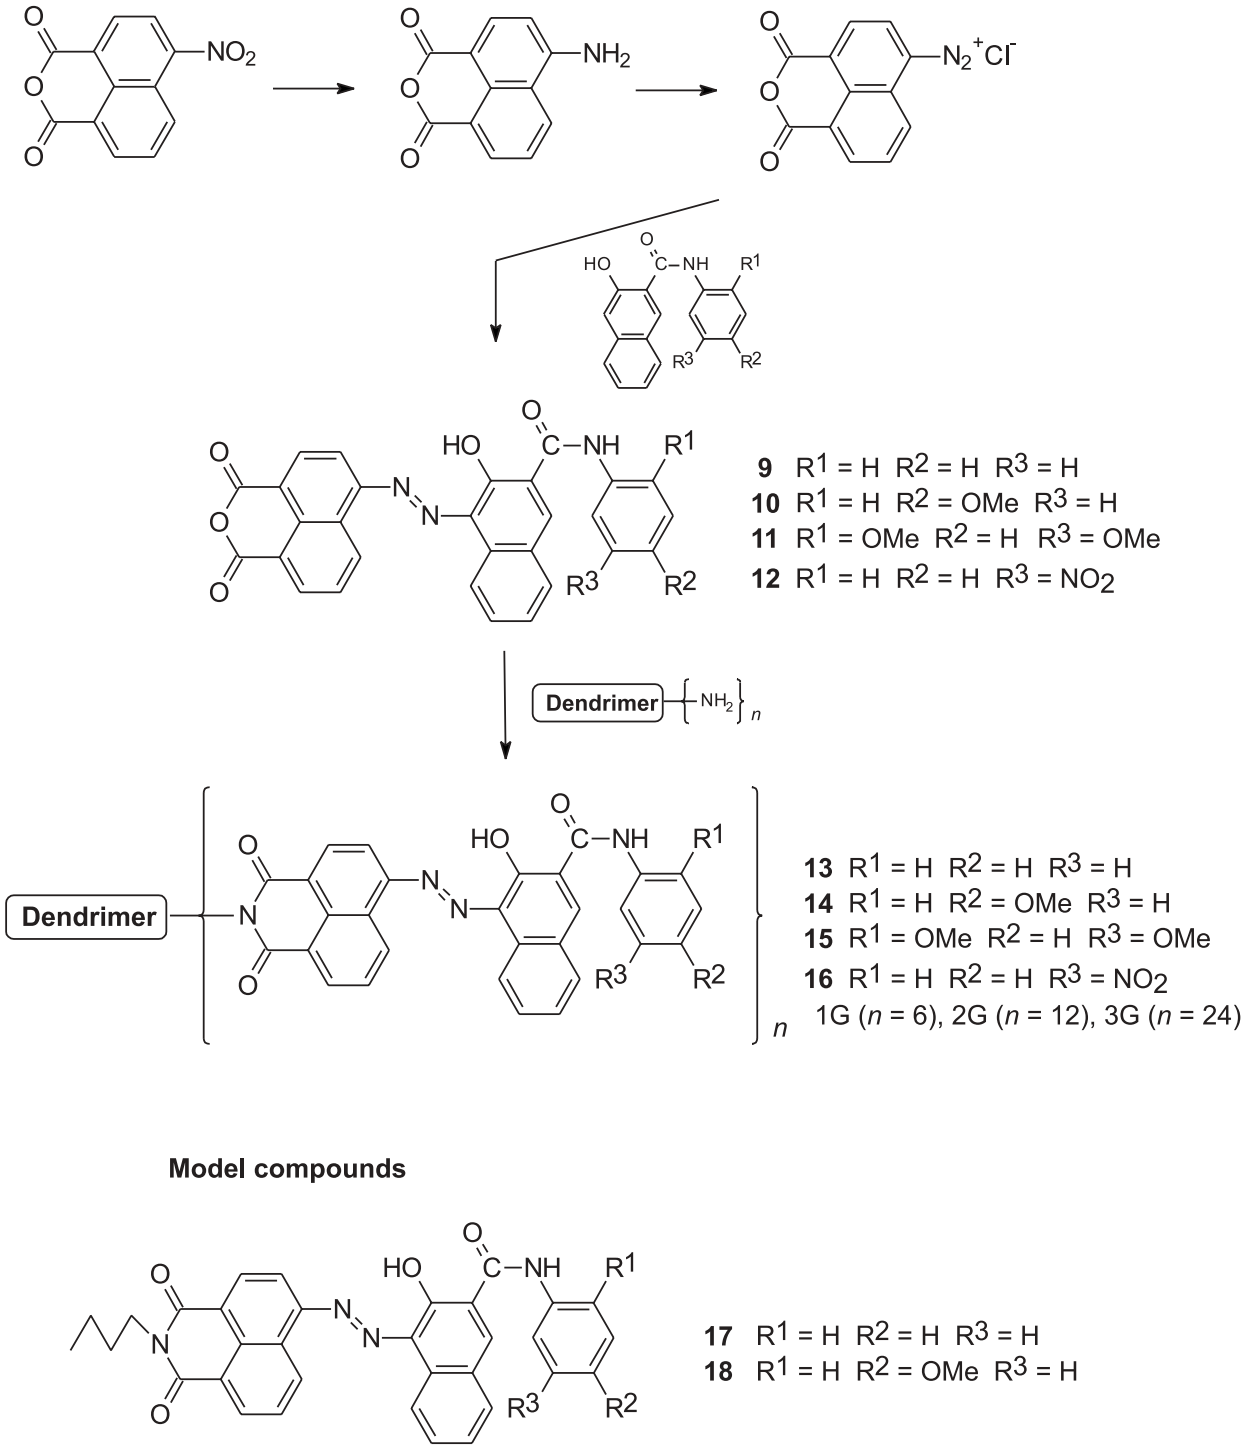
Scheme 1.



Model compounds

tions are shown in Schemes 1–3. A key feature of this chemistry is to select reaction conditions that take advantage of the water solubility of dendrimers and allow functionalization of the dendrimers under reaction conditions that do not lead to degradation of the dendrimer core. Polyamidoamine (PAMAM) dendrimers have been chosen for functionalization by azo dyes in this study because they are commercially available and have been well studied in terms of characterization and properties. The number of ending sites and molecular weights in each generation (G) of PAMAM dendrimers are as follows: 1st G (6 groups, 1043); 2nd G (12 groups, 2411); 3rd G (24 groups, 5147); 4th G (48 groups, 10 619). The present work encompasses up to the fourth generation of PAMAM dendrimers.

Since azo dyes and pigments containing the 2-naphthol-3-anilide moiety have shown high photoconductivity (low dark decay values; high photosensitivity) (8, 9), the derivatives of 2-naphthol-3-anilide were used as couplers for the synthesis of all azo-functionalized PAMAM dendrimers, as well as model compounds. The structure of the azo-modified gener-

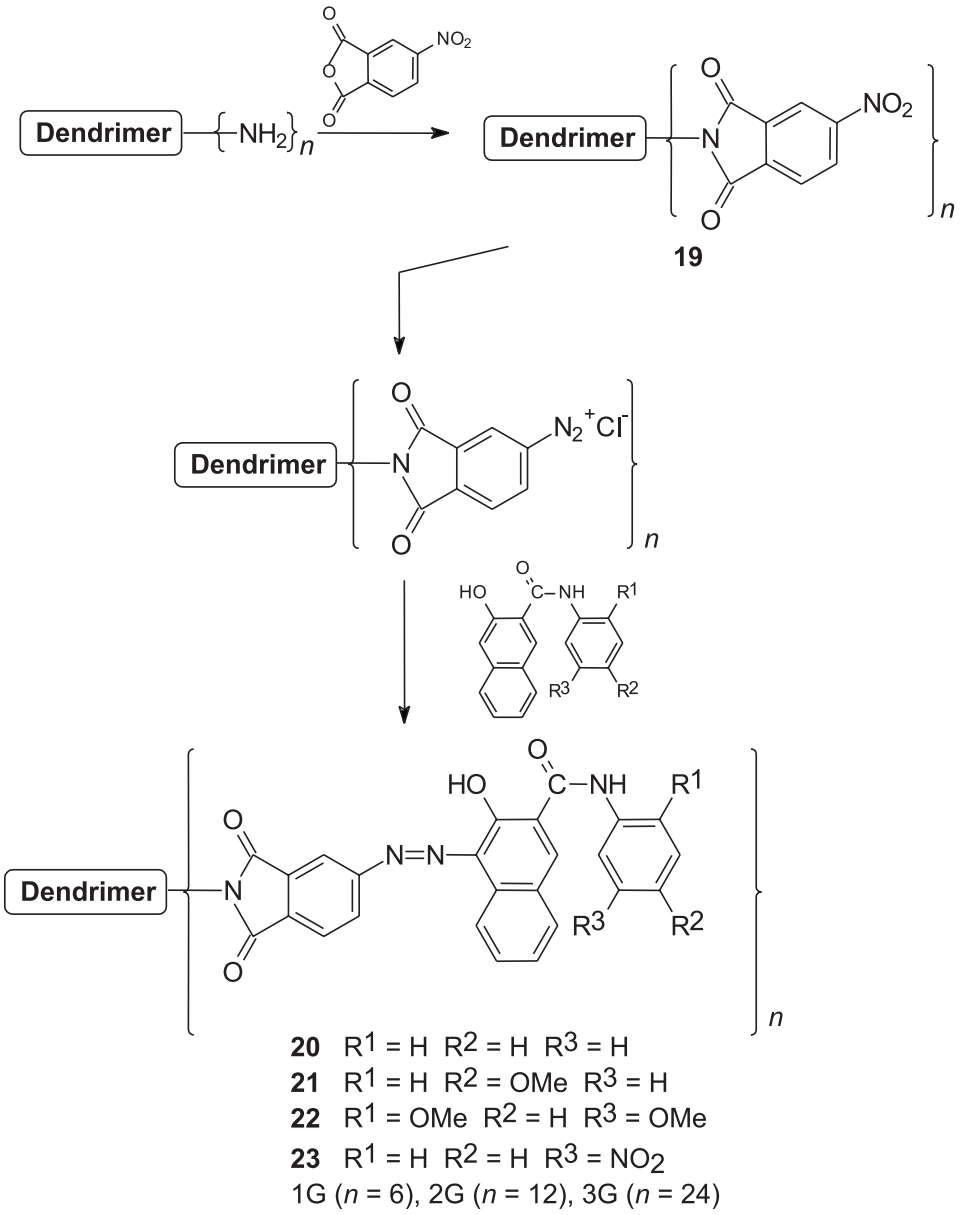
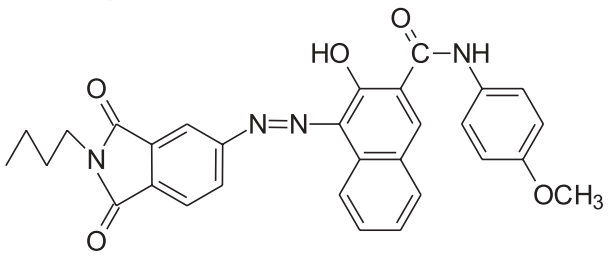
ation 1 of PAMAM dendrimers synthesized and characterized in this study is exemplified in Fig. 1 (see also Schemes 1–3). Hereafter, the symbol Dendrimer will be used for the generic structure of the PAMAM dendrimer.



Results and discussion

The following three systems of azo-functionalized polyamidoamine (PAMAM) dendrimers were examined in this study: (*i*) phenylazo derivatives (Scheme 1); (*ii*) naphthalimide azo derivatives (Scheme 2); (*iii*) phthalimide azo derivatives (Scheme 3). Note that, since the three systems contain the same 2-naphthol-3-anilide moiety, for simplicity the naming of the three systems excludes the 2-naphthol-3-anilide portion. Several model compounds for the three systems were prepared in order to validate the synthetic methods. Furthermore, the spectroscopic characteristics of the model compounds were useful for identifying structures of the azo-functionalized dendrimers.



Structural confirmation and the determination of the de-

gree of functionalization were achieved using a combination of ^{1}H NMR, ^{13}C NMR, and IR spectroscopy to ascertain the site of azo coupling and the functional sites (i.e., the cyclic imides), while mass spectrometry and UV–vis spectrophotometry were employed to ascertain the extent of periphery substitution. UV–vis and ^{13}C NMR evidence revealed that the model compounds and dendrimers exist as equilibrium mixtures of azo and hydrazone tautomeric forms, with the

position of equilibrium being dependent on both structure and solvent medium.

Synthesis and characterization[2]

Phenylazo derivatives

The synthesis of phenylazo derivatives of polyamidoamine (PAMAM) dendrimers was achieved by the route shown in Scheme 1. Reactions of the various generations (from 1st G to 4th G) of PAMAM with *p*-fluoronitrobenzene provided the nitrophenyl moiety to the ending sites of the dendrimer. The structure of the nitrophenyl derivative **1** was identified by ^{1}H and ^{13}C NMR. Reduction of the pendent nitro group to the aromatic amine was accomplished by hydrogenation in the presence of Pd–C catalyst, giving almost quantitative yields of the amino compounds, **2**. ^{13}C NMR spectroscopy was used to verify complete reduction; the absence of a trace of carbon peaks corresponding to the nitro derivative indicated complete reduction. The resulting aminophenyl derivatives were used for formation of the diazonium salts, followed by the diazo-coupling reactions with 2-hydroxynaphthoic acid couplers, giving dendrimer compounds **3**–**6.** Model compounds **7** and **8** were synthesized by the same methods and fully characterized to facilitate the spectroscopic characterization of the resulting phenylazo derivatives of the dendrimer. The sites of azo coupling for the resulting azo-functionalized dendrimers were confirmed by ^{13}C NMR spectroscopy. The ^{13}C chemical shifts of the aromatic portion for the dendrimers are similar to those of the model compound **7**, which confirms the functionalization of the azo moiety at the surface of the dendrimer.

UV–vis spectroscopy was employed to determine the degree of functionalization. The molar extinction coefficient (ε) value at 384 nm of the nitrophenyl derivatives was taken as a measure of the degree of the functionalization by comparison with the corresponding ε value of *N*-methyl-4-nitroaniline (model compound). In other words, the ε value of the nitrophenyl derivative of the PAMAM dendrimer 1G, which has 6 reaction sites, should be 6 times that of the model compound if the reaction sites were fully functionalized. Adherence to the Beer–Lambert law was checked by measuring the absorbance *A* at different concentrations (from 1.04×10^{-5} to 1.51×10^{-4} mol L^{-1}) and plotting *A* vs. concentration. The degree of functionalization could be deduced from a comparison of the ε values of the dendrimer and the model compound, as summarized in Table 1.

According to the UV–vis results, the ending sites of the nitrophenyl-derivatized dendrimers **1**–**1G** to **1**–**4G** were not fully functionalized, i.e., the first generation of PAMAM, having 6 ending sites, was functionalized on 5 sites; for the 2nd G, 9 sites were functionalized; 17 sites and 30 sites were functionalized for the 3rd G and 4th G dendrimers, respectively. This lack of full functionalization with generation could be caused by reduced nucleophilicity of the ending amine moieties of the dendrimers with increasing generation because of crowdedness of the dendrimer surface.

Comparison of ε values between the azo-functionalized dendrimers **3** and the model compound **7** provided the de-

[2] Spectroscopic data of compounds synthesized are provided as supplementary material. Copies of material on deposit may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

gree of functionalization summarized in Table 2. Though, in principle, the above method for evaluation of the number of azo pendent sites (i.e., loading) should be applicable, in the present system an uncertainty arises as a result of a solvent-dependent azo-hydrazone tautomerism, which is exhibited by both the model compounds and the dendrimers (vide infra) (10). In an attempt to circumvent this uncertainty, UV–vis measurements have been made in two solvents — toluene and 2,2,2-trifluoroethanol — these solvents having different polarities and H-bonding properties. The results presented in Table 2 show that there is fair agreement in the two sets of data, giving some credence to their validity. Both

sets show that there is incomplete functionalization. The number of azo pendent groups is similar to that for the *p*-nitrophenyl derivatives shown in Table 1, which indicates that the crucial step for this synthesis is the nucleophilic aromatic substitution reaction with *p*-fluoronitrobenzene.

The results of the degree of functionalization deduced from UV–vis data were comparable with those obtained from MS (ES) data. A series of multiply charged species (A_5–A_{10}) was recognized by the automated MS spectrometer. For example, in the case of dendrimer **3–1G**, multiply

charged peaks (A_8, A_7, etc.) yielded an average *m/z* 2978.53, which corresponds to the mass of a five-sites-functionalized dendrimer (Table 2). A series of multiply charged species originated from one species, while other series of multiply charged species were not found. Thus, the MS spectrum showed that dendrimer **3–1G** is the homogeneously five-sites-functionalized dendrimer by the azo moiety.

Naphthalimide azo derivatives

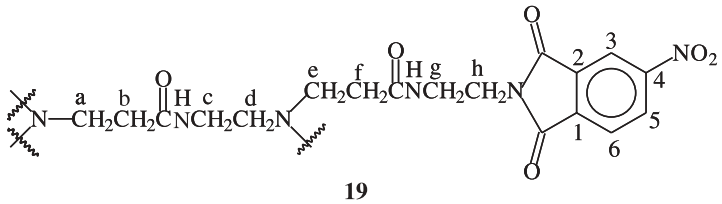
The synthetic method for the naphthalimide azo-functionalized dendrimers is described in Scheme 2. Initially, various azo dyes containing the naphthoic anhydride moiety were synthesized, using a standard diazo-coupling reaction. Then, the naphthoic anhydride moiety was attached to the ending sites of the dendrimers as the cyclic imides. The synthetic advantage of this method over the phenylazo system is that problems caused in purification of the modified PAMAM dendrimers formed in each step would be diminished, since attachment of the azo moiety to the dendrimer only occurred in the last step.

In the first step of the reaction sequence (Scheme 2), hydrogenation of the nitro group produced the amino compound, followed by a standard diazo coupling with the couplers to give the naphthoic anhydride azo compounds (**9–12**). These were coupled with PAMAM dendrimers by cyclic imide formation to give the azo-functionalized dendrimers (**13–16**). For the higher generations of PAMAM (2G and 3G), **9** was chosen for cyclic imide formation with the dendrimers. The model compounds (**17**, **18**) for this system were also synthesized. In the final step, *n*-$BuNH_2$ was used as the model compound for the PAMAM dendrimer, to determine the optimum reaction for the dendrimer synthesis and to compare its spectroscopic characteristics with those of the dendrimers. Two model compounds, **17** and **18**, were prepared.

The compounds **9–12** were fully characterized by NMR, IR, and CI mass spectroscopy. IR spectroscopy was specially useful for the characterization because the cyclic anhydride moiety shows two strong C=O stretching bands, resulting from asymmetrical and symmetrical C=O stretching modes; e.g., **9** (1773, 1734 cm^{-1}), **10** (1768, 1731 cm^{-1}), **11** (1771, 1734 cm^{-1}), and **12** (1773, 1736 cm^{-1}).

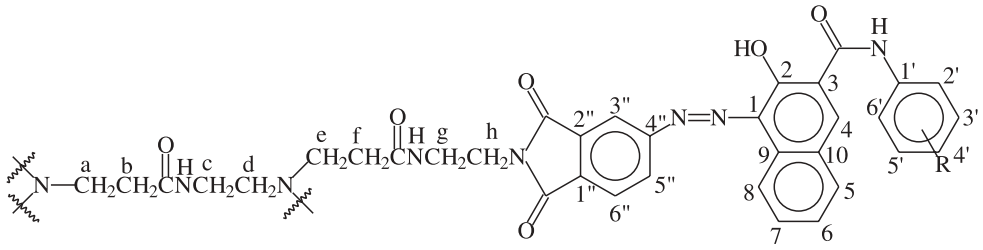
The model compounds (**17**, **18**) were first fully characterized. Formation of the cyclic imide linkage was indicated by the following: (*i*) ^1H NMR, the peak at 4.16 parts per million (ppm) being ascribed to the methylene protons attached to the cyclic imide nitrogen and (*ii*) IR C=O stretching bands for the naphthoic anhydrides, which shift to lower values because of the resonance effect of the imide linkage.

The naphthalimide azo-functionalized dendrimers (**13–16**) were insoluble in common organic solvents, making it difficult to obtain well-resolved ^1H and ^{13}C NMR spectra, even at a higher temperature and using a 10 mm NMR tube. Although complete NMR data of the dendrimers cannot be reported because of poor resolution of the spectra, peaks at 4.14 ppm and at ca. 6.9–8.6 ppm correspond to the characteristic methylene protons attached to the nitrogen of the cyclic imide and the protons of the azo moiety, respectively. Another characteristic for the dendrimers (**13–16**) is the shift of the C=O IR stretching frequencies to lower values, indicating formation of the cyclic imide linkage; e.g., 1658 and 1697 cm^{-1} for **13**, 1655 cm^{-1} for **14**, 1658 cm^{-1} for **15**, and 1696 and 1661 cm^{-1} for **16**.



The degree of functionalization was determined through comparison of the UV data of dendrimers **13–16** with that of model compound **17**, measured in two solvents to lessen the uncertainty in interpretation of the results because of azo-hydrazone tautomerism. The results (Table 3) showed that the endings of the G1 dendrimers are fully functionalized by the azo naphthalimide fragment. Note that UV data for the higher generations of the dendrimers (**13–2G**, **13–3G**) could not be obtained because of their insolubility.

The molecular weights of the first generation of the azo-modified dendrimers were determined by MALDI (matrix-assisted laser desorption ionization) MS, Table 3 (MALDI results for the higher generations of the dendrimers (2nd G and 3rd G) could not be obtained because of their insolubility). The mass data of the dendrimers **13–1G** to **16–1G** are reasonably close to calculated values for the six-sites functionalized by the azo naphthalimide fragment, which places some confidence in the capacity of the UV method to allow for estimation of the degree of functionalization of the dendrimers.



Phthalimide azo derivatives

The synthetic design toward phthalimide azo derivatives of the PAMAM dendrimers was initially similar to that of the naphthalimide system, as follows: preparation of azo compounds containing the phthalic anhydrides, followed by cyclic imide formation with PAMAM dendrimers. However, difficulty was encountered in formation of the cyclic imide linkage because of ring strain in the five-membered phthalimide ring, contrasting with the six-membered ring in the naphthalimide system. When more vigorous reaction

24

conditions (i.e., high reaction temperature, 150–200 °C) were attempted (11), the azo chromophore was found to be unstable. Hence, an alternative synthetic strategy for this system was employed, as described in Scheme 3. The cyclic imide reaction between 4-nitrophthalic anhydride and the PAMAM dendrimers was first carried out at high temperature (130–150 °C), which was followed by catalytic hydrogenation to produce the corresponding amine derivatives and then diazo coupling with the couplers. For the synthesis of higher dendrimer generations (2nd G and 3rd G), naphthol AS-RL (**21** R^1 = H, R^2 = OMe, R^3 = H) was used as the coupler in the diazo coupling.

Formation of the cyclic imide linkage for dendrimer **19** was confirmed by ^{1}H and ^{13}C NMR, i.e., chemical shifts data for the CH_2 attached to the cyclic imide nitrogen (3.65 ppm in ^{1}H NMR and 36.57 ppm in ^{13}C NMR). The degree of functionalization in dendrimer **19** (G1, molecular weight 2093) was determined by MS (FAB+) ([M + 1]), which showed a peak at 2094, indicating full functionalization.

The model compound **25** was synthesized as an aid for structural verification of the phthalimide azo-functionalized dendrimers **20**–**23**. The ^{13}C NMR spectra (not shown) for the aromatic portion of **25** and of the dendrimer **21**–**1G** were compared. The similarity of the chemical shifts in the two ^{13}C NMR spectra provides confirmatory evidence for the structure of the dendrimer **21**. Another piece of information obtained from the ^{13}C NMR spectra (not shown) was that the peak corresponding to the CH_2 attached to the cyclic imide nitrogen appears at 36.82 ppm, in accord with the formation of the cyclic imide linkage. The cyclic imide linkage of the dendrimers (**20**–**23**) can be confirmed by the similar IR stretching frequency of the C=O group for the model and dendrimer compounds, e.g., 1770 and 1712 cm^{-1} for dendrimer **21** and 1769 and 1711 cm^{-1} for model compound **25**.

The UV data (measured in two solvents) of the phthalimide azo-functionalized dendrimers **20**–**23** are compared with that of the model compound **25** in Table 4. The results in 1,4-dioxane indicate that for 1G and 2G dendrimers, one site remains unfunctionalized, while for the 3G dendrimer, two sites are not functionalized by the phthalimide azo fragment. Note that the results in 2,2,2-trifluoroethanol (TFE) are slightly different from those in 1,4-dioxane, owing to an increase in the azo tautomer with dendrimer generations in TFE (10). Molecular weights of the dendrimers were also determined by MALDI MS and are summarized in Table 4. The MS data of the dendrimers (1G) are comparable to five-sites azo-functionalized dendrimers.

Thermal stability studies and xerographic properties

The thermal stability of the azo-functionalized dendrimers was evaluated by thermogravimetric analysis (TGA). The results of TGA weight-loss data obtained at 300 °C are summarized in Table 5. The TGA results of the azo-

functionalized dendrimers may be compared with those of the non-functionalized PAMAM dendrimers to investigate the effect of the azo moiety on thermal stability.

According to Table 5, the thermal stability of the azo-functionalized dendrimers shows no clear correlation with different substituents and with dendrimer generations. However, the azo-functionalized dendrimers are, in general, thermally more stable than the non-functionalized PAMAM dendrimers. The naphthalimide azo-functionalized dendrimers show especially good thermal stability (TGA wt loss ≈ 5% up to 300 °C). It can therefore be concluded that the thermal stability of the PAMAM dendrimers is increased through functionalization by the azo moiety.

Conclusions

In summary, three systems of the azo-functionalized PAMAM dendrimers were synthesized by different synthetic routes. The synthetic methods for the naphthalimide azo and the phthalimide azo systems were found to be more efficient than for the phenylazo system in terms of high yield, easy work-up, and high degree of functionalization. Significantly, formation of the six-membered cyclic imide in the naphthalimide azo system gave fully functionalized denderimers by the naphthalimide azo fragment. On the other hand, nucleophilic substitution involving *p*-fluoronitrobenzene and the dendrimeric amines employed for the phenylazo system revealed the limitation of the degree of functionalization with the higher dendrimer generations. ^1H and ^{13}C NMR and IR spectroscopy were employed to confirm structural identification of the dendrimers. Mass spectrometry (ES and MALDI) and UV–vis spectrophotometry (comparison of UV–vis data of the dendrimer compounds with those of the model compounds) were useful in the determination of the degree of functionalization. Thermogravimetric analysis showed that azo-functionalization increased the thermal stability of the PAMAM dendrimers.

Since one of the purposes of this study was to synthesize electronic materials that can show improved xerographic properties, and continuing with our investigations with dye and pigment molecules (e.g., azo (12), azoxy (13), spiropyran (14), and squaraine (15) dyes), the xerographic properties of the azo-modified dendrimers prepared will also be determined, via single-discharge measurements, surface potential vs. exposure (SPE) measurements, spectral sensitivity measurements, and xerographic cyclic stability measurements (16). The results of these studies will be reported in due course.

Experimental

Compounds synthesized were characterized by a combination of ^1H NMR, ^{13}C NMR, UV, IR, and mass spectroscopy and melting point and elemental analysis. ^1H and ^{13}C NMR spectra were obtained with a Bruker AM400 (^1H, 400.1 MHz; ^{13}C, 100.6 MHz) or Bruker AC - F 200 spectrometer (^1H, 200.1 MHz; ^{13}C, 50.3 MHz). Normally, $CDCl_3$

© 2004 NRC Canada

and DMSO-d_6 were used as the solvents and served as deuterium lock standards. Chemical shifts are reported in parts per million (ppm) relative to residual $CHCl_3$ (δ ^1H = 7.24 ppm, δ ^{13}C = 77 ppm) and DMSO (δ ^1H = 2.50 ppm, δ ^{13}C = 49 ppm) in the solvents. Infrared spectra were obtained using a Bomen MB - 120 spectrophotometer with samples prepared as KBr disks. The low-resolution MS results were recorded with a Fison's VG Quattro (Triple-Quadrople MS–MS). Several techniques were used, as follows: chemical ionization (CI), fast atom bombardment (FAB), and electrospray (ES). MALDI (matrix-assisted laser desorption ionization) technique was used for dendrimer compounds. MALDI MS results were recorded with a Kompact MALDI III by Kratos Analytical, with sinapinic acid as the matrix. High-resolution MS analyses were performed at either the University of Ottawa (Ontario) or the Scripps Research Institute of California. UV–vis absorption spectra were obtained using a Hewlett-Packard HP8452A Diode Array spectrophotometer fitted with a thermostated cell compartment. Melting points were measured using a Thomas Hoover apparatus and are uncorrected. Elemental analyses were performed by Canadian Microanalytical Service Ltd., Delta, B.C.

For UV–vis spectrophotometric studies, the solvents DMSO and EtOH were purified by distillation from calcium hydride and magnesium, respectively (17). Other organic solvents used in this study were the following: *N*,*N*-dimethylformamide (DMF), 2,2,2-trifluoroethanol (TFE), acetonitrile, toluene, chloroform, 1,4-dioxane, acetone, methanol, and hexane. These solvents were of spectroscopic grade and were purified, when necessary, according to literature procedures (17).

Stock solutions (0.1–1 mmol) of the dendrimer compounds were prepared by accurately weighing 1–10 mg and dissolving these in 1–5 mL of DMF or DMSO in volumetric flasks, which were wrapped in aluminum foil so as to prevent possible photochemical processes. Stock solutions (1–10 mmol) of the model compounds were prepared in $CHCl_3$ or DMF and were stored in the refrigerator. All UV–vis spectra in this study were obtained by injecting 20–50 µL of the stock solution into a 10 mm cell containing 2.5 mL of the solvent, followed by shaking the cell a few times and allowing a few seconds to pass to allow any air bubbles entrapped on mixing to escape, before taking the spectrum.

Compounds were purified by a combination of several techniques, as follows: thin layer and column chromatography, recrystallization, sonication, and ultrafiltration. Thin layer chromatography (TLC) was performed using silica gel 60 F_{254} plates (BDH) in various eluting solvent systems. Silica gel 60 (BDH, 230–400 mesh) was used for column chromatography. An Amicon ultrafiltration cell model 8400 was used for purification of high generations of the dendrimers. A Branson model 2200 sonication bath was used in all experiments requiring sonication.

The couplers (naphthol AS-RL, naphthol AS-BG, and naphthol AS-BS) for the diazo coupling reactions were supplied by Xerox Research Centre of Canada (XRCC). Various generations of polyamidoamine (PAMAM) dendrimers (1–4 G) were purchased from Michigan Molecular Institute, while the other starting materials were obtained from Aldrich Chemical Company.

Preparation of dye compounds

Phenylazo derivatives of the PAMAM dendrimers

*p-Nitrophenyl derivative of PAMAM dendrimer (**1**)*

The first generation polyamidoamine dendrimer (0.50 g, 0.48 mmol) was dissolved in 10 mL absolute ethanol, and to this was added 4-fluoronitrobenzene (0.41 g, 2.9 mmol), and the reaction mixture was refluxed for about 12 h. The solvent was removed in a rotary evaporator; the yellow oil was dissolved in 50 mL water, and the aqueous solution was washed four times with 50 mL portions of chloroform to remove any unreacted 4-fluoronitrobenzene. Removal of the water in a rotary evaporator gave 0.60 g of product (71% yield) as a yellow oil.

The synthetic method for the *p*-nitrophenylation of the 2nd, 3rd, and 4th generation (G) of PAMAM followed closely the above. The yields obtained were as follows: 2nd G (81%), 3rd G (85%), and 4th G (85%). The NMR characteristics of the *p*-nitrophenyl derivative of the PAMAM dendrimer 1G (**1**) are as follows:

1: ^1H NMR (DMSO-d_6) δ: 8.16 (outer amide NH, s), 7.96 (H_3, d), 7.86 (inner amide NH, s), 6.65 (H_2, d), 3.89 (NH, s), 3.08 (H_g, H_c, t), 2.79 (H_h, t), 2.63 (H_d, t), 2.42 (H_e, H_a, t), 2.20 (H_f, H_b, t). ^{13}C NMR (DMSO-d_6) δ: 171.88 (C=O-outer), 171.46 (C=O-inner), 154.46 (C_1), 135.70 (C_4), 126.22 (C_3), 110.75 (C_2), 52.11 (C_d), 49.59 (C_e, C_a), 41.87 (C_g), 37.71 (C_h), 36.90 (C_c), 33.23 (C_b, C_f).

*p-Aminophenyl derivative of polyamidoamine dendrimer (**2**)*

To a solution of dendrimer **1** (0.65 g, 0.37 mmol) in 150 mL of a 1:1 (volume fraction) mixture of water–ethanol in a glass Parr shaker bottle was added palladium on charcoal (100 mg of 5% Pd–C). The reaction mixture was pressurized to 45 psi (1 psi = 6.894 kPa) of hydrogen, and the Parr hydrogenation apparatus was shaken at room temperature for about 12 h. The reaction mixture was then filtered to remove the Pd–C, and the solvent was removed in vacuo to give the products **2–1G** (89% yield), **2–2G** (83%), **2–3G** (81%), and **2–4G** (34%).

2: ^1H NMR (DMSO-d_6) δ: 8.01 (outer amide NH, s), 7.83 (inner amide NH, s), 6.39 (H_2, H_3, m), 3.82 (NH_2, NH, s), 3.17 (H_g, H_c, t), 2.95 (H_h, t), 2.65 (H_d, t), 2.42 (H_e, H_a, t), 2.20 (H_f, H_b, t). ^{13}C NMR (DMSO-d_6) δ: 171.61 (C=O-outer), 171.19 (C=O-inner), 139.97 (C_4), 139.12 (C_1), 115.53 (C_2), 113.67 (C_3), 52.14 (C_d), 49.65 (C_e, C_a), 43.89 (C_g), 36.90 (C_h), 35.95 (C_c), 33.30 (C_b, C_f).

Phenylazo derivatives of PAMAM dendrimers

To a solution of the *p*-aminophenyl polyamidoamine dendrimer derivative **2–1G** (0.58 g, 0.37 mmol) in aqueous hydrochloric acid (0.64 mL concd HCl and 2 mL water) cooled below 2 °C in ice-water was added, slowly with stirring, a solution of sodium nitrite (0.15 g, 2.20 mmol) in 2 mL water. The resulting diazonium salt solution was coupled with various couplers (naphthol AS, naphthol AS-BG, naphthol AS-RL, and naphthol AS-BS). The diazo-coupling reaction with naphthol AS as the coupler is described below.

To the solution of the diazonium salt solution was added, slowly with stirring, naphthol AS (0.58 g, 2.2 mmol) in 6 mL *N*,*N*-dimethylformamide (DMF) and 1.8 mL 10%

aqueous sodium hydroxide solution, keeping the temperature below 2 °C, which gave a purplish-red precipitate. After all the diazonium salt solution had been added, the reaction mixture was allowed to stand in an ice bath for 1 h with stirring. The resulting precipitate was filtered and washed with cold water several times to remove residual DMF. The unreacted naphthol AS in the crude product was removed by soxhlet extraction with acetonitrile to give 0.48 g of pure product (39% yield, mp 216–218 °C).

The diazo-coupling reaction with other couplers (naphthol AS-RL, naphthol AS-BG, and naphthol AS-BS) was carried out by same method as above. Naphthol AS-RL azo derivative (**4**; 10% yield, mp > 250 °C); naphthol AS-BG azo derivative (**5**; 10% yield, mp 182–184 °C); naphthol AS-BS azo derivative (**6**; 14% yield, mp 188–190 °C). The diazo coupling reaction between higher generations of the aminophenyl derivative of the dendrimer (2G, 3G, and 4G) and naphthol AS was carried out by same method as above. 2G (20% yield, mp 178–180 °C); 3G (12% yield, mp 207–209 °C); 4G (14% yield, mp 211–213 °C). The characteristics of the phenylazo derivatives of the PAMAM dendrimers are as follows:

Naphthalimide azo derivatives of the PAMAM dendrimers

4-Amino 1,8-naphthoic anhydride

This compound is commercially available but, because of its high cost, was instead synthesized in 97% yield by the hydrogenation (Pd–C catalyst) of 4-nitro 1,8-naphthoic anhydride.

Azo naphthoic anhydrides (9–12)

To a solution of 4-amino-1,8-naphthoic anhydride (0.82 g, 3.85 mmol) in 100 mL DMF and 10 mL water, cooled to 2 °C, was added concd. HCl (1.60 mL, 10.9 mmol), and to the cooled reaction mixture was added, slowly with stirring, a solution of sodium nitrite (0.37 g, 3.85 mmol) in 6 mL water. The resulting diazonium salt solution was coupled with various couplers (naphthol AS, naphthol AS-RL, naphthol AS-BG, and naphthol AS-BS). **9** (58% yield, mp > 250 °C); **10** (64% yield, mp > 250 °C); **11** (66% yield, mp > 250 °C); **12** (77% yield, mp > 250 °C).

The characteristics of the azo naphthoic anhydrides (**9**–**12**) are as follows:

9–12

*R = H (**9**)*: IR (KBr disk) (cm^{-1}): 3133, 1773, 1734, 1675, 1596, 1308, 1154, 1011, 817, 757, 693, 541. ^1H NMR (DMSO-d_6) δ: 13.39 (O-H, s, 1H), 9.27 (H_5, d, 1H), 9.20 ($H_{5''}$, d, 1H), 8.70 (H_4, s, 1H), 8.53 ($H_{7''}$, d, 1H), 8.49 ($H_{2''}$, d, 1H), 8.07 ($H_{3''}$, d, 1H), 7.96 ($H_{6''}$, t, 1H), 7.80 ($H_{2'}$, $H_{6'}$, d, 1H), 7.80 (H_8, d, 2H), 7.62 (H_6, t, 1H), 7.40 ($H_{3'}$, $H_{5'}$, t, 2H), 7.28 ($H_{4'}$, d, 1H), 7.10 (H_7, t, 1H). Naphthalimide azo derivatives of PAMAM dendrimers

The PAMAM 1G dendrimer (33.5 mg, 0.029 mmol) solution (8.8% in methanol) was evaporated to remove the methanol, and the residue was dissolved in 2 mL 1-methyl-2-pyrrolidinone (NMP). The resulting dendrimer solution was added to a solution of azo naphthol-AS naphthoic anhydride **9** (0.1 g, 0.21 mmol) and DABCO (39.4 mg, 0.35 mmol) in 5 mL, and the reaction mixture was stirred at 85 °C for 2 h. After cooling to room temperature, 200 mL of toluene was added, and the precipitate that formed was filtered, washed with toluene and petroleum ether, and dried at 80 °C for about 12 h. The crude product was sonicated in water for 10 min to remove protonated DABCO and unreacted PAMAM. After filtration, the solid was sonicated in acetone for 10 min to remove excess DABCO and unreacted azo starting compound. The solid obtained on filtration was checked by TLC using acetone as eluent; this showed the absence of starting materials and DABCO. The yields and mp are as follows: **13**–**1G** (81%, 242–244 °C); **13**–**2G** (68%, 234–236 °C); **13**–**3G** (69%, 241–243 °C); **14** (81%, >250 °C); **15** (50%, >250 °C); **16** (75%, 244–246 °C).

The characteristics of the azo naphthalimide deivatives of PAMAM dendrimers are as follows:

*Azo napthol AS derivative (1G), **13**–**1G***

IR (KBr disk) (cm^{-1}): 3376, 2892, 2361, 1941, 1697, 1658, 1589, 1546, 1011, 777, 755. ^1H NMR (DMSO-d_6) δ: 9.0–7.1 (aromatic protons, broad m), 4.2 (NH, s), 3.5 (H_g, H_c, bs), 2.9 (H_h, bs), 2.6 (H_d, bs), 2.4 (H_e, H_a, bs), 2.2 (H_f, H_b, bs). Model naphthalimide derivatives of PAMAM dendrimers

The reaction conditions for synthesis of the model compounds (**17**, **18**) were closely similar to those for the dendrimer compounds; *n*-$BuNH_2$ was used as a model amine for the PAMAM dendrimer. **17** (29% yield, mp > 250 °C); **18** (28% yield, mp > 250 °C).

The characteristics of the model naphthalimide derivatives of the PAMAM dendrimers (**17** and **18**) are as follows:

17, 18

R = H (17): IR (KBr disk) (cm^{-1}): 3215, 2933, 1697, 1659, 1588, 1547, 1353, 1008, 767, 750. ^{1}H NMR ($CDCl_3$) δ: 14.10 (O-H, s, 1H), 11.12 (amide NH, s, 1H), 8.93 (H_4, s, 1H), 8.66 ($H_{5''}$, d, 1H), 8.62 ($H_{2''}$, d, 1H), 8.44 ($H_{7''}$, d, 1H), 8.40 (H_5, d, 1H), 8.29 ($H_{3''}$, d, 1H), 7.93 ($H_{6''}$, t, 1H), 7.76 ($H_{2'}$, $H_{6'}$, d, 2H), 7.70 (H_8, d, 1H), 7.65 (H_6, t, 1H), 7.49 (H_7, t, 1H), 7.38 ($H_{3'}$, $H_{5'}$, t, 1H), 7.15 ($H_{4'}$, t, 1H), 4.16 (H_a, t, 2H), 1.71–1.36 (H_b, H_c, m, 4H), 0.99 (H_d, t, 3H). ^{13}C NMR ($CDCl_3$) δ: 179.53 (C_2), 163.18 (C=O amide), 162.65 (C=O at $C_{1''}$), 161.19 (C=O at $C_{8''}$), 150.57 (C_4), 141.84 ($C_{4''}$), 138.09 ($C_{1'}$), 134.50 (C_{10}), 133.11 ($C_{1''}$), 132.19 ($C_{2''}$), 131.73 (C_8), 131.70 ($C_{5''}$), 131.56 (C_6), 129.17 (C_9), 129.05 ($C_{3'}$), 128.24 (C_7), 127.74 ($C_{6''}$), 127.24 (C_3), 126.29 (C_1), 125.77 ($C_{7''}$), 124.60 ($C_{4'}$), 123.58 ($C_{8''}$), 122.53 (C_5), 121.57 ($C_{10''}$), 120.79 ($C_{2'}$), 119.88 ($C_{9''}$), 112.96 ($C_{3''}$), 40.39 (C_a), 30.24 (C_b), 20.42 (C_c), 13.84 (C_d). Phthalimide azo derivatives of the PAMAM dendrimers

Phthalimide azo derivatives of PAMAM dendrimers

Cyclic imide formation between the PAMAM dendrimer and 4-nitrophthalic anhydride was carried out as follows: To a solution of 4-nitrophthalic anhydride (1.25 g, 6.48 mmol) in 5 mL NMP was added a solution of PAMAM (0.97 g, 0.93 mmol) and DABCO (0.63 g, 5.55 mmol) dissolved in 5 mL NMP, and the reaction mixture was stirred at 130 °C for 40 min. After cooling to room temperature, 200 mL of toluene was added to give a white precipitate, which was washed with toluene and acetone several times to remove excess starting materials. Yield 78% (**19–1G**); 88% (**19–2G**); 90% (**19–3G**). The characteristics of compound **19** are as follows:

19

IR (KBr disk) (cm^{-1}): 3288, 3073, 2948, 1781, 1720. 1656, 1539, 1437, 1396, 1348, 1194, 1160, 1063, 720. ^{1}H NMR (DMSO-d_6) δ: 8.59 (H_5, dd), 8.47 (H_3, d), 8.10 (H_6, d), 8.02 (outer amide NH, s), 7.70 (inner amide NH, s), 3.65 (H_h, t), 3.30 (H_c, H_g, t), 2.61 (H_d, t), 2.36 (H_a, H_e, t), 2.29 (H_b, H_f, t). ^{13}C NMR (DMSO-d_6) δ: 171.63 (outer C=O), 171.02 (inner C=O), 166.31 (C=O at C_1), 166.03 (C=O at C_2), 151.31 (C_4), 136.38 (C_2), 133.11 (C_1), 129.47 (C_6), 124.46 (C_5), 117.68 (C_3), 52.01 (C_d), 48.47 (C_e, C_a), 44.38 (C_g), 36.57 (C_h), 32.94 (C_c), 30.09 (C_b, C_f). MS *m/z* (FAB^+) calcd. for $C_{93}H_{99}N_{25}O_{33}$: 2093.7; found: 2094.0 ([M + 1]).

The nitro compound (**19**) was reduced by hydrogenation in the presence of Pd–C catalyst to give the amino derivative used for the diazo coupling reaction with the couplers (naphthol AS, AS-RL, AS-BG, and AS-BS). The experimental procedure for the diazo coupling reaction followed standard reaction conditions and gave the following yields and mp: **20** (58%, 230–232 °C); **21** (63%, 218–220 °C); **21–2G** (31%, 218–221 °C); **21–3G** (38%, 225 to 226 °C); **22** (56%, 220–222 °C); **23** (55%, 231–233 °C).

The characteristics of azo phthalimide derivatives of PAMAM dendrimers are as follows:

20–23

Model phthalimide derivatives of PAMAM dendrimers

The experimental procedure for the model azophthalimide derivatives of the PAMAM dendrimer was identical to that used for the dendrimers.

The cyclic imide reaction between 4-nitrophthalic anhydride and *n*-$BuNH_2$ was carried out according to literature procedure (18), to give **24** (81% yield). The NMR and IR characteristics of **24** are as follows:

24

IR (KBr disk) (cm^{-1}): 3111, 3055, 2948, 2870, 1771, 1702, 1623, 1536, 1439, 1402, 1347, 1069, 1051, 940, 866, 710, 603. ^{1}H NMR (DMSO-d_6) δ: 8.62 (H_5, dd, 1H), 8.48 (H_3, d, 1H), 8.11 (H_6, d, 1H), 3.61 (H_a, t, 2H), 1.62–1.26 (H_b, H_c, m, 4H), 0.90 (H_d, t, 3H). ^{13}C NMR (DMSO-d_6) δ: 166.30 (C=O at C_2), 166.03 (C=O at C_1), 151.30 (C_4), 136.31 (C_2), 133.04 (C_1), 129.48 (C_6), 124.40 (C_5), 117.69 (C_3), 37.66 (C_a), 29.80 (C_b), 19.43 (C_c), 13.43 (C_d).

Hydrogenation of the nitro compound **24** in the presence of Pd–C catalyst gave the amino compound (93% yield), which was used for the standard diazo coupling reaction with coupler (naphthol AS-RL), giving the model compound (**25**); 82% yield, mp 169 to 170 °C.

The characteristics of the model compound (**25**) are as follows:

IR (KBr disk) (cm^{-1}): 3246, 2940, 2867, 2863, 1769, 1711, 1672, 1608, 1544, 1499, 1445, 1382, 1245, 1199, 1158, 1010, 822, 748, 533. ^{1}H NMR ($CDCl_3$) δ: 14.94 (OH, s, 1H), 11.03 (amide NH, s, 1H), 8.84 (H_4, s, 1H), 8.31 (H_5, d, 1H), 8.02 ($H_{3''}$, d, 1H), 7.86 ($H_{6''}$, d, 1H), 7.75 ($H_{5''}$, dd, 1H), 7.63 ($H_{2'}$, d, 1H), 7.60 (H_6, t, 1H), 7.60 (H_8, d, 1H), 7.40 (H_7, t, 1H), 6.85 ($H_{3'}$, d, 1H), 3.79 (OCH_3, s, 3H), 3.69 (H_a, t, 2H), 1.68 (H_b, m, 2H), 1.40 (H_c, m, 2H), 0.97 (H_d, t, 3H). ^{13}C NMR ($CDCl_3$) δ: 178.42 (C_2), 167.22 (C=O at $C_{1''}$), 167.11 (C=O at $C_{2''}$), 159.83 (C=O at C_3), 155.82 ($C_{4'}$), 149.20 (C_4), 146.00 ($C_{4''}$), 134.06 ($C_{1'}$), 133.71 ($C_{2''}$), 131.48 (C_6), 131.17 (C_{10}), 130.82 (C_8), 130.52 (C_9), 128.31 ($C_{1''}$), 127.32 (C_7), 126.36 (C_3), 125.33 (C_1), 124.37 ($C_{6''}$), 121.92 (C_5), 121.04 ($C_{5''}$), 120.89 ($C_{2'}$), 113.60 ($C_{3'}$), 111.24 ($C_{3''}$), 55.15 (OCH_3), 37.86 (C_a), 30.53 (C_b), 20.05 (C_c), 13.59 (C_d). MS *m/z* (CI+): 523.3 ([M + 1]). MS *m/z* (high-resolution FAB+) calcd. for $C_{30}H_{27}O_5N_4$: 523.1981; found: 523.1970. Anal. calcd. for $C_{30}H_{26}N_4$ (MW 523.20): C 68.94, H 4.98, N 10.73; found: C 68.20, H 5.14, N 10.74.

Studies of thermal stability

Thermal analyses were performed under N_2 using a high-resolution TGA 2950 Thermogravimetric Analyzer at a heating rate of 20 °C/min.

Regioselectivity in S_NH reactions of some 3-nitro-1,5-naphthyridines with chloromethyl phenyl sulfone

Maria Grzegożek and Barbara Szpakiewicz

Abstract: 3-Nitro-1,5-naphthyridine and its 2-substituted derivatives react with the carbanion of chloromethyl phenyl sulfone to give hydrogen-substitution products at position 4 in high yield. The intermediacy of 4-(phenylsulfonyl)-chloromethyl σ adducts of 2-R-3-nitro-1,5-naphthyridines (R = H, D, Cl, OC_2H_5, $NHCH_3$, OH) was established by ^1H NMR spectroscopy. A convenient synthesis of 2-*N*-methylamino-3-nitro-1,5-naphthyridine is reported.

Key words: 3-nitro-1,5-naphthyridines, anionic (phenylsulfonyl)chloromethyl σ adducts, vicarious nucleophilic substitution.

Résumé : La 3-nitro-1,5-naphtyridine et ses dérivés substitués en position 2 réagissent avec le carbanion de la chlorométhyl(phényl)sulfone pour conduire à la formation de produits de substitution de l'hydrogène en position 4, avec des rendements élevés. Faisant appel à la spectroscopie RMN du ^1H, on a établi que les adduits σ 4-(phénylsulfonyl)chlorométhyle des 2-R-3-nitro-1,5-naphtyridines (R = H, D, Cl, OC_2H_5, $NHCH_3$, OH) sont impliqués comme intermédiaires dans ces réactions. On rapporte une méthode pratique de synthèse de la 2-*N*-méthylamino-3-nitro-1,5-naphtyridine.

Mots clés : 3-nitro-1,5-naphtyridines, adduits anioniques σ du (phénylsulfonyl)chlorométhyle, substitution nucléophile indirecte.

[Traduit par la Rédaction]

Introduction

Our interest in the reactivity of nitronaphthyridines towards nucleophilic agents induced us to study the reaction of vicarious nucleophilic substitution of hydrogen (VNS), as described by Mąkosza (1). In a previous paper we reported that 3-nitro-1,8-naphthyridine and some of its 2-substituted derivatives undergo VNS reactions with chloromethyl phenyl sulfone to the corresponding 4-(phenylsulfonyl)methyl-3-nitro-1,8-naphthyridines (2).

Extending these studies, we investigated the VNS reactions of chloromethyl phenyl sulfone with 2-R-3-nitro-1,5-naphthyridines (R = H, D, Cl, OC_2H_5, $NHCH_3$, OH) (**1a**–**e**). Nitronaphthyridines, applied as substrates, were obtained according to literature procedures (3–6), except for 2-*N*-methylamino-3-nitro-1,5-naphthyridine (**1d**). The new compound **1d** was prepared by the reaction of 2-chloro-3-nitro-1,5-naphthyridine (**1b**) with a saturated methanol solution of methylamine (see Experimental section).

The S_NH reactions occur very selectively and give, exclusively, products of substitution at position 4. They were carried out in the following base–solvent system: sodium hydroxide – dimethyl sulfoxide.

The reaction process takes place between 3-nitro-1,5-naphthyridines (**1**) and the carbanion generated from chloromethyl phenyl sulfone (Scheme 1). In the first step, addition of the carbanion to the nitro compound **1** results in the formation of σ adduct **2**, which undergoes base-induced β-elimination of HCl to form a carbanion that is subsequently protonated during the workup procedure, giving product **3**.

3-Nitro-1,5-naphthyridine (**1a**) reacts with chloromethyl phenyl sulfone very easily to give, in high yield (87%), 3-nitro-4-(phenylsulfonyl)methyl-1,5-naphthyridine (**3a**). The structure of compound **3a** was proved by ^1H NMR spectroscopy. In the ^1H NMR spectrum of **3a**, besides the presence of double doublets of 6-H and 8-H, a multiplet (7-H) of the unsubstituted pyridine ring, the phenyl multiplet (δ 7.58–7.38), and a CH_2 singlet (δ 5.96), a singlet of 2-H in the region at δ 9.53 was observed. This observation showed that substitution had occurred in either the 2 or 4 position. To be able to distinguish between substitution at the 2 or 4 position, we synthesized 2-deuterio-3-nitro-1,5-naphthyridine (**1a′**, R = D) and found that in the ^1H NMR spectrum of the product (obtained after the reaction with chloromethyl phenyl sulfone), the singlet at δ 9.53 was absent. Since, in the ^1H NMR spectra of the compounds **3b**–**e**, no singlet in the range δ 9.25–8.46 is present, the conclusion that substitu-

[a]The signals of these protons form a complex multiplet and cannot be exactly assigned.

tion in **1b**–**e** has also occurred at the C-4 position is justified.

All experimental results show that for the 3-nitro-1,5-naphthyridines **1a**–**e**, the C-4 position is strongly favoured in the attack of the carbanion of chloromethyl phenyl sulfone (Scheme 1); likewise, in the reaction of 3-nitro-1,8-naphthyridines with chloromethyl phenyl sulfone (2).

To confirm that the intermediates in the above-mentioned reactions are detectable anionic σ adducts like **2**, we measured the ^{1}H NMR spectra of 3-nitronaphthyridines **1a**–**e** in a solution of NaOD in DMSO, containing 1.1 equiv. of chloromethyl phenyl sulfone. In the spectra, it was observed that nearly all signals are shifted upfield, particularly the signals of the protons at the carbon atoms that form σ adducts. Addition of the carbanion of chloromethyl phenyl sulfone to the sp^2 carbon atom of 3-nitronaphthyridines induces a change in its hybridization, from sp^2 to sp^3 (tetrahedral centre of σ adduct). This change is reflected in a considerable upfield shift of the signal of the hydrogen atom attached to that particular carbon atom. This rehybridization — sp^2 to sp^3 — is due to the σ adduct formation. The corresponding ^{1}H NMR data of 3-nitro-1,5-naphthyridines **1a**–**e** and their (phenylsulfonyl) chloromethyl σ adducts **2a**–**e** are compiled in Table 1.

The upfield shift, Δδ, of the signals of the C-4 hydrogen atom at the tetrahedral centre of the 4-(phenylsulfonyl)-chloromethyl σ adducts **2a**–**e** lie between 2.56–3.51 parts per million (ppm) and are in the same range as those found for the amino σ adducts of some 3-nitro-1,5-naphthyridines (Δδ, 2.55–3.81 ppm (2)) and for σ adducts of nitroquinolines with chloromethyl phenyl sulfone (Δδ, 2.90–4.11 ppm (7)). To explain whether we observed the first addition step in our study, we measured the ^{1}H NMR spectrum of 2-chloro-3-nitro-1,5-naphthyridine (**1b**) in a solution of NaOD in

© 2004 NRC Canada

DMSO, containing 1.1 equiv. of methyl phenyl sulfone instead of chloromethyl phenyl sulfone. In this case, if the first addition step takes place, the second stage of the reaction (elimination of HCl) cannot occur. It was observed that the value of the upfield shift ($\Delta\delta$) of the signal of the C-4 hydrogen atom that forms the σ adduct is the same ($\Delta\delta$ 3.39) as the case with chloromethyl phenyl sulfone (**2b**; Table 1). As shown by ^{1}H NMR spectroscopy, all of the compounds **1a–e** undergo covalent addition at C-4 when dissolved in a solution of NaOD in DMSO with chloromethyl phenyl sulfone, to give intermediate 4-(phenylsulfonyl)chloromethyl σ adducts **2a–e** (Table 1). In the case of **1a**, additional evidence that addition has taken place at C-4 and not at C-2 was provided by the ^{1}H NMR spectrum of 2-deuterio-3-nitro-1,5-naphthyridine, performed under the above-mentioned conditions. The spectrum showed the signal of the C-4 hydrogen at 5.77 ppm and its upfield shift $\Delta\delta$ 3.40 ppm. These values are identical to the 4-H of **2a** (Table 1).

Summary

In conclusion, all the results of the experimental data and the ^{1}H NMR study of the anionic intermediate (phenylsulfonyl)chloromethyl σ adducts indicate that the C-4 position in the 3-nitro-1,5-naphthyridines is strongly favoured for the attack of the carbanion of chloromethyl phenyl sulfone, and these results also confirm the regioselectivity of the studied *vicarious* S_NH reaction.

Experimental

Melting points (uncorrected) were determined on a Kofler plate. The ^{1}H NMR spectra were recorded on Mercury 300 varian (300 MHz) and Tesla BS-587A (80 MHz) spectrometers. The infrared spectra were recorded on a Bio-Rad FTS-175C spectrometer (in potassium bromide pellets). The mass spectra were recorded on an LKB GC–MS 9000 spectrometer.

Synthesis of starting and reference compounds

3-Nitro- (**1a** (3)), 2-deuterio-3-nitro- (**1a′** (4)), 2-chloro-3-nitro- (**1b** (4)), 2-ethoxy-3-nitro- (**1c** (5)), and 2-hydroxy-3-nitro-1,5-naphthyridine (**1e** (6)) were prepared according to the literature procedures. Chloromethyl phenyl sulfone was obtained from sodium benzenesulfinate and dichloroacetic acid (8). Methyl phenyl sulfone was prepared from tiophenol (9).

*2-*N*-Methylamino-3-nitro-1,5-naphthyridine 1d*

2-Chloro-3-nitro-1,5-naphthyridine (100 mg, 0.35 mmol) was dissolved in 8 mL of saturated methanol solution of methylamine at room temperature. A change of colour from light cream to red was observed. After 1 h, precipitated red needles were filtered off and washed with cold methanol to yield 50 mg of **1d**, mp 165–167 °C. The methanol filtrates were evaporated to 3 mL. Additionally, 6 mg of **1d** was obtained. Yield 58%. Reaction of 3-nitro-1,5-naphthyridines 1a–e with chloromethyl phenyl sulfone

General procedure

To a stirred suspension of powdered sodium hydroxide (100 mg, 2.5 mmol) in dimethyl sulfoxide (2 mL), a solution of the respective 3-nitro-1,5-naphthyridines **1a–e** (0.25 mmol) and chloromethyl phenyl sulfone (47 mg, 0.25 mmol) was added at room temperature (temp.). The reaction mixture was stirred for 2 h at room temp. Then the mixture was poured into 50 mL of a 5% aqueous solution of acetic acid. The crude products were filtered off, washed with water, dried, and crystallized from convent solvent, as described below.

3-Nitro-4(phenylsulfonyl)methyl-1,5-naphthyridine, 3a

Pale cream needles (71 mg, 87%) with mp 204 to 205 °C (*iso*-PrOH). IR (ν_{max})(cm^{-1}): 1532 (NO_2, as), 1349 (NO_2, s), 1318, 1163 (SO_2). ^{1}H NMR ($CDCl_3$) δ: 9.53 (s, 2H), 8.90 (d.d, 6-H), 8.46 (d.d, 8-H), 7.73 (m, 7-H), 7.58–7.38 (m, Ph), 5.96 (s, CH_2), $J_{6,7}$ = 3,8 Hz, $J_{6,8}$ = 1,6 Hz, $J_{7,8}$ = 8,67 Hz. MS (70 eV) *m/z* (%): 265 ([M$^+$ – SO_2]), 248 (64, [M$^+$ – SO_2 – OH]), 188 ([M$^+$ – SO_2Ph]). Anal. calcd. for $C_{15}H_{11}N_3O_4S$ (329.34): C 54.71, H 3.37, N 12.76; found: C 54.37, H 3.33, N 12.41.

2-Deuterio-3-nitro-4(phenylsulfonyl)methyl-1,5-naphthyridine, 3a′

This compound was obtained in an identical manner to the compound **3a**, starting from 2-deuterio-3-nitro-1,5-naphthyridine. The ^{1}H NMR analysis showed that the content of deuterium in position 2 was >95%.

2-Chloro-3-nitro-4-(phenylsulfonyl)methyl-1,5-naphthyridine, 3b

Light cream needles (66 mg, 73%), mp 211 °C (MeOH). IR (ν_{max})(cm^{-1}): 1542 (NO_2, as), 1324 (NO_2, s), 1295, 1166 (SO_2). ^{1}H NMR (DMSO) δ: 8.84 (d, 6-H), 8.55 (d, 8-H), 7.91 (q, 7-H), 7.77–7.65 (m, Ph), 5.57 (s, CH_2), $J_{6,7}$ = 3.9 Hz, $J_{7,8}$ = 8.01 Hz. MS (70 eV) *m/z* (%): 299–301([M$^+$ – SO_2]), 282–284 (56–17, [M$^+$ – SO_2 – OH]), 222–224 ([M$^+$ – SO_2Ph]). Cyclization of 2-(2-bromoethoxy)-acetophenones and 5-(ω-haloalkoxy)-1,5-dihydro-2*H*-pyrrol-2-ones — Formation of five- to eight-membered oxygen-containing heterocycles via intramolecular alkylation

Kirill V. Nikitin and Nonna P. Andryukhova

Abstract: Under basic conditions (lithium diisopropylamide or sodium hydride in THF) 2-(2-bromoethoxy)-acetophenones were transformed to 3,4-dihydro[1]benzoxepin-5(2*H*)-ones (homochromanones) in high yields. The preparation of novel tetrahydropyrano[2,3-*b*]pyrrol-6(2*H*)-ones and 3,4-dihydro-2*H*-pyrrolo[2,1-*b*][1,3]oxazin-6(8*aH*)-ones and spiro compounds was performed using similar cyclization in moderate to good yields.

Key words: cyclization, lithiation, spiro heterocycles.

Résumé : Dans des conditions basiques (diisopropylamidure de lithium ou hydrure de sodium dans le THF), les 2-(2-bromoéthoxy)-acétophénones se transforment en 3,4-dihydro[1]benzoxépin-5(2*H*)-ones (homochromanones) avec des rendements élevés. Utilizant une méthode de cyclisation semblable, on a aussi réalisé la préparation, avec des rendements allant de moyens à bons, de nouvelles tétrahydropyrano[2,3-*b*]pyrrol-6(2*H*)-ones et de 3,4-dihydro-2*H*-pyrrolo[2,1-*b*][1,3]oxazin-6(8*aH*)-ones ainsi que de composés spiro apparentés.

Mots clés : cyclisation, lithiation, composés spiro hétérocycliques.

Introduction

The cyclization via intramolecular enolate alkylation is a well-known route to the synthesis of carbocycles (1, 2). However that chemistry has rarely been used for the preparation of saturated heterocycles. We applied intramolecular enolate coupling to the formation of an oxygen-containing ring fused to an aromatic ring or to another heterocyclic ring.

As a model to find the optimum conditions for the cyclization, the 3,4-dihydro[1]benzoxepin-(2*H*)-ones (homochromanones) **2** were chosen as a family of potentially appealing synthetic targets (Scheme 1). Homochromanones **2** can be prepared by acid-catalyzed intramolecular acylation of γ-aryloxybutyric acids (3, 4). The cyclization of 2-(δ-bromoalkyl)-phenol under basic conditions (5) leads to homochromans. Similar heterocylclic systems are available (6). Noteworthy, compounds **2** were extensively studied particularly as potent diabetes remedies (7).

We also studied the cyclization of bromoalkoxy-1,5-dihydro-2*H*-pyrrol-2-ones (Scheme 2) to get biologically important partially saturated fused pyrano[2,3-*b*]pyrroles **10** (8, 9) and pyrrolo[2,1-*b*][1,3]oxazines **11** (10). Substituted 1,5-dihydro-2*H*-pyrrol-2-ones are attracting a growing interest in synthetic chemistry for pharmacological and pesticide activity (11). The compounds **10** and **11** are unknown to the best of our knowledge though they most probably indicate biological activity (12–15).

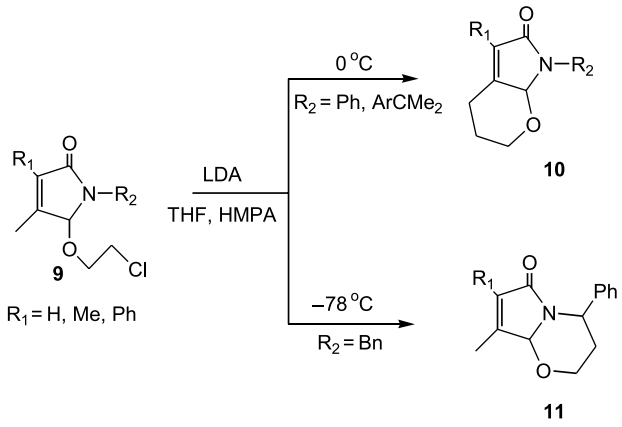
Results and discussion

The preparation of oxygen-containing heterocycles involved two steps. At the first step the carbonyl compound (hydroxylated ketone or pyrrolone) was conventionally converted into the corresponding ω-chloro- or bromoalkoxy derivative. At the second step the later derivative was cyclized in the presence of a strong base. That methodology has been successfully applied for the synthesis of **2** (Scheme 1), but limitations were found for the formation of eight- and nine-membered rings (**3**, **4**, respectively).



The availability of starting 2-(ω-bromoalkoxy)-ketones **5**–**8** depends upon the number *n* (Scheme 3). While the compounds **6a**–**6f** were obtained in good yields (52%–65%) along with considerable amount of corresponding bis(aryloxy)alkanes **13**, we failed to obtain 2-(bromomethoxy)acetophenone **5** ($n = 1$) by alkylation of 2-hydroxyacetophenone with methylene halides. Under phase transfer conditions (16) bis-(2-acetylphenoxy)methane **12** was solely produced. The attempts to use 1,2-dibromopropane and 2,3-dibromobutane as alkylating reagents were unsuccessful.

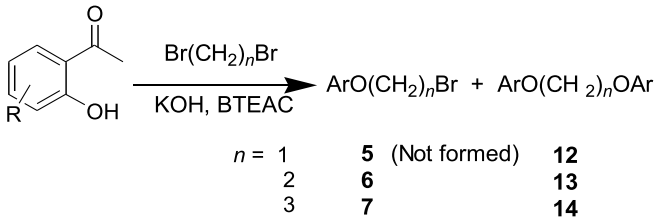
Scheme 1. Cyclization of 2-(ω-bromoalkoxy)-acetophenones).

Scheme 2. Transformations of 5-(2-chloroethoxy)-pyrrol-2-ones.



The cyclization of **6** to form **2** (Scheme 1) was performed in tetrahydrofuran (THF). In most cases (Table 1), the use of either lithium diisopropylamide (LDA) in the presence of hexamethylphosphoramide (HMPA) (conditions A, runs 1, 7, 9, 13, 15) or sodium hydride (conditions B, runs 2, 8, 10, 14, 16) allowed good yields of the cyclization product. The reaction with sodium hydride takes longer time but it is more convenient.

In the case of 2-(2-chloroethoxy)propiophenone **6f** no cyclization product was observed under either conditions A or B (Table 1, runs 11, 12). Instead, we found 2-hydroxypropiophenone as a sole product (run 11). It is likely that the abstraction of a proton from the -CH_2Cl group of **6f** is followed by formation of vinyl chloride and 2-propionylphenoxide anion.

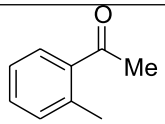
The attempts to convert **7** and **8** into corresponding eight- and nine-membered heterocycles (Table 1, runs 3–6) showed that ω-halogenated hydrocarbon chains were prone to elimination or intermolecular alkylation rather than intramolecular cyclization process. The transformation of 2-(3-bromopropoxy)acetophenone **7a** in the presence of LDA led mainly to 2-allyloxyketone (Table 1, run 3) via elimination. In the presence of NaH (run 4), 2,3,4,5-tetrahydro[1]benzoxocin-6-one was still obtained though in poor yield (22%). The application of weaker bases was expected to minimize the contribution of the elimination pathway; nevertheless, only the elimination product was found in the presence of KOBu-*t*, while in the presence of NaOEt no reaction took place.

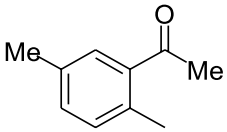
2-(4-Bromobutoxy)acetophenone **8a** in the presence of LDA (Table 1, run 5) furnishes an elimination product and intermolecular coupling products (Scheme 4). It is likely that the conformation of the ω-bromobutoxy chain of the respective enolate ion is unfavorable for intramolecular nucleophilic substitution. Under milder conditions in the presence of NaH (run 6) the concentration of enolate ion is lower and **8a** furnishes only the elimination product.

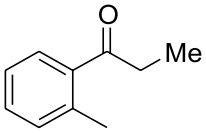
Scheme 3. Preparation of 2-(ω-bromoalkoxy)-acetophenones.

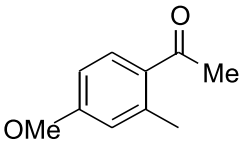
To apply the cyclization for the formation of a six-membered heterocyclic ring as a part of a fused heterocyclic system we studied the transformations of 5-chloroethoxy pyrrolones **9**. The starting materials **9** are directly available by etherification of the corresponding 5-hydroxy-1,5-dihydro-2*H*-pyrrol-2-ones (17).

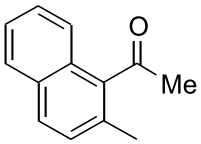
We found that a ring fused to the pyrrolone ring could be successfully locked in the presence of a strong base (LDA) giving rise to **10** or **11** (Scheme 2) in moderate to good yields. Preliminary results obtained for the intramolecular cyclization of **9a** (R_1 = 2-FC_6H_4, R_2 = 3,5-$Cl_2C_6H_3CMe_2$) are summarized in Table 2. The use of HMPA drastically improved the cyclization yield (runs 1, 2). Since the dilution of the initial reaction mixture increased the yield (run 3), it is anticipated that an intermolecular process competed with the cyclization pathway.











The syntheses of the compounds **10** and **11** (Table 3) were carried out under the optimum conditions found (Table 1, run 3). It is noteworthy that the formation of **10** proceeds relatively slow (1 h at 0 °C) and tolerates only phenyl or substituted α,α-dimethylbenzyl moieties at the nitrogen atom (Table 3, **10a**, **10b**). In the presence of a *tert*-butyl or an *iso*-propyl substituent at the nitrogen atom (Table 3, **10c**, **10d**) the cyclization fails.

The cyclization of **9**, containing a benzyl group at the nitrogen atom, led to **11** rather than **10** (Scheme 2). The process was unexpectedly fast compared to the formation of **10**. At –78 °C (Table 3, **11a**–**11c**), the reaction furnishes **11** from *N*-benzylated **9** (R_2 = $PhCH_2$). Rapid intramolecular alkylation of the benzyl carbon (formation of **11**) may account for the relatively high reactivity of the corresponding benzylic carbanion compared to the less reactive γ-anion of the α,β-unsaturated amide (formation of **10**). Nuclear Overhauser enhancement (NOE) measurements showed that irradiation of the proton at C8a in **11a** did not significantly enhance the signal of the proton at C4 (i.e., the benzylic position), compared to the considerable enhancement of the signal of the methyl protons. On the basis of NOE observations, we believe that the product **11a** has a 4,8a-*trans* configuration.

It appeared that the cyclization yield can be improved by the use of 2-bromoethoxy analogs of **9**. For example, the preparation of **10e** bearing base-susceptible 2-chloro-4-fluoro-5-hydroxyphenyl at the nitrogen is more successful (68% yield) when starting from the bromoethoxy compound (Table 3) than from the chloroethoxy derivative (20% yield).

1	0.1	0	2	7
2	0.1	4	1	45
3	0.04	4	1	67

We applied the cyclization methodology to the formation of spiro heterocyclic compounds. The cyclization of 3-(3-bromopropoxy)-2-phenyl-2,3-dihydro-isoindol-1-one **15** in the presence of LDA (Scheme 5) furnished in good yield (50%) only one possible cyclization spiro product (**16**).

At the same time, the cyclization of an analogous pyrrolone derivative **17** (Scheme 5) resulted in the formation of two possible cyclization products (**18** and **19**) in moderate yields.

Conclusively, intramolecular cyclization of (2-bromoalkoxy) derivatives of aromatic ketones or 2,5-dihydro-2*H*-pyrrol-2-ones leads to the formation of a fused oxygen-containing heterocyclic system and can be efficiently applied for the preparation of homochromanones and several novel heterocyclic systems using a simple two-step protocol.

Experimental

Tetrahydrofuran was distilled from benzophenone–sodium under nitrogen. Melting points were measured with a Thomas–Hoover capillary melting point apparatus and are not corrected. ^{1}H NMR spectra were recorded on a Varian GEMINI-200 spectrometer. All chemical sifts are in ppm (δ),

for 16 h, cooled, the organic layer was separated, washed with aq. NaOH, water, then dried ($MgSO_4$), evaported under reduced pressure, and subjected to column chtomatography separation (20% ethyl acetate – hexane) to afford 2-(2-bromoethoxy)-acetophenone (**6a**) (1.86 g, 65% yield) as a colorless solid; mp 45 °C. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.68 (s, 3H), 3.70 (t, 2H, J = 5.8 Hz), 4.39 (t, 2H, J = 5.8 Hz), 6.8–7.8 (m, 4H). MS (70 eV) m/z: 242, 244 (M + 2); and 1,2-bis(2-acetylphenoxy)-ethane (**13a**) (0.31 g, 20% yield) as colorless solid; mp 125 °C. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.59 (s, 6H), 4.50 (s, 4H), 6.9–7.1 (m, 4H), 7.5 (m, 2H), 7.7–7.8 (m, 2H). MS (70 eV) m/z: 298.

2-(3-Bromopropoxy)-acetophenone (**7a**) (1.5 g, 52% yield) was obtained from 2-hydroxyacetophenone (1.36 g) and 1,3-dibromopropane (**7g**) as a colorless liquid. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.37 (tt, 2H, $J_1 = J_2$ = 6.3 Hz), 2.59 (s, 3H), 3.61 (t, 2H, J = 6.3 Hz), 4.22 (t, 2H, J = 6.3 Hz), 6.9–7.8 (m, 4H). MS (70 eV) m/z: 286, 288 (M + 2); along with 1,3-bis(2-acetylphenoxy)-propane (**14a**) (0.30 g, 18% yield) as colorless solid; mp 107 °C. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.42 (quintet, 2H, J = 6.1 Hz), 2.62 (s, 6H), 4.30 (t, 4H, J = 6.1 Hz), 6.9–7.1 (m, 4H), 7.4–7.5 (m, 2H), 7.7–7.8 (m, 2H). MS (70 eV) m/z: 313 (M + 1).

2-(4-Bromobutoxy)-acetophenone (**8a**) (1.0 g, 33% yield) was obtained from 2-hydroxyacetophenone (1.36 g) and 1,4-dibromobutane (**8g**) as a colorless liquid. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.9–2.2 (m, 4H), 2.62 (s, 3H), 3.49 (t, 2H, J = 5.8 Hz), 4.10 (t, 2H, J = 5.8 Hz), 6.9–7.1 (m, 2H), 7.4–7.5 (m, 1H), 7.7–7.8 (m, 1H). MS (70 eV) m/z: 300, 302 (M + 2).

2-Bromomethoxy-acetophenone (**5a**) was not obtained from 2-hydroxyacetophenone (1.36 g) and dibromomethane (**7g**) but only 1,1-bis(2-acetylphenoxy)-methane (**12a**) (1 g, 70% yield) was obtained as colorless solid; mp 97 °C. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.59 (s, 6H), 5.93 (s, 2H), 7.0–7.75 (m, 8H). MS (70 eV) m/z: 149 (M – AcC_6H_4O).

2-(2-Bromoethoxy)-5-methylacetophenone (**6b**) (1.6 g, 62% yield) was obtained from 2-hydroxy-5-methylacetophenone (1.5 g) and 1,2-dibromoethane (**11g**) as a colorless solid; mp 66 °C. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.30 (s, 3H), 2.67 (s, 3H), 3.70 (t, 2H, J = 5.8 Hz), 4.38 (t, 2H, J = 5.8 Hz), 6.8–7.1 (m, 2H), 7.4 (m, 1H), 7.7 (m, 1H). MS (70 eV) m/z: 256, 258 (M + 2); along with 1,2-bis(2-acetyl-4-methylphenoxy)ethane (**13b**) (0.2 g, 12% yield) as a colorless solid; mp 127 °C. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.31 (s, 6H), 2.57 (s, 6H), 4.44 (s, 4H), 6.9 (m, 2H), 7.2–7.2 (m, 2H), 7.54 (s, 2H). MS (70 eV) m/z: 326.

2-(2-Bromoethoxy)-propiophenone (**6c**) (1.55 g, 60% yield) was obtained from 2-hydroxypropiophenone (1.5 g) and 1,2-dibromoethane (**11g**) as a colorless solid; mp 36 °C. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.17 (t, 3H, J = 7.1 Hz), 3.05 (t, 2H, J = 7.1 Hz), 3.69 (s, 3H), 3.69 (t, 2H, J = 5.9 Hz), 4.37 (t, 2H, J = 5.9 Hz), 6.8–7.7 (m, 4H). MS (70 eV) m/z: 256, 258 (M + 2); along with 1,2-bis(2-propionylphenoxy)ethane (**13c**) (0.3 g, 18% yield) as a colorless solid; mp 97 °C. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.08 (t, 6H, J = 7.3 Hz), 2.95 (quartet, 4H, J = 7.3 Hz), 4.45 (s, 4H), 7.0 (m, 4H), 7.4–7.6 (m, 2H), 7.7 (m, 2H). MS (70 eV) m/z: 326.

2-(2-Bromoethoxy)-4-methoxyacetophenone (**6d**) (1.65 g, 61% yield) was obtained from 2-hydroxy-4-methoxyacetophenone (1.66 g) and 1,2-dibromoethane (**11g**) as a colorless solid; mp 69 °C. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.65 (s, 3H), 3.72 (t, 2H, J = 5.8 Hz), 3.85 (s, 3H), 4.38 (t, 2H, J = 5.8 Hz), 6.39 (d, 1H, J = 2.2 Hz), 6.46 (dd, 1H, J = 2.2 Hz, J = 8.8 Hz), 7.87 (d, 1H, J = 8.8 Hz). MS (70 eV) m/z: 272, 274 (M + 2).

2-(2-Bromoethoxy)-acetonaphthone (**6e**) (1.0 g, 63% yield) was obtained from 2-hydroxyacetonaphthone (1.0 g) and 1,2-dibromoethane (**11** g) as a colorless solid; mp 89 °C. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.72 (s, 3H), 3.68 (t, 2H, J = 6 Hz), 4.48 (t, 2H, J = 6 Hz), 7.2–7.9 (m, 6H). MS (70 eV) m/z: 292, 294 (M + 2).

2-(2-Chloroethoxy)-propiophenone (**6f**) (1.32 g, 64% yield) was obtained from 2-hydroxypropiophenone (1.5 g) and 1,2-dichloroethane (**15** g) as a colorless solid; mp 56 °C. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.17 (t, 3H, J = 7.2 Hz), 3.05 (t, 2H, J = 7.2 Hz), 3.86 (t, 2H, J = 5.5 Hz), 4.32 (t, 2H, J = 5.5 Hz), 6.8–7.1 (m, 2H), 7.4 (m, 1H), 7.7 (m, 1H). MS (70 eV) m/z: 212; along with **13c** (0.22 g, 14% yield).

Pyrrolones **9a**–**9i**, **15**, and **17** were prepared via the standard procedure including reduction of maleimides (17, 18).

1-(α,α-Dimethyl-3,5-dichlorobenzyl)-3-(2-fluorophenyl)-4-methyl-5-(2-chloroethoxy)-(2,5)-dihydro-2-pyrrolone (**9a**) as a colorless oil. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.79 (s, 3H), 1.88 (s, 3H), 2.04 (s, 3H), 3.4–3.7 (m, 4H), 5.75 s (s, 1H), 7.0–7.4 (m, 7H).

1-Phenyl-3,4-dimethyl-5-(2-chloroethoxy)-(2,5)-dihydro-2-pyrrolone (**9b**) as a colorless oil. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.90 (s, 3H), 2.03 (s, 3H), 3.2–3.5 (m, 4H), 5.79 (s, 1H), 7.1–7.8 (m, 5H).

1-Isopropyl-3,4-dimethyl-5-(2-chloroethoxy)-(2,5) dihydro-2-pyrrolone (**9c**) was obtained as a colorless oil. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.22 (d, 6H, J = 7 Hz), 1.72 (s, 3H), 184 (s, 3H), 3.15 (m, 1H), 3.5 (m, 3H), 4.11 (m, 1H), 5.23 (s, 1H).

1-*tert*-Butyl-3,4-dimethyl-5-(2-chloroethoxy)-(2,5)-dihydro-2-pyrrolone (**9d**) was obtained as a colorless oil. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.47 (s, 9H), 1.76 (s, 3H), 1.88 (s, 3H), 3.2 (m, 1H), 3.6 (m, 3H), 5.37 (s, 1H).

1-(2-Fluoro-4-chloro-5-hydroxyphenyl)-3,4-dimethyl-5-(2-chloroethoxy)-(2,5)-dihydro-2-pyrrolone (**9e**) was obtained as a solid; mp 148 °C. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.92 (s, 3H), 2.05 (s, 3H), 3.3–3.7 (m, 4H), 5.75 (s, 1H), 6.79 (s, 1H), 7.0–7.3 (m, 2H).

1-(2-Fluoro-4-chloro-5-hydroxyphenyl)-3,4-dimethyl-5-(2-bromoethoxy)-(2,5)-dihydro-2-pyrrolone (**9f**) was obtained as a solid; mp 149 °C. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.90 (s, 3H), 2.05 (s, 3H), 3.3–3.7 (m, 4H), 5.74 (s, 1H), 6.9–7.3 (m, 2H).

1-Benzyl-4-methyl-5-(2-chloroethoxy)-(2,5)-dihydro-2-pyrrolone (**9g**) was obtained as a colorless oil. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.92 (s, 3H), 3.2–3.5 (m, 4H), 4.12 (d, 1H, J = 15 Hz), 4.8 (d, 1H, J = 15 Hz), 5.06 (s, 1H), 5.89 (s, 1H), 7.25 (s, 5H).

1-Benzyl-3,4-dimethyl-5-(2-chloroethoxy)-(2,5)-dihydro-2-pyrrolone (**9h**) as a colorless oil. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.80 (s, 3H), 1.83 (s, 3H), 3.1–3.5 (m, 4H), 4.17 (d, 1H, J = 15 Hz), 4.83 (d, 1H, J = 15 Hz), 4.99 (s, 1H), 7.25 (s, 5H).

1-Benzyl-3-phenyl-4-methyl-5-(2-chloroethoxy)-(2,5)-dihydro-2-pyrrolone (**9i**) was obtained as a colorless oil. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.11 (s, 3H), 3.3–3.6 (m, 4H),

3-(3-Bromopropoxy)-2-phenyl-2,3-dihydro-isoindol-1-one (**15**) was obtained as a solid; mp 107 °C. ^1H NMR (200 MHz, $CDCl_3$) δ: 1.8 (m, 2H), 3.03.3 (m, 4H), 6.42 (9s, 1H), 7.15 (t, 1H, *J* = 8 Hz), 7.37 (t, 2H, *J* = 8 Hz), 7.5 (m, 3H), 7.73 (d, 2H, *J* = 8 Hz), 7.84 (d, 1H, *J* = 8 Hz).

5-(3-Bromopropoxy)-3,4-dimethyl-2-phenyl-1,5-dihydro-4-methyl-2*H*-pyrrol-2-one (**17**) was obtained as a solid; mp 68 °C. ^1H NMR (200 MHz, $CDCl_3$) δ: 1.95 (s, 3H), 2.0 (m, 2H), 2.04 (s, 3H), 3.2–3.4 (m, 4H), 5.76 (s, 1H), 7.16 (t, 1H, *J* = 8 Hz), 7.40 (t, 2H, *J* = 8 Hz), 7.77 (d, 2H, *J* = 8 Hz).

3,4-Dihydro[1]benzoxepin-5(2*H*)-ones (2)

Method A

Into a nitrogen-purged flask equipped with a stirrer and cooled to –78 °C (dry ice acetone bath), THF (5 mL) and diisopropylamine (0.152 g, 1.5 mmol) were charged, then BuLi (1.5 mmol as 2.5 mol L^{-1} solution) was added. After 30 min a solution of **6** (0.5 mmol) in 5 mL of THF was added slowly followed by HMPA (0.3 mL, 1.5 mmol). The reaction mixture was stirred at –78 °C for 15 min and was warmed up to between 0–5 °C (ice bath). After 1.5 h a methanolic HCl (1 mL, 1 mol L^{-1}) was added. The mixture was concentrated, extracted with ethyl acetate, the extract washed with water, and dried ($MgSO_4$). Column chromatography gave **2**.

Method B

Into a nitrogen-purged flask equipped with a stirrer, NaH (0.100 g 60% dispersion in oil, 2 mmol) was charged, the mixture was cooled to 0 °C (ice bath) and a solution of **6** (1 mmol) in 5 mL THF was added. The mixture was warmed to 25 °C, kept for 80 h, and 1 mL of methanolic HCl was added. The mixture was concentrated, the residue was extracted with ethyl acetate, washed with water, and dried ($MgSO_4$). Column chromatography furnished **2**.

Characterization data for compounds **2** were in good accordance with the literature and are summarized in Table 4.

2,3,4,5-Tetrahydro-6*H*-1-benzoxocin-6-one (3a)

Method A

3a was not found. Only 2-allyloxyacetophenone was isolated as a colorless liquid. ^1H NMR ($CDCl_3$–TMS) δ: 2.64 (s, 3H), 4.63 (d, 2H, *J* = 5.3), 5.32 (d, 1H, *J* = 11), 5.45 (d, 1H, *J* = 17), 6.0–6.2 (m, 1H), 7.0 (m, 2H), 7.4 (m, 1H), 7.72 (d, 1H, *J* = 6). MS *m/z*: 176 (M^+).

Method B

3a was isolated as a colorless liquid and 2-allyloxyacetophenone (20% yield) was also obtained.

Attempted preparation of 3,4,5,6-tetrahydro-1-benzoxonin-7(2*H*)-one (4a)

Method A

4a was not found. The isolated products were: 2-(1-buten-4-yloxy)-acetophenone (28% yield) as a colorless liquid. ^1H NMR ($CDCl_3$–TMS) δ: 2.63 (s, 3H), 2.6 (m, 2H), 4.13 (t, 2H, *J* = 6.3), 5.2 (m, 2H), 5.95 (m, 1H), 6.9 (m, 2H), 7.4 (m, 1H), 7.7 (d, 1H, *J* = 8). MS *m/z*: 190 (M^+); 5-(2-acetylphenoxy)-pentyl-2′-(1-buten-4-yloxy)-phenyl ketone (20% yield) as a colorless liquid. ^1H NMR ($CDCl_3$–TMS) δ: 1.5–2.0 (m, 6H), 2.62 (m, 3H), 2.6 (m, 2H), 3.05 (d, 2H, *J* = 7), 4.0–4.2 (m, 4H), 5.2–5.3 (m, 2H), 5.8 (m, 1H), 6.9 (m, 4H), 7.4 (m, 2H), 7.7 (m, 2H). MS *m/z*: 381 (M + 1); 5-(2-acetylphenoxy)-pentyl-2′-(4-bromobutyloxy)phenyl ketone (15% yield) as a colorless liquid. ^1H NMR ($CDCl_3$–TMS) δ: 1.5–2.0 (m, 6H), 2.0 (m, 4H), 2.62 (s, 3H), 3.03 (t, 2H, *J* = 7), 3.47 (t, 2H, *J* = 7), 4.1 (m, 4H), 6.9 (m, 4H), 7.5 (m, 2H), 7.5–7.8 (m, 2H). MS *m/z*: 462, 464 (M + 2).

Method B

4a was not found. 2-(1-Buten-4-yloxy)-acetophenone (20% yield) was isolated.

3,4,7,7a-Tetrahydro-5-(2-fluorophenyl)-7-(α,α-dimethyl-3,5-dichloro-benzyl)-pyrano[2,3-*b*]pyrrol-6(2*H*)-one (10a)

All reactions were carried out under a nitrogen atmosphere. To a mixture of 2 mol L^{-1} LDA solution in hexane

© 2004 NRC Canada

(1 mL) and dry THF (12 mL) at –78 °C (a dry ice bath) a solution of 5-(2-chloroethoxy)-1-(α,α-dimethyl-3,5-dichlorobenzyl)-3-(2-fluorophenyl)-1,5-dihydro-4-methyl-2*H*-pyrrol-2-one (**9a**) (0.439 g, 0.96 mmol) in dry THF (12 mL) was added with vigorous stirring. Then dry HMPA (0.72 g, 4 mmol) was added dropwise and the mixture was stirred for 15 min at –78 °C. The mixture was allowed to warm to 0 °C and was stirred at this temperature for 1 h. The reaction mixture was quenched with 1 mol L^{-1} methanolic HCl (2 mL) and the solvent was evaporated to give an oily residue. The residue was separated by flash chromatography using silica and hexane – ethyl acetate (4:1) to give 0.269 g (67%) of **10a** as a colorless solid, mp 135 to 136 °C (ethyl acetate). ^{1}H NMR ($CDCl_3$) δ: 1.76 (s, 3H, CH_3), 1.78 (s, 3H, CH_3), 1.85 (m, 2H, CH_2), 2.5 (m, 1H), 2.8 (m, 1H), 3.75 (m, 1H, CH_2O), 4.1 (m, 1H, CH_2O), 5.25 (s, 1H, C_8-H), 7.0–7.5 (m, 7H, aryl protons). MS *m*/*z*: 419 (M^+, 8%), 233 (M^+ – CH_2=CMe-Ar, 16%). Anal. calcd. for $C_{22}H_{20}Cl_2FNO_2$: C 62.85, H 4.76, N 3.33; found: C 62.86, H 4.82, N 3.39.

3,4,7,7a-Tetrahydro-5-methyl-7-phenyl-pyrano[2,3-*b*]pyrrol-6(2*H*)-one (**10b**) was obtained as a colorless solid; mp 109 to 110 °C (ethyl acetate). ^{1}H NMR ($CDCl_3$) δ: 1.8 (m, 2H, CH_2), 1.84 (s, 3H, CH_3), 2.35 (m, 1H), 2.85 (m, 1H), 3.7 (m, 1H, CH_2O), 4.1 (m, 1H, CH_2O), 5.29 (s, 1H, C8-H), 7.11 (t, *J* = 8.3 Hz, 1H, Ph), 7.35 (t, *J* = 8.3 Hz, 2H, Ph), 7.72 (d, *J* = 8.3 Hz, 2H, Ph). ^{13}C NMR ($CDCl_3$) δ: 170.1, 148.0, 136.9, 128.7, 127.1, 122.6, 120.4, 91.5, 64.1, 30.3, 29.0, 9.1. MS *m*/*z*: 229 (M^+, 18%), 214 (M^+ – CH_3, 20%). Anal. calcd. for $C_{14}H_{15}NO_2$: C 73.36, H 6.55, N 6.11; found: C 73.31, H 6.65, N 6.11.

3,4,7,7a-Tetrahydro-5-methyl-7-(2-fluoro-4-chloro-5-hydroxyphenyl)-pyrano[2,3-*b*]pyrrol-6(2*H*)-one (**10e**) was obtained as a colorless solid; mp 158 °C (ethyl acetate). ^{1}H NMR ($CDCl_3$) δ: 1.88 (s, 3H), 1.6–2.0 (m, 2H, CH_2), 2.4 (m, 1H), 2.9 (m, 1H), 3.7 (m, 1H, CH_2O), 4.1 (m, 1H, CH_2O), 5.30 (s, 1H, C8-H), 7.1 (m, 2H, aryl). ^{13}C NMR ($CDCl_3$) δ: 169.7, 150.2, 149.0, 147.9, 124.6, 122.6, 118.2, 117.5, 110.6, 99.5, 65.1, 31.0, 30.2, 9.6. MS *m*/*z*: 297 (M^+, 17%). Anal. calcd. for $C_{14}H_{13}ClFNO_3$: C 56.48, H 4.40, N 4.70; found: C 56.70, H 4.27, N 4.92.

Spiro[2-phenyl-1-isoindolinone-2′-tetrahydrofuran] (16)

To a mixture of 2 mol L^{-1} LDA solution in hexane (1 mL) and dry THF (10 mL) at –78 °C (a dry ice bath), a solution of **15** (0.173 g, 0.5 mmol) in dry THF (1 mL) was added with vigorous stirring. Dry HMPA (0.18 g, 1 mmol) was then added dropwise and the mixture was allowed to warm to room temperature for 1 h. The reaction mixture was quenched by 1 mol L^{-1} HCl in methanol (2 mL), and the solvent was evaporated to give an oily residue. The residue was separated by flash chromatography to give **16** (0.067 g, 50%) as a colorless solid; mp 118 °C (ethyl acetate). ^{1}H NMR ($CDCl_3$) δ: 1.6 (m, 1H), 2.1 (m, 1H), 2.3 (m, 2H), 4.0–4.2 (m, 2H), 7.4–7.65 (m, 8H), 7.80 (d, 1H, *J* = 7.5 Hz). ^{13}C NMR ($CDCl_3$) δ: 166.90, 147.88, 135.97, 133.00, 130.96, 129.69, 129.51, 129.46, 128.35, 123.92, 121.75, 100.33, 70.38, 35.57, 26.58. MS *m*/*z*: 265 (M^+). Anal. calcd. for $C_{17}H_{15}NO_2$: C 76.96, H 5.70, N 5.28; found: C 76.56, H 5.64, N 5.07.

Spiro[5-(1-phenyl-3,4-dimethyl-1,5-dihydro-4-methyl-2*H*-pyrrol-2-one)-2′-tetrahydrofuran] (18) and 6-methyl-8-phenyl-2,3,4,5,8,8a-hexahydro-oxepino[2,3-*b*]pyrrol-7-one (19)

To a solution of **17** (0.162 g, 0.5 mmol) in dry THF (10 mL), 1.5 mol L^{-1} LDA solution in hexane (1 mL) at –78 °C (a dry ice bath) was added with vigorous stirring. Dry HMPA (0.18 g, 1 mmol) was then added dropwise and the mixture was allowed to warm to 0 °C for 1 h. The reaction mixture was quenched by a 1 mol L^{-1} HCl solution in methanol (2 mL), and the solvent was evaporated to give an oily residue. The residue was separated by chromatography to give **18** (0.039 g, 32%) and **19** (0.044 g, 36%). **18**: a colorless glassy solid. ^{1}H NMR ($CDCl_3$) δ: 1.6 (m, 1H), 1.88.(s, 3H), 1.94 (s, 3H), 2.1 (m, 1H), 2.3 (m, 2H), 4.0–4.2 (m, 2H), 7.4–7.65 (m, 8H), 7.80 (d, 1H, *J* = 7.5 Hz). ^{13}C NMR ($CDCl_3$) δ: 170.2, 150.5, 136.5, 129.3, 129.1, 128.3, 127.7, 101.4, 70.5, 32.5, 26.6, 10.3, 8.7. MS *m*/*z*: 243 (M^+, 8%), 228 (M – CH_3, 10%). Anal. calcd. for $C_{15}H_{17}NO_2$: C 74.06, H 7.04, N 5.76; found: C 73.90, H 7.16, N 5.56. **19**: a colorless glassy solid. ^{1}H NMR ($CDCl_3$) δ: 1.5 (m, 1H), 1.8 (m, 2H), 1.93 (s, 3H), 2.0 (m, 1H), 2.4 (m, 1H), 2.8 (m, 1H), 3.4–3.7 (m, 2H), 5.82 (s, 1H), 7.16 (t, 1H, *J* = 8Hz), 7.40 (t, 2H, *J* = 8 Hz)), 7.71 (d, 1H, *J* = 7 Hz). ^{13}C NMR ($CDCl_3$) δ: 170.5, 151.9, 138.1, 131.4, 129.2, 124.7, 121.0, 90.0, 64.9, 32.0, 27.2, 26.6, 8.6. MS *m*/*z*: 243 (M^+, 9%). Anal. calcd. for $C_{15}H_{17}NO_2$: C 74.06, H 7.04, N 5.76; found: C 73. 77, H 6.92, N 5.73.

3,4-Dihyro-8-methyl-4-phenyl-2*H*-pyrrolo[2,1-*b*][1,3]-oxazin-6(8a*H*)-one (11a)

All reactions were carried out under a nitrogen atmosphere. To the mixture of 2 mol L^{-1} LDA solution in hexane (1 mL) and dry THF (10 mL) at –78 °C (a dry ice bath) a solution of 1-benzyl-5-(2-chloroethoxy)-1,5-dihydro-4-methyl-2*H*-pyrrol-2-one (0.255 g, 0.96 mmol) in dry THF (5 mL) was added with vigorous stirring. Dry HMPA (0.90 g, 5 mmol) was then added dropwise and the mixture was stirred at –78 °C for 1 h. The reaction mixture was quenched by 1 mol L^{-1} methanolic HCl (2 mL), and the solvent was evaporated to give an oily residue. The residue was separated by flash chromatography to give 0.088 g (40%) of **11a** as a colorless solid; mp 114 to 115 °C (ethyl acetate). ^{1}H NMR ($CDCl_3$) δ: 2.02 (s, 3H, CH_3), 2.2 (m, 2H, C_3-CH_2), 3.74 (m, 1H, CH_2O), 4.0 (m, 1H, CH_2O), 5.05 (s, 1H, C8a-H), 5.54 (s, 1H, C4-H), 5.98 (s, 1H, =CH), 7.1–7.5 (m, 5H, Ph). MS *m*/*z*: 229 (M^+, 10%), 214 (M^+ – CH_3, 14%). Anal. calcd. for $C_{14}H_{15}NO_2$: C 73.36, H 6.55, N 6.11; found: C 73.32, H 6.63, N 6.17.

3,4-Dihydro-7,8-dimethyl-4-phenyl-2*H*-pyrrolo[2,1-*b*][1,3]-oxazin-6(8a*H*)-one (**11b**) was obtained as a colorless solid, mp 64 to 65 °C (ethyl acetate). ^{1}H NMR ($CDCl_3$) δ: 1.85 (s, 3H, CH_3), 1.92 (s, 3H, CH_3), 2.2 (m, 2H, C_3-CH_2), 3.7 (m, 1H, CH_2O), 4.0 (m, 1H, CH_2O), 4.97 (s, 1H, C8a-H), 5.52 (s, 1H, C_4-H), 7.2–7.4 (m, 5H, Ph). MS *m*/*z*: 243 (M^+, 11%), 228 (M^+ – CH_3, 10%). Anal. calcd. for $C_{15}H_{17}NO_2$: C 74.06, H 7.04, N 5.76; found: C 74.04, H 7.24, N 5.78.

3,4-Dihydro-8-methyl-4,7-diphenyl-2*H*-pyrrolo[2,1-*b*][1,3]-oxazin-6(8a*H*)-one (**11c**) was obtained as a colorless oil. ^{1}H NMR ($CDCl_3$) δ: 2.14 (s, 3H, CH_3), 2.2 (m, 2H, C_3-H), 3.85

© 2004 NRC Canada

(m, 1H, CH_2O), 4.1 (m, 1H, CH_2O), 5.14 (s, 1H, C8a-H), 5,64 (d, J = 4.5 Hz, 1H, C4-H), 7.2–7.5 (m, 10H, phenyls). MS m/z: 305 (M^+, 6%), 290 ($M^+ - CH_3$, 5%). Anal. calcd. for $C_{20}H_{19}NO_2$: C 78.68, H 6.23, N 4.59; found: C 78.43, H 6.48, N 4.57.

3-Amino-1-hydroxyacetone

Nisar Ullah, Clara Nanfe Fali, and Ian D. Spenser

Abstract: 3-Amino-1-hydroxypropan-2-one (3-amino-1-hydroxyacetone) was prepared in an overall yield of 52% in 6 steps starting with *N*-phthaloylglycine. This synthesis is readily adaptable for the preparation of bond-labeled samples, i.e., samples that are labeled intramolecularly at contiguous sites.

Key words: 3-amino-1-hydroxyacetone, 3-amino-1-hydroxypropan-2-one.

Résumé : On a préparé la 3-amino-1-hydroxypropan-2-one (3-amino-1-hydroxyacétone), avec un rendement global de 52 %, en six étapes à partir de la *N*-phtaloylglycine. La synthèse peut facilement être adaptée à la préparation d'échantillons portant des marqueurs intramoléculaires sur des sites voisins.

Mots clés : 3-amino-1-hydroxyacétone, 3-amino-1-hydroxypropan-2-one.

[Traduit par la Rédaction]

Introduction

3-Amino-1-hydroxyacetone 1-O-phosphate (**2**), derived by oxidative decarboxylation of 4-hydroxy-L-threonine 4-O-phosphate (**1**), serves as a precursor of the C_3N unit, N-1,C-6,5,5′ of vitamin B_6 (**3**) in *Escherichia coli* (Scheme 1) (1).

In connection with our continuing investigations of the biosynthesis of vitamin B_6 in *E. coli* (2) and in yeast (3–5), we required a sample of aminohydroxyacetone that was intramolecularly contiguously $^{13}C,^{13}C$ or $^{15}N,^{13}C$ labeled, i.e., bond labeled. None of the reported syntheses of the compound (6–8) were readily adaptable to this purpose, since the starting materials employed in these synthetic sequences are not available in labeled form. The synthetic sequence here described starts from *N*-phthaloylglycine (**4**). Several syntheses of labeled samples of this compound, from commercially available labeled starting materials in almost quantitative yields, have been reported (see Scheme 2) in connection with the preparation of labeled samples of δ-aminolevulinic acid.

The preparation of the following singly and multiply labeled samples of *N*-phthaloylglycine (**4**) has been described: 1-^{14}C- (9–11), 1-^{13}C- (12–14), 2-^{13}C- (13–15), 1,2-$^{13}C_2$- (15), ^{15}N- (13, 14), 1-^{13}C,^{15}N- (16), 2-^{13}C,^{15}N- (16), and 1,2-$^{13}C_2$,^{15}N- (17). The corresponding acyl chloride (**5**), which was obtained quantitatively on treatment of the acid with thionyl chloride (9–17), was then converted into δ-aminolevulinic acid by several different routes.

In one of these routes, the labeled phthaloylglycyl chloride (**5**) was treated with diazomethane, an Arndt–Eistert reaction that was originally described by Balenović (18), yielding the correspondingly labeled 1-diazo-3-phthalimidopropan-2-one (**6**) (9, 10, 17), which was then used in the next step of the synthetic sequence, leading to labeled δ-aminolevulinic acid.

In the present preparation of aminohydroxyacetone, an acid-catalyzed decomposition of the diazo compound (**6**) (18) gave 1-hydroxy-3-phthalimidopropan-2-one (**7**), the *N*-phthaloyl derivative of the desired product. However, attempts to obtain (**10**) by hydrolytic removal of the phthaloyl group of (**7**) were unsuccessful.

The phthaloyl unit was removed by reaction with hydrazine. Before doing so, the keto group of (**7**) had to be protected. This was done by reaction with ethyleneglycol to yield 2-hydroxymethyl-2-phthalimidomethyl-1,3-dioxolane (**8**). This compound had been prepared previously by somewhat different reaction sequences (19, 20). Treatment of the ketal (**8**) with hydrazine, followed by dilute HCl, gave 2-hydroxymethyl-2-aminomethyl-1,3-dioxolane hydrochloride (**9**). For hydrolysis, the ketal was suspended in aqueous acetonitrile, and the mixture was refluxed in the presence of an ion-exchange resin, from which the product, 3-amino-1-hydroxyacetone hydrochloride (**10**), was eluted with 2 mol L^{-1} HCl and obtained in high yield.

When acetone, in place of acetonitrile, was employed as the solvent in the above procedure, the yield of product was less than 40%. Other methods used to carry out the deprotection of **9** were entirely unsuccessful. Attempted hydrolysis of **9** with HCl, with HCl in THF solution, or with CF_3CO_2H was unsuccessful, as was attempted hydrolysis with pyridinium *p*-toluenesulfonate (0.33, 0.66, 1.0, 1.5, and 2.0 g equiv.) and with *p*-toluenesulfonic acid in acetone at reflux temperature for 24 h. Hydrolysis with dilute sulfuric acid and cerium ammonium nitrate was successful, but the product could not be isolated since it could not be separated from the other water-soluble solids.

The unlabeled aminohydroxyacetone (**10**) was employed in two displacement experiments to test whether the compound serves as an intermediate in the biosynthesis of vitamin B_6 from glucose in yeast, as it does in *E. coli* (1).

Scheme 1. Biosynthetic origin, in *E. coli*, of the C_3N unit N-1,C-6,5,5′ of pyridoxine phosphate.

1 **2** **3**

Scheme 2. Synthesis of 3-amino-1-hydroxyacetone.

Incorporation of label from [$^{13}C_6$]glucose into pyridoxamine was not displaced by aminohydroxyacetone (**10**), either in *Saccharomyces cerevisiae* or in *Candida utilis* (5). This result made it unlikely that incorporation of a label from a sample of this compound into vitamin B_6 would be observed in these yeasts. The preparation of bond-labeled samples of aminohydroxyacetone was therefore not pursued.

Experimental

N-Phthaloylglycyl chloride (5) (18)

Phthaloylglycine (**4**) (15.4 g, 75 mmol) was suspended in thionyl chloride (21 mL, 40.2 g, 336 mmol), and the mixture was refluxed until a clear solution was obtained (ca. 35 min). Excess thionyl chloride was pumped off in vacuo,

© 2004 NRC Canada

and the residue solidified to yield the product (**5**) as a light yellow crystalline mass. mp 85 to 86 °C (lit. (18) value mp 84 to 85 °C). Yield 16.7 g, 99%. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.93–7.89 (m, 2H), 7.80–7.76 (m, 2H), 4.82 (s, 2H). ^{13}C NMR (75.5 MHz) δ: 169.0, 166.6, 134.6, 131.5, 123.9, 47.5.

1-Diazo-3-phthalimidopropan-2-one (6) (18)

Phthaloylglycyl chloride (**5**) (10.7 g, 48 mmol) in 500 mL dry ether was treated with excess diazomethane (generated from 49 g methylnitronitrosoguanidine in 500 mL dry ether, adding 112 mL 40% KOH). The product crystallized from the ether solution after being kept at room temperature overnight. It was recrystallized from ethyl acetate. mp 163–165 °C (with decomposition (decomp.)) after sintering from 158 °C (lit. (18) value mp 168 °C (decomp.)). Yield 11.0 g (98%). IR (KBr pellet) (cm^{-1}) ν: 2128, 1774, 1733, 1629. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.88–7.86 (m, 2H), 7.76–7.74 (m, 2H), 5.40 (s, 1H), 4.44 (s, 2H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 186.5, 167.6, 134.2, 132.0, 123.6, 53.8, 44.1. MS (CI, NH_3) *m/z* (%): 247 (70, [M + NH_4^+]), 202 (100, [M – N_2 + H^+]). MS (DEI) *m/z* (%): 201 (43, [M – N_2^+], 160 (15, [M – $COCHN_2^+$]).

1-Hydroxy-3-phthalimidopropan-2-one (7)

1-Diazo-3-phthalimidopropan-2-one (**6**) (10.9 g, 47.6 mmol) was suspended in dilute sulfuric acid (20% volume fraction) and stirred at 50 °C for 3 h until all the solid had gone into solution. The mixture was then extracted with ethyl acetate, and the solution was dried over $CaCl_2$. The solvent was removed, and the product was recrystallized from ethanol. Yield 9.3 g (82%). mp 119–121 °C (lit. (18) value mp 121 °C, rising to 142 °C on recrystallization). ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.91–7.87 (m, 2H), 7.78–7.76 (m, 2H), 4.59 (s, 2H), 4.45 (s, 2H), 2.50 (s, 1H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 202.4, 167.5, 134.4, 131.9, 123.7, 66.8, 43.5.

2-Hydroxymethyl-2-phthalimidomethyl-1,3-dioxolane (8)

To a soluton of (**7**) (8.5 g, 39 mmol) in 500 mL toluene was added ethylene glycol (19.5 g, 310 mmol) and *p*-toluenesulfonic acid monohydrate (0.28 g, 2 mmol). The mixture was refluxed using a Dean–Stark trap to remove water. After 5 h, the mixture was allowed to cool to room temperature and was then concentrated. Purification by flash column (diethyl ether, 100%) gave the product (**8**). Yield 7.9 g, 77%. mp 98–100 °C (lit. (20) value mp 114–117 °C). ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.84–7.80 (m, 2H), 7.72–7.67 (m, 2H), 4.13–3.97 (m, 4H), 3.85 (s, 2H), 3.49 (s, 2H), 2.98 (s, 1H, OH). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 168.4, 134.1, 131.6, 123.4, 108.0, 65.3, 63.6, 38.8.

2-Hydroxymethyl-2-aminomethyl-1,3-dioxolane hydrochloride (9)

To a solution of the ketal (**8**) (7.5 g, 28.5 mmol) in 500 mL ethanol was added hydrazine monohydrate (3 mL) in ethanol (350 mL), and the mixture was allowed to stand at room temperature for 36 h. The mixture was then refluxed for 7 h, and the solvent was evaporated in vacuo to dryness. The residue was suspended in 1 mol L^{-1} HCl (300 mL), and the mixture was cooled to 0 °C, allowed to stand for 1 h, and filtered. The solid was washed with a little dilute HCl, and the filtrate was evaporated at 40 °C under reduced pressure to a thick syrup. Addition of methanol, followed by diethyl ether gave the product (**9**) as a crystalline solid. mp. 175–178 °C. Yield 4.2 g, 87%. ^{1}H NMR (200 MHz, D_2O) δ: 4.00 (s, 4H), 3.46 (s, 2H), 3.18 (s, 2H). ^{13}C NMR (75.5 MHz, D_2O) δ: 106.4, 65.8, 61.9, 41.5.

3-Amino-1-hydroxypropan-2-one (3-amino-1-hydroxyacetone) hydrochloride (10)

The ketal (**9**) (2.0 g, 12 mmol) (MW 169.5) was suspended in aqueous acetonitrile (5%, 100 mL). Dowex 50W-X8, 20–50 mesh (20 g) was added, and the mixture was refluxed for 5 h. The solvent was filtered off; the resin was applied to a column, and the column was eluted with 2 mol L^{-1} HCl. The eluate was evaporated in vacuo at 40 °C, and the residue was recrystallized from ethanol–ether to give the product. Yield 1.38 g, 93%. The procedure was repeated on a larger scale, when 3.3 g product (95%) was obtained from 4.85 g (29.1 mmol) ketal (**9**). mp 136 to 137 °C. (lit. (6) value mp 136 to 137 °C; lit. (8) value mp 134–136 °C; lit. (7) value mp 139 °C). ^{1}H NMR (200 MHz, D_2O) δ: 4.37 (s, 2H), 4.04 (s, 2H). ^{13}C NMR (75.5 MHz, D_2O) δ: 206.6, 65.7, 44.3.

Acknowledgments

This paper is dedicated to the memory of Dr. Clara Nanfe Fali (born 26 October 1960) (M.Sc., University of Jos, Nigeria; Ph.D., University of Florida), who initiated this investigation. Clara died unexpectedly and suddenly in May 2000 in Hamilton. She was a gifted organic chemist, a hard-working research associate, and a delighful person. She is sadly missed by the members of the McMaster Chemistry Department.

A research grant from the Natural Sciences and Engineering Research Council of Canada (NSERC) is gratefully acknowledged.

A study of the electrochemical behaviour of cobalt in aqueous $H_2CO_3/HCO_3^-/CO_3^{2-}$ solutions at pH 7–9

Stéphan Simard and Danick Gallant

Abstract: The electrochemical behaviour of a cobalt rotating electrode in $H_2CO_3/HCO_3^-/CO_3^{2-}$ aqueous solutions was investigated in the pH region from 7 to 9. The effects of $H_2CO_3/HCO_3^-/CO_3^{2-}$ concentration, pH, and the presence of phosphates as inhibitors was explored using a rotating disc electrode at 1000 rpm. Some potentiodynamic experiments indicate that for pH 8.5 and higher, carbonate and bicarbonate species play a key role on the rate of electrooxidation of cobalt. For pH lower than 8.5, the electrochemical behaviour of cobalt changes drastically and very aggressive corrosion is observed. The involvement of carbonic acid must be considered in the corrosion process of cobalt in this pH region. The study of passive film potential decay under open circuit potential and galvanostatic reduction was performed on preanodized cobalt electrodes in solutions of various compositions. These experiments indicated the phenomena occurring at the electrode–solution interface during the corrosion process. A mechanism involving competitive adsorption of different species is suggested on the basis of the experimental evidence.

Key words: cobalt, bicarbonate, phosphate, carbonic acid, corrosion.

Résumé : Le comportement électrochimique d'une électrode tournante de cobalt dans des solutions aqueuses de $H_2CO_3/HCO_3^-/CO_3^{2-}$ a été étudié dans la zone de pH 7 à 9. L'effet de la concentration de $H_2CO_3/HCO_3^-/CO_3^{2-}$, du pH et de la présence de phosphates agissants comme inhibiteurs a été exploré à l'aide d'une électrode tournante à disque à 1000 rpm. Des expériences potentiodynamiques montrent que pour les pH supérieurs ou égaux à 8.5, les espèces carbonates et bicarbonates jouent un rôle déterminant sur le taux d'électrooxydation du cobalt. Pour les pH inférieurs à 8.5, le comportement électrochimique du cobalt change drastiquement et un phénomène agressif de corrosion est noté. L'implication de l'acide carbonique dans le processus de corrosion du cobalt dans cette zone de pH doit être considérée. Des mesures de potentiel en circuit ouvert et sous contrôle galvanostatique ont été effectuées sur des électrodes de cobalt préanodisées dans des solutions de diverses compositions. Ces expériences ont permis de déduire les phénomènes qui se produisent à l'interface métal–solution durant le processus de corrosion. Un mécanisme impliquant l'adsorption compétitive de différentes espèces est suggéré sur la base d'évidences expérimentales.

Mots clés : cobalt, bicarbonate, phosphate, acide carbonique, corrosion.

Introduction

Transition metals such as iron, nickel, and cobalt are often employed in industrial applications and the construction of transportation vehicles. Cobalt is a particularly useful material because its hardness allows its use under conditions leading to wear. Also, cobalt is often used as a metallic matrix for cemented carbide coatings which are good replacement materials for hard chrome plated coatings.

Despite the fact that many investigations on the corrosion of cobalt have been performed, its corrosion behaviour is not completely understood and different interpretations are often reported in the literature. Moreover, the corrosion behaviour of cobalt in highly dilute solutions at near-neutral pH has not been extensively studied.

In early studies, the passivation of cobalt in alkaline solutions was attributed to the formation of $Co(OH)_2$ films initiated by the reaction of adsorbed OH^- species on the metal surface (1). In other studies, the presence of CoO is preferred but the existence of $Co(OH)^+$ species is still identified as a precursor for the passive film formation (2). This anodic film formed in the potential range close to the active dissolution potential region is generally called the primary passive region. More recently, an investigation including X-ray photoelectron spectroscopy (XPS) surface analysis reported that the passive film previously formed on cobalt in alkaline solutions consists of an inner layer of α-$Co(OH)_2$ plus CoO and an outer layer consisting of the CoOOH species (3). Further oxidation of the passive film previously formed in the primary passive region occurs in a region called the secondary passive region. Another XPS study of passive films formed in similar solutions reveals that the composition of the primary passive film consists of a thick $Co(OH)_2$ layer and at a more anodic potential, i.e., in the secondary passive region, the film composition changes to Co_3O_4, CoOOH, and Co_2O_3 (4). Other early studies have been dedicated to

the understanding of the cobalt oxidation in neutral and alkaline buffered solutions. The passivation of cobalt by anodic polarization in borate solutions at pH ranging from 7 to 11 was described as beginning by the formation of a hydrous CoO layer. Polarization toward more anodic potentials generates further oxidation of the outer layer to obtain bilayered $CoO–Co_3O_4$ and finally a $CoO–Co_2O_3$ film (5).

The electrochemical behaviour of cobalt in slightly alkaline solutions, more precisely in borate and bicarbonate, has been investigated by Davies and Burstein (6). Their work was performed in solutions having an ionic strength around 0.8 mol L^{-1} and at pH 8.8. Under such conditions, they demonstrated that in bicarbonate solutions, HCO_3^- ionic species are aggressive toward cobalt and cobalt(II) oxides by promoting the dissolution of the bare metal and the primary passive film. It was reported that the primary passivation occurs through the formation of CoO or mainly $CoCO_3$(s) (6). It was then suggested that the dissolution of $CoCO_3$(s) occurs by the following equilibrium

$$[1] \quad CoCO_3(s) + HCO_3^-(aq) \rightleftharpoons Co(CO_3)_2^{2-}(aq) + H^+(aq)$$

and the dissolution of CoO can occur by a sequence of rxns. [2] and [1]

$$[2] \quad CoO(s) + HCO_3^-(aq) \rightarrow CoCO_3(s) + OH^-(aq)$$

Later, these dissolution pathways were supported by Gervasi et al. (7) and another process was suggested

$$[3] \quad Co(s) + H_2O \rightarrow Co(OH)(ad) + H^+(aq) + e^-$$

followed by

$$[4] \quad Co(OH)(ad) \rightarrow CoO(s) + H^+(aq) + e^-$$

or

$$[5] \quad Co(OH)(ad) + HCO_3^-(aq) + CO_3^{2-}(aq) \rightleftharpoons Co(CO_3)_2^{2-}(aq) + H_2O + e^-$$

In the region of higher anodic potentials (secondary passive region), the anodic dissolution process of cobalt is replaced by the formation of a more stable oxide film such as Co_3O_4 (7, 8). At higher pH values, where the concentration of HCO_3^- species in solution becomes less important, the formation of different oxides is directly promoted. A recent spectroelectrochemical study suggests that the formation of Co_3O_4 originates from a further oxidation of CoO species previously produced in parallel with active cobalt dissolution (9).

In carbonate–bicarbonate solutions at pH ranging from 8 to 10, it is clearly demonstrated that the solution composition in the vicinity of the metal is the determining factor for the dissolution and passivation of cobalt. However, the ionic composition of the H_2CO_3(aq)/HCO_3^-(aq)/CO_3^{2-}(aq) system changes strongly in the pH range from 7 to 9. Then, it can be deduced that the corrosion behaviour of cobalt can be largely affected by the pH in such a situation, or more accurately, by the nature of the dissolved species in aqueous media.

In natural environments such as marine media, the pH is slightly alkaline (usually $8.0 < pH < 8.2$) due to the presence of the H_2CO_3(aq)/HCO_3^-(aq)/CO_3^{2-}(aq) system at concentrations of a few mmol L^{-1} (10). Moreover, since the salinity of the marine environment (typically 35 (10)) is also an important parameter, another study on the influence of chlorides on cobalt corrosion is in progress in our laboratory. In the past, less attention has been paid to the corrosion behaviour of cobalt in low and intermediate bicarbonate concentrations and especially in media presenting a pH from 7 to 9. pH values lower than 8.3 are rarely considered in corrosion studies in the $H_2CO_3/HCO_3^-/CO_3^{2-}$ system and, to the best of our knowledge, no study has been performed at $pH < 8$. To understand the corrosion mechanisms of cobalt in such media, the present work is then dedicated to the study of the electrochemical behaviour of cobalt in bicarbonate solutions at pH ranging from ~7 to ~9. It will be demonstrated that the pH has a dramatic effect on the electrochemical behaviour of cobalt in this pH range. This is of primary importance considering that such media are omnipresent in the environment and that cobalt is an important component of several industrial alloys that are exposed to these conditions.

Experimental

The experiments were carried out with a rotating disc electrode at 1000 rpm to render mass transfer limitations marginal and to study the kinetics of the surface reactions. The working disc electrode was made with a cobalt disc from a cylindrical rod (99.95%) and had a surface area of 0.283 cm^2. The cobalt rod was set in a Kel-F holder sealed with epoxy resin. The auxiliary electrode was a platinized platinum sheet separated from the main compartment by a Nafion® membrane. The reference electrode was a saturated calomel electrode (SCE) connected to the cell by a bridge and a Luggin capillary. All potentials are referenced to this electrode. The volume of the electrochemical cell was 0.5 L or more, so that the concentration of dissolved cobalt in the bulk could be neglected. Aqueous solutions were prepared with ACS grade chemicals and deionized water. Solutions containing bicarbonate were deaerated by bubbling high-purity nitrogen or mixtures of nitrogen and carbon dioxide depending on the pH. The pH values under ~8.3 were reached by using an appropriate mixture of $N_2–CO_2$; pH values above ~8.3 were reached by using different $N_2–CO_2$ mixtures and (or) by addition of small volumes of concentrated NaOH solutions. For each experiment over the entire pH range, the pH was maintained at a stable value by bubbling an appropriate $N_2–CO_2$ mixture. Solutions not containing bicarbonate were deaerated by bubbling high-purity nitrogen before and during the course of the experiments. The electrode surface was ground successively with 600 and 1200 grit emery paper and mechanically polished with 5.0, 1.0, and 0.05 μm alumina suspensions before all immersions. At the beginning of each experiment, the electrode potential was held at –1.05 V for 4 min to produce a perceptible hydrogen evolution reaction. This preparation procedure ensured a mirror-like finish and oxide-free surface that gives reproducible results. All experiments were performed at room temperature.

© 2004 NRC Canada

The measurements on the rotating disc electrode were performed with a PAR 263-2A potentiostat controlled by a computer, and with a Pine Instrument Company bipotentiostat model AFCBP1, using a LabVIEW™ (National Instruments™) control software for signal acquisition. The electrode rotator was a Pine Instrument analytical rotator model AFSAR.

The composition of all buffer solutions used in the present work was linked to the pH through the following equilibria and equilibrium constants.

For $NaHCO_3$ (11):

[6] $H_2CO_3(aq) \rightleftharpoons HCO_3^-(aq) + H^+(aq)$

$$K_{a1} = 4.45 \times 10^{-7}$$

[7] $HCO_3^-(aq) \rightleftharpoons CO_3^{2-}(aq) + H^+(aq)$

$$K_{a2} = 4.69 \times 10^{-11}$$

For CO_2 dissolution (12):

[8] $CO_2(g) \rightleftharpoons CO_2(aq)$

$$K = \frac{[CO_2(aq)]}{P_{CO_2}} = 0.0334$$

[9] $CO_2(aq) + H_2O \rightleftharpoons H_2CO_3(aq)$

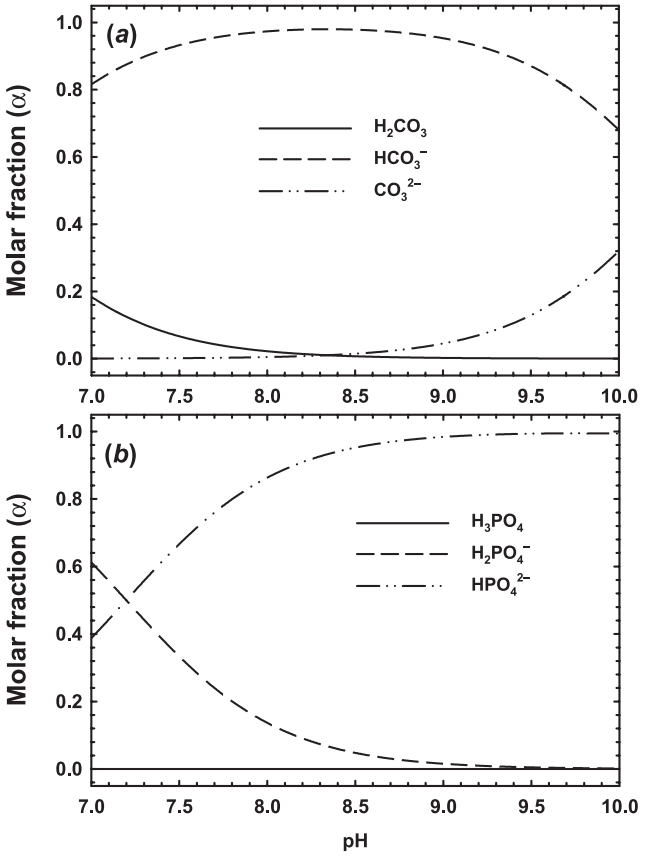
$$K = 1.3 \times 10^{-3}$$

For Na_2HPO_4 (11):

[10] $H_3PO_4(aq) \rightleftharpoons H_2PO_4^-(aq) + H^+(aq)$

$$K_{a1} = 7.11 \times 10^{-3}$$

[11] $H_2PO_4^-(aq) \rightleftharpoons HPO_4^{2-}(aq) + H^+(aq)$



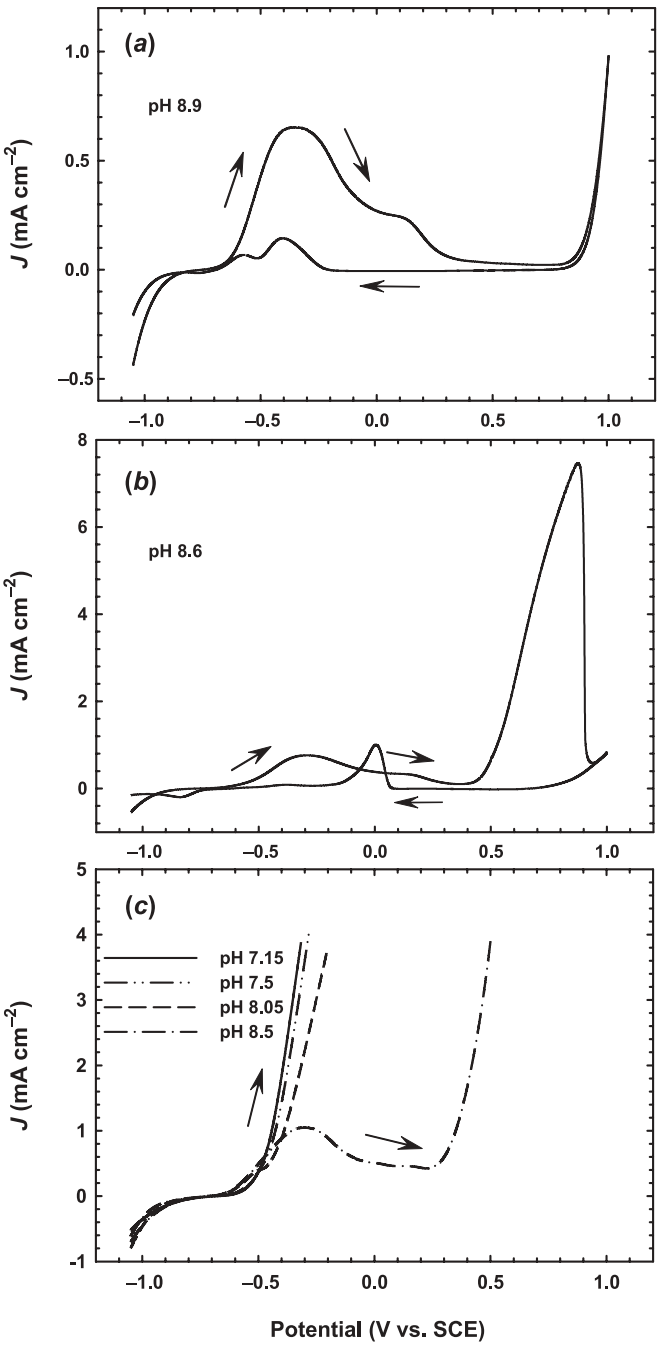
$$K_{a2} = 6.32 \times 10^{-8}$$

[12] $HPO_4^{2-}(aq) \rightleftharpoons PO_4^{3-}(aq) + H^+(aq)$

$$K_{a3} = 4.5 \times 10^{-13}$$

For both buffer systems ($NaHCO_3$ and Na_2HPO_4), the composition diagrams in the pH range of interest (i.e., pH 7–10) were calculated and are presented in Fig. 1.

Fig. 1. Calculated concentrations of dissolved species at various pH values for: (*a*) $H_2CO_3/HCO_3^-/CO_3^{2-}$; and (*b*) $H_3PO_4/H_2PO_4^-/HPO_4^{2-}/PO_4^{3-}$ buffer systems.



Results

The effect of pH on the electrochemical behaviour of cobalt is examined in $H_2CO_3/HCO_3^-/CO_3^{2-}$ solutions. Figure 2 displays the effect of different pH values on the potentiodynamic curves in a 0.1 mol L^{-1} $NaHCO_3$ buffer solution. At pH 8.9 (Fig. 2*a*), the voltammogram obtained from the potential sweep in the anodic direction displays a broad anodic peak located at –0.36 V followed by a smaller peak that produces a shoulder located at 0.10 V. Toward more anodic potentials, the anodic current diminishes and remains low until an increasing current is noted that corresponds to the solution oxidation wall. The low current region located between 0.30 and 0.85 V is attributed to the passive region. On the voltammogram obtained by the potential sweep in the cathodic direction, two reactivation current peaks are observed at –0.40 and –0.575 V. Figure 2*b* presents the resulting voltammogram obtained from the same triangular potentiodynamic program as at pH 8.9 in 0.1 mol L^{-1} $NaHCO_3$ solution except that the pH is lowered to 8.6. Within the anodic peak region, the shape of the anodic current trace is similar to the one observed at pH 8.9. However, the maximum peak current is slightly shifted toward a more positive potential and a higher peak current is recorded. Interestingly, it is observed that the electrochemical behaviour of cobalt in the passive region is significantly affected by the small pH difference. On the potentiodynamic curve obtained at pH 8.6, the passive region is strongly disturbed by the presence of an important asymmetric anodic current peak that starts to grow at 0.4 V and the current intensity culminates at 0.875 V. The strong anodic process stops at higher anodic potentials and the current falls abruptly. When the potential sweep is switched in the cathodic direction, the current remains small up to 0.075 V and a reactivation peak is observed at 0.00 V. A small reduction peak is also observed at –0.84 V.

The importance of the pH on the electrochemical behaviour of the cobalt electrode is also indicated by potentiodynamic curves obtained at pH 8.5 and lower as presented in Fig. 2*c*. Again, it is interesting to notice that only a slight pH change from 8.6 to 8.5 generates significant modification of the anodic processes. The intensity of the current peak located at ~ –0.36 V increases and, at a more anodic potential, the large asymmetric peak observed at pH 8.6 becomes, at pH 8.5, a nearly vertical current increase that starts at

Fig. 2. Potentiodynamic curves for a cobalt electrode in 0.1 mol L^{-1} $NaHCO_3$ solution at: (*a*) pH 8.9; (*b*) pH 8.6; (*c*) pH 8.5, 8.05, 7.5, and 7.15. ω = 1000 rpm; d*E*/d*t* = 0.005 V s^{-1}.

+0.25 V. The current traces obtained by scanning potentials in the anodic direction in a 0.1 mol L^{-1} $NaHCO_3$ buffer solution at pH 8.05, 7.50, and 7.15 are overlaid in Fig. 2*c*. Their shape displays an essentially linear anodic current increase instead of a peak as observed near –0.36 V at pH ≥ 8.5. The lower the pH is, the larger the magnitude of the anodic process is and the passive region is no longer observed. For a constant pH of 8.05, the effect of the $H_2CO_3/HCO_3^-/CO_3^{2-}$ buffer concentration is presented in Fig. 3. It is observed that a higher buffer concentration (0.4 mol L^{-1} $NaHCO_3$) inhibits the vertical current increase that is observed in 0.1 mol L^{-1} $NaHCO_3$, and the peak shape of the anodic current at –0.36 V is recovered.

Fig. 3. Potentiodynamic curves for a cobalt electrode in 0.1 mol L^{-1} (——) and 0.4 mol L^{-1} (- - - -) $NaHCO_3$ aqueous solutions at pH 8.05. ω = 1000 rpm; d*E*/d*t* = 0.005 V s^{-1}.

The effect of buffer concentration on the anodic peaks and reactivation regions has been studied more extensively for $NaHCO_3$ buffer solutions at a constant pH of 8.9 (Fig. 4). The peak current located at –0.36 V increases linearly with the buffer concentration (Fig. 4*a*) and the same behaviour is observed for the reactivation peak located at –0.3 V in the cathodic part of the sweep (Fig. 4*b*).

Figure 5 displays the anodic traces obtained for selected pH values ranging from 7.85 to 9.20 for the cobalt electrode in 0.4 mol L^{-1} $NaHCO_3$ buffer solutions. It is observed that the current in the anodic peak region (from –0.6 to 0.3 V) increases as the pH drops. Also, an anodic current peak located at –0.14 V becomes more evident as the pH diminishes. At pH 9.2 and 8.7, the electrochemical behaviour of the cobalt electrode is similar to the behaviour observed in 0.1 mol L^{-1} $NaHCO_3$ solution at pH 8.9 (Fig. 2*a*) except that there is a larger magnitude for the anodic peak currents in the region from –0.6 to –0.3 V (Fig. 5*a*) and in the reactivation region (Fig. 5*b*).

For lower pH values, it is observed that lowering the pH in 0.4 mol L^{-1} $NaHCO_3$ solution generates more moderated changes on the voltammograms than in 0.1 mol L^{-1} $NaHCO_3$ solutions for the same pH value. The asymmetric anodic peak located at 0.66 V appears only as a small bump at pH 8.05 in 0.4 mol L^{-1} $NaHCO_3$ buffer solution, while an almost linear anodic current increase was observed in 0.1 mol L^{-1} solution at the same pH (Fig. 3). At pH values below 8.3 in 0.4 mol L^{-1} $NaHCO_3$ buffer solutions (Fig. 5*a*), the asymmetric anodic peak grows as the pH decreases. For potentials in the more anodic direction, a sudden current decrease is observed near 0.75 V. When the potential is scanned in the cathodic direction, the current remains very small until a sharp anodic current peak appears at 0.110 V (Fig. 5*b*). Toward more cathodic potentials from that sharp peak, the current trace has a similar shape to that observed at higher pH. Further measurements were performed at pH 7.70, 7.55, and 7.20 in 0.4 mol L^{-1} $NaHCO_3$ solution

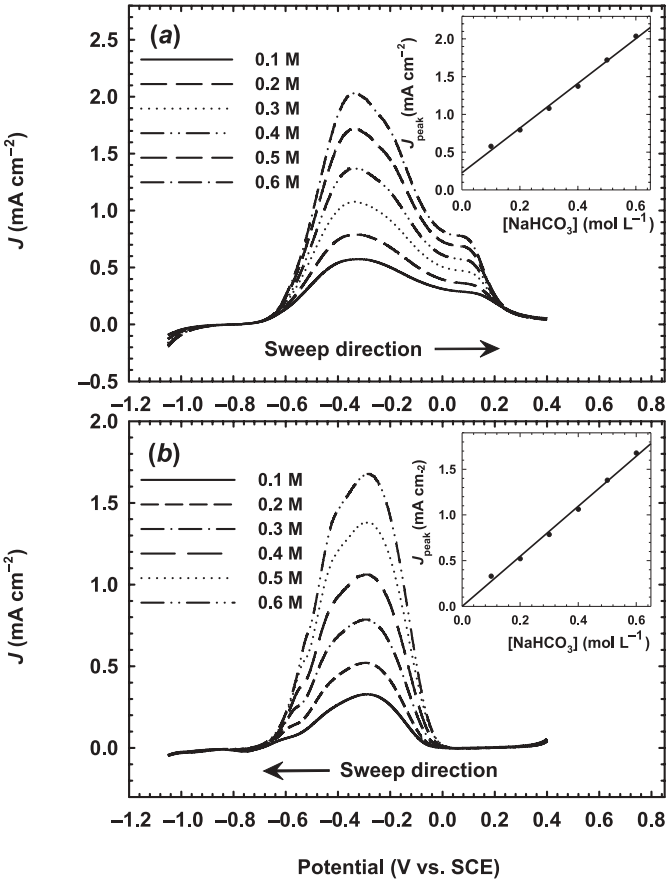
Fig. 4. Voltammograms at various $NaHCO_3$ concentrations for: (*a*) the anodic part of the potential sweep; and (*b*) the cathodic part of the potential sweep at pH 8.9. ω = 1000 rpm; d*E*/d*t* = 0.005 V s^{-1}.



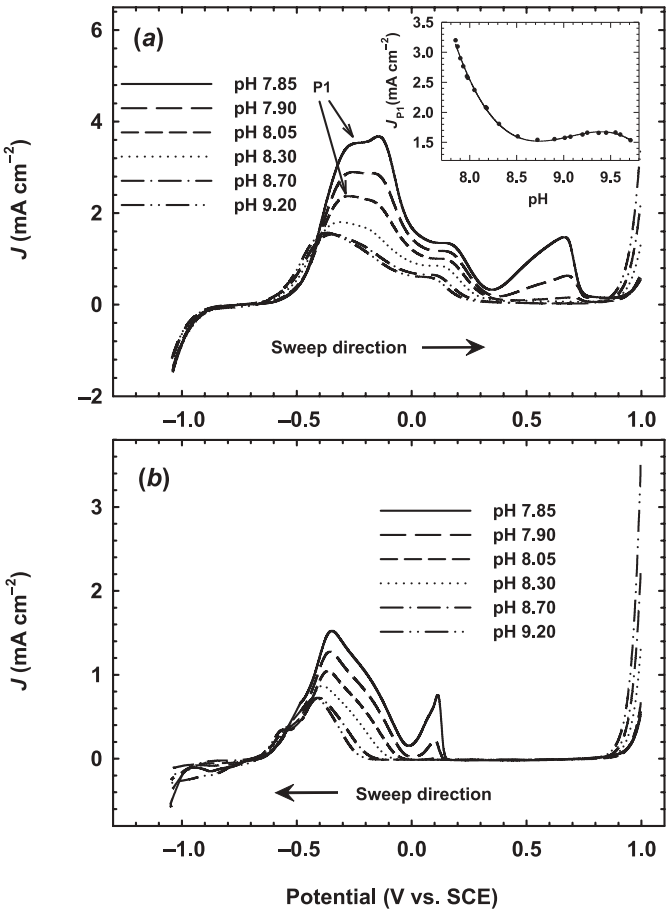


Fig. 5. Influence of pH (7.85–9.70) on: (*a*) the anodic portion; and (*b*) the cathodic portion of the potential sweep for a cobalt electrode in 0.4 mol L^{-1} $NaHCO_3$ solution. ω = 1000 rpm; d*E*/d*t* = 0.005 V s^{-1}.

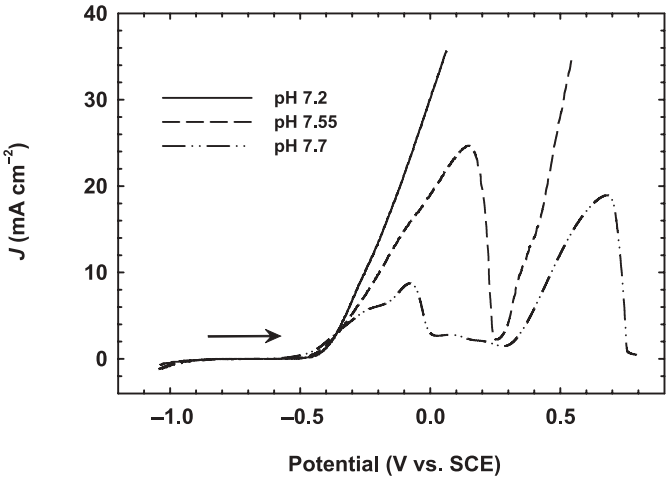

(Fig. 6). It is observed that an important anodic current starts to grow near –0.4 V for pH 7.55 and 7.2. At pH 7.2 the current increases almost linearly while a decreasing current is observed between 0.15 V and 0.25 V at pH 7.55. At pH 7.7, a potentiodynamic curve shape intermediate between those observed at pH 7.85 and 7.55 is obtained, which indicates a change in the dominant oxidation processes. All these data clearly demonstrate that changes in solution pH in the region from 7 to 8 in the $H_2CO_3/HCO_3^-/CO_3^{2-}$ system drastically affects the potentiodynamic behaviour of cobalt.

The effect of the hydrodynamic conditions on the electrochemical behaviour of cobalt in 0.4 mol L^{-1} $NaHCO_3$ buffer was studied at pH 7.9, where most of the individual electrochemical signals are noticeable. On the voltammograms in Fig. 7, four current peaks (P1–P4) are identified on the current trace of the anodic potential sweep (Fig. 7*a*) and two other major current peaks are identified on the current trace of the cathodic sweep (P5 and P6) (Fig. 7*b*). It is noted that only P1, P3, and P6 are clearly dependent on the rotation speed, while the other peaks do not show any obvious dependence on the hydrodynamic conditions.

Therefore, further experiments were carried out to understand the role played by the solution species on the electrochemical behaviour of cobalt, especially in the pH range from 7 to 8. One of the goals was to investigate whether the

Fig. 6. Effect of near-neutral pH on the potentiodynamic curve for a cobalt electrode. ω = 1000 rpm in 0.4 mol L^{-1} $NaHCO_3$ solution; d*E*/d*t* = 0.005 V s^{-1}.

effect of pH on the electrochemical behaviour of cobalt is linked only to the OH^- concentration, or if more complex considerations regarding changes in the concentrations of

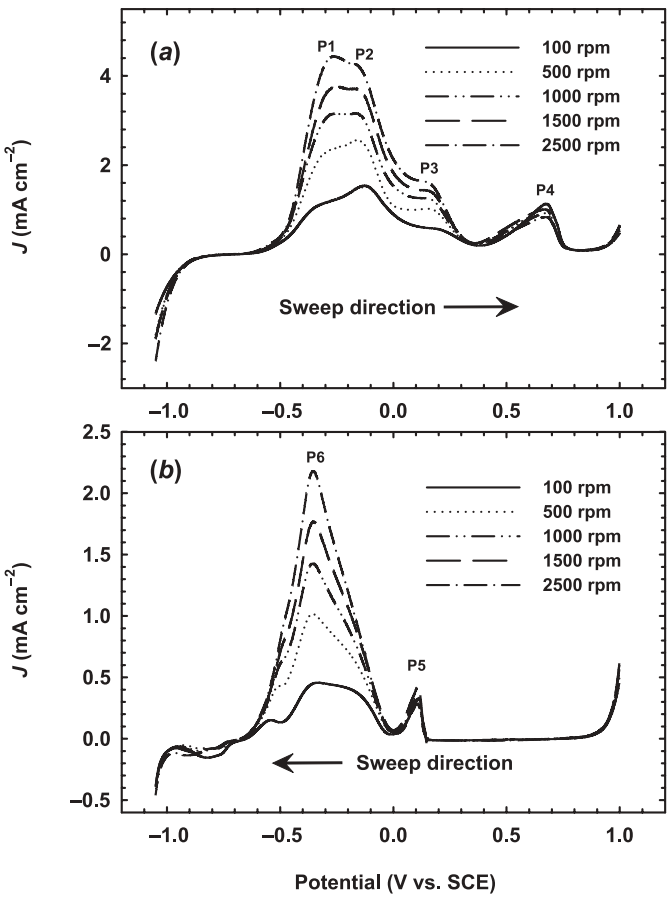
Fig. 7. Potentiodynamic curves for: (*a*) the anodic portion; and (*b*) the cathodic portion of a potential sweep for a cobalt electrode at various rotation speeds (ω) in 0.4 mol L^{-1} $NaHCO_3$ solution at pH 7.9. d*E*/d*t* = 0.005 V s^{-1}.



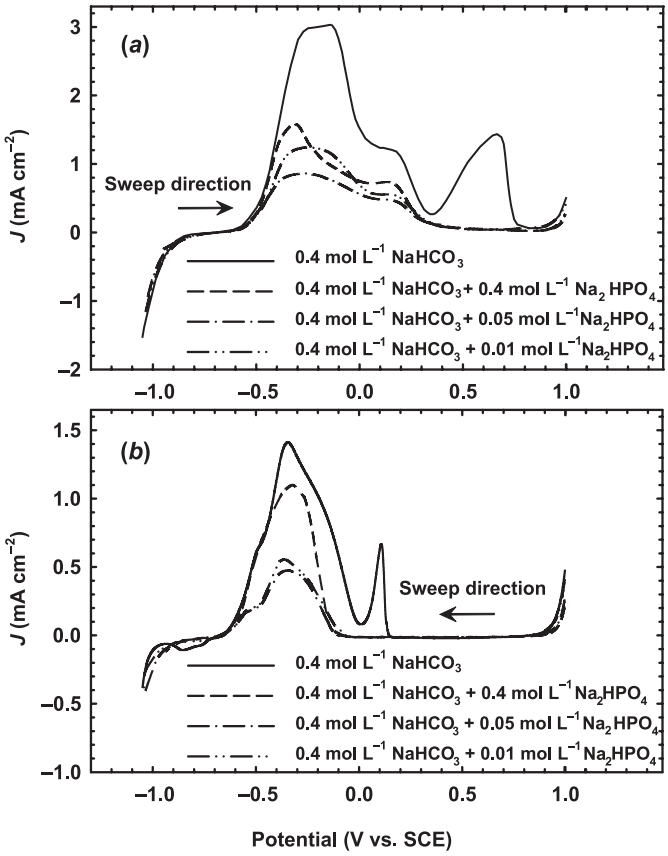


Fig. 8. Effect of Na_2HPO_4 concentration in 0.4 mol L^{-1} $NaHCO_3$ solution on: (*a*) the anodic portion; and (*b*) the cathodic portion of a potential sweep at pH 7.9. ω = 1000 rpm; d*E*/d*t* = 0.005 V s^{-1}.

dissolved species are more important factors. From these considerations, further experiments have been conducted in bicarbonate, bicarbonate–phosphate, and phosphate solutions at constant pH. Figure 8*a* displays the overlay of the anodic current traces obtained for the cobalt electrode in bicarbonate solution and in mixtures of bicarbonate–phosphate at pH 7.9. It is evident that an addition of only 0.01 mol L^{-1} phosphate (as Na_2HPO_4) in 0.4 mol L^{-1} $NaHCO_3$ solution decreases significantly the oxidation current in the anodic peak region located between –0.5 and 0.3 V. Moreover, the important asymmetric anodic current peak located between 0.2 and 0.8 V observed in 0.4 mol L^{-1} $NaHCO_3$ at pH 7.9 is totally inhibited by the presence of 0.01 mol L^{-1} Na_2HPO_4. For the portion of the voltammogram where the potential is swept in the cathodic direction (Fig. 8*b*), the sharp anodic peak observed in 0.4 mol L^{-1} $NaHCO_3$ solution at pH 7.9 and located at 0.1 V is completely inhibited by the presence of 0.01 mol L^{-1} Na_2HPO_4. The anodic current measured for the rest of the sweep is also significantly reduced. A higher Na_2HPO_4 concentration (0.05 mol L^{-1}) in 0.4 mol L^{-1} $NaHCO_3$ diminishes the anodic current for the whole voltammogram relative to 0.01 mol L^{-1} Na_2HPO_4 in 0.4 mol L^{-1} $NaHCO_3$. For 0.4 mol L^{-1} Na_2HPO_4 + 0.4 mol L^{-1} $NaHCO_3$ solutions, the shape of the anodic current trace is significantly modified and an anodic peak located at –0.315 V followed by a shoulder at 0.135 V are observed. Similar behaviour for the current trace obtained during the potential scan in the cathodic direction is noticed.

The comparison between the anodic traces obtained for phosphate solutions with and without bicarbonate at pH 7.9 is presented in Fig. 9*a*. It clearly demonstrates that for solutions equimolar in $NaHCO_3$ and Na_2HPO_4 at the same pH, the electrochemical signature is largely dominated by the presence of Na_2HPO_4. However, the presence of $NaHCO_3$ still contributes to the increase in the magnitude of the anodic current. Again, similar observations can be made for the current trace obtained during the potential scan in the cathodic direction (Fig. 9*b*).

The investigation of the effect of phosphate on the electrochemical behaviour of cobalt in $NaHCO_3$ solutions has been extended to pH 7.5 and 7.2 where strong corrosion was noted in bicarbonate solutions alone (Figs. 10 and 11). Figure 10 presents an overlay of the potentiodynamic curves recorded for 0.4 mol L^{-1} $NaHCO_3$ solutions with and without Na_2HPO_4 at pH 7.5 and 7.2. In 0.4 mol L^{-1} $NaHCO_3$ solutions at both pH values, the beginning of a very strong oxidation process starting near –0.4 V is evident. The presence of small amounts of Na_2HPO_4 in the $NaHCO_3$ solutions at these pH values is amazingly efficient at totally inhibiting

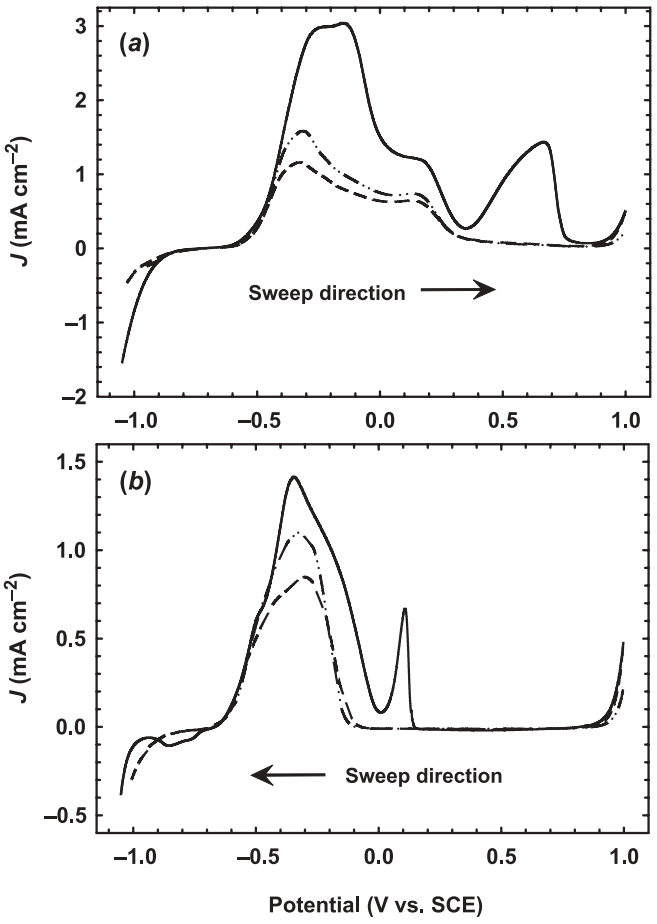

Fig. 10. Effect of Na_2HPO_4 concentration in 0.4 mol L^{-1} $NaHCO_3$ solution on potentiodynamic curves for a cobalt electrode at: (*a*) pH 7.5; (*b*) pH 7.2. ω = 1000 rpm; d*E*/d*t* = 0.005 V s^{-1}.

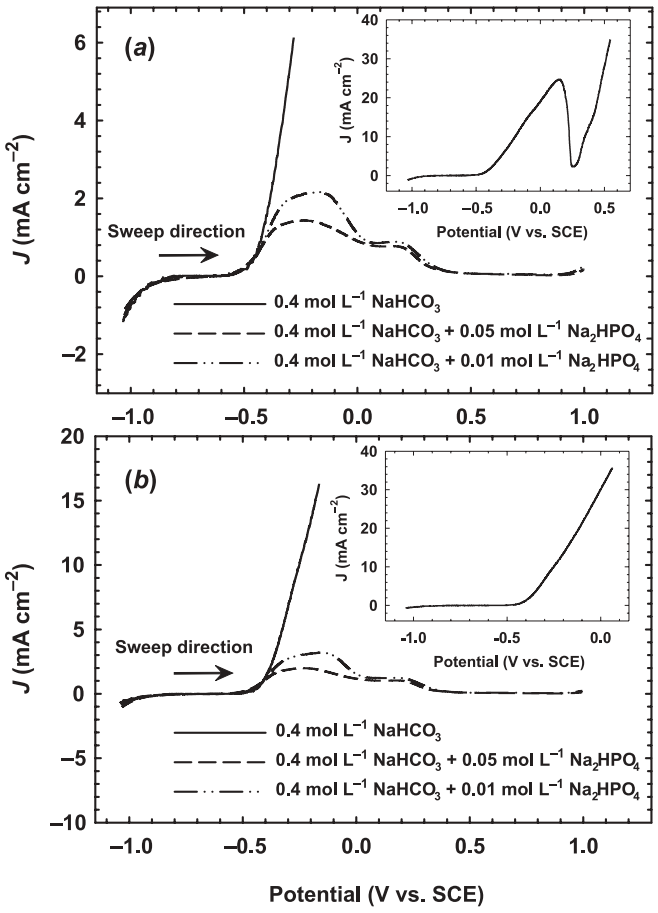

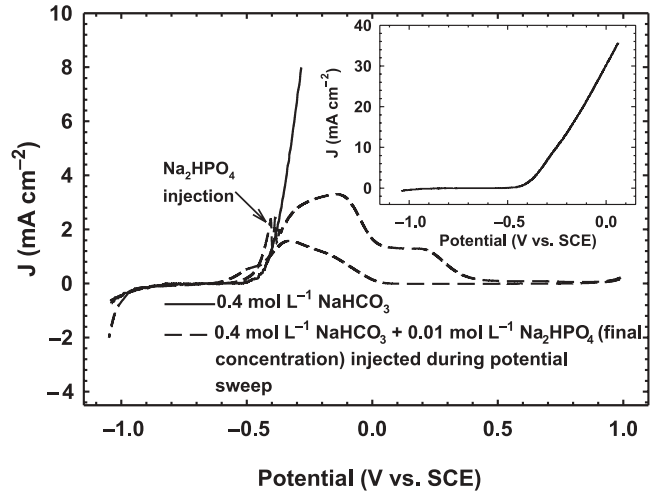

Fig. 11. Effect of Na_2HPO_4 addition (final Na_2HPO_4 concentration, 0.01 mol L^{-1}) in 0.4 mol L^{-1} $NaHCO_3$ solution during a potential sweep at pH 7.2. ω = 1000 rpm; d*E*/d*t* = 0.005 V s^{-1}.

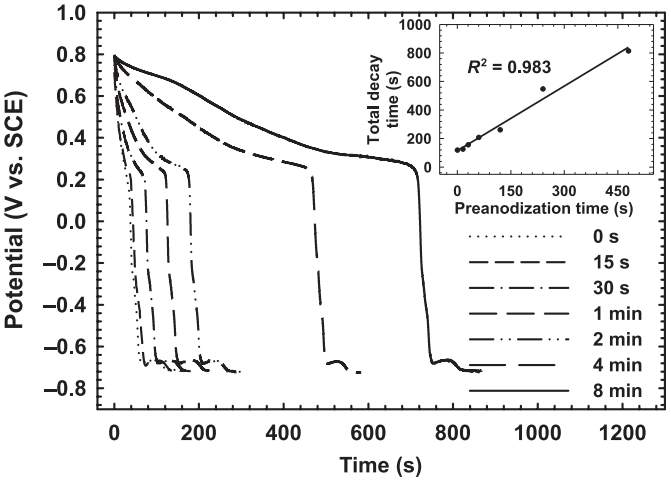
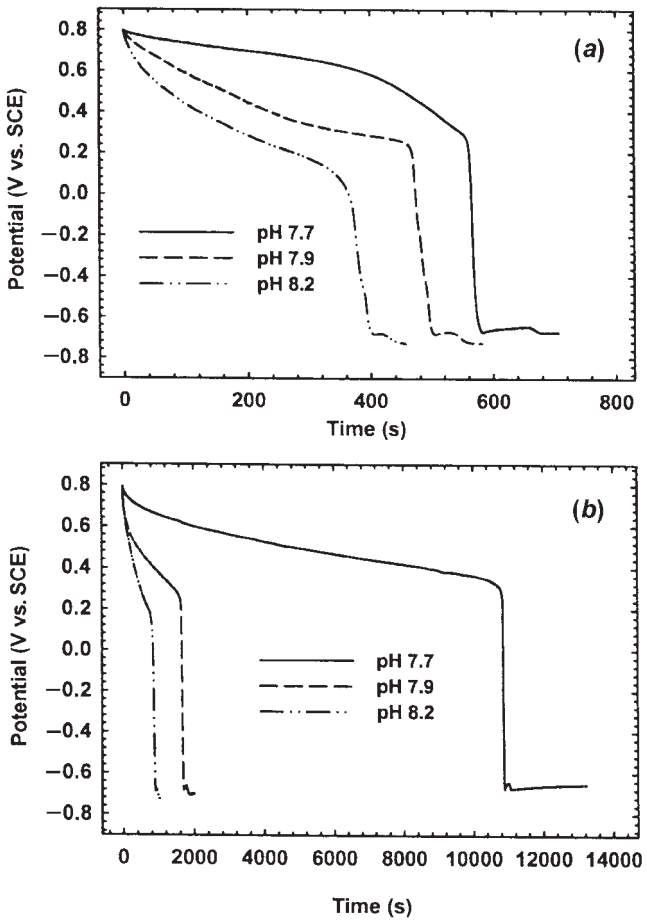


the oxidation process. Moreover, it is demonstrated in Fig. 11 that the strong oxidation process of cobalt (starting at –0.4 V) in 0.4 mol L^{-1} $NaHCO_3$ solution at pH 7.2 can be inhibited by the direct injection of a small volume of concd. Na_2HPO_4 solution (the resulting Na_2HPO_4 concentration is 0.01 mol L^{-1}) after the beginning of the process.

To understand the influence of pH on the cobalt passive film in $NaHCO_3$ solutions and to find out the inhibition mode of phosphate, the transient potential of prepassivated cobalt electrode was studied in bicarbonate solutions with and without phosphate. In all cases, the potential was swept in the anodic direction and held at 0.8 V, where passivation of cobalt is possible for all studied pH conditions. Thereafter, the open circuit potential (OCP) was measured until the potential of the bare cobalt electrode was reached. Figure 12 presents the potential decay curves for a preanodized cobalt electrode in 0.4 mol L^{-1} $NaHCO_3$ buffer solution at pH 7.9. It is possible to detect four arrest potential regions that are more evident after the 8 min preanodization. A first arrest potential region is located from 0.8 to 0.7 V, followed by a second dominant region between 0.7 and 0.3 V. The time corresponding to these two arrest potential regions are obviously dependent on the duration of the preanodization. When the potential reaches a value close to 0.3 V, it starts to change rapidly and a very small arrest potential region is observed from –0.2 to –0.4 V and another one at –0.675 V.

© 2004 NRC Canada

Fig. 12. Effect of preanodization time at +0.80 V on the open circuit potential curve in 0.4 mol L^{-1} $NaHCO_3$ at pH 7.9 for a cobalt electrode rotated at 1000 rpm. Potential swept from –1.05 to +0.80 V at 0.005 V s^{-1} and held at +0.80 V for the preanodization period.



These last two potential arrest regions seem to be independent of the preanodization time. The total time elapsed to reach the potential of the bare metal in solution is directly proportional to the preanodization duration up to 8 min.

The effect of pH on the decay potential traces for the cobalt electrode was studied in 0.4 mol L^{-1} $NaHCO_3$ buffer solution at pH 7.7, 7.9, and 8.2 as presented in Fig. 13*a*. It was discovered that the higher the pH is, the shorter the decay time is. Moreover, it is observed that the first arrest potential region (0.8–0.7 V) becomes dominant at pH 7.7. The global amounts of oxide produced at pH 7.7 and pH 8.2 are similar since a galvanostatic reduction on the preanodized cobalt electrode gives a similar charge that is required to reduce the oxide films. Therefore, the study of the influence of solution composition was extended to the introduction of phosphate species in the bicarbonate buffer solution. Fig. 13*b* demonstrates that when 0.01 mol L^{-1} Na_2HPO_4 is added after the preanodization (just at the beginning of OCP measurement) in the 0.4 mol L^{-1} $NaHCO_3$ buffer solution at pH 8.2, 7.9, and 7.7, the decay time is significantly increased by a factor of 2, 3, and 20, respectively, relative to the decay time at the same pH in 0.4 mol L^{-1} $NaHCO_3$ solution (Fig. 13*a*). Another OCP measurement was performed in 0.4 mol L^{-1} $NaHCO_3$ buffer solution containing 0.01 mol L^{-1} Na_2HPO_4 during polarization (Fig. 14). It is very interesting to observe that the increase in the potential decay time observed in Fig. 13*b* is lost when phosphate is present in the solution during the preanodization and not only during the OCP measurement. A comparison of the open circuit potential curves obtained for 0.4 mol L^{-1} $NaHCO_3$ and for 0.4 mol L^{-1} Na_2HPO_4 buffer solutions at pH 7.7 and 8.2, demonstrates that the passive film electrogenerated on a cobalt in phosphate solution disappears more rapidly than in bicarbonate solutions (Fig. 15).

To estimate the amount of reducible oxides on the electrode surface, galvanostatic reduction experiments were performed and the transient potential curves are displayed in Fig. 16. It is found that at the same pH and nominal solution concentration, the charge required for the reduction of the electrogenerated passive film in the $NaHCO_3$ solution is 1.52 mC cm^{-2}, which is approximately twice the charge required to reduce the film electrogenerated in the Na_2HPO_4 solution, which is 0.80 mC cm^{-2}.

Fig. 13. Effect of pH on the open circuit potential for a cobalt electrode in (*a*) 0.4 mol L^{-1} $NaHCO_3$, and (*b*) 0.4 mol L^{-1} $NaHCO_3$ + 0.01 mol L^{-1} Na_2HPO_4 (added at the beginning of the OCP measurement) after a preanodization for 4 min at +0.80 V in 0.4 mol L^{-1} $NaHCO_3$. Potential swept from –1.05 to +0.80 V at 0.005 V s^{-1} and held at +0.80 V for preanodization. ω = 1000 rpm.

Discussion

Anodic dissolution region

In $NaHCO_3$ solutions near pH 9 (Figs. 2*a* and 5*a*), the anodic current peak located at –0.36 V is attributed to the dissolution of cobalt into a carbonato-complex as suggested in the literature (6, 7). The rate-determining species in the cobalt electrodissolution is identified as HCO_3^- following the reactions presented in eqs. [1] and [5] in the *Introduction*. However, a recent study reported that both bicarbonate and carbonate species can be important in the catalysis of cobalt dissolution in moderately alkaline solutions (9). The effect of ionic species on the dissolution rate of cobalt in bicarbonate buffer solution is confirmed in Fig. 4*a*, where a linear re-

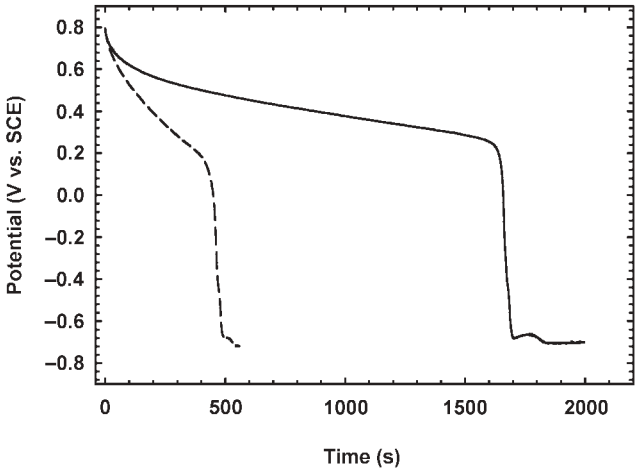
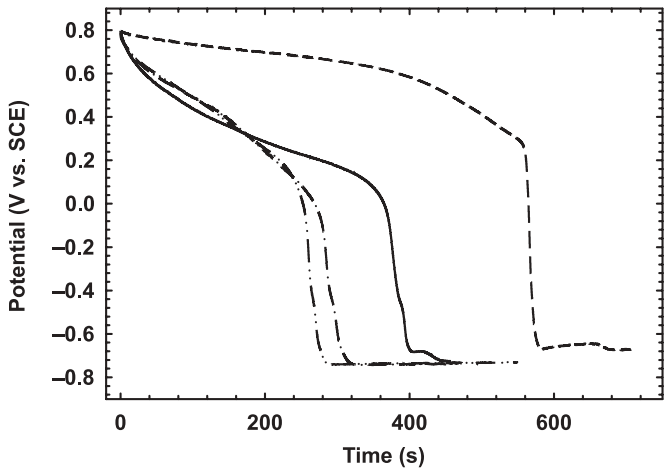
Fig. 14. Open circuit potential curves for a cobalt electrode in 0.4 mol L^{-1} $NaHCO_3$ + 0.01 mol L^{-1} Na_2HPO_4 preanodized for 4 min at +0.80 V in: (*a*) 0.4 mol L^{-1} $NaHCO_3$ + 0.01 mol L^{-1} Na_2HPO_4 (- - - -); (*b*) 0.4 mol L^{-1} $NaHCO_3$ (——) (0.01 mol L^{-1} Na_2HPO_4 added to the 0.4 mol L^{-1} $NaHCO_3$ solution at the beginning of the open circuit potential measurement). Potential swept from –1.05 to +0.80 V at 0.005 V s^{-1} and held at +0.80 V for preanodization. ω = 1000 rpm; pH 7.9.





