house elemental analysis services. In a very few cases, despite repeated analyses and the use of added oxidant, C analyses yielded deviations from calculated values. We attribute this to partial formation of Ti–C during combustion of the Ti-organometallic derivatives. Gel permeation chromatography (GPC) was performed employing a Waters 150C GPC using 1,2,4-trichlorobenzene as the mobile phase at 140 °C at NOVA Research and Technology Centre (Calgary, Alta.). The samples were prepared for GPC analyses by dissolving the polymer in the mobile-phase solvent in an external oven at 0.1% (*w*/*v*) and were filtered before injection. Molecular weights are expressed as polyethylene equivalents with a relative standard deviation of 2.9% and 5.0% for M_n and M_w, respectively. Reagent-grade solvents and NEt_3 were purchased from Aldrich Chemical Co. Benzene, toluene, and Et_2O were dried over Na, MeOH was dried over Mg, and NEt_3 was dried over KOH prior to distillation. C_6D_6 and CD_2Cl_2 were purchased from Cambridge Isotopes Laboratories (Andover, Mass.) and degassed by at least 4 freeze/pump/thaw cycles before storing over 4Å molecular sieves. The compounds R_2BnP and $R_2BnPNSiMe_3$ (Bn = benzyl; R = *t*-Bu, Cy) (35) and $CpTiCl_3$ (41) were prepared according to literature methods, and the phosphines were prepared via a modification of a literature procedure (36). The reagents MeMgBr, Me_3SiN_3, and *p*-$C_6H_4(CH_2Br)_2$ were purchased from Aldrich Chemical Co., and $HP(t\text{-}Bu)_2$, $HPCy_2$, and Cp^*TiCl_3 were purchased from Strem Chemical Co. (Newburyport, Mass.); all were used without further purification.

Synthesis of *p*-$C_6H_4(CH_2PR_2)_2$ (R = *t*-Bu, Cy)

Compounds **1** (R = *t*-Bu) and **2** (R = Cy) were prepared in a similar manner to a literature method for the related meta-substituted analogs (36). *p*-$C_6H_4(CH_2Br)_2$ (0.88 g, 3.3 mmol) was slurried in MeOH, and $HP(t\text{-}Bu)_2$ (1.08 g, 7.3 mmol) was added via syringe. The mixture was stirred at 25 °C for 16 h, during which time the mixture became a homogeneous solution. NEt_3 (0.74 g, 7.3 mmol) was added via syringe, and a fine white solid precipitated from solution. The solid was washed with MeOH (3 × 20 mL) and dried in vacuo for 5 h. A second crop was obtained by concentrating the mother liquor and precipitating the product with degassed water; no degradation in purity was evidenced by the ^1H NMR spectrum. Compound **1**: White solid. Yield 1.16 g (88%). ^1H NMR: 7.38 (s, 4H, C_6H_4), 2.73 (s, 4H, CH_2), 1.06 (d, 36H, J_{P-H} = 10 Hz, *t*-Bu). $^{13}C\{^1H\}$ NMR: 138.4 (s, C_6H_4), 130.1 (s, C_6H_4), 32.1 (d, J_{P-C} = 54 Hz, *t*-Bu), 30.1 (s, *t*-Bu), 29.0 (d, J_{P-C} = 48 Hz, CH_2). $^{31}P\{^1H\}$ NMR: 33.4 (s). Crystals suitable for X-ray diffraction were grown by slow evaporation from benzene. Anal. Calcd. for $C_{24}H_{44}P_2$: C 73.06, H 11.24; found: C 72.36, H 11.05. Compound **2**: White solid. Yield 4.23 g, 85%. ^1H NMR: 7.33 (s, 4H, C_6H_4), 2.72 (s, 4H, CH_2P), 1.80–1.51 (m, 18H, Cy), 1.25–1.12 (m, 26H, Cy). $^{13}C\{^1H\}$ NMR: 137.9 (s, C_6H_4), 129.7 (s, C_6H_4), 34.0 (d, J_{P-C} = 17 Hz, Cy), 30.3 (d, J_{P-C} = 14 Hz, CH_2P), 29.7 (d, J_{P-C} = 10 Hz, Cy), 27.6 (s, Cy), 26.9 (s, Cy). $^{31}P\{^1H\}$ NMR: 1.2 (s). Anal. Calcd. for $C_{32}H_{52}P_2$: C 77.07, H 10.51; found: C 76.42, H 10.68.

Synthesis of *p*-$C_6H_4(CH_2PR_2NSiMe_3)_2$ (R = *t*-Bu, Cy)

Compounds **3** (R = *t*-Bu) and **4** (R = Cy) were both prepared in a similar manner, and one sample preparation is detailed. Solid **1** (0.69 g, 1.7 mmol) and Me_3SiN_3 (1.00 g, 8.7 mmol) were combined to generate a slurry. The mixture was heated at reflux for 15 h, after which time the excess Me_3SiN_3 was removed in vacuo. The beige solid was crushed with a mortar and pestle into a fine powder, washed with hexanes (3 × 10 mL), and dried in vacuo for an additional 5 h. Compound **3**: Yield 0.88 g, 88%. Crystals suitable for X-ray diffraction were grown by slow evaporation from hexanes. ^1H NMR: 7.39 (s, 4H, C_6H_4), 2.73 (d, 4H, J_{P-H} = 10 Hz, CH_2), 0.99 (d, 36H, J_{P-H} = 13 Hz, *t*-Bu), 0.35 (s, 18H, Me). $^{13}C\{^1H\}$ NMR: 133.4 (s, C_6H_4), 130.4 (s, C_6H_4), 37.1 (d, J_{P-C} = 60 Hz, CH_2), 30.1 (d, J_{P-C} = 57 Hz, CH_2), 27.6 (s, *t*-Bu), 1.4 (s, Me_3). $^{31}P\{^1H\}$ NMR: 24.6 (s). Anal. Calcd. for $C_{30}H_{62}N_2P_2Si_2$: C 63.33, H 10.98, N 4.92; found: C 63.34, H 10.36, N 4.93. Compound **4**: Yield 2.77 g, 94%. ^1H NMR: 7.34 (s, 4H, C_6H_4), 2.67 (d, 4H, J_{P-H} = 12 Hz, CH_2P), 1.78–1.58 (m, 18H, Cy), 1.45–1.07 (m, 26H, Cy), 0.41 (s, 18H, Me). $^{13}C\{^1H\}$ NMR: 132.9 (s, C_6H_4), 130.1 (s, C_6H_4), 37.6 (d, J_{P-C} = 65 Hz, Cy), 33.7 (d, J_{P-C} = 60 Hz, CH_2P), 27.2 (d, J_{P-C} = 13 Hz, Cy), 26.5 (s, Cy), 26.2 (s, Cy), 5.2 (s, Me_3). $^{31}P\{^1H\}$ NMR: 13.5 (s). Anal. Calcd. for $C_{38}H_{70}N_2P_2Si_2$: C 67.81, H 10.48, N 4.16; found: C 68.08, H 10.85, N 3.89.

Synthesis of $(R_2BnPN)Cp'TiCl_2$ (Cp′ = Cp*, Cp; R = *t*-Bu, Cy)

Compounds **5** (Cp′ = Cp*; R = *t*-Bu), **6** (Cp′ = Cp*; R = Cy), **7** (Cp′ = Cp; R = *t*-Bu), and **8** (Cp′ = Cp; R = Cy) were all prepared in a similar manner, and thus only one preparation is detailed. Solid Cp^*TiCl_3 (1.12 g, 3.8 mmol) was dissolved in toluene (100 mL) to give a clear, red solution. Liquid $(t\text{-}Bu)_2BnPNSiMe_3$ (1.24 g, 3.8 mmol) was added dropwise at 25 °C, and the mixture was stirred for 24 h. The volatile products were removed in vacuo, and the bright orange solid was washed with hexanes (3 × 10 mL) and dried. Compound **5**: Yield 1.73 g, 91%. ^1H NMR: 7.39 (d, 2H, J_{H-H} = 8 Hz, C_6H_5), 7.19 (t, 2H, J_{H-H} = 8 Hz, Ph), 7.08 (t, 1H, J_{H-H} = 8 Hz, Ph), 2.92 (d, 2H, J_{P-H} = 12 Hz, CH_2), 2.21 (s, 15H, Cp*), 1.10 (d, 18H, J_{P-H} = 14 Hz, P*t*-Bu_2). $^{13}C\{^1H\}$ NMR: 140.8 (s, Ph), 131.2 (s, Ph), 128.7 (s, Ph), 127.1 (s, Ph), 125.9 (s, Cp*), 39.6 (d, J_{P-C} = 52 Hz, *t*-Bu), 30.9 (d, J_{P-C} = 48 Hz, CH_2), 27.8 (s, *t*-Bu), 13.1 (s, Cp*). $^{31}P\{^1H\}$ NMR: 35.3 (s). Anal. Calcd. for $C_{25}H_{40}Cl_2NPTi$: C 59.54, H 7.99, N 2.78; found: C 59.74, H 7.88, N 2.95. Crystals suitable for X-ray diffraction were grown by slow evaporation from benzene. Compound **6**: Bright orange solid. Yield 580 mg, 93%. ^1H NMR δ: 7.20 (d, 2H, $^3J_{H-H}$ = 8 Hz, Ph (*o*-H)), 7.15 (dd, 2H, $^3J_{H-H}$ = 8 Hz, Ph (*m*-H)), 7.04 (t, 1H, $^3J_{H-H}$ = 8 Hz, Ph (*p*-H)), 3.01 (d, 2H, $^2J_{P-H}$ = 14 Hz, CH_2P), 2.20 (s, 15H, Cp*), 1.71–0.96 (m, 22H, Cy). $^{13}C\{^1H\}$ NMR δ: 132.6 (d, $^2J_{P-C}$ = 7 Hz, Ph (*ipso*-C)), 130.5 (d, $^3J_{P-C}$ = 5 Hz, Ph (*o*-C)), 128.9 (s, Ph (*m*-C)), 127.2 (s, Ph (*p*-C)), 125.9 (s, Cp*), 37.2 (d, $^1J_{P-C}$ = 59 Hz, Cy (*ipso*-C)), 32.2 (d, $^1J_{P-C}$ = 52 Hz, CH_2P), 26.8 (d, $^2J_{P-C}$ = 12 Hz, Cy (*o*-C)), 26.7 (d, $^2J_{P-C}$ = 12 Hz, Cy (*o*-C)), 26.1 (s, Cy (*m*-C)), 26.0 (s, Cy (*p*-C)), 13.2 (s, Cp*). $^{31}P\{^1H\}$ NMR δ: 23.0 (s). $^{31}P\{^{1}H\}$ NMR (121.5 MHz, C_6D_6) δ: 21.6 (s). Anal. Calcd. for $C_{22}H_{36}NPTi$: C 67.17, H 9.22, N 3.56; found: C 67.09, H 9.03, N 3.02. Compound **16**: Beige solid. Yield 230 mg, 46%. ^{1}H NMR δ: 7.33 (d, 2H, $^{3}J_{H-H}$ = 8 Hz, Ph (*o*-H)), 7.18 (dd, 2H, $^{3}J_{H-H}$ = 8 Hz, Ph (*m*-H)), 7.06 (t, 1H, $^{3}J_{H-H}$ = 8 Hz, Ph (*p*-H)), 6.18 (s, 5H, Cp), 2.71 (d, 2H, $^{2}J_{P-H}$ = 13 Hz, CH_2P), 1.62–0.98 (m, 22H, Cy), 0.73 (s, 6H, TiMe). $^{13}C\{^{1}H\}$ NMR δ: 133.5 (d, $^{2}J_{P-C}$ = 7 Hz, Ph (*ipso*-C)), 130.5 (d, $^{3}J_{P-C}$ = 5 Hz, Ph (*o*-C)), 128.5 (s, Ph (*m*-C)), 127.0 (s, Ph (*p*-C)), 110.8 (s, Cp), 40.7 (s, TiMe), 37.6 (d, $^{1}J_{P-C}$ = 60 Hz, Cy (*ipso*-C)), 32.9 (d, $^{1}J_{P-C}$ = 53 Hz, CH_2P), 26.8 (d, $^{2}J_{P-C}$ = 12 Hz, Cy (*o*-C)), 26.3 (s, Cy (*p*-C)), 26.0 (d, $^{3}J_{P-C}$ = 8 Hz, Cy (*m*-C)). $^{31}P\{^{1}H\}$ NMR δ: 10.2 (s). Anal. Calcd. for $C_{26}H_{40}NPTi$: C 70.11, H 9.05, N 3.14; found: C 69.03, H 9.20, N 3.08. Yellow crystals suitable for X-ray diffraction were grown by slow evaporation from pentanes.

Synthesis of *p*-$C_6H_4(CH_2PR_2NTiCp'Me_2)_2$ (Cp′ = Cp*, Cp; R = *t*-Bu, Cy)

Compounds **17** (Cp′ = Cp*; R = *t*-Bu), **18** (Cp′ = Cp*; R = Cy), **19** (Cp′ = Cp; R = *t*-Bu), and **20** (Cp′ = Cp; R = Cy) were all prepared in a similar manner and one sample preparation is detailed. Compound **5** (0.21 g, 0.27 mmol) was slurried in Et_2O (25 mL), and a solution of MeMgBr in the same solvent (1.4 mmol) was added dropwise via syringe at 25 °C. The heterogeneous solution was stirred for 15 h, after which time the solvent was removed in vacuo. Extraction with hexanes (3 × 10 mL) and filtration through Hyflo Super Cel® afforded a colorless liquid. Removal of the solvent in vacuo generated a white solid. The yield increased when extraction was performed with toluene. Compound **17**: Yield 0.23 g, 77%. ^{1}H NMR: 7.50 (s, 4H, C_6H_4), 2.96 (d, 4H, J_{P-H} = 11 Hz, CH_2), 2.12 (s, 30H, Cp*), 1.17 (d, 36H, J_{P-H} = 14 Hz, *t*-Bu), 0.46 (s, 12H, TiMe). $^{13}C\{^{1}H\}$ NMR: 133.4 (s, C_6H_4), 130.8 (s, C_6H_4), 118.4 (s, Cp*), 44.4 (s, TiMe), 38.9 (d, J_{P-C} = 54 Hz, *t*-Bu), 31.6 (d, J_{P-C} = 48 Hz, CH_2), 28.0 (s, *t*-Bu), 12.3 (s, Cp*). $^{31}P\{^{1}H\}$ NMR: 22.0 (s). Anal. Calcd. for $C_{48}H_{86}N_2P_2Ti_2$: C 67.91, H 10.21, N 3.30; found: 67.51, H 9.96, N. 2.95. Compound **18**: White solid. Yield 0.41 g, 73%. ^{1}H NMR: 7.35 (s, 4H, C_6H_4), 2.92 (d, 4H, J_{P-H} = 13 Hz, CH_2P), 2.10 (s, 30H, Cp*), 1.81–1.10 (m, 44H, Cy), 0.43 (s, 12H, TiMe). $^{13}C\{^{1}H\}$ NMR: 132.5 (s, C_6H_4), 130.5 (s, C_6H_4), 122.3 (s, Cp*), 42.7 (s, TiMe), 38.2 (d, J_{P-C} = 61 Hz, Cy), 34.0 (d, J_{P-C} = 52 Hz, CH_2P), 27.1 (d, J_{P-C} = 12 Hz, Cy), 26.5 (d, J_{P-C} = 6 Hz, Cy), 26.4 (s, Cy), 11.9 (s, Cp*). $^{31}P\{^{1}H\}$ NMR: 8.0 (s). Anal. Calcd. for $C_{54}H_{94}N_2P_2Ti_2$: C 69.81, H, 10.20, N 3.02; found: 69.56, H, 9.94, N 2.94. **19**: Colorless block crystals. Yield 0.16 g, 83%. ^{1}H NMR: 7.48 (s, 4H, C_6H_4), 6.18 (s, 10H, Cp), 2.80 (d, 4H, J_{P-H} = 10 Hz, CH_2P), 1.06 (d, 36H, J_{P-H} = 14 Hz, *t*-Bu), 0.72 (s, 12H, TiMe). $^{13}C\{^{1}H\}$ NMR: 132.5 (s, C_6H_4), 130.8 (s, C_6H_4), 110.9 (s, Cp), 41.3 (s, CH_2P), 38.4 (d, J_{P-C} = 54 Hz, *t*-Bu), 31.7 (s, TiMe), 27.4 (s, *t*-Bu). $^{31}P\{^{1}H\}$ NMR: 22.6 (s). Anal. Calcd. for $C_{38}H_{66}N_2P_2Ti_2$: C 64.41, H 9.39, N 3.95; found: C 64.15, H 9.39, N 3.47. Crystals suitable for X-ray diffraction were grown by slow evaporation from toluene. Compound **20**: White solid. Yield 0.45 g, 77%. ^{1}H NMR δ: 7.48 (s, 4H, C_6H_4), 6.22 (s, 10H, Cp), 2.70 (d, 4H, J_{P-H} = 12 Hz, CH_2P), 1.65–1.06 (m, 44H, Cy), 0.74 (s, 12H, TiMe). $^{13}C\{^{1}H\}$ NMR: 132.1 (s, C_6H_4), 130.6 (s, C_6H_4), 110.8 (s, Cp), 40.8 (s, TiMe), 37.6 (d, J_{P-C} = 60 Hz, Cy), 32.4 (d, J_{P-C} = 53 Hz, CH_2P), 26.9 (d, J_{P-C} = 12 Hz, Cy), 26.3 (s, Cy), 26.1 (s, Cy). $^{31}P\{^{1}H\}$ NMR: 10.1 (s). Anal. Calcd. for $C_{52}H_{80}N_2P_2Ti_2$: C 70.10, H 9.05, N 3.14; found: C 70.30, H 9.45, N 3.06. Crystals suitable for X-ray diffraction were grown by slow evaporation from benzene.

Polymerization protocol

Two protocols were employed. In the first, a Schlenk flask was charged with toluene (50 mL) and MAO (1000 equiv., 10% in toluene), and the solution was presaturated with the monomer by briefly evacuating/backfilling (4×) and then stirring under an atmosphere of C_2H_4 for 5 min. A toluene, solution of the catalyst precursor (350 μmol) was injected, and the mixture was stirred at 25 °C for 30 min. The reaction was quenched with 1 mol/L HCl in MeOH, and the precipitated polymer was subsequently washed with HCl, HCl/MeOH, and toluene before drying at 50 °C for at least 48 h prior to weighing. In the second protocol, a 1-L Buchi reactor was dried in vacuo (10^{-2} mm Hg (1 mm Hg = 133.322 Pa)) for several hours. Toluene (500 mL) was transferred into the vessel under a positive pressure of N_2 and was heated to 30°C. The temperature was controlled (to ca. ±2 °C) with an external heating/cooling bath and was monitored by a thermocouple that extended into the polymerization vessel. The vessel was vented of N_2 and then pressurized with C_2H_4 (12 psig) while the solvent stirred at a rate of 150 rpm. A solution of MAO (1000 equiv., 10% in toluene) was injected and the mixture was stirred for 5 min. A toluene solution, of the precatalyst (50 μmol) was injected, the rate of stirring was increased to 1000 rpm, and the solution was stirred for 30 min. Any recorded exotherm was within the allowed temperature differential of the heating/cooling system. The quenching of the reaction and the collection/treatment of the polymer were as described above.

X-ray data collection and reduction

Crystals were manipulated and mounted in capillaries in a glove box, thus maintaining a dry, O_2-free environment for each crystal. Diffraction experiments were performed on a Siemens SMART System CCD diffractometer. The data were collected in a hemisphere of data in 1329 frames with 10-s exposure times. The observed extinctions were consistent with the space groups in each case. The data sets were collected ($4.5° < 2\theta < 45–50.0°$). A measure of decay was obtained by re-collecting the first 50 frames of each data set. The intensities of reflections within these frames showed no statistically significant change over the duration of the data collections. The data were processed using the SAINT and XPREP processing packages (Bruker AXS, Madison, Wis.). An empirical absorption correction based on redundant data was applied to each data set. Subsequent solution and refinement was performed using the SHELXTL solution package (Bruker AXS, Madison, Wis.).

Structure solution and refinement

Non-hydrogen atomic scattering factors were taken from the literature tabulations (42). The heavy-atom positions were determined using direct methods employing the SHELXTL direct methods routine. The remaining non-hydrogen atoms were located from successive difference

© 2004 NRC Canada

Fourier map calculations. The refinements were carried out by using full-matrix least-squares techniques on F^2, minimizing the function $\omega(|F_o| - |F_c|)^2$, where the weight ω is defined as $4F_o^2/2\sigma(F_o^2)$, and F_o and F_c are the observed and calculated structure factor amplitudes. In the final cycles of each refinement, all non-hydrogen atoms were assigned anisotropic temperature factors in the absence of disorder or insufficient data. In the latter cases, atoms were treated isotropically. C-H atom positions were calculated, and the hydrogens were allowed to ride on the carbon to which they are bonded assuming a C–H bond length of 0.95 Å. H-atom temperature factors were fixed at 1.10 times the isotropic temperature factor of the C-atom to which the hydrogens are bonded. The H-atom contributions were calculated but not refined. The locations of the largest peaks in the final difference Fourier map calculation as well as the magnitude of the residual electron densities in each case were of no chemical significance. Details are provided in Table 1 and the supplementary data.

A facile synthesis of 3,4-dialkyl-3,4-dihydro-2*H*-1,3-benzoxazin-2-ones and naphthoxazin-2-ones and their reactions with organolithium and Grignard reagents — Preparation of *N*-[1-(2′-hydroxyphenyl)alkyl]amides

Cristina Cimarelli, Gianni Palmieri, and Emanuela Volpini

Abstract: A facile and simple method for the preparation of 3,4-dialkyl-3,4-dihydro-2*H*-1,3-benzoxazin-2-ones or naphthoxazin-2-ones in high yields from aminoalkylphenols and aminoalkylnaphthols is described. The reactions of the products obtained with organolithium and Grignard reagents were studied, and a method for the preparation of *N*-[1-(2-hydroxyphenyl)alkyl]-*N*-alkylamides, which are of pharmaceutical interest, from benzoxazinones was developed. A possible reaction mechanism is also proposed. The relative configuration of chiral products was determined from conformational analysis of ^{1}H NMR spectra.

Key words: benzoxazinones, naphthoxazinones, organometallic reagents, amide preparation, aminoalkylphenols.

Résumé : On décrit une méthode simple et efficace de préparer avec des rendements élevés des 3,4-dialkyl-3,4-dihydro-2*H*-1,3-benzoxazin-2-ones ou naphtoxazin-2-ones à partir d'aminoalkylphénols ou d'aminoalkylnaphtols. On a étudié les réactions des produits avec les réactifs de Grignard et les organolithiens et on a mis au point une méthode de préparation de *N*-[1-(2-hydroxyphényl)alkyl]-*N*-alkylamides, des produits présentant un intérêt pharmaceutique, à partir de benzoxazinones. On propose une hypothèse de mécanisme réactionnel. La configuration relative des produits chiraux a été déterminée par une analyse conformationnelle appliquée aux spectres de résonance magnétique du proton.

Mots clés : benzoxazinones, naphtoxazinones, réactifs organométalliques, préparation d'amides, aminoalkylphénols.

[Traduit par la Rédaction]

Introduction

3,4-Dialkyl-3,4-dihydro-2*H*-1,3-benzoxazin-2-ones are a class of compounds studied because of their diverse biological properties as potential antimicrobial agents (1), as anti-inflammatory agents (2), as acetylcholinesterase inhibitors (3), and as analgesics, bactericides, and muscle relaxants (4). At the same time they are also known to originate from the photodegradation of pesticides such as ethiofencarb (5). Several synthesis methods for benzoxazinones have been reported in the literature (4, 6–9). All of these methods suffer from the same drawbacks, specifically the use of toxic solvents (benzene) or reagents (carbamyl chlorides, isocyanates, phosgene), or they require a two-step synthesis sequence.

On the other hand, 3,4-dialkyl-3,4-dihydro-2*H*-1,3-naphthoxazin-2-ones are known in the literature (10) for their activity against several bacterial species, and they have also been used as precursors in the preparation of phosphinic ligands for asymmetric catalysis (11); however, only very few methods for their preparation have been reported (10, 12).

Recently, we became interested in the synthesis of aminoalkylphenols (13) and aminoalkylnaphthols (14), two classes of compounds studied for their pharmaceutical properties (15) but also widely used as ligands in ligand-accelerated catalysis (LAC) (16), in particular in the asymmetric catalyzed addition of organozinc reagents to aldehydes (17). We have developed a series of synthetic procedures that lead to aminoalkylphenols and aminoalkylnaphthols in a simple and straightforward way.

Now we wish to report a new, direct, and mild method for the preparation of 3,4-disubstituted 3,4-dihydro-2*H*-1,3-benzoxazin-2-ones and naphthoxazin-2-ones that we have developed using aminoalkylphenols and aminoalkylnaphthols as precursors. Moreover, the results of the study of the reactions of these compounds with alkyllithium and Grignard reagents and a method for the preparation of *N*-[1-(2-hydroxyphenyl)alkyl]amides and of the corresponding naphthyl derivatives, which are known for their pharmaceutical properties (10, 18), are described.

Scheme 2.

methane, in the presence of dimethylaminopyridine (DMAP) (19), produce the desired 3,4-dialkyl-3,4-dihydro-2*H*-1,3-benzoxazin-2-ones (**2**) (Scheme 1) and naphthoxazin-2-ones (**5**) (Scheme 2), respectively, in reasonable reaction times and in good yields. This procedure allows the one-step preparation of cyclized products in a mild and straightforward way. It is very simple and quick and does not require dangerous or expensive chemicals. Moreover, when the reaction is complete, simple filtration of the reaction mixture on a thin pad of silica gel provides a quick and easy method for obtaining a high yield of purified product. The silica gel isolates the excess carbonyldiimidazole and DMAP and the basic by-products. The absolute configuration of chiral centres remains unaltered under these reaction conditions. The results obtained for several aminoalkylphenols and aminoalkylnaphthols are reported in Tables 1 and 2, respectively.

Cyclization with carbonyldiimidazole was previously reported in the literature (22) for the preparation of 1-benzyl-4-(2-oxo-3,4-dihydro-2*H*-1,3-benzoxazine-3-yl)piperidine from 1-benzyl-4-(2-hydroxyphenylmethyl)aminopiperidine, a product unsubstituted at the C-4 carbon atom. The described methodology, without DMAP, requires heating of the reaction mixture in THF to reflux and a longer reaction time.

The reactivity of the synthesized 3,4-dialkyl-3,4-dihydro-2*H*-1,3-benzoxazin-2-ones (**2**) towards organometallic reagents has been studied, in particular with alkyllithium and Grignard reagents. 3,4-Dialkyl-3,4-dihydro-2*H*-1,3-benzoxazin-2-ones (**2**) react with organolithiums at 0 °C in toluene in reasonable times and give satisfactory yields of *N*-[1-(2-hydroxyphenyl)alkyl]-*N*-alkylamides (**3**) (Scheme 3). Naphthoxazin-2-one (**5a**), under the same reaction conditions, reacts with *n*-butyllithium to afford the corresponding amide **(6ab)** but only in poor yield (28%). The reaction gives satisfactory yields with methyllithium, isopropyllithium, *n*-butyllithium, and phenyllithium. Only allyl- and benzyl-Grignard reagents are reactive towards the substrates studied, while MeMgBr and PhMgCl are nonreactive.

Alkyllithiums and Grignard reagents have been used in a slight excess (10%) with respect to the starting material. With a large excess, the double addition of organometallic

Scheme 3.

reagent to the carbonyl group of the starting benzoxazinone is observed, and the reaction produces the original aminoalkylphenol **1** and the corresponding symmetric ketone. In fact, GC–MS analysis of the crude mixtures of the reactions of **2b**, **2h**, and **2e** with 2.5 equiv. of phenyllithium and butyllithium reveals the chromatographic peaks and mass spectra of aminoalkylphenols **1b**, **1h**, and **1e** and of dibutylketone and benzophenone.

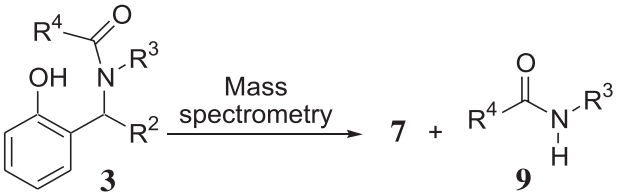
[b](*l*) = like (*RR*, *SS*); (*u*) = unlike (*RS*, *SR*).

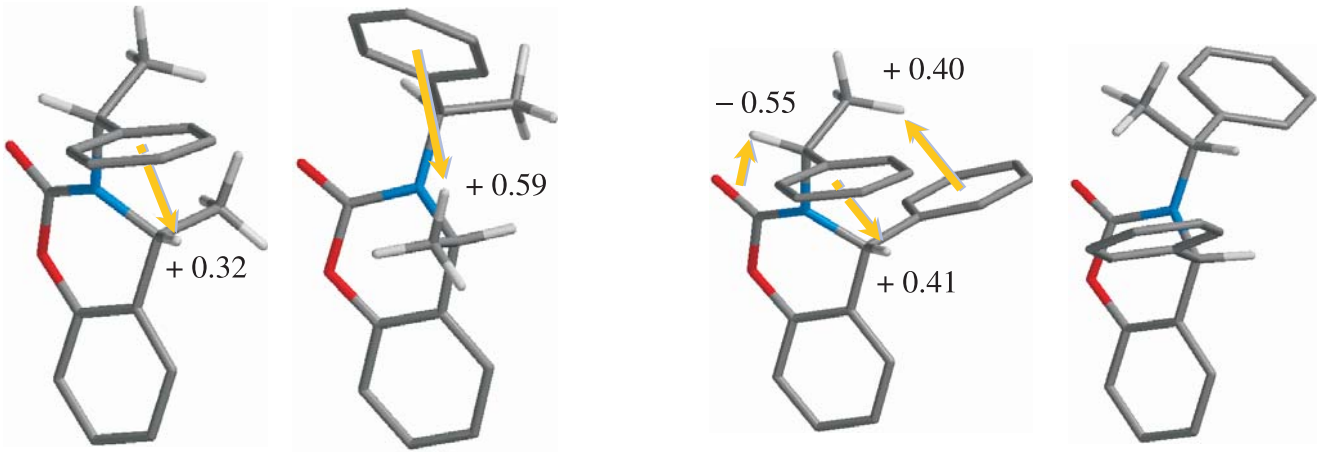


In several cases the reaction proceeds with comparable results in *n*-hexane, but when the starting materials are poorly soluble in this solvent, toluene gave the best results. The results obtained in the reactions of benzoxazinones **2b**, **2d**, **2e**, **2h**, and **2i** with some organolithiums and Grignard reagents are reported in Table 3.

A hypothesized mechanism for these reactions is presented in Scheme 4. Moreover, it is possible to make some observations for the behaviour of these compounds when they are subjected to GC–MS analysis. Within the mass spectra of pure benzoxazinones **2b** and **2e**, we observed the fragmentation pattern corresponding to the enone **7** and the isocyanate **8**, as depicted in Scheme 5. In a similar fashion, in 1,4-dihydro-2*H*-3,1-benzoxazin-2-one derivatives, under flash vacuum pyrolysis conditions, CO_2 extrusion was observed (23). Naphthoxazinones **5** under the same conditions decompose during the gas chromatographic analysis to give a complex mixture of unidentified products. The final amide **3** decomposes in a similar way, and it is possible to observe in the mass spectra the peaks corresponding to the enone **7**

Scheme 5.

Scheme 6.



and the amide **9**, as depicted in Scheme 6 for **3bb**, **3db**, **3bd**, **3bf**, and **3eb**.

Stereochemistry

The relative configurations of benzoxazinones and naphthoxazinones were assigned by analogy with the chiral starting aminophenols. To confirm that cyclization took place with retention of configuration, the stereochemistry of the prepared oxazinones was confirmed by conformational analysis on the diastereomeric couples (*R*,*R*)-**2c**/(4*S*,1*R*)-**2c** and (*R*,*R*)-**2i**/(4*S*,1*R*)-**2i**. The more stable conformations for (*R*,*R*)- and (4*S*,1′*R*)-**2c** and (*R*,*R*)- and (4*S*,1′*R*)-**2i**, obtained by PM3 semi-empirical minimization, are reported in Fig. 1. A comparison of the differences in ^{1}H NMR chemical shifts ($\Delta\delta$) observed for the diastereomeric couples, resulting from the anisotropic effects of the phenyl and carbonyl groups, as indicated in Fig. 1, allowed us to assign relative configurations.

Experimental

General methods

Proton and ^{13}C NMR spectra were recorded with a Varian VXR 300 instrument. Chemical shifts are given in ppm downfield from Me_4Si in $CDCl_3$ solution. Coupling constants are given in Hz. IR spectra were recorded with a Perkin-Elmer 257 spectrometer. GC–MS analyses were performed with a HP-59970 workstation consisting of a HP-5890 gas chromatograph equipped with a methyl silicone capillary column and a HP-5970 mass detector. All melting points are uncorrected. Toluene and hexane were dried by refluxing over sodium wires and then distilled into a dry receiver under a nitrogen atmosphere. All reagents were of commercial quality from freshly opened containers. Commercial alkyllithium and Grignard reagent solutions (Aldrich) were used in a dry atmosphere.

Preparation of starting aminoalkylphenols 1a–1i and aminoalkylnaphthols 4a–4e

Starting aminoalkylphenols and aminoalkylnaphthols were prepared according to previously reported procedures (11) using (±)-phenylethylamine as the chiral starting material instead of the (*R*) enantiomer. Spectral data for the unknown starting materials **1e, 1f**, **1j**, and **1k** follow.

2-[1-(Methylamino)pentyl]phenol (1e)

Yield 98%. Oil. IR ν_{max} (liquid film) (cm^{-1}): 2950, 2836, 1482, 1447, and 1270. ^{1}H NMR ($CDCl_3$) δ: 0.89 (t, 3H, *J* = 6.6 Hz), 1.10–1.50 (m, 4H), 1.60 (bs, 1H), 1.60–1.90 (m, 2H), 2.43 (s, 3H), 3.61 (t, 1H, *J* = 7.0 Hz), 6.70–7.30 (m, 4 H), and 9.00 (s, 1H). Anal. calcd. (%) for $C_{12}H_{19}NO$, MW 193.288: C 74.45, H 9.91, N 7.25; found: C 74.56, H 10.04, N 7.27.

2-[1-(Benzylamino)pentyl]phenol (1f)

Yield 80%. Oil. IR ν_{max} (liquid film) (cm^{-1}): 2968, 2943, 2870, 1527, 1488, and 1243. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 0.83 (t, 3H, *J* = 7.0 Hz), 1.09–1.34 (m, 4H), 1.62–1.85 (m, 3H), 3.60 (d, 1H, *J* = 12.8 Hz), 3.74 (t, 1H, *J* = 7.2 Hz), 3.83 (d, 1H, *J* = 12.8 Hz), 6.80–7.20 (m, 9H), and 13.40 (bs, 1H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 13.9, 22.6, 28.4, 35.7, 51.8, 63.6, 116.8, 118.9, 127.5, 128.4, 128.5, 128.7, 129.2, 132.4, 157.4, and 165.6. Anal. calcd. (%) for $C_{18}H_{23}NO$, MW 269.386: C 80.26, H 8.61, N 5.20; found: C 80.21, H 8.86, N 5.37.

2-[1-(Methylamino)-1-phenylethyl]phenol (1j)

Yield 91%. Oil. IR ν_{max} (liquid film) (cm^{-1}): 3308, 2981, 1494, 1262, 820, 754, and 720. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.86 (s, 3H), 2.29 (s, 3H), 2.65 (s, 1H), 6.66–7.44 (m, 9H), and 12.30 (s, 1H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 24.6, 28.9, 64.7, 117.4, 118.8, 126.7, 127.5, 128.5, 128.6, 129.1, 129.8, 144.7, and 158.3. Anal. calcd. (%) for $C_{15}H_{17}NO$, MW 227.30: C 79.26, H 7.54, N 6.16; found: C 79.48, H 7.32, N 6.27.

2-[1-(Benzylamino)-1-phenylpentyl]phenol (1k)

Yield 84%. Oil. IR ν_{max} (liquid film) (cm^{-1}): 2954, 1606, 1455, 1295, 753, and 699. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 0.99 (t, 3H, *J* = 7.0 Hz), 1.20–1.60 (m, 4H), 2.30–2.70 (m, 3H), 3.62 (bs, 2H), 6.70–7.70 (m, 14H), and 12.20 (bs, 1H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 14.4, 23.3, 25.4, 36.1, 47.0, 55.8, 117.5, 118.9, 126.7, 127.1, 128.0, 128.4, 129.0, 129.1, 129.2, 139.0, 143.8, 158.1, 163.5, and 175.1. Anal. calcd. (%) for $C_{24}H_{27}NO$, MW 345.48: C 83.44, H 7.88, N 4.05; found: C 83.30, H 7.57, N 4.23.

Preparation of benzoxazinones 2a–2k and naphthoxazinones 5a–5e

Aminoalkylphenols **1b**–**1i** (2 mmol) or aminoalkylnaphthols **3a**–**3e** (2 mmol), in a 50-mL round-bottom flask equipped with a magnetic stirring bar, were dissolved in 10 mL CH_2Cl_2 at room temperature (RT) to which was added DMAP (0.2 mmol) and carbonyldiimidazole (3 mmol). The reaction mixture was allowed to stand at RT for 1 h and then the mixture was filtered on a thin pad of silica gel, affording almost pure **2a**–**2k** or **5a**–**5e.** When necessary, the final benzoxazinones or naphthoxazinones were purified further by recrystallization or chromatographic separation.

Spectral data for the products obtained follow. In the numerical designations of the compounds below, the prefixes *(l)* and *(u)* mean *like* (*RR*, *SS*) and *unlike* (*RS*, *SR*), respectively.

3-(1′-Phenylethyl)-3,4-dihydro-1,3-benzo[e][1,3]oxazin-2-one (2a)

White crystals; mp 98–100 °C (*n*-hexane/CH_2Cl_2). IR ν_{max} (Nujol) (cm^{-1}): 2930, 1712, 1500, 1415, 1238, 797, and 734. ^1H NMR (300 MHz, $CDCl_3$) δ: 1.68 (d, 3H, *J* = 7.0 Hz), 3.91 (d, 1H, *J* = 14.3 Hz), 4.30 (d, 1H, *J* = 14.6 Hz), 5.92 (q, 1H, *J* = 7.2 Hz), and 6.95–7.43 (m, 9H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 15.2, 41.3, 53.8, 116.3, 117.8, 124.3, 125.7, 127.6, 128.1, 128.9, 129.0, 138.8, 149.7, and 151.3. MS (EI) *m/z* (%): 253 (M^+, 10), 148 (7), 105 (100), and 77 (18). Anal. calcd. (%) for $C_{16}H_{15}NO_2$, MW 253.30: C 75.87, H 5.97, N 5.53; found: C 75.92, H 6.21, N 5.79.

3-Benzyl-4-methyl-3,4-dihydro-1,3-benzo[e][1,3]oxazin-2-one (2b)

White crystals; mp 110–112 °C (*n*-hexane). IR ν_{max} (Nujol) (cm^{-1}): 2924, 1709, 1497, 1423, 1371, 1253, 761, and 746. ^1H NMR (300 MHz, $CDCl_3$) δ: 1.44 (d, 3H, *J* = 6.6 Hz), 4.28 (d, 1H, *J* = 15.4 Hz), 4.39 (q, 1H, *J* = 6.6 Hz), 5.26 (d, 1H, *J* = 15.4 Hz), and 7.00–7.50 (m, 9H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 22.5, 50.1, 52.9, 116.7, 124.1, 124.5, 125.4, 128.1, 128.2, 129.0, 129.1, 136.2, 149.4, and 151.8. MS (EI) *m/z* (%): 253 (M^+, 9), 238 (20), 162 (11), 120 (48), and 91 (100). Anal. calcd. (%) for $C_{16}H_{15}NO_2$, MW 253.30: C 75.87, H 5.97, N 5.53; found: C 75.78, H 5.90, N 5.64.

(l)-(±)-4-Methyl-3-(1′-phenylethyl)-3,4-dihydro-1,3-benzo[e][1,3]oxazin-2-one ((l)-2c)

Oil. IR ν_{max} (liquid film) (cm^{-1}): 2932, 1715, 1503, 1423, 1369, 1248, 760, and 744. ^1H NMR (300 MHz, $CDCl_3$) δ: 1.43 (d, 3H, *J* = 6.6 Hz), 1.81 (d, 3H, *J* = 7.3 Hz), 4.15 (q, 1H, *J* = 6.6 Hz), 5.65 (q, 1H, *J* = 7.0 Hz), and 7.00–7.60 (m, 9H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 18.4, 29.9, 50.5, 55.7, 116.6, 124.4, 124.5, 126.5, 127.5, 128.0, 128.7, 128.9, 139.6, 149.8, and 152.2. Anal. calcd. (%) for $C_{17}H_{17}NO_2$, MW 267.322: C 76.38, H 6.41, N 5.24; found: C 76.29, H 6.54, N 5.18.

(u)-(±)-4-Methyl-3-(1′-phenylethyl)-3,4-dihydro-1,3-benzo[e][1,3]oxazin-2-one ((u)-2c)

Oil. IR ν_{max} (liquid film) (cm^{-1}): 2930, 1712, 1428, 1243, 763, and 748. ^1H NMR (300 MHz, $CDCl_3$) δ: 0.83 (d, 3H, *J* = 6.6 Hz), 1.66 (d, 3H, *J* = 7.0 Hz), 4.47 (q, 1H, *J* = 6.6 Hz), 5.70 (q, 1H, *J* = 7.1 Hz), and 7.00–7.60 (m, 9H). Reaction of oxazinones 2b, 2d, 2e, 2h, 2i, and 5a with organolithiums and Grignard reagents

Oxazinones **2** or **5** (3 mmol) in a three-necked round-bottom flask, equipped with a magnetic stirring bar and rub-

© 2004 NRC Canada

ber septum, were dissolved in anhydrous toluene (10 mL) under a nitrogen atmosphere at 0 °C and were then treated with 3.3 mmol of a commercial solution of alkyllithium or Grignard reagent. The reaction was monitored by TLC using *n*-hexane/ethyl acetate (80/20) as an eluent. After a variable time (2–3 h) at RT, when the starting material was consumed, the reaction was quenched with a NH_4Cl saturated solution (5 mL) and the brine was extracted with CH_2Cl_2 (2 × 20 mL). The solution was dried with anhydrous Na_2SO_4 then filtered, and the solvent was evaporated under reduced pressure. Chromatographic separation of the crude oil obtained, with cyclohexane/ethyl acetate (80/20) as an eluent afforded products **3** and **6** in yields of 28% and 90%, respectively. Spectral data follow.

N-*Benzyl*-N-*[1-(2-hydroxyphenyl)ethyl]acetamide (3ba)

Oil. IR ν_{max} (liquid film) (cm^{-1}): 3138, 2966, 1630, 1484, 1445, 1223, and 758. ^1H NMR (300 MHz, $CDCl_3$) δ: 1.49 (d, 3H, *J* = 7.1 Hz), 2.04 (s, 3H), 4.47 (s, 2H), 6.11 (q, 1H, *J* = 7.1 Hz), 6.80–7.40 (m, 9H), and 9.20 (bs, 1H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 17.4, 22.5, 27.1, 47.3, 47.5, 117.9, 119.6, 125.9, 126.8, 127.6, 129.1, 129.8, 137.4, 156.0, and 174.9. Anal. calcd. (%) for $C_{17}H_{19}NO_2$, MW 269.34: C 75.81, H 7.11, N 5.20; found: C 75.58, H 7.38, N 5.32.

N-*Benzyl*-N-*[1-(2-hydroxyphenyl)ethyl]pentanamide (3bb)

Oil. A simple synthesis of benzimidazole *N*-oxides from 2-nitroaniline derivatives — Scope and limitations

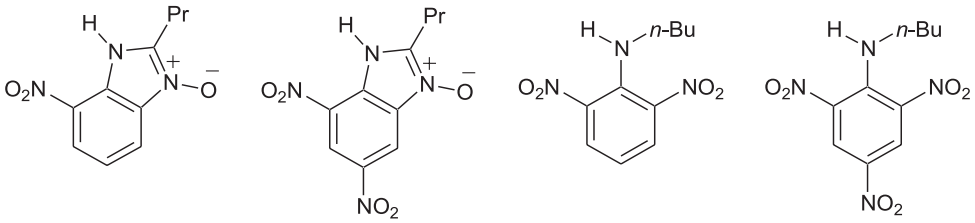
Elba I. Buján and María Laura Salum

Abstract: Several benzimidazole *N*-oxide derivatives were synthesized in very good yield by heating at reflux the corresponding *N*-alkyl-2-nitroaniline derivative with NaOH in 60% 1,4-dioxane–water. The effect of substituents on the aromatic ring and amino group on the reaction is discussed.

Key words: synthesis, benzimidazole *N*-oxides.

Résumé : On a réalisé la synthèse de plusieurs dérivés de *N*-oxydes de benzimidazole avec de très bons rendements en chauffant au reflux le dérivé *N*-alkyl-2-nitroaniline correspondant avec du NaOH dans un mélange à 60 % de 1,4-dioxane/eau. On discute de l'effet sur la réaction des substituants présents sur le noyau aromatique ainsi que sur le groupe amino.

Mots clés : synthèse, *N*-oxydes de benzimidazole.



[Traduit par la Rédaction]

Introduction

Benzimidazole and benzimidazole *N*-oxides have biological activity. Some benzimidazole derivatives are known as antivirals, antifungals, and antibacterials (1). Fluorinated benzimidazoles are insecticides or herbicides (2). *N*-Oxides derived from purines have antitumoral, antimicrobial, or antiviral activity (3, 4). Some 1-alkoxy-2-alkylbenzimidazoles derived from 2-nitroanilines also exhibit activity against HIV-1 (5).

Although several classes of amines are oxidized to their corresponding *N*-oxides (6), we could find no reports on direct oxidation of benzimidazoles to benzimidazole *N*-oxides. Synthetic methods known to give benzimidazole *N*-oxides include Pt-catalyzed hydrogenation of 2′-nitro-*N*-phenylacetanilide in EtOH–HCl (7), cyclization of 2-nitroaniline derivatives having electron-withdrawing substituents β to the amino group in basic media (3, 8, 9), photolysis in aqueous methanolic hydrochloric acid of 1-amino-2-nitrobenzene and 1-amino-4-chloro-2-nitrobenzene with pyrrolidine, piperidine, or morpholine as the amino group (10), and photolysis in 0.5% acetic acid of *N*-(2′,6′-dinitro-4′-trifluoromethylphenyl)-2-aminobutyric acid (11). Recently, examples of cyclization of *N*-alkyl-2,4-dinitro-6-trifluoromethylanilines in 50% EtOH–H_2O with $KHCO_3$ resulting in 2-alkyl-substituted benzimidazole *N*-oxides have been reported (12).

We have previously reported on the synthesis of benzimidazole *N*-oxides by cyclization of two 2-nitroaniline derivatives having electron-donating groups β to the amino group; namely, 7-nitro-2-*n*-propyl-1*H*-benzimidazole-3-oxide (**1**) and 5,7-dinitro-2-*n*-propyl-1*H*-benzimidazole-3-oxide (**2**) were synthesized by cyclization of *N*-*n*-butyl-2,6-dinitroaniline (**3**) and *N*-*n*-butyl-2,4,6-trinitroaniline (**4**), respectively (13). The method that we proposed was superior to all others because shorter reaction times were required, there was no need for a substituent in the *N*-alkyl group, generally

better yields were obtained, and the reaction could be carried out in a solvent with high water content.

To determine the scope of the method in regard to the derivatives that can be prepared, we carried out a study on the reaction of substrates **5a**–**5d** and the results are reported here.

Results and discussion

When compounds **5a**–**5d** were heated at reflux in 60% (*v*/*v*) 1,4-dioxane–H_2O with NaOH, they afforded the corresponding benzimidazole *N*-oxides **6a–6d** in very good yields (Scheme 1, Table 1). The structures of **6a**–**6d** were confirmed by their ^{1}H NMR, ^{13}C NMR, and IR spectra. In some cases, substitution of the amino group competed with *N*-oxide formation. For instance, in the reaction of *N*-*n*-butyl-2,6-dinitro-4-trifluoromethylaniline (**5a**) and *N*-*n*-propyl-2,6-dinitro-4-trifluoromethylaniline (**5d**), 2,6-dinitro-4-trifluoromethylphenol (**7**) was also formed (Table 1). The substitution product was also found in the reaction of **3** in 10% 1,4-dioxane–H_2O at 25 °C (14) and in the reaction of **4** in 60% 1,4-dioxane–H_2O at reflux (13). In all cases, the yield of the phenol decreased with decreasing NaOH concentration.

When the reaction of **5a** was performed under a N_2 atmosphere with 0.2 mol/L NaOH, the yield of **6a** increased approximately 10% (Table 1). This is consistent with the mechanism previously proposed (14).

An *N,N*-disubstituted derivative of **5d,** namely, *N,N*-di-*n*-propyl-2,6-dinitro-4-trifluoromethylaniline (trifluralin) (**8**), yielded the phenol **7** along with unreacted substrate after 18 h at reflux with 0.01 mol/L NaOH in 60% 1,4-dioxane–H_2O. It was previously reported that with other *N,N*-dialkylated anilines, namely, *N*-*n*-butyl-*N*-methyl-2,6-dinitroaniline (**9**) (14) and *N,N*-diethyl-2,4-dinitro-6-trifluoromethylaniline (**10**) (12), cyclization requires the presence of the NH proton. This is in agreement with the mechanism proposed for cyclization that requires ionization of the amino group as the initial step (14).

In the reactions of compounds **5b** and **5c**, the only products isolated were benzimidazole *N*-oxides **6b** and **6c**, respectively. Although the yield of both reactions was ~75%, neither the corresponding phenol nor the unreacted substrate or any other product was observed by TLC so the actual yield was probably higher, with some product being lost during work-up. Benzimidazole *N*-oxide was also the only product found in the reaction of **3** in 60% 1,4-dioxane–H_2O at 25 °C (14) or at reflux (13). These results indicate that the formation of benzimidazole *N*-oxide is not dependent on the length of the alkyl chain (3 or 4 carbon atoms).

Another derivative of 2-nitroaniline, namely, *N*-*n*-butyl-4-cyano-2,6-dinitroaniline (**5e**), was also tested as a precursor for an *N*-oxide. In this case, with NaOH concentrations of both 0.20 and 0.01 mol/L, four products were detected by TLC, but they could not be isolated. While one of them seemed to be the *N*-oxide, the others may have originated from the reaction of base with the cyano group, as was observed for other cyanobenzenes (15).

The substituents on the aromatic ring have an important effect on the competition between substitution and cyclization. The absence of a second group *ortho* to the amino group prevents cyclization, as was observed with *N*-*n*-butyl-2,4-dinitroaniline, which gave 2,4-dinitrophenol in 100% yield after 24 h at reflux with 0.01 mol/L NaOH (13). When both of the substituents *ortho* to the amino group are NO_2, the yield of the cyclization product increases as the electron-

Table 2. UV–visible data for 2,4,6-trinitroaniline (**11**),[a] *N*-*n*-butyl-2,6-dinitro-4-trifluoromethylaniline (**5a**), *N*-*n*-butyl-2,4-dinitro-6-trifluoromethylaniline **(4b),** and *N*-*n*-butyl-2,4,6-trinitroaniline (**4**).

Compound	λ (nm)	ε (L mol^{-1} cm^{-1})	λ (nm)	ε (L mol^{-1} cm^{-1})
11	318	12 000	408	7800
4	338	16 588	413	6336
5a	416	7 026	325	1893
5b	340	16 507		

[a] Data from ref. 16.

withdrawing ability of the *para* substituent decreases. This is evident from the fact that with an NaOH concentration of 0.20 mol/L, the yield of *N*-oxide is 95.6%, 61.6%, and 0% for **3** (13), **5a**, and **4** (13), respectively. The replacement of an *o*-NO_2 group by an *o*-CF_3 completely inhibits the substitution reaction (compare the results for **5a** and **5b**). Because of this and the fact that the absence of a second *ortho* substituent inhibits cyclization (12–14), we believe that the substituent on C(6) plays a very important role in the reaction. We propose that the conformation of compounds having two *ortho* substituents may favour the cyclization reaction.

To investigate the conformation of compounds **5a**, **5b,** and **4** in solution, we analyzed their UV–visible spectra in methanol; the spectral data are summarized in Table 2. The spectrum of 2,4,6-trinitroaniline (**11**) in methanol shows two absorption bands: one at 318 nm (band 1) and the other at 408 nm (band 2). These bands correspond to electronic transitions from the amino group to the *p*-nitro (band 1) and *o*-nitro (band 2) groups, respectively (16). In compound **4,** bathochromic displacements of bands 1 and 2 relative to those of **11** were observed. Similar bathochromic displacements in related 2,4-dinitroaniline and 2,4,6-trinitroaniline derivatives were interpreted as a consequence of destabilization of the ground state of the molecule due to rotation around the C(1)–N bond or to steric enhancement of resonance caused by rotation around the C(2)–N and (or) the C(6)–N bond or by a combination of both factors (16–19). In related nitroanilines, hypsochromic and hypochromic displacement of band 2 was attributed to rotation around the C(2)–N and (or) the C(6)–N bond, while a decrease in the intensity of band 1 was attributed to rotation around the C(1)–N bond (16–19). Compound **5a** shows a bathochromic and hypochromic displacement of band 1 as well as a hypsochromic and hypochromic displacement of band 2 when compared to **11**. These observations indicate nonplanarity of the two *o*-nitro groups and the amino group with the aromatic ring. The bathochromic displacement and increased intensity (increase in ε due to steric effects) of band 1 and the complete disappearance of band 2 in **5b** point to nonplanarity of the *o*-nitro group with the aromatic ring.

Analysis of the ^{1}H NMR chemical shifts of the methylene protons α to the nitrogen was performed to confirm the nonplanarity of the amino group (Table 3). The chemical shifts of the methylene protons α to the amino group in **5a**, **5b,** and **4** were calculated by computational methods (20). The difference between the calculated and observed values shows shielding of the protons of the butylamine moiety in **4** and **5a**, which could be attributed to the ring current produced by the electrons of benzene (21). Therefore, the butylamine moiety must be out-of-plane with respect to the plane of the aromatic ring in these compounds. The fact that the chemical shift of the α-methylene protons in **5b** is nearly the same as the calculated value could mean that there is no rotation around the C(1)–N bond. However, considering that CF_3 is sterically more bulky than the NO_2 group as evidenced by its steric substituent constant E_S or ν (22), it is reasonable to think that there must be some loss of coplanarity between the lone pair of electrons on nitrogen and the π electrons of the benzene ring.

Table 3. Experimental and calculated ^{1}H NMR chemical shifts for aliphatic protons in compounds **5a**, **5b**, and **4**.

	5a		**5b**		**4**	
Atom	Exptl.	Calcd.	Exptl.	Calcd.	Exptl.	Calcd.
H(1′)	3.03	3.48	3.37	3.30	3.11	3.48

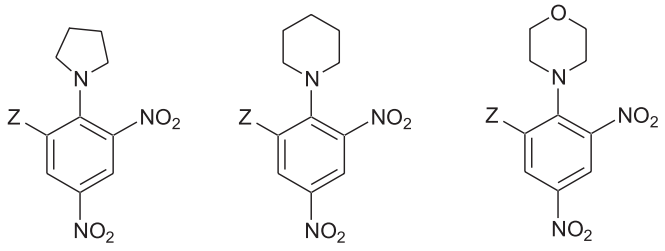
H(3′)	1.42	1.43	1.45	1.43	1.44	1.43
H(4′)	0.94	0.95	0.97	0.95	0.97	0.95

Note: Chemical shifts were calculated with ACD/Chem Sketch (20).

Table 4. C(1)–N(7) bond length (Å) and selected torsion angles (°) for **5a**, **5b,** and **4**.

	5a	5b	4
C(1)–N(7)	1.356	1.363	1.352
C(3)–C(2)–N(8)–O(9)	–41.06	– 46.05	–40.63
C(3)–C(2)–N(8)–O(10)	136.36	131.56	136.95
C(6)–C(1)–N(7)–H	–17.32	–7.468	–16.51
C(6)–C(1)–N(7)–C(1′)	152.95	153.47	156.53
C(5)–C(6)–C(1)–N(7)	–168.72	–175.014	–165.95
C(3)–C(2)–C(1)–N(7)	172.55	166.52	163.85



Note: Calculated with MOPAC program (23).

We have also performed geometry optimization of the structures of compounds **5a**, **5b,** and **4** using the quantum chemistry program MOPAC (23); some of the results are shown in Table 4. The length of the C(1)–N bond varies in the order **5b > 5a > 4**, indicating the greatest double bond character in **4**. The rotation around the C(2)–N bond is greater in **5b** than in the other compounds, in agreement with the UV–visible spectra. Rotation around the C(1)–N bond can be inferred by comparing the dihedral angles defined by C(6)–C(1)–N–H (**5a > 4 > 5b**) or C(6)–C(1)–N–C(1′) (**5a ≈ 5b > 4**). In addition, the bending of the amino nitrogen out of the aromatic plane is evidenced by the dihedral angles C(5)–C(6)–C(1)–N and C(3)–C(2)–C(1)–N; the deviation from planarity is 6.5°, 12.5°, and 15° for **5b**, **5a,** and **4**, respectively.

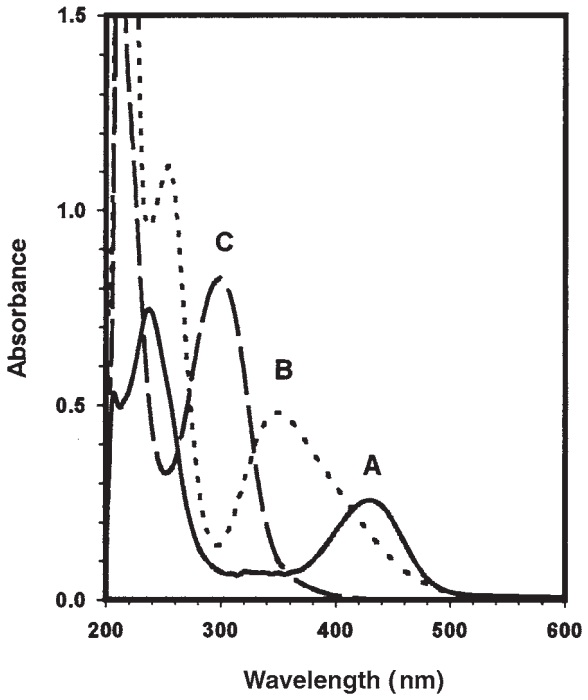
These results indicate that rotation of the *ortho* substituents favours cyclization while nonplanarity of the amino group favours the substitution reaction. We have shown in previous work that in 2,4,6-trinitro-1-pyrrolidinobenzene (**12a**), 2,4,6-trinitro-1-piperidinobenzene (**13a**)**,** and 1-morpholino-2,4,6-trinitrobenzene (**14a**) (17), in 2,4-dinitro-1-piperidinobenzene (**13b**) (18), and in 2,4-dinitro-1-pyrrolidinobenzene (**12b**) and 1-morpholino-2,4-dinitrobenzene (**14b**) (19), nonplanarity of the *o*-nitro groups and the amino

© 2004 NRC Canada

group relative to the aromatic ring occurs both in the solid state and in solution. The decrease of the interaction of the lone pair of electrons of the amino nitrogen with the π system due to nonplanarity and the formation of σ complexes

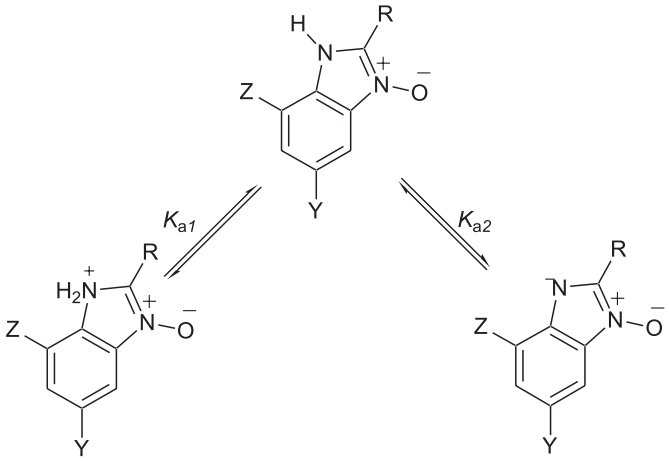
by addition of a nucleophile to an unsubstituted position on the aromatic ring favours substitution of the amino group (24).

The UV–visible spectra of **6a**–**6d** change with the pH of the solution (in the range 1.00 < pH < 8.00) as shown for **6a** in Fig. 1. These spectra are attributed to acid–base equilibria as shown in Scheme 2 (25). Spectrophotometric titration gave two inflection points corresponding to two pK_as; the values are summarized in Table 1 and are similar to those reported for **1** (13) and 6-nitro-3*H*-benzimidazole-1-oxide (8).



We conclude that benzimidazole *N*-oxides can be obtained in a very simple way and with good yields starting with *N*-alkylanilines that have two *ortho* substituents, one of them being a nitro group. Several new derivatives have been prepared and isolated. The method offers advantages over previously reported procedures since easily available materials can be used, shorter reaction times are required, and compounds with a nitro group at the C(7) position of benzimidazole can be obtained.

Experimental



1,4-Dioxane was purified as described previously (26). Water purified in a Millipore Milli-Q apparatus was used throughout. All of the inorganic reagents were of analytical-reagent grade and were used without further purification. NaOH concentrations are expressed in terms of total solvent volume (1,4-dixane–H_2O). Melting points were determined on an electrothermal apparatus. Proton (200 MHz) and ^{13}C (50 MHz) NMR spectra were recorded on a Bruker ACE 200 spectrometer. Chemical shifts in $CDCl_3$ are reported as δ values downfield from Me_4Si, and those in $(CD_3)_2SO$ are referenced to the solvent signal. The mass spectra (EI) and HRMS (EI) were done at Unidad de Espectrometría de Masas, Universidad de Santiago de Compostela, Spain. IR spectra in KBr were obtained on a Nicolet 5SXC FT-IR spectrometer. UV–visible spectra in 10% (*v*/*v*) 1,4-dioxane–H_2O or methanol were obtained on a Shimadzu UV 2101 spectrophotometer. TLC was carried out using silica gel 60 F_{254} (Merck), and spots were visualized by UV or I_2. Silica gel, 60 mesh size (0.063–0.200 nm) (Merck), was used for column chromatography.

The second product formed in the reaction of **5a** and **5d** was identified as 2,6-dinitro-4-trifluoromethylphenol (**7**) by

Fig. 1. (A) Spectrum of **5a** in 10% 1,4-dioxane–H_2O at pH 7.22 (Na_2HPO_4/KH_2PO_4 buffer); $[\mathbf{5a}]_0 = 3.91 \times 10^{-5}$ mol/L. (B, C) Spectra of **6a** in 10% 1,4-dioxane–H_2O at different pHs; $[\mathbf{6a}]_0 = 1.00 \times 10^{-4}$ mol/L: (B) pH 7.22 (Na_2HPO_4/KH_2PO_4 buffer); (C) pH 1.11 (HCl 0.1 mol/L).

Scheme 2.

TLC comparison with an authentic sample. It was contaminated with solvent, and no further attempts to purify it were made. The phenol **7** was synthesized in DMSO–H_2O by following a reported method (27); the reaction mixture was subjected to liquid–liquid extraction with Et_2O, the solvent was evaporated, and the solid obtained was recrystallized in $CHCl_3$ (mp 49–51 °C (lit. (27) 46–48 °C)). ^1H NMR ($(CD_3)_2SO$, 200 MHz): δ = 8.10.

The pK_as of compounds **6a**–**6d** were determined by spectrophotometric titration in 10% 1,4-dioxane–H_2O at 25 °C. Solutions for the various pH ranges were prepared using HCl (0.7–3.0 mol/L), acetic acid/sodium hydroxide (3.5–5.5 mol/L), and Na_2HPO_4/KH_2PO_4 (5.8–8.0 mol/L).

Synthesis of *N*-alkyl-2-nitroanilines

Compounds **5a–5c** were synthesized and isolated by the methods previously described (28) from the corresponding 1-chloro derivative and *n*-butylamine or *n*-propylamine in DMF. Compound **5d** was synthesized as described elsewhere (11) and recrystallized from MeOH.

N-n-*Butyl-2,6-dinitro-4-trifluoromethylaniline* (5a)

Yellow solid; mp 35.5–37.5 °C. Yield 81%. ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 0.94 (t, 3H, J = 7.2 Hz, CH_3), 1.42 (m, 2H, J = 7.2 Hz, CH_2CH_3), 1.69 (m, 2H, J = 7.1 Hz, $CH_2CH_2CH_3$), 3.03 (td, 2H, J = 6.9 Hz, 4.7 Hz, $CH_2CH_2CH_2CH_3$), 8.38 (s, 2H, Ar), and 8.62 (s, 1H, NH). ^{13}C NMR ($CDCl_3$, 50 MHz) δ: 13.47, 19.83, 31.94, 46.38, 115.98 (q, J_{CF} = 36 Hz, C-CF_3), 122.45 (q, J_{CF} = 270 Hz, CF_3), 128.99, 137.16, and 141.44. MS *m/z*: 308.1 ([M+1]$^+$, 10.3), 307.0 (M$^+$, 17.6), 264.0 (100), 218.2, 201.4, 248.2, 218.2, 202.1, 70.9, 68.9, 43.0, 41.0, and 30.2. HRMS (EI): *m/z* calcd. for $C_{11}H_{12}N_3O_4F_3$: 307.0780; found: 307.0784.

N-n-*Butyl-2,4-dinitro-6-trifluoromethylaniline* (5b)

Yellow oil. ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 0.97 (t, 3H, J = 7.2 Hz, CH_3), 1.45 (m, 2H, J = 7.3 Hz, CH_2CH_3), 1.71 (m, 2H, J = 7.1 Hz, $CH_2CH_2CH_3$), 3.37 (q, 2H, J = 5.8 Hz, $CH_2CH_2CH_2CH_3$), 7.74 (s, 1H, NH), 8.63 (d, 1H, J = 2.5 Hz, Ar), and 9.05 (d, 1H, J = 2.9 Hz, Ar). MS *m/z*: 309.1 ([M+1]$^+$, 12.1), 307.8 (M$^+$, 88.8), 264.1 (100), 218.4, 201.4, 247.9, 218.4, 202.2, 70.9, 68.8, 42.9, 40.9, and 30.2. HRMS (EI): *m/z* calcd. for $C_{11}H_{12}N_3O_4F_3$: 307.0780; found: 307.0773.

N-n-*Propyl-2,6-dinitroaniline* (5c)

Yellow solid; mp 79–80 °C. Yield: 83%. ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 0.99 (t, 3H, J = 7.2 Hz, CH_3), 1.71 (m, 2H, J = 7.2 Hz, CH_2CH_3), 2.96 (td, 2H, J = 6.9 Hz, 4.7 Hz, $CH_2CH_2CH_3$), 6.74 (t, 1H, J = 8.2 Hz, Ar), 8.17 (d, 2H, J = 8.0 Hz, Ar), and 8.35 (s, 1H, NH). MS *m/z*: 226.2 ([M+1]$^+$, 16.3), 225.0 (M$^+$, 54.4), 196.0 (100), 179.8, 150.1, 134.1, 132.9, 56.9, 40.9, 29.1, and 28.1. HRMS (EI): *m/z* calcd. for $C_9H_{11}N_3O_4$: 225.0749; found: 225.0748.

N-n-*Propyl-2,6-dinitro-4-trifluoromethylaniline* (5d)

Yellow solid; mp 61–62 °C (lit. (11) 62.5–63.0 °C). Yield: 85%. ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 1.02 (t, 3H, J = 7.3 Hz, CH_3), 1.74 (m, 2H, J = 7.2 Hz, CH_2CH_3), 3.01 (td, 2H, J = 6.9 Hz, 4.8 Hz, $CH_2CH_2CH_3$), 8.40 (s, 1H, Ar), and 8.65 (s, 1H, NH).

Synthesis of benzimidazole *N*-oxides; general procedure

The corresponding *N*-alkyl-2-nitroaniline derivative was heated at reflux in 60% (*v*/*v*) 1,4-dioxane–H_2O with NaOH. The reaction was followed by TLC; when no remaining reactant was observed, the heating was stopped; the solution was cooled to room temperature and acidified to pH ≤ 4 with 3.2 mol/L HCl.

***7-Nitro-2*-n-*propyl-5-trifluoromethyl-1*H-*benzimidazole 3-oxide* (6a)**

A solution prepared by dissolving 200 mg (0.65 mmol) of **5a** in 100 mL of solvent was heated at reflux with NaOH (0.20–0.01mol/L) for 10–15 min. The reaction mixture was acidified to pH 4 and the solvent was evaporated in a rotary evaporator. The salts were separated from the products by column chromatography on silica gel by eluting with variable amounts of hexane–EtOAc. The products were treated with acetone, in which the phenol is completely soluble while the *N*-oxide precipitates. The *N*-oxide was isolated by vacuum filtration as a yellow powder that decomposed at 196 °C.

^{1}H NMR ((CD_3)$_2$SO, 200 MHz) δ: 1.02 (t, 3H, J = 7.3 Hz, CH_3), 1.86 (m, 2H, J = 7.5 Hz, CH_2CH_3), 2.98 (t, 2H, J = 7.3 Hz, $CH_2CH_2CH_3$), 8.25 (s, 1H, Ar), 8.26 (s, 1H, Ar), and 12.52 (s, 1H, NH). ^{13}C NMR ((CD_3)$_2$SO, 50 MHz) δ: 13.40, 19.68, 27.26, 111.99 (q, J_{CF} = 4.0 Hz, CHAr), 114.58 (q, J_{CF} = 4.0 Hz, CHAr), 121.41 (q, J_{CF} = 33.5 Hz, C-CF_3), 123.43 (q, J_{CF} = 270 Hz, CF_3), 133.12, 134.77, 137.36, and 158.08. IR (KBr, ν_{max} cm^{-1}): 1539.4 (s), 1337.4 (s, 1288.9 (s), and 1258.2 (s). MS *m/z*: 291.2 ([M+1]$^+$, 20.4%), 289.8 (M$^+$, 82.2), 272.1, 260.8, 244.5, 226.1, 199.3, 142.8, 70.9 (100), 68.8, 42.9, and 41.0. HRMS (EI): *m/z* calcd. for $C_{11}H_{10}N_3O_3F_3$: 289.0674; found: 289.0676.

***5-Nitro-2*-n-*propyl-7-trifluoromethyl-1*H-*benzimidazole 3-oxide* (6b)**

A solution prepared by dissolving 50 mg (0.16 mmol) of **6b** in 25 mL of solvent was heated at reflux with NaOH (0.20 mol/L) for 40 min. Only the *N*-oxide was formed; it precipitated upon acidification of the solution with HCl and was separated by vacuum filtration. It decomposed at 183 °C (lit. (12) 213 °C).

^{1}H NMR ((CD_3)$_2$SO, 200 MHz) δ: 1.01 (t, 3H, J = 7.4 Hz, CH_3), 1.85 (m, 2H, J = 7.4 Hz, CH_2CH_3), 2.98 (t, 2H, J = 7.6 Hz, $CH_2CH_2CH_3$), 8.31 (d, 1H, J = 2.0 Hz, Ar), and 8.57 (d, 1H, J = 2.0 Hz, Ar). ^{13}C NMR ((CD_3)$_2$SO, 50 MHz) δ: 13.67, 19.95, 27.63, 109.33, 114.31 (q, J_{CF} = 4.9 Hz, CHAr), 118.29 (q, J_{CF} = 33.0 Hz, C-CF_3), 122.93 (q, J_{CF} = 271 Hz, CF_3), 132.69, 138.60, 141.34, and 158.65. IR (KBr, ν_{max} cm^{-1}): 1540.8 (s), 1362.4 (s), 1287.2 (s), and 1254.9 (s). MS *m/z*: 291.1 ([M+1]$^+$, 18.4%), 289.7 (M$^+$, 64.7), 272.1, 260.8, 244.3 (100), 226.1, 199.1, 143.0, 68.6, 71.1, 43.1, and 40.9. HRMS (EI): *m/z* calcd. for $C_{11}H_{10}N_3O_3F_3$: 289.0674; found: 289.0681.

***2-Ethyl-7-nitro-1*H-*benzimidazole 3-oxide* (6c)**

A solution prepared by dissolving 50 mg (0.22 mmol) of **5c** in 25 mL of solvent was heated at reflux with NaOH (0.20 mol/L) for 30 min. The only product formed was isolated by column chromatography over silica gel by eluting with variable amounts of hexane–EtOAc. The solid decomposed at 163 °C.

^{1}H NMR ((CD_3)$_2$SO, 200 MHz) δ: 1.36 (t, 3H, J = 7.4 Hz, CH_3), 2.96 (q, 2H, J = 7.6 Hz, CH_2CH_3), 7.41 (t, 1H, J = 8.04 Hz, Ar), 7.88 (d, 1H, J = 7.66 Hz, Ar), 8.02 (d, 1H, J = 8.02 Hz, Ar), and 12.23 (s, 1H, NH). ^{13}C NMR ((CD_3)$_2$SO, 50 MHz) δ: 10.98, 18.93, 115.09, 117.87, 120.94, 130.86, 134.82, 137.54, and 155.95. IR (KBr, ν_{max} cm^{-1}): 1526.1 (s), 1338.7 (s), 1321.2 (s), and 1251.5 (s). MS *m/z*: 208.1 ([M+1]$^+$, 5.1%), 207.3 (M$^+$, 85.1), 193.2, 189.9 (100), 178.1, 143.8, 132.1, 74.9, 56.9, 41.1, and 29.1. HRMS (EI): *m/z* calcd. for $C_9H_9N_3O_3$: 207.0644; found: 207.0645.

***2-Ethyl-7-nitro-5-trifluoromethyl-1*H-*benzimidazole 3-oxide* (6d)**

A solution prepared by dissolving 100 mg (0.34 mmol) of

© 2004 NRC Canada

1d in 50 mL of solvent was heated at reflux with NaOH (0.05 or 0.01 mol/L) for 20–35 min. The reaction mixture was acidified to pH 2 and the products were extracted with CH_2Cl_2. The combined extracts were dried over anhydrous Na_2SO_4, filtered, and the solvent evaporated in a rotary evaporator. The solid obtained was a mixture of **6d** and **7**; the *N*-oxide **6d** was isolated as described for **6a**. The solid decomposed at 196 °C (lit. (11) 215–216 °C).

^{1}H NMR ($(CD_3)_2SO$, 200 MHz) δ: 1.38 (t, 3H, J = 7.5 Hz, CH_3), 3.02 (q, 2H, J = 7.5 Hz, CH_2CH_3), 8.24 (s, 1H, Ar), 8.25 (s, 1H, Ar), and 12.48 (s, 1H, NH). ^{13}C NMR ($(CD_3)_2SO$, 50 MHz) δ: 10.65, 19.06, 111.81 (q, J_{CF} = 4.0 Hz, CHAr), 114.47 (q, J_{CF} = 4.0 Hz, CHAr), 121.43 (q, J_{CF} = 33.5 Hz, C-CF_3), 123.41 (q, J_{CF} = 270 Hz, CF_3), 133.04, 134.85, 137.36, and 159.11

AWARD LECTURE / CONFÉRENCE D'HONNEUR

Prospects for controlling plant fungal diseases — Alternatives based on chemical ecology and biotechnology[1]

M. Soledade C. Pedras

Abstract: Plants produce a diverse array of secondary metabolites associated with important defence and resistance mechanisms. In general, within the same plant family the chemical structures of these metabolites are related and suggest common biogenetic precursors. Crucifers are known to produce constitutive and induced tryptophan derived metabolites. Pathogenic fungi can resist such defences utilizing a variety of processes, as for example, enzymatic detoxification. On the other hand, to facilitate their penetration and colonization of the plant tissues, fungal phytopathogens can produce phytotoxic metabolites, some of which are selectively toxic to host-plants. However, plants may be resistant to these pathogens partly due to their ability to detoxify these selective phytotoxins. Nonetheless, the outcome of these interactions frequently favours the pathogen and can lead to enormous yield losses or even major plant epidemics. An overview of some of the most recent studies of metabolic pathways and stress responses in crucifers and several of their pathogens is presented. Potential strategies to prevent and control plant microbial diseases based on chemical ecology studies and biotechnology will be discussed.

Key words: phytoalexin, phytotoxin, chemical defence, metabolic detoxification, destruxin B.

Résumé : Les plantes produisent une variété de métabolites secondaires associés à d'importants mécanismes de défense et de résistance. En général, dans une même famille de plantes, les structures chimiques de ces métabolites sont apparentées, ce qui suggère des précurseurs biogénétiques communs. Les crucifères sont bien connus pour produire des métabolites à base de ou apparentés au tryptophane. Les champignons pathogènes peuvent résister à de telles défenses en faisant appel à une grande variété de processus, tels que la détoxification enzymatique. Par ailleurs, afin de faciliter leur pénétration et leur colonisation des tissus des plantes, les phytopathogènes fongiques peuvent produire des métabolites phytotoxiques dont quelques-uns sont sélectivement toxiques aux plantes hôtes. Toutefois, les plantes peuvent être résistantes à ces pathogènes en raison de leur habilité à détoxifier ces phytotoxines sélectives. Malgré tout, le résultat de ces interactions favorise fréquemment le pathogène et peut conduire à des pertes énormes de rendement ou même à des épidémies majeures pour les plantes. On présente une revue de quelques études récentes sur les voies métaboliques et les réponses au stress dans les crucifères ainsi que sur plusieurs de leurs pathogènes. On discute aussi de stratégies potentielles, basées sur des études d'écologie chimique et de biotechnologie, pour prévenir et contrôler les maladies microbiennes des plantes.

Mots clés : phytoalexine, phytoxine, défense chimique, détoxification métabolique, dextruxine B.

[Traduit par la Rédaction]

Introduction

Plant diseases caused by fungi are responsible for about 50% of the worldwide losses (1). Through the ages, examples of devastating fungal disease epidemics causing complete depletion of staple crops such as potatoes, rice, and maize have demonstrated the critical need to control phytopathogenic fungi. In general, plants show resistance to certain fungal species and susceptibility to others, suggesting that effective control of fungal infections requires a combination of structurally diverse compounds. Thus, it is not surprising to find that plants produce a vast array of

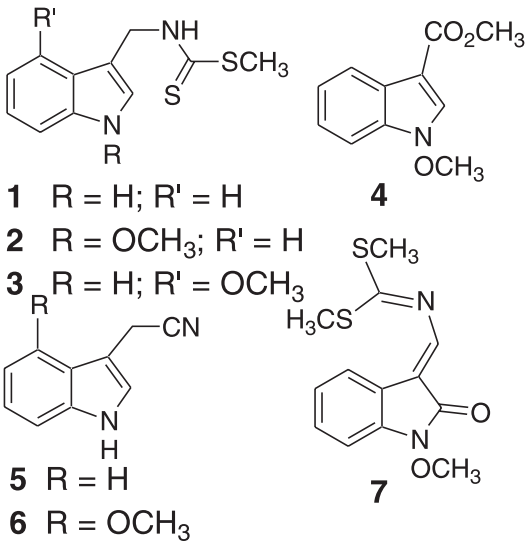
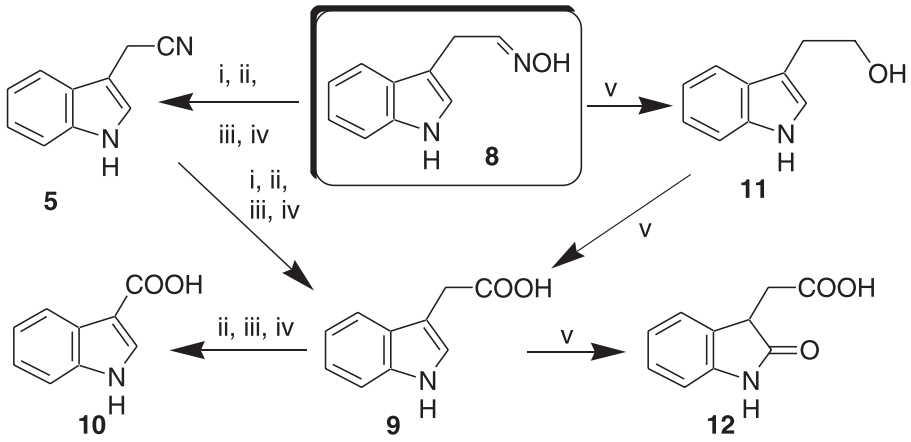
products with very diverse roles in defence against microorganisms and other pests, generally known as secondary metabolites (2). The importance of secondary metabolites in plant defence and fungal attack has been shown in numerous situations through the use of transgenic and (or) mutant organisms (3).

Fungal infection of plants is a complex process, which starts with fungal penetration of plant tissues mediated by secretion of enzymes such as cutinases, cellulases, pectinases, and polygalacturonases, to degrade the protective barriers covering the aerial plant organs and (or) cell wall polymers (4). After penetration, to colonize plant tissues many fungal pathogens produce secondary metabolites that can damage the plant cells irreversibly, phytotoxins. Some phytotoxins cause plant disease symptoms similar to the fungus and affect only host plants, thus they are named host-selective toxins (HST); others affect a much broader range of hosts than the fungus and are known as nonselective toxins (5). The importance of HSTs has been shown in a few important fungal diseases where resistance or susceptibility to the pathogen correlated positively with susceptibility to the HST. On the other hand, plants detect the fungal invader through elicitors, small compounds generated during the penetration of the tissues by fungi, and respond with a sophisticated arsenal of secondary metabolites and enzymes. However, when constitutive (e.g., phytoanticipins) and induced (e.g., phytoalexins) defences (6) are insufficient to deter the invader, the outcome may favour the pathogen. Frequently, fungal pathogens can overcome the plant chemical defences (phytoanticipins and phytoalexins) and plants can overcome fungal phytotoxins through detoxifying enzymes. While phytoalexins are an important part of the plants' defence mechanism, phytotoxins are virulence and (or) pathogenicity factors of phytopathogenic fungi. Overall, the interaction of plants with their pathogens involves an array of chemical reactions, some of which transform highly bioactive secondary metabolites into harmless products, (i.e., detoxification). A simplistic overview of the chemical interaction between plants and fungal pathogens is summarized in Fig. 1.



The family Cruciferae comprises a number of major crops, including the oilseeds canola, rapeseed, and mustard, and the vegetables cauliflower, broccoli, cabbage, rutabaga, turnip, etc. Oilseed crucifers (mainly *Brassica* species) constitute the third largest source of edible vegetable oils. A number of cruciferous weeds are well-known for their negative effects on cultivated systems. Besides their economic importance, crucifers are also interesting plant model systems, containing the first example of a completely sequenced plant genome (7). Interestingly, a number of epidemiological studies suggest that cruciferous vegetables protect against cancer by modulating carcinogen metabolism (8). My research group has been investigating the secondary metabolites of both cultivated and wild crucifers in connection with some of the main fungal diseases of economically important crops. Our approach to design strategies to control plant fungal diseases requires a chemical–ecological understanding of the plant and the pathogen secondary metabolism. Here, I attempt to give a glimpse of how we are using chemistry to decipher and control metabolic processes underlying important plant fungal diseases.

Fig. 1. Chemical interaction between plant and fungal pathogens.



Crucifer phytoalexins and phytoanticipins

Crucifers are the only plants known to produce compounds containing a dithiocarbamate group (e.g., **1**–**3**), although some of the important pesticides and herbicides developed in the 1960s are dithiocarbamates (9). Except for methyl 1-methoxyindole-3-carboxylate (**4**) (10), indolyl-3-acetonitrile (**5**) (11), and arvelexin (**6**) (12), all cruciferous phytoalexins reported thus far contain sulfur. We found that indolyl-3-acetonitrile (**5**) is a phytoalexin in brown mustard (*B. juncea*) but a phytoanticipin in canola (*B. rapa* and *B. napus*) (11). Recently, our search for phytoalexins from cruciferous plants resistant to economically important fungal diseases led us to examine stinkweed (*Thlaspi arvense*) (12), a potential source of disease resistance to the virulent blackleg fungus, and wasabi (*Wasabia japonica*, syn. *Eutrema wasabi*) (13), a perennial plant widely cultivated in Japan. Unexpectedly, we have discovered that both wasabi and stinkweed produce wasalexin A (**7**), although these plants are from rather different genera. Wasalexin A (**7**) production might suggest that it has a role

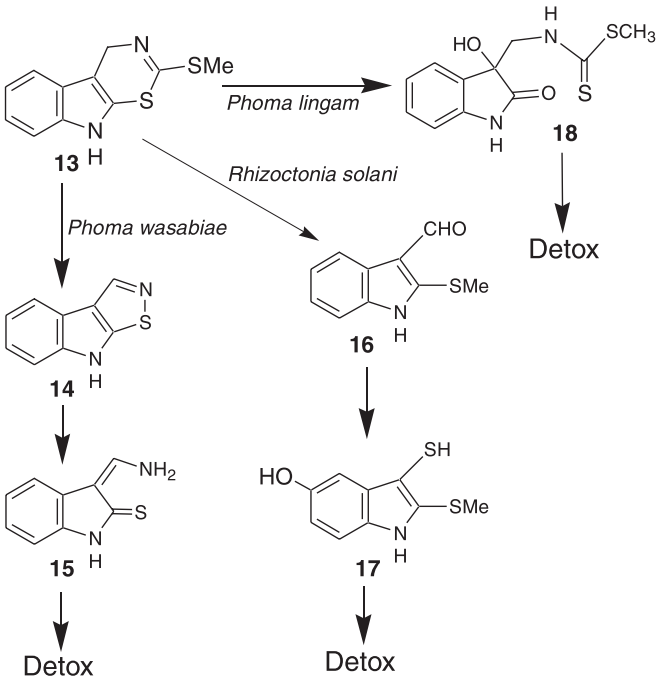
Scheme 1. Metabolism of indole-3-acetaldoxime (**8**) by fungi: (*i*) *P.* lingam virulent to canola; (*ii*) *P. lingam* virulent to brown mustard; (*iii*) *S. sclerotiorum* virulent to canola and mustard; (*iv*) *R. solani* virulent to canola and mustard; (*v*) *B. bassiana*, insect pathogen.

in the resistance and (or) defence of these two unrelated species against virulent blackleg isolates. It is anticipated that the "design" of plants producing desirable phytoalexin blends active against a range of pathogens can become a feasible strategy as phytoalexins from unrelated cruciferous species are discovered and biological activities established. Such a strategy could be applicable through either classic or biotechnological plant breeding techniques.

Overcoming plant chemical defences



Despite producing multiple chemical defences, crucifers are susceptible to numerous pests and diseases. The susceptibility of crucifers to infection by a wide range of fungi appears to be related with an effective detoxification of their chemical defences by these phytopathogens. Phytopathogenic fungi are able to circumvent some of the plant chemical defences through metabolism and detoxification; to date, our work demonstrates that cruciferous phytoalexins and precursors can be detoxified efficiently by some of their fungal pathogens. For example, because indole-3-acetaldoxime (**8**) is a key precursor of most of the cruciferous defences (11), it was important to establish if common fungal pathogens can metabolize it, as such a process could be highly detrimental to the plant. Towards this end, we investigated the metabolism of **8** by fungi that cause important plant diseases in crucifers: *Leptosphaeria maculans* (Desm.) Ces. et Not. asexual stage *Phoma lingam* (Tode ex Fr.) Desm., the causative agent of blackleg disease, *Rhizoctonia solani* Kuhn, the causative agent of root rot disease, and *Sclerotinia sclerotiorum* (Lib.) de Bary, causative agent of stem rot disease (14). As well, we examined the metabolism of **8** by a fungus pathogenic to insects (*Beauveria bassiana*) but not to plants, to determine if these transformations were common to non-plant pathogenic fungi. As summarized in Scheme 1, the cruciferous pathogens and the insect pathogen metabolized indolyl-3-acetaldoxime (**8**) to the corresponding carboxylic acid **9**; however, while the plant pathogens transformed **8** via indolyl-3-acetonitrile (**5**), transformation of **8** by the insect pathogen occurred via tryptophol (**11**) (14). It could be suggested that the enzymes responsible for this transformation might be specific to crucifers and to their pathogens, especially considering that the biotransformation of **8** by a non-phytopathogen (*B. bassiana*) yielded indole-3-acetic acid via a different intermediate, tryptophol (**11**) (14). Due to the central biogenetic role played by intermediate **8** in crucifer metabolism, it is of interest to establish if the fungal enzymes involved in these transformations are related with currently known plant enzymes; these data should provide a better understanding of the plant–pathogen co-evolution. Interestingly, the antifungal activity of indole-3-acetaldoxime (**8**) to both types of *P. lingam* and to *R. solani* was lower that that of indole-3-acetonitrile (**5**). By contrast, oxime **8** was more inhibitory to *S. sclerotiorum* than nitrile **5**, whereas indole-3-acetic acid (**9**) had no substantial inhibitory effect on any of the species. Neither indole-3-acetaldoxime (**8**) nor indole-3-ethanol (**11**) showed inhibitory activity against *B. bassiana*.

Detoxifying reactions

In cases where phytopathogenic fungi can effectively disarm the plant by detoxifying chemical defences such as phytoalexins, it is expected that the isolation of fungal enzymes involved in crucial detoxification steps will assist the biorational design of antifungal agents selective against cruciferous phytopathogens. Current work with plant pathogenic fungi suggests that such detoxification mechanisms are both substrate and pathogen specific (15). We have analyzed the reactions of cruciferous pathogens to several phytoalexins and found that each fungal species metabolizes and detoxifies phytoalexins via different pathways. For example, as shown in Scheme 2, cyclobrassinin (**13**) a phytoalexin produced by canola, rapeseed, mustards, etc., was metabolized by *P. wasabiae* to brassilexin (**14**) and to a mixture of 3-aminomethylen-2,3-dihydroindole-2-thione (**15**), and (or) related tautomers (16). Two days after incubation of the avirulent isolate with cyclobrassinin, no brassilexin or other phytoalexins or putative metabolites were detected in any of the cultures or their extracts. Similar experiments carried out with virulent isolates of *P. lingam* incubated with cyclobrassinin (**13**) afforded yet another known phytoalexin, dioxibrassinin (**18**), which was further transformed into nontoxic products. Additional biotransformation studies with *R.*

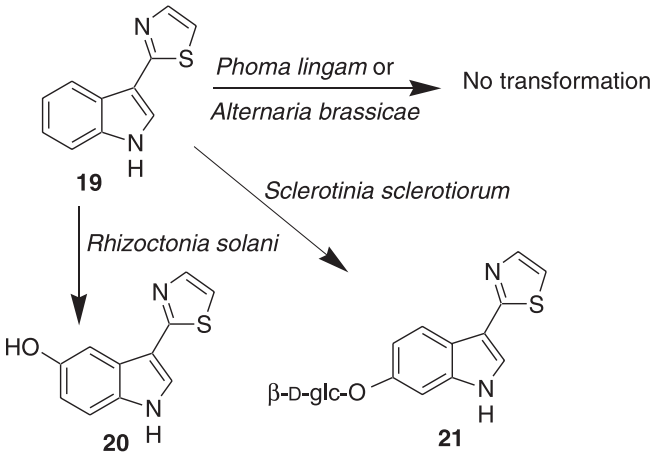
Scheme 2. Metabolism of cyclobrassinin (**13**) by virulent fungi: *P. lingam*, *P. wasabiae*, and *R. solani*.



solani established that this pathogen metabolized and detoxified cyclobrassinin via the phytoalexin brassicanal A (**16**), which was further metabolized into nontoxic products. These results demonstrated that cyclobrassinin (**13**) was detoxified via the phytoalexins dioxibrassinin (**18**), brassilexin (**14**), or brassicanal A (**16**), depending on the fungal species, as shown in Scheme 2 (16).

None of the fungal isolates of *P. lingam* or *Alternaria brassicae* metabolized camalexin (**19**) to a detectable level; however, both *R. solani* (17), a pathogen of a plant that produces camalexin (*Camelina sativa*, false flax), and *S. sclerotiorum* (18) metabolized **19** as shown in Scheme 3. While *R. solani* oxidized the C-5 of the indole moiety of camalexin to a more polar and substantially less-toxic metabolite, *S. sclerotiorum* oxidized and glucosylated C-6 to yield a derivative devoid of antifungal activity.

To probe the selectivity of the fungal enzymes involved in detoxification of phytoalexins such as brassinin (**1**) and camalexin (**19**), the metabolism and antifungal activity of analogs was investigated (15, 18). The much slower rates of transformation of some analogs were partly attributed to the specificity of the enzymes involved in the detoxification steps. Further work to better understand phytoalexin detoxification mechanisms employed by plant pathogens, particularly where the outcome of the plant–pathogen interaction is highly detrimental to the plant, should lead to new strategies to control plant fungal diseases. In this connection, a new term coined "paldoxin" has been proposed to designate potential phytoalexin detoxification inhibitors (19). By design, paldoxins are nontoxic selective inhibitors that could be used as a mixture against a variety of plant pathogens, according to crop and region. Upon optimization, such mixtures might have the advantage of acting synergistically with the natural

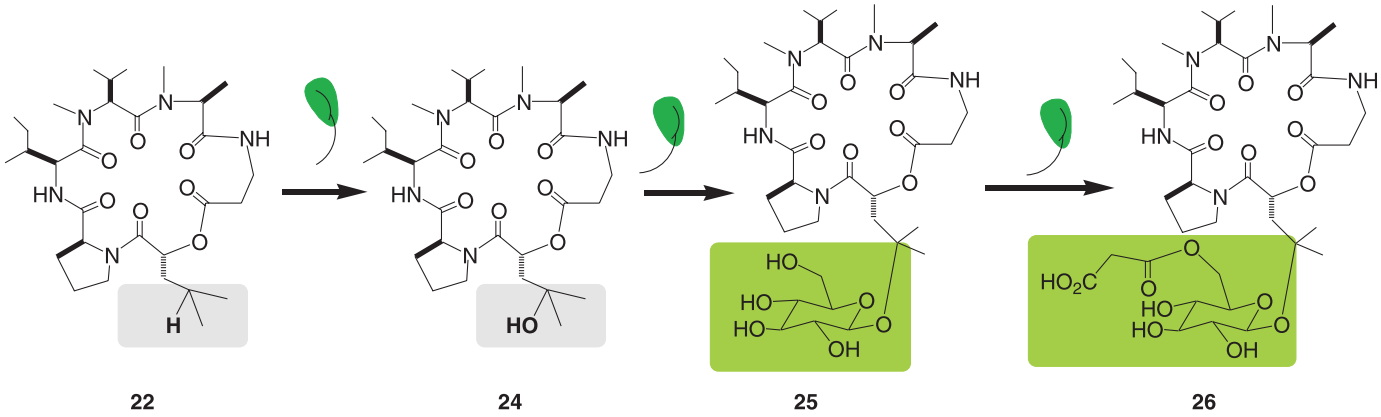
disease resistance factors of plants and be very effective crop protection agents.

Overcoming fungal attack

Necrotrophic fungal phytopathogens are known to produce phytotoxins to damage plant tissues and facilitate colonization, while in response to this attack plants may synthesize detoxifying enzymes. Plants may be resistant to a particular pathogen if they produce enzyme(s) that catalyze detoxification of the pathogen's toxin(s) (20). Consequently, such detoxification traits are desirable and of much importance in classic plant breeding or in engineering disease resistance. While a number of phytoalexin detoxifying reactions have been shown to occur in various plant pathogenic fungi (15, 21),[2] detoxification of phytotoxins were reported in only a few plant species (22).

Plant reactions to the Alternaria blackspot pathogen



Alternaria blackspot is one of the most damaging and widespread fungal diseases of rapeseed (*B. napus* and *B. rapa*), an oilseed crop of great economic importance worldwide (23). *Alternaria brassicae* (Berk.) Sacc., the blackspot causing fungus, produces the cyclic depsipeptide toxins destruxin B (**22**) and homodestruxin B (**23**), both in vitro (24) and in planta (25). Ultrastructural studies have shown that destruxin B causes tissue damage similar to that observed in plants naturally infected with *A. brassicae*, that is, destruxin B showed selective phytotoxicity. We proposed that this apparent selectivity might be due to detoxification

[2] For a review of the detoxification of crucifer phytoalexins see ref. 15.

Fig. 2. Metabolism of the phytotoxin destruxin B (**22**) by cruciferous plant leaves.

reactions occurring in tissues of plant species resistant to *A. brassicae*. Considering that no sources of Alternaria blackspot resistance are known within *Brassica* species, such information would be of great importance to generate blackspot resistant plant lines. Consequently, we became interested in investigating the metabolism of destruxins in plants susceptible and resistant to *A. brassicae*. Sources of blackspot resistance within the family Cruciferae include cultivars of *Sinapis alba*, a mustard used as a condiment and vegetable.

Recently, using ^{14}C-labelled synthetic compounds, we demonstrated that complete detoxification of destruxin B (**22**) in plants resistant to *A. brassicae* is a two-step process involving sequential hydroxylation to **24** and glucosylation to **25** (26). The chemical structure of the nontoxic destruxin B product (β-D-glucosyl hydroxydestruxin B (**25**)) was determined by a combination of spectroscopic analyses and chemical synthesis of both the β- and α-glucosides of **25**, as well as the tetracetyl derivative. The chemical synthesis of ^{14}C-labelled hydroxydestruxin B (**24**), and results of phytotoxicity assays (27) of hydroxydestruxin B (**22**), hydroxyhomodestruxin B (**24**), and β-D-glucosyl hydroxydestruxin B (**25**) have been described (28). Interestingly, although the hydroxylation and glucosylation reactions occur in both resistant and susceptible species, hydroxylation was the rate-limiting step in the susceptible species, whereas glucosylation was the rate-limiting step in the resistant species (Fig. 2). Remarkably, it was established that hydroxydestruxin B (**24**) induced the biosynthesis of phytoalexins in the resistant white mustard (*S. alba*) but not in the susceptible canola or brown mustard. Taken together our studies suggest that white mustard can overcome the fungal invader through detoxification of destruxin B (**22**) coupled with production of phytoalexins (26).

Further investigation of the metabolism of ^{14}C-destruxin B (**22**) and ^{14}C-hydroxydestruxin B (**24**) in additional crucifers showed that three resistant cultivars of white mustard metabolized destruxin B (**22**) to hydroxydestruxin B (**24**) substantially faster than cultivars of any other species. Among the *Brassica* species, a cultivar of brown mustard (Cutlass, *B. juncea*) appeared to metabolize destruxin B (**22**) to hydroxydestruxin B (**24**) faster. On the other hand, a contrasting trend was observed for the metabolism of hydroxydestruxin B (**24**) to β-D-glucosyl hydroxydestruxin B (**25**); cultivars of canola (susceptible) appeared to transform hydroxydestruxin B (**24**) to **25** substantially faster than cultivars of white mustard, while brown mustard Cutlass showed an intermediate rate. Importantly, leaf and cell culture assays showed that hydroxydestruxin B (**24**) was substantially less toxic to the susceptible species than destruxin B (**22**), and β-D-glucosyl hydroxydestruxin B (**25**) showed no toxicity at all. In summary, these studies indicated that the rate of hydroxylation of destruxin B in cruciferous plants correlated with species resistance to *A. brassica.* Furthermore, we observed that during this detoxification process the phytoalexins sinalexin and sinalbin A were produced in white mustard, however no phytoalexins were detected in canola or brown mustard (26). Although it is well-known that phytoalexins can be biosynthesized in response to a variety of elicitors, including phytotoxins, to the best of my knowledge this is the first and only example of phytoalexin elicitation by a detoxification product of a phytotoxin. Thus, the relatively slower glucosylation rate of hydroxydestruxin B (**24**) in resistant white mustard may be favourable since **24** also elicits biosynthesis of phytoalexins in this species, but not in susceptible species. β-D-Glucosyl hydroxydestruxin B (**25**) was further metabolized to the malonyl derivative **26**, as shown in Fig. 2 (29).

Our results of destruxin B (**22**) detoxification suggest that resistance of mustard to blackspot might be due to detoxification of destruxin B and be amplified by well-synchronized phytoalexin elicitation. This hypothesis, however, does not imply that all blackspot resistant species have the same resistance mechanism. Since the resistance to *A. brassicae* of the cruciferous weeds false flax (*Camelina sativa*) and shepherd's purse (*Capsella bursa-pastoris*) was proposed to be due to production of the phytoalexin camalexin (**19**), we have investigated destruxin B metabolism in these species as well (29). This work showed that *C. bursa-pastoris* metabolized ^{14}C-destruxin B to ^{14}C-hydroxydestruxin B glucoside substantially faster than *C. sativa*, even though uptake of toxin solutions by *C. bursa-pastoris* was slower. Furthermore, *Eruca sativa* transformed hydroxydestruxin B glucoside to the malonylated derivative substantially faster than *C. sativa* or *C. bursa-pastoris.* Comparison of these results with our previous work (26) demonstrates that the transformation of destruxin B in *C. sativa* (69% in 168 h) was much slower than in *S. alba* (ca. 100% in 48 h). Although *C. sativa* and

© 2004 NRC Canada

C. bursa-pastoris produce the phytoalexin camalexin, which is highly inhibitory to *A. brassicae,* these wild species still metabolize destruxin B similar to cultivated species. Phytoalexins did not appear to be elicited by destruxin B or hydroxydestruxin B either in *C. sativa* and *C. bursa-pastoris*. In conclusion, since the destruxin B detoxification pathway present in *S. alba* is also present in three other unrelated species, it was suggested a conservation of this pathway across crucifers. Considering that *C. sativa* and *C. bursa-pastoris* detoxify destruxin B and produce the phytoalexins camalexins, it appears that these wild crucifers represent unique sources of Alternaria blackspot resistance (29).

Conclusions and future prospects

Our work on the biotransformation of cruciferous phytoalexins indicated that different pathogens utilized different pathways to transform the same phytoalexin, and that those processes might contribute to successful plant colonization (15–18). On the other hand, work on the biotransformation of phytotoxins demonstrated that different plants transformed a pathogen's HST using identical pathways (26, 29). These results suggest that such plant pathways are conserved across species and genera; however, the rates of such transformations are substantially different. It would be important to establish if such differences exist among other taxa and between monocotyledons and dicotyledons, to better understand the co-evolution of plant–pathogen populations.

Over the past 50 years, the control of plant pests and diseases has relied mainly on chemical pesticides. However useful and necessary, it is clear that sustainable agriculture practices demand control strategies other than massive application of pesticides. It is anticipated that future approaches to control pests and diseases will rely on more selective and environmentally friendly control methods. Such methods require a much better understanding of the ecological roles of secondary metabolites of plants and their pathogens. Ultimately, systematic modification of metabolite profiles will demonstrate their significance in plant defence and disease resistance. For example, glucosinolates play a role in plant defence as attractants and deterrents against herbivorous insects. A key step in glucosinolate biosynthesis is the conversion of amino acids to the corresponding aldoximes, which is catalyzed by cytochromes P 450 belonging to the CYP79 family. Expression of a CYP79 from cassava in Arabidopsis resulted in the production of new glucosinolates. Metabolically engineered plants producing these new glucosinolates have acquired novel properties with great potential for improvement of resistance to herbivores (30).

In conclusion, considering the diversity of strategies that fungal pathogens use as well as their ability to quickly adapt, it is difficult to predict which developments will lead to durable and broad-spectrum disease resistance. No matter what sophisticated methodologies may be discovered, it is clear that effective plant protection will require a better understanding of the ecological roles of secondary metabolites, their metabolic pathways, and the integration of the various agricultural practices and control procedures.

Acknowledgements

I am very grateful to the Canadian Society for Chemistry (CSC) for having chosen me to receive the Clara Benson Award. It is a great honor and particularly meaningful to be the recipient of this award in 2003, the year celebrating the centenary of the Ph.D. award to Clara Benson, at the University of Toronto.

I have a number of people whom I owe my deepest gratitude for their immense support and trust in my abilities. First and foremost, I thank Dale and João (Tuco) for their unrelenting faith in me. I wish to acknowledge the support of my early collaborators from whom I learned so much about fungi and plants, in particular my "blacklegger" colleague Ginette Séguin-Swartz, and my senior colleagues in the Department of Chemistry of the University of Saskatchewan.

I am in debt to a group of hard working and talented young researchers with whom I have worked during the past 9 years. While a number of these people worked on chemistries not referenced herein, their contributions remain very important to our program progress and success. These include the postdoctoral fellows and technical associates: Farooq Biabani, Corinne Biesenthal, Vera Cekic, Ashlesha Deshpande, Ravi Gadagi, Nargis Ismail, Yanqiu Jiang, Abdul Khan, Iwona Kowalczyk, Ali Loukaci, Sabine Montaut, Oladapo Okeola, Soroush Sardari, Kevin Smith, Mojmir Suchy, Venkat Uppala, Yiming Xu, Dongfeng Zhan, Yifa Zhou; as well as the graduate and undergraduate students: Pearson Ahiahonu, Keith Block, Paulos Chumala, Claudia Erosa-Lopez, Heather Filson, Mohammad Hossain, Mukund Jha, Mohammad Kabir, Soong Lee, Jun Liu, Tyler Norsten, Corwin Nycholat, Francis Okanga, Denis Owiti, Gopal Sarwar, John Sorensen, Shawndra Sttetner, and Irina Zaharia.

In addition, financial support from the Natural Sciences and Engineering Research Council of Canada (NSERC), The Canada Foundation for Innovation (CFI), the Government of Saskatchewan (Saskatchewan Agricultural Development Fund), the University of Saskatchewan, the Canola Research Council of Canada, the Saskatchewan Canola Development Commission, and the Saskatchewan Wheat Pool, is very gratefully acknowledged.

Kinetic evidence for the importance of solvent-separated ion pairs during the solvolyses of adamantylideneadamantyl derivatives

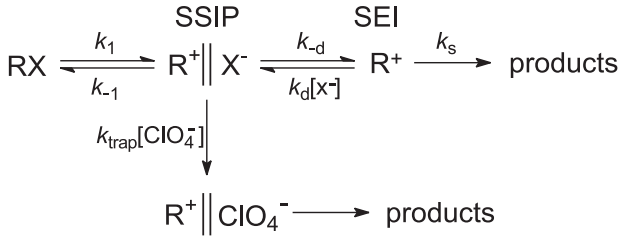
Xicai Huang and Andrew J. Bennet

Abstract: The aqueous ethanolysis reactions of adamantylideneadamantyl tosylate, -bromide, and -iodide (**1-OTs**, **1-Br** and **1-I**) were monitored as a function of ionic strength. Special salt effects are observed during the solvolyses of both homoallylic halides, but not in the case of the tosylate **1-OTs**. The measured α-secondary deuterium kinetic isotope effects for the solvolysis of **1-Br** in 80:20 and 60:40 v/v ethanol–water mixtures at 25 °C are 1.110 ± 0.018 and 1.146 ± 0.009, respectively. The above results are consistent with the homoallylic halides reacting via a virtual transition state in which both formation and dissociation of a solvent-separated ion pair are partially rate-determining. While the corresponding transition state for adamantylideneadamantyl tosylate involves formation of the solvent-separated ion pair.

Key words: salt effects, kinetic isotope effect, internal return, solvolysis, ion pairs.

Résumé : On a examiné les réactions d'éthanolyse aqueuse du tosylate, du bromure et de l'iodure d'adamantylidène-adamantyle (**1-OTs**, **1-Br** et **1-I**) en fonction de la force ionique. On a observé des effets de sel spéciaux au cours des solvolyses de chacun des halogénures homoallyliques, mais ce n'est pas le cas pour le tosylate **1-OTs**. On a déterminé que les effets isotopiques cinétiques du deutérium secondaire en α sur la solvolyse du **1-Br** dans des mélanges 80:20 et 60:40 v/v d'éthanol et d'eau, à 25 °C, sont respectivement de 1,110 ± 0,018 et 1,146 ± 0,009. Ces résultats sont en accord avec un mécanisme par lequel les halogénures homoallyliques réagissent par le biais d'un état de transition virtuel dans lequel la formation ainsi que la dissociation d'une paire d'ions séparés par le solvant sont toutes les deux partiellement cinétiquement déterminantes. Dans le cas du tosylate d'adamantylidèneadamantyle, l'état de transition correspondant implique toutefois une paire d'ions séparés par le solvant.

Mots clés : effets de sel, effet isotopique cinétique, retour interne, solvolyse, paires d'ions.



[Traduit par la Rédaction]

Introduction

In 1956, Winstein reported that addition of $LiClO_4$ to the solvolytic reactions of several structurally diverse arylsulfonates resulted in a nonlinear correlation between the rate constant for acetolysis and the ionic strength of the solution (1–4). These observations were rationalized within the mechanism shown in Scheme 1. In this scheme, a simplified version of Winstein's ion-pair mechanism (5–7), two separate carbenium ion intermediates are incorporated: (*i*) the solvent-separated ion pair (SSIP); and (*ii*) the solvent-equilibrated ion (SEI). Furthermore, the observed nonlinearity is a consequence of SSIP trapping by the added perchlorate with the result that "external" ion-pair return is prevented (1, 2).

In 1994, Huang and Bennet reported that in 80% v/v ethanol–water the homoallylic adamantylideneadamantyl tosylate (**1-OTs**) solvolyzed 4×10^5 faster than did 2-adamantyl tosylate (**2-OTs**) at 25 °C (8). This observation led to the conclusion that at the solvolytic transition state π-electron delocalization was occurring into the developing carbenium ion *p*-orbital (8). In a separate study, it was shown that the corresponding halides (**1-Br** and **1-I**) displayed the phenomenon of common-ion rate depression during their solvolyses. Thus, it was inferred that these reactions entail formation of the solvent-equilibrated homoallylic carbenium ion **3**, an intermediate that has a lifetime of $\geq 6.4 \times 10^{-9}$ s in 60:40 v/v EtOH–H_2O at 25 °C (9).

4-X: X = OH, OTs or Br

Given that one of the substrates on which Winstein reported observing a special salt effect was cholesteryl tosylate (4), a homoallylic system, it seemed appropriate to investigate the kinetic behavior of adamantylideneadamantyl derivatives upon addition of perchlorate to the solvolytic medium. Thus, this report addresses several questions concerning the solvolysis reactions of adamantylideneadamantyl tosylate, -bromide, and -iodide (**1-OTs**, **1-Br** and **1-I**). For example, are solvent-separated ion pairs (SSIPs) kinetically important intermediates in these dissociative reactions? How does modification of the nucleofuge perturb the transition-state structure in these reactions?

Materials and methods

Flash column chromatography was performed using Merck silica gel 60 (230–400 mesh). All reagents were used as purchased. NMR spectra were recorded on a Bruker AMX-400 NMR spectrometer operating at 400.13 MHz and 100.61 MHz for ^{1}H and ^{13}C, respectively. Chemical shifts (δ) for all compounds are listed in ppm downfield from TMS using residual $CHCl_3$ (δ 7.24 ppm) as the internal reference for ^{1}H spectra and $CDCl_3$ (δ 77.0 ppm) as the internal reference for ^{13}C spectra. Synthesis of adamantylidene adamantyl compounds **1-OTs**, **1-Br**, and **1-I** were accomplished by following the published procedures (8, 9).

(1*R,2*R**)-1-Bromo-2-*deuterio*-4-tricyclo[3.3.1.1^{3,7}]dec-2-ylidene tricyclo[3.3.1.1^{3,7}]-decane (4-Br)**

The deuterated alcohol **4-OH** (10) (0.16 g) was added to a solution of HBr (1.08 g) in CH_2Cl_2 (30 mL), made by the in situ reaction of acetyl bromide (1.0 mL) and methanol (0.54 mL). This solution was stirred at 0 °C for 60 min, followed by the removal of volatile components under reduced pressure. Purification of the residue by flash column chromatography on silica gel with hexane as the eluent gave **4-Br** as a white solid (0.18 g, 90%), mp 121 to 122 °C (lit. value for **1-Br** (8) mp 129 to 130 °C). EI-MS *m*/*z* **4-Br**: 347 (M^+, 10.7), 348 (2.6), 349 (12.0), and 350 (2.5); data for **1-Br**: 346 (M^+, 10.5), 347 (2.7), 348 (10.0), and 349 (2.4). The ^{1}H NMR spectrum for **4-Br** is essentially identical to that of **1-Br** except that the broad singlet for the secondary bromide (δ 4.4) is absent in the spectrum of **4-Br**.

Kinetics

Solvolysis kinetics were monitored as previously described (8, 10).

Results

To investigate whether significant external ion-pair return (Scheme 1) occurs during the solvolysis of **1-OTs**, **1-Br**, and **1-I** rate constants were measured as a function of sodium perchlorate concentration. The measured values are listed in Tables S1 and S2 of the supporting information.[2] Two typical plots of the measured solvolysis reaction rate constant vs. ionic strength data are displayed in Fig. 1.

In contrast to the expected behavior for a normal salt effect (3, 11), the observed rate constants for the solvolyses of **1-Br** and **1-I** in both 60:40 and 80:20 v/v EtOH–H_2O mixtures varies in a nonlinear fashion at low ionic strength.

For reactions that exhibit a special salt effect, the addition of "common ion" can cause a reduction in the importance of the perchlorate ion-containing SSIP ($R^+ \parallel ClO_4^-$), thereby reducing the observed "special salt" effect (12). Therefore, the effect of ionic strength on the rate constant for solvolysis of **1-I** was measured in the presence of the common ion ([NaI] = 0.02 mol/L) and these measured rate constants are catalogued in Table S3.[2] Shown in Fig. 2 is the kinetic data for solvolysis of **1-I** (60:40 v/v, EtOH–H_2O) measured in the presence and absence of the common ion.

Additionally, secondary deuterium kinetic isotope effects (α-SDKIEs: $k_{\mathbf{1\text{-}Br}}/k_{\mathbf{4\text{-}Br}}$) were measured for the solvolysis of the homoallylic bromide in 60:40 and 80:20 v/v EtOH–H_2O at 25 °C. The calculated α-SDKIEs are listed in Table 1. Also, listed in Table 1 are the previously reported α-SDKIEs for the solvolysis reactions of **1-OTs** ($k_{\mathbf{1\text{-}OTs}}/k_{\mathbf{4\text{-}OTs}}$) (10).

Discussion

The curvature seen in the plots of solvolysis reaction rate constant vs. ionic strength data (e.g., Fig. 1) is modest. However, such nonlinearity is still evidence that the addition of the non-nucleophilic ClO_4^- anion to the reaction mixture can

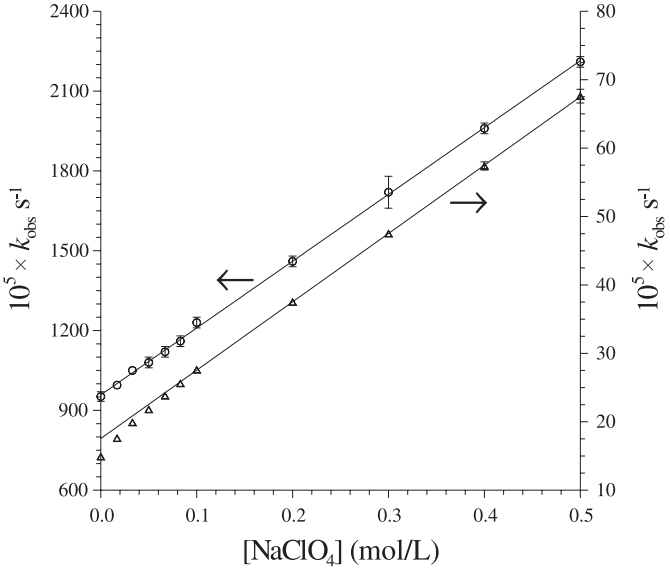
[b]The reported values for **1-OTs** are taken from ref. 10.

Fig. 1. Plot of k_{obs} vs. [$NaClO_4$] for the solvolysis of **1-OTs** (○) and **1-Br** (△) in 80% v/v aqueous ethanol at 25 °C. The line through the data points (**1-OTs**) is the best linear fit for all data and the second line is the best linear fit for the **1-Br** data where [$NaClO_4$] ≥ 0.1 mol/L. Error limits are encompassed within the symbol diameter except where shown explicitly.



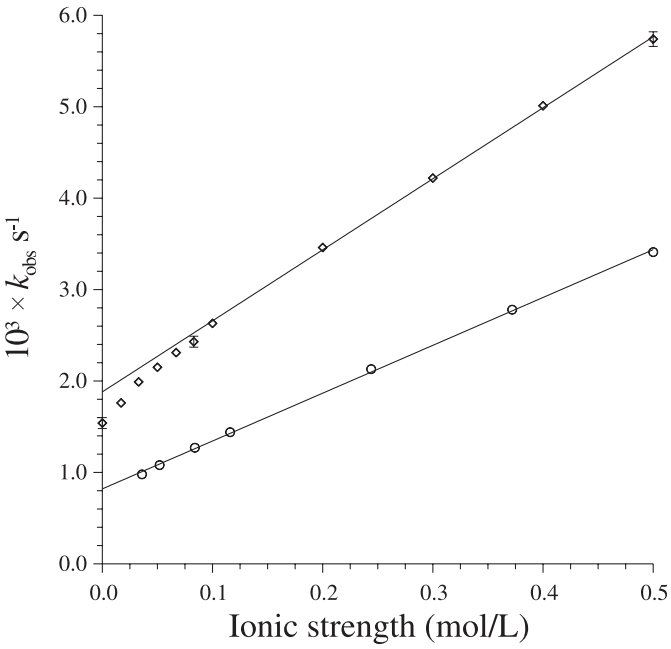


Fig. 2. Plot of k_{obs} vs. ionic strength for the solvolysis of **1-I** in 60% v/v aqueous ethanol at 25 °C. The line through the data points (**1-I**, [NaI] = 0.02 mol/L (○)) is the best linear fit for all data and the second line is the best linear fit for the **1-I** ([NaI] = 0.0 mol/L: (◇)) data where [$NaClO_4$] ≥ 0.1 mol/L. Error limits are encompassed within the symbol diameter except where shown explicitly.

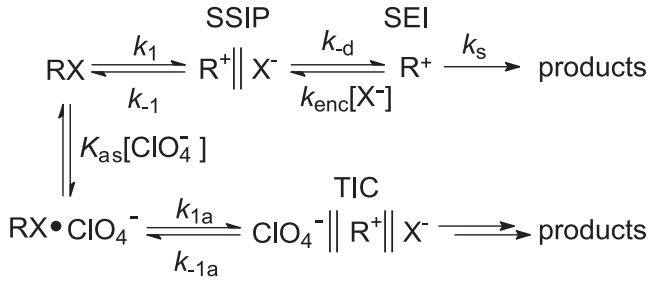

result in a reduction of external ion return (k_{-1}, Scheme 1) from the SSIP ($R^+ \parallel X^-$).

The mechanistic scheme utilized by Winstein and others (Scheme 1) to analyze their observed special salt effects must be modified in the present case. That is, because the current reactions were performed in aqueous solutions it is possible to rule out certain mechanistic pathways based on literature precedent. Specifically, the rate constant for SSIP dissociation to give SEI (Scheme 1, $k_{-d} = 1.6 \times 10^{10}$ s^{-1} (13) is much faster than the maximal rate for the second-order interception of $R^+ \parallel X^-$ by ClO_4^- (Scheme 1, $k_{trap}[ClO_4^-] \leq 5 \times 10^8$ s^{-1}, when $[ClO_4^-] = 0.1$ mol/L). It can therefore be concluded that perchlorate is incapable of trapping the SSIP as depicted in Scheme 1. As a consequence, the modified reaction mechanism for aqueous solvolyses includes a "preassociation" pathway (Scheme 2).

The rate and equilibrium constants shown in Scheme 2 are: (*a*) ionization of the starting material to the SSIP (k_1); (*b*) reformation of starting material by collapse of the SSIP intermediate (k_{-1}); (*c*) dissociation of the SSIP to form the SEI (k_{-d}); (*d*) capture of the SEI by solvent (k_s); (*e*) encounter of the SEI with the common ion to regenerate the $R^+ \parallel X^-$ SSIP (k_{enc}); (*f*) formation of a preassociation complex between R–X and ClO_4^- (K_{as}); (*g*) ionization of the preassociation complex (k_{1a}); and (*h*) capture of the triple ion complex (TIC) to give, after several steps, the reaction products.

Scheme 2.

The degree of curvature apparent in Figs. 1 and 2 is much less than that reported in many other studies on special salt effects, such as those of Allen et al. (14, 15). Therefore, in the interpretation of the present data, a simple first-order analysis was employed using eq. [1].

$$[1] \qquad k_{obs} = k^0(1 + b[salt])$$

© 2004 NRC Canada

In eq. [1], k^0 is the rate constant extrapolated from the linear portion of the solvolytic rate constant data ($I \geq 0.1$, $NaClO_4$) to zero ionic strength, and b is the magnitude for the normal salt effect.

In mainly aqueous solutions, the value of K_{as} should be <<1.0 mol/L^{-1} (16, 17), therefore, the curvature in the rate vs. ionic strength plots is not caused by complete formation of the preassociation complex. On the contrary, the observed nonlinearity is consistent with the degree of reversion back to starting material being greater when the solvolyses are performed at low ionic strength (reaction proceeds via SSIPs) than at high ionic strength (where TICs are implicated).

In addition, when the solvolysis of **1-I** is performed in the presence of added common ion ([I^-] = 0.02 mol/L) the reaction rate is about 50% of that in the absence of iodide ion (Fig. 2, Tables S1 and S3[2]). While the corresponding figure at high ionic strength is around 60% (μ = 0.5 mol/L). In other words, common-ion rate depression is less prevalent at high ionic strength (TIC pathway) than at low ionic strength (SSIP pathway).

Of note, compound **1-OTs** shows no detectable special salt effect (Fig. 1) and therefore, formation of the SSIP is irreversible. In contrast, the non-zero special salt effect observed for both **1-Br** and **1-I** (Figs. 1 and 2) requires that in the absence of salt no single step is entirely rate-limiting and that the virtual transition state for solvolysis incorporates both the formation and the breakdown of the SSIP.

Secondary deuterium kinetic isotope effects

For many years, the magnitude of an observed α-secondary deuterium kinetic isotope effect (α-SDKIE) in solvolysis reactions has been used as a transition-state structure probe (18). For instance, in $D_N + A_N$ reactions (19), the predominant factor for the generation of an observed α-SDKIE is the weakening of the out-of-plane C-H bending vibration as the hybridization of the reacting center changes from sp^3 to an sp^2-like transition state (18). The predicted maximal values for α-SDKIEs at 25 °C for solvolysis of secondary alkyl tosylates and bromides are approximately 1.225 and 1.125, respectively (20, 21). Indeed, two separate research groups reported α-SDKIEs for solvolyses of two different 2-adamantyl sulfonates at 25 °C that are indistinguishable from the predicted maximal value (22, 23). In contrast, the documented α-SDKIE values for the aqueous ethanolysis of **1-OTs** fall in the range of 1.14–1.17 at 25 °C (10). Mechanistically, the observed α-SDKIEs for the reactions of **1-OTs** are indicative of an earlier solvolytic transition state, one which involves a smaller decrease in the C-H bending force constant at the reaction centre, than at the corresponding TS for the solvolysis of 2-adamantyl tosylate (**2-OTs**). In contrast, the observed α-SDKIEs for solvolysis of **1-Br** (Table 1) are identical to the predicted maximal value for reaction of a secondary alkyl bromide. This indicates that the rate-limiting TS for the S_N1 ($D_N + A_N$) solvolyses of **1-Br** is "later" than that for the reactions of **1-OTs**. An interpretation that is in agreement with the conclusions reached above concerning the observed special salt effects. Thus, the rate-limiting TS for reaction of **1-OTs** occurs prior to dissociation of the SSIP (Fig. 1 displays a strict linear correlation of rate constant and ionic strength), but the corresponding solvolysis of **1-Br** proceeds via a virtual TS that incorporates components of SSIP formation and dissociation (vide supra).

Differences between 1-OTs and cholesteryl tosylate

As a final point, a comment is warranted on the different salt effects observed during the solvolyses of **1-OTs** and cholesteryl tosylate (4). In their salt effect study on cholesteryl tosylate solvolysis, Winstein and Clippinger (4) used the poorly ionizing solvent acetic acid (Y_{OTs} = –0.61 (24)), but in the current study the solvents employed are more polar (e.g., Y_{OTs} (80% v/v EtOH–H_2O) = 0.00 (24)). Therefore, it is likely that in the less polar solvent the associated slower rates for ion-pair dissociation give rise to the observed special salt effect phenomenon (4).

Growth and morphological evolution of hexapod-shaped cuprous oxide microcrystals at room temperature

Xu Zhang, Yi Xie, Fen Xu, Di Xu, and Huarong Liu

Abstract: Growth and morphological evolution of hexapod-shaped Cu_2O microcrystals is carefully studied via a γ-irradiation reduction route at room temperature and under ambient pressure. The products are examined by means of XRD patterns and FE-SEM images. The as-obtained hexapod-shaped Cu_2O microcrystal is composed of six legs, whose adjacent legs are perpendicular to each other and each leg is composed of two perpendicular cross blades. A simple reaction system, excluding the influence of surfactant and thermal disturbance, would favor revelation of the inherent growth habit of Cu_2O microcrystals under relatively mild experimental conditions. Furthermore, the effects of several factors on the final product and morphology are investigated.

Key words: hexapod-shaped, γ-irradiation, cuprous oxide, morphological evolution.

Résumé : Faisant appel à une réduction de l'irradiation γ, à la température et à la pression ambiante, on a étudié avec soin la croissance et l'évolution morphologique de microcristaux de Cu_2O en forme d'hexapode. Les produits ont été examinés par le biais de patrons XRD et d'images FE-SEM. Le microcristal de Cu_2O en forme d'hexapode tel qu'il est obtenu est formé de six membres dans lesquels les membres adjacents sont perpendiculaires les uns aux autres alors que chaque membre est composé de deux lames qui leur sont perpendiculaires. Un système réactionnel simple, qui exclurait l'influence de l'agent de surface et les perturbations thermiques, favoriserait la façon de croissance inhérente des microcristaux de Cu_2O dans des conditions expérimentales relativement douces. On a étudié de plus les effets de plusieurs facteurs sur la nature et la morphologie du produit final.

Mots clés : en forme d'hexapode, irradiation γ, oxyde cuivreux, évolution morphologique.

Introduction

Among the numerous transition metal semiconductor oxides, cuprous oxide is of intense interest and has been investigated extensively for its distinctive properties. Firstly, cuprous oxide (Cu_2O) is an important metal-oxide *p*-type semiconductor (1–3) with a direct band gap of 2 eV, which makes it a promising material for the conversion of solar energy into electrical or chemical energy (4, 5). Moreover, Cu_2O has also been widely exploited for use in coloring of glass, in catalysts (6, 7) and antifouling coatings (8), or for killing snails to prevent schistosomiasis. Recently, it has also been found that Cu_2O submicrospheres can be used as the negative electrode material for lithium ion batteries (9).

Cuprous oxide (Cu_2O) crystallizes in the cuprite structure. It belongs to an isometric system and its space symmetry is expressed as *Pn*3*m* (Fig. 1). The coordination of the copper atoms is twice that of the oxygen atoms in the unit cell. The structure can be described as a cubic close packing of copper atoms, some of the tetrahedral sites of which are situated by oxygen atoms (10, 11). Cuprous oxide microcrystals are usually octahedral, less often dodecahedral or cubic, occasionally elongated along the <001> directions into capillary fibers.

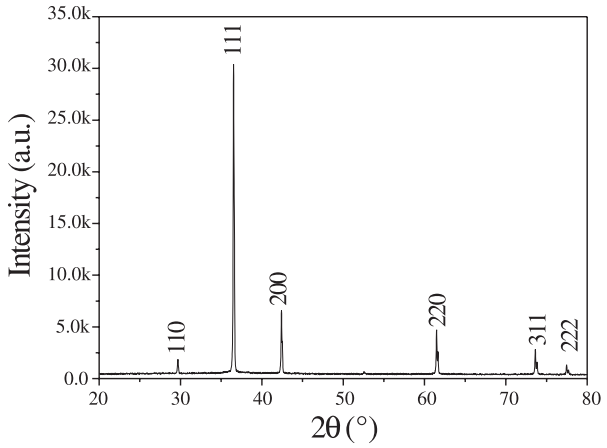
It is well-known that some chemical and physics properties of materials are dependent, to a large extent, on their shapes and textures. Thus, several methods have been developed to prepare Cu_2O microcrystals with different shapes, including electrodeposition (12, 13), reduction of metal salts in solution (14–20), and vacuum evaporation (21) most of which employed either template or surfactant or thermal disturbance and the products belong to the final growth stage. Therefore, it is difficult to trace the growth history of the product and further reveal the inherent growth habit of Cu_2O for lack of the detailed information on the evolution sequence from the initial nuclei to the intermediate geometries to the final product. It is meaningful to investigate the morphological evolution of Cu_2O, especially the multipod-shaped microcrystals, which can provide important information to the fields of crystal growth, design, and morphology-

 doi: 10.1139/V04-108 © 2004 NRC Canada

Fig. 1. Structure and microcrystal form of cuprous oxide.

controlled synthesis of Cu_2O, and further other inorganic building blocks. Therefore, it is necessary to find another simple, relatively mild approach to investigate the whole growth process of multipod-shaped Cu_2O.

In the latest decades, the γ-irradiation technique has been developed as a novel method to prepare nanoscale materials, including metal, metal oxides, chalcogenides, and inorganic–polymer nanocomposite (22–27). It is well-known that γ-irradiation can induce solvated electrons (e^-_{aq}) at room temperature and under ambient pressure, which are totally clean reductive agents from the green chemistry point of view because it can avoid the by-products coming from chemical reducing agents and the pollution to the environment. Moreover, it is technologically important for solvated electrons to make metal ions reduce gradually to lower valence ions (28). It is the virtue of slow reduction that gives us an inspiration that γ-irradiation may be an ideal method to trace the morphological evolution of multipod-shaped Cu_2O in the whole growth process.



In this paper, we firstly apply the relatively mild γ-irradiation reduction route to prepare pure cubic phase Cu_2O microcrystals with special morphology at room temperature and under ambient pressure. The whole growth process of Cu_2O microcrystals has been carefully studied through a series of detailed pictures taken at different radiation times. Our experimental results are different from that of a previous study (29), which may be attributed to the difference of the detailed experimental parameters employed.

Experimental section

All reagents were of analytical grade and were purchased from Shanghai Chemical Co. Ltd. All of the reactions were conducted at room temperature and under ambient pressure. In a typical procedure, 0.50 g of cupric acetate ($Cu(CH_3COO)_2{\cdot}H_2O$) was dissolved in 50 mL distilled water. Isopropanol (10 mL) was added into the above solution as a scavenger for hydroxyl radicals. After deaeration by bubbling with pure nitrogen for 30 min to remove oxygen, the solution was irradiated in the field of 2.59×10^{15} Bq of ^{60}Co γ-ray source for 8 h at room temperature. After γ-irradiation, the precipitate was separated from solution, washed with distilled water and absolute ethanol several times, then dried in vacuum at 25 °C for 5 h. In the controlled experiments, different radiation times and different precursors were applied.

The purity of the products was determined by X-ray powder diffraction (XRD) with a Philips X' Pert PRO SUPER

Fig. 2. Typical XRD pattern of the as-prepared product.

X-ray diffractometer with Cu Kα radiation (λ = 1.541 8 Å). The scan rate of $0.06°{\cdot}s^{-1}$ was applied to record the patterns in the 2θ range of 20°–80°. Field emission scanning electron microscopy (FE-SEM) was performed on a JEOL JSM-6700F scanning electron microanalyzer.

Results and discussion

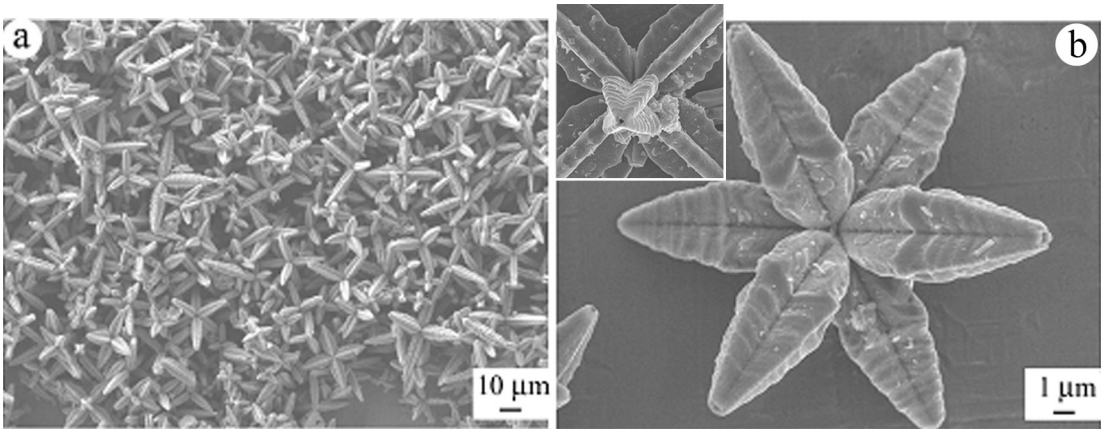
Figure 2 shows the typical XRD pattern of the as-prepared product. All of the reflections in Fig. 2 can be indexed to a pure cubic phase of cuprous oxide with the lattice constant a = 4.264 5 Å, compatible with the literature value of a = 4.269 6 Å (JCPDS file No. 05-0667). No other peaks of impurities were detected.

The morphology of the Cu_2O products was observed by FE-SEM. Figure 3*a* shows that a large number of hexapod-shaped microcrystals are obtained and Fig. 3*b* presents a high-magnification image of a single microcrystal, in which the average length of each leg is about 15 μm. Observed along a leg growth direction (as shown in the inset of Fig. 3*b*), is that each leg is composed of two perpendicular-cross blades and some stacking faults were also observed, which may be attributed to the heterogeneous crystal growth under static conditions during the growth process.

In the present approach, γ-irradiation is a prerequisite for the synthesis of hexpod-shaped Cu_2O microcrystals and the observation of morphological evolution at room temperature. If the reaction is conducted with the same reaction conditions without γ-irradiation, no solid phase is obtained, and no hexapod-shaped Cu_2O particles were found, which was also confirmed by a previous study (18).

In addition, it was also found that the in situ formed acetic acid and acetate ion buffer pair had a crucial influence on the final product in this approach. The formation of Cu_2O involves the reduction reactions of cupric ions with solvated electrons when the solution is γ-irradiated, which may be easily understood as follows:

$$[1] \quad H_2O \xrightarrow{\text{irradiation}} e^-_{aq}, H_3O^+, H_2, H_2O_2, \cdot H, \cdot OH$$



$$[2] \quad e^-_{aq} + Cu^{2+} \rightarrow Cu^+$$

$$[3] \quad 2Cu^+ \rightarrow Cu^0 + Cu^{2+}$$

$$[4] \quad 2Cu^+ + 2OH^- \rightarrow 2CuOH \rightarrow Cu_2O + H_2O$$

© 2004 NRC Canada

Fig. 3. FE-SEM images of hexapod-shaped Cu_2O microcrystals: (*a*) a panorama image, (*b*) showing a single microcrystal and the inset is the view of a leg along its growth direction.

As can be seen from eq. [1], hydrogen ion can be produced gradually in the process of the irradiation, and the acidity of the solution increases with the progress of the rxn. [1]. The formed oxidative hydroxyl radicals (·OH) have been scavenged by isopropanol. Pure Cu_2O can only be obtained in the pH range of 4.0–5.6 as is observed experimentally. Therefore, cupric acetate is selected to be an effective reagent because a buffer system can be in situ formed by the cooperation of acetate ion (CH_3COO^-) and the hydrogen ion (H_3O^+), which can keep the pH value of the reaction system in the range of 4.0 ~ 5.6. Moreover, the appropriate pH value was confirmed by the pH meter: the pH value of the solution was ~5.6 before the reaction and the pH value decreased to ~4.0 after the reaction finished. Under this pH value range, the reduction and dismutation (rxn. [3]) of cuprous ions are completely suppressed. In addition, the unstable cuprous hydroxide (CuOH) can also decompose rapidly to cuprous oxide, which can guarantee the formation of a large quantity of pure Cu_2O. In the controlled experiments, if $Cu(CH_3COOH)_2$ was replaced by $CuSO_4$ or $CuCl_2$ in the reactions, the product was the mixture of copper and cuprous oxide, which should be attributed to the absence of the in situ formed buffer pair. Because the pH value cannot be kept in the range of 4.0 ~ 5.6 under such conditions, the reduction and dismutation of cuprous ions (rxn. [3]) predominates in the reaction system, while the formation and the decomposition of cuprous hydroxide (CuOH) (rxn. [4]) is subsidiary.

To study the morphological evolution and further know the inherent growth habit of Cu_2O at room temperature, different radiation times were used in the experimental process by keeping the other experimental parameters constant. A set of FE-SEM images (shown in Fig. 4) taken at different radiation times clearly illustrates the nucleation and growth processes of the hexapod-shaped microcrystals. In our experimental process, the Cu_2O octahedra are found as the initial nuclei, while the legs grow from the six corners of the octahedral nuclei. Moreover, it was found that the remarkable transformation of morphology occurs when the radiation time was in the range of 2 ~ 4 h. When the reaction system was irradiated for 2 h, a large quantity of Cu_2O octahedral first-order structures formed initially. As a cubic structure, Cu_2O has a growth habit of an octahedral morphology enclosed by lowest-energy (111) facets, which can be used as the core for the following growth (Fig. 4*a*). After the Cu_2O cores are formed, new reactants are continuously arriving at the site. When the radiation time increases from 2.5 to 3 to 3.5 h, the emerged octahedral first-order structures nucleate secondary microcrystals and begin to develop their legs on their six corners along six directions according to the symmetry of the Cu_2O octahedron (Figs. 4*b*–*4d*), then eight intracrystal holes on the centers of (111) planes are generated. After irradiation for 4 h, secondary octahedral structures were formed, resulting in a face-centered close packing of crystal octahedra where the interconnectivity is generated by edge sharing (shown in Fig. 4*e*). Because the (001) face is dipolar and unstable (18), such anisotropic growth along the energetically favorable <001> direction progressed gradually with the increase of the radiation time from 5 to 6 h (Figs. 4*f* and 4*g*) and meanwhile, four edges also elongated along the <001> direction and obtained two perpendicular-cross blades in one leg. Finally, the hexapod-shaped Cu_2O microcrystals were formed after the reaction system was irradiated for 8 h (Fig. 4*h*). In the growth process, some symmetrical stacking faults occured at the surface of each blade, which may be attributed to the existence of the concentration gradient of some reactants (i. e. Cu^+ and OH^-) in the static growth process. Since the nucleus takes an exact octahedron form, the inter-leg angles are kept at precise angles as the legs continued to grow. The growth scheme of Cu_2O particles is summarized in Fig. 5. The angle between the adjacent two legs of the final hexapod-shaped microcrystal is 90°, which corresponds to the angle between the body diagonals of the initial octahedron.

Conclusion

In summary, hexapod-shaped cuprous oxide microcrystals were prepared via a γ-irradiation reduction route at relatively mild conditions. As a relatively mild reduction process, the γ-irradiation route not only makes the as-grown Cu_2O microcrystal fully exhibit its anisotropism at room temperature, but also provides us a simple means to study the morphological evolution of Cu_2O microcrystals. The phase and morphology of the as-prepared products are investigated by XRD and FE-SEM, respectively. This work shows that complex structures and morphologies can be derived from the

fundamental microscopic building units, and the final morphologies are correlated with the structure and shape of the basic microcrystal. This method may be extended to study the growth process of some special materials and prepare different materials with interesting morphology for special practical applications.

Synthesis and structural characterization of *m*-terphenyl Schiff base ligands and their aluminum complexes

Diane A. Dickie, Hanifa Jalali, Rahul G. Samant, Michael C. Jennings, and Jason A.C. Clyburne

Abstract: 2,4,6-Triphenylbenzaldehyde **1** undergoes a condensation reaction with 2-aminophenol to give *N*-(2′,4′,6′-triphenylbenzylidene)-2-iminophenol (TPIP) **2**. The imine **2** can be reduced with $NaBH_4$ in ethanol to form *N*-(2′,4′,6′-triphenylbenzyl)-2-aminophenol (TPAP) **3**. Addition of trimethylaluminum to **2** or **3** results in the formation of the complexes TPIP-$AlMe_2$·$AlMe_3$ (**4**) or TPAP-$AlMe_2$ (**5**). Compounds **2**, **3**, and **4** have been crystallographically characterized.

Key words: N,O ligands, aluminum, *m*-terphenyl, Schiff bases, X-ray crystallography.

Résumé : Le 2,4,6-triphénylbenzaldéhyde **1** subit une réaction de condensation avec le 2-aminophénol qui conduit à la formation du *N*-(2′,4′,6′-triphénylbenzylidène)-2-iminophénol (TPIP, **2**). L'imine **2** peut être réduite à l'aide de $NaBH_4$, dans l'éthanol, pour conduire à la formation du *N*-(2′,4′,6′-triphénylbenzyl)-2-aminophénol (TPAP, **3**). L'addition de triméthylaluminium aux composés **2** ou **3** conduit à la formation de complexes TPIP-$AlMe_2$·$AlMe_3$ (**4**) ou TPAP-$AlMe_2$ (**5**). Les composés **2**, **3** et **4** ont été caractérisés par cristallographie par diffraction des rayons X.

Mots clés : ligands N,O, aluminium, *m*-terphényle, bases de Schiff, cristallographie par diffraction des rayons X.

Introduction

The chemistry of *m*-terphenyl ligands is a rapidly developing field of research (1, 2). These molecules feature a central phenyl ring with two meta-aryl substituents that twist out of the plane of the central ring to form a bowl-shaped pocket into which numerous metals or functional groups can be placed (Fig. 1). The steric demands of the ligand can be tuned by varying the substituents of the aryl groups. Synthetically, the steric demands of *m*-terphenyl ligands have been used to stabilize unusual coordination environments and multiple bonds between heavy main group elements (3–6).

Organoaluminum compounds are widely used as catalysts or co-catalysts in numerous polymerization reactions (7–10). When developing a new homogeneous catalyst, it is important to have the ability to control the coordination environment around the metal centre (11). *m*-Terphenyl ligands, because of their ability to protect the space around the metal centre, have the potential to be useful in the field of catalysis. We have previously used amidine-substituted *m*-terphenyl ligands for the preparation of robust aluminum complexes (12, 13) and related compounds have been used as olefin polymerization catalysts (14). As a continuation of our studies on *m*-terphenyl substituted compounds, we decided to incorporate other catalytically active functional groups into the *m*-terphenyl pocket. An ideal candidate for the pocket appeared to be a Schiff base. We chose phenyl as the aryl substituent because it is less bulky than other substituted aryls, and it is also affordably and reliably synthesized.

Multidentate ligands such as Schiff bases, which contain both an imino (C=N) and a phenolic (OH) functional group, are potentially useful monoanionic ligands. While they can exhibit two different structural isomers (Fig. 2), the isomer featuring a three-carbon bridge (**A**) between the heteroatoms is much more common, with only a few published examples of main group Schiff base complexes containing a bridge of only two carbons (**B**) (15–18). Schiff bases are useful for varying the coordination number of the metal centre as the heteroatoms can bind in a monodentate fashion, chelate the metal, or bridge multiple metal centres (Fig. 3) (19). The tetradentate Salen family of ligands are perhaps the best known Schiff bases, and the coordination chemistry of main group elements with this class and the saturated Salan-type ligands has been extensively reviewed (20, 21).

In an attempt to incorporate Schiff bases onto an *m*-terphenyl ligand, we have prepared and structurally charac-

terized two ligands as well as a complex with aluminum. These molecules are related to bulky Schiff base ligands and complexes reported by Chisholm et al. (22), Gibson and co-workers (23), and Grubbs and co-workers (24).

Results and discussion

2,4,6-Triphenylbenzaldehyde **1** is readily synthesized on a large scale with good yield (80%) according to a variation of literature procedures (25) (Scheme 1). The white crystalline product was characterized by NMR spectroscopy. The aldehyde *H* resonance is observed at 10.0 ppm in the ^{1}H NMR spectrum. In the ^{13}C NMR, the aldehyde carbon signal appears at 193 ppm. Further confirmation of the assigned structure was provided by IR spectroscopy (ν C=O 1698 cm^{-1}; ν C-H 2747 cm^{-1}).

Aldehyde **1** was treated with 2-aminophenol in ethanol solution to form *N*-(2′,4′,6′-triphenylbenzylidene)-2-iminophenol (TPIP) **2** (Scheme 1). The product was isolated in high yield (>90%) as a yellow crystalline compound. Characterization of **2** was achieved by ^{1}H and ^{13}C NMR spectroscopy. The imine functionality was indicated by the peak at 8.59 ppm in the ^{1}H NMR spectrum as well as by the C=N stretch at

Fig. 3. Schiff base coordination patterns.

1625 cm^{-1} in the IR spectrum. These values are consistent with those reported by Yamamoto and co-workers (26) for the related 2-(phenylmethylene)aminophenol (δ N*H* 8.68 ppm, ν C=N 1630 cm^{-1}). The alcohol functionality was observed as a sharp singlet at 5.49 ppm in the ^{1}H NMR spectrum and at 3419 cm^{-1} in the IR. The value of the OH stretch in **2**, while higher than that of Yamamoto and co-workers at 3130 cm^{-1}, is comparable to other molecules that feature *intramolecular* [O-H···π] interactions, such as 2,6-diphenylphenol with an OH stretch of 3565 cm^{-1} (27).

X-ray crystallographic studies of a single crystal of **2** were performed and the results are presented in Table 1. As is typical in terphenyl molecules, the ortho phenyls are twisted out of the plane of the central phenyl ring to form a protective bowl around the imino functional group (Fig. 4). As expected from the spectroscopic data, an [O-H···π] interaction is observed between the phenolic proton and the centroid of one phenyl ring.

Reduction of the C=N double bond in TPIP was achieved by the addition of $NaBH_4$ in ethanol solution to give TPAP **3** (Scheme 2). The ^{1}H NMR spectrum showed a peak for the methylene protons at 4.05 ppm. This is consistent with data presented by Endo et al. (28) for the related *N*-benzyl-2-aminophenol where the methylene resonance is observed at 4.37 ppm. In the IR spectrum, the NH stretch appeared as a sharp peak at 3321 cm^{-1} while the OH appeared as a weak signal at 3391 cm^{-1}. X-ray crystallographic studies of a single crystal of **3** (Fig. 5) showed that the $C_{terphenyl}$—N bond length increased from 1.222(4) Å in TPIP to 1.448(3) Å in TPAP while the C_{phenol}—N bond shortened slightly from 1.427(4) to 1.394(3) Å. The [O-H···π] interaction noted in **2** is not observed in **3**.

TPIP **2** reacts with 2 equiv. of trimethylaluminum to give TPIP-$AlMe_2$·$AlMe_3$ (**4**) (Scheme 2), which features one aluminum chelated by the two heteroatoms as well as a second aluminum coordinated in Lewis acid–base fashion to the oxygen atom. In the presence of only 1 equiv. of $AlMe_3$, compound **4** is still formed, along with a yellow powder that was not further characterized because of its insolubility in conventional solvents.

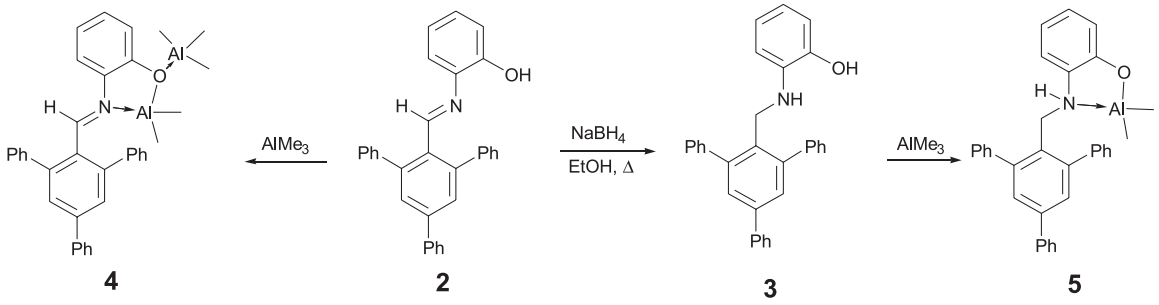

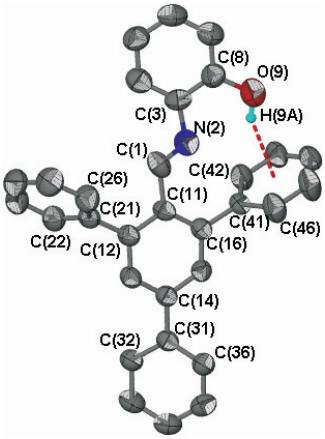

Fig. 4. The structure of TPIP (**2**) showing the numbering scheme. Hydrogen atoms, except the phenolic H, have been removed for clarity. Selected bond lengths (Å): C(1)—N(2) 1.222(4), C(1)—C(11) 1.505(5), N(2)—C(3) 1.427(4), C(8)—O(9) 1.393(5), H(9a)···centroid 2.986, O(9)···centroid 3.562. Selected bond angles (°): C(11)-C(1)-N(2) 123.2(4), C(1)-N(2)-C(3) 119.0(3), O(9)-H(9a)···centroid 139.73.

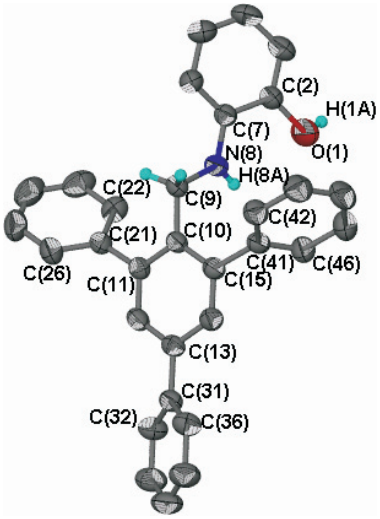

^{1}H NMR data indicated the presence of two different aluminum methyl environments with resonances observed at –1.31 and –0.89 ppm, with relative integrated intensities of 2:3. These signals were assigned to a *N*,*O*-chelated dimethylaluminum centre and the *O*-coordinated trimethylaluminum centre, respectively. Noticeably absent from the IR spectrum of **4** was the OH stretch observed in **2**. X-ray crystallographic studies confirmed the proposed structure (Fig. 6).

The coordination pattern observed in **4**, while unexpected, is not unprecedented (Fig. 7). Similar five-membered N-Al-O heterocycles with a second trialkylaluminum coordinated to the oxygen atom have been reported by Atwood et al. (17), Barron and co-workers (29), and van Koten and co-workers (30, 31). The Al—N and both Al—O bond lengths of **4** are consistent with the literatures values (Table 2). The environment around each aluminum centre in **4** is that of a distorted tetrahedron, with bond angles ranging from 84.13°–120.30° in the chelated aluminum, Al(13), and 102.02°–115.47° for the other, Al(4). The large distortions seen in the chelated centre are likely due to the steric constraints imposed by the formation of a five-membered ring, as well as the presence of the bulky *m*-terphenyl fragment.

The aluminum complex TPIP-$AlMe_2$·$AlMe_3$ (**4**) was tested as a catalyst in the ring-opening polymerization of ε-

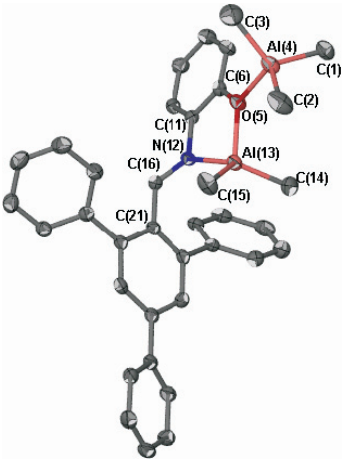

Fig. 5. The structure of TPAP (**3**) showing the numbering scheme. Aryl hydrogen atoms have been removed for clarity. Selected bond lengths (Å): C(10)—C(9) 1.517(3), C(9)—N(8) 1.448(3), N(8)—C(7) 1.394(3), C(2)—O(1) 1.375(3). Selected bond angles (°): C(10)-C(9)-N(8) 112.14(17), C(9)-N(8)-C(7) 118.91(18).

caprolactone (9) and propylene oxide (7). Complex **4** was found to give poly(caprolactone) with M_w = 10 964 and polydispersity of 1.50. Under similar conditions, the bulky alkylaluminum catalysts described by Okuda and co-workers (9) produced polymers with M_w in the range of 50 000 with polydispersities between 1.8–3.3. Complex **4** was not active in the polymerization of propylene oxide. This is poor compared with other alkylaluminum compounds featuring nitrogen and oxygen donors (7).

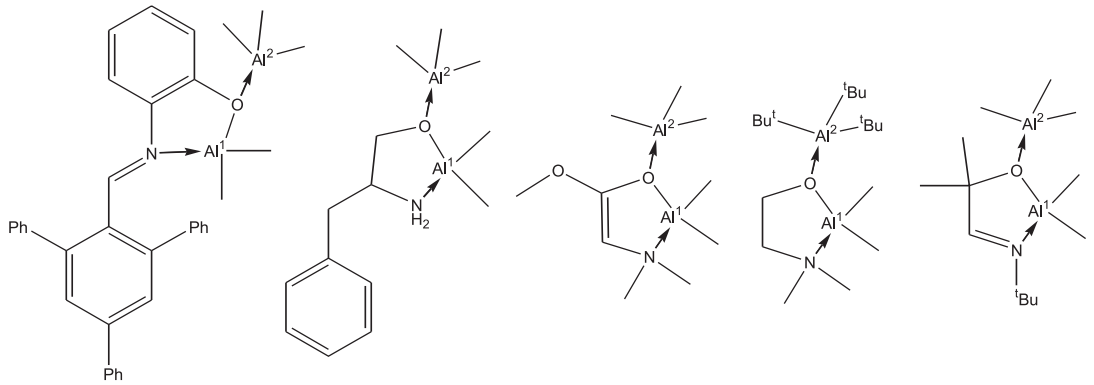
Finally, when TPAP **3** was combined with trimethylaluminum, the anticipated product TPAP-AlMe·$AlMe_3$ was not detected. To our surprise, the mononuclear complex TPAP-$AlMe_2$ (**5**) was isolated (Scheme 2). Complex **5** was characterized by IR, ^{1}H and ^{13}C NMR spectroscopy. The IR spectrum showed a peak assigned to an NH stretch at 3321 cm^{-1} (cf. TPAP N-H observed at 3291 cm^{-1}). In the ^{1}H NMR spectrum, the signal for the methylene protons was resolved into a doublet ($^3J_{H-H}$ = 7 Hz) and the N*H* signal appeared as a triplet at 3.08 ppm ($^3J_{H-H}$ = 7 Hz). Also observed in the ^{1}H NMR spectrum was a sharp singlet at –1.35 ppm that integrated to six hydrogens. This signal was assigned to six aluminum methyl hydrogen atoms. Similarly, the signal at –8.1 ppm in the ^{13}C NMR spectrum was assigned to the two aluminum methyl carbons. These spectroscopic observations, specifically the decreased frequency of ν_{N-H} in the IR spectrum and the N*H*-C*H* $^3J_{H-H}$ coupling constant in the ^{1}H NMR spectrum, are consistent with our suggested structure **5** and this structure is reminiscent of trialkylaluminum-dialkylamine adducts previously reported by Bradley et al. (32). Elemental analyses was performed on samples of **5**, and the results agree more closely with the suggested structure of **5** than any of the other likely reaction products. Unfortunately, despite numerous attempts in various solvents and conditions, we were not able to grow crystals suitable for X-ray crystallographic studies.

Fig. 6. Structure of TPIP-$AlMe_2$·$AlMe_3$ (**4**) showing the numbering scheme. Hydrogen atoms have been removed for clarity. Selected bond lengths (Å): C(21)—C(16) 1.470(3), C(16)—N(12) 1.289(3), N(12)—Al(13) 2.013(2), N(12)—C(11) 1.430(3), C(6)—O(5) 1.386(3), O(5)—Al(4) 1.936(2), O(5)—Al(13) 1.870(2), Al(13)—C(15) 1.939(3), Al(13)—C(14) 1.932(3), Al(4)—C(3) 1.972(3), Al(4)—C(1) 1.977(3), Al(4)—C(2) 1.970(3). Selected bond angles (°): C(21)-C(16)-N(12) 122.5(2), C(16)-N(12)-C(11) 120.3(2), N(12)-Al(13)-O(5) 84.13(8), N(12)-Al(13)-C(15) 108.27(12), N(12)-Al(13)-C(14) 115.13(12), C(15)-Al(13)-C(14) 120.30(15), O(5)-Al(13)-C(15) 116.83(14), O(5)-Al(13)-C(14) 106.74(12), C(6)-O(5)-Al(13) 112.72(16), C(6)-O(5)-Al(4) 123.28(16), O(5)-Al(4)-C(1) 106.45(11), O(5)-Al(4)-C(2) 102.01(12), O(5)-Al(4)-C(3) 105.25(12), C(1)-Al(4)-C(2) 112.31(15), C(1)-Al(4)-C(3) 115.47(15), C(2)-Al(4)-C(3) 113.82(17), Al(13)-O(5)-Al(4) 123.50(9).

Polymerization of ε-caprolactone and propylene oxide were attempted under similar conditions to those described for **4** but no reaction was observed. The reasons for this difference in activity are not immediately clear.

Summary

Two new aminophenol *m*-terphenyl derivatives were synthesized and characterized. The aluminum complexes of these ligands were also synthesized. The activity of TPIP-$AlMe_2$·$AlMe_3$ as a ring-opening polymerization catalyst was examined. Poly(caprolactone) with M_w = 10 964 and polydispersity of 1.50 was produced, however the molecule was not catalytically active in the presence of propylene oxide.



Experimental

General

An MBraun UL-99–245 dry box and standard Schlenk techniques on a double manifold vacuum line were used in the manipulation of air and moisture sensitive compounds. NMR spectra were recorded on a Bruker AMX 400 or a Varian AS 500 spectrometer in 5 mm quartz tubes. ^{1}H and ^{13}C chemical shifts are reported in parts per million (ppm) downfield from tetramethylsilane (TMS) and are calibrated to the residual signal of the solvent. Infrared spectra were obtained using a Bomem MB spectrometer with the % trans-

mittance values reported in cm^{-1}. Melting points were measured using a Mel-Temp apparatus and are uncorrected. Elemental analysis were obtained by M.K. Yang on a Carlo Erba Model 1106 CHN analyzer.

2,4,6-Triphenylbenzaldehyde (25) (1)

2,4,6-Triphenylbromobenzene (20 g, 52 mmol) was suspended in ca. 200 mL anhydrous ether and *n*-butyllithium (1.6 mol L^{-1} in hexane, 36 mL, 57 mmol) was added dropwise. The reaction was stirred at room temperature for 3 h and an excess of DMF (17 mL) was then added dropwise. After 2 h, the reaction was quenched with H_2O and extracted with ether. The combined ether portions were dried with $MgSO_4$, concentrated under vacuum, and stored at −20 °C. Yellow crystals were isolated and characterized as 2,4,6-triphenylbenzaldehyde (13.8 g, 41 mmol, 80%), mp 128 to 129 °C. IR (Nujol): 2747 (m), 1698 (s), 1590 (s), 1343 (s), 1198 (s), 892 (m), 764 (vs). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.40–7.71 (m, 17H), 10.00 (s, 1H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 127.4, 127.7, 128.2, 128.5, 129.0, 129.1, 129.6, 131.6, 139.4, 139.8, 144.2, 145.2, 193.0.

N-*(2′,4′,6′-Triphenylbenzylidene)2-iminophenol (TPIP) (2)*

2,4,6,-Triphenylbenzaldehyde (10.0 g, 29.9 mmol) and 2-aminophenol (3.7 g, 29.9 mmol) were suspended in ca. 200 mL of anhyd. EtOH and heated to reflux. Glacial acetic acid (5 mL) was then added and reflux continued for 3 h. The mixture was allowed to cool to room temperature and bright yellow needle-like crystals were filtered off (11.5 g, 26.9 mmol, 90%), mp 158 to 159 °C. IR (Nujol): 3417 (m), 1625 (m), 1584 (m), 1297 (m), 1249 (m), 1212 (m), 887 (m), 699 (s). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 5.49 (s, 1H, O*H*), 6.68–6.72 (m, 1H), 6.76–6.79 (m, 2H), 7.01–7.06 (m, 1H), 7.38–7.53 (m, 15H), 7.65 (s, 2H), 8.59 (s, 1H, N=C*H*). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 119.7, 127.2, 127.4, 127.7, 128.0, 128.2, 128.4, 128.9, 129.0, 129.4, 129.5, 193.0 (quaternary carbons not observed). Anal. calcd. for $C_{31}H_{23}NO$: C 87.50, H 5.45, N 3.29; found: C 87.42, H 5.47, N 3.41.

N-*(2′,4′,6′-Triphenylbenzyl)-2-aminophenol (TPAP) (3)*

TPIP (4.05 g, 9.52 mmol) and sodium borohydride (0.90 g, 23.8 mmol) were suspended in ca. 200 mL of anhyd. EtOH. The mixture was heated slowly to reflux over 1 h and then allowed to cool to room temperature. The reaction was quenched with H_2O and extracted with CH_2Cl_2. The organic layer was washed with H_2O and a saturated sodium chloride solution and dried with $MgSO_4$. The solvent was removed under vacuum to give a brown powder that was recrystallized from Et_2O at room temperature (2.54 g, 5.94 mmol, 62.4%), mp 174–176 °C. IR (Nujol): 3391 (w), 3321 (m), 1595 (m), 1493 (m), 1480 (s), 1275 (m), 1251 (m), 886 (m), 702 (s). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 4.06 (s, 2H, CH_2), 5.06 (br s, 1H, O*H*), 6.24 (s, 1H, N*H*), 6.63 (s, 4H), 7.38–77.67 (m, 17H). ^{13}C NMR (125 MHz) δ: 44.6, 114.2, 115.4, 119.5, 120.9, 127.1, 127.4, 127.5, 128.3, 128.8, 129.1, 132.8, 135.6, 139.9, 140.1, 141.3, 144.0, 145.5. Anal. calcd. for $C_{31}H_{25}NO$: C 87.09, H 5.89, N 3.28; found: C 87.13, H 5.97, N 3.21.

TPIP-$AlMe_2AlMe_3$ (4)

TPIP (0.5 g, 1.18 mmol) was dissolved in ca. 15 mL of anhydrous toluene under a N_2 atmosphere. Trimethyl-

© 2004 NRC Canada

aluminum (2.0 mol L^{-1} in toluene, 1.4 mL, 2.8 mmol) was added dropwise to the stirred TPIP solution. Evolution of methane was observed immediately but ceased after the halfway point of the addition. The solution was allowed to stir for 15 min and then the solvent was removed under vacuum. The resulting yellow powder was recrystallized by slow evaporation of a CH_2Cl_2 solution to give yellow crystals (0.58 g, 1.05 mmol, 89%), mp 276 °C (dec.). IR (Nujol): 3058 (w), 3029 (w), 1596 (vs), 1575 (s), 1556 (m), 1485 (s). ^{1}H NMR (400 MHz, CD_2Cl_2) δ: –1.31 (s, 6H), –0.89 (s, 9H), 7.19–7.54 (m, 17H), 7.73–7.82 (m, 4H), 8.98 (s, 1H). ^{13}C NMR (100 MHz, CD_2Cl_2) δ: –10.5, –7.2, 25.6, 117.5, 119.2, 120.8, 127.6, 127.7, 128.7, 128.9, 129.2, 129.4, 129.5, 130.3, 131.8, 138.8, 129.5, 143.7. Anal. calcd. for $C_{36}H_{37}Al_2NO$: C 78.10, H 6.74, N 2.53; found: C 77.80, H 6.70, N 2.26.

TPAP-AlMe$_2$ (5)

TPAP (250 mg, 0.58 mmol) was dissolved in ca. 5 mL anhyd. CH_2Cl_2. Trimethylaluminum (2.0 mol L^{-1} in hexane, 0.32 mL, 0.64 mmol) was added dropwise to the stirred TPAP solution. Evolution of methane was observed and the solution turned reddish brown. Upon completion of the addition, stirring was stopped and the flask was left to sit at room temperature to allow slow evaporation of solvent to give a pale brown powder (230 mg, 0.47 mmol, 82%), mp > 260 °C. IR (Nujol): 3291 (w), 1595 (s), 1574 (m), 1564 (m), 1493 (s). ^{1}H NMR (400 MHz, CD_2Cl_2) δ: –1.35 (s, 6H, Al(CH_3)$_2$), 3.08 (t, $J_{H\text{-}H}$ = 7 Hz, 1H, N*H*), 4.01 (d, $J_{H\text{-}H}$ = 7 Hz, 2H, CH_2), 6.17 (d of d, $J_{H\text{-}H}$ = 8 Hz, 1 Hz, 1H), 6.54 (t of d, $J_{H\text{-}H}$ = 8 Hz, 1 Hz, 1H), 6.80 (d of d, $J_{H\text{-}H}$ = 8 Hz, 1 Hz, 1H), 7.02–7.73 (m, 15H), 7.56 (s, 2H). ^{13}C NMR (100 MHz) δ: –8.1, 50.6, 118.7, 120.7, 127.3, 128.9, 129.5, 129.6, 129.7, 129.9, 130.6, 130.7, 130.8, 133.1, 133.5, 141.7, 142.0, 142.5, 145.8, 154.1. Anal. calcd. for $C_{33}H_{30}AlNO$: C 81.96, H 6.25, N 2.90; found: C 80.57, H 6.40, N 2.65.

Polymerization studies

TPIP-$AlMe_2$·$AlMe_3$ (**4**) (0.1 g, 0.2 mmol) was dissolved in 5 mL of warm anhydrous toluene. ε-Caprolactone (1.21 g, 0.011 mol) was added to the toluene solution. Over the course of 1 h, the solution became noticeably more viscous. The reaction was quenched with ca. 50 mL of methanol and the resulting yellow powder was filtered off. The solid poly(caprolactone) (0.48 g, 40%) was characterized by GPC as a THF solution.

X-ray crystallography

Crystals of **2** and **3** were grown from concentrated ethanol solutions. Crystals of **4** were grown from a concd. CH_2Cl_2 solution. Single crystals of **2**, **3**, and **4** were mounted on a glass fibre and data were collected at room temperature (**2**, **3**) or –123 °C (**4**) on a Nonius Kappa-CCD diffractometer with COLLECT (33). The unit cell parameters were calculated and refined from the full data set. Crystal cell refinement and data reduction were carried out using DENZO (34). The data were scaled using SCALEPACK (35). The SHELXTL/PC for Windows-NT Version 6.12 (36) suite of programs was used to solve the structure by direct methods. Subsequent difference Fouriers allowed the remaining atoms to be located. The molecule was very well behaved. All of the non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atom positions were calculated geometrically and were included as riding on their respective carbon atoms. The crystal data and refinement parameters are listed in Table 1. Thermal ellipsoids in Figs. 4–6 are shown at 50% probability.

Solubility of crystalline nonelectrolyte solutes in organic solvents — Mathematical correlation of 2-methoxybenzoic acid and 4-methoxybenzoic acid solubilities with the Abraham solvation parameter model

Kaci R. Hoover, Dawn M. Stovall, Eric Pustejovsky, Rodrick Coaxum, Krisztina Pop, William E. Acree, Jr., and Michael H. Abraham

Abstract: The Abraham solvation parameter model is used to calculate the numerical values of the solute descriptors for 2-methoxybenzoic acid and 4-methoxybenzoic acid from experimental solubilities in organic solvents. The mathematical correlations take the form of

$$\log(C_S/C_W) = c + e\mathbf{E} + s\mathbf{S} + a\mathbf{A} + b\mathbf{B} + v\mathbf{V}$$

$$\log(C_S/C_G) = c + e\mathbf{E} + s\mathbf{S} + a\mathbf{A} + b\mathbf{B} + l\mathbf{L}$$

where C_S and C_W refer to the solute solubility in the organic solvent and water, respectively, C_G is a gas phase concentration, **E** is the solute excess molar refraction, **V** is the McGowan volume of the solute, **A** and **B** are measures of the solute hydrogen-bond acidity and hydrogen-bond basicity, **S** denotes the solute dipolarity–polarizability descriptor, and L is the logarithm of the solute gas phase dimensionless Ostwald partition coefficient into hexadecane at 298 K. The remaining symbols in the above expressions are known solvent coefficients, which have been determined previously for a large number of gas–solvent and water–solvent systems. The Abraham solvation parameter model was found to describe the experimental solubility data and published literature partitioning data of 2-methoxybenzoic acid and 4-methoxybenzoic acid to within overall standard deviations of 0.146 log units and 0.114 log units, respectively.

Key words: 2-methoxybenzoic acid solubilities, 4-methoxybenzoic acid solubilities, partition coefficients, molecular solute descriptors, solubility predictions.