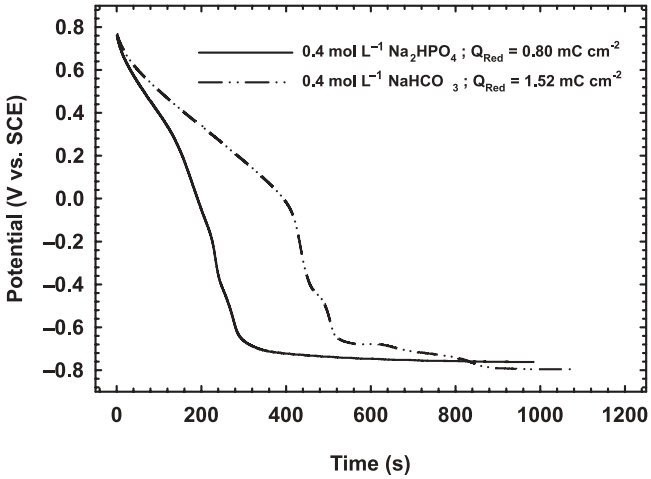


Fig. 15. Effect of pH and solution composition on the open circuit potential for a cobalt electrode preanodized for 4 min at +0.80 V in 0.4 mol L^{-1} $NaHCO_3$ solution at pH 8.2 (——), and pH 7.7 (- - - -); and in 0.4 mol L^{-1} Na_2HPO_4 solution at pH 8.2 (·—·), and 7.7 (··—··). Potential swept from –1.05 to +0.80 V at 0.005 V s^{-1} and held at +0.80 V for preanodization. ω = 1000 rpm.

lationship between the anodic peak current and the $NaHCO_3$ concentration is obtained. This behaviour is observed for both the anodic and cathodic parts of the potential sweep. These results are in good agreement with other results reported in the literature (6, 7, 9). When the potential reaches a sufficient anodic value, the dissolution process is being gradually replaced by a parallel passive film formation process.

As illustrated in Fig. 5*a* for a constant concentration of 0.4 mol L^{-1} $NaHCO_3$ buffer solution, the anodic peak current in the region from pH 8.5 to 9.7 is almost constant. As discussed above, the kinetics of cobalt electrodissolution in carbonate–bicarbonate solutions is catalyzed by both HCO_3^- and CO_3^{2-} ionic species (9). In this case, considering that Fig. 1*a* clearly demonstrates that $\alpha_{HCO_3^-} + \alpha_{CO_3^{2-}} \approx 1$ at pH values above 8.3, the cobalt electrodissolution rate should not be significantly influenced by pH. Therefore, it can be suggested that the cobalt electrodissolution process at pH > 8.5 is mainly influenced by the carbonate–bicarbonate solution concentration, and both ionic species (HCO_3^- and CO_3^{2-}) are most likely taking part in the process. Approaching the pH 9.7 region, the oxidation process becomes gradually dominated by the direct formation of cobalt oxide (7), which may explain why that the peak current is no longer constant.

Fig. 16. Effect of solution composition on chronopotentiometric curves recorded with a reduction current of 3.5 μA cm^{-2} preanodization for 20 min at +0.80 V. Potential swept from –1.05 to +0.80 V at 0.005 V s^{-1} and held at +0.80 V for preanodization. ω = 1000 rpm during potential sweep; ω = 0 rpm during galvanostatic reduction to minimize dissolution effect. pH 8.2.

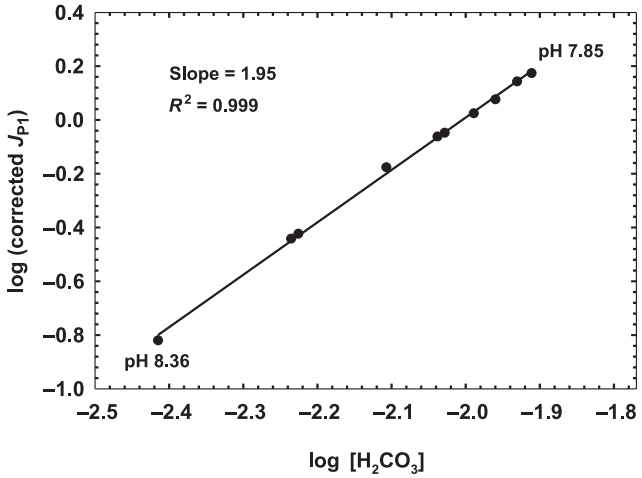
At lower pH values in the region between pH 8.50 and 7.85, the anodic current peak increases exponentially as the pH is lowered (Fig. 5*a*). From Fig. 1*a*, it can be deduced that the CO_3^{2-} contribution to the anodic process must be negligible, or at least should diminish as the pH becomes lower. Moreover, the HCO_3^- concentration also decreases as the pH drops below 8.3 while, as mentioned above, the anodic peak current increases in this pH region. Consequently, the explanation based solely on the aggressiveness of the HCO_3^- and (or) CO_3^{2-} species becomes unrealistic for pH values lower than 8.3. In this pH range, therefore, the influence of dissolved species other than HCO_3^- and CO_3^{2-} must be considered to explain the anodic dissolution of cobalt. Examination of the pH-composition diagram for the $H_2CO_3/HCO_3^-/CO_3^{2-}$ system indicates that the H_2CO_3 fraction increases as the pH drops below 8.3. However, the trend of anodic peak current vs. the carbonic acid concentration does not fit with a linear relationship. It must be pointed out that as the pH diminishes, the anodic region from –0.6 to 0.3 V exhibits an overlap of few anodic peaks (Fig. 5*a*). In this case it can be deduced that the anodic behaviour of cobalt is not a unique process and several electrochemical processes may occur at

© 2004 NRC Canada

the same time but at different rates. It is reported in the literature that the anodic behaviour of cobalt in aq. $H_2CO_3/HCO_3^-/CO_3^{2-}$ solutions can be described by the coupling of two independent anodic processes sharing the electrode surface and generating a total current (9). One of the processes is independent of diffusion and the other one is under diffusion control. This behaviour is illustrated on Fig. 7, where the anodic peak region exhibits two components: the first one (P1) being under diffusion control and the second one (P2) being independent of hydrodynamic conditions. To clarify the anodic dissolution kinetics at pH < 8.5, the anodic peak current measured near –0.3 V was corrected by subtracting a current value estimated in the limit $[H_2CO_3] \rightarrow 0$. The logarithm of the value of the corrected current value was then plotted against the logarithm of the calculated H_2CO_3 concentration for each pH value, as shown on Fig. 17. It is especially interesting to see that a linear relationship is obtained with a slope close to 2 (1.95 with r^2 = 0.999). For pH values below 7.85, a linear relationship cannot be verified because the magnitude of the peak located near –0.15 V becomes predominant and inhibits an accurate determination of the peak current at ~ –0.3 V.

Considering the linearity of the log(corrected J_{P1}) vs. log$[H_2CO_3]$ plot, it can be suggested that cobalt dissolution for pH < 8.5 is mostly catalyzed by the presence of carbonic acid and the process could take place by the following overall reaction

$$[13] \quad Co + 2H_2CO_3(aq) \rightarrow Co(CO_3)_2^{2-}(aq) + 4H^+(aq) + 2e^-$$



It is interesting to notice that for two different $NaHCO_3$ concentrations at the same pH (i.e., same ratio H_2CO_3/HCO_3^-), the electrochemical behaviour of cobalt is different (Fig. 3). At pH 8.05 in 0.1 mol L^{-1} $NaHCO_3$ buffer solution, the cobalt electrode is strongly oxidized without perceptible passivation while in the 0.4 mol L^{-1} solution, a passivation process is found adjacent to the active dissolution region. In that pH region, as discussed above, the mechanisms involving HCO_3^- and H_2CO_3 can occur competitively. Hence, it can be deduced that increasing the $NaHCO_3$ concentration at pH 8.05 or lower has an inhibitive effect on the attack of cobalt. This behaviour may be explained by a competitive adsorption between dissolved species in the environment. It is realistic to consider anion adsorption in the corrosion mechanism of cobalt because its zero charge potential (ZCP) is estimated to –0.550 V vs. SCE (13). As a result, when the electrode is polarized at higher potentials than the ZCP, adsorption of anions or polar molecules can occur (14).

The influence of competitive adsorption is well supported by the effect of a small amount of phosphate on the anodic dissolution of cobalt in bicarbonate buffer solutions. Figs. 8, 10, and 11 show that the presence of phosphate drastically diminishes the anodic dissolution intensity at pH 7.9 and also eliminates the aggressive attack at pH 7.2 and 7.5.

Passive region

In Figs. 2*a* and 2*b*, it is shown that the electrochemical behaviour of cobalt in the passive region is strongly affected by a small pH variation in 0.1 mol L^{-1} $NaHCO_3$ solutions.

Fig. 17. Plot of log(corrected J_{P1}) against log$[H_2CO_3]$ for a cobalt electrode in 0.4 mol L^{-1} $NaHCO_3$. ω = 1000 rpm; dE/dt = 0.005 V s^{-1}.

When the pH is changed from 8.9 to 8.6, a strong oxidation process takes place in the passive region observed at pH 8.9. In 0.4 mol L^{-1} $NaHCO_3$ buffer solutions, the passive region is preserved at pH values as low as 8.3. The important oxidation process, appearing gradually as the pH decreases, suggests strongly that the H_2CO_3 species is most likely aggressive toward the cobalt passive film. However, at highly anodic potentials (0.9 V in 0.1 mol L^{-1} $NaHCO_3$ and 0.7 V in 0.4 mol L^{-1} $NaHCO_3$), repassivation is taking place, which can be ascribed to the formation of Co(III) oxides, since no carbonato-complexes of Co(III) are known to exist (6). When the potential is swept in the cathodic direction, the cobalt(III) oxide is probably reduced to near 0.0 V in 0.1 mol L^{-1} $NaHCO_3$ (Fig. 2*b*) and 0.11 V in 0.4 mol L^{-1} $NaHCO_3$ (Fig. 5*b*), potentials at which a sharp anodic reactivation peak is recorded. This reactivation peak shows that the cobalt oxides formed at lower anodic potentials are not efficient at protecting cobalt from dissolution attack by bicarbonate ions, as previously reported (6).

It is also deduced that raising the $NaHCO_3$ buffer solution concentration at constant pH inhibits the passive film attack in the passive region. If one considers that the passive film attack is initiated by some adsorption phenomenon of the dissolved species on the electrode surface, it can be suggested that a competitive adsorption between H_2CO_3 and other species in solution reduces the access of H_2CO_3 to the surface. That competition effect may be less efficient at lower concentrations if the surface coverage from species in solution is possibly not complete. It is useful to point out that H_2CO_3 does not carry any charge and when the electrode is polarized at anodic potentials, the negatively charged species in solution should be adsorbed preferentially simply on an electrostatic basis. Also for that reason, catalysis efficiency of the passive film dissolution may be influenced by the pH of the solution. Considering that in the pH range from 8.2 to 7.7 the amount of HCO_3^- diminishes while H_2CO_3 increases, different rates of passive film dissolution should be expected. That is exactly what is indicated in Fig. 13*a*, since the OCP measurement at the solution pH corresponding to the highest amount of HCO_3^- (pH 8.2) pres-

© 2004 NRC Canada

ents the most rapid passive film dissolution. The effect of the amount of oxide cannot be taken into account to explain the different decay time since similar oxide amounts are found at pH 8.2 and 7.7. Nevertheless, at pH 7.7 the OCP curve suggests that a higher amount of Co(III) oxide is present since the potential remains in the region from 0.8 to 0.7 V, much longer than at more alkaline pH values. Considering that H_2CO_3 is not known to be aggressive toward this type of oxide, the passive film will take longer to disappear.

The explanation of the cobalt corrosion mechanism in $H_2CO_3/HCO_3^-/CO_3^{2-}$ solutions involving competitive adsorption is strengthened by experimental evidence obtained when phosphate is added to the system. Remarkably, it is observed that only a small addition of Na_2HPO_4 to the $NaHCO_3$ solution in a molar ratio of 1:40 has a great inhibitive effect on the corrosion of cobalt (Figs. 8, 10, and 11). From potentiodynamic experiments, it could be suggested that phosphate may improve the passive film quality as observed for iron in oxygenated phosphate solutions (see, for example, refs. 15 and 16). However, a different scenario must be considered for cobalt in phosphate solutions because the presence of phosphate diminishes the passive film decay time (Fig. 15) and the amount of film (Fig. 16) for OCP and galvanostatic measurements, respectively. Under these conditions, a specific adsorption of phosphate species on the cobalt electrode surface must be considered to be involved in the inhibition mechanism. Because the aggressive nature of $H_2CO_3/HCO_3^-/CO_3^{2-}$ solutions is explained by a catalysis effect on the cobalt passive film dissolution, the presence of phosphate species at the electrode surface will obstruct their access to the surface and then slow down considerably the passive film dissolution process. This explanation is supported by the influence of the presence of phosphate species during the OCP experiments for preanodized cobalt electrodes in 0.4 mol L^{-1} $NaHCO_3$ buffer solutions without added phosphate during preanodization. It is clearly demonstrated that the decay time of the anodic film is significantly increased by added phosphate at the beginning of the OCP measurement. The effect is enhanced at lower pH values. For example, dissolution is 20 times slower at pH 7.7 in the presence of phosphate species than in absence of these species (see Fig. 13). The enhancement of the inhibitive effect of phosphate observed when the pH is lower may be explained by the higher proportion of H_2CO_3 species in solution. Only on an electrostatic basis, this uncharged species is disadvantaged to compete adequately with the adsorption of charged phosphate species. Also, because the inhibitive effect of phosphate is enhanced when the pH is lowered from 8.2 to 7.7, it can be proposed, considering Fig. 1*b*, which $H_2PO_4^-$ is mainly adsorbed on the cobalt electrode and inhibits the dissolution of passive films previously formed in bicarbonate buffers. Al-Kharafi et al. (17) recently reported that phosphate ions are included in the passive film when a cobalt electrode is immersed in a phosphate buffer at pH 7. It can therefore be deduced that the nature of the passive film formed in a 0.4 mol L^{-1} $NaHCO_3$ solution and in the presence of a 0.4 mol L^{-1} $NaHCO_3$ + 0.01 mol L^{-1} Na_2HPO_4 solution is quite different, the last one containing phosphate. This can explain why the decay potential profiles during the OCP measurements of passive films formed in these two solutions are very different, even if both are dissolved in the same media (0.4 mol L^{-1} $NaHCO_3$ + 0.01 mol L^{-1} Na_2HPO_4). The passive film formed in 0.4 mol L^{-1} $NaHCO_3$ + 0.01 mol L^{-1} Na_2HPO_4 solutions dissolves more rapidly (Fig. 14) because phosphate salts included in passive films present preferential attack sites for aggressive species (17). This is consistent with the dissolution time observed for a preanodized electrode in $NaHCO_3$ solutions and Na_2HPO_4 solutions at the same pH and concentration (Fig. 15).

Conclusions

The potentiodynamic experiments on rotating cobalt electrodes in aq. $H_2CO_3/HCO_3^-/CO_3^{2-}$ solutions demonstrate that carbonate and bicarbonate species promote the anodic dissolution of cobalt in the pH range from 8.5 to 9.7. In this buffer system, the pH zone between 7 to 8 was studied for the first time and it is evident that for pH values below 8.5, the involvement of carbonic acid as a new aggressive species toward cobalt must be considered. Indeed, in this pH region where the H_2CO_3 concentration becomes important, the passivation of cobalt is completely inhibited.

The effect of solution composition on the cobalt passive film was studied on a prepassivated cobalt electrode using open circuit potential and galvanostatic measurements. It can be deduced that competitive adsorption mechanisms play a key role in the attack of passive films on cobalt. It was shown that the presence of a small amount of phosphate species in carbonic acid – bicarbonate – carbonate solutions is an efficient corrosion inhibitor, especially against the carbonic acid species. The inhibition mode of phosphate is most likely linked to a specific adsorption phenomenon since its beneficial contribution to the stability of passive films must be discarded.

Telechelic poly(ε-caprolactones) with tethered mixed ligand ruthenium(II) chromophores

Abdiaziz A. Farah and William J. Pietro

Abstract: Well-characterized templates of polymer-forming ligands and their ruthenium tris(α,α′-diimine) initiators were utilized to divergently ring open an ε-caprolactone monomer. The same polymers were also obtained through the synthesis of quinoline and bipyridine diimine ligands incorporating poly(ε-caprolactone) (PCL) chains. These polymers contain vacant molecular recognition sites, enabling subsequent chelation of these macroligands to metal precursors. Both methods provided telechelic (ε-caprolactone) ruthenium(II)-centered polyesters of various hierarchy. Solution properties and thermal behaviour of such polyesters are described.

Key words: redox polymers, poly(ε-caprolactone), telechelics, metal–polymer complexes, macroligands, ring-opening polymerization (ROP).

Résumé : On a utilisé des gabarits bien caractérisés de ligands conduisant à la formation de polymères et leurs initiateurs ruthénium tris(α,α′-diimine) pour provoquer des ouvertures de cycle divergentes d'un monomère ε-caprolactone. On a pu aussi obtenir les mêmes polymères en effectuant la synthèse de ligands quinoléine ou bipyridine diimine incorporant des chaînes poly(ε-caprolactone) (PCL). Ces polymères contiennent des sites vacants de reconnaissance moléculaire qui permettent d'effectuer une chélation subséquente de ces macroligands sur des précurseurs métalliques. Les deux méthodes permettent d'obtenir des polyesters téléchéliques centrés sur le (ε-caprolactone)ruthénium(II). On décrit les propriétés en solution et le comportement thermique de tels polyesters.

Mots clés : polymères redox, poly(ε-caprolactone), téléchéliques, complexes métal–polymère, macroligands, polymérisation par ouverture de cycle (POC).

Introduction

The design and the study of functional polymers containing metal centers in their structure remains an area of growing interest (1). Such materials exhibit attractive electrical, electrochemical, magnetic, and optical properties associated with the metal (2). Inorganic and organometallic polymers are relatively underrepresented in the available literature concerning polymeric functional materials. Hence, the synthesis of analogous polymeric architecture with inorganic fragments would expand the structural features and properties of the resulting inorganic–organic hybrid materials. New applications in supramolecular chemistry and the need for new materials are the driving forces for the development of inorganic and organometallic polymeric systems. Owing to the lack of appropriate organic–inorganic hybrid monomers, along with poorly optimized reaction conditions that otherwise would ensure homogeneous and quantitative conversion of these monomers, the synthesis of long chains of inorganic elements becomes rather difficult if not impossible. Radical or ionic chain polymerization of unsaturated monomers proved to be possible only in some specific cases (3). Even the apparently easier step-growth polymerizations were also problematic because of the necessity of strict stoichiometric balance and monomer purity. Consequently, only low-molecular-weight products have been available in most cases (4).

Progress in inorganic polymer chemistry became possible when more specialized polymerization reactions were applied, such as ring-opening polymerization (ROP) (5) or transition-metal-catalyzed processes (6). These techniques, along with solubilizing side-chain moieties, provided a wide range of inorganic macromolecules with valuable properties. Four possible synthetic methods have been utilized for the incorporation of metal complexes into polymeric structures: binding via coordination site from a polymer-bound ligand (7); covalent attachment by reaction of a functionalized complex with a functionalized polymer (8); homopolymerization of metal-containing monomers incorporating polymerizable groups; and copolymerization of a complex bearing a polymerizable group with other selected monomers (9). Recently, Fraser and co-workers (10) have elegantly demonstrated that the combination of coordination chemistry with controlled polymerization methodologies would lead to a variety of functional materials. In contrast to the conventional way of synthesizing functional polymeric materials via post-polymer modification of end-reactive oligomers and polymeric precursors (11), this synthetic ap-

proach provides polymers of controlled molecular weights and, in particular, unique and well-defined spatial shapes. Almost none of these characteristics are found in conventional, mostly linear synthetic polymers. In turn, metal moieties in well-defined microdomains in the polymer chain allow the precise incorporation of functional groups, an indispensable feature in developing specific material functions with multi-dimensional environments.

In this contribution the synthesis and characterization of telechelic linear and multi-dimensional poly(ε-caprolactones) tagged with ruthenium(II)-centered chromophores of the general structure in Fig. 1 will be described. These polyesters have been prepared by two distinct approaches: macroligand-chelation and metalloinitiation. Both methods proceed under mild conditions and provide polymers with controlled properties, i.e., molecular weight and molecular-weight distributions.

Fig. 1. General structure of the telechelic ruthenium-centered poly(ε-caprolactones).

Experimental

Methods and materials

All reagents were obtained from Aldrich Chemicals Canada/Fluka and Alfa Aesar (Ward Hill, Mass). Reagent-grade solvents were obtained from Caledon and BDH Inc. Electrochemical solvents were freshly distilled over P_2O_5 under inert atmosphere, and electrolytes were twice recrystallized from absolute ethanol and dried in vacuum. All chemicals and solvents were purified where necessary, according to the conventional laboratory techniques (12), or were used as received. *cis*-$Ru(bpy)_2Cl_2 \cdot xH_2O$ (bpy = bipyridine) and metal complexes (**5**), (**6**), (**7**), (**8**), (**9**), and (**10**) were obtained as described in refs. 13 and 14, respectively. Analytical thin layer chromatography (TLC) was done on commercially prepared silica gel 60F 254 coated plastic sheets (Aldrich). Preparative TLC was performed on Aldrich silica gel 60F 254 precoated glass plates. For column chromatography, high-purity grade (70–230 mesh, 60 Å) silica gel and neutral standard grade (150 mesh, 58 Å) aluminum oxide were used. Melting points (mp) were recorded using a Laboratory Devices U.S.A. MEL-TEMP II and were uncorrected. Infrared spectra were recorded neat, as KBr pellets, or as solution-casted films with a Mattson 3000 Fourier transform infrared spectrophotometer. ^1H and ^{13}C NMR spectra were obtained on a Bruker ARX 400-MHz nuclear magnetic resonance spectrometer in an appropriate solvent, using tetramethylsilane as an internal standard. Electronic spectroscopy was performed using a Hewlett-Packard 8452 diode array spectrophotometer. Fluorimetry experiments were conducted in a Shimadzu RF 551 fluorimeter or a PerkinElmer LS-50B luminescence fluorimeter on argon or N_2 deaerated samples prior to recording. Electron impact (EI) mass spectrometry (positive mode) was carried out using a Kratos 902 mass spectrometer. Electrochemistry experiments were performed in a conventional three-electrode cell using a platinum working electrode, a platinum counter electrode, and an Ag/Ag^+ wire "quasi" reference electrode referenced to the ferrocenium–ferrocene couple (15). The solvent used was dimethylformamide (DMF), with tetrabutylammonium hexafluorophosphate ($TBAPF_6$) as the supporting electrolyte. A Princeton Applied Research Corp. 174 Potentiostat or an RDE3 potentiostat (Pine Instrument) with an *x*–*y* recorder or a computerized Cypress workstation was used for all electrochemical studies. All electroanalytical solutions were degassed with N_2 or argon for 20 min prior to each experiment. Molecular weights were determined by gel permeation chromatography (GPC) with a Waters Associates 2690 separation module accessoried inline solvent degasser, a high performance liquid chromatography (HPLC) pump, and an autosampler. The separation module was equipped with a Waters 410 differential refractometer as the concentration detector and was connected in parallel. A Viscotek T60A dual detector consisted of a right-angle laser light scattering detector with a laser source of 670 nm and a four-capillary differential viscometer. Software from Viscotek was used to analyze the data. Columns from Polymer Laboratories with pore sizes of 5×10^2, 1×10^4, and 1×10^5 Å were used with THF as the eluent at a flow rate of 1.0 mL/min. Polystyrene standards purchased from Aldrich and Viscotek were used for calibration. Absolute molecular weights were determined by low angle laser light scattering (LALLS) performed on a Chromatix KMX-6 instrument at a wavelength of 632.8 nm and a scattering angle of 6°–7°. Measurements were carried out at room temperature with a metal cell 4.93 mm long. Each solution was filtered three times through a MILEX filter with an average pore size of 0.2 μm before injection into the cell. The refractive index increment (dn/dc) of the polymer solution was obtained with a Chromatix KMX-16 differential refractometer, operating at a wavelength of 632.8 nm. The instrument was calibrated with NaCl solutions. A PerkinElmer DSC7 equipped with a TAC7 instrument controller or TA instrument DSC 2920 was used to study polymer thermal behavior. For differential scanning calorimetry (DSC) experiments, the instruments were calibrated with melting transitions of decane and indium, and

samples were heated under N_2 atmosphere at a heating rate of 10 °C/min. Reported thermal parameters were taken from the second heating cycle if not otherwise indicated. The glass transition (T_g) value was the mid-point of the heat capacity change, whereas the melting point (T_m) was the peak maximum. Thermogravimetric analyses (TGA) were also obtained on the same instrument, TGA7, and the temperature was calibrated with the transitions of Perkalloy and Nicoseal. Thermograms were obtained at a heating rate of 20 °C/min under an N_2 atmosphere.

2-(2-Pyridyl)-4-hydroxymethylquinoline (pq) ligand (1)

Lithium aluminum hydride (2.3 g, 52 mmol) was added into 200 mL of anhydrous diethyl ether under nitrogen. To this suspension was added 3.2 g (13 mmol) of 2-(2-pyridyl)-4-methylcarbonylquinoline (16) in 20 mL of dry THF over a period of 30 min at room temperature. The reaction mixture was allowed to reflux gently for 3 h and then cooled to room temperature. The excess lithium aluminum hydride was decomposed by gentle addition of 5% H_2SO_4, and the phases were separated. The organic phase was washed with 5% $NaHCO_3$ (3 × 30 mL) and water (2 × 30 mL) and then dried over Na_2SO_4. After removal of the solvent, the desired product was obtained as an orange crystalline solid. Yield 2.2 g (64%); mp 108 °C.

IR (KBr pellets, ν in cm^{-1}) ν: 3355 (s, broad, O-H str), 2924 (m, sharp, arom C-H str), 2859 (m, sharp, aliph C-H str), 1991–2058 (m, broad, arom overtone bands), 1602 (s, sharp, C=C ring str), 1310 (s, sharp, arom C-N str), 1260 (w, sharp, C-O-C str), 1037 (s, broad, C-H in-plane bend), 745 (s, sharp, arom C-H out-of-plane bend). ^{1}H NMR (DMSO-d_6, δ in ppm) δ: 9.08 (s, H3 of quinoline), 8.82 (d, H5 of quinoline, J = 9.6 Hz), 8.79 (d, H12 of pyridine, J = 12 Hz), 8.68 (d, H9 of pyridine, J = 8 Hz), 8.24 (d, H8 of quinoline, J = 8 Hz), 7.89 (dd, H10 of pyridine, J = 8 Hz), 7.79 (dd, H7 of quinoline, J = 7.5 Hz, J = 15 Hz), 7.67 (dd, H6 of quinoline, J = 7.5 Hz, J = 15 Hz), 7.38 (dd, H11 of pyridine, J = 8 Hz, J = 12 Hz), 5.23 (s, 2H, OCH_2), 3.72 (br. 1H, OH). EI-MS (*m*/*z*) (%): 236 (65), 205 (21), 178 (12).

4,4′-Dimethyl-2,2′-bipyridine (2)

4,4′-Dimethyl-2,2′ bipyridine (**2**) was prepared following the Sassi method (17), using 220 g (2.36 mol) of 4-picoline and 10 g of 10 wt % palladium on activated carbon. Yield 8.2 g (59%). (lit. (17) value 1.4 g/g of 10 wt % Pd–C). mp 174 °C (lit. (17) value mp 174–176 °C). IR (KBr pellets, ν in cm^{-1}) ν: 3037 (s, sharp, arom C-H str), 2967 (m, sharp, aliph C-H str), 2017–1677 (m, broad, arom overtone bands), 1598 (s, sharp, C=C ring str), 1369 (s, sharp, arom C-N str), 1119–1045 (m, sharp, aliph C-H in-plane bend), 725 (s, sharp, arom C-H out-of-plane bend). ^{1}H NMR ($CDCl_3$, δ in ppm) δ: 8.54 (s, 2H, H6, J = 4.9 Hz), 8.23 (d, 2H, H3, J = 1.7 Hz), 7.12 (d, 2H, H5, J = 4.7 Hz), 2.45 (s, 6H, CH_3). EI-MS (*m*/*z*) (%): 184 (100), 169 (14), 156 (11).

4-Methyl-2,2′-bipyridine-4′-carboxaldehyde (3)

A mixture of 5.27 g (28.6 mmol) of (**2**) and 3.48 g (31.4 mmol) of SeO_2 in 1,4-dioxane was refluxed for 24 h with vigorous stirring and hot filtered. The filtrate was cooled to room temperature, and the resulting light-brown precipitate was filtered and discarded. After the solvent was removed by rotary evaporation, the residue was partially dissolved in 450 mL of ethyl acetate and filtered to remove the insoluble fraction. The filtrate was extracted with 0.1 mol/L Na_2CO_3 (2 × 100 mL) and 0.3 mol/L $Na_2S_2O_5$ (2 × 100 mL). The combined aqueous extracts were adjusted to pH 10 with Na_2CO_3, extracted with dichloromethane (3 × 50 mL), and dried over Na_2SO_4. The solvent was removed under reduced pressure, affording an off-white solid. Yield 2.8 g (50%); mp 130 to 131 °C (lit. (18) value mp 130.9–131.7 °C).

IR (KBr pellets, ν in cm^{-1}) ν: 3061 (m, sharp, arom C-H str), 2961 (s, sharp, aliph C-H str), 2093–1817 (m, sharp, arom overtone bands), 1702 (s, sharp, C=O aldehyde str), 1593 (s, sharp, C=C ring str), 1350 (s, sharp, arom C-N str), 1090–1031 (m, sharp, aliph C-H in-plane bend), 754 (s, sharp, arom out-of-plane bend). ^{1}H NMR (DMSO-d_6, δ in ppm) δ: 10.18 (s, 1H, CHO), 8.93 (d, 1H, H6, J = 4.8 Hz), 8.76 (s, 1H, H3), 8.57 (d, 1H, H6′, J = 4.8 Hz), 8.23 (s, 1H, H3′), 7.81 (d, 1H, H5, J = 4.8 Hz, J = 1.3 Hz), 7.30 (d, 1H, H5′, J = 4.2 Hz), 2.47 (s, 3H, CH_3). ^{13}C NMR (DMSO-d_6, δ in ppm) δ: 193.46, 157.01, 154.15, 150.71, 149.28, 148.30, 142.68, 125.54, 121.40, 119.46, 20.73. EI-MS (*m*/*z*) (%): 198 (100), 170 (68), 169 (52).

4-Methyl-4′-hydroxymethyl-2,2′-bipyridine (4)

After 2.2 g (10 mmol) of (**3**) in 50 mL of ethanol were cooled in an ice-bath while stirring for 20 min, 1.9 g (50 mmol) of $NaBH_4$ dissolved in 20 mL of 0.2 mol/L NaOH (aq) was added. The reaction mixture was left reacting under vigorous stirring for 4 h. Excess $NaBH_4$ was destroyed by treatment with dilute H_2SO_4, and most of the ethanol was removed under reduced pressure. The remaining white slurry was diluted with water and extracted with chloroform (3 × 40 mL). The chloroform extracts were washed with $NaHCO_3$ (3 × 30 mL) and water (3 × 30 mL) and dried with Na_2SO_4. The desired product was obtained following removal of the solvent. Yield 1.6 g (78%); mp 122 °C.

IR (KBr pellets, ν in cm^{-1}) ν: 3470 (w, shoulder, O-H str), 3185 (s, sharp, arom str), 2833 (s, sharp, aliph str), 2064 (w, broad, arom overtone), 1586 (m, sharp, C=C ring str), 1454 (s, sharp, arom C-N str), 1247 (s, sharp, C-O str), 758 (s, sharp, C-H out-of-plane bend). ^{1}H NMR (DMSO-d_6, δ in ppm) δ: 8.50 (d, 1H, H6′, J = 3.4 Hz), 8.42 (d, 1H, H6, J = 5 Hz), 8.22 (s, 1H, H3′), 8.11 (s, 1H, H3), 7.20 (d, 1H, H5′, J = 4.9 Hz), 7.07 (d, 1H, H5, J = 4.9 Hz), 4.69 (s, 1H, CH_2O), 2.37 (s, 1H, CH_3). ^{13}C NMR (DMSO-d_6, δ in ppm) δ: 155.25, 152.74, 148.91, 148.88, 147.81, 124.82, 121.34, 121.27, 121.24, 117.87, 117.85, 61.85, 61.85, 20.68. Synthesis of ruthenium-centered polyesters via ring-opening polymerization of ε-caprolactone with ruthenium(II) metalloinitiators

Ru(bpy)$_2$(bpyPCL)(PF$_6$)$_2$ (11)

Initiator (**5**) (91 mg, 0.11 mmol) and 2.3 g (18 mmol) of ε-caprolactone were charged into an N_2-filled polymerization flask and immersed into a preheated oil at 110 °C for 20 min before addition of a catalytic amount (0.60 μL) of stannous octanoate ($Sn(Oct)_2$). The polymerization reaction mixture was then left reacting with stirring at 110 °C for

© 2004 NRC Canada

24 h. The resulting viscous product was diluted with THF while still warm and precipitated in cold MeOH. The polymer was further purified by precipitation twice from THF solution into MeOH. Yield 2.6 g (91%) of a red-orange polymeric product.

IR (KBr pellets, ν in cm^{-1}) ν: 3442 (s, broad, OH str), 2944 (m, sharp, arom C-H str), 2863 (m, sharp, aliph C-H str), 2195–1890 (m, broad, arom overtone bands), 1723 (s, sharp, C=O ester str), 1592 (s, sharp, C=C ring str), 1471 (m, sharp, arom C-N str), 1092 (s, broad, C-O-C str), 729 (s, sharp, arom out-of-plane bend). UV–vis (DMF) λ_{max}: 286 nm (ε = 78 500 $(mol/L)^{-1}$ cm^{-1}), 456 nm (ε = 12 700 $(mol/L)^{-1}$ cm^{-1}). ^1H NMR (DMSO-d_6, δ in ppm) δ: 4.05 (m, broad, CH_2O of PCL), 2.30 (m, broad, $OCCH_2$ of PCL), 1.64 (m, broad, CH_2 of PCL), 1.39 (m, broad, CH_2 of PCL). GPC (LALLS): M_w: 28 130; M_w/M_n: 1.26.

Ru(bpyPCL)$_2$(bpy)(PF$_6$)$_2$ (12)

The two-dimensional (**12**) polymer was synthesized by a similar experimental procedure to that described above for (**11**), using 45 mg (0.047 mmol) of (**6**), 2.4 g (18 mmol) of ε-caprolactone, and 0.63 μL of $Sn(Oct)_2$. Yield 1.6 g (52%) of a red-orange polymeric product.

IR (KBr pellets, ν in cm^{-1}) ν: 3445 (s, broad, OH str), 2945 (m, sharp, arom C-H str), 2863 (m, sharp, aliph C-H str), 2199–1891 (m, broad, arom overtone bands), 1721 (s, sharp, C=O ester str), 1592 (s, sharp, C=C ring str), 1479 (m, sharp, arom C-N str), 1090 (s, broad, C-O-C str), 743 (s, sharp, arom out-of-plane bend). UV–vis (DMF) λ_{max}: 289 nm (ε = 71 400 $(mol/L)^{-1}$ cm^{-1}), 452 nm (ε = 10 900 $(mol/L)^{-1}$ cm^{-1}). ^1H NMR (DMSO-d_6, δ in ppm) δ: 4.06 (m, broad, CH_2O of PCL), 2.37 (m, broad, $OCCH_2$ of PCL), 1.65 (m, broad, CH_2 of PCL), 1.40 (m, broad, CH_2 of PCL). GPC (LALLS): M_w: 47 300, M_w/M_n: 1.37.

Ru(bpyPCL)$_3$(PF$_6$)$_2$ (13)

The three-dimensional (**13**) was synthesized by a similar procedure to that described for (**11**), using 60 mg (0.060 mmol) of (**7**), 2.5 g (22 mmol) of ε-caprolactone, and 0.60 μL of $Sn(Oct)_2$. Yield 2.3 g (82%) of a red-orange polymeric product.

IR (KBr pellets, ν in cm^{-1}) ν: 3442 (s, broad, OH str), 2940 (m, sharp, arom C-H str), 2863 (m, sharp, aliph C-H str), 2191–1898 (m, broad, arom overtone bands), 1719 (s, sharp, C=O ester str), 1597 (s, sharp, C=C ring str), 1471 (m, sharp, arom C-N str), 1092 (s, broad, C-O-C str), 733 (s, sharp, arom out-of-plane bend). UV–vis (DMF) λ_{max}: 292 nm (ε = 79 300 $(mol/L)^{-1}$ cm^{-1}), 458 nm (ε = 12 800 $(mol/L)^{-1}$ cm^{-1}). ^1H NMR (DMSO-d_6, δ in ppm) δ: 4.03 (m, broad, CH_2O of PCL), 2.31 (m, broad, $OCCH_2$ of PCL), 1.69 (m, broad, CH_2 of PCL), 1.37 (m, broad, CH_2 of PCL). GPC (LALLS): M_w: 64 300, M_w/M_n: 1.45.

Ru(bpy)$_2$(pqPCL)(PF$_6$)$_2$ (17)

The one-dimensional (**17**) was synthesized by a similar procedure to that described for (**11**), using 74 mg (0.070 mmol) of (**8**), 2.3 g (18 mmol) of ε-caprolactone, and 0.54 μL of $Sn(Oct)_2$. Yield 1.1 g (82%) of a dark-red polymeric product.

IR (KBr pellets, ν in cm^{-1}) ν: 3440 (s, broad, OH str), 2951 (m, sharp, arom C-H str), 2857 (m, sharp, aliph C-H str), 2095–2019 (m, broad, arom overtone bands), 1730 (s, sharp, C=O ester str), 1595 (s, sharp, C=C ring str), 1471 (m, sharp, arom C-N str), 1100 (s, broad, C-O-C str), 842 (s, sharp, arom out-of-plane bend). UV–vis (DMF) λ_{max}: 290 nm (ε = 47 100 $(mol/L)^{-1}$ cm^{-1}), 500 nm (ε = 8 900 $(mol/L)^{-1}$ cm^{-1}). ^1H NMR (DMSO-d_6, δ in ppm) δ: 4.03 (m, broad, CH_2O of PCL), 2.39 (m, broad, $OCCH_2$ of PCL), 1.69 (m, broad, CH_2 of PCL), 1.31 (m, broad, CH_2 of PCL). GPC (LALLS): M_w: 19 150, M_w/M_n: 1.52.

Ru(pqPCL)$_2$(bpy)(PF$_6$)$_2$ (18)

The two-dimensional (**18**) was synthesized by a similar procedure to that described for (**11**), using 46 mg (0.045 mmol) of (**9**), 1.5 g (13 mmol) of ε-caprolactone, and 0.46 μL of $Sn(Oct)_2$. Yield 0.81g (62%) of a dark-red polymeric product.

IR (KBr pellets, ν in cm^{-1}) ν: 3442 (s, broad, OH str), 2939 (m, sharp, arom C-H str), 2857 (m, sharp, aliph C-H str), 2095–2019 (m, broad, arom overtone bands), 1721 (s, sharp, C=O ester str), 1591 (s, sharp, C=C ring str), 1475 (m, sharp, arom C-N str), 1100 (s, broad, C-O-C str), 842 (s, sharp, arom out-of-plane bend). UV–vis (DMF) λ_{max}: 300 nm (ε = 46 200 $(mol/L)^{-1}$ cm^{-1}), 486 nm (ε = 10 200 $(mol/L)^{-1}$ cm^{-1}). ^1H NMR (DMSO-d_6, δ in ppm) δ: 4.08 (m, broad, CH_2O of PCL), 2.41 (m, broad, $OCCH_2$ of PCL), 1.60 (m, broad, CH_2 of PCL), 1.39 (m, broad, CH_2 of PCL). GPC (LALLS): M_w: 28 500, M_w/M_n: 1.51.

Ru(pqPCL)$_3$(PF$_6$)$_2$ (19)

The three-dimensional (**19**) was synthesized by a similar procedure to that described for (**11**), using 40 mg (0.036 mmol) of (**10**), 1.5 g (13 mmol) of ε-caprolactone, and 0.60 μL of $Sn(Oct)_2$. Yield 0.98 g (79%) of a dark-red polymeric product.

IR (KBr pellets, ν in cm^{-1}) ν: 3449 (s, broad, OH str), 2951 (m, sharp, arom C-H str), 2857 (m, sharp, aliph C-H str), 2095–2019 (m, broad, arom overtone bands), 1725 (s, sharp, C=O ester str), 1594 (s, sharp, C=C ring str), 1471 (m, sharp, arom C-N str), 1100 (s, broad, C-O-C str), 842 (s, sharp, arom out-of-plane bend). UV–vis (DMF) λ_{max}: 311 nm (ε = 57 500 $(mol/L)^{-1}$ cm^{-1}), 480 nm (ε = 8 600 $(mol/L)^{-1}$ cm^{-1}). ^1H NMR (DMSO-d_6, δ in ppm) δ: 4.00 (m, broad, CH_2O of PCL), 2.31 (m, broad, $OCCH_2$ of PCL), 1.68 (m, broad, CH_2 of PCL), 1.29 (m, broad, CH_2 of PCL). GPC (LALLS): M_w: 34 540, M_w/M_n: 1.47

Synthesis of ruthenium-centered polyesters via macroligand–chelation approach

bpyPCL macroligand (23)

This macroligand was synthesized by a similar procedure to that described for (**11**), using 0.52 g (3.2 mmol) of (**4**) initiator, 33 g (289 mmol) of ε-caprolactone, and 16 μL of $Sn(Oct)_2$. Yield 35 g (94%) of a white polymeric product.

IR (KBr pellets, ν in cm^{-1}) ν: 3439 (s, broad, OH str), 2951 (m, sharp, arom C-H str), 2857 (m, sharp, aliph C-H str), 2095–2019 (m, broad, arom overtone bands), 1719 (s, sharp, C=O ester str), 1594 (s, sharp, C=C ring str), 1471 (m, sharp, arom C-N str), 1100 (s, broad, C-O-C str), 849 (s, sharp, arom out-of-plane bend). ^1H NMR (DMSO-d_6, δ in ppm) δ: 8.65 (d, broad, H6′ of bpy), 8.53 (d, broad, H6 of

© 2004 NRC Canada

bpy), 8.36 (s, broad, H3′ of bpy), 8.23 (s, broad, H3 of bpy), 7.13–7.18 (d, broad, H5′ & H5 of bpy), 5.20 (s, broad, CH_2O of bpy), 4.05 (m, broad, CH_2O of PCL), 2.30 (m, broad, $OCCH_2$ of PCL), 1.64 (m, broad, CH_2 of PCL), 1.39 (m, broad, CH_2 of PCL). GPC (LALLS): M_w: 27 900, M_w/M_n: 1.27.

Ru(bpy)$_2$(bpyPCL)(PF$_6$)$_2$ (14)

cis-Ru(bpy)$_2$Cl$_2$ (50 mg, 0.11 mmol) was dissolved in 20 mL of methanol; 43 mg (0.25 mmol) of $AgNO_3$ were added to the dissolved substrate, and the solution was left stirring for 2 h at room temperature. The resulting white precipitate was filtered off and evaporated to dryness, then redissolved in 30 mL of an acetonitrile–DME (1:1) mixture. To this was added 2.9 g (0.10 mmol) of (**23**) macroligand polymer, and the mixture was refluxed for 24 h with vigorous stirring. The solvent was then removed using a rotary evaporator, and the resulting red-orange product was purified by column chromatography (silica), using methylene chloride as the eluent. After reducing the solvent volume to 5–10 mL, the product was precipitated by addition with stirring to a methanolic potassium hexafluorophosphate solution. The product was then filtered, washed with ether, and vacuum dried. Yield 2.5 g (89%) of a red-orange polymeric product.

IR (KBr pellets, ν in cm^{-1}) ν: 3440 (s, broad, OH str), 2945 (m, sharp, arom C-H str), 2863 (m, sharp, aliph C-H str), 2195–1890 (m, broad, arom overtone bands), 1719 (s, sharp, C=O ester str), 1592 (s, sharp, C=C ring str), 1471 (m, sharp, arom C-N str), 1092 (s, broad, C-O-C str), 729 (s, sharp, arom out-of-plane bend). UV–vis (DMF) λ_{max}: 288 nm (ε = 79 600 $(mol/L)^{-1}$ cm^{-1}), 456 nm (ε = 12 900 $(mol/L)^{-1}$ cm^{-1}). ^{1}H NMR (DMSO-d_6, δ in ppm) δ: 7.63–8.66 (m, broad, bpy ArH), 5.33 (s, broad, CH_2O of bpy), 4.06 (m, broad, CH_2O of PCL), 2.37 (m, broad, $OCCH_2$ of PCL), 1.69 (m, broad, CH_2 of PCL), 1.41 (m, broad, CH_2 of PCL). GPC (LALLS): M_w: 28 430, M_w/M_n: 1.29.

Ru(bpyPCL)$_2$(bpy)(PF$_6$)$_2$ (15)

$RuCl_3 \cdot xH_2O$ (30 mg, 0.062 mmol), 3.5 g (0.13 mmol) of (**23**) macroligand polymer, and 2.1 g (50 mmol) of lithium chloride were dissolved in 30 mL of acetonitrile–DME (1:1) and refluxed overnight while stirring. The resulting intense dark-blue reaction product was evaporated to dryness, then dissolved in 10 mL of acetonitrile–DME (1:1) and reacted with 54 mg (0.32 mmol) of $AgNO_3$ under vigorous stirring for 6 h at room temperature. After filtering out the white AgCl precipitate through a Celite pad, 9.67 mg (0.063 mmol) of 2,2′-bipyridine was added to the filtrate and refluxed for 16 h. The desired polymer was then isolated from the reaction mixture by addition to a cold methanolic potassium hexafluorophosphate solution and filtered. It was further purified by column chromatography on silica and eluted with methylene chloride. Yield 2.7 g (70%) of an orange-red polymer.

IR (KBr pellets, ν in cm^{-1}) ν: 3449 (s, broad, OH str), 2945 (m, sharp, arom C-H str), 2866 (m, sharp, aliph C-H str), 2195–1890 (m, broad, arom overtone bands), 1722 (s, sharp, C=O ester str), 1598 (s, sharp, C=C ring str), 1471 (m, sharp, arom C-N str), 1092 (s, broad, C-O-C str), 756 (s, sharp, arom out-of-plane bend). UV–vis (DMF) λ_{max}: 290 nm (ε = 73 500 $(mol/L)^{-1}$ cm^{-1}), 456 nm (ε = 9 800 $(mol/L)^{-1}$ cm^{-1}). ^{1}H NMR (DMSO-d_6, δ in ppm) δ: 7.58–8.60 (m, broad, bpy ArH), 5.31 (s, broad CH_2O of bpy), 4.06 (m, broad, CH_2O of PCL), 2.33 (m, broad, $OCCH_2$ of PCL), 1.69 (m, broad, CH_2 of PCL), 1.45 (m, broad, CH_2 of PCL). GPC (LALLS): M_w: 29 870, M_w/M_n: 1.31.

Ru(bpyPCL)$_3$(PF$_6$)$_2$ (16)

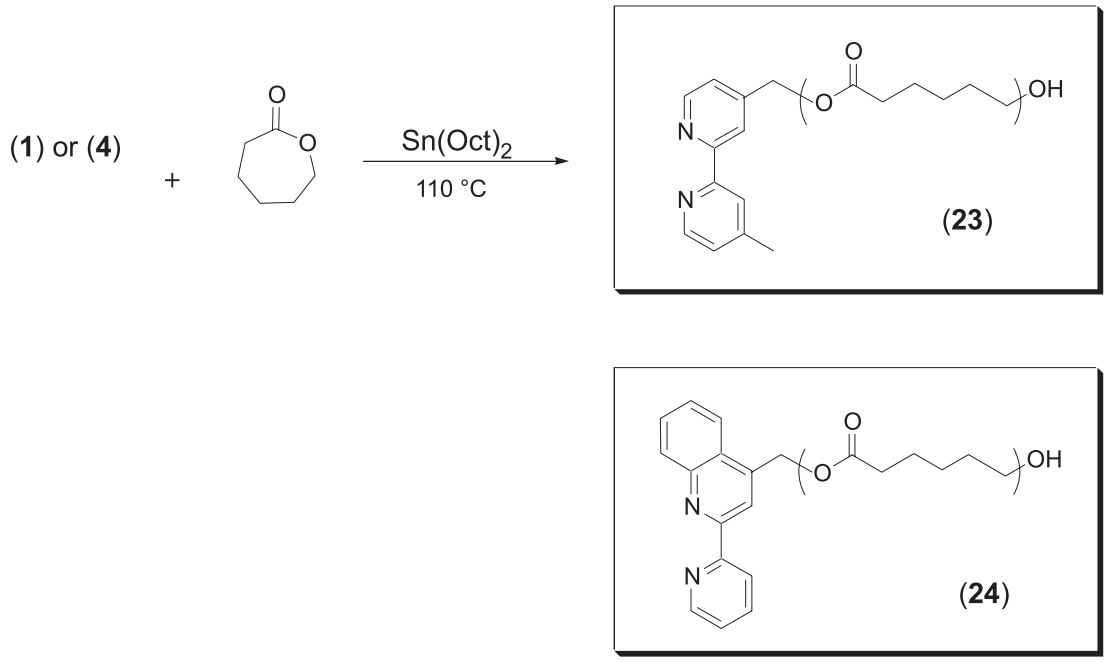
This three-dimensional (**16**) polymer was obtained from 40 mg (0.082 mmol) of $RuCl_3 \cdot xH_2O$ and 6.9 g (0.33 mmol) of (**23**) macroligand polymer in 30 mL of acetonitrile–DME (20:80 volume fraction), using the procedure described for (**14**). Yield 5.1 g (61%).

IR (KBr pellets, ν in cm^{-1}) ν: 3455 (s, broad, OH str), 2942 (m, sharp, arom C-H str), 2866 (m, sharp, aliph C-H str), 2195–1890 (m, broad, arom overtone bands), 1729 (s, sharp, C=O ester str), 1602 (s, sharp, C=C ring str), 1471 (m, sharp, arom C-N str), 1098 (s, broad, C-O-C str), 756 (s, sharp, arom out-of-plane bend). UV–vis (DMF) λ_{max}: 286 (ε = 78 400 $(mol/L)^{-1}$ cm^{-1}), 456 (ε = 12 700 $(mol/L)^{-1}$ cm^{-1}). ^{1}H NMR (DMSO-d_6, δ in ppm) δ: 7.52–8.67 (m, broad, bpy ArH), 5.28 (s, broad CH_2O of bpy), 4.08 (m, broad, CH_2O of PCL), 2.31 (m, broad, $OCCH_2$ of PCL), 1.65 (m, broad, CH_2 of PCL), 1.42 (m, broad, CH_2 of PCL). GPC (LALLS): M_w: 53 370, M_w/M_n: 1.37.

pqPCL macroligand (24)

This macroligand polymer was synthesized by a similar procedure to that described for (**23**), using 0.59 g (2.5 mmol) of (**1**) initiator, 35 g (306 mmol) of ε-caprolactone, and 17 μL of Sn(Oct)$_2$. Yield 23 g (66%) of a white polymeric product.

IR (KBr pellets, ν in cm^{-1}) ν: 3356 (s, broad, O-H str), 2928 (m, sharp, arom C-H str), 2860 (m, sharp, aliph C-H str), 1991–2058 (m, broad, arom overtone bands), 1726 (s, sharp, C=O ester str), 1609 (s, sharp, C=C ring str), 1315 (s, sharp, arom C-N str), 1260 (w, sharp, C-O-C str), 1037 (s, broad, C-H in-plane bend), 749 (s, sharp, arom C-H out-of-plane bend). ^{1}H NMR (DMSO-d_6, δ in ppm) δ: 9.05 (s, broad, H3 of quinoline), 7.35–8.80 (m, complex, quinoline & bpy ArH), 5.27 (s, broad CH_2O of quinoline), 4.07 (m, broad, CH_2O of PCL), 2.32 (m, broad, $OCCH_2$ of PCL), 1.65 (m, broad, CH_2 of PCL), 1.43 (m, broad, CH_2 of PCL). GPC (LALLS): M_w: 19 800, M_w/M_n: 1.54.



Ru(bpy)$_2$(pqPCL)(PF$_6$)$_2$ (20)

The one-dimensional polymer (**20**) was synthesized by a similar procedure to that described for (**14**), using 45 mg (0.093 mmol) of *cis*-Ru(bpy)$_2$Cl$_2$, 40 mg (0.23 mmol) of $AgNO_3$, and 2.7 g (0.091 mmol) of (**24**) macroligand polymer. Yield 1.7 g (90%) of a dark-red polymeric product.

IR (KBr pellets, ν in cm^{-1}) ν: 3356 (s, broad, O-H str), 2928 (m, sharp, arom C-H str), 2860 (m, sharp, aliph C-H str), 1991–2058 (m, broad, arom overtone bands), 1726 (s, sharp, C=O ester str), 1609 (s, sharp, C=C ring str), 1315 (s, sharp, arom C-N str), 1260 (w, sharp, C-O-C str), 1037 (s, broad, C-H in-plane bend), 749 (s, sharp, arom C-H out-of-plane bend). UV–vis (DMF) λ_{max}: 290 nm (ε = 41 200 $(mol/L)^{-1}$ cm^{-1}), 496 nm (ε = 8 900 $(mol/L)^{-1}$ cm^{-1}). ^{1}H NMR (DMSO-d_6, δ in ppm) δ: 8.87 (s, broad, H3 of quinoline), 7.35–8.97 (m, complex, quinoline & bpy ArH),

Results and discussion

Macroligand synthesis

Polymeric macroligands (**23**) and (**24**) of controlled molecular weight, bearing end-reactive functional groups, were prepared by insertion–coordination ring-opening polymerization of ε-caprolactone with high yield (19). The polymerization was initiated by 2-(2-pyridyl)-4-hydroxymethylquinoline ligand (**1**) and 4-methyl-4′-hydroxymethyl-2,2′-bipyridine (**4**) in the presence of stannous octanoate ($Sn(Oct)_2$) as a catalyst, as shown in Scheme 1. As expected, the resulting polymeric macroligands possess one chain terminated with a hydroxy group, active in post-polymerization reactions originating from the (ε-caprolactone) ring-opening polymerization reaction (19), and another terminus end-capped with an α,α′-diimine ligand, providing a free coordination site originating from the initiators. This synthetic approach has a notable advantage over the other conventional methods of synthesizing telechelic polymers, as it provides macromers with two distinct end functional groups per polymeric chain.

GPC, thermal, and electronic absorption data of these macroligands are collected in Table 1. UV–vis spectra of

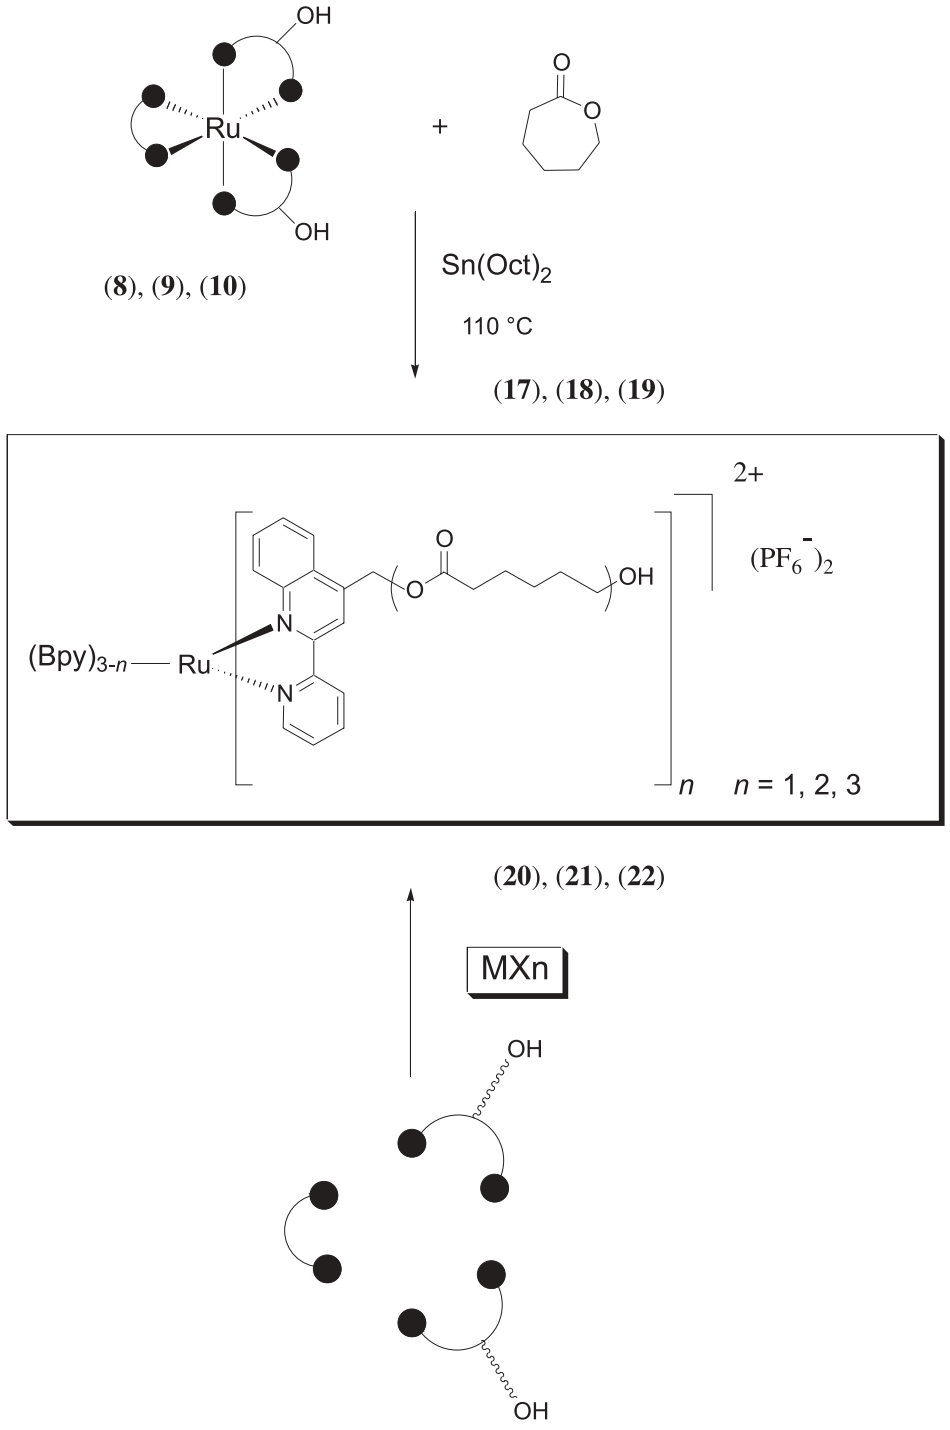

Fig. 2. ^{1}H NMR of macroligand (**23**) in $CDCl_3$.

(**23**) and (**24**) macroligands clearly revealed the presence of π–π* transitions typical of polypyridyl chromophores in the polymer chain. ^{1}H NMR analysis of these macroligands (macroligand (**23**), for example, is shown in Fig. 2) revealed well-resolved characteristic signals of the bipyridine units, as well as those of poly(ε-caprolactone). The ratios of integration between the bipyridine and quinoline ligand signals and the methylene units of the macroligand were approximately 1:1, suggesting that ligands (**1**) and (**4**) were the sole polymerization initiators. Although ^{1}H NMR spectroscopy has previously been utilized in determining the molecular weight of similar polymers with low monomer loading

(10*b*), in our samples it would be difficult and inaccurate because of their relatively high molecular weight.

Metal complexes of polymeric ligands

The design and synthesis of our metal-containing polyesters was based principally on two different approaches (Schemes 2 and 3). The first, a metalloinitiation approach, uses appropriately functionalized heteroleptic Ru(II) complexes for the ring-opening polymerization of ε-caprolactone, producing multi-functional macromolecules with a well-defined transition-metal locus at the end of the polymer chain. The second approach, termed macroligand–chelation, involves the synthesis of polymeric macroligands that are subsequently chelated to metal ions or complex precursors through standard inorganic reactions. In the latter method, the reaction medium is modified to provide fully compatible reaction conditions between the metal precursors and the polymeric macroligands. With controlled experimental reaction settings and the use of an increasing number of polymeric macroligands, both methods generate linear and

Scheme 3. Synthesis of functionalized bipyridine ligand based Ru(II) metal-centered polyesters.

multi-dimensional ruthenium-centered polyesters. In the metalloinitiation approach, mixed ligand ruthenium(II) complexes (**5**), (**6**), (**7**), (**8**), (**9**), and (**10**), bearing peripheral OH groups, were utilized as initiating sites for further ring-opening polymerization of ε-caprolactone, employing similar procedures as those described in the preparation of the macroligands. Thus, metal complexes of polymeric ligands (**11**), (**12**), (**13**), (**17**), (**18**), and (**19**) were obtained in high yield in a one-pot synthesis, as red-orange products. In this method, chains propagate divergently outward and away from the congested metal center and can consequently provide materials of relatively high molecular weight. Very often the purification of the resulting polymeric metal complex is facile, as polymeric products can be separated from unreacted monomers by precipitation or by column chromatography. Metal complexes must be soluble in the polymerization conditions and be thermally stable so they do not decompose during the polymerization process. Ru(II)

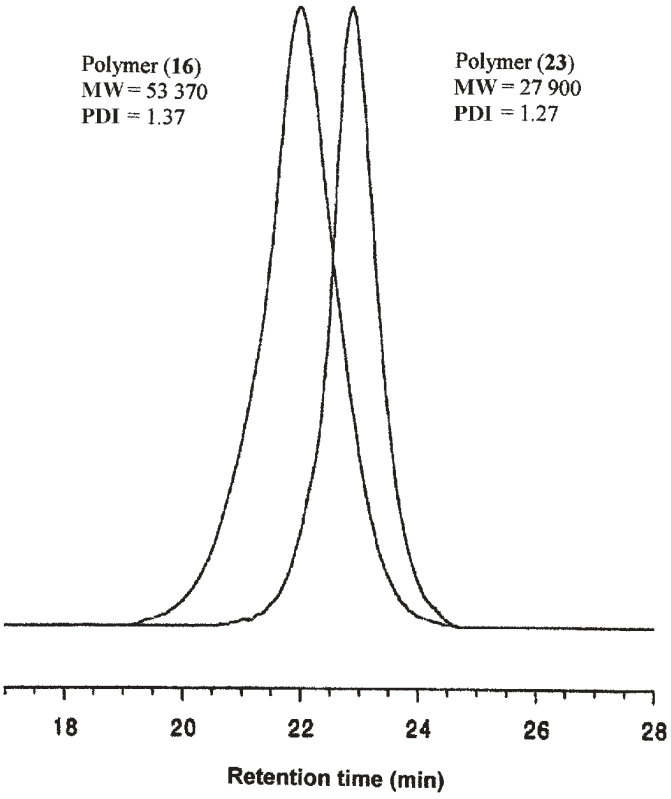
tris(bipyridine) complex initiators have been reported to be stable in various polymerization reactions (20). In our hands, bulk polymerization of ε-caprolactone with the aforementioned complexes under the conditions of our study provided homogenous monomer–metal complex initiator solutions with no evident metal residue upon reaction completion.



The macroligand–chelation approach is conceptually an extension of normal chelation reactions of small molecules and metal ion precursors in standard inorganic reactions (21). However, it is generally difficult to extrapolate chemistry from inorganic–organic synthesis to polymer reactions because the kinetics are usually different for each case. Polymer chain entanglement always limits the collision between active coordination sites in the polymer and metal ions. In the case of high-molecular-weight polymeric macroligands, additional reaction parameters have to be taken into account (22). The reaction medium must be capable of efficiently solubilizing both the metal ion precursors and the polymeric macroligand undergoing the substitution. More importantly, the solvent has to facilitate ligand substitution by solvating leaving groups or by providing labile metal ion solvent-coordinated intermediates, making the metal center sites prone to facile coordination. Macroligand solution phenomena, such as chain conformation and aggregation, have to be considered as well (23). Thus, in employing the macroligand–chelation method to prepare the mono-ligated metal complexes of polymeric ligands (**14**) and (**20**), *cis*-$Ru(bpy)_2Cl_2$ was first dehalogenated with $AgNO_3$ in methanol. After solvent removal, the resulting solvent-coordinated species $[Ru(bpy)_2(MeOH)_2]^{2+}$ was reacted with polymeric macroligands (**23**) and (**24**) in an acetonitrile–DME (1:1 volume fraction) mixed solvent medium to generate the desired polymers after column chromatography. The bis-ligated metal complexes of polymeric ligands (**15**) and (**21**) and also the tris-ligated metal complexes of polymeric ligands (**16**) and (**22**) were obtained with controlled combination of the metal source and the appropriate mole ratio of macroligands (**23**) and (**24**) in a polar reaction medium. For samples (**15**) and (**21**), for example, $RuCl_3{\cdot}xH_2O$ was heated with 2 equiv. of the desired macroligand in the presence of lithium chloride to prevent total substitution of the ligands around the coordination sphere of the metal center. This has provided dark, intense blue halogenated reaction intermediates of type $[Ru(\mathbf{23})_2Cl_2]$ or $[Ru(\mathbf{24})_2Cl_2]$. These intermediate species were then dehalogenated in situ with $AgNO_3$ and subsequently reacted with 2,2′-bipyridine to produce the desired red-orange bis-ligated metal complexes of polymeric ligands. In the case of tris-ligated metal complexes of polymeric ligands (**16**) and (**22**), $RuCl_3{\cdot}xH_2O$ was reacted with 3 equiv. of (**23**) and (**24**) macroligands in polar reaction medium for a longer time.

Summaries of molecular weight, thermal, electronic absorption, and emission analysis data for the ruthenium-centered polyesters prepared via macroligand–chelation and via metalloinitiation are presented in Tables 1 and 2, respectively. The presence of the ruthenium chromophore in the polymer chain was verified by ^1H NMR spectroscopy and electrochemical and UV–vis emission analysis. Metal-to-ligand charge-transfer (MLCT) bands around 460 nm, characteristic of $[Ru(bpy)_3]^{2+}$, and at 490 nm for $[Ru(pqX)_3]^{2+}$ (X = hydroxymethyl functionality) cores were observed. An emission band around 600–610 nm (excitation 400 nm) for all $[Ru(bpy)_3]^{2+}$-containing polymers was observed. For mixed quinoline ligand based ruthenium-centered polymers, mono-ligated metal complexes of polymeric ligands (**17**) and (**20**) were emissive at 670 nm (excitation 400 nm), while the rest of the series were either weakly emissive or not emissive at all. Molar absorptivities (ε) of the MLCT bands for all the polymers obtained via macroligand–chelation were determined using known masses and absolute molecular weights of the polymers. From these determinations, the estimated chelation efficiencies relative to the corresponding ruthenium complexes presented in Table 1 were obtained (24) to account for factors that might influence substitution reactions of macroligands of different molecular weights.

An overlay GPC trace of the tris-ligated metal complex of polymeric ligand (**16**) and the macroligand (**23**) from which it originated is shown in Fig. 3. As predicted, there was an increase in molecular weight for the formation of the metal-centered polymeric ligand (**16**), albeit lower than the theoretical calculated value. An increase in polydispersity index (PDI) of the target polymers and the existence of a shoulder in the GPC traces were also evident for the series of ruthenium-centered polymeric ligands, indicating the existence of small amounts of unreacted macroligands in our polymers. Although a small amount of uncomplexed macroligand does not affect the bulk properties of polymeric metal complexes or their usefulness in practical application, it can be removed by iterative column chromatography. In the ^1H NMR analysis of our polymers, the presence of characteristic signals of

the metal-complex core was observed, along with caprolactone resonances, for all polymers obtained via the macroligand approach. For polymers obtained via metalloinitiation, the situation was different. Only caprolactone peaks were observable in the ^{1}H NMR spectra. Similar observations were previously reported by McAlvin and Fraser (25) using hexafunctional tris(bipyridine) metalloinitiators for cationic polymerization of 2-ethyl-2-oxazolines.

The cyclic voltammogram of polymeric metal complex (**14**) is depicted in Fig. 4 as a representative example of the electrochemical behaviour of these series of polyesters. Half-wave potentials ($E_{1/2}$) in acetonitrile for all polymers obtained via the macroligand approach are collected in Table 3. For all metal-centered polymers, one reversible oxidation and two irreversible reduction waves were observed. Within each series, these electrochemical processes occur at nearly the same potential, regardless of the polymer dimensionality. Electrode passivation due to polymer film formation was also observed in equilibrium scans.

The macroligands and the ruthenium-centered polyesters were also analyzed by differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA). There were no substantial differences in the melting points for the macroligands and the ruthenium-centered polyesters, regardless of molecular weight increase and polymer dimensionality or the metal presence in the polymer chain. As a typical example, an overlay DSC thermogram of macroligand (**23**) and the tris-ligated metal complex polymeric ligand (**16**) is shown in Fig. 5. Thermogravimetric analyses (TGA) of these series of ruthenium-centered polyesters show that they possess a high thermal stability under N_2 atmosphere. The

onset of their thermal decomposition was high, as demonstrated in Fig. 6 for polyester (**16**), and varied from 275 to 350 °C. Moreover, the onset of decomposition temperature, as well as the apparent enthalpy of melting, increased slightly with the number of macroligands present around the metal center. This occurred with concomitant increase of molecular weight of the resulting polymeric metal complexes. This observation could be related to an increase of crystallinity of the metal-centered polymers due to the increasing content of semicrystalline poly(ε-caprolactone) macroligands coordinated to the metal ion.

Concluding remarks

Mixed ligand ruthenium-centered poly(ε-caprolactones) of various dimensionality were synthesized and characterized. These materials were obtained by preparing linear polymers with binding sites by ring-opening polymerization of ε-caprolactone, by using bpy or quinoline ligand initiators followed by chelation to metal ions. The same polymers were also obtained from ring-opening polymerization of ε-caprolactone via metal complexes with initiator sites in their ligand periphery. Both strategies produced polymers of relatively high molecular weight, possessing good filming properties and high thermal stability.

Selective end functionalization of macroligands, with the coordination site of the diimine ligands remaining intact, and the possibility for further functionalization of the metal-

centered polyesters both merit further studies. They could potentially provide a wide of range of functionalized macromolecules of tailored properties. In turn, these polymers with luminescent chromophores in a well-defined location in the polymer chain have fulfilled our primary investigation in designing a new class of organic polymers with polypyridyl ruthenium(II) luminophores, a basis of transition-metal-mediated electroluminescent devices. A full account of such

A new method of syntheses of 18-membered macrocyclic diphenyltin(IV) compounds and crystal structures of $\{Ph_2Sn[S(C_6H_3NO)O]\}_3 \cdot Y$ (Y = $2H_2O$ or $4C_6H_6$) and $\{Ph_3Sn[S(C_6H_3NO)O]SnPh_3(EtOH)\} \cdot [EtOH]$

Chunlin Ma, Qin Jiang, and Rufen Zhang

Abstract: Two diphenyltin(IV) compounds: $\{Ph_2Sn[S(C_6H_3NO)O]\}_3 \cdot Y$ (Y = $2H_2O$, **1**; $4C_6H_6$, **2**) have been unexpectedly obtained by the reactions of triphenyltin chloride with 2-mercaptonicotinic acid in the presence of Et_3N. However, by the reaction of the same reactants in the presence of EtONa, only a new triphenyltin(IV) compound ($\{Ph_3Sn[S(C_6H_3NO)O]SnPh_3(EtOH)\} \cdot [EtOH]$, **3**) was obtained. The X-ray analyses reveal that compounds **1** and **2** are trinuclear, 18-membered macrocyclic compounds while **3** is a dinuclear compound. Specially, π-π stacking interaction was recognized in crystals of compound **1**, which makes it a dimer. Co-crystallization was found in the crystals of all the three compounds **1**, **2**, and **3**, the co-crystallized solvent molecules are water, benzene, and ethanol molecules, respectively. A possible dephenylation mechanism of **1** and **2** was illustrated in detail.

Key words: triphenyltin, 2-mercaptonicotinic acid, dephenylation, macrocyclic, π-π stacking interaction, co-crystallization, crystal structure.

Résumé : Les réactions du chlorure de triphénylétain avec l'acide 2-mercaptonicotinique, en présence de Et_3N, conduisent à la formation inattendue de deux composés diphénylétain(IV): $\{Ph_2Sn[S(C_6H_3NO)O]\}_3 \cdot Y$ (Y = 2 H_2O, **1**; $4C_6H_6$, **2**). Toutefois, les mêmes réactifs en présence de EtONa ne conduisent qu'à la formation d'un seul nouveau composé triphénylétain(IV), le $\{Ph_3Sn[S(C_6H_3NO)O]SnPh_3(EtOH)\} \cdot [EtOH]$, **3**. Des études par diffraction des rayons X révèlent que les composés **1** et **2** sont des composés trinucléaires comportant des macrocycles à dix-huit chaînons alors que le composé **3** est un composé dinucléaire. On a particulièrement noté la présence d'une interaction d'empilement π-π dans les cristaux du composé, ce qui en fait un dimère. On a observé de la cocristallisation dans les cristaux de trois composés **1**, **2** et **3** dans lesquels les molécules de solvant cocristallisées sont respectivement des molécules d'eau, de benzène et d'éthanol. On a illustré en détail le mécanisme possible de la déphénylation des composés **1** et **2**.

Mots clés : triphénylétain, acide 2-mercaptonicotinique, déphénylation, macrocycles, interaction d'empilement π-π, cocristallisation, structure cristalline.

Introduction

Heterocyclic thiolates are ligands that contain at least one deprotonated heterocyclic thioamide group $(N\text{-}C\text{-}S)^-$. The aforementioned systems, which can act as monodentate, chelating, and bridging ligands, have been extensively studied in the field of coordination chemistry (1). In particular, many thionate-containing organotin complexes have been prepared and characterized due to their potential industrial applications and biological activities (2). Among them some exotic structures were obtained via self assembly determined by the types and geometries of the connecting ligands (3, 4), preference of tin atom for different donor atoms, as well as the competing specific intra- and intermolecular interactions such as H-bonds (5), π-π stacking interactions, and so on (6). The 2-mercaptonicotinic acid is an interesting ligand in this respect for its multiple coordination possibilities as well as its particular stereochemistry.

In our previous work, we studied the reactions of diphenyltin dichloride with the ligand and obtained two distinct trinuclear 18-membered macrocyclic compounds: $\{Ph_2Sn[S(C_6H_3NO)O]\}_3 \cdot 2.67H_2O$ and $\{Ph_2Sn[S(C_6H_3NO)O]\}_3 \cdot 4C_6H_6$ (7). To continue our investigation on organotin(IV) compounds, we carried out a series of reactions of triphenyltin chloride with the ligand to obtain some discrete triphenyltin(IV) compounds. To our surprise, we obtained three distinct compounds (**1**, **2**, and **3**) under different experimental conditions. Single crystal X-ray diffraction data reveal that **1** and **2** are trinuclear 18-membered macrocyclic diphenyltin(IV) compounds, while **3** is a dinuclear triphenyltin(IV) compound. Co-crystallization is found in crystals of all the three compounds **1**, **2**, and **3**, and the co-

Scheme 1.

crystallized solvent molecules are water, benzene, and ethanol, respectively. It is worth noting that π-π stacking interaction was observed in crystals of compound **1**, which makes it a dimer. In this paper, we report the syntheses and characterizations of compounds **1**, **2**, and **3**. Crystal structures of the new compounds **1** and **3** are also given. The reaction procedure and possible dephenylation mechanism are shown in Scheme 1.

Experimental

Materials and measurements

Triphenyltin chloride and 2-mercaptonicotinic acid were commercially available, and they were used without further purification. The melting points were obtained with a Kofler micro melting point apparatus and are uncorrected. Infrared spectra were recorded on a Nicolet-460 spectrophotometer using KBr discs and sodium chloride optics. ^{1}H NMR spectra were obtained on a JEOL-FX-90Q NMR spectrometer, chemical shifts were given in ppm relative to Me_4Si in $CDCl_3$ solvent. Elemental analyses were performed with a PE-2400II apparatus.

Syntheses

Preparation of {Ph$_2$Sn[S(C$_6$H$_3$NO)O]}$_3$·2H$_2$O (1)

The reaction was carried out under a nitrogen atmosphere. Triphenyltin chloride (0.385 g, 1 mmol) and 2-mercaptonicotinic acid (0.155 g, 1 mmol) were added to the solution of absolute toluene (20 mL) in a Schlenk flask and stirred for 1.5 h at 90 °C. Then in the presence of triethyl amine (0.2 mL, 1mmol), the reaction mixture was stirred for 6 h at 110 °C, and then filtered. The filtrate was gradually removed by evaporation under vacuum until a solid product was obtained. The solid was then recrystallized from ethanol (95%) and the colorless block-like crystals of compound **1** were obtained.

Preparation of {Ph$_2$Sn[S(C$_6$H$_3$NO)O]}$_3$·4C$_6$H$_6$ (2)

The reaction was carried out under a nitrogen atmosphere. Triphenyltin dichloride (0.771 g, 2 mmol) and 2-mercaptonicotinic acid (0.155 g, 1 mmol) were added to the solution of absolute toluene (20 mL) in a Schlenk flask and stirred for 1.5 h at 90 °C. Then in the presence of triethyl amine (0.4 mL, 2 mmol), the reaction mixture was stirred for 6 h at 110 °C, and then filtered. The filtrate was gradually removed by evaporation under vacuum until a solid product was obtained. The solid was then recrystallized from benzene and the colorless block-like crystals of compound **2** were obtained.

Preparation of {Ph$_3$Sn[S(C$_6$H$_3$NO)O]SnPh$_3$(EtOH)}·[EtOH] (3)

2-Mercaptonicotinic acid (0.155g, 1 mmol) and sodium ethoxide (0.136 g, 2 mmol) were added to the solution of absolute benzene (20 mL) in a Schlenk flask and stirred for 0.5 h. After the triphenyltin chloride (0.771 g, 2 mmol) was added to the reactor, the reaction mixture was stirred for 20 h at 35 °C, and then filtered. The filtrate was gradually removed by evaporation under vacuum until a solid product was obtained. The solid was then recrystallized from ethanol. Colorless crystal compound **3** was formed.

X-ray structure determination

All X-ray crystallographic studies were done by using a Bruker Smart 1000 diffractometer fitted with graphite-monochromated MoKα radiation (λ = 0.71073 Å). The structure was solved by using direct methods and refined by a full-matrix least-squares procedure based on F^2 using the SHELXL-97 program system. All data were collected at a temperature of 298(2) K. Table 1 lists the crystal data and structure refinement parameters for complexes **1** and **3**. Table 2 lists the comparative structural data for **1** and **3** and related organotin(IV) compounds. The crystal structures and unit cells in the crystals of compounds **1** and **3** are shown in Fig. 1, Fig. 2, Fig. 3, and Fig. 4, respectively. Selected bond distances and angles are listed in Table 3 and Table 4, respectively.

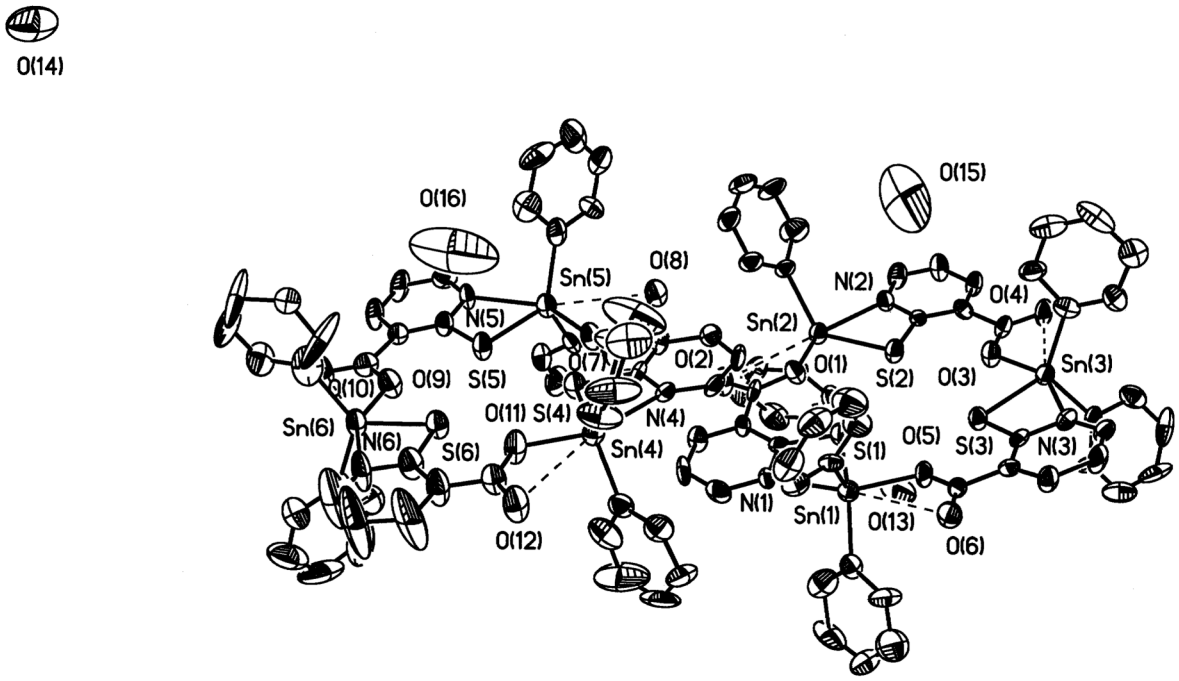
Results and discussion

Syntheses aspects

It was surprising that we obtained three distinct products based on the same reactants under different conditions. When mixing triphenyltin chloride with 2-mercaptonicotinic

© 2004 NRC Canada

Fig. 1. Molecular structure of complex **1**.



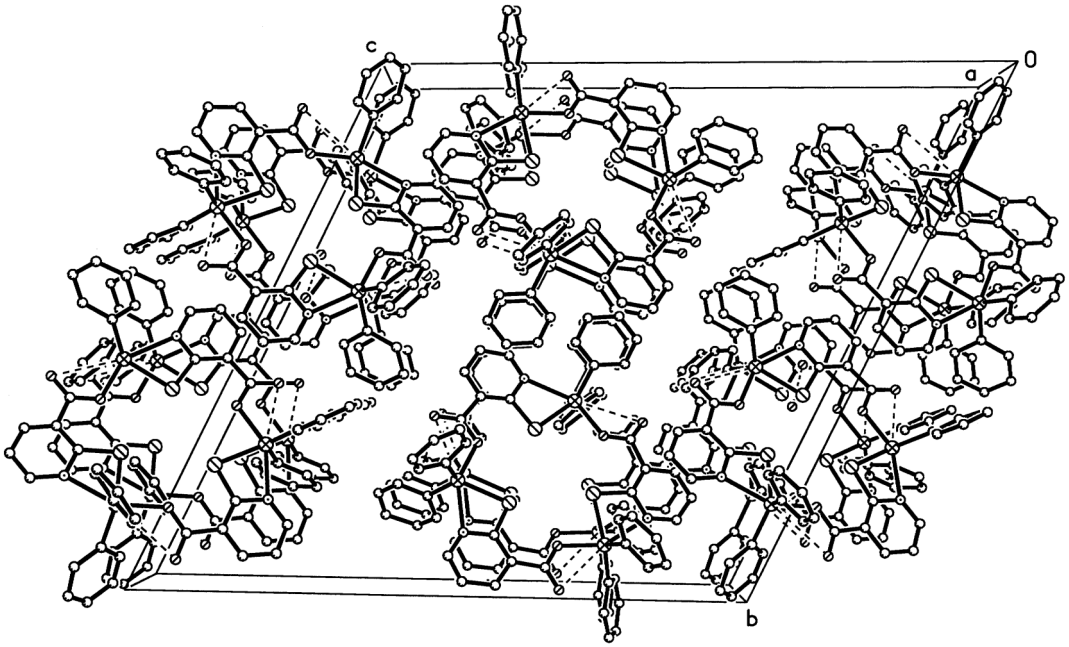


Fig. 2. Unit cell of complex **1**.

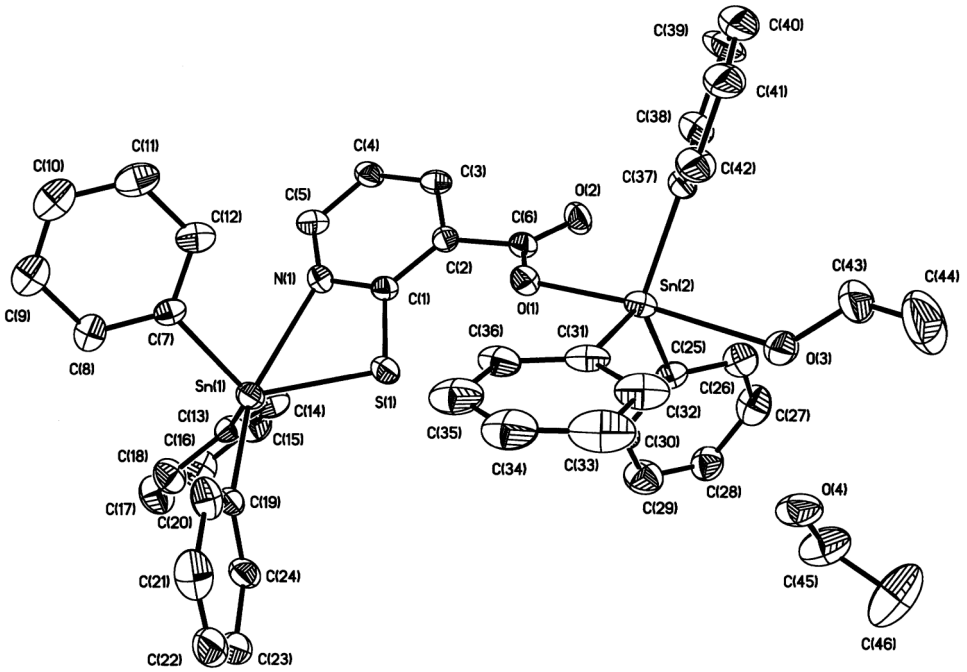
acid in the presence of Et_3N, we got two diphenyltin(IV) compounds: $\{Ph_2Sn[S(C_6H_3NO)O]\}_3 \cdot Y$ (Y = $2H_2O$ (**1**), $4C_6H_6$ (**2**)). However, by the reaction of the same reactants in the presence of EtONa, we got a triphenyltin(IV) compound: $\{Ph_3Sn[S(C_6H_3NO)O]SnPh_3(EtOH)\} \cdot [EtOH]$ (**3**).

According to the results of our experiments, together with those reported in the literature (8, 9), we can conclude that the reaction to produce compound **1** may undergo a three-step process as follows: first, the 2-mercaptonicotinic acid reacts with triphenyltin chloride to produce the triphenyltin complex **A**. Hydrogen chloride is the by-product from this reaction and more important is that it is the necessary reactant for dephenylation. Second, hydrogen chloride attacks the tin atom of **A** and makes one of the three Sn-C break, thus producing a diphenyltin chloride complex **B**. Third, in the presence of triethyl amine, molecules of complex **B** react with each other to produce a trinuclear 18-membered macrycyclic complex **C**. Complex **C** cannot exit discretely because of its weak interaction with solvent molecules. Therefore, when it is recrystallized from ethanol (95%), it co-crystallizes with double water molecules (**C**:H_2O) and produces compound **1**.

As far as compound **2** is concerned, the dephenylation is the same as that of **1**, what is different is its recrystallization.

© 2004 NRC Canada

Fig. 3. Molecular structure of complex **3**.



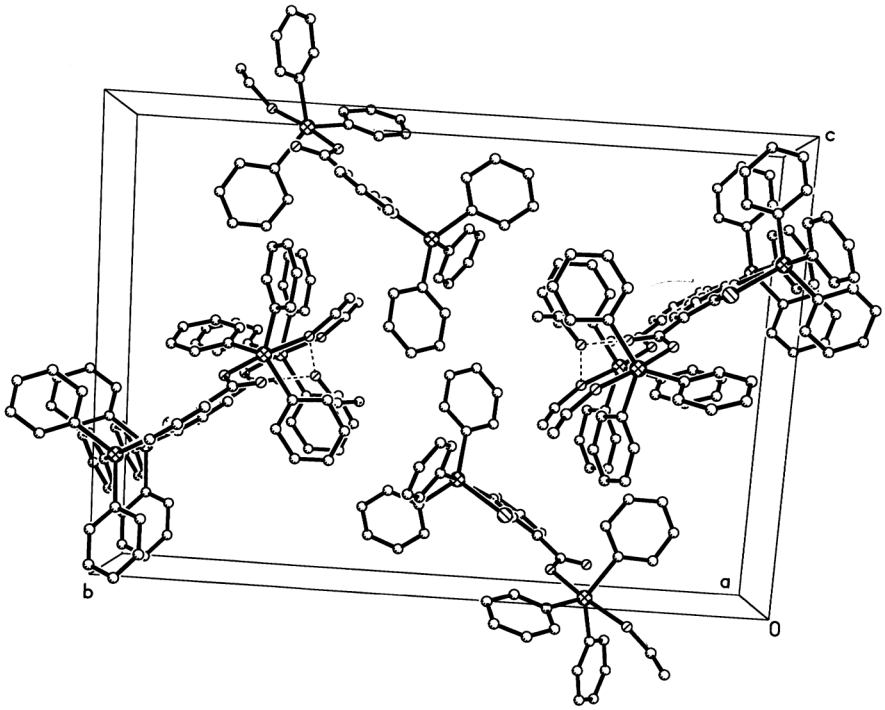


Fig. 4. Unit cell of complex **3**.

Compound **2** is recrystallized from benzene with four benzene molecules (**C**:C_6H_6) in each crystal unit. And as the X-ray data shows, complex **2** is the same compound as realized by the reaction of diphenyltin dichloride and 2-mercaptonicotinic acid (7).

Comparing the synthetic mechanism of **1** and **2**, we found that it does not matter what molar ratio of the ligand and triphenyltin chloride was applied, but the production of hydrogen chloride is crucial to break the Sn—C bond. A similar synthetic strategy has been used for preparation of mixed trialkyltin derivatives (9).

Concerning the reaction that affords compound **3**, a possible mechanism is presented in following description. In the presence of sodium ethoxide, 2-mercaptonicotinic acid converts into its sodium salt **D**, and then **D** reacts with triphenyltin chloride in the ratio of 1:2 to afford dinuclear triphenyltin complex **E**. When **E** recrystallizes from ethanol, because of the coordination between ethanol and one tin

atom of **E**, and also because of the hydrogen bonds between {$Ph_3Sn[S(C_6H_3NO)O]SnPh_3(EtOH)$} and EtOH, compound **3** was formed.

IR data

Comparing the IR spectra of the free ligands with compounds **1**, **2**, and **3**, several obvious differences are apparent. First, the band at 2642 cm^{-1}, which appears in the spectra of the free ligand as the ν(S-H) vibration, is absent in those of compounds **1**, **2**, and **3**, thus indicating metal–ligand bond formation through this site. Correspondingly, the strong absorptions at 290 cm^{-1} for both compounds **1** and **2**, and 305 cm^{-1} for compound **3**, which is absent in the spectrum of the ligand, are assigned to the Sn-S stretching mode of vibration, and all these values are consistent with that detected for a number of organotin(IV)-sulfur derivatives (10–12). Second, the ν(C=N) band, occurring at 1577 cm^{-1} for both compounds **1** and **2**, and at 1575 cm^{-1} for compound **3**, are considerably shifted towards a lower frequency with respect to that of the free ligand (1622 cm^{-1}), confirming the coordination of the heterocyclic N to the tin. The stretching frequency is lowered owing to the displacement of electron density from the N to Sn atom, thus resulting in the weakening of the C=N bond as reported in the literature (13). Therefore, the weak- or medium-intensity bands at 448, 446, and 448 cm^{-1} for compounds **1**, **2**, and **3**, respectively, can be assigned to Sn-N stretching vibrations. Third, the ν_{as}(COO) and ν_{as}(COO) occur at 1638 and 1365 cm^{-1} for both compounds **1** and **2** and at 1635 and 1366 cm^{-1} for compound **3**. The corresponding Δν values are 273, 273, and 269 cm^{-1}, meaning that the carboxyl groups in all three compounds are monodentate (14). Consequently, the new bands appearing at 585, 587, and 497cm^{-1} for compounds **1**, **2**, and **3**, respectively, have been assigned to Sn—O bond vibrations.

Also, the broad strong absorption at 3434 cm^{-1}, appearing in both spectras of compounds **1** and **3**, but absent in the spectra of compound **2**, has been assigned to ν(O-H) of H_2O and EtOH, respectively, which demonstrates the difference in their co-crystallized solvent molecules.

^{1}H NMR data

^{1}H NMR showed that the signal of the -SH proton in the spectrum of the ligand is absent in both compounds **1** and **3**, indicating the removal of the SH proton and the formation of Sn—S bonds. The signal of the -OH proton is also absent for the spectra of compound **2** but appears in both spectras of compounds **1** and **3**, which further proved the difference in their co-crystallized molecules. The information agrees well with what the IR data have revealed.

Molecular structures

Single crystal X-ray diffraction data revealed that **1** and **2** are trinuclear 18-membered macrocyclic compounds, while **3** is a dinuclear triphenyltin compound. Co-crystallization is

© 2004 NRC Canada

found in crystals of all the three compounds **1**, **2**, and **3**, which may be realized by face-to-face/edge-to-face π-π interactions and aromatic C-H···O (for benzene), or by C=O···H (for H_2O) weak hydrogen-bonding interactions as reported in the literature (15–17). It is worth noting that that the X-ray data revealed that compound **2** is the same compound as reported previously (7), thus in this paper, we only give some comparative structural data of compound **2**, together with those of **1** and **3** and related analogous compounds, which are shown in Table 2. Detailed discussion for the structures of compound **1** and **3** follows.

Structures $\{Ph_2Sn[S(C_6H_3NO)O]\}_3 \cdot 2H_2O$ (1)

As shown in Fig. 1, compound **1** contains a symmetrical trinuclear macrocyclic component with the deprotoned ligand 2-mercaptonicotinic acid bridging the adjacent tin atoms, which can be given the formula $\{Ph_2Sn[S(C_6H_3NO)O]\}_3$. The repeated unit is $Ph_2Sn[S(C_6H_3NO)O]$, in which the primary bondings of the ligand to tin occur through its sulfur atom and endocyclic carboxyl oxygen atom, while the nitrogen atom of the ligand is involved in a fifth weaker bonding interaction with tin. All the tin atoms have the same geometry as a distorted cis-trigonal bipyranid. The corresponding bond lengths and angles are listed in Table 3. All these values are consistent with those of analogous diphenyltin macrocycles, and are especially, similar to those of the compound $\{Ph_2Sn[S(C_6H_3NO)O]\}_3 \cdot 2.67H_2O$ (see Table 2).

It is worth noting that besides the difference in the number of co-crystallized water molecules, an obvious difference between the crystal structures of compound **1** and $\{Ph_2Sn[S(C_6H_3NO)O]\}_3 \cdot 2.67H_2O$ resides in that **1** is a dimer staked by a π-π staking interaction between heterocyclic rings from adjacent $\{Ph_2Sn[S(C_6H_3NO)O]\}_3$. Each pair of neighboring heterocyclic rings in the dimer are almost parallel with the dihedral angle being 4.9° (ring N(1), C(1)-C(5) and ring N(4), C(55)-C(59)), and separated by 3.49 vs. 3.58 Å (the distances between the ring centroids). The shortest distance of C(3) to ring C(55)-C(59) is 3.42 Å and that of C(56) to ring C(1)-C(5) is 3.41 Å. All theses values are consistent with that of the benzene polymer in theoretical studies (3.4 Å) (18) and approaches that of imidazole–imidazole (3.29–3.47 Å) (19, 20), indicating the presence of significant face-to-face π-π stacking interactions (21, 22).

Structure of $\{Ph_3Sn[S(C_6H_3NO)O]SnPh_3(EtOH)\} \cdot [EtOH]$ (3)

As Fig. 3 shows, compound **3** is a dinuclear triphenyltin(IV) co-crystallized compound with the formula $\{Ph_3Sn[S(C_6H_3NO)O]SnPh_3(EtOH)\} \cdot [EtOH]$. The co-crystallization is realized by hydrogen bonds between carboxyl oxygen and ethanol molecules. Both tin atoms (Sn(1) and Sn(2)) have the same geometry as a distorted cis-trigonal bipyramid but their environments are quite different.

For Sn(1), there are four primary bonds to the centered tin atom: three to the phenyl groups and one to the sulfur atom. In addition, there exists an interaction between the tin and the nitrogen atoms. The Sn(1)—N(1) bond length (2.638(4) Å) is a little longer than the sum of the covalent radii of the tin and nitrogen atoms, but much shorter than that of the van der Waals radii of the two atoms (2.15 and 3.75 Å, respectively) (23). Including the tin–nitrogen interaction, the geometry at Sn(1) becomes a distorted cis-trigonal bipyramid with one of the phenyl carbon (C(19)) and nitrogen (N(1)) atoms in the axial sites. Another two phenyl carbon (C(7) and C(13)) and sulfur (S(1)) atoms occupy the equatorial plane. The sum of the angles encircling the Sn(1) atom in the trigonal plane is 346.4°. The Sn(1) atom is 0.48 Å displaced out of the basal plane in the direction of C(19). Due to being part of a chelate ligand, the angle S(1)-Sn(1)-N(1) is not 90° but 61.13(11)°. Thus, the N(1) cannot occupy exactly the corresponding trans axial position of C(19) and the angle for C(19)-Sn(1)-N(1) is 159.31(17)°. The Sn(1)—S(1) bond length (2.4389(17) Å) lies in the range recently reported for triphenyltin thiolates (2.405–2.48 Å) (24–26), close to the sum of the covalent radii of the tin and sulfur atoms (2.42 Å) (27).

For Sn(2), the configuration about the tin atom is also a distorted cis-triagonal bipyramid but it is the three phenyl groups that occupy the equatorial sites. The valence extension is performed via the oxygen atom of ethanol (O(3)), which coordinats to tin along with the deprotonated oxygen of the monodentate carboxyl group of 2-mercaptonicotinic acid (O(1)). The Sn(2) atom is displaced from the C_3 plane for the phenyl carbon atom by only 0.08 Å, reflecting the strength of the bond between the metal and the solvent. The near linearity of the angle O(1)-Sn(2)-O(3) (174.33(13)°) also reflects the strength of coordination of the solvate molecule.

The two Sn—O bonds (Sn(2)-O(1) (2.125(4)) and Sn(2)-O(3) (2.468(4) Å)) are typical of their type (Table 3). In related diorganotin systems, the C-O distance increases upon coordination of the oxygen atom to the tin atom (28–30). However, in compound **3** the unique monodentate nature of the carboxyl group of the ligand means that the C(6)-O(2) distance of 1.229(5) Å has the lowest value yet observed among the relevant trialkyltin analogues.

The carboxyl oxygen atom O(2) is thus not involved in any intramolecular interactions involving tin. This fact may be partly explained on the basis of hydrogen bonding. Each coordinated ethanol atom serves as the acceptor of a hydrogen bond with an adjacent ethanol molecule, and this ethanol molecule also forms an acceptor of the hydrogen bond with the uncoordinated oxygen donor O(2) of the carboxyl group. The corresponding bond lengths for the hydrogen bonding are O(4)···H(4) = 0.82 Å, H(4)···O(2) = 1.89 Å, O(2)···O(4) = 2.70 Å, and O(3)···H(3) = 0.93 Å, H(3)···O(4) = 1.76 Å, O(3)···O(4) = 2.65 Å. Due to the existence of the two kinds of H-bond, the co-crystallized compound **3** was thus obtained at the ratio of 1:1 ($\{Ph_3Sn[S(C_6H_3NO)O]SnPh_3(EtOH)\}$:EtOH).

A novel self-complementary three-dimensional inorganic network organized by H-bond dimers of inorganic chains — Synthesis and crystal structure of $(C_6H_{16}N_2)[Zn(HPO_4)_2]$

Xian-Ming Zhang, Chan-Juan Bai, Yan-Li Zhang, and Hai-Shun Wu

Abstract: A novel organic-templated zincophosphate, namely $(C_6H_{16}N_2)[Zn(HPO_4)_2]$, was hydrothermally synthesized and X-ray single-crystal structural analysis reveals that the anions $[Zn(HPO_4)_2]^{2-}$, which have square-twisted chains containing corner-sharing four-rings of alternating ZnO_4 and PO_4 tetrahedra, are assemblied via self-complementary strong and symmetrical hydrogen-bonding $R_2^2(8)$ synthons between the phosphate groups into three-dimensional hydrogen bond frameworks featuring three-dimensional intersecting pseudochannels. The doubly protonated 2,5-dimethylpiperazinium cations are attached to the three-dimensional inorganic framework via N-H··O hydrogen bonds to strengthen the 3-D network.

Key words: hydrogen bond dimer, intersecting pseudochannel, linear chain.

Résumé : On a réalisé une synthèse hydrothermique d'un nouveau zincophosphate à patron organique, soit le $(C_6H_{16}N_2)[Zn(HPO_4)_2]$. Une étude par diffraction des rayons montre que les anions $[Zn(HPO_4)_2]^{2-}$ sont des chaînes carrées déformées comportant quatre cycles de tétraèdres de ZnO_4 et de PO_4 qui occupent les coins en alternance, qui sont reliées par de fortes liaisons hydrogènes symétriques et autocomplémentaires de synthons $R_2^2(8)$ entre les groupes phosphates et qui forment un squelette tridimensionnel de liaisons hydrogènes comportant des pseudocanaux tridimensionnels qui présentent des intersections. Les cations 2,5-diméthylpipérazinum doublement protonés sont attachés au squelette inorganique tridimensionnel par le biais de liaisons hydrogènes N-H··O qui renforcissent le réseau tridimensionnel.

Mots clés : dimère par liaison hydrogène, pseudocanal avec intersection, chaîne linéaire.

[Traduit par la Rédaction]

Introduction

Metal phosphates have been of intensive interest due to structural diversity and potential applications in catalysis, adsorption, and ion exchange (1–6). A subclass of metal phosphates is zinc phosphates, which are generally synthesized by hydrothermal method with organic amine as the structural directing agent (7–30). Although most zinc phosphates have layered or three-dimensional structures (7–24), several zinc phosphates with one-dimensional structures have also been investigated. The one-dimensional structures of zinc phosphates include linear chains formed by corner-shared four-membered rings (25–28) and ladders formed by edge-shared four-membered rings (29). Recently, the zero-dimensional monomer comprising the four-membered ring has also been isolated (25, 30). Despite the importance of layered and three-dimensional networks in practical applications, the zero-dimensional monomer and linear chains are more important from the hydrothermal mechanism point of view because the zero-dimensional monomer and linear chains are thought as possible primary and secondary building units (SBUs) for layered and three-dimensional networks (25, 30). In particular, Rao et al. (25, 30) prepared a layered zinc phosphate via mild heating of monomeric zinc phosphate containing only the four-membered ring as well as a family of zinc phosphates of different hierarchy containing piperazine template.

In the formation of zinc phosphate frameworks, the protonated organic amines play an important role. These amines could act as structure-directing agents, or merely fill the available voids and stabilize the structure through hydrogen bonding and other interactions. The charge, shape, and size of the organic amine cations have significant influences on the structures of the framework. One-dimensional simple linear zinc phosphate chains $[Zn(HPO_4)_2]^{2-}$ (25, 26, 28) possess corner-shared ZnO_4 and HPO_4 tetrahedra (Fig. 1*b* and Scheme 1) and are generally stabilized by van der Waals interactions or by strong hydrogen bonds with the organic templates. Each HPO_4^{2-} group in the $[Zn(HPO_4)_2]^{2-}$ chain has one pendent O-H and one pendent oxo that can be the potential donor and acceptor groups for the hydrogen bond

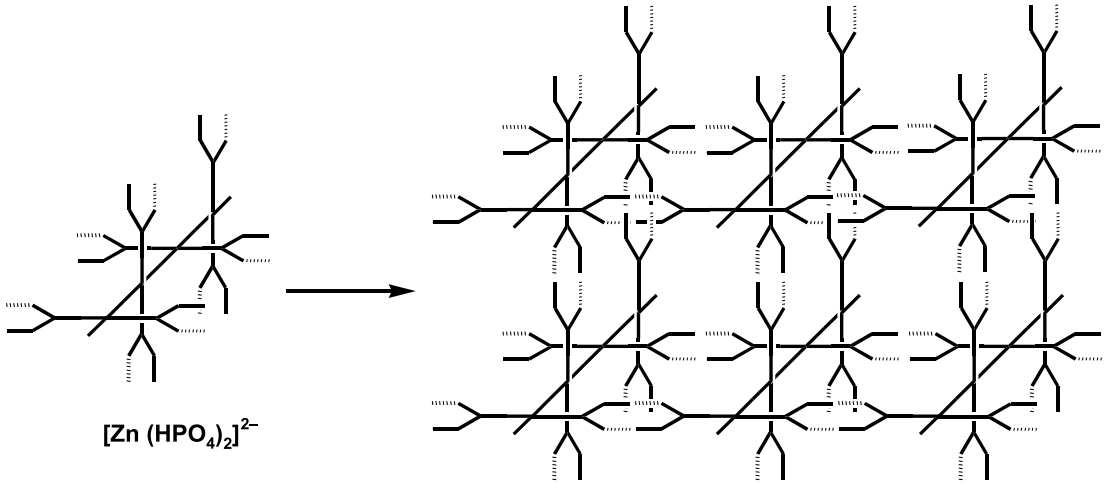
Scheme 1. Schematic view of the assembly of $[Zn(HPO_4)_2]^{2-}$ chains into a 3-D supramolecular inorganic open framework via strong and symmetrical hydrogen-bonding dimers.



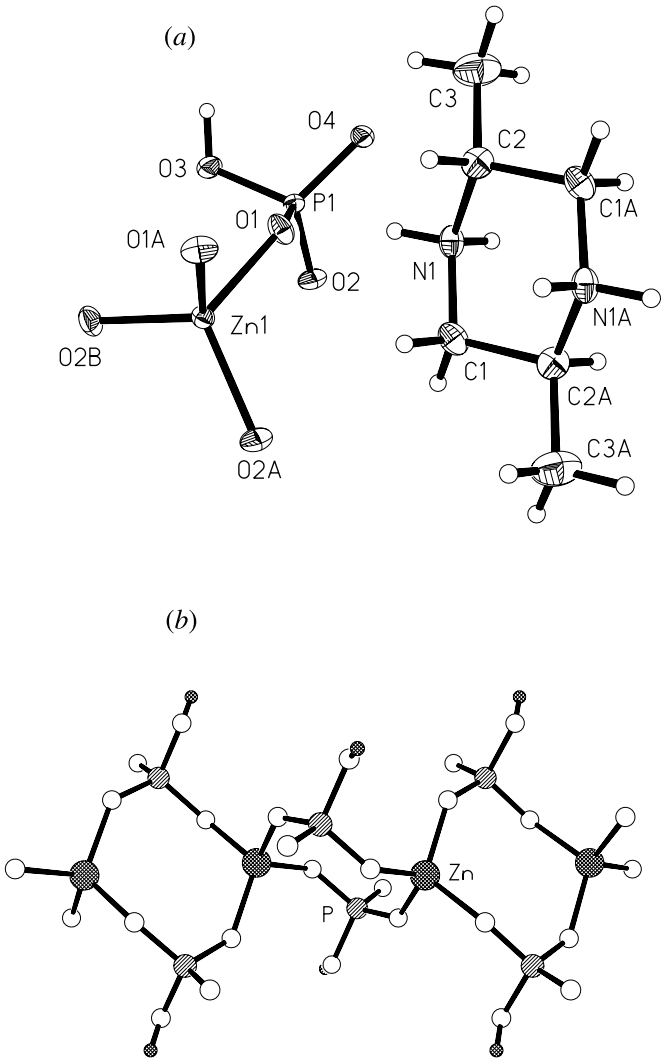


Fig. 1. Pespective views of atomic coordination environments showing the atom-labeling scheme and 35% thermal ellipsoids (*a*), and the chain-like structure (*b*) in **1**.

or the hydrogen dimer. Besides, the $[Zn(HPO_4)_2]^{2-}$ chain has a suitable geometry in which a pair of HPO_4^{2-} groups from each four-membered ring has the same orientation but is perpendicular to adjacent pairs of HPO_4^{2-} groups. Furthermore, Clearfield's studies on organo phosphonic acids demonstrated that deprotonated organo phosphonic acids having potential donor and acceptor groups for the hydrogen bond results in very strong and predictable structural aggregates through symmetrical O-H··O hydrogen dimers (31). Therefore, it occurred to us that we may be able to assemble $[Zn(HPO_4)_2]^{2-}$ chains into very stable three-dimensional inorganic networks (Scheme 1) by selecting a suitable template via strong hydrogen bond dimers. The expectation was realized in the synthesis of the 2,5-dimethylpiperazine templated compound $(C_6H_{16}N_2)[Zn(HPO_4)_2]$, which has a three-dimensional inorganic supramolecular network and three-dimensional pseudochannels occupied by organic guest cations.

Experimental

Synthesis of $(C_6H_{16}N_2)[Zn(HPO_4)_2]$ (1)

A mixture of $Zn(MeCO_2)_2{\cdot}2H_2O$ (0.220 g, 1 mmol), H_3PO_4 (0.2610 g, 85%, 2 mmol), 2,5-dimethylpiperazine (dmpip) (0.180 g, 1.5 mmol), and water (10 mL) in a molar ratio of 1:2:1.5:550 was stirred and transferred and sealed in a 23 mL teflon-lined stainless container that was heated to 150 °C for 120 h. After cooling to room temperature at the rate of 5 ° C/h, colourless needle-like crystals in a single phase were recovered in 60% yield. IR (KBr, cm^{-1}): 3433w, 3359m, 3224w, 2956m, 2603m, 1501m, 1395m, 1360s, 1307(w), 1085(s), 1008(s), 720(s), 643(w), 497(m). Anal. calcd. for $C_6H_{18}N_2O_8P_2Zn$ (**1**): C 19.29, H 4.86, N 7.50; found: C 19.19, H 4.94, N 7.46.

Physical measurements

Elemental analyses were performed on a PerkinElmer 240 elemental analyzer. The FT-IR spectra were recorded from KBr pellets in the range 400–4000 cm^{-1} on a Nicolet 5DX spectrometer.

X-ray crystallography

Diffraction intensities were collected at 293 K on a Bruker Smart 1000 diffractometer (MoKα, l λ = 0.71073 Å). The structure was solved with the direct methods and refined with the full-matrix least-squares technique (SHELX-97) (32). Analytical expressions of neutral atom scattering factors were employed, and anomalous dispersion corrections were incorporated. All non-hydrogen atoms were refined anistropically and all hydrogen atoms were refined isotropically. Hydrogen atoms of organic ligands were geometrically placed; the hydrogen of phosphate was found from the difference Fourier map. The crystallographic data are listed in Table 1 and the selected interatomic distances and angles are given in Table 2.

Results and discussion

X-ray single crystal structural analysis revealed that the asymmetric unit contains one Zn(II) ion, one HPO_4^{2-} group, and 0.5 of a dimpip cation. As expected, the structure consists of a one-dimensional linear $[Zn(HPO_4)_2]^{2-}$ chain constructed from corner-shared four-membered rings and each of the four-membered rings is formed by two phosphate groups and two zinc ions via oxygen sharing. The Zn ion is tetrahedrally coordinated to four oxygen atoms from four HPO_4 tetrahedra with Zn—O bond lengths of 1.9181(14) and 1.9531(14) Å. The O-Zn-O bond angles are in the range of 95.48(9)–115.62(7)° (avg. for O-Zn-O is 109.3°). The phosphorus atom has P—O bond lengths in the range of 1.5149(14)–1.5753(14) Å. Each Zn atom in **1** is connected to four neighboring P atoms but each P atom is connected to two neighboring zinc atoms via Zn-O-P linkages (Zn-O-P, 136.25(9)° and 135.28(9)°). A framework structure of $Zn(PO_4)_2$ would result in a net framework charge of –4 and the presence of $[C_6N_2H_{16}]$ would account for the +2 charge arising from the diprotonation of dmpip. The excess negative charge of –2 is then balanced by the protonation of the PO_4 moieties, as given in the formula. Bond valence sum calculations (33) and a larger P(1)—O(3) bond distance of 1.5753(14) Å indicate that O(3) is attached by hydrogen (28). The hydrogen atom of -O(3)-H group was also found in the difference Fourier maps.

The most interesting feature of **1** is its 3-D supramolecular inorganic network constructed from the assembly of linear $[Zn(HPO_4)_2]^{2-}$ chains via strong and symmetrical hydrogen-bonded $R_2^2(8)$ dimers (19) between a pair of phosphate groups as shown in Fig. 2*a* and Table 3, which can be regarded as the supramolecular synthons. The terminal -O(3)-H and O(4) groups in PO_4 involve the formation of the

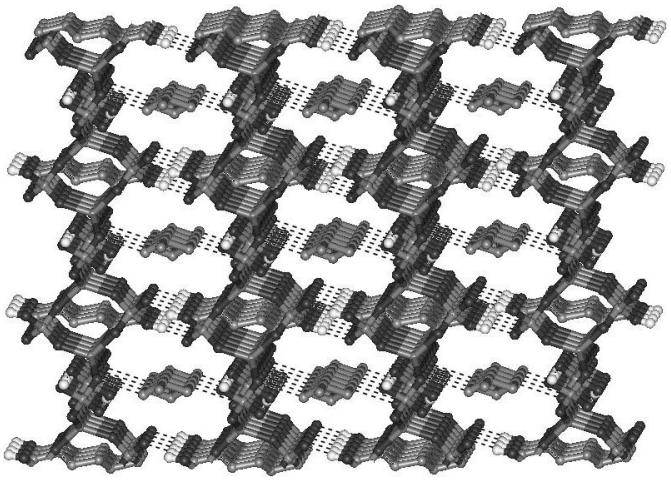
synthons with a short O(3)··O(4) distance (2.605 Å) and an approximately linear O(3-H··O(4) angle (173° based on restrained refinement of the hydrogen). These synthons extend the one-dimensional chains into a very rigid three-dimensional cooperative hydrogen-bonded network featuring three-dimensional intersecting pseudochannels. Two types of the pseudochannels run along the [110] and [–100] directions and have the same shape, whereas the third type runs along the *c*-axis direction. The organic dmpip cations occupy the pseudochannels and are attached to the three-dimensional inorganic framework via N-H··O hydrogen bonds to further strengthen the 3-D network (Fig. 3). Each nitrogen atom of dmpip is dually hydrogen bonded to the phosphate oxygen atoms with N(1)··O(1) and N(1)··O(4) distances of 2.767(2) and 2.708(2) Å, respectively. The strong symmetrical hydrogen bonds have stabilization energies up to 10 times greater than those of normally occurring hydrogen bonds (31). Hydrogen bonding synthons are important in the design of persistent supramolecular arrays because they have good strength, directionality, cooperativity, and complementarity (34). In **1**, the hydrogen bonding synthons play an important role in the stabilization of the three-dimensional network. The powder XRD pattern in combination with thermogravimetric analyses show compound **1** as a phase-ordered solid and is stable in air below 180 °C.



The overall structure of **1** is different than that of other linear zinc phosphates with *N*,*N*′-dimethylpiperazine, piperazine, and 2-methylpiperazine as templates, although they all have the same anionic $[Zn(HPO_4)_2]^{2-}$ chain (25–28). In other linear phosphates, HPO_4^{2-} groups only form the hydrogen bonds with organic amine and (or) lattice water molecules but no self-complementary hydrogen bond dimers exist between adjacent HPO_4^{2-} groups. Thus, the self-complementary three-dimensional inorganic network is a unique behavior of **1** among linear zinc phosphates.

The structure of **1** is also related to some piperazine-templated three-dimensional compounds ($[C_4N_2H_{12}][Zn_2(HPO_4)_3]$, $[C_4N_2H_{12}][Zn_2(PO_4)(H_{1.5}PO_4)_2]$, and $[C_4N_2H_{12}][Co_{0.14}Zn_{1.86}(PO_4)(H_{1.5}PO_4)_2]$) (25, 30, 35, 36) because they all contain square-twisted linear $[M(HPO_4)_2]^{2-}$ chains. In these piperazine-templated compounds, $[M(HPO_4)_2]^{2-}$ chains are linked by covalent bonds into a three-dimensional inorganic network. In contrast, $[Zn(HPO_4)_2]^{2-}$ chains are linked by hydrogen bond dimers (synthons) into a three-dimensional hydrogen bond network.

The linear chains are more important than layered and three-dimensional zincophosphate networks from the forming mechanism point of view because they are thought of as SBUs for layered and three-dimensional networks. Rao and et al. (25, 30) have recently isolated a monomeric zinc phosphate formulated as $[Zn_2(HPO_4)_2(H_2PO_4)_4]^{4-}$, which is the only known monomer of the zinc phosphate family containing only the four-membered ring and can transform into a layered structure on mild heating. The authors thought that the transformation of monomeric $[Zn_2(HPO_4)_2(H_2PO_4)_4]^{4-}$ into layers involves a simple chain $[Zn_2(HPO_4)_2(H_2PO_4)_2]^{2-}$, which is formed by losing the H_2PO_4 groups and the congregating of monomeric $[Zn_2(HPO_4)_2(H_2PO_4)_4]^{4-}$ units (30). Similarly, Oliver et al. (37) proposed a linear chain with corner-shared four-membered rings to be the fundamental building unit in the aluminophosphate framework solids. The difference between Rao and Oliver in the treatment of linear

© 2004 NRC Canada

Fig. 3. Pespective view of the self-complementary three-dimensional hydrogen bond framework approximately running along the [110] direction with H_2dmpip molecules.

chains only lies on secondary building units and fundamental building units. As for the formation of $[Zn(HPO_4)_2]^{2-}$ in the work, it may be the result of simply losing H_3PO_4 and the congregating of monomeric $[Zn_2(HPO_4)_2(H_2PO_4)_4]^{4-}$ units if the $[Zn_2(HPO_4)_2(H_2PO_4)_4]^{4-}$ units are universal primary building units in the formation of zinc phosphates.

$$n[Zn_2(HPO_4)_2(H_2PO_4)_4]^{4-} \xrightarrow{-2nH_3PO_4} [Zn(HPO_4)_2]_{2n}^{4n-}$$

It is also interesting to think about the further loss of H_2PO_4 groups and the congregating of the three-dimensional inorganic hydrogen bond network of **1**. If a pair of HPO_4^{2-} groups lose one $H_2PO_4^{2-}$ without destroying the symmetry of the network of **1**, which is accompanied by the further coordination of PO_4 groups, the network of **1** will transform into a fully four-connected and highly negatively charged three-dimensional network with analcime topology (38).

Stereoselective synthesis of naturally occurring unsaturated amide alkaloids by a modified Ramberg–Bäcklund reaction

Yang Li, Yu Zhang, Zhi Huang, Xiaoping Cao, and Kun Gao

Abstract: A convenient and rapid approach for the synthesis of naturally occurring unsaturated amide alkaloids **1a**–**1n** by the recently developed one-flask Ramberg–Bäcklund reaction is described. The starting material was alcohol **3**, which was transformed into thiolacetate **4** using the Mitsunobu reaction. In situ cleavage of acetyl moiety of **4**, followed by alkylation of the resulting thiol with appropriate chloroacetamide **5**, provided the sulfide **6**. Oxidation of sulfide **6** gave the corresponding sulfone **2**. Treatment of the sulfone **2** with the dibromodifluoromethane in the presence of alumina-supported potassium hydroxide in dichloromethane solution afforded unsaturated amide alkaloids **1a**–**1n**. To the best of our knowledge, the synthesis of **1e** and **1i** was reported for the first time.

Key words: synthesis, unsaturated amide alkaloids, Ramberg–Bäcklund reaction.

Résumé : Faisant appel à la réaction de Ramberg–Bäcklund monotope développée récemment, on a mis au point une méthode pratique et rapide de réaliser la synthèse des alcaloïdes naturels **1a**–**1n** comportant une fonction amide non saturée. Le produit de départ est l'alcool **3** qui est transformé en thiolactate **4** à l'aide d'une réaction de Mitsunobu. Le clivage in situ de la portion acétyle du composé **4**, suivi d'une alkylation à l'aide du chloroacétamide **5** approprié du thiol qui en résulte conduit à la formation du sulfure **6**. L'oxydation du sulfure **6** fournit la sulfone **2**. Le traitement de la sulfone **2** à l'aide de dibromodifluorométhane, en présence d'hydroxyde de potassium supporté par de l'alumine dans le dichlorométhane, conduit à la formation des alcaloïdes recherches **1a**–**1n**. À notre connaissance, il s'agit des premières synthèses des composés **1e** et **1i**.

Mots clés : synthèse, alcaloïdes comportant une fonction amide non saturée, réaction de Ramberg–Bäcklund.

Introduction

Various unsaturated amide alkaloids bearing pyrrolidine, isobutyl, and piperidine moieties are interesting targets of numerous synthetic investigations, presumably because of their significant biological activities (1, 2). They are distributed widely in the plant kingdom. The series of compounds mostly isolated from the genus *Piper*, which is used in folk medicine, are amides of unsaturated alkanoic or arylalkanoic acids. These compounds display antiinflammatory, antidiarrheal, insecticidal, antifungal, antimalarial, as well as 5-lipoxygenase and cyclooxygenase-1 inhibitory activities (2). For example, piperine was the first amide to be isolated from the *Piper* species. Pharmacological studies reported that piperine had antipyretic, analgesic, and antiinflammatory activities (1*j*), and that it could also inhibit gastric emptying and gastrointestinal transit in rats and mice (2*c*). Sarmentine was isolated from *P. sarmentosum*, which showed larvicidal activity against second stage larva of *Toxocara canis* (1*a*). Recently, pellitorine and neopellitorine B were isolated from *Artemisia dracunculus*, which showed insectical activity against *Sitophilus oryzae* and *Rhyzopertha dominica* (1*i*). Pellitorine was also found as having antimalarial properties (2*a*), which can be explained by the tendency of the nucleic acids of the parasites to react with the α,β-unsaturated carbonyl moiety of pellitorine in a Michael addition fashion (2*a*). Pellitorine and piperine also exhibited antifungal activity against *Cladosporium sphaerospermum* (2*b*). Thus, it was concluded that the presence of a methylenedioxyphenyl and an unsaturated alkanoic amide group in the compounds may be crucial for high biological activity. The fact that unsaturated amide alkaloids occur naturally in very limited amounts in some rather inaccessible plant species has stressed the need for good synthetic methods. A perusal of numerous reviews on the chemistry of the unsaturated amide alkaloids reveals that the field is mainly dominated by two general strategies for the assembly of the unsaturated amide alkaloids skeleton units. One approach makes use of amidation with various amines of the stereochemically defined unsaturated acids or esters that are prepared by: (*a*) the

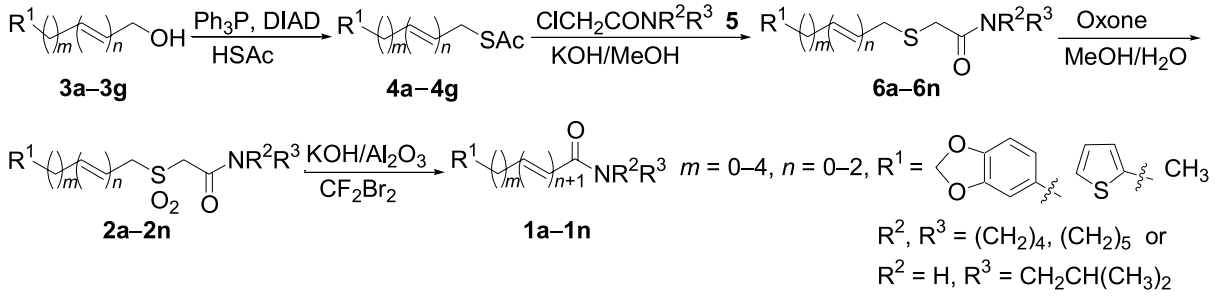
Wittig type approaches (3*a*–3*d*); (*b*) Pummerer-type reaction intermediates (3*e*); (*c*) Still cross-coupling reactions (3*f*); (*d*) palladium-phase transfer co-catalyzed couplings of vinylic iodide and acrylate (3*g*); (*e*) allyl acetates eliminating the elements of acetic acid in the presence of *O*,*N*-bis(trimethylsilyl) acetamide and molybdenum hexacarbonyl (3*h*); (*f*) rearrangement of the corresponding 2-ynoic esters in the presence of Ph_3P (3*i*); and (*g*) addition of carbon nucleophiles to aldehyde tosylhydrazones of aromatic and heteroaromatic compounds (3*j*). Another method entails the anchoring of the amide unit to the end of a variable olefinic double bond that involves: (*a*) the Wittig methodology (4*a*); (*b*) Knoevenagel condensations (4*b*–4*c*); (*c*) thermal SO_2 extrusion from *cis*-2,5-disubstituted 2,5-dihydrothiofene-1,1-dioxides (4*d*); (*d*) a double elimination of β-acetoxy sulfones (4*e*); (*e*) further functionalization containing the sulfonyl and the cyano group (4*f*); (*f*) isomerization of 2-ynoic amides catalyzed by ruthenium or iridium complexes (4*g*); (*g*) hydrozirconation of the terminal acetylene using Schwartz's reagent ($Cp_2ZnCl(H)$) followed by Pd(0)-catalyzed coupling with the iodo-amide (4*h*–4*i*); (*h*) an easily accessible bifunctional dienyl compound based upon a double selective electrophilic substitution followed by coupling reaction (4*j*); and (*i*) the use of δ-tosyl dienamide as δ-acyldienyl cation equivalents (4*k*). Although numerous methods have been reported for the synthesis of unsaturated amide alkaloids, there still remains the necessity and urgency to discover milder and newer methods for the construction of the series of unsaturated amide alkaloids. We recently reported a new protocol of the Ramberg–Bäcklund reaction to effect the transformation of the α- and α′-hydrogen bearing sulfones directly into alkenes (5). From this investigation emerged the highly stereoselective generation of a new (*E*)-double bond with the retention of the configurations of the preexisting ones. We became interested in establishing a convenient and stereoselective new route to synthesize unsaturated amide alkaloids (**1**) (Scheme 1), without resorting to the prior preparation of the α-halosulfone precursors in a separate step (6). In this paper we extend this methodology to the synthesis of unsaturated amide alkaloids (**1**). The preparation of 13 natural products and one related analogue, as well as their full details are reported.

Results and discussion

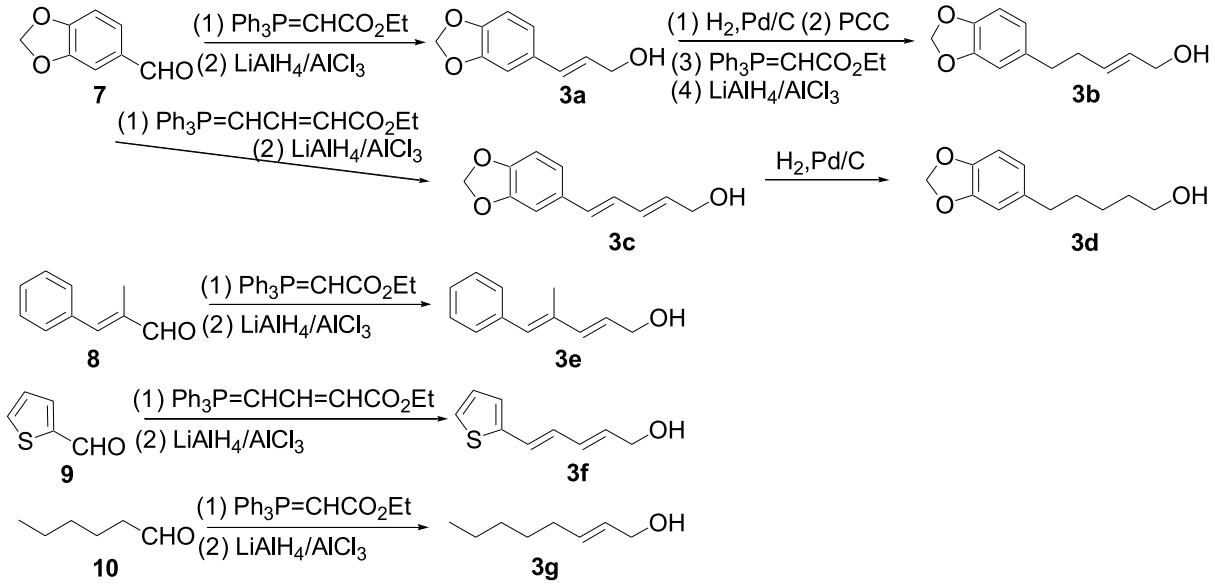
Scheme 1 outlines the strategy we pursued in the quest for stereo-pure unsaturated amide alkaloids **1**. We wished to prepare it from functional sulfones **2**. The strategy shown in Scheme 1 was thought to be feasible because of the successful application of our procedure to the formation of conjugated trienes from diallylic sulfones (5*b*), conjugated tetraenes from allylic dienylic sulfones (5*d*), and linear and cyclic enediynes from dipropargylic sulfones (5*e*). Our synthetic method was also applied to the synthesis of natural products containing a triene unit such as galbanolenes. The procedure reported here started with a functional sulfones **2**, with the amide group and the functional carbon chain already in place and the new double bond to be realized by our modified Ramberg–Bäcklund procedure. This disconnection approach relied on the stereocontrolled synthesis of the functional sulfones **2**, which was in turn prepared by a

Scheme 1. Strategy of constructed unsaturated amide alkaloids **1**.



stereocontrolled preparation of alkenyl or alkyl thiolacetates **4** and chloroacetamides **5** (7). The coupling reaction between stereodefined thiolacetates **4** to pure chloroacetamides **5** assembled the sulfides **6**, from which the corresponding sulfones **2** could be obtained after oxidation. This procedure invariably demanded a stereoselective preparation of alcohols **3**, the common intermediate for the requisite thiolacetates **4** (Scheme 2). Several synthetic methods were tried. In the end, the alcohols **3** were secured by the Wittig reaction, and followed by reduction.

The alcohols **3** (R^1 = piperonyl, thienyl, or methyl) were prepared according to the Scheme 3. The commercially available aldehyde **7**, **8**, **9**, or **10** was used as a starting material for the preparation of the alcohols **3**. Treatment of **7**, **8**, or **10** with $Ph_3P{=}CHCO_2Et$ afforded an ester with good (*E*)-selectivity, which was followed by regioselective reduction of the ester moiety with aluminum hydride (AlH_3, from $LiAlH_4$:$AlCl_3$ = 3:1) to furnish the alcohols **3a**, **3e**, or **3g** (76%, 66%, 51%), respectively. The alcohol **3a** was hydrogenated, oxidized with pyridinium chlorochromate (PCC), then its carbon chain elongated by a Wittig reaction ($Ph_3P{=}CHCO_2Et$), and followed by a reduction of the resulting ester with aluminum hydride selectively to give the primary alcohol **3b** in 59% yield. On the other hand, treatment of aldehyde **7** or **9** with $Ph_3P{=}CHCH{=}CHCO_2Et$ followed by a reduction of the ester moiety with aluminum hydride gave alcohol **3c** or **3f** in 60% and 68% yield, respectively. Hydrogenation of **3c** afforded the saturated alcohol **3d** in nearly quantitative yield.



Alcohols **3a**–**3g** were transformed into the corresponding thiolacetates **4a**–**4g** using the Mitsunobu reaction with thiolacetic acid in the presence of triphenylphosphine and diisopropyl azodicarboxylate (DIAD) (8). In situ cleavage of acetyl moieties of **4a**–**4g** with potassium hydroxide in methanol, followed by alkylation of the resulting thiols with the appropriate chloroacetamides **5**, provided the sulfides **6a**–**6n** in good yields (Table 1) with no S_N2' substitution products. Oxidation of the sulfides **6** by oxone ($2KHSO_5{\cdot}KHSO_4{\cdot}K_2SO_4$) (9) in methanol–water (1:1) gave high yields of the corresponding sulfones **2** except **2j** and **2k** (Table 1). This is probably due to the side reaction of the heteroaromatic sulfides. As expected, stereochemistry of the double bonds was retained during these transformations. Subjecting the sulfones **2a**–**2n** to the modified Ramberg–Bäcklund reaction protocol (CBr_2F_2, KOH–Al_2O_3, CH_2Cl_2), previously described by us, invariably gave the geometrically defined unsaturated amide alkaloids **1a**–**1n** with the newly formed double bond that had the (*E*)-configuration in good yields (Table 2). The stereochemistry of the newly formed carbon–carbon bond in **1a**–**1n** was readily diagnosed by a typical coupling constant of 14.2–15.0 Hz for trans-olefinic protons. Examination of the ^{13}C NMR spectra of the products indicated the presence of one isomer in each case. Thus, the stereoselectivity of the reaction was >95%. All the compounds were characterized by IR, ^1H and ^{13}C NMR, and

Piperylin (**1a**), piperlonguminine (**1b**), piperine (**1c**), pipercallosidine (**1d**), piperine S (**1e**), chingchengenamide A (**1f**), piperdardine (**1g**), piperettine (**1h**), *N*-isobutylotanthusic acid amide (**1j**), *N*-piperdineotanthusic acid amide (**1k**), sarmentine (**1l**), pellitorine (**1m**), neopellitorine B (**1n**).

Scheme 3. Synthesis of alcohols **3a**–**3g**.

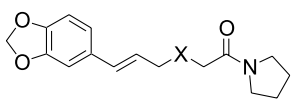
high resolution mass spectra. The data of the natural unsaturated amide alkaloids **1a**–**1h**, **1j**–**1n** were in agreement with those reported in the literature (1). It is noteworthy that **1i** is not a natural alkaloid but one prepared for the first time with the readily available material in our laboratory. The synthesis of **1i** also relied on the functional sulfone **2i**, which could be prepared by the method similar to that used for the other sulfones (Scheme 4). To the best of our knowledge, **1e** and **1i** were synthesized for the first time.

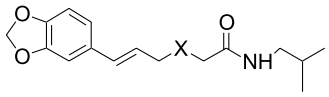
Chloroacetamides **5** were prepared by acylation of various amines with chloroacetylchloride in high yields (7).

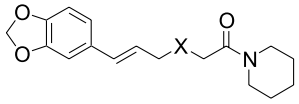
Conclusion

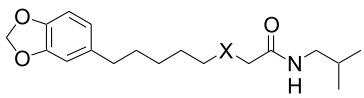
We have presented a rapid route with our protocol of the Ramberg–Bäcklund reaction as a key step to stereochemically defined naturally occurring unsaturated amide alkaloids. The synthetic transformation utilized readily available aldehydes as starting materials. The synthesis routes are facile, the yields are satisfactory, and the reactions can be performed in molar scales. We have also shown that the double bonds of stereochemically defined sulfone retain their stereochemistry and that the newly formed double bond has an (*E*)-configuration in our modified Ramberg–Bäcklund reaction. Investigation of the structure biological activity of these unsaturated amide alkaloids is in progress.

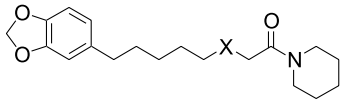
Experimental

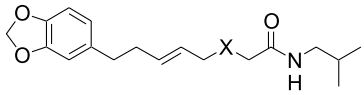


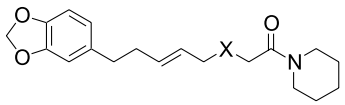


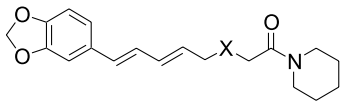


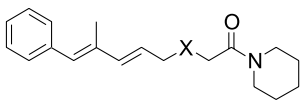












Melting points were measured on a Kofler apparatus and were uncorrected. IR spectra were recorded on a Nicolet NEXUS 670 FT-IR spectrophotometer, and reported in wave number (cm^{-1}). ^1H and ^{13}C NMR spectra were recorded on an Avance-200 or a Mercury Plus-300 spectrometer. The chemical shifts (δ) are reported in ppm and coupling constants (*J*) in Hz. Mass spectra (MS) were obtained on a HP-5988A mass spectrometer. High resolution mass spectra (HR-MS) were obtained on a Bruker Daltonics APEX II 47e mass spectrometer. Elemental analyses were performed on a Germany Varioel elemental instrument. Column chromatography was generally performed on silica gel (200–300 mesh), and TLC inspection on silica gel GF_{254} plates. All the aldehydes were purchased and used without further purification.

Alcohols 3

A solution of individual aldehyde **7** (50 mmol), **8** (50 mmol), **9** (50 mmol), or **10** (50 mmol) in benzene (25 mL) was added dropwise to a well-stirred solution of

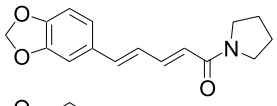
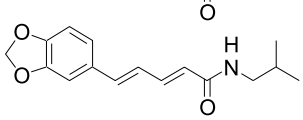
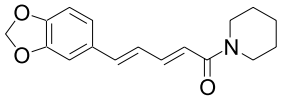
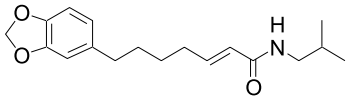
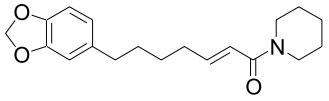
[a]X = S for entry **6** and X = SO_2 for entry **2**.
[b]^{1}H and ^{13}C NMR were recorded on an Avance-200 or a Mercury Plus-300 spectrometer; coupling constants (*J*) in Hz.

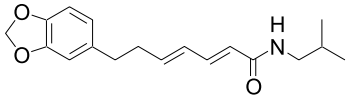


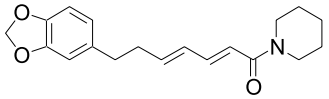


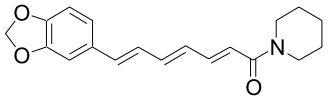


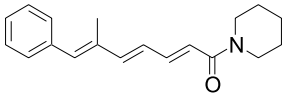


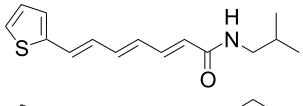


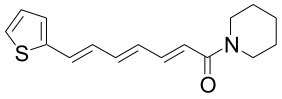


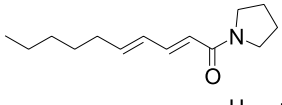


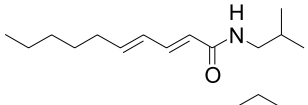


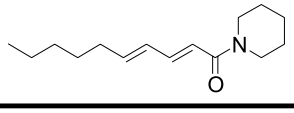












$Ph_3P{=}CH_2CO_2Et$ (60 mmol) in benzene (150 mL) or $Ph_3P{=}CHCH{=}CHCO_2Et$ (60 mmol) in benzene (200 mL). The reaction mixture was refluxed for 4 h and then the solvent was evaporated in vacuo. Flash chromatography of the residue over silica gel (petroleum ether (boiling range 60–90 °C) : ethyl acetate, 8:1) afforded the (*E*)-α,β-unsaturated esters or (*E*,*E*)-dienylesters. These esters (40 mmol) in THF (25 mL) were added dropwise to a well-stirred suspension of $LiAlH_4$ (120 mmol) and $AlCl_3$ (40 mmol) in THF (150 mL) at 0 °C, respectively. The reaction mixture was stirred at this temperature for 1 h and quenched by water (8 mL). The solid aluminates were removed by filtration. The combined filtrates were dried ($MgSO_4$) and concentrated in vacuo. Flash chromatography of the residue over silica gel (petroleum ether : ethyl acetate, 4:1) afforded alcohol **3a**, **3c**, **3e**, **3f**, or **3g** (76%, 60%, 66%, 68%, and 51% yield, respectively). The solution of **3a** (15 mmol) in EtOAc–EtOH (2:1, 60 mL) was hydrogenated under a hydrogen atmosphere (10% Pd–C, 10 mg) for 4 h to give the corresponding saturated alcohol. This saturated alcohol (15 mmol) in CH_2Cl_2 (10 mL) was added to a suspension of pyridinium chlorochromate (PCC) (18 mmol) in CH_2Cl_2 (60 mL). The reaction mixture was stirred at room temperature for 4 h and filtered, and the filtrate was concentrated in vacuo. Flash chromatography of the residue over silica gel (petroleum ether : ethyl acetate, 8:1) afforded the corresponding saturated aldehyde. After the treatment of this aldehyde with $Ph_3P{=}CH_2CO_2Et$, the resulting ester was reduced with $LiAlH_4$–$AlCl_3$ as above and alcohol **3b** was obtained in 59% yield. Alcohol **3c** was hydrogenated under a hydrogen atmosphere (10% Pd–C, 10 mg) to give saturated alcohol **3d** in nearly quantitative yield. All of these products were easily confirmed by their ^{1}H NMR and MS spectra. The focal methylene protons linked within the hydroxyl group of the unsaturated alcohols **3a**–**3c** and **3e**–**3g** have a chemical shift value of δ 3.94–4.59 ppm, and the chemical shift of methylene protons linked within the hydroxyl group of the saturated alcohol **3d** is 3.66 ppm (10).

Thiol acetates 4

A solution of DIAD (6 mmol) in dry C_6H_6 (5 mL) was added to a stirred solution of Ph_3P (6 mmol) in C_6H_6 (5 mL) at 0 °C. The resulting yellow solution was kept at 0 °C for 15 min and then a precooled mixture of the individual alcohols **3a**–**3g** (5 mmol) and CH_3COSH (6 mmol) in dry C_6H_6 (50 mL) was added in one portion. The mixture was stirred at room temperature for 1 h and the solvent was removed in vacuo. Flash chromatography of the residue over silica gel (petroleum ether : ethyl acetate, 10:1) afforded thiol acetate **4a**, **4b**, **4c**, **4d**, **4e**, **4f**, or **4g** in 83%, 95%, 93%, 85%, 88%,

[a]^{1}H NMR were recorded on an Avance-200 or a Mercury Plus-300 spectrometer; coupling constants (*J*) in Hz.

Scheme 4. Synthesis of 1-[(2*E*,4*E*,6*E*)-1-oxo-6-methyl-7-phenylheptatrienyl]piperidine (**1i**).

2i **1i**

© 2004 NRC Canada

82%, and 90% yield, respectively. These thiol acetates can be easily characterized by a comparison with their analogues (11). The focal methylene protons linked within the *S*-thioacetate group of the unsaturated thiol acetates **4a**–**4c** and **4e**–**4g** have a chemical shift value of δ 3.43–4.03 ppm, and the methylene protons of the saturated thiol acetate **4d** have a chemical shift of δ 3.00 ppm, whereas those of the corresponding thiol acetates experience a similar shift value to that of the alcohols.

Chloroacetamides 5

A solution of an appropriate amine (200 mmol) in anhyd THF (50 mL) was added to chloroacetylchloride (100 mmol) in anhyd THF (50 mL) under a nitrogen atmosphere. The reaction mixture was stirred for 10–12 h at room temperature. The side product ammonium chloride was filtered off and the solvent evaporated in vacuo to afford the chloroacetamides **5** in nearly quantitative yields. They were easily confirmed by their ^{1}H NMR and MS spectra (7).

General procedure for the preparation of sulfides 6

An individual solution of thiol acetates **4a**–**4g** (3 mmol) in MeOH (25 mL) was added to the solution of KOH (6 mmol) in MeOH (5 mL). After being stirred at 0 °C for 10 min, a solution of the appropriate chloroacetamide **5** (2.8 mmol) in MeOH (5 mL) was added to this well-stirred thiol solution and the stirring was continued for 1 h at 0 °C. The reaction mixture was poured into water (10 mL) and extracted with ethyl acetate (3 × 25 mL). The combined extract was washed with brine, dried with $MgSO_4$, filtered, and concentrated in vacuo. Flash chromatography of the residue over silica gel (petroleum ether : ethyl acetate, 5:1 gradient to 3:1) afforded the sulfides **6a**–**6n**. The important data for sulfides **6a**–**6n** are described in Table 1 and their full data are available as supplementary data.[3]

General procedure for the preparation of sulfones 2

The individual sulfide **6** (2 mmol) was added to a well-stirred solution of oxone (6 mmol) in MeOH–H_2O (1:1, 4 mL). The mixture was then stirred at 0 °C for 2–4 h. The reaction mixture was diluted with water (10 mL) and extracted with ethyl acetate (3 × 25 mL). The combined organic phase was washed with brine, dried with $MgSO_4$, filtered, and concentrated in vacuo. Flash chromatography of the residue over silica gel (petroleum ether : ethyl acetate : CH_2Cl_2, 4:1: 1 gradient to 2:1:1) afforded the sulfones **2**. The important data for sulfones **2a**–**2n** are described in Table 1 and their full data are available as supplementary data.[3]

General procedure for the preparation of unsaturated amide alkaloids 1

A solution of sulfone **2** (1 mmol) in dry CH_2Cl_2 (6 mL) was added to a stirred suspension of KOH–Al_2O_3 (10 mmol of KOH) in CBr_2F_2–CH_2Cl_2 (1:10, 10 mL). This mixture was then stirred for 1 h at room temperature, the KOH–Al_2O_3 was removed by filtering, and the filtrate was concentrated in vacuo. Flash chromatography of the residue over silica gel (petroleum ether : ethyl acetate : CH_2Cl_2, 5:1:1 gradient to 3:1:1) gave the unsaturated amide alkaloids **1a**–**1n**. The important data for unsaturated amide alkaloids **1a**–**1n** are described in Table 2 and their full data follows.

1-[(2*E*,4*E*)-1-Oxo-5-(3,4-methylenedioxyl)phenylpentadienyl]pyrrolidin (piperylin, 1a) (1*a*)

White needles, 85%; mp 147 to 148 °C (lit. (1*a*) 148 to 149 °C). IR ν_{max} (KBr disc) (cm^{-1}): 2876, 1636, 1420, 1249, 1037, 993, and 841. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.86–2.05 (4H, m, 2 × CH_2), 3.45–3.55 (4H, m, 2 × CH_2N), 5.98 (2H, s, OCH_2O), 6.26 (1H, d, J = 15.0, 2-CH=), 6.74 (1H, d, J = 15.0, ArCH=), 6.75 (1H, d, J = 8.1, ArH), 6.76–6.99 (3H, m, 2ArH, CH=), and 7.43 (1H, dd, J = 15.0 and 9.0, CH=). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 24.3, 26.1, 45.9, 46.4, 101.2, 105.6, 108.4, 121.4, 122.5, 125.1, 130.9, 138.6, 141.7, 148.1, 148.1 and 164.9. MS (EI) *m*/*z* (%): 271 (M$^+$, 32), 201 (100), 173 (38), 121 (53), and 115 (86).

(2*E*,4*E*)-N-Isobutyl-5-(3,4-methylenedioxyl)phenylpentadienamide (piperlonguminine, 1b) (1*b*)

White needles, 84%; mp 169 to 170 °C. IR ν_{max} (KBr disc) (cm^{-1}): 3463, 2985, 1741, 1374, 1245, 1046, 936, and 848. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 0.94 (6H, d, J = 6.6, 2 × CH_3), 1.78–1.89 (1H, m, C*H*$(CH_3)_2$), 3.17–3.21 (2H, m, C*H*$_2$NH), 5.78 (1H, br s, NH), 5.95 (1H, d, J = 14.4, 2-CH=), 5.98 (2H, s, OCH_2O), 6.67 (1H, dd, J = 15.6 and 10.5, CH=), 6.76 (1H, d, J = 8.1, ArH), 6.77 (1H, d, J = 15.6, ArCH=), 6.88 (1H, d, J = 8.1, ArH), 6.96 (1 H, s, ArH), and 7.36 (1H, dd, J = 14.4 and 10.5, CH=). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 20.1, 20.1, 28.6, 47.0, 101.3, 105.6, 108.4, 122.5, 123.2, 124.6, 130.8, 138.7, 140.9, 148.1, 148.1, and 166.2. MS (EI) *m*/*z* (%): 273 (M$^+$, 37), 201 (100), 173 (71), and 115 (97).

1-[(2*E*,4*E*)-1-Oxo-5-(3,4-methylenedioxyl)phenylpentadienyl]piperidine (piperine, 1c) (1*a*, 1*c*)

Yellow needles, 82%; mp 131 to 132 °C (lit. (1*a*) 132 to 133 °C). IR ν_{max} (KBr disc) (cm^{-1}): 2935, 1636, 1444, 1251, 1036, 929 and 854. ^{1}H NMR (300 MHz; $CDCl_3$) δ: 1.58–1.67 (6H, m, 3 × CH_2), 3.50–3.62 (4H, m, 2 × CH_2N), 5.97 (2H, s, OCH_2O), 6.44 (1H, d, J = 14.1, 2-CH=), 6.70 (1H, d, J = 15.9, ArCH=), 6.71–6.76 (1H, m, CH=), 6.78 (1H, d, J = 8.1, ArH), 6.90 (1H, d, J = 8.1, ArH), 6.99 (1H, s, ArH), and 7.41 (1H, dd, J = 14.1 and 10.2, CH=). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 24.6, 25.6, 26.7, 43.2, 46.9, 101.3, 105.6, 108.5, 120.0, 122.5, 125.3, 130.9, 138.2, 142.5, 148.1, 148.1, and 165.4. The catalytic effect of boron substitution in MCM-41-type molecular sieves

V. Sundaramurthy, I. Eswaramoorthi, and N. Lingappan

Abstract: A series of B-MCM-41 samples has been synthesized with a wide range of boron content (SiO_2:B_2O_3 ratio from 20 to 200), using ethyl silicate ester-40 (ES-40) as the silica source and characterized by XRD, BET, FT-IR, ^{11}B-MAS NMR, SEM, pyridine adsorption, TPDA, and chemical analysis. The interplanar d_{100} spacing varies from 40 to 45 Å, depending on the Si:B ratio. On calcination, a significant amount of four-coordinated boron is converted into less stable three-coordinated boron, and some boron is removed from the framework. The degree of deboronation increases with an increase of boron content of the sample. The B substitution in the MCM-41 framework results in only weak and mild acid sites. The isomerization of 1-hexene is found to be influenced by the boron content in the framework. The isomerization leads to both a hydrogen shift and skeletal rearrangement. The selectivity ratios of *cis*-2-hexene to *trans*-2-hexene and 2-hexene to 3-hexene were found to decrease with an increase of temperature and a decrease of the SiO_2:B_2O_3 ratio of the catalysts. Skeletal isomerization starts at 250 °C, forming secondary products, and increases with an increase of temperature and an increase of boron content of the catalysts.

Key words: ES-40, B-MCM-41, deboronation, catalyst characterization, XRD, BET, FT-IR, ^{11}B-MAS NMR, SEM, 1-hexene isomerization, 2-hexene.

Résumé : Utilisant l'ester silicate d'éthyle-40 (ES-40) comme source de silicium, on a synthétisé une série d'échantillons B-MCM-41 comportant des quantités très variables de bore (rapport SiO_2:B_2O_3 allant de 20 à 200) qu'on a caractérisé par analyse chimique ainsi que par XRD, BET, FT-IR, RMN du ^{11}B-MAS, SEM, adsorption de la pyridine et TPDA. L'espace interplanaire d_{100} varie de 40 à 45 Å suivant la valeur du rapport Si:B. Par calcination, une quantité importante de bore tétracoordiné est transformée en bore tricoordiné et moins stable et une certaine quantité de bore est éliminée du squelette. Le degré de déboration augmente avec une augmentation dans la teneur en bore de l'échantillon. La substitution du bore dans les échantillons de MCM-41 ne conduit qu'à des sites acides faibles et doux. On a observé que l'isomérisation de l'hex-1-ène est influencée par la teneur en bore du squelette. L'isomérisation conduit à des migrations d'hydrogène et à des réarrangements du squelette. On a observé que les rapports de sélectivité *cis*-hex-2-ène:*trans*-hex-2-ène et de hex-2-ène:hex-3-ène diminuent avec une augmentation de la température et une diminution du rapport SiO_2:B_2O_3 des catalyseurs. L'isomérisation du squelette commence à 250 °C avec formation de produits secondaires et elle augmente avec la température et avec une augmentation dans la teneur en bore des catalyseurs.

Mots clés : ES-40, B-MCM-41, déboration, caractérisation du catalyseur, XRD, BET, FT-IR, RMN, ^{11}B-MAS, SEM, isomérisation du hex-1-ène, hex-2-ène.

[Traduit par la Rédaction]

Introduction

MCM-41 is a novel mesoporous material first described by Kresge et al. (1) in 1992. MCM-41 possesses unidirectional channel-like pores of uniform size, which are arranged in a regular hexagonal pattern. The pore diameters are adjustable in the range 15–100 Å, depending on the synthesis conditions, such as temperature, type, and size of the templating detergent cations. Current research on MCM-41 has two major aims. One is to find cheaper raw materials for synthesis. The other aim is to modify the framework of MCM-41, to generate catalytic sites needed for different types of reactions. Isomorphous substitution of Al (2–8), Ti (9, 10), Ga (11), and V (12, 13) in the MCM-41 framework has been described in the literature. The incorporation of boron in the MCM-41 structure has been claimed since 1994 (14). Definite evidence for boron in the MCM-41 framework position (14–23) and MCM-48 framework position (23) has been provided using various techniques. The growing interest in the synthesis of borosilicates is because they could be useful for synthesizing other metallosilicate analogues, which are sometimes difficult to synthesize by direct hydro-

thermal methods (24, 25). Mixtures of silica sources such as Cab-O-Sil M5 fumed silica, sodium silicate, and tetramethylammonium silicate (17), Cab-O-Sil M5 fumed silica and sodium silicate (19), and Ludox and sodium silicate (15) were used to synthesize B-MCM-41. Oberhagemann et al. (22) used a single silica source, tetramethoxysilane. The synthesis of B-MCM-41 using ethyl silicate-40 (ES-40) has not been studied so far. ES-40 is an oligomer silica with a molecular formula of $(C_2H_5O)_3Si\text{-}[O\text{-}Si(OC_2H_5)_2]_3\text{-}O\text{-}Si(OC_2H_5)_3$. It is a transparent liquid containing 40% silica (SiO_2) by mass. ES-40 is perfect for industrial use, considering the efficiency with which it supplies silica and its viscosity, specific gravity, stability when stored, and ease of handling during use. With its high silica content and cost, which has been kept low, ES-40 is widely used in industrial applications. We have already reported the synthesis of B-ZSM-5 using ES-40 as the silica source (26). Dongare and co-workers (27) and Mrowiec-Bialon and Jarzebski (28) reported synthesis of titanium silicalite-1 and sol–gel composites using ES-40.

The protonic form of borosilicate molecular sieves is less acidic than their aluminosilicate counterparts because of a lack of strong Brønsted acidity. Hence, the catalytic properties of borosilicate zeolites, especially B-ZSM-5, are being used for less acidity-demanding reactions such as double-bond migration in olefins (26, 29, 30), dehydration of aldehydes (31), *N*-methylaniline synthesis from aniline (32), and Beckmann rearrangement of cyclohexanone oxime to caprolactum (33). The weakly acidic sites in B-MCM-41 are reported to show high selectivity of isoprene by Prins condensation of isobutylene with formaldehyde (34). In the literature no report is available in detail on B-MCM-41 catalytic activity, particularly in hexene isomerization. Pines and Haag (35), Brouwer (36), and West et al. (37) used 1-hexene isomerization as a catalytic test for the evaluation of the relative acidity of alumina, silica alumina, and silica gel, respectively. The reports are available on 1-hexene isomerization over HY (38) and ZSM-5 zeolite (39, 40). Gati and Resofszki (41) and Paal et al. (42) studied double-bond isomerization over metal oxides and EUROPT-1, respectively. Zhiping and Changqing (43) studied the same reaction over phosphatotungstic acid catalyst. In this paper, we describe the synthesis of B-MCM-41 using ES-40, characterization of this molecular sieve by physico-chemical techniques, and its catalytic activity in 1-hexene isomerization. Further, the significant differences between the catalytic effects of B-MCM-41 and Al-MCM-41 were studied, and the ratio of selectivity of 2-hexenes was compared with those previously obtained (26) for B-ZSM-5 under similar conditions.

Experimental

Synthesis

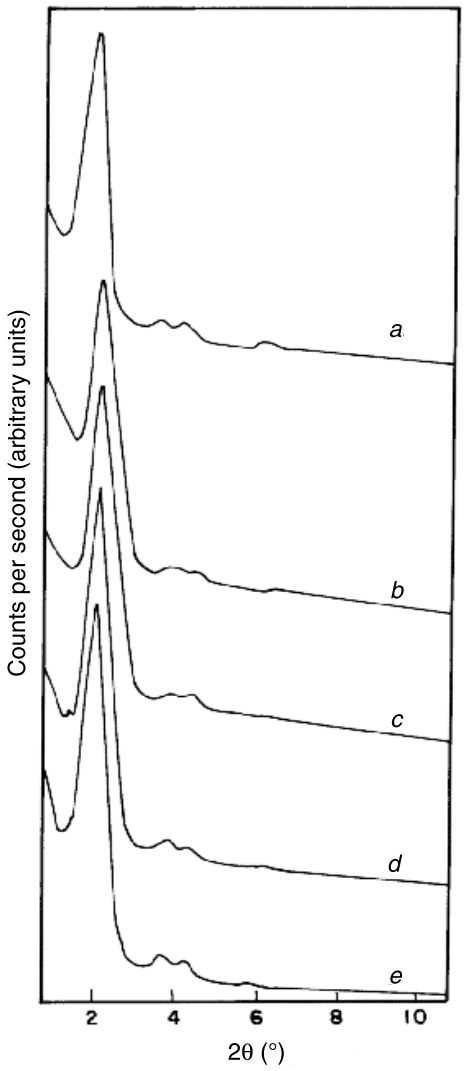
Materials used were ethyl silicate-40 (ES-40, 40% SiO_2) (Mettur Chemicals, South India), sodium aluminate (AR), boric acid (Baker), cetyltrimethylammonium bromide (CTAB) (Ottokemi), sodium hydroxide (E. Merck), sulphuric acid (AR), and demineralized water.

A series of boron-containing MCM-41 samples were synthesized hydrothermally, using gel with the following molar composition: SiO_2 : 0.19 Na_2O : 0.25 CTAB : 63 H_2O : x B_2O_3.

The SiO_2:B_2O_3 ratio (i.e., 1:x) was varied from 20 to 200. The following is the experimental procedure adopted in the preparation of a sample with an SiO_2:B_2O_3 ratio of 50, as a typical case.

Diluted H_2SO_4 (30 mL water containing 0.5 mL concd. H_2SO_4) was added to ethyl silicate ester (20 g) and stirred mechanically. After 1 h, a solution of 12 g of CTAB in 50 mL of water was added to the previous silica–water slurry. After another 15 min, 20 mL of an aqueous solution containing 0.34 g of H_3BO_3 was added. Subsequently, a solution of sodium hydroxide (2 g in 50 mL water) was added carefully, to get a gel at pH 11. The gel obtained was transferred into a 300-mL stainless steel autoclave, and the sealed autoclave was heated statically in an air oven at 120 °C for 10 days. The crystallized mass was filtered, thoroughly washed, and then dried in static air at 120 °C. The solid product, which weighed about 7.0 g, constituted 87% yield on the basis of SiO_2. By varying the SiO_2:B_2O_3 ratio in the initial gel to 20, 50, 100, and 200, samples B-1, B-2, B-3, and B-4, respectively, were synthesized at 120 °C. The Al-MCM-41 (sample A-1) with gel SiO_2:Al_2O_3 = 20 was synthesized from a gel of molar composition SiO_2 : 0.19 Na_2O : 0.25 CTAB : 63 H_2O : 0.05 Al_2O_3, following the experimental procedure described above for B-MCM-41 but with H_3BO_3 replaced by sodium aluminate (2.4 g). Siliceous MCM-41 was crystallized using the same procedure but with no boron or aluminum. The organic cations in the channels were removed by calcination of samples under flowing dry nitrogen with a raise in temperature to 550 °C at a rate of 5 °C min^{-1}. The temperature was kept constant at 550 °C for 2 h before switching over slowly from N_2 to dry air. After an additional 4 h at 550 °C, the samples were cooled to room temperature under flowing air and stored in a desiccator. The calcinated samples were exchanged with a 1 mol L^{-1} solution of NH_4Cl (50 mL g^{-1} sample) at 80 °C for 10 h. The samples were filtered, washed with hot water, and dried at 120 °C. The procedure was repeated two more times to obtain maximum exchange. The acidic or protonated form of the catalyst was obtained by calcination of the NH_4 form of the sample at 550 °C, with a raise in temperature as described earlier.

Characterization



The powder X-ray diffraction patterns of samples were recorded on a Rigaku X-ray diffractometer in the scan range of 2θ between 1° and 10°, using Cu–Ni 40-kV/30-mA radiation. The unit cell parameter (a_o) was calculated using the formula $a_o = 2d_{100}/\sqrt{3}$. The IR spectra of the samples were recorded on a Testscan Shimadzu FT-IR 8000 series FT-IR spectrophotometer using KBr pellets. Each IR spectrum was recorded in the range 2000–250 cm^{-1}. Boron-11 magic angle spinning (MAS) NMR spectra were recorded on a Bruker Avance 400 spectrometer operating at 128.33 MHz. The zirconia rotor (7 mm o.d.) was spun at 6 kHz about the magic angle. The spectra were obtained with a π/2 pulse duration of 2.3 μs and a repetition time of 1.8 s. To prevent rehydration, the dehydrated protonated B-MCM-41 sample was transferred into the NMR rotor in a glove box under dry nitrogen gas. Chemical shifts were determined relative to

$BF_3{\cdot}O(C_2H_5)_2$. The morphology of samples was investigated using scanning electron microscopy (Leica, Stereoscan). The samples were suspended in acetone, and the specimen stub was dipped into the liquid and removed. The powder got deposited onto the surface of the stub evenly when the acetone evaporated. This specimen was coated with an Au–Pd evaporated film to prevent sample charging. Surface area measurements were carried out in a Sorptometric 1990 CE instrument following the BET procedure, using nitrogen as the adsorbent at liquid nitrogen temperatures. Prior to adsorption, the calcinated samples were degassed at 200 °C for 15 h under pressure. Helium was the carrier gas and a thermal conductivity detector was used. The molar compositions of the samples were obtained by wet chemical analysis. Silica in each sample was determined by taking the weight loss after treatment with hydrofluoric acid. Quantitative estimations of boron and sodium were done using inductively coupled plasma atomic emission spectrometry (ICPAES). The organic cation and water contents in the samples were determined by weight loss in TGA (Mettler TA 3000). FT-IR spectra of chemisorbed pyridine was recorded using a specially designed, all-silica, in situ controlled-environment cell. The samples were activated under vacuum (10^{-6} torr (1 torr = 133.322 Pa)) at 400 °C for 5 h and then cooled to 100 °C. Then the samples were allowed to adsorb pyridine for 1 h. Excess and physisorbed pyridine was removed by evacuation for 1 h before the spectra were recorded at 100 °C. Similarly, the pyridine-adsorbed samples were heated to 150, 200, and 250 °C successively under vacuum for 1 h at each temperature before the spectra were recorded. For the studies of temperature-programmed desorption of ammonia (TPDA), samples in H-form were activated at 500 °C for 1 h in a flow of He and then cooled to 120 °C in an He atmosphere; then, ammonia was sorbed at 120 °C. The He flow rate was increased to 40 mL min^{-1} for 1 h to remove the physically adsorbed ammonia. Thermal desorption was carried out in a stream of dry He at a heating rate of 10 °C min^{-1}. The desorbed amount of NH_3 was recorded continuously using a thermal conductivity cell.

The catalytic runs were carried out in a fixed-bed downflow reactor in the temperature range 200–350 °C. The H-form of the catalyst of particle size 20–40 mesh was kept in the middle of the reactor and was activated in pure dry air at 550 °C for 4 h, and the reaction temperature was brought down. The feed (1-hexene of 97.78% purity (Fluka)) was passed at a liquid hourly space velocity (LHSV) of 3 h^{-1}. The products were analyzed by a Hewlett-Packard 5890 A gas chromatograph. Identification of products was facilitated by use of a Finnigan MAT MS automated GC mass spectrometer. At the end of the reaction run, the reactor was flushed with nitrogen to remove the adsorbed hydrocarbons. A portion of the catalyst was removed, and the coke deposited on the catalyst was estimated from the weight loss in TGA (Mettler TA 3000). In this study, about 20–30 mg of the spent catalyst sample was subjected to temperature-programmed TGA (20 °C min^{-1}). The heating was done from ambient temperature to 800 °C in the presence of an air stream with a flow rate of 25 mL min^{-1}. A correction was made for weight loss due to moisture in the sample from the temperature profile (the weight loss from room temperature to 250 °C being ascribed to moisture). The low-temperature (250–500 °C) TGA weight loss corresponds to soft coke, whereas the high-temperature (500–800 °C) weight loss is attributed to hard coke molecules (44).