Résumé : On a utilisé le modèle du paramètre de solvatation d'Abraham pour calculer les valeurs numériques des descripteurs de soluté des acides 2-méthoxybenzoïque et 4-méthoxybenzoïque à partir de leurs solubilités expérimentales dans des solvants organiques. Les corrélations mathématiques sont de la forme

$$\log(C_S/C_W) = c + e\mathbf{E} + s\mathbf{S} + a\mathbf{A} + b\mathbf{B} + v\mathbf{V}$$

$$\log\ (C_S/C_G) = c + e\mathbf{E} + s\mathbf{S} + a\mathbf{A} + b\mathbf{B} + l\mathbf{L}$$

dans lesquelles C_S et C_W se réfèrent à la solubilité du soluté respectivement dans le solvant organique et dans l'eau, C_G se réfère à la concentration en phase gazeuse, **E** est la réfraction molaire en excès du soluté, **V** est le volume de McGowan du soluté, **A** et **B** sont des mesures de l'acidité et de la basicité de la liaison hydrogène du soluté, **S** correspond au descripteur du caractère dipolaire–polarisabilité du soluté et L est le logarithme du coefficient de partage sans dimension d'Ostwald du soluté en phase gazeuse, dans l'hexadécane, à 298 K. Les autres symboles des expressions présentées plus haut sont des coefficients connus du solvant qui ont été déterminés antérieurement pour un grand nombre de systèmes gaz–solvant et eau–solvant. On a trouvé que le modèle du paramètre de solvatation d'Abraham permet de décrire les données expérimentales de solubilité ainsi que les valeurs publiées dans la littérature relatives aux données de partition des acides 2-méthoxybenzoïque et 4-méthoxybenzoïque avec des déviations standard globales respectivement de 0,146 et 0,114 unités logarithmiques.

[Traduit par la Rédaction]

Introduction

This work continues a systematic application of the Abraham solvation parameter model for describing the solubility behavior of both inert and self-associating crystalline organic solutes dissolved in neat organic solvents of varying polarity and hydrogen-bonding characteristics. The basic model relies on two linear free energy relationships, one for processes within condensed phases (1–10)

$$[1] \qquad SP = c + e\mathbf{E} + s\mathbf{S} + a\mathbf{A} + b\mathbf{B} + v\mathbf{V}$$

and one for processes involving gas to condensed phase transfer

$$[2] \qquad SP = c + e\mathbf{E} + s\mathbf{S} + a\mathbf{A} + b\mathbf{B} + l\mathbf{L}$$

The dependent variable in eqs. [1] and [2] (SP) is some property of a series of solutes in a fixed phase. The independent variables, or descriptors, are solute properties as follows: **E** and **S** refer to the excess molar refraction and dipolarity–polarizability of the solute, respectively, **A** and **B** denote the overall solute hydrogen-bond acidity and basicity, **V** is the McGowan volume of the solute, and L is the logarithm of the solute gas-hexadecane partition coefficient at 298.15 K. The first four descriptors can be regarded as measures of the tendency of a solute to undergo various solute–solvent interactions, all of which are energetically favorable. The L and **V** descriptors are both measures of the size of the solute, and will be measures of the cavity term that will accommodate the solute, plus will describe general solute–solvent interactions. The equation coefficients (*c*, *e*, *s*, *a*, *b*, *v*, and *l*) depend upon the process or solvent system under consideration. In the case of partition coefficients, where two solvent phases are involved, the equation coefficients represent differences in the solvent phase properties.

To date we have shown that eqs. [1] and [2] are capable of mathematically correlating the observed solubility behavior of anthracene (11), fluoranthene (12), pyrene (12), benzil (13), ferrocene (14), buckminsterfullerene (15), monuron (16), diuron (16), *trans*-stilbene (17), acetylsalicylic acid (18), 3-methylbenzoic acid (19), 4-chlorobenzoic acid (19), 4-nitrobenzoic acid (20), and 2-methylbenzoic acid (21) in a large number of organic solvents. Differences between the experimental and back-calculated SP values (SP calculated as the logarithm of the solute molar solubility in the organic solvent divided either by the solute molar solubility in water or by the solute gas phase concentration) were on the order of 0.12 log units or less for most of the fore-mentioned solutes. In the case of the five carboxylic acid solutes, the studies were limited to organic solvents in which the solute was believed to exist almost entirely in monomeric form. Alkane and aromatic hydrocarbon solvents were excluded from consideration, except in the case of a few published practical partition coefficients where the reported values had been corrected to account for dimerization effects. Carboxylic acids are known to dimerize in saturated hydrocarbons and in nonpolar aromatic hydrocarbons.

Presently, we are in the process of updating the numerical values of previously calculated molecular descriptors of carboxylic acid solutes. The calculated values that we have in our database for carboxylic acid solutes were derived almost entirely from "practical" partitioning data. For some of the carboxylic acid solutes there was only very limited experimental partitioning data, and one or two incorrect data points could lead to the calculation of incorrect values for the molecular descriptors, as was the case in a recently completed solubility study involving acetylsalicylic acid (18). To better characterize the carboxylic acid solutes that we plan to use in future studies, we have measured the solubilities of both 2-methoxybenzoic acid and 4-methoxybenzoic acid in several alcohol, ether, and alkylacetate solvents. Results of these measurements are interpreted using the Abraham solvation parameter model.

Materials and methods

2-Methoxybenzoic acid (Aldrich, 99%) and 4-methoxybenzoic acid (Aldrich, 99%) were purchased from a commercial source and were used as received. The purity of both samples was 99.8% (±0.3%), as determined by nonaqueous titration with freshly standardized sodium methoxide solution to the thymol blue endpoint according to the method of Fritz and Lisicki (22) except that toluene was substituted for benzene. Methanol (Aldrich, 99.8%, anhydrous), ethanol (Aaper Alcohol and Chemical Company, absolute), 1-propanol (Aldrich, 99+%, anhydrous), 1-butanol (Aldrich, HPLC, 99.8+%), 1-pentanol (Aldrich, 99+%), 1-hexanol (Alfa Aesar, 99+%), 1-heptanol (Alfa Aesar, 99+%), 1-octanol (Aldrich, 99+%, anhydrous), 2-propanol (Aldrich, 99+%, anhydrous), 2-butanol (Aldrich, 99+%, anhydrous), 2-methyl-1-propanol (Aldrich, 99+%, anhydrous), 3-methyl-1-butanol (Aldrich, 99%, anhydrous), 1-decanol (Alfa Aesar, 99+%), 2-pentanol (Acros, 99+%), 2-methyl-2-propanol (Arco Chemical Company, 99+%), 4-methyl-2-pentanol (Acros, 99+%), 2-methyl-1-pentanol (Aldrich, 99%), 2-methyl-1-butanol (Aldrich, 99%), tetrahydrofuran (Aldrich, 99.9%, anhydrous), methyl acetate (Aldrich, 99.5%, anhydrous), ethyl acetate (Aldrich, HPLC, 99.9%), pentyl acetate (Aldrich, 99%), butyl acetate (Aldrich, HPLC, 99.7%), diethyl ether (Aldrich, 99+%, anhydrous), diisopropyl ether (Aldrich, 99%, anhydrous), dibutyl ether (Aldrich, 99.3%, anhydrous), propylene carbonate (Aldrich, 99.7%, anhydrous), and 1,4-dioxane (Aldrich, 99.8%, anhydrous) were stored over molecular sieves and distilled shortly before use. Gas chromatographic analysis showed solvent purities to be 99.7 mol % or better.

Excess solute and solvent were placed in amber glass bottles and allowed to equilibrate in a constant temperature water bath at 25.0 ± 0.1 °C for at least 24 h (often longer) with periodic agitation. After equilibration, the samples stood

unagitated for several hours in the constant temperature bath to allow any finely dispersed solid particles to settle. Attainment of equilibrium was verified both by repetitive measurements the following day (or sometimes after 2 days) and by approaching equilibrium from supersaturation by pre-equilibrating the solutions at a slightly higher temperature. Aliquots of saturated methoxybenzoic solutions were transferred through a coarse filter into a tared volumetric flask to determine the amount of sample and diluted quantitatively with methanol for spectrophotometric analysis at 295 nm (2-methoxybenzoic acid) and 273 nm (4-methoxybenzoic acid) on a Bausch and Lomb Spectronic 2000. Concentrations of the dilute solutions were determined from a Beer–Lambert law absorbance vs. concentration working curve.

Experimental molar concentrations were converted to (mass/mass) solubility fractions by multiplying by the molar mass of carboxylic acid solute, volume(s) of volumetric flask(s) used, and any dilutions required to place the measured absorbances on the Beer–Lambert law absorbance vs. concentration working curve, and then dividing by the mass of the saturated solution analyzed. Mol fraction solubilities were computed from solubility mass fractions using the molar masses of the solute and solvent. Experimental 2-methoxybenzoic acid and 4-methoxybenzoic acid solubilities (X_S) in the organic solvents studied are listed in Tables 1 and 2, respectively. Numerical values represent the average of between four and eight independent determinations, and were reproducible to within ±1.5%.

Results and discusion

Correlation of the measured solubility data using eqs. [1] and [2] is relatively straightforward. We start with the set of equations that have been constructed for the partition of solutes between water and a given solvent. Table 3 gives the coefficients in eq. [1] for the condensed phase processes we shall consider. Note that in the case of the organic solvents, the process may pertain to either the "wet" practical partition of the solute between water (saturated with the organic solvent) and organic solvent (saturated with water) or to the hypothetical "dry" partition, which for a solid solute, is calculated as

$$[3] \qquad SP = \log P = \log C_S - \log C_W$$

the ratio of the molar solute solubility in the organic solvent (C_S), divided by the molar solute solubility in water (C_W). Hence, if C_W is known predicted SP values based upon eq. [1] will lead to predicted molar solublities through eq. [3]. For solutes that are ionized in aqueous solution, C_W refers to the solubility of the neutral form. The correction for ionization should be fairly small, provided that the carboxylic acid solute is not highly insoluble or has a large acid dissociation constant. We use the solubilities of 2-methoxybenzoic acid, log C_W = –1.554 (23, 24) (corrected for ionization), and 4-methoxybenzoic acid, log C_W = –2.800 (23, 25) (corrected for ionization), to convert the predicted partition coefficients to saturation solublities, which

[a]Numerical values of the descriptors used in these calculations are: **E** = 0.899, **S** = 1.410, **A** = 0.450, **B** = 0.620, **V** = 1.1313 and **L** = 5.636.
[b]Experimental data taken from ref. 29.

can then be compared with the experimentally determined values. Ionization is not a concern in the organic solvents that have dielectric constants much smaller than water.

Equation [2] is used for processes involving gas phase transfers. Equation coefficients are given in Table 3 for several organic solvents. Predicted SP values can also be converted to saturation molar solubilities, provided that the solid saturated vapor pressure at 298.15 K (VP^o), is available. VP^o can be transformed into the gas-phase concentration (C_G), and the gas–water and gas–solvent partitions (L_W and L_S) can be obtained through eqs. [4] and [5], respectively.

$$[4] \qquad SP = \log L_W = \log C_W - \log C_G$$

$$[5] \qquad SP = \log L_S = \log C_S - \log C_G$$

If one is unable to find an experimental vapor pressure for the given solute molecule, an estimated value can be used in the preliminary computations. The value can be adjusted then, if necessary, to reduce the log L deviations and to make the log P and log L predictions internally consistent.

To determine the solute descriptors for 2-methoxybenzoic acid and 4-methoxybenzoic acid, we first convert the experimental mol fractions in Tables 1 and 2 into molar solubilities by dividing X_S by the ideal molar volume of the saturated solution (i.e., $C_S \approx X_S/[X_S V_{Solute} + (1 - X_S)V_{Solvent}]$). A value of V_{Solute} = 124.1 cm^3 mol^{-1} was used for the molar volume of the two hypothetical subcooled liquid methoxybenzoic acids. Any errors resulting from the estimation of the hypothetical liquid molar volumes of the carboxylic acids (V_{Solute}) or from the ideal molar volume approximation should have only a very small effect on the calculated C_S values. 2-Methoxybenzoic acid and 4-methoxybenzoic acid are not overly soluble in many of the solvents considered, and the $X_S V_{Solute}$ term contributes very little to the molar volume of the saturated solutions. Dibutyl ether was excluded from the solubility analysis because we felt that dimerization of carboxylic acids was inevitable in this larger ether solvent. Carboxylic acids are known to dimerize in saturated hydrocarbon and aromatic hydrocarbon solvents. It was noted when the equation coefficients for dibutyl ether were calculated that the derived equations did not describe the solubility behavior of several carboxylic acids (benzoic acid, 2-hydroxybenzoic acid, 4-hydroxybenzoic acid, and 3-nitrobenzoic acid) (6). The calculated log P values were always less than observed log P values by the solubility method, as would be expected if dimerization did occur in dibutyl ether. Solubility measurements determine the total carboxylic acid concentration in the organic solvent, and unlike in the case of practical partition measurements, there is no convenient experimental means to correct the measured value for dimerization effects. Correlation equations for diethyl ether, tetrahydrofuran, and 1,4-dioxane did describe the solubility behavior of benzoic acid, 2-hydroxybenzoic acid, and 4-hydroxybenzoic acid (4). The latter three ether

[c]Experimental value taken from ref. 30.

solvents are included in the solubility analysis. Equation coefficients for dry diisopropyl ether have not been determined yet, and the solubility data for both 2-methoxybenzoic acid and 4-methoxybenzoic acid will be added to our existing data base for use in subsequent studies.

Available practical partition coefficient (26–28) and chromatographic retention (29, 30) data are retrieved from the chemical literature. Combining the two sets of linear free-energy relationships, we have a total of 47 equations for 2-methoxybenzoic acid and a total of 44 equations for 4-methoxybenzoic acid, for which partition data and equation coefficients are available. The McGowan volume of 2-methoxybenozic acid (**V** = 1.1313) and 4-methoxybenzoic acid (**V** = 1.1313) are calculated from the individual atomic sizes and number of bonds in each molecule (31). The excess molar refraction of both solutes is estimated as **E** = 0.899. The sets of 47 and 44 equations were then solved, using Microsoft Solver, to yield the numerical values of the remaining solute descriptors that best described the experimental log P and log L values. The two log C_G values were also calculated to give an internally consistent set of log P and log L values. The vapor concentration corresponds to a gas-to-water partition of log L_W = 6.80 (2-methoxybenzoic acid) and log L_W = 6.70 (4-methoxybenzoic acid), which is in good agreement with the calculated values based upon eqs. [1] and [2] (last numerical entries in Tables 4 and 5). Numerical values of the solute descriptors are given in Table 6. Molecular descriptors reproduce the experimental log P and log L values for 2-methoxybenzoic and 4-methoxybenzoic acid to within an overall standard deviation of 0.146 log units and 0.114 log units, respectively, as shown in Tables 4–6. Based on our past experience with the Abraham solvation parameter model, we expect that one could use the molecular descriptors in Table 6 to predict both the solubility and practical organic solvent–water partition coefficients of the two methoxybenzoic acids to within 0.20 log units for organic solvents in which carboxylic acid dimerization does not occur.

Table 6. Molecular descriptors and input properties for 2-methoxybenzoic acid and 4-methoxybenzoic acid.

Descriptor	2-Methoxybenzoic acid	4-Methoxybenzoic acid
Molecular descriptors		
E	0.899	0.899
S	1.410	1.250
A	0.450	0.620
B	0.620	0.520
V	1.1313	1.1313
L	5.636	5.741
Input properties		
log C_W	–1.554	–2.800
log C_G	–8.354	–9.500
Statistical information		
Log P standard deviation	0.146	0.119
Log L standard deviation	0.146	0.110

Calculated descriptors account very well for the experimental data on solubilities and partition coefficients; how-

ever, the values must reflect chemical properties of the solute, otherwise, the descriptors are simply "fitting parameters". The hydrogen-bond acidity (**A** = 0.620) and basicity (**B** = 0.520) descriptors of 4-methoxybenzoic acid are slightly larger than the known acidity (**A** = 0.590) and basicity (**B** = 0.400) values for benzoic acid. The two lone electron pairs on the oxygen atom of the methoxy-substituent group provide additional donor sites, and increase the electron density of the aromatic ring. The calculated descriptors reflect this effect. The lower calculated hydrogen-bond acidity value (**A** = 0.450) of 2-methoxybenzoic acid is likely due to intramolecular hydrogen-bond formation, which is indicated by both solution IR, and proton, ^{13}C, and ^{17}O NMR measurements (32–36). Spectroscopic studies further suggest that a substituent at the 6-ring position inhibited the formation of hydrogen bonding, and that a substituent at the 3-ring position had some unfavorable steric effects (37). Interestingly, the hydrogen-bond basicity of 2-methoxybenzoic acid (**B** = 0.62) is larger than that of 4-methoxybenzoic acid (**B** = 0.52). However, whilst internal hydrogen bonding will reduce the basicity of the methoxy oxygen atom, it will actually increase the basicity of the oxygen atom in the carboxylic -OH group. A similar effect is found in 2-nitrophenol and 4-nitrophenol. The former has a very strong intramolecular hydrogen-bond (**A** = 0.05 and **B** = 0.37), whereas 4-nitrophenol (**A** = 0.82, **B** = 0.26) has no internal hydrogen-bond at all. Just as for the methoxybenzoic acids, the hydrogen-bond basicity of the internally hydrogen-bonded 2-nitrophenol is larger than that of 4-nitrophenol. Future studies will examine steric substituent effects in greater detail. Intramolecular hydrogen-bond formation is also suggested in molecular orbital computations. (36, 38) The degree of intramolecular hydrogen-bond formation is, of course, solvent dependent, and the solute descriptors that have been calculated for 2-methoxybenzoic acid do not correspond to a single geometric conformation, but rather correspond to an average of the different conformations that the molecule adopts in the solvents studied.

Readers will note that while the Abraham solvation parameter model has been employed to mathematically describe the solubility of 2-methoxybenzoic acid and 4-methoxybenzoic acid in organic solvents, the computational methodology can be applied to other molecules of interest. The computational methodology requires experimental solubility data of the solute molecule in water and in a dozen or solvents for which equation coefficients are known. The solute descriptors, after they have been calculated, can be used to predict the solute solubility in any of the organic solvents for which equation coefficients are known. To date we have derived equation coefficients for 40 or so dry organic solvents and have calculated molecular descriptors for over 3000 common organic and pharmaceutical compounds. In addition, the solvation descriptors can be estimated from the structure of a compound ((39), thus increasing the number of compounds whose log *P* and log *L* values can be predicted.

Synthesis and biological evaluation of a bicyclo[4.1.0]heptyl analogue of glucose-1-phosphate

Veedeeta Dookhun and Andrew J. Bennet

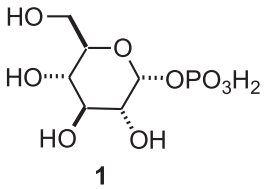
Abstract: The synthesis of a bicyclo[4.1.0]heptyl analogue of glucose-1-phophate, (1*R*,2*R*,3*S*,4*S*,5*S*,6*S*)-3,4,5-trihydroxy-6-(hydroxymethyl)-bicyclo[4.1.0]heptan-2-yl dihydrogen phosphate (**5**) is reported. The synthetic route chosen started with methyl α-D-glucopyranoside and was accomplished in 11 steps with an overall yield of 3%. Compound **5** was tested as a potential substrate of UTP:α-D-glucose-1-phosphate uridylyltransferase, the enzyme that converts glucose-1-phosphate into UDP-glucose. However, the conformationally restricted glucose-1-phosphate analogue **5** was found to be a weakly binding inhibitor, rather than a substrate, of the yeast transferase (12% inhibition at a concentration of 0.1 mmol L^{-1}).

Key words: glucose 1-phosphate, inhibition, UTP:α-D-glucose-1-phosphate uridylyltransferase.

Résumé : On a réalisé la synthèse d'un analogue bicyclo[4.1.0]heptyle du 1-phosphate de glucose, le dihydrogène phosphate de (1*R*,2*R*,3*S*,4*S*,5*S*,6*S*)-3,4,5-trihydroxy-6-(hydroxyméthyl)bicyclo[4.1.0]heptan-2-yle (**5**). La voie de synthèse choisie utilise l'α-D-glucopyranoside de méthyle comme produit de départ et implique onze étapes avec un rendement global de 3 %. Le composé **5** a été évalué comme substrat potentiel de l'uridylyltransférase UTP:1-phosphate d'α-D-glucose, l'enzyme qui transforme le 1-phosphate de glucose en UDP-glucose. On a toutefois trouvé que, en raison de ses restrictions conformationnelles, l'analogue **5** un faible inhibiteur de fixation plutôt qu'un substrat de la transférase de la levure (12 % d'inhibition à une concentration de 0,1 mmol L^{-1}).

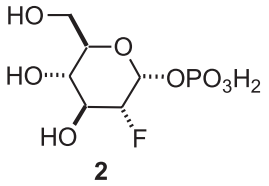
Mots clés : 1-phosphate de glucose, inhibition, uridylyltransférase UTP:1-phosphate d'α-D-glucose.

[Traduit par la Rédaction]



Introduction

Complex glycoconjugates are involved in numerous biochemical recognition processes, examples include fertilization, immune defense, viral and parasitic infections, cell growth, cell adhesion, and inflammation (1, 2). The assembly of oligosaccharides in living systems requires sugar nucleotide donors, compounds that are biosynthesized from glycosyl phosphates (3). For example, uridine 5′-(α-D-glucopyranosyl diphosphate) (UDP-Glc), a key intermediate in many biochemical pathways including that of glycogen formation, is made enzymatically from α-D-glucopyranosyl phosphate (Glc1P) and uridine 5′-triphosphate (UTP) (Scheme 1) (3).



The biological importance of glycosyl phosphates has resulted in many researchers investing considerable effort to synthesize analogues of this important class of compounds. In the specific case of α-D-glucopyranosyl phosphate (**1**), analogues that have been reported include: (*i*) **2** a compound in which the C-2 hydroxyl group has been replaced by a fluorine atom (4); (*ii*) **3** an analogue that is hydrolytically stable (5, 6); and (*iii*) **4** a mimic where O-5 has been substituted by a phosphate group (7–9).

4

The synthesis and characterization of a novel, conformationally rigid, carbocyclic analogue of Glc1P is described. The target compound (**5**) was chosen on the basis of the potent α-glucosidase inhibition reported by Tanaka et al.

Scheme 2. Synthesis of **5**, a bicyclo[4.1.0]heptyl analogue of glucose-1-phosphate: (*a*) $LiCl{\cdot}H_2O$, Et_3N, CH_2Cl_2; (*b*) L-selectride, THF, 0 °C; (*c*) $(Me)_2Zn$, CH_2I_2, toluene, –10 °C; (*d*) dibenzyl diisopropylphosphoramidate, tetrazole, CH_2Cl_2; (*e*) bleach, THF at RT; (*f*) 10% Pd-C, MeOH.

(10) of the compound **6**, which is a rigid carbocyclic analogue of α-D-glucopyranosylamine. In compound **6** the fused cyclopropane ring forces the six-membered ring into a half-chair conformation (10). In addition, **5** was examined with the yeast UTP:α-D-glucose-1-phosphate uridylyltransferase (Scheme 1) to test whether the UDP-analogue **7** could be made by a chemoenzymatic approach.

Results and discussion

Enone **9** was synthesized from methyl α-D-glucopyranoside in seven steps according to a literature procedure (11) except that triethylamine and LiCl were used to cyclize compound **8** (see Experimental section for full details). This modification was made because the cyclization of **8** proceeded faster with these reagents than it did when the combination of 18-crown-6 and K_2CO_3 (11) was used. As a consequence of this modification, it was observed that the enone product was less prone to aromatize. Attempted reduction of enone **9** with several reagents such as $LiAlH_4$, $LiAl(OBu\text{-}t)_3H$, and $ZnBH_4$ resulted in the formation of mixtures, of varying ratio, of two diastereomeric alcohols. However, the use L-selectride in THF at 0 °C gave a stereospecific reduction that produced only the pseudo-axial allylic alcohol **10** in 78% yield (Scheme 2). The stereochemistry of **10** was assigned based on the smaller coupling constant observed between H-1 and H-6 in the ^1H NMR spectrum in comparison to the reported value for the pseudo-equatorial diastereomer (11). Alcohol **10** was then reacted using Furakawa et al.'s protocol (12) to afford compound **11** as the only observable diastereomer in a 62% yield. The stereochemistry of bicyclo-[4.1.0]heptane **11** was confirmed by an nOe experiment to be equivalent to that of D-glucose rather than L-idose. Specifically, a strong nOe contact was observed between H-7*S* and H-4 (see numbering labels in Scheme 2).

Reaction of **11** with reagents such as diphenylphosphochloridate (13, 14) and tetraphenylpyrophosphate (15) in the presence of various bases failed to yield any phosphorylated products. However, the use of the phosphitylation method gave the expected phosphite product (16–18). The phosphite was immediately oxidized using a solution of bleach in THF–water. Standard work up procedures when followed by column chromatography afforded analytically pure **12** in a yield of 52%. Subsequent removal of the benzyl protecting groups was realized, in a quantitative yield, by hydrogenation in the presence of 10% Pd-C.

Enzymatic studies

Compound **5** was tested as a potential substrate for Baker's yeast UTP:α-D-glucose-1-phosphate uridylyltransferase (EC 2.7.7.9). Formation of the UDP-glucose analogue (**7**) would be accompanied by the simultaneous production of pyrophosphate (Scheme 1). The production of pyrophosphate was monitored by use of a commercial assay (19). Unfortunately, compound **5** was shown not to be a substrate for the Baker's yeast uridylyltransferase as no pyrophosphate was detected. Moreover, addition of **5** (0.1 mmol L^{-1}) to a UTP:α-D-glucose-1-phosphate uridylyltransferase-catalyzed reaction containing Glc1P (0.1 mmol L^{-1}) and UTP (0.1 mmol L^{-1}) resulted in a 12% reduction in the rate of pyrophosphate production. Therefore, it can be concluded that **5**, a conformationally rigid Glc1P analogue, is a weakly binding inhibitor of the yeast uridylyltransferase enzyme.

Experimental

General

Toluene and dichloromethane were distilled from CaH_2 prior to use. THF was dried over sodium in the presence of benzophenone. NMR spectra were recorded on Varian 500 MHz spectrometer. Chemical shifts (δ in ppm) are given relative to tetramethylsilane for (^1H and ^{13}C) and external 85% H_3PO_4 (for ^{31}P). Only definitive ^1H and ^{13}C assignments, which were made using standard 1D, ^1H–^1H COSY, and HMQC NMR experiments, are listed. All glassware was flame-dried before use. Dibenzyl diisopropylphosphor-

© 2004 NRC Canada

amidite was stored as a 50 mg/mL solution in anhydrous dichloromethane under an atmosphere of nitrogen.

(4*R*,5*S*,6*R*)-4,5,6-Tris(benzyloxy)-3-((benzyloxy)methyl)-2-cyclohexen-1-one (9)

To a stirred solution of 3,4,5,7-tetra-*O*-benzyl-1-deoxy-1-(dimethoxyphosphoryl)-D-*xylo*-2,6-heptodiulose **8** (11) (9.4 g, 14 mmol) in dry CH_2Cl_2 (300 mL) was added $LiCl{\cdot}H_2O$ (0.30 g, 0.5 equiv.) and Et_3N (2.18 mL, 1.1 equiv.). The reaction mixture was stirred for about 6 h. The organic phase was washed with aq. H_2SO_4 (100 mL, 5% v/v), satd. aq. $NaHCO_3$ (100 mL), brine (100 mL) and concentrated at aspirator pressure to afford a yellow syrup. The crude product material was purified by flash column chromatography (hexanes–EtOAc, 2:1) to give the product (4.17 g, 60%) as a colorless syrup. This material exhibited identical ^1H and ^{13}C NMR data to those reported in the literature (11).

(1*S*,4*R*,5*S*,6*S*)-4,5,6-Tris(benzyloxy)-3-((benzyloxy)methyl)-2-cyclohexen-1-ol (10)

A 1 mol L^{-1} solution of L-selectride in THF (11.7 mL, 1.5 equiv.) was added in a dropwise manner to a stirred and cooled (0 °C) solution of enone **9** (4.17 g, 7.8 mmol) in THF (200 mL) under a nitrogen atmosphere. The mixture was stirred for 18 h as it warmed to room temperature gradually. A saturated solution of NH_4Cl (50 mL) was added and the resulting mixture was stirred for 15 min after which water (100 mL) was added. Then the aqueous solution was extracted with EtOAc (2 × 150 mL), the organic extracts were washed with brine and dried over Na_2SO_4. A pale yellow syrup was obtained upon removal of the volatiles under reduced pressure. The resultant crude product was purified by column chromatography (hexanes–EtOAc, 2:1 v/v) to afford allylic alcohol **12** as a colourless syrup (3.22 g, 77%). $[\alpha]_D^{20}$ –39.0 (*c* 1.00, CH_2Cl_2). ^1H NMR ($CDCl_3$) δ: 2.57 (bs, 1H, OH), 3.59 (dd, 1H, $J_{6,5}$ = 9.3 Hz, $J_{6,1}$ = 4.1 Hz, H-6), 3.94 (d, 1H, $J_{7a,7b}$ = 12.3 Hz, CH_{7a}H$_{7b}$OBn), 4.05 (dd, 1H, $J_{5,4}$ = 6.8 Hz, H-5), 4.16 (dd, 1H, $J_{4,2}$ = 1.0 Hz, H-4), 4.23 (dd, 1H, $J_{7b,2}$ = 1.0 Hz, CH$_{7a}$$H_{7b}$OBn), 4.30 (t, 1H, $J_{1,2}$ + $J_{1,6}$ = 8.9 Hz, H-1), 4.46 (d, 1H, $J_{A,B}$ = 11.9 Hz, CH_ACH$_B$C$_6$H$_5$), 4.48 (d, 1H, CH$_A$CH_BC$_6$H$_5$), 4.66 (d, 1H, $J_{C,D}$ = 10.3 Hz, CH_CH$_D$C$_6$H$_5$), 4.68 (d, 1H, $J_{E,F}$ = 11.5 Hz, CH_EH$_F$C$_6$H$_5$), 4.74 (d, 1H, $J_{G,H}$ = 11.2 Hz, CH_GH$_H$C$_6$H$_5$), 4.78 (d, 1H, CH$_C$$H_DC_6H_5$), 4.79 (d, 1H, CH$_E$$H_FC_6H_5$), 4.87 (d, 1H, CH$_G$$H_HC_6H_5$), 5.91 (dd, 1H, $J_{2,1}$ = 4.9 Hz, $J_{2,6}$ = 1.4 Hz, H-2) 7.10–7.52 (m, 20H, H-Ar). ^{13}C NMR ($CDCl_3$) δ: 65.1 (C-1), 70.2 (C-7), 72.6 (*C*H$_A$H$_B$C$_6$H$_5$), 72.9 (*C*H$_E$H$_F$C$_6$H$_5$), 74.0 (*C*H$_C$H$_D$C$_6$H$_5$), 74.7 (*C*H$_G$H$_H$C$_6$H$_5$), 78.7 (C-4), 78.8 (C-6), 79.1 (C-5), 124.6 (C-2), 127.5, 127.6, 127.7, 127.9 (2 C), 128.0, 128.3 (2 C), 128.4, 128.5, 137.9, 138.1, 138.5, 138.6. Anal. calcd. for $C_{35}H_{37}O_5$: C 78.33, H 6.76; found: C 78.17, H 6.65.

(*1S*,2*S*,3*S*,4*S*,5*R*,6*R*)-3,4,5-Tris(benzyloxy)-6-((benzyloxy)methyl)-bicyclo[4.1.0]heptan-2-ol (11)

To rigorously dried allylic alcohol **12** (500 mg, 0.9 mmol) in dry toluene (100 mL) under nitrogen at –10 °C was added a 2 mol L^{-1} solution of Me_2Zn in toluene (4.00 mL, 8 mmol) dropwise. The mixture was stirred for 15 min, following which CH_2I_2 (1.4 mL, 18 mmol) was added dropwise and the resulting mixture was stirred overnight as the solution was allowed to warm up to room temperature. A saturated solution of NH_4Cl (50 mL) was added and the mixture was stirred for another 30 min. The resulting solution was then diluted with water (100 mL) and extracted with EtOAc (3 × 100 mL). The combined organic extracts were washed with 10% H_2SO_4 (150 mL), $NaHCO_3$ (150 mL), and brine (150 mL), and then dried over Na_2SO_4. Removal of the volatiles gave a yellow oil that was purified by column chromatography (hexanes–EtOAc, 2:1 v/v) to afford the cyclopropanated allylic alcohol **11** as a colourless syrup (317 mg, 62%). $[\alpha]_D^{20}$ +24.5 (*c* 1.10, CH_2Cl_2). ^1H NMR ($CDCl_3$) δ: 0.52 (dd, 1H, $J_{7R,1}$ = 9.5 Hz, $J_{7R,7S}$ = 5.8 Hz, H-7*R*), 1.14 (t, 1H, $J_{7S,7R}$ + $J_{7S,1}$ = 11.4 Hz, H-7*S*), 1.34 (m, 1H, H-1), 2.55 (bs, 1H, OH), 2.67 (d, 1H, $J_{8a,8b}$ = 10.0 Hz, H-8a), 3.42 (dd, 1H, $J_{4,3}$ = 9.6 Hz, $J_{2,3}$ = 4.6 Hz, H-3), 3.60 (dd, 1H, $J_{4,5}$ = 7.8 Hz, 1H, H-4), 3.81 (d, 1H, H-8b), 4.18 (d, 1H, H-5), 4.31 (d, 1H, $J_{A,B}$ = 12.1 Hz, CH_AH$_B$C$_6$H$_5$), 4.38 (d, 1H, CH$_A$$H_BC_6H_5$), 4.43 (dd, 1H, $J_{1,2}$ = 7.9 Hz, H-2), 4.61 (d, 1H, $J_{C,D}$ = 11.4 Hz, CH_CH$_D$C$_6$H$_5$), 4.63 (d, 1H, $J_{E,F}$ = 11.5 Hz, CH_EH$_F$C$_6$H$_5$), 4.70 (d, 1H, $J_{G,H}$ = 10.8 Hz, CH_GH$_H$C$_6$H$_5$), 4.78 (d, 1H, CH$_C$$H_DC_6H_5$), 4.82 (d, 1H, CH$_G$$H_HC_6H_5$), 4.84 (d, 1H, CH$_E$$H_FC_6H_5$), 7.18–7.42 (m, 20H, H-Ar). ^{13}C NMR ($CDCl_3$) δ: 8.8 (C-7), 22.3 (C-1), 28.3 (C-6), 64.6 (C-2), 72.7 (*C*H$_A$H$_B$C$_6$H$_5$), 73.1 (*C*H$_C$H$_D$C$_6$H$_5$), 74.5 (*C*H$_E$H$_F$C$_6$H$_5$), 74.9 (2 C, C-8, *C*H$_G$H$_H$C$_6$H$_5$), 78.6 (C-4), 79.2 (C-5), 80.9 (C-3), 127.4, 127.6 (2 C), 127.7, 127.8, 128.2, 128.3, 128.4 (2 C), 138.0, 138.2, 138.6, 139.0. (1*S*,2*S*,3*R*,4*S*,5*R*,6*R*)-3,4,5-Tris(benzyloxy)-6-((benzyloxy)methyl)-bicyclo[4.1.0]heptan-2-yl dibenzyl phosphate (12)

Dibenzyl diisopropylphosphoramidite (358 mg, 1.03 mmol) and tetrazole (105 mg, 1.50 mmol) were mixed vigorously in dry CH_2Cl_2 (30 mL) under nitrogen for about 30 min after which time the tetrazole had partially dissolved. A solution of alcohol **11** (275 mg, 0.5 mmol), which had previously been co-evaporated with dry toluene (3 × 50 mL), in dry CH_2Cl_2 (20 mL) was added to the above reaction mixture via a syringe. The resulting reaction mixture was stirred until the starting material had disappeared (monitored by TLC, hexanes – ethyl acetate, 2:1 v/v). Then the solution was concentrated under reduced pressure and the resulting residue was purified by column chromatography (hexanes–EtOAc, 2:1 v/v) to give the expected phosphite. After this material had been dissolved in THF (75 mL), a 5% v/v bleach solution (2 mL) was added and this mixture was stirred for about 1 h. The solvent was removed under reduced pressure, and then water (100 mL) was added and the aqueous solution was extracted with CH_2Cl_2 (3 × 50 mL). The combined organic extracts was washed with water (100 mL) and dried over $MgSO_4$. After removal of the solvent under reduced pressure, the residue was purified by column chromatography (toluene–acetone, 8:1 v/v) to afford a colorless oil (213 mg, 52%). $[\alpha]_D^{20}$ +58.0 (*c* 1.00, CH_2Cl_2). ^1H NMR ($CDCl_3$) δ: 0.53 (dd, 1H, $J_{7R,1}$ = 9.5 Hz, $J_{7R,7S}$ = 5.8 Hz, H-7*R*), 1.12 (t, 1H, $J_{7S,7R}$ + $J_{7S,1}$ = 11.4 Hz, H-7*S*), 1.41 (m, 1H, H-1), 2.60 (d, 1H, $J_{8a,8b}$ = 10.0 Hz, H-8a), 3.44 (m, 1H, H-3), 3.56 (dd, 1H, $J_{4,5}$ = 8.1 Hz, $J_{3,4}$ = 10.1 Hz, H-4), 3.72 (d, 1H, H-8b), 4.16 (d, 1H, H-5), 4.30 (d, 1H, $J_{A,B}$ =

To a solution of **12** (200 mg) in dry methanol (20 mL) was added 10% Pd on carbon (84 mg). The mixture was stirred under an atmosphere of hydrogen for 24 h. The solution was filtered and the residue was washed thoroughly with MeOH. The combined filtrate was evaporated to dryness and dried under vacuum to afford a colourless solid (66.4 mg, 99% yield). $[\alpha]_D^{20}$ +23 (c = 1.00, H$_2$O). ^{1}H NMR (D$_2$O) δ: 0.58 (dd, 1H, $J_{7R,1}$ = 9.5 Hz, $J_{7R,7S}$ = 5.9 Hz H-7*R*), 0.91 (t, 1H, $J_{7S,7R}$ + $J_{7S,1}$ = 11.3 Hz, H-7*S*), 1.50 (m, 1H, H-1), 2.84 (d, 1H, $J_{8a,8b}$ = 11.9 Hz, H-8), 3.29–3.39 (m, 2H, H-3, H-4), 3.94 (d, 1H, H-8b), 4.00 (d, 1H, $J_{4,5}$ = 7.6 Hz, H-5), 4.71 (td, 1H, $J_{2,3}$ = 4.5 Hz, $J_{2,1}$ + $J_{2,P}$ = 15.4 Hz, H-2). ^{13}C NMR (D$_2$O) δ: 12.0 (C-7), 24.7 (C-1), 33.4 (C-7), 68.3 (C-8), 72.3 (C-3), 73.9 (C-4), 74.7 (C-5), 74.9 (C-2). ^{31}P NMR (D$_2$O) δ: –0.59.

Biological activity assays

To a solution of 2-amino-6-mercapto-7-methylpurine riboside (0.2 mmol L^{-1}) in 50 mmol L^{-1} Tris HCl buffer pH 7.5 (1 mL) was added pyrophosphorylase (1 × 10^{-3} units), purine nucleoside phosphorylase (PNP) (1 × 10^{-2} units), compound **5** (0.1 mmol L^{-1}), glucose-1-phosphate (0.1 mmol L^{-1}), and UTP (0.1 mmol L^{-1}). This mixture was equilibrated at 22 °C for 10 min. The reaction was then initiated by the addition of UTP:glucose-1-phosphate uridylyltransferase (1 × 10^{-4} units) and the production of 2-amino-6-mercapto-7-methylpurine was monitored using a Cary 3E spectrophotometer at a wavelength of 360 nm. Similar assays were performed in the absence of either glucose-1-phosphate or compound **5**.

Synthesis of phosphonium salts under microwave activation — Leaving group and phosphine substituents effects

Ján Cvengros, Stefan Toma, Sylvain Marque, and André Loupy

Abstract: The specific nonpurely thermal effects of microwaves were evidenced according to neutral or charged leaving groups during nucleophilic substitution of benzylic electrophiles with triphenylphosphine and tributylphosphine. Microwave (MW) irradiation considerably enhanced the reactions with charged alkylating agents, especially under solvent-free conditions. Results are interpreted considering the magnitude of MW effects according to the position of the transition state along the reaction coordinates.

Key words: microwave irradiation, specific effects, phosphonium salts, leaving group effects.

Résumé : Des effets spécifiques non purement thermiques des micro-ondes ont été mis en évidence. Ils dépendent de la nature neutre ou chargée des groupes partants au cours de la substitution nucléophile par la triphénylphosphine ou la tributylphosphine sur des agents benzylants. L'irradiation micro-onde augmente considérablement les vitesses de réaction avec les agents alkylants chargés, particulièrement dans des conditions sans solvant. Les résultats sont interprétés en considérant les effets des micro-ondes en fonction de la position de l'état de transition sur les coordonnées réactionnelles.

Mots clés : irradiation aux micro-ondes, effets spécifiques, sels de phosphonium, effets de groupes partants.

[Traduit par la Rédaction]

Introduction

Application of microwave (MW) irradiation in organic synthesis is well documented (1–10). Most of the publications describe significant accelerations for a wide range of organic reactions especially when carried out under solvent-free conditions. They can find their origins in either thermal effects and (or) specific nonpurely thermal effects. Therefore, a vivid discussion was going on the possible intervention of any specific microwave effect resulting from decrease in the free energy of activation or if the enhancement of the reactions is due to a local overheating of the reaction mixture (11–13) (a hot spot effect as advocated in sonochemistry) (14).

Microwaves consist of electromagnetic waves generated by an alternating electric field of high frequency. The energy associated with a MW photon (1 J mol^{-1} by application of Planck's law $E = h\nu$ with $\nu = 2450$ MHz) is by far too small to induce any excitation of molecules. It can, however, provoke thermal effects because of some internal friction among polar molecules during their changes in orientation with each alternation of the electric field. In addition, they can induce some electrostatic interactions with polar materials by dipole–dipole interactions, rather similar to the behaviour of a dipolar solvent. It was, for instance, shown that the regioselectivity of phenacylation of 1,2,4-triazole is the same under conventional heating in a dipolar aprotic solvent (DMF) and under MW irradiation in a non-polar medium (xylene), or even in the absence of any solvent (15). By analogy and extension of the interpretation of solvent effects, the carbon–halogen bond breaking in S_N2 reactions can be facilitated by an increase in the polarity of the system during the reaction progress from the ground state to its transition state and could depend on the leaving group ability.

A working hypothesis was therefore advanced very recently according to which it is possible to predict (according to the type of reaction) if a significant specific (non-purely thermal) MW effect can be observed (15, 16). It considers medium and mechanism influences on the MW-assisted reactions. MW stabilizations by electrostatic dipole–dipole interactions between materials and the electromagnetic field are foreseen to be increased if the polarity of the systems are increased when the reaction is progressing. From a reactivity point of view, a decrease in the energy of activation by extending stabilization from the ground state can be expected towards the transition state can be expected (15–17). It would be the case when polar mechanisms are concerned, i.e., when there is a development of charge during the course of the reaction. It would also be the case if the position of

the transition state lies later along the reaction coordinates (Hammond's postulate) (18).

MW syntheses of several triphenylalkylphosphonium salts were recently described by Kiddle (19–21). Several representative organic halides were treated with triphenylphosphine to afford phosphonium salts in excellent yields. The reaction times were reduced to 4 min or less from conventional heating times ranging from 30 min to 14 days. However, owing to the lack of accurate control of the temperature and to strict comparisons with conventional heating under similar conditions, the real intervention of MW activation is questionable and needs more detailed experiments for better understanding (22). This prompted us to publish our results on the study and interpretation of the microwave effects on the S_N2 reactions of alkylating agents (neutral or charged) with neutral nucleophiles (phosphines) (eq. [1]). This kind of experiment was synthetically exploited for the preparation of imidazolium and ephedrinium salts as ionic liquids by the alkylation of imidazole (23–26) or *N*-methylephedrine (27). Some preliminary results were previously presented at an international microwave chemistry meeting (28).

Results

Reactions of benzyl halides and benzyl trimethylammonium chloride with triphenyl-phosphine **1b** were carried out either in xylene (a non-polar solvent, i.e., transparent to MW) or under solvent-free conditions. To check the possible intervention of specific (non-purely thermal) MW effects, control experiments were performed using conventional heating (CH) in a thermostated oil bath at the same temperature for the same time. Identical profiles for increasing temperature were maintained for both types of activation mode, allowing for the elimination of the purely thermal contribution of MW radiation (Fig. 1).

Table 1 gives the main results for the reaction of **1b** with the benzylating electrophiles **2a**–**2c**.

Solvent-free conditions were by far the most convenient and efficient ones (entry 3). With benzyl bromide at 100 °C, no special microwave effects were observed (entries 1 and 2).

When using benzyl chloride, similar yields (>90%) of product **3** were obtained both under MW and CH within 10 min at 150 °C. Although the MW effect is not appreciable at 150 °C, it was however possible to put into evidence an important specific MW effect by lowering the temperature to 100 °C (entry 5).

When benzyl trimethylammonium chloride **2c** was used as the electrophile, no reaction took place under thermal heating at 150 °C whereas 70% of the product was formed after 10 min at 150 °C under MW irradiation. A very noticeable specific MW is therefore clearly revealed in this case. The yield reached 95% at 250 °C under MW and remained limited to 70% by CH.

By comparing the magnitude of the specific MW effects according to electrophile, we have thus established the sequence: **2c** >> **2b** > **2a**.

In Table 2, we give the main results obtained for the reaction of tributylphosphine with **2a**–**2c** under solvent-free conditions.

In the case of the reaction with benzyl bromide, yields are quite similar whatever the mode of activation (entries 8 and 9).

Using benzyl chloride, a quite important specific MW effect was revealed by shortening the reaction time at 100 °C (entry 11). These observations are in agreement with some

Fig. 1. Profiles for the rise in temperature for the MW and CH methods.

previous ones. To find any evidence of specific MW effects, a reduction in the temperature and (or) reaction time under CH is needed to start from a rather poor yield to have the possibility of observing any specific MW effects. These cases have been revealed in some studies where MW effects appeared at lower temperatures. They can be masked at higher temperatures when yields of CH reactions are high (29–32).

With the charged electrophile **2c**, a very decisive specific effect is evidenced within 10 min at 100 °C; the reaction only occurred under MW and not at all by CH (entry 12).

The order of relative magnitude of specific MW effects leads to the same sequence as with **1b**: **2c** >> **2b** > **2a.** By comparing the two phosphines, it can be established that the specific MW effects are: **1b** > **1a** (compare entries 5 and 11 with **2b**).

We finally examined the reaction of the two phosphines with *n*-hexyl halides (eq. [2]). The main results are given in Table 3.

$$\underset{\mathbf{1}}{PR_3} + \underset{\mathbf{4}}{n\text{-}C_6H_{13}} \longrightarrow \underset{\mathbf{5}}{n\text{-}C_6H_{13}{}^+PR_3X^-} \quad [2]$$

Scheme 1.

(GS) (Dipolar TS)

Scheme 2.

(Tight ion pair) (Loose ion pair)

In the case of **1a**, within 5 min at 100 °C, the reaction essentially occurred with hexyl bromide and with only slight MW effects (entry 13). With hexyl chloride at 150 °C within 90 min in closed vessels, a yield of 81% was obtained under MW and only 40% via CH. The magnitude of specific MW effects is clearly **4b** > **4a**.

With **1b**, satisfactory yields were obtained as well with bromide and chloride. Important MW specific effects were revealed (entries 16 and 18). The magnitude of these specific MW effects are clearly **1b** > **1a**.

Discussion

If the problem of thermal homogeneity can be taken into account, essentially when the reaction gave a solid during the reactions of triphenylphosphine **1b** (Table 1, most of the products are solids), this is not the case for the reactions of tributylphosphine **1a** (Table 2, most of the products are liquids). These problems are, however, largely minimized due to efficient mechanical stirring and accurate measurement of the temperature with an optical fiber inside the mixture.

In recent reviews (15, 16, 33), a lot of specific MW effects were explained and foreseen by considering the enhancement in polarity during the progress of the reaction. It is stated, from numerous experiments from our laboratory and the literature that they can be observed in a reaction if the transition state (TS) is more polar than its ground state (GS). It thus results in an increase in its stabilization by dipole–dipole electrostatic interactions and, consequently, a decrease in the activation energy.

Another important rule for the observation of MW effects is connected to the position of the TS along the reaction coordinates. In a polar mechanism, the later the TS (more product-like) the most important the MW effects; they will be weak if the TS is more reactant-like.

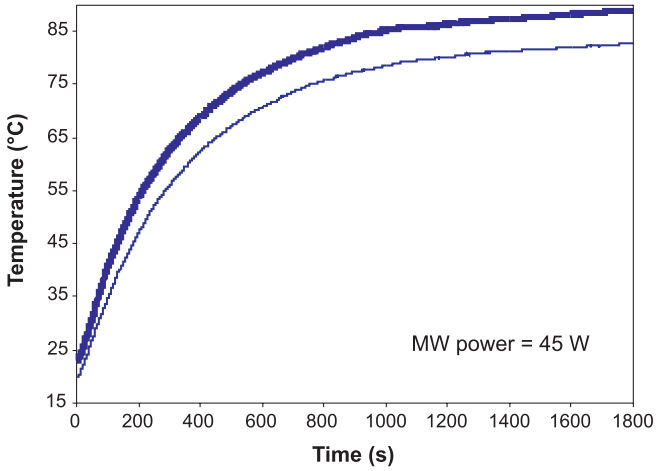
Benzyl halides

It was shown in both cases that benzyl chloride is more prone to lead to MW effects. The mechanism of the reaction concerns two neutral reagents leading to a dipolar TS (Scheme 1).

Concerning the leaving group ability, it is clear that chloride is a poorer electrofugal group when compared to the bromide equivalent, if we consider, for instance, the bond energies (C-Br, 66 kcal mol^{-1} and C-Cl 79 kcal mol^{-1}) (34). Therefore, the TS involving C—Cl bond breaking will occur later on the reaction coordinates than the one involving C-Br. It, therefore, can justify the increase in the magnitude of MW effects according to the sequence **2b** > **2a**.

Charged electrophiles

When benzyl trimethylammonium chloride **2c** was used as the reagent no reaction took place under thermal heating at 150 °C, whereas 70% of the product was formed after 10 min at 150 °C under MW irradiation. The magnitude of the specific MW effect is strongly amplified. It can be readily attributed to the very loose structure of the ion pairs in the TS (additionally involving the phenyl groups of the phosphine) and which are therefore far more polar than the initial tight ion pairs in the GS (positive charge is localized on the nitrogen atom) (Scheme 2).



This behavior can also be foreseen if one considers the poor leaving ability of the ammonium moiety and which induces a late TS along the reaction coordinates, and consequently, important MW effects.

Phosphine substituent effects

Effects are more important with triphenylphosphine **1b**. If one considers the reaction between two neutral reagents (Scheme 1), the polarity of the TS may be deeply affected by the substituent on the phosphorous atom. Triphenylphosphine is less nucleophilic than tributylphosphine and the phenyl ring being able to delocalize the δ^+ charge, the structure of the transition state is shifted to the product (late transition state), which results in the increase of the polarity of the TS when compared to an alkyl group. The consequence is that the MW effects are increased according to **1b** > **1a**,

Fig. 2. Profiles for the rise in temperature for the MW absorption of **1a** (▬) and **1b** (–) in toluene.

essentially due to the extended polarity of the TS when an aromatic ring is concerned.

This interpretation is corroborated by the fact the two phosphines in their initial states have similar polarities if one considers their rises in temperature during MW irradiation (Fig. 2). A careful comparison between the two phosphines needs the addition of toluene for solubility (**1a** being liquid and **1b** solid).

Conclusions

We have observed specific MW effects depending essentially on the leaving group. Whereas they are rather weak with benzyl bromide, they are increased with chloride and even more with benzyl trialkylammonium salts. This behavior is compatible with the consideration of the position of the TS along the reaction coordinates, which induces an increase in the MW effects. The effects are more pronounced with triphenylphosphine **1b** due to the partial positive charge delocalization in the phenyl ring in the TS. The result is an enhancement in the polarity of the TS and consequently an improvement in the MW effects' magnitude. They could be perhaps better quantitatively understood in the future by consideration of some theoretical approaches including quantification of the polarity of the transition state when compared to the ground state (17, 35, 36).

Experimental

Microwave equipment

We have used a monomode reactor Synthewave® 402 from Prolabo (France) (37). The temperature was measured all along the reaction by IR detection, which indicates the surface temperature after previous calibration of emissivity in each case using an optical fibre inside the reaction mixture. The representative given temperatures are therefore accurate measurements of bulk homogeneous temperatures. The reactions were conducted using a cylinder tube in Pyrex under mechanical stirring to allow homogeneity inthe temperature. The power was monitored during irradiation to maintain a constant temperature. Occasionally, when reactions under closed vessels were necessary (entries 15 and 18), a CEM Discover microwave device was used.

Typical MW reactions

A mixture of 10 mmol of benzylating or alkylating electrophiles with 10 mmol of phosphine (**1a** (2.49 mL), **1b** (2.62 g)) was homogenized by stirring and shaking. It was irradiated in the Synthewave® monomode MW reactor for the times and the temperatures indicated in the tables. After cooling down to room temperature, the solid materials were filtered off, washed with toluene, and dried. They were analyzed by ^{1}H and ^{13}C NMR and the spectra were in agreement with authentic samples and the literature (38). They were also characterized by their melting points.

In the case where products are ionic liquids, they were washed with organic solvents to remove starting materials: cold diethyl ether for **5aa** and **5ab**, cold diethyl ether then hot toluene for **5ba** and **5bb**.

Experiments with xylene as the solvent (20 mL) were performed with 20 mmol of both starting materials. The product (phosphonium salts) were insoluble in xylene and were isolated by filtration followed by washing of the solid materials with fresh portions of xylene and diethyl ether.

Control experiments under conventional heating (Fig. 1)

In a thermostated oil bath at the same temperature as for MW irradiation, inside identical vessels and mechanical stirring, the two reactants were independently heated and mixed together. Temperature was evaluated inside the reaction mixture using the same optical fibre as for the MW evaluation (FISO, Universal Fiber Optic Sensor, FT1-10). Then the reaction was pursued for the same reaction time. The treatment and analysis remained identical.

Benzyltriphenylphosphonium bromide (3ba) (21, 38)

White crystals, mp 296 to 297 °C. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 5.44 (d, 2H, $^{2}J_{Hgem}$ = 14.56 Hz, -CH_2), 7.11–7.13 (m, 4H, -Ph), 7.60–7.66 (m, 6H, -Ph), 7.72–7.79 (m, 10H, -Ph). ^{1}H NMR (DMSO-d_6, 200 MHz) δ: 5.25 (d, 2H, $^{2}J_{Hgem}$ = 15.6 Hz, -CH_2), 7.0 (d, 2H, ^{3}J = 6.8 Hz, -Ph), 7.24 (m, 2H, -Ph), 7.6–7.8 (m, 14H, -Ph), 7.8–8.0 (m, 2H, -Ph). ^{13}C NMR (DMSO-d_6, 200 MHz) δ: 28.0 (d, $^{1}J_{CP}$ = 46.7 Hz), 117.8 (d, $^{1}J_{CP}$ = 85.1 Hz), 127.8 (d, $^{2}J_{CP}$ = 8.5 Hz), 128.2, 128.7, 130.0 (d, $^{3}J_{CP}$ = 12.2 Hz), 130.7, 133.9 (d, $^{2}J_{CP}$ = 8.9 Hz), 135.0.

Benzyltriphenylphosphonium chloride (3bb) (38)

White crystals, mp 333–337 °C. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 5.59 (d, 2H, $^{2}J_{Hgem}$ = 14.40 Hz, -CH_2), 7.10–7.12 (m, 4H, -Ph), 7.59–7.65 (m, 6H, -Ph), 7.71–7.78 (m, 10H, -Ph).

Benzyltributylphosphonium bromide (3aa) (39):

White crystals, mp 149 °C. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 0.93 (t, 9H, $^{3}J_{HH}$ = 6.96 Hz, 3 × -CH_3), 1.42–1.50 (m, 12 H, 3 × -CH_2CH_2), 2.38–2.47 (m, 6H, 3 × -CH_2P), 4.28 (d, 2H, $^{2}J_{Hgem}$ = 15.02 Hz, -CH_2P), 7.33–7.39 (m, 3H, -Ph), 7.45–7.49 (m, 2H, -Ph). ^{1}H NMR (DMSO-d_6, 200 MHz) δ: 0.90 (t, 9H, $^{3}J_{HH}$ = 6.6 Hz, 3 × -CH_3), 1.30–1.50 (m, 12H, 3 × -CH_2CH_2), 2.10–2.30 (m, 6H, 3 × -CH_2P), 3.95 (d, 2H,

$^2J_{Hgem}$ = 15.6 Hz, -CH_2P), 7.30–7.50 (m, 5H, -Ph). ^{13}C NMR (DMSO-d_6, 200 MHz) δ: 13.1, 16.9 (d, $^1J_{CP}$ = 46.7 Hz), 22.5 (d, $^2J_{CP}$ = 4.2 Hz), 23.3 (d, $^3J_{CP}$ = 15.5 Hz), 25.4 (d, $^1J_{CP}$ = 44.2 Hz), 127.8, 129.0, 129.3, 129.9.

Benzyltributylphosphonium chloride (3ab) (40, 41)

White crystals, mp 163 to 164 °C. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 0.92 (t, 9H, $^3J_{HH}$ = 6.59 Hz, 3 × -CH_3), 1.43–1.48 (m, 12H, 3 × -CH_2CH_2), 2.38–2.48 (m, 6H, 3 × -CH_2P), 4.31 (d, 2H, $^2J_{Hgem}$ = 15.38 Hz, -CH_2P), 7.33–7.39 (m, 3H, -Ph), 7.45–7.49 (m, 2H, -Ph). ^{1}H NMR (DMSO-d_6, 200 MHz) δ: 0.90 (t, 9H, $^3J_{HH}$ = 6.75 Hz, 3 × -CH_3), 1.30–1.50 (m, 12H, 3 × -CH_2CH_2), 2.10–2.30 (m, 6H, 3 × -CH_2P), 3.90 (d, 2H, $^2J_{Hgem}$ = 15.6 Hz, -CH_2P), 7.30–7.50 (m, 5H, -Ph). ^{13}C NMR (DMSO-d_6, 200 MHz) δ: 13.0, 17.5 (d, $^1J_{CP}$ = 46.8 Hz), 22.5 (d, $^2J_{CP}$ = 5 Hz), 23.5 (d, $^1J_{CP}$ = 15.7 Hz), 25.5 (d, $^1J_{CP}$ = 80 Hz), 128.0, 129.0, 129.5, 130.0

Hexyltriphenylphosphonium bromide (5ba) (42, 43)

mp 195–198 °C. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 082 (t, 3H, ^3J = 6.78 Hz, -CH_3), 1.19–1.28 (m, 4H, 2 × -CH_2), 1.57–1.69 (m, 4H, 2 × -CH_2), 3.80 (m, 2H, -CH_2P), 7.68–7.89 (m, 15H, 3 × -Ph). Insoluble in diethyl ether or toluene at their respective boiling points; soluble in acetone.

Hexyltriphenylphosphonium chloride (5bb)

mp 209 to 210 °C. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 0.82 (t, 3H, ^3J = 6.87 Hz, -CH_3), 1.18–1.28 (m, 4H, 2 × -CH_2), 1.57–1.68 (m, 4H, 2 × -CH_2), 3.92 (m, 2H, -CH_2P), 7.67–7.92 (m, 15H, 3 × –Ph). ^{13}C NMR ($CDCl_3$, 200 MHz) δ: 13.0, 21.2, 21.5 (d, $^2J_{CP}$ = 3.7 Hz), 21.5 (d, $^1J_{CP}$ = 49.6 Hz), 29.1 (d, $^3J_{CP}$ = 15.3 Hz), 30.2, 117.3 (d, $^1J_{CP}$ = 82.5 Hz), 129.6 (d, $^3J_{CP}$ = 12.3 Hz), 132.6 (d, $^2J_{CP}$ = 9.8 Hz), 134.2. Insoluble in diethyl ether or toluene at their respective boiling points; soluble in acetone.

Hexyltributylphosphonium bromide (5aa)

^{1}H NMR ($CDCl_3$, 300 MHz) δ: 0.87–1.01 (m, 12H, 4 × –CH_3), 1.29–1.35 (m, 4H, 2 × –CH_2), 1.47–1.60 (m, 16H, 8 × –CH_2), 2.40–2.53 (m, 8H, 4 ×-CH_2P). The product behaves like an ionic liquid and becomes solid upon freezing (–18 °C); insoluble in diethyl ether at room temperature.

Hexyltributylphosphonium chloride (5ab)

^{1}H NMR ($CDCl_3$, 250 MHz) δ: 0.90 (t, 3H, ^3J = 6.96 Hz, -CH_3), 1.00 (t, 9H, ^3J = 6.79 Hz, 3 × -CH_3), 1.20–1.40 (m, 4H, 2 × -CH_2), 1.40–1.70 (m, 16H, 8 × -CH_2), 2.30–2.60 (m, 8H, -CH_2P). ^{13}C NMR ($CDCl_3$, 250 MHz) δ: 13.2, 13.7, 18.7 (d, $^1J_{CP}$ = 47.4 Hz), 18.9 (d, $^1J_{CP}$ = 47.0 Hz), 21.5 (d, $^2J_{CP}$ = 5 Hz), 22.1, 23.6, 23.7 (d, $^3J_{CP}$ = 15.2 Hz), 30.2 (d, $^3J_{CP}$ = 14.7 Hz), 30.8. The product behaves like an ionic liquid and becomes solid upon freezing (–18 °C); insoluble in diethyl ether at room temperature.

The kinetics and the mechanism of oxidative decarboxylation of benzilic acid by acidic permanganate (stopped-flow technique) — An autocatalytic study

Sairabanu A. Farokhi and Sharanappa T. Nandibewoor

Abstract: The kinetics of the oxidation of benzilic acid by potassium permanganate in an acidic medium were studied spectrophotometrically. The reaction followed a two-stage process, wherein both stages of the reaction followed first-order kinetics with respect to permanganate ion and benzilic acid. The rate of the reaction increased with an increase in acid concentration. Autocatalysis was observed by one of the products, i.e., manganese(II). A composite mechanism involving autocatalysis has been proposed. The activation parameters of the reaction were calculated and discussed and the reaction constants involved in the mechanisms were calculated. There is a good agreement between the observed and calculated rate constants under different experimental conditions.

Key words: oxidation, autocatalysis, benzilic acid, two-stage kinetics.

Résumé : Faisant appel à la spectrophotométrie, on a étudié la cinétique de l'oxydation de l'acide benzilique par le permanganate de potassium en milieu acide. La réaction se produit en deux étapes et chacune d'elles est du premier ordre par rapport aux concentrations de l'ion permanganate et de l'acide benzilique. La vitesse de la réaction augmente avec une élévation de la concentration d'acide. On a observé de l'autocatalyse par l'un des produits, soit le manganèse(II). On propose un mécanisme composé impliquant de l'autocatalyse. On a calculé et on discute des paramètres d'activation de la réaction; on a aussi calculé les constantes de réaction impliquées dans les mécanismes. On a observé un bon accord entre les constantes de vitesses observées et calculées dans différentes conditions expérimentales.

Mots clés : oxydation, autocatalyse, acide benzilique; cinétique à deux étapes.

[Traduit par la Rédaction]

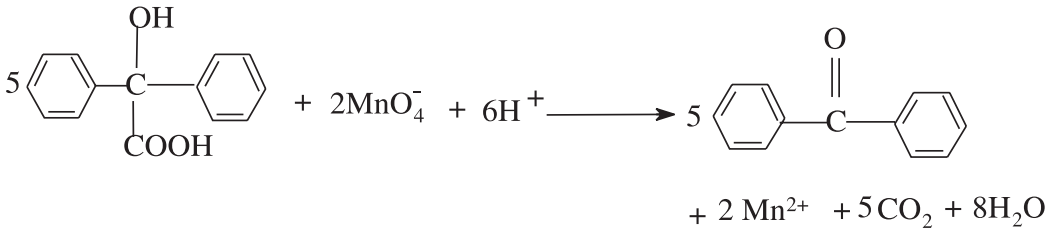
Introduction

It is evident that manganese(VII) is reduced to various oxidation states in acidic, alkaline, and neutral media during oxidation by permanganate. Out of the six oxidation states of manganese (1), from 2^+ to 7^+, permanganate Mn(VII), is the most powerful oxidant in a dilute acid medium with reduction potentials of 1.69 V for the Mn(VII)/Mn(IV) couple and 1.51 V for the Mn(VII)/Mn(II) couple.

Oxidations by permanganate ion are applied extensively in organic syntheses (2–8), especially since the advent of phase-transfer catalysis (4, 5, 7). Kinetic studies are important sources of mechanistic information on the reactions, as demonstrated by the results for unsaturated acids both in aqueous (2, 4, 8) and nonaqueous media (9).

Furthermore, the mechanism by which this multivalent oxidant oxidizes a substrate depends not only on the substrate but also on the medium (10, 11) used for the study. In some cases the mechanistic approach is based on the intermediate complex formation, and in others, the results are interpreted by a free radical mechanism. The mechanisms suggested by various authors are not uniform, indicating that a wide variety of mechanisms are possible depending on the nature of the reactive species of permanganate as well as the substrate.

Several studies have been reported on the oxidation of benzilic acid by other oxidants such as cerium(IV) (12, 13), ferricyanide (14), chromic acid (15), thallium(III) (16), persulphate (17), and *N*-bromosacharin (18). Even though the oxidation product of benzilic acid is the same in both acidic and alkaline media, the reactions differ in many kinetic parameters. Interest in kinetic studies, in particular of α-hydroxy acids (19), has developed and no attempts have been made to correlate the rate data with the structural differences in these acids.



In view of the lack of reports in the literature on the oxidation of benzilic acid by acidic $KMnO_4$, we have selected it as a substrate for study. The present study deals with the ki-

[1] 

netics of the oxidation of benzilic acid by $KMnO_4$ in an acidic medium to arrive at a plausible mechanism and to determine the active species of permanganate in such media.

Experimental

Since the initial reaction was too fast to monitor by the usual method, kinetic measurements were performed on a Hitachi 150-20 spectrophotometer connected to a rapid kinetic accessory (HI-TECH SFA-12).

Materials and methods

All chemicals used were of BDH Analar specifications. Potassium permanganate (BDH) was prepared in doubly distilled water and its strength was ascertained (20*a*) by titrating against standard $H_2(CO_2)_2$ solution in hot acidic medium. The solubility of benzilic acid (Merck) (BA) is low and it was prepared in water by warming. Perchloric acid (Merck) and sodium perchlorate (BDH) were used to provide the required acidity and ionic strength, respectively. Mn(II) was prepared by dissolving manganese(II) sulphate (Riedel). Doubly distilled conductivity water was used to prepare all the solutions.

The optical density vs. concentration plot for acidified permanganate ion showed that Beer's law, under the reaction conditions in 6.0×10^{-5} to 2.0×10^{-4} mol dm^{-3} in 0.01 mol dm^{-3} $HClO_4$, was obeyed at a wavelength of 526 nm and the molar absorptivity of permanganate was found to be 2300 ± 50 dm^3 mol^{-1} cm^{-1}, which was in good agreement with previous results (21, 22).

Kinetic measurements

All kinetic measurements were performed under pseudo-first-order conditions where [benzilic acid] was always in excess over [MnO_4^-] at a constant ionic strength of 5.0×10^{-3} mol dm^{-3} in acidic medium at a constant temperature of 21 ± 0.1 °C.

The progress of the reaction was followed by monitoring the decrease in MnO_4^- in a 1 cm quartz cell of a Hitachi model 150-20 spectrophotometer at its absorption maximum (526 nm) as a function of time. Earlier, it was verified that there is negligible interference from other reaction species at this wavelength. The pseudo-first-order rate constants were obtained from the plots of log $(A_t - A_\infty)$ vs. time and the plot of log $[(A_t - A_\infty) - (A_{t'} - A_\infty)]$ vs. time, where A_t and A_∞ represent the absorbance at time t and ∞, respectively. $A_{t'}$ represents the absorbance for the extrapolated point at time t'. The plots of log $(A_t - A_\infty)$ vs. time and of log $[(A_t - A_\infty) - (A_{t'} - A_\infty)]$ vs. time indicate that there was a two-stage process and that both stages were linear. In the first slow process, the linearity was observed up to 60% completion of the reaction and in the second fast process, linearity was observed from 60% to 80% completion of the reaction. k_{obs} values were reproducible within ±5%, where the first slow stage is followed by a second fast stage process (Fig. 1). This type of two-stage process has been observed in a few cases (23, 24). During the progress of the reaction, the colour of the solution changed from violet to colourless, indicating the formation of Mn(II), which was verified by a spot test (20 *b*). The formation of Mn(II) is shown spectrally in Fig. 2.

Results

Stoichiometry and product analysis

Different sets of reaction mixtures containing excess [MnO_4^-] over [benzilic acid] were mixed in the presence of 1.0×10^{-3} mol dm^{-3} perchloric acid, adjusted to an ionic strength of 5.0×10^{-3} mol dm^{-3}, and kept for 12 h in an inert atmosphere at 21 °C. After completion of the reaction, the remaining permanganate was then determined spectrophotometrically. The results indicated that 5 mol of benzilic acid were consumed by 2 mol of permanganate as in eq. [1].

The main oxidation products were identified as benzophenone, CO_2, and manganese(II). The product, manganese(II) in acid medium, was analyzed using EDTA solution with Erichrome black-T as the indicator (20*b*). The formation of benzophenone was confirmed by its IR and NMR spectra (25). Further, the yield was quantitatively estimated to ca. 85%, evidence for which is provided by isolation of its 2,4-DNP derivative (26), with a mp of 236 °C. Benzophenone did not undergo further oxidation under the stated kinetic conditions. The test for the probable oxidation product of the ketone, i.e., benzoic acid, was negative.

Reaction orders

The reaction order for benzilic acid and perchloric acid was investigated by varying one of these concentrations while keeping all other concentrations and conditions constant and studying the effect of its concentration on the rate of the reaction.

Kinetic data were collected for initial [MnO_4^-] in the $(0.40–4.0) \times 10^{-4}$ mol dm^{-3} range. In an acid medium, the reaction followed a two-stage process (Fig. 1). All the experiments exhibited an identical pattern, with the initial slow reaction followed by a faster one. The plots of log $(A_t - A_\infty)$ vs. time and log $[(A_t - A_\infty) - (A_{t'} - A_\infty)]$ vs. time ($r > 0.9355$, $s \leq 0.0144$ for stage 1, $r > 0.9951$, $s \leq 0.4480$ for stage 2) for different initial concentrations of MnO_4^- exhibit two distinct straight lines for the slow and fast stages of the reaction (Fig. 1). The fairly constant k_s (s^{-1}) values for the slow stage and k_f (s^{-1}) values for the fast stage confirms that slow and fast depletions in MnO_4^- follow first-order kinetics. The concentration of benzilic acid was varied in the range of $(0.40–4.0) \times 10^{-3}$ mol dm^{-3}, keeping all other reactant con-

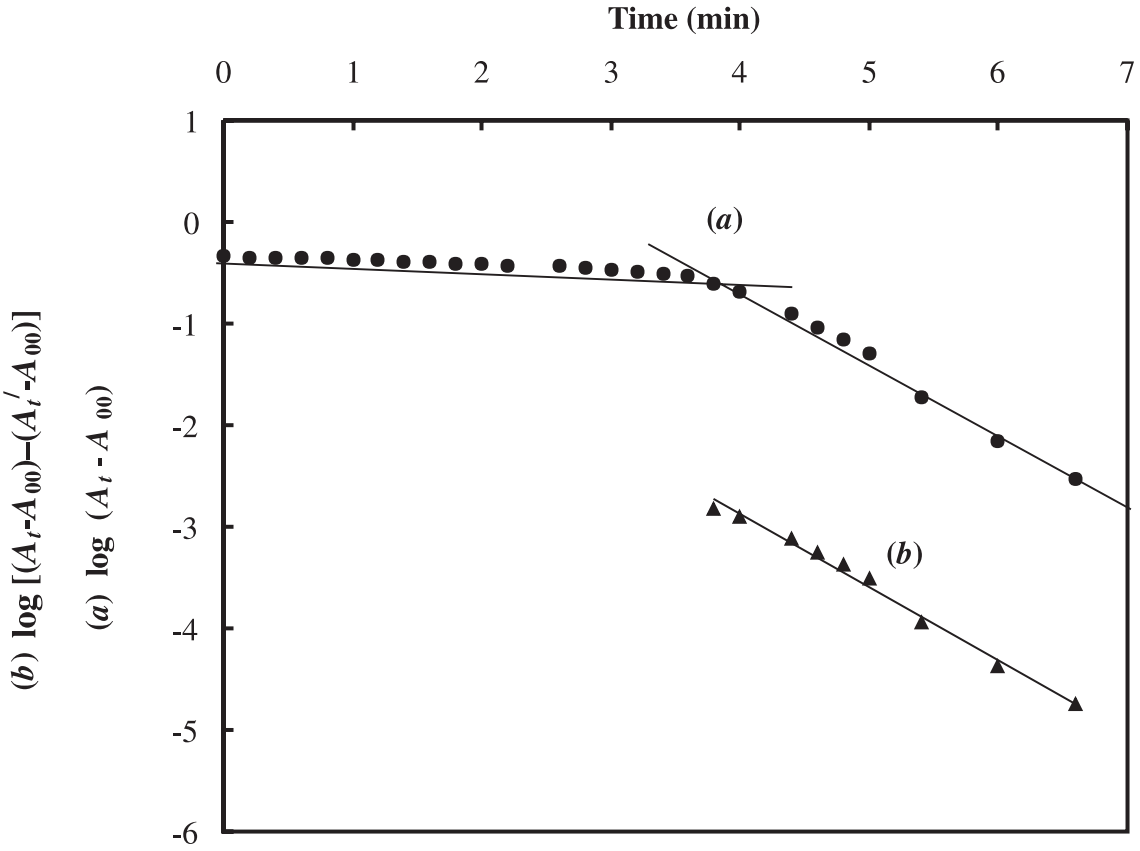
Fig. 1. Plot of (*a*) $\log(A_t - A_\infty)$ vs. time and (*b*) $\log[(A_t - A_\infty) - (A_{t'} - A_\infty)]$ vs. time in an acidic medium ($[MnO_4^-]$ = 2 × 10^{-4} mol dm^{-3}, [BA] = 2 × 10^{-3} mol dm^{-3}, $[H^+]$ = 1.0 ×10^{-3} mol dm^{-3}, and I = 5.0 × 10^{-3} mol dm^{-3}.



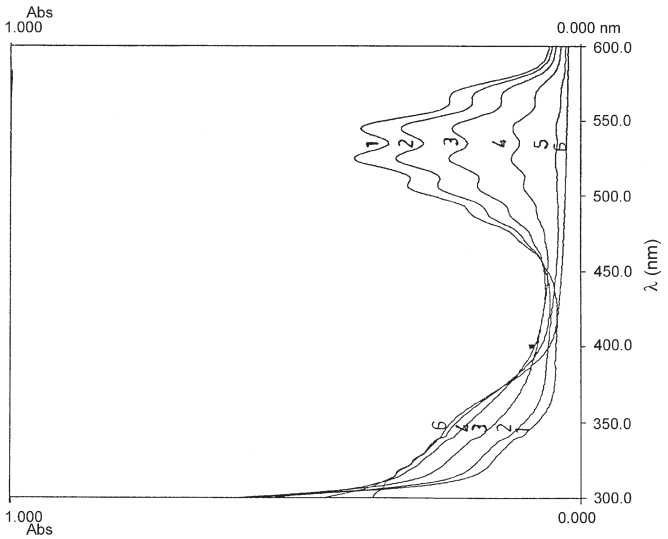


Fig. 2. Spectroscopic changes occurring in the oxidation of benzilic acid by permanganate with $[MnO_4^-]$ = 2.0 × 10^{-4} mol dm^{-3}, [BA] = 2.0 × 10^{-3} mol dm^{-3}, $[H^+]$ = 1.0 × 10^{-3} mol dm^{-3}, and I = 5.0 × 10^{-3} mol dm^{-3} at 21 °C (scanning time interval = 1 min).

centrations and conditions constant. In an acidic medium, the k_s and k_f values (Table 1) increased with increasing concentration of benzilic acid indicating first-order dependence on the [substrate] in both the stages. To study the effect of $[H^+]$ on the rate of the reaction, the $[H^+]$ was varied from (0.50–5.0) × 10^{-2} mol dm^{-3} at a constant concentration of MnO_4^- and benzilic acid, maintaining a constant ionic strength of 5.0 × 10^{-3} mol dm^{-3}. It was found that in both stages the rate increased with an increase of $[H^+]$. The order in both stages was less than unity (Table 1). It was found that the ionic strength and dielectric constant of the medium have no significant effect on the rate of reaction.

Effect of added products

The addition of the product benzophenone did not show any significant effect on the rate of the reaction. However, the initial addition of the product Mn(II) in the range of (0.20–2.0) × 10^{-4} mol dm^{-3}, keeping other conditions constant, had an appreciable increasing effect on the rate of the reaction. As the initial concentration of Mn(II) was increased, the rate progressively increased at an order of around 0.62 and 0.26 in the slow and fast stages, respectively. This illustrates the autocatalytic nature of the product (Table 2), which is also evident from the concentration vs. time plot (Fig. 3) and the linear plot of k_{obs} vs. k_{cal} for manganese(II) variation (Fig. 3, inset), as observed in earlier cases (27).

Polymerization study

To test for free radical intervention, the reaction mixture containing $[MnO_4^-]$ = 2 × 10^{-4} mol dm^{-3} and [BA] = 2 × 10^{-3} mol dm^{-3} were taken, and the pH of the solution was adjusted to 3.0 The solution was then degassed with nitrogen

and acrylonitrile (5 mL, 20% v/v) was added to the solution at room temperature and was kept for 24 h. On diluting the reaction mixture with methanol, no precipitate resulted indicating no polymerization of acrylonitrile. This observation indicates that the oxidation of benzilic acid by acidic potassium permanganate proceeds through the absence of polymer formation and, as well, any intervention of free radicals. There is evidence of polymerization with acrylonitrile in the earlier studies (28).

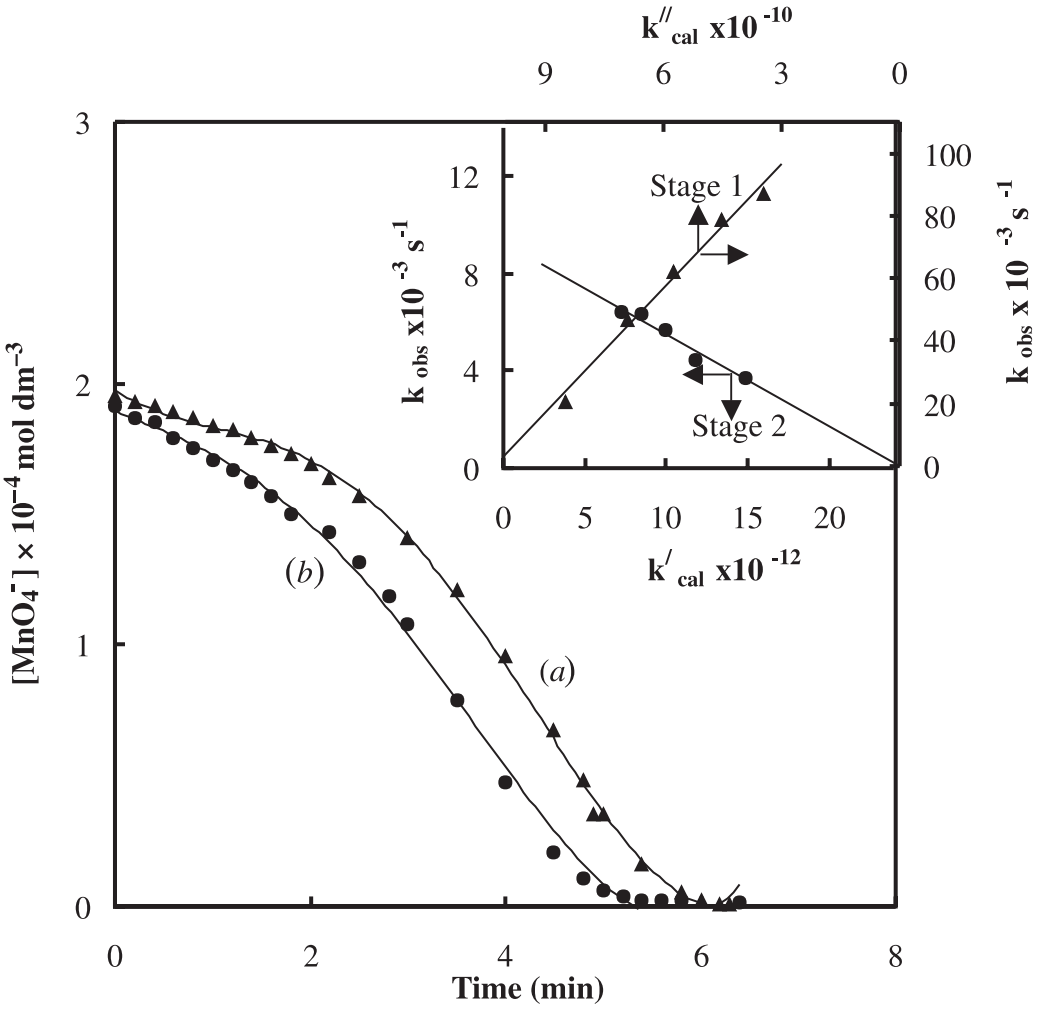
Effect of temperature

The effect of temperature on the reaction was studied at four different temperatures. The rate increased with an increase in temperature. The $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values were obtained from a $\log(k_{obs}/T)$ vs. $1/T$ plot ($r > 0.9719$, $s \leq 0.01298$ for stage 1, $r > 0.9839$, $s \leq 0.07748$ for stage 2). The activation parameters $\Delta H^{\ddagger}$ (kJ mol^{-1}), $\Delta S^{\ddagger}$ (J K^{-1} mol^{-1}), and $\Delta G^{\ddagger}$ (kJ mol^{-1}) were found to be 64 ± 2, –79 ± 6, and 87 ± 4 for stage 1 and 28 ± 2, –181 ± 16, and 81 ± 4 for stage 2, respectively.

Discussion

Oxidation of benzilic acid by permanganate in a $HClO_4$ medium is a noncomplementary reaction in which the oxidant undergoes five equivalent changes. In this experiment, the reaction between benzilic acid and MnO_4^- had a stoichiometry of 5:2 with first-order dependence on [MnO_4^-] and [BA] and fractional order dependence on both [H^+] and [Mn(II)]. Stoichiometric studies revealed 5-equivalent changes in Mn(VII). Hence, the formation of Mn(IV) as a reduced product of Mn(VII) in the reaction was excluded, although formation of Mn(IV) had been observed in earlier studies (29, 30). The strong reducing character of benzilic acid was evident in the reduction of Mn(VII) to Mn(II) in the $HClO_4$ medium.

The active species of permanganate in an aqueous acid medium may be deduced from the dependence of the rate on [H^+] in the reaction medium. The apparent order of less than unity in [H^+] may be an indication of the permanganate species as permanganic acid. In an acidic medium, permanganic acid ($HMnO_4$) is a more efficient oxidant species of manganese(VII) than permanganate ion (29–31). In addition, it was observed that the reaction rate increased with an increase in [H^+] and tended to attain a limiting value at high acidities. The plot of k_{obs} vs. [H^+] in an acidic medium is a curve of decreasing slope (convex to the rate axis) and passing through the origin (Fig. 4) from which it can be inferred (32) that a rapid equilibrium between the protonated and unprotonated form is involved. At higher acidities protonation is almost complete, leading to the limiting rate, which indicates that only the protonated form is active. The negligible ionic strength effect on the rate of the reaction also confirms $HMnO_4$ as the active species of MnO_4^-. Thus, the acid permanganate equilibrium is represented as



$$[2] \qquad H^+ + MnO_4^- \overset{K_1}{\rightleftharpoons} HMnO_4$$

where K_1 is the formation constant of $HMnO_4$.

Based on the experimental results, the following mechanism can be proposed in which all the observed orders with respect to each constituent such as [oxidant], [reductant], and [H^+] may be well accommodated. The results suggest the formation of a protonated form of permanganate as the

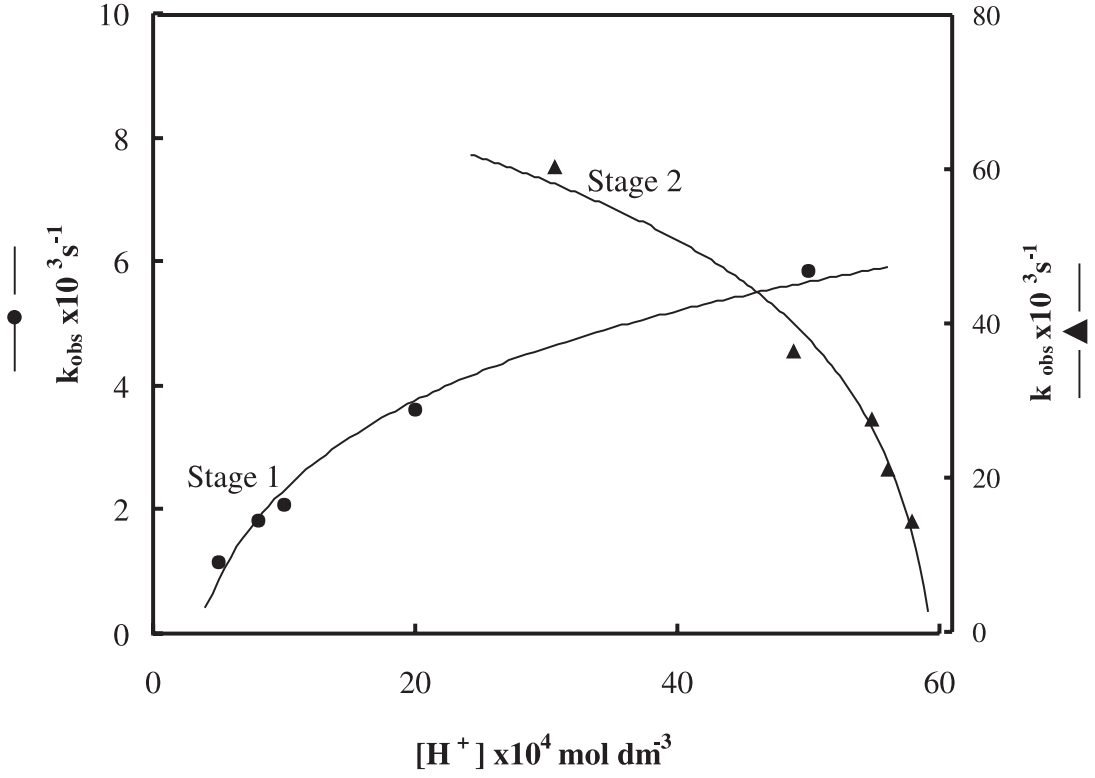
(*a*) [BA] = 2.0×10^{-3} mol dm^{-3}, [MnO_4^-] = 2.0×10^{-4} mol dm^{-3}, [H^+] = 1.0×10^{-3} mol dm^{-3}, $I = 5.0 \times 10^{-3}$ mol dm^{-3} (*b*) [BA] = 3.0×10^{-3} mol dm^{-3}, [MnO_4^-] = 2.0×10^{-4} mol dm^{-3}, [H^+] = 1.0×10^{-3} mol dm^{-3}, $I = 5.0 \times 10^{-3}$ mol dm^{-3}. Inset: plot of k_{expt} vs $k'_{cal} = [BA]^1[Mn(II)]^{0.62}[H^+]^{0.70}[MnO_4^-]^1$ for stage 1 and $k''_{cal} = [BA]^1[Mn(II)]^{0.26}[H^+]^{0.6}[MnO_4^-]^1$ for stage 2 for the variation of manganese(II) (Table 2).

active species of MnO_4^- in a prior equilibrium, which reacts with 1 mol of benzilic acid in a rate-determining step to give a complex (C_1) that further decomposes in a fast step to give benzophenone and the intermediate Mn(V). The intermediate Mn(V), being unstable in an acidic medium, reacts with another mol of benzilic acid in a fast step to Mn(III), which is subsequently reduced to the end product Mn(II) in further fast steps satisfying stoichiometric observations. The spectral evidence for the formation of complex C_1 was obtained from UV–vis spectra of both benzilic acid and the mixture of benzilic acid and permanganic acid, which indicated a bathochromic shift from 325 to 347 nm. The steps proposed are shown in Scheme 1.

Since none of the intermediates of Mn(VII) could be detected, Scheme 1 is only one of the possible mechanisms for the reaction in the absence of free radicals. Attempts were made to allow spectrophotometric detection (in terms of wavelengths) of Mn^{5+} and Mn^{3+} intermediates as the reaction proceeded in the oxidation of benzilic acid by $HMnO_4$. Unfortunately, the low concentration of Mn^{3+} and Mn^{5+} intermediates obtained under our experimental conditions made the detection unsuccessful. However, there are reports of their existence in the earlier literature (33, 34). Scheme 1 leads to the rate law (eq. [3] that explains all the observed orders except autocatalysis.

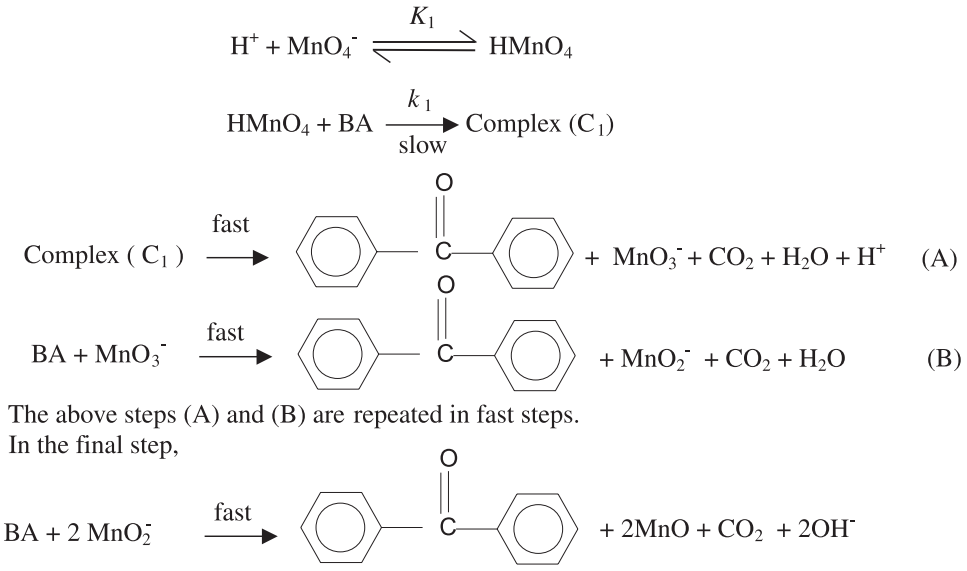
$$[3] \qquad -\frac{d[Mn(VII)]}{dt} = \frac{k_1K_1[H^+]_T[Mn(VII)]_T[BA]}{(1+K_1[H^+])(1+K_1[Mn(VII)])}$$

$$[4] \qquad = \frac{k_1K_1[H^+][BA][Mn(VII)]}{1+K_1[H^+]+K_1[Mn(VII)])+K_1^2[H^+][Mn(VII)]}$$



The terms such as $K_1[Mn(VII)]$ and $K_1^2[H^+][Mn(VII)]$ in the denominator of eq. [4] are negligibly small compared with unity, in view of the low concentration of [Mn(VII)] used in the experiments. Hence, eq. [4] becomes eq. [5]

$$[5] \qquad k_{obs} = \frac{\text{Rate}}{[Mn(VII)]} = \frac{k_1K_1[H^+][BA]}{1+K_1[H^+]}$$



The mechanism of Scheme 1 and rate law (eq. [3]) may be verified by rearranging to the form

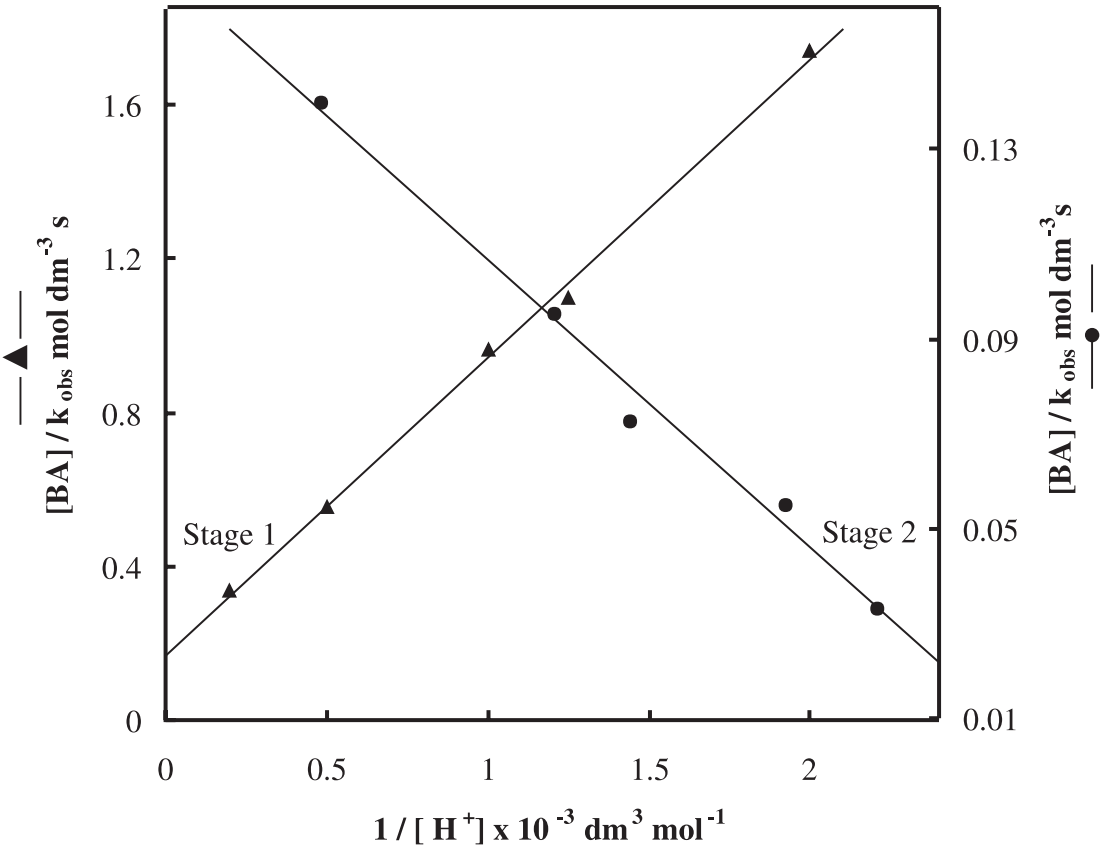
Fig. 4. The plot of k_{obs} vs. [H^+] (a curve of decreasing slope (convex to the rate axis)).

Scheme 1.



$$[6] \qquad \frac{[BA]}{k_{obs}} = \frac{1}{k_1 K_1 [H^+]} + \frac{1}{k_1}$$

where k_{obs} is first-order rate constant. According to eq. [6], the plot of $[BA]/k_{obs}$ vs. $1/[H^+]$ ($r > 0.999$, $s \leq 0.06990$ for stage 1, $r > 0.9946$, $s \leq 0.06993$ for stage 2) is expected to be linear, which is verified in Fig. 5. The slope and intercept of this plot lead to values of K_1 and k_1 at 21 °C of 221 ± 9 dm^3 mol^{-1}, 5.8 ± 0.3 dm^3 mol^{-1} s^{-1} for stage 1 and 371 ± 13 dm^3 mol^{-1}, 46 ± 2 dm^3 mol^{-1} s^{-1} for the fast stage 2, respectively. The experimental rate constants can be computed for both stages using these values. There is a reasonable agreement between the calculated and experimental rate constants (Table 1). The negligible effect of ionic strength

and relative permitivity on rate is qualitatively consistent with the reaction between two neutral molecules as in Scheme 1.

Autocatalysis by Mn(II) in an acidic medium

The autocatalysis by one of the products (Mn(II)) is interesting. The effect of Mn(II) as a catalyst in the case of the oxidation of permanganate is well-known (35–37). In the present case, Mn(II) was found to catalyse the rate of oxidation of benzilic acid (Table 2).

The apparent order of less than unity with respect to the Mn(II) ion may be attributed to a complex formation between benzilic acid and Mn(II). The complex (C_2) is then subsequently involved in the interaction with $HMnO_4$. These steps shown in Scheme 2 will form a part of Scheme 1.

The evidence for complex formation (C_2) was obtained from UV–vis spectra of both benzilic acid and mixtures of

© 2004 NRC Canada

benzilic acid and Mn(II), which indicated a hypsochromic shift of about 4 nm from 338 to 334 nm and a new band appeared at 372 nm. Indeed, such complex formation between substrates such as styrene and Mn(II) has been observed in the literature (38, 39).

Thus, when Mn(II) is initially present, a composite scheme involving all the steps of Schemes 1 and 2 operates and the rate law becomes

$$k_{gross} = k_{obs} + k_{autocat}$$

$$[7] \quad k_{gross} = \frac{k_1 K_1 [BA][H^+]}{1 + K_1[H^+]} + \frac{k_2 K_2 [Mn(II)][BA]^2}{\{1 + K_2[BA]^2\}\{1 + K_2[Mn(II)][BA]\}^2}$$

$$k_{autocat} = k_{gross} - k_{obs}$$

$$[8] \quad k_{autocat} = \frac{k_2 K_2 [Mn(II)][BA]^2}{\{1 + K_2[BA]^2\}\{1 + K_2[Mn(II)][BA]\}^2}$$

where k_{gross} and $k_{autocat}$ refer to the rate paths of the overall and autocatalytic paths, respectively. At constant concentrations of oxidant and substrate, a plot of $[BA]^2/k_{autocat}$ in eq. [8] vs. 1/[Mn(II)] ($r > 0.9987$, $s \leq 0.1566$ for stage 1, $r > 0.9596$, $s \leq 0.1574$ for stage 2) for both stages was found to be linear. Indeed, it is to be noted that the plot shows an intercept that is in agreement with the complex formation as shown in Scheme 2. The high negative values of $\Delta S^{\ddagger}$ indicate that complex (C_1) is more ordered than the reactants (40).

Reason for the two stages

Details regarding the occurrence of two successive stages, slow and fast, might be due to the creation of an optimum concentration of some intermediates (41–43). It might be possible that up to a certain range of MnO_4^- concentration (first slow stage), the active species of the oxidant (i.e., the protonated form of MnO_4^- ($HMnO_4$) is reactive) while in the second stage of the reaction, autocatalysis due to one of the products (Mn(II)) is operative. The product Mn^{2+} ions formed in the first slow stage, after achieving an optimum concentration, start reducing MnO_4^- ions to Mn^{3+} and or Mn^{4+} ions (44), ($MnO_4^- + 3Mn^{2+} + 8H^+ = 3Mn^{3+} + Mn^{4+} + 4H_2O$) indicating that the intermediate manganese ions are the active oxidizing species. On addition of Mn^{2+}, the acceleration of rate is due to the existence of Mn^{3+} or Mn^{4+} as the principal reactive species in the second fast stage. But the oxidation of benzilic acid by Mn(III), as well as the continuous increase in the oxidation rate with increasing Mn^{2+} added to the MnO_4^- – benzilic acid reaction mixture, indicates that Mn^{3+}, but not Mn^{4+}, is the sole oxidant throughout the auto acceleration stage.

Conclusions

In an acidic medium, the reaction exhibits an autocatalytic nature and follows two stages, as one of the products (Mn(II)) enhances the rate of the reaction. Mn(II) as the reduced product of Mn(VII) in the reaction may suggest that benzilic acid shows a strong reducing character in a $HClO_4$ medium. The overall mechanistic sequences described in the media are consistent with product, mechanistic, and kinetic studies.

Appendix

According to Scheme 1,

$$[A1] \quad \text{Rate} = k_1[HMnO_4][BA] = k_1K_1[Mn(VII)]_f[BA]_f[H^+]_f$$

The total concentration of MnO_4^- is given by (where "T" and "f "stand for total and free)

$$[Mn(VII)]_T = [Mn(VII)]_f + [HMnO_4] = [Mn(VII)]_f(1 + K_1[H^+])$$

Therefore,

$$[A1a] \quad [Mn(VII)]_f = [MnO_4^-]_T/1 + K_1[H^+]$$

Similarly,

$$[A1b] \quad [H^+]_f = [H^+]_T/1 + K_1[Mn(VII)]$$

Substituting eqs. [A1*a*]and [A1*b*] in eq. [A1]

$$[A1c] \quad \text{Rate} = -d[Mn(VII)]/dt = \frac{k_1K_1[H^+][BA][Mn(VII)]_T}{(1 + K_1[H^+])\,(1 + K_1[Mn(VII)])}$$

The term $(1 + K_1[Mn(VII)])$ in the denominator of eq. [A1*c*] approximates unity in view of the low concentration of Mn(VII) used.

Autocatalysis

According to Scheme 2,

$$[A1d] \quad \text{Rate} = k_2[C_2][HMnO_4] = k_2K_2[Mn(II)]_f[BA]_f^2[HMnO_4]$$

$$[Mn(II)]_T = [Mn(II)]_f + [C_2] = [Mn(II)]_f(1 + K_2[BA]^2)$$

Therefore,

$$[A1e] \quad [Mn(II)]_f = [Mn(II)]_T/1 + K_2[BA]^2$$

Similarly,

$$[A1f] \quad [BA]_f = [BA]_T/1 + K_2[Mn(II)][BA]$$

Substituting eqs. [A1*e*] and [A1*f*] in eq. [A1*d*]

$$[A1g] \quad \text{Rate} = \frac{k_2K_2[Mn(II)][BA]^2[HMnO_4]}{\{1 + K_2[BA]^2\}\{1 + K_2[Mn(II)][BA]\}^2}$$

Fluorine chemistry. Part 2. Synthesis and characterization of 2*H*-heptafluoropropane (HFC-227ea)

Pinaki S. Bhadury, Sapna Singh, Mamta Sharma, Ramesh C. Malhotra, and Krishnamurthy Sekhar

Abstract: A facile method has been developed for the synthesis and characterization of volatile 1,1,1,2,3,3,3-heptafluoropropane (HFC-227ea), a potential non-ozone depleting hydrofluorocarbon substitute for Halon 1301 (CF_3Br). The method involves hydrofluorination of hexafluoropropene using in situ generated onium bifluoride obtained from the decomposition of anhydrous tetrabutylammonium fluoride. The reagent acts as an excellent equivalent to hydrogen fluoride and permits the use of normal glassware.

Key words: 2*H*-heptafluoropropane, hydrofluorocarbon, hexafluoropropene, tetrabutylammonium fluoride, hydrofluorination.

Résumé : On a développé une méthode simple de synthèse et de caractérisation du 1,1,1,2,3,3,3-heptafluoropropane (HFC-227ea), un hydrofluorocarbone volatil sans effet nocif sur la couche d'ozone qui pourrait éventuellement remplacer le Halon 1301 (CF_3Br). La méthode implique l'hydrofluoration de l'hexafluoropropène en faisant appel à bifluorure d'onium généré in situ par décomposition du fluorure de tétrabutylammonium anhydre. Le réactif agit comme un excellent équivalent pour le fluorure d'hydrogène et permet d'utiliser de la verrerie normale.

Mots clés : 2*H*-heptafluoropropane, hydrofluorocarbone, hexafluoropropène, fluorure de tétrabutylammonium, hydrofluoration.

[Traduit par la Rédaction]

Introduction

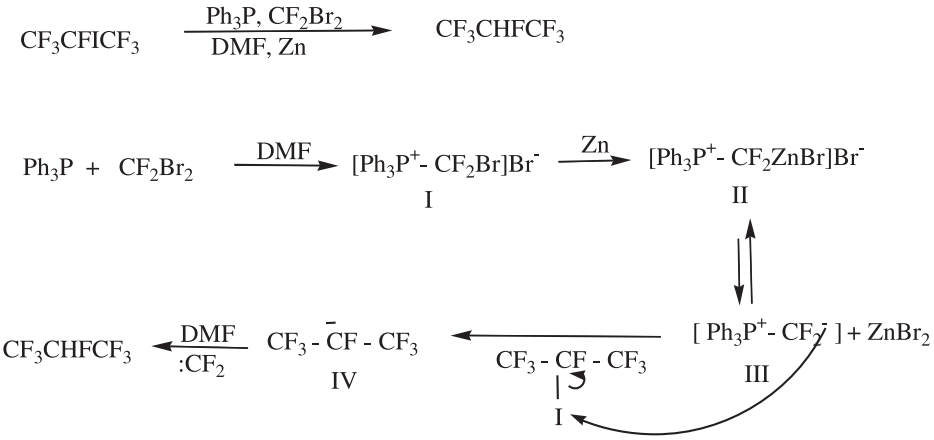
Chlorofluorocarbons (CFCs) and bromine-containing halons are recognized as potent contributors to the depletion of earth's stratospheric ozone layer. In accordance with the Montreal Protocol, consumption of CFCs and halons is prohibited (to be phased out over the period 1996–2030) (1, 2). According to the United States Environmental Protection Agency (USEPA), 2*H*-heptafluoropropane (HFC-227ea) does not deplete stratospheric ozone. In addition, HFC-227ea is the most effective of the proposed hydrofluorocarbon (HFC) substitutes for Halon 1301 (CF_3Br) in fire protection applications (3).

Although various synthetic procedures for chlorofluorocarbons and hydrochlorofluorocarbons have been reported in the literature, those actually used in manufacturing processes are limited. By far the most important is the original Swarts reaction, which has the limitation of employing corrosive reagents (anhyd. HF, SbF_3, and SbF_5) and is associated with poor yield with a number of side reaction products (4). The specific information on the synthesis of HFC-227ea and related chemicals is again very limited and involves either reaction of elemental fluorine gas with 2-trifluoromethyl-3,3,3-trifluoropropionic acid (5) or high-temperature, vapour-phase addition of corrosive HF on hexafluoropropene (HFP) in the presence of a fluorination catalyst (6).

Anhydrous hydrogen fluoride as such or its equivalent such as Olah's reagent (pyridinium poly(hydrogen fluoride)) (4, 7), essentially employs free HF. These reagents are highly toxic, corrosive to the skin, and readily attack glass. In addition, owing to the strong H-bond and the relatively weak acidic nature of HF, they possess poor fluoride activity and are not suitable for conversion of HFP into HFC-227ea.

Earlier, we developed methodologies for the synthesis of hydrofluorocarbons such as CF_2ClH, CF_2BrH, $CFBr_2H$, CF_2H_2, and $CF_3CF_2CF_2H$ (HFC-227ca, isomer of HFC-227ea) based on in situ generated reactive fluorinated phosphonium ylide and the related Wittig reaction (8, 9). This methodology has now been extended to HFC-227ea. Another useful and facile method developed utilizes the reaction of HFP with anhydrous tetrabutylammonium fluoride (TBAF) at higher temperature with the latter serving as a potential source for hydrogen fluoride. The results of this interesting finding are summarized in this communication.

Results and discussion



A Wittig reaction involving in situ difluoromethylene triphenylphosphonium ylide [$Ph_3P^+–^-CF_2$] in DMF has been successfully employed by us to convert several activated aromatic ketones and aldehydes into their corresponding termi-

Scheme 2. Proposed mechanism for the formation of HFC-227ea by the salt method.

nal 1,1-difluoroolefins (8, 10, 11). The study has recently been extended to yield perfluoroisobutylene (PFIB), a Schedule 2 higly toxic chemical (9). The fate of this highly reactive nucleophilic ylide in the presence of a non-carbonyl moiety, e.g., positive iodine- or bromine-containing electrophiles has further been studied to yield volatile organofluorins such as CF_2=CF_2, perfluorocyclobutane, CF_3CF=$CFCF_3$, and HFC-227ca (9). The formation of [Ph_3P^+–$^-CF_2$] by zinc metal dehalogenation of in situ generated (bromodifluoromethyl) triphenylphosphonium bromide salt has now been utilized for the synthesis of HFC-227ea.

The (bromodifluoromethyl) triphenylphosphonium bromide salt (**I**, Scheme 1) was formed when an equimolar amount of CF_2Br_2 was added in one installment to a well-stirred solution of triphenylphosphine at room temperature in dry DMF. This was followed by the addition of a half molar equivalent of 2-iodoheptafluoropropane to the salt solution at room temperature. Then 1 g atom equivalent of Zn powder was added slowly into the reaction mixture. Within 1 to 2 min an exothermic reaction ensued owing to the formation of organozinc bromide (**II**) in equilibrium with difluoromethylene triphenylphosphonium ylide (**III**). Volatile HFC-227ea was generated and directly collected in a tedlar bag attached to the reaction system. The nucleophilic ylide (**III**) under the reaction conditions can abstract labile positive iodine from the substrate 2-iodoheptafluoropropane to give a carbanion (**IV**). The intermediate carbanion, stabilized largely by negative hyperconjugation because of the presence of six β fluorine atoms, abstracts a proton from the solvent to form 2*H*-heptafluoropropane. As observed earlier, the solvent DMF can provide a proton in the presence of difluorocarbene (**:**CF_2), which in turn is generated by the de-

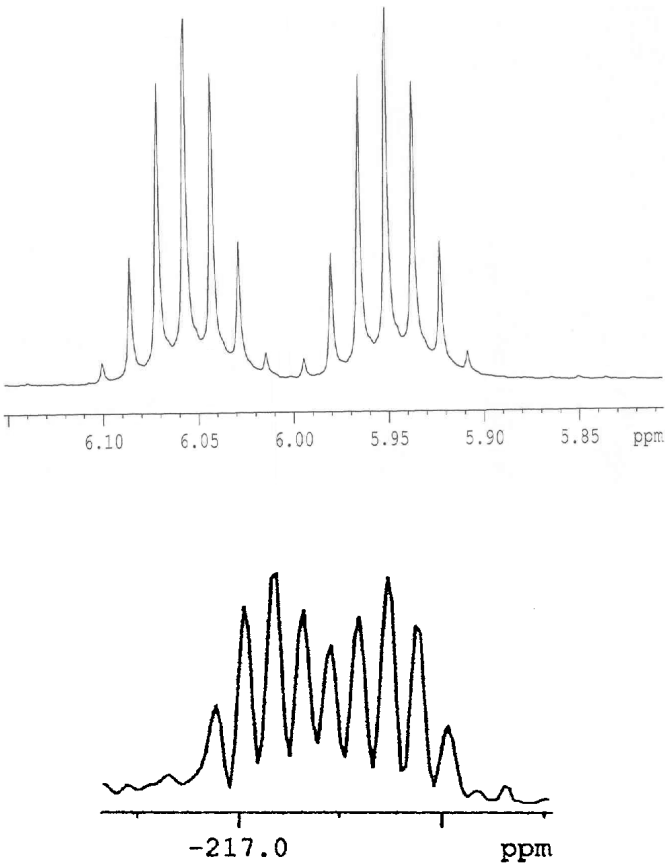
GC–MS (NCI)	169 (M – 1)

composition of excess ylide under reaction conditions (8, 10). A similar observation was noted during the synthesis of HFC-227ca, the other isomer of HFC-227ea, when 1-iodoheptafluoropropane was subjected to reaction with in situ generated [Ph_3P^+–$^-CF_2$] ylide in DMF (9).



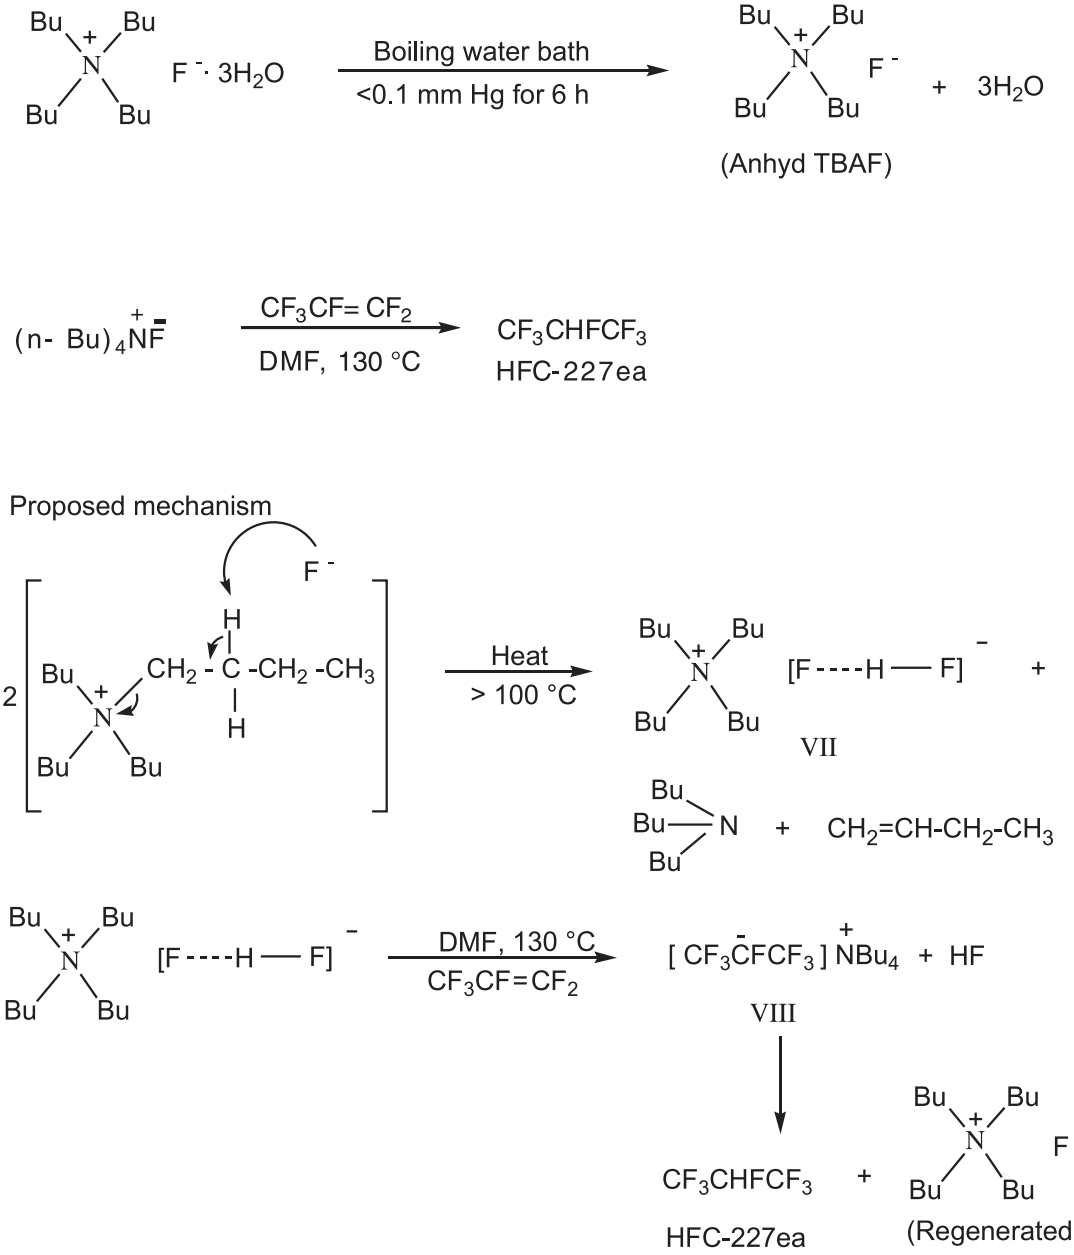
The ylide method, despite being facile, is highly expensive. Therefore, an alternative method using in situ hydrofluorination of hexafluoropropene has been developed.

The difluorocarbene intermediate can be generated in situ at high temperature by the decarboxylation of sodium chlorodifluoroacetate (12, 13). When this decarboxylated salt is reacted with HFP at 150 °C in the solvent DMF, HFC-227ea is formed. Under the influence of difluorocarbene obtained by heating $ClCF_2COONa$, the solvent DMF generates an active fluoro Vilsmeier–Haack intermediate (**V**, Scheme 2). Proof of the formation of this strong Lewis acid intermediate [Me_2N–$^+$CHF]F^- has been provided by Burton et al. (14). This intermediate can act not only as a source of H^+ but also for F^- ion. The S_N2 attack by F^- ion on the terminal carbon atom of fluoroolefin HFP generates carbanion (**VI**), which is stabilized by negative hyperconjugation. Abstraction of a proton by the carbanion results in the formation of the desired product. However, the yield of the final product is low due to the formation of side reaction products including free HF from the decomposition of salt and (or) a Vilsmeier–Haack intermediate.

Onium fluorides such as tetrabutylammonium fluoride ($(Bu)_4N^+F^-$, (TBAF)), tetrabutylammonium bifluoride ($(Bu)_4N^+HF_2^-$, (TBABF)), etc., if free from water, can be employed as a potential fluorinating agent in nucleophilic fluoride exchange reactions on different substrates (15–18). Unfortunately, these salts are invariably associated with water and the presence of water molecules largely diminishes fluoride activity because of hydrogen bonding. To overcome this limitation we have earlier worked on in situ generated onium fluorides by using a semi-molten mixture of onium bromide and alkali metal fluoride for studying fluorodehalogenation reactions (19, 20). We further believe that in situ generated and largely unsolvated TBABF should act not only as a strong source of F^- ion, but also as an equivalent to HF for hydrofluorination reaction. Therefore, we have employed anhydrous tetrabutylammonium fluoride at high temperature as a possible in situ source of hydrogen fluoride and studied its reaction with HFP for the synthesis of HFC-227ea.

Commercially available TBAF·$3H_2O$ was heated on a boiling water bath under high vacuum until a highly viscous oil was obtained. The oil was immediately diluted with DMF and heated on an oil bath up to 150 °C. The mixture was then cooled to 130 °C and the required amount of HFP was bubbled into the solution when almost instantaneously

Fig. 1. ^{1}H and ^{19}F NMR patterns of the central hydrogen and fluorine atoms of HFC-227ea.



an exothermic reaction ensued. The highly volatile HFC-227ea evolved was directly collected in a tedlar bag attached to the reaction system. Toxic HFP was not been detected in the tedlar bag (confirmed by ^{19}F, ^{13}C NMR and GC–MS studies). The product was successfully collected up to the 5 g level and completely characterized by spectral data (Table 1). The distinctive and interesting NMR pattern of the central hydrogen and fluorine atom of HFC-227ea in their respective proton and fluorine spectrums is depicted in Fig. 1.

The spectral results have been compared and completely found to match with that of a standard sample supplied by Great Lakes Chemical Corporation, USA.

Presumably, extensively dried, largely unsolvated "naked" in situ source of F^- ion in TBAF loses its H-bonded stabilizing force and can behave as a base (21). Abstraction of a proton by F^- ion from a second molecule of TBAF in a β-elimination reaction generates higly reactive in situ

Scheme 3. Formation of HFC-227ea by the TBAF method.

hydrofluorinating agent tetrabutylammonium bifluoride ($(Bu)_4N^+HF_2^-$) (**VII**, Scheme 3) along with tributylamine and 1-butene. This type of F^- ion induced β-elimination of onium salts has earlier been noted by Sharma and Fry (22) but has never been utilized in synthetic transformations. Fluoride ion attack on the terminal carbon atom of HFP generates intermediate (**VIII**), which after abstracting a proton from generated HF leads to the formation of HFC-227ea. The mechanism is further supported by the fact that liquid tributylamine and volatile 1-butene (in the tedlar bag) have been detected during the process. Pure HFC-227ea was obtained after removal of butene (see Experimental).

Thus, reaction of HFP with in situ generated TBABF obtained from the decomposition of commercial TBAF·$3H_2O$ appears to be the most practical method for the synthesis of 2*H*-heptafluoropropane.

Conclusion

Of the various methods developed for the synthesis of 2*H*-heptafluoropropane, the one using anhydrous onium fluoride at high temperature holds considerable promise. The in situ generated and largely unsolvated hydrofluorination agent acts as an excellent equivalent to hydrogen fluoride. The reagent is highly reactive, easy to handle, noncorrosive, and permits the use of normal glass apparatus for storage of the agent and execution of the reaction.

Experimental

The volatile HFC-227ea generated can be safely stored in 1 and 2 L capacity tedlar bags procured from Supelco, USA. The analysis was effected either by bubbling the gas into a

© 2004 NRC Canada

NMR tube in deuterated solvent at low temperature or by gas phase injection after drawing the sample through the septum for MS. The NMR spectra were recorded on a Bruker Avance DPX 400 spectrometer in acetone-d_6 solution using TMS for ^{1}H NMR and $CFCl_3$ for ^{19}F NMR as internal references, respectively. Mass spectra were recorded on a TSQ 7000 mass spectrometer (Finnigan MAT, USA) as described earlier (8, 9).

Synthesis of HFC-227ea

TBAF method

Commercial tetrabutylammonium fluoride trihydrate ($TBAF{\cdot}3H_2O$) (20 g, 0.063 mol) was transferred into a round-bottomed flask and heated on a boiling water bath under vacuum (<0.1 mmHg, 1 mmHg = 133.322 4 Pa) for 6 h when a highly viscous liquid (anhyd. TBAF; about 13 mL) was obtained; 20 mL of dry DMF was then added to this oil. The resultant homogenous solution was heated up to 150 °C in a two-necked 100 mL round-bottomed flask containing a stirring bar and a dry nitrogen inlet for 45 min. The flask was connected to a condenser fitted with a $CaCl_2$ guard tube. The solution was then cooled to 130 °C and hexafluoropropene (5 g, 0.033 mol) from a tedlar bag was bubbled into the flask. At this stage, nitrogen flow was stopped and the guard tube was replaced by an evacuated and preweighed tedlar bag by connecting the end of its valve stem to a 3/16 in (1 in = 25.4 mm) i.d. tubing fitted to an adapter. To open the valve, the tubing was pushed onto the stem to the appropriate overlap distance. As soon as HFP was bubbled into the mixture, a highly exothermic reaction occurred and gaseous product (volatile HFC-227ea along with 1-butene) was collected in the tedlar bag (total 4.5 g) attached to the reaction system. To close the valve of the tedlar bag, the stem was pulled outward until it stopped. To disconnect the tubing, it was pulled upward or was cut off just above the stem as described in our earlier work (8, 9). The mixture of volatile products from the tedlar bag was passed into another round-bottomed flask containing a solution of bromine (3 g in 6 mL of chloroform) at 0 °C. Butene was completely consumed by bromine and pure gaseous HFC-227ea was collected in another tedlar bag (4.01 g, 70%).

Ylide method

Triphenylphosphine (12.6 g, 0.048 mol) was dissolved in 35 mL of dry DMF and placed in a dried three-necked 250 mL round-bottomed flask containing a stirring bar and a dry nitrogen inlet, at room temperature. The middle neck of the flask was connected to a condenser fitted with a $CaCl_2$ guard tube. Dibromodifluoromethane (10.08 g, 0.048 mol) was added in one installment to the well-stirred solution, when a mildly exothermic reaction occurred. After stirring the mixture for another 30 min, 2-iodoheptafluoropropane (7.1 g, 0.024 mol) was added at room temperature. Nitrogen flow was stopped and the guard tube at this stage was replaced by an evacuated and preweighed tedlar bag as described above. Zinc powder (3.14 g, 0.048 mol) was then slowly added to the reaction mixture through a solid addition tube when almost immediately a violent exothermic reaction occurred. Gaseous product could be seen evolving and HFC-227ea was collected in the tedlar bag (2.61 g, 64%).

Three validated stripping voltammetric procedures for determination of the anti-prostate cancer drug flutamide in tablets and human serum at a mercury electrode

E. Hammam, H.S. El-Desoky, K.Y. El-Baradie, and A.M. Beltagi

Abstract: Flutamide is a nonsteriodal anti-androgen drug, which is commonly used in the treatment of advanced prostate cancer. Based on the reduction of the nitro organic moiety of the drug molecule in acetate buffer of pH 5 at the hanging mercury drop electrode, three adsorptive cathodic stripping voltammetric procedures were optimized for determination of flutamide in bulk, tablets, and human serum applying linear-sweep, differential-pulse, and square-wave waveforms. The achieved limits of detection of the bulk drug were 1.9×10^{-7}, 8.7×10^{-8}, and 9.7×10^{-9} mol L^{-1} by using the optimized differential-pulse, linear-sweep, and square-wave adsorptive stripping voltammetric procedures, respectively. Repeatability of the results was studied for 1×10^{-6} mol L^{-1} of the drug and the recoveries obtained were 98.51 ± 1.56% (LSV), 98.89 ± 0.87% (DPV), and 99.21 ± 1.03% (SWV). The proposed procedures were successfully applied to the determination of the drug in pharmaceutical formulation (Eulexin® tablets) and human serum. The detection limits of the drug in bulk, pharmaceutical formulation, and human serum achieved by means of the proposed procedures showed that the square-wave mode was more reliable for determination of the drug especially in its low concentration levels.

Key words: flutamide, linear-sweep, differential-pulse, square-wave, cathodic adsorptive stripping voltammetry, determination, Eulexin® tablets, human serum.

Résumé : Le flutamide est un médicament antiandrogène non-stéroïdal qui est couramment utilisé dans le traitement du cancer avancé de la prostate. En se basant sur la réduction de la portion nitro de la molécule, dans un tampon acétate à un pH de 5, à une électrode à goutte de mercure pendante, on a optimisé trois méthodes voltampérométriques à redissolution cathodique absorbante pour la détermination du flutamide en vrac, dans des comprimés et dans le sérum humain en appliquant un des formes d'onde à balayage linéaire, à pulsation différentielle et en ondes carrées. Les limites de détection réalisées pour le médicament en vrac ont été de $1{,}9 \times 10^{-7}$, $8{,}7 \times 10^{-8}$ et $9{,}7 \times 10^{-9}$ mol L^{-1} pour les méthodes voltampérométriques à redissolution cathodique absorbante optimisées respectivement avec une pulsation différentielle (PD), un balayage linéaire (BL) et des ondes carrées (OC). On a étudié la répétabilité des résultats à l'aide d'une solution 1×10^{-6} mol L^{-1} du médicament et les degrés de récupération obtenus ont été de 98,51 ± 1,56 % (BL), 98,89 ± 0,87 % (PD) et 99,21 ± 1,03 % (OC). Les méthodes proposées ont été appliquées avec succès à la détermination de la quantité de médicament présente dans la formulation pharmaceutique (cachets d'Eulexin®) et dans le sérum humain. Les limites de détection du médicament en vrac, dans la formulation pharmaceutique et dans le sérum humain à l'aide des méthodes proposées ont montré que le mode des ondes carrées est le plus fiable pour la détermination du médicament, particulièrement aux concentrations les plus faibles.

Mots clés : flutamide, balayage linéaire, pulsation différentielle, onde carrée, voltampérométrie à redissolution cathodique absorbante, détermination, cachets d'Eulexin®, sérum humain.

Introduction

Flutamide (FM), 2-methyl-*N*-[4-nitro-3-(trifluoromethyl) phenyl] propanamide (Scheme 1), is a nonsteroidal anti-androgen drug that blocks androgen receptor sites. It is commonly used in the treatment of advanced prostate cancer (1–3). FM is reported to be rapidly and completely metabolized with the major metabolite 2-hydroxyflutamide, which also possesses active anti-androgenic properties.

The half-life of both FM and the major metabolite, 2-hydroxy flutamide, is about 5 to 6 h. Excretion is predominantly in urine with only minor amounts appearing in the

Scheme 1.

faeces (4). Analysis of flutamide in serum samples collected from 16 healthy volunteers following an oral administration of a 250 mg flutamide single dose provided the following pharmacokinetic data: C_{max} = 776–400 ng mL^{-1} (2.8 × 10^{-6} – 1.5 × 10^{-6} mol L^{-1}), T_{max} = 2.6–1.6 h, and elimination half-life k_{el} = 5.2–2.0 1/h (5, 6).

Many analytical methods were described in the literature for determination of FM in bulk form, pharmaceutical formulations, and human plasma. These methods include: spectrophotometry (7–12), high-performance liquid chromatography (HPLC) (5, 12–14), polarography (15), and differential-pulse polarography (12). No stripping voltammetric procedures for determination of flutamide have been reported in the literature yet.

We demonstrate here the electrochemical behavior of the FM drug at the hanging mercury drop electrode. Based on the reduction of the nitro group of the drug molecule, three stripping voltammetric procedures were optimized for determination of FM in bulk drug, pharmaceutical formulation (Eulexin® tablets), and human serum, using the linear-sweep, differential-pulse, and square-wave waveforms.

Experimental

Instrumentation

Electrochemical analyzer models 394 and 263A-PAR (Princeton Applied Research, Oak Ridge, Tenn., USA) were used for the voltammetric measurements. The electrode assembly model 303A-PAR incorporated with a dark micro-electrolysis cell of a three-electrode system comprised of a hanging mercury drop electrode (HMDE) as a working electrode (area = 0.026 cm^2), an Ag/AgCl (saturated KCl) reference electrode, and a platinum wire counter electrode was used. Stirring of the solution in the micro-electrolysis cell was performed using a magnetic stirrer (model 305-PAR) with a star-shaped magnet to provide the convective transport during the preconcentration step. The whole measurements were automated and controlled through the programming capacity of the apparatus. Recovery and quantification of the drug in different samples were performed by means of calibration curve and standard addition methods. The data were treated through a personal computer connected to the potentiostat and loaded with the Analytical voltammetry software (16).

The deionized water used throughout the present study was supplied from a Purite-Still Plus deionizer connected to a Hamilton-AquaMatic bidistillation water system.

A Mettler balance (Toledo-AB104, Greifensee, Switzerland) was used for weighing the solid materials. An Orion SA-720 pH meter incorporated with combined glass and saturated calomel electrodes was used for the pH measurements. A centrifuge (Eppendorf-5417 C, Hamburg, Germany) was used for separation of the precipitated proteins from human serum samples prior to assay of the drug. A micopipetter (Eppendorf-Multipette® plus) was used for transfer of the reactant solutions throughout the present experimental work. All data were obtained at room temperature.

Materials and reagents

Bulk flutamide drug was kindly supplied from the Egyptian International Pharmaceutical Industries Company (EIPICO). A standard stock solution of 1 × 10^{-3} mol L^{-1} flutamide was prepared in methanol (Merck) and stored in the dark at 4 °C. A more dilute solution of 1 × 10^{-5} mol L^{-1} FM was prepared daily in methanol just before use. Eulexin® tablets (Schering-Plough, Kenilworth, N.J., USA), labeled to contain 250 mg FM per tablet, were used for the present analytical application.

Britton-Robinson (B-R) buffers of pH 2–11 (17) and acetate buffers of pH 4–6 (18) were prepared then used as supporting electrolytes. All chemicals and reagents were of analytical grade.

Procedures

General analytical procedure

A 10 mL volume of the supporting electrolyte was introduced into a dark micro-electrolysis cell then deaerated with pure nitrogen for 10 min. A selected preconcentration potential was then applied to the hanging mercury drop electrode for a selected preconcentration time period, while the solution was stirred at 400 rpm. The stirring was then stopped, and after a 15 s rest period, the voltammogram was recorded by applying a negative-going scan. After the background voltammogram was recorded, an aliquot of the drug solution was introduced into the micro-electrolysis cell, deaerated again with pure nitrogen for 3 min, then the voltammogram was recorded at a new mercury drop.

Analysis of Eulexin® tablets

The drug content of five tablets was weighed, finely powdered, then mixed. The average mass per tablet was determined. A quantity of the homogenous powder equivalent to 250 mg FM was transferred accurately into a 100 mL volume calibrated flask contained 70 mL of methanol. The content of the flask was shaken for about 15 min and then made up to volume with methanol. The solution was then filtered through a 0.45 μm millipore filter (Gelman, Germany), to separate the insoluble excipients, rejecting the first portion of the filtrate. The desired concentration of the drug was obtained by accurate dilution with methanol and the analysis was followed up as indicated in the general analytical procedure.

Analysis of human serum samples

Serum samples, obtained from healthy volunteers, were collected and stored frozen until assay. Aliquots of human serum sample (each of 100 μL) were fortified with FM in a

© 2004 NRC Canada

small tube to achieve serum samples spiked with different concentrations of FM ($1 \times 10^{-8} - 1 \times 10^{-5}$ mol L^{-1}), then the volume of each sample was made up to 1 mL with methanol (as a protein precipitating agent). After vortexing each serum sample for 30 s, the precipitated proteins were separated by centrifugation for 3 min at 14 000 rpm. The clear supernatant layer was filtered through a 0.45 μm millipore filter to obtain protein-free human serum samples, which were used as standard solutions. Then the analysis was followed up as indicated in the general analytical procedure.

Results and discussion

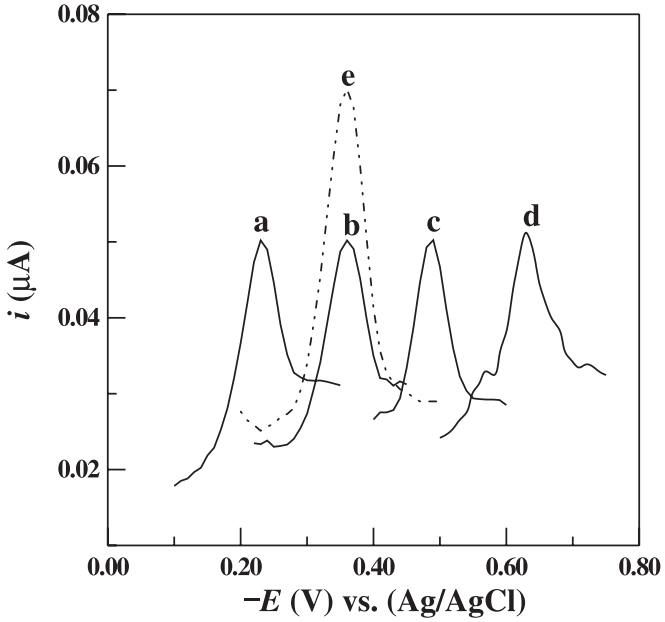
Effect of type and pH of the supporting electrolyte

The influence of pH on the linear-sweep voltammetric response of 1×10^{-6} mol L^{-1} FM was examined in B-R buffers (pH 2–11) and acetate buffers (pH 4–6) following preconcentration for 30 s at a scan rate of 100 mV s^{-1}. The voltammograms showed a single well-defined irreversible peak over the whole pH range of both B-R and acetate buffers. This peak may be attributed to the reduction of the aromatic nitro group of the drug molecule to the amine stage via the consumption of six electrons. The peak potential shifted to more negative values on the increase of pH of the medium, denoting the involvement of H^+ ions in the electrode reaction process and that the proton-transfer reaction precedes the electrode process proper (19). As shown in Fig. 1, the linear-sweep voltammogram of the drug in the acetate buffer of pH 5 at the HMDE showed a single cathodic peak (E_p = – 0.37 V) with a more developed peak current intensity compared to that obtained in a B-R buffer of the same pH value. Therefore, the acetate buffer of pH 5 was chosen as a supporting electrolyte in the rest of the present work.

Cyclic voltammetry

The interfacial adsorptive character of FM onto the HMDE was studied by means of cyclic voltammetry in an acetate buffer of pH 5. A single well-defined irreversible cathodic peak was obtained (E_p = –0.41 V vs. $Ag/AgCl/KCl_s$). Figure 2 shows the cyclic voltammograms of 1×10^{-5} mol L^{-1} bulk FM recorded in the acetate buffer of pH 5 without preconcentration of the drug, t_{acc} = 0 s (dashed curve), after preconcentration onto the HMDE for 30 s (curve 1), and then its repetitive cycle at the same mercury drop (curve 2). A more developed peak current intensity was achieved following preconcentration of the bulk drug onto the electrode surface, whereas the repetitive cycle at the same mercury drop exhibited a lower peak current intensity, which may be attributed to the desorption of drug species out of the mercury electrode surface. This behavior indicated the interfacial adsorptive accumulation of the drug onto the mercury electrode surface. The cycles carried out for increased values of the scan rate (ν) gave rise to a cathodic peak with current intensities that showed a linear increase with the scan rate between 20–200 mV s^{-1}, following the relation: $\log i_{pc} = 0.84 \log \nu - 1.85$ (r = 0.996 and n = 8). Its slope value (0.84) was close to that expected for an ideal reaction of surface species (20).

Fig. 1. Linear-sweep adsorptive cathodic stripping voltammograms of 1×10^{-6} mol L^{-1} FM recorded in B-R buffers of different pH values: (*a*) 3, (*b*) 5, (*c*) 7, (*d*) 9, and (*e*) in an acetate buffer of pH 5. Scan rate = 100 mV s^{-1} and t_{acc} = 30 s.



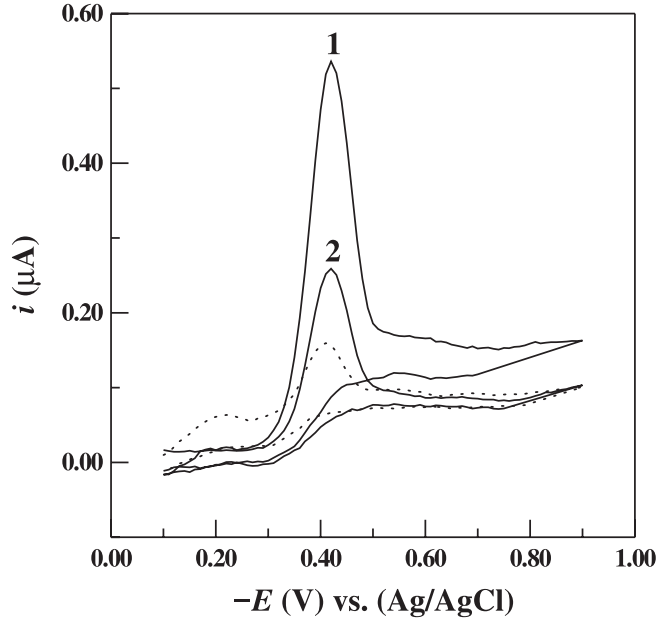


Fig. 2. Cyclic voltammograms of 1×10^{-5} mol L^{-1} FM in an acetate buffer of pH 5: without preconcentration (t_{acc}= 0 s, dashed curve), following preconcentration for 30 s (curve 1), and then its repetitive cycle at the same mercury drop (curve 2). Scan rate ν = 100 mV s^{-1} and E_{acc} = –0.10 V.

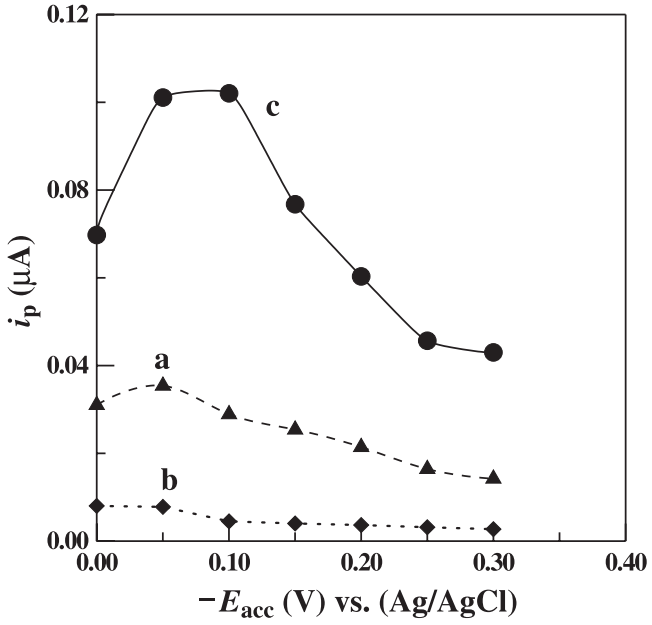
For a totally irreversible electrode reaction, the relationship between the peak potential (E_p) and scan rate (ν) was expressed as (21):

$$E_p = (2.303RT/\alpha n_a F) \log(RTk_f^0/\alpha n_a F) - (2.303RT/\alpha n_a F) \log \nu$$

© 2004 NRC Canada

Fig. 3. Effect of preconcentration potential (E_{acc}) on the adsorptive cathodic stripping peak current (i_p) of 1×10^{-6} mol L^{-1} FM in an acetate buffer of pH 5 using different waveforms: (*a*) linear-sweep (ν = 10 mV s^{-1} and E_{dp} = 25 mV), (*b*) differential-pulse (ν = 10 mV s^{-1} and E_{dp} = 25 mV), and (*c*) square-wave (f = 60 Hz, Δs = 10 mV, and E_{sw} = 25 mV). t_{acc} = 30 s.



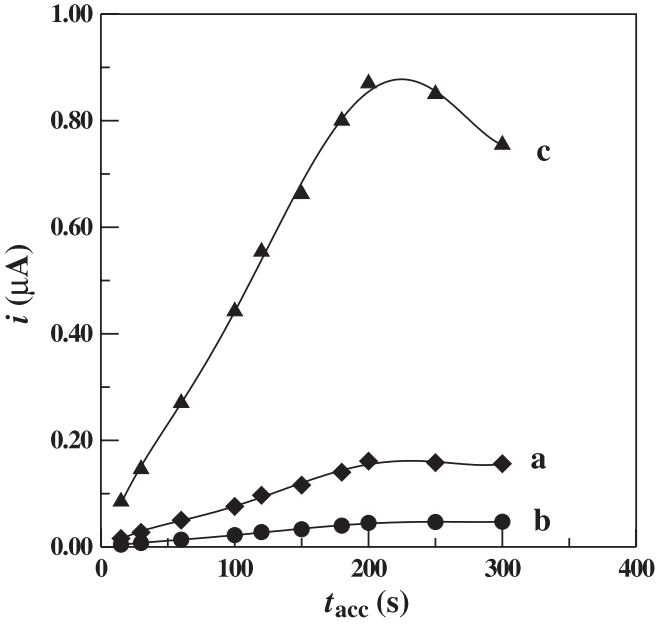


Fig. 4. Effect of preconcentration time (t_{acc}) on the adsorptive cathodic stripping peak current (i_p) of 1×10^{-6} mol L^{-1} FM in an acetate buffer of pH 5 using different waveforms: (*a*) linear-sweep, (*b*) differential-pulse, and (*c*) square-wave. Other operational parameters are as those given in Fig. 3.

The dependence of the peak potential (E_p) of bulk FM on the decimal logarithm of the scan rate (ν) was linear, following the relationship:

$$E_p \text{ (V)} = 0.058 \log \nu - 0.416$$

From its slope, a value of αn_a = 1.02 was obtained. Accordingly, the number of electrons (n_a) transferred in the rate-determining step should be two (n_a = 2). Hence, the estimated value of the transfer coefficient (α) was 0.51.

Optimization of the electroanalytical procedures

Linear-sweep voltammetry procedure

The linear-sweep adsorptive cathodic stripping (LSAdCS) voltammograms of the drug in an acetate buffer (pH 5) at the HMDE showed a single cathodic peak (E_p = – 0.37 V). The effect of scan rate (ν) on the linear-sweep peak current of 1×10^{-6} mol L^{-1} FM was studied within the range 25–200 mV s^{-1}. Although the peak current intensity increased with an increase of scan rate, the peak morphology was sharper at a scan rate of 100 mV s^{-1}. The effect of preconcentration potential on the linear-sweep peak current was also studied over the potential range 0.0 to –0.30 V (vs. Ag/AgCl/KCl_s). As shown in Fig. 3, a higher peak current intensity was achieved at a preconcentration potential of –0.05 V (curve a). The effect of the preconcentration time on the peak current of 1×10^{-6} mol L^{-1} FM in the acetate buffer of pH 5 (E_{acc} = –0.05 V) was studied and a linear relation up to 200 s preconcentration time was obtained. At longer preconcentration time, saturation of the mercury surface was achieved (Fig. 4, curve a). Therefore, the optimal conditions used throughout the rest of the present linear-sweep measurements were: scan rate (ν) = 100 mV s^{-1}, pulse amplitude (E_{ls}) = 25 mV, preconcentration potential (E_{acc}) = –0.05 V, and preconcentration time = 60–150 s.

Differential-pulse voltammetry procedure

The differential-pulse adsorptive cathodic stripping (DPAdCS) voltammogram of bulk FM in an acetate buffer of pH 5 showed a single cathodic stripping peak (E_p = –0.4 V). The effect of scan rate showed a gradual increase of the differential-pulse peak current intensity within the range 2–20 mV s^{-1}. A scan rate of 10 mV s^{-1} was chosen where a sharper peak was obtained. As 25 mV pulse-height gave rise to the best peak morphology; it was chosen for the further investigations. Figure 3 (curve b) shows the effect of the preconcentration potential on the peak current of 1×10^{-6} mol L^{-1} bulk FM (t_{acc} = 30 s) over the potential range 0.0 to –0.3 V. There was almost no change in the peak current over the potential range 0.0 to –0.05 V. Therefore, a preconcentration potential (E_{acc}) of –0.05 V (vs. Ag/AgCl/KCl_s) was considered throughout the present differential-pulse measurements. Figure 4 (curve b) shows the plot of the peak current of 1×10^{-6} mol L^{-1} bulk FM vs. preconcentration time (t_{acc}) in the acetate buffer of pH 5. A straight line was obtained and the magnitude of the peak current increased with an increase of preconcentration time. Saturation of the mercury surface with the drug was achieved after preconcentration for about 200 s. Therefore, the optimal conditions used throughout the rest of the present differential-pulse measurements were: scan rate (ν) = 10 mV s^{-1}, pulse amplitude (E_{dp}) = 25 mV, preconcentration potential (E_{acc}) = –0.05 V, and preconcentration time (t_{acc}) = 60–150 s.

[a]Average of three determinations.

buffer of pH 5 gave rise to a single well-defined cathodic peak (E_p = –0.56 V). The optimum instrumental conditions (such as frequency f, scan increment Δs, and pulse-amplitude E_{sw}) were achieved from study of the variation of the peak current of 5×10^{-7} mol L^{-1} FM in the acetate buffer of pH 5, following preconcentration for 30 s. At a scan increment of 10 mV and a pulse amplitude of 25 mV, the peak current increased gradually with an increase in frequency up to 60 Hz. At a frequency higher than 60 Hz, a peak with poorer resolution was obtained. At a frequency of 60 Hz and 25 mV pulse amplitude, the peak current increased linearly with the scan increment up to 10 mV. At f = 60 Hz and Δs = 10 mV, although the peak current increased linearly with the increase of the pulse amplitude from 25 to 100 mV, peak distortion resulted in a poorer resolution observed over 25 mV. Thus, a pulse amplitude of 25 mV was applied in the rest of the study, as it was better for analytical purposes.

The effect of varying the preconcentration potential (E_{acc}) over the range 0.0 to –0.3 V on the peak current intensity of the square-wave adsorptive cathodic stripping voltammogram of 1×10^{-6} mol L^{-1} FM in an acetate buffer of pH 5 following preconcentration for 30 s was also evaluated under the optimized conditions (Fig. 3, curve c). A more developed peak current intensity was achieved over the potential range –0.05 to –0.10 V (f = 60 Hz, Δs = 10 mV, and E_{sw} = 25 mV). The observed gradual decrease in the peak current intensity may be attributed to the consequence of desorption of the drug at more higher or lower potential values than the zero charge potential, where a maximum adsorption of uncharged organic molecules can be expected. Hence, a preconcentration potential of –0.10 V was applied throughout the present analytical study. On the other hand, a linear relationship between peak current (i_p) intensity and preconcentration time up to 200 s was obtained (Fig. 4, curve c). Therefore, the optimal experimental conditions of the present proposed square-wave adsorptive cathodic stripping voltammetry procedure were: frequency (f) = 60 Hz, scan increment (Δs) = 10 mV, pulse amplitude (E_{sw}) = 25 mV, preconcentration potential (E_{acc}) = –0.10 V, and preconcentration time (t_{acc}) = 60–150 s.

The ability to readily assay nanomolar concentrations was attributed not only to both the effective preconcentration potential and time, but also to the improved sensitivity of the applied voltammetric waveform for monitoring of the preconcentrated drug. Figure 5 shows the adsorptive cathodic stripping (AdCS) voltammograms recorded for 1×10^{-6} mol L^{-1} FM in an acetate buffer of pH 5 following preconcentration for 60 s using three different waveforms: (*a*) linear-sweep (LS), (*b*) differential-pulse (DP), and (*c*) square-wave (SW). The signal intensity obtained by means of the proposed SWAdCS voltammetric procedure was found to be 20 and 5 times higher than those obtained by means of the proposed LSAdCS and DPAdCS voltammetric procedures, respectively.

Fig. 5. Adsorptive cathodic stripping voltammograms of 1×10^{-6} mol L^{-1} FM drug recorded in an acetate buffer of pH 5 following preconcentration for 30 s using different voltammetric waveforms: (*a*) linear-sweep (ν = 100 mV s^{-1} and E_{acc} = –0.05 V), (*b*) differential-pulse (ν = 10 mV s^{-1}, E_{dp} = 25 mV, and E_{acc} = –0.05 V), and (*c*) square-wave (f = 60 Hz, Δs = 10 mV, E_{sw} = 25 mV, and E_{acc} = –0.10 V).

The calibration curves within the concentration levels of 10^{-8} and 10^{-5} mol L^{-1} FM were attempted following different preconcentration time periods. The regression equations associated with the calibration plots exhibited a good linearity (r = 0.995–0.998) that supported the validation of the proposed procedures (Table 1). Limits of detection (LOD) and quantitation (LOQ) were calculated using the relation

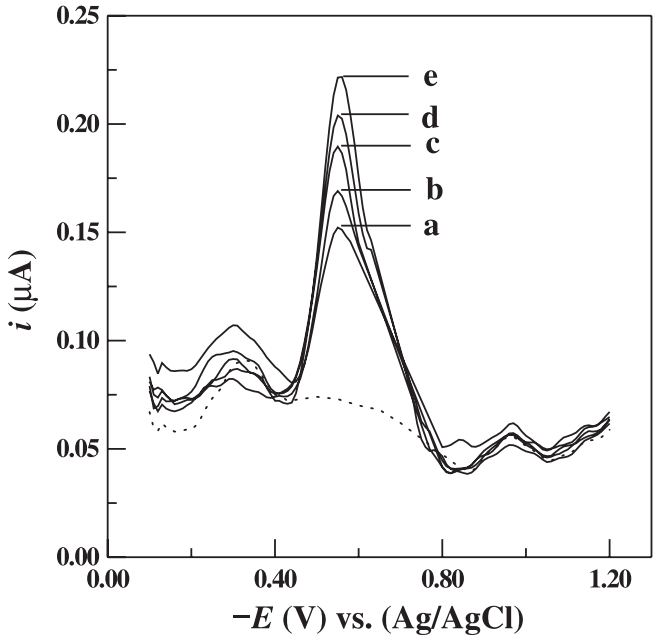
kSD_a/b (22), where $k = 3$ for LOD and 10 for LOQ, SD_a is the standard deviation of the intercept, and *b* is the slope of the calibration curve. LOD and LOQ values, shown in Table 1, confirmed the sensitivity of the proposed procedures compared with those obtained by means of the reported polarographic methods (12, 15).

Validation of the present proposed procedures for the quantitative assay of FM was examined via repeatability, recovery, selectivity, robustness, and ruggedness (22). The obtained results confirmed the reliability of the proposed procedures for the trace quantitation of FM.

Application



Analysis of Eulexin® tablets

The three proposed stripping voltammetric procedures were successfully applied to the determination of the FM drug in tablets (Eulexin®, 250 mg FM per tablet) following preconcentration onto the HMDE for 60 s, without the necessity for sample pretreatment or time-consuming extraction steps prior to analysis of the drug. The mean recoveries of FM, based on the average of five replicate measurements using both the calibration curve and the standard addition (23) methods, are reported and statistically compared with those obtained by a reported HPLC method (13) in Table 2. Values of *F*-calculated, *F*-theoretical, *t*-calculated and *t*-theoretical are also included in Table 2. Since the calculated value of *F* did not exceed the theoretical value, there was no significant difference between the proposed and reported methods with respect to reproducibility. Also, no significant difference was noticed between the proposed and reported methods regarding accuracy and precision as revealed by the *t* value (24).

Analysis of human serum

Voltammograms of different concentrations of the drug spiked in human serum were recorded using the three proposed voltammetric procedures. Figure 6 illustrates the

Fig. 6. SWAdCS voltammograms of different concentrations of FM spiked in human serum in an acetate buffer of pH 5: (*a*) 2×10^{-7}, (*b*) 4×10^{-7}, (*c*) 6×10^{-7}, (*d*) 8×10^{-7}, and (*e*) 1×10^{-6} mol L^{-1} FM. The dotted curve represents the blank solution. $E_{acc} = -0.10$ V and $t_{acc} = 150$ s. Other operational parameters are as those given in Fig. 3.

SWAdCS voltammograms of successive additions of spiked human serum following preconcentration onto the HMDE for 150 s. The variations of the peak current vs. the drug concentrations applying the three proposed voltammetric procedures were represented by straight lines, their characteristics are reported in Table 3. Mean recoveries of the drug in human serum, based on the average of five replicate measurements of 96.51 ± 3.67%, 95.57 ± 2.88%, and 98.24 ±

© 2004 NRC Canada

1.54% were achieved using LSAdCS, RPAdCS, and SWAdCS voltammetric procedures, respectively. The LOD and LOQ of the drug in spiked human serum samples using the three proposed voltammetric procedures were calculated (Table 3). Although, the achieved LOD and LOQ of the drug using the three proposed stripping voltammetric procedures were low enough to allow determination of the FM drug in serum samples of a volunteer who administrated an oral 250 mg FM single dose, the square-wave adsorptive cathodic stripping voltammetric procedure was preferred due to its high sensitivity and precision; also, it is the faster procedure compared with both DPAdCS and LSAdCS voltammetric procedures.

Conclusion

Linear-sweep, differential-pulse, and square-wave adsorptive cathodic stripping voltammetric procedures were optimized for the determination of the FM drug based on the reduction of its nitro aromatic moiety and its strong adsorptive character onto the mercury electrode surface. The three optimized procedures were successfully applied for determination of the drug in bulk, pharmaceutical formulation, and human serum. The results showed that the SWAdCS voltammetric procedure was more sensitive and precise compared with LSAdCS and DPAdCS voltammetric procedures. The three proposed procedures were simple, sensitive, fast, and selective. Unlike most of the reported methods, the optimized procedures for assay of flutamide did not require sample pretreatment or time-consuming extraction steps prior to assay of the drug.

Multi-armed, TEMPO-functionalized unimolecular initiators for starburst dendrimer synthesis via stable free radical polymerization. 1. Tri azo-functionalized unimer

Dalia Abdallah, Mohmad Asri Abd Ghani, Michael F. Cunningham, Peter M. Kazmaier, Barkev Keoshkerian, and Erwin Buncel

Abstract: The synthesis of azobenzene-functionalized multi-armed unimolecular initiators or "*unimers*" that can be polymerized using styrene or styrenic derivatives via TEMPO (2,2,6,6-tetramethylpiperidenyl-1-oxyl) mediated stable free radical polymerization (SFRP) is described. The unimers are composed of an azobenzene-functionalized core and a TEMPO-modified unit. Homopolymers and copolymers of styrene and acetoxystyrene were synthesized using the mono-and trifunctionalized unimers as initiators under bulk conditions with average molecular weights and polydispersities reported. The studies lay the groundwork for further investigations involving SFRP towards building a light harvesting system by introducing chromophores onto the polymer chains for capturing light and thence transferring it to the azobenzene core.

Key words: azo-functionalized unimolecular initiator, stable free radical polymerization, starburst dendrimer.

Résumé : On décrit la synthèse d'initiateurs unimoléculaires tentaculaires à base d'azobenzènes, dénommés unimères, qui peuvent être polymérisés à l'aide de styrène ou de ses dérivés par le biais d'une polymérisation avec un radical libre stable catalysée par le 2,2,6,6-tétraméthylpipéridinyl-1-oxyle (TEMPO). Les unimères sont formés d'un noyau azobenzène fonctionnalisé et d'une unité TEMPO modifiée. On a synthétisé des homopolymères et des copolymères du styrène et de l'acétoxystyrène en utilisant des unimères mono- et trifonctionnalisés comme initiateurs, dans des conditions globales, et on rapporte des poids moléculaires et des polydispersités moyennes. Les études posent les fondements pour des études ultérieures, impliquant des polymérisations avec un radical libre stable, dans l'élaboration d'un système permettant de recueillir la lumière en introduisant sur les chaînes de polymère des chromophores qui pourraient capter la lumière et par la suite la transmettre au noyau azobenzène.

Mots clés : initiateur unimoléculaire à base d'azobenzène fonctionnalisé, polymérisation avec un radical libre stable, dendrimère en « éclatement d'étoile ».

Introduction

The synthesis of macromolecules with "complex" and controlled architecture is becoming increasingly important in the field of polymer chemistry (1). There are two categories of complexity that one can introduce: functional complexity and architectural complexity. Azo moieties are an example of functional complexity since they can operate as optical transducers, i.e., through light absorption, energy transfer, and cis/trans isomerism. The second category, architectural complexity, can be achieved by introducing branches into the polymer backbone, which leads to the formation of graft or star polymer systems. In our study, we would like to couple these two categories of complexity in a single system to enable the investigation of the unique properties of this system.

Traditional methods of synthesizing well-defined macromolecular architectures involve *living* polymerization techniques such as anionic (2), cationic (3), group transfer polymerization (4), and transition-metal catalysis (5). However, as a result of work over the past decade living free radical polymerization is now possible where there is control over the molecular weight, the end group, and the ability to synthesize block copolymers.

Georges et al. (6) were the first to report the synthesis of low polydispersity polystyrene using free radical polymer-

ization, based on use of the stable nitroxide radical 2,2,6,6-tatramethylpiperdinyloxy (TEMPO) in combination with benzoyl peroxide (BPO) as a *bimolecular* initiating system. The TEMPO unit acts as a "capping" agent for the growing polymer chain and controls the polymerization (7). The use of stable nitroxides to control free radical polymerization was originally stimulated by the work of Moad and Rizzardo (8) who employed TEMPO to reversibly terminate a growing polymer chain.

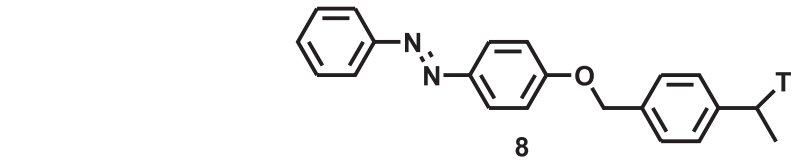
During the past decade much work has been done on designing and synthesizing functionalized *unimolecular* initiators that contain the TEMPO unit. Some examples of unimolecular initiators synthesized by Hawker and coworkers (9, 10) are shown below. Compounds **1**, **2**, **3**, and **4** are *monofunctionalized* unimolecular initiators that form linear polymers upon polymerization, while compound **5** is a *trifunctionalized* unimolecular initiator that forms a star polymer upon polymerization, where T stands for the TEMPO moiety.

The work described in this paper focuses on the synthesis of *multiazofunctionalized* azo unimolecular initiators, which we call "unimers", for stable free radical polymerization (SFRP). The structures of the unimers are shown below, where **6** and **7** are used in the synthesis of **8**, **9**, and **10**, i.e., monoazofunctionalized, diazofunctionalized, and triazofunctionalized unimers, respectively. The mono- and trifunctionalized unimers were used in the polymerization of styrene and acetoxystyrene to form homopolymers, block copolymers, and random copolymers, where we report the average molecular weights and polydispersities based on GPC analysis.

We are specifically interested in azobenzene-modified polymers to study and compare cis/trans isomerization of the azobenzene units of the mono-, di-, and trifunctionalized polymers upon irradiation. It is anticipated that cis/trans isomerism of the azo core should have a profound effect on the overall tertiary structure of the molecules.

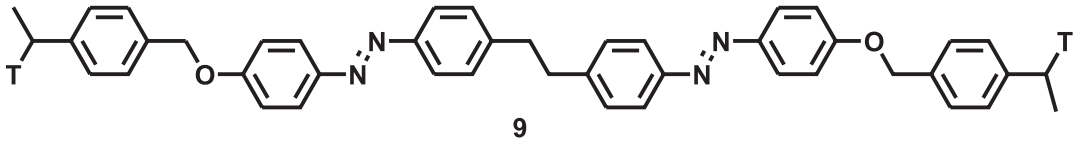
The present work continues our studies with azo, azoxy, and hydrazo arenes, encompassing various structure reactivity studies, such as rearrangements (Wallach, benzidine), spiropyran-merocyanine interconversion systems, and periphery-modified dendrimers, with applications in optical data storage, holography and drug delivery, as well as light harvesting properties (11).

Results and discussion



Our strategy is to develop the chemistry on a monoazofunctionalized unimer **8** and then extend this chemistry to the more complex difunctionalized **9** and trifunctionalized **GEN 0** unimer systems.

Monoazofunctionalized unimolecular initiator 8



The monoazofunctionalized unimer **8** is composed of two parts, the core, *p*-hydroxyazobenzene **14** and the TEMPO-containing unit, TEMPO modified 4-ethylbenzyl iodide **7**. Scheme 1 shows the preparation of TEMPO-modified 4-ethylbenzyl iodide **7** starting from commercially available 4-ethylbenzaldehyde **11**.

To introduce a TEMPO unit and form the TEMPO-modified derivative of compound **13**, a carbon-centered radical must be generated in the presence of TEMPO. Hawker et al. (9) used di-*tert*-butyl peroxide to generate the carbon-

7

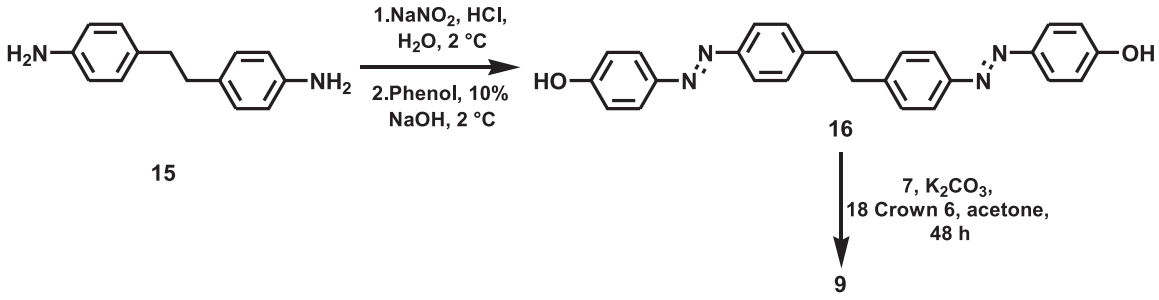
centered radicals at ca. 125 °C. We used di-*tert*-butyl peroxyoxalate instead since it undergoes facile decomposition in solvents such as benzene below 50 °C to give *tert*-butoxy radicals.

Coupling of the azobenzene core with the TEMPO-containing unit was first attempted using the bromo derivative **6** with poor yield (9%) (12). To optimize the yield, the iodo derivative **7** was synthesized using the Finkelstein reaction.

The monofunctionalized azobenzene unimer was synthesized as shown in Scheme 1 in 75% yield (16). The proton NMR spectrum confirms that the azobenzene core became attached to the TEMPO-containing unit. The aromatic protons on the azobenzene unit appear at 7 to 8 ppm and the TEMPO unit protons at 0.5–0.6 ppm.

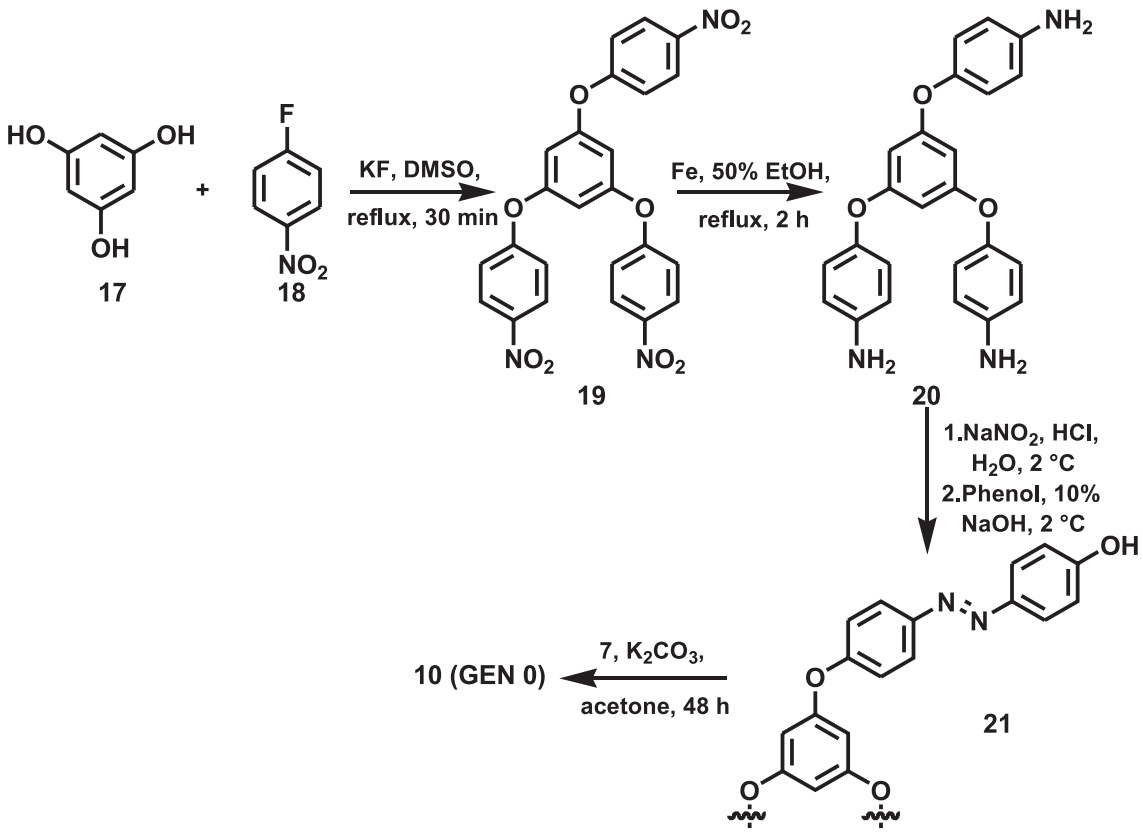
Diazofunctionalized unimolecular initiator 9

The difunctionalized azobenzene unimer **9** is composed of a core containing two azobenzene units and two TEMPO-modified units attached to the ends of the core. The synthesis of **9** was accomplished in 62% yield as shown in Scheme 2.



Coupling of the TEMPO units onto bis(4-aminophenyl)-1,2-ethane **16** to form the difunctionalized azobenzene-modified unimer was effected by reaction with **7** (Scheme 1) (18% yield).

Triazofunctionalized unimolecular initiator 10, GEN 0



The trifunctionalized unimer is the zeroth generation of a dendrimer, i.e., **GEN 0**, a star-shaped unimer composed of a

Scheme 2.

Scheme 3.

core with three azobenzene units and three TEMPO-modified units attached to the ends of the core.

The preparation of **GEN 0** (Scheme 3) involved first the synthesis of the core **21** in three steps:

(1) Nucleophilic aromatic substitution yielded **19**.

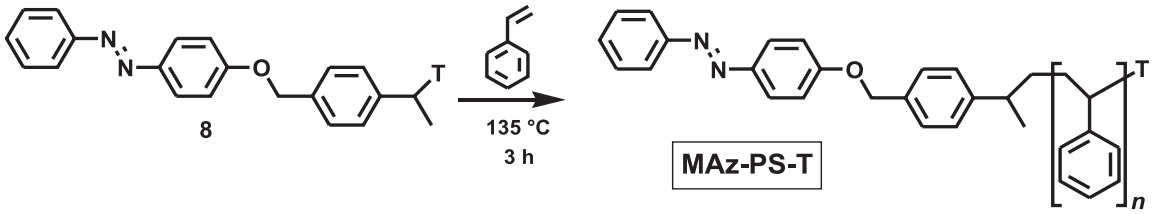
(2) Reduction of **19** gave **20** in 94% yield.

(3) Diazotization and coupling gave **21** in 73% yield.

Introduction of the TEMPO units to form **GEN 0** was effected by Williamson ether coupling between the azobenzene core and the TEMPO-modified 4-ethylbenzyl iodide **7** (Scheme 1) in 22% yield (12). **Gen 0** is readily soluble in halogenated solvents such as dichloromethane or chloroform, and can be distinguished from the starting compound **21**, which dissolves only in acetone or DMSO. ^{1}H NMR shows the TEMPO moiety between 0.7 and 1.7 ppm and the aromatic protons between 7 and 8 ppm.

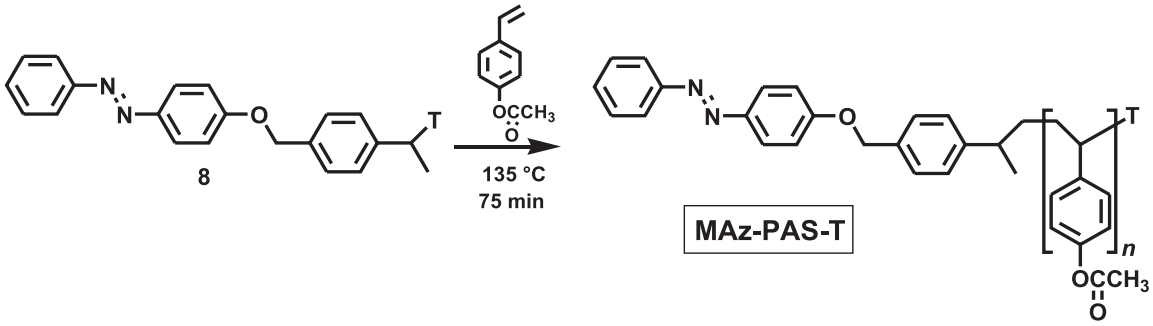
Controlled free radical polymerizations

We now describe polymerization studies that have been performed towards synthesis of polymers having an azobenzene unit at the core. The studies entailed the mono- and trifunctionalized azobenzene unimers that were used in the polymerization of styrene and acetoxystyrene, to give homopolymers, block and random copolymers.