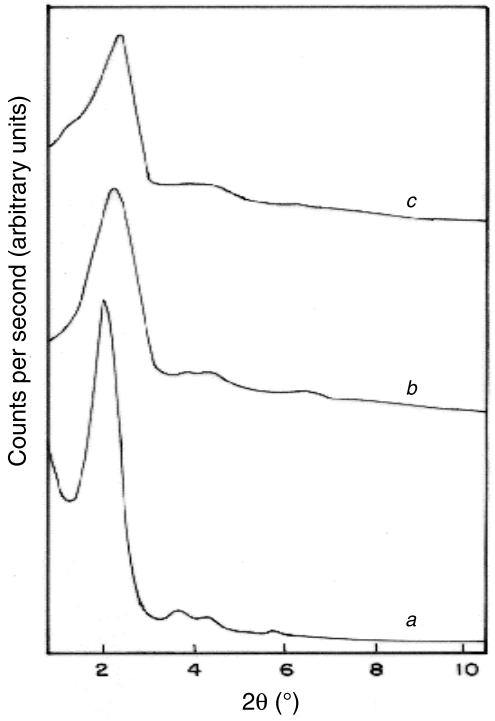
Results and discussion

X-ray diffraction



The X-ray diffraction patterns of the synthesized B-1 to B-4 and A-1 samples shown in Fig. 1 match well with that of the boron-free silicious MCM-41 and also with the patterns reported by Sayari et al. (17) and Oberhagemann et al. (14) for B-MCM-41 and that of Kresge et al. (2) for Al-MCM-41. One major peak, at $2\theta = 2.0°$, along with three peaks at $2\theta = 3.7°$, 4.2°, and 6.0° are observed for all the five samples. Beck et al. (3) indexed these peaks for a hexagonal unit cell. The unit cell parameter (a_o) and d_{100} spacing are given in Table 1. Thus, it is observed that the a_o and d_{100} spacing decrease with an increase of the boron content of the synthesized samples (B-4 to B-1). Further, the decrease in the a_o and d_{100} spacings of B-MCM-41, as compared with its pure silica analogue, is evidence for the boron in the sili-

Table 1. The unit cell parameter (a_o), d_{100} spacing, pore diameter, and pore volume of M-MCM-41 samples (M = B, Al, and Si).

Sample	d_{100} spacing (Å)	a_o (Å)	Pore diameter (Å)	Pore volume ($cm^3\ g^{-1}$)
B–1	40.5	46.7	29.2	1.02
B–2	42.3	48.8	30.3	1.16
B–3	43.8	50.6	31.0	1.06
B-4	44.7	51.6	31.6	0.92
Si-MCM-41	45.9	53.0	31.9	1.08
A-1	48.5	56.0	32.7	1.15

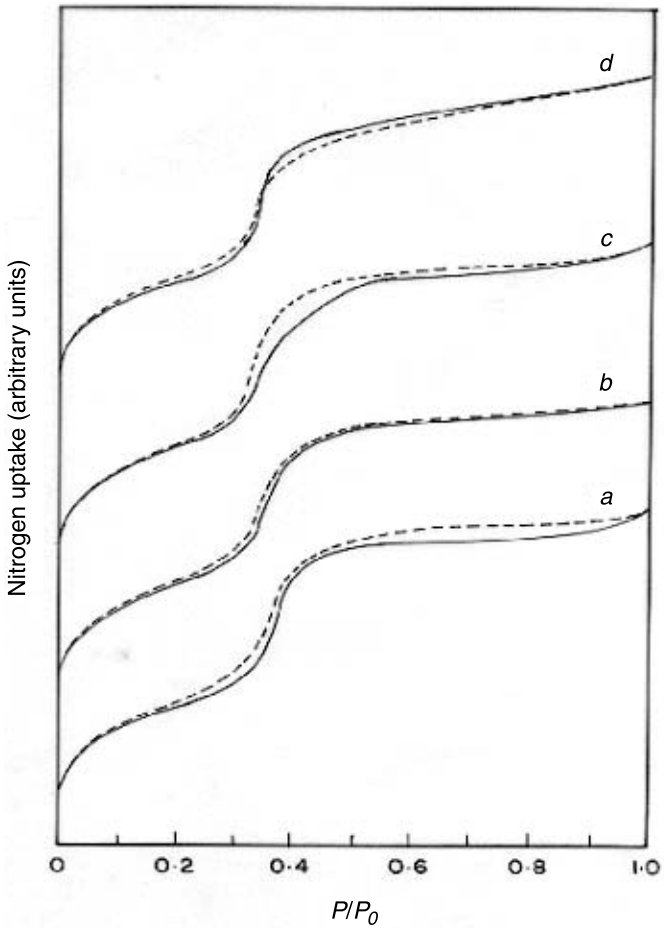

Fig. 2. X-ray diffraction patterns of the (*a*) synthesized, (*b*) calcinated Na-form, and (*c*) H-form of B-1.

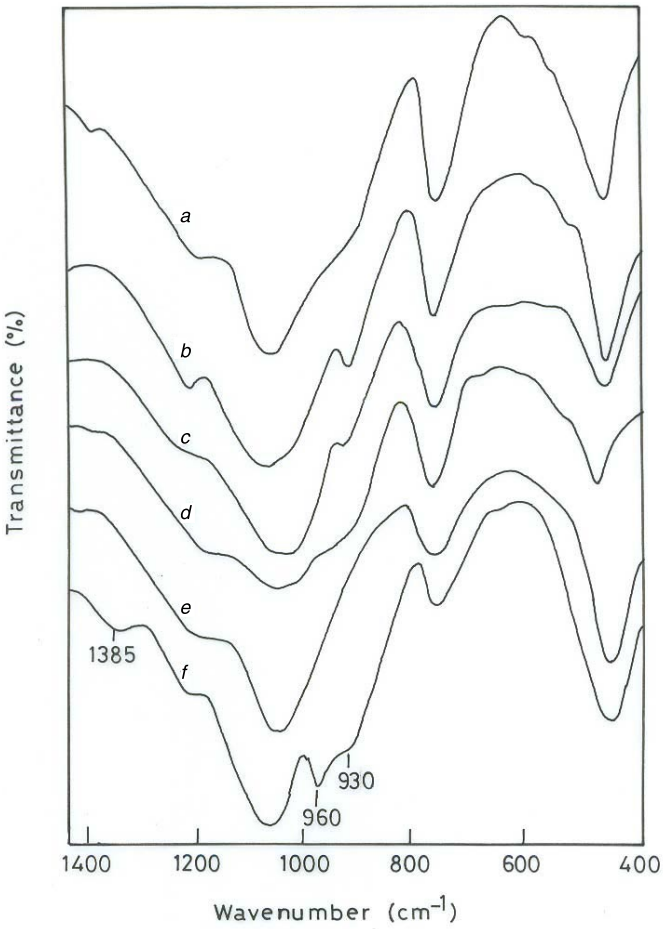
cate framework. This is akin to the observation of Liu et al. (19) in their B-MCM-41 study, where a decrease in the d_{100} value with an increase of the boron content was observed. The increasing *d* spacing for the Al-MCM-41, compared, on similar lines, with Si-MCM-41, indicated that Al was incorporated into the framework.

The stability of the MCM-41 structure after removal of the template and conversion into the protonated form has also been studied using XRD. The X-ray diffraction patterns of the synthesized, calcinated, and protonated forms of a typical sample B-1 are shown in Fig. 2. On calcination (to remove the template), the peak at $2\theta = 2°$ becomes weaker and broader than that of the synthesized sample. On further conversion to the ammonium form and then to the hydrogen form, the intensity of the peak decreases slightly, and the peak becomes significantly broader than that of the calcinated form. The observed changes are attributed to the increasing formation of nonstructural B and the accompanying collapse of a portion of the borosilicate framework.

Fig. 3. N_2 isotherms of B-MCM-41 samples: (*a*) B-1; (*b*) B-2; (*c*) B-3; (*d*) B-4; (——) adsorption; (- - - -) desorption.



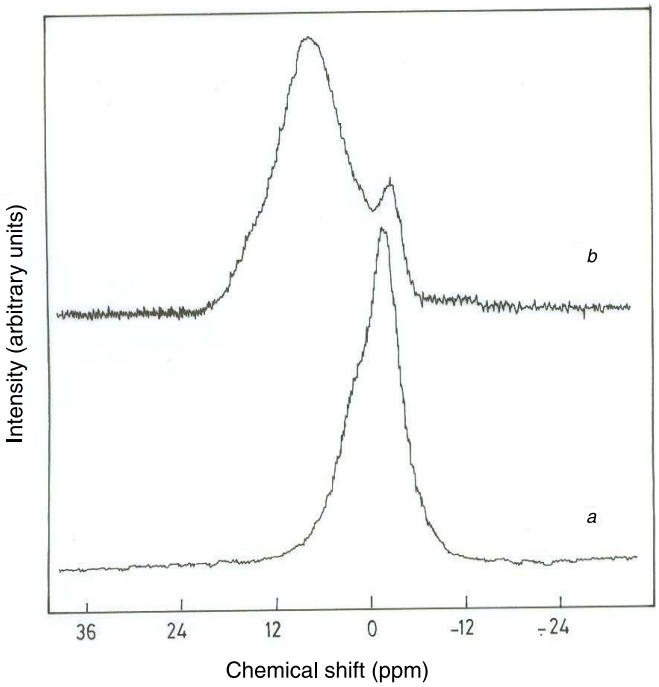
Samples B-1, B-2, B-3, B-4, and A-1 have a specific surface area of 920, 905, 935, 940, and 950 $m^2\ g^{-1}$, respectively, and exhibit type IV N_2 adsorption isotherms with the characteristic step at $P/P_0 = 0.4$ (Fig. 3). This further confirms the mesoporous nature of the samples (45, 46). The average pore diameters and specific pore volume for the B-MCM-41 samples are presented in Table 1. The average pore diameters decrease slightly with increasing B content of the sample. This may be because of the nature of the synthesis mixture, perhaps a salt effect.

Infrared spectroscopy of B-MCM-41

The IR spectra of the synthesized B-1, B-2, B-3, and B-4 samples exhibit a series of bands in the 1600–250 cm^{-1} region, which are characteristic of the SiO_2 tetrahedron unit and its modification by the introduction of boron into the framework (Fig. 4). The location of boron in the synthesized samples B-1 to B-4 is confirmed from the presence of an IR band at 930 cm^{-1}, which is characteristic of tetracoordinated boron in the MCM-41 framework (15). The intensity of this peak decreases as we go along from curves *b* to *e* in Fig. 4, and their decreasing trend is attributed to a decrease of boron content in the framework. The IR spectra of the Na-form and H-form of the typical sample B-1 are also shown in Fig. 4. The sample in its Na-form and dehydrated

© 2004 NRC Canada

Fig. 4. FT-IR spectra of the synthesized Al-MCM-41 and B-MCM-41 samples: (*a*) A-1; (*b*) B-1; (*c*) B-2; (*d*) B-3; (*e*) B-4; (*f*) H-form of B-1.



H-form exhibits weak bands at 930 and 1385 cm^{-1}, respectively, which are characteristic of tetra-coordinated boron and tri-coordinated boron in the MCM-41 framework, respectively (15). The fall in the IR band at 930 cm^{-1} and the appearance of a band at 1385 cm^{-1}, observed on the conversion of the Na-form of the sample to the H-form, show that, during the conversion, tetra-coordinated boron is converted to tri-coordinated boron. This observation was reported for both microporous (47, 48) and mesoporous borosilicates (15). This study shows that the tetra-coordinated boron is stable when sodium is counterbalancing the framework negative charge but unstable in the hydrogen form. The stability of these sites is caused by the formation of Na^+–$B(OSi)_4^-$ units, which are coordinatively saturated and stable to hydrolysis (49). The H-forms of the B-MCM-41 samples also exhibit a new band at 960 cm^{-1}. Sayari et al. (13) and Ruiter et al. (49) assigned this band to the Si–OH groups in the silanol nests.

^{11}B-MAS NMR spectroscopy

Boron-11 MAS NMR spectra of a typical B-1 sample are shown in Fig. 5. The synthesized sample has one signal at −2.3 ppm. A similar signal was reported earlier in studies dealing with boron-modified MCM-41 and is assigned to B

Fig. 5. ^{11}B-MAS NMR spectra of B-1: (*a*) synthesized; (*b*) H-form.

in the framework tetrahedral coordination (17–20). The ^{11}B-MAS NMR spectrum of dehydrated, protonated B-MCM-41 reveals that most of the tetrahedral-coordinated boron has undergone a change in coordination. In addition to a small signal at –2.3 ppm, a very broad signal appears, which is typical for trigonal boron species in the MCM-41 framework (17–20). The FT-IR studies also support these findings.

Scanning electron microscopy

Figure 6 represents the set of scanning electron micrographs of the B-MCM-41 samples. All B-MCM-41 samples have spherical particles. The size of these spheres is in the 500–1000 nm range. Small particles with size 100–300 nm with no distinct morphology also coexist with the spheres in all the samples. Among the samples, the change in morphology is small, and that change is only in size and not in the shape of the spheres.

Chemical composition

The molar compositions of the synthesized samples are shown in Table 2. The number of moles of Na_2O is lower than that of B_2O_3, suggesting that not only Na^+ ions but also cetyltrimethylammonium cations are involved in neutralizing the negative charges of the framework. Chemical analysis shows that boron is released from the MCM-41 framework during (*i*) thermal decomposition of the template and (*ii*) thermal conversion of the NH_4 form to the H-form.

In each of the above-mentioned processes, the released boron was found to come out as H_3BO_3 and to stay as the extra framework material and was extracted out of the channels by washing with distilled water at room temperature. The SiO_2:B_2O_3 ratio of the washed samples was analyzed by

chemical analysis. The extent of boron released is expressed in terms of % deboronation (β) and is given in Table 2.

$$\beta = (1 - n_{syn}/n) \times 100$$

where n_{syn} and n denote the molar SiO_2:B_2O_3 ratio of the synthesized B-MCM-41 and that of the modified B-MCM-41, respectively. Table 2 shows that the deboronation level (β) decreases with an increase of the SiO_2:B_2O_3 ratio in the samples. This leads to the conclusion that the more boron is found in the MCM-41 framework, the weaker it is bound, and it is more likely that it is released during heat treatment.

FT-IR spectra of chemisorbed pyridine

Figure 7 depicts the FT-IR spectra of pyridine adsorbed on a B-1 sample in the region 1600–1400 cm^{-1}. The sample exhibits IR bands at 1595, 1545, and 1445 cm^{-1}. The bands at 1595 and 1445 cm^{-1} are characteristic of physisorbed pyridine and hydrogen-bonded pyridine, respectively (15). The weak band at 1545 cm^{-1} is characteristic of Brønsted acid sites (15). The thermal stability of pyridine sorbed on the catalyst was measured by increasing the desorption temperature from 100 to 250 °C. These bands are decreased sharply upon evacuation at elevated temperatures and disappear at 250 °C. This shows that B-MCM-41 possesses only weak and mild acid sites.

TPDA of B-MCM-41 and Al-MCM-41

TPDA spectra of Al-MCM-41 and B-MCM-41 samples are shown in Fig. 8. The TPDA spectra of Al-MCM-41 exhibit three maxima, viz. at ca. 167, 340, and 500 °C. The low-temperature peak is caused by desorption of ammonia from weak Brønsted and Lewis acid sites (50). The weak Brønsted acid sites appear as a result of surface hydroxyl groups, whereas the structural weak Lewis acid sites may arise from tricoordinated metal ion in the framework (51). The medium-temperature peak at 340 °C is assigned to weak- to medium-acidic Brønsted sites. Such sites are well known from medium-pore zeolites (52) and have been detected in substituted MCM-48 (53). The high-temperature signal is caused by ammonia desorbed from strong Lewis

acid sites (53). The concentration of strong Lewis sites points to the dispersion of the extra framework aluminum species in the channels of MCM-41.

The major deviations observed in the TPD spectra on isomorphous substitution of B for Al are the absence of medium- and high-temperature signals and the presence of only low-temperature signals corresponding to weak Lewis and Brønsted acid sites. This study shows that boron substitution in the MCM-41 framework results in only weak acid sites like those of B-ZSM-5 samples (54, 55).

Catalytic studies

Isomerization of 1-hexene was carried out in the temperature range 200–350 °C and at a liquid hourly space velocity

Fig. 9. 1-Hexene conversion (wt %) at different temperatures, LHSV = 3 h^{-1}: (●) B-1; (■) B-2; (△) B-3; (○) B-4; (□) A-1.

(LHSV) of 3 h^{-1} over the H-form of catalysts B-1 to B-4 and A-1, all of which were activated at 500 °C. LHSV is the ratio of the weight of the liquid feed per hour (g h^{-1}) and the weight of the catalyst (g). The conversion of 1-hexene at different temperatures is presented in Fig. 9. At any given temperature, a decreasing trend of isomerization was observed with increasing SiO_2:B_2O_3 ratio of the catalyst, viz. 91%, 81.5%, 74.6%, and 64.7% conversions were obtained over catalysts B-1, B-2, B-3, and B-4, respectively, at 300 °C. The decrease in conversion is attributed to the decrease in the number of acid sites present in the catalyst as the SiO_2:B_2O_3 ratio increases. At all temperatures, higher conversion was obtained over the A-1 catalyst than over boron-substituted catalysts because of the presence of strong Brønsted acidic sites associated with the presence of Al^{3+}. As the temperature increased from 200 °C, the conversion of 1-hexene was found to increase for all the catalysts, and a maximum conversion (93%) of 1-hexene over the A-1 catalyst was observed at 300 °C, whereas for the B-1, B-2, B-3, and B-4 catalysts, the maximum conversions of 91%, 90%, 85.2%, and 80.5% were observed at 350 °C. Si-MCM-41 was also tested under similar conditions and was found to have no catalytic activity in the temperature range 200–350 °C.

Table 3 shows the product selectivity of 1-hexene isomerization at the following temperatures: 200, 250, 300, and 350 °C. The reaction products shown in the above-mentioned table are formed generally via double-bond shift, *cis–trans* isomerization, and skeletal rearrangement. The major isomerization products *trans*-2-hexene (t-2H), *cis*-2-hexene (c-2H), and (*cis*+*trans*)-3-hexene ((c+t)-3H) are formed by a 1–2 double-bond shift. For instance, at 300 °C *trans*-2-hexene, *cis*-2-hexene, and (*cis*+*trans*)-3-hexene constitute 95.9% of the total, from 88% conversion on B-1. This is comparable to the 94.75% double-bond shift at 54% conversion reported by Ko and Wojciechowski (38) on an HY catalyst at 200 °C and to that of 95% on ZSM-5 at 52% conversion reported by Abbot et al. (39) at 280 °C.

The increase of temperature from 200 to 350 °C shows a decrease in the selectivity of 2-hexene with a simultaneous increase in selectivity of 3-hexene. However, between the 2-hexenes, the selectivity of *trans*-2-hexene is not affected as

Note: t-2H, *trans*-2-hexene; c-2H, *cis*-2-hexene; (c+t)-3H, (*cis*+*trans*)-3-hexene; 2M2P, 2-methyl-2-pentene; 3M2P, 3-methyl-2-pentene; 4M2P, 4-methyl-2-pentene; 2M1P, 2-methyl-1-pentene; 3M1P, 3-methyl-1-pentene.

much by temperature as that of *cis*-2-hexene. Over the A-1 catalyst, the selectivities of both t-2H and c-2H are affected similarly by a raise in temperature. Similarly, at any fixed temperature studied, an increase of boron content in the catalyst increases the selectivity of 3-hexenes and decreases that of 2-hexenes.

Skeletal isomerization products in considerable quantity are found to form on the A-1 catalyst as secondary products from 250 °C onwards, and they increase with an increase in temperature. They are 2-methyl-2-pentene (2M2P), 3-methyl-2-pentene (3M2P), 4-methyl-2-pentene (4M2P), 2-methyl-1-pentene (2M1P), and 3-methyl-1-pentene (3M1P). Among them, 2M2P and 3M2P are the major ones. At 250 °C and above, only small amounts of 2M2P and 3M2P are formed with each of the boron catalysts, as compared to the aluminum catalyst. For example, at 300 °C, the maximum skeletal isomerization product formed over B-1 amounts to 4.0% compared to 21.5% over A-1. Similarly, at any fixed temperature studied, selectivity of the skeletal isomerization products was found to increase with an increase of the boron content of the catalysts.

The mechanism of the reported double-bond shift (30) involves interaction of 1-hexene with the acid sites of the catalysts, leading to the formation of the C_6 carbenium ion. The carbenium ion can undergo deprotonation, hydrogen shift, cyclization, or oligomerization. The formation of 2-hexene is attributed to deprotonation and that of 3-hexene to a hydrogen shift. The large difference in the selectivity of 2-hexenes from that of 3-hexenes suggests that the rate of deprotonation from the carbenium ion is much faster than that of the hydrogen transfer from the C_6 carbenium ion. Skeletal isomerization products are formed by a sequence of hydrogen and methyl shifts. These are energy-demanding steps and, hence, register low selectivity over boron-substituted catalysts compared with the aluminum-substituted catalyst.

Ratios of selectivity of double-bond shift products of hexene (c-2H:t-2H and (c+t)-2H:(c+t)-3H) at four different temperatures over all the catalysts are shown in Table 4. The thermodynamic equilibrium ratios 0.39, 0.44, and 0.44 have been reported by Abbot et al. (39) for c-2H to t-2H at 200, 250, and 280 °C, respectively. Any different ratio of c-2H to t-2H than the above-mentioned ones is a clear indication that the reaction is kinetically controlled. Thus, ratios in Table 4 show that the reaction is kinetically controlled, with higher relative rates of production of *cis* isomers at all temperatures. Similar preferential formation of *cis* isomers has been reported by Abbot and Wojciechowski (40) over ZSM-5 and by Ko and Wojciechowski (38) over HY catalysts. We also observed and reported a similar result over B-ZSM-5 catalysts (26). The excess of the *cis* isomer with respect to the *cis*:*trans* equilibrium ratio is attributed to (*i*) steric effects on the C_6 carbenium ion leading to its preferential formation of c-2H (45) and (*ii*) the formation of a more stable intermediate π complex between the *cis* isomer and the proton on the Brønsted sites (38).

It is apparent from Table 4 that the c-2H:t-2H ratio decreases with an increase of temperature with all the catalysts. Similar results have been reported over the ZSM-5 catalyst (39). We have already reported the 1-hexene isomerization on B-ZSM-5 catalysts (26). The c-2H:t-2H ratio obtained with the B-ZSM-5 samples (26) is significantly lower than with the B-MCM-41 samples under similar conditions. This is probably a result of different pore structures and dimensions in the two molecular sieves. The elliptical channels in B-ZSM-5 have diameters (5 to 6 Å) in a range approaching the kinetic diameters of straight-chain olefins (4.3 Å). This property has led to a wide interest in the reactions (which are said to control shape selectivity) of hydrocarbons in this microporous molecular sieve. The reason for *cis*:*trans* ratios closer to equilibrium in B-ZSM-5 is associated with the initial spatial requirements of the transition state followed by equilibration encouraged by diffusional limitations. There is a high probability that a particular 2-hexene molecule, once formed, will undergo repeated collision with the channel walls before escaping from ZSM-5 channels. The above-mentioned equilibration is absent in B-MCM-41 because of the *meso* pore size, and it shows higher c-2H:t-2H ratios in relation to those of the B-ZSM-5 catalysts.

From the percentage of selectivity of c-2H, t-2H, and (c+t)-3H, values of the 2-hexenes:3-hexenes ratio, (c+t)-2H:(c+t)-3H, have been calculated and are presented in Table 4. At all temperatures, as the SiO_2:B_2O_3 ratio of catalysts

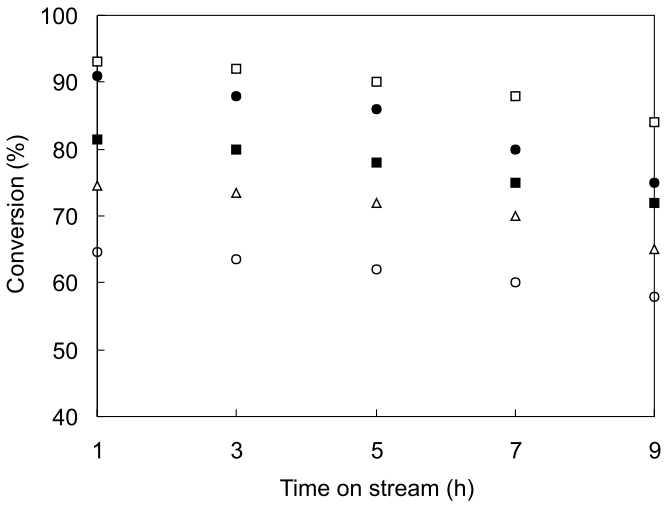
B-ZSM-5[a]	0.62	0.42	0.41	0.34	12.3	7.6	4.6	3.8
B-ZSM-5[b]	0.64	0.44	0.44	0.37	15.6	10.7	7.2	4.7



[a] SiO_2:B_2O_3 ratio = 180.
[b] SiO_2:B_2O_3 ratio = 350 (from ref. 26).

decreases, the (c+t)-2H:(c+t)-3H ratio decreases. This is ascribed to the increase in the number of acid sites of the catalyst with an increase of boron content in the framework, which in turn increases the rate of hydrogen shift from the 3- to the 2-carbon and enhances the formation of 3-hexene. Similarly, an increase of temperature from 200 to 350 °C increases the rate of hydrogen shift to form 3-hexene. A similar observation was also reported (39) over the ZSM-5 catalyst in the 1-hexene isomerization with an increase of reaction temperature.

The conversions of 1-hexene vs. time on stream over all the catalysts at 300 °C are shown in Fig. 10. The conversion of 1-hexene decreases steadily over all the catalysts with increasing time on stream, though the actual decrease is different for different catalysts. This is mainly because catalysts lose their activity steadily with time on stream. The activity loss is attributed to coke formation, which increases with time on stream, thereby poisoning the active acidic sites. The wt % coke formed is 7.4%, 6.9%, 6.6%, 6.1%, and 4.0% on the B-1, B-2, B-3, B-4, and A-1 catalysts, respectively, at the end of 9 h at 300 °C. It was observed that an increase of boron content in the framework slightly increases the coking and aging during time on stream. The amount of coke accumulation on boron-containing catalysts is greater than that on the corresponding aluminum-containing catalyst. Cornaro and Wojciechowski (30) also observed a greater amount of coke accumulation over the B-ZSM-5 catalyst than the Al-ZSM-5 catalyst in the 1-hexene isomerization. The difference in the coke content is a result of the difference in the acidity of the catalysts. Al-MCM-41 can crack off the precoke oligomer in the process of coke hardening because of the presence of a greater number of strong acidic sites, thus resulting in a lesser amount of coke. The boron catalysts, which have a mild acidity, are apparently not able to crack the precoke (26, 30) and, hence, accumulate a greater amount of coke.

FT-IR spectra of coke-deposited catalysts show the prominent IR band in the C-H deformation region around 1600 cm^{-1} (this figure is not shown). Eberly (56) ascribed this band to highly unsaturated carbonaceous residues, most likely adsorbed olefins. Abbot et al. (39) also observed the presence of mainly adsorbed olefins in the coke deposit on the ZSM-5 catalyst in the 1-hexene isomerization in the temperature range 200–350 °C. A TGA study of the coke formed on catalysts shows the formation of only soft coke molecules (TGA weight loss occurs between 300 and 500 °C) on the B-MCM-41 and the Al-MCM-41 catalysts in the above-mentioned reaction temperature range.

Fig. 10. Effect of time on stream on 1-hexene conversion at 300 °C, LHSV = 3 h^{-1}: (●) B-1; (■) B-2; (△) B-3; (○) B-4; (□) A-1.

Conclusion

The B-MCM-41 samples, with differing amounts of boron in the framework, were synthesized by a hydrothermal method using ES-40. Evidence for the presence of B in the silica network of MCM-41 was obtained by different characterization techniques. In the synthesized samples, boron was present in the four-coordinated state. Calcination and further conversion into the H-form converted a significant part of the boron into a three-coordinated state. The % deboronation of B-MCM-41 was found to be dependent on the concentration of boron in the silicate framework. Investigation of the acidity of B-MCM-41 revealed that the materials have only a weak acidity and a lower acidity than that of Al-MCM-41. The catalytic effect of framework boron, explored by means of 1-hexene isomerization, reveals that the extent of 1-hexene conversion changes with boron content and, hence, the acidity of the catalysts. The isomorphous substitution of B for Al in the MCM-41 framework changes both the conversion of 1-hexene and the selectivity of the products. The selectivity of the double-bond shift products is enhanced with the substitution of B for Al in the MCM-41 framework.

Experimental and computational investigation of the electrocatalytic hydrogenation of phenol in an electrochemical cell

A. Chagnes, F. Laplante, F. Kerdouss, P. Proulx, and H. Ménard

Abstract: The electrocatalytic hydrogenation (ECH) of phenol was carried out in aqueous media with a commercial Pd/Al_2O_3 (5% w/w) catalyst. A porous matrix of reticulated vitreous carbon (RVC) was used to study the porosity – stirring speed coupling (PSSC) effect on the phenol hydrogenation to form cyclohexanone and cyclohexanol. In accordance with the PSSC, the electrode can act as a fluidized bed electrode or as an agglomerated electrode. Fluidized bed electrodes develop for low porosity matrices (10–30 ppi, ppi = pores per inch) at high stirring speeds (>600 rpm), while agglomerated electrodes are obtained for high porosity matrices (60–100 ppi) with moderate stirring speeds under cathodic polarization. The distribution of the volume fraction of the particles and the agglomeration of the particles have been simulated by computational fluid dynamic (CFD) methods with FLUENT software. For the agglomerated electrode, the numerical simulations demonstrate the beneficial contribution of the cathodic polarization to the agglomeration process. However, at 650 rpm, for the fluidized bed electrode, the volume fraction of the particles in the RVC does not account for the distinction in the ECH efficiency between the 30 ppi matrix and the 100 ppi matrix. For a given amount of Pd/Al_2O_3 catalyst, it is observed that the ECH rates depend on the PSSC and increase in the following order: 100/650 < 30/650 < 100/200.

Key words: electrocatalytic hydrogenation (ECH), CFD, fluid mechanics, porous media, powder, porosity – stirring speed coupling (PSSC), reticulated vitreous carbon (RVC).

Résumé : On a effectué l'hydrogénation électrocatalytique (HEC) du phénol en milieu aqueux, à l'aide d'un catalyseur commercial de Pd/Al_2O_3 (5% p/p). Afin d'étudier l'effet de couplage de la vitesse d'agitation et de la porosité (CVAP) sur l'hydrogénation du phénol avec formation de cyclohexanone et de cyclohexanol, on a utilisé une matrice de charbon vitreux réticulé (CVR). Suivant le CVAP, l'électrode peut agir comme électrode à lit fluidisé ou comme électrode agglomérée. Les électrodes à lit fluidisé se développent avec des matrices de faibles porosités (10–30 ppi, ppi = pores per inch), à des vitesses élevées (>600 rpm) alors que les électrodes agglomérées sont obtenues avec des matrices de porosité élevée (60–100 ppi) et des vitesses d'agitation modérées, sous une polarisation cathodique. La distribution de la fraction volumique des particules et l'agglomération des particules ont été simulées par les méthodes de calculs dynamiques des fluides (CDF) à l'aide du logiciel FLUENT. Pour l'électrode agglomérée, les simulations numériques permettent de mettre en évidence la contribution bénéfique de la polarisation cathodique du processus d'agglomération. Toutefois, à 650 rpm, pour l'électrode à lit fluidisé, la fraction volumique des particules dans le CVR ne permet pas d'expliquer la distinction dans l'efficacité de l'HEC entre la matrice à 30 ppi et la matrice à 100 ppi. Pour une quantité donnée de catalyseur Pd/Al_2O_3, on a observé que les vitesses d'HEC dépendent du CVAP et qu'elles augmentent dans l'ordre 100/650 < 30/650 < 100/200.

Mots clés : hydrogénation électrocatalytique (HEC), CDF, mécanique des fluides, milieu poreux, poudre, couplage de la vitesse d'agitation et de la porosité (CVAP), carbone vitreux réticulé (CVR).

Introduction

The electrocatalytic hydrogenation (ECH) of phenol is a relevant electrochemical process used to produce cyclohexanone and cyclohexanol from phenol (1–3). The products can be used to produce solvents for varnishes, resins, dyes, or to produce "KA oil", a precursor of adipic acid (4). Computational simulation is an interesting tool to optimize the electrochemical cell design and the electrocatalytic hydrogenation conditions. To enhance the conversion rate of cyclohexanol obtained from hydrogenation of phenol, several studies have focused on the concept of optimized new cata-

lysts (5–7). ECH is another way to hydrogenate organic compounds with high efficiency. The more convenient approach is to carry out the hydrogenation process using electricity to generate in situ atomic hydrogen at room temperature and under normal pressure.

It is well established in the literature (8, 9) that the generation of atomic hydrogen (H_{ads}) and molecular hydrogen (H_2) on metal (M) in solutions can proceed through any of the following reactions:

[1] $H_2O + M + e^- \leftrightarrows MH_{ads} + OH^-$ (Volmer reaction)

[2] $H_2O + MH_{ads} + e^- \leftrightarrows M + H_2 + OH^-$ (Heyrovsky reaction)

[3] $2MH_{ads} \leftrightarrows 2M + H_2$ (Tafel reaction)

The efficiency of the electrocatalytic hydrogenation of phenol is determined by the preceding reactions, the adsorption and desorption power of the substrate toward the organic molecules, and other properties as well as the nature of the electrode, the current density, the pH, the solvent composition (6). Heyrovsky and Tafel reactions are competive reactions for the hydrogenation of organic compounds.

Recent developments in the preparation of catalytic electrode materials having high efficiency and long term stability have raised new interest in electrocatalytic hydrogenation (6, 7, 10–12). There are several methods to produce composite materials with a metallic matrix: powder metallurgy (13), metal plasma spraying (14), chemical and physical vapour deposition (15), liquid metal forging (15), and electrocodeposition (16).

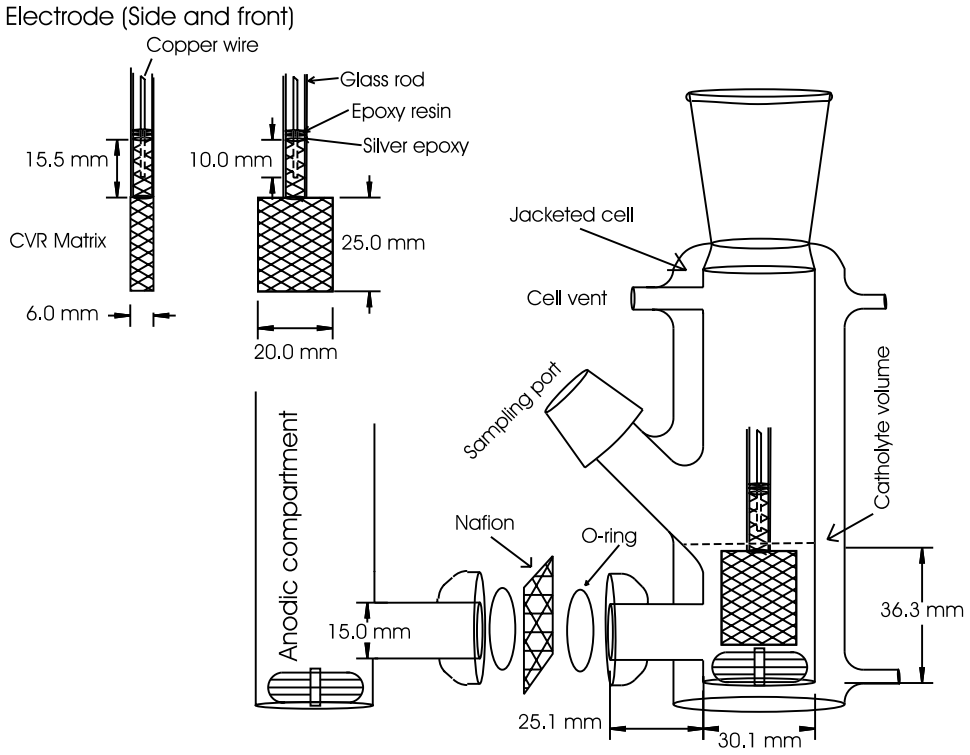
In this paper, the effect of the porosity of the RVC foam vs. the stirring speed on the efficiency of commercial Pd/Al_2O3 5% catalysts for the hydrogenation of phenol was investigated. The experimental results were compared with a computer simulation of the hydrodynamic behaviour of catalyst particles for a RVC matrix of various porosity in the electrochemical cell described in a previous paper (17).

Experimental

The electrodes

The electrochemical cell used in this paper has been previously described (17) and is shown in Fig. 1. The electrode was made from the entrapment of catalytic powder particles in a piece of reticulated vitreous carbon (RVC) matrix. The RVC matrix was a piece of foam (25 mm × 20 mm × 6 mm, 30 pores per inch (ppi) or 100 ppi, Electrosynthesis Co.). The conducting matrix was mounted by inserting a glass rod (OD 5 ~ 6 mm, ID 3.5 mm) in the horizontal axis of a piece of RVC (20 mm × 40 mm × 6 mm). The excess RVC was then removed and a copper wire was inserted into the RVC to be further cemented with silver epoxy (Epoxy Technology). Finally, the electrical contact zone on the RVC matrix was glued to the glass rod with epoxy to isolate the electrical contact from the electroactive part of the electrode. The use of a nickel strip as a contact with the RVC electrode should be avoided because the nickel activity towards the electrocatalytic hydrogenation of ketone may affect the data (18).

The physical entrapment of the composite material in the RVC foam occurred under moderate stirring of the catholyte (~450 rpm), and the catalyst powder particles were trapped into the RVC matrix pores spontaneously. The catalytic powder remained in the pores of the RVC electrode cathodically polarized (j = 100 mA/dm²) for the electrohydrogenation process and was in electrical contact with the matrix (17). With such an RVC, the average diameter of the particle is 12.4 μm. The entrapment process is completed within 2 h, up to a charge of 50 C. The dimensions of the H-cell and those related to the other parts are described in a previous paper (17).



Electrolysis

The electrolysis was carried out in a two-compartment jacketed glass H-cell having a Nafion-117 (E.I. Dupont de Nemours and Co.) membrane as a separator. The cell temperature was fixed at 21 °C during the electrocatalytic hydrogenation process by a circulating thermostated bath (VWR 1160A). To prevent analyte evaporation, a water-cooled condenser was added to the top of the cell. Afterwards, the cathodic compartment was filled with a phosphate buffer (29 mL, 1 mol/L KH_2PO_4 + 1 mol/L NaOH) previously adjusted to pH 7 and 200 mg of the composite powder was added to the catholyte. The electrode was built-up in situ with the previously described technique. The anodic compartment was filled with a 1 mol/L NaOH solution (Fisher); the counter-electrode was a platinum mesh. Prior to the electrocatalytic hydrogenation process, 1 mL of a phenol solution in water (25 mg/mL) was added to the catholyte giving a total volume of 30 mL and a phenol concentration of 8.8×10^{-3} mol/L. The electrocatalytic hydrogenation was performed under galvanostatic control (j = 1 mA/cm²) using EG&G PAR model 273 for 25 h (450 C at 5 mA). The commercial powder catalyst considered in the present paper (Pd/Al_2O_3, 5%) was provided by Aldrich and used as received.

During the electrocatalytic hydrogenation process (ECH), aliquots of 500 μL were withdrawn from the catholyte, saturated with NaCl, and acidified to pH 1 with HCl (conc. HCl, 10 mol/L), and then extracted with 1 mL ethyl acetate and dried under sodium sulfate. After the completion of ECH, both the RVC electrode and the whole cell were rinsed with pure water. An internal standard (ISTD, 2-cyclohexen-1-one) was added to the cell solution; further, the extraction was carried out twice (2 × 20 mL) with distilled ethyl acetate. The organic layer was dried on sodium sulfate and filtered. The filtrate was collected in a 50 mL volumetric flask containing an external standard (ESTD, 3-methylcyclohexanol). The GC analyses were carried out using a Hewlett-Packard 6890 chromatograph equipped with a FID detector on a 30 m HP-5 column. The products were identified by comparison with the retention time of the authentic compound and the mass balance was obtained from the ISTD/ESTD ratio of the corrected peak surface area. In accordance to the ISTD/ESTD ratio, a recovery percentage greater than 85% was observed.

Computer simulation

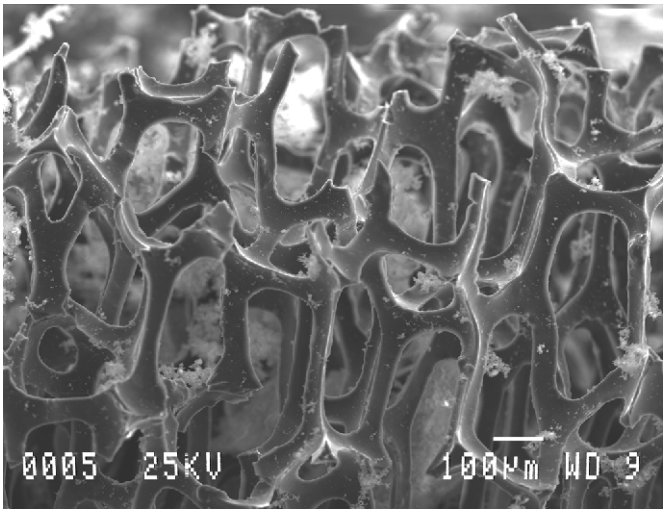
The computer simulation of the hydrodynamic behaviour of the catalyst particles in the electrochemical cell was performed by the computational fluid dynamic method (CFD). The multiphase model, described in the computation simulation section of this paper, was solved using FLUENT version 6.0.1 with nonstructured mesh adapted to the geometry. The phase-coupled SIMPLE (PC-SIMPLE) algorithm was used for the pressure–velocity coupling. A first-order upwind discretization scheme was used for spatial derivatives and a first-order discretisation scheme was used for temporal derivatives. A time step of 10^{-4} s was used initially and augmented progressively to 10^{-2} s. A description of the mathematical techniques used in FLUENT is detailed in the computation simulation section of this paper.

Results and discussion

Electrochemical efficiency

During the electrohydrogenation of phenol, the chemisorbed hydrogen (MH_{ads} in eq. [1]) is generated in situ by electroreduction of water and reacts with the absorbed phenol substrate according to the following steps reported in the literature (19):

[4] 



The electrochemical efficiency of the catalyst particles (Pd/Al_2O_3, 5% w/w) was investigated with an electrochemical cell described in a previous paper (17) (Fig. 1). Our work demonstrates that the stirring speed and the matrix porosity affect considerably the ECH process. According to the porosity – stirring speed coupling (PSSC–ppi/rpm), we determined that the RVC matrix can act as an agglomerated electrode or a fluidized bed electrode. First, for the high porosity electrode with moderate stirring, the electrode behaves as an agglomerated electrode, suggesting that the catalyst is entirely trapped inside the RVC pores and remains in electrical contact with the RVC matrix during the HEC process. With the high porosity matrix (60–100 ppi), the agglomeration must be complete prior to the ECH otherwise the hydrogenation of phenol is impossible (Fig. 2).

The second kind of electrode is inspired by fluidized bed systems. Fluidized bed systems are observed only with the low porosity matrix (between 30 and 10 ppi) at high stirring speeds (>600 rpm). With this type of porosity – stirring speed couple, there is no agglomeration of the catalyst powder in the matrix. For a PSSC of 30/650, the powder is free to circulate through the matrix and to establish brief electrical contacts with the RVC conductor. In such a way, the catalyst particles are charged with hydrogen and free to react with the phenol in solution.

The effects of the stirring speed (200 and 650 rpm) on the RVC porosity (30 and 100 ppi) on the electrocatalytic hydrogenation of phenol are displayed in Fig. 3. In accordance with the PSSC used, the ECH efficiency varies significantly. To study the electrohydrogenation efficiency at 200 rpm with the agglomerated electrodes, a new protocol was used: the particles were forced to agglomerate inside the electrode at 450 rpm during a charge of 50 C (I_{app} = 5 mA). When phenol was added, the stirring speed was lowered to 200 rpm and the electrocatalytic hydrogenation was studied. Results

Fig. 2. SEM picture of catalyst particles trapped in the porous RVC electrode (100 ppi).

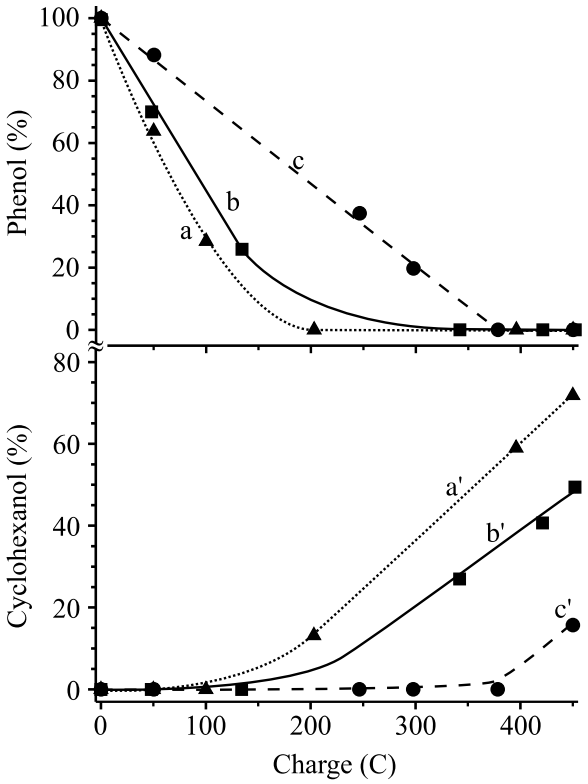
obtained at 200 rpm with a porosity of 100 ppi (Fig. 3, curves a and a′) show improvement as compared with results obtained with a stirring speed of 650 rpm (Fig. 3, curves c and c′). The enhanced efficiency recorded at 200 rpm for the cyclohexanol production can be explained by the conservation of electrode integrity, which remains agglomerated during the entire process. Above 600 rpm, the agglomerated catalyst powder is washed out from the RVC matrix and the reagglomeration becomes impossible due to the turbulence of the fluid in the cell.

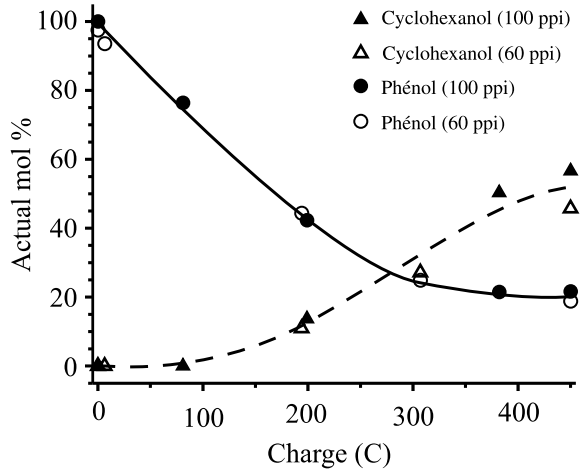
The PSSC of 30/650 (Fig. 3, curves b and b′) represents an alternate way to achieve HEC with non-agglomerating catalysts. The high void volume of the RVC foam permits the catalyst to penetrate into the RVC and to achieve brief electrical contacts with the matrix. These intermittent contacts cover the catalyst with electrosorbed hydrogen. The low porosity matrix should be employed at high stirring speed (>600 rpm) to optimize the uniformity of the distribution of the catalytic powder in the matrix.

In the preceding experiments, the hydrogenation was performed with convection. To investigate the impact of diffusion on the electrocatalytic hydrogenation, the stirring was stopped after trapping the particles into the RVC electrode, and the formation of cyclohexanol was studied during the electrolysis for different matrix porosities (between 60 and 100 ppi) (Fig. 4). Hydrogenation occurs with lower efficiencies but the porosity of the electrode does not influence the electrocatalytic hydrogenation in the absence of convective flow.

The optimal conditions for the ECH of phenol in the electrochemical cell can be deduced from Fig. 5, which shows the reaction map of the experimental results concerning the effect of the PSSC on the conversion efficiency. The electrocatalytic hydrogenation is quite dependent on the stirring and the porosity. The agglomerating electrodes (Fig. 5, sector A) have higher efficiency at high porosity with moderate stirring (PSSC 100/200), while the nonagglomerating electrodes (Fig. 5, sector B) reach their maximum efficiency for a PSSC of 30/650. The slight discrepancy observed between the experimental results (Fig. 4) and the graphical representation (Fig. 5) (between PSSC 60/0 and PSSC 100/0) is attributed to the smoothing process needed to plot the reaction map.

Fig. 3. Phenol depletion to cyclohexanol. Curve a and a′ (▲), 100 ppi at 200 rpm (catalyst Pd/alumina 5% previously trapped inside the RVC pores at 450 rpm); Curve b and b′ (■), 30 ppi at 650 rpm; and Curve c and c′ (●), 100 ppi at 650 rpm.





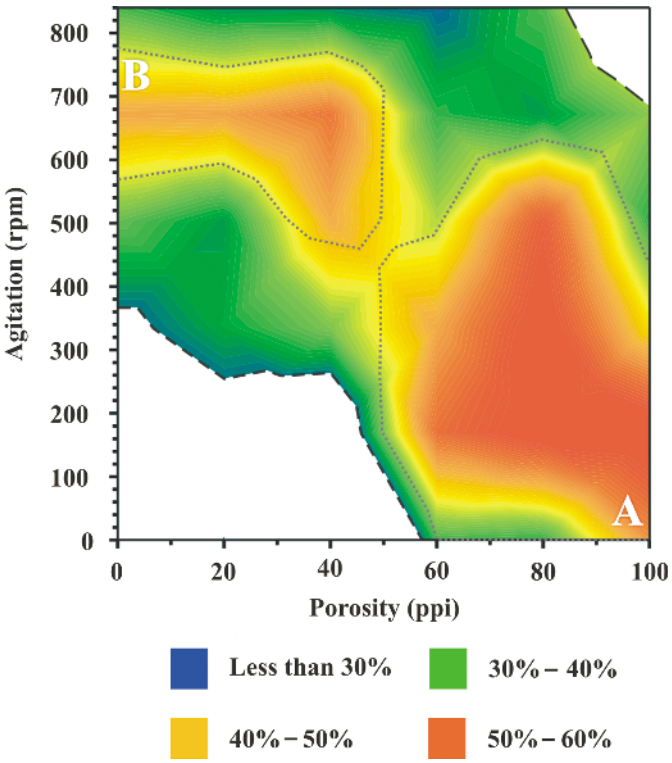


Fig. 4. Cyclohexanol yield from the ECH of phenol with Pd/alumina 5% (w/w) catalyst at 0 rpm after a complete trapping of the particles in the RVC electrode at 450 rpm.

To further investigate the roles of the porosity and the stirring on the electrohydrogenation efficiency, a CFD (computational fluid dynamic) simulation has been performed. Moreover, the CFD simulation was used to clarify the polarization effect on the agglomeration process.

CFD simulation

As previously stated, the hydrodynamic properties of the fluid in an electrochemical cell play important roles. A CFD simulation of the hydrodynamic behaviour of particles composed of alumina and palladium was realized by a CFD simulation using the commercial software package FLUENT. FLUENT uses finite volume mathematical procedures to solve the equations for fluid velocities, mass flow, pressure, temperature, species concentration, turbulence parameters, and fluid properties. Numerical techniques involve the subdivision of the domain into a finite set of neighbouring cells known as "control volumes" and applying discretized partial differential equations over each cell. This yields a large set of simultaneous algebraic equations that are highly nonlinear. These equations are in turn solved by iterative means until a converged solution is achieved.

The mathematical techniques are based on the solutions of Navier–Stokes equations for the Eulerian multiphase granular model along with the multiphase k–ε turbulence model. Multiple reference frame (MRF) and porous models are used, respectively, to account for the stirring and porous cathode in the cell.

The governing equations

The multiphase granular model was used to simulate monodispersed particles (S) in the electrolyte (L) (20). The mass conservation equation for each phase is written as

$$[5] \quad \frac{\partial}{\partial t}(\rho_q \alpha_q) + \nabla \cdot (\alpha_q \rho_q \vec{U}_q) = 0.0$$

where ρ_q, α_q, and $\vec{U}_q$ represent the density, volume fraction, and mean velocity, respectively, of phase q (L or S).

The momentum conservation equation for the liquid phase after Reynolds averaging is written as

$$[6] \quad \frac{\partial}{\partial t}(\alpha_L \rho_L \vec{U}_L) + \nabla \cdot (\alpha_L \rho_L \vec{U}_L \vec{U}_L) = -\alpha_L \nabla p + \nabla \cdot \bar{\bar{\tau}}_{\text{eff L}} + \vec{R}_{SL} + \alpha_L \rho_L \vec{g}$$

and for the dilute solid phase as

$$[7] \quad \frac{\partial}{\partial t}(\alpha_S \rho_S \vec{U}_S) + \nabla \cdot (\alpha_S \rho_S \vec{U}_S \vec{U}_S) = -\alpha_S \nabla p + \nabla p_S + \nabla \cdot \bar{\bar{\tau}}_{\text{eff S}} + \vec{R}_{LS} + \alpha_S \rho_S \vec{g} + \vec{F}_{\text{Selec}}$$

ρ is the pressure shared by the two phases, and p_s is the solid pressure modeled with the granular multiphase model (FLUENT) (19). $\vec{R}_{SL}$ represents the interfacial transfer term due to drag force. FLUENT uses a simple interaction term of the following form

$$[8] \quad \vec{R}_{SL} = -\vec{R}_{LS} = K_{SL}(\vec{U}_S - \vec{U}_L)$$

L_{SL} is the liquid–solid exchange coefficient calculated using the Syamlal–O'Brien model (21).

The external force due to the presence of an electrical field is written as

$$[9] \quad \vec{F}_{\text{Selec}} = q_s \cdot \vec{E}$$

where q_s is the solid particle charge, and $\vec{E}$ is the electrical field derived from the electrical potential (ϕ).

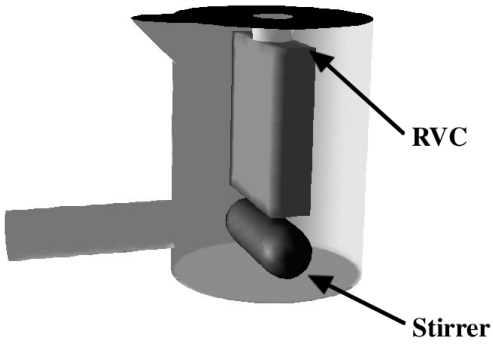
$$[10] \quad \vec{E} = -\nabla \phi$$

$\bar{\bar{\tau}}_{\text{eff L}}$ is the effective liquid phase stress–strain tensor defined as

$$[11] \quad \bar{\bar{\tau}}_{\text{eff L}} = -\frac{2}{3}\alpha_L(\rho_L k_L + (\mu_{\text{lam,L}} + \mu_{t,L})\nabla \cdot \vec{U}_L)\bar{\bar{I}} + \alpha_L(\mu_{\text{lam,L}} + \mu_{t,L})(\nabla \vec{U}_L + \nabla \vec{U}_L{}^T)$$

The liquid turbulent viscosity is written as

$$[12] \quad \mu_{t,L} = \rho_L C_\mu \frac{k_L^2}{\varepsilon_L}$$



where k_L is turbulent kinetic energy, and ε_L is the turbulent energy dissipation rate in the liquid phase. The predictions are obtained from the modified standard k–ε model

$$[13] \quad \frac{\partial}{\partial t}(\alpha_L \rho_L k_L) + \nabla \cdot (\alpha_L \rho_L \vec{U}_L k_L) = \nabla \cdot \left(\alpha_L \frac{\mu_{t,L}}{\sigma_k} \nabla k_L\right) + \alpha_L G_{k,L} - \alpha_L \rho_L \varepsilon_L + \alpha_L \rho_L \Pi_{kL}$$

$$[14] \quad \frac{\partial}{\partial t}(\alpha_L \rho_L \varepsilon_L) + \nabla \cdot (\alpha_L \rho_L \vec{U}_L \varepsilon_L) = \nabla \cdot \left(\alpha_L \frac{\mu_{t,L}}{\sigma_\varepsilon} \nabla \varepsilon_L\right) + \alpha_L \frac{\varepsilon_L}{k_L}(C_{1\varepsilon} G_{k,L} - C_{2\varepsilon} \alpha_L \rho_L \varepsilon_L) + \alpha_L \rho_L \Pi_{\varepsilon L}$$

© 2004 NRC Canada

Fig. 6. Cathodic compartment used for the CFD simulation.

C_μ, $C_{1\varepsilon}$, $C_{2\varepsilon}$, σ_k, and σ_ε are parameters of the standard k–ε model used for single-phase flows (C_μ = 0.09, $C_{1\varepsilon}$ = 1.44, $C_{2\varepsilon}$ = 1.92, σ_k = 1.0, σ_ε = 1.3). G_{KL} is the production of turbulent kinetic energy based on single-phase flow. Π_{KL} and $\Pi_{\varepsilon L}$ represent the influence of the dispersed phase S on the continuous phase L. $\bar{\bar{\tau}}_{\text{eff S}}$ is the effective liquid phase stress–strain tensor defined as

$$[15]\quad \bar{\bar{\tau}}_{\text{eff S}} = \alpha_S\left(-\frac{2}{3}\rho_S k_S + \left(\lambda_S - \frac{2}{3}(\mu_{\text{lam,S}} + \mu_{t,S})\nabla\cdot\vec{U}_S\right)\right)\bar{\bar{I}} + \alpha_S(\mu_{\text{lam,S}} + \mu_{t,S})(\nabla\vec{U}_S + \nabla\vec{U}_S^{\,T})$$

The solid stress tensor contains the shear viscosity ($\mu_{\text{lam,S}}$) and the bulk viscosity (λ_S) arising from particle momentum exchange due to translation and collision. For the expression of $\mu_{\text{lam,S}}$ and λ_S, FLUENT uses the forms from Syamlal et al. (20) and Lun et al. (22), respectively. According to Simonin (23), FLUENT provides the turbulence quantities k_S and $\mu_{t,S}$.

The porous electrode was modelled by adding a momentum sink in the governing momentum equations. This sink term is nothing more than a viscous loss term representing the simple case of homogeneous porous media written as

$$[16]\quad \vec{S}_{\text{porous}} = -\frac{\mu_q}{\alpha}\vec{U}_q$$

where μ_q is the dynamic viscosity of phase q (L or S), $\vec{U}_q$ is the time-averaged velocity of phase q, and α is the porosity of the electrode.

The solution of flows in moving reference frames induced by the magnetic rotor requires the use of moving cell zones. This cell zone motion is interpreted as the motion of a reference frame to which the cell zone is attached. In this situation, the acceleration of the coordinate system is included in the equations of motion describing the flow. In FLUENT, multiple reference frame (MRF) is used including a rotating frame of reference attached to the magnetic rotor and a stationary frame of reference attached to the rest of the cell model.

Powder entrapment with no electric field

The CFD simulation was performed without an electric field, and the distribution of the volume fraction of the particles in the porous electrode was calculated for stirring speeds of 200 and 650 rpm for a given porosity of 100 ppi. The viscosity and the density of the electrolyte (60 mL of 1 mol/L KH_2PO_4 + 35 mL of 1 mol/L NaOH) are 0.001436 kg m^{-1} s^{-1} and 1069 kg m^{-3}, respectively, at 25 °C. The cathodic compartment of the electrochemical cell, used for CFD simulation, is presented at Fig. 6.

Fig. 7. Distribution of the particles in the RVC matrix for a porosity of 100 ppi at: (*a*) 200 rpm, and (*b*) 650 rpm.

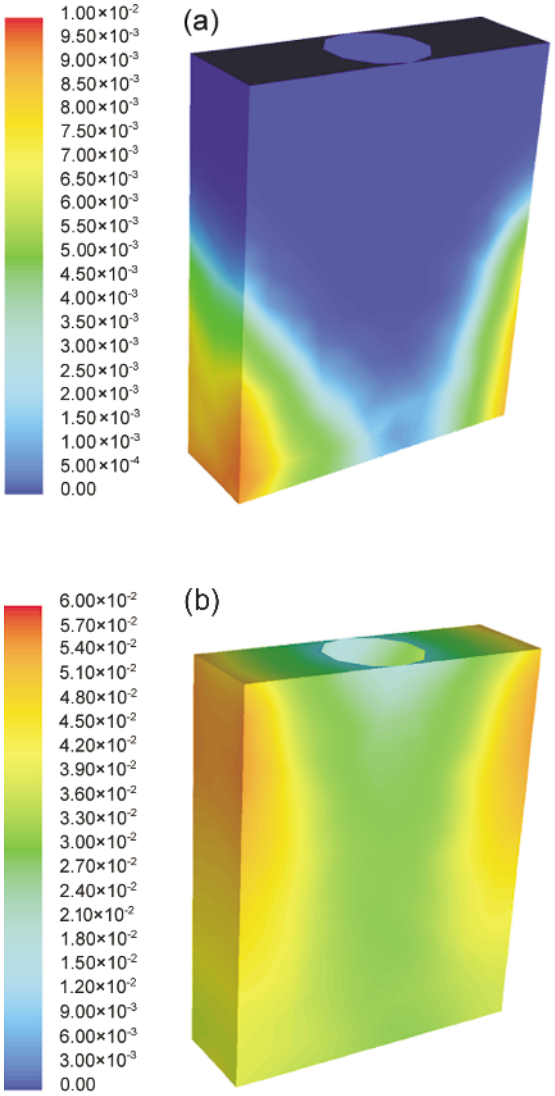


Figure 7 (A and B) displays the volume fraction of the particles for stirring speeds of 200 and 650 rpm in a RVC electrode (100 ppi). At 650 rpm, the particles are uniformly distributed in the porous electrode and the volume fraction is higher than the volume fraction at 200 rpm. The volume fraction of the particles in the RVC electrode at 200 rpm is not homogeneous. This difference of volume fraction and uniformity of the particles distribution may explain why no aggregation of particles in the porous electrode was observed at 200 rpm.

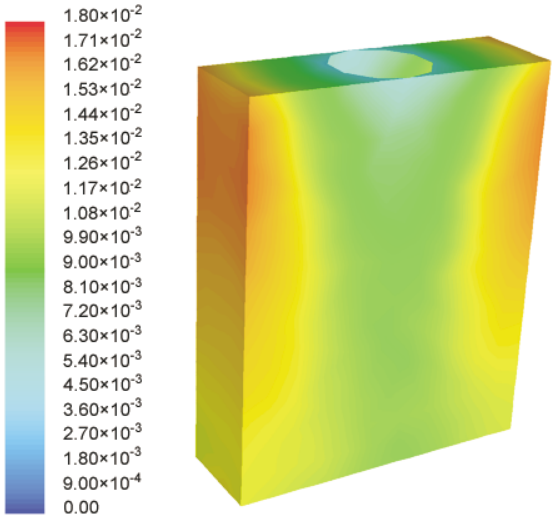
A similar study was realized at 650 rpm with a RVC porosity of 30 ppi to investigate the impact of the porosity on the distribution of the particles (Fig. 8). The porosity plays

© 2004 NRC Canada

Fig. 8. Distribution of the particles in the RVC matrix for a porosity of 30 ppi at 650 rpm.



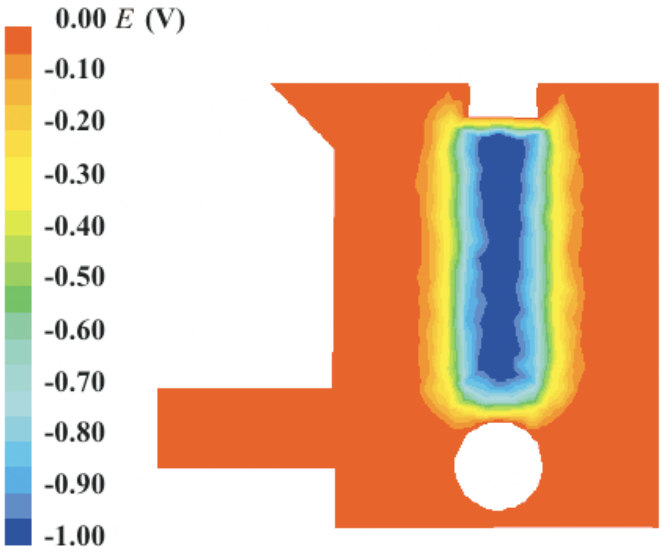


Fig. 9. Potential distribution in the electrochemical cell.

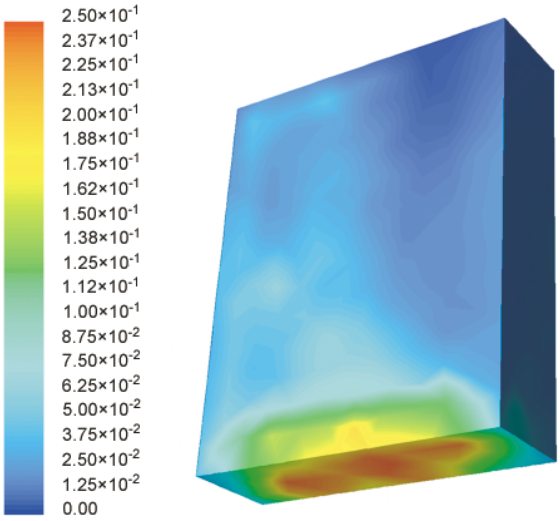
an important role concerning the distribution of the particles in the porous electrode as the volume fraction is divided by three when the electrode porosity is divided by three. However, the low hydrogenation efficiency obtained at 100 ppi (Fig. 3, curves c and c′) compared with 30 ppi (Fig. 3, curves b and b′) can not be explained by the volume fraction of catalyst particles in the RVC matrix. Assuming that the catalytic particles are in constant motion and free to travel through the matrix, it is reasonable to assume that the 30 ppi matrix has more electrical contact with the catalytic powder than the 100 ppi matrices.



Powder entrapment in the presence of an electric field

Aggregation of the particles was only observed in the presence of an electric field in the electrochemical cell. The effect of the electric field on the volume fraction was studied by a CFD simulation to explain this experimental observation. The distribution of potential (ϕ) in the cell was calculated with eq. [5] and was implemented with a user-defined scalar in FLUENT version 6.0.1 with zero potential at the walls of the electrochemical cell and a negative potential (–1 V) in the RVC electrode (Fig. 9). The electric field in the cell was computed assuming that the potential distribution can be approximately described by Laplace's equation (i.e., reactions on the electrode do not significantly perturb the potential distribution (24)).

$$[17] \quad \frac{\partial^2 \phi}{\partial x^2} = 0$$

In this simulation, aggregation in the RVC electrode occurs only if the value of the charge on the particles (q) is larger than 5×10^{-7} C (Fig. 10).

Fig. 10. Distribution of the volume fraction of the particles in the presence of an electric field for $q = 5 \times 10^{-7}$ C.

Conclusion

The ECH efficiency of phenol depends on the electrode material but also on the electrochemical cell. In this study, the electrolysis was carried out in a two-compartment jacketed glass H-cell and it was demonstrated that the stirring and the porosity of the RVC electrode play important roles in determining the distribution of the particles in the porous electrode. The best hydrogenation efficiency was obtained with a high porosity electrode (between 60 and 100 ppi) with a moderate stirring speed. The CFD model used to describe the catalyst particle distribution in the RVC electrode when an electric field is applied confirms the catalyst entrapment phenomenon observed during the experiments. However, simulation does not allow us to show a direct correspondence between the volume fraction of the catalyst particles and the porosity of the reticulated vitreous electrode for the electrochemical hydrogenation of phenol.

Novel mixed-ligand Pt(II) complexes: Synthesis, multinuclear magnetic resonance, and crystal structures of *cis*- and *trans*-Pt(R_2SO)(pyrazine)Cl_2

Fernande D. Rochon and Julien R.L. Priqueler

Abstract: A new type of mixed-ligand Pt(II) complexes, Pt(R_2SO)(pyrazine)Cl_2, was synthesized from the aqueous reaction of K[Pt(R_2SO)Cl_3] with pyrazine. The compounds were characterized mainly by IR and multinuclear magnetic resonance spectroscopies (^{1}H, ^{13}C, and ^{195}Pt) and crystallography. Compounds with dimethylsulfoxide, tetramethylenesulfoxide, di-*n*-propylsulfoxide, di-*n*-butylsulfoxide, dibenzylsulfoxide, and diphenylsulfoxide were studied. IR spectroscopy suggested a cis geometry for the di-*n*-propylsulfoxide complex and trans geometry for the other compounds. The ^{195}Pt NMR resonances of the complexes were observed between –3042 and –3121 ppm, with that of the diphenylsulfoxide complex being at higher field than those of the others. The pyrazine $^3J(^{195}Pt\text{-}^1H)$ coupling constant was observed for the DMSO compound (33 Hz), suggesting a trans geometry. No $J(^{195}Pt\text{-}^{13}C)$ coupling could be detected. The crystal structures of *trans*-Pt(tetramethylenesulfoxide)(pyrazine)Cl_2 and of *cis*-Pt(di-*n*-propylsulfoxide)(pyrazine)Cl_2 were determined and confirmed the geometry suggested by IR and NMR spectroscopies. The compound with di-*n*-butylsulfoxide could not be isolated, because it rapidly formed the pyrazine-bridged dimer.

Key words: platinum, sulfoxide, pyrazine, crystal structure, NMR, IR.

Résumé : Un nouveau type de complexes du platine(II) contenant des ligands mixtes a été synthétisé lors de la réaction en milieu aqueux de K[Pt(R_2SO)Cl_3] avec la pyrazine. Les composés Pt(R_2SO)(pyrazine)Cl_2 ont été caractérisés par spectroscopie infrarouge, par résonance magnétique multinucléaire (^{1}H, ^{13}C et ^{195}Pt) et par cristallographie. Des complexes avec les ligands diméthylsulfoxyde, tétraméthylènesulfoxyde, di-*n*-propylsulfoxyde, di-*n*-butylsulfoxyde, dibenzylsulfoxyde et diphénylsulfoxyde ont été étudiés. La spectroscopie IR a suggéré une géométrie cis pour le composé contenant le ligand di-*n*-propylsulfoxyde et une isomérie trans pour les autres complexes. Les résonances en RMN du ^{195}Pt ont été observées entre –3042 et –3121 ppm. Le composé contenant diphénylsulfoxyde a été observé à plus haut champ que les autres. La constante de couplage de la pyrazine $^3J(^{195}Pt\text{-}^1H)$ a été observé pour le composé contenant le DMSO (33 Hz) suggérant une géométrie trans. Aucun couplage de type $J(^{195}Pt\text{-}^{13}C)$ n'a été détecté. Les structures cristallines des deux composés *trans*-Pt(tétraméthylènesulfoxyde)(pyrazine)Cl_2 et *cis*-Pt(di-*n*-propylsulfoxyde)-(pyrazine)Cl_2 ont été déterminées par diffraction des rayons-X et les résultats ont confirmé les géométries suggérées par les spectroscopies IR et RMN. Le composé avec le ligand di-*n*-butylsulfoxyde n'a pas été isolé, car le dimère à pont pyrazine se forme trop rapidement.

Mots clés : platine, sulfoxyde, pyrazine, structures cristallines, RMN, IR.

Introduction

The antitumor activity of Pt(II) complexes of the type *cis*-Pt(amine)$_2Cl_2$ is well known. Cisplatin (*cis*-Pt(NH_3)$_2Cl_2$) remains the most commonly used anticancer agent in chemotherapy (1, 2), even though it exhibits numerous and significant side effects, but the search for more specific and less toxic drugs is still continuing.

A few *trans* Pt(II) complexes with amine ligands have shown anticancer activity in specific organs (3). Compounds with neutral ligands containing other donor atoms such as S have also shown some antitumor properties (4). Several Pt(II) complexes of the types [Pt(R_2SO)(diamine)Cl]NO_3 (5) and *cis*- and *trans*-Pt(R_2SO)(quinoline)Cl_2 (6) have shown biological activity, depending on the sulfoxide chain. Recently, it was reported that the pyrazine–Pt(II) complex [*cis*-{Pt(NH_3)$_2$Cl}$_2$(μ-pz)]Cl_2 and its derivatives showed good potential as anticancer compounds, especially because they largely seem to overcome the cross-resistance of cisplatin (7). The compounds possess an appropriate flexibility to provide the cross-links with a minimal distortion of the DNA.

Our group has been involved in research on Pt–sulfoxide complexes for many years. Sulfoxides are interesting ligands because they can accept π electron density from the metallic center. For these types of ligands, the cis complexes are usually more stable than the trans compounds (contrary to the amine systems). We have recently reported a study on mixed-ligand Pt(II) complexes containing pyrimidine (pm)

and sulfoxide ligands (8, 9). Pyrimidine also has empty π antibonding orbitals that could accept electron density from Pt. The aqueous reaction of $K[Pt(R_2SO)Cl_3]$ with pyrimidine (1:1 ratio) produced first *trans*-$Pt(R_2SO)(pm)Cl_3$, which could then isomerize to the *cis* compound (8).

To determine the influence of the pyrimidine ligand in these reactions, we have started a new study with pyrazine (pz) instead of pyrimidine. Unlike the latter, pyrazine is a symmetric molecule, but it too has empty π* orbitals that could form π bonds with Pt. We have recently published the results of the first part of this study, on the pyrazine-bridged dinuclear compounds $\{Pt(R_2SO)Cl_2\}_2(\mu\text{-pz})$ (10), which were found to have the trans-trans geometry. Pyrazine can form bridges between two metallic centers quite easily, even when an excess of pyrazine is used. Most reported works in the literature involve pyrazine-bridged oligomers.

There is no reported research on Pt compounds containing both sulfoxides and pyrazine except our recent publication of the pyrazine-bridged dimers (10). Only four papers on Pt compounds with nonsubstituted pyrazine were found in the literature. Among them, only two papers involve Pt(II) monomeric compounds. Albinati et al. (11) synthesized and characterized *trans*-Pt(phosphine)$(pz)Cl_2$, while Siedle et al. (12) prepared *trans*-$Pt(C_2H_4)(pz)Cl_2$ and its derivatives and used them as catalysts in hydrosilation reactions. No cis mixed-ligand Pt monomeric compounds with pyrazine have been reported. The nature of the Pt–pyrazine bond has not been investigated yet.

In the present publication, we report the results of our study on the aqueous reactions of $K[Pt(R_2SO)Cl_3]$ with pyrazine. Six sulfoxides that differ in steric hindrance were studied: dimethylsulfoxide (DMSO), tetramethylenesulfoxide (TMSO), di-*n*-propylsulfoxide (DPrSO), di-*n*-butylsulfoxide (DBuSO), dibenzylsulfoxide (DBzSO), and diphenylsulfoxide (DPhSO). The products $Pt(R_2SO)(pz)Cl_2$ were characterized by IR and multinuclear magnetic resonance (^1H, ^{13}C, and ^{195}Pt) spectroscopies. The crystal structures of two compounds with different geometies were determined.

Experimental

$K_2[PtCl_4]$ was obtained from Johnson Matthey Inc. and was purified by recrystallization from water before use. $CDCl_3$ was purchased from CDN Isotopes. Pyrazine and the sulfoxide ligands were purchased from Aldrich except DMSO, which was bought from Anachemia Chemicals Ltd., and DPrSO, acquired from Phillips Petroleum Company. The latter was purified by distillation before use.

The decomposition points were measured on a Fischer-Johns instrument and were not corrected. The IR spectra were recorded in the solid state (KBr pellets) on a PerkinElmer 783 spectrometer between 4000 and 280 cm^{-1}. All NMR spectra were measured in $CDCl_3$ on a Varian Gemini 300BB spectrometer operating at 300.069, 75.460, and 64.326 MHz for ^1H, ^{13}C, and ^{195}Pt, respectively. The chloroform peaks were used as an internal standard for the ^1H (7.24 ppm) and ^{13}C (77.00 ppm) NMR spectra. For ^{195}Pt, the external reference was $K[Pt(DMSO)Cl_3]$ (in D_2O, adjusted to –2998 ppm from $K_2[PtCl_6]$). The ^{195}Pt NMR spectra were measured between –2500 and –4000 ppm.

The TMSO compound (crystal **I**) was crystallized from a dichloromethane–acetone (1:1) mixture, and the DPrSO crystal (crystal **II**) was obtained from a chloroform–acetone–methanol (3:1:1) solution. The crystallographic measurements were done on a Siemens P4 diffractometer using graphite-monochromatized Mo Kα (λ = 0.71073 Å (1 Å = 0.1 nm) radiation. The crystals were selected after examination under a polarizing microscope for homogeneity. The cell dimensions were determined at room temperature, from a least-squares refinement of the angles 2θ, ω, and χ obtained for well-centered reflections. The data collections were made by the 2θ/ω scan technique using the XSCANS (13) program. The coordinates of the Pt atoms were determined from Patterson map calculations. All the other non-hydrogen atoms were found by the usual Fourier methods. The refinement of the structures was done on F^2 by full matrix least-squares analysis. The hydrogen atoms were fixed in their calculated positions with U_{eq} = 1.2 x U_{eq} of the carbon to which they are bonded (or 1.5 x U_{eq} for methyl groups). Corrections were made for absorption (integration for *trans*-$Pt(TMSO)(pz)Cl_2$ and semiempirical for *cis*-$Pt(DPrSO)(pz)Cl_2$), Lorentz, and polarization effects. Crystal **II** did not diffract very well. It was also measured with Cu Kα radiation, but the results did not improve. Attempts to prepare crystals of better quality were not successful. The residual peaks were located in the close vicinity of the Pt atoms. The calculations were done using the Siemens SHELXTL (13) system. The pertinent crystal data and the experimental details are summarized in Table 1.

The $K[Pt(R_2SO)Cl_3]$ complexes were synthesized according to the method described by Kukushkin et al. (14). The DBzSO and DPhSO complexes were obtained in small quantities because of the aqueous insolubility of the ligands and the very favorable formation of the insoluble disubstituted compound $Pt(R_2SO)_2Cl_2$.

Preparation of *trans*-$Pt(R_2SO)(pz)Cl_2$

Pyrazine was dissolved in a minimum amount of water. The $K[Pt(R_2SO)Cl_3]$ compound, dissolved also in a minimum amount of water, was added gently to the pyrazine solution in a 1:1.1 proportion at room temperature. A pale yellow to yellow-orange precipitate appeared rapidly, but the stirring of the solution was continued until precipitation was complete. After filtration, the precipitate was dried, washed with ether, and dried in vacuum. For the DBzSO complex, the reaction was done in a 2:1 MeOH–H_2O mixture, while for the DPhSO complex, the reaction was done in a 3:1 EtOH–H_2O mixture.

Preparation of *cis*-Pt(DPrSO)(pz)Cl_2 (II)

Pyrazine was dissolved in a minimum amount of water. The K[Pt(R_2SO)Cl_3] compound, dissolved also in a minimum amount of water, was added gently to the pyrazine solution in a 1:1 proportion at room temperature. A yellow sticky paste formed immediately and stuck to the magnetic agitator. The paste was dissolved in chloroform and the solution evaporated to dryness. The residue was recrystallized in chloroform, filtered, washed with ether, and dried in vacuum.

Yield 68%; dec. 183–220 °C. IR (cm^{-1}): (vibration numbers assigned using the notation in ref. 15): 3086 w (ν_{13} (B_{1u})), 1457 m (ν_{19a} (B_{1u})), 1412 s (ν_{19b} (B_{3u})), 1379 m (ν_{19b} (B_{3u})), 1130 s (ν_{18a} (B_{1u})), 1111 w (ν_3 (B_{2g})), 1069 s (ν_{14} (B_{3u})), 807 m (ν_{11} (B_{2u})); ν(S-O) 1152 s, ν(Pt-N) 515 w, ν(Pt-S) 448 m, br, ν(Pt-Cl) 345 m, 341 m. ^{1}H NMR (ppm): H_{pz} 8.707 (d, 3.3), 8.685 (d, 3.3); H_α 3.76 (m), 3.12 (m); H_β 2.36 (m), 2.03 (m); H_γ 1.18 (t, 7.5). ^{13}C NMR (ppm): C_{pz} 147.59, 147.40; C_α 56.51, C_β 16.68, C_γ 12.75.

Results and discussion

Synthesis of the complexes

The aqueous reaction of K[Pt(R_2SO)Cl_3], where R_2SO = DMSO, TMSO, DBzSO, and DPhSO, with pyrazine in a 1:1.1 proportion produced the monomeric complexes *trans*-Pt(R_2SO)(pz)Cl_2 (eq. [1]). The K[Pt(R_2SO)Cl_3] solution must be added to the pyrazine solution to have an excess of pyrazine throughout the reaction because an excess of the Pt(II) salt will produce the pyrazine-bridged dimer recently reported (10), prepared by a similar reaction using a Pt:pz ratio of 2:1. For the DBzSO complex, the reaction was performed in a 1:2 water–methanol mixture, while a 1:3 water–ethanol solution was preferred for the DPhSO compound.

$$[1] \qquad K[Pt(R_2SO)Cl_3] + pz \rightarrow \textit{trans}\text{-}Pt(R_2SO)(pz)Cl_2 + KCl$$

A pale yellow to yellow-orange precipitate was formed. The time at which precipitation was observed varied with the bulkiness of the sulfoxide. The yields varied between 84% and 89%.

The characterization of the products has shown that these compounds have the trans configuration, as expected be-

© 2004 NRC Canada

cause of the large trans effect of sulfoxides. Sulfoxide complexes having the cis configuration are usually more stable than the trans compounds, because the π bonding is more effective in the cis configuration. For example, the aqueous reaction of $K[Pt(R_2SO)Cl_3]$ with R_2SO produces first the trans isomer, which rapidly isomerizes in water to the cis compound except in the case of very sterically demanding sulfoxides. Similarly, the reaction of $K[Pt(R_2SO)Cl_3]$ with pyrimidine produces first *trans*-$Pt(R_2SO)(pm)Cl_2$, which can isomerize to the cis compound (8). Since pyrazine is a very similar ligand to pyrimidine, both of them having empty π* orbitals that can accept electron density from Pt, the *trans*-$Pt(R_2SO)(pz)Cl_2$ compounds were expected to undergo isomerization, at least in organic solvents. However, several attempts in different solvents to isomerize the four *trans*-$Pt(R_2SO)(pz)Cl_2$ compounds were without success. Therefore, it appears that the reactivity of the R_2SO–pyrazine complexes is quite different from that of the R_2SO–pyrimidine compounds (8, 9). The pyrazine-bridged dimers recently published were identified as the trans-trans isomers (10), and various attempts to isomerize them were also not successful.

The aqueous reaction of $K[Pt(DPrSO)Cl_3]$ with pyrazine under the same conditions as for the other $K[Pt(R_2SO)Cl_3]$ complexes was quite different. With a Pt:pz ratio of 1:1 to 1:1.1, a bright yellow sticky paste formed immediately upon mixing. After the purification process in $CHCl_3$, the product was identified as the mononuclear complex *cis*-$Pt(DPrSO)(pz)Cl_2$.

[2] $K[Pt(DPrSO)Cl_3] + pz \rightarrow$ *cis*-$Pt(DPrSO)(pz)Cl_2 + KCl$

The lower yield of this reaction (68%) can be attributed to the oily nature of the product. When the Pt:pz ratio was greater than 1:1, the pyrazine-bridged dimeric species *trans*-$\{Pt(DPrSO)Cl_2\}_2(\mu\text{-pz})$ was formed as reported earlier. The fact that the final dinuclear product exhibits the trans-trans geometry (10) suggests that the mononuclear intermediate is *trans*-$Pt(DPrSO)(pz)Cl_2$. However, with a Pt:pz ratio of 1:1.1, the trans monomeric compound, which should first be produced, could not be isolated, suggesting that the compound *trans*-$Pt(DPrSO)(pz)Cl_2$ isomerized rapidly. This was quite surprising since all the complexes formed with the other ligands are believed to have the trans configuration and did not isomerize even upon heating in organic solvents.

The aqueous reaction of $K[Pt(DBuSO)Cl_3]$ with pyrazine under the same conditions (Pt:pz ratio of 1:1) produced the pyrazine-bridged dinuclear species *trans*-$\{Pt(DBuSO)Cl_2\}_2(\mu\text{-pz})$. No monomeric compound was obtained with the ligand DBuSO. The experimental conditions were varied (different solvents) and the Pt:pz ratio was varied from 1:1 to 1:15, but no monomeric mixed-ligand complex could be detected. It seems that in the case of $K[Pt(DBuSO)Cl_3]$, unlike the other $K[Pt(R_2SO)Cl_3]$ complexes, the binding of the first N atom of pyrazine to Pt activates the second N atom to react more rapidly than the first

All the mixed-ligand monomeric species were characterized by IR and multinuclear magnetic resonance spectroscopies. The low solubility of these complexes was a major problem in this project. The compound *trans*-$Pt(DBzSO)(pz)Cl_2$ could not be analyzed by NMR spectroscopy, being insoluble in all the solvents tested (H_2O, MeOH, EtOH, $CHCl_3$, CH_2Cl_2, CH_3COCH_3, and DMF).

The synthesized complexes were pure, since only one resonance was observed in their ^{195}Pt NMR spectra (confirmed by ^1H and ^{13}C NMR). The complexes *trans*-$Pt(TMSO)(pz)Cl_2$ and *cis*-$Pt(DPrSO)(pz)Cl_2$ were also studied by X-ray diffraction methods, which confirmed the geometry of the complexes.

IR spectroscopy

The IR spectrum of pyrazine has been reported (15), and our IR band assignments (Experimental section) are based on that study. The vibrations of coordinated pyrazine in the Pt complexes were observed at energies higher than or identical to those reported for the free ligand. The ν(S-O) vibrations absorb at higher energy than in the free sulfoxides (avg. +120 cm^{-1}), since the ligands are bonded to Pt by the S atom. The pπ–dπ bond is strengthened upon coordination in the complexes. The ν(S-O) energies (avg. 1151 cm^{-1}) are identical with those observed in the pyrazine-bridged dimeric compounds (avg. 1157 cm^{-1} (10)) and can be compared with the values reported for $Pt(DMSO)(NH_3)Cl_2$ and $Pt(DMSO)(2\text{-Me-py})Cl_2$ (1128 and 1138 cm^{-1}, respectively (16)).

For all the complexes except $Pt(DPrSO)(pz)Cl_2$, only one ν(Pt-Cl) vibration was observed, between 348 and 350 cm^{-1}. This suggests a trans geometry because, although two bands are predicted by group theory for both cis (C_s skeletal symmetry) and trans isomers (C_{2v}) of this type, two bands are usually observed for the cis compounds and only one band for the trans isomers (as reported, for example, for the complexes *cis*- and *trans*-$Pt(DMSO)(L)Cl_2$, where L = 2,6-lutidine and dimethylamine (17) and pyrimidine (8)). However, for $Pt(DPrSO)(pz)Cl_2$, two ν(Pt-Cl) bands located at 341 and 345 cm^{-1} were observed, suggesting a cis geometry.

An absorption band observed around 460 cm^{-1} was assigned to a ν(Pt-S) vibration as suggested in the literature (8–10, 16, 18–21), while a band around 515 cm^{-1} was assigned to the ν(Pt-N) vibration, based also on some published results (8–10, 22, 23).

^{195}Pt NMR spectroscopy

The ^{195}Pt NMR spectra of the monomeric compounds $Pt(R_2SO)(pz)Cl_2$ (except the DBzSO complex) were measured in $CDCl_3$, and the results were compared with those observed for the pyrimidine analogues $Pt(R_2SO)(pm)Cl_2$ (8) and for the pyrazine-bridged dimeric species *trans*-$\{Pt(R_2SO)Cl_2\}_2(\mu\text{-pz})$ (10). The chemical shifts are summarized in Table 2. All the synthesized complexes were pure as shown by multinuclear (^{195}Pt, ^1H, and ^{13}C) magnetic resonance spectroscopy. The compound containing a DBzSO ligand was found to be insoluble in all the classical organic solvents.

Except for the DPhSO complex, the ^{195}Pt NMR chemical shifts vary between –3042 and –3046 ppm. The $\delta(^{195}Pt)$ values of these monomers are very close to those determined for the pyrazine-bridged dimeric species (Table 2). In the pyrimidine series, the signals of the monomers were observed at slightly lower fields (avg. –3065 ppm) than those of the pyrimidine-bridged dimers (avg. –3075 ppm) (8, 9). Our re-

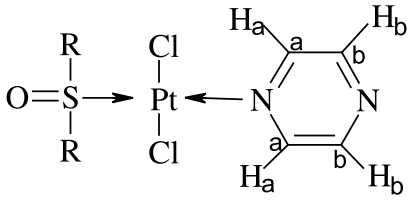
sults are also in agreement with the published work on analogues with phosphine ligands (11), where the ^{195}Pt NMR chemical shift of *trans*-$Pt(PR_3)(pz)Cl_2$ was reported at –3589 ppm, and that of the dinuclear coompound *trans*-$\{Pt(PR_3)Cl_2\}_2(\mu\text{-pz})$ at –3587 ppm. These results seem to indicate that the electron density on the Pt atom is the same in the monomers as in the pyrazine-bridged dimers.

The value of $\delta(^{195}Pt)$ for the *cis*-DPrSO complex was within the range observed for the trans monomers (except the DPhSO compound), which was not expected. In the pyrimidine series (8), the signals of the cis compounds were reported at much lower fields than those of the trans isomers (avg. $\Delta\delta$ ($\delta_{cis} - \delta_{trans}$) = 132 ppm). For sulfoxide Pt(II) complexes, the cis isomers are more stable than the trans compounds since the π(d-d) bonding is more efficient in the cis geometry, resulting in a lower electron density on the Pt center. The δ(Pt) are therefore observed at lower field for the cis isomers. For mixed-ligand complexes, the value of $\Delta\delta$ ($\delta_{cis} - \delta_{trans}$) will also depend on the second ligand. If the latter can form π bonds, the difference between the two isomers should increase, while an amine ligand should reduce the $\Delta\delta$ ($\delta_{cis} - \delta_{trans}$) values. In $Pt(DMSO)(NH_3)Cl_2$, the signal of the cis isomer was reported at –3045 ppm, whereas that of its trans analogue was observed at –3067 ppm (16, 24). In our R_2SO-pz compounds, only one cis compound (with DPrSO) was prepared, and its signal was observed at the same field as those of the trans isomers of the other R_2SO-pz compounds. We do not have enough data at the moment to reach a sound conclusion and will continue our attempts, which have not been successful up to now, to prepare other cis compounds and the trans DPrSO complex.

The ^{195}Pt NMR signal of the DPhSO complex was observed at much higher fields than those of the other compounds, as also reported for the other DPhSO complexes in Table 2 and for a series of compounds of the types $Pt(R_2SO)(R\text{-}CN)Cl_2$ (25) and $K[Pt(R_2SO)Cl_3]$ (25, 26). DPhSO is not only the most sterically hindered ligand, but also it is different from the other sulfoxides in that it contains aromatic groups directly attached to the sulfur atom. These groups are probably responsible for the different electronic effects observed for this compound. The electron density on the Pt atom is increased in the DPhSO complex compared to the complexes containing the other sulfoxide ligands. The shielded resonance is probably not caused by the bulkiness of the substituents on the sulfur, because the presence of bulky substituents on the atom bonded to Pt usually has a deshielding effect. For Pt–amine complexes, δ(Pt) was found at lower fields for amines having bulky substituents on the nitrogen atom (27, 28). For $K[Pt(R_2SO)Cl_3]$ (29) and the corresponding pyrazine-bridged dimeric complexes (10), we have suggested that the difference was caused by inverse polarization of the π electrons of the S=O bond, and this concept might be an interesting interpretation of our results in the present study as well. This phenomenon has been suggested in the literature to explain some ^{13}C NMR results for Pt–carbonyl (30) and Pt–carboxylato complexes (31). Such an effect would be present in all Pt–R_2SO complexes but would be more important for sulfoxide ligands containing electron-attracting aromatic groups attached directly to the S atom. This effect would increase the electron density on the atoms in close proximity to the S atom, especially the Pt atom, which would result in a higher field δ(Pt) signal.

^{1}H and ^{13}C NMR spectroscopies

The pyrazine signals of the complexes will first be discussed. Pyrazine is a symmetric molecule, and only a single resonance is observed in the ^{1}H and ^{13}C spectra at 8.59 and 145.07 ppm, respectively, in $CDCl_3$. When pyrazine is bonded to a metal, the molecule is no longer symmetric, as shown in Scheme 1. Two signals should now be observed for the coordinated molecule in the ^{1}H NMR (H_a and H_b) and ^{13}C NMR (C_a and C_b) spectra. The atoms H_a and C_a should be more affected by coordination to the metal than H_b and C_b.



The chemical shifts and the coupling constants of the complexes are presented in the Experimental section, and the values $\Delta\delta$ ($\delta_{complex} - \delta_{pyrazine}$) are listed in Table 3. Coordination of pyrazine to the Pt atom causes a deshielding of all the pyrazine atoms. The chemical shifts of H_a and C_a are more deshielded than those of H_b and C_b as expected, resulting in larger $\Delta\delta$ values for H_a and C_a. For the DPhSO complex, the two multiplets were not separated. The reduction of electron density in bonded pyrazine is a consequence of the σ bond (N→Pt), which causes a deshielding effect in ^{1}H and ^{13}C NMR. In the literature, for a few complexes of the type *trans*-$Pt(PR_3)(pz)Cl_2$ (11), the reported $\Delta\delta_a$ values in ^{1}H NMR (avg. 0.38 ppm) were larger than ours, while their $\Delta\delta_b$ value was 0.15 ppm. The difference might be caused by the larger trans effect of phosphine ligands compared to that of sulfoxides (10). For the trans-trans pyrazine-bridged dimers $\{Pt(R_2SO)Cl_2\}_2(\mu\text{-pz})$ (in which the pyrazine is symmetric), the average $\Delta\delta$ value was around 0.52 ppm (10). It seems

Scheme 1.

that the formation of two σ bonds (N→Pt) by pyrazine decreases further the electron density on pyrazine.

The ^{1}H $\Delta\delta$ values for *cis*-Pt(DPrSO)(pz)Cl_2 are smaller than those of the trans complexes (Table 3). These differences might be due to the different geometry, but more cis compounds are needed before a conclusion can be reached. Steric hindrance in the cis complex is an important factor that must be considered. In the trans compounds, the rotation around the Pt—N bond is not very restricted because the π component of the bond is probably not very important. For the cis isomers, the rotation of the pyrazine ring around the Pt—N bond is more hindered, and the planar ligand is probably close to being perpendicular to the Pt(II) coordination plane to reduce the steric hindrance. The rotation will be more restricted with more bulky sulfoxides.

The chemical shifts of the pyrazine protons in *trans*-Pt(DPhSO)(pz)Cl_2 were at lower fields ($\Delta\delta_{avg}$ = 0.311 ppm) than those of the other trans compounds ($\Delta\delta_{avg}$ = 0.20 ppm). This is in agreement with the observation of the ^{195}Pt NMR signal of this compound at higher field than those of the other complexes, since an increase of electron density on the Pt atom (upfield shift in ^{195}Pt NMR) corresponds to a reduction of electron density on the ligand (downfield shift in ^{1}H and ^{13}C NMR).

The coupling constants $^3J(^1H_a\text{-}^1H_b)$ are 3.0 Hz for *trans*-Pt(DMSO)(pz)Cl_2 and *trans*-Pt(TMSO)(pz)Cl_2 and 3.3 Hz for *cis*-Pt(DPrSO)(pz)Cl_2. A coupling constant with the Pt(II) nucleus, $^3J(^{195}\text{Pt-}^1\text{H})$ = 33 Hz, was also observed for the DMSO complex. This value is in agreement with the results in the literature reported for *trans*-Pt(DMSO)(Ypy)Cl_2 (Ypy = pyridine derivative) (32) and for *trans*-Pt(Ypy)$_2X_2$ (33). The coupling constants $^3J(^{195}\text{Pt-}^1\text{H})$ are usually smaller for trans isomers. For example, the values of $^3J(^{195}\text{Pt-}^1\text{H})$ for Pt(DMSO)(pm)Cl_2 are 31 and 44 Hz for the trans and cis compounds, respectively (8).

In ^{13}C NMR spectroscopy, similar results were observed. The two pyrazine signals in the spectra of the complexes were observed at lower fields than the single ^{13}C resonance of free pyrazine, with C_a being more affected ($\Delta\delta_a$ ~ 2 ppm) by coordination to the metal than C_b (Table 3). The formation of the N→Pt σ bond reduces the electron density on the pyrazine ligand. Surprisingly, $\Delta\delta$ for C_b is much larger for *cis*-Pt(DPrSO)(pz)Cl_2 ($\Delta\delta_b$ = 2.33 ppm) than for the other complexes ($\Delta\delta_b$ = 0.26–0.86 ppm). The difference is probably due to the cis geometry of the DPrSO compound. The latter ligand is very sterically demanding, and the rotation around the Pt—N bond is restricted. In solution, the pyrazine plane would probably be almost perpendicular to the Pt(II) coordination plane to reduce the steric hindrance to a minimum. The ^{13}C $\Delta\delta_{avg}$ of *cis*-Pt(DPrSO)(pz)Cl_2 is larger (2.44 ppm) than the corresponding values of the trans compounds (avg. 1.38 ppm). A similar observation was previously reported for $Pt(R_2SO)(pm)Cl_2$, where the value $\Delta\delta_{avg}$ was 2.13 ppm for the cis isomers and 1.51 ppm for the trans complexes (8). For *trans*-Pt(PR_3)(pz)Cl_2, the C_a and C_b signals were observed at 147.2 and 145.0 ppm, respectively (11). We have not observed any $J(^{195}\text{Pt-}^{13}\text{C})$ couplings for the pyrazine carbon atoms.

The chemical shifts and the coupling constants $J(^1\text{H-}^1\text{H})$ of the sulfoxide ligands are presented in the Experimental section, and the values of $\Delta\delta$ ($\delta_{complex} - \delta_{sulfoxide}$) are listed in Tables 4 (^{1}H NMR) and 5 (^{13}C NMR). In ^{1}H NMR, the $\Delta\delta$ values are positive, indicating that the sulfoxide protons are more deshielded in the ligands than in the free molecules. The protons located in positions α to the binding atom are the most affected by coordination to the metallic center. For the DMSO complex, only one signal at 3.48 ppm was observed; this chemical shift is close to that reported for *trans*-Pt(DMSO)(pm)Cl_2 (3.45 ppm (8)) and for *trans*-Pt(DMSO)(thiazole)Cl_2 (3.48 ppm (34)). For the other complexes, two series of signals were observed. For the TMSO complex, the two geminal protons of each CH_2 group are in different environments. Those closer to the O atom will be more deshielded than the others. For the other ligands, the two series of signals result from restricted rotation around the S—C bonds. The difference between the two series of resonances decreases as the distance from the S atom increases.

A coupling constant $^3J(^{195}\text{Pt-}^1\text{H})$ = 23 Hz was observed for *trans*-Pt(DMSO)(pz)Cl_2. This is in agreement with results reported for the similar trans complexes Pt(DMSO)(thiazole)Cl_2 (22 Hz) (34) and $Pt(R_2SO)(pm)Cl_2$ (22 Hz) (8). The other ligands gave low-intensity multiplets, and the coupling with ^{195}Pt could not be seen.

In ^{13}C NMR, the resonances of the C atoms in α positions were observed at lower fields than those of the corresponding atoms in the free sulfoxides ($\Delta_\alpha\delta$ = 2.31–3.76 ppm), except for the DPhSO complex (Table 5). These values are quite small compared to similar values for other types of ligands such as amines. Sulfoxides can accept electron density from the metal center, and the π (Pt→S) bond will increase the electron density on the sulfoxide ligand. Furthermore, the inverse polarization of the π electrons of the $^{\delta-}$S—O$^{\delta+}$

trans-$Pt(DMSO)(pz)Cl_2$	3.76			
trans-$Pt(TMSO)(pz)Cl_2$	2.66	–0.75		
cis-$Pt(DPrSO)(pz)Cl_2$	2.31	0.54	–0.52	
trans-$Pt(DPhSO)(pz)Cl_2$	–6.99	2.86 (*ortho*)	–0.34 (*meta*)	2.12 (*para*)

Note: C_α is the C atom closest to the S atom, C_β is the second C from S, etc.

bond would increase the electron density on the S atom and its neighbouring atoms, especially the α carbon atoms. This inverse polarization of the S—O π bond was first suggested by Cooper and Powell (30) to explain the ^{13}C NMR spectra of some Pt–carbonyl complexes and was later put forward in the interpretation of the ^{13}C NMR spectra of some Pt–carboxylate complexes (31). The chemical shifts in ^{13}C NMR spectroscopy are particularly dependent on such mesomeric effects.

For *trans*-$Pt(DPhSO)(pz)Cl_2$, the signals of the α carbon atoms were observed at much higher field than those of the free ligand ($\Delta_\alpha\delta$ = –6.99 ppm). Similar behavior was reported for the pyrazine-bridged dimer *trans*-$\{Pt(DPhSO)Cl_2\}_2(\mu\text{-pz})$, with $\Delta_\alpha\delta$ = –6.61 ppm (10). We suggest that the inverse polarization of the π electrons in the S=O bond would be greater in this ligand because of the presence of two strongly electron-attracting phenyl groups located directly on the S atom. This phenomenon would increase the electron density on the C atoms located in positions α to the S atom. The π component of the Pt—S bond (back-donation) might also be more important for this ligand because of the presence of the two electron-attracting groups on the ligand.

The NMR results for these complexes are very similar in general to those reported for the pyrazine-bridged dimers (10). This behavior is different from that reported for the R_2SO-pm complexes (8, 9). Since the two bridging atoms in pyrazine are far from each other, the presence of a second Pt atom does not influence the chemical shifts of the sulfoxides. There are seven bonds between C_α and the second Pt atom in the dinuclear species. In the pyrimidine series, the distances are shorter, and the influence of the second metal center is more important.

The results of this study seem to indicate that the Pt–pyrazine bond is more complicated than expected. Pyrazine has π^* orbitals that could form π bonds with Pt, but to a much reduced extent as compared to sulfoxides. Some published work on pyridine (33) and pyrimidine (8, 9) complexes seems to indicate the presence of some π bonding in the Pt—N bonds, although this is not easy to study.

Crystal structures

The crystal structures of one trans complex, $Pt(TMSO)(pz)Cl_2$ (**I**), and the one cis compound produced, $Pt(DPrSO)(pz)Cl_2$ (**II**), were studied by X-ray diffraction methods. The results confirmed the geometry of the complexes suggested by IR and NMR spectroscopies. Figures 1 and 2 show the labeled diagrams of the two complexes. The bond distances and angles are listed in Table 6. The CIF tables of the two crystal structure determinations have been deposited as supplementary material.[2]

The coordination around the Pt atoms is square planar as expected. The bond angles around the Pt atom are close to the ideal values. The largest deviation can be seen in the cis compound (**II**), where the N-Pt-Cl angle is reduced to 87.7(4)° while the N-Pt-S angle is increased to 92.0(4)°, to reduce the steric hindrance caused by the bulky sulfoxide ligand. In Pt–sulfoxide complexes, the O atom of the sulfoxide is often in the Pt coordination plane, which reduces the steric hindrance caused by the presence of the sulfoxide. In the cis compound (**II**), where this factor is very important, the O is almost in the coordination plane, with a deviation of 0.12(3) Å, while in the trans compound (**I**), the deviation is 1.41(1) Å.

The pyrazine ring is planar in both **I** and **II**. The dihedral angle between the pyrazine plane and the Pt coordination plane is 54.6(4)° and 60.3(5)° for the trans (**I**) and cis (**II**) complexes, respectively. This angle is usually larger in cis

compounds, where the bulkiness of the ligands is a more important factor.

The Pt—S bond lengths in the two structures are within the range reported for other Pt–sulfoxide complexes (8–10, 16, 34–36). In terms of trans influence, pyrazine and chloride are not very different, and the lengths of the Pt—S bonds do not seem to be very sensitive to the trans ligand. In *cis*-Pt(DPrSO)(pz)Cl_2, the Pt—Cl bond trans to the sulfoxide ligand is longer (2.316(5) Å) than the one trans to pyrazine (2.292(5) Å). The large trans influence of sulfoxides is well known. In crystal **I**, the Pt—Cl bonds are trans to each other, and their lengths (avg. 2.293(3) Å) are within the normal range. The lengths of Pt—N bonds are usually more sensitive to the trans ligands. In crystal **II**, where the trans ligand is a chloro ligand, the length of the Pt—N bond is 2.004(14) Å. In **I**, the Pt—N bond is trans to the sulfoxide and is significantly longer (2.053(11) Å). These results are close to those reported for similar compounds (8–10, 33, 34, 37, 38). All these data confirm that the trans influence of the sulfoxide ligand is clearly larger than that of the chloro ligand or pyrazine.

The bond distances and bond angles in the sulfoxide ligands are as expected and agree with published data on Pt–R_2SO complexes (8–10, 16, 39). As observed in other TMSO compounds, the C-S-C angle in *trans*-Pt(TMSO)(pz)Cl_2 is small (94.0(7)°) since the S atom is in a five-membered ring. The conformation of the TMSO ligand is of the envelope type, as seen in Fig. 1. The four C atoms are planar, and the S atom is 0.75(2) Å out of the plane. The dihedral angle between this plane and the Pt coordination plane is

C-C-N (pz) (avg.)	122(2)	123(2)
S-C-C (R_2SO) (avg.)	104.1(11)	109(2)
C-C-C (R_2SO) (avg.)	109.1(12)	111(3)

[a]trans to DPrSO.

17.1(10)°. In *cis*-Pt(DPrSO)(pz)Cl_2, the C-S-C angle is smaller (100.9(12)°) than the other angles around the S atom, since the multiple S—O bond occupies more space than the single S—C bonds.

The average pyrazine C-N-C and C-C-N internal angles are 116.4(13)° and 122(2)°, respectively, for **I** and 115(2)° and 123(2)°, respectively, for **II**. For the free molecule, these angles were reported to be 115.1° and 122.4°, respectively (40). Therefore, the structure of pyrazine does not change upon coordination to Pt(II).

Preparation of 4-anilino-6-aryl-2*H*-pyran-2-ones from trilithiated acetoacetanilides and aromatic esters

Jennifer R. Downs, Sally P. Grant, Jessica D. Townsend, Deborah A. Schady, Stefan J. Pastine, Mildred C. Embree, Clyde R. Metz, William T. Pennington, Rosa D. Bailey Walsch, and Charles F. Beam

Abstract: Acetoacetanilide and 4′-chloroacetoacetanilide were trilithiated with excess lithium diisopropylamide and condensed with several aromatic esters, followed by neutralization, separate acid cyclization, and rearrangements. After *C*-acylation of trilithiated acetoacetanilides and cyclization to 4*H*-pyran-4-ones, these compounds underwent multistep rearrangements to 4-anilino-6-aryl-2*H*-pyran-2-ones.

Key words: pyranones, trianions, Claisen-type condensations, rearrangements.

Résumé : L'acétoacétanilide et le 4′-chloroacétoacétanilide ont été trilithiés à l'aide d'un excès de diisopropylamidure de lithium et ces sels ont été soumis à une condensation avec plusieurs esters aromatiques, suivie d'une neutralisation, d'une cyclisation acide et de réarrangements. Après une *C*-acylation des acétoacétanilides trilithiés et une cyclisation en 4*H*-pyran-4-ones, ces composés donnent lieu à des réarrangements en plusieurs étapes qui conduisent à des 4-anilino-6-aryl-2*H*-pyran-2-ones.

Mots clés : pyranones, trianions, condensation du type de Claisen, réarrangements.

[Traduit par la Rédaction]

Introduction

The preparations, reactions, spectral studies, biological potential, and uses of 2*H*-pyran-2-ones **1** have been well documented (1). Strong base methods for preparing these compounds can involve the dianion of ethyl or methyl acetoacetate (2), which have had follow-up application studies (3). These dianions underwent a Claisen-type *C*-acylation with benzoate and related esters, and the resulting diketoester intermediates could undergo cyclization to 6-substituted 4-hydroxy-2*H*-pyran-2-ones **1** (R_4 = OH and R_6 = aryl, Fig. 1).

Related syntheses deal with 2,6-disubstituted 4*H*-pyran-4-ones **2** (R_2 and R_6 = aryl, Fig. 1) that were obtained by *C*-acylation of β-diketone dianions, such as dilithiated 1-benzoylacetone, with aromatic esters. This was then followed by acid cyclization of the resulting triketones to expected 2,6-disubstituted 4-pyranones **2** (R_2 and R_6 = aryl, Fig. 1) and other compounds (4, 5).

Of interest to this investigation is the rearrangement of 4-pyranones **2** (R_2 and R_6 = methyl or phenyl, Fig. 1) to 2-pyranones **1** (R_4 and R_5 = methyl or phenyl, Fig. 1) (6). For example, there are several select preparations of 4,5-disubstituted 2-pyranones **1** from 2,6-disubstituted 4-pyranones **2**, which involve an intramolecular multistep thermal or photochemical sequence containing several epoxide-type intermediates. Other 2-pyranones **1** have also undergone rearrangements to differently substituted 2-pyranones **1** (7). Several reports have dealt with the preparations of 4-amino-2*H*-pyran-2-ones **1** (R_4 = NH_2, *N*-alkyl or *N*,*N*-dialkyl), but 4-anilino-2*H*-pyran-2-ones **1** have not been reported. One of these recent syntheses deals with a selective *C*-acylation of enaminone lithium dianions followed by cyclization to 4-amino-2-pyranones **1** (R_4 = *N*-CH_3) (8*a*). Others have also involved related rearrangements of 4-alkylamino-2-pyranones **1** (8*b*–8*f*).

While the chemistry of β-ketones and β-ketoester dianions has been well investigated (9), there are limited studies reported concerning the use of β-ketoamide trianions (10–12) in syntheses. Their utilization has resulted in the preparations of chromone-2-acetamides (10) and chromone-2-thioacetamides (11), where the trianion-type intermediates were condensed–cyclized with anionic electrophiles, lithiated methyl salicylates, or lithiated methyl thiosalicylate.

Results and discussion

What at first appeared to be a routine *C*-acylation of acetoacetanilide trianion with esters, such as methyl 4-methoxybenzoate or methyl 4-chlorobenzoate, with the potential to cyclize the 4*H*-pyran-4-ones **2** or 2(1*H*)-pyridones **3** (Fig. 1), gave, after several rearrangements, substituted 4-anilino-6-aryl-2*H*-pyranones **1** (Scheme 1; numbering of Ar_4 and Ar_6 in products used).

The two challenges that these results presented were the development of a reproducible experimental procedure, beyond a chance reaction or two, and the preparation of suitable crystals for X-ray crystal structure analysis. The initial study is now completed, and it has been extended to the current report.

Acetoacetanilide and 4′-chloroacetoacetanilide were trilithiated with excess lithium diisopropylamide (LDA), in tetrahydrofuran (THF) at 0 °C and condensed with several substituted benzoate esters, such as methyl 4-bromobenzoate, to give *C*-acylated intermediates that were not isolated. Attempts to isolate these compounds, or the possibility of

Scheme 2. Mechanistic details for the preparation of 4-anilino-6-aryl-2*H*-pyran-2-ones (**1a**–**1g**) (Ar_4 and Ar_6 numbering of products).

isolating a cyclized 4-pyranone **2** (or pyridone **3**, Fig. 1) only resulted in the eventual isolation of rearrangement products that were shown, primarily by X-ray crystal structural analysis, to be 4-anilino-6-aryl-2-pyranones **1a** and **1b**. The developing synthon indicated that additional examples of the polylithiation, condensation, cyclization, and rearrangements could be affected when the products from the initial condensation with the esters were not isolated, but separately acid cyclized with benzene or toluene using a water trap (see *Experimental*). The 2-pyranones, **1a**–**1g**, were obtained in 23%–68% yield without need of chromatographic purification.

The 1,6-diphenyl-4*H*-pyran-4-ones **2** (Fig. 1) can result from the cyclization of an expected *C*-acylated intermediate (Scheme 2) (2*a*). An acidic intermolecular pathway ((**A**) → (**B**) → (**C**)) is probable, and an intramolecular pathway (**2** → **3** → **1**) is overly complex, even though both may explain the formation of 4,6-disubstituted 2-pyranones **1**. The intermolecular pathway would involve the 1,4-addition of water–H^+ to anilinopyranone **2** to (**A**) with elimination of a substituted aniline to the 2-hydroxy-4-pyranone (**B**). This intermediate (**B**) would undergo a 1,2-addition of the substituted aniline to (**C**), followed by elimination of water, and give the 2-pyranones **1a**–**1g**, isolated. The less likely intramolecular path, usually representing a photochemical or thermal route, has seven steps involving several epoxide-type intermediates involving the rearrangement of a 1,6-disubstituted 4-pyranone **2** to a 4,5-disubstituted, 2-pyranone **1** (6). The remaining steps involve the rearrangement of a 4,5-disubstituted 2-pyranone **3** to a 4,6-disubstituted 2-pyranone **1** (7, 8*b*–8*f*, 13).

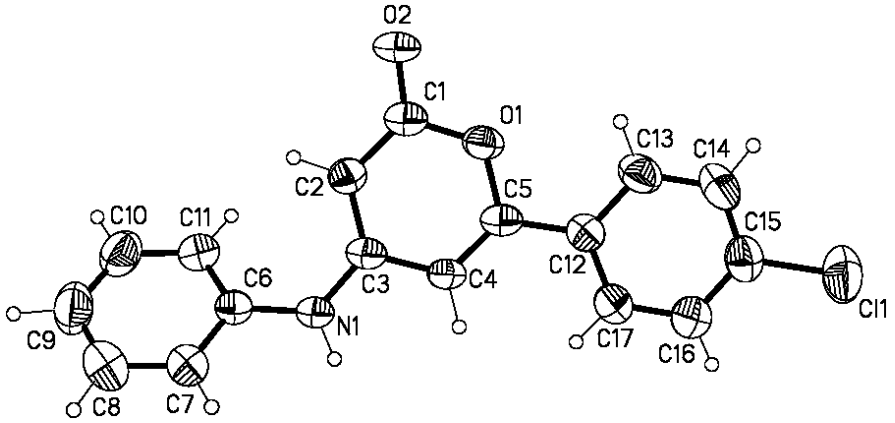
Fig. 2. Thermal ellipsoid plot (50% ellipsoids for non-hydrogen atoms) for **1a** ($C_{17}H_{12}ClNO_2$).



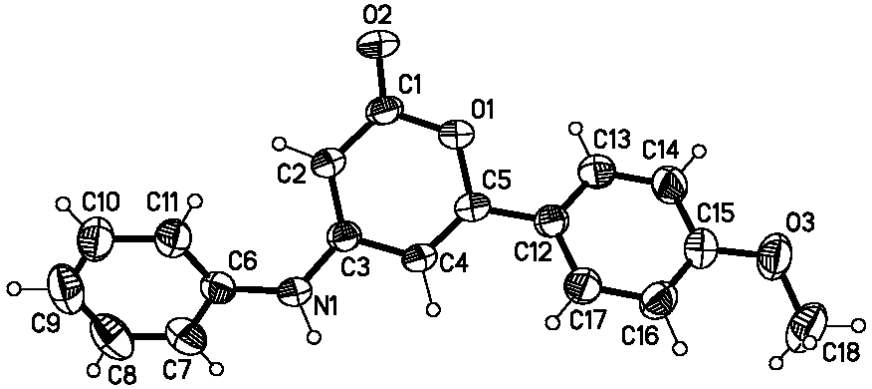


Fig. 3. Thermal ellipsoid plot (50% ellipsoids for non-hydrogen atoms) for **1b** ($C_{18}H_{15}NO_3$).

X-ray analysis for 2-pyranones **1a** and **1b** are shown in Figs. 2 and 3, respectively (14–17). Atomic positional parameters are listed in the *Supplementary material*,[3] and selected bond distances and angles are listed in the *Supplementary material*.[3] In 2-pyranone **1a**, the dihedral angles between the heterocycle ring and the phenyl ring containing C-6 is 46.2° and the phenyl ring containing C-12 is 8.4°, and in 2-pyranone **1b** the angles are 41.4° and 25.3°, respectively. Both compounds consist of hydrogen-bonded chains through the N-H group and the carbonyl oxygen atom. In 2-pyranone **1b**, adjacent molecules in the chain are related by translation, and in 2-pyranone **1a**, they are related by a *c*-glide.

Additional spectral data for 2-pyranones **1a**–**1g** were consistent with structural assignments with the following indicative absorptions: IR (cm^{-1}): NH, 3253–3275 and C=O, 1657–1673. ^{1}H NMR (ppm) δ: 5.32–5.37 (C_5-H) and 6.57–6.70 (C_3-H). ^{13}C NMR (ppm) δ: 162.3–163.5 (C=O). MS for 2-pyranone **1g**: [M + H] 360, 358, with loss of CO_2 at *m*/*z* 316 and 314.

Conclusions

This study demonstrates that trilithiated acetoacetanilides can undergo a Claisen-type condensation with benzoate esters, followed by an acid cyclization and several rearrangements to yield new 2-pyranones (**1a**–**1g**). The new synthesis of these 2-pyranones **1a**–**1g** has been developed utilizing strong-base multiple anion synthesis techniques that require an experimental set-up that is on the order of complexity required for standard Grignard syntheses, and the procedures can be reproduced by someone who is not necessarily experienced with these techniques. While the general procedure may not be under the optimal conditions for the preparation of a single compound, multigram quantities of products can be obtained, which is especially attractive for characterization, biological testing, and other uses. The syntheses are regioselective, and the products were readily purified by recrystallization from routine solvents.

Experimental section

Melting points were obtained with a Mel-Temp II melting point apparatus in open capillary tubes and are uncorrected. Fourier transform IR spectra were obtained with a Nicolet Impact 410 FT-IR or a Mattson Genesis II FT-IR with Specac Golden Gate Accessory. Proton and ^{13}C magnetic

resonance spectra were obtained with a Varian Associates Mercury Oxford 300 MHz, NMR spectrometer, and chemical shifts are recorded in δ ppm downfield from an internal tetramethylsilane (TMS) standard. Combustion analyses were performed by Quantitative Technologies, Inc., P.O. Box 470, Whitehouse, N.J. 08888, USA. The mass spectrum for 2-pyranone **1g** was acquired by nanospray ionization on an LCQ Classic quadrupole ion trap mass spectrometer (ThermoFinnigan, San Jose, Calif.).

Single crystal X-ray measurements for crystals of 2-pyranone **1a** and 2-pyranone **1b** were collected on a Mercury CCD area detector coupled with a Rigaku AFC8 diffractometer with graphite monochromated Mo Kα (λ = 0.71073 Å) radiation. The data were collected at a temperature of 20 °C to a maximum 2θ value of 52.8°. Data for 2-pyranone **1a** were collected in 0.50° oscillations in ω with 45 s exposures (two identical scans were performed at each position to identify detector anomalies) and data for 2-pyranone **1b** were collected in 0.50° oscillations in ω with 5 s exposures. A sweep of data was done using ω oscillations from –90.0 to 90.0° at χ = 45.0° and ϕ = 0.0°; a second sweep was performed using ω oscillations from –30.0 to 30.0° at χ = 45.0° and ϕ = 90.0°. The crystal-to-detector distance was 26.92 mm. The detector swing angle was 0.00°. Cell parameters and additional details of the data collection are reported in the *Supplementary material*.[3]

Of the 14 171 reflections collected for 2-pyranone **1a**, 3058 were unique (R_{int} = 0.071), and of the 7022 reflections collected for 2-pyranone **1b**, 2962 were unique (R_{int} = 0.038); equivalent reflections were merged. Data was collected, processed, and corrected for Lorentz polarization and for absorption using CrystalClear (Rigaku) (14). The structures were solved by direct methods and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically and hydrogen atoms were refined isotropically. The final cycle of full-matrix least-squares refinement on F^2 for 2-pyranone **1a** converged with R_1 = 0.0805 (2928 observed reflections ($I > 2.00\sigma(I)$), wR_2 = 0.1087 (all data). Likewise, for 2-pyranone **1b** the refinement converged with R_1 = 0.0528 (based on 2961 observed reflections ($I > 2.00\sigma(I)$), wR_2 = 0.1233 (all data). Structure solution, refinement, and the calculation of derived results were performed using the SHELXTL (15) package of computer programs. Neutral atom-scattering factors were those of Cromer and Waber (16), and the real and imaginary anomalous dispersion corrections were those of Cromer (17).

General procedure for preparation of 2*H*-pyran-2-ones (1a–1g)

(Ratio of reagents – acetoacetanilide or 4′-chloroacetoacetanilide: LDA: ester, 1:4:1)

In a typical reaction sequence, LDA (0.064 mol) was prepared by the addition of 40 mL of 1.6 mol L^{-1} *n*-butyllithium (0.064 mol) to a three-neck round-bottomed flask (e.g., 500 mL), equipped with a nitrogen inlet tube, a side-arm addition funnel (e.g., 125 mL), and a magnetic stir bar. The flask was cooled in an ice bath and 6.41 g (0.064 mol) of diisopropylamine (Aldrich Chem. Co., 99.5%), dissolved in 25–30 mL of dry tetrahydrofuran (THF) (sodium–benzophenone-ketyl), was added from the addition funnel at a fast dropwise rate during a 5 min period (0 °C, N_2). The solution was stirred at 0 °C for an additional 15–20 min, and then treated via the addition funnel with 2.67 g (0.0150 mol) acetoacetanilide (99.5%, Aldrich) or 3.24 g (0.0150 mol) of 4′-chloroacetoacetanilide (Aldrich, 98%) dissolved in 35–45 mL of THF. The addition time was 5 min. After 2.5 h of continuous stirring at 0 °C, 0.0158 mol of ester, dissolved in 25–35 mL of THF, was added to the trilithiated intermediate, and the solution was stirred for 1 h (0 °C, N_2). Then, 100 mL of 3 mol L^{-1} hydrochloric acid was added, and the two-phase mixture was poured into a large flask containing ice (ca., 100 g) followed by 100 mL of solvent grade ether. The mixture was then neutralized with solid sodium bicarbonate and the layers separated, extracted with ether (2 × 75 mL), and the organic layer was concentrated using a rotary evaporator. The crude material, usually solid, was cyclized using 150 mL of toluene, 15 drops of methanesulfonic acid (70%), and a water trap. The mixture, and then solution, was heated under reflux for 2 h with good stirring during the last step. The solution could then be transferred to a beaker and allowed to evaporate in a hood, or the toluene could be removed with a rotary evaporator.

*6-(4-Chlorophenyl)-4-(phenylamino)-2*H*-pyran-2-one (1a)*

Pyranone **1a** was prepared by the general polylithiation–condensation–cyclization–rearrangements procedure from trilithiated acetoacetanilide and methyl 4-chlorobenzoate, and yielded 3.20 g (68%), mp 305–307 °C (benzene–ethanol). IR (cm^{-1}): 3253, 3195, and 1658. ^{1}H NMR (DMSO-d_6) δ: 5.34 (s, 1H, C_5-H), 6.70 (s, 1H, C_3-H), 7.18–7.29, 7.41–7.46, 7.59–7.62, 7.77–7.80 (m, 9H, ArH), and 9.45 (s, 1H, NH). ^{13}C NMR (DMSO-d_6) δ: 83.1, 98.3, 123.3, 125.6, 127.7, 129.9, 130.2, 131.0, 136.0, 138.9, 156.0, 158.1, and 163.0. Anal. calcd. for $C_{17}H_{12}ClNO_2$: C 68.58, H 4.06, N 4.70; found: C 68.44, H 4.21, N 4.88.

*6-(4-Methoxyphenyl)-4-(phenylamino)-2*H*-pyran-2-one (1b)*

Pyranone **1b** was prepared by the general polylithiation–condensation–cyclization–rearrangements procedure from trilithiated acetoacetanilide and methyl 4-methoxybenzoate and yielded 1.76 g (40%), mp 238–240 °C (benzene–ethanol). IR (paraffin oil) (cm^{-1}): 3271, 3197, 1668. ^{1}H NMR (DMSO-d_6) δ: 3.81 (s, 3H, OCH_3), 5.27 (s, 1H, C_5-H), 6.57 (s, 1H, C_3-H), 7.06–7.27, 7.39–7.44, 7.68–7.71 (m, 9H, ArH), and 9.36 (s, 1H, NH). ^{13}C NMR (DMSO-d_6) δ: 56.1, 82.3, 96.2, 115.2, 123.2, 124.5, 125.5, 127.6, 130.2, 139.1, 156.3, 159.5, 161.9, and 163.5. Anal. calcd. for $C_{18}H_{15}NO_3$: C 73.71, H 5.15, N 4.78; found: C 73.37, H 5.13, N 4.58.

*4-(4-Chlorophenylamino)-6-(3,5-dimethoxyphenyl)-2*H*-pyran-2-one (1c)*

Pyranone **1c** was prepared by the general polylithiation–condensation–cyclization–rearrangements procedure from trilithiated 4′-chloroacetoacetanilide and methyl 3,4-dimethoxybenzoate and yielded 1.23 g (23%), mp 258–260 °C (benzene–ethanol). IR (paraffin oil) (cm^{-1}): 3263, 3188, 1667. ^{1}H NMR (DMSO-d_6) δ: 3.79 (s, 6H, OCH_3), 5.35 (s, 1H, C_5-H), 6.64 (s, 1H, C_3-H), 6.85 (s, 3H, ArH), 7.28 (d, 2H, ArH), and 7.45 (d, 2H, ArH), and 9.44 (s, 1H, NH). ^{13}C NMR (DMSO-d_6) δ: 56.2, 98.5, 103.4, 103.9, 121.9, 124.7, 130.1, 134.1, 138.1, 155.7, 159.1, 161.5, and

*6-(4-Chlorophenyl)-4-(4-chlorophenylamino)-2*H*-pyran-2-one (1d)*

Pyranone **1d** was prepared by the general polylithiation–condensation–cyclization–rearrangements procedure from trilithiated 4′-chloroacetoacetanilide and methyl 4-chlorobenzoate and yielded 1.20 g (24%), mp 294–297 °C (benzene–ethanol). IR (paraffin oil) (cm^{-1}): 3263, 3181, 1673. ^{1}H NMR (DMSO-d_6) δ: 5.37 (s, 1H, C_5-H), 6.70 (s, 1H, C_3-H), 7.31 (d, 2H, ArH), 7.49 (d, 2H, ArH), 7.61 (d, 2H, ArH), 7.80 (d, 2H, ArH), and 9.50 (s, 1H, NH). ^{13}C NMR (DMSO-d_6) δ: 83.1, 97.5, 124.2, 127.1, 128.6, 129.3, 129.5, 130.2, 135.4, 137.4, 155.1, 157.6, and 162.3. Anal. calcd. for $C_{17}H_{11}Cl_2NO_2$: C 61.47, H 3.34, N 4.22; found: C 61.27, H 3.32, N 4.11.

*4-(4-Chlorophenylamino)-6-(4-methoxyphenyl)-2*H*-pyran-2-one (1e)*

Pyranone **1e** was prepared by the general polylithiation–condensation–cyclization–rearrangements procedure from trilithiated 4′-chloroacetoacetanilide and methyl 4-methoxybenzoate and yielded 2.46 g (50%), mp 282–285 °C (benzene–ethanol). IR (paraffin oil) (cm^{-1}): 3275, 3194, 1666. ^{1}H NMR (DMSO-d_6) δ: 3.83 (s, 3H, OCH_3), 5.32 (s, 1H, C_5-H), 6.58 (s, 1H, C_3-H), 7.08 (d, 2H, ArH), 7.31 (d, 2H, ArH), 7.47 (d, 2H, ArH), 7.72 (d, 2H, ArH), and 9.42 (s, 1H, NH). ^{13}C NMR (DMSO-d_6) δ: 55.4, 82.2, 95.4, 114.6, 123.7, 124.1, 126.9, 128.4, 129.4, 137.5, 155.4, 158.9, 161.2, and 162.6. Anal. calcd. for $C_{18}H_{14}ClNO_3$: C 65.96, H 4.31, N, 4.27; found: C 65.75, H 4.46, N 4.04.

*6-(4-Bromophenyl)-4-(4-chlorophenylamino)-2*H*-pyran-2-one (1f)*

Pyranone **1f** was prepared by the general polylithiation–condensation–cyclization–rearrangements procedure from trilithiated 4′-chloroacetoacetanilide and methyl 4-bromobenzoate and yielded 3.67 g (65%), mp 294–296° (benzene–ethanol). IR (cm^{-1}): 3261, 3183, 1658. ^{1}H NMR (DMSO-d_6) δ: 5.36 (s, 1H, C_5-H), 6.70 (s, 1H, C_3-H), 7.28–7.31, 7.45–7.48, 7.69–7.75 (m, 8H, ArH), and 9.48 (s, 1H, NH). ^{13}C NMR (DMSO-d_6) δ: 83.1, 97.5, 124.2, 124.3, 127.2, 128.7, 129.5, 130.6, 132.2, 137.4, 155.1, 157.7, and 162.3. Anal. calcd for $C_{17}H_{11}BrClNO_2$: C 54.21, H 2.94, N 3.72; found: C 54.05, H 3.09, N 3.60.

*4-(4-Chlorophenylamino)-6-(3,4-dimethoxyphenyl)-2*H*-pyran-2-one (1g)*

Pyranone **1g** was prepared by the general polylithiation–condensation–cyclization–rearrangements procedure from trilithiated 4′-chloroacetoacetanilide and methyl 3,4-dimethoxybenzoate and yielded 2.73 g (51%), mp 262–264 °C (benzene–ethanol). IR (cm^{-1}): 3264, 3188, and 1657. ^{1}H NMR (DMSO-d_6) δ: 3.81 (s, 3H, OCH_3), 3.83 (s, 3H, OCH_3), 5.32 (s, 1H, C_5-H), 6.59 (s, 1H, C_3-H), 7.09 (d, 2H, ArH), 7.24–7.46 (m, 5H, ArH), and 9.38 (s, 1H, NH). ^{13}C NMR (DMSO-d_6) δ: 56.3, 56.4, 82.9, 96.6, 108.9, 112.6, 119.3, 124.6, 124.7, 129.1, 130.1, 138.3, 149.6, 151.7, 156.0, 159.6, and 163.4. MS: [M + H] 360, 358, 316, 314; [M + H – 44 (CO_2)] 205, 157, 155. Anal. calcd. for $C_{19}H_{16}ClNO_4$: C 63.78, H 4.51, N 3.91; found: C 64.24, H 4.47, N 3.68.

Gerhard Herzberg — A personal appreciation[1]

G. Winnewisser

Abstract: Some important contributions of Gerhard Herzberg to molecular astronomy and the study of free radicals are highlighted and placed in the context of the history of spectroscopy.

Key words: molecular spectroscopy, free radicals, methylene, interstellar lines.

Résumé : On met en relief quelques-unes des contributions de Gerhard Herzberg à l'astronomie moléculaire ainsi qu'à l'étude des radicaux et on les place dans le contexte de l'histoire de la spectroscopie.

Mots clés : spectroscopie moléculaire, radicaux libres, méthylène, raies interstellaires.

[Traduit par la Rédaction]

Introduction

The great contributions of Gerhard Herzberg to molecular science illustrate that spectroscopy advances quite often through significant, even monumental, individual achievements. Herzberg's long scientific life and his strong interaction with science demonstrate this in many ways.

It is most fitting to commemorate Gerhard Herzberg's 100th birthday in pausing for a moment and looking back to the very early beginnings of spectroscopy. Gerhard's birthday on Christmas Day 1904 happens to fall approximately half way between the 1814 recording of the first Fraunhofer lines in the solar spectrum, and the present time. Thus, it arbitrarily divides the nearly 200 years of spectroscopic science into two almost equal periods. The first time interval, approximately coincident with the 19th century, one might loosely call the pre-Herzberg era of spectroscopy.

The pre-Herzberg era

This era opened in southern Germany in 1814. In Bavaria, the talented young Joseph von Fraunhofer succeeded in manufacturing high quality lenses and constructed one of the finest refractory telescopes ever built (1). He invented a heliometer and a diffraction grating for measuring the wavelength of light precisely. In addition, he acquired great skill in the manufacture of homogenous glass prisms, which reached unparalleled quality. These technical achievements, in particular his uniquely homogeneous glass prisms, gave him the edge over all his predecessors and contemporaries in dispersing light. Pointing his refracting telescope together with his "self-built spectrograph" towards the sun and some of the close by stars, he discovered that the sun's spectrum, when sufficiently dispersed, was punctuated by a large number of fine dark lines, about 700 of which he studied in great detail. He collected an atlas of these lines, naming the strongest features consecutively A, B, C, D,….

Today a few of these catalogued lines are still known to spectroscopists by the famous Fraunhofer notation, such as the sodium D-lines. Fraunhofer found that the D feature consists of two lines, which he named $D_{1,2}$. We now know that the 3*p* level of Na displays an observable fine structure, so that the transition between the 3*s* and 3*p* levels appears as a closely spaced doublet. Thus, the two Fraunhofer lines correspond to the following transitions: $D_1 = {}^2P_{1/2} - {}^2S_{1/2}$ = 5895.940 Å and $D_2 = {}^2P_{3/2} - {}^2S_{1/2}$ = 5889.973 Å.

In retrospect, the discovery that the Sun and the stars are made up of the same chemical elements as the Earth is one of the earliest and greatest achievements of spectroscopy and its first application to astronomical objects. The identification of the Fraunhofer lines was begun in the years 1859–1861 by the new methods of spectral analysis introduced by R.W. Bunsen and G.R. Kirchhoff. This correlation marked the time and place of the establishment of spectroscopy as an analytical tool with an unparalleled power to study both physical and chemical processes in the laboratory and in cosmic dimensions. The power of this new tool "spectroscopy" and its potential for future applications were recognized by Kirchhoff and Bunsen, who stated that it would open "an entirely untrodden field, stretching far beyond the limits of the Earth, or even of our solar system" and who noted the "almost inconceivable" sensitivity of spectroscopy that would lead to the detection of hitherto unknown elements (2). Indeed many new elements, such as Cs, Rb, and He, were subsequently detected by their atomic spectra, in the laboratory and in stars. A detailed understanding of the spectra and their associated energy level diagrams had to await the advent of quantum mechanics in the 1920s. With

this understanding, and subsequent technological development, the early predictions of Kirchoff and Bunsen have surely been surpassed.

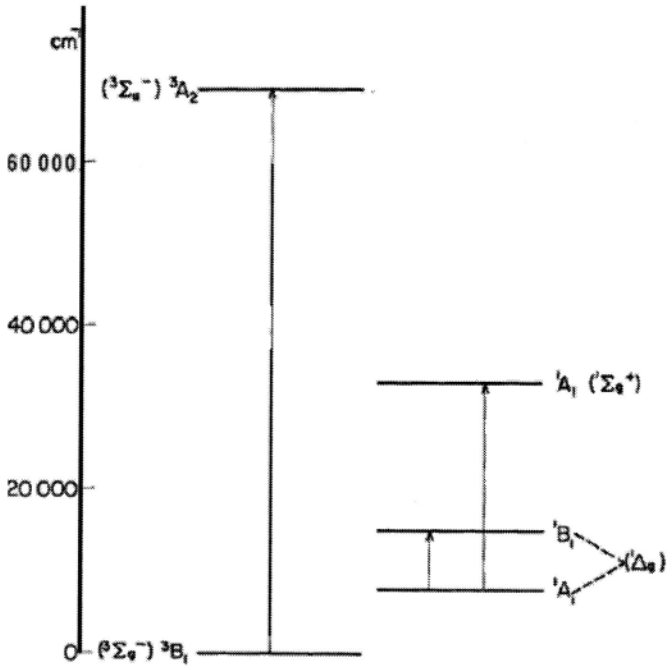
The Herzberg era and nonterrestrial molecules

It would be impossible to describe the many achievements of Gerhard Herzberg in a short appreciation (3). Late in his life, as Guest of Honour at our 1st Zermatt Meeting in 1988, GH chose to talk about the start of interstellar spectroscopy and his major role in it: "I was, however, there in that prehistoric time at the very beginning of the study of molecules in the interstellar medium which occurred in 1937. Many years before that, molecules had been identified in comets and planetary atmospheres, and even in some stellar atmospheres. In 1937, Adams and Dunham had obtained the first high resolution spectra of O and B stars. They observed a number of very sharp absorption lines in the violet, some of which they could identify as interstellar lines of a number of atoms and ions while others they had to leave unidentified. It was Swings who discovered the very first interstellar molecule, CH" (4).

GH went on in his description of the situation at that time that "Soon after Swings and Rosenfeld, Andy McKellar at Victoria identified another electronic transition of CH and in addition the well-known CN lines near 3883 Å, also on the basis of Adams and Dunham's spectra. There was left a series of four lines at 4232, 3938, 3745, and 3579 Å in Adams and Dunham's spectra that remained unidentified for another two years. In June 1941, a few of us including Swings, Beutler, Mulliken, and Teller met at an informal meeting at Yerkes Observatory to discuss this question. The structure of the observed spectrum made it certain that it was molecular in origin. Mulliken suggested CH_2 ($^1B_1$–$^1A_1$); Teller and I suggested CH^+ because of the similarity to BH. In Saskatoon, where I worked at the time, Alex Douglas and I had an apparatus available that could be used to test the assumption. Within a few days we observed a new band system whose 0–0,1–0,2–0 bands were approximately at the place of the first three unidentified interstellar lines coming from the lowest rotational level ($J = 0$). It took some time to make certain that the new spectrum was due to CH^+ since there was no isotope shift observed. The discovery of the next interstellar molecule accomplished by radio astronomical methods took place 22 years later. As you all know, 5 years after that the floodgates were opened with the discovery of interstellar NH_3 and H_2O by C.H. Townes and his associates" (4).

Gerhard Herzberg and free radicals (especially CH_2)

Throughout his entire scientific life, Gerhard Herzberg pursued an abiding interest in free radicals. As a consequence of having an open outer shell of electrons, molecular species in this class are chemically rather unstable. The citation for his 1971 Nobel Prize in Chemistry reads: "for contribution to the knowledge of electronic structures and geometry of molecules, especially free radicals" and implies that the Prize had been awarded for a long series of studies extending virtually over his entire scientific life (5).



Due to one or more free electrons, molecular free radicals have a strong tendency to form more stable, larger molecules. In interstellar molecular clouds, gas-phase free-radicals are particularly abundant. In particular, the triatomic and very light methylene radical (CH_2) is a prime constituent in gas-phase chemical models of both diffuse and dense interstellar clouds, where it is produced early in the sequence of ion–molecule reactions. The appropriate processes have been summarized in our following paper (6) in this issue of *Can. J. Chem.*

The methylene radical was very early subjected to Gerhard's scrutiny: "While in Saskatoon I had tried to obtain the spectrum of CH_2" (7). In 1942, when he started to measure the electronic spectra of free radicals, he thought that he had produced methylene by discharging methane (CH_4). But the photographed UV-spectrum always fell short of showing traces of the CH_2 spectrum. One other experiment, intended to prove the presence of CH_2 in such a discharge, was to discharge fully deuterated methane (CD_4) and observe the CDH and CD_2 isotopomers with the appropriate isotope shifts. But this latter experiment produced the identical spectrum as did the CH_4 gas discharge. What a surprise! Since there was no isotope shift observed, Herzberg finally concluded that they had produced the radical C_3, which has recently been discovered in space and has been precisely measured in the laboratory. Indeed, the C_3 molecule is now considered to be essential in forming larger carbon chain species. Our KOSMA laboratory has produced various carbon chain clusters, such as C_{10} and others.

It became clear to Gerhard that the methylene spectrum would not reveal itself quickly. In reality, it took GH many more years than anticipated before he could overcome the substantial difficulties that beset the measurement of the methylene spectrum. But finally his determination and devotion prevailed. "It was ten years after I came to Ottawa and 17 years after the first experiments in Saskatoon that I finally observed the absorption spectrum of CH_2 in the vacuum ultraviolet. … Before CH_2 was found, the CH_3 radical was observed with much less difficulty" (7). It was Herzberg and Shoosmith (8) who found "the first true spectrum" of CH_2 as a prominent feature in the extreme UV region at 1415 Å. This spectral feature actually did shift when hydrogen was replaced by deuterium. Detailed analysis of the 1415 Å spectrum revealed the structural parameters of the CH_2 molecule. After initial uncertainty about whether the molecule was linear or bent, it was realized that it may be considered quasilinear, or just barely bent, and the electronic ground state was determined to be of $^3B_1$ symmetry. The geometrical structure is similar to water (H_2O) with a C—H bond distance of 1.071 Å but with a much wider HCH angle of about 140° (9). Indeed, the structure cannot be properly described independently of the electronic potential functions for the lowest electronic states. In his Nobel lecture (5) Gerhard discussed some of the details of finally securing beyond any doubt the unusual energy level diagram of the observed electronic states of CH_2. We reproduce his energy level diagram in Fig. 1 to honor the results, representing significant progress, which could only be achieved by tremenduous devotion and endurence. A problem that may

Fig. 1. Observed electronic states of CH_2.

look deceivingly simple from today's standpoint of knowledge may have posed a quite different challenge when faced for the first time. As Gerhard admitted in his Nobel lecture, "… of course the spectrum of CH_2 has given me a great deal of pleasure…".

The CH_2 radical turned out to be one of those molecular species that display spectra that are extremely difficult to analyze. And for methylene this holds true for all wavelength regions, from the UV through the visible spectrum clear down into the IR and on to the pure rotational spectrum. In the early eighties, the spectroscopy group at NRC Ottawa, led by Bunker and McKellar with support from Jensen (theoretical) and Sears (mainly experimental), pushed ahead with LMR techniques to detect and disentangle the hitherto unknown IR spectrum. We are presently investigating the last, rotational, part of the CH_2 spectrum, trying to measure it very precisely and understand it in detail. In our contribution to this volume, we describe our progress on the high-resolution rotational spectrum of CH_2 in its vibrational and electronic ground state. Based on technical developments at Cologne University (10, 11), it has now become possible with the introduction of terahertz techniques to measure the pure rotational transitions at Doppler resolution and thus with very high accuracy and sensitivity. These new data will give us further valuable information for understanding the dynamical idiosyncracies of this cosmically significant species to which GH persistently showed us the way.

A final word

Upon his return from Stockholm, as we picked him up at the Ottawa airport, I asked GH how he felt about receiving the Nobel Prize. After a short pause he answered, "I feel that my scientific life has been rewarding beyond anything that I deserve." The award did not change him at all; he remained, in his modest way, the world's foremost molecular spectroscopist and the leader in a research field of fundamental importance. His attitude to scientific work is best summarized by the following verse, written in stone over an archway at Cambridge University, and which I copied down as a young student:

Use every hour for time goes fast,
And what is now may soon be past,
A future time may never be,
The present is the time for thee!

Abstract: The methylene radical (CH_2) was very important to Gerhard Herzberg. We have carried out high-resolution spectroscopic measurements on two energetically low-lying, pure rotational transitions of methylene in its ground vibrational–electronic state at frequencies near 2 THz. One of the transitions — the $N_{KaKc} = 2_{11} \leftarrow 2_{02}$ multiplet — belongs to *ortho*-CH_2 and is centered at 1.954 THz. The other rotational transition — the $N_{KaKc} = 1_{10} \leftarrow 1_{01}$ multiplet — belongs to *para*-CH_2 and is centered at 1.915 THz. Since the ground electronic state of methylene has $^3B_1$ symmetry, the rotational transitions are split into three fine-structure components, while the ortho transitions are split additionally by hyperfine structure. In total, we have measured 29 new lines, six for the para transition and the remainder for the ortho transition. The newly measured lines can be added to high-resolution spectral data obtained by ourselves and others at lower frequencies. Progress towards a global fit is discussed.

Key words: spectroscopy, THz frequencies, radicals, methylene, interstellar medium.

Résumé : Le radical méthylène (CH_2) a été très important pour Gerhard Herzberg. On a effectué des mesures spectroscopiques à haute résolution sur deux transitions de rotation pure, de basses énergies, du méthylène dans l'état électronique–vibrationnel fondamental, à des fréquences proches de 2 THz. L'une des transitions, celle du multiplet $N_{KaKc} = 2_{11} \leftarrow 2_{02}$, appartient au CH_2 ortho et elle est centrée à 1,954 THz. L'autre transition rotationnelle, celle du multiplet $N_{KaKc} = 1_{10} \leftarrow 1_{01}$, appartient au CH_2 para et elle est centrée à 1,915 THz. Puisque l'état électronique fondamental du méthylène est de symétrie $^3B_1$, les transitions rotationnelles sont dédoublées en une structure de trois composantes alors que les transitions ortho subissent un dédoublement additionnel par une structure hyperfine. Au total, on a mesuré 29 nouvelles raies, six pour la transition para et le reste pour la transition ortho. On peut ajouter les raies nouvellement mesurées aux données spectrales obtenues par nos soins et à celles obtenues à des fréquences plus faibles par d'autres. On discute des progrès réalisés dans le développement d'un ajustement global.

Mots clés : spectroscopie, fréquences THz, radicaux, méthylène, système interstellaire.

Introduction

Gerhard Herzberg and methylene

The methylene radical (CH_2) was of great interest to Gerhard Herzberg (1). The initial attempt to discover this species in the laboratory dates back to the year 1942, when Gerhard Herzberg was first trying to study the electronic spectra of free radicals. By discharging methane (CH_4), Herzberg thought very early on that he had produced the spectrum of the free radical CH_2. But in reality, it took many more years than anticipated before the methylene radical was finally discovered. This seminal event took place "seventeen years after Herzberg's first involvement with CH_2; proving his persistence and determination to finally solve this puzzle" (1). The discovery took place when Herzberg and Shoosmith (2) located a prominent new feature on their photographic plate in the extreme UV region at 1415 Å. Although Herzberg initially thought that methylene was linear in its ground state, detailed analyses of the spectra led eventually to the assignment of the ground state as one of $^3B_1$ symmetry with a nonlinear symmetrical structure, C–H bond distances of 1.071 Å, and an H-C-H angle of 140° (3), settling another long-standing problem. According to Herzberg's Nobel lecture (4), he had spent more than 20 years determining the nature of the electronic states of this difficult radical.

Gerhard Herzberg was so interested in improving our knowledge of methylene that after his successful assignment of the ground electronic state, he soon thought in terms of studying its rotational spectrum. One of us (G. Winnewisser) was a postdoctoral associate at NRC in Ottawa during the years 1968–1970. He had recently constructed a submillimeter-wave spectrometer for the NRC, so Herzberg asked him to attempt to study methylene. The request was then regretfully de-

clined; Herzberg's requests for CH_2 microwave data were, just as the man himself, simply 25 years ahead of the time.

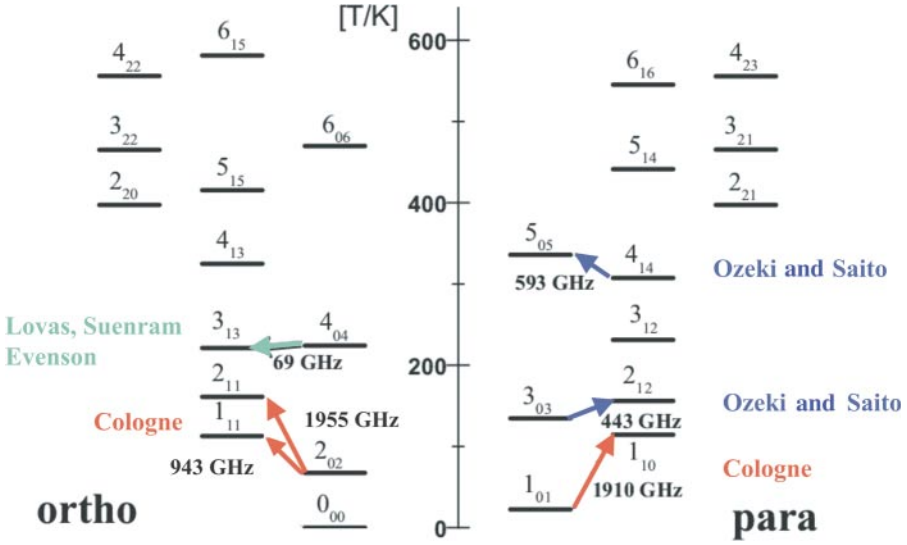
More than 10 years after Herzberg's success, work on methylene began anew. In the early eighties, there was a strong push within the spectroscopy group at NRC, led by P.R. Bunker and A.R.W. McKellar, and with the strong involvement of T.J. Sears and P. Jensen, to detect the IR spectrum of CH_2. The goal was to find vibration–rotation transitions of the ν_2 bending vibration of the radical in its $^3B_1$ electronic ground state. After much effort, the ν_2 bending vibration was finally detected using laser magnetic resonance (LMR) techniques in the wavenumber range 880–940 cm^{-1} (5). The present best numerical value for the bending frequency of CH_2 is 963 cm^{-1} (6). Although the symmetric and antisymmetric stretching vibrations (the ν_1 and ν_3 modes) remain undetected, reasonable estimates for these frequencies (2992 and 3213 cm^{-1}) are available from calculations based on the MORBID approach (6). Another push at NRC involved using the very sensitive LMR technique to study the rotational spectrum of methylene. Eventually, LMR was used to study the rotational spectrum through 6 THz in frequency (7, 8). In addition, diode laser spectroscopy was used to study five rotational transitions involving $K_a = 4 \leftarrow 3$ at frequencies near 12 THz (9).

Although the LMR technique possesses great frequency agility for the study of rotational spectra, it does not approach the accuracy of millimetre- and submillimetre-wave methods. But, the field-free rotational spectrum of methylene, a near-prolate asymmetric top with a dipole moment of 0.57 D along the intermediate *b* axis (10), has proved a difficult one to measure because of its wide-open structure due to the lightness of the radical, because of large amplitude motions, and because of both fine and hyperfine splittings. The wide spacings between most pairs of rotational levels mean that much of the rotational spectrum lies in the THz region.

The rotational energy levels of methylene are characterized by the quantum number N and the pseudo-quantum numbers K_a and K_c. The quantum number N refers to rigid-body angular momentum of the asymmetric top and replaces the normal symbol J, which is used here for the total nonnuclear angular momentum (rigid-body + electronic spin). The pseudo-quantum numbers K_a and K_c refer to the rigid-body angular momentum projection on the symmetry axes of the limiting prolate and oblate symmetric tops, respectively. Since the electronic spin quantum number $S = 1$ for CH_2 in its $^3B_1$ ground state, the values of J are N, $N + 1$, $N - 1$ for $N > 0$. Energy levels of the same N and differing J are split by fine-structure effects. In addition to the fine structure, N,J levels of *ortho*-CH_2, which possesses a total hydrogenic nuclear spin I_H of unity, are split by hyperfine effects into energy levels characterized by the total angular momentum quantum number $F = J$, $J + 1$, $J - 1$ for $J > 0$. On the other hand, the N,J levels of *para*-CH_2, where $I_H = 0$, are not split further by hyperfine effects. Given the splittings and the dipolar selection rules ($\Delta N = 0, \pm1$; $\Delta J = 0, \pm1$, $\Delta F = 0, \pm1$) rotational transitions of *ortho*- and *para*-CH_2 occur in multiplets of lines, with the components for the ortho form much more numerous and closely spaced. For *ortho*-CH_2, only rotational levels characterized by an even value for the sum $K_a + K_c$ are allowed (e.g., 4_{04} and 3_{13}), whereas for *para*-CH_2 levels, the sum must be odd. The allowed changes in these two pseudo-quantum numbers for *b*-type transitions are $\Delta K_a = \pm1, \pm3\ldots$, $\Delta K_c = \pm1, \pm3\ldots$.

Lovas et al. (11) were the first to study the high-resolution rotational spectrum; they measured the multiplet of lines in the 68–71 GHz range belonging to the rather high-lying $N_{KaKc} = 4_{04} \leftarrow 3_{13}$ transition of *ortho*-CH_2. These lines were later used to detect methylene in certain regions of dense interstellar clouds known as "hot cores" (12). The work of Lovas et al. (11) was followed by studies in the submillimeter-wave region by Ozeki and Saito (13), who measured the $N_{KaKc} = 2_{12} \leftarrow 3_{03}$ and $N_{KaKc} = 5_{05} \leftarrow 4_{14}$ multiplets of *para*-CH_2 at frequencies around 440–445 GHz and 592–594 GHz, respectively. Most recently, we studied the $N_{KaKc} = 1_{11} \leftarrow 2_{02}$ rotational transition of *ortho*-CH_2 in the 931–956 GHz range, inaugurating the study of its THz spectrum at high resolution (14). A global data set consisting of all of the high-resolution spectral transitions was fit to an asymmetric top, Watson-type Hamiltonian with additional fine-structure and hyperfine-structure terms.

In this paper, we report the measurement of two new rotational transitions of the methylene radical in its ground vibrational–electronic state at frequencies near 2 THz. One of the transitions — the $N_{KaKc} = 2_{11} \leftarrow 2_{02}$ multiplet of *ortho*-CH_2 — is centered at 1.954 GHz and consists of 23 detected components split by fine-structure and hyperfine effects. The other rotational transition is the $N_{KaKc} = 1_{10} \leftarrow 1_{01}$ multiplet of *para*-CH_2, which is split by fine-structure only, and is centered at 1.915 THz. Figure 1 shows the lowest lying rotational levels of methylene divided into ortho levels on the left and para levels on the right. Rotational transitions measured in the laboratory (including the present measurements) are depicted with arrows. The energy scale is in units of K, a convention favored by astronomers.



The remainder of this paper is divided as follows. First, we discuss the techniques used in the experimental measurements and show some of our spectral results. Then, we discuss the spectral assignments at 2 THz and our progress in fitting a global data set including the newly measured transitions to a standard Watson-type Hamiltonian with additional terms for fine-structure and hyperfine interactions. Progress has so far been partial only, and attempts with a nonrigid bender Hamiltonian will also be undertaken (6, 15). Afterwards, we discuss the role of methylene as an interstellar molecule. A discussion of current progress ends the paper.

Experimental measurements

For the reported measurements, the Cologne sideband spectrometer for Terahertz applications (COSSTA) was used. A detailed description of the experimental setup to generate frequencies in the range from 1.75 to 2.01 THz is given by Gendriesch et al. (16). Here we only give a short summary of the techniques employed. The basic idea of a sideband system is to mix the outputs of two sources of radiation by means of a nonlinear device such as a fast Schottky diode, and filter out the generated sum frequency, known as the upper sideband, for spectroscopy. In our laser sideband system, one radiation source is a frequency stabilized FIR laser operated at a fixed frequency. The second frequency source is a

Fig. 1. Rotational levels of *ortho*- and *para*-methylene through an energy of 600 K (1 K = 1.99 × 10^{-3} kcal mol^{-1}). Measured transitions to microwave accuracy are indicated by arrows with names of groups.

backward wave oscillator (BWO) with a tunable frequency output that is phase, and therefore, frequency stabilized (17).

A sketch of the experimental setup, found in Fig. 2, is divided into four parts: (*i*) the phase-locked BWO unit with its frequency synthesizers (left), (*ii*) the sideband mixer inside the evacuated optics box (center), (*iii*) the optically pumped difluoromethane FIR laser system (lower right), and (*iv*) the cooled discharge cell with the major components necessary for efficient methylene production (upper right). The laser system is stabilized to the 15th harmonic of a 108 GHz Gunn oscillator followed by a THz quasi-optical harmonic mixer. The resulting IF is processed with an analog frequency demodulator to derive a sensitive control signal for the CO_2 laser stabilization, and hence for the FIR laser.

Sideband radiation is generated by mixing the output radiation of a phase-stabilized BWO with frequency-stabilized radiation of the FIR ring laser on a whisker-contacted, low-capacitance Schottky diode. The FIR laser system operates at a fixed frequency of 1.626 THz. Since the BWOs used can be continuously tuned within a frequency range from ~130 to 390 GHz, the produced upper sideband radiation (at a frequency given by the sum of BWO and FIR-laser frequency) covers a frequency region from 1.75 to 2.01 THz. The frequency stability of the whole system is determined by the loop error of the AFC (automatic frequency control). The error was measured to be less than 5 kHz.

The CH_2 was generated in two steps. First, commercially available diketene was pyrolyzed through quartz wool at 650 °C over a length of 20 cm to form ketene. The pure ketene was then discharged in a DC glow discharge at 40 mA and 50–80 μbar (1 bar = 100 kPa). The active region was ~80 cm with a cell diameter of 10 cm and could be cooled down to 170 K by a LN2-flowing copper jacket.

As in our previous work (14), fast square-wave Zeeman modulation was used to detect the CH_2 lines; the technique was adapted for the first time with the Cologne sideband spectrometer. For this purpose, a copper wire coil, able to withstand 30 A current, was attached surrounding the glass cell over the whole discharge length. An axial magnetic field with B_{max} = 2 to 3 G and a modulation frequency of 4.3 kHz could then be applied.

To shield the background earth magnetic field of 300–500 mG, a box of high permeable mu-metal (1mm thick) was constructed to cover the entire discharge region of the absorption cell. The residual magnetic field was measured to be below 10 mG. Special attention was paid to minimize induced eddy currents inside the shielding box that arise from the Zeeman modulation and may cause field inhomogeneities.

Table 1 contains the measured frequencies of the newly studied lines in MHz along with their quantum assignments and the uncertainties (one standard deviation) in the measured frequencies. Assignments with asterisks next to them are to be regarded as doubtful. The measurement uncertainties are typically 200 kHz for the components of the 1_{10}–1_{01} transition of *para*-CH_2 and 200–500 kHz for the corresponding components of the 2_{11}–2_{02} transition of *ortho*-CH_2. The largest uncertainties arise from the weakness of some transitions and the overlapping of lines. These transitions were nonetheless included since the available rotational data for methylene are so sparse. Figure 3 shows the actual measured hyperfine structure for the $J = 3 \leftarrow 3$ fine-structure component of the 2_{11}–2_{02} transition in the region 1954.910–1954.930 GHz, while Fig. 4 shows a stick spectrum with the complete fine-structure, hyperfine pattern for this rotational transition, which occurs over a much wider region between 1943 and 1964 GHz. Note that the assorted hyperfine-structure multiplets are designated by the letter *G* and an appropriate subscript. Figure 5 shows both the $J = 2 \leftarrow 2$ and $1 \leftarrow 0$ fine-structure components of the 1_{10}–1_{01} transition, split by more than 8 GHz, while Fig. 6 shows both the actual $J = 2 \leftarrow 2$ component and a stick spectrum of all of the fine-structure components that extend over the region between 1902 and 1926 GHz.

Spectral analysis

In our previous work on methylene, it was possible to uti-

lize a Watson-type Hamiltonian plus assorted fine-structure and hyperfine-structure terms to fit the then global rotational spectrum to experimental accuracy (14). A total of 23 lines were fit to a Hamiltonian with 15 variable parameters and seven parameters held fixed at values derived by previous authors. As can be seen, there is an unusually large number of parameters needed compared with the number of lines, a common problem for other small, light asymmetric tops such as water.

The previous fit to the spectrum of methylene (14) based on the augmented Watson Hamiltonian was used to predict the frequencies of the components for the two rotational transitions studied here to perhaps 10 MHz accuracy. A similar degree of accuracy comes from the predictions based on the LMR work of Sears et al. (8). The Hamiltonian H can be written as:

$$[1] \qquad H = H_{rot} + H_{spin-spin} + H_{spin-rot} + H_{hfs}$$

where the first term consists of the rigid-body and centrifugal distortion contributions (18), the second and third terms comprise the fine-structure interactions, and the last term represents the hyperfine contribution. For a light and floppy species such as CH_2, the centrifugal distortion is appreciably large and cannot be neglected. The fine-structure terms arise from the electron spin–spin interaction, and the interaction of the electron spin with the rigid-body rotation of the molecule. As with the fine structure, there are two contributions to the hyperfine term, both of which have to do with the interaction among the electronic and nuclear spins. One term represents the so-called Fermi-contact interaction, while the second represents the dipole–dipole interaction. Matrix elements were derived for the Hamiltonian in the coupling scheme $\mathbf{J} = \mathbf{N} + \mathbf{S}$, $\mathbf{F} = \mathbf{J} + \mathbf{I_H}$, $\mathbf{I_H} = \mathbf{I_{H(1)}} + \mathbf{I_{H(2)}}$. More detail on the various terms in the Hamiltonian and the procedure used to fit and predict the spectrum can be found in our previous publication (14).

A global data set comprising the previously measured transitions and those reported here was fit to the Hamiltonian discussed above. Based on this information, Figs. 7 and

Note: The asterisks represent lines for which the assignment is ambiguous.

[a]The numbers in parentheses represent experimental uncertainties (one standard deviation) in terms of the right-most significant figures.

8 summarize how the rotational levels for the $1_{10}–1_{01}$ transition are split and shifted by fine-structure interactions and for the $2_{11}–2_{02}$ transition by both fine- and hyperfine-structure interactions. Although the qualitative aspects of the figures are certainly correct, the detailed numbers must be taken with caution since they may not be accurate to the 1 MHz level depicted. The current status of the fit *as it pertains to the newly measured transitions* is that the individual components show observed – calculated deviations from a low of 0.1 MHz to a high of 8 MHz, the latter far greater than the experimental uncertainty. For the fine-structure components of the $1_{10}–1_{01}$ transition of *para*-CH_2, the separation is sufficiently great that the assignments are unambiguous. But, for the $2_{11}–2_{02}$ transition of *ortho*-CH_2, the hyperfine components of each group G_i of lines can lie sufficiently close together so as to leave the assignment ambiguous. For such lines, Table 1 contains an asterisk next to the measured frequency. Currently, eight out of the 23 measured components of this rotational transition lie in this category.

Interstellar importance

Almost four decades after its original detection in the laboratory, CH_2 was finally detected in emission in the interstellar medium by Hollis et al. (12), based on the *ortho*-CH_2 rotational transition $N_{KaKc} = 4_{04} \leftarrow 3_{13}$ at 68–71 GHz, previously studied in the laboratory in absorption by Lovas et al. (11). As can be seen in Fig. 1, the upper level of this rotational transition lies at an excitation of approximately 240 K, which means that for collisional excitation to populate it appreciably, the temperature of the medium has to be comparable. Dense interstellar clouds are mainly colder than this, with kinetic temperatures in the region 10–50 K, but exceptions are found in regions associated with star formation. When high-mass stars are formed, there is enough energy to heat surrounding regions to 300 K and even beyond. It is in two such regions, labelled hot cores by astronomers, that Hollis et al. found methylene.

According to chemical models of interstellar gas (19), however, the methylene radical should be an ubiquitous tracer of colder interstellar gas. To detect CH_2 in colder gas requires lower-lying upper states, which tend, however, to be associated with transitions that possess frequencies in the THz region of the spectrum. For example, the lowest-lying emitting level of *ortho*-CH_2 is the 1_{11} level, which lies at little over 100 K above the ground. This level can emit to either the 2_{02} level, at frequencies around 943 GHz, measured by us previously (13), or to the ground 0_{00} level, at frequencies around 2345 GHz (8). For *para*-CH_2, the lowest emitting level is the 1_{10} level, which also lies at an excitation of little more than 100 K. This level can emit to the ground state of *para*-CH_2 at the frequencies reported here, in the vicinity of 1910 GHz.

Transitions that occur at frequencies in the submillimeter-wave region cannot easily be measured from the ground because of the water vapor in the atmosphere of the earth. Although some ground-based facilities do exist for which strong transitions can be measured up to frequencies near 1 THz, the THz region is essentially inaccessible from the ground. For this and other reasons, astronomers have launched satellites and flown high-elevation airplanes to detect submillimeter-wave and shorter radiation from high up or above the atmosphere. Two future missions will be suited to study spectral transitions in the THz region. The project named SOFIA (http://sofia.arc.nasa.gov) will contain a telescope in a Boeing 747-SP aircraft and will have a high-resolution spectrometer in the region between 500 GHz and 4 THz. An even more sensitive telescope, named Herschel, is to be placed in orbit around the so-called L2 point of the earth–sun system (http://herschel.jpl.nasa.gov). The high-resolution THz spectrometer for Herschel, named HIFI, will operate in several bands through 1910 GHz. Detection of methylene with either of these telescopes should be achievable in cold regions of the interstellar medium if the current predictions of chemical models are accurate.