Controlled free radical polymerization of monoazo-functionalized unimer

Monoazo-functionalized polystyrene ***MAz-PS-T***



Polymerization of styrene with monofunctionalized azobenzene unimer **8** was effected under bulk conditions (Scheme 4) at 135 °C. The polymerization was stopped after 2 h by cooling to room temperature. The polymer **MAz-PS-T** was dissolved in THF and precipitated from methanol to give a yellow powder (26%) with an average molecular weight of 13 500 g/mol and a narrow polydispersity of 1.26

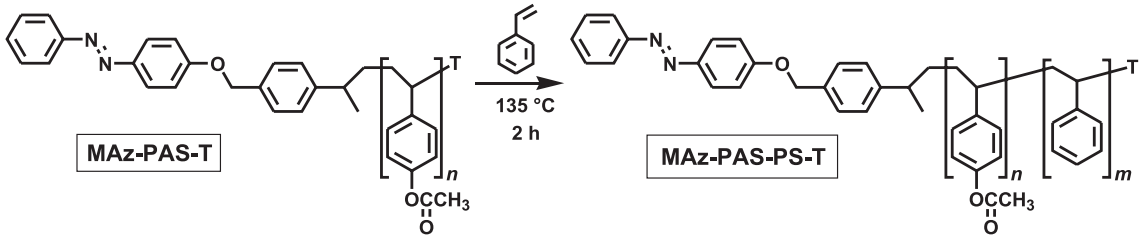


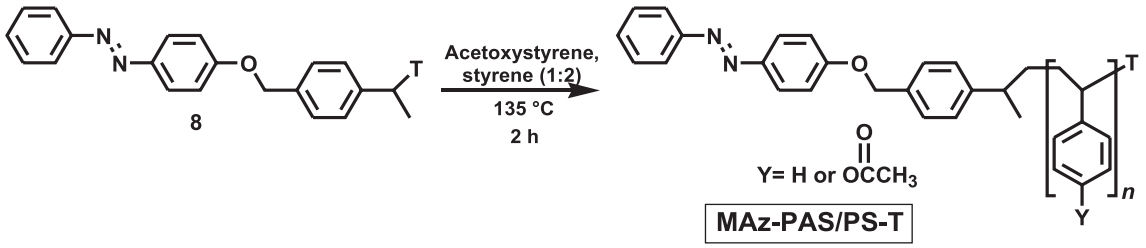
Scheme 4.

Scheme 5.

Scheme 6.

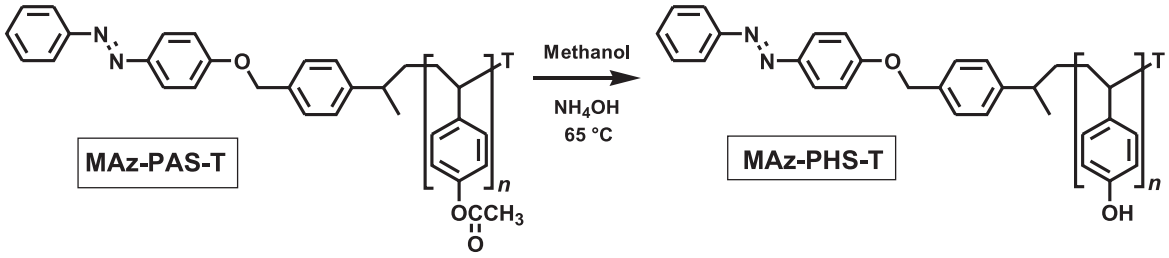
based on GPC analysis. The ^{1}H NMR shows broad peaks at 1.4 and 1.8 ppm representing the aliphatic hydrogens of the polystyrene, the methylene and methine protons, respectively. Aromatic hydrogens of polystyrene appear as broad peaks between 6.4 and 7.2 ppm. The ^{13}C NMR shows a peak at 145.6 ppm for the quaternary carbon of the aromatic moiety of polystyrene while the other carbons of the aromatic moiety appear at 128.4, 128.1, and 126.1 ppm. Aliphatic carbons appear at 44.3 and 40.7 ppm. The UV–vis absorption spectrum of **MAz-PS-T** in THF showed distinct π–π* and *n*–π* absorption bands of azobenzene appearing at ca. 350 and 450 nm, respectively, confirming that the polymer sample contains the azobenzene unit.

*Monoazofunctionalized polyacetoxystyrene **MAz-PAS-T***



The polymerization of acetoxystyrene with **8** was effected under the same conditions as for **MAz-PS-T**, in bulk, under nitrogen and heating at 135 °C as illustrated in Scheme 5. The polymerization was stopped after 75 min at which point the mixture became too viscous for stirring. A yellow powder (**MAz-PAS-T**) with an average molecular weight of 35 300 g/mol and a polydispersity of 1.34 formed upon dissolving the reaction mixture in THF and precipitating from methanol (49%). The ^{1}H NMR shows two broad peaks between 1.2 and 2.0 ppm representing the aliphatic protons of polyacetoxystyrene and a broad peak between 6.2 and 6.9 ppm for the aromatic protons of polyacetoxystyrene. The methyl protons of the acetoxy group appear as a singlet at 2.3 ppm. The ^{13}C NMR shows a peak at 169.5 ppm representing the carbonyl carbon of the acetate group. Peaks at 149.1 and 142.6 ppm represent the quaternary carbons of the aromatic moiety of the polyacetoxystyrene while peaks at 128.8, 127.6, 122.0, and 121.5 represent the rest of the aromatic carbons. Aliphatic carbons of polyacetoxystyrene appear at 44.1 and 40.5 ppm representing the methylene and methine protons, respectively. The methyl carbon of the acetate group appears at 21.6 ppm.

*Monoazofunctionalized block (acetoxystyrene–styrene) copolymer **MAz-PAS-PS-T***



Chain extension of **MAz-PAS-T** with styrene under bulk conditions yielded **MAz-PAS-PS-T**, a block copolymer of acetoxystyrene and styrene, as illustrated in Scheme 6. The polymerization was stopped after 2 h and the reaction mixture was dissolved in THF and precipitated from methanol to give an off-white – yellow powder with an average molecular weight of 40 400 g/mol and 1.54 polydispersity. The ^{1}H NMR shows the aliphatic protons of the polymer chain between 1.2 and 2.2 ppm and the aromatic protons between 6.2 and 7.5 ppm. The methyl protons of the acetate group appear as a singlet at 2.3 ppm. The ^{13}C NMR shows the carbonyl carbon of the acetate group at 169.5 ppm, the quaternary aromatic carbons of the polyacetoxystyrene at 149.1 and 142.6 ppm and the quaternary aromatic carbon of polysty-

© 2004 NRC Canada

Scheme 7.

Scheme 8.

rene at 145.7 ppm. The rest of the aromatic carbons of the polymer chain appear at 128.4, 128.1, 126.0, and 121.5 ppm. The aliphatic carbons appear at 46.2, 44.0, 43.2, and 40.8 ppm. The methyl carbon of the acetoxy group appears at 21.6 ppm consistent with the block copolymer structure.

*Monoazofunctionalized random (acetoxystyrene–styrene) copolymer **MAz-PAS/PS-T***

Contrasting with the design for block copolymer **MAz-PAS-PS-T**, where the strategy is to begin with polymer **MAz-PAS-T** and under SFRP react that with acetoxystyrene, the second monomer was reacted simultaneously to give a random copolymer.

Thus, polymerization of acetoxystyrene, styrene (1:2 volume ratio), and monofunctionalized azobenzene unimer **8** under bulk conditions yielded the random copolymer **MAz-PAS/PS-T** as shown in Scheme 7. The polymer was dissolved in THF and precipitated from methanol, filtered and dried to give a yellow solid with an average molecular weight of 16 400 g/mol and a polydispersity of 1.24.

*Monoazofunctionalized poly(4-hydroxystyrene) **MAz-PHS-T***

The hydrolysis of **MAz-PAS-T** was effected by adding ammonium hydroxide to a solution of **MAz-PAS-T** in methanol under reflux conditions as shown in Scheme 8. The polymer was precipitated from water, filtered and dried to give yellow crystals in 40% yield. The absence of a ^{13}C carbonyl peak at 165.9 ppm confirms that the hydrolysis is complete. The aromatic quaternary carbon attached directly to the hydroxy group appears at 155.3 ppm while the other aromatic quaternary carbon appears at 137.0 ppm. The other aromatic carbons of the polymer chain appear at 128.8 and 115.1 ppm. Aliphatic carbons of the polymer chain appear between 28.6 and 39.7 ppm.

Controlled free radical polymerization of a triazo-functionalized unimer

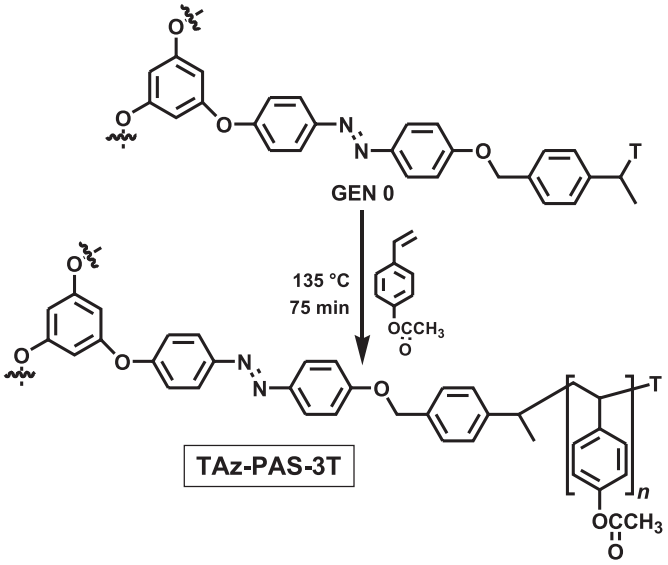
*Polyacetoxystyrene starburst azo dendrimer **TAz-PAS-3T***

Polymerization of acetoxystyrene with triazofunctionalized unimer **GEN 0** was done under bulk conditions by heating the reaction mixture at 135 °C as illustrated in Scheme 9. The polymerization was stopped after 75 min. The polymer was dissolved in THF and precipitated from methanol, filtered and dried to give a yellow powder (**TAz-PAS-3T**) a star polymer, with an average molecular weight of 74 400 g/mol and a polydispersity of 1.49 based on light scattering detector analysis.

*Starburst block (acetoxystyrene–styrene) azo dendrimer **TAz-PAS-PS-3T***

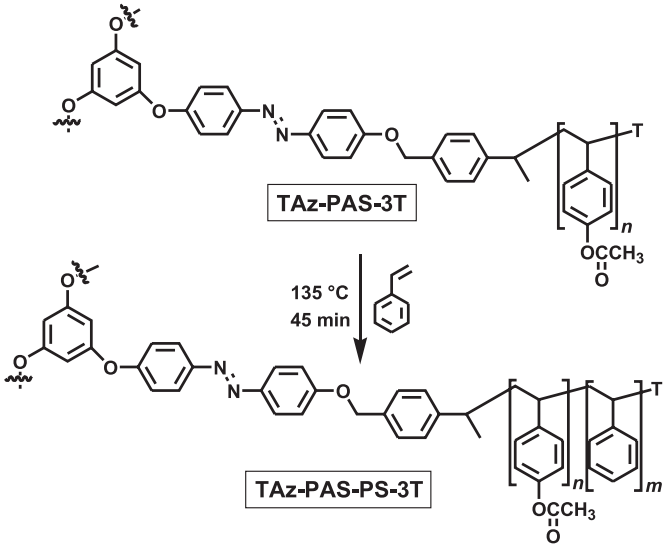
The block copolymer **TAz-PAS-PS-3T** was synthesized by polymerizing **TAz-PAS-3T** with styrene under bulk conditions at 135 °C, as shown in Scheme 10. The polymerization was stopped after 45 min and the reaction mixture was dissolved in THF and precipitated from methanol, filtered and dried to give an off-white – yellow solid with an average molecular weight of 126 000 g/mol and a polydispersity of 1.64 based on light scattering detector analysis.

Conclusions



In conclusion, it has been shown in this work that functionally and architecturally dendritic structures with azo cores can be synthesized using controlled radical polymerization.

The synthesis of mono-, di-, and triazofunctionalized unimers was accomplished by coupling of the azobenzene cores, **14**, **16**, and **21**, with TEMPO-modified 4-ethylbenzene **7**. A combination of ^{1}H and ^{13}C NMR and mass spectra was used for full characterization of the unimers.



The mono- and trifunctionalized unimers were used in polymerization reactions with styrene and acetoxystyrene. Structures of the azobenzene-modified polymers were characterized by means of a combination of ^{1}H and ^{13}C NMR and UV–vis spectra. The monoazofunctionalized unimer **8** was polymerized with styrene to form a homopolymer, **MAz-PS-T**, with M_n value 13 500 and PD 1.26. Polymerization with acetoxystyrene yielded a polymer, **MAz-PAS-T**, with M_n 35 300 and PD 1.34. Copolymers of styrene and acetoxystyrene were also synthesized, where a block copolymer, **MAz-PAS-PS-T**, with M_n 40 400 and a PD 1.54 and a

© 2004 NRC Canada

Scheme 9.

Scheme 10.

random copolymer, **MAz-PAS/PS-T**, with M_n 16 400 and PD 1.24 were obtained.

The trifunctionalized unimer, **GEN 0**, was also polymerized with acetoxystyrene to yield a polymer, **TAz-PAS-3T**, with M_n 74 400 and PD 1.49. This polymer was copolymerized with styrene to give a block copolymer, **TAz-PAS-PS-3T**, with an M_n value of 126 000 and a PD of 1.64.

It is anticipated that the present polymers would have to be modified at the periphery to achieve light harvesting properties by functionalization with naphthyl moieties. The studies predict the formation of an *on*/*off* molecular switch through trans to cis isomerization of the azobenzene unit by irradiation of the naphthyl moieties and then energy transfer to the azo core.

Experimental section

IR spectra were recorded on a Bomen MB-120 spectrophotometer as KBr disks. ^{1}H and ^{13}C NMR spectra were recorded on Bruker AM300 spectrophotometer (^{1}H 300.1 MHz, ^{13}C 75.5 MHz). Chemical shifts are reported in parts per million (ppm) relative to the peaks for residual $CHCl_3$ in $CDCl_3$ (δ 7.28 ppm) and acetone-d_5H in acetone-d_6 (δ 2.05 ppm). Mass spectrometry results were recorded on a Fisons VG Quattro (triple-quadropole MS–MS). Several techniques were used to identify the mass of the parent ion, such as electron ionization (EI), chemical ionization (CI), fast atom bombardment (FAB), and electrospray (ES). High-resolution mass spectrometry (HR-MS) to establish molecular weights of new compounds was performed by the University of Ottawa Mass Spectrometry Service and University of Alberta Mass Spectrometry Service. Melting points were determined on a Mel-Temp capillary melting point apparatus and were not corrected.

4-Ethylbenzyl alcohol 12 (13)

12 was prepared by reduction of **11** as outlined in Scheme 1. To a stirred solution of **11** (13.1 g, 97.8 mmol) in methanol (100 mL) was added a solution of sodium borohydride (1.4 g, 37.0 mmol) in sodium hydroxide (2 mL, 2 mol/L) and water (18 mL) dropwise while maintaining the temperature at 23 °C. After removing the solvent on a rotary evaporator, the residue was dissolved in water (200 mL) and extracted with CH_2Cl_2 (3 × 100 mL). Drying ($MgSO_4$), filtration, and solvent removal on a rotary evaporator followed by column chromatography using hexanes – ethyl acetate (2:1) as the eluant yielded **12** as a pale yellow oil (10.0 g, 82%). IR (KBr disk, cm^{-1}): 3340, 2969, 2933, 2868, 1417, 1032, 813. ^{1}H NMR ($CDCl_3$) δ: 7.28 (4H, dd), 4.61 (2H, s), 1.06 (1H, d), 2.73 (2H, q), 1.33 (3H, t). ^{13}C NMR ($CDCl_3$) δ: 143.34, 138.03, 127.75, 127.00, 64.57, 28.39, 15.48.

4-Ethylbenzyl bromide 13 (12)

Triphenyl phosphine (11.8 g, 45.0 mmol) was added in two parts to a mixture of **12** (5.0 g, 36.8 mmol) and CBr_4 (14.8 g, 44.6 mmol) in dry THF (75 mL) and stirred under argon for 2 h. After removing the solvent by rotary evaporation, the residue was dissolved in water (100 mL) and extracted with CH_2Cl_2 (3 × 50 mL), dried over $MgSO_4$,

© 2004 NRC Canada

filtered, and the solvent was evaporated on a rotary evaporator. Column chromatography using CH_2Cl_2 as the eluant yielded a pale yellow oil (7.0 g, 95%). IR (KBr disk, cm^{-1}): 3062, 2962, 2926, 2868, 1898, 1618, 1510, 1438, 1222, 827. ^1H NMR ($CDCl_3$) δ: 7.40, 7.26 (4H, dd), 4.58 (2H, s), 2.74 (2H, q), 1.34 (3H, t). ^{13}C NMR ($CDCl_3$) δ: 144.72, 135.08, 129.11, 128.36, 33.81, 28.66, 15.49. EI-MS *m/z*: 198.4 and 199.9 (calcd. for $C_9H_{11}Br$: 198.0 and 200.0).

Di-*tert*-butylperoxyoxalate (14)

A solution of oxalyl chloride (2.5 mL) in petroleum ether (25 mL) was added slowly to a stirred cold solution of anhydrous pyridine (4 mL) and 5.5 mol/L solution of *tert*-butyl hydroperoxide (5 mL) in petroleum ether (50 mL) over 20 min while maintaining the temperature at –4 °C. The reaction mixture was then warmed to 15 °C where the white precipitate formed was filtered and the filtrate was cooled for 15 min in dry ice – acetone (–78 °C) to allow crystallization of peroxyoxalate as fine white crystals. The solvent was decanted and the peroxyoxalate crystals, 4.01 g (69%), dried under argon and stored in the refrigerator.

TEMPO-modified 4-ethylbenzyl bromide 6 (15)

As outlined in Scheme 1, a mixture of **13** (5 g, 25.1 mmol), TEMPO (3 g, 19.2 mmol) and di-*tert*-butylperoxyoxalate (4 g, 1.59 mmol) in benzene (40 mL) was stirred and heated to 35 °C under argon for 24 h. After removing the solvent by rotary evaporation the product was purified by column chromatography using hexanes–dichloromethane (1:1) as the eluant to give the TEMPO modified 4-ethylbenzyl bromide **6** as a white solid (1.78 g, 20%), mp 63 to 64 °C. IR (KBr disk, cm^{-1}): 3013, 2969, 1509, 1442, 1227, 1056, 842, 697. ^1H NMR ($CDCl_3$) δ: 7.36 (4H, dd), 4.80 (1H, q), 4.52 (2H, s), 1.50 (3H, d), 1.41–1.11 (6H, m), 1.31, 1.27, 1.09, 1.05 (18H, each br s). ^{13}C NMR ($CDCl_3$) δ: 146.20, 136.17, 128.79, 126.98, 82.71, 59.69, 40.35, 34.19, 33.72, 23.51, 20.36, 17.22. CI-MS *m/z*: 354.144 548 and 356.141 660 (1:1) (calcd. for $C_{18}H_{28}NOBr$: 353.135 41 and 355.133 54).

TEMPO-modified 4-ethylbenzyl iodide 7 (16)

Following the Finkelstein reaction outlined in Scheme 1, **6** (0.90 g, 2.91 mmol) was added to a stirred solution of sodium iodide (7.5 g, 50 mmol) in dry acetone (20 mL), which was refluxed under argon for 3 h. After filtering and removal of the solvent by rotary evaporation, the solid was dissolved in CH_2Cl_2 (50 mL) and extracted with water (50 mL) and CH_2Cl_2 (2 × 50 mL) where the extracts were dried over $MgSO_4$, filtered and the solvent evaporated to yield a white solid (**7**) (1.1 g, 94%), mp 72 °C. IR (KBr disk, cm^{-1}): 3004, 2922, 1506, 1446, 1280, 1055, 874, 836, 699. ^1H NMR ($CDCl_3$) δ: 7.36, 7.27 (4H, dd,), 4.77 (1H, q), 4.49 (2H, s), 1.61–1.18 (6H, m), 1.47 (3H, d), 1.23, 1.18, 1.04, 0.68 (12H, each br s). ^{13}C NMR ($CDCl_3$) δ: 145.51, 137.51, 128.35, 126.92, 82.55, 59.57, 40.23, 34.33, 23.26, 20.30, 17.10, 5.96. CI-MS *m/z*: 402.131 155 (calcd. for $C_{18}H_{28}NOI$: 401.121 6).

Monoazofunctionalized unimer 8 (12)

8 was synthesized by the coupling of **7** and *para*-hydroxyazobenzene **14** as illustrated in Scheme 1. A mixture of **7** (1.0 g, 2.49 mmol), **14** (0.60 g, 3.03 mmol), anhyd. K_2CO_3 (0.54 g, 3.91 mmol), and crown ether (0.24 g, 0.91 mmol) in dry acetone (50 mL) was refluxed (60 °C) under argon for 48 h. After removal of the solvent by rotary evaporation, the residue was dissolved in CH_2Cl_2 (50 mL) and extracted with water (3 × 50 mL). The organic layer was dried over $MgSO_4$, filtered, and the solvent was removed by rotary evaporation. Column chromatography using CH_2Cl_2 as the eluant yielded an orange solid **7** (0.75 g, 75%), mp 125 to 126 °C. IR (KBr disk, cm^{-1}): 3064, 2968, 1497, 1457, 1251, 1145, 930, 836, 687. ^1H NMR ($CDCl_3$) δ: 7.94 (2H, d), 7.90 (2H, d), 7.55–7.32 (3H, m), 7.40 (4H, d), 7.12 (2H, d), 5.16 (2H, s), 4.83 (1H, q), 1.51 (3H, d), 1.58–1.26 (6H, m), 1.26, 1.19, 1.06, 0.70 (12H, each br s). ^{13}C NMR ($CDCl_3$) δ: 160.10, 158.30, 145.92, 130.77, 129.44, 127.75, 127.29, 125.14, 122.97, 115.53, 83.21, 70.70, 59.97, 40.76, 30.83, 23.60, 20.44, 17.26. CI-MS *m/z*: 472.294 317 (calcd. for $C_{30}H_{37}N_3O_2$: 471.2885).

Diazofunctionalized core 16 (16)

16 was synthesized from 4,4′-ethylenedianiline **15** via diazotization and coupling as shown in Scheme 2. The diazonium salt solution resulting when a solution of stirred sodium nitrite (4.16 g, 60.3 mmol) in water (5 mL) was added slowly to a solution of **15** (5.0 g, 23.6 mmol) in aq. HCl (17 mL of HCl in 5 mL of water) cooled below 2 °C in an ice-water bath, was coupled with phenol as follows. The diazonium salt solution was added slowly with stirring to a solution of phenol (5.6 g, 59.6 mmol) in 10% sodium hydroxide (12.8 g NaOH in 120 mL water) while maintaining the reaction temperature below 2 °C and was allowed to stand in an ice-water bath for 1 h with stirring. After the solution was acidified slowly with concd. HCl, the resultant precipitate was filtered, washed with cold water several times, recrystalized from ethanol, and precipitated with ice to give a diazofunctionalized core **16** as a light orange solid (6.2 g, 62%), mp 245 to 246 °C. ^1H NMR (acetone-d_6) δ: 9.10 (2H, s), 7.84 (4H, d), 7.79 (4H, d), 7.41 (4H, d), 7.01 (4H, d), 3.08 (4H, s). ^{13}C NMR (acetone-d_6) δ: 37.60, 116.14, 122.73, 125.09, 129.72. EI-MS *m/z*: 422.174 20 (calcd. for $C_{26}H_{22}N_4O2$ 422.174 28).

Diazofunctionalized unimer 9 (12)

9 was synthesized by the coupling of **7** with **16** as illustrated in Scheme 2. A mixture of **7** (0.50 g, 1.41 mmol), diazofunctionalized core **16** (0.24 g, 0.57 mmol), anhyd. K_2CO_3 (0.040 g, 0.30 mmol), and crown-ether (0.030 g, 0.11 mmol) in dry acetone (20 mL) was refluxed (60 °C) under argon for 48 h. After removal of solvent by rotary evaporation, the residue was dissolved in CH_2Cl_2 (50 mL) and extracted with water (3 × 50 mL), dried over $MgSO_4$, filtered, and the solvent was removed by rotary evaporation. Column chromatography using hexanes – ethyl acetate (3:2) as the eluent yielded an orange solid **9** (0.1 g, 18%). ^1H NMR ($CDCl_3$) δ: 7.90 (4H, d), 7.80 (4H, d), 7.38 (8H, d), 7.29 (4H, d), 7.09 (4H, d), 5.13 (4H, s), 4.82 (2H, q), 3.04 (4H, s), 1.48 (6H, d), 1.60–0.60 (12H, m), 1.29, 1.18, 1.03, 0.68 (24H, each br s). ^{13}C NMR ($CDCl_3$) δ: 124.47, 122.49, 127.59, 126.87, 126.87, 114.88, 82.67, 69.74, 37.39, 23.38, 34.06, 29.51, 28.44, 20.77, 20.23, 20.20. EI-MS *m/z*: 969.600 22 (calcd. for $C_{62}H_{76}N_6O4$: 969.600 08).

1,3,5-Tris(4′-nitrophenoxy)benzene 19 (17)

1,3,5-Tris(4′-nitrophenoxy)benzene was prepared via S_NAr displacement as outlined in Scheme 3. A mixture of 1,3,5-trihydroxybenzene dihydrate (phloroglucinol) **17** (12.40 g, 76.50 mmol), 4-fluoronitrobenzene **18** (24.4 mL, 230 mmol), potassium fluoride (26.70 g, 460.0 mmol), and 150 mL of DMSO was heated to reflux temperature for 30 min. The reaction mixture was then cooled to room temperature (r.t.), and the precipitate was filtered, washed with water (150 mL), and allowed to dry to give a crude product as a tan flaky solid, which was recrystallized from ethyl acetate – charcoal and followed by chloroform–hexanes to give 1,3,5-tris(4′-nitrophenoxy)benzene **19** as a creamy white solid (25.0 g, 50%), mp 203 to 204 °C (lit. value (7) 203.5–205.5 °C). IR (KBr disk, cm^{-1}): 3091, 2840, 2448, 1918, 1591, 1561, 1468, 1340, 1230, 1114, 994, 848, 741, 632. ^1H NMR ($CDCl_3$) δ: 8.27 (6H, d), 7.15 (6H, d), 6.67 (3H, s). ^{13}C NMR ($CDCl_3$) δ: 161.30, 157.77, 143.60, 126.09, 118.21, 107.60. EI-MS *m/z*: 489.081 9 (calcd. for $C_{24}H_{15}N_3O9$ 489.080 1).

1,3,5-Tris(4′-aminophenoxy)benzene 20 (18)

The synthesis of **20** is outlined in Scheme 3. To a stirred solution of **19** (8.0 g, 16 mmol) and Fe powder (8.10 g, 145 mmol) in 50% ethanol (100 mL) was added slowly HCl (0.6 mL concd. HCl in 10 mL of 50% ethanol) and the reaction mixture was refluxed for 2 h. After the reaction mixture was made alkaline by addition of 15% KOH, the iron was filtered quickly and washed with 95% ethanol (2 × 50 mL). The solvent was removed by rotary evaporation and the residue was dissolved in chloroform (100 mL) and extracted with water (3 × 500 mL). The organic layer was dried over $MgSO_4$, filtered, and the solvent was evaporated on a rotary evaporator. The residue was dried under vacuum for 48 h to give 1,3,5-tris(4′-aminophenoxy)benzene **20** as a light purple solid (6.10 g, 94%), mp 88–90 °C (lit. value (8) 88 to 89 °C). IR (KBr disk, cm^{-1}): 3424, 3352, 3212, 1606, 1503, 1451, 1214, 1113, 1003, 8.31. ^1H NMR ($CDCl_3$) δ: 6.86 (6H, d), 6.65 (6H, d), 6.18 (3H, s), 3.67 (6H, br s). ^{13}C NMR ($CDCl_3$) δ: 160.77, 147.84, 142.90, 121.23, 116.17, 99.97. EI-MS *m/z*: 399.157 3 (calcd. for $C_{24}H_{21}N_3O3$ 399.158 4).

Triazofunctionalized core 21 (13)

The trifunctionalized core **21** was synthesized from **20** via diazotization and coupling as illustrated in Scheme 3. A diazonium salt solution resulted when sodium nitrite (1.56 g, 22.6 mmol) in water (12 mL) was added slowly with stirring to a solution of **20** (3 g, 7.52 mmol) in aq. HCl (5 mL of HCl in 12 mL of water) cooled below 2 °C in an ice-water bath. The diazonium salt was added slowly with stirring to phenol (2.1 g, 22.3 mmol) in 10% sodium hydroxide (48 mL) while maintaining the reaction temperature below 2 °C and was allowed to stand in an ice-water bath for 1 h with stirring. After the solution was acidified with HCl the resultant precipitate was filtered, washed with cold water several times, and air-dried for a few days to give the trifunctionalized azobenzene core (**21**) as a dark red solid (4.50 g, 84%), mp 190 °C. IR (KBr disk, cm^{-1}): 3405, 3168, 1451, 1312, 1225, 1146, 999, 685. 638. ^1H NMR (acetone-d_6) δ: 7.89 (6H, d), 7.81 (6H, d), 7.24 (6H, d), 6.99 (6H, d), 6.63 (3H, br s), 6.62 (3H, s). ^{13}C NMR (acetone-d_6) δ: 160.85, 159.55, 158.52, 149.35, 146.54, 125.17, 124.60, 119.72, 116.10, 105.45. EI-MS: 714.222 683 (calcd. for $C_{42}H_{31}N_6O6$ 714.222 7).

Triazofunctionalized unimer 10 (GEN 0) (12)

GEN 0 was synthesized by coupling of **7** with **21** as illustrated in Scheme 3. A mixture of **7** (0.15 g, 0.37 mmol), the azo core **21** (0.11 g, 0.15 mmol), and anhyd. K_2CO_3 (0.050 g, 0.58 mmol) in dry acetone (20 mL) was heated at reflux (60 °C) under argon for 48 h. After removal of the solvent by rotary evaporation, the residue was purified by column chromatography using CH_2Cl_2 as the eluant to give **GEN 0** (0.05 g, 22%) as an orange thick oil. IR (KBr disk, cm^{-1}): 2968, 2926, 2868, 2362, 2335, 1584, 1496, 1455, 1370, 1225, 1095, 1005, 838. ^1H NMR ($CDCl_3$) δ: 7.91 (12H, d), 7.40 (12H, d), 7.18 (12H, d), 7.10 (2H, d), 6.58 (3H, s), 5.15 (6H, s), 4.84 (3H, apparent d), 1.51 (9H, d), 1.66–1.00 (18H, m), 1.32, 1.20, 1.07, 0.71 (36H, each br s). ^{13}C NMR ($CDCl_3$) δ: 161.28, 159.07, 158.13, 149.12, 145.95, 134.85, 127.39, 126.93, 124.69, 124.47, 119.33, 115.18, 105.09, 82.86, 70.34, 59.76, 40.41, 34.50, 23.64, 20.37, 17.28. ES-MS: $(M + H)^+$ 1535.2 (calcd. for $C_{96}H_{111}N_9O9$ 1533.85).

Polymerization of styrene with monoazofunctionalized unimer (MAz-PS-T)

MAz-PS-T was synthesized by polymerizing styrene with **8** under bulk conditions as illustrated in Scheme 4. A mixture of monofunctionalized unimer **8** (0.10 g, 0.20 mmol) and styrene (18.2 g, 17 5mmol) was heated at 135 °C under nitrogen for 3 h. The polymerization mixture was dissolved in 50 mL of THF and precipitated from 750 mL of methanol, filtered and dried in a vacuum oven at 70 °C resulting in a yellow powder (4.69 g, 26%). M_n = 13 500, M_w/M_n = 1.26.

Polymerization of acetoxystyrene with monoazofunctionalized unimer (MAz-PAS-T)

MAz-PAS-T was synthesized by polymerizing acetoxystyrene with **8** under bulk conditions as illustrated in Scheme 5. A mixture of monofunctionalized unimer **8** (0.10 g, 0.20 mmol) and acetoxystyrene (26.6 g, 164 mmol) was heated at 135 °C under nitrogen for 75 min. The polymerization mixture was dissolved in 50 mL of THF and precipitated from 750 mL of methanol, filtered and dried in a vacuum oven at 70 °C resulting in a yellow powder (12.9 g, 49%). M_n = 35 300, M_w/M_n = 1.34.

Block copolymer of acetoxystyrene–styrene with monoazofunctionalized unimer (MAz-PAS-PS-T)

MAz-PAS-PS-T was synthesized by polymerizing **MAz-PAS-T** with styrene under bulk conditions as illustrated in Scheme 6. A mixture of **MAz-PAS-T** (3.00 g) and styrene (18.2 g, 175 mmol) was heated at 135 °C under nitrogen for 2 h. The polymerization mixture was dissolved in 50 mL of THF and precipitated from 750 mL of methanol, filtered and dried in a vacuum oven at 70 °C resulting in an off-white – yellow powder (5.49 g). M_n = 40 400, M_w/M_n = 1.54.

Random copolymer of acetoxystyrene–styrene with monoazofunctionalized unimer (MAz-PAS/PS-T)

MAz-PAS/PS-T was synthesized by polymerizing

acetoxystyrene and styrene with monofunctionalized unimer **8** under bulk conditions as illustrated in Scheme 7. A mixture of **8** (0.1 g, 0.20 mmol), styrene (12.7 g, 123 mmol) and acetoxystyrene (7.45 g, 45.0 mmol) was heated at 135 °C under nitrogen for 2 h. The polymerization mixture was dissolved in 50 mL of THF and precipitated from 750 mL of methanol, filtered and dried in a vacuum oven at 70 °C resulting in a yellow powder (4.36 g). M_n = 16 400 g/mol, M_w/M_n = 1.24.

Synthesis of monofunctionalized azobenzene poly(4-hydroxystyrene) (MAz-PHS-T) (19)

MAz-PHS-T was synthesized by hydrolysis of **MAz-PAS-T** as illustrated in Scheme 8. Concd. ammonium hydroxide (1.5 mL) in 5 mL of water was added dropwise to a 0.5 g solution of **MAz-PAS-T** in 20 mL of methanol. The reaction mixture was refluxed at 65 °C under nitrogen and was stopped after 24 h and was left to cool at room temperature. The polymer was precipitated from 200 mL of water, filtered and dried in an oven at 50 °C to yield yellow crystals (0.20 g, 40%).

Polymerization of acetoxystyrene with triazofunctionalized unimer (TAz-PAS-3T)

TAz-PAS-3T was synthesized by polymerizing acetoxystyrene with **10** under bulk conditions as illustrated in Scheme 9. A mixture of trifunctionalized unimer **10** (0.10 g, 0.07 mmol) and acetoxystyrene (26.6 g, 164 mmol) was heated at 135 °C under nitrogen for 75 min. The polymerization mixture was dissolved in 50 mL of THF and precipitated from 750 mL of methanol, filtered and dried in a vacuum oven at 70 °C resulting in a yellow powder (13.66 g, 51%). M_n = 74 400, M_w/M_n = 1.49.

Block copolymer of acetoxystyrene–styrene with triazofunctionalized unimer (TAz-PAS-PS-3T)

TAz-PAS-PS-3T was synthesized by polymerizing **TAz-PAS-3T** with styrene under bulk conditions as illustrated in **Scheme 10**. A mixture of **TAz-PAS-3T** (3.00 g) and styrene (18.2 g, 175 mmol) was heated at 135 °C under nitrogen for 45 min. The polymerization mixture was dissolved in 50 mL of THF and precipitated from 750 mL of methanol, filtered and dried in a vacuum oven at 70 °C resulting in an off-white – yellow powder (6.13 g). M_n = 126 000, M_w/M_n = 1.64.

Multi-armed, TEMPO-functionalized unimolecular initiators for starburst dendrimer synthesis via stable free radical polymerisation. 2. Tris (1,3,5)benzyloxy unimers[1]

Mohmad Asri Abd Ghani, Dalia Abdallah, Peter M. Kazmaier, Barkev Keoshkerian, and Erwin Buncel

Abstract: The synthesis of the trifunctionalized TEMPO-modified unimolecular initiators, unimers I, II, and III is described. Unimer I was prepared via an S_N2 type Williamson ether coupling of 1,3,5-tris(iodomethyl)benzene with a TEMPO-containing ethylbenzene hydroxy derivative. The synthesis of unimer II, however, was accomplished through S_N1 reaction of 1,3,5-tris(bromomethyl)benzene with the hydroxy-ethylbenzene TEMPO derivative in the presence of silver triflate. Synthesis of unimer III started from phloroglucinol and an S_NAr reaction with 1-fluoro-4-nitrobenzene, followed by reduction to the amino compound and Schiff base formation with the TEMPO-derivatized aromatic aldehyde. Stable free radical polymerisation (SFRP) of styrene and acetoxystyrene with unimer I are also described with molecular weights and polydispersities reported. It is concluded that the SFRP of styrene with a triradical initiator meets the requirements of a living system.

Key words: stable free radical polymerisation, starburst dendrimer, multi-armed unimolecular initiators.

Résumé : On décrit la synthèse d'initiateurs unimoléculaires trifonctionnalisés à base de 2,2,6,6-tétraméthylpipéridinyloxyle (TEMPO), les unimères I, II et III. L'unimère I a été préparé par le biais d'une réaction S_N2, de type formation d'éther de Williamson, par le couplage du 1,3,5-tris(iodométhyl)benzène avec un dérivé hydroxylé de l'éthylbenzène portant le radical TEMPO. Toutefois, la synthèse de l'unimère II a été réalisée par le biais d'une réaction S_N1 du 1,3,5-tris(iodométhyl)benzène avec le dérivé hydroxylé de l'éthylbenzène portant le radical TEMPO, en présence de triflate d'argent. La synthèse de l'unimère III a été réalisée à partir du phloroglucinol et une réaction S_NAr avec le 1-fluoro-4-nitrobenzène, suivie d'une réduction en dérivé amino et de la formation d'une base de Schiff avec un aldéhyde aromatique portant le radical TEMPO. On décrit aussi la polymérisation avec un radical libre stable du styrène et de l'acétoxystyrène catalysée par l'unimère I et on rapporte les poids moléculaires et les polydispersités moyennes. On conclut que la polymérisation avec un radical libre stable du styrène catalysée par un initiateur triradicalaire satisfait les besoins d'un système vivant.

Mots clés : polymérisation avec un radical libre stable, dendrimère en « éclatement d'étoile », initiateur unimoléculaire tentaculaire.

[Traduit par la Rédaction]

Introduction

The achieving of controlled architecture in macromolecules is at the forefront in the synthesis of novel materials with improved properties. In the realm of polymers, profound changes in properties accompany the introduction of branches into the polymer backbone, which leads to the formation of graft or star polymer systems.

The present work forms part of a series of investigations where controlled architecture in a star polymer is achieved through stable free radical polymerisation (SFRP) using the stable nitroxide radical 2,2,6,6-tetramethylpiperidinyloxy (TEMPO) (1). Our approach is to synthesize unimolecular initiators containing the TEMPO unit, termed unimers, which are then employed in synthesis of star polymers and copolymers. We describe here the synthesis of three trifunctionalized unimers (I, II, III). The polymerisations of styrene and acetoxystyrene with unimer I to form homopolymers and co-

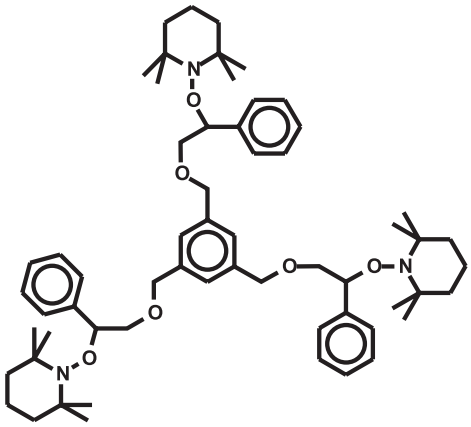
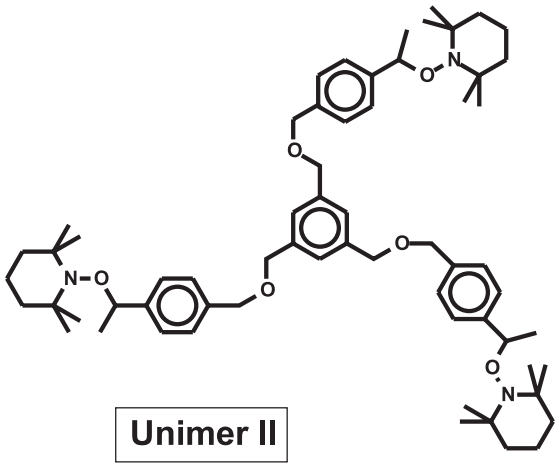
polymers are also described. This work is a continuation of our structure-property studies of functionalized dendrimers (2).



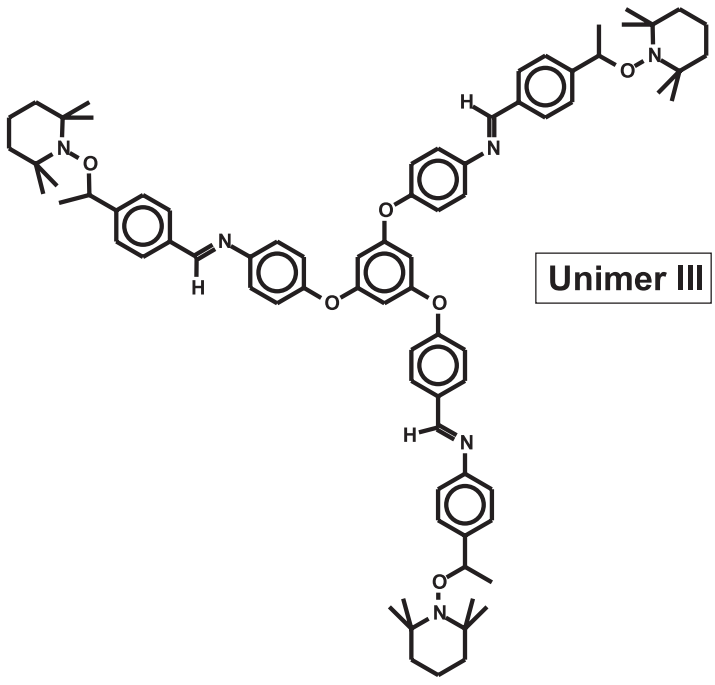
Results and discussion

Unimolecular initiator I synthesis



The synthesis of unimer I consisted of a three-step sequence (Scheme 1): (*i*) The benzyloxyamine ester **1** was first prepared by a modification of the method reported by Veregin (3), Hawker (4), Kobatake (5), and their co-workers, by heating benzoyl peroxide and TEMPO with excess styrene at 80 °C for 30 min (82% yield after recrystallization from 2-propanol). (*ii*) Saponification of **1** (4, 6) by heating at reflux with 2 mol L^{-1} KOH in ethanol and flash chromatography gave the alcohol **2** as a light yellow oil (97%). (*iii*) Williamson ether coupling of **2** with 1,3,5-tris(iodomethyl)benzene in THF under reflux (24 h) in the presence of sodium hydride, after flash chromatographic separation, gave unimer I as a light yellow thick syrup (97%).

Unimolecular initiator II synthesis



The unimer II was prepared by the following sequence (Scheme 2): (*a*) Initially the benzyloxamine derivatives **3** (X = H, CH_2Cl, CH_2Br, CH_2I, CH_2OH) were synthesized starting with commercially available ethylbenzene derivatives and using modifications of the methods of Georges and co-workers (7), Hawker et al. (8), Priddy and co-workers (9), and Miura et al. (10). In our hands the highest yield of **3** (X = H), 93% after crystallization from ethanol, was obtained by reacting ethylbenzene with *tert*-butyl peroxyoxalate and TEMPO (10); (*b*) in an alternative method, use of Jacobson's catalyst (Salem (10, 11)) with the ethylbenzene derivatives in the presence of di-*tert*-butyl peroxide, sodium

borohydride, and TEMPO (12) gave alkoxyamines **3** in yields ranging over 20% (X = CH_2Cl), 41% (X = H), and 51% (X = CH_2OH). Attempted formation of unimer II through S_N2 Williamson ether coupling of **3** (X = CH_2OH) with 1,3,5-tris(iodomethyl)benzene as in the case of unimer I, was unsuccessful in our hands. The preparation of unimer II was then accomplished via an S_N1 type reaction of 1,3,5-tris(bromomethyl)benzene with **3** (X = CH_2OH) in the presence of silver triflate (17% after column chromatographic separation).

Unimolecular initiator III synthesis

The reaction scheme followed the sequence shown in Scheme 3.

(1) The triamine core **4** was obtained in two steps: an S_NAr reaction between 1,3,5-trihydroxy-benzene and 1-fluoro-4-nitrobenzene in the presence of KF in DMSO produced the 1,3,5-tris(4-nitrophenyl)benzene derivative **4**-NO_2 in 50% yield. The triamino core **4**-NH_2 was then obtained through Fe–HCl reduction in 94% yield after purification.

(2) Unimer III was obtained as the Schiff base adduct on reaction of the triamino core compound **4**-NH_2 with the benzyloxyamine derivative **3** (X = CHO) (85% yield after column chromatographic purification).

Controlled free radical polymerisation of unimolecular initiator I

Polystyrene starburst dendrimer I

Two polymerisations of styrene were performed with Unimer I under bulk conditions at 135 °C, **SFRP 1** and **SFRP 2**. The progress of the SFRP processes was monitored by withdrawal of aliquots from the reaction mixture at different times for % conversion and molecular weight determinations.

In the first polymerisation (**SFRP 1**), 1200 equiv. of styrene to 1 equiv. of unimer I were used under the above conditions for 3 h. The polymer was precipitated from methanol to give star polystyrene with terminal TEMPO end groups (**PS-3T1**), as a white solid (15 g), average molecular weight (M_n) 34 200 and polydespersity (PD) 1.29.

The second polymerisation (**SFRP 2**) was performed using 400 equiv. of styrene to 1 equiv. of unimer I for 4 h to give **PS-3T2** (8.70 g) after precipitation from methanol. The polystyrene had a M_n value of 12 700 and a PD of 1.34.

The ^{1}H NMR for both polymer samples showed broad peaks between 1.50 and 1.87 ppm representing the methylene and methine protons. Aromatic protons of polystyrene appear as a broad multiplet between 6.49 and 7.10 ppm.

The polymerisation results are shown in Table 1. The conversion-time relationship is plotted for the formation of

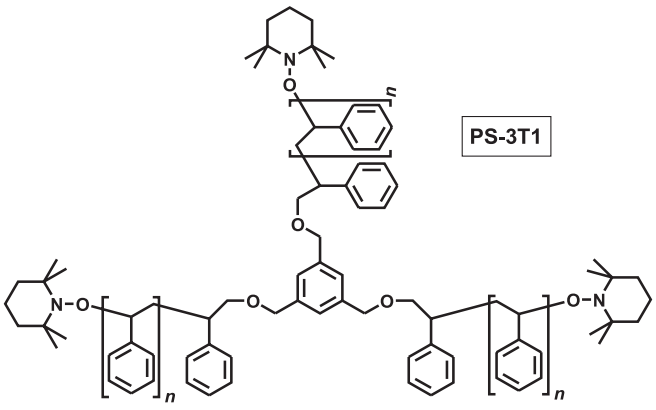
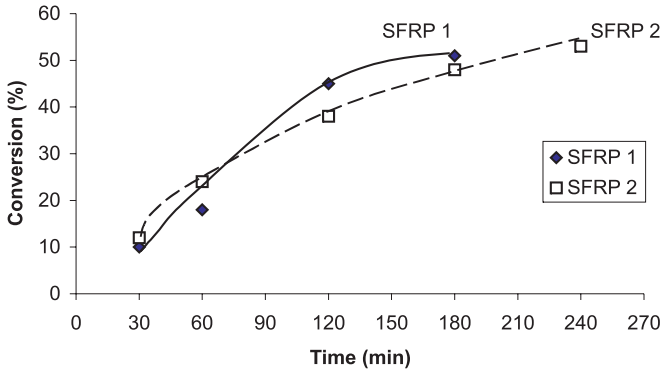
	60	24	9 600	8 951	1.23
	120	38	15 200	11 690	1.27
	180	48	19 200	14 350	1.27
	240	53	21 200	12 710	1.34

[a]Based on TGA.
[b]Calculation of M_n (Theo.): (*i*) for **SFRP 1**: M_n (Theo.) = conversion (%) × molecular weight (monomer) × 1200 (ratio of styrene to unimer I); (*ii*) for **SFRP 2**: M_n (Theo.) = conversion (%) × molecular weight (monomer) × 400 (ratio of styrene to unimer I).
[c]Estimated by GPC based on polystyrene standards.
[d]PD = M_n/M_w estimated by polystyrene standards.





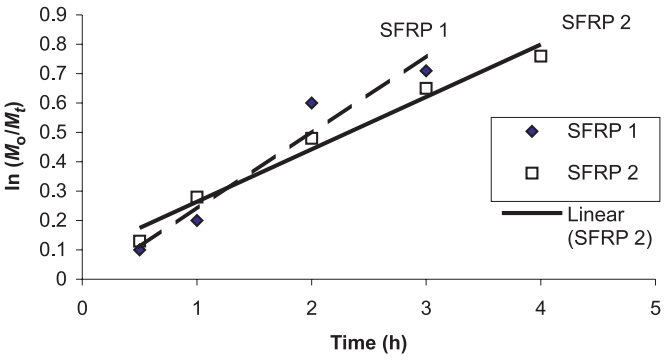


Fig. 1. Plot of % conversion vs. time for **SFRP 1** and **SFRP 2** with unimer I.

PS-3T1 and **PS-3T2** in Fig. 1. As the polymerisation time increases, monomer conversion also increases. Even though the ratio of styrene : unimer I for **SFRP 1** and **SFRP 2** is 3:1, the rate of conversion is almost constant for the two polymerisations. Thus, the polymerisation rate is independent of unimer I concentration.

© 2004 NRC Canada

Fig. 2. Semilogarithmic plot of conversion with reaction time for the SFRP processes with varying initial concentration for **SFRP 1** and **SFRP 2**.

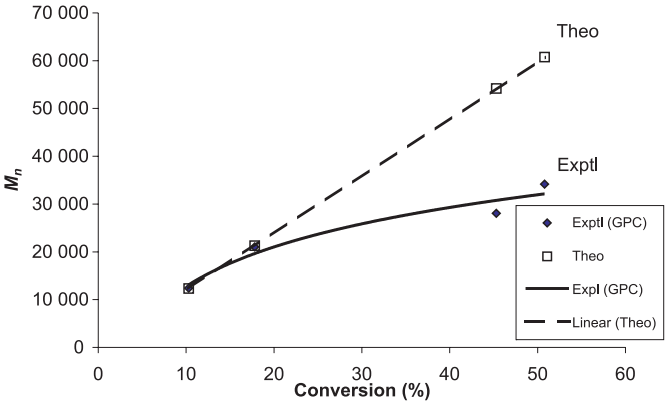
A kinetic plot in semilogarithmic coordinates showing the variation of monomer consumption with time is presented in Fig. 2. M_o represents the initial monomer concentration while M_t is the concentration after time t. Thus, the SFRP of styrene at 135 °C with a triradical initiator (unimer I) meets the requirement of a living system.

Number average molecular weights (M_n) and polydispersities were determined by GPC with polystyrene standards. The plot of the theoretical and experimental M_n data against % conversion are shown in Figs. 3 and 4 for **SFRP 1** and **SFRP 2**, respectively. The experimental M_n data are very close to the calculated theoretical values at the early stages of the polymerisation, which indicates that the formed styryl radicals initiated all growing chains at the same time. There are large deviations of M_n compared with the theoretical values after 40% conversion, which suggests that determination of molecular weight using polystyrene standards (linear chains) is not suitable for star polystyrene. At higher molecular weights the multi-armed polystyrene has a totally different structure and properties compared to the linear analog and will have less hydrodynamic volume. In a related SFRP study with a trifunctionalized unimer, Hawker (13) found that the experimental M_n = 16 500 of the star polymer was lower than the theoretical value (M_n = 21 000). However, when the star polymer was hydrolyzed and the molecular weight of the individual arms measured it was fully consistent with the proposed structure and that each arm of the initiator can actively initiate the monomer similar to the monoinitiator system.

Polyacetoxystyrene starburst dendrimer I

The polymerisation of acetoxystyrene (400 equiv. to 1 equiv. of unimer I) was effected under bulk conditions at 135 °C for 3 h. The polymer was precipitated from methanol to give 5.0 g of a white solid (**PAS-3T**) with an average molecular weight of 21 100 and a PD of 1.30. The ^{1}H NMR shows broad peaks between 1.78 and 1.40 ppm representing the aliphatic protons and a broad multiplet between 7.08 and 6.33 ppm for the aromatic protons of polyacetoxystyrene. The methyl protons of the acetoxy group appear as a singlet at 2.81 ppm. The ^{13}C NMR shows a peak at 169.2 ppm for the carbonyl carbon and 21.23 ppm for the methyl carbon of the acetate group.

Fig. 3. Theoretical and experimental molecular weights for **SFRP 1** plotted against % conversion.



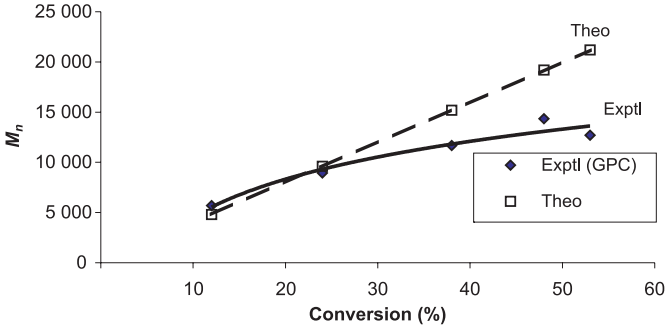


Fig. 4. Theoretical and experimental molecular weights for **SFRP 2** plotted against % conversion.

Hydrolysis of polyacetoxystyrene starburst dendrimer I

Removal of the acetyl group from **PAS-3T** was carried out in methanol by treatment with ammonium hydroxide (15) to give a light yellow solid with an average molecular weight of 16 500 and a PD of 1.23. The decrease in average molecular weight in comparison to **PAS-3T** (M_n = 21 100) is in good agreement with calculated values for deacetylation. The ^{1}H NMR shows the disappearance of the singlet at 2.81 ppm for the methyl protons of the acetoxy group; also, the disappearance of the carbonyl carbon and the methyl group carbon peaks at 196.2 and 21.23 ppm, respectively, confirming that the hydrolysis is complete.

Starburst block copolymer (styrene–acetoxystyrene) dendrimer I

The synthesis of block copolymer was undertaken from **PS-3T1**. A diblock copolymer was obtained via the SFRP technique using 4-acetoxystyrene (25 mL) as the feed monomer at 135 °C for 4 h. A white powder precipitated from methanol (26 g, M_n 95 500, and PD 1.23). The ^{1}H NMR shows two broad peaks at 7.10 and 6.25 ppm corresponding to the protons of the aromatic rings of polystyrene and polyacetoxystyrene, while an intense peak at 2.25 ppm represents the methyl protons of the acetyl group.

Conclusions

The synthesis of unimers I, II, and III was accomplished by reaction sequences outlined in Schemes 1, 2, and 3. Each

© 2004 NRC Canada

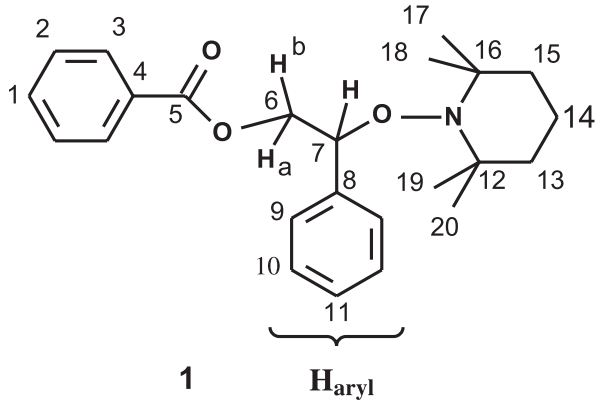
unimer contains one stereogenic center at the TEMPO junction and the products are obtained as complex diastereomeric mixtures.

The polymerisation of styrene and acetoxystyrene was effected with unimer I to form homopolymers and copolymers. For styrene, two polymerisations (**SFRP 1** and **SFRP 2**) were done using different ratios of unimer I to styrene. A polymer with a M_n of 34 200 and a PD of 1.29 was produced from **SFRP 1** while **SFRP 2** yielded a polymer with a M_n of 12 700 and a PD of 1.34. Conversion-time relationships for **SFRP 1** and **SFRP 2** were plotted and an equivalent rate of polymerisation in both cases was obtained, i.e., the rate is independent of unimer I concentration. Linear semilogarithmic kinetic plots of monomer consumption vs. time were obtained, which meets the requirements of a living system. On plotting the theoretical and experimental M_n data against % conversion, the experimental data correlate with theoretical at low M_n while a variance at higher M_n values is in accord with the star-shaped structure of the polymer.

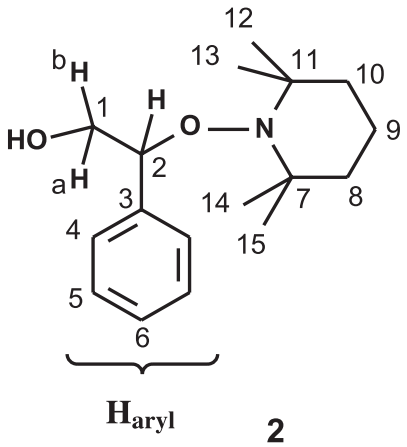
With acetoxystyrene, unimer I gave a polymer (**PAS-3T**) with a M_n of 21 100 and a PD of 1.30. This was hydrolyzed to yield the hydroxystyrene polymer (**PHS-3T**) with a M_n of 16 500 and a PD of 1.23.

A star block copolymer of styrene and acetoxystyrene was obtained from polymerisation of **PS-3T** with acetoxystyrene to give a polymer with a M_n of 95 500 and of PD 1.23.

Experimental section



Unimer I

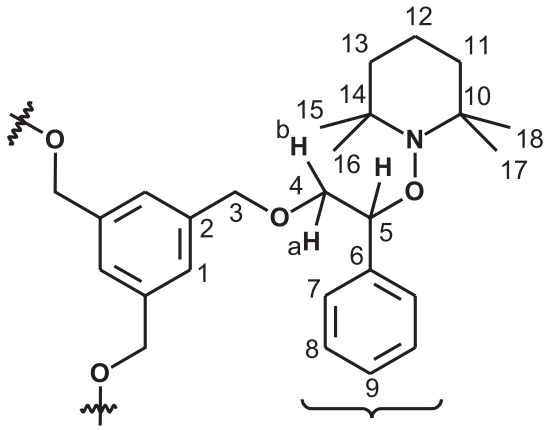


Phenethyloxy(2,2,6,6-tetramethylpiperidino)benzoate 1

A solution of TEMPO (3.43 g, 22.0 mmol) and BPO (8.0 g, 33.0 mmol) in repurified styrene (150 mL) in a round-bottomed (RB) flask was heated under argon at 80 °C for 30 min while stirring, during which period the solution changed from red to light yellow. After cooling, excess styrene was removed under reduced pressure at ca. 50 °C and the residue was purified by flash column chromatography using CH_2Cl_2 as the eluant to give a pale yellow oil. Recrystallization from 2-propanol yielded **1** as a white solid (7.0 g, 82%), mp 72 °C (lit. value (5) mp 72.2–72.6 °C). IR (KBr disk, cm^{-1}): 2928, 1713, 1460, 1371, 1264, 1129, 1100, 997, 700. ^{1}H NMR ($CDCl_3$) δ: 7.95 (2H, d, $J_{H\text{-}H}$ ortho = 6.9, H_3), 7.57–7.26 (8H, m, H_{aryl}, $H_{1,2}$), 5.09 (1H, app. t (overlapping d, d), J_{6b7} = 6.3, J_{6a7} = 5.1, H_7), 4.85 (1H, d, d, J_{6a6b} = 11.1, J_{6a7} = 5.1, H_{6a}), 4.55 (1H, d, d, J_{6a6b} = 11.1, J_{6b7} = 6.3, H_{6b}), 1.66–1.02 (6H, m, $H_{13,14,15}$), 1.39, 1.23, 1.09, 0.78 (12H, br s, $H_{17,18,19,20}$). ^{13}C NMR ($CDCl_3$) δ: 166.38 (C_5), 140.76 (C_8), 132.88 (C_9), 130.24 (C_4), 129.63 (C_3), 128.33, 128.10 ($C_{1,11}$), 127.68 ($C_{2,10}$), 84.01 (C_7), 66.83 (C_6), 60.16 ($C_{12,16}$), 40.48 ($C_{13,15}$), 34.11 ($C_{17,18}$ or $C_{19,20}$), 20.37 ($C_{19,20}$ or $C_{17,18}$), 17.21 (C_{14}). CI-MS *m/z*: 382.3 (calcd. for $C_{24}H_{31}NO_3$ 381.2).

Benzyloxyamine of styrenic alcohol 2

The reaction mixture consisting of ester **1** (4.0 g, 10 mmol) in ethanol (ca. 150 mL) and 2 mol L^{-1} KOH (25 mL) was heated under reflux for 3 h. After removal of ethanol on a rotary evaporator, the residue was dissolved in CH_2Cl_2 (100 mL), which was extracted with water (3 × 100 mL). The residual CH_2Cl_2 solution was dried over anhyd. $MgSO_4$. After removal of the solvent, the product was purified by flash column chromatography using CH_2Cl_2 as the eluant to give **2** as a light yellow oil (2.70 g, yield 97%). IR (neat, cm^{-1}): 3421–3302, 2930, 1739; 1721, 1606, 1458, 1360, 1248, 1125, 1027, 920, 762, 703. ^{1}H NMR ($CDCl_3$) δ: 7.43–7.32 (5H, m, H_{aryl}), 5.92 (1H, br s, H_{OH}), 1.64–1.46 (6H, m, $H_{8,9,10}$), 1.58, 1.39, 1.30, 1.22 (12H, br s, $H_{12,13,14,15}$). The signals for H_{1a}, H_{1b}, and H_2 could not be fully resolved, however, the ^{13}C NMR signals were in satisfactory agreement with the reported data (15) and the MS is also satisfactory. ^{13}C NMR ($CDCl_3$) δ: 138.31 (C_3), 127.72 (C_5), 127.27 (C_6), 126.17 (C_4), 83.02 (C_2), 69.05 (C_1), 61.04 (C_7 or C_{11}), 59.76 (C_7 or C_{11}), 39.78, 39.60 ($C_{8,10}$), 33.99, 32.45 ($C_{12,13}$ or $C_{14,15}$), 20.11, 19.79 ($C_{14,15}$ or $C_{12,13}$), 16.53 (C_9). CI-MS *m/z*: 278.2 (calcd. for $C_{17}H_{27}NO_2$ 277.20).



Williamson ether coupling of 2 and 1,3,5-tris(iodomethyl)benzene

A solution of alcohol **2** (2.50 g, 10 mmol) in dry THF (50 mL) in a RB flask fitted with a reflux condenser was treated with dry sodium hydride (1.10 g, 5 mmol) and the reaction mixture was stirred under argon at room temperature for 4 h. The iodo compound (1.25 g, 2.50 mmol) in dry THF (20 mL) was added slowly to the reaction mixture that was then heated at reflux for 24 h. On cooling, the resultant precipitate was filtered and the filtrate was evaporated to dryness. The residue in CH_2Cl_2 (100 mL), was washed with water (3 × 100 mL), and purified by flash column chromatography using ethyl acetate – hexanes – CH_2Cl_2 (1:3:6) as

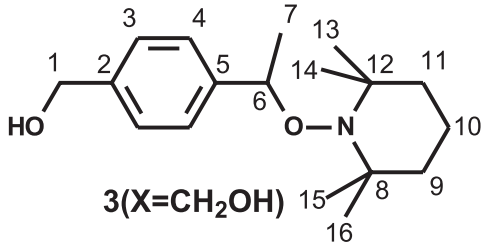
Illustrative synthesis of the benzyloxyamine of ethylbenzene (3 (X = H)) via the peroxyoxalate method

Di-*tert*-butylperoxyoxalate (2.21 g, 9.6 mmol), prepared by a modification of Bartlett's method (16) in 25 mL of ethylbenzene was treated with TEMPO (1.0 g, 6.4 mmol) and the mixture was stirred under argon at 35 °C. The red colour of the solution disappeared to give a light yellow solution within 30 min. Excess ethylbenzene was removed under reduced pressure at r.t. to give a viscous oil that solidified on standing in the refrigerator. The solid was repeatedly recrystallized from ethanol to provide the benzyloxyamine of 4-ethylbenzene (**3** (X = H)) (1.55 g, 93%) as colourless needles, mp 44 °C (lit. value (16) mp 44–46 °C). IR (KBr disk, cm^{-1}): 2977, 2936, 1461, 1366, 1283, 1244, 1218, 1126, 1064, 980, 927, 778, 699. ^1H NMR ($CDCl_3$) δ: 7.36–7.25 (5H, m, H_{aryl}), 4.82 (1H, q, $J_{H\text{-}H}$ = 6.6, H_5), 1.52 (3H, d, $J_{H\text{-}H}$ = 6.6 H_6), 1.42–1.28 (6H, m, $H_{8,9,10}$), 1.36, 1.21, 1.07, 0.700 (12H, each br s, $H_{12,13,14,15}$). ^{13}C NMR ($CDCl_3$) δ: 145.86 (C_4), 128.02 (C_2), 126.77 (C_1), 126.61 (C_3), 83.13 (C_5), 59.67 ($C_{7,11}$), 40.39 ($C_{8,10}$), 34.19 ($C_{12,13}$ or $C_{14,15}$), 23.58 (C_6), 20.32 ($C_{14,15}$ or $C_{12,13}$), 17.25 (C_9). CI-MS *m/z*: 262.3 (calcd. for $C_{17}H_{27}NO$ 261.2).



Illustrative synthesis of the benzyloxyamine of 4-ethylbenzyl alcohol (3 (X = CH_2OH)) via Jacobson's method

The Jacobson reaction (11, 12) was carried out with 4-vinylbenzyl alcohol (2.0 g, 15 mmol), TEMPO (3.51 g, 23 mmol), [salen]MnCl (1.90 g, 3 mmol), di-*tert*-butyl peroxide (2.20 g, 15 mmol), sodium borohydride (1.14 g, 30 mmol) in toluene–ethanol (1:1) (300 mL) medium at r.t. for 30 h. Removal of solvent under vacuo, extraction (CH_2Cl_2), H_2O wash, drying ($MgSO_4$), followed by flash column chromatography (CH_2Cl_2 eluant) yielded **3** (X = CH_2OH) as a light yellow solid (2.20 g., 51%), mp 40 °C. IR (neat, cm^{-1}): 3326 (broad), 2932, 1457, 1365, 1250, 1199, 1128, 1055, 944, 829, 732. ^1H NMR ($CDCl_3$) δ: 7.33 (4H, s, $H_{3,4}$), 4.81 (1H, q, $J_{H\text{-}H}$ = 6.6, H_5), 4.70 (2H, s, H_1), 2.20 (1H, br s, H_{OH}), 1.49 (3H, d, $J_{H\text{-}H}$ = 6.9, H_7), 1.48–1.10 (6H, m, $H_{9,10,11}$), 1.33, 1.21, 1.07, 0.71 (12H, each br s, $H_{13,14,15,16}$). ^{13}C NMR ($CDCl_3$) δ: 144.95 (C_5), 138.99 (C_2), 126.45, 126.35 ($C_{3,4}$), 82.52 (C_6), 64.80 (C_1), 59.32($C_{8,12}$), 39.94 ($C_{9,11}$), 34.08, 33.84 ($C_{13,14}$ or $C_{15,16}$), 23.34 (C_7), 19.99 ($C_{15,16}$ or $C_{13,14}$), 16.84 (C_{10}). Silver-assisted S_N1 reaction for the formation of unimer II

Silver trifluoromethanesulfonate (silver triflate, $CF_3SO_3^-Ag^+$) was employed for the etherification of **3** (X = CH_2OH) with the core (1,3,5-tris(bromoethyl)benzene).

A solution of the alcohol **3** (X = CH_2OH) (0.47 g, 1.60 mmol) and silver triflate (0.33 g, 1.60 mmol) in dichloromethane (10 mL) at 0 °C was stirred for 1 h following which the tris bromide (0.15 g, 0.42 mmol) was added and stirring was continued for another 6 h. The solution was then diluted with CH_2Cl_2 (20 mL), filtered through a plug of Celite, and the filtrate was washed with 1 mol L^{-1} HCl (50 mL), then satd. $NaHCO_3$ (50 mL), brine (50 mL), dried ($MgSO_4$), and finally concentrated by rotary evaporation. The crude product was purified by flash column chromatography using hexanes – ethyl acetate (3:1) as the eluant to give unimer II as a light yellow thick syrup (70 mg, 17%) and other complex by-products that could not be assigned. IR (neat): 2972, 2930, 2869, 1449, 1360, 1259, 1209, 1131, 1064, 1019, 935, 821, 680 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 7.33

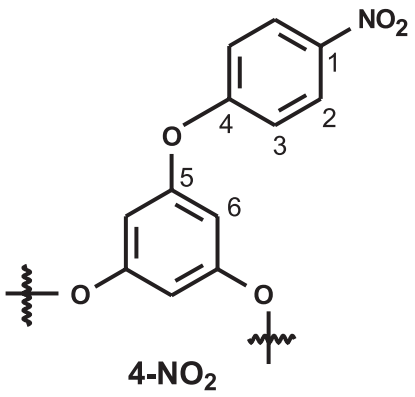
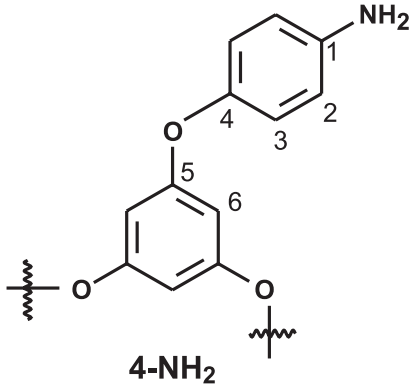
Unimer III

1,3,5-Tris(4′-nitrophenoxy)benzene (4-NO_2)



1,3,5-Tris(4′-nitrophenoxy)benzene (**4**-NO_2) was prepared via S_NAr displacement according to the method of Takeichi and Stille (17).

A mixture of 1,3,5-trihydroxybenzene dihydrate (phloroglucinol) (12.40 g, 76.50 mmol), 4-fluoronitrobenzene (24.4 mL, 230 mmol), potassium fluoride (26.70 g, 460.0 mmol), and 150 mL of DMSO was heated under reflux for 30 min. After cooling the precipitate that formed was filtered, washed with water (150 mL), and allowed to dry to give a crude product as a tan flaky solid. The supernatant of the initial filtrate on adding water (100 mL) gave more precipitate, which was filtered, washed with water (400 mL), and allowed to dry to give additional crude product. The combined crude products were recrystallized from ethyl acetate – charcoal and followed by chloroform–hexanes to give 1,3,5-tris(4′-nitrophenoxy)benzene (**4**-NO_2) as a creamy white solid (25.0 g, 50%), mp 203 to 204 °C (lit. value (17) mp 203.5–205.5 °C). IR (KBr disk, cm^{-1}): 3091, 2840, 2448, 1918, 1591, 1561, 1468, 1340, 1230, 1114, 994, 848, 741, 632. ^{1}H NMR ($CDCl_3$) δ: 8.27 (6H, d, $J_{H\text{-}H}$ ortho = 9.3, H_2), 7.15 (6H, d, $J_{H\text{-}H}$ ortho = 7.2, H_3), 6.67 (3H, s, H_6). ^{13}C NMR ($CDCl_3$) δ: 161.30 (C_4), 157.77 (C_5), 143.60 (C_1), 126.09 (C_2), 118.21 (C_3), 107.60 (C_6). HR-MS (EI) *m*/*z* calcd. for $C_{24}H_{15}N_3O_9$: 489.0801; found: 489.0819.



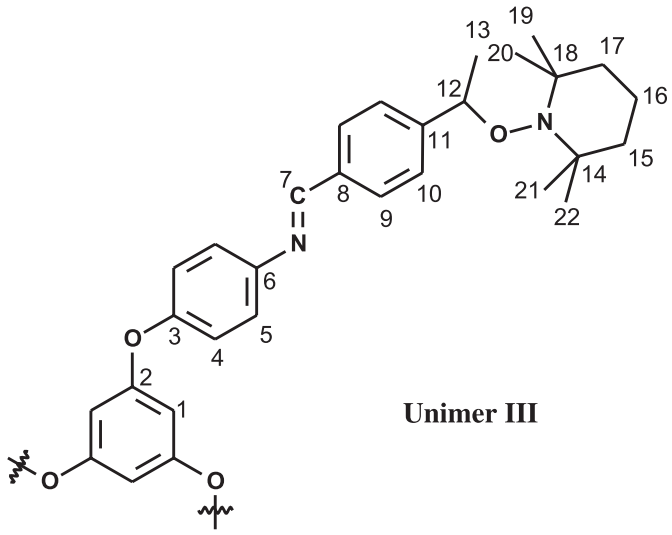
1,3,5-Tris(4′-aminophenoxy)benzene (4-NH_2)

Reduction of **4**-NO_2 was performed according to an experimental procedure adapted from the synthesis of 2,4-toluenediamine as described by Mahood and Schaffner (18).

To a stirred solution of **4**-NO_2 (8.0 g, 16 mmol) and Fe powder (8.10 g, 145 mmol) in 50% ethanol (100 mL) was added slowly HCl (0.6 mL concd. HCl in 10 mL of 50% ethanol). The reaction mixture was heated at reflux for 2 h and was then made alkaline to litmus with 15% aq. KOH. Without allowing the mixture to cool, the iron was filtered quickly and washed with 95% ethanol (2 × 50 mL). The solvent was removed by rotary evaporation and the residue was redissolved in chloroform (100 mL) and extracted with water (3 × 500 mL). The organic layer was dried ($MgSO_4$), filtered from the desiccant, evaporated to dryness, and further dried in vacuo for 48 h to give 1,3,5-tris(4′-aminophenoxy)benzene (**4**-NH_2) as a light purple solid (6.10 g, 94%), mp 88–90 °C (lit. value (18) mp 88 to 89 °C). IR (KBr disk, cm^{-1}): 3424, 3352, 3212 (NH_2), 1606, 1503, 1451, 1214 (C-O), 1113, 1003, 8.31 (C-N). ^{1}H NMR ($CDCl_3$) δ: 6.86 (6H, d, $J_{H\text{-}H}$ ortho = 8.7, H_3), 6.65 (6H, d, $J_{H\text{-}H}$ ortho = 8.7, H_2), 6.18 (3H, s, H_6), 3.67 (6H, br s, (H_{amino})). ^{13}C NMR ($CDCl_3$) δ: 160.77 (C_5), 147.84 (C_4), 142.90 (C_1), 121.23 (C_3), 116.17 (C_2), 99.97 (C_6). HR-MS (EI) *m*/*z* calcd. for $C_{24}H_{21}N_3O_3$: 399.1584; found: 399.1573.

4-NO_2

4-NH_2



Synthesis of the Schiff base adduct (unimer III)

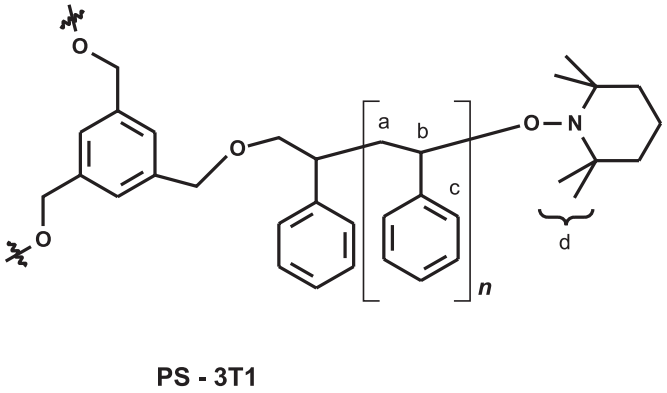
Unimer III was prepared by the reaction of aldehyde **3** (X = CHO) with amine **4**-NH_2 via a method modified from Furniss et al. (19).

A solution of **3** (X = CHO) (0.60 g, 2.10 mmol) and **4**-NH_2 (0.25 g, 0.63 mmol) in 95% ethanol (10 mL) was stirred at reflux for 30 min after which water (3 mL) was added until cloudy and the solution was allowed to cool and induced to crystallize. The product was filtered, rinsed with cold aqueous ethanol, and purified by flash column chromatography using CH_2Cl_2 as the eluant to give unimer III, as a light yellow rubber-like solid (0.675 g, 85%). IR (KBr disk, cm^{-1}): 3435, 2969, 2928, 2869, 1614, 1497, 1453, 1366, 1218, 1121, 1064, 1003, 937, 836, 700. ^{1}H NMR ($CDCl_3$) δ: 8.47 (3H, s, H_7), 7.86 (6H, d, $J_{H\text{-}H}$ ortho = 8.1, H_9), 7.43 (6H, d, $J_{H\text{-}H}$ ortho = 8.1, H_{10}), 7.23 (6H, d, $J_{H\text{-}H}$

© 2004 NRC Canada

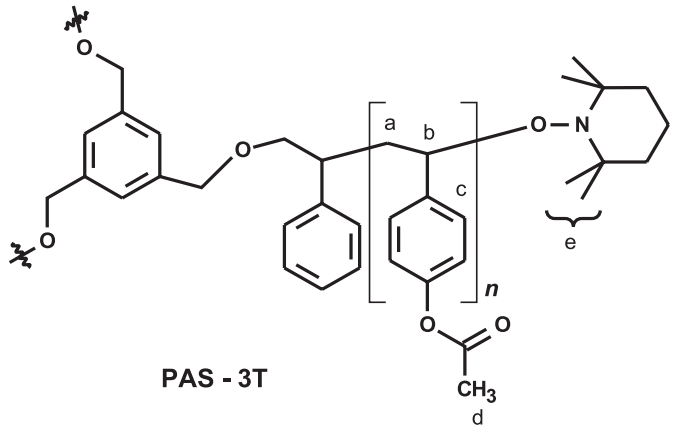
ortho = 8.7, H_5), 7.09 (6H, $J_{H\text{-}H}$ ortho = 8.7, H_4), 6.43 (3H, s, H_1), 4.85 (3H, q, $J_{H\text{-}H}$ = 6.6, H_{12}), 1.68–1.39 (18H, m, $H_{15,16,17}$), 1.52 (9H, d, $J_{H\text{-}H}$ = 6.6, H_{13}), 1.32, 1.20, 1.06, 0.69 (36H, each br s, $H_{19,20,21,22}$). ^{13}C NMR ($CDCl_3$) δ: 159.92 (C_7), 159.84 (C_2), 154.28 (C_8), 149.63 (C_{11}), 148.25 (C_6), 134.84 (C_3), 128.69 (C_9), 127.00 (C_{10}), 122.35 (C_5), 120.18 (C_4), 102.99 (C_1), 83.17 (C_{12}), 59.76 ($C_{14,18}$), 40.39 ($C_{15,17}$), 34.50 ($C_{19,20}$ or $C_{21,22}$), 23.64 (C_{13}), 20.37 ($C_{21,22}$ or $C_{19,20}$), 17.23 (C_{16}). ES-MS *m/z* calcd. for $C_{78}H_{96}N_6O_6$: 1213.7: found: 1214.3.

Synthesis of PS-3T1



SFRP 1 polymerisation of styrene (50 mL, 0.44 mol) using unimer I (0.36 g, 0.38 mmol) was carried out at 135 °C under nitrogen via bulk polymerisation (no solvent added) for 4 h. As the reaction proceeded, the clear solution became viscous over time. Intermediate samples (0.5 mL) were withdrawn at times 0.5 h, 1 h, 2 h, 3 h, and 4 h to follow the progress of polymerisation. Each intermediate sample was transferred into two small vials for thermal gravimetric analysis (TGA) and gel permeation chromatography (GPC) purposes. To determine conversion, the sample was transferred directly from the vial to the TGA apparatus. The second vial was evaporated to remove the excess styrene, diluted with THF (ca. 1 mL), and analyzed by GPC. Polymerisation was stopped after 4 h. The polymer was precipitated from methanol (500 mL), redissolved in dichloromethane (100 mL), and finally polystyrene with a terminal TEMPO group (**PS-3T1**) was isolated as a white powder, after drying in a vacuum oven at 50 °C for 12 h, yield 15.0 g. M_n = 34 200, M_n/M_w = 1.29.

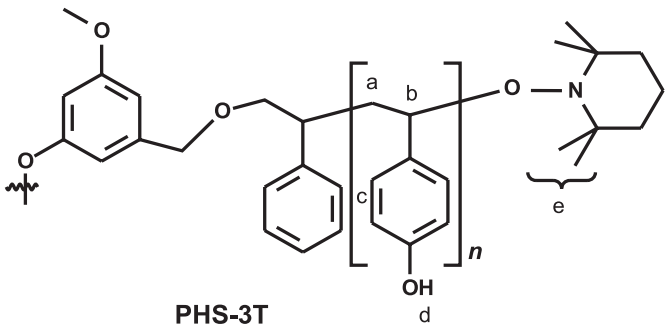
Synthesis of PS-3T2



SFRP 2 polymerisation of styrene (25 mL, 0.22 mol) using unimer I (0.418 g, 0.500 0 mmol) was repeated in the identical manner as described above, forming **PS-3T2** as a white solid, 8.70 g. M_n = 12 700, M_n/M_w = 1.34.

Synthesis of PAS-3T

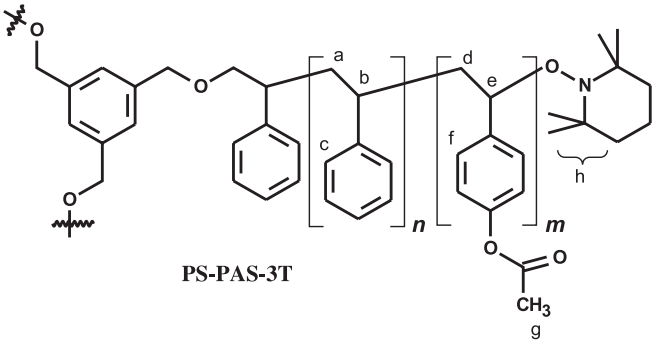
Bulk polymerisation of acetoxystyrene (25 mL, 0.164 mol) using unimer I (0.18 g, 0.38 mmol) was performed in an identical manner to the synthesis of **PS-3T1**. The product



PAS-3T was obtained as a white powder (5.0 g). M_n = 21 100, M_n/M_w = 1.30.

Synthesis of PHS-3T

To a solution of **PAS-3T** (0.50 g) in methanol (20 mL) at reflux under nitrogen was added dropwise ammonium hydroxide (1.5 mL in 5 mL water). After the addition, heating of the reaction mixture was continued at reflux for 24 h. The reaction mixture was then cooled to room temperature, the polymer was isolated by precipitation in water (200 mL), filtered, and washed several times with water. The polymer was dried in a vacuum oven at 50 °C for 12 h to give star polyhydroxystyrene (**PHS-3T**) as a light yellow solid (0.3 g). Molecular weights and polydispersities of **PHS-3T** were estimated by GPC. M_n = 16 400, M_n/M_w = 1.23.



Synthesis of block copolymer PS-PAS-3T

To a solution of acetoxystyrene (25.00 mL, 0.164 mmol) was added **PS-3T1** (10.0 g) and the reaction mixture was de-

© 2004 NRC Canada

gassed under nitrogen for 30 min. The reaction mixture was then stirred and heated at 135 °C for 4 h. During this time the polymerisation mixture became progressively more viscous. The reaction mixture was cooled to room temperature, redissolved in dichloromethane (200 mL), and precipitated with methanol (1000 mL). The product was dried in a vacuum oven at 60 °C for 12 h to give **PS-PAS-3T** as a white powder (26.0 g). Molecular weights and polydispersities of **PS-PAS-3T** were estimated by GPC. M_n = 95 500, M_n/M_w = 1.21.

PS-PAS-3T

Liaison hydrogène des arylamines : compétition des sites π et N

Eric Marquis, Jérôme Graton, Michel Berthelot, Aurélien Planchat et Christian Laurence

Résumé : L'étude infrarouge, dans la région ν(OH), d'un donneur de liaison hydrogène de référence, le 4-fluorophénol, en présence d'arylamines primaires, secondaires et tertiaires différemment substituées sur le noyau et sur l'azote, montre la formation de deux complexes de stœchiométrie 1 : 1 en solution dans CCl_4, un complexe OH···π et un complexe OH···N. Une méthode est proposée pour décomposer la constante globale (K_t) de complexation en une composante K_π pour le complexe π et une composante K_N pour le complexe sur l'azote. Cette méthode est validée par comparaison des valeurs K_π et K_N obtenues avec des descripteurs calculés théoriquement, géométriques (direction de la paire libre de l'azote), électrostatiques (potentiels électrostatiques) et énergétiques (enthalpie de complexation avec HF). Les principaux facteurs stériques, inductifs et de résonance modifiant le pouvoir accepteur de liaison hydrogène des sites π et N sont analysés. La meilleure base π est la julolidine, et la meilleure base azotée est la base de Tröger. La triphénylamine, base de Brønsted azotée, se comporte essentiellement comme une base π de liaison hydrogène. Cette molécule constitue un exemple instructif des différences importantes existant entre les échelles de basicité de liaison hydrogène et de basicité de Brønsted.

Mots clés : liaison hydrogène, arylamines, échelle pK_{HB}, compétition de sites π et N.

Abstract: An IR study, in the region of OH stretching, of a reference hydrogen-bond donor, 4-fluorophenol, hydrogen bonded to primary, secondary, and tertiary arylamines differently substituted on the ring and on the nitrogen, shows the formation of two kinds of 1:1 complexes in CCl_4 solution: an OH···π and an OH···N hydrogen-bonded complex. The IR method gives only access to a global complexation constant K_t. A method is proposed for separating K_t into a K_π component for hydrogen bonding to the π system and a K_N component for hydrogen bonding to the nitrogen atom. This method is validated by comparing the estimated K_π and K_N values to theoretically calculated descriptors of basicity: the nitrogen lone pair orientation towards the aromatic ring, the molecular electrostatic potentials around the nitrogen and the π cloud, and the enthalpy of hydrogen bonding of hydrogen fluoride with the π system of selected arylamines. The main electronic and steric factors governing the competition between π and N sites are analysed. The strongest π and N bases among the arylamines are julolidine and Tröger's base, respectively. Triphenylamine and diphenylamine, which are nitrogen Brønsted bases, become π bases in hydrogen bonding. Moreover, there is no correlation between the pK_{HB} and the pK_{BH^+} scales of basicity of arylamines. The use of the pK_{BH^+} scale is therefore not recommended in hydrogen-bonding studies.

Key words: hydrogen bonding, arylamines, pK_{HB} scale, competition of π and N hydrogen-bonded sites.

Introduction

Les arylamines se comportent comme des bases de Brønsted azotées et non pas carbonées en solution aqueuse. Par exemple, le pK_{BH^+} de l'acide conjugué de l'aniline $PhNH_2$ (4,61) (1) dérive de celui de la méthylamine (10,65) (2) par l'effet électroattracteur et donc réducteur de basicité du phényle, et non de celui de l'hexaméthylbenzène (–14,65) (3). En phase gazeuse l'azote reste généralement le site de protonation, mais le noyau aromatique a été proposé comme site de protonation de certaines anilines (4–7). L'azote est également généralement considéré comme le site de liaison hydrogène (liaison H) des anilines (8–10). Cependant quelques travaux en spectrométrie infrarouge (IR) ont remarqué qu'un phénol en présence d'arylamine montre deux bandes de complexe dans la région de la vibration d'élongation OH (11, 12), qu'ils attribuent aux vibrations ν(OH···π) pour la moins large et la moins déplacée et ν(OH···N) pour la plus large et la plus déplacée. Ces bandes démontrent l'existence de deux types de complexes que nous appellerons π et N (Schéma 1). Cette dualité est générale pour tout accepteur de liaison H comprenant un hétéroatome (N, O, S, P, As, Sb) fixé sur un noyau aromatique (11–14).

Ces travaux anciens (11, 12) n'ont étudié que le déplacement de fréquence OH par liaison H, et seulement pour quelques arylamines simples. Ils n'ont pas effectué d'étude

Schéma 1.

thermodynamique sur les stabilités respectives des complexes π et N. Lorsque des constantes de complexation ont été déterminées (9), elles ont été attribuées uniquement, et donc de manière erronée, au complexe N.

Dans le cadre de nos travaux sur la construction d'une échelle thermodynamique de basicité de liaison H des bases organiques, notée pK_{HB} et définie par les équations [1]–[3],

[1] base + 4-FC_6H_4OH ⇌ 4-FC_6H_4OH···base

[2] $$\frac{K_c}{\mathrm{dm^3\ mol^{-1}}} = \frac{[\text{4-FC}_6\text{H}_4\text{OH···B}]}{[\text{B}][\text{4-FC}_6\text{H}_4\text{OH}]}$$

[3] $$pK_{HB} = \log_{10} K_c = -\Delta G^\circ_{298}/5{,}7\ \mathrm{kJ\ mol^{-1}}$$

et après avoir déterminé l'échelle pK_{HB} des bases π (15) et des amines aliphatiques primaires (16), secondaires (17) et tertiaires (18), nous rapportons dans ce travail la mesure des constantes de complexation par liaison H du 4-fluorophénol avec des arylamines dans CCl_4 à 25 °C, par spectrométrie IR à transformée de Fourier (IRTF) sur la bande ν(OH) à 3614 cm^{-1} du 4-fluorophénol. Toutes les arylamines forment deux complexes de stœchiométrie 1 : 1 en solution diluée (un excès d'amine empêche la formation de complexes 2 : 1 (2 phénols : 1 amine)) selon les équilibres [4] et [6] de constantes d'équilibre K_π (équation [5]) et K_N (équation [7]). La

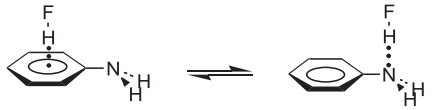
[4] ArNRR′ + 4-FC_6H_4OH ⇌ 4-FC_6H_4OH···ArNRR′

[5] K_π = [complexe π]/[ArNRR′][4-FC_6H_4OH]

[6] ArNRR′ + 4-FC_6H_4OH ⇌ 4-FC_6H_4OH···N(Ar)RR′

[7] K_N = [complexe N]/[ArNRR′][4-FC_6H_4OH]

diminution d'absorbance, par ajout d'amine à la solution de 4-FC_6H_4OH, de la bande OH du 4-fluorophénol libre est due à la formation simultanée de complexes π et N. La méthode IRTF ne permet donc de déterminer que la constante apparente K_t (équation [8]) qui est évidemment égale à $K_\pi + K_N$.



[8] K_t = ([complexe π] + [complexe N])/[ArNRR′][4-FC_6H_4OH]

Si l'arylamine possède *m* noyaux aromatiques équivalents et *n* atomes d'azote équivalents, la correction statistique (19) conduit à l'équation générale [9].

[9] $K_t = mK_\pi + nK_N$

Contrairement aux valeurs pK_{HB} (équation [3]) des bases monofonctionnelles, proportionnelles à une énergie de Gibbs, la quantité log K_t n'a aucune signification thermodynamique. Nous proposons donc d'abord une méthode pour déterminer séparément K_π et K_N. Les valeurs $pK_{HB}(\pi) = \log K_\pi$ et $pK_{HB}(N) = \log K_N$ pourront alors être comparées aux valeurs pK_{HB} des bases monofonctionnelles, bases π (15), amines aliphatiques (16–18) ou toute autre base organique (20).

Puis, pour valider notre méthode et les valeurs K_π et K_N obtenues, nous effectuerons une étude théorique des arylamines et de leurs complexes de liaison H, de trois manières différentes. Premièrement nous comparerons $pK_{HB}(\pi)$ et $pK_{HB}(N)$ aux potentiels électrostatiques à la surface moléculaire autour de l'azote ($V_{S,min}(N)$ (minimum absolu)), et sur le nuage aromatique ($V_S(\pi)$). Ce premier test se justifie par le fait que la liaison H est principalement électrostatique et que des relations satisfaisantes sont observées entre pK_{HB} et $V_{S,min}$ pour les bases monofonctionnelles, à condition de considérer des familles de bases homogènes, par exemple les nitriles (21), les amines aliphatiques (16, 17) ou les pyridines (22). Deuxièmement nous calculerons l'énergie de Gibbs de la réaction [10], c'est-à-dire la proportion de complexes π

[10] 

et N pour le système aniline – fluorure d'hydrogène. Nous avons sélectionné une seule et la plus simple des arylamines, l'aniline, et remplacé le 4-fluorophénol par HF, le plus petit donneur de liaison H, car le calcul des énergies de Gibbs de complexation du 4-fluorophénol sur les sites π et N ne peut actuellement être envisagé à un niveau de calcul satisfaisant pour un si grand nombre de complexes avec des molécules de si grande taille. Une étude récente (23) a montré que HF pouvait constituer un modèle raisonnable du pouvoir donneur de liaison H du 4-fluorophénol. Troisièmement nous calculerons l'enthalpie de complexation de HF sur le site π du benzène et de quelques arylamines (réaction [11]); depuis

[11] HF + C_6H_6 ou ArNRR′ ⇌ FH···π

la plus faible (3-chloroaniline) jusqu'à la plus forte (julolidine) valeur de $pK_{HB}(\pi)$. Nous avons ici choisi de calculer ΔH plutôt que ΔG à cause des calculs imprécis des fréquences de vibration intermoléculaires, et donc de l'entropie de vibration, et du fait de l'existence de relations $\Delta G/\Delta H$ pour de nombreuses familles de complexes de liaison H (24).

Enfin nous mettrons en évidence les principaux facteurs structuraux qui déterminent la sélectivité du site de fixation de liaison H des arylamines. Pour cela nous avons étudié un échantillon de 26 arylamines primaires, secondaires et tertiaires, où peuvent s'exprimer les principaux effets stériques et électroniques (inductif et de résonance) de la chimie organique. Un facteur évident de la compétition des sites π et N est la conjugaison de la paire libre de l'azote avec le(s) noyau(x) aromatique(s) : une augmentation de conjugaison diminue la basicité de l'azote et augmente la basicité π et vice-versa. Cette conjugaison dépend en particulier de l'orientation de la paire libre par rapport au noyau. Nous étudierons avec soin la géométrie des arylamines autour de

© 2004 CNRC Canada

l'azote et essaierons de localiser la paire libre par la méthode NBO (« natural bond orbital ») (25, 26).

Partie expérimentale

Produits

Toutes les amines étudiées sont des composés commerciaux purifiés par les méthodes usuelles puis contrôlés par chromatographie gazeuse sur colonne SE30 ou chromatographie sur couche mince. Les solvants CCl_4 et C_2Cl_4 (pour deux amines qui semblaient réagir avec CCl_4) sont de qualité spectroscopique; ils sont stockés sur tamis moléculaire 4 Å (1 Å = 0,1 nm) avant d'être soutirés. Le 4-fluorophénol est purifié par sublimation. Les produits sont manipulés en boîte sèche pour préparer les solutions et remplir la cellule IR.

Spectres IR

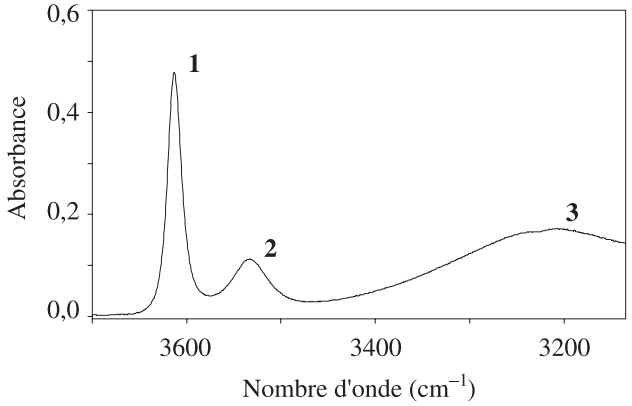
Ils sont enregistrés sur des spectromètres Bruker IFS48 ou Vector22 avec une résolution de 1 cm^{-1}. La cellule en quartz possède un trajet optique de 1 cm. Elle est thermorégulée à 25,0 ± 0,2 °C à l'aide d'un système thermoélectrique à effet Peltier.

Constantes K_t

Elles sont définies par l'équation [12] dans laquelle C_c est la somme $C_\pi + C_N$ des concentrations en complexes π et N; C_a, la concentration du 4-fluorophénol et C_b,

$$[12] \quad K_t = \frac{C_c}{C_a C_b} = \frac{C_a^\circ - C_a}{C_a(C_b^\circ - C_a^\circ + C_a)}$$

la concentration d'amine non complexés (à l'équilibre et en mol dm^{-3}). C_a° et C_b° sont les concentrations initiales déterminées par pesées. C_a° est de l'ordre de 4 mmol dm^{-3} pour éviter l'autoassociation du 4-fluorophénol. C_b° est ajustée de manière à ce que 20 % à 80 % de phénol soit complexé et varie de 0,01 à 0,6 mol dm^{-3} selon la basicité de l'amine. La concentration C_a en phénol non complexé est déterminée à partir de l'absorbance de la bande ν(OH) à 3614 cm^{-1} par la loi de Beer–Lambert. Cinq déterminations de K_t sont effectuées à cinq concentrations différentes d'amine. L'erreur relative sur K_t est estimée à ±8 % (27).



Déplacements de fréquence Δν(OH)

Le déplacement de la fréquence d'élongation ν(OH) du 4-fluorophénol par formation d'un complexe de liaison H sur le site π est défini par la différence [13]. La précision sur Δν(OH···π) est estimée à ±1 cm^{-1} (car la bande ν(OH···π) est peu élargie par rapport à ν(OH)).

$$[13] \quad \Delta\nu(OH\cdots\pi) = \nu(OH, \text{phénol libre}) - \nu(OH\cdots\pi)$$

Pour le complexe OH···N le déplacement ne peut être mesuré facilement, car la bande ν(OH···N) est très large et peut être recouverte par les bandes ν(NH) de l'amine et les bandes ν(CH) du 4-fluorophénol et de l'amine. Ce déplacement ne sera donné qu'à titre indicatif (il est cependant souvent meilleur que ±10 cm^{-1}).

Fig. 1. Spectre IR dans la région ν(OH) d'une solution dans CCl_4 de 4-fluorophénol (4 mmol dm^{-3}) et de *N*,*N*-diméthylaniline (en large excès) montrant (**1**) la bande ν(OH) du 4-fluorophénol libre à 3614 cm^{-1}, (**2**) la bande ν(OH···π) d'un premier complexe 1 : 1, déplacée de 80 cm^{-1} et (**3**) la bande ν(OH···N) d'un second complexe 1 : 1 déplacée de 394 cm^{-1}.

Un spectre IR représentatif de la région ν(OH) des complexes des arylamines avec le 4-fluorophénol est montré sur la figure 1.

Calculs

Ils ont été effectués avec Gaussian 98 (28), le programme NBO (29) et, pour les potentiels électrostatiques, Molden (30), sur des ordinateurs bi-processeurs Xeon 2,2 GHz ou sur les calculateurs du Centre informatique national de l'enseignement supérieur et de l'Institut du développement et des ressources en informatique scientifique. Nous avons sélectionné 13 arylamines (composés **1**, **6–8**, **9–11**, **14**, **16**, **20**, **22**, **25**, **26** du tableau 1) couvrant toute la gamme de basicité π et N pour limiter le coût des calculs.

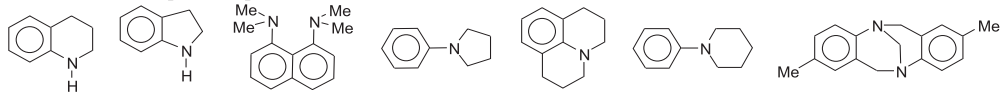
Géométrie des amines

Elles ont été totalement optimisées au niveau B3LYP/6-31+G(d,p). La conformation trouvée la plus stable par ce niveau de calcul est toujours en accord avec celle, expérimentale, des bases de données MOGADOC (31) pour la phase gazeuse ou CSD (32) pour l'état solide (la comparaison a pu être effectuée pour les composés **1**, **6**, **8**, **11**, **15**, **16**, **20**, **25** et **26** du tableau 1).

Potentiels électrostatiques

Ils sont calculés au niveau B3LYP/6-31+G(d,p)//B3LYP/6-31+G(d,p) sur la surface moléculaire définie, selon Bader et al. (33), par la surface d'isodensité électronique 0,001 e $bohr^{-3}$. Les premiers minima sont trouvés soit autour de l'azote soit au-dessus du nuage π. Ils sont notés $V_S(N)$ et $V_S(\pi)$.

Complexes de liaison H avec HF



Leur géométrie est optimisée au niveau B3LYP/6-31+G(d,p). Un calcul de fréquences confirme que la géométrie trouvée est un vrai minimum. L'énergie électronique de complexation est calculée au niveau MP2/6-31+G(d,p) par la méthode de la super-molécule (34). Elle doit donc être corrigée de l'erreur de superposition des bases (BSSE) (34).

Fig. 2. Géométries B3LYP/6-31+G(d,p) des complexes π de liaison H du fluorure d'hydrogène avec (*a*) l'aniline et (*b*) la 3-chloroaniline.

(***a***) (***b***)

Nous avons estimé cette correction par la méthode de Xantheas (35).

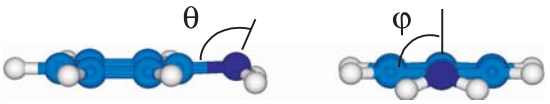
Pour la fixation de HF sur l'azote, la géométrie de départ choisie correspond à celle du complexe eau–aniline déterminée par spectrométrie micro-ondes (36). Pour la fixation sur le nuage π, nous avons placé HF perpendiculairement au noyau et pointant soit au centre, soit sur chacun des six carbones et nous avons considéré les deux faces du noyau (soit 14 géométries de départ). Pour l'aniline nous aboutissons sur chaque face à trois minima très proches en énergie, au niveau des carbones para et ortho (soit six minima au total). Le minimum absolu est trouvé au niveau du carbone para sur la face ne contenant pas la paire libre (fig. 2*a*). Pour les autres arylamines le minimum absolu est trouvé autour d'un carbone en ortho du groupe amino (fig. 2*b*) sur la même face.

Analyse NBO

Nous avons calculé au niveau MP2/6-31+G(d,p)//B3LYP/6-31+G(d,p), par la théorie de perturbation du second ordre, l'énergie d'interaction $E^{(2)}_{n\rightarrow\pi^*}$ entre la paire libre de l'azote et les orbitales antiliantes π* du cycle aromatique. Cette grandeur mesure la conjugaison de la paire libre de l'azote avec le nuage π du cycle.

De plus la localisation de la paire libre de l'azote permet de connaître son orientation à partir de deux angles θ et φ (fig. 3). L'angle θ (C_{ar}-N*n*) est défini par l'axe de la paire libre (*n*) et la liaison C_{ar}—N, tandis que l'angle de torsion φ (C_{ar}-C_{ar}-N*n*) est défini par l'axe de la paire libre (*n*) et le plan aromatique (C_{ar}-C_{ar}-N). L'orientation idéale pour une conjugaison maximum correspond à θ = 90° et φ = 90°.

Résultats et discussion



Détermination des constantes K_π et K_N

La détermination de K_π repose sur une relation (équation [14]) que nous avons établie

[14] $$pK_{HB}(\pi) = 1{,}09[\Delta\nu(OH)/100] - 1{,}02$$

dans un travail précédent (15) entre les valeurs pK_{HB} (pour un sextet π) et Δν(OH) de 17 bases π aromatiques (coefficient de corrélation r = 0,978 ; écart type s = 0,02). Cette relation entre l'énergie de Gibbs de complexation (c'est-à-dire pK_{HB} au facteur 2,303*RT* près) et le déplacement de la fréquence ν(OH) naît de la combinaison de la relation de Badger–Bauer (24) entre l'enthalpie de complexation et le déplacement Δν(OH) avec la relation de compensation entre

Fig. 3. Représentation des angles θ et φ mesurant l'orientation de la paire libre de l'azote de l'aniline.

l'enthalpie et l'entropie de complexation (24). Son domaine de validité est limité aux bases π dont le nuage π ne subit pas l'effet stérique de substituants encombrants (15). À partir des valeurs Δν(OH···π) expérimentales reportées dans le tableau 1 et de l'équation [14], on obtient donc K_π. Ces valeurs K_π ainsi que leur logarithme décimal $pK_{HB}(\pi)$ sont rassemblées dans le tableau 1.

La valeur K_N se déduit au moyen de l'équation [9] par différence entre la valeur K_t déterminée expérimentalement et la valeur K_π calculée ci-dessus.

Connaissant K_π (pour un sextet π) et K_N (pour un atome d'azote), on peut calculer les pourcentages de complexes π et N par les équations [15] et [16].

[15] $$\%C_\pi = 100mK_\pi/K_t$$

[16] $$\%C_N = 100 - \%C_\pi$$

Le tableau 1 rassemble (*i*) les valeurs expérimentales K_t, Δν(OH···π) et, à titre indicatif, Δν(OH···N), (*ii*) les valeurs calculées K_π et K_N, et le pourcentage de complexe π ($\%C_\pi$) et (*iii*) pour comparaison, les valeurs pK_{BH^+} de la littérature (1, 37) pour la protonation en phase aqueuse sur l'azote (en général à 25 °C).

Validation des constantes K_π et K_N

Notre méthode de séparation de la valeur expérimentale K_t en valeurs estimées K_π et K_N repose lourdement sur les qualités des déterminations expérimentales de K_t et Δν(OH···π) et de la relation [14] entre pK_{HB} (π) et Δν(OH···π), puisque nous n'avons pas trouvé de méthode pour estimer indépendamment K_N et que nous ne pouvons donc pas vérifier si la somme des valeurs estimées K_π et K_N (relation [9]) est bien égale à K_t.

Il est donc important de confronter les valeurs K_π et K_N estimées dans le paragraphe précédent à des descripteurs théoriques reconnus de la basicité de liaison H. Nous avons donc calculé (*i*) les potentiels électrostatiques autour de l'azote et du nuage π (tableau 2), (*ii*) l'enthalpie de complexation de HF avec le nuage π des arylamines (tableau 2) et (*iii*) l'énergie de Gibbs de l'échange de HF entre les sites π et N de l'aniline (réaction [10]).

Nous trouvons :

1° Une relation [17] satisfaisante entre les valeurs de K_π et le potentiel électrostatique minimum du nuage π, depuis l'arylamine de plus faible valeur K_π (3-chloroaniline **1**) jusqu'à celle de plus forte valeur K_π (julolidine **22**) :

[17] $$pK_{HB}(\pi) = 0{,}97(-V_S(\pi)/100) - 1{,}06$$

$$n = 13\ (\mathbf{1}, \mathbf{6}–\mathbf{11}, \mathbf{14}, \mathbf{16}, \mathbf{20}, \mathbf{22}, \mathbf{25}, \mathbf{26}),$$

$$r^2 = 0{,}885, \qquad s = 0{,}05$$

[a]Calculs au niveau B3LYP/6-31+G(d,p)//B3LYP/6-31+G(d,p).
[b]Calculs au niveau MP2/6-31+G(d,p)// B3LYP/6-31+G(d,p), avec correction de BSSE.

2° De bonnes relations entre les valeurs K_N des arylamines primaires [18], secondaires [19] et tertiaires [20] et le potentiel électrostatique minimum autour de l'azote :

[18] $pK_{HB}(N) = 1{,}63(-V_S(N)/100) - 1{,}63$

$n = 4$ (**1**, **6**–**8**), $r^2 = 0{,}970$, $s = 0{,}04$

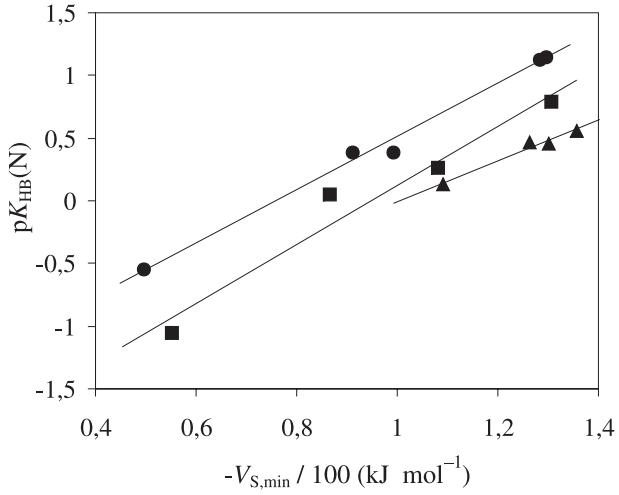
[19] $pK_{HB}(N) = 2{,}36(-V_S(N)/100) - 2{,}23$

$n = 4$ (**9**–**11**, **14**), $r^2 = 0{,}956$, $s = 0{,}20$

[20] $pK_{HB}(N) = 2{,}12(-V_S(N)/100) - 1{,}61$

$n = 5$ (**16**, **20**, **22**, **25**, **26**), $r^2 = 0{,}992$, $s = 0{,}07$

La séparation des arylamines en trois sous-familles (primaires, secondaires et tertiaires, fig. 4) est conforme à ce que nous avons déjà observé pour les amines aliphatiques (27).



3° Une excellente relation [21] entre les valeurs K_π d'arylamines et l'enthalpie de complexation de HF sur leur site π (la géométrie de ces complexes est illustrée par la fig. 2). À titre de comparaison nous avons calculé l'enthalpie de complexation de HF avec une base π monofonctionnelle, le benzène. Nous trouvons une valeur de –9,5 kJ mol^{-1}. Il est satisfaisant de remarquer (fig. 5) que le benzène, de $pK_{HB}(\pi)$ égal à –0,49 (15), vérifie la relation [21].

[21] $pK_{HB}(\pi) = 0{,}078(-\Delta H^\circ_{298}\ [11]) - 1{,}22$

$n = 6$ (**1**, **6**, **8**, **11**, **22** et C_6H_6), $r^2 = 0{,}998$, $s = 0{,}01$

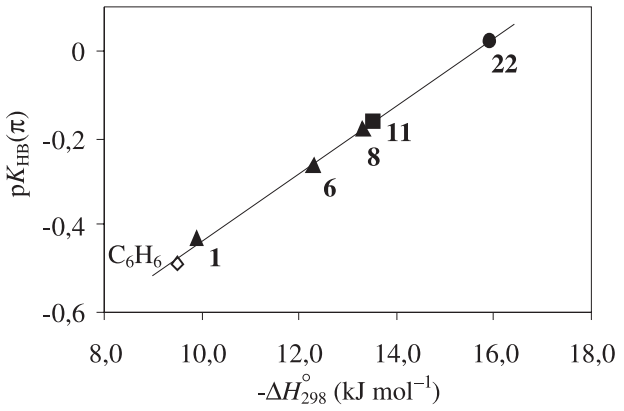
4° Un pourcentage de complexe π de 6 % (donc 94 % de complexe N) pour la liaison H de l'aniline avec HF. Ce pourcentage est obtenu à partir des paramètres thermodynamiques calculés au niveau MP2/6-31+G(d,p)//B3LYP/6-31+G(d,p) (avec correction de BSSE) pour la réaction d'isomérie de complexation [10], c'est-à-dire d'échange de HF entre les sites π et N de l'aniline :

Fig. 4. Relations entre le logarithme décimal des valeurs estimées K_N, $pK_{HB}(N)$, et le potentiel électrostatique minimum sur la surface moléculaire autour de l'azote ($V_{S,min}$(N)) pour des arylamines primaires (▲), secondaires (■) et tertiaires (●).

ΔH°_{298} [10] = –15,83 kJ mol^{-1}

ΔS°_{298} [10] = –29,8 J K^{-1} mol^{-1}

ΔG°_{298} [10] = –6,96 kJ mol^{-1}



K [10] = 16,3

Cette constante d'équilibre est égale à K_N/K_π, c'est-à-dire C_N/C_π. Le calcul de ΔS°_{298} [10] tient compte d'un facteur statistique R ln 6 correspondant aux six complexes π d'énergies très proches (vide supra).

Ce pourcentage de complexe π est en accord qualitatif satisfaisant avec la valeur de 16 % (K = 5,3) trouvée pour le complexe π de l'aniline avec le 4-fluorophénol. Il n'y a en effet aucun espoir de calculer avec précision les paramètres thermodynamiques, et en particulier l'entropie, de la réac-

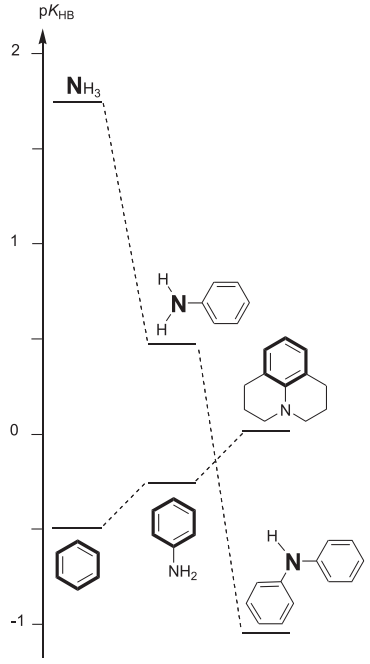
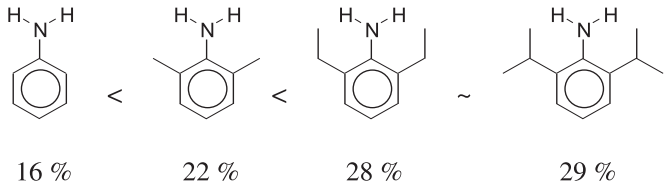
Fig. 5. Relation entre le logarithme décimal des valeurs estimées K_π, $pK_{HB}(\pi)$, et l'enthalpie de complexation de HF sur le site π d'arylamines primaires (▲), secondaire (■) et tertiaire (●), et du benzène (◇). Pour ce dernier la valeur K_π est une valeur expérimentale (15).

tion [10] (même si certaines erreurs de calcul peuvent se compenser dans cette réaction d'échange), ni aucune raison pour que les liaisons H avec l'aniline de HF in vacuo et du 4-fluorophénol en solution dans CCl_4 conduisent au même rapport de complexes π et N. Les calculs théoriques indiquent seulement, en accord avec les observations expérimentales, que si l'aniline accepte la liaison H majoritairement sur l'azote, le site π ne peut cependant pas être négligé.



Effets structuraux sur la compétition des sites π et N

Le chef de file des arylamines, l'aniline, est, en liaison H, une base π plus forte que le benzène ($pK_{HB}(\pi)$ = –0,26 et –0,49 respectivement) et une base azotée beaucoup plus faible que l'ammoniac ($pK_{HB}(N)$ = 0,46 et 1,74). Ces variations de basicité proviennent principalement de l'effet de résonance électrodonneur du groupe NH_2, pour la basicité π, et, pour la basicité N, des effets inductif et de résonance électroattracteurs du groupe C_6H_5. L'optimisation de ces effets, ainsi que l'introduction d'autres effets structuraux, peut conduire à des liaisons H plus fortes sur le site π que sur le site N dans certaines arylamines. Ainsi le nuage π de la julolidine ($pK_{HB}(\pi)$ = 0,02) est un meilleur accepteur de liaison H que l'atome d'azote de la diphénylamine ($pK_{HB}(N)$ = –1,05), par plus d'une unité de p*K*, c'est-à-dire plus de 6 kJ mol^{-1} en énergie de Gibbs. La figure 6 illustre ces effets sur l'échelle pK_{HB} de liaison H.



Dans une même molécule, il est ainsi possible de beaucoup moduler la basicité relative de liaison H des sites π et N, puisque la proportion de complexe π de l'aniline, qui est de 16 % vis-à-vis du 4-fluorophénol, peut monter à 92 % pour la diphénylamine (et probablement plus pour la triphénylamine) et descendre à 3 % ou 4 % pour la base de Tröger et la diamine 4-$Me_2NC_6H_4NMe_2$.

Certains effets structuraux influencent les basicités π et N dans le même sens et n'ont donc pas un effet décisif sur la compétition des sites π et N. C'est le cas de l'effet inductif électroattracteur des halogènes 3-F, 3-Cl, 4-Cl, 4-Br qui diminuent à la fois les basicités π et N. Ainsi $\%C_\pi$ de la 4-bromo-*N*,*N*-diméthylaniline (21 %) est pratiquement le même que celui de la *N*,*N*-diméthylaniline (22 %). De même

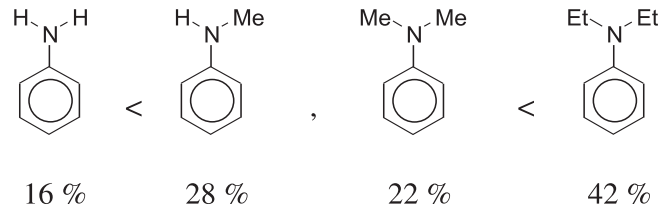


Fig. 6. Variations du pouvoir accepteur de liaison H des sites π du benzène, de l'aniline et de la julolidine et des sites N de l'ammoniac, de l'aniline et de la diphénylamine sur l'échelle pK_{HB}. La valeur pK_{HB} = 1,74 de l'ammoniac provient de la référence 27.

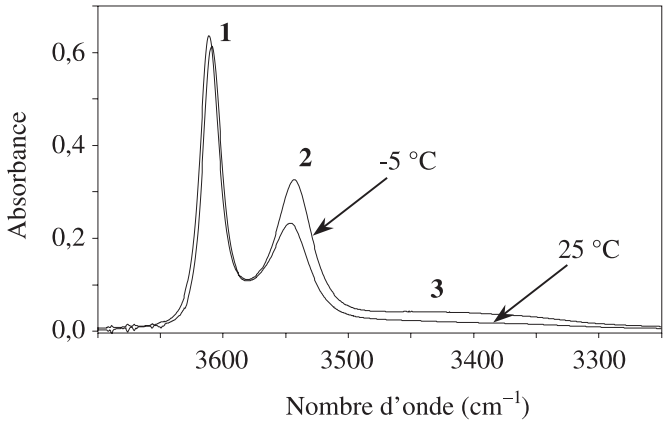
une alkylation du noyau aromatique augmente à la fois les basicités π et N et la 4-toluidine a un $\%C_\pi$ (15 %) très voisin de celui de l'aniline (16 %). Cependant une dialkylation en ortho de l'azote diminue la basicité de l'azote par effets stériques tout en augmentant la basicité π par effets électroniques, et on observe la séquence suivante de $\%C_\pi$:



L'alkylation de l'azote entraîne des effets stériques et électroniques complexes qui peuvent se contrarier. La séquence ci-dessous n'est donc pas régulière, bien qu'une alkylation croissante augmente généralement $\%C_\pi$. Les effets stériques d'encombrement de l'azote ont un effet spectaculaire dans l'éponge à proton qui devient très majoritairement (81 %) une base π de liaison H.

© 2004 CNRC Canada

Fig. 7. Spectres IR dans la région ν(OH) d'une solution de 4-fluorophénol (4 mmol dm^{-3}) et de triphénylamine (0,45 mol dm^{-3}) dans C_2Cl_4 à –5 et 25 °C montrant (**1**) la bande ν(OH) de 4-fluorophénol libre à 3614 cm^{-1}, (**2**) la bande ν(OH···π) d'un premier complexe 1 : 1 déplacée de 67 cm^{-1} et (**3**) la bande ν(OH···N) d'un second complexe 1 : 1 déplacée de 227 cm^{-1}.

La phénylation de l'azote augmente considérablement $\%C_\pi$ comme le montre le passage de l'aniline (16 %) à la diphénylamine (92 %). Le facteur statistique (deux phényles) s'ajoute ici aux autres effets structuraux. Nous n'avons pu calculer ce pourcentage de complexe π pour la triphénylamine, car cette molécule n'obéit pas à la relation [14]. En effet en multipliant par trois (trois phényles) la valeur de K_π calculée par [14] on aboutit à une valeur sensiblement supérieure à K_t, ce qui est impossible. Nous avons déjà observé (15) la même anomalie avec le triphénylméthane. Elle résulte probablement d'une non-équivalence des trois sites π et (ou) d'effets stériques qui sont bien connus (15) être un facteur limitant la validité de la relation [14]. La question se pose cependant de l'existence de complexes N pour la triphénylamine. Nous avons vérifié expérimentalement que la constante K_N de complexation sur l'azote n'est pas complètement nulle. Avec une solution concentrée en triphénylamine (0,5 mol dm^{-3}) et en diminuant la température jusqu'à –5 °C pour déplacer les équilibres vers la formation des complexes, nous voyons en effet apparaître (fig. 7) une très faible bande vers 3387 cm^{-1} que nous attribuons au complexe sur l'azote ($\Delta\nu$(OH···N) = 227 cm^{-1}).

La conjugaison de la paire libre de l'azote avec le système π du cycle aromatique constitue un facteur décisif dans la compétition entre sites π et N des arylamines, puisqu'elle fait varier les basicités π et N dans des sens opposés; la délocalisation de la paire libre vers le système π augmente la densité électronique π (38) (donc la basicité π) et diminue la densité électronique de l'azote (38) (donc la basicité N). Plus la conjugaison $n \rightarrow \pi^*$ est importante plus l'azote devient trigonal. Il est donc possible de mesurer cette conjugaison par (*i*) l'angle dièdre τ entre le plan NH_2 et le plan C_6H_5N (schéma 2) ou (*ii*) la somme Σα des angles autour de l'azote (schéma 3). Pour un azote tétraédrique τ = 54,7° et Σα = 328,4° et pour un azote trigonal τ = 0° et Σα = 360°. Il est aussi possible de localiser la paire libre de l'azote par la méthode NBO (25, 26) et de définir l'orientation de l'axe de cette paire par rapport au noyau aromatique par les angles θ et φ définis dans la figure 3. La conjugaison $n \rightarrow \pi^*$ est

Schéma 2.

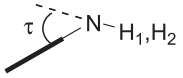


Schéma 3.

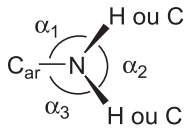

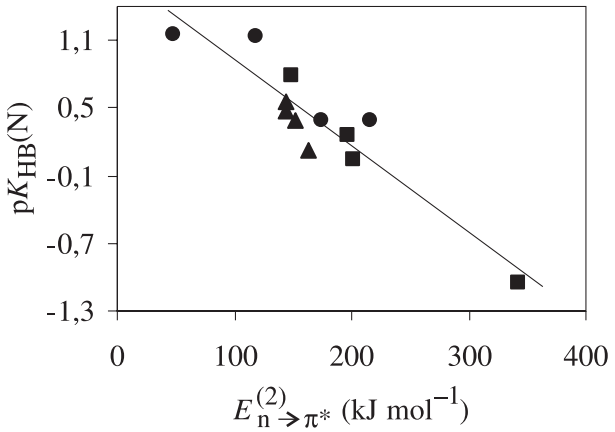

Fig. 8. Relation entre le pouvoir accepteur de liaison H de l'azote d'arylamines primaires (▲), secondaires (■) et tertiaires (●), mesuré par pK_{HB}(N), et l'énergie d'interaction $E^{(2)}_{n\rightarrow\pi^*}$: l'azote est d'autant plus basique que sa paire libre est moins conjuguée.

maximale quand θ et φ sont tous les deux égaux à 90°. La conjugaison augmente également comme l'énergie d'interaction calculée au second ordre ($E^{(2)}_{n\rightarrow\pi^*}$) entre l'orbitale (*n*) de la paire libre de l'azote et les orbitales π* du cycle aromatique. Nous avons calculé la géométrie B3LYP/6-31+G(d,p) de 13 amines et effectué leur analyse NBO au niveau MP2/6-31+G(d,p)//B3LYP/6-31+G(d,p). Les valeurs des angles τ, θ, φ et Σα, et de l'énergie ($E^{(2)}_{n\rightarrow\pi^*}$) sont reportées dans le tableau 3.

Ces valeurs permettent de montrer que la conjugaison $n \rightarrow \pi^*$ constitue un facteur significatif de la basicité π. L'énergie d'interaction $E^{(2)}_{n\rightarrow\pi^*}$ explique 41 % de la variance de $pK_{HB}(\pi)$ (r = +0,642, corrélation positive) pour neuf arylamines. Les amines chlorées **1** et **10** et celles ayant sur le noyau deux méthyles (**7**) ou deux méthylènes résidus de cycles (**22**) sont écartées de la corrélation, car leurs effets électroniques propres modifient fortement $pK_{HB}(\pi)$ et diluent l'effet de conjugaison de l'azote.

La conjugaison $n \rightarrow \pi^*$ est surtout déterminante pour la basicité N. L'énergie d'interaction $E^{(2)}_{n\rightarrow\pi^*}$ explique 86 % de la variance de pK_{HB}(N) (r = –0,930, corrélation négative) pour 12 arylamines (l'éponge à proton est écartée à cause des effets stériques) (fig. 8). Ainsi l'atome d'azote de la base de Tröger constitue-t-il le meilleur accepteur de liaison H, car la cyclisation contraint la paire libre à une orientation très défavorable à la conjugaison (θ = 108°, φ = 41°); les angles τ = 49,6° et Σα = 332,7° montrent également qu'il se rapproche de l'azote tétraédrique des amines aliphatiques.

Tableau 3. Paramètres géométriques (τ, θ, φ et Σα, (°)), et énergétique ($E^{(2)}_{n\rightarrow\pi^*}$, kJ mol^{-1}) pouvant décrire la conjugaison de la paire libre de l'azote avec le noyau aromatique dans les arylamines.

N°	Arylamine	τ	θ	φ	Σα	$E^{(2)}_{n\rightarrow\pi^*}$
1	3-Chloroaniline	37,0	105	89	345,2	163,2
6	Aniline	38,7	106	89	343,9	152,3
7	2,6-Diméthylaniline	38,5	106	88	343,9	144,3
8	4-Toluidine	40,0	106	89	342,6	143,9
9	Diphénylamine	0	90	64	360,0	171,5[a]
10	4-Chloro-*N*-méthylaniline	26,8	100	84	352,4	201,7
11	*N*-Méthylaniline	27,6	101	86	351,9	196,2
14	2,3-Dihydroindole	44,4	107	83	340,3	149,0
16	Éponge à proton	36,5	104	49	345,3	90,0
20	*N*,*N*-Diméthylaniline	20,9	98	90	355,5	215,5
22	Julolidine[b]	27,5	100	89	351,9	174,1
25	*N*,*N*,*N*′,*N*′-Tétraméthylbenzène-1,4-diamine[b]	35,7	103	60	346,1	118,8[c]
26	Base de Tröger	49,6	108	41	332,7	48,5

[a]À multiplier par 2 pour la corrélation avec pK_{HB}(N).
[b]Conformère le plus stable.
[c]À multiplier par 2 pour la corrélation avec pK_{HB} (π).

La cyclisation et la benzofusion contraignent également la paire libre de l'azote du 2,3-dihydroindole à une mauvaise orientation pour sa conjugaison (θ = 107°, φ = 83°), ce qui en fait l'azote secondaire le plus basique. Au contraire, la double cyclisation de la julolidine oriente favorablement la paire libre pour une conjugaison (θ = 100°, φ = 89°), ce qui rend l'azote peu basique (au contraire la julolidine est la meilleure base π par synergie de cette conjugaison et de l'effet donneur des deux méthylènes résidus de cycle).

Il est enfin intéressant de remarquer que chaque azote de la diamine 4-$Me_2NC_6H_4NMe_2$ est beaucoup plus tétraédrique (τ = 35,7°) que celui de la monoamine correspondante $C_6H_5NMe_2$ (τ = 20,9°), et que les paires libres de 4-$Me_2NC_6H_4NMe_2$ sont beaucoup moins bien orientées pour la conjugaison (θ = 103°, φ = 60°) que celles de $C_6H_5NMe_2$ (θ = 98°, φ = 90°). Il s'agit de la manifestation géométrique de l'effet de saturation de résonance observée sur les pK_{BH^+} des anilines substituées par un donneur π en para (39). Les effets que chaque groupe NMe_2 exerce sur l'autre dans 4-$Me_2NC_6H_4NMe_2$ conduisent à un azote pratiquement aussi bon accepteur de liaison H (pK_{HB}(N) = 1,13) que chaque azote de la base de Tröger (pK_{HB}(N) = 1,15).

Comparaison des échelles pK_{HB}(N) et pK_{BH^+}

Même pour des composés structuralement voisins comme les arylamines, nous n'observons pas de corrélation utile (n = 19, r^2 = 0,004, r^2 = 0,606 en excluant l'éponge à proton) entre les valeurs pK_{BH^+} et pK_{HB}(N) des amines pour lesquelles à la fois pK_{BH^+} et pK_{HB}(N) ont pu être déterminés. Nous avions déjà noté cette absence de corrélation pour les amines aliphatiques secondaires (17) et tertiaires (18).

Nous notons également dans ce travail des différences importantes entre sites de protonation et sites de liaison H : la liaison H se forme majoritairement sur le(s) nuage(s) π de l'éponge à proton, de la diphénylamine et de la triphénylamine, alors que ces composés sont des bases de Brønsted azotées. Ils rejoignent la tribenzylamine (18) et la 2,6-di-*tert*-butylpyridine (40) comme exemples supplémentaires de bases azotées aromatiques qui se protonent sur l'azote mais acceptent majoritairement la liaison H sur les électrons π.

L'usage de l'échelle pK_{BH^+} pour prévoir la basicité de liaison H doit donc cesser. C'est l'échelle pK_{HB} qui est l'échelle de choix pour étudier le comportement accepteur de liaison H des bases organiques.

Remerciements

Les auteurs remercient le Professeur Frank Weinhold (Université du Wisconsin, Madison) pour son aide dans l'analyse NBO et l'Institut du développement et des ressources en informatique scientifique (IDRIS, Orsay, France) et le Centre informatique national de l'enseignement supérieur (CINES, Montpellier France) pour l'attribution d'heures de calculs.

Tetraphosphinitoresorcinarene complexes — A new structural form of a rhodium(I) diphosphine complex[1]

Dana J. Eisler and Richard J. Puddephatt

Abstract: Tetrakis(diphenylphosphinito)resorcinarene ligands are shown to react with $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ to give tetrarhodium(I) complexes in which there are two dirhodium units, each having the unprecedented structure *syn*-$[Rh_2(\mu\text{-}Cl)_2(CO)_2P_2]$, P = phosphinite donor.

Key words: rhodium, resorcinarene, tetraphosphinite, carbonyl.

Résumé : On démontre que les ligands tétrakis(diphénylphosphinito)résorciranène réagissent avec le $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ pour conduire à la formation de complexes tétrarhodium(I) dans lesquels on retrouve deux unités dirhodiium de structure *syn*-$[Rh_2(\mu\text{-}Cl)_2(CO)_2P_2]$ inconnue jusqu'à maintenant et dans lesquelles P = donneur phosphinite.

Mots clés : rhodium, résorcinarène, tétraphosphinite, carbonyle.

[Traduit par la Rédaction]

Introduction

Rhodium complexes with phosphorus-donor ligands often display useful catalytic activity and so there has been intense interest in the synthesis and chemistry of such compounds. Some examples of chloro carbonyl complexes of rhodium(I) with phosphine ligands are illustrated in Chart 1 (1–4). For monodentate phosphine ligands, structures **A** and **B** are observed when the rhodium to phosphine ligand stoichiometry is 1:1, while the mononuclear structure **C** is formed when this ratio is 1:2 (1). In the case of diphosphine ligands, the chelate structure (**D**) and, more commonly, the bridged structure (**E**) have been observed when Rh:PP = 1:1 (2).

There is also much current interest in the development of ligands derived from calixarenes or resorcinarenes, which are bowl-shaped macrocyclic molecules that have a rich host–guest chemistry (4, 5). If the host–guest chemistry can be introduced adjacent to a catalytically active metal, it may be possible to discover size- and shape-selective catalysis. In this context, there have been several studies of rhodium complexes of calixarene based phosphorus-donor ligands, but there are no reports of similar complexes of resorcinarenes (4, 5). This article reports the first such rhodium(I) complexes, derived from the recently reported tetraphosphinitoresorcinarene ligands (6), and shows that they contain the structural type **F** (Chart 1), which is unprecedented for a diphosphine ligand (2).

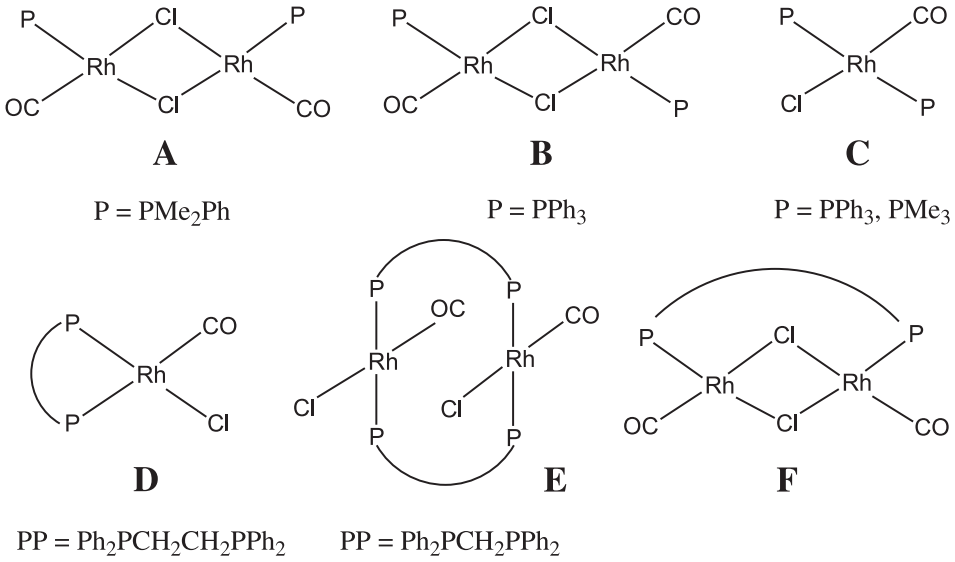
Results and discussion

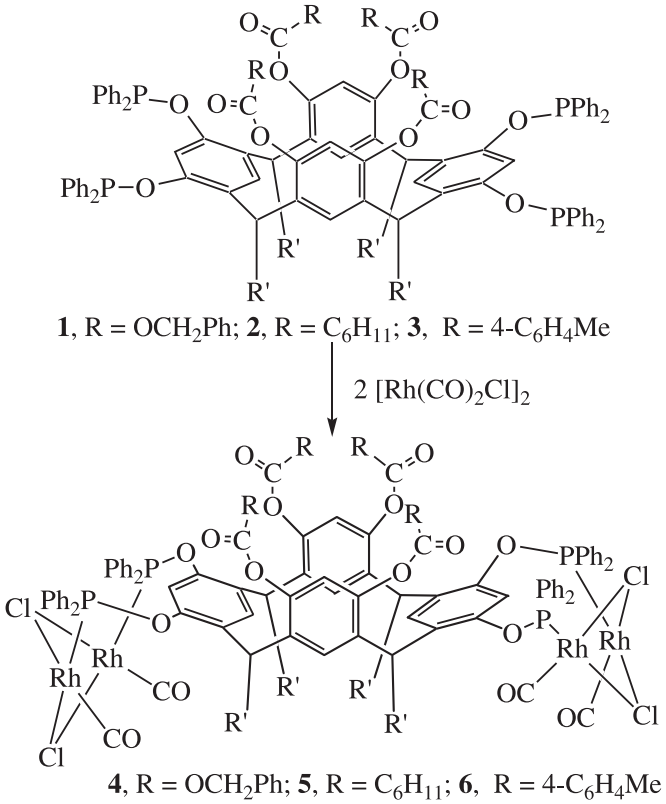
Synthesis of the complexes

The new chemistry is shown in Scheme 1. The tetrakis (diphenylphosphinito)resorcinarene compounds, **1**–**3**, tend to adopt a boat conformation and, if the phosphinite groups are in the equatorial positions, the compounds can act as bis(diphosphinite) ligands, with well-separated pairs of phosphorus donors (6).



Reaction of the tetrakis(diphenylphosphinito)resorcinarene compounds **1**–**3** with 2 equiv. of $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ gave the tetrarhodium(I) complexes **4**–**6**, as outlined in Scheme 1, in high yield. In these complexes, the ratio Rh:P = 1:1. Attempts to prepare complexes with ratio Rh:P = 1:2, as found in the known diphosphine complexes **D** and **E** (Chart 1), were unsuccessful. The complexes **4**–**6** were isolated as yellow solids, which were characterized spectroscopically and, in the case of complex **4**, by an X-ray structure determination.

Structural characterization of complex 4



The structure of complex **4** was determined crystallographically and is illustrated in Fig. 1, with selected bond distances and angles listed in Table 1. The resorcinarene skeleton of **4** adopts a boat conformation, with the phosphinite-derivatized arene rings in the flattened position and the acylated arene rings in the upright position. The angle between the planes made by the upright arene rings is 28° while the angle between the planes of the flattened arene rings is 154°. The resorcinarene skeleton is considerably twisted, as seen by the dihedral angles between opposing arene rings (upright 23°, flattened 22°).

Chart 1.

Scheme 1.

Each phosphorus donor (P) of the tetraphosphinito-resorcinarene ligand is involved in forming a *syn*-[$Rh_2(\mu\text{-}Cl)_2(CO)_2P_2$] unit. The type of dinuclear rhodium(I) unit present in **4** has been observed previously with monodentate phosphine ligands such as PMe_2Ph (**A**, Chart 1) and even for a monodentate calixarene-based phosphite ligand (4*b*). However, for diphosphine ligands, only chelate structures (**D**, Chart 1) or bridged structures (**E**, Chart 1), each with ratio Rh:P = 1:2, have been observed (2). No other diphosphine complex containing the binuclear $Rh_2(CO)_2(\mu\text{-}Cl)_2$ unit (**F**, Chart 1) has been structurally characterized, though a similar structure has been considered for a 1,4-bis(diphenylphosphino)butane derivative, based only on analytical data (2*c*). The unusual architecture of the resorcinarene ligands **1**–**3** is evidently suited for the selective formation of structure **F**. In particular, the P.P separations P1···P2 = 5.46 Å and P3···P4 = 5.44 Å are ideal for spanning the $Rh_2(\mu\text{-}Cl)_2$ unit, while the phosphorus donors are too far apart to chelate to a single rhodium atom as in **D** (Chart 1). Steric effects prevent formation of structure **E**. There is potential to form dirhodium complexes with similar structures by using simpler ligands of the type 1,3-$C_6H_4(CH_2PR_2)_2$.

The rhodium(I) centers have the usual square-planar stereochemistry in each case, and the angles between the planes of the adjacent $PRh(CO)Cl_2$ units (the fold angles) are 117° for each of the two [$Rh_2(CO)_2(\mu\text{-}Cl)_2P_2$] groups. The Rh—Cl bonds that are trans to the CO are all significantly shorter (2.377(1)–2.386(1) Å) than the Rh—Cl bonds trans to the phosphorus atoms (2.421(2)–2.424(1) Å).

For each molecule **4** there are 6.5 molecules of CH_2Cl_2 in the lattice. Most of these are in the voids between molecules, but two solvates can be considered as guest molecules, as illustrated in Fig. 2. One is in the cavity of the bowl structure, sandwiched between the benzylcarbonate groups, while the second is in the cavity beneath the bowl sandwiched between the phenethyl groups. This second dichloromethane solvate is loosely attached to one of the rhodium atoms, with the associated distance Rh(4)···Cl(1Q) = 3.90 Å.

Spectroscopic characterization and reactivity studies of the complexes

The ^1H and ^{31}P NMR spectra of complexes **4**–**6** were, in each case, consistent with the presence of a single species with effective C_{2v} symmetry. For example, in the ^1H NMR spectra, only single resonances were observed for the bridging methine protons and for the arene protons of the macrocyclic skeleton. The ^{31}P NMR spectra of the complexes each contained a single resonance, which appeared as a 1:1 doublet because of the coupling $^1J(^{103}Rh^{31}P)$, indicating equivalence of all four phosphorus atoms. For example,

Fig. 2. A view of the structure of complex **4** showing the positions of the two "guest" molecules of dichloromethane. The $Rh_2(\mu\text{-}Cl)_2(CO)_2P_2$ units are shown in red and the heavy atoms of the CH_2Cl_2 molecules are shown in blue. All phenyl groups are omitted for clarity.

complex **4** gave $\delta(^{31}P)$ = 126.0 (d, $^1J_{RhP}$ = 197 Hz). It has previously been shown that the conformation of the tetraphosphinitoresorcinarene ligand can be determined from the ^1H-, ^{13}C gHMBC-, and ^1H-, ^{31}P gHMBC-correlated NMR spectra (6). From similar studies, it was established that the resorcinarene skeleton in complexes **4** and **5** adopts the same boat conformation as found in the solid state structure of complex **4**, with the phosphinite-derivatized rings in the flattened position. The IR spectra of the complexes each showed two bands in the carbonyl region, separated by ca. 10 cm^{-1}, which is consistent with the cis arrangement of the rhodium dinuclear unit observed in the solid state structure of complex **4** (1*a*–1*k*).

The tetrarhodium(I) complexes **4**–**6** were stable to air in both solid and solution states, and they displayed low reactivity towards oxidative addition reactions. Thus, complex **4** failed to react with dihydrogen at 10 atm (1 atm = 101.325 kPa) pressure over 2 days. Complex **4** was found to react very slowly with excess methyl iodide, apparently mostly by halogen exchange. Thus, when monitored by the ^{31}P NMR spectrum, the doublet due to complex **4** at $\delta(^{31}P)$ = 126.0 (d, $^1J_{RhP}$ = 197 Hz) was replaced over a 10 day period

© 2004 NRC Canada

at room temperature by a new doublet at $\delta(^{31}P)$ = 120.7 (d, $^1J_{RhP}$ = 201 Hz). The similarity in these parameters suggests a very similar structure as **4**, but several minor products were formed that could not be separated. The reaction of complex **4** with excess trimethylphosphine led to complete displacement of the rhodium atoms to give the known complex *trans*-[RhCl(CO)$(PMe_3)_2$] (1) and the free resorcinarene ligand **1**. The low reactivity of complex **4** compared with analogous rhodium(I) complexes with simpler phosphorus-donor ligands (1, 2) is most easily rationalized in terms of the high steric hindrance at the rhodium(I) centers. Although dihydrogen is small, the required cis stereochemistry of oxidative addition will lead to unfavorable steric effects between the other substituents.

In summary, the tetraphosphinitoresorcinarene ligands **1**–**3** have given the first examples of dirhodium(I) complexes with the *syn*-[$Rh_2(\mu\text{-}Cl)_2(CO)_2P_2$] stereochemistry and it is shown that the new geometrical form is favoured by the natural bite distance of pairs of phosphinite donors of the ligands. The dirhodium(I) units are sterically shielded, and therefore, exhibit only low reactivity.

Experimental

All reactions were performed under a nitrogen atmosphere using standard Schlenk techniques. Solvents were freshly distilled, dried, and degassed prior to use. NMR spectra were recorded using a Varian Inova 400 NMR spectrometer. The tetraphosphinite resorcinarene ligands **1**–**3** were prepared as reported elsewhere (6*a*). In the following formulae, the resorcinarene skeleton $(C_6H_2CH\{CH_2CH_2Ph\})_4$ is represented as Resorcinarene

[Resorcinarene$(OC(O)OCH_2Ph)_4(OPPh_2\{Rh(CO)Cl\})_4$] (4)

A mixture of ligand **1** (0.100 g, 0.046 mmol) and [$Rh(CO)_2\mu$-Cl]$_2$ (0.036 g, 0.093 mmol) in CH_2Cl_2 (10 mL) was stirred for 16 h. The resulting yellow solution was filtered through Celite and a yellow solid was precipitated with *n*-hexane. The solid was collected and washed with diethyl ether (5 mL). Yield 0.095 g, 73%. FT-IR ν(CO) (cm^{-1}): 2007, 1997. ^{1}H NMR (CD_2Cl_2) δ: 2.04, 2.19 (m, 8H, $CHCH_2CH_2Ph$), 2.30, 2.40 (m, 8H, $CHCH_2CH_2Ph$), 4.85 (m, 8H, $^2J_{HH}$ = 12 Hz, OCH_2Ph), 4.89 (t, 4H, $^3J_{HH}$ = 5 Hz, $CHCH_2CH_2Ph$), 6.53 (s, 2H, Ar-*H*, meta to *C*$OPPh_2$), 7.08 (s, 2H, Ar-*H*, ortho to *C*$OC(O)OCH_2Ph$), 7.76 (s, 2H, Ar-*H*, meta to *C*$OC(O)OCH_2Ph$), 7.77 (s, 2H, Ar-*H*, ortho to *C*$OPPh_2$), 6.61–8.12 (m, 80H, Ar-*H*, *Ph*). 31P NMR δ: 126.0 (d, $^1J_{RhP}$ = 197 Hz). Anal. calcd. for $C_{144}H_{116}Cl_4O_{20}P_4Rh_4$ (%): C 60.82, H 4.11; found: C 60.65, H 4.00.

[Resorcinarene$(OC(O)C_6H_{11})_4(OPPh_2\{Rh(CO)Cl\})_4$] (5)

This was prepared similarly from ligand **2** (0.100 g, 0.048 mmol) and [$Rh(CO)_2\mu$-Cl]$_2$ (0.038 g, 0.098 mmol). Yield 0.088 g, 67%. FT-IR ν(CO) (cm^{-1}): 2008, 1996. ^{1}H NMR (CD_2Cl_2) δ: 1.22–2.08 (m, 48H, $CHCH_2CH_2Ph$, C_6H_{11}), 2.29 (m, 4H, $CHCH_2CH_2Ph$), 2.51, 2.65 (m, 8H, $CHCH_2CH_2Ph$), 4.72 (m, 4H, $CHCH_2CH_2Ph$), 6.46 (s, 2H, Ar-*H*, meta to *C*$OPPh_2$), 6.84 (s, 2H, Ar-*H*, ortho to *C*$OC(O)C_6H_{11}$), 7.74 (s, 2H, Ar-*H*, meta to *C*$OC(O)C_6H_{11}$), 7.80 (s, 2H, Ar-*H*, ortho to *C*$OPPh_2$), 6.20–7.20 (m, 60H, Ar-*H*, *Ph*). ^{31}P NMR δ: 128.7 (d, $^1J_{RhP}$ = 199 Hz). Anal. calcd. for $C_{140}H_{132}Cl_4O_{16}P_4Rh_4$ (%): C 61.19, H 4.84; found: C 60.93, H 4.76.

[Resorcinarene$(OC(O)C_6H_4CH_3)_4(OPPh_2\{Rh(CO)Cl\})_4$] (6)

This was prepared similarly from ligand **3** (0.100 g, 0.047 mmol) and [$Rh(CO)_2\mu$-Cl]$_2$ (0.037 g, 0.095 mmol). Yield 0.094 g, 72%. ^{1}H NMR (CD_2Cl_2) δ: 1.92, 2.12 (m, 8H, $CHCH_2CH_2Ph$), 2.52 (s, 12H, $C_6H_4CH_3$), 2.61 (m, 8H, $CHCH_2CH_2Ph$), 4.94 (m, 4H, H^i), 6.26–8.04 (m, 84H, Ar-*H*, *Ph*, $C_6H_4CH_3$). ^{31}P NMR δ: 128.3 (d, $^1J_{RhP}$ = 200 Hz). FT-IR ν(CO) (cm^{-1}): 2007, 1995. Anal. calcd. for $C_{144}H_{116}Cl_4O_{16}P_4Rh_4$ (%): C 62.22, H 4.21; found: C 62.16, H 4.41.

X-ray structure determination

Crystals of [Resorcinarene$(OC(O)OCH_2Ph)_4(OPPh_2\{Rh(CO)Cl\})_4$] (**4**) as the dichloromethane solvate ($[C_{144}H_{116}Cl_4O_{20}P_4Rh_4]\cdot 6.5(CH_2Cl_2)$) were grown by diffusion of *n*-hexane into a dichloromethane solution. A crystal was mounted on a glass fiber, and data were collected using a Nonius-Kappa CCD diffractometer using COLLECT software (7). The unit cell parameters were calculated and refined from the full data set. Crystal cell refinement and data reduction were carried out using the Nonius DENZO package (7). The data were scaled using SCALEPACK (7). The SHELXTL V6.1 program package was used to solve and refine the structure (7). The structure was solved by direct methods. The hydrogen atoms were calculated geometrically and were riding on their respective carbon atoms. Except as mentioned, all non-hydrogen atoms were refined with anisotropic thermal parameters. Crystal data are summarized in Table 2.[3] The thermal ellipsoid diagram is shown at 30% probability.

There was some disorder of the molecules, as follows. One of the O*CH$_2$Ph* groups was modeled as a 55:45 isotropic mixture, and one of the phenethyl substituents was modeled as a 50:50 isotropic mixture; in both cases geometric restraints were applied. The carbon–chlorine bond lengths of the solvent molecules were fixed at the standard distance. The largest residual electron density peak (3.053 e/Å^3) was associated with one of these solvent molecules.

Coordination arrays — Synthesis and characterization of tetranuclear complexes of grid-type[1]

Garry S. Hanan, Dirk Volkmer, and Jean-Marie Lehn

Abstract: A series of tetranuclear metal complexes of grid-type consisting of four bis-tridentate ligands and four divalent transition metal ions were synthesized and characterized. The ^{1}H NMR spectra of diamagnetic complexes containing Zn(II), Cd(II), Fe(II), and Ru(II) was correlated to the radius of the metal ion. The UV–vis and electrochemical results indicated that the bridging ligand π^* orbital and the d_π metal orbital are stabilized by complexation of more than one metal ion. Furthermore, the Co(II) and Fe(II) grids exhibit metal–metal interaction mediated by the bis-tridentate ligands as indicated by electrochemical and spectroscopic methods. These results provide guidelines for the design of larger grids bearing several metal centres in a square arrangement, which also represent potential components of molecular electronic devices.

Key words: complexes with nitrogen ligands, octahedral metal ions, self-assembly, supramolecular chemistry.

Résumé : Des complexes tetramétalliques composés de métaux de transitions et des ligands bis-tridentates ont été synthétisés et caractérisés. Les interactions métales-métales de ces « grilles moléculaires » ont été mesurées par des méthodes spectroscopiques et électrochimiques et ont indiqué des fortes interactions entre les métaux pour les grilles de Co(II) et Fe(II). Les spectres de rmn ^{1}H des complexes diamagnétiques du Zn(II), Cd(II), Fe(II) et Ru(II) ont été corrélées au rayons des ions métalliques. Ces résultats permettent le design de nouvelles grilles carrées comme éléments des appareils électroniques moléculaires.

Mots clés : complexes avec des ligands azotés, ions métalliques octaédriques, autoassemblage, chimie supramoléculaire.

Introduction

Polynuclear metal complexes can perform useful functions that mononuclear metal complexes cannot, such as multi-electron redox (1) and light-harvesting processes (2). Our early work concerned the assembly of inorganic architectures based on tetrahedral metal ions, exemplified by the formation of helicates (3, 4), rods (5), and cylinders (6). The thermodynamic and entropic factors involved in the assembly of these polynuclear complexes have also been studied (7, 8). We previously established that structures of defined nuclearity, *coordination arrays*, could be assembled (9). Rack- (10, 11), ladder- (12), and grid-type (13–15) molecules are ordered inorganic architectures comprising one- or two-dimensional geometries of $[m \times n]$ nuclearity and presenting — in sequence of increasing complexity — basic geometries that may be termed *racks* $[n]$R, *ladders* $[2n]$L, and *grids* $[m \times n]$G (Fig. 1), where the nuclearity of the R, L, and G species is given by $[n]$, $[2n]$, and $[m \times n]$, with n (for a square grid) representing their rank.

Although metal ions that prefer a tetrahedral coordination environment are well suited for the assembly of ladder- and grid-like molecules (12, 13), their response to electrochemical and photonic stimuli are of limited interest as they may change coordination geometry during redox processes. Metal ions with octahedral coordination environments are better suited for building up coordination arrays due to their stability under a range of redox and excitation conditions. The complexes of octahedrally coordinated metal ions also present a much richer palette of physical and chemical properties than tetrahedrally coordinated metal ions such as Ag(I) and Cu(I).

In this paper, we describe the general synthesis and properties of [2 × 2] grids incorporating bis-tridentate ligand **1a** and two paramagnetic metal ions ($[Co(\mathbf{1a})]_4[PF_6]_8$ (**2a**), $[Ni(\mathbf{1a})]_4[PF_6]_8$ (**3a**)) and four diamagnetic metal ions ($[Zn(\mathbf{1a})]_4[PF_6]_8$ (**4a**), $[Cd(\mathbf{1a})]_4[PF_6]_8$ (**5a**), $[Fe(\mathbf{1a})]_4[PF_6]_8$ (**6a**), and $[Ru(\mathbf{1a})]_4[PF_6]_8$ (**7a**)). The synthesis and properties of the Co(II) complex of ligand **1b** $[Co(\mathbf{1b})]_4[PF_6]_8$ (**2b**) are also described.

Results and discussion

The synthetic strategy follows that previously reported for [2 × 2] grid-type structures (15) and the one established for polypyridyl helicates (16, 17). The metal salt and the ligand are combined in equimolar amounts in protic solvents (or a mixture of protic solvent and water), heated to reflux, and precipitated by the addition of NH_4PF_6. For Zn(II), Cd(II), Co(II), and Ni(II), analytically pure complexes are obtained by treating an acetonitrile solution of the isolated solid with activated charcoal, filtration, and recrystallization. The yields varied between 48% and 82% for reactions with **1a** with the various metal ions. The reaction of **1b** with Co(II) gave **2b** in 28% yield. For the reactions of **1a** with Fe(II) or Ru(II), **6a** and **7a** were only isolable in small quantities. Purification was afforded by repeated chromatography on Sephadex CM-25 (18). The use of alumina or silica as for other polynuclear metal complexes led to complete adsorption of the cations to the chromatographic support. The low yield of the Ru complex (2%) precluded its complete characterization.

^{1}H NMR spectra

The ^{1}H NMR chemical shifts of ligand **1a** and the diamagnetic complexes **4a**–**7a** are reported in Table 1. The proton labelling scheme is given in Fig. 2. The symmetric nature of the grids is demonstrated by the relative simplicity of the ^{1}H NMR spectra of **4a**–**7a**. A total of 64 protons are accounted for by nine peaks, seven of which integrate to eight protons each, and are ascribed to the protons on the bipyridyl moieties. The coupling constants (J (H_5H_6) ≈ 5; J (H_3H_4) = J (H_4H_5) ≈ 7; J (H_3H_5) ≈ 1 Hz) are typical for pyridyl protons. Decoupling experiments reveal the locations of $H_{3''}$ relative to the $H_{3'}$–$H_{5'}$ pair. $H_{6''}$ is evident from its upfield shift and coupling constant. The pyrimidine protons stand out either as doublets with J (H_2H_5) ≈ 1 Hz or as broadened singlets. One of the pyrimidinyl protons is shifted upfield relative to its position in uncoordinated ligand **1a** and is ascribed to the pyrimidine H_2 proton, which is found in a shielding environment upon metal complexation.

The radius of the coordinated metal ion plays an important role in the amount of pinching found in metal bis–tpy complexes in the solid state. In general, the smaller the cation, the more the ligands distort as they "pinch in" around the metal ions (19). Solid state structural information was related to solution ^{1}H NMR results and gave a general idea of the solution structure of a complex by the relative shifts of H_2, $H_{4'}$, and $H_{6''}$ (11, 20). By relating the proton NMR chemical shifts to cation size a qualitative degree of pinching in can be determined for the grids.

Two pairs of metals from the same group can be compared (Table 2). The chemical shifts of H_2 and $H_{6''}$ are less shielded in the cadmium complex relative to the zinc complex. The iron and ruthenium pair show similar effects; the larger Ru(II) cation causes less shielding of H_2 and $H_{6''}$ relative to the Fe(II) cation (Table 2). The opposite effect is noted for $H_{4'}$: for each pair of metal ions, the larger cation causes less deshielding of $H_{4'}$ as the ligand pinches in less, moving the deshielding zone of the terminal pyridine farther away from $H_{4'}$. The metal ion is farther away from $H_{4'}$ than H_2 and $H_{6''}$, and contributes little to shielding factors at this position.

When a larger cation is coordinated, $H_{6''}$ is farther away from the shielding effects of the orthogonal ligand (less pinching-in). The shielding of H_2, therefore, is not as pronounced when a larger cation is coordinated. This is clearly evident in the larger shielding of H_2 and $H_{6''}$ by coordination of the d^6 metals relative to the d^{10} metals. Since the d^6 metal

[c]In DMF.

ions in low-spin configuration have smaller atomic radii than d^{10} metal ions in the same row (21), they should cause a greater convergence of the ancillary ligands, and hence, greater shielding of H_2 and $H_{6''}$. The greater charge density on the smaller cation may also contribute to the greater shielding of H_2 and $H_{6''}$ (22).

The assignment of $H_{3'}$ — $H_{5'}$ and H_2 — H_5 for the zinc complex **4a** was made by nOe experiments. In the free ligand, $H_{3'}$, $H_{5'}$, and H_5 do not interact with neighbouring protons on the adjacent rings via nOe owing to ligand preference for a transoid conformation. However, upon complexation the ligand lines up in cisoid conformation, allowing nOe interactions between heterocycles. Distinct nOe interactions occur along the ligand backbone with selective irradiation of **4a**. The relative positions of $H_{3'}$, $H_{5'}$, and H_5 for the other complexes may be inferred from these results (i.e., downfield position of $H_{5'}$ relative to $H_{3'}$, and downfield position of H_5 relative to H_2).

Infrared spectroscopy and mass spectrometry

All of the complexes exhibited ligand-based IR bands near 1600, 1450, and 560 cm^{-1}. Very strong bands near 845 cm^{-1} associated with the $[PF_6]^-$ counteranions were also present. The presence of both the $[PF_6]^-$ and the ligand bands is indicative of metal-to-ligand coordination (16).

Positive-ion FAB-MS was informative about the nature of these complexes, particularly for complexes of paramagnetic metal ions. The parent ion minus one counteranion was found in all cases. After the loss of the first $[PF_6]^-$ anion, successive losses of $[PF_6]^-$ counterions ensued, with losses of up to five $[PF_6]^-$ anions. The zinc and cadmium complexes (**4a** and **5a**) fragmented under FAB conditions. Losses of ligand **1a** from **4a**, and **1a** and two Cd(II) from **5a** were observed. In both cases, the peaks at the corresponding masses could be ascribed with certainty to a fragmentation since a M_4L_3 complex would exhibit a less symmetric ^{1}H NMR spectrum.

UV–vis spectroscopy

The UV–vis band maxima (λ_{max}) and molar absorptivities (ε) for the complexes and the free ligands **1a** and **1b** are listed in Table 3. Two types of bands, those involving pyridine and pyrimidine transitions, are observed in the UV region. The intensities of the ligand-centered (LC) transitions increase upon complexation by metal ions as the relative concentration of ligand increases in the complex compared to the free ligand. In the spectra of the metal complexes, these bands generally appear at slightly lower energies, but with greater intensities. Similar LC transitions have been described as roughly additive in other polypyridyl complexes (23). Metal complexes of **1a** and **1b** all exhibit a red-shift in the lower energy pyrimidine π–π^* transitions. The λ_{max} for the higher energy pyridine π–π^* transitions shift only slightly, whereas their intensity increases considerably (Table 3).

The orange nickel complex **3a** exhibits a single band in the visible region at 511 nm (ε = 2020 L mol^{-1} cm^{-1}). The relatively strong molar absorptivity for **3a** is unusual as the ε values for metal-centred (MC) transitions in Ni(II) octahedral complexes are normally lower (21). Distortions in the coordination environment of Ni(II) in **3a** may account for the greater ε value. A sterically strained Ni(II) catenate was reported and the orange complex was found to exhibit a MC transition in the visible region (λ_{max} ~ 480 nm, ε ~ 450 L mol^{-1} cm^{-1}) (24).

The green iron complex **6a** exhibits two distinct absorption maxima in the visible region at 490 and 616 nm, respectively (Fig. 3). The bands are attributed to MLCT transitions to the bipyridyl and pyrimidinyl moieties of **1a**, respectively, as the pyrimidine LUMO should be at lower energy than the

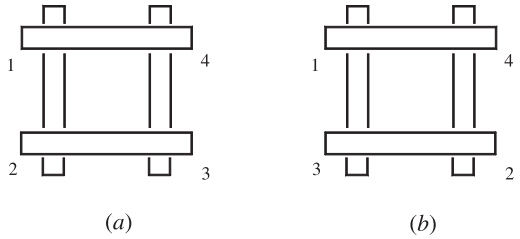
pyridine LUMO. This is further supported by electrochemical studies of **6a** (vide infra).

The visible absorption spectra of the brown cobalt complexes **2a** and **2b** exhibit a broad band near 445 nm that was ascribed to the bipyridyl MLCT transition. A broad, lingering band out to approximately 550 nm was attributed to the pyrimidinyl MLCT transition.

Electrochemical measurements

In general, the complexes exhibit several metal- and ligand-based reductions, and in a few cases, reversible metal-based oxidations are observed. In dinuclear ruthenium complexes, ligands **1a** and **1b** mediate significant metal–metal electronic communication (11). In the grids, owing to the D_{2d} symmetry of the complexes, each metal and ligand coordination environment is identical and, thus, different reduction potentials for the bridging ligand and oxidation potentials for the metals are an indication of electronic communication (23, 25). The redox potentials vs. SCE for the complexes and ligands **1a** and **1b** are given in Table 4.

Nickel complex **3a** displays an irreversible [Ni^{II}–Ni^{III}] oxidation at +2.17 V, at the edge of the solvent potential window. On scanning the potential past the oxidation at +2.03 V, upon return, irreversible waves are observed at +0.43, –0.16, and 0 V. These waves are not observed if the scans return before +1.90 V. As Ni(III) complexes are generally highly reactive (21), oxidation of **1a** and the return to a Ni(II) state may be occurring. The first two reductions may be associated with reduction of previously oxidized ligands. It was previously shown that various divalent metals (i.e., Ni, Fe, and Co) in phenanthroline catenates do not oxidize to their trivalent state, instead, ligand-based oxidations occur at $E^{\circ} >$ +1.4 V (26).



In the negative potential region, the first two reductions occur at –0.40 and –0.52 V and are ascribed to the reduction of the four pyrimidines in **3a**. Each reduction involves two electrons and is fully reversible. These reduction potentials are quite positive compared to Ni(II) bis–tpy metal-based reductions (–1.53 V) (27), which supports their assignment as ligand-based processes. Four irreversible reductions occur thereafter (–0.98, –1.18, –1.32, –2.00 V) with adsorption of the formally neutral complex to the electrode, as exemplified by a stripping peak at –1.22 V.

The zinc **4a** and cadmium **5a** complexes exhibit neither metal- nor ligand-based oxidations, as expected for d^{10} metal ions. The ligand-based reductions in **4a** were grouped in two sections: two reversible one-electron processes at –0.28 and –0.38 V, followed by a two simultaneous and reversible one-electron process at –0.48 V. At more negative potentials, two reversible one-electron processes at –0.90 and –1.09 V are followed by adsorption of the complex to the electrode at –1.25 V, and a stripping peak at –2.08 V. Complex **5a** undergoes a single ligand-based reversible reduction at –0.46 V upon scanning to –0.5 V. Scanning to further negative potentials renders the first reduction irreversible. The reduction is assigned to a ligand-based process rather than a cadmium-based reduction by analogy to the zinc case. An irreversible process at –0.58 V is followed by a succession of adsorptions and stripping peaks at similar potentials to those of the zinc complex.

Iron complex **6a** displays four reversible one-electron oxidation processes at +1.39 V, +1.52 V, +1.71 V, and +1.83 V, and are considerably more positive than those reported for $Fe(tpy)_2$ (+1.18 V) and are similar to those reported for the dinuclear helicate Fe_2(2,2′:6′,2″:6″,2‴:6‴,2⁗:6⁗,2⁗′:6⁗′,2⁗″-sexipyridine)$_2$ (+1.35, +1.50 V) (16). The $\Delta E^{\circ\prime}$ values between successive oxidations have previously been used as a measure of metal–metal communication (28–33). The four one-electron oxidations in **6a** occur most likely by the successive oxidations of opposing metal centres ($\Delta E^{\circ\prime}$ (Fe(1)–Fe(2)) = 0.13 V; $\Delta E^{\circ\prime}$ (Fe(2)–Fe(3)) = 0.19 V; $\Delta E^{\circ\prime}$ (Fe(3)–Fe(4)) = 0.12 V). The postulated order of metal oxidations maintains a maximum distance between oxidized species to

© 2004 NRC Canada

Fig. 4. Possible order of Fe(II) oxidations in the tetranuclear Fe(II) grid **6a**: (*a*) sequential adjacent Fe(II) centres; (*b*) double diagonal Fe(II) centres.

minimize electrostatic repulsion between them (Fig. 4). The greater difficulty in oxidizing the third Fe(II), with two adjacent Fe(II), relative to the second Fe(II), with no adjacent Fe(II), supports the diagonal oxidation pathway (Fig. 4*b*). The difference in the Fe(II) oxidation potentials can be explained by direct electronic communication through the pyrimidine–Fe(II)–pyrimidine bridge and the increase in positive charge on the complex as it is oxidized.

In the negative potential region, a reversible two-electron reduction occurred at –0.19 V, followed by two reversible one-electron reductions at –0.31 and –0.45 V. These four ligand-based reductions are ascribed to the reduction of the central pyrimidines in each strand of **1a**. The coincidental positioning of the first two reductions supports the diagonally opposed metal oxidation route; two adjacent pyrimidines should not reduce at the same potential. The next four one-electron reductions are irreversible.

The oxidation of cobalt complex **2a** in DMF was similar to that of **7**, except that it occurred at less positive values. This is in accord with potentials reported for $M(tpy)_2$ complexes (M = Fe(II), Co(II), Ni(II)) (28). However, the metal-based oxidations are not strictly reversible. The first oxidation at +0.46 V vs. SCE is quasireversible with $\Delta E1/2$ = 70 mV. For the following two-electron oxidation, $\Delta E1/2$ = 110 mV, which is ascribed to the close proximity of two oxidation waves, and not to the irreversibility of the wave. These values are lower than the values for $Co_2(sexipy)_2$, which show metal oxidation at +0.84 and +1.17 V (16). The $\Delta E°'$ values for the [Co^{III}–Co^{II}] and [Co^{II}–Co^{I}] processes in DMF are (0.20, 0, and 0.25 V) and (0.10, 0.20, and 0.41 V), respectively.

The [Co^{II} – Co^{I}] reduction in **2a** was more positive than that of $Co_2(sexipy)_2$ (–0.51 and –0.67 V), which is consistent with earlier work (16). The difference in formal potentials for the four metal-based reductions is greater than those of the metal-based oxidations. There are four reversible one-electron reductions at –0.83, –1.09, –1.33, and –1.77 V, as well as a reversible two-electron reduction at –1.54 V and an irreversible one-electron reduction at –1.94 V, attributable to ligand-localized reductions.

Conclusion

The grid-like complexes described herein exhibit several interesting features: (1) highly symmetric ^{1}H NMR spectra for the diamagnetic complexes; (2) successive loss of $[PF_6]^-$ counterions from the parent molecular ions in FAB-MS; and (3) intermetallic electronic communication for oxidation and reduction processes in electrochemical measurements. Indeed, single site redox processes are possible with these highly symmetric complexes. The best example ($[Fe(\mathbf{1a})]_4[PF_6]_8$, (**7**)) exhibits total communication among the metal centres electrochemically, yet has high symmetry in solution on the NMR timescale. The rigid nature of these ligands is well suited for the synthesis of tetrametallic grids. The assembly of larger grids using longer rigid polytridentate ligands (31) and by the stringing together of smaller 2 × 2 grids via hydrogen bonding (32) has led to novel applications for grid-like complexes, such as their surface ordering as models of molecular-level information storage devices (33).

Experimental

Reagent solvents, chromatographic supports, TLC supports, and analytical instrumentation were as described previously (34). Unless otherwise noted, materials were obtained from commercial suppliers and used without further purification. Ligands **1a** and **1b** were synthesized as described (34). ^{1}H and ^{13}C NMR spectra were measured in CD_3CN locked to the deuterated solvent and calibrated to the residual solvent peak. The proton labelling is as shown in Fig. 2. Brief synthetic details for complexes **2a** and **2b** were given previously (15).

Preparation of $[Co(\mathbf{1a})]_4[PF_6]_8$ (2a)

To a suspension of **1a** (0.0510 g, 0.131 mmol) in methanol (15 mL) was added cobalt acetate tetrahydrate (0.0080 g, 0.0278 mmol) in methanol (5 mL). The reaction mixture was heated at reflux for 1.5 h. The colourless suspension gave way to a dark brown solution. Excess methanolic ammonium hexafluorophosphate was added to the hot reaction mixture leading to immediate precipitation of a brown solid. The solid was washed with methanol (2 × 10 mL) and water (2 × 10 mL) and was filtered. The solid was dissolved in acetone and was reprecipitated by the addition of diethyl ether giving **2a** (0.0796 g, 82%) as a brown solid; mp > 300 °C. IR (cm^{-1}): 1606, 1466, 844, 559. *m/z* (FAB): 2802 (M – 145 (-PF_6)), 2659 (M – 288 (-2PF_6)), 2516 (M – 431 (-3PF_6)), 2369 (M – 578 (- PF_6)). Anal. calcd. for $C_{96}H_{64}F_{48}N_{24}P_8Co_4$: C (39.09), H (2.19), N (11.40); found: C (38.78), H (2.63), N (11.01).