Discussion

We have chosen in part to study the molecular radical CH_2 because it played an important role in Gerhard Herzberg's scientific life. In addition, CH_2 appears to be one of the sim-

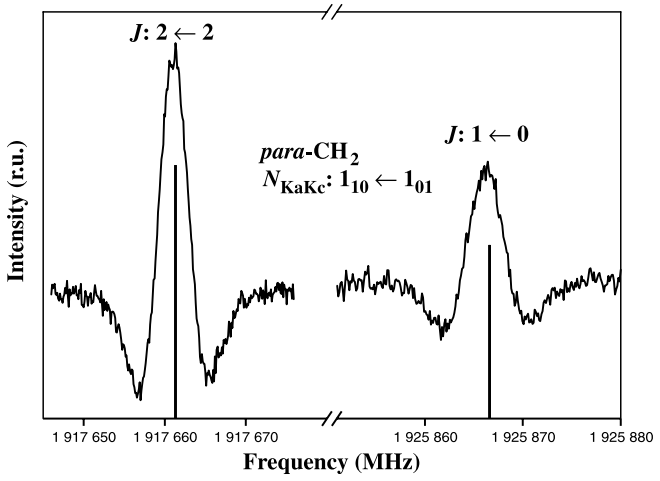

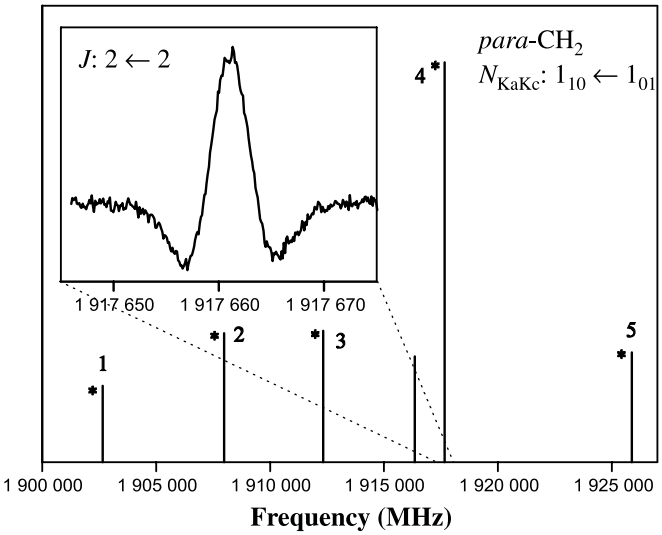

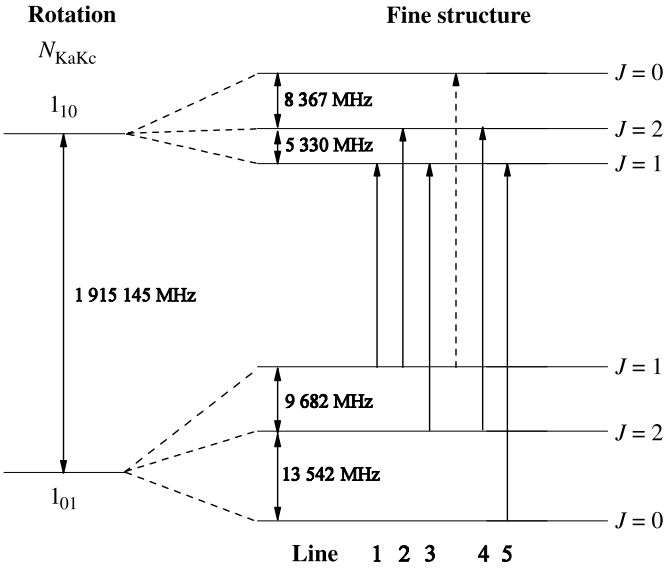

Fig. 6. A stick spectrum showing the frequencies and relative intensities of the six fine-structure components of the $1_{10} \leftarrow 1_{01}$ rotational transition of *para*-CH_2. All lines shown are measured and assigned. The actual measured spectral line designated by the number 4 (the $J = 2 \leftarrow 2$ component) is also shown.

plest free radicals in chemistry. But, the laboratory spectrum of CH_2 has proven difficult to study in all wavelength regions for a variety of reasons, including its lightness, and its intricate fine and hyperfine structure. For its rotational spectrum, CH_2 displays a perpendicular *b*-type spectrum, which is proving to be one of the most difficult to understand. One reason for the difficulty is the fact that the rotational spectrum is not confined to the rather standard microwave region, but ranges through the THz region into the far-IR! Perhaps the dominant reason for the difficulty is the fact that

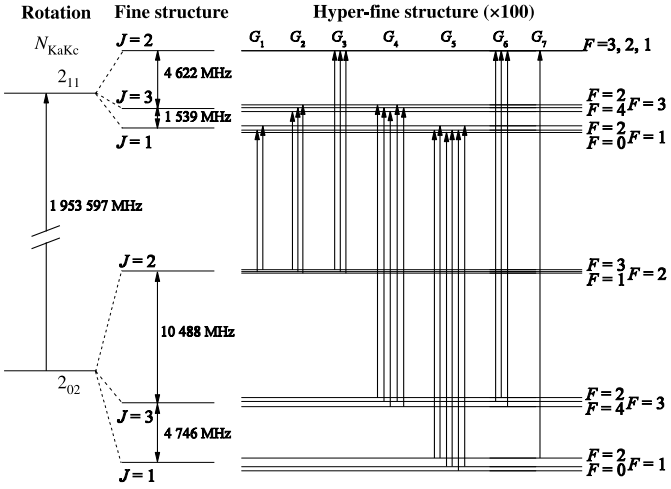
Fig. 7. Energy level diagram of the 1_{10}–1_{01} rotational transition of *para*-CH_2. The splitting of the rotational levels by fine-structure interactions is shown. The six allowed rotational-fine structure transitions, all of which have been measured, are also shown. Actual numbers shown are uncertain due to the incomplete nature of the fit to the data.



the molecule undergoes large amplitude motion so that the coordinates of the two hydrogen atoms and the carbon atom are not strictly defined. Indeed, the potential function along the appropriate coordinates is very shallow and fairly flat near the equilibrium position, lending the three atoms a restricted freedom to move around their equilibrium positions.

In the problem of large amplitude motions, methylene is not unique. The spectroscopic properties of other light asymmetric rotors such as H_2O, H_2S, NH_2 ($X\ ^2B_1$), and PH_2 ($X\ ^2B_1$), have been analyzed, in some cases with extreme difficulty, with the aid of the Watson Hamiltonian for asymmetric rotors (20–22). All of these triatomic molecules display large amplitude motions to various degrees, producing convergence problems of the angular momentum power representation for the Hamiltonian. For light molecules, higher order effects become appreciably large even at low rotational quantum numbers, because the rotational energies are already high. One is therefore forced to include into the rotational Hamiltonian high-order centrifugal distortion terms.

In this paper, we have reported our current state of progress on measuring, assigning, and fitting the pure rotational spectrum of the methylene radical (CH_2). Although we were able to fit a small number of fine- and hyperfine-split components of several rotational transitions in a previous investigation (14), addition of the newly measured lines reported here appears to exacerbate previous difficulties in fitting the global spectrum to a standard Watson-type effective Hamiltonian. At present, we can fit most of the newly measured lines that belong to the 1_{10}–1_{01} rotational transition of *para*-CH_2 at 1902–1926 GHz, and the 2_{11}–2_{02} rotational transition of *ortho*-CH_2 at 1943–1964 GHz, as part of a global fit to an accuracy good enough for assignment purposes. A significant minority of lines, however, especially those lying in closely spaced multiplets split by hyperfine effects, cannot be unambiguously assigned. Nor is the average deviation between the newly observed and calculated frequencies anywhere near experimental measurement accuracy. Indeed, some lines have observed–calculated frequencies as large as 8 MHz. The rotational, fine structure, and hyperfine structure constants obtained from fits that include our new data at 2 THz are distinctly not improved over our previous values (14).

Fig. 8. Energy level diagram of the 2_{11}–2_{02} rotational transition of *ortho*-CH_2. The splitting of the rotational levels by fine-structure and hyperfine interactions is depicted. The 23 measured components, divided into seven groups designated by G_i (i = 1–7) are also indicated. Actual numbers shown are uncertain due to the incomplete nature of the fit to the data.

To better our understanding of the spectrum, we are currently trying two alternative approaches to conventional spectroscopy. The first is the use of the Morse oscillator-rigid bender internal dynamics (MORBID) Hamiltonian (6, 15) to determine the rotational energy levels in place of the standard Watson-type Hamiltonian. The second is an Euler expansion of the rotational parameters to constrain the rotational structure, an approach that works nicely for water (23).

The MORBID approach is different from the Watsonian-type treatment of rotation–vibration states in that it provides an, in principle complete, solution of the rotation–vibration Schrödinger equation for the electronic state in question. Thus, it is possible to calculate the energies of a large number of rotation–vibration energies directly from the potential energy surface, which is represented by a parameterized analytical function, the parameter values of which are the input data for the calculation of this electronic state. Also, the potential energy parameters can be refined in fittings to experimental rotation–vibration data, as done by Jensen and Bunker (6), who used all extant rotation–vibration data for $\tilde{X}^3\ B_1\ CH_2$. MORBID is based on a theory first proposed by Hougen et al. (24) and designed so that it is applicable to both linear and bent triatomic molecules. Therefore, it describes well, for example, the dramatic change of the *A* rotational constant resulting from excitation of the bending vibration in the $\tilde{X}$-state of CH_2. Since *all* rotation–vibration energies of the electronic state are determined in terms of a rather small number of potential energy parameters (which

© 2004 NRC Canada

are the only parameters that can be adjusted in least-squares fittings to experimental data), the residuals observed in the fittings are generally larger by orders of magnitude than those obtained in fittings with Watsonian models. However, because of the shortcomings of the Watsonian model for light molecules with highly anharmonic potential energy surfaces, such as $\tilde{X}^3$ B_1 CH_2, the predictive power of MORBID is sometimes better than that of the Watsonian model.

Gerhard Herzberg said in his Nobel lecture "… of course the spectrum of CH_2 has given me a great deal of pleasure…" (4). His first attempts to savour it date back to 1942, and the story of its discovery is long, difficult, slow, and not yet finished. Now, more than 60 years later and despite much progress, the CH_2 problem remains with us.

CH_2 revisited[1]

Apostolos Kalemos, Thom H. Dunning, Jr., Aristides Mavridis, and James F. Harrison

Abstract: The first four states of the CH_2 molecule ($\tilde{X}^3B_1$, $\tilde{a}^1A_1$, $\tilde{b}^1A_1$, and $\tilde{c}^1A_1$) are examined using state-of-the-art ab initio methods and basis sets. The construction of potential energy curves with respect to the C + H_2 and CH + H channels provides significant clues to understanding the geometric and electronic structure of the above states. All of our numerical findings are in excellent agreement with the existing experimental data.

Key words: CH_2, MRCI, potential curves, vbL icons.

Résumé : Les quatre premiers états électroniques de la molécule CH_2 ($\tilde{X}^3B_1$, $\tilde{a}^1A_1$, $\tilde{b}^1A_1$ et $\tilde{c}^1A_1$) ont été examinés en utilisant des méthodes ab initio et à l'aide des bases les plus étendues. Des courbes d'énergie potentielle par rapport aux C + H_2 et CH + H, nous donnent des renseignements importants pour la structure géométrique et électronique de ces états. Tous nos résultats sont en excellent accord avec les valeurs expérimentales.

Mots clés : CH_2, MRCI, courbes de potentiel, icônes vbL.

Introduction

The methylene molecule continues to be of interest to experimentalists and theoreticians alike (1–121) some 70 years after Mulliken's (1) pioneering theoretical work on its structure, and 60 years after Herzberg's (2) note on the 4050 group in cometary spectra. The reasons for this interest have been detailed in several reviews (8, 21, 27, 28, 65, 67, 70).

Methylene (CH_2) is: (*i*) the basic unit for divalent carbon chemistry, (*ii*) the smallest polyatomic radical with a ground triplet state and several low-lying singlets, (*iii*) a molecule with a remarkably complex electronic spectrum, and (*iv*) small enough to be studied by sophisticated ab initio methods. As discussed by Schaefer (70) the story of methylene is the story of the coming of age of computational quantum chemistry and, indeed, methylene has become a "paradigm for quantitative theoretical chemistry". We agree whole-heartedly with this assessment and in particular with the identification of the year 1970 as the origin of the coming of age (70). When one looks back on 1970 by citing the papers published during that year, one misses part of the excitement of the times, because much was going on in the background vis-à-vis preprints and personal communications. Some hint of this is found in the Herzberg and Johns 1971 paper (16) where the authors reinterpret the vacuum UV spectrum of methylene in terms of a bent structure of the radical. The acknowledgement in this paper reads "We are much indebted to Dr. Bernheim, Dr. Wasserman, Dr. Bender, and Dr. Harrison for sending us preprints of their papers." While both the Bernheim and Wasserman papers had appeared in print by the time the Herzberg and Johns paper was published, the referenced preprints of Bender and Harrison had not. From an historical perspective it is interesting to revisit the activities of 1970 by looking at the submission dates of the various CH_2-related papers.

The first of the 1970 papers was submitted in May by Bernheim et al. (10), and was the opening salvo that something might be wrong with the widely held belief that the ground triplet state of CH_2 was linear. On the basis of ESR measurements these authors suggested that the ground state of CH_2 was indeed a triplet and was slightly bent in a xenon matrix at 4.2 K.

A few weeks later the manuscript by Bender and Schaefer (9) was received and these authors explicitly challenged experiment, declaring that "... on the basis of the present and

previous ab initio calculations and the stated numerical uncertainties, we conclude that the CH_2 ground state is nonlinear with a geometry close to r = 1.096 Å, θ = 135.1°." The previous ab initio calculations referred to were those of Foster and Boys (4) and Harrison and Allen (8).

In the ensuing month of July 1970, Harrison (13) submitted a manuscript describing an ab initio calculation of the angular dependence of the zero-field splitting (ZFS) parameters (D and E) of CH_2. If one could compare the computed D, and, in particular the E parameter, to the experimental, one could provide additional evidence for the CH_2 bond angle. In the course of these calculations the bond angle of CH_2 in the $\tilde{X}^3B_1$ state was computed to be 132.5°. Noting the disagreement with Herzberg and theoretical predictions, Harrison stated: "It seems that this persistent discrepancy between theory and experiment warrants a critical evaluation of the experimental data." This was the second formal challenge, following Bender and Schaefer (9), to the accepted view that CH_2 was linear.

August passed uneventfully and in September Wasserman et al. (11) submitted a manuscript in which they challenged the status quo by suggesting that CH_2 has a bond angle of 136°, in good agreement with the theoretical values (9, 13).

October saw two submissions. The first was a theoretical study by O'Neil et al. (20) in which they calculated potential energy surfaces for seven electronic states of CH_2, and an experimental ESR study of CH_2, CD_2, and CHD by Wasserman et al. (12), who concluded that the ground triplet state of CH_2 is bent with an angle of 136°.

In November, Harrison (14) submitted a second paper focused on the geometry and electronic structure of CH_2, CHF, and CF_2 and concluded again that the CH_2 $\tilde{X}^3B_1$ angle was 132.5°.

In the following month of December 1970, Herzberg and Johns (16) submitted their reinterpretation of the CH_2 angle and noted: "The considerations given here point strongly toward the bent structure of the triplet ground ($\tilde{X}^3B_1$) state of CH_2, as suggested by the electron-spin resonance work and the ab initio calculations."

Soon afterwards three important experimental ESR papers appeared. The first was titled "^{13}C Hyperfine Interactions in CD_2" by Bernheim et al. (17), (received on 11 January 1971), concluding that the CH_2 angle was 137.7°. The second was titled "^{13}C Hyperfine Interactions and Geometry of Methylene" by Wasserman et al. (18), (received in February 1971) concluding that the angle was 136 ± 5°. The third was also from the Wasserman group (19), "Zero-Field Parameters of Free CH_2; Spin-Orbit Contributions in Xenon" (received on 14 June 1971). This report concluded that the xenon matrix has a large effect on the observed zero-field parameters of CH_2 via intermolecular spin-orbit interactions and once this is accounted for, the experimental ZFS parameters were in good agreement with the calculations of Harrison (13).

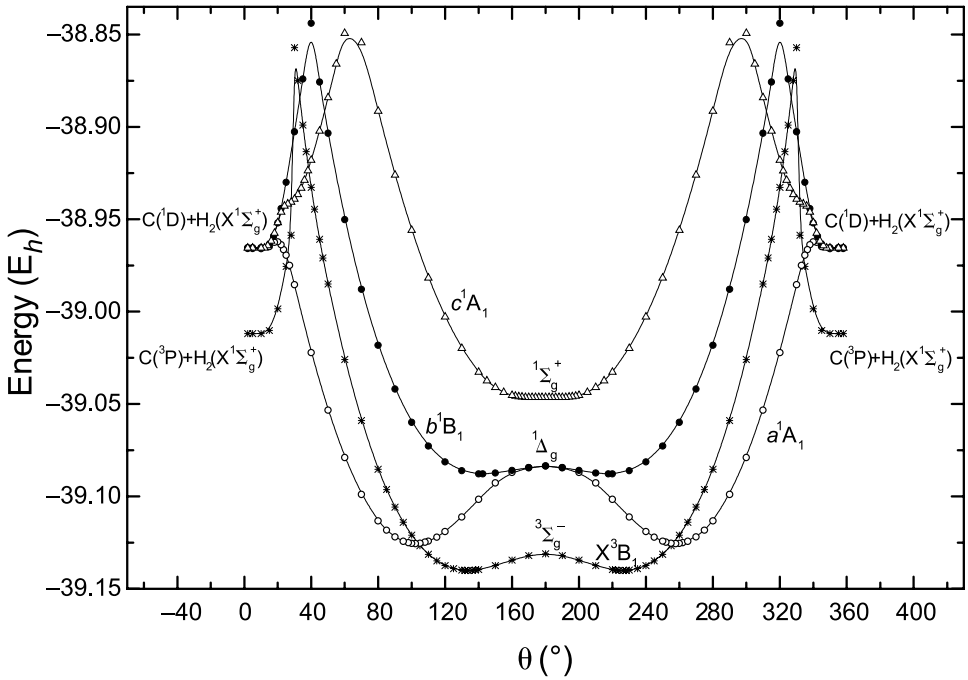
The second problem of great importance with methylene was the singlet-triplet splitting ($\tilde{a}^1A_1 \leftarrow \tilde{X}^3B_1$) and this was resolved over a longer period of time and has been discussed in the excellent reviews of Shavitt (65), Goddard (67), and Schaefer (70).

In spite of the phenomenal interest in the CH_2 molecule, truly definitive calculations on other than the lowest $\tilde{X}^3B_1$ and $\tilde{a}^1A_1$ states are rare. It is our intention to study the electronic and geometric structure of the ground and excited states of CH_2 as accurately as conventional theory will permit. To this end, we report on the first four states of CH_2 ($\tilde{X}^3B_1$, $\tilde{a}^1A_1$, $\tilde{b}^1B_1$, and $\tilde{c}^1A_1$) employing all-electron variational multireference calculations in conjunction with very large basis sets. For all states above, potential energy profiles were constructed with respect to the HĈH (= θ) angle, and to the $CH_2 \rightarrow CH + H$ channel. We believe that our interpretation, coupled with our consistent numerical results, offers a fresh view in the conceptual saga of the CH_2 molecule.

Methodology and insights

For the C atom, the doubly augmented correlation consistent polarized core-valence basis set of sextuple quality (d-aug-cc-pCV6Z, 22*s*16*p*10*d*9*f*6*g*4*h*2*i*) of Dunning and coworkers (122) was employed. The core set was that of quintuple quality basis (i.e., 4*s*4*p*3*d*2*f*1*g*). For the H atom the plain sextuple cc-basis set (10*s*5*p*4*d*3*f*2*g*1*h*) was used (123).[3] Both were generally contracted to [13*s*12*p*10*d*8*f*6*g*4*h*2*i*/$_C$ 6*s*5*p*4*d*3*f*2*g*1*h*/$_H$] resulting in 461 spherical Gaussian functions. The spherically averaged SCF energy of the ^{3}P ground state of the C atom using the above basis set is –37.688 612 E_h, just 7 μE_h above the numerical value (124).

The method of choice followed in the present work is the standard internally contracted multireference CISD, based on a full valence (2*s* + 2*p* on C and 1*s* on Hs) complete active SCF zero order wave function (CASSCF). By distributing the six valence (active) electrons in the six orbitals, the CASSCF wave functions obtained contain 51, 56, 39, and 56 configuration functions (CF) for the $\tilde{X}^3B_1$, $\tilde{a}^1A_1$, $\tilde{b}^1A_1$, and $\tilde{c}^1A_1$ states, respectively.



The CI expansion is generated by single and double replacements of all eight electrons (the ~$1s^2$ e^- of C included) out of the reference space (CASSCF(6e^-/6 orbitals) + 1 + 2 = MRCI(8e^-)) within the internally contracted ansatz as implemented in the MOLPRO package (125). The uncontracted MRCI expansions comprise 27.5 × 10^6 ($\tilde{X}^3B_1$), 18.3 × 10^6 ($\tilde{a}^1A_1$, $\tilde{c}^1A_1$), 15.9 × 10^6 ($\tilde{b}^1B_1$) CFs, reduced to about 1.3 × 10^6 CFs in the internally contracted approximation.

Due to the extended basis sets used no corrections for basis set superposition errors (BSSE) were considered. Size non-extensivity errors are reasonably small: at the MRCI level non-extensivity with respect to C(^{3}P; ^{1}D) + $H_2(X^1\sum_g^+)$ amounts to 1.59, 1.43, 1.42, and 1.42 mE_h for the $\tilde{X}^3B_1$,

[3] Basis sets were obtained from the Extensible computational chemistry environment basis set database, version 6/19/03, as developed and distributed by the Molecular Science Computing Facility, Environmental and Molecular Sciences Laboratory which is part of the Pacific Northwest Laboratory, PO Box 999, Richland, Washington 99352, USA, and funded by the US Department of Energy. The Pacific Northwest Laboratory is a multiprogram laboratory operated by Battelle Memorial Institute for the US Department of Energy under contract DE–AC06–76RLO 1830. Contact David Feller or Karen Schuchardt for further information.

Fig. 1. Potential energy profiles of the $\tilde{X}^3B_1$, $\tilde{a}^1A_1$, $\tilde{b}^1B_1$, and $\tilde{c}^1A_1$ CH_2 states at the all-electron MRCI level along the HĈH bending mode.

$\tilde{a}^1A_1$, $\tilde{b}^1B_1$, and $\tilde{c}^1A_1$ states, respectively. Restricted coupled cluster singles and doubles with perturbative triples computations (RCCSD(T)) were also performed for the $\tilde{X}^3B_1$ state around the equilibrium geometry.

For the first four states of the CH_2 molecule studied in the present work ($\tilde{X}^3B_1$, $\tilde{a}^1A_1$, $\tilde{b}^1B_1$, and $\tilde{c}^1A_1$) in ascending energy order, two obvious channels of formation can be considered, C + H_2 → CH_2 or H + CH → CH_2. In detail,

[1*a*] $CH_2(\tilde{X}^3B_1) \xrightarrow{C_{2v}} C(2p_z^1 2p_x^1; {}^3P) + H_2(X^1\Sigma_g^+)$

↓

[1*b*] $HCH(^3\Sigma_g^-) \xrightarrow{C_{\infty v}} CH(a^4\Sigma^-) + H(^2S)$

[2*a*] $HCH(^1\Delta_g) \xrightarrow{C_{2v}} CH_2(\tilde{a}^1A_1) \xrightarrow{C_{2v}}$

$C[1/\sqrt{2}(2p_z^2 - 2p_y^2); {}^1D] + H_2(X^1\Sigma_g^+) \xrightarrow{C_{2v}}$

$CH_2(\tilde{b}^1B_1) \xrightarrow{C_{2v}} C(2p_z^1 2\bar{p}_x^1; {}^1D) + H_2(X^1\Sigma_g^+)$

↓

[2*b*] $\xrightarrow{C_{\infty v}} CH(A^2\Delta) + H(^2S)$

[3*a*] $CH_2(\tilde{c}^1A_1) \xrightarrow{C_{2v}} C\{1/\sqrt{6}[2(2p_z^2) - 2p_x^2 - 2p_y^2]; {}^1D\} + H_2(X^1\Sigma_g^+)$

↓

[3*b*] $HCH(^1\Sigma_g^+) \xrightarrow{C_{\infty v}} CH(C^2\Sigma^+) + H(^2S)$

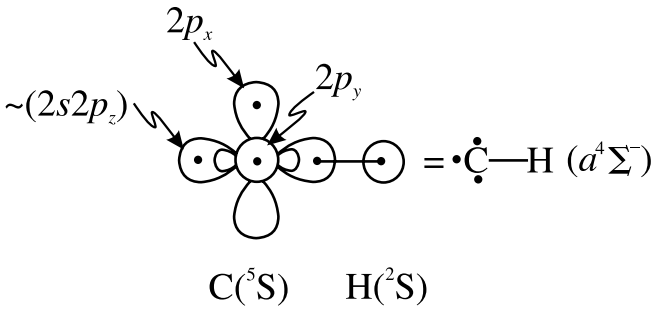
Two sets of fully optimized potential energy curves have been constructed at the all-electron MRCI level; one along the bending coordinate HĈH = θ (eqs. [1*a*], [2*a*], and [3*a*]), and a second one along the asymmetric CH + H dissociation mode (eqs. [1*b*], [2*b*], and [3*b*]) (Figs. 1 and 2). For the first set of curves, the C—H bond distance was optimized for each angle (HĈH); for the second set of curves HĈH = 180° and the C—H bond distances were optimized for each HC-H separation.

Results and discussion

Table 1 lists the most recent and reliable theoretical and experimental results of the literature on the first four states of the CH_2 carbene pertaining to the present work, while Tables 2 and 3 refer to this work. Figures 1 and 2 depict potential energy curves with respect to the HĈH = θ angle (eqs. [1*a*], [2*a*], and [3*a*]) and to the HCH → CH + H dissociation channel (eqs. [1*b*], [2*b*], and [3*b*]).

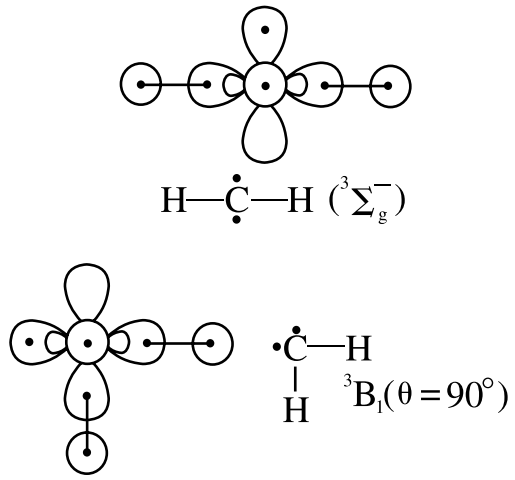
$\tilde{X}^3B_1$

The leading CASSCF configuration is



$$\left|\tilde{X}^3B_1\right\rangle \sim 0.99\left|1a_1^2\ 2a_1^2 3a_1^1\ 1b_1^1\ 1b_2^2\right\rangle$$

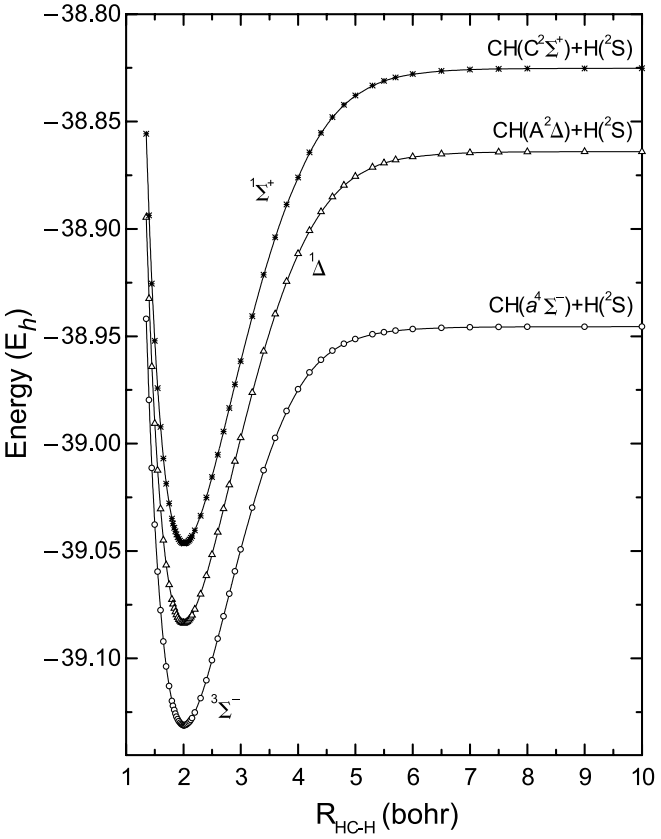
where $1a_1 \sim 1s_C$, $2a_1 \sim 0.79(2s)_C + 0.20(2p_z)_C + 0.73(1s_A + 1s_B)_H$, $3a_1 \sim 0.38(2s)_C - 0.85(2p_z)_C - 0.29(1s_A + 1s_B)_H$, $1b_1 \sim (2p_x)_C$, $1b_2 \sim 0.70(2p_y)_C + 0.93(1s_A - 1s_B)_H$ with corresponding CASSCF atomic Mulliken populations (C/H) ($1s^{2.0}2s^{1.38}2p_z^{0.90}2p_x^{0.98}2p_y^{1.03}/1s^{0.80}2p^{0.03}$).



The analogous distributions of the $a^4\Sigma^-$ CH diatomic at the same level of theory are ($1s^{2.0}2s^{1.42}2p_z^{0.71}2p_x^{0.98}2p_y^{0.98}$/ $1s^{0.72}2p^{0.03}$), indicating clearly the common ancestry of both species to the $^5S(2s^12p^3)$ atomic state of carbon atom.

© 2004 NRC Canada

The valence-bond Lewis (vbL) diagram of the parental CH $a^4\Sigma^-$ state (see also ref. 126)



suggests two modes of attack of the second H(^{2}S) atom to form CH_2, linear and perpendicular, (i.e., along the z and x (or y) axes) predicting in turn a linear ($^3\Sigma_g^-$) or a bent ($^3B_1(\theta = 90°)$) CH_2 ground state, respectively. Diagrammatically,

The binding energy with respect to CH($a^4\Sigma^-$) + H(^{2}S) of the $^3\Sigma_g^-$ configuration is 116.5 kcal/mol (Fig. 2), 15.9 kcal/mol *higher* than that of the bent structure at θ = 90°. The equilibrium geometry is determined by the differences in energy between binding to the ($2s$–$\lambda 2p_z$) orbital and the $2p_x$ orbital, which favors a bond angle less than 180°, and the repulsion between the CH bond pairs, which favors a bond angle greater than 90°. This may also be viewed as the vibronic interaction of the two limiting $^3\Sigma_g^-$ and $^3B_1(\theta = 90°)$ structures through a pseudo Jahn–Teller effect. The result is a final bent geometry of θ_e = 133.66° (Table 2). Remarkably enough, the arithmetic average of the angles of the two limiting structures is (180° + 90°)/2 = 135°. This analysis supports a rather low inversion barrier, which, indeed, according to our calculations is just 1982.5 cm^{-1} (= 5.668 kcal/mol).

Our geometrical results (r_e, θ_e) are in complete agreement with the most recent theoretical results of Császár et al. (121), and in excellent agreement with existing experimental numbers (Tables 1 and 2) in both RCCSD(T) and MRCI methodologies. Our predicted atomization energy (AE_e) at the RCCSD(T)[MRCI+Q] level of theory is 190.06 [189.9] kcal/mol, as compared to a mixed experimental (AE_0) (127) plus theoretical (ZPE) (121) value of AE_e = AE_0 + ZPE = 180.043 + 10.683 = 190.73 kcal/mol.

Fig. 2. Potential energy profiles of the CH + H channel at the all-electron MRCI level.

$\tilde{a}^1A_1$

The two most important configurations of the $\tilde{a}^1A_1$ state (CASSCF) are

$$\left|\tilde{a}^1A_1\right\rangle \sim \left|1a_1^2\ 2a_1^2[0.97(3a_1^2) - 0.21(1b_1^2)]1b_2^2\right\rangle$$

where the "0.21" contribution is a symmetry dictated determinant (at the linear configuration). This configuration can also be viewed as a GVB angular correlation term arising from the $2s$–$2p$ near degeneracy in the carbon atom. At θ = 180° the $\tilde{a}^1A_1$ state of CH_2 correlates to the linear $^1\Delta_g$ symmetry (Fig. 1). Returning now to the low-lying states of the CH diatomic (126), it is observed that the linear $^1\Delta_g$ structure correlates to the CH($A^2\Delta$) + H(^{2}S) fragments (Fig. 2), while the bent structure ($^1A_1$) emanates from the $X^2\Pi$ state of CH, 67.46 kcal/mol *below* the $A^2\Delta$ state (Table 3). Pictorially, the two CH states can be represented as follows (126): Mutatis mutandis with the $\tilde{X}^3B_1$ discussion, a linear and perpendicular H attack on the $A^2\Delta$ and $X^2\Pi$ states of CH is pos-

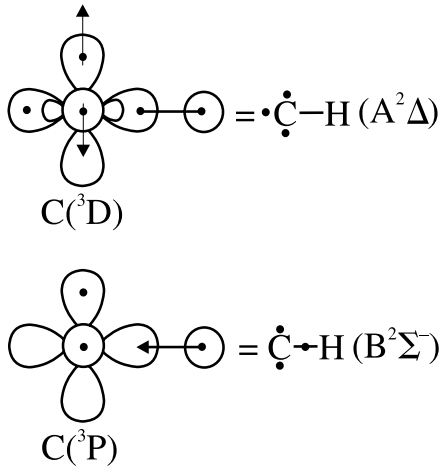
sible, resulting in the $^1\Delta_g$ and $^1A_1(\theta = 90°)$ symmetries of CH_2, or using the vbL iconal language,

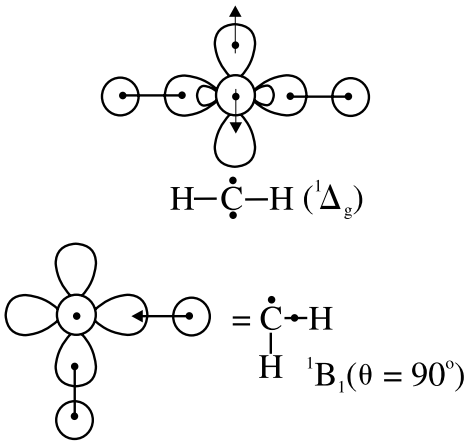
The CH-H binding energies are 94.42 kcal/mol with respect to $CH(X^2\Pi) + H(^2S)$, and 137.77 kcal/mol with respect to $CH(A^2)) + H(^2S)$ for the $^1A_1(\theta = 90°)$ and $^1\Delta_g$ symmetries, respectively (Fig. 2). The linear $^1\Delta_g$ configuration is stabilized by 137.77 – T_e(CH; $A^2\Delta \leftarrow X^2\Pi$) = 137.77 – 67.46 = 70.31 kcal/mol with respect to the ground CH state. Therefore, the bent $^1A_1(\theta = 90°)$ structure of CH_2 is favoured by 94.42 – 70.31 = 24.11 kcal/mol and mildly "relaxed" to a final angle of 102.20° ($\tilde{a}^1A_1$); see Table 2. The high energy inversion barrier of this state corresponds to the energy difference of the two limiting structures ($^1\Delta_g$, $^1A_1(\theta = 90°)$) increased by the relaxation energy $^1A_1(\theta = 90°) \rightarrow \tilde{a}^1A_1$ (θ_e = 102.20°) or IB = 67.46 – 43.35 + 2.24 = 26.35 kcal/mol (Table 2).

The geometrical values (r_e, θ_e) of Table 2 are in complete agreement with the focal point analysis of ref. 121. The $\tilde{a}^1A_1 \leftarrow \tilde{X}^3B_1$ splitting corrected for ZPE from ref. 121 is 8.822 kcal/mol as contrasted to the most recent experimental value of 8.998 ± 0.014 kcal/mol (82).



$\tilde{b}^1B_1$

The CASSCF main configuration for the $\tilde{b}^1B_1$ state is



$$\left|\tilde{b}^1B_1\right\rangle \sim 0.99 \left|1a_1^2\, 2a_1^2 3a_1^1 1\bar{b}_1^1 1b_2^2\right\rangle$$

As can be seen, this state is the open-shell singlet analog of the $\tilde{X}^3B_1$ state. As expected, the $\tilde{b}^1B_1$ molecular orbitals and Mulliken atomic distributions are very similar to those of the ground state (vide supra).

At linearity the symmetry of this state is $^1\Delta_g$; it is the Renner–Teller companion of the previously discussed $\tilde{a}^1A_1$ state (Fig. 1). The $A^2\Delta$ and $B^2\Sigma^-$ states of the diatomic CH molecule, differing in energy by 7.21 kcal/mol (Table 3), can be considered as the parental states of the $CH^2\tilde{b}\,^1B_1$ state. This is clearly seen from the following vbL diagrams:

Two modes of H attack resulting in the formation of CH_2 are conceivable: a linear attack on the $A^2\Delta$ state of CH along the z axis and a perpendicular attack on the $B^2\Sigma^-$ state along the x (or y) axis, giving rise to $^1\Delta_g$ and $^1B_1(\theta = 90°)$ CH_2 symmetries, respectively. Diagrammatically,

The binding energies of the $^1\Delta_g$ and $^1B_1(\theta = 90°)$ CH_2 configurations with respect to $CH(A^2\Delta$ or $B^2\Sigma^-) + H(^2S)$ are 137.77 and 118.86 kcal/mol, respectively (Fig. 2, Table 3). Therefore, the $^1\Delta_g$ structure is *lower* in energy by 137.77 – 118.86 + 7.21 = 26.12 kcal/mol. The pseudo Jahn–Teller interaction between the two limiting cases ($^1\Delta_g$ and $^1B_1(\theta = 90°)$) results in the $\tilde{b}^1B_1$ state with a final θ_e angle of 142.44° (Table 2), again very close to (180° + 90°)/2 = 135°. It is clear by now that everything else being equal, the inversion barrier is strongly related to the energy separation of the CH states involved, i.e., the relative low IB = 2.72 kcal/mol (Table 2) of the $\tilde{b}^1B_1$ state is related to the small CH $A^2\Delta \leftarrow B^2\Sigma^-$ splitting.

Our predicted $\tilde{b}^1B_1 \leftarrow \tilde{X}^3B_1$ separation is T_e =

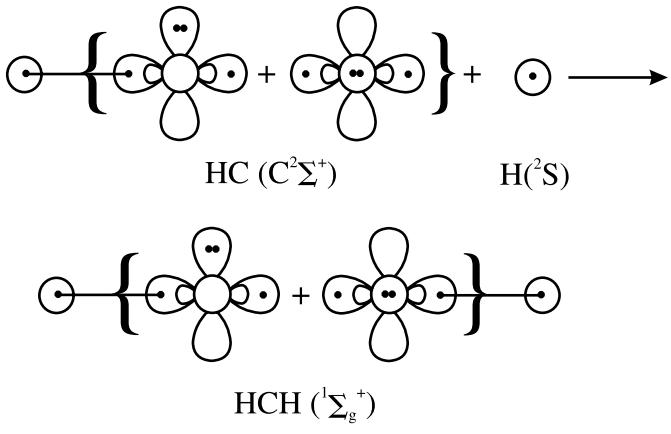
[a]r_0 and T_0 values.

32.807 kcal/mol, in excellent agreement with the best available experimental/theoretical value of 32.911 ± 0.014 kcal/mol (Tables 1 and 2).



$\tilde{c}^1A_1$

This is the highest energy state examined in the present report with a $\tilde{c}^1A_1 \leftarrow \tilde{X}^3B_1$ splitting T_e (T_0) = 58.811 (59.345) kcal/mol at the MRCI level (Table 2). Unfortunately, there are no experimental results in the literature for this state. However, there is no reason to assume that our results for $\tilde{c}^1A_1$ are any less reliable than those for the other states. So, we believe they also are of experimental accuracy.

The leading CASSCF configurations for the $\tilde{c}^1A_1$ state are

$$\left|\tilde{c}^1A_1\right\rangle \sim \left|1a_1^2\,2a_1^2[0.67(3a_1^2) + 0.73(1b_1^2)]1b_2^2\right\rangle$$

The quasilinear character of this state (θ_e = 171.92°, IB = 10.3 cm^{-1}; Table 2) is its unique feature. This structure is easily rationalized after examining its linear limiting configuration ($^1\Sigma_g^+$), which correlates to CH($C^2\Sigma^+$) + H(^{2}S) (Fig. 2). The nature of this state becomes obvious upon considering the following diagram showing the unique way that $CH_2(^1\Sigma_g^+)$ is formed from CH + H:

© 2004 NRC Canada

With no other competitive CH state available (126) the final CH_2 state is, indeed, essentially vibrationally linear with an inversion energy barrier that is close to zero.

Conclusions

Using all electron multireference calculations and large basis sets we constructed potential energy curves along the HĈH and CH + H coordinates for the four lowest states of the CH_2 system, namely $\tilde{X}^3B_1$, $\tilde{a}^1A_1$, $\tilde{b}^1B_1$, and $\tilde{c}^1A_1$. Our geometrical results, binding energies, and energy separations are in excellent agreement with existing experimental values.

Taking into account the low-lying states of the CH diatomic molecule ($X^2\Pi$, $a^4\Sigma^-$, $A^2\Delta$, $B^2\Sigma^-$, and $C^2\Sigma^+$), we can rationalize the bonding schemes and geometrical characteristics of the four states of CH_2 examined in this paper. In particular, the large range of inversion barriers to linearity (5.668, 26.355, 2.725, 0.029 kcal/mol, respectively) can be comprehended in terms of the energy splittings among the related states of the CH fragment.

The spectrum of singlet SiH_2[1]

S.N. Yurchenko, P.R. Bunker, W.P. Kraemer, and P. Jensen

Abstract: We report a theoretical study of the two lowest singlet electronic states ($\tilde{X}\,^1A_1$ and $\tilde{A}\,^1B_1$) of silylene SiH_2. These states become degenerate as a $^1\Delta_g$ state at linear configurations and are subject to the Renner effect. In ab initio calculations we have determined the potential energy and dipole moment surfaces for each state, and the transition moment surface between the states. Parameterized analytical functions have been fitted through the various sets of ab initio points, and the parameter values obtained for the potential energy surfaces have been further refined in fittings to experimental spectroscopic data. In these latter fittings, we use as input data experimentally derived energy differences together with ab initio points. In this manner, we achieve refined potential energy surfaces that behave reasonably also in regions of configuration space that are not sampled by the wavefunctions of the states for which experimentally derived energies are available. The calculation of rovibronic energies, the fittings to experimentally derived energies, and simulations of $\tilde{A}\,^1B_1 \rightarrow \tilde{X}\,^1A_1$ emission spectra of SiH_2 have been carried out with the RENNER program system. The higher excited vibrational states of $\tilde{X}\,^1A_1$ SiH_2 form polyads of heavily interacting states and many polyad states have been observed in dispersed fluorescence studies. The present theoretical work shows that owing to the heavy interaction between the states in the polyads, it is difficult to obtain unambiguous assignments for them.

Key words: silylene, RENNER, ab initio.

PACS Nos.: 31.15.Ar, 33.20.Wr, 33.20.Ea

Résumé : On a effectué une étude théorique des deux états électroniques singulets les plus faibles, $\tilde{X}\,^1A_1$ et $\tilde{A}\,^1B_1$ du silylène, SiH_2. Ces états deviennent dégénérés sous la forme d'un état $^1\Delta_g$ à configurations linéaires et ils sont sujets à l'effet de Renner. Dans les calculs ab initio, il a été possible de déterminer pour chaque état les surfaces de l'énergie potentielle et du moment dipolaire et la surface du moment de transition entre les états. Faisant appel à divers ensembles de points ab initio, on a ajusté des fonctions analytiques paramétrisées et on a mieux affiné les valeurs des paramètres obtenus pour les surfaces d'énergie potentielle en les ajustant aux données spectroscopiques expérimentales. Dans ces derniers ajustements, on a utilisé les données de base les différences d'énergie obtenues expérimentalement ainsi que les points *ab initio*. De cette façon, on a réussi à affiner les surfaces d'énergie potentielle de façon à ce qu'elles se comportent raisonnablement aussi dans des régions de l'espace de configuration qui ne sont pas soumises à l'échantillonnage des fonctions d'onde des états et pour lesquelles des énergies obtenues à partir de données expérimentales sont disponibles. Le calcul des énergies rovibroniques, les ajustements aux énergies obtenues à partir de données expérimentales et les simulations des spectres d'émission $\tilde{A}\,^1B_1 \rightarrow \tilde{X}\,^1A_1$ du SiH_2 ont été réalisés à l'aide du système de programme RENNER. L'état vibrationnel excité le plus élevé ($\tilde{X}\,^1A_1$) du SiH_2 forme des polyads d'états interagissant fortement et on a observé plusieurs états polyads dans le cadre d'études de fluorescence dispersée. Le présent travail théorique montre qu'en raison des fortes interactions entre les états des polyads, il est difficile d'obtenir des attributions non ambiguës pour eux.

Mots clés : silylène, RENNER, ab initio.

[Traduit par la Rédaction]

1. Introduction

Thin silicon films are essential for the industrial production of solar cells and semiconductor devices, and such films are produced by chemical vapour deposition following the decomposition of silane SiH_4. Silylene SiH_2 is a significant intermediate formed during decomposition reactions of SiH_4, and this paper is a contribution to the theoretical analysis of its spectra.

In contrast to the situation for methylene, the ground state of silylene is a singlet state: $\tilde{X}\,^1A_1$. The first excited state is the $\tilde{a}\,^3B_1$ state, and above that is the first excited singlet state $\tilde{A}\,^1B_1$. All these states are bent at equilibrium. At linearity the two singlet states become degenerate forming a $^1\Delta_g$ electronic state. As a result of this degeneracy at linearity there is a Renner effect interaction between the rovibronic levels of the $\tilde{X}$ and $\tilde{A}$

electronic states. The theory of the Renner effect is reviewed, for example, in refs. 1 and 2. We report here a theoretical study of the spectra associated with the $\tilde{X}$ and $\tilde{A}$ singlet states of silylene.

The first observation of SiH_2 was made by Dubois et al. (3) who recorded the $\tilde{A}\,^1B_1 \leftarrow \tilde{X}\,^1A_1$ absorption spectrum in the visible region. Dubois and co-workers (4,5) subsequently rotationally analyzed the progression of bands $\tilde{A}\,^1B_1\ (0, v_2, 0) \leftarrow \tilde{X}\,^1A_1\ (0, 0, 0)$ with $v_2 = 1-6$ and Francisco et al. (6) obtained the vibrational energies of the $\tilde{A}\,^1B_1$ (0,7,0) and $\tilde{A}\,^1B_1$ (0,8,0) states. We use the notation $\tilde{X}\,^1A_1\ (v_1, v_2, v_3)$ or $\tilde{A}\,^1B_1\ (v_1, v_2, v_3)$ for the vibronic states, where v_2 is the vibrational quantum number appropriate for a bent molecule. Escribano and Campargue (7) observed and analyzed the $\tilde{A}\,^1B_1\ (0, 0, 0) \leftarrow \tilde{X}\,^1A_1\ (0, 0, 0)$ band in 1998 with significantly higher resolution than had been available in the earlier studies. Laser-induced fluorescence (LIF) studies of the $\tilde{A}$ state were reported by Ishikawa and Kajimoto (8). In 1989, Yamada et. al (9) used IR diode laser kinetic spectroscopy to observe the v_2 band of the $\tilde{X}$ state, and 2 years later Ishikawa and Kajimoto (10) obtained several $\tilde{X}$ state vibrational term values in a dispersed fluorescence experiment. This latter work was reanalyzed by Ishikawa and Kajimoto (11) and updated by Hirota and Ishikawa (12) in their analysis of the vibrational energy level structure of the $\tilde{X}$ state. LIF excitation and dispersed fluorescence studies of SiH_2 and SiD_2 were reported by Fukushima et al. (13) and Fukushima and Obi (14). Finally, in 2002 Ishikawa et al. (15) carried out an extensive stimulated emission pumping study of the $\tilde{A}$–$\tilde{X}$ system, obtaining a wealth of $\tilde{X}$-state vibrational term values (up to 9800 cm^{-1}above the $\tilde{X}$ vibrational ground state level) together with some information about the spin-orbit interaction between the $\tilde{X}\,^1A_1$ and the $\tilde{a}\,^3B_1$ electronic states.

On the theoretical side ab initio work involving limited dimensionality calculations of the potential energy surfaces have been performed, and the only full three-dimensional surfaces are those of the $\tilde{X}$ and $\tilde{a}$ states by Gabriel et. al (16) in a coupled-electron-pair-approach (CEPA) calculation (17). They calculated also rovibronic energies, spectroscopic constants, dipole moment parameters, and intensities. In 1993, Duxbury et. al (18) reanalyzed the available experimental data on $\tilde{X}$-state and $\tilde{A}$-state SiH_2 with a semiquantitative model incorporating the Renner interaction between the two states and the spin-orbit interaction with the $\tilde{a}\,^3B_1$ electronic state.

In the present study, we first made an ab initio calculation of the potential energy surfaces, and the dipole moment and transition moment surfaces, for the $\tilde{X}\,^1A_1$ and $\tilde{A}\,^1B_1$ states of SiH_2. Using the ab initio potential surfaces, we calculated rovibronic energies and compared them with experimental results. We then refined the potential energy surfaces in fittings to the large amount of experimentally derived rovibronic energy values available for the $\tilde{X}$ state of SiH_2, and to the energies available for the $\tilde{A}$ state. In these fittings, we used the ab initio information to constrain the potential energy surfaces so that they remained relatively close to the initial ab initio surfaces in regions of configuration space that are not sampled by the wavefunctions for the experimentally characterized states. We also present predictions for the energies of highly excited vibrational states calculated with the refined potential energy parameters, and we simulate the $\tilde{A}\,^1B_1 \rightarrow \tilde{X}\,^1A_1$ emission spectrum for comparison with the results of the stimulated emission pumping experiments of Ishikawa et al. (15). In some of these experiments, the molecules are pumped to the 0_{00} rotational level in either the $\tilde{A}(060)$ or $\tilde{A}(070)$ state, and the measured emission

Table 1. Potential energy parameters[a] for the $\tilde{X}\,^1A_1$ and $\tilde{A}\,^1B_1$ electronic states of SiH_2 (see eqs. [1]–[5] for the definitions of the parameters).

[a]Quantities in parentheses are standard errors in units of the last digit quoted.
[b]Standard deviation of the fitting to the ab initio points.

spectra consist of the allowed $1_{10} \leftarrow 0_{00}$ rotational transition to vibrational levels of the $\tilde{X}$ state. In other experiments the $\tilde{A}(010)\ 1_{01}$ level is pumped and the spectra then consist of rotational transitions to both the 1_{11} and 2_{11} levels of vibrational levels of the $\tilde{X}$ state.

2. Ab initio calculations

Ab initio calculations of the potential energy surfaces were performed for the $\tilde{X}\,^1A_1$ and $\tilde{A}\,^1B_1$ singlet electronic states. The geometries involved a range of the HSiH bond angles (30°–160°) and SiH bond lengths (1.27–1.72 Å) including asymmetric bond stretches. The C_s point group symmetry was therefore used to classify the electronic wavefunctions.

General contraction type atomic natural orbital (ANO) bases were chosen to approximate the molecular orbitals. They consist for silicon of $17s$-, $12p$-, $5d$-, and $3f$-type functions contracted to $(7s6p4d3f)$-functions, and for the hydrogens of $8s$-, $4p$-, and $3d$-type functions contracted to $(6s4p3d)$-functions; in total 176 primitive functions contracted to 132 functions.

The energies were evaluated at the multireference configuration interaction (MR-CI) level of theory using molecular orbital bases that were optimized for each state separately by complete-active-space (CASSCF) calculations. The CASSCF partitioning scheme adopted here keeps the 10 electrons occupying the Si $1s$, $2s$, and $2p$ orbitals inactive and allows the remaining six valence electrons to be distributed among six active orbitals (4 a' orbitals and 2 a'' orbitals) in all possible ways consistent with the respective space and spin symmetries. In the MR-CI calculations these CASSCF wavefunctions (100 configuration state functions (CSFs) for the $\tilde{X}$ state and 80 CSFs for the $\tilde{A}$ state) are used as reference configurations from which all single and double excitations are generated. The total CI-expansions of the two states comprise 763 860 and 776 750 CSFs, respectively. The present calculations made use of the MOLCAS program system (19).

The equilibrium geometry parameters determined at this level of theory are close to the r_0 experimental parameters (4), and to those obtained recently in other high accuracy ab initio studies (16, 20, 21). For the strongly bent $\tilde{X}$ state the equilibrium bond angle is obtained as 92.4°, and the SiH bond length as $r_e = 1.5185$ Å. For the $\tilde{A}$ state, the equilibrium angle is 122.9° and the equilibrium bond length is found to be slightly shorter at $r_e = 1.4874$ Å. The equilibrium energy separation between the two singlet states is calculated as $T_e(\tilde{A}) = 15\,677\ cm^{-1}$, and from experiment (7) $T_0(\tilde{A}) = 15\ 547.773\ cm^{-1}$. Corresponding calculations that were also performed here for the excited $\tilde{a}^3B_1$ state of SiH_2 yield a singlet–triplet energy separation of

[e]Reference for the experimentally derived ("Observed") term value.

$T_e(\tilde{a}) = 7140\ cm^{-1}$ (0.8852 eV). Experimentally (22), $T_0(\tilde{a})$ has been determined as being either 0.78 ± 0.03 eV or 0.91 ± 0.03 eV, and our result would suggest that the latter value is appropriate.

The two Renner states correlate with $Si(^1D) + H_2(\tilde{X}\,^1\Sigma_g^+)$ at dissociation (lowest dissociation channel) and hydrogen abstraction in the $\tilde{X}$ state leads to the higher dissociation channel: $SiH(\tilde{X}\,^2\Pi) + H(^2S)$. A wide variation in fluorescence lifetimes has been observed for individual rovibronic levels in the $\tilde{A}$ state that has been attributed to predissociation of these levels via random couplings to background levels of the $\tilde{a}\,^3B_1$ state (23). Some effort has been put recently into theoretical studies of the dissociation dynamics of the low-lying electronic states of SiH_2 including the triplet $\tilde{a}$ state (6). In these studies, both dissociation pathways of the ground electronic state have been found to be barrier free (without an energy maximum) whereas for the $\tilde{A}$

[a]Polyad quantum number $P = 2v_1 + v_2 + 2v_3$.
[b]Following ref. 15, we use i as a running number index within each polyad.
[c]The vibrational assignment of each state is that state which has the largest eigenvector coefficient from the output of the RENNER program using the fitted potentials.
[d]Experimentally derived term values from (15). The values in parentheses are calculated values from ref. 15.
[e]Residuals (observed–calculated) obtained using the MCI ab initio parameters from Table 1. For the levels that were not observed the MCI calculated value is placed here in parentheses.
[f]Residuals (observed–calculated) obtained using the fitted parameters from Table 1. For the levels that were not observed the calculated value obtained using the fitted potential is placed here in parentheses.
[g]Deperturbed from the triplet interaction (15).

state a very small energy maximum has been discovered in calculations at a medium accuracy level. To get reliable estimates of the basic energetics of these processes the relevant dissociation energies were calculated here at the theory level of the present study. For the two singlet states, the dissociation energies corresponding to the lower dissociation channel are 21 500 cm^{-1} and 5823 cm^{-1}, respectively, whereas for the higher dissociation channel of the $\tilde{X}$ state an energy of 27 545 cm^{-1} is obtained. The energy difference between the two dissociation limits of the $\tilde{X}$ state is thus 6045 cm^{-1}. This can be compared to the value of 6470 cm^{-1} that can be derived for this energy difference from the dissociation energies of H_2 and SiH, and the ^3P and ^1D term values for Si. Comparing the lower dissociation energies of the two singlet states with the corresponding energy barriers to linearity, we see that the barrier heights exceed the dissociation limits by several hundred wavenumbers.

The in-plane dipole moment components of the two singlet states were calculated relative to the molecular center of mass directly as expectation values from the previously iterated MR-CI wavefunctions for all different molecular geometries. The out-of-plane dipole transition moment was obtained at the CASSCF level from the individually optimized wavefunctions for each state, appying the restricted active space state interaction (RASSI) method of Malmqvist and Roos (24).

3. The potential energy and dipole moment surfaces

To calculate the rovibronic energies associated with the Renner-interacting $\tilde{X}\,^1A_1$ and $\tilde{A}\,^1B_1$ electronic states of SiH_2, we follow the approach described in refs. 25 and 26.

[d]Residuals (observed–calculated) obtained using the fitted parameters from Table 1.
[e]Reference for the experimentally derived ("Observed") term value.

The rotational and vibrational motions in the two interacting Renner states are described in terms of a reference configuration with constant internuclear distances. This reference configuration is common for both electronic states and displacements due to stretching vibration are measured relative to it. As is customary (see (25–27)), since the two electronic surfaces are degenerate at linear configurations, we choose the bond lengths of the reference configuration to be those that minimize the electronic energy at linearity.

The Born–Oppenheimer potential energy function for the $\tilde{X}\,^1A_1$ electronic state is denoted by $V_-(\Delta r_{12}^{(\mathrm{ref})}, \Delta r_{32}^{(\mathrm{ref})}, \bar{\rho})$, and that for the $\tilde{A}\,^1B_1$ state is denoted $V_+(\Delta r_{12}^{(\mathrm{ref})}, \Delta r_{32}^{(\mathrm{ref})}, \bar{\rho})$, with

$$[1]\qquad V_{\pm}(\Delta r_{12}^{(\mathrm{ref})}, \Delta r_{32}^{(\mathrm{ref})}, \bar{\rho}) = V_{\mathrm{ref}} + V_0^{(\pm)}(\bar{\rho}) + \sum_j F_j^{(\pm)} y_j^{(\mathrm{ref})} + \sum_{j\le k} F_{jk}^{(\pm)} y_j^{(\mathrm{ref})} y_k^{(\mathrm{ref})} + \sum_{j\le k\le m} F_{jkm}^{(\pm)} y_j^{(\mathrm{ref})} y_k^{(\mathrm{ref})} y_m^{(\mathrm{ref})} + \sum_{j\le k\le m\le n} F_{jkmn}^{(\pm)} y_j^{(\mathrm{ref})} y_k^{(\mathrm{ref})} y_m^{(\mathrm{ref})} y_n^{(\mathrm{ref})} + \ldots$$

[c]Residuals (observed–calculated) obtained using the fitted parameters from Table 1.

where j, k, m, and n = 1 or 3. $V_-(\Delta r_{12}^{(\mathrm{ref})}, \Delta r_{32}^{(\mathrm{ref})}, \bar{\rho})$ and $V_+(\Delta r_{12}^{(\mathrm{ref})}, \Delta r_{32}^{(\mathrm{ref})}, \bar{\rho})$ depend on the stretching displacements

$$[2] \qquad \Delta r_{j2}^{(\mathrm{ref})} = r_{j2} - r_{j2}^{(\mathrm{ref})}$$

where r_{j2} is the instantaneous value of the distance between the proton labeled j (= 1 or 3) and the Si nucleus (labeled 2), and $r_{j2}^{(\mathrm{ref})}$ is the reference value of this quantity. As mentioned above, the $r_{j2}^{(\mathrm{ref})}$ are taken as the optimum bond lengths at linearity. In eq. [1],

$$[3] \qquad y_j^{(\mathrm{ref})} = 1 - \exp\left(-a\Delta r_{j2}^{(\mathrm{ref})}\right)$$

and $\bar{\rho} = \pi - \angle(\mathrm{HSiH})$, where $\angle(\mathrm{HSiH})$ is the instantaneous value of the bond angle. The functions $V_0^{\pm}(\bar{\rho})$ and $F_{jk\ldots}^{\pm}(\bar{\rho})$ are expressed as cosine series:

$$[4] \qquad V_0^{\pm}(\bar{\rho}) = \sum_{i=1}^{8} f_0^{(i,\pm)}(1 - \cos\bar{\rho})^i$$

and

$$[5] \qquad F_{jk\ldots}^{\pm}(\bar{\rho}) = f_{jk\ldots}^{(0)} + \sum_{i=1}^{N} f_{jk\ldots}^{(i,\pm)}(1 - \cos\bar{\rho})^i$$

where $f_0^{(i,\pm)}$, $f_{jk\ldots}^{(0)}$ and $f_{jk\ldots}^{(i,\pm)}$ are expansion coefficients. In eq. [5], the expression for $F_j^{\pm}(\bar{\rho})$ has $N = 4$, that for $F_{jk}^{\pm}(\bar{\rho})$ has $N = 3$, $F_{jkl}^{\pm}(\bar{\rho})$ has $N = 2$, and $F_{jklm}^{\pm}(\bar{\rho})$ has $N = 1$. Since the expansion coefficients $f_{jk\ldots}^{(0)}$ are chosen to be common for both electronic states, the potentials given by eq. [1] are degenerate for linear configurations; the term V_{ref} in eq. [1] is the energy for $\bar{\rho} = 0$, and $r_{12} = r_{32} = r_{12}^{(\mathrm{ref})}$, and it is also common for the two potential surfaces.

We describe the molecular dipole moment in terms of its components along three axes xqp (taken to form a right-handed axis system with origin in the nuclear center of mass) that are attached directly to the instantaneous nuclear configuration of the molecule (see Fig. 1 of ref. 28). For SiH_2, the q axis bisects the bond angle $\angle(\mathrm{HSiH})$ and is directed so that the q coordinates of the H nuclei 1 and 3 are positive. The p axis is perpendicular to the q axis and its direction is such that the p coordinate of nucleus 3 is positive, and the x axis is perpendicular to the molecular plane.

The expressions for the intensities of individual rovibronic transitions within the two Renner-degenerate electronic states are given in ref. 29. These intensities depend on electronic dipole moment and transition moment surfaces. We denote the electronic wavefunction for the $\tilde{X}\,^1A_1$ state as $\psi_{\mathrm{elec}}^{(-)}$, and that for the $\tilde{A}\,^1B_1$ state as $\psi_{\mathrm{elec}}^{(+)}$. In this notation we obtain the following non vanishing dipole and transition moments:

$$[6] \qquad \bar{\mu}_p^{(\sigma)}(\Delta r_{12}^{(\mathrm{ref})}, \Delta r_{32}^{(\mathrm{ref})}, \bar{\rho}) = \langle\psi_{\mathrm{elec}}^{(\sigma)}|\mu_p|\psi_{\mathrm{elec}}^{(\sigma)}\rangle_{\mathrm{el}}$$

$$[7] \qquad \bar{\mu}_q^{(\sigma)}(\Delta r_{12}^{(\mathrm{ref})}, \Delta r_{32}^{(\mathrm{ref})}, \bar{\rho}) = \langle\psi_{\mathrm{elec}}^{(\sigma)}|\mu_q|\psi_{\mathrm{elec}}^{(\sigma)}\rangle_{\mathrm{el}}$$

where, in eqs. [6] and [7], $\sigma = -$ or $+$, and

$$[8] \qquad \bar{\mu}_x^{(-+)}(\Delta r_{12}^{(\mathrm{ref})}, \Delta r_{32}^{(\mathrm{ref})}, \bar{\rho}) = \langle\psi_{\mathrm{elec}}^{(-)}|\mu_x|\psi_{\mathrm{elec}}^{(+)}\rangle_{\mathrm{el}}$$

where, in eqs. [6]–[8], the subscript "el" indicates that integration is over the electronic coordinates only.

The functions $\bar{\mu}_p^{(\sigma)}$ and $\bar{\mu}_q^{(\sigma)}$ are represented as (see ref. 28)

$$[9] \qquad \bar{\mu}_p^{(\sigma)}(\Delta r_{12}^{(\mathrm{ref})}, \Delta r_{32}^{(\mathrm{ref})}, \bar{\rho}) = \mu_0^{(p;\sigma)}(\bar{\rho}) + \sum_j \mu_j^{(p;\sigma)}(\bar{\rho})\Delta r_{j2}^{(\mathrm{ref})} + \sum_{j\le k} \mu_{jk}^{(p;\sigma)}(\bar{\rho})\Delta r_{j2}^{(\mathrm{ref})}\Delta r_{k2}^{(\mathrm{ref})} + \sum_{j\le k\le m} \mu_{jkm}^{(p;\sigma)}(\bar{\rho})\Delta r_{j2}^{(\mathrm{ref})}\Delta r_{k2}^{(\mathrm{ref})}\Delta r_{m2}^{(\mathrm{ref})} + \sum_{j\le k\le m\le n} \mu_{jkmn}^{(p;\sigma)}(\bar{\rho})\Delta r_{j2}^{(\mathrm{ref})}\Delta r_{k2}^{(\mathrm{ref})}\Delta r_{m2}^{(\mathrm{ref})}\Delta r_{n2}^{(\mathrm{ref})}$$

© 2004 NRC Canada

and

$$[10]\quad \bar{\mu}_q^{(\sigma)}(\Delta r_{12}^{(\mathrm{ref})}, \Delta r_{32}^{(\mathrm{ref})}, \bar{\rho}) = \sin\bar{\rho}\Bigg[\mu_0^{(q;\sigma)}(\bar{\rho}) + \sum_j \mu_j^{(q;\sigma)}(\bar{\rho})\Delta r_{j2}^{(\mathrm{ref})} + \sum_{j\le k} \mu_{jk}^{(q;\sigma)}(\bar{\rho})\Delta r_{j2}^{(\mathrm{ref})}\Delta r_{k2}^{(\mathrm{ref})} + \sum_{j\le k\le m} \mu_{jkm}^{(q;\sigma)}(\bar{\rho})\Delta r_{j2}^{(\mathrm{ref})}\Delta r_{k2}^{(\mathrm{ref})}\Delta r_{m2}^{(\mathrm{ref})} + \sum_{j\le k\le m\le n} \mu_{jkmn}^{(q;\sigma)}(\bar{\rho})\Delta r_{j2}^{(\mathrm{ref})}\Delta r_{k2}^{(\mathrm{ref})}\Delta r_{m2}^{(\mathrm{ref})}\Delta r_{n2}^{(\mathrm{ref})}\Bigg]$$

with $j, k, m, n = 1$ or 3. The angle-dependent coefficients are given by

$$[11]\quad \mu_{jk\ldots}^{(w;\sigma)}(\bar{\rho}) = \sum_{i=0}^{N} w_{jk\ldots}^{(i;\sigma)}(1-\cos\bar{\rho})^i$$

with $w = p$ or q. The function $\mu_0^{(w;\sigma)}(\bar{\rho})$ has $N = 8$, $\mu_j^{(w;\sigma)}(\bar{\rho})$ has $N = 4$, $\mu_{jk}^{(w;\sigma)}(\bar{\rho})$ has $N = 3$, $\mu_{jkm}^{(w;\sigma)}(\bar{\rho})$ has $N = 2$ and $\mu_{jkmn}^{(w;\sigma)}(\bar{\rho})$ has $N = 1$.

The function $\bar{\mu}_x^{(-+)}$ is parameterized as

$$[12]\quad \bar{\mu}_x^{(-+)}(\Delta r_{12}^{(\mathrm{ref})}, \Delta r_{32}^{(\mathrm{ref})}, \bar{\rho}) = \sin\bar{\rho}\Bigg[\mu_0^{(x;-+)}(\bar{\rho}) + \sum_j \mu_j^{(x;-+)}(\bar{\rho})\Delta r_{j2}^{(\mathrm{ref})} + \sum_{j\le k} \mu_{jk}^{(x;-+)}(\bar{\rho})\Delta r_{j2}^{(\mathrm{ref})}\Delta r_{k2}^{(\mathrm{ref})} + \sum_{j\le k\le m} \mu_{jkm}^{(x;-+)}(\bar{\rho})\Delta r_{j2}^{(\mathrm{ref})}\Delta r_{k2}^{(\mathrm{ref})}\Delta r_{m2}^{(\mathrm{ref})} + \sum_{j\le k\le m\le n} \mu_{jkmn}^{(x;-+)}(\bar{\rho})\Delta r_{j2}^{(\mathrm{ref})}\Delta r_{k2}^{(\mathrm{ref})}\Delta r_{m2}^{(\mathrm{ref})}\Delta r_{n2}^{(\mathrm{ref})}\Bigg]$$

with

$$[13]\quad \mu_{jk\ldots}^{(x;-+)}(\bar{\rho}) = \sum_{i=0}^{N} x_{jk\ldots}^{(i;-+)}(1-\cos\bar{\rho})^i$$

where the number of summation terms N is given exactly as for eq. [11].

For SiH_2, relations exist between the expansion coefficients in eqs. [11] and [13], so that the functions $\bar{\mu}_q^{(\sigma)}$ and $\bar{\mu}_x^{(-+)}$ are unchanged under the interchange of the two protons, whereas the function $\bar{\mu}_p^{(\sigma)}$ is antisymmetric under this operation.

4. Fitting to the ab initio points

The analytical expression for the potential energy function defined in eqs. [1]–[5] contains as adjustable parameters the coefficients $f_0^{(i,\pm)}$ in eq. [4], and $f_{jk\ldots}^{(0)}$ and $f_{jk\ldots}^{(i,\pm)}$ in eq. [5], and the parameters a in eq. [3] and V_{ref} in eq. [1]. We aim to determine values of these parameters in fittings to the MCI ab initio points. Since we define the reference bond length $r_{j2}^{(\mathrm{ref})}$ to be equal to the optimum bond length at linearity, this parameter can also be adjusted in the fittings.

Attempts to determine the parameter a in the fittings led to divergence of the least-squares-fitting procedure and so we had to constrain it. It was constrained to the value $a = 1.58$ Å^{-1} determined by fitting to the ab initio energies of the points with $r_{32} = r_{12}$ and $\bar{\rho} = 90°$ (close to the equilibrium value of $\bar{\rho}$ in the $\tilde{X}\,^1A_1$ electronic state). The energies in these points depend only on r_{12} and we fitted a Morse potential

$$[14]\quad V_{\mathrm{Morse}}(r_{12}) = V_{\mathrm{e}} + f_{11}^{(0)}\left[1 - e^{-a\Delta r_{12}^{(\mathrm{ref})}}\right]^2$$

through them, thus determining the value of a.

We carried out initial fittings to the ab initio points and used the resulting parameter values as input for the program RENNER (25, 26, 29), which calculates rovibronic energies and intensities for Renner-degenerate electronic states of triatomic molecules. This calculation produced values of the lowest $\tilde{A}\,^1B_1$ $(0, v_2, 0)$ energies that were consistently about 150 cm^{-1} higher than their respective experimental counterparts. This type of effect is often encountered in ab initio calculations of rovibronic energies associated with Renner-degenerate electronic states; it simply indicates that the $\tilde{A}$-state potential energy surface lies too high by 150 cm^{-1} relative to the $\tilde{X}$-state surfaces. To improve the agreement with experiment of the the rovibronic energies calculated from the ab initio results, we subtracted 150 cm^{-1} from all the $\tilde{A}$-state ab initio energies, and fitted the analytical expression for the potential energy function defined in eqs. [1]–[4] through these corrected $\tilde{A}$-state ab initio points and through the $\tilde{X}$-state points. The two analytical surfaces obtained in this fitting have barriers to linearity approximately 150 cm^{-1} lower than obtained in the initial fitting. In the final fitting, we used 250 ab initio points as input and we could usefully vary 34 potential parameters. The standard deviation was 20 cm. The optimized parameter values and their

standard errors are given in Table 1 under the heading "MCI ab initio".

The MCI ab initio fitted analytical potential functions (with the barrier to linearity lowered by 150 cm^{-1} as discussed above) are such that the equilibrium geometry (r_e, α_e) is (1.518 Å, 92.4°) for the $\tilde{X}$ state and (1.487 Å, 122.9°) for the $\tilde{A}$ state. The barrier heights at linearity in these functions are 22 139.2 and 6612.8 cm^{-1}, respectively, for the $\tilde{X}$ and $\tilde{A}$ states, so that $T_e(\tilde{A}) = 15\,526.4\ cm^{-1}$.

For the dipole moment and transition moment surfaces we obtain values for the $p^{(i;\sigma)}_{jk...}$, $q^{(i;\sigma)}_{jk...}$, and $x^{(i;-+)}_{jk...}$ parameters by fitting eqs. [9]–[13] through the ab initio dipole moment values. The results of the fittings (parameter values, standard errors, and the standard deviations of the fittings) are given in Table 2.

From the ab initio calculation we determine that the dipole moment for the $\tilde{X}$ state at its equilibrium configuration is 0.14 D, and for the $\tilde{A}$ state at its equilibrium configuration it is 0.01 D. The $\tilde{A} - \tilde{X}$ transition moment at the equilibrium geometry of the $\tilde{X}$ state is calculated to be 1.21 D.

5. Rovibronic energy calculations

In the RENNER calculations, the eigenvalues for the rovibronic Hamiltonian $\hat{H}_{Renner}$ were obtained by diagonalization of the matrix representation of $\hat{H}_{Renner}$ in the basis set $|v_2^{(\eta)}, K\rangle$ $|N_{vib}^{(\eta)}, \Gamma_{vib}^{(\eta)}\rangle$ $|\eta; NJSKM_J\tau\rangle$ defined in ref. 25. We used the 27 lowest bending basis functions $|v_2^{(\eta)}, K\rangle$ for both electronic states for every K block (where $K \leq J$). The $\tilde{X}\,^1A_1$ electronic state basis set included the $N_A = 20$ lowest stretching functions $|N_{vib}^{(\eta)}, A_1\rangle$ of A_1 symmetry and the $N_B = 15$ lowest stretching functions $|N_{vib}^{(\eta)}, B_2\rangle$ of of B_2 symmetry. For the $\tilde{A}\,^1B_1$ state we used $N_A = 15$ and $N_B = 10$ stretching functions. These stretching functions were constructed from Morse oscillator functions $|n_1\rangle$ $|n_3\rangle$ with $n_1 + n_3 \leq N_{stretch} = 17$.

Rovibronic energies calculated with the RENNER program from the ab initio parameters in Table 1 are compared with experimental values for SiH_2 in Tables 3–5 under the heading "O–C/MCI". In Table 3, the comparison is made for $J \leq 2$ term values for vibrational states in the $\tilde{X}\,^1A_1$ electronic state. In Table 4, the comparison is made for the extensive set of $\tilde{X}\,^1A_1$ term values (which all have $J_{K_aK_c} = 1_{10}$) obtained experimentally in the recent stimulated emission pumping study by Ishikawa et al. (15). The energies in Table 4 are labeled by the polyad quantum number

$$P = 2v_1 + v_2 + 2v_3.$$

Since, for $\tilde{X}\,^1A_1$ SiH_2, the three harmonic vibrational wavenumbers ω_1, ω_2, and ω_3 approximately satisfy the relation $\omega_1 =$

[a]From ref. 15.
[b]Observed–calculated obtained using the fitted parameters from Table 1.

$2\omega_2 = \omega_3$, vibrational states with a common value of P will be close in energy and form polyads labeled by $P = 0, 1, 2, 3, \ldots$. Within each polyad the energies in Table 4 are labeled by the running number index i as in ref. 15. In Table 5, we make the comparison for $J \leq 2$ term values in the $\tilde{A}\,^1B_1$ state.

The energies calculated using RENNER with the ab initio parameters in Table 1 reproduce the experimental energies for SiH_2 in Tables 3–5 with a root-mean-square deviation of 41.7 cm^{-1}. It is noticeable that while the agreement between theory and experiment is fairly good for low-lying states, there are substantial deviations for the highly excited states, in particular for the $\tilde{X}\,^1A_1$ -levels characterized experimentally by Ishikawa et al. (15) in stimulated emission pumping experiments. To analyze theoretically these highly excited states and, hopefully, explain the intensities of the emission spectra observed by Ishikawa et al. (15), we have refined the potential energy surfaces of $\tilde{X}\,^1A_1$ and $\tilde{A}\,^1B_1$ SiH_2 in a least-squares fitting to the available low-J experimental data. This refinement is the subject of the following section.

Table 11. Term values (in cm^{-1}) for the rotational level $J_{K_aK_c} = 1_{10}$ in the polyad states with $P = 10$ of $\tilde{X}\,^1A_1$ SiH_2.

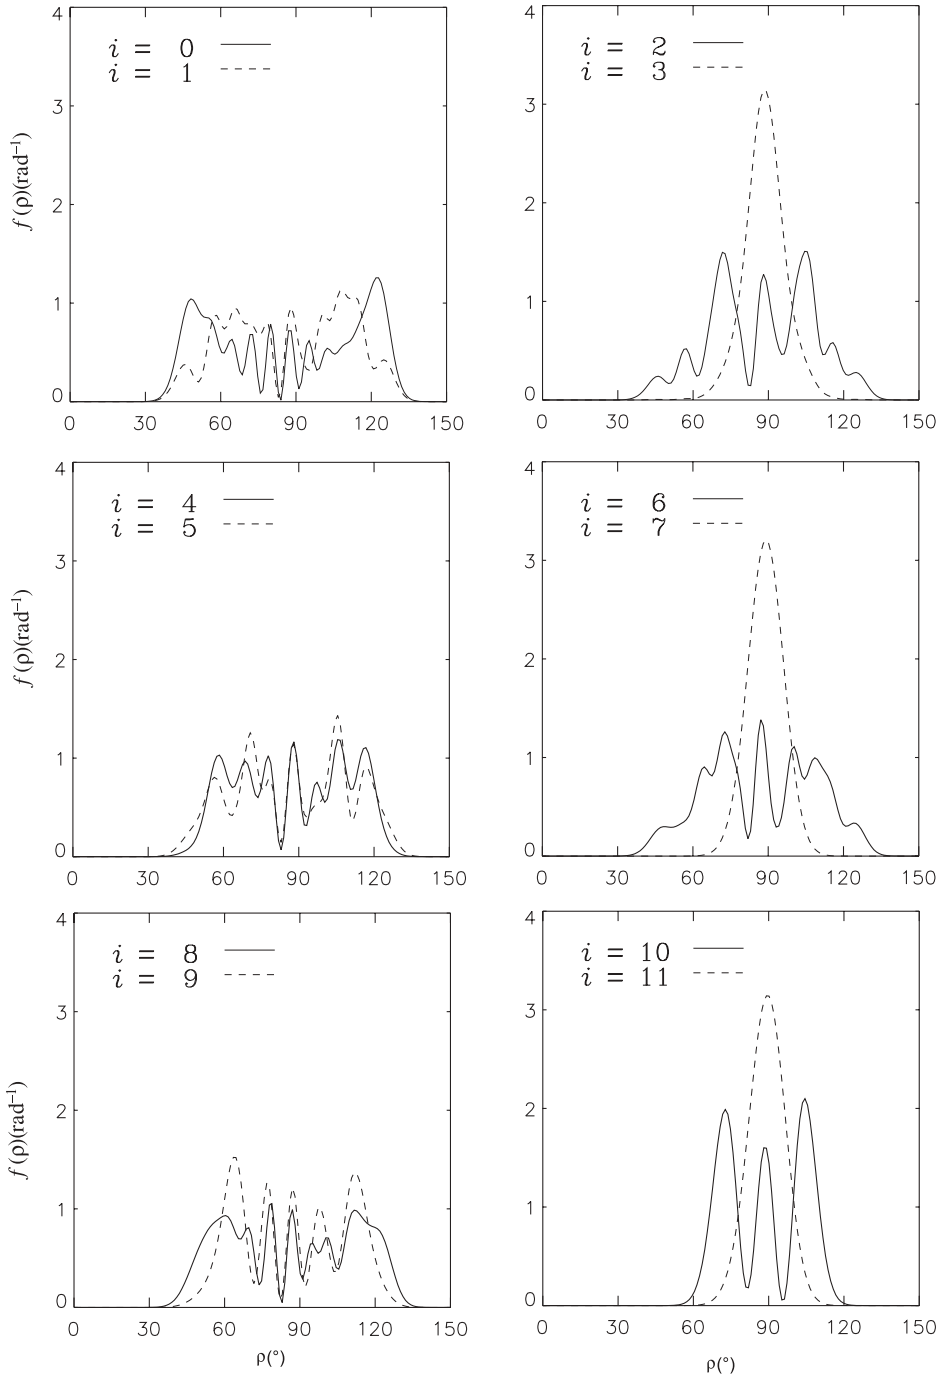
[a]Obtained using the fitted potentials with the parameters from Table 1.
[b]The result using the alternative potentials (see text).
[c]This would be assigned as $i = 11$ using our fitted potentials, but as $i = 10$ using the alternative potentials.

6. Refinement of the potentials



The adjustment of potential energy parameters in a fitting to experimental data can sometimes lead to an unrealistically shaped potential energy surface (PES). To constrain the shape of the PES during the fitting process we performed a simultaneous fitting of the potential parameters both to the observed data and to ab initio energies. By introducing the ab initio energies as input data for the fitting, we can constrain the fitted potential energy surface to be close to the initial ab initio one. This approach has been discussed in detail in ref. 30 and we give a brief outline here.

The ab initio parameters from Table 1 were first used to generate a grid of ab initio energy points that we used in the simultaneous fitting procedure. Some of these points involved extrapolation outside the region of the ab initio calculation and they were given low weight. In the simultaneous fitting procedure we must decide on a particular value for the ratio of the weights used for the experimental data (W_i^{exp}) to that used for the ab initio points (W_i^{points}), and in this work the weight for the data was taken to be 5.5 times larger than that on the ab initio points.

In the refinement we first fitted to levels with $J \leq 1$ for SiH_2 (excluding the levels from the 10th polyad (15) in the $\tilde{X}$ state). We added levels with $J = 2$, and levels for SiD_2 (see Table 6) as we achieved reasonable agreement with the experimental data. Finally, the energy levels of the $P = 10$ polyad were included; the vibrational assignments of these levels were very sensitive

Fig. 1. Probability distributions $f(\rho)$ for the rotational level $J_{K_aK_c} = 1_{10}$ in the polyad states with $P = 10$ of $\tilde{X}\,^1A_1$ SiH_2. The energies of these states are given in Table 11.

to any parameter change. The resultant parameters are listed in column three of Table 1, and the residuals "O–C/fitted" are given in Tables 3–6. The vibronic assignment of each state is that state which has the largest eigenvector coefficient from the output of the RENNER program. These assignments are of help in understanding the polyad structure of the vibrational levels in the ground electronic state. For example, one can learn from Table 4 that for the ground electronic state the highest level in every Pth polyad is the level $(v_1, v_2, v_3) = (1, P - 2, 0)$ for $P > 5$. In Table 7, we show the percentages of each (v_1,v_2,v_3) state that occurs in each of the $P = 10$ polyad states, and in Table 8, we show the percentages of neighboring polyads basis functions that are mixed into the $P = 10$ polyad states.

In Table 9 we give the predicted term values for the $J_{K_aK_c} = 1_{10}$ levels of the polyads having $P = 11$ and 12, and in Table 10 we compare calculated and observed $\tilde{A}$-state levels hav-

Fig. 2. Probability distributions $f(\rho)$ for the the rotational level $J_{K_aK_c} = 0_{00}$ in the $7\nu_2$ state of $\tilde{A}\,^1B_1$ SiH_2.

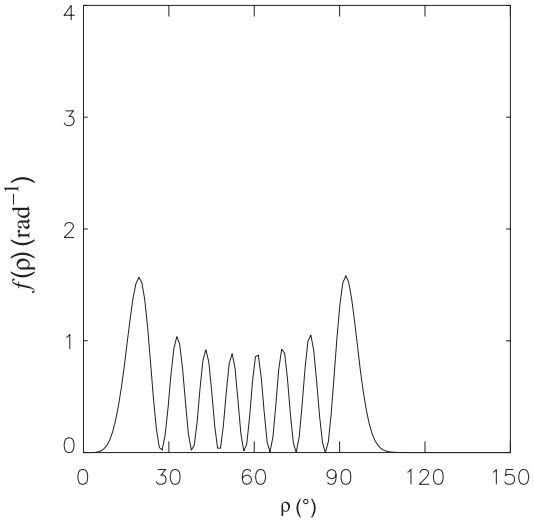

Fig. 3. Probability distributions $f(\rho)$ for the rotational level $J_{K_aK_c} = 0_{00}$ in the (*a*) ν_1 and (*b*) $2\nu_2$ states of $\tilde{X}\,^1A_1$ SiH_2.

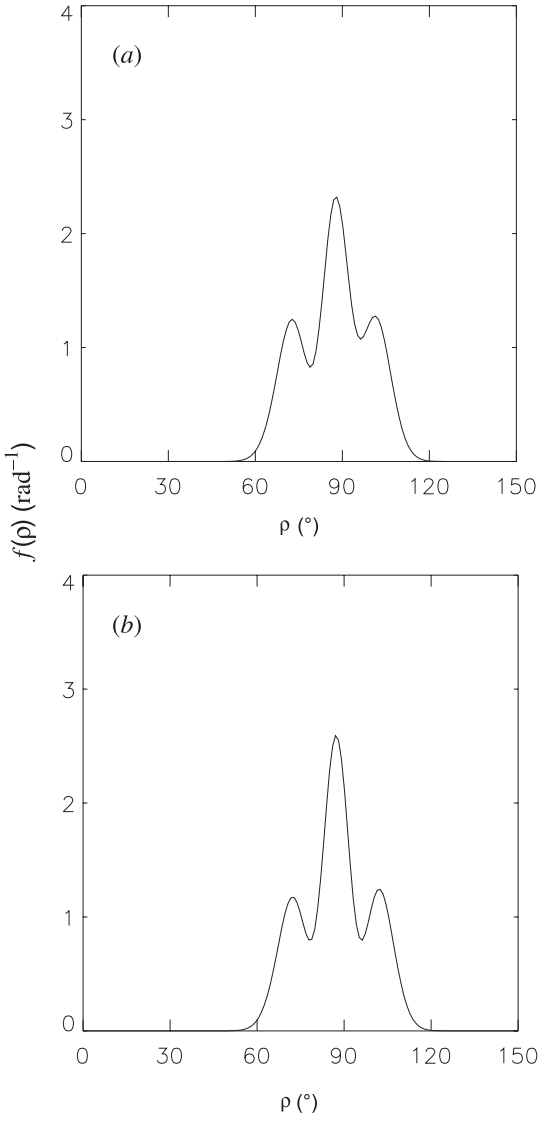

Fig. 4. The upper emission spectrum is the observed $P = 10$ spectrum (15) (see footnote 3), and the lower stick spectrum is the simulation using our fitted potentials and ab initio dipole moment and transition moment surfaces. The doublet in the observed spectrum at around 9645 cm^{-1} results from the presence of a triplet state perturber that we do not include in our simulation.

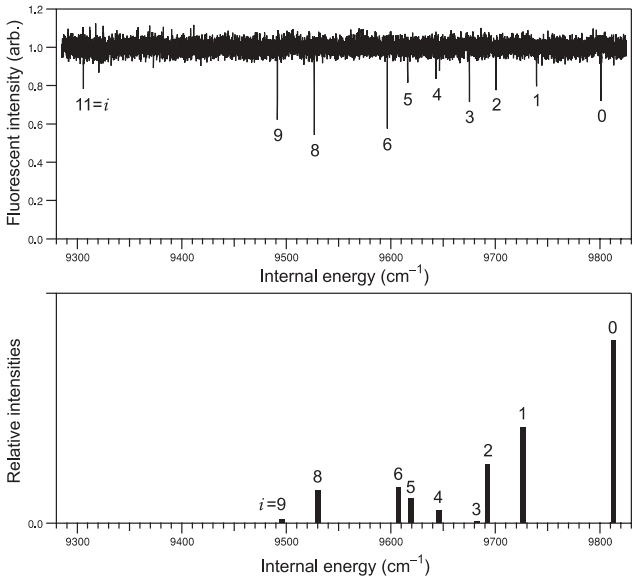

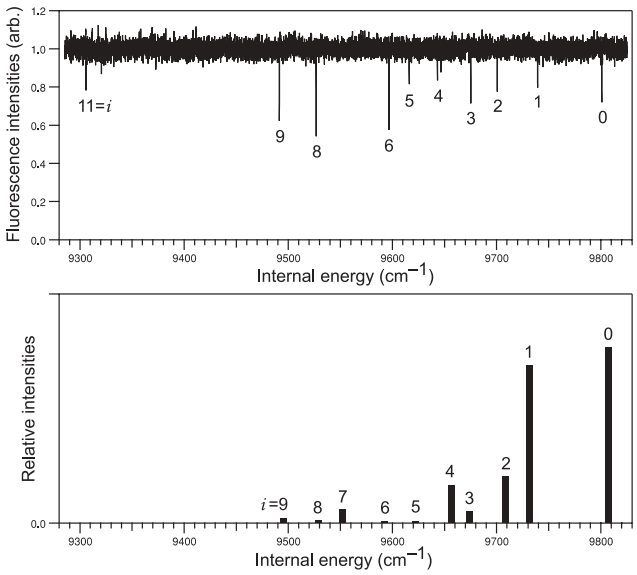

Fig. 5. The upper emission spectrum is the observed $P = 10$ spectrum (15) (see footnote 3), and the lower stick spectrum is the simulation using our alternative potentials (see text) with the ab initio dipole moment and transition moment surfaces. The reproduction of the intensities is worse than that in Fig. 4 and this leads us to discard the alternative potentials.

ing higher values of J and K_a. This latter comparison is a check that our calculation treats the Renner effect appropriately in higher angular momentum states.

The observed data, for $J = 0$, 1, and 2, are reproduced with a root-mean-square error of 5.8 cm^{-1} for the $\tilde{X}\,^1A_1$ state and

© 2004 NRC Canada

7.3 cm^{-1} for the $\tilde{A}\,^1B_1$ state. The energies of the ab initio points are reproduced with root-mean-square error of 30.0 cm^{-1} for the $\tilde{X}\,^1A_1$ state and 42.0 cm^{-1} for the $\tilde{A}\,^1B_1$ state.

The fitted potentials are such that the equilibrium geometry (r_e, α_e) is (1.518 Å, 92.4°) for the $\tilde{X}$ state and (1.486 Å, 123.0°) for the $\tilde{A}$ state. The barrier heights at linearity are obtained from the fitted potentials as 21 882.4 and 6340.6 cm^{-1}, respectively, for the $\tilde{X}$ and $\tilde{A}$ states, so that $T_e(\tilde{A})$ = 15 541.8 cm^{-1}.

7. Rovibronic wavefunctions and probability density functions

An eigenfunction obtained from the rovibronic RENNER calculation is given as a superposition of basis functions, and we can write it as

$$[15]\quad \psi_{\text{evr-ns}}^{(i,J,M_J,S,\Gamma_{\text{evr}};\tau)} = \Phi_{\text{ns}} \sum_{\eta=a,b} \sum_{N=|J-S|}^{J+S} \sum_{K=0}^{N} \sum_{v_2^{(\eta)},N_{\text{vib}}^{(\eta)},\Gamma_{\text{vib}}^{(\eta)}} c_{\eta,N,K,v_2^{(\eta)},N_{\text{vib}}^{(\eta)},\Gamma_{\text{vib}}^{(\eta)}}^{(i,J,M_J,S,\Gamma_{\text{evr}},\tau)} \times \Phi_{v_2^{(\eta)},K}(\rho)\, \Phi_{N_{\text{vib}}^{(\eta)},\Gamma_{\text{vib}}^{(\eta)}}(r_{12},r_{32})\, |\eta; NJSKM_J\tau\rangle$$

where the $c_{\eta,N,K,v_2^{(\eta)},N_{\text{vib}}^{(\eta)},\Gamma_{\text{vib}}^{(\eta)}}^{(i,J,M_J,S,\Gamma_{\text{evr}},\tau)}$ are expansion coefficients, and the functions $\Phi_{v_2^{(\eta)},K}(\rho)$ (called $|v_2^{(\eta)},K\rangle$ in ref. 25) and $\Phi_{N_{\text{vib}}^{(\eta)},\Gamma_{\text{vib}}^{(\eta)}}(r_{12},r_{32})$ (called $|N_{\text{vib}}^{(\eta)},\Gamma_{\text{vib}}^{(\eta)}\rangle$ in ref. 25) are basis functions describing the bending and stretching motions, respectively. $\Phi_{v_2^{(\eta)},K}(\rho)$ depends on the bending coordinate ρ which is almost, but not quite, equal to $\bar{\rho}$. The rigid-bender functions $\Phi_{v_2^{(\eta)},K}(\rho)$, and Morse oscillator stretching functions $\Phi_{N_{\text{vib}}^{(\eta)},\Gamma_{\text{vib}}^{(\eta)}}(r_{12},r_{32})$, are defined in ref. 25; $v_2^{(\eta)}$ is the bending quantum number appropriate for a bent molecule (See section 13.4.1 and eqs. [13]–[177] of ref. 1). $\Gamma_{\text{vib}}^{(\eta)}$ is the irreducible representation spanned by the function $\Phi_{N_{\text{vib}}^{(\eta)},\Gamma_{\text{vib}}^{(\eta)}}$ in the molecular symmetry group of the molecule and, $N_{\text{vib}}^{(\eta)}$ = 1, 2, 3, … numbers the functions with a given $\Gamma_{\text{vib}}^{(\eta)}$ in order of ascending energy. For SiH_2, the molecular symmetry group is C_{2v}(M) (1) and $\Gamma_{\text{vib}}^{(\eta)} = A_1$ or B_2. The basis functions $|\eta; NJSKM_J\tau\rangle$ describe the motion of the electrons, the electron spin, and the rotational motion (where $K = K_a$). These functions are given as

$$[16]\quad |a; NJSKM_J\tau\rangle = \cos\left[\gamma_K(\rho)\right] \Phi_{\text{elec}}^{(-)}\, |NJSKM_J\delta_{0\,\tau}\rangle + \sin\left[\gamma_K(\rho)\right]\, i\, \Phi_{\text{elec}}^{(+)}\, |NJSKM_J\tau\rangle$$

$$[17]\quad |b; NJSKM_J\tau\rangle = \cos\left[\gamma_K(\rho)\right]\, i\, \Phi_{\text{elec}}^{(+)}\, |NJSKM_J\tau\rangle - \sin\left[\gamma_K(\rho)\right] \Phi_{\text{elec}}^{(-)}\, |NJSKM_J\delta_{0\,\tau}\rangle$$

where $\Phi_{\text{elec}}^{(-)}$ is the electronic wavefunction for the lower Renner component $\tilde{X}\,^1A_1$, and $\Phi_{\text{elec}}^{(+)}$ is the electronic wavefunction for the upper component $\tilde{A}\,^1B_1$. In eqs. [16] and [17], $\delta_{0\,\tau}$ is a Kronecker Delta with $\delta_{00} = 1$ and $\delta_{01} = 0$. The angle $\gamma_K(\rho)$ determines, in a first approximation, the Renner interaction between these two electronic states. It is discussed in detail in section 15.4.2 of ref. 31. The rotation-spin basis functions $|NJSKM_J\tau\rangle$ (see refs. 25, 31) are symmetrized, simultaneous eigenfunctions of $\widehat{\mathbf{N}}^2$ [with eigenvalue $\hbar^2N(N+1)$], $\widehat{\mathbf{J}}^2$ [with eigenvalue $\hbar^2J(J+1)$], $\widehat{\mathbf{S}}^2$ [with eigenvalue $\hbar^2S(S+1)$], and $\widehat{J}_Z$, the component of $\mathbf{J}$ along the space-fixed quantization axis Z [with eigenvalue $\hbar M_J$] (see refs. 25, 31). Here, $\widehat{\mathbf{N}}$ is the total angular momentum of the molecule excluding spin, $\widehat{\mathbf{S}}$ is the electron spin, and $\widehat{\mathbf{J}} = \widehat{\mathbf{N}} + \widehat{\mathbf{S}}$. We assume that no electronic state other than the $\tilde{X}\,^1A_1$ – $\tilde{A}\,^1B_1$ pair of states contributes significantly to $\psi_{\text{evr-ns}}^{(i,J,M_J,S,\Gamma_{\text{evr}};\tau)}$. As indicated in eq. [15], the internal wavefunctions are labeled by the good quantum numbers J, M_J, S, and by Γ_{evr}, the irreducible representation spanned by $\psi_{\text{evr-ns}}^{(i,J,M_J,S,\Gamma_{\text{evr}};\tau)}$ in the molecular symmetry group C_{2v}(M) (1). The running index i numbers states with the same values of the good quantum numbers. This i is not to be confused with the i in Table 4. The parity of $\psi_{\text{evr-ns}}^{(i,J,M_J,S,\Gamma_{\text{evr}};\tau)}$ is $(-1)^\tau$, and $\tau = 0$ or 1. Φ_{ns} is an appropriate nuclear spin function.

The rovibronic wavefunctions given in eq. [15] are mathematically complicated, but they contain all accessible information about each rovibronic state. To obtain insight into the nature of the eigenfunctions, we have previously introduced and calculated the overall bending probability density function $f(\rho)$ of the states (32, 33). The quantity $\mathrm{d}p = f(\rho)\,\mathrm{d}\rho$ is the differential probability of finding the molecule with its bending angle between ρ and $\rho + \mathrm{d}\rho$. For the ith state $\psi_{\text{evr-ns}}^{(i,J,M_J,S,\Gamma_{\text{evr}};\tau)}$, having energy E_i, the normalized probability density function for the bending angle $f_i(\rho)$ is given by

$$[18]\quad f_i(\rho) = \int_0^\infty \mathrm{d}r_{12} \int_0^\infty \mathrm{d}r_{32} \int_{\text{rot,e,es,ns}} \mathrm{d}V\, |\psi_{\text{evr-ns}}^{(i,J,M_J,S,\Gamma_{\text{evr}};\tau)}|^2 = \sum_{\eta=a,b} \sum_{N=|J-S|}^{J+S} \sum_{K=0}^{N} \sum_{v_2^{(\eta)},v_2^{(\eta)\prime},N_{\text{vib}}^{(\eta)},\Gamma_{\text{vib}}^{(\eta)}} \left(c_{\eta,N,K,v_2^{(\eta)},N_{\text{vib}}^{(\eta)},\Gamma_{\text{vib}}^{(\eta)}}^{(i,J,M_J,S,\Gamma_{\text{evr}},\tau)}\right)^* \times c_{\eta,N,K,v_2^{(\eta)\prime},N_{\text{vib}}^{(\eta)},\Gamma_{\text{vib}}^{(\eta)}}^{(i,J,M_J,S,\Gamma_{\text{evr}},\tau)} \left(\Phi_{v_2^{(\eta)},K}(\rho)\right)^* \Phi_{v_2^{(\eta)\prime},K}(\rho)$$

© 2004 NRC Canada

where dV is the volume element associated with integration over the coordinates describing rotation, electronic orbital motion, electron spin, and nuclear spin.

In Fig. 1 we plot the bending probability distributions $f(\rho)$ for the the rotational level $J_{K_aK_c} = 1_{10}$ of the 12 members of the $P = 10$ polyad of the $\tilde{X}\,^1A_1$ state. In the following we shall be discussing emission transitions to these levels from the $J_{K_aK_c} = 0_{00}$ rotational level of the $7\nu_2$ state of $\tilde{A}\,^1B_1$ SiH_2; we plot the probability distribution of this level in Fig. 2.

A problem for $\tilde{X}\,^1A_1$ SiH_2 has been the assignment of the ν_1 and $2\nu_2$ states; these two states are in a strong Fermi resonance. The two $J = 0$ states of A_1 symmetry are observed at 1978.153 and 2005.469 cm^{-1}, respectively (12). Whereas Ishikawa and Kajimoto (10) initially assigned the highest level as $2\nu_2$ and the lowest level as ν_1, Hirota and Ishikawa (12) reversed these assignments. The wavefunction for the state at lower wavenumber has a 51.5% contribution from the $2\nu_2$ basis state and a 47.8% contribution from the ν_1 basis state. The state at higher wavenumber has a 51.7% contribution from ν_1 and a 46.7% contribution from $2\nu_2$. Consequently, as in ref. 12, we assign the lower state as $2\nu_2$ and the upper one as ν_1. The heavy mixing between the two states is also apparent in the probability distributions given in Fig. 3.

8. Simulation of spectra

To simulate spectra we use line positions obtained by calculating appropriate energy level differences, and intensities obtained from line strengths that are calculated from the square of the transition moment matrix elements involving the wavefunctions and ab initio transition moment surfaces given in eqs. [9]–[13]. The details of such a calculation are given in ref. 29. In Fig. 4 we show the result of simulating the emission spectrum from the 0_{00} rotational level of the $\tilde{A}$ (0,7,0) vibronic state to the 1_{10} levels of the $P = 10$ polyad of the $\tilde{X}$ state. For comparison we also show in this figure the observed spectrum from ref. 15[3] The relative intensities are extraordinarily sensitive to small changes in the potential energy functions and the agreement with experiment is not perfect; we underestimate the intensity of the transitions to the $i = 3$, 9, and 11 components. However, the weakness of the $i = 7$ and 10 components is correctly accounted for. The intensity distributions in our simulations of the emission spectra involving the other polyads are in broad agreement with the results in ref. 15, and all lines that could not be found experimentally are calculated as having low intensity relative to the observed lines. The strong transitions are generally those to states with high excitation of the bending mode. In such states, we get the highest vibronic transition moments with the initial state ($\tilde{A}\,^1B_1$ (0,7,0)), whose bending angle probability distribution is given in Fig. 2.

Initially in our fitting there seemed to be an interesting ambiguity in the assignment of the lowest two members ($i = 10$ and 11) of the polyad $P = 10$. In ref. 15 a level at 9306.07 cm^{-1} is observed and it is assigned as the $i = 11$ component of the $P = 10$ polyad; no level is assigned as the $i = 10$ component. Using the ab initio potential energy surfaces we find (see under the column headed "MCI Calc" in Table 4) that the $i = 10$ and 11 components of the $P = 10$ polyad are calculated at 9326.83 and 9151.24 cm^{-1}. Just looking at this result one would assign the 9306.07 observed term value as the $i = 10$ level rather than as the $i = 11$ level. However, the (obs–calc) deviations are large and negative for the lowest components of each polyad, and the assignment of the 9306.07 cm^{-1} level as $i = 11$, as done in ref. 15, is not unreasonable. Using this assignment we made the fitting to obtain the fitted potentials quoted here, and the simulation given in Fig. 4. We did try another fitting done just as above but with the single change of assigning the level at 9306.07 cm^{-1} as $i = 10$ in $P = 10$; the result for the $P = 10$ polyad is given in the column headed "Alternative" in Table 11, and the simulated $P = 10$ emission spectrum obtained using the alternative parameters is compared with the experimental spectrum[3] in Fig. 5. The relative intensities in the calculated spectrum using the alternative parameters are in very poor agreement with experiment, so although the fitting to the term values with the assignment of the 9306.07 cm^{-1} term value as $i = 10$ does not lead to unreasonable calculated term values it does lead to unreasonable calculated intensities. However, it is quite remarkable and alarming to us that with so much vibrational data there is still enough flexibility that it is possible to adjust the potential in a way that allows an alternative fitting to the same term value data but with a single level reassigned to have a substantial shift of about 100 cm^{-1}. We await with interest the results of further experiments to find more vibrational term values for singlet silylene.

Collisions and reactions of ultracold molecules[1]

William C. Stwalley

Abstract: It is argued that collision dynamics of atoms and molecules at ultracold temperatures (below 1 mK) are not readily predictable from knowledge of collision dynamics above 100 K. In the case of elastic collisions, it is well known that the collision cross section is constant as $T \rightarrow 0$ K but mass and symmetry effects are dramatic. The cases of inelastic and reactive collisions are less studied, but a $T^{-1/2}$ dependence of the cross section as $T \rightarrow 0$ K is expected. It seems that extrapolations of high-temperature inelastic and reactive behavior normally greatly underestimate ultracold-temperature rates. The prospects for experimental observation of ultracold collision dynamics are rapidly improving.

Key words: ultracold molecules, collisions, reactions, hydrogen, scattering length.

Résumé : Dans cet article, on avance que la dynamique des collisions d'atomes et des molécules à des températures ultrafroides (en dessous de 1 mK) ne peut pas être prédite sur la base de nos connaissances de la dynamique des collisions à des températures supérieures à 100 K. Dans le cas des collisions élastiques, il est bien connu que la section droite de collision est constante lorsque la température tend vers 0 K, toutefois les effets de masse et de symétrie sont dramatiques. Les cas des collisions inélastiques ou réactives ont moins bien été étudiées, mais il est prévu que la section droite adoptera un comportement $T^{-1/2}$ lorsque la température tendra vers 0 K. Il semble que, d'une manière générale, les extrapolations du comportement inélastique ou réactif à température élevée sous-estiment grandement les vitesses à des températures ultrafroides. Les possibilités de pouvoir observer directement la dynamique de collisions à des températures ultrafroides augmentent rapidement.

Mots clés : molécules ultrafroides, collisions, réactions, hydrogène, longueur de diffusion.

[Traduit par la Rédaction]

Introduction

The study of chemical reactions and elastic and inelastic nonreactive collisions at ultracold (<1 mK) temperatures is a frontier in chemistry where many surprising results are expected. These collisions are sensitive to the details of atomic and molecular interactions such as small potential energy barriers (including centrifugal), fine and hyperfine structure, Stark shifts, and Zeeman shifts. They are highly quantum-mechanical, exhibiting large effects from resonances, tunneling, and identical particles. They are highly constrained by the precisely known energetics and by angular momentum barriers. Techniques for study of cold reactions include matrix isolation spectroscopy (since the 1950s), van der Waals photochemistry, low-temperature ion–molecule reactions, and, most recently, reactions in/on liquid helium (bulk or clusters) (1). A number of two-body and three-body ion–molecule reactions have been studied in the 0.3–1 K temperature range (2), but we are not aware of any neutral gas-phase reactions studied below 1 K and especially below 1 mK. However, ultracold photoassociation (PA) (the absorption of a photon by a colliding pair of atoms to produce an electronically excited molecule) has been studied extensively (3).

It is my contention here that ultracold (<1 mK) collision cross sections are basically independent of normal thermal ($\sim 10^2$–10^3 K) collision cross sections. This is true for elastic, inelastic, and reactive collisions. Moreover, the low-temperature cross sections, unlike those at normal thermal temperatures, depend strongly on the reduced mass of the collisions.

Elastic collisions

It is well known that two-body elastic collisions (as well as two-body bound states) are governed by the radial Schrödinger equation (RSE), here written in "reduced" form:

$$[1] \qquad \left[-\eta \frac{d^2}{dr^{*2}} + V^*(r^*)\right]\Psi(r^*) = E^*\Psi(r^*)$$

where $r^* = r/\sigma$ is the dimensionless reduced interatomic distance, $V^* = V/\varepsilon$ is the dimensionless reduced potential energy, $E^* = E/\varepsilon$ is the dimensionless reduced total energy, σ is the "hard sphere radius" where $V^*(\sigma) = 0$, ε is the potential-well depth, and $\eta = \hbar^2/2\mu\varepsilon\sigma^2$, where μ is the reduced mass (4).

Table 1. Total elastic collision cross sections at 0 K for spin-polarized isotopic hydrogen atoms (5) and for isotopic helium atoms (4).

Species	a (a_0)	Q (a_0^2)
H + H	1.335	44.8[a]
H + D	–0.448	2.52
H + T	–1.597	32.0
D + D	6.907	0[b]
D + T	–15.53	3 031
T + T	–81.55	167 100[a]
^{3}He + ^{3}He	–13.19	0[b]
^{3}He + ^{4}He	–31.82	12 720
^{4}He + ^{4}He	231.0	1 341 000[a]

[a]Assuming identical boson spin states.
[b]Assuming identical fermion spin states (no s-wave scattering).

Of particular significance for this work is the solution of the RSE for small positive energy (ultracold temperatures below 1 mK). In particular as $T \rightarrow 0$ K, only "head-on" s-wave ($\ell = 0$) collisions penetrate to short "chemical" distances, all ($\ell \geq 1$) collisions being repelled by centrifugal barriers (3). The s-wave collisions are described by the s-wave phase shift δ_0, which in turn is conventionally related to the scattering length a and the effective range r_0 by the equation

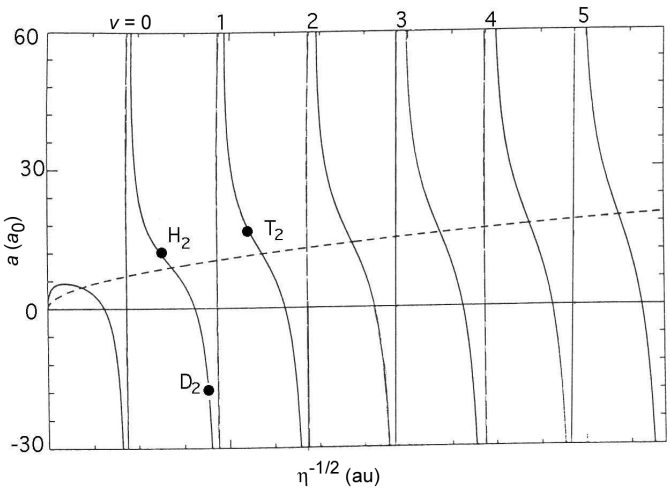
$$[2] \qquad k \cot \delta_0 = -\frac{1}{a} + \frac{1}{2} r_0 k^2 + 0(k^4)$$

where $\hbar k$ is the momentum and the kinetic energy of collision $E_k = \hbar^2 k^2 / 2\mu$.

For two distinguishable particles, the low-temperature limit of the elastic scattering cross section Q is given by

$$[3] \qquad \lim_{T \rightarrow 0} Q^D = 4\pi a^2$$

For two indistinguishable bosons, this limit is



$$[4] \qquad \lim_{T \rightarrow 0} Q^{IB} = 8\pi a^2$$

while for two indistinguishable fermions, this limit is

$$[5] \qquad \lim_{T \rightarrow 0} Q^{IF} = 0$$

In this last case, "head-on" s-wave collisions are forbidden by symmetry and the p-wave collisions are suppressed by the $\ell = 1$ centrifugal barrier. Examples of scattering lengths and cross sections for nine light and weakly interacting systems are given in Table 1. Note the wide variation among systems that would have similar collision cross sections at room temperature. For two of the systems, the cross section is zero by symmetry (eq. [5]), but the cross sections of the others vary by 6 orders of magnitude! The largest is that for ^{4}He + ^{4}He, as this is the only case where there is a (barely) bound vibrational level ($v = 0$, $J = 0$) in the potential well. The cross section for the T + T case is also large (but the scattering length is opposite in sign) because there is not yet a bound level (a reduced mass of 1.62 amu (vs. 1.50 amu for T_2) would just give a bound level and an extremely large a approaching infinity). Remember that in the first six cases and in the last three cases in Table 1, the interactions are virtually identical; only the mass and symmetry are changing, but these have major dramatic effects.

Fig. 1. The scattering length for collisions of isotopic hydrogen molecules (all $J = 0$) based on spectroscopic experiments, collision experiments, and scattering calculations using ab initio potential surfaces (see text), plotted versus $\eta^{-1/2} = (2\mu\varepsilon\sigma^2/\hbar^2)^{1/2}$. Adapted from the work of Gribakin and Flambaum (13).

In general, molecule–molecule scattering lengths are unknown and hard to determine. We point out here an exception: the isotopic H_2 molecules ($v = 0$, $J = 0$). In particular, there is a variety of impressive experiments and calculations relating to the H_2–H_2 system. Early work by Watanabe and Welch on the $(H_2)_2$ van der Waals molecule (6) and by Bauer et al. on para-H_2 – para-H_2 scattering at low energies (7) highly constrained the molecule–molecule interaction. An excellent but now somewhat old review was published by Silvera (8). More recently, precise spectra of the $(H_2)_2$, $(HD)_2$, and $(D_2)_2$ van der Waals molecules were obtained by McKellar and others (see, e.g., refs. 9 and 10). Simultaneously, Schaefer and co-workers refined theoretical calculations of the interactions, cross sections, and bound states (see e.g., refs. 10–12). In particular, ref. 11 shows a low-energy limiting elastic H_2–H_2 cross section of ~3210 a_0^2, corresponding to a scattering length of +11.3 a_0 (which must be positive since it implies a value by simple mass scaling of –17 a_0 for D_2–D_2, consistent with the observation that the $(D_2)_2$ dimer has only a $v = 0$ level, and a value of +17 a_0 for T_2–T_2) as shown in Fig. 1. Thus, purely by accident, Q^{IB} for D_2–D_2 collisions and Q^{IB} for T_2–T_2 collisions are nearly identical as $T \rightarrow 0$ K (7800 a_0^2). Note that these limiting cross sections, as well as those in Table 1, can be much larger or much smaller (even zero) than room temperature cross sections.

Inelastic collisions

Wigner's work on threshold laws for excitation by collision (14) in combination with microscopic reversibility implies that de-excitation collision cross sections become infinite as the collision energy approaches zero (15). In particular, the inelastic nonreactive atom–molecule collisions of ^{4}He + I_2 ($v = 0$, $J = 0$) (15) and H + H_2 ($v = 0$, $J = 0$), ^{3}He + H_2 ($v = 0$, $J = 0$), and ^{4}He + H_2 ($v = 0$, $J = 0$) (16, 17) have

© 2004 NRC Canada

been studied theoretically down to $<10^{-3}$ K, where Wigner threshold law behavior is expected and found; the inelastic cross section increases as $T^{-1/2}$ as $T \rightarrow 0$ K, giving a constant relaxation rate at microKelvin temperatures and below. It is important to realize how erroneous any sort of extrapolation of results obtained for >100 K would be. For example, for vibrational relaxation of H_2 ($v = 1$, $J = 0$) by ^{3}He (17), the room temperature rate and the low-temperature ($T = 10^{-3}$ K) Wigner law rate are nearly identical ($\sim 3 \times 10^{-17}$ cm^3 molecule^{-1} s^{-1}). However, rough extrapolation of the 100–300 K results yields a ridiculously low rate of 10^{-29} cm^3 molecule^{-1} s^{-1} at 10^{-2} K and 10^{-40} cm^3 molecule^{-1} s^{-1} at 10^{-6} K, an error of >20 orders of magnitude!

Similar results are expected for other inelastic processes, for example, electronic and nuclear spin-flip collisions (18). One complication in the above picture, which can be written in terms of a complex scattering length (16), is the presence of resonances (15). If shape or Feshbach resonances occur in the $T < 10^{-3}$ K regime, where Wigner behavior is normally expected, the cross section will not show a simple $T^{-1/2}$ dependence. This becomes more of a problem as the masses of the atoms involved become heavier and the likelihood of sub-milliKelvin resonances becomes greater.

An interesting prediction was made many years ago that the rate of vibrational de-excitation might drop dramatically for the highest vibrational levels near dissociation (18). This is because the last level will have a very small average kinetic energy and the atoms will spend most of their time at much larger internuclear distances than in the next highest level; at room temperature, this would mean collision-induced dissociation would dominate over de-excitation. However, at the microKelvin temperatures, collision-induced dissociation is no longer possible, so such levels may be remarkably stable. This may be related to the exciting new announcements of Bose–Einstein condensation of "Cooper paired" molecules of $^6Li_2$ (19) and $^{40}K_2$ (20) in their last bound vibrational level.

Reactive collisions

It is useful to distinguish between reactions that are exoergic (e.g., $D + H_2 \rightarrow HD + H$) and those that are thermoneutral (e.g., $H + H_2 \rightarrow H_2 + H$), where the atoms and molecules are in their lowest energy states. In the former case, as for inelastic collisions (and for the same reason (14, 15)), the cross section increases like $T^{-1/2}$ as $T \rightarrow 0$, and the rate becomes constant. The latter case is not of practical importance here since it would not be "reaction" for truly indistinguishable particles. Since the isotopic variants of the $H + H_2$ reaction at thermal energies and above are well known and in excellent agreement with theory (21), it is appropriate to ask about them at ultracold temperatures (22). Rather surprisingly, careful calculations using variational transition-state theory with a transmission coefficient for tunneling (22) show a $T^{-1/2}$ dependence of the rate (T^{-1} dependence of the cross section) as $T \rightarrow 0$ K, in contrast to the expected constant rate and $T^{-1/2}$ dependence of the cross section. However, more recent close-coupling calculations by Simbotin and Côté show the predicted threshold behavior of constant rate and $T^{-1/2}$ dependence of the cross section (I. Simbotin and R. Côté, private communication, 2004). The tunneling transmission coefficients of ref. 22 do give far larger and far more reasonable rates at low temperatures than any simple extrapolation of the high-temperature results (21), but they do not give the correct Wigner behavior. Perhaps multiple traversals of the tunneling region could be contributing.

Again, the uppermost long-range molecular levels were discussed long ago (23), using the notation M_2^∞ to indicate that the radial extension was quite large (albeit not ∞). Such molecules, it was speculated, might selectively react

[6] $$A_2^\infty + B \rightarrow A + AB^\infty$$

even though the A_2 and AB bond strengths are different. Even more likely to be selective would be isotopic reactions, such as the one given in ref. 23:

[7] $$^6Li_2^\infty + {}^7Li \rightarrow {}^6Li^7Li^\infty + {}^6Li$$

The remarkable stability that the $^6Li_2$ and $^{40}K_2$ molecule Bose–Einstein condensates mentioned in the previous section show may be related in part to the above speculation.

Summary

We have argued that collisional behavior at very low "ultracold" temperatures (below 10^{-3} K), which are now becoming accessible experimentally, is dramatically different from that at room temperature. Elastic collision cross sections can be larger or smaller, depending more on the mass and symmetry than on the interaction. Inelastic and reactive collision rates are usually larger, often far larger, than any rates estimated from results obtained at $T > 100$ K. Thus, study of ultracold atomic and molecular collisions should be a rich and surprising field to study.

Acknowledgements

The beautiful low-temperature, rotationally limited spectra of molecular hydrogen obtained by Gerhard Herzberg (24) and his colleagues inspired my long-term interest in H_2 and its more laser-friendly analogues, the alkali-metal dimers. Their work also inspired my interest in detailed comparisons of experiment and theory, especially in diatomic molecules near dissociation where long-range interactions play a dominant role. The entire field of photoassociative spectroscopy of ultracold atoms (3) was in several ways brilliantly foreshadowed by the work of Herzberg and his colleagues (24).

Highly accurate transition frequencies in the H_2 Lyman and Werner absorption bands[1]

J. Philip, J.P. Sprengers, Th. Pielage, C.A. de Lange, W. Ubachs, and E. Reinhold

Abstract: The transition frequencies of low-J excitation lines in the $B^1\Sigma_u^+ - X^1\Sigma_g^+$, $(v', 0)$ Lyman bands have been measured for $v' = 2$–18 and in the $C^1\Pi_u - X^1\Sigma_g^+$, $(v', 0)$ Werner bands for $v' = 0$–4, using a narrow-band tunable extreme UV laser source at wavelengths $\lambda = 92$–105 nm in conjunction with the technique of $1 + 1'$ two-photon ionization. The measurements can be divided into three categories for which varying absolute accuracies were obtained. Special focus was on the B, $v' = 2$–5 bands, where an accuracy of 0.004 cm^{-1} or $\delta\nu/\nu = 4 \times 10^{-8}$ is achieved. For transitions to B, $v' \leq 13$ and C, $v' \leq 3$ states the accuracy is 0.005 cm^{-1} or $\delta\nu/\nu = 5 \times 10^{-8}$. Due to a different frequency mixing scheme uncertainties for B, $v' \geq 13$ and C, $v' = 4$ are at the level of 0.011 cm^{-1} or $\delta\nu/\nu = 1.1 \times 10^{-7}$. Inspection of combination differences between R(J) and P($J + 2$) lines shows that the accuracies are even better than estimated in the error budget. Based on the measurements of 138 spectral lines and the known combination differences, transition frequencies of 60 P-lines could be calculated as well, so that a data base of 198 accurately calibrated lines results for the Lyman and Werner bands of H_2.

Key words: vacuum UV, molecular spectroscopy, hydrogen, precision metrology.

Résumé : On a mesuré les fréquences de transition des raies d'excitation de faible J dans les bandes de Lyman $B^1\Sigma_u^+ - X^1\Sigma_g^+$, $(\nu', 0)$, pour des valeurs de ν' allant de 2 à 18 ainsi que dans les bandes de Werner $C^1\Pi_u - X^1\Sigma_g^+$, $(\nu', 0)$, pour des valeurs de ν' allant de 0 à 4 en faisant appel à une source laser UV extrême, ajustable et à bande mince, à des longueurs d'onde, λ, allant de 92 à 105 nm, utilisée de concert avec la technique d'ionisation à deux photons $1 + 1'$. Les mesures peuvent être divisées en trois catégories qui diffèrent entre elles par la précision des mesures obtenues. On a concentré nos efforts sur les bandes B, $\nu' = 2$–5, pour lesquelles la précision a été de 0,004 cm^{-1} ou $\delta\nu/\nu = 4 \times 10^{-8}$. Pour les transitions vers B, $\nu' \leq 13$ et C, $\nu' \leq 3$, la précision est de 0,005 cm^{-1} ou $\delta\nu/\nu = 5 \times 10^{-8}$. En raison d'une méthode différente de combinaison des fréquences, les incertitudes associées à B, $\nu' \geq 13$ et C, $\nu' = 4$, le niveau de précision est de 0,011 cm^{-1} ou $\delta\nu/\nu = 1{,}1 \times 10^{-7}$. Un examen des différences des combinaisons entre les raies R(J) et P($J + 2$) montre que les précisions sont meilleures que celles évaluées dans le budget des erreurs. Sur la base de mesures de 138 raies spectrales et de différences de combinaison connues, on a pu aussi calculer les fréquences de transition de 60 raies P et il en résulte qu'une base de données de 198 raies bien calibrées est disponible pour les bandes de Lyman et de Werner du H_2.

[Traduit par la Rédaction]

1. Introduction

Molecular hydrogen is the smallest neutral molecule and the most abundant molecular species in the universe. The Lyman bands, corresponding to the $B^1\Sigma_u^+ - X^1\Sigma_g^+$ system, and the Werner bands, corresponding to the $C^1\Pi_u - X^1\Sigma_g^+$ system, connect the electronic ground state to the lowest excited states of singlet and *ungerade* symmetry in a dipole-allowed transition, making them the most prominent features in the H_2-spectrum. Both systems relate to the $1s$–$2p$ resonance line of the H_2 molecule in analogy to the Lyman-α line in the H atom. In case of the $B^1\Sigma_u^+$ state the electron is promoted to a $2p\sigma$ orbital, whereas for the $C^1\Pi_u$ state the electron is in $2p\pi$. In his pioneering studies on the vacuum UV emission spectrum, now a century ago, Lyman was the first to positively assign a spectrum to the H_2 molecule (1, 2): the $B^1\Sigma_u^+ - X^1\Sigma_g^+$ system. Later, in 1926, Werner was the first to assign spectral lines pertaining to the $C^1\Pi_u - X^1\Sigma_g^+$ system (3). Dr. Herzberg, to whom we dedicate the present study, devoted an appreciable part of his career to the study of the spectrum of molecular hydrogen. Among his pioneering breakthroughs we mention the observation of the IR quadrupole spectrum (4), his analysis of the Rydberg spectrum, with Jungen (5), laying the foundations for the application of quantum defect theory in molecules, the determination of the dissociation energy (6), and his work with Jungen, Dabrowski, and Vervloet (7) on the measurement of IR inter-Rydberg transitions, leading to a determination of the ionization potential. Also, for the Lyman and Werner bands Herzberg made cru-

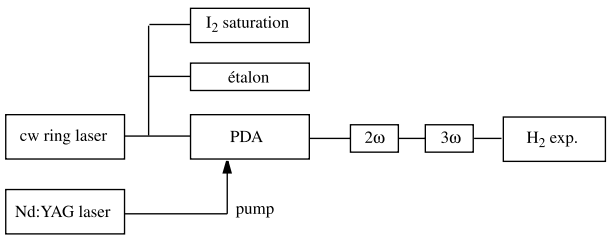
cial contributions, with Howe (8) and with Dabrowski (9), on a full rotational analysis of the emission spectra. High resolution absorption spectra of the Lyman and Werner band systems, using classical grating spectrometers, were investigated by Namioka (10) and by Dabrowski (11). The classical studies culminated in a comprehensive study of the H_2 VUV-spectrum by scientists at the Meudon Observatory, which was published in the form of a high-resolution spectroscopic atlas (12).

Developments on the experimental side were, over the years, accompanied by theoretical studies, for which the H_2 molecule is a benchmark system. Ab initio calculations of the potential energy curves have been produced using the Born–Oppenheimer approximation and calculating separately the mass-dependent adiabatic corrections to the potential curves as well as the non-adiabatic corrections for determination of accurate level energies. Advanced calculations for the $X^1\Sigma_g^+$ electronic ground state are those of Wolniewicz (13). An accurate potential energy curve for the $B^1\Sigma_u^+$ state was reported by Cencek et al. (14) and for the $C^1\Pi_u$ state by Wolniewicz (15). For a calculation of level energies in the $B^1\Sigma_u^+$ and $C^1\Pi_u$ excited states the couplings between the $B^1\Sigma_u^+$, $B'^1\Sigma_u^+$, $C^1\Pi_u$, and $D^1\Pi_u$ states and the resulting interferences have to be treated, based upon the input of ab initio potentials. The Meudon group has calculated those coupling effects in a number of studies of increasing accuracy (16) finally resulting in tables of transition frequencies for the Lyman bands (17) and Werner bands (18). Based upon these studies, a vast amount of rotationally resolved lines of the H_2 atlas (12) could be assigned.

The first observation of molecular hydrogen in space was performed with a rocket-borne spectrometer detecting Lyman band absorption in the optical path toward ξ Persei (19). Since then various satellite-based telescopes including spectrometers in the vacuum UV range have been launched for the study of H_2 and other molecules. The *Copernicus* satellite telescope (20) was in operation for many years, while the better resolving instruments ORFEUS and IMAPS were flown aboard the Space Shuttle for limited periods. The Hubble Space Telescope yielded a greatly improved sensitivity combined with a good resolving power and absorption from H_2 vibrationally excited levels could even be recorded (21). The *Galileo* orbiter, equipped with an UV (113–432 nm) as well as an extreme-UV (54–128 nm) spectrometer, recorded the Lyman and other H_2 bands from the north and south polar regions of Jupiter (22). Since June 1999, the Far ultraviolet spectroscopic explorer (FUSE) is in flight and detecting hydrogen in space. It covers the wavelength range 90.5–118.7 nm, the range of the strong Lyman and Werner absorption bands, with high resolution (23) and with a 10^4 greater sensitivity than Copernicus.

The present paper reports on a high-resolution laser spectroscopic study of the Lyman and Werner bands. A narrow-band tunable extreme ultraviolet (XUV) laser source is used in a $1 + 1'$ resonance-enhanced multi-photon ionization (REMPI) scheme to determine transition frequencies of various low-J lines in $B^1\Sigma_u^+ - X^1\Sigma_g^+(v', 0)$ bands for $v' = 2$–18 and in $C^1\Pi_u - X^1\Sigma_g^+(v', 0)$ bands for $v' = 0$–4. In previous high-resolution studies by our group, a coherent laser-based XUV-source was also used, but now the resolution has been increased by an order of magnitude, while at the same time the methods for absolute calibration have been improved. Initially, in a pilot study, the $B–X(10, 0)$ band had been studied (24). This work was extended to a comprehensive laser excitation study of 291 lines in Lyman $B–X(v', 0)$ bands for $v' = 10$–19 and Werner $C–X(v', 0)$ bands for $v' = 0$–5 (25). Later, a further extension was performed for $B–X(v', 0)$ bands for $v' = 20, 22, 23, 25$–27, and $C–X(v', 0)$ bands for $v' = 6$–10 (26). The absolute accuracies on the transition frequencies in these laser-based measurements varied between 0.02 and 0.06 cm^{-1}. These accuracies have been improved now by almost an order of magnitude.

2. Experiment and assessment of error budget



The Amsterdam narrow-band tunable XUV radiation source and its application in atomic (27) and molecular (28) spectroscopy have been described previously. A schematic layout of two slightly differing experimental setups, further referred to as schemes I and II, are displayed in Fig. 1. In short, the radiation source consists of a tunable ring-dye-laser delivering continuous wave (cw) radiation in the range 570–660 nm, a three-stage pulsed-dye amplifier (PDA) pumped by a pulsed Nd:YAG laser, a frequency-doubling crystal for converting the visible output of the PDA to the UV range, and a pulsed gas jet in which the pulsed UV radiation is frequency-tripled to cover the wavelength range 95–110 nm. The bandwidth of the XUV light in this range was previously estimated at 250–300 MHz, slightly below 0.01 cm^{-1} (see also ref. 28). The pulsed-XUV beam is crossed perpendicularly by a molecular beam obtained from a pulsed nozzle. In the interaction zone signal is generated by $1 + 1'$ photo-ionization, whenever the XUV radiation is tuned in resonance with a Lyman or Werner absorption line. In view of the cooling effect of the pulsed molecular beam, only transitions originating in the low rotational levels can be accessed. Spectral lines are recorded by scanning the cw laser system and monitoring the H_2^+-ion production in the interaction zone. The wavelength used in the ionizing step is the UV wavelength before tripling, corresponding to $\lambda_{UV} = 3\lambda_{XUV}$ at each H_2 resonance. For the $B–X(2, 0)$ band the total energy of the XUV and UV photons is not sufficient to produce H_2^+ ions directly. Nevertheless, this band could be recorded from the signal induced by a $1 + 2'$ process using the region of high Rydberg states for resonance enhancement. In this case, the H^+ signal was monitored, which originates from photo-dissociated H_2 molecules, producing $H(n = 2)$ atoms that are subsequently ionized. The $B–X$ (0,0) and (1,0) bands were not covered in this study because the saturation I_2 standard does not extend to these wavelengths for the fundamental (29, 30).

At the short wavelength limit (at $\lambda < 570$ nm), problems arose with the operation of the cw ring-dye laser, which was pumped by a Millennia 5W laser at 532 nm. Hence, the study was limited to $B(v' \leq 13)$ and $C(v' \leq 3)$ when using scheme I as displayed in Fig. 1. For this reason, wavelengths in the range $\lambda < 95$ nm were produced via an alternative frequency mixing scheme (shown as scheme II in Fig. 1). The green output of the Nd:YAG laser was used, both for pumping the PDA as well as for sum-frequency mixing with the output of the PDA, to reach shorter wavelengths. These methods have been described in more detail in a separate paper (31). Although the output frequency of the Nd:YAG laser is in principle fixed, temperature drifts caused slowly varying frequency excursions of several

(*a*) Scheme I

(*b*) Scheme II

GHz during a measurement session. Its frequency was therefore monitored on-line by a four-étalon wavelength meter (ATOS), which was calibrated on an absolute scale by comparison to I_2 saturated lines, during each measurement session. This method yields an absolute accuracy of 100 MHz for the Nd:YAG output at 18 788 cm^{-1}.

The linewidths observed in the recording of the Lyman and Werner lines are ≈500 MHz, and slightly dependent on the measurement geometry and molecular beam conditions chosen. The bandwidth of the XUV laser source of ≈300 MHz (see refs. (27, 28)) is independent of the choice of scheme I or II. The upper $B^1\Sigma_u^+$ and $C^1\Pi_u$ states have lifetimes of 0.5–1 ns causing a Lorentzian type broadening of up to 300 MHz. For experimental geometries in which the nozzle–skimmer distance in the molecular beam was set at 15 cm (typical measurement conditions), the Doppler contribution was found to be negligible, particularly for molecular beams in which 25% H_2 was seeded in krypton gas to lower the average velocity of the molecules. Additional broadening was found if the nozzle–skimmer distance was lowered (i.e., when the signal intensity had to be increased). At very short nozzle–skimmer distances, we found increased population of high rotational states ($J = 4$ and $J = 5$), possibly due to glancing collisions at the conical skimmer surface. Detailed studies were performed comparing the transition frequencies and their Doppler shifts on the nearby lying transitions B–$X(12, 0)$ R(1) in H_2 and $4p^6\,{}^1S$–$5d_{1/2}(J = 1)$ in ^{84}Kr, at various beam conditions (i.e., beam velocities and nozzle–skimmer distances). From these measurements an estimate was made of the Doppler shift and of its effect on the uncertainty of the transition frequencies. The latter is included in the error budget for an amount of 60 MHz. For the set of measurements on B–$X(v', 0)$, $v' = 2$–5 lines an even more careful analysis of the Doppler shift, involving seeding H_2 gas in xenon, yields a maximal systematic error of only 40 MHz.

Calibration of the source was performed by reference measurements with the visible output of the cw ring-dye laser. Simultaneously with the H_2 spectrum, transmission fringes of a pressure- and temperature-stabilized étalon and the saturation spectrum of molecular iodine were recorded. The free spectral range (FSR) of the étalon was well calibrated at 148.9567 MHz and the t-hyperfine components of the I_2 saturation spectrum were calibrated in our laboratory with an absolute accuracy (2σ) of 2 MHz (29, 30). Hence, the XUV frequency scale can be obtained by multiplication of the scale for visible frequencies by a factor of six (i.e. for scheme I in Fig. 1), thus accounting for frequency doubling and subsequent frequency tripling. Estimates were made of the uncertainty caused by frequency drift of the pressure- and temperature-stabilized étalon. In the most unfortunate cases, when useful I_2 saturation lines were far away, continuous scans of ≈ 20 min duration had to be recorded, resulting in contributions to the error budget of 20 MHz (scheme I) or 10 MHz (scheme II). Special precautions were taken during measurements of the B–$X(v', 0)$ Lyman bands for $v' = 2$–5. During these recordings the étalon was actively stabilized with the aid of a HeNe laser, which was itself frequency-locked to an I_2 saturation line.

Two examples are presented of spectral recordings of the H_2 spectrum that elucidate the high-resolution capabilities of the setup. Fig. 2 shows the R(0) and R(1) lines in the C–$X(1, 0)$ Werner band, clearly separated by 1.09 cm^{-1}; in the classical absorption spectrum these lines were determined at a separation of 2 cm^{-1}, most likely because of partial overlap (9). A second spectrum, displayed in Fig. 3, shows the nearby lying P(3) line of the C–$X(1, 0)$ band and the R(0) line of the B–$X(9, 0)$ band, separated by only 0.16 cm^{-1}. Recordings of H_2^+ and H^+ signals show that excitation of Werner lines usually yields only parent ions, while excitation of Lyman lines also produces a H^+ signal. Absolute calibration is performed with respect to the t-component of the P(126) line of the B–$X(15, 2)$ band in iodine. Computerized fitting procedures to the spectral lineshapes aid in determining the line centers with high precision. The contribution of the uncertainty of the reference spectrum is minor (10 MHz). A statistical uncertainty in the determination of line centers is caused by the fitting of the observed line profiles. Slight variations in the central frequencies obtained in repeated scans of a transition are also treated as statistical uncertainty. The final value for a line position is obtained by the weighted mean deduced line centers from all scans, using the number of laser pulses per wavelength interval as a weight factor. In this procedure a final statistical uncertainty is derived. For ease of representation, and to take a conservative estimate, an upper limit of the statistical uncertainty in each of the measurement schemes is used, instead of slightly different values for each line. For the very weak lines, and the lines recorded under conditions of additional broadening, a higher estimate of the uncertainty is listed in the Tables. Most lines were recorded three times, except for the set of Lyman bands B–$X(v', 0)$ for $v' = 2$–5, where the lines were recorded 10 or more times. In cases where frequency-mixing scheme II was employed, the calibration uncertainty was dominated by the frequency measurement of the green output of the Nd:YAG laser. Since $\omega_{XUV} = 3\omega_{PDA} + 3\omega_{Nd:YAG}$, the uncertainty of this measurement comes into the error budget three times (i.e., 300 MHz).

The AC-Stark effect in the H_2 Lyman bands was investigated recently by Wetzig et al. (32). The intensity of the XUV beam

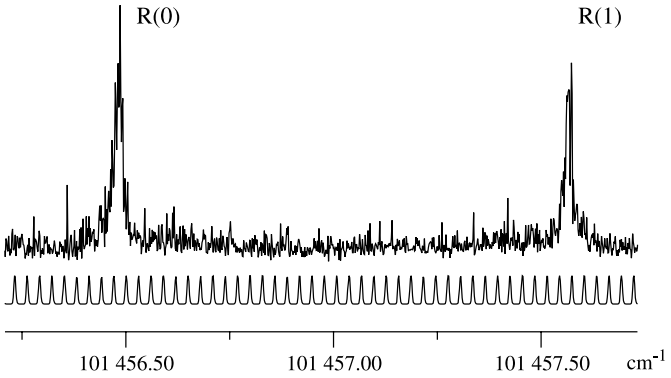
Fig. 2. Recording of the R(0) and R(1) lines of the $C–X(1, 0)$ Werner band separated by 1.09 cm^{-1}.



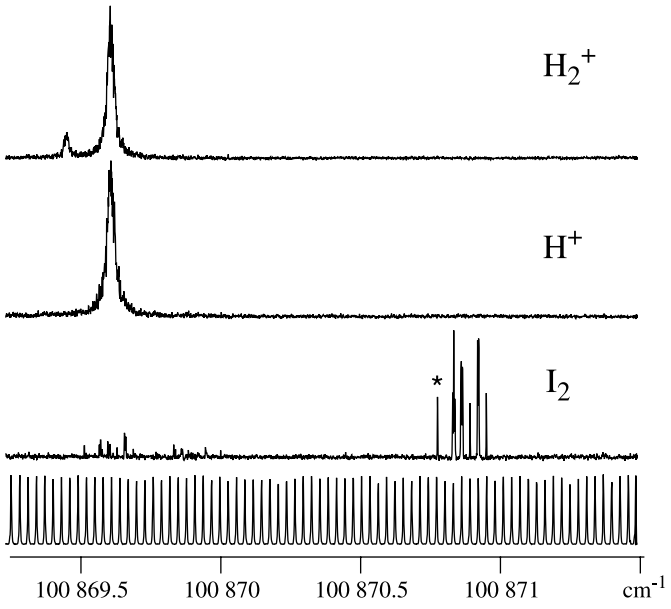


Fig. 3. Recording of the P(3) line of the $C–X(1, 0)$ Werner band and the R(0) line of the $B–X(9, 0)$ Lyman band of H_2 for both the H_2^+ and H^+ signals in the XUV domain. Below: simultaneous recordings of transmission fringes of the stabilized étalon and the saturation spectrum of molecular iodine at the fundamental frequency ($\nu_{XUV}/6$). The line marked with an asterisk denotes the P(126) line in the $B–X(15, 2)$ at 16 811.7958 cm^{-1}.

in the present experiment is so low (sub-nJ pulse energies in a diverging beam) that its AC-Stark inducing effects may be neglected, and the UV-ionizing laser in the $1 + 1'$ two-photon ionization process dominates the AC-Stark shifts. The maximum UV intensity in the interaction zone is 4 MW/cm^2 (20 mJ/pulse, 5 ns pulse duration, 1 cm^2 area) at the highest pulse energies used. By taking into account the quadratic Stark effect for $^1\Sigma$ states and the polarizabilities for the $B\,^1\Sigma_u^+$ state as calculated by Rychlewski et al. (33), as well as effective polarizabilities obtained from experimental data, they estimate for the case of $1 + 1'$ REMPI (UV intensities of $I = 10$ GW/cm^2 and parallel polarizations of XUV and UV beams, asymmetrically shaped lines with an intensity maximum shifted by -4.0 cm^{-1}, and a shift of the effective line center by -3.0 cm^{-1}. The polarizability of the $X\,^1\Sigma_g^+$ ground state is orders of magnitude smaller and can be neglected. With the estimated polarizability of ref. 32, this yields a shift of 0.0015 cm^{-1} or less for the line center at the highest pulse energies used in the present study. The work of Wetzig et al. (32), dealing with the $B\,^1\Sigma_u^+$, $v' = 3$ and $v' = 4$ levels, provides an exemplary case. If their analysis may be taken as a guidance, this would result in an upper limit of 50 MHz for the AC-Stark shift for spectral lines recorded at the highest laser pulse energies. In the case of frequency mixing scheme II, lower laser pulse energies (< 10 mJ/pulse) were produced, and hence limits to the AC-Stark shift could be relaxed accordingly. Eikema et al. (27) performed measurements on the $1 + 1'$ REMPI excitation mechanism via the $(2p)\,^1P$ state in He; such a scheme can be considered to represent the unified-atom limit to excitation via $(2p\sigma)$ and $(2p\pi)$ in the H_2 Lyman and Werner bands. From the study on He an AC-Stark shift of 2.5 MHz per MW/cm^2 can be deduced, confirming the estimate on an upper limit for the AC-Stark effect of less than 50 MHz.

In addition to these estimates, an experimental assessment was made of the AC-Stark effect. A large set of over 30 recordings was taken for the R(1) line of the $C–X(1, 0)$ Werner band in a pulse energy range of 2–15 mJ/pulse. From an analysis of these data it follows that a possible AC-Stark shift is smaller than the statistical spread in the data set; no intensity-dependent trend is observed. From these data we conclude that the estimated contribution of 50 MHz to the AC-Stark shift is conservative. In the study of the $B–X(v', 0)$ bands for $v' = 2$–5 another large data set was gathered focusing on laser intensity effects in the range of pulse energies 2–5 mJ/pulse. Even though the statistical error was smaller, no systematic trend that might possibly be attributed to an AC-Stark effect was found; for this particular data set the estimate of the error contribution by the AC-Stark effect is taken at the lower value of 30 MHz.

Two final remarks can be made on perturbing influences of the AC-Stark effect in the present absolute frequency measurements. If the total energy in the $1 + 1'$ REMPI scheme accidentally hits a resonance in the autoionization continuum, the AC-Stark effect may be enhanced, resulting in a possibly larger shift of the observed resonance in the Lyman or Werner bands. Such phenomena might be verified by using a wavelength-tunable ionization laser, but the procedures are too elaborate for addressing all lines in the present data set. Hence, it is not excluded that one or more of the lines undergoes an enhanced AC-Stark effect and the uncertainty in the transition frequency is then larger than specified. However, in the consistency checks (see next section) no such enhanced shifts were found. Secondly, AC-Stark effects on spectral lines induce asymmetric profiles (see e.g., ref. 32), due to splitting of m_J components. No such signatures were observed.

As was discussed in previous studies using the PDA-based narrow-band XUV source, frequency chirp (i.e., frequency excursions during the laser pulses of 5 ns duration as a result of time-dependent gain in the dye amplifiers) form a major limitation in precision studies involving pulsed lasers (27, 34). Although it was demonstrated that the chirp effect, giving rise to a net shift between the center frequency of the pulsed output of the PDA with respect to the cw-laser output (27), can be actively compensated, the procedures to do so are too cumbersome to apply in a study of 70 spectral lines. From the same studies it followed, however, that the chirp effect in a PDA-based XUV

Table 1. Error budget for the transition frequencies in the present high-precision 1 XUV + 1 UV two-photon ionization spectroscopic study in H_2.

Source	Scheme I	Ia	Scheme II
Doppler	60	40	60
AC Stark	50	30	30
Chirp	100	100	70
I_2 calibration	10	10	10
Etalon drift	20	—	10
Nd:YAG calibration	—	—	300
Statistical	80	30	80
Total	152	117	326

Note: The columns under scheme I and scheme II refer to the experimental configurations as shown in Fig. 1, where the data under Ia specifically denote transitions to the $B^1\Sigma_u^+$, $v' = 2$–5 states, where special care was taken to further reduce the uncertainties. All values are given in MHz.

source is limited to systematic shifts of 100 MHz, for the center frequency determined in a $1 + 1'$ two-photon ionization experiment. We adopt this value as an upper limit in the error budget (Table 1). It should be noted that, while this shift is systematic, there is a distribution of chirp shifts over the spectral lines measured in this study. As discussed in refs. 27 and 34, the systematic shift varies and changes sign when tuning a PDA over a single-dye curve; in the present study, full tuning curves of a number of different dyes and dye mixtures were used. For these reasons the chirp contribution to the error budget may be treated as a statistical summation of independent errors.

The contributions to the error budget are given in Table 1 for mixing schemes I and II. The separate column Ia relates to measurements of lines in B–$X(v', 0)$ Lyman bands for $v' = 2$–5, where special caution was taken to minimize some of the contributing causes of uncertainty, while using the measurement geometry of scheme I. For the major fraction of spectral lines this uncertainty was adopted in the list of resulting transition frequencies displayed in the tables. Some of the lines gave larger statistical uncertainties or were measured at unfavorable conditions (low intensity or very short nozzle–skimmer distance); the estimated uncertainties for these lines are indicated in the tables. Particularly in the wavelength range near 615 nm, problems were encountered in running the PDA laser system. As a result only weak signals could be observed in a geometrical configuration with a small nozzle–skimmer distance; the uncertainties in the transition frequencies are therefore higher.

In the measurements performed with scheme I, the frequency chirp in the PDA is the determining factor in the error budget, while in the measurements using scheme II, the uncertainty in the Nd:YAG frequency outweighs other error contributions. In the best case the uncertainty in the absolute frequency corresponds to 1/3 of the line width, while in the other cases it amounts to 2/3 of the line width of the observed resonances.

3. Results, discussion and conclusion

The data on the experimental transition frequencies are arranged in five tables. In Tables 2 and 3 transition frequencies in the H_2 Lyman bands for $v' = 2$–5 and $v' = 6$–13 as obtained with mixing scheme I are presented. Table 4 presents the Lyman lines for $v' = 14$–18, obtained with mixing scheme II. Finally, the transition frequencies of the Werner bands obtained in mixing schemes I and II are listed in Tables 5 and 6. The fact that the study is limited to transitions originating in low J levels is inherently connected to the use of a molecular beam, necessary to enter the regime of sub-Doppler accuracy.

Table 2. Observed transitions of the $B^1\Sigma_u^+ - X^1\Sigma_g^+(v', 0)$ Lyman bands in H_2 for $v' = 2$–5, obtained with frequency mixing scheme I.

Note: For this set of measurements the étalon was actively locked to a stabilized HeNe laser, while the Doppler effect was assessed through a number of experiments. The values between parentheses are the uncertainties of the last digits. The transition energies are compared with the experimental values by the Meudon group (Δ_{o-m}) (16).

A first comparison can be made with the classical data of Dabrowski and Herzberg (9), in which an accuracy of 0.15 cm^{-1} is claimed; we find that the data of ref. 9 are on average higher by 0.2 cm^{-1}, with a standard deviation of $\sigma = 0.4$ cm^{-1}. In the tables, the transition frequencies are compared with those of the most accurate values in the literature. On the one hand those are the values of the Meudon group, where we have not adopted the values obtained in direct measurements, as given in the Lyman (17) and Werner tables (18), but rather the experimentally deduced values of the level energies, which relate to an average over emission lines in various bands (16). We converted these values into transition frequencies of the Lyman and Werner bands by adding the most accurate values for the level energies of $X^1\Sigma_g^+$, $v" = 0$ rotational states (36). The transition frequencies of the Meudon analysis are found to be higher by 0.06 cm^{-1} on average, with some scatter that has a standard deviation of 0.047 cm^{-1}. Based on the latter one would expect that the average deviation of our entire data set from the Meudon data is on the order of 0.008 cm^{-1}. This implies that the difference of 0.06 cm^{-1} must be interpreted as a systematic shift. This is not disturbing since in the Meudon analysis an accuracy of 0.15 cm^{-1} is claimed, part of which may be systematic. In measurements of a classical spectrum, the calibration by reference lines is performed for the entire data set

and hence a systematic shift may be introduced.

A second accurate, but less extensive, data set is that of Hinnen et al. (25); wherever possible a comparison was made in the tables with those data as well. The previous laser-based data of Hinnen et al. (25) are found to be systematically higher by 0.07 cm^{-1}, where an experimental accuracy on the order of 0.05 cm^{-1} was estimated. A statistical analysis would again imply that there is a systematic off-set in the data of Hinnen et al. at the level of 1/4 of the line width in that experiment. We do not have an explanation for this phenomenon, other than that it may somehow be related to the procedures of comparison with the Doppler-broadened I_2-atlas (35) as a reference spectrum.

At the present level of accuracy it is not useful to attempt fitting procedures to derive effective molecular constants. A band-by-band analysis lacks sufficient data, while a global fit has to consider the non-adiabatic interactions, which cannot be dealt with at this level of accuracy. The present status of state-of-the-art close-coupling models are no better than 0.1 cm^{-1}. Calculations by the Meudon group (16–18) take into account non-adiabatic couplings between the four lowest electronic

states of singlet character and u-symmetry. Such calculations have been refined since the publication of refs. 16, 17, but the improvements have not led to changes in level energies or transition frequencies, but rather in line strengths. We note here that the present study only produces accurate line positions. In a $1 + 1'$ photo-ionization study only relative intensities are measured that largely depend on the wavelength and intensity of the UV laser probing the ionization continuum. Hence, the ob-

served intensities do not give reliable information on the B–X line strengths.

A Dunham analysis was performed on a limited set of data with the aim of verifying the consistency of the data. In the region of excited energies below 99 000 cm^{-1}, the $B^1\Sigma_u^+$, $v' =$ 0–7 levels have no accidental perturbations with the $C^1\Pi$ state; interactions with higher lying states only cause small global shifts. Hence, in a Dunham analysis the data obtained for $B^1\Sigma_u^+$, $v' = 2$–7 were fitted to the functional form:

$$[1] \qquad E(v, J) = \sum_{k,j} Y_{k,j}(v + \frac{1}{2})^k [J(J+1)]^j$$

In total, 26 rotational states were observed in these bands as listed in Tables 2 and 3. Energies of the $v = 6$ band, which are measured with less accuracy, are used with reduced weight in the fit. Eleven Y_{kl} constants are determined and listed in Table 7, leaving 15 degrees of freedom for the fit. The constants have been chosen such that the sum of square deviations χ^2, divided by the number of degrees of freedom, is minimized; actually a small number of parameters could be added without a significant change, but none can be omitted. The main conclusion of this analysis is that the rovibrational structure of this part of the data set is smooth with an accuracy of 0.0135 cm^{-1}. There are no obvious drop-outs; the maximum deviation found is 0.030 cm^{-1} for $B^1\Sigma_u^+$, $v = 6$, $J = 2$, +0.023 cm^{-1} for $v = 7$, $J = 2$, and −0.021 cm^{-1} for $v = 7$, $J = 0$. We conclude further that the identification and use of specific I_2 saturation lines is unambiguous and correct for the bands in Tables 2 and 3.

Combination differences between P($J + 2$) and R(J) lines can further be verified with calculated ground state rotational splittings to test the accuracy and the internal consistency of the present data set. From the constants of Jennings et al. (36) the three lowest splittings can be calculated: 354.3734(2) cm^{-1}, 587.0325(2) cm^{-1}, and 814.4246(3) cm^{-1}. These splittings are consistent with the most accurate non-adiabatic calculations by Wolniewicz (13). The entire data set of Lyman and Werner band lines contains 11 measurements of the R(0)–P(2) energy splitting, of which the combination differences are plotted in Fig. 4. This shows the consistency of the data set involving these 22 spectral lines. The deviation of the combination differences from their average value amounts to much less than the typical uncertainties of 0.008 cm^{-1} (combined errors). This suggests that the determination of transition frequencies is more accurate than follows from the evaluation of the error budget for these pairs of lines. A statistical analysis yields a value for the combination difference of 354.3720(23) cm^{-1}, in agreement with the IR data (36). A similar procedure can be performed for the R(1)–P(3) combination differences where an average value of 587.031(3) cm^{-1} is derived from a set of nine pairs. The statistics are shown in Fig. 5. For the next combination difference, between R(2) and P(4) lines there are only two observations, in the B–X(13, 0) and C–X(2, 0) bands, yielding an average value of 814.426(8) cm^{-1}, which is in perfect agreement with the IR data (36).

Table 7. Dunham coefficients Y_{kl} representing the energies of observed rovibrational $B^1\Sigma_u^+$, $v = 2$–7 states, all values in cm^{-1}.

Y_{00}	89 533.70
Y_{10}	1352.907
Y_{20}	−18.4749
Y_{30}	0.1914
Y_{40}	−0.005075
Y_{01}	19.8673
Y_{11}	−1.0224
Y_{21}	0.06165
Y_{31}	−0.002808
Y_{02}	−0.01391
Y_{12}	0.000933

Note: The root mean square deviation of the representation from experimental energies is 0.0135 cm^{-1}.

On the basis of the ground state rotational energy splittings, accurately known from ref. 36, a number of transition frequencies for P-lines can be calculated, therewith extending the data set of Lyman and Werner bands spectral lines. Apart from the three lowest splittings cited above, we adopt values for higher lying combination differences: $\Delta_{53} = 1034.6703(1)$ cm^{-1}, $\Delta_{64} = 1246.098(1)$ cm^{-1}, and $\Delta_{75} = 1447.279(2)$ cm^{-1}. The calculated transition frequencies for the 60 P-lines and their estimated uncertainties are listed in Table 8.

The presently obtained data, measured at a greatly improved accuracy, provide a challenging test ground for future ab initio and close-coupling calculations. The accurately determined $B^1\Sigma_u^+$, v, J excited state level energies can be employed in multiple resonance studies to also determine accurate level energies of higher lying electronic states in H_2 as was demonstrated for some states of g symmetry by de Lange et al. (37). Also, the values can be incorporated in existing data sets on transitions between excited states to derive level energies of improved accuracy. One such example is that of the bound energy levels just below the $n = 2$ dissociation threshold in

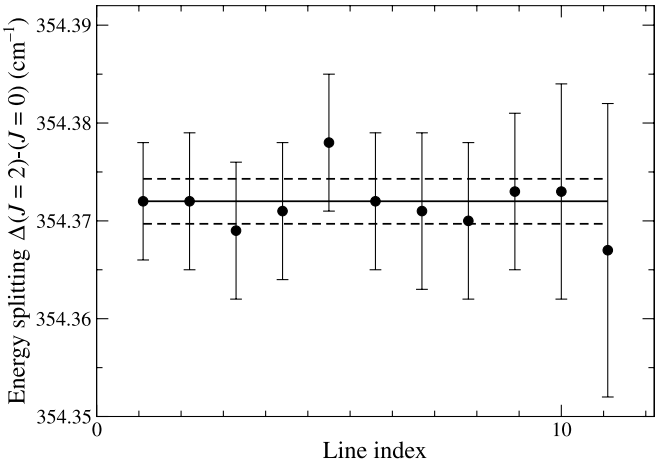
Fig. 4. Combination differences between 11 sets of R(0) and P(2) lines measured in a number of Lyman and Werner bands. Indicated are the (weighted) average value from the 11 pairs and the resulting uncertainty: 354.3720(23) cm^{-1}.



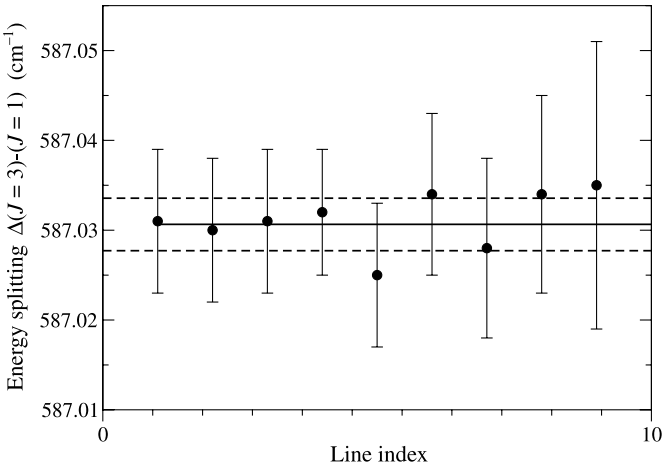


Fig. 5. Combination differences between nine sets of R(1) and P(3) lines measured in a number of Lyman and Werner bands. Indicated are the (weighted) average value and resulting uncertainty: 587.031(3) cm^{-1}.

H_2 (38). Combination with the present data on the $B^1\Sigma_u^+$, $v = 14$, $J = 0$ level energies yields improved values for level energies in the $II'^1\Pi_g$ potential: 118 361.202(13) cm^{-1} for the $II'^1\Pi_g$, $v = 2$, $J = 1(e)$ level, 118 373.169(13) cm^{-1} for the $II'^1\Pi_g$, $v = 3$, $J = 1(e)$ level, and 118 376.618(16) cm^{-1} for the $II'^1\Pi_g$, $v = 4$, $J = 1(e)$ level. The assignment of the latter two levels is tentative.

The accurate zero-velocity line centers form a set of lines for deducing accurate velocities of astrophysical objects, when ultra-high-resolution XUV spectrometers are used aboard satellites. At temperatures of 10 K the FWHM-Doppler width of the H_2 lines is 4.5 GHz; this may be compared with the width (0.55 GHz) and accuracy (<0.3 GHz) obtained in the present laboratory investigation. Finally, the present data may be implemented in improved comparisons between laboratory data and observed spectra from distant quasars, thus revealing possible cosmological variations of the proton-to-electron mass ratio (39–41).

Line strength factors for E,F$^1\Sigma_g^+(v' = 0, J' = J'')$ – X$^1\Sigma_g^+$ (v'', J'') (2 + 1) REMPI transitions in molecular hydrogen[1]

Andrew E. Pomerantz, Florian Ausfelder, Richard N. Zare, and Winifred M. Huo

Abstract: Experimentally and theoretically determined line strengths are presented for E,F$^1\Sigma_g^+(v' = 0, J' = J'')$ – X$^1\Sigma_g^+$ (v'', J'') (2 + 1) REMPI transitions in H_2, HD, and D_2. The experimental technique employs a hot filament source of internally excited hydrogen that allows experimental determination of line strengths for the low rotational states of highly excited vibrational manifolds ($v'' \leq 4$). The line strengths are found to depend only weakly on J'' for the states measured here, and theoretical results indicate that the line strengths depend strongly on v''. These values are combined with previously measured and calculated line strengths for these transitions (K.-D. Rinnen, M.A. Buntine, D.A.V. Kliner, R.N. Zare, and W.M. Huo. J. Chem. Phys. **95**, 214 (1991)), resulting in a more complete compilation of REMPI line strengths for molecular hydrogen.

Key words: hydrogen, spectroscopy, REMPI, line strength, multiphoton.

Résumé : Nous avons déterminé théoriquement et expérimentalement les forces de raies pour les transitions REMPI E,F$^1\Sigma_g^+(v' = 0, J' = J'')$ – X$^1\Sigma_g^+(v'', J'')$ (2 + 1) de H_2, HD et D_2. La technique expérimentale, qui utilise un filament chauffé comme source d'hydrogène rovibrationnellement excité, permet de mesurer les forces de raies pour les états rotationnels bas des niveaux vibrationnels excités ($v'' \leq 4$). Nos mesures montrent que les forces de raies ne dépendent que faiblement de J'', et les résultats théoriques indiquent que les forces de raies dépendent fortement de v''. Ces valeurs sont combinées aux forces de raies mesurées et calculées antérieurement pour ces mêmes transitions (K.-D. Rinnen, M.A. Buntine, D.A.V. Kliner, R.N. Zare, and W.M. Huo. J. Chem. Phys. **95**, 214 (1991)), ce qui conduit à une compilation plus complète des forces de raies REMPI pour l'hydrogène moléculaire.

Mots clés : hydrogène, spectroscopie, REMPI, force de raie, multiphoton.

Introduction

The electronic spectroscopy of molecular hydrogen has been studied extensively over the past century, beginning with the measurement of emission spectra by Lyman (1) and Werner (2). The classic investigation by Herzberg and Howe (3) on the H_2 B–X system exemplified the richness of information that can be obtained from photographic spectroscopy. More recent work has employed laser-based techniques that sacrifice the ability to observe many transitions simultaneously while allowing quantitative measurements of quantum state selective molecular concentrations. In particular, rovibrational state selective populations of hydrogen molecules resulting from gas-phase chemical reactions (4–7) or gas-surface interactions (8–10) have been studied using resonant enhanced multiphoton ionization (REMPI). The interpretation of experimental data requires an understanding of the relationship between the measured signals (ion currents) and populations of rovibrational states. Accurate line strengths for these REMPI transitions are essential for performing this transformation.

Most previous attempts to measure state specific concentrations of molecular hydrogen using REMPI have employed Q-branch members of the E,F$^1\Sigma_g^+$ – X$^1\Sigma_g^+$ transitions. Pożgainer et al. (11) have measured line strengths for the (0,0) and (1,1) transitions by analyzing state distributions produced by a Knudsen source. Marinero et al. (4) have measured line strengths for the (0,1) and (0,2) transitions in HD by calibrating against a rotationally relaxed microwave discharge source. Rinnen et al. (12) have employed a hot nozzle source to measure line strengths for these (0,0), (0,1), and (0,2) transitions in H_2, HD, and D_2. They were able to measure line strengths for 102 rovibrational levels, typically including Q(0)–Q(15) for each molecule at each vibrational level, although they were unable to determine line strengths for the low J'' levels of the $v'' = 1, 2$ manifolds. Huo et al.

(13) have performed calculations using adiabatic potentials and summing of 124 intermediate states to provide theoretical values for these same line strengths.

The conclusions of these studies were that experiment and theory agreed very well and that the line strengths depend strongly on v'' but only weakly on J''. For each isotope, the experimentally determined line strengths increase with v'' up to $v'' = 2$, but calculations predict the line strengths to decrease sharply for higher v''. Line strengths typically increase slowly with J'' (constant to within 10% for the first 10 J'' states) although there are some deviations starting at $J'' = 12$ for H_2, 17 for HD, and 24 for D_2, arising from resonant tunneling between the two wells of the E,F state at high J'' levels (14).

Here we present relative line strengths measured using a hot filament source and absolute values of the square of the two-photon transition moment calculated using previously described theoretical methods (13). The measurements are sensitive to line strengths for the low-lying rotational states of $v'' = 1$–4 in HD and D_2 and of $v'' = 1$–3 in H_2. For completeness, the previously determined line strengths are also presented.

Experimental methods

The line strength measurements require a source of internally excited hydrogen with two characteristics: there must be sufficiently high concentrations in internally excited states as to allow detection, and the relative concentrations of each excited state must be known. Relative line strengths are then determined by comparing the measured concentration to the concentration the source is known to produce; if the measured concentrations equal the known concentrations for a given set of states, then the line strengths are constant within the experimental error for transitions originating from those states. The source of internal excitation of hydrogen used in this measurement is a hot filament. This hot filament promotes recombination reactions that populate excited states of molecular hydrogen, and the excited products can be rotationally but not vibrationally relaxed by collisions before detection. This technique has been shown previously to produce high concentrations of vibrationally excited hydrogen that is rotationally thermalized to slightly above room temperature (15–18).

The filament used in this experiment is the tungsten filament of a nude ionization gauge (Granville Phillips 274-025 gauge with series 330 controller). The ion gauge is operated with an emission current of 10 mA, and the flow of hydrogen is metered with a dual-stage micrometer valve to maintain a nominal pressure of 9×10^{-5} to 10×10^{-5} torr (1 torr = 133.322 Pa) in the ion gauge during the course of an experiment. The chamber walls immediately surrounding the filament are water-cooled to approximately room temperature. The hydrogen excited by the filament flows through a collision cell en route to a high vacuum chamber evacuated with two turbopumps to a base pressure of 10^{-7} torr (1 torr = 133.322 Pa) when the hydrogen flow is stopped. The collision cell is a 3″ long piece of 3/4″ (1 inch = 25.4 mm) inner diameter stainless steel tubing with a 90° bend. The mean free path at this pressure is on the order of 10 cm, so most of the thermalizing collisions occur with the room temperature chamber walls; thus, the bend in the cell promotes collisions with the chamber walls, thereby promoting relaxation. Because the rotational levels are much more closely spaced than the vibrational levels ($2B \approx 100$ cm^{-1}, $\omega \approx 4000$ cm^{-1}), collisions can almost completely relax the rotational excitation while still leaving a measurably high concentration in vibrationally excited states.

The collision cell is connected to the main vacuum chamber near the ionization region of a Wiley–McLaren time-of-flight mass spectrometer (19). A pulsed, tunable UV laser (see below) is focused in the ionization region, and hydrogen molecules that intersect the laser focus are ionized via (2 + 1) REMPI on the $E,F\,^1\Sigma_g^+ - X\,^1\Sigma_g^+$ band of interest. The resulting photoions are detected with the mass spectrometer, and he signal is corrected for variation in laser power. Concen - trations are measured by recording the ion current as the laser is scanned over the Doppler profile and then integrating the spectral line. Line strengths are then extracted by comparing the measured concentrations to the expected concentrations.

Resonant ionization of these three different isotopes and four different vibrational manifolds requires pulsed, tunable UV light in the wavelength range 207–234 nm. Three different frequency-mixing schemes were implemented to cover this range. All schemes involved a dye laser pumped by the second or third harmonic of a Nd:YAG laser. For the reddest wavelength range (229–234 nm), corresponding to $H_2(v'' = 3)$ and $HD(v'' = 4)$, a frequency-doubling scheme was employed. For the bluest wavelength range (207–215 nm), corresponding to $H_2(v'' = 1)$, $HD(v'' = 1)$ and $D_2(v'' = 1, 2)$, a frequency-tripling scheme was used. For the intermediate range, a less common 355 nm mixing scheme was employed. In this technique, the Nd:YAG laser is frequency doubled and tripled, and the residual second harmonic pumps the dye laser. The dye laser fundamental is then frequency summed with the Nd:YAG third harmonic to produce UV light in the range 216–229 nm. These techniques all produce approximately 1 mJ of UV light in a 5 ns pulse.