Preparation of $[Co(\mathbf{1b})]_4[PF_6]_8$ (2b)

To a suspension of **1b** (0.0402 g, 0.100 mmol) in methanol (15 mL) was added cobalt acetate tetrahydrate (0.0177 g, 0.100 mmol) in methanol (5 mL). The reaction mixture was heated at reflux for 1.5 h. The colourless suspension gave way to a pale brown solution. Excess methanolic ammonium hexafluorophosphate was added to the hot reaction mixture leading to immediate precipitation of a brown solid. The solid was washed with methanol (2 × 10 mL) and water (2 × 10 mL) and was filtered. The solid was dissolved in acetone and was reprecipitated by the addition of diethyl ether giving **2b** (0.0213 g, 28%) as a pale brown solid. *m/z* (FAB): 2861 (M – 145 (-PF_6)), 2716 (M – 290 (-2PF_6)), 2571 (M – 435 (-3PF_6)), 2426 (M – 580 (-4PF_6)).

Preparation of $[Ni(\mathbf{1a})]_4[PF_6]_8$ (3a)

To a suspension of **1a** (0.0210 g, 0.0541 mmol) in ethanol–water (12 mL, 1:1) was added nickel acetate tetrahydrate (0.0135 g, 0.0541 mmol) dissolved in ethanol–

water (2 mL, 1:1). The mixture was heated at reflux for 16 h. The colourless suspension gave way to a dark red brown homogeneous solution. Excess aqueous ammonium hexafluorophosphate was added to the hot mixture leading to immediate precipitation of an orange solid. Recrystallization from acetonitrile–ether gave **3a** (0.0265 g, 66%) as an orange solid. mp > 300 °C. IR (cm^{-1}): 1619, 1606, 1466, 1450, 847, 559. *m/z* (FAB): 2804 (M – 145 (-PF_6), 5%), 2675 (M – 274 (-2PF_6 + O), 24%), 2529 (M – 419 (-3PF_6 + O), 70%), 2384 (M – 564 (-4PF_6 + O), 70%), 2239 (M – 710 (-5PF_6 + O), 32%), 2093 (M – 856 (-6PF_6 + O), 8%), 1265 ([M – 419]$^{2+}$ (-3PF_6 + O), 50%), 1192 ([M – 564]$^{2+}$ (-4PF_6 + O), 100%), 1120 ([M – 710]$^{2+}$ (-5PF_6 + O), 80%), 1047 ([M – 856]$^{2+}$ (-6PF_6 + O), 36%). Anal. calcd. for $C_{96}H_{64}F_{48}N_{24}P_8Ni_4$: C (39.10) H (2.19), N (11.40); found: C (40.60), H (2.30), N (11.88).

Preparation of [Zn(1a)]$_4$[PF$_6$]$_8$ (4a)

To a suspension of **1a** (0.0875 g, 0.225 mmol) in methanol (20 mL) was added zinc acetate dihydrate (0.0495 g, 0.225 mmol) in water (2 mL). The reaction mixture was heated at reflux for 5 h. The colourless suspension gave way to a clear solution. Excess aqueous ammonium hexafluorophosphate was added to the hot reaction mixture leading to immediate precipitation of a white solid. The solid was washed with methanol (2 × 10 mL) and water (2 × 10 mL), and was reprecipitated from acetone with diethyl ether. The solid was isolated and dried. Recrystallization from acetonitrile–ether gave **4a** (0.0799 g, 48%) as an off-white solid. mp dec. 290 °C. ^{1}H NMR (300 MHz, ppm) δ: 9.40 (s, H_5, 1H), 9.16 (d, $H_{5'}$, *J* = 7.7 Hz, 2H), 8.86 (t, $H_{4'}$, *J* = 7.9 Hz, 2H), 8.78 (d, $H_{3'}$, *J* = 7.7 Hz, 2H), 8.35 (d, $H_{3''}$, *J* = 8.1 Hz, 2H), 8.02 (dt, $H_{4''}$, *J* = 7.8, 1.7 Hz, 2H), 7.40 (s, H_2, 1H), 7.28 (d, $H_{6''}$, *J* = 4.0 Hz, 2H), 7.23 (ddd, $H_{5''}$, *J* = 7.4, 5.2, 0.8 Hz, 2H). ^{13}C NMR (DEPT, ppm) δ: 159.9, 151.8, 148.9, 146.2, 142.5, 128.9, 128.1, 126.8, 124.5. *m/z* (FAB): 2832 (M – 143 (-PF_6)), 2686 (M – 290 (-2PF_6)), 2557 (M – 418 (-3PF_6 + O)), 2540 (M – 435 (-3PF_6)), 2395 (M – 580 (-4PF_6)), 2250 (M – 725 (-5PF_6)), 1732 (M – 1243 (-**1a**, 5PF_6 + O)), 1586 (M – 1389 (-**1a**, 6PF_6 + O)), 1441 (M – 1534 (-**1a**, 7PF_6 + O)), 1270 ([M – 435]$^{2+}$ (-3PF_6)), 1198 ([M – 580]$^{2+}$ (-4PF_6), 1125 ([M – 725]$^{2+}$ (-5PF_6). Anal. calcd. for $C_{96}H_{64}F_{48}N_{24}P_8Zn_4$: C 38.75, H 2.17, N 11.30; found: C 38.72, H 2.61, N 11.60.

Preparation of [Cd(1a)]$_4$[PF$_6$]$_8$ (5a)

To a suspension of **1a** (0.0108 g, 0.0278 mmol) in methanol (10 mL) was added cadmium acetate dihydrate (0.0080 g, 0.0278 mmol) in methanol (1 mL). The reaction mixture was heated at reflux for 1.5 h. The colourless suspension gave way to a clear solution. Excess aqueous ammonium hexafluorophosphate was added to the hot reaction mixture leading to immediate precipitation of a white solid. The solid was washed with methanol and recrystallized from acetonitrile–ether giving **5a** (0.0131 g, 60%) as an off-white solid. mp > 300 °C. IR (cm^{-1}): 1601, 1580, 1464, 1447, 1024, 843, 558. ^{1}H NMR (ppm) δ: 9.36 (s, H_5, 1H), 9.10 (dd, $H_{5'}$, *J* = 6.9, 1.5 Hz, 2H), 8.74 (m, $H_{3',4'}$, 4H), 8.41 (d, $H_{3''}$, *J* = 8.0 Hz, 2H), 8.06 (m, $H_{4'',5}$, 3H), 7.70 (d, $H_{6''}$, *J* = 4.0 Hz, 2H), 7.32 (dd, $H_{5''}$, *J* = 6.9, 5.1 Hz, 2H). ^{13}C NMR (ppm) δ: 159.6 (CH), 151.6, 150.4 (CH), 145.0 (CH), 142.3 (CH), 128.5 (CH), 127.9 (CH), 127.8, 127.5, 127.2, 127.1 (CH), 124.7 (CH), 118.4 (CH). *m/z* (FAB): 3018 (M – 144 (-PF_6)), 2873 (M – 290 (-2PF_6)), 2728 (M – 435 (-3PF_6)), 2395 (M – 581 (-4PF_6)), 1824 (M – 1339 (- **1a**, 2Cd, 5PF_6)), 1680 (M – 1483 (-**1a**, 2Cu, 6PF_6)). Anal. calcd. for $C_{96}H_{64}F_{48}N_{24}P_8Cd_4$: C 36.45, H 2.04, N 10.63; found: C 36.32, H 2.33, N 10.40.

Preparation of [Fe(1a)]$_4$[PF$_6$]$_8$ (6a)

To a suspension of **1a** (0.0108 g, 0.0278 mmol) in chloroform–acetonitrile (10 mL, 1:1) was added iron tetrafluoroborate (0.0080 g, 0.0278 mmol) in MeCN (1 mL). The reaction mixture was heated at reflux for 5 h. The colourless suspension gave way to a deep green solution. The solvent was removed under reduced pressure and the remaining solid dissolved in acetone. Addition of excess ammonium hexafluorophosphate in acetone afforded a green precipitate. After anion exchange with tetrabutylammonium chloride in acetonitrile, the green solid was dissolved in a minimum of water and was chromatographed on Sephadex with increasingly concentrated NaCl solutions. A green band was collected with 0.4 mol L^{-1} NaCl and was treated with ammonium hexafluorophosphate giving **6a** (0.0013 g, 6.0%). IR (cm^{-1}): 1605, 846, 558. ^{1}H NMR (ppm) δ: 9.28 (d, $H_{3'\text{ or }5'}$, *J* = 7.6 Hz, 2H), 9.09 (s, H_5, 1H), 8.93 (t, $H_{4'}$, *J* = 7.9 Hz, 2H), 8.85 (td, $H_{3''}$, *J* = 8.0, 1.0 Hz, 2H), 8.22 (d, $H_{3'\text{ or }5'}$, *J* = 7.8 Hz, 2H), 7.67 (dt, $H_{4''}$, *J* = 7.8, 1.3 Hz, 2H), 6.82 (ddd, $H_{5''}$, *J* = 7.6, 5.6, 1.1 Hz, 2H), 6.61 (d, $H_{6''}$, *J* = 4.0 Hz, 2H), 5.14 (d, H_2, *J* = 0.5 Hz, 1H). *m/z* (FAB): (M – 144 (-PF_6), 10%), (M – 288 (-2PF_6), 30%), (M – 333 (-3PF_6), 20%). Anal. calcd. for $C_{96}H_{64}F_{48}N_{24}P_8Fe_4$: C 39.26, H 2.20, N 11.45; found: C 39.36, H 2.52, N 11.17.

Preparation of [Ru(1a)]$_4$[PF$_6$]$_8$ (7a)

To a suspension of **1a** (0.0210 g, 0.0541 mmol) in ethylene glycol (12 mL, 1:1) was added ruthenium trichloride trihydrate (0.0141 g, 0.0541 mmol). The reaction mixture was heated at reflux for 16 h. The colourless suspension gave way to a dark purple-black homogeneous solution. Excess aqueous ammonium hexafluorophosphate was added to the hot reaction mixture leading to immediate precipitate formation. The solid was isolated by filtration, was dissolved in acetone and the chloride salt was recipitated by the addition of tetrabutylammonium chloride in acetone. The purple-black solid was dissolved in a minimum of water and was chromatographed on Sephadex with increasingly concentrated NaCl solutions. A purple-black band was collected (0.4 mol L^{-1} NaCl) and was treated with ammonium hexafluorophosphate giving **7a** (0.008 g, 2%). ^{1}H NMR (ppm) δ: 10.56 (s, H_5, 1H), 10.08 (d, $H_{3'\text{ or }5'}$, *J* = 7.8 Hz, 2H), 8.73 (d, $H_{3'\text{ or }5'}$, *J* = 8.1 Hz, 2H), 8.59 (t, $H_{4'}$, *J* = 8.0 Hz, 2H), 8.33 (d, $H_{3''}$, *J* = 8.0 Hz, 2H), 7.77 (dt, $H_{4''}$, *J* = Hz, 2H), 7.11 (d, $H_{6''}$, *J* = 4.5 Hz, 2H), 6.95 (m, $H_{5''}$, 2H), 5.75 (s, H_2, 1H). *m/z* (FAB): 2866 (M – 252 (-2PF_6 + 2H + Cl)), 2719 (M – 399 (-3PF_6 + Cl)), 2572 (M – 546 (-4PF_6 – 2H + Cl)), 2426 (M – 692 (-5PF_6 + Cl)).

Surface-enhanced Raman spectroscopy with a laser pointer light source and miniature spectrometer[1]

Matthew A. Young, Douglas A. Stuart, Olga Lyandres, Matthew R. Glucksberg, and Richard P. Van Duyne

Abstract: The initial steps toward a miniature, field portable sensor based on surface-enhanced Raman spectroscopy (SERS) are presented. It is demonstrated that a low-cost miniaturized Raman system can be used in place of a larger, higher-cost conventional Raman system. This system was developed by sequentially replacing components of a laboratory scale Raman spectroscopy system with smaller, lower-cost, commercially available components. For example, a green laser pointer was used as the excitation source, a reflectance probe fiber-optic cable was used for laser delivery and collection, and a compact card-based spectrometer was used for dispersion and detection. Spectra, collected with the laser pointer Raman system, are presented of a resonant (Rhodamine 6G) and a non-resonant (*trans*-1,2-bis(4-pyridyl)ethylene) molecule as well as a self-assembled monolayer (1-decanethiol). Small, low-cost sensors are in demand for a variety of applications, and SERS is positioned to contribute significantly with its remarkable sensitivity and molecular specificity.

Key words: Raman, SERS, fiber-optics, sensor.

Résumé : On présente les étapes initiales dans le développement d'une sonde miniature, à base de spectroscopie Raman de surface améliorée (SERS), qui serait utilisable sur le terrain. On a démontré qu'un système Raman miniaturisé et peu coûteux pourrait être utilisé à la place d'un système Raman conventionnel, plus volumineux et de coût plus élevé. Ce système a été mis au point en remplaçant successivement des composants d'un système de spectroscopie Raman normal de laboratoire par des composants plus petits et moins coûteux et commercialement disponibles. Par exemple, on a utilisé un laser vert pointeur comme source d'excitation, un câble en fibre optique d'une sonde de réflectance pour distribution et la collection du laser ou un spectromètre compact à base de carte pour la dispersion et la détection. Utilisant le système Raman à laser pointeur, on a recueilli les spectres de molécules résonante (Rhodamine 6G) et non résonante [*trans*-1,2-bis(4-pyridyl)éthylène] ainsi que d'une monocouche autoassemblée (décane-1-thiol). Les petites sondes peu coûteuses sont très en demande pour un grand nombre d'applications et la technique SERS est en bonne position pour faire des contributions importantes en raison de sa sensibilité remarquable et de sa spécificité moléculaire.

Mots clés : Raman, SERS, fibre optique, sonde.

[Traduit par la Rédaction]

Introduction

In the past few years, surface-enhanced Raman spectroscopy (SERS) has generated significant interest as a method for various sensing applications (1–10). Most chemical sensors rely on properties such as mass, fluorescence, or refractive index, which are often not specific for the substance in question. In contrast, Raman spectroscopy offers rich molecular information, and thus often provides unequivocal identification of chemical and biological materials of interest. Unfortunately, Raman spectroscopy is limited in its applicability to sensing schemes that require trace analysis because of the inefficiency of the Raman scattering process. Since 1977, it has been known that significant enhancement of the Raman scattering, and subsequent improvement in the detection, can be realized from molecules adsorbed on specifically roughened metal surfaces (11), and tremendous effort has been expended to explore and exploit this property. Generally, in ensemble averaged systems, SERS enhancement factors as large as 10^8 have been realized (12). Under certain

Fig. 1. Experimental set-ups. (*a*) Conventional Raman system and (*b*) miniaturized system assembled with available lab equipment. Most of the cumbersome and expensive elements have been replaced with compact, off-the-shelf components to realize a savings in cost, size, and weight.

experimental conditions, enhancement factors of ~10^{14} have been achieved (13, 14), making SERS the only vibrational spectroscopy capable of both detecting and identifying single molecules under ambient conditions. With this enhancement, SERS provides exquisite sensitivity, which is complemented by the molecular specificity inherent to vibrational spectroscopy. SERS has been employed in the development of a myriad of sensors, including those detecting chemical and biological agents (15–18), explosives (19, 20), glucose (9, 10, 21), aromatics (22, 23), proteins (24, 25), and DNA (26–29).

In addition to being highly sensitive and selective, attractive properties for sensors include rapid response, ease of use, reliability, and low cost. Raman spectroscopy has taken several steps in this direction. The developments of sensitive charge-coupled device (CCD) detectors and holographic notch filters have allowed the rapid and facile implementation of Raman spectroscopy in a range of applications. The development of the silver film over nanosphere (AgFON) surface (30, 31), with reproducible nanoscale roughness features, has enabled stable and consistent SERS measurements to be taken. In addition, Ag colloids have proven to be reliable SERS active substrates and are used by a large number of researchers. Thus, SERS has become a relatively fast, simple, and reliable spectroscopy.

There remains a major limiting factor for the implementation of Raman spectroscopy to widespread sensing applications. This drawback is that for Raman (and SERS) experiments, large and expensive equipment is required. The major components of a typical Raman instrument are the laser, the delivery optics, the sample, the collection optics, the spectrograph, and the detector (Fig. 1*a*). Each component can take up significant space, be extremely expensive, and be difficult to assemble, align, and maintain. These factors, particularly the physical dimensions and cost, are important obstacles for the realization of Raman spectroscopy for use in critical routine situations such as blood glucose monitoring, drinking water testing, forensics, remote field defense sensing, and environmental sampling. Several small Raman systems have been recently developed to address these issues. These include systems from InPhotonics (Norwood, Mass.), Digilab (Randolph, Mass.), Enwave Optronics (Irvine, Calif.), and Delta Nu (Laramie, Wyo.). Towards this same end, the present work focuses on decreasing the cost and size of the typical Raman setup. Replacing many of the classic elements of the Raman setup listed above with smaller, lower-cost alternatives will be an important step in the realization of simple, field-worthy spectrometers and sensors based on the SERS phenomenon.

The work presented in this paper describes the first steps towards replacing the most cumbersome and costly elements of a traditional Raman system with significantly smaller and cheaper components (Fig. 1*b*). AgFON surfaces are used as SERS active substrates because they have been shown to be reproducible and stable in electrochemical, ultrahigh vacuum, and ambient experimental conditions (30, 32, 33) Thus, AgFONs are well-suited to the wide range of environments in which SERS sensors would be deployed. This work adds substantially to the growing literature demonstrations that SERS is feasible utilizing low-cost, compact, and readily available components while retaining the necessary sensitivity for sensing applications.

Experimental

Materials and equipment

Ag wire (99.99%, 0.04″ diameter (1 inch = 25.4 mm)) was purchased from D.F. Goldsmith (Evanston, Ill.). The Ag disk electrodes consisted of a Ag rod sealed with an epoxy (Torr Seal, Varian) into a Teflon® frame. The glass substrates were 18 mm diameter, No. 2 cover slips from Fisher Scientific (Pittsburgh, Penn.). Pretreatment of glass substrates required H_2SO_4, H_2O_2, and NH_4OH, all purchased from Fisher Scientific (Pittsburgh, Penn.). Surfactant-free white carboxyl-substituted polystyrene latex nanospheres with diameters of 410 nm were obtained from Interfacial Dynamics Corp. (Portland, Ore.). Tungsten vapor deposition boats were purchased from R.D. Mathis (Long Beach, Calif.). Rhodamine 6G (98%) was purchased from Sigma (St. Louis, Mo.) and was used as received. *trans*-1,2-Bis(4-pyridyl)ethylene (97%), 1-decanethiol (96%), and benzene (99%) were purchased from Aldrich (Milwaukee, Wis.) and used as received.

AgFON surface preparation

AgFON surfaces were fabricated with the use of a modified Consolidated Vacuum Corporation vapor deposition system. The steps included: (1) polishing an electrode surface with 0.3 and 0.05 μm alumina; (2) coating the smooth electrode surface with 410 nm diameter surfactant-free white carboxyl-substituted polystyrene latex nanospheres and allowing to dry; (3) masking off the area where deposited metal is not desired; (4) depositing 200 nm Ag; and (5) removing the mask after metal deposition. When glass was used instead of the electrode surfaces, the same procedure was followed, but without the polishing and masking. The glass also required a pretreatment consisting of: (1) piranha etch, H_2SO_4 – 30% H_2O_2 (3:1) at 80 °C for 1 h to clean the substrate; and (2) base treatment, H_2O – NH_4OH – 30%

Raman spectroscopy

Sequential instrumental configurations were implemented to evaluate the efficiency and performance characteristics of the miniature Raman system. A variety of molecules were probed to establish the applicability and utility of the instrument to the detection of molecules differing in chemical structure and scattering cross sections. In the first series of experiments, the AgFON substrates were incubated in both resonant and non-resonant molecules. The first instrumental configuration closely approximates that used in conventional, lab-scale Raman spectroscopy. The first step taken in this work was to replace the excitation Argon ion laser (Spectra-Physics, Mountain View, Calif.) with an inexpensive CW green laser pointer (JD Photonics, Renton, Wash.). The battery powered green laser pointer consists of a high power IR laser diode at 808 nm pumping a tiny block of Nd:YVO_4, which generates light at 1064 nm. This feeds a KTP intracavity frequency doubling crystal to produce the green beam at 532 nm. The Raman instrument was further modified by replacing the bulky collection and focusing optics with a low profile 200 μm core reflection fiber-optic probe (Ocean Optics, Dunedin, Fla.). Raman spectra for the resonant and non-resonant molecules were collected by focusing the output of the fiber onto the entrance slit of the large scale Acton VM-505 dispersion spectrograph (Acton, Mass.) with a Roper Scientific (Trenton, N.J.) Spec-10:400B liquid N_2 cooled CCD detector. Finally, we evaluated the use of a compact, off the shelf, card-based, USB interface Ocean Optics (Dunedin, Fla.) model SD2000 spectrometer as a replacement for the critical dispersion and detection components. The dual channel spectrometer is configured with a 600 lines mm^{-1} grating and a 1200 lines mm^{-1} grating. Conveniently, the fiber-optic bearing the Raman scattered light can be coupled directly into this spectrometer, allowing for quick and simple alignment.

Results and discussion

Clearly, experimental Raman spectroscopy has traditionally been an expensive endeavor. In addition to being costly, the large components have prevented an easily portable system. Figure 1 depicts our miniaturized (and lower cost) Raman setup and compares it to a traditional system. Table 1 summarizes the approximate cost, size, and weight of the components for both the conventional and miniature Raman instruments. This does not depict the lowest-cost or highest-cost systems that one could construct. It is an estimate based on the systems used in our lab. Readily available components have been used to demonstrate the feasibility of performing SERS experiments with a small and relatively inexpensive setup. Obviously, conventional setups have many advantages (e.g., wavelength selection, more power, higher sensitivity, and high resolution) over the presented low-cost prototype. However, for many applications this approach presents an attractive alternative. The significant savings in resources and space generously offsets the compromise in resolution and sensitivity. Additionally, a miniaturized system will increase the use of Raman and SERS for portable environmental testing and in undergraduate teaching laboratories.

We have used an *aufbau* approach to demonstrate the concept of an economical, miniaturized SERS instrument. We have systematically built up this system by consecutively replacing components of a conventional system with lower-cost, smaller items. The project began with the replacement of the traditional excitation source (Ar^+, Ti:S, HeNe, or dye laser) with a simple green laser pointer (GLP), λ_{ex} = 532 nm. Figures 2 and 3 show the applicability of the GLP as a SERS excitation source for both resonant and non-resonant molecules. While Rhodamine 6G (R6G) is resonant at 532 nm, *trans*-1,2-bis(4-pyridyl)ethylene (BPE) is not. BPE is a relatively strong Raman scatterer and it has been a molecule of interest for many SERS studies (34–38). For the R6G experiment, the AgFON on a polished electrode was

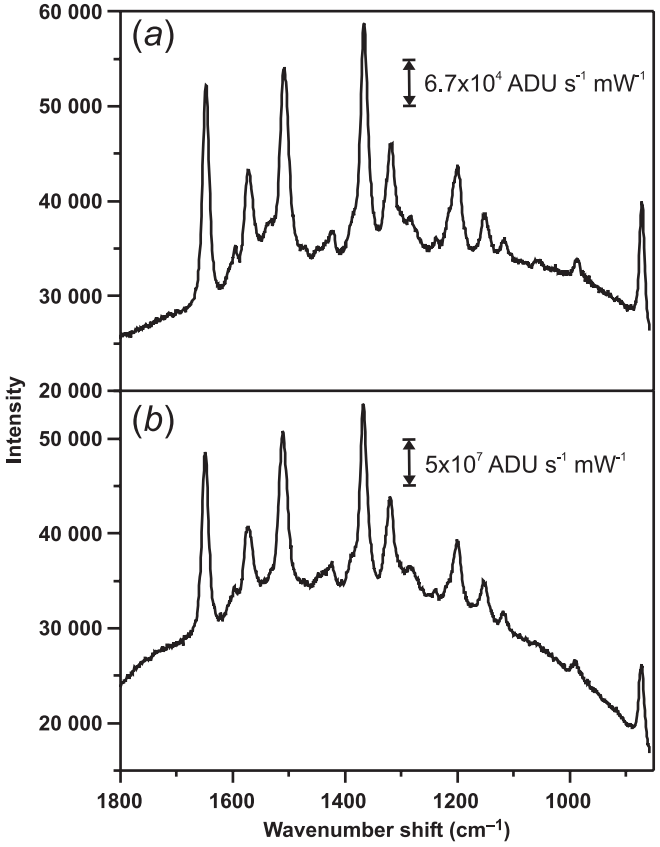
Fig. 2. SER spectrum of R6G on a AgFON electrode (dry). λ_{ex} = 532 nm (GLP). (*a*) *P* = 0.25 mW, acquisition time = 300 ms. (*b*) Laser delivered and collected with reflectance probe fiber-optic. *P* = 10 μW, acquisition time = 10 s.



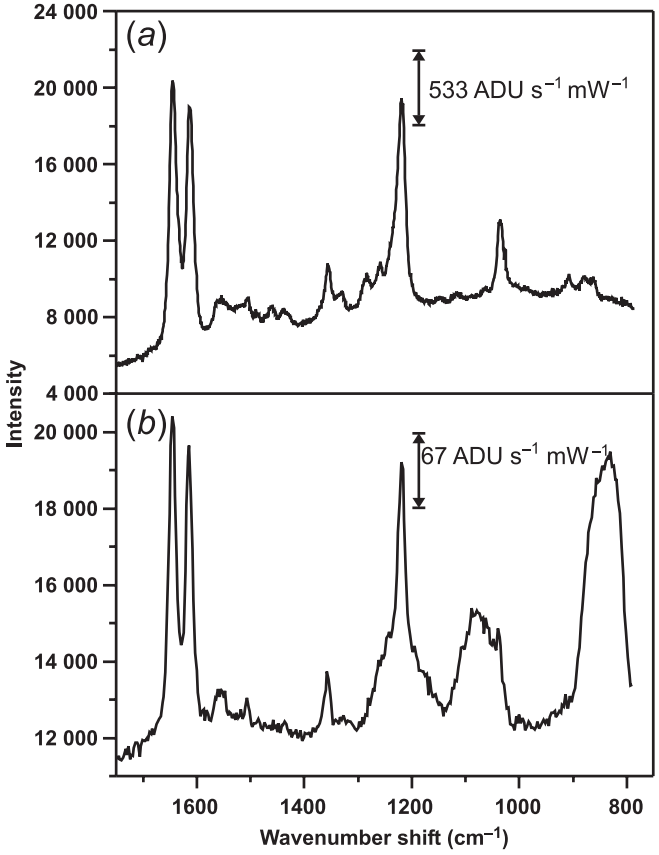


Fig. 3. SER spectrum of BPE on a AgFON electrode in flow cell. λ_{ex} = 532 nm (GLP). (*a*) *P* = 1.5 mW, acquisition time = 5 s. (*b*) Laser delivered and collected with reflectance probe fiber-optic. *P* = 0.25 mW, bin 3, acquisition time = 40 s.

incubated in 2.4 μmol L^{-1} R6G solution for 10 min., then rinsed carefully with water and allowed to dry. In the case of BPE, a 0.5 mmol L^{-1} solution was introduced into a flow cell containing a AgFON on a polished Ag electrode. Figures 2*a* and 3*a* show high quality SER spectra acquired using the GLP as the excitation source. The spectra exhibit intense, well-defined peaks characteristic of the given molecule.

A second set of experiments was conducted to determine the effect of altering the collection optics and light delivery of the system. Figures 2*b* and 3*b* show the case where the light delivery, focusing, and collection optics are replaced by a fiber-optic probe. The light was delivered from the GLP to the sample through the probe, and the scattered light was collected by the probe and focused onto the slit of the Acton spectrometer. The spectra compare quite favorably to those using conventional delivery and collection optics. In the case of R6G, little to no signal intensity is lost with the fiber-based delivery and collection. For BPE, the signal is slightly attenuated, but an ample amount of Raman scattered light is transmitted back through the fiber to generate a strong SER spectrum in a short collection time. The broad featureless peaks on the right side of the BPE spectrum (~1225, ~1075, and ~840 cm^{-1}) are due to Raman scattering generated inside the fiber itself. Altering the filter design of the fiber-optic probe can eliminate these broad peaks. They could also be removed by background subtraction since they are constant at a given excitation power.

In addition to strong scatterers such as R6G and BPE, it is important to demonstrate the acquisition of spectra of molecules with smaller Raman scattering cross sections. Many analytes of interest in sensing applications are not strong scatterers. Figure 4 depicts an SER spectrum with a laser pointer utilizing a self-assembled monolayer (SAM) of 1-decanethiol (1-DT). SAMs have generated enormous interest in many areas of chemistry, including SERS; and they are vital for many sensing applications including their use as species selective partition layers (9, 10, 27, 39–42). 1-DT is a relatively poor Raman scatterer, but a SER spectrum was readily obtained using the GLP as the excitation source.

The final components to be replaced in the conventional Raman apparatus are the spectrograph and detector. We replaced these components by coupling the collection fiber directly into an SD2000 spectrometer from Ocean Optics. Because these spectrometers are designed for UV–vis spectroscopy, it was necessary to determine if the sensitivity of the detector would be adequate for the low level of radiated photons generated by SERS and if the grating would provide sufficient dispersion to adequately resolve the narrow Raman peaks. While small laser diodes are available with adequate power (e.g., >10 mW), the GLP used in the above experiments supplies only 3 to 4 mW. Therefore, for this experi-

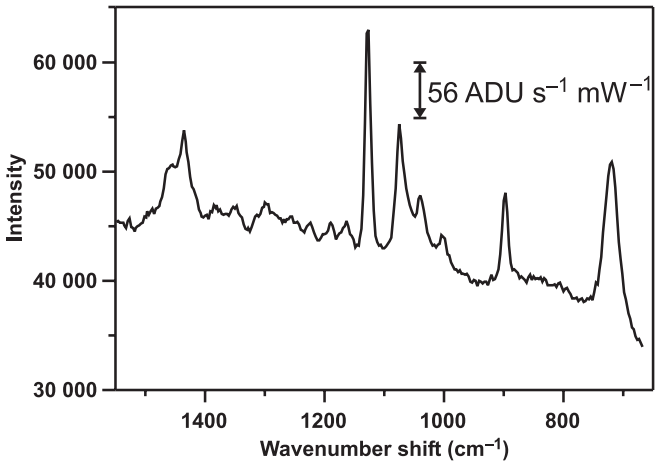
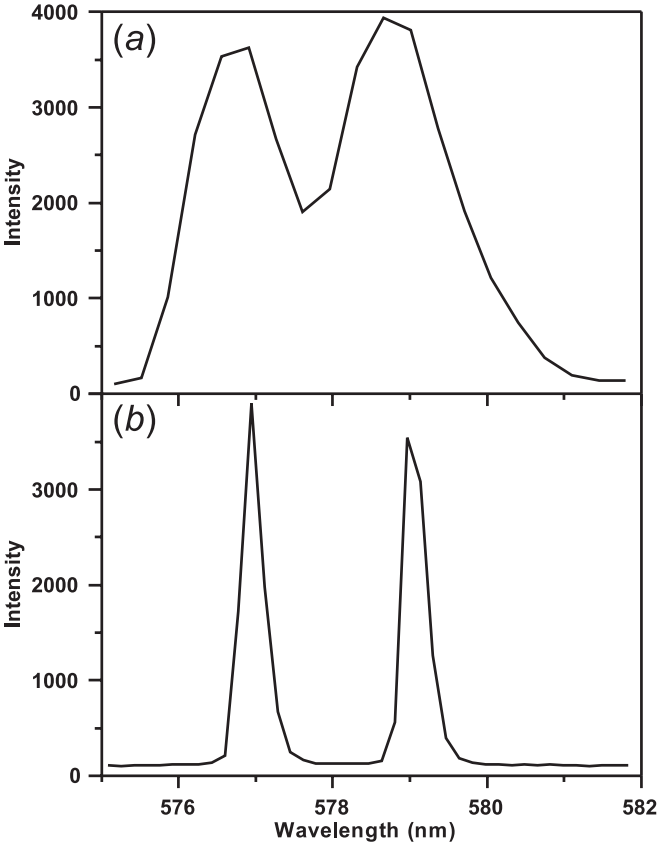
Fig. 4. SER spectrum of 1-DT on a AgFON on clean glass (dry). λ_{ex} = 532 nm (GLP). P = 0.5 mW, acquisition time = 60 s.





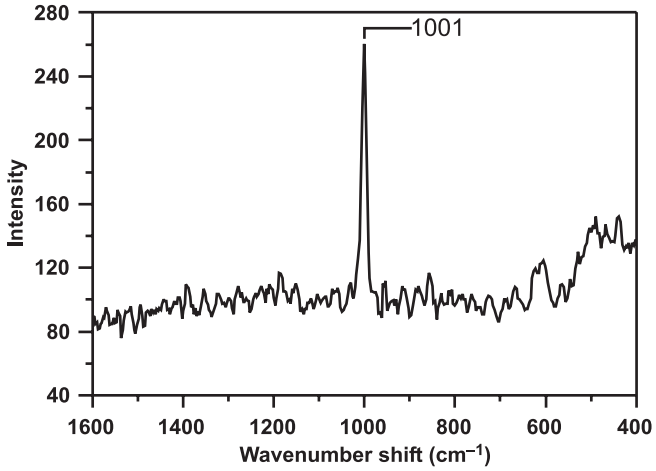


Fig. 5. Mercury emission lines recorded with SD2000 spectrometer. (*a*) Grating 1 (600 lines/mm) and (*b*) grating 2 (1200 lines/mm).

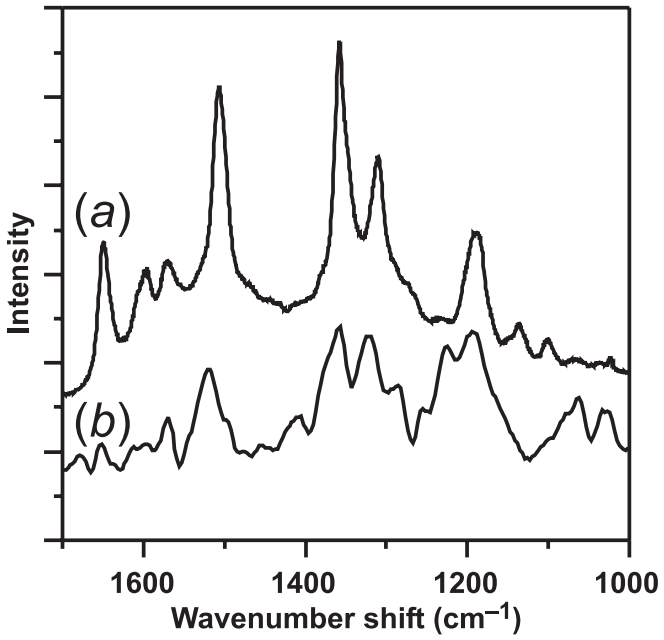
ment ~20 mW of laser light was coupled into the fiber using a Coherent (Santa Clara, Calif.) model 590 dye laser operating at λ_{ex} = 632.8 nm. This was done simply to allow more power to be coupled into the fiber, and to decrease the acquisition time. The SD2000 spectrometer used here is configured with two different gratings. Figure 5 shows a comparison of the two gratings using mercury emission

Fig. 6. Raman spectrum of neat benzene recorded with SD2000 spectrometer. λ_{ex} = 632.8 nm. Acquisition time = 30 s. S/N ~ 7.



lines. It is clear that grating 2 has significantly higher resolution. Following Sommer and Stewart (43), band fitting of the 577 and 579 emission lines of the Hg lamp gave values of 0.32 nm and 0.37 nm at FWHM. These values were used to determine that the spectral resolution of this instrument is ~10 cm^{-1} at 632.8 nm excitation. Although the spectrometer was not originally optimized for the high resolution generally demanded for Raman spectroscopy, it gives sufficient resolution for identification of Raman signatures. This is clearly demonstrated in Fig. 6, which shows a normal Raman spectrum of benzene, with an estimated signal-to-noise ratio of ~7. While this is certainly less than ideal relative to spectra obtained on a commercial FT-Raman instrument, it is a positive step in the development of the miniaturized system. The measurement of a Raman spectrum of neat benzene is, however, substantially different than in a typical SERS experiment, in which the concentration of the analyte is significantly lower. Figure 7 directly compares SER spectra collected with the Acton spectrograph and the SD2000 spectrograph with R6G on a dried AgFON as the analyte. Figure 7*a* corresponds to the SER spectrum recorded on the Acton and Fig. 7*b* to the SER spectrum recorded on the SD2000 spectrograph. The intensity of the 7*a* spectrum was significantly reduced so that 7*a* and 7*b* could be on the same scale. The spectra compare quite favorably. While there is much room for improvement, this demonstration of SERS utilizing such a small and low-resolution piece of equipment is significant. The signature of R6G is clear and represents a considerable step towards the miniaturization of SERS instrumentation.

Conclusions

Here, we demonstrated that a low-cost miniaturized Raman system could be used in place of a larger, higher-cost conventional Raman system. There are clearly several advantages that remain with the larger and more expensive components of a Raman setup. In addition, the components that have been used in this work as a technology demonstration test-bed are far from optimized. While the ability to obtain adequate SERS spectra with small and cheap equipment has been clearly shown, the components used were selected

Fig. 7. SER spectrum of R6G on a AgFON on clean glass (dry). λ_{ex} = 632.8 nm. (*a*) Acton VM-505 spectrometer, *P* = 1.8 mW, acquisition time = 10 s. (*b*) Ocean Optics SD2000 spectrometer, acquisition time = 30 s.

primarily for being convenient, readily available, off the shelf components. Vast improvements in sensitivity and resolution can be made by carefully selecting each component (e.g., using smaller filters, altering the probe configuration, more sensitive detector, etc.). With continued optimization, smaller and less expensive equipment will allow SERS to enter into a variety of field-sensing applications that will contribute to public safety and improved quality of life.

A vibrational spectroscopic study of the thermal behavior of $Re_2(CO)_{10}$ on zeolite Y[1]

Robert R. Poissant and Yining Huang

Abstract: This work describes the thermal decomposition of $Re_2(CO)_{10}$ in zeolite Y, which generates the zeolite-supported complex $Re^0(CO)_3(O\text{-}Z)_3$, where (O-Z) represents a framework oxygen. The adsorption and thermal decomposition of $Re_2(CO)_{10}$ was performed on dehydrated and hydrated zeolite NaY. The conversion to $Re^0(CO)_3(O\text{-}Z)_3$ was not significantly affected by the presence of water within the supercages as the supported complex formed at around 200 °C no matter what the initial water content of the zeolite was. However, when the zeolite sample was treated at ≥200 °C for long periods, the adsorbed H_2O became involved in the reactivity, playing a role as an oxidant. The subcarbonyl complex $Re^0(CO)_3(O\text{-}Z)_3$ was oxidized, generating isolated Re_2O_7 or $HReO_4$, or a mixture of both, which was dispersed inside the zeolite host. This result suggests that thermal decomposition of $Re_2(CO)_{10}$ on a hydrated zeolite under mild conditions can be a convenient route for preparation of zeolite-supported Re_2O_7 catalysts. $Re^0(CO)_3(O\text{-}Z)_3$ was also formed in siliceous zeolite Y (SiY) upon heating. But it quickly decomposes into metal Re at around 200 °C, suggesting that the tricarbonyl species is destabilized in the almost natural zeolite framework. The present study also shows that FT-Raman spectroscopy is a useful technique for monitoring the behavior of the metal carbonyl species in zeolitic hosts.

Key words: Raman spectroscopy, zeolite Y, rhenium carbonyl, rhenium oxide.

Résumé : Ce travail décrit la décomposition thermique de $Re_2(CO)_{10}$ dans du zéolite Y qui génère le complexe $Re^0(CO)_3(O\text{-}Z)_3$ déposé sur le zéolite et dans lequel (O-Z) représente un oxygène du squelette. On a procédé à l'adsorption et la décomposition thermique du $Re_2(CO)_{10}$ sur du zéolite NaY hydraté ainsi que déshydraté. Quelle que soit la quantité d'eau contenue initialement sur le zéolite, la conversion en $Re^0(CO)_3(O\text{-}Z)_3$ n'est pas affectée d'une façon significative par la présence d'eau dans les supercages du complexe déposé qui se forment aux environs de 200 °C. Toutefois, quand l'échantillon de zéolite est traité, pour de longues périodes, à des températures égales ou supérieures à 200 °C, l'eau adsorbée devient impliquée dans la réactivité alors qu'elle joue un rôle d'oxydant. On a oxydé le complexe de sous-carbonyle, $Re^0(CO)_3(O\text{-}Z)_3$, et on a pu isoler du Re_2O_7 ou du $HReO_4$ ou un mélange des deux qui était dispersé à l'intérieur du zéolite hôte. Ce résultat suggère que la décomposition thermique, dans des conditions douces, du $Re_2(CO)_{10}$ sur un zéolite hydraté est une méthode pratique de préparer des catalyseurs de Re_2O_7 déposés sur du zéolite. Le $Re^0(CO)_3(O\text{-}Z)_3$ se forme aussi par chauffage dans le zéolite Y (SiY). Toutefois, il se décompose rapidement en Re métallique aux environs de 200 °C, ce qui suggère que l'espèce tricarbonyle est déstabilisée dans le squelette d'un zéolite pratiquement naturel. Dans le présent travail, on montre aussi que la spectroscopie FT-Raman est une technique utile pour suivre le comportement des espèces carbonyles des métaux dans des hôtes zéolites.

Mots clés : spectroscopie Raman, zéolite Y, rhénium carbonyle, oxyde de rhénium.

Introduction

Rhenium complexes supported on metal oxide surfaces have been of technological interest for some time because they can be easily prepared, are generally stable, and can catalyze several reactions (1, 2). For example, the supported complex Re_2O_7–Al_2O_3, has been extensively studied with respect to the activity it shows as an alkene metathesis catalyst (3, 4). One of the difficulties in gaining a better understanding of these type of systems lies in the fact that the dispersed metal complexes are typically very small and nonuniform, making characterization difficult. Metal complexes grafted to the internal walls of zeolites have the potential to offer the same catalytic activity observed on other metal oxide supports, but offer the additional advantage of providing shape-selectivity (5). Gallezot et al. (6) first examined the

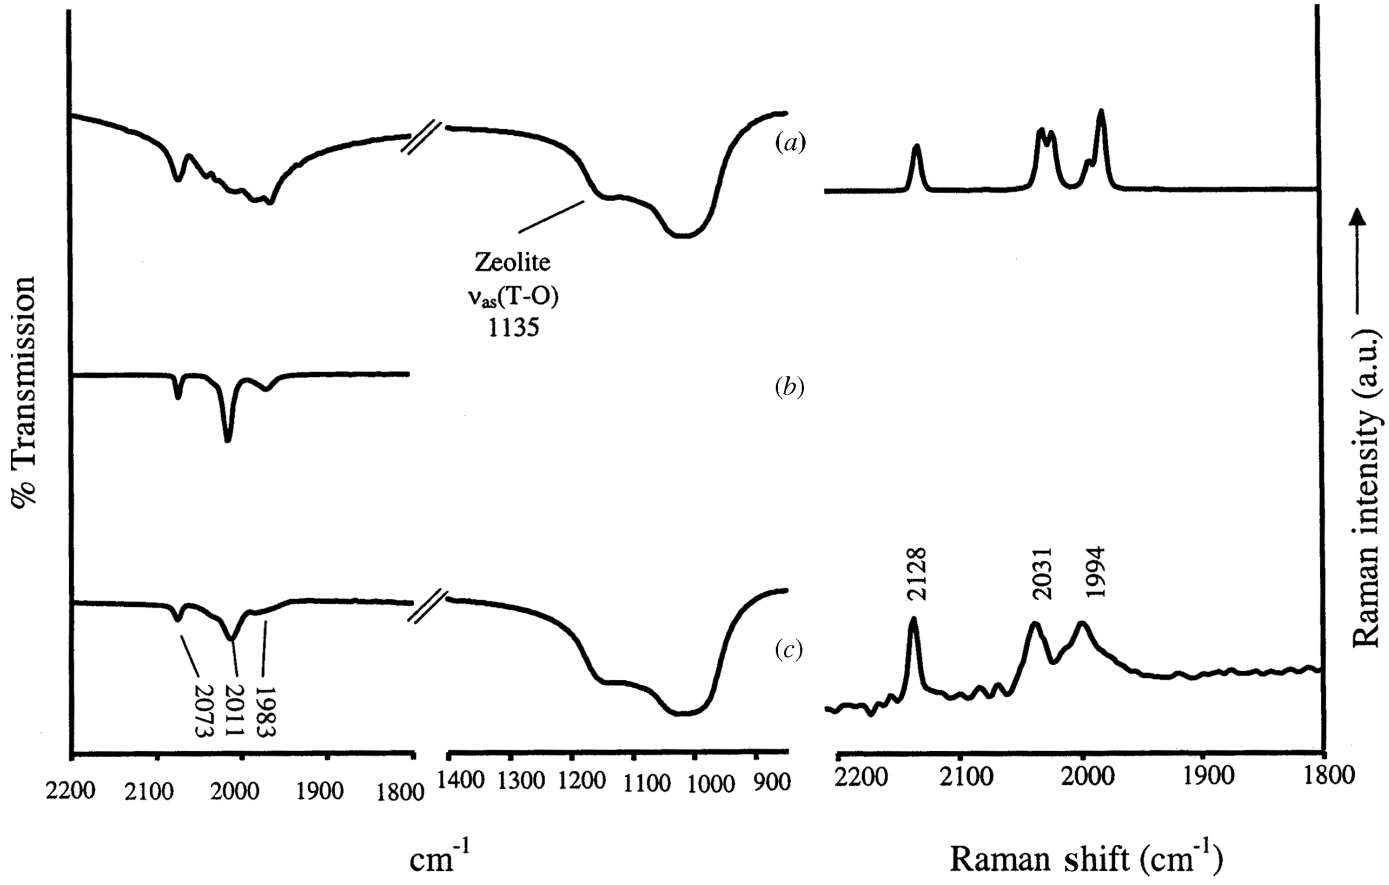
adsorption of $Re_2(CO)_{10}$ on the surface of acidic zeolite Y (HY). When $Re_2(CO)_{10}$ was adsorbed on HY and treated at 110 °C, the authors suggested that $Re_2(CO)_{10}$ was located inside the supercages of HY. After heating near 300 °C, the FT-IR spectra pointed towards the presence of a $Re(CO)_3$ moiety. Dossi et al. (7) also examined the thermal decomposition of $Re_2(CO)_{10}$ on HY. Their temperature-programmed decomposition studies suggested that $Re_2(CO)_{10}$ first decomposed to generate $Re(CO)_3$ at 207 °C and the rhenium tricarbonyl species underwent further decomposition, yielding metal Re at 351 °C. $Re_2(CO)_{10}$ has also been adsorbed on non-acidic zeolite Y. Zecchina et al. (8) used FT-IR to obtain evidence for several different types of $Re_2(CO)_{10}$ molecules upon mild thermal activation in NaY. The authors briefly examined the thermal decomposition of the metal carbonyl after adsorption onto the zeolite. However, the IR spectrum in the ν(CO) region obtained after heating the $Re_2(CO)_{10}$/zeolite sample at 250 °C displayed an overall very broad band profile, which little information could be extracted from. The observation of low-frequency ν(CO) absorption bands suggested the presence of subcarbonylic entities. However, owing to the broad bands, the structural nature of these subcarbonyls could not be unambiguously identified by the IR spectra alone. All the above-mentioned literature work was carried out by using dehydrated zeolite Y.

To gain a better understanding of the adsorption and thermal decomposition of rhenium carbonyl on zeolite Y, we have carefully examined the reactivity of $Re_2(CO)_{10}$ in both hydrated and dehydrated NaY, as well as siliceous zeolite Y. Our work shows that the hydrated zeolite NaY can actually be used to prepare Re_2O_7 supported in a zeolite via thermal decomposition using $Re_2(CO)_{10}$ as a precursor. In the present study, we have used FT-Raman in combination with FT-IR spectroscopy to follow the behavior of various surface-bound species.

In the past, the IR method has been extensively employed to obtain the structural information on the metal carbonyl species formed or adsorbed in zeolitic hosts by monitoring the ν(CO) vibrations. It has been recently shown that Fourier transform (FT)-Raman spectroscopy is also a useful technique for investigation of organometallic compounds supported on the zeolites (9). Because zeolite frameworks exhibit very weak Raman signals owing to their small scattering cross sections (10), the behavior of the guest species can be easily probed by observing the Raman spectra of the guest molecules. The Raman spectra can provide information on the metal carbonyl species not only from the ν(CO) bands, but also from the ν(M-C) and δ(M-CO), ν(M-X) and ν(M-M) modes, which appear in the region below 700 cm^{-1}. In the corresponding mid-IR spectra, the very strong bands owing to zeolitic framework appearing in the region of 1300–300 cm^{-1} usually mask the signals from the guest molecules in this region. For metal carbonyl – zeolite systems, FT-Raman is advantageous compared to conventional visible Raman. This is because FT-Raman instrumentation uses the 1064 nm excitation line from a near-IR laser, which largely minimizes laser-induced photodecomposition and significantly reduces fluorescence background (a problem often associated with zeolites (11)). In the present study, we wish to show that the combination of FT-Raman and FT-IR methods can furnish unambiguous information on the behavior of metal carbonyl species inside zeolites.

Experimental

$Re_2(CO)_{10}$ (98%) was purchased from Strem Chemical Inc., and used without further purification. NaY (Si/Al = 2.35) and siliceous zeolite Y (Si/Al = 300) were obtained from Strem Chemical Inc. and Degussa, respectively. The crystallinity and identification of zeolite Y were checked by powder X-ray diffraction. The typical experimental procedure for the dehydrated zeolite samples was the following: zeolite Y was first dehydrated at 550 °C under vacuum. The dehydrated zeolite was then mixed mechanically with crystalline $Re_2(CO)_{10}$ under nitrogen (1.8 molecules/super cage) in a Schlenk tube. After heating the mixture at a desired temperature under nitrogen flow, the sample was cooled down to room temperature and taken out from the Schlenk tubes under a nitrogen atmosphere for IR and Raman studies. The samples for Raman study were sealed in the capillary tubes. For the samples prepared using the hydrated form of NaY, the hydrated zeolite (water content 25% wt) was directly loaded into a Schlenk tube without any prior thermal treatment. Crystalline $Re_2(CO)_{10}$ was then added (1.8 molecules/super cage) and the sample was heated at a desired temperature. All Raman spectra were recorded on a Bruker RFS 100/S FT-Raman spectrometer equipped with a Nd^{3+}:YAG laser operating at a wavelength of 1064.1 nm and a liquid-nitrogen-cooled Ge detector. The laser power was typically 80 mW at the sample. We varied the laser power level and found that laser-induced photodecomposition only occurs when the power level is above 160 mW. The IR spectra were obtained on a Bomem MB-100 FT-IR spectrometer equipped with a DTGS detector, using the standard KBr method. The resolution for both the Raman and IR measurements was 4 cm^{-1}.



Results and discussion

$Re_2(CO)_{10}$ / hydrated NaY

The mixture of $Re_2(CO)_{10}$ and hydrated NaY was heated at several temperatures to examine the thermal stability of $Re_2(CO)_{10}$. When the sample was heated at 60 °C, the resulting IR spectrum (Fig. 1*a*) closely resembled that of pure $Re_2(CO)_{10}$ in the solid state (Fig. 2*b*), which contains very broad and closely overlapping and featureless bands in the ν(CO) region. When the same sample was washed with excess chloroform, the IR spectrum of the washing (Fig. 1*b*) was identical to that of pure $Re_2(CO)_{10}$ in solution (Fig. 2*c*), which exhibits three ν(CO) bands corresponding to the $2b_2$ and e_1 modes expected for an isolated $Re_2(CO)_{10}$ molecule with D_{4d} symmetry. In addition, upon washing of the sample $Re_2(CO)_{10}$/NaY heated at 60 °C, the overall band intensity in the ν(CO) region decreased significantly relative to that of the 1135 cm^{-1} band, which is assigned to the asymmetric zeolite T-O (T= Si, Al) stretching mode (ν_{as}(T-O)) (Figs. 1*a* and 1*c*). These results suggest that after heating at 60 °C, a significant portion of the metal carbonyl species was still located on the external surface of NaY as small crystallites, which can be easily removed by washing with $CHCl_3$. The

Fig. 1. IR and Raman spectra of: (*a*) $Re_2(CO)_{10}$/NaY heated at 60 °C for 1 h; (*b*) $CHCl_3$ washing solution resulting from treatment of sample (*a*); (*c*) $Re_2(CO)_{10}$/NaY heated at 60 °C for 1 h and then washed with $CHCl_3$.

IR spectrum of the resulting washed solid (Fig. 1*c*) exhibited three ν(CO) bands at 2073, 2011, and 1983 cm^{-1}, which match those of pure $Re_2(CO)_{10}$ in solution (Fig. 2*c*) very well (2071 (b_2), 2013 (e_1), and 1968 (b_2) cm^{-1}) (12*a*). This indicates that after washing with $CHCl_3$, the sample contained metal carbonyl species in the form of isolated $Re_2(CO)_{10}$ molecules that had retained D_{4d} symmetry. Examination of the Raman spectra of the same sample before and after washing, provides further evidence for the presence of the isolated $Re_2(CO)_{10}$ species. Before washing with $CHCl_3$, the Raman spectrum (Fig. 1*a*) was identical to that of pure crystalline $Re_2(CO)_{10}$ (Fig. 2*b*), where the splitting because of the solid-state effect (factor group splitting) is clearly evident. After washing, the Raman spectrum of the washed solid (Fig. 1*c*) displayed three principal ν(CO) bands at 2128, 2031, and 1994 cm^{-1}, which are in excellent agreement with those observed for pure $Re_2(CO)_{10}$ in solution (12) at 2127 (a_1), 2030 (e_2), and 1989 (a_1) cm^{-1} (Fig. 2*c*). All these results suggest that before washing with chloroform, $Re_2(CO)_{10}$ is present in the solid sample in two different forms: (*i*) $Re_2(CO)_{10}$ crystallites and (*ii*) isolated $Re_2(CO)_{10}$ molecules located both on the exterior and the interior of zeolite Y. Washing with $CHCl_3$ removes the metal carbonyl species located on the exterior of the zeolite surface, leaving only isolated $Re_2(CO)_{10}$ molecules located inside the supercages of NaY.

After treatment of the sample at 150 °C, the IR spectrum of the sample contains a relatively sharp band (2074 cm^{-1}), and a broad, featureless envelope centered near 2000 cm^{-1} (Fig. 2*a*). The most striking feature of the IR spectrum is a broad, low-frequency ν(CO) band, positioned at 1891 cm^{-1} (Fig. 2*a*), which is also present in the corresponding Raman spectrum with much weaker intensity (Fig. 2*a*). In addition to a sharp peak at 2127 cm^{-1}, the Raman spectrum in Fig. 2*a* also contains four sharp ν(CO) bands, which are sitting on top of a rather broad base. It appears that after treatment at 150 °C, the Raman spectrum of the $Re_2(CO)_{10}$/zeolite sample (Fig. 2*a*) is the superposition of the Raman spectra of $Re_2(CO)_{10}$ in the solid state (Fig. 2*b*) and in solution (Fig. 2*c*). This indicates that the sample contains $Re_2(CO)_{10}$ in the form of isolated molecules as well as crystallites. The broad IR band near 1891 cm^{-1} indicates that some $Re_2(CO)_{10}$ molecules had started to decompose.

Heating at 200 °C facilitated a dramatic change in the spectra of the resulting sample. The IR spectrum in the ν(CO) region now consisted of two overlapping bands centered at 2013 and 2003 cm^{-1}, and an extremely broad band centered around 1895 cm^{-1} (Fig. 3*a*). The band at 2013 cm^{-1} is positioned very similar to that of pure $Re_2(CO)_{10}$ in solution (Fig. 2*c*). However, the overall broad profile of the IR spectrum does not allow one to definitively conclude if $Re_2(CO)_{10}$ is still present in the sample after treatment at 200 °C. The corresponding Raman spectrum is much more informative. It contains several ν(CO) bands at 2128, 2033,

Fig. 4. IR and Raman spectra of: (*a*) $Re_2(CO)_{10}$/NaY heated at 200 °C for 4 h; and (*b*) $Re_2(CO)_{10}$/NaY heated at 200 °C for 4 h and then washed with $CHCl_3$.

2023, 2001, and 1900 (broad) cm^{-1} (Fig. 3*a*). The band at 2128 cm^{-1} is the characteristic a_1 ν(CO)(eq) mode of $Re_2(CO)_{10}$ in solution, indicating that, indeed, $Re_2(CO)_{10}$ is still present after treatment at 200 °C. After extraction with excess $CHCl_3$, the IR spectrum of the solution (not shown) did not display any bands in the ν(CO) region, indicating that very little, if any, carbonyl species were extracted from the solid sample. This is confirmed upon inspection of the overall IR band intensity in the ν(CO) region, before and after washing (relative to the ν_{as}(T-O) zeolite band), which remained approximately constant (Figs. 3*a* and 3*b*). Once again, the corresponding Raman spectrum exhibits better resolution. Examination of the Raman spectrum of the washed solid revealed three peaks at 2128, 2023, and 2001 cm^{-1} corresponding to those of pure $Re_2(CO)_{10}$ in solution, clearly indicating the presence of $Re_2(CO)_{10}$. The Raman peak at 2033 cm^{-1} and the broad peak around 1900 cm^{-1} did not decrease in intensity relative to the zeolite symmetric (T-O) stretching mode at 516 cm^{-1} (Figs. 3*a* and 3*b*), suggesting that these bands are due to a second metal carbonyl species within NaY. Thus, the Raman spectrum of the sample $Re_2(CO)_{10}$/NaY treated at 200 °C consists of two sets of bands: (*i*) three peaks at 2128, 2023, and 2001 cm^{-1} are assigned to the a_1(eq), e_2(eq), and a_1(ax) ν(CO) modes, respectively, of isolated $Re_2(CO)_{10}$ and (*ii*) two other bands at 2033 and 1894 cm^{-1} (very broad) are representative of a new rhenium subcarbonyl species (the nature of which will be discussed below).

After the $Re_2(CO)_{10}$/NaY sample was heated at 200 °C for longer periods (4 h), the IR spectrum of the sample displayed a significant reduction in the overall ν(CO) intensity, relative to the ν_{as}(T-O) zeolite band (Fig. 4*a*). The ν(CO) region of the IR spectrum consisted of two main bands at 2023 and 1904 cm^{-1}. Two new IR bands were observed at 934 and 910 cm^{-1} (Fig. 4*a*). In the corresponding Raman spectrum (Fig. 4*a*), three new bands appeared positioned at 982, 932, and 332 cm^{-1}. The regions 900–1200 cm^{-1} and 200–400 cm^{-1} coincide with that observed for Re=O stretching ν(Re=O), and bending δ(O=Re=O) vibrations (13), respectively, suggesting the possible formation of rhenium oxides. It appears that a large portion of the metal carbonyl had converted to a new species, possibly a rhenium oxide, which gave rise to new bands in the IR and Raman spectra. It seems that after prolonged treatment at 200 °C (4 h), the sample $Re_2(CO)_{10}$/NaY consists of three different rhenium species: (*i*) isolated $Re_2(CO)_{10}$ molecules, (*ii*) rhenium subcarbonyl species, and (*iii*) rhenium species containing Re=O bonds.

Structural nature of the rhenium subcarbonyl species

An obvious choice for the subcarbonyl species formed in zeolite is a $Re(CO)_3$ fragment (6). An isolated $Re(CO)_3$ fragment possessing C_{3v} point symmetry should exhibit two vibrational modes (a_1 + e) in the ν(CO) region, which are both IR and Raman active (14). The IR spectrum of the sample treated at 200 °C for 4 h does principally exhibit two ν(CO) bands at 2023 and 1904 cm^{-1} (Fig. 4*a*). These frequencies agree well with several reports in the literature of similar rhenium tricarbonyls formed on magnesium oxide powder (15). Upon washing of the sample $Re_2(CO)_{10}$/NaY heated at 200 °C (4 h) with $CHCl_3$, the two bands at 2043 and 1900 cm^{-1} in the corresponding Raman spectra remain unchanged in intensity (Figs. 4*a* and 4*b*). These two bands are close in frequency, relative intensity, and bandwidth to the corresponding ν(CO) bands in the IR spectrum. Therefore, these bands are assigned to the a_1 and e modes of the species *fac*-$Re(CO)_3(O\text{-}Z)_3$, where (O-Z) represents a framework oxygen. The Raman spectrum (Fig. 4*a*) also contains a weak band at 646 cm^{-1}. The Raman spectrum of pure $Re_2(CO)_{10}$ in either the solid or solution does not contain any band in this region. However, this is the region where Re-CO bend-

© 2004 NRC Canada

ing vibrations (δ(ReCO)) occur in species containing a $Re(CO)_3$ fragment (15*a*,16), providing further evidence that the new carbonyl species has a $Re(CO)_3$ moiety. Our results are in agreement with those of previous studies of $Re_2(CO)_{10}$ adsorbed in NaY by Dossi et al. (7) and Gallezot et al. (6), and similar studies reported in the literature describing $Re_2(CO)_{10}$ adsorbed on magnesium oxide powder. The fact that the species containing the $Re(CO)_3$ moiety cannot be extracted from the zeolite sample with $CHCl_3$, suggests that the supported complex is tightly bonded to the internal zeolite surface.

Structural nature of the rhenium oxide species

When considering the structure of the species responsible for the new bands observed in the IR and Raman spectra in the 900–1000 cm^{-1} and 200–400 cm^{-1} region, several possibilities must be entertained. For example, when $Re_2(CO)_{10}$ is thermally decomposed in air, the oxides Re_2O_7, ReO_3, and ReO_2 have all been identified upon heating between the temperatures 200–300 °C (17). To help discriminate between these and other possible metal oxides, magnetic susceptibility measurements were performed. The gram susceptibility of a physical mixture of $Re_2(CO)_{10}$/NaY prior to heating is diamagnetic ($\chi_g = -1.9 \times 10^{-7}$ cgs units). The same measurement on the sample $Re_2(CO)_{10}$/NaY after treatment at 200 °C for 4 h revealed that this sample is also diagmagnetic ($\chi_g = -5.4 \times 10^{-8}$ cgs units). Since ReO_3 (18) and ReO_2 (19) both exhibit temperature-independent paramagnetism, it is unlikely that either of these species could be predominantly responsible for the new peaks observed in our spectra. Therefore, Re_2O_7 is a viable possibility, since Re(VII) does not contain any 5*d* electrons. Interestingly, in a study by Nakamura et al. (20), the IR spectrum obtained of Re_2O_7 supported on Al_2O_3 exhibited ν(Re=O) bands, which are close in frequency to those observed in our study. Depending on the ratio Re/Al, the authors found that upon deposition of Re_2O_7 on Al_2O_3, the adsorbed rhenium oxide species displayed two different structural forms: (*i*) a species of the type Re_2O_7 (925 and 915 cm^{-1}) and (*ii*) a species of the type $H^+(ReO_4)^-$ (915 cm^{-1}). We have observed similar IR bands at 934 and 910 cm^{-1} (Fig. 4). Our Raman spectrum (Fig. 4) exhibits two bands at 982 and 932 cm^{-1} and a low-frequency band at 332 cm^{-1}. The frequencies and relative intensities of these bands are similar to those of the Raman spectrum of pure gaseous Re_2O_7 (21). Another possible form of the oxide present in our samples is $HReO_4$ (also diamagnetic) since the Raman spectrum of ReO_4^-(aq) also has three bands at 970, 916, and 332 cm^{-1} (22). Based on the above information, we believe that the most likely form of the rhenium oxide formed in our samples is Re_2O_7, but $HReO_4$ cannot be ruled out.

To determine other possible decomposition reactions of rhenium carbonyl, we further heated the sample $Re_2(CO)_{10}$/NaY at 270 °C for 3 h. The IR spectrum of this sample (supplementary material Fig. S1A)[3] did not differ significantly from those obtained after treatment at lower temperatures. The corresponding Raman spectrum exhibited significant fluorescence as indicated by the sloping baseline (supplementary material Fig. S1A).[3] The bands owing to $Re_2(CO)_{10}$ were still observed at 2129 and 2006 cm^{-1}, which exhibited intensities comparable to the other ν(CO) bands present. The bands owing to the rhenium oxide species clearly dominated the spectrum. Instead of chloroform, this sample was washed with a more polar solvent (water) and the IR and Raman spectra of the resulting solid were taken (supplementary material Fig. S1B).[3] The peaks owing to the metal oxide have essentially disappeared in both the IR and Raman spectra. The Raman bands at 2129 and 2006 cm^{-1}, owing to $Re_2(CO)_{10}$, also disappeared upon washing with H_2O (supplementary material Fig. S1B)[3], leaving only two ν(CO) Raman bands at 2042 and 1915 cm^{-1}. Therefore, the intensity of the ν(CO) Raman bands at 2043 and ~1900 cm^{-1} remain unchanged upon extraction with $CHCl_3$ and H_2O, suggesting that the grafted complex $Re(CO)_3(O\text{-}Z)_3$ is tightly bound to the zeolite wall.

$Re_2(CO)_{10}$ / *dehydrated* NaY

To investigate the possible involvement of water in the reactivity of $Re_2(CO)_{10}$ on zeolite Y, we performed the same experiments using NaY, which had been carefully dehydrated before the introduction of rhenium carbonyl. Figure 5*a* shows the IR and Raman spectra after heating the sample $Re_2(CO)_{10}$ / dehydrated NaY at 200 °C. The spectra are virtually identical to those obtained using the hydrated analogue of NaY (Fig. 3*a*). This indicates that upon treatment at 200 °C, the reactivity of $Re_2(CO)_{10}$ in NaY is not affected by the presence of H_2O, and that the solid sample contained a mixture of $Re_2(CO)_{10}$ and $Re(CO)_3(O\text{-}Z)_3$. Upon heating for longer periods at 200 °C (Figs. 5*b* and 5*c*) the IR spectra did not change significantly. However, the corresponding Raman spectra showed a gradual decrease in the intensity of the ν(CO) peaks owing to $Re_2(CO)_{10}$ at 2129, 2022, and 2003 cm^{-1}. Interestingly, the bands in the regions 900–1000 cm^{-1} and 200 – 400 cm^{-1} in the IR and Raman spectra, owing to the rhenium oxides, are barely visible even after prolonged treatment at 200 °C (Fig. 5*c*).

To further mimic the conditions used in the experiments with hydrated NaY, we heated the sample $Re_2(CO)_{10}$ / dehydrated NaY at 270 °C for 3 h (Fig. 6*a*). Even after this heat treatment, the intensity of the bands owing to the rhenium oxide species still remained very weak. In addition, the ν(CO) bands owing to $Re_2(CO)_{10}$ continued to decrease in intensity, essentially leaving those of $Re(CO)_3(O\text{-}Z)_3$ (Fig. 6*a*). These results confirm that in the absence of water, the majority of the original $Re_2(CO)_{10}$ is converted to the subcarbonyl species $Re(CO)_3(O\text{-}Z)_3$; this process is not accompanied by the formation of rhenium oxide. A sample of hydrated NaY contains approximately 25% water by weight, as indicated by thermogravimetric analysis. This amount of water was added to the sample $Re_2(CO)_{10}$ / dehydrated NaY treated at 270 °C for 3 h, and then the sample was subsequently heated another hour at 270 °C, and the IR and Raman spectra were taken. The spectra indicate a dramatic increase in the amount of rhenium oxide species present in the sample. This is evidenced by the growth of bands at 982, 931, and 332 cm^{-1} in the Raman spectrum and 937 and

910 cm^{-1} in the corresponding IR spectrum (Fig. 6*b*). At the same time, the bands at 2129 and 2008 cm^{-1} grew in intensity, suggesting that a portion of the metal carbonyl species $Re(CO)_3(O\text{-}Z)_3$ had converted back to $Re_2(CO)_{10}$. Further treatment at 270 °C confirmed this trend (Fig. 6*c*), as evidenced by the continued growth of the bands at 2129 and 2008 cm^{-1}. At the same time, a slight growth in the Raman bands owing to the rhenium oxide was observed (Fig. 6*c*). All these results indicate that in the absence of water, heating the sample $Re_2(CO)_{10}$ / dehydrated NaY results in an almost complete conversion of rhenium carbonyl:

[1] $$Re_2(CO)_{10} + 3(O\text{-}Z) \rightarrow 2Re(CO)_3(O\text{-}Z)_3 + 4CO$$

Upon addition of water, a portion of the $Re(CO)_3(O\text{-}Z)_3$ species is converted into the metal oxide Re_2O_7. This is accompanied by a slight reformation of $Re_2(CO)_{10}$.

Reaction schemes

Our experimental data provide some new insight concerning the adsorption and thermal reactivity of $Re_2(CO)_{10}$ on zeolite Y. Upon mild treatment at 60 °C, the hydrated NaY – carbonyl sample consists mostly of rhenium carbonyl, which is located on the exterior of the zeolite as crystallites, although some $Re_2(CO)_{10}$ molecules had already diffused into the supercages of NaY. Decomposition begins to occur near 150 °C. The development of a broad band near 1891 cm^{-1} suggests the onset of the decarbonylation reaction outlined in eq. [1]. Treatment at 200 °C facilitates the conversion of a significant portion of the subcarbonyl species into the rhenium oxide Re_2O_7. Photo-oxidation of $Re_2(CO)_{10}$ with O_2, generating the metal oxide Re_2O_7, has been reported (23). However, in our case, hydrated NaY contains primarily sorbed H_2O. Our results indicate that the adsorbed water plays an important role in the formation of the rhenium oxide and is responsible for the oxidation of the rhenium carbonyl species present in our samples. The hydroxyl groups present on Al_2O_3 were shown to oxidize the zero valent carbonyl species of Cr, W, and Mo to various metal oxides (24). Following these reports, a very thorough study was conducted by Hucul and Brenner (25), who examined this redox behaviour for alumina-supported complexes of many known transition metals that form stable carbonyls. The authors concluded that upon thermal reaction with alumina, all of the zero valent metal carbonyls underwent partial oxidation:

[2] $$M(CO)_j + n(Z\text{-}OH) \rightarrow (O^-)_nM^{n+} + (n/2)H_2 + jCO$$

(Z-OH) represents a surface hydroxyl group. In the case of $Re_2(CO)_{10}$, the oxidation began to occur at 200 °C, the same temperature that we first observed the formation of metal oxide on hydrated NaY (Fig. 4*a*). Hucul and Brenner (25) determined that after the thermal reaction of $Re_2(CO)_{10}$ with alumina was complete, the final average oxidation number of the rhenium atom was approximately +5.4. In view of this redox behaviour, we suggest that the oxidation observed in our study is the result of the presence of H_2O molecules inside the supercages of NaY. Since the interactions between the Na^+ ions and H_2O molecules polarize the O—H bonds, the polarized H_2O molecules exhibit similar oxidizing char-

© 2004 NRC Canada

acteristics to that of the surface hydroxyl groups present on metal oxides such as Al_2O_3.

When H_2O was added to the sample $Re_2(CO)_{10}$ / dehydrated NaY treated at 270 °C, we observed a partial reformation of $Re_2(CO)_{10}$, in addition to the formation of rhenium oxide (Figs. 6*b* and 6*c*). This is attributed to the carbonylation of the species $Re(CO)_3(O\text{-}Z)_3$. Upon thermal decomposition of $Re_2(CO)_{10}$ in NaY, Zecchina et al. (8) detected the presence of subcarbonyl species. Exposure to CO was shown to result in a recarbonylation of the subcarbonyls, leading to the partial reformation of $Re_2(CO)_{10}$. Figure 6*a* shows that upon prolonged treatment at 270 °C, the sample $Re_2(CO)_{10}$ / dehydrated NaY consists mainly of the species $Re(CO)_3(O\text{-}Z)_3$. Upon the introduction of H_2O into the sample and further heating, the rhenium tricarbonyl species undergoes oxidation, which can be approximated as:

$$[3]\qquad 2Re(CO)_3(O\text{-}Z)_3 + 7[H_2O\cdots Na^+] \rightarrow Re_2O_7 + 6CO + 7H_2 + 6(O\text{-}Z) + 7Na^+$$

The CO released from the reaction is responsible for the recarbonylation of $Re(CO)_3(O\text{-}Z)_3$, leading to the partial reformation of the original metal carbonyl ($Re_2(CO)_{10}$). It is worth noting that the Raman spectra of Re_2O_7 formed inside zeolite Y are very similar to those of Re_2O_7 in solution, liquid as well as gas phase, but distinctly different from that of crystalline Re_2O_7, which exhibits more than 20 bands owing to factor group splitting (21).

$Re_2(CO)_{10}$ / *siliceous* zeolite Y

To investigate the role played by the Na^+ cations on the reactivity of $Re_2(CO)_{10}$ within zeolite Y, we performed similar experiments using siliceous Y (SiY), which had been dehydrated before introduction of $Re_2(CO)_{10}$. Figure 7*a* shows the IR and Raman spectra of the sample $Re_2(CO)_{10}$/SiY heated at 130 °C. Both the IR and Raman spectra in the ν(CO) region look very similar to those of pure $Re_2(CO)_{10}$ in solution, indicating that the solid sample consists mainly of isolated $Re_2(CO)_{10}$ molecules. Treatment of the sample at 200 °C did not result in significant changes in the appearances of either the IR or Raman spectra in the ν(CO) region (Fig. 7*b*). However, weak bands at 985 and 944 appeared in the Raman spectrum (Fig. 7*b*). These results suggest that the same rhenium oxide species that formed in the $Re_2(CO)_{10}$/NaY sample had also formed in the $Re_2(CO)_{10}$/SiY sample, albeit in a much smaller amount. This is likely due to a small concentration of hydroxyl groups (Si-OH) present within SiY.

Further treatment of the $Re_2(CO)_{10}$/SiY sample at 200 °C resulted in the solid sample turning from a white to a grey solid. The Raman spectrum of this sample (not shown) exhibited intense fluorescence, rendering any peak identification virtually impossible. The corresponding IR spectrum in the ν(CO) region still exhibited an overall profile that was indicative of isolated $Re_2(CO)_{10}$ molecules (supplementary material Fig. S2A).[3] A weak, broad IR band at 1931 cm^{-1} was also evident, suggesting a decomposition reaction had started to occur. This was accompanied by a slight overall reduction in the total ν(CO) band intensity relative to the various ν_{as}(T-O) modes of SiY (supplementary material Fig. S2A).[3] Treatment at 200 °C for a total of 3 h resulted in a further decrease in the overall ν(CO) IR band intensity, which was accompanied by another colour change from a grey to a dark black solid (supplementary material Fig. S2B).[3] The Raman spectrum of this sample (not shown) also exhibited intense fluoresence. The corresponding IR spectrum now consisted of two sets of bands: (*i*) bands at 2072, 2020, and 1974 cm^{-1} are indicative of isolated $Re_2(CO)_{10}$ molecules and (*ii*) two bands at 2030 and 1932 cm^{-1} are assigned to the complex $Re(CO)_3(O\text{-}Z)_3$.

Heating the $Re_2(CO)_{10}$/SiY sample at 200 °C (4 h total) facilitated the almost complete decomposition of the metal carbonyl species present as indicated by the very weak ν(CO) bands in the IR spectrum of the resulting sample (supplementary material Fig. S2C).[3] The ν(CO) region did not display any of the characteristic bands owing to isolated $Re_2(CO)_{10}$ molecules. Only two bands were observed at 2032 and 1931 cm^{-1} indicating that the only metal carbonyl species present in the solid sample was $Re(CO)_3(O\text{-}Z)_3$. The same sample was extracted with $CHCl_3$. The IR spectra of the solid sample before and after washing were identical (supplementary material Figs. S2C and S2D),[3] indicating that a very small amount of residual $Re(CO)_3(O\text{-}Z)_3$ is tightly bound to the zeolite wall.

The ν(CO) IR frequencies of $Re(CO)_3(O\text{-}Z)_3$ supported in SiY at 2032 and 1931 cm^{-1} are shifted considerably to a higher frequency relative to those observed for the same complex in NaY (Si/Al = 2.35) at 2023 and 1904 cm^{-1} (Fig. 4*a*). The lower ν(CO) frequencies observed in NaY (Si/Al = 2.35) are reflective of the presence of Na^+ ions, which interact with the carbonyl ligands of the supported complex $Re(CO)_3(O\text{-}Z)_3$ [Re-CO···Na^+], causing a weakening of the C—O bonds.

Summary

In the absence of water, $Re_2(CO)_{10}$ supported in NaY (Si/Al = 2.35) undergoes the decomposition reaction outlined in eq. [1]. The decomposition begins near 150 °C and is essentially complete at 270 °C. In the presence of H_2O, $Re_2(CO)_{10}$ is first converted to $Re(CO)_3(O\text{-}Z)_3$ and the latter is partially converted to the metal oxide Re_2O_7. The study suggests that thermal decomposition of $Re_2(CO)_{10}$ on hydrated zeolite under mild conditions may serve as a convenient route to form highly dispersed Re_2O_7 in a zeolite host for catalysis. $Re_2(CO)_{10}$ adsorbed in SiY decomposes to metal Re almost completely at 200 °C, indicating that zerovalent rhenium carbonyl species are considerably destabilized within the supercages of the highly siliceous SiY relative to the same species present in NaY.

In the present work, we have shown that the FT-Raman spectra have been more informative in terms of providing structural data, whereas the corresponding IR spectra often contain rather broad peaks, which can be difficult to interpret.

New insights about the host–guest chemistry of the tungsten oxo complex of calix[4]arene, and novel "one pot" difunctionalizations of calix[4]arene using tetrachlorometal(VI) oxide (M = Mo, W)[1]

Pascal Mongrain, Jasmin Douville, Jonathan Gagnon, Marc Drouin, Andreas Decken, Daniel Fortin, and Pierre D. Harvey

Abstract: The strong Lewis acid tungsten oxo complex of calix[4]arene can be obtained in both hydrated and non-hydrated forms. This complex coordinates a water molecule inside the cavity via strong O···W interactions with relatively short distances of 2.284(4) and 2.329(2) Å for the tungsten oxo complex of calix[4]arene··H_2O·aniline (**1**), and the tungsten oxo complex of calix[4]arene·H_2O·toluene (**2**·toluene), respectively. The strong interactions are also deduced by the relatively high H_2O elimination temperature observed by TGA and DSC (above 200 °C). The coordinated water molecule inside the calix[4]arene cavity is characterized by a strong IR absorption at 3616 cm^{-1}, and a narrow resonance at ~1.2 ppm (the chemical shifts of the uncoordinated water are 1.55 and 1.60 ppm in C_6D_6 and $CDCl_3$, respectively). This water molecule gives rise to H-bonds with aniline in **1**. The tungsten oxo complex of 5,11,17,23-tetrabromocalix[4]arene (**4**), also binds H_2O as the characteristic signatures are observed. The successful removal of H_2O in **2**, is performed under mild conditions using bis(tetrahydrofuran)-uranyl nitrate as a competitive Lewis acid. When this reaction is performed in acetonitrile, butyronitrile or *tert*-butylnitrile, the corresponding tungsten oxo complexes of calix[4]arene·acetonitrile (**3**), ·butyronitrile (**5**), and ·*tert*-butylnitrile (**6**) are obtained. The use of uranyl as a H_2O abstractor is unprecedented. The X-ray structure of **3** consists of a tungsten oxo complex of calix[4]arene coordinated by an acetonitrile molecule (d(W···N = 2.412(2) Å). The tetra-5,11,17,23-choromethyl-25,26,27,28-tetrahydroxycalix[4]arene reacts with $M(O)Cl_4$ (M = Mo, W) in a 1:1 stoichiometry, via a tetra Friedel–Crafts addition of benzene or toluene, followed by a lower-rim complexation of the metal oxide, to form "flower-shaped" calix[4]arenes. This "one pot" double functionalization is unprecedented.

Key words: calix[4]arene, tungsten, molybdenum, X-ray, host–guest, Friedel–Crafts, Lewis acid, uranyl, DSC, TGA.

Résumé : Le complexe très fort de l'oxo tungstène avec calix[4]arène peut être obtenu sous les formes hydratée et non hydratée. Ce complexe donne lieu à une coordination avec une molécule d'eau à l'intérieur de la cavité, par le biais d'interactions O···W relativement courtes de 2,284(4) et 2,329(2) Å respectivement pour le complexe de l'oxo tungstène avec calix[4]arène··H_2O·aniline (**1**) et le complexe de l'oxo tungstène avec calix[4]arène·H_2O·toluène (**2**·toluène). On peut aussi déduire le caractère très fort des interactions de la température relativement élevée (supérieure à 200 °C) de l'élimination de l'eau observée par analyse thermogravimétrique et par calorimétrie à balayage différentiel. La molécule d'eau coordinée à l'intérieur de la cavité du calix[4]arène est caractérisée par une forte bande d'absorption IR à 3616 cm^{-1} et par une résonance étroite à environ 1,2 ppm (les déplacements chimiques de l'eau qui n'est pas coordinée absorbant à 1,55 et 1,60 ppm respectivement dans le C_6D_6 et le $CDCl_3$). Cette molécule d'eau donne aussi lieu à des liaisons hydrogènes avec l'aniline dans le composé **1**. Le complexe de l'oxo tungstène du 5,11,17,23-tétrabromocalix[4]arène (**4**) fixe aussi une molécule d'eau observée par les signatures caractéristiques. On peut réussir à enlever la molécule d'eau du composé **2** dans des conditions douces en utilisant du nitrate de bis(tétrahydrofurane)-uranyle comme acide de Lewis compétitif. Lorsqu'on effectue cette réaction dans l'acétonitrile, le butyronitrile ou le *tert*-butylnitrile, on obtient les

complexes de l'oxo tungstène de calix[4]arène·acétonitrile (**3**), ·butyronitrile (**5**) et de ·*tert*-butylnitrile (**6**). Il n'existe pas de précédent pour l'utilisation de l'uranyle pour l'enlèvement d'une molécule d'eau. La structure cristalline du complexe **3**, telle que déterminée par diffraction des rayons X, est formée d'un complexe de l'oxo tungstène du calix[4]arène comportant une coordination à une molécule d'acétonitrile (d(W···N) = 2,412(2) Å). Le 5,11,17,23-tétra(chlorométhyl)-25,26,27,28-tétrahydroxycalix[4]arène réagit avec le $M(O)Cl_4$ (M = Mo, W) suivant une stoechiométrie 1:1 par le biais d'une tétraaddition de Friedel–Crafts du benzène ou du toluène, qui est suivie d'une complexation de l'oxyde métallique à la ceinture inférieure, qui conduit à la formation de calix[4]arènes en forme de fleur. Cette double fonctionnalisation monotope n'a pas non plus de précédent.

Mots clés : calix[4]arène, tungstène, molybdène, rayons X, hôte–invité, Friedel–Crafts, acide de Lewis, uranyle, calorimétrie à balayage différentiel, analyse thermogravimétrique.

Introduction

The syntheses and investigations of calix[4]arene macrocycles and derivatives continue to be very active fields (1). Applications for cation extractions, biomimetics, luminescence probes, sensors, nuclear waste treatment, and catalysis are well-known (1, 2). Among these species, calix[4]arene is certainly the most investigated compound. The cyclic structure composed of four aryl groups exhibits four conformations (cone, partial cone, and 1,2- and 1,3- alternated), where the first, may allow host–guest interactions between a substrate, ordinarily a neutral organic molecule, and the cavity formed by the cone. This property is highly variable, as empty flattened structures often exist because of the relative flexibility of the macrocycles (3). The coordination of a metal atom such as Nb(V) (4–6), Mo(VI) (7, 8), and W(VI) (9–11) for example, in the calix[4]arene narrow rim has been used to secure the cone conformation and to open the hydrophobic cavity wide enough to allow guest molecules such as benzene, tetrahydrofuran, dimethylamine, pyridine, acetic acid, and even water, to penetrate. The common point in these reported systems is that the wide rim is functionalized by four tert-butyl groups, thus enhancing the cavity size. The use of larger groups such as -N=NR can even let another calix[4]arene compound penetrate the cavity (12, 13). Numerous questions arise such as what happens when the wide rim is unfunctionalized, what other organic substrates can interact with the calix[4]arene's cavity, and can one take advantage of the presence of a water molecule at the bottom of the cavity.

In the first section of this paper, we wish to report the preparation of the tungsten oxo complexes of calix[4]arene that is not functionalized at the wide rim, along with three X-ray structures in which a water or an acetonitrile molecule is held inside the cavity with W···O or W···N interactions. In one structure, H-bonds with the aniline molecule are observed, and supramolecular construction is possible above the cavity. In the other case, the coordination of a nitrile molecule also indicates that the calix[4]arene cavity can also be functionalized at the upper and lower rims. The water molecule can be removed by the use of the Lewis acid UO_2^{2+}, or by heating the solid samples at temperatures of about 200 °C. In the second section, we wish to report an unprecedented reactivity in the calix[4]arene chemistry, which consists of tetra Friedel–Craft additions of an aromatic to tetra-5,11,17,23-chloromethyl-25,26,27,28-tetrahydroxycalix[4]arene (**1**), hence expanding the cavity, followed by the coordination of the metal oxide.

Experimental section

Materials

Calix[4]arene (14), tungsten oxo complex of calix[4]arene (8), bis(tetrahydrofuran)uranyl nitrate (15), and tetra-5,11,17,23-chloromethyl-25,26,27,28-tetrahydroxycalix[4]arene (16) (**7**) were prepared according to procedures reported in the literature. The tetrachloride(oxo)tungsten(VI) and uranyl nitrate were purchased from Aldrich and were used as received.

Tungsten oxo complex of calix[4]arene·H_2O·aniline (1)

The tungsten oxo complex of calix[4]arene (0.1 g, 0.16 mmol) was treated with 3 mL of aniline in 20 mL of benzene and 0.2 mL of water. The solution was refluxed for 8 h and cooled to room temperature. The solution was evaporated until it reached 2 mL. The solute was precipitated by diffusion of diethyl ether. Yellow crystals were obtained in 70% yield (79.9 mg). IR (solid) (cm^{-1}): ~3600, br (ν(OH···N)). ^{1}H NMR ($CDCl_3$): 7.13 (d, 8H, meta H Ph_{calix}, $J_{H\text{-}H}$ = 7.45), 7.05 (t, 3H, meta and para H of aniline, $J_{H\text{-}H}$ = 7.70), 7.71 (t, 4H, para H Ph_{calix}, $J_{H\text{-}H}$ = 7.63), 6.34 (d, 2H, ortho H of aniline, $J_{H\text{-}H}$ = 7.91), 4.68 (d, 4H, Ar-CH_2-Ar, $J_{H\text{-}H}$ = 12.71), 3.34 (d, 4H, Ar-CH_2-Ar, $J_{H\text{-}H}$ = 12.71), 2.35 (NH_2), 1.21 (s, 2H, H_2O···W). ^{13}C NMR (CD_3Cl): 156.2, 130.3, 129.2, 128.3, 123.9, 119.1, 115.4, 32.2. EI-MS: 620 M^+.

Tungsten oxo complex of calix[4]arene·H_2O·toluene (2·toluene)

A solution of calix[4]arene (0.5 g, 1.18 mmol) and 40 mL of toluene was treated with $WOCl_4$ (400 mg, 1.18 mmol). The solution was refluxed for 48 h. Then, the solution was filtered and was extracted with toluene. The solution was evaporated with a flux of argon and a purple crystalline material identified as the tungsten oxo complex of calix[4]arene·H_2O (**2**) was obtained in 72% yield (60.5 mg). IR (solid) (cm^{-1}): 3616, s (ν(OH)). ^{1}H NMR (C_6D_6): 6.80 (d, 8H, ortho H Ph, $J_{H\text{-}H}$ = 7.57), 6.55 (t, 4H, para H Ph, $J_{H\text{-}H}$ = 7.57), 4.62 (d, 4H, Ar-CH_2-Ar, $J_{H\text{-}H}$ = 12.71), 2.94 (d, 4H, Ar-CH_2-Ar, $J_{H\text{-}H}$ = 12.71), 1.10 (s, 2H, H_2O···W). EI-MS: 620 M^+. Anal. calcd. for $C_{28}H_{20}O_5W{\cdot}H_2O$: C 52.69, H 3.47; found: C 52.33, H 3.57. Compound **2**·toluene obtained when

the product was dissolved in toluene and acetonitrile was slowly vapour diffused through it, and crystals suitable for X-ray analysis were obtained.

Tungsten oxo complex of calix[4]arene·acetonitrile (3)

A solution containing 28 mg (0.045 mmol) of **2**, 3.5 mL of CH_2Cl_2, and 3.5 mL of acetonitrile was treated with 31 mg (0.068 mmol) of $(UO_2)(NO_3)_2(THF)_2$. The solution was stirred for 24 h and a precipitate was formed. The solution was filtered and yellow crystals were obtained in 62% yield (18 mg). IR (solid) (cm^{-1}): 2285, s (ν(CN)). ^1H NMR (C_6D_6): 6.80 (d, 8H, Ph, J_{H-H} = 7.57 Hz), 6.55 (t, 4H, Ph, J_{H-H} = 7.57 Hz), 4.62 (d, 4H, Ar-CH_2-Ar, J_{H-H} = 12.71Hz), 2.93 (d, 4H, Ar-CH_2-Ar, J_{H-H} = 12.71Hz), 1.21 (s, 3H, N=C-CH_3). EI-MS: 620 M^+.

Tungsten oxo complex of 5,11,17,23-tetrabromocalix[4]arene·H_2O (4)

A solution of **2** (47 mg, 0.076 mmol) with 10 mL of $CHCl_3$ was treated with 0.02 mL of Br_2. The solution was stirred for 24 h. The reaction was quenched twice with $Na_2S_2O_3$ and washed with H_2O. A yellow solid was obtained in 99% yield (70.7 mg). IR (solid) (cm^{-1}): 3616, s (ν(OH)). ^1H NMR ($CDCl_3$): 7.28 (s, 8H, Ph), 4.59 (d, 4H, Ar-CH_2-Ar, J_{H-H} = 12.70 Hz), 3.37 (d, 4H, Ar-CH_2-Ar, J_{H-H} = 12.70 Hz), 1.25 (2H, H_2O···W). EI-MS: 936 M^+.

Tungsten oxo complex of calix[4]arene·butyronitrile (5)

This compound was prepared according to the same procedure described for **3** using butyronitrile as the solvent. A yellow solid was obtained in 59% yield. IR (solid) (cm^{-1}): 2283, s (ν(CN)). ^1H NMR ($CDCl_3$): 7.14 (d, 8H, meta Ph, J_{H-H} = 7.61), 6.72 (t, 4H, ortho H Ph, J_{H-H} = 7.49) 4.68 (d, 4H, Ar-CH_2-Ar, J_{H-H} = 12.50), 3.65 (t, 2H, N=C-CH_2-, J_{H-H} = 7.18) 3.37 (d, 4H, Ar-CH_2-Ar, J_{H-H} = 12.52), 1.25 (m, 2H, -CH_2-CH_3) 0.86 (m, 3H, -CH_2-CH_2-CH_3). EI-MS: 620 M^+.

Tungsten oxo complex of calix[4]arene·*tert*-butylnitrile (6)

This compound was prepared according to the same procedure described for **3** using *tert*-butylnitrile as the solvent. A yellow solid was obtained in 64% yield. IR (solid) (cm^{-1}): 2263, s (ν(CN)). ^1H NMR ($CDCl_3$): 7.14 (d, 8H, meta Ph, J_{H-H} = 7.53), 6.72 (t, 4H, ortho H Ph, J = 7.51) 4.68 (d, 4H, Ar-CH_2-Ar, J_{H-H} = 12.55), 3.33 (d, 4H, Ar-CH_2-Ar, J_{H-H} = 12.87), 1.37 (s, 9H, -C-(CH_3)$_3$, J = 6.86). EI-MS: 620 M^+.

5,11,17,23-Tetrabenzyl-25,26,27,28-oxomolybdenum(VI)calix[4]arene (8)

A benzene (15 mL) suspension of $MoOCl_4$ (0.070 g, 0.27 mmol) was reacted with **7** (0.100 g, 0.16 mmol). The suspension was refluxed overnight. The solvent was evaporated in vacuo and the residue was dissolved in CH_2Cl_2 (40 mL). The solution was washed three times with water. The organic phase was separated, dried with $MgSO_4$, and filtered. The solvent was evaporated to afford a dark blue solid. Yield: 53% (0.076 g). ^1H NMR ($CDCl_3$): 7.29–6.87 (m, 28H, Ar), 4.39 (d, 4H, J_{H-H} = 12.7, ArCH_2Ar), 3.80 (s, $C_6H_5CH_2$Ar), 3.17 (d, 4H, J_{H-H} = 12.5, ArCH_2Ar). ^{13}C NMR ($CDCl_3$): 156.88, 140.86, 137.10, 129.73, 128.71, 128.45, 126.17, 41.09, 32.50. EI-MS *m*/*e*: 892 (M^+). Anal. calcd. for $C_{56}H_{40}O_5Mo·H_2O$: C 74.17, H 4.67; found: C 73.23, H 5.40.

5,11,17,23-Tetrabenzyl-25,26,27,28-oxotungsten(VI)calix[4]arene (9)

First method

A benzene (15 mL) suspension of $WOCl_4$ (0.160 g, 0.47 mmol) was reacted with **7** (0.200 g, 0.32 mmol). The suspension was refluxed overnight. The solvent was evaporated in vacuo and the residue was dissolved in CH_2Cl_2 (40 mL). The solution was washed three times with water. The organic phase was separated, dried with $MgSO_4$, and filtered. The solvent was evaporated to produce a black solid. Yield: 52% (0.17 g). ^1H NMR ($CDCl_3$): 7.29–6.89 (m, 28H, Ar), 4.58 (d, 4H, J_{H-H} = 12.8, ArCH_2Ar), 3.80 (s, $C_6H_5CH_2$Ar), 3.20 (d, 4H, J_{H-H} = 12.9, ArCH_2Ar). ^{13}C NMR ($CDCl_3$): 154.33, 140.87, 136.71, 130.82, 128.64, 128.45, 126.19, 41.02, 32.21. EI-MS: 980 (M^+). Anal. calcd. for $C_{56}H_{40}O_5W·H_2O$: C 67.21, H 4.83; found: C 67.07, H 5.07.

Second method

The procedure was identical to that used for the first method, except that **12** was used instead of **7**.

5,11,17,23-Tetra(4-methylbenzyl)-25,26,27,28-oxomolybdenum(VI)calix[4]arene (10)

A toluene (20 mL) suspension of $MoOCl_4$ (0.029 g, 0.11 mmol) was reacted with **7** (0.040 g, 0.06 mmol). The suspension was refluxed overnight. The solvent was evaporated in vacuo and the residue was dissolved in CH_2Cl_2 (50 mL). The solution was washed three times with water. The organic phase was separated, dried with $MgSO_4$ and filtered. The solvent was evaporated to afford a golden brown solid. Yield: 92% (0.052 g). ^1H NMR ($CDCl_3$): 7.18–6.80 (m, 24H, Ar), 4.39 (d, 4H, J_{H-H} = 12.5, ArCH_2Ar), 3.78 (d, 8H, J_{H-H} = 11.2, $C_6H_4CH_2$Ar), 3.15 (d, 4H, J_{H-H} = 12.6, ArCH_2Ar), 2.36 (s, 12H, $CH_3C_6H_4$). ^{13}C NMR ($CDCl_3$): 156.93, 138.86, 137.92, 137.46, 136.48, 136.35, 135.70, 130.36, 129.75, 129.21, 129.00, 128.74, 126.99, 126.57, 126.08, 40.76, 38.61, 32.56, 21.11, 19.76. EI-MS: 949 (M^+). Anal. calcd. for $C_{60}H_{52}O_5Mo·H_2O$: C 74.52, H 5.63; found: C 74.46, H 5.12.

5,11,17,23-Tetrakis(methylbenzyl)-25,26,27,28-oxotungsten(VI)calix[4]arene (11)

A toluene (20 mL) suspension of $WOCl_4$ (0.192 g, 0.56 mmol) was reacted with **7** (0.250 g, 0.40 mmol). The suspension was refluxed overnight. The solvent was evaporated in vacuo and the residue was dissolved in CH_2Cl_2 (50 mL). The solution was washed three times with water. The organic phase was separated, dried with $MgSO_4$, and filtered. The solvent was evaporated to give the product as a dark blue solid. Yield: 98% (0.041 g). ^1H NMR ($CDCl_3$): 7.17–6.89 (m, 24H, Ar), 4.56 (d, 4H, J_{H-H} = 12.6, ArCH_2Ar), 3.78 (d, 8H, J_{H-H} = 12.3, $C_6H_4CH_2$Ar), 3.15 (d, 4H, J_{H-H} = 12.6, ArCH_2Ar), 2.34 (s, 12H, $CH_3C_6H_4$). ^{13}C NMR ($CDCl_3$): 154.25, 138.79, 137.88, 136.99, 135.88, 135.69, 130.77, 130.31, 129.60, 129.15, 128.57, 126.55, 126.03, 40.62, 38.44, 32.18, 21.04, 19.72. EI-MS: 1036

(M^+). Anal. calcd. for $C_{60}H_{52}O_5W{\cdot}H_2O$: C 68.31, H 5.16; found: C 68.51, H 5.23.

5,11,17,23-Chloromethyl-25,26,27,28-oxotungsten(IV)calix[4]arene (12)

2 (0.050 g, 0.083 mmol) and chloromethyl octyl ether (0.3 mL, 2.4 mmol) were dissolved in CH_2Cl_2 (15 mL). The solution was cooled to –5 °C and $SnCl_4$ (0.2 mL, 1.7 mmol) was added dropwise over 15 min under agitation. The solution was then warmed up to room temperature and was further stirred for 1 h. Water (15 mL) was slowly added to the solution and the organic phase was separated. The organic phase was washed twice with brine (20 mL), then dried with $MgSO_4$ and filtered. The solvent was evaporated until a yellow paste formed. The residue was washed with cooled hexane (50 mL; 4 °C) to afford a yellow powder. Yield: 79% (0.053 g). ^{1}H NMR ($CDCl_3$): 7.19 (s, 8H, Ar), 4.66 (d, 4H, $J_{H\text{-}H}$ = 12.9, Ar*CH*$_2$Ar), 4.46 (s, 8H, Ar*CH*$_2$Cl), 3.35 (d, 4H, $J_{H\text{-}H}$ = 13.0, Ar*CH*$_2$Ar). ^{13}C NMR ($CDCl_3$): 141.32, 131.18, 128.87, 45.44, 32.15. EI-MS: 672 (M^+ – 4Cl). Anal. calcd. for $C_{32}H_{24}O_5Cl_4W{\cdot}H_2O$: C 46.18, H 3.15; found: C 46.11, H 3.08.

Apparatus

The NMR spectra were acquired on a 300 MHz Bruker instrument (^{1}H, 300.15 MHz). The chemical shifts (δ) are reported with respect to tetramethylsilane (TMS = 0 ppm) (^{1}H). The chemical shifts and coupling constants are reported in ppm and Hz, respectively. The FT-IR data were obtained on a PerkinElmer spectrometer Model 1600. The mass spectra (EI) were measured on a ZAB-1F instrument (VG model). The TGA analyses were performed using a PerkinElmer TGA 7 apparatus operating between 50 and 700 °C scanning at the rate of 3 °C/min. under N_2 atmosphere. The glass transition temperatures (Tg) were measured using a PerkinElmer 5A DSC7 equipped with a thermal controller 5B TAC 7/DS. The temperature calibrations were done with water and metallic indium as standards. The accuracy is ±0.1 °C and ±0.1% for the temperature and heat capacity, respectively. The sample weights ranged from 5 to 10 mg, and the scan rate was 10°/min.

Crystallography

Tungsten oxo complex of calix[4]arene·H_2O·aniline (1)

Intensity data were collected at 293 K on an Enraf Nonius CAD-4 automatic diffractometer at the Université de Sherbrooke. Table 1 provides crystallographic and data collection details. The NRCCAD programs were used for centering, indexing, and data collection (17). The structure was solved by the application of direct methods using the NRCVAX (18) program and refined by least-squares using SHELXL-93 (19). Hydrogen atoms were geometrically placed at idealized positions and not refined except for those of the water molecule, which were located by Δ*F*. The aniline molecule was disordered and occupancy refinement showed a 0.316(7)/0.684(7) ratio. The ORTEP diagram (20) includes only the aniline with higher occupancy factor.

Tungsten oxo complex of calix[4]arene·H_2O·toluene (2·toluene) and of calix[4]arene·acetonitrile (3)

Crystals of **2**·toluene and 3 were grown by a slow evaporation method using toluene and acetonitrile, respectively, at 25 °C. Single crystals were coated with Paratone-N oil, mounted using a glass fibre and frozen in the cold nitrogen stream of the goniometer. A hemisphere of data was collected on a Bruker AXS P4/SMART 1000 diffractometer at the University of New Brunswick, using ω and θ scans with a scan width of 0.3° and 10 s exposure times. The detector distance was 6 cm. The data were reduced (SAINT) (21) and corrected for absorption (SADABS) (22). The structures were solved by direct methods and refined by full-matrix least-squares on F^2 (SHELXTL) (23). All non-hydrogen atoms were refined anisotropically. For calix[4]arene·H_2O·toluene (2·toluene), the hydrogen atoms were found in Fourier difference maps and refined isotropically. For calix[4]arene·acetonitrile (**3**), the hydrogen atoms were included in calculated positions and refined using a riding model.

5,11,17,23-Tetrabenzyl-25,26,27,28-oxotungsten(VI)calix[4]arene (9)

Crystals of **9** were obtained from the evaporation of an acetonitrile–hexane solution. Single crystals were coated with Paratone-N oil, mounted using a glass fibre and frozen in the cold nitrogen stream of the goniometer at 198 K. A hemisphere of data was collected on a Bruker AXS P4/SMART 1000 diffractometer at the University of New Brunswick, using ω and θ scans. The detector distance was 6 cm. The data were analyzed at the Université de Sherbrooke. The data were reduced with Bruker SHELXTL but not corrected for absorption, solved by direct methods with SHELXS-86 (24) and refined by full-matrix least-squares on F^2 with SHELXL-93 (19). All the hydrogen atoms were placed at idealized calculated geometric positions and refined using a riding model. The phenyl groups were disordered on two positions (1) C10-C15 and (2) C10′-C15′ with 50.8% relative occupation for (1) that were kept fixed in the ORTEP drawing. All non-hydrogen atoms included of the calix[4]arene molecule were refined anisotropically with FLAT 66, DELU and SIMU (all included in SHELXL-93), with constrains on the phenyls (1) and (2) groups. One oxygen atom belonging to a water molecule trapped inside the calix[4]arene cavity and one oxygen outside (W=O) were given a fixed occupation factor of 100%. The crystallization acetonitrile molecule was refined isotropically with fixed bond lengths and thermal restrains. The occupation factor was 0.51. The remaining electronic density found above the cavity was assigned to water crystallization molecules based on ^{1}H NMR and IR data. These water molecules (O4, O5, O6) were refined isotropically with fixed thermal parameters. The total refined occupation factors for these were approximately 1.48 water molecules per assymetric unit.

Results and discussion

Host–guest chemistry

The tungsten oxo complex of calix[4]arene is very hydroscopic as it picks up water readily when synthesized or handled in air or in the presence of wet solvents as described

in the Experimental section for compounds **1** and **2**. This behaviour is not uncommon (8, 10, 11). The coordinated water molecule inside the tungsten oxo complex of calix[4]arene is characterized by a strong narrow IR absorption at 3616 cm^{-1}, and a narrow resonance at ~1.2 ppm in the ^1H NMR spectra (the chemical shifts of the uncoordinated water are 1.55 and 1.60 ppm for C_6D_6 and $CDCl_3$, respectively). This water molecule can be removed by heating the samples under vacuum, or at room pressure at temperatures approaching 200 °C (see AGT/DSC data).

The tungsten oxo complex of 5,11,17,23-tetrabromocalix[4]arene (**4**) was prepared taking advantage of the potential H-bonding network between the Br lone pairs and the H_2O protons, and to investigate the inductive effect on the W···OH_2 binding strength. The spectroscopic IR and ^1H NMR W···OH_2 signatures are clearly observed in this product, but all attempts to obtain crystals suitable for crystallography failed, as low diffracting, very thin rectangular green plates were always obtained.

Recently, we demonstrated that the strongly bonded halide ions on the unsaturated face of the $Pd_3(dppm)_3(CO)^{2+}$ cluster (25–27) could be removed with the use of another Lewis acid such as Cu^+ and Ag^+ (28, 29). In this work, anhydrous uranyl compound $(THF)_2(UO_2)(NO_3)_2$ is successfully used to abstract water from **2** (rxn. 1). Because of the strong ionic character of this reactant, acetonitrile, butyronitrile, and *tert*-butylnitrile were used as solvents, while the co-solvent dichloromethane dissolves the calix[4]arene complex. The uranyl compound shows affinity for calix[4]arene derivatives only if O atoms containing residues are present in the macrocycle forming multi-dentate ligand structures (see ref. 30 as an example) to form stable chelates. This is not the case here. The identity of **3** has been confirmed on the basis of crystallography, and **5** and **6** from IR and ^1H NMR spectroscopy. In all three cases, the nitrile molecule coordinates to the W atom in the final products (rxn. 2).

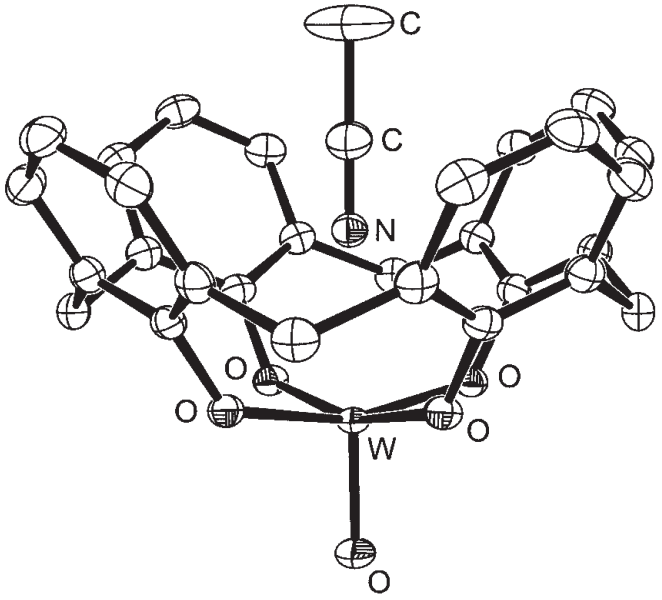
X-ray structure of 1, 2·toluene, and 3



Tables 1 and 2, and Figs. 1–3 present the X-ray data for the three investigated compounds. **1** exhibits a H_2O molecule inside the cavity strongly interacting with the W atom. The short W···O contact (2.284 Å) is the shortest ever to be reported for this family of complexes (Table 3). This distance is still longer by about ~0.3 Å than what it is expected for a covalent W—O single bond (1.89–1.92 Å, see Tables 2 and 3). The O=W···O angle is linear, certainly because of the constraint imposed by the cavity. The key feature is the presence of an aniline molecule held by H-bonds. The aniline is disordered as described in the Experimental section and two nonbonding distances are depicted for the two occupancies (d(O···N) = 2.625 and 2.740 Å). The supramolecular structure bears similarities with the structure reported for (*t*-Bu)$_4$calix[4]arene(Mo=O)·H_2O·$C_6H_5NO_2$ where the H-bonds retain the nitrobenzene over the calix[4]arene·H_2O moiety (8).

Compound **2**·toluene is similar to **1**, where a toluene crystallization molecule is found in the crystal lattice, also located on top of the cavity. A short W···O distance is observed (2.329 Å). The WO_5 core remains identical to that found for **1** where the bond distances and angles are identical within the experimental uncertainties. The toluene molecule is found tilted towards the cavity where the phenyl group exhibits the closest carbon–oxygen distances (3.079 (para from CH_3), 3.301 and 3.418 Å), suggesting some weak O-H···C interactions.

Compound **3** does not exhibit a water molecule inside the cavity, indicating that the H_2O abstraction was successful, consistent with the ^{1}H NMR and IR data. Instead, an acetonitrile molecule is located inside the cavity with the N atom directed towards the W metal with a short distance of 2.412(5) Å. Host–guest assemblies of the type calix[4]arene–acetonitrile are rare with respect to other organic substrates (31–34). Amoung these examples, some cases involve interactions of the N atom with a metal, which

© 2004 NRC Canada

Fig. 3. ORTEP diagram of **3**. The ellipsoids are shown at 30% probability and the H atoms are not shown for clarity.

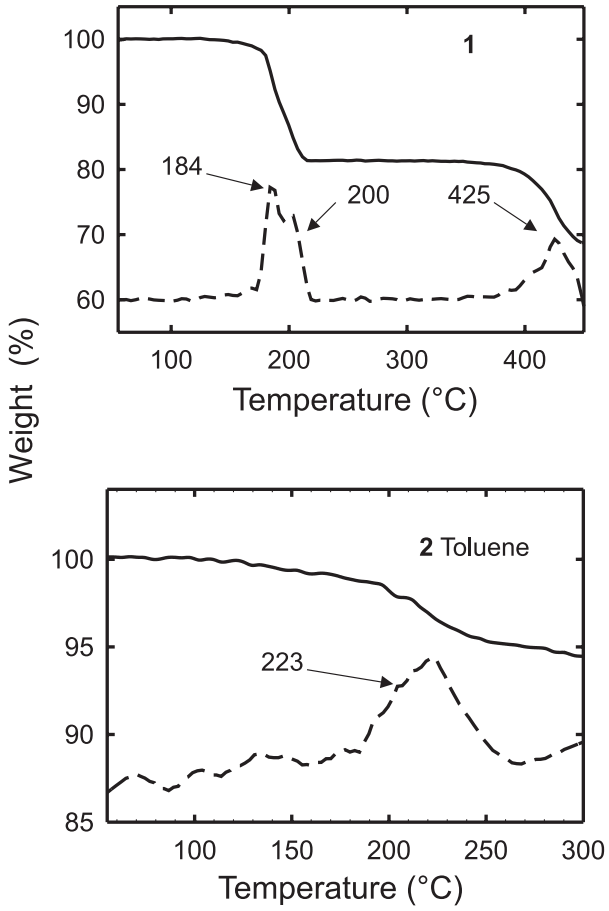
are even more unusual (34). Again the molecular skeleton of this metallated host remains unchanged by these interactions.

Table 3 allows a number of comparisons. The O=W···OH_2 distance is found to be shorter for the unfunctionalized metallated macrocycles (2.284(4) and 2.329(2) Å for **1** and **2**·toluene, respectively) than that of the *tert*-butylated species (2.370(1) Å for (*t*-Bu)$_4$calix[4]arene-(W=O)·H_2O). The *tert*-butyl groups render the phenolate fragments more electron rich, such that the W atom is also richer, promoting weaker W···OH_2 interactions. An examination of the O-W=O angles also shows a slightly smaller cone angle of ~0.5° for the *tert*-butylated derivatives (in comparison with the unfunctionalized systems). In addition, the M···NCMe distances reported for the related compounds (*t*-Bu)$_4$calix[4]arene(Mo=$NCMe_3$)·NCMe (2.343(9)) (33), (*t*-Bu)$_4$calix[4]arene(Mo=NC-Mes)·NCMe (2.303(3)) (33), (*t*-Bu)$_4$calix[4]arene(W=NCMes)·NCMe (2.314(3)) (33), and (*t*-Bu)$_4$calix[4]arene(Mo=NCAr)·NCMe (2.324(7) Å) (Ar = 2-$C_6H_4CH_2CH_2C_6H_4$N-2´-CHC_5H_5N) (32), are also shorter than that found in **3** (2.412(2) Å).

TGA/DSC data

These measurements were performed to determine the relative binding strength of the water inside the cavity (Figs. 4 and 5). The weight loss observed for **1** in the 180–210 °C window corresponds to the loss of aniline and water. The assignment is confirmed with a sample that contains only a tungsten oxo complex of calix[4]arene·H_2O·toluene (**2**·toluene). In this case, a small weight loss (~3%) is observed at ~200–220 °C corresponding to the loss of H_2O. On the other hand, the loss of toluene occurs slowly between 100 and 200 °C. The examination of the first derivative of the weight loss curves indicates a maximum at 184 and 200, and 205 °C for **1** and **2**, respectively. By DSC, the latter decomposition process is observed in the 180–220 °C window as anticipated for **2**·toluene. Indeed, a heat absorption maximum at 197 °C exhibiting an exothermic change in heat capacity (ΔCp) of –116 J/g is observed. The cyclic thermogram of the sample between 25 and 300 °C results in the disappearance of the DSC signal, consistent with the water loss. **1** and **2** decompose at temperatures exceeding 380–400 °C.

Fig. 4. TGA traces for compounds **1** and **2**·toluene.



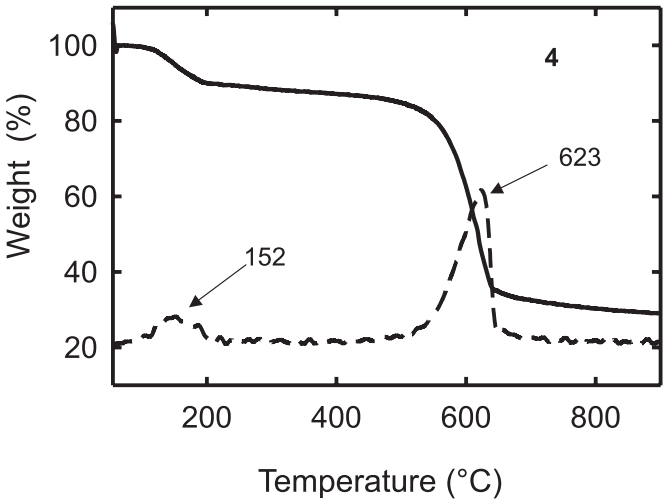


Fig. 5. TGA traces for compound **4**.

For **4**, the first weight loss occurs in the 180–200 °C window, but the corresponding mass (10%) is exactly the mass

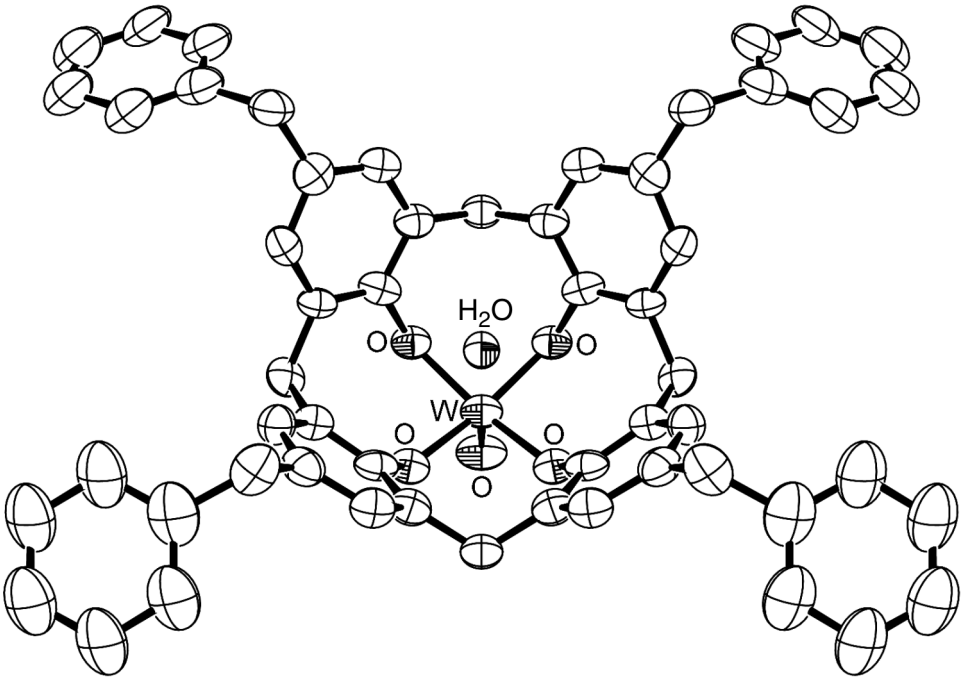
[a]Average values. The data for (*t*-Bu)$_4$calix[4]arene(W=NCMe$_3$)·H_2O, (*t*-Bu)$_4$calix[4]arene(W=O)·H_2O, (*t*-Bu)$_4$calix[4]arene(W=O)·CH_3CO_2H, and (*t*-Bu)$_4$calix[4]arene(Mo=O)·H_2O·$C_6H_5NO_2$ are from refs. 33, 11, 10, and 8, respectively.

Scheme 1.

8 (R = H; M = Mo), **9** (R = H; M = W)
10 (R = Me; M = Mo), **11** (R = Me; M = W)



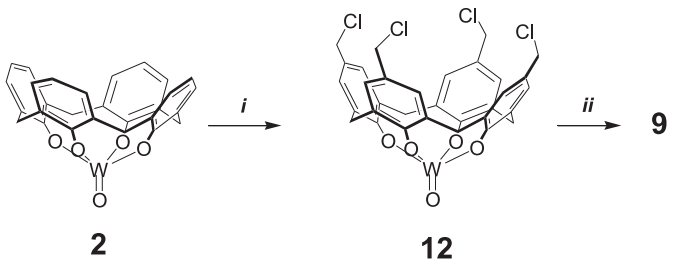
of Br and H_2O, indicating the facile Br elimination in this compound. It is not possible to tell whether the C-Br scission induces a simultaneous H_2O loss, or if both occur simultaneously yet independently. Examination of the first derivative of the ATG traces indicates a maximum at 160 ± 5 °C, which also corroborates the DSC data that exhibit an irreversible exothermic process at 171 °C. The TGA traces exhibit a smooth weight loss, from which it is not possible to say which thermal event occurs first. A long plateau with a slope indicating a second but slower weight loss is observed in the traces between 200 and 500 °C, but a third but rapid weight loss occurs about 550–610 °C. The residual mass corresponds to about 30%, which indicates the presence of C remaining in the samples.

Double functionalization

7 reacts with a slight excess of M(O)Cl_4 (M = Mo, W) in benzene or toluene to afford in moderate (benzene) to good yields (toluene) the corresponding metal oxide complexes of the tetra-5,11,17,23-benzyl- and *para*-methylbenzyl-25,26,27,28-tetrahydroxycalix[4]arene (compounds **8**–**11**, Scheme 1). The identities of the compounds have been unambiguously demonstrated by ^{1}H NMR spectroscopy, mass spectrometry, and by chemical analysis. In addition, X-ray data for **9** have been obtained (Fig. 6). Because of the poorer quality of the crystal, and the presence of disorder and partial occupancies of the molecules of crystallization, the *R*1 and *wR*2 values are somewhat large (Table 1). In this case, a water molecule is also found inside the cavity because the crystallization solutions were handled in the presence of air.

© 2004 NRC Canada

Fig. 6. ORTEP diagram of **9**. The ellipsoids are shown at 30% probability. The H atoms and acetonitrile and other water molecules of crystallization are not shown for clarity. Only one orientation of the phenyl groups is shown.



In addition, an acetonitrile molecule is found in the lattice, where no obvious interaction, such as H-bonding, is observed. The key feature is that H_2O binds the W centre selectively over acetonitrile. Both the d(W=O) (1.732(19) Å) and d(W···O) (2.423(18) Å) values are greater than that found for **1** and **2**, while d(W-O) is shorter (1.904(11) Å). The phenyl groups are disordered, where two orientations of the aromatic planes are depicted in the structure. The dihedral angles about the calix-CH_2-Ph single bonds are 110(2)° and 95(3)° for conformation 1, and 92(2) and 139(2)° for conformation 2, with occupancies of 51 and 49, respectively.

These products (**8**–**11**) result from a tetra Friedel–Crafts reaction followed by a coordination of the metal oxide. This tetra Friedel–Crafts reactivity on the calix[4]arene is unique for two reasons. First, the use of the $M(O)Cl_4$ complexes (M = Mo, W) as Friedel–Crafts catalysts is to our knowledge, unprecedented (35). Second, and more importantly, the catalyst completes these reactions by coordinating the lower rim, hence leading to the one-step functionalization of both the lower and upper rim. This strategy differs from the common cyclisation of a prefunctionalized unit (36). The structure exhibits a "flower-shape" geometry similar to that reported for the unmetallated analogue tetra-5,11,17,23-benzyl-25,26,27,28-tetrahydroxycalix[4]arene (36), but differs from the tetra-5,11,17,23-benzylhydroxy-25,26,27,28-tetra-*n*-propoxycalix[4]arene compound for which host–guest interactions and H-bonds promote the formation of a cage structure (37).

For comparison purposes, compound **9** has also been prepared in two steps from the unfunctionalized tungsten oxo complex of calix[4]arene (**2**) (10) (Scheme 2). The first step uses the $ROCH_2Cl$ reactant (R = octyl) with **2** to produce the tungsten oxo complex of tetra-5,11,17,23-chloromethylcalix[4]arene (**12**) cleanly and in good yield. The upper-rim functionalization of **2** or a related complex is novel

Scheme 2.

i = $CH_3(CH_2)_7OCH_2Cl$ / $SnCl_4$ / -5 °C; *ii* = $W(O)Cl_4$, reflux / benzene

(4–6, 8, 10, 11). The reaction proceeds without the loss of the W=O group. Then, the tetra Friedel–Crafts addition of benzene proceeds as described for **8** and **9**. The overall yield for the two reactions going from **2** to **12** (i.e., **2** → **12** → **9**) is 42%. By considering the 60% yield reported for the synthesis of tetra-5,11,17,23-benzyl-25,26,27,28-tetrahydroxycalix[4]arene from *p*-benzylphenol (36), and the 68% yield for the metallation of unfunctionalized calix[4]arene by W=O (6), the predicted yield for this two-step synthesis of **9** would be 41%. The "one pot" methodology described above is obviously more convenient and less expensive than the two step procedures.

Concluding remarks

This work shows that the title complex coordinates water and nitrile molecules strongly. The removal of water can be performed by extraction with another strong Lewis acid, or by heating the solid samples at about 200 °C. This information is important when the use of a rigid cavity is necessary, for example in the preparation of mesophasic-containing ma-

© 2004 NRC Canada

terials (13), the probing of guest molecules by UV–vis and luminescence spectroscopy (12), and catalysis (38). On the other hand, the presence of coordinated water offers the possibility of H-bond interactions and supramolecular architecture (8) Similarly, the use of nitrile-containing substrates is convenient for the same purpose, since the nitrile residue can anchor a molecule bearing a desired function. This area has surprisingly been neglected in the literature, and the reported reactions in Schemes 1 and 2 open the door to new "cavity extensions" of calix[4]arene derivatives. Further research in this area is anticipated.

New method of energy–mass dispersion applied to mass spectral data from positively charged water vapor clusters[1]

George E. Walrafen and Hugh R. Carlon

Abstract: A new method is presented by which energy–mass, volume–mass, and enthalpy–mass dispersion curves may be determined for charged water vapor clusters. This method involves two closely spaced partial pressures at a fixed temperature. The method is exemplified by using mass spectral data from positively charged water vapor clusters ($H^+(H_2O)_M$) where $6 \leq M \leq 45$. A ΔG–mass dispersion was also determined using the ΔH–mass dispersion for comparison. ΔG displays an enormous minimum, which is of signal importance because it indicates that a size of maximum stability (SMS) exists. The SMS corresponds to $M = 13$ for pressures between 0.056 and 0.151 bar (1 bar = 100 kPa) at 373.15 K, and to $M = 32 \pm 1$ for pressures between 0.473 and 0.556 bar at 372.15 K. The free energy corresponding to $M = 45$ occurs far above that corresponding to the SMS. The resultant instability leads to condensation for pressures above 0.556 bar at 372.15 K.

Key words: clusters, mass spectrometry, thermodynamics, water vapour.

Résumé : On présente une nouvelle méthode de déterminer les courbes de dispersion énergie–masse, volume–masse et enthalpie–masse d'agrégats de vapeur d'eau chargés. Cette méthode implique deux pressions partielles rapprochées dans l'espace à une température donnée. On donne un exemple de la méthode à l'aide de données de spectres de masse d'agrégats de vapeur d'eau portant des charges positives partielles ($H^+(H_2O)_M$) dans lesquels $6 \leq M \leq 45$. On a aussi déterminé une dispersion ΔG–masse en utilisant une dispersion ΔH–masse pour fins de comparaison. Le ΔG présente un immense minimum qui peut être très important comme signal puisqu'il indique l'existence d'une taille de stabilité maximale (TSM). La TSM correspond à $M = 13$ pour des pressions allant de 0,056 à 0,151 bar (1 bar = 100 kPa), à 373,15 K, et à $M = 32 \pm 1$ pour des pressions allant de 0,473 à 0,556 bar, à 372,15 K. L'énergie libre correspondant à $M = 45$ est beaucoup plus élevée que celle qui correspond à la TSM. L'instabilité qui en résulte conduit à une condensation à des pressions supérieures à 0,556 bar, à 372,15 K.

Mots clés : agrégats, spectrométrie de masse, thermodynamique, vapeur d'eau.

[Traduit par la Rédaction]

Introduction

Carlon and Harden (1) examined mass spectra from positively charged water vapor clusters ($H^+(H_2O)_M$), produced by intense β irradiation of moist air. The mass spectra consist of a series of very sharp peaks, whose amplitude-mass envelope is roughly bell-shaped. The peaks are distributed over a range of cluster sizes, e.g., from 6 to 17 at 373.15 K and partial pressures between 0.056 to 0.151 bar (1 bar = 100 kPa), or from 21 to 45 at 372.15 K and partial pressures between 0.473 and 0.556 bar. The M value corresponding to the average of the distribution decreases with rising temperature at constant partial pressure (1, 2) or rises with increasing partial pressure at constant temperature (1, 2).

Walrafen et al. (2) presented a thermodynamic analysis of the above-described mass spectral data (2). This analysis involved solution of simultaneous equations of the form $\ln \langle c \rangle = A/T + B \times P$ for various partial pressures (P) at a fixed T. The form of the equation relates to the temperature and pressure dependence of the Gibbs free energy, and $\langle c \rangle$ is the most probable cluster size determined by the method described in ref. 2. Values of the H-bond energy, and of the volume change related to condensation of gaseous water on the clusters resulted (2).

The dispersion of the H-bond energy as a function of Raman frequency (ω) was recently reported for liquid water (3). Values of the H-bond energy (more exactly enthalpy) were obtained from $\partial[\ln(I_i/I_{REF})/\partial(1/T)]_P$, where I_i is the Raman contour height at $i = \omega$, and I_{REF} is the contour height at some suitable reference frequency, usually the isosbestic frequency (3). This method of obtaining the H-bond energy–frequency dispersion curve inspired the current work, in

which energy–mass and volume–mass dispersion curves were calculated.

The current method is different from the energy–frequency dispersion method in that two simultaneous equations are solved for each mass point on the dispersion curve, as opposed to obtaining a least-squares fit of Raman intensities at a series of temperatures for each ω in the Raman spectrum (3). However, both methods employ a reference point. In the instant case a normalization factor was used that required scaling of the high and low pressure peak amplitudes at some convenient M at which the signal-to-noise of the mass peaks was large.

Minima were observed in the energy, enthalpy, and free energy for different sets of mass spectral data obtained at different partial pressures. Such minima indicate that a size of maximum stability (SMS) exists. This is a very important finding because the SMS increases with increasing partial pressure at constant temperature. This increase leads to large instability at the high mass end of the distribution (M = 45) for a partial pressure of 0.556 bar at 372.15 K, finally resulting in condensation for partial pressures above 0.556 bar.

The method of calculation for ΔE, ΔV, and ΔH is described in the next section. This is followed by results presented in various figures. The article ends with a discussion section in which the method of calculating the free energy is presented and discussed.

Method of calculation

The calculation method used for the mass spectral data of Carlon and Harden (1) employs two equations related to two closely spaced partial pressures at a fixed temperature. Mass spectral data are not available for the parallel calculation involving the temperature dependence of the peak amplitudes at a fixed partial pressure. The two equations used for each M in the mass spectrum are:

$$[1] \qquad \ln H_E = A/T + BP_E$$

and

$$[2] \qquad \ln H_F = A/T + BP_F$$

$P_E > P_F$ and A and B are constants at a specific T and P, and for a given M. H_E and H_F are heights for peaks whose Ms range over the entire mass distribution. Normalization may be employed, if desired, as described by the following. Subtraction of eq. [2] from eq. [1] gives

$$[3] \qquad \ln H_E - \ln H_F = B(P_E - P_F)$$

Substitution of the resulting B value into either eq. [1] or eq. [2] with the appropriate partial pressure yields A. ΔE and ΔV were then obtained from $\Delta E = -AR$, and $\Delta V = -BRT$.

ΔE and ΔV were calculated for each mass peak throughout the entire distribution, except for peaks whose amplitudes were so small that accurate calculation was precluded. Plots were then made of ΔE vs. M and of ΔV vs. M. These plots were not continuous functions because the M values were integers. Nevertheless, curves were drawn through the data points as an aid in visualization.

Several methods of referencing the data, i.e., of normalization may be employed. A simple method, used here, involves choosing two mass peaks from different mass spectra whose amplitudes are nearly the same.

The amplitude of one mass peak, corresponding to M = 33 at P_F = 0.4733 bar was chosen as the reference. A normalization factor (NF) was then determined from $H_E(33)/H_F(33)$ = NF. All peak amplitudes of the E spectrum were then multiplied by NF. This yielded two sets of amplitude vs. M data, for which $H_E(33) = H_F(33)$. This normalization condition means that B = 0 at M = 33 (see eq. [3]).

The choice of the reference mass peak is completely arbitrary. Any choice involving reasonably large signal-to-noise ratios for H_E and for H_F is suitable. Moreover, it should be emphasized that the shapes of the ΔE vs. M and ΔV vs. M dispersion curves are invariant relative to the reference mass peak employed, as well as to no choice of reference mass peak. The various reference choices simply translate the dispersion curves up or down on the ordinate.

The ΔH–mass dispersion curve may be obtained after the ΔEs and ΔVs have been calculated for a range of Ms. This calculation involved the use of the average $P_{av} = (P_E + P_F)/2$. The average P is a property of the simultaneous solution, just as ΔE and ΔV are averages over the pressure range of the simultaneous solution ($\Delta H = \Delta E + P_{av}\Delta V$). This allows an enthalpy–mass dispersion curve to be constructed. Note also that $\Delta H = -AR + P_{av}(-BRT)$. Moreover, both A and B are functions of M, T, and P.

The free energy–mass dispersion does not result from the simultaneous equations. It was determined by comparing $\Delta G = -RT\ln H(M)$ with ΔH, where $H(M)$ is the peak height for mass M.

The calculated dispersion curves

The dispersion curves corresponding to the smaller partial pressures are shown first in Figs. 1, 2, and 3. A reference mass of M = 13 was chosen for these three curves. ΔE is not zero at M = 13 because the normalization makes $\ln H_E(M = 13) = \ln H_F(M = 13) = A/T$, when $BP = 0$. T = 373.15 K for Figs. 1–3. (A = 182 at M = 13, $\Delta E = -AR$ = –362 cal/mol, $\Delta H = \Delta E$ = –362 cal/mol, and ΔV = 0; B = 0, P_E = 0.1507 bar and P_F = 0.056 bar.

From Fig. 1 it is evident that a pronounced minimum occurs in the ΔE–mass dispersion at $M = 11\pm1$. This minimum is very important because it is the first indication of a SMS. This minimum suggests that the stability decreases as M increases or decreases compared to the M value of the SMS (see ΔG discussion).

The average ΔE per M increment was obtained from the data of Fig. 1, namely, ≈453 cal/mol. This value, and the maximum difference per M increment (904 cal/mol) are too small to refer to the H-bond energy per se (2). They refer to changes in the H-bond energy with the change in cluster size and structure.

The ΔV–mass dispersion curve is shown in Fig. 2. The average volume change per M increment is ≈140 000 cm^3/mol. This average volume change is roughly one-half of the ideal gas molal volume of water vapor at 373.15 K and P_{av} = 0.1033 bar, ≈300 000 cm^3/mol. The ΔV–mass dispersion curve displays a maximum at $M = 8\pm1$; not far from the SMS of Fig. 1, at which $M = 11\pm1$.

Fig. 1. Energy–mass dispersion for positively charged water vapor clusters containing from 6 to 17 water molecules. The partial pressures were 0.056 and 0.151 bar (1 bar = 100 kPa).

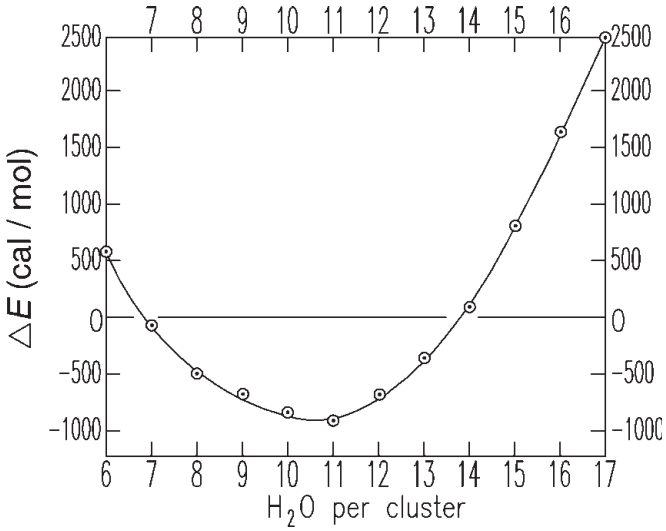

Fig. 2. Volume–mass dispersion for positively charged water vapor clusters containing from 6 to 17 water molecules. The partial pressures are the same as for Fig. 1.

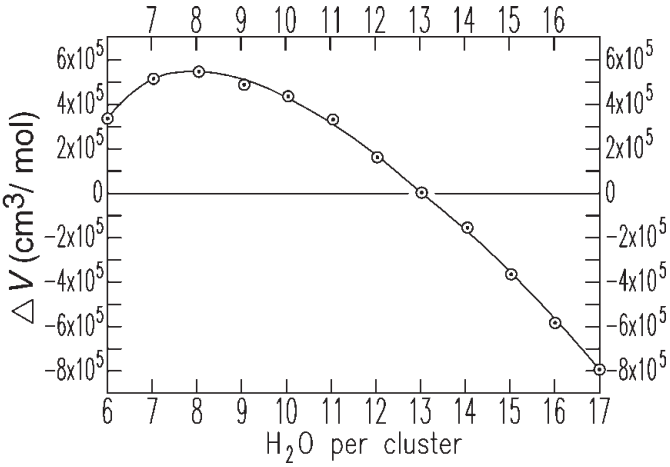

Fig. 3. Enthalpy–mass dispersion for positively charged water vapor clusters containing from 6 to 17 water molecules. The partial pressures are the same as for Fig. 1.

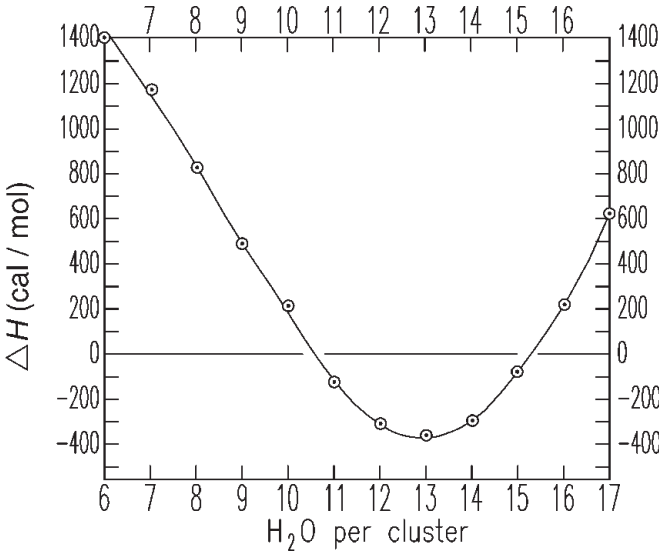

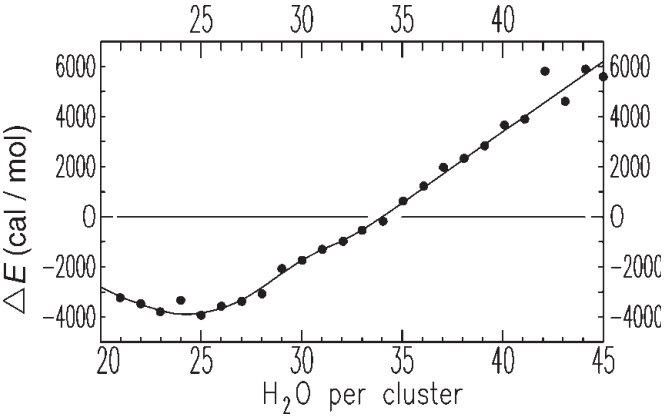

Fig. 4. Energy–mass dispersion for positively charged water vapor clusters containing from 21 to 45 water molecules. The partial pressures were 0.4733 and 0.5560 bar (1 bar = 100 kPa).

The ΔH–mass dispersion curve is shown in Fig. 3. It displays a pronounced minimum near $M = 13\pm1$, which is about $2M$ units above that for ΔE (Fig. 2). The ΔH–mass dispersion curve also displays an average value of ≈250 cal/mol between M increments.

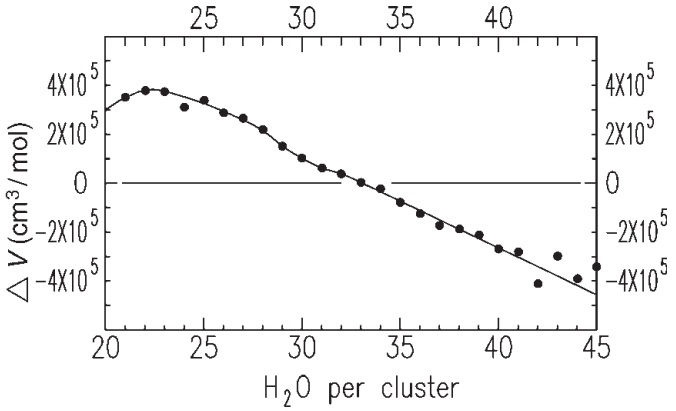
The ΔH–mass dispersion curve is shown in the Discussion section to be extremely important because it is used, by comparison, to calibrate the free energy–mass dispersion curve.

Dispersion curves are displayed in Figs. 4–6 for $21 \leq M \leq 45$ at $P_E = 0.5560$ bar, $P_F = 0.4733$ bar, $P_{av} = 0.5146$ bar, and $T = 372.15$ K. The reference mass is $M = 33$.

Figure 4 indicates that an energy minimum occurs at $M = 24\pm2$. The rise in the mass corresponding to the minimum compared to the minimum of Fig. 1 suggests that the SMS rises with partial pressure.

The magic number peaks observed in the original mass spectra occur at $M = 21$ (very obvious) and $M = 28$ (less prominent). The $M = 29$ mass peak also seems too small in amplitude, as opposed to too large for $M = 21$ and $M = 28$. The minimum in Fig. 4 is not well-correlated with the magic number peaks.

The minimum of Fig. 4 is important because partial pressures above 0.5560 bar are known to lead to condensation (1). Condensation is shown in the following to be related to the fact that the $M = 45$ peak is far removed from the SMS (1), a separation which corresponds to instability.



The average ΔE per M increment is $(\Delta E_{45} - \Delta E_{26})/19 \approx$ 9900 cal/19 mol ≈ 520 cal/mol. This value has roughly the same magnitude as the ≈453 cal/mol value obtained from Fig. 1.

Figure 5 indicates a maximum in the ΔV–mass dispersion curve at $M = 22$ that is experimentally the same as the $M = 24\pm2$ value, which corresponds to the minimum of Fig. 4.

Figure 5 also indicates that the average volume change per M increment is $(\Delta V_{45} - \Delta V_{25})/20 = -749\,000$ cm^3/20 mol = $-39\,500$ cm^3/mol. This value has the same approximate magnitude and sign as those reported previously (2), which

© 2004 NRC Canada

Fig. 5. Volume–mass dispersion for positively charged water vapor clusters containing from 21 to 45 water molecules. The partial pressures are the same as for Fig. 4.

averaged –31,300 cm^3/mol H-bond for the same partial pressures and the same T.

The ΔH–mass dispersion curve is shown in Fig. 6 ($\Delta H_{45} - \Delta H_{36}$)/9 ≈ 180 cal/mol. A large minimum occurs in Fig. 6 at $M = 31 \pm 2$. This minimum is directly related to the SMS, as shown below because it agrees with the minimum in free energy.

The ΔH–mass dispersion curve of Fig. 6 is only roughly symmetrical about its minimum. But the ΔH–mass dispersion curve of Fig. 3, truncated at $M = 17$, is very nearly symmetrical (about $M = 13$) from $M = 9$ to $M = 17$. The curve of Fig. 3 fits $\Delta H \approx$ constant × $(M - 13)^2$ within experimental error between $M = 9$ and $M = 17$ when it is translated upward to make $\Delta H = 0$ at $M = 13$.

$M = 13$ *might* correspond to H_3O^+ surrounded by three nearest-neighbors, i.e., Eigen's structure, $H_9O_4^+$, plus nine second-nearest (tetrahedrally H-bonded) neighbors. This would be an especially stable structure. See the minimum in the free energy in the following.

Discussion

Relation to the equilibrium constant and free energy

Equation [3] refers to constant temperature. Substitution of $\Delta V = -BRT$ into eq. [3] gives

$$[4] \qquad [\Delta \ln H(M)/\Delta P]_T = -\Delta V/RT$$

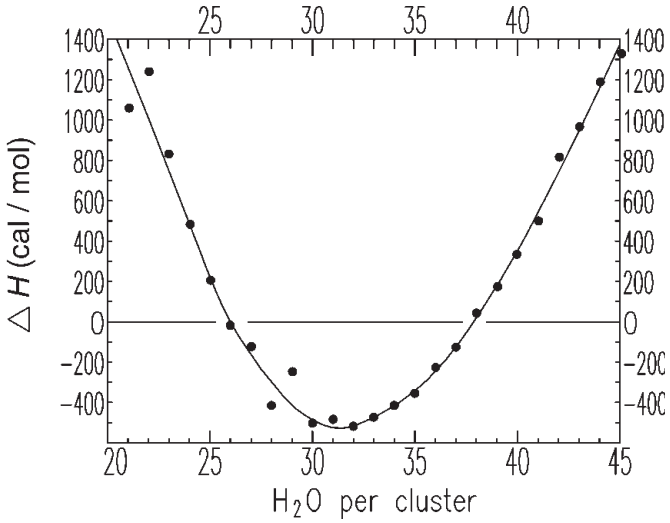
where $\Delta \ln H(M) = \ln H_E(M) - \ln H_F(E)$, and $\Delta P = P_E - P_F$. But eq. [4] is simply the difference equation analog of

$$[5] \qquad (\partial \ln K/\partial P)_T = -\Delta V/RT$$

Hence,

$$[6] \qquad K(M) = \text{constant} \times H(M)$$

Substitution of eq. [6] into eq. [1] yields



$$[7] \qquad \ln K_E - \ln \text{constant} = A/T + BP_E$$

Then from the thermodynamic relation

$$[8] \qquad \ln K_E = -\Delta E/RT - P_E/RT + \Delta S/R$$

one identifies the constant in eq. [6] as

Fig. 6. Enthalpy–mass dispersion for positively charged water vapor clusters containing from 21 to 45 water molecules. The partial pressures are the same as for Fig. 4.

$$[9] \qquad \text{constant} = \exp(\Delta S/R)$$

Hence,

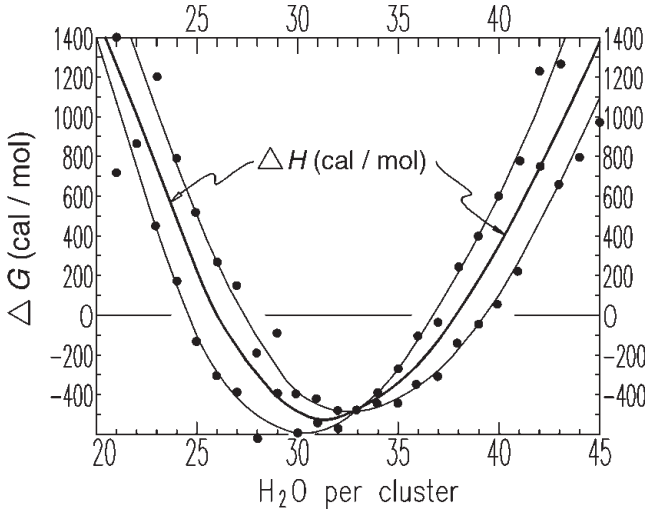
$$[10] \qquad K(M) = H(M)\exp(\Delta S/R)$$

or

$$H(M) = \exp(-\Delta S/R)K(M)$$

Because of the relation between $H(M)$ and $K(M)$ and $\Delta G = -RT \ln K$, it was possible to construct a ΔG–mass dispersion curve from the data used for Figs. 4–6. The same normalization was employed, viz., $M = 33$, i.e., the same normalized amplitude values were used without further scaling.

The results of the calculations for partial pressures $P_E = 0.5560$ bar and $P_F = 0.4733$ bar are compared with the ΔH–mass dispersion curve obtained from simultaneous equations in Fig. 7. The solid curve, without experimental points, is the same curve drawn through the ΔH data of Fig. 6. The curve drawn through the filled circles refers to the partial pressure $P_E = 0.5560$ bar. The curve drawn through the open circles refers to $P_F = 0.4733$ bar.



It is obvious from examination of Fig. 7 that the ΔH–mass dispersion curve, labelled ΔH, is the *average* of the curves corresponding to P_E and P_F. The curve related to P_F lies to the left, below, and to the right, above, the ΔH curve, whereas the curve related to P_E lies to the left, above, and to the right, below, the ΔH curve. The fact that the ΔH–mass curve is the average of the individual ΔG dispersion curves is to be expected because ΔH is an average over the partial pressure range of P_F to P_E.

Accretion of water by the clusters

Water vapor clusters in the mass range of say, 6–45, exist in a sea of smaller charged clusters, as well as a range of neutral clusters and neutral monomers (1). The neutral monomer concentration is large (1). Moreover, an H_2O mass balance exists for a fixed and confined volume of moist air at a given water partial pressure.

© 2004 NRC Canada

Fig. 7. Comparison of the ΔH–mass dispersion obtained from Fig. 6 (solid center curve without experimental points) to $\Delta G = -RT \ln H(M)$. The ΔG–mass dispersion for $P_F = 0.4733$ bar (1 bar = 100 kPa) is displayed by open circles. The ΔG–mass dispersion for $P_E = 0.5560$ bar is displayed by filled circles. Note that the ΔH–mass dispersion is, within experimental error, the average of the two ΔG–mass dispersion curves. The points that appear to lie on or near the solid heavy line corresponding to ΔH actually refer to scattered points from the two sets of ΔG data.

The mass balance is epitomized by the reaction

[11] $(H_2O)_N(g) + H^+(H_2O)_L = H^+(H_2O)_M$ with $L >> N$

which constitutes a mechanism for increase, in the forward direction, of the M numbers of the clusters. Note that the forward reaction refers to two-body collisions. Such two-body collisions are much more probable than three-body or higher-body collisions.

Successive two-body collisions with water monomers, dimers, or with other neutral water clusters increase the M of a positively charged cluster.

It is known that condensation occurs when the partial pressure of water vapor rises above 0.5560 bar at 372.15 K (1). A scheme in which a positively charged cluster of M = 45 may lose its proton and condense, as well as simultaneously lower the free energy, is as follows

[12] $(H_2O)_{32} + H^+(H_2O)_{45} = H^+(H_2O)_{32} + (H_2O)_{45}$

This equation amounts to a proton transfer occuring as a result of a two-body collision between a charged M = 45 species and an uncharged M = 32 species. Note that the free energy of the charged M = 32 species corresponds to the minimum value, and to the SMS, which lowers the free energy of the charged product cluster.

Equation [12] is tantamount to the formation of an extremely small droplet of liquid water, because a neutral cluster of M = 45 is beginning to have the physical properties of the liquid as explained in the next section.

What cluster size is needed to mimic the physical properties of liquid water?

The size of a water cluster that assumes the properties of bulk liquid water may be estimated from the wavelength of the transverse acoustic (TA) phonon which gives rise to the 50–60 cm^{-1} Raman peak from pure liquid water (4). This TA wavelength is about 9 Å (4) and it corresponds to the structural correlation length that refers to the O-third-O or O-fourth-O distance in the X-ray pair correlation function of water (5). The corresponding number of water molecules has been estimated to be 53 for the O-third-O neighbors (4).

The point is that a cluster having M = 45 is just barely beginning to reach a size capable of sustaining a TA phonon of the required 9 Å length. The properties of the cluster should be similar to those of bulk liquid water once this 9 Å length has been attained or exceeded.

The above considerations are approximate. Most of the water molecules in a cluster of 45 water molecules are near the surface, and thus the structure differs from the bulk liquid.

Smallness of the ΔE and ΔH values per M increment

Values of the average ΔE per M increment are ≈453 cal/mol (Fig. 1) and ≈520 cal/mol (Fig. 4). Values of the average ΔH per M increment are ≈250 cal/mol (Fig. 3) and ≈180 cal/mol (Fig. 6). None of these values is large enough to correspond to the H-bond energy because the maximum H-bond energy for liquid water is 5100 ± 500 cal/mol H-bond (3), and the average H-bond energy for liquid water is 2830 ± 50 cal/mol H-bond (3).

The average ΔV per M increment is –39 500 cm^3/mol (Fig. 5). This value has roughly the same magnitude and it has the same sign as the ΔV from previous work, which is –31 300 cal/mol.

The above described energy and enthalpy values are only a few % of the maximum H-bond energy for liquid water. Such values probably refer to changes of H-bond energy in clusters of different size and structure.

The H-bond strength in the M = 6 cluster, which probably refers to $H_3O^+(H_2O)_5$, is unlikely to be the same as the H-bond strength in the M = 21 cluster, which probably refers to a hydrogen-bonded pentagonal dodecahedron with H_3O^+ included.

Addendum on mechanism

One H_2O per cluster necessarily separates all of the adjoining peaks in the mass spectrum. But the consecutive ΔV differences observed here are equivalent to the volume of ≈0.5 mol of monomers, or to roughly 0.5 mol of (ideal) gas, both at low and at high partial pressures. This difficulty presents a serious problem.

One conceivable solution to the problem results if dimers react with the clusters as follows:

[13] $0.5(H_2O)_2 + H^+(H_2O)_M = H^+(H_2O)_{M+1}$

Reaction [13] adds one H_2O to the cluster M yielding the cluster M + 1, but the volume change per increment is equivalent to the volume of 0.5 mol of *monomers* or 0.5 mol of an ideal gas of dimers.

The above mechanism fits the present experimental facts. However, it raises new questions. For example, why should

© 2004 NRC Canada

dimers constitute the primary reactant that increases the mass of the charged clusters? And, because reaction [13], when multiplied by 2, must refer to a three-body reaction, why should it be so important?

Other currently unknown mechanisms may ultimately resolve the difficulties presented above. In any case, the addition of one water to a cluster increases the *M* value by one unit, and this produces a redistribution that results in a new structure having somewhat different H-bond energies than the parent structure.

A Raman study of aqueous DMF and DMA solutions at low temperatures[1]

K. Tomikawa, H. Kanno, and H. Kimoto

Abstract: Hydrogen bonding in aqueous *N*,*N*-dimethylformamide (DMF) and *N*,*N*-dimethylacetamide (DMA) solutions was studied by Raman spectroscopy of the OH-stretching spectra of water as functions of solute concentration and temperature (from –50 to 50 °C). The Raman spectra were decomposed successfully into two components (the low- and high-frequency components). The peak area ratio of the low-frequency component to the high-frequency component increases exponentially with decreasing temperature. The frequency of the low-frequency component decreases linearly with lowering temperature down to –50 °C at all solute concentrations (solute mol fraction from 0.3 to 0.7). It is shown that the hydrogen bonds in the clathrate structures around DMA molecules are stronger than those around DMF molecules.

Key words: Raman spectrum, DMF, DMA, aqueous solution, low temperature.

Résumé : On a étudié la formation de liaisons hydrogènes dans des solutions aqueuses de *N*,*N*-diméthylformamide (DMF) et de *N*,*N*-diméthylacétamide (DMA) en faisant appel à la spectroscopie Raman et examinant la bande d'élongation du OH de l'eau en fonction de la concentration du soluté et de la température (de –50 à 50 °C). On a pu décomposer le spectre Raman en deux composantes, l'une de basse fréquence et l'autre de fréquence plus élevée. Le rapport des pics de la composante de basse fréquence à celui de la composante de haute fréquence augmente d'une façon exponentielle avec une diminution de la température. À toutes les concentrations de soluté (allant d'une fraction molaire de soluté de 0,3 jusqu'à 0,7), la fréquence de la composante de basse fréquence diminue d'une façon linéaire avec une diminution de la température jusqu'à –50 °C. On montre que les liaisons hydrogènes dans les structures de clathrate autour des molécules de DMA sont plus fortes que celles autour des molécules de DMF.

Mots clés : spectre Raman, DMF, DMA, solution aqueuse, basse température.

[Traduit par la Rédaction]

Introduction

Raman spectroscopy is one of the best spectroscopic methods for probing structural changes in aqueous solutions (1). There have been a number of reports devoted to structural studies of aqueous solutions (1–4). Early Raman studies of aqueous electrolyte solutions by Walrafen (2, 5, 6) demonstrated that both Raman OH-stretching and low-frequency (<600 cm^{-1}) spectra are very sensitive to the nature of the electrolyte. There is a clear trend that structure-breaking ions weaken the strength of hydrogen bonds, thereby shifting the frequency of the Raman OH-stretching spectrum to a higher frequency region while structure-making ions strengthen hydrogen bonds in aqueous solution, moving the OH-stretching spectrum to lower frequencies.

Kanno and Hiraishi (7) reported that the characteristic nature of dissolved ions is well-represented in the Raman spectrum for solutions at low temperatures, especially for glassy solutions. There have been many Raman studies on water at various temperatures (3, 8–12). From these studies, it is clear that hydrogen bonds become stronger with decreasing temperature. In view of these Raman studies, it would be interesting and important to study aqueous solutions of molecular solutes to see how hydrogen bonds are perturbed by dissolved molecular solutes as functions of solute concentration and temperature since Raman studies of aqueous solutions of molecular solutes are scarce as compared with those of electrolytes.

In this study we have measured Raman OH-stretching spectra of aqueous *N*,*N*-dimethyl formamide (DMF) and *N*,*N*-dimethyl acetamide (DMA) solutions as functions of solute concentration and temperature to investigate how hydrogen bond strength changes with solute concentration and temperature.

Experimental

All aqueous DMF and DMA solutions were prepared by dissolving DMF or DMA in distilled water by weight. Guaranteed grade DMF and DMA were purchased from Wako and used as received.

Raman spectra were measured with a JASCO NR-1800 Raman spectrometer equipped with a microscope and a CCD detector. The spectra were excited with about 100 mW of

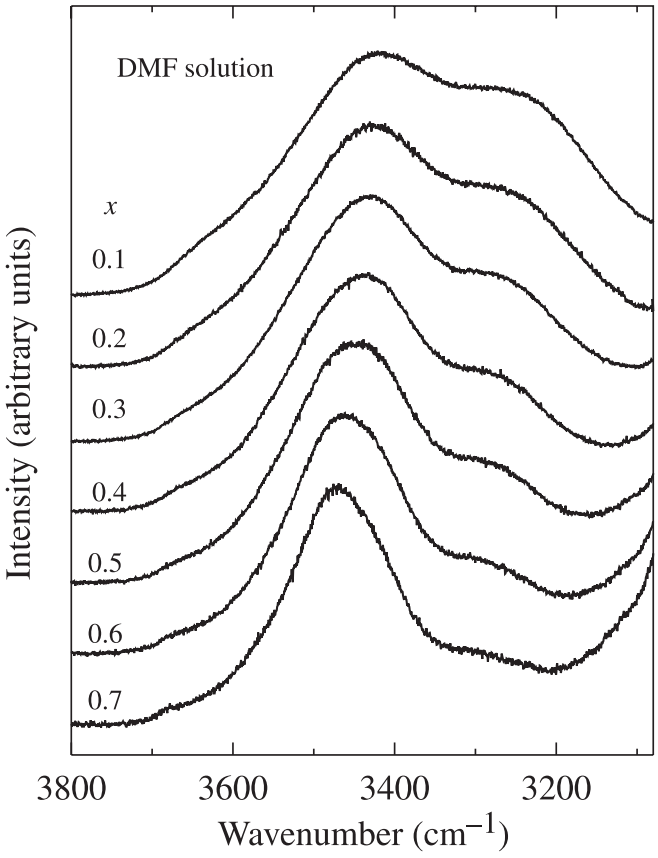
Fig. 1. Raman OH-stretching spectra of the XDMF·$(1 - X)H_2O$ solutions. The Raman intensity increase below 3200 cm^{-1} with an increase in DMF content is due to the intensity increase of the C-H stretching Raman bands of DMF.



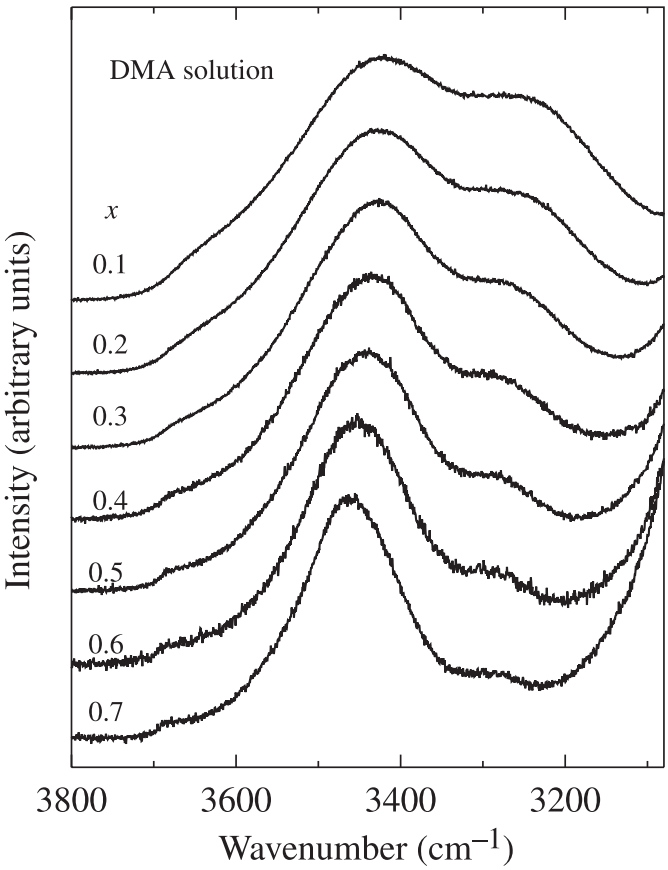


Fig. 2. Raman OH-stretching spectra of the XDMA·$(1 - X)$ H_2O solutions. The Raman intensity increase below 3200 cm^{-1} with an increase in DMA content is due to the intensity increase of the C-H stretching Raman bands of DMA.

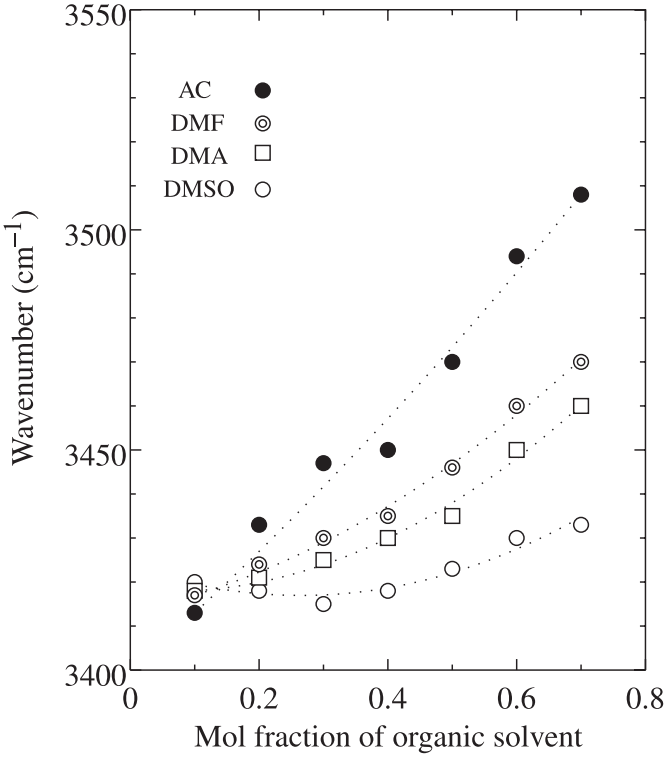
the 514.5 nm line from a Lexcel argon ion laser. When Raman spectra of the aqueous DMF and DMA solutions were measured, we used a Japan High-Tech model LK-600PH temperature controller with which the temperature of the sample solution was maintained at a specified temperature (between –196 °C and 200 °C) to within ±2 °C.

Results and discussion

First of all, we present the OH-stretching Raman spectra of aqueous DMF and DMA solutions as a function of the organic solute concentration in Figs. 1 and 2. As expected from literature data for various aqueous solutions, the entire OH-stretching spectrum gradually shifts to the higher frequency side with an attendant decrease in the low-frequency region. These spectral changes indicate that the addition of DMF or DMA to water results in the weakening of hydrogen bonds in the resulting aqueous solution. This trend is rather general and is observed in many aqueous systems (1, 3, 8). The existence of foreign particles (ions) generally interferes or prohibits the formation of strong hydrogen bonds among water molecules.



At low concentrations of DMF or DMA, the shape of the OH-stretching spectrum is similar to that of liquid water. The spectrum appears to consist of three component bands. They are centered at about 3250, 3450, and 3650 cm^{-1} (8). The ~3250 cm^{-1} component can be ascribed mainly to the collective OH-stretching vibrations of water molecules in the intrinsic tetrahedral structures of liquid water. The ~3450 cm^{-1} component becomes progressively larger with increasing DMF or DMA concentration and is mainly due to the OH-stretching vibrations of water molecules coordinating to DMF or DMA molecules and of water molecules in the deformed tetrahedral structures. It must be stressed that this component is dominant even in liquid water. The ~3650 cm^{-1} component is usually assigned to the OH-stretching vibrations of the weakly hydrogen-bonded water molecules in strongly deformed tetrahedral structures of liquid water and of imperfect hydration spheres surrounding DMF or DMA molecules.

In the intermediate to higher solute concentration range, the component at ~3250 cm^{-1} progressively gets smaller and smaller. On the other hand, the component at about 3450 cm^{-1} becomes more dominant and shifts to higher frequency with an increase in solute concentration. It appears that the ~3650 cm^{-1} component becomes a part of the ~3450 cm^{-1} component and therefore, the spectrum can be approximated by the combination of the two components.

Figure 3 gives the frequency variations of the high-frequency peaks of the OH-stretching spectra for aqueous DMF and DMA solutions together with other solute solutions (other solutes are acetone (AC) and dimethyl sulfoxide (DMSO)) as a function of solute concentration. As is easily

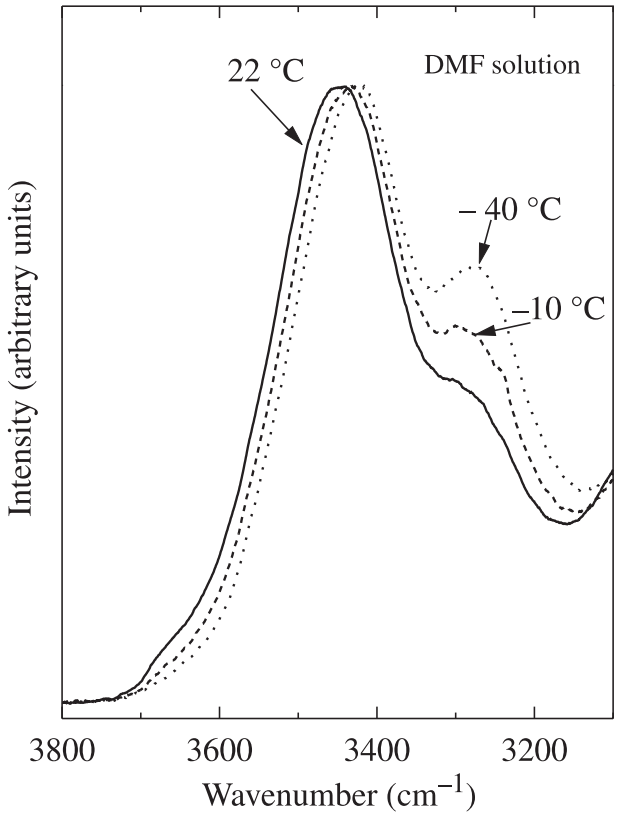
Fig. 3. Variation of the high-frequency peak of the OH-stretching spectrum for the $XA\cdot(1 - X)H_2O$ solution (X = 0.1~0.7, A = Ac, DMF, DMA, and DMSO). The Raman results for aqueous acetone and DMSO solutions are from unpublished data from this laboratory.



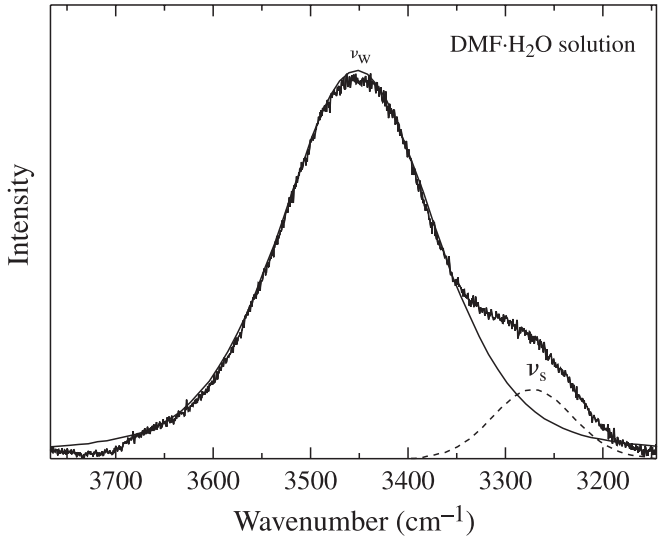
noticed, the peak frequency rapidly increases with increasing solute concentration. The intensity of the high-frequency region is also increased with an increase in solute concentration. These changes are a clear manifestation of the weakening of hydrogen bonds because of the breaking of strong hydrogen bonds in water and to rearrangements of water molecules in the solution.

The frequency increase at X = 0.6 is in the order: AC > DMF > DMA > DMSO. This order is in good correlation with the decreasing order of the donor number: DMSO (29.8) > DMA (27.8) > DMF (26.6) > AC (17.0) (the numerical value in parentheses is the donor number of the solute) (13, 14), although the order of DMF and DMA does not follow the order of donor number. Thus, it is considered that with increasing solute concentration of the hydrogen bonds between water molecules are gradually replaced with the hydrogen bonds between water molecules and solute molecules and those in the hydration spheres of solute molecules.

The viscosity of aqueous solutions of these solutes shows a maximum at the mol fraction of ~0.2 (AC), ~0.25 (DMA and DMF) and ~0.33 (DMSO) (15, 16). Since our Raman measurements are not made at very small intervals of solute concentration, the peak frequency increase with solute concentration looks rather smooth so that the average hydrogen bond strength in each solution appears to become weaker with increasing solute concentration. Therefore, the appearance of the maximum in viscosity at the mol fraction of ~0.25 appears to be irrelevant to the variation of hydrogen

Fig. 4. Raman OH-stretching spectra for the $DMF\cdot H_2O$ solution at 22, –10, and –40 °C.

bond strength, but may be related to the structural changes of the solution.



Next, we examined the spectral changes with temperature. Special emphasis is placed in the temperature region below 0 °C since characteristic features of the solution should appear at low temperatures. Figure 4 shows the spectral changes of the DMF solution at three different temperatures. The low-frequency component below 3350 cm^{-1} increases rapidly and the whole spectrum moves to the lower frequency side with decreasing temperature. These spectral changes are a clear indication that the hydrogen bonds become stronger with decreasing temperature. Although the spectra are not shown here, similar spectral changes were also observed for the DMA solution.

Scherer et al. (8, 17) reported in their Raman study of pure water and aqueous DMSO solutions that there are two kinds of water molecules: one involves two strong symmetric hydrogen bonds and the other has one strong and one weak hydrogen bond. They also assumed that the strongly hydrogen bonded OHs of both types of water molecules have distributions of hydrogen bond strengths. The broadness of the OH-stretching spectra suggests that the strength of hydrogen bonds in aqueous solution has a wide distribution, depending on temperature and solute concentration, not to mention the nature of the solute. They decomposed the spectrum into four Raman components and interpreted their temperature dependencies.