Theoretical methods

The present study follows the same computational steps as described earlier. (13, 20, 21). The two-photon transition moment (M_{fo}) is given by

$$[1] \qquad M_{fo} = \sum_i \frac{\langle f|\bar{r}\cdot\hat{\varepsilon}|i\rangle\langle i|\bar{r}\cdot\hat{\varepsilon}|o\rangle}{(E_i - E_o - \hbar\omega)}$$

The summation is over all rovibrational states that can be coupled to the initial and final states by dipole-allowed transitions. In total, 124 intermediate states are used in the summation. For the four lowest electronic states that are dipole coupled to the ground state (i.e., the $B\,^1\Sigma_u^+$, $C\,^1\Pi_u$, $B'\,^1\Sigma_u^+$, and $D\,^1\Pi_u$ states) explicit summation is carried out over their vibrational levels. For the remainder, a nuclear sudden approximation (21) is used. The calculation of the vibrational wave functions of the X state is based on the adiabatic potential compiled by Schwartz and Le Roy (22). For the (E,F), B, C, B′, and D states, the calculations are based on the adiabatic potentials of Wolniewcz and Dressler (23, 24).

Results and discussion

Relative line strengths are extracted from the concentration measurements by comparing the measured concentrations to a Boltzmann distribution. This hot filament excitation technique is known to produce relative rotational concentrations that are well described by a Boltzmann distribution at slightly above room temperature (15–18). As the rotational line strengths are expected to be independent of J'', the experimentally determined concentrations are taken to be proportional to the area under the Doppler profile, without requiring a line strength correction. If this method of analysis returns an experimental distribution of concentrations that is well described by a Boltzmann distribution at slightly above room temperature then it represents experimental confirmation that the relative rotational line strengths are independent of J'' to within the experimental uncertainty. The experimental error is estimated to be approximately 10%. Further experimental determination of the relative rotational line strengths is impossible because the rotational temperature of the sample is not known precisely. Experimental determination of the v'' dependence of the line strengths is similarly impossible because the vibrational temperature of the sample is unknown.

It is important to note that the measured concentrations have been corrected for differences in the nuclear spin degeneracy. Because of these nuclear statistics, the concentration of $H_2(J'' = \text{odd})$ (*ortho*-hydrogen) is three times larger than the concentration of $H_2(J'' = \text{even})$ (*para*-hydrogen). To prepare the Boltzmann plots, the concentrations of $H_2(J'' = \text{odd})$ have been divided by three; similarly, the concentrations of $D_2(J'' = \text{even})$ have been divided by two. No correction is necessary for HD because the nuclei are not identical.

Boltzmann plots of the measured concentrations are presented in Figs. 1–3, and the resulting rotational temperatures are presented in Table 1. The Boltzmann plots present the natural logarithm of the population divided by the rotational degeneracy ($g_J = 2J''+1$) and the nuclear spin degeneracy

Fig. 3. Boltzmann plots of the measured concentrations in D_2. The rotational and nuclear spin degeneracies are represented by g_J and g_N, respectively.

Note: Rotational line strengths that have been confirmed by the current or previous (12) experiment are listed in bold.

(g_N) as a function of rotational energy; they are fit to a straight line whose slope depends inversely on temperature. The measured rotational temperatures all lie in the expected range, indicating that the relative rotational line strengths are independent of J'' within the 10% experimental uncertainty for the rotational states measured here. This finding is confirmed by the theoretical values of the square of the two-photon transition moment $|M_{fo}|^2$, which are presented in Tables 2–4. For completeness, previously determined $|M_{fo}|^2$ are also presented in Tables 2–4 (12). The vibrational dependence of the line strengths is known theoretically, so the theoretical line strengths presented include the dependence on v''. Although the current experiment is insensitive to vibrational line strengths, a previous measurement of the vibrational line strengths is in good agreement with the theory for $v'' = 1, 2$ (12). Relative rotational line strengths that have been measured here or previously and shown to be in good agreement with theory are indicated in the tables. We find virtually no transitions in which experimental line strengths significantly disagree with the theoretical ones; the only exceptions occur at very high rotational levels ($J'' \sim 15$) of the lowest vibrational manifold. We note that the numbers presented here are line strengths, so concentrations should be

of nonadiabatic and relativistic corrections, these frequencies are not of spectroscopic accuracy. For the X state, nonadiabatic corrections have been reported by Schwartz and Le Roy (22). However, similar calculations have not been done for the (E,F) state. To be consistent, the present calculation chooses to use the adiabatic approximation and does not incorporate nonadiabatic corrections for the X state. The calculated frequencies are expected to be of similar accuracy as the D_2 data where extensive comparisons with experiment have been made (25). Most differences are within a few cm^{-1}. The tabulated frequencies should be sufficiently accurate to allow determination of line positions in future experiments. We note that the simple appearance of these spectra (the spacing between rotational lines grows at a roughly constant rate in each vibrational manifold) will facilitate line identification. As the two-photon transition moments do not depend on the separation between the energy levels, any inaccuracies in the calculated line positions will not affect the accuracy of the line strength calculations.

Conclusions

Line strengths for many $E,F^1\Sigma_g^+(v' = 0, J' = J'') - X^1\Sigma_g^+$ (v'', J'') (2 + 1) REMPI transitions in H_2, HD, and D_2 are presented. Experimental and theoretical values for these line strengths show good agreement, and the line strengths are found to depend strongly on v'' but only weakly on J''. Knowledge of these line strengths should be useful whenever rovibrationally state resolved concentrations of molecular hydrogen are of interest, particularly in the study of the nascent populations of gas-phase or gas-surface interactions.

CN spectroscopy and cosmic background radiation measurements[1]

Sydney Leach

Abstract: A source of possible error, not previously considered, in the determination of the cosmic background radiation (CBR) temperature T_γ(CN) from interstellar CN absorption is proposed. This concerns the intrinsic assumption of the validity of using Hönl–London rotational line intensity factors to determine the rotational components of the oscillator strengths of the R(0), R(1), and P(1) lines of the CN $B^2\Sigma^+$–$X^2\Sigma^+$ (0,0) transition. Published data on interstellar CN absorption shows that T_γ(CN) is slightly greater than the standard cosmological CBR temperature, T_γ(COBE) = 2.725 K, determined by the COBE satellite, even when local excitation effects of CN are taken into account. From this difference, an estimation was made of the maximum corrections, a few percent, to the ratio of the line strengths and to the ratio of the Hönl–London factors. Fluorescence lifetime data were shown to give similar values for the corrections as well as providing evidence for intramolecular coupling between the relevant $B^2\Sigma^+$ state rotational levels and close-lying levels of the $A^2\Pi$ state, this being responsible for rendering the standard Hönl–London factors invalid.

Key words: CN spectroscopy, cosmic background radiation, Hönl–London factors.

Résumé : La détermination de T_γ(CN), la température du rayonnement de fond cosmologique, à partir du spectre d'absorption de CN interstellaire pourrait être entachée d'une erreur qui n'avait jamais été envisagée jusqu'à présent. Il s'agit de l'hypothèse selon laquelle on peut utiliser les facteurs de Hönl–London pour déterminer les composantes rotationnelles des forces d'oscillateurs des raies R(0), R(1), and P(1) de la transition $B^2\Sigma^+$–$X^2\Sigma^+$ (0,0) du radical CN. Les données publiées sur le spectre d'absorption du CN interstellaire montrent que même en tenant compte des effets de l'excitation locale du CN, la valeur de T_γ(CN) est légèrement plus grande que celle du standard cosmologique, T_γ(COBE) = 2.725 K, mesurée par la satellite COBE. La différence entre T_γ(CN) et T_γ(COBE) a servi pour faire une estimation des corrections maximales, quelques pour cent, au rapport des forces de raies et au rapport des facteurs de Hönl–London. Des valeurs similaires pour ces corrections ont été obtenues à partir de données sur les durées de vie de fluorescence de CN. Ces données traduisent, d'autre part, l'existence de couplages intramoléculaires entre les niveaux rotationnels en jeu de l'état $B^2\Sigma^+$ et des niveaux voisins de l'état $A^2\Pi$, ces couplages étant responsables de la non-validité des facteurs Hönl–London classiques.

Mots clés : spectroscopie de CN, rayonnement de fond cosmologique, facteurs Hönl–London.

Introduction

Gerhard Herzberg's contributions to the application of molecular spectroscopy to astrophysics were very considerable during his long career, and his influence was profound in this respect. Herzberg was a pioneer in the electronic spectroscopy of the CN radical (1), and it is particularly fitting that the later use of interstellar CN absorption as a cosmic thermometer is of fundamental importance in studies of the cosmic background radiation (CBR) and its cosmological significance. The present work reviews the relevant spectroscopy and astrophysical observations of CN and discusses the validity of a hitherto unconsidered assumption in the spectroscopic derivation of CBR temperatures.

The first experimentally observed clear manifestation of CBR was through optical absorption spectroscopy of the CN radical in the interstellar medium (2–4), but its cosmological significance was not recognized at the time. The CN doublet at 3874 Å (1 Å = 0.1 nm) consists of the R(0) (3874.608 Å) and R(1) (3873.998 Å) lines of the $B^2\Sigma^+$–$X^2\Sigma^+$ (0,0) transition of CN (Fig. 1). The energy separation between the $N'' = 1$ and $N'' = 0$ levels (N = quantum number of angular momentum without spin) of the ground state is 3.94 cm^{-1}, which corresponds to a photon excitation wavelength of 2.64 mm. McKellar, in a paper written in 1941 (5), determined an excitation (rotational) temperature of 2.3 K, based on the (unpublished) estimation by Adams of the ratio of the relative intensities of the R(0) and R(1) lines, $I[R(0)]/I[R(1)] = 5$, in the spectrum observed in the line of sight of the star ξ Ophiuchi. The excitation mechanisms considered were those involving collisions with charged or neutral particles or the interstellar radiation field due to galactic stars. These mechanisms were later discussed by Field and Hitchcock (6) and by Thaddeus and Clauser (7).

Fig. 1. Simplified energy level diagram illustrating rovibronic absorption transitions of the $B^2\Sigma^+$–$X^2\Sigma^+$ (0,0) band of CN observed in the interstellar medium.

Herzberg (8) considered the interstellar CN rotational temperature of 2.3 K to have "only a restricted meaning", which later turned out to be one of the great understatements in science. We now know that this temperature is an expression of the blackbody character of the CBR and that the quality of the Planck function, the degree of anisotropy of the radiation, its power spectrum, and the dependence of the CBR temperature on red shift restrict cosmological models (9, 10).

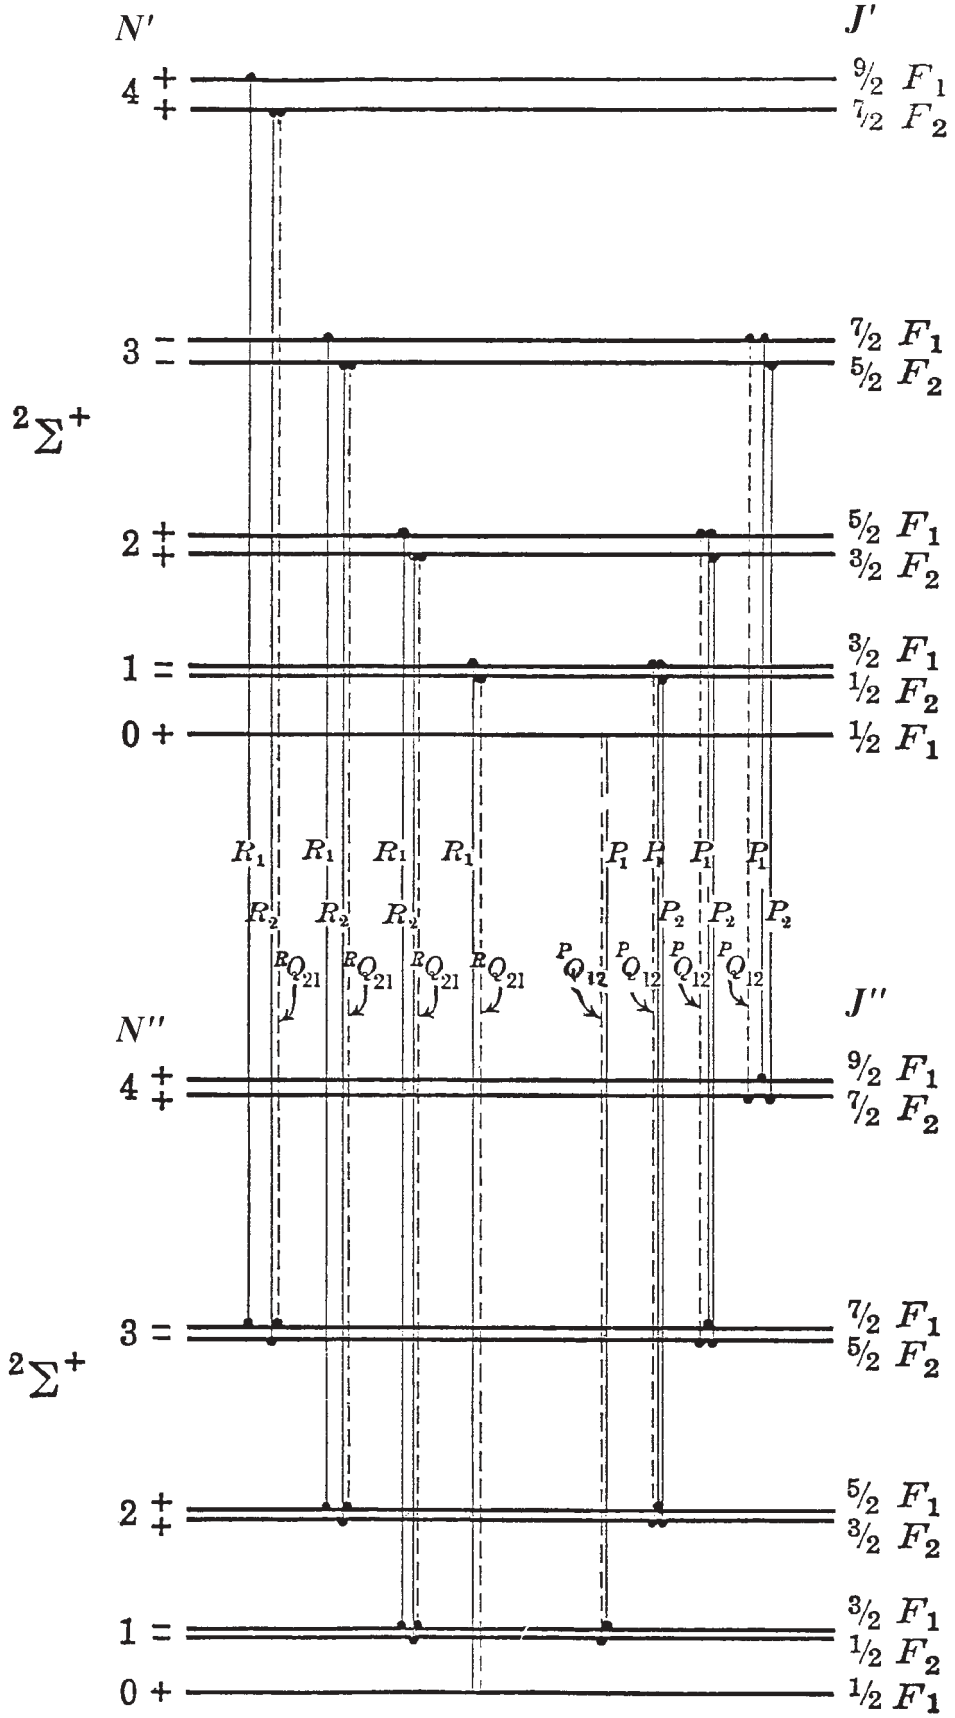
In 1965, Penzias and Wilson (11) observed cosmic microwave background radiation (CMBR) at $\lambda = 7.35$ cm and determined the temperature of the radiation field to be $T_\gamma = 3.5 \pm 1$ K. This brightness temperature was much more intense than that expected from extrapolation, to this wavelength region, of measurements of background radiation at wavelengths greater than 100 cm and smaller than 0.1 mm (12, 13). Dicke et al. (14) suggested that the origin of the $\lambda = 7.35$ cm radiation was related to the Big Bang, this radiation being a residue of the primeval fireball after expansion of the Universe.

The recognition that the CN observations were also manifestations of the CBR, i.e., that interstellar CN is in thermodynamic equilibrium with the CMBR at temperature T_γ, occurred in 1966, when it was shown (6, 7, 15) that the CN ground-state $N'' = 1$ rotational level could not be sufficiently populated by collisions or by transitions from higher levels but must be directly excited by photons of $\lambda = 2.64$ mm, which is close to the spectral peak of the CMBR flux. Since then, there have been many observations of interstellar CN absorption lines in a number of lines of sight, from which increasingly accurate (spectroscopic) values of T_γ have been obtained.

Determination of T_γ from CN absorption requires a number of corrections, in particular for line saturation and for eventual local electron collisional excitation (16). The present work considers a further possible source of error, not previously treated in this context. This concerns the intrinsic assumption, made in previous determinations of T_γ from CN absorption, of the validity of using Hönl–London rotational factors to express the rotational components of the transition oscillator strength values. The Hönl–London formulas are derived under the assumption of negligible interaction of rotation and electronic motion (8). Since the $v = 0$ and $v = 1$ levels of the $B^2\Sigma^+$ state of CN are affected by rotational perturbations (1, 17, 18), it is legitimate to question the validity of the assumption of negligible rotational coupling.

Direct measurements of T_γ have also been made by bolometer and radiometer techniques, which are not subject to the spectroscopic caveats, although they have other sources of error (13, 19–21). The values of T_γ obtained from these direct measurements are smaller than those deduced from CN absorption spectra. Up until now, the observed differences have been interpreted in terms of local excitation effects, mainly due to electron excitation of CN in the interstellar medium. It will be shown that even when local excitation effects are taken into account, there still exists an apparent small excess excitation temperature. The principal objective of the present investigation is to examine whether invalid Hönl–London factors can be responsible, at least in part, for the existence of an apparent difference between the T_γ values determined by these two types of measurement.

Discussion



CN $B^2\Sigma^+$–$X^2\Sigma^+$ energy levels and transitions

Figure 1 presents the term diagram for the levels of most astrophysical concern in the (0,0) band of the CN $B^2\Sigma^+$–$X^2\Sigma^+$ electronic transition. Spin doubling (Fig. 2) and hyperfine structure have not been fully resolved in the optical observations of CN absorption in the interstellar medium. Therefore, the observed R(0), R(1), R(2), P(1), and P(2) lines have the following unresolved components, given in brackets: R(0) = $\{R_1(0), {}^RQ_{21}(0)\}$; R(1) = $\{R_1(1), {}^RQ_{21}(1), R_2(1)\}$; R(2) = $\{R_1(2), {}^RQ_{21}(2), R_2(2)\}$; P(1) = $\{P_1(1), {}^PQ_{12}(1)\}$; and P(2) = $\{P_1(2), {}^PQ_{12}(2), P_2(2)\}$.

From measurement of the strengths of the R(0), R(1), R(2), P(1), and P(2) absorption lines in a particular line of sight, the relative populations of CN molecules in the $N'' = 0$, 1, and 2 levels of the ground electronic state can be determined, enabling one to deduce the excitation temperatures corresponding to the $N'' = 0 \rightarrow N'' = 1$ and $N'' = 1 \rightarrow N'' = 2$ photon population processes at, respectively, $\lambda = 2.64$ mm and $\lambda = 1.32$ mm in the cosmic background blackbody radiation spectrum. As discussed later, rotational lines in the interstellar CN $B^2\Sigma^+$–$X^2\Sigma^+$ absorption transition have mainly been measured for the (0,0) band and, to a lesser extent, for the (1,0) band. The most precise data are from R(0), R(1), and P(1) lines of the (0,0) band, and these are exclusively discussed below.

Determination of T_γ from CN observations

The relative populations of CN molecules in lower (″) and upper (′) rotational levels of the $v = 0$ level of the $X^2\Sigma^+$ electronic ground state are determined by the cosmic background radiation field temperature T_γ via an equation that rests on the assumption that the molecules are in thermal equilibrium and are therefore distributed in accordance with the Maxwell–Boltzmann law (8):

$$[1] \qquad N_c''/N_c' = (g''/g')\cdot\exp(h\nu/kT_\gamma)$$

where N_c'' and N_c' are the column densities of CN in lower and upper levels in the $X^2\Sigma^+$ electronic state, g' and g'' are statistical weights of the upper and lower levels, ν is the frequency difference between these levels (e.g., $\nu[(N'' = 1) - (N'' = 0)] = 1.134 \times 10^{11}$ Hz = 3.8 cm^{-1}, corresponding to the wavelength $\lambda[(N'' = 1) - (N'' = 0)] = 2.64$ mm (Fig. 1)), and k is Boltzmann's constant. If there are other sources of excitation, for example by collisions, the temperature derived from eq. [1] is an upper limit on T_γ.

The column densities, N_c, are obtained from measurement of the equivalent widths W_λ of the absorption lines (22, 23), via the following expression:

$$[2] \qquad N_c = (1.13 \times 10^{12}\ \text{cm}^{-1})(W_\lambda/\lambda^2 f)\ (\text{cm}^{-2})$$

where f is the oscillator strength of the absorption transition. The value of f for the CN $B^2\Sigma^+$–$X^2\Sigma^+$ transition is not known with very great precision (24–26), which can lead to uncertainties in column density determinations. The curve of growth (27) of W_λ as a function of a suitable parameter expressing the increasing amount of material traversed by the source photons is informative on the quality of the N_c determination.

The CBR temperature T_γ can be determined, for example, from the R(0) and R(1) absorption lines using the following equation:

$$[3] \qquad T_\gamma = (h\nu/k)/\ln[(f'/f'')(g'/g'')\{W_\lambda[\text{R}(0)]/W_\lambda[\text{R}(1)]\}]$$

with the approximation that the wavelengths of the R(0) and R(1) (and P(1)) lines are the same. In this equation, f' and f'' are the oscillator strengths of the rovibronic absorption transitions from the $X^2\Sigma^+$ ($v = 0$) ground state rotational levels $N'' = 1$ and $N'' = 0$, respectively, to specific rotational levels of the $B^2\Sigma^+$ excited state; i.e., in the case discussed here as an example, f' and f'' are, respectively, the R(1) and R(0) line transition strengths.

It should be noted that eq. [2] assumes unsaturated absorption lines, so that the temperature obtained from eq. [3] will be an upper limit on T_γ because correcting for line saturation would lead to an increase in the R(0)/R(1) intensity ratio, since the R(0) line is stronger than the R(1) line. Thus, corrections for line saturation are important. These require good knowledge of the true line profile. Very often, the assumption is made that the CN molecules have a Gaussian velocity dispersion and that the profile of the observed line corresponds to a convolution of the instrumental and intrinsic line profiles. Important in practice is the velocity width parameter b (Doppler parameter), which is related to the full width at half-maximum (fwhm) of the line profile, and its value should be consistent with the results of curve of growth studies. In all CN measurements discussed here, the observed line profiles were such that the separation between unresolved components is less than the Doppler width, so that the blend can be represented as a single line, to which is assigned an effective oscillator strength.

Interstellar CN absorption observations

The discovery of the CMBR by Penzias and Wilson in 1965 (11) soon led to a renewal of observations of interstellar CN. For 10 stars in various directions in the Galaxy, it was found that the observed CN interstellar absorption spectra were all consistent with an excitation temperature $T_{\text{rot}} \approx 2.8$ K, which showed, within experimental error, no significant difference among the different lines of sight (16). If collisions had played an important role in populating the excited rotational levels of the ground state, there should have resulted significantly different values of the CN rotational temperature in the various interstellar clouds, since physical conditions, and therefore collisional possibilities, vary from cloud to cloud. The possible contributions to CN ground-state rotational level excitation by the following four types of collision or other processes have been discussed and estimated for typical target lines of sight (16): (*i*) neutral particle impact, (*ii*) collisions with residual electrons, in HI regions, (*iii*) collisions with protons on an ionization front, and (*iv*) resonance fluorescence. Of these processes, the only one that usually has to be taken into account in CN spectroscopy determinations of T_γ is electron collisions, which generally contribute to only a very small fraction of the CN rotational temperature (16, 23, 28). A confirmation that this contribution is small is the absence of $N'' = 1 \rightarrow N'' = 0$ emission in the direction of the star BD +66° 1675, which has the highest concentration of CN in the 10 lines of sight mentioned above (29). A more recent measurement looked for CN emission towards ζ Oph, again with a null result (30). Even more recent emission measurements are discussed later.

The first measurements of the CBR temperature from optical CN observations were made on photographic plates (16). This has been found to introduce a number of errors in measurements of equivalent widths of the spectral lines (23). High-precision measurements became possible with the introduction of multichannel photoelectric detectors. Our further discussion will be based essentially on photoelectric detector measurements since 1984.

CN temperature measurements: 1984–86

The CN temperature measurements in the period 1984–86 showed increasing sophistication in dealing with the data analysis and corrections for saturation effects and collisional excitation. One of the first CN studies using photoelectric detection was that of Meyer and Jura (31), who measured CN lines at a signal-to-noise ratio (S/N) of 2000 in a molecular cloud in front of ζ Oph. After correction for saturation, the excitation temperatures were determined to be $T_{10} = 2.73 \pm 0.04$ K and $T_{21} = 2.8 \pm 0.3$ K. Electron collisional effects on the T_{10} temperature were estimated to be $T_e < 0.10$ K.

Federman et al. (24) observed the CN (0,0) band R(0), R(1), and P(1) lines along 15 lines of sight whose column density of H_2 is known. The spectral resolution R was 74 250 for 11 stars and 50 000 for 4 others. The observa-

© 2004 NRC Canada

tions were used for determining column densities for comparison with those of H_2. However, there was no discussion of T_γ, which was assumed to be 2.8 K in the calculation of CN column densities. The cosmochemistry of CN formation and destruction was the main issue in this study.

In a paper published in 1985 (23), Meyer and Jura measured CN lines in three lines of sight at $R \approx 60\,000$ and S/N » 1000. Various corrections to the raw data were discussed in detail. The sensitivity of the measurements revealed a weak broadened O_{II} line encompassing R(0) and R(1) in ζ Oph, which would have been lost in the spectral noise in the case of all previous measurements. The background continuum fit was therefore improved. Shifting photospheric lines in the spectrum of o Per (a spectroscopic binary) over 3 nights made possible measurement of CN line strengths with respect to different continua. Uncertainties in measured line strengths were due to (*i*) statistical channel-to-channel signal fluctuations, (*ii*) continuum placement errors due to noise in the continuum, (*iii*) the shape of the underlying photospheric structure, and (*iv*) the presence of weak telluric lines.

The excitation temperature T_{10} was determined with corrections for saturation, assuming Gaussian line profiles. These corrections are used to relate the observed equivalent widths to the relative rotational state populations. Taking into account the calculated correction to T_{10} for local excitation by electrons, based on a determination of the electron density in the three molecular clouds studied, the values of T_γ(CN) were as follows, where the 1σ errors were derived from equivalent width uncertainties: ζ Oph, T_γ(CN) = 2.663 ± 0.059 K; ζ Per, T_γ(CN) = 2.720 ± 0.049 K; o Per, T_γ(CN) = 2.698 ± 0.082 K. The weighted mean was T_γ(CN) = 2.70 ± 0.04 K (23).

CN temperature measurements since 1986

CN temperature measurements since 1986 are at higher spectral resolution and (or) at higher S/N than earlier measurements (28). Crane et al. (32) observed CN lines towards ζ Oph at $R = 156\,000$. They measured precise values of the equivalent widths of the (0,0) band R(0), R(1), and P(1) lines. They also detected the R(2) line uncontaminated by telluric lines. The linewidths were determined on the assumption that the interstellar cloud contains a single component with a Gaussian velocity spread. CN linewidths were narrower than those previously reported, which led to larger curve of growth corrections to the observed equivalent widths than in previous analyses. As a result, the measured equivalent widths of the R(0), R(1), and P(1) lines differ significantly from those of Meyer and Jura (23). In 1989, Crane et al. (30) reanalyzed their CN absorption data towards ζ Oph to provide even more accurate equivalent widths. To improve saturation corrections, they used new CO millimetre observations data to better understand the velocity structure of the interstellar clouds. They also searched for CN emission at 2.64 mm. From the null result, their analysis gives $T_e = 0.000(+0.031, -0.000)$ K for the electron collision component of the excitation temperature.

The nature of the possible errors on T_γ in this work is typical of all T_γ(CN) measurements. These errors and their estimated magnitudes (in parentheses) are (*i*) statistical error (±13.3 mK) in the equivalent widths; (*ii*) uncertainty due to possible scale error in the equivalent widths (±5 mK); (*iii*) error due to local excitation of CN (a maximum of −31 mK); and (*iv*) error introduced by uncertainty in the model for the saturation correction (–18 mK).

The final T_γ(CN) temperature values obtained are given in Table 1 separately for R(0)/R(1) and R(0)/P(1) measurements, as is done for all further T_γ(CN) measurements discussed in this work. These two sets of T_γ(CN) determinations involve different probes of the ground state $N = 1$ level population and therefore different f'/f'' values in eq. [3]. The significance of this distinction will be addressed later.

Meyer et al. (33) observed with high S/N the CN $B^2\Sigma^+$–$X^2\Sigma^+$ (1,0) 3580 Å and (0,0) 3874 Å lines towards HD 21483, providing very accurate measurements of the (0,0) band R(2) and P(2) and the (1,0) band R(0) lines. Measurement of the optically thin (1,0) band R(0) line allowed correction of CN lines for saturation and the determination of accurate $N'' = 0$ column densities. CN emission at 2.64 mm was searched for but not observed. Excitation temperatures were determined, with correction for saturation, and the resulting T_γ(CN) temperature values are listed in Table 1. It should be noted that other high-S/N observations of the CN $B^2\Sigma^+$–$X^2\Sigma^+$ (1,0) band R(0) line were made by Meyer and Roth, towards ζ Oph (34). Measurement of the equivalent width of the R(0) line provided column density values consistent with the earlier assumption of a single-component line profile, and this in spite of the complex velocity structure revealed by CO millimetre-wave observations in the ζ Oph line of sight. The data on a tentatively identified R(1) line in the (1,0) band were insufficient to determine a value of T_γ(CN) from this vibronic transition.

In 1990, Kaiser and Wright (35) published a study of the CN (0,0) band lines towards ζ Per at a high resolution, $R = 150\,000$–$170\,000$. They obtained a very accurate value of 1.25 ± 0.02 km s^{-1} for the R(0) linewidth parameter *b* along this line of sight. Kaiser and Wright consider that Meyer and Jura (23) did not have sufficient spectral resolution to determine *b* from their data along this same line of sight. Consequently, they believe that the uncertainty in the saturation corrections to the equivalent width measurements of Meyer and Jura was their dominant error along the line of sight to ζ Per. In determining T_γ, Kaiser and Wright adopted the collisional excitation correction determined for ζ Per by Meyer and Jura (23), $T_e = 0.04 \pm 0.02$ K. The T_γ values for the R(0)/R(1) and R(0)/P(1) measurements of Kaiser and Wright, separately averaged over four different nights of observation, are given in Table 1.

Measurements of CN towards HD 154368 were made by Palazzi et al. (36). This line of sight has a CN column density at least 7 times greater than that towards ζ Oph. Observation of weak CN emission at a wavelength of 2.64 mm enabled estimates to be made of the contribution of electron collisions to the excitation temperatures. After corrections for line saturation, the CN excitation temperatures obtained for HD 154368 were R(0)/R(1) $T_{10} = 2.849 \pm 0.037$ K and R(0)/P(1) $T_{10} = 2.889 \pm 0.037$ K, and the calculated correction to T_{10} for local excitation by electrons was $T_e = -0.035 \pm 0.009$ K. The ensuing T_γ values are given in Table 1.

This group of workers also observed the CN (0,0) band R(0), R(1), and P(1) lines in 10 other lines of sight (37) but

Table 1. Cosmic background radiation temperature T_γ from selected CN $B^2\Sigma^+$–$X^2\Sigma^+$ (0,0) band absorption observations.

		T_γ(CN) (K)	
Reference	Star	R(0)/R(1) measurements	R(0)/P(1) measurements
Crane et al. (30)	ζ Oph	2.796±0.016	2.797±0.025
Meyer et al. (33)	HD 21483	2.767±0.072	2.751±0.083
Kaiser and Wright (35)	ζ Per	2.792±0.025	2.707±0.045
Palazzi et al. (36)	HD 154368	2.814±0.035	2.854±0.037
Roth and Meyer (28)	ζ Oph	2.734±0.025	2.740±0.035

reported only the weighted averages of R(0)/R(1) and R(0)/P(1) values of the T_{10} excitation temperature, with quite large error bars. They also made a statistical analysis of all 35 (weighted average) excitation temperatures measured using interstellar CN, to which I will return later.

CN absorption of the (1,0) and (0,0) bands in lines of sight towards five diffuse interstellar clouds, ζ Oph, ζ Per, HD 27778, HD 21483, and HD 154368, was studied by Roth et al. (38) and by Roth and Meyer (28) at high S/N. The excitation temperatures they reported are weighted averages of R(0)/R(1) and R(0)/P(1) values of T_{10} and were corrected for estimated local collisional excitation processes. The best measurements are for the ζ Oph line of sight. From the column densities for the R(0), R(1), and P(1) lines reported by Roth and Meyer (28), and using their same local excitation correction, I determined T_γ for separate R(0)/R(1) and R(0)/P(1) measurements. The values obtained are reported in Table 1.

Direct bolometer and radiometer measurements of T_γ

Early radiometer measurements were made from the ground (39, 40) and from balloons with far-infrared (FIR) spectrometers. Measurements using rockets (COBRA (41)) and an orbiting observatory, the Cosmic Background Explorer (COBE) containing a Far IR Absolute Spectrophotometer (FIRAS) (42, 43), provided an initial value of T_γ = 2.726 ± 0.010 K. The best COBE value to date is T_γ(COBE) = 2.725 ± 0.001 K (9, 21, 43, 44). This is recognized as the standard value of T_γ for cosmological purposes (9).

Recent measurements of the CBR, in particular using the Wilkinson Microwave Anisotropy Probe (WMAP), have not provided new values of T_γ but have been concerned essentially with the CMB power spectrum, its analysis, and its cosmological implications (10).

Comparison between T_γ(COBE) and T_γ(CN)

Bolometer and radiometer measurements give local values of T_γ, i.e., at about 1 AU from the Sun, whereas T_γ measurements via CN absorption have provided values of interstellar T_γ in several clouds within 1 kpc. An analysis by Palazzi et al. (37) of 35 CN measurements of T_γ carried out by various authors, including some of their own measurements, during the period 1985–92, gave a weighted average value T_γ(CN) = 2.818 ± 0.018 K that is above the COBE value of 2.725 ± 0.001 K by 93 ± 19 mK. These authors examined all known mechanisms that could contribute to local rotational excitation of CN, in particular, electron and neutral particle collisions and radiative fields such as diffuse galactic starlight, stellar radiation beyond the molecular cloud, and radiation emanating from dust within the clouds. None of these mechanisms was found to account for the 93 ± 19 mK excess in the CN measurements.

Wright et al. (45) made a critique of the compilation of CN data by Palazzi et al. (37). They suggest that the local excitation corrections made by Palazzi et al. may not be justified and that there is a small statistical bias in the histogram technique used, the latter having been introduced previously by Palazzi and co-workers (46). This critique mainly stresses the difficulties, due to low optical depth, that are encountered in using CN millimetre emission to determine the extent of local excitation above the CBR temperature.

A more recent statistical study by Crane (47) is based on published CN data from a sample of the 13 most accurate measurements published during the period 1985–93. He used a common procedure to process the different data sets, i.e., for correcting the measured equivalent widths for saturation effects and for calculating the errors associated with the uncertainty in both the equivalent widths and the *b* values. In this way, he obtained a weighted average value T_γ(CN) = 2.762 ± 0.012 K from the CN data. The difference from the COBE value is 37 ± 13 mK, which is about 3 standard deviations.

I have also chosen to examine what I consider to be the 10 best measurements of T_γ(CN), including saturation corrections and electron excitation corrections, where the values determined from R(0)/R(1) and R(0)/P(1) intensity ratios are specified separately (Table 1). The average of the 10 CN measurements in Table 1 gives T_γ(CN) = 2.775 K. Since T_γ(COBE) = 2.725 K, it follows that T_γ(CN) - T_γ(COBE) = 50 mK. The statistical error of the weighed average of T_γ(CN) is of the order of 15 mK (47). I concur with a concluding remark of Crane (47) that this difference may be due to underestimated local excitation effects, but he also added that there could be a new effect, not previously considered, that could explain a difference between the COBE and CN values of T_γ. Invalid Hönl–London factors, as suggested in the present study, is indeed a "new effect" that I have considered as worth exploring.

The possible effects of intramolecular state mixing on the rotational component of the CN line oscillator strengths

Invalid Hönl–London factors are equivalent here to incorrect ratios f'/f'' of the oscillator strengths in eq. [3]. As

© 2004 NRC Canada

mentioned earlier, the $B^2\Sigma^+$–$X^2\Sigma^+$ transition oscillator strength f is not known with very great precision (24–26), and this leads to uncertainties in column density determinations. However, assuming the validity of the Born–Oppenheimer approximation, this oscillator strength can be factorized into three components, f_{el}, f_{vib}, and f_{rot}, which are, respectively, the purely electronic, the vibrational (Franck–Condon), and the rotational components. For a given vibronic transition, e.g., $B^2\Sigma^+$–$X^2\Sigma^+$ (0,0), and insofar as differential rovibronic effects on f are negligible, the binary product $f_{ev} = f_{el} \times f_{vib}$ would thus be the same for the upper ($N'' = 1$) and lower ($N'' = 0$) rotational levels of the $X^2\Sigma^+$ $v = 0$ ground state, so that the ratio f'/f'' is determined only by the rotational components, f'_{rot}/f''_{rot}. However, in all T_γ determinations from CN optical spectra, it was assumed that f_{rot} is given by Hönl–London factors, where these factors are summed for each unresolved component of each line.

Taking into account the blends of unresolved components in the rotational lines, the normalized Hönl–London factors $S_{J'J''}$ for the observed absorption lines of a CN $^2\Sigma$–$^2\Sigma$ transition are $S(R(0)) = 1$, $S(R(1)) = 2/3$, and $S(P(1)) = 1/3$. The normalization has been carried out according to the sum rule for $^2\Sigma^+ \rightarrow {}^2\Sigma^+$ transitions (48): $\sum S_{J'J''} = 2S(2J''+1)$, where the sum, over all J' values, covers the transitions R_1, R_2, $^RQ_{21}$, P_1, $^PQ_{12}$, and P_2 shown in Fig. 2. It follows that the Hönl–London factor ratios f'/f'' in eq. [3] have effective values for the CN ground state (24) of 2/3 for the R(1)/R(0) transitions and 1/3 for the P(1)/R(0) transitions.

As mentioned in the *Introduction*, the Hönl–London formulas are derived under the assumption of negligible interaction of rotation and electronic motion (8). However, it has been known since the pioneer study of Herzberg (1) that the $B^2\Sigma^+$ state of CN is affected by rotational perturbations. In particular, the $v' = 0$, $N' = 4$ rotational level is quite strongly coupled to the $N = 4$ rotational level of the $A^2\Pi$, $v = 10$ state of CN (18, 49). It is thus of interest to consider whether there exist intramolecular interstate coupling effects for lines involved in the CN interstellar absorption observations. In that case, the Hönl–London formulas would no longer be valid. Perturbation interactions between the $B^2\Sigma^+$ and $A^2\Pi$ states must obey Kronig's selection rules (8): $\Delta J = 0$; $\Delta S = 0$; $\Delta\Lambda = 0, \pm 1$, and interacting levels of the same parity, i.e., both + or both –, where the symbols are as defined by Herzberg (8).

Whether interstate coupling exists can be ascertained by observation of evident spectral perturbations or, possibly more sensitively, by determination of oscillator strengths, via lifetime measurements of fluorescence from the suspected rotational levels of the $B^2\Sigma^+$ state. The relevant information will be discussed later.

Comparison between T_γ(COBE) and T_γ(CN) values obtained from R(0)/R(1) and from R(0)/P(1) intensity ratios

R(0) is the only line that can effectively suffer from any saturation effects. Since R(0) is common to both sets of intensity ratios, the saturation correction uncertainty and local excitation uncertainty should be same for the R(0)/R(1) and R(0)/P(1) measurements. A comparison between the T_γ(CN) for the two sets of measurements should be independent of the absolute value of T_γ(CN), thereby permitting a test of whether there is a difference in their values.

The separate R(0)/R(1) and R(0)/P(1) data in Table 1 give average T_γ(CN) values: of 2.780 and 2.770 K, respectively. The COBE value of $T_\gamma = 2.725$ K is smaller than each of the two values of T_γ(CN): for R(0)/R(1), $T_\gamma(CN) - T_\gamma(COBE) = 55$ mK, and for R(0)/P(1), $T_\gamma(CN) - T_\gamma(COBE) = 45$ mK. The error bars on the weighted average values of T_γ(CN) are of the order of 15 mK (47), so that these results do not reveal a definite difference of the T_γ(CN) value in the two sets of measurements. However, they do corroborate previous findings (37, 47) that there is a significant difference between T_γ(CN) and T_γ(COBE) and that T_γ(CN) is greater than T_γ(COBE).

Following the discussion in the previous section, the existence of a difference between T_γ(CN) and T_γ(COBE) can be interpreted as indicating that in the CN $B^2\Sigma^+$ state, $v = 0$ level, the $N' = 2$ and $N' = 0$ rotational levels (i.e., the upper level of the R(1) and P(1) lines, respectively) are involved in intramolecular radiationless coupling between the $B^2\Sigma^+$ and the $A^2\Pi$ states of CN. As shown below, the effect would be to diminish the effective oscillator strength of these transitions, thus modifying the effective Hönl–London rotational line factors.

The oscillator strength of the $B^2\Sigma^+$–$X^2\Sigma^+$ transition is known to be much greater than that of the $A^2\Pi$–$X^2\Sigma^+$ transition (50). Therefore, intramolecular radiationless coupling between rovibronic levels of the $B^2\Sigma^+$ and $A^2\Pi$ states will lead to a decrease in the oscillator strengths of radiative transitions involving the rotational levels of the B state that are coupled to the A state levels (18). The $X^2\Sigma^+$ $v = 0$ ground state is not affected by intramolecular coupling. In the case of the R(1), R(0), and P(1) lines, the upper-state rotational levels have rotational quantum numbers $N' = 2$, $N' = 1$, and $N' = 0$, respectively. The f' value of eq. [3] refers to the R(1) and P(1) line transitions; i.e., the ground-state $N'' = 1$ level is probed by two lines, giving rise to two different f' values, while the f'' value is that of the R(0) line transition, which alone probes the $N'' = 0$ level (Fig. 1).

As mentioned above, interelectronic state coupling is certainly negligible for the $X^2\Sigma^+$ $v = 0$ level. Thus, if all other sources of error are equal, a comparison between T_γ values deduced from CN rotational level populations and the values of T_γ obtained from direct measurements, which are not subject to the spectroscopic caveats, can allow estimates to be made of the relative errors of the Hönl–London factor ratios in eq. [3] due to coupling between $B^2\Sigma^+$ and $A^2\Pi$ state rovibronic levels.

From eqs. [1]–[3], one obtains that the CN excitation temperature $T_\gamma(CN) \propto \beta[\ln \theta(f'/f'')]^{-1}$, where β and θ are constants whose values are specific to each line-of-sight measurement. Thus, the observational result $T_\gamma(CN) > T_\gamma(COBE)$ implies that the ratio f'/f'' must be increased to diminish T_γ(CN) so that it becomes equal to T_γ(COBE). In terms of Hönl–London factors, this implies that the standard Hönl–London factor ratios used in all previous determinations of T_γ(CN) from eq. [3] should be modified.

As an illustration, using eqs. [1]–[3], it is possible to estimate the values of these parameter modifications from the T_γ(CN) data discussed above. From the differences $T_\gamma(CN)$ –

Table 2. Radiative lifetimes of the $N' = 0$–4 rotational levels of the $B^2\Sigma^+$ state $v = 0$ vibrational level.

	Fluorescence lifetime (ns)	
Rotational level N'	Jackson (53)	Duric et al. (54)
0	65.1±0.8	66.7±1.4
1	66.9±0.5	64.8±1.4
2	64.8±0.6	65.8±1.4
3	65.0±0.6	68.0±1.4
4	71.3±0.3	72.9±0.6

T_γ(COBE) of 55 mK (R(0)/R(1) measurements) and 45 mK (R(0)/P(1) measurements), the correction should be an increase of 3.87% in the $f'(N' = 2)/f''(N' = 1)$ ratio and of 3.19% in the $f'(N' = 0)/f''(N' = 1)$ ratio. The corresponding Hönl–London factor ratios are then 0.6925 (instead of 0.6667) and 0.3440 (instead of 0.3333) for the R(0)/R(1) measurements and R(0)/P(1) measurements. respectively. These are order-of-magnitude values and can be refined by taking into account error estimates in T_γ(CN).

Is there spectroscopic or excited-state lifetime evidence for coupling between the CN $B^2\Sigma^+$, $v = 0$, $N' = 0$–2 rotational levels and the $A^2\Pi$ state?

Examination of the observed and calculated high-resolution spectral line position data for the (0,0) band of the CN $B^2\Sigma^+$–$X^2\Sigma^+$ transition, obtained by Prasad et al. (51) in two different laboratory emission sources, did not reveal any evident marked perturbation of the R(0), R(1), and P(1) lines. However, a weak line appears to exist close to the P(1) line in the published spectrum of the P branch (no spectrum of the R branch was published), obtained using a discharge source (51), and is possibly an extra-line which, if confirmed, is indicative of a perturbation of the $N' = 0$ level of the $B^2\Sigma^+$ $v = 0$ excited state.

Another test of intramolecular coupling between rotational levels of the $B^2\Sigma^+$ and $A^2\Pi$ states is possible from fluorescence lifetime measurements of individual rotational levels of the $B^2\Sigma^+$ $v = 0$ state, since there is an inverse relation between lifetime and oscillator strength (8, 52). Measurements of radiative lifetimes of up to 16 rotational states of the CN $B^2\Sigma^+$ $v = 0$ level have been carried out by Jackson (53) and by Duric et al. (54). The lifetimes of the individual rotational levels are sensitive to the degree of coupling between the $B^2\Sigma^+$ and $A^2\Pi$ states. For $v'' > 0$, only bandheads were measured. The method used by Jackson involved measuring the decay of CN $B^2\Sigma^+$ state fluorescence excited by a tunable dye laser, whereas Duric et al. used electron beam excitation coupled to the high-frequency deflection technique. It should be noted that the $B^2\Sigma^+$ state can also decay radiatively to the $A^2\Pi$ state (55). The B $\rightarrow$ A branching ratio for the $B^2\Sigma^+$ $v = 0$ level is of the order of 0.003 (56, 57) so that this radiative "leakage" has negligible effect on the lifetimes of the $N' = 0$–2 rovibronic levels of the $B^2\Sigma^+$ state.

Table 2 gives the values of the measured fluorescence lifetimes of the $N' = 0$–4 rotational levels. The measurements of Jackson (53) and Duric and al. (54) are generally in good agreement but differ significantly for the crucial $N' = 1$ rotational level. The error limits are 2σ in the case of Jackson's measurements and were not specified for those of Duric et al.

Because the oscillator strength is inversely proportional to the lifetime, a longer lifetime implies a smaller oscillator strength. In the case of the R(0)/R(1) measurements of T_γ(CN), the ratio f'/f'' is that of $f(N' = 2)/f(N' = 1)$, while for the R(0)/P(1) measurements, the ratio f'/f'' is that of $f(N' = 0)/f(N' = 1)$. The lifetime measurements of Jackson favour both $f(N' = 2) > f(N' = 1)$ and $f(N' = 0) > f(N' = 1)$. These results are consistent with the conclusion of the previous section that the ratio f'/f'' should be increased over that given by the standard Hönl–London factor ratios. The lifetime values of Duric et al., which are of lesser precision, and are possibly also subject to population cascade effects (54), also support $f(N' = 2) > f(N' = 1)$ but favour $f(N' = 0) < f(N' = 1)$. It is the different values of the $N' = 1$ lifetime in the two measurements that is responsible for this disagreement.

Quantitatively, the lifetime data of Jackson (53) indicate that for the determination of T_γ(CN) from R(0)/R(1) measurements, the f'/f'' ratio should be increased by 3.24% ± 1.7% and that of the R(0)/P(1) measurements by 2.76% ± 2.0%. These values are of the same order of magnitude as those deduced in the previous section (3.87% and 3.19%, respectively) from the T_γ(CN) – T_γ(COBE) data. The corresponding modifications of the Hönl–London factor ratios, from the mean values of the lifetimes, are 0.6883 (instead of 0.6667) and 0.3425 (instead of 0.3333) for the R(0)/R(1) and R(0)/P(1) measurements, respectively.

It should be noted that the lifetime of the $N' = 4$ state is markedly different from those of the other N' levels in Table 2. This longer lifetime results from the well-known perturbation of the $N' = 4$, $J' = 3.5$ rotational level of the $B^2\Sigma^+$ $v = 0$ state with an energetically quasi-degenerate rotational level, $N = 4$, $J = 4.5$, of the $v = 10$ vibrational level of the $A^2\Pi$ state (18), which shows up spectacularly in producing a strong extra-line in the CN absorption or emission spectrum (18, 49). The intrastate mixing coefficient can be estimated from the relative intensities of the main and extra-lines (18, 49) as well as from differences between the lifetimes of perturbed and unperturbed levels, as has been achieved for the $N' = 4$ level of the $B^2\Sigma^+$ $v = 0$ state (53, 54). For the $N' = 0$, 1, and 2 levels, the variation in the measured lifetimes, although real, is not large. This indicates that the coefficients of intrastate mixing of the $N' = 0$, 1, and 2 rovibronic levels with the appropriate $A^2\Pi$ state levels obeying the Kronig selection rules would be relatively small, thus making it difficult, in these cases, to observe any corresponding perturbations from spectral line positions.

Conclusion

Observations have been reviewed which indicate that the cosmic background radiation temperature T_γ determined from CN $B^2\Sigma^+$–$X^2\Sigma^+$ absorption line intensities is higher than that determined by direct methods such as from COBE satellite measurements. Even when CN local excitation processes have been taken into account, there still remains a small excess temperature. This excess temperature has been previously interpreted as due to insufficient corrections for electron excitation processes. This may indeed be the case,

© 2004 NRC Canada

since knowledge of electron densities n(e) in interstellar clouds is necessary for the determination of local excitation (16) but the estimation of n(e) by excitation modelling (37) or from CN emission measurements (45) is fraught with many difficulties and subtleties.

An alternative explanation of, or at least a contributory factor to, the excess temperature, given in the present study, is the use of invalid Hönl–London factor ratios in T_γ(CN) determinations from eq. [3], i.e., inadequate ratios of rotational line strengths. These inadequacies could arise from intramolecular coupling between the $B^2\Sigma^+$ state rotational levels involved in the R(0), R(1), and P(1) transitions and close-lying rotational levels of the $A^2\Pi$ state obeying the Kronig selection rules. Estimates of the necessary corrections to the f'/f''oscillator strength ratios and to the ratios of Hönl–London factors were made, assuming that the entire apparent excess temperature is due to invalid Hönl–London factor ratios. These corrections were determined from the differences between T_γCN) and T_γ(COBE) values obtained from R(0)/R(1) and R(0)/P(1) CN line intensity ratio measurements.

Similar correction values were obtained using values of the lifetimes of the $N' = 0$–2 rotational levels of the $B^2\Sigma^+$ $v = 0$ state. The lifetime measurements of Jackson (53) showed evidence for interstate coupling, but the mixing coefficients would be too small for these effects to show up as marked perturbations of the $N'= 0$–2 levels in the CN absorption or emission spectra.

Confirmation of the thesis of the present study, and determination of the extent of the contribution of invalid Hönl–London factors to the excess excitation temperature of CN, requires further studies: more precise interstellar CN measurements, better determinations of local excitation effects, and laboratory investigations, including both spectral and lifetime measurements, of possible interactions between the CN $A^2\Pi$ state and low-lying rotational levels of the $B^2\Sigma^+$ $v = 0$ state.

SiO as a chemical signature of outflows from bright, compact sources in MSX IR-dark clouds[1]

P.A. Feldman, R.O. Redman, L.W. Avery, J. Di Francesco, J.D. Fiege, S.J. Carey, and F. Wyrowski

Abstract: The line profiles of dense cores in infrared-dark clouds indicate the presence of young stellar objects (YSOs), but the youth of the YSOs and the large distances to the clouds make it difficult to distinguish the outflows that normally accompany star formation from turbulence within the cloud. We report here the first unambiguous identification of a bipolar outflow from a young stellar object (YSO) in an infrared-dark cloud, using observations of SiO to distinguish the relatively small amounts of gas in the outflow from the rest of the ambient cloud.

Key words: infrared-dark clouds, star formation, bipolar outflows, SiO, G81.56+0.10.

Résumé : Les profils des raies des parties centrales denses de nuages infrarouges sombres signalent la présence de jeunes objets stellaires (JOS) ; toutefois, la jeunesse de ces objets et leur grande distance par rapport aux nuages fait qu'il est difficile de distinguer entre les écoulements vers l'extérieur qui accompagnent normalement la formation d'une étoile de la turbulence à l'intérieur du nuage. Dans ce travail, en utilisant des observations de SiO pour distinguer les quantités relativement faibles de gaz s'écoulant vers l'extérieur du reste du nuage ambiant, on rapporte la première identification non ambiguë d'un écoulement bipolaire à partir d'un jeune objet stellaire dans un nuage infrarouge sombre.

Mots clés : nuages infrarouges sombres, formation d'étoile, écoulement bipolaire, SiO, G81.56+0.10.

[Traduit par la Rédaction]

1. Introduction

Infrared-dark clouds (IRDCs) are a population of several thousand molecular clouds, which have been identified by their substantial mid-IR (8–25 μm) extinctions in MSX images (1). Egan et al. (1) concluded that the IRDCs possess hundreds of magnitudes of visual extinction and contain large column densities of cold dust. Spectral-line observations of several of these clouds by Carey et al. (2) revealed that much of the gas inside the IRDCs has $T_K \approx$ 10–15 K, $n(H_2) \gtrsim 10^6$ cm^{-3}, and $N(H_2) \lesssim 10^{23}$ cm^{-2}. Their kinematic distances range between 1 and 8.5 kpc.

Subsequent observations (3–6) found that the MSX IRDCs contain many bright, compact (<30″) submillimetre sources, which appear to be molecular cores in a variety of early stages of star formation. These objects have masses in the range $\approx$ 10–10^3 $M_\odot$, large enough for them to be pre-protocluster cores, the presumed precursors of ultra-compact H II regions and high-mass stars (5, 6), even if the star-forming efficiencies are low. Some of them show evidence of on-going star formation in the form of weak 8 μm emission sources, but most appear completely dark in the MSX 8 μm images. They may contain Class-0 protostars or may be stable, quiescent globules.

The presence of bipolar outflows would provide evidence of on-going star formation even if the protostars are too young or the clouds too opaque to allow IR radiation to escape. Our previous observations gave ambiguous evidence for bipolar outflows. The sources exhibited line profiles characteristic of outflow and (or) infall, but the outflow wings were unresolved and did not show bipolar structure. On the one hand, this is expected because of the large (0.5–5 kpc) distances of the IRDCs and the early state of their star formation. On the other hand, line profiles can be deceiving; the strong "blue wing" on the HCO^+ (3−2) line that we initially interpreted as evidence of infalling gas in G79.3+0.3 P1 proved on closer examination to be most likely due to the impact on the back of the cloud of the wind from a nearby Herbig Ae/Be star (6).

Our observations of H_2CO emission from several of these sources implied that the gas responsible for the line wings typically has temperatures in the range 40–60 K (see Fig. 1), using the calculations of Mangum and Wootten (7). Note that the gas responsible for the line wings is warmer than the bulk of the material in the IRDCs, which has temperatures in the range 15–30 K.

To provide more convincing evidence for the presence of bipolar outflows in the IRDCs, we decided to employ a chemical approach by searching for emission from SiO, a trace gas-phase species known to be enhanced behind the shocks driven by

Fig. 1. Spectrum of H_2CO (3_{03}–2_{02}) with the ratio of the lines (3_{22}–2_{21})/(3_{03}–2_{02}) shown in red. The H_2CO (3_{03}–2_{02}) line intensity was reduced by a factor of 2 so that both graphs can use the same ordinate.

outflows. Enhancements of SiO by as much as a factor of 10^6 over its abundance in background gas have been observed (8,9). Desorption of SiO from grains and (or) sputtering of the grains themselves in the postshocked material behind the jet is believed to be the cause. This phenomenon is commonplace: Codella et al. (10) found that more than 50% of their survey sample of outflows were readily detected in SiO.

The H_2CO observations made us reasonably confident that the temperatures in the shocked gas would be high enough to excite SiO (6–5) emission. Furthermore, SiO emission in molecular outflows is more likely to be found from regions of high molecular density where shocks have succeeded in compressing gas to number densities of 10^{5-6} cm^{-3} (10), which are the gas densities deduced for the compact, bright sources in the IRDCs.

2. JCMT observations

In August 2003, we used the 15 m James Clerk Maxwell Telescope (JCMT) on Mauna Kea in Hawaii to observe nine bright, compact sources in six IRDCs using the SiO (6–5) transition at 260.518 GHz with the 18.3″ beam of receiver A3. We found that four of these objects clearly showed SiO emission. In Fig. 2 we show the brightest of these spectra, for the source G81.56+0.10 P1. Interestingly, all of these sources appear dark in the MSX images, with no obvious evidence of on-going star formation. Detecting the J = 6–5 line of SiO, which has an excitation temperature of 44 K, provides strong evidence for the presence of unresolved molecular outflows in cores large enough to form massive stars but that otherwise appear quiescent.

3. BIMA observations

To obtain higher spatial resolution images, we observed the SiO (2–1) transition at 86.847 GHz towards the bright, compact

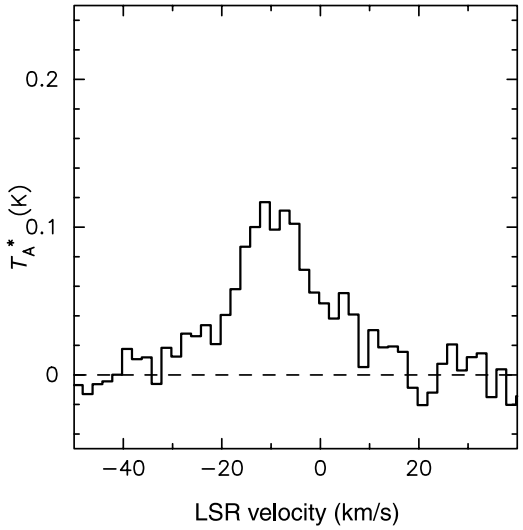

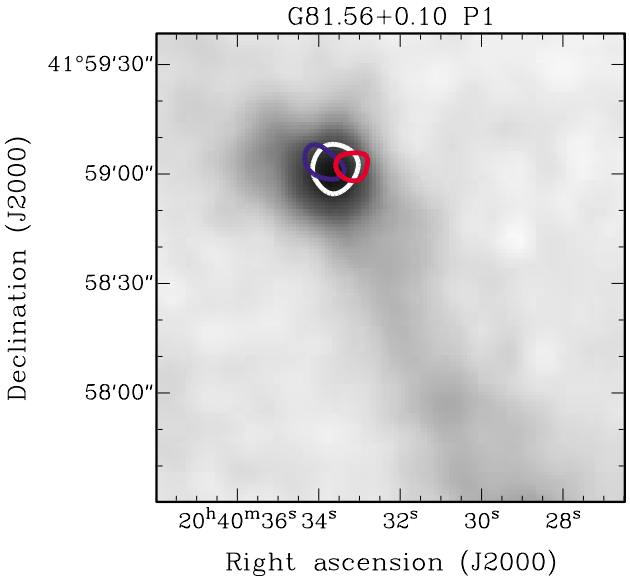

Fig. 3. SCUBA 850 μm image of G81.56+0.10 P1 made with the JCMT, with superimposed contours of integrated SiO (2–1) emission (blue and red) and 88.6 GHz dust continuum (white) made with BIMA. The contour parameters are: blue (velocity range [–26, –9] km s^{-1}, contour at 2.0 Jy/beam); red (velocity range [–3, 14] km s^{-1}, contour at 1.0 Jy/beam); white (contour at 0.01 Jy/beam).

source G81.56+0.10 P1 with the BIMA millimeter interferometer located at Hat Creek, California. The P1 object was observed for over 8 h on 29 September 2003 when the array was in its relatively compact "C" configuration. Clear evidence for a bipolar outflow was found (see Fig. 3).

The BIMA correlator was set such that a single 50 MHz window centered on SiO (2–1) would be sampled over 128 channels, yielding a velocity resolution of 1.25 km s^{-1}. In addition, eight 100 MHz correlator windows were also placed away from known line freqencies to sample continuum emission at an effective frequency of 88.592 GHz. The data were inverted with

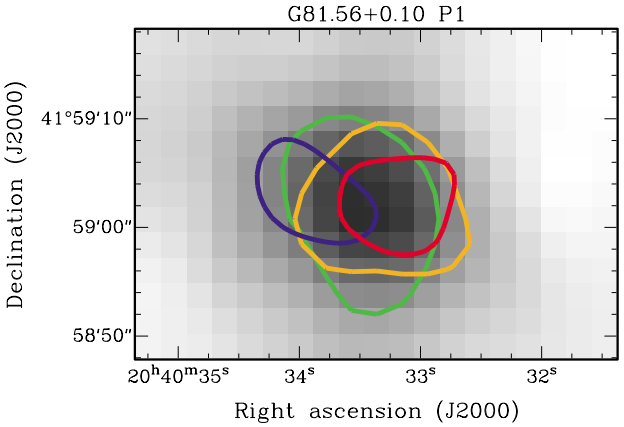
uniform weighting of the visibilities to obtain a synthesized beam of size 7.5″ × 6.5″ FWHM (P.A. = 24.4°). The data cube was deconvolved using a standard Högbom CLEAN algorithm (see Cornwell and Braun (11) and refs. therein). The resulting (1 σ rms) sensitivity of the line data was δT_{mb} = 0.31 K and that of the continuum data was δS_ν = 1.6 mJy beam^{-1}.

4. Results



G81.56+0.10 is the filamentary IRDC that appears in Fig. 3 as the diagonal band of 850 μm emission. (We note in passing that this IRDC was formerly known as G81.50+0.14 due to the difficulty of distinguishing absorption patches from voids in this complicated region.) The bright, compact source G81.56+0.10 P1 is prominent at the northeast end of the filament. We have observed the P1 source in a variety of molecular tracers of high-density gas, such as HCO^+ (3–2), HCO^+ (4–3), and CS (7–6), all of which have line profiles qualitatively very similar to the H_2CO (3_{03}–2_{02}) line shown in Fig. 1. There is a tendency for the higher-excitation lines to have more prominent line wings relative to the line centers. The strong line wings suggested the presence of outflows from an embedded YSO, but we were unable to find convincing evidence for a bipolar outflow even in our HCO^+ (4–3) maps made with a 14″ beam and sampled on a 7″ grid.

Figure 2 shows the SiO (6–5) line from G81.56+0.10 P1. Notably, the narrow line core seen in the H_2CO (3_{03}–2_{02}) line, as well as all other high-density molecular-line tracers we have observed to date, is absent in the SiO line. Moreover, the SiO line wings are roughly twice as wide as, for example, the H_2CO (3_{03}–2_{02}) line. In fact, the center of the SiO line is shifted about 4 km s^{-1} to the blue of the mean velocity of the cloud.

The blue and red contours in Fig. 3, showing the integrated intensity of the line wings in SiO (2–1), provide the first unambiguous detection of a bipolar outflow from a YSO in an IRDC. The red and blue line wings peak about 8″ apart in the plane of the sky. At the (uncertain) kinematic distance quoted by Carey et al. (2) of 1.3 kpc, this corresponds to a physical separation of 0.05 pc. The blue lobe is substantially stronger than the red lobe, which explains the blue shift in the apparent line center of the JCMT SiO (6–5) line. There is good positional agreement between the peaks of the 88.6 GHz dust continuum and the midpoint of the bipolar outflow where we anticipate the YSO is located.

These results are consistent with the conclusions of previous observers (8–10) that the SiO abundance is greatly enhanced in the outflow over its normal value in the ambient cloud. By contrast, we find that the HCO^+ (4–3) emission is not significantly enhanced in the outflow. This can be seen in Fig. 4, which overlays the half-power contours of the blue-shifted and red-shifted line wings of HCO^+ (4–3) and SiO (2–1) on an image of the integrated emission of HCO^+ (4–3) in the line core of the ambient cloud. Note that the centers of the contours of the line wings of HCO^+ (4–3) are barely displaced, if at all, from the peak of the line core. If the HCO^+ (4–3) line wings had been enhanced and (or) displaced as much as the SiO (2–1) line wings, the separation of the green and orange contours in Fig. 4 would have been obvious. We suggest that the wings of the HCO^+ lines might come from a compact, turbulent region closer to the YSO. It is not clear what the relationship is between the outflow and the region of enhanced turbulence.

Fig. 4. JCMT image of G81.56+0.10 P1 showing the integrated emission of HCO^+ (4–3) in the velocity range [–9, –3] km s^{-1} of the line core, which arises in the ambient cloud. The super imposed contours show the integrated emission in the blue-shifted and red-shifted line wings of HCO^+ (4–3) (green and orange contours, respectively) and of SiO (2–1) (blue and red contours, respectively). The contour parameters are: green (velocity range [–19, –9] km s^{-1}, contour at 3.0 Jy/beam); orange (velocity range [–3, 7] km s^{-1}, contour at 1.5 Jy/beam); blue (velocity range [–26, –9] km s^{-1}, contour at 2.0 Jy/beam); red (velocity range [–3, 14] km s^{-1}, contour at 1.0 Jy/beam).

5. Conclusions

We have utilized SiO as a chemical tracer to make the first unambiguous identification of a bipolar outflow from a YSO in an IR-dark cloud. The enhanced abundance of SiO behind strong shocks in the outflow enabled us to detect a bipolar outflow in G81.56+0.10 P1 despite the presence of very large amounts of gas in the ambient cloud. We have also found evidence in the line wings of HCO^+ and H_2CO for what we suggest may be a compact, turbulent region in the dense ambient gas close to the YSO within G81.56+0.10 P1.

Photoionization dynamics in CS fragmented from CS_2 studied by high-resolution photoelectron spectroscopy[1]

Anouk M. Rijs, Ellen H.G. Backus, and Cornelis A. de Lange

Abstract: The photoionization dynamics of CS have been studied using high-resolution laser photoelectron spectroscopy. The photodissociation of CS_2 at ~308 nm results in highly rotationally excited CS in its $X^1\Sigma^+$ singlet ground state, as well as in rotationally cold CS in the excited $a^3\Pi$ triplet state. The ground-state CS fragments are formed together with sulfur in its ^3P, ^1D, and ^1S electronic states; triplet CS is produced in coincidence with ground-state sulfur (^3P). In both channels the photoelectron spectra are dominated by $\Delta v = 0$ propensity, but transitions involving $\Delta v = 1$ and 2 are also observed.

Key words: photoelectron spectroscopy, photoionization, photodissociation, excited states, reactive intermediates.

Résumé : On a étudié la dynamique de photoionisation du CS en faisant appel à la spectroscopie photoélectronique laser à haute résolution. La photodissociation du CS_2 à environ 308 nm conduit à la formation de CS fortement excité d'un point de vue rotationnel, dans son état fondamental singulet $X^1\Sigma^+$, ainsi que de CS rotationnellement froid dans un état triplet excité $a^3\Pi$. Les fragments CS dans l'état fondamental se forment en même temps que du soufre dans les états électroniques ^3P, ^1D et ^1S; les quantités de CS à l'état triplet se forment en coïncidence avec le soufre à l'état fondamental (^3P). Dans les deux voies, les spectres photoélectroniques sont dominés par la propensité $\Delta v = 0$, mais on observe aussi des transitions de $\Delta v = 1$ et 2.

Mots clés : spectroscopie photoélectronique, photoionisation, photodissociation, états excités, intermédiaires réactifs.

Introduction

Resonance-enhanced multiphoton ionization, in combination with kinetic energy resolved photoelectron spectroscopy (REMPI-PES), has proven to be an excellent and powerful method to study rotationally resolved photoionization and photodissociation dynamics of rotationally hot photofragments (1–3). In particular, with REMPI-PES, detailed information about the spectroscopy and photoionization dynamics of the intermediate state can be obtained. Fragments formed in a photofragmentation process are often generated with an appreciable degree of electronic, vibrational, and rotational excitation. With sufficient rotational excitation, even for fragments with small rotational constants, the spacings between excited rotational levels in the ion may exceed the energy resolution of the magnetic bottle electron spectrometer used, and rotationally resolved photoelectron spectra can be obtained. These rotationally resolved photoelectron spectra provide information on the photoionization dynamics.

In the present work the photodissociation of CS_2, resulting in CS photofragments, has been studied. The ionization energy of CS from its neutral ground state to the lowest $X^2\Sigma^+$ ionic state amounts to 11.33 eV (4). The rotational constant of CS^+ in its ionic ground state is only 0.857662 cm^{-1} (5). However, when the CS photofragments are formed with sufficient rotational excitation, rotational levels in the ion with high J^+ are accessed, and rotationally resolved PES can be observed.

Carbon disulphide (CS_2) has a structure and a photodissociation behavior similar to that of the previously studied N_2O and OCS (1–3). These molecules all possess a linear ground-state geometry with a 16 valence electron configuration. The absorption spectrum of CS_2 shows many absorption bands between ~100 and 400 nm (6). The photo-

chemistry of CS_2 is strongly dependent on the wavelength of photolysis. Absorption of one photon of 193 nm results in the production of singlet CS ($X^1\Sigma^+$) fragments and sulfur atoms in the singlet or triplet state (^1D or ^3P) (7, 8). For photolysis wavelengths towards the ultraviolet, the production of triplet CS ($a^3\Pi$) becomes more important, and between 140 and 125 nm, the CS fragments are almost completely produced in the triplet state (9). CS_2 shows a strong absorption band around 340–290 nm. This band has been assigned to the $^1\tilde{B}_2 \leftarrow \tilde{X}^1\Sigma_g^+$ transition. This $^1\tilde{B}_2$ upper state is bent with an SCS angle of 131° and correlates to the $^1\Delta_u$ valence state in the linear configuration (10). One-photon excitation of CS_2 at ~308 nm (4.03 eV) correlates to the transition to the $^1\tilde{B}_2$ state. CS photofragments are formed by the sequential (1+1) absorption of two photons at ~308 nm (total energy 8.06 eV) via the $^1\tilde{B}_2$ intermediate state to a predissociative excited state lying near 150 nm (6). This state predissociates, yielding CS photofragments in combination with S atoms. There are several dissociation pathways in our energy region that can be accessed, producing singlet and triplet CS fragments (see Table 1), as follows:

[1] $CS_2 \rightarrow CS\ (X^1\Sigma^+) + S\ (^3P_J)$

[2] $CS_2 \rightarrow CS\ (X^1\Sigma^+) + S\ (^1D_2)$

[3] $CS_2 \rightarrow CS\ (X^1\Sigma^+) + S\ (^1S_0)$

[4] $CS_2 \rightarrow CS\ (a^3\Pi) + S\ (^3P_J)$

Dissociation pathways [2], [3], and [4] are spin-allowed processes from the optically prepared state. The first dissociation pathway [1] is a spin-forbidden process, which becomes weakly allowed by the spin–orbit interaction associated with the presence of the two sulfur atoms in CS_2.

The present paper is concerned with rotationally and vibrationally resolved laser photoelectron spectroscopy of CS fragments. At about 308 nm, the CS photofragments can be produced either in the singlet or the triplet state. The CS fragments formed in the $X^1\Sigma^+$ ground state are rotationally hot and are studied via a (2+1) ionization scheme using the intermediate $B^1\Sigma^+$ Rydberg state as a stepping-stone. The intermediate $B^1\Sigma^+$ Rydberg state represents the lowest member of a Rydberg series converging upon the $X^2\Sigma^+$ ionic ground state of CS^+ and is located at about 8.04 eV above the CS ($X^1\Sigma^+$) ground state (11). Together with the CS fragments formed in their singlet state, S atoms are also produced. These sulfur atoms can be formed via dissociation pathways [1], [2], and [3], resulting in ground- (^3P_J) and excited-state ($^1D_2$, $^1S_0$) S atoms. Various (2+1) ionization transitions of S (^3P_J, $^1S_0$) are used for calibration.

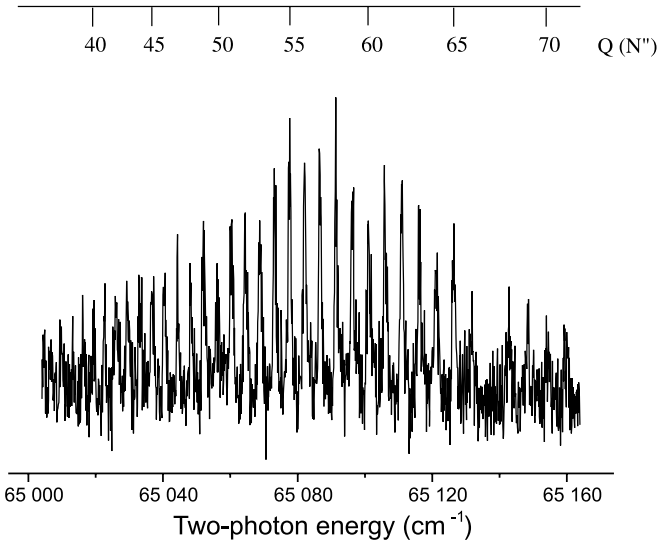
In addition to ground-state CS ($X^1\Sigma^+$) fragments, excited CS fragments can also be formed in the triplet state ($a^3\Pi$) via the dissociation route [4]. The electronically excited triplet CS ($a^3\Pi$) fragments, which possess low rotational excitation, are studied employing a (1+1) excitation step via the intermediate CS ($^3\Sigma^+$) state, resulting in CS^+ ($X^2\Sigma^+$) ionic fragments. With our photon energies, the CS ($a^3\Pi$) fragments can only be formed together with ground-state S (^3P_J) atoms. The appearance energy of the other dissociation channels of triplet CS ($a^3\Pi$) + S ($^1D_2$, $^1S_0$) lies above our two-photon dissociation energy.

Table 1. Threshold energies of the product states in the photodissociation of CS_2.

Pathway	CS channel	S channel	Energies (eV)
[1]	CS ($X^1\Sigma^+$)	S (^3P_J)	4.46
[2]	CS ($X^1\Sigma^+$)	S ($^1D_2$)	5.61
[3]	CS ($X^1\Sigma^+$)	S ($^1S_0$)	7.21
[4]	CS ($a^3\Pi$)	S (^3P_J)	7.88

Experimental

The experimental setup has been reported in great detail previously (1). Briefly, the laser system consists of an XeCl excimer laser (Lumonics HyperEx-460), producing pulsed radiation with a fixed wavelength of 308 nm and a pulse duration of ~10 ns. The laser pulses are generated with a repetition rate of 30 Hz and have an energy of 200 mJ pulse^{-1}. The excimer laser output is used to pump a dye laser (Lumonics HyperDye 500), operating on Rhodamine (bandwidth ~0.08 cm^{-1}). The dye laser output (about 615 nm) is frequency-doubled in a Lumonics HyperTrak 1000, using a KD*P crystal, resulting in 10-ns pulses with a maximum energy of about 15 mJ and a bandwidth of ~0.2 cm^{-1}. The laser light is focused into the ionization region of a magnetic bottle spectrometer by a quartz lens with a focal length of 25 mm. The laser pulse intensity is kept low enough to avoid nonresonant ionization of the parent compound CS_2. In the present experiments, the magnetic bottle spectrometer is used in the electron detection mode for both wavelength scans and photoelectron spectra and operates with a collection efficiency of ~50%. Since a time-of-flight method is used, time windows can be selected to achieve optimum resolution. Signal intensities are essentially independent of kinetic energies (1).



The CS photofragments are generated in situ by two-photon dissociation of CS_2 (Sigma-Aldrich, HPLC grade). The CS_2 gas sample is effusively introduced into the ionization chamber through a 13 mm outer diameter Pyrex flow tube, leading to a pressure in the ionization region of typically 10^{-3} mbar (1 bar = 100 kPa). The photodissociation of CS_2 and the subsequent ionization of the CS fragments are performed with the same laser photons of about 308 nm. For calibration of both the wavelength and the photoelectron kinetic energies, well-known resonances of sulfur atoms at two-photon energies of 64 889.0 and 66 741.6 cm^{-1} are used (12, 13).

Results and discussion

At 308 nm, the dissociation of CS_2 produces CS in the $X^1\Sigma^+$ ground state or in the $a^3\Pi$ triplet state. Figure 1 shows a two-photon excitation spectrum of CS fragments in the two-photon energy range 65 000 – 65 170 cm^{-1}. The spectrum was obtained by monitoring electrons with a kinetic energy of about 0.75 eV (flight time range of 2840–3000 ns). These photoelectrons arise from a (2+1) ionization process, starting from the $X^1\Sigma^+$ ($v'' = 1$; N'') electronic ground state via the intermediate $B^1\Sigma^+$ ($v' = 1$; N') Rydberg state to the $X^2\Sigma^+$ ($v^+ = 1$; N^+) ionic ground state. The rotationally resolved excitation spectrum shows the rotational distribution

Fig. 1. Rotationally resolved (2+1) REMPI excitation spectrum with electron detection of the Q branch of the $B^1\Sigma^+ \leftarrow\leftarrow X^1\Sigma^+$ transition of hot CS fragments in the two-photon energy range 65 000 – 65 170 cm^{-1} (vacuum energies).

of the Q branch ($\Delta N = 0$) of CS in the $B^1\Sigma^+$ ($v' = 1$) state, extending from $N' = 35$ up to $N' = 71$. The comb above the spectrum in Fig. 1 indicates the assignment of the N' rotational levels.

In the absorption step, only the transition from the $v'' = 1$ level of $X^1\Sigma^+$ to the $v' = 1$ level of $B^1\Sigma^+$ is observed. No transitions arising from $X^1\Sigma^+$ for $v'' \neq 1$ were observed. This unusual situation has to do with the properties of the vibrational levels associated with the $B^1\Sigma^+$ state. It is known from the literature (14) that the $B^1\Sigma^+$ Rydberg state predissociates, especially from the $v' = 0$ and the $v' = 2$ levels. Moreover, Sapers and Donaldson (15), who studied the rovibrational states of the CS $X^1\Sigma^+$ fragments formed in the CS_2 308-nm two-photon photolysis with laser-induced fluorescence detection, observed that CS was formed in its electronic ground state with a bimodal vibrational distribution that peaked at $v'' = 1$ with a secondary maximum at $v'' = 5$. In view of the fact that the CS $X^1\Sigma^+$ fragments are predominantly formed in their $v'' = 1$ vibrational state, and considering the significant predissociation of the $v' = 0$ and $v' = 2$ levels of the $B^1\Sigma^+$ Rydberg state, it is not surprising that we observe the CS $X^1\Sigma^+$ fragments only in their $v'' = 1$ vibrational state. The O and S branches associated with the $B^1\Sigma^+$ ($v' = 1$) $\leftarrow X^1\Sigma^+$ ($v'' = 1$) transition are not observed because of the great difference in line strengths between the Q and the O and S branches (16).

The assignment of the peaks in the excitation spectrum of Fig. 1 and the rotational analysis of the Q branch were performed by assigning the measured rotational lines in an iterative fashion. By using the published ground-state rotational constants (17), the $B^1\Sigma^+$ excited-state rotational constants B' were determined by fitting all the rotational energies of the Q branch to the following expression:

$$[5] \quad Q(N'') = \nu_{11} + (B_1' - B_1'')N''(N'' + 1) - (D_1' - D_1'')N''^2(N'' + 1)^2$$

Fig. 2. (*a*) Rotational fit of the measured line positions for the $B^1\Sigma^+$ ($v' = 1$) Rydberg state, based on the rotational constants of the $X^1\Sigma^+$ ground state of CS ($v'' = 1$) (17). Results are given in Table 2; (*b*) Residual plot, the difference between the experimental and calculated line positions.

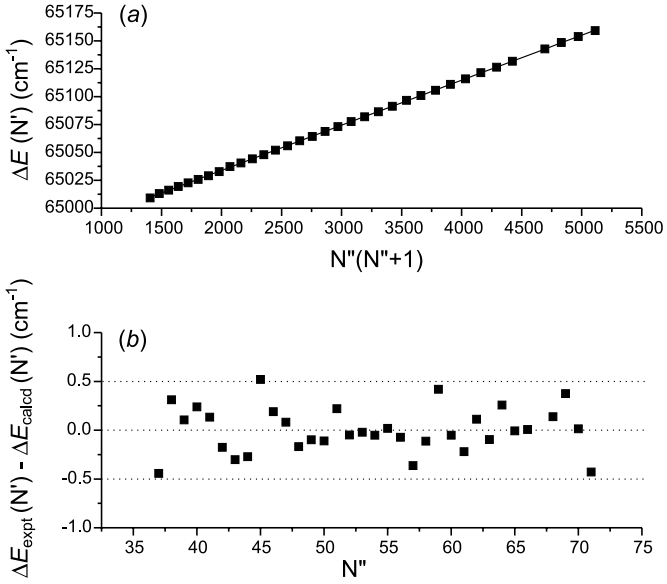

Table 2. Rotational constants (in cm^{-1}) for the $B^1\Sigma^+$ ($v' = 1$) Rydberg state of CS (left column), and a comparison with the literature (14) (central column).

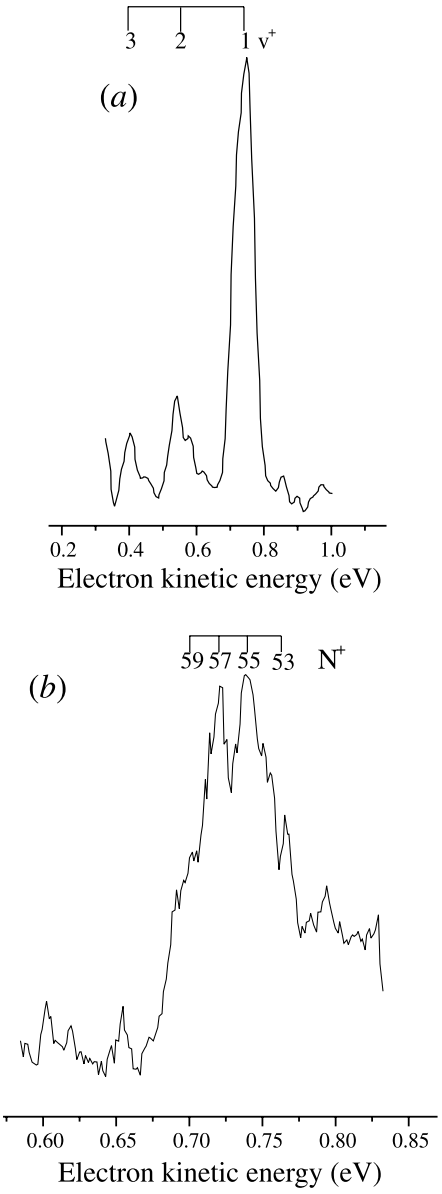
	$B^1\Sigma^+$ ($v' = 1$)	$B^1\Sigma^+$	$X^1\Sigma^+$
ν_{11}	64 952.60(36)	—	—
B_1	0.85188(24)	0.8520	0.811163722
D_1	$1.3802(38)\times10^{-6}$	1.56×10^{-6}	1.337566×10^{-6}

Note: The ground-state rotational constants of CS ($X^1\Sigma^+$) (refs. 17 and 18) are presented in the right column.



In our excitation spectrum of rotationally excited CS, we measured only high rotational levels, from $N' = 35$ up to $N' = 71$. Because we observe these high rotational levels, the centrifugal distortion constant D_1 of the $B^1\Sigma^+$ ($v' = 1$) state can be determined. The results of the rotational fit are shown in Fig. 2*a*, and the difference plot between the experimental and calculated line positions is presented in Fig. 2*b*. The improved rotational constants for the CS $B^1\Sigma^+$ ($v' = 1$) state are listed in Table 2 together with the CS $X^1\Sigma^+$ ground-state constants of refs. 17 and 18.

The two-photon dissociation of CS_2 at about 308 nm produces, in addition to CS fragments, S atoms in various states (see dissociation pathways [1], [2], and [3]). Several transitions of the S (^3P_J) and S ($^1S_0$) fragments are observed following (2+1) ionization. These well-known absorption lines are used for wavelength and kinetic-energy calibration. Dissociation resulting in S ($^1D_2$) (route [2]) is not observed because no transitions can be excited via a (2+1) ionization scheme with 308-nm photons. To observe S ($^1D_2$) atoms, the photon energy must be shifted to higher energies.

Photoelectron kinetic energy scans were obtained by one-photon ionization from the intermediate CS $B^1\Sigma^+$ ($v' = 1$; N') state into the continua of the ionic ground state $X^2\Sigma^+$ ($v^+ = 1$;

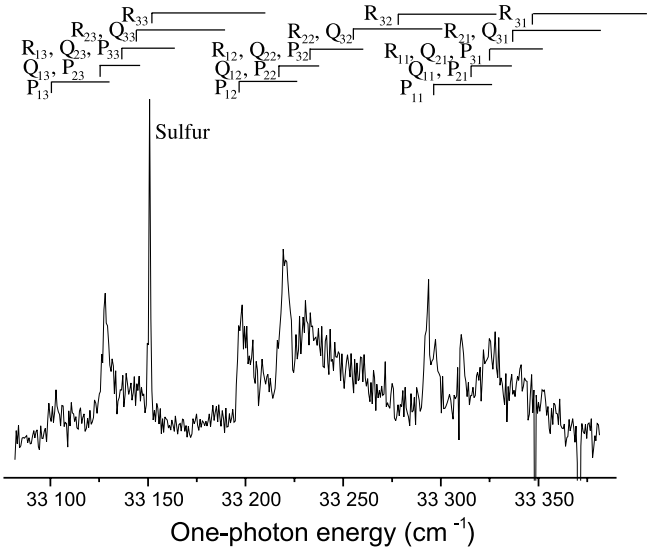

Fig. 3. Photoelectron spectrum of rotationally hot CS, produced in the two-photon dissociation of CS_2. The spectrum is obtained by (2+1) ionization, by employing the Q(55) transition via the $v' = 1$ level of the intermediate $B^1\Sigma^+$ Rydberg state. (*a*) In the spectrum, transitions to $X^2\Sigma^+$ ($v^+ = 1, 2, 3$) are shown; (*b*) more detailed scan for $\Delta v = 0$ ($v^+ = 1$), showing some rotational structure.

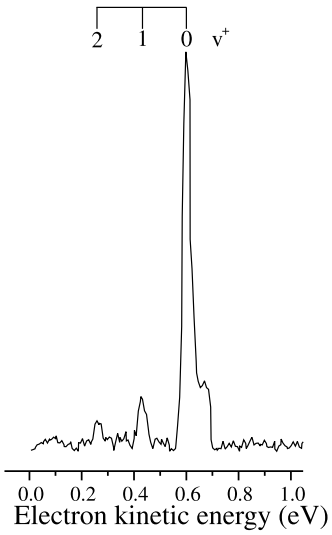
N^+). Figure 3*a* presents the photoelectron spectra associated with the Q(55) rotational transition at 65 077.6 cm^{-1} via $v' = 1$. The dominant peak at about 0.74 eV arises from the $\Delta v = 0$ transition. The smaller peaks can be assigned to the $\Delta v = (v^+ - v') = +1, +2$ transitions. The vibrational $\Delta v = 0$ propensity observed for this $X^2\Sigma^+ \leftarrow B^1\Sigma^+$ step is expected for one-photon ionization of a Rydberg state.

Despite the high rotational excitation of the CS fragment, the ionic spacings are not large enough to measure good-quality rotationally resolved photoelectron spectra. However, if we make a more detailed scan for the $\Delta v = 0$ transition at about 0.74 eV, some partially resolved rotational structure is

Fig. 4. (1+1) REMPI excitation spectrum with electron detection of the $^3\Sigma^+ \leftarrow a^3\Pi$ transition of CS photofragments in the one-photon energy range 33 075 – 33 400 cm^{-1} (vacuum energies).



observed (see Fig. 3*b*). Besides the Q(55) ($\Delta N = 0$) feature, peaks are also observed at about 20–25 meV from the Q(55) peak. These peaks can be assigned to $\Delta N = \pm 2$ transitions. The rotational spacings between the $\Delta N = 0$ peak and the $\Delta N = +2$ and -2 peaks are expected to be $B^+(4N^+ + 6)$ (24 meV) and $B^+(4N^+ - 2)$ (23 meV), respectively. Here $B^+ = 0.857662$ cm^{-1} (5) is the ionic rotational constant, and N^+ is the rotational quantum number of CS^+. Higher order rotational contributions are neglected in this estimate. The rotational structure in the photoelectron spectra of CS is subject to selection rules. For one-photon ionization from the $B^1\Sigma^+$ (v') state, the selection rule $\Delta N + \ell = odd$ applies, where $\Delta N = N^+ - N'$ and ℓ is a partial wave component of the photoelectron (19, 20). In the present case, the CS Rydberg electron occupies a $3s\sigma$ molecular orbital. In an atomic-like picture, ionization of this $3s\sigma$ Rydberg electron is expected to lead to p ($\ell = 1$) partial waves, and, on this basis, strong $\Delta N = even$ transitions would be expected; $\Delta N = \pm 1$ transitions are forbidden on the basis of these selection rules. However, with the present quality of the rotationally resolved photoelectron spectra, no firm conclusions can be drawn.

Following two-photon dissociation of CS_2 at 308 nm, the CS photofragments can be formed in the triplet state, resulting in CS ($a^3\Pi$) + S (^3P_J). Figure 4 shows the one-photon excitation spectrum in the energy range 33 075 – 33 500 cm^{-1}, corresponding to the CS fragment produced in its $a^3\Pi$ state. The features observed belong to the $^3\Sigma^+$ ($v' = 0$) $\leftarrow a^3\Pi$ ($v'' = 2$) transition (21, 22). The origin (v_{00}) of this transition lies at 282 nm, whereas we excite with ~300 nm. Ono and Hardwick (21) observed three absorption bands at 282, 291, and 300 nm. These bands are assigned to the $^3\Sigma^+$ ($v' = 0$) $\leftarrow a^3\Pi$ ($v'' = 0, 1, 2$) transitions, respectively. In our experiment, we have studied only the $^3\Sigma^+$ ($v' = 0$) $\leftarrow a^3\Pi$ ($v'' = 2$) transition. Since the same photons are used for the photodissociation of CS_2 and for the spectroscopy of CS, the other transitions could not easily be accessed in a one-color experiment. Our rotational assignment is based on the results of

Fig. 5. Photoelectron spectrum of CS ($a^3\Pi$), resulting from the (1+1) photoionization via the $^3\Sigma^+$ Rydberg state.

Ono and Hardwick (21). The complexity of the rotational structure that is evident from Fig. 4 is typical for a $^3\Sigma^+ \leftarrow {}^3\Pi$ transition between the two states described in Hund's case (b) (23). Because of the high threshold energy of 7.88 eV for the formation of CS ($a^3\Pi$) (see Table 1) and the vibrational excitation (v''= 2), less energy is available for excitation of the internal degrees of freedom, resulting in rotationally cold (N''= 4–22) CS ($a^3\Pi$) (21). This situation is in sharp contrast to the formation of CS ($X^1\Sigma^+$) with significant rotational excitation. Since CS ($X^1\Sigma^+$) is produced in a (2+1) and CS ($a^3\Pi$) in a (1+1) REMPI experiment, the very different conditions do not allow any reliable conclusions about branching ratios between both channels.

Figure 5 presents the experimental photoelectron spectrum obtained for (1+1) photoionization of CS ($a^3\Pi$, v'' = 2) via the CS ($^3\Sigma^+$, v′ = 0) Rydberg state at 33 327.8 cm^{-1}, producing the $X^2\Sigma^+$ (v^+) ionic ground state of CS^+. The dominant peak in the photoelectron spectrum at about 0.60 eV is the Δv = 0 transition. The neighboring peaks at the left-hand side of the spectrum arise from Δv = +1, +2 transitions. No rotationally resolved features are observed in the photoelectron spectrum of CS ($a^3\Pi$, v'' = 2) because of the low rotational excitation and the small rotational B^+ constant. The shoulder on the right-hand side of the Δv = 0 peak is the result of nonresonant multiphoton ionization of ^{1}S sulfur atoms.

In summary, the photodissociation of CS_2 produces CS molecules both in the singlet ground state and in a triplet excited state. The ground state ($X^1\Sigma^+$, v'' = 1) formed is highly rotationally excited, while the triplet state ($a^3\Pi$, v'' = 2) generated is rotationally cold. Comparing the results of the photodissociation of CS_2 with previous studies of the photodissociation of the similar molecules N_2O (2) and OCS (3), the photodissociation of these molecules produced rotationally hot N_2 and CO photofragments and O and S atoms in their $^1D_2$ singlet excited states. In the photodissociation of CS_2 we observe both similarities and differences. In the case of photodissociation of N_2O and OCS, the N_2 and CO photofragments are only formed in their electronic ground states, and nearly all them are formed in their ground vibrational states (2, 3). The photodissociation of CS_2 produces both ground-state and excited-state CS fragments and results in vibrationally excited CS species, both in the singlet electronic $X^1\Sigma^+$ ground state and in the electronically excited triplet $a^3\Pi$ state. In the photodissociation process of OCS and N_2O, the C—O and the N—N fragments appear to act solely as spectators, while in CS_2 the nonbonding electrons of both S atoms contribute to the absorption and both C—S bonds are excited and stretched (24). Ultimately, if one C—S bond breaks, the other is strongly vibrationally excited.

The photoelectron spectra of ground-state CS photofragments are dominated by Δv = 0 propensity, as was the case with the photoelectron spectra of ground-state N_2 and CO. However, the photoelectron spectra of N_2 and CO could be measured with excellent rotational resolution, whereas in the case of CS it appears more difficult to obtain rotationally resolved photoelectron spectra. This is mostly because the rotational constant of the CS^+ ion is approximately half that of N_2^+ or CO^+.

Finally, the fact that our experiments on CS, both in its singlet and triplet electronic states, have been performed in the ~1 T field of a magnetic bottle spectrometer should not affect the observed dynamics. Systematic studies have shown that possible magnetic field effects in this type of spectrometer may only be significant for high Rydberg states close to the ionization threshold (25–27).

Conclusions

The photodissociation dynamics of CS_2 at about 308 nm encompasses a singlet and a triplet CS dissociation channel. The photodissociation via the singlet channel produces rotationally hot CS ($X^1\Sigma^+$) fragments in their first vibrationally excited level. A rotational distribution of CS extending from N' = 35 up to N' = 71 (with a maximum at N' = 58) has been observed and assigned. For the first time, a (2+1) high-resolution partly rotationally resolved excitation spectrum of CS ($X^1\Sigma^+$) via the Rydberg level $B^1\Sigma^+$ has been recorded. Improved spectroscopic rotational parameters have been obtained for the CS ($B^1\Sigma^+$) state. The other dissociation channel of CS_2 at 308 nm results in the production of CS ($a^3\Pi$) in its v'' = 2 vibrational level, with low rotational excitation. In both cases the photoelectron spectra were dominated by Δv = 0 propensity, with much weaker transitions involving Δv = 1 and 2.

High-resolution vacuum ultraviolet laser spectroscopy of the C $0_u^+ \leftarrow$ X 0_g^+ transition of Xe_2[1]

A. Wüest, U. Hollenstein, K.G. de Bruin, and F. Merkt

Abstract: Rotationally resolved (1 + 1′), resonance-enhanced, two-photon ionization spectra of the C $0_u^+ \leftarrow$ X 0_g^+ transition of several isotopomers of Xe_2 have been recorded. Rotational constants have been determined for the $v' = 14$–26 levels of the C 0_u^+ Rydberg state and the $v'' = 0$ and 1 levels of the X 0_g^+ ground state, and band origins have been determined with an absolute accuracy of 0.015 cm^{-1} for the transitions to the $v' = 14$–26 levels of the C 0_u^+ state of the $^{129}Xe_2$, ^{129}Xe–^{132}Xe, and ^{131}Xe–^{136}Xe isotopomers. The equilibrium internuclear separation of the X 0_g^+ ground state ($R_e = 4.3773(49)$ Å) was determined from the rotational constants of the $v'' = 0$ and 1 levels. The analysis of the isotopic shifts of the band origins enabled the confirmation of the absolute numbering of the vibrational levels of the C 0_u^+ state determined by Lipson et al. (R.H. Lipson, P.E. Larocque, and B.P. Stoicheff. J. Chem. Phys. **82**, 4470 (1985)). A semiempirical interaction potential for the X 0_g^+ ground state was derived in a nonlinear fitting procedure using the present spectroscopic results, the positions of the $v'' = 2$–9 levels determined by Freeman et al. (D.E. Freeman, K. Yoshino, and Y. Tanaka. J. Chem. Phys. **61**, 4880 (1974)) and experimental values for the second virial coefficient. The interaction potential is similar to previous semiempirical potentials but the dissociation energy ($D_e = (196.1 \pm 1.1)$ cm^{-1}) differs from the value of 183.1 cm^{-1} determined in the latest ab initio calculation (P. Slavíček, R. Kalus, P. Paška, I. Odvárková, P. Hobza, and A. Malijevský. J. Chem. Phys. **119**, 2102 (2003)).

Key words: high-resolution vacuum ultraviolet laser spectroscopy, rare gas dimers and their cations, photoionisation, Xe_2, rotationally resolved electronic spectrum.

Résumé : On a enregistré les spectres d'ionisation biphotonique améliorés en résonance et résolus en rotation (1 + 1′) de la transition C $0_u^+ \leftarrow$ X 0_g^+ de plusieurs isotopomères de Xe_2. On a déterminé les constantes rotationnelles des niveaux $v' = 14$–26 de l'état de Rydberg C 0_u^+ et des niveaux $v'' = 0$ et 1 de l'état fondamental X 0_g^+ et on a déterminé les origines des bandes avec une précision absolue de 0,015 cm^{-1} pour les transitions des niveaux $v' = 14$–26 de l'état C 0_u^+ des isotopomères $^{129}Xe_2$, ^{129}Xe–^{132}Xe et ^{131}X–^{136}Xe. On a déterminé la séparation internucléaire à l'équilibre de l'état fondamental X 0_g^+ (R_e = 4,3773(49) Å) à partir des constantes rotationnelles des niveaux $v'' = 0$ et 1. L'analyse des déplacements isotopiques des origines des bandes a permis de confirmer la numérotation absolue des niveaux vibrationnels de l'état C 0_u^+ déterminée par Lipson et al. (R.H. Lipson, P.E. Larocque, et B.P. Stoicheff. J. Chem. Phys. **82**, 4470 (1985)). On a dérivé le potentiel d'interaction semi-empirique de l'état fondamental X 0_g^+ à l'aide de la méthode d'ajustement non linéaire en utilisant les données expérimentales obtenues dans ce travail ainsi que les positions des niveaux $v'' = 2$–9 déterminées par Freeman et al. (D.E. Freeman, K. Yoshino, et Y. Tanaka. J. Chem. Phys. **61**, 4880, 1974) et les valeurs expérimentales pour le deuxième coefficient viriel. Le potentiel d'interaction est semblable aux potentiels semi-empiriques obtenus antérieurement, mais l'énergie de dissociation (D_e = (196,1 ± 1,1) cm^{-1}) diffère de la valeur de 183,1 cm^{-1} déterminée dans le dernier calcul ab initio (P. Slavíček, R. Kalus, P. Paška, I. Odvárková, P. Hobza, et A. Malijevský. J. Chem. Phys. **119**, 2102 (2003)).

1. Introduction

In their electronic ground state, the homonuclear rare gas dimers are bound solely by dispersion forces. They represent model systems to study van der Waals interactions, and considerable experimental and theoretical efforts have been invested to derive the interaction potentials of He_2, Ne_2, Ar_2, Kr_2, and Xe_2. The body of literature is so vast that it is impossible to cite all relevant contributions in a research article and the references cited in the following merely list the most recent contributions.

The van der Waals interactions between the rare gas atoms are conveniently described by a one-dimensional interaction potential. Two approaches can be followed to derive the potential function: ab initio quantum chemistry and semiempirical methods.

Ab initio potentials of close to spectroscopic accuracy (± 1 cm^{-1}) have been reported for the lighter dimers He_2 and Ne_2 (1–3). The larger number of electrons and the growing importance of relativistic effects render ab initio calculations on the heavier dimers more demanding, and the determination of accurate interaction potentials for Kr_2 and Xe_2 by ab initio quantum chemistry remains a challenge (4).

High quality semiempirical potentials are currently known for all homonuclear rare gas dimers (5–9). The primary source of experimental data needed to derive such potentials are high-resolution spectra of dimers in the gas phase, atom–atom scattering cross sections, and physical properties in the condensed phases such as viscosity and diffusion coefficients, compressibilities, and lattice distances. A widely used model for the potential resulting from the van der Waals interaction was introduced by Tang and Toennies (5, 10)

$$[1] \qquad V(R) = V_{\text{repl}}(R) + V_{\text{attr}}(R) = A\,\mathrm{e}^{-bR} - \sum_{n=3}^{8} f_{2n}(R,b)\frac{C_{2n}}{R^{2n}}$$

and consists of a repulsive Born–Mayer term and a damped attractive dispersion series. In eq. [1], A and b are adjustable parameters, and $f_{2n}(R,b)$ and C_{2n} represent damping functions and dispersion coefficients of order $2n$, respectively. The damping functions prevent the R^{-2n} terms from dominating at short internuclear distances and have the form

$$[2] \qquad f_{2n}(R,b) = 1 - \mathrm{e}^{-bR}\sum_{k=0}^{2n}\frac{(bR)^k}{k!}$$

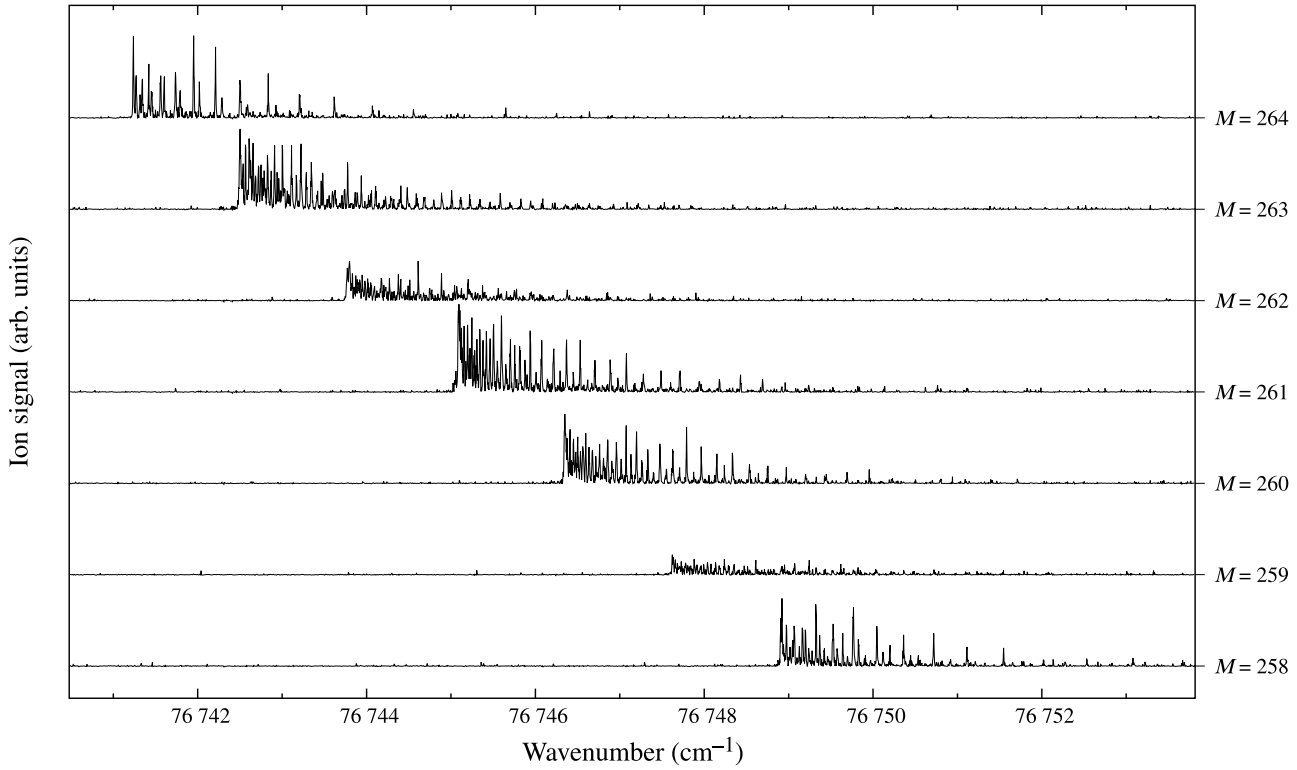
The dispersion coefficients are usually not adjusted to reproduce experimental data but are taken from atomic properties (either empirical or ab initio).

Spectroscopic data such as rotational constants B_v and vibrational energy intervals $\Delta G_{v+1/2}$ represent the most stringent tests of the quality of ab initio and semiempirical potentials. However, such information is not easily obtained for the homonuclear rare gas dimers because they lack a permanent dipole moment, and thus, do not have an electric dipole allowed rotational or vibrational spectrum. Rotational constants and vibrational intervals are determined in these systems from the rovibrational fine structure of electronic transitions from the ground neutral state to the lowest electronic states. These transitions all lie in the vacuum ultraviolet (VUV) region of the electromagnetic spectrum where high-resolution spectroscopic measurements are not as easy to carry out as in the microwave, IR, visible, or near-UV regions. For this reason, Xe_2 is one of the most important diatomic molecules for which no rotationally resolved spectroscopic information was available when Huber and Herzberg (11) published their classic reference work on the constants of diatomic molecules. For Ar_2 and Kr_2, rotationally resolved electronic spectra of excellent quality have been obtained in the pioneering investigations of Yoshino and co-workers (12, 13) and Stoicheff and co-workers (14, 15). The lowest excited electronic states of Ne_2 lie further in the VUV (beyond 16 eV) and fully rotationally resolved spectra have only been reported recently (6). The very small rotational constant of Xe_2 and the spectral congestion resulting from the large number of isotopomers have so far prevented the obtaining of rotationally resolved spectra. In this case, semiempirical potentials have primarily relied on isotopically averaged vibrational intervals for $v'' = 0$–9 from the work of Freeman et al. (16).

In this contribution, fully rotationally resolved spectra of the C $0_u^+ \leftarrow$ X 0_g^+ transition of selected isotopomers of Xe_2 are reported for the first time. The analysis of these spectra provides new information on the equilibrium internuclear distance and the first vibrational interval in the ground electronic state. This new measurement was combined with earlier spectroscopic and thermodynamical data to derive an improved semiempirical potential.

This article is structured as follows: the experimental procedure is described in Sect. 2. The analysis of the spectra of the C $0_u^+ \leftarrow$ X 0_g^+ transition carried out in terms of the standard expansion series for the term values is summarized in Sect. 3. Finally, Sect. 4 is devoted to the determination of a semiempirical potential for the ground electronic state of Xe_2 and to a comparison with earlier ab initio and semiempirical potentials.

2. Experimental



The spectra have been recorded using a narrow bandwidth (0.008 cm^{-1}), VUV laser system coupled to a time-of-flight mass spectrometer. The laser system and the procedure for the VUV wavenumber calibration have been described in detail earlier (17, 18), and only the aspects specific to the present study are summarized here.

Tunable VUV radiation in the range $\tilde{\nu}_{\text{VUV}} = 76\,000$ – $77\,000$ cm^{-1} was generated by resonance-enhanced, difference-frequency mixing ($\tilde{\nu}_{\text{VUV}} = 2\tilde{\nu}_1 - \tilde{\nu}_2$) in an atomic beam of krypton using two near-Fourier-transform-limited pulsed dye lasers. The dye laser pulses were produced by pulse amplifying the cw output of two single-mode ring dye lasers using chains of three dye amplification stages pumped transversally by the doubled output (532 nm) of an injection-seeded Nd:YAG laser. The resonance enhancement of the four-wave mixing process is achieved at the two-photon level by locking the wavenumber $\tilde{\nu}_1$ of the tripled output of the first pulsed dye laser to the position $2\tilde{\nu}_1 = 94\,092.906(9)$ cm^{-1} located close to the maximum of the $4p^5 5p[1/2]_0 \leftarrow {}^1S_0$ two-photon resonance of atomic krypton (18). The locking was achieved by stabilizing the fundamental frequency of the dye laser to a neighboring I_2 line according to the procedure described in ref. 19. The VUV wavenumber was tuned by scanning the wavenumber $\tilde{\nu}_2$ of the second pulsed dye laser. The wavenumber $\tilde{\nu}_2$ was calibrated by recording with each VUV spectrum several étalon spectra and a laser-induced fluorescence spectrum of I_2, and making reference to the iodine atlasses (20, 21).

The VUV wavenumber was determined with an absolute accuracy of 0.015 cm^{-1} from the wavenumbers $\tilde{\nu}_1$ and $\tilde{\nu}_2$ by building the difference $2\tilde{\nu}_1 - \tilde{\nu}_2$. The uncertainty of 0.015 cm^{-1} primarily originates from the chirp shifts arising in the pulse amplification and the nonlinear frequency upconversion processes (19). The difference-frequency VUV beam was separated

Fig. 1. $(1 + 1')$ Resonance-enhanced, two-photon ionization spectrum of the C 0_u^+ $(v' = 21) \leftarrow$ X 0_g^+ $(v'' = 0)$ transition of Xe_2. The different traces were recorded by collecting the ion signal corresponding to the mass numbers between $M = 258$ and 264. The spectra are rotationally resolved and display a P-branch band head on the low wavenumber side.

from the fundamental beams and beams generated in other nonlinear processes using a vacuum monochromator described in ref. 22.

The xenon dimers were formed in a pulsed supersonic expansion of pure xenon (Pan Gas, spectroscopic grade purity) using a nozzle stagnation pressure of 4 bar (1 bar = 100 kPa). The timing of the nozzle opening with respect to the Q-switch of the Nd:YAG laser was set so as to maximize the dimer production and minimize the formation of larger xenon clusters. The gas pulses entered the spectrometer through the 0.5 mm diameter orifice of a skimmer and crossed the VUV beam at a right angle in the middle of a set of cylindrical molybdenum plates designed for the application of homogeneous electric fields and used to extract the charged particles. Ionization of the xenon dimers after resonant VUV excitation was achieved in a $(1 + 1')$ two-photon ionization process using the 532 nm output of the Nd:YAG laser in the ionization step. The ions were extracted by applying pulsed voltages on the cylindrical plates and detected at the end of a 30 cm time-of-flight (TOF) tube using a microchannel plate (MCP) detector. The resolution of the TOF mass spectrometer was amply sufficient to fully separate ion peaks originating from xenon dimers differing by one mass unit.

The ion signals were transferred to a digital oscilloscope and spectra of the different isotopomers were recorded separately as a function of the VUV wavenumber by setting temporal gates on the TOF spectrum corresponding to the respective arrival times at the MCP detector. A slow drift of the TOF positions prevented measurements of more than typically 1 h. Under these conditions, the successive vibrational bands of the C–X transition had to be recorded in separate scans, thus preventing the determination of reliable relative vibrational band intensities. The relative rotational line intensities, on the other hand, could be measured reliably and indicated a rotational temperature of ≈ 4 K in the supersonic expansion. Only the lowest two vibrational levels of the ground state were sufficiently populated in the supersonic expansion to be detected in our measurements.

Of the nine natural isotopes of Xe, only two have a nonzero nuclear spin (^{129}Xe ($I = 1/2$) and ^{131}Xe ($I = 3/2$)). Forty-five dimers can be formed from these isotopes, 19 of which have a relative abundance of more than 1%. The most abundant dimers are ^{129}Xe–^{132}Xe (14.2%), ^{131}Xe–^{132}Xe (11.4%), and ^{129}Xe–^{131}Xe (11.2%). The resolution of our mass spectrometer being insufficient to distinguish between isotopomers of the same mass number, spectra obtained by collecting the ionization signal at a given mass peak typically corresponds to a superposition of contributions from several isotopomers. As an illustration of a typical measurement, Fig. 1 shows spectra of the C$(v' = 21) \leftarrow$ X$(v'' = 0)$ band recorded simultaneously by collecting the ionization signals at the times-of-flight corresponding to the mass numbers $M = 258$–264. The spectra recorded at $M = 258$, 260, and 261 are dominated by a single isotopomer ($^{129}Xe_2$, ^{129}Xe–^{131}Xe, and ^{129}Xe–^{132}Xe, respectively), and have a simpler and more regular structure than the other spectra to which several isotopomers contribute.

For the analysis, the isotopomers $^{129}Xe_2$, ^{129}Xe–^{132}Xe, and ^{131}Xe–^{136}Xe were chosen because: (*i*) they represent strongly dominant isotopomers at mass numbers 258, 261, and 267 (relative abundances of 96.9%, 89.1%, and 100%, respectively); (*ii*) the natural abundances (6.97%, 14.20%, and 3.77%, re-

© 2004 NRC Canada

spectively) are large enough for spectra of satisfactory signal-to-noise ratios to be recorded; and (*iii*) the large differences in reduced masses greatly facilitated the analysis of the isotopic shifts and the determination of the absolute vibrational numbering of the C state.

3. Results

The electronic states of Xe_2 are conveniently labeled using Hund's case c notation ($\Omega_{g/u}^{+/-}$) (23), which specifies the value of the quantum number Ω for the projection of the electronic angular momentum onto the internuclear axis, the gerade/ungerade (g/u) symmetry of the electronic wave function with respect to inversion of the electronic coordinates in the molecule fixed axis system, and the symmetry (+/−) of the electronic wave function with respect to a plane containing the internuclear axis (24). Because of the $\Delta J = \pm 1$ electric dipole selection rule accompanying $0_u^+ \leftrightarrow 0_g^+$ transitions, the rotational structure of each of the vibrational bands of the C $0_u^+ \leftarrow$ X 0_g^+ transition consists of a P- ($\Delta J = -1$) and an R-branch ($\Delta J = 1$). As examples, the rotational structures of the C($v' = 20$) $\leftarrow$ X($v'' = 0$) band of ^{129}Xe–^{132}Xe and of the C($v' = 16$) $\leftarrow$ X($v'' = 1$) band of ^{131}Xe–^{136}Xe are displayed in Figs. 2*a* and 2*b*, respectively. The C state of Xe_2 being more strongly bound than the X state, the rotational constants of most vibrational levels of the C state are larger than those of the lowest vibrational levels of the X state, and the P-branches display a band head at low J'' values. The rotational structure of each band is straightforward to analyze with the standard formula (25):

$$[3] \qquad \tilde{\nu} = \tilde{\nu}_{v'v''} + B_{v'}J'(J'+1) - D_{v'}J'^2(J'+1)^2 - B_{v''}J''(J''+1) + D_{v''}J''^2(J''+1)^2$$

At the low temperature of the supersonic expansion (4 K), only transitions out of J'' levels up to 40 of the $v'' = 0$ and 1 vibrational levels of the X state could be observed. Table 1 summarizes the positions of all rotational lines of the $v' = 16, 17 \leftarrow v'' = 0, 1$ bands of the ^{129}Xe–^{132}Xe isotopomer. Similar data were obtained for many other bands of ^{129}Xe–^{132}Xe and other isotopomers, and are available on request. Fully satisfactory simulations of the rotational structure of all bands could be obtained by fitting the band origins $\tilde{\nu}_{v'v''}$, the rotational constants $B_{v''}$ and $B_{v'}$, and the centrifugal distortion constants $D_{v''}$ and $D_{v'}$ to the experimental line positions. Unfortunately, because of the low rotational temperature and the strong correlation between the values of the centrifugal constants in the lower and upper levels, these constants could not be well determined from the experimental data.

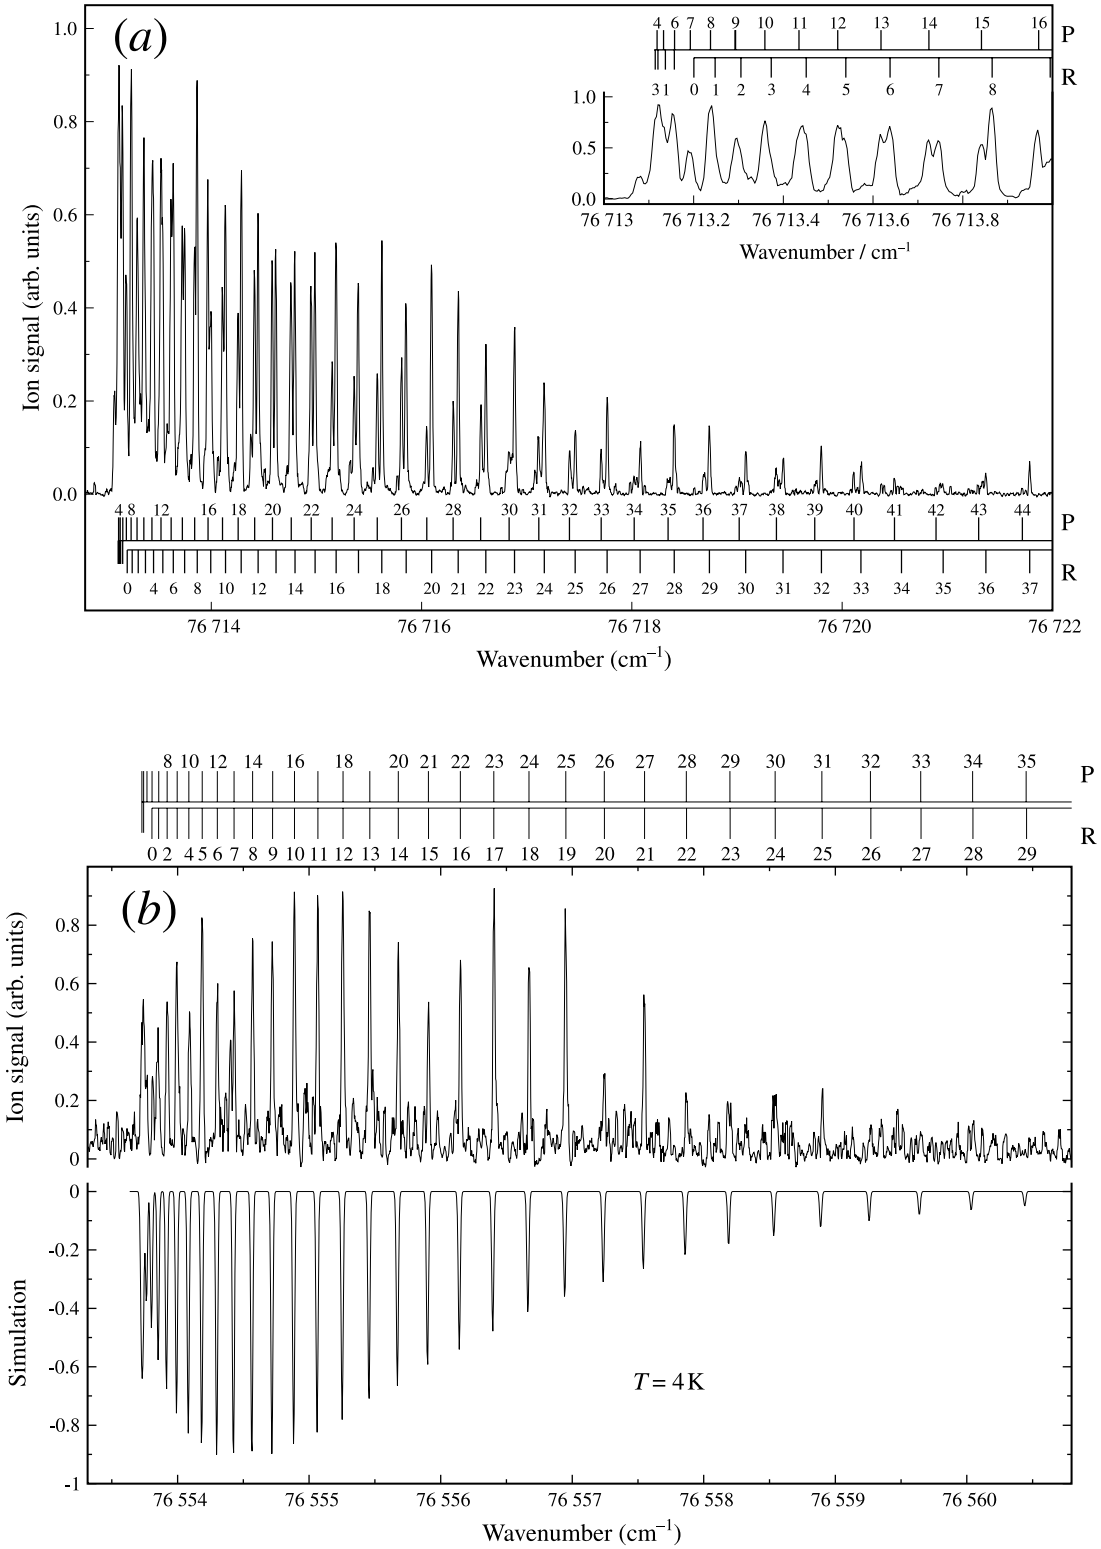
Table 2 lists the origins and the rotational and centrifugal constants for all bands observed in the spectra of the three isotopomers $^{129}Xe_2$, ^{129}Xe–^{132}Xe, and ^{131}Xe–^{136}Xe. As expected, the vibrational intervals and the rotational constants decrease with increasing vibrational quantum number v'. The centrifugal distortion constants of the vibrational levels of the C state appear to increase with increasing vibrational excitation. However, given the large uncertainties, this trend may be fortuitous.

The first vibrational interval $\Delta G''_{1/2}$ could be measured to be 19.4060(41) cm^{-1} for ^{129}Xe–^{132}Xe and 19.206(13) cm^{-1} for ^{131}Xe–^{136}Xe. These values can be compared with the earlier result of 19.04 cm^{-1} for ^{129}Xe–^{132}Xe determined by Mao et al. (26). Several other values for $\Delta G''_{1/2}$ were determined from spectra in which the isotopic structure could not be resolved. Freeman et al. (16) reported an isotopically averaged value of 19.9 cm^{-1} determined from their emission spectrum. Tonkyn and White (27) determined values of $\Delta G''_{1/2}$ between 17.8 cm^{-1} and 21.6 cm^{-1} from the PFI-ZEKE photoelectron spectrum of the B $\leftarrow$ X photoionizing transition, and Dehmer et al. (28) reported values between 17.1 cm^{-1} and 19.8 cm^{-1} from measurements of dissociation thresholds.

To obtain satisfactory fits of the vibrational band origins using the standard expansion (25)

$$[4] \qquad \tilde{\nu}_{v'v''} = \tilde{\nu}_e + \left[\omega'_e\left(v'+1/2\right) - \omega_e x'_e(v'+1/2)^2 + \omega_e y'_e\left(v'+1/2\right)^3 - \ldots\right] - \left[\omega''_e\left(v''+1/2\right) - \omega_e x''_e\left(v''+1/2\right)^2 + \omega_e y''_e\left(v''+1/2\right)^3 - \ldots\right]$$

it was necessary to retain terms up to seventh order in $v'+1/2$. Moreover, the constants turned out to be correlated and to vary strongly with the number of terms retained in the expansion. The slow convergence of the expansions in eq. [4] is likely to originate from: (*i*) the *R*-dependent changes in the configurational mixing of the Rydberg state potential curve and of the ionic states to which the Rydberg series converge; and (*ii*) the fact that the vibrational levels probed experimentally ($v' = 14$–26) are located in a region where the contribution of the long-range dispersion interactions to the potential becomes substantial. The analysis of the isotopic shifts of the band origins using the well-known dependence of the vibrational constants on the reduced mass enabled the unambiguous determination of the absolute vibrational quantum number in the C state. The analysis confirmed the vibrational assignment made by Lipson et al. (29) and is indicated in Table 2. Further work on the lower vibrational levels of the C state would be desirable to obtain a more complete description of the potential curve of this state.



With the rotational constants B''_0 and B''_1 listed for ^{129}Xe–^{132}Xe in Table 2 and the relation

$$[5] \qquad B''_v = B''_e - \alpha''_e(v''+1/2)$$

B''_e and α''_e could be determined to be 0.013495(30) cm^{-1} and $3.02(33) \cdot 10^{-4}$ cm^{-1}, respectively. From the value of B''_e, the internuclear distance in the X ground state was estimated to

Note: The experimental uncertainties in the transition wavenumbers amount to 0.005 cm^{-1} (one standard deviation). The calculated transition wavenumbers were determined from the semiempirical potentials derived in Sect. 4. The deviations between calculated and experimental positions are listed for both potential fits as $\Delta\tilde{\nu} = \tilde{\nu}_{calc} - \tilde{\nu}_{exp}$.
[a]From spectroscopic data alone.
[b]From spectroscopic data and virial coefficients.

Table 2. Band origins, ground and excited rotational and centrifugal distortion constants of all measured bands of the C $0_u^+ \leftarrow$ X 0_g^+ transition of $^{129}Xe_2$, ^{129}Xe–^{132}Xe, and ^{131}Xe–^{136}Xe. The numbers in parentheses represent one standard deviation.

be 4.3773(49) Å by assuming that the reduced mass can be calculated using the atomic masses, an assumption that can be justified by the weakly bound nature of the ground electronic state of Xe_2. This internuclear equilibrium separation is in good agreement with the value of 4.37 Å of the semiempirical curve of Tang and Toennis (5).

4. Semiempirical potential for the X 0_g^+ ground state of Xe_2

In their determination of the semiempirical potential curve of the X 0_g^+ ground state of Xe_2, Dham et al. (9) optimized the potential parameters using, among other empirical data, the vibrational intervals determined by Freeman et al. (16). Consequently, their reported value for $\Delta G''_{1/2} = 19.61\ \mathrm{cm}^{-1}$ agrees within the uncertainty with the results of Freeman et al. (16), but differs by $\sim 0.3\ \mathrm{cm}^{-1}$ from our result (see Table 6).

To assess whether this discrepancy in the first vibrational interval has an effect on the interaction potential, the semiempirical potential parameters were fitted to a global empirical data set including: (*i*) the present set of line positions from Table 1, which contains implicitly a very accurate value of the first vibrational interval (see above); (*ii*) the vibrational intervals $\Delta G''_{v''+1/2}$ for $v'' = 1$–9 from the work of Freeman et al. (16) (the values are listed with their estimated uncertainties of 0.3 cm^{-1} in the second column of Table 3); and (*iii*) values of the second virial coefficient at several temperatures taken from a recent compilation (30) and listed with their uncertainties in the second column of Table 4.

A total of eight potential parameters were needed to describe our potential (see eqs. [1] and [2]): A, b, C_6, C_8, C_{10}, C_{12}, C_{14}, and C_{16}. Of these, only two were fitted to the experimental data, the long-range coefficients being kept fixed. The coefficient $C_6 = 285.9\ E_h a_0^6$ was taken from ref. 31, and the values of $C_8 = 12807\ E_h a_0^8$ and $C_{10} = 619840\ E_h a_0^{10}$ were adopted

Table 4. Comparison between experimental values of the second virial coefficient of Xe from ref. 30 and values calculated from the semiempirical potentials determined solely from spectroscopic data (third column) and from the spectroscopic data and the virial coefficients (fourth column).

from ref. 32. The next three long-range coefficients (see Table 5) were determined from the values of C_6, C_8, and C_{10} using the recursion relation (33)

$$[6] \qquad C_{2n+4} = \Omega_n\, C_{2n-2} \left(\frac{C_{2n+2}}{C_{2n}}\right)^3$$

where Ω_n represents a factor that only slightly deviates from 1 and can be estimated using (33)

$$[7] \qquad \Omega_n \simeq \frac{(2n+1)\,(2n-3)\,n^3\,(n-2)\,(2^n-1)\left(2^{n-2}-1\right)^3}{(2n-1)^2\,(n+1)\,(n-1)^3\left(2^{n-3}-1\right)\left(2^{n-1}-1\right)^3} \quad \text{for } n \geq 4$$

Instead of fitting the parameters A and b, it turned out to be advantageous to use the boundary condition

$$[8] \qquad \left.\frac{\mathrm{d}V(R)}{\mathrm{d}R}\right|_{R=R_e} = 0$$

to express A as a function of R_e

$$[9] \qquad A = \frac{\mathrm{e}^{bR_e}}{b} \left.\frac{\mathrm{d}V_{\mathrm{attr}}(R)}{\mathrm{d}R}\right|_{R=R_e}$$

and to fit the parameters R_e and b.

To optimize the potential parameters on the basis of the $C(v' = 16, 17) \leftarrow X(v'' = 0, 1)$ transition wavenumbers

[d]Parameter calculated with eq. [9].

listed in Table 1, these wavenumbers were calculated using the expression

$$[10] \quad \tilde{\nu}_{v'J',v''J''} = \tilde{\nu}_{v',v''} + F_{v'}(J') - F_{v''}(J'')$$

where $\tilde{\nu}_{v',v''}$ represents the band origins. Because the contribution of the centrifugal distortion to the rotational term values was found to be negligible (see previous section), the rotational term values of the vibronic levels of the C state were calculated using the relation $F_{v'}(J') = B_{v'}\,J'(J'+1)$. The rotational term values of the vibronic levels of the X state $F_{v''}(J'') = \left[E_{v'',J''} - E_{v'',J''=0}\right]$ were determined by solving the radial Schrödinger equation

$$[11] \quad \left[-\frac{\hbar^2}{2\mu}\frac{\mathrm{d}^2}{\mathrm{d}R^2} + hc\,V_{J''}(R)\right]\psi_{v''J''}(R) = hc\,E_{v''J''}\,\psi_{v''J''}(R)$$

numerically using a discrete variable representation with 1001 equidistant points between 2 and 12 Å in a procedure analogous to that used in our previous determination of the ground state potential of Ne_2 (6). The effective potential $V_{J''}(R)$ in eq. [11] includes the centrifugal potential

$$[12] \quad V_{J''}(R) = V(R) + \frac{h}{8\pi^2\mu\,c}\frac{J''(J''+1)}{R^2}$$

Next to the two potential parameters R_e and b, four parameters ($\tilde{\nu}_{16,0}$, $\tilde{\nu}_{17,0}$, B'_{16}, and B'_{17}) had to be included in the fit procedure to account for the C state energy level structure.

To incorporate the vibrational intervals from the work of Freeman et al. (16) into the fitting procedure, the vibrational intervals were determined from the computed eigenvalues of eq. [11] using the relation

$$[13] \quad \Delta G''_{v''+1/2} = E_{v''+1,J''=0} - E_{v'',J''=0}$$

and then compared with the experimental values listed in Table 3. In this procedure, an average was built over all isotopomers because the isotopic structure was not resolved in the experimental spectra.

Finally, to include the values of the second virial coefficient into the fitting procedure, eqs. [14]–[18] were used, which express the various contributions to the second virial coefficients as a function of the potential function $V(R)$ (34–38):

$$[14] \quad B_2(T) = B_{\mathrm{cl}}(T) + \left(\frac{h^2}{m}\right)B_{\mathrm{I}}(T) + \left(\frac{h^2}{m}\right)^2 B_{\mathrm{II}}(T) + \cdots \mp \left(\frac{h^2}{m}\right)^{3/2} B_0(T) = B_{\mathrm{cl}}(T) + B^{\mathrm{I}}(T) + B^{\mathrm{II}}(T) + \cdots \mp B^0(T)$$

$$[15] \quad B_{\mathrm{cl}}(T) = -2\pi N_{\mathrm{A}}\int_0^\infty \left[\mathrm{e}^{-(V(R)/kT)} - 1\right]R^2\,\mathrm{d}R$$

$$[16] \quad B_{\mathrm{I}}(T) = +2\pi N_{\mathrm{A}}\frac{1}{48\pi^2k^3T^3}\int_0^\infty \mathrm{e}^{-(V(R)/kT)}\left(\frac{\mathrm{d}V(R)}{\mathrm{d}R}\right)^2 R^2\,\mathrm{d}R$$

$$[17] \quad B_{\mathrm{II}}(T) = -2\pi N_{\mathrm{A}}\frac{1}{1920\pi^4k^4T^4}\int_0^\infty \mathrm{e}^{-(V(R)/kT)}\left[\left(\frac{\mathrm{d}^2V(R)}{\mathrm{d}R^2}\right)^2 + \frac{2}{R^2}\left(\frac{\mathrm{d}V(R)}{\mathrm{d}R}\right)^2 + \frac{10}{9kT}\frac{1}{R}\left(\frac{\mathrm{d}V(R)}{\mathrm{d}R}\right)^3 - \frac{5}{36k^2T^2}\left(\frac{\mathrm{d}V(R)}{\mathrm{d}R}\right)^4\right]R^2\,\mathrm{d}R$$

$$[18] \qquad B_0(T) = \frac{N_A}{2^{5/2}} \left(\frac{1}{2\pi kT} \right)^{3/2}$$

In these equations, h, N_A, and k are Planck's, Avogadro's, and Boltzmann's constants, respectively, and m represents the atomic mass of the gas particles. $B_{cl}(T)$ corresponds to the classical expression for the second virial coefficient; $B^{I}(T)$ and $B^{II}(T)$ represent the first and second quantum mechanical corrections; finally, $B^0(T) = (h^2/m)^{3/2} B_0(T)$ is the second virial coefficient for an ideal gas, whereby a plus sign has to be used in eq. [14] for fermions and a minus sign for bosons (39). The contribution of this last term to the second virial coefficient is negligible in the temperature range $T = 165$–970 K where experimental data are available.

To fit the potential parameters to the three very different sets of empirical data, a weighted nonlinear, least-squares fitting procedure was employed, the weights of each data point being determined from the corresponding experimental uncertainty. A fit was considered acceptable when the normalized root-mean-square (rms) deviation of the fit amounted to less than 1.

Two fits were performed, the first one relying solely on the spectroscopic data, i.e., the data set from the present work, and the vibrational intervals from the work of Freeman et al. (16), the second also including the second virial coefficients. Whereas it was possible to reach a rms deviation of less than one (rms = 0.891) in the former case, the rms deviation of the second fit amounted to 1.109. Table 5 lists the potential parameters determined in both fits, and Table 6 compares the dissociation energies (D_e), the equilibrium internuclear distances (R_e) and the calculated values of the first vibrational interval ($\Delta G''_{1/2}$) with earlier results. Both potentials are very similar to previously reported semiempirical potentials but lead to dissociation energies D_e that are significantly higher than predicted in the latest ab initio quantum chemical calculation.

Although both fits resulted in values of the internuclear distance and first vibrational interval that are compatible with the results of the spectroscopic analysis presented in the previous section, the results of the fit based on the spectroscopic data alone is in closer agreement. The rotational constants of the $v' = 16$ and 17 vibrational levels of the C state obtained from the fits are equal, within two standard deviations, to those determined in the fit to eq. [3]. This observation validates the procedure used to derive the X state potential parameters and also confirms that the effects of the centrifugal distortion can be neglected in good approximation.

For both fits, the deviations between experimental and calculated transition wavenumbers (see Table 1) and vibrational intervals (see Table 3) do not exceed two standard deviations. In contrast, the deviations between experimental and calculated second virial coefficients are often more than twice, at low temperatures even more than four times, larger than the experimental uncertainties given in ref. 30 (see Table 4). This behavior is not typical for the potentials determined here, but is also found (40) when calculating the second virial coefficients using the semiempirical potentials of refs. (5, 9, 41). It thus appears that the experimental uncertainties in the second virial coefficients may have been slightly underestimated, effectively leading to too large weights of these data in the fitting procedure and to an undesirable bias in the determination of the potential parameters. For this reason, the X state potential determined from the spectroscopic data alone, and which is described by the potential parameters listed in the second column of Table 5, is to be preferred. With this potential, the existence of 25 bound vibrational levels is predicted for the most abundant dimer ^{129}Xe–^{132}Xe.

5. Conclusions

When combined with mass spectrometry, high-resolution VUV laser spectroscopy can be successfully used to obtain rotationally resolved spectra of mass-selected species having small rotational constants. In the present investigation, this combination enabled the first experimental determination of the rotational structure of the ground electronic state of Xe_2 from a measurement of the rotational structure of the C $0^+_u \leftarrow$ X 0^+_g transition of several isotopomers of Xe_2. The analysis of the spectra led to the derivation of a set of rotational constants for the $v'' = 0$, 1 level of the X ground state, and the $v' = 14$–26 levels of the C state. The information contained in the rotational structure of the lowest two levels of the ground state of Xe_2 was combined with previous results on the vibrational intervals and on the second virial coefficients to determine an accurate semiempirical interaction potential for the X state. This potential differs only very slightly from earlier semiempirical potentials, and primarily in the fact that it leads to a smaller value for the first vibrational interval. The deviations between the equilibrium internuclear distance and dissociation energies of the X ground state ($R_e = 4.3773(49)$ Å, $D_e = 196.1 \pm 1$ cm^{-1}) determined here, and the results of the latest ab initio quantum chemical calculations ($R_e = 4.42$ Å, $D_e = 183.1 \pm 1$ cm^{-1}) (4) illustrate the difficulties that are still associated with the accurate theoretical treatment of molecules containing heavy atoms.

Rydberg states of the rare gas dimers[1]

Marshall L. Ginter and J. Gary Eden

Abstract: This work is dedicated to Gerhard Herzberg and his prodigious contributions to molecular spectroscopy. Of particular relevance here is Herzberg's seminal 1987 article (Annu. Rev. Phys. Chem. **38**, 27 (1987)) in which he discussed the electronic structures of several groups of molecules he termed "Rydberg molecules". Among these are the rare gas dimers (Rg_2), a group whose study has benefited significantly from recent advances in laser excitation and synchrotron-based spectroscopies, as well as in theory. Following the spirit of Herzberg's 1987 article, this paper reviews some of the more prominent features of Rydberg states in the Rg_2 family as viewed from the current perspective.

Key words: rare gas dimers, rare gas dimer excited states, Rg_2 electronic structures, Rydberg states of He_2, Ne_2, Ar_2, Kr_2, and Xe_2, electronic states of He_2, Ne_2, Ar_2, Kr_2, and Xe_2.

Résumé : Ce travail est dédié à Gerhard Herzberg et à ses contributions exceptionnelles à la spectroscopie moléculaire, plus particulièrement à son important article de 1987 (Annu. Rev. Phys. Chem. **38**, 27 (1987)) dans lequel il a discuté des structures électroniques de plusieurs groupes de molécules appelées "molécules de Rydberg". Parmi ces groupes se trouvent les dimères de gaz rares (Rg_2), un groupe dont l'étude a bénéficié largement des récents progrès théoriques et des spectroscopies basées sur des excitations au synchrotron ou au laser. Dans l'esprit de l'article de Herzberg de 1987, ce travail passe en revue quelques-unes des caractéristiques principales des états de Rydberg dans la famille Rg_2, dans une optique contemporaire.

Mots clés : dimères de gaz rares, états excités des dimères de gaz rares, structures électroniques Rg_2, états de Rydberg de He_2, de Ne_2, de Ar_2, de Kr_2 et de Xe_2, états électroniques de He_2, de Ne_2, de Ar_2, de Kr_2 et de Xe_2.

[Traduit par la Rédaction]]

Introduction

In his classic 1987 paper in the *Annual Review of Physical Chemistry* (1), Gerhard Herzberg discussed several distinctive aspects of the spectroscopy and structure of three groups of molecules for which the electronic excited states were considered to be essentially Rydberg in character. As recounted by Stoicheff (2), the preface to this 1987 work (1) was Herzberg's search for H_3^+ and his subsequent discovery of emission spectra for H_3 and D_3 which he termed Rydberg molecules. In this molecular clasification, he "…included [the] dimers and hydrides of the rare gases and their respective ions" (2). Of special interest here are Herzberg's comments regarding prominent features in the Rydberg series for the rare gas (Rg_2) dimers, assessments based in part on the then recently reported (3, 4) Rydberg series spectra for Ne_2–Xe_2 and on spectral observations for He_2 (5) that extended back to the early 1900s.

This paper follows the spirit of ref. 1 by identifying and discussing key characteristics of a selected portion of the Rydberg electronic structures of the Rg_2 molecules and emphasizing Rydberg electronic structures that exist below, and converge on, the lowest ionization limit of the dimers, the $X^2\Sigma_u^+$ state of Rg_2^+. Thus, the following provides a brief discussion of specific aspects of the $X^2\Sigma_u^+$ core-based Rydberg structures in the Rg_2 family in toto and is not intended as a detailed review.

The remainder of the introduction is devoted mainly to definitions and nomenclature (Rydberg level energies, electronic state labels, molecular parameters, etc.). The article then proceeds with introductions to the Rydberg states built on ground-state $Rg^+ + Rg$ core structures, to spectroscopies utilized in characterizing Rg_2 Rydberg structures, to brief outlines of the known Rydberg structures and spectra for each dimer and, finally, to discussions of several issues involving the family as a whole that include a summary of suggested future work.

Rydberg electronic states for neutral molecules generally can be described in terms of series that converge on energy levels of the molecular ion core (5–7). The expression for the energy (E_n) of the nth member of a series is expressed:

$$[1] \qquad E_n = E_\infty - \Re/n^{*2} = E_\infty - \Re/(n - \delta)^2$$

where n is the principal quantum number (an integer), E_∞ is the series limit, $\Re$ is the mass-dependent Rydberg constant, δ is the quantum defect, and n^* is the effective quantum

number. Bonding in a Rydberg state is considered to reflect that of its core ion, while bonding in a valence state is determined by valence electron and configuration interactions. In some diatomic molecules, valence states interact so strongly with the Rydberg states that Rydberg – valence state distinctions tend to be less meaningful. However, the electronic excited states of the Rg_2 molecules built on their ground-state ionic cores are ideal for studying Rydberg character because they are seldom perturbed by valence levels or by Rydberg states built on excited ionic cores, at least for internuclear separations (R) in the vicinity of the equilibrium internuclear separation (R_e) of their $X^2\Sigma_u^+$ core.

The $^{2S+1}\Sigma_p^{p'}$ electronic state labels (term symbols) apply to the Λ,S coupling scheme (5) and include quantum numbers for the total electron spin (S), the component of electronic orbital angular momentum along the internuclear axis (Λ; $\Lambda = 0 \rightarrow \Sigma$, $\Lambda = 1 \rightarrow \Pi$, etc.), and the wave function's inversion parity ($p = g$ if even and u if odd) and reflection parity ($p' = +$ or $-$) in a plane containing the internuclear axis. States having $\Lambda = 0$ are either Σ_p^+ or Σ_p^-. Each state with $\Lambda_p > 0$ comprises two symmetry states (Λ_p^+ and Λ_p^-, sometimes referred to as lambda doublets), with the superscript + or – having the same meaning as that for the $\Lambda = 0$ states. Also associated with each Λ,S state are substates labeled by values of the quantum number Ω, which specifies the value of the total electronic angular momentum along the internuclear axis. For Λ,S coupling (5), Ω is the sum of Λ and the component of the total electron spin along the internuclear axis.

When considering electronic state behavior at large R or the structure of the heavier dimers Rg_2 or Rg_2^+, Λ,S representations break down because of spin–orbit and configuration interactions. However, in such instances, Ω-based representations, sometimes referred to as *case c* representations, remain valid (5). The Ω-based states are $\Omega_p^{p'}$ states, with both Ω_p^+ and Ω_p^- existing for $\Omega_p^{p'} > 0$ and with $\Omega_p^{p'}$ either 0_p^+ or 0_p^- for $\Omega = 0$. Thus, singlet and doublet sigma states map directly to their Ω values, such as $^1\Sigma_p^{p'} \rightarrow 0_p^{p'}$, $^1\Pi_p \rightarrow 1_p^{\pm}$, $^2\Sigma_p^{p'} \rightarrow 1/2_p^{p'}$, etc., while Λ,S-based triplet states can break down into collections of $\Omega_p^{p'}$ states, such as $^3\Sigma_p^+ \rightarrow 1_p^{\pm}$, 0_p^-, $^3\Pi_p \rightarrow 2_p^{\pm}$, $1_p^{\pm}$, $0_p^{\pm}$, $^3\Delta_p \rightarrow 3_p^{\pm}$, $2_p^{\pm}$, $1_p^{\pm}$, etc., where the $\Omega_p^{p'}$ states will generally have different energies.

Molecular parameters discussed here appear in polynomials representing the state energies (terms), $T(v,N)$, given by

$$[2] \quad T(v,N) = T(^{2S+1}\Lambda_p) + T_v^o + B_v N(N+1) - D_v[N(N+1)]^2 + H_v[N(N+1)]^3 + \ldots$$

where the T_v^o value is the energy for $N = 0$ (real, or extrapolated for $\Lambda > 0$) of vibrational level v, $T(^{2S+1}\Lambda_p)$ is the energy of the state being parameterized (in parentheses), defined relative to the zero energy reference employed (i.e., the energy of the $N = 0$, $v = 0$ level in the $a^3\Sigma_u^+$ state for He_2, etc.), and B_v, D_v, H_v,... are effective rotational and rotational distortion parameters (5). When several vibrational levels are observed, it is customary to parameterize T_v^o values and to reparameterize the rotational parameters in eq. [2] by fitting the following expressions (5):

$$[3] \quad T_v^o = \omega_e(v+1/2) - \omega_e x_e(v+1/2)^2 + \omega_e y_e(v+1/2)^3 + \ldots$$

Table 1. Representative values for the dissociation energy, the equilibrium internuclear separation (R_e), and other parameters for the weakly bound $X^1\Sigma_g^+$ states of Rg_2.

Rg_2	D_0 (cm^{-1})[a]	D_e (cm^{-1})[a]	R_e (Å)	ω_e (cm^{-1})	$\omega_e x_e$ (cm^{-1})
He_2		7.63[b]	2.97[b]	3.3[b]	
Ne_2	16.8[c]	29.4[c]	3.09[c]	28.6[c]	6.84[c]
Ar_2		99.2[d]	3.76[d]	30.7[d]	2.4[d]
Kr_2		138[e]	4.02[e]	23.53[e]	1.07[e]
Xe_2	186.0[f]	196.3[f]	4.37[f]	20.9[f]	

[a] D_0 and D_e are the dissociation energy relative to $v = 0$ and to the potential minimum (at R_e), respectively. These values are selected as being representative of values in the literature and demonstrate that the $X^1\Sigma_g^+$ potential energy curves are strongly repulsive except for shallow minima in the large-R van der Waals regions. When necessary, values of energy in hartrees, eV, or K were converted to cm^{-1} (1 hartree = 2.1947×10^5 cm^{-1}, 1 eV = 8065.54 cm^{-1}, 1 K = 0.6948 cm^{-1}) and R values in bohr to Å (1 bohr = 0.52917 Å). Values for D_0 and D_e are approximately related by $D_0 = D_e - 1/2\omega_e + 1/4\omega_e x_e$, while ω_e and $\omega_e x_e$ are defined in eq. [3].

[b] D_e value is from Anderson's Table I summary (ref. 8), while R_e and ω_e values are from ref. 9.

[c] The D_e and R_e values are from ref. 11 and are in agreement with refs. 9 and 13. Reference 9 provides $\omega_e = 28.6$ cm^{-1}, while ref. 10 lists $\omega_e = 31.3$ and $\omega_e x_e$ ($\equiv x\omega_e$) = 6.8 cm^{-1}.

[d] Values are from ref. 16 and are in agreement with refs. 9, 12, 14, and 15.

[e] Values are from refs. 17 and 18. Reference 14 gives $D_e = 139.9$ cm^{-1} and $R_e = 4.01$ Å, which agrees with ref. 21.

[f] Values are from refs. 19 and 20, with D_e and R_e in agreement with ref. 21. Reference 11 gives $D_e = 183$ cm^{-1} and $R_e = 4.42$ Å.

and

$$[4] \quad B_v = B_e - \alpha_e(v+1/2) + \beta_e(v+1/2)^2 + \gamma_e(v+1/2)^3 + \ldots$$

where ω_e, $\omega_e x_e$,... and B_e, α_e,... are referred to as equilibrium vibrational and rotational parameters, respectively. Finally, R_e is related (5) to B_e by the relation $B_e = \hbar(8\pi^2 c\mu R_e^2)^{-1}$, so that R_e determinations require either rotationally resolved experimental data or appropriate theoretical and (or) modeling calculations.

The potential energy curves for the $X^1\Sigma_g^+$ ground states, the principal and best determined of the valence states of the Rg_2 molecules, are repulsive except for a shallow van der Waals minimum at large R. This can be seen in part from the representative sample of D and R_e values in Table 1, where the dissociation energies (8–21) of the dimer ground states are low, ranging from 7.63 cm^{-1} (9.5×10^{-4} eV) for He_2 to 196 cm^{-1} (0.024 eV) for Xe_2. In addition, the R_e values for $X^1\Sigma_g^+$ are larger than the R_e values for their corresponding $X^2\Sigma_u^+$ ion cores (see Table 2). Finally, it should be noted that only these general properties of the R dependencies of the $X^1\Sigma_g^+$ potentials are important here.

Higher-lying (above X) valence states also tend to be unstable, and some states that are Rydberg in the vicinity of $R_e(Rg_2^+)$ have potential energies that exhibit "anomalies" at large R values, resulting from strong configuration interactions between the bound Rydberg states and dissociative valence states of the same symmetry. In an adiabatic picture, such strong interactions lead to noncrossings of the potential energy curves and to associated maxima and minima at large R.

Table 2. Representative values for the dissociation energy (D_0 (cm^{-1})) and R_e (Å) for the Rg_2^+ states derived from the ground separated atom limits.[a]

Rg_2^+	Ω	$X^2\Sigma^+_{1/2u}$	$A^2\Pi_{3/2g,1/2g}$	$B^2\Pi_{3/2u,1/2u}$	$C^2\Sigma^+_{1/2g}$
He_2^+	1/2	19 114 [1.081][b]	—	—	Repulsive
Ne_2^+	3/2		1174 [2.22][c]	96 [3.34][c]	
	1/2	10 856 [1.756][c]	670 [2.2][c]	261[c,d] [3.1][c]	63[c,d] [3.90][c]
Ar_2^+	3/2		1540 [≤2.99][f]	312 [3.80][g]	
			≥1509 [2.98][g]		
	1/2	10 604[e] [2.39][g]	686 [3.00][f]	≥616 [≤3.63][g]	625 [3.63][g]
			≥616 [≤2.98][g]		
Kr_2^+	3/2		1646[h] [6.33][h]	369[i] [7.77][h]	
	1/2	9 268[i] [2.75][i]	Repulsive[i]	1072[i]	609[i]
Xe_2^+	3/2		1793[j] [3.70][k]	437[j] [4.40][k]	
	1/2	7861[j] [3.11][k]	158[k] [5.77][k]	1447[j] [3.98][k]	842[j] [4.77][k]

[a]See footnote *a* to Table 1. The R_e values appear in square brackets. For He_2, the limit is $1s\ ^2S(He^+) + 1s^2\ ^1S(He)$. For the heavier members, the limit is $mp^5\ ^2P^o(Rg^+) + mp^6\ ^1S(Rg)$ with m = 2, 3, 4, and 5 for Ne, Ar, Kr, and Xe, respectively. The alphameric state designations follow the spectroscopic convention (22) of labeling the ground state X and excited states of the same multiplicity by alphabetic capitals in order of increasing energy rather than the labeling used for Xe_2 by Mulliken (23) in which X was labeled A, A was labeled B, and so forth. For members larger than Ne_2^+, *case c* designations for the A and B states become important. See text for discussion.

[b]Values from ref. 25, where D_e = 2.474 eV = 19 954 cm^{-1} has been changed to D_0 using the vibrational parameters for $X^2\Sigma^+_u$ in ref. 22. Reference 22 also lists R_e = 1.081 Å.

[c]Values from ref. 27. For $X^2\Sigma^+_{1/2u}$, ref. 28 gives D_0 = 10 410 cm^{-1}, which may be ~300 cm^{-1} low if the v numbering is increased by 1 as suggested by ref. 27. Reference 4 gives D_0 = 10 900 cm^{-1}.

[d]Values represent D_e.

[e]Values from ref. 26. For X, ref. 28 gives D_0 = 10 646 ± 40 cm^{-1}.

[f]Values from ref. 29.

[g]Values from ref. 24.

[h]Values from ref. 31.

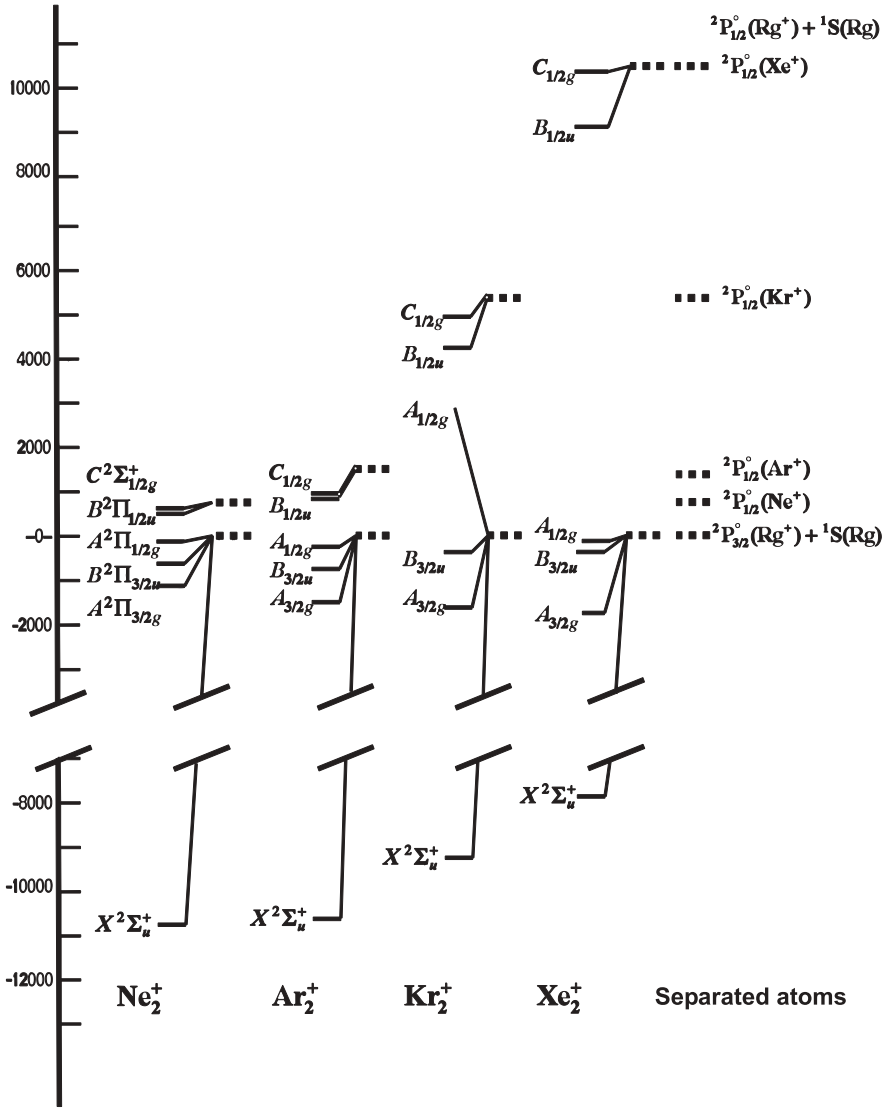
[i]Values from ref. 30. Reference 28 gives D_0 = 9283 ± 25, 379, 1048, and 590 cm^{-1} for X, B(3/2), B(1/2), and C, respectively, and A(1/2) was designated repulsive.

[j]Values from refs. 28 and 33.

[k]Values from ref. 32, which also gives D_0 values of 7842, 1876, 582, 1577, and 359 cm^{-1}, for X, A(3/2), B(3/2), B(1/2), and C, respectively.

Rydberg configurations and associated electronic states

The rare gas dimer family He_2, Ne_2, Ar_2, Kr_2, Xe_2, and Rn_2 ranges from molecules among the lightest of the diatomics to nearly the largest dimers having stable or noninfinitesimally short half-life nucleoids. The ground states of the singly charged ions, the $X^2\Sigma^+_u$ states of Rg_2^+, are all stable (see Table 2). Consequently, the associated Rydberg states are also intrinsically stable although, for the dimers heavier than He_2, the lifetimes of the $X^2\Sigma^+_u$ ion core Rydberg-based states are often reduced drastically by predissociation.



The Rydberg states built on the cores in Table 2 are associated with the configurations $[Rg_2^+]n\ell\lambda_p$, where $[Rg_2^+]$ represents the electronic configuration of the core and $n\ell\lambda_p$ designates the Rydberg electron in the united atom molecular orbital (UAMO) notation. UAMO designations are commonly adopted in place of $m\lambda_p$ orbital notation, valid for all values of R, or linear combination of atomic orbitals (LCAO) designations ($\pi_p n\ell$), generally applicable only for large R (5–7). The inversion parity (p) of the UAMO-based Rydberg orbital varies as $(-1)^\ell$, so that ℓ = 0, 2, 4,… (i.e., *s*, *d*, *g*,…) orbitals are *gerade* and ℓ = 1, 3, 5,… (i.e., *p*, *f*, *h*,…) orbitals are *ungerade*. Because the $X^2\Sigma^+_u$ cores are *ungerade*, the singlet and triplet states associated with ℓ even or odd will be *u* or *g*, respectively. It should be noted that, for clarity, all orbital and state symbols will be retained in the discussion to follow despite the risk of redundancies.

For He_2, the only possible ion core states associated with the ground-state $1s\ ^2S(He^+) + 1s^2\ ^1S(He)$ limit are the bound $X^2\Sigma^+_u$ and unbound $^2\Sigma^+_g$ states. The heavier dimer ions, however, have four electronic states correlated with their lowest energy atomic $mp^5\ ^2P^o(Rg^+) + mp^6\ ^1S(Rg)$ limits: $^2\Sigma^+_u$, $^2\Sigma^+_g$, $^2\Pi_u$, and $^2\Pi_g$. For rare gas atoms heavier than He, these states are $X^2\Sigma^+_u$ (strongly bound), $A^2\Pi_g$ (weakly to very weakly bound), $B^2\Pi_u$ (very weakly bound), and $C^2\Sigma^+_g$ (very weakly bound). Note that the standard practice for labeling electronic states (5, 22) is adopted here rather than a notation that originated with Mulliken's discussions (6, 23) of four *types* of Rg_2^+ core states, which he referred to as A through D. Subsequently, X, A, B, C state labels often have been denoted as A, B, C, D, respectively, in conflict with international convention.

Table 2 provides a representative sample for the dissociation energies, D_0 (defined relative to the v = 0 level), for the Rg_2^+ ion states associated with the ground $^2P^o(Rg^+) + {}^1S(Rg)$ limits (24–33). Also included in Table 2 are values of R_e expressed in Å and identified by square brackets. Finally, Fig. 1 provides a representation of the energies of the

Fig. 1. Relative energies of the electronic states of Rg_2^+ associated with the ground $mp^5\ ^2P^o_{3/2,1/2}(Rg^+) + mp^6\ ^1S(Rg)$ separated atom limits based on their $^2P^o_{3/2} + {}^1S$ limits. Level values were obtained from energy cycle calculations using values quoted in Tables 2 and 3. All energies are expressed in cm^{-1}.

$5p^5\ ^2P^o(Rg^+) + 5p^6\ ^1S(Rg)$-based Rg_2^+ core states in Table 2 with correlations to their appropriate dissociation limits.

Several other angular momentum coupling cases besides *case c* mentioned in the preceding section are encountered in the Rg_2 structures. Most important of these are *cases a*, *b*, *b′*, *d*, and *d′* (5, 34, 35). Often referred to as "Hund's cases", they describe the order and strength in which the angular momenta associated with a molecule are coupled. In *cases a* and *b*, for example, the electronic orbital angular momentum is strongly coupled to the internuclear axis, and Λ is considered well defined. *Cases a* and *b* differ in the strength of *electron spin* coupling with the internuclear axis, which is weak in *case b* but strong in *case a*. In both *cases a* and *b*, Ω is well defined, and multiplet spacings generally are not strongly affected by molecular rotation. Case *b′* is a subcase of *b* representing singlet or triplet states in which multiplet splittings are negligible. *Case d* describes the recoupling of *case a* or *b* states produced by molecular rotation and is associated with the phenomenon of ℓ-uncoupling (discussed below), while *case d′* is a subcase of *case d* for negligible multiplet splittings.

Electronic structures below and converging on the $[Rg_2^+, X^2\Sigma_u^+]$ limit

Introductory comments

The lowest-energy Rydberg states for Rg_2 are the $a^3\Sigma_u^+$ and $A^1\Sigma_u^+$ states associated with $[Rg_2^+, X^2\Sigma_u^+]ns\sigma_g$, with relative energy ordering being triplet below singlet and with n = 2, 3, 4,... for He_2, Ne_2, Ar_2,..., respectively. In addition to being the lowest-energy stable states, the $a^3\Sigma_u^+$ states are metastable (with respect to dipole-allowed transitions to $X^1\Sigma_g^+$) and have been exploited as "platform" states from which to optically pump higher-lying excited states. For He_2, the next states in order of increasing energy are the $b^3\Pi_g$ and $B^1\Pi_g$

[a]The values of the ionization energies (IE) for A, B, and C were obtained using the values for IE($X^2\Sigma_{1/2u}^+$), appropriate values from Table 2 (see Fig. 1 for limit correlations), and $mp^5\ ^2P_{3/2}^\circ - ^2P_{1/2}^\circ$ separations of 782, 1432, 5371, and 10 537 cm^{-1} from ref. 36 for Ne^+, Ar^+, Kr^+, and Xe^+, respectively (see the text for discussion). Reported experimental uncertainty estimates (in last places indicated) appear in parentheses.

[f]From the difference between the ionization potential for $X^2\Sigma_{1/2u}^+(1/2_u^+) \leftarrow X^1\Sigma_g^+$ photoionization in ref. 33 and the $T_0 = T_e + \omega_e - \omega_e x_e$ value (see the Xe_2 section in the text) for $a^3\Sigma_{1u}^+(1_u^\pm) \leftarrow X^1\Sigma_g^+$. Reference 4 reports 26 664(250) cm^{-1}.

states associated with $[Rg_2^+, X^2\Sigma_u^+]np\pi_u$ and the $c^3\Sigma_g^+$ and $C^1\Sigma_g^+$ states associated with $[Rg_2^+, X^2\Sigma_u^+]np\sigma_u$. Note that the $np\pi_u$ and $np\sigma_u$ energy ordering is reversed for the heavier Rg_2 molecules. For the Rg_2 family, the lowest n values for $np\pi_u$ are the same as those for $ns\sigma_u$, while the $np\sigma_u$ series is promoted (7, 23, 35). Consequently, the lowest value of n for the $np\sigma_u$ series is $n = 3$ for He_2. Additional states associated with $[Rg_2^+, X^2\Sigma_u^+]n\ell\lambda_p$ that have been observed experimentally (although not necessarily for all Rg_2 molecules) include $nd\lambda_g$ ($^{1,3}\Sigma_u^+$, $^{1,3}\Pi_u$, and $^{1,3}\Delta_u$ for $\lambda = \sigma$, π, and δ, respectively) and $nf\lambda_u$ ($^{1,3}\Sigma_g^+$, $^{1,3}\Pi_g$, $^{1,3}\Delta_g$, and $^{1,3}\Phi_g$ for $\lambda = \sigma$, π, δ, and ϕ, respectively), where for He_2 the lowest n values for d-type and f-type structures are 3 and 4, respectively.

At this point, a caveat is in order: occasionally one finds in the literature *different n* values attributed to the *same* electronic state. A root cause of such labeling differences is the fact that n, such as appears in eq. [1] or in the UAMO and LCAO orbital labels, is often not a valid quantum number, although it can serve as a useful sequential index label.

Table 3 summarizes the ionization energies (31, 33, 36–39) for Rydberg series that converge on the lowest-energy core states listed in Table 2. The value given for each series limit (E_∞) is based on the lowest stable state (the $a^3\Sigma_u^+$ state) in each Rg_2 molecule. The specific values for the A, B, and C states in Table 3 are obtained from the experimental value for the ionization energy for the $X^2\Sigma_{1/2u}^+$ state in Table 3, modified by adding the difference between the value of D_0 for X and D_0 for the upper state being considered (see Fig. 2 and Table 2), plus the $^2P_{3/2}^\circ$ and $^2P_{1/2}^\circ$ separation (see footnote *a* to Table 3) for the states dissociating to the $^2P_{1/2}^\circ + {}^1S_0$ limit (i.e., the $B^2\Pi_{1/2u}$ and $C^2\Sigma_g^+$ states). For example, in Ar_2, the ionization energy (IE) for $B^2\Pi_{3/2u}$ is 29 373 cm^{-1} + 10 604 cm^{-1} – 312 cm^{-1} = 39 665 cm^{-1}, while for $C^2\Sigma_g^+$, the IE is 29 373 cm^{-1} + 10 604 cm^{-1} – 625 cm^{-1} + 1432 cm^{-1} = 40 784 cm^{-1}. The values in the A through C columns of Table 2 can be obtained from other data, but the results are the same as those in Table 3 within experimental errors. For example, in Ar_2, the difference between the ionization potentials for $X^2\Sigma_{1/2u}^+$ and $B^2\Pi_{3/2u}$ from ref. 28 (synchrotron-based threshold photoelectron spectroscopy) is –116 547 ± 40 cm^{-1} + 126 879 ± 40 cm^{-1} = 10 332 ± 80 cm^{-1}, while from ref. 26 (laser-based ZEKE photoelectron spectroscopy) the $B^2\Pi_{3/2u} - X^2\Sigma_{1/2u}^+$ difference is 10 293 ± 10 cm^{-1}. The 10 332 ± 80 cm^{-1} and 10 293 ± 10 cm^{-1} values yield IE($B^2\Pi_{3/2u}$) = 39 705 ± 80 cm^{-1} and 39 666 ± 13 cm^{-1}, respectively, when combined with the 29 373 ± 3 cm^{-1} value for $X^2\Sigma_u^+$ in Table 3. Both are in agreement with the 39 665 cm^{-1} value for the IE of $B^2\Pi_{3/2u}$ in the table.

Table 4 lists a representative collection of energies (40–53) of the $v = 0$ levels for the first members of each $[X^2\Sigma_u^+]n\ell\lambda_p$ $^{1,3}\Lambda_{p'}$ Rydberg series with $\ell \leq 3$ and their associated n^* values. To be referenced in Table 4 implies the existence of specific spectral or theoretical assignments for the level listed. The n^* values in Table 4 were obtained using eq. [1], appropriate energies from Tables 3 and 4, and $\Re$ values of 109 729.800, 109 735.812, 109 736.565, 109 736.959, and 109 737.089 cm^{-1} for $^4He_2$, $^{20}Ne_2$, $^{40}Ar_2$, $^{84}Kr_2$, and $^{132}Xe_2$, respectively. These values were determined from the mass-dependent expression (54) for neutral molecules

$$[5] \qquad \Re = \Re_\infty/(1 + m/M)$$

where m and M are the masses of the electron and the charged core, respectively, and $\Re_\infty$ = 109 737.318 cm^{-1} is the Rydberg constant for infinite mass ($M = \infty$) (55).

Among other things, the data in Table 4 serve to introduce several general trends. For example, note that the n^* values for all the $a^3\Sigma_u^+$ states of Rg_2 are nearly the same (~1.9 ± 0.1). Thus, with n^* being approximately constant, the mutually compensating n and δ values successively increase by about 1 per molecular step as one progresses from He_2 to Xe_2. Comparable variations in n and δ are well known from Rydberg states in atomic, or other molecular, families. The past use of such observations in arguments attributing quantal significance to integral values of n in n^* and in state designations within a family should be considered questionable. Therefore, as mentioned above, in this work n will serve primarily as an index specifying ordering within a

[a]There are two entries for each electronic state listed. The top entry is the energy of $v = 0$, expressed in cm^{-1}. The bottom entry is the n^* value for the level in question. Values for n^* were obtained using eq. [1], the ionization energies in Table 3, and the mass-dependent Rydberg constant of eq. [5]. The n values ("Orbital" column) and state labels are those for He_2 (see text for discussion). Note that the b, B and c, C labeling would invert for molecules heavier than He_2.

[b]The singlet and triplet states are placed on the same basis, the $N = 0$, $v = 0$ level of $a^3\Sigma_u^+$ taken as the zero energy reference and 2343.91 cm^{-1} for the singlet–triplet separation (40).

[c]An asterisk (*) denotes an experimentally uncharacterized level. Energies in square brackets are based on theoretical calculations. Reference 44 calculates the singlet–triplet separations to be ~700, ~100, and 1300 cm^{-1} for the a–A, b–B, and c–C separations, respectively. Note that the b, B and c, C state labeling is reversed in going from He_2 to Ne_2 because of the energy inversion of the lowest $p\pi_u$- and $p\sigma_u$-based states (see text).

[d]Energy values in square brackets are theoretical energies for transitions originating at T_e of $(1)^3\Sigma_u^+$ (the $a^3\Sigma_u^+$ state here) from ref. 49.

[e]References 50 and 16 report T_e values for a and A from high v (see text) that imply the a–A separation is ~760 cm^{-1} with a high uncertainty. Also, a is designated as A, and A as B in the labeling scheme adopted in these references.

[f]References 16 and 50. In the labeling scheme adopted in these references, a is designated as A, and A as B.

particular Rydberg series, and secondarily as relating similar $n\ell\lambda_p$ series within a family to one another.

One might expect from Fig. 1 that some of the lower-energy members of Rg_2 Rydberg series associated with the excited core states in Table 3 would exist below the $X^2\Sigma_u^+$ limit. As will be discussed later, however, relatively few spectral features or Rydberg series perturbations have been attributable to excited core-based states. Thus, while perturbations between Rydberg states associated with different cores can exist, the significant differences in the shapes (see Table 2) of the X-based and A-, B-, and C-based potential energy curves should greatly reduce the strength of such interactions, especially in the R region around R_e for $X^2\Sigma_u^+$.

The Rydberg states built on the $A^2\Pi_g$ core would be associated with the $[Rg_2^+, A^2\Pi_g]n\ell\lambda_p$ configurations. The states associated with $ns\sigma_g$, $nd\sigma_g$, $ng\sigma_g$,... orbitals are $^{1,3}\Pi_g$; those with $np\sigma_u$, $nf\sigma_u$,... are $^{1,3}\Pi_u$; those with $np\pi_u$, $nf\pi_u$,... are $^{1,3}\Sigma_u^+$ and $^{1,3}\Delta_u$; and those with $nf\delta_u$, are $^{1,3}\Pi_u$ and $^{1,3}\Phi_u$. Rydberg states for $[Rg_2^+, B^2\Pi_u]n\ell\lambda_p$ would be similar to those for $[Rg_2^+, A^2\Pi_g]n\ell\lambda_p$, but with the u, g parities of the states reversed. Rydberg states for $[Rg_2^+, C^2\Sigma_g^+]n\ell\lambda_p$ would be similar to those for $[Rg_2^+, X^2\Sigma_u^+]n\ell\lambda_p$, but with the u, g parities of the states also reversed.

Electronic spectra — Emission, absorption, and laser excitation spectroscopy

The vacuum ultraviolet (VUV) continua produced by $A^1\Sigma_u^+ \rightarrow X^1\Sigma_g^+$ $(0_u^+ \rightarrow 0_g^+)$ transitions in the rare gas dimers have served for more than half a century as background sources for VUV absorption spectra (56, 57), as well as for excitation of photochemical processes or fluorescent devices (including, more recently, plasma display panel pixels).

© 2004 NRC Canada

These continua generally exhibit two intensity maxima, often referred to as the first (shorter λ) and second continua. For He_2, this emission band lies in the ~600–1000 Å region and is known as the Hopfield continuum (58). The Hopfield continuum exhibits a weak intensity maximum near 675 Å and a much stronger peak in the vicinity of 815 Å that are attributed to optical transitions from low vibrational levels of the $D^1\Sigma_u^+$ and $A^1\Sigma_u^+$ excited states (59), respectively, to a dissociative portion of the He_2 $X^1\Sigma_g^+$ state. Similar continua are also prominent in the heavier rare gas dimers and have long been of interest as gain media for VUV lasers. As the mass of the dimer is increased, both the first and second continua shift progressively to the red, with the well-known Xe_2 continuum peaking near 172 nm (1720 Å). An alternate explanation for the first continuum in the heavier dimers was proposed by Kiik et al. (60), who attributed the emission to transitions from high-lying vibrational levels of the $A^1\Sigma_u^+$ ($A0_u^+$) state rather than from low vibrational levels of a more highly excited electronic state.

Most, but not all, of the electronic structure of He_2 has been characterized from the analyses of extensive emission spectra observed in the ~2500 – 15 000 Å region, arising from transitions between hundreds of stable Rydberg states. However, relatively little information is available from emission spectra of the heavier Rg_2 molecules because most of the levels above the $a^3\Sigma_u^+(1_u^\pm, 0_u^-)$ and $A^1\Sigma_u^+(0_u^+)$ states are predissociated to various degrees. Thus, a marked disparity has existed between the experimental database available to characterize the excited electronic state structure of He_2 and those for the heavier dimers. Nevertheless, high-resolution synchrotron and laser spectroscopic techniques developed over the past two decades to examine the Rydberg states of Ne_2 through Xe_2, primarily by photoexcitation from $X^1\Sigma_g^+$ or $a^3\Sigma_u^+$, have revealed considerable detail regarding electronic structures in the heavier dimers. The following sections summarize key aspects of the structure of each dimer with emphasis on recent progress resulting from advances in both experiment and theory.

He_2

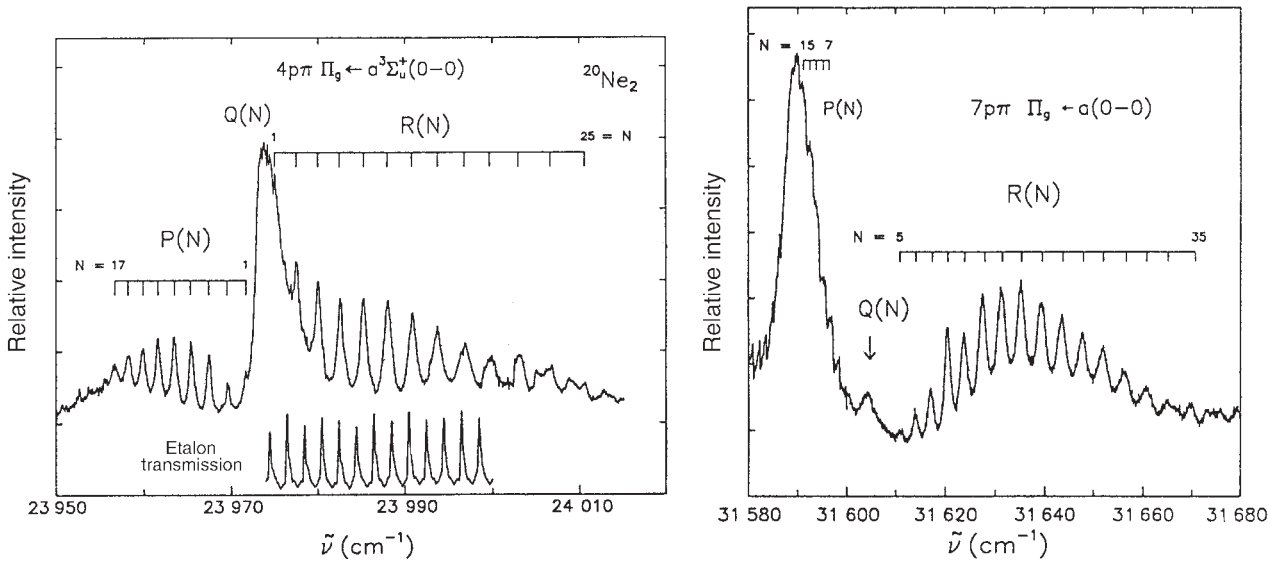
In addition to the VUV Hopfield continuum, absorption spectra are observed in He_2 in the region around 600 Å (61). This band-like absorption is attributed to transitions from $X^1\Sigma_g^+$ to excited vibrational levels in the $A^1\Sigma_u^+$ state of He_2. Known spectra and electronic structures of He_2 reported before 1970 and molecular parameters derived from data available before 1979 were summarized in refs. 62 and 22, respectively. No comprehensive reviews have been published subsequently.

The state designations and n^* values for the first members of the $[X^2\Sigma_u^+]n\ell\lambda_p$ $^{1,3}\Lambda$ states for $\ell \le 3$ are included in Table 4. The $\ell \le 2$ series have been observed to n members in the 15–20 range with vibrational development nominally in the $v = 0$ to $v = 2$–4 range observed for the lower n members. All of these characterizations are based on the analysis of rotationally resolved spectra, as are the $v = 0$ levels of the $4f\lambda_u$ $^{1,3}\Lambda_g$ states, the only $nf\lambda_u$ member observed experimentally to date (43). The reader is referred to refs. 41, 43, and 63–68 and the literature cited therein for spectral data published since the earlier reviews (22, 62).

At present, experimental observations of fully resolved multiplet splittings in the electronic states of He_2 are limited to $v = 0$–2 in the $a^3\Sigma_u^+$ state and a relatively few rotational levels in $v = 0$ and 1 of the $b^3\Pi_g$ state (see ref. 41 and refs. therein). The $[X^2\Sigma_u^+]4f\lambda_u$ $^{1,3}\Lambda_g$ states, the $[X^2\Sigma_u^+]nd\lambda_g$ $^{1,3}\Lambda_u$ states with $n \ge 3$, and the $[X^2\Sigma_u^+]np\lambda_u$ $^{1,3}\Sigma_g^+, ^{1,3}\Pi_g^+$ states for $n \ge 4$ are significantly ℓ-uncoupled, but the parameterizations for the lower n members can be corrected for this effect by using isolated complex models (37, 42, 43). The $[X^2\Sigma_u^+]np\lambda_u$ $^{1,3}\Pi_g^-$ states are relatively free from ℓ-uncoupling and other perturbations, and experimental data from these series are the basis for the determination of the He_2 ionization energy in Table 3.

Increased configuration interactions from outside the state set in an $n\ell$-complex decrease the applicability of isolated ℓ-complex models. The breakdown of these models occurs for $n \ge 6$ in the $[X^2\Sigma_u^+]np\lambda_u$ $^{1,3}\Lambda_g$ series and for $n \ge 4$ in the $[X^2\Sigma_u^+]ns\sigma_g, nd\sigma_g$ $^{1,3}\Lambda_u$ series, in which case the data are best treated using coupled-channel models. In such models, a channel corresponds to a Rydberg series of energy levels, all with the *same* angular momentum (N in this case because multiplet splittings are often unresolved) and parity, plus its associated continuum. Multichannel quantum defect theory (MQDT)-based models (69–71) have provided precise representations (66) of the energy levels determined from emission spectra for the $v = 0$ levels of $np\lambda_u$ $^3\Lambda_g$ (n = 3–20) with N values in the 1–19 range for $^3\Pi_g^-$ and in the 2–20 and 3–13 intervals for $^3\Pi_g^+$ and $^3\Sigma_g^+$, respectively. Energies for the $v = 0$ levels of the even-N channels in the 2–20 range associated with n = 3–14 for $nd\lambda_g(^3\Pi_u^-, ^3\Delta_u^-)$ and of the odd-N channels in the 1–17 range associated with n = 3–18 for $ns\lambda_g, nd\lambda_g(^3\Sigma_u^+, ^3\Sigma_u^+, ^3\Pi_u^+, ^3\Delta_u^+)$ were also precisely correlated (67) with a similar coupled-channel model. Because a full discussion of these coupled-channel results in He_2 is too extensive for presentation here, the reader is referred to the referenced articles for further details.

There are large R maxima in a number of the lower-energy Rydberg states of He_2, the most thoroughly studied being the maxima of the a, A, c, and C states. Mulliken (6) discussed reasons for the existence of such maxima and summarized the experimental evidence available as of the early 1960s. Subsequent refinements include contributions from both theory (72) and experiment (73, 74).



For He_2 there are no experimentally observed spectra attributed to transitions involving Rydberg states built on the unbound $^2\Sigma_g^+$ core (cf. Table 2). However, it should be noted that Mulliken (75) postulated the existence of at least a few $^2\Sigma_g^+$ ion core-based states as part of his explanation of the Hornbeck–Molnar effect, the process in which the collision of highly excited helium atoms with the ground state ($^1S_0$) species generates a He_2^+ ion.

Ne_2

In addition to the Ne_2 VUV emission continua mentioned previously, absorption spectral series have been observed (76) in the ~746–736 Å and ~660–600 Å regions and assigned to transitions between $X^1\Sigma_g^+$ and several excited electronic states. Analysis of the longer wavelength segment yielded $D_e = 30.2$ cm^{-1} and $\Delta G_{1/2} = 13$ cm^{-1} for $X^1\Sigma_g^+$, which compare favorably with the more recent values quoted in Table 1 and discussed below.

Fig. 3. Laser excitation spectra of $^{20}Ne_2$: (left) $4p\pi_u\ ^3\Pi_g \leftarrow a^3\Sigma_u^+$ (0–0) and (right) $7p\pi_u\ ^3\Pi_g \leftarrow a^3\Sigma_u^+$ (0–0) from ref. 80. Note the loss of the relative intensity of the Q(*N*) branches to the P(*N*) and R(*N*) branches with increasing *n* (see text for discussion). Figure reprinted with permission of the American Institute of Physics.

The state designations and *n** values for the first members of the $[X^2\Sigma_u^+]n\ell\lambda_p\ ^{1,3}\Lambda$ states for $\ell \leq 3$ were included in Table 4. Most of the rotationally resolved spectral data available for characterizing such Rydberg states have been obtained by laser excitation spectroscopy from the metastable $a^3\Sigma_u^+$ state (produced in the afterglow of pulsed electric discharges) or by single- or multiphoton absorption from the $X^1\Sigma_g^+$ state.

Based on the *n*-value labeling scheme mentioned above, the $np\sigma_u\ ^3\Sigma_g^+$ states for Ne_2 would begin with $n = 4$. The $np\sigma_u\ ^3\Sigma_g^+ - a^3\Sigma_u^+$ series has been observed in the $n = \sim 4$–22 range (38, 45), of which the first observed member (45) appears to be a diffuse band with a peak near 9090 cm^{-1} and assigned (46, 47) on the basis of theoretical calculations (47). The second member of the series, the lowest energy term observed by Kim et al. (38), occurs near 23 510 cm^{-1} and was labeled as $n = 6$ rather than with the index $n = 5$ employed here (see *Discussion*).

In 1989, Kane et al. (77) observed the rotationally resolved (0–0) band of the $4p\pi_u\ ^3\Pi_g \leftarrow a^3\Sigma_u^+$ system of $^{20}Ne_2$ and $^{22}Ne_2$. Giessl et al. (78) subsequently reported rotationally unresolved spectra for the principal sequence ($\Delta v = v' - v'' = 0$) of this system with $v'' = 0$–3. These earlier observations (77, 78) are superseded by more recent measurements (79) of rotationally resolved $4p\pi_u\ e^3\Pi_g \leftarrow a^3\Sigma_u^+(v' - v'')$ spectra in $^{20}Ne_2$ and $^{22}Ne_2$ that provide characterizations of the $v = 0$ through $v = 3$ levels in both states. The first member of the $np\pi_u\ ^3\Pi_g$ series is indexed $n = 3$ and has been assigned by Giessl et al. (78) from rotationally unresolved absorption spectra for the five principal sequence members (0–0) to (5–5). The four strongest members of this sequence had been reported previously (45, 46). The $np\pi_u\ ^3\Pi_g$ series has been recorded (38) to $n = 17$ in laser excitation spectra obtained by pumping $a^3\Sigma_u^+$ state.

Strongly ℓ-uncoupled $^3\Sigma_g^+$ and $^3\Pi_g$ components of the $v = 0$ levels in the $nf\lambda_u(^3\Sigma_g^+, ^3\Pi_g, ^3\Delta_g, ^3\Phi_g)$ complexes, labeled with $n = 4$, 5, and 6 in ref. 48, have been observed in transitions from $a^3\Sigma_u^+$, and a representative spectrum (reprinted from ref. 48) appears in Fig. 2. Also reported (48) were the $4f\lambda_u\ ^3\Sigma_g^+$ and $^3\Pi_g \leftarrow a(1–0)$ bands. Portions of $5f$ – a(1–0), $6f$ – a(1–0), and $7f$ – a(0–0) bands were observed at that time (48) but considered too fragmentary to warrant a full report. Subsequently, the spectra and analyses of the $5f\lambda_u\ ^3\Sigma_g^+, ^3\Pi_g \leftarrow a(1–0)$ bands were published (Table IV in ref. 80), and the involvement of the $5f$ states in a perturbation with the $N \sim 26$–28 levels of $6p\lambda_u\ ^3\Pi_g(v = 0)$ was identified. The $X^2\Sigma_u^+$ ionization energy for $^{20}Ne_2$ in Table 3 was determined with the aid of the $nf\lambda_u\ ^3\Sigma_g^+, ^3\Pi_g$ and $np\lambda_u\ ^3\Sigma_g^+, ^3\Pi_g$ data for $v = 0$ outlined above. The current series numbering scheme would label the first $nf\lambda_u$ as $5f\lambda_u$ rather than $4f\lambda_u$ as in refs. 48 and 80, which would increase all of the *n* values in this paragraph by +1. Altering the *n* labeling of the $nf\lambda_u$ orbital series does not affect any observable results presented in refs. 48 and 80.

Most of the $np\lambda_u\ ^3\Pi_g \leftarrow a^3\Sigma_u^+$ excitation spectra just discussed (38) were obtained by monitoring fluorescence from excited atoms produced by predissociation of the $^3\Pi_g$ states. These spectra present an intensity anomaly not fully rationalized at this time. As evident in Fig. 3*a*, low *n*-value members show normal Π–Σ branch intensities (5) with a strong Q-type branch. However, as *n* increases (Fig. 3*b*), the Q branch progressively weakens relative to the P and R branches, eventually disappearing altogether around $n = 10$. Such an effect is not consistent with intensity expectations in *cases b* or *d*, or ℓ-uncoupling intermediates, and does not appear to be produced by differences in the stabilities of the $^3\Pi_g^+$ and $^3\Pi_g^-$ components to predissociation (see section IV.B in ref. 80). Because most, but not all, of the higher *n* measurements were made monitoring the $3p(1/2)_1 - 3s(3/2)_2^o$ transition in Ne I, it is possible that as *n* increases the Π_g^- components predissociate to excited atoms that do not lead ultimately to $3p(1/2)_1$ production, but such a possibility is purely speculative.

One- and two-color laser excitation spectra have been observed (81) for transitions from $a^3\Sigma_u^+$ to the complex Ne_2 structures that exist between the $v = 0$ and 1, 1 and 2, and 2 and 3 levels in the $X^2\Sigma_{1/2u}^+$ state of the $^{20}Ne_2^+$ and $^{22}Ne_2^+$ dimer

© 2004 NRC Canada

ions. Analysis (81) indicates $\Delta G_{1/2}(X^2\Sigma^+_{1/2u}) = 575.2$ cm^{-1} and $\Delta G_{3/2}(X^2\Sigma^+_{1/2u}) = 564.4$ cm^{-1} for $^{20}Ne_2^+$, and $\Delta G_{3/2} = 539.70$ cm^{-1} for $^{22}Ne_2^+$, but a full coupled-channel treatment of these data has not been performed to date.

Rough estimates of energy structures built on excited cores imply that transitions involving such structures might be expected in the ~10 020, 13 000, and 25 600 cm^{-1} regions. The lowest-energy system could be a contributor to the broad, diffuse feature assigned (45) to the $4p\sigma_u\ ^3\Sigma^+_g - a$ system, but the higher energy estimates remain uncorrelated. In short, there are no spectral features observed below the $X^2\Sigma^+_u$ limit that are associated currently with Rydberg states built on excited ion core levels, although it is quite possible that several exist among weak, currently unassigned spectral features.

Ar_2

The state designations and n^* values for the first members of the $[X^2\Sigma^+_u]n\ell\lambda_p\ ^{1,3}\Lambda$ states for $\ell \leq 3$ are included in Table 4. As with Ne_2, much of the spectral data available for characterizing the Rydberg states in these series comes from laser excitation spectroscopies based on the $a^3\Sigma^+_u$ state, with additional information provided by single- or multiphoton absorption from the $X^1\Sigma^+_g$ state. For Ar_2, however, fewer assignments are supported by rotational analyses than is the case in Ne_2 because of decreased rotational level spacings. Rydberg series converging on the $X^2\Sigma^+_u$ core of the Ar_2 molecule were first observed in electron beam excitation experiments (3, 4) and discussed by Herzberg in ref. 1. An overview of the *laser* excitation spectrum of Ar_2 (39) in the 335–470 nm region, a spectrum of considerably higher resolution than that available in 1987, is presented in Fig. 4.

Triplet splitting is small and not resolved in most of the Ar_2 spectral data. An exception is data obtained recently by Herring et al. (82) for the transition labeled $7p\sigma_u\ ^3\Sigma^+_g - a^3\Sigma^+_u$. The (1–0) band for this system, shown in Fig. 5, provides an example of the spectra obtainable by laser excitation spectroscopy at moderate gas pressures (~30 torr Ar, 300 K). The n-indexing of the $np\sigma_u$-based states in refs. 39 and 82 is +3 higher than that for the $3p\sigma_u$ orbital of He_2. Doubts were expressed about this labeling scheme at the time (38) and it is no longer favored (see *Discussion*). Thus, $5p\sigma_u$ would be the first $np\sigma_u$ Rydberg indexing label for Ar_2 and the spectrum of Fig. 5 is assigned to the $6p\sigma_u\ ^3\Sigma^+_g - a^3\Sigma^+_u$ (1–0) band in the indexing scheme employed here.

In Λ,S notation, $np\sigma_u\ ^3\Sigma^+_g -$, $np\pi_u\ ^3\Pi_g -$, $nf\sigma_u\ ^3\Sigma^+_g -$, $nf\pi_u\ ^3\Pi_g -$, and $n\ell\lambda_g\ \Pi_g - a^3\Sigma^+_u$ series have been assigned by Kane et al. (39) for Rydberg levels with n^* values up to ~25.4, 25.4, 8.8, 8.0, and 8.5, respectively. The lowest-energy members of the $np\sigma_u\ ^3\Sigma^+_g$ and $np\pi_u\ ^3\Pi_g$ series ($5p\sigma_u$ and $4p\pi_u$) were not observed in ref. 39, but transitions from the a state to these levels had been observed and assigned previously (45, 46, 83, 84) to systems near 7900 and 10 120 cm^{-1}, respectively. Other possible contributors to spectra in the ~7000 – 11 000 cm^{-1} region are discussed by Dupláa and Spiegelmann (49), as are their predictions of Rydberg states associated with excited cores. However, as in Ne_2, no correlation of excited core-based Rydberg states to experimental observations seems to exist for Ar_2 at present.

The $n\ell\lambda\ \Pi_g - a$ and $nf\pi_u\ ^3\Pi_g - a$ series of ref. 39 subsequently were reassigned to $nf\pi_u\ ^3\Pi_g - a$ and $nf\delta_u\ ^3\Delta_g - a$ series, respectively, by Dupláa and Spiegelmann (49) based on their extensive theoretical calculations. Note that the reassignment inverts the relative energy order of $nf\sigma_u$ and $nf\pi_u$ from that observed in He_2 and Ne_2. In addition, rotational analyses of the reassigned $nf\sigma_u\ ^3\Sigma^+_g - a$ and $nf\pi_u\ ^3\Pi_g - a$ (0–0) bands (51) (see next paragraph) show that the upper states are not strongly affected by ℓ-uncoupling, raising additional questions about the mainly nf-based nature of these states that remain as yet unanswered (see ref. 51 for further discussion). Regardless of series labels, etc., the data (39) lead to an ionization energy for the $X^2\Sigma^+_u$ limit, relative to $v = 0$ in $a^3\Sigma^+_u$, of 29 373 ± 3 cm^{-1}.

The higher-resolution laser excitation spectra introduced above in connection with Fig. 5 provided rotationally resolved data for the $6p\sigma_u\ ^3\Sigma_g{}^+ - a^3\Sigma^+_u$ (0–0), (1–1), (1–0), and (0–1) bands (82), as well as the $5f\sigma_u\ ^3\Sigma^+_g - a^3\Sigma^+_u$ (0–0) and (0–1) and $5f\pi_u\ ^3\Pi_g - a^3\Sigma_u{}^+$ (0–0) and (0–1) bands (51), where the ℓ-labeling of the upper state of the $5f\pi_u\ ^3\Pi_g - a$ transition is that proposed by Dupláa and Spiegelmann (49). The numbering scheme employed here would label the first $nf\lambda_u$ as $6f\lambda_u$ rather than $5f\lambda_u$ as adopted in refs. 39, 51, and 82, with appropriate increases to the n label for other $nf\lambda_u$ orbitals in this paragraph. The rotationally resolved spectra of refs. 51 and 82 yield $\omega_e = 298$ cm^{-1}, $\omega_e x_e = 3.0$ cm^{-1}, and $R_e = 2.44$ Å for the $a^3\Sigma^+_u$ state, and, when combined with the high-v data from Herman et al. (16) (see the following), suggest $D_0 = 5700 \pm 200$ cm^{-1} and $D_e = 5850 \pm 200$ cm^{-1} for the $a^3\Sigma^+_u$ state. These values for the $a^3\Sigma^+_u$ state compare favorably with those calculated by Dupláa and Spiegelmann (49).

Herman et al. (16, 50) reported rotationally resolved VUV absorption spectra of Ar_2 cooled in a supersonic beam expansion and associated these spectra with transitions from $X^1\Sigma^+_g(0^+_g)$ to three excited electronic states designated in refs. 16 and 50 as $A1_u$, $B0^+_u$, and $C0^+_u$. The Al_u state is part, at least, of the $a^3\Sigma^+_u(1^\pm_u, 0^-_u)$ state, while the $B0^+_u$ state is the $A^1\Sigma^+_u(0^+_u)$ state of Table 4. Because of large differences in the shapes and positioning of the potential energy curves for X and the a and A states (see Tables 1 and 2), transitions were observed from $X^1\Sigma^+_g$ ($v = 0$) to excited-state vibrational levels in the $v \cong 20$–30 range in both upper states. Extrapolated origins and molecular parameters were determined to be (16) $T_e = 87\,458 \pm 500$ cm^{-1} for $a^3\Sigma^+_u$ and $T_e = 88\,210 \pm 400$ cm^{-1}, $\omega_e = 265$ cm^{-1}, $\omega_e x_e = 2.52$ cm^{-1}, and $\omega_e y_e = -0.0061$ cm^{-1} for $A^1\Sigma^+_u$. Spectra assigned to $C0_u{}^+ - X^1\Sigma^+_g$ (v–0) transitions were observed in the $v = 0$–9 range, indicating that the R_e values for X and C are similar, with effective parameters given (16) as $T_e = 95\,033.6$ cm^{-1}, $\omega_e = 68.16$ cm^{-1}, $\omega_e x_e = 4.63$ cm^{-1}, $\omega_e y_e = 0.049$ cm^{-1}, $\omega_e z_e = 0.007$ cm^{-1}, and $D_e = 466$ cm^{-1}. Subsequently, the $C0^+_u$ state was assigned (49) to a minimum at large R produced by the avoided crossing of an attractive $^1\Sigma^+_u(0^+_u)$ state, probably the second member of the $ns\sigma_g\ ^1\Sigma^+_u(0^+_u)$ series, and a repulsive $^3\Pi_g$ "valence" state. As with the lighter Rg_2 molecules, there are a number of other potential energy maxima besides the distinct peak in the $^1\Sigma^+_u(0^+_u)$ potential that arises from the other half of the avoided crossing described in the preceding sentence. The reader is referred to ref. 49 for further details.

There are predictions and observations of transitions to Rydberg states built on excited cores that bear mainly on questions relating to the large-R behavior of the Rydberg

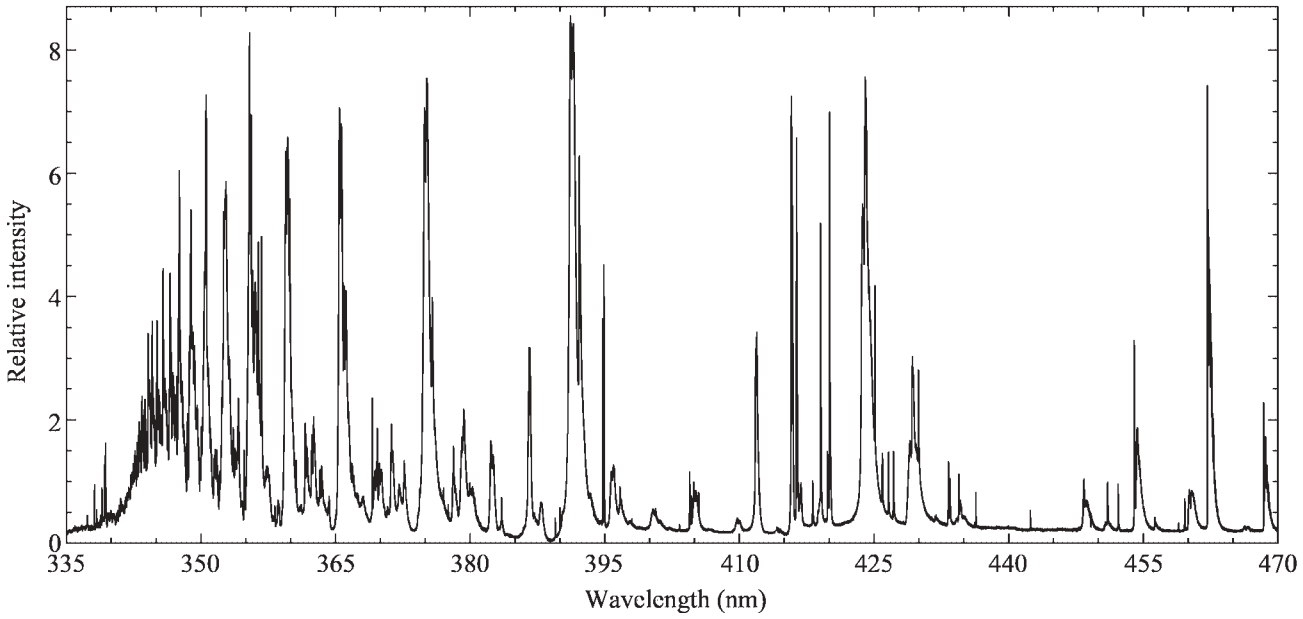
Fig. 4. Panoramic view of the laser excitation spectrum of Ar_2 $a^3\Sigma_u^+$ in the 335–470 nm region. These data were obtained by D.J. Kane, S.B. Kim, and C.M. Herring in 1991 and published in sections in ref. 39.



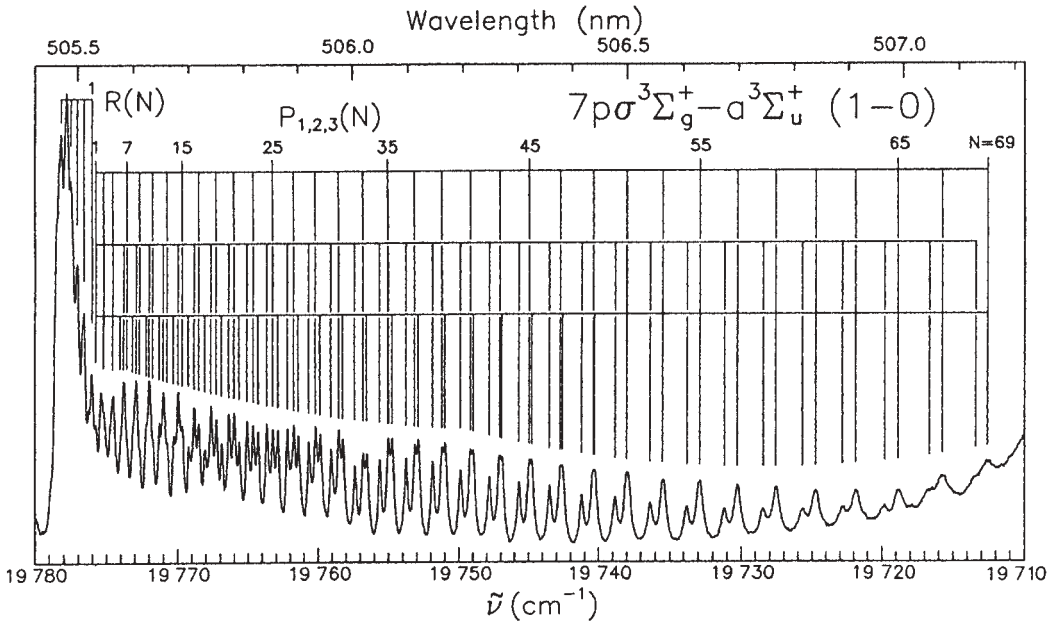


Fig. 5. Laser excitation spectrum of the $6p\sigma_u$ $^3\Sigma_g^+$ – $a^3\Sigma_u^+$ (1–0) band of Ar_2 with triplet splitting partially resolved (82). The label n = 7 in the reproduced figure is taken currently to be n = 6 (see text for discussion). Figure reproduced with permission of the American Institute of Physics.

states converging on the $X^2\Sigma_u^+(1/2_u^+)$ core, at least for the n^* ranges currently observed. The complexities resulting from increased configuration interactions of all types at large R are outside the scope of this article, and further discussion will be limited to brief commments in the following section dealing with excited core-based structures.

Kr_2

As was the case for Ne_2 and Ar_2, Rydberg series for Kr_2 converging on the $X^2\Sigma_{1/2u}^+(1/2_u^+)$ core were first observed in electron beam excitation experiments (3, 4). The first members of the $[X^2\Sigma_{1/2u}^+(1/2_u^+)]n\ell\lambda_p$ $^{1,3}\Lambda$ states for $\ell \leq 3$ are included in Table 4 and, again, much of the available spectral data comes from laser excitation and absorption spectroscopy of the $a^3\Sigma_u^+(1_u^\pm, 0_u^-)$ state, augmented by ground-state absorption experiments. Rotational structures generally have not been resolved for Kr_2, with notable exceptions including spectra associated with single-photon transitions from the ground state to three excited electronic states (17). Consequently, most assignments are not supported by rota-

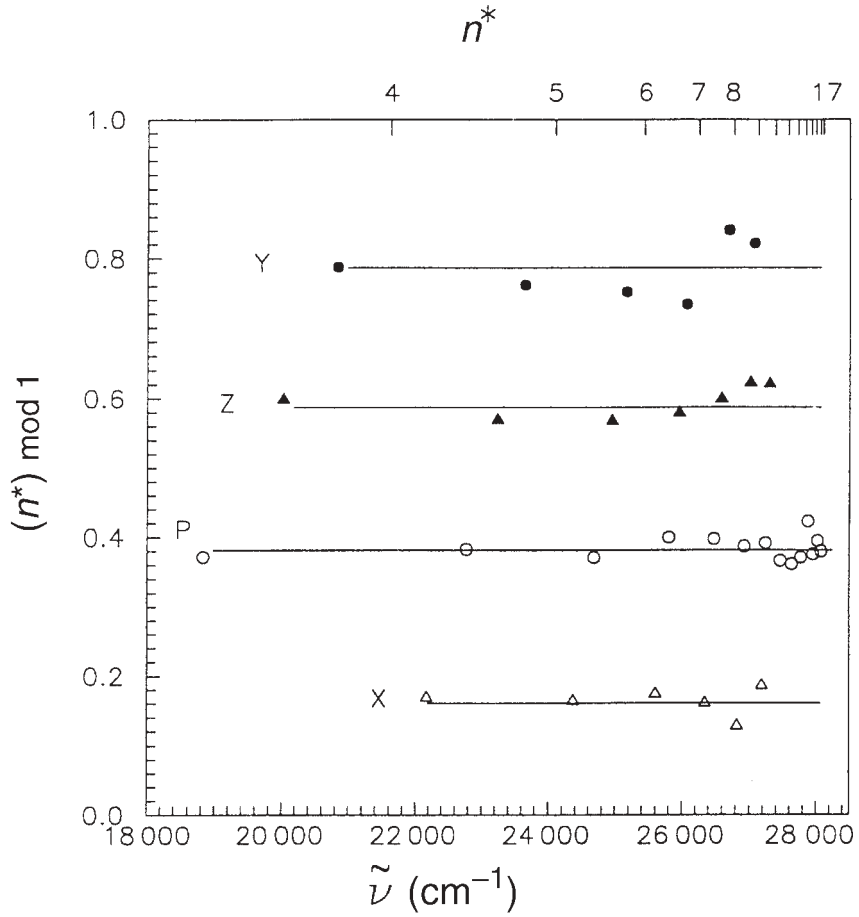
© 2004 NRC Canada

tional analyses. Finally, it is most likely that $\Omega_p^{p'}$-type state (*case c*) designations are more appropriate for Kr_2, but the Λ,S -type labeling will also be retained to facilitate continuity.

LaRocque et al. (17) reported three rotationally resolved VUV absorption band systems (upper states A, B, and C) in jet-cooled Kr_2 that are analogous to the Ar_2 spectra (16, 50) discussed in the previous section. In the notation adopted here, the first two systems would be $a^3\Sigma_u^+(1_u^\pm, 0_u^-)$ – X and $A^1\Sigma_u^+(0_u^+)$ – X. The third system ($C0_u^+$ – X) might be considered analogous to the C – X transition in Ar_2, where the $C0_u^+$ state was assigned as a large-R minimum state produced by the avoided crossing of an attractive $^1\Sigma_u^+(0_u^+)$ state and a repulsive valence state. Transitions (17) to a and A from $v = 0$ in X involved bands in the $v' = 38$–32 and 38–30 ranges, respectively, observations that are consistent with substantial differences in the equilibrium internuclear separations (R_e) for the $X^1\Sigma_g^+(0_g^+)$ ground state and the a (and A) states. Thus, determinations of dissociation energies (D_0), equilibrium molecular parameters, and related constants involve long extrapolations in the upper-state vibrational quantum number v'. LaRocque et al. (17) reported $T_e = 74\,303.9$ cm^{-1}, $\omega_e = 244.6$ cm^{-1}, $\omega_e x_e = 2.60$ cm^{-1}, and $D_e = 5607$ cm^{-1} for $a^3\Sigma_u^+(1_u^\pm, 0_u^-)$, which gives $D_0(a) \cong 5475$ cm^{-1}. They (17) also reported $T_e = 75\,426.8$ cm^{-1}, $\omega_e = 219.5$ cm^{-1}, $\omega_e x_e = 2.23$ cm^{-1}, and $D_e = 5629$ cm^{-1} for $A^1\Sigma_u^+(0_u^+)$, which yields $D_0(A) \cong 5425$ cm^{-1}. In addition, the T_e- values cited in ref. 17 imply a separation between the $v = 0$ levels in $a^3\Sigma_u^+(1_u^\pm, 0_u^-)$ and $A^1\Sigma_u^+(0_u^+)$ of 1100 ± 10 cm^{-1}. Extrapolated values for B_e, α_e, and R_e are given (17) as 0.0817 cm^{-1}, 0.00128 cm^{-1}, and 2.214 Å, respectively, for $a^3\Sigma_u^+(1_u^\pm, 0_u^-)$; 0.06282 cm^{-1}, 0.00091 cm^{-1}, and 2.426 Å for $A^1\Sigma_u^+(0_u^+)$; and 0.02489 cm^{-1}, 0.0010 cm^{-1}, and 4.017 Å for $X^1\Sigma_g^+(0_g^+)$. LaRocque et al. (17) observed transitions from X to $v = 0$–5 in $C0_g^+$ and reported $T_e = 85\,520$ cm^{-1}, $\omega_e = 44$ cm^{-1}, $\omega_e x_e = 1.81$ cm^{-1}, and $D_e = 465$ cm^{-1} for the C state.

Infrared spectra observed (45, 46) near 7700 and 10 170 cm^{-1} were assigned (46), in terms of configuration and state designations employed here, to the first members of the $[X^2\Sigma_{u}^+(1/2_u^+)]mp\sigma_u\ ^3\Sigma_g^+(1_g^\pm, 0_g^-)$ – $a^3\Sigma_u^+(1_u^\pm, 0_u^-)$ and $[X^2\Sigma_{u}^+(1/2_u^+)]np\pi_u\ ^3\Pi_g\ (2_g^\pm, 1_g^\pm, 0_g^\pm)$ – a series, respectively, where $m = 6$ and $n = 5$ in the labeling system in present use. Kane et al. (85) reported nine absorption features, classified tentatively as vibronic structures of a $5p\pi_u\ ^{1,3}\Pi_g(1_g^\pm, 2_g^\pm, 1_g^\pm, 0_g^\pm)$ – $a^3\Sigma_u^+$ system, with (0–0) bands near 10 113 cm^{-1} $[^3\Pi_{0g}(0_g^\pm)]$, 10 167 cm^{-1} $[^3\Pi_{1g}(1_g^\pm)]$, 10 261 cm^{-1} $[^3\Pi_{2g}(2_g^\pm)]$, and 10 354 cm^{-1} $[^1\Pi_g(1_g^\pm)]$, with n^* values of 2.444, 2.448, 2.454, and 2.560, respectively. Alternatively, the 10 354 cm^{-1} band can be assigned as the (1–0) band of $5p\pi_u\ ^3\Pi_{1g}(1_g^\pm)$ – a rather than the $^1\Pi_g$ – a (0–0) band (85). These four bands comprise the 10 170 cm^{-1} system observed previously (45) and assigned (52) to the $\Omega_p^{p'}$ – a analogs of the transitions listed. To still lower energies are bands (45, 46) near 9488 cm^{-1} ($n^* = 2.403$) and 7692 cm^{-1} ($n^* = 2.297$), where the 7692 cm^{-1} feature was assigned as the lowest member of the $np\sigma$ series (46, 52). Kane et al. (85) proposed assigning the 7692 cm^{-1} feature as a transition from $a^3\Sigma_u^+(1_u^\pm, 0_u^-)$ to states associated with $[A^2\Pi_{3/2g}(3/2_g^+)]ns\sigma_g$ and the 9488 cm^{-1} feature as the lowest-energy member of the $[X^2\Sigma_{1/2u}^+(1/2_u^+)]np\sigma_u\ ^3\Sigma_g^+$ series, but unambiguous assignments are not possible from the present database.

Extensive spectra (85) involving transitions from the $a^3\Sigma_u^+(1_u^\pm, 0_u^-)$ levels to states energetically below the $[X^2\Sigma_{1/2u}^+(1/2_u^+)]$ limit were separable into four series. Figure 6 illustrates the variation of $(n^*)_{mod1}$ [$\equiv n^*|_{mod1}$] for the higher-n members of these series with n^* and ν (cm^{-1}) for the $v = 0$ levels. The data of Fig. 6 with $(n^*)_{mod1}$ near 0.8, 0.6, 0.4, and 0.2 were labeled series Y, Z, P, and X, respectively, with Y, Z, and P tentatively correlated with $nf\lambda$-, $n\ell\lambda$ Π-, and $np\lambda$-based series (85). Note that the ~7700 cm^{-1} and 10 170 cm^{-1} systems mentioned above could be lower members of the P series or possibly the P and the X series, depending on the variations of $(n^*)_{mod1}$ with n^* for these series.



The strongest features among the four spectral series illustrated in Fig. 6 are those with $(n^*)_{mod1} \cong 0.40$, the P series. The first P member in Fig. 6 has a (0–0) band at 18 831 cm^{-1}, with the upper state being assigned as $[X^2\Sigma_u^+(1/2_u^+)]6p\sigma_u$ – $a^3\Sigma_u^+(1_u^\pm, 0_u^-)$ by Audouard and Spiegelmann (52) on the basis of theoretical calculations. This band system shows extensive vibrational development (85) and was designated P(2) with a tentative assignment of $8p\sigma_u\ ^3\Sigma_g^+$ – a (now $7p\sigma_u$). Audouard and Spiegelmann (52) also predicted a system near 19 200 cm^{-1}, arising from transitions to $[X^2\Sigma_u^+(1/2_u^+)]6p\pi_u\ ^{1,3}\Pi_g(1_g^\pm, 2_g^\pm, 1_g^\pm, 0_g^\pm)$, with singlet-triplet and multiplet splittings of ~80 and 40 cm^{-1}, respectively, and individual states described in a *case c* (Ω-state) distribution. Energetically, the nearest transition to these "$6p\pi_u$" predictions is the first member of series Z (ref. 85) in Fig. 6 at 20 022 cm^{-1}, a peak previously reported in refs. 3, 4, and 83 to be in the ~20 023 – 20 040 cm^{-1} spectral interval. The 18 831 and 20 022 cm^{-1} bands would have n^* values of 3.37 and 3.60, respectively, with the latter band being a member of the Kr_2 analog of an $n\ell\lambda\ \Pi_g$ series (85) assigned (52) to the $nf\pi_u\ ^3\Pi_g$ series in Ar_2.

The potential ambiguities in assignments discussed previously for the lower-energy states of Kr_2 propagate to higher energies. Thus, for example, it is not clear whether (*i*) the higher members of the P series are simply the $[X^2\Sigma_{1/2u}^+(1/2_u^+)]np\pi_u\ ^3\Pi_g\ (2_g^\pm, 1_g^\pm, 0_g^\pm)$ – a series, with a possible additional contribution from spin–orbit mixing allowed transitions to the associated $^1\Pi_g(1_g^\pm)$ states, or (*ii*) this series also includes transitions to the $[X^2\Sigma_u^+(1/2_u^+)]np\sigma_u\ ^{1,3}\Sigma_g^+(0_g^+, 1_g^\pm, 0_g^-)$ members energetically collapsed onto the $np\pi_u$ state manifold. If one adopts premise (*i*), then it is most likely that the X series is the $[X^2\Sigma_{1/2u}^+(1/2_u^+)]np\sigma_u\ ^3\Sigma_g^+(1_g^\pm, 0_g^-)$ – a series, with possible contributions from transitions to the "singlet" 0_g^+ states associated with $np\sigma_u$. Given that the X and P series can be assigned based on premise (*i*), there remains the Z series [$(n^*)_{mod1} \cong 0.6$] and the Y series [$(n^*)_{mod1} \cong 0.8$]. The Z and Y series might be associated with the $[X^2\Sigma_{1/2u}^+(1/2_u^+)]nf\pi_u\ ^{1,3}\Pi_g(1_g^\pm, 2_g^\pm, 1_g^\pm, 0_g^\pm)$ – a series and the $nf\sigma_u\ ^{1,3}\Sigma_g^+(0_g^+, 1_g^\pm, 0_g^-)$ – a series, respectively, but such assignments, along with their Ar_2 counterparts, remain tentative. Thus, because of inconsistencies, both observational and theoretical, a completely unambiguous description of the excited-state structures for Kr_2 must await improved data.

There can be additional complications in describing the states in Rydberg series converging on $[X^2\Sigma_{1/2u}^+(1/2_u^+)]$ produced by their interactions with states built on excited cores and with other large-R configuration interaction effects. As

Fig. 6. Plots of $(n^*)_{mod1}$ vs. n^* and $\tilde{\nu}$ (cm^{-1}) for the $v = 0$ levels of four Rydberg series observed (85) for Kr_2. See text for discussion. Figure reproduced with permission of the American Institute of Physics.

noted before, such complexities are beyond the scope of this article and will only be critiqued briefly in the following.

Xe_2

Experimental studies of the Xe_2 excimer extend back more than 50 years. Aside from fundamental interest in the dimer and its application as a VUV continuum light source, much of the recent experimental and theoretical work on this molecule has been motivated by its potential to produce a tunable laser in the second continuum (λ ~172 nm) region. Despite such continued activity, however, the Rydberg states of Xe_2 converging on $X^2\Sigma^+_{1/2u}(1/2^+_u)$ are the least well-characterized of the Rg_2 family, with the exception only of Rn_2. Rotationally resolved spectra have not yet been reported for Xe_2, but isotopically resolved vibronic spectra, photoexcitation of rotationally cold dimers produced in a supersonic jet, and transient absorption and laser excitation spectroscopic experiments have provided new insights into the structure of this molecule.

Lipson et al. (53) employed a coherent, tunable VUV source to observe absorption from Xe dimers produced in a supersonic jet. Vibrationally resolved spectra associated with transitions from $X^1\Sigma^+_g(0^+_g)$ to three low-lying *ungerade* excited states were reported for Xe_2, observations apparently analogous to those discussed previously for Ar_2 and Kr_2. Isotopic analyses revealed that the v' levels accessible within the Franck–Condon corridor were $v' = 36$–43 for $a^3\Sigma^+_u(1_u)$, $v' = 35$–46 for $A^1\Sigma^+_u(0^+_u)$, and $v' = 16$–27 for $C0^+_u$. Extrapolations of these data obtained at larger R yielded (53) the following "equilibrium" parameters: $T_e = 63\,089.9$ cm^{-1}, $\omega_e = 137.5$ cm^{-1}, $\omega_e x_e = 1.167$ cm^{-1}, and $D_e = 4174.$ cm^{-1} for $a^3\Sigma^+_u$; $T_e = 63\,795.6$ cm^{-1}, $\omega_e = 124.8$ cm^{-1}, $\omega_e x_e = 0.937$ cm^{-1}, and $D_e = 4446.$ cm^{-1} for $A^1\Sigma^+_u$; and $T_e = 75\,881.7$ cm^{-1}, $\omega_e = 49.7$ cm^{-1}, $\omega_e x_e = 0.422$ cm^{-1}, and $D_e = 1500.$ cm^{-1} for $C0^+_u$.

Kasama et al. (46) and Jonin et al. (86) observed a number of absorption features in the 9090–9800 cm^{-1} region that have been attributed by Jonin and Spiegelmann (87) on the basis of theoretical considerations to $[X^2\Sigma^+_{1/2u}(1/2^+_u)]6p\pi_u$ $^{1,3}\Pi_g$ $(1_g,2_g,1_g, 0^\pm_g)$ – $a^3\Sigma^+_u(1_u, 0^-_u)$ transitions, with ref. 86 using separated atom $\pi_u 6p$ notation. Jonin et al. (86) employed a fluorescence ($A \rightarrow X$) suppression approach to verify the existence of features reported by ref. 46 in the 9090–9800 cm^{-1} region and broad quasi-continua peaking at ~6780 and 7580 cm^{-1}. The former has been tentatively assigned (87) to transitions terminating on $[X^2\Sigma^+_{1/2u}(1/2^+_u)]0^-_g$ and 1_g states, and the latter to transitions terminating on the $[A^2\Pi_{3/2g}]1_g$ and 2_g states.

Two short Rydberg series were observed in absorption (4) in electron beam excited Xe and attributed to two members of the $np\sigma\ ^3\Sigma^+_g$ – a and four members of the $np\pi$ – a transitions. These series exhibited $n^*|_{mod1}$ values of ~0.7 and ~0.3, with first members tentatively assigned to $n = 8$ and 7,

© 2004 NRC Canada

respectively. Fluorescence suppression experiments (88) probed the structure superimposed onto a strong feature at ~549.4 nm previously assigned (4) to $[X]8p\sigma\ ^3\Sigma_g^+$ – a and assigned (86, 87) these structures to transitions from $a^3\Sigma_u^+(1_u,\ 0_u^-)$ to $[X^2\Sigma_{1/2u}^+(1/2_u^+)]7p\pi_g\ ^{1,3}\Pi_g(1_g,\ 2_g,\ 1_g,\ 0_g^\pm)$ in the notation employed here. In short, there is good reason to believe that states associated with at least the lowest two to four members of the $np\lambda_g$ series converging on $[X^2\Sigma_{1/2u}^+(1/2_u^+)]$ have been observed experimentally, although most of the members are not well characterized.

Reference 87 compares the meager experimental information available for $[X^2\Sigma_{1/2u}^+(1/2_u^+)]$ core-based Rydberg structures with their extensive theoretical calculations. Reference 87 also discusses lower-lying, excited core-based levels and other large-*R* phenomena. Some of these structures are relatively well characterized experimentally, but they are outside the principal area of emphasis of this work.

Heteronuclear rare gas diatomics

Theoretical and experimental investigation of the heteronuclear rare gas diatomics has also been considerable, particularly in the last decade. Although closely related, the structure of the RgRg′ molecular family is beyond the scope of this article, and the reader is referred to refs. 89 through 95, and references cited therein for an introduction to the subject. It should be noted that the preponderance of the recent experiments on RgRg′ electronic structures have involved one- or two-photon excitation of molecules, often produced in a supersonic jet, with subsequent photoionization of the diatomic species followed by analysis by mass spectrometry or photoelectron spectroscopy. Rydberg states built on a variety of molecular ion cores have been reported, and Lipson and Field (95) have proposed a model for interpreting the experimentally observed irregularities of the variation of interatomic potentials with *n**.

Diatomic Rn_2

At present, it appears that neither experimental nor theoretical studies of the excited electronic structure of Rn_2 has appeared in the literature. For the ground state $(X0_g^+(^1\Sigma_g^+))$, however, relativistic pseudopotential (96) and model potential (97) calculations have been reported. The former includes calculations for Xe_2 and RnXe, while the latter contains parameterizations of potentials for all of 21 possible Rg_2 and Rg′Rg molecules from Rg = He, Ne, Ar, Kr, Xe, and Rn.

Additional comments

There have been a number of experimental observations of electronic structures in the $R > R_e$ regions most easily accessible by absorption from the $X^1\Sigma_g^+(0_g^+)$ states. These observations fall mainly into two categories: transitions to the large-*R* portions of Rydberg states built on the $[X^2\Sigma_{1/2u}^+(1/2_u^+)]$ cores (as sometimes modified by interactions with valence states) and transitions to states built on the excited core states listed in Tables 2 and 3. The low-energy portions of states in the former category were encountered above in connection with observations of the C-state large-*R* minimum for Ar_2, Kr_2, and Xe_2. Few of the large-*R* observations of structures associated with more highly excited $[X^2\Sigma_{1/2u}^+(1/2_u^+)]n\ell\lambda_p\ ^{1,3}\Lambda_p$ levels have been correlated with electronic structures near the R_e of their core. At this time, such measurements at large *R* and observations of excited core-based states have not appeared as major contributors to the structures or perturbations of the $[X^2\Sigma_u^+(1/2_u^+)]$-based Rydberg states in the *R* regions near R_e for their core, nor to spectra associated with these states. However, such states certainly will be extremely important as the database is improved and to any future attempts to describe $[X^2\Sigma_u^+(1/2_u^+)]$-based Rydberg state behavior in the very complex region extending from $R > R_e$ to the dissociation limit. Thus, a few additional words seem appropriate even though they are outside the content bounds set forth in the *Introduction*.

Observations in the two categories listed in the preceding paragraph generally are associated with upper states labeled by the atomic limit to which the states dissociate (or are believed to dissociate). Early examples of this labeling appear in the Ne_2 work of ref. 10, where vibrationally resolved absorption spectra from $X^1\Sigma_g^+$ were grouped into 12 systems. The two lowest-energy systems were labeled (10) $I(0_u^+)$ (denoted here as the A state) dissociating to $2p^6\ ^1S + 2p^5\ 3s$ and $II(0_u^+)$ dissociating to $2p^6\ ^1S + 2p^5\ 3s'$, where $2p^5\ 3s$ is associated with $^3P_1$ and $2p^5\ 3s'$ with the more highly excited $^1P_1$ state of Ne. The remaining systems were then assigned (10) as transitions converging on *ns*,*ns*′ with *n* = 4 and 5 and *nd*,*nd*′ with *n* = 3 and 4. Thus, the upper-state labeling procedures follow the Rg atomic level labels in Moore (36) with subsequent correlations to levels built on the excited ion core states listed in Tables 2 and 3.

For Ar_2, spectra have been reported for transitions from X to states associated with $3p^5$ *ns*, *nd*, *ns*′, and *nd*′ for *n* values up to ~17, 15, 8, and 21, respectively, and the reader is referred to refs. 98–101 and references cited therein. For Kr_2, spectra have been reported for transitions from X to states associated with $4p^5$ *ns*, *np*, *np*′, *nd*, and *nd*′ for *n* values up to ~6, 4, 6, 5, and 9, respectively. For additional details concerning these experiments, the reader is referred to refs. 99, 102, and 103 and references cited therein.

The breadth of the experimental work reported for Xe_2 over the past several decades warrants an expanded discussion. In the 1970s and early 1980s, Castex and Damany (104, 105) and Castex (106) observed more than a dozen electronic states of Xe_2 by examining the temperature and pressure dependence of absorption by ground-state collision pairs in the VUV. Excited states correlated with Xe (6*s*, 6*s*′, 6*p*, 5*d*, 7*s*) + Xe $(5p^6\ ^1S_0)$ in the separated atom limit were reported (20, 104–106), while Dehmer and Pratt (99) reported observations of *nd*′ up to *n* = 10. Gornik et al. (107) subsequently introduced two-photon excitation spectroscopic techniques to detect stable Xe_2 excited states derived from Xe (6*p*, 5*d*).

More recently, two-photon excitation of dimers produced in a jet was combined with mass spectrometry and electrostatic energy analysis by Dehmer et al. (108, 109) to investigate the electronic states derived from Xe (6*p*, 5*d*) + Xe $(^1S_0)$. The states correlated with Xe $(6p[5/2]_2$, $6p[3/2]_2$, or $6p[1/2]_0)$ + Xe $(^1S_0)$ in the separated atom limits were found to be shallow ($D_0 \simeq$ 290–580 cm^{-1}) and were attributed to Rydberg states having the $B^2\Pi_{3/2g}$ or $C^2\Pi_{3/2u}$ ion cores. Similar results were reported for the observed states correlated with Xe (5*d*) + Xe $(^1S_0)$; except for a strongly bound state

© 2004 NRC Canada

associated with the Xe ($5d[7/2]_3$) + Xe ($^1S_0$) limit, most appeared to have dissociation energies of <600 cm^{-1} and $C^2\Pi_{3/2u}$ or $B^2\Pi_{3/2g}$ molecular ion cores. Resonantly enhanced multiphoton ionization (REMPI) combined with mass spectrometry were used by Dimov et al. (110) and Hu et al. (111, 112) in a series of experiments that observed and characterized more than 15 states correlated with the Xe ($6p$, $5d$, or $4f$) + Xe ($^1S_0$) separated atom limits. Again, the dissociation energies for most of the observed states were determined to be $\lesssim$1000 cm^{-1}. The exception was a strongly bound (D_e = 3470.4 cm^{-1}) state associated with the Xe ($6p[5/2]_2$) + Xe ($^1S_0$) limit.

Discussion

As already noted on several occasions, differing n and ℓ designations exist in the literature for the same Rydberg state. It also has been mentioned that the origin of these description differences is that n and ℓ are not meaningful quantum numbers for most of the Rg_2 Rydberg configurations. In the presence of configuration interactions, only Ω, p' and the $\Omega^{\pm}$ reflection parities are approximately valid state labels for all R and Rg_2 members, with spin–orbit effects also coupling states with $\Delta\Omega^{p''}_{p'} = 0$. However, molecular rotation couples states with $\Delta\Omega^{p''}_{p'} = \pm 1$ with identical values of p' but opposite values of p'' (i.e., $\Omega_p{}^+$ and $\Omega_p{}^-$) so that not even single $\Omega^{p''}_{p'}$ labels are valid state representations under some circumstances.

Values for n^* are a direct measure of the energy of the Rydberg state, given by eq. [1]. Fractional representations of n^*, such as $n^*|_{mod1}$ or $\delta|_{mod1} = (n - n^*)|_{mod1}$, indicate a relative phase shift of the wave function for a given Rydberg channel that arises from the interaction of the Rydberg electron with the ion core (69–71). These phase shifts can be determined semiempirically (see refs. 66, 67, and 113 and references cited therein) or from the polarization characteristics of the core (see ref. 43 and references cited therein) and are independent of any assumptions regarding the existence of n or ℓ, or the necessity of equating n^* to $n - \delta$. However, it is convenient to label successive members of a Rydberg series with an indexing number, and it has been the convention for presumptions regarding the lowest integer in eq. [1] to provide the initial value for an indexing protocol. Different presumptions invariably lead to different n labels for the same level. Although not currently in use, an approach to Rydberg series indexing that is more consistent with the $n^*|_{mod1}$ phase shift interpretation would be to adopt a labeling system similar to that for the all-R-valid $m\lambda_p$ orbital notation, in which the first member of a Rydberg $m\ell\lambda_p\ ^{2S+1}\Lambda_{p'}$ series would be designated m = 1 (as is the first $m\lambda_p$ orbital), and successive series members labeled by incrementing m by the appropriate integer. Such a labeling scheme would also be similar to the listing of excited electronic states associated with the same $^{2S+1}\Lambda_{p'}$ symmetries in order of ascending energies (i.e., $1^3\Pi_g$, $2^3\Pi_g$, $3^3\Pi_g$,... are the first, second, third,... $^3\Pi_g$ states in order of increasing energy), a practice employed by many theorists (see, for example, refs. 44, 47, 49, and 52). In any case, continuing to regard n as having integral quantal significance implies that the labeling of many molecular Rydberg series can be expected to be plagued by ambiguities and (or) inconsistencies.

The breakdown in the ability to interpret n as being semihydrogenic (i.e., the breakdown in the utilization of demi H_2^+ models (114)) occurs for even the lightest member of the Rg_2 series, He_2). In He_2, the breakdown manifests itself in the necessity of using coupled-channel methods to correlate quantitatively the higher n portions of much of the experimental database for the $[X^2\Sigma_u^+]n\ell\lambda_p\ ^{1,3}\Lambda_{p'}$ manifolds (see the *He_2* section). Even more extensive configuration interaction effects occur for the heavier Rg_2 members, but most of these effects have not been quantified experimentally because of the lack of rotationally resolved data for many of the Rydberg states in Ar_2, the majority of the Rydberg states in Kr_2, and all the Ryberg states of Xe_2.

Despite the progress of the last few decades in the observation and analysis of $[X^2\Sigma_u^+]$ core-based Rydberg series in the Rg_2 family, much of the observed structure of the heaviest of these molecules remains ambiguously characterized. Thus, the final comments in this article offer suggestions for steps to be taken to remove these ambiguities and to otherwise improve our understanding of the Rg_2 Rydberg structures.

For molecules heavier than He_2, there are two general areas involving the $[X^2\Sigma^+_{1/2u}(1/2^+_u)]n\ell\lambda_p$-based Rydberg states where new experimental data are of most immediate importance. Both areas require new spectra from the $a^3\Sigma_u^+(1_u^{\pm}, 0_u^-)$ state. The first involves obtaining two-photon spectra of sufficient quality to characterize excited Rydberg states of u symmetry, and the second pertains to obtaining one-photon spectra with increased vibrational band development. Results from both these areas are necessary to better understanding the Rydberg structures in the region of R near R_e of $Rg_2^+(X^2\Sigma_u^+)$ and to correlate these structures with observations in the larger-R regions leading eventually to dissociation.

There are two Ne_2 specific areas, outlined in the *Ne_2* section, that would clearly benefit from additional efforts. One involves determining the nature of the Q-branch intensity anomaly in the $np\pi\ ^3\Pi_g$ – a (0–0) series, while the other involves application of coupled-channel approaches to characterizing the complex spectral structures observed within a thousand or so wavenumbers on both sides of the $X^2\Sigma_u^+$, v = 0 ionization limit.

There are several areas for improvement outlined in the *Ar_2* section, but the one of most importance involves unequivocal assignment of the Rydberg series currently labeled as belonging to the $[X^2\Sigma_u^+(1/2_u^+)]nf\lambda_u$-based triplet series (see the *Ar_2* section). Obvious initial needs include new rotationally resolved spectra for the next higher members of the "$[X^2\Sigma_u^+(1/2_u^+)]nf\lambda_u\ ^3\Pi_g,\ ^3\Sigma_g^+$" ← $a^3\Sigma_u^+(1_u^{\pm}, 0_u^-)$ (0–0) transitions (n = 7 and 8 for the current n indexing system), as well as for the first member of the "$[X^2\Sigma_u^+(1/2_u^+)]6f\delta_u\ ^3\Delta_g$" ← a (0–0) transitions. The labels in quotations represent the theory-based labeling discussed in the *Ar_2* section.

For Kr_2, the most critical initial need is for the unequivocal assignment of the four series (Y, Z, P, X) tentatively assigned in the *Kr_2* section. This process will require rotationally resolved spectra for at least the most *easily accessible* low-n member of each of these series, which probably will prove to be transitions from the set $[X^2\Sigma_u^+(1/2_u^+)]np\lambda_u\ 3\Sigma_g{}^+(1_g^{\pm}, 0_g^-)$, $^3\Pi_g(2_g^{\pm}, 1_g^{\pm}, 0_g^{\pm})$ ← a (0–0)

© 2004 NRC Canada

and $nf\lambda_u$ $^3\Delta_g(2_g^{\pm})$, $^3\Pi_g(2_g^{\pm}, 1_g^{\pm}, 0_g^{\pm})$, $^3\Sigma_g^+(1_g^{\pm}, 0_g^-) \leftarrow$ a (0–0). This area of Kr_2 assignments will also benefit from unique assignments for several Rydberg series in Ar_2 discussed in the preceding paragraph.

As implied in the *Xe_2* section, a completely new, much more extensive database for transitions to states associated with $[X^2\Sigma_u^+(1/2_u^+)]np\lambda_p$ and $nf\lambda_p$ from the $a^3\Sigma_u^+(1_u^{\pm}, 0_u^-)$ state will be a starting point, to be followed by Xe_2 data of the types discussed previously which are representative of that necessary for all of the rare gas dimers heavier than He_2. In all cases, the highest practical resolution will be useful, and most Rydberg series assignments will likely rely on analogies with the lighter Rg_2 molecules as well as theoretical results.

A study of the $A^2\Pi/B^2\Sigma^+ - X^2\Sigma^+$ band systems of calcium monohydride (CaH) using a supersonic molecular beam source and laser-induced fluorescence detection[1]

T.C. Steimle, Jamie Gengler, and Jinhai Chen

Abstract: The high-resolution laser-induced fluorescence spectrum of a molecular beam sample of calcium monohydride (CaH) in the region of the strongly overlapped (1,0) $A^2\Pi - X^2\Sigma^+$ and (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ band systems near 630 nm and the (0,0) $A^2\Pi - X^2\Sigma^+$ band system near 690 nm have been recorded and analyzed. The spectral features exhibit a small splitting that is attributed to proton magnetic hyperfine interaction in the $X^2\Sigma^+(v = 0)$ state. The energy levels of the $A^2\Pi(v = 0)$ vibronic state were modeled using a traditional "effective" Hamiltonian approach, whereas those for the interacting $A^2\Pi(v = 1)/B^2\Sigma^+(v = 0)$ vibronic levels were modeled by augmenting the traditional effective Hamiltonian with terms to account for local perturbations. An interpretation of the field-free parameters is presented.

Key words: calcium monohydride, molecular beam, fluorescence.

Résumé : On a enregistré et analysé le spectre de fluorescence induite au laser et à haute résolution d'un échantillon à l'état de faisceau moléculaire du monohydrure de calcium (CaH) dans la région de fort recouvrement des systèmes de bandes (1,0) $A^2\Pi - X^2\Sigma^+$ et (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ près de 630 nm et du système de bande (0,0) $A^2\Pi - X^2\Sigma^+$ près de 690 nm. Les caractéristiques spectrales présentent un faible dédoublement qui a été attribué à l'interaction hyperfine magnétique du proton dans l'état $X^2\Sigma^+(v = 0)$. On a développé un modèle des niveaux d'énergie de l'état vibronique $A^2\Pi(v = 0)$ en utilisant une approche traditionnelle d'Hamiltonien effectif alors que ceux des niveaux vibroniques $A^2\Pi(v = 1)/B^2\Sigma^+(v = 0)$ ont été évalués à l'aide d'un modèle qui ajoute à l'Hamiltonien effectif des termes qui tiennent compte des perturbations locales. On présente une interprétation des paramètres à champ nul.

Mots clés : monohydrure de calcium, faisceau moléculaire, fluorescence.

Introduction

Dr. Herzberg was instrumental in the transformation of spectroscopy from a purely phenomenological endeavor to a discipline where high-resolution spectra are now routinely used both as a venue for extracting structure and serving as diagnostic probes of ambient environmental conditions such as temperature, velocity, and magnetic and electric fields. Simple free radical molecules such as calcium monohydride (CaH) are particularly useful molecular probes of ambient fields because of their intense visible transitions, which have readily resolved rotational structure, and because the electronic states involved in these transitions have sizable electric and magnetic dipole moments. The evolution of the understanding of the spectroscopy and associated quantum levels of CaH, which consist of three distinct periods, is a case study of this maturation of the discipline. The first period of this process began nearly a century ago with the identification of the visible and near-UV spectrum of CaH in the sun by Olmsted (1) and soon thereafter in the laboratory by Eagle (2). The unusual fine structure on the electronic band systems, which could readily be resolved with the spectrographs of the day, prompted notable spectroscopists to pursue the analysis of the near-UV $C^2\Sigma^+ - X^2\Sigma^+$ (3) and visible $A^2\Pi - X^2\Sigma^+$ and $B^2\Sigma^+ - X^2\Sigma^+$ band systems (4). The early developments of the theory associated with the rotational and spin-orbit mixing of electronic states (i.e., Born–Oppenheimer breakdown) in open shell molecules, most notably by Mulliken and Christy (5), were motivated in a large part by attempts to explain this fine structure. CaH is ideal for the development of this theory because to a first approximation the $A^2\Pi$ and $B^2\Sigma^+$ states are described by a single configuration that differs solely in the occupation of either a calcium centered $4p(\pi)$ or $4p(\sigma)$ orbital, respectively. The Born–Oppenheimer breakdown is manifested as a splitting of rotational energy levels in the $A^2\Pi$ state (i.e.,

the Λ-doubling) and in the $B^2\Sigma^+$ state (i.e., the ρ-doubling). The Mulliken and Christy (5) formulas for the Λ- and ρ-doubling are the first application of the seminal theoretical work done by Hill and Van Vleck (6) and Van Vleck (7) on development of "effective" Hamiltonian methods, which are widely applied today in spectroscopy (8). Consequently, CaH is extensively used as a pedagogical example in Herzberg's 1939 monograph on diatomic molecules (9) because even at that early date in the history of spectroscopy the well-resolved visible and near-UV band systems had been subjected to more than 30 years of recording and modeling.

The second period of activity in the study of the visible spectrum of CaH began in the late 1960s. On the analysis front, Veseth (10, 11) extended Van Vleck's approach to fourth order and used the resulting expressions in an attempt to fit the previously recorded data. The derived analytical formulas were not satisfactory for modeling the spin splitting in the $A^2\Pi(v = 1)$ state. These formulas, as well as the previously derived lower-order formulas, are restricted to cases where the separation between the interacting $^2\Pi$ and $^2\Sigma$ states is large compared with the spin-orbit induced separation between the $^2\Pi_{1/2}$ and $^2\Pi_{3/2}$ components. The lowest rotational level of the $B^2\Sigma^+(v = 0)$ state is only approximately 20 cm^{-1} below the lowest rotational level of the $A^2\Pi_{3/2}(v = 1)$ state while the spin-orbit splitting between the $A^2\Pi_{1/2}$ and $A^2\Pi_{3/2}$ components is approximately 80 cm^{-1}, precluding the use of these expressions for the spectral analysis.

On the experimental front during this same period, high-resolution absorption spectra in the visible region were recorded (12–14). The Stockholm group (13, 14) made significant progress on the analysis of these spectra by abandoning the conventional effective Hamiltonian method and explicitly considering $A^2\Pi(v)/B^2\Sigma^+(v)$ and $A^2\Pi(v+1)/B^2\Sigma^+(v)$ interactions. A satisfactory modeling of the energy levels for the problematic $A^2\Pi(v = 1)$ and $B^2\Sigma^+(v = 0)$ states could only be achieved by excluding the low rotational levels ($J < 10.5$) (14). The first laser excitation spectroscopy measurements were performed during this period (15), which assisted in the assignment of the existing spectra. This period culminated in a grand analysis performed by Martin (16) in which new features in the earlier recorded absorption spectra were assigned and others reassigned based upon analysis of the polarization of laser-induced fluorescence signals. The modeling of the energy levels required more than 50 parameters to fit 655 term values for the $A^2\Pi(v = 0, 1, 2, 3)/B^2\Sigma^+(v = 0, 1, 2, 3) - X^2\Sigma^+(v = 0, 1, 2, 3)$ band systems. Numerous anomalies between the predicted and observed intensities were noted particularly for the (1,0) $A^2\Pi - X^2\Sigma^+$ and (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ band systems where, for example, the R_2 branch features of the (1,0) $A^2\Pi - X^2\Sigma^+$ were missing.

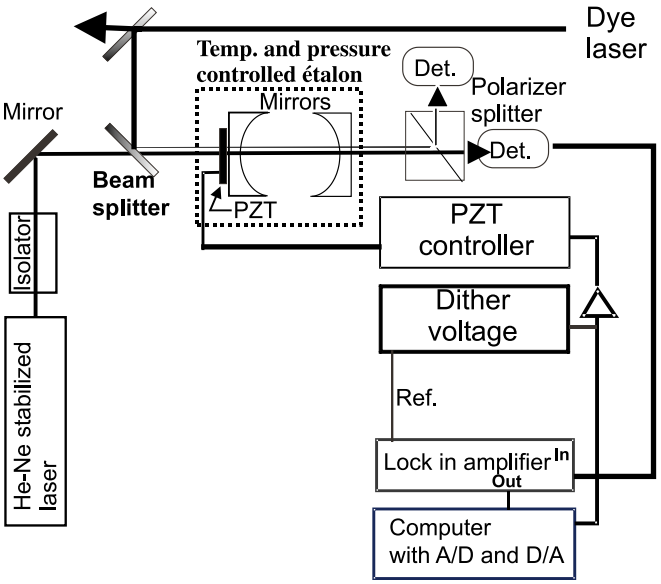
The third and current period of the spectroscopy of CaH has been motivated in part by the desire to generate ultracold molecules (17, 18) as well as the speculation that CaH may be used as a probe of magnetic fields in astrophysical sources (19). In experiments by Dolye and co-workers (17, 18), CaH molecules were generated by laser ablation of solid CaH_2 and cooled by thermalizing collisions with a ^3He buffer gas at approximately 0.4 K and the low magnetic field seeking states were subsequently trapped. In all previous spectroscopic studies the CaH sample had been produced at temperatures of 900 °C or greater, which, for the most part, had precluded the observation of the spectral features associated with low rotational levels. On the contrary, the very low rotational temperature of the CaH sample in the magnetic trap reduced the overlapped (1,0) $A^2\Pi - X^2\Sigma^+$ and (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ band systems to a few branch features associated with the very lowest rotational level of the $X^2\Sigma^+(v = 0)$ state. The Zeeman effect of the R_1 (0.5) branch feature in the intense (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ band system was used as a diagnostic for determining the magnetic field in the trap. In modeling the Zeeman effect the interaction between the nearly degenerate $A^2\Pi(v = 1)$ and $B^2\Sigma^+(v = 0)$ states was accounted for explicitly in a fashion similar to Martin (16), but expanded to include the mixing due to the Zeeman operator. The orbital and spin gyromagnetic ratios (g_L and g_S, respectively) were held fixed to 1 and 2.0023. In reality, these values should be considered as adjustable parameters of the effective Hamiltonian operator and measurements of the magnetic induced shifts for additional branch features are required to fully determine the parameters of the Zeeman operator. An interesting result of the analysis was that the orbital angular momentum factor that describes mixing between the $A^2\Pi(v = 1)$ and $B^2\Sigma^+(v = 0)$ states, $\langle A^2\Pi \mid \hat{L}^+ \mid B^2\Sigma^+ \rangle$, was determined to be approximately a factor of two smaller than that predicted for a $4p(\pi)/4p(\sigma)$ "pure precession" pair of electronic states. A similar conclusion was reached in the analysis of the field-free spectrum (16). In support of the magnetically trapped measurements, interaction potentials for the He–CaH system has been calculated (20) and used for collision cross-section predictions (21). To access the accuracy of the interaction potentials the dipole moment at the equilibrium separation ($\mu(r_e)$) of the $X^2\Sigma^+$ state was calculated (= 0.9123 a.u.).

Recently, the first molecular beam study of CaH was reported (22). In this work on the (1 + 1′) resonance-enhanced multiphoton ionization (REMPI) spectrum, the (0,0) $A^2\Pi - X^2\Sigma^+$ and (1,0) $B^2\Sigma^+ - X^2\Sigma^+$ bands were recorded and analyzed. The overlapped and more problematic (1,0) $A^2\Pi - X^2\Sigma^+$ and (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ bands were excluded. The beam was generated by skimming the free jet expansion output formed by a laser ablation of solid calcium in the presence of a helium–H_2 pulsed supersonic expansion. The spectral resolution of approximately 0.08 cm^{-1} was insufficient to resolve much of the fine and magnetic hyperfine structure. Inconsistencies with the measured transition frequencies and those obtained by Hulthén (4) for the (0,0) $A^2\Pi - X^2\Sigma^+$ band system and with those obtained by Berget al. (15) for the (1,0) $B^2\Sigma^+ - X^2\Sigma^+$ band system were noted.

Other spectroscopic studies relevant to the analysis performed here are the millimeter wave, pure rotational, spectroscopy of the $X^2\Sigma^+$ state (23, 24), the sub-Doppler optical spectroscopic study of the (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ band system (25) and the FT-IR emission study of the vibrational transitions of the $X^2\Sigma^+$ state (26). A combined fit of all the data for the $X^2\Sigma^+$ state was performed by the University of Waterloo group and is presented in ref. 26 as is a more extensive review of the spectroscopy. Our ultimate goal is to fully characterize the optical Stark and Zeeman effects in the visible band systems of CaH. The resulting magnetic and electric dipole moments for the ground and excited electronic states are needed before CaH can be used as a probe

© 2004 NRC Canada

of fields both in electrostatic traps and astrophysical sources (27). A prerequisite for the Stark and Zeeman studies is the recording and analysis of the near natural line width limit, field-free, spectrum of a supersonic molecular beam sample of CaH and a subsequent understanding of the energy level pattern of the low rotational features. The vexing issue of modeling and interpreting the anomalous ρ-type and Λ-type doubling in the $B^2\Sigma^+(v = 0)$ and the nearly degenerate $A^2\Pi(v = 1)$ states, respectively, needs to be accomplished.



Experimental

A modified version of the laser ablation – supersonic expansion production scheme used in the REMPI measurement (22) was selected for sample preparation. A variable speed rotating Ca metal rod was irradiated by the third harmonic (355 nm) light originating from a Q-switched Nd:YAG laser operating at approximately 10 mJ/pulse. The 20 Hz pulses were focused onto the Ca sample with a 0.5 m focal length quartz lens. A commercial solenoid type valve was used to introduce an inert gas – H_2 mixture such as to entrain and react with the laser-vaporized metal. Initially a 5%–10% mixture of H_2 gas in Ar was employed, as done previously in our laboratory, but yielded very weak CaH LIF signals. Following the procedure of ref. 22, a H_2–He mixture was used. Although the production efficiency increases with the H_2:He ratio, the rotational temperature also increases. In most cases a 50:50 mixture with a backing pressure of approximately 2400 kPa was selected. A 5 mm diameter skimmer, situated approximately 15 cm downstream from the ablation source, separated the two compartments of the differentially pumped chambers of the molecular beam apparatus. Typical operating pressures of approximately 5×10^{-5} torr and 1×10^{-6} torr (1 torr = 133.322 Pa) for the source and detection chambers, respectively, were maintained. The gas pulses were variably timed relative to the Nd:YAG ablation pulses to optimize production of CaH.

Two types of spectra were recorded: (*i*) broad survey scans (>100 cm^{-1}) using a continuous wave, multilongitudinal mode, linear dye laser, which utilized a birefringent filter for wavelength tuning; (*ii*) narrow scans (<1 cm^{-1}) using a stabilized, single longitudinal mode, continuous wave ring dye laser. In both cases, the dye laser radiation intersected the molecular beam sample at a 90° angle 10 cm downstream from the skimmer. The bandwidths of the linear and ring dye laser systems are approximately 5 GHz and 10 KHz, respectively. The survey scans were recorded using powers of approximately 300 mW, whereas in the high-resolution scans the power was reduced to approximately 10 mW for the intense (0,0) $A^2\Pi - X^2\Sigma^+$ and (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ band systems, and 50 mW for the weaker (1,0) $A^2\Pi - X^2\Sigma^+$ system to minimize power broadening.

The resulting laser-induced fluorescence was collected and collimated with a lens assembly and directed through a band-pass filter to minimize background light associated with the ablation plasma. The (1,0) $A^2\Pi - X^2\Sigma^+$ and (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ bands both absorb near 637 nm, but while the (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ system fluorescence is primarily at the absorbing wavelength, the (1,0) $A^2\Pi - X^2\Sigma^+$ band preferentially fluoresces at 690 nm corresponding to the (1,1) $A^2\Pi - X^2\Sigma^+$ system emission. The (0,0) $A^2\Pi - X^2\Sigma^+$ band system primarily fluoresces at the 690 nm excitation wavelength. Therefore, a ±10 nm filter centered either at 640 or 690 nm was used to process the signal. The filtered laser-induced fluorescence was detected via a cooled photomultiplier tube and processed using gated, single-photon, counting techniques.

Fig. 1. A block diagram of the actively stabilized confocal étalon used for extrapolation between I_2 wavelength calibration features.

The wavelength calibration of the broadband scans relied solely on a commercial wavemeter, which is accurate to ±0.01cm^{-1}. The single-frequency, high-resolution scans required simultaneous monitoring of the CaH LIF signal and the absorption spectrum of a heated gaseous I_2 cell for wavelength calibration (28, 29). The number of precisely measured I_2 features is relatively sparse in portions of the desired spectral range. Simultaneous recording of the transmission of two confocal étalons assisted the required long wavelength extrapolation from I_2 calibration lines to the CaH LIF features. One étalon, depicted in Fig. 1, was thermally stabilized, evacuated, and with 10 cm confocal optics whose mirror spacing was actively controlled by monitoring the transmission of a frequency stabilized He–Ne laser. Application of a variable voltage to a lead zirconate titanate (PZT) crystal attached to one of the confocal mirrors was used to adjust the spacing. A small, approximately 800 Hz, dithering voltage modulated the He–Ne laser transmission. The modulated transmission intensity was detected with a photodiode and used as input to a commercial lock-in amplifier. The output of the lock-in amplifier was monitored with a microcomputer and a correction voltage sent to the driving electronics of the PZT crystal to keep the He–Ne transmission intensity constant. The free spectral range (fsr) of this étalon (= 753.58 MHz) was very accurately determined by simultaneously recording the cw-dye laser transmission and the LIF signal from the $R_{11b}(J = 1)$ and $P_{11b}(J = 3)$ branch features of the (0,0) $B^3\Pi - X^3\Delta$ band system of TiO. The method for production of beams of TiO are described elsewhere (30). These two spectral features share the common $J = 2$ level in the $B^3\Pi(v = 0)$ state making the separation between the two spectral features the difference between the

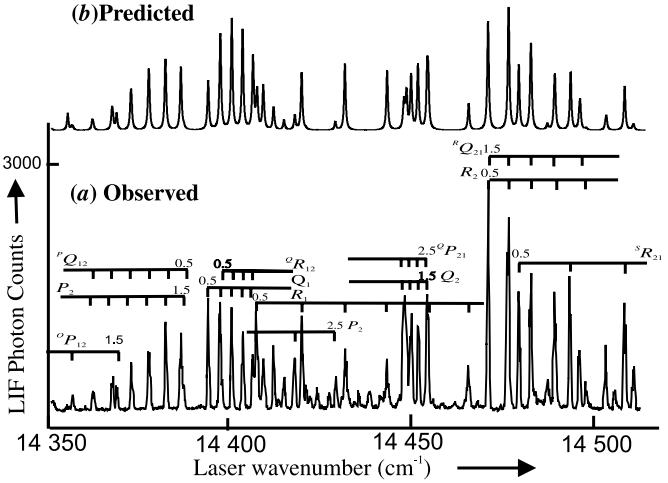
Fig. 2. The low-resolution LIF spectrum of the (0,0) $A^2\Pi - X^2\Sigma^+$ band system of CaH. The fluorescence was filtered using a ±10 nm band pass filter centered at 690 nm. The prediction was obtained using the final optimized parameters (Table 4), a rotational temperature of 70 K, and a Lorentzian function having a FWHM line width of 15 GHz.



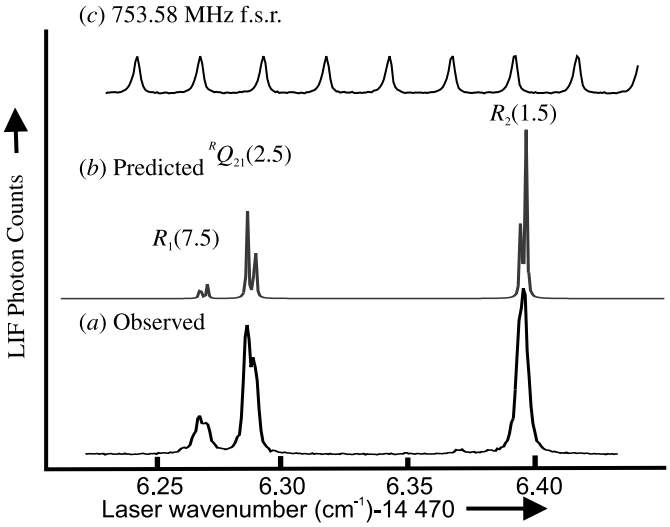


Fig. 3. A portion of the observed and calculated high-resolution LIF spectra of the (0,0) $A^2\Pi - X^2\Sigma^+$ band system of CaH in the region of the $R_2(1.5)$ and $^RQ_{21}(2.5)$ branch features. The predicted spectrum was obtained using the optimized set of spectroscopic parameters, a rotational temperature of 70 K, and a Lorentzian function having a FWHM line width of 40 MHz.

lower energy parity components of the $J = 1$ and $J = 3$ levels of the $X^3\Delta(v = 0)$ state. This spacing has been very precisely measured to be 158281.707(5) MHz (31). A second, unstabilized, 1 m confocal étalon (fsr = 74.5 MHz) was used to extrapolate between transmission peaks of the 10 cm, stabilized, confocal étalon.

Observations

A low-resolution LIF survey scan in the region of the (0,0) $A^2\Pi - X^2\Sigma^+$ band system is presented in Fig. 2. Twenty ablation pulses at a given excitation wavelength were co-added and a 25% H_2–He mixture employed. The low rotational energy levels of both the $X^2\Sigma^+(v = 0)$ and $A^2\Pi(v = 0)$ states exhibit a pattern typical of a molecule near the *case* $b_{\beta J}$ and *case* $a_{\beta J}$ coupling scheme limit, respectively, because in both states the proton hyperfine interaction is much smaller than that of fine structure and, in the case of the $A^2\Pi$ state, the spin-orbit interaction is much larger than the rotational spacing. The rotational levels of the $X^2\Sigma^+$ state, which has no electronic orbital angular momentum, are labeled by the approximately good quantum number N, associated angular momentum of the nuclear framework rotation. These levels are spilt into a pair (ρ-doubling) due to the coupling of the electronic spin and rotational angular momenta and are labeled by the intermediate quantum number J ($\equiv N \pm S$). By convention "F_i" indices are used to label the energy order of the various electron spin-split eigenvalues for a given J (9). In a doublet electronic state ($S = 1/2$), F_1 and F_2 label the lowest and highest energy levels for a given J, respectively, and each ρ-doublet consist of an F_1/F_2 pair. The rotational levels of the $A^2\Pi$ state separate into two widely spaced (≈80 cm^{-1}) groups due to the strong coupling of the electronic spin to the nuclear frame via spin-orbit interaction. The two groups are distinguished by the magnitude of the sum of the projection of electronic orbital angular momentum (Λ) and the spin angular momentum (Σ) designated with the subscript $|\Omega|(\equiv\Lambda \pm \Sigma)$. All the rotational levels of the $A^2\Pi_{1/2}$ group correspond to the coupling that produces values for J that correlate to $N + S$, whereas all the levels of the $A^2\Pi_{3/2}$ group correspond to the coupling that produces J values that correlate to $N - S$. The $A^2\Pi$ state has a positive spin-orbit coupling parameter making all the levels in the $A^2\Pi_{1/2}$ group have an F_1 index and those for the $A^2\Pi_{3/2}$ group an F_2 index.

The branch designation of Fig. 2 is the conventional labeling scheme of $^{\Delta N}\Delta J_{F_i' F_i''}$ (9) with the subscripts F_i taking on the corresponding "i" values of 1 or 2. There are 12 possible branch features: six branch features for the $A^2\Pi_{1/2} - X^2\Sigma^+$ sub-band corresponding to the $\Delta J = -1$, 0, and +1 with $F_i'' = 1,2 \rightarrow F_i' = 1$ transitions, and six branch features for the $A^2\Pi_{3/2} - X^2\Sigma^+$ sub-band corresponding to the $\Delta J = -1$, 0 and +1, $F_i'' = 1,2 \rightarrow F_i' = 2$ transitions. All 12 branches are readily identified in Fig. 2. Also presented in Fig. 2 is a prediction of the LIF spectrum for the (0,0) $A^2\Pi - X^2\Sigma^+$ band system, which agrees very well with the observation. The prediction was obtained using the final optimized parameters, a rotational temperature of 70 K, and a Lorentzian function having a full width half maximum (FWHM) line width of 15 GHz. Details of the prediction procedure are given in the next section. The relative intensities of the predicted spectral features show some deviation from the observation particularly for high-J branch features and are attributed to saturation effects associated with the relatively intense (>300 mW) excitation radiation.

The high-resolution scans of the low rotational features ($J'' < 6.5$) of the (0,0) $A^2\Pi - X^2\Sigma^+$ band system were recorded. Illustrated in Fig. 3 are the measured and predicted LIF spectra of the R_2 (1.5) and associated satellite $^RQ_{21}(2.5)$ branch features. The splitting between the R_2 (1.5) and $^RQ_{21}$ (2.5) branch features (≈3260 MHz) is due to the ρ-doubling in the $N = 2$ levels of the $X^2\Sigma^+(v = 0)$ state. The partially re-

[a]The total angular momentum for the $A^2\Pi$ state (F') value was obtained from the $\Delta F = \Delta J$ relationship.
[b]Calculated value. Feature not measured.

solved splitting of the $^RQ_{21}(2.5)$ branch feature (≈50 MHz) and the broadening of the R_2 (1.5) feature are due to the proton magnetic hyperfine interaction in the F_1 and F_2 components, respectively, of the $N = 2$ rotational level in the $X^2\Sigma^+$ state. It was observed that the proton magnetic hyperfine interaction is larger in the F_1 levels than the F_2 levels and decreases with increasing N. The predicted spectrum of Fig. 3 was obtained using the optimized set of spectroscopic parameters, a rotational temperature of 70 K, and a FWHM line width of 40 MHz. The resulting complete set of measured transition frequencies, quantum number assignments, and deviation from predicted frequencies are given in Table 1. These values are in general agreement, but approximately 100 times more precisely determined, with those of refs. 13 and 16. Neither the branch assignments nor transition frequencies agree with those of the REMPI measurements of ref. 22.

The low-resolution LIF survey scan in the region of the intense (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ band system is presented in Fig. 4. Features in all six possible branches are readily identified.

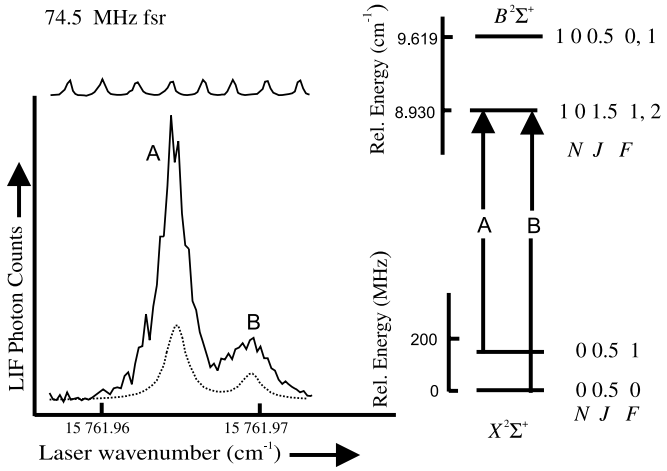
Fig. 4. The low-resolution LIF spectrum of the overlapped (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ and (1,0) $A^2\Pi - X^2\Sigma^+$ band systems of CaH. The fluorescence was filtered using a ±10 nm band pass filter centered at 640 nm that selectively detects the fluorescence from the (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ band system. The predicted spectrum was obtained using the final optimized parameters, a rotational temperature of 70 K, and a Lorentzian function having a FWHM line width of 15 GHz.

The predicted spectrum was obtained using the final optimized parameters, a rotational temperature of 70 K, and Lorentzian line width of 15 GHz (FWHM). The agreement between the predicted and observed spectra is not as good as in the case of the (0,0) $A^2\Pi - X^2\Sigma^+$ band system, particularly for the features at the low wavenumber end of the spectrum. This can be attributed in part to the fact that the transmission of the 640 ± 10 nm filter is centered at this portion of the spectrum. In addition, this portion of the spectrum may have some features from the overlapping (1,0) $A^2\Pi_{1/2} - X^2\Sigma^+$ band, which gain transition intensity due to mixing.

The observed and predicted high-resolution spectrum on the $R_1(0.5)$ spectral feature, which was used to probe the magnetic field in the trapping experiments (18), is presented in Fig. 5 along with the associated energy level. The approximate 155 MHz splitting of this spectral feature is due to the proton magnetic hyperfine splitting between the $F = 0$ and $F = 1$ (F = total angular momentum) of the $N = 0$, $J = 0.5$ level of the $X^2\Sigma^+(v = 0)$ state. This splitting was not resolved in the magnetic trap experiments. Both the frequency and intensity of the predicted spectrum (dashed line) are in good agreement with the observation. The measured and predicted high-resolution spectra of the $R_2(0.5)$ and associated satellite $^RQ_{21}(1.5)$ branch features of the (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ band system are presented in Fig. 6. The splitting between the $R_2(0.5)$ and $^RQ_{21}(1.5)$ branch features (≈1950 MHz) is due to the ρ-doubling in the $N = 1$ levels of the $X^2\Sigma^+(v = 0)$ state. The partially resolved splitting of the $^RQ_{21}(1.5)$ branch feature (≈60 MHz) and the broadening of the $R_2(0.5)$ feature are due to the proton magnetic hyperfine interaction in the F_1 and F_2 components, respectively, of the $N = 1$ rotational level in the $X^2\Sigma^+$ state. The predicted spectra of Figs. 5 and 6 were obtained using the final optimized parameters, a rotational temperature of 70 K, and Lorentzian line width of 40 MHz (FWHM). The resulting complete set of measured

Fig. 5. A portion of the observed and predicted (dashed line) high-resolution LIF spectra of the $R_1(0.5)$ branch feature of the intense (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ band system and associated energy levels. The energy level diagram was calculated using the parameters of ref. 23 for the $X^2\Sigma^+(v = 0)$ state and those of Table 5 for the interaction $B^2\Sigma^+(v = 0)/A^2\Pi(v = 1)$ systems.



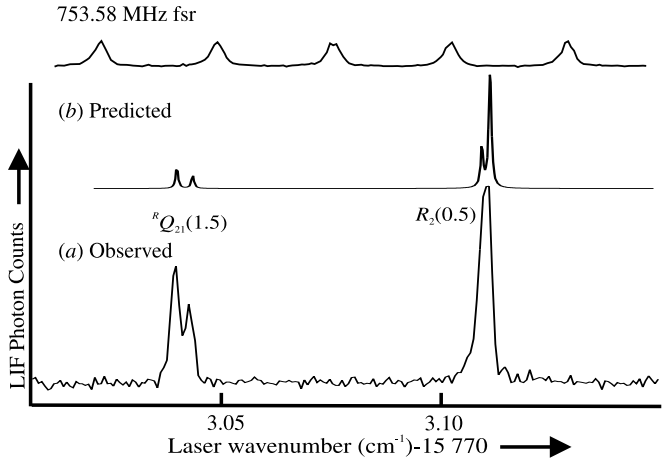


Fig. 6. The measured and predicted high-resolution spectra of the $R_2(0.5)$ and associated satellite $^RQ_{21}(1.5)$ branch features of the (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ band system.

transition frequencies, quantum number assignments, and deviation from predicted frequencies for the (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ band system is given in Table 2.

The low-resolution LIF survey scan in the region of the weak (1,0) $A^2\Pi - X^2\Sigma^+$ band is presented in Fig. 7. The Franck–Condon factor for this band is approximately a factor of 100 less than that of the (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ band. Most of the 12 possible branch features can be identified. The measured and predicted LIF spectra of the $R_2(J'')$ and associated satellite $^RQ_{21}(J''+1)$ branch features of the weak (1,0) $A^2\Pi - X^2\Sigma^+$ band are presented Fig. 8. The predictions were done using the optimized parameters, a rotational temperature of 70 K, and Lorentzian line width of 50 MHz (FWHM). These two branch features can unambiguously be assigned because they are separated by the very accurately determined ρ-type doubling of the $X^2\Sigma^+(v = 0)$ state. Unlike the identical transitions for the (0,0) $A^2\Pi - X^2\Sigma^+$ band (see

[a]The total angular momentum for the $B^2\Sigma^+$ state (F') value was obtained from the $\Delta F = \Delta J$ relationship.

Fig. 7. The low-resolution LIF spectrum of the overlapped (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ and (1,0) $A^2\Pi - X^2\Sigma^+$ band systems of CaH. The fluorescence was filtered using a ±10 nm band pass filter centered at 690 nm that selectively detects the fluorescence from the (1,0) $A^2\Pi - X^2\Sigma^+$ band systems.

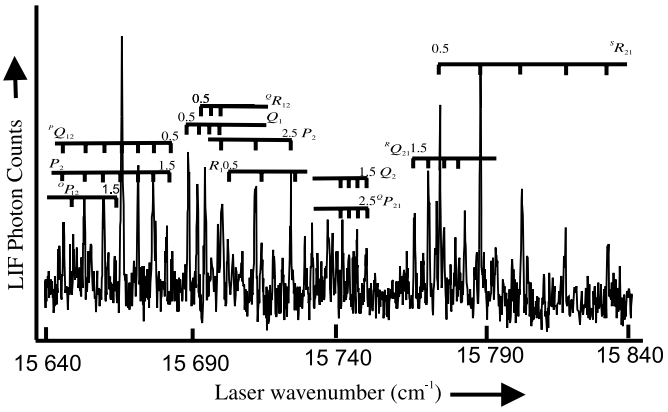

Fig. 3), the prediction does not reproduce the relative intensities. The transition frequency and the relative intensity of the overlapped hyperfine components that compose the R_2 branch features are reproduced, but the intensity of these features relative to the $^RQ_{21}$ (J'' + 1) and other branch features is not reproduced. The R_2 (0.5) feature was not detected and the higher branch features (J'' = 1.5–3.5) grow in intensity. None of the R_2 branch features had previously been identified in the high-temperature spectra (16) suggesting that for the still higher values of J'', where the previous data were most sensitive, the intensity of the R_2 branch becomes small. The resulting complete set of measured transition frequencies and quantum number assignments for the (1,0) $A^2\Pi - X^2\Sigma^+$ band system are given in Table 3.

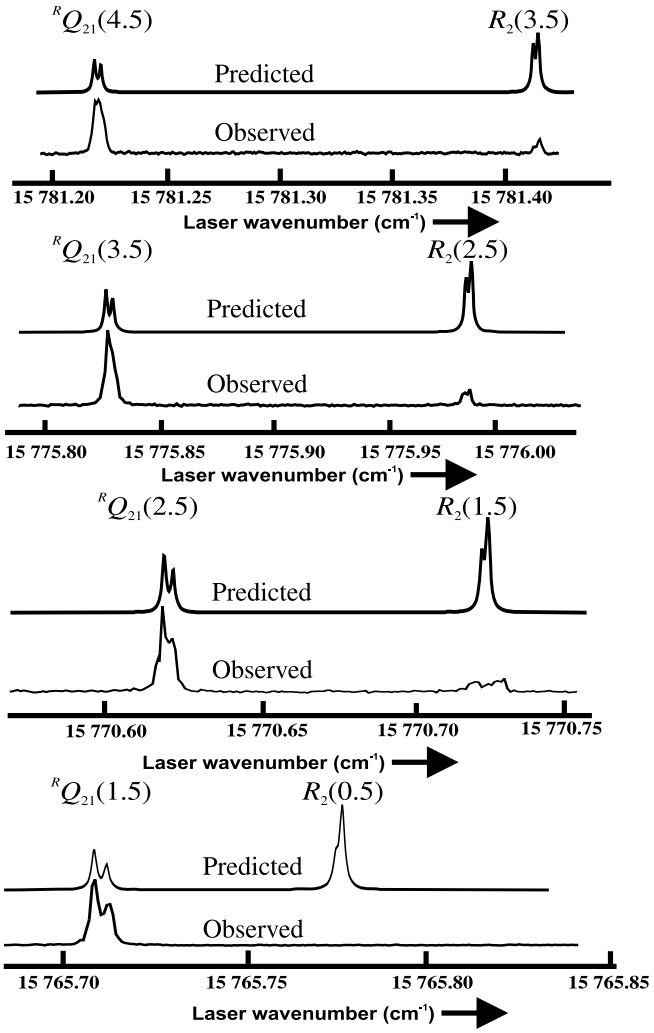
Analysis

The analysis of the (0,0) $A^2\Pi - X^2\Sigma^+$ band system was straightforward. The energy levels of the $X^2\Sigma^+$ were modeled by including the rotation and its centrifugal distortion, the spin-rotation and the magnetic hyperfine interactions (8):



$$[1] \quad \mathbf{H}^{\mathbf{eff}}(^2\Sigma) = B\mathbf{N}^2 - D\mathbf{N}^4 + \gamma\mathbf{N}\cdot\mathbf{S} + b_F\mathbf{I}\cdot\mathbf{S} + c(\mathrm{I_zS_z} - 1/3\mathbf{I}\cdot\mathbf{S})$$

In eq. [1], **N** is the angular momentum operator excluding electronic and nuclear spin, **S** and **I**, respectively. The rotational fine structure parameters B (= 4.2286902 cm^{-1}), D (= 1.851405 × 10^{-4} cm^{-1}), and γ (= 4.3566 ×10^{-2} cm^{-1}) were held fixed to those of ref. 26 and the magnetic hyperfine parameters b_F (= 5.243 × 10^{-3} cm^{-1}) and c (= 1.39 × 10^{-4} cm^{-1}) to those of ref. 23. A 4 × 4 matrix representation, constructed using a *case* $a_{\beta J}$, nonparity basis set, $\Psi = |n\Lambda; S\Sigma;(\mathrm{JI})\mathrm{F}\Omega\mathrm{M_F}\rangle$, was numerically diagonalized to produce the eigenvalues and eigenvectors.

A check of the combination differences revealed that there was no evidence of magnetic hyperfine interaction in the excited $A^2\Pi(v = 0)$ state. The energies of this state were modeled by including the origin, spin-orbit interaction and associated centrifugal distortion correction, rotation and associated centrifugal distortion correction, and the Λ-doubling interaction terms (8):

© 2004 NRC Canada

Fig. 8. Portions of the observed and calculated high-resolution LIF spectra of the (1,0) $A^2\Pi - X^2\Sigma^+$ band system of CaH in the region of the $R_2(J'')$ and associated satellite ${}^RQ_{21}(J'' + 1)$ branch features. The predicted spectrum was obtained using the parameters of Table 5 to calculate the energies of the $A^2\Pi(v = 1)$ state. The anomalous intensity is an unsolved problem.

[2] $$\mathbf{H}^{\mathrm{eff}}(^2\Pi) = T_v + AL_zS_z + 1/2A_D[\mathbf{N}^2L_zS_z + L_zS_z\mathbf{N}^2] + B\mathbf{N}^2 - D(\mathbf{N}^2)^2 + 1/2(p + 2q)(e^{-2i\phi}J_+S_+ + e^{+2i\phi}J_-S_-) - 1/2q(J_+^2e^{-2i\phi} + J_-^2e^{2i\phi})$$

where $J_\pm$ are the shift operators of the total angular momentum in the absence of nuclear spin (**J**). Although the hyperfine splitting was not resolved in the $A^2\Pi(v = 0)$ state, a *case* $a_{\beta J}$, nonparity, basis set was still employed to facilitate intensity calculations. A 8 × 8 matrix representation was constructed and numerically diagonalized to produce the eigenvalues and eigenvectors.

A nonlinear least-squares fitting procedure program was written that used as input initial guesses of the $A^2\Pi(v = 0)$ state parameters, the observed transition frequencies of Table 1, and quantum number assignments of the associated levels. Initial guesses for the Λ-doubling fitting parameters ($p + 2q$ and q) were obtained using the approximate second-order perturbation expressions (32):

[3] $$p \approx 2\frac{\langle A^2\Pi(v = 0)|\,AL_+|B^2\Sigma(v = 0)\rangle\langle B^2\Sigma(v = 0)|BL_-|\,A^2\Pi(v = 0)\rangle}{E(A^2\Pi(v = 0)) - E(B^2\Sigma(v = 0))}$$

and

[4] $$q \approx 2\frac{\langle A^2\Pi(v = 0)\left|BL_+\right|B^2\Sigma(v = 0)\rangle^2}{E(A^2\Pi(v = 0)) - E(B^2\Sigma(v = 0))}$$

The $\langle A^2\Pi|\,AL_+|B^2\Sigma\rangle$ and $\langle A^2\Pi|\,BL_+|B^2\Sigma\rangle$ matrix elements were taken from Martin's paper (16) to be 73.6 cm^{-1} and 6.988 cm^{-1}, respectively. Using the term values of 15 725 cm^{-1} and 16 996 cm^{-1} for the $A^2\Pi(v = 0)$ and $B^2\Sigma^+(v = 0)$ levels results in estimates of $p \approx -0.81$ cm^{-1} and $q \approx -0.077$ cm^{-1}. The centrifugal distortion constant (D) was also held fixed to the value (= 1.896×10^{-4} cm^{-1}) given by Martin (16). The resulting optimized parameters, associated errors, and the correlation coefficients for the $A^2\Pi(v = 0)$ state are given in Table 4.

Modeling the energy levels of the $A^2\Pi(v = 1)/B^2\Sigma^+(v = 0)$ interacting vibronic levels was more complicated because of local perturbations. Based upon the analysis of the (0,0) $A^2\Pi - X^2\Sigma^+$ band system, the $B^2\Sigma^+(v = 0)$ state interacts strongly with the well-separated $A^2\Pi(v = 0)$ state in a predictable fashion. Similar to the treatment of the $A^2\Pi(v = 0)$ levels, this interaction in the $B^2\Sigma^+(v = 0)$ state was described using an effective Hamiltonian by the inclusion of the spin-rotation operator. The second-order perturbation expression predicts that (32):

[5] $$\gamma^{\mathrm{eff}}(B^2\Sigma^+(v = 0)) \approx -p(A^2\Pi(v = 0))$$

The $A^2\Pi(v = 1)$ state interacts strongly with the well-separated $B^2\Sigma^+(v = 1)$ levels and these interactions are accounted for by inclusion of the Λ-doubling interaction terms in the effective Hamiltonian.

The local perturbations arise from the $\langle A^2\Pi(v = 1)|AL_+|B^2\Sigma(v = 0)\rangle$ and $\langle A^2\Pi(v = 1)|BL_+|B^2\Sigma(v = 0)\rangle$ matrix elements, which are approximately a factor 100 and 10, respectively, smaller than the corresponding values for the $A^2\Pi(v = 0)/B^2\Sigma^+(v = 0)$ interaction (16). These interactions only become important because of the very near degeneracy of levels of the $A^2\Pi(v = 1)$ state with those of the $B^2\Sigma^+(v = 0)$ state that have the same total angular momentum and parity. To simultaneously account for local and remote interactions, a 12 × 12 Hamiltonain representation was constructed using the eight non-parity *case* $a_{\beta J}$ basis functions for a $^2\Pi$ state and the four non-parity *case* $a_{\beta J}$ for a $^2\Sigma$ state. The elements of the 4 × 4 block were constructed using the effective operator of eq. [1], and those of the 8 × 8 block constructed using the effective operator of eq. [2]. Matrix elements between the two sets of basis functions were taken from ref. 8 with the adjustable parameters being:

[6] $$M_1 \equiv \langle A^2\Pi(v = 1)\left|BL_+\right|B^2\Sigma(v = 0)\rangle$$

and

[a]The total angular momentum for the $A^2\Pi$ state (F') value was obtained from the $\Delta F = \Delta J$ selection rule.

[7] $$M_2 \equiv \langle A^2\Pi(v = 1)|(A/2 + B)L_+|B^2\Sigma\rangle$$

In the end, the data were not sensitive enough to determine the M_2 parameter and it was constrained to zero. The centrifugal distortion constant (D) for the $A^2\Pi(v = 1)$ and $B^2\Sigma^+(v = 0)$ states were held fixed to the values of 1.901×10^{-4} cm^{-1} and 2.024×10^{-4} cm^{-1}, respectively, given by Martin (16). The resulting optimized parameters, associated errors, and the correlation coefficients for the $A^2\Pi(v = 1)/B^2\Sigma^+(v = 0)$ states are given in Table 5.

Modeling the spectra greatly assisted in the assignment of quantum numbers, particularly in the case of the overlapped (1,0) $A^2\Pi - X^2\Sigma^+$ and (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ band systems. Either a 4×12 or 4×8 *case* $a_{\beta J}$ transition moment matrix for the $A^2\Pi(v = 1)/B^2\Sigma^+(v = 0) - X^2\Sigma^+$ and (0,0) $A^2\Pi - X^2\Sigma^+$ band system, respectively, was constructed. The transition moment was obtained by cross multiplication of the transition matrix by the *case* $a_{\beta J}$ eigenvectors for the $X^2\Sigma^+$ and *case* $a_{\beta J}$ eigenvectors for either the $A^2\Pi(v = 0)$ or the $A^2\Pi(v = 1)/B^2\Sigma^+(v = 0)$ vibronic state. The transition mo-

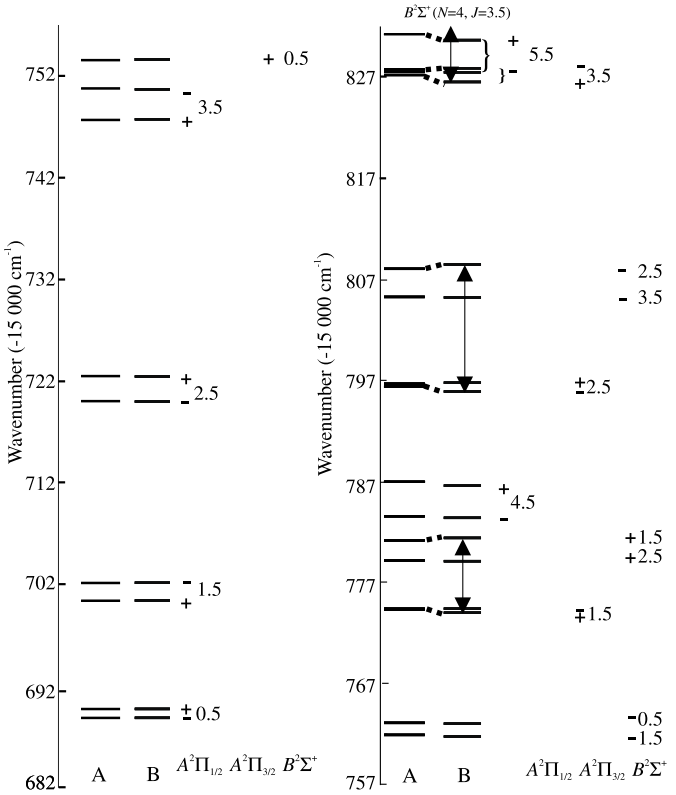
Discussion

The (0,0) $A^2\Pi - X^2\Sigma^+$ band system

The standard deviation of the fit (= 0.004 cm^{-1}) is commensurate with the measurement uncertainties, demonstrating that the effective Hamiltonian operator method is adequate for modeling both the transition frequencies and relative intensities of the low rotational levels of the (0,0) $A^2\Pi - X^2\Sigma^+$ band system. This is in contrast to the findings of refs. 14 and 16, which explicitly include interaction terms evidently because of the inclusion of higher rotational levels. There are no local perturbations in the range of J' (<6.5) investigated. The optimized set of spectroscopic parameters of Table 5 produce term values for the $A^2\Pi(v = 0)$ state that differ from those given in ref. 14 by up to 0.16 cm^{-1} over the range probed. There is no systematic trend in these deviations. The standard deviation of the fit (0.004 cm^{-1}) is a reflection of the standard deviation of the calculated energy levels $A^2\Pi(v = 0)$ state because the ground-state energy levels are very accurately determined.



The Λ-doubling fitting parameters $p + 2q$ (= –0.88336(69) cm^{-1}) and q (= –0.06753(17) cm^{-1}) are in qualitative agreement of those predicted based upon second-order perturbation approximate expressions, which give –0.96 cm^{-1} and –0.077 cm^{-1}, respectively. The values of B and A from ref. 14 are (in cm^{-1}) 4.34769(4) and 79.01(2), which differ from those determined here of 4.31223(6) and 80.326(2), due presumably to the form of the effective Hamiltonian operator.

The overlapped (1,0) $A^2\Pi - X^2\Sigma^+$ and (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ band systems

The standard deviation of the fit (= 0.003 cm^{-1}) is commensurate with the measurement uncertainties, indicating that the combination of using an effective Hamiltonian operator for the remote ($\Delta v = 0$) interactions and an inclusion of the explicit interaction terms for the local ($\Delta v = \pm 1$) interactions between $B^2\Sigma^+$ and $A^2\Pi$ vibronic levels is adequate for modeling the transition frequencies of the low rotational levels of the overlapped (1,0) $A^2\Pi - X^2\Sigma^+$ and (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ band systems. The local perturbations are significant as

Fig. 9. The energy levels of the $B^2\Sigma^+(v = 0)$ and interacting $A^2\Pi(v = 1)$ vibronic states predicted using the optimized parameters of Table 5 without (*a*), and with (*b*), the inclusion of the M_1 term, which accounts for the local perturbations. The strong interactions are indicated by the double-headed arrows.

indicated in Fig. 9, where the predicted energy level diagram with and without the inclusion of the M_1 interaction term is presented. The strong interactions are indicated by double-headed arrows. The most marked effect of the $\Delta v = \pm 1$ interaction is an irregular Λ-doubling in the $A^2\Pi_{3/2}$ levels. A more subtle effect, which was noted by Martin (16), is the switching of the ordering of the Λ-doubling in the $A^2\Pi_{1/2}$ at about $J' = 9.5$.

There are many internal consistencies that demonstrate that the fitting parameters are physically meaningful. First, the Λ-doubling interactions for the $A^2\Pi(v = 1)$ state are very similar to those for the $A^2\Pi(v = 0)$ state, which lacks complication due to local perturbations. Second, the spin rotation parameter for the $B^2\Sigma^+(v = 0)$ follows the predicted relationship of eq. [5]. Finally, the change in the rotational constants for the $A^2\Pi(v = 1)$ and $A^2\Pi(v = 0)$ states is realistic.

Conclusions

After nearly a century since the first detection of CaH, the low rotational energy levels of the $A^2\Pi(v = 0$ and 1) state and the $B^2\Sigma^+(v = 0)$ states have been precisely (± 0.003 cm^{-1}) measured and modeled. The high-resolution LIF study of a molecular beam of CaH has been accomplished, which, along with the field-free frequencies, will facilitate optical Stark and Zeeman measurements that are currently in progress. Modeling of the $A^2\Pi(v = 0)$ state was successfully performed using a conventional effective Hamiltonian operator with a very limited number of terms. The determined spectroscopic parameters are physically meaningful. The energy levels of the $A^2\Pi(v = 1)/B^2\Sigma^+(v = 0)$ interacting system were successfully modeled using a hybrid approach of combining the effective Hamiltonian operator with explicit terms to account for local perturbations. The resulting parameters are consistent with those of the $A^2\Pi(v = 0)$ state. An interpretation of the anomalous intensity of the R_2 branch in the overlapped (1,0) $A^2\Pi - X^2\Sigma^+$ and (0,0) $B^2\Sigma^+ - X^2\Sigma^+$ band systems still needs to be made. This must be due to an intensity cancellation phenomena (33) and not predissociation or local perturbation by a yet to be identified state.

"Spectrum-only" assignment of core-penetrating and core-nonpenetrating Rydberg states of calcium monofluoride[1]

Jeffrey J. Kay, Daniel S. Byun, Jason O. Clevenger, Xing Jiang, Vladimir S. Petrović, Robert Seiler, Jonathan R. Barchi, Anthony J. Merer, and Robert W. Field

Abstract: Rydberg states of calcium monofluoride in the n^* = 17–20 region have been observed by ionization-detected optical–optical double-resonance spectroscopy via the $D^2\Sigma^+$ v = 1 intermediate state. All members of the six core-penetrating Rydberg series in the n^* = 17–20 region and several components of the 17*f* and 17*g* core-nonpenetrating Rydberg states have been assigned. While the assignment of core-penetrating Rydberg states is straightforward without use of an effective Hamiltonian model, "spectrum-only" assignment of core-nonpenetrating states is complicated because strong ℓ-uncoupling causes the core-nonpenetrating states to evolve rapidly from Hund's case (b) to Hund's case (d) coupling. We describe "spectrum-only" assignment procedures, developed in the spirit of Gerhard Herzberg, that can be used to assign optical–optical double-resonance spectra of core-penetrating and core-nonpenetrating Rydberg states using only information contained in the spectrum rather than predictions derived from an effective Hamiltonian model. The ambiguities that arise in the assignment of each class of states are discussed in detail.

Key words: CaF, electric quadrupole moment, Rydberg states, laser spectroscopy.

Résumé : On a observé les états de Rydberg du monofluorure de calcium dans la région de n^* = 17–20, par le biais de l'état intermédiaire $D^2\Sigma^+$ v = 1, en faisant appel à spectroscopie de double résonance optique-optique détectée par ionisation. On a attribué tous les membres des six séries de Rydberg pénétrant le coeur, dans la région de n^* = 17–20, ainsi que plusieurs composants des états 17*f* et 17*g* de Rydberg ne pénétrant pas le coeur. Alors que l'attribution des états de Rydberg pénétrant le coeur peut se faire facilement sans avoir recours à l'utilisation d'un modèle à hamiltonien effectif, l'attribution uniquement sur la base du spectre des états ne pénétrant pas le coeur est compliquée par le fait que le fort découplage ℓ amène les états ne pénétrant pas le coeur à se transformer rapidement d'un couplage de Hund d'un type (b) à un type (d). On décrit une méthode d'attribution des états qui se fait sur la base uniquement du spectre, qui a été développée dans l'esprit de Gerhard Herzberg, qui peut être utilisée pour attribuer les spectres de double résonance optique-optique d'états de Rydberg pénétrant ou ne pénétrant pas le coeur et qui ne fait appel qu'aux informations contenues dans le spectre plutôt qu'aux prédictions obtenues à partir d'un modèle à hamiltonien effectif. On discute en détail des ambiguïtés rencontrées dans l'attribution de chacune des classes d'état.

Mots clés : CaF, moment quadripolaire électrique, états de Rydberg, spectroscopie laser.

[Traduit par la Rédaction]

Introduction

Characterization of the mechanisms of electron ↔ nuclear energy exchange is central to the development of global models of molecular electronic structure and intramolecular dynamics. Molecular Rydberg states are instructive because the orbital and precessional motions of a single electron are weakly coupled to the rotational and vibrational motions of the molecular ion core (1–18). Because of this weak coupling, and because the frequencies of electronic and rotational motions are systematically adjustable, it is possible to tune specific motions of these two molecular subsystems into resonance. Observation of resonances, through spectroscopic perturbations between electronic and nuclear motions, allows for measurement of the coupling strengths between molecular subsystems, namely the multipole moments and

polarizabilities of the ion core. These are the fundamental mechanisms by which electrons communicate with nuclei at long range.

The alkaline-earth monohalides (especially CaF, CaCl, and BaF) are important in the context of electron ↔ nuclear energy exchange because they have the largest multipole moments of any class of molecules studied to date (19, 20). Because the ion-core multipole moments are so large, the signatures of electron ↔ nuclear interactions are easily recognizable. However, the Rydberg states that appear in the spectra of these molecules are often severely intertwined, and many nominally allowed rotational transitions that terminate on these states are unexpectedly and systematically weak. Disentanglement of the spectra of these Rydberg states by rigorous spectral assignment procedures is a necessary prerequisite for the location of perturbations and comparison of experimental data with the predictions of theoretical models. Assignment of states based exclusively on information contained in the spectrum, as opposed to an assumed effective Hamiltonian model, minimizes possibilities for misidentification of states. "Spectrum-only" assignment also facilitates detection of tiny level shifts and splittings and circumvents some ambiguities associated with overly flexible effective Hamiltonian and multichannel quantum defect theory (MQDT) fit models. The Rydberg states of the alkaline-earth monohalides have been described (21–27) as simple two-body systems consisting of a single optically active electron weakly bound to a closed-shell $^1\Sigma^+$ molecular ion core. The electronic energies of each of the Rydberg states may be expressed by a modified Rydberg formula,

$$[1] \qquad E_{n^*,v^+,N^+} = \mathrm{IP}_{v^+,N^+} - \frac{RZ^2}{n^{*2}}$$

where n^* is the effective principal quantum number (given by $n^* = n - \delta$, where n is an integer and δ is the quantum defect), IP_{v^+,N^+} is the energy of the v^+, N^+ state of the ion core, E_{n^*,v^+,N^+} is the Rydberg energy, R is the Rydberg constant, and Z is the integer charge of the ion core. Molecular Rydberg orbitals may be divided into two classes: "core-penetrating" and "core-nonpenetrating". A Rydberg orbital may be classified as core-penetrating or core-nonpenetrating based on the location of the inner lobe of the Rydberg electron wave function relative to the spatial extent of the ion core r_{core}, defined as the distance from the molecular center of mass to the far side of the more distant atom (treated as a hard-sphere atomic ion) (28). The location of the inner lobe of the electronic wave function may be estimated by approximating the ion-core potential as a hydrogen atom effective radial potential:

$$[2] \qquad V_{\mathrm{eff}}(r) = -\frac{1}{r} + \frac{\ell(\ell+1)}{2r^2}$$

where ℓ is the electronic angular momentum quantum number and r is the distance between the Rydberg electron and the ion-core center of mass. The location of the inner lobe of the electronic wave function is determined by the inner turning point of $V_{\mathrm{eff}}(r)$. Rydberg orbitals are termed "core-penetrating" when the inner lobe of the electronic wave function lies within the spatial extent of the ion core, and "core-nonpenetrating" when the inner lobe is excluded from the core. For example, the inner turning point of $V_{\mathrm{eff}}(r)$ for $n = 3$, $\ell = 2$ occurs at approximately 3.8 au, whereas the inner turning point for $n = 4$, $\ell = 3$ occurs at approximately 8.0 au. For CaF^+, r_{core} is approximately 5.1 au. This indicates that CaF Rydberg orbitals derived from basis states with $\ell \leq 2$ will penetrate the core significantly. Owing to penetration of the core, these orbitals experience the nonspherical electric field of the ion core at short range, resulting in s~p~d mixed character. Orbitals derived from $\ell \geq 3$ basis states do not penetrate the core (with the exception of $f\sigma$) and therefore sample the ion-core electric field exclusively at long range. Core-nonpenetrating orbitals retain nearly pure ℓ character.

That these two classes of Rydberg states experience the ion core profoundly differently is reflected by their angular momentum coupling case, which in turn determines the rotational pattern exhibited by these states in a spectrum (29–32). The core-penetrating states, which include the energetically low-lying Rydberg terminus (or valence) states, are well described in the Hund's case (b) basis set, $|\lambda NSJ\rangle$, in which ℓ is not a good quantum number but λ, the projection of $\vec{\ell}$ along the internuclear axis, remains well defined, and N (total angular momentum apart from spin) is the rotational pattern-forming quantum number. The rotational energy of case (b) states is given by $E_{\mathrm{rot}} = BN(N+1) - \lambda^2$. In contrast, the core-nonpenetrating states are well described in the Hund's case (d) basis set, $|\ell NN^+SJ\rangle$, in which ℓ remains an approximately good quantum number, and N^+ (the total angular momentum of the ion core exclusive of spin) is the rotational pattern-forming quantum number.

Because the core-penetrating states are described in the Hund's case (b) basis and the valence intermediate states from which the Rydberg states are excited are described in either the case (a) or case (b) basis, the core-penetrating states appear in double-resonance spectra in rotational patterns that are relatively simple. Thus, the spectra may be assigned using the traditional method of lower-state rotational combination differences. The ability to assign core-penetrating states in double-resonance spectra by lower-state rotational combination differences is facilitated by the fact that Rydberg states are always excited from an a priori known rotational and e/f-symmetry level of the intermediate valence state. Rigorous assignment is frustrated only when multiple rotational transitions to a common upper state are unobservable because of systematic intensity effects.

The assignment of core-nonpenetrating states is complicated by the fact that the core-nonpenetrating states are better described in Hund's case (d) coupling case. In previous double-resonance studies (33) of the CaF ($n^* = 13$–14 and 17–18) Rydberg states, difficulties were encountered in the rotational assignments of the core-nonpenetrating states because the Rydberg states were excited from either the A or C intermediate state, both of which are case (a) $^2\Pi$ states. Often, the lowest rotational levels of the A and C states could not be accessed owing to spectral congestion, and many transitions terminating on core-nonpenetrating states are naturally weak because the $\Delta N = \Delta N^+$ propensity rule is not satisfied. To overcome this difficulty, we have recorded optical–optical double-resonance spectra of the Rydberg states of CaF in the $n^* = 17$–20 region using the case (b)

$D^2\Sigma^+$ state as the intermediate state. The present data set, which extends further in n^* and higher in rotation than previous data sets, also features factor of 3 improvements in spectral resolution and wavenumber precision and an increase in dynamic range. The increased precision and dynamic range afforded by the present data set has facilitated detection of numerous perturbations and long series of weak transitions that had previously been unobservable. This has led to reassignment of several components of the 17*f* and 17*g* nonpenetrating states.

Experimental

The experimental apparatus consists of a laser ablation/molecular beam source coupled to a time-of-flight mass spectrometer, housed in separate "source" and "detection" chambers. The source and detection chambers are separately pumped. A molecular beam of calcium monofluoride is produced in the source chamber by direct reaction of calcium vapor with fluoroform. A 350-μs pulse of 5% CHF_3 in He formed by a pulsed nozzle (General Valve Series 9, 0.5 mm orifice, 40 psi stagnation pressure, 20 Hz duty cycle) is synchronized with the pulsed production of a calcium plasma formed by laser ablation of a 1/4" diameter calcium rod by the third harmonic of a pulsed Nd:YAG laser (Spectra Physics GCR-130, 5–7 ns pulse, 7 mJ/pulse, 20 Hz repetition rate). The duration of the fluoroform pulse and the energy of the ablation laser are both adjusted to optimize the production of CaF and to reduce the amount of unreacted calcium. The dominant ions observed are Ca^+ (m/z = 40) and CaF^+ (m/z = 59), and no other ions with greater than 5% of the intensity of CaF^+ are observed. The rotational temperature of the molecular beam is ~30 K. The molecular beam is collimated by a 0.5-mm conical skimmer placed between the source and detection chambers, and again by a 3.0-mm skimmer prior to entering the excitation region of the detection chamber. Autoionizing Rydberg states are excited in the detection chamber by two collinear laser beams that intersect the molecular beam at a 90° angle. The CaF^+ ions that result from autoionization are accelerated down the 75-cm flight tube of the mass spectrometer by a 250-V electric field pulse that arrives 200 ns after the laser excitation pulse. Ions are detected by two microchannel plates (Burle Electro-optics, 10 μm channel diameter, 12 μm channel spacing) arranged in a chevron configuration. The ion signals are amplified by a low-noise voltage amplifier (FemtoAmp, 30 dB gain, 30 MHz low-pass filter) and averaged over 40 shots by a LeCroy 300-MHz digital oscilloscope. The ion extraction assembly is contained within a Ni-plated shroud to isolate the excitation region from stray electric fields.

Autoionizing CaF Rydberg series in the n^* = 17–20 region, converging to the v = 1 level of the ion core, were accessed by two-step excitation through the $D^2\Sigma^+$ intermediate state. Pump and probe laser pulses were produced by two pulsed dye lasers (Lambda Physik Scanmate 2E, <10 ns, 0.03 cm^{-1} fwhm) simultaneously pumped by the second harmonic of a single Nd:YAG laser (Spectra Physics GCR-290, 5–7 ns pulse, 2 × 80 mJ/pulse). The first dye laser, operating with DCM and equipped with a β-BBO frequency-doubling crystal, was tuned to a single rotational line of the $D^2\Sigma^+ \leftarrow X^2\Sigma^+$ transition. Due to unresolved spin structure, this apparently single rotational line terminates on two same-parity $J = N + 1/2$ and $J = N - 1/2$ levels. The second dye laser, operating with Rhodamine B, stimulates Rydberg $\leftarrow D^2\Sigma^+$ transitions and was swept in frequency across the n^* = 17–20 region. The two laser pulses were separated in time by approximately 10 ns to prevent undesired multiphoton transitions. The frequencies of the pump and probe laser pulses were calibrated by simultaneously recording high-temperature absorption and room-temperature fluorescence spectra of molecular iodine, respectively. The Rydberg states studied here have one quantum of ion-core vibration and lie above the $v^+ = 0$ ionization threshold, and transitions into these states are detected through CaF^+ ions produced by vibrational autoionization. Spectra in the n^* = 17, 18, and 20 regions were recorded using each of the N = 1–9 rotational levels of the $D^2\Sigma^+$ state as intermediates, and spectra in the n^* = 19 region were recorded using the N = 1–25 rotational levels of the $D^2\Sigma^+$ state as intermediates.

Results and discussion

Assignment of core-penetrating states

The $D^2\Sigma^+$ intermediate state and the six core-penetrating upper states are known from previous studies (6, 7) to be well described in terms of Hund's case (b) basis states, $|\lambda NSJ\rangle$. The case (b) – case (b) optical selection rules (34) are

$$[3] \qquad \Delta J = 0, \pm 1; \qquad \Delta\lambda = 0, \pm 1$$

A schematic energy level diagram with allowed $^2\Sigma^+ \leftarrow {}^2\Sigma^+$ and $^2\Pi \leftarrow {}^2\Sigma^+$ transitions is shown in Fig. 1. Branches are designated by $^{\Delta N}\Delta J$ (read "ΔN-form ΔJ"; e.g., "P-form Q"). Since the spin structure of the $D^2\Sigma^+ \leftarrow X^2\Sigma^+$ transitions is not resolvable, Rydberg states are simultaneously excited from both the $J = N + 1/2$ and $J = N - 1/2$ levels of the $D^2\Sigma^+$ state. Initial tests for partial resolution of spin splittings, involving excitation of Rydberg states from either the higher- or lower-energy side of a $D^2\Sigma^+ \leftarrow X^2\Sigma^+$ rotational line, failed to produce noticeable intensity effects in the spectra, and the Rydberg $\leftarrow D^2\Sigma^+$ spectra show no evidence of systematic spin-doubling. This unresolved spin structure of both the upper and lower states leads to the collapse of the $^{\Delta N}\Delta J$ branches into simple ΔN-form branches. Only the N, N^+ (not J) rotational structure of Rydberg states is resolvable (see Fig. 2). The observed term values for the n^* = 16 and n^* = 17 core-penetrating states of CaF are listed in Table 1.

Since each rotational level N' of $^2\Sigma^+$ and $^2\Pi$ core-penetrating states is nominally accessible from at least two rotational levels of the $D^2\Sigma^+$ state, it is reasonable to attempt rotational assignment of the core-penetrating states based exclusively on lower-state rotational combination differences. Lower-state combination differences are identified by plotting the spectra recorded from each of the rotational levels of the $D^2\Sigma^+$ intermediate state against their upper-state term values, which are the sum of the Rydberg $\leftarrow D^2\Sigma^+$ transition frequencies and the term value of the $D^2\Sigma^+$ rotational state from which they are recorded. The "term value" spectra are then stacked vertically, in order of increasing N'', and compared against each other to locate lines on separate spectra with identical term values. The observation of two or more lines with the same upper-state term value (the same

vertical position on the term value stacked plot) suggests the occurrence of transitions from two or more $D^2\Sigma^+$ state rotational levels to a common upper state rotational level. Figure 3 shows the possible combination differences for $^2\Sigma^+ \leftarrow {}^2\Sigma^+$ and $^2\Pi \leftarrow {}^2\Sigma^+$ transitions. Rotational levels of $^2\Sigma^+$ and $^2\Pi^+$ core-penetrating states are each accessible from two rotational levels of the $D^2\Sigma^+$ state, and rotational levels of $^2\Pi^-$ core-penetrating states are accessible from three rotational levels of the $D^2\Sigma^+$ state. However, in our spectra, lower-state rotational combination differences are only observed between *at most* two states on N'' and $N''+2$ spectra (see Fig. 4), indicating that these states are populated by either O- and Q-, P- and R-, or Q- and S-form transitions. Many of the observed upper states do not exhibit lower-state

Fig. 3. Schematic energy level diagram showing transitions into $^2\Sigma^+$ and $^2\Pi$ states from different rotational levels of the $D^2\Sigma^+$ intermediate state.

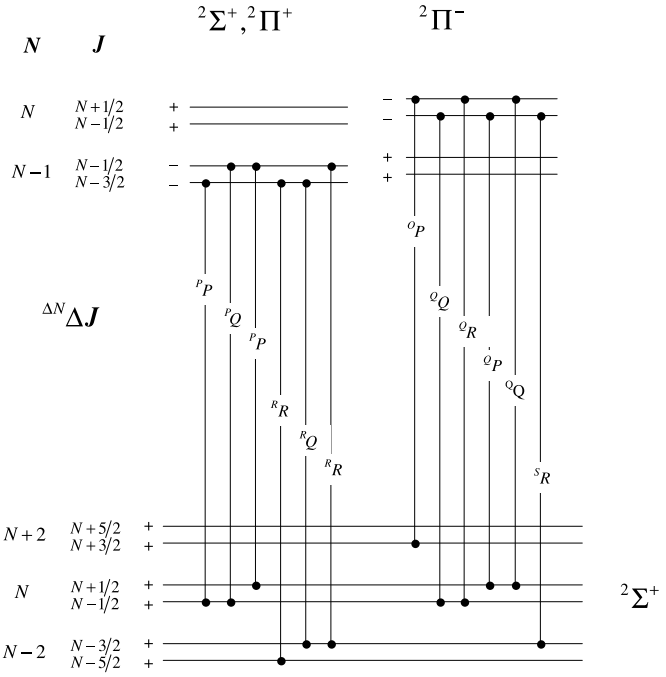

Fig. 4. "Term value" stacked plot: double-resonance spectrum plotted against upper-state term value. Combination differences are indicated with dashed lines.

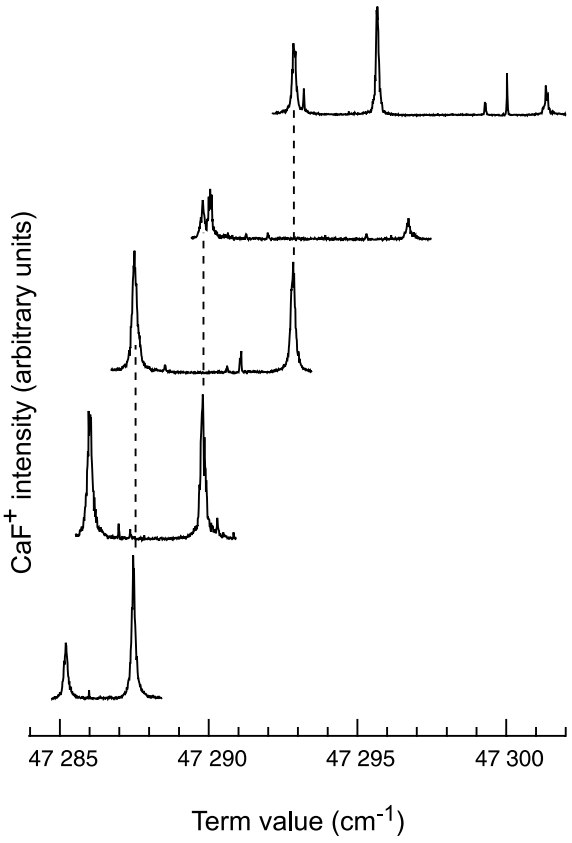

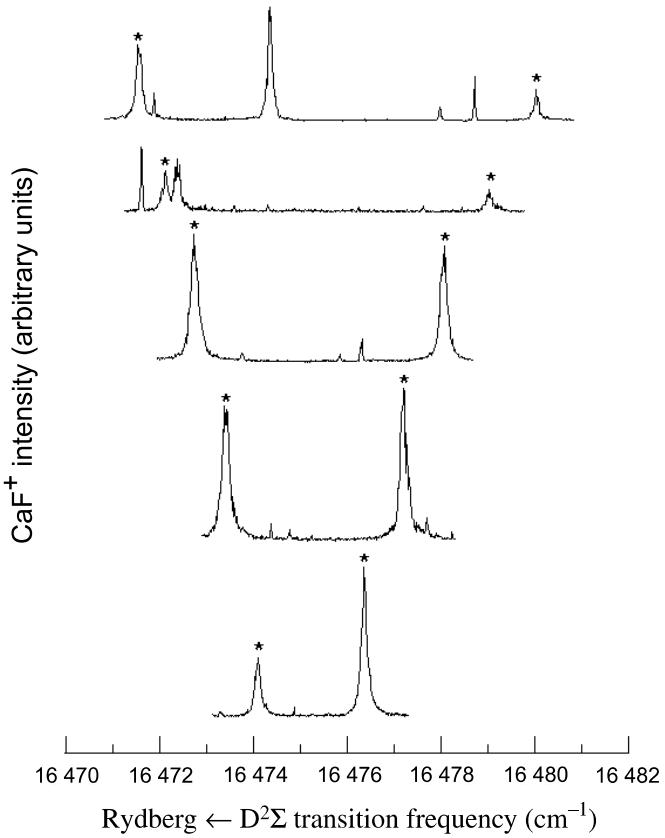

Fig. 5. "Raw spectrum" stacked plot: double-resonance spectrum plotted against Rydberg ← $D^2\Sigma^+$ transition frequency.

rotational combination differences. Rotational assignment is more secure for upper states that exhibit lower-state rotational combination differences, and these states are analyzed first.

Following identification of all bona fide combination differences, the spectra were replotted against the observed Rydberg ← $D^2\Sigma^+$ transition frequency and stacked vertically in order of increasing N'' to enable organization of the transitions into rotational branches (see Fig. 5). The transition frequencies of the members of the thus identified Rydberg ← $D^2\Sigma^+$ rotational branches were each fit to a polynomial in N'' to determine $\Delta N = N'' - N'$ for each branch. The difference $\Delta N = N'' - N'$ may be derived from the polynomial fit based on the difference in rotational energy between the $D^2\Sigma^+$ state and the core-penetrating states:

$$[4] \qquad \Delta E_{\text{rot}} = \nu_0 + B'\mathrm{N}'(N' + 1) - B''N''(N'' + 1)$$

The difference in rotational energies is related to the Rydberg ← $D^2\Sigma^+$ transition frequency through

$$[5] \qquad \Delta E_{\text{Rydberg}\leftarrow D^2\Sigma^+} = \Delta E_{\text{el}} + \Delta E_{\text{vib}} + \Delta E_{\text{rot}}$$

Hence

$$[6] \qquad \Delta E_{\text{Rydberg}\leftarrow D^2\Sigma^+} = \Delta E_{\text{rot}} + \text{const.}$$

where the constant on the right is independent of N. Substituting eq. [4] into eq. [6] and using the relation $N' = N'' + \Delta N$,

© 2004 NRC Canada

$$[7]\quad \Delta E_{\text{Rydberg}\leftarrow D^2\Sigma^+} = B'(N'' + \Delta N)(N'' + \Delta N + 1) - B'' N''(N'' + 1)$$

Expanding eq. [7],

$$[8]\quad \Delta E_{\text{Rydberg}\leftarrow D^2\Sigma^+} = N''^2(B' - B'') + N''(B'(2\Delta N + 1) - B'') + B'((\Delta N)^2 + \Delta N)$$

Since N'' is known a priori from the N-selectivity of the first step of the double-resonance excitation and B'' is known from previous rotational analyses of the $D^2\Sigma^+$ state (35), the linear term of eq. [8] yields the difference in rotational quantum number $\Delta N = N' - N''$ and the quadratic term yields the effective rotational constant, B', of the upper state. The rotationless upper-state quantum defects, δ, are then calculated from eq. [1] using the independently determined ionization thresholds of the $v^+ = 1$ or $v^+ = 2$ levels of the ion core (47 686 and 48 369 cm^{-1}, respectively) to establish membership in core-penetrating series converging to the $v^+ = 1$ and $v^+ = 2$ vibrational levels of the ion core. The calculated values of ΔN and B' and comparisons of the calculated rotationless quantum defects with the known quantum defects of the core-penetrating states allow many of the branches that are linked by lower-state rotational combination differences to be conclusively assigned as P- and R-form branches terminating on $v^+ = 1$ and $v^+ = 2$ core-penetrating states.

The fact that O-, Q-, and S-form branches were not observed to be linked to the assigned P- and R-form branches through lower-state combination differences reveals the presence of interactions that lift the degeneracy of the nominally near-degenerate positive and negative Kronig symmetry components. A systematic examination of the spectra of assigned core-penetrating states for evidence of nearby O-, Q-, or S-form branches showed additional branches consisting of strong, broad lines in the vicinity of the 0.36 $^2\Pi$ and 0.14 $^2\Delta$ states. A fit of the observed transition frequencies to the polynomial in eq. [8] indicated that these branches are Q-form branches, and extrapolation of the upper-state term values to $N = 0$ indicated that these branches terminate on the negative Kronig symmetry components of the 0.36 $^2\Pi$ and 0.14 $^2\Delta$ states. However, no O- or S-form branches terminating on the negative Kronig symmetry components of the 0.36 $^2\Pi$ or 0.14 $^2\Delta$ states could be located. This is likely due to the weakness of $\Delta N = 2$ case (b) – case (b) transitions, which are predicted to be weaker than $\Delta N = 1$ transitions (36). Although it was not possible to rigorously assign the negative Kronig symmetry components of the 0.36 $^2\Pi$ or 0.14 $^2\Delta$ states through lower-state rotational combination differences, the assignments are considered to be secure because no other rotational branches are expected to be present outside of the near-integer-n^* region. It has not been possible to securely assign any transitions as terminating on the negative Kronig symmetry components of the 0.98 $^2\Pi$ states as they lie very close to the integer-n^* region and likely overlap and (or) are perturbed by core-nonpenetrating states.

Assignment procedure for core-nonpenetrating states

Owing to strong ℓ-uncoupling interactions, the core-nonpenetrating states of CaF evolve rapidly from Hund's case (b) to Hund's case (d), and at even moderate N ($N = 8$), the core-nonpenetrating states are better described by Hund's case (d) basis states, $|\ell N^+ N \ell_R\rangle$. Core-nonpenetrating states are labeled by $n\ell(\ell_R)^{\pm}$ (e.g., $17f(-3)^+$), where ± refers to the σ_v reflection symmetry (Kronig symmetry) of the state and $\ell_R = N - N^+$. The case (d) – case (b) selection rules depend on the mechanism by which the core-nonpenetrating states are accessed from the $D^2\Sigma^+$ intermediate state. One mechanism by which core-nonpenetrating state $\leftarrow D^2\Sigma^+$ transitions are observed is based on the partial-ℓ composition of the $D^2\Sigma^+$ state. If the $D^2\Sigma^+$ state has significant $\ell = 2$ character, for example, it is possible to observe strong transitions to f states. In this case, the case (d) – case (b) selection rules are (37, 38)

$$[9]\quad \Delta N = 0, \pm 1;\quad N^{+\prime} = |\, N'' - \ell'' \,| \ldots |\, N'' + \ell'' \,|;\quad \pm \leftrightarrow \mp$$

Here, ℓ'' is the ℓ-value of the mixed-ℓ intermediate state that provides intensity for the transition into the core-nonpenetrating state, and ± is the overall parity of the molecular wave function, which in case (d) is $(-1)^{N^+ + \ell}$. Core-nonpenetrating states may also be excited due to intensity borrowing from nearby core-penetrating states. In this case, the selection rules are

$$[10]\quad \Delta N = 0, \pm 1; \qquad \pm \leftrightarrow \mp$$

All N^+ rotational states with $|\ell_R| = |\, N - N^+ \,| \leq \ell$ are accessible in this case, provided that the $\Delta N = 0$ core-penetrating ~ core-nonpenetrating interactions are strong enough to transfer significant intensity into the core-nonpenetrating state. A schematic energy level diagram is shown in Fig. 6. Owing to the selection rules on total parity outlined above, only odd (even) rotational levels of even-ℓ (odd-ℓ) states are accessible from odd (even) N levels of the $D^2\Sigma^+$ state. For example, the $N^+ = 3$ level of a g state is inaccessible from the $N = 3$ level of the $D^2\Sigma^+$ state. Because of this parity restriction, many rotational levels of a core-nonpenetrating state are accessible from only one rotational level of the $D^2\Sigma^+$ state, and not all core-penetrating rotational levels can be rigorously assigned through lower-state rotational combination differences. The observed term values for the $n^* = 17$ core-nonpenetrating states of CaF are listed in Table 2.

An attempt was made to determine the change in pattern-forming quantum number, $\Delta Q = N^{+\prime} - N''$, from a fit of the Rydberg $\leftarrow D^2\Sigma^+$ transition frequencies, just as was done for the core-penetrating states. Substituting $\Delta Q = N^{+\prime} - N''$ for $\Delta N = N' - N''$, one may derive an expression similar to eq. [8]:

$$[11]\quad \Delta E_{\text{Rydberg}} \leftarrow D^2\Sigma^+ = N''^2(B' - B'') + N''(B'(2\Delta Q + 1)) - B''((\Delta Q)^2 + \Delta Q)$$

However, for many of the branches, the calculated value of ΔQ turns out to be nearly half-integral. The reason for non-integer values of ΔQ is that ℓ-uncoupling is incomplete at low rotation. To demonstrate the effect of incomplete ℓ-uncoupling on the value of ΔQ obtained from a polynomial fit to eq. [11], an effective Hamiltonian was constructed. This Hamiltonian is identical to the effective Hamiltonian in

ref. 6 and will only be discussed briefly here. The effective Hamiltonian is divided into diagonal and off-diagonal terms:

[12] $H = H^{(0)} + \mathrm{H}^{(1)}$

where

[13] $H^{(0)} = H_{\mathrm{el}} + H_{\mathrm{rot}}$

and

[14] $H^{(1)} = H_{\ell\text{-uncoupling}}$

Here, H_{el} is the electronic Hamiltonian and consists of the hydrogen-atom Hamiltonian and electric dipole and quadrupole interaction terms. Its eigenvalues are

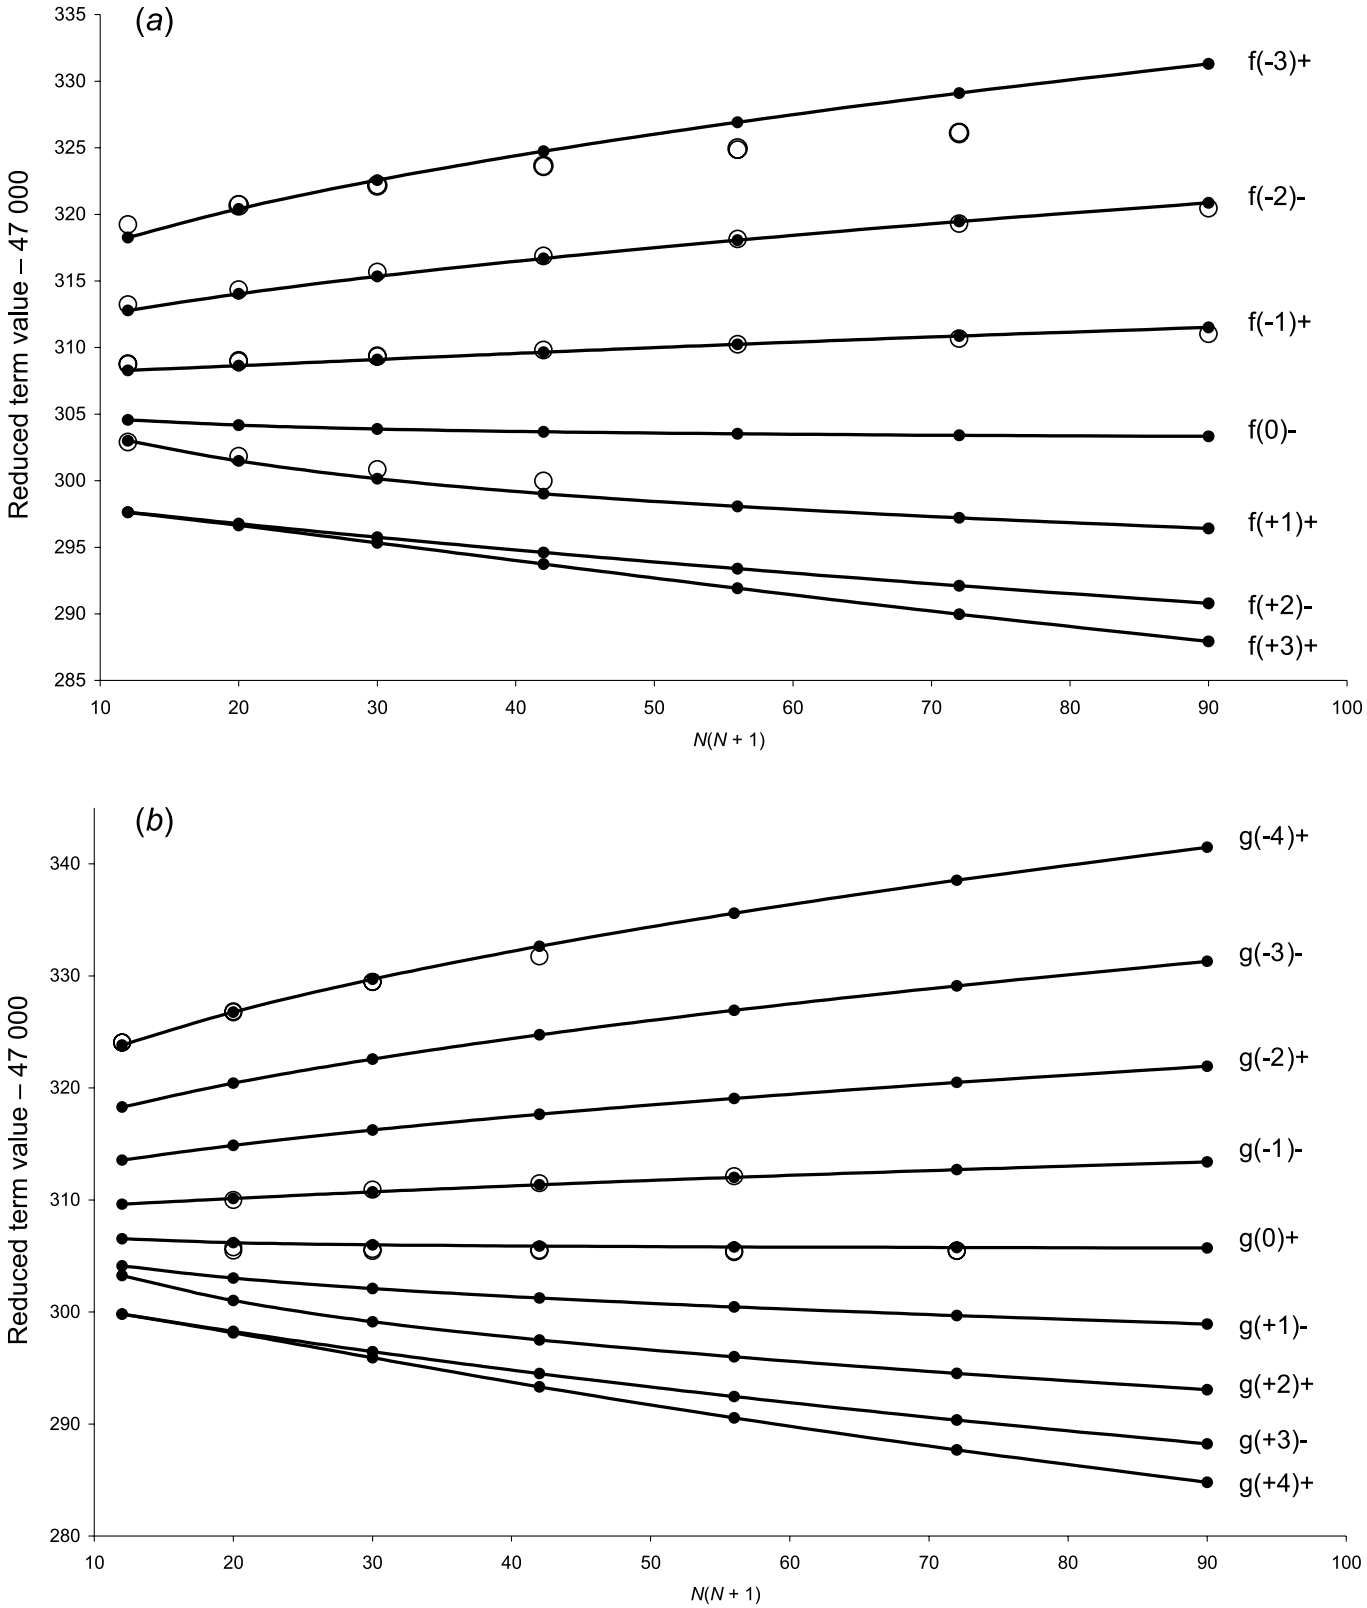
Fig. 8. Superposition of $17f \leftarrow D^2\Sigma^+$ and $17g \leftarrow D^2\Sigma^+$ transitions. Note interleaving of opposite-parity N^+ clusters.

$$[15] \quad H_{\text{el}} = \left(\text{IP}_v - \frac{1}{n^2}\right) + \frac{2Z^2(\mu^2 - Q)(\ell(\ell+1) - 3\lambda^2)}{n^3(2\ell+3)(2\ell+1)(2\ell-1)\ell(\ell+1)}$$

The second term in eq. [13], H_{rot}, is the case (b) rotational Hamiltonian and has eigenvalues

$$[16] \quad H_{\text{rot}} = B(N(N+1) + \ell(\ell+1) - 2\lambda^2)$$

$H^{(1)}$ is the off-diagonal portion of the ℓ-uncoupling operator



$$[17] \quad H_{\ell\text{-uncoupling}} = B(N^+\ell^- + N^-\ell^+)$$

This Hamiltonian matrix was diagonalized for each total angular momentum from $N = 3$ to $N = 9$ using the best-fit parameters of Gittins et al. (33) for both $17f$ and $17g$ states. The eigenvalues of this Hamiltonian were converted to transition frequencies by subtracting the term value of the rotational level of the $D^2\Sigma^+$ state from which each nonpenetrating state is accessible, and the calculated transition frequencies were fit to eq. [11]. Plots of the calculated transition frequencies vs. N'' are shown in Fig. 7.

As can be seen in Fig. 7, ℓ-uncoupling alters the calculated ΔQ values significantly and nonsystematically from their actual values, even for calculated data in which core-penetrating ~ core-nonpenetrating interactions are not treated explicitly. However, what is apparent from Fig. 7 is a clustering of branches in groups of three according to a common value of $N^{+\prime} - N$. This clustering of branches reflects the fact that N^+ is the rotational pattern-forming quantum number in case (d). In Fig. 7, the three groups of branches terminating on f states have $N^{+\prime} - N = 0, \pm 2$, and the four groups of branches terminating on g states have $N^{+\prime} - N = \pm 1, \pm 3$. By superimposing the $17f$ and $17g$ transition frequencies (see Fig. 8), it is seen that the transitions into the f and g states form a staggered pattern, reflecting the parity selection rules outlined above. The staggered pattern of f and g states in Fig. 8 is indeed observed in the double-resonance spectrum and allows branches terminating on core-nonpenetrating states to be organized into f and g $N^{+\prime} - N$ clusters. Six f (two $N^{+\prime} - N = 0$, three $N^{+\prime} - N = +2$, and one $N^{+\prime} - N = +4$) branches and five g (one $N^{+\prime} - N = -1$, two $N^{+\prime} - N = +1$, one $N^{+\prime} -$

N = +3, and one $N^{+\prime} - N$ = +5) branches are identified by inspection.

Following the identification of 17*f* and 17*g* components, a value of ℓ_R is assigned to each branch by the method of lower-state rotational combination differences outlined in the previous section. This allows rigorous assignment of the $f(-3)^+$, $f(-1)^+$, $g(-4)^+$, and $g(0)^+$ states. The assignment of $f(-3)^+$ and $f(-1)^+$ in the $N^{+\prime} - N$ = +2 cluster by lower-state

Table 3. Observed perturbations in the n^* = 16–17 region.

16.36 Π^+ ~ 16$g(-4)^+$
16.55 Σ^+ ~ 16$g(-4)^+$
16.88 Σ^+ ~ 10$f(-3)^+$, v = 2
17.36 Π^+ ~ 17$g(-4)^+$
16.55 Σ^+ ~ 17$g(-4)^+$

combination differences allows assignment of $f(-2)^+$ by process of elimination. An unpaired branch in the $N^{+\prime} - N$ = 0 cluster is securely assigned as $f(+1)^+$, as it is nearly coincident with transitions into the 0.98 Π^- state yet does not appear perturbed. A pair of intertwined branches that lie between the branches terminating in the $f(-1)^+$ and $f(+1)^+$ states are likely the 0.98 Π^- and $f(0)^-$ states and appear to exhibit strong mutual perturbations. An unpaired branch in the $N^{+\prime} - N$ = +1 g cluster is tentatively assigned as $g(-1)^-$. It is interesting to note that the observation of $N^{+\prime} - N$ = +4 f branches and $N^{+\prime} - N$ = +5 g branches, which violate the triangle rule condition in eq. [9], implies that the core-nonpenetrating states are accessible in our experiment through intensity borrowing from nearby penetrating states and not from the partial-ℓ characters of the $D^2\Sigma^+$ state. A comparison of observed and calculated term values is shown in Fig. 9.

Location of core-penetrating ~ core-nonpenetrating perturbations

Following assignment of all observed states in the n^* = 17 region, a reduced term value plot that includes all core-penetrating and core-nonpenetrating states was constructed. Reduced term value plots are constructed by subtracting the quantity $BN(N + 1)$ from the term value of each state and plotting the difference against $N(N + 1)$. All perturbations (excluding spin–orbit perturbations) have the selection rule $\Delta N = 0$ and act between states of identical Kronig symmetry. Hence, perturbations will be located in regions of the reduced term value plot where states of the same Kronig symmetry cross. Figure 10*a* shows an example of a weak level repulsion, while Fig. 10*b* depicts a case where the lines are dramatically split. Table 3 summarizes all of the observed perturbations in the n^* = 16–17 region of the double-resonance spectrum.

Conclusions

Rydberg states of calcium monofluoride in the n^* = 17–20 region have been observed by optical–optical double-resonance spectroscopy via the $D^3\Sigma^+$ intermediate state. While the assignment of core-nonpenetrating states in previous studies was complicated by many weak transitions and the inaccessibility of the lowest rotational levels of the $A^2\Pi$ and $C^2\Pi$ intermediate states, we have been able to assign all of the observable core-nonpenetrating states in the n^* = 17 region by excitation from the $D^2\Sigma^+$ state. The traditional assignment techniques presented here, fashioned in the style of Gerhard Herzberg, have allowed spectrum-only assignment of states and the location of numerous weak perturbations between core-penetrating and core-nonpenetrating states. The assignment of these states and the location of these perturbations by purely model-based predictions would be untenably complicated by the flexibility of model-based fits.

The assignment of states in the n^* = 18, 19, and 20 regions using these techniques is underway, and effective Hamiltonian and MQDT fits of states in all four regions will be performed. Analysis of the core-penetrating ~ core-nonpenetrating perturbations is in progress, and it is hoped that these perturbations between mixed-ℓ and pure-ℓ states will allow disentanglement of the polarizabilities and the dipole, quadrupole, and higher-order multipole moments of the ion core.

New applications of the genetic algorithm for the interpretation of high-resolution spectra[1]

W. Leo Meerts, Michael Schmitt, and Gerrit C. Groenenboom

Abstract: Rotationally resolved electronic spectroscopy yields a wealth of information on molecular structures in different electronic states. Unfortunately, for large molecules the spectra get rapidly very congested owing to close-lying vibronic bands, other isotopomers with similar zero-point energy shifts, or large-amplitude internal motions. A straightforward assignment of single rovibronic lines and, therefore, line position assigned fits are impossible. An alternative approach is unassigned fits of the spectra using genetic algorithms (GAs) with special cost functions for evaluation of the quality of the fit. This paper decribes the improvements we established on the GA method discussed before (J.A. Hageman, R. Wehrens, R. de Gelder, W.L. Meerts, and L.M.C. Buydens. J. Chem. Phys. **113**, 7955 (2000)). In particular, we succeeded in obtaining a dramatic reduction in computing time that made it possible to apply the GA process in a large number of cases. A completely automated fit of a rotationally resolved laser-induced fluorescence spectrum without any prior knowledge of the molecular parameters can now be performed in less than 1 h. We demonstrate the power of the method on a number of typical examples such as very dense rovibronic spectra of van der Waals clusters and overlapping spectra due to different isotopomers. The discussed results demonstrate the extreme power of the GA in automated fitting and assigning of complex spectra. It opens the road to the analysis of complex spectra of biomolecules and their building blocks.