Kanno et al. (18) reported that hydrogen bonds whose strength is clearly manifested in the frequency of the OH-stretching spectrum become stronger with decreasing tem-

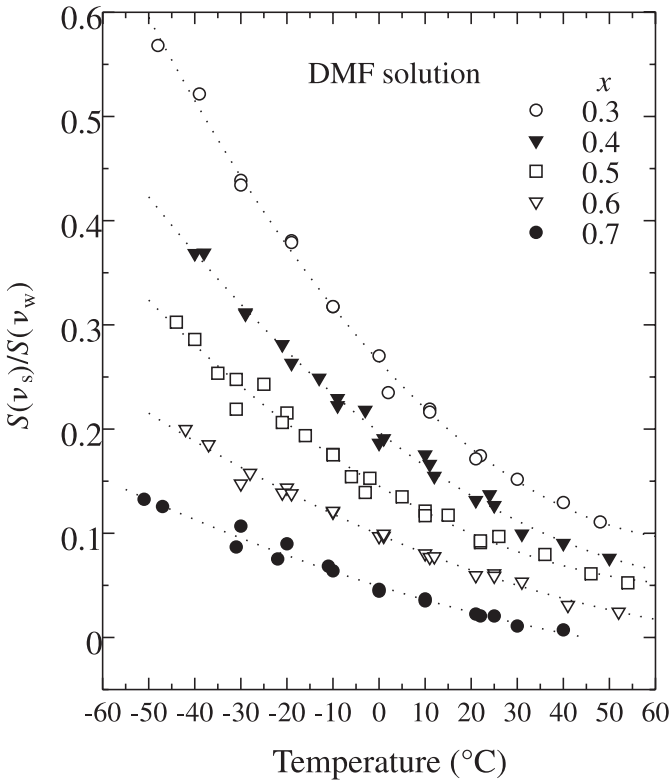
Fig. 5. Decomposition of the OH-stretching spectrum into two components. Solid curve: the high-frequency component (peak wavenumber: ν_w, peak area: $S(\nu_w)$). Dotted curve: the low-frequency component (peak wavenumber: ν_s, peak area: $S(\nu_s)$).



perature in aqueous tetraalkylammonium chloride solutions. They considered that water molecules around alkyl groups form clathrate-like structures with strong hydrogen bonds, especially at low temperatures. In fact, the intensity of the low-frequency region of the OH-stretching spectrum in glassy state solutions is dramatically large at low solute concentrations. The spectral features of the glassy Y = 24 tetrapropylammonium chloride solution (Y = mol of water / mol of salt) are very similar to those of low density amorphous solid water in which the strength of the hydrogen bonds is only a few wavenumbers weaker than that in crystalline ice (19).

On the other hand, the strength of hydrogen bonds in aqueous inorganic salt solutions is generally weakened as compared with that in pure liquid water. In particular, large anions such as ClO_4^- and PF_6^- ions exert large structure-breaking effects on water, thereby weakening hydrogen bonds (20, 21). Molecules such as urea and large ions such as ClO_4^- and I^- are regarded as structure breakers, whereas molecules such as sucrose and hydrophobic ions such as tetraalkylammonium ions are considered as structure makers (1).

To investigate the structural changes associated with the addition of DMF or DMA in more detail, the OH-stretching spectrum was decomposed into two components by a least-squares curve fitting method. After subtracting the background spectrum from the observed OH spectrum, the resulting OH spectrum was decomposed into two components. It is assumed to be represented by Gaussian and Lorentzian mixed curves. A typical example is shown in Fig. 5. The peak frequency of each component (the low- and the high-frequency components) is denoted as ν_s and ν_w, respectively, and the peak area is designated as $S(\nu_s)$ and $S(\nu_w)$, respectively. As our main objective was the observation of overall changes in the OH-stretching spectrum in the solution with solute concentration or temperature, we considered that the present method is sufficiently reliable and sensitive to probe

Fig. 6. Variation of the $S(\nu_s)/S(\nu_w)$ ratio for the XDMF·$(1 - X)H_2O$ solution with temperature.

structural changes in these aqueous solutions. Although only one case is shown in Fig. 5, all of the spectra were successfully decomposed into two components.

First, we see how the $S(\nu_s)/S(\nu_w)$ ratio changes with decreasing temperature. The $S(\nu_s)/S(\nu_w)$ results are shown in Figs. 6 and 7. An important aspect is that the ratio increases exponentially with decreasing temperature, although the trend becomes weaker with increasing solute concentration and shifts to the low-temperature side. These features are in common with many thermodynamic and transport properties observed in water and aqueous solutions at low temperatures. Angell and co-workers (22, 23) showed that many thermodynamic and transport properties of water give divergent behavior at the expected singularity temperature of −45 °C.

These features are closely connected with the cooperative increase of strong hydrogen bonds with decreasing temperature. Oguni and Angell (24) measured heat capacities (Cp) of aq. H_2O_2 and N_2H_4 solutions as a function of solute concentration and reported that the anomalous increase in Cp was eliminated by addition of about 20% (by mol fraction) of the solute (H_2O_2 or N_2H_4). On the other hand, an interesting point is that the increases in the $S(\nu_s)/S(\nu_w)$ ratio at lower temperatures in the DMF and DMA solutions remain qualitatively unchanged even at very high solute concentrations (up to X = 0.7), but seem to shift to lower temperatures. In fact, similar increases in $S(\nu_s)/S(\nu_w)$ at lower temperatures were observed even in aqueous electrolyte solutions at very high salt concentrations. Thus, it is evident that the rapid $S(\nu_s)/S(\nu_w)$ increases at low temperatures is a common phenomenon in aqueous solutions.

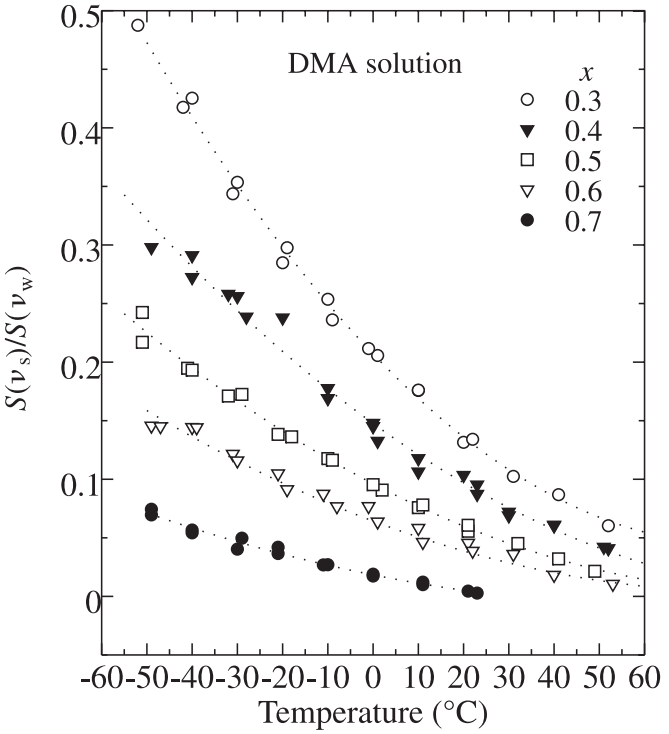
Fig. 7. Variation of the $S(\nu_s)/S(\nu_w)$ ratio for the XDMA·(1 – X)H_2O solution with temperature.



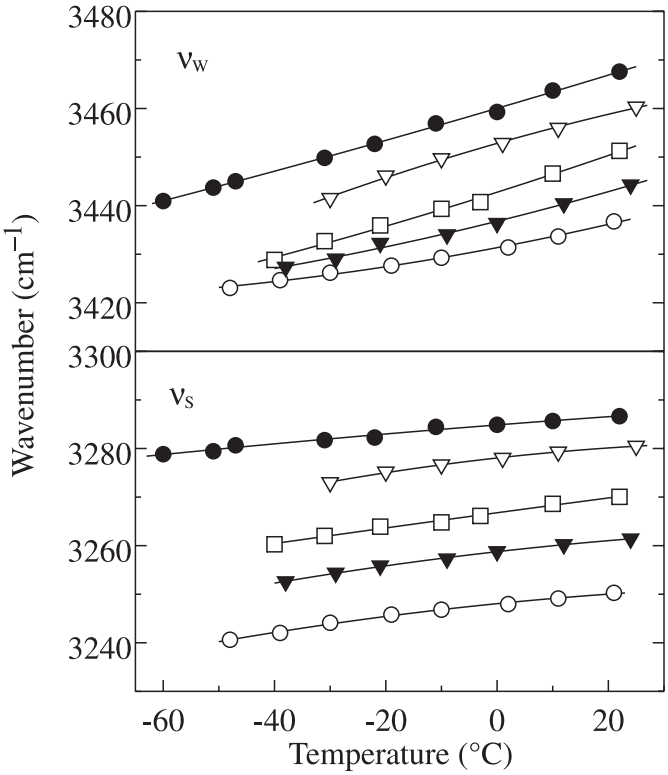


Fig. 8. Frequency variations of the ν_s and ν_w components for the XDMF·(1 – X)H_2O solution with temperature (X = 0.7 (●), X = 0.6 (▽), X = 0.5 (□), X = 0.4 (▼), X = 0.3 (○)).

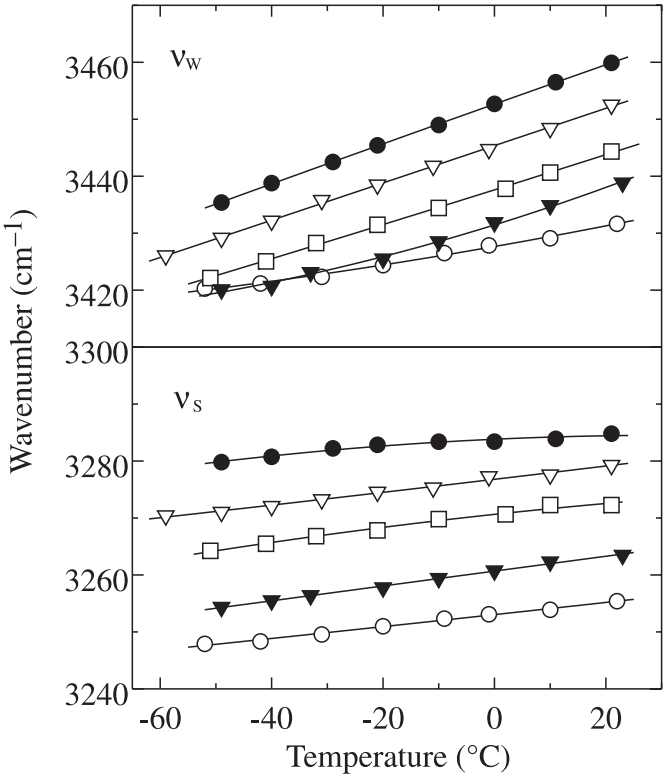
Next, we compare the frequency changes of the ν_s and ν_w components with temperature. Figures 8 and 9 show the frequency changes of the ν_s and ν_w components with decreasing temperature. Both ν_s and ν_w decrease linearly in most cases with decreasing temperature, indicating that the strength of the hydrogen bonds increases linearly with decreasing temperature. Considering the fact that the $S(\nu_s)/S(\nu_w)$ value increases exponentially with decreasing temperature, it is evident that the average strength of the hydrogen bonds in both the DMF and DMA solutions increases rapidly with decreasing temperature.

Both DMF and DMA have two methyl groups and therefore, hydrophobic hydration around two methyl groups exerts an important effect on the hydrogen bond strengths in the solutions. Although they are structurally similar and their liquid properties such as donor and acceptor numbers are also similar, it is interesting to see the differences in their aqueous solutions. We can point out the following differences from Figs. 6–9.

(1) The $S(\nu_s)/S(\nu_w)$ ratio is always larger for the DMF solution than for the DMA solution, implying that DMA is more destructive to water hydrogen bonds.

(2) The ν_s frequency of the DMF solution is always lower than that of the DMA solution while the reverse is the case for the ν_w frequency.



The first result can be ascribed to the fact that DMA molecules are larger than DMF molecules. On the other hand, the fact that the ν_w frequency is lower for the DMA solution than for the DMF solution suggests that the water molecules around DMA molecules have stronger hydrogen bonds than those around DMF molecules. Therefore, clathrate structures around DMA molecules are more stable than those around DMF molecules. This feature is consistent with the view that hydrophobic hydration is important in aqueous solutions of solutes having alkyl group(s). There are number of organic substances that form stable clathrate hydrates. Among tetraalkylammonium ions, tetrabutylammonium and tetraamylammonium ions form very stable clathrate hydrates while tetraalkylammonium ions of small alkyl groups (methyl, ethyl, and propyl) rarely form stable clathrate hydrates (25–27). Although both DMF and DMA are structure breakers in water, DMA is considered to be more suitable in size for clathrate formation.

An interesting aspect is that at low solute concentrations (less than X = 0.4), the ν_w frequency decreases with decreasing temperature, reaching a plateau value at around −30 °C, indicating that solvation structure around a DMA molecule becomes a more stable structure at low temperatures.

Comparing the temperature variations of the ν_s and ν_w frequencies, the lowering rate of the frequency with decreasing temperature is larger for the ν_w component than the ν_s component at most solute concentrations. In the case of the X = 0.5 solution, the ν_w frequency decrease from 20 to −40 °C is ~21 °C for the DMF solution and ~19 °C for the DMA solution, while the ν_s frequency decrease is ~7 °C and ~7 °C for the DMF and DMA solutions, respectively. Therefore, the frequency decrease with decreasing temperature is almost the same for the two solutions at X = 0.5. A remarkable point is that the $(d\nu_s/dT)$ value is almost invariant with the change in solute concentration while the $(d\nu_w/dT)$ value becomes larger with an increase in solute concentration. This feature may indicate that at higher temperatures (higher than

room temperature) clathrate-like structures are destabilized and that at lower temperatures (lower than 0 °C) they regain their stability with decreasing temperature. In fact, most clathrates are stable only at temperatures lower than room temperature (25, 26).

Finally, it is worth mentioning that there have been several reports on the solvated complex formation between water molecules and organic solute molecules (28, 29). The observation of no irregular variations in the $S(\nu_s)/S(\nu_w)$ ratio and ν_s and ν_w frequencies with temperature suggests that solvated complex formation, if any, is not important in aqueous DMF and DMA solutions.

Surface-enhanced Raman scattering (SERS) from a silver electrode modified with oxazine 720[1]

Alexandre G. Brolo and Aaron C. Sanderson

Abstract: Electrochemical and spectroelectrochemical data was obtained for a silver electrode modified with oxazine 720 immersed in 0.2 mol L^{-1} KCl solution. A quasi-reversible redox behaviour was observed for the modified electrode. The electrochemical charges, obtained during either the anodic or the cathodic processes, were higher than expected for a monolayer of flat-adsorbed oxazine 720. Surface-enhanced Raman scattering (SERS) was recorded in situ for different applied potentials. Although the tilt angle was not determined, the analysis of the most enhanced vibrational modes in the SERS data, in conjunction with results of a DFT calculation, suggest that the molecule is adsorbed with its ring perpendicular to the electrode surface. This adsorption mode allows a higher surface packing than for flat-adsorbed molecules, consistent with the electrochemically estimated surface coverage. The potential dependence of the SERS signal is consistent with the redox process observed from cyclic voltammetry. The SERS intensities remain relatively constant between –200 and –500 mV (vs. Ag | AgCl | Cl^-_{sat}), but decrease drastically as the applied potential is made more negative than the onset of oxazine 720 reduction at –500 mV. The spectroelectrochemical data indicate that the molecule remains adsorbed at the SERS active sites even in its reduced form.

Key words: phenoxazine electrochemistry, oxazine 720, modified electrodes, surface-enhanced Raman scattering, SERS, molecular orientation.

Résumé : On a obtenu des données électrochimiques et spectroélectrochimiques pour une électrode d'argent modifiée avec de l'oxazine 720, immergée dans une solution 0,2 mol L^{-1} de KCl. On a observé un comportement redox quasi-réversible pour l'électrode modifiée. Les charges électrochimiques, obtenues durant les processus tant anodique que cathodique, sont plus élevés que ceux attendus pour une monocouche d'oxazine 720 adsorbée à plat. On a enregistré in situ des spectres améliorés de diffraction Raman de la surface (« SERS ») pour différents potentiels appliqués. Même si l'angle d'inclinaison n'a pas été déterminé, l'analyse de la plupart des modes vibrationnels améliorés des données SERS en relation avec les résultats d'un calcul selon la théorie de la densité fonctionnelle suggère que la molécule est adsorbée avec son cycle perpendiculaire à la surface de l'électrode. Avec ce mode d'adsorption, l'empilement est plus facile qu'avec des molécules adsorbées à plat et ceci est en accord avec la surface de couverture évaluée d'une façon électrochimique. La dépendance du signal SERS sur le potentiel est en accord avec le processus redox observée à l'aide de la voltampérométrie cyclique. Les intensités SERS demeurent relativement constantes entre –200 et –500 mV (vs. Ag | AgCl | Cl^-_{sat}), mais elles diminuent d'une façon drastique lorsque le potentiel appliqué est rendu plus négatif que celui nécessaire pour le début de la réduction de l'oxazine 720, à –500 mV. Les données spectroélectrochimiques indiquent que la molécule demeure adsorbée sur les sites actifs en SERS, même dans sa forme réduite.

Mots clés : électrochimie de la phénoxazine, oxazine 720, électrodes modifiées, spectres améliorés de diffraction Raman de la surface, SERS, orientation moléculaire.

Introduction

Oxazine 720 (alternatively called oxazine 170) is a typical laser dye used in the production of coherent radiation in the range 660–730 nm. Oxazine 720 contains a phenoxazine ring in its chemical structure, which is responsible for the strong photoabsorption band in the visible range (λ_{max} at ca. 620 nm) and its reversible electrochemistry at metallic (1) and semiconducting surfaces (2). These physical properties make phenoxazine compounds suitable to applications in several industrial fields, including electrocatalysis (3) and energy conversion (4). The hydrophobic phenoxazine ring promotes molecular aggregation in aqueous solution (5), and such dye aggregates are important for several photoconversion applications such as photography (6), solar energy collection (4), and photocatalytic remediation of groundwater (7). Phenoxazines can also be used as a mediator in charge transfer involving biological molecules (1, 8). For instance,

the oxidation of NADH occurs at +1.1 V (vs. SCE) on carbon electrodes, but this oxidation potential is shifted to a region between −200 and –600 mV when the carbon surface is modified by phenoxazines (8). The electrocatalytic behaviour of the oxidation of NADH for several phenoxazines adsorbed on different electrode materials has been widely investigated (1, 8). Electrodes modified by polymeric phenoxazine compounds have also shown electrocatalytic activity, and, for example, can be used for the voltammetric determination of dissolved molecular oxygen in water at the μmol L^{-1} level (9).

Although the electrochemistry of electrodes modified by phenoxazines is regularly reported in the contexts mentioned above, there are few reports in the literature on the application of spectroelectrochemical methods to elucidate the electrochemical behaviour. This is particularly true for oxazine 720, where the utilization of in situ electronic spectroscopy to evaluate the redox potential of manganese(III) reconstituted mioglobin (10) is among the few examples available. Surface-enhanced Raman scattering (SERS) is an ideal tool to investigate this class of compounds adsorbed on gold, silver, or copper electrodes because adsorbed phenoxazines yield a very large enhancement of their Raman signal, especially when excited with radiation within their electronic resonance (in this condition the effect is termed surface-enhanced resonance Raman scattering (SERRS)) (11). In fact, the SERRS signal from dyes adsorbed on aggregated silver nano particles are capable of producing Raman signals up to 10^{15} times larger than the free molecule. This spectacular increase in the Raman cross section has allowed the observation of extremely low concentrations and even the detection of single dye molecules (11). This high sensitivity has recently led to the exploration of the use of dyes as SERS (and SERRS) labels for the detection of minute amounts of biological species (12).

Although there are no reports in the literature related to the SERS of oxazine 720 adsorbed on electrode surfaces under potential control (in situ SERS), the SERS spectra of oxazine 720 adsorbed on silver colloids were reported by Schneider et al. (13). It was noted that the relative SERS intensities of several dyes (including oxazine 720) adsorbed on silver colloids were dependent on the nature of the anion presented in the aqueous environment (13). Two processes could explain the origin of this phenomenon as reported in ref. 13: Firstly, the dependence can be related to the "chemical" contribution to the overall SERS effect (13). This enhancing mechanism may be related to a charge transfer (CT) between the metal and the adsorbed molecule in a resonance Raman-like process (14). According to ref. 13, the coupling between the electronic states of the metal and the dye depends on the strength of the interaction between the co-adsorbed anion and the dye. Therefore, the anions can tune the resonance and provoke spectral shifts and changes in relative SERS intensities. On the other hand, the observed difference in the SERS spectra of oxazine 720 obtained in media containing different anions could also be explained by anion-induced reorientation (13). The relative contribution of the CT mechanism to the overall SERS signal can easily be manipulated in an electrochemical environment since the energy of the Fermi level is related to the applied electrical potential (14). Therefore, in situ spectroelectrochemical SERS measurements would be useful to clarify some of these aspects discussed in ref. 13.

In this paper, we present electrochemical and SERS results from a silver surface modified with oxazine 720 in a 0.2 mol L^{-1} KCl solution. The electrochemical data show that oxazine 720 undergoes reduction at ca. –500 mV (vs. Ag | AgCl | Cl^-_{sat}). The dependence of the SERS intensities on the applied potential provides insights into the molecular orientation and the role of the CT mechanism (14). It will also be demonstrated that the reduced form of oxazine 720 remains adsorbed at the SERS active sites on the silver surface even at potentials as negative as –1000 mV.

Experimental

Solutions

Solutions for electrochemical and spectroelectrochemical measurements were prepared using KCl 99% (ACP) and ultra-pure water (18.2 MΩ.cm) from a Barnstead NANOpure Diamond water purification system. Analyte solutions were prepared with oxazine 720 (Lambdachrome) and HPLC grade methanol (Aldrich).

Cell, electrodes, and electrochemical equipment

The working electrode was fabricated using a 99.99% silver rod (Premion – Alfa Aesar), machined into a silver disk of ca. 6.35 mm diameter and mounted in a Teflon holder. Electrical contact was made to the silver electrode by an externally threaded stainless-steel rod. The silver electrode was polished before each experiment with emery paper, and then with progressively finer grades of alumina powder down to 0.05 μm. After the surface polishing treatment, the silver electrode was rinsed with copious amounts of ultra-pure water and then transferred to the appropriate cell. The reference electrode was a saturated silver–silver chloride electrode, and all potentials in this work are quoted against this reference. A 0.3 mm platinum wire (Alfa Aesar) was used as the counter electrode. The spectroelectrochemical cell used for the SERS measurements has been described in a previous publication (15). A Hokuto Denko potentiostat–galvanostat (HAB-151) was used to control the potential applied to the silver surface. The assembled cell was purged with prepurified nitrogen for 30 min prior to taking measurements, and a gentle stream of nitrogen was maintained to blanket the solution during data acquisition.

Activation procedure

The "activation procedure" used to prepare the SERS active (rough) silver surface consisted of a sequence of oxidation–reduction cycles (ORCs) performed on the polished silver electrode immersed in a 0.2 mol L^{-1} KCl aqueous solution. A triangular potential sweep program was applied, changing the surface potential from –700 to +250 mV and back to –700 mV at a scan rate of 5 mV s^{-1}. Typically, three such cycles were performed to produce the desired roughness. The metallic silver oxidizes in this medium at potentials more positive than +50 mV, producing an insoluble salt (AgCl). During the reverse scan, the AgCl film is reduced back to metallic silver at ca. –100 mV. The freshly formed silver surface obtained during the reduction

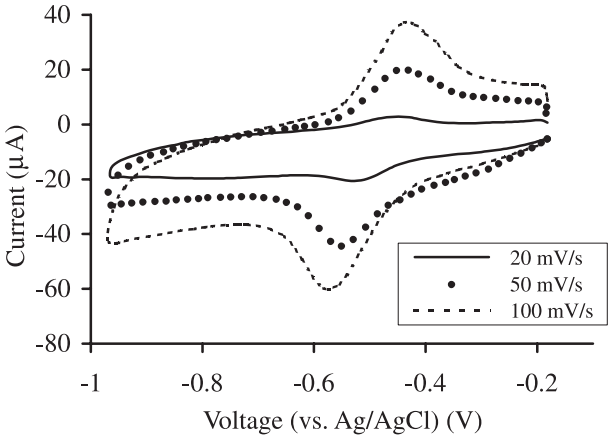
© 2004 NRC Canada

is naturally rough, and sustains significant enhancement of the Raman signal for adsorbed molecules (16, 17).

The modified electrode was prepared using a droplet evaporation procedure. After the activation procedure, the rough silver electrode was removed from the cell and a drop of a ca. 10 μmol L^{-1} solution of the dye in methanol was added to the electrode surface. The solvent was allowed to evaporate, after which the surface was rinsed with ultra-pure water. The modified electrode was then placed back into the cell. Electrochemical control was resumed and the desired potential was applied. The objective of this procedure was to adsorb a single monolayer of the dye on the surface. The high quality of the SERS spectra obtained from oxazine 720 adsorbed using this procedure indicates that an extremely large enhancement of the Raman cross section was achieved for these molecules.

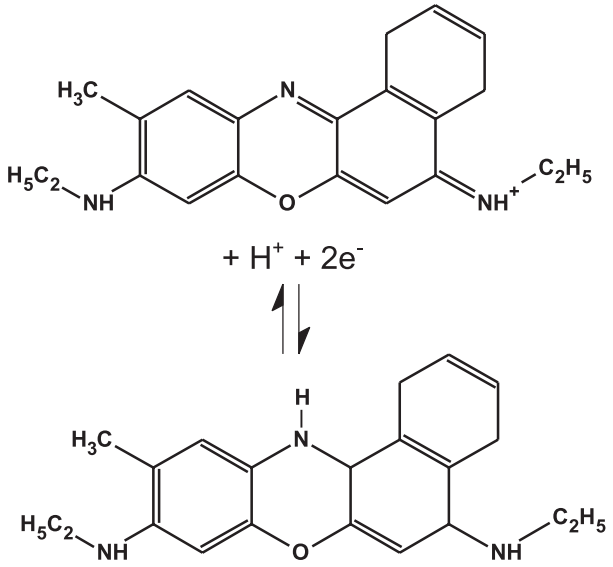
The silver electrode was never oxidized in the presence of oxazine 720. This ensured that the dye molecules were neither trapped nor electrochemically degraded by the activation ORC (18).

Raman instrumentation



SERS spectra were collected using a Dilor OMARS89 spectrometer coupled to an optical multichannel analyzer. The detector was a thermoelectricaly cooled (ca. –15 °C) intensified diode array (512 diodes) interfaced to a computer for data collection. Excitation at 514.5 nm was provided by a Spectra-Physics model 2020 argon ion laser with the power set to less than 40 mW at the laser head. Excitation at 632.8 nm was provided by a Melles Griot He–Ne laser at similar power levels. The acquisition time for each measurement was 1 s and a minimum of 10 accumulations were summed for each spectrum. The laser light was chopped to allow background spectra to be obtained and subtracted during each accumulation. The resulting spectra were then baseline corrected during analysis.

The normal Raman spectra of solid oxazine 720 were collected with a Renishaw inVia microscope Raman spectrometer system utilizing a Spectra-Physics argon ion laser to produce excitation at 514.5 nm.



Results

Figure 1 shows cyclic voltammograms at different scan rates for a silver electrode modified with oxazine 720 immersed in a 0.2 mol L^{-1} KCl solution. The cathodic and anodic peaks are related to the redox of the phenoxazine ring as proposed elsewhere (19). At neutral pH, the electrochemical process (depicted in Scheme 1) involves the transfer of two electrons and one proton. The process is pH-dependent and two protons should be exchanged in acidic medium (19). The electrochemical mechanism may involve the formation of a radical cation intermediate (20). Both the cathodic and the anodic peaks presented in Fig. 1 shift with the scan rate, but this effect is more pronounced for the reductive process. The cathodic peak moves from ca. –525 mV at 20 mV s^{-1} to ca. –590 mV at 200 mV s^{-1} (not shown) and the anodic peak shifts from –460 to –430 mV at 20 mV s^{-1} and 200 mV s^{-1} (not shown), respectively, (all potentials are reported against a Ag | AgCl | Cl^-_{sat} reference electrode). The redox potential observed here is more negative than the formal redox potential of –325 mV reported for the reduction of oxazine 720 (10), although the redox potential of surface-confined phenoxazines may differ significantly from that observed for the molecule in solution (8). The peak currents presented a linear relationship with the square root of the scan rate. A direct relationship with the scan rate is expected for strongly bound species (21), and the dependence with $v^{1/2}$ indicates that diffusion from solution is playing a significant role in the electrochemical mechanism. This is not surprising considering that protons are involved in the electrochemical reaction. The cathodic charge (Q_c) is ca. 40% higher than the anodic charge (Q_a) at slow scan rates. This difference decreases as the scan rate increases and a Q_c/Q_a ratio equal to one is observed for sweep rates faster than 100 mV s^{-1}. The electrochemical charges were corrected for the surface roughness (19) and used to estimate the amount of oxazine 720 at the solid–liquid interface. The calculated values depend on the sweep rate and on the nature of the process (cathodic or anodic), with the amounts ranging between 3 and 8×10^{-10} mol cm^{-2}. The expected coverage for a monolayer of a phenoxazine species adsorbed flat on the metallic

Fig. 1. Cyclic voltammograms of oxazine 720 on a silver electrode in a 0.2 mol L^{-1} KCl solution.

Scheme 1.

© 2004 NRC Canada

surface is estimated to be between 1 and 2×10^{-10} mol cm^{-2} (22). Therefore, if oxazine 720 is flat-adsorbed on the modified surface, multilayers must be present. On the other hand, the higher surface coverage reported here may also indicate that the molecule is adsorbed end-on, probably attached by the nitrogens from the amino groups. Finally, oxazine 720 is known to form dimers in aqueous solution (5). In fact, second-harmonic generation measurements have demonstrated that oxazine 720 dimers are the main species present at a liquid–air interface (23). Therefore, the discrepancy in the expected and experimental surface coverage may also be related to the preferential adsorption of the dimer.

The normal Raman spectrum of solid oxazine 720 is compared to the SERS signal from the modified electrode in Fig. 2. These spectra were obtained using 514.5 nm laser excitation, which is away from the visible-range absorption maximum for oxazine 720 (ca. 620 nm). The vibrational assignment of selected oxazine 720 modes (presented in Table 1 and shown in Fig. 3) was performed using previous work for other dyes that contains the phenoxazine ring (19, 24) and our own DFT calculations using Gaussian 98W®, carried out at the B3LYP level using the 6-31G(d)5D basis set. Figure 2 shows that there are two regions that contain a wealth of vibrational information in both the solid and the adsorbed molecule spectra: the region between 500 and 700 cm^{-1} and the region between 1100 and 1700 cm^{-1}. A specific set of bands are enhanced under adsorption and appear in the SERS spectrum at 546, 585, 675, 1339, 1395, and 1644 cm^{-1}. The vibrational frequencies from the adsorbed molecule are similar to the ones observed for the solid, suggesting a relatively weak adsorption to the surface. Representations of the normal modes of the most surface-enhanced bands are presented in Fig. 3.

Further analysis of the SERS spectrum shows the lack of enhanced out-of-plane ring vibrations (Fig. 3), which, according to the SERS selection rules, are expected to show significant intensity if the ring is adsorbed flat to the surface (18). It is known that the breathing mode of benzene shifts to lower frequency as the flat-adsorbed molecule interacts with the surface (25), and although the multi-ring oxazine 720 system is much more complex than benzene, some shift to lower frequency should be observed for vibrations that are dominated by ring modes if the molecule is adsorbed flat. All these pieces of evidence indicate that the oxazine 720 ring is not completely flat-adsorbed, but is interacting with the surface through the aliphatic amino groups. The tilt angle between the molecule and the surface normal cannot be evaluated solely from the data presented in Fig. 2, but it suggests that the oxygen–nitrogen axis is in an upright position, with the ring in a position perpendicular to the surface. Since such an orientation allows more molecules to be packed on the silver surface, the spectroscopic data is in agreement with the high surface coverage obtained from the electrochemical data presented in Fig. 1, where cyclic voltammetry suggested coverage in excess of a monolayer of flat-adsorbed oxazine 720. This upright orientation was also suggested by Schneider et al. (13) for high coverage of oxazine 720 adsorbed on silver colloidal particles. The end-on orientation is also consistent with the tendency of oxazine 720 to form H-aggregates in aqueous environments (5). Spectroelectrochemical SERS studies involving other phenoxazine rings, such as nile blue, also suggest the end-on orientation for the adsorption from acidic solutions (19).

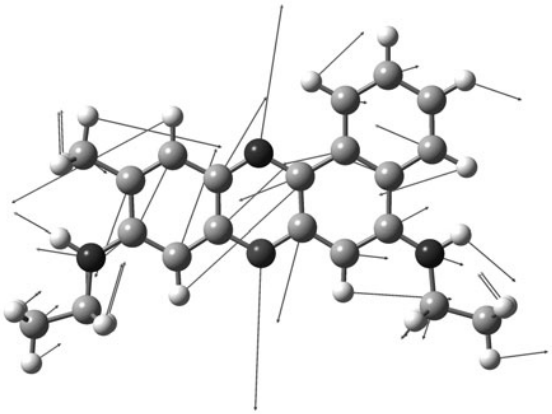
[a]From ref. 24.



SERS spectra from a silver electrode modified with oxazine 720, obtained at different applied potentials, are shown in Fig. 4. The spectra in Fig. 4 were collected using green excitation at 514.5 nm. Experiments using red (632.8 nm) excitation (not shown), which is within the absorption band of the free molecule, were also performed, but no significant differences in the relative intensities of the main modes indicated in Fig. 3 and Table 1 were observed. A plot of the intensities of selected peaks from Fig. 4 vs. the applied potential (potential profile) is presented in Fig. 5. The intensities of most of the SERS bands did not change significantly when the applied potentials were more positive than –500 mV. This can be clearly observed in the potential profile for the 1644 and 1545 cm^{-1} bands shown in Fig. 5. On the other hand, a band at 1475 cm^{-1} was absent in the SERS spectrum for applied potential more positive than –250 mV, while the intensity of this mode increased as the potential was scanned more negative, reaching a maximum at around −450 mV. Figure 5 indicates that the SERS intensities for all modes of adsorbed oxazine 720 decreased sharply as the potential is made more negative than –500 mV. This behaviour can be correlated to the electrochemical curves presented in Fig. 1, demonstrating that the SERS intensities decrease as

the onset of oxazine 720 reduction is reached. Two explanations can be considered for the transient nature of the 1475 cm^{-1} band. Firstly, this mode may indicate some sort of molecular rearrangement that occurs just before reduction or, alternatively, the increase in the 1475 cm^{-1} band can be explained using charge transfer (CT) arguments. The CT theory of electrochemical SERS explains the potential dependence of the SERS intensities as an electron transfer res-

onance between the metal and the molecular orbitals of the adsorbed species (14, 15). This resonance is modulated by the applied potential, which controls the position of the Fermi level. The CT contribution can then be probed in electrochemical SERS by obtaining the potential profile at different excitation wavelengths and observing the shift in the potential where the SERS intensity is maximized (15). The SERS spectra from a silver electrode modified with oxazine 720 using 632.8 nm excitation presented potential profiles similar to those observed in Fig. 5 for most of the bands, including the ones at 1644 and 1545 cm^{-1}. In these cases, the SERS intensity remained almost constant for potentials between –200 and –500 mV and then decreased as the applied voltages became more negative than –500 mV. The potential-transient 1475 cm^{-1} band was not observed at any applied potential for experiments using red excitation. This behaviour shows that this mode is not related to reorientation. The intensity of the 1475 cm^{-1}-mode has been reported to be sensitive to the nature of the anion in solution for oxazine 720 adsorbed on colloidal silver (13). This was interpreted as an indication that this vibration could be tuned in and out of resonance by the anion-induced modification

Fig. 6. SERS spectra of oxazine 720 showing the recoverability of the SERS signal. (*a*) The initial spectrum was collected with an applied potential of –200 mV. (*b*) The potential was then changed to –1000 mV, where the SERS signal is no longer visible. (*c*) The applied potential was then returned to –200 mV, and the SERS signal was recovered.

of the electronic properties of the silver particles (13). The results reported here confirm the role of the CT mechanism for this specific mode.

As discussed above, the decrease in intensity of the SERS bands as the potential is made more negative than –500 mV is obviously related to the reduction of oxazine 720. Interestingly, however, the SERS signal is recovered when the potential is returned to values more positive than –500 mV. This process is illustrated in Fig. 6. The initial SERS spectrum was collected with an applied potential of –200 mV (Fig. 6*a*), after which the potential was gradually swept to –1000 mV, where the SERS signal completely vanished because of the reduction (Fig. 6*b*). The potential was then returned to –200mV, where a good quality SERS signal was recovered (Fig. 6*c*). Figure 1 indicates that the electrochemical behaviour of oxazine 720 adsorbed on silver is quasi-reversible, in agreement with the observations from Fig. 6. It is well-established, however, in the SERS literature that the active sites that support the enhancement are lost during incursions to highly negative potentials (26). This is due to potential-induced morphological changes related to molecular (or anionic) desorption followed by surface diffusion and incorporation of the roughness features (26). The fact that the SERS signal is recovered in Fig. 6*c* is the result of the molecule remaining adsorbed at the SERS active sites in its reduced form. This is in agreement with the observed Raman bands of the reduced form of other phenoxazine dyes adsorbed at negative potentials (19). It is important to stress, however, that SERS signals originate only from specific active sites. The observation that the molecule stays adsorbed at highly negative potentials (Fig. 6) may not represent an average behaviour that would be observed from a smooth surface. The weak SERS signal from the reduced form of oxazine 720 reported here is not related to molecular desorption: the reduction populates the low-lying LUMO, shifting the CT resonance to higher energies not accessible using the laser excitations used in this work.

Conclusions

The redox behaviour of a silver electrode modified by oxazine 720 was investigated by SERS and cyclic voltammetry. The combination of electrochemical and spectroelectrochemical data indicate that oxazine 720 adsorbs in an upright position, interacting with the surface by the nitrogens from the amino side chains. A quasi-reversible redox was observed around –500 mV, and the reduced molecule was shown to remain adsorbed to the surface down to an applied potential of –1000 mV. The role of the CT mechanism on the overall SERS intensity was explored and specific SERS bands were found to be significantly enhanced only over a short potential window, indicating a resonant behaviour. This resonant characteristic was confirmed by collecting SERS spectra using different excitation energies. These results should help in understanding the role of phenoxazines in electrocatalysis and photon conversion applications.

In situ ATR-SEIRAS study of adsorption and phase formation of trimesic acid on Au(111-25 nm) film electrodes[1]

B. Han, Z. Li, S. Pronkin, and Th. Wandlowski

Abstract: The adsorption and phase formation of 3 mmol L^{-1} trimesic acid (TMA) on Au(111-25 nm) film electrodes in contact with aq. 0.1 mol L^{-1} $HClO_4$ electrolyte have been investigated by in situ ATR-SEIRAS, cyclic voltammetry, chronoamperometry, and STM measurements. Depending on the applied electrode potential, TMA molecules assemble in three distinctly different 2D ordered adlayers. In the range $0.10 < E < 0.50$ V, planar-oriented molecules form an open ring honeycomb pattern (phase I) stabilized by directional hydrogen bonds. Interfacial water molecules are being replaced. A close-packed, physisorbed adlayer II forms at higher potentials in the range $0.58 < E < 0.75$ V. Further increase of the electrode potential causes an orientation change. An initially disordered phase transforms into an ordered, stripe-like chemisorbed adlayer III of perpendicularly oriented TMA molecules ($0.90 < E < 1.20$ V). One *carboxylate* group per molecule is bound to the electrode surface, while the two other *protonated carboxyl* groups are directed toward the electrolyte, and act as structure-determining components of a hydrogen-bonded molecular ladder network. Strongly hydrogen-bonded and isolated water species are co-adsorbed. The potential-induced formation of chemisorbed TMA proceeds in two steps: (*i*) orientation change from planar to a disordered tilted and (or) perpendicular phase III_a ($\tau < 5$ ms) according to a Langmuir-type kinetics; (*ii*) subsequently, the chemisorbed TMA molecules align into a highly ordered, stripe-like phase III_b with co-adsorbed water species.

Key words: ATR-SEIRAS, trimesic acid, Au(111), supramolecular assembly.

Résumé : Faisant appel à des mesures in situ d'ATR-SEIRAS, de voltampérométrie cyclique, de chronoampérométrie et de STM, on a étudié l'adsorption et la formation de la phase de 3 mmol L^{-1} d'acide trimésique (ATM) sur des électrodes en film de Au(111-25 nm) en contact avec une solution aqueuse 0,1 mol L^{-1} de $HClO_4$ agissant comme électrolyte. Suivant le potentiel d'électrode applique, les molécules d'ATM s'assemblent dans trois couches d'adsorption différentes organisées en deux dimensions. Dans la plage de $0{,}10 < E < 0{,}50$ V, les molécules orientées dans un plan forment une structure alvéolée à cycle ouvert (la phase I) stabilisée par des liaisons hydrogènes orientées. Les molécules d'eau interfaciales sont déplacées. À des potentiels plus élevés, dans la plage de $0{,}58 < E < 0{,}75$ V, il se forme une couche d'adsorption physique serrée, II. Une augmentation du potentiel d'électrode provoque un changement d'orientation. Une phase initialement désordonnée se transforme en une phase d'adsorption chimique (III) bien ordonnée et en forme de rayure avec des molécules d'ATM orientées perpendiculairement ($0{,}90 < E < 1{,}20$ V). Un groupe carboxylate par molécule est attaché à la surface de l'électrode alors que les deux autres groupes carboxyles protonés sont orientés vers l'électrolyte et agissent comme composants déterminants la structure d'un réseau en escabeau moléculaire formé par des liaisons hydrogènes. La formation induite par le potentiel de l'ATM s'effectue en deux étapes: (*i*) un changement d'orientation de la phase planaire vers une phase désordonnée et inclinée et (ou) une phase perpendiculaire III_a ($\tau < 5$ ms) qui suit une cinétique de type Langmuir; (*ii*) et, subséquemment, les molécules d'ATM chimisorbées s'alignent dans la phase bien orientée et en forme de rayure, III_b, coadsorbées avec des molécules d'eau.

Mots clés : ATR-SEIRAS, acide trimésique, Au(111), assemblage supramoléculaire.

chemical system, the electrode surface acts as an electron (charge) source or sink and additional coordination center. The electrode potential assumes the role of an universal tuning source to fabricate and address nano-structures (2). The selectivity and directional nature of hydrogen bonding has led to its extensive use in the construction and stabilization of non-covalently bonded molecular and supramolecular structures (3–5). Hydrogen bonds are formed when a donor (D) with an available acidic hydrogen atom is brought into contact with an acceptor (A). Hydrogen bonding is not random, but controlled by the directional strength of intermolecular interactions and can be used to tune spatial arrangement of functional molecules and ions in bulk systems and on surfaces (2, 5–8).

Carboxylic acids are commonly used as pattern-controlling functional groups for the purpose of crystal engineering. They can form hydrogen-bonded structures that contain a center of symmetry (dimer motif) and also aggregate in acentric one-dimensional chains (catemer motif) resulting from the formation of hydrogen bonds to two or more neighboring acids (5). The dimer synthon has been used to assemble a variety of super-molecules. For example, terephthalic or 1,4-benzenedicarboxylate acid (TA) (9), isophthalic or 1,3-benzenedicarboxylate acid (IA) (10), and a wide variety of their derivatives (11) are known to form one-dimensional tapes and ribbons. Trimesic or 1,3,5-tricarboxylic acid (TMA), which is composed of a phenyl ring and three trigonal exodentate carboxyl groups, arranges in two-dimensional networks with characteristic honeycomb units (12, 13). TMA and its metal and inclusion complexes represent prototype materials for supramolecular assemblies involving directional hydrogen bonding and (or) metal ion | ligand coordination (13–24).

The assembly of TMA on surfaces was recently studied under UHV conditions (25, 26) as well as at electrified solid–liquid interfaces (27, 28) employing scanning tunneling microscopy (STM). Griessl et al. (25) reported on highly oriented pyrolytic graphite (HOPG), the coexistence of two hexagonal ring structures composed of TMA with hydrogen bonds formed either between two ("chicken wire" or "honeycomb" motif) or between three ("flower" motif) adjacent molecules. Dmitriev et al. (26) reported in a temperature-dependent study on Cu(100) two different 2D structures: a honeycomb structure at low temperature (200 K), and a more densely packed stripe arrangement at room temperature. The latter was assigned to upright standing TMA molecules, which are adsorbed on Cu(100) via one or two deprotonated carboxylate groups. Under electrochemical conditions, Ishikawa et al. (27) found for Au(111) – 0.1 mol L^{-1} $HClO_4$ a honeycomb-type (8 × 8) two-dimensional network of flat oriented TMA molecules, which transforms at higher potentials into a close-packed structure of dimers. Under similar experimental conditions, Su et al. (28) found three ordered adlayers: a quasi-hexagonal (4 × 4) phase of planar-oriented molecules at low coverage, a mixed (5 × 2√3) adlayer, and a striped phase represented by (2√3 × 4√3) or (7 × 2√3). The latter was tentatively ascribed to perpendicularly adsorbed molecules. Despite the detailed structure information, the reported results do not provide direct insight into the chemical composition and formation kinetics of the TMA-modified electrochemical interfaces. This knowledge can be developed from surface spectroscopic experiments employing classical (IRAS) or surface-enhanced IR reflection absorption spectroscopy (SEIRAS) (29, 30). Both techniques were already used to study the adsorption and phase formation of simple carboxylic acids, such as benzoic acid (BA) (31–33), *p*-nitrobenzoic acid (34, 35), fluorobenzoic acid (36), terephthalic acid (37), and fumaric acid (38) on Au(*hkl*), Ag(*hkl*), or Pt(*hkl*). The application of in situ SEIRAS in an attenuated total reflection configuration (ATR-SEIRAS) has several advantages in comparison to IRAS studies employing the so-called thin layer configuration (29, 39): (*i*) high and specific surface sensitivity with an enhancement of the IR response up to ca. 100 times stronger; (*ii*) dominant first layer effect (Helmholtz region) with a short decay length of the locally enhanced field of 3 to 4 nm towards the bulk electrolyte; (*iii*) signals from the interface and the solution background are of comparable magnitude and can be separated by applying the potential difference tactics; (*iv*) no severe limitations because of mass transport and advanced potential perturbations allowing a time resolution of up to 50 μs in in situ step-scan experiments (limited by the time constant of double layer charging).

In this paper, we are presenting a comprehensive in situ ATR-SEIRAS study of the vibrational properties of TMA and co-adsorbed water species on quasi-single crystalline Au(111-25 nm) film electrodes in contact with aq. 0.1 mol L^{-1} $HClO_4$. First, we report on the steady state properties of the potential dependent adlayer structures with special emphasis on the role of interfacial water. The second part of this contribution is focused on exploring the kinetics of phase formation employing time-resolved measurements in the rapid-scan and step-scan regimes, respectively. The IR spectroscopic results will be compared with in situ STM and electrochemical experiments employing well-defined single crystal electrodes.

Experimental

Spectroscopic setup

The SEIRAS experiments were carried out in a vertical spectroelectrochemical cell in the Kretschmann ATR configuration (39, 40). The working electrode was prepared by electron beam evaporation (deposition rate 0.005–0.007 nm s^{-1}, base pressure < 2 × 10^{-7} mbar (1 bar = 100 kPa)) of a thin gold film (25 nm mass thickness) onto the (111)-plane of a highly refractive Si hemisphere. The geometrical area of the electrode in direct contact with the electrolyte solution was 1.53 cm^2. The gold films were electrochemically annealed by cycling the potential in the double layer region at 50 mV s^{-1} for 1.5 h after deaeration. The primary reference electrode (RE) was either a trapped hydrogen electrode (RHE) or a mercury sulfate electrode (MSE). The counter electrode (CE) was a large-area platinum spiral. The electrode potential was controlled and synchronized with a HEKA potentiostat PG 310. All potentials in this paper are quoted with respect to the trapped hydrogen electrodes (0.310 V vs. SCE).

The IR spectra were measured with a Bruker IF66 V/s Fourier transform spectrometer. The spectral resolution was 4 cm^{-1} in slow-scan or rapid-scan experiments, and 8 cm^{-1} in the step-scan regime. Unpolarized IR radiation from a

© 2004 NRC Canada

globar source was focused onto the electrode | electrolyte interface by passing through the back of the Si prism. The incident angle was typically 70° referred to the surface normal. The IR radiation totally reflected at the interface was measured with a liquid-nitrogen-cooled MCT detector (Model Colmar Technologies MCT 317). The spectroelectrochemical experiments were carried out under potential sweep or potential step conditions. In the potential sweep experiments (10 mV s^{-1}), the spectrometer was operated in the slow-scan mode. 160 sequentially acquired interferograms were co-added into each single beam spectrum. The potential step experiments were carried out either in the rapid-scan mode (28 ms time resolution, average of 256 traces) or in the step-scan regime (200 μs time resolution, 10 traces averaged, 1000 time slices). The spectra were plotted in absorbance units defined as $A = -\log (I/I_o)$, where I and I_o represent the intensities of the reflected radiation at the sample and the reference potentials, respectively. Positive (negative) going bands indicate accumulation (decay) of the species with respect to the reference.

Single crystal experiments

The ideal Au(111) or stepped Au(n n n-2) = Au [n(111)-110] electrodes were single crystal cylinders of 4 mm height and 4 mm diameter. The massive gold single crystals were flame-annealed in a butane flame at red heat and then cooled in high purity argon before immersion into ultrapure water. Contact with the electrolyte was established under potential control. A detailed description of the custom-made electrochemical setup being employed in these experiments was given in ref. 41.

In situ STM setup

The in situ STM experiments were carried out with a Molecular Imaging Pico-SPM on disc-shaped Au(111) massive single crystal electrodes in 0.1 mol L^{-1} $HClO_4$ or 0.1 mol L^{-1} H_2SO_4. The STM tips were electrochemically etched W tips (0.25 mm diameter), coated with polyethylene. Pt wires served as reference and counter electrodes. All STM images were recorded at room temperature in constant current mode with tunneling currents ranging between 3 and 200 pA.

Electrolyte solution

The solutions were prepared with Milli-Q water (18 MΩ cm, 1 to 2 ppb TOC), $HClO_4$ (suprapure, Merck), TMA (for synthesis, Lancaster, twice recrystallized in water), benzoic acid (standard for element analysis, Merck), and isophthalic acid (for synthesis, Merck, twice recystallized in water). All electrolytes (EC, SEIRAS) were deareated with argon before and during the experiments. The measurements were carried out at 20 ± 0.5 °C.

The glassware was cleaned either in a 1:1 mixture of hot H_2SO_4 and HNO_3, or by soaking in caroic acid, followed by rinsing cycles with Milli-Q water.

Results and discussions

Steady-state voltammetry

Figure 1*a* shows typical cyclic voltammograms of Au(111) in 0.1 mol L^{-1} $HClO_4$ solution in the absence (dotted) and in the presence (full, dashed curve) of 3 mmol L^{-1}

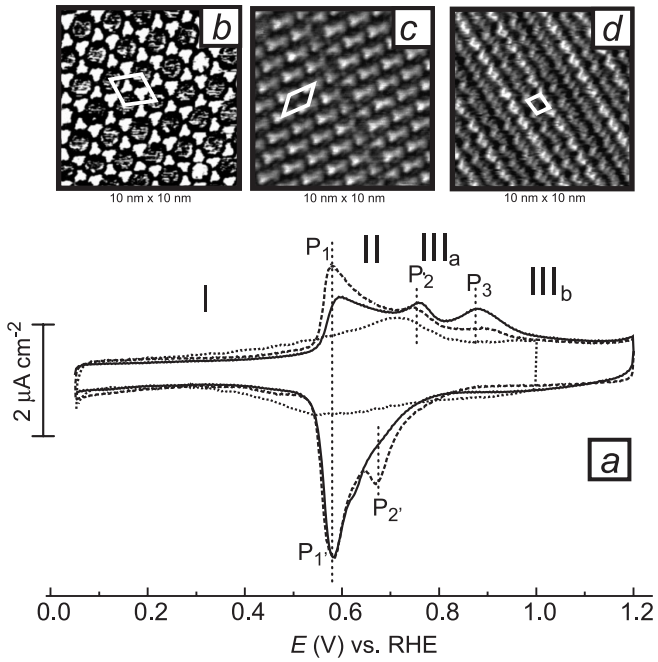

Fig. 1. (*a*) Cyclic voltammograms of an ideal Au(111) electrode (miscut angle <0.2°) in 3 mmol L^{-1} TMA – 0.1 mol L^{-1} $HClO_4$, scan rate of 10 mV s^{-1}. The solid curve represents the steady-state curve recorded after three complete potential cycles, the dashed curve was obtained after 10 min cycling from 0.85 to 1.20 V. The base electrolyte voltammogram is plotted as a dotted curve. The various adlayer regions are labeled I, II, III_a, and III_b. (*b*), (*c*), and (*d*) represent high-resolution, in situ STM images of the ordered phases recorded at 0.10, 0.70, and 1.0 V, respectively (42).

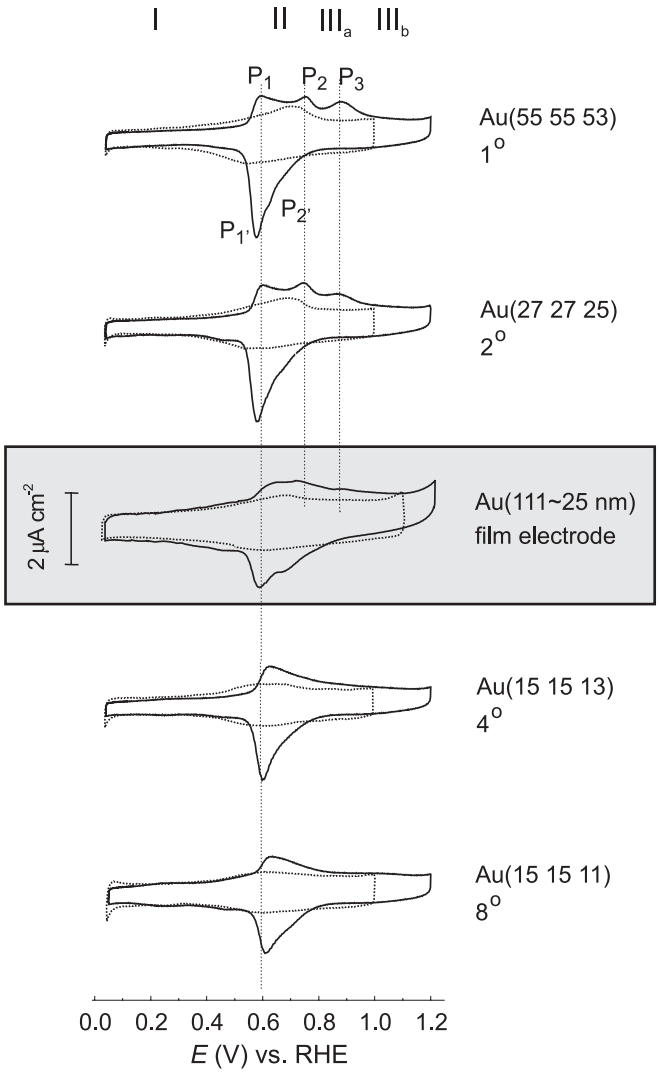
TMA. The experiment started with a thermally reconstructed Au(111) electrode immersed in the electrolyte at 0.30 V. The trace represented by the solid line was recorded after three subsequent cycles in the double layer region. The dashed curve was obtained after 10 min of cycling the potential from 0.85 to 1.20 V. Four characteristic potential regions (labeled I, II, III_a, and III_b), which are separated by the current peaks $P_1/P_{1'}$, $P_2/P_{2'}$, and P_3, can be readily distinguished. Based on previous in situ STM experiments, the following tentative assignment is suggested (28, 42): a physisorbed adlayer develops in region I during the positive potential scan, followed by a transition phase II ($E > P_1$ = 0.59 V), which transforms into a chemisorbed adlayer at $E >$ 0.76 V (P_2). The chemisorbed region III is further separated into III_a and III_b by a broad current peak P_3 ~0.88 V indicating a slow disorder–order transformation (42). Extended potential cycling in region III facilitates the formation of a long-range ordered chemisorbed adlayer. The subsequent dissolution upon a negative potential excursion gives rise to a characteristic cathodic current peak P_2'.



The in situ STM images in Figs. 1*b*–1*d* illustrate the molecular arrangements of TMA in the three ordered phases I, II, and III_b, respectively (42). Figure 1*b* shows the open honeycomb pattern of planar-oriented, physisorbed TMA molecules, which are connected by symmetrical hydrogen bonds between neighboring carboxyl groups (dimer motif). The rhombohedral unit cell with a = (1.65 ± 0.08) nm and α =

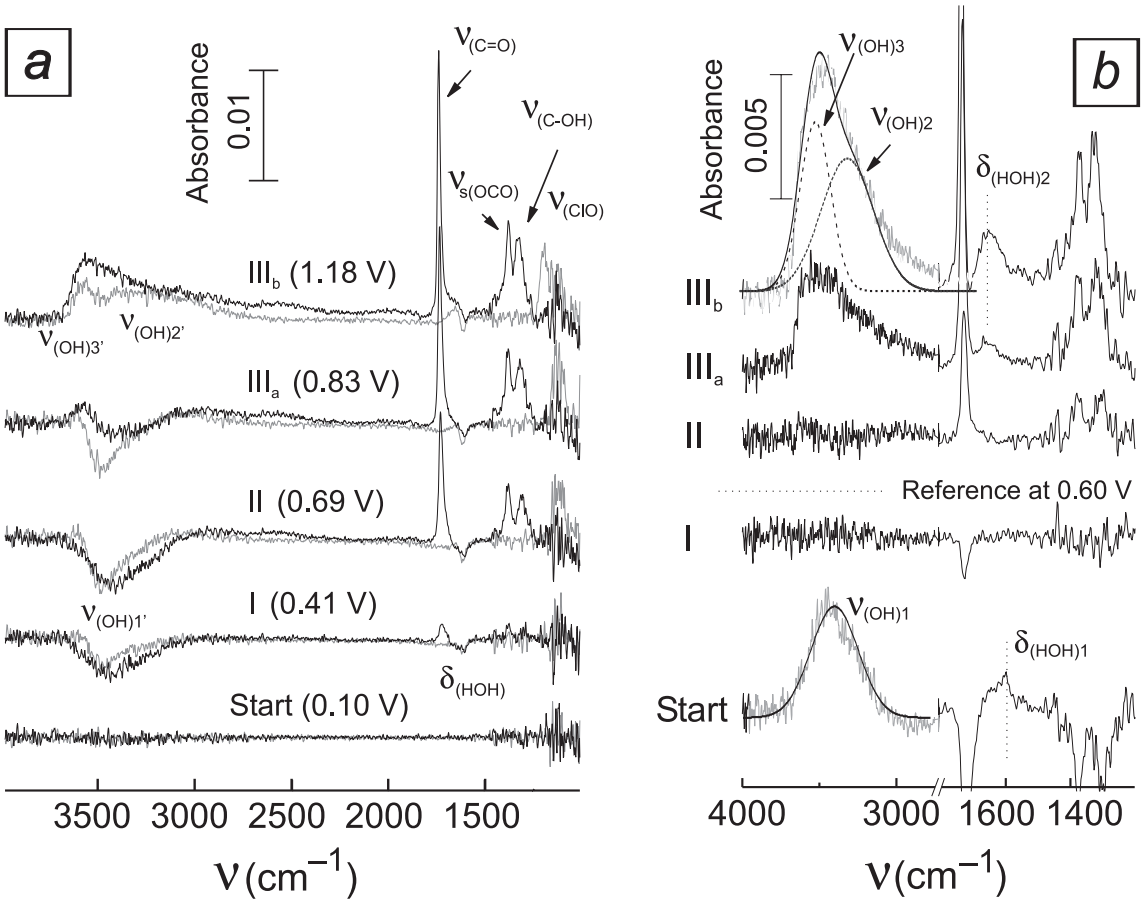
© 2004 NRC Canada

(60 ± 6)° contains two molecules, which gives rise to a coverage of Γ_{mI} = (1.4 ± 0.2) 10^{-10} mol cm^{-2} or an area per molecule of A_I = (1.18 ± 0.06) nm^2. Similar structures were reported previously under UHV conditions as well as in solution on HOPG, Cu(100), and Au(111) (25–28, 42). At higher electrode potentials, in region II (Fig. 1*c*), an assembly of physisorbed, quasi-linear rows is observed. Within the rows adjacent molecules appear to be connected by hydrogen bonds in an alternating arrangement of centrosymmetric and macrocyclic dimers (42). The unit cell, composed of two TMA molecules, is represented by a parallelogram with a = (1.47 ± 0.05) nm, b = (1.22 ± 0.20) nm, and α = (57 ± 5)°. The corresponding coverage and area per molecule are estimated to be Γ_{mII} = (2.2 ± 0.2) 10^{-10} mol cm^{-2} and A_{II} = (0.75 ± 0.05) nm^2 (42). At more positive electrode potentials, in region III_b, STM experiments revealed a close-packed, striped TMA phase with a suggested unit cell of a = (1.15 ± 0.05) nm, b = (0.95 ± 0.06) nm, α = (80 ± 5)°, Γ_{mIIIb} = (3.1 ± 0.2) 10^{-10} mol cm^{-2}, and A_{IIIb} = (0.54 ± 0.05) nm^2 (42). This tentative assignment is based only on the assumption that TMA molecules are perpendicularly adsorbed on the positively charged electrodes, similar to behaviour reported for other aromatic carboxylic acids (31–33, 35, 36, 38). A comprehensive structural analysis of the interfacial adlayer will be given in the following.

We also compared the voltammetric profiles of TMA on the Au(111-25 nm) film electrodes with the corresponding response obtained from a series of monatomically stepped single crystals Au[n(111)-110] for internal calibration. Figure 2 shows that, with higher step density, the characteristic phase transition peaks decrease in magnitude, broaden, and finally merge. These trends indicate the increasing disorder within the TMA adlayers. The cyclic voltammogram of an electrochemically annealed Au(111-25 nm) film electrode (shaded panel in Fig. 2) exhibits all the characteristic potential-dependent features of an Au(111)-oriented surface, except that the current peaks are broader than on an ideally smooth single crystalline electrode. The comparison demonstrates that the response of carefully prepared Au(111-25 nm) film electrodes is comparable to that of a stepped Au(111) electrode with an equivalent miscut angle ranging between 2° and 4°. Therefore, the film electrodes employed in the present ATR-SEIRAS study represent a rather good approximation to an ideal Au(111) single crystal electrode. Similar conclusions were also reported in our previous studies for sulfate and uracil on Au(111-20 nm) in aqueous electrolytes (39, 40).

Fig. 2. Steady-state cyclic voltammograms of a series of stepped single crystals Au(n n n-1) = Au[n(111)-(110)] in 0.1 mol L^{-1} $HClO_4$ without (dashed curves) and with (solid curves) 3 mmol L^{-1} TMA, scan rate 10 mV s^{-1}. The miscut angles are indicated in the figure. The shaded frame shows the corresponding cyclic voltammograms of an Au(111–25 nm) film electrode for comparison.

Steady-state ATR-SEIRAS



Overview and band assignments

Figure 3 shows selected slow-scan SEIRA spectra of 3 mmol L^{-1} TMA in 0.1 mol L^{-1} $HClO_4$ on Au(111-25 nm) acquired simultaneously with the potentiodynamic cyclic voltammogram (scan rate 10 mV s^{-1}). The corresponding data of the TMA-free "blank" electrolyte are also plotted as gray traces. Each set of spectra represents one of the characteristic adlayer phases (I, II, III_a, and III_b) aquired during a positive potential scan. A set of single beam spectra recorded at E = 0.10 V was chosen as the reference. For reasons of clarity, the continuous evolution of the spectral features during a complete potential cycle is shown separately in Fig. 4 for the two intervals 1200 < ν < 1800 cm^{-1} and 2750 < ν < 4000 cm^{-1}. The spectra in the OH-stretching region are plotted choosing either E = 0.10 V (Fig. 4*b*) or E = 0.60 V (Fig. 4*c*) as the reference.

As the potential increases from 0.10 V to more positive values, three sharp positive-going IR bands appear in the presence of 3 mmol L^{-1} TMA at 1720–1735 cm^{-1}, around 1375 cm^{-1}, and at 1300–1320 cm^{-1} (black traces in Fig. 3*a*). Comparison with the solid-state and solution spectra of BA, IA, and TMA as well as their potassium salts supports the assignment of these spectral features to the following TMA vibrations: the stretching mode of C=O in COOH ($\nu_{(C=O)}$), the symmetric stretching mode of O-C-O in COO^- ($\nu_{s(OCO)}$), e.g., a deprotonated carboxylate group, and the stretching mode of C-OH in COOH (ν(C-OH)), respectively (43, 44).

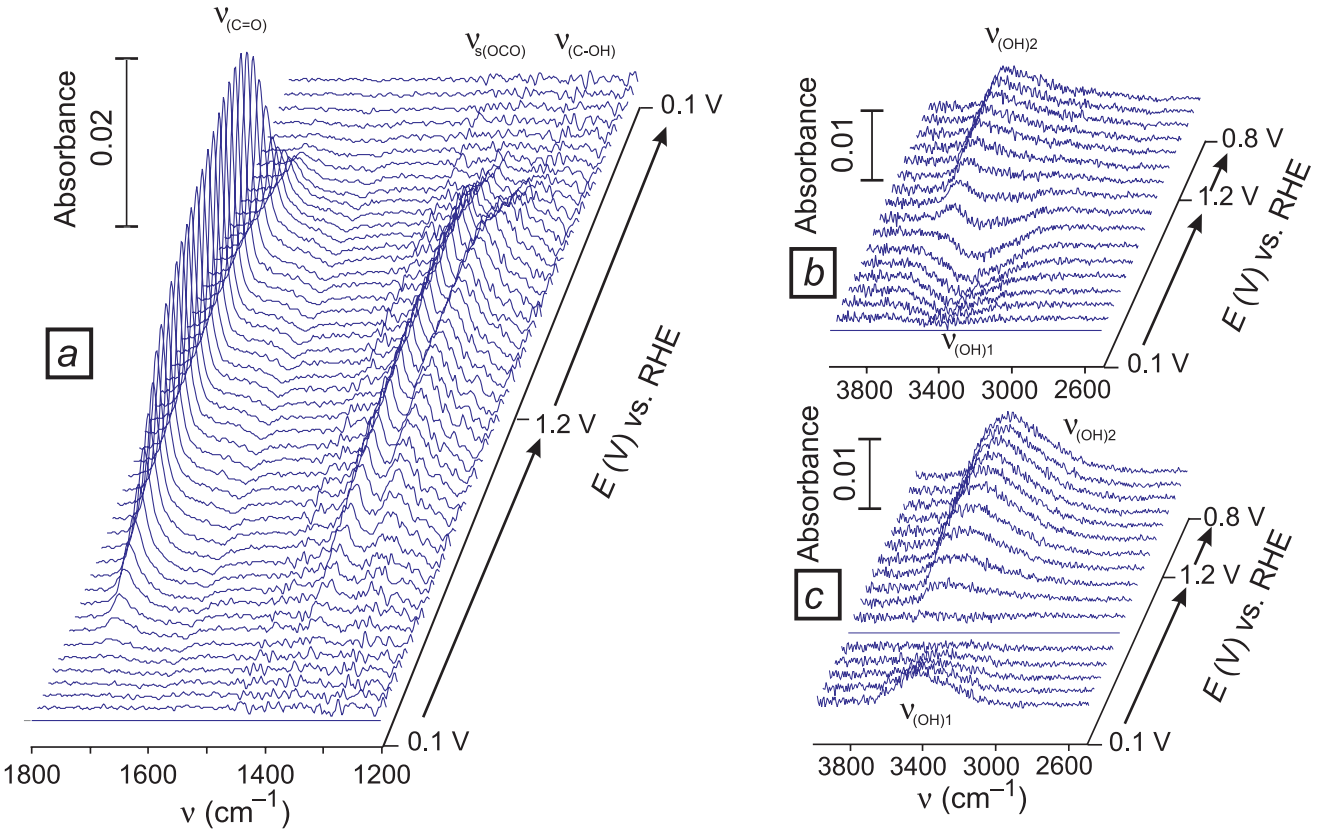
Fig. 3. (*a*) Selected SEIRA spectra of Au(111-25 nm) | 0.1 mol L^{-1} $HClO_4$ in the absence (gray traces) and in the presence of 3 mmol L^{-1} TMA (black traces) recorded simultaneously during a positive-going potential from 0.10 to 1.20 V, scan rate 10 mV s^{-1}. The background spectra were measured at 0.10 V. The data represent different potential regions of the various adlayer phases of TMA: Start (0.10 V), I (0.41 V), II (0.69 V), III_a (0.83 V), and III_b (1.18 V). (*b*) Selected SEIRA spectra of the characteristic potential regions, I, II, III_a, and III_b from 4000 to 2750 cm^{-1} and 1800 to 1200 cm^{-1} with the reference voltage chosen at E = 0.60 V. A typical result of the deconvolution of the OH-stretching region is illustrated in the top of panel (*b*).

A correlation analysis suggests that both sets of vibration modes originate from the same molecule. The intensities of these TMA bands increase with positive potential, reach their maximum in the chemisorbed region III, and decrease during the subsequent negative potential scan.

Simultaneously, broad IR bands are observed between 3000 and 3600 cm^{-1} corresponding to $\nu_{(OH)}$ stretching vibrations of interfacial water molecules (39, 45, 46). The potential-dependent evolution of the OH-stretching modes ($\nu_{(OH)}$) and of the HOH-bending mode ($\delta_{(HOH)}$) is plotted in Figs. 3 and 4. The reference spectrum was either recorded at E = 0.10 V (most negative potential) or at E = 0.60 V (close to the potential of zero charge for the present system). Qualitatively, the spectra in Figs. 3*a* and Fig. 4*b* illustrate that the intensity of a broad negative-going band centered around 3410 cm^{-1}, which starts to grow in phase I, reaches its maximum at 0.65 V. This band is labeled $\nu_{(OH)1}$, and corresponds to the replacement of weakly hydrogen-bonded interfacial water by physisorbed TMA molecules (40, 45). At more positive potentials, a new, positive-going water stretching mode centered at 3500 cm^{-1}, which is labeled $\nu_{(OH)2}$, starts to evolve. This vibration is attributed to water species coadsorbed with the chemisorbed TMA adlayer.



The SEIRA spectra of the supporting electrolyte (0.1 mol L^{-1} $HClO_4$, gray traces in Fig. 3*a*) show the existence of weakly hydrogen bonded water at $E < 0.60$ V as indicated by $\nu_{(OH)1'}$, a negative-going band centered around 3500 cm^{-1}. At $E > 0.60$ V, a broad positive-going $\nu_{(OH)2'}$ band centered at 3400 cm^{-1} starts to grow, followed at $E >$ 0.80 V by a rather sharp feature $\nu_{(OH)3'}$ with a center at 3600 cm^{-1}. The former is assigned to strongly hydrogen-bonded interfacial water while the later indicates the presence of non-hydrogen-bonded OH species caused by the onset of specific adsorption of the structure breaking perchlorate ion ($\nu_{(ClO)}$) at 1100–1130 cm^{-1} (45).

Local structure of chemisorbed TMA molecules

Both calculations and experimental evidence support that a deprotonated carboxylate group has a strong preference for the occupation of a bridge site with the carbon atom positioned midway between two neighboring metal atoms via chemical bonds including two oxygen atoms (47–49). At sufficient positive potentials, perpendicularly oriented TMA molecules could be chemisorbed onto the electrode surface via one or two deprotonated carboxylate groups (26, 28, 50). To resolve the issue on surface coordination, we carried out

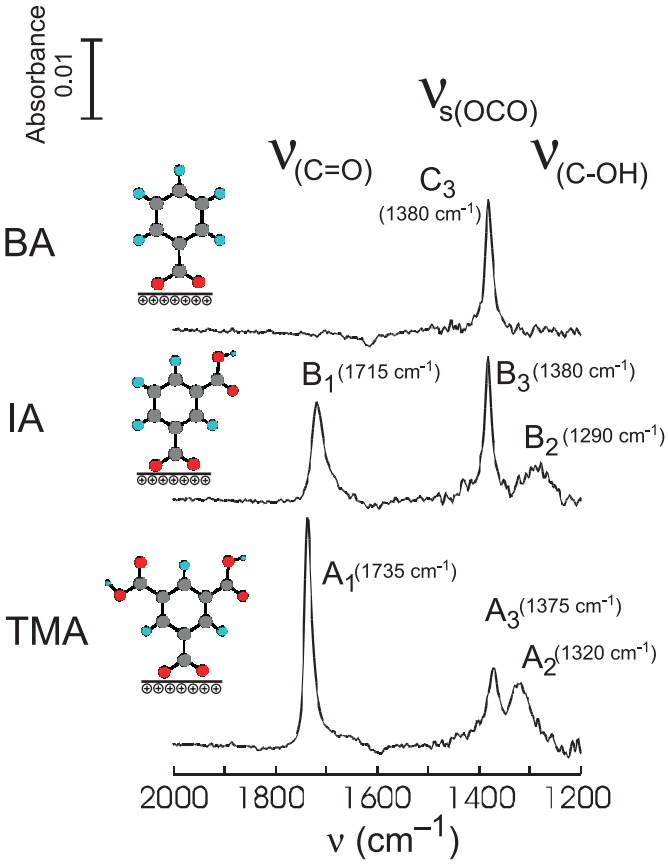
Fig. 4. Typical set of 3D SEIRA spectra measured simultaneously with a slow-scan voltammogram (10 mV s^{-1}) during a potential cycle from E = 0.10 to E = 1.20 V and back to E = 0.10 V. Each spectrum represents the average of 160 single traces within a potential interval of 50 mV. (*a*) Shows the wavenumber region from 1800 to 1200 cm^{-1} with a single beam at 0.10 V as the reference; (*b*) and (*c*) represent the $\nu_{(OH)}$ region from 4000 to 2750 cm^{-1} choosing the reference spectra at E = 0.10 V (*b*) and E = 0.60 V (*c*), respectively. For clarity, the spectra in panels (*b*) and (*c*) do not show the complete sets of data for the negative-going potential cycle.

a comparative study with BA, IA, and TMA in the high coverage region III. These carboxylic acids have different numbers of identical carboxyl groups but similar conjugated structures. Figure 5 shows SEIRA equilibrium spectra of the three molecules at E = 1.1 V, as recorded during slow potential scanning experiments. The symmetric mode $\nu_{s(OCO)}$ at 1370–1390 cm^{-1} (FWHM ~ 2 cm^{-1}) was observed in all three spectra (labeled as A_3, B_3, and C_3 in Fig. 5), indicating that these three acids are coordinated to the positively charged electrode by at least one deprotonated carboxylate group. The spectrum of IA shows the $\nu_{s(OCO)}$ mode (B_3) and two additional vibrations, $\nu_{(C=O)}$ at 1715 cm^{-1} (B_1) and $\nu_{s(COOH)}$ at 1290 cm^{-1} (B_2), which originate from a protonated -COOH group. This signature indicates that IA is coordinated to the electrode surface with one carboxylate group, while the other (protonated) carboxyl group faces the electrolyte.



One may assume that position and surface coordination of carboxylate and carboxyl groups should be constant after adsorption equilibrium has been established. Therefore, we can conclude from the approximately identical ratio of the integrated intensities $I_{B1}/I_{B2} \approx I_{A1}/I_{A2} \approx 1.40$ that the chemisorbed adlayers of IA and TMA exhibit structural similarities. With I_{A3} and I_{B3} as an internal standard, one obtains $I_{A1}/I_{A3} \approx 2 \times I_{B1}/I_{B3}$ indicating that the TMA adlayer exhibits two protonated -COOH groups while IA has only one. This quantitative estimation also implies that both acids are coordinated via one carboxylate group to the positively charged electrode in the chemisorbed phase under equilibrium conditions.

Adlayer structure

The slow-scan SEIRA spectra plotted in Fig. 4 indicate that the adsorption and surface orientation of TMA are potential dependent and major changes occur upon the transition from physisorption to chemisorption. Based on the surface selection rule of SEIRAS, only those molecular vibrations that induce dipole moments normal to the local surface give enhanced IR absorption (29, 30). No vibration modes related to TMA adsorption were observed at E < 0.35 V. The absence of the characteristic TMA bands $\nu_{(C=O)}$, $\nu_{s(OCO)}$, and $\nu_{(C-OH)}$, which induce dipole moments parallel to the plane of the phenyl ring, indicates that TMA molecules are oriented with the phenyl ring parallel to the electrode surface. Locally, the organic molecules appear to change their orientation at E > 0.35 V. To describe this structural transition in detail, we plotted in Fig. 6 the potential dependence of intensity, peak position, and full-width at half maximum (FWHM) of $\nu_{(C=O)}$, $\nu_{s(OCO)}$, and $\nu_{(C-OH)}$. These three characteristic IR bands are related to the -COOH side groups ($\nu_{(C=O)}$ and $\nu_{(C-OH)}$) and to the coordinating carboxylate group ($\nu_{s(OCO)}$), respectively.

Fig. 5. Equilibrium SEIRA spectra of TMA (3 mmol L^{-1}), isophthalic acid (IA, saturated solution), and benzoic acid (BA, 3 mmol L^{-1}) in 0.1 mol L^{-1} $HClO_4$ obtained at 1.10 V in region III_b, reference spectrum taken at E = 0.10 V. The inset illustrates the derived molecular orientations of the three molecules chemisorbed on a positively charged Au(111-25 nm) film electrode.

$\nu_{(C=O)}$ *and* $\nu_{(C\text{-}OH)}$

The intensities of $\nu_{(C=O)}$ and $\nu_{(C\text{-}OH)}$ are directly influenced by the TMA orientation and the number of uncoordinated -COOH side groups. The rapid intensity increase upon changing the potential from region I to region II indicates the onset of an orientation change from planar to tilted or perpendicular. The intensity of $\nu_{(C=O)}$ and $\nu_{(C\text{-}OH)}$ increases only moderately in region III_a and reaches a plateau in region III_b, indicating the formation of a stable chemisorbed adlayer III_b. Reversing the direction of the potential scan exhibits a distinct hysteresis in $1.00 > E > 0.40$ V, which suggests a rather slow structural transition in this potential range. We notice further that in situ STM experiments of TMA on ideally smooth Au(111) single crystal electrodes show long-range ordered physisorbed adlayers of hydrogen-bonded and still planar-oriented molecules in region II (e.g., up to $E \sim 0.80$ V) (42). The more negative onset of the structural transition of TMA on the Au(111-25 nm) electrodes is most probably related to the surface morphology of the gold film. The latter is composed of 20–30 nm size, interconnected islands with a preferential (111) surface orientation, which have inherently a higher defect density and larger grain boundaries than an ideal Au(111) single crystal surface (39). In consequence, the molecular film appears to be more disordered in the physisorbed regions I and II, and the uneven potential distribution near defect sites might facilitate localized orientation changes at lower potentials, as observed in the in situ ATR-SEIRA spectra.

Both bands ($\nu_{(C=O)}$ and $\nu_{(C\text{-}OH)}$) shift to higher wavenumbers with increasing electrode potential. A plateau is reached after establishing an equilibrated chemisorbed phase in III, the most pronounced change occurs in region II. This evolution is reversible, but shows a distinct hysteresis. Potential-dependent peak shifts of vibration modes may be attributed to three different factors: Stark tuning effect, metal–adsorbate electron back donation, and lateral interactions such as dipole–dipole coupling (51, 52). There is no strong experimental evidence for a predominant Stark tuning effect because the potential-dependent peak shifts are not as linear as expected (40, 51), and the electric field around the -COOH side groups is rather weak. Peak shifts preferentially attributed to strong dipole–dipole coupling have been suggested for the adsorption of several organic molecules capable of forming close-packed adlayers, such as cytosine (53), 4,4′-bipyridine (54), BA (31, 32), and uracil (40). For the present system, the ladder-type network of chemisorbed TMA appears to be still too open to support strong interactions between the oscillating dipoles of adjacent -COOH groups. Although a direct substrate | -COOH side group electron donation can be ruled out, an indirect electron transfer via the π-electron system of TMA appears to be possible. The molecule represents a perfectly conjugated system. In consequence, changes in the electron (charge) density in one -COOH group can be partly "transferred" to the other two -COOH or $-COO^-$ groups, respectively. An electron back donation to the coordinating carboxylate group at positive potentials may generate a simultaneous electron donation to both -COOH side groups, which results in a shift of $\nu_{(C=O)}$ and $\nu_{(C\text{-}OH)}$ to higher wavenumbers. A similar blue shift of the $\nu_{(C=O)}$ and $\nu_{(C\text{-}OH)}$ bands is observed in the potential-dependent SEIRA spectra of IA. An additional contribution to the observed blue shift in phase III could be induced due to directional hydrogen bonding between the -COOH side groups, which should increase the stretching constant of the in-phase $\nu_{(C=O)}$ and $\nu_{(C\text{-}OH)}$ vibrations. Table 1 compares the peak shifts $\Delta\nu$ for the characteristic vibrations of BA, IA, and TMA. The smaller values of $\Delta\nu$ of the $\nu_{(C=O)}$ and $\nu_{(C\text{-}OH)}$ vibrations of IA could be attributed to the weaker hydrogen-bonding interactions when compared to TMA.

Simultaneously, the FWHM of $\nu_{(C=O)}$ and $\nu_{(C\text{-}OH)}$ decrease from phase I to III_b, and reaches a minimum in the potential region III. This trend suggests an increasing long-range lateral order with the establishment of the chemisorbed phase III_b. The present SEIRAS experiment demonstrates, in combination with an in situ STM study (42), that TMA molecules form a highly ordered two-dimensional ladder network. The molecules are coordinated via one $-COO^-$ group to the electrode surface, while the two remaining -COOH side groups give rise to rows of hydrogen-bonded dimers (42).

$\nu_{s(OCO)}$

The three carboxyl groups of TMA are protonated in 0.1 mol L^{-1} $HClO_4$ (pH = 1 and pK_a = 2.12, 4.10, and 5.18, respectively (55)). The $\nu_{s(OCO)}$ vibration appears only when TMA molecules are deprotonated and chemisorbed onto the

[a]Z. Li and Th. Wandlowski. Unpublished. 2004.

surface via one carboxylate group. Similar $\nu_{s(OCO)}$ vibrational bands were observed for chemisorbed benzoic acid (31, 32, 36, 47), fumaric acid (35), fluorobenzoic acid (33), and *p*-nitrobenzoic acid (35) on various gold electrodes.

As illustrated in Fig. 6, the plot of the intensity of $\nu_{s(OCO)}$ shows a similar potential dependence as $\nu_{(C=O)}$ and $\nu_{(C\text{-}OH)}$: It grows slowly with increasing potential in phase I, and reaches a constant value in phase III_b. This intensity increase in region II suggests deprotonation and a change in molecular orientation. Similar trends were observed for benzoic acid on Au(111) (31, 32).

The frequency of the $\nu_{s(OCO)}$ band is almost potential independent. We notice that $\nu_{s(OCO)}$ shows a strong potential dependence and a characteristic blue shift with Δν up to 16 cm^{-1} for closely packed carboxylic acids such as BA (31, 32) and fumaric acid (38). This observation was attributed to strong dipole–dipole coupling at high surface coverages. STM experiments (Fig. 1*d*) (42) revealed that the packing of TMA in the chemisorbed phase III appears to be less compact resulting in rather large distances between the oscillating dipoles of neighboring carboxylate groups. Table 1 illustrates that Δν changes in the following sequence: fumaric acid > BA > IA > TMA. One also needs to consider a strong adsorbate substrate interaction between the surface-coordinated carboxylate group and the positively charged gold electrode, which should result in a red shift of $\nu_{s(OCO)}$. This trend appears to be compensated by a Stark shift in the opposite direction.

Interfacial water

The high sensitivity of ATR-SEIRAS enables us to monitor structural properties of electrolyte species in the electrochemical double layer associated with the adsorption of TMA (39, 40, 45, 46). Figures 3 and 4 demonstrate the strong potential-dependence of the vibrational signatures of interfacial water species.

© 2004 NRC Canada

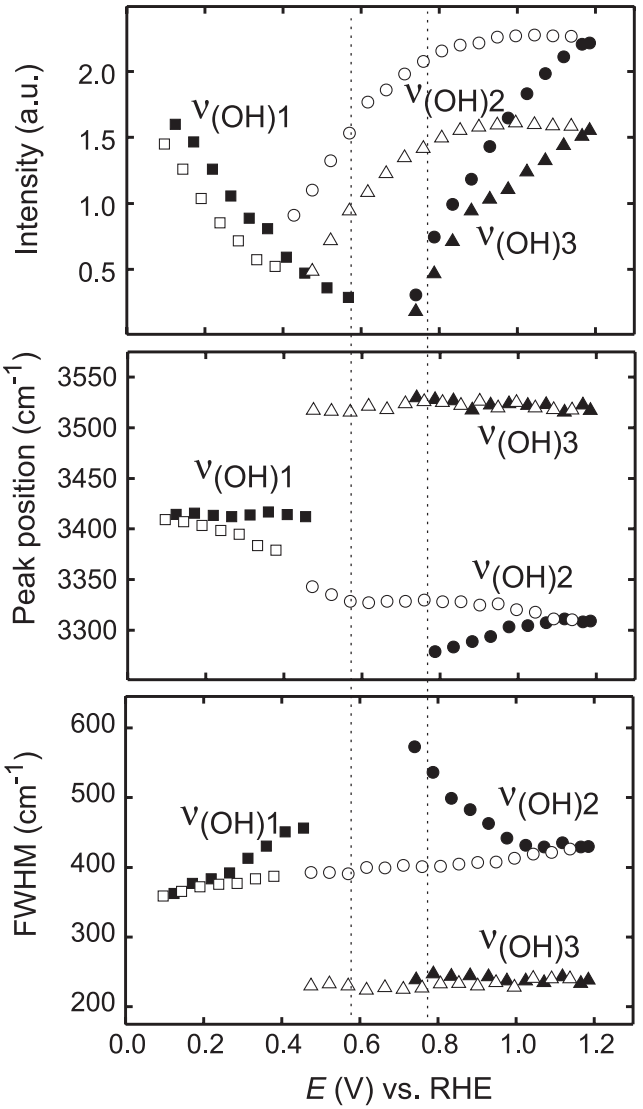
As discussed in the Overview and band assignements section, the overlap of positive- and negative-going OH-stretching modes ($\nu_{(OH)}$) complicates the analysis. To deconvolute the contributions of different interfacial water species, we adapted a strategy proposed in ref. 45 and have chosen the spectrum at $E = 0.60$ V, which is close to the potential of zero charge for the present system, as the new reference spectrum. The recalculated spectra are plotted in Figs. 3*b* and 4*c*. At $E < 0.60$ V, a broad band ($\nu_{(OH)1}$) centered at 3410 cm^{-1} and a weak band ($\delta_{(HOH)1}$) at 1600 cm^{-1} are observed. The shape of the $\nu_{(OH)1}$ band is rather symmetric, suggesting the preference of only one type of water species. At more positive potentials, in regions II and III, an asymmetric band with a distinct shoulder at higher wavenumber evolves. The deconvolution allows the identification of two contributions: one broad band ($\nu_{(OH)2}$) centered at 3320 cm^{-1} and a sharper band ($\nu_{(OH)3}$) around 3520 cm^{-1} (Fig. 3*b*). The stretching mode ($\nu_{(OH)2}$) as well as a weak bending mode ($\delta_{(HOH)2}$) at 1650 cm^{-1}, indicate the existence of strongly H-bonded water species in phase III_b.

Based on the above analysis, at least three different co-adsorbed water species appear during a slow scan from negative to positive potentials accompanied with the formation of the various TMA adlayers. Figure 7 shows the potential-dependence of peak intensity, peak position, and FWHM of the OH-stretching modes $\nu_{(OH)1}$, $\nu_{(OH)2}$, and $\nu_{(OH)3}$. $\nu_{(OH)1}$ corresponds to weakly hydrogen-bonded water species that are adsorbed on the surface at negative charge densities and in the absence of TMA. They are subsequently replaced by physisorbed TMA molecules in phase I giving rise to a decreasing spectroscopic feature. $\nu_{(OH)2}$ and $\nu_{(OH)3}$ start to grow in phase III_a simultaneously with the physisorption | chemisorption transition and the formation of a chemisorbed TMA adlayer, indicating that interfacial water is co-adsorbed within or next to the ordered TMA adlayer. Their intensities increase until a maximum is reached in the potential regions of an equilibrium phase III_b, and subsequently decrease upon the onset of TMA desorption. Weakly hydrogen-bonded water appears again as indicated by an increase of the intensity of $\nu_{(OH)1}$ in phase I at negative charge densities.

Additional knowledge has been obtained from the potential-dependence of the respective peak positions. The vibration mode indicating strongly hydrogen-bonded water ($\nu_{(OH)2}$) appears in region III_a and shifts to a higher wavenumber ($\Delta\nu \approx 50$ cm^{-1}) with increasing potential. Such water molecules could be hydrogen-bonded to the oxygen atoms of the -COOH side groups of TMA, which are directed toward the electrolyte. The small blue shift shows that the hydrogen-bonding interaction between interfacial water and the -COOH groups is weakened upon the formation of the long-range ordered ladder network between adjacent TMA molecules in III_b. Simultaneously, the FWHM of $\nu_{(OH)2}$ decreases in phase III_a and reaches a minimum in phase III_b.

Compared to $\nu_{(OH)2}$, $\nu_{(OH)3}$ is less synchronized with the formation | dissolution of the chemisorbed TMA adlayer. Peak position and FWHM are almost potential-independent. The integrated intensity of $\nu_{(OH)3}$ increases towards phase III_b. The high wavenumbers and narrow bands suggest attributing $\nu_{(OH)3}$ to weakly hydrogen-bonded or isolated water species next to the chemisorbed TMA adlayer and (or) at defect sites not being in direct contact with the electrode surface. The location of these water species appears to be different from those discussed for blank supporting electrolytes such as $HClO_4$ (45), where a direct contact to the electrode surface is proposed.

Fig. 7. Potential dependencies of integrated intensity, peak position, and FWHM of the OH-stretching modes for 3 mmol L^{-1} TMA – 0.1 mol L^{-1} $HClO_4$ on Au(111-25 nm) film electrodes: $\nu_{(OH)1}$ (■, □), $\nu_{(OH)2}$ (●, ○), and $\nu_{(OH)3}$ (▲, △) as obtained from the data plotted in Figs. 3 and 4. The solid (open) symbols represent the positive- (negative-) going potential scan.



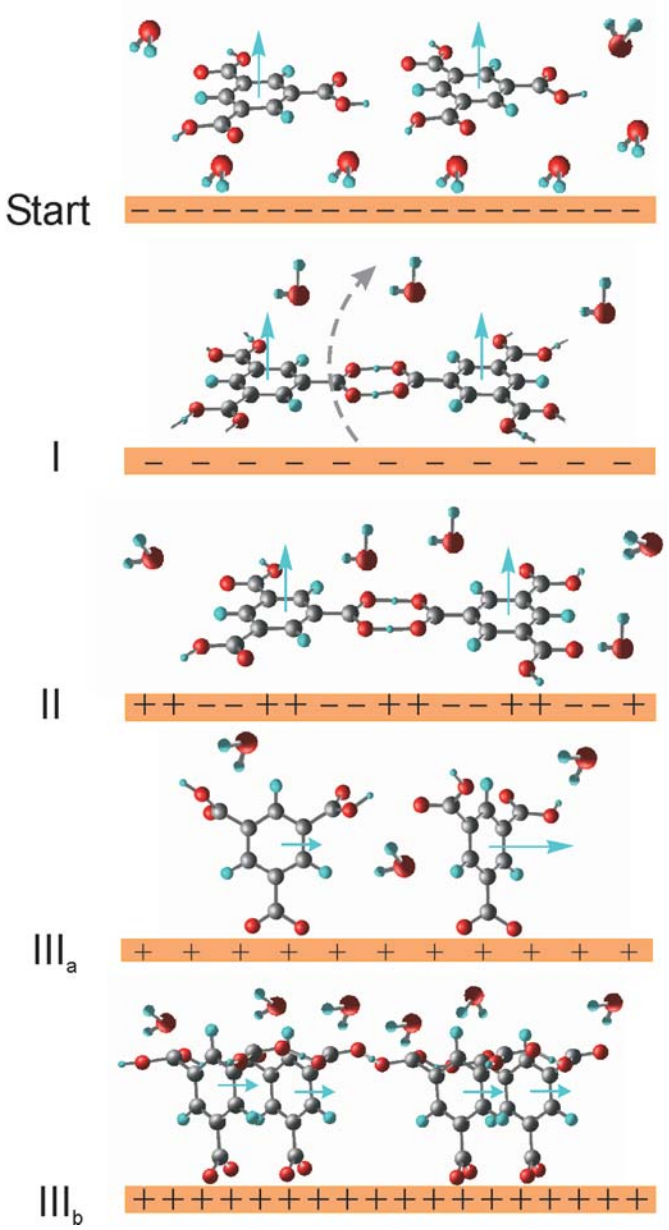


Figure 8 summarizes schematically the potential-dependent evolution of the TMA adlayer structures on Au(111-25 nm) film electrodes in contact with 0.1 mol L^{-1} $HClO_4$ aqueous electrolyte.

2D phase formation kinetics

After the discussion of the potential-dependent, steady-state TMA adlayer structures, we focus next on the kinetics of structural transitions between the different adlayer phases. Data acquisition modes such as rapid-scan and step-scan enable us to study potential-induced structural changes with high time resolution. Potential steps from the physisorbed

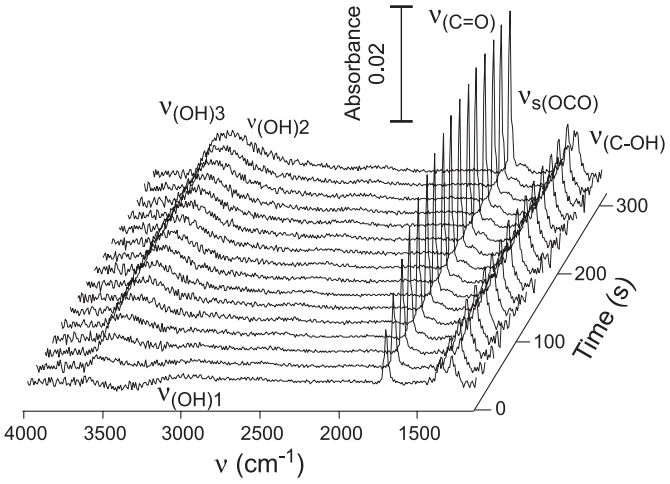
Fig. 8. Model of steady-state TMA adlayer structures in the potential regions I, II, III_a, and III_b.

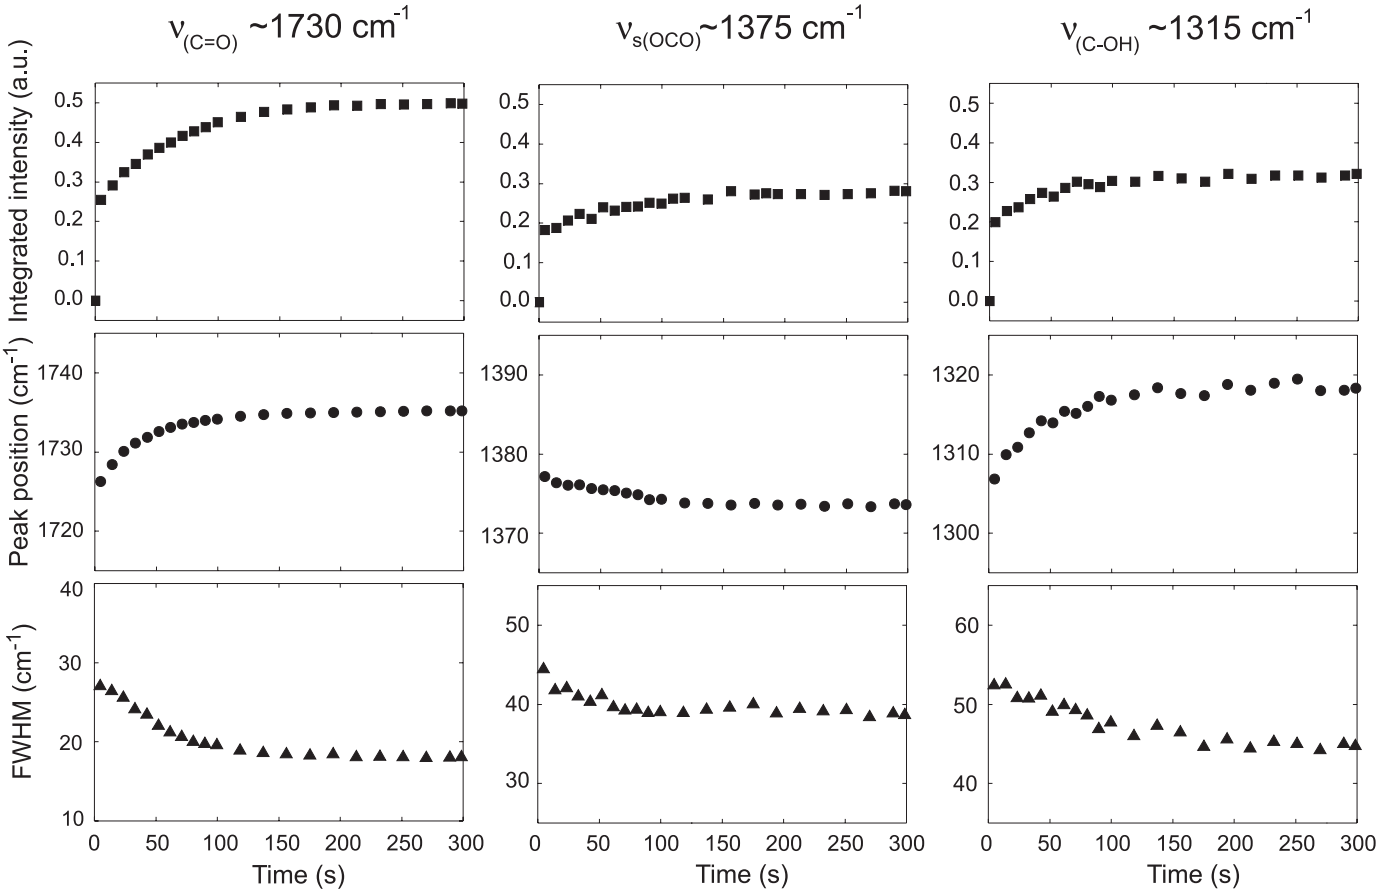


phase I into the chemisorbed phase III_b were applied to monitor the formation kinetics of the chemisorbed TMA adlayer. The corresponding current transients are recorded simultaneously. We have chosen the following regime: E_i = 0.45 V (10 s) → E_f = 0.90 V for rapid-scan experiments and E_i = 0.50 (250 ms) → E_f = 0.90 V for the step-scan studies. The reference spectra were measured at each starting potential before stepping the potential.

Rapid scan

Figure 9 shows selected SEIRAS spectra recorded in rapid-scan mode for a single potential step from E_i = 0.45 (10 s) to E_f = 0.90 V. The three characteristic bands of chemisorbed TMA start to grow immediately after the potential step, indicating an orientation change from planar to perpendicular within << 5 s. Subsequently, these bands become gradually stronger and sharper until a maximum is reached, suggesting a rather slow increase of surface coverage and two-dimensional long-range order in region III_b. The time dependencies of intensity, peak position, and FWHM are plotted in Fig. 10. The evolution of the simultaneously co-adsorbed water species is shown in Fig. 11.

Fig. 9. Time-resolved SEIRA spectra for the formation of a chemisorbed TMA adlayer III_b on Au(111-25 nm) – 0.1 mol L^{-1} $HClO_4$ + 3 mmol L^{-1} TMA, recorded in a rapid-scan regime after a single potential step from E_i = 0.45 to E_f = 0.90 V. The waiting time at E_i was 10 s. Each spectrum plotted was acquired in intervals of 9.7 s and represents the average of 256 individual traces.



The intensities of $\nu_{(C=O)}$, $\nu_{s(OCO)}$, and $\nu_{(C\text{-}OH)}$ indicate that a final steady state is reached approximately 150 s after triggering the potential step. The lateral alignment of TMA to establish the long-range ordered, hydrogen-bonded, and surface-coordinated molecular network is rather slow, which is consistent with the result of our recent in situ STM measurements (42). Further insight into the kinetics of ordering can be provided by the analysis of the time dependencies of the FWHM and the peak positions of the TMA modes, as well as of the structural feature of co-adsorbed water.

The FWHM values of $\nu_{(C=O)}$, $\nu_{s(OCO)}$, and $\nu_{(C\text{-}OH)}$ decrease with time and reach a steady state after 150 s, indicating the formation of a long-range ordered adlayer (Fig. 10). The simultaneously recorded time dependencies of the peak positions of $\nu_{(C=O)}$ and $\nu_{(C\text{-}OH)}$ exhibit a slow shift to higher wavenumbers ($\Delta\nu$ ~ 10 cm^{-1}). This is partly due to the increasing lateral interactions as a result of directional hydrogen bonds formed between neighboring TMA molecules. The electron donation may also contribute to the blue shift representing an increase of substrate | adsorbate interactions upon the formation of a long-range ordered adlayer at the positively charged electrode surface.

Compared with the blue shift of $\nu_{(C=O)}$ and $\nu_{(C\text{-}OH)}$, the $\nu_{s(OCO)}$ band shifts to lower wavenumbers ($\Delta\nu \approx 5$ cm^{-1}) reaching a constant position at 1373 cm^{-1}. As described in the Overview and band assignments section, $\nu_{s(OCO)}$ is related to carboxylate co-ordinated in a perpendicular position to the positively charged electrode surface. The red shift of the $\nu_{s(OCO)}$ band can be attributed to the increase of electron back-donation when the substrate | adlayer interaction increases with surface order.

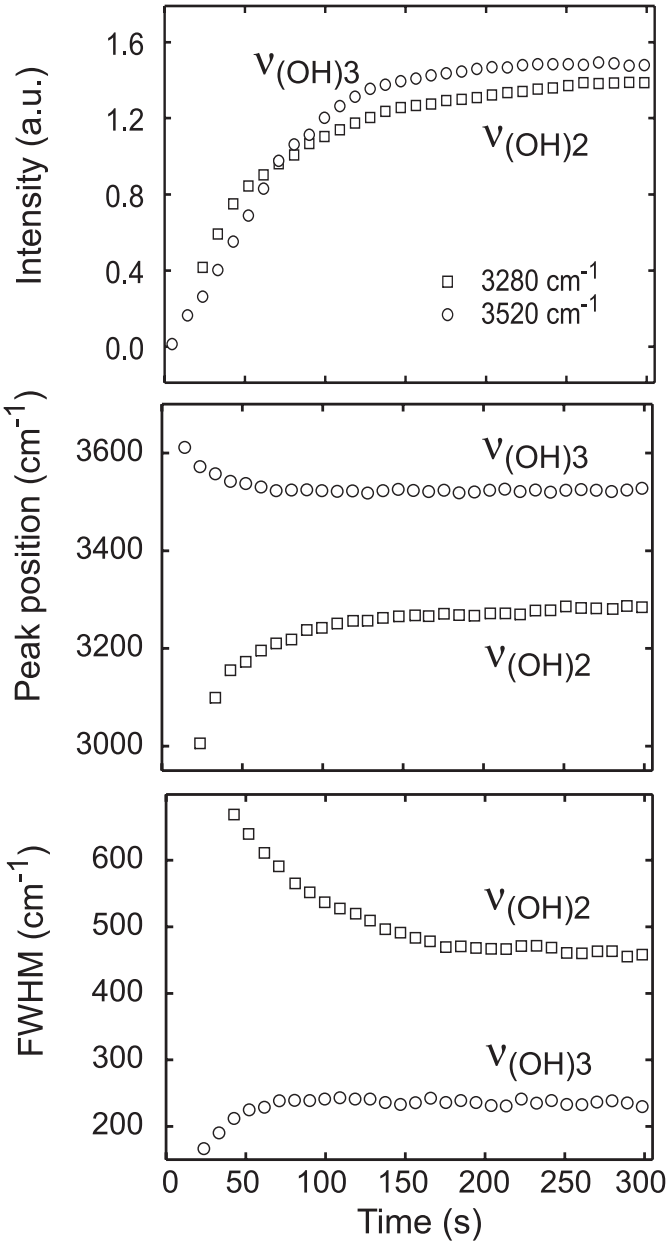
Fig. 10. Time dependence of integrated intensity (■), peak position (●), and FWHM (▲) of the ν(C=O) (~1730 cm^{-1}), $\nu_{s(OCO)}$ (~1375 cm^{-1}), and $\nu_{s(C\text{-}OH)}$ (~1315 cm^{-1}) bands of TMA as obtained from the data plotted in Fig. 9.

The appearance of the negative going band $\nu_{(OH)1}$, immediately after application of the potential step (<< 5 s, Fig. 9), represents the displacement of weakly hydrogen-bonded water molecules from the electrode surface by additionally adsorbed TMA. Its intensity is small because the experiment starts from a rather positive potential with a significant amount of TMA adsorbed in a planar orientation. The intensities of $\nu_{(OH)2}$ and $\nu_{(OH)3}$ increase simultaneously with the evolution of the characteristic bands for perpendicularly adsorbed TMA (Fig. 10) indicating co-adsorption with the organic molecules in phase III_b. Interestingly, the peak position and FWHM of the $\nu_{(OH)3}$ band reach steady state values somewhat faster (~100 s) than the $\nu_{(OH)2}$ band (~150 s). Such a delay between $\nu_{(OH)2}$ and $\nu_{(OH)3}$ shows that the isolated water species are co-adsorbed with the TMA adlayer before the equilibrated ordered TMA structure is formed, while the strongly hydrogen-bonded water forms simultaneously with the ordered TMA structure.

Step scan



To explore the kinetics of the structural transition within the TMA adlayer when stepping the potential from E_i = 0.50 to E_f = 0.90 V at very short times, we carried out simultaneous electrochemical and spectroscopic step-scan experiments. This regime enables us to increase the time resolution with our current setup to 10^{-5} s. Figure 12*a* shows a 3D plot for the evolution of the TMA marker band $\nu_{(C=O)}$ after application of a single potential step from E_i = 0.50 to E_f = 0.90 V. The time dependence of the integrated intensity of the $\nu_{(C=O)}$ TMA marker band, as calculated from time slices of 0.2 ms, is plotted in Fig. 12*b*. A similar time dependence was observed for $\nu_{s(OCO)}$ and $\nu_{(C\text{-}OH)}$. For clarity, we plotted as an inset of Fig. 12*a* only one typical spectrum recorded after 8 ms in $1200 < \nu < 1800$ cm^{-1}.

The electrochemical current transient, as monitored after the potential step, is characterized by a single exponential decay (cf. solid line in Fig. 12*b*). This macroscopic response may contain several different contributions such as double layer charging, deprotonation of -COOH groups, reorientation of the organic molecule, and (or) co-adsorbed water species. However, the chronoamperometric experiment does not provide direct information on structural changes within the adlayer. To address this issue we carried out electrochemical measurements with synchronized step-scan SEIRAS experiments.

Figure 12*b* demonstrates that the intensity of the $\nu_{(C=O)}$ mode increases rapidly and reaches its maximum after 8 ms, which is much longer than the time constant of our IR cell (ca. 50 μs (39)). This result suggests a fast orientation change of TMA from planar to randomly oriented perpendicular molecules. The simultaneous evolution of $\nu_{s(OCO)}$ also indicates the deprotonation of the carboxyl group. The observed transition is significantly faster than the establishment of a two-dimensional order within the organic adlayer. The

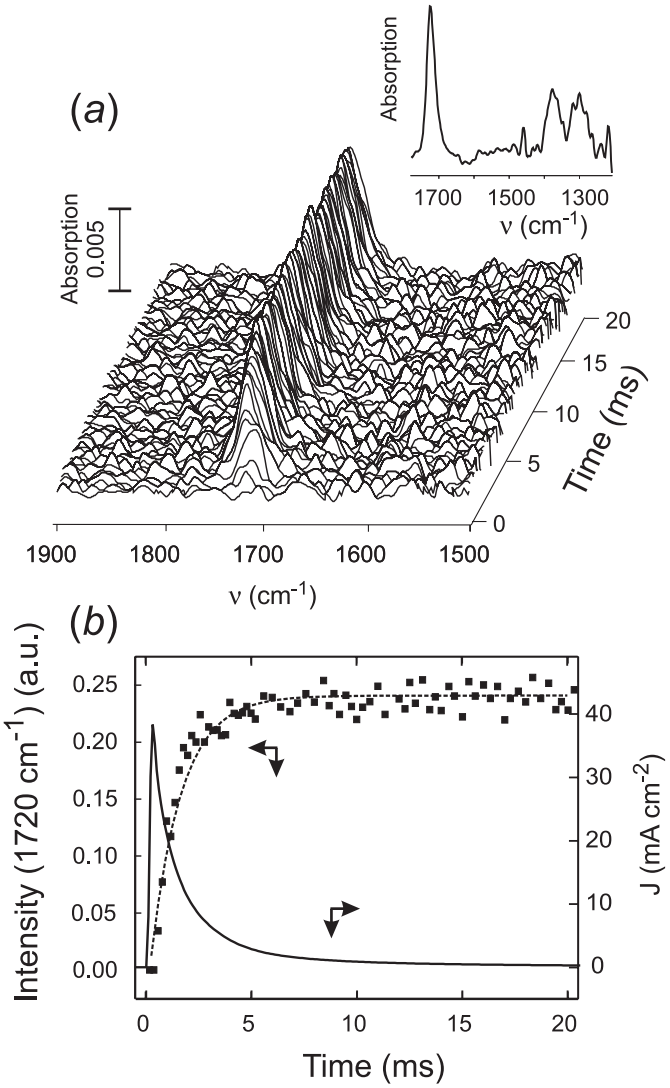
Fig. 11. Time dependence of integrated intensity, peak position, and FWHM of the OH-stretching modes $\nu_{(OH)2}$ (□) and $\nu_{(OH)3}$ (○) of co-adsorbed water species as obtained from the rapid-scan spectra plotted in Fig. 9 after deconvolution.



intensity vs. time curve in Fig. 12*b* is represented by a first-order, Langmuir-type rate equation

$$[1] \qquad I = I_\infty \{1 - \exp[-K(t - t_0)]\}$$

with I_∞ as the integrated intensity at $t \to \infty$, K is the rate coefficient, and t_0 an induction time (dotted line in Fig. 12*b*). The model suggests that the reorientation of TMA molecules is initialized at randomly distributed defect sites, and no long-range order of the chemisorbed TMA phase is established within the short time scale of 20 ms. Similar transitions were reported previously in kinetic SEIRAS studies with fumaric acid (38), which give rises to a completely disordered adlayer, and for *p*-nitrobenzoic acid on Au(111-20 nm) film electrodes (35).

Fig. 12. (*a*) Series of time-dependent SEIRAS spectra for the formation of a chemisorbed TMA adlayer on Au(111-25 nm) in 0.1 mol L^{-1} $HClO_4$ + 3 mmol L^{-1} TMA after a single potential step from E_i = 0.50 (t_w = 0.25 s) to E_f = 0.90 V as measured in the step-scan regime. The inset shows a typical extended spectrum recorded after 8 ms in 1200 < ν < 1800 cm^{-1}. (*b*) Time dependence of the integrated intensity of the TMA marker band $\nu_{(C=O)}$ (■) as calculated from the spectra shown in panel (*a*). The dotted line represents the fit of eq. [1] to the spectroelectrochemical transients with the following parameters: I_∞ = 0.237, K = 0.686 ms^{-1}, t_0 = 0 ms. The experimental time resolution is 200 μs. The simultaneously measured current transient is shown as a solid curve.

Such a two-step scenario and the disorder | order evolution of chemisorbed TMA are consistent with our STM results (42).

Summary and conclusions

We have investigated the adsorption and phase formation of TMA on Au(111) single crystal and Au(111-25 nm) film electrodes in 0.1 mol L^{-1} $HClO_4$ by combining in situ ATR-SEIRAS with simultaneous electrochemical experiments.

© 2004 NRC Canada

At 0.10 V (starting potential), TMA molecules are randomly adsorbed on the negatively charged gold surface in a planar orientation together with weakly hydrogen-bonded interfacial water molecules. In phase I, $0.10 < E < 0.50$ V, planar-oriented TMA molecules form a two-dimensionally ordered physisorbed adlayer. STM experiments show that the TMA molecules are interconnected by centrosymmetric hydrogen bonds giving rise to a honeycomb network of open rings. Weakly hydrogen-bonded water species are displaced by the organic molecules. At more positive potentials, but still in phase I ($E > 0.30$ V), TMA molecules at grain boundaries and defect sites start to tilt and break apart the long-range, hydrogen-bonded network. At higher potentials, in $0.58 < E < 0.75$ V (phase II), a close-packed physisorbed adlayer composed of linear dimers forms slowly, but only on ideally smooth spots of the electrode surface (42), accompanied by the replacement of additional interfacial water species. Further increase of the electrode potential, $0.75 < E < 0.88$ V (phase III_a), causes an orientation change from planar to perpendicular, accompanied by the deprotonation of one -COOH group that is chemically bonded to the positively charged electrode surface. Each TMA molecule is chemisorbed via one deprotonated carboxylate group in the "atop" model leaving the two -COOH side groups available for further hydrogen bonding between neighboring TMA molecules (42). Simultaneously, two types of water species start to co-adsorb, weakly hydrogen-bonded water at intermolecular defect sites and strongly hydrogen-bonded water interacting with the noncoordinated -COOH side groups. The chemisorbed TMA molecules are still mobile and not yet incorporated into an ordered two-dimensional network. Phase III_a represents a "disordered chemisorption" phase. At $E > 0.90$ V, in region III_b, almost all surface-coordinated TMA molecules are interconnected via intermolecular hydrogen bonds between adjacent -COOH side groups, resulting in a stable and highly ordered ladder network.

The formation kinetics of the chemisorbed TMA adlayer was explored by electrochemical transient experiments and time-resolved ATR-SEIRAS employing rapid-scan and step-scan acquisition modes. The analysis of the SEIRAS transients shows that the formation of chemisorbed TMA in phase III_b proceeds in two steps: (*i*) TMA molecules change their orientation from planar to tilted or perpendicular accompanied by the deprotonation of one carboxyl group immediately after a potential step in region III. This process involves the breakdown of the hydrogen-bonded network of the physisorbed phase I and a fast incorporation of additional TMA molecules from the bulk electrolyte into the interfacial region. The process follows a Langmuir-type kinetics indicating randomly triggered orientation changes with rather weak lateral interactions between the active species; (*ii*) In a subsequent and much slower process, the chemisorbed TMA molecules start to gradually align into a highly ordered two-dimensional network III_b. At the same time, small amounts of TMA molecules appear to be co-adsorbed with strongly hydrogen-bonded and isolated water species.

Based on a detailed analysis of carboxyl and carboxylate vibration modes and OH-stretching modes, the present ATR-SEIRAS study reveals a comprehensive understanding of steady-state structures and dynamic changes as triggered by the electrode potential for TMA and co-adsorbed water species on a Au(111-25 nm) film electrode in 0.1 mol L^{-1} $HClO_4$. The combination of macroscopic electrochemical experiments (in situ STM and SEIRAS) provided details of structural changes and of the chemical composition of TMA adlayers on well-defined gold–electrolyte interfaces.

Distribution of oxides on iron materials used for remediation of organic groundwater contaminants — Implications for hydrogen evolution reactions[1]

M.S. Odziemkowski and R.P. Simpraga

Abstract: The distribution of oxides on commercial iron materials used for remediation of organic groundwater contaminants was studied using confocal Raman microspectroscopy. Raman microprobe mapping experiments revealed that commercial iron materials used for the construction of permeable reactive barriers are covered with an oxide film consisting of an inner film of magnetite Fe_3O_4 and an outer film of Fe_2O_3. The calculated probability of the charge transfer process (i.e., electron tunnelling probability) at commercial Fe | Fe_2O_3 (semiconductor) | solution interfaces approaches zero, indicating that "as received" commercial iron materials should not be reactive towards both organic contaminants and water. The combination of OCP (corrosion potential) – time measurements with in situ Raman spectroscopy demonstrated that the breakdown of the protective Fe_2O_3 oxide film followed by autoreduction of Fe_2O_3 is a requirement for the commercial materials to be chemically active towards both water and organic contaminants. Hydrogen evolution reactions on metals and oxide-covered iron were also investigated. In particular, spectroscopic evidence for adsorption of atomic hydrogen on polycrystalline Pt is presented. The possibility of adsorption of H on magnetite-covered iron was considered using thermodynamic calculations after Marcus and Protopopoff. The evolution of hydrogen on commercial iron materials is described. It is suggested that the separation of the anodic and cathodic sites because of opening of pores in the bulk metallic Fe and the involvement of spill-over hydrogen may play a crucial role in the catalytic hydrogenation of groundwater contaminants.

Key words: Raman microprobe confocal spectroscopy, iron oxides, hydrogen evolution, remediation of organic groundwater contaminants.

Résumé : Faisant appel à la microspectroscopie Raman confocale, on a étudié la distribution des oxydes présents sur les produits commerciaux du fer utilisés pour remédier aux contaminants organiques des eaux de puits. Des expériences de relevés à l'aide de microsondes Raman ont permis d'observer que les produits commerciaux du fer utilisés pour la construction de barrières réactives perméables sont couverts d'un film d'oxyde formé d'une couche intérieure de magnétite, Fe_3O_4, et d'un film extérieur de Fe_2O_3. La probabilité d'un processus de transfert de charge (c'est-à-dire la probabilité d'un effet tunnel d'un électron) aux interfaces Fe commercial | Fe_2O_3 (semiconducteur) | solution est pratiquement nulle, ce qui indique que les produits du fer utilisés tels que reçus ne devraient pas être réactifs vis-à-vis des contaminants organiques ou de l'eau. La combinaison de la spectroscopie Raman in situ avec des mesures de potentiel de corrosion (OCP) en fonction du temps a permis de démontrer que la détérioration complète du film protecteur d'oxyde de fer, Fe_2O_3, suivie d'une autoréduction du Fe_2O_3 est un prérequis à la transformation des produits commerciaux en entités chimiquement actives vis-à-vis de l'eau et des contaminants organiques. On a aussi étudié les réactions des métaux et du fer couvert d'oxydes qui conduisent à l'évolution d'hydrogène. En présente en particulier des données spectroscopiques relatives à l'adsorption d'hydrogène atomique sur du Pt polycristallin. Faisant appel à des calculs de Marcus et Protopopoff, on a considéré la possibilité d'adsorption de H sur du fer couvert de magnétite. On décrit l'évolution d'hydrogène de produits commerciaux du fer. On suggère que la séparation des sites anodique et cathodique qui résulte d'une ouverture des pores de la masse du fer métallique et l'implication d'hydrogène qui se répand jouent un rôle crucial dans l'hydrogénation catalytique des contaminants de l'eau de puits.

Mots clés : microspectroscopie Raman confocale, oxydes de fer, évolution d'hydrogène, remédiation des contaminants organiques de l'eau de puits.

Introduction

Over the past few decades, the development of methods for remediation of groundwater contaminated with various organic or inorganic compounds has emerged as a significant environmental priority. The growing awareness of the limitations of pump-and-treat technologies has shifted attention to in situ treatment methods such as permeable reactive barrier (PRB) technology. PRB technology combines subsurface fluid-flow management with contaminant treatment by chemical, physical, or biological processes, or by combinations of those processes. The concept is remarkably simple, involving the construction of a permeable curtain containing appropriate reactive material across the path of a contaminant plume. PRB methodology has advantages over traditional pump-and-treat systems in that it is passive and a large plume can be treated in a cost-effective manner (1).

Granular iron is most often used as a reactive medium in full-scale site remediation efforts using PRB technology. The prevalent use of scrap iron mainly stems from its low cost, availability, and documented ability to degrade a wide variety of organic contaminants (1). The first environmental application of iron for removal of chlorinated organic contaminants from aqueous solution was reported in the patent literature by Sweeny and Fischer (2) and later by Sweeny (3). Both inventions addressed the removal of organic compounds from wastewater streams. To the best of the authors' knowledge, these methods have not been applied on a broad industrial scale. One possible reason could be the mismatch of the relatively low degradation rates and the requirement for high 5 up to 150 gallon/min (1 gallon (US) = 3.78 dm^3) water flow rates in modern wastewater treatment systems.

In the late 1980s, Gillham and and co-workers (4), unaware of the earlier work of Sweeny, observed sampling bias caused by the use of inexpensive steel (i.e., unalloyed steel) wells to monitor halocarbons in groundwater. Interestingly, this bias was removed by using stainless steel (i.e., highly alloyed steel) or plastic wells. These empirical observations prompted Gillham and O'Hannesin (5) to extend the work to a broad range of halogenated aliphatic compounds. They confirmed the degradation of many halogenated aliphatic compounds in the presence of metallic iron with half-lives from 0.13 to 400 h (5). For normal groundwater velocities (5–50 cm/day), they proposed the use of scrap iron materials in the form of a permeable reactive barrier for in situ removal of a wide range of organic contaminants (6).

Over the past decade, a number of research groups confirmed the degradation of several chlorinated solvents by metallic iron (7–9) and the technology has since been evaluated for degradation of nitroaromatic compounds (10–12), nitramines (13, 14), azo dyes (15, 16), nitrate (17), and removal of arsenate, arsenite, and radionuclides (18) from groundwater.

The first proposal of possible dechlorination mechanisms was given by Matheson and Tratnyek (7). Three possible dechlorination mechanisms have been proposed: (A) direct electron transfer from iron metal to the adsorbed alkyl halide; (B) reduction by Fe^{2+} resulting from corrosion of metal; and (C) catalysed hydrogenolysis by the H_2 that is formed by reduction of H_2O during anaerobic corrosion. According to these authors (7), dissolved Fe^{2+} is a reductant capable of causing dehalogenation of some alkyl halides, although these reactions are generally quite slow. It was also noted (7) that the inner-sphere complexation of Fe^{2+} to metal oxides can create more reducing species, but at the time of publication it was uncertain whether these species could significantly influence the rate of dechlorination. With regards to the third mechanism (C), it was noted (7) that excessive H_2 accumulation at the metal surface could inhibit the corrosion and reduction of organic contaminants. According to the authors, rapid dehalogenation is still possible if an effective catalyst is available; the surface of iron, its defects, or other solid phases present in the system could provide this catalysis (7). Using spectroelectrochemical measurements, Bonin et al. (19) modified the latter conceptual model of the reaction, suggesting that the reduction of CCl_4 is controlled by electron transfer through an oxide film such as magnetite. With regard to catalysed hydrogenolysis (mechanism C), Bonin et al. (19) suggested involvement of atomic H in the hydrogenation reaction rather than molecular hydrogen H_2. The work of Matheson and Tratnyek (7) prompted researchers to apply so-called bi-metals (i.e., metals partially deposited with electrocatalytically active Pd, Pt, or Ni), Fe/Pd (20, 21), Pt/Fe (21), and Fe/Ni (22) for the degradation of organic groundwater contaminants.

It is beyond the scope of the present work to discuss hundreds[3] of publications regarding the use of iron in the remediation of groundwater contaminants. Instead, one of the objectives of this study is to address issues related to the mechanism of degradation of organic contaminants, which have not been addressed in previous publications and those which remain controversial, such as hydrogen evolution reactions on metals or oxide-covered metal surfaces.

Experimental

Materials

The granular iron samples used in the experiments were obtained from three suppliers of commercial iron materials used for PRB field installations: Connelly-GPM (Chicago, Illinois); Peerless Metal Powder and Abrasive (Detroit, Michigan); Master Builders (Cleveland, Ohio). All solutions were prepared from Milli-Q water unless stated otherwise and analytical reagent grade KOH (Aldrich), $NaHCO_3$ (Baker), H_2SO_4, and $HClO_4$ (Aldrich). D_2O (purity 99%) was obtained from CIL Isotopes. Hydrogen adsorption studies were performed using 6.0 mm Pd (99.95%), Pt (99.99%), and 5 mm Ni (99.999%) polycrystalline rods (Johnson Matthey).

Methods

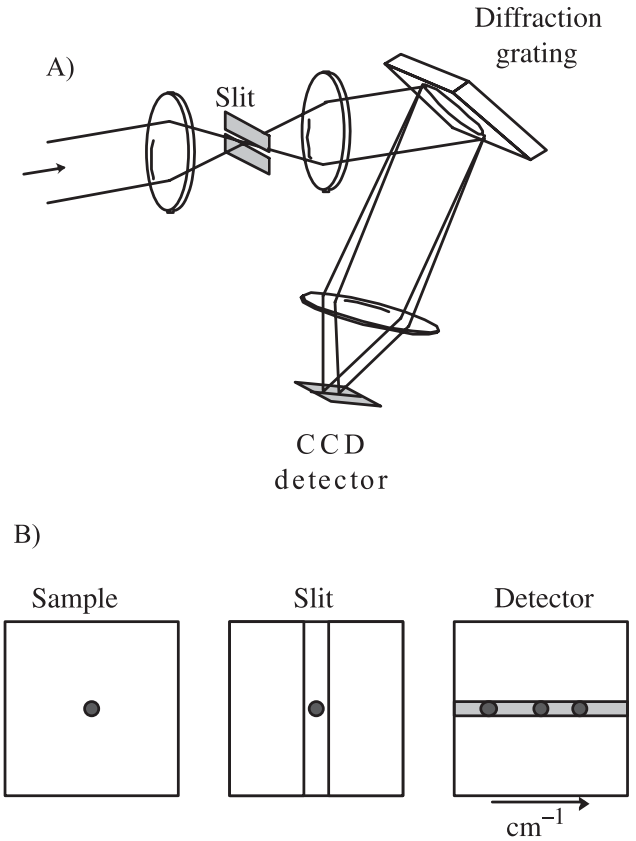
Ex situ Raman spectral studies of the distribution of oxides on "as received" commercial iron

Raman spectra were obtained with a Renishaw 1000 microscope system with a CCD detector (400 pixels × 600 pixels) using a 30 mW HeNe (632.8 nm) laser. The optical throughput of the instrument is high (≥30%), as is the sensitivity. The detection of a very weak signal (1 photon/s) is

[3] Database available at http://cgr.ese.ogi.edu/ironrefs/Process.pl.

© 2004 NRC Canada

possible. Raman spectra of as received iron materials were obtained using a 100× magnification objective and the confocal mode of instrument operation. Raman results were analysed based on available literature data and (or) compared with Raman spectra of standards.



The confocal mode of operation was achieved by decreasing the slit width to 15 μm and the area of the CCD detector to 4 pixels × 600 pixels, as demonstrated in Fig. 1. The slit is used as the primary aperture in the system and, as such, provides an additional spatial filter for the confocal measurements. The optical design of the system produces an image spot size of ca. 15 μm (depending on objective used) at the slit, and thus, it discriminates against the out-of-focus sample region. The optical alignment of the instrument was optimized using the 521 cm^{-1} Raman signal from a silicon wafer. The confocal setting and 100× magnification objective should give a 2 μm sampling depth (23). The proper confocal optical alignment and the depth of field was confirmed by plotting the Si signal intensity as a function of position through focus (Z distance profile) of the silicon wafer. The use of confocal Raman microspectroscopy was important for two reasons: (*i*) it dramatically diminishes undesirable fluorescence and (*ii*) allows for the filtration of the signal from the nearest neighbouring species in the sequential mapping of the iron surface with 1 μm resolution (for the 100× objective). All in situ studies presented in this work were carried out using the non-confocal setting of the Raman instrument.

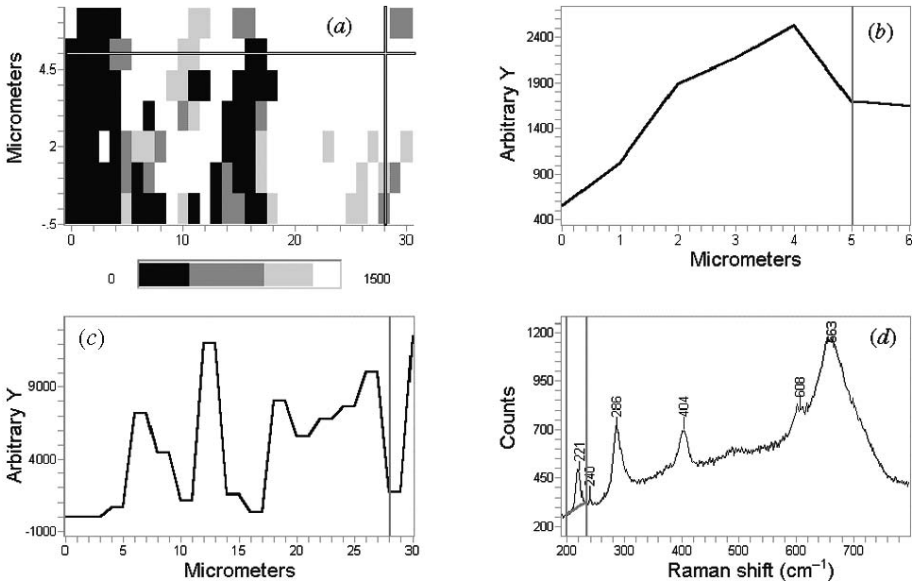
Electrochemical measurements (cells and electrode preparation)

The open-circuit potential (OCP) of a single grain of Connelly™ iron was measured in a simple two-electrode cell with a $Ag/AgCl/Cl_{sat}$ or Hg/HgO/0.1 mol/L OH^- electrode used as an external reference electrode. The cell was purged with ultra-pure argon and filled with Milli-Q water containing 25 mg/L of *N*-nitrosodimethylamine (NDMA) or, in the second experiment, with 0.12 mol/L $NaHCO_3$ + 0.1 mol/L KOH. The solution was introduced into the cell and deaerated for 30 min. To simulate the batch–column kinetic experiments, 150–200 g of sieved granular Connelly™ iron was added at the bottom of the cell. All OCP data were converted to the standard hydrogen electrode (SHE) as a common reference scale.

Hydrogen adsorption experiments were carried out in a three-electrode spectroelectrochemical cell described in detail in an earlier publication (24). A double-junction $Ag|AgCl|Cl_{sat.}$ reference electrode was used. The Luggin capillary was terminated with a second glass-sealed asbestos frit to avoid possible contamination of the electrolyte by Cl^- ions. The cell construction unfortunately did not allow the use of a reversible hydrogen electrode (RHE) as the reference electrode, which would be preferred for this type of study. A platinum mesh sealed into glass was used as the counter electrode. The working electrodes were mechanically polished with 0.3 and 0.05 μm alumina powder to a mirror finish followed by ultrasonic cleaning in Milli-Q water. The Pt and Pd electrodes underwent 24 h of electrochemical polishing by potential cycling between –0.20 and 1.20 or 1.25 V (vs. $Ag|AgCl|Cl_{sat.}$). Pt, Pd, and Ni are not surface-enhanced Raman active metals. Therefore, to observe very weak signals from adsorbates the Raman scattering cross-section needs to be increased. In practice this can be achieved by creation of roughness at the metal electrode surface. The roughening procedure was adapted from Ariva and co-workers (25) and successfully applied to Raman spectroscopic studies of hydrogen adsorption by Tian and co-workers (26). Namely, potential steps from –0.20 up to 2.45 V with a frequency of 2 kHz were applied to the electrodes in deaerated 0.1 mol/L H_2SO_4 or 0.1 mol/L $HClO_4$ for 10 min. After roughening, the electrodes underwent further potential cycling at a sweep rate of 20 mV/s between –0.20 and 1.20 or 1.25 V depending on the electrolyte. The cycling was continued until all unstable atoms or metal clusters were removed, as indicated by a reproducible cyclic voltammogram (CV), which was usually achieved after the third cycle.

Fig. 1. The optical configuration of the Renishaw 1000 system — confocal mode. (*a*) Confocal optics. (*b*) CCD pixel binning. Slit width 15 μm (or less), CCD area 4 pixels (or less) by 600 pixels.

All OCP and CV measurements were carried out using an AutoLab PGSTAT 30 potentiostat interfaced to a personal computer. Electrochemical roughening of the Pt and Pd electrodes was performed using an EG&G PAR model 273 potentiostat and a Wavetek Model 142 high frequency wave generator.



Results and discussion

Raman confocal mapping of commercial iron materials

Literature data on the remediation of groundwater contaminants by iron filings lack comprehensive studies of the

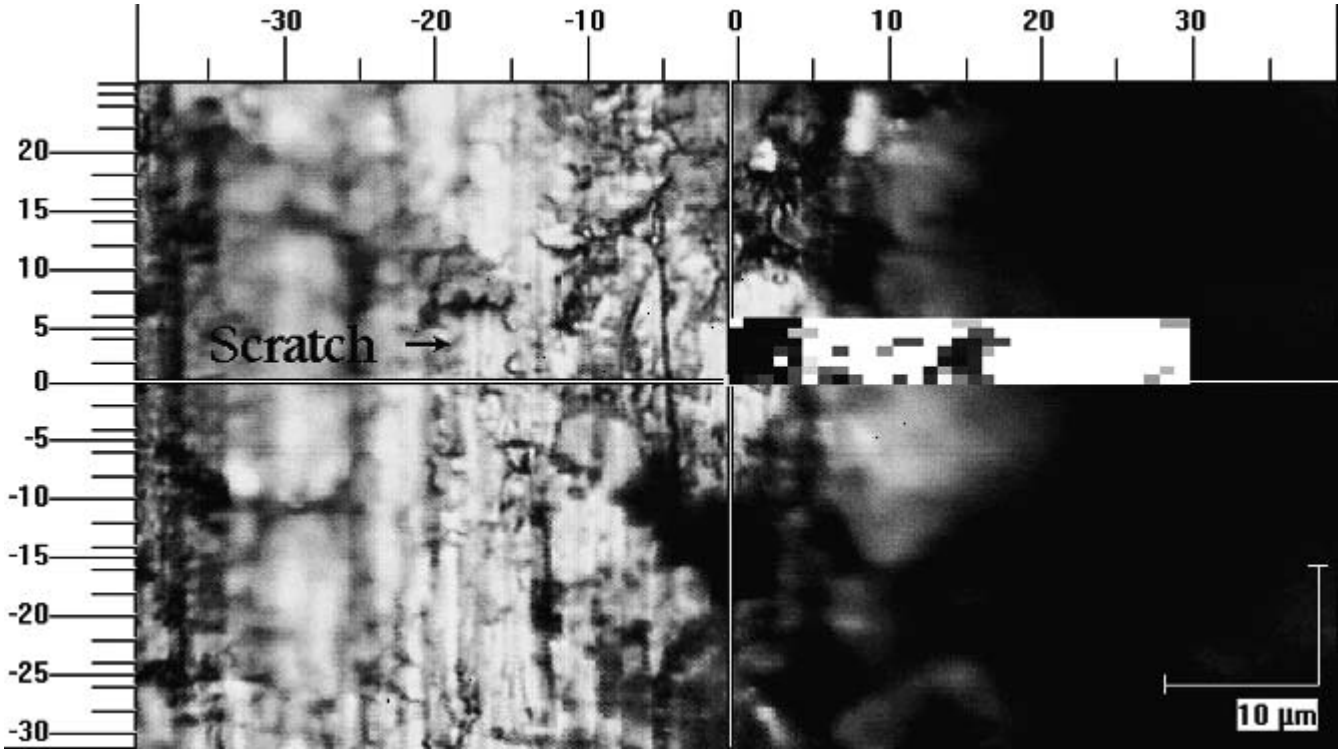
distribution of various oxides on the surface of the commercial materials used for PRB construction, or at the best are limited to maximum of nine arbitrary chosen points at the surface (27).



During production of commercial materials used for construction of PRBs, the low alloy scrap steel and (or) cast iron undergo high-temperature thermal treatment in rotary kiln ovens. The temperature and partial pressures of gases maintained in the rotary kilns are considered proprietary by the suppliers and therefore, are not readily available. A randomly chosen, but relatively flat, grain of Connelly™ iron was scratched to reveal the underlying material. In the mapping experiment, Raman spectra were taken over a 30 μm × 6 μm area covering both scratched and unscratched grain regions. In total, this corresponds to 217 Raman spectra taken over 12 h of measurements. The mapping process was fully automated by using a computer-controlled XYZ motorized stage. For XY movement, a 1 μm × 1 μm scan step pattern was chosen. To account for surface height changes (i.e., scratch, roughness, etc.), the autofocussing spectra acquisition mode was chosen with Z-direction step movements of 1 μm. The Raman map of hematite (α-Fe_2O_3) is presented in Fig. 2. It was generated using the signal to baseline calculation method, where the Raman peak at 221 cm^{-1} (A_{1g} mode of α-Fe_2O_3) was used as the fingerprint of hematite. Figure 3 represents the overlay of the α-Fe_2O_3 Raman map with the white light image of a grain of the Connelly™ iron. Raman mapping of maghemite (γ-Fe_2O_3) and magnetite (F_3O_4) are presented in Figs. 4*a* and 5*a*, respectively. The fingerprint Raman signals for γ-Fe_2O_3 and F_3O_4 do not exist because the strongest A_{1g} mode of F_3O_4 at 663–673 cm^{-1} overlaps very broad complex Raman bands of γ-Fe_2O_3 at 643, 671, and 718 cm^{-1} (see Fig. 4*b*). Therefore, the simple method of signal to background calculation cannot be applied. In this case, the map components calculation method was used. This method searches for the best match of the combination of the differential of the component spectrum (Raman spectrum of γ-Fe_2O_3 standard in Fig. 4*b*) to the differentials of the spectrum taken at each X-Y coordinate (Fig. 4*c*). This method effectively compares the shape of the component spectra to the unknown at different XY positions. The comparison of the Raman spectrum of the γ-Fe_2O_3 standard with Raman spectra obtained at X = 28 μm, Y = 5 μm (Fig. 2*d*), and X = 12 μm, Y = 0 μm (Fig. 4*c*) indicates that at these locations the Raman band at 663–665 cm^{-1} should not be attributed to γ-Fe_2O_3, but rather to the A_{1g} mode of Fe_3O_4. The mapping of Fe_3O_4 was performed using many different calculation methods, including peak half-width mapping, mapping data by curve fitting, and component mapping. The most reliable results were obtained using component mapping with the background offset correction. The Fe_3O_4 mapping results are presented in Fig. 5*a*. The latter calculation method generates an extra map of the background offset (Fig. 5*b*), which is in fact the map of underlying fluorescence.

The same mapping procedure was used to study oxide distribution on both the Peerless™ and Master Builder™ samples. The white light image of a grain of Peerless™ iron is presented in Fig. 6. The distribution of hematite (α-Fe_2O_3) on the surface of Peerless™ iron is shown in Fig. 7. The entire surface of Peerless™ iron is covered by a thick layer of hematite. Because of space constraints, the distribution of oxides for Master Builder™ is not shown in this work.

Raman microprobe mapping experiments revealed that the commercial iron materials used for the construction of permeable reactive barriers are covered with an inner film of magnetite Fe_3O_4 (scratched area) and an outer film of Fe_2O_3. The majority of the outer film (unscratched area) consists of hematite (α-Fe_2O_3). Maghemite γ-Fe_2O_3 was only observed at a few locations and was accompanied by very strong fluorescence as indicated by comparison of the γ-Fe_2O_3 map in Fig. 4*a* with the map of fluorescence in Fig. 5*b*. Wüstite, which can be nominally written as FeO, is characterized by a very broad single Raman band at 652 cm^{-1} (28). The

wüstite phase is unstable below 570 °C and was not observed in our experiments. The Raman results are in very good agreement with the high-temperature oxidation model of ferric materials (29).

The charge transfer processes at the metal | oxide | solution interface

Oxide-covered metals represent intermediate systems that have similarities to metal and semiconductors. According to the charge transfer theory of Gerischer (30), charge transfer proceeds at constant electronic energy and can be described using a diagram of electron terms at the interface. With regard to the reduction of chlorinated solvents by iron, the elements of Gerischer's theory of charge transfer were used by Balko and Tratnyek (31) to explain the effects of light on the reduction of CCl_4 by high purity iron. This interesting work prompted us to make similar considerations for the commercial Fe materials.

The probability of charge transfer at an oxide-covered metal can be estimated using the Gamov formula (30)

$$[1] \qquad \ln W = -4\pi d(2m_e \Delta E)^{0.5}/h$$

where m_e is rest mass of the electron and h is Planck's constant. W is the electron-tunnelling probability, which depends strongly on the thickness (d) and the height of the semiconductor energy barrier (ΔE). Using the known value of the complex part of the refractive index for the high-temperature grown Fe_2O_3, $k = 0.326$ (32), the laser penetration depth can be estimated using the following formula (33)

$$[2] \qquad d = c/2k\nu = \lambda/2k$$

where ν, λ, and c are the frequency, wavelength, and velocity of light in a vacuum, respectively. In the case of the commercial iron materials, the Raman signal of the inner Fe_3O_4 layer was not visible, indicating that the thickness of the outer Fe_2O_3 is greater than 970 nm, the calculated laser penetration depth for the outer oxide.

For a typical energy barrier $\Delta E = 1$ eV for a semiconductor film on iron (30) and 970 nm thick Fe_2O_3, the probability of charge transfer by tunnelling is $W = 10^{-4307}$. Therefore, as received commercial iron materials for the construction of permeable reactive barriers should not be reactive towards not only chlorinated solvents but also chemically inert towards groundwater. The calculation assumed the inner Fe_3O_4 to be electronically conducting. The tunnelling probability calculation might be slightly misleading since the calculation assumes an ideal passive film, free of local defects. The reason behind the effectiveness of commercial iron materials in the reductive destruction of organic contaminants is considered in the next section.

Autoreduction of the outer protective Fe_2O_3 film

In the earlier stages of PRB technology development, research was directed towards identification of precipitates formed during solvent remediation. This is understandable considering the fact that the activity of a PRB must be maintained for 10 to 20 years to be economically superior over pump-and-treat groundwater systems. In this way, the reactions that are responsible for the effectiveness of the technology have been largely neglected (34). These are autoreduction reactions that can be written as (35*a*)

$$[3] \qquad Fe_2O_3 + 6H^+ + 2e^- \rightarrow 2Fe^{2+} + 3H_2O$$

or (35*b*)

[4] $Fe_2O_3 + 2H^+ + 2e^- \rightarrow 2Fe_3O_4 + H_2O$

PRB reactive barriers are passive treatment methods, and hence, operate under OCP conditions. At the OCP, electrons for reductive dissolution of the protective oxides (rxns. [3] and [4]) are supplied by the anodic corrosion process (12, 35, 36).

[5] $Fe \rightarrow Fe^{2+} + 2e^-$

Over several years we have collected considerable experimental evidence that confirms the occurrence of these reactions in both pure water and groundwater solutions. The experimental evidence includes: (*i*) colour changes of the commercial materials from reddish to black when exposed to deaerated aqueous solutions; (*ii*) in situ Raman spectroscopic data confirming the disappearance of Fe_2O_3 from the surface with simultaneous occurrence of the Fe_3O_4 Raman signal (27, 35c); and (*iii*) OCP-time potential transients (see, for example, Fig. 8).

The potential-time transient presented in Fig. 8 is in good agreement with OCP-time transients measured for low alloy pipeline steel covered with a thick layer of millscale oxides in groundwater solutions (36). The millscale-covered pipeline steel most closely resembles the commercial iron materials used for PRB construction. Therefore, the most recent electrochemical impedance and potential-time transients measurements of Qin et al. (36) are particularly important for understanding the processes occurring on Fe used in PRBs. According to Qin et al. (36), three regions of OCP-time transients can be observed, which correspond to: (*i*) the initial attempts at breakdown of the millscale (positive potentials in this first region indicate that only the millscale is exposed to the solution); (*ii*) coupling of the dissolution of underlying iron to the reductive dissolution of the millscale oxides in the intermediate potential range; (*iii*) active corrosion of the material at the base of the pores in the film supported by water reduction either on the metal or on the conducting (i.e., magnetite) millscale at the most negative potentials (36).

The white light image of the cross section of the grain of Connelly^{TM} iron used in the mapping experiment is presented in Fig. 9. The as received material is cracked. The cracks penetrate deep into the bulk material. The cracking of commercial Fe is evidently the result of the thermal treat-

ment of the scrap material in the kiln ovens. Raman microspectroscopy of the different areas inside the cracks revealed (data not illustrated) the presence of graphite, carbides, and stressed α-Fe_2O_3 oxide. The stress in the oxide was evident from the shift of the A_{1g} mode of α-Fe_2O_3 from 225 cm^{-1} to as low as 217 cm^{-1}. Sometimes the splitting of

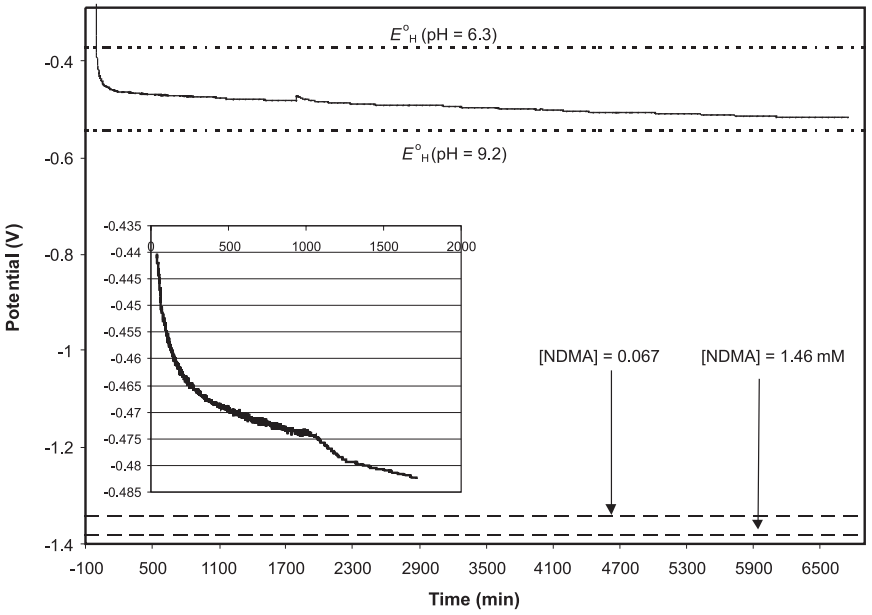
Fig. 8. OCP-time dependence of a single grain of Connelly^{TM} iron immersed in distilled water containing 25 mg/L NDMA. The potential arrest after ca. 1100 min (see inset) represents autoreduction of the outer protective Fe_2O_3 oxide film. The dotted lines indicate the equilibrium potentials for hydrogen evolution for the pH range observed in the column experiment during degradation kinetic studies of NDMA. The broken lines indicate potentials required for the electroreduction of NDMA, obtained from differential pulse voltammetry on mercury electrodes. Further experimental details can be found in our earlier publication on mechanistic studies of the reduction of NDMA in the presence of granular iron (37). The potential spike at ca. 1700 min is an experimental artifact. Its occurrence does not influence the interpretation of the present results.



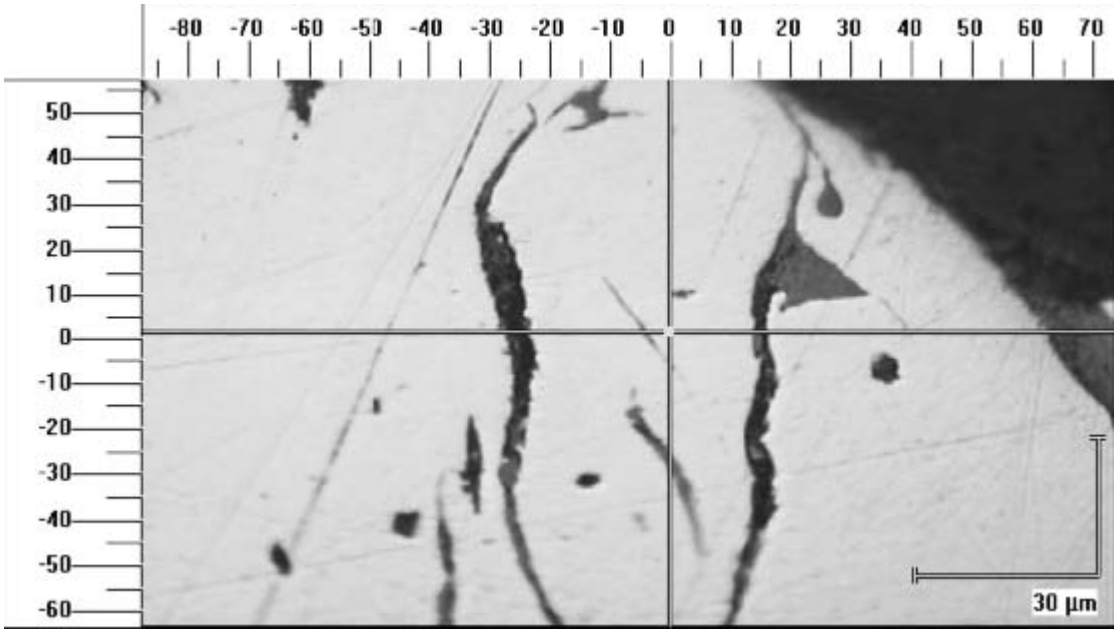


Fig. 9. The white light image of the cross section of the grain of the Connelly^{TM} iron used for the Raman mapping experiment. Cracks penetrate from the oxide layer (right upper corner) deep into bulk of the material.

this band was observed. Cracking and stressing create ideal conditions for the autoreduction processes described by Qin et al. (36).

The potential in the intermediate potential region (see Fig. 8) never reaches a steady-state value but decreases continuously. This would suggest that the autoreduction process opens up the porous structure of the oxide (36) and possibly the underlying metal as the oxide dissolves. The deeply cracked structure of the commercial iron materials increases the possibility of local separation of anodic and cathodic sites, which would promote localized corrosion and, as a consequence, the degradation of organic contaminants.

Hydrogen evolution reactions (HER) on metals and oxide cover iron

Processes involving hydrogen evolution are important in many applications, such as catalysis, electrocatalysis, metallurgy, and corrosion engineering. With regards to degradation of organic contaminants by scrap iron materials, these processes have received very little attention. In the environmental literature, for example, the corrosion reaction for iron in water is frequently written as $Fe + H_2O \rightarrow Fe^{2+} + H_2 + 2OH^-$. The work of Wang and Farrell (38) is the rare exception. Wang and Farrell (38) addressed the issue of atomic hydrogen only in low pH environments (see rxns. [1]–[3] in ref. 38). However, the low pH environment is not typical for PRB operation. We believe that the hydrogen evolution reactions on metals such as Pt, Pd, Fe, and Ni are more complex and strongly pH dependent.

It is commonly agreed that the HER on metals such as Pt, Pd, Fe, and Ni takes place in several steps and the mechanism strongly depends upon the pH of the solution (39).

At low pH (i.e., pH < 5), the first reaction step involves the discharge of hydrated protons

[6] First step $Me + H_3O^+ + e^- \rightleftarrows MeH_{ads} + H_2O$ (Volmer reaction)

followed by electrochemical desorption

[7] Second step (*a*) $MeH_{ads} + H_3O^+ + e^- \rightleftarrows H_2 + H_2O + Me$ (Heyrovsky reaction)

or by chemical desorption (also called catalytic recombination)

[8] Second step (*b*) $MeH_{ads} + MeH_{ads} \rightleftarrows 2Me + H_2$ (Tafel reaction)

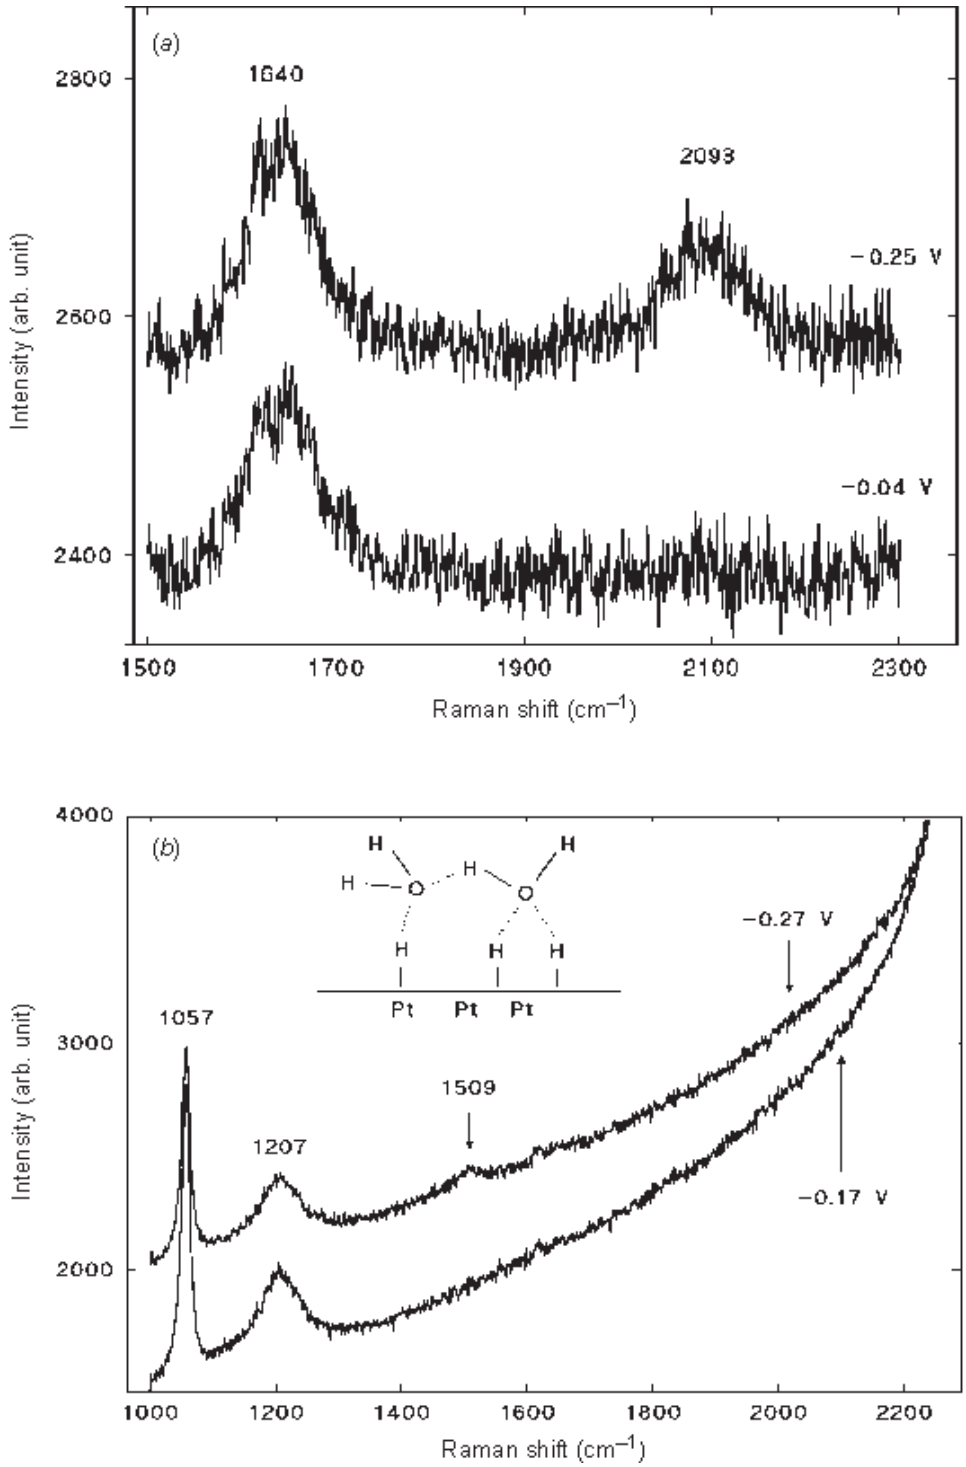
In alkaline solutions (pH > 5), the first reaction step involves the electrolysis of water

[9] First step $Me + H_2O + e^- \rightleftarrows MeH_{ads} + OH^-$ (Volmer reaction)

followed by electrochemical desorption

[10] Second step (*a*) $MeH_{ads} + H_2O + e^- \rightleftarrows H_2 + OH^- + Me$ (Heyrovsky reaction)

or by chemical desorption



[11] Second step (*b*) $MeH_{ads} + MeH_{ads} \rightleftarrows 2Me + H_2$ (Tafel reaction)

It is important to note that the formation of adsorbed hydrogen changes the free energy of the electron transfer step by an amount equal to the free energy of the bond formation between the hydrogen atom and the surface of the metal. The consecutive rxns. [6]–[9] for many metals, including Fe, Ni, Pt, Pd, etc., can occur at potentials more positive than the equilibrium potential for the hydrogen evolution reaction (39). The spectroscopic evidence for adsorption of atomic hydrogen on Pt is presented in Fig. 10*a*. Our results are in good agreement with those of Tian and co-workers (26) who observed singly coordinated H on the surface of Pt at 2088 cm^{-1}. The confirming evidence that the presently observed band at 2093 cm^{-1} indeed arises from adsorbed H is provided by an experiment carried out in heavy water. Namely, the band at 2093 cm^{-1} shifts by a factor of 1.39 (see Fig. 10*b*), which is expected for the isotopic shift. Changing the anion in the electrolyte from SO_4^{2-} to ClO_4^- (not specifically adsorbable) shifted the hydrogen band from 2093 to 2098 cm^{-1}, suggesting that a stronger bond was created in the electrolyte free of specifically adsorbable anions. The other bands in Fig. 10 at 1640, 1207, and 1057 cm^{-1} arise from the bending mode of water and heavy water and the stretching mode of the SO_4^{2-} anion, respectively. In our studies, we carefully scrutinized the potential region for hydrogen adsorption. In agreement with Tian and co-workers (26), we could observe adsorbed hydrogen at potentials just before the onset of formation of molecular hydrogen by rxns. [7] and [8]. This indicates that we observed both "strongly" (first cathodic peak-cycling voltamograms for Pt (not presented) can be found in ref. 39) and "weakly" (second cathodic peak) adsorbed hydrogen. Distinguishing these different species will be difficult using normal Raman spectroscopy (NRS). Until now, attempts to obtain Raman spectra of adsorbed H on Pd, Ni, and Fe were not successful. The success of NRS in the research on hydrogen adsorption will depend upon finding the suitable roughening procedure that would increase the intrinsically weak Raman signal of adsorbates. Furthermore, the use of vibrational spectroscopy based on nonlinear optics, for example, visible-IR sum-frequency generation providing more surface sensitivity, should be considered as a better method for detection of atomic hydrogen on Pd, Ni, and Fe.

While there exists a considerable amount of spectroscopic and electrochemical evidence concerning adsorption of atomic hydrogen on transition metals such as Fe, Co, and Ni, the adsorption of H on magnetite-covered Fe surfaces is more speculative and requires confirmation by independent spectroscopic experiments. Thermodynamic calculations by Marcus and Protopopoff (40), however, indicate such a possibility. The thermodynamic stability region of H_{ads} (i.e., under-potential deposited (UPD) H) on Fe overlaps the region of Fe_3O_4 stability. Calculations in ref. 40 assume a simplified model of competitive Langmuir adsorption of H and O atoms. In the case where adsorbed O has a strong blocking effect, the domain of FeH_{ads} would be shifted to more cathodic potentials, outside the stability region of Fe_3O_4 (see Fig. 11). While the latter may be true in normal aqueous solutions, in column experiments on the kinetics of degradation of organic contaminants, O_2 is consumed at the inlet of the column. Thus, it is not available as a competitor for hydrogen adsorption. Furthermore, the stress induced during thermal treatment of commercial scrap iron in kiln ovens induces nano-cracks both in the oxide layer and in the matrix of the metal (see Fig. 9). Hydrogen evolution in occluded cells such as cracks, pits, and crevices can take place even at anodic potentials (i.e., potentials more positive than the measured OCP) (41). The latter is the result of the acidification of the solution inside the local defect. Moreover, hydrogen evolution is further supported by the shift of the potential inside the crack in the negative direction because of the ohmic potential drop. All of the above factors increase the probabil-

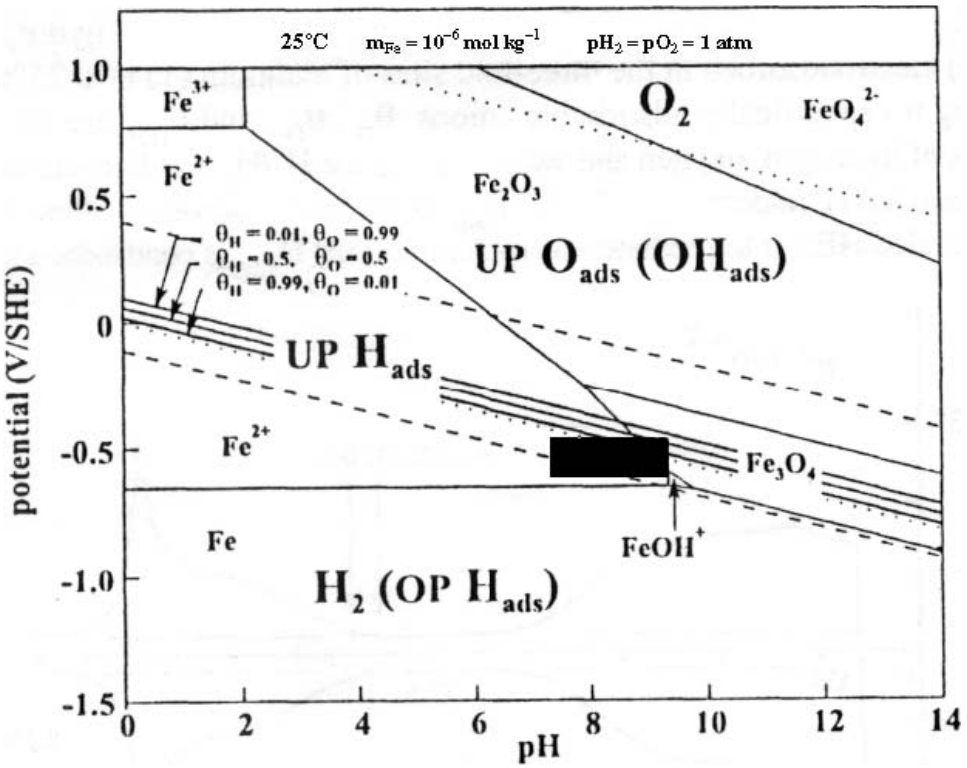
Fig. 10. Potential dependent surface Raman spectra of: (*a*) hydrogen adsorption in 0.1 mol/L H_2SO_4 in water and (*b*) deuterium adsorption in 0.1 mol/L H_2SO_4 in heavy water. The insert in Fig. 10*b* represents possible coordination of atomic hydrogen at the interface.



ity of the local separation of anodic and cathodic sites, which are known in the corrosion literature as Evans cells. In earlier work (7) on the dehalogenation of chlorinated methanes by iron, the separation of local anodes and cathodes was questioned.

Further supporting evidence for the existence of atomic hydrogen, despite the presence of a thick layer of magnetite at pH > 5, comes from hydrogen permeation experiments in neutral and alkaline solutions (41). Note here that only hydrogen in the atomic form can enter the lattice of iron metal.

In recent years there is growing evidence (12, 37) that despite the existence of a thick layer of magnetite on the commercial iron, many groundwater organic contaminants can be destroyed by catalytic action of atomic hydrogen. The

Fig. 11. Equilibrium potential – pH diagrams for the strongly bonded hydrogen and oxygen species electroadsorbed in the high coordination sites of iron at 25 °C in an electrolyte containing no specifically adsorbable anions. θ_H and θ_O are the fractional surface coverages of adsorbed hydrogen and oxygen, respectively. UP H_{ads} denotes the strongly bonded H electroadsorbed at underpotential, i.e., above the equilibrium line (dotted line) for hydrogen evolution. Below this line, the weakly bonded, overpotential (OP) H_{ads} is coadsorbed. The dashed lines are the lines for the hypothetical case where H and O species would be electrosorbed independently (for $\theta = 0.5$). *Reproduced by permission of The Electrochemical Society.* Details of the calculations are provided in ref. 40. The black area superimposed on the equilibrium diagram represents a collection of published (27, 37) and unpublished experimental data for the pH and OCP observed during batch or column experiments on the degradation of organic contaminants by commercial iron materials. The pH and OCP are given after autoreduction of Fe_2O_3 and confirmed by Raman microspectroscopy of the existence of magnetite on the surface of the commercial materials.

separation of the anodic and cathodic sites and spillover atomic hydrogen can play a crucial role in these processes.

Conclusions

Raman microprobe mapping experiments reveal that commercial iron materials used for the construction of permeable reactive barriers are covered with an inner film of magnetite Fe_3O_4 (scratched area) and an outer film of Fe_2O_3 (unscratched area). This observation is in good agreement with the high-temperature oxidation model of ferric materials.

The charge transfer process at Fe | iron oxide (semiconductor) | solution interfaces has been briefly discussed. In particular, it was estimated that the probability of charge transfer process (by electron tunnelling) at commercial Fe | Fe_2O_3 (semiconductor) | solution interfaces approaches zero. It was concluded that as received commercial iron materials should not be reactive towards both organic contaminants and water.

The combination of OCP (corrosion potential)-time measurements with in situ Raman spectroscopy demonstrated that the breakdown of the protective Fe_2O_3, oxide film, followed by autoreduction of Fe_2O_3, is a required step to make the commercial materials chemically active towards both water and organic contaminants. Based on OCP-time behaviour and available literature data, it was suggested that the autoreduction process opens up the porous structure of the oxide and cracks in the underlying metallic iron. The opening of defects in the bulk iron metal creates conditions for the local separation of anodic and cathodic sites and the formation of so-called Evans galvanic cells.

Hydrogen evolution reactions on metals and oxide-covered iron was also described. In particular, spectroscopic evidence for adsorption of atomic hydrogen on polycrystalline Pt was presented. The possibility of adsorption of H on magnetite-covered iron was considered using thermodynamic calculations of Marcus and Protopopoff (40). The evolution of hydrogen on the commercial iron materials was described. It was suggested that the separation of the anodic and cathodic sites and involvement of spillover hydrogen may play a crucial role in the catalytic hydrogenation of groundwater contaminants.

Synthesis and transformations of 60-, 62-, and 64-electron $Co_4(CO)_x(PNR_2)_2$ (x = 8, 9, 10) clusters[1]

Javier Sánchez-Nieves, Brian T. Sterenberg, Konstantin A. Udachin, and Arthur J. Carty

Abstract: A unique family of bis-(amino)phosphinidene Co_4 clusters with electron counts in the 60–64 e regime is described. The 62-electron (5 Co–Co) butterfly compound $[Co_4(CO)_8(\mu\text{-}CO)\{\mu_3\text{-}P(TMP)\}_2]$ (TMP = 2,2,6,6-tetramethylpiperidyl) (**1a**) is obtained via condensation of the bridged (amino)phosphinidene complex $[Co_2(CO)_6\{\mu\text{-}P(TMP)\}]$. Further heating and removal of CO gives the 60-electron (6 Co–Co) tetrahedral compound $[Co_4(CO)_6(\mu\text{-}CO)_2\{\mu_3\text{-}P(TMP)\}_2]$ (**3a**). The reaction of $K[Co(CO)_4]$ with $PCl_2(N\text{-}i\text{-}Pr_2)$ gives the 64-electron (4 Co–Co) square-planar derivative $[Co_4(CO)_8(\mu\text{-}CO)_2(\mu_4\text{-}PN\text{-}i\text{-}Pr_2)_2]$ (**2**), which loses one carbonyl ligand to form the 62-electron (5 Co–Co) butterfly compound $[Co_4(CO)_8(\mu\text{-}CO)(\mu_3\text{-}PN\text{-}i\text{-}Pr_2)_2]$ (**1b**). Complex **1b** releases another carbonyl to form the 60-electron (6 Co–Co) tetrahedral compound $[Co_4(CO)_6(\mu\text{-}CO)_2(\mu_3\text{-}PN\text{-}i\text{-}Pr_2)_2]$ (**3b**). X-ray structural analyses of compounds **1a**, **1b**, **2**, and **3a** have been carried out. The reversibility of the CO elimination reactions and the structural rearrangements accompanying changes in electron count in this series are discussed.

Key words: cobalt, cluster compounds, phosphinidene, skeletal rearrangement.

Résumé : On décrit une famille unique d'agrégats de la famille du bis-(amino)phosphinidène Co_4 comportant de 60 à 64 électrons. Le composé en forme de papille comportant 62 électrons (5 Co–Co), le $[Co_4(CO)_8(\mu\text{-}CO)\{\mu_3\text{-}P(TMP)\}_2]$ (TMP = 2,2,6,6-tétraméthylpipéridyl) (**1a**) est obtenu par condensation du complexe (amino)phosphinidène ponté $[Co_2(CO)_6\{\mu\text{-}P(TMP)\}]$. Un chauffage additionnel avec élimination du CO conduit au composé tétraédrique à 60 électrons (6 Co–Co) $[Co_4(CO)_6(\mu\text{-}CO)_2\{\mu_3\text{-}P(TMP)\}_2]$ (**3a**). La réaction du $K[Co(CO)_4]$ avec le $PCl_2(N\text{-}i\text{-}Pr_2)_2$ conduit au dérivé plan carré à 64 électrons (4 Co–Co) $[Co_4(CO)_8(\mu\text{-}CO)_2(\mu_4\text{-}PN\text{-}i\text{-}Pr_2)_2]$ (**2**) qui perd un ligand carbonyle pour former le composé en forme de papillon comportant 62 électrons (5 Co–Co), le $[Co_4(CO)_8(\mu\text{-}CO)(\mu_3\text{-}PN\text{-}i\text{-}Pr_2)_2]$ (**1b**). Le composé **1b** perd un autre ligand carbonyle pour former le composé tétraédrique à 60 électrons (6 Co–Co) $[Co_4(CO)_6(\mu\text{-}CO)_2(\mu_3\text{-}PN\text{-}i\text{-}Pr_2)_2]$ (**3b**). On a déterminé les structures des composés **1a**, **1b**, **2** et **3a** par diffraction des rayons X. On discute de la réversibilité des réactions d'élimination du CO et des réarrangements de structure qui accompagnent les changements dans les nombres d'électrons dans ces séries.