Key words: high-resolution spectroscopy, genetic algorithm, biomolecules, structure, van der Waals clusters.

Résumé : La spectroscopie électronique résolue en fonction de la rotation fournit une profusion d'informations relatives aux structures moléculaires dans les différents états électroniques. Malheureusement, dans les cas de molécules de taille importante, les spectres deviennent rapidement très congestionnés en raison des bandes vibroniques adjacentes, d'autres isotopomères ayant des déplacements semblables de l'énergie du point zéro ou des mouvements internes de grandes amplitudes. Il est toutefois impossible de faire des attributions non ambiguës des raies rovibroniques simples et, par extension, des ajustements des positions de raies attribuées. Une autre méthode est de faire l'ajustement des raies non attribuées des spectres en faisant appel à des algorithmes génétiques (AG) et en appliquant des fonctions spéciales de coûts pour l'évaluation de la qualité des ajustements. Dans ce travail, on décrit les améliorations qu'on a apporté à la méthode des AG discutée antérieurement (J.A. Hageman, R. Wehrens, R. de Gelder, W.L. Meerts, et L.M.C. Buydens. J. Chem. Phys. **113**, 7955 (2000)). On a réussi, en particulier, à obtenir une diminution dramatique du temps de calcul nécessaire pour appliquer le processus d'AG à un grand nombre de cas. Il est maintenant possible de réaliser en moins d'une heure un ajustement complètement automatique d'un spectre de fluorescence induite au laser et résolue en fonction de la rotation, sans avoir recours à une connaissance préalable des paramètres moléculaires. On a démontré la puissance de la méthode sur un grand nombre d'exemples typiques, tels que les spectres rovibroniques très denses d'agrégats de van der Waals et les spectres comportant des recouvrements en raison d'isotopomères différents. Les résultats discutés démontrent la très grande puissance des AG dans l'ajustement automatique et l'attribution de spectres complexes. Ils ouvrent la voie à une analyse des spectres complexes de biomolécules et de leur composantes.

Mots clés : spectroscopie à haute résolution, algorithme génétique, biomolécules, structure, agrégats de van der Waals.

[Traduit par la Rédaction]

1. Introduction

Rotationally resolved electronic spectroscopy provides a valuable tool for determination of molecular structures in different electronic states. An implicit problem of this method is that for larger molecules the spectra rapidly get very congested. Additionally, overlapping bands due to (*i*) close-spaced vibronic bands, (*ii*) other isotopomers with similar zero-point energy

shifts, or (*iii*) split bands due to large-amplitude internal motions might complicate the experimental spectrum further. All these factors make a straightforward assignment of single rovibronic lines and, therefore, line position assigned fits impossible. In Neusser's group (1), a procedure has been developed that directly fits the experimental data without prior assignments. This method, which is called "correlation automated rotational fitting", was pioneered by Levy and co-workers (2–4) and uses the correlation between the experimental and the simulated spectrum as a measure of the quality of the fit. Unfortunately, the method still has limited applicability. An alternative approach is unassigned fits of the spectra using genetic algorithms (GAs) with special cost functions for evaluation of the level of the fit.

It has been shown by Hageman et al. (5) that a GA with a properly defined cost function was capable of performing automated fitting of spectra without any prior knowledge of the molecular parameters. The cost function used by Hageman et al. (5) is able to smooth the error landscape and, therefore, allows the GA to locate the global minimum. Unfortunately, this method is quite time-consuming, compared to other cost functions like simple least-squares or peak picking functions. The automated fitting of several overlapping bands requires, therefore, fast parallel processing and long computing times. In the present paper, we show how the computing time of the cost function can be reduced drastically, so that the automated fit of a rovibronic spectrum can be performed in less than 1 h using a standard desktop PC. The performance of the GA for spectral simulations has been described in detail elsewhere (5). A good introduction to the vocabulary and theory of GAs as a tool for solving optimization problems can be found in refs. 6 and 7.

In this paper, we extend the automated fit to the case of several overlapping spectra, i.e., the fitting of molecular parameters that belong to different molecular species or spectral components. The method is applied to a synthetic spectrum, which consists of two completely overlapping bands, to adapt the internal parameters for the GA fit. The refined method is then applied to a series of experimental rovibronic spectra of isotopomers of phenol and benzonitrile, and clusters thereof. The discussed results demonstrate the extreme power of the GA in automated fitting and assigning of complex spectra.

2. Experimental

The experimental setup for the rotational resolved laser-induced fluorescence (LIF) is described elsewhere (8). Briefly, it consists of a ring dye laser (Coherent 899-21) operated with Rhodamine 110, pumped with 6 W of the 514 nm line of an Ar^+-ion laser. The light is coupled into an external folded ring cavity (9) for second-harmonic generation (SHG). The molecular beam is formed by expanding the vaporized sample, seeded in 400−1000 mbar of argon (1 bar = 100 kPa), through a 70 μm hole into the vacuum. The molecular beam machine consists of three differentially pumped vacuum chambers that are linearly connected by skimmers (1 and 3 mm, respectively) to reduce the Doppler width. The molecular beam is crossed at right angles in the third chamber with the laser beam 360 mm downstream of the nozzle. The resulting fluorescence is collected perpendicular to the plane defined by the laser and molecular beam by an imaging optics setup consisting of a concave mirror and two plano-convex lenses. The resulting Doppler width in this setup is 25 MHz (fwhm). The integrated molecular fluorescence is detected by a photomultiplier tube, and the output is discriminated and digitized by a photon counter and transmitted to a PC for data recording and processing. The relative frequency is determined with a quasi-confocal Fabry−Perot interferometer with a free spectral range (FSR) of 149.9434(56) MHz. The FSR was calibrated using the combination differences of 111 transitions of indole for which the microwave transitions are known (10, 11). The absolute frequency was determined by recording the iodine absorption spectrum and comparing the transitions to the tabulated lines (12).

3. Theory

3.1. The Hamiltonian

For the simulation of the rovibronic spectra, a rigid asymmetric rotor Hamiltonian was employed (13):

$$[1] \qquad \widehat{H} = A P_a^2 + B P_b^2 + C P_c^2$$

Here, $P_g (g = a, b, c)$ are the components of the body-fixed angular momentum operator, and A, B, and C are the three rotational constants. The resulting Hamiltonian matrix is factorized into four submatrices using the Wang transformation (14). This enhances the computation speed because of the reduced dimension of the matrix to be diagonalized. The transition frequencies are determined by the rotational constants A, B, C in both electronic states and by the frequency of the origin ν_0 of the vibronic band. The line intensities depend on the rotational temperature, the orientation of the transition dipole moment with respect to the inertial axes, and, in some cases, the nuclear spin statistic. The temperature dependence of the intensities might be considered in a simple one-temperature model, which is sufficient for simulation of most of the rovibronic spectra, or in a more advanced two-temperature model, which should be applied in cases where line shape parameters are fitted (cf. Sect. 4.4.2). The orientation of the dipole moment vector is determined by the polar angle θ and the azimuthal angle ϕ.

3.2. The genetic algorithm

A description of the GA used in this investigation can be found in ref. 5. The GA library PGAPack version 1.0, which can run on parallel processors, was used (15). The calculations were performed on four processors of a SUN UltraSPARC 333 MHz and on a 2.6 GHz PC with two processors under Linux. The GA is basically a global optimizer, which uses concepts copied from natural reproduction and selection processes. For a detailed description of the GA, the reader is referred to the original literature (16–18). We introduce the elements of the GA that will be used in the following.

- Representation of the parameters: The molecular parameters are encoded binary or as real data type, each parameter representing a gene. A vector of all genes, which contains all molecular parameters, is called a chromosome. In an initial step the values for all parameters are set to random values between lower and upper limits, which have to be chosen by the user. No prior knowledge of the parameters is necessary. A total of 300−500 chromosomes are randomly generated, forming a population.

© 2004 NRC Canada

- The solutions (chromosomes) are evaluated by a fitness function (or cost function), which is a measure of the quality of the individual solution. The fitness function that is used here is described in Sect. 3.3.
- One optimization cycle, including evaluation of the cost of all chromosomes, is called a generation. Generally, convergence of the fit in our case is reached after 300−500 generations.
- Pairs of chromosomes are selected for reproduction, and their information is combined via a crossover process. This crossover might take place as a one-point, two-point, or uniform crossover. A crossover just combines information from the parent generations and basically explores the error landscape.
- The value of a small number of bits is changed randomly. This process is called mutation. Mutation can be viewed as exploration of the cost surface. The best solutions within a generation are excluded from mutation. This elitism prevents already good solutions from being degraded.

The performance of the GA depends on internal parameters like mutation probability, elitism, crossover probability, and population size, which therefore should also be optimized for a given problem. Fortunately, this meta-optimization results in similar parameters for quite different problems of optimization. The meta-optimization for some of the parameters is described in Sect. 4.2.

3.3. The fitness function

3.3.1. Definition

In the current paper we will use both the terms *fitness function* (F_{fg}) and *cost function* (C_{fg}), where $C_{fg} = 100(1 - F_{fg})$, to characterize the quality of a solution. The fitness function for the fit of the spectra with N points using the GA has been defined in eq. [5] of ref. 5 (in which C_{fg} is identical to F_{fg} in this paper) as:

$$[2] \qquad F_{fg} = \frac{\sum_{r=-l}^{l} w(r) \sum_{i=1}^{N} f(i)g(i+r)}{\sqrt{\sum_{r=-l}^{l} w(r) \sum_{i=1}^{N} f(i)f(i+r)}\sqrt{\sum_{r=-l}^{l} w(r) \sum_{i=1}^{N} g(i)g(i+r)}}$$

In this equation, f and g represent the experimental and calculated spectra, respectively. The function $w(r)$ determines the sensitivity of the fitness function for a shift of the two spectra relative to each other. This can be rewritten by interchanging the sums and substituting $i + r = j$ as

$$[3] \qquad F_{fg} = \frac{\sum_{i,j}^{N} f_i W_{ij} g_j}{\sqrt{\sum_{i,j}^{N} f_i W_{ij} f_j}\sqrt{\sum_{i,j}^{N} g_i W_{ij} g_j}}$$

where

$$[4] \qquad W_{ij} = w(|j - i|)$$

and $f_i = f(i)$ and $g_i = g(i)$.

F_{fg} in eq. [3] can be interpreted as the cosine of the "angle" between the experimental and the theoretical spectrum. With the column vectors

$$[5] \qquad \boldsymbol{f} = (f_1, f_2, ..f_N)^T$$
$$\boldsymbol{g} = (g_1, g_2, ..g_N)^T$$

and the symmetric matrix $\boldsymbol{W}$, which has the matrix elements W_{ij}, we can write:

$$[6] \qquad F_{fg} = \cos(\alpha) = \frac{(\boldsymbol{f}, \boldsymbol{g})}{\|\boldsymbol{f}\| \, \|\boldsymbol{g}\|}$$

Here the inner product $(\boldsymbol{f}, \boldsymbol{g})$ is defined with the metric $\boldsymbol{W}$ as:

$$[7] \qquad (\boldsymbol{f}, \boldsymbol{g}) = \boldsymbol{f}^T \boldsymbol{W} \boldsymbol{g}$$

and the norm of $\boldsymbol{f}$ as $\|\boldsymbol{f}\| = \sqrt{(\boldsymbol{f}, \boldsymbol{f})}$; similarly for $\boldsymbol{g}$. For $w(r)$ we used a triangle function (5) with a width the base of Δw:

$$[8] \qquad w(r) = \begin{cases} 1 - |r| \,/\, (1/2\Delta w) & \text{for } |r| \leqslant 1/2\Delta w \\ 0 & \text{otherwise} \end{cases}$$

In order for F_{fg} to serve as a good fitness function for the quality of the fit, it should have the property that it reaches its maximum value if and only if $\boldsymbol{f}$ and $\boldsymbol{g}$ are identical (apart from a normalization). This condition is fulfilled provided the matrix $\boldsymbol{W}$ is positive definite. In Appendix A, we show this holds if the Fourier transform of the function w is positive. The Fourier transform of $w(r)$ defined in eq. [8] is

$$[9] \qquad \tilde{w}(t) = \int_{-\infty}^{\infty} \mathrm{e}^{-2\pi i r t} w(r) \, \mathrm{d}r = \frac{\Delta w}{2} \, \mathrm{sinc}^2 \left(\frac{\Delta w}{2} \pi t \right)$$

where $\mathrm{sinc}\,(x) = \sin(x)/x$, so $\tilde{w}(t) \geqslant 0$.

3.3.2. Numerical evaluation of the fitness

Let us now consider the numerical evaluation of the fitness function F_{fg} from eq. [3] in its relation with the calculated spectrum. The calculated spectrum is obtained by a convolution of each calculated transition k with intensity s_k by the line shape function L:

$$[10] \qquad g_j = \sum_{k=1}^{N} L_{jk} s_k$$

© 2004 NRC Canada

with $L_{jk} = l(|j - k|)$. In matrix notation this can be rewritten as

[11] $$\boldsymbol{g} = \boldsymbol{L}\boldsymbol{s}$$

As it turned out, at least 50% of the computing time in ref. 5 was used to perform a straightforward calculation of F_{fg} from eq. [3]. For a typical GA fit, F_{fg} must be calculated 150 000 times. Hence, a considerable reduction in computing time can be obtained by a more efficient calculation of F_{fg}. We start with a rearrangement of the order of the evaluation of eq. [6] and using the properties of $\boldsymbol{W}$ and $\boldsymbol{L}$. The numerator of eq. [6] is evaluated first:

[12] $$(\boldsymbol{f}, \boldsymbol{L}\boldsymbol{s}) = \boldsymbol{f}^T\boldsymbol{W}\boldsymbol{L}\boldsymbol{s} = \tilde{\boldsymbol{f}}\boldsymbol{s}$$

[13] $$\tilde{\boldsymbol{f}} = \boldsymbol{f}^T\boldsymbol{W}\boldsymbol{L}$$

From eqs. [12] and [13] it is obvious that the effect of $w(r)$ can be interpreted as an effective line broadening of the experimental[3] spectrum. The use of the broadening function $w(r)$ results in a smoother error landscape, which allows an easier optimization of the GA process. It should be noted that the simple least-squares fitness function, where all spectral points have the same weight, is also described by F_{fg} for the limiting case that the width of $w(r)$ is zero and $\boldsymbol{W}$ becomes the identity matrix.

The transformed experimental spectrum from eq. [13] has to be evaluated only once. Formally, the sum on the right-hand side of eq. [12] runs over all N points of the spectrum. However, the stick spectrum array is a very sparse one: Typically, N is of the order of 60 000 − 250 000, while the number of sticks (nonzero values of s_k) is only about 1000−3000. Therefore, the use of eq. [12] strongly reduces the necessary computing time. The reduction of computing time is actually more dramatic since the double sum in the numerator of eq. [3] over N points is reduced to a single sum over a sparse array in eq. [12]. Furthermore, the theoretical spectrum itself $\{g_i\}$ does not have to be calculated anymore. The first term in the denominator of eq. [3] also has to be evaluated only once. The second term in this denominator has to be calculated every time a value of F_{fg} is needed in the process of the GA. Fortunately, this term can also be expressed in terms of the stick spectrum $\boldsymbol{s}(\{s_k\})$:

[14] $$\|\boldsymbol{g}\|^2 = \boldsymbol{s}^\dagger(\boldsymbol{L}^\dagger\boldsymbol{W}\boldsymbol{L})\boldsymbol{s}$$

Since $(\boldsymbol{L}^\dagger\boldsymbol{W}\boldsymbol{L})$ is a banded matrix, the evaluation of $\|\boldsymbol{g}\|^2$ from eq. [14] is in practice almost linear in the number of sticks rather than quadratic. Again, $(\boldsymbol{L}^\dagger\boldsymbol{W}\boldsymbol{L})$ has to be evaluated only once. It turned out that the effect of the above-discussed modifications of the calculation of F_{fg} was that its calculation time became negligible with respect to the total computing time.

The use of the stick spectrum, described in this section, is limited to applications in which the line shape parameters, like Gaussian or Lorentzian width in the Voigt profile, do not have to be fitted. Inclusion of the line width parameters in the fit requires the reevaluation of eq. [12] during the GA process, which in practice dramatically increases the computing time. Therefore, a line width fit should be performed after a determination of all other parameters in a separate fitting procedure. An example of this will be given in Sect. 4.4.2.

3.3.3. Further reduction of computing time

Further reduction of the computing time for the fitness function is made possible by setting the maximum J value in the evaluation of the simulated spectrum dynamically. In the first step of the evaluation, a maximum J value is taken, which is specified by the user. In the subsequent steps, the necessary $J_{\max}$ is computed from the temperature and the rotational constants using a cut-off factor of 0.001 for the intensities. In this way, the size of the matrices to be set up and diagonalized in the course of the computation of the simulated spectrum is minimized.

4. Results and discussion

4.1. Influence of the width (Δw) of the weight function *w(r)* on the convergence of the GA

The relative broadening of the spectra, introduced by the weight function $w(r)$, described in Sect. 3.3.2, critically determines the ability of the GA to converge to the global minimum and also the speed of convergence. The smoothing of the error landscape allows the sensing of regions far from the minimum. In the first step, the function $w(r)$ should be chosen relatively broad; $\Delta w \approx$ 15–20 times the line widths of an individual rovibronic line in the spectrum (Δ_{lw}). In this way, a first set of molecular parameters is obtained, which still has to be refined. This is done by decreasing Δw and narrowing the limits of the parameter space to be searched in the fit. Decreasing Δw improves the accuracy of the molecular parameters obtained from the fit, while narrowing the parameter space leads to an improved sampling in the region of the minimum. This of course is the critical step in the procedure. Too strong narrowing of the parameter space leads to premature convergence of the fit — with a high probability into a local minimum.

We performed a fit of a synthetic spectrum that consisted of two overlapping sub-spectra. It was generated using the molecular parameters from the "Best value" column in Table 1. A single-temperature model for the calculation of the intensities has been used. The maximum J value used in the computation of the cost function for this spectrum is 22. Table 2 lists the results of five GA calculations stopped after 500 generations, each started with a different randomly generated initial set of parameters. In Table 2, $\Delta w/\Delta_{lw} = 20$. This process has been repeated for different values of $\Delta w/\Delta_{lw}$. The convergence of the fit using different $\Delta w/\Delta_{lw}$ is shown in Fig. 1.

A ratio of $\Delta w/\Delta_{lw} = 20$ leads to convergence for all five initial seeds into the same minimum. Inspection of the parameters in Table 2 shows that the minimum found is the global one. Nevertheless, the deviations of the fitted parameters from the best values of Table 1 are quite large, owing to the large value of Δw, which leads to broad minima at the cost surface. As seen in Fig. 1, smaller values of Δw may lead to convergence into other (local) minima of the cost surface. With $\Delta w/\Delta_{lw}$ of 10, still three of the fits converge to the global minimum, with a ratio of 5, only one fit converges to the global minimum, and with 2.5, none of the fits converges to the global minimum.

[3] A different arrangement of the equations shows that $w(r)$ also can be interpreted as an effective broadening of the calculated spectum g. Actually, the experimental and the calculated spectra are broadened relative to each other.

Table 1. Input for the genetic algorithm (GA) fit of the synthetic spectrum.

Parameter	Best value	Lower limit	Upper limit	Coupling [a]
Parameters of the first spectrum				
A_1''	3 000.00	2 900.00	3 100.00	
B_1''	1 000.00	910.00	1 100.00	
C_1''	800.00	700.00	900.00	
T_1	2.00			
θ_1	54.74	0.00	90.00	
ϕ_2	45.00	0.00	90.00	
$\nu_0^{(1)}$	80 000.00	79 000.00	81 000.00	
ΔA_1	100.00	10.00	150.00	
ΔB_1	−50.00	−150.00	50.00	
ΔC_1	−50.00	−150.00	50.00	
Gaussian width	20.00			
Parameters of the second spectrum				
$A_2'' - A_1''$	10.00	5.00	15.00	D
$B_2'' - B_1''$	5.00	0.00	10.00	D
$C_2'' - C_1''$	−5.00	−10.00	0.00	D
T_1	2.00			C
θ_2	56.74			
ϕ_2	44.00			
$\Delta\nu_0^{(2)} - \Delta\nu_0^{(1)}$	500.00	0.00	1 000.00	D
$\Delta\Delta A$	2.00	−3.00	3.00	D
$\Delta\Delta B$	−1.00	−3.00	3.00	D
$\Delta\Delta C$	1.00	−3.00	3.00	D
Gaussian width	20.00		C	
Ratio scaling	1.00		R	

Note: All values are in MHz except T, which is in K, and θ and ϕ, which are in degrees. The Lorentzian contribution to the line width was sert to zero. $\Delta A_1 = A_1' - A_1''$; ΔB_1 and ΔC_1 correspondingly. $\Delta\Delta A = \Delta A_2 - \Delta A_1 = \left(A_2' - A_2''\right)\left(A_1' - A_1''\right)$; etc.

[a] C, parameters of spectrum 2 are taken the same as those of spectrum 1; D, parameters of spectrum 2 are those of spectrum 1 with the corresponding value in the table added; R, parameters of spectrum 2 are those of spectrum 1 multiplied by the corresponding value from the table.

In the next step, the fit has to be refined with a limited parameter space centered around the best fit (fit No. 4 in Table 2) and with successively smaller values of Δw. We could not establish a hard criterion for the reduction of the parameter space. A successfull reduction depends critically on the quality of the first series of fits. On the other hand, the parameter space cannot always be reduced by the same factor for each of the parameters. As a rule of thumb, we found that the parameter limits can be reduced to one-tenth of the initial range. This reduction depends on the quality (signal-to-noise (S/N)) of the spectrum and has to be checked carefully after each successive step. Table 3 gives the new input parameters for a refined fit, using a ratio $\Delta w/\Delta_{lw} = 5$, along with the result of the best of five fits with different starting populations.

As can be inferred from Table 3, the fit with the reduced line width ratio and the reduced parameter space is already quite close to the "real" values given in Table 1. It can further be improved by decreasing $\Delta w/\Delta_{lw}$ and the parameter search space in an iterative manner until convergence for the molecular parameters is reached.

To generate a more realistic spectrum, we added a randomly Gaussian-distributed noise to the synthetic spectrum, resulting in a S/N of 10:1 for the strongest lines. The GA performed equally well in this case, yielding the molecular parameters given in the last column of Table 3. The deviations of the parameters from the true values are similarly small as for the "perfect" spectrum without noise.

4.2. Meta-optimization of the internal GA parameters

The need to optimize the internal parameters of the GA (meta-optimization) for a given problem has been discussed to be a major drawback of this method (19). The speed and convergence of GAs depend on the data representation (binary or real), the crossover type (one-point, two-point, uniform), the size of the starting population, the rate of elitism, and the mutation probability. Several other factors that also influence the performance of the GA fit have been kept fixed. They will be discussed shortly. The crossover probability was chosen as 85%. Selection of the best solutions is performed via a tournament selection, which means that a random subset of the chromosomes is taken, and within each subset the chromosomes are selected by their cost. Duplicates within one generation are allowed for.

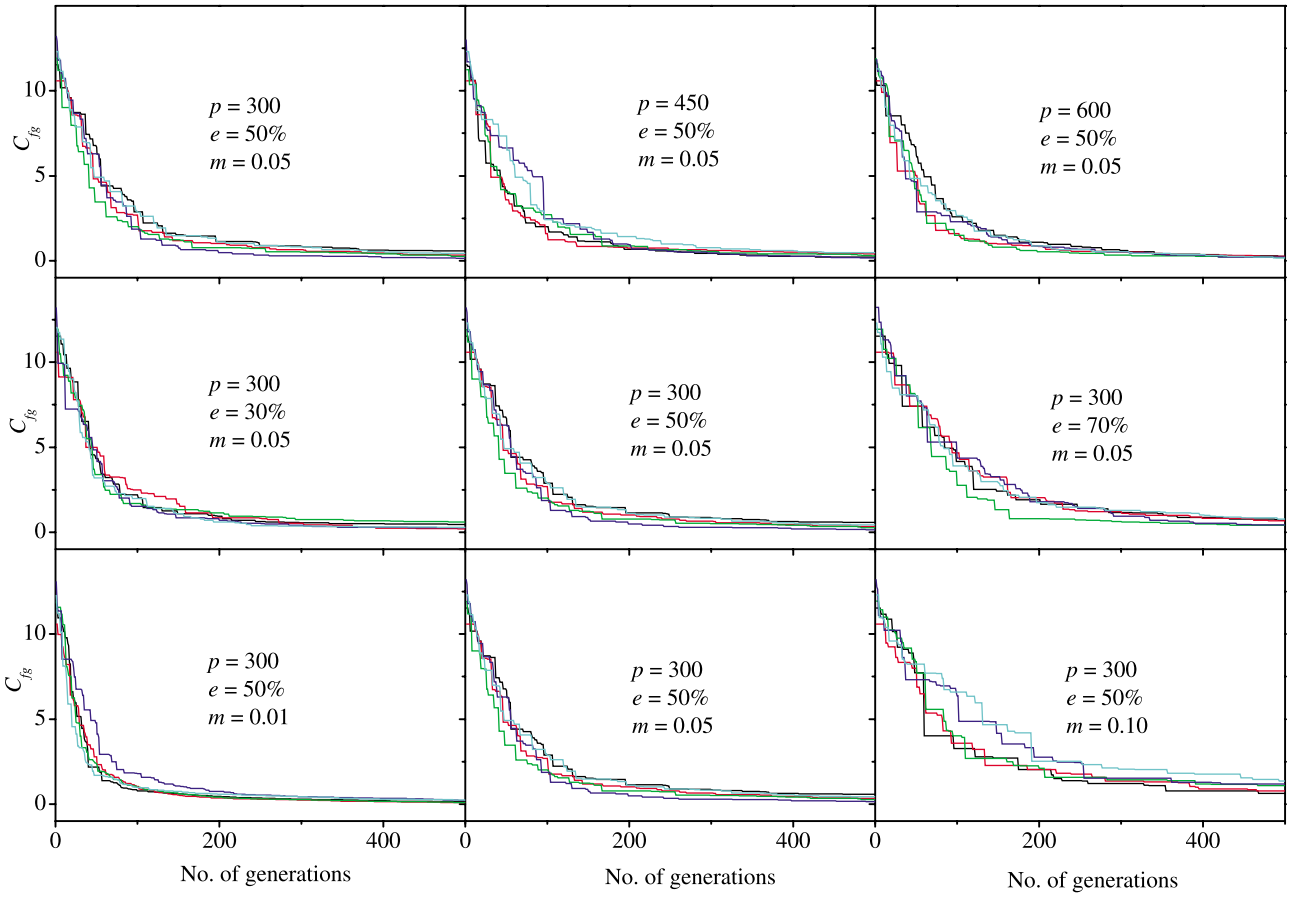
C_{fg}	0.162	—	—	0.297

The "natural" choice for a genetic algorithm is a binary representation of the data. It has been discussed that a direct representation of the parameters as real-type data is advantageous if the type of data to be fitted is real. All tests performed with the data set given in Table 1 show that the binary encoding of the parameters leads to a smaller cost and converges more rapidly, compared to real-type representation. For the real-type data encoding, a number of runs do not even reach the global minimum.

© 2004 NRC Canada

Fig. 1. Dependence of the convergence of five fits of a synthetic spectrum that consists of two overlapping sub-spectra with different starting populations on the ratio $\Delta w/\Delta_{lw}$.

A change of the encryption depth for the binary representation from 10 bit to 20 bit virtually does not change the performance of the GA. A Gray code (20) is used throughout the present investigations in order to ensure a Hamming distance of one (21). Comparing uniform and two-point crossover, a clear advantage of the two-point crossover regarding speed of convergence and fitness of the solutions was found. Just in the case of real-type encoding, the uniform crossover forces more runs of the GA into the global minimum than the two-point.



The first row of Fig. 2 shows the convergence of five fits with different starting populations as a function of the number of generations for different sizes of the starting population, using the parameters from Table 1 and $\Delta w/\Delta_{lw} = 20$ (cf. Sect. 4.1). The elitism was kept at 50% and mutation probability at 0.05 in these calculations. For a population of 300, the best value of the cost function was 0.15, the mean of five runs using different starting populations was 0.35, and the cost function dropped below 0.5 after 372 generations. The larger population of 450 had a slightly better mean of 0.30 and dropped below 0.5 after 324 generations. The largest population we investigated contained 600 chromosomes and resulted in a mean of the cost function of 0.21 and dropped below 0.5 after 278 generations. The better performance regarding the convergence as a function of the number of generations for the larger populations is more than compensated for by the increasing CPU time for increasing populations. One run for a population of 300 takes 21 min, for a population of 450 takes 43 min, and for 600, 52 min using four processors on a SUN UltraSPARC 333 MHz. All subsequent computing times are for this configuration. Almost the same computing time was attained on a dual processor PC with two Pentium 2.6 GHz processors.

The variation of elitism between 30% and 70% is shown in the second row of Fig. 2. The size of the population is kept fixed at 300 for these fits. An elitism of 30% means that the best 30% of one generation are passed unchanged to the next generation. Elitism helps to prevent good solutions from being lost from one generation to the next. As can be inferred from Fig. 2, a fit with an elitism of 30% converges more rapidly than one with 50% or 70%. Nevertheless, the mean cost function of five runs for an elitism of 50% is slightly better. For an elitism of 70%, the mean cost function never drops below 0.5 because too many bad solutions are kept. With regard to CPU time, an elitism of 30% is the most time-consuming (36 min) compared to 50% (21 min) and 70% (12 min).

The third row of Fig. 2 shows the variation of convergence with the mutation probability. Population size is kept fixed at 300 and elitism at 50%. Mutation is introduced to allow for a thorough exploration of the whole cost surface and prevents the algorithm from prematurely converging into a local minimum. With a mutation probability of 0.01, the mean value of the cost function is 0.15, and the cost function drops below 0.5 after 204 generations. With a mutation probability of 0.05, the

© 2004 NRC Canada

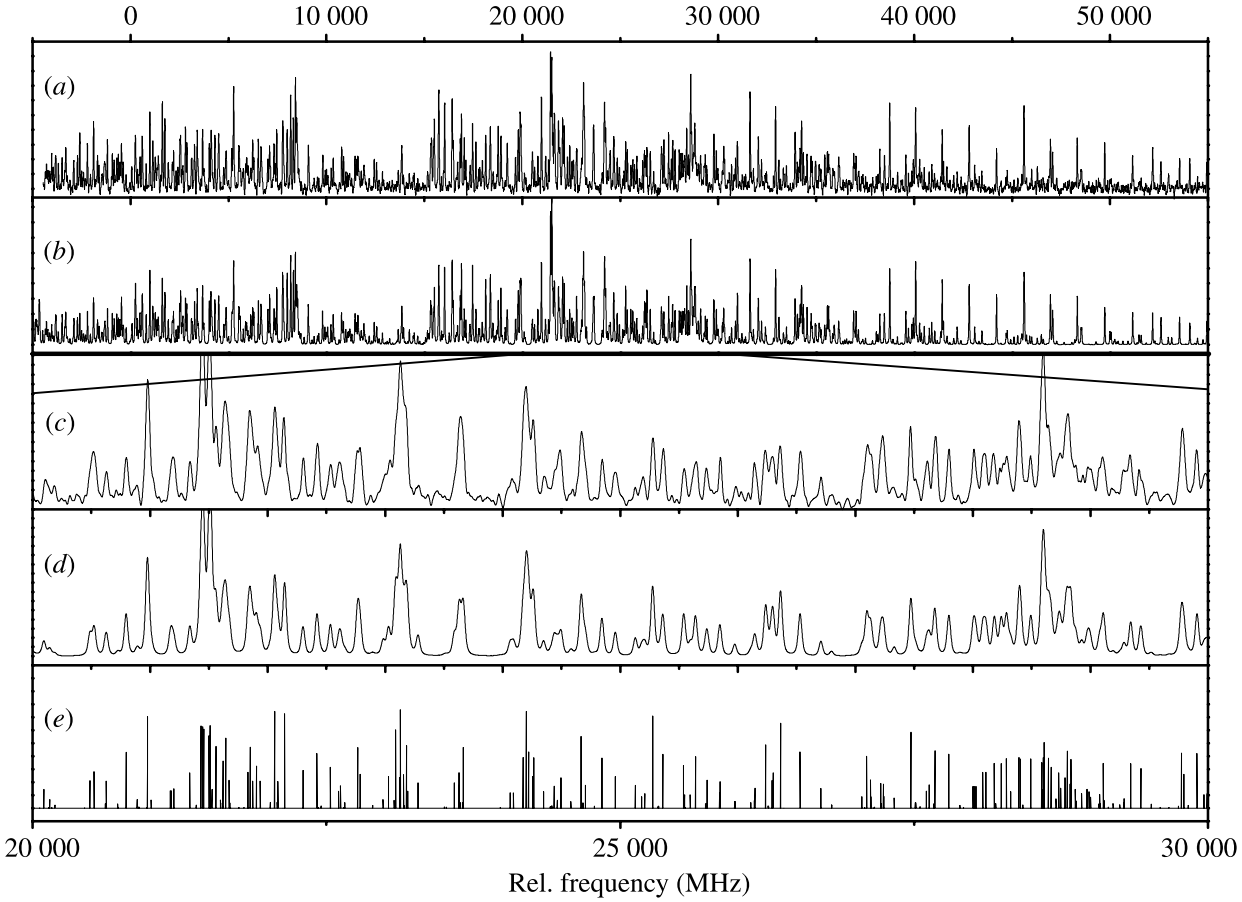
Fig. 2. Convergence of the GA as a function of population size (p), rate of elitism (e), and mutation probability (m). The cost function C_{fg} is plotted on the vertical axis.

mean of the cost function increases to 0.35 (drops below 0.5 after 372 generations), while for a mutation probability of 0.10, the mean cost function value is 1.00. Although all five runs converged to the same global minimum for mutation probabilities of 0.01, 0.05, and 0.10, the mutation probability of 0.01 performed best, considering mean cost function and speed of convergence. However, one has to be careful not to underestimate the risk of converging to a local minimum due to bad exploration of the cost surface. The CPU time as a function of the mutation probability virtually does not change (21 min for probabilities of 0.01, 0.05, and 0.10).

To conclude, the population size should not exceed 300 because of the bad time performance with larger populations, which is not compensated by a much better convergence of the algorithm. An elitism of 30% is advantageous regarding the convergence, but also very time-consuming. The best trade-off between time and convergence performance is found at 50% elitism. A mutation probability of only 0.01 leads to a very fast convergence, with very exactly determined parameters. Nevertheless, in cases where many local minima at the cost surface are present, such a low mutation probability might lead into a local minimum. Reduction of the value of this parameter has therefore to be performed with great care.

4.3. GA fit of very dense rovibronic spectra

In the following, we will present the automated-GA fits of some rovibronic spectra, which are very congested due to small rotational constants. These spectra normally do not represent a great difficulty for the GA, as will be shown in the next sections.



4.3.1. [7-D]Phenol–N_2

We recently performed a fit of the rovibronic spectra of several isotopomers of the phenol–nitrogen cluster (22). The nitrogen is located in the plane of the phenol, hydrogen bonded to the OH group with a bond length of 225.5 pm. In the following, we present the rovibronic spectra of different [7-D]phenol clusters. [7-D]Phenol means replacement of hydrogen by deuterium at the hydroxy group of phenol. The choice of [7-D]phenol instead of the normal isotopomer was made because of the longer lifetime of the deuterated isotopomers, yielding smaller line widths and, therefore, better signal-to-noise ratios. The rotationally resolved electronic spectrum of the electronic origin of [7-D]phenol–N_2 is shown in trace (*a*) of Fig. 3. The observed spectrum consists of about 400 clusters of lines, with only a few single rovibronic lines (cf. the simulated stick spectrum shown in trace (*e*) of Fig. 3).

An assigned fit for such a congested spectrum is very dif-

© 2004 NRC Canada

Fig. 3. (*a*) Experimental rotationally resolved electronic spectrum of the electronic origin of phenol−N_2. (*b*) Simulation, using the parameters given in Table 4. (*c*) Expanded view of trace (*a*). (*d*) Simulation in the same spectral range with Voigt-convoluted line shapes, using a Gaussian width of 26 MHz and a Lorentzian width of 39.4 MHz. (*e*) Stick spectrum in the given spectral range. Intensities are given in arbitrary units.

ficult because the shape changes considerably upon moderate changes of the molecular parameters. The initial search range for the parameters in the GA fit was obtained from a preliminary ab initio calculation. This calculation was based on a "hydrogen" structure as proposed by Ford et al. (23). The molecular parameters obtained from the GA fit with $\Delta w/\Delta_{lw} = 5$ are presented in the second column of Table 4. The values given and the quoted uncertainties are the result of statistics on 10 independent GA runs, with different initial seeds, i.e., different starting populations of the evolution. In a second step, we used the result of the GA calculation to assign quantum numbers to the individual transitions and clusters of lines. Because of the high quality of the GA fit, this was possible in spite of the large number of overlapping lines. With these line position assignments, a second fit to the parameters of the rigid rotor Hamiltonian of eq. [1] was performed. The latter fit yields better values, in particular for the uncertainties of the parameters. For most parameters, the values obtained from the assigned fit (Table 4, column 3) agree within their uncertainties to the corresponding GA results. This spectrum presents an example in which the rovibronic spectrum could be fitted by the GA in a single step, without further refinement of Δw.

Table 4. Comparison of the molecular parameters of the phenol−nitrogen cluster as obtained from an assigned fit and from the GA fit.

Parameter	GA fit	Assigned fit
A'' (MHz)	4071.06 (13)	4072.18(25)
B'' (MHz)	647.89(2)	648.01(4)
C'' (MHz)	559.13(2)	559.26(4)
T (K)	1.6(5)	2.0
θ (°)	62.53(7)	60.0
ΔA (MHz)	−140.99(6)	−141.560(91)
ΔB (MHz)	15.71(1)	15.708(13)
ΔC (MHz)	8.70 (1)	8.671(9)

The computation time for the GA fit of the spectrum with 12 parameters and the direct evaluation of F_{fg} by the full sum of all data points (eq. [3]) was 12 min. It could be reduced to 5 min using the sparse stick array. Thus, a very complex spectrum could be completely fit by the GA within 50 min of computation time.

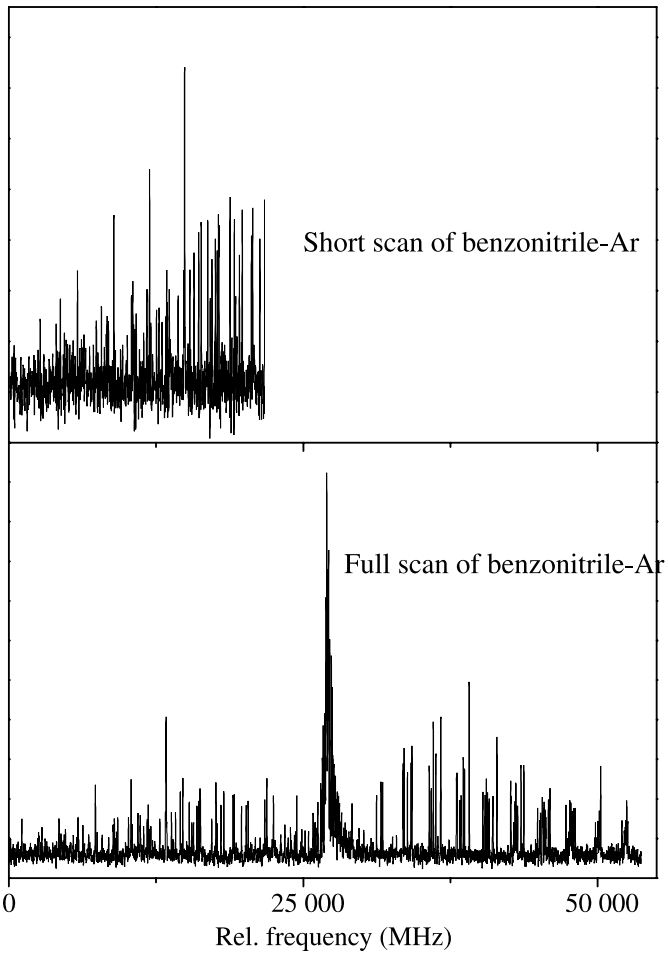
ΔB (MHz)	25.15(13)	25.191(31)
ΔC (MHz)	23.24(6)	23.227(20)

4.3.2. [7-D]Phenol−Ar

The phenol−Ar cluster is an example of a weakly van der Waals-bonded molecular cluster. Owing to the weak binding forces, centrifugal distortion (24, 25) might play a role in the determination of the molecular parameters. We included the five quartic centrifugal distortion constants for each electronic state in the fit. Compared to an equivalent fit without centrifugal constants, no significant improvement of the fit could be obtained. We performed the GA fit, where the azimuthal and polar angles of the transition dipole moment were allowed to vary between 0° and 90°, i.e., within their complete definition range. Further parameters to be varied were the rotational constants of ground and excited state, the center frequency,[4] and a single temperature. We used $\Delta w/\Delta_{lw} = 10$. As in the case of the [7-D]phenol−N_2 spectrum, the spectrum could be fitted without refining Δw. The resulting molecular parameters from the GA and from an assigned fit are presented in Table 5. While the rovibronic spectrum of phenol is of pure *b*-type, the argon atom, which is located above the aromatic ring and shifted slightly towards the hydroxy group, switches the axes, so that the transition moment in the cluster is oriented nearly along the inertial *c*-axis. From the parameters given in Table 5, we calculated the perpendicular r_0-distance of the argon atom to the aromatic ring with the program pKrFit (26). In the electronic ground state this distance is found to be 352.1 pm, while in the electronically excited state the distance is slightly reduced to 350.3 pm. Both values are in good agreement with distances found for other aromatic − noble gas clusters.



The GA fit of 10 molecular parameters was terminated in 6 min, using the sparse stick array implementation described in Sect. 3.3.2. Doubling of the dimension of the fitness surface by adding the 10 centrifugal distortion constants resulted in a computation time of 9 min. With the chosen ratio of $\Delta w/\Delta_{lw} = 10$, all five initial seeds converged to the same minimum within 500 generations.

4.3.3. Benzonitrile−Ar

If due to experimental limitations only the outermost parts of the *P*- or the *R*-branch can be recorded, and the electronic origin of a rovibronic band is missing, the task of performing an assigned fit gets tedious or even impossible. However, also in this difficult case the GA succeeds in finding the global minimum and assigning the spectrum properly. As an example we chose the spectrum of the electronic origin of benzonitrile−Ar, shown in the upper trace of Fig. 4. Obviously, the low-frequency side of the spectrum has been measured with a quite bad signal-to-noise ratio. Nevertheless, the GA was able to determine the molecular parameters. The result is given in the first column of Table 6. The computing time was the same as for a complete spectrum discussed in the previous section. The electronic origin is found by the GA to be 8000 MHz to the blue of the high-frequency end of the spectrum. A GA fit to the complete spectrum with good signal-to-noise (lower trace in Fig. 4) yields slightly different molecular parameters (second column of Table 6). Nevertheless, the quality of the parameters obtained from the fit to the partial spectrum is surprisingly good. The only parameters that have relatively large deviations are the polar and azimuthal angles of the transition dipole moment. This is obviously due to the fact that the band type cannot be determined accurately from a fit of a single branch only.

Results from previous studies on benzonitrile−Ar are also given in the last column of Table 6. The current results for the excited state are more accurate than those of Helm et al. (1) because of the substantially lower resolution of their experiment.

Fig. 4. Upper trace: low-frequency part of the spectrum of benzonitrile−Ar. Lower trace: complete rovibronic spectrum. Intensities are given in arbitrary units. For details see the text.

[4]The value for the center frequency is omitted in all tables, as it is a relative number.

[c]From ref. 27.

[d]From ref. 1.

Our ground-state values do not completely agree with the very accurate microwave results from Dreizler and co-workers (27). This is an indication that the uncertainties in our parameters, based on the statistical behavior of the GA fits, are slightly underestimated.

4.4. Simultaneous GA fit of two overlapping rovibronic spectra

A much more demanding task than a fit of a single rovibronic spectrum is the simultaneous fit of two (or more) overlapping spectra. First of all, the number of transitions within a spectral interval is doubled, leading to very dense and congested spectra. Secondly, the number of molecular parameters is also doubled, which generates quite a large parameter space.

Overlapping spectra occur in particular if several isotopic species are investigated. While mass resolution techniques like resonance two-photon ionization with time-of-flight mass spectroscopy are able to separate the isotopic species with a different mass, the technique normally lacks experimental resolution owing to the pulse-width-limited resolution used in these studies. On the other hand, mass selection cannot be combined with high-resolution LIF spectra. In the next sections, we show that the GA spectrum assignments are capable of handling overlapping spectra both from different isotopomers as well as from different conformers.

4.4.1. [7-D][^{18}O]Phenol and [7-D][^{16}O]phenol

Further tests of the GA were performed with experimental spectra consisting of two sub-spectra, which originate from two isotopomers. As a first example, we chose the rovibronic spectrum of [^{18}O][7-D]phenol/[^{16}O][7-D]phenol, which had been assigned and published before (26). The isotopic enrichment of the phenol sample resulted in an isotopic purity of about 50% for the oxygen isotopes and of 100% for hydrogen. Since the spectral shift of the two spectra is about 3 GHz, the spectra completely overlap within the rovibronic contour. Both sub-spectra are of pure b-type, and thus the polar and azimuthal angles θ and ϕ do not need to be fit in this case. The rovibronic lines have a Voigt profile with a Gaussian line width of 20 MHz and a Lorentzian contribution of 12 MHz because of the fluorescence lifetime of 12.5 ns. The maximum J value in the calculation of the cost function is 15. Due to the smaller number of lines in the calculated spectrum, the computation time for the cost function drops drastically, and throughout all calculations on the phenol system, a population of 600 could be employed. The method for the GA evaluation employed is the same as described in Sect. 4.1. An initial fit was performed with a large value of $\Delta w/\Delta_{lw} = 15$. Table 7 gives the results of a GA fit, the limits of the molecular parameters used in the fit, and the results of a previously published assigned fit for comparison. Four GA evaluations with different starting values all converge to the same global minimum. Thus, $\Delta w/\Delta_{lw}$ was chosen correctly in the first step of the analysis. The comparison with the results from an assigned fit nevertheless shows deviations of about 2 MHz for the inertial parameters and their changes upon electronic excitation.

A second fit is performed with $\Delta w/\Delta_{lw} = 4$. The limits for the rotational constants and ΔA were reduced by a factor of 5 compared to the fit with $\Delta w/\Delta_{lw} = 15$, while the limits for ΔB and ΔC, which were already quite small, were reduced only by a factor of approximately 2. The results given in Table 8 clearly show not only that the GA fit converged to the global minimum, which is determined unambiguously from the assigned fit, but that the values of the inertial parameters are reproduced within their experimental accuracies. Figure 5 shows the experimental spectrum, along with the simulated spectra, using the parameters from the GA fit and from the assigned fit.

One run of the GA calculation with a population size of 600, a mutation probability of 0.05, and an elitism of 50% takes only about 10 min. This is due to the small J_{max} in the calculation of the simulated spectrum. With an initial seed of five different starting populations and two successive fits with different line width ratios and parameter spaces, a complete automated assignment was performed in less than 2 h.

In summary, in a two-step fit the GA evaluation succeeded in determining all molecular parameters for both completely overlapping spectra of [^{18}O][7-D]phenol and [^{16}O][7-D]phenol. The accuracy is comparable to an assigned fit of individual

rovibronic transitions. This evaluation is performed in less than 2 h, without any prior knowledge of the molecular parameters.

4.4.2. [3-D][7-D]Phenol and [5-D][7-D]phenol

Another example of overlapping electronic origins of different isotopomers of phenol is the pair [3-D][7-D]phenol and [5-D][7-D]phenol. Here, we have to assign simultaneously two bands with different Lorentzian widths in the Voigt profiles. In a recent publication (26), the line widths of both isotopomers were obtained from a fit of some individual rovibronic lines of each species (26). Since the GA performs a line shape fit of the complete spectrum, it should yield more accurate values. In a first step, the inertial parameters were determined using the GA with $\Delta w/\Delta_{lw} = 5$. For the determination of the line

shape parameters, the parameter space for the inertial parameters was narrowed down to 1 MHz and the GA fit was performed with $\Delta w = 0$. The Gaussian width was fixed to the experimentally determined value of 25 MHz. The temperature dependence of the relative intensity n is described by a two-temperature model (28):

$$[15] \qquad n(T_1, T_2, w_T) = \mathrm{e}^{-E/kT_1} + w_T \mathrm{e}^{-E/kT_2}$$

Here, E is the energy of the lower state, w_T a weight factor, and T_1 and T_2 the two temperatures. The intensity ratio between the spectra is fit as well. This resulted in improved values for the Lorentzian component of the line width. The resulting parameters are presented in Table 9 and compared with the values of an assigned fit. While the inertial parameters all agree within their uncertainties, the line width parameters are quite different. From the Lorentzian widths, the S_1-state lifetimes could be determined to be 23.5 ns for [3-D][7-D]phenol and 18.5 ns for [5-D][7-D]phenol. These values differ considerably from 38.8 ns and 15.6 ns obtained from a line shape fit to individual transitions in the spectrum. We attribute this difference to the limited number of single rovibronic transitions that could be used in the analysis of the line shapes, given in ref. 26.

As discussed before, the sparse stick spectrum array cannot be used for a fit of a line shape parameter. Instead, the sum in eq. [3] runs over all 80 700 data points, compared to just 745 lines with an intensity of more than 0.001 in the stick spectrum. This of course slows down the calculation of the fitness function considerably. A fit using the sparse array was finished in only 4.5 min, while the calculation with all data points needed 12 min.

4.4.3. Benzonitrile–^{20}Ne and benzonitrile–^{22}Ne

In all the cases discussed so far, the relative intensity of the two spectra is approximately 1:1. The situation is much more complicated if both isotopomers have very different abundances.

We performed a fit of the rovibronic spectrum of the isotopomeric pair benzonitrile–^{20}Ne/benzonitrile–^{22}Ne in the natural abundance of ^{20}Ne/^{22}Ne (91:9). In this case, the GA has the much more difficult task of fitting quite a weak spectrum in the presence of a strong spectrum. The situation is further complicated by the fact that some of the lines present in the spectrum are due to benzonitrile monomer lines (the electronic origin of the monomer is shifted by about 4.3 cm^{-1} to higher frequency). Although the monomer origin has already been assigned (29), these monomer lines cannot be predicted with sufficient accuracy because they belong to very high J states.

The rovibronic spectrum of benzonitrile is of pure b-type. The neon atom is located above the aromatic ring, shifted slightly towards the cyano group. This structure gives rise to an axis switching. As a consequence, the transition moment in the cluster is oriented nearly along the inertial c-axis. For this molecular structure, an ac-hybrid is expected with strong c-type lines and much weaker a-type lines.

The results for the ac-hybrid type were checked against ab-, bc-, and abc-hybrid fits for consistency. The mean values for

the cost functions are 7.95, 29.26, 9.27, and 7.18, respectively. Therefore, *ab*-hybrids can be discarded, which is in agreement with the geometry of the cluster. The *bc*-hybrid type fits slightly worse than the *ac*- type. However, the cost function differs only slightly because the spectrum is dominated by *c*-type lines. The *abc*-type did not improve the fit considerably. In conclusion, the initial assumption of the *ac*-hybrid type based on the approximate knowledge of the geometry was confirmed. Table 10 gives the molecular parameters obtained from a four-step GA fit. In the first step, $\Delta w/\Delta_{lw} = 10$ was employed. The search limits for the rotational constants were ±100 MHz for both isotopomers. The parameter limits were narrowed down to one-tenth that of the original size, centered around the best fit value of the first step. While the more abundant species (benzonitrile–^{20}Ne) presented no difficulties, the fit of the weaker component spectrum got trapped in a local minimum. This had two reasons: the intensity of the sub-spectrum of benzonitrile–^{22}Ne is only one-tenth that of the stronger component and the additional monomer lines have comparable intensities to the transitions of the stronger isotopic species. Thus, the parameter limits for the weaker sub-spectrum had to be reduced more slowly and in more steps. First, the parameter limits were reduced by only a factor of two, while $\Delta w/\Delta_{lw}$ was reduced to 7.5. In a subsequent step, $\Delta w/\Delta_{lw} = 5$ and limits of ±20 MHz for the rotational constants were employed. Finally, the molecular constants given in Table 10 were obtained for $\Delta w/\Delta_{lw} = 1.5$.

Fig. 6. Upper trace: experimental spectrum of benzonitrile–^{20}Ne/benzonitrile–^{22}Ne. Lower trace: simulation using the best parameters from Table 10. Intensities are given in arbitrary units.

In this case, the fit required some "fine tuning", which had to be done manually. Nevertheless, the results of the fit of the rovibronic spectrum of benzonitrile–^{20}Ne/benzonitrile–^{22}Ne (Fig. 6) show that even very congested spectra, with one spectral component much weaker than the other, can be assigned using the GA without any prior knowledge of geometry or molecular parameters.

5. Summary

In this paper we have shown that the GA is capable of treating a wide range of different spectra with complexity ranging from highly overlapping transitions to coinciding spectra of different isotopomers. Even if only a partial spectrum is available, the method is still successful. The GA succeeds in assigning the spectra and determines the molecular parameters without any prior knowledge of their values.

If the spectrum under study originates from a single vibronic transition, convergence could be reached in a one-step fit with a typical value for $\Delta w/\Delta_{lw}$ of 10. A great enhancement is obtained in the accuracy of the line shape and intensity parameters. While the assigned fit always uses the information from a few selected single rovibronic lines, the GA utilizes all transitions in the spectrum to adapt these parameters. In particular, the Lorentzian width (lifetime), the temperature, and the orientation of the transition dipole moment in the molecule or in the molecular cluster are determined more accurately from GA fits.

In cases in which the spectrum is composed of two subspectra, a more advanced strategy has to be followed. A preliminary fit with a relatively broad weight function was performed and subsequently refined with both smaller weight function widths and narrowed parameter search space. Using this technique, very complicated spectra of two overlapping bands could be fitted using the GA. Even a large difference in intensity between the overlapping band forms no obstacle.

The success of the GA procedure of automated fitting is based on the existence of a good model for the prediction of the spectra. This seems to be the only drawback until now. However, there are many cases for which a good model prediction exists, in particular in absorption, cavity ringdown, and laser-induced fluorescence spectra. We even expect that in the case of small and (or) local perturbations, the main spectral features that conform to the model can be extracted and hence the perturbations are isolated.

The examples discussed demonstrate the extreme power of the GA in automated fitting and assigning of very complex spectra, spectra that can hardly be assigned and analyzed with conventional methods. It has been shown that the evaluation of the fitness function can be made to a minor contribution in the computing time if the particular properties of F_{fg} are fully exploited. The computing power of modern PCs is more than adequate to perform the job in an acceptable time. This new technique opens the road to the analysis of the complex spectra of biomolecules and their building blocks.

Appendix A.

In this appendix we show that the real or complex matrix $\boldsymbol{W}$ with matrix elements $W_{ij} = w(r_i - r_j)$ is positive definite if $w(r)$ can be written as the inverse Fourier transform of a positive function $\tilde{w}(t)$. Let

$$[A.1] \quad w(r) = \int_{-\infty}^{\infty} \tilde{w}(t) e^{2\pi i r t} \mathrm{d}t$$

then

$$[A.2] \quad \boldsymbol{x}^{\dagger} \boldsymbol{W} \boldsymbol{x} = \sum_{i,j} x_i^* W_{ij} x_j$$

$$= \sum_{i,j} x_i^* \int_{-\infty}^{\infty} \tilde{w}(t) \exp\left[2\pi i (r_i - r_j) t\right] \mathrm{d}t \; x_j$$

$$= \int_{-\infty}^{\infty} \left| \sum_i x_i \exp\left[-2\pi i r_i t\right] \right|^2 \tilde{w}(t) \, \mathrm{d}t$$

Hence, if $\tilde{w}(t) > 0$ then $\boldsymbol{x}^{\dagger} \boldsymbol{W} \boldsymbol{x} > 0$ for any vector $\boldsymbol{x}$ and so $\boldsymbol{W}$ is positive definite. If $\tilde{w}(t)$ is zero for certain values of t, the integral is still positive. Note: one should read in eq. [4] $r_i = i$.

RKR-type inversion of the diatomic energy shifts due to breakdown of the Born–Oppenheimer approximation[1]

James K.G. Watson

Abstract: The principal effects of the breakdown of the Born–Oppenheimer approximation on the vibration–rotation energies of a diatomic molecule can be represented by the expectation values of terms to order (m_e/M_i) in the effective Hamiltonian, where m_e is the electron mass and M_i is the mass of atom i. This paper examines the possibility of inverting these expectation values to obtain the correction functions as functions of the internuclear distance r, using a generalization of the semiclassical Rydberg–Klein–Rees method. It is shown that the correction functions are not completely determinable from the inversion, and the form of the determinable combinations is obtained.

Key words: diatomic molecules, vibration–rotation energies, isotope effects, Born–Oppenheimer breakdown, Rydberg–Klein–Rees method.

Résumé : Les principaux effets de l'échec de l'approximation Born–Oppenheimer sur les énergies de vibration–rotation d'une molécule diatomique peuvent être représentés par les valeurs moyennes des termes d'ordre (m_e/M_i) de l'Hamiltonien effectif dans lequel m_e est la masse de l'électron et M_i est la masse de l'atome i. Dans ce travail, on a examiné la possibilité d'invertir ces valeurs moyennes afin d'obtenir les corrections comme fonctions de la distance internucléaire, r, en utilisant une généralisation de la méthode semi-classique Rydberg–Klein–Rees. On a démontré qu'il n'est pas possible de déterminer complètement les fonctions de correction à partir de l'inversion et on a obtenu la forme de combinaisons qui peuvent être déterminées.

Mots clés : molécules diatomiques, énergies de vibration–rotation, effets isotopiques, échec de l'approximation Born–Oppenheimer, méthode de Rydberg–Klein–Rees.

[Traduit par la Rédaction]

1. Introduction

The vibration–rotation energy levels of a set of isotopomers of a given diatomic molecule are frequently represented by the formula (1, 2)

$$[1] \qquad E_{vJ} = \sum_{kl} U_{kl} \left(1 + \sum_i \frac{m_e}{M_i} \Delta_{kl}^i\right) \times \left(\frac{v + 1/2}{\mu_C^{1/2}}\right)^k \left(\frac{J(J+1)}{\mu_C}\right)^l$$

where the coefficients U_{kl} and Δ_{kl}^i are isotope-independent. The coefficients U_{kl} come from a first-order semiclassical treatment (3) of the Born–Oppenheimer (BO) Hamiltonian for motion in the internuclear coordinate r,

$$[2] \qquad H_0 = \frac{1}{2\mu_C} p_r^2 + V_J(r)$$

[1]This article is part of a Special Issue dedicated to the memory of Professor Gerhard Herzberg.

which contains the charge-modified reduced mass

$$[3] \qquad \mu_C = \frac{M_A M_B}{(M_A + M_B - C m_e)}$$

where C is the electric charge of the molecule AB in units of e, and

$$[4] \qquad V_J(r) = V(r) + \frac{\hbar^2 J(J+1)}{2\mu_C r^2}$$

is the effective potential energy. The correction terms in $U_{kl}\Delta_{kl}^i$ in eq. [1] are partly "Dunham corrections" from second-order semiclassical contributions (3) and partly contributions from H_1 due to Born–Oppenheimer breakdown (BOB) (2),

$$[5] \qquad H_1 = \sum_i (m_e/M_i) \left[\frac{1}{2\mu_C} p_r Q^i(r) p_r + \frac{\hbar^2}{2\mu_C r^2} R^i(r) J(J+1) + S^i(r)\right]$$

for a $^1\Sigma$ electronic state, where $Q^i(r)$, $R^i(r)$, and $S^i(r)$ are functions allowing for non-adiabatic and adiabatic electronic effects. The corrections $U_{kl}\Delta_{kl}^i$ in eq. [1] do not factorize naturally in this form (2, 4), and so there may occasionally seem to be anomalously large values of Δ_{kl}^i when U_{kl} is small. The remainder of the effective internuclear Hamiltonian,

$$[6] \qquad H = H_0 + H_1 + O\left(m_e^2/M_i^2\right)$$

 doi: 10.1139/V04-049 © 2004 NRC Canada

is usually regarded as negligible unless there is a near-degeneracy of electronic states.

The expectation value of H_1 over a radial wavefunction $|v, J\rangle$ is

$$[7] \qquad \langle v, J|H_1|v, J\rangle = \sum_i (m_e/M_i)\epsilon^i_{vJ}$$

where ϵ^i_{vJ} is the expectation value

$$[8] \qquad \begin{aligned}\epsilon^i_{vJ} &= \langle v, J|p_r Q^i(r) p_r/2\mu_C \\ &\quad + \hbar^2 J(J+1)R^i(r)/2\mu_C r^2 + S^i(r)|v, J\rangle \\ &= \sum_{kl} U_{kl}\left(\Delta^i_{kl} - \Delta^D_{kl}\right) \\ &\quad \times \left(\frac{v+1/2}{\mu_C^{1/2}}\right)^k \left(\frac{J(J+1)}{\mu_C}\right)^l\end{aligned}$$

where the Δ^D_{kl} are the Dunham corrections, which are the same for both atoms i, and can be calculated from the parameters of the BO potential (3).

Equation [8] raises the problem of the "inversion" of the ϵ^i_{vJ}, which can be regarded as observed quantities, to obtain, as far as possible, the functions $Q^i(r)$, $R^i(r)$, and $S^i(r)$. This is discussed here from a semiclassical point of view, as an extension of the familiar RKR (5–8) inversion of the BO energies. Previously, the inversion of the expectation values of a J-independent operator has been discussed (9, 10), but the fact that the present operator is J-dependent requires an extension of the theory.

2. Indeterminacy of $Q^{i(r)}$

The usual first-order semiclassical quantization condition is

$$[9] \qquad \int_{r^-_{vJ}}^{r^+_{vJ}} p_r\, dr = (h/2)(v+1/2)$$

where $r^\pm_{vJ}$ are the classical turning points in the effective potential $V_{\rm eff}$, which is taken in this section to be the full potential in $H_0 + H_1$. If we solve for p_r, the quantization condition gives

$$[10] \qquad \int_{r^-_{vJ}}^{r^+_{vJ}} (E_{vJ} - V_{\rm eff})^{1/2}\,(1+Q)^{-1/2}\, dr = \pi k(v+1/2)$$

where $Q = \sum_i (m_e/M_i)\, Q^i(r)$,

$$[11] \qquad \begin{aligned}V_{\rm eff}(r) &= V(r) + \frac{\hbar^2 J(J+1)}{2\mu_C r^2} + \sum_i (m_e/M_i) \\ &\quad \times \left[\frac{\hbar^2}{2\mu_C r^2} R^i(r) J(J+1) + S^i(r)\right]\end{aligned}$$

and

$$[12] \qquad k = \hbar/(2hc\mu_C)^{1/2}$$

if it assumed that the energies are in wavenumber units. Taking $(1+Q)^{-1/2} \approx 1 - \frac{1}{2}Q$, and then integrating the Q term by parts according to

$$[13] \qquad \begin{aligned}&-\frac{1}{2}\int_{r^-_{vJ}}^{r^+_{vJ}} [E_{vJ} - V_{\rm eff}(r)]^{1/2}\, Q(r)\, dr \\ &\quad = -\Big[[E_{vJ} - V_{\rm eff}(r)]^{1/2}\, A(r)\Big]_{r^-_{vJ}}^{r^+_{vJ}} \\ &\qquad - \frac{1}{2}\int_{r^-_{vJ}}^{r^+_{vj}} [E_{vJ} - V_{\rm eff}(r)]^{-1/2} V'_{\rm eff}(r) A(r)\, dr\end{aligned}$$

where

$$[14] \qquad A(r) = \frac{1}{2}\int_{r_0}^{r} Q(r')\, dr'$$

we find that the integrated part vanishes in eq. [13]. The second term on the right of eq. [13] can then be taken as the first correction term in a binomial expansion, to give the quantization condition

$$[15] \qquad \int_{r^-_{vJ}}^{r^+_{vJ}} [E_{vJ} - \tilde{V}_{\rm eff}(r)]^{1/2}\, dr = \pi k(v+1/2)$$

where

$$[16] \qquad \tilde{V}_{\rm eff}(r) = V_{\rm eff}(r) + V'_{\rm eff}(r)A(r)$$

The prime ($'$) here means differentiation with respect to r. Note that r_0 in the definition of $A(r)$ is arbitrary. This equivalence of the expectation value of a kinetic energy term to that of a potential energy term is a generalization of the virial theorem (11).

It is seen that the $Q^i(r)$ correction has the same effect on the energies as contributions from the $R^i(r)$ and $S^i(r)$ corrections. Thus, if we ignore higher-order terms by using $V_J(r)$ rather than $V_{\rm eff}(r)$, we see that the expectation value in eq. [8] is unchanged when $Q^i(r)$, $R^i(r)$, and $S^i(r)$ are replaced by

$$[17] \qquad \tilde{Q}^i(r) = 0$$

$$[18] \qquad \tilde{R}^i(r) = R^i(r) - 2A^i(r)/r$$

$$[19] \qquad \tilde{S}^i(r) = S^i(r) + V'(r)A^i(r)$$

where

$$[20] \qquad A^i(r) = A^i_0 + \frac{1}{2}\int_{r_e}^{r} Q^i(r')\, dr'$$

and $V(r)$ is the BO potential energy. The value of A^i_0 is arbitrary. The value of ϵ^i_{vJ} is therefore,

$$[21] \qquad \epsilon^i_{vJ} = \langle v, J|\tilde{S}^i(r) + \hbar^2 J(J+1)\tilde{R}^i(r)/2\mu_C r^2|v, J\rangle$$

and it is seen that $Q^i(r)$ is not separately determinable from the expectation values. At most, the combinations obtained from eqs. [18] and [19] by eliminating the arbitrary A^i_0 will be determinable.

© 2004 NRC Canada

3. Inversion of expectation values

The semiclassical expectation value of an operator $X_J(r)$ is (12)

$$[22] \qquad X_{vJ} = \frac{1}{\pi k}\frac{\partial}{\partial v}\int_{r_{vJ}^-}^{r_{vJ}^+} X_J(r)[E_{vJ} - V_J(r)]^{1/2}\,\mathrm{d}r$$

The classical turning points r_{vJ}^- and r_{vJ}^+ are the solutions of

$$[23] \qquad V_J(r_{vJ}^{\pm}) = E_{vJ}$$

A solution to this inversion problem for J-independent $X(r)$ has been given by Stwalley (9) and Watson (10). Here, we consider a more general version that is applied in Sect. 4 to the case of J-dependent $X_J(r)$. By changing v to v' in eq. [22], multiplying by $(E_{vJ} - E_{v'J})^{n-1/2}$, and integrating over v' from –1/2 to v, we find the master equation for inversion

$$[24] \qquad \int_{r_{vJ}^-}^{r_{vJ}^+} X_J(r)[E_{vJ} - V_J(r)]^n\,\mathrm{d}r = 2k\frac{2^{2n}(n!)^2}{(2n)!}\int_{-1/2}^{v} X_{v'J}(E_{vJ} - E_{v'J})^{n-1/2}\,\mathrm{d}v'$$

where the (now) left side has been evaluated by changing the order of integration. Note that for $n \geq 1$ the integrand on the left side of eq. [24] vanishes at both end points, and the integrand on the right vanishes at the upper end point.

The familiar RKR equations can be obtained by taking $X_J(r) \equiv 1$ in this equation. For the first RKR equation we take $n = 0$ and $J = 0$, to get

$$[25] \qquad r_v^+ - r_v^- = 2k\int_{-1/2}^{v}(E_v - E_{v'})^{-1/2}\,\mathrm{d}v'$$

The second RKR equation is obtained by taking $n = 1$, differentiating with respect to $J(J+1)$, putting $J = 0$, noting that $[\partial E_{vJ}/\partial J(J+1)]_{J=0} = B_v$, and using the first RKR equation. This procedure is simplified by introducing the operator

$$[26] \qquad D_j = \left[\frac{\partial}{\partial j} - \frac{\partial E_{vJ}/\partial j}{\partial E_{vJ}/\partial v}\frac{\partial}{\partial v}\right]$$

where j is defined as

$$[27] \qquad j = \hbar^2 J(J+1)/2hc\mu_C = k^2 J(J+1)$$

so that $V_J(r) = V(r) + j/r^2$. Then D_j commutes with E_{vJ}. If we operate with D_j on eq. [24] with $X_J(r) \equiv 1$ and $n = 1$ and then set $J = 0$, we get the second RKR equation

$$[28] \qquad \left[(r_v^+)^{-1} - (r_v^-)^{-1}\right] = -\frac{2}{k}\int_{-1/2}^{v} B_{v'}(E_v - E_{v'})^{-1/2}\,\mathrm{d}v'$$

because $D_j E_{v'J}|_{J=0} = B_{v'}/k^2$.

Let us now take $n = 0$ in eq. [24], and differentiate it with respect to v. For the derivatives of the turning points, we have from eq. [23]

$$[29] \qquad \frac{\partial r_{vJ}^{\pm}}{\partial v} = \frac{\omega_{vJ}}{V_J'(r_{vJ}^{\pm})}$$

where

$$[30] \qquad \omega_{vJ} = \partial E_{vJ}/\partial v$$

We, therefore, obtain

$$[31] \qquad \left[\frac{X_J(r)}{V_J'(r)}\right]_{r_{vJ}^-}^{r_{vJ}^+} = \frac{2k}{\omega_{vJ}}\frac{\partial}{\partial v}\int_{-1/2}^{v} X_{v'J}(E_{vJ} - E_{v'J})^{-1/2}\,\mathrm{d}v'$$

This is the first RKR-type equation for inverting expectation values. For $J = 0$, it is equivalent to eq. [15] of ref. 10.

The apparently singular terms on the right side of equations such as [31] can be avoided by integration by parts, which gives, for example,

$$[32] \qquad \int_{-1/2}^{v} X_{v'J}(E_{vJ} - E_{v'J})^{n-1/2}\,\mathrm{d}v' = -\frac{1}{(n+1/2)}\left[\frac{X_{v'J}}{\omega_{v'J}}(E_{vJ} - E_{v'J})^{n+1/2}\right]_{-1/2}^{v} + \frac{1}{(n+1/2)}\int_{-1/2}^{v}\frac{\partial}{\partial v'}\left(\frac{X_{v'J}}{\omega_{v'J}}\right) \times (E_{vJ} - E_{v'J})^{n+1/2}\,\mathrm{d}v' = \frac{1}{(n+1/2)}\left\{\frac{X_{eJ}}{\omega_{eJ}}(E_{vJ} - E_{eJ})^{n+1/2} + \int_{-1/2}^{v}\frac{\partial}{\partial v'}\left(\frac{X_{v'J}}{\omega_{v'J}}\right)(E_{vJ} - E_{v'J})^{n+1/2}\,\mathrm{d}v'\right\}$$

where e refers to equilibrium, $v = -1/2$. The right side can now be differentiated with respect to v, and gives an integrable singularity in the integrand. In the following equations, it is assumed that apparent singularities on the right sides have been removed by integrations by parts, repeatedly if necessary.

To obtain the second equation for inverting expectation values, we assume that $X_J(r)$ in eq. [24] is replaced by $X(r)$, independent of J, take $n = 1$, operate with D_j and then $\partial/\partial v$,

© 2004 NRC Canada

and put $J = 0$. The result is

$$[33]\quad \left[\frac{X(r)}{r^2V'(r)}\right]_{r_v^-}^{r_v^+} = \frac{2}{k\omega_v}\frac{\partial}{\partial v} \times \left\{\int_{-1/2}^{v} X_{v'}B_{v'}(E_v - E_{v'})^{-1/2}\,\mathrm{d}v' - 2\int_{-1/2}^{v} X_{Dv'}(E_v - E_{v'})^{1/2}\,\mathrm{d}v'\right\}$$

where $X_{Dv} = \partial X_{vJ}/\partial J(J+1)|_{J=0}$. Equation [33] is equivalent to eq. [16] of ref. 10.

The left sides of eqs. [31] and [33] can be solved for $X(r_v^{\pm})$ if the potential is known. Thus, there is in principle no indeterminacy in the solution for $X(r_v^{\pm})$.

4. RKR-type inversion of BOB functions

We now consider the J-dependent operator $X_J(r)$ given by

$$[34]\quad X_J(r) = \tilde{S}^i(r) + j\tilde{R}^i(r)/r^2$$

whose expectation values are the corrections ϵ^i_{vJ}.

To invert eq. [22] we want to evaluate both $\tilde{S}^i(r_v^{\pm})$ and $\tilde{R}^i(r_v^{\pm})$ at the classical turning points $r_v^{\pm}$. For each v we therefore need four equations. These are obtained by successive differentiations with respect to J, or equivalently with respect to j. For the first equation, we can use eq. [31] with this particular $X_J(r)$.

If we now take $n = 0$ in eq. [24] and operate with D_j, the left side gives

$$[35]\quad \int_{r_{vJ}^-}^{r_{vJ}^+} \frac{\partial X_J(r)}{\partial j}\,\mathrm{d}r - \left[\frac{X_J(r)}{r^2V_J'(r)}\right]_{r_{vJ}^-}^{r_{vJ}^+}$$

where

$$[36]\quad D_j r_{vJ}^{\pm} = -\frac{1}{(r_{vJ}^{\pm})^2 V_J'(r_{vJ}^{\pm})}$$

has been used. Then a differentiation by v gives

$$[37]\quad \left[\frac{1}{V_J'(r)}\left\{\frac{\partial X_J(r)}{\partial j} - \frac{\partial}{\partial r}\left(\frac{X_J(r)}{r^2V_J'(r)}\right)\right\}\right]_{r_{vJ}^-}^{r_{vJ}^+} = \frac{2k}{\omega_{vJ}}\frac{\partial}{\partial v}D_j\int_{-1/2}^{v} X_{v'J}(E_{vJ} - E_{v'J})^{-1/2}\,\mathrm{d}v'$$

This generalization of eq. [33] is the second RKR-type equation.

For the next equation, we take $n = 1$ in eq. [24] and operate twice with D_j and then once with $\partial/\partial v$. The result on the left side, using the fact that $X_J(r)$ is linear in j, is

$$[38]\quad -\left[\frac{\omega_{vJ}}{V_J'(r)}\left\{\frac{2}{r^2}\frac{\partial X_J(r)}{\partial j} - \frac{\partial}{\partial r}\left(\frac{X_J(r)}{r^4V_J'(r)}\right)\right\}\right]_{r_{vJ}^-}^{r_{vJ}^+}$$

Similarly, the fourth equation is obtained by taking $n = 2$, operating three times with D_j, and then differentiating with respect to v. The resulting left side is

$$[39]\quad \left[\frac{2\omega_{vJ}}{V_J'(r)}\left\{\frac{3}{r^4}\frac{\partial X_J(r)}{\partial j} - \frac{\partial}{\partial r}\left(\frac{X_J(r)}{r^6V_J'(r)}\right)\right\}\right]_{r_{vJ}^-}^{r_{vJ}^+}$$

Equations [31] and [37] and expressions [38] and [39] give the quantities obtained by inversion of the X_{vJ} values. Substituting eq. [34] into [31] and [37]–[39], letting $J \to 0$, and for convenience increasing n by 1, we see that the quantities determined are

$$[40]\quad \left[\frac{\tilde{S}^i(r)}{V'(r)}\right]_{r_v^-}^{r_v^+} = \frac{2k}{\omega_v}\frac{\partial}{\partial v}\int_{-1/2}^{v}\epsilon^i_{v'0}(E_v - E_{v'})^{-1/2}\,\mathrm{d}v'$$

and

$$[41]\quad \left[\frac{1}{V'(r)}\left\{\frac{n}{r^{2n}}\tilde{R}^i(r) - \frac{\mathrm{d}}{\mathrm{d}r}\left(\frac{\tilde{S}^i(r)}{r^{2n}V'(r)}\right)\right\}\right]_{r_v^-}^{r_v^+} = \left[\frac{n}{r^{2n}V'(r)}\left\{\tilde{R}^i(r) + \frac{2\tilde{S}^i(r)}{rV'(r)}\right\} - \frac{1}{r^{2n}V'(r)}\frac{\mathrm{d}}{\mathrm{d}r}\left(\frac{\tilde{S}^i(r)}{V'(r)}\right)\right]_{r_v^-}^{r_v^+} = (-1)^{n-1}\frac{2k}{\omega_{vJ}}\frac{2^{2n-2}(n-1)!}{(2n-2)!}\frac{\partial}{\partial v}D_j^n \times \int_{-1/2}^{v}\epsilon^i_{v'J}\,(E_{vJ} - E_{v'J})^{n-3/2}\,\mathrm{d}v'\Big|_{J=0}$$

with n= 1–3.

5. Solution of inversion equations

To discuss the solutions of these equations, we can first combine the three rotational equations corresponding to eq. [41] with n= 1–3 to eliminate $\tilde{R}^i(r_v^+)$ and $\tilde{R}^i(r_v^-)$ and produce a single equation for the quantity

$$[42]\quad 3\left[\frac{1}{r^2}\frac{\mathrm{d}}{\mathrm{d}V(r)}\left(\frac{\tilde{S}^i(r)}{V'(r)}\right)\right]_{r_v^-}^{r_v^+} - \left(r_v^+r_v^-\right)^2\left[\frac{1}{r^6}\frac{\mathrm{d}}{\mathrm{d}V(r)}\left(\frac{\tilde{S}^i(r)}{V'(r)}\right)\right]_{r_v^-}^{r_v^+}$$

© 2004 NRC Canada

We now have to consider the solution of eqs. [40] and [42] for $\tilde{S}^i(r_v^-)$ and $\tilde{S}^i(r_v^+)$.

The expansion of $\tilde{S}^i$ can be written

$$[43] \qquad \tilde{S}^i(r) = \tilde{S}^i_0 + \tilde{S}^i_1(r - r_e) + \tilde{S}^i_2(r - r_e)^2 + \ldots$$

Now, following Sandeman (13), we can expand the turning points in powers of the potential as

$$[44] \qquad r^{\pm} = \sum_{n=0} \alpha_n [V(r^{\pm})]^n \pm \sum_{n=0} \beta_n [V(r^{\pm})]^{n+1/2}$$

with $\alpha_0 = r_e$. This gives

$$[45] \qquad \frac{1}{V'(r^{\pm})} = \sum_{n=1} n\alpha_n [V(r^{\pm})]^{n-1} \pm \sum_{n=0} (n + 1/2)\beta_n [V(r^{\pm})]^{n-1/2}$$

Combining these equations, we get the expansion

$$[46] \qquad \frac{\tilde{S}^i(r^{\pm})}{V'(r^{\pm})} = \pm C^i(r^{\pm}) + D^i(r^{\pm})$$

$$[47] \qquad C^i(r^{\pm}) = \sum_{n=0}^{\infty} c^i_n [V(r^{\pm})]^{n-1/2}$$

$$[48] \qquad D^i(r^{\pm}) = \sum_{n=0}^{\infty} d^i_n [V(r^{\pm})]^n$$

where c^i_n and d^i_n are functions of the $\tilde{S}^i_n$, α_n, and β_n coefficients whose precise form is not required here. Expansions of this kind are also useful in evaluating RKR-type integrals (12). Here we get

$$[49] \qquad \left[\frac{\tilde{S}^i(r)}{V'(r)}\right]_{r_v^-}^{r_v^+} = 2C^i = 2\sum_{n=0}^{\infty} c^i_n E_v^{n-1/2}$$

and so, in principle, the c^i_n coefficients can be determined from eq. [40].

Substitution of eq. [46] in expression [42] gives, after some manipulation, the quantity

$$[50] \qquad \frac{\left[(r_v^+)^2 + (r_v^-)^2\right]\left[4(r_v^+ r_v^-)^2 - (r_v^+)^2 - (r_v^-)^2\right]}{(r_v^+ r_v^-)^4}\frac{dC^i}{dV} + \frac{\left[(r_v^+)^2 - (r_v^-)^2\right]^3}{(r_v^+ r_v^-)^4}\frac{dD^i}{dV}$$

As C^i is known from eq. [40], this allows the solution for dD^i/dV. Thus, all the d^i_n coefficients can be determined, in principle, except for d^i_0, which does not contribute to eq. [50].

From eqs. [46] and [48] it is seen that d^i_0 is the coefficient of $V'(r)$ in the expansion of $\tilde{S}^i(r)$. From eq. [19] this indeterminacy of d^i_0 therefore corresponds to the arbitrariness of A^i_0.

If $\tilde{S}^i(r)$ is known, it is then possible to determine $\tilde{R}^i(r) + 2\tilde{S}^i(r)/rV'(r)$ from eq. [41]. Thus, the only indeterminacy in $\tilde{R}^i(r)$ follows from the indeterminacy in A^i_0. In fact, the variation

$$[51] \qquad \delta\tilde{R}^i(r) = -2\delta A^i_0/r$$

$$[52] \qquad \delta\tilde{S}^i(r) = V'(r)\delta A^i_0$$

leaves eq. [41] invariant for all values of n, and so the indeterminacy cannot be resolved by using higher derivatives with respect to j.

These results show that there is only one degree of indeterminacy, corresponding to A^i_0, in the inversion of the ϵ^i_{vJ} data to give the functions $\tilde{R}^i(r)$ and $\tilde{S}^i(r)$. If these functions are combined to eliminate A^i_0, then the remaining combinations of parameters are determinable (14).

6. Discussion

There already exist a number of computer programs, such as those in refs. 15–22, to fit vibration–rotation frequencies of a range of isotopomers of a diatomic molecule, including the BOB terms, and there seems no reason for an additional program based on RKR-type inversion. However, it is valuable to consider such analytical approaches, because they help to distinguish between indeterminacies that are due to shortage of data and indeterminacies that are intrinsic to the Hamiltonian employed.

The present considerations show that there are intrinsic indeterminacies in the BOB Hamiltonian [5]. In the first place, the $Q^i(r)$ contribution is not distinguishable from those of $R^i(r)$ and $S^i(r)$. This leads to the problem of the inversion of eq. [21]. Since it is known (9, 10) that expectation values of J-independent operators can be inverted without indeterminacy, it may seem somewhat surprising that this does not apply to the expectation values ϵ^i_{vJ}. The reason is that there is a variation of the parameters given by eqs. [51] and [52], which is equivalent to

$$[53] \qquad \delta\tilde{S}^i(r) + j\delta\tilde{R}^i(r)/r^2 = \delta A^i_0 V'_J(r)$$

The expectation value [22] of this term involves the integral

$$[54] \qquad \int_{r_{vJ}^-}^{r_{vJ}^+} V'_J(r)\,[E_{vJ} - V_J(r)]^{1/2}\,dr = -\frac{2}{3}\left[\{E_{vJ} - V_J(r)\}^{3/2}\right]_{r_{vJ}^-}^{r_{vJ}^+} = 0$$

Thus, this variation of parameters does not affect the energy levels in first order. There is therefore a degree of indeterminacy in the values of the parameters. This possibility does not exist for a J-independent operator.

If we consider the expansion [43] and the similar expansion for $\tilde{R}^i(r)$, it is seen from eqs. [18] and [19] that

$$[55] \qquad \tilde{R}^i_0 = R^i_0 - \frac{2}{r_e}A^i_0$$

© 2004 NRC Canada

[56] $$\tilde{S}_1^i = S_1^i + V''(r_e)A_0^i$$

are not contaminated by terms from $Q^i(r)$. Only the combination $\tilde{R}_0^i + 2\tilde{S}_1^i/r_e V''(r_e)$ of these two parameters is independent of A_0^i and so is determinable. The way in which this indeterminacy affects actual fits is described in ref. 22. If we choose A_0^i to make $\tilde{S}_1^i = 0$, then

[57] $$\tilde{R}_0^i = R_0^i + 2S_1^i/r_e V''(r_e)$$

To break this indeterminacy requires additional data. The theoretical expression for the R^i function is (14)

[58] $$R^i = C_i - \sum_j \frac{C_j z_j^2}{r^2} + \frac{\mu_C g_J}{m_p}$$

where the C_j are effective charges on the atoms defined by

[59] $$\sum_j C_j = C, \qquad \sum_j C_j z_j = p/e$$

where p is the electric dipole moment, g_J is the rotational g-factor, m_p the proton mass, and z_j the coordinate of atom j referred to the nuclear centre of mass. While R^i and C_i are the same for all isotopomers, the second and third terms of eq. [58] are isotopomer-dependent. Thus, R^i can be calculated from measurements in electric and magnetic fields (or for several isotopomers in magnetic fields only). Constraining R_0^i to the equilibrium value is sufficient to remove the degree of indeterminacy represented by A_0^i, and allow a complete inversion to obtain $\tilde{R}^i(r)$ and $\tilde{S}^i(r)$.

Can resonances occur in the photodissociation continuum of a diatomic molecule? The role of potential discontinuities[1]

Joel Tellinghuisen

Abstract: Continuum resonances are standard fare in the instructional literature for quantum mechanics, where they arise from the continuity conditions imposed on one-dimensional wavefunctions for piecewise-constant potential energy functions. Such resonance structure weakens progressively as the discontinuity in the potential is smoothed, showing that the structure is specifically attributable to the discontinuity. Since diatomic molecular potential energy curves seldom vary rapidly on the distance scale of the period of the wavefunction, such continuum resonances are not expected in absorption continua. A historically interesting prediction of such structure in the Schumann–Runge continuum ($B \leftarrow X$) of O_2 is attributed to the inadvertent incorporation of discontinuity in the B-state potential curve employed in the computations.

Key words: quantum mechanics, continuum resonance, diatomic absorption, photodissociation continuum, numerical methods.

Résumé : Les continuum de résonance sont des entités normales dans la littérature des étudiants de la mécanique quantique où elles découlent des conditions de continuité qui sont imposées aux fonctions d'ondes unidimensionnelles des fonctions d'énergie potentielle constantes. De telles structures de résonance perdent progressivement de l'importance lorsqu'on étale la discontinuité du potentiel, ce qui démontre que la structure peut être attribuée spécifiquement à la discontinuité. Comme les courbes d'énergie potentielle des molécules diatomiques varient rarement rapidement en fonction de l'échelle de distance de la période de la fonction d'onde, on ne s'attend pas à retrouver des tels continuum de résonances dans les continuum d'absorption. Une prédiction historiquement intéressante d'une telle structure dans le continuum de Schumann–Runge ($B \leftarrow X$) du dioxygène, O_2, est attribuée à l'incorporation accidentelle de la discontinuité dans la courbe de potentiel de l'état B utilisée dans les calculs.

Mots clés : mécanique quantique, continuum de résonance, absorption diatomique, continuum de photodissociation, méthodes numériques.

[Traduit par la Rédaction]

Introduction

The Schumann–Runge (SR) absorption transition of O_2 ($B^3\Sigma_u^- \leftarrow X^3\Sigma_g^-$) represents a prototypal diatomic photodissociation spectrum having an adjoining discrete spectrum. From a practical standpoint, this system is arguably the most important case of this type, since it largely accounts for the "vacuum" in "VUV". As such it received significant attention from Herzberg, especially in his landmark book on diatomics (1–3). Although the nature of the continuous absorption is now fairly well understood, it is only recently that it has arrived at this state (4–11). The absorption is essentially structureless in the region from the photodissociation limit at 175 nm to the peak near 143 nm. Structure does occur at shorter wavelengths, because of a strong *R*-dependence in the transition strength and a "ledge" in the adiabatic approximation of the B potential, resulting from interactions between the valence and Rydberg $^3\Sigma_u^-$ states that produce the adiabatic B and E states. However, an early attempt at quantitative analysis of the SR continuum predicted the occurrence of "wiggles" in the region of the strongest absorption, which were attributed to continuum resonances resulting from the presence of an attractive well in the potential (12). This result was never confirmed in subsequent treatments, but it was also never explained. A reexamination of the original treatment by Bixon et al. (12) has led me to conclude that the interesting structure in their computed spectrum was an artifact very likely stemming from an unphysical discontinuity inadvertently included in their B-state potential energy function. The present paper offers a more comprehensive look at the role of potential discontinuities in continuum resonances, with the conclusion that such structure must be very rare and weak in diatomic spectra, since realistic diatomic potentials are normally too smooth to support it.

To illustrate the last point first, consider the partial potential energy diagram for O_2 shown in Fig. 1 and the bound-free absorption spectra computed with these potentials in Fig 2. The two spectra in the latter figure are virtually identical, which implies that the B-state continuum wave-

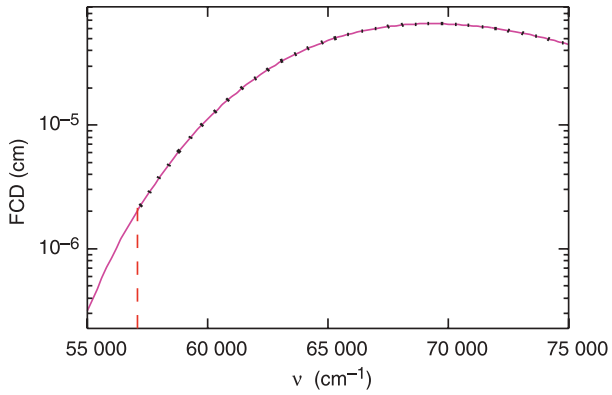
Fig. 1. Potential curves and wavefunctions for the B state of O_2. The solid-black B curve consists of RKR turning points (13), extended at small R with an R^{-8} repulsion function. The magenta-coloured potential curve shares the same repulsive branch but dissociates to two ground state ^{3}P O atoms at 42 046 cm^{-1} above the ground-state minimum (cf. ^{3}P + ^{1}D at 57 914 cm^{-1} for the B state, marked by the lower dashed line segment to right). The dashed vertical lines denote the classical turning points for $v = 0$ in the X state. The wavefunctions are energy-normalized functions at an energy of 58 147 cm^{-1}, marked by the horizontal dotted line.

functions are identical where they overlap significantly with the X-state wavefunction. The energy-normalized wavefunctions shown in Fig. 1 indeed coincide at small R, in both shape and amplitude, and this in spite of their quite different nature where they diverge at larger R. This relationship has been illustrated before for a system in I_2 (14), and it is key to the realization that the Franck–Condon properties of such simple absorption spectra are determined solely by the shape of the final potential in the Franck–Condon region. This is true for the discrete region, too, in the case of a potential with a bound well, where the attractive branch of the potential serves just to "discretize" the spectrum (15, 16). From the standpoint of the continuum wavefunctions (ψ) themselves, which are obtained numerically in one pass by generating outward to large R and then normalizing (17), in a very real sense the ψs "know where they are going" right from the outset. So we might then ask, what could cause them to deviate from this course?

Figures 3 and 4 provide an answer to the question just posed: the ψs deviate when they encounter a sharp "bump", where sharp means abrupt on a distance scale comparable to the period of the wavefunction. However, even the small amount of smoothing illustrated by the dashed potential in Fig. 3 suffices to eliminate most of the resonance structure, the exception being the region very near threshold.

The properties exhibited for the wavefunctions in Fig. 3 can be seen also for the simple piecewise constant potentials used to illustrate continuum resonances in quantum mechan-

Fig. 2. Franck–Condon density (FCD) computed for absorption from $v = 0$ in the X state of O_2 to the two potentials illustrated in Fig. 1. The vertical line marks the photodissociation limit for the "real" potential, having the dashed spectrum.



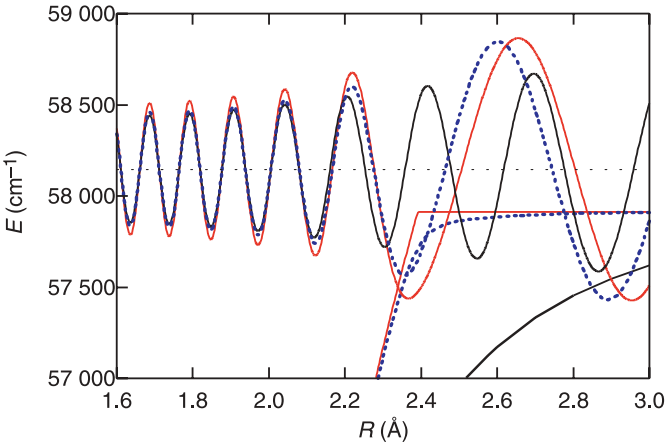


Fig. 3. Segment of RKR potential for B state (solid, lower right) and alternative extensions obtained by defining a Morse potential by ω_e and $\omega_e x_e$ for the B state (giving D_e = 11 800 cm^{-1}) and then chopping the attractive branch of the potential off at the true dissociation limit (D_e = 8121 cm^{-1}). The dashed potential curve was produced using an "avoided crossing" smoothing function. The wavefunctions were obtained for an energy of 58 147 cm^{-1} (dotted horizontal line), as in Fig. 1.

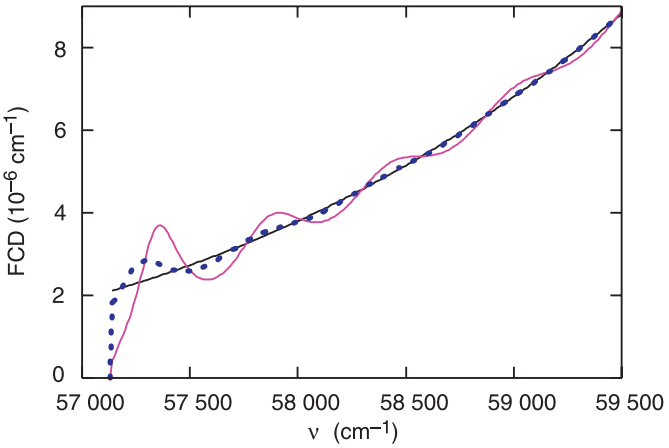
ics textbooks. Such examples prove both instructive and useful for checking computational procedures, so I turn my attention to them before returning to the O_2 historical puzzle.

Models and methods

The simplest model potential for a bound molecule is the piecewise constant potential illustrated in Fig. 5. The wavefunction in regions 1 and 2 can be taken as



$$[1] \qquad \psi_1 = b_1 \sin k_1 x \text{ and } \psi_2 = b_2 \sin(k_2 x + \delta)$$

where k in each region is related to the kinetic energy ε in that region by

$$[2] \qquad k^2 = \frac{2\mu\varepsilon}{\hbar^2}$$

© 2004 NRC Canada

Fig. 4. FCD just above the photodissociation threshold, for potentials illustrated in Fig. 3. The continuum resonance at 57 360 cm^{-1} (magenta) corresponds to the energy used to generate the wavefunctions in Fig. 3. The three spectra are associated with the similarly depicted potential curves and wavefunctions in Fig. 3.

with μ the reduced mass and $\hbar$ Planck's constant divided by 2π. By making the wavefunction and its first derivative continuous at $x = a$, we obtain

$$[3] \qquad \left(\frac{b_1}{b_2}\right)^2 = \frac{\varepsilon_2}{\varepsilon_2 + (\varepsilon_1 - \varepsilon_2)\cos^2 k_1 a}$$

One of the two amplitudes is arbitrary until some normalization is chosen. In energy normalization, the amplitude is proportional to $\varepsilon^{-1/4}$ (17). Thus, if our wavefunction is normalized at large x, ${b_2}^2 \propto {\varepsilon_2}^{-1/2}$, and

$$[4] \qquad {b_1}^2 \propto \frac{{\varepsilon_2}^{1/2}}{\varepsilon_2 + (\varepsilon_1 - \varepsilon_2)\cos^2 k_1 a}$$

Alternatively, if ψ_1 were energy normalized in region 1 (e.g., for the dashed potential having $V = 0$ for all $x > 0$ in Fig. 5), it would have ${b_1}'^2 \propto {\varepsilon_1}^{-1/2}$. Any spectrum involving these wavefunctions would sense the square of the amplitude, so the ratio

$$[5] \qquad Q = \left(\frac{b_1}{b_1'}\right)^2 = \frac{(\varepsilon_1\varepsilon_2)^{1/2}}{\varepsilon_2 + (\varepsilon_1 - \varepsilon_2)\cos^2 k_1 a}$$

constitutes the continuum resonance spectrum. It shows specifically the effect of the potential step at $x = a$, and it varies between a maximum of $(\varepsilon_1/\varepsilon_2)^{1/2}$ and a minimum of $(\varepsilon_2/\varepsilon_1)^{1/2}$.

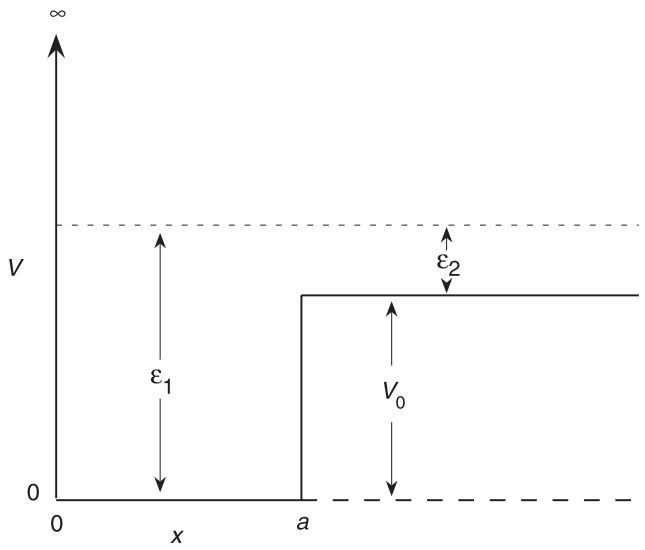
To investigate the effect of smoothing the discontinuity in $V(x)$ at $x = a$, we represent the potential by a hyperbolic tangent type function

$$[6] \qquad V(x) = \frac{V_0 y}{y + y^{-1}}, \qquad x > 0$$

where $y = \exp[p(x - a)]$. A large value of the parameter p gives a sharp step, while a small value yields a soft step.

All of the computations employed numerical methods like those described in ref. 17.

Fig. 5. Potential diagram for square well model. The energy goes to ∞ at $x = 0$. The subscripts on the kinetic energy ε designate regions 1 ($0 < x < a$) and 2 ($x \geq a$).



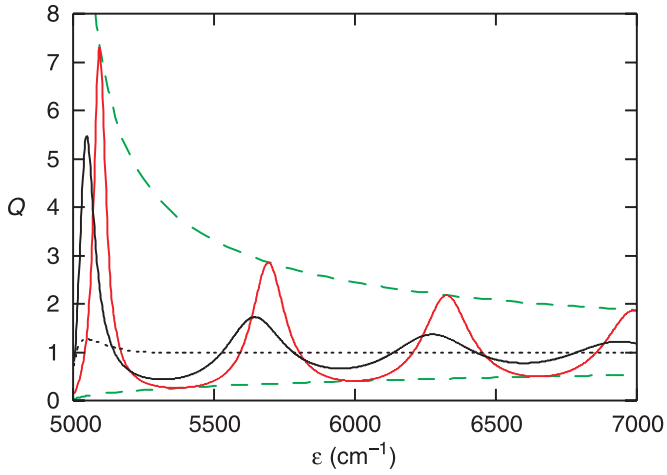


Fig. 6. Continuum resonance spectra for modified square well potential of eq. [6] having $V_0 = 5000$ cm^{-1}, $a = 1$ Å, μ = 10 amu, and $p = 1000$ $Å^{-1}$ (red), 50 $Å^{-1}$ (solid black), and 10 $Å^{-1}$ (fine dash). The broad dash lines delimit the extreme values of Q for $p = \infty$.

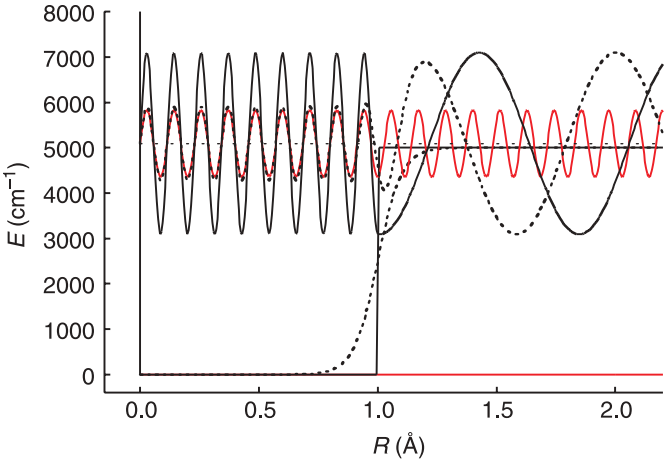


Results and discussion

Figure 6 illustrates continuum resonance spectra for the modified square well potential of eq. [6] with varying degrees of smoothing, while Fig. 7 shows the potentials and representative wavefunctions. The results for $p = 1000$ $Å^{-1}$ confirm the validity of the numerical methods, since a p this large gives essentially the original box potential. With $p =$ 10 $Å^{-1}$ (dashed potential in Fig. 7), the resonance structure is almost gone. Correspondingly, in region 1, the energy-normalized ψ at the energy of the strongest resonance is only slightly larger than that for $V_0 = 0$ (no well). (Of course, the dashed ψ matches the solid ψ in amplitude at large x, as it must.)

I return now to the O_2 puzzle that prompted this study. Bixon et al. (12) (BRJ) adjusted a linear repulsion potential

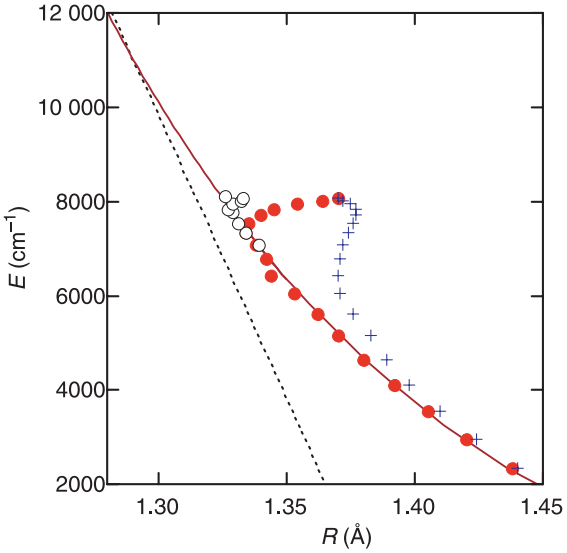
© 2004 NRC Canada

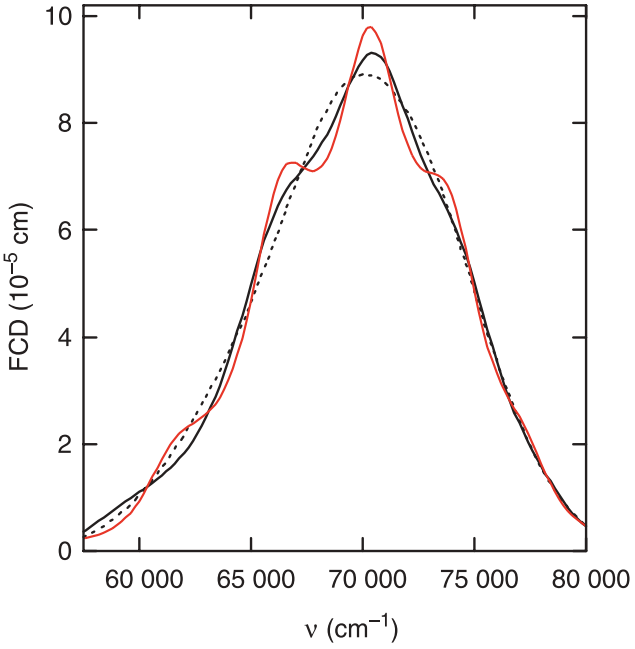
Fig. 7. Potential energy functions and wavefunctions relevant to Fig. 6 for p = 1000 (solid black) and 10 (dashed) Å^{-1}. Also shown (red) are $V(x)$ and $\psi(x)$ for V_0 = 0. Wavefunctions are centered at the energy ε_1 = 5094 cm^{-1} where they were generated (horizontal dashed line), corresponding to the first peak for p = 1000 Å^{-1} in Fig. 6.

in position and slope to achieve approximate agreement with the experimental B ← X data. When they attached a bound well to this potential at large R and repeated the computation, they obtained oscillations in the spectrum. For the well they used RKR points from Singh and Jain (18) and Richards and Barrow (19). Both of these show a great deal of scatter at high energy (Fig. 8), and BRJ did not explain how they dealt with this problem. Furthermore, the RKR curves and the derived linear potential are disjointed, suggesting that the BRJ working potential included an inadvertent discontinuity. I have checked this possibility by using the potential of Fig. 1 (with which the points of Richards and Barrow are reasonably consistent) at large R, and the linear potential of BRJ at small R, and repeating the computation of the spectrum for various assumed switchover distances. The two potential segments intersect near 1.29 Å with only a 20% slope discontinuity; when this distance is taken for switchover, the resulting spectrum agrees well with the spectrum of BRJ for the linear potential (Fig. 9). The spectrum obtained by jumping from the linear potential to the RKR curve at R = 1.326 Å (the minimum R of the Richards and Barrows points) agrees well in the positions of the wiggles but undershoots in their amplitudes. Moving the jump point to larger R increases the magnitude of the discontinuity and hence of the resonance structure; however, it also decreases the spacing of the peaks, so that for switchover at 1.365 Å, the structure more nearly matches that of BRJ in amplitude but includes an extra shoulder at low frequency.

Without detailed knowledge of how the RKR data were actually incorporated in the computations of BRJ, it is probably not possible to reproduce their results any better than shown in the solid spectrum of Fig. 9. For example, most commonly used algorithms for generating the wavefunctions (including the Numerov method used here and by BRJ) employ a working potential of points evenly spaced in R, which requires interpolation when RKR data are used to define the potential. The interpolators can perform badly on noisy data like those near dissociation in Fig. 8. To illustrate, if just the

Fig. 8. Repulsive branch of the O_2 B-state potential, from RKR calculations: ref. 18 (+), ref. 19 (○), ref. 20 (●) (cited by Richards and Barrow (19) for ν levels lower than those reported). The solid curve is that shown in Fig. 1, and the dashed line is as reported by Bixon et al. (12). Energies are relative to the minimum of the B potential.





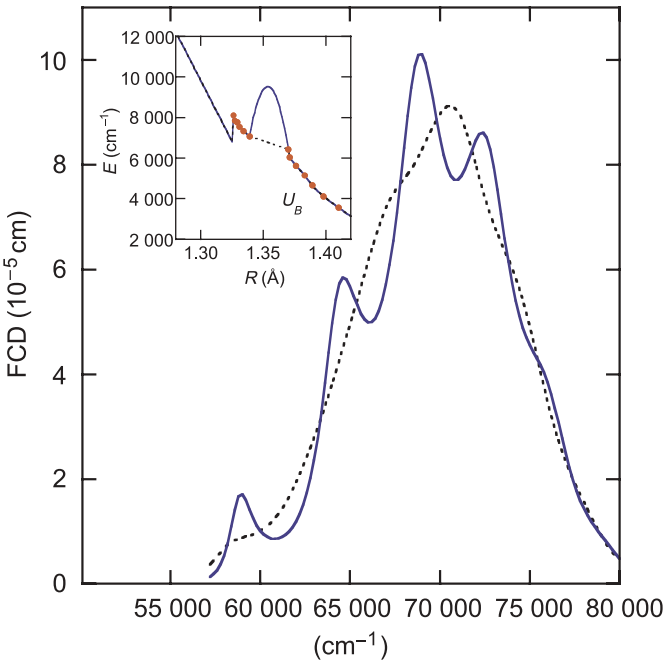


Fig. 9. O_2B ← X FCD computed for absorption from ν″ = 0 using linear potential from ref. 12 and Fig. 8 merged smoothly with potential of Fig. 1 at R = 1.29 Å (dashed), or discontinuously at 1.326 Å (solid black), and 1.365 Å (red).

monotonically varying (in R) data from refs. 18 and 19 are used to define the curve, even a quadratic Lagrangian interpolation can produce an anomalous bump in the potential at small R, which is sharp enough to act just like the other forms of discontinuity considered here, giving pronounced structure in the spectrum (Fig. 10). Thus, it seems likely that the computations reported in (12) were afflicted with artifactual potential errors of one or both of the types consid-

Fig. 10. O_2 B ← X FCD for v″ = 0 computed using linear potential from ref. 12 and selected, monotonically varying RKR points from refs. 18 and 19, with three-point (solid) and two-point (dashed) Lagrangian interpolation to produce the working potential. A segment of the latter is illustrated together with the relevant RKR points in the inset.

ered here; as concluded by others long ago, the resonance structure is not real.

A secondary moral of the present story is that in such molecular applications, one must take care to devise model potential energy functions that are realistic. Another illustration of this point comes from a study of the predissociation of the C state of N_2^+ by the B state. The C state is embedded in the continuum of the B state, with only very small Franck–Condon overlap between the two, making the computations very sensitive to the potentials (21, 22). When the B-state potential was represented by a cut-off Morse curve like that shown in Fig. 3 instead of by its RKR curve, the predicted C → B predissociation rates decreased by four orders of magnitude, causing earlier workers to dismiss this process as the major mode of C-state predissociative decay (21).

Conclusion

I return now to the question posed in the title. Most realistic potentials do not include the kinds of discontinuities and abrupt changes considered here, so we expect any actual continuum resonance structure to be subtle to the point of possibly escaping experimental detection. Since the requirement is a relatively rapid variation of the potential energy function on the distance scale of the wavefunction, the best chances for observation would seem to be in light molecules (small μ) at small kinetic energies, for example just above a barrier. Le Roy and Bernstein (23) computed several such resonances in the ground state of H_2 but noted that they were "too diffuse to be spectroscopically observable". Another qualifying example is the very narrow "hole" in the Franck–Condon density right at threshold, as noted by Allison and Dalgarno (15). In this case, as the kinetic energy approaches zero, the period of the wavefunction becomes infinite, so that even the very small variation in the potential energy function in the approach to dissociation might be viewed as significant on the distance scale of the wavefunction.

With the unintentional exception of the lowest frequencies in the highly structured spectrum in Fig. 10, I have specifically excluded from consideration here cases where the continuum levels are partially bound behind a potential barrier. Such shape resonances are certainly real and observable. The presence of a barrier can also affect the structure in the continuum. For example, if the model square well potential treated above and illustrated in Figs. 5 and 7 is altered to include a square barrier $V_1 > V_0$ in a region $a \le x \le a_1$, the continuity conditions on the wavefunction lead to a much richer interference-type structure in the pure continuum ($\varepsilon > V_1$). By using smoothing functions like eq. [6], one can "turn off" the structure associated with either the discontinuity at $x = a$ or that at $x = a_1$, or both.

Attosecond molecular spectroscopy — The one-electron H_2^+ system[1]

André D. Bandrauk and Hong Shon Nguyen

Abstract: Numerical solutions of the time-dependent Schrödinger equation for a 1-D model non-Born–Oppenheimer H_2^+ are used to illustrate the nonlinear, nonperturbative response of molecules to intense ($I \geq 10^{13}$ W/cm^2), ultrashort ($t < 10$ fs) laser pulses. Molecular high-order harmonic generation (MHOHG) is shown to be an example of such response, and the resulting nonlinear photon emission spectrum is shown to lead to the synthesis of single attosecond (10^{-18} s) pulses. Application of such ultrashort pulses to the H_2^+ system results in localized electron wave packets whose motion can be detected by asymmetry in the photoelectron spectrum generated by a subsequent probe attosecond pulse, thus leading to measurement of electron motion in molecules on an attosecond time scale.

Key words: attosecond spectroscopy, attosecond photoionization.

Résumé : On utilise des solutions numériques de l'équation de Schrödinger qui dépend du temps pour un modèle 1-D non-Born–Oppenheimer du H_2^+ pour illustrer la réponse non perturbante et non linéaire de molécules à d'intenses ($I \geq 10^{13}$ W/cm^2) et ultracourtes ($t < 10$ fs) pulsions laser. On montre que la génération d'harmonique moléculaire d'ordre élevée, « MHOHG », est un exemple d'une telle réponse et on montre aussi que le spectre d'émission photonique non linéaire qui en résulte conduit à la synthèse de pulsations attoseconde (10^{-18} s). L'application de telles pulsations ultracourtes au système H_2^+ conduit à des paquets d'onde électronique localisés dont on peut détecter le mouvement par asymétrie dans le spectre photoélectronique généré par une sonde subséquente de pulsation attoseconde qui conduit donc à la mesure du mouvement électronique dans les molécules à une échelle de temps de l'attoseconde.

Mots clés : spectroscopie attoseconde, photoionisation attoseconde.

[Traduit par la Rédaction]

Introduction

Advances in current laser technology allow experimentalists to have access to new laser sources for examining molecular structure and dynamics on the natural time scales for atomic (vibrational) motion, femtoseconds (1 fs = 10^{-15} s). These new sources are ultrashort ($t_p \leq 10$ fs) and intense ($I \geq 10^{14}$ W/cm^2) (1). Such pulses lead to a new regime of laser–matter interaction, the nonlinear, nonperturbative regime. Thus, since the atomic unit (au) of electric field strength $E_0 = e/a_0^2 = 5 \times 10^9$ V/cm ($a_0 = 1$ au $= 0.0529$ nm) corresponds to an au of intensity, $I_0 = cE_0^2/8\pi = 3.5 \times 10^{16}$ W/cm^2, laser intensities approaching I_0 have led to the discovery of new nonlinear phenomena in laser–atom experimental and theoretical studies (2), such as above–threshold ionization (ATI), the multiphoton equivalent of single-photon photoionization, and high-order harmonic generation (HOHG).

The study of interactions of intense, ultrashort laser pulses with molecules is a relatively new science (3) with the first discovery of nonlinear, nonperturbative laser–molecule interaction leading to a new concept, laser–induced molecular potentials (LIMPs), predicted as early as 1981 (4) and confirmed experimentally recently (5, 6). At the very high intensities now available ($I \geq 10^{14}$ W/cm^2), one now must consider dissociative ionization so that one must deal with bound–continuum transitions both in the electronic and nuclear Hilbert space. Multiphoton, nonperturbative transitions in the nonlinear Hilbert space describing photodissociation only via LIMPs can be treated adequately using a coupled-equations approach based on the dressed molecule representation (3). Inclusion of ionization involves treating numerically the complete field–electron–nuclear, non-Born–Oppenheimer problem, and this has been exactly solved recently for the 1-D H_2^+ system (7), leading to the first calculation of nonlinear molecular photoelectronic spectra or ATI (8), and the concomitant Coulomb explosion (CE) spectra (9, 10). This benchmark calculation has led to a new method of measuring nuclear wave functions by laser Coulomb explosion imaging (LCEI) (9, 10).

Electronic interaction with radiation in molecules differs from that of atoms due to the large delocalization of electrons in the former. As early as 1939, Mulliken explained intense absorption bands due to large transition moments in molecules (11). Thus, in H_2^+, the electronic transition moment between the HOMO ($1\sigma_g$) and LUMO ($1\sigma_u$) $\mu(R) = \langle 1\sigma_g|z|1\sigma_u\rangle = R/2$ leads to large nonperturbative radiative interactions at large distances ($V(R) = RE/2$) in a field of strength E. As an example, 1 au of field strength leads to 1 au = 27.2 eV of radiative interaction at the equilibrium dis-

tance $R \simeq 2$ au in H_2^+. Thus, the combination of large electronic transition moments in symmetric molecules and current high laser intensities results readily in nonperturbative radiation–molecule interactions. Such effects lead to LIMPs (4–6) and charge resonant enhanced ionization (CREI), whereby molecular ionization rates can exceed that of atomic fragments by orders of magnitude at large critical internuclear distance $R_c \simeq 2R_e$, where R_e is the equilibrium distance (12–14). Quasi-static models of atom–laser field interaction (2) have been extended to nonperturbative laser–molecule interactions with the tunnelling ionization of Stark-displaced LUMOs leading to a simple, consistent explanation of CREI and CE in molecules for one- or odd-electron molecular systems (12–14).

Exact numerical solution of two-electron molecules H_2 (15, 16) and H_3^+ (17) in intense laser fields in the Born–Oppenheimer approximation (static nuclei) has shown the importance of the *ionic* states (e.g., H^+H^- in H_2), predicted by Herzberg to exist in the UV spectral region (18), as *doorway* states for CREI in these systems. Recently, the ionic state of O_2, O^+O^-, has been identified by ZEKE experiments (19). Such states have large dipole moments equal to the internuclear distance R and thus can lead to large radiative interactions $V(R) = ER$ exceeding molecular dissociation energies at current laser intensities. The study of molecules in the nonlinear, nonperturbative regime of molecule–radiation interaction is thus a new science requiring nonperturbative theories and numerical methods to treat laser control and manipulation of molecules in this regime (20, 21).

One of the seminal ideas emanating from simple quasi-static models of electron ionization in atoms is the possibility of *recollision* of the ionized electron with its parent ion (22). The returning energy of the electron at the nuclei can be shown to satisfy a simple law, which explains the maximum energy of harmonics emitted by such a recolliding electron,

$$[1] \qquad N_m \hbar\omega = I_p + 3.17U_p$$

where N_m is the maximum harmonic order, I_p is the ionization potential, and U_p is the ponderomotive or oscillatory energy of an electron of mass m in a pulse of frequency ω and intensity I,

$$[2] \qquad U_p(\text{au}) = I/4m\omega^2 = 3.4 \times 10^{21} I\,(\text{W/cm}^2)\lambda^2(\text{nm})$$

The corresponding field-induced displacement of such an ionized electron is given by the expression

$$[3] \qquad \alpha(\text{au}) = eE/m\omega^2 = 2.4 \times 10^{-12}\left[I\left(\text{W/cm}^2\right)\right]^{1/2}\lambda^2(\text{nm})$$

Thus, at an intensity $I = 10^{14}$ W/cm^2 and wavelength $\lambda = 1064$ nm, $U_p = 10.5$ eV and $\alpha = 1.2$ nm. We have shown that collision of ionized electrons with neighboring ions in molecules can lead to even larger harmonic orders with photon energies of $6U_p$ up to $12U_p$, thus extending the recollision energy cut-off law (eq. [1]) (23).

Using ultrashort pulses ($t \leq 5$ fs) results in continuum HOHG in the region of the cut-off law (eq. [1]) from which by selecting a slice of the spectrum one can synthesize *attosecond* (as) pulses. First experimental results on the production and measurement of a 650-as soft-X-ray pulse from high-intensity ionization of Ar atoms was reported in refs. 24 and 25. This opens up new possibilities for studying and controlling electron dynamics in atoms and molecules on attosecond time scales. We have recently shown that attosecond pulses can be used to measure the absolute electric field of few-cycle laser pulses (26) and to attain *attosecond control* of ionization and increase HOHG intensities, and thus create new single X-ray or UV pulses as short as 250 as (27). We illustrate, in the present paper, from numerical solutions of the time-dependent Schrödinger equation (TDSE) for a 1-D H_2^+ model with full electron–nuclear dynamics, i.e., from non-Born–Oppenheimer simulations, our proposed methodology for producing attosecond pulses from a molecular medium. Finally, we demonstrate from solutions of the TDSE how a pump–probe experiment of the photoionization of H_2^+ using attosecond pulses can allow one to study the evolution of the movement of localized electron wave packets, thus leading to a new attosecond molecular spectroscopy. Such experiments should now be feasible with the recent discovery of HOHG from ions themselves at high intensities (28).

A non-Born–Oppenheimer 1-D TDSE for H_2^+ in intense laser fields

The exact 1-D TDSE for H_2^+ is solved numerically, describing both coupled electron (Z-coordinate) and internuclear (R-coordinate) proton coordinates by the following equation in atomic units ($\hbar = m_e = e = 1$, $m_p/m_e = 1837$, $c = 137$; m_e and m_p are electron and proton masses) (7):

$$[4] \qquad i\frac{\partial\psi(Z,R,t)}{\partial t} = \hat{H}(Z,R,t)\psi(Z,R,t)$$

where

$$[5] \qquad \hat{H}(Z,R,t) = \hat{H}_R(R) + V_C(Z,R) + \hat{H}_Z(Z)$$

$$[6] \qquad \hat{H}_Z(Z) = -\beta\frac{\partial^2}{\partial Z^2} - \kappa E(t); \qquad \hat{H}_R(R) = -\frac{1}{m_p}\frac{\partial^2}{\partial R^2} + \frac{1}{R}$$

$$[7] \qquad \beta = \frac{2m_p + m_e}{4m_p + m_e}; \qquad \kappa = 1 + \frac{m_e}{2m_p + m_e}$$

$$[8] \qquad V_C(Z,R) = -\frac{1}{\left[a + (Z \pm R/2)^2\right]^{1/2}}$$

The Hamiltonian (eq. [5]) is the exact three-body Hamiltonian obtained after separation of the center-of-mass motion, since we are working in the dipole approximation ($r/\lambda \ll 1$), where the electric field is time-dependent only (3). The Coulomb potential now is a 1-D potential requiring a softening parameter a, which is set at $a = 1$ to obtain the correct I_p for H_2^+ near equilibrium. The corresponding I_p of a 1-D H atom with $a = 1$ is 0.67 au.

The softened V_C now contains no singularity so a high-order split-operator method (29) is used to propagate the total TDSE (eq. [4]) for a pulse length t_p. The integration step in space is $\delta z = 0.25$ au $\sim 10^{-2}$ nm, which means that grids with $3000^2 \simeq 10^7$ points are used. The temporal time step is $\delta t = 0.03$ au $= 0.7$ as, so that over a thousand time steps are required for a 10-fs pulse. The electric field $E(t)$ needs special care since pulse fields must have total area zero, a consequence of

© 2004 NRC Canada

Maxwell's equations (1). Thus, the electric field $E(t)$ is defined from the vector potential

$$[9] \qquad A(t) = -cE_0(t)\sin\left[\omega(t - t_m) + \phi\right]/\omega$$

$$[10] \qquad E(t) = -(1/c)\partial A(t)/\partial t$$

where $t_m = \tau/2$, i.e., half the pulse length. We generally used the pulse envelope $E_0(t)$ in the following form:

$$[11] \qquad E_0(t) = E_0 \sin^2(\pi t/\tau), \qquad 0 \le t \le \tau$$

With a pulse length $t_p = 4$ cycles $= 10.6$ fs for a 800 nm Ti:Sapphire laser, the pulse half-width (FWHM) is then given by $\tau_p = 0.3641 t_p \simeq 4$ fs. Our definition of $E(t)$ via $A(t)$ guarantees that $A(0) = A(\tau) = E(0) = E(\tau) = 0$.

The emitted radiation spectrum, constituting the HOHG spectrum in the presence of an intense laser field, can be obtained from the time-dependent acceleration for an electron in a potential $V(r)$ (29),

$$[12] \qquad a(t) = \frac{\mathrm{d}^2}{\mathrm{d}t^2}\langle r\rangle = \langle\psi(t)| - \partial V/\partial r|\psi(t)\rangle$$

The wave function $\psi(t)$ is the solution of the TDSE (eq. [4]). The Fourier transform of $a(t)$ — $a(\omega)$, from which one obtains the power spectrum of HOHG, $|a(\omega)|^2$ — is given by

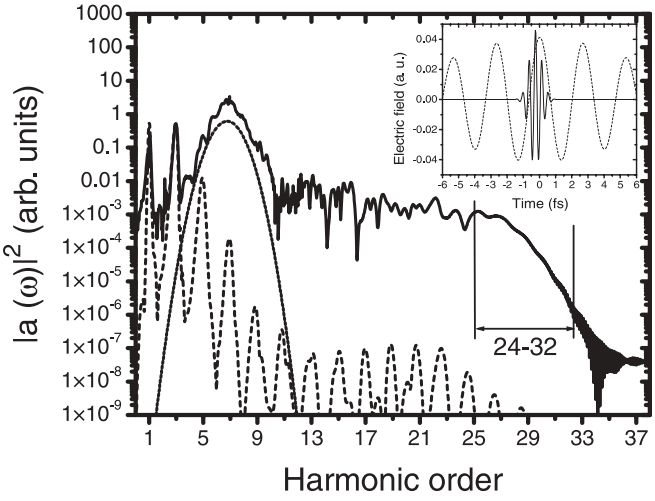
$$[13] \qquad a(\omega) = i(2\pi)^{-1/2}\mathrm{e}^{-i\omega\tau}\dot{d}(\tau) + i\omega\mathrm{e}^{i\omega\tau}d(\tau) - \omega^2\int_0^\tau \mathrm{e}^{-i\omega t}d(t)\,\mathrm{d}t$$

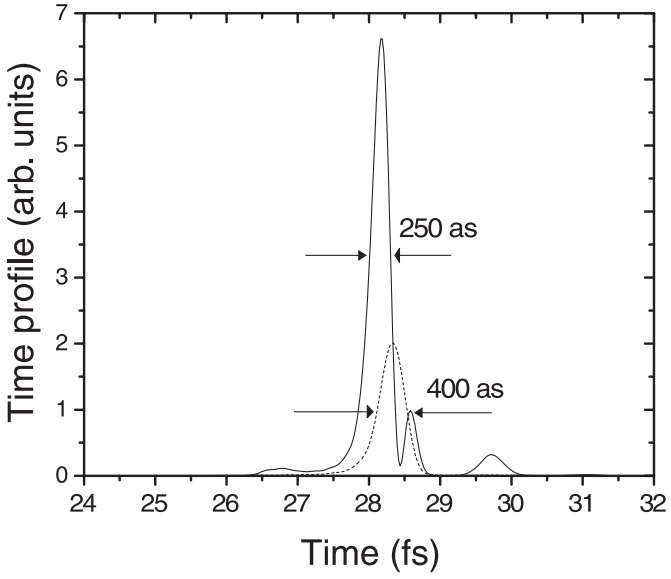
The final integral in eq. [13] is the HOHG power spectrum using the dipole form $d(t) = \langle\psi(t)|r|\psi(t)\rangle$. Clearly, this is only valid if the transient $\dot{d}(\tau) = \frac{\mathrm{d}}{\mathrm{d}t}(d(t))|_{t=\tau}$ and $d(\tau)$ vanish at the end of the pulse. The acceleration form emphasizes maximum acceleration as in the case of a recolliding electron (22, 23). Since the energy E of such an electron is $3U_p \le E \le 10U_p$, where U_p is the ponderomotive energy (eq. [2]), at high intensities one has highly oscillatory electron wave functions so that solving the TDSE (eq. [4]) requires highly accurate numerical procedures (7, 29).

Attosecond pulse synthesis

As hinted in the *Introduction*, one of the great advances, if not breakthroughs, emanating from research on the nonlinear, nonperturbative response of atoms to short intense laser pulses has been the synthesis of attosecond pulses (24, 25). The source of attosecond radiation is HOHG by recollision of the ionized electron with its parent (22) or neighboring ions (23). Unfortunately, the efficiency of such spectra is low, as illustrated in Fig. 1. The dashed line represents the HOHG of H_2^+ with *moving* nuclei (i.e., non-Born–Oppenheimer) exposed to a single 10 fs, 800 nm pulse with peak intensity $I = 6 \times 10^{13}$ W/cm^2. Perusal of the spectrum shows the high inefficiency of the radiation coherently emitted owing to low ionization from tunnelling and the uncontrolled spreading of the ionized but returning (recolliding) electon wave packet (22, 23).

Fig. 1. HOHG power spectrum $|a(\omega)|^2$ (arbitrary units) for non-Born–Oppenheimer H_2^+ excited by an 800 nm, 10 fs, 6×10^{13} W/cm^2 IR pulse in combination with a 600 as (0.6 fs), 115 nm, UV probe at 2×10^{13} W/cm^2 and phase difference $\phi = \omega t = -0.2\pi$ (see inset). Solid line: fs + as pulse excitation. Dashed line: single fs pulse excitation.





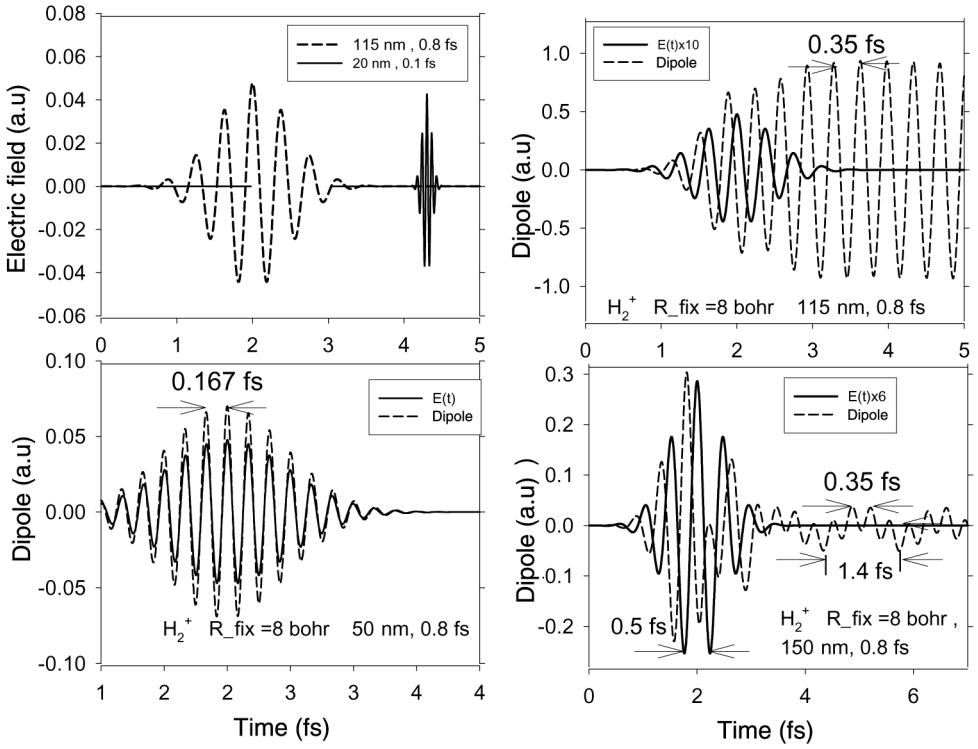


Fig. 2. Attosecond (as) pulses obtained from the continuous harmonics at relative phase $\phi = \omega t = -0.2\pi$ (inset Fig 1): 400 as from $24 < N < 32$; 250 as from $21 < N < 32$ (N is the order of the harmonic).

To enhance such low HOHG efficiencies, we originally suggested two-colour excitation to pre-ionize the electron by a high-frequency (3ω) field with subsequent control by an intense fundamental field (ω) (30). We have recently reformulated this idea by proposing a combination of an attosecond VUV pulse and an intense, short, 800 nm pulse (26). The advantage of this new approach is that the *pump* attosecond pulse has a large energy bandwidth and thus produces an initially narrow spatial electron wave packet, which is subsequently *controlled* by intense, short (fs) low-frequency pulses. As seen in Fig. 1, the

Fig. 3. Resulting induced dipoles (in atomic units) for H_2^+ at $R = 8$ au excited by 50 nm, 115 nm, and 150 nm 0.8 fs (800 as) pulses.

HOHG spectrum is now enhanced by several orders of magnitude. The spectrum is broad and quasi-continuous near the maximum order cut-off (N_m) predicted by eq. [1].

Such a spectrum can be used to synthesize new single UV pulses as short as 250 as, as illustrated in Fig. 2. This is obtained by combining continuous coherent radiation as an example for the order $24 \leq N \leq 32$, i.e.,

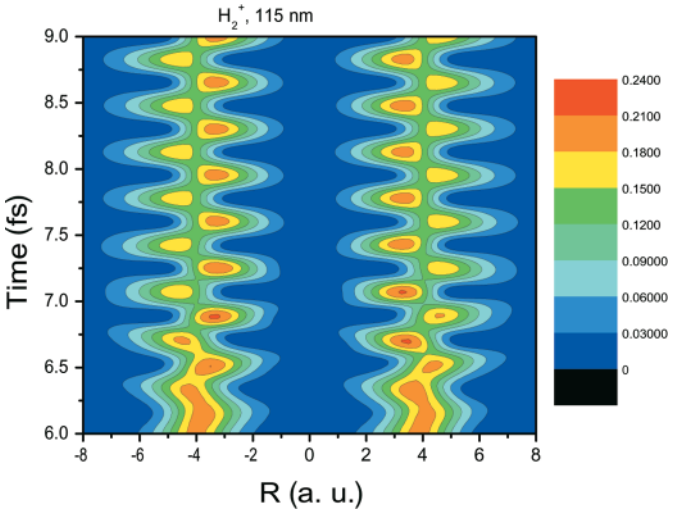
$$[14] \qquad a(t) = \int_{24\omega}^{32\omega} a(\omega) \mathrm{e}^{i\omega t} \mathrm{d}\omega$$

The end result is more intense attosecond pulses that are sensitive to the relative phase of the two colours (see inset of Fig. 1). Maximum enhancement of the new attosecond pulses is obtained at the relative phase $\phi = \omega t = -0.2\pi$, in contradiction to the atomic recollision model, which predicts the maximum order N_m for ionization at phase $\omega t = +0.1\pi$, with zero initial velocity due to tunnelling ionization (22,23). This phase sensitivity is an extension of *coherent control* of multiphoton processes (31) into the nonlinear, nonperturbative regime of laser–molecule interaction studied in the present paper.

Electron localization

In the previous section, we showed how the molecular ion H_2^+ can be used to create intense sub-femtosecond or, equivalently, attosecond pulses in the VUV frequency (wavelength) region. Thus, as shown in Figs. 1 and 2, combining harmonics by filtering techniques (2,3) between the 24th and 32nd will create sub-femtosecond pulses in the 30 nm region with considerable bandwidth. In the present section, we examine the broadband electronic excitation of H_2^+ at fixed internuclear distance $R = 8$ au, which is excited by an 800 as (0.8 fs), 115 nm *pump* pulse followed by a 100 as (0.1 fs), 20 nm *probe* pulse (Fig. 3). The latter induces direct one-photon ionization and we use the corresponding photoelectron spectrum to monitor the subsequent electron motion. All calculations were performed using the numerical code to solve the TDSE (eq. [4]) but with nuclei fixed at $R = 8$ au since the pulses are much shorter than the typical H atom motion time of ~10 fs. The TDSE thus yields the exact electronic wave function $\psi(Z, t)$, from which one can calculate the induced dipole moment $d(t) = \langle \psi(Z, t)|Z|\psi(Z, t)\rangle$.

Excitation at 50 nm shows that the induced dipole (Fig. 3) is completely in phase with the field $E(t)$, since such short wavelengths ionize the electron, which then follows the field. At 115 nm, which corresponds nearly to the H atom 1*s*–2*p* transition, one observes that the dipole is out of phase with the electric field $E(t)$ but shows a periodic oscillation of 0.35 fs or equivalently a photon energy at 105 nm ($\lambda = \tau c$). The dipole oscillations resulting from 800 as, 150 nm excitations are much more reduced in intensity. The obvious explanation is that at 115 nm excitation, one is exciting electronic states by transition to $2\sigma_u$ orbitals and others formed from 2*s* and (or) $2p\sigma$ atomic orbitals of H, whereas at 150 nm one is below such resonances and the induced dipole is much reduced. Thus, the resulting electronic wave function can be represented as the combination



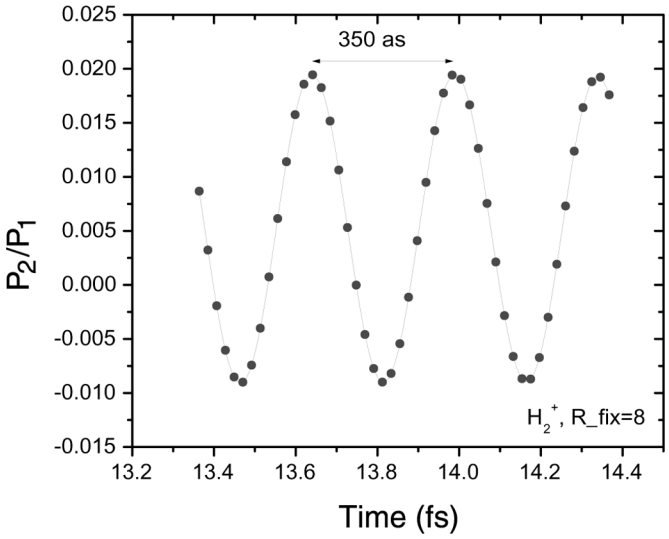
$$[15] \qquad \psi(t) = c_1(t)\psi_{1\sigma_g} + c_2(t)\psi_{2\sigma_u}$$

The corresponding induced dipole can be readily calculated to be

$$[16] \qquad d(t) = \langle \psi(t)|Z|\psi(t)\rangle = c_1(t)c_2^*(t)\langle 1\sigma_g|Z|2\sigma_u\rangle \, \mathrm{e}^{i(E_1 - E_2)t} + \text{c.c.}$$

© 2004 NRC Canada

Fig. 4. Electron probability $|\psi(Z,t)|^2$ at $R = 8$ au following excitation at 115 nm with a 0.8 fs pulse (see Fig. 3).



where c.c. is the complex conjugate. This induced dipole oscillates at the frequency corresponding to the energy difference $E_1 - E_2$ between the ground $1\sigma_g$ and excited $2\sigma_u$ molecular orbitals at $R = 8$ au. Furthermore, since $1\sigma_g \simeq (1/\sqrt{2})[1s_a + 1s_b]$ and $2\sigma_u \simeq (1/\sqrt{2})[2p\sigma_a - 2p\sigma_b]$ have the largest dipole $\langle 1\sigma_g|Z|2\sigma_u\rangle \simeq \langle 1s|Z|2p\sigma\rangle$, then the resulting time-dependent wave function $\psi(t)$ is an *sp* hybrid $(1s \pm 2p\sigma)$ situated on each proton. This laser-induced hybridization is clearly evident in Fig. 4, where we illustrate the electron density $|\psi(Z,t)|^2$ as a function of time. One observes initially that the electron is delocalized equally between the two protons at $Z = \pm 4$ au. After excitation with a 0.8 fs, 115 nm pulse, one sees the electron density polarized inside the molecular bond towards $Z = 0$, corresponding to a single *sp* hybrid (i.e, $s + p$), which oscillates between the two nuclei with the period of the energy difference $E_1 - E_2 = 0.35$ fs or 350 as. Since this oscillation is an induced dipole corresponding to oscillation from H^+H to HH^+ electronic configurations, emitted radiation will occur at the wavelength 105 nm. However, this will give no indication of the position of the electron.

We, therefore, propose herein a spectroscopic method of spatially locating the electron. This is based on the resulting ionization asymmetry predicted from ionization by intense, ultrashort pulses and used to measure the electric field phase profile of such pulses by attosecond probe pulses (26). Thus, as shown in Fig. 3, a 20 nm, 100 as pulse is used to ionize the *sp* hybrids prepared by the 115 nm, 800 as prepulse. As illustrated in Fig. 5, the resulting ionization asymmetry is defined as

$$[17] \qquad P_2/P_1 = \frac{P_- - P_+}{P_- + P_+}$$

where $P_{-(+)}$ is the left (right) ionization probability collected at opposing directions. This asymmetry pulsates precisely with the frequency corresponding to the energy difference $E_1 - E_2$ between the ground and excited states, which are coherently excited by the first (115 nm) attosecond pulse.

Fig. 5. Asymmetry in the ionization yield (P_2/P_1, eq. [17]) of the directional photoelectron spectrum of the electron distributions (Fig. 4) as a function of time delay between a 20 nm, 0.1 fs (100 as) ionization pulse and the pump probe.

Conclusion

We have shown from solution of the TDSE for H_2^+ that we can generate efficiently new ultrashort single attosecond pulses by the combination of a previously obtained attosecond probe with an intense, short IR pulse such as a 10 fs, 800 nm Ti:Sapphire pulse. Other methods have produced trains of attosecond pulses (33). Single attosecond pulses (as demonstrated) can be used to create localized electron wave packets in molecules that oscillate between nuclei on these attosecond time scales. Measuring the directional photoelectron spectrum of such wave packets or hybrids produces ionization asymmetries, which follow the electon position in the molecule on attosecond time scales.

Spectroscopy of the XeC_2 molecule in xenon, argon, and krypton matrices[1]

Marcin Frankowski, Alice M. Smith-Gicklhorn, and Vladimir E. Bondybey

Abstract: A self-igniting DC-electric discharge of C_2H_2 in Xe (matrix gas) or C_2H_2 and Xe in Ar or Kr (matrix gas) is used to produce and study the XeC_2 molecule in these various rare gases at 12 K. Unlike in Ar and Kr, the well-known electronic spectra of C_2 is completely absent in a Xe matrix. This together with annealing experiments in Ar matrices indicate that ground state Xe and C_2 react uniquely and without a barrier to form the XeC_2 molecule. The IR-active C-C stretch of this compound is found to be close to the C-C stretching frequency of the C_2 anion, in excellent agreement with our density functional theoretical (DFT) calculations, which yield a XeCC singlet species bent by 148.6° and with substantial charge separation approaching $Xe^+C_2^-$ and a notably short (2.107 Å) Xe—C bond. The spectra of the Xe–^{13}C–^{12}C, Xe–^{12}C–^{13}C, and Xe–^{13}C–^{13}C species are also obtained and the isotopic shifts are in excellent agreement with the DFT predictions, although not sufficient to distinguish a bent from a linear structure. Numerous broad absorptions centered near 423 nm (in Xe) are observed, which are clearly due to the XeC_2 molecule. Laser-induced fluorescence studies reveal a near-IR emission likely due to XeC_2 but not yet understood. Infrared spectra in the Xe matrix reveal also formation of the HXeCCH molecule.

Key words: matrix-isolation spectroscopy, rare gas compounds, charge transfer compounds, xenon–carbon bonds.

Résumé : On a utilisé une décharge électrique, à courant direct et à auto-ignition, de C_2H_2 dans du Xe (matrice gazeuse) ou de C_2H_2 et Xe dans Ar ou Kr (matrice gazeuse) pour produire et pour étudier la molécule de XeC_2 dans ces divers gaz rares, à 12 K. Contrairement à ce qui est observé dans les gaz Ar ou Kr, le spectre électronique bien connu du C_2 est complètement absent dans une matrice de Xe. Ce résultat considéré à la lumière des expériences de recuisson dans les matrices de Ar indique que l'état fondamental du Xe et du C_2 réagissent d'une façon particulière, et sans barrière, pour former la molécule de XeC_2. L'élongation C-C de ce composé, active en infrarouge, se retrouve près de la fréquence d'élongation C-C de l'anion C_2^-, en excellent accord avec nos calculs théoriques de densité fonctionnelle (TDF) qui conduisent à une espèce XeCC singulet comportant un angle de 148,6°, une séparation de charge importante se rapprochant de $Xe^+C_2^-$ et une longueur de liaison Xe—C relativement courte, 2,107 Å. On a aussi obtenu les spectres des espèces Xe–^{13}C–^{12}C, Xe–^{12}C–^{13}C et Xe–^{13}C–^{13}C et les déplacements chimiques sont en excellent accord avec les prédictions faites sur la base de la TDF, même s'ils ne sont pas suffisants pour permettre de distinguer une structure linéaire ou repliée. On a aussi observé de nombreuses absorptions larges autour de 423 nm (dans le Xe) qui sont sans ambiguïtés dues à la molécule de XeC_2. Des études de fluorescence induite au laser révèlent l'existence d'une émission infrarouge probablement due à XeC_2, mais il est pour l'instant impossible de la comprendre. Les spectres infrarouges dans une matrice de Xe révèlent aussi la formation de la molécule de HXeCCH.

Mots clés : spectroscopie avec molécules isolées dans une matrice, composés des gaz rares, composés de transfert de charge, liaisons xénon–carbone.

[Traduit par la Rédaction]

Introduction

The C_2 molecule was observed as early as 1857 in the spectrum of flames (1). The numerous studies of its rich electronic spectrum, with many low-lying electronic states, have contributed significantly to the development of molecular spectroscopy (2–4). Investigations of C_2 in rare gas matrices have also made meaningful contributions (5). They also provided useful information about nonradiative relaxation processes in the solid medium and led to the first observation of stimulated emission in matrices (6). Up to recently, it was presumed that C_2 could be isolated and observed in all of the condensable noble gas matrices, but the literature shows that the spectrum of C_2, unlike that of C_2^-, (7, 8) has only been observed in Ne, Ar, and Kr, but never in a Xe matrix. The reason is, as we show here, the facile for-

mation of the XeC_2 molecule, whose bonding can be largely described as $Xe^+C_2^-$.

The list of rare gas compounds has increased dramatically since the pioneering work of Bartlet and co-workers in 1962 (9, 10). Although most compounds known today contain either a Xe—F or Xe—O bond, examples of Xe—Cl, Xe—Br, Xe—I, Xe—S, Xe—N, Xe—C, and Xe—B (tentatively) have also been found by now. Although many of these may be regarded as metastable species, several (such as XeF_2) salt-like compounds with a C—Xe bond in the cationic part, and recently a neutral C_6H_5XeF compound, are actually thermodynamically stable compounds used in preparative chemistry (11–13).

Another breakthrough in rare gas chemistry was the discovery of a new family of compounds, rare-gas hydrides HRgY (where Y is an electronegative fragment like F or other halogens, OH, SH, CN, etc.), prepared in xenon matrices using UV-laser photolysis of a HY precursor and subsequent mobilization of H atoms (14). Up to recently, since these Xe compounds were only observed in a Xe matrix, it was questionable whether these highly polar species could exist in a less-stabilizing environment. Lorenz et al. (15) have recently shown that these species, in particular HXeCl and HXeBr, can be formed with similar efficiencies in a highly dilute, weakly interacting neon matrix, and this, together with the results of extensive DFT calculations, suggests that they should be capable of independent existence as free molecules in the gas phase.

Nowadays, the rapid development of quantum chemistry is such that the predictions of stable compounds precede the experiments. A recently predicted family of Xe compounds involve C—H and O—H bond insertion products; from the computational viewpoint, species such as HXeCCH, $HXeC_6H_5$, $HXeOC_6H_5$, and even HXeCCXeH, etc., could exist (16). HXeOH was found in 1999 by the Räsänen group (17), and quite recently, by the same group (18), and independently by Feldman et al. (19), HXeCCH and HXeCCXeH were found.

The XeC_2 molecule was first discovered by Maier and Lautz (20) in 1998 through UV (193 or 248 nm) laser irradiation of C_2H_2:Xe matrices and identified via its IR-active C=C stretch. They found this species to be the sole contributor to the IR and UV–vis spectrum and that the intensity of the signal was insensitive to annealing (30 min at 38, 46, or 50 K), but decreased upon UV–vis irradiation ($\lambda \geq 254$ nm), with no new signals appearing. In contrast to this, Räsänen et al. (18) found that subsequent annealing of such samples led to the formation of HXeCC, HXeCCH, and even HXeCCXeH molecules. At the same time, Feldman et al. (19) bombarded C_2H_2:Xe matrices with high energy electrons (1 MeV) and found after subsequent annealing to 40–45 K, IR absorptions due to HXeCCH, with no mention of XeCC and the other related compounds.

Our work on XeC_2 also started with attempts at making HXeCCH in a pulsed DC discharge source of transients. In those experiments, a discharge of C_2H_2 diluted in the Xe matrix gas led to a very strong XeC_2 signal and a very weak HXeCCH signal, even after annealing to 50 K. Thus, we proceeded in the study of the XeC_2 molecule and its ^{13}C isotopic analogues, both experimentally and computationally. The Fourier-transform (FT) absorption spectra from 500–30 000 cm^{-1} and FT-emission spectra from 4000–30 000 cm^{-1} were recorded in an attempt to decipher the electronic spectra of this unusual molecule. By performing similar experiments with dilute mixtures of C_2H_2 and Xe with a large excess of argon or krypton, we were able to observe the spectra of the novel XeC_2 species in Ar and Kr matrices, and thus can address the important question of solvent effect on this highly polar, charge-transfer molecule.

Experimental section

The samples were generated by electric discharge through xenon gas doped with acetylene, as well as through gas mixtures with small amounts of acetylene and xenon diluted by Ar and Kr matrix gases. The products were deposited onto a KCl window cooled down to 12.5 K by a closed-cycle helium cryostat (APD Cryogenics, Berkshire, UK). The gas samples (C_2H_2 (99%), $^{13}C_2H_2$ (99%), C_2D_2 (99%), Xe (99.998%), Ar (99.999%), Kr (99.99%)) were mixed in various ratios, typically C_2H_2:Xe (1:800–1100), C_2H_2:Xe:Ar (1:1–5:1000), and C_2H_2:Xe:Kr (1:5:1000). Usually 8 mmol of the gaseous mixture was deposited for 2 h as estimated from the pressure drop and volume of the gas container and handling system. The self-igniting DC electric source with the pulsed gas inlet system has been already described in detail in refs. 21 and 22.

All absorption and emission spectra of the deposited samples were recorded using a Fourier transform Bruker IFS 120 HR spectrometer equipped with an Opus NT control and data acquisition system. Absorption spectra were measured in a wide spectral range from 400–31 000 cm^{-1} usually with a 0.06 cm^{-1} resolution in the IR and 1 cm^{-1} resolution in the UV–vis region. Although samples were always cooled down to 12.5 K after deposition, use of the broadband light sources caused an increase of the temperature up to 14 K at which all absorption measurements were performed.

Emission in the near-IR region was obtained by exciting the matrix samples using cw lasers, including intensity stabilized tunable dye lasers (Coherent 899-01 ring laser operated with stilbene 3; Coherent 599 standing wave laser with rhodamine 6G (Coherent, Palo Alto, CA, USA)). The dye lasers were optically pumped by Ar^+ ion lasers (Coherent) operating in multi-line UV (Coherent, Innova-200) and multiline visible (Coherent, Innova-70) modes. In some experiments, the Ar ion lasers were also used directly for the sample excitation. The Innova-70 laser operating in single line mode allowed for selection of discrete emission wavelengths between 514 and 466 nm. In all cases the laser beams were transmitted via fiber optics and focused onto the matrix sample.

XeC_2 — Density functional theory calculations

The optimized geometry and vibrational frequencies of the XeC_2 molecule were calculated using the hybrid DFT technique as implemented in the Gaussian98 suite of programs (23) at the B3LYP level of theory. All electrons on the carbon atoms were explicitly treated with the 6-311++G(3df,3pd) basis set. For the rare gas atom, the quasi-

relativistic effective core potential SDD basis set was used (24). The lowest electronic singlet and triplet states of the C_2 are known experimentally to be very close in energy, with the triplet lying only 716 cm^{-1} above the ground state singlet. The theoretical results and experimental spectroscopic data for the lowest singlet and triplet states of XeC_2 are summarized in Tables 1*a* and 1*b*, respectively, with the data for C_2 and the C_2^- anion being also included for comparison. Corresponding geometries of the molecules are shown in Fig. 1. The binding in the singlet and triplet XeC_2 molecules is predicted to be considerably different in character. The singlet molecule was found to have a relatively strong, 82.4 kJ/mol bond and exhibit an appreciable (0.72 e^-) charge transfer from xenon to the C_2 unit. The triplet C_2, on the other hand, interacts with xenon more weakly (33 kJ/mol), with only 0.09 e^- being transferred. Particularly striking are the differences in geometry, with the linear (or nearly linear, see the next section) singlet XeC_2 molecule displaying a remarkably short, 2.107 Å Xe—C bond. The triangular triplet, on the other hand, exhibits much longer (3.26 and 3.39 Å) bonds to both the carbon atoms, and is probably best described as a weakly bound van der Waals complex.

This point of view is also confirmed by the computed vibrational frequencies. For the singlet, the computed C=C frequency decreases somewhat compared with free C_2, reflecting probably the fact that the corresponding mode in molecular XeC_2 involves also some motion of the heavy xenon atom. This is also consistent with the relatively high "skeletal" low frequency modes computed to be 325 and 87 cm^{-1}. On the other hand, in the triplet complex the C=C frequency is found to display a smaller shift in the opposite direction, and the "skeletal" distortion modes decrease to 73 and 30 cm^{-1}, respectively. Again, the results are consistent with the novel singlet species being best described as a discrete ionic $Xe^+C_2^-$ molecule (see Tables 1*a* and 1*b*), but the triplet being described as a weakly bound Xe···C_2 complex.

Returning to the structure of the singlet XeC_2 species, the optimizations converge smoothly to a linear Xe-C-C structure when the relatively primitive SDD basis set is used on all the atoms, including the carbons. On the other hand, with

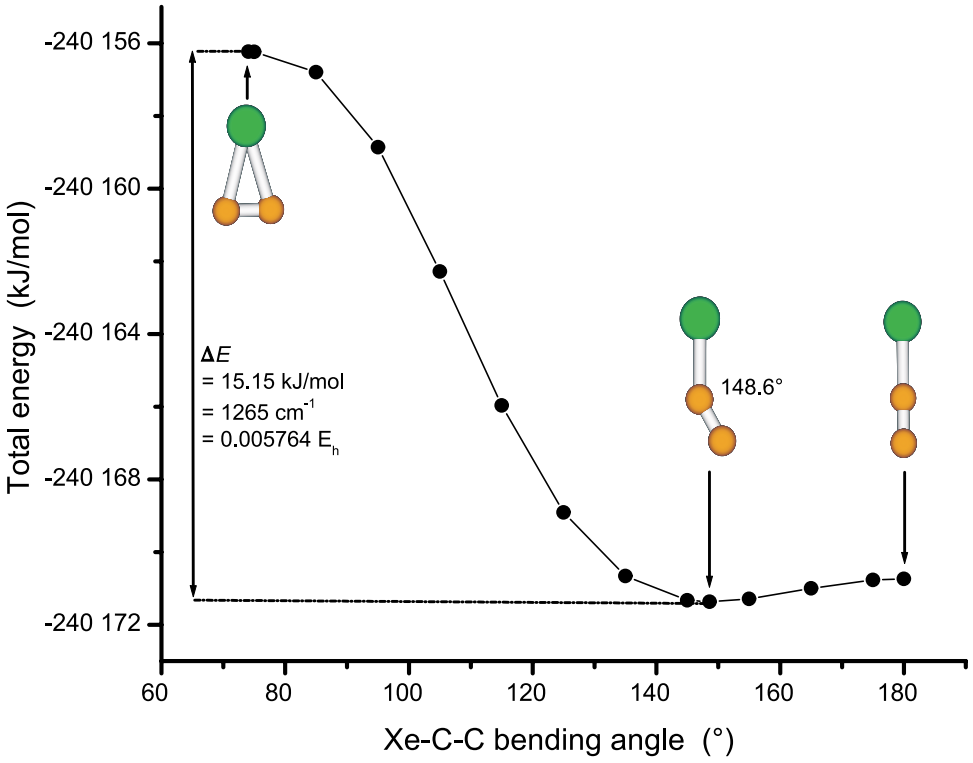
Fig. 1. The calculated geometries of the XeC_2 molecule in singlet and triplet states with charge distribution obtained from natural population analysis.

the larger 6-311++G(3df,3pd) or similar basis set, including diffuse and polarization functions on the carbon atoms, the computation yields for the linear geometry imaginary frequencies. Allowing the symmetry to be lowered, the optimization converges to a slightly bent structure with all real frequencies. The computed dependence of the total energy of singlet XeC_2 molecule as a function of the Xe-C-C bending angle is shown in Fig. 2. It can be seen that the bending potential is very flat with the linear and bent (140°–180°) structures nearly isoenergetic, but the optimizations converge consistently to a bending angle around 148.6°. Some support for the bent structure can be also seen in the high intensity of the observed C=C stretching frequency for XeC_2. While for the linear arrangement the IR intensity predicted for this mode is extremely low (1 km/mol), the bent solutions give more than an order of magnitude higher IR intensities (20 km/mol) of the C=C stretch, more consistent with the experimental results to be discussed in the next section.



Besides computations on XeC_2, we have also explored the interaction of C_2 with more than one xenon atom. Starting from a linear, centrosymmetric $D_{\infty h}$ XeCCXe structure, the optimization with the all SDD basis set results in two relatively long (2.717 Å Xe—C bonds), and yields one rather high imaginary frequency. When the initial geometry is made slightly asymmetric ($C_{\infty h}$), the energy of the converged geometry drops substantially by nearly 22 kJ/mol, and the imaginary frequency disappears. The lengths of the two Xe—C bonds are now quite different, 2.139 and 4.063 Å, respectively. The converged structure is basically XeC_2, with essentially identical geometry and frequencies as in the three-atom computations, very weakly bound to the additional Xe atom. A very similar result is obtained for a linear Xe-Xe-CC arrangement, where the optimized geometry again yields a Xe atom weakly interacting with the Xe end of the unperturbed triatomic XeC_2, and with a Xe···Xe distance of 4.47 Å. As well, other geometries where the C_2 is forced to interact simultaneously with more than one xenon atom yield high energy optimized structures. For instance, a T-shaped C_{2v} Xe_2-C-C geometry where one of the carbon atoms interacts with two xenon atoms results in two long, 2.97 Å Xe—C bonds, and more than 45 kJ/mol above the asymmetric, linear global minimum.

Quite similar results were obtained with the larger, 6-311++G(3df,3pd) basis set on the carbon atoms. Again, trying to enforce a symmetric configuration results in a high energy structure with large imaginary frequencies, but allowing symmetry lowering, optimization converges to an XeC_2···Xe structure, with a bent XeC_2 structure essentially identical to that obtained in the three-atom computation, that is, with C=C and C-Xe distances of 1.258 and 2.107 Å, respectively, and a C-C-Xe bending angle of 146.8°, and with a weakly bound additional xenon atom at a large, 4.235 Å distance.

The conclusions of these computations seem therefore inescapable: XeC_2 is a well-defined, strongly bound discrete molecule, and the C_2 dimer prefers to interact with one, and only one, xenon atom. The presence of any additional ligand atoms has very little influence upon the geometry and vibrational frequencies of the XeC_2 molecule. When the starting geometry involves two equivalent xenon ligands (and similar

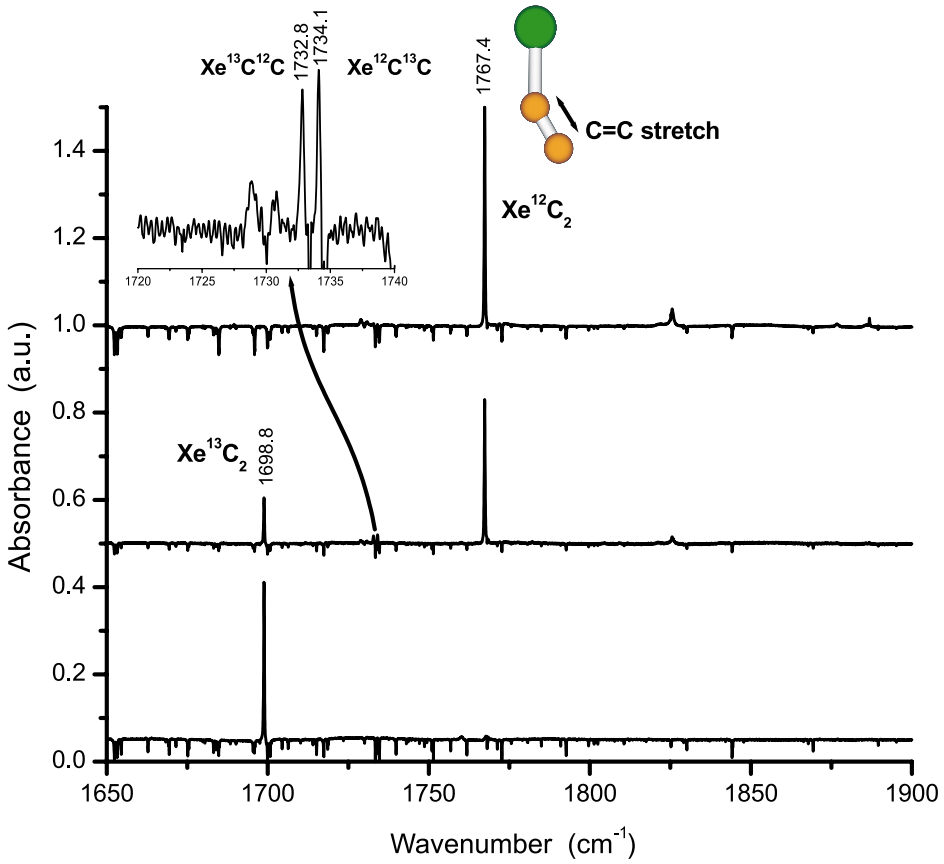
Fig. 2. The total energy of the XeC_2 molecule as a function of the Xe-C-C bending angle determined from density functional theory (DFT) calculations. Basis set: 6-311++G(3df,3pd) for carbon atoms and SDD for the rare gas atom.

results were obtained for Kr and Ar as well), one of these is in the optimization process tightly bound, while the other is pushed away. In other words, independent of the number of ligands used, there is a strong interaction with one. These results contradict a previous prediction of a T-shaped equilibrium structure of Ar_2C_2 (25), which is clearly not a global minimum in our calculations, both with the SDD and the 6-311++G(3df,3pd) basis sets.

Besides the calculations involving XeC_2, we have also carried out computations on a variety of related species, on similar molecules involving Kr or Ar, as well as on the $HXeC_2H$ molecule, acetylene with a Xe atom inserted into the C—H bond. The DFT calculations on all these species were performed at the same level of theory, and with the same basis sets as described for XeC_2 above.

XeC_2 in a xenon matrix

The IR spectra of a matrix obtained by discharging mixtures of acetylene and its ^{13}C isotopomer with xenon are presented in Fig. 3. Specific ratios of $^{12}C_2H_2$:Xe (1:870), $^{13}C_2H_2$:$^{12}C_2H_2$:Xe (1:1:1130), and $^{13}C_2H_2$:Xe (1:810) were used for the spectra in the top, middle, and bottom panel, respectively, and the measured vibrational frequencies are summarized in Table 1*a*. Analysis of the spectra and of the observed isotopic shifts, combined with the theoretical calculations described above, clearly identify 1767.4 cm^{-1} as the C=C stretch of the XeC_2 molecule, and confirm the previous assignment (20). The lack of any shift with deuterated $^{12}C_2D_2$ confirms the absence of hydrogen in the carrier, and the clearly resolved doublet of lines due to the mixed $Xe^{13}C^{12}C$ (1732.8 cm^{-1}) and $Xe^{12}C^{13}C$ (1734.1 cm^{-1}) species clearly demonstrates the presence of two inequivalent carbon atoms. Unfortunately, the frequencies cannot be used to distinguish between the linear or 148.6° bent configuration, since the effect of the angle is too small, and the agreement with the predicted isotopic shifts is good for both geometries.



XeC_2 in argon and krypton matrices

Quite noteworthy is the absence of the so-called *Phillips bands* characteristic of C_2 in the visible absorption region. These are always prominent in matrices other than xenon, whenever acetylene or another unsaturated hydrocarbon is discharged, as also exemplified by Fig. 4, which compares the visible and near-IR spectra of discharged acetylene in argon, krypton, and xenon matrices. Apparently, the C_2 produced in the discharge reacts in the xenon matrix with the Xe atoms to produce "in situ" the XeC_2 molecules. This reaction must be nearly quantitative and proceed with essentially no activation barrier, since no trace of the Phillips bands is observed, and no further increase in the XeC_2 band absorption intensity can be detected when the xenon matrix is annealed to 40 K. It may be noted that we also did not observe the peak at 1852 cm^{-1} previously assigned to the ethynyl radical C_2H (19). A weak but unidentified feature appears at 1825.6 cm^{-1}.