Mots clés : cobalt, agrégats, phosphinidène, réarrangement des squelettes.

[Traduit par la Rédaction]

Introduction

One of the most interesting regimes of low nuclearity metal cluster chemistry is that involving four metal atoms where structural changes in the M_4 skeletal framework accompany variations in cluster valence electron counts. Neither of the two principal models for bonding and structure, namely the effective atomic number rule (EAN) and the polyhedral skeletal electron pair theory (PSEPT) (1), satisfactorily account for all of the diverse structural features of molecules with 60–64 valence electrons. Thus, for example, the EAN rule, which describes the metal–metal interaction as a 2-centre 2-electron bond, predicts $E = (18n - N)/2$ metal–metal bonds between n transition metal atoms when the number of valence electrons is N e, leading to 6 M—M bonds in a 60 e tetrahedral framework, 5 M—M bonds (butterfly, 62 e), and 4 M—M bonds (square, rectangle, spiked triangle, 64 e). Exceptions to these rules include several electron deficient 62 e "square" M_4 frameworks such as $[Ru_4(CO)_{10}(\mu\text{-}CO)(\mu_4\text{-}PR)_2]$ (2) and a class of "electron-rich" butterfly 64 e molecules (3) such as $[Ru_4(CO)_{13}(\mu\text{-}PR_2)_2]$, which exhibit one or more elongated metal–metal

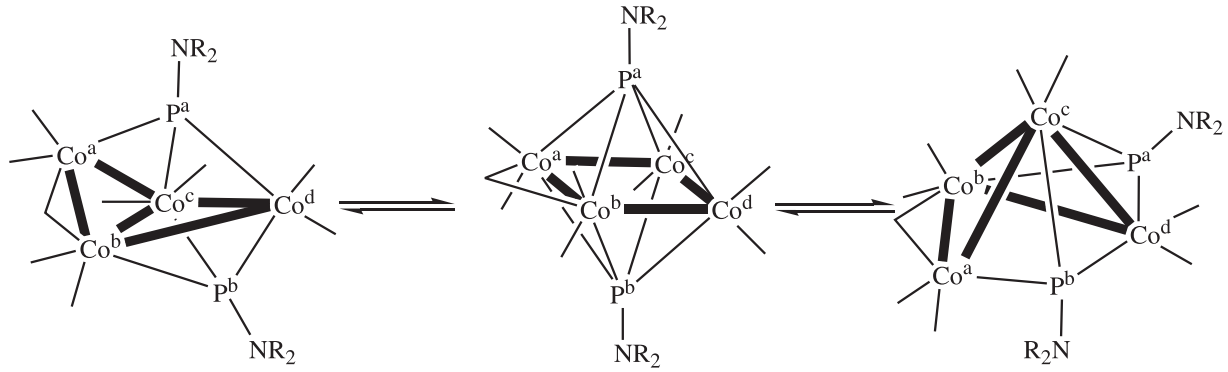
Scheme 1.

bonds. On the other hand, in the PSEPT framework, the 7 skeletal electron pair (SEP) count of $[Ru_4(CO)_{10}(\mu\text{-CO})(\mu_4\text{-PPh})_2]$ is consistent with the square M_4 (or closo M_4P_2) polyhedron, whereas the 8 SEP molecules $[Co_4(CO)_{10}(\mu_4\text{-PR})_2]$ with a similar square Co_4 structure are electron rich (4). There are other anomalies within the 60–64 e regime including a 64-electron (8 SEP) puckered square framework in $[Ru_4(CO)_{12}(\mu_4\text{-PNR}_2)_2]$ where the nonconical nature of the ligands contributes to metal framework distortions (2*c*, 5). EHMO and DFT calculations have provided satisfactory answers to some of these structural features (3*e*, 3*f*, 5, 6). Although examples of single-step transformations (tetrahedron (60 e) ↔ butterfly (62 e) and butterfly ↔ square (64 e)) via 2 e donor additions or eliminations have been described (1*b*, 7), there are very few instances of sequential electronic and structural changes within a single family of compounds. Reversible transformations are even scarcer (1*b*, 3*b*–3*d*, 7*a*–7*b*, 8). One example is the spiked triangular osmium cluster $[Os_4(CO)_{15}(PMe_3)]$, which loses carbonyl ligands to give the planar butterfly (or rhomboidal) cluster $[Os_4(CO)_{14}(PMe_3)]$ and tetrahedral $[Os_4(CO)_{13}(PMe_3)]$ (9). The 64–60 e conversion has also been reported for the electron-rich (64 e) rhomboidal cluster $[Ru_4(CO)_{13}\{\mu\text{-P(N-}i\text{-Pr}_2)_2\}_2]$ (3*f*, 3*g*), although in this case, the reactions involved CO loss and μ_4-η^2-CO coordination to afford 62 e $[Ru_4(CO)_9(\mu\text{-CO})(\mu_4\text{-}\eta^2\text{-CO})\{\mu\text{-P(N-}i\text{-Pr}_2)_2\}]$ and hydrogenolysis of a phosphido bridge to afford 60 e $[(\mu_3\text{-H})Ru_4(CO)_9(\mu\text{-CO})\{\mu\text{-}P(N\text{-}i\text{-Pr}_2)_2\}(\mu_3\text{-PN-}i\text{-Pr}_2)]$.



Through our recent synthetic work on stable Fischer type electrophilic terminal phosphinidene complexes (10), we prepared the unstable, doubly bridged phosphinidene compound $[Co_2(CO)_6\{\mu\text{-P(TMP)}\}]$ (TMP = 2,2,6,6-tetramethylpiperidyl) (11). This binuclear complex and its μ-PN-*i*-Pr_2 analogue undergo facile condensation reactions and CO loss to afford a unique family of 60, 62, and 64 e clusters whose structures and interconversions are described herein.

Results and discussion

We have reported that the reaction of $K[Co(CO)_4]$ with $PCl_2(TMP)$ in THF affords the unstable μ-(amino)phosphinidene complex $[Co_2(CO)_6\{\mu\text{-P(TMP)}\}]$, which can be stabilized by disubstitution with the bridging bis-diphenylphosphinomethane ligand (dppm) to form $[Co_2(CO)_4\{\mu\text{-P(TMP)}\}(dppm)]$ (11). In the absence of stabilizing ligands, the (amino)phosphinidene complex $[Co_2(CO)_6\{\mu\text{-P(TMP)}\}]$ loses carbonyl ligands in solution to give the tetracobalt cluster $[Co_4(CO)_8(\mu\text{-CO})\{\mu_3\text{-P(TMP)}\}_2]$ (**1a**) after 36 h of stirring in hexane (Scheme 1). The compound **1a** was identified by IR and NMR spectroscopies, X-ray diffraction studies, and elemental analysis. In the IR spectrum both terminal and bridging carbonyl bands were

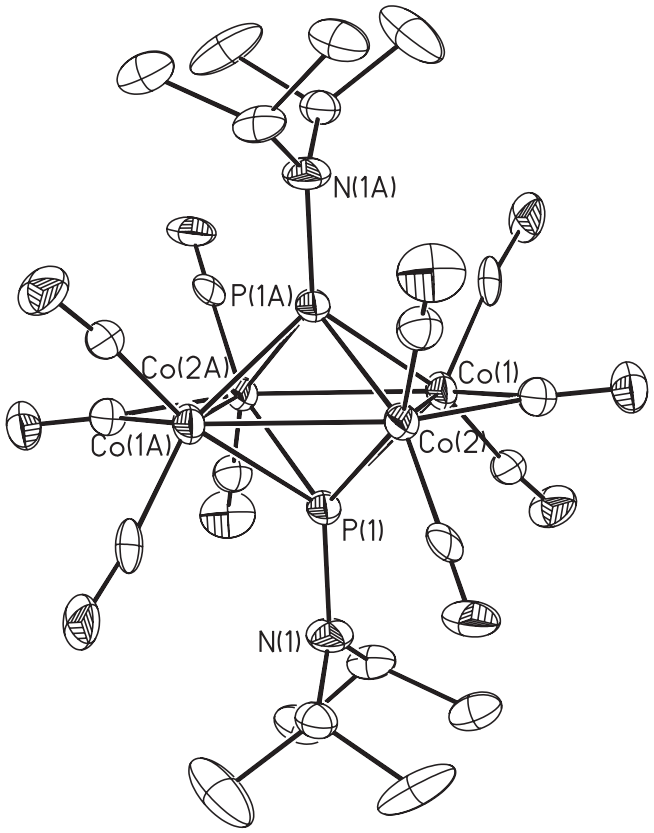
© 2004 NRC Canada

Scheme 2.

observed. In the ^{31}P NMR spectrum at room temperature two broad resonances were found at δ 542.4 and δ 471.8. No coupling was observed between the phosphorus nuclei, probably as a result of broadening of the resonances via quadrupolar coupling to ^{59}Co and ^{14}N but also perhaps because of the onset of exchange (vide infra). We measured the ^{31}P NMR spectrum of **1a** at –40 °C and observed that each resonance was split into a doublet (J(PP) = 213 Hz) at this temperature. The formation of compound **1a** can be rationalised as the condensation of two $[Co_2(CO)_6\{\mu\text{-}P(TMP)\}]$ molecules with the loss of three CO groups. This process likely leads in a first step to the 64-electron cluster $[Co_4(CO)_{10}\{\mu_3\text{-}P(TMP)\}_2]$, which would possess a Co_4 rectangular framework (vide infra). Then, probably because of the bulky TMP group, it loses one carbonyl ligand to give the 62-electron compound $[Co_4(CO)_9\{\mu_3\text{-}P(TMP)\}_2]$ (**1a**).

We were not able to observe the proposed intermediate, though compounds of the type $[Co_4(CO)_{10}(\mu_4\text{-}PR)_2]$ with a planar Co_4 core are well-known in the literature (4). They can be prepared via reaction of $[Co(CO)_4]^-$ with dichlorophosphines (4*a*–4*c*), so we decided to carry out the reaction of $[Co(CO)_4]^-$ with the less bulky phosphinidene source $PCl_2(N\text{-}i\text{-}Pr_2)$ in an attempt to synthesize the analogous 64-electron cluster $[Co_4(CO)_{10}(\mu_4\text{-}PN\text{-}i\text{-}Pr_2)_2]$ to study whether this compound would release a carbonyl ligand to afford the 62-electron butterfly cluster $[Co_4(CO)_9(\mu_3\text{-}PN\text{-}i\text{-}Pr_2)_2]$.

Fast addition of a $K[Co(CO)_4]$ solution in THF to a solution of $PCl_2(N\text{-}i\text{-}Pr_2)$ in THF gave the expected 64-electron (8 SEP) cluster $[Co_4(CO)_8(\mu\text{-}CO)_2(\mu_4\text{-}PN\text{-}i\text{-}Pr_2)_2]$ (**2**) (Scheme 1), identified by means of IR and NMR spectroscopies, single-crystal X-ray diffraction, and elemental analysis. In this reaction we did not observe the parent compound $[Co_2(CO)_6(\mu\text{-}PN\text{-}i\text{-}Pr_2)]$, although we believe it should be formed as a necessary intermediate prior to the formation of compound **2**. The ^{31}P NMR spectrum of **2** showed a single resonance at δ 258 typical of *closo* octahedral $[Co_4(CO)_{10}(\mu_4\text{-}PR)_2]$ clusters (4), with both phosphorus atoms in apical positions in a Co_4P_2 framework, and in the IR spectrum we observed bands for both terminal and bridging carbonyl ligands again as expected for this type of complex.



Once we had obtained the pure cluster $[Co_4(CO)_{10}(\mu_4\text{-}PN\text{-}i\text{-}Pr_2)_2]$ (**2**), we proceeded to charge an NMR tube equipped with a valve containing a solution of complex **2** in C_6D_6 and heated the contents at 60 °C with frequent removal of the inner atmosphere. We followed the course of the reaction by NMR spectroscopy and observed in the ^{31}P NMR spectrum the slow growth of a new broad resonance at δ 524 and in the ^1H NMR spectrum new resonances for the N-*i*-Pr_2 groups. We isolated the new compound by repeating the experiment in toluene and characterized it as the 62-electron butterfly cluster $[Co_4(CO)_8(\mu\text{-}CO)(\mu_3\text{-}PN\text{-}i\text{-}Pr_2)_2]$ (**1b**) (Scheme 1). In the IR spectrum we observed stretching bands for both terminal and bridging carbonyl ligands. As in compound **1a**, two different μ_3-phosphinidene ligands are present in the molecule, but in the ^{31}P NMR spectrum of compound **1b** only one broad resonance was observed for both phosphorus atoms. We carried out a variable-temperature ^{31}P NMR experiment of a solution of **1b** in CH_2Cl_2 and observed that the broad resonance was split into two new resonances upon cooling the sample, although we were unable to observe coupling between the two phosphorus nuclei even at –85 °C. At ambient temperature, both phosphorus atoms are equivalent on the NMR timescale presumably because of a dynamic process that essentially results in a "flapping of the wings" of the butterfly with Co–Co bond cleavage and reformation, which renders the two phosphinidene ligands equivalent on the NMR timescale (Scheme 2). The energy barrier for this process was estimated as 9.6 ± 0.5 kcal/mol (T_c = –27 °C). A possible intermediate in the dynamic process converting **A** to **C** in Scheme 2 is the octahedral cluster Co_4P_2 **B** with equivalent phosphinidene ligands. It is clear from the variable-temperature ^{31}P spectra described above that the barrier to the fluxional process in **1a** is considerably higher than in **1b**. Indeed, the fluxionality of **1b** even at –85 °C is sufficient to prevent the observation of any P–P coupling.

The loss of one carbonyl ligand from an octahedral $M_4(\mu_4\text{-}PR)_2$ cluster compound with 64 MVEs (8 SEP) has been reported previously (12), but in such cases the $M_4(\mu_4\text{-}PR)_2$ octahedral core is retained and the product is an unsaturated 62 MVE cluster according to the EAN rule.

When the same procedure as above was applied to solutions of the 62-electron butterfly clusters $[Co_4(CO)_9(\mu_3\text{-}PNR_2)_2]$ (NR_2 = TMP (**1a**), N-*i*-Pr_2 (**1b**)) in C_6D_6 new resonances appeared in the ^1H and ^{31}P NMR spectra. The same experiment was then carried out in toluene allowing

Fig. 1. ORTEP diagram of $[Co_4(CO)_8(\mu\text{-}CO)_2(\mu_4\text{-}PN\text{-}i\text{-}Pr_2)_2]$ (**2**). Hydrogen atoms have been omitted and thermal ellipsoids are shown at the 50% level.

isolation of the new tetrahedral 60-electron compound $[Co_4(CO)_6(\mu\text{-}CO)_2\{\mu_3\text{-}P(TMP)\}_2]$ (**3a**), while for the less bulky phosphinidene ligand PN-*i*-Pr_2 a mixture of **1b** and $[Co_4(CO)_6(\mu\text{-}CO)_2(\mu_3\text{-}PN\text{-}i\text{-}Pr_2)_2]$ (**3b**) was obtained (Scheme 1). In an attempt to obtain the derivative **3b** as the sole product, we added an equivalent of Me_3NO to a solution of **1b** in hexane. This procedure did not lead to the formation of compound **3b** and instead led to the precipitation of a dark solid. The remaining solution contained the cluster compounds **1b** and **2**. Thus, it seems that the presence of the bulky TMP group helps to stabilize the tetrahedral core in **3a**. In the ^{31}P NMR spectra, a single resonance was observed at δ 521 for **3a** and at δ 522 for **3b**. In the IR spectra, bands for terminal and bridging carbonyl ligands were observed. Suitable crystals for X-ray diffraction studies were obtained for **3a**. The carbonylation–decarbonylation processes described above are reversible and the cycle of loss and addition can be repeated, but eventually a dark decomposition product precipitated.

X-ray structural analyses

The X-ray structure of $[Co_4(CO)_8(\mu\text{-}CO)_2(\mu_4\text{-}PN\text{-}i\text{-}Pr_2)_2]$ (**2**) is shown in Fig. 1 and selected bond distances and angles are given in Table 1. The Co_4 framework forms a rectangle capped by two μ_4-(amino)phosphinidene ligands to give a Co_4P_2 octahedral core. Each Co atom is bound to two terminal carbonyl ligands and there are two μ_2-carbonyl ligands bridging opposite Co–Co edges, resulting in a total electron count of 64 e. This stereochemistry is typically

found in complexes of the type $[Co_4(CO)_{10}(\mu_4\text{-}PR_2)_2]$ (4), and no distortion in the planar M_4 core is observed, in contrast to the isoelectronic 8-skeletal electron pair bis-(amino)phosphinidene compounds $[Ru_4(CO)_{12}(\mu_4\text{-}PNR_2)_2]$ (2*c*, 5) where the Ru_4 skeleton is significantly distorted from planarity and the phosphinidene ligands have two short and two long bonds to the ruthenium atoms. In the present case, it appears that the presence of a nonconical, electron releasing amino group bound to the phosphorus atom does *not* induce changes in the Co_4P_2 framework when compared with the analogous complexes $[Co_4(CO)_{10}(\mu_4\text{-}PR_2)_2]$ where $R \neq NR_2$. The P–P distance in **2** of 2.605(1) Å is similar to those found in other clusters $[Co_4(CO)_{10}(\mu_4\text{-}PR)_2]$, where the phosphinidene bears a bulky substituent (e.g., R = *t*-Bu, 2.608 Å (4*d*); $CH(SiMe_3)_2$, 2.627 Å (4*c*)) or where a less bulky aryl or alkyl phosphinidene is present (e.g., Ph, 2.533 Å (4*b*) and 2.544 Å (4*a*); *i*-Pr, 2.553 Å (4*e*)). These distances can be compared with twice the covalent radius of phosphorus (2.20 Å) indicating that there is a weak bonding interaction "through the cluster" between the two phosphorus atoms (4*a*, 6*a*). The value of the P—N bond length in **2** (1.671(2) Å) and the planar environment at the nitrogen atom (Σ = 358.5°) indicate π donation from the nitrogen atom to the phosphinidene phosphorus atom (11, 13).

The X-ray structures of $[Co_4(CO)_8(\mu\text{-}CO)(\mu_3\text{-}PNR_2)_2]$ (NR_2 = TMP (**1a**), N-*i*-Pr_2 (**1b**)) are shown in Figs. 2 and 3, respectively, and selected bond distances and angles are given in Table 2. The compounds **1a** and **1b** have a Co_4-butterfly framework with two different types of μ_3-phosphinidene ligands, one of which caps a closed Co_3 triangular face while the other is bound to an open Co_3 face consisting of two wing-tip cobalt atoms and one of the hinge cobalt atoms. All Co atoms have two terminal carbonyls and there is one bridging carbonyl between the two Co atoms bound to only one phosphorus atom, resulting in a total electron count of

62 e or 7-skeletal electron pairs. This result is somewhat surprising since all of the structures known for complexes of the type $[Co_4(PR)_2]$ have an octahedral core as previously discussed for compound **2**. There are, however, well-known clusters of the type $[Co_4L_2]$ (L_2 = alkyne (14, 15), Al_2 (16), B_2 (17)) in which the tetracobalt core has a butterfly configuration, but these molecules, which have only 60 MVEs and are therefore electron deficient according to the EAN rule, are probably best described within the PSEPT framework as *closo* Co_4L_2 octahedra in which each main group fragment contributes three electrons to a 6-skeletal pair count.

The unsymmetrical disposition of the two phosphinidene ligands gives rise to an asymmetrical butterfly core, as reflected in the four Co—Co bond lengths between the hinge and wing-tip Co atoms. The shortest Co—Co bond distance (Co(1)—Co(2) = 2.4585(4) Å (**1a**), 2.4889(5) Å (**1b**)) lies between the two cobalt atoms supporting both μ_3-phosphinidene ligands, and is in the range of bond lengths found in cobalt carbonyl butterfly clusters of the type $[Co_4(CO)_{10}L_2]$ (L_2 = alkyne) (14). The longest bond (Co(2)—Co(4) = 2.6670(5) Å (**1a**), 2.6474(5) Å (**1b**)) is that between the wing-tip cobalt atom bound to only one μ_3-phosphinidene ligand (Co(4)) and the hinge cobalt atom bound to both μ_3-phosphinidene ligands (Co(2)). The other two Co—Co bond lengths are intermediate between the previous two (Co(1)—Co(3) = 2.5494(5) Å (**1a**), 2.5741(6) Å (**1b**); Co(3)—Co(4) = 2.5770(5) Å (**1a**), 2.5944(5) Å (**1b**)). The hinge Co(2)—Co(3) bond length (2.5566(4) Å (**1a**), 2.5547(5) Å (**1b**)) is a typical one, but the nonbonding wing-tip Co(1)—Co(4) distance (3.487 Å (**1a**), 3.467 Å (**1b**); dihedral angle = 103.5° (**1a**), 101.5° (**1b**)) is shorter than in the butterfly carbonyl clusters $[Co_4(CO)_{10}L_2]$ (L_2 = alkyne) (3.541–3.575 Å) (14) and longer than in the cyclopentadienyl butterfly molecules $[(\eta^5\text{-}C_5H_5Co)_4L_2]$ (L_2 = alkyne) (3.306–3.401 Å) (15). From the values of the Co—P bond distances it is clear that one stands out. This is the bond between the hinge Co atom bound to both phosphorus atoms and the phosphorus atom located between the wings (Co(2)—P(2) = 2.2118(7) Å (**1a**), 2.2258(8) Å (**1b**)), which is considerably longer than the remainder of the Co—P bond distances undoubtedly because this phosphorus atom is bound to an open Co_3 face with one nonbonding Co···Co contact. Although the two clusters **1a** and **1b** are very similar, all of the Co—P distances in **1a**, with the exception of Co(2)—P(2), are slightly longer than the corresponding values in **1b**, possibly because of the steric requirements imposed by the more bulky TMP ligand. Overall, the Co—P bond lengths lie within the range of values found in other cobalt μ_3-phosphinidene complexes (11, 13, 18). The N—P bond distances do not differ significantly from those in related μ_3-(amino)phosphinidene complexes, where π donation from the nitrogen atom to phosphorus atom is proposed (11, 13, 18). Accordingly the sums of angles at both nitrogen atoms indicate a planar environment (358.5° and 358.7° (**1a**), 359.9° and 359.3° (**1b**)).

The X-ray structure of the cluster $[Co_4(CO)_6(\mu\text{-}CO)_2\{\mu_3\text{-}P(TMP)\}_2]$ (**3a**) is shown in Fig. 4 and selected bond distances and angles are given in Table 3. This molecule consists of a tetrahedral Co_4 metallic core with two μ_3-(amino)phosphinidene ligands on two faces of the tetrahedron. There are two Co atoms that bear two terminal carbonyl ligands and two bound to only one terminal carbonyl ligand. Another two bridging carbonyl ligands are present in the molecule, sharing one Co atom, for a total electron count of 60 e. The Co_4 tetrahedral framework is distorted with one Co—Co bond distance being clearly shorter (Co(2)—Co(4) = 2.3847(4) Å) than the others, which range from 2.5323(4) to 2.6797(3) Å. The shortest bond is associated with the two cobalt atoms that share a bridging carbonyl ligand and a μ_3-phosphinidene ligand. The remainder of the values, except for the longest one (Co(1)—Co(4) = 2.6797(3) Å), are close to the Co—Co distances in the related tetrahedral μ_3-phosphinidene clusters $[Co_4(\mu_3\text{-}PPh)_4(PPh_3)_4]$ (2.571(3)–2.586(2) Å) (19) and $[Co_4(\mu_3\text{-}PPh)_4(PPh_3)_4][CoCl_3(PPh_3)]$ (2.527(6)–2.611(6) Å) (19), the only other reported tetrahedral phosphinidene Co_4 compounds. The Co—P bond lengths are within the normal range for μ_3-phosphinidene compounds (2.1412(5)–2.1788(5) Å) (11, 13, 18). The environments around both nitrogen atoms are close to planarity (357.97° and 357.23°) and the P—N bonds are typical of μ_3-(amino)phosphinidene clusters (1.658(2) and 1.664(1) Å) (11, 13, 18).

Fig. 4. ORTEP diagram of $[Co_4(CO)_6(\mu\text{-}CO)_2\{\mu_3\text{-}P(TMP)\}_2]$ (**3a**). Hydrogen atoms have been omitted and thermal ellipsoids are shown at the 50% level.

An examination of structural parameters for the entire set of clusters that were structurally characterized, namely **1a**, **1b**, **2**, and **3b**, reveals some interesting trends. Thus, for example, the average Co—Co bond length decreases from **2**, which has a 64 e count and square Co_4 framework (Co—Co avg. 2.618 Å), to **1a** (2.562 Å) and **1b** (2.572 Å), which have 62 e counts and butterfly Co_4 cores, to **3a** (2.553 Å), with a 60 e count and tetrahedral Co_4 skeleton. The metal–metal connectivity (i.e., the number of M—M bonds per metal atom) increases in the opposite sense from two in cluster **2** to two and three in clusters **1a** and **1b** to three in cluster **3b**. The difference in these values is small for the compounds **1a**, **1b**, and **3a**, where the phosphinidene ligands are of the μ_3-type. In the case of the tetrahedral compound **3a**, the average Co—Co bond length is rather similar to that found in the non-carbonyl cluster compounds $[Co_4(\mu_3\text{-}PPh)_4(PPh_3)_4]$ (2.578 Å) (19) and $[Co_4(\mu_3\text{-}PPh)_4(PPh_3)_4]^+$ (2.565 Å) (19), but longer than that in the homoleptic carbonyl $[Co_4(CO)_{12}]$ (2.490 Å) (20), where there are no ligands capping a face of the tetrahedral core. A shortening of the average Co—P bond distance is observed as expected when changing the coordination number of phosphorus from μ_4- (2.235 Å in **2**) to μ_3-phosphinidene (2.174 Å in **1a**, 2.159 Å in **1b**, and 2.159 Å in **3a**), these values being close to those in $[Co_4(\mu_3\text{-}PPh)_4(PPh_3)_4]$ (2.164 Å) (19) and $[Co_4(\mu_3\text{-}PPh)_4(PPh_3)_4]^+$ (2.160 Å) (19).

Conclusion

We have succeeded in synthesizing an entire family of tetracobalt clusters, namely 64 e square $[Co_4(CO)_{10}(\mu_4\text{-}PN\text{-}i\text{-}Pr_2)_2]$ (**2**), 62 e butterfly $[Co_4(CO)_9(\mu_3\text{-}PN\text{-}i\text{-}Pr_2)_2]$ (**1b**), and 60 e tetrahedral $[Co_4(CO)_8(\mu_3\text{-}PN\text{-}i\text{-}Pr_2)_2]$ (**3b**) via the reaction of $K[Co(CO)_4]$ and the dichloroaminophosphine $PCl_2N\text{-}i\text{-}Pr_2$. When the amino group is 2,2,6,6-tetramethylpiperidinyl (TMP), the intermediate observed en route to 62 e $[Co_4(CO)_9\{\mu_3\text{-}P(TMP\}_2]$ (**1a**) is the binuclear μ-P(TMP) phosphinidene complex $[Co_2(CO)_6\{\mu\text{-}P(TMP)\}]$. The clusters **1b**, **2**, and **3b** bearing diisopropylaminophosphinidene ligands undergo facile interconversion via a sequence of 2 e additions or eliminations of carbon monoxide. Similarly, **1a** and **3a** can be interconverted. The skeletal frameworks of this family of clusters are all in accord with the predictions of the EAN rule and provide a textbook illustration not only of electron count, structure, and bonding relationships within the 60–64 e regime, but also of the interconversion between structures through 2 e ligand gain or loss.

Experimental section

All procedures were carried out under a nitrogen atmosphere using standard Schlenk techniques or a glovebox. THF was distilled from Na–benzophenone and hexane was purified using solvent purification columns containing alumina and copper catalyst. Deuterated chloroform was vacuum distilled from P_2O_5. The compound $[Co_2(CO)_6\{\mu_2\text{-}P(TMP)\}]$ was prepared and used in situ from the reaction of $K[Co(CO)_4]$ and $PCl_2(TMP)$ (11). $PCl_2(N\text{-}i\text{-}Pr_2)$ and $PCl_2(TMP)$ were prepared according to published procedures (21) as was KC_8 (22) and $[Co_2(CO)_8]$ was purchased from Fluka. The NMR spectra were recorded on a Bruker Avance 400 spectrometer at 400 MHz (^1H) or 161.975 ($^{31}P\{^1H\}$).

$[Co_4(CO)_8(\mu\text{-}CO)\{\mu_3\text{-}P(TMP)\}_2]$ (1a)

A solution of $[Co_2(CO)_6\{\mu_2\text{-}P(TMP)\}]$ (1.46 mmol) in hexane (15 mL) was stirred at room temperature for 36 h. The solution was filtered, concentrated to 3 mL, and cooled to –40 °C, yielding **1a** as black needles (0.24 g, 40%). Spectral data for **1a**: IR (hexane, ν(CO), cm^{-1}): 1862 w, 2017 m, 2028 s, 2067 w. ^1H NMR (C_6D_6, δ): 1.34 (s, 12H, CH_2), 1.60 (s, 24H, Me). ^{31}P NMR (C_6D_6, δ): 471.8 (bs), 542.4 (bs). Anal. calcd. for $C_{27}H_{36}Co_4N_2O_9P_2$ (830.27): C 39.06, H 4.37, N 3.37; found: C 38.53, H 3.99, N 3.06.

$[Co_4(CO)_8(\mu\text{-}CO)(\mu_3\text{-}PN\text{-}i\text{-}Pr_2)_2]$ (1b)

A solution of $[Co_4(CO)_8(\mu\text{-}CO)_2(\mu_4\text{-}PN\text{-}i\text{-}Pr_2)_2]$ (**2**) (1.46 mmol, prepared in situ) in toluene (10 mL) was heated at 50 °C under vacuum for 14 h. Afterwards, the solvent was removed and the residue was extracted with hexane (10 mL). The solution was concentrated to approximately 4 mL and cooled to –40 °C, yielding **1b** as black crystals (0.19 g, 35%). Spectral data for **1b**: IR (hexane, ν(CO), cm^{-1}): 1866 w, 1990 w, 2009 m, 2026 s, 2062 w. ^1H NMR (C_6D_6, δ): 1.15 (d, ^3J(HH) = 6.55 Hz, 24H, CHMe_2), 3.86 (sept., ^3J(HH) = 6.55 Hz, 4H, CHMe$_2$). ^{31}P NMR (C_6D_6, δ): 526. Anal. calcd. for $C_{21}H_{28}Co_4N_2O_9P_2$ (750.14): C 33.62, H 3.76, N 3.73; found: C 33.56, H 3.51, N 3.64.

$[Co_4(CO)_8(\mu\text{-}CO)_2(\mu_4\text{-}PN\text{-}i\text{-}Pr_2)_2]$ (2)

$[Co_2(CO)_8]$ (0.50 g, 1.46 mmol) and KC_8 (0.45 g, 0.33 mmol) were stirred in THF (20 mL) for 45 min. The solution was filtered and added dropwise (10 min) to a solution of PCl_2(N-i-Pr_2) (0.21 mL, 1.46 mmol) in THF (10 mL) at room temperature. When the addition was complete, the solvent was removed. The residue was extracted with hexane (10 mL), concentrated to approximately 4 mL, and cooled to –40 °C, yielding **2** as black crystals (0.27 g, 48%). Spectral data for **2**: IR (hexane, ν(CO), cm^{-1}): 1867 w, 2000 m, 2030 s, 2089 w. ^1H NMR ($CDCl_3$, δ): 1.42 (d, ^3J(HH) = 6.92 Hz, 24H, CHMe_2), 3.86 (sept., ^{3}(HH) = 6.92 Hz, 4H, CHMe$_2$). ^{31}P NMR ($CDCl_3$, δ): 258. Anal. calcd. for $C_{22}H_{28}Co_4N_2O_{10}P_2$ (778.15): C 33.96, H 3.63, N 3.60; found: C 33.57, H 3.57, N 3.41.

$[Co_4(CO)_6(\mu\text{-}CO)_2\{\mu_3\text{-}P(TMP)\}_2]$ (3a)

A solution of $[Co_2(CO)_6\{\mu\text{-}P(TMP)\}]$ (1.46 mmol) in toluene (10 mL) was heated at 50 °C under vacuum for 16 h. Afterwards, the solvent was removed and the residue was extracted with hexane (10 mL). The solution was concentrated to 3 mL and cooled to –40 °C, yielding **3a** as black crystals (0.22 g, 38%). Spectral data for **3a**: IR (hexane, ν(CO), cm^{-1}): 1872 w, 2005 s, 2016 w, 2026 w, 2038 w. ^1H NMR (C_6D_6, δ): 1.19 (s, 12H, CH_2), 1.55 (s, 24H, Me). ^{31}P NMR (C_6D_6, δ): 521. Anal. calcd. for $C_{26}H_{36}Co_4N_2O_8P_2$ (802.26): C 38.93, H 4.52, N 3.49; found: C 38.43, H 4.23, N 3.06.

$[Co_4(CO)_6(\mu\text{-}CO)_2(\mu_3\text{-}PN\text{-}i\text{-}Pr_2)_2]$ (3b)

A solution of $[Co_4(CO)_8(\mu\text{-}CO)_2(\mu_4\text{-}PN\text{-}i\text{-}Pr_2)_2]$ (**2**) in C_6D_6 was introduced into an NMR tube sealed with a valve. The atmosphere was removed and the tube was heated at 50 °C. After 16 h, the ^{31}P and ^1H NMR spectra showed that the starting product **2** had disappeared and resonances for **1b** were observed. The sample was heated for another 16 h and a 1:1 mixture of **1b** and **3b** was observed. NMR data for **2** (C_6D_6, δ): ^1H: 1.10 (d, ^3J(HH) = 6.84 Hz, 24H, CHMe_2), 3.80 (sept., ^3J(HH) = 6.84 Hz, 4H, CHMe$_2$). ^{31}P: 257.0. NMR data for **1b** (C_6D_6, δ): ^1H: 1.15 (d, ^3J(HH) = 6.69 Hz, 24H, CHMe_2), 3.93 (sept., ^3J(HH) = 6.69 Hz, 4H, CHMe$_2$); ^{31}P: 527.1 broad. NMR data for **3b** (C_6D_6, δ): ^1H: 1.07 (d,^3J(HH) = 6.76 Hz, 24H, CHMe_2), 3.69 (sept., ^3J(HH) = 6.76 Hz, 4H, CHMe$_2$); ^{31}P: 523.8.

X-ray crystallographic study

Crystals of compounds **1a**, **1b**, **2**, and **3a** were mounted on glass fibres. Intensity data were collected on a Siemens SMART CCD diffractometer using graphite-monochromated Mo K_α radiation. Unit cells were determined from randomly selected reflections obtained using the SMART CCD automatic search, centre, index, and least-squares routines. Integration was carried out using SAINT and empirical absorption corrections were applied using SADABS. The structure solution and refinement were carried out using the SHELXTL 5.1 suite of programs. Initial solutions were ob-

Phase behaviour and dynamics in ethylammonium halide salts[1]

Christopher I. Ratcliffe

Abstract: ^{1}H and ^{2}H NMR spin-lattice relaxation times (T_1) have been studied as a function of temperature to obtain activation energies for the threefold reorientations of CH_3 groups (Ea = 22.83, 18.95, and 18.39 kJ mol^{-1}) and NH_3 groups (Ea = 47.64, 45.31, and 28.74 kJ mol^{-1}) in the β-phases of ethylammonium chloride, -bromide, and -iodide, respectively, for comparison with barriers determined from Raman torsional frequencies. T_1, ^{2}H NMR lineshapes, and DSC studies have been used to clarify the existence of a $\beta \rightarrow \alpha$ phase transition above room temperature in all three salts, and the absence of a transition at low temperature. ^{2}H NMR lineshape analysis indicates a rapid *n*-fold (probably fourfold) reorientation of the whole molecule in the α-phase. This motion occurs about an axis in the molecular CCN mirror plane in the bromide and iodide. In the chloride, the axis is in the plane perpendicular to the bisector of the DCD bond angle.

Key words: ethylammonium halides, solid state ^{1}H and ^{2}H NMR, molecular dynamics, rotational barriers, phase behaviour.

Résumé : On a mesuré les temps de relaxation spin-réseau (T_1) en RMN du ^{1}H et du ^{2}H, en fonction de la température, dans les phases β respectivement du chlorure, du bromure et de l'iodure d'éthylammonium afin de déterminé les énergies d'activation des réorientations ternaires des groupes CH_3 (Ea = 22,83, 18,95 et 18,39 kJ mol^{-1}) et des groupes NH_3 (Ea = 47,64, 45,31 et 28,74 kJ mol^{-1}) et de pouvoir les comparer avec les valeurs des barrières déterminées à partir des fréquences de torsion Raman. On a utilisé les valeurs des T_1, les formes des raies en RMN du ^{2}H et des études d'analyse calorimétrique différentielle (ACD) pour clarifier l'existence d'une transition de phase $\beta \rightarrow \alpha$ au-dessus de la température ambiante, dans chacun des trois sels, et de l'absence d'une transition à basse température. L'analyse de la forme des raies de la résonance du ^{2}H indique qu'il se produit une réorientation rapide, probablement quaternaire, de l'ensemble de la molécule dans la phase α. Dans le bromure et l'iodure, ce mouvement se produit autour d'un axe dans le plan miroir CCN. Dans le chlorure, l'axe se trouve dans un plan perpendiculaire à la bissectrice de l'angle de liaison DCD.

Mots clés : halogénures d'éthylammonium, RMN du ^{1}H et du ^{2}H à l'état solide, dynamique moléculaire, barrières à la rotation, comportement des phases.

[Traduit par la Rédaction]

Introduction

The ethylammonium halide salts $C_2H_5NH_3^+X^-$, where X = Cl, Br, or I, form a series that is unusual in that all three salts have the same crystal structure, generally referred to as the β-phase, at room temperature and below (1–3). The NH_3^+ group is surrounded by and has hydrogen-bonding interactions with three halide ions in a roughly threefold arrangement. This environment gives rise to a fairly large external contribution to the barrier to rotation about the threefold axis of the group. The fact that the structures are alike thus makes possible a fairly direct comparison of the hydrogen-bonding strengths from measurements of the rotational barriers. In previous work, barriers were determined from values of the torsional mode frequencies obtained from IR and Raman spectroscopy (4). Another method, employed in the current study, is to obtain activation energies for the NH_3^+ and CH_3 group reorientations by measuring NMR spin-lattice relaxation times (T_1) as a function of temperature. It is then of great interest to be able to compare the NMR activation energies with the IR and Raman barrier values, since it is found that when hydrogen bonding occurs there is generally an appreciable difference between the two, which might be explained by a larger sixfold term in the barrier potential (5–7). The strengths of the external interactions of each group are also reflected in the results of high pressure Raman studies of the bromide up to several kilobars (8), where the torsional mode and barrier were found to have a strong pressure dependence for CH_3 (in a soft environment), but not for NH_3 (in a hard environment).

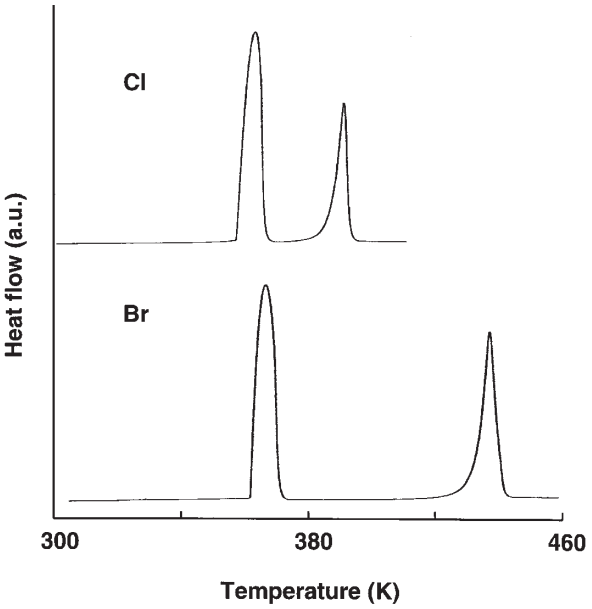
Also of interest are the phase transitions, to which NMR is often quite sensitive, and the changes in the dynamics of the ethylammonium ion associated with these. ^{2}H NMR lineshape studies are particularly useful with regard to the latter. There seems to be some conflicting information regarding phase transitions in the chloride and bromide. Phase transitions from the room temperature β-phase to a high temperature α-phase in the bromide and iodide are well-established (3, 9, 10), though a similar transition for the chloride has only been reported in one study (10) and was not detected in DSC and TGA studies (11, 12). IR and Raman studies of all three salts (4, 8–10, 13, 14) and NQR studies of the bromide and iodide (15) all seem to indicate that the room temperature β-phase is stable down to liquid nitrogen temperatures. However, the DSC results of Rao et al. (10) on the chloride and bromide show thermal events at 221 and 236 K, respectively, which they suggest are phase transitions. They also reported a larger thermal change in the chloride at 345 K, which they interpreted as a $\beta \rightarrow \alpha$ transition, though other studies have suggested that the chloride remains in the β-phase up to its melting point at 369 K (3, 9).

Experimental

The salts were prepared by neutralization of a solution of ethylamine, $C_2H_5NH_2$ (Aldrich) or $C_2D_5NH_2$ (MSD Isotopes), by the appropriate acids followed by evaporation to dryness and several hours pumping under vacuum. The deuterated materials $C_2H_5ND_3X$ were prepared by dissolving the $C_2H_5NH_3X$ salts in D_2O (MSD Isotopes) and evaporating to dryness and repeating this twice.



^{1}H T_1 measurements on $C_2H_5NH_3I$ and $C_2H_5ND_3I$ were obtained at 31 MHz using a Bruker BKR-322s spectrometer and temperature control as previously described (16, 17). All other measurements of ^{1}H T_1 of $C_2H_5NH_3^+$ chloride and bromide at 18 MHz and ^{2}H T_1 of $C_2H_5ND_3^+$ in all three salts at 9.2 MHz were obtained on a Bruker SXP spectrometer and electromagnet with temperature controlled in an Andonian cryostat. The ^{1}H T_1 values were generally measured with a $\pi - \tau - \pi/2$ pulse sequence. For $T_1 > 3$ s, a saturation sequence ($(\pi/2)_n - \tau - \pi/2$) was used. The ^{1}H spin-lattice relaxation was quite exponential on the low temperature side of the low-temperature T_1 minimum in all cases, but for the chloride and bromide around the minimum and to higher temperatures there was marked nonexponential behaviour (in both cases in the approximate temperature range 220–295 K). This problem became much less pronounced as T_1 began to decrease again towards the high-temperature T_1 minimum. In the problem region, a nominal "T_1" was estimated from a linear fit to the initial magnetization recovery, over about $2 \times T_1$, since this gave less scatter of points than estimates made from null times or forced linear fits over longer times.

To obtain more reliable values of the activation energies for the $-NH_3^+$ motion, without the complications of an overlapping relaxation process for the $-CH_3$ group and the nonexponential relaxation behaviour described above, ^{2}H T_1 measurements were obtained for the $C_2H_5ND_3^+$ salts. $\pi/2 - \tau - \pi/2$ or $\pi - \tau - \pi/2$ pulse sequences were used followed by generation of a quadrupolar echo using a 90° phase-shifted $\pi/2$ pulse after a delay of ~40 μs. It is known from T_1 measurements based on anisotropic ^{2}H lineshapes that T_1 values vary slightly across the spectrum (18). One assumes that this small variation is averaged in obtaining a T_1 from measurements of the quadrupolar echo amplitudes. Indeed, in the experiments reported here the measured relaxation was found to be exponential within experimental error. In both $C_2H_5NH_3Cl$ and $C_2H_5ND_3Cl$, the T_1 measurements were restricted somewhat at the high-temperature end approaching the melting point, by the appearance of a much longer free-induction decay component. This might be associated with the suggested phase transition at ~345 K (10) or possibly due to a trace of highly concentrated solution as the salt is very hygroscopic and difficult to dry.

^{2}H NMR lineshapes were obtained on a Bruker CXP-180 NMR spectrometer at 27.63 MHz using quadrupole echo techniques (19), with 90° pulse lengths of 2.7–3.0 μs and recycle times of 0.25–60 s, using a variable-temperature N_2 gas-flow probe with a Bruker B-VT-1000 temperature controller.

DSC traces for the chloride and bromide were obtained using a Tian-Calvet (Setaram model BT) heat flow calorimeter.

Fig. 1. DSC plots for $C_2H_5NH_3Cl$ and $C_2H_5NH_3Br$.

Results and analysis

Calorimetry

Figure 1 shows the DSC scans for the chloride and bromide above room temperature. Both are very similar in appearance and show two major thermal events that correspond to the known $\beta \rightarrow \alpha$ and melting transitions. The enthalpies for the $\beta \rightarrow \alpha$ transitions are almost identical. A comparison of these and previous results is given in Table 1. A scan on the chloride starting at 200 K showed no trace of the thermal event at 221 K reported earlier (10), also the $\beta \rightarrow \alpha$ and melting temperatures for the chloride in the current study are also significantly higher, suggesting that perhaps the earlier measurements were influenced by impurities.

[a]Values in brackets are enthalpies (kJ mol^{-1}) for the phase change.
[b]Values on warming and cooling.

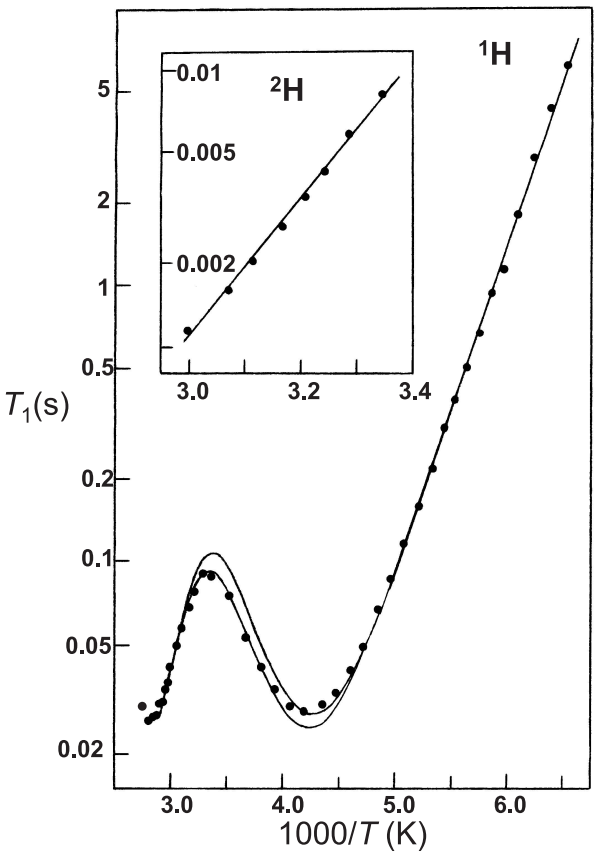
^{1}H and ^{2}H spin-lattice relaxation

Log plots of T_1 vs. 1000/T are shown in Figs. 2–4. All three $C_2H_5NH_3^+$ salts show two overlapping relaxation processes corresponding to threefold reorientation of NH_3^+ and CH_3 and the results for the deuteriated materials very clearly show that NH_3^+ reorientation is the higher temperature process, as expected based on the barriers calculated from the Raman torsional frequencies (4).

The BPP theory (20) as extended and modified by others (21, 22) forms the basis for understanding the ^{1}H T_1 results. Relaxation is effected by reorientation of the internuclear dipole–dipole vectors in the applied field. The general expression for threefold reorientation of an equilateral triangle of protons is given by

$$[1] \quad (1/T_1)_{H-H} = (9/20)(\gamma_H^4\hbar^2/r^6_{H-H})\{\tau_c/(1 + \omega_H^2\tau_c^2) + 4\tau_c/(1 + 4\omega_H^2\tau_c^2)\}$$

where γ_H = ^{1}H magnetogyric ratio, $\hbar = h/2\pi$, $r_{H\text{-}H}$ = interproton distance, ω_H = ^{1}H Larmor frequency, and τ_c = correlation time for the motion. τ_c is generally assumed to have an Arrhenius dependence on the activation energy for the motion (Ea) and on temperature (T)



$$[2] \quad \tau_c = \tau_c^0 \exp(Ea/RT)$$

For NH_3^+, the expression must be modified to account for the ^{14}N–^{1}H dipolar interactions, which make a small but significant contribution to the relaxation (about 14% at the T_1 minimum (23)). The effective T_1 is given to a good approximation by

$$[3] \quad 1/T_1 = [1/T_1]_{H\text{-}H} + [1/T_1]_{N\text{-}H}$$

where the first term is the same as eq. [1] and the modifying term is given by

[4] $$[1/T_1]_{N\text{-}H} = [2\gamma_H^2\gamma_N^2\hbar^2 g(\Delta)/r^6_{N\text{-}H}]\{\tau_c/(1 + \omega_H^2\tau_c^2)\}$$

[5] $$g(\Delta) = (\sin^2(2\Delta) + \sin^4\Delta)$$

and Δ = the angle between the N-H vector and the threefold rotation axis.

T_1 minima are predicted from eq. [1] when $\omega_H\tau_c = 0.616$ and, assuming $\Delta = (180 - Td)$ for the NH_3^+ group (where Td = tetrahedral angle), from eq. [4] when $\omega_H\tau_c = 0.663$ (23). Assuming values of C-H = 1.10 Å and N-H = 1.04 Å and tetrahedral bond angles, one can calculate theoretical T_1 minima. In the case of $C_2H_5NH_3^+$, the motion of three protons effects relaxation of all eight protons (via spin diffusion) and hence, for CH_3 motion at 31 MHz one calculates 48.00 ms and for $-NH_3^+$ motion 29.33 ms. Equivalent empirical values are 52–63.5 ms (for CH_3) (24) and 32–38 ms (for NH_3) (25). It is almost invariably found that the calculated values are less than experimental values. Thus, the observed depths of the T_1 minima for the iodide (51 and 38 ms) are quite consistent with threefold reorientation of CH_3 and NH_3^+, respectively. The minimum of 22 ms observed for NH_3^+ for the bromide at 18 MHz, which scales to 38 ms at 31MHz, is also consistent. Although accurate values for the minima for CH_3 for the chloride and bromide cannot be obtained because of the problems with nonexponential relaxation, the results are nevertheless quite close to the expected value (51 ms converts to 30 ms at 18 MHz). ^{1}H T_1 measurements have previously been obtained for ethylammonium nitrate (26) and ethylammonium tetrabromomercurate(II) (27). In the former, CH_3 group reorientation again occurs at lower temperatures than for NH_3 and the T_1 minimum for $C_2H_5ND_3NO_3$ is consistent with the numbers above for CH_3 after correction for frequency and spin diffusion. The $HgBr_4$ salt is different in that the relaxation is clearly due to whole molecule reorientation.

Deuterium spin-lattice relaxation is effected by reorientation of the ^{2}H nuclear quadrupolar coupling tensor in the applied field. For the threefold reorientation of a $-ND_3^+$ group, the relaxation behaviour can be expressed as (22, 28, 29)

[6] $$(1/T_1)_D = (9\pi^2/40)C_Q^2(1 + \eta^2/3)g(\Delta)\{\tau_c/(1 + \omega_D^2\tau_c^2) + 4\tau_c/(1 + 4\omega_D^2\tau_c^2)\}$$

where C_Q and η are the quadrupole coupling constant and asymmetry parameters for the deuteron when the ND_3^+ group is static. Strictly speaking, Δ is the angle between the threefold rotation axis and the unique component of the electric field gradient tensor (q_{zz}), which in the present case is reasonably assumed to be along the N—D bond. Based on the static ^{2}H quadrupolar coupling constants observed for the bromide and iodide at low temperatures (see the following) the T_1 minimum calculated using eq. [6] is ~0.485 ms.

Table 3. Comparison of NMR activation energies and potential barriers calculated from Raman torsional modes (cm^{-1}).

Group	Halide	V_3	Δν	$V_3 - 0.5\Delta\nu$	Ea	$V_3 - 0.5\Delta\nu$ – Ea
NH_3	Cl	4534	464	4297	3980	317
	Br	3948	441	3728	3785	–57
	I	3255	399	3056	2401	655
CH_3	Cl	2158	308	2004	1908	96
	Br	2068	301	1918	1583	335
	I	1895	287	1752	1518	234

Note: V_3 = sum of internal and external barriers. Zero point energy estimated at half the fundamental Raman B_g torsional frequency Δν/2. From Raman data at 77 K.

This compares reasonably well with experimental values 0.63 ms (bromide) and 0.56 ms (iodide).

All the T_1 results for the β-phase of the iodide can be fit consistently with one set of parameters (Table 2). Not surprisingly, however, there are difficulties for the chloride and bromide for those results that are most affected by the nonexponential behaviour, as these points do not fall on the expected BPP curves. Consequently the analysis for the chloride and bromide proceeded as follows: (*i*) the results on the low-temperature slopes of the plots ($\omega_H\tau_c >> 1$) are well-behaved and give a good linear correlation from which an activation energy for CH_3 reorientation can be determined; (*ii*) the ^2H results are also well-behaved and give activation energies for NH_3 reorientation; (*iii*) these Ea parameters were then used to calculate the solid curves shown in the ^1H T_1 plots with the constant factors simply adjusted to give the T_1 minima shown. Thus, although there is clearly a problem in the mid-region, good values for the activation energies can be obtained. Values of Ea are given in Table 2.

Phase behaviour from the T_1 results

The bromide and iodide show very sudden and drastic increases (greater than two orders of magnitude) in their ^1H T_1 between 364 and 370 K and 324 and 335 K, respectively, corresponding quite well with the $\beta \rightarrow \alpha$ phase transition temperatures from DSC and indicative of a dramatic change in the dynamics of the ethylammonium ion. The chloride is less definitive, though there is a small but rapid increase between 357 and 367 K. (The transition temperatures indicated are listed in Table 1 for comparison). An estimate of the activation energy for a motion in the α-phase of $C_2H_5NH_3I$ (Ea = 8.8 ± 0.5 kJ/mol) was obtained from the three T_1 points obtained (Fig. 4). This is significantly smaller than for the CH_3 and NH_3 group motions in the β-phases and it is clear that the motion is rapid since the points are on the high-temperature slope of the relaxation curve.

It is interesting to note that the relaxation begins to show nonexponentiality at ~210 K, which happens to be just a little below the small thermal anomalies seen by Rao et al. (10). This could just be coincidence or some connection might be inferred. Although it is not possible to offer any concrete explanation for this behaviour, one possibility that comes to mind is that trace water may cause some unusual phase behavior. This is not unprecedented and one example is the case of tetramethylammonium chloride (30). However, a counter argument is the absence of thermal events in this region in the DSC scan of the chloride.

Barriers vs. activation energies

The comparison between NMR Ea values and barriers calculated from torsional mode frequencies is summarized in Table 3. The parameters being compared are ($V_3 - \Delta\nu/2$), which is the sum of the internal and external threefold potential barriers minus the zero point energy, estimated as half the Raman fundamental torsional frequency vs. Ea, the NMR activation energy. Overall, the values compare quite favourably and the general trends are reproduced. As can be seen from the differences, however, Ea is generally smaller (the only exception is a small negative value for NH_3 for the bromide). It is also clear that it would not be reasonable to make conclusions about the premise of sizeable sixfold terms in the potential in cases of strong hydrogen bonding, since the differences for CH_3, with no hydrogen bonding, are of the same magnitude as for NH_3. The barriers from torsional frequencies rely on models of the potential surface, which in the case of the ethylammonium halides is complicated by interactions between rotor groups on adjacent molecules. Furthermore, the torsional modes do not sample the

higher parts of the potential surfaces and thus, the calculated barriers reflect the quality of the model, whereas the Eas are a more direct measurement and should give a reasonable and more reliable value for the barrier (minus the zero point energy).

Dynamics in the α-phase

^{2}H NMR lineshapes

^{2}H NMR lineshapes are shown in Figs. 5–9. The lineshapes at *RT* and up to the $\beta \rightarrow \alpha$ transition for all three salts confirm that threefold reorientation of the CD_3 and ND_3 groups occur in the β-phases. They also show well-defined changes at the phase transition, from which it is possible to develop a dynamic model for the α-phase.

^{2}H NMR in solids is dominated by first-order perturbation of the Zeeman interaction by the nuclear quadrupolar coupling between the nuclear electric quadrupole moment and the electric field gradient (EFG), usually denoted by the tensor ***V*** (31, 32). There are two transitions, displaced equally on either side of the Zeeman frequency, whose frequencies depend on the orientation of the quadrupolar coupling tensor with respect to the magnetic field. The ^{2}H NMR powder lineshape has either two or three pairs of characteristic features (edges, shoulders, and peaks) separated by frequencies

Fig. 9. ^{2}H NMR lineshapes of $C_2H_5ND_3I$ showing the β-phase at 148 and 325 K and the α-phase at 327 K.

[7] $\Delta\nu_{zz} = 3C_Q/2$

[8] $\Delta\nu_{yy} = 3C_Q(1 + \eta)/4$

[9] $\Delta\nu_{xx} = 3C_Q(1 - \eta)/4$

where $\eta = (\Delta\nu_{yy} - \Delta\nu_{xx})/\Delta\nu_{zz}$. These $\Delta\nu_{ii}$ are proportional to the magnitudes of the principal axis components V_{ii} of the effective quadrupolar coupling tensor. These values can thus be read from the spectra and are important because they reflect the dynamic behaviour of the molecule. Any motion that causes a change in the orientation of the tensor can bring about changes in the ^{2}H NMR lineshape. Once the reorientational rates are about 10^7 jumps s^{-1} or faster (i.e., the fast motion limit, FML), the line takes on a shape that can be described by an averaged effective tensor. Such lineshapes are very sensitive to specific details of the motion and may be used to determine models for the molecular motion, since analytical expressions for the parameters governing the FML lineshapes are relatively easy to obtain (33–35). The orientation of the EFG tensor must first be described in a final reference frame in terms of the Euler angles α, β, γ

[10] $V(\alpha, \beta, \gamma) = \mathbf{R}V_{pas}\mathbf{R}^{-1}$

where **R** is the Euler angle rotation matrix describing the coordinate transformation and $\boldsymbol{V}_{pas}$ is the tensor in its principal axis system. The FML lineshape then represents the effective tensor $\boldsymbol{V}_{eff}$, which is the population weighted average of the tensor components in the final frame for all the sites (orientations) visited during the motion:

[11] $$\boldsymbol{V}_{eff} = \frac{\sum_{i=1}^{n} V_i(\alpha, \beta, \gamma)p_i}{\sum_{i=1}^{n} p_i}$$

with p_i the population factor of site *i*. Note that to understand and calculate the dynamically averaged lineshapes it is necessary to have some knowledge of the quadrupolar parameters for the starting tensor.

The observed lineshapes can now be examined in light of this background.

Parameters derived from the spectra at various temperatures are given in Table 4.

β-*Phase*

The β-phases of the $C_2H_5ND_3$ salts below 200 K show static ^{2}H lineshapes characteristic of axially symmetric tensors, but by room temperature (in fact by 268 K for the iodide) dynamic averaging produces FML axial tensor lineshapes reduced in width by a factor of ~3. This is quite characteristic for threefold reorientation of the ND_3 group. Both the bromide and iodide show ~0.4 kHz reduction in these FML linewidths over 50°, typically seen in all ^{2}H spectra and believed to be due to additional averaging from small amplitude librational motions. The static tensor coupling constants for the bromide (173.9 kHz) and iodide (177.8 kHz) are in agreement with a value of 168–177 kHz measured for the chloride by NQR at 77 K (36).

For the $C_2D_5NH_3$ salts at room temperature the CD_2 group is effectively static and the nonaxially symmetric tensors of its two D give rise to the broad component of the lineshape, whereas threefold averaging of the CD_3 group produces an FML axial component, which is narrowed by a factor of ~3. The observed parameters are typical for both (32). Furthermore, the relaxation behaviour and intensities confirm this assignment: Long recycle times (~60 s) are required to observe the broad lineshape at its full intensity, in which case a 2:3 (broad: narrow) intensity ratio is observed. If a short recycle time of 1 s is used instead, the narrow lineshape is observed selectively, since the dynamics of the CD_3 group make its ^{2}H T_1 considerably shorter.

α-*Phase*

Of greater interest, however, is that the ^{2}H NMR gives information about the behaviour at and above the $\beta \rightarrow \alpha$ phase transition: Over a very short temperature range, the $C_2D_5NH_3$ lineshapes show some dramatic changes. The component owing to CD_2 narrows somewhat and becomes axial and the CD_3 component narrows (drastically in the cases of Br and I) and remains axial. Likewise the $C_2H_5ND_3$ lineshapes also narrow, though much less dramatically, and remain axial, over a very short temperature range (The transition temperatures indicated by these changes are listed in Table 1). These all appear to be FML lineshapes as might have been anticipated from the T_1 results. One cooling run for the bromide showed a marked hysteresis, since reversion to the β-phase did not begin until about 353 K. The phase transition is accompanied by a sudden change in ^{2}H T_1: typically for the $C_2H_5ND_3^+$ salts the recycle times were changed from 0.5 s or less in the β-phase to 4–10 s in the α-phase, and in the

$C_2D_5NH_3^+$ salts, the recycle time could be decreased from 16 s or more in the β-phase to about 8 s in the α-phase.

^{2}H NMR lineshape analysis

The fact that the averaged lineshapes indicate axial tensors in the α-phase is a crucial observation, since it implies a new rotation of the whole molecule about an n-fold axis with $n > 2$. Following from the theory behind eqs.[10] and [11] for n-fold reorientation ($n > 2$), the averaged tensor components are given by

$$[12]\quad V_{xx}' = V_{yy}' = 0.5[(\cos^2\alpha\cos^2\beta + \sin^2\alpha)V_{xx} + (\sin^2\alpha\cos^2\beta + \cos^2\alpha)V_{yy} + (\sin^2\beta)V_{zz}]$$

$$[13]\quad V_{zz}' = (\cos^2\alpha\sin^2\beta)V_{xx} + (\sin^2\alpha\sin^2\beta)V_{yy} + (\cos^2\beta)V_{zz}$$

Note, this always gives an axial averaged tensor. For an axial starting tensor the dependence on α is lost ($V_{xx} = V_{yy}$ and $V_{zz} = -2V_{xx}$) and these equations reduce to

$$[14]\quad V_{zz}' = 0.5[3\cos^2\beta - 1]V_{zz}$$

$$[15]\quad V_{xx}' = V_{yy}' = -0.5V_{zz}$$

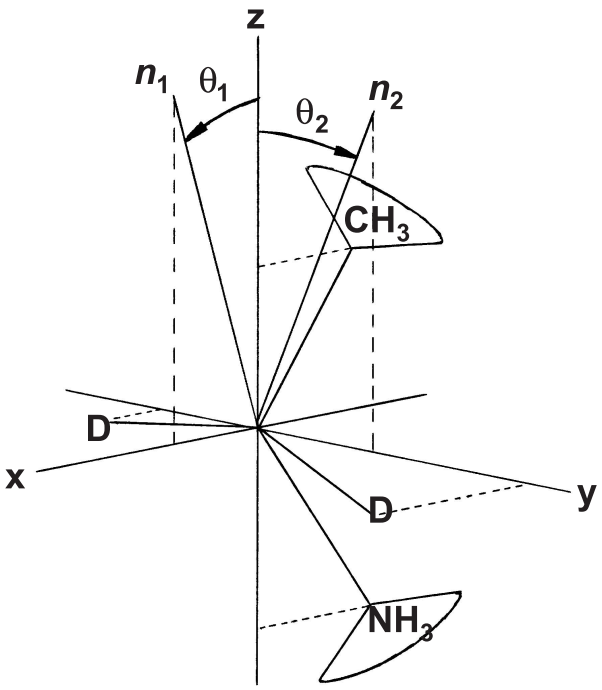
The threefold averaged CD_3 or ND_3 groups have axial averaged tensors in the β-phase with V_{zz} aligned along the threefold axis. Thus, we can readily calculate the β angles for the n-fold rotation in the α-phase using eq. [14] where β is the angle between the threefold axis of the CD_3 or ND_3 group and the n-fold axis (Table 5).

The CD_2 groups are more of a challenge since (*i*) the static β-phase tensors are nonaxial and (*ii*) the orientations of V_{xx} and V_{yy} are not determined by any symmetry elements. Thus, we must use the more general eqs. [12] and [13].

From eq. [13] we can derive

$$[16]\quad \cos^2\beta = [\cos^2\alpha(V_{yy} - V_{xx}) - V_{yy} \pm V_{zz'}]/[V_{zz} - V_{yy} + \cos^2\alpha(V_{yy} - V_{xx})]$$

From known starting and averaged tensor values we can then calculate the possible values of β for α = 0°–90°. The ranges of β values obtained turn out to be quite small (Table 5).



So far this determination of the β angles has made no assumptions; it is based strictly on the theoretical background. However, it will be seen from Table 5 that in some cases two solutions are possible and one must then decide which values are physically reasonable. Ultimately one wants to be able to decide on the position of the n-fold axis with respect to the molecule such that it is consistent both with the deter-

Table 5. β-Angles of the ^2H quadrupolar coupling tensors with respect to the *n*-fold rotation axis in the α-phases.

Ion	ND_3	CD_3	CD_2
Cl	**35.3** or 89.6	**41** or 72	38.7–39.3 or **74.3–77.0**
Br	**22.5**	**51.2** or 58.4	37.5–38.2 or **76.1–80.3**
I	**17.2**	**52.5** or **57.1**	36.9–37.6 or **77.3–82.6**

Fig. 10. Molecular reference frame and orientation of *n*-fold axes.

mined angles and the geometry of the molecule. In this regard, another important observation is that the averaged lineshapes of the CD_2 groups in the α-phase indicate that both C-D behave identically. There are two general situations where this can happen under an *n*-fold reorientation and here the description refers to the reference frame indicated in Fig. 10:

(1) Where the *n*-fold axis is in the plane containing the CCN backbone of the molecule, i.e., the xz reference plane.

(2) Where the *n*-fold axis is in the yz reference plane.

If the *n*-fold axis departs from either of these two planes then the two D of CD_2 will no longer behave identically. A special case of (1) is if the motion incorporates a rotation about the CD_2 bisector (coincident with the reference x axis), but with bond angles close to the tetrahedral angle (Td), this would require *n*-fold rotation of the tensors at an angle β ~ Td/2 (i.e., close to the magic angle) resulting in very considerable narrowing for CD_2, ND_3, and CD_3. In fact, the averaged CD_2 and ND_3 lineshapes are still quite large for all the salts and so this case can be ruled out. A special case of (2) is when the *n*-fold axis coincides with the reference y axis, but then CD_2 will have β ~ (90 – Td/2) and thus, reduce by a factor of ~2, which is significantly more than observed, and CD_3 and ND_3 will rotate in a plane that also produces a reduction factor of 2, which in their cases is not enough. So this case can also be ruled out. Another special case of both (1) and (2) is when the *n*-fold axis coincides with the reference z axis, but the CD_2 would then average by a factor of 2, which again is more than observed. Note model (2) will require CD_3 and ND_3 to have very similar β values, which means that the chloride might fit this model, but the bromide and iodide probably will not.

Table 6. Closest fits for the two models.[a]

Ion	θ	CCN angle	Inter-bisector angle
Cl	*16.0 (Model 2)*	*109.8*	*176.8*
	22.9 (Model 1)	103.7	160.0
Br	*17.0 (Model 1)*	*106.3*	*177.4*
	17.1 (Model 2)	108.4	159.0
I	*17.7 (Model 1)*	*110.3*	*180.0*
	9.08 (Model 2)	108.7	159.0

[a]The best fit for each salt is in italics.

It then remains to decide which of the determined angles (where there were more than one solution) are consistent with either of these models. In either model (1) or (2) one must first determine the angle θ by which the *n*-fold axis has to be rotated away from the reference z axis in either the xz or yz planes to give the correct β-angle for the CD_2 deuterons. One can then calculate other relevant angles and use two criteria to judge how well the model fits:

(*a*) The sum of the angle between the CD_3 axis and the z axis plus the angle between the ND_3 axis and the z axis when subtracted from 180° gives a value for the CCN bond angle. This must be quite comparable to the XRD-determined angle of 109.25°.

(*b*) The angle between the CD_2 bisector and the CCN bisector should be close to 180° if all bond angles are to be close to tetrahedral.

Table 6 gives the solutions with the closest fits for both models. It is quite clear that the bromide and iodide fit model (1) quite well but not model (2), whereas the chloride gives a much better fit with model (2). This suggests that the bromide and iodide probably have identical α-phases, while the chloride may be different. Alternatively, it could be that the structural arrangement of halide anions and molecular cations are basically the same in all three, but that packing constraints (largely owing to the different sizes of and interactions with the anions) force the molecules to orient differently.

Unfortunately, the crystal structures of the α-phases are not known. However, they are probably related to the room-temperature phases of methylammonium chloride (37) and -bromide (38) and of *n*-propylammonium chloride, -bromide, and -iodide (39), which are tetragonal (*P*4/*nmm*). The common feature of these structures is that the molecules sit on a fourfold crystal axis and must, therefore, be disordered. The mismatch of molecular and crystal site symmetries also usually means that the barrier to rotation is low and the disorder is dynamic. All have low-temperature phase transitions and the NH_3 rotational barriers in these phases are generally high, indicative of threefold H-bonding situations (40, 41). The structure of *n*-propylammonium chloride is monoclinic (*C*2/*m*) (42), as is ethylammonium bromide β-

© 2004 NRC Canada

phase at room temperature ($P2_1/m$) (3). Thus, the α-phases of the halides of ethylammonium may be structurally similar to the room-temperature phases of these other alkylammonium halides, in which case the rotational axis in the α-phase would be fourfold.

Conclusions

^{1}H and ^{2}H NMR and DSC studies have been used to study the phase behaviour and molecular dynamics in ethylammonium chloride, -bromide, and -iodide. It has been firmly established that all three salts exhibit a $\beta \rightarrow \alpha$ phase transition above room temperature and that the previously reported low-temperature transitions are probably related to impurities or trace water. It has been found that static or very slow motion prevails below 180 K, followed by reorientation, first of CH_3 then NH_3 groups, which are rapid by at least room temperature. After the $\beta \rightarrow \alpha$ phase transition, in addition to these group motions, the whole molecule rotates rapidly about an n-fold axis ($n > 2$), which by analogy with structures of other alkylammonium halides is probably fourfold. ^{2}H NMR lineshape analysis has allowed the determination of the orientation of this n-fold axis with respect to the molecular frame. In the cases of the bromide and iodide, the axis is in the molecular mirror plane, but in the chloride it is in the plane perpendicular to the bisector of the DCD bond angle. The activation energies for CH_3 and NH_3 group motions in the β-phase compare quite favourably with barriers determined from torsional mode frequencies. Eas for NH_3 reorientation reflect decreasing hydrogen bond strength in the order Cl > Br > I.

Acknowledgements

I would like to thank Dr. Paul Handa for obtaining the DSC scans of the chloride and bromide and Prof. B.A. Dunell in whose lab the ^{1}H T_1 measurements of the iodide were obtained.

Insertion of acetone molecules in the nanostructured tunnels of palygorskite[1]

Wenxing Kuang and Christian Detellier

Abstract: The insertion of acetone molecules in the nanostructured tunnels of palygorskite (PFl-1) was studied by thermal gravimetric analysis connected with mass spectrometry and ^{29}Si and ^{13}C solid-state NMR techniques. In comparison with palygorskite, new weight losses appear at 130 and 340 °C for palygorskite previously heated at 150 °C for 20 h then exposed to acetone for a week. Two types of water molecules occupy the palygorskite tunnels: weakly bound zeolitic water and structural water molecules coordinated to Mg(II) cations at the edge of the octahedral sheets. Acetone molecules that intercalate in the nanostructured tunnels replace the zeolitic water and are H-bonded to structural water. The mass loss at 130 °C is accounted for by the release of structural water and acetone. The loss at 340 °C is due to the release of acetone molecules that coordinate directly to terminal cations in the nanostructured tunnels and to residual structural water. A nanostructured hybrid material, with a structure similar to the parent palygorskite, can be formed through the direct coordination of acetone molecules to the terminal cationic coordination sites in the nanostructured tunnels of palygorskite. There is evidence for the fixation of two different types of acetone on palygorskite: mobile acetone molecules on the external surface and acetone molecules more rigidly fixed inside the nanotunnels. The former ones are detected by the ^{13}C magic-angle spinning NMR experiment and can be easily removed by gentle heating at 60 °C, while the latter ones are detected by ^{13}C cross-polarization magic-angle spinning NMR. It is also demonstrated that nearly complete recovery of the original structure is achieved by exposing palygorskite previously dehydrated at 150 or 300 °C to acetone vapor at room temperature.

Key words: insertion, intercalation, nanostructured tunnels, palygorskite, acetone, nanocomposite materials, nanohybrid.

Résumé : Faisant appel à une analyse gravimétrique thermique reliée à de la spectrométrie de masse et à des techniques de RMN à l'état solide du ^{29}Si et du ^{13}C, on a étudié l'insertion de molécules d'acétone dans les tunnels nanostructurés de la palygorskite (PFl-1). Par comparaison avec la palygorskite, de nouvelles pertes de poids sont observées à 130 et à 340 °C pour de la palygorskite qui a déjà été portée à 150 °C, pendant 20 h, puis exposée à l'acétone pendant une semaine. Deux types de molécules occupent les tunnels de la palygorskite, de l'eau zéolitique faiblement liée et des molécules d'eau structurales coordinées aux cations Mg(II) à la périphérie des feuillets octaédriques. Les molécules d'acétone qui s'intercalent dans les tunnels nanostructurés remplacent l'eau zéolitique et sont rattachées à l'eau structurale par des liaisons hydrogènes. On peut expliquer la perte de masse à 130 °C par la perte d'eau structurale et d'acétone. La perte à 340 °C est due à la perte d'eau structurale résiduelle et de molécules d'acétone coordinées directement aux cations terminaux dans les tunnels nanostructurés. Un matériau hybride nanostructuré, ayant une structure similaire à celle de la palygorskite parente, peut se former par une coordination directe de molécules d'acétone aux sites de coordination cationiques terminaux dans les tunnels nanostructurés de la palygorskite. Il existe des données qui suggèrent la fixation de deux types différents d'acétone sur la palygorskite, des molécules d'acétone mobiles sur la surface externe et des molécules d'acétone fixées d'une façon plus rigide à l'intérieur des nanotunnels. Les premières sont détectées par l'expérience de RMN du ^{13}C avec rotation à l'angle magique et elles peuvent être facilement enlevées par un chauffage à 60 °C alors que le deuxième type est détecté par RMN du ^{13}C avec polarisation croisée à l'angle magique. On a aussi démontré que, une palygorskite qui aurait été déshydratée antérieurement à 150 ou 300 °C peut récupérer pratiquement complètement sa structure originale en l'exposant à de l'acétone à la température ambiante.

Mots clés : insertion, intercalation, tunnels nanostructurés, palygorskite, acétone, matériaux nanocomposites, nanohybride.

Introduction

Palygorskite is a naturally occurring, fibrous magnesium and aluminum silicate clay mineral with important sorptive, colloidal-rheological, and catalytic properties (1). It is a 2:1 phyllosilicate the hormite group that forms with sepiolite. In the past decades, the structure of palygorskite was studied by powder X-ray diffraction, TEM, IR, NMR, and Mössbauer spectroscopy. Two main structural models were proposed for palygorskite, i.e., monoclinic (2) and orthorhombic (3). In both models, talc-like tetrahedral-octahedral-tetrahedral

 doi: 10.1139/V04-130 © 2004 NRC Canada

(T-O-T) ribbons expand along the axis of the fibers, resulting in the fibrous morphology. Each T-O-T ribbon is connected to the next through an inverted Si-O-Si bond, which produces a staggered talc layer with a continuous tetrahedral sheet and a discontinuous octahedral sheet. Terminal cations (mainly Mg(II)) located at the edges of the ribbons complete their coordination shell with two structural water molecules, which are in turn hydrogen bonded to zeolitic water molecules occupying the channels and tunnels that run parallel to the fiber axis. These nanostructured tunnels have a cross section of approximately 3.7 Å × 6.4 Å. They account in large part for the high specific surface area and excellent sorptive properties of palygorskite once the zeolitic water molecules have been removed by thermal treatment that does not exceed 150 °C (1*b*).

The nitrogen adsorption–desorption isotherm of palygorskite (PFl-1), is of type I at lower relative pressures, characteristic of microporous solids, and of type IV at higher relative pressures, indicative of the presence of interparticle mesopores (4). The BET surface area is 196 m^2/g, with a micropore area of 93 m^2/g, a micropore volume of 47 mm^3/g, and an external surface area of 103 m^2/g. The differential pore volume plot of palygorskite reveals a median micropore equivalent spherical diameter of 6.1 Å. Similar results were also reported for palygorskite samples of other origins (5). The high external surface area, micropore area and micropore volume result in the high sorptive properties of palygorskite.

Currently, palygorskite is used in several industrial applications on the basis of its high absorption capacity. The sorption can occur either in the nanostructured tunnels or on the external surfaces. Compounds with a small molecular size have a possibility of penetrating the nanostructured tunnels, while larger molecules can just access the external surfaces. It was previously reported (5*a*, 6) that small organic molecules with high polarity (i.e., alcohol), could penetrate into the tunnels and interact with structural water molecules through H-bonding. This leads to the possibility of the design of highly structured nanohybrid materials based on naturally occurring magnesio-silicates.

In the present work, the insertion of acetone molecules in the nanostructured tunnels of palygorskite was studied by using thermal gravimetric analysis and multinuclear solid-state NMR. It is demonstrated that the original palygorskite structure is recovered by exposing a previously dehydrated sample at 150 or 300 °C to acetone vapor at room temperature, acetone molecules replacing zeolitic water molecules, and consequently filling the nanostructured tunnels.

Experimental section

Materials

Palygorskite (PFl-1) from Gadsden County, Florida, was obtained from the Source Clays Repository of the Clay Minerals Society (Purdue University), with a chemical composition (%) of SiO_2 (60.35), Al_2O_3 (11.13), Fe_2O_3 (3.74), TiO_2 (0.48), MgO (10.58), CaO (1.89), Na_2O (0.05), K_2O (0.87), P_2O_5 (0.92) (7). As reported by Güven et al. (2*f*), palygorskite makes up about 85% of the fine (<2 μm) fraction. Smectite (10%), quartz (1%–3%), apatite (2%), carbonates (1%), and mica (<1%) were identified as the main impurities in the fine fraction. These data are close to those given by Chipera and Bish (8). Acetone (>99.5%) was obtained from BDH Inc. Acetone-d_6 (>99%), was obtained from Aldrich Chemical Co.

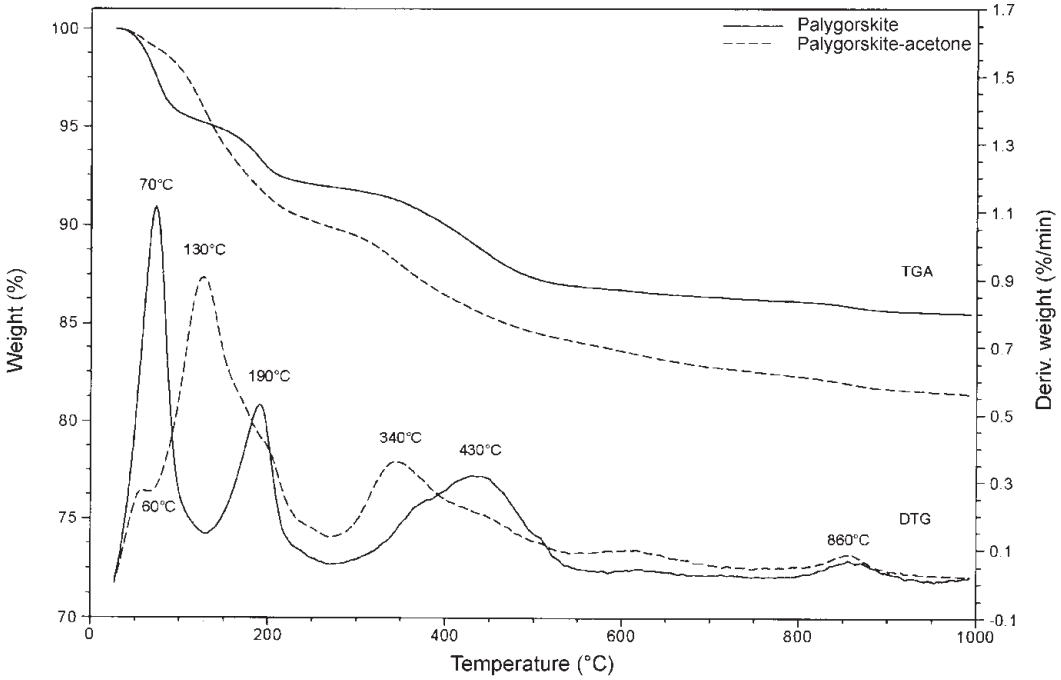
Preparation of the samples

Palygorskite was heated with a ramp rate of 1 °C/min to 150 °C (or 300 °C) and then kept at 150 °C (or 300 °C) for 20 h under air in a baffle furnace to selectively eliminate the surface-bound water and zeolitic water (and partially structural water) from the nanoporous tunnels. The vials containing approximately 0.1 g of the partially dehydrated palygorskite were immediately transferred from the furnace into capped bottles containing a few mL of acetone or acetone-d_6. The partially dehydrated samples were then kept in contact with acetone vapor for various amounts of time at room temperature.

Thermal analysis

Differential thermal analysis (DTA), thermal gravimetric analysis (TGA), and derivative thermal gravimetric analysis (DTG) were performed on a TA SDT 2960 instrument. Approximately 10–20 mg of the sample was placed in a platinum crucible on the pan of a microbalance and then heated from room temperature to 1000 °C at a heating rate of 10 °C/min while being purged with helium at a flowing rate of 100 mL/min and constantly weighed. The gases were drawn down a capillary in the SDT furnace. MS spectra were recorded on a Pfeiffer GSD 301 instrument. The mass spectrum was run in the scanning mode from mass 10 to mass 80, at a scan rate of 0.2 s per mass.

NMR spectroscopy



Solid-state ^{29}Si magic-angle spinning (MAS) and cross-polarization (CP)/MAS NMR and ^{13}C MAS and CP/MAS NMR spectra were recorded at 39.75 and 50.32 MHz, respectively, at room temperature on a Bruker ASX-200 spectrometer. Typical spinning rates of 4 kHz (^{29}Si) and 5 kHz (^{13}C) were used. As many of the NMR runs were long, a ramped CP sequence (9) using an X (^{13}C, ^{29}Si) ramp varying in field strength from 59 to 66 KHz was used to compensate for potential drift in probe tuning or amplifier output over the long data acquisition times. The recycle delay time was 2 s and the proton 90° pulse was 4 μs. The contact time to allow the transfer of magnetization between protons and ^{29}Si (and ^{13}C) nuclei was 10 ms for ^{29}Si and 2 ms for ^{13}C NMR. All MAS and CP/MAS experiments employed a 63 KHz CW decoupling field during the acquisition times. The ^{29}Si NMR signals were externally referenced to the $-Si(CH_3)_3$ resonance of tetrakis(trimethylsilyl)silane at –9.9 ppm, corresponding to tetramethylsilane (TMS) at 0 ppm. The ^{13}C NMR signals were externally referenced to the high frequency signal of adamantane at 38.4 ppm, corresponding to TMS at 0 ppm.

Results and discussion

Palygorskite (PFl-1) is progressively dehydrated in the range of temperatures from room temperature to 1000 °C

© 2004 NRC Canada

Fig. 1. TGA and DTG of palygorskite (—) and of palygorskite previously heated at 150 °C for 20 h then exposed to acetone (-----).

(1*b*). As shown in Fig. 1, the TGA curve of PFl-1 can be divided into four major weight losses at maxima of 70, 190, 430 (with a shoulder at 370 °C), and 860 °C under He flow. These steps were previously assigned, respectively, to the release of zeolitic water, the partial release of structural water, the release of the residual structural water, and the dehydroxylation of the Mg-OH groups (10). Since the terminal cations are plausibly coordinated to two water molecules to complete their coordination shell, the two steps corresponding to the loss of structural water can be attributed to the release of a first structural water leading to a distorted tunnel-like structure where the terminal cations are coordinated to one water molecule (the terminal cations may complete its coordination with the oxygen of the neighboring silica surface), and the second loss of water corresponds to the complete dehydration accompanied by the collapse of the tunnel structure. Frost and Ding (11) recently reported the thermal behavior of PFl-1 under nitrogen flow. They speculated that the weight losses at 370 and 430 °C (357 and 415 °C in their experiment) could be due to the dehydroxylation of the OH units from octahedral Fe(III) and Al(III) sites, respectively. However, they indicated that another more likely interpretation is that these two temperatures represent the irreversible dehydration of residual bound water and the folding of the tunnels (at 370 °C) and partial dehydroxylation (at 430 °C).

Consequently, heating palygorskite from room temperature to 130 °C selectively removes water adsorbed on the external surfaces and the zeolitic water from the nanostructured tunnels, while leaving the structural water and the hydroxyl groups unaffected. The elimination of the first coordinated, structural water starts above 130 °C. Folding of the palygorskite crystals occurs when partial structural water has been removed, which plausibly allow terminal cations to complete their coordination shell with oxygens from the neighboring silica surface (2*b*). Structural folding is nearly completely reversible provided that the treatment temperature does not exceed 350 °C (1*b*), but becomes irreversible once all the structural water molecules are removed and partial dehydroxylation has occurred forming an anhydride form. Finally, the remaining Mg-OH hydroxyl groups are released at about 860 °C (11, 12).

The TGA and DTG curves of palygorskite previously heated at 150 °C for 20 h then exposed to acetone for a week are also shown in Fig. 1. Weight losses appear now at 130 and 340 °C, with several shoulders approximately at 60, 190, 430, and 600 °C. Finally the peak at 860 °C characteristic of the dehydroxylation of Mg-OH groups is also observed. Similar results were obtained for TGA and DTG when the nature of the flux gas was changed from He to air. The observed major weight losses at 130 and 340 °C are an indication that acetone molecules were intercalated into the nanotunnels of palygorskite.

Figure 2 shows the mass detection of water (*m*/*e* = 18) in the released gases for palygorskite and for palygorskite previously heated at 150 °C for 20 h then exposed to acetone. For palygorskite, the water mass trace is almost identical to the DTG curve (Fig. 1). In the case of the palygorskite–acetone sample, the water mass trace is similar to the DTG curve but the relative intensity of the peak at 130 °C has decreased. Figure 3 gives the corresponding mass trace for acetone (*m*/*e* = 58). It shows a major loss of acetone at 120 °C, accounting mainly for the DTG peak maximum observed at 130 °C, and a minor loss at 330 °C. Consequently, the two maxima observed on the TGA and DTG curves at 130 and 340 °C are partially due to the release of acetone molecules that intercalate in the nanotunnels of palygorskite. Their loss at these temperatures is accompanied by the loss of structural water molecules. In addition, the loss of some structural water molecules is also observed at temperatures

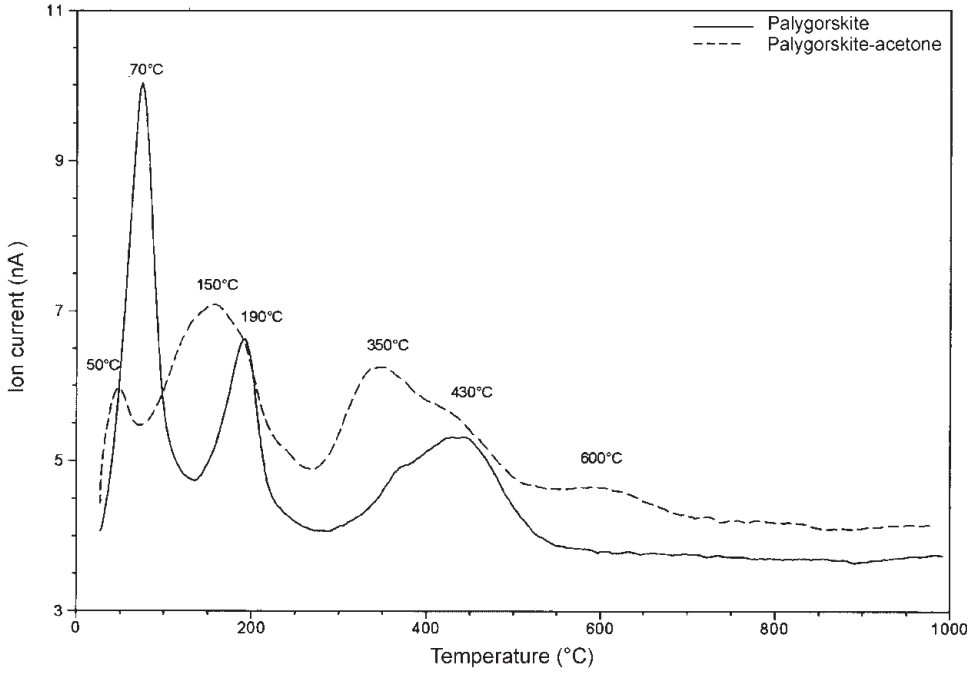
Fig. 2. Mass spectrometry of water (*m/e* = 18) for palygorskite (—) and for palygorskite previously heated at 150 °C for 20 h then exposed to acetone (----).



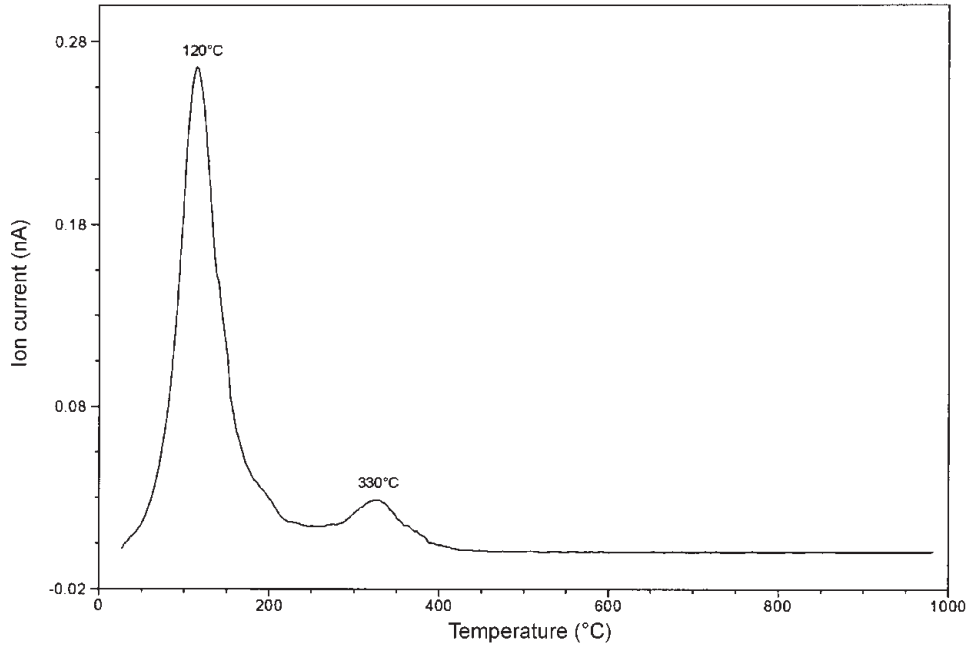


Fig. 3. Mass spectrometry of acetone (*m/e* = 58) for palygorskite previously heated at 150 °C for 20 h then exposed to acetone.

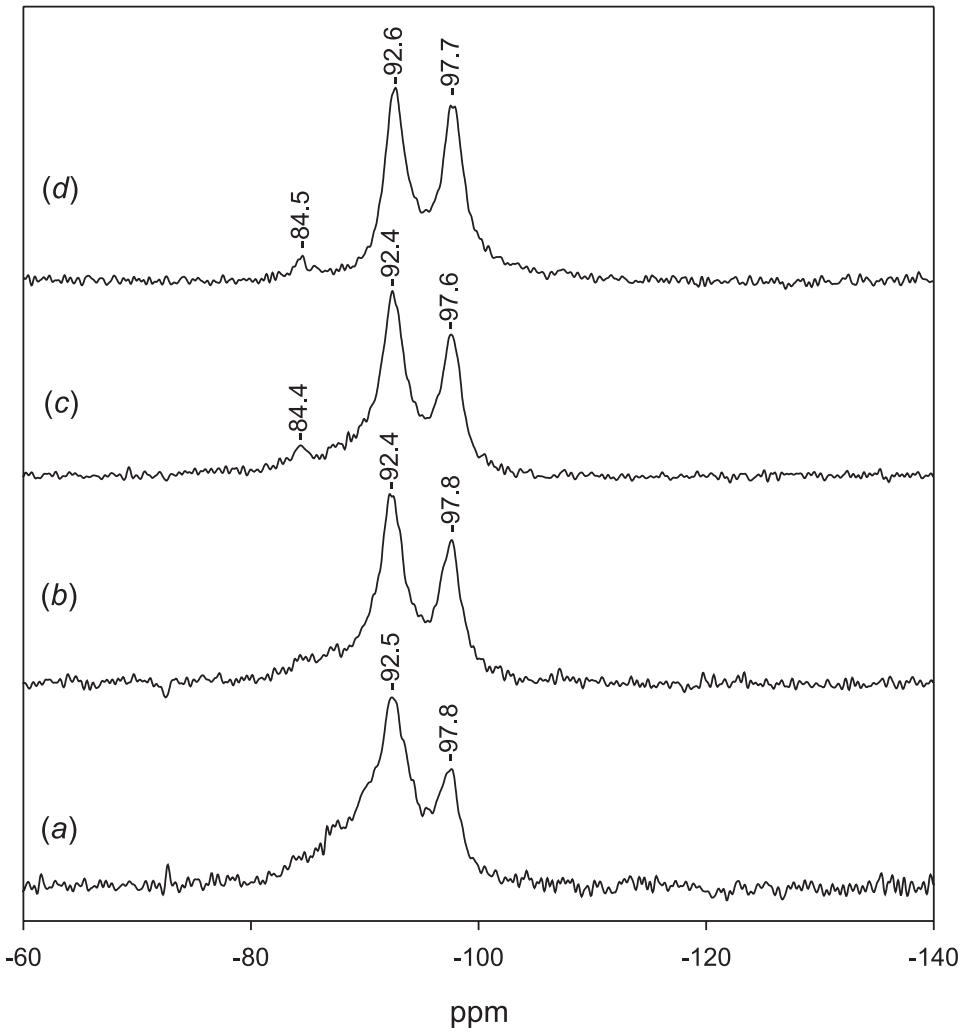

similar to palygorskite (190 and 430 °C). When the TGA–DTA analysis is performed in air, two major weight losses also appear at 130 and 370 °C, with a strong exothermic peak at 340 °C on the DTA, indicating the combustion of acetone molecules at this temperature.

The results of Figs. 1–3 permit an interpretation of the thermal behaviour of the palygorskite-acetone nanohybrid. When acetone is inserted in the nanotunnels of palygorskite, the release of the first structural water starts at a lower temperature than in the case of palygorskite (a broad peak maximum is observed at 150 °C compared to 190 °C). This water loss is accompanied by the partial release of acetone molecules (peak maximum at 120 °C). The loss of some first structural water molecules is still observed as a shoulder at 190 °C indicating the presence of zones in the nanotunnels that were not perturbed by the insertion of acetone. When this step is completed (around 260 °C), there are still acetone molecules in the nanotunnels. It is plausible that at this

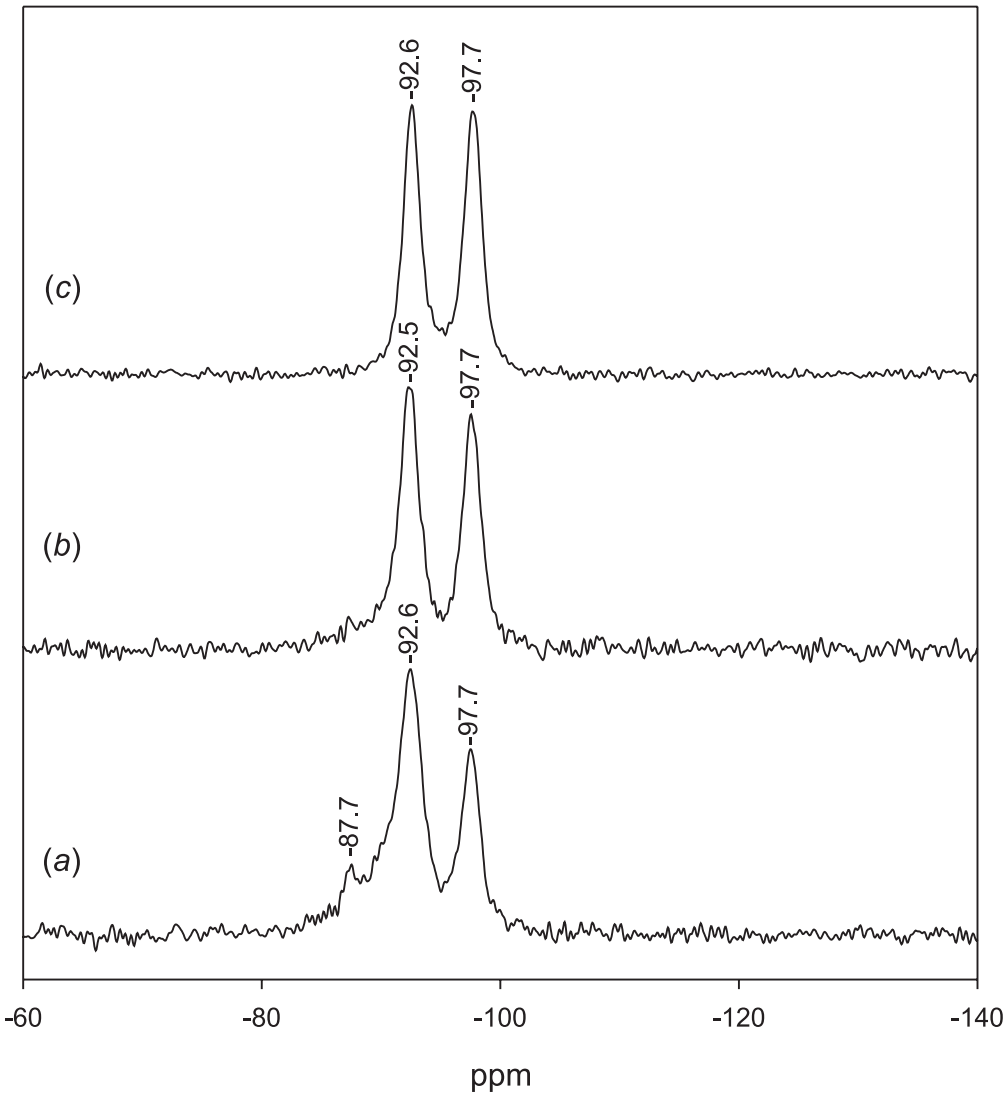
Fig. 4. ^{29}Si MAS NMR spectra of palygorskite heated at 150 °C for 20 h then exposed to acetone-d_6 for (*a*) 4 h; (*b*) 1 day; (*c*) 5 days; (*d*) 1 month (exposed to acetone).



stage the terminal cations are coordinated either by acetone or residual structural water molecules. This is in agreement with the observation that the remaining acetone molecules are released only at 330 °C, accompanied by the residual structural water molecules (seen as a broad peak with a maximum at 350 °C on the water trace in Fig. 2). The shoulder at 430 °C corresponds to zones of palygorskite not affected by the insertion of acetone, as seen above for the loss at 190 °C. These results are similar to those obtained in the case of a sepiolite–pyridine nanohybrid material reported recently (13).

Figure 4 shows the ^{29}Si MAS NMR spectra of palygorskite heated at 150 °C for 20 h then exposed to acetone-d_6 (or acetone) for various amounts of time, from 4 h to 1 month. In a previous study (4), the two main resonances at –92.0 and –97.5 ppm in the ^{29}Si NMR spectra of palygorskite were attributed to the central silicon position and to the edge silicon sites, respectively. A minor resonance at –84.3 ppm was attributed to Q^2(Si-OH) silicon nuclei, and the integral ratio is approximately 1:7:6 for the resonances at –84.4, –92.0, and –97.5 ppm, respectively. Upon heating at 150 °C for 20 h, the two main resonances shift to –93.1 and –96.9 ppm, respectively. As shown in Fig. 4, the characteristic ^{29}Si NMR spectrum of palygorskite is gradually recovered over time when heated palygorskite is exposed to acetone. After 5 days, the recovery is almost complete, and three well-resolved signals at –84.4, –92.4, and –97.6 ppm are obtained. These results are an indication that acetone molecules do intercalate into the nanotunnels and that the original structure of palygorskite is recovered. Similar results were recently reported in the case of sepiolite–acetone samples (14). The same experiment was performed under CP/MAS conditions with similar results (shown in Fig. 5). In comparison with the ^{29}Si CP/MAS NMR spectrum of palygorskite (4), the signal of the edge silicium atoms at –97.7 ppm is stronger. This is attributed to a strong H-bonding directed organization of water and acetone molecules in the nanotunnels.

Figure 6*a* presents the ^{13}C MAS NMR spectra of palygorskite previously heated at 150 °C for 20 h then exposed to acetone. The signals at 205.8 and 29.5 ppm can be assigned to the carbonyl and methyl carbons, respectively.

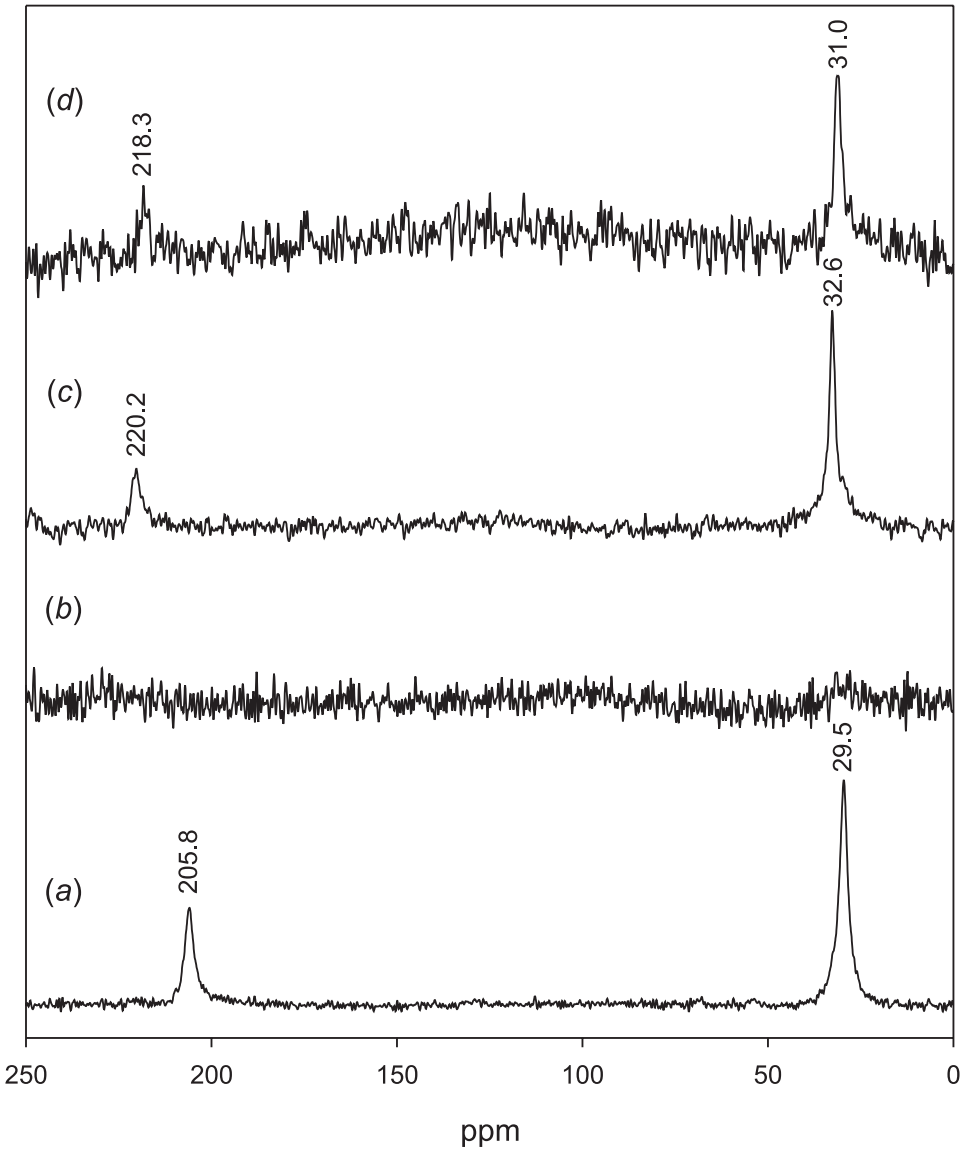
Fig. 5. ^{29}Si CP/MAS NMR spectra of palygorskite heated at 150 °C for 20 h then exposed to acetone-d_6 for (*a*) 4 h; (*b*) 1 day; (*c*) 1 month (exposed to acetone).



These chemical shift values are almost identical to the chemical shifts observed for the pure solvent. These peaks can be attributed to liquid-like acetone on the surface of the clay. This liquid-like acetone moves essentially isotropically and does not cross polarize very efficiently because of the motionally averaged dipolar coupling. This accounts for the very low intensity of these two peaks under CP/MAS conditions (Fig. 6*c*). However, under these conditions, two other peaks appear at 220.2 and 32.6 ppm. These signals can be attributed to acetone molecules intercalated into the congested space of the nanotunnels of palygorskite where they interact with the structural water molecules and cross polarize efficiently. As shown in Figs. 6*b* and 6*d*, gentle heating of the sample at 60 °C for 1 day leads to the removal of the liquid-like acetone molecules, while the intercalated acetone is kept in the nanotunnels. The intercalated acetone peaks are barely detectable in the MAS spectra because of the very small amounts present. Also the MAS measurements provide no sensitivity enhancement for the detection of intercalated acetone. These results can be interpreted as evidence for the fixation of two different types of acetone on palygorskite: mobile acetone molecules on the external surface and acetone molecules more rigidly fixed inside the nanotunnels. The former ones are detected by the MAS NMR experiment, while the latter ones are detected by CP/MAS.

Figure 7 presents the ^{29}Si MAS and CP/MAS NMR spectra of palygorskite heated at 300 °C for 20 h then exposed to acetone-d_6. As mentioned above, heating at 300 °C for 20 h could produce a folding of the structure because of the partial removal of the structural water molecules. As shown in Figs. 7*c* and 7*d*, the ^{29}Si MAS and CP/MAS NMR spectra of palygorskite after treatment at 300 °C for 20 h show several broad signals, with a peak maximum around –92.4 ppm for MAS and –92.8 ppm for CP/MAS, in agreement with a loss of symmetry and folding of the structure (4). However, the spectra of the same sample exposed to acetone vapor (Figs. 7*a* and 7*b*) are very similar to that of the original

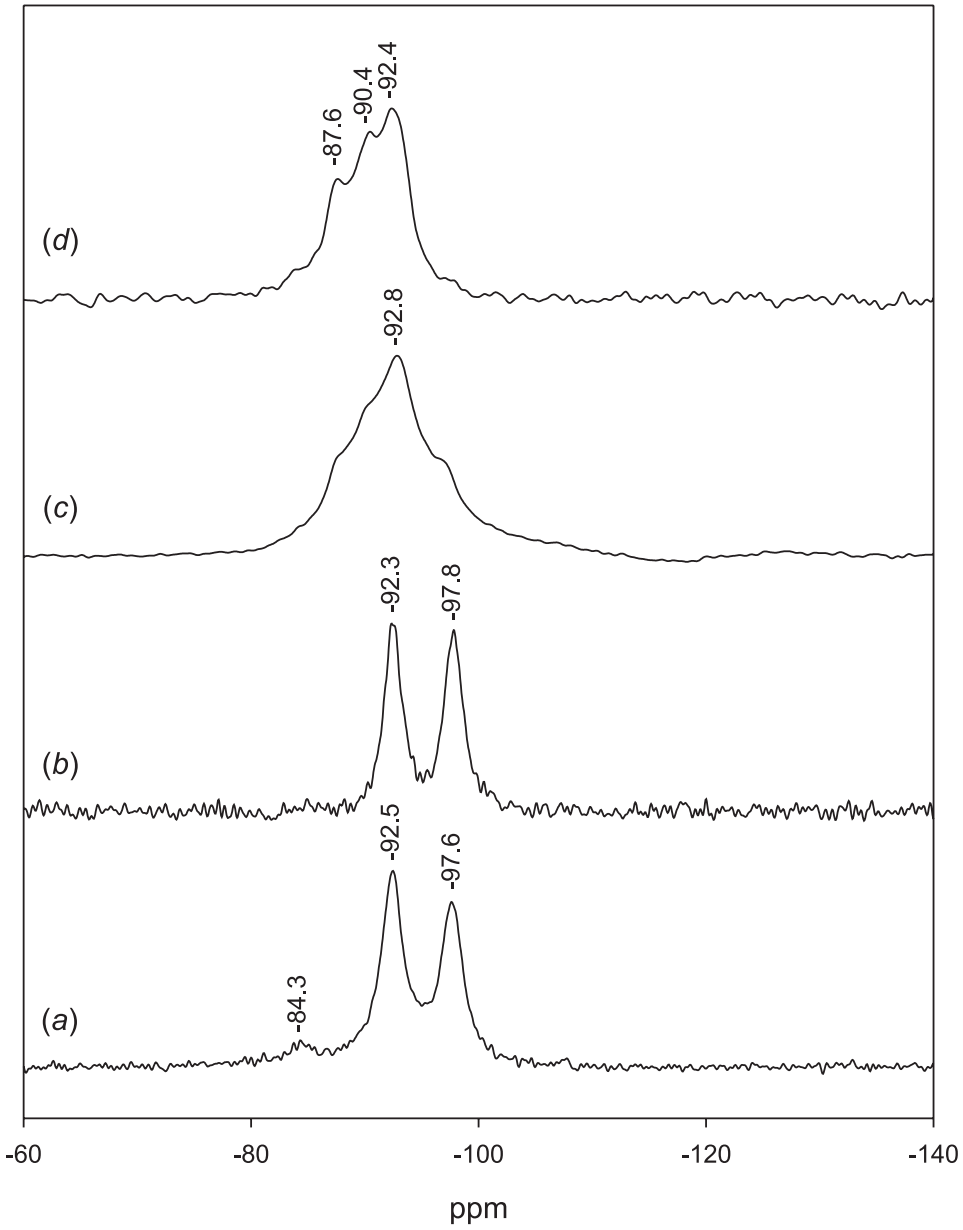
Fig. 6. ^{13}C NMR spectra of samples: (*a*) MAS of palygorskite heated at 150 °C for 20 h then exposed to acetone (sample A); (*b*) MAS of sample A but after heating at 60 °C for 1 day; (*c*) CP/MAS of sample A; (*d*) CP/MAS of sample A but after heating at 60 °C for 1 day.

palygorskite and to that of the restored structure after heating at 150 °C (see Fig. 4*d* and ref. 4). Consequently, exposure to acetone vapor restores the original structure even when palygorskite was previously heated to 300 °C. This implies that the acetone molecules can still access the interior of the folded structure, restoring the nanotunnel structure. Nearly complete recovery is achieved by exposing palygorskite samples, which have been partially dehydrated at 300 °C, to acetone vapor at room temperature.



This study confirms that the structural changes of palygorskite are reversible when it is heated at temperatures up to 300 °C, even if, at that temperature, approximately 50% of the structural water molecules have been removed, causing the folding of the tunnel structure with an associated loss in microporosity. In a previous study (4), the ^{29}Si and ^{1}H NMR spectra indicated that exposure to D_2O or water vapor at room temperature restored the original structure when palygorskite was previously heated at 150 or 300 °C. Since the molecular dimensions of acetone are 6.6 Å × 4.1 Å × 5.2 Å (15), much larger than that of D_2O or water (3.2 Å × 2.9 Å × 3.9 Å), it is of great interest that acetone molecules can be inserted in the nanostructured tunnels of palygorskite, even after their folding at 300 °C. Moreover, similarly to what was reported in the case of the sepiolite–pyridine system (13), a nanohybrid material with a structure similar to the parent palygorskite can be formed through the direct coordination of acetone molecules to the terminal cation coordination sites in the tunnels of palygorskite.

The reductive deposition of quaternary pyridinium corrosion inhibitor multilayers on glassy carbon electrodes[1]

Rick P.C. Wong, Jennifer E. Wong, and Viola I. Birss

Abstract: The redox behaviour of several quaternary pyridinium corrosion inhibitors ("Quats") at glassy carbon (GC) electrodes has been investigated in neutral aqueous solutions. The primary emphasis is on *n*-butyl-3-(*N*-octylcarbamyl)pyridinium bromide, one of the Quats determined to have very good corrosion inhibition properties based on parallel weight loss experiments. It is demonstrated that the reduction of the Quats, which occurs in a two-electron reaction at potentials negative of –1.0 V vs. SSCE, results in the formation of a neutral product. This forms a porous film on the electrode surface, with clusters that expand and thicken as more Quat deposits, as confirmed by atomic force microscopy. The film charge density reaches a maximum of ~4 mC/cm^2, equivalent to more than 100 monolayers of Quat, after which no further Quat can be deposited, suggesting full surface coverage by a nonconducting product. The Quat multilayer can then be redissolved at potentials positive of ~ –0.2 V, during its oxidation back to its original solution-soluble form.

Key words: quaternarized pyridinium compounds, reductive film deposition, glassy carbon, multilayer, corrosion inhibitors, cyclic voltammetry, AFM.

Résumé : Opérant dans des solutions aqueuses neutres, on a étudié le comportement redox, au niveau d'électrodes de carbone vitreux (CV), de plusieurs sels de pyridinium quaternaires, des inhibiteurs de la corrosion (« Quats »). L'accent a principalement été mis sur le bromure de *n*-butyl-3-(*N*-octylcarbamyl)pyridinium, un des quatre Quats qui, sur la base d'expériences parallèles de pertes de poids, devrait présenter de très bonnes propriétés d'inhibition de la corrosion. Il a été démontré que la réduction du Quats, une réaction à deux électrons à des potentiels négatifs de –1,0 V vs. SSCE, conduit à la formation d'un produit neutre. Tel que confirmé par une microscopie de forces atomiques, celui-ci forme un film poreux sur la surface de l'électrode, avec des agrégats qui conduisent à une expansion et un épaississement avec les dépôts additionnels de Quats. La densité de charge du film atteint un maximum de ~4 mC/cm^2, équivalent à plus de 100 monocouches de Quat, après quoi il ne peut plus se déposer de Quat, ce qui suggère que la surface totale est couverte par un produit qui ne conduit pas l'électricité. La multicouche de Quat peut alors être redissoute à des potentiels positifs de ~ –0.2 V, durant sa réoxydation à sa forme originale soluble dans la solution.

Mots clés : dérivés pyridinium quaternaires, dépôt d'un film de réduction, carbone vitreux, multicouche, inhibiteurs de corrosion, voltampérométrie cyclique, AFM.

[Traduit par la Rédaction]

Introduction

Quaternary pyridinium compounds ("Quats", Fig. 1*a*) are a class of cationic organic corrosion inhibitors used for the protection of metals such as carbon steel in pipeline and drilling equipment. These inhibitors are relatively low in cost and are especially effective in environments that contain brine and high concentrations of H_2S or CO_2. While the mechanism of the corrosion protection of metals by Quats remains essentially unknown, it has been surmised that Quats adsorb strongly, thus blocking local anodic and cathodic surface sites.

We have recently examined (1)[3,4] the impact of the addition of Quats to aqueous neutral and weakly alkaline solutions on Pt electrochemistry. It was demonstrated that Pt oxide formation and reduction, as well as hydrogen adsorption and evolution, could be essentially fully suppressed by the presence of certain Quats in solution, at concentrations >40 μmol/L (1). Quats that showed a high propensity for adsorption on Pt also served to protect carbon steel from corro-

Fig. 1. (*a*) Generic structure of quaternary pyridinium compounds (Quats) and structures of (*b*) *n*-butyl-3-[hydroxy(octylamino)methyl] pyridinium bromide (Quat 1); (*c*) *n*-butyl-3-(*N*-octylcarbamyl)pyridinium bromide (Quat 2); (*d*) *n*-benzyl-3,5-dimethyl pyridinium bromide (Quat 3); (*e*) *n*-decyl-3-(*N*-hexylcarbamyl) pyridinium bromide (Quat 4).

sion in parallel tests in brine solutions. It was generally observed (1) that Quats containing alkyl chains of C-8 or longer, either in the meta position or attached to the pyridinium nitrogen (Fig. 1*a*), were most effective in decreasing the corrosion rate of carbon steel. Corresponding quartz crystal microbalance (QCMB) results (1) showed a mass increase equivalent to about two monolayers of adsorbed molecules in these experiments. It was also shown that (1), once Pt electrochemistry was blocked by Quat adsorption, the normal potential window could be widened well beyond the normal limit defined by hydrogen evolution, allowing potentials to be reached at which the Quats can be reduced. This led to the deposition of a Quat multilayer.

The reduction of related compounds (e.g., 4-cyano-1-methyl pyridinium) has been reported previously, and it has been suggested that they can be reductively dimerized, forming the viologen form of the compound (2). Nicotinamide, another compound with a closely related structure, has also been shown to reduce electrochemically (3–5), forming a neutral hydropyridine monomer or dimer, while dimerization is proposed during reduction in acidic environments. 2-Vinyl pyridine has also been shown to reduce on a steel electrode (6), possibly forming a polymeric surface product.

In the present work, the behavior of Quats at a stable electrode surface, not susceptible to dissolution, was examined using a combination of cyclic voltammetry and constant potential methods, as well as atomic force microscopy (AFM). Glassy carbon (GC) was chosen for this purpose, primarily because of its high overpotential for hydrogen evolution, allowing easy access to negative potentials. Also, GC electrodes are not readily oxidized and display only minimal surface electrochemistry.

In this paper, the primary focus is on the electrochemical behavior of a specific Quat, namely *n*-butyl-3-(*N*-octylcarbamyl)pyridinium bromide (Quat 2, Fig. 1*c*), chosen because of the high degree of protection it offers carbon steel from corrosion in weight loss experiments in brine solutions (7). A pure form of this Quat was synthesized to avoid the impurities commonly encountered in the commercial Quat mixtures. Three other Quats (Quats 1, 3, and 4, Figs. 1*b*–1*e*) were also examined for comparison purposes. Cyclic voltammetric studies show that all of the Quats (8) can be reduced, resulting in the deposition of a Quat multilayer on the GC surface. The properties of this layer and its impact on the corrosion inhibition properties of Quats will also be discussed.

Experimental methods

Electrodes and surface preparation

The working electrode consisted of an 11 mm diameter glassy carbon (GC) rod, electrically connected to a copper wire using conducting silver epoxy (Allied Electronics, 2400 Circuit Works). To ensure a high quality connection and good adhesion, a layer of standard epoxy was applied on top of the conducting silver epoxy. The GC rod was then imbedded in an inert resin (Scandia, 58 Hagen), exposing only its cross-sectional end (0.95 cm^2). All current and charge densities in this paper are calculated on the basis of this apparent electrode area.

Prior to use, the GC electrode was hand-polished on a flat surface using 600 grit silicon carbide emery paper. The electrode was then polished using a coarse suspension of alumina (Metaserv, 7.0 μm) on a Rayfinal polishing cloth (Micro-Metallurgical Ltd.). Progressively finer alumina powder (E.T. Enterprises, 1.0, 0.3, and 0.05 μm) was then used, until a mirror-like surface was obtained (9, 10). The polished electrode was then cleaned with triply distilled water in an ultrasonic bath for at least 10 min to remove any alumina powder left on the surface.

The counter electrode (CE) was a large surface area Pt gauze electrode, embedded in soft glass tubing. A saturated sodium calomel electrode (SSCE, 0.235 V vs. SHE) was used as the reference electrode (RE) and all potentials are referred to the SSCE in this paper.

Instrumentation, cells, and solutions

All CV measurements were performed using an EG&G PARC 273 potentiostat/galvanostat and all data were recorded on a Hewlett-Packard 7045B X-Y recorder. A two-compartment electrochemical cell was employed, with the RE in one compartment joined to the main compartment containing the WE and CE, via a Luggin capillary. The GC electrode was suspended face-downwards in this cell configuration. Nitrogen bubbling, either through or above the cell solution, served to deaerate the cell solutions.

Water was triply distilled using a Corning Mega-Pure-6A system. A 0.05 mol/L KH_2PO_4 + 0.03 mol/L NaOH pH 7.2 phosphate buffer solution was prepared according to the CRC Handbook (11). All reagents were Fisher Certified or

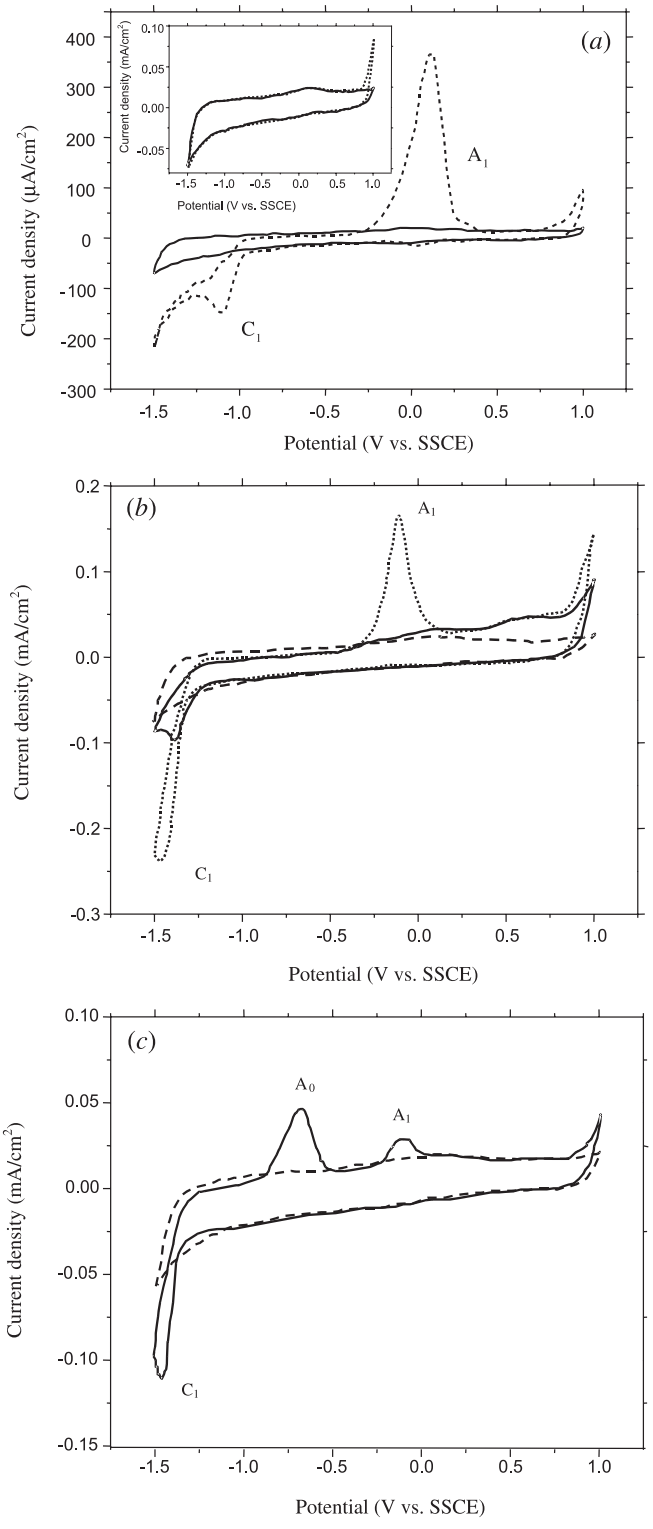
© 2004 NRC Canada

ACS grade and were used as received. The temperature of the solutions ranged from 20 to 22 °C. Quaternary pyridinium compounds (Quats) were provided by Brenntag Canada (formerly Travis Chemicals), either in solution or in crystalline form, and their general structure is presented in Fig. 1*a*. The primary emphasis of this paper is on the *n*-butyl-3-(*N*-octylcarbamyl)pyridinium bromide (Quat 2), as shown in Fig. 1*c*, but *n*-butyl-3-[hydroxy(octylamino)methyl] pyridinium bromide (Quat 1, Fig. 1*b*), *n*-benzyl-3,5-dimethyl pyridinium bromide (Quat 3, Fig. 1*d*), and *n*-decyl-3-(*N*-hexylcarbamyl) pyridinium bromide (Quat 4, Fig. 1*e*) were also investigated. Stock solutions of these Quats of 100 mmol/L were used in this work.

Atomic force microscopy (AFM)

Samples were prepared using a lithographically deposited (for ease of positioning of the AFM tip) Pt sputtered coated glass working electrode (apparent area 0.75 cm^2), cleaned electrochemically in stirred, deaerated 1 mol/L H_2SO_4 until a steady-state CV was observed. The potential was then cycled between –0.6 and 1.0 V vs. SSCE in a stirred, deaerated pH 7.2 phosphate buffer solution. An aliquot of the 100 mmol/L Quat stock solution was added such that the final solution concentration was 0.25 mmol/L and after a period of potential cycling, the potential was held at –0.9 V to deposit the Quat multilayer. The electrode was then rinsed, allowed to air-dry, and imaged using a Molecular Imaging, Inc. Nanoscope II instrument in MacMode in air. The cantilever used had a force constant ranging from 2 to 5 N/m.

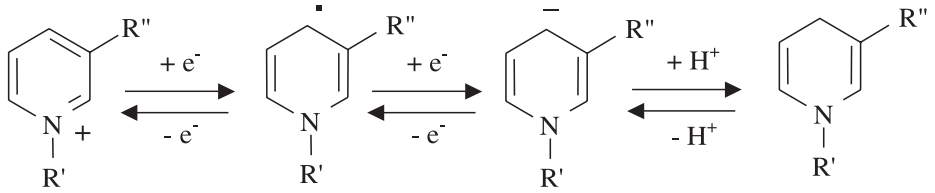
Results and discussion



General electrochemical behaviour of Quats at GC in neutral phosphate buffer solutions

After 30 min of cycling in a pH 7.2 phosphate buffer solution in the range of –1.5 to 1.0 V vs. SSCE, the bare, polished GC electrode reveals an almost featureless cyclic voltammetric (CV) response (Fig. 2*a*), as previously reported in the literature (12–17). Only capacitive current is seen over the entire potential range from –1.5 to 1.0 V, with no evidence for the onset of the HER until potentials below –1.2 V.

Upon the addition of an aliquot (2 mmol/L in cell) of *n*-butyl-3-(*N*-octylcarbamyl)pyridinium bromide (Quat 2) to the phosphate buffer solution, the magnitude of the charging current does not change significantly, suggesting that Quat 2 does not adsorb on the GC surface (Fig. 2*a*). However, at more negative potentials, an obvious set of redox peaks (A_1 and C_1) are seen. Notably, these features are quite similar to those observed at Pt (1), although the anodic peak potential is more positive on Pt (0.3 V) than on GC (0.1 V) under otherwise the same conditions. Also, previous work on Pt in pH 7.2 phosphate buffer demonstrated that the Quat reduction peak was sometimes difficult to resolve from the currents because of hydrogen evolution, which is the main reason that GC electrodes were chosen for the present work.



In the case of the addition of Quats 1 and 3 to the phosphate buffer solution, Figs. 2*b* and 2*c*, respectively, show very similar results, except that the anodic peak A_1 is actually composed of two peaks in the first few cycles of potential. The origin of these two anodic peaks is still unclear.

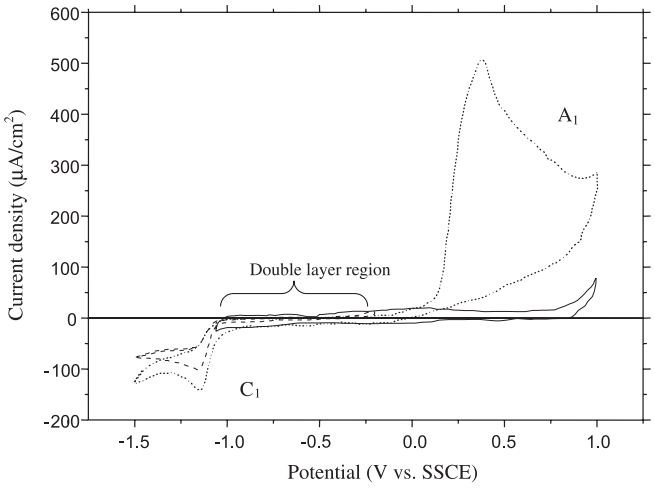
Scheme 1. Proposed redox mechanism of a typical Quat monomer.

However, based on the discussion below, it is possible that the two anodic peaks often observed for the Quats reflects the stabilization of the one-electron oxidation product (Scheme 1), such that the transfer of each of the electrons is seen in a separate peak. Notably, their appearance separately seems to be related to the cycling time (exposure time) and the scan rate employed. Also, the size of the two anodic peaks decreases slightly and their potential shifts positively with increased time of cycling. Earlier published work with similar compounds, employing the dropping mercury electrode, showed two peaks during the reduction step, an example being the work of Carelli and Cardinali (2) for 4-cyano-1-methyl pyridinium in aqueous solutions of varying pH. Galvin and co-workers (4, 5) also observed two peaks during the reduction of nicotinamide under similar conditions and attributed the first reduction peak to the dimerization of the pyridinium rings, while the second peak was considered to be due to the reduction of the radical to form a neutral hydropyridine monomer.

The anodic current observed at potentials greater than ca. 0.85 V vs. SSCE, after the addition of the Quats to the cell solution (Fig. 2*a*), is due to the oxidation of bromide ions (rxn. [1]) (17), as was confirmed by the addition of 2 mmol/L KBr alone to the buffer solution (Fig. 2 inset).



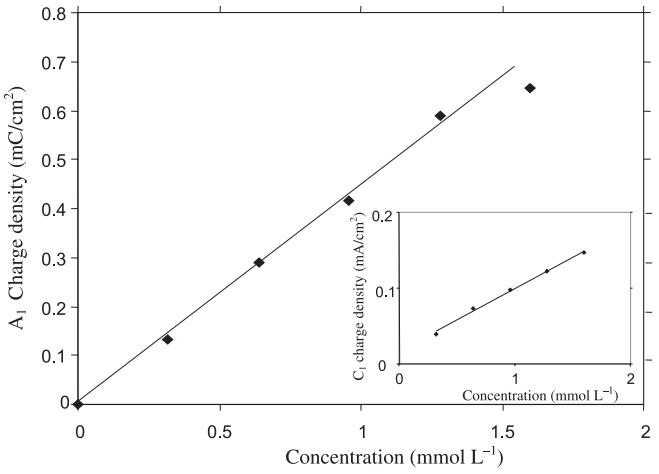
[1] $2Br^- \rightarrow Br_2(aq) + 2e^-$

$E^0 = 0.863$ V (vs. SSCE)

To study Quat redox chemistry further, the lower potential limit (E_-) was changed from –1.5 V vs. SSCE to a less negative value of –1.0 V, as shown in Fig. 3 for Quat 2 (curve a). Both the C_1 and A_1 peaks have now disappeared, confirming that these peaks are coupled and that it is essential to first reduce the Quat to then allow its reoxidation. In another experiment, E_+ was lowered to –0.2 V, to prevent the oxidation process, while retaining an E_- of –1.5 V. The size of the C_1 peak decreases with each cycle of potential, as shown in Fig. 3 (curve b). The currents owing to double layer charging, between the A_1 and C_1 peaks, also then decrease with each cycle. Both of these results indicate that the C_1 peak reflects the deposition of a product on the electrode surface. Hence, when the potential is maintained negative of the A_1 peak, more Quat can be deposited on the GC surface with time. This appears to serve to increasingly block the electrode surface, reducing the activity of the surface towards further Quat reduction and also decreasing the capacitance of the double layer.

When E_+ was then increased back to its original value (from –0.2 to 1.0 V), a very large anodic peak was seen in the next anodic cycle, as shown in Fig. 3 (curve c). The potential of the A_1 peak is also shifted positively, implying that a more resistive (e.g., thicker) surface layer is now present.

Fig. 3. Effect of potential limits on CV response of GC electrode in 2 mmol/L Quat 2 in deaerated pH 7.2 phosphate buffer solution at 100 mV/s: steady-state response for $E_+ = 1.0$ V and $E_- = -1.0$ V, curve a (—); fifth cycle for $E_+ = -0.2$ V and $E_- = -1.5$ V, curve b (– – – –); first cycle with $E_+ = 1.0$ V and $E_- = -1.5$ V, curve c (·····).



This likely indicates that the surface product, formed at negative potentials, is not very conductive. The reappearance of both redox peaks after extension of the potential limits beyond both the A_1 and C_1 peaks shows clearly that the A_1 peak depicts the removal of the surface product, allowing more Quat to be reduced and deposited in the following cathodic scan.

As a final confirmation of the deposition of a surface film in peak C_1, the GC electrode was removed from the Quat containing solution at $E_- = -1.5$ V, rinsed and blotted carefully with a tissue to remove any adhering solution, and then placed in a fresh phosphate buffer solution (without any added Quat). When the potential of this electrode was scanned positively from –1.5 V, the A_1 peak was clearly observed. However, the C_1 peak at –1.0 V was not seen in the following cathodic scan, and only a very small A_1 peak was seen in the next few anodic cycles. These results show clearly that the deposition of a reduced surface film occurs at negative potentials in the Quat-containing solution, and that it is oxidized and concurrently lost from the surface in the A_1 peak.

Overall, the results of Figs. 2 and 3 confirm that the Quats can be reduced at potentials negative of ca. –1.0 V, forming a surface product. However, this material is not oxidized at the GC electrode until a potential of ca. –0.3 V is reached. These electrochemical characteristics, seen for all of the Quats studied here, are very similar to those reported previously for NADH (3–5, 18), as discussed above (16). It

Fig. 4. Anodic peak (A_1) charge density as a function of Quat 2 concentration in stirred, deaerated pH 7.2 phosphate buffer solution after scanning negatively to –1.5 V at 100 mV/s. Inset: cathodic peak (C_1) charge density as a function of Quat 2 concentration in deaerated pH 7.2 phosphate buffer solution after scanning negatively to –1.5 V at 100 mV/s.

should be noted that the formation of a poorly conducting surface product at relatively negative potentials may be related to the corrosion inhibiting nature of the Quats at carbon steel electrodes, at which the corrosion potential can be quite negative at neutral pH.

Kinetics of Quat deposition

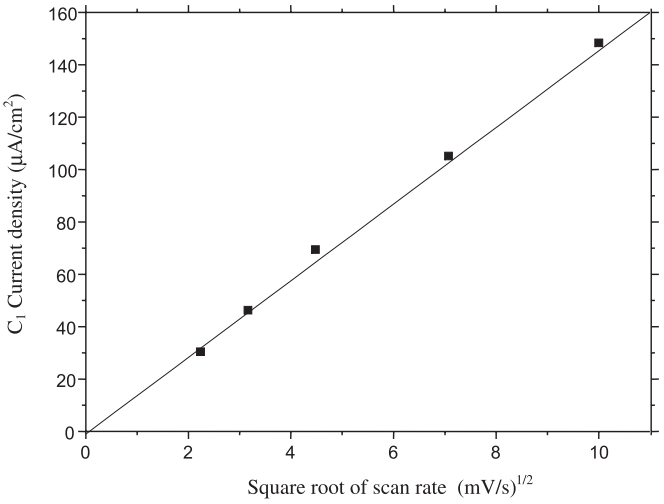
To determine the dependence of the Quat multilayer formation rate on Quat concentration, different volumes of the Quat stock solutions were added to the cell solution during continuous potential cycling, all at 100 mV s^{-1}. The CVs were recorded after a steady state was reached ~2 min after each addition. Figure 4 shows that the A_1 and A_2 (Fig. 4, inset) peak charge densities are linearly dependent on the Quat 2 concentration in the phosphate buffer solution. The results of Fig. 4 suggest that the rate of the C_1 deposition process, and hence, also of the A_1 oxidation reaction, is controlled by the rate of diffusion of Quat 2 to the electrode surface.

It is notable that the peak currents also increased significantly in size with solution stirring, consistent with this hypothesis. To test this further, the effect of the scan rate on the peak currents was examined. The zero current baseline for the C_1 peak was estimated consistently at each scan rate, assuming that the rate of the HER would be the same in each experiment. The results reveal that the C_1 peak current density exhibits a square root dependence on the scan rate, as shown in Fig. 5, again indicative of the control of Quat 2 reduction and deposition (peak C_1) rate by the transport of the Quat from solution to the electrode. Similar results were seen with Quats 1, 3, and 4, and also for Quats 1 and 2 at Pt.

Characteristics of Quat film at GC electrodes

The effect of holding the potential for various periods of time at –1.5 V in the presence of 4 mmol/L Quat 1 in the pH 7.2 phosphate buffer solution (stirred) was then examined. The results showed that the A_1 peak in the following anodic scan initially increased in size, at a rate proportional

Fig. 5. Dependence of the C_1 peak current density on the square rate of the sweep rate for 2 mmol/L Quat 2 in deaerated pH 7.2 phosphate buffer solution.



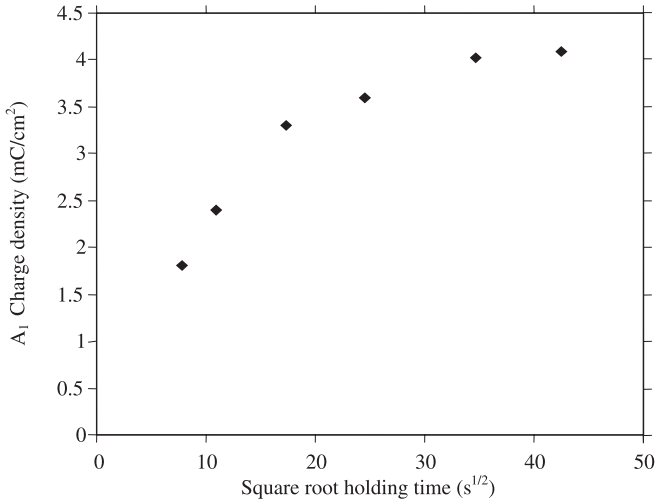


Fig. 6. Charge density of A_1 peak at GC as a function of holding time at –1.5 V vs. SSCE for 4 mmol/L Quat 2 in deaerated pH 7.2 phosphate buffer solution (100 mV/s).

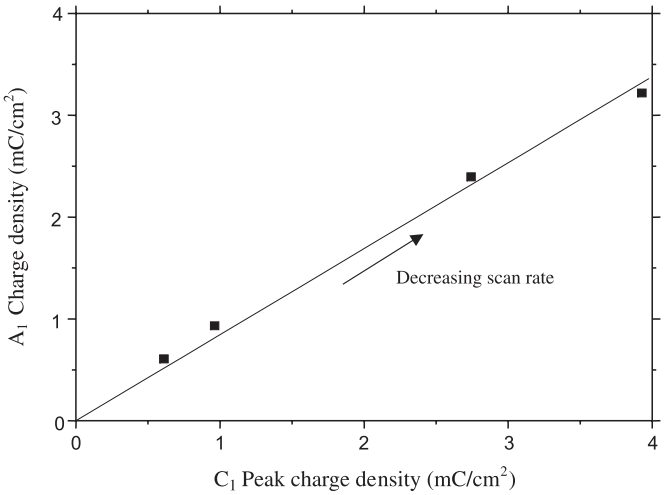

to the square root of the holding time. As shown in Fig. 6, the A_1 charge density appears to reach a threshold value of ca. 4 mC/cm^2 after about 30–40 min under these conditions (note that the dependence of the amount of deposited Quat is linear with the square root of holding time at earlier times, again indicative of diffusion-controlled Quat film deposition). In our earlier work with Pt substrates (1), the highest charge densities seen during Quat 2 deposition (at constant potential) and subsequent stripping at 2 mV/s were in the range of 2 to 5 mC/cm^2.

A parallel set of experiments in the 4 mmol/L Quat 1 solution, aimed at reaching an upper limit to the amount of Quat deposited by sweeping more slowly through the –1.5 to 1.0 V range, was then carried out. Figure 7 shows that the charge increases at slower sweep rates, which is expected if the rate of Quat deposition is diffusion controlled. At 5 mV/s, a charge of ca. 3 mC/cm^2 is seen, and it appears that

Fig. 7. Anodic vs. cathodic charge density obtained from 4 mmol/L Quat 2 in deaerated pH 7.2 phosphate buffer solution at different scan rates.

the plot would taper off at a somewhat higher charge density. Figure 7 also shows that the anodic and cathodic charges are very similar, especially at high scan rates, confirming that essentially all of the reduced product can be reoxidized under these conditions and also that the current baselines beneath the C_1 and A_1 peaks are being appropriately selected.

It is also possible that, as more Quat is deposited (higher concentrations, slower reduction sweep rates), not all of it is fully removed in the anodic scan. This would then lead to the curvature developing at high charge densities in Fig. 7. This is also consistent with the fact that with long times of continuous potential cycling at slow sweep rates, both the A_1 and C_1 peaks decrease in size somewhat, consistent with some residue building up on the electrode surface with time.

Based on the fact that an upper limit to Quat deposition is seen (Fig. 6), this suggests that further Quat reduction is limited by the film thickness and (or) resistance. Even so, for film quantities below 4 mC/cm^2 on GC, there is clearly sufficient conductivity present for film reoxidation to occur, although the large separation of the A_1 and C_1 peaks may also be an indication of the presence of some film resistance.

It is clear that the charge densities observed in these experiments are significantly greater than expected for monolayer coverage. Rahman and Ghosh (15) reported that an unsubstituted pyridine molecule occupies ca. 24 Å^2 on various oxide surfaces, based on the analysis of adsorption data using the Langmuir equation. Assuming that the reduction of the Quat involves a two-electron process (see the following section) and that each Quat molecule occupies a minimum area of 24 Å^2 (expected to be larger than this because of the attached groups (Fig. 1)), this yields 4×10^{14} molecules/cm^2 for a single monolayer of reduced Quat 1 (i.e., 130 μC/cm^2 for a two-electron reaction (19)). Therefore, 4 mC/cm^2 would be equivalent to at least 30 monolayers of the reduced Quat film. In fact, it is likely that the film is much thicker than this, even up to the equivalent of 100 monolayers, allowing for a variety of surface configurations, more open packing, and porosity for ion transport during film growth and oxidation.

To understand what the limitations might be in terms of charge transport through the Quat multilayer, the film morphology was examined using AFM, using a lithographically deposited Pt surface to facilitate the positioning of the AFM tip. Figure 8 shows that the Quat film deposits in the form of clusters, and that at longer deposition times, the clusters grow and coalesce. These images are of two different Quat 4 multilayer samples in air. The sample shown in Fig. 8*a* was prepared by holding at –0.9 V for 10 min in a 0.25 mmol/L Quat 4 solution, while the sample shown in Fig. 8*b* was held at –0.9 V for 60 min. The observed morphology of the Quat multilayer, together with the electrochemistry discussed above and the anticipated poor electronic conductivity of the multilayer (see below), suggests that charge transfer during multilayer formation and oxidative dissolution involves the transfer of the cationic Quat monomer to and (or) from the GC substrate via the pores between the Quat clusters. A more detailed discussion of Quat multilayer formation and removal from Pt is presented elsewhere.[5]

Proposed mechanism of Quat reduction–oxidation

As indicated above, the A_1 and C_1 peaks were observed for all quaternary pyridinium compounds examined electrochemically at the GC electrode, indicating that the redox reaction is associated with the pyridinium ring itself, rather than of any of the functional groups attaching the side chain to the meta-position to the ring or of the chains themselves. Indeed, within the group of Quats studied at GC, Table 1 shows that, when the pyridinium charge is more positive because of the electron-withdrawing nature of the attached groups, the C_1 peak potential is less negative under otherwise identical conditions. These data again demonstrate that the C_1 peak is associated with the reduction of the pyridinium nitrogen of the ring.

Scheme 1 shows a possible mechanism for the reduction of the Quat monomer. Previous workers (15, 20) have suggested a similar mechanism for the reduction of NADH (3–5, 18), which has a very similar structure to that of the Quats studied here. Others (3–5) have proposed a series of possible reaction routes for the reduction of nicotinamide under varying pH conditions. Also, a similar reduction mechanism to that in Scheme 1 for analogous substituted pyridinium compounds, but in aprotic solvents, has been suggested (18, 21). In addition, it has been reported that dialkylcarbamoylpyridinium could be reduced to form 1,4-dihydropyridine in an aqueous solution (22). Further, polypyridinium cations of very high molecular weight (> 30 000 g/mol) have been shown to be reduced in nonaqueous solutions on bismuth by the reduction of the pyridinium ring (23). Interestingly, in a separate paper by the same group, it was shown that monopyridinium and polypyridinium cations can cross-link on the bismuth surface to form dimers after the pyridinium ring has been reduced (24).

This proposed two-electron mechanism shown in Scheme 1 demonstrates that the reduced product can be reoxidized, forming the original structure and hence, that the reaction should be reversible, consistent with our observations. When

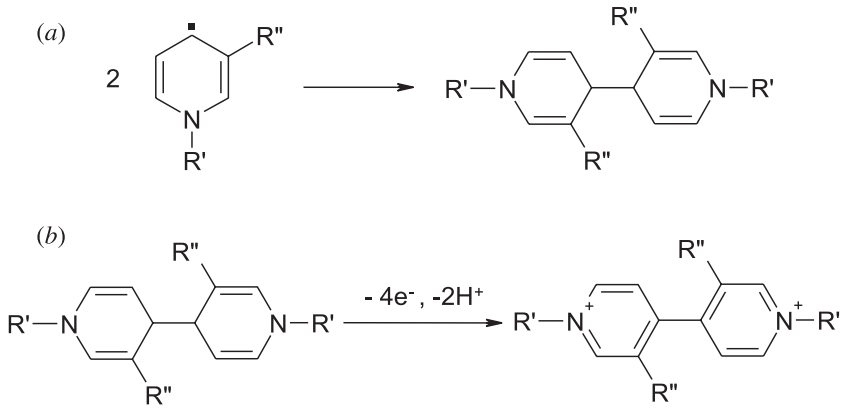
Table 1. Summary of observed peak potentials of Quats 1–3 (1.25 mmol/L Quat in stirred, deaerated pH 7.2 phosphate buffer solution, E_{-} = –1.5 V, E_{+} = 1.0 V, 100 mV/s).

Quat	Reduction peak potential (V)	Oxidation peak potential (V)
1	–1.1	0.1
2	–1.35	–0.2
3	–1.45	–0.55 and –0.1

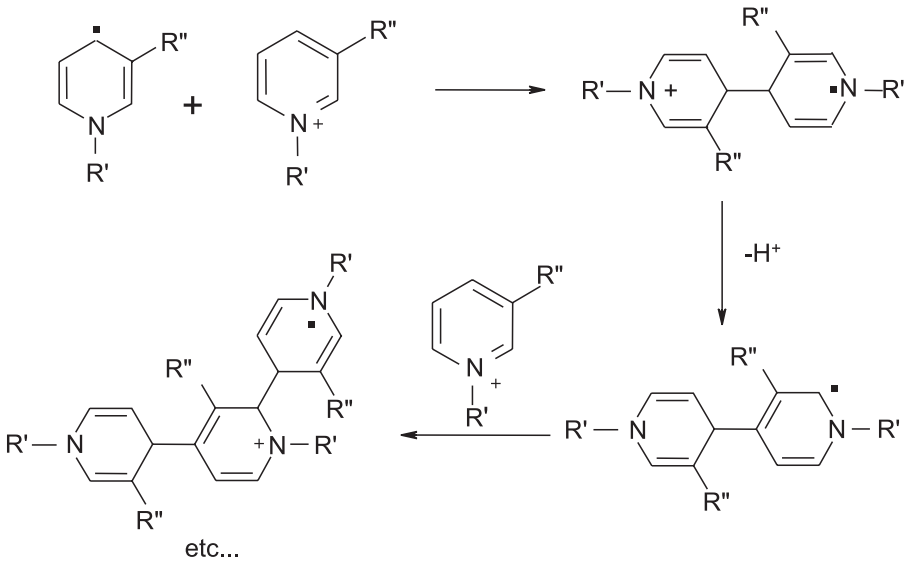
the Quat is reduced, its positive charge is lost so that a neutral species is generated. This neutral organic molecule would tend to come out of the polar aqueous solution employed in the present work and deposit on the GC electrode surface. When reoxidized, the Quat would regain its positive charge and, therefore, should readily redissolve into the aqueous medium.

Two electrons and one proton are required to reduce the positively charged pyridinium compound to a neutral species, according to this mechanism. This would predict a shift of the reaction redox potential negatively by –29.5 mV per pH unit. It was not possible to test this prediction in this study, as the peak potentials varied with the experimental variables employed, related also to the rate of the concurrent hydrogen evolution reaction on GC.



The radical intermediate suggested in Scheme 1 could potentially initiate the formation of other products. For example, when two of these species react together, a dimer (Scheme 2*a*) could be formed if steric hindrance is not a factor (21). Each dimer would then undergo a two-electron reduction process, not involving protons. However, cleavage of the joining bond in the reoxidation step is not likely and therefore, the reaction in Scheme 2*a* would be irreversible. Instead, a dimeric oxidation product could be formed, as shown in Scheme 2*b*. This redox mechanism would result in an anodic to cathodic charge ratio of two. One electron would be required to form each radical (two electrons per dimer molecule), while four would be required in the oxidation step. As shown in Fig. 7, the charge density in the A_1 and C_1 peaks are very similar, and thus, the formation of this dimeric compound as a primary reaction product is not considered likely in the present case.

After long times of potential cycling, a nonoxidizable residue did seem to build up on the electrode surface, which could be related to the formation of a small amount of the dimeric product. Discrimination between a monomeric vs. dimeric product turned out to be very difficult when GC–MS and NMR analyses were attempted. This is due, in part, to the similarities of the responses of these two products. Also, the ex-situ analysis of this film product was complicated by the possibility of air oxidation of the reduced product once the film-covered electrode was removed from solution.



The radical intermediate shown in Scheme 2*a* could also initiate a nonelectrochemical polymerization process, as depicted in Scheme 3. This polymerization reaction would require the loss of one proton per Quat for its propagation and

© 2004 NRC Canada

Scheme 2. (*a*) Dimerization of two radical intermediate species and (*b*) possible reoxidation of the dimer.

Scheme 3. Possible non-electrochemical polymerization route of a typical Quat.

would be expected to occur to a more significant extent in basic solutions, assuming that the OH^- ion will react with the proton to initiate this propagation. Indeed, in exploratory experiments carried out in 0.1 mol/L NaOH solutions, a yellow product was often seen to deposit on the electrode surface (K. Dang, Personal communication, 1998). This may reflect the formation of some polymeric product under these conditions. However, as in the case of the dimeric product, a polymeric product is not likely to be electrochemically oxidizable and is, therefore, inconsistent with the results of Fig. 5. The formation of a polymeric product could potentially explain the slow build-up of nonreactive residue on the GC electrode surface with long times of cycling and as more Quat is deposited (slow sweep rates and long times at E_-).

Summary

In this paper, we have examined the reductive behaviour primarily of *n*-butyl-3-(*N*-octylcarbamyl)pyridinium bromide (Quat 2), but also of *n*-butyl-3-[hydroxy(octylamino)methyl] pyridinium bromide (Quat 1), *n*-benzyl-3,5-dimethyl pyridinium bromide (Quat 3), and *n*-decyl-3-(*N*-hexylcarbamyl) pyridinium bromide (Quat 4) on a glassy carbon (GC) in neutral phosphate buffer solutions. While there is no evidence for the adsorption of the Quats on GC in the normal range of potential, we have demonstrated that all of these Quats can be reduced at potentials more negative that –1.0 V vs. SSCE and that the product deposits as a film on the electrode surface. The corresponding oxidation process, which is seen at ca. –0.2 or –0.3 V, sometimes in two anodic peaks, involves the oxidative dissolution of the film, reforming the original cationic monomer form of the Quat. In general, the amount of Quat that is reduced and deposited is equal to the charge density that passes during its oxidation, although after long times of potential cycling, not all of the surface film can be electrochemically removed.

We have also shown that under the conditions of our experiments, the rate of Quat reduction is likely diffusion controlled, at least initially. At higher Quat concentrations, using slow potential sweep rates, or long times of potential holding, a limit to the amount of Quats that deposits is reached (ca. 4 mC/cm^2), equivalent to ca. 100 monolayers of film. This result, together with the anticipated poor electronic conductivity of the film, argues for a porous film structure. Indeed, AFM studies have shown that the Quat multilayer is composed of clusters, which aggregate together

© 2004 NRC Canada

as more Quat is deposited, thus, ultimately preventing access to the cationic Quat starting material and blocking further multilayer formation.

In terms of the mechanism of Quat reduction, it is shown that the redox chemistry is associated with the pyridinium ring itself, and not with the attached functional groups or side chains. Further, the formation of reduced, neutral monomers is the mostly likely process occurring. Products such as dimers or oligomers may also form, but only after long cycling times, when not all of the Quat reduced can be reoxidized and a residue is observed to build up on the GC electrode surface.

Acknowledgements

We are grateful to the Natural Sciences and Engineering Research Council of Canada (NSERC) Industrial Postgraduate Scholarship program and Brenntag Canada (formerly Travis Chemicals) for the financial support of R.P.C. Wong and J.E. Wong. The authors would also like to thank Dr. Neil Warrender and John Cossar, both formerly of Brenntag Canada, for provision of the Quats and for many helpful discussions. We would also like to acknowledge very useful discussions with Professor Jean Lessard, University of Sherbrooke, in relation to this work.

Bovine serum albumin adsorption on passivated porous silicon layers[1]

L. Tay, N.L. Rowell, D. Poitras, J.W. Fraser, D.J. Lockwood, and R. Boukherroub

Abstract: Hydrogen-terminated porous silicon (pSi-H) films were fabricated through electrochemical anodization of crystalline silicon in hydrofluoric-acid-based solutions. The pSi-H surface was chemically functionalized by thermal reaction with undecylenic acid to produce an organic monolayer covalently attached to the silicon surface through Si—C bonds and bearing an acid terminal group. Bovine serum albumin (BSA) was adsorbed onto such surface-modified pSi structures. The resulting surfaces were characterized using scanning electron microscopy (SEM), reflection FT-IR spectroscopy, and ellipsometry. SEM showed that the porous films were damaged and partially lifted off the silicon substrate after a prolonged BSA adsorption. Ellipsometry analysis revealed that the BSA penetrated ~1.3 μm into the porous structure. The film damage is likely a result of BSA anchoring itself tightly through strong electrostatic interaction with the acid-covered Si sidewalls. A change in surface tension during BSA film formation then causes the pSi layer to buckle and lift off the underlying Si substrate. FT-IR results from the undecylenic-acid-modified pSi surfaces before and after BSA adsorption showed the presence of strong characteristic amide I, II, and III vibrational bands after BSA adsorption. The surface properties of the pSi matrix and its interactions with BSA are examined in this study.

Key words: ellipsometry, porous silicon, protein adsorption, surface passivation.

Résumé : Des films de silicium poreux se terminant par de l'hydrogène (pSi-H) ont été préparés par une anodisation électrochimique de silicium cristallin à l'aide de solutions à base d'acide fluorhydrique. La surface des pSi-H a été fonctionnalisée par le biais d'une réaction thermique avec de l'acide undécylénique qui a conduit à la formation d'une monocouche organique qui est liée à la surface de silicium par des liaisons Si—C covalentes et qui porte un groupe acide terminal. On a absorbé de l'albumine de sérum bovin (ASB) sur de telles surfaces à structures de pSi modifiées et on a caractérisé les surfaces qui en résultent par microscopie électronique à balayage (MEB), spectroscopie IR à transformée de Fourier (FT-IR) et ellipsométrie. Les données de la microscopie électronique à balayage montrent que les films poreux ont été endommagés et soulevés du substrat de silicium après une absorption prolongée de l'ASB. L'ellipsométrie révèle que l'ABS pénètre environ ~1,3 μm dans la structure poreuse. Il est probable que le dommage au film résulte du fait que l'ASB se lie fortement aux côtés du Si couvert d'acide par le biais d'une interaction électrostatique. Un changement dans la tension au cours de la formation du film d'ASB provoque alors déformation de la couche pSi et le soulèvement du substrat Si qui se trouve en dessous. Les résultats de la spectroscopie FT-IR sur des surfaces de pSi modifiées par de l'acide undécylénique, avant et après l'absorption d'ASB permettent de mettre en évidence, après l'adsorption de l'ASB, la présence de bandes fortes caractéristiques de vibrations amides I, II et III. Dans ce travail, on a aussi examiné les propriétés de la surface de la matrice pSi et ses interactions avec l'ASB.

Mots clés : ellipsométrie, silicium poreux, adsorption de protéine, passivation de la surface.

[Traduit par la Rédaction]

Introduction

Porous silicon (pSi) films fabricated through chemical or electrochemical etching of crystalline silicon in hydrofluoric acid solution have attracted much attention owing to their strong room-temperature photoluminescence (PL) properties (1). The origin of the PL has been attributed to quantum confinement effects within the silicon nanocrystallites comprising pSi (2). A freshly prepared pSi surface is covered with Si—H_x bonds. A slow oxidation takes place when pSi is exposed to ambient air and this results in the degradation of its optical and electronic properties. A significant research effort has been directed towards passivating the hydrogen-terminated pSi surface, thereby stabilizing the PL for potential use in optoelectronic applications (3). Organic modification of the pSi-H surfaces through Si—C bond formation has emerged as a feasible solution towards pSi surface passivation and prohibiting its oxidation. Various methods (such as, photochemical, electrochemical, thermal, and catalytic reactions) have all been successfully demon-

strated for covalently attaching monolayers of simple and functional alkenes, and aldehydes to both porous and planar Si surfaces through Si—C and Si—O—C bonds, respectively (4, 5). We have used a thermal treatment to functionalize the pSi surface with a high coverage and to introduce different functional groups (ester and acid) on the surface (6–10). We have successfully used this approach to stabilize the photoluminescent properties of the pSi surfaces (11), as well as the electroluminescence (EL) efficiency and EL output intensity of a pSi-based diode under continuous operation (12). The selection of the terminal functional group in the alkyl chain plays an important role on the wetting properties of the functionalized surface and subsequent functionalization processes.

The enormously large surface area within a small volume is an attractive advantage in pSi for other potential applications. It has been employed as a substrate for matrix-free biomolecular mass spectrometry based on a pulsed-laser desorption–ionization technique. In the study carried out by Wei et al. (13), analyte molecules trapped in the chemically modified pSi were vaporized and ionized by laser pulses and their fragments analyzed by mass spectroscopy. Sailor and co-workers (14) have demonstrated pSi optical interferometric biosensors by detecting the change in the film refractive index caused by the analyte binding at the functionalized pSi surface. In addition, its biocompatibility is an important issue to be considered in the biosensor application. Earlier studies have shown that silicon material does not exhibit a significant amount of cytotoxicity (15). Hence, pSi material has the distinct advantage over the other semiconductor-based materials such as III-V-, SiC-, and SiN-based materials. In fact, Bayliss et al. (16) have investigated the adherence and viability of rat neuronal (B50) cells cultured directly on the pSi structure and Canham et al. (17) studied the lifetime of derivatized pSi in a simulated human blood plasma environment. Biocompability can be either active or passive (16). A bioactive material encourages the wanted species and prohibits the production of unwanted species, whereas a biopassive substrate would not interfere with the local or remote functionality of the biosystem. It has been shown that while low-porosity pSi films promoted bioactivities such as hydroxyapatite growth in-vitro, the high-porosity pSi films exhibited substantial dissolution abilities implying its biodegradability in-vivo (18). Hence, pSi has a higher biocompatibility compared with other bulk polycrystalline or amorphous silicon-based substrates.

The binding of protein to solid surfaces has an important function in the chemical and pharmaceutical industries. More specifically, in many biosensor-related applications, the pSi surfaces must be functionalized with highly specific biological or chemical recognition species. Hence, an understanding of the protein–solid substrate interaction and diffusion of protein inside the pSi matrix has a great impact on pSi-based biosensors. Here, we investigate the interaction between carboxylic acid functionalized pSi surfaces and a protein molecule, bovine serum albumin (BSA). The resulting surfaces were characterized using ellipsometry, Fourier transform infrared spectroscopy (FT-IR), and scanning electron microscopy (SEM). We also compare and contrast the results obtained from pSi surfaces to those of planar Si surfaces, both being functionalized with identical chemical species.

Experimental

All cleaning and etching reagents were clean room grade and all other reagents were of the highest purity available from Aldrich.

Sample preparation

Double-side polished Si(100) oriented p-type silicon wafers (boron-doped, 1–15 Ω cm resistivity) were first cleaned in 3:1 concd. H_2SO_4 – 30% H_2O_2 for 15 min at 80 °C and then rinsed copiously with Milli-Q water. The clean wafers were immersed in 5% aq. HF solution for 1 min at room temperature to remove the native oxide. The hydrogen-terminated surfaces were electrochemically etched in a 1:1 (v/v) solution of pure ethanol and 48% aq. HF for 2 min at a current density of 40 mA/cm^2. After etching, the samples were rinsed with pure ethanol and were dried under a stream of dry nitrogen prior to use. SEM showed that pSi films prepared in this way are 3.8 μm thick with an average pore diameter of ca. 10 nm.

pSi functionalization

The freshly prepared pSi surface was placed under argon gas in a Schlenk tube containing deoxygenated neat undecylenic acid and allowed to react at 95 °C for 16 h. The excess of unreacted and physisorbed reagent was removed by rinsing with tetrahydrofuran and 1,1,1-trichloroethane at room temperature and then the sample was dried under a stream of nitrogen.

Acid-terminated monolayer on Si(111)-H

Single side polished silicon crystals were cleaned with piranha solution (H_2SO_4:H_2O_2, 3:1) at 100 °C for 30 min then hydrogen terminated by etching in ammonium fluoride. The resulting hydrogen-terminated surfaces Si(111)-H were placed under argon gas in a Schlenk tube containing a previously deoxygenated neat or toluene solution of undecylenic acid and irradiated in a photochemical reactor at 300 nm for 3 h. The excess of unreacted and physisorbed reagent was removed by rinsing with tetrahydrofuran and 1,1,1-trichloroethane at room temperature and the sample was dried under a stream of nitrogen.

BSA functionalization

BSA was obtained from Sigma (Sigma, B4287-1G, USA). The BSA solution was prepared by dissolving 2 mg of BSA in 1 mL of deionized water (18 MΩ). The resulting solution had a pH value of 6.4. The undecylenic-acid-modified planar and pSi samples were immersed in the BSA solution for 4 days at room temperature. At the end of the incubation period, both silicon surfaces were removed from the BSA solution and rinsed with copious amounts of deionized water and dried under a steady stream of nitrogen gas. In a separate experiment, an incubation solution was prepared with concentration of 0.02 mg of BSA per 1 mL of water. An undecylenic-acid-functionalized pSi surface was immersed in this solution for 3 days at room temperature.

© 2004 NRC Canada

FT-IR spectroscopy

Oblique angle IR external reflectance spectroscopy was performed on the samples with p-polarized radiation from 580 to 4000 cm^{-1} at a 60° angle of incidence using an evacuated Fourier transform spectrometer (Model DA3, ABB Bomem Inc., Québec, Quebec). An angle of incidence near Brewster's angle for silicon and in-plane polarization were employed to enhance the method's sensitivity to the surface layers in the structure. We also obtained results for the BSA adsorption on the planar silicon in an attenuated total reflection (ATR) FT-IR configuration using a single-bounce Ge internal reflection hemisphere.

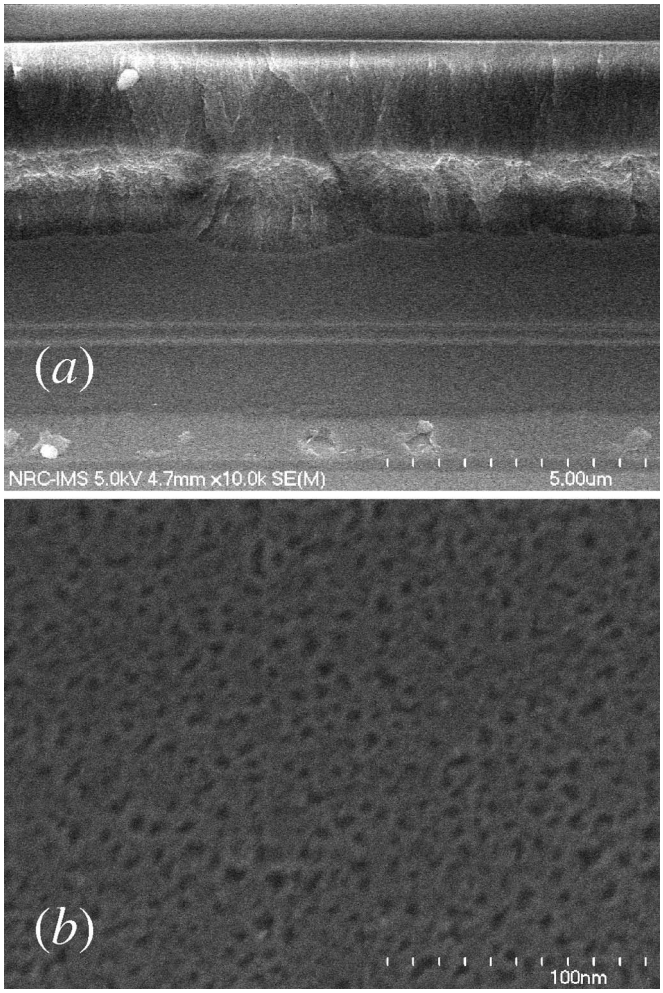
Ellipsometry

Ellipsometric measurements were performed in air with a variable-angle spectroscopic ellipsometer (VASE, J.A. Woollam Co., Lincoln, Nebraska) from 300 to 800 nm and at three different angles of incidence (55°, 65°, and 75°). Ellipsometry provided a measurement of the complex reflectance ratio:

$$\rho \equiv \frac{R_p}{R_s} = \tan(\Psi)\exp(i\Delta)$$

where R_p and R_s represent the complex reflection coefficients of the light polarized parallel and perpendicular to the plane of incidence, respectively, and Ψ and Δ are the ellipsometric angles. Optical models including parameters such as the refractive indices and thicknesses of the materials involved were used for analyzing the data (using the WVASE32 software package). Some of these models included birefringent porous layers modeled by Bruggeman effective medium approximation (BEMA) layers and graded interfaces, as described by quintic transition layers (19).

SEM



SEM was carried out with a Hitachi (S4700) field emission SEM with an image resolution of 2.1 nm at 1 kV and 1.5 nm at 15 kV at the analytical working distance. Both planar and pSi samples were cleaved through their center to provide clean edges to determine the layer thickness of the BSA and pSi films. The topography and cross-sectional SEM images of a reference pSi sample, which was anodized under the same conditions as the acid-modified pSi sample, were also obtained. It provided a reference for the porous layer thickness and average pore diameter of the acid-modified sample.

Results

SEM

Cross-sectional SEM analysis of the hydrogen-terminated pSi sample (reference sample), prepared under the same experimental condition as the pSi films modified with organic acid, indicated the porous layer thickness to be of the order of 3.8 μm (see Fig. 1*a*). The average pore diameter of the reference pSi sample was found to be approximately 10 nm (see inset Fig. 1*b*). The porosity of films prepared with this process is estimated to be ~70%. Owing to the BSA build up and the damage it produced in the acid-modified pSi film, the pore diameter and porous layer thickness for such films had to be inferred from the reference pSi material.

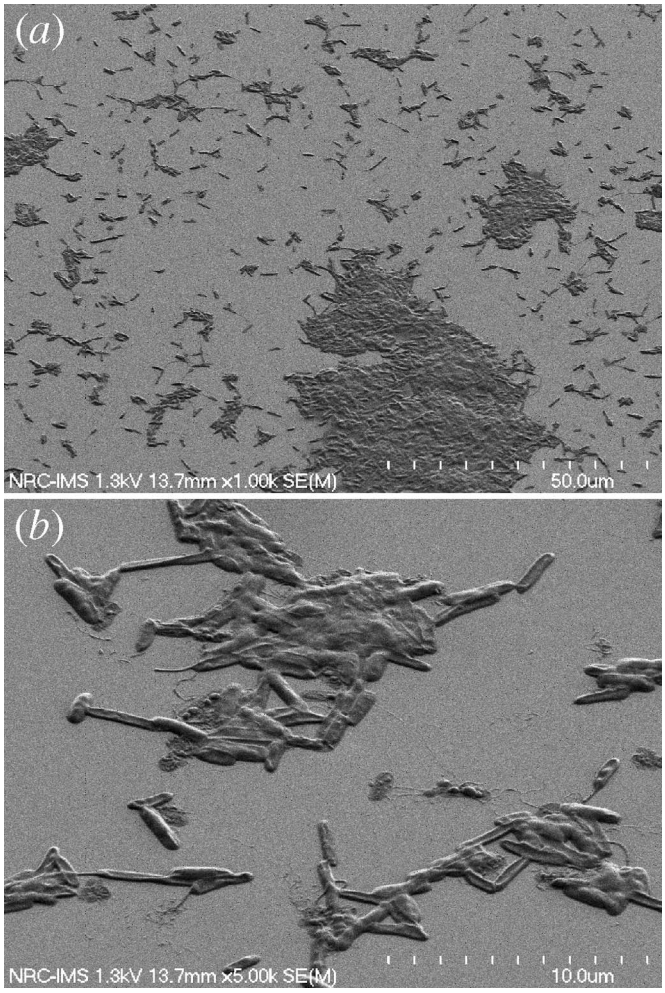


Fig. 1. (*a*) Cross-sectional SEM image of the reference pSi film. The average thickness of the porous film is approximately 3.8 μm. (*b*) Planar view of the pSi film.