Spectra obtained in experiments done under almost identical conditions, but using argon and krypton samples doubly doped with small amounts of Xe and acetylene, are presented in Figs. 4 and 5. The visible and near-IR spectra show, as noted previously, a prominent progression of absorptions due to the A–X C_2 transition in solid argon and

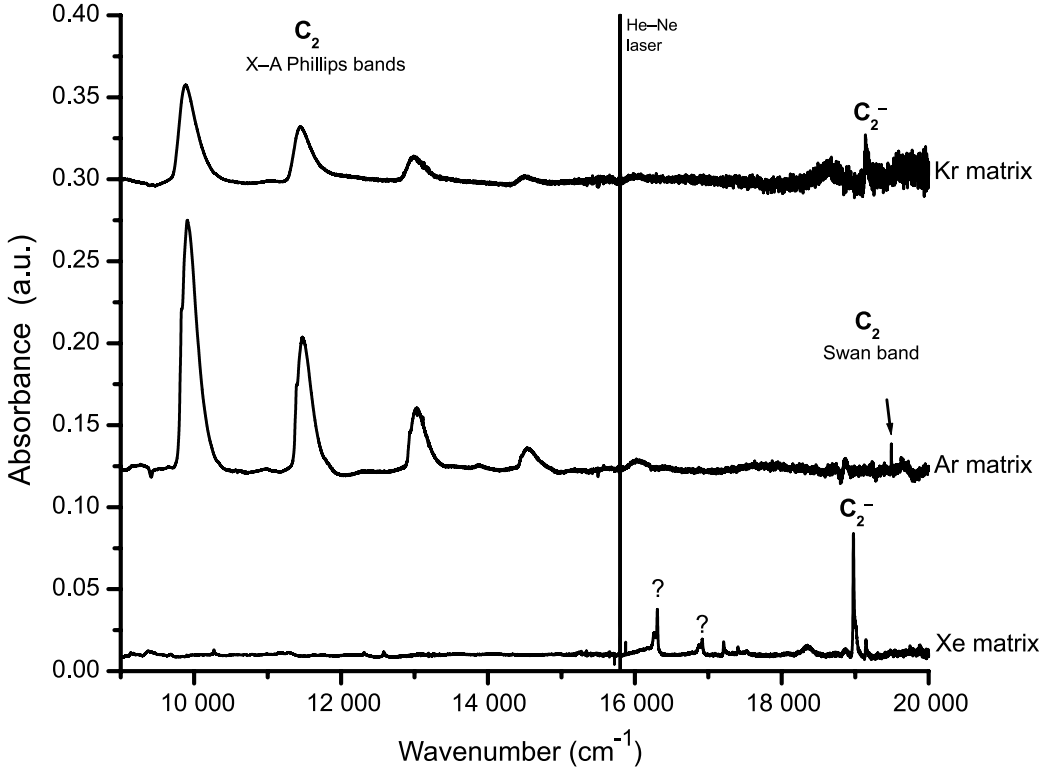
© 2004 NRC Canada

Fig. 3. Infrared spectra of the XeC_2 molecule and its isotopomers identified through its C=C stretching vibration. The spectra were recorded in a Xe matrix at 14 K after deposition at 30 K from discharge through $^{12}C_2H_2$:Xe (1:870), top; $^{13}C_2H_2$:$^{12}C_2H_2$:Xe (1:1:1130), middle; and $^{13}C_2H_2$:Xe (1:810), bottom. The expanded region shows C=C stretching at 1732.8 cm^{-1} of $Xe^{13}C^{12}C$ and 1734.1 cm^{-1} of $Xe^{12}C^{13}C$ isotopomers.

krypton, which is, however, quite absent in the xenon matrix. On the other hand, the strong band due to the origin of the Herzberg–Lagerqvist bands near 19 000 cm^{-1} (27) is present in all three matrices, indicating that C_2^-, unlike C_2 can be isolated in solid xenon also. Interestingly, the argon sample also shows a weak absorption due to the origin of the "Swan bands" of triplet neutral C_2.

Infrared spectra obtained with the doubly doped argon (C_2H_2:Xe:Ar = 1:5:1000) and krypton (C_2H_2:Xe:Kr = 1:5:960) samples are presented in Fig. 5. The presence of moderately intense, sharp bands at 1770.6 and 1774.6 cm^{-1} in solid krypton and argon, respectively, only moderately blue-shifted from the XeC_2 absorption at 1767.4 cm^{-1} in solid xenon, shows that the molecule can be isolated, alongside C_2, C_2^-, and other carbon cluster molecules, in solid Ar and Kr environments. The assignment of these bands to XeC_2 is further confirmed by their strong dependence on the concentrations of both Xe and acetylene. Using isotopically labeled acetylene, one obtains in solid argon a peak at 1705.2 cm^{-1}, which is clearly due to $Xe^{13}C_2$ (Table 1*a*). It may also be noted that the C=C stretching absorption band of this compound in solid Ar (1774.6 cm^{-1}) is just 5 cm^{-1} to the red from the vibrational frequency of the C_2^- anion, which is consistent with the appreciable charge separation predicted by the DFT results.

The three traces in the middle of Fig. 5 show the results of an annealing experiment, where the sample was deposited at 12 K, and then progressively warmed up for 30 min to 25 and 35 K respectively, recooling each time to 12 K before recording the spectrum. It can clearly be seen that the 1774.6 cm^{-1} band, which is rather weak in the original, at 12 K deposited sample (in the lowest trace), increases in intensity with each annealing step (the traces above it). The straightforward conclusion that can be drawn from this experiment is that during the annealing process and the resulting diffusion, the ground-state Xe atoms and C_2 can react essentially without the barrier to form the chemically bound XeC_2 molecule.



The results in the krypton and argon matrices are clearly in excellent agreement with the theoretical computations discussed in an earlier section. The diatomic C_2 prefers to react and interact strongly with a single xenon atom. Once this reaction occurs, and the molecular XeC_2 forms, its solvation by other atoms makes little difference. The vibrational frequencies, and presumably the structure of the molecule, are essentially independent of whether it is surrounded by additional xenon atoms, or whether it is isolated in solid krypton or argon matrices.

$HXeC_2H$ in a xenon matrix

Besides the recent observation of XeC_2 (20), the motivation for the present work was calculations done by Lundell et al. (16), which suggested that HXeCCH should exist as a stable molecule. Unfortunately, in contrast with the results

Fig. 4. Comparison of the spectra in the near-IR–vis absorption region of the C_2 molecule (Phillips band: $X^1\Sigma_g^+ \rightarrow A^1\Pi_u$ and Swan band: $a^3\Pi_u \rightarrow d^3\Pi_g$) for Xe, Ar, and Kr matrices. No C_2 bands are observed in Xe matrix.

recently reported by Khriachtchev et al. (18) and Feldman et al. (19) on this molecule in a xenon matrix, our experiments using a discharge source produce it in very small yields, and the very weak bands obtained in our early experiments unfortunately escaped detection. With the help of the previous assignments, these bands could, however, be identified in our spectra. Their analysis and the production of the molecule by a different technique provide some additional information and insights, complementary to the previous experimental work and earlier theoretical studies (16), and we will therefore discuss briefly our results here.

The experimental data, as well as the results of our DFT computations, are summarized in Table 2, where for the ease of comparison, the measured intensities given in parentheses are scaled to the computed intensity of the strongest band. With the help of the previous assignments (18, 19), the Xe-H and CH-stretching vibrations of HXeCCH at 1486.1 and 3273.5 cm^{-1}, respectively, can be easily identified. In similar experiments using deuterated or ^{13}C-substituted species, the corresponding vibrational modes of DXeCCD as well as the previously unknown vibrations of the $HXe^{13}C^{13}CH$ isotopomer could be established.

All the bands described above exhibit an interesting behavior upon photolysis and sample annealing, which is useful in confirming their assignment to the same carrier. The very weak absorption bands present right after sample deposition almost completely disappear when the matrix is irradiated by the visible light of a tungsten lamp for 2 to 3 h. When the sample is then annealed to 40–50 K, they reappear, and grow appreciably, undoubtedly due to reactions of the hydrogen atoms produced in the discharge. Unlike the photolysis experiments, however, which produce the H and C_2H pairs in close proximity, in our discharge setup the fragments are essentially randomly distributed through the matrix. In the former experiments, the two radical fragments have an appreciable probability of reacting with the same xenon atom to form the HXeCCH species, while in the random walk-like diffusion of the fragments in our discharge studies this probability is greatly reduced. We suspect that a substantial fraction of the hydrogen atoms produced by the discharge in our experiments recombine, during either the sample deposition or the diffusion, to form molecular H_2, and are thus from the point of observable product formation irretrievably lost.

Electronic spectra

While the interpretation of the XeC_2 IR absorption is rather straightforward, the corresponding electronic spectra are more difficult to understand. The absorption spectra observed in the visible and near-UV, which are presented in Fig. 6, exhibit a series of broad bands between 22 000 and 26 000 cm^{-1}, whose approximate frequencies are both for the $^{12}C_2H_2$–Xe and $^{13}C_2H_2$–Xe experiments summarized in Table 3. The excellent correlation between the intensity of these bands and that of the IR spectrum strongly suggests that they are also due to the XeC_2 molecule, as also suggested previously (20). When pure argon or krypton with no xenon is used, the broad bands are absent, but much sharper bands due to a well-known transition of C_3 appear approximately in this region. It seems, however, that C_3 can be safely excluded as a carrier of the broad bands.

In view of the width of the bands, and lack of spectral detail, a specific assignment or interpretation of these bands is difficult, in particular since no theoretical information on the

excited electronic states of XeC_2 is available. The spacing of the bands decreases in the ^{13}C experiment, with the approximate isotopic frequency ratio of $\rho \approx 0.97$ being relatively close to that expected for pure carbon motion (0.961). The spectrum appears relatively complex for a molecule as simple as XeC_2, and it is conceivable that overlapping progressions of two or more electronic states are present in this region.

If emission from the excited electronic state of the species of interest is observable, analysis of the fluorescence provides information complementary to the absorption spectrum, and often is of considerable help in untangling its structure. In the present case, however, even though an intense IR fluorescence is observed, it only serves to further deepen the mystery. Unfortunately, we do not have an excitation source capable of exciting the sample in the strongest absorption bands, and the two traces in Fig. 7 result from excitation of matrices obtained in $^{12}C_2H_2$:Xe and $^{13}C_2H_2$:Xe experiments, in each case near the low-energy end of the absorption, around 23 000 cm^{-1}. The emission bands are again relatively broad, and so the accuracy of their positions listed in Table 3 is probably not better than ±10 cm^{-1}. The bands exhibit distinct isotopic shifts, with their spacing reduced in the $^{13}C_2H_2$ experiment on the average by about a factor $\rho \approx 0.965$, very close to what would be expected, for instance, for diatomic XeC or C_2. The band at 5883 cm^{-1} shows es-

Fig. 7. Near-IR emission under excitation at 431 nm by means of stilbene 3 dye laser recorded after $^{12}C_2H_2$:Xe and $^{13}C_2H_2$:Xe discharge products deposition. The frequency intervals are shown with arrows and values (band locations are given in Table 3).

sentially no isotopic shift, and should therefore be the electronic origin. With this assignment, however, all the other observed bands occur at higher energies, suggesting that much of the emission would have to originate from vibrationally excited levels, which is rather unusual for polyatomic molecules. Furthermore, if this interpretation is accepted, the spectrum exhibits a strong negative anharmonicity, with the band spacing appearing to increase with increasing vibrational energy.

Also puzzling is the absence of any emission at energies below the 5883 cm^{-1} origin, which could be assigned to excited levels of the ground state. While part of the reason may be the sensitivity of the detector, which cuts off around 4000 cm^{-1}, but certainly some emission to the low ground state levels would be expected. In the absence of such emission, no information about the ground state is obtained. We must conclude that even though there appears to be strong evidence for assigning the electronic spectrum to the XeC_2 molecule, we have at this point little understanding of its structure. Clearly, additional experimental and, in particular, theoretical work would be desirable.

Summary

A self-igniting DC-electric discharge of C_2H_2 in Xe (matrix gas) produces no C_2, little C_2^-, and mainly the XeC_2 molecule, as revealed by its IR spectrum. The same molecule can be isolated in Ar and Kr matrices alongside C_2 and C_2^- and other carbon cluster molecules in discharges of C_2H_2:Xe diluted in Ar or Kr as the matrix gas. The IR-active C-C stretch of this compound is found just 5 cm^{-1} to the red (in Ar at 1774.6 cm^{-1}) from the C-C stretch of the C_2 anion, in excellent agreement with DFT calculations at the B3LYP level (basis sets 6-311++G(3df,3pd) on C, SDD on Xe), which yield a XeCC singlet species with substantial charge separation (natural charge populations of +0.72 e^- (Xe), –0.7 e^- (C), and –0.02 e^- (C)), and a remarkably short (2.107 Å) Xe—C bond. The spectra of the Xe–^{13}C–^{12}C, Xe–^{12}C–^{13}C, and Xe–^{13}C–^{13}C species are also obtained and the isotopic shifts are in excellent agreement with the DFT predictions, although not sufficient to distinguish a bent (a 148.6° structure is a shallow minimum) from a linear structure. More difficult to interpret are the broad electronic spectra of this species. Numerous broad absorptions centered near 423 nm (in xenon) are observed, which are clearly due to the XeC_2 molecule. Laser-induced fluorescence studies reveal a near-IR emission with origin at 5883 cm^{-1} likely due to XeC_2. The spectrum is rather unusual for a triatomic molecule and indicates a nonrelaxed vibrational emission.

The Xe matrix IR spectra reveal XeH and CH stretching vibrations of the HXeCCH molecule, observed also for its fully deuterated or all-^{13}C isotopomers. However, deposition from a gas discharge leads to a random distribution of radical fragments through the matrix and consequently its formation is fairly inefficient.

Electronic spectroscopy of the nonlinear carbon chains $C_4H_4^+$ and $C_8H_4^+$ [1]

Mitsunori Araki, Pawel Cias, Alexey Denisov, Jan Fulara, and John P. Maier

Abstract: The electronic spectrum of a nonlinear carbon chain radical $C_4H_4^+$ was observed after mass-selective deposition in a 6 K neon matrix. The corresponding gas-phase spectra of $C_4H_4^+$ and $C_4D_4^+$ have been observed in the 512 to 513 nm region and at 710 nm for $C_8H_4^+$. These were detected in direct absorption by cavity ringdown spectroscopy through a supersonic planar discharge. The electronic transition energies of these nonlinear carbon chain radicals correlate well with those of the polyacetylene cations HC_nH^+ (n = 4, 6, 8). The observed profiles are reproduced with rotational constants obtained by ab initio geometry optimizations and extrapolation between the ground and excited electronic states.

Key words: nonlinear carbon chain, carbon cation, electronic transition, diffuse interstellar bands, molecular structure.

Résumé : On a observé le spectre électronique d'un cation $C_4H_4^+$ correspondant à une chaîne carbonée non linéaire déposée par un procédé sélectif en fonction de la masse dans une matrice de néon, à 6 K. Les spectres correspondants en phase gazeuse des cations $C_4H_4^+$ et $C_4D_4^+$ ont été observés dans la région de 512–513 nm et à 710 nm dans le cas du $C_8H_4^+$. Ces spectres ont été détectés par absorption directe par la technique CRDS (« cavity ringdown spectroscopy ») grâce à une décharge supersonique planaire. Il existe une bonne corrélation entre les énergies de transition électronique de ces cations à chaîne carbonée non linéaire et celles des cations polyacétyléniques HC_nH^+ (n = 4, 6, 8). Les profils obtenus peuvent être reproduits à l'aide de constantes rotationnelles obtenues par des optimisations ab initio de géométrie et une extrapolation entre les états électroniques excités et fondamentaux.

Mots clés : chaîne carbonée non linéaire, cation carbone, transition électronique, bandes interstellaires diffuses, structure moléculaire.

[Traduit par la Rédaction]

Introduction

High-resolution spectroscopy of unsaturated carbon chain radicals is of interest in view of interstellar chemistry, as well as terrestrial discharge and flame processes. Electronic transitions of the polyacetylene cations HC_nH^+ (1–4) and radicals C_nH (5) with even number carbons have now been studied. Recently a nonlinear planar carbon chain radical $C_6H_4^+$, H-C≡C-C≡C-CH=CH_2^+, was detected in a supersonic planar discharge with cavity ring down spectroscopy in the 604 nm region (6). Therefore, the related $C_4H_4^+$ and $C_8H_4^+$ nonlinear chains were expected to be produced in the plasma discharge in a sufficient concentration for detection.

Hydrogenated nonlinear chains can exist in dark interstellar clouds as well as linear ones, e.g., the column densities of C_2O, H_2CCO, and CH_3CHO are of the same order of magnitude in Taurus Molecular Cloud-1 (7). However, the intensity of rotational transitions for a linear molecule with a smaller rotational partition function is stronger than for an asymmetric top, and thus, a long nonlinear carbon chain has not yet been detected by radio astronomy, even though the population may be comparable. In the case of electronic transitions, an asymmetric top molecule is not at a disadvantage compared with the linear one. Thus, the nonlinear chains can be considered as candidates, causing the diffuse interstellar band (DIB) absorptions in much the same way as the linear series (8).

The short nonlinear carbon chain H-C≡C-CH=CH_2 is predicted to be an intermediate between acetylene and polyaromatic hydrocarbons in the interstellar chemistry of circumstellar envelopes (9). Laboratory experiments indicate that photodissociation of aromatic molecules produces a nonlinear carbon chain (10). The potential energy surface for three C_4H_4 isomers is also of relevance in the fields of organic chemistry and reaction dynamics (11). Therefore, species and their ions having H-C_n-CH=CH_2 (n = 2, 4, 6,...) nonlinear chain structures are of interest, and information by high-resolution spectroscopy is needed.

The 604 nm origin of the $^2A''$–X^2A'' transition of $C_6H_4^+$ (6) is close to the 600 nm $^2\Pi_u$–$X^2\Pi_g$ one of HC_6H^+ (2). Both transitions involve the same $\pi \leftarrow \pi$ excitation. The transition energy difference in a homologous series should be comparable because $C_6H_4^+$ and HC_6H^+ are produced by an extension of the acetylene chain from $C_4H_4^+$ or HC_4H^+ (12). The

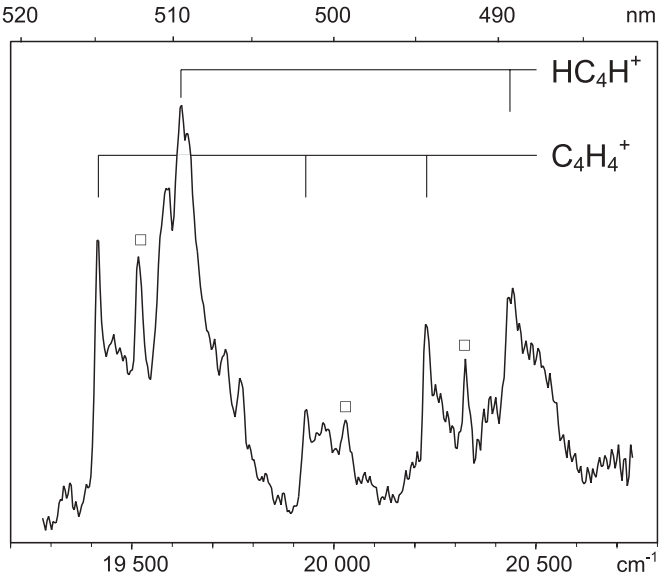
Fig. 1. (*a*) Energies of the origin bands in the $^2\Pi_u$–$X^2\Pi_g$ transition of HC_nH^+ and the $^2A''$–X^2A'' transition of $C_nH_4^+$. For HC_nH^+ (n = 4, 6, 8) and $C_6H_4^+$, those are the observed values reported in refs. 1–3 and 6, respectively. The transitions of $C_4H_4^+$ and $C_8H_4^+$ were estimated by shifting the HC_4H^+ and HC_8H^+ values down by the difference of HC_6H^+ to $C_6H_4^+$; (*b*) Observed transition-energy differences between HC_nH^+ and $C_nH_4^+$ with the same number of carbon atoms.



same argument may be applied to the six- and eight-carbon chain species. This trend is shown in Fig. 1*a*, and the transition energies of $C_4H_4^+$ and $C_8H_4^+$ are consequently estimated to lie near 510 and 712 nm, respectively.

The electronic transition of mass-selected $C_4H_4^+$ was subsequently observed in a neon matrix with origin band at 515 nm, in good agreement with the estimated value. Based on this, the gas-phase spectrum was searched for in a cavity ring down spectrometer, and the origin band was observed at 513 nm. Similarly the electronic transition of $C_8H_4^+$ was also detected in the gas phase in the expected 712 nm region. The observed rotational structure in the gas-phase spectra indicates that these are due to the nonlinear, planar carbon chains H-C≡C-CH=CH_2^+ and H-C≡C-C≡C-C≡C-CH=CH_2^+.

Experimental observations

To locate the electronic transition of $C_4H_4^+$, neon-matrix isolation spectroscopy in combination with mass selection was used at first. The $C_4H_4^+$ cation was produced from a benzene–helium mixture in a hot cathode discharge source. A 90° deflector and a quadrupole mass spectrometer were used to steer the ion beam onto the substrate, where the mass-selected ions were codeposited with excess of neon at 6 K (13). The absorption spectra were recorded by guiding monochromatized light (0.1 nm bandpass) through the matrix onto a photomultiplier. The observed spectrum is shown in Fig. 2. All bands observed in the absorption spectrum disappeared upon UV irradiation of the matrix, a test used to indicate that the species is a cation. Three bands of $C_4H_4^+$ were observed; the one at 19 416 cm^{-1} can be assigned to the origin of the electronic transition and the 19 931 and 20 229 cm^{-1} ones to transitions to excited levels in the upper electronic state corresponding to vibrational frequencies of 515 and 813 cm^{-1}, because the population of the species at 6 K is entirely in the lowest level of the ground state.

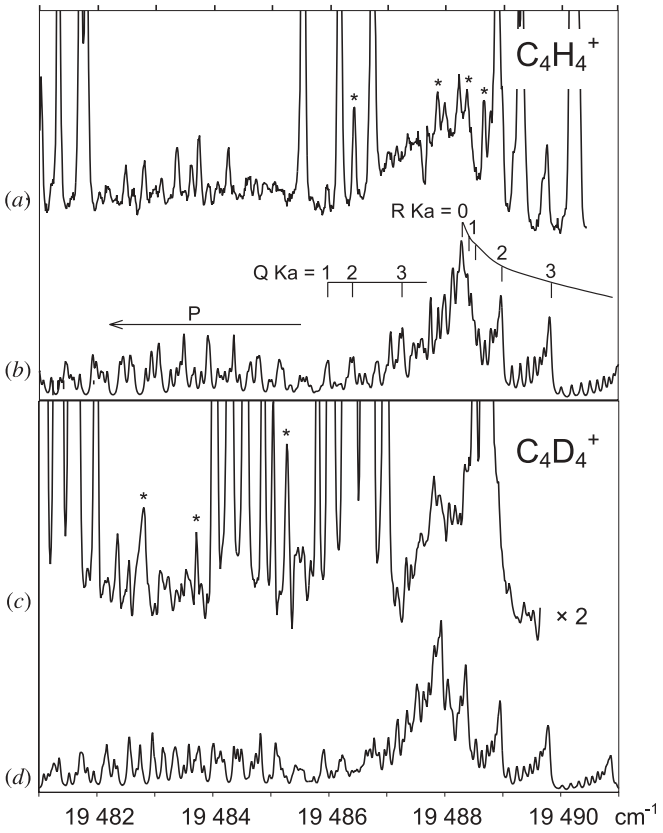


Fig. 2. The electronic absorption spectrum of $C_4H_4^+$, measured in a 6 K matrix after codeposition of mass-selected cations with excess of neon. The band at 19 416 cm^{-1} corresponds to the gas-phase spectrum shown in Fig. 3. The weaker bands at 19 931 and 20 229 cm^{-1} decrease at the same rate as the 19 416 cm^{-1} one upon UV radiation and are due to transitions to vibrationally excited levels in the upper $^2A''$ state. The three peaks (□) 100 cm^{-1} to the blue from the dominant ones are matrix artefacts, site structure. The bands at 19 630 and 20 440 cm^{-1} are due to the diacetylene cation HC_4H^+.

The gas-phase measurement used a cavity ring down spectrometer sampling a supersonic planar plasma (14). The latter was generated by a discharge through a gas pulse (30 Hz repetition rate) of a sample in a buffer gas mixture with a backing pressure of 1000 kPa in the throat of a 3 cm ×

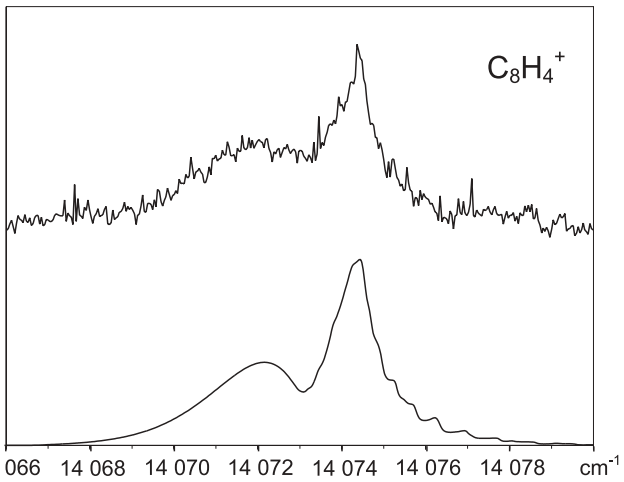

Fig. 3. The origin bands of the $^2A''$–X^2A'' electronic transition for $C_4H_4^+$ and $C_4D_4^+$ observed using cavity ring down spectroscopy through a supersonic planar plasma expansion. The rotational structure observed (traces *a* and *c*) can be simulated with a temperature of 30 K using constants derived from geometry optimization by ab initio calculation (traces *b* and *d*). Bands marked with * are due to another carrier. The peaks going off-scale are due to the Swan bands of C_2 and were used for the frequency calibration. The spectrum of $C_4D_4^+$ is shifted by –51.64 cm^{-1} for comparison with $C_4H_4^+$.

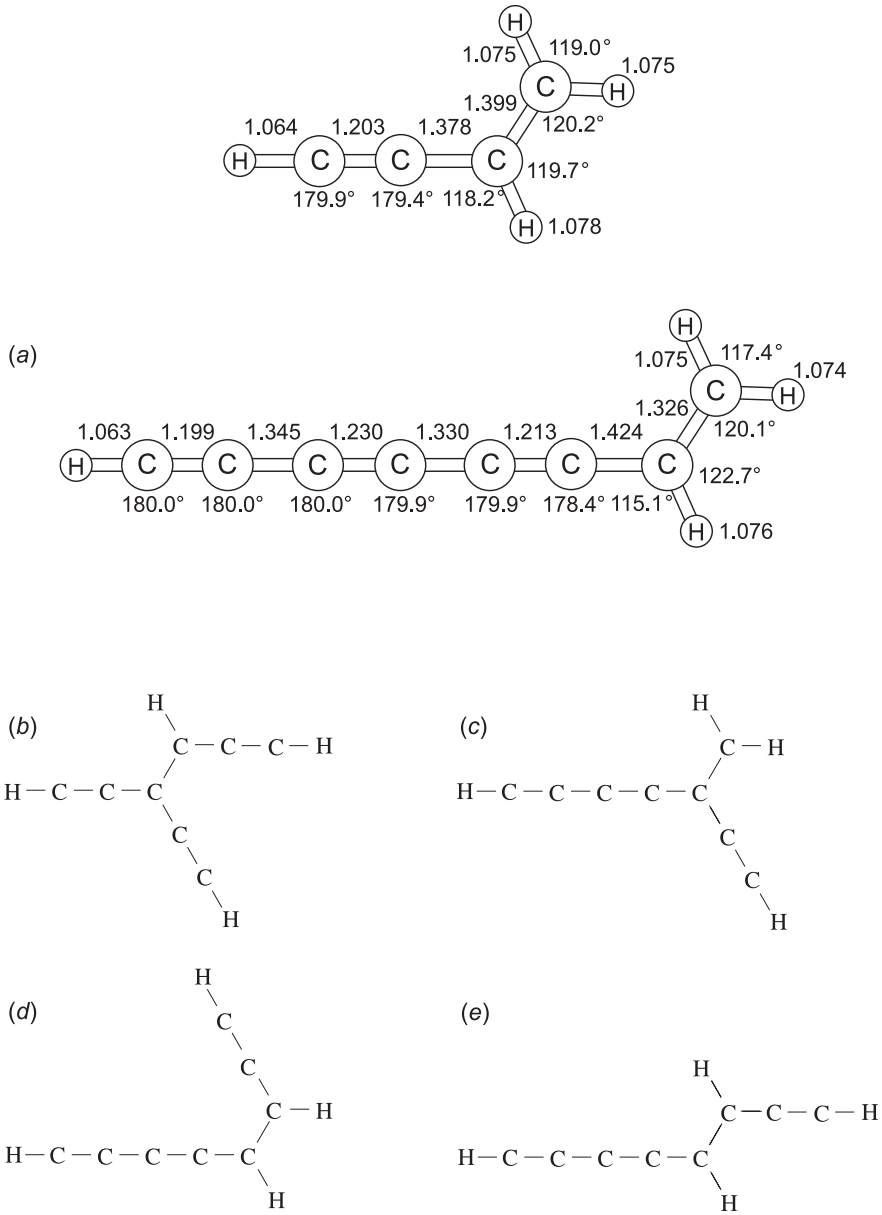
100 μm multilayer slit-nozzle geometry. Rotational temperatures of the order 30–50 K are routinely achieved. The nozzle was mounted in an optical cavity where the expansion was intersected ~2 mm downstream by the pulsed light of a tunable dye laser. The line width of the dye laser was 0.15 cm^{-1} when scanning with a grating and 0.04 cm^{-1} with an intracavity etalon. The light leaking out of the cavity was detected with a photodiode and was used as input for a standard ring down analysis (15). A spectrum was recorded by determining an averaged decay time as a function of the laser frequency.

The origin transition of $C_4H_4^+$ was searched for around the 19 416 cm^{-1} region, and a band having P- and R-branches was found at 19 486 cm^{-1}, as shown in Fig. 3*a*. When C_2D_2 was used as the sample gas, another band, having a similar profile, was detected around 19 537 cm^{-1} (Fig. 3*c*). The shift on deuteration is 51 cm^{-1}, which is comparable with the 67 cm^{-1} one for the $C_6H_4^+$–$C_6D_4^+$ pair (6). The 19 486 cm^{-1} band lies 70 cm^{-1} to the red in a neon matrix, comparable with the 79 cm^{-1} shift in HC_4H^+ (12). The optimized condition for the production of $C_4H_4^+$ used a mixture of 0.5% C_2H_2 in argon and a –700 V discharge while sampling 2 mm downstream from the discharge slit. The signals could not be detected when helium was used as the buffer gas. The behaviour of the HC_4H^+ absorption signals was similar.

Fig. 4. The $^2A''$–X^2A'' origin band in the electronic transition for $C_8H_4^+$ observed using cavity ring down spectroscopy through a supersonic planar plasma expansion. The rotational structure observed (upper trace) can be simulated (lower trace) using constants derived from geometry optimization by an ab initio calculation and a temperature of 50 K.



The energy of the electronic transition of $C_8H_4^+$ was expected around 14 030 cm^{-1} by reference to Fig. 1. One band was found in the gas phase at 14 073 cm^{-1}, as shown in Fig. 4. The optimized condition was quite similar to that for $C_6H_4^+$, a –300 V discharge through a mixture of 0.5% C_2H_2 in helium and with probing 1.5 mm downstream from the slit.

Results and discussion

The differences in frequency between the observed origin bands of $C_4H_4^+$, $C_6H_4^+$, and $C_8H_4^+$ and of the corresponding HC_nH^+ series (1–3) are 237, 110, and 70 cm^{-1}, as shown in Fig. 1*b*. The shifts decrease with increasing number of carbon atoms. This indicates that the contribution of the nonlinear part, -CH=CH_2, to the molecular orbital decreases on extension of the carbon chain. This trend in the two homologous series suggests that the observed bands can be assigned to $C_4H_4^+$ and $C_8H_4^+$ with the common chain structures. $C_8H_4^+$ has five isomers constructed by combination of ethylene and acetylene, as shown in Fig. 5. Structure (*b*) is intermediate between a prolate and an oblate top, but the observed spectrum has the profile of a typical near-prolate top and a-type transition. In the view of this, structure (*b*) is rejected as the carrier of the observed spectrum. Geometries (*b*) and (*c*) do not have eight carbons in a line but instead have a branching structure. Owing to the correlation of the transition energy of $C_nH_4^+$ and HC_nH^+ (Fig. 1), these should be π–π type electronic excitations in the conjugated system. Transition energies of the structures (*b*) and (*c*) would not show the correlation with the HC_nH^+ series. Structures (*d*) and (*e*) are cis and trans isomers, and both should have

Fig. 5. Optimized molecular structure in the ground state of $C_4H_4^+$ and $C_8H_4^+$ using ab initio calculations. The bond lengths are given in Å. Other isomers of $C_8H_4^+$ are indicated by simple pictures.

their electronic transition close to each other. No other signal could be detected within ±100 cm^{-1} from the observed band. Thus, the structures (*c*), (*d*), and (*e*) can be rejected as candidates for the observed spectrum. There remains structure (*a*), which would correlate with the HC_nH^+ series, and therefore this is the best candidate for the assignment. Consequently the symmetry of the electronic transitions observed for $C_4H_4^+$ and $C_8H_4^+$ is $^2A''$–X^2A''.

Determination of the rotational constants from the observed spectra is difficult because of overlap by the Swan bands of C_2 (16) in the case of $C_4H_4^+$ (Fig. 3) and the nonresolved rotational contour on $C_8H_4^+$ (Fig. 4). Thus, the rotational constants and molecular structure in the ground state of $C_4H_4^+$ and $C_8H_4^+$ were determined by ab initio calculations using GAMESS (17) with ROHF/6-31G**, the same method used in previous works (6, 18). The optimized bond lengths and angles are given in Fig. 5. From the latter, the rotational constants were calculated (Table 1).

In the case of the polyacetylene cations HC_nH^+, the ratio B''/B' of rotational constants between the ground and excited states decreases and approaches 1.0 on extension of the carbon chain (Fig. 6). The ratios B''/B' and C''/C' for the $C_nH_4^+$ series should follow the same trend and converge to the HC_nH^+ value for the long chains. Ratio A''/A' should increase and approach 1.0 on extension of the carbon chain. These trends were assumed in order to estimate the rotational constants in the excited states of $C_4H_4^+$ and $C_8H_4^+$ (Table 1). The profiles of the origin bands in the electronic transitions of $C_4H_4^+$ and $C_8H_4^+$ were then simulated using the ground-state rotational constants given by the ab initio calculation and the extrapolated excited-state values from the $C_6H_4^+$ data. The observed profiles are then well repro-

duced (Figs. 3 and 4) using the WANG program (19). By comparison of the simulated and observed spectra, the assignments were confirmed, and more accurate transition frequencies were inferred. These are given in Table 2.

Astrophysical relevance

The optical spectrum obtained for $C_8H_4^+$ allows a comparison with the available lists of DIB positions (20, 21). This shows that there is an overlap between the band observed around 14 073 cm^{-1} and two DIBs reported at 14 068.9 and 14 078.4 cm^{-1}. To check whether these differences in frequency might be due to a temperature effect, a comparison was made between an artificial DIB spectrum in the 709–714 nm range and the simulated $C_8H_4^+$ spectrum for low (10 K), intermediate (40 K), and high (150 K) temperature. This is shown in Fig. 7. From this it is clear that the absorption band of the nonlinear $C_8H_4^+$ does not fit the DIB absorption at any temperature.

A DIB having a double peak structure and similar rotational profile (with P- and R-branches) to that observed for $C_8H_4^+$ is located between 14 000 and 14 010 cm^{-1} (Fig. 7).

Fig. 7. Artificial diffuse interstellar band absorptions in the 709–714 nm range (lower trace reproduced from ref. 20) and the simulated $C_8H_4^+$ laboratory spectra at 10, 40, and 150 K (upper traces).

However, no absorption was detected in this region in the laboratory measurements. In the case of the $C_4H_4^+$ absorptions, there are no overlaps with DIBs.

An upper limit of the column density for the $C_nH_4^+$ series in diffuse clouds can be estimated by comparison of the laboratory and DIB data in a similar fashion to that used before (22). For this, it is assumed that the oscillator strengths of the 0–0 band in the $^2A''$–X^2A'' transition for $C_nH_4^+$ (n = 4, 6, 8) and $A^2\Pi_u$–$X^2\Pi_g$ for HC_nH^+ (22) are equal (i.e., 0.04, 0.06, and 0.08 for $C_4H_4^+$, $C_6H_4^+$, and $C_8H_4^+$) and that a signal-to-noise ratio of 5 is required for detection of a DIB absorption. The fwhm of the bands is about 2 Å, and the sensitivity limit for a DIB detection is 0.002 Å (20). This leads to upper limits for their column densities of 2×10^{12}, 1×10^{12}, and 0.6×10^{12} cm^{-2} for $C_4H_4^+$, $C_6H_4^+$, and $C_8H_4^+$, respectively.

The rotationally resolved electronic spectra of several conformers of 1-hexoxy and 1-heptoxy[1]

Lily Zu, Jinjun Liu, Sandhya Gopalakrishnan, and Terry A. Miller

Abstract: Laser-induced fluorescence excitation spectra of five vibronic bands of 1-hexoxy and three bands of 1-heptoxy have been recorded in a jet-cooled environment. Experimental values of rotational constants for both the $\widetilde{X}$ and $\widetilde{B}$ states and components of the spin-rotational tensor for the $\widetilde{X}$ state were obtained by an analysis of the partially resolved rotational structure of the vibronic bands. Comparing these experimental results with quantum chemistry calculations, and using corresponding assignments of smaller alkoxy radicals as a guide, permitted unambiguous conformational assignments for the bands. The extension of similar assignments to larger alkoxy radicals is also discussed.

Key words: electronic spectroscopy, organic radicals, combustion, atmospheric chemistry.

Résumé : Les spectres de fluorescence induite par laser de cinq bandes vibroniques du 1-hexoxy et de trois bandes du 1-heptoxy ont été enregistrés en jet froid. Une analyse de la structure rotationnelle partiellement résolue des bandes vibroniques a permis d'obtenir les valeurs expérimentales des constantes rotationnelles des deux états $\widetilde{X}$ et $\widetilde{B}$, ainsi que les composantes tensorielles de spin-rotation de l'état $\widetilde{X}$. La comparaison des résultats expérimentaux avec des calculs de chimie quantique, ainsi qu'une utilisation des attributions correspondantes de plus petits radicaux alkoxy comme guide, a permis une attribution des conformères sans ambiguité possible pour chaque bande. L'extension d'attribution similaire à de plus gros radicaux de type alkoxy est discutée.

Mots clés : spectroscopie électronique, radicaux organiques, combustion, chimie de l'atmosphère.

1. Introduction

It is a privilege to contribute to this Gerhard Herzberg memorial issue. One of his abiding interests was the spectroscopy of free radicals (1). Arguably his electronic spectra of the simplest hydrocarbon free radicals (2–6) CH, CH_2, and CH_3, rank among the most significant achievements in his illustrious career.

In this spirit, this paper reports the electronic spectroscopy of some simple hydrocarbon-derived, oxygen-containing, free radicals, the alkoxies ($C_nH_{2n+1}O$). The importance of alkoxy radicals in atmospheric chemistry is well known (7). They are key intermediates in the oxidation of hydrocarbons. More than 100 studies have been published alone over the last 50 years on the spectroscopic studies of the smallest alkoxy radical, methoxy. Other small alkoxies like ethoxy (8, 9), C_2H_5O, and 2-propoxy (9, 10), $(CH_3)_2HCO$, have also been studied intensively.

The early laser magnetic resonance investigation of Radford and Russell (11) in the far-IR and the microwave studies of Endo et al. (12) yielded considerable information about the ground ^{2}E state of methoxy. Its electronic transition has long been known to be an excitation from the ground $\widetilde{X}^2$E state to the $\widetilde{A}^2$A state (13). When a hydrogen is substituted in methoxy, the C_{3v} symmetry of CH_3O is at least lowered to C_s; the excited $\widetilde{A}$ A_1 state of CH_3O correlates to a $\widetilde{B}$ A' state while the degenerate E ground state decomposes into $\widetilde{A}$ and $\widetilde{X}$ states, of A' and A'' symmetry assuming a plane of symmetry exists. Whether the $\widetilde{X}$ state is A' or A'' depends upon the radical. Tan et al. (14) determined the symmetry of the $\widetilde{X}$ and $\widetilde{A}$ electronic states of ethoxy, vinoxy, and isopropoxy, using the technique of laser-induced fluorescence (LIF) combined with supersonic jet cooling. The complete rotational analysis of the LIF spectrum of the ethoxy (14) $\widetilde{B} - \widetilde{X}$ transition further revealed a significant ground-state, spin-rotation splitting due to the close spacing of the low-lying $\widetilde{A}$ and $\widetilde{X}$ states. Within experimental resolution (≈200 MHz) no excited-state, spin-rotation splitting was observed.

While the smaller alkoxy radicals have drawn significant attention, the spectroscopic study of larger alkoxy radicals is much sparser. It was generally felt that the fluorescence quantum yield for the $\widetilde{B} - \widetilde{X}$ transition would rapidly decrease as non-radiative decay processes became dominant in the larger alkoxy radicals. That perception began to change when LIF spectra of *t*-pentoxy, 3-pentoxy, *t*-butoxy, and 2-butoxy were observed at near ambient temperature in 1999 (15, 16). However, the failed attempts to observe several other larger alkoxy radicals in the same LIF studies left the overall situation unclear. Clarification occurred when the LIF spectra of nearly 20 large alkoxy radicals containing 5–12 carbon atoms were reported by Carter et al. (17) in 2001. The studies showed that under

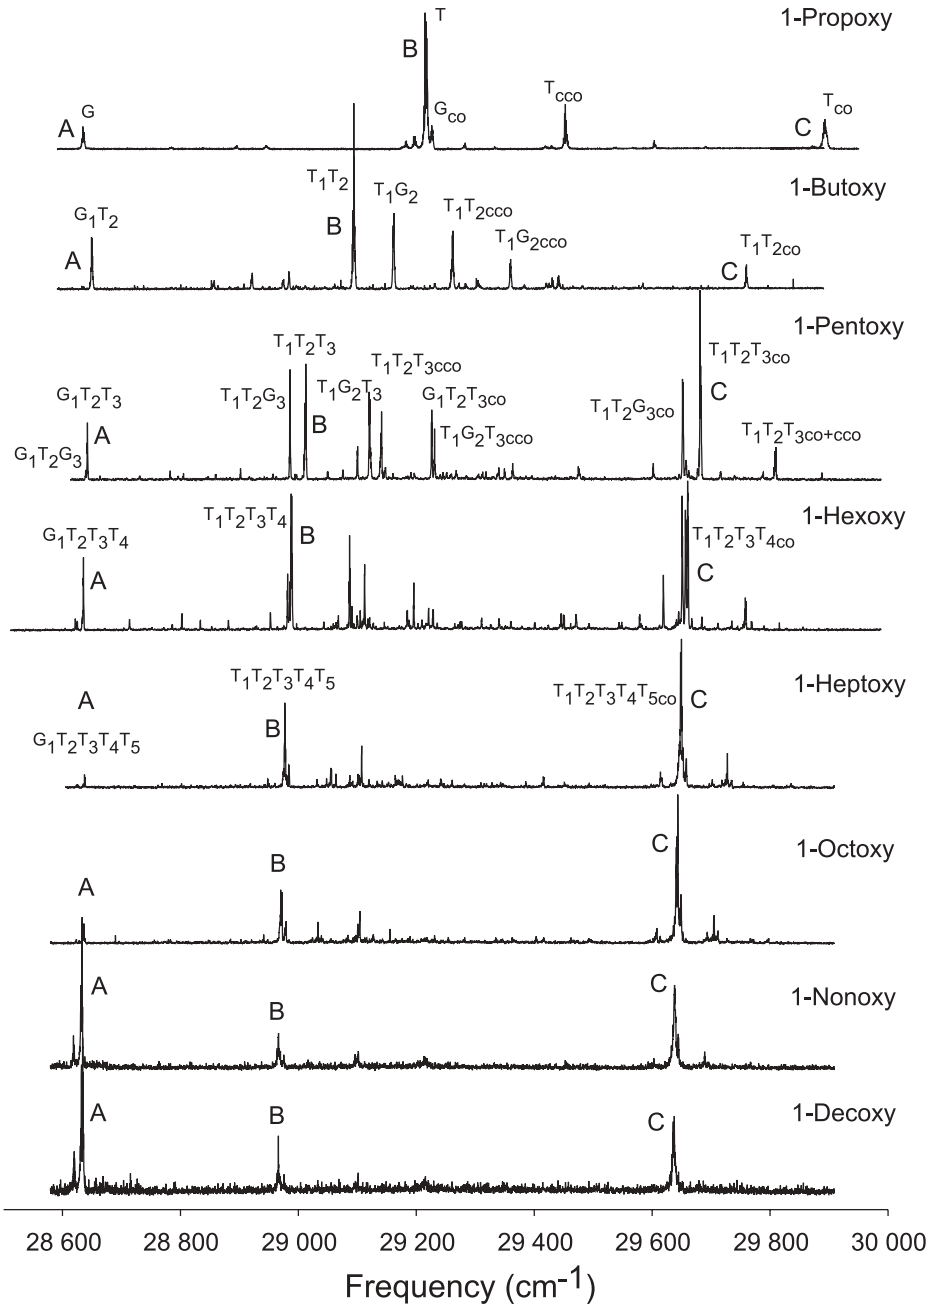
Fig. 1. Structures of representative examples of the (*a*) 41 1-hexoxy conformers and (*b*) 122 1-heptoxy conformers. The corresponding Newman projections are also shown.

cold jet conditions, all of the alkoxy radicals exhibit sharp LIF excitation spectra with well-characterized vibrational structure. The S/N ratio of the spectra did become somewhat poorer as the number of carbon atoms (n) increased but not dramatically so, and the authors attributed the gradual reduction to the decreased vapor pressure of the higher molecular weight precursors.

Assignment of the observed spectral bands in the large alkoxy radicals has turned out to be very challenging. Unlike methoxy and ethoxy, larger alkoxy radicals have structural isomers, and the same structural isomer can exist in different conformations. Alkoxy conformers are typically labelled according to whether the non-H substituents are *gauche* (G) or *trans* (T) with respect to one another for each of the C—C bonds in the molecules, (with the C—C bond labelled 1 being the one that is closest to the O atom) (Fig. 1).



The spectral positions of structural isomers are usually well-separated but those of conformers are not. Indeed, closely-spaced vibronic bands can be expected from the various conformers, e.g., an origin band from one conformer can lie close to a C-O stretch band belonging to an entirely different conformer of the radical. Gopalakrishnan et al. (18) made significant progress analyzing the rotationally resolved $\tilde{B} - \tilde{X}$ LIF spectra of all the strong bands of 1-propoxy. Five vibronic bands were unambiguously assigned to two conformers (G and T). Experimental rotational constants for both $\tilde{X}$ and $\tilde{B}$ states as well as components of the electron spin-rotation tensor in the $\tilde{X}$ state were determined for each conformer. Similar rotational analyses (19) were recently published for 1-butoxy and 1-pentoxy, again correlating the strongest spectral lines with specific conformers.

The method used in the 1-propoxy, 1-butoxy, and 1-pentoxy analyses is computationally intensive (18, 19). It involves identifying all likely stable conformations using the systematic pseudo-Monte Carlo (SPMC) methods (20) available in MacroModel (21). This is followed by quantum chemistry calculations for both the $\tilde{X}$ and $\tilde{B}$ states, optimizing each of these geometries to predict rotational constants. Components of the ground-state electronic spin – molecular rotation tensor were also predicted by a semiempirical method using the experimentally observed spin-rotation tensor of ethoxy as a reference. Finally, comparisons between molecular constants obtained experimentally and those from the calculations are used to identify the carrier of a given band.

When one examines larger open-chain, primary alkoxies, the number (19) of conformers expected (41 for 1-hexoxy, 122 for 1-heptoxy) becomes so large that the computations described above become infeasible. In this paper, we suggest a new technique, which lets us select a candidate conformer for a given band based only upon a comparison of the given experimental spectra with those of smaller alkoxy radicals. Using this ap-

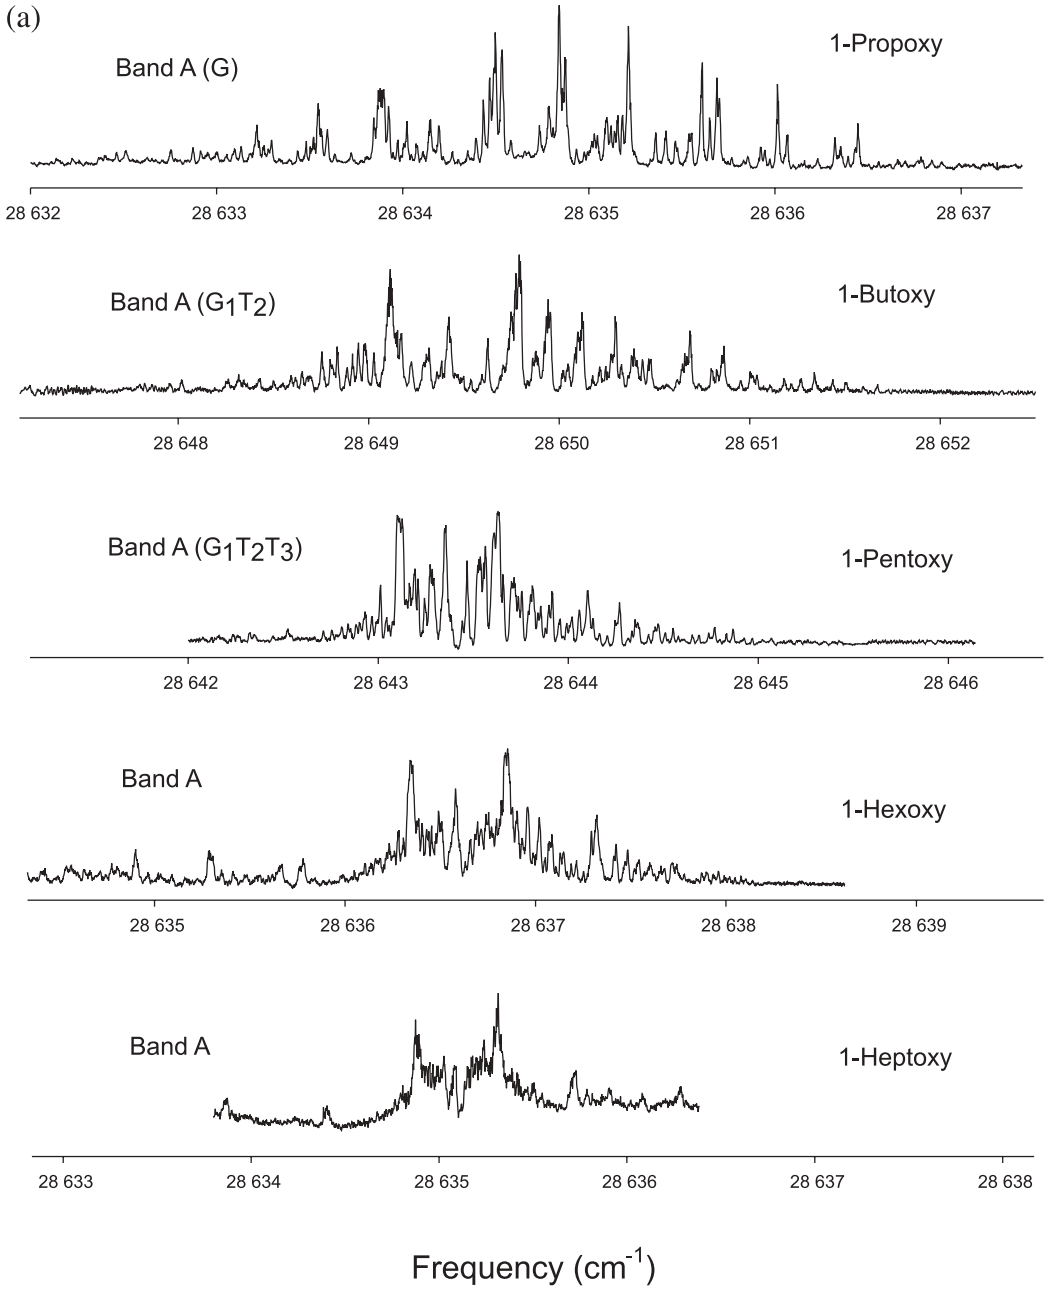
Fig. 2. LIF excitation spectra of the primary alkoxy radicals ($C_nH_{2n+1}O$) from $n = 3 - 10$. Persistent lines in the spectrum are marked A, B, and C. Conformationally assigned bands are labeled (G for gauche, T for trans) (18, 19) according to the various dihedral angle minima. Excited vibrational levels are indicated as subscripts by their approximate motion, e.g., CO (stretch), CCO (bend), etc.

proach, four conformers were assigned for five vibronic bands of 1-hexoxy and two conformers for three vibronic bands of 1-heptoxy. Extending the analysis to even larger alkoxy radicals is also discussed.



2. Experimental

The alkoxy radicals were generated in a supersonic free jet expansion by UV laser photolysis (XeF) of the corresponding alkyl nitrites at the base of a 0.5 mm circular nozzle. The alkyl nitrites were synthesized according to well-known procedures (22). A few torr (1 torr = 133.322 Pa) of the alkyl nitrite vapor was entrained into the jet flow by passing helium at 6 atm (1 std atm = 101.325 kPa) over the liquid contained in a steel bomb maintained at a suitable temperature depending upon the vapor pressure.

The rotationally resolved LIF spectra of the 1-alkoxy radicals were obtained on our high-resolution apparatus, which has been described elsewhere (23). Briefly, a cw ring dye laser (Coherent 899-29 Autoscan) pumped by an Ar^+ laser (Coherent Innova Sabre) was pulse amplified and frequency doubled using a KDP crystal to generate the UV radiation required to

pump the $\widetilde{B} - \widetilde{X}$ transition of the alkoxy radicals. The pulse amplifier (Lambda Physik, FL 2003 model) was pumped by an excimer laser (XeCl, Lambda Physik, MSC 103 model) with a resulting line width of ≈100 MHz in the fundamental (200 MHz when doubled into the UV). This radiation was directed into a vacuum chamber ≈15 mm downstream of the nozzle orifice to excite the $\widetilde{B} - \widetilde{X}$ transition. The resulting fluorescence was collected perpendicular to the probe laser beam with a 2.5 cm f/1 lens. The light was then focused with a f/3 lens through an adjustable slit onto a photomultiplier tube (PMT). The slit can be adjusted to allow only the central portion of the fluorescence from the jet to be detected by the PMT, thereby reducing the Doppler width of the signal from off-axis velocity components in the jet expansion. This signal was then preamplified and sent to a boxcar averager (Stanford Research, SR250 boxcar) for integration. The amplified signal was then sent to the Coherent Autoscan unit for signal averaging and recording.

3. Theory

The theory upon which the analysis of the rotational structure of the bands is based is described in detail in ref. 18, hence only a brief description will be provided here. An asymmetric top Hamiltonian is used to model the rotational structure of the high-resolution electronic spectra of the primary alkoxy radicals. Because of the very low temperature in the jet, only

© 2004 NRC Canada

Fig. 3. (*continued*).

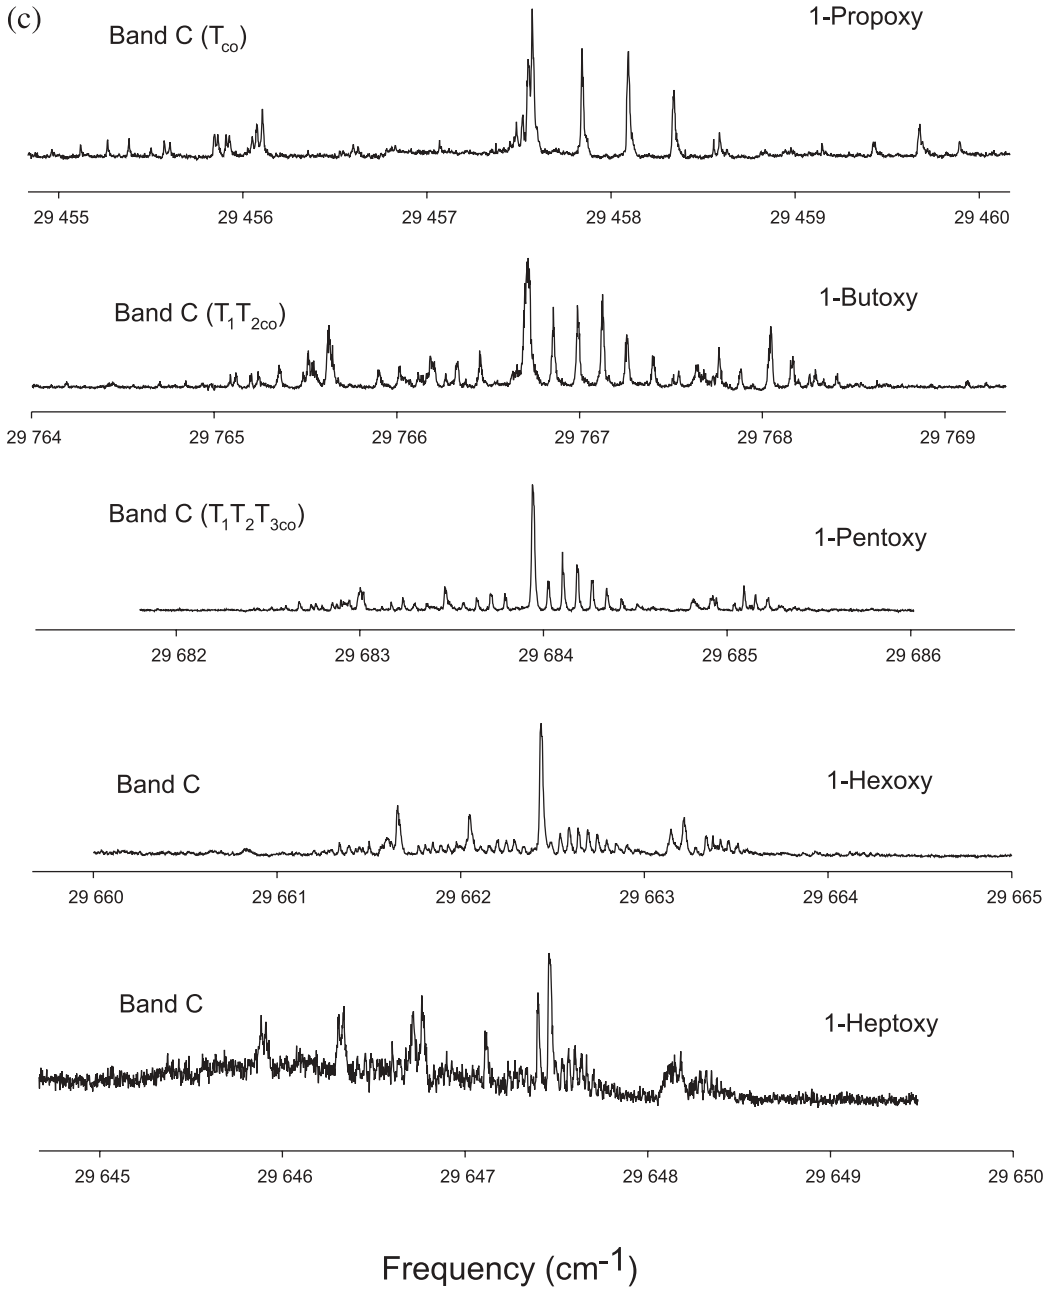
the lowest few rotational states are populated. Therefore, centrifugal terms in the rotational Hamiltonian ($\mathcal{H}_{Rot}$) may be neglected. However, the spin-rotation coupling certainly needs to be considered. Hence, the total Hamiltonian can be written:

[1] $$\mathcal{H} = \mathcal{H}_{Rot} + \mathcal{H}_{SR}$$

In which

[2] $$\mathcal{H}_{Rot} = AN_a^2 + BN_b^2 + CN_c^2$$

[3] $$\mathcal{H}_{SR} = \frac{1}{2}\sum_{\alpha\beta}\epsilon_{\alpha\beta}(N_\alpha S_\beta + S_\beta N_\alpha)$$



where **N** and **S** are the molecular rotational and electron spin angular momentum, respectively. A, B, and C are the rotational constants, and $\epsilon_{\alpha\beta}$ are the components of the spin-rotation tensor in the inertial axis system (*a, b, c*).

The matrix elements of the Hamiltonian of a nonrigid, nonlinear, polyatomic molecule in a multiplet electronic state have been derived by Raynes (24), and these were programmed into a graphical user interface program SpecView, which was developed in our laboratory (25) to model the spectra of the alkoxy radicals.

The six rotational constants, namely, A'', B'', and C'' in the ground state and A', B', and C' in the excited $\tilde{B}$ state, need to be fit to the spectra. For the spin-rotation interaction,

© 2004 NRC Canada

Fig. 3. (*concluded*).

only ground-state constants need to be fitted because the spin-rotation interaction in the excited state causes splittings unresolvable with the experimental resolution, as confirmed by the study of ethoxy (14). According to Brown et al. (26), six unique spin-rotation constants can be determined for molecules with C_1 symmetry, while only four can be determined for molecules with C_s symmetry. In the general case, the spin-rotation constants that can be determined for a single isotopic species are given below in terms of their relationship to the components of the reduced spin-rotation tensor $\tilde{\epsilon}$ introduced by Brown et al.:

$$T_0^0(\tilde{\varepsilon}) = (-1/\sqrt{3})(\tilde{\varepsilon}_{aa} + \tilde{\varepsilon}_{bb} + \tilde{\varepsilon}_{cc}) = \sqrt{3}a_0$$

$$T_0^1(\tilde{\varepsilon}) = (-1/\sqrt{2})i(\tilde{\varepsilon}_{cb} - \tilde{\varepsilon}_{bc}) = 0$$

$$T_{\pm1}^1(\tilde{\varepsilon}) = (1/2)[(\tilde{\varepsilon}_{ba} - \tilde{\varepsilon}_{ab}) \pm (\tilde{\varepsilon}_{ca} - \tilde{\varepsilon}_{ac})] = 0$$

$$T_0^2(\tilde{\varepsilon}) = (1/\sqrt{6})(2\tilde{\varepsilon}_{aa} - \tilde{\varepsilon}_{bb} - \tilde{\varepsilon}_{cc}) = \sqrt{6}a$$

$$T_{\pm1}^2(\tilde{\varepsilon}) = \pm(1/2)[(\tilde{\varepsilon}_{ba} + \tilde{\varepsilon}_{ab}) \pm (\tilde{\varepsilon}_{ca} + \tilde{\varepsilon}_{ac})] = \pm(d \pm ie)$$

$$T_{\pm2}^2(\tilde{\varepsilon}) = (1/2)[(\tilde{\varepsilon}_{bb} - \tilde{\varepsilon}_{cc}) \pm (\tilde{\varepsilon}_{bc} + \tilde{\varepsilon}_{cb})] = (b \mp ic)$$

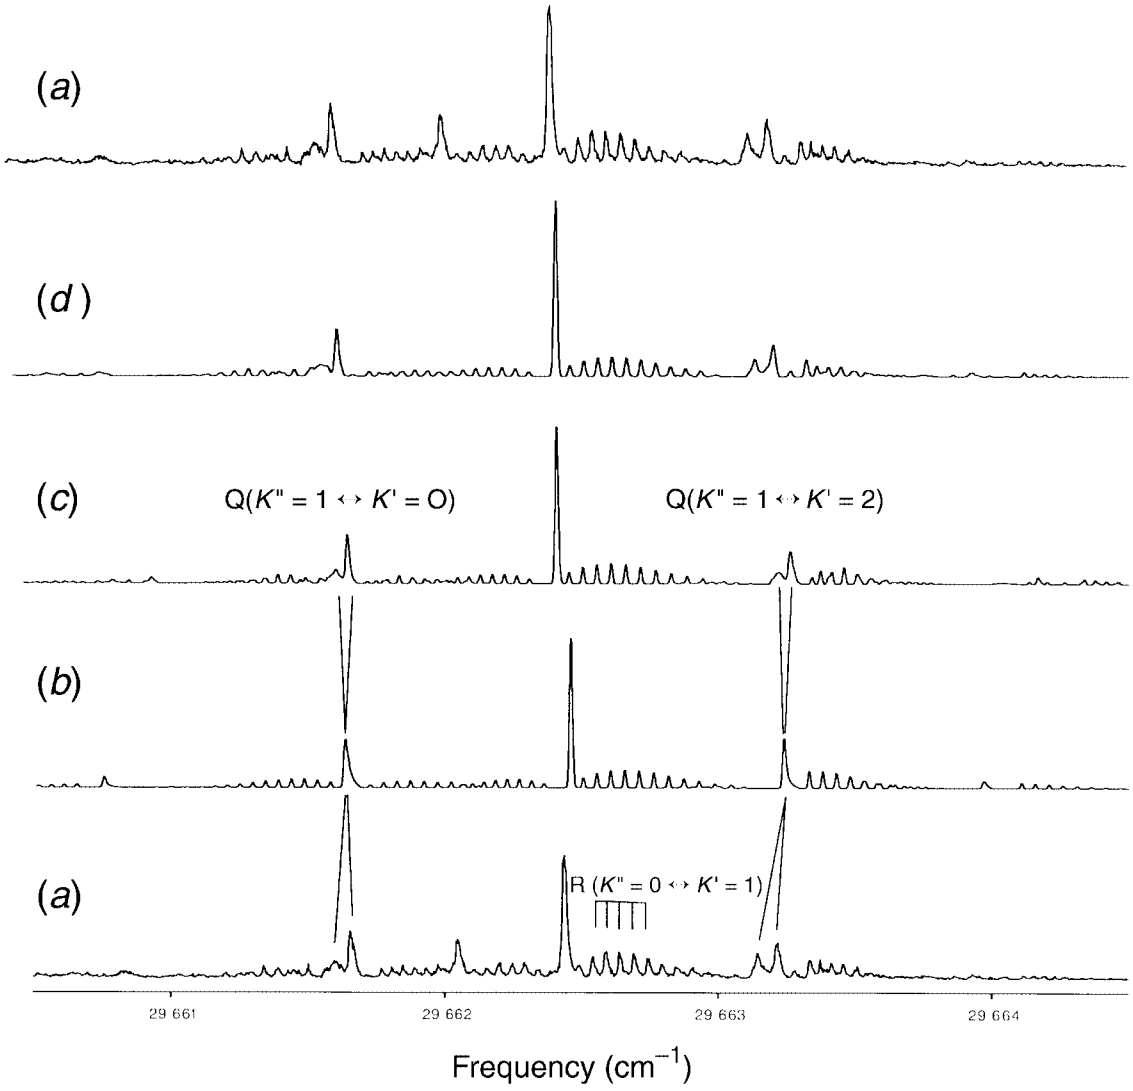
The parameters a_0, *a, b, c, d*, and *e* were defined by Raynes (24) and because of their notational convenience are used in our spectral analysis.



The prediction of rotational constants was performed via calculations using the Gaussian98 program (27) at the B3LYP/6-31+G* and the CIS/6-31+G* levels for the $\widetilde{X}$ and $\widetilde{B}$ states, respectively. As already mentioned in the *Introduction*, a semi-empirical approach based upon the knowledge of the experimentally determined spin-rotation constants of the ethoxy radical was used to estimate the spin-rotation constants (28).

4. Results

The number (N) of conformers grows rather dramatically according to the formula (19), $N = \frac{3^{n-2}-1}{2} + 1$, as the number ($n$) of carbon atoms in the alkoxy radical increases. However, the LIF excitation spectra (Fig. 2) show, if anything, fewer features with an increase of n instead of more congestion. Our approach to understanding these spectra builds upon corresponding analyses (18, 19) for 1-propoxy, 1-butoxy, and 1-pentoxy for which multiple conformers were "frozen out" in the jet. For these

species, detailed spectroscopic analyses determined rotational and spin-rotation constants for two of two 1-propoxy conformers, three of a possible five 1-butoxy conformers, and five of 14 possible conformers of 1-pentoxy.

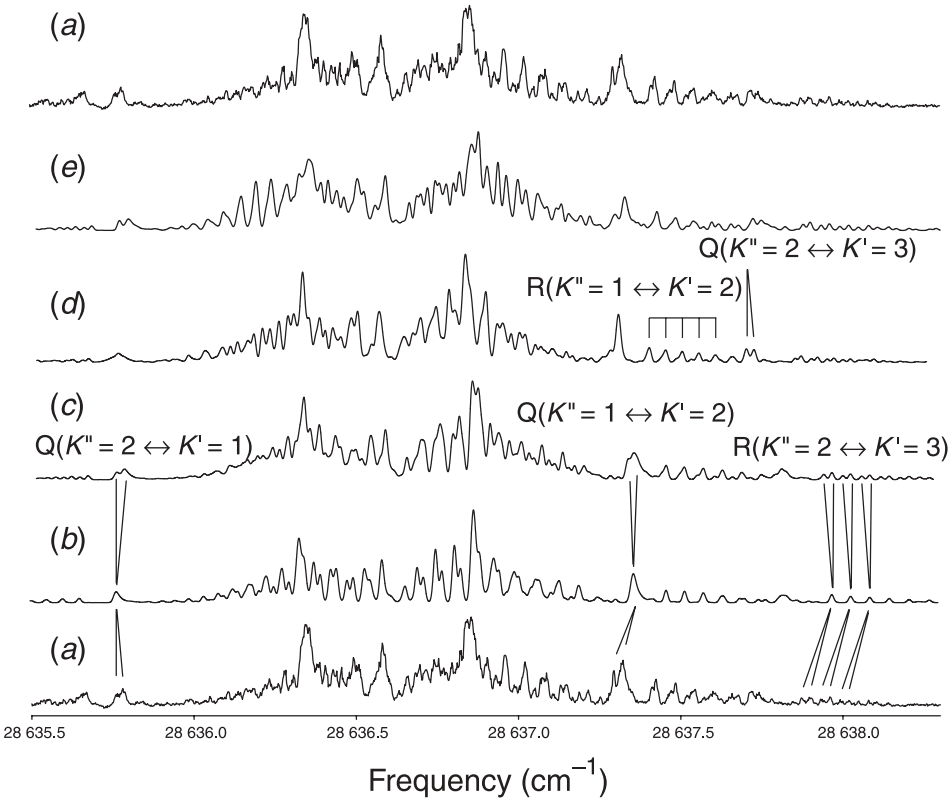

Figure 2 also shows that there are three bands that appear persistently for all the alkoxy radicals, labelled bands A, B, and C. Interestingly, for 1-propoxy, 1-butoxy, and 1-pentoxy, band B is always correlated with the all-trans conformer, which uniquely has C_s symmetry. Band B has been assigned as the origin band of the $T_1T_2...T_{n-2}$ conformer with all the bands C being assigned as the C-O stretch vibrational fundamental of the same conformer. Similarly, all A bands are assigned to the $G_1T_2...T_{n-2}$ conformer, which retains the C_s symmetry of the carbon chain but has the oxygen rotated 60° out of the carbon-chain plane. The structures of these conformations are illustrated in Fig. 1.

Figure 2 shows that nearly all the strong bands in the spectra of pentoxy and smaller alkoxy radicals have been assigned to specific conformers and their vibronic structure. Figure 3 compares the rotational structure for bands A, B, and C for the alkoxy radicals ($C_nH_{2n+1}O$) with $3 \leq n \leq 7$. Figure 3 shows, as expected, that the rotational structure becomes increasingly compressed as the molecule increases in size and its rotational constants concomitantly decrease. However, allowing for this compression, we see clearly a great deal of similarity in structure in each labelled band for all the alkoxy radicals. Previous detailed assignments for the propoxy, butoxy, and pentoxy radicals helped guide our present assignments. Based upon the absolute and relative positions of the lines relative to the smaller alkoxies, it seems very reasonable to assign bands B and C to the origin and first C-O stretch of the conformer with C_s symmetry (in 1-hexoxy and 1-heptoxy $T_1T_2T_3T_4$ and $T_1T_2T_3T_4T_5$, respectively), while band A is assigned to the origin of the conformer with the oxygen out of the C_s plane ($G_1T_2T_3T_4$ and $G_1T_2T_3T_4T_5$ for 1-hexoxy and 1-heptoxy, respectively).

Ab initio calculations were performed for these two conformers for both 1-hexoxy and 1-heptoxy, and the calculated molecular constants are given in Tables 1 and 2 and were used

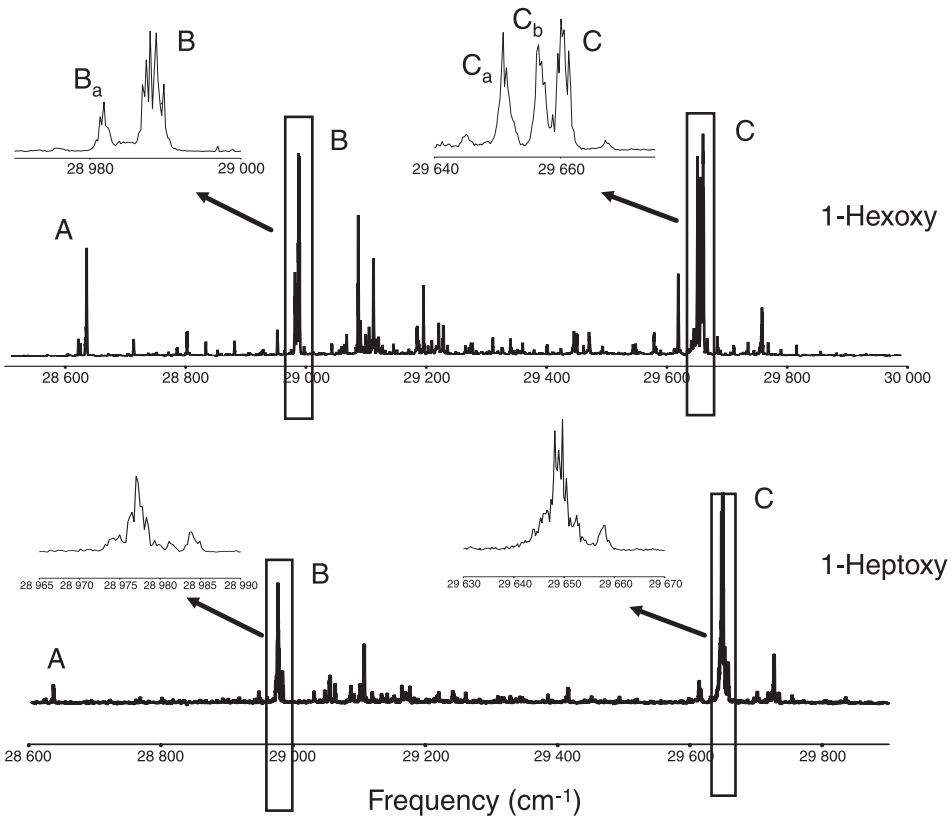
as a starting point for a full rotational analysis. Details of the analysis are given below for bands A and C of 1-hexoxy. The assignments of other bands were performed in a similar manner.

Figure 4 shows the experimental trace of band C and the simulation of the $\widetilde{B} - \widetilde{X}$ transition using the rotational constants from the ab initio calculations of conformer $T_1T_2T_3T_4$ of 1-hexoxy. As the $T_1T_2T_3T_4$ conformer has C_s symmetry, only a *c*-type transition dipole is allowed, making the structure of band C (or B) rather simple. The simulation in Fig. 4*b* clearly resembles the experimental spectrum (trace *a*). The P and R branches of the $K'' = 0 \leftrightarrow K' = 1$ transition can be easily identified and assigned although there are clearly small discrepancies between the experimental and simulated structure. The positions of the Q branch for $K'' = 0 \leftrightarrow K' = 1$ as well as $K'' = 1 \leftrightarrow K' = 0$ and $K'' = 1 \leftrightarrow K' = 2$ can easily be located, but the latter two appear as doublets experimentally. At this stage, combinations of rotational constants, $(B + C)/2$ and $A - (B + C)/2$ of the ground state and $(B + C)/2$ of the excited $\widetilde{B}$ state, can be fitted.

The splitting between the doublets of the Q branches is about 2.2 GHz. It is close to the calculated splitting of 2.6 GHz $[3/2(a_0 + a/2)]$ for transitions involving $|K''| = 1$ and $N'' = 1$, due to the spin-rotation interaction in the ground $\widetilde{X}$ state. Smaller splittings are observed in the P($K'' = 0 \leftrightarrow K' = 1$) and R($K'' = 0 \leftrightarrow K' = 1$) branches (but not completely resolved); these observations are consistent with the calculated value of 0.06 GHz for transitions involving $K'' = 0$, which are split by the term $(N'' + 1/2)(a_0 - a)$.



Simulations including the calculated spin-rotational component $a_0 + a/2$ (Fig. 4*c*) enabled us to assign most of the remaining experimental lines. At this point, least-square fits of 111 lines were used to determine the origin frequency, $\widetilde{X}$ and $\widetilde{B}$ state rotational constants, and the two most significant $\widetilde{X}$ state spin-rotation tensor components ($\widetilde{\epsilon}_{aa}, \widetilde{\epsilon}_{bb}$). The simulation based upon this fit is given in Fig. 4*d* and the corresponding molecular parameters are listed in Table 1. Good agreement is seen between the experimental results and values from the ab initio calculations. For the rotational constants, the values are within ±5% for both ground and excited states. For the spin-rotation constants, the values were within 7% for the larger component, $\widetilde{\epsilon}''_{aa}$. Several of the spin-rotation constants could not be determined experimentally because the effect they had on the spectrum was below the experimental resolution (≈200 MHz). In this case, those spin-rotation constants were fixed at zero in the fitting.

Band B was assigned according to the same procedure as described for band C. Its analysis was made after the assignment of band C because there was another band partially overlapping it (Fig. 3*b*). The overlap will be discussed later in this paper. In spite of the overlap, unambiguous assignments can still be made and the resulting parameters are listed in Table 1.

As noted in the beginning of this section, the likely assignment for band A is to conformer $G_1T_2T_3T_4$. The structure of band A appears more complicated than that of bands B and C because conformer $G_1T_2T_3T_4$ only has C_1 symmetry rather than

Fig. 6. Survey LIF spectra of 1-hexoxy and 1-heptoxy. Expanded views of the regions of bands B and C show additional lines in the 1-hexoxy spectrum, but not in the 1-heptoxy spectrum.

C_s symmetry as for the $T_1T_2T_3T_4$ conformer. There are now three nonzero components of the transition dipole rather than one. The increase in allowed transitions leads to increased spectral congestion, making the spectral analyses somewhat more difficult.

However, the analysis of bands B and C and other alkoxy bands in our previous work (18, 19) indicated that ab initio predictions of the molecular constants should be quite reliable. Indeed, the simulation using the calculated molecular constants of conformer $G_1T_2T_3T_4$ shows rather good agreement with the experimental spectrum of band A (Fig. 5*b*). Nonetheless, the spectral congestion makes it difficult to distinguish the rotational and spin-rotation splittings in the center of the band. The spin-rotation splitting is more easily discerned at the ends of the spectrum where higher N'', $|K''| > 0$ transitions lie. By including the calculated value of the spin-rotation constants $\widetilde{\epsilon}''_{aa}$ and $\widetilde{\epsilon}''_{bb}$ in the simulation, all the doublets at the ends of the experimental spectrum are accounted for in the simulation (Fig. 5*c*). Then assignments can be made for branches Q($K'' = 1 \leftrightarrow K' = 2$), R($K'' = 2 \leftrightarrow K' = 3$), and Q($K'' = 2 \leftrightarrow K' = 1$). Using these assignments, an initial fit can be made to obtain experimental rotational constants and spin-rotation components, and the resulting simulation is shown in Fig. 5*d*. At this stage, more lines in Q($K'' = 2 \leftrightarrow K' = 3$), R($K'' = 1 \leftrightarrow K' = 2$), P($K'' = 1 \leftrightarrow K' = 0$), and R($K'' = 0 \leftrightarrow K' = 1$) branches can be assigned. The final fit was then performed with all the off-diagonal spin-rotation components fixed at zero. The resulting simulation is shown in Fig. 5*e*, and the corresponding molecular constants are listed in Table 1.

For 1-heptoxy, band A is assigned to conformer $G_1T_2T_3T_4T_5$ despite the increasing congestion in the rotationally resolved spectrum. For bands B and C, overlap with an additional band makes the structure even more complicated. However, a reasonable fit can still be made for the $T_1T_2T_3T_4T_5$ conformer portion of the spectrum using the same approach as for the 1-hexoxy analysis. The results are given in Table 2.

Bands from additional conformers were identified in 1-butoxy and 1-pentoxy. The bands identified included the origin of the T_1G_2 conformer of 1-butoxy, the origin of the $T_1T_2G_3$ and $T_1G_2T_3$ conformers of 1-pentoxy, and the C-O stretch bands of the $T_1T_2G_3$ and $T_1T_2T_3$ conformers of the 1-pentoxy spectrum. In addition, low-frequency fundamentals and combination bands of these conformers appeared in the spectra. The additonal conformers observed in 1-butoxy and 1-pentoxy all have a nearly straight chain structure obtained by rotating one C-C-C dihedral angle of the C_s (all-trans) conformer. One expects that bands of this nature will shift closer to each other in 1-hexoxy as the difference between these conformers becomes less significant with the increasing length of the carbon chain. The expanded region in Fig. 6 of the 1-hexoxy LIF spectrum shows one extra band (B_a) close to band B and two extra bands (C_a and C_b) close to band C. From 1-heptoxy to 1-decoxy, there is no clear separation between these bands, implying they might completely overlap. An expanded view of the 1-heptoxy

LIF spectrum in the band B and C region only shows a single band, but the rotationally resolved spectra of each band displays overlap with an additional transition.

High-resolution spectra of bands B_a, C_a, and C_b were obtained and are shown in Fig. 7. Of the 41 conformers of 1-hexoxy, there are three conformers derived from the all-trans T conformer by changing only one C-C-C dihedral angle, i.e., $T_1T_2T_3G_4$, $T_1T_2G_3T_4$, and $T_1G_2T_3T_4$. Simulations using the computed rotational constants (Fig. 7) indicated that the $T_1T_2T_3G_4$ conformer yields the closest match for band C_b, and the $T_1T_2G_3T_4$ conformer for B_a. Results of fits to these are given in Fig. 8 and Table 1. There is no obvious conformer assignment for band C_a.

Band B_a is assigned as the origin band of conformer $T_1T_2G_3T_4$, as no band with comparable intensity was assigned below this frequency. A definite vibrational assignment cannot be made for band C_b, although it appears in the C-O stretch frequency region. A band partially overlapped with band B appearing in the rotationally resolved spectrum might be the buried origin of the $T_1T_2T_3G_4$ conformer, but an unambiguous assignment cannot be made due to the low signal-to-noise ratio and the congestion.

With these results in hand, we can return to the spectra of 1-octoxy, 1-nonoxy, and 1-decoxy in Fig. 2. As with 1-hexoxy, 1-heptoxy, and the smaller alkoxies, it is easy to identify bands A, B, and C. We have not attempted to obtain rotationally resolved spectra of these bands to obtain a definitive conformational assignment. Nonetheless, we feel that the close analogy between the 1-octoxy to 1-decoxy spectra in Fig. 2 and the spectra of the smaller alkoxies leaves little doubt as to the conformational assignments. It appears highly probable that band A is the origin of the $G_1T_2...T_{n-2}$ conformer, while bands B and C are, respectively, the origin and CO stretch fundamental of conformer $T_1T_2...T_{n-2}$. One would also expect this pattern to continue in even larger alkoxy radicals.

5. Conclusions

Rotationally resolved spectra of six bands of 1-hexoxy and three bands of 1-heptoxy were obtained. A new strategy was used for the analysis of the 1-hexoxy and 1-heptoxy spectra and is applicable for larger primary alkoxy radicals. Using this approach, five bands of 1-hexoxy were assigned to four different conformers, i.e., band A to $G_1T_2T_3T_4$, bands B and C to $T_1T_2T_3T_4$, band B_a to $T_1T_2G_3T_4$, and band C_b to $T_1T_2T_3G_4$. For 1-heptoxy, band A was assigned to conformer $G_1T_2T_3T_4T_5$, while bands B and C were assigned to conformer $T_1T_2T_3T_4T_5$. Experimental molecular parameters were obtained from the rotational analyses, which are in rather good agreement with the values predicted for the given conformers by quantum chemistry calculations.

In earlier work (29, 30), probing a jet-cooled sample via microwave spectroscopy, it was suggested that little conformation relaxation takes place from the room-temperature conformer distribution. This work includes studies on 1-pentene and 1-hexene, which of course bear similarities to the presently studied alkoxies. However, with the alkoxy radicals there is an important difference in that they are created by photolysis in the jet.

Our earlier work on smaller alkoxies reached the conclusion (18,19) that multiple conformers exist in the cold-jet environment, i.e., the sample is not at thermal equilibrium with the rotational temperature — indeed the conformers do not appear to form an equilibrium distribution for any temperature. However, the conformers are not all populated. The bands assigned arise from all-trans conformers or conformers with at most one gauche linkage. Three bands, the $T_1T_2...T_{n-2}$ origin and CO stretch and the $G_1T_2...T_{n-2}$ origin, form the main "structure" of the LIF spectra of large primary alkoxy radicals. The origin, and occasionally the CO stretch fundamental bands from other nearly straight chain conformers, "decorate" the spectra and coalesce into the three dominant bands as the number of carbons in the radicals increases.

Ultraviolet cavity ringdown spectra of 2-cyclohexen-1-one and its potential energy function and structure for the electronic ground state[1]

Emily J. Gilles, Jaebum Choo, Daniel Autrey, Mohamed Rishard, Stephen Drucker, and Jaan Laane

Abstract: The $S_1(n,\pi^*) \leftarrow S_0$ cavity ringdown spectrum of 2-cyclohexen-1-one vapor has been recorded in the vicinity of the 0_0^0 band, which is at 26 089.1 cm^{-1}. Observation of hot bands in the spectrum has permitted the determination of several low-frequency fundamentals and overtones in the ground electronic state. The lowest two excited quantum states for the inversion vibration (ν_{39}) were found to be at 99.0 and 197.0 cm^{-1}. Together with previously published far-IR spectra and vapor-phase Raman spectra, the fundamental frequencies for ν_{39}, ν_{38}, and ν_{37} have been determined. From observed ν_{39} levels, the barrier to inversion has been determined experimentally to be 1900 ± 300 cm^{-1}, which is very different from values of 935 and 3379 cm^{-1} previously reported from Raman and far-IR data, respectively. Density functional calculations carried out in this paper give a barrier value of 2090 cm^{-1} when the B3LYP/6-311+G(d,p) basis set is used.

Key words: cavity ringdown spectra, 2-cyclohexen-1-one, Raman spectra, potential energy function, inversion barrier.

Résumé : Faisant appel à la technique CRDS (« cavity ringdown spectroscopy »), on a étudié la transition $S_1(n,\pi^*) \leftarrow S_0$ de la cyclohex-2-èn-1-one en phase vapeur, aux environs de la bande 0_0^0 qui se trouve à 26 089,1 cm^{-1}. L'observation de bandes chaudes dans le spectre a permis de déterminer plusieurs bandes fondamentales et harmoniques de basse fréquence dans l'état électronique fondamental. Les deux états quantiques excités les plus bas pour la vibration d'inversion (ν_{39}) ont été observés à 99,0 et 197,0 cm^{-1}. Ces données utilisées de concert avec les spectres infrarouge lointain et les spectres Raman en phase gazeuse ont permis de déterminer les fréquences fondamentales ν_{39}, ν_{38} et ν_{37}. En se basant sur les niveaux ν_{39}, on a déterminé expérimentalement que la barrière à l'inversion est de 1900 ± 300 cm^{-1} et cette valeur est très différente des valeurs de 935 et 3379 cm^{-1} rapportées antérieurement sur la base respectivement de données Raman et infrarouge lointain. Les calculs de densité fonctionnelle effectués dans le cadre de ce travail en utilisant un ensemble de base B3LYP/6-311+G(d,p) conduisent à une valeur de 2090 cm^{-1} pour la barrière.

Mots clés : CRDS, cyclohex-2-èn-1-one, spectres Raman, fonction d'énergie potentielle, barrière à l'inversion.

[Traduit par la Rédaction]

Introduction

2-Cyclohexen-1-one (2CHO) is a non-planar, six-membered ring molecule for which conjugation between the C=O and C=C groups is expected to provide extra rigidity to the ring. Furthermore, the conjugation should make it possible to treat the ring inversion process using a one-dimensional potential energy function. In that sense, the inversion is similar to that of 1,3-cyclohexadiene (1) and 1,2-dihydronaphthalene (2), which we have recently studied using Raman and fluorescence spectroscopies as well as density functional (DFT) calculations. In 1970 Manley and Tyler (3) reported the microwave spectrum of 2CHO along with the rotational constants. They proposed a structure for which only the carbon atom in the 5 position was significantly out-of-plane. In 1979 Carreira et al. (4) published the low-frequency, vapor-phase Raman spectrum of 2CHO and concluded that the molecule had an inversion barrier of

935 cm^{-1} based on an assignment where the $0 \rightarrow 2/1 \rightarrow 3$ degenerate transitions for ν_{39}, the lowest frequency vibration, were at 248 cm^{-1}. One year later, Smithson and Wieser (5) analyzed the far-IR spectrum, which showed a series of Q branches in the 96.9–99.8 cm^{-1} range. From these, a potential function with a barrier of 3379 cm^{-1} was calculated. A type B band at 247 cm^{-1} was assigned to ν_{38}, the second-lowest frequency vibration.

To better understand the inversion process for this molecule, we have undertaken further spectroscopic work as well as DFT calculations. Here, we present the UV cavity ringdown spectra of 2CHO along with the vapor-phase Raman spectra and DFT computations, and then use these to determine the one-dimensional vibrational potential energy function for the ring inversion in the electronic ground state. In the future, we will also present data for the $S_1(n,\pi^*)$ and $T_2(n,\pi^*)$ electronic excited states. We have recently published the $T_1(n,\pi^*) \leftarrow S_0$ cavity ringdown spectra (6) and DFT calculations (7) for 2-cyclopenten-1-one (2CPO), and compared the potential energy functions for the S_0, S_1, and T_1 states. The experimental work and computations for the present paper were carried out in a similar manner.

Experimental and computational

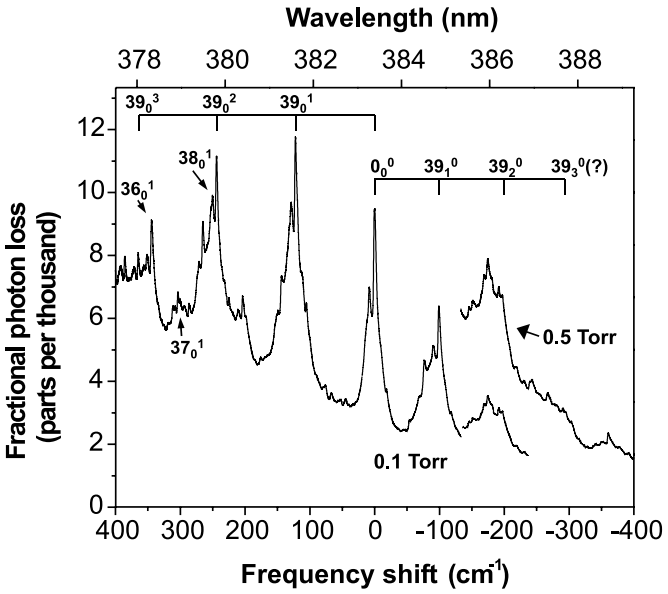
2CHO was purchased from Acros and purified by vacuum transfer to the sample cells. The cavity ringdown spectra were recorded in a manner similar to that used for 2CPO (6). The details of the system have been presented elsewhere (8). The vapor-phase Raman spectra were recorded on a JY U-1000 instrument using a Coherent I-20 argon ion laser operating at 5145 Å with 2 W of laser power. Vapor cells previously described were also used (9). DFT calculations were carried out utilizing the same programs and methods previously described for 2CPO (7).

Results and discussion

Cavity ringdown (CRD) spectra

Figure 1 shows the CRD spectrum of 2CHO in the 400 to –400 cm^{-1} region relative to the 0_0^0 band for the S_1 state at 26 089.1 cm^{-1}. Figure 2 shows the difference band region in expanded form. A broader range of frequencies was examined but in the present paper we will only concentrate primarily on this region. Some of the more relevant transition frequencies for understanding the S_0 electronic ground state have been selected and are shown in Table 1. Most importantly, the ν_{39} inversion band ($\nu_I = 0 \rightarrow 2$ and $1 \rightarrow 3$) can be seen at –99.0 cm^{-1}. (The labeling scheme for inversion levels is indicated in Fig. 3.) The next band in the series corresponding to $0 \rightarrow 4$ and $1 \rightarrow 5$ occurs at –197.0 cm^{-1}, thus showing the next spacing (3 to 4) to be 98.0 cm^{-1}. There is also a weak band at –294.9 cm^{-1}, which seems to indicate that the 5 to 6 spacing is 97.9 cm^{-1}. A weak band also is present at –391.6 cm^{-1} indicating another possible spacing of 96.7 cm^{-1}. The reported far-IR spectrum (5) has bands listed at 99.85, 99.23, 98.63, 98.02, 97.48, and 96.87 cm^{-1}. Since these were recorded at 0.5 cm^{-1} resolution and the spectral points were probably calculated for each 0.25 cm^{-1}, the accuracy of these numbers can be taken to be ±0.3 cm^{-1}. It is not clear why they were reported to two-decimal place

Fig. 1. Cavity ringdown spectra of 2CHO relative to the $S_1\ 0_0^0$ band at 26 089.1 cm^{-1} in the 400 to –400 cm^{-1} region. The spectra were recorded using a 1 m cell.



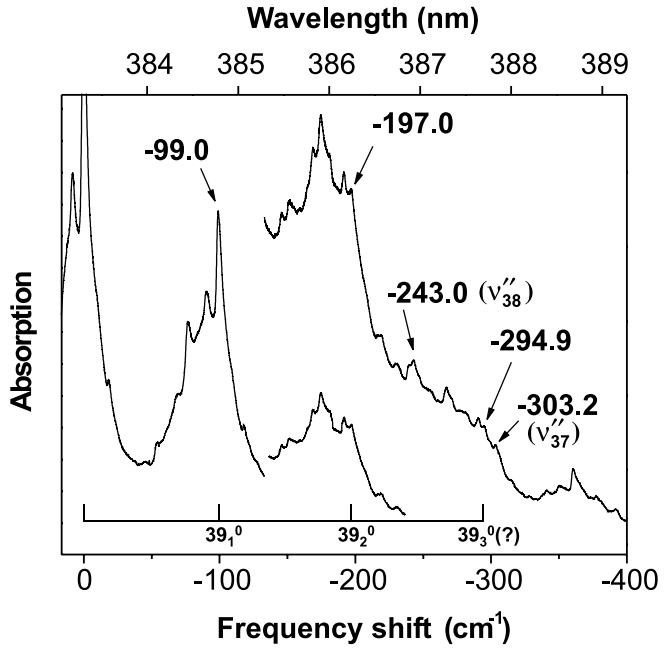


Fig. 2. Cavity ringdown spectra of 2CHO relative to the $S_1\ 0_0^0$ band at 26 089.1 cm^{-1} in the difference band region.

accuracy. In any case, since ν_{38} occurs at 243 cm^{-1} and since its excited vibrational state will be 30% as populated as the ground state at room temperature, a second superimposed series of ν_{39} bands can be expected in this region. The two strongest far-IR peaks occur at 99.2 and 98.0 cm^{-1}, so it seems apparent that these correspond to the first two spacings of 99.0 and 98.0 cm^{-1} obtained from the CRD spectra. The 99.8 and 98.6 cm^{-1} bands then arise within the ν_{38} excited state and not from the principal series as previously assumed. Moreover, the close spacing assumed by Smithson

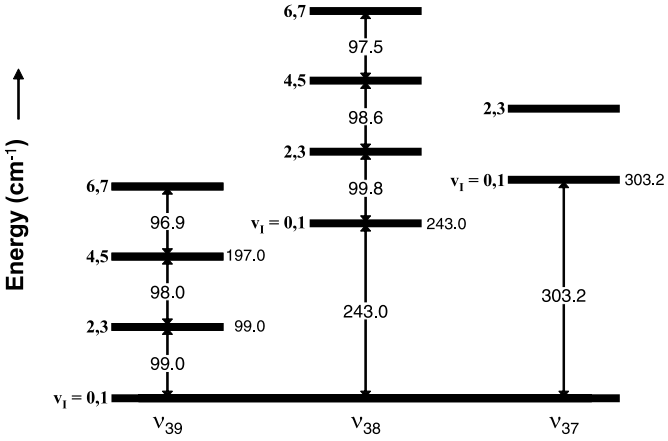
[c]From the Raman spectrum.

and Wieser (5) led them to calculate an unreasonably high barrier to inversion of 3379 cm^{-1} (9.65 kcal/mol).

The remaining question then is whether the weak –294.9 and –391.6 bands in the CRD spectra arise from ν_{39} or from some other combinations. With the 39 vibrations of 2CHO there are many possibilities for combinations when various excited states are considered. If the –294.9 cm^{-1} CRD band is part of the ν_{39} series, then the 97.9 cm^{-1} spacing probably results from a small perturbation, since a value near 97 cm^{-1} is expected. Similarly, the 96.7 cm^{-1} inferred from the CRD spectrum for the following spacing seems to be almost 1 cm^{-1} too high. The presence of both spacings, however, would not conflict with the far-IR spectrum as the 98.0 and 97.9 cm^{-1} bands would be superimposed, and the 96.7 cm^{-1} CRD spacing would correspond to the 96.9 cm^{-1} far-IR band. Nonetheless, we prefer to assign the third spacing to the 96.9 cm^{-1} far-IR band and ascribe the two CRD bands in question to other combinations. For the computation of the potential energy function below, we utilize the energy levels and transitions in Fig. 3, where the energy levels are based on a combination of the CRD and far-IR spectra data for ν_{39}, ν_{38}, and ν_{37}. The –243.0 cm^{-1} band for ν_{38} can be seen in the CRD spectrum and was observed as a far-IR band of type B with a band center at 247 cm^{-1} (5). In the excited state of ν_{38}, the ring inversion (ν_{39}) bands can be seen in the far-IR at 99.8, 98.6, and 97.5 cm^{-1}, and as expected, on the whole, are somewhat weaker than the bands assigned as the principal series without ν_{38} excitation. For ν_{37}, the CRD spectra show

Fig. 3. Vibrational energy levels for the S_0 state of 2CHO for ν_{39} (inversion), ν_{38}, and ν_{37}. The ν_{39} levels are doubly degenerate. v_I represents the ν_{39} quantum number.



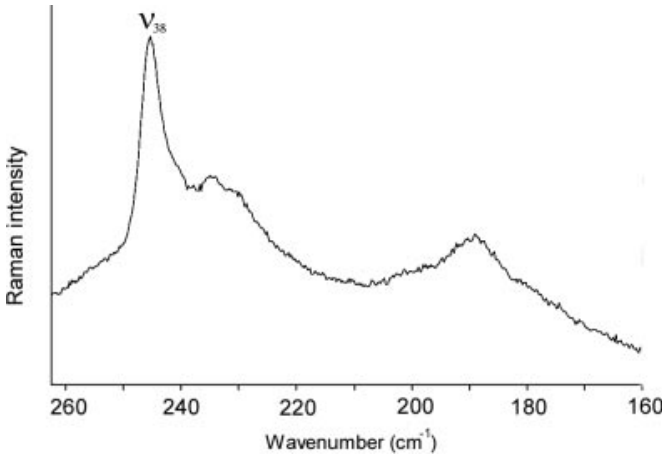


Fig. 4. Raman spectra of 2CHO vapor (0.6 atm, 1 std atm = 101.325 kPa) in the low-frequency region.

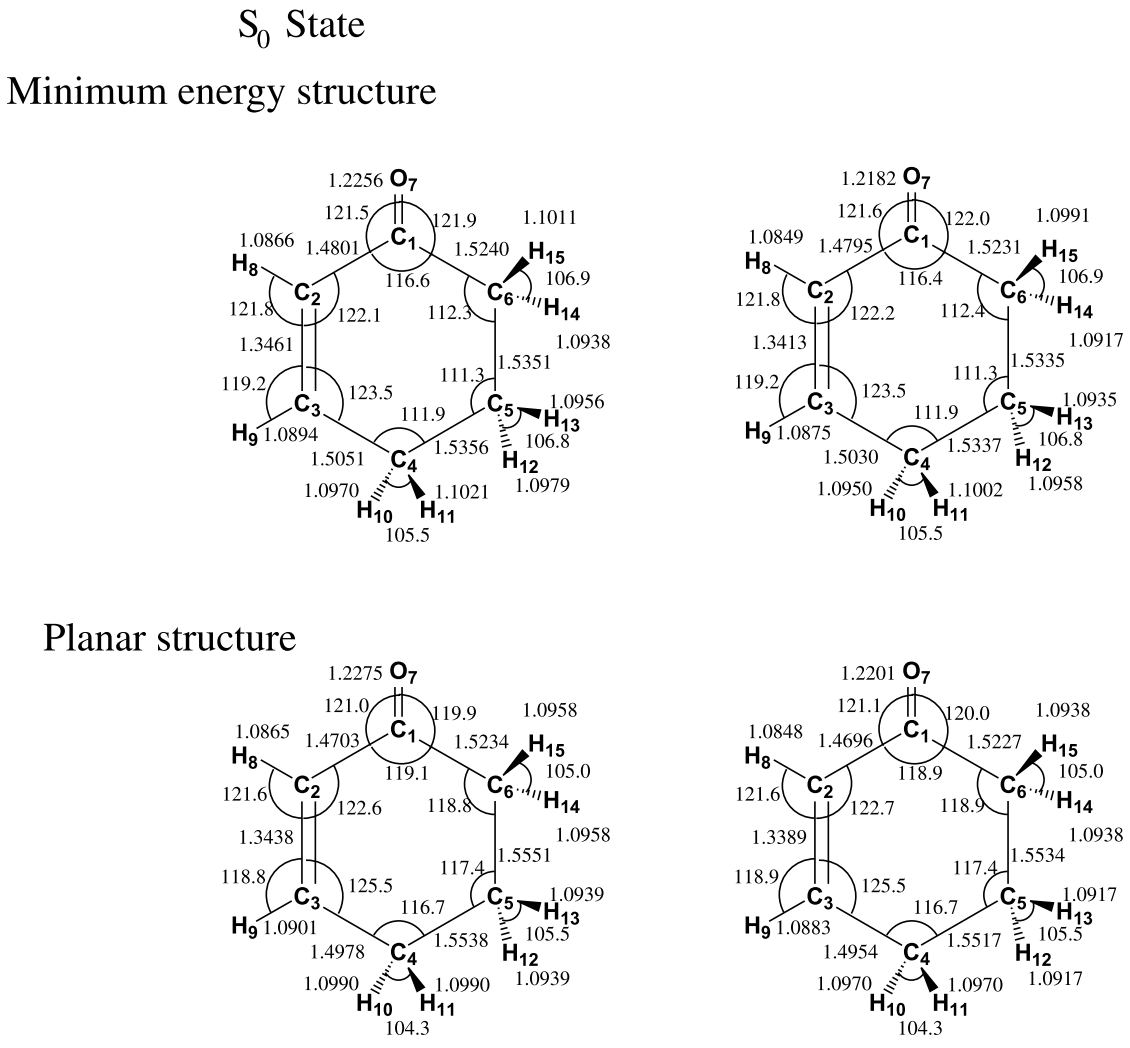
this level to be at 303.2 cm^{-1} as compared to 304.1 cm^{-1} in the far-IR.



An important comment should be made about the band maxima listed in Table 1. The maxima themselves should be accurate to ±0.1 cm^{-1}. However, the maxima will not exactly correspond to the pure vibrational transitions, namely from $J = 0$ to $J = 0$ in the rotational quantum number. For the $S_1(n,\pi^*)$ state, several of the bond distances, notably for the C=O and C=C bonds, will be longer than for S_0. Hence, the moments of inertia will be larger for the S_1 state and the rotational constants will be smaller. This means that the rotationless Q branches actually will be on the high frequency extreme of each observed band in the spectrum. It also means that the combination bands listed in Table 1 cannot be expected to add up to yield the exact ground-state intervals since the band maxima are reported there. To a lesser extent, the rotational constants for the vibrational excited states of the inversion will, on the whole, also be smaller than for the $v_I = 0,1$ state.

Raman spectra

The low-frequency Raman spectrum of 2CHO vapor is shown in Fig. 4. This is similar to that reported previously

© 2004 NRC Canada

Fig. 5. Calculated structures for 2CHO using two different basis sets.

(4), except that the increased vapor pressure resulting from heating the sample to near its boiling point in a sealed cell results in high vapor pressure (0.6 atm, 1 std atm = 101.325 kPa) and a better signal-to-noise ratio. The band maximum for ν_{38} in the Raman spectrum is at 244 cm^{-1} and broad bands with maxima at 233 and 188 cm^{-1} can also be seen. Bands at 248, 230, 212, 165, and 145 cm^{-1} were previously reported (4), but we feel the last three of these are probably noise in the spectrum. A broad feature centered at about 190 cm^{-1} was also shown and this corresponds to our 188 cm^{-1} band. The origins of our 233 and 188 cm^{-1} bands are clearly not from any fundamentals, and this is supported by both the DFT calculations and the CRD spectra. The 233 cm^{-1} band could result from the $1 \rightarrow 2$ transition of ν_{38} but a shift of more than 10 cm^{-1} from the $0 \rightarrow 1$ band is larger than expected. Moreover, the band type appears to be broader than the 244 cm^{-1} band, and this would indicate it has a different assignment. A second possibility is that it may arise from ν_{36}–ν_{39} difference bands (from different inversion states), which are expected near 230 cm^{-1}. For example, the $\nu_{39}(v_I = 4,5) \rightarrow \nu_{36}(v_I = 0,1)$ band is expected at 228 cm^{-1}. The broad 188 cm^{-1} band is somewhat too low to correspond to $2\nu_{39}$ transitions expected in the 190–197 cm^{-1} region for the first several v_I states. Similarly, it is a bit higher than expected for the ν_{36}–ν_{38} bands, which should be near 182 cm^{-1}. However, the latter may be the best explanation. No Raman bands were detected between 90 and 100 cm^{-1} corresponding to ν_{39} as the rotational envelope for the molecule is still quite strong there.

DFT calculations

Several different basis sets were utilized to calculate the structure of 2CHO in its S_0 electronic ground state. Figure 5 shows the bond distances and angles calculated for the minimum energy structures and constrained planar structures using the B3LYP/6-31+G(d,p) and B3LYP/6-311+G(d,p) basis sets. The energy differences between the minimum energy structure and the planar structure were calculated to be 2098 and 2090 cm^{-1}, respectively. Table 2 shows the out-of-plane displacements for both calculations for the minimum energy

structure for carbon atoms 1, 4, 5, and 6. The other atoms lie in the plane. Table 3 shows the rotational constants calculated for the two DFT theoretical structures and compares these to the experimental values from the microwave work (3). Also shown are the MMPI molecular mechanics results (4). It can be seen that the two DFT calculations, and especially that with the larger basis set, provide very good agreement with the microwave experiments. Table 3 also shows the rotational constants for the $v_I = 4$ quantum state of ν_{39} from the microwave study. These values have some relevance in helping us to better understand the band profiles in the far-IR and CRD spectra. The table also shows the rotational constants for the hypothetical planar structure; these values are sufficiently different from the microwave ones, confirming the non-planarity of the ring.

The S_0 vibrational frequencies were also calculated and the values for the low-frequency bands (ν_{39}, ν_{38}, and ν_{37}) are shown in Table 1 for the larger basis sets. A scaling factor of 0.9613 was used and the agreement with experiment is remarkably good, not only for these vibrations but for all of the others also.

Kinetic energy functions

We have previously described the calculation of the kinetic energy function (reciprocal reduced mass) for 1,2-dihydronaphthalene (2), and we have used the computer program for that molecule, with only slight modifications, to calculate the function for 2CHO. The vibrational model in the present work assumed that the inversion vibration labeled S follows the out-of-plane displacements according to those in Table 2. Hence, if the model is totally correct, the energy minima should correspond to an inversion coordinate value of $S = 1.0$ Å. The calculated function for which S is in Å for ν_{39} is

$$[1] \quad g_{44}(S) = 0.03119 - 0.04782S^2 - 0.1153S^4 + 0.1490S^6$$

Fig. 6. Ring-inversion potential energy function for 2CHO corresponding to eq. [2].

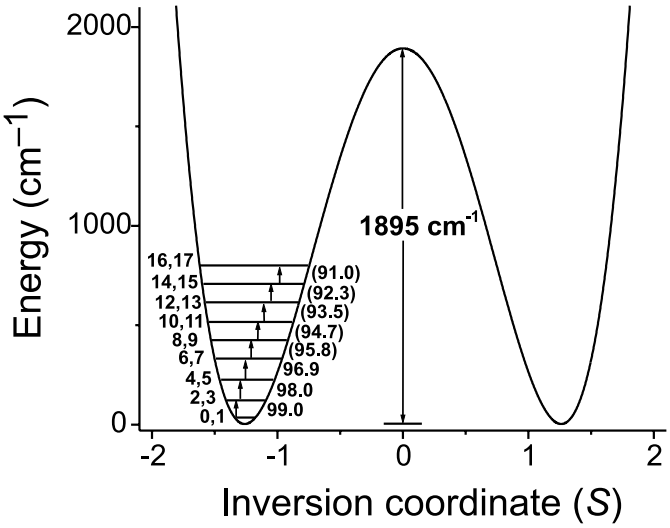

Table 4. Observed and calculated frequencies (cm^{-1}) for the ν_{39} vibration of 2-cyclohexen-1-one in its S_0 state.

	Frequency (cm^{-1})	
Separation	Experimental	Calculated
0–1	—	0.00
1–2	99.0	99.0
2–3	—	0.00
3–4	98.0	98.0
4–5	—	0.00
5–6	96.9[a]	96.9
6–7	—	0.00
7–8	—	95.8

[a]From reference 3.

The reciprocal of the first term, 32.06 in atomic units, corresponds to the reduced mass for the planar structure. The higher-order terms characterize the coordinate dependence of the function.

Ring-inversion potential energy function

As shown in Fig. 3, the first three levels of the ring-inversion vibration have been determined, the first two from the cavity ringdown spectra (±0.1 cm^{-1}), and all three from far-IR data (±0.3 cm^{-1}). These were used to determine the potential function

$$[2] \quad V = 7.459 \times 10^2 S^4 - 2.378 \times 10^3 S^2$$

based on the kinetic energy function in eq. [1]. The function is shown in Fig. 6, and it has a barrier of 1895 cm^{-1}, in very close agreement with the DFT results. However, it should be recognized that the observed levels only go up to about 340 cm^{-1} including the zero point energy, so the barrier is obtained by extrapolation. Moreover, if we changed the values for the spectral spacing even a small amount, large changes would be observed. For example, if the first transition is assumed to be 99.2 cm^{-1}, the barrier drops to

© 2004 NRC Canada

1687 cm^{-1} or 14% lower. Hence, the barrier is best stated to be 1900 ± 300 cm^{-1}. However, it is clearly very different from the values previously reported (3, 4). Table 4 compares the observed and calculated frequencies for ν_{39}, and the agreement is excellent.

Conclusions

The CRD spectra of 2CHO in the $S_1(n,\pi^*)$ region have allowed us to clarify the level spacings for the low-frequency vibrations (Fig. 3). Previous Raman and far-IR work had misinterpreted the spectra and resulted in incorrect values calculated for the inversion barrier. In this paper, we have experimentally determined the inversion barrier to be 1900 ± 300 cm^{-1}, with the large uncertainty arising from the need to extrapolate the potential energy function to values above the experimental data. Nonetheless, this barrier value is in excellent agreement with the DFT value of 2090 cm^{-1} from the B3LYP/6-311+G(d,p) calculation. The inversion model for the vibration, which does not affect the barrier height, was based on the out-of-plane displacements for the minimum energy structure obtained from the DFT computations. Using the kinetic energy function for this model produces an energy minimum occurring at 1.26 Å. Since S = 1.0 Å would indicate perfect correspondence with the DFT calculation, the minimum for our potential energy function shows the model to be quite reliable although the out-of-plane displacements of the atoms are likely to be somewhat larger than those calculated and shown in Table 2.

Work on this molecule is continuing so that we can determine the potential energy functions for the $S_1(n,\pi^*)$ and $T_2(n,\pi^*)$ states.

This manuscript is dedicated to the memory of Gerhard Herzberg and his many contributions to science.

Configuration of ring-down spectrometers for maximum sensitivity[1]

Michael Jakubinek, Zhaoguo Tong, Sergei Manzhos, and Hans-Peter Loock

Abstract: Cavity ring-down (CRD) spectrometers used for analytical applications frequently have design requirements different from spectrometers used for gas-phase spectroscopic applications. A formalism that allows for maximization of the relative sensitivity by adapting the cavity length and absorption path through the sample is presented. These experimental configurations may not reduce the detection limit but do allow for a high sensitivity of the ring-down time measurement in the concentration range of interest. The formalism is applied to two common CRDS experimental configurations and to a fiber-loop ring-down experiment.

Key words: cavity ring-down (CRD), absorption, detector, fiber-loop, sensitivity, detection limit.

Résumé : Les spectromètres CRDS (utilisés pour la spectroscoie par temps de déclin d'une cavité optique) utilisés à des fins analytiques ont souvent des exigences de construction qui diffèrent de celles des spectromètres utilisés dans des applications spectroscopiques en phase gazeuse. On propose ici un formalisme qui permet de maximiser la sensibilité relative en adaptant la longueur de la cavité et celle d'absorption à travers l'échantillon. Bien que ces configurations expérimentales ne reduisent pas la limite de détection, elles permettent une grande sensibilité de la mesure du temps de declin dans le domaine operationnel de concentration. On a appliqué ce formalisme à deux configurations expérimentales courantes de CRDS et à une expérience en cavité impliquant une boucle en fibre.

Mots clés : spectromètre CRDS (spectroscopie par temps de déclin d'une cavité optique), absorption, détecteur, boucle en fibre, sensibilité, limite de détection.

[Traduit par la Rédaction]

Introduction

In recent years cavity ring-down laser absorption spectroscopy (CRDS or CRLAS) has been applied to a variety of gas-phase analytical measurement problems (1), ranging from the detection of trace gases in ambient air samples (2–4), to detection of stable or unstable compounds formed in a molecular beam environment (5, 6), or even in plasmas and flames (7). Recently our group and others have also developed detection techniques, based on CRD, that are capable of measuring absorption of liquid samples (8–11). In particular, it has been noted that CRDS is capable of identifying small amounts of absorbers in dilute solutions of picoliter-sized liquid samples (9, 12). It appears then that CRD has the potential to serve as an optical detection method suitable for microfluidic devices, capillary electrophoresis, or any other technique in which the absorption path is constrained by the instrumental architecture.

There exist a large number of implementations of CRD (*cw* laser and pulsed-laser light sources, phase-shift measurements, Fourier transform CRD, CRDS based on fiber optic cavities, etc.), and an equally large number of environments in which CRDS has been applied (13). For this report it is important to distinguish among CRDS devices in which the sample fills the entire cavity and those in which the sample fills only a fraction of the cavity. Further, we will only explicitly discuss the common scenario in which the individual round-trips are well-separated, i.e., the laser pulse width is short compared with the time for a cavity round-trip.

If the sample fills only part of the cavity, the experimenter frequently has the choice of adjusting the length of the cavity and the length of the sample's absorption path independently. This report is concerned with those values for each of these two lengths, which maximize the sensitivity of the concentration measurement. While our immediate interest lies in finding the optimum configuration for a fiber-loop ring-down spectroscopy (FLRDS) experiment, the formalism is applicable to many other CRDS problems.

Sensitivity issues have been addressed before. A general treatment of the use of CRDS as a quantitative absorption technique was given by Zalicki and Zare (14), and was later adapted to fiber-optic ring-down cavities (15). As was pointed out by many authors, the time it takes for a light pulse in a high finesse optical cavity to decay to *1/e* of its initial intensity is given to a very good approximation by

$$[1] \qquad \tau = \frac{t_r}{2[\alpha d - \ln R]}$$

This expression assumes the applicability of Lambert–Beer's law. Here the round-trip time in the cavity ($t_r = 2L/c_0$)

depends on the length of the cavity (L), and the speed of light in the cavity medium (c_0). The reflectivities of the two mirrors are combined to $R = (R_1\ R_2)^{1/2}$ and the loss in the cavity medium is expressed by a product of the frequency dependent absorption coefficient (α), and the length of the sample's absorption path (d). For high reflectivities many workers set $-\ln R \approx (1 - R)$, but to keep general applicability we retain $\ln R$ in the following. As Zalicki and Zare (14) point out, the minimum absorbance that can be measured depends on both the quality of the mirrors that define the cavity and on the experimental accuracy with which ring-down times can be determined

$$[2] \qquad [\alpha d]_{\min} = -\ln R \frac{\Delta\tau}{\tau}$$

For a typical system the uncertainty of the time measurement is given by the laser jitter or temporal response of the data acquisition and is on the order a few nanoseconds — say $\Delta\tau = 3$ ns. With a reflectivity of $R = 99.9\%$ in a 1 m long cavity the ring-down time of the empty cavity is calculated as $\tau = 1.6$ μs and the minimum absorbance is about 1 to 2 ppm. Strictly speaking this number is a detection limit but not the sensitivity of the apparatus, since both $\Delta\tau$ and τ depend strongly on the concentration of the sample. Here it is demonstrated how one can optimize a ring-down apparatus for sensitivity as opposed to detection limit. The distinction is important since in analytical applications it may be more important to reliably measure a small increase of an otherwise large analyte concentration as opposed to a small absolute concentration on a "zero absorption" background.

Results

The sensitivity is usually defined as the derivative of the measurement variable, here the ring-down time (τ) with respect to concentration. If CRDS is used for absorption measurements on liquid samples, one can either fill the entire cavity with the sample solution or only a fraction. In the latter case, eq. [1] can be rewritten as

$$[3] \qquad \tau = \frac{L}{c_0[-\ln R + \varepsilon_A C_A d + \varepsilon_S C_S d + \alpha L]}$$

Here L and d are the lengths of the cavity and the absorption path, respectively. The frequency dependent absorption coefficients (ε) for the analyte and the solvent are given with respect to base-e and are multiplied by their respective concentrations. The frequency dependent absorption coefficient (α) accounts for the absorption of the cavity medium itself. If the length of the cavity (L) is comparable to the absorption path of the sample (d) one needs to replace L with L-d. Note that a very similar expression also holds for the fiber-loop ring-down experiments described in ref. 9. The derivative of eq. [3] is simply

$$[4] \qquad \frac{\partial\tau}{\partial C_A} = -\frac{L\varepsilon_A d}{c_0[-\ln R + \varepsilon_A C_A d + \varepsilon_S C_S d + \alpha L]^2}$$

From this expression it appears as if the highest sensitivity is achieved when d approaches L and the sample fills the entire cavity. In practice, this is true only if the absorptivities of the analyte and solvent are very small ($\varepsilon_A C_A \to 0$), since in all other cases the absorptivity of the sample will lead to a dramatic decrease in ring-down time and thereby to a large measurement uncertainty. Therefore, it appears reasonable to weight the above expression with the uncertainty in the ring-down time measurement $\delta\tau$, which in turn is a function of the concentration and the experimental parameters. Note that this expression for the sensitivity then has units of inverse concentration and therefore reflects the sensitivity of the measurement to an absolute concentration change. In a practical application it may be more convenient to use a dimensionless expression for the sensitivity obtained by multiplying the above expression with the analytes' concentration. This will produce the sensitivity of the measurement to a relative concentration change,

$$[5] \qquad S \equiv \left| \frac{\partial\tau / \partial C_A}{\delta\tau} \right| C_A$$

The difference between eqs. [4] and [5] is that the former is the sensitivity of only the observable and the second the dimensionless sensitivity of the measurement.

By adjusting the design parameters of the experiment one can now maximize the sensitivity of a concentration measurement in a particular concentration range. For example, being able to distinguish between a 1 mmol L^{-1} and 1.02 mmol L^{-1} solution (a 2% change) may require different experimental conditions than distinguishing between a 10 μmol L^{-1} and 30 μmol L^{-1} solution although the absolute concentration change is the same.

The uncertainty in the ring-down time, $\delta\tau$ in eq. [5], is the sum of the experimental time resolution and the uncertainty of the fit to the optical decay. A constant term, $\delta\tau_{exp}$, that accounts for the bandwidth of the data acquisition (arising from e.g., detector amplification circuitry, time-to-digital converters, pulse width of light source, etc.), has therefore been included in the sum, and the overall uncertainty is

$$[6] \qquad \delta\tau = T_{95}(N - M)\,\mathrm{RMS}\sqrt{V_{\tau\tau}} + \delta\tau_{exp}$$

where T_{95} is the Student 95% confidence t value, RMS is the fit error, N is the number of round trips, M is the number of parameters in the model (3 for a simple exponential decay), and $V_{\tau\tau}^{-1}$ is the correlation matrix:

$$[7] \qquad V_{\tau\tau}^{-1} = \sum_{i=1}^{N} \left(\frac{\delta I_i}{\delta\tau} \right)^2$$

where I_i is the intensity of the ith round-trip. The intensity in the cavity is assumed to decay exponentially with time

$$[8] \qquad \frac{\delta I_i}{\delta\tau} = I_0 \frac{t_i}{\tau^2} \exp\left(-\frac{t_i}{\tau} \right)$$

and consequently

$$[9] \qquad V_{\tau\tau}^{-1} = \frac{I_0^2}{\tau^4} \sum_{i=1}^{N} t_i^2 \exp\left(-\frac{2t_i}{\tau} \right)$$

Replacing the sum with an integral

© 2004 NRC Canada

$$[10] \quad V_{\tau\tau}^{-1} = \frac{I_0^2}{\tau^2}\int_0^\infty \frac{t^2}{\tau^2}\exp\left(-2\frac{t}{\tau}\right)\mathrm{d}\frac{t}{\tau} = \frac{I_0^2}{4\tau^2}$$

and substituting into eq. [6] yields

$$[11] \quad \delta\tau = T_{95}(N-M)\,\mathrm{RMS}\frac{2\tau}{I_0} + \delta\tau_{\mathrm{exp}}$$

Both the root mean square fit error of the ring-down time measurement

$$[12] \quad RMS = \sqrt{\frac{1}{N-M}\sum_{i=1}^{N}(I_i^{\mathrm{fit}} - I_i)^2} \equiv \sigma\sqrt{\frac{N}{N-M}}$$

and the Student T_{95} function depend on the number of points (N) used for obtaining the ring-down time and therefore on the dynamical range of detection.

The dynamical range of detection, which is assumed to be constant with respect to the above parameters, is determined by the minimum detectable relative intensity,

$$[13] \quad I_{\mathrm{min}}^{\mathrm{rel}} \equiv \frac{I_{\mathrm{min}}}{I_0} = \frac{3\sigma_{\mathrm{background}}}{I_0}$$

where $\sigma_{\mathrm{background}}$ is the standard deviation of the background noise. The intensity after n round-trips is given by

$$[14] \quad I_{\mathrm{rel}}(n) = R^{2n}e^{-2n\varepsilon_A C_A d}e^{-2n\varepsilon_S C_S d}e^{-2n\alpha L}, \qquad n = 0,1,2\ldots$$

and thus the number of rings observed, which is the total number of data points N that can be fitted to, is given by

$$[15] \quad N(d, L, C_A) = \frac{\ln I_{\mathrm{min}}^{\mathrm{rel}}}{2(\ln R - \varepsilon_A C_A d - \varepsilon_S C_S d - \alpha L)}$$

rounded down to the nearest integer. Ultimately, the minimum detectable relative intensity is an instrument function and may be on the order of 10^{-4} or less.

By combining eqs. [4], [5], [11], and [12], one obtains for the sensitivity

$$[16] \quad S(L, d|C_A) = \frac{\varepsilon_A C_A}{c_0}\left|\frac{\dfrac{Ld}{[-\ln R + \varepsilon_A C_A d + \varepsilon_S C_S d + \alpha L]^2}}{\delta\tau_{\mathrm{exp}} + \dfrac{2}{3}I_{\mathrm{rel}}^{\mathrm{min}}T_{95}(N(L,d)-M)\tau\sqrt{\dfrac{N(L,d)}{N(L,d)-M}}}\right|$$

and the optimal values of L and d are those that maximize this expression within the concentration range of interest. For the sample calculations presented here, the standard deviation of the data set in eq. [12] (σ) was approximated by the standard deviation of the background noise ($\sigma_{\mathrm{background}}$). This permits σ to be expressed in terms of the minimum detectable relative intensity, $I_{\mathrm{min}}^{\mathrm{rel}}$ (see eq. [13]). Equation [16] can be considered rather general: it also holds for fiber-loop ring-down spectroscopy and related techniques, and for devices in which the sample fills the entire cavity (i.e., $d = L$).

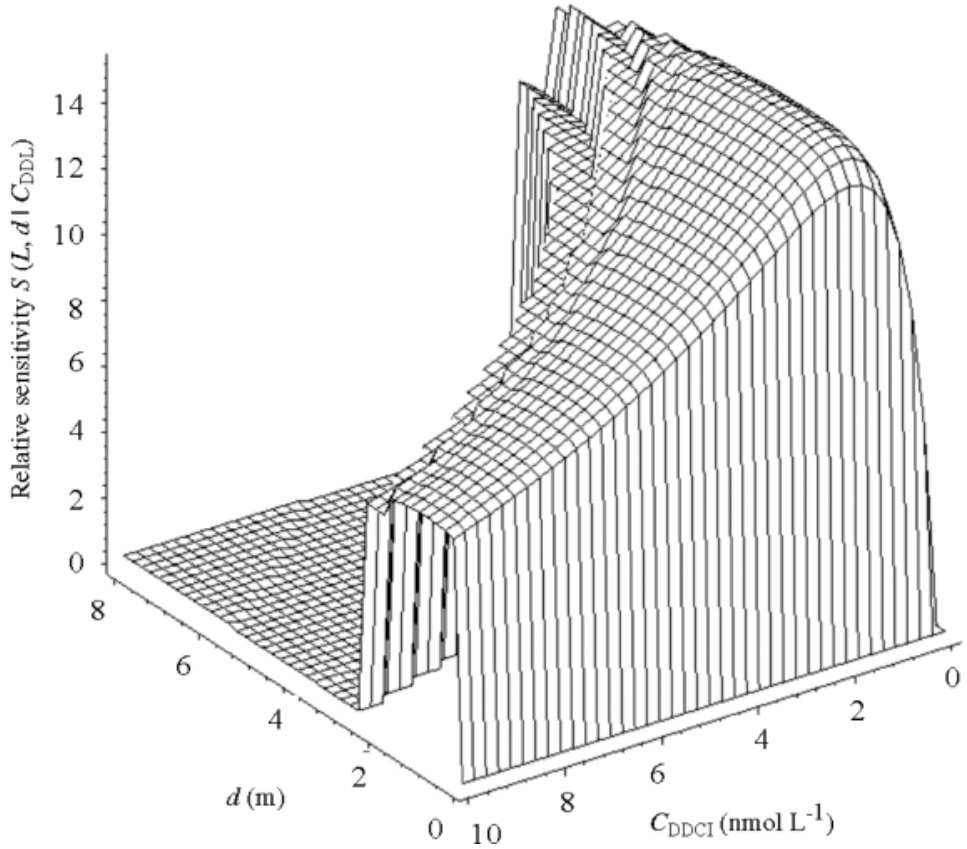
In the following sections, eq. [16] is applied to three problems of interest to researchers using CRDS for analytical measurements on liquid samples. The first two are related to a fictitious example of a liquid sample introduced into a "conventional" cavity defined by two high-reflectance mirrors. The third example is more closely related to experiments performed in our laboratory: the optimum configuration for a fiber-loop ring-down experiment.

Discussion

Example I: Liquid filled cavity

CRDS has found an interesting application in the sensing of trace gas species in a number of laboratory and industrial environments. Frequently, it is advantageous and practical to fill the entire cavity with the gas to be studied. The lower limit to the cavity length is determined by the reflectivity of the mirrors. As the cavity becomes very small the transmission and absorption losses at the mirrors dominate, thus decreasing the ring-down times and sensitivity. There also exists an upper limit to the desirable cavity size, since a very long cavity filled with a strong absorbing gas will return too few rings for an accurate exponential fit. Similar considerations also hold for liquid filled cavities, with the main difference being that in a dilute solution the solvent absorption and scattering may significantly contribute to the optical losses in the cavity. Other technical problems, such as changed optical properties of the mirrors can be overcome as recently demonstrated by Zare and co-workers (11).

Figure 1 illustrates that in the very low concentration range it is advantageous to use large cavities to obtain the highest relative sensitivity. As in all examples given below, the sample is assumed to consist of a solution of the strongly absorbing dye 1,1′-diethyl-4,4′-dicarbocyanide iodide (DDCI-4: $\varepsilon_{\mathrm{DDCI}}$ (825 nm) = 3.3×10^7 L mol^{-1} m^{-1}) in a fictitious solvent with absorptivity $\alpha = 10^{-2}$ m^{-1} and a refractive index of $n = 1.0$. Only when the solvent absorptivity or the analyte concentrations are large, will the decreased number of round-trips limit the optimum cavity length (not shown in Fig. 1). On the other hand, for many practical applications this upper limit is given by the necessity to align the cavity mirrors with high precision and stability. Disregarding this experimental aspect there exists an optimum length, which is a strong function of both the concentration and the absorption cross section of the sample and solvent.



Example II: Cavity containing a small liquid sample

Recently, there has been interest in using CRDS as an absorption sensor in small flow channels (12, 16). One elegant way of implementing this idea is by introduction of a small flow channel on a transparent support medium into the cavity. Losses can further be minimized if the support is Brewster-angled with respect to the cavity axis. Since here the absorbing sample fills only a small fraction of the cavity — the absorption path is typically on the order of a few tens of microns — this arrangement resembles, at least conceptually, CRDS of a gas sample seeded in a molecular beam.

Figure 2*a* illustrates the strong dependence of the relative sensitivity on the concentration and absorption path of the

Fig. 1. Dimensionless relative sensitivity for a completely filled cavity. The absorptivity of the cavity medium was set to $\alpha_{cavity} = 5 \times 10^{-2}$ m^{-1}, $I_{min}^{rel} = 0.2\%$, $M = 3$, $\delta\tau_{exp} = 1$ ns, and the cavity losses were 0.1% so that $R = 0.999$. The maximum sensitivity is achieved for $L = d = 1.5$ m and $C_{DDCI} = 1.6 \times 10^{-9}$ mol L^{-1}. The stepwise reduction of the sensitivity with increasing concentration and increasing length of the cavity is due to the reduced number of available round-trips in the exponential fitting procedure.

sample solution. In the calculation it was assumed that the mirror losses and the scattering losses on the liquid–air interface add up to 0.1% per pass. Of course, the optimum path length (d) through the sample depends on its absorption coefficient. It is apparent that the highest sensitivity is achieved when $dC_{DDCI} = constant$. From Fig. 2*b* it is apparent that, if the cavity medium itself was not absorbing at all, there is no dependence of the measurement uncertainty on the distance between the mirrors, since the number of points being fitted to is the same for small or large mirror separation. It is therefore advisable to use a very large distance to reduce the contribution of the experimental uncertainty $\delta\tau_{exp}$ to the measurement. In practice, of course, there is an upper limit set by the difficulty to keep a large optical cavity well aligned. More interestingly, both figures show that for a given cavity length and concentration there is a strong dependence of the sensitivity on the absorption path (d) leading to a pronounced maximum.

Example III: Fiber-loop ring-down spectroscopy

In a fiber-loop ring-down experiment (Fig. 3), the experimenter is free to choose the length of the loop (L) and separation of the fiber ends (d). As such, it is desirable to choose values for those parameters so as to obtain maximum sensitivity to relative changes in the sample concentration. The following development considers the detection of a sample of DDCI in dimethyl sulfoxide (DMSO). Equation [3] may be rewritten as (9, 16)

$$[17] \qquad \tau = \frac{L}{c_0[-\ln T_{sp} + \varepsilon_{DDCI} C_{DDCI} d + \alpha_{DMSO} d + \alpha_{fiber} L]}$$

where ε_{DDCI} is the wavelength dependent absorption coefficient of DDCI in L mol^{-1} m^{-1}, α_{DMSO} is the absorption coefficient of DMSO in m^{-1}, α_{fiber} is the absorption coefficient of the fiber in m^{-1} and $c_0 = 2.07 \times 10^8$ m s^{-1} is the speed of light in the fiber.

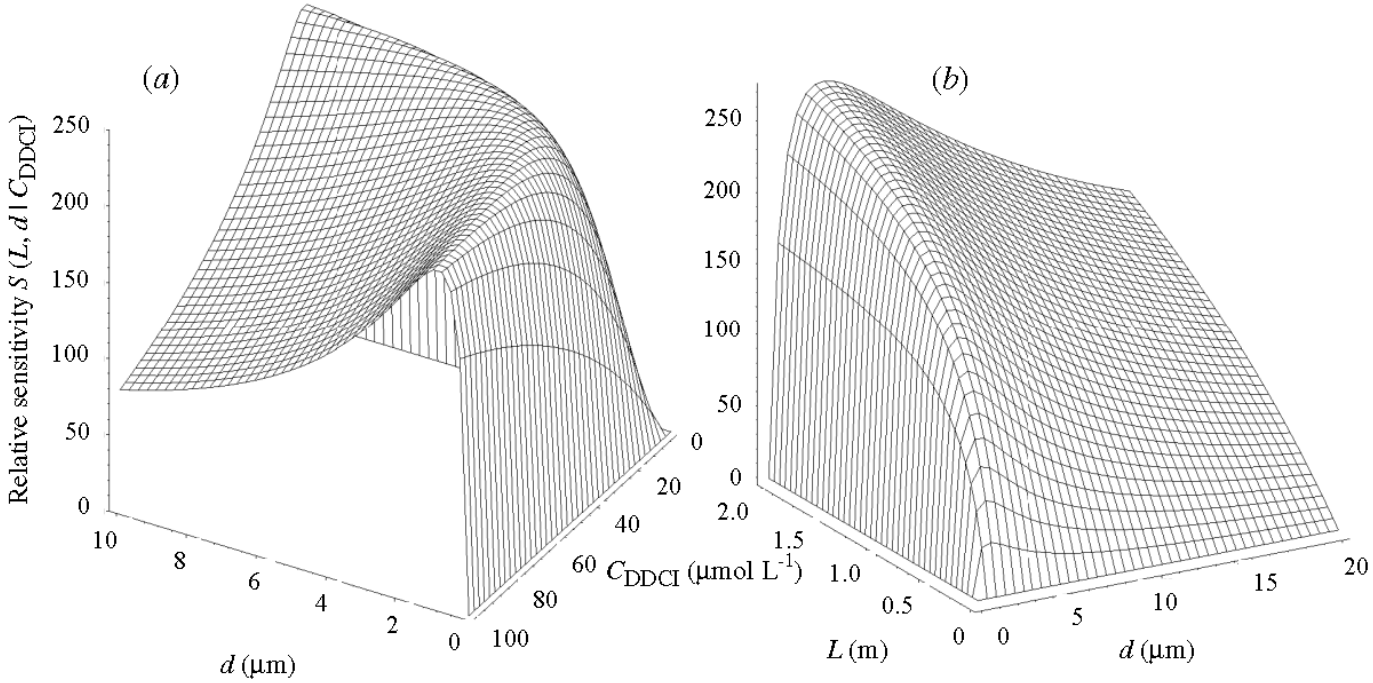
In eq. [17] the transmittance of the fiber splice is expressed by T_{sp} and is a weak function of the distance between the fiber ends (i.e., the absorption path through the sample (d)). The transmission of the fiber–fiber connection can be approximated by (16)

$$[18] \qquad T_{sp} = T_0\left(1 - \frac{NA_0 d}{4 n_0 r}\right)$$

where r and n_0 are the radius and refractive index of the fiber core, NA_0 is the input numerical aperture, and T_0 is the experimentally determined transmission at zero separation (i.e., $d = 0$). Figure 4*a* shows that for our experimental conditions and a concentration of $C_{DDCI} = 1.5$ mmol L^{-1} the sensitivity is maximal when the length of the fiber loop is about

© 2004 NRC Canada

Fig. 2. Dimensionless relative sensitivity for a partially filled cavity. The absorptivity of the cavity medium was set to $\alpha_{cavity} = 5 \times 10^{-2}$ m^{-1}, $I_{min}^{rel} = 0.2\%$, $M = 3$, $\delta\tau_{exp} = 1$ ns, and the cavity losses were 0.1% so that $R = 0.999$. The sensitivity now depends on the length of the cavity (L) the absorption path (d), and the concentration (C_{DDCI}). (*a*) The length of the cavity was held constant at $L = 1$ m and the sensitivity is maximal for $dC_{DDCI} = 10^{-10}$ Mm. (*b*) The concentration was held constant at $C_{DDCI} = 4 \times 10^{-5}$ mol L^{-1} and there is a clear maximum sensitivity at about 2.5×10^{-6} m, largely independent of the cavity length.



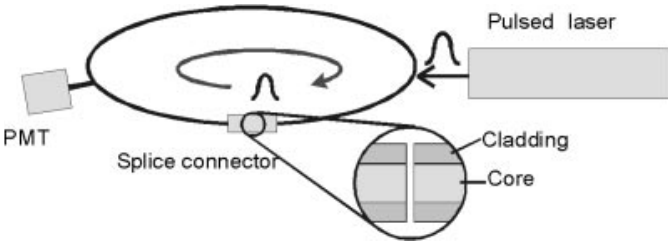


Fig. 3. Diagram of the fiber-loop ring-down experiment. A Nd:YAG pumped dye laser injects a ns pulse into a loop made of multimode optical fiber. A PMT detector monitors the intensity of each round-trip by detecting scattered light from the fiber core and cladding. After averaging a few thousand laser shots, a waveform is obtained that is then fitted using a bi-exponential decay function.

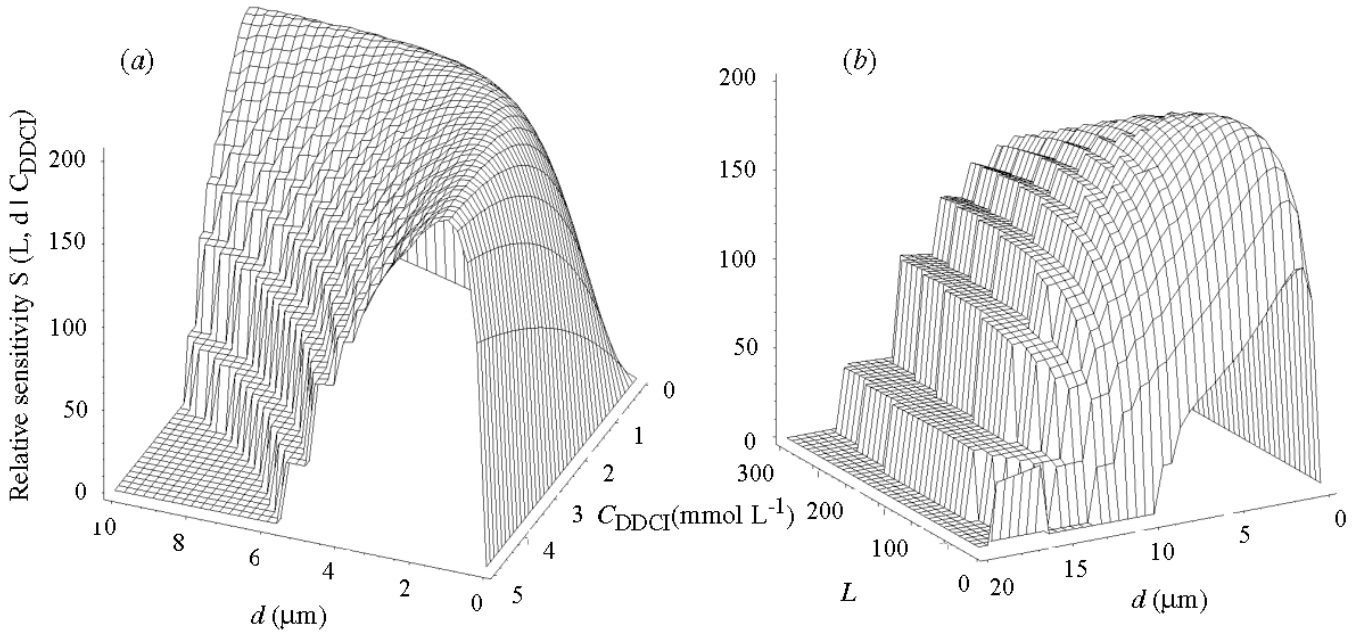
60 m and the distance between the fiber ends is 4 μm. If the absorption path is much larger, the ring-down time decreases and with it the number of data points (N) that can be used for fitting. The step-like appearance of that dependence is therefore due to the rounding to the nearest integer in eq. [15].

The minimal practical length of the fiber loop is given by the dramatic reduction in ring-down time as the transmission losses of the fiber splice begin to dominate the loss processes in eq. [17]. If those transmission losses were made very small, the lower limit is given by the macrobending losses, which increase dramatically as the radius of the loop approaches about 30 mm. The effect of macrobending losses is negligible for any loop with $L > 30$–40 cm and was ignored in this calculation. The upper practical limit of the loop length (L) depends on the number of round-trips necessary for a reliable fit to the ring-down time. It is ultimately limited when the optical losses in the fiber core begin to dominate the absorption losses in the sample.



For a given L, the highest sensitivity is obtained when increasing d as the concentration is decreased (Fig. 4*b*). As in Fig. 2*a*, the relation for maximum relative sensitivity is very close to $dC_{DDCI} = constant$. However, eventually the sensitivity will decrease with very large d as in the FLRDS device the absorption path is limited by the fiber-to-fiber coupling losses described in eq. [18]. Figure 4*b* displays the dependence of the dimensionless sensitivity for a given length of the fiber loop ($L = 60$ m). It is clearly advantageous to use a short distance between the fiber ends ($d < 2$ μm) for all but the lowest concentrations. More importantly, it is possible to adjust the distance between the fiber ends in such a way that the same high relative sensitivity of about 200 (i.e., a detectable 0.5% change of the base concentration) can be obtained for a wide range of base concentrations, albeit in a concentration range about 100 times higher than the one for which a regular cavity with only 0.1% losses was optimized.

Conclusion

In the preceding paragraphs a simple formalism that allows for optimization of a ring-down spectrometer for particular analytical applications was derived. In particular it is apparent that a cavity ring-down spectrometer optimized for the highest detection limit may not give the highest sensitiv-

© 2004 NRC Canada

Fig. 4. Dimensionless relative sensitivity for a fiber-loop ring-down spectrometer. The absorptivity of the fiber core was set to $\alpha_{fiber} = 7 \times 10^{-4}$ m^{-1}, $c_0 = 2.07 \times 10^8$ m s^{-1}, $I_{min}^{rel} = 0.2\%$, $\delta\tau_{exp} = 1$ ns, the coupling losses were set to 3% so that $T_0 = 0.97$. Since both the fiber cladding and fiber core contribute to the exponential decay, five fitting parameters are needed and $M = 5$. The sensitivity depends on the length of the loop (L), the absorption path (d), and the concentration C_{DDCI}. (*a*) The length of the cavity was held constant at $L = 60$ m and the sensitivity is maximal for $dC_{DDCI} = 5 \times 10^{-9}$ Mm. (*b*) The concentration was held constant at $C_{DDCI} = 1.5 \times 10^{-5}$ mol L^{-1} and there is a clear maximum sensitivity at about 3.7×10^{-6} m, largely independent of the cavity length. The stepwise reduction with increasing concentration and increasing length of the loop is due to the reduced number of available round-trips in the exponential fitting procedure.

ity for large analyte concentrations and absorption cross sections. The formalism can easily be adapted to account for the effect of averaging (i.e., the time constant of the measurement) by including a functional dependence of the minimum relative detectable intensity on the number of laser shots sampled. The application of the formalism to the filled cavity shows no surprises and confirms what spectroscopists know by intuition, i.e., that the sensitivity is determined by a delicate balance between the length of the cavity and the absorptivity ($\alpha = Cd$) of the sample. For very weakly absorbing samples it is advisable to use the longest practical cavity, simply to increase the effective absorption path, whereas for more strongly absorbing species a very long cavity eventually reduces the accuracy of the measurement by reducing the number of data points that is available for the exponential fit.

Of more interest to analytical applications is the fact that when only part of the cavity is filled with sample there exists an optimum path length through the sample that depends on the concentration range over which a change should be measured. Again, this is known in molecular beam spectroscopy where the "concentration" of the sample is typically held constant but the absorptivity changes as a function of wavelength.

If the cavity medium itself contributes to the absorption losses, the sensitivity will more strongly depend on the length of the cavity or fiber-loop and the absorption path through the sample and the discretization of the sensitivity because of decreasing number of round-trips in the cavity becomes more apparent. These results are potentially useful not only for the FLRDS example that is given here but also for sensors and detectors based on fiber-Bragg gratings and even "conventional" optical cavities, when the cavity is filled with a medium that contributes considerably to background optical losses, such as in solvent-filled cavities. Of course, one can still obtain high sensitivity under those circumstances. Comparing the sensitivity in the conventional optical cavities with the FLRDS apparatus, a similar relative sensitivity of $S = 200$ is achieved (a detectable concentration change of 0.5%), although the transmission through the fiber splice with $T_0 = 97\%$ is considerably worse than common mirror reflectivities of $R = 99.9\%$ with base optical losses of 0.1% assumed for these cavities. FLRDS compensates the poor transmission per pass with a very long cavity ($L = 65$) and thereby allows for large ring-down times at comparably high sample absorptivities. Again it is important to distinguish between the dimensionless sensitivity that is discussed here, and the detection limit. The detection limit is rather high for FLRDS and is directly influenced by the poor transmission of the fiber–fiber joint.

Probing of the hot-band excitations in the photodissociation of OCS at 288 nm by DC slice imaging[1]

Myung Hwa Kim, Wen Li, Suk Kyoung Lee, and Arthur G. Suits

Abstract: The photodissociation dynamics of OCS at 288 nm has been investigated using the DC (direct current) slice imaging technique, which is a recently developed high-resolution "slicing" approach that directly measures the central slice of the photofragment distribution in imaging experiments. By analyzing a DC sliced image of $S(^1D_2)$ photofragments we observe dissociation originating from OCS molecules excited up to $v_2 = 4$ in the molecular beam. The measured translational energy distribution was used to determine the branching ratio for the contribution from each initial bending state ($0\ v_2\ 0$) of OCS and relative photodissociation cross section ratios compared to $v_2 = 1$. Large negative anisotropy parameters determined as a function of the $S(^1D_2)$ fragment recoil speed indicate that the photodissociation of OCS at 288 nm occurs exclusively from the $1^1A''(^1\Sigma^-)$ bending excited potential surface that can be accessed through a perpendicular transition.

Key words: DC slicing imaging, OCS, photodissociation, hot-band excitation.

Résumé : On a étudié la dynamique de la photodissociation du OCS à 288 nm en faisant appel à la technique de l'imagerie de raccordement à courant direct, une approche de « raccordement » à haute résolution développée récemment qui mesure directement le raccordement central de la distribution des photofragments dans des expériences d'imagerie. En analysant une image coupée en courant direct de photofragments de $S(^1D_2)$, on observe la photodissociation qui tire son origine dans les molécules de OCS excitées jusqu'au niveau $v_2 = 4$ dans un faisceau moléculaire. On a utilisé la distribution d'énergie de translation mesurée pour déterminer le rapport de bifurcation pour la contribution à partir de chaque état initial de déformation ($0\ v_2\ 0$) de OCS ainsi que les rapports de section droite de photodissociation relatifs comparés à $v_2 = 1$. Les valeurs très négatives des paramètres d'anisotropie qui ont été déterminées en fonction de la vitesse de recul de la fragment $S(^1D_2)$ indiquent que la photodissociation de OCS à 288 nm ne se produit qu'à partir de la surface potentielle excitée de déformation $1^1A''(^1\Sigma^-)$ à laquelle on peut accéder par une transition perpendiculaire.

Mots clés : imagerie de couplage en courant direct, OCS, photodissociation, excitation d'une bande chaude.

Introduction

Carbonyl sulfide (OCS) has been of considerable interest from a spectroscopic point of view (1–3) as a prototypical triatomic molecule, and in the earth's atmosphere as a primary source of sulfate for the stratospheric aerosol layer (4–6). Extensive studies have thus been performed to elucidate the photodissociation dynamics of OCS using laser-induced fluorescence (LIF) (7, 8), ion imaging (9–12), and photoelectron spectroscopy (13).

From these previous works (7–9), it is well known that photodissociation of $OCS(X^1\Sigma^+)$ in a range between 222 and 248 nm produces rotationally hot, but vibrationally cold $CO(X^1\Sigma^+)$ fragments along with $S(^1D_2)$ or $S(^3P_j)$ atoms in the branching ratio 95:5, through the $2^1A'(^1\Delta)$ and $1^1A''(^1\Sigma^-)$ excited states. Excitation of these excited states is weakly allowed in the bent geometry (C_s), but forbidden in the linear equilibrium geometry of the ground state molecule. Dissociation is thus strongly favored for the molecule in bent geometries on the ground electronic potential surface. The results obtained also show the bimodal distributions (7, 9, 11) for both the rotational levels of $CO(X^1\Sigma^+)$ and the translational energy of $S(^1D_2)$ because of two different dissociation pathways on the $2^1A'(^1\Delta)$ surface, which are ascribed to adiabatic and non-adiabatic processes. It is generally believed that the $2^1A'(^1\Delta)$ excited surface, corresponding to a parallel transition, is located higher in energy than the $1^1A''(^1\Sigma^-)$ excited surface corresponding to a perpendicular transition (7, 9). Katayanagi and Suzuki (11) reported that the transition probability of this non-adiabatic process is typically 0.35 at

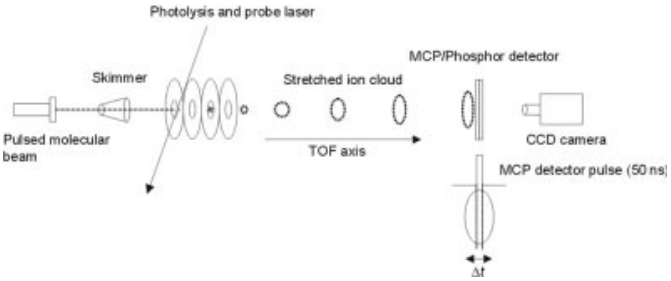
230 nm from the rotational distribution of $CO(X^1\Sigma^+)$ and the $S(^1D_2)$ image obtained by using conventional velocity map ion imaging technique (14).

One particularly interesting result from the recent work (9–12) is that, owing to the fact that the transition is forbidden from the linear geometry, bent geometries, and in particular vibrational bending excitation of OCS, can play an important role in the excitation and dissociation dynamics even if the molecular beam is translationally and rotationally very cold. This is also true for the isoelectronic N_2O molecule. These studies have largely been performed in the vicinity of the local maximum in the absorption around 230 nm, where both the $2^1A'(^1\Delta)$ and $1^1A''(^1\Sigma^-)$ may contribute. Both surfaces cross repulsive $^1\Pi$ states in the linear geometry, but these crossings are avoided (and become conical intersections) for the bent molecule. Very recently, the presence of vibrationally excited OCS molecules in a cold molecular beam was experimentally reported from only the rotational state selection of $CO(X^1\Sigma^+)$ at 230 nm in velocity map ion imaging by Sugita et al. (10), Katayanagi and Suzuki (11), and Janssen and co-workers (12), independently. Janssen and co-workers used the hexapole state selection technique (12) to study the state-resolved angular recoil distribution of $CO(X^1\Sigma^+; v = 0|J)$ from the photodissociation of $OCS(\nu_2 = 0|JM = 10)$ and $OCS(\nu_2 = 1|JlM = 111)$. Here, we present a study of OCS photodissociation via hot-band absorption in the very long wavelength tail of the absorption at 288 nm.



As shown in our previous papers (15, 16), DC (direct current) slice imaging techniques, refined from the original slicing approach (17), can measure directly the center slice of the photofragment distribution and can be effectively used to resolve more clearly some of the structures in the kinetic energy release or velocity distribution for any molecule without the need for numerical reconstruction methods. We achieved this by employing a low voltage, multilens velocity mapping assembly that eliminates the need for pulsed electric fields and grids, and therefore, considerably enhances the experimental resolution attainable. Also, this slicing approach is a highly sensitive and widely applicable technique for the study of orbital polarization (16, 17).

In the present study, we apply the high-resolution DC slice imaging technique to detection of the $S(^1D_2)$ photofragments following excitation of OCS at 288 nm. Even though this photolysis wavelength is placed far away from the weak absorption maximum of OCS around 230 nm, and the photoabsorption cross section is very small (4, 5), the yield of photodissociation is still sufficient to get meaningful information about the dissociation dynamics related to the vibrationally excited states of the parent molecules.

Experimental

The DC slice imaging apparatus used in this study, shown in Fig. 1, has been described in more detail elsewhere in our previous work (15) and only a brief description will be given here. A pulsed supersonic molecular beam of OCS is formed by expanding OCS molecules diluted about 30% with Ar gas into the source chamber of our differentially pumped apparatus at a backing pressure of 3 bar (1 bar = 100 kPa). After passing through a skimmer and collimator, the molecular beam enters into a velocity mapping ion optics assembly

Fig. 1. Experimental schematic showing the slice imaging approach.

consisting of four electrodes. The beam is perpendicularly intersected with a laser beam tuned to a two-photon resonant excitation of $S(^1D_2)$. The operating pressures were ~2.5×10^{-5} in the source chamber and ~5×10^{-7} torr (1 torr = 133.322 4 Pa) in the main chamber.

The wavelength of laser light in the present study was produced by frequency doubling the output of a dye laser (Continuum Jaguar, R590/R610 dyes) pumped by a Nd:YAG system (Quanta Ray GCR-5). The vertical polarization of the laser beam in the laboratory frame was achieved using a Soleil-Babinet compensator (Special Optics) with its optical axis set at 45° with respect to the horizontal polarization vector of the laser beam and was then focused with a lens (f = 30 cm) into the interaction volume with the pulsed molecular beam of OCS diluted in Ar. This linearly polarized laser beam was used for both photolysis of OCS and ionization of S atoms in a one-color experiment. Typical output power for the doubled dye laser beam entering the chamber was 2 mJ/pulse and accurate wavelength calibration was achieved using a wavemeter (Coherent WaveMaster). The $S(^1D_2)$ photofragments were ionized by using the following (2 + 1) resonance enhanced multiphoton ionization (REMPI) scheme:

$$S\ 3p^4(^1D_2) \xrightarrow{2h\nu} S\ 3p^3 4p(^1F_3) \xrightarrow{h\nu} S^+$$

at 288.18 nm

and then accelerated through the multilens velocity mapping assembly optimized for DC slicing of the ion cloud.

After flying through the field free flight path, ions were impacted on a position-sensitive dual MCP/phosphor screen detector of 120 mm diameter (Burle electro-optics). The flight path was extended up to 192.5 cm from the interaction region to the front face of the MCP to improve the velocity resolution. In addition, a repeller voltage was set at +500 V, keeping the optimized velocity mapping condition to stretch the photofragment ion cloud along the time-of-flight axis to the order of about 400 ns. We applied a narrow time gate (effectively 50 ns) at the detector to select the central section of the distribution. The fact that the slice is a finite fraction of the recoil velocity distribution, and in fact this fraction is itself speed dependent, might suggest that the accurate speed dependence will not be faithfully reproduced by the slicing technique. However, extensive Monte Carlo simulations have shown that the speed dependence of the distribution is remarkably faithful over all recoil speeds, although the velocity resolution does suffer for the poorly sliced slow fragments. The reasons for this are subtle and nonintuitive,

and beyond the scope of the current paper. However, a detailed treatment of these issues is in preparation. The velocity resolution of the experiment is largely determined by the S^+ recoil owing to excess energy in the ionization step. This is about 18 m/s, (implying an energy resolution of ~60 cm^{-1} at the $v = 2$ peak) and is large enough that neighboring rotational levels will not be resolved.

The image was accumulated for 5.4×10^5 laser shots. In this case, it was not necessary to scan the probe laser wavelength owing to the small Doppler width of the transition and the relatively broad laser line width. The image magnification factor (1.157) was obtained from Simion simulations of the ion optics. These simulations were also found to give accurate reproduction of the focusing conditions and ion time-of-flight.

Results and discussion

Figure 2 shows a DC sliced image of the $S(^1D_2)$ photofragments from the photodissociation of OCS at 288 nm. The electric vector of the photolysis light is parallel to the vertical direction in the plane of the image. As can be seen in Fig. 2, four distinct rings are clearly visible with different intensities. All of the rings exhibit strong anisotropic angular distributions corresponding to a perpendicular transition, in which the transition dipole moment is perpendicular to the recoil direction. Thus, it is immediately apparent that the contribution from the $1^1A''(^1\Sigma^-)$ state, which is accessed through a perpendicular transition, is predominant. According to previous results by Suzuki and co-workers (9, 11), this observation can be interpreted more clearly from the result that the image of fast $S(^1D_2)$ photofragments changes from rather isotropic distribution ($\beta \sim 0$) to the anisotropic distribution ($\beta < 0$) corresponding to a perpendicular transition with changing photoexcitation wavelength from 223 to 248 nm. This implies that the contribution from the $2^1A'(^1\Delta)$ excited state in a mixed transition (9, 18) attributed to both $2^1A'(^1\Delta)$ and $1^1A''(^1\Sigma^-)$ excited states relatively decreases for decreasing excitation energy. In addition, although the bimodal distribution is still shown at 248 nm in the previous works, the contribution of the slow component corresponding to a non-adiabatic process through only the $2^1A'(^1\Delta)$ excited surface is considerably reduced due to the lowering of the excitation energy. These previous experimental investigations strongly suggest that the $2^1A'(^1\Delta)$ excited surface cannot be reached with a 288 nm photolysis wavelength because of insufficient energy. Our observed image is also consistent with this expectation, showing a predominantly perpendicular transition related to the exclusive excitation of the $1^1A''(^1\Sigma^-)$ excited state.

The available energy for our system is 151 cm^{-1} from energy conservation using the dissociation energy D_0 (0 K) of 25 311 ± 72 cm^{-1} recently reported by Janssen and co-workers (12), (this gave better results than scaling the NIST values (19) to 0 K), the spin-orbit energy of $S(^1D_2)$ (9239 cm^{-1}) (20) with respect to the ground state $S(^3P_2)$, and the photon energy at 288.18 nm. There is insufficient energy for vibrational excitation of $CO(X^1\Sigma^+)$ photofragments following dissociation at 288 nm. Given the low recoil energy and the rotationally cold starting sample, angular momentum considerations predict modest rotational excitation in the CO photoproduct, discussed further in the next section.

Fig. 2. DC sliced image of the $S(^1D_2)$ from the photodissociation of OCS at 288 nm. The probe laser polarization is aligned vertically in the plane of the image.

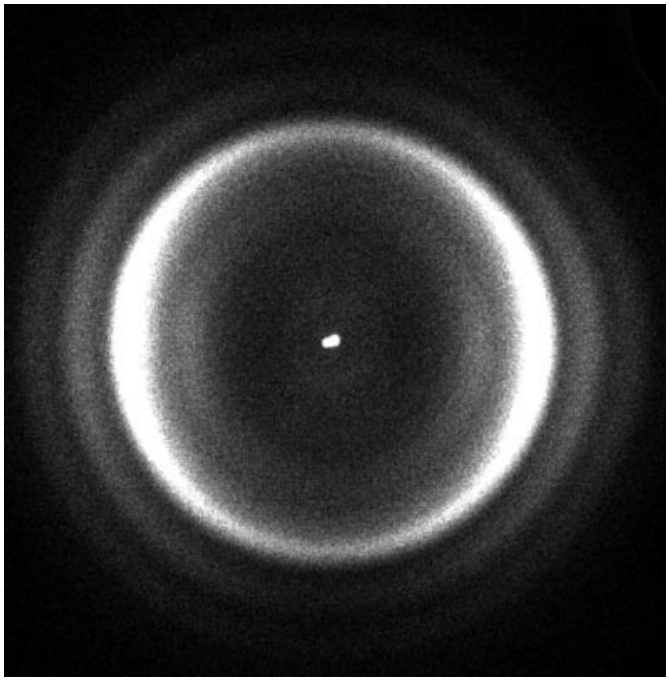

Figure 3(*a*) gives the translational energy distribution determined from the sliced image. The peaks in the distribution clearly correspond to a hot-band bending progression in the parent molecule, showing a maximum at two quanta initial excitation. If we assume no rotational excitation in the parent molecule, then the translational energy origins for the hot bands should be 151, 671, 1198, 1724, and 2257 cm^{-1} for $v_2 = 0$–4, respectively (21). The deviations of the peak maxima from these positions may be used to estimate (albeit crudely) the level of rotational excitation in the CO product. On this basis, we find the most probable J values for the CO product to be 8, 12, 13, and 14 for $v_2 = 1$–4, respectively. For the most intense peak ($v_2 = 2$), this implies an exit impact parameter of 0.43 Å. By way of comparison, Suzuki et al.'s results at 248 nm (9), show the product CO rotational distribution peaking at a roughly $J = 32$, corresponding to an exit impact parameter of 0.52 Å, in quite reasonable agreement with our determination. The increasing rotational excitation we observe with increasing hot-band excitation is a natural consequence of the increasing product orbital angular momentum (i.e., the increasing relative velocity between the photofragments).

These results show for the first time the contribution of the hot-band excitations up to $v_2 = 4$ in photodissociation originating from the different bending excited states of OCS parent molecules in a cold molecular beam. As seen in Table 1, the branching ratios for the contribution from the initial vibrational bending state of OCS were determined by the integration of each contribution obtained in Gaussian fits to the peaks, a somewhat arbitrary choice that nevertheless gave good fits to the resolved peaks. Our results clearly show that the absorption cross section for bend-excited OCS

to the $1^1A''(^1\Sigma^-)$ surface at 288 nm is greatly enhanced relative to the vibrationless molecule. If we assume a Boltzmann distribution to calculate the relative thermal populations for each excited vibrational bending state relative to ground state of OCS parent molecules at 298 K and 200 K (the actual vibrational temperature of the beam is not well known), the relative cross section ratio compared to the $v_2 = 1$ vibrational bending state can be simply estimated as given in Table 1. It should be noted that since the vibrational temperature is possibly much lower than the values used to calculate the relative thermal populations in this study, the relative cross section ratios here are a lower limit. Since the vibrational origin gives a negligible contribution to the translational energy release, we only indicate an upper bound for its relative population. In comparison, even though Katayanagi and Suzuki (11) reported the photodissociation cross section for $v_2 = 1$ is at least 7 times larger than that of $v_2 = 0$ at 230 nm excitation, our results indicate that the cross sections of hot bands from bending excited states of OCS are significantly enhanced at 288 nm excitation relative to that at 230 nm. It is likely owing to several key factors: the transition moment increases, as shown theoretically by Suzuki et al. (9); the energy gap between the two surfaces drops dramatically with the bend angle; and because the bending excitations of OCS parent molecules considerably increase Franck–Condon overlaps between the ground electronic state and excited states at the lower excitation energy region (10–12).

Also shown in Fig. 3 is the recoil speed dependence of the anisotropy parameter (β) for the $S(^1D_2)$ photofragments extracted by least-squares fit of the angular distribution with respect to recoil velocity with the following equation:

© 2004 NRC Canada

$$I(\theta) = \left(\frac{1}{4\pi}\right)[1 + \beta P_2(\cos\theta)]$$

where θ is the recoil angle relative to the electric vector of the dissociating laser beam, and P_2 is the second-order Legendre polynomial ($P_2(\cos\theta) = (3\cos^2\theta - 1)/2$). Although there is a possibility for orbital alignment in the $S(^1D_2)$ product to modulate the signals and add additional terms, in this "one-laser" experiment we cannot directly probe this phenomenon. However, inasmuch as our angular distributions fit quite well with these contributions omitted, we feel confident in neglecting this effect. The β values correlated with each ring of the sliced image are approximately in the range between –0.55 and –0.75, indicating a predominantly perpendicular transition. However, the magnitude of the anisotropy parameters are close to, but slightly lower than the theoretical limiting value of $\beta = -1$ anticipated for the case of a pure perpendicular transition. This kind of behavior may be rationalized in terms of the breakdown of the axial recoil approximation for near-threshold photodissociation (10, 22) or the partial contribution from the higher $2^1A'(^1\Delta)$ excited surface (11, 12). The latter can likely be ruled out from the previous result (12) that if both the $2^1A'(^1\Delta)$ and $1^1A''(^1\Sigma^-)$ excited states are simultaneously involved in dissociation, the β value should be largely dependent on the vibrational bending excitation of OCS because of the difference of the angle dependence of the transition dipole moment between two surfaces. According to the calculations of Suzuki et al. (9), the transition dipole moment of the $2^1A'(^1\Delta)$ state increases more steeply than that of the $1^1A''(^1\Sigma^-)$ state for the bending angle of OCS. In the most recent work (12), the average β values were 0.24 for $v_2 = 0$ and 0.71 for $v_2 = 1$ at 230 nm. The data presented here show that the β values do not change dramatically with each initial bending excitation for the 288 nm excitation. This provides further evidence that the photodissociation of OCS at 288 nm purely occurs from the $1^1A''(^1\Sigma^-)$ excited potential energy surface.

Conclusions

We have studied the photodissociation dynamics of OCS at 288 nm by applying the high-resolution DC slice imaging technique. The results obtained clearly showed that there are progressions up to $v_2 = 4$ in dissociation starting from the bend-excited vibrational states of OCS parent molecules in a cold molecular beam. Large negative anisotropy parameters suggest that the photodissociation of OCS at 288 nm purely occurs on the $1^1A''(^1\Sigma^-)$ bending excited potential surface that can be accessed through a perpendicular transition. DC slice imaging has been shown as a highly sensitive probe technique able to give more detailed information about the photodissociation dynamics.