A planar Si(111) sample modified with undecylenic acid was functionalized with BSA according to the procedure described in the Experimental section. Topographical SEM images in Fig. 2 showed an interesting topology on the acid-modified surfaces. As Fig. 2*a* shows, there are islands of BSA distributed all over the planar Si surfaces. Though some aggregates form large islands, as shown in the bottom images of Fig. 2*a*, most of the aggregates have a rod-like structure with an average length of 25 μm and width of 2 μm. At higher magnifications, the rod-like structures are actually comprised of two parallel ridges separated by a distance of ~2 μm. This observation is consistent with the formation of BSA thin films through solvent evaporation (20). Figure 2*b* shows interesting fiber-like features among the rod-like BSA aggregates. It is important to point out that the seemingly flat and featureless areas between the BSA aggregates are actually covered with a very thin layer of BSA film. This is confirmed by cross-sectional SEM imaging and ellipsometry. The film thickness in these flat regions is estimated to be of the order of 7~10 nm.

Fig. 2. SEM images of the BSA film formed on top of the undecylenic-acid-modified planar Si surfaces. The seemingly flat area between the protein aggregates are covered with an ~10 nm thick smooth layer of BSA film.

Results from the acid-modified pSi sample present the most intriguing information. The topographic SEM image shown, for example, in Fig. 3*a* indicate that the film was cracked over the entire pSi sample and in many areas was partially detached from the substrate. Within the cracks in the broken films, one can clearly see a sponge-like pSi layer lying underneath. At higher magnification, one can, again, observe the rod-like BSA aggregates and the fiber-like linkage lying on top of the BSA films. These are similar to the structures observed on the BSA films formed on the planar Si samples (Fig. 2*a*). This implies that the fiber-like features are due to the inherent nature of BSA film formation and not a consequence of the surface morphology of the pSi samples. It is likely that the BSA aggregates observed on both planar and porous substrates are the result of the lengthy incubation time and incubation using a relatively high BSA concentration in solution. SEM images of the sample incubated at a concentration of 0.02 mg/mL showed only minor BSA aggregation with most of the aggregates ranging from 100 to 800 nm in size. By cleaving the sample and examining its cross section, it was confirmed that most of the broken pSi film has lifted off the substrate, as can be seen in

Fig. 3. (*a*) SEM image of BSA adsorption on pSi film. The pSi film is broken into many pieces. The cross-sectional image in (*b*) shows the broken film lifting off the crystalline Si substrate. The porous structure can be seen on the sidewall and underneath of the lifted-off film pieces. The image also shows that only a small portion of the porous film still remains intact with the crystalline substrate. Part (*c*) shows a layer of BSA film 270 nm in thickness formed on top of the lifted-off pSi structure.

Figs. 3*b* and 3*c*. More importantly, the porous structures are clearly observed at the sidewall of the lifted-off film. The sponge-like porous structure left intact on top of the crystal-

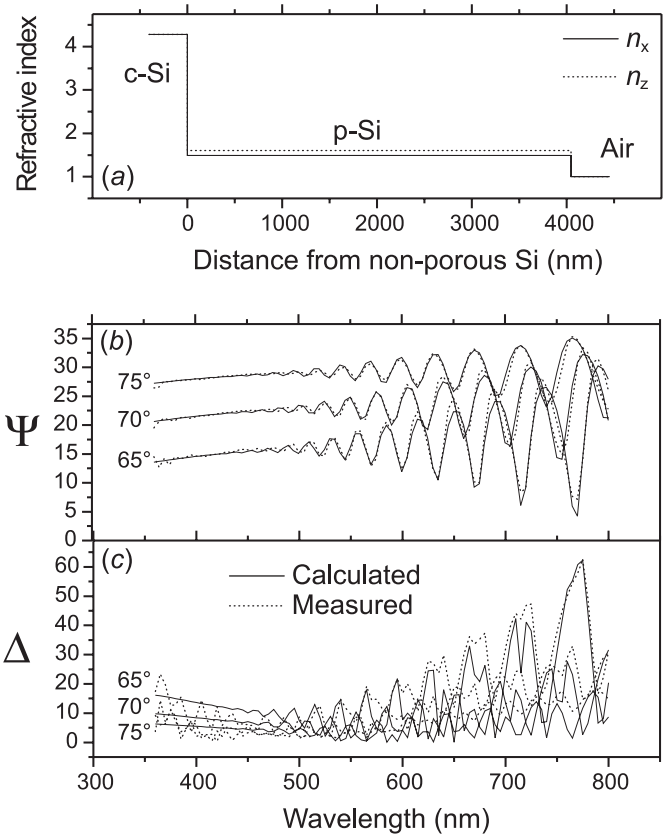

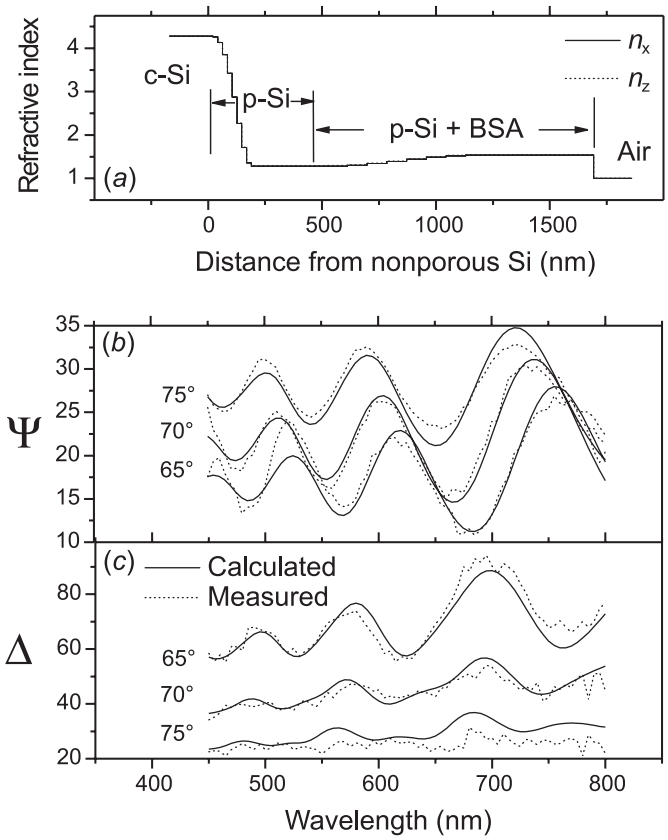

Fig. 5. (*a*) The modeled refractive indices n_x and n_z at 550 nm are shown. Room temperature experimental (dashed lines) and modeled (solid lines) ellipsometry for (*b*) Ψ and (*c*) Δ results obtained at 65°, 70°, and 75° for the pSi:BSA sample.

line Si substrate is estimated by SEM cross-section imaging to be less than 1 μm thick. It is not obvious what has led to the loss of the ~2.8 μm of porous film from the surface, however, the surface tension from the formation of the BSA film in and on top of the pSi layer during the drying phase is a likely cause for such film damage. In many of the lifted-off pSi pieces, there were small portions of the pSi that remained in contact with the rest of the substrate. The attachment is usually through a small piece of pSi structure, as shown underneath the lifted-off films in Fig. 3*b*. In both Figs. 3*b* and 3*c*, one can also observe a layer of smooth and homogeneous BSA film deposited on top of the pSi structure. From the cross-sectional images, we estimate the thickness of this smooth BSA film on top of the porous structure to range between 160 and 270 nm.

Ellipsometry

The results obtained from the ellipsometric study of the reference pSi sample are shown in Fig. 4. The best fit to the observed reflectivity through the visible wavelength region was obtained with a single birefringent porous layer on top of the crystalline Si substrate. For good fits, it was essential to include the weak birefringent nature of the porous layer. The calculated refractive indices are shown in Fig. 4*a* and these indicate an abrupt substrate – porous layer interface and a film thickness of 4.05 ± 0.02 μm. The pSi layer porosity was found to be 75.9 ± 0.1% and the refractive indices at 550 nm are $n_x = n_y = 1.474$ and $n_z = 1.579$ (perpendicular to the plane of the layer). The refractive indices exhibit dispersion varying from $n_x = 1.58$ and $n_z = 1.73$ at 360 nm to $n_x = 1.43$ and $n_z = 1.48$ at 800 nm. The birefringence is quite small ($\Delta n = n_z - n_x = 0.105$). Overall, these ellipsometry results confirm the data obtained by SEM from this air-oxidized sample.

The ellipsometry results for the BSA protein covered pSi sample look quite different from those of untreated pSi (compare Figs. 4 and 5). The spacing between fringes is greater for pSi:BSA indicating a thinner pSi layer. A two-layer model is required to fit this data, including a pSi and pSi plus adsorbed BSA protein layer. In addition it was necessary to include the birefringence of the pSi, a concentration gradient at each interface, and a nonuniformity of overall thickness across the layer (to account for the pSi layer delamination). From the model fit to Δ and Ψ (see Figs. 5*b* and 5*c*), we find a pSi:BSA layer thickness of 388 ± 202 nm, a pSi:BSA graded composition layer of thickness of 867 ± 333 nm, a pSi layer thickness of 226 ± 183 nm, and a pSi graded composition layer thickness of 211 ± 28 nm, giving a total pSi layer thickness of 1.7 ± 0.7 um. The large uncertainties in the fitted parameters are attributed to the fractured nature of the film. This may also explain why the ellipsometry determined layer thickness is smaller than the value measured by SEM. The thickness nonuniformity was found to be 12.1 ± 0.7%, and the pSi porosity was deter-

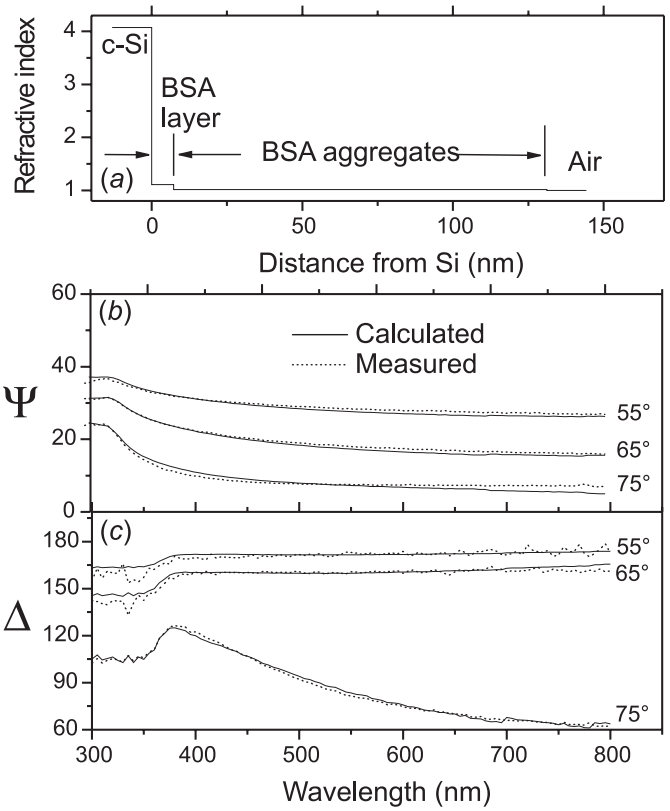
Fig. 6. (*a*) The modeled refractive indices n_x and n_z at 550 nm are shown. Room temperature experimental ellipsometry results (dashed lines) measured at 55°, 65°, and 75° for (*b*) Ψ and (*c*) Δ for BSA adsorbed on planar Si. The modeled fits are shown by the solid lines.



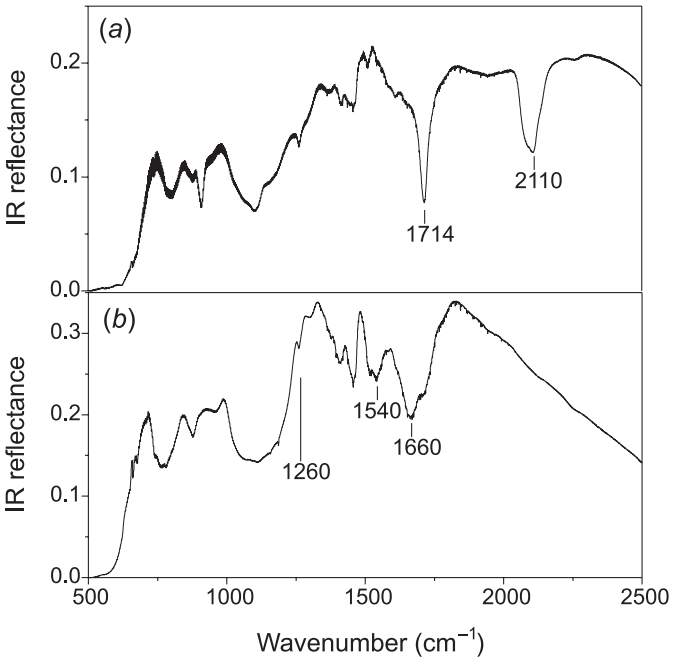


Fig. 7. Oblique incidence FT-IR spectra of the undecylenic-acid-modified pSi substrate (*a*) prior to the BSA incubation and (*b*) after incubating in 2 mg/mL of BSA for 4 days.

mined to be 83% with a large uncertainty (~100%). The calculated refractive indices are given in Fig. 5*a*. At 550 nm, n_x = 1.283 and n_z = 1.291. The pSi refractive index is lower than that for the pSi reference sample shown in Fig. 4, which is consistent with the higher porosity of this BSA treated sample. Also, the birefringence Δn = 0.008 is smaller. The graded composition layer between the c-Si substrate and the p-Si layer accounts for the film peeling shown in Fig. 3. The ellipsometry results confirm the penetration of the BSA protein deep into the pSi layer. The BSA concentration slowly decreases to zero through the film, but appears to fill the pores down to about 400 nm from the surface. The lack of an abrupt interface explains why it is difficult to observe the BSA penetration by SEM.

Ellipsometric data from the BSA protein treated planar Si sample are shown in Fig. 6. Here, a best fit was obtained with a two-layer model on top of a crystalline Si substrate. Such a model was necessary to reproduce the strong variation in Δ at high angle of incidence: a fit with a single homogeneous layer of BSA proved to be quite inappropriate for this data. The model comprised a Bruggeman effective medium approximation for the inner layer (assuming n = 1.57) and a Cauchy dispersion relation for the outer layer. The layer thicknesses determined from the model fits (see Fig. 6) were 124 ± 4 and 7.3 ± 4.2 nm for the outer and inner layers, respectively. The thickness of the inner layer is in accord with the SEM determination of ~10 nm. Its porosity was determined to be 80 ± 7%. The top layer thickness represents an average value for the conglomerated lumps of BSA protein. The scattering of light produced by the BSA conglomerates had to be accounted for in the model by fixing, artificially, the extinction coefficient k at a small value (0.02). The refractive indices for these layers exhibit dispersion and were determined at 550 nm to be 1.016 ± 0.002 for the outer layer (corresponding to a porosity of 97.9 ± 0.1%) and 1.097 for the inner layer, which are smaller than the value of 1.57 found by Arwin (21). Arwin obtained this value from thin BSA protein layers (2–3 nm thick) on substrates other than Si, as he was not successful in obtaining high-density layers on Si. We believe a large part of the difference in these two determinations can be attributed to film morphology: our films grown on Si are less dense than those of Arwin, which were grown on HgCdTe.

FT-IR

Figures 7*a* and 7*b* show the oblique incidence FT-IR spectrum of the pSi samples before and after the BSA incubation, respectively. Prior to BSA incubation, the pSi spectrum is dominated by a strong absorption at 1714 cm^{-1} because of the carbonyl (C=O) stretching. The stretching and deformation of CH_2 of the alkyl chain at 2922 and 1460 cm^{-1}, respectively, are also observed. In addition to the vibrational modes related to the undecylenic acid, the broad peak located at 2110 cm^{-1} showed three different Si-H stretching modes. It is due to the presence of unreacted Si—H bonds remaining after the thermal modification of the pSi surfaces. Indeed, the steric hindrance of the organic molecule limits the surface coverage during the grafting process. The ob-

© 2004 NRC Canada

served spectrum is in agreement with previously published data (9). The spectrum after BSA incubation shows the characteristic IR bands of BSA: the amide I (C=O stretching) and the amide II (N-H bending) and the less obvious amide III (C-N) peaks are observed at 1660, 1540, and 1260 cm^{-1}, respectively. It is important to point out that the enormous surface area in the pSi samples contributes positively towards the observation of the vibrational signatures in the surface modification species (undecylenic acid). As for observation of the BSA vibrational signal, the extra volume provided by the porous medium essentially increased the effective sampling volume of the BSA molecules and hence made the detection possible. Although there appeared to be a smooth ~200 nm thick BSA film formed on top of the damaged and partially peeled-off pSi layer, its presence is unlikely to be the sole contribution to the intense amide vibrational bands observed. On the contrary, as demonstrated in the ellipsometry results, it is likely the appreciable amount of BSA, which slipped into the pores utilizing the natural advantage of a porous medium that produced a strong and thus easily detectable vibrational signature. Similar amide I and II bands were also observed on the pSi sample, which was incubated in the 0.02 mg/mL BSA solution for 3 days. Since a BSA vibrational signature is not likely from such sparse BSA aggregates in the oblique angle reflectance FT-IR measurement, the presence of the amide bands suggests there are BSA molecules in the pSi matrix.

In contrast with the pSi sample, the IR spectra obtained from the acid-terminated planar Si sample did not show any signature of either undecylenic acid or protein when measured under oblique-angle reflectance FT-IR. SEM characterization showed that the smooth continuous layer of BSA formed on the planar surface is ~10 nm thick. A similar BSA vibrational signature from planar Si samples was detected by variable-angle single-bounce ATR-FT-IR. The spectrum of the BSA on planar Si showed the characteristic amide I and II bands at 1660 and 1533 cm^{-1}.

Discussion

The interaction between the protein molecule and the pSi layer is a complex matter. Many factors contribute to the protein adsorption in pSi substrates: the size of the protein, the protein conformation, the protein's overall charge, the pore diameter of pSi, its porosity and surface state (hydrophobicity–hydrophilicity), and the chemical functionality of the surface-modified layer all play very important roles. With an average pore diameter of 10 nm and layer thickness of 3.2–4.1 μm (as determined from the reference sample), the irregularity and depth of the pores in pSi present quite a challenge for the large albumin molecules (14 nm × 4 nm in globular form) to penetrate them. Several prior studies (21–23) have investigated the protein adsorption in either a bare pSi substrate terminated with hydrogen or its oxidized surface. In these ellipsometry based studies, the porous film thickness ranges from 240 to 370 nm. In all three cases, the ellipsometry analysis indicated protein penetration deep into the pores, reaching 90% of the overall film thickness. Of course, the amount of protein mass appeared to be higher closer to the surface of the porous layer and the albumin mass percentage in the porous layer drops closer to the crystalline silicon. Our ellipsometry results similarly echo the tapering-off of the protein penetration behavior despite the presence of the carboxyl terminal group covering the pSi sidewalls and the presence of a much thicker porous layer (~3.8 μm).

Penetration of protein into the porous layer is likely to play an important role in the break up of the porous film. It is well-established that the structural integrity of the porous film is fragile (2) and that the entire film can be removed from the crystalline Si substrate by electropolishing with a high current density. Also, for films with relatively high porosity, the film can peel-off the supporting crystalline Si substrate simply from the capillary effect of the water during the film's fabrication process (2, 24). Control experiments performed on our samples showed no film damage after soaking both acid- and hydrogen-terminated pSi films in water for 3 days and drying them with nitrogen gas. It is likely that the presence of the BSA film was responsible for the damage to the porous film. A possible explanation is that when the protein molecules penetrated deep into the pores they tightly anchored themselves to the acid-covered sidewalls of the pSi matrix (through strong electrostatic interaction) during the BSA film formation and caused a ~2.8 μm thick layer of pSi to peel off the substrate. The damage incurred on the pSi film is likely a result of the prolonged (4 days) incubation period in a solution of relatively high BSA concentration causing a substantial amount of BSA build-up on and inside the porous layer. Other studies on unmodified pSi substrates incubated in a similar albumin protein medium over a time period of several hours did not show such pSi film damage (22). Experiments performed here at 1/100th of the initial BSA concentration also showed no film damage.

There are several factors that favor the penetration of albumin into pSi pores. First, we consider the hydrophilicity of the binding surfaces. As discussed earlier, the electrochemical fabrication of pSi in HF leaves the pSi surfaces covered with hydrophobic Si—H bonds. The hydrophobicity is reduced by surface modification with undecylenic acid coating the porous walls. This reduction of hydrophobicity allows aqueous solvents to wet the pores better and help to transport albumin molecules deeper into the pores. Second, it is important to point out that BSA has a high affinity towards the acid-ligands. In fact, a BSA molecule contains several high affinity acid-binding sites (25). It is well-known that a protein will modify its conformational structure to adapt to the substrate that it interacts with (26). The acid-modified pSi surface, no doubt, presents lots of active binding sites for the albumin and quite possibly prompted such structural changes of the BSA to aid the surface-protein interaction. Arwin et al. (23) have examined the penetration of human serum albumin (HSA), a protein that is very similar to BSA both structurally and in its dimensions, into unmodified pSi structures. In their studies, albumin protein was found to reach ~200 nm into the pore structure. In addition, Arwin et al. found that the penetration of HSA depends on both a critical porosity of pSi and the acidity of the incubating medium. More protein adsorption on the interior surfaces was found on the high porosity (~70%) samples, while

© 2004 NRC Canada

the adsorbed protein mass is substantially higher at lower pH (pH 4) as supposed to the physiological pH of 7.4. At low porosity, Arwin et al. observed that adsorption of the protein occurs mainly on top of the porous layer or in the outer most region of the porous medium. They pointed out that a minimum porosity (~70% in the case of HSA) is necessary to stimulate the penetration deep into the porous layer. The estimated porosity of our pSi samples found from X-ray reflectivity and ellipsometry studies is 70% and 76%, respectively. Although the surface properties of our chemically modified surfaces differ from the hydrogen terminated pSi films, it is likely that the high porosity still played a favourable role in the penetration of the protein into the porous medium.

In addition to the porosity, the overall pH value of the incubation solution plays an important role in the protein interaction with the porous layer. The isoelectric point of BSA is 4.7 and this implies that the BSA molecules will carry overall negative charges in the pH 6.4 incubating medium. The pK_a of the surface-bound carboxylic acids are in the range of 4–6, hence, in the pH of 6.4 incubation medium, the acid terminal group is present mostly in the deprotonated conjugated base (COO^-) form. In addition, it is unlikely that BSA will accept the proton from the carboxylic acid unless the overall incubating medium has a pH below the isoelectric point. This means that both the BSA molecules and pSi surfaces are both negatively charged. The similar charge on both mediums may not necessarily hamper the interaction between the two molecules. In fact, an ellipsometry-based study (27) has found that regardless of the cationic or anionic nature of the surface functional group, the intake of BSA mass is higher in the coated pSi matrix compared to the bare (hydrogen-terminated) pSi matrix. Studies have shown that proteins that carry the same net charge as the surface might still bind through local patches of opposite charges (26). In addition, the binding can be dominated by electrostatic interaction between polar group interactions such as hydrogen bonding or ligand-like interactions (28). It is likely that the interaction between the protein and the surface COO^- group is dominated by hydrogen bonding or through electrostatic interactions of specific groups in the BSA molecule (e.g., lysines, arginine, and tyrosines), which have high binding affinity for the carboxylate group (29). Serum albumin contains multiple fatty acid binding sites. For most of the binding sites, the carboxylate moieties of the fatty acids are strongly anchored by electrostatic interactions to the polar side chains (often through hydrogen bonding) and the methylene tails are accommodated within hydrophobic cavities (30). In the case of the carboxylate covered sidewalls, the electrostatic interaction and hydrogen bonding between the surface and protein is likely to overcome the charge repulsion between them and dominate the bonding mechanism of the albumin to the sidewall of the porous matrix. It is not impossible that some acid binding sites become available through structural changes of the protein and this allows the oppositely charged protein and carboxylate-covered surfaces to form chemical bonds. To address the interaction between the protein molecule and the functionalized surfaces, we intend to carry out pH dependent protein adsorption studies in future. In addition, investigation of a pSi matrix terminated with other functional groups such as long chain alkyl molecules or amines will provide valuable information in the study of the protein and porous matrix interaction.

Conclusion

We have presented the first results of BSA adsorption on undecylenic-acid-modified planar Si and pSi layers. Cross-sectional SEM images show damages in the porous film with a layer of BSA (160–280 nm thick) formed on top of the damaged porous layer. Ellipsometry confirmed the penetration of BSA molecules (~1.3 μm into the porous layer). The presence of the BSA penetration into the porous structure probably caused the porous film to buckle and peel off the Si substrate possibly because of the change in surface tension during the drying phase. We have examined interactions between BSA and the carboxyl terminal groups in aiding the penetration of protein into the porous structure. In future work, protein adsorption on other functional groups (e.g., amide- or alkyl-terminated surfaces) as well as the pH dependent adsorption need to be examined in more detail. This will help to elucidate the role played by the hydrophobicity, surface charge, and the interaction of BSA molecules with the porous structure.

A solid-state NMR investigation of orexin-B[1]

Guy M. Bernard, Mark Miskolzie, George Kotovych, and Roderick E. Wasylishen

Abstract: Some key aspects of the secondary structure of solid orexin-B, a 28 amino-acid peptide, have been investigated by solid-state NMR spectroscopy. The $^{13}C–^{15}N$ dipolar coupling between the carbonyl carbon of Leu^{11} and the nitrogen of Leu^{15}, as determined by rotational echo double resonance (REDOR) experiments, is 35 Hz, indicating that these nuclei are separated by approximately 4.5 Å. This distance is consistent with the α-helical structure determined for this segment of orexin-B by solution NMR measurements. REDOR measurements of the dipolar coupling between the carbonyl carbon of Ala^{17} and the nitrogen of Ala^{22} support the contention in an earlier solution NMR study that a bend exists between the two α helices of orexin-B. However, in the solid state the internuclear distance (6.4 Å) is significantly greater than that observed for orexin-B in aqueous solution. In addition to the distance measurements, the principal components of the amide carbonyl carbon chemical shift (CS) tensors for Leu^{11} and Ala^{17} and of the amide nitrogen CS tensors for Leu^{15} and Ala^{22} are reported. There are only minor differences between the amide carbonyl carbon CS tensors for Leu^{11} and Ala^{17} and between the nitrogen CS tensors for Leu^{15} and Ala^{22}.

Key words: orexin-B, solid-state NMR, REDOR, chemical shift tensors.

Résumé : Faisant appel à la spectroscopie RMN à l'état solide, on a étudié quelques aspects de la structure secondaire de l'orexine-B solide, un peptide comportant 28 acides aminés. Le couplage dipolaire $^{13}C–^{15}N$ entre le carbone du carbonyle de la Leu^{11} et l'azote de la Leu^{15}, tel que déterminé par des expériences de double résonance avec écho rotationnel (REDOR), est égal à 35 Hz et cette valeur indique que ces noyaux sont séparés par environ 4,5 Å. Cette distance est en accord avec la structure α-hélicoïdale déterminée pour ce segment de l'orexine-B sur la base d'expériences de RMN en solution. Des mesures REDOR du couplage dipolaire entre le carbone du carbonyle du Ala^{17} et l'azote du Ala^{22} est aussi en accord avec l'hypothèse émise antérieurement, sur la base d'une étude RMN en solution, à l'effet qu'il existe une déviation entre les deux hélices α de l'orexine-B. Toutefois, à l'état solide, la distance internucléaire de 6,4 Å est significativement plus élevée que celle observée pour l'orexine-B en solution. En supplément aux mesures de distances, on rapporte aussi les principaux composants des tenseurs des déplacements chimiques (DC) du carbone du carbonyle de l'amide pour les Leu^{11} et Ala^{17} et pour les tenseurs des DC de l'azote de l'amide des Leu^{15} et Ala^{22}. On n'observe que des différences mineures entre les tenseurs des DC du carbone du carbonyle de l'amide des Leu^{11} et Ala^{17} et entre les tenseurs des DC de l'azote de l'amide des Leu^{15} et Ala^{22}.

Mots clés : orexine-B, RMN à l'état solide, REDOR, tenseurs des déplacements chimiques.

[Traduit par la Rédaction]

Introduction

Orexin-B, together with its closely related analogue orexin-A, were first identified in 1998 (1). The orexins have been implicated in numerous physiological processes. For example, they coordinate the complex behaviour in sleep and (or) wakefulness and in feeding (2) and also control several functions outside the central nervous system (3).

Orexins A and B are 33 and 28 amino-acid peptides, respectively. Orexin-B, also known as hypocretin-2 (1, 4), whose primary sequence is linear, shares 46% sequence homology with orexin-A; both are C-terminally amidated. The amino acid sequence for orexin-B is:

H-Arg-Ser-Gly-Pro-Pro-Gly-Leu-Gln-Gly-Arg-Leu^{11}-Gln-Arg-Leu-Leu^{15}-Gln-Ala^{17}-Ser-Gly-Asn-His-Ala^{22}-Ala-Gly-Ile-Leu-Thr-Met-NH_2

The amino acids of importance in this study have been numbered. The conformation of Phe^{1}-orexin-B has been determined by Lee and co-workers (5) from an analysis of two-dimensional NMR data for the peptide dissolved in water at a pH of 3.5 and in water–trifluoroethanol mixtures. They reported that in both solvent systems, Phe^{1}-orexin-B consists of two α helices (helix I, spanning Leu^{7} to Gly^{19} and helix II, spanning Ala^{23} to Met^{28}). These helices are connected by a short flexible region containing a bend, such

 doi: 10.1139/V04-131 © 2004 NRC Canada

that the axis of helix I is oriented 60°–80° relative to that of helix II (Fig. 1). In a more recent solution NMR study, Miskolzie et al. (6) investigated orexin-B dissolved in aqueous solutions of sodium dodecylsulphate (SDS). These authors confirmed the presence of the two α helices but found that in aqueous SDS solution, helix I spans Leu^{7} to Ser^{18} and helix II spans Ala^{22} to Leu^{26}. They did not have sufficient data to confirm the bend reported by Lee and co-workers. Overall, the results of the two studies are in qualitative agreement; the minor differences in the secondary structure were attributed to the choice of solvent (6). Analogous solvent effects on secondary structure have been found for other peptides (7).

Solid-state NMR spectroscopy is becoming an important technique to elucidate the secondary structure of proteins and peptides (8–16), particularly when obtaining crystallites of suitable size or quality for X-ray diffraction studies is impractical. For example, diffraction data is not available for orexin-B; hence we have undertaken a solid-state NMR investigation to further characterize its secondary structure. Rather than reinvestigating the entire molecule, we undertook rotational echo double resonance (REDOR) (10, 17–26) measurements of two distances that might help define important fragments of the secondary structure for orexin-B. First, we investigated the internuclear separation between the amide carbonyl carbon of Leu^{11} and the amide nitrogen of Leu^{15} ($r_{C11,N15}$). This separation was selected to investigate whether the α helix, an important structural unit observed in both previous solution NMR studies of orexin-B (5, 6), is also present in the solid state. Second, we used the REDOR technique to measure $r_{C17,N22}$; if the bend between the two helices is present in the solid state, there should be a measurable dipolar interaction between the carbonyl carbon of Ala^{17} and the nitrogen of Ala^{22}. Based on the structure deposited in the Protein Data Base (pdb, access code 1CQ0) by Lee et al. (5), the internuclear separation between the amide carbonyl carbon of Ala^{17} and the amide nitrogen of Ala^{22} ($r_{C17,N22}$) is approximately 4 Å. Since peptides and proteins naturally exist in an aqueous environment, an important issue is whether secondary structure determined for solids via X-ray crystallography or solid-state NMR correspond to those found for the same molecule when it is solvated (27). Because solution NMR data is available for orexin-B (5, 6), another objective of this study is to determine whether distances measured for the molecule in the solid state correspond to those determined for the molecule in solution.

Since the REDOR experiment was first proposed (17), the technique has been used to elucidate structures for numerous peptides. Recent examples include investigations of: the antibiotic peptide KIAGKIA-KIAGKIA-KIAGKIA (28, 29), the elasticity in an elastin-mimetic peptide (30), derivatives of β-amyloid (31), *Staphylococcus aureus* (32), a model peptide for the silkworm *Samia cynthia ricini* (33), the role of proline residues in the photo cycle of bacteriorhodopsin (34), the arrangement of peptide strands in HIV-1 (35), a bisubstrate inhibitor (36), and a ^{13}C–^{2}H REDOR study of the silk fibroins from *Bombyx mori* (37). As well, Vogt et al. (38) have recently investigated triply labelled uracil and glycine using θ-REDOR (39) to demonstrate that the technique may also provide the angle between two internuclear vectors.

Fig. 1. Molecular structure of orexin-B deposited in the Protein Data Bank (pdb, access code 1CQ0) (5). The horizontal helix (helix I) spans Leu^{7} to Gly^{19} while the vertical helix (helix II) spans Ala^{23} to Met^{28}.

Isotropic NMR chemical shifts generally are sensitive to hydrogen bonding, a key factor controlling the secondary structure of peptides (40, 41). In solution NMR studies of peptides, one often obtains a trial structure based on a comparison of measured chemical shifts with those for samples with a known structure (42). To facilitate these studies, extensive databases summarizing isotropic ^{1}H, ^{13}C, and ^{15}N chemical shifts measured in solution have been compiled (43–45). While isotropic chemical shifts measured for peptides in solution are a weighted average of the various rotational isomers, this is generally not a factor in the solid state, particularly for micro-crystalline samples. One benefit of solid-state NMR measurements is that chemical shift (CS) tensors may in principle be characterized (vide infra). Such measurements can be challenging, particularly when only small amounts of sample are available, as is often the case for NMR studies of solid peptides. However, the three-dimensional nature of the CS tensor (46) can provide significant information about secondary structure (12, 47, 48). A wide range of CS tensor data for peptides with known secondary structure is required to determine reliable relationships between secondary structure and CS tensors. Hence, as part of our solid-state NMR investigation of orexin-B, the CS tensors for the isotopically enriched samples used for the REDOR measurements, the amide carbonyl carbons of Leu^{11} and Ala^{17}, and the amide nitrogens of Leu^{15} and Ala^{22}, are presented.

Background

REDOR

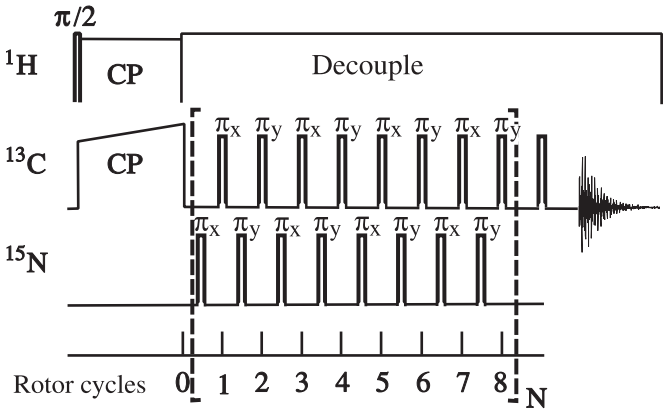
For spin-1/2 nuclei in an applied magnetic field ($\mathbf{B}_0$) typically used in NMR experiments, the Zeeman interaction dominates, but spin-spin interactions with neighbouring magnetically active nuclei may also manifest themselves in the NMR spectra of solid samples. These are the direct dipolar interaction (**D**) transmitted through space and the indirect interaction (**J**) transmitted via the intervening electrons (49). Both spin-spin interactions are described by second-rank tensors. In the absence of molecular symmetry, six parameters are required to fully characterize the symmetric part of these tensors: three principal components and three angles that orient the principal axis system in the molecular axis system. The indirect spin-spin interaction is usu-

© 2004 NRC Canada

ally described by its isotropic value (J_{iso} = (1/3)Tr**J**), while the dipolar interaction is characterized by the dipolar coupling constant (R_{DD}), which depends on the inverse cube of the internuclear separation (r_{AB}):

$$[1] \qquad R_{DD} = \left(\frac{\mu_0}{4\pi}\right)\left(\frac{\hbar}{2\pi}\right)\gamma_A\gamma_B\left\langle r_{AB}^{-3}\right\rangle$$

where μ_0 is the permeability constant and $\hbar$ is Planck's constant divided by 2π, while γ_A and γ_B are the magnetogyric ratios for nuclei A and B, respectively. Rapid molecular motion, such as that which occurs for molecules dissolved in isotropic solutions, leads to an averaging of the values for **D** and **J**. The direct spin-spin interaction is not directly observed in isotropic fluids, since the trace of **D** is zero (49); averaging of **J** manifests itself as the so-called scalar coupling (J_{iso}).



NMR spectra of spin-1/2 nuclei in solid samples are complicated not only by spin-spin interactions, but also by anisotropic magnetic shielding. Rapid magic-angle spinning (MAS) of the sample leads to "solution-like" NMR spectra by averaging to zero both **D** and the anisotropic magnetic shielding. Since the direct relationship between R_{DD} and the internuclear separation renders knowledge of R_{DD} very desirable for structure elucidation, numerous dipolar recovery techniques (17, 25, 26, 50, 51, 52) have been developed. These techniques reintroduce the dipolar interaction while still averaging the magnetic shielding to its isotropic value through MAS. Such techniques are particularly useful when the magnetic shielding anisotropy is much greater than the dipolar interaction. Experimentally, one reintroduces the effective dipolar coupling (R_{eff}) equal to $R_{DD} - 1/3\Delta J$, where the latter term is the anisotropy in **J** (53). Because indirect spin-spin interactions are transferred through the electrons, ΔJ is not significant when there are several intervening bonds between the interacting nuclei, as for the systems considered here. Hence, in the ensuing discussion, R_{eff} is assumed to be equal to R_{DD} (54).

The REDOR technique (10, 17–26) is the most frequently used method for the recovery of heteronuclear dipolar interactions in MAS experiments. Although described as a double resonance technique, typically three rf fields are employed for REDOR experiments, since ^{1}H irradiation is generally used for cross-polarization (CP) and for ^{1}H decoupling. The typical ^{13}C{^{15}N} experiment (22) entails CP from ^{1}H to ^{13}C under the Hartmann–Hahn match condition (55), insertion of rotor-synchronized ^{15}N π pulses to reintroduce $R_{DD}(^{13}C,^{15}N)$, insertion of a refocusing ^{13}C π pulse, and ^{1}H-decoupled data acquisition. In the absence of the ^{15}N π pulses, dephasing arising from $R_{DD}(^{13}C,^{15}N)$ is refocused by the π pulse on the observed ^{13}C nucleus. With the ^{15}N π pulses, the magnetization is not completely refocused, resulting in reduced signal intensity. The REDOR difference ($\Delta S = S_0 - S$) is the difference in signal intensity obtained without S_0, and with, S, ^{15}N dephasing pulses. Regardless of the magnitude of the dipolar interaction, the ratio $\Delta S/S_0$ has the same dependence on the parameter λ_D (23), where:

$$[2] \qquad \lambda_D = N_c T_r R_{DD}$$

In eq. [2], N_c is the number of rotor cycles and T_r is the rotor period. The dependence of $\Delta S/S_0$ on λ_D is described by the universal REDOR curve (22). Knowledge of a few values of $\Delta S/S_0$ yields λ_D. Since N_c and T_r are known, R_{DD} (22) may be determined; the internuclear separation follows from eq. [1]. In the work presented here, $\Delta S/S_0$ is plotted vs. the dephasing time (N_cT_r). Since this is equal to λ_D/R_{DD}, the universal curve can be fit to the experimental points by scaling λ_D by the magnitude of the dipolar interaction.

Fig. 2. REDOR-*xy*8 pulse sequence (56) preceded by CP with a ramped ^{13}C mixing pulse. Note that the $\pi/2$ and π pulses are not drawn to scale.

For the measurement of small heteronuclear interactions and to compensate for possible fluctuations in rf power during the experiment, a modified REDOR pulse sequence has been developed (22, 56). In this pulse sequence (REDOR-*xy*8), phase-alternating π pulses are applied to both ^{13}C and ^{15}N, followed by a refocusing ^{13}C π pulse; this is usually preceded by CP from ^{1}H (Fig. 2). As for most REDOR experiments on peptides, in the present work the ^{1}H-decoupled ^{13}C NMR signal, modified by ^{15}N dephasing pulses, is observed; however readers should recognize that REDOR experiments may in principle be performed between any isolated heteronuclear spin pair (22, 36) and that the technique may also be applied to more complex spin systems (39).

A significant REDOR difference signal will be measured if the dephasing time is equal to or greater than $1/R_{DD}$ (57). Distance measurements based on a smaller REDOR difference are expected to be qualitatively correct but have a greater relative uncertainly. The dephasing time is limited by the effective spin-spin relaxation time and by limits imposed by the hardware, particularly if high-power proton decoupling is required during the dephasing period.

All possible contributions to S or S_0 must be considered when assessing REDOR data. For example, contributions from ^{13}C nuclei present at natural abundance from other residues must be considered when determining the REDOR difference for a ^{13}C NMR signal from a specific residue (20). A more detailed discussion of the corrections required for our data is presented with the results. An article by Naito and Saitô (58) discussing the factors affecting the accuracy of REDOR measurements is highly recommended.

^{13}C and ^{15}N NMR spectroscopy of solid stationary samples

The ^{13}C and ^{15}N NMR line shapes of stationary solid sam-

ples are defined by the span (Ω) and the skew (κ) (59) of the CS tensor:

$$[3] \qquad \Omega = \delta_{11} - \delta_{33}$$

and

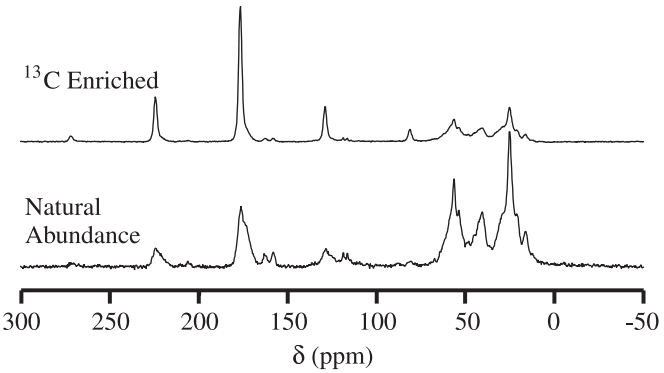
$$[4] \qquad \kappa = \frac{3(\delta_{22} - \delta_{iso})}{\Omega}$$

where the δ_{ii} (i = 1–3) are the principal components of the chemical shift tensor, defined such that $\delta_{11} \geq \delta_{22} \geq \delta_{33}$ and $\delta_{iso} = (1/3)(\delta_{11} + \delta_{22} + \delta_{33})$. For a sample containing isolated ^{13}C or ^{15}N nuclei, the principal components of the CS tensor may be obtained directly from the NMR powder pattern (55, 60–62). While these experiments provide the principal components of CS tensors, they do not yield information about the orientations of the CS tensors in the molecular framework. For the data presented here, CS tensor orientations will be proposed based on those determined for closely related compounds.

Experimental details

Sample preparation

Samples of orexin-B, either at natural abundance or doubly enriched at Leu^{11}-1-^{13}C, Leu^{15}-^{15}N, or at Ala^{17}-1-^{13}C, Ala^{22}-^{15}N, were synthesized by the Alberta Peptide Institute of the University of Alberta from enriched samples of *N*-fmoc-L-leucine and *N*-fmoc-L-alanine; the latter samples were obtained commercially (Cambridge Isotope Laboratories, 99% 1-^{13}C or 98% ^{15}N) and characterized by high-performance liquid chromatography (HPLC). The purity of the orexin-B samples was also confirmed by HPLC. Following purification, the orexin-B samples were lyophilized and stored at 0 °C.



NMR Spectroscopy

Spectra were acquired on a Bruker Avance 500 NMR spectrometer operating at 500.3, 125.8, and 50.7 MHz for ^{1}H, ^{13}C, and ^{15}N, respectively. Samples were packed into 4 mm o.d. zirconia rotors; teflon spacers were placed at the top and bottom of the rotor to ensure that the samples (approximately 20 mg) were centred in the NMR coil.

One-dimensional ^{13}C NMR spectra were acquired using RAMP CP (63) under the Hartmann–Hahn matching condition (55), with a 4.0 μs ^{1}H $\pi/2$ pulse, a 1.0 ms contact time, and 3.0–5.0 s recycle delays. A Hahn echo preceded by CP from ^{1}H was used to acquire ^{15}N NMR spectra of stationary samples. A 3.5 μs ^{1}H $\pi/2$ pulse, 3.0 ms contact time, 70 μs delay before a 13 μs refocusing π pulse and 3–5 s recycle delays were used to acquire these spectra. All spectra were acquired with the two-pulse phase modulation (TPPM) decoupling scheme of Bennett et al. (64). Carbon-13 NMR spectra were referenced to TMS (δ_{iso} = 0) by setting the high-frequency isotropic peak of an external solid adamantane sample to 38.56 ppm (65); those for ^{15}N were referenced to a neat liquid of CH_3NO_2 (δ_{iso} = 0) by setting the isotropic peak for an external NH_4Cl sample to –341.2 ppm (66).

REDOR-*xy*8 (56), with the pulse sequence illustrated in Fig. 2, was used to acquire REDOR data. CP from ^{1}H to ^{13}C was obtained using the same parameters as was used for the one-dimensional ^{13}C NMR spectra. The π pulses were 9.0 and 8.5 μs, respectively, for ^{15}N and ^{13}C. These pulses were optimized by observing the minimum and maximum signals in spectra of a glycine sample that was 10% 1-^{13}C,^{15}N enriched, acquired with the REDOR-*xy*8 pulse sequence using a dephasing time of 1.5 ms. For the orexin-B sample enriched at Leu^{11} and Leu^{15}, 20 points were acquired with an increment of eight rotor cycles between points, corresponding to a maximum dephasing time of 26.7 ms for the sample spinning at 6.0 kHz. For the sample enriched at Ala^{17} and Ala^{22}, three points, with dephasing times of 21.3, 24.0, and 26.7 ms, were acquired; the spinning frequency was also 6.0 kHz. Spectra with short dephasing times contained first- and second-order spinning sidebands; the intensity of these were added to that of the isotropic peak before analysis of the data. The universal REDOR curve was obtained using data generated by the program SIMPSON (67). The program ORIGIN, Version 3.0, was used to fit the universal curve to the experimental points.

Fig. 3. Carbon-13 NMR spectra for orexin-B obtained at 11.75 T with ν_{rot} = 6.0 kHz. The upper trace is that for the sample enriched in ^{13}C at the Leu^{11} carbonyl site and in ^{15}N at Leu^{15}. The lower trace is that for the sample at natural abundance. 13 020 and 13 600 transients were added for the upper and lower traces, respectively.

Results and discussion

REDOR

Determination of $r_{C11,N15}$

Before presenting the data used to extract R_{DD}, spectra of MAS samples and corrections to the data because of ^{13}C nuclei present at natural abundance are considered. Figure 3 illustrates the ^{13}C NMR spectra of orexin-B, obtained at 11.75 T with a rotor frequency (ν_{rot}) of 6 kHz. The spectrum of the sample that is ^{13}C enriched at the amide carbonyl of Leu^{11} contains an isotropic peak at δ_{iso} = 176.3 ± 0.5 ppm, typical of values observed for amide carbonyl carbons (16, 45, 68). The peak width at half height ($\Delta\delta_{1/2}$) is slightly more than 2 ppm at B_0 = 11.75 T, normal for carbonyl carbons of lyophilized peptide samples (15). Residual dipolar coupling to the neighbouring ^{14}N nucleus (I = 1) is expected to only contribute approximately 0.2 ppm to the line width of the isotropic amide carbonyl peak of a spectrum acquired at 11.75 T (69, 70). Furthermore, the line broadening is not

© 2004 NRC Canada

thought to be a consequence of variations in the secondary structure. However, variations in the conformations of the side chains, leading to a distribution of values for δ_{iso}, have been suggested as a cause for broad isotropic peaks in spectra of lyophilized samples (15). DePristo et al. (71) have recently provided a comprehensive discussion of heterogeneity in protein structures. The intensity of the peaks centred at approximately 176 ppm in the spectrum of the natural-abundance sample demonstrates that most amide carbonyl ^{13}C nuclei of orexin-B appear near the position of the Leu^{11} carbonyl carbon and must be considered in the analysis of the REDOR data. However, because these do not all have exactly the same isotropic chemical shift as does the carbonyl carbon of Leu^{11}, the correction cannot be based solely on the number of natural-abundance amide carbonyl carbons in orexin-B. To determine the correction required for the intensity of the peak at 176 ppm, the sharp peaks at 25 ppm are considered, since these arise solely from ^{13}C present at natural abundance in either spectrum. Since the spectra of the labelled and unlabelled samples were acquired under identical experimental conditions, the small difference in intensity at this shift must arise from different sample masses and the difference in the number of scans. By normalizing the intensities of these peaks, the contribution to the peak at 176.3 ppm from ^{13}C nuclei at natural abundance was determined to be 11%, suggesting that 10 ^{13}C nuclear sites in each molecule contribute intensity to the peak at 176.3 ± 0.5 ppm. Other amide carbonyl carbons of orexin-B also appear near 176.3 ppm, but they are sufficiently different to avoid affecting the peak intensity; the broadening of the base of the isotropic peak is attributed to these nuclei. Since one of the 10 carbonyl carbons appearing at 176.3 ppm in the spectrum of the natural-abundance sample is that from Leu^{11}, nine carbonyl carbon atoms present at natural abundance contribute to the signal intensity of the isotropic peak for the spectrum of the ^{13}C-enriched sample. Hence, 9.9% of the peak intensity observed for the peak at δ = 176.3 ppm was subtracted from the values of S_0 in the calculation of the REDOR data.

Most amide carbonyl carbon nuclei present at natural abundance are distant from the site of ^{15}N enrichment and hence are unaffected by ^{15}N dephasing pulses. Thus, for these nuclei, $S_0 - S = 0$ and a correction is not required for ΔS. Exceptions are the natural-abundance carbonyl ^{13}C for Leu^{15} and the backbone carbonyl ^{13}C for Gln^{16}, which are one- and two-bonds distant, respectively, from the site of ^{15}N enrichment, Leu^{15}. If these nuclei appear at the same frequency as the carbonyl ^{13}C of Leu^{11}, a correction to the ΔS term is required. The initial points of the REDOR data (Fig. 4*a*) do indeed show stronger than expected dephasing, since the intercept of the points at the ordinate axis is greater than zero and a fit to the universal REDOR curve is not possible. Based on the structure for DL-alanine (72), ^{13}C–^{15}N dipolar interactions of approximately 900 and 200 Hz, respectively, are expected for the carbonyl carbons of Leu^{15} and Gln^{16} present at natural abundance. By correcting for the dephasing of these nuclei (Fig. 4*b*), the fit to the curve is much better and the intercept is near the origin as expected. This confirms that the isotropic resonances for the carbonyl ^{13}C nuclei for Leu^{15} and Gln^{16} are at approximately 176.3 ppm. In their investigation of glutamine-binding protein, Hing et al. (73) found that the contribution to the observed dephasing from neighbouring carbons present at natural abundance reaches a maximum of 2% after a dephasing period of 4.25 ms, but is negligible after 8.5 ms; similar results are observed here.

The ^{15}N nuclei present at natural abundance (0.366%) are subject to the dephasing pulses and could in principle affect the ^{13}C signal, but Naito et al. (74) have shown that the effect on ΔS is negligible; hence, no corrections to the data were made for this factor. Likewise, the data were not corrected for intermolecular dipolar interactions, since these are not expected to be significant for a large molecule such as orexin-B. In REDOR investigations of (Phe-Leu-Ala)$_6$, Kimura et al. (75) found that intermolecular effects are negligible when measuring distances within α helices.

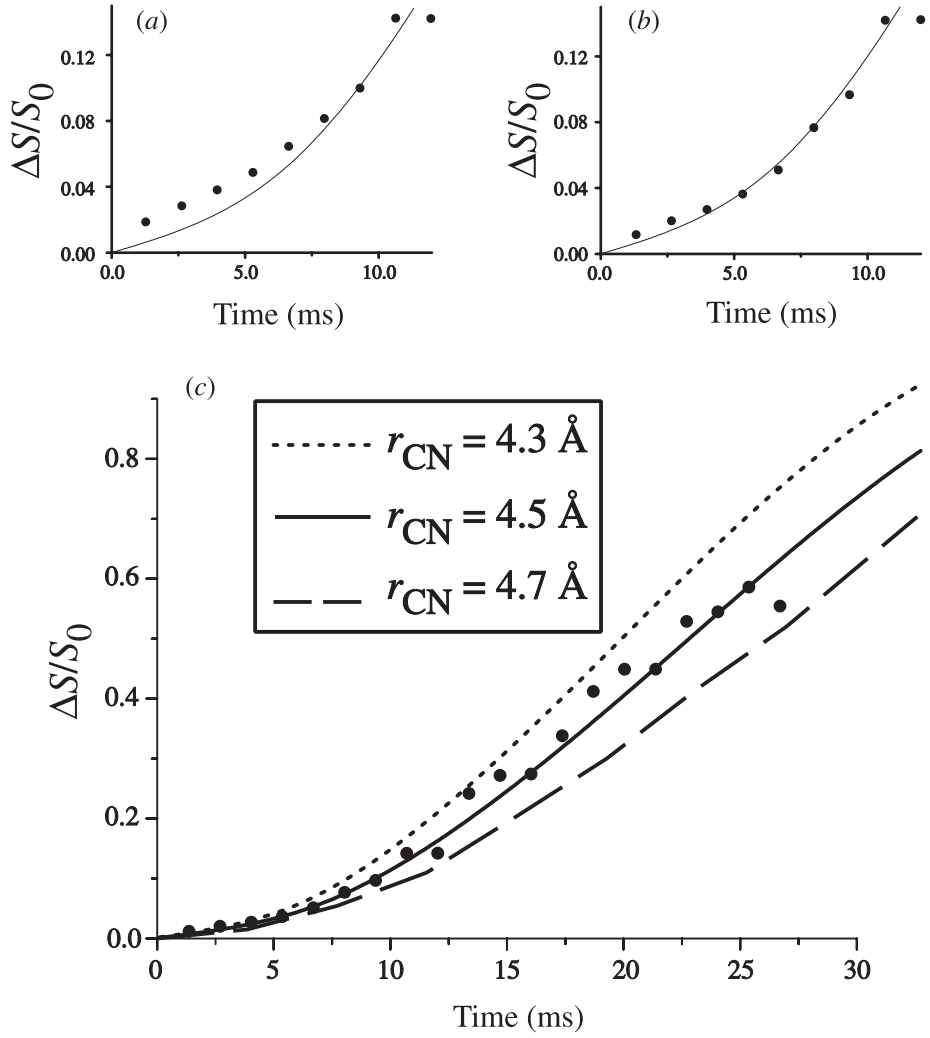


Figure 4*c* illustrates a plot of $\Delta S/S_0$ as a function of dephasing time for orexin-B ^{13}C and ^{15}N enriched at Leu^{11} and Leu^{15}, respectively. Data used to prepare this plot were corrected as already discussed. The fit of the data yields a value of 35 ± 3 Hz for $R_{DD}(^{15}N,^{13}C)$, corresponding to $r_{C11,N15}$ = 4.5 ± 0.2 Å. This value has not been corrected for librational averaging (76); at 20 °C, this may lead to dipolar coupling constants that are approximately 10% less than that expected for a rigid lattice (20). This leads to an error in the internuclear distance of approximately 2%, which is much smaller than the value of ±0.2 Å arising from other sources. The value for $r_{C11,N15}$ is in agreement with those reported for other α helices (75) and is within the range of values (3.6 Å (5) and 5.1 Å (6)) measured in the solution NMR studies of orexin-B. The distance between the corresponding nuclei of an idealized structure consisting of seven alanine residues is 4.12 Å for the nuclei in an α helix, but 12.1 Å if the polyalanine is extended. Therefore, our data strongly suggests that the α helix for the Leu^{11} to Leu^{15} fragment of orexin-B found in solution studies (5, 6) is also present in the solid state.

Determination of $r_{C17,N22}$

To investigate the relative orientations of the two α helices of orexin-B (5, 6), we undertook a REDOR experiment on solid orexin-B with ^{13}C and ^{15}N enrichment at Ala^{17} and Ala^{22}, respectively. Within experimental error, the isotropic peak for the amide carbonyl carbon is the same as for Leu^{11} (176.1 ± 1.0 ppm), but it is considerably broader ($\Delta\delta_{1/2} \approx$ 6.4 ppm, Fig. 5). Broad peaks (>6 ppm) have been observed for other amide carbonyl carbons in lyophilized peptides (77). Because this line width is three times greater than that observed for the amide carbonyl carbon for Leu^{11}, the possibility that this is a consequence of sample preparation was considered. The sample was redissolved and lyophilized; the line widths were unchanged. The purity was verified by acquiring a ^{13}C NMR spectrum of the sample dissolved in aqueous SDS solution — a single peak was observed for the carbonyl carbon of Ala^{17}. To further verify that all samples of orexin-B were the same, apart from the sites of enrichment, other peaks in the ^{13}C NMR spectrum of the sample enriched at Ala^{17} were compared with those for orexin-B ^{13}C enriched at Leu^{11} and at natural abundance. A peak at 158 ppm, attributed to C_ε of one of the arginine residues of orexin-B (78), has the same line width in spectra of the natural abundance sample and of the sample enriched at Ala^{17};

Fig. 4. Dependence of $\Delta S/S_0$ on the dephasing time (points) for the Leu[11] carbonyl carbon. The solid lines are the universal REDOR curve for a dipolar interaction of 35 Hz. The data arising from the first 11 ms of dephasing time, calculated *without* (*a*) and *with* (*b*) the correction for dephasing of the amide carbonyl ^{13}C nuclei of Leu[15] and Gln[16] are shown at the top. The complete plot (*c*) is shown at the bottom; the dashed and dotted lines indicate the uncertainty in the data.

the peaks at 25 ppm for all three samples also have the same line widths. In addition, the isotropic ^{15}N peak of the sample ^{15}N enriched at Leu[15] has the same line width as that for this sample, which is ^{15}N enriched at Ala[22]. Hence, the broad line width for the carbonyl carbon of Ala[17] is indeed specific to that site, suggesting a greater degree of disorder in this portion of orexin-B than is found about Leu[11]. Belton et al. (79) have presented a detailed discussion of factors affecting ^{13}C NMR line widths in the spectra of solid proteins.

Considering the broad peaks in the ^{13}C NMR spectra for Ala[17], acquiring multiple points for a REDOR curve as was done for the sample enriched at Leu[11] and Leu[15] was impractical. Three points, with dephasing times of 21.3, 24.0, and 26.7 ms, were collected yielding dipolar coupling constants of 12, 14, and 10 Hz, respectively. As for the data used in the determination of $r_{C11,N15}$, these data were corrected for the effects of ^{13}C nuclei present at natural abundance. Because of the broad peaks and the long dephasing time, spectra had lower signal-to-noise than those for the sample enriched at Leu[11]. Figure 5 illustrates the spectra obtained with and without the ^{15}N dephasing pulses for a dephasing time of 24 ms. From these spectra, a dipolar interaction of 12 ± 3 Hz is determined. This corresponds to an internuclear separation of 6.4 ± 0.5 Å, but considering the broad isotropic carbonyl ^{13}C peak, the possibility of multiple relative orientations for the two α helices cannot be discounted. Hence, the value of 6.4 Å may be a weighted average. For example, similar REDOR data would be obtained if 90% of the sample had a structure such that $r_{C17,N22}$ = 8 Å and 10% had a structure such that $r_{C17,N22}$ = 4 Å. Experiments to resolve this issue are not practical with the limited sample available. Although dynamic disorder would also reduce the measured dipolar coupling, this may be discounted since the spans of the ^{13}C and ^{15}N NMR spectra (vide infra) of a stationary sample are typical of these samples in the absence of motion (80). Finally, we note that a distance of 6.0 Å is expected for a nitrogen five residues distant from a carbonyl carbon in an idealized polyalanine α helix, within error of the value for $r_{C17,N22}$. However, considering the solution NMR data (5), a bend between two helices in

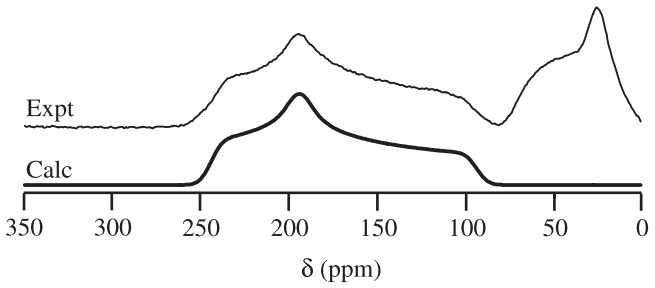
Nitrogen						
L-Leu[15]	–158(3)	–303(3)	–322(3)	–260.7(15)	164	–0.77
L-Ala[22]	–159(5)	–296(4)	–319(5)	–258.2(15)	160	–0.71

[a]Data are in ppm, apart from κ, which has no units; estimated uncertainties in the last digits are in parentheses.
[b]Measured from spectra of MAS samples. δ_{iso} may not be exactly equal to the average of the principal components because of the greater uncertainty in the values of the latter.
[c]$\Omega = \delta_{11} - \delta_{33}$.
[d]$\kappa = 3(\delta_{22} - \delta_{iso})/\Omega$.

Fig. 5. Carbon-13 NMR spectra for orexin-B ^{13}C enriched at the amide carbonyl of Ala[17] and ^{15}N enriched at Ala[22] obtained at 11.75 T with ν_{rot} = 6.0 kHz. Traces S_0 and S, respectively, were acquired without and with ^{15}N dephasing pulses in the REDOR-*xy*8 pulse sequence. 15 120 transients were acquired for each spectrum. The REDOR difference (ΔS) is shown in the lower trace.



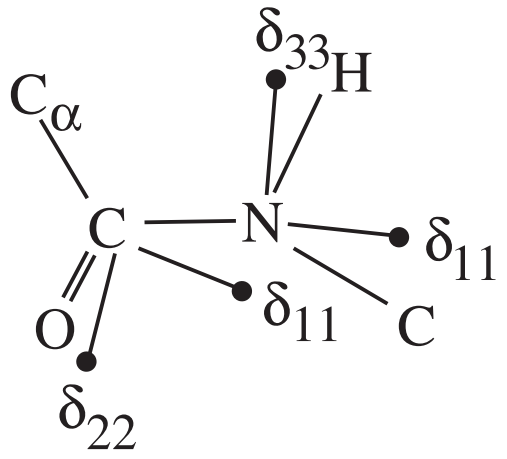
orexin-B is thought to be the more likely explanation for the relative proximity of Ala[17] and Ala[22].

Summarizing, our REDOR experiments are consistent with the presence of an α helix that incorporates Leu[11] and Leu[15]; the dipolar coupling between the carbonyl carbon of Ala[17] and the nitrogen of Ala[22] suggests a value of 6.4 Å for $r_{C17,N22}$. Although the latter value may be a weighted average, it is compatible with a bend between the two α helices of orexin-B. Examination of the solution NMR data (6) indicates that a bend could lead to a value for $r_{C17,N22}$ between 5 and 9 Å.

Chemical shift tensors

The carbon and nitrogen CS tensors for the nuclei involved in the REDOR investigation discussed above were determined via the analyses of NMR spectra of stationary samples. The spin systems were assumed to be isolated — the small ^{13}C–^{15}N dipolar interactions amount to less than 1 ppm at 11.75 T and hence are negligible.

Fig. 6. Experimental and calculated ^{13}C NMR spectra for the carbonyl carbon nucleus of the Leu[11] residue of a stationary sample of orexin-B acquired at 11.75 T. The peaks in the 0–80 ppm region of the experimental spectrum arise from aliphatic ^{13}C nuclei at natural abundance; 21 875 transients were acquired.



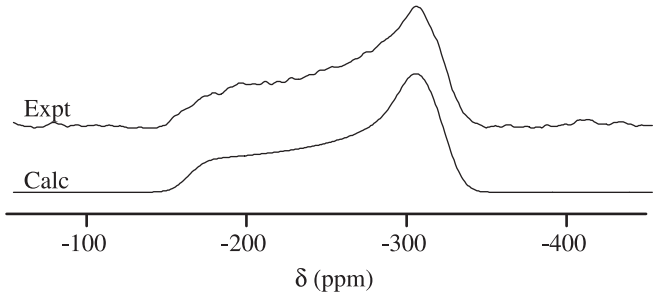
Carbon CS tensors

The ^{13}C NMR spectra of MAS samples of orexin-B have been discussed above. These consist of relatively broad isotropic peaks for Leu[11] (Fig. 3) and for Ala[17] (Fig. 5) with first- and second-order spinning side bands at ν_{rot} = 6 kHz, suggesting significant spans. Figure 6 illustrates the ^{13}C NMR spectra of the carbonyl ^{13}C nuclei of Leu[11] for a stationary sample of orexin-B; those for Ala[17] are similar. The principal components of the CS tensors derived from simulations of these spectra are listed in Table 1. These are within the range of values reported in previous studies of carbonyl carbon CS tensors for leucine (68, 81–83) and alanine (68, 81, 84–86) residues in various peptides.

Before proceeding with a comparison of the CS tensor data, consideration of the CS tensor orientations is important. Those for the nuclei of orexin-B were not determined directly, since they are not thought to vary significantly for amide carbonyl carbons in peptides. Calculations (81, 83) and experiment (83, 87, 88), including a single-crystal NMR study of Gly containing peptides (89), suggest that the CS tensors are oriented such that δ_{11} and δ_{22} are in the peptide plane, with the latter component approximately along the C—O bond and with δ_{33} perpendicular to this plane, as shown in Fig. 7.

© 2004 NRC Canada

Fig. 7. General orientation of amide carbonyl carbon and amide nitrogen CS tensors in peptides. The δ_{33} component for the carbonyl carbon and the δ_{22} component for the nitrogen are perpendicular to the page.



The carbon CS tensors for Leu[11] and for Ala[17] (Table 1) are very similar; only the shielding in the direction of δ_{22} has a difference greater than the experimental error. Although magnetic shielding in this direction is particularly sensitive to hydrogen bonding (48, 81, 90, 91), the difference observed here is too small to draw any conclusions about hydrogen bonding. The similarity of the CS tensors is not surprising, since solution NMR studies (5, 6) suggest that both Leu[11] and Ala[17] form part of the α helix I.

Nitrogen CS tensors

Nitrogen-15 NMR spectra for MAS samples of orexin-B ^{15}N-enriched at Leu[15] and Ala[22] (not shown) are relatively broad ($\Delta\delta_{1/2}$ = 8 ppm); within error, they have the same isotropic values. Figure 8 illustrates the ^{15}N NMR spectra for the Leu[15] residue of a stationary sample of orexin-B; similar spectra were obtained for the Ala[22] residue. The principal components of the nitrogen CS tensors, obtained from fits to these spectra, are listed in Table 1. These data fall within the standard deviation of a compilation of nitrogen CS tensors for 61 amides (68). Likewise, the isotropic chemical shifts are in the range of solution NMR values obtained for Leu and Ala residues in peptides (45) and also for these residues in ubiquitin, measured in the solid state (92). The ^{15}N NMR properties for the Leu residues of solid gramicidin A have been investigated by several groups (93–95); our results for Leu[15] are similar. Likewise, those for the amide nitrogen of Ala[22] are similar to those reported for other Ala residues (88, 93–100). A summary of solid-state ^{15}N NMR studies of peptides has recently been published (101).

The nitrogen CS tensor orientation for glycyl-[^{15}N]glycine hydrochloride monohydrate was determined from a single-crystal NMR study (102). An axially symmetric CS tensor was determined, with the unique component in the peptide plane, approximately orthogonal to the carbonyl carbon-to-nitrogen bond. Later powder NMR (69, 95, 103–106) and quantum chemical studies (83) found similar orientations; for non-axially symmetric CS tensors, the δ_{11} and δ_{33} components lie approximately in the peptide plane, as illustrated in Fig. 7.

Fig. 8. Experimental and calculated ^{15}N NMR spectra for the Leu[15] residue of a stationary sample of orexin-B acquired at 11.75 T; 27 400 transients were acquired.

There are no significant differences between the nitrogen CS tensors for Leu[15] and Ala[22]. This is consistent with the data of Miskolzie et al. (6), who reported that both residues form part of the α helices and therefore are expected to have similar local environments. A complex relationship between isotropic ^{15}N chemical shifts and hydrogen bonding, depending on the orientation of the hydrogen bond, has been suggested (81). Considering the similar nitrogen CS tensors for Leu[15] and Ala[22], it is not possible to surmise any differences in the hydrogen bonding environments between these two sites.

Conclusions

REDOR experiments were undertaken on orexin-B to investigate the secondary structure in the solid state. Measurement of the internuclear distance between the carbonyl carbon of Leu[11] and the nitrogen of Leu[15] yields a value of 4.5 ± 0.2 Å, consistent with an α helix for this segment of orexin-B, as reported by Lee and co-workers (5) and by Miskolzie et al. (6). Distance measurements between the carbonyl carbon of Ala[17] and the amide nitrogen of Ala[22] yield an effective value of 6.4 ± 0.5 Å. This distance is compatible with a bend between two α helices in orexin-B, but other structures, such as that of an α helix that includes Ala[17] and Ala[22], would also yield the same value.

To obtain more information about the secondary structure of orexin-B in the solid state, it would be desirable to prepare other samples of orexin-B containing selectively labelled ^{13}C and ^{15}N spin pairs. Because the REDOR technique works best for isolated spin pairs, a separate sample must be prepared for every distance required. Obviously future experiments must be planned carefully since the cost of preparing selectively ^{13}C, ^{15}N enriched samples is significant.

We have also determined the amide carbonyl carbon and amide nitrogen CS tensors for the labelled residues of orexin-B. There is no significant variation between the amide carbonyl carbon CS tensors for Leu[11] or Ala[17], nor between the amide nitrogen CS tensors for Leu[15] and Ala[22].

This study has demonstrated the value of REDOR to complement solution NMR data. It is hoped that this work will encourage researchers to consider these or related techniques when investigating the secondary structure of peptides.

Acknowledgments

We thank the members of the solid-state NMR group at the University of Alberta for many helpful comments and suggestions. We are grateful to Dr. Anil Mehta of Washington University for his advice on the REDOR experiments. We acknowledge Robert Parker and the Alberta Peptide Institute, as well as Richard Tomski of the machine shop, for their assistance. R.E.W. and G.K. acknowledge funding from the Natural Sciences and Engineering Research Council of Canada (NSERC). R.E.W. thanks the Government of Canada for a Canada Research Chair in physical chemistry at the University of Alberta. Finally, R.E.W. is grateful to the late Professor Don Irish who introduced him to spectroscopy in an undergraduate class at the University of Waterloo.

TRIBUTE / HOMMAGE

This issue of the *Canadian Journal of Chemistry* contains papers dedicated to the memory of Professor Donald Edward Irish. It was with great sadness that we heard that Don had passed away on 26 October 2002 in Waterloo, Ontario, after a two-year battle with cancer. Don had many friends and colleagues across the scientific community, both at home in Canada and abroad, and it is fitting that we have been able to put together in the *Canadian Journal of Chemistry* a tribute to his life and career.

Don was born on 14 June 1932 in Uxbridge, Ontario, and grew up in Port Elgin, Ontario. He obtained his B.Sc. in 1955 with Honours in Chemistry and Physics at the University of Western Ontario and then went on to a obtain a Master's degree under R.H. Tomlinson at McMaster University in 1956, for which he studied yields in the thermal neutron fission of ^{233}U. He earned his Ph.D. in 1962 under T.F. Young at the University of Chicago, where he began his lifelong interest in Raman spectral studies of electrolyte solutions.

After a short spell as a chemistry teacher at the Central Technical School in Toronto, Don's long association with Waterloo began on 1 July 1957, when he was appointed Lecturer in the Waterloo College Associate Faculties (which shortly thereafter became the University of Waterloo). He was the first Lecturer in Chemistry to be hired at the fledgling university. He became Assistant Professor in 1962 and reached the level of Full Professor in 1971. He served as Chairman of the Department of Chemistry from 1977 to 1983. He also served the university on numerous committees at the university, provincial, and national levels. Don was an avid international traveler and spent time at laboratories in several countries, including Bell Laboratories in New Jersey, the University of Newcastle-upon-Tyne, CNRS Laboratories in Thiais, the University of Karlsruhe, DSIR New Zealand, the University of Queensland, and the University of Geneva. Not one to sit back, he stayed active as Adjunct Professor Emeritus upon his retirement on 1 July 1996 and was named Distinguished Professor Emeritus in 1999.

Don will be remembered by his many former undergraduate and graduate students as a great science teacher, a facet of his abilities for which he was honoured with three awards: the University of Waterloo Distinguished Teacher Award in 1987, the Ontario Confederation of University Faculty Associations' Teaching Award in 1988, and The Union Carbide Award of the Chemical Institute of Canada for Chemical Education in 1990.

As a member of the broader scientific community, Don was a very active member of the Chemical Institute of Canada (CIC) and the Canadian Society for Chemistry (CSC), serving on committees both at the national and local levels, and he became a Fellow of the CIC in 1974. He was on the organizing committees of several international conferences and served on the editorial board of the *Journal of Solution Chemistry* for many years. A special symposium was arranged for the 82nd CSC Congress held in Toronto in 1999 to honour Don on his retirement, and the proceedings fittingly were published in a special issue of the *Journal of Solution Chemistry* (Vol. 29, No. 10, October 2000). This symposium, and the dinner that followed, was a testimonial to Don's high standing amongst his colleagues both nationally and internationally and amongst his former students.

Don was primarily a physical chemist, specializing in Raman and IR spectroscopy of electrolyte solutions, probing both solvent and solute. By observing the various species as

Ce numéro de la *Revue canadienne de chimie* réunit des articles dédiés à la mémoire du professor Donald Edward Irish. C'est avec une profonde émotion que nous avons appris le décès de Don, le 26 octobre 2002, à Waterloo, en Ontario, au terme d'une lutte de deux ans contre le cancer. Don comptait de très nombreux amis et collègues dans la collectivité scientifique, tant au Canada qu'à l'étranger. La publication d'un numéro spécial de la *Revue canadienne de chimie* nous a donc paru une élégante façon d'honorer sa vie et son oeuvre.

Don est né le 14 juin 1932 à Uxbridge, en Ontario, et a grandi à Port Elgin, dans cette même province. Il a obtenu un baccalauréat *ès* sciences spécialisé en chimie et en physique à l'Université Western Ontario (1955), puis une maîtrise à l'Université McMaster (1956), où il a analysé la puissance de la fission induite par neutron thermique de l'uranium 233, sous la direction de R.H. Tomlinson. Il a obtenu son doctorat aux côtés de T.F. Young, en 1962, dans les laboratoires de la University of Chicago, point de départ d'un intérêt pour les études par spectroscopie Raman de solutions électrolytiques que Don cultivera toute sa vie.

Après une brève période comme professeur de chimie à la Central Technical School de Toronto, Don a amorcé sa longue carrière à Waterloo, le 1er juillet 1957, à titre de chargé de cours aux Waterloo College Associate Faculties, appelées à devenir l'Université de Waterloo. De fait, il a été le premier chargé de cours en chimie dans les effectifs de la nouvelle université. Il a ensuite gravi les échelons : professeur adjoint (1962), professeur titulaire (1971) et président du département de chimie (1977–1983). Don a aussi représenté l'Université auprès de nombreux comités universitaires, provinciaux et nationaux. « Globe-trotter » invétéré, Don a exercé son art dans des laboratoires des quatre coins du monde, y compris aux laboratoires Bell (New Jersey, É.-U.), à la University of Newcastle-upon-Tyne (R.-U.), aux laboratoires du CNRS (Thiais, France), à la Universität Karlsruhe (Allemagne), au DSIR (Nouvelle-Zélande), à la University of Queensland (Australie) et à l'Université de Genève (Suisse). D'un caractère énergique, il a continué à contribuer activement au domaine à titre de professeur émérite adjoint après sa retraite, le 1er juillet 1996, et a été reçu professeur émérite distingué en 1999.

Ses anciens étudiants de premier et de deuxième cycles se souviendront toujours de Don comme d'un enseignant doué. De fait, son talent de pédagogue a été confirmé par trois honneurs : le prix du mérite en enseignement de l'Université de Waterloo (1987), le prix d'excellence en enseignement de l'Union des associations des professeurs des universités de l'Ontario (1988) et le Prix Union Carbide pour l'enseignement de la chimie de l'Institut de chimie du Canada (1990).

Au sein de la collectivité scientifique, Don a été un membre assidu de l'Institut de chimie du Canada (ICC) et de la Société canadienne de chimie (SCC), auprès desquels il a participé à plusieurs comités nationaux et locaux. Il a notamment été reçu Fellow de l'ICC en 1974. Il a siégé au comité organisateur de nombreux congrès internationaux et a été membre du comité de rédaction du *Journal of Solution Chemistry* pendant plusieurs années. Incidemment, un symposium en son honneur a été organisé en 1999, dans le cadre du 82e congrès de la SCC, à Toronto, à l'occasion de sa retraite. Les actes de ce symposium ont fait l'objet, fort opportunément, d'un numéro spécial du *Journal of Solution*

© 2004 NRC Canada

a function of concentration and temperature he was able to determine, often in minute detail, the various processes that can occur and thereby extract equilibrium constants and other thermodynamic parameters. Over the years he made invaluable contributions to our understanding of species and processes in solution, such as complex formation, acid dissociation, hydrated proton species, solvation, ion–ion interactions, solvent structure making and breaking, and the structure of water and solutions at high temperature. His high-temperature work was of great interest to Canada's energy industries. Also, in the early days of computers, Don was a strong proponent of their use in the collection and analysis of spectral data. As time went by he became more involved in surface enhanced Raman spectroscopy (SERS) for the study of adsorbates at electrode surfaces, both in understanding the phenomenon itself and the processes occurring at the electrode–electrolyte interface and in the potential application of SERS in areas such as corrosion and electrocatalysis.

Throughout his career Don authored about 170 publications, including eight monographs. His scientific work earned him an outstanding international reputation in physical chemistry. He supervised 16 Ph.D. and 13 M.Sc. students and his lab hosted 18 visiting scientists and post-doctoral fellows. These graduates and fellows went on to positions in universities, colleges, industry, NRC, AECL, and NSF. He gave much help to these and many other individuals over the years in their scientific careers. One of us (DJL) experienced this first hand when Don visited Canterbury University in 1969 and responded to a request for help in a way that significantly and positively altered his eventual Postdoctoral fellow's life and career. In all this he was characteristically modest and unassuming, enjoying a love for science with an enthusiasm that infected all who worked with him.

Don was not just a one-track scientist: he had many other interests and hobbies. He and his wife, Shirley, loved to travel, and they visited most of the world together over the years, with Don recording these events with his trusty camera that was always at hand. These trips were regaled with a slide show to his current crop of graduate students at the frequent pleasant dinner evenings he and Shirley graciously hosted for them. He ensured his own physical fitness mainly through the ritual of walking the family dog each evening, but he also firmly encouraged his graduate students to maintain a regime of regular physical activity. Don thoroughly enjoyed hiking in the countryside and observing nature and he shared this enthusiasm with anyone who was willing to accompany him on his frequent expeditions. He took an active role in the movement to preserve the Bruce Trail and the Niagara Escarpment in Southern Ontario. Don and Shirley eventually purchased a cottage overlooking Georgian Bay so that they could be closer to this significant life-long interest. He was interested in reading, music, and drama, and was a keen sailor. Don was also a profoundly religious man and was an active member of the United Church of Canada, serving on many committees. He was closely involved with St. Paul's United College from its founding as an Affiliated College of the University of Waterloo. Those of us who knew him well marveled at how Don managed to fit so many activities into a normal day; he was always moving on from one event to another without missing a beat!

We celebrate Don's life, which was dedicated to his family, his friends, his community, and to science and education and the beneficial influence he has had on our own lives that will not be forgotten.

Chemistry (vol. 29, n° 10, octobre 2000). Ce symposium et les agapes qui ont suivi ont mis en lumière l'énorme respect qu'inspirait Don à ses anciens disciples de même qu'à ses collègues du Canada et du monde entier.

Don était avant tout un physicochimiste, spécialisé en spectroscopie Raman et infrarouge appliquée aux solvants et aux solutés de solutions électrolytiques. En observant diverses espèces chimiques en fonction de leur concentration et de leur température, Don est arrivé à définir, souvent très précisément, les processus chimiques susceptibles de se manifester et, par conséquent, à dégager des constantes d'équilibre et d'autres paramètres de thermodynamique. Au fil des ans, il a sensiblement enrichi notre connaissance des espèces chimiques et des phénomènes en présence dans les solutions, tels que la formation de complexes, la dissociation des acides, les espèces à protons hydratés, la solvatation, les interactions ion–ion, l'élaboration et la fragmentation des structures de solvant ainsi que la structure de l'eau et des solutions à température élevée. Ses travaux à température élevée ont d'ailleurs fait date dans l'industrie énergétique canadienne. En outre, dès l'apparition des ordinateurs, Don a loué haut et fort l'efficacité de ces appareils pour la collecte et l'analyse des données spectrales. Ultérieurement, Don a eu recours à la spectrométrie laser de l'effet Raman exalté de surface (SERS) pour étudier les adsorbats à la surface des électrodes, ceci en vue de comprendre non seulement le phénomène en tant que tel mais encore les processus qui se produisent à l'interface électrode–électrolyte de même que l'utilité de la SERS pour l'étude de mécanismes tels que la corrosion et l'électrocatalyse.

Au cours de sa carrière, Don a signé environ 170 publications, dont huit monographies. Ses recherches scientifiques lui ont permis d'acquérir des lettres de noblesse dans la collectivité mondiale de la chimie physique. Il a supervisé 16 doctorants et 13 mastères, et son laboratoire a accueilli 18 chercheurs invités et boursiers postdoctoraux. Les étudiants et confrères qu'il a encadrés oeuvrent aujourd'hui auprès d'universités, de collèges, de l'industrie, du CNRC, d'EACL et de la NSF. Don n'hésitait pas à épauler ses protégés et ses collègues au cours de leur carrière. Un de nous, DJL, peut en attester : Don, alors en visite à la Canterbury University, en 1969, lui a prêté une aide bénéfique et déterminante pour ses études postdoctorales, voire pour sa carrière. En dépit de sa vaste influence, Don a toujours fait preuve de modestie et de simplicité, conjuguées à une passion communicative pour la science.

Pour autant, Don ne restait pas claquemuré dans les laboratoires : il se consacrait à de nombreux intérêts et passe-temps. Ainsi, Don et son épouse Shirley adoraient voyager et ont sillonné le monde pendant leur vie commune. Don, sa caméra fétiche au cou, se faisait un devoir de croquer sur le vif les moments passés outre frontière en vue de projections souvenir qui concluaient souvent les soirées gourmandes qu'il organisait avec Shirley pour ses étudiants. Il gardait la forme surtout par des promenades avec son chien dans l'air du soir et ne se lassait pas de rappeler à ses étudiants l'importance de l'exercice physique. Don affectionnait aussi les promenades en campagne et la communion avec la nature. Il partageait cette passion avec quiconque daignait l'accompagner dans ses nombreuses expéditions. Don a fait partie du mouvement de préservation du sentier Bruce et de l'escarpement de Niagara, dans le sud de l'Ontario. Pour étancher leur soif d'immersion dans la nature, Don et Shirley se sont acheté un chalet sur la Baie Georgienne. Don passait aussi beaucoup de temps à la lecture, la musique et le théâtre. Il était également un mordu de la voile. Don était un homme foncièrement croyant : il servait activement son

église, l'Église unie du Canada, autant comme fidèle que comme membre de divers comités. Il a étroitement contribué à la fondation du St. Paul's United College et à son affiliation avec les collèges de l'Université de Waterloo. Ceux d'entre nous qui le connaissaient bien s'émerveillaient de la façon dont il arrivait à sertir ses journées de si nombreuses activités. Il semblait passer d'un rôle à l'autre sans jamais perdre son souffle!

Nous sommes fiers de pouvoir célébrer ici la vie de Don, qu'il a su pleinement investir dans sa famille, ses amis, sa communauté, la science et l'enseignement, et de souligner l'enrichissante et l'inoubliable influence que Don Edward Irish aura eue sur nos vies.

AWARD LECTURE / CONFÉRENCE D'HONNEUR

2003 Fred Beamish Award Lecture — Exploring the dynamics of biological systems by mass spectrometry

Lars Konermann

Abstract: This review describes the use of electrospray ionization mass spectrometry (ESI-MS) in conjunction with on-line rapid mixing techniques. This combination, termed "time-resolved" ESI-MS, provides a powerful approach for studying solution-phase reactions on timescales as short as a few milliseconds. Of particular interest is the application of this technique for monitoring protein folding reactions. Time-resolved ESI-MS can provide detailed information on structural changes of the polypeptide chain, while at the same time probing the occurrence of noncovalent ligand–protein interactions. Especially when used in combination with hydrogen–deuterium pulse labeling, these measurements yield valuable structural information on short-lived folding intermediates. Similar approaches can be used to monitor the dynamics of proteins under equilibrium conditions. Another important application of time-resolved ESI-MS are mechanistic studies on enzyme-catalyzed processes. These reactions can be monitored under presteady-state conditions, without requiring artificial chromophoric substrates or radioactive labeling. We also discuss the use of ESI-MS for monitoring noncovalent ligand–protein interactions by diffusion measurements. In contrast to conventional MS-based techniques, this approach does not rely on the preservation of noncovalent interactions in the gas phase. It appears that diffusion measurements by ESI-MS could become an interesting alternative to existing methods for the high throughput screening of compound libraries in the context of drug discovery.

Key words: reaction intermediate, rapid mixing, kinetics, protein conformation, protein function.

Résumé : Cette revue décrit l'utilisation de la spectrométrie de masse avec ionisation par électronébulisation (SM-IEN) en relation avec les techniques de mixage rapide en ligne. Cette combinaison, à laquelle on se réfère comme SM-IEN résolue en fonction du temps, fournit une approche puissante à l'étude des réactions en solution, à des échelles de temps aussi rapides que quelques millisecondes. Il est particulièrement intéressant que cette technique puisse être appliquée au monitoring des réactions de repliement des protéines. La SM-IEN résolue en fonction du temps peut fournir des informations détaillées sur les changements structuraux de la chaîne polypeptidique tout en examinant l'apparition d'interactions non covalentes ligand–protéine. Lorsqu'on les utilise en combinaison avec un marquage pulsé hydrogène–deutérium, ces mesures fournissent en particulier des informations importantes relatives à la structures des intermédiaires de repliement de courte vie. On peut utiliser des approches semblables pour suivre la dynamique des protéines dans des conditions équilibrantes. Les études mécanistiques des processus catalysés par les enzymes correspondent à un autre champ d'application important pour la SM-IEN résolue en fonction du temps. On peut suivre ces réactions dans des conditions antérieures à l'état d'équilibre, sans avoir besoin de substrats chromophoriques artificiels ou de marquages radioactifs. On discute aussi de l'utilisation de la SM-IEN pour détecter et suivre les interactions ligand–protéine non covalentes par des mesures de diffusion. Par opposition aux techniques conventionnelles de SM, cette approche ne repose pas sur la préservation d'interactions non covalentes en phase gazeuse. Il semble que les mesures de diffusion par SM-IEN pourraient devenir une alternative intéressante aux méthodes actuelles pour l'évaluation à grand volume de librairies de composés dans le contexte de la découverte de nouveaux médicaments.

Mots clés : intermédiaire réactionnel, mélange rapide, cinétique, conformation des protéines, fonction des protéines.

Introduction

The following is a written account of the Fred Beamish Award Lecture, which was given in August 2003 at the 86th Canadian Society for Chemistry Conference and Exhibition in Ottawa, Ontario. It is the aim of this article to provide an overview of recent developments in the area of biological

 doi: 10.1139/V04-132 © 2004 NRC Canada

mass spectrometry (MS), with focus on work from the author's laboratory. Modern MS-based techniques represent some of the most powerful analytical tools for a wide range of quantitative and qualitative applications. Traditional MS studies are usually carried out under the premise that the chemical composition of the sample under consideration does not change during the time required for the analysis, i.e., from injection of the sample until ionization takes place. The information obtained from these measurements is *static* in nature. In contrast, the work in our laboratory focuses on the use of MS for studying the *dynamics* of biological systems. We will describe methods that permit the detection of short-lived reaction intermediates and that allow measuring of the rates at which individual species are formed or consumed. The results of these studies can provide a detailed understanding of (bio)chemical reaction mechanisms.

The entire area of biological MS has experienced explosive growth since the early 1990s. This process was triggered by the development of two novel ionization methods, namely electrospray ionization (ESI) (1) and matrix-assisted laser desorption/ionization (MALDI) (2, 3). Besides their versatility, the most important feature of both ionization techniques is their "softness", a term often used to describe the fact that little or no fragmentation occurs during ion formation. Consequently, both ESI-MS and MALDI-MS are powerful tools for studying a wide range of analytes, including biological macromolecules and other large nonvolatile species. This is in contrast to more traditional MS-based approaches, which can only be used for the analysis of relatively small molecular species, and where extensive fragmentation of covalent bonds is the norm. ESI-MS is particularly well-suited for studies on biologically relevant reactions because it allows the direct on-line coupling of solution-phase processes with gas phase analysis and detection methods. The softness of ESI-MS is best demonstrated in experiments involving the ionization of intact noncovalent assemblies, such as ligand–protein complexes (4), cell organelles (5), or even whole viruses (6). Another important factor for the rapidly growing popularity of MS-based techniques are recent dramatic improvements of the mass analyzers used, leading to ever-increasing sensitivity, accuracy, resolution, and mass range. In particular, the development of quadrupole-time-of-flight (Q-TOF) (7) and Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometers (8) has had a major impact.

One of the major driving forces behind the technological advances in the area of MS was the need to identify and characterize large numbers of proteins in a high throughput fashion, resulting in the emergence of a new field of research termed "proteomics" (9). Initially, this term almost exclusively encompassed the MS analysis of proteins separated by two-dimensional gel electrophoresis. Today, proteomics has grown into a much broader research area that also uses numerous non-MS approaches and that heavily relies on bioinformatics for data mining (10). The goal of proteomics research is the characterization of the entire protein complement of selected organisms, and to understand the dependence of this "proteome" on factors such as environmental stress, diseases, drugs, etc. These global approaches undoubtedly hold great promise for unraveling some of the complexity of biological systems, and for developing new therapeutic agents. However, it appears that this kind of research is not always well-suited to provide a detailed understanding of molecular structure–function relationships, which hold the key for deciphering many of the intricate processes taking place in living organisms. There definitely remains an urgent need for novel biophysical and bioanalytical approaches that can be used for exploring the molecular features of smaller subsystems. Accordingly, work in the author's laboratory is *not* geared towards the development of large scale protein identification strategies. Instead, ESI-MS is used for gaining a better understanding of protein dynamics, folding, catalysis, and binding.

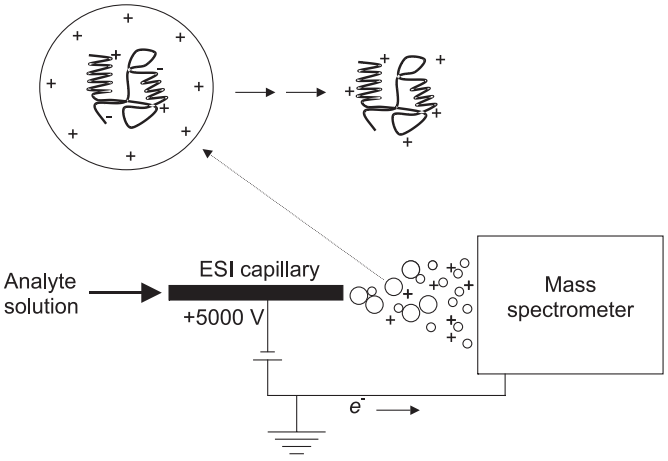

Fig. 1. Schematic depiction of the electrospray ionization (ESI) process. Analyte solution is injected into a metal capillary to which a positive potential has been applied. At the tip of this ESI capillary the solution is turned into a mist of small and highly charged droplets. Gas-phase analyte ions are generated from these droplets as indicated in the inset, where the analyte is assumed to be a protein. Further details are given in the text.

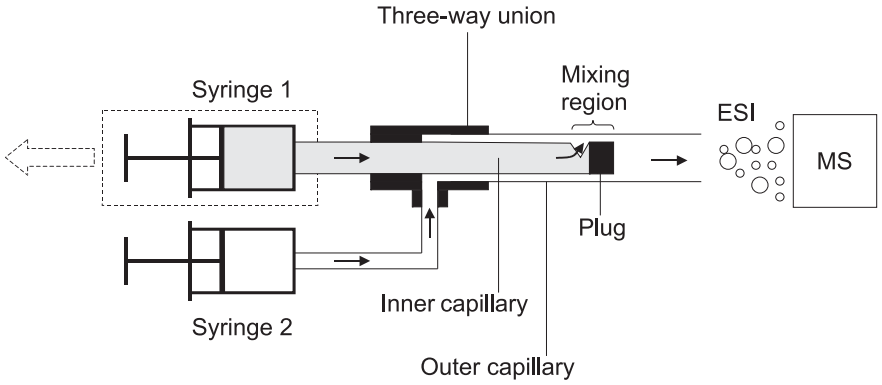

Kinetic studies by time-resolved ESI-MS

The ESI process

A typical ESI-MS setup is schematically depicted in Fig. 1 (11). Analyte solution is continuously infused into a metal capillary that is held at a high electric potential (typically 2–5 kV). The polarity of this electrospray voltage can be positive or negative. We will focus our discussion on the commonly used positive ion mode, where the applied potential is positive. Highly charged solvent droplets are emitted from the capillary tip. The excess charge on these droplets is primarily due to protons that are spread across the droplet surface. One important proton source is the electrolytic oxidation of water within the ESI capillary ($H_2O \rightarrow 2H^+ + 2e^- + 1/2O_2$) (12). Electrons generated by this reaction (or by other charge-balancing redox processes) flow to the mass spectrometer, thus completing a series circuit. The droplets sprayed from the tip of the ESI capillary undergo shrinkage because of rapid solvent evaporation. This process leads to the so-called Rayleigh limit, where the surface tension is balanced by the electrostatic repulsion of the charges within a droplet. At this point fission events start to occur, thus causing the formation of smaller offspring droplets. The continuation of this evaporation–fission cycle generates

Fig. 2. Schematic representation of a continuous-flow mixing setup for kinetic measurements by time-resolved ESI-MS. Syringes 1 and 2 deliver a continuous-flow of reactants; mixing of the two solutions initiates the reaction of interest. The plug at the end of the inner capillary ensures that all the liquid from syringe 1 is expelled through a notch at the capillary end into the narrow inter-capillary space. The inner capillary can be automatically pulled back, together with syringe 1 (as indicated by the dashed arrow). This provides a means to control the "age" (reaction time) of the mixture at the capillary outlet. Arrows indicate the direction of liquid flow.

smaller and smaller droplets, and eventually leads to the formation of gas phase ions from the solution phase analytes that were contained within the droplets. At present, many aspects of this ionization process are not fully understood and the mechanism(s) of ESI are a very active field of research (13). Ion formation during ESI occurs at atmospheric pressure. A suitable ion sampling interface is required to capture the ions and to inject them into the vacuum chamber of the mass spectrometer where they are analyzed according to their mass to charge (m/z) ratio. A wide array of different mass analyzers can be used for this purpose. The experiments described in the following were mostly performed on quadrupole instruments.

As mentioned previously, ESI is an extremely gentle process that allows the formation of intact gas phase ions even from large biomolecules in solution. Another important feature of ESI is that it tends to result in the formation of multiply charged ions, an effect that is especially pronounced for proteins. Typically, not all analyte ions acquire exactly the same number of protons, thus leading to the formation of several charge states that can be observed in the mass spectrum. The m/z values at which multiply protonated ions appear in the spectrum are given by $(M + 1.008 \times z)/z$, where M is the mass of the neutral analyte, 1.008 is the mass of a proton (in Da), and z is the number of protons attached to the analyte.

ESI-MS as a tool for studying solution-phase kinetics

Kinetic studies are of fundamental importance for the understanding of biochemical processes. They provide information on reaction mechanisms, intermediate species, reaction rates, thermodynamic parameters, etc. Many physiologically important reactions occur on fairly rapid timescales. This often represents a problem when attempting to study these processes by traditional analytical approaches. Therefore, techniques capable of providing kinetic data with a time resolution of milliseconds (or even sub-milliseconds) are of particular importance for addressing a wide range of issues (14). Kinetic experiments require a trigger that perturbs an equilibrium situation, thus defining a zero time point where all the molecules within the sample start to undergo a certain process simultaneously. One of the most common kinetic triggers is the mixing of two solutions, which can routinely be achieved within milliseconds; even microsecond mixing techniques have been reported (15).

Biochemical kinetics can be monitored by exposing the reaction mixture to a suitable quenching agent (e.g., acid, base, liquid nitrogen, etc.) after selected time intervals. Various analytical methods including MS or NMR can be used for the off-line analysis of the quenched reaction mixture. Problems encountered with this approach include the possible degradation or chemical modification of labile species in the reaction mixture prior to or during the analysis (16). These limitations can be avoided when using on-line detection methods. Optical stopped-flow spectroscopy is probably the most common tool for experiments of this kind. One major drawback of this approach is the poor selectivity of optical detection techniques, and the fact that numerous biochemical processes are not associated with any significant chromophoric changes. The use of ESI-MS as a highly selective and sensitive detection technique for on-line kinetic studies represents an obvious and attractive solution to these problems (16–18). ESI-MS allows the relative concentrations of multiple reactive species to be recorded as a function of time, without any need for chromophoric changes during the reaction. Transient intermediates may be identified based on their mass-to-charge ratio and (or) their MS–MS characteristics (19). One possible approach for on-line kinetic experiments by ESI-MS is the direct coupling of a stopped-flow instrument to a mass spectrometer (20–23). An alternative method, which is conceptually much simpler, is the use of continuous-flow methods in conjunction with ESI-MS.

A continuous-flow setup for "time-resolved" ESI-MS is depicted in Fig. 2 (24). This system represents a concentric capillary mixer with adjustable reaction chamber volume. In contrast to previously described rapid mixing devices (25), this instrument operates under laminar flow conditions, a fact that has to be taken into account for the data analysis (24). Reactant solutions are continuously expelled from two syringes. The first of these syringes is connected to the inner capillary, whereas the solution delivered by the second syringe flows through the outer capillary. The reaction of interest is initiated by mixing the two solutions at the end of the

© 2004 NRC Canada

inner capillary. The reaction then proceeds, while the mixture flows towards the outlet of the apparatus, where ESI takes place. The reaction time is determined by the solution flow rate, the diameter of the outer tube and, most importantly, by the distance between the mixing point and the outlet. This distance can be modified by adjusting the position of the inner capillary, as indicated in Fig. 2. Kinetic experiments are typically performed by initially positioning the mixer directly at the outlet of the apparatus, corresponding to a reaction time of zero. The mass spectrometer then continuously monitors the ions emitted from the capillary outlet, while the mixer is slowly pulled back. These experiments provide data in three dimensions; the time axis is determined by the mixer position, the *m*/*z* axis provides information on the identity of the species in the reaction mixture, and the intensity axis is related to the concentration of each of these species. The kinetic data obtained can be visualized by either displaying mass spectra for specific reaction times or by plotting intensity–time profiles for selected ionic species. The time resolution of this system is suitable for measuring rate constants in the range of ca. 1 min^{-1} up to at least 100 s^{-1} (24). In the following sections we will discuss several applications of this on-line ESI-MS rapid mixing system.

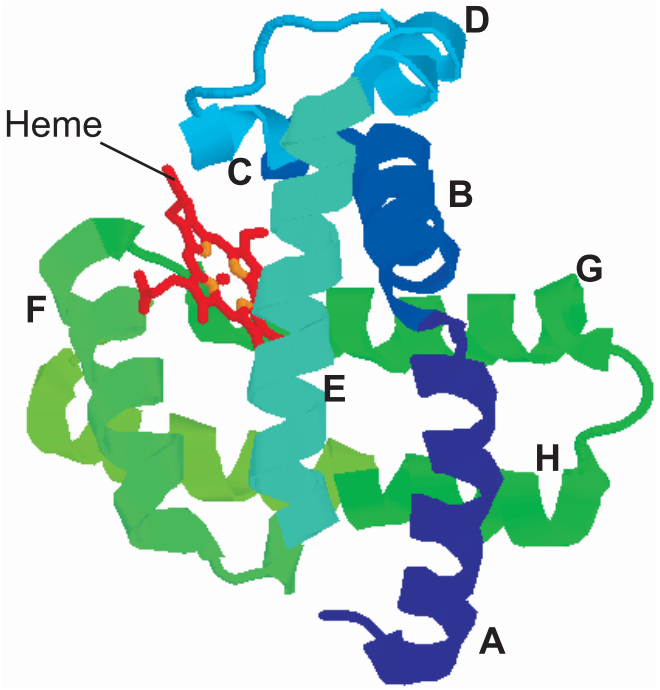
Monitoring protein folding and ligand binding kinetics

The protein folding problem

The three-dimensional structure adopted by the polypeptide chain of a protein depends on its solvent environment. Under physiological conditions of pH and temperature and in the absence of chemical denaturants, many proteins fold into a unique, highly ordered, and compact structure. This "native" conformation usually represents the biologically active state of a protein. Denaturing agents such as acid or heat can induce a transition to a largely disordered conformation (26). Many unfolded proteins can spontaneously refold to their native structures once the denaturant is removed. This remarkable observation implies that all of the information required to attain the native structure is contained within the amino acid sequence of the polypeptide chain. The native state of a protein corresponds to the conformation with the lowest overall free energy, taking into account the contributions from the polypeptide chain and the surrounding solvent (27). Although a lot of progress has been made in protein folding research over the last 40 years, the question of how and why proteins fold remains one of the major unsolved problems in biophysical chemistry (28). The "protein folding problem" is not only a fascinating challenge from an intellectual point of view, it also has important biomedical implications. For example, misfolding and aggregation are related to diseases like Alzheimer's, Parkinson's, Creutzfeldt–Jakob syndrome, type II diabetes, BSE ("mad cow disease"), and many others (29).

Folding processes involve conformational ensembles of proteins that undergo a biased diffusion on a multidimensional energy landscape. The global minimum of this landscape corresponds to the native conformation, thus resulting in a "folding funnel". Because of the enormous conformational space that is available to an unfolded polypeptide chain, every protein may start its folding process from a different point on the rim of the funnel, and thus follow a different trajectory to the native state (30). The topologic features of the energy landscape that govern the overall folding mechanism are determined by various enthalpic and entropic contributions such as hydrogen bonding, polar interactions, hydrophobic interactions, etc. Despite its complexity, the description of protein folding in terms of simple pathway models is often very helpful. However, it has to be understood that individual reactive species used in these models represent ensembles of polypeptide chains that can exhibit a fair amount of structural heterogeneity (31).

Of particular importance for the mechanistic understanding of folding processes is the detection and structural characterization of transient folding intermediates. This task is not straightforward, mostly because the lifetimes of these species are often very short, spanning a range from submilliseconds to seconds, which prevents the use of X-ray or NMR methods for direct structural studies (32–36). Another important aspect that has received surprisingly little attention is the fact that many proteins adopt their biologically active conformation only after binding metal ions, prosthetic groups, or other proteins. Very little is known about the interplay of folding and binding, and about the interactions of noncovalent binding partners with short-lived folding intermediates. Only very recently have these important questions come to the forefront of research (37–39). In the following sections we hope to demonstrate that time-resolved ESI-MS has the potential to address these and other questions, thus contributing to a better understanding of protein folding in general.



Protein folding and ligand binding monitored by time-resolved ESI-MS

As outlined above, ESI produces intact and multiply charged protein ions in the gas phase. The charge states observed in ESI-MS depend critically on the protein conformation in solution. Unfolded proteins form higher protonation states than those with tightly folded structures, thus providing a highly sensitive probe for protein conformational changes in solution (40–42). A particularly attractive feature of this approach is that it can be used to probe structural features of the protein, while at the same time providing information on noncovalent protein–ligand and protein–protein interactions through the direct observation of these complexes in the gas phase (43–46). Using the on-line rapid mixing setup of Fig. 2, it thus becomes possible to monitor structural changes and binding events as a function of time.

Myoglobin is a convenient model protein for studying the interplay between folding and ligand binding. Holomyoglobin (hMb) is an oxygen storage protein of 17.5 kDa. The native protein has eight α-helices, and forms a hydrophobic pocket into which a heme group is bound (Fig. 3). Unfolding of the protein leads to a disruption of the heme–protein interactions. The reverse process ("reconstitution") involves refolding of the polypeptide chain and rebinding of the heme group. The mechanism of reconstitution can be studied by recording mass spectra at different times after mixing acid-unfolded apo-myoglobin (heme-free protein, aMb) with basic heme solution (47). The spectrum of acid-unfolded aMb is depicted in Fig. 4*a*. It shows a wide distribution of peaks with a maximum at fairly high charge

states, around aMb^{16+} (labeled as a). The spectrum shown in Fig. 4*b* was recorded 90 ms after initiation of reconstitution, and it shows a more complex pattern of ionic signals. The observation of highly charged hMb ions (around hMb^{15+}, labeled as h) indicates the formation of an intermediate that is bound to a heme group, but still retains a largely unfolded conformation. The spectrum also shows strong signals for aMb ions in low charge states (aMb^{9+}, aMb^{8+}) that indicate the formation of a compact apo-protein intermediate. In addition, there is a subpopulation of proteins that adopt a compact conformation, while being bound to two heme groups (labeled as 2h). Tandem MS experiments showed this species to be bound to heme dimers, not to two separate heme moieties. The observation of hMb^{9+} and hMb^{8+} ions in Fig. 4*a* indicates that even after 90 ms a subpopulation of proteins has already reached a native-like conformation. With increasing reaction time, the relative abundance of protein ions in high charge states decreases as more and more proteins adopt tightly folded conformations (Fig. 4*c*). Eventually, for $t \approx 1$ h (Fig. 4*d*), hMb^{9+} and hMb^{8+} are the only protein ions observed. The spectrum depicted in Fig. 4*d* is virtually indistinguishable from that of native (unreconstituted) hMb.

Based on the time-resolved mass spectra depicted in Fig. 4, an overall model for the myoglobin reconstitution process can be proposed (Fig. 5) (45, 47). Unfolded aMb (top row, purple) represents a conformationally heterogeneous ensemble. Individual protein chains can undergo one of three different processes, all of which result in the formation of a transient intermediate. Folding into a compact conformation without heme binding leads to a "folded" aMb species (red). Alternatively, the protein can bind to a heme

Fig. 4. Time-resolved mass spectra recorded at selected times during myoglobin reconstitution. (*a*) Spectrum of acid-unfolded aMb prior to initiation of reconstitution; (*b*) 90 ms; (*c*) 1.3 s; and (*d*) 1 h. The spectrum depicted in panel (*d*) was obtained with manual mixing. Notation: (a) apo-myoglobin (aMb); (h) holo-myoglobin (hMb); (2h) myoglobin with two heme groups attached (2hMb); (*) heme; (**) heme dimer. The charge states of selected protein ions are as indicated. The occurrence of residual heme in panel (*d*) stems from the use of a slight heme excess in the reconstitution experiment. group, while maintaining a largely unfolded conformation (green). The third alternative involves the formation of proteins that are transiently bound to a heme dimer (pink). Time-resolved ESI-MS allows the detection of all of these three short-lived species in parallel, although none of them becomes strongly populated during reconstitution. The schematic representation in Fig. 5 suggests that all three intermediates are "productive", in a sense that they are direct precursors of the native state (blue). However, based on the data that are presently available we cannot strictly rule out the possible occurrence of off-pathway intermediates during myoglobin reconstitution (48).

Time-resolved ESI-MS with on-line pulse labeling

protein are labile, i.e., these sites can undergo hydrogen–deuterium exchange (HDX) when the protein is exposed to D_2O. Of particular importance for isotope exchange studies are the amide hydrogens located along the polypeptide backbone. A labile hydrogen can only undergo exchange (*i*) if it is accessible to the solvent, and (*ii*) if it is not involved in a stable hydrogen bond. Therefore, the HDX pattern of a protein depends strongly on its solution-phase conformation. The properties of short-lived folding intermediates can be probed by using pulse-labeling strategies. In these experiments, the protein is allowed to refold for a controlled period of time until it is briefly exposed to a large excess of labeling solvent. Conventionally, the labeling pulse is terminated by a rapid pH change that quenches exchange. The quenched reaction mixture can then be analyzed off-line by multidimensional NMR spectroscopy (49, 50) or by MS (31, 51). NMR measurements are based on the different nuclear spins of H (spin 1/2) and D (spin 1), while MS relies on the different mass of the two isotopes (1.0078 vs. 2.0141 Da). NMR provides spatially resolved information on the proton occupancy of individual exchangeable sites. However, the information obtained is averaged over all the protein molecules within the sample. In contrast, MS allows the detection of coexisting protein populations, such that their HDX properties can be monitored individually. Spatially resolved information can be obtained by MS when the off-line analysis of the experiment is coupled with proteolytic digestion and liquid chromatography (52), or with gas phase fragmentation techniques (53). The conventionally performed off-line analysis of pulse-labeled proteins after quenching has an inherent limitation. The conformation and ligand-binding state of individual protein molecules at the time of analysis is *not* correlated with the protein's H–D exchange pattern. As a result, ESI mass spectra of proteins that were pulse-labeled in quench-flow experiments show the same mass distribution for all charge states.

Recently, our group has shown that time-resolved ESI-MS can be used to analyze pulse-labeled proteins on-line, in a "quasi-instantaneous" fashion (47). Instead of quenching isotope exchange through a rapid mixing step, the protein solution is injected directly into the ESI source of the mass spectrometer. Here, the labeling pulse is terminated by desolvation within less than 1 ms (11). With this approach, the different charge- and ligand-binding states in the ESI mass spectrum are directly correlated with the HDX levels observed for each peak. Therefore, this technique allows the exchange behavior of different protein conformations and different ligand-binding states to be monitored with extremely high selectivity. This type of experiment requires a setup similar to that shown in Fig. 2, but with an additional on-line mixing step added immediately upstream from the ion source. Protein refolding is initiated at the first mixer, and labeling occurs at the second mixer. The refolding time is varied by changing the distance between the two mixers, while the duration of the labeling pulse is held constant at a few milliseconds.

The described on-line pulse-labeling approach was applied to study the reconstitution of acid-induced myoglobin under the conditions of Fig. 4. Selected peaks of pulse-labeled myoglobin for a reconstitution time of 240 ms are depicted in Fig. 6. As expected, the greatest extent of HDX was observed for unfolded apo-protein (e.g., aMb^{19+}, Fig. 6*a*). Ions corresponding to unfolded holo-myoglobin species in solution (Fig. 6*b*) show exchange levels slightly lower than the unfolded apo-protein. Much of this effect may be due to the steric protection of labile sites by the heme group. Ions corresponding to compact apo-protein species and those that are bound to two heme groups show a very similar exchange behavior (Fig. 6*c*). Based on their ESI charge state distributions, the two underlying solution-phase conformations are expected to have an overall compactness close to that of the native protein. However, the HDX level in Fig. 6*c* is evidently higher than that observed for native hMb (Fig. 6*d*), thus indicating that these two compact folding intermediates must exhibit a significantly perturbed structure. The fact that compact conformations can show dramatically different HDX levels demonstrates that ESI charge state distribution and HDX behavior represent com-

plementary, rather than redundant probes of protein structure in solution.

Figure 7 shows the peak shape of hMb^{8+} ions after pulse labeling for three different reconstitution times. As discussed previously, these ions are derived from holo-proteins in a native-like conformation. The observed peak width decreases notably as time proceeds. We attribute this observation to changes in the structural heterogeneity of the protein conformation. Following pulse labeling, a structurally heterogeneous protein ensemble will show a wider mass distribution than a homogeneous ensemble. Consequently, the data in Fig. 7 indicate that hMb^{8+} ions observed early during reconstitution are derived from solution-phase proteins in somewhat different conformations, presumably because some of them have not reached the global energy minimum of the folding funnel yet. Structural relaxation processes eventually allow all proteins to fold into the fully native state. This interpretation is consistent with the view that the energy landscapes of proteins exhibit a certain "roughness", giving rise to multiple local energy minima in the vicinity of the native conformation that can act as conformational traps (54, 55).

It is worth noting that the mass shift distributions for all the different protein species obtained after pulse labeling show a significant overlap (see Fig. 6). It is only because of the quasi-instantaneous nature of the on-line labeling–analysis strategy used that the distributions of individual species can be discerned. Different protein species appear in distinct ESI charge- and ligand-binding states, thus providing additional structural dimensions that allow the determination of individual HDX levels in a straightforward manner. In contrast, conventional quench-flow studies would have resulted

Fig. 7. Mass spectral data and Gaussian fits (solid lines) measured after pulse labeling for hMb^{8+} (*a*) 90 ms, (*b*) 240 ms, (*c*) and 3 h after initiation of reconstitution. Horizontal arrows represent FWHMs of the fitted peaks.

in broad unstructured mass distributions, and it would have been impossible to assign mass shifts to individual protein species.

Monitoring protein conformational dynamics under equilibrium conditions

HDX methods for monitoring protein dynamics

Many proteins are known to adopt partially folded conformations when they are exposed to mildly denaturing solvent conditions. These semi-denatured species are structurally heterogeneous ensembles, undergoing conformational fluctuations on various time scales. Studies on partially folded proteins are of great importance for understanding a wide range of biological processes such as amyloid formation, signal transduction, ligand binding, and protein transport across membranes (56). Interestingly, partially folded proteins under equilibrium conditions often resemble intermediates formed in kinetic experiments (57). Recent work has shown that some proteins exhibit a significant degree of disorder, even under physiological conditions where they are biologically active (58).

Experimental techniques capable of probing the dynamic nature of partially folded proteins are crucial for obtaining a better understanding of their biophysical properties. Once again, the most powerful approaches for studies in this area are based on HDX techniques (59, 60). In contrast to the pulse-labeling strategies introduced in the previous section, studies on conformational dynamics require the use of continuous-labeling approaches. For these experiments, a protein is incubated in an isotopic labeling buffer and its HDX properties are probed as a function of labeling time. For exchangeable sites that are sterically shielded from the solvent and (or) involved in stable hydrogen bonds, HDX is mediated by structural fluctuations of the protein. Therefore, the exchange kinetics are related to the conformational dynamics of the polypeptide chain. Opening–closing events mediating exchange may correspond to global or subglobal unfolding–refolding transitions, or to local fluctuations (61–63). The exchange mechanism is commonly described by Scheme 1 (64)

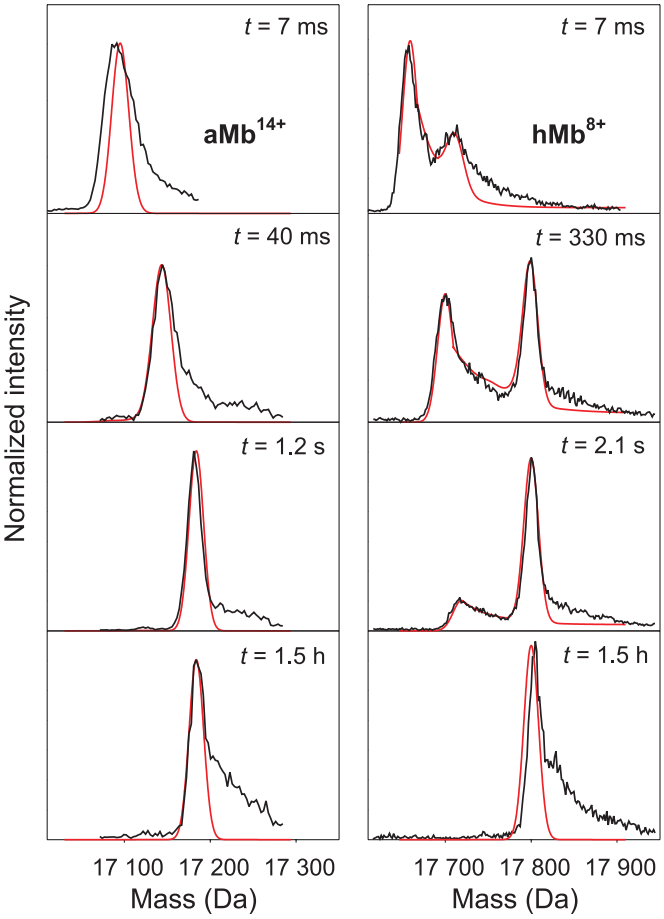
$$[1] \qquad X-H_{closed} \underset{k_{cl}}{\overset{k_{op}}{\rightleftharpoons}} X-H_{open} \xrightarrow[D_2O]{k_{ch}} \text{exchanged}$$

where k_{op} and k_{cl} are the rate constants for the opening and closing, respectively, of a particular exchangeable site. The intrinsic exchange rate constant (k_{ch}) represents the kinetics that would be expected for a fully unprotected hydrogen. For amide hydrogens, the k_{ch} value of any individual site depends on its neighboring amino acids and on pD. Reference data are available that allow the estimation of amide k_{ch} values for any set of solvent conditions (65). Two different exchange regimes can be distinguished, depending on whether the conformational dynamics are fast (EX2) or slow (EX1) compared to k_{ch}. In the EX2 limit, characterized by $k_{cl} >> k_{ch}$, the overall exchange rate constant (k_{ex}) is given by $k_{ex} = K_{op}k_{ch}$, where $K_{op} = (k_{op}/k_{cl})$ is the equilibrium constant of the opening reaction. Under EX2 conditions, most sites have to visit the open conformation many times before exchange occurs. Conversely, if $k_{ch} >> k_{cl}$ (EX1 regime), complete labeling will occur with the first opening event, such that $k_{ex} = k_{op}$.

NMR spectroscopy has traditionally been the method of choice for analyzing proteins in continuous-labeling experiments. However, in recent years, the use of ESI-MS for this purpose has become increasingly popular (42). One particularly attractive feature of ESI-MS is the possibility to clearly distinguish EX1 from EX2 exchange events. In the former case, spectra recorded at different times exhibit peaks corresponding to the fully labeled and the unlabeled protein, respectively. As time proceeds, the intensity ratio of these peaks changes, but not their individual mass values. In contrast, EX2 kinetics give rise to a single peak that gradually moves to higher mass as HDX proceeds (66, 67).

Conformational dynamics of semi-denatured myoglobin

In a recent study, our group has described continuous-labeling experiments by time-resolved ESI-MS on the millisecond timescale (56). These experiments employed a rapid mixing setup similar to that depicted in Fig. 2. The studies



© 2004 NRC Canada

were carried out at slightly basic pD, where k_{ch} for amide hydrogens is around 650 s^{-1}. Once again, Mb was used as the model system. The formation of partially folded Mb conformations under equilibrium conditions can be promoted through the presence of an organic cosolvent. The Mb ESI mass spectrum recorded at pH 9.3 in the presence of 27% acetonitrile resembles the reconstitution spectra depicted in Figs. 4*b* and 4*c* (data not shown). Mass distributions obtained in continuous-labeling experiments for two representative ions are shown in Fig. 8. aMb^{14+} represents a semi-unfolded apo-protein species in solution. With increasing labeling time these ions shift to higher mass, indicating EX2 exchange, i.e., the occurrence of rapid unfolding–refolding events with closing rate constants $k_{cl} >> 650$ s^{-1}. A more complex exchange behavior is exhibited by hMb^{8+}, which represents a native-like conformation of the holo-protein. For labeling times up to roughly 2 s, these protein ions show bimodal mass distributions. The relative intensity of the low mass peak decreases and that of the high mass peak increases (EX1 behavior). This observation shows that the corresponding solution-phase proteins are involved in slow unfolding–refolding processes with $k_{cl} << 650$ s^{-1}. In addition, a gradual shift to higher mass is observed for both peaks, which shows that the proteins also undergo more rapid structural fluctuations (EX2 exchange).

Upon combining the data obtained in these HDX experiments with previous results from the literature, we were able to develop a detailed kinetic model for the conformational dynamics of myoglobin under the conditions of ref. 56. The HDX peak shapes predicted by this model for different exchange times are shown as red curves in Fig. 8. A simplified version of the model is shown in Fig. 9. It assumes that the Mb structure can be dissected into three distinct folding–unfolding units (48, 62). It is proposed that unit 1 encompasses the heme binding region (68), unit 3 includes the folding core (A-G-H helices) (69), while the remaining structural elements of the protein are assigned to unit 2. Each unit can be in an open (O) or in a closed (C) conformation. The two major species observed in the spectrum, semi-unfolded aMb and native-like hMb, are assigned to the structures (O,C,C) and ^{Heme}(C,C,C), respectively. The EX1 process seen for hMb^{8+} is attributed to slow opening–closing events of unit 1, presumably in conjunction with heme loss–binding. These transitions are associated with the crossing of a major free energy barrier. Rapid opening–closing events on both sides of this major barrier involve all three units and give rise to EX2 kinetics. It has been suggested that proteins may cross major free energy barriers not by surmounting them, but by circumventing them through a long diffusive journey on a multidimensional energy landscape (70). Accordingly, slow conformational transitions could be mediated by rapid, thermally activated dynamics. Such a view is consistent with the model suggested in Fig. 9, where rapid structural fluctuations on each side of a major barrier may represent conformational sampling processes that on rare occasions result in barrier crossing.

In summary, ESI-MS used in conjunction with rapid mixing techniques and on-line HDX provides an extremely powerful tool for monitoring the folding and structural dynamics of proteins. The on-line approaches described in the previous sections allow the correlation of three complementary

Fig. 8. Conformational dynamics of semi-denatured myoglobin (in water:acetonitrile, 73:27 v/v, pD 9.3) studied in continuous-labeling HDX experiments. structural probes: ESI charge state distribution, ligand-binding state, and isotope exchange kinetics. All of this information is obtained simultaneously for coexisting protein conformations in solution. One limitation of the described experimental strategies is the lack of direct insights into the spatial hydrogendeuterium distribution within the protein. However, this type of information should be obtainable by on-line fragmentation of gas-phase protein ions in tandem MS experiments (53). Another important aspect are improvements of the time resolution; this goal should be achievable through the use of microfluidic devices that allow reactions to be initiated by ultra-rapid mixing (15, 71). Modifications of this kind could allow detailed studies on even the very earliest events in protein folding. Efforts in these directions are currently underway in our laboratory.

Mechanistic studies on enzyme reactions by time-resolved ESI-MS

Why study enzymes?

Enzyme catalysis is a vital component of all biological systems. Enzyme mechanisms range from simple two-step

Fig. 9. Simplified energy profile used for modeling the conformational dynamics of myoglobin under mildly denaturing conditions. Different protein conformations are represented in "vector notation", where each of the three structural units of the protein can be either open (unfolded, O) or closed (folded, C). The presence of a heme group is denoted as a superscript H.

processes to complex multistep reactions. Kinetic experiments are among the most important tools for elucidating these reaction mechanisms. Most of these studies are carried out under steady-state conditions where high time resolution is usually not required. However, kinetic experiments in the *pre*steady-state regime often provide more mechanistic information. These studies focus on the short period of time immediately following the initiation of an enzymatic reaction. It is during this period that reaction intermediates become successively populated, such that the rate constants of individual steps can be measured (16, 72, 73). Rapid mixing experiments with optical detection are a well-established tool for presteady-state kinetic experiments. However, most reactions of enzymes with their "natural" substrates cannot be studied in this way because there are no associated chromophoric changes. For this reason, kineticists often use artificial substrate analogs that undergo a color change upon turnover. Obviously, this approach is problematic because the kinetics observed with these analogs may be different from those that would be observed with the natural substrate(s). In some cases, the use of radioactively labeled substrates provides an alternative approach (74). However, radiochemical methods are somewhat cumbersome, and problems can arise due to nonspecific entrapment of the label. Kinetic studies by time-resolved ESI-MS do not require chromophoric substrates or radioactive labeling and, therefore, the application of this approach to enzymatic systems seems very attractive (17–19, 22, 75). The time resolution of this approach should be sufficient for exploring the presteady-state of a wide array of different enzyme systems.

Kinetics of chymotrypsin-catalyzed reactions

We explored the application of our rapid mixing system (Fig. 2) in experiments on chymotrypsin (76). This enzyme is a serine protease, with Ser_{195} representing the reactive nucleophile (77). Although the physiological role of chymotrypsin is to serve as an endopeptidase, it also catalyzes the hydrolysis of esters including numerous synthetic substrate analogs. The generally accepted reaction mechanism for chymotrypsin-catalyzed hydrolysis is depicted in Scheme 2 (72, 73, 78).

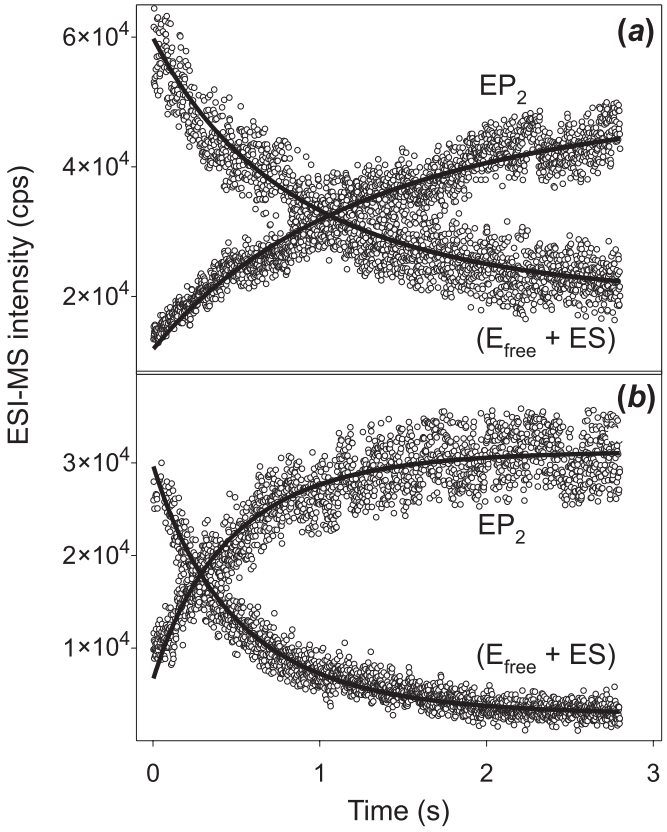
$$[2]\quad E_{free} + S \underset{}{\overset{K_d}{\rightleftharpoons}} ES \xrightarrow{k_2} EP_2 \xrightarrow{k_3} E_{free} + P_2$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\quad \downarrow$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\quad P_1$$

In the first step of this reaction sequence, the free enzyme E_{free} and the substrate S form a noncovalent enzyme–substrate complex (ES) that is characterized by the dissociation constant K_d. Subsequently, Ser_{195} forms a covalent bond with the carbonyl carbon of the substrate, thus releasing the first hydrolysis product P_1. The rate constant of this acylation step is denoted as k_2. The subsequent deacylation has a rate constant of k_3 and it leads to regeneration of the free enzyme by hydrolysis of the Ser_{195}–ester bond, through release of the second hydrolysis product P_2. For conditions where S is present in large excess, it can be shown that the concentration of EP_2 as a function of time t in the presteady-state regime is given by (72, 73)

$$[3]\quad [EP_2](t) = A(1 - \exp(-k_{obs}t))$$

Consequently, the sum of the concentrations of E_{free} and ES are given by

$$[4]\quad ([E_{free}] + [ES])(t) = B\exp(-k_{obs}t) + C$$



A, B, and C in these expressions are constants and k_{obs} can be expressed as

$$[5]\quad k_{obs} = k_3 + \frac{k_2[S]}{K_d + [S]}$$

where [S] is the substrate concentration. Measurements of k_{obs} as a function of substrate concentration should allow the determination of the parameters k_2, k_3, and K_d in Scheme 2. For $t >> 1/k_{obs}$, the exponential terms in eqs. [3] and [4] become negligible, thus marking the transition from the presteady-state to the steady-state regime.

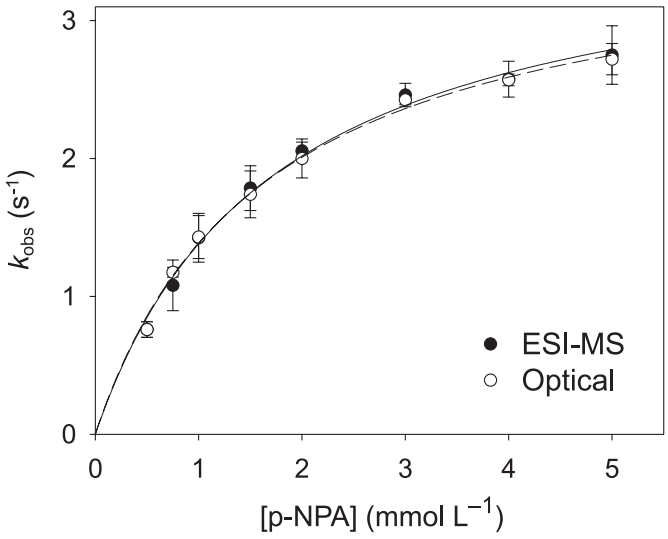

Fig. 10. Presteady-state kinetics of *p*-NPA hydrolysis by chymotrypsin monitored by ESI-MS. The two panels depict the depletion of unmodified enzyme (E_{free} + ES), and the formation of acetylated chymotrypsin (EP_2), at substrate concentrations of (*a*) 1 mmol L^{-1} and (*b*) 5 mmol L^{-1}. The data were obtained by monitoring the 12^+ charge state of free and acetylated enzyme at *m*/*z* 2103 and 2107, respectively. Solid lines are fits to the experimental data based on eqs. [3] and [4]. Adapted with permission from ref. 76. Copyright 2004 American Chemical Society.

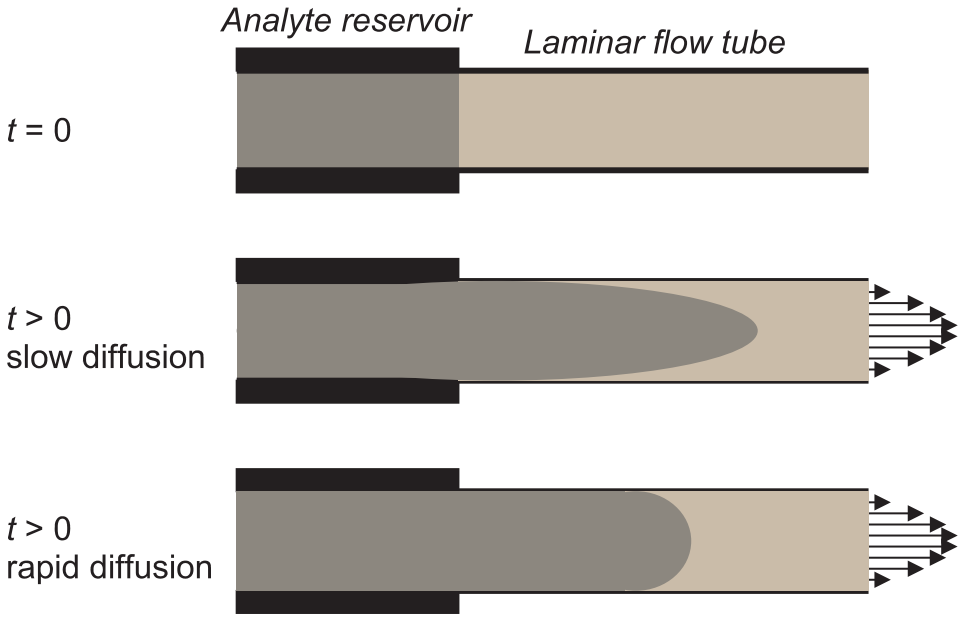
For testing the applicability of our rapid mixing ESI-MS setup to studies on chymotrypsin kinetics, a two-step strategy was used (76). We initially monitored the hydrolysis of the chromophoric substrate *para*-nitrophenyl acetate (*p*-NPA) to *para*-nitrophenol (*p*-NP) and acetate. In the framework of Scheme 2, *p*-NP corresponds to P_1, and acetate corresponds to P_2. *p*-NPA was chosen as the substrate because the released *p*-NP has an intense yellow color, thus providing a way to compare the ESI-MS-based kinetic experiments with the results of optical control experiments. Subsequently, we studied the chymotrypsin-catalyzed hydrolysis of a peptide that cannot be monitored by optical means.

Figure 10 shows ESI-MS presteady-state kinetics obtained for two different *p*-NPA concentrations. The signals monitored in these experiments correspond to the accumulation of the acetylated enzyme (EP_2) and the decay of the free- and substrate-bound chymotrypsin (E_{free} + ES). The kinetics obtained for a *p*-NPA concentration of 1 mmol L^{-1} (Fig. 10*a*) are notably slower than those for a substrate concentration of 5 mmol L^{-1} (Fig. 10*b*). The dependence of the measured k_{obs} values on the *p*-NPA concentration is depicted in Fig. 11. These data can be fitted according to eq. [5], resulting in a

Fig. 11. Measured k_{obs} values for *p*-NPA hydrolysis by chymotrypsin as a function of substrate concentration. Solid circles represent ESI-MS measurements; open circles depict values determined by optical stopped-flow spectroscopy. Fits to these k_{obs} values based on eq. [5] are given as a solid line for the ESI-MS kinetics and as a dashed line for the optical data. Adapted with permission from ref. 76. Copyright 2004 American Chemical Society.



K_d value of (1.6 ± 0.2) mmol L^{-1} and a rate constant k_2 of (3.5 ± 0.3) s^{-1}. Unfortunately, k_3 is too small to be determined by this method (the y-axis intercept of the curves in Fig. 11 is close to zero). These results show the deacylation step (k_3) to be rate limiting for the hydrolysis of *p*-NPA by chymotrypsin. Also shown in Fig. 11 are the results of control experiments where the release of *p*-NP was monitored by optical stopped-flow spectroscopy. The corresponding values of K_d and k_2 are very close to those obtained by ESI-MS, (1.6 ± 0.1) mmol L^{-1} and (3.6 ± 0.2) s^{-1}, respectively.

The chymotrypsin-catalyzed hydrolysis of the non-chromophoric peptide bradykinin results in the release of the N-terminal arginine residue. In contrast to the *p*-NPA data described above, acylation (k_2) was found to be rate limiting for the hydrolysis of this peptide bond, such that the EP_2 complex in Scheme 2 cannot accumulate. Because this scenario precludes a presteady-state analysis of the reaction, time-resolved ESI-MS was used to monitor the production of the hydrolysis products under steady-state conditions, resulting in a Michaelis constant of K_M = (0.51 ± 0.08) mmol L^{-1} and a k_{cat} value of (43 ± 2) s^{-1} (data not shown) (76).

These results clearly demonstrate the feasibility of kinetic measurements on enzymatic systems by time-resolved ESI-MS. One limitation of the current on-line method is its incompatibility with high concentrations of salts, buffers, and other solvent additives that have detrimental effects on the ionization process (79). Currently, this factor does not permit MS experiments to be carried out at physiological salt concentrations. The development of rapid desalting devices (79), fused droplet ESI (80), or on-line MALDI-MS methods (81) is likely to provide ways to overcome this limitation in the foreseeable future.

© 2004 NRC Canada

Fig. 12. Diagram illustrating how solution-phase diffusion coefficients can be determined by ESI-MS. A thin capillary tube is initially filled with solution having a low analyte concentration. The tube inlet is then connected to a reservoir that contains analyte solution at a higher concentration, thus generating a sharp boundary between the two solutions (top panel). Subsequently, solution is pumped from the reservoir into the tube. Laminar flow leads to a parabolic flow velocity distribution within the tube, i.e., the flow velocity in the capillary center is highest, whereas it is zero at the tube walls (indicated by the arrows in the middle and bottom panels). This velocity distribution leads to a dispersion of the initially sharp boundary between the two solutions. However, radial diffusion of analyte molecules counteracts this dispersion, because the molecules constantly migrate between zones of different flow velocity. This compensating effect is relatively small in the case of slow diffusion (middle panel), but it is large in the case of rapid diffusion (bottom panel). Diffusion coefficients can thus be determined by monitoring the analyte signal intensity at the tube outlet by ESI-MS. All of the dispersion profiles obtained in this way have a sigmoidal appearance. Analytes with small diffusion coefficients D show more extended profiles than those with larger values of D. It is noted that the effects of *axial* diffusion are negligible under typical operating conditions (99).

Noncovalent ligand–protein interactions probed by ESI-MS-based diffusion measurements

Noncovalent interactions

The previous chapters of this review have described various strategies for studying rapid processes in biochemical systems. The key to observing events in the range of milliseconds to seconds was the use of ESI-MS in conjunction with on-line rapid mixing techniques. This final chapter will focus on measurements that take place on somewhat longer timescales. It will be demonstrated how ESI-MS can be used for monitoring the diffusion behavior of biological molecules, and how measurements of this type can provide information on how these molecules interact with each other in solution.

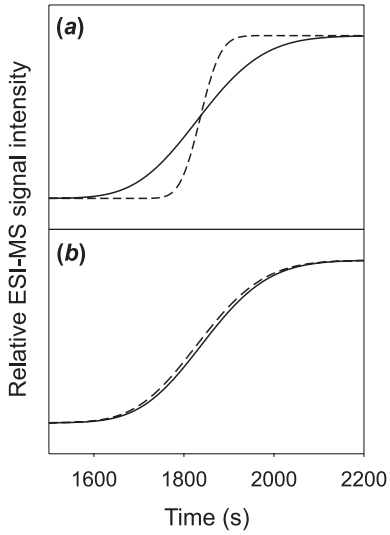
Numerous physiological processes are mediated by noncovalent interactions involving biological macromolecules; examples include signaling and regulation, immune response, protein biosynthesis, and enzyme catalysis. Many drugs act by noncovalently binding to proteins or other biopolymers, often mimicking structural features of naturally occurring ligands (82). Experimental methods capable of monitoring these interactions are of great importance. Of particular interest is the identification of high-affinity ligands for macromolecular drug targets in high-throughput screening tests of compound libraries (83, 84).

The myoglobin studies summarized previously attest to the fact that ESI-MS is a sensitive and highly selective approach for monitoring ligand–protein interactions. This is in line with a large number of other studies, all confirming that numerous noncovalent complexes can survive the ESI process, thus making them amenable to direct mass spectrometric analysis (4, 43, 85). However, it is well-known that the presence of noncovalent complexes in solution is *not always* correlated with the observation of the corresponding species in the mass spectrum. "False-negative" results are obtained when solution-phase complexes dissociate prior to detection. Noncovalent binding partners that are held together primarily by hydrophobic interactions are thought to be particularly prone to dissociation during ESI, whereas electrostatic complexes are often considered to be more stable (86). On the other hand, extensive dissociation during ESI is also observed for some electrostatically stabilized complexes, even under the most gentle ionization conditions (87). ESI-MS can also produce "false-positive" results, as some analytes tend to form noncovalent gas-phase assemblies during ESI, despite the nonexistence of the corresponding complexes in solution (88–90). These considerations imply that the pres-

© 2004 NRC Canada

ence or absence of noncovalent complex ions in an ESI mass spectrum does not always allow conclusions to be drawn regarding specific solution-phase interactions. It appears that this issue is at least partly responsible for the limited acceptance of ESI-MS as a general tool for "mix and measure" experiments in the context of high-throughput screening tests (84). Not surprisingly, the development of alternative techniques for monitoring ligand–protein interactions is an area of great interest (91–93).

Noncovalent interactions and diffusion



A number of optical and NMR-based techniques make use of the fact that noncovalent interactions affect the diffusion behavior of ligands that bind to a target macromolecule. Typically, the potential ligands used in screening assays are relatively small compounds that have large diffusion coefficients, as long as they are free in solution. However, once a ligand is bound to a protein or nucleic acid target, its translational motions will be governed by the slow diffusion of the macromolecule. In other words, *noncovalent binding will drastically reduce the diffusion coefficient of the ligand*. This phenomenon can be exploited for the screening of compound libraries by fluorescence correlation spectroscopy (94, 95) and diffusion-ordered nuclear magnetic resonance spectroscopy (DOSY-NMR) (83).

Unfortunately, many of the existing screening methods suffer from certain limitations. Fluorescence-based approaches are only applicable in cases where suitable chromophores are available. The selectivity of NMR techniques may be limited by overlapping analyte resonances, especially when studying mixtures of structurally related compounds (83). In addition, analyte concentrations in the millimolar range are often required for NMR. Not only does this result in large sample consumption, but also nonspecific aggregation may become an issue. Other methods for studying noncovalent interactions, such as affinity chromatography and surface-plasmon resonance-based assays require the chemical immobilization of ligand or target molecules on a solid support, which may impede binding because of restrictions in the orientation of the immobilized molecules. Furthermore, nonspecific binding to carrier materials may occur (96). Our group has devised an approach for monitoring noncovalent interactions that may help to overcome these limitations. It is based on diffusion measurements of analytes in solution by ESI-MS.

Measuring diffusion coefficients by ESI-MS

Initially, we will contemplate a single analyte species in solution to illustrate how solution-phase diffusion coefficients can be measured by ESI-MS (Fig. 12). The extension of this approach to studies on noncovalent interactions will be straightforward. Consider the case where analyte solution is infused into a capillary tube that has previously been filled with another solution containing the same analyte, but at a different concentration. Because of the laminar flow conditions within the tube, the flow velocity distribution is parabolic. This leads to a dispersion of the initially sharp boundary between the two solutions as liquid flows through the tube. However, diffusion causes a constant radial mixing of analyte molecules, thereby counteracting the dispersion because of laminar flow (97, 98). The outlet of the tube is connected to the ESI source of a mass spectrometer, where the signal intensity of the analyte is monitored as a function of time. The resulting dispersion profile shows a sigmoidal intensity transition from low to high or from high to low, depending on the concentrations of the two solutions used. The diffusion coefficient of the analyte can be determined from a fit to the measured profile. Analytes with large diffusion coefficients will show relatively steep transitions, whereas smaller diffusion coefficients result in more extended dispersion profiles (99). Figure 13*a* represents simulated profiles for a small molecule and a ligand that do not interact with each other in solution, such that the diffusion behavior of the two species is independent. In contrast, Fig. 13*b* depicts the situation expected for tight noncovalent binding between the two species. In the latter case, the diffusion of the (small) ligand is governed by the Brownian motion of the (large) protein. The profile of the ligand will become more extended upon complex formation and it will approach the profile exhibited by the protein. Unlike conventional ESI-MS studies on noncovalent complexes, this approach does *not* rely on the preservation of solution-phase interactions in the gas phase. In fact, very harsh conditions are employed at the ion source to disrupt any residual interactions, thereby ensuring that the dispersion profiles of individual analytes can be monitored separately (100).

Fig. 13. Simulated dispersion profiles, representing the ESI-MS signal intensity of two analytes at the end of a laminar flow tube under different conditions. (*a*) Dispersion profiles expected for a protein ($D = 1 \times 10^{-10}$ m^2/s, solid curve) and a small molecule ($D = 10 \times 10^{-10}$ m^2/s, dashed curve). It is assumed that the two analytes do *not* interact in solution. (*b*) Dispersion profiles as in panel *a*, but under the assumption of tight noncovalent binding between the two analytes. Under these conditions the profiles measured for the two species will be identical (for better visualization, one of the profiles has been slightly shifted).

Screening of libraries for binding to a protein target

The described approach was tested in experiments that monitored the noncovalent binding of mono-, di-, and trisaccharides to lysozyme (101). This 129 amino acid protein (MW 14.3 kDa) hydrolyzes polysaccharides containing *N*-

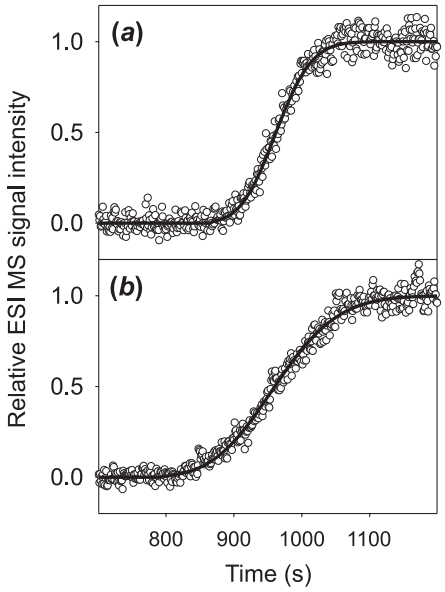
Fig. 14. Dispersion profiles of NAG_3 recorded (*a*) in the absence and (*b*) in the presence of lysozyme. Solid lines represent fits to the experimental based on eq. [17] of ref. 99. Close inspection reveals that the profile depicted in panel *b* is more extended than that in panel *a*. Adapted with permission from ref. 101. Copyright 2004 American Chemical Society.



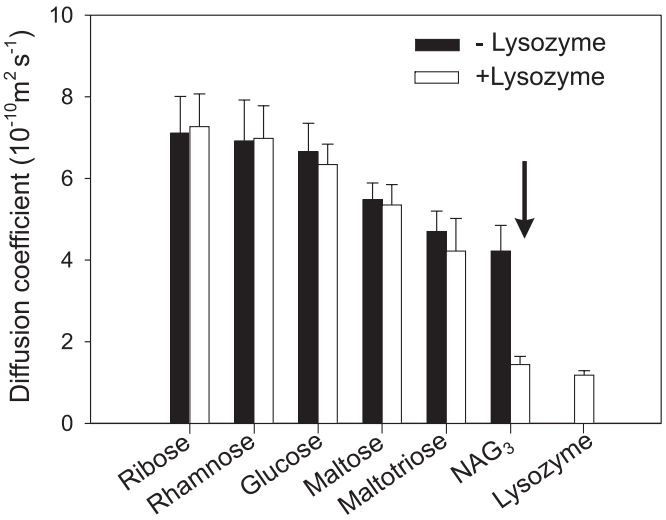


Fig. 15. Diffusion coefficients of saccharides determined from ESI-MS dispersion profiles measured in the absence (black bars) and in the presence (white bars) of lysozyme. Only NAG_3 shows a significant change upon addition of the protein, as indicated by the arrow. The diffusion coefficient of lysozyme is shown for comparison. Adapted with permission from ref. 101. Copyright 2004 American Chemical Society.

acetylated monomers (102). Short oligomers of *N*-acetyl glucosamine (NAG) represent competitive inhibitors of lysozyme. In our experiments, we monitored the diffusion behavior of six different saccharides (ribose, rhamnose, glucose, maltose, maltotriose, and NAG_3) in parallel. In an initial run, the dispersion profiles of all these compounds were monitored in the absence of the protein receptor; subsequently, they were repeated in the presence of lysozyme. For five of the saccharides, dispersion profiles recorded with and without the protein were indistinguishable, thus indicating that their diffusion behavior is independent of the presence of lysozyme. Only for NAG_3, the profile recorded in the presence of the protein was significantly more extended than that observed in a protein-free solution (Fig. 14). This result shows that of the six compounds tested, only NAG_3 forms a noncovalent complex with lysozyme. The results of this screening experiment are summarized in Fig. 15, where the diffusion coefficients of all compounds measured with and without lysozyme are depicted.

The successful application of this approach for screening a small "compound library" strongly indicates that this experimental technique might become an interesting alternative to existing methods for monitoring noncovalent interactions. Automation of the described diffusion-based method could provide a new and powerful tool for the high-throughput screening of compound libraries, with possible applications in the area of drug discovery. ESI-MS dispersion measurements are not necessarily restricted to water-soluble proteins; studies on nucleic acids, solubilized membrane receptors, or on entire organelles may also be feasible. Another interesting aspect is the determination of dissociation constants directly from the measured dispersion profiles (103). These and other research directions are currently being explored in our laboratory.

Conclusions

This review has summarized some recent developments in the area of biological MS. The combination of on-line rapid mixing with ESI-MS provides a unique opportunity to probe the structure and function of biological systems as a function of time. These *dynamic* studies are in contrast to most traditional MS-based approaches that provide a static picture of the system under investigation. Time-dependent changes of proteins and other biological molecules include folding and unfolding processes, structural fluctuations, and transient chemical modifications. The diffusion behavior of biological molecules in solution also represents a dynamic feature. It has been demonstrated how diffusion measurements can reveal the occurrence of intermolecular binding events. Much remains to be learned and explored, and it may take researchers considerable time to fully understand the intricate factors determining the structure and function of biological molecules and assemblies. In any case, MS-based approaches are certain to play an ever increasing role for these endeavors, not only in bioanalytical and biophysical chemistry, but also in many other areas.

Acknowledgments

Over the last couple of years, the author has had the privilege of working with a number of extremely talented undergraduates, graduate students, and post-doctoral fellows. In particular, the contributions of Sonya M. Clark, Beata M. Kolakowski, Douglas A. Simmons, and Derek J. Wilson deserve special recognition. The synthesis of some mechanistic probes for sialic acid processing enzymes and the labeling of a sialidase from *Trypanosoma rangeli*

Andrew G. Watts and Stephen G. Withers

Abstract: Sialyl hydrolases, *trans*-sialidases, and sialyl transferases are biologically important enzymes that are responsible for the incorporation and removal of sialic acid residues, which decorate many cell surface glycocongugates. Two fluorinated sialic acid derivatives have been synthesized as mechanism-based inactivators, to probe the catalytic mechanisms through which sialidases and *trans*-sialidases operate. Both compounds are known to be covalent inactivators of a *trans*-sialidase from *Trypanosoma cruzi*. Here, 3-fluorosialosyl fluoride has been found to covalently label the catalytic nucleophile of a sialidase from *T. rangeli*, and the residue involved is shown to be Tyr346 within the sequence DENSGYSSVL. This is the first demonstration that sialidases operate through a covalent glycosyl-enzyme intermediate, strongly suggesting a common catalytic mechanism amongst all members of the sialidase superfamily. CMP-3-fluorosialic acid is a competitive inhibitor of sialyl transferases and was synthesized via a two-step enzymatic process from commercially available *N*-acetyl mannosamine, 3-fluoropyruvic acid, and cytidine triphosphate in around 84% yield.

Key words: sialidase, mechanism, labeling, nucleophile, inhibitor.

Résumé : Les hydrolases de sialyle, les sialidases *trans* et les transférases de sialyle, sont des enzymes biologiquement importants qui sont responsables de l'incorporation et de l'élimination des résidus d'acide sialique qui décorent plusieurs glycoconjugués de la surface des cellules. Dans le but d'étudier les mécanismes catalytiques par lesquels les sialidases et les sialidases *trans* opèrent, on a synthétisé deux dérivés fluorés de l'acide sialique à utiliser comme inactivateurs basés sur le mécanisme. Il est connu que les deux composés sont des inactivateurs covalents d'une sialase trans issue de *Trypanosoma cruzi*. Dans notre cas, on a trouvé que le fluorure de 3-fluorosialosyle marquent d'une façon covalente le nucléophile catalytique d'une sialidase issue de *T. rangeli* et on a montré que le résidu impliqué est la Tyr346 de la séquence DENSGYSSVL. Il s'agit de la première démonstration que les lialidases opèrent par le biais d'un intermédiare covalent glycosyle-enzyme, ce qui suggère fortement l'existence d'un mécanisme catalytique commun pour tous les membres de la superfamille des sialidases. L'acide CMP-3-fluorosialique est un inhibiteur compétitif des transférases de sialyle et on l'a synthétisé en deux étapes, avec un rendement de 84 %, à partir de la *N*-acétyl mannosamine disponible commercialement, de l'acide 3-fluoropyruvique et du triphosphate de cytidine.

Mots clés : sialidase, mécanisme, marquage, nucléophile, inhibiteur.

[Traduit par la Rédaction]

Introduction

Sialic acids are considered as very important biomolecules since they are commonly displayed as the terminal sugar residues on cell surface glycocongugates and macromolecules (1–3). These nine-carbon sugars, which bear a negative charge at physiological pH, are known to be involved in many important ligand-receptor interactions that can greatly affect specific cell–cell, pathogen–cell, or drug–cell communications (4–6). Consequently, the enzymes responsible for the synthesis and hydrolysis of sialic acid linkages (sialyl transferases and sialidases, respectively) are of great medical interest and a number of such enzymes are considered to be potential targets for the therapeutic treatment of various diseases (7, 8). This has inspired a great deal of work into the synthesis of sialic acids and their analogues (9, 10), resulting in the development of at least two competitive sialidase inhibitors, Zanamivir® (GlaxoSmithKline) and Oseltamivir® (Roche), which are currently being prescribed for the treatment of influenza virus A and B. Yet, despite the obvious importance of these enzymes, the mechanisms through which sialyl transferases and hydrolases operate have remained relatively unexplored. To generate new classes of inhibitors a better understanding of these mechanisms is needed, as well as structural studies on complexes of these enzymes with their substrates and reaction intermediates.

Sialidases (EC: 3.2.1.18) catalyze the hydrolytic cleavage of sialosidic linkages with a net retention of anomeric configuration and have been assigned to CAZy (11) families GH

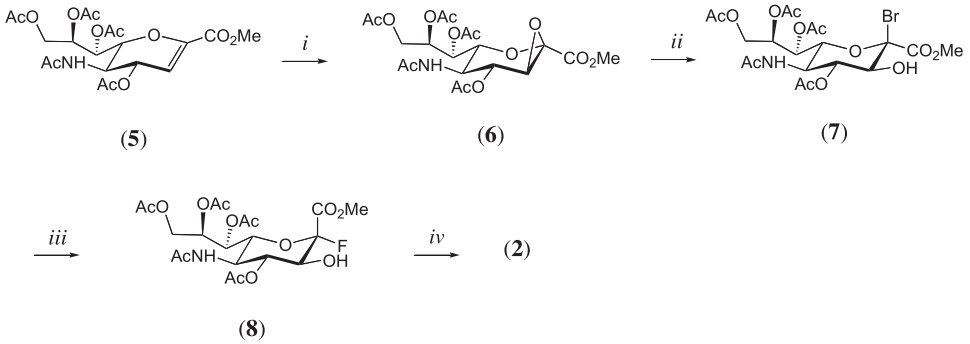
33, 34, and 83. Kinetic studies (12) and recent trapping experiments (13, 14) performed on a *trans*-sialidase from family GH 33 have shown that these enzymes use an analogous mechanism to that of other retaining glycosidases, involving a covalent glycosyl-enzyme intermediate, but utilizing a tyrosine as the catalytic nucleophile. Sialyl transferases (EC: 2.4.99.–.) are responsible for the transfer of the sialic acid moiety from CMP-sialic acid to the terminal carbohydrate of various glycoconjugates with an inversion of anomeric configuration. They have been assigned to CAZy families GT 29, 42, and 52 yet, to date, little is known about the catalytic mechanism of these enzymes with only one X-ray crystal structure so far reported (15).

Small molecule inhibitors that interact with enzyme active sites, either competitively or through the generation of a covalent linkage, have proven to be valuable tools for gaining insights into the catalytic mechanisms of various enzymes. Carbohydrate derivatives with an electronegative fluorine atom adjacent to the anomeric center have proved particularly useful in this regard and have been used successfully to label the catalytic nucleophiles of several retaining glycosidases via the formation of stable, covalent glycosyl-enzyme intermediates (16–18). The electronegative substituent destabilizes the oxocarbenium ion-like transition state, slowing both glycosylation (k_1) and deglycosylation steps (k_2). However, the presence of a good leaving group, fluoride, allows glycosylation to proceed efficiently and results in accumulation of the intermediate. Since sialic acid itself (**1**) bears no electronegative substituent at C-3, adjacent to the anomeric center, the introduction of a fluorine atom or even a hydroxyl group at C-3 might serve the same end, while incorporation of a fluoride leaving group should render the intermediate kinetically accessible. Based on previous studies, the fluorinated derivatives **2** and **3** were considered suitable targets for attempts to label the catalytic nucleophile of retaining sialidases (16–18). Inhibitors for glycosyl transferases can be designed on a similar basis, with a fluorine substituent dramatically slowing turnover. However, since the requirement for nucleotide phosphate leaving groups appears to be absolute, it has not proved possible to trap intermediates with such analogues since the initial step of glycosyl-enzyme formation remains rate-limiting. These analogues have, therefore, best served as inert substrate analogues. Through mechanistic and crystallographic analysis, these analogues have yielded important information on active site architecture and substrate binding interactions (15, 19–21).

This article describes the synthesis of the fluorinated sialic acid derivatives **2** and **3**, which are known mechanism-based inactivators of *Trypanosoma cruzi trans*-sialidase (13, 14). Further, compound **3** is shown here to label the catalytic nucleophile of a sialidase from *T. rangeli*. Also, a convenient two-step synthesis of a non-hydrolysable, competitive inhibitor of sialyl transferases (15, 21), namely **4**, is described.

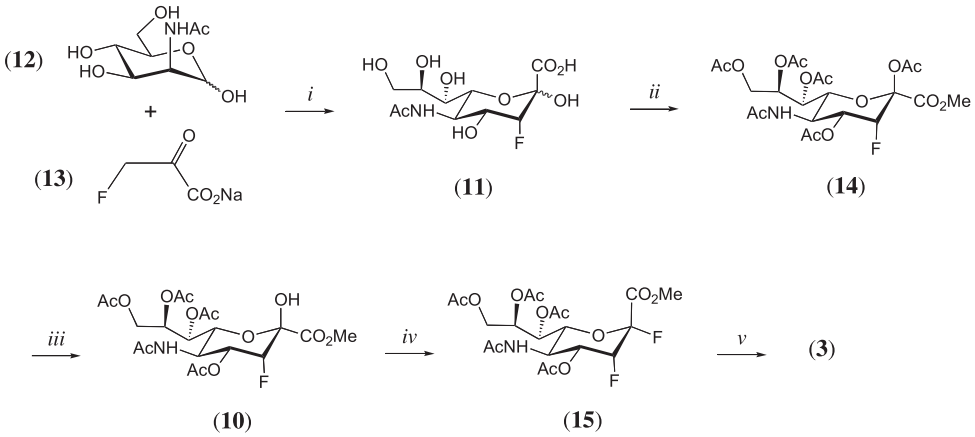
Results and discussion

Covalent inactivators of sialidases and *trans*-sialidases



The 3-hydroxy sialic acid derivative **2** was synthesized from the easily accessible 2,3-dehydro derivative **5** (Scheme 1) (22). Treatment of **5** with dimethyl dioxirane for 3 h gave the epoxide **6**, which was directly opened using titanium(IV) bromide to give the known 3-hydroxy-sialyl bromide **7**. Treatment of the β-bromide **7** with AgF according to the procedure of Okomato et al. (23), then gave the α-sialyl fluoride **8** in moderate yield. The epoxide **6** was also isolated from this reaction, owing to participation by the 3-hydroxyl group. In an attempt to overcome the formation of **6**, the bromide **7** was acetylated prior to fluorination with AgF. This resulted in a slightly higher yield for the fluorination reaction, though there was little difference in the overall yield. Deacetylation of **8** with sodium methoxide in methanol, followed by saponification with aqueous sodium hydroxide, afforded the target fluoride **2**.

The synthesis of 3-fluorosialosyl fluoride **3** requires incorporation of a fluorine at C-3 and several methods currently exist for such a reaction. Treatment of the 2,3-dehydro derivative **5** with Selectfluor™ (**9**), in the presence of water, has been reported to give the 3-fluoro derivative **10** (24). However, in our hands this method was found to be sluggish and ineffective, owing to the unreactive nature of this alkene. Xenon difluoride is known to react with **5** in good yield (25). Unfortunately, owing to the acidity of the reaction conditions, only the thermodynamically more stable β-anomer was ever isolated, rather than the desired α-anomer.



An alternative approach to the synthesis of sialic acid derivatives involves the use of the biosynthetic enzymes. *N*-Acetylneuraminic acid aldolase (Neu5Ac aldolase, EC: 4.1.3.3) catalyses the biosynthesis of sialic acid, from *N*-

acetyl mannosamine and pyruvic acid. A recent patent describes the use of Neu5Ac aldolase of high specific activity (>24 U/mL), to synthesize **11** in high yield, directly from *N*-acetyl mannosamine (**12**) and 3-fluoropyruvic acid (**13**) (Scheme 2) (26). The aldolase was found to be active for several days at room temperature, in the absence of buffer, and could be used in multiple reaction cycles (26). In our hands, Neu5Ac aldolase (>24 U/mL) effectively catalyzed the synthesis of **11**, from **12** and **13**, as described in ref. 26. Further, we also found that this reaction could be efficiently monitored by ^{19}F NMR spectroscopy, following the disappearance of **13**.

3-Fluorosialic acid (**11**) was acetylated with acetic anhydride in pyridine, then converted to its methyl ester using tetramethylsilyl diazomethane, to give **14** in high yield (Scheme 2). Selective deacetylation at the anomeric position was then achieved using hydrazine acetate, yielding the hemi-acetal **10**. Compound **10** was treated with diethylamino sulfurtrifluoride at –30 °C to give the α-fluoride **15** in good yield. The anomeric stereochemistry of **15** was assigned on the basis of the small ^{19}F NMR coupling constant for $J_{F2,F3}$ (11 Hz), which is indicative of an equatorial–axial configuration (27). The opposite anomeric configuration would place the two fluorine atoms in a trans-diaxial arrangement, which is known to give large F–F couplings (20 Hz) (28). Deacetylation of **15** with sodium methoxide, followed by saponification with aqueous sodium hydroxide, afforded the target compound **3**. Compound **3** has been shown to react with wild type *T. cruzi trans*-sialidase (13, 14), further supporting the stereochemical assignment of the anomeric fluoride.

Labeling of the catalytic nucleophile of a sialidase from *T. rangeli*

A wild-type sialidase from *T. rangeli* (TrSA) was inactivated upon incubation with the 3-fluorosialosyl fluoride derivative **3**. Mass spectral analysis of the inactivated protein revealed a single species of mass 71 380 ± 6 Da, greater in mass by 318 ± 12 Da than the wild-type protein (71 062 ± 6 Da), as shown in Fig. 1. This increase of 318 ± 12 Da is that expected for the covalent attachment of one 3-fluorosialosyl moiety (310 Da). To identify the site of covalent attachment, TrSA was incubated with **3** and then immediately subjected to peptic digestion at pH 2, in parallel with a sample of unlabeled protein. The peptic digests from both labeled and unlabeled enzymes were then purified by RP-HPLC coupled with on-line MS analysis. Comparison of the two LC–MS elution profiles revealed that a peptide of mass 1379 Da was observed only in the chromatogram for the labeled sample, with a corresponding peptide of m/z = 1069 present in the unlabeled sample. Daughter-ion fragmentation analysis of this 1379 Da peptide revealed a sequence of DENSGYSSVL – 3-fluorosialic acid, and identified Tyr 346 as the site of sialic acid attachment (Fig. 2). This is the first evidence to confirm that sialidase-catalyzed hydrolysis proceeds through a covalent glycosyl-enzyme intermediate in-

volving a tyrosine residue (Scheme 3), and supports earlier findings that a *trans*-sialidase from *T. cruzi* operates through a similar mechanism (12–14).

Enzymatic synthesis of the competitive sialyl transferase inhibitor 4

The fluorinated CMP-sialic acid derivative **4** is known to be a noncleavable, competitive inhibitor of sialyl transferases, having a K_i = 5.1 μmol/L for an α-(2,6)-sialyltransferase (21). This value compares well to the K_m value for the natural substrate CMP-sialic acid (K_m = 15 μmol/L) (29). Compound **4** is also a competitive inhibitor for the sialyl transferase CstII from *Campylobacter jejuni* (K_i = 657 μmol/L compared to a K_m = 460 μmol/L for CMP-sialic acid) (15). Recent crystallographic studies of CstII with **4** bound in the active site provide unique insights into the catalytic mechanism of sialyl transferases (15). For this reason, a convenient synthesis of **4** would be desirable. However, the only synthesis of **4** reported is both lengthy (10 steps from sialic acid) and low yielding (27% from the alkene **5**) (29).

Here, we find that CMP-sialic acid synthetase (30) efficiently catalyzes the synthesis of **4** directly from 3-fluorosialic acid (**11**) and CTP, in high yield (91%). This is

© 2004 NRC Canada

in contrast to a previous report that the enzymatic synthesis of **4** using CMP-sialic acid synthetase is not viable as 3-fluorosialic acid (**11**) is not a substrate for CMP-sialic acid synthetase (29). Coupled with the one-step enzymatic synthesis of **11** using NeuAc aldolase, we report here the total enzymatic synthesis of **4** from *N*-acetyl mannosamine (**12**), 3-fluoropyruvic acid (**13**), and CTP in only two steps, in around 84% yield.

Conclusion

Facile and efficient chemoenzymatic syntheses are described for three useful probes of enzymes involved in sialic acid biotransformations. The two mechanism-based inactivators **2** and **3** have recently been used to label the catalytic nucleophile of *T. cruzi trans*-sialidase (13, 14), while **3** has been shown here to covalently label a sialidase from *T. rangeli*, allowing identification of Tyr346 as the catalytic nucleophile. This is the first report describing the labeling of the catalytic nucleophile of a sialidase, and supports earlier mechanistic studies on the closely related *T. cruzi trans*-sialidase. Combined, these labeling studies suggest that all members of the sialidase superfamily may operate through a similar catalytic mechanism, one that proceeds through the transient formation of a covalent glycosyl-enzyme intermediate (Scheme 3). An efficient synthesis is described for CMP-3-fluorosialic acid **4**, which has been used in the structural analysis of Cst-II to provide important insights into the catalytic mechanism of this enzyme (15).

Experimental

Moisture-sensitive reactions were carried out under an atmosphere of dry nitrogen. HPLC grade solvents (acetonitrile, pyridine, ethyl acetate, hexane, diethyl ether, and dichloromethane) were used without further purification. All reagents were purchased from Sigma-Aldrich unless otherwise stated, and used without further purification. *N*-Acetyl neuraminic acid aldolase (Neu5Ac aldolase, 4.1.3.3) was purchased from Jülich Fine Chemicals (Germany) and used without further purification. CMP-sialic acid synthetase was expressed and purified as described previously (30). HPLC purification was carried out using an Amide-80 column (TosoHaas, 20 cm × 2.5 cm) on a Waters 2400 System. Thin layer chromatography was performed using 0.25 mm silica gel F_{254} (EM Science-Merck) and visualized by charring with 10% sulfuric acid in ethanol. Flash chromatography was performed using silica gel Kieselgel 60 (230–400 mesh ASTM).

All NMR spectra were acquired on a Bruker AV-300 or Bruker AV-400. Chemical shifts are reported in ppm (δ) relative to tetramethylsilane (^{1}H NMR), $CDCl_3$ (^{13}C NMR), or trifluoroacetic acid (^{19}F NMR).

Methyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-5-deoxy-2-bromo-D-*erythro*-α-L-gluco-2-nonulopyranosonate (7)

The alkene **5** (22) (500 mg, 1.06 mmol) was dissolved in a solution of DMDO in acetone (20 mL, 0.1 mol/L) and allowed to react at room temperature (3 h). The solution was then concentrated in vacuo to give the epoxide **6** as a colorless oil, which was used without further purification. The oil was dissolved in dry CH_2Cl_2 (10 mL) and treated with $TiBr_4$ (0.47 g, 1.3 mmol) with vigorous stirring (10 min). The mixture was then concentrated in vacuo, dissolved in EtOAc and washed with saturated aq. Na_2SO_4, 5% aq. $NaHCO_3$, and then brine. The organic phase was then concentrated in vacuo and the residue purified by flash chromatography (EtOAc) to give the title compound as a colourless oil (510 mg, 86%). The ^{1}H NMR spectrum was consistent with that reported in the literature (23).

5-Acetamido-5-deoxy-2-fluoro-D-*erythro*-β-L-gluco-2-nonulopyranosonic acid (2)

The β-bromide (**7**) (980 mg, 1.8 mmol) was treated with AgF (330 mg, 2.6 mmol) according to the procedure of Okomato et al. (23) gave the α-fluoride **8** as a colorless oil (483 mg, 54%). A small amount of sodium metal (2 mg) was added to a solution of the fluoride **8** (140 mg, 0.28 mmol) in dry methanol (4 mL) at 0 °C and the mixture allowed to stir for 1 h at this temperature. The mixture was then neutralized (Amberlite IR120, H^+ form) and concentrated in vacuo. The resultant oil was then dissolved in water (2 mL), 1 mol/L NaOH (280 μL) added and then allowed to stand at room temperature until no starting material remained (TLC). The solution was neutralized (Amberlite IR120, H^+ form) and lyophilized to give the title compound **2** as a colorless solid (90 mg). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.92 (s, 3H, Ac), 3.48 (br d, 1H, $J_{7,8}$ = 9.8 Hz, H-7), 3.57 (br dd, 1H, $J_{8,9}$ = 6.9, $J_{9,9'}$ = 12.1 Hz, H-9), 3.67 (br d, 1H, $J_{5,6}$ = 10.0 Hz, H-6), 3.73–3.83 (m, 3H, H-3, 8, 9′), 3.95 (dd, 1H, $J_{3,4}$ = 9.5, $J_{4,5}$ = 10.5 Hz, H-4), 4.14 (t, 1H, H-5). ^{13}C NMR (100.6 MHz, $CDCl_3$) δ: 22.45 (Me), 47.10 (C-5), 64.10 (C-9), 68.14 (C-7), 69.49 (d, 1C, $J_{4,F2}$ = 4 Hz, C-4), 70.23 (d, 1C, $J_{3,F2}$ = 18 Hz, C-3), 71.02 (C-8), 72.99 (d, 1C, $J_{6,F2}$ = 4 Hz, C-6), 105.32 (d, 1C, $J_{2,F2}$ = 220 Hz, C-2), 169.03 (d, 1C, $J_{1,F2}$ = 24 Hz, C-1), 175.36 (C=O). ^{19}F NMR (282.4 MHz, $CDCl_3$) δ: –40.5 (d, $J_{3,F2}$ = 12 Hz, F-2). LR-MS calcd. for $C_{11}H_{17}FNO_9$: 326.1; found: 326.0.

5-Acetamido-3,5-dideoxy-3-fluoro-D-*erythro*-L-manno-2-nonulopyranosonic acid (11)

A solution of Neu5Ac aldolase (15 mg, 23 U/mg) in water (4 mL) was added to a solution of 3-fluoropyruvic acid (150 mg, 1.2 mmol) and *N*-acetyl-D-mannosamine monohydrate (1.0 g, 4.2 mmol) in water (8 mL) and the mixture was left to stand at 25 °C (10 h). The mixture was then filtered (Amicon, 30 kDa) to remove small molecule substrates and products, and the protein used again with 3-fluoropyruvic acid and *N*-acetyl mannosamine as described above. After three such cycles, the filtrates were combined and then purified by ion exchange chromatography (Dowex, formate form) eluting with 0 → 1 mol/L formic acid. Lyophilisation gave 3-fluorosialic acid (**11**) as a colorless hygroscopic solid (1.1 g). ^{1}H and ^{13}C NMR spectra were consistent with those reported in the literature (31). ^{19}F NMR (282.4 MHz) δ: –131.9 (dd, $J_{3,F}$ = 43, $J_{4,F}$ = 31 Hz, F-3).

Methyl 5-acetamido-2,4,7,8,9-penta-*O*-acetyl-3,5-dideoxy-3-fluoro-D-*erythro*-α-L-manno-2-nonulopyranulosate (14)

Ac_2O (5 mL) was added to a solution of the 3-fluorosialic acid (**11**) (890 mg, 2.8 mmol) in pyridine (6 mL) at 0 °C, and the solution left to warm to room temperature (12 h).

© 2004 NRC Canada

The mixture was then concentrated in vacuo, and residual pyridine removed by azeotropic distillation with toluene (3 × 10 mL) to give a pale yellow oil (1.6 g). A solution of ethereal TMS–diazomethane (1.5 mol/L) was then added dropwise to a solution of the yellow oil (1.6 g) in MeOH–Et_2O (2:1, 15 mL) at –10 °C until a darker yellow color persisted (≈3 mL). The mixture was left to stir at this temperature for 10 min then concentrated in vacuo and the residue subjected to a standard work up (EtOAc) to give a light yellow oil. Purification of the yellow oil by flash chromatography (EtOAc) gave **14** as a colorless oil (1.4 g, 90%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 5.60 (br d, 1H, $J_{NH,5}$ = 9.3 Hz, NH), 5.51 (ddd, 1H, $J_{4,F}$ = 27.8, $J_{3,4}$ = 2.3, $J_{4,5}$ = 10.6 Hz, H-4), 5.33 (dd, 1H, $J_{6,7}$ = 1.8, $J_{7,8}$ = 5.0 Hz, H-7), 5.07 (ddd, 1H, $J_{8,9}$ = 2.3, 6.6 Hz, H-8), 4.88 (dd, 1H, $J_{F,3}$ = 49 Hz, H-3), 4.52 (dd, 1H, $J_{9,9}$ = 12.5 Hz, H-9), 4.15–4.24 (m, 2H, H-5,6), 4.12 (dd, 1H, H-9), 3.78 (s, 3H, OMe), 2.14, 2.12, 2.07, 1.98, 1.94 (5 s, 15H, OAc), 1.85 (s, 3H, NHAc). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 20.28–23.07 (5 s, 6C, Ac), 45.21 (C-5), 53.41 (OMe), 62.02 (C-9), 67.85 (C-7), 71.43 (C-8), 71.85 (C-6), 71.87 (d, 1C, $J_{4,F}$ = 32 Hz, C-4), 87.18 (d, 1C, $J_{3,F}$ = 185 Hz, C-3), 95.01 (d, 1C, $J_{2,F}$ = 29 Hz, C-2), 165.02 (C-1), 167.02–170.53 (5 s, 6C, C=O). ^{19}F NMR (282.4 MHz) δ: –132.2 (dd, F-3).

Methyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-3,5-dideoxy-3-fluoro-D-*erythro*-α-L-manno-2-nonulopyranulosate (10)

A solution of hydrazine acetate (550 mg, 6.0 mmol) in MeOH (10 mL) was added to a solution of the 3-fluorosialic acid (**14**) (1.1 g, 2.0 mmol) in CH_2Cl_2 (10 mL) at 0 °C and the mixture left to stand at this temperature (3 h). The mixture was then concentrated in vacuo, subjected to a standard work up (EtOAc), and the residue purified by flash chromatography (EtOAc) to give the hemiacetal (**10**) as a colourless oil (850 mg, 84%). ^{1}H and ^{13}C NMR spectra were consistent with those reported in the literature (24). ^{19}F NMR (282.4 MHz, $CDCl_3$) δ: –128.9 (dd, $J_{F,3}$ = 48, $J_{F,4}$ = 28 Hz, F-3).

Methyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-3,5-dideoxy-3-fluoro-D-erythro-β-L-manno-2-nonulopyranosyl fluoride (15)

DAST (95 µL, 0.70 mmol) was added dropwise to a stirred solution of the hemiacetal (**10**) (240 mg, 0.47 mmol) in CH_2Cl_2 (10 mL) at –30 °C and the mixture held at this temperature with stirring (30 min). The reaction was quenched by the addition of methanol (20 µL) then subjected to a standard work up (CH_2Cl_2) and the resultant residue purified by flash chromatography (EtOAc) to give the difluorosialic acid derivative (**15**) as a colorless oil (197 mg, 82%). Crystallization (EtOAc–*i*-Pr_2O) gave **15** as long white needles, mp 68–70 °C. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 5.55 (br d, 1H, $J_{NH,5}$ = 9.0 Hz, NH), 5.41 (br dd, 1H, $J_{F,4}$ = 27.1, $J_{4,5}$ = 10.5 Hz, H-4), 5.33 (ddd, 1H, $J_{7,8}$ = 5.1, $J_{8,9}$ = 2.5, $J_{8,9}$ = 7.7 Hz, H-8), 5.28 (br d, 1H, H-7), 5.08 (dt, 1H, $J_{F2,3}$ = $J_{3,4}$ = 2.5, $J_{F3,3}$ = 51 Hz, H-3), 4.28–4.35 (m, 2H, H-6, 9), 4.03–4.15 (m, 2H, H-5, 9′), 3.88 (s, 3H, OMe), 2.13, 2.08, 2.07, 2.00 (4 s, 12H, OAc), 1.89 (s, 3H, NHAc). ^{13}C NMR (282.4 MHz, $CDCl_3$) δ: 21.93, 22.06, 22.23, 22.40 (OAc), 24.53 (NHAc), 46.63 (C-5), 55.13 (OMe), 63.31 (C-9), 68.43 (C-7), 69.2–70.1 (m, C-4), 70.54 (C-8), 73.54 (d, $J_{F3,6}$ = 4 Hz, C-6), 86.92 (dd, $J_{F2,3}$ = 19, $J_{F3,3}$ = 194 Hz, C-3), 106.06 (dd, $J_{F3,2}$ = 18, $J_{F2,2}$ = 226 Hz, C-2), 166.02 (br d, $J_{F2,1}$ = 21 Hz, C-1), 171.25, 171.35, 171.553, 171.745, 171.976 (CO). ^{19}F NMR (282.4 MHz, $CDCl_3$) δ: –46.7 (br d, $J_{F2,F3}$ = 11 Hz, F-2), –140.2 (ddd, $J_{F3,3}$ = 50, $J_{F3,4}$ = 25 Hz, F-3). LR-MS calcd. for $C_{20}H_{28}F_2NO_{12}$: 512.8; found: 512.2.

5-Acetamido-3,5-dideoxy-3-fluoro-D-*erythro*-β-L-manno-2-nonulopyranosonic acid (3)

A small amount of sodium metal (2 mg) was added to a solution of the difluoride (**15**) (180 mg, 0.35 mmol) in dry methanol (5 mL) at 0 °C and the mixture allowed to stir at this temperature (2 h). The mixture was then neutralized (Dowex IR120, H^+ form) and concentrated in vacuo. The resultant oil was dissolved in water (2 mL), treated with 1 mol/L NaOH (360 µL) and allowed to stand at room temperature until no starting material remained (TLC). The solution was neutralized (Amberlite IR120, H^+ form) and lyophilized to give the title compound (**3**) as a colorless solid (120 mg). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 5.10 (br dt, 1H, $J_{3,4}$ = 2.5, $J_{3,F2}$ = 2.5, $J_{3,F3}$ = 51 Hz, H-3), 4.15 (t, 1H, $J_{4,5}$ = 10.5 Hz, H-5), 4.04 (br dd, 1H, $J_{4,F3}$ = 28.5 Hz, H-4), 3.73–3.78 (m, 2H, H-8, 9′), 3.68 (br d, 1H, $J_{5,6}$ = 10.5 Hz, H-6), 3.53 (br dd, 1H, $J_{8,9}$ = 6.9, $J_{9,9'}$ = 12.1 Hz, H-9), 3.45 (br d, 1H, $J_{F,4}$ = 9.8 Hz, H-7), 1.93 (s, 1H, Ac). ^{13}C NMR (100.6 MHz, $CDCl_3$) δ: 22.39 (Me), 47.17 (d, 1C, $J_{5,F3}$ = 3 Hz, C-5), 63.22 (C-9), 68.16 (C-7), 69.40 (dd, 1C, $J_{4,F2}$ = 6, $J_{4,F3}$ = 18 Hz, C-4), 70.85 (C-8), 72.92 (d, 1C, $J_{6,F2}$ = 4 Hz, C-6), 89.05 (dd, 1C, $J_{3,F2}$ = 19, $J_{3,F3}$ = 184 Hz, C-3), 107.03 (dd, 1C, $J_{2,F2}$ = 220, $J_{2,F3}$ = 15 Hz, C-2), 169.78 (dd, 1C, $J_{1,F2}$ = 26, $J_{1,F3}$ = 3 Hz, C-1), 175.36 (C=O). ^{19}F NMR (282.4 MHz, $CDCl_3$) δ: –45.5 (br d, $J_{F2,F3}$ = 11 Hz, F-2), –141.3 (br ddd, F-3). LR-MS calcd. for $C_{11}H_{16}F_2NO_8$: 328.1; found: 328.0.

Cytidine 5′-phosphate, *P*′-(5-acetamido-3,5-dideoxy-3-fluoro-2-D-*erythro*-α-L-manno-2-nonulopyranosonic acid (4)

A 20 mL solution of 3-fluorosialic acid (**11**) (130 mg, 0.37 mmol), 20 mmol/L CTP, 25 mmol/L $MgCl_2$, CMP-Neu5Ac synthetase (30) (10 U, 109 U/mL), and pyrophosphatase (5 U) in 50 mmol/L Tris-HCl (pH 8.5) was left to stand overnight at room temperature. The mixture was purified by HPLC (30% H_2O–MeCN, 6 mL/min), then lyophilized to give the title compound (**4**) as a white solid (210 mg, 91%). ^{1}H NMR was consistent with that reported (21). ^{19}F NMR (282.4 MHz, $CDCl_3$) δ: –131.5 (dd, $J_{3,F3}$ = 42, $J_{4,F3}$ = 28 Hz, F-3).

Labeling and proteolysis of wild-type *T. rangeli* sialidase

Labeling of wild-type *T. rangeli* sialidase (2.1 mg/mL) was accomplished by incubating the enzyme (40 µL) in pH 7.1, 50 mmol/L phosphate buffer, containing 50 mmol/L 3-fluorosialosyl fluoride (**3**) (30 µL) for 30 min at room temperature. After this time, digestion buffer (120 µL, pH 2.0) containing pepsin (0.3 mg/mL) was added. Proteolytic digestion was performed for 1 h and the sample was frozen prior to mass spectrometric analysis. A sample of unlabeled enzyme for comparison was also prepared in the same manner.

© 2004 NRC Canada

ES-MS analysis of the proteolytic digest

Mass spectra were recorded on a PE-Sciex API 300 triple-quadrupole mass spectrometer and a PE-Sciex API QSTAR pulsar i (Sciex, Thornhill, Ontario, Canada) equipped with an Ionspray ion source. Peptides were separated by reverse-phase HPLC on a LC Packing UltiMate Micro HPLC system (Dionex, Sunnyvale, California) directly interfaced with the mass spectrometer. In each of the MS experiments, the proteolytic digest was loaded onto a C-18 column (LC Packing, 100 Å pepMap, 1 mm × 150 mm) equilibrated with solvent A (solvent A: 0.05% trifluoroacetic acid – 2% acetonitrile in water). Elution of the peptides was accomplished using a gradient (0%–60%) of solvent B over 60 min followed by 85% solvent B over 20 min (solvent B: 0.045% trifluoroacetic acid – 80% acetonitrile in water). Solvents were pumped at a constant flow rate of 50 μL/min. Spectra were recorded in the single quadrupole scan mode (LC–MS) or the tandem MS product-ion scan mode. In the single-quadrupole mode (LC–MS), the quadrupole mass analyzer was scanned over a mass-to-charge ratio (m/z) range of 100–2200 Da with a step size of 0.5 Da and a dwell time of 1.5 ms per step. The ion source voltage (ISV) was set at 5.5 kV and the orifice energy (OR) was 45 V. In the tandem MS daughter-ion scan mode, the spectra were obtained in a separate experiment by selectively introducing the labeled (m/z = 1379) or unlabeled (m/z = 1069) parent ion from the first quadrupole (Q1) into the collision cell (Q2) and observing the product ions in the third quadrupole (Q3). The scan range of Q3 was 100–1400, the step size was 0.5 Da, the dwell time was 1 ms, ISV was 5 kV, OR was 45 V, Q0 = –10, IQ2 = –48.

Acknowledgements

We thank the Human Frontiers Science Program for their generous financial assistance. We thank Dr. W. Wakarchuck for his kind gift of CMP-sialic acid synthetase and Dr. Carlos Frasch and Dr. Pedro Alzari for the *T. rangeli* sialidase. Shouming He is thanked for performing the MS analysis.

Exo selectivity and the effect of disubstitution in the Diels–Alder reactions of butadiene with 3,3-disubstituted cyclopropenes

Tammy L. Gosse and Raymond A. Poirier

Abstract: A density functional computational study was performed to accomplish two tasks: to examine the endo–exo selectivity in the Diels–Alder reactions of 3,3-disubstituted cyclopropenes with *s-cis*-butadiene, and to study the effect of disubstitution on the reactivity of the cyclopropene dienophile. Cyclopropene is substituted at C-3 with CH_3, SiH_3, NH_2, PH_2, OH, SH, F, and Cl; both 3-substituted and 3,3-disubstituted ground states are examined to determine relative reactivities. The exo transition-state structures are consistently lower in energy than the endo transition-state structures for the 3,3-disubstituted cyclopropene – butadiene system, and surprisingly, both modes of addition have lower activation barriers than the syn 3-substituted cyclopropene – butadiene system. Through a series of isodesmic reactions, we have concluded that there is an additional stabilization in the transition-state structures of the 3,3-disubstituted system that can account for the lowering of the activation barriers below that of the 3-substituted cases. This stabilization is a combination of the anomeric effect and the ring relaxation that occurs in the transition-state structure.

Key words: Diels–Alder reaction, cyclopropene, exo selectivity, anomeric effect.

Résumé : On a réalisé une étude théorique à l'aide de la théorie de la densité fonctionnelle pour examiner la sélectivité endo–exo des réactions de Diels–Alder de cyclopropènes 3,3-disubstitués avec le *s-cis*-butadiène ainsi que pour étudier l'effet de la disubstitution sur la réactivité du cyclopropène diénophile. Le cyclopropène est substitué en position C-3 avec des CH_3, SiH_3, NH_2, PH_2, OH, SH, F et Cl et, dans le but de déterminer leurs réactivités relatives, on a examiné les états fondamentaux produits tant mono- que disubstitués en position C-3. Pour le système cyclopropène 3,3-disubstitué – butadiène, les structures de l'état de transition exo ont systématiquement des énergies plus faibles que celles de l'état de transition endo et, à notre grande surprise, les barrières d'activation pour les deux modes d'addition sont plus faibles que celles du système cyclopropène 3-monosubstitué syn – butadiène. Par le biais d'une série de réactions isodesmiques, on en est venu à la conclusion qu'il y a une stabilisation additionnelle dans les structures de l'état de transition du système 3,3-disubstitué qui permet d'expliquer l'abaissement des barrières d'activation à des niveaux inférieurs à celles observées dans les cas 3-substitués. Cette stabilisation est une combinaison d'effet anomère et de relaxation du cycle qui se produit dans l'état de transition.

Mots clés : réaction de Diels–Alder, cyclopropène, sélectivité exo, effet anomère.

[Traduit par la Rédaction]

Introduction

It has been demonstrated both experimentally and theoretically that the majority of Diels–Alder cycloadditions show a preference for the formation of endo products (1, 2). This preponderance for endo selectivity has been shown in a variety of studies involving cyclopropene and its 3-substituted derivatives (3). There have been some specific instances of exo selectivity encountered for this family of cyclic dienophiles with various dienes (4), however, this phenomenon is typically not seen and no explanation exists for the exo selectivity.

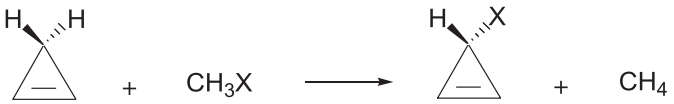
The endo preference of chemical systems has been explained mainly by the argument of favourable "secondary orbital interactions" (SOI) in the endo geometry, first suggested by Woodward and Hoffmann (5); these interactions are defined as the overlap of the frontier molecular orbitals at the nonreacting π centers of the diene and dienophile at the transition state. In the case of the cyclopropene and butadiene reaction, this interaction would occur between the syn methylene hydrogen at C-3 of cyclopropene and the π system of butadiene. While SOI has been the most popular argument discussed in terms of explaining endo selectivity, there are an increasing number of studies providing evidence that lessens its significance. Xidos et al. (6) deduced that these "H–π" interactions were not energetically significant enough to be a deciding factor of endo-exo selectivity and Salvatella and co-workers (7) also disputed the importance of SOI in Diels–Alder reactions; both groups state that steric interaction arguments may be invoked to explain endo–exo selectivity. A recent paper by Ogawa and Fujimoto (8) employed numerical analysis in the examination of the endo

 doi: 10.1139/V04-115 © 2004 NRC Canada

transition state of butadiene and maleic anhydride; they deduced that SOI is much less significant than previously thought.

In recent literature, we have not encountered a theoretical examination of the 3,3-disubstituted cyclopropene and butadiene system and this is the focus of the present study. An extensive analysis of the facial and endo–exo selectivity of the 3-substituted cyclopropene and butadiene addition reaction (6) suggested that the disubstituted system should show considerable preference for exo addition. Latypova et al. (9) examined the Diels–Alder reactions of 3-methyl-3-cyanocyclopropene with a variety of dienes experimentally, and all cases were shown to be stereospecific with the cyano group in the syn position of the transition state; exo selectivity was found for the furan-type dienes. Apeloig et al. (10) determined the stereoselectivity of three different cyclopropene derivatives (none of which were 3,3-disubstituted as in the present study) with a series of substituted dienes by using X-ray and NOE studies; one of the cyclopropene reactants, 1,2,3,3-tetrachlorocyclopropene, was shown to be exo selective when reacted with some 1-substituted-1,3-dienes. This group predicted at that time that 3,3-disubstituted cyclopropenes would yield exo selective products with open-chain dienes. Boger and Brotherton (11) studied the Diels–Alder reactions of cyclopropenone ketals with electron-rich, electron-poor, and neutral dienes; nearly all of the reactions produced the exo cycloadduct only, and it was concluded that this exo preference was a result of steric factors in the transition state.



Cyclopropene is the simplest cyclic dienophile and its reactivity can be easily modified by substitution at the C-3 position. The cycloaddition reaction of 3,3-disubstituted cyclopropene to butadiene is an ideal system for studying reactivity and steric effects on the endo–exo selectivity. Herein we examine a series of these reactions, and where applicable, compare the results with those obtained for the previously studied 3-substituted cyclopropene – butadiene system (6).

Computational methods

Ground-state minima for cyclopropene and its derivatives, disubstituted at C-3 by CH_3, SiH_3, NH_2, PH_2, OH, SH, F, and Cl, and *s-cis*-butadiene, as well as transition-state structures for the endo and exo Diels–Alder cycloadditions were initially obtained using MUNgauss (12) at the HF/6-31++G(*d*) level of theory. All subsequent calculations were performed with Gaussian 98 (13). The ground-state and transition-state structures were further optimized using B3LYP/6-31++G(d). All probable rotational minima were determined for those 3,3-disubstituted cyclopropene ground states with conformational mobility; the ground-state cyclopropenes reported here refer to the rotational global minimum determined at B3LYP/6-31++G(d), unless otherwise noted. Likewise, all probable rotational minima for the endo and exo transition states with CH_3, SiH_3, NH_2, PH_2, OH, and SH disubstituted at C-3 on the dienophile, were obtained. In all cases, the *s-cis*-butadiene with a four-carbon torsion of 31.9° was used as the ground-state minimum for the diene. Gaussian 98 confirmed that all ground-state minima had no imaginary frequencies and all transition-state structures had a single imaginary frequency.

All ground-state and transition-state structures for the previously studied 3-substituted cyclopropene – butadiene system (6) were updated to the B3LYP/6-31++G(*d*) level of theory to allow for comparison to the present 3,3-disubstituted system.

Results and discussion

Ground-state cyclopropenes

The stabilization of the various 3-substituted cyclopropene ground states was quantified in a previous examination via an isodesmic reaction, which quantified the effect of substitution at C-3 of cyclopropene relative to a similarly substituted methane derivative. These isodesmic energies showed a good correlation with the electronegativity (14) of the substituent atom or group. The examined substituents, with the exception of SiH_3, showed a stabilization of the cyclopropene ring upon substitution and that the degree of stabilization increased with increasing electronegativity, suggesting that the stabilization of cyclopropene is strongly influenced by the strength of σ-withdrawal by the substituent.

A similar investigation was conducted in the present study for the 3,3-disubstituted cyclopropenes and the results then compared with those obtained for the updated 3-substituted cyclopropenes. Schemes 1 and 2 show the isodesmic reactions considered here and Table 1 includes the isodesmic stabilization energies (ΔE^{X}_{stab} and ΔE^{XX}_{stab}) for both reactions.

Scheme 1 represents the effect (stabilization or destabilization) on the cyclopropene ring that results from the addition of one substituent (X) to C-3 of cyclopropene relative to a similarly substituted methane. The X substituents of these methane derivatives all have a staggered conformation. Scheme 2 represents the stabilization – destabilization of 3-substituted cyclopropene resulting from the addition of the second X to C-3 of the 3-substituted cyclopropene relative to a similarly monosubstituted methane derivative.

Table 1 shows that upon the addition of the first X to C-3 of cyclopropene, we see a stabilization of the cyclopropene ring for all examined substituents except SiH_3, which is only slightly destabilized. These results are comparable to the previous energies obtained at the Hartree–Fock level. The value of ΔE^{X}_{stab} increases with the electronegativity of X, suggesting a gradual reduction in the reactivity of the dienophile with increasing electronegativity. The energies of Scheme 2 show a further stabilization upon the addition of the second X to 3-substituted cyclopropene for all examined

Scheme 3.

substituents with the exception of SiH_3, which is further destabilized upon disubstitution.

It is clear that the addition of X to unsubstituted cyclopropene and the addition of the second X to the 3-substituted cyclopropene are not equivalent. Generally, the greatest degree of stabilization (or destabilization) of the cyclopropene ring comes with the addition of the first X. The most electronegative substituents (X = NH_2, OH, and F) show significantly larger stabilization energies, especially NH_2 and OH, upon the addition of the second X to the 3-substituted cyclopropene. This can be explained by the occurrence of the anomeric effect (15), which measures the extent to which two substituents bonded to the same sp^3-hybridized carbon interact with each other. For NH_2, OH, and F, this large stabilizing interaction results from the lone pair of one substituent donating electron density to the σ system of the other substituent and vice versa. As a means of expressing this effect quantitatively for the most basic molecular system of 3,3-disubstituted methane, we considered the isodesmic reaction in Scheme 3*a*.

The result obtained at B3LYP/6-31++G(*d*) for X = OH (ΔE = –63.6 kJ mol^{-1}) clearly shows a significant anomeric stabilization. The two other electronegative substituents, NH_2 (ΔE = –31.9 kJ mol^{-1}) and F (ΔE = –46.6 kJ mol^{-1}) gave similar results; however, the remaining substituents in this study showed significantly less stabilization upon disubstitution.

The other substituent worthy of note here is Cl, which generally shows a slightly destabilizing anomeric effect (Scheme 3*a*, calculated ΔE of CH_2Cl_2 = 4.9 kJ mol^{-1}). As can be seen from Table 1, the addition of the second Cl to C-3 of 3-Cl-cyclopropene results in little stabilization (ΔE^{XX}_{stab} = –4.04 kJ mol^{-1}) compared to the addition of the first Cl to cyclopropene, which is very stabilizing. This indicates that the second Cl should have very little effect on the stability and reactivity of the 3-Cl-cyclopropene.

An examination of the 3,3-disubstituted cyclopropene ground-state geometries (Table 1) reveals trends similar to that of the 3-substituted cyclopropenes as the electronegativity of the substituents increase. Table 1 includes the C—C single bonds and the C=C double bonds of both types of dienophiles with the various substituents. As shown, the addition of increasingly electronegative substituents results in a longer, and thus more electron deficient, C=C double bond, as well as generally shorter C—C single bonds of the cyclopropene ring, in comparison to cyclopropene itself. In comparing the 3-substituted to the 3,3-disubstituted cyclopropenes for each substituent, we see the effect of disubstitution on the geometry. The C=C bonds are generally longer in the 3,3-disubstituted cyclopropenes, and the degree of elongation increases upon the disubstitution of stronger electron-withdrawing groups. An exception is SiH_3, which

NH_2	**2D**	**2B**	12.4
OH	**3A**	**3A**	14.2
F	—	—	12.2

exhibits a further shortening of the C=C bond. This geometric trend supports the energetic data; the cyclopropenes with the longer, more electron-deficient C=C bonds are also the more stable structures. In addition, the C—C single bonds get substantially shorter upon disubstitution of electron-withdrawing groups and generally longer for electron-donating groups. In relation to the unsubstituted cyclopropene, it can be seen that 3,3-disubstitution has similar effects on the ring as 3-substitution. The nature of the substituent (electron-withdrawing or -donating) affects the geometry and stabilization energies in a similar way; however, the anomeric effect that results from 3,3-disubstitution can also contribute to the geometrical changes in the ring as well as the stabilization energies.

Fig. 1. Transition-state structures for 3,3-CH_3-cyclopropene with butadiene, endo and exo addition (**1A**); 3,3-SiH_3-cyclopropene with butadiene, endo addition (**1B**); and 3,3-SiH_3-cyclopropene with butadiene, exo addition (**1C**).

Transition-state structures

Because the dienophile of the present reaction is disubstituted at the C-3 position, we are removing the possibility of facial selectivity and are thus dealing with endo–exo selectivity only. In ref. 6, plots of activation energies of the four modes of addition (endo-syn, endo-anti, exo-syn, and exo-anti) of 3-substituted cyclopropene to butadiene against electronegativities show that the syn transition states are higher in energy than the anti transition states in all cases. However, in looking solely at the syn additions, we see that additions take place more favourably in the exo geometry than in the endo geometry. This suggested that if the Diels–Alder reactions could occur via syn addition only, as would be the case with 3,3-disubstituted cyclopropene and butadiene, the exo geometry would be favoured.

The transition-state structures of disubstituted CH_3-, SiH_3-, F-, and Cl-cyclopropenes with butadiene each have one endo and one exo structure that are first-order saddle points. In the case of the two halogens examined, we see 100% exo selectivity with $\Delta E_{endo\text{-}exo}$ of 12.2 and 12.0 kJ mol^{-1} at B3LYP/6-31++G(*d*) for F and Cl, respectively (Table 2). The conformations of the CH_3 substituents in the transition states for endo and exo addition are the same (conformation **1A**). However, the SiH_3 groups in the endo transition state are in a staggered conformation (**1B**) and for exo addition, in a slightly skewed conformation (**1C**) (Fig. 1). In addition, the $\Delta E_{endo\text{-}exo}$ value for the 3,3-SiH_3-cyclopropene – butadiene case is small; the exo addition is favoured by a mere 2.8 kJ mol^{-1}, indicating no real preference for either mode of addition. The $\Delta E_{endo\text{-}exo}$ for the CH_3 substituent is calculated to be 7.2 kJ mol^{-1}.

For the Diels–Alder reactions of disubstituted NH_2-, PH_2-, OH-, and SH-cyclopropenes with butadiene, there were multiple first-order saddle points. Figure 2 illustrates examples of the four possible conformations for 3,3-NH_2- and 3,3-PH_2-cyclopropene addition to butadiene, and Table 2 lists the lowest energy conformer for each mode. Conformations **2A**, **2B**, and **2D** were identified for 3,3-NH_2-cyclopropene – butadiene endo and exo addition; **2C** is a confirmed second-order saddle point for exo addition, but no such conformation was found for endo addition. For the 3,3-PH_2-cyclopropene – butadiene cases, conformations **2A**–**2D** were found for both endo and exo addition. All, except for **2D** endo addition, which is second-order, are first-order saddle points. The exo geometries are favoured over the endo forms for each conformation. The lowest energy conformation for 3,3-NH_2-cyclopropene – butadiene endo addition is **2D**, unlike the other additions for NH_2 and PH_2, in which **2B** is the preferred conformer.

For both OH and SH substituents, two different first-order conformations (**3A** and **3B**) were obtained for both endo and exo addition, as shown in Fig. 3. The **3A** and **3B** exo transition-state structures for both OH and SH are favoured over their endo counterparts. Interestingly, the same conformation (**3A**) is preferred for both endo and exo addition for 3,3-OH-cyclopropene – butadiene, and the other conformation (**3B**) is the lowest in energy for both endo and exo addition for

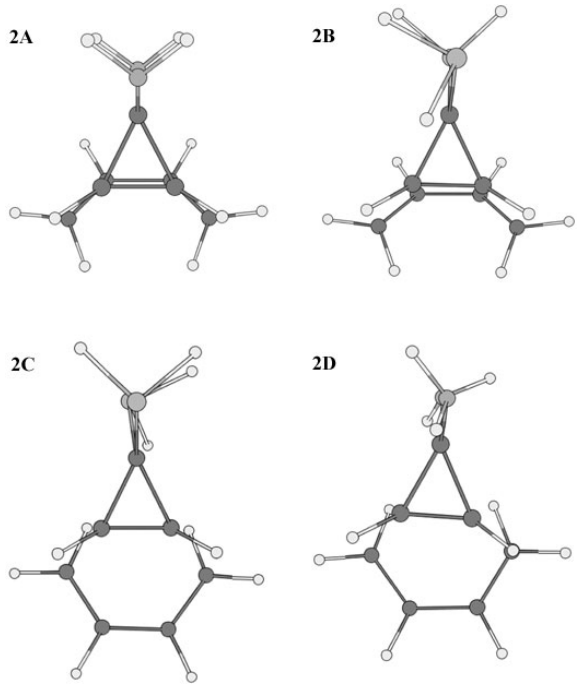
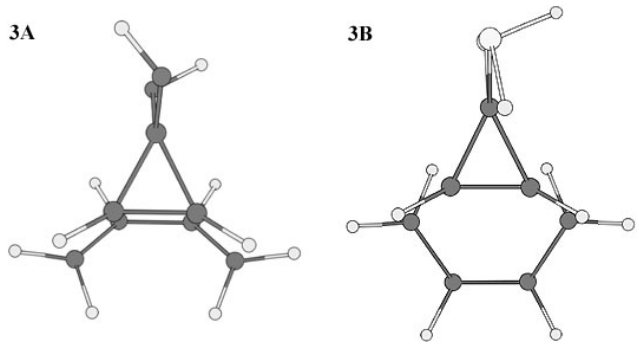
Fig. 2. Examples of transition-state structures obtained for 3,3-NH_2(or PH_2)-cyclopropene with butadiene; NH_2 endo addition (**2A**), PH_2 endo addition (**2B**), PH_2 exo addition (**2C**), and NH_2 exo addition (**2D**).





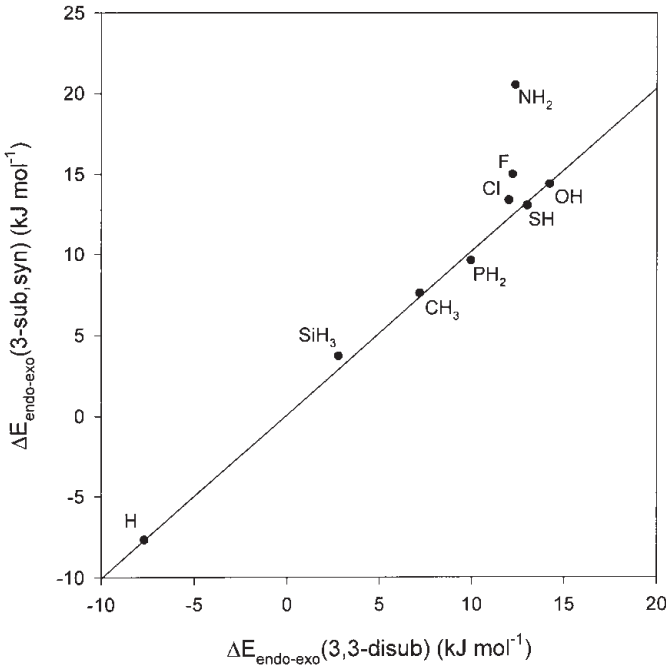


Fig. 3. Examples of transition-state structures obtained for 3,3-OH(or SH)-cyclopropene with butadiene; OH endo addition (**3A**) and SH exo addition (**3B**).

3,3-SH-cyclopropene – butadiene. These reactions exhibit 100% exo selectivity with $\Delta E_{\text{endo-exo}}$ of 14.2 and 13.0 kJ mol^{-1} at B3LYP/6-31++G(*d*) for OH and SH, respectively (Table 2). In both conformers, the H of the syn substituent is pointing away from the π bond (in endo addition) and away from the Hs of C-1 and C-4 of butadiene (in exo addition). The OH and SH substituents in both of their **3A** and **3B** conformations are positioned so as to minimize steric interactions with one another.

The 3-substituted cyclopropene with butadiene syn transition states from ref. 6 were optimized at B3LYP/6-31++G(*d*) to investigate the effects of disubstitution on energetics and structure. Figure 4 is a plot of $\Delta E_{\text{endo-exo}}$ of 3-substituted cyclopropene (syn) with butadiene vs. $\Delta E_{\text{endo-exo}}$ of 3,3-disubstituted cyclopropene with butadiene, illustrating

Fig. 4. Plot of $\Delta E_{\text{endo-exo}}$(3-substituted, syn, kJ mol^{-1}) vs. $\Delta E_{\text{endo-exo}}$(3,3-disubstituted, kJ mol^{-1}) at B3LYP/6-31++G(d).

the effect on the selectivity of adding the second substituent to the anti position of the monosubstituted syn transition state. The negative values of both Δ*E*s for cyclopropene are a result of the endo preference in the cyclopropene–butadiene parent system. As indicated in Table 3, many of the values for ΔΔ*E* between the 3-substituted and 3,3-disubstituted cases are essentially zero. Since the addition of the substituent to the anti position of the syn transition state has very little effect on the endo–exo selectivity in general, it may be deduced that the change in the nature of the dienophile (from monosubstituted to disubstituted) does not play as important a role when the steric interactions in the transition state are very similar, as is the case here. These similar steric interactions (syn substituent positioned over the diene) translate into very similar selectivities. In addition, it can be stated that, for this system, if there is a substituent *other than H* at the syn position of the transition state, exo selectivity will prevail irrespective of the electron-withdrawing or electron-donating nature of the group.

In Fig. 4, the one substituent worthy of note is NH_2 with a ΔΔ*E* of 8.2 kJ mol^{-1}. An examination of the ground-state and transition-state structures reveal that for both the mono- and disubstituted NH_2 dienophiles, there is a change in conformation of the substituent(s) from the ground state to the *exo* transition state. The NH_2 group of 3-NH_2-cyclopropene changes from the preferred gauche conformation in the ground state to a staggered conformation in the exo-syn transition-state structure, with the nitrogen lone pair pointing down towards the C-1 and C-4 Hs of butadiene. Based on

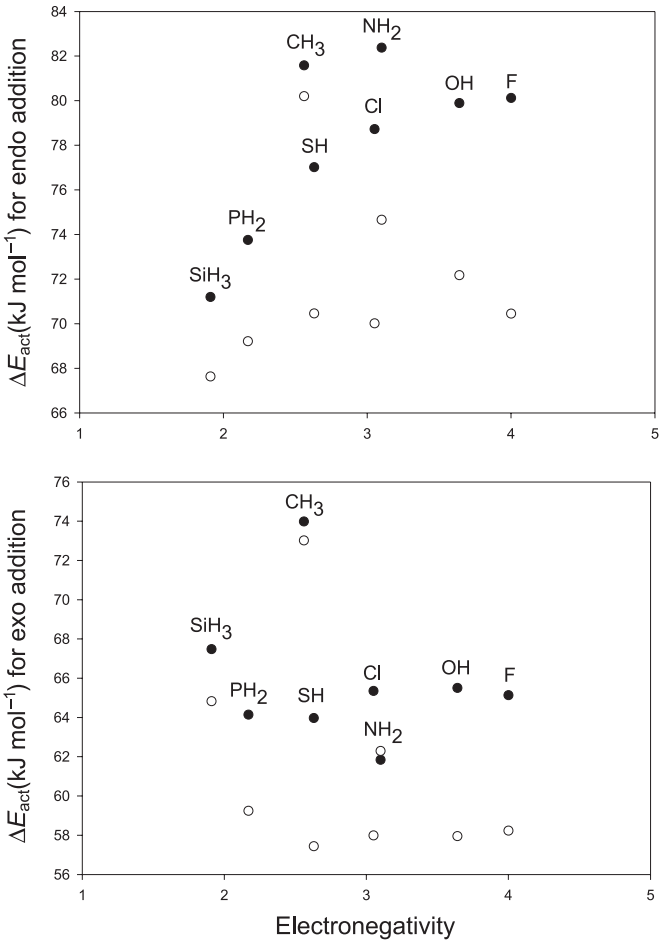
Table 3. A comparison of the calculated selectivities of 3-substituted cyclopropenes with butadiene (syn, endo and exo addition) with 3,3-disubstituted cyclopropenes with butadiene (endo and exo addition).

		3-Substituted cyclopropene		3,3-Disubstituted cyclopropene	
Substituent	$\Delta\Delta E^a$	Conf change from GS / mode of addition	GS ΔE_{conf}	Conf change from GS / mode of addition	GS ΔE_{conf}
SiH_3	0.9	Yes / endo	2.6	Yes / endo	1.1
PH_2	–0.4	No	0	No	0
H	0.0	No	0	No	0
CH_3	0.4	No	0	No	0
SH	0.0	No	0	Yes / endo, exo	1.4
Cl	1.4	No	0	No	0
NH_2	8.2	Yes / exo	2.2	Yes / exo	8.9
OH	0.2	Yes / exo	1.9	No	0
F	2.8	No	0	No	0

Note: All (Δ)ΔEs are in kJ mol^{-1}.
[a]Calculated as $\Delta E_{endo\text{-}exo}$(3-substituted, syn) – $\Delta E_{endo\text{-}exo}$(3,3-disubstituted).



computed ground-state energies, the energy cost of this conformational change (ΔE_{conf}) is estimated to be 2.2 kJ mol^{-1}. Likewise, we see a change in conformation for the 3,3-NH_2-cyclopropene from the **2D** conformation in the ground state to **2B** in the exo transition state. This involves a rotation of the NH_2 group syn to the butadiene, which becomes staggered in the exo transition-state structure much like the NH_2 group of the 3-NH_2-cyclopropene in its exo-syn structure. However, we see that there is no conformational change of the anti NH_2 substituent from the ground state to the exo transition state, and it is likely that this introduces steric interactions between the two NH_2 groups. The ΔE_{conf} for the ground-state 3,3-NH_2-cyclopropene is 8.9 kJ mol^{-1}; thus, the estimated energy cost for the change in conformation for the 3,3-NH_2-cyclopropene system is about 6.7 kJ mol^{-1} greater than for the 3-substituted case, which compares favourably with the $\Delta\Delta E$ of 8.2 kJ mol^{-1}. It is concluded that while the presence of the second substituent at the anti position generally has very little effect on the endo–exo selectivity (Fig. 4), a *change in conformation* of one or more substituents in the transition state can have a significant effect on the selectivity if the conformational changes introduce unfavourable steric interactions. In this case, the activation energy required for the exo addition of 3,3-NH_2-cyclopropene to butadiene increases because of the energy cost of conformational change, resulting in a smaller endo–exo selectivity.

The effect of disubstitution on activation energy

Figure 5 depicts the plots of activation energies (ΔE_{act}) of the endo and exo modes of addition vs. electronegativities for the 3-substituted (syn) and 3,3-disubstituted cyclopropene with butadiene Diels–Alder reactions. As shown, for both endo and exo addition, the 3,3-disubstituted system has activation energies that are consistently *lower* than for the 3-substituted system for all substituents examined, with the single exception of NH_2 exo addition, where the 3-NH_2-cyclopropene with butadiene activation energy is lower than that of the 3,3-disubstituted analog ($\Delta\Delta E_{act}$ is approximately 0.5 kJ mol^{-1}).

It has been previously established that the 3,3-disubstitution of the cyclopropene ground state yields an additional stabilization of the ring and therefore should be less reactive. In view of this, one would expect an increase in activation energy for the disubstituted system above that for

Fig. 5. Plots of ΔE_{act} for endo (top) and exo (bottom) addition (kJ mol^{-1}) vs. the electronegativity of the substituent at B3LYP/6-31++G(d). For each plot, the filled circles represent the ΔE_{act} for the 3-substituted cyclopropene – butadiene syn addition, and the open circles represent the ΔE_{act} for the 3,3-disubstituted cyclopropene – butadiene addition.

Scheme 4.

the 3-substituted case; however, we see that the opposite is true. This implies that there is a significant stabilization component in the transition-state structure of 3,3-disubstituted cyclopropene and butadiene that enables an overall decrease in the activation barrier for the reaction. In Scheme 2, the addition of the second substituent to the ground-state 3-substituted cyclopropene results in a total stabilization–destabilization that is composed of two effects: the anomeric effect and the overall effect on the cyclopropene ring itself (represented as ΔE^{XX}_{stab} (anom-ring)). Scheme 3*b* illustrates a similar isodesmic reaction using cyclopropane.

The 3-substituted and 3,3-disubstituted cyclopropanes have the same substituent conformations as the corresponding substituted cyclopropenes, with the exception of SiH_3; the 3,3-SiH_3-cyclopropene has a slightly skewed conformation whereas the 3,3-SiH_3-cyclopropane has an eclipsed conformation. The cyclopropane isodesmic reaction (cyclopropane closely resembling the molecule of interest, cyclopropene) is a measure of the anomeric effect only (ΔE_{anom}). Assuming that the anomeric effect is energetically similar in both 3,3-disubstituted cyclopropenes and cyclopropanes for the same substituent, the difference between these reactions represents the degree to which the ring is affected upon disubstitution (Scheme 4), represented as $\Delta\Delta E_{ring}$.

Table 1 contains the ground-state cyclopropene and cyclopropane energetic data. The ΔE_{anom} of Scheme 3*b* compares favourably with the calculated values of the anomeric effect in a system of similarly substituted methanes and thus has no effect on the ring itself. The anomeric effect is stabilizing for all substituents except Cl, which is slightly destabilizing. The values for $\Delta\Delta E_{ring}$ are intended to show the degree of stabilization–destabilization that occurs because of the changes in the ring upon 3,3-disubstitution; these values are supported by observing the *actual* geometric changes that occur in the ground state upon substitution. Many of the substituents yield small negative values for $\Delta\Delta E_{ring}$ and these correlate well with the degree of elongation that occurs in the C=C bond of the ground-state cyclopropene upon addition of the second substituent (Table 1). The CH_3 substituent has almost zero $\Delta\Delta E_{ring}$ and likewise exhibits virtually no change in C=C bond length; the SiH_3 group, however, is substantially destabilizing ($\Delta\Delta E_{ring}$ = 10.38 kJ mol^{-1}) and shows a shortening of the C=C bond. The actual amount of ring stabilization–destabilization, given by $\Delta\Delta E_{ring}$ that results from the 3,3-disubstitution of cyclopropene is significantly less than the stabilization–destabilization observed for the first substitution represented in Scheme 1. In other words, the 3-substituted cyclopropenes exhibit a large stabilization (destabilization for SiH_3) as compared to cyclopropene itself; this is evident in both the stabilization energies as well as the geometrical changes that occur in the ring (Table 1). While the ground-state 3,3-disubstituted cyclopropenes show greater stabilities overall (again, greater destabilization for SiH_3) as compared with the 3-substituted analogs, the majority of this stability is a consequence of the anomeric effect, not the ring stabilization–destabilization. In some cases, the ring effect upon 3,3-disubstitution is actually destabilizing ($\Delta\Delta E_{ring}$ is positive for SiH_3, CH_3, and OH).

The question to address now is, what produces the drop in activation energy for the 3,3-disubstituted system below that of the 3-substituted case? It is assumed that the anomeric effect in the ground-state cyclopropenes and the transition-state structures for the 3,3-disubstituted system remain constant during the reaction. The 3,3-disubstituted cyclopropene–butadiene transition state must be stabilized due to the substantial relief of ring strain as the cyclopropene ring becomes more like cyclopropane. Therefore, the remaining stabilization (after accounting for the anomeric effect) is mostly due to the relaxation of the ring. This further stabilization of the cyclopropene ring produces a drop in the transition-state energy and an overall lowering of the energy barrier.

As an example and because it deserves comment, the OH substituent has a $\Delta\Delta E_{ring}$ that is destabilizing ($\Delta\Delta E_{ring}$ = 11.81 kJ mol^{-1}). Disubstitution with OH has a huge stabilizing anomeric effect (Table 1, ΔE_{anom}), and although there is the expected shortening of the C—C single bonds of 3,3-OH-cyclopropene upon disubstitution, there is no change in the C=C bond length. Normally, the C=C bond would lengthen to relieve bond–bond repulsion that derives from the increased electron density in the C—C bonds. As a consequence, the 3,3-OH-cyclopropene is destabilized by a large ring strain, which is relieved in the transition-state structure and corresponds to a large drop in activation energy.[2]

Conclusions

We have shown in the present computational study that for the Diels–Alder reactions of 3,3-disubstituted cyclopropenes with butadiene:

- The analysis of the 3-substituted and 3,3-disubstituted cyclopropene ground states shows the important role that the second substituent plays in the stability and reactivity of the dienophile. The anomeric effect produces an increased stability upon disubstitution, the consequence of which can be seen in the geometry of the ring.
- For all substituents examined, the transition-state structures of 3,3-disubstituted cyclopropene with butadiene is shown to prefer the exo isomer.
- The comparison of selectivities ($\Delta E_{endo\text{-}exo}$) between the syn 3-substituted cyclopropenes with butadiene and the 3,3-disubstituted cyclopropenes with butadiene correlated well with each other, and conformational analysis can be used to explain the deviation of the NH_2 substituent. It is concluded that for this system, the presence of a substituent *other than H* at the syn position of the transition state will result in exo selectivity, irrespective of the

electron-withdrawing or electron-donating nature of the substituent.

- Interestingly, the activation energy barriers of the 3,3-disubstituted cyclopropene systems were lower than the syn 3-substituted cyclopropene systems, despite the expectant lower reactivity of the disubstituted analogs. Isodesmic reactions using ground-state cyclopropenes and cyclopropanes indicate that the anomeric effect accounts for the majority of the stabilization in the 3,3-disubstituted cyclopropenes, and only a small portion can be attributed to ring stabilization–destabilization.
- In summary, the effect of 3-substitution of an electron-withdrawing or -donating group on cyclopropene can be rationalized based on simple arguments; however, 3,3-disubstitution complicates matters considerably when investigating reactivity in the Diels–Alder reaction, and at times energetics and geometric changes need to be examined on a case-by-case basis.

Liquid-phase oxidation of benzene to phenol by copper catalysts in aqueous solvent with a high acetic acid concentration

Takahiro Kitamura, Hiroshi Kanzaki, Rei Hamada, Satoru Nishiyama, and Shigeru Tsuruya

Abstract: The liquid-phase catalytic oxidation of benzene was carried out under mild reaction conditions over Cu-impregnated zeolite catalysts (Cu/NaX, Cu/HX, Cu/NaY, Cu/HY, Cu/NaZSM-5, Cu/HZSM-5, Cu/Namordenite, Cu/Hmordenite, and Cu/Hbeta) using both molecular oxygen and ascorbic acid as the oxidant and the reducing reagents, respectively. Phenol was exclusively produced as the oxidation product and no other product was detected. Among the catalysts tested in this study, the Cu/HY catalyst had the highest activity for phenol formation. H-type zeolites were more effective supports for phenol formation than the corresponding Na-type ones. The yield of phenol was found to increase with the simultaneous increase in the amounts of both the supported Cu and the added ascorbic acid. The Cu species supported on HY began to elute as Cu^{2+} species in the solvent from the HY support with the initiation of the oxidation of benzene. The dissolved Cu^{2+} species were reduced to form precipitated Cu^{1+} species during the benzene oxidation. The homogeneous Cu species dissolved from the Cu/HY catalyst were thus suggested as mainly contributing to the phenol formation. The precipitated Cu^{1+} species that had no activity for the benzene oxidation were found to be regenerated in their oxidation activity toward phenol formation by calcination of the Cu^{1+} species in flowing air, although parts of the Cu species were found to be converted to aggregated CuO during the calcination.

Key words: supported copper catalysts, zeolite, oxidation, benzene, phenol, oxygen, ascorbic acid.

Résumé : On a effectué l'oxydation catalytique du benzène en phase liquide, dans des conditions douces, sur des catalyseurs de zéolite imprégnée de cuivre (Cu/NaX, C/HX, Cu/NaY, Cu/HY, Cu/NaZSM-5, Cu/HZSM-5, Cu/Namordenite, Cu/Hmordenite et Cu/Hbeta), en utilisant de l'oxygène moléculaire et de l'acide ascorbique respectivement comme agents oxydant et réducteur. Le seul produit d'oxydation est le phénol et aucun autre produit n'a été détecté. Parmi les catalyseurs évalués dans cette étude, le catalyseur Cu/HY présente l'activité la plus élevée pour la formation de phénol. Les zéolites du type H sont des supports plus efficaces que les supports correspondants de type Na pour la formation de phénol. On a observé que le rendement en phénol augmente avec une augmentation simultanée dans les quantités à la fois du Cu supporté et de l'acide ascorbique ajouté. Les entités de Cu supportées sur HY commencent à s'éluer du support HY vers le solvant, sous la forme de cations Cu^{2+}, dès le début de l'oxydation de benzène. Au cours de l'oxydation du benzène, les cations Cu^{2+} sont réduits en espèces Cu^{1+} qui précipitent. On suggère donc que les espèces Cu homogènes, dissoutes du catalyseur Cu/HY, sont les principales à contribuer à la formation du phénol. On a observé que, si on soumet les espèces Cu^{1+} qui ont précipité à une calcination avec circulation d'air, elles peuvent être partiellement régénérées dans leur activité oxydante conduisant à la formation de phénol, même si une certaine partie de ces entités est transformée en CuO agrégé au cours de cette calcination.

Mots clés : catalyseurs de cuivre supportés, zéolite, oxydation, benzène, phénol, oxygène, acide ascorbique.

Introduction

Phenol, one of the key chemicals that serve as a precursor for resins, synthetic fibers, agrochemicals, and dyestuffs, has been mostly produced using the cumene process developed by BP Chemicals and Hercules (1). This process consists of three steps in which each step is highly selective and produces acetone as a by-product, in addition to phenol. The production of phenol using the toluene process (2) that consisted of two steps and produced no acetone has been carried out at a few plants. One-step synthesis of phenol by a direct oxygenation of benzene must have an advantage in the sim-

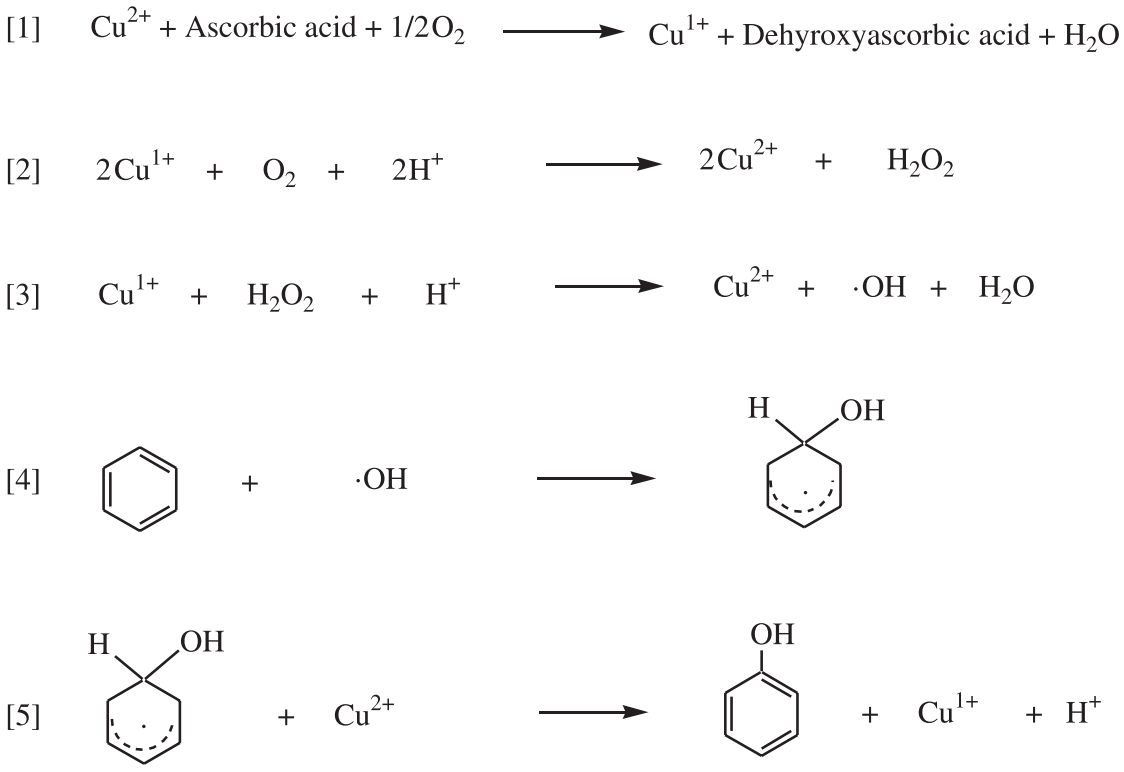
plicity of the process and the saving of production costs. From an organic synthetic chemical point of view, the direct insertion of an oxygen atom into the benzene ring is one of the most difficult and challenging steps among a variety of oxidation steps. The liquid-phase oxidation of benzene to phenol was reported using a ferric sulfate – hydrogen peroxide system (3) (Fenton reagent) and a Fe^{3+}–H_2O_2–catechol system (4) (Hamilton reagent). More recently, phenol syntheses from benzene utilizing the activation of molecular oxygen with various reducing reagents have been studied under relatively mild reaction conditions. The oxidation of benzene to phenol using a $Pt/V_2O_5/SiO_2$ (5) or $Pd/V_2O_5/SiO_2$ (6) catalyst in the presence of both O_2 and H_2, and using a $EuCl_3$-$TiO(acac)_2$ catalyst (7) in an aqueous acetic acid solvent in the presence of both O_2 and Zn^0 has been reported. The catalytic activities for hydroxylation of benzene in the presence of aq. H_2O_2 were examined using site-substituted vanadium(V) heteropolyacids (8). The oxidation of benzene to phenol at 130 °C using molecular oxygen was reported (9) in the presence of palladium and heteropolyacids, which is used as a promoter for the reoxidation of the palladium (the yield of phenol: 10.5%). Further, titanium silicalite (TS-1) was studied (10) as the catalyst for phenol production by the benzene oxidation under solvent-free, triphase conditions using aq. H_2O_2 as an oxidant. More recently, direct oxidation of benzene to phenol in sulfolane solvent at 100 °C with hydrogen peroxide was reported (11) using a titanium silicate catalyst modified with NH_4HF_2 and H_2O_2 (the yield of phenol: 8.1%). We have also attempted the liquid-phase oxidation of benzene to phenol using Cu ion-exchanged zeolites (12), Cu catalysts impregnated on some amorphous oxide supports (13), Cu catalysts supported on MCM-41 (14), Cu catalysts prepared by coprecipitation of both Cu and Al nitrates (15), and Cu catalysts supported on Al_2O_3 (16) in the presence of both O_2 and ascorbic acid. The vanadium catalysts supported on SiO_2 (17) (the yield of phenol: 4.1%) and Al_2O_3 (18) (the yield of phenol: 8.4%) have been reported to function as catalysts for the phenol formation in the presence of O_2 and ascorbic acid. An aqueous solution with high acetic acid concentration has been found to be an effective solvent for phenol formation, irrespective of the supported Cu (15, 16) (the yield of phenol: 3.0%) or V (18) catalysts. We have been interested in the liquid-phase oxidation of benzene to phenol using gaseous O_2 as an oxidant, rather than H_2O_2, because of its economical and safety point of views, although the yield of phenol using O_2, in place of H_2O_2, was rather low. The liquid-phase oxidation of benzene to phenol over supported Cu catalysts using molecular O_2 as an oxidant has hardly been reported, although the reports on the corresponding oxidation using H_2O_2 as an oxidant have been so far published.

In this study, the liquid-phase oxidation of benzene to phenol in an aqueous solvent with high acetic acid concentration was investigated using the Cu catalysts supported on zeolites, mainly HY zeolite. A variety of reaction conditions were attempted to promote the phenol production. The fate and the oxidation states of the Cu species supported on HY zeolite were followed during the oxidation of benzene to phenol to seek the cause of deactivation of the supported Cu catalysts in the initial stage of the benzene oxidation. Homogeneous Cu species that were dissolved in the solvent from the Cu-supported HY catalyst were suggested to be the main active Cu species for phenol formation.

Experimental

Catalysts



NaX (Tosoh, Si/Al = 1.25), NaY (Tosoh, Si/Al = 2.85), and mordenite (JRC-Z-M2O, Si/Al = 13) were used as supports after washing in water, drying at 393 K overnight, and calcining at 773 K for 5 h. NaZSM-5 was prepared according to a patent (19). The prepared ZSM-5 zeolite (Si/Al = 58) was treated twice with aq. 1 mol/L $NaNO_3$ solution at 353 K for 1 h, dried at 393 K overnight, and calcined at 773 K for 5 h in flowing air. HX, HY, H-mordenite, and HZSM-5 zeolites were prepared by treating the corresponding Na-zeolites three times with aq. 1 mol/L NH_4NO_3 solution at 343–353 K for 6 h, drying at 393 K overnight, and calcining at 773 K for 5 h in flowing air. HBeta support was used as received (JRC-Z-HB25, Si/Al = 16). The corresponding Cu-impregnated zeolites (Cu/zeolite) were prepared by the usual impregnation method using $Cu(CH_3COO)_2 \cdot H_2O$ (Nacalai, guaranteed reagent). The Cu/zeolite was dried at 393 K overnight and calcined at 773 K for 5 h in flowing air. In the case of the HY support, Cu ion-exchanged HY (Cu/HY) was also prepared by the usual ion-exchange method at 353 K for 2 h. The Cu/Y was dried at 393 K overnight and calcined at 773 K for 5 h in flowing air. The alkali metal-added Cu/HY catalysts were prepared by impregnating the alkali metal acetate on the Cu/HY, drying at 393 K overnight, and calcining at 773 K for 5 h. The Fe- and the Sn-added Cu/HY catalysts were prepared by impregnating $Fe(NO_3)_2 \cdot 9H_2O$ (Nacalai, guaranteed reagent) and $SnCl_2 \cdot 2H_2O$ (Nacalai, guaranteed reagent) on the Cu/HY, respectively, drying at 393 K overnight, and calcining at 773 K for 5 h in flowing air. The amounts of the various metals supported on the zeolites were determined using an atomic absorption spectrometer (Shimazu type AA-6200) after the catalyst was dissolved homogeneously by adding a few drops of hydrogen fluoride (Sterachemifer, guaranteed reagent 46%–48%).

Liquid-phase oxidation of benzene

All the reagents, except CuCl, were used as received without further purification. CuCl (Nacalai, guaranteed reagent) was treated with aqueous ascorbic acid and dried at 373 K for 3 h in flowing N_2. The liquid-phase oxidation of benzene was carried out using a 50 cm^3 flat-bottomed flask with a magnetic stirrer under the standard conditions of 20 cm^3 aqueous acetic acid solvent, 0.1 MPa O_2, a reaction temperature of 303 K, and a reaction time of 24 h. After removing the solid catalyst by centrifuging the reaction mixture mixed with 2-propanol as an internal standard, the reaction solution was analyzed at 463 K under a N_2 carrier (44 cm^3/min) using a gas chromatograph (Shimazu type GC-8A) with a 3 m stainless column packed with silicon OV-17. No 2-propanol was confirmed to be oxidized during the analytical treatment. The quantitative analyses of the amount of the "apparent" (see the Results and discussion section) Cu leaching were carried out by measuring the Cu amount dissolved in the filtrate using atomic absorption equipment after separating the solid catalyst from the reaction solution by centrifugation.

Scheme 1.

Instrumental analyses

The X-ray diffraction (XRD) patterns of both the fresh and the used Cu/HY catalysts were observed at room temperature using a Rigaku RINT 2000 XRD instrument with an X-ray source of Cu Kα. The used catalyst, before the XRD measurement, was separated from the reaction solution by centrifuging, washed with acetone, and dried at 393 K overnight or calcined at 773 K for 5 h in flowing air.

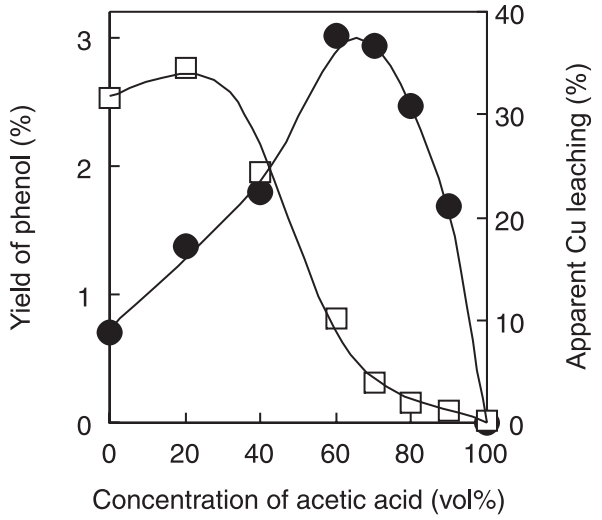
UV–vis ray absorption spectra of the Cu species in the solution were measured in an air atmosphere using a Shimazu UV-240 spectrophotometer.

Diffuse reflectance (DR) spectra of the fresh, the used, and the reduced Cu/HY catalysts were measured at room temperature using a Hitachi type U-3210 spectrophotometer equipped with an integral sphere. The obtained data were transformed to the corresponding Kubelka–Munk (K-M) function using an applied program. Before the DR measurement, the used catalyst was washed several times with acetone and dried at 393 K overnight or calcined at 773 K for 5 h. The reduced catalyst was prepared by treating the Cu/HY catalyst with 100 torr H_2 (1 torr = 133.322 4 Pa) at 573 K for 1 h followed by degassing at the same temperature for 30 min.

The fluorescence spectra of the fresh, the used, and the reduced Cu/HY catalyst were measured at room temperature using a Nihon Bunkoh type FP-750 spectrophotometer with an excitation energy source of 267.0 nm. All the catalysts were treated in the same manner as those in the DR measurement.

The electron spin resonance (ESR) spectra of the catalysts were measured at room temperature using a JEOL type JES-TE-300 instrument. The fresh catalyst was degassed at 473 K for 2 h before the ESR measurement. The used catalysts, which were centrifuged from the reaction solution and washed with acetone several times and dried at 393 K overnight or calcined at 773 K for 5 h in flowing air, were also degassed at 473 K for 2 h before the ESR measurement.

Results and discussion



Liquid-phase oxidation of benzene to phenol with supported Cu catalysts

No other product except phenol was detected using the Cu catalysts supported on various zeolites under the reaction conditions (thus, the selectivity toward phenol is 100%). A plausible catalytic scheme of the phenol formation over the Cu catalysts supported on zeolites using both oxygen and ascorbic acid as an oxidant and a reducing reagent, respectively, will be substantially similar to the previously proposed one (Scheme 1) (3, 15). The proposed scheme includes H_2O_2 as an intermediate, although the catalysts deactivate at the initial stage of the benzene oxidation because of the irreversible reduction of the Cu^{2+} species to Cu^{1+} ones, as discussed afterward.

The amount of Cu dissolved from the Cu/HY catalyst during the benzene oxidation was obtained by measuring the Cu amount dissolved in the filtrate of the reaction solution after separating the solid catalyst by centrifugation. However, some of the dissolved Cu species are considered to become insoluble Cu^{1+} species during the benzene oxidation (14, 15). We observed Cu^{1+} species on the recovered Cu/HY catalyst as described in the redox behavior of the Cu species of the Cu/HY catalyst during benzene oxidation section. Thus, the solid catalyst separated by centrifugation seems to con-

Fig. 1. Dependence of both the yield of phenol and the percentage of apparent Cu leaching on the volumetric concentration of acetic acid. Catalyst (0.4 g of Cu(2)/HY, Cu amount (2 wt%)), benzene (22.5 mmol), reducing reagent (4 mmol of ascorbic acid), solvent (20 cm^3 of aqueous acetic acid), 0.1 MPa of O_2, reaction temperature (303 K), reaction time (24 h), yield of phenol (●), percentage of apparent Cu leaching (□).

tain the insoluble Cu^{1+} species originated from the Cu (possibly Cu^{2+} species) species leached from the Cu/HY catalyst. Owing to these quite complex situations of the Cu species in the measurement of dissolved Cu species, the amount of leached Cu measured will underestimate the amount actually leached from the Cu/HY catalyst. This is the reason why the term apparent was used in both the amount and the percentage of the leached Cu thereinafter.

The dependence of both the yield of phenol and the percentage of apparent Cu leaching on the concentration of acetic acid using the Cu(2)/HY (Cu amount, 2 wt%) catalyst are illustrated in Fig. 1. The yield of phenol obtained over the Cu/HY catalyst was comparable to the one over the Cu catalyst supported on Al_2O_3 (15). The yield of phenol, being 0.7% in H_2O solvent, increased with the increase in the amount of acetic acid and had a maximum value at an acetic acid concentration of around 60 vol%. A further increase in the volumetric concentration of acetic acid caused a sharp decline in the yield of phenol, and no phenol was obtained in pure acetic acid. If the medium is too acidic, reduction of Cu^{2+} to Cu^{1+} will be difficult (20). The Cu^{1+} ions are necessary for the formation of H_2O_2 that is used in the phenol formation (15). The high yield of phenol in the aqueous solvent with the higher acetic acid concentration was due to the fact that H_2O_2 has been reported (21) to be stable in acid media. The maximum yield of phenol at the acetic acid concentration of around 60 vol% is thought to be due to the trade-off between the easiness of the reduction of Cu^{2+} species and both the effective production and the stability of the produced H_2O_2, which is crucial for phenol formation. Similar results were obtained using other supported Cu (15) and V (17, 18) catalysts.

The percentage of the apparent Cu leaching was significantly inhibited with increasing acetic acid volumetric concentration and fell to less than 2% at an acetic acid concentration of more than 80 vol% (Fig. 1). Hereafter, aqueous 80 vol% acetic acid solvent was used because of both the low apparent Cu leaching and the comparatively high yield of phenol.

Table 1. Effect of zeolite support on both the yield of phenol and the apparent Cu leaching.[a]

Catalyst	Phenol yield (%)	Apparent Cu leaching (%)
Cu/NaX	2.0	6.5
Cu/HX	2.3	1.5
Cu/NaY	2.2	0.5
Cu/HY	2.5	2.0
Cu/NaZSM-5	1.5	0.1
Cu/HZSM-5	1.7	0.1
Cu/Namordenite	0.8	Trace
Cu/Hmordenite	0.9	0.4
Cu/Hbeta	1.8	0.3

[a]Cu content (2 wt% (0.31 mmol/g-cat)), catalyst (0.4 g), benzene (22.5 mmol), solvent (20 cm^3 of aqueous solution containing 80 vol% acetic acid), reducing reagent (4 mmol ascorbic acid), oxidant (0.1 MPa O_2), reaction temperature (303 K), reaction time (24 h).

The effect of the zeolite support on the yield of phenol and the apparent Cu leaching was investigated as summarized in Table 1. H-type zeolite had a higher yield of phenol than the Na-type zeolite in comparison with the same structural zeolites, though the Cu species supported on the H-type zeolite tended to leach more easily. Hereafter, the liquid-phase oxidation of benzene using the Cu/HY catalyst in aqueous solvent containing 80 vol% acetic acid was investigated in detail.

Some reducing reagents, $SnCl_2 \cdot H_2O$, Zn powder, $Zn(CH_3COO)_2$, Na_2SO_3, sodium thiosulfate, hydroquinone, and pyrocatechol, were tried in the place of ascorbic acid (0.4 g of Cu/HY (Cu, 2 wt%), benzene (22.5 mmol), 20 mL of aqueous acetic acid (80 vol%) solvent, reducing reagent (4 mmol), 0.1 MPa of O_2, reaction temperature (303 K), reaction time (24 h)). However, all these reagents have no activity for phenol formation, except $SnCl_2 \cdot H_2O$, the use of which as a reducing reagent produced a low yield of phenol (0.4%). Alkali metal, Fe, or Sn added to the Cu/HY (Cu, 2 wt%; added metal/Cu atomic ratio = 2) catalyst hardly promoted the catalytic activity for the phenol formation using ascorbic acid as a reducing reagent.

The dependence of the yield of phenol on the amount of impregnated Cu using 0.4 g of the Cu/HY catalyst is illustrated in Fig. 2. The yield of phenol obtained using the Cu ion-exchanged HY catalyst (Cu-HY) is also shown in Fig. 2. The yield of phenol had a maximum value at the amount of supported Cu of around 2.5 wt% (Cu, around 0.19 mmol), irrespective of the supported method of Cu, though the yield of phenol catalyzed by the Cu-HY considerably decreased at a higher amount of supported Cu. The dependence of the yield of phenol on the amount of the Cu(2)/HY catalyst was investigated (Fig. 3). The yield of phenol had a maximum value at an amount of the Cu(2)/HY catalyst of around 0.6 g, of which Cu corresponds to 0.19 mmol. All the results of Figs. 1–3 were obtained under the condition of a constant amount of ascorbic acid. The dependence of the amount of ascorbic acid on the phenol yield using a 0.4 g Cu(2)/HY catalyst is illustrated in Fig. 4. The yield of phenol increased

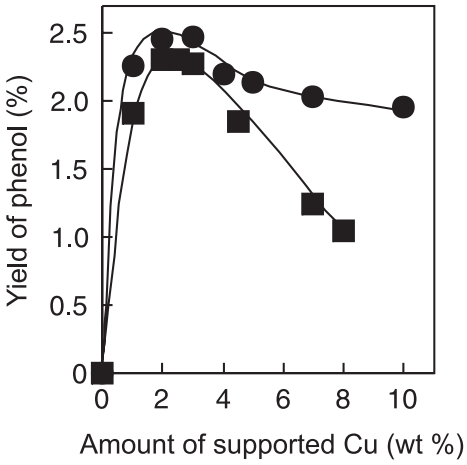
Fig. 2. Dependence of the yield of phenol on the amount of supported Cu. Benzene (22.5 mmol), reducing reagent (4 mmol of ascorbic acid), solvent (20 cm^3 of aqueous acetic acid), 0.1 MPa of O_2, reaction temperature (303 K), reaction time (24 h), 0.4 g of Cu/HY (impregnated Cu) catalyst (●), 0.4 g of Cu-HY (ion-exchanged Cu) catalyst (■).



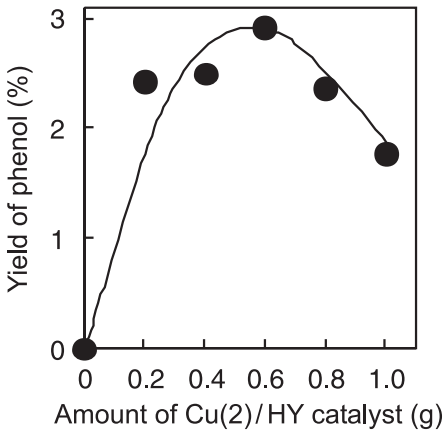


Fig. 3. Dependence of the yield of phenol on the amount of Cu(2)/HY catalyst. Benzene (22.5 mmol), reducing reagent (4 mmol of ascorbic acid), solvent (20 cm^3 of aqueous acetic acid), 0.1 MPa of O_2, reaction temperature (303 K), reaction time (24 h).

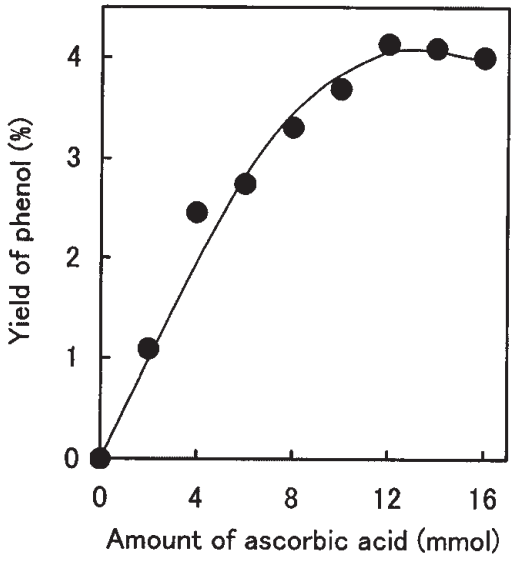
with the increase in the amount of ascorbic acid and passed through a maximum. A further increase in ascorbic acid tended to cause a decrease in the yield of phenol. The H_2O_2 produced during the oxidation, which is necessary for phenol formation, may be consumed by excess ascorbic acid. The dependence of the yield of phenol on the amount of supported Cu under the condition of constant supported Cu/ascorbic acid ratios is illustrated in Fig. 5. The yield of phenol increased almost linearly with the amount of supported Cu at a constant ascorbic acid/Cu ratio.

Contribution of the leached Cu species to phenol formation

The relationships between both the phenol yield and the percentage of apparent Cu leaching, and the reaction time were investigated using the Cu(2)/HY catalyst (Fig. 6). The yield of phenol sharply increased up to an initial reaction

Fig. 4. Dependence of the yield of phenol on the amount of ascorbic acid. Catalyst (0.4 g of Cu(2)/HY), benzene (22.5 mmol), reducing reagent (4 mmol of ascorbic acid), solvent (20 cm^3 of aqueous acetic acid), 0.1 MPa of O_2, reaction temperature (303 K), reaction time (24 h).



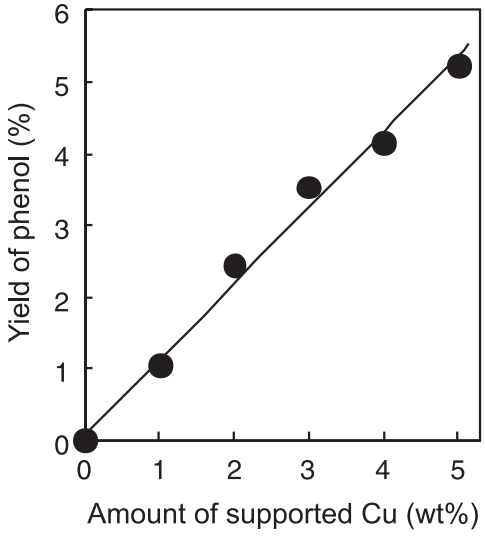


Fig. 5. Dependence of the yield of phenol on the amount of impregnated Cu at constant impregnated Cu/ascorbic acid ratios. Catalyst (0.4 g of Cu(2)/HY), benzene (22.5 mmol), solvent (20 cm^3 of aqueous acetic acid), 0.1 MPa of O_2, reaction temperature (303 K), reaction time (24 h).

time of around 5 h followed by an almost leveling off of the phenol production. The percentage of the apparent Cu leaching abruptly increased up to a reaction time of around 5 h followed by a significant decline in the apparent Cu leaching and the retention of a low percentage of Cu leaching. This observation will be interpreted as follows: the Cu species are eluted from the Cu/HY catalyst in the initial stage of the reaction, and afterward the eluted Cu species are rapidly precipitated followed by an apparently low percentage of Cu leaching (apparent Cu leaching). The combined results between the yield of phenol and the apparent Cu leaching in

Fig. 6. Dependence of both the yield of phenol and the percentage of the apparent Cu leaching on the reaction time. Catalyst (0.4 g of Cu(2)/HY, Cu amount, 2 wt%)), benzene (22.5 mmol), reducing reagent (4 mmol of ascorbic acid), solvent (20 cm^3 of aqueous acetic acid), 0.1 MPa of O_2, reaction temperature (303 K), reaction time (24 h), yield of phenol (●), percentage of apparent Cu leaching (□).

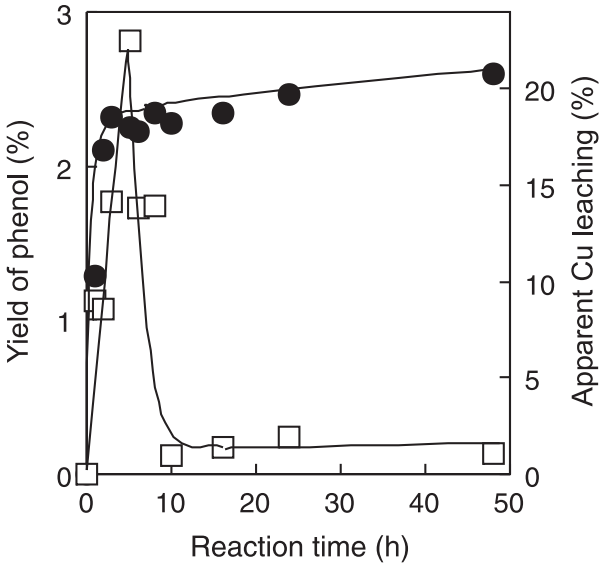

Fig. 6 suggest that the Cu species leached into the reaction solution in the initial stage are responsible for the phenol formation and are rapidly deactivated to form an insoluble Cu species during the oxidation of benzene to phenol. Thus, the soluble Cu species will be the main active species for phenol formation. To confirm the behavior of the Cu species during the reaction, the oxidation of benzene was attempted using unsupported $Cu(CH_3COO)_2{\cdot}H_2O$, instead of the Cu(2)/HY catalyst (Fig. 7). The concentration of soluble Cu species decreased rapidly with the reaction time, together with a sharp increase in the yield of phenol in the initial stage of the benzene oxidation. To investigate the activity of the Cu species supported on the zeolite for phenol formation, rather than the eluted Cu species, the time dependence of both the yield of phenol and the apparent Cu leaching were observed using the Cu(2)/NaM catalyst, of which the apparent Cu leaching was very low (Fig. 8). The yield of phenol sharply increased in the initial stage and almost leveled off after a reaction time of around 5 h similar to that demonstrated in Figs. 6 and 7. However, the percentage of the apparent Cu leaching remained very low irrespective of the reaction time. Thus, the amount of phenol detected (Fig. 8) will be mainly formed by the Cu species supported on the NaM zeolite, rather than by the eluted Cu species. The Cu species supported on a zeolite were also found to be active for the phenol formation, though the intrinsic activity of the supported Cu species is lower than that of the eluted Cu species.

Deactivation and regeneration of the Cu/HY catalyst in benzene oxidation

As evidenced from the dependence of the yield of phenol on the reaction time illustrated in Figs. 6–8, the Cu/HY catalyst (including the eluted Cu species) was quickly deactivated in the initial stage of the benzene oxidation. Both the supported and the eluted Cu species may be irreversibly reduced to the Cu^{1+} species accompanying the formation of phenol in the initial stage, of which the reduced Cu^{1+} species are precipitated and cause the low apparent Cu leaching as illustrated in Fig. 6. To attempt regeneration of the used Cu/HY catalyst, the catalyst was retrieved by centrifugation from the reaction solution after a reaction time of 24 h, washed with acetone, and dried at 393 K overnight. The used catalyst calcined at 773 K for 5 h after drying was also

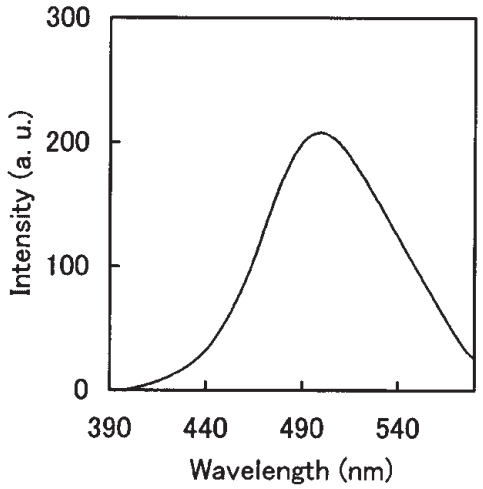
Table 2. Benzene oxidation to phenol using the used Cu/HY catalysts.[a]

Catalyst	Phenol yield (%)
Fresh Cu/HY[b]	2.5
Used Cu/HY (without calcination)[c]	1.1
Used Cu/HY (with calcination)[d]	2.3

[a]Benzene (22.5 mmol), solvent (20 cm^3 of aqueous 80 vol% acetic acid), ascorbic acid (4 mmol), O_2 (0.1 MPa), reaction time (303 K), reaction time (24 h).
[b]Catalyst (0.4 g of Cu(2)/HY).
[c]Only dried at 303 K overnight.
[d]Calcined at 773 K for 5 h in flowing air.

Fig. 9. DR spectra of the fresh Cu/HY catalyst and both the recovered counterparts with and without calcination. (*a*) Fresh Cu(2)/HY catalyst (○); (*b*) recovered catalyst without calcination (□); (*c*) recovered catalyst calcined at 773 K for 1 h in flowing air (△).



tried as the catalyst for the benzene oxidation (Table 2). The yield of phenol with the used catalyst being treated only by drying was significantly lower than that with the fresh one. On the other hand, the used Cu/HY calcined at 773 K for 5 h after the recovery was found to have an activity for phenol formation almost similar to that of the fresh one. The inactive reduced Cu species is thought to be thoroughly oxidized by the calcinations to reform the active Cu species for the phenol formation.

Redox behavior of the Cu species of the Cu/HY catalyst during benzene oxidation

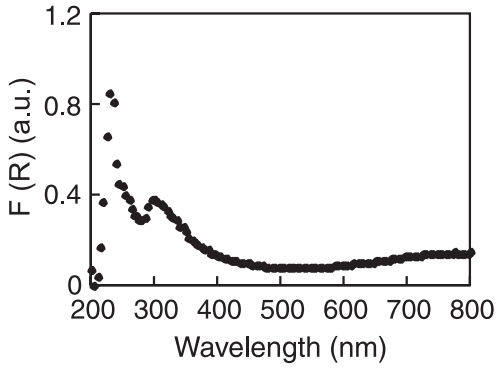
The DR spectra of the fresh catalyst showed a broad band at around 800 nm that is due to a *d–d* transition of an octahedral Cu^{2+} and a band appeared at around 230 nm, which will be identified (20) as one based on the charge transfer from the zeolite framework O species to Cu^{2+} (Fig. 9*a*). The recovered catalyst without calcination (Fig. 9*b*) showed a new band at around 305 nm, in addition to the bands of 220–240 nm and around 800 nm. The corresponding catalyst with calcination (Fig. 9*c*) showed a very broad absorption in the visible region in addition to the peak at around 230 nm (22). The presence of CuO was reported (23) to show the DR absorption over the visible region. A DR band at around 305 nm observed in the recovered catalysts without calcination disappeared during calcination. To clarify the identification of the DR band at around 305 nm of the recovered catalyst without calcination, the fluorescence emission spectrum of the fresh Cu(2)/HY catalyst reduced at 573 K for 1 h in H_2 was measured (Fig. 10). H_2 treatment of Cu ion-exchanged Y (Cu-Y) zeolite at 573 K was reported (24) to produce Cu^{1+}. A broad band was observed at around 500 nm as illustrated in Fig. 10. It was reported (25) that the bands based on the Cu^{1+} of the H_2-reduced Cu-Y zeolites with the Cu ion-exchanged percentage of 2% and 60% were observed at around 480 and 523 nm, and that the fluorescence band based on the Cu^{1+} shifted to a longer wavelength with an increase in the percentage of the Cu ion exchange of the reduced Cu-Y zeolite. Because the present Cu(2)/HY (Cu, 2 wt%) catalyst corresponds to the percentage of Cu ion-exchange of about 18%, it will be reasonable that the fluorescence band observed at around 500 nm is identified to be Cu^{1+}. Accordingly, a band at around 300 nm appearing in the DR spectrum of the H_2-reduced Cu(2)/HY catalyst is due to reduced Cu^{1+} (Fig. 11). From these results, the DR band at 305 nm of the recovered Cu/HY catalyst without calcination was confirmed to be due to Cu^{1+}.

Fig. 10. Fluorescence emission spectrum of the reduced Cu/HY catalyst. Cu(2)/HY catalyst reduced at 573 K for 1 h in flowing H_2.

The ESR spectrum of the fresh Cu(2)/HY catalyst (Fig. 12*a*) is similar to one in which the Cu^{2+} species are mainly aggregated and undergo Cu^{2+} spin-spin interaction with each other (26). The ESR intensity of the recovered catalyst not precalcined was lower than the unused catalyst and a new sharp peak appeared at the position of a *g* value of around 2 (Fig. 12*b*). The calcination of the recovered catalyst caused the disappearance of the sharp ESR peak at g = ca. 2.0 (Fig. 12*c*), together with the reappearance of the broad peak based on aggregated Cu^{2+}. However, the intensity of the ESR peak based on aggregated Cu^{2+} was much smaller than that (Fig. 12*a*) of the fresh Cu/HY catalyst. This can be interpreted in that the calcination of the recovered catalyst produced CuO, which is apparently undetectable by ESR, in agreement with the results of the very broad DR spectrum in the visible region of the corresponding catalyst (Fig. 9*c*). The ESR peak at g = ca. 2.0 appearing in the ESR spectrum of the recovered catalyst without calcination almost completely disappeared on calcining of the recovered

© 2004 NRC Canada

Fig. 11. DR spectrum of the reduced Cu/HY catalyst. Cu(2)/HY catalyst reduced at 573 K for 1 h in flowing H_2.



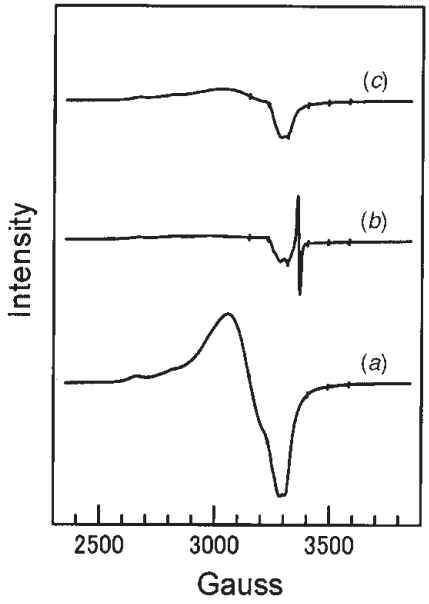


Fig. 12. ESR spectra of the fresh Cu/HY catalyst and both the recovered counterparts with and without calcination. Mn^{2+} used as a g-marker. (*a*) Fresh Cu(2)/HY catalyst; (*b*) recovered catalyst without calcination; (*c*) recovered catalyst calcined at 773 K for 1 h in flowing air.

catalyst (Fig. 12*b* → Fig. 12*c*). This result suggests that the sharp ESR peak at g = ca. 2.0 (Fig. 12*b*) might be due to organic radical(s) and (or) carbonaceous radical(s), though we have no idea of the definite structure.

Based on the obtained DR and ESR spectral data, Cu^{2+} species on the Cu/HY catalyst are dissolved into the reaction solution and reduced to Cu^{1+} species during the benzene oxidation. The almost insoluble Cu^{1+} species are collected together with the Cu/HY catalyst through centrifugation to form the recovered Cu/HY catalyst. The Cu^{1+} species in the recovered catalyst is reoxidized to the Cu^{2+} species and in part, CuO, because of the disappearance of the DR band based on Cu^{1+} and the appearance of the very broad absorption over visible region based on CuO by calcination of the recovered Cu/HY catalyst. We are currently investigating the identity of the insoluble Cu^{1+} species formed during the benzene oxidation to phenol.

Conclusions

The liquid-phase catalytic oxidation of benzene to phenol with Cu catalysts supported on zeolites was attempted using gaseous oxygen as an oxidant and ascorbic acid as a reducing reagent. Only phenol was selectively obtained. The usage of an aqueous solvent containing a high acetic acid concentration of around 80 vol% caused both enhancement of the yield of phenol and inhibition of apparent Cu leaching from the Cu/HY catalyst. The simultaneous increase in both the amount of Cu and the concentration of ascorbic acid caused an increase in the yield of phenol. Both the yield of phenol and the percentage of the apparent Cu leaching of the Cu species impregnated on HY (Cu/HY) had a correlation during the initial stage of the benzene oxidation. The eluted Cu species was thought to be the main active species for the phenol formation. The irreversible reduction of the Cu^{2+} species to Cu^{1+} ones was suggested as causing the deactivation of the catalyst for the benzene oxidation to phenol. The calcination of the recovered Cu catalyst caused the regeneration of the catalyst for phenol formation.

Multinuclear magnetic resonance studies of the aqueous products of the complexes *cis*- and *trans*-Pt(amine)$_2$(NO$_3$)$_2$

Fernande D. Rochon and Viorel Buculei

Abstract: The hydrolyis or the aquation reactions of the compounds *cis*- and *trans*-Pt(amine)$_2$(NO$_3$)$_2$ were studied in D$_2$O in different conditions of pH. The products were characterized by multinuclear (^{195}Pt, ^{13}C, and ^{1}H) magnetic resonance spectroscopy. In acidic medium, the product was [Pt(amine)$_2$(D$_2$O$_2$)]$^{2+}$ and for a few amines, *trans*-[Pt(amine)$_2$(D$_2$O)(NO$_3$)]$^{+}$ was detected. The ^{195}Pt NMR resonances of the diaqua complexes were observed at higher fields for the cis compounds (avg. –1727 ppm) than for the trans isomers (avg. –1560 ppm). At basic pH, Pt(amine)$_2$(OD)$_2$ was formed and for ethylamine, *trans*-Pt(EtNH$_2$)$_2$(OD)(NO$_3$) was detected. The cis compounds were also observed at higher fields than the trans isomers (–1706 ppm vs. –1574 ppm). The coupling constants with ^{195}Pt were geometry dependent. The avg. ^{2}J(^{195}Pt-^{1}H) values for the diaqua species were 66 (cis) and 57 (trans) Hz, while the avg. ^{3}J(^{195}Pt-^{1}H) were 43 (cis) and 34 (trans) Hz for the diaqua compounds, and 43 and 37 Hz, respectively, for the dihydroxo species. The ^{2}J(^{195}Pt-^{13}C) avg. values were 18 (cis) and 12 (trans) Hz and the avg. ^{3}J(^{195}Pt-^{13}C) were 31 (cis) and 23 (trans) Hz for both the diaqua and dihydroxo compounds. For the cis isomers, at neutral pH, the monoaqua–monohydroxo species (avg. –1721 ppm) and the dihydroxo-bridged dimer (avg. –1353 ppm) were observed. For a few amines, the monohydroxo-bridged dimer was observed (avg. –1684 ppm) and its concentration increased with time. For the trans compounds, the monoaqua–monohydroxo species was observed at –1563 ppm (avg.). For a few amines, the hydroxo-bridged dimer was present. For methylamine, a third species assigned to a higher oligomer was observed after 6 months.

Key words: platinum, amine, nitrato, hydrolysis, NMR, aquation.

Résumé : Les réactions d'hydrolyse ou d'aquation des composés *cis*- et *trans*-Pt(amine)$_2$(NO$_3$)$_2$ ont été étudiées dans D$_2$O à plusieurs pH. Les produits ont été caractérisés par résonance magnétique multinucléaire (^{195}Pt, ^{13}C et ^{1}H). En milieu acide, le produit est [Pt(amine)$_2$(D$_2$O)$_2$]$^{2+}$ et pour quelques amines, *trans*- [Pt(amine)$_2$(D$_2$O)(NO$_3$)]$^{+}$ a été détecté. En RMN du ^{195}Pt, les résonances des composés diaqua ont été observées à champ plus élevé pour les composés cis (moy. –1727 ppm) que pour les isomères trans (moy. –1560 ppm). En milieu basique, Pt(amine)$_2$(OD)$_2$ se forme et *trans*-Pt(amine)$_2$(OD)(NO$_3$) a été détecté pour éthylamine. Les composés cis ont aussi été observés à plus haut champ que les analogues trans (–1706 ppm vs. –1574 ppm). Les constantes de couplage dépendent de la géométrie du complexe. Les valeurs moyennes ^{2}J(^{195}Pt-^{1}H) pour les espèces diaqua sont 66 (cis) et 57 (trans) Hz, tandis que celles de ^{3}J(^{195}Pt-^{1}H) sont 43 (cis) et 34 (trans) Hz pour les composés diaqua et 43 et 37 Hz pour les espèces dihydroxo. Les valeurs moyennes ^{2}J(^{195}Pt-^{13}C) sont 18 (cis) and 12 (trans) Hz tandis que les ^{3}J(^{195}Pt-^{13}C) sont 31 (cis) et 23 (trans) Hz pour les complexes diaqua et dihydroxo. Pour les isomères *cis* en milieu neutre, les espèces monoaqua–monohydroxo (moy. –1721 ppm) et les dimères à double ponts hydroxo (moy. –1353 ppm) ont été caractérisés. Pour quelques amines, le dimère à simple pont hydroxo a été observé (moy. –1684 ppm) et sa concentration augmente avec le temps. Pour les composés trans, l'espèce monoaqua–monohydroxo a été observé à –1563 ppm (moy.). Pour quelques amines, le dimère à pont hydroxo est présent. Pour méthylamine, une troisième espèce attribuée à un plus grand oligomère a été observée après 6 mois.

Introduction

The antitumor properties of diamine Pt(II) compounds have been known for a few decades. The drug *cisplatin* (*cis*-Pt(NH$_3$)$_2$Cl$_2$) is still the most widely used in chemotherapy. A good review of the influence of the structure on the activity of Pt drugs has been published (1). The drug remains mainly unchanged in the plasma because of the presence of a large chloride concentration (103 mmol L^{-1}) and can cross the cell membrane because of its neutrality. Inside the cells, the chloride ion concentration is much lower (4 mmol L^{-1}) and in these conditions, *cis*-Pt(NH$_3$)$_2$Cl$_2$ can produce differ-

ent ionic species. Its mechanism of action seems extremely complex (2, 3) and involves aquation or hydrolysis reactions, which have been studied in a few laboratories. One of the ionic species is the aqua-chloro complex *cis*-$[Pt(NH_3)_2(OH_2)Cl]Cl$, which can either bind to DNA (4) leading to the eventual destruction of the cell, or react with water to produce the diaqua species. At neutral pH, the latter compound will exist mainly in the form of the monoaqua–monohydroxo complex (4–7) *cis*-$[Pt(NH_3)_2(OH)(OH_2)]^+$, which can also bind to DNA (4). It has also been shown in laboratories to produce different oligomeric species, which have been characterized by ^{195}Pt NMR (8) and by crystallographic methods (9, 10). Some of these compounds are toxic to humans and could be partially responsible for the toxicity of cisplatin (11). It is, therefore, very important to study the aquation and hydrolysis reactions of a complex prior to its development as an antitumor drug.

It has been observed that when NH_3 is replaced by primary amines, the antitumor properties can increase, especially with cyclic amines (12, 13), but the latter compounds have often a more limited activity spectrum. Furthermore, several very active compounds are too insoluble to become useful anticancer drugs (14). In the amine system, the most active compounds usually have the cis geometry, although a few trans compounds have been shown to possess some antitumor properties. Our research group has recently undertaken a systematic study on complexes of the types *cis*- and *trans*-$Pt(amine)_2I_2$ with 10 different amines (15). We have transformed these complexes into *cis*- and *trans*-$Pt(amine)_2(NO_3)_2$, which have also been studied in the solid state by IR and in solution in acetone by ^{195}Pt, ^{1}H, and ^{13}C NMR spectroscopy (16). The results have shown that all these compounds were pure except for $Pt(Et_2NH)_2X_2$, which was a mixture of the cis and trans isomers. Conductivity measurements in acetone have shown that the dinitrato complexes are not dissociated. We have characterized these dinitrato complexes to subsequently study their aquation and hydrolysis reactions. The solubility of the dichloro and the diiodo complexes in water is very low, but substitution of the halides by nitrato ligands leads to a greater aqueous solubility. We have now completed our NMR study on the cis and trans dinitrato compounds and the results are reported in this paper. We have studied the aqueous reactions at three different conditions of pH (acidic, neutral, and basic). Although a few studies in the literature were made on cis compounds (8, 17–23) (especially *cis*-$Pt(NH_3)_2Cl_2$), only one study has been reported on a trans compound, namely on *trans*-$Pt(NH_3)_2Cl_2$ (24). A tentative preliminary study has also been reported (22) on *trans*-$Pt(Ypy)_2(NO_3)_2$ where Ypy = pyridine derivative.

Experimental

$K_2[PtCl_4]$ was purchased from Johnson–Matthey and was recrystallized in water before use. The amines were bought from Aldrich, while silver nitrate was purchased from Analar. D_2O was obtained from CDN Isotopes.

The NMR spectra were measured on a Varian Gemini 300BB in D_2O. The fields were 300.070, 75.460, and 64.395 MHz for ^{1}H, ^{13}C, and ^{195}Pt, respectively. For the ^{195}Pt NMR spectra, $K_2[PtCl_4]$ (–1628 ppm in D_2O with KCl) was the external standard. The pH values were measured on a Fisher Scientific Accumet-15 pH meter, using a combined electrode Ag/AgCl (Fisher Scientific) at room temperature. For the pD values, the pH values were increased by 0.4 (25).

The NaOD solution was prepared by dissolving NaOH in D_2O to make a 0.4 mol L^{-1} solution. The complexes *cis*- and *trans*-$Pt(amine)_2(NO_3)_2$ were prepared and characterized as reported in our recent publication (16). The aquation or hydrolysis of the dinitrato complexes were studied in three different conditions of pH. The dinitrato complexes (12–15 mg) were dissolved in 1 mL of D_2O with slight heating (40°–45°). The concentration of the solution was about 0.03 mol L^{-1} and the pH was acidic (2.0–2.4 or pD = 2.4–2.8). The ^{195}Pt, ^{1}H, and ^{13}C NMR were measured directly on these fresh D_2O solutions. The pD of another fresh solution was adjusted to about 7 with NaOD and the NMR spectra were measured immediately. The pD of a third fresh D_2O solution of the dinitrato complex was adjusted between 9.9 and 10.4 just before recording the NMR spectra. In a typical experiment, the dinitrato compound was dissolved in D_2O with heating in a hot water bath. For the products in acidic and basic pH, the ^{195}Pt NMR spectrum was measured immediately during about 1–3 h, the ^{1}H spectrum was then recorded for 30–60 min, and the ^{13}C spectrum was measured overnight (~15 h). At neutral pH, where the number of species in solution is usually greater, the accumulation time was 2 to 3 times longer. A few NMR tubes were left standing at about 4° and the ^{195}Pt NMR spectra were later remeasured to see the evolution of the different species with time.

Results and discussion

The dinitrato complexes were prepared by the reaction (in the dark around 5 °C) of the diiodo complexes with a slight excess (10%) of silver nitrate in acetone, as recently described (16).

$$Pt(amine)_2I_2 + 2Ag(NO_3) \rightarrow Pt(amine)_2(NO_3)_2 + 2AgI\downarrow$$

Compounds (cis and trans) with amine = methylamine ($MeNH_2$), ethylamine ($EtNH_2$), *n*-propylamine (*n*-$PrNH_2$), *n*-butylamine (*n*-$BuNH_2$), isopropylamine (iso-$PrNH_2$), iso-butylamine (iso-$BuNH_2$), *sec*-butylamine (*sec*-$BuNH_2$), dimethylamine (Me_2NH), and trans compounds with *tert*-butylamine and diethylamine were synthesized and characterized by multinuclear magnetic resonance in acetone. For the chiral molecule *sec*-butylamine, the racemate mixture was used. The *tert*-butylamine dinitrato complex could not be dissolved in D_2O and the diethylamine compound contained some cis complex that could not be well separated. These two amines were therefore not included in the present study. The other dinitrato complexes were pure and were not dissociated in acetone as shown by conductivity measurements. The aquation and hydrolysis reactions of the eight cis and eight trans dinitrato compounds were studied in three different conditions of pH (acidic, neutral, and basic).

Aquation in acidic pH

When the dinitrato compounds are dissolved in water or D_2O (~0.03 mol L^{-1}), heating in a water bath is required by

most samples (especially the trans isomers), and the pH of the solution is acidic (pH = 2.0–2.4 or pD = 2.4–2.8). In these conditions, the diaqua species are formed.

$$Pt(amine)_2(NO_3)_2 + 2D_2O \rightarrow [Pt(amine)_2(D_2O)_2](NO_3)_2$$

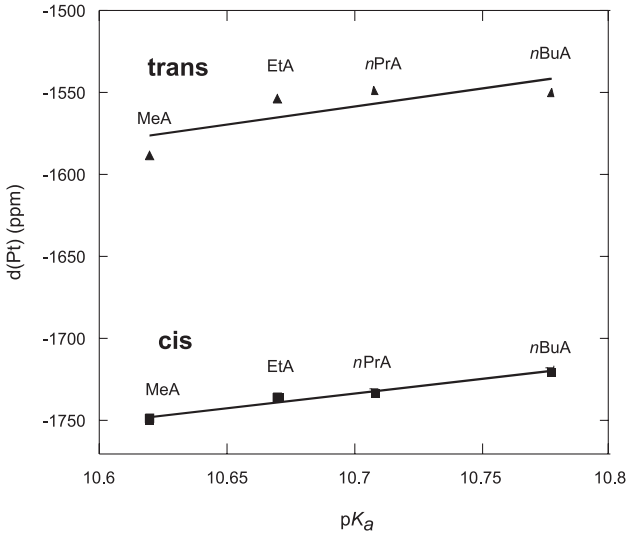
These D_2O solutions were characterized by multinuclear (^{195}Pt, ^{1}H, and ^{13}C) magnetic resonance spectroscopy.

For the cis isomers, the ^{195}Pt NMR spectra of these solutions showed the presence of only one signal, corresponding to the diaqua species. The chemical shifts of the complexes varied between –1699 and –1749 ppm. Surprisingly, the secondary amine complex was not observed at lower fields than the others. These results are shown in Table 1 along with some published values on similar compounds. The chemical shifts of the NH_3 (8, 17, 24) and pyridine (22) complexes are usually found at lower fields than those of amine complexes. Our values are at much lower fields than those reported for Pt(II) compounds with ethylenediamine and its derivatives (–1867 to –1999 ppm) (19, 20) or with 1,2-diaminocyclohexane (–1998 ppm) (23). Complexes containing five-membered chelate rings produce signals at much higher fields than those containing monodentate ligands.

The trans diaqua compounds were observed at lower fields (avg. –1547 ppm) than the cis isomers (avg. –1727 ppm) with an avg. $\Delta\delta$ ($\delta_{cis} - \delta_{trans}$) = –179 ppm for the primary amines and –81 ppm for Me_2NH. There are not many results in the literature for trans compounds. Only the NH_3 and some pyridine derivatives Pt(II) complexes are known (included in Table 1). Our results on the primary amines are close to the $\Delta\delta$ value (–210 ppm) observed for the NH_3 system (8, 17, 24), while our results on the secondary amine are closer to those observed with pyridine derivatives ($\Delta\delta$ = –90 ppm) (22).

The *trans*-$MeNH_2$ and -$EtNH_2$ compounds showed a second signal of lower intensity (about 10%) at slightly higher field than the diaqua species (35 ppm). We have assigned this signal to the presence of *trans*-$[Pt(amine)_2(NO_3)(D_2O)](NO_3)$. This type of compound has not been observed yet on trans complexes, but the group of Appleton (17) has studied the aquation of *cis*-$Pt(NH_3)_2(NO_3)_2$ and have suggested the presence of *cis*-$[Pt(NH_3)_2(NO_3)(H_2O)](NO_3)$ to a signal found at higher field (14 ppm) than the one of the diaqua species. Their ratio of the monoaqua–mononitrato to the diaqua compounds was about 0.1, as we have observed. Monoaqua–mononitrato species were also reported for some ethylenediamine derivatives at slightly higher fields (about 20 ppm) than the diaqua system in about the same ratio (19). To confirm the identity of the monoaqua–mononitrato species, we synthesized *trans*-$Pt(EtNH_2)_2(ClO_4)_2$ and studied its aquation products at the same pH. Only one species was observed at –1552 ppm, where the signal of the trans diaqua complex was found, which confirmed our hypothesis. This monoaqua–mononitrato complex was not observed for any of the cis compounds.

Although the chemical shift of the cis compound with the secondary amine Me_2NH was not different from the others, it was found at higher field in the trans series. Its δ(Pt) was observed at –1650 ppm compared to an avg. value of –1547 ppm for the primary amine complexes. This result was quite surprising and it was repeated to ascertain it. The δ(Pt) of secondary amine complexes were expected to be found at lower fields than primary amine compounds because of the solvent effect. For square-planar complexes, the molecules of solvent can normally approach and weakly bind to the Pt atom on both sides of the coordination plane. When the amines are more bulky, the approach of the molecules of solvent is more limited, which decreases the electronic density around the Pt atom, causing a deshielding effect in ^{195}Pt NMR. This solvent effect is particularly important in a coordinating solvent like water. The solvent effect is probably more different in the cis compounds where the steric hindrance is a more important factor than in the



© 2004 NRC Canada

trans configuration. In the trans isomers, the solvation of the Pt atom should be more uniform, unless the amines are very sterically demanding. Downfield ^{195}Pt NMR shifts were thus observed for the Pt cis and trans diaqua (22) and the cis dinitrato complexes (26) with pyridine derivatives that have ortho substituents, and also for the complexes K[Pt(pyridine)Cl_3] (27). In the diamine systems, downfield shifts were also observed for the diiodo complexes (15) and some dichloro compounds (28). But for the dinitrato diamine complexes (16) that we have recently reported, opposite results were observed. The δ(Pt) of cis secondary amine complexes were observed at the same fields as the primary amine compounds, while for the trans isomers, the δ(Pt) of the secondary amine complexes were found at slightly higher fields than the primary amine compounds. It seems that the dinitrato and diaqua systems behave in a similar fashion. In the trans configuration, the electron density on the Pt atom is larger for the secondary amine complex than primary amine compounds. It might be attributed to the larger basicity of the secondary amines or to different conformations of the molecules in solution, but more data are needed before a sound conclusion can be made. In the *trans*-Pt(pyridine)$_2I_2$ series (29), the compounds with ortho methyl substituents were also observed at higher fields than the others.

All these ^{195}Pt NMR studies are difficult to compare, since the neutral dihalo compounds and the dinitrato complexes have been reported in an organic solvent, while the diaqua systems and the ionic compounds K[Pt(pyridine)Cl_3] have been studied in water. The solvation of the Pt atom is a very important factor and is quite dependent on the solvent. Therefore, several factors are responsible for these different results. The solvent plays probably a very important role. Water, which can coordinate to platinum, can be responsible for the solvent effect discussed previously in this work. The charge on the complex might also be an important factor, but is difficult to evaluate at the moment, since the ionic compounds are normally studied in D_2O, while the spectra of the neutral complexes are measured in organic solvents. For pyridine ligands, the orientation of the pyridine ring is also an important factor and free rotation around the Pt—N bond will be limited in the presence of ortho substituents on the pyridine ligand, especially in the cis geometry. For diamine compounds, there is almost free rotation about the Pt—N bond in most of the trans compounds, but in the cis geometry, the rotation might be more limited, especially with more bulky ligands. The two cis amine ligands are probably mostly in the anti conformation as observed in the solid state for *cis*-Pt($MeNH_2$)I_2 (15), or the alkyl groups are far from each other as observed in the solid state for *cis*-Pt(Et_2NH)I_2 (15), where the amine H of the two ligands face each other in the Pt coordination plane, pushing the ethyl groups far from each other. The second type of ligand is also an important factor. For example, nitrato ligands are more bulky than iodo ligands, which are also further away from the Pt atom. Since the amines studied in this project are quite different, all these factors contribute to their ^{195}Pt chemical shifts, especially since the second ligand in this project (D_2O) is the same as the solvent.

Attempts were made to correlate the δ(Pt) of the diaqua complexes to the basicity of the amine, since amines cannot form multiple bonding with Pt. The pK_a of the protonated amines are shown in Table 1 (30). If we use all the data, there is no correlation. If we use only the linear amines, we can see a linear relationship, but not as expected. An increase in the basicity of the ligand should produce a stronger σ bond with Pt, resulting in a shielding effect in ^{195}Pt NMR. Figure 1 shows the reverse, although the differences in pK_a are not very large (from 10.56 to 10.78). The pK_a values are measured in a solvent and are sensitive to the environment of the protonated atom. Furthermore, the errors are probably quite large. The proton affinity of the amines, which are measured in the gas phase, might be a better indicator of the basicity of the ligands. But these data are not easily available in the literature. Figure 2 shows the correlation between the δ(Pt) vs. the proton affinity of the amines (31) for the cis and trans compounds. Again, a linear correlation was found, but not in the expected direction. These results indicate that the most important factor for these diamine compounds is not the basicity of the amine. Other factors like the solvent effect and the different conformations of the ligands in solution are probably more important.

Fig. 1. δ(Pt) (ppm) of $[Pt(amine)_2(D_2O)_2]^{2+}$ vs. pK_a of the protonated linear amine.

The ^{1}H NMR chemical shifts of the diaqua complexes are listed in Table 2, as well as the Δδ values ($\delta_{complex} - \delta_{amine}$). The NMR spectra of the amines were also measured in D_2O. Although the NH protons in the free amines are not detected in D_2O because of fast exchange, they were observed in the complexes. Their chemical shifts are at much lower fields for the cis isomers, which is in agreement with the ^{195}Pt NMR results, where the cis compounds were observed at higher fields than the trans isomers. An increase of electron density on the Pt atom (shielding effect) will correspond to a decrease of electron density on the ligands (deshielding effect). Furthermore, the $^2J(^{195}Pt\text{-}^1HN)$ coupling constants could be calculated and they are larger for the cis isomers, with an average value of 66 Hz, while it is 57 Hz for the trans complexes.

Surprisingly, most of the H-1 signals (in the α position to the amine group) were found at higher fields that the corresponding protons in the free ligand, except for the secondary amine compound (Table 2). This table also shows the ΣΔδ,

[a]Monoaqua–mononitrato species.

Fig. 2. δ(Pt) (ppm) vs. proton affinity of the amine for the complexes $[\text{Pt(amine)}_2(\text{D}_2\text{O})_2]^{2+}$.

which is the sum of the $\Delta\delta$ for all the protons, except those on the amine. For most of the diamine complexes, this value is larger for the trans compounds, except for the secondary amine complex. For a few compounds, the $^3J(^{195}\text{Pt-}^1\text{H})$ coupling constants were calculated. They are greater for the cis compounds (avg. 43 Hz) than for their trans analogues (avg. 34 Hz). These coupling constants depend on the geometry of the compounds as observed for other similar Pt(II) compounds (15, 16, 22, 26, 29).

For the trans monoaqua–mononitrato species, the signal of the NH proton was found at slightly lower fields than the one of the diaqua compound as expected from the ^{195}Pt NMR results. The other H signals were observed at slightly higher fields. No $J(^{195}\text{Pt-}^1\text{H})$ coupling could be detected for this species because of its low concentration.

The ^{13}C NMR chemical shifts, the $\Delta\delta$ values ($\delta_{\text{complex}} - \delta_{\text{free amine}}$), the $\Sigma\Delta\delta$, as well as the $J(^{195}\text{Pt-}^{13}\text{C})$ coupling constants are listed in Table 3. The $\Delta\delta$ values for C-1 are quite large and are greater for the cis compounds as expected from the ^{195}Pt NMR results, where the cis compounds were observed at higher fields. Again, an increase of electron density on Pt (shielding effect) will correspond to a deshielding effect on the ligand as observed also in ^{1}H NMR for the NH protons. Most of the other C atoms were observed at higher fields than in the free amines ($\Delta\delta$ is negative). The $\Sigma\Delta\delta$ values are all greater for the cis compounds because of the larger values for C-1. The coupling constants $^2J(^{195}\text{Pt-}^{13}\text{C}_1)$ are larger in the cis configuration (avg. 18 vs. 13 Hz). These values are quite small probably due to inadequate orientation of the orbitals. Similar values were observed for other Pt(II) complexes (15, 16, 27). The $^3J(^{195}\text{Pt-}^{13}\text{C})$ values are larger in the cis configuration (avg. 31 Hz) than in the trans geometry (avg. 23 Hz) as observed for other related compounds (15, 16, 22, 26, 29).

Hydrolysis in basic pH

When the pH of the diaqua complex is raised with NaOD to about 10, the dihydroxo species *cis*-$\text{Pt(amine)}_2(\text{OD})_2$ are formed. The ^{195}Pt NMR spectra of these solutions have shown the presence of a single signal, except for the *trans*-

[a](Hydroxo)(nitrato) species.
[b]Hydrolysis of *trans*-$Pt(EtNH_2)_2(ClO_4)_2$.

$EtNH_2$ complex, which showed a second weaker signal at slightly higher field (Table 4). The latter was assigned to the presence of *trans*-$Pt(EtNH_2)_2(OD)(NO_3)$. To verify the hypothesis, *trans*-$Pt(EtNH_2)_2(ClO_4)_2$ was synthesized and its hydrolysis studied at the same pH. Only one peak corresponding to the dihydroxo species was observed at –1574 ppm, which confirmed our assignments.

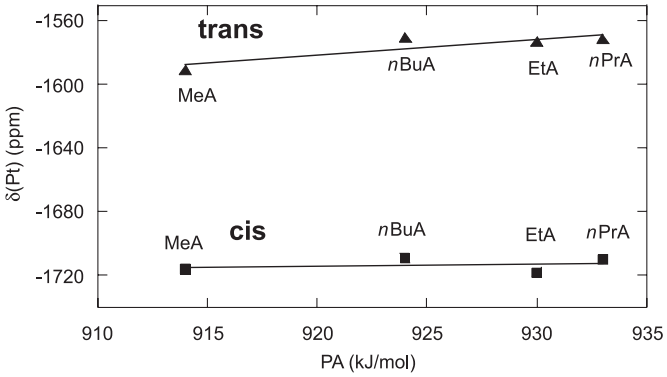
Similarly to the diaqua species, the cis dihydroxo compounds with primary amines were observed at higher fields (avg. –1706 ppm) than the trans analogues (avg. –1574 ppm). The cis secondary amine compound is at slightly lower fields than the primary amine complexes, but again surprisingly, the secondary amine trans compound was found at higher field than the primary amine analogues. The difference between the two isomers $\Delta\delta_{cis\text{-}trans}$ is larger for the primary amines (avg. –140 ppm) than for the secondary amine (–79 ppm) as observed for the diaqua species. The pertinent data found in the literature are included in Table 4. Our $\Delta\delta$ values on the primary amine compounds are close to the one reported for the $Pt(NH_3)_2$ system (24), while our value on

© 2004 NRC Canada

the secondary amine is close to those reported for complexes containing pyridine ligands (22).

Table 4 also shows the $\Delta\delta_a$ ($\delta_{diaqua} - \delta_{dihydroxo}$) values for the cis and trans compounds. For the cis analogues, all the dihydroxo compounds were observed at lower fields than the diaqua compounds. The average $\Delta\delta_a = -16$ ppm for the primary amines and –50 ppm for Me_2NH. Our results on the primary amine compounds are in agreement with those of the $Pt(NH_3)_2$ system (24), and our results on the secondary amine complexes agree with those published for the pyridine system (22) as shown in Table 4.

All the trans dihydroxo compounds with primary amines were observed at slightly higher fields than the diaqua species (avg. $\Delta\delta_a = 23$ ppm) as observed for the NH_3 and pyridine series. For the secondary amine Me_2NH, the trans dihydroxo complex was found at lower field ($\Delta\delta_a = -48$ ppm), which is very different from all other works. We have repeated our experiments on the Me_2NH complexes with similar results.



For all the cis compounds, the signals of the dihydroxo complexes are observed at slightly lower fields than the corresponding diaqua compounds ($\Delta\delta_a$ is negative). The shielding of a heavy atom like the ^{195}Pt nucleus has been expressed in the Ramsey equation, which contains some C terms representing the metallic coefficients of the platinum *d* orbitals. A more covalent bond will result in a decrease in the C terms and hence a shielding of the ^{195}Pt signals. D_2O is a more polarizable molecule than OD^-, leading to a more covalent Pt—OD_2 bond (in the diaqua system) compared to the Pt—OD bond in the dihydroxo complex. A greater covalency leads to a reduction of the C terms on the Pt atom and therefore, an increase in the shielding in the Ramsey equation. Therefore, the diaqua compounds should be observed at higher fields than the dihydroxo complexes, as observed in the literature cited previously and in our cis diamine complexes.

In the trans series, except for Me_2NH, which behaves like a cis compound, the reverse was observed. The trans dihydroxo complexes were observed at higher fields than the diaqua compounds as observed in the pyridine series (22). The solvent effect probably plays a more important role in the trans geometry, where the bulkiness of the amine is less important and the molecules of solvent can more easily approach the Pt atom. It might also be quite different for an ionic complex like $[Pt(amine)_2(D_2O)_2]^{2+}$ and for a neutral compound such as $Pt(amine)_2(OD)_2$. The different conformations of the molecules in solution might also be an important factor.

When the pH is acidic, the monoaqua–mononitrato species were observed for the *trans*-$MeNH_2$ and -$EtNH_2$ complexes. At basic pH, the monohydroxo–mononitrato was observed only for the *trans*-$EtNH_2$ compound, which was found at slightly higher field (17 ppm) than the dihydroxo complex. Monohydroxo–mononitrato species have not been reported yet in the literature for either cis or trans Pt(II) amine compounds.

Correlations of the δ(Pt) of the dihydroxo compounds with the basicity of the amines were studied. There is no general trend, but if only the linear amines are chosen, there is a tendency towards lower fields as the pK_a of the protonated amine increases. The same trend is observed for the proton affinity in the gas phase. Figure 3 shows the δ(Pt) vs. the proton affinity of the linear amines. For the cis compounds, the chemical shifts δ(Pt) are constant, while for the trans isomers, it slightly increases towards lower fields as the proton affinity increases. Again, this correlation is not as expected. These results seem to indicate that the basicity of the amine is not a very large factor in the ^{195}Pt chemical shifts. The basicity of the different amines are quite close to each other and the solvent effect is a more important factor for these diamine complexes.

Fig. 3. δ(Pt) (ppm) vs. proton affinity of the amine for the complexes $Pt(amine)_2(OD)_2$.

The ^1H NMR spectra of the dihydroxo complexes are shown in Table 5, as well as the $\Delta\delta$ values ($\delta_{complex} - \delta_{amine}$). In basic solution, the NH protons exchange rapidly and are not detected. Similarly to the diaqua species, the resonances of the C protons in the trans compounds are observed at lower field than those of the cis isomers. Table 5 shows that the $\Sigma\Delta\delta$ values are larger for the trans isomers, except for the secondary amine compounds. The $^3J(^{195}Pt\text{-}^1H)$ couplings were observed only for the $MeNH_2$ and Me_2NH complexes. As for similar compounds, this constant is larger in the cis geometry (43 vs. 36 Hz). The proton chemical shifts in the trans monohydroxo–mononitrato $EtNH_2$ complex were found at slightly higher fields than in the corresponding dihydroxo species.

The ^{13}C NMR spectra of the dihydroxo complexes are shown in Table 6. The signals of C-1 of the trans compounds were observed at higher fields than those of the corresponding cis complexes as expected from the ^{195}Pt NMR results. No correlation with the pK_a or the proton affinity was found. The $^2J(^{195}Pt\text{-}^{13}C)$ coupling constants could be measured. The average value is 18 Hz for the cis compounds and 11 Hz for the trans isomers. These values are relatively small, probably because of inadequate orientations of the orbitals. The $^3J(^{195}Pt\text{-}^{13}C)$ coupling constants are larger, with average values of 31 Hz for the cis complexes and 22 Hz for the trans isomers. For *sec*-$BuNH_2$, the ^{195}Pt coupling with the terminal C-2′ atoms is smaller (20–22 Hz) than with the other C-2 atoms (23–29 Hz).

sec-Butylamine is a chiral molecule and for the cis dihydroxo complex, the two enantiomers could be detected. Only one series of signals was found for the corresponding diaqua species and in the trans complexes.

The ^{13}C chemical shifts of the trans monohydroxo–mononitrato $EtNH_2$ complex were found at slightly higher fields than the corresponding dihydroxo species. No $J(^{195}Pt\text{-}$

[a]Monohydroxo–mononitrato species.

^{1}H) coupling could be detected for this species because of its low concentration.

Hydrolysis of the cis complexes at neutral pH

The study on the cis compounds at neutral pH was made only by Pt NMR spectroscopy. The ^{195}Pt NMR spectra of these fresh solutions were recorded immediately. For all the complexes, the spectra have shown two or three species in solution. The results are shown in Table 7 with the proportion of each species. The percentage values are very approximate. Our assignments for the different signals are based on the results published in the literature, especially for the *cis*-$Pt(NH_3)_2$ system (17, 24) and the dipyridine complexes (22). The reported results are also shown in Table 7.

For all the amines, the signal observed at highest field (between –1714 and –1734 ppm) was assigned to the monoaqua–monohydroxo complex, *cis*-$[Pt(amine)_2(D_2O)(OD)]^+$, which is found close to the diaqua and the dihydroxo species. In fresh solutions, the proportion of this species varied between 13% and 75%. The δ(Pt) of the secondary amine complex was found at the same field as the other diamine compounds. No correlation could be found between the ^{195}Pt chemical shifts of these species with either the pK_a of the protonated amines or the proton affinity.

The signals observed at lowest fields (avg. –1355 ppm) were assigned to the dihydroxo-bridged species *cis*-$[Pt(amine)_2(\mu\text{-}OD)_2Pt(amine)_2]^{2+}$ (Scheme 1), at 371 ppm (avg.) from the diaqua compounds. These results are in agreement with those reported for a few similar studies (17, 18, 22). In the *cis*-$Pt(NH_3)_2$ system, this dimer was observed at 423 ppm from the diaqua complex (8, 17). The crystal structures of several compounds of this type have been published (9, 10, 20). The chemical shifts for these species are found at much lower fields than the other compounds because of the important strain inside the four-membered ring. The proportion of this species varied between 25% and 73% in fresh solutions.

A third signal was observed in fresh solutions of the *cis*-$MeNH_2$, *n*-$BuNH_2$, and *sec*-$BuNH_2$ compounds at –1684 ppm (avg.). It was assigned to the monohydroxo-bridged dimer *cis*-$[Pt(amine)_2(D_2O)(\mu\text{-}OD)Pt(amine)_2(OD)]^{2+}$ (Scheme 1), which is probably in equilibrium with its diaqua analogue *cis*-$[Pt(amine)_2(D_2O)(\mu\text{-}OD)Pt(amine)_2(D_2O)]^{3+}$ and its dihydroxo analogue. The monohydroxo-bridged dimer was found at lower field (avg. 39 ppm) than the *cis*-$[Pt(amine)_2(D_2O)_2]^{2+}$ species. This dimer has been reported for $EtNH_2$ at –1680 ppm (18) and for *cis*-$[Pt(NH_3)_2(D_2O)(\mu\text{-}OD)Pt(NH_3)_2(D_2O)]^{3+}$,at 47 ppm (17) from the diaqua monomer *cis*-$[Pt(NH_3)_2(D_2O)_2]^{2+}$. It was also reported for the dipyridine systems (22).

No hydroxo-bridged trimers or tetramers could be detected in this study. Trimers have been reported for the ligands NH_3 (8, 9), ethylenediamine and its methyl derivatives (20), and diaminocyclohexane (23). The structure of a cyclic hydroxo-bridged tetramer was also reported with ethylenediamine (32). These species are usually formed after a longer time in solution. Our study was done mostly on fresh solutions.

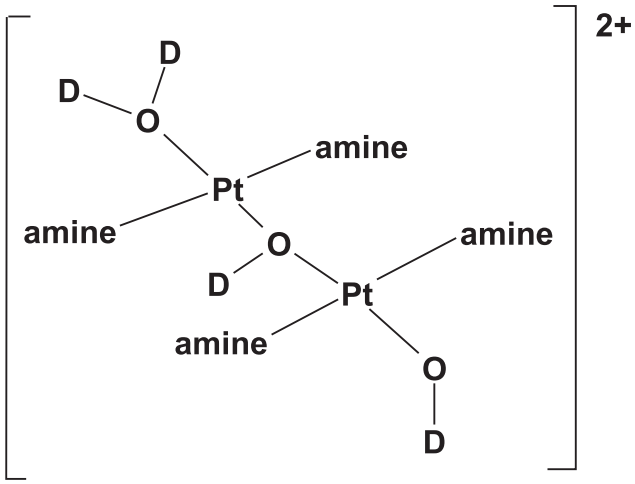
cis(Monoaqua)(monohydroxo) monomer



Monohydroxo-bridged dimer

$Y = H_2O$ or OH^-

Dihydroxo-bridged dimer

trans Dimer

The ^{195}Pt NMR spectrum of the $MeNH_2$ complex was remeasured after 5 days. The same three signals were observed, but the intensity of the monomer was lower (19% to 11%), while the monohydroxo-bridged dimer increased from 9% to 17%. The concentration of the dihydroxo-bridged dimer was about the same. The iso-$PrNH_2$ solution was also remeasured after standing in the refrigerator for 1 week. Three species were again detected. The concentration of the monomers had decreased from 75% to 12%, the monohydroxo-bridged dimer increased from 0% to 27%, while the concentration of the dihydroxo-bridged dimer also increased from 25% to 61%. Finally, the *sec*-$BuNH_2$ solution was remeasured after standing in the cold for 3 months. The monomers were absent (25% in the fresh solution), the monohydroxo-bridged dimer increased from 19% to 49%, while the concentration of the dihydroxo-bridged dimer slightly decreased from 56% to 51%.

These preliminary results on the changes of these solutions with time show that the monomer is rapidly formed and its concentration decreases with time, while the formation on the monohydroxo-bridged dimer is much slower. The dihydroxo-bridged dimer is also formed quite rapidly and stays in the solution for a long time. The proportions of the different species depend also on the pH, which might vary slightly for the different compounds.

Study of the trans isomers at neutral pH

A similar study on the trans complexes was performed by ^{195}Pt and ^{1}H NMR spectroscopy. For most compounds, only one ^{195}Pt NMR signal was observed (Table 8). For the primary amine systems, the avg. value is –1555 ppm, an intermediate value between the diaqua compounds (avg. –1547 ppm) and the dihydroxo species (avg. –1574 ppm). The signal was assigned to the monoaqua–monohydroxo monomers *trans*-$[Pt(amine)_2(D_2O)(OD)]^+$. For $MeNH_2$, *n*-$PrNH_2$, and Me_2NH, a second weak signal (5%–8% concentration) was observed. It was assigned to the monohydroxo-bridged dimer (Scheme 1), which has been suggested for the *trans*-$Pt(NH_3)_2$ system (24) and for the trans pyridine compounds (22). This signal was observed at slightly lower field than the one of the monomer and it has been suggested (24) (for the *trans*-$Pt(NH_3)_2$ system) that the concentration of this species increases with time. We have remeasured the ^{195}Pt NMR spectrum of the $MeNH_2$ com-

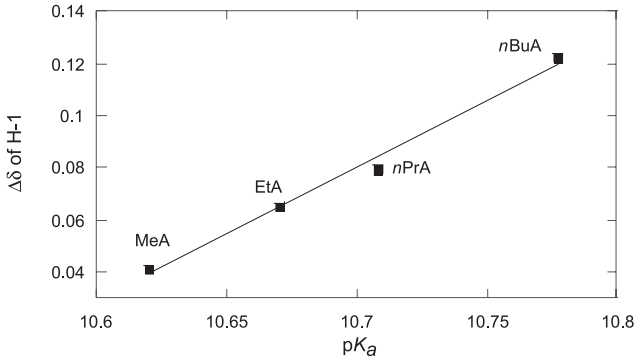
[a]Hydroxo-bridged dimer.

pound after 3 months, and the weak signal had now increased to 45%, which seemed to confirm our assignments. The old $MeNH_2$ compound solution also showed a third weak signal at –1541 ppm, which was assigned to a longer chain hydroxo-bridged oligomer or polymer, which could be linear or cyclic. For the *trans*-$Pt(NH_3)_2$ system, Appleton et al. (24) have isolated a solid that formed at pH = 5 to 6, after the solution was allowed to stand. The authors have formulated the solid as containing hydroxo-bridged polymeric cations ($[\{trans\text{-}Pt(NH_3)_2(\mu\text{-}OH)\}_n]^{n+}$), which could be linear or cyclic. The published work on pyridine complexes also suggested this type of polymer in small concentration in fresh solutions (about 5%), but its formation increased with time to about 30% after 7 months (22).

No correlation could be found between the δ(Pt) of the complexes *trans*-$[Pt(amine)_2(D_2O)(OD]^+$ with the pK_a or the proton affinity values.

The chemical shifts in ^1H NMR and the $\Delta\delta$ values of the fresh solutions are shown in Table 9. The amine protons were not detected. In general, the δ(H-1) are between those of the corresponding dihydroxo and diaqua compounds. Only one series of peaks was observed for the chiral ligand *sec*-$BuNH_2$. The $^3J(^{195}Pt\text{-}^1H)$ were detected for the $MeNH_2$ and Me_2NH complexes. They are about 35 Hz.



An attempt was made to correlate the $\Delta\delta$(H-1) with the pK_a of the protonated amines. Figure 4 shows the results with the linear amines. An increase in the basicity of the amine leads to a greater $\Delta\delta(H_1)$ value as expected. This is the first time that such a correlation is observed. If we use all the primary amines in this study, we have the same correlation, although the fit is not as perfect.

Conclusion

When the complexes $Pt(amine)_2(NO_3)_2$ were dissolved in D_2O, the diaqua complexes were observed in acidic media, while hydrolysis occurs at basic pH to produce the dihydroxo compounds. In acid solution, the monoaqua–mononitrato species were detected for the trans complexes of $MeNH_2$ and $EtNH_2$, while in basic medium the monohydroxo–mononitrato compound was found only for the *trans*-$EtNH_2$ complex. This is the first report on the presence of monohydroxo–mononitrato compounds in solution.

Fig. 4. Δδ(H-1) (ppm) vs. pK_a of the protonated linear amine for the complexes $[Pt(amine)_2(D_2O)(OD)]^+$.

In ^{195}Pt NMR spectroscopy, the cis diaqua complexes were observed at higher fields than the trans analogues. The difference in δ(Pt) is probably due to differences in the Δ*E* values for the two isomers in the Ramsey equation (33) as suggested in the literature (24). For complexes of the type $Pt(amine)_2X_2$, the Δ*E* difference will be larger when the two ligands (amines and X) are far from each other in the trans influence series (34). The trans influence difference between amine and aqua ligands is quite large (35), resulting in a much lower shielding for the trans complexes than for the cis isomers (Δδ(Pt) ~ 180 ppm). The same is true for the diamine dihydroxo complexes, although the difference is slightly smaller (Δδ(Pt) ~ 140 ppm). This might suggest that the trans influence of the hydroxo ligand is closer to the one of amines than the one of the aqua ligand.

At neutral pH, two or three species were found for the cis isomers. The concentration of these varies with time. We have not made a systematic study of the different species, but a few compounds were remeasured later in time. The presence of the monoaqua–monohydroxo compound is important in fresh solutions and decreases with time. Two oligomeric ionic species were detected. The dihydroxo-bridged dimers are observed at very low fields and they are present in fresh solutions and in older solutions. The second oligomer is the monohydroxo-bridged dimers, which are present in only three of the eight amine complexes in fresh solutions. The concentration of this species increases with time. After 6 months, its concentration is about 50% for the *sec*-butylamine complex. No cyclic trimers or tetramers could be detected. A more systematic study of the different species present in solution as a function of time might show the presence of these species in small concentration.

For the trans compounds at neutral pH, the monoaqua–monohydroxo compound is the only species found in fresh solutions for five of the eight complexes. For $MeNH_2$, *n*-$PrNH_2$, and Me_2NH, a second species identified as the hydroxo-bridged dimer was observed in low concentration in fresh solution. After 6 months, the concentration of the latter increased to about 50% for the $MeNH_2$ complex and a new weak signal (7%) was found at slightly lower field. It was assigned to a larger hydroxo-bridged cyclic or linear oligomer.

The species in solution vary slightly with concentration and the time of heating to dissolve the dinitrato complexes. The latter complexes are not very soluble and must be heated in hot water and it was difficult to reproduce the exact experimental conditions of sample preparation. Furthermore, there sometimes was a residue at the bottom of the NMR tube after the experiment was completed, especially for the cis complexes. Therefore, there were some variations in the proportions of each species when the experiments were repeated.

Molecular modeling utilizing purple acid phosphatase biomimetic models

Lilian W. Paes, Roberto B. Faria, Juan O. Machuca-Herrera, Ademir Neves, and Sérgio P. Machado

Abstract: Purple acid phosphatases (PAPs) constitute a new class of metalloenzymes that catalyze the hydrolysis of certain phosphate esters, including nucleoside di- and triphosphates and aryl phosphates, under acidic conditions. To provide some insight into these metalloenzymes we have performed quantum chemical and molecular mechanics calculations based on the mixed-valence $[Fe^{II}Fe^{III}(BPBPMP)(OAc)_2]^+$ model complex (**1**) (H_2BPBPMP = 2-bis[{(2-pyridylmethyl)-aminomethyl}-6-{(2-hydroxybenzyl)-(2-pyridylmethyl)}-aminomethyl]-4-methylphenol). The geometric and the vibrational parameters calculated by molecular mechanics show that the force fields established in this work reproduce the binuclear iron core with μ-phenoxo or μ-alkoxo and di-μ-acetate bridges presented in the PAPs model complexes. The atomic orbital analysis of the SOMO contributions indicated that the Fe^{III} atom and the terminal phenolate are involved in the phenolate to Fe^{III} charge transfer electronic transition in **1** as argued from electronic spectroscopic data in the PAPs.

Key words: mixed-valence $Fe^{II}Fe^{III}$ complex, purple acid phosphatases, molecular modeling.

Résumé : Les phosphatases acides violettes (PAV) constituent une nouvelle classe de métalloenzymes qui catalysent, en milieu acide, l'hydrolyse de certains esters de l'acide phosphorique, y compris des di- et des triphosphates de nucléoside et des phosphates d'aryle. Afin de mieux comprendre ces métalloenzymes, des calculs théoriques de mécanique moléculaire et de chimie quantique ont été effectués sur le complexe modèle de valence mixte $[Fe^{II}Fe^{III}(BPBPMP)(OAc)_2]^+$ (**1**) (H_2BPBPMP = 2-bis[{2-pyridylméthyl)-aminométhyl}-6-{(2-hydroxybenzyl)(2-pyridylméthyl)}aminométhyl]-4-méthylphénol). Les paramètres géométriques et vibrationnels calculés sur la base de la mécanique moléculaire montrent que les champs de force établis dans ce travail correspondent au noyau binucléaire de fer avec des ponts μ-phénoxo ou μ-alkoxo et di-μ-acétatate qui ont été présentés dans les complexe du modèle de PAV. L'analyse de l'orbitale atomique des contributions SOMO indique que l'atome de Fe^{III} et le phénolate terminal sont impliqués dans la transition électronique detransfert de charge du phénolate au Fe^{III} du composé **1**, tel qu'il avait été suggéré à partir des données de spectroscopie électronique des PAV.

Mots clés : complexe $Fe^{II}Fe^{III}$ de valence mixte, phosphatases acide violettes, modélisaton moléculaire.

[Traduit par la Rédaction]

Introduction

Purple acid phosphatases (PAP) represent a new class of non-heme proteins, which catalyze the hydrolysis of a wide range of phosphate esters and anhydrides including nucleoside di- and triphosphates under acidic conditions. The active site of these PAPs from mammalian sources consists of a binuclear center with two accessible oxidation states of $Fe^{III}M^{II}$ and $Fe^{III}M^{III}$ (M = Fe) (1). The reduced form of the enzyme is active for hydrolysis while the oxidized form is inactive. The PAPs have been isolated from a variety of mammalian, plant, and microbial sources. In mammalian PAPs there is a Fe^{III}–Fe^{II} center, while plant PAPs from red kidney bean have a Fe^{III}–Zn^{II} center in their enzymatically active form (2, 3).

Crystal structures (4, 5) of PAPs show that seven conserved protein residues, including a monodentate bridging carboxylate, occupy eight coordination sites on the two metals, leaving four possible sites for the exogenous ligands. The presence of a hydroxy bridge occupying two of the exogenous ligand sites has been proposed on the basis of spectroscopic and magnetic measurements of the active mixed valence $Fe^{III}Fe^{II}$ enzyme. Their purple color originates from the tyrosinate-to-Fe^{III} charge-transfer band. In both reduced and oxidized forms, the iron atoms are antiferromagnetically spin coupled giving rise to S = 1/2 and S = 0 ground states, respectively. Magnetic susceptibility measurements (6) of the reduced form have revealed that the Fe^{II} and Fe^{III} centers are weakly coupled with *J* values in the range of –5 to –15 cm^{-1}. The binuclear iron center of purple acid phosphatases (PAPs) has been studied extensively using various spectroscopic techniques (7–10). It seems that the pres-

ence of at least one terminal phenolate ligand bound to the Fe^{III} center is required to obtain suitable dinuclear biomimetic complexes. Moreover, the stabilization of these complexes in the reduced and oxidized forms, displaying reversible redox properties, appears to be essential to the biological activity of these metalloproteins.

The initial goal in modeling the active site of the purple acid phosphatases is to synthesize an inorganic compound having structural and spectroscopic features as similar as possible to the active site in stable states. The biomimetic synthesis and characterization of new binuclear complexes with relevant N,O-donor ligands (amines, phenolate, imidazole, and pyridine), therefore, offers a useful contribution to the understanding of the electronic and structural properties of these metalloproteins. These ligands must induce unsymmetrical M–L environments and vacant or labile sites for reactivity, and must be capable of stabilizing both $Fe^{III}Fe^{III}$ and $Fe^{II}Fe^{III}$. Recently, various model complexes have been synthesized with polypodal ligands (11–18) such as 2-bis[{(2-pyridylmethyl)-aminomethyl}-6-{(2-hydroxybenzyl)-(2-pyridylmethyl)}-aminomethyl]-4-methylphenol (H_2BPBPMP). Also, effective computational methods have emerged that provide some insight into bioinorganic systems. Accurate and efficient approaches combining quantum chemical and molecular mechanics models have been developed, complementing experimental work, to study these metalloproteins. Molecular mechanics is an efficient approach to optimizing molecular structures with generally high accuracy and comparably little computational expense (19–22). The choice of the force field and its parameterization, is dictated by the problem to be solved and the available experimental data. In the last decade, various papers have discussed the application of molecular mechanics programs in many chemistry areas showing the efficiency of the empirical force field calculations, and the variety of force fields developed.

Despite the increase in computer power, modeling of large molecules continues to depend on the evolution of simplified representations at all levels. Considering the size of most bioinorganic systems, semiempirical models and molecular mechanics still seem to be the tools of choice in the description of relevant systems, allowing a large number of atoms to be worked with, giving reductions in the cost:performance ratio of the computational hardware. However, in the last few years high-level, large-scale computational models of diiron complexes have been developed (23, 24).

To provide some insight into this class of metalloenzymes, in this study we performed molecular mechanics, quantum chemical and semiempirical calculations for some PAPs model compounds to complement experimental studies of these metalloenzymes. The calculation consisted firstly of the use of molecular mechanics, with the FORCES program (25, 26). After the molecular mechanics optimized structures were obtained, the ab initio "single point" calculations were carried out using the GAMESS program with the ECP-SBK basis set (27). This basis has been shown to be a good choice in treating heavier elements and to be useful for the lower transition metal series as well (28). The semiempirical extended Hückel (EHT) (29) calculations were carried out with the EXTEN program developed in our laboratory, which considers the Pearson's atomic local hardness (30, 31) following the Dronskowski (32) approach, to calculate the reactivity of the metal centers.

Computational details

All the calculations were carried out on a Pentium 200 MHz computer with 256 Mb RAM and a 10 Gb HD under the Windows operational system for the FORCES and EXTEN programs, and an Athlon 1 GHz PC, with 512 Mb RAM and a 20 Gb HD running under UNIX Free BSD 4.X operational system for the GAMESS program.

The methodology adopted for the calculations consisted firstly of the use of molecular mechanics with the FORCES program developed in the Laboratory of Computational Inorganic Chemistry, for the geometry optimization of the model complexes. The force field employed was developed specifically for diiron core centers. The optimized structures were submitted to the ab initio ROHF (Restrict Open Hartree Fock) MO single point calculations performed by the GAMESS program with the ECP-SBK basis set, with multiplicity equals 2 for electronic analysis. The semiempirical molecular orbital calculation was made considering Pearson's atomic local hardness following the Dronskowski approach, using the extended Hückel method approximations given by the EXTEN program developed in our laboratory.

Results and discussion

The MM, EHT, and QM theory (ab initio – single point) calculations were performed on a series of model complexes, according to the experimentally available information (11–18). The model complexes are shown in Fig. 1. These compounds have an asymmetric binuclear structure with two iron atoms in the oxidation states (Fe^{II}, Fe^{III}), and each iron center with a six-coordinated octahedral environment. The iron ions are bridged by alkoxo or phenoxo groups and two carboxylate ligands, nitrogen's amine and phenolate or alkoxo groups complete the coordination environment.

Table 1 shows the bonds, angles, and dihedral angles force constants that were used in this work, and Table 2 presents the experimental and calculated structural parameters.

Comparison between the geometric parameters of the model with the experimental data shows that the force field adopted for these binuclear iron complexes performed very well, although some calculated angles did not present values close to the experimental data. This difference is due to the fact that the model complexes present some free dihedral angles, supplying lesser rigidity to the system when compared with experimental parameters.

It is important to note that the experimental and calculated (Fe^{II}-O_b-Fe^{III}) bridging angle presented very close values, indicating a good reproduction of the binuclear core. The oxygen bridge was coordinated asymmetrically with the two metallic centers, as has been observed in other iron mixed valence complexes (13).

Table 3 shows the experimental and vibrational frequencies analysis calculated by the FORCES program for the model complexes.

Table 1. Select bonds, angles and dihedral angle force constants.

Bond	K_h (mydna/Å)
Fe—O_b	1.30
Fe—O_t	1.50
N_p—C_{ar}	3.00
C—O_p	6.0
Angle and dihedral	K_θ (mydnaÅ/rad^2)
Fe-O_b-Fe	0.80
Fe-O_p-C_{ar}	0.90
O_p-Fe-O_b	0.80
Fe-O_p-C_{ar}-C_{ar}	0.07
Fe-O_c-C-H	0.08
Fe-O_c-C-O_c	0.09

Note: O_b = bridge oxygen, O_t = terminal oxygen (-CH_3), O_c = carboxylate oxygen, O_p = phenolate oxygen, C_{ar} = aromatic carbon, N_{am} = amine nitrogen, N_p = pyridyl nitrogen.

Many IR and Raman studies of the Fe–O fragment have been published (33–36). In a recent paper (37), the band in the Raman spectra at approximately 340 cm^{-1} was tentatively assigned to the ν_s (Fe–O_{bridge}). Such assignment was based on standard coordination analysis of compounds such as M_2X_{10} that indicated the following relative energy order: δ (M–X–M) < ν_s (M–X_{bridge}) < ν (M–$X_{terminal}$) < ν_{as} (M–X_{bridge}). This assignment was reinforced by the density functional theory (DFT) that indicated a ν_s Fe–O vibration chelate band at approximately 320 cm^{-1}.

The same order was established in this work, where the region of lower frequency was at 300 cm^{-1} (ν_s M–O_{bridge}) and the region of higher frequency was at 600 cm^{-1} (ν_{as} M–O_{bridge}), while the ν(M–$O_{terminal}$) was in the intermediate region. Based on these results, we assign the band at ~314 cm^{-1} to Fe–O_{bridge} stretching. To analyze the electronic structure, quantum chemical calculations were performed on the optimized structure of the model complexes. Figure 2 presents the graphic representation of the frontier orbitals SOMO in the ground state for the model complexes. The calculated single occupied higher molecular orbitals (SOMO) show only the participation of the d_{xy} iron(III) atomic orbital together with the p_y oxygen atomic orbital of the phenolate ligands in all of the model complexes. The atomic orbital d_{xy} of Fe^{II} and the atomic orbital of the oxygen bridge do not contribute to this molecular orbital.

The characteristic electronic absorption spectrum of the PAPs consists of a broad band centered at 555 nm; this band is assigned to a tyrosinate-to-iron(III) charge transfer transition. The ground state graphical representations calculated for the SOMO show that the Fe^{III} atom from the metal center and the terminal phenolate are involved in this electronic transition. For a better analysis, a configuration interaction (CI) calculation was attempted, but the model complexes present a large number of atoms, making the calculation impossible.

The Mulliken population analyses of the SOMO for the oxygen atoms are shown in Table 4.

In recent years, many studies of magnetic properties on binuclear iron complexes have been carried out (38–44). This class of binuclear iron complexes can be divided into two groups: the strong, antiferromagnetically coupled oxo-

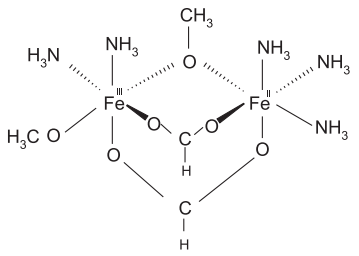
Fig. 2. Surface representation of the SOMO obtained from the ab initio calculation by the ECP-SBK basis set for models A–D.

bridged complexes and weak, antiferromagnetically coupled hydroxy-, alkoxo-, and phenoxo-bridge complexes. It has been suggested, on the basis of semiquantitative MO theory, that the strength of antiferromagnetic interaction should increase since the higher electron density of the oxo-bridge leads to a much stronger antiferromagnetic coupling (~–55 > J > ~–135 cm^{-1}) when compared with hydroxy-, alkoxo-, or phenoxo-bridged iron compounds (+1.2 > J > ~–30 cm^{-1}). The electron density of the bridging oxygen atom should increase in the series Ph < H < R. It was observed that the electronic effect of the ligand in the trans position must be considered in the antiferromagnetic interaction. In Scheme 1, we show the charge density and bond order for the A and C models.

Analyzing the data in the Scheme 1, we note that the model A presents a higher electronic density on the oxygen bridge. The aromatic substituents show a weak negative inductive effect while aliphatic substituents show a weak positive inductive effect, causing a decrease in the J values. The Fe—O bond order for model A is higher than that for model C, showing that the electronic density on the oxygen bridge in model A is higher than that of model C.

Scheme 2 shows that the electronic density on the oxygen bridge for model D is smaller than the oxygen bridge for model B, which can be explained by the phenoxo bridge and the Fe—O bond order that show the same tendency.

Although we show another effect on the charge density when comparing models A and B, the oxygen bridge is the same, but the terminal ligands in the trans position are different. We expected the same electronic density on the oxygen bridge for models A and B because of the CH_3 substitute on the oxygen bridge, but the electronic density on the oxygen bridge in model A is higher than that in model B. In other words, when the ligand in the trans position is a phenolate group, the electronic density on the oxygen bridge decreases. The same tendency was observed for models C and D. The less electronegative atoms in the trans position result in a somewhat stronger magnetic interaction, and this electronic effect might be responsible for the decrease in the magnitude of antiferromagnetic interaction on substitution that was also observed in this work (45).



The semiempirical calculated reactivity indices for models A–D are listed in Table 5.

The reactivity indices calculated by the semiempirical MO program (EXTEN) for the Fe^{II} and Fe^{III} were 0.341 and 0.00 eV, respectively, indicating that the Fe^{II} presents higher reactivity than the Fe^{III} in agreement with one of the hydrolysis mechanisms proposed (46, 47), where the dianionic

B	0.000	0.439
C	0.282	0.000
D	0.000	0.341

phosphate monoester substrate preferentially binds the Fe^{II}, which is subsequently attacked by the Fe^{III}–OH nucleophile.

Conclusions

The geometric and the vibrational parameters calculated by molecular mechanics show that the force fields established in this work reproduce very well the binuclear iron core, with μ-phenoxo and μ-alkoxo bridges present in the PAPs model complexes.

The ab initio single point (SP) calculated for the SOMO shows the participation of the d_{xy} iron(III) atomic orbital together with the p_y oxygen atomic orbital of the phenolate ligands (terminal) for all models. Therefore, the atomic orbital analysis of the SOMO contributions indicated that the Fe^{III} atom from the dinuclear $Fe^{II}Fe^{III}$ center and the terminal phenolate may be involved in the tyrosinate-to-iron(III) charge transfer electronic transition in PAPs.

The reactivity indices calculated for Fe^{II} and Fe^{III} indicate that the Fe^{II} presents an atomic local hardness higher than Fe^{III}, in agreement with one of the mechanisms proposed.

The results above reflect the progress that has been made in modeling metalloprotein active sites. The agreement between the experimental data and calculated results validates the methodology used in this work.

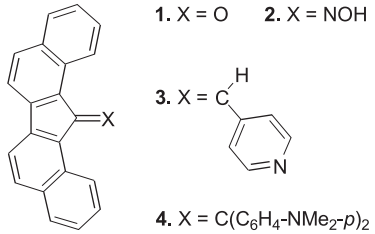
The chiral oxime of 13*H*-dibenzo(*a*,*i*)fluoren-13-one

Sean Higgins, David G. Morris, Kenneth W. Muir, and Karl S. Ryder

Abstract: On the basis of single crystal diffraction analyses it is shown that conversion of 13*H*-dibenzo(*a*,*i*)fluoren-13-one into its oxime causes distortion of the aromatic framework because of steric crowding. The oxime is, in consequence, chiral.

Key words: oxime, crystal structure, chirality.

Résumé : Sur la base d'analyses de diffraction de rayons X par un cristal unique, on montre que la conversion de la 13*H*-dibenzo(*a*,*i*)fluorén-13-one en son oxime provoque une distorsion du squelette aromatique en raison d'un encombrement stérique. En conséquence, l'oxime est chiral.



Mots clés : oxime, structure cristalline, chiralité.

[Traduit par la Rédaction]

Introduction

We have recently shown that the carbon skeleton of the aromatic ketone (**1**) is almost exactly planar: the angle between the two naphthalene residues is only 1.9(1)° (1). This has led us to consider overcrowding in derivatives of **1**, such as its oxime **2**. For steric reasons **2** cannot adopt a planar structure. A major departure from planarity in **2** would render the molecule chiral, with the proviso that the oxime is configurationally stable. Previous work indicates that this is certainly the case; thus, the barrier to in-plane nitrogen inversion for methanal oxime has been estimated to be greater than 160 kJ mol^{-1} and the barrier to rotation around the >C=N bond in an oxime is even larger — a value of ca. 210 kJ mol^{-1} has been suggested (2). Optical isomerism of this type has not previously been demonstrated in oximes. There appears to be no *published* discussion of distortions of the 13*H*-dibenzo(*a*,*i*)fluoren-9-one skeleton induced by sterically demanding substituents. However, the structures of **3** and **4**, both of which contain such substituents, have recently been deposited in the Cambridge Structural Database (hereinafter CSD) (3) by Scherschlicht et al. (4) (Scheme 1).

Scheme 1.

Results and discussion

A sample of **2** was made from **1** by established methods (5). X-ray analysis[2] of a twinned crystal reveals a structure built from pairs of hydrogen-bonded molecules (Fig. 1). This $R_2^2(6)$ motif is typical of oxime structures, though other patterns of hydrogen bonding are also found (6), and it underlies their use as well-defined crystalline derivatives of carbonyl compounds.

Conversion of **1** into its oxime **2** distorts the central C1-C2-C11-C12-C21 cyclopentadiene ring into an envelope

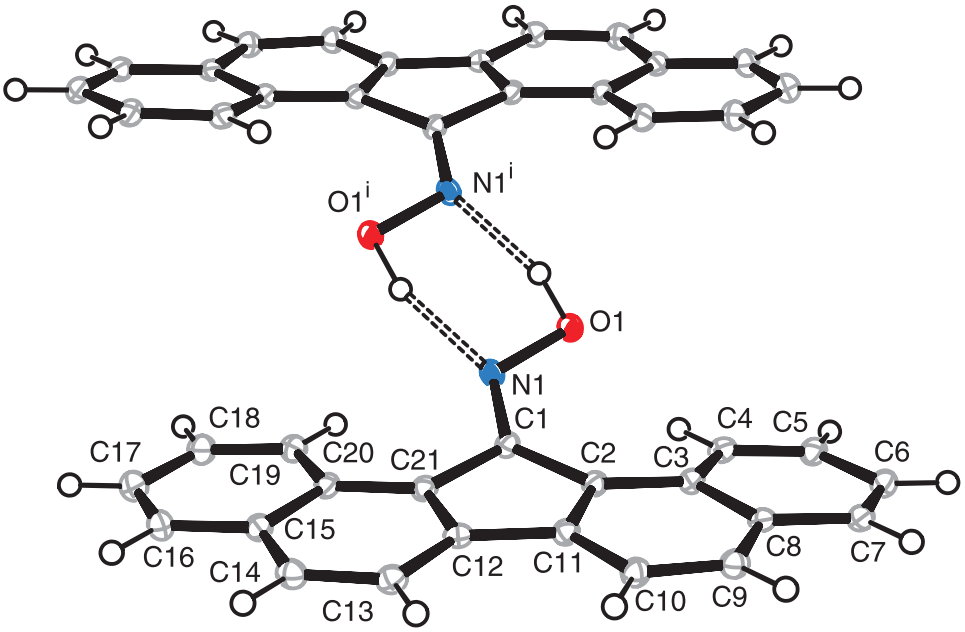
Fig. 1. A view of two centrosymmetrically related molecules of **2** linked by O1-H···N1^{i} hydrogen bonds (O1-H1 (0.97(4) Å), H1···N1^{i} (1.85(4) Å), and O1···N1^{i} (2.786(3) Å)); O1-H1···N1^{i} 161(4)°; $i = 1 - x, -y, -z$]. Probability ellipsoids at 50% are shown. Selected bond lengths and angles : O(1)—N(1) (1.396(2) Å), N(1)—C(1) (1.293(3) Å), C(1)—C(21) (1.488(3) Å), C(1)—C(2) (1.485(3) Å), C(11)—C(12) (1.475(3) Å), C(1)-N(1)-O(1) (114.9(2)°), N(1)-C(1)-C(2) (132.9(2)°), N(1)-C(1)-C(21) (117.5(2)°), O(1)-N(1)-C(1)-C(2) (9.0(4)°), N(1)-C(1)-C(2)-C(3) (–30.5(5)°), and N(1)-C(1)-C(21)-C(20) (24.0(4)°).



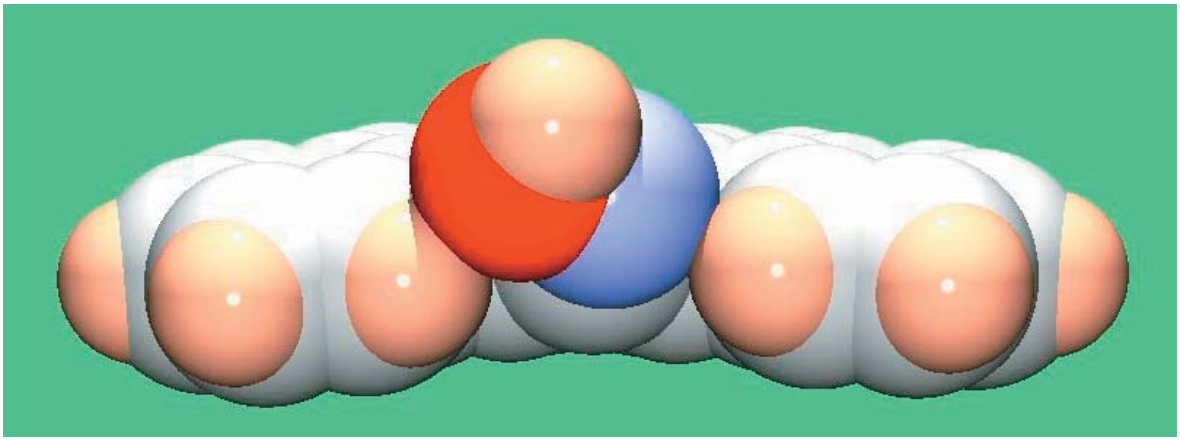


Fig. 2. View of a space-filling model of a molecule of **2**.

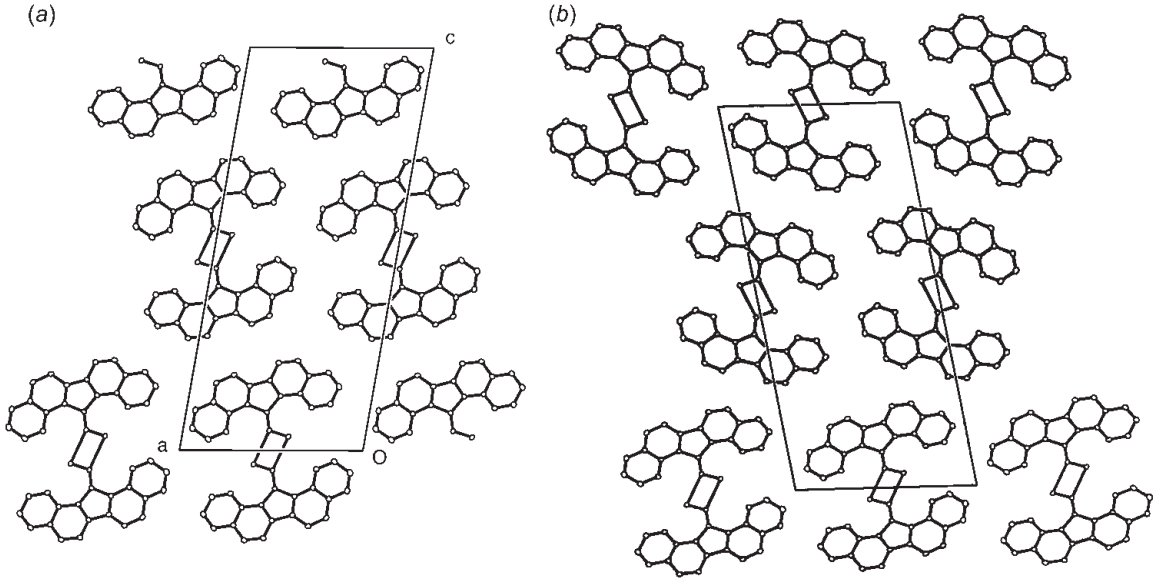

with C1 at the flap: successive endocyclic torsion angles, starting with that across C1-C2, are –11.9(2), 7.9(2), –0.8(3), –6.8(3), and 11.5(2)° in **2**, whereas the corresponding angles in **1** do not exceed 0.4(2)°. This distortion reflects intramolecular overcrowding of the oxime substituent (Fig. 2): the O1···H4 contact of 2.24 Å is particularly short, but that of 2.54 Å between H19 and N1 should also be noted. These interactions are relieved by folding the cyclopentadiene ring across the C2-C21 flap by 11.9(2)° and by a further bending of the C1-N1 vector by 13.9(2)° from the C1-C2-C21 plane. In consequence, the N1-C1-C2-C3 and N1-C1-C21-C20 sequences (respective torsion angles –30.5(5)° and 24.0(4)°) are appreciably nonplanar. From Figs. 1 and 2, it is apparent that the intramolecular overcrowding causes the atom sequence O1-N1-C1-C2-C3-C4 to define a helix and that there is no low energy path between enantiomeric forms of this helix.

The CSD contains 354 ketoxime structures with mean N-O and N=C distances (1.399(1) and 1.282(1) Å), which agree well with values in **2** (1.396(2) and 1.293(3) Å). In **2** the cisoid N1-C1-C2 angle (132.9(2)°) is appreciably more obtuse than the N1-C1-C21 angle (117.5(2)°); this difference is greater than that between the corresponding average values in ketoximes (125.3(1)° and 116.6(1)°) and may reflect the overcrowding in **2**. An unusual feature of **2** is the nonplanarity of the oxime function (O(1)-N(1)-C(1)-C(2) = 9.0(4)°); the average value of this angle in ketoximes is only 1.4(1)° and it exceeds 6° in only three published structures: the largest previously reported value is that of 7.9° for 2′,5′-bis(*O*-trityl)-oximinouridine (7). It should be noted that the

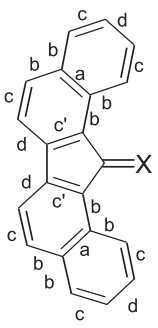
Fig. 3. (*a*) The packing viewed down the *b*-axis. Hydrogen atoms are omitted, but the formation of dimers through N-OH···N hydrogen bonds is indicated. These dimers are repeated by translation along *a* and *b* to form layers parallel to the (001) cell faces. Along *b*, the stacking involves π–π interactions; of these C3···C4 (*x*, *y* – 1, *z*) = 3.313(3) Å is the shortest. Packing between layers is fairly loose; an H7···H7 contact of 2.46 Å represents the closest interlayer interaction. (*b*) A hypothetical composite packing showing how twinning might arise. The bottom layer of molecules is the same as in the previous diagram and the twin boundary is roughly at *z* = 1/4.

direction of this distortion in **2** takes O1 *closer* to C4. **3** contains an envelope-shaped central ring like **2**, though the torsion angle across the exocyclic C=C bond is near zero (2.5(4)°). In **4** there is a twist of nearly 40° about the C=C bond (C-C=C-C torsion angles 37.6(4)° and 42.0(4)°).



Corresponding bond lengths in the naphthalene nuclei of **1**–**4** are compared in Table 1 with those in naphthalene **5** itself (8). The *c′* bonds in the five-membered rings of **1**–**4** are 0.02–0.03 Å longer than other bonds of type *c*. In **2** the nucleus containing C2 through to C11, where steric strain is greater, is less planar (rmsΔ 0.050 Å) than the C12-C21 nucleus (rmsΔ 0.028 Å); these planes define a dihedral angle (τ) of 6.2(1)°.

Table 1. Mean bond lengths (Å) and the dihedral angle (τ°) between the mean naphthalene planes in **1**–**4** (see bond key). Mean bond lengths for naphthalene (**5**) are given for comparison.

Bond	**1**	**2**	**3**	**4**	**5**

Note: (1) Results for **2** and **5** refer to 100 K whereas those for **1**, **3**, and **4** were measured at room temperature and are more likely to be affected by thermal shrinkage. (2) The individual *c′* bonds in **2** differ significantly (see Fig. 1).

Bond key

Nature of the twinning

The crystal structure analysis was based on KappaCCD diffractometric data measured at 100(2) K. Standard computational procedures were used (9). As noted above, crystals of **2** are non-merohedral twins, the separate components being related by rotation about the *a*-axis by 180°. In the final refinement F^2calc = $\alpha F^2(hkl)+(1-\alpha)F^2(h'k'l')$ where $h' = h$, $k' = -k$ and $l' = -0.757h - l$ and $\alpha = 0.634(2)$. Exact overlap occurs only when *h* is divisible by 4. The 982 reflections meeting this condition were used in a preliminary refinement; the resulting F^2calc values were then used to decide whether both twin components contributed to F^2obs of other reflections: specifically, a SHELXL HKLF 5 file was prepared on the basis that all reflections with modulo(*h*,4) = 0 contained contributions from both twin components, all those with modulo(*h*,4) = 2 contained contributions only from the major component, while those with modulo(*h*,4) = 1 or 3 were deemed to contain contributions from both components only if a lower Δ*F* was thereby obtained. This approach allowed 96% of the unique reflections with θ(Mo-*K*α) < 30.2° to be used in a final refinement. The results, not significantly different from the preliminary refinement, have internally consistent bond lengths (Table 1) and thermal parameters that give a satisfactory rigid body analysis: $R(\Delta U^2) = 0.10$ and a maximum difference in the

© 2004 NRC Canada

Hirshfeld rigid bond test of 0.0023(13) $Å^2$ (10). We conclude that systematic error arising from uncertainties in modelling the twinning is probably not significant.

Inspection of the packing down the short *b* axis (Fig. 3) allows the nature of the twinning to be tentatively and qualitatively described. Layers of hydrogen-bonded dimers run parallel to the (001) planes. Successive glide-related layers, rather loosely bound together, propagate the structure in the *c* direction. Figure 3*a* shows the actual structure. Figure 3*b* is a composite, showing the twin boundary. We have previously noted that tertiary alcohols crystallize with unusual frequency in tetragonal and trigonal space groups and often with two or more crystallographically independent molecules. These features help them to saturate their capacity for hydrogen bonding (11). The space groups and crystal systems adopted by the 354 CSD oxime structures show no unusual features, being distributed in much the same way as the contents of the database as a whole.

Conclusions

Previously, certain oximes have been shown to be chiral although their molecules lack stereogenic centres; this was first demonstrated for the oxime of cyclohexanone-4-carboxylic acid (12). The present work indicates that a second class of oxime, exemplified by **2**, which also lacks a stereogenic centre and in which all carbon atoms are sp^2 hybridized, will be chiral by virtue of the nonplanarity of the molecule brought about by steric crowding. However, we have not been able to resolve **2** because insufficient material was available to us.

Syntheses and electropolymerization behavior of ethylenedioxythiophene-substituted silanes

M'hamed Chahma and Robin G. Hicks

Abstract: Silicon-bridged thiophene oligomers have been prepared via the reactions of lithiated (3,4-ethylenedioxy)thiophene (EDOT) (**1**) or 2,2′-bis-(3,4-ethylenedioxy)thiophene (biEDOT) (**2**) with dichlorodimethylsilane to afford bis-(2,3-dihydro-thieno[3,4-*b*][1,4]dioxin-5-yl)-dimethylsilane (**3**) and dimethyl-bis-(2,3,2′,3′-tetrahydro-[5,5′]bi[thieno[3,4-*b*][1,4]dioxinyl]-7-yl)silane (**4**). Products **3** and **4** were characterized and show good stability in organic solvent and in air. The electropolymerization of these monomers affords stable and highly conducting polymers. The conductivity was found to be 25 and 60 S/cm for **Poly3** and **Poly4**, respectively. Characterization data for the polymers suggested that the resulting materials have a backbone identical to p(EDOT), which formed through cleavage of the silicon–carbon (Si—C) bonds during electropolymerization.

Key words: polythiophenes, EDOT, silicon, electropolymerization, Si—C bond cleavage, conductivity.

Résumé : Faisant appel à des réactions de (3,4-éthylènedioxy)thiophène (EDOT) (**1**) ou de 2,2′-bis-(3,4-éthylènedioxy)thiophène (biEDOT) avec du dichlorodiméthylsilane, on a préparé des oligomères de thiophène avec pont de silicium, les bis-(2,3-dihydro-thiéno[3,4-*b*][1,4]dioxin-5-yl)diméthylsilane (**3**) et diméthyl-bis-(2,3,2′,3′-tétrahydro-[5,5′]bi[thiéno[3,4-*b*][1,4]dioxinyl]-7-yl)silane (**4**). Les produits **3** et **4** ont été caractérisés et présentent une bonne stabilité dans les solvants organiques et dans l'air. L'électropolymérisation de ces monomères conduit à des polymères stables et très bons conducteurs. On a trouvé que les conductivités respectives des **Poly3** et **Poly4** sont de 25 et 60 S/cm. Les données de caractérisation des polymères suggèrent que les produits obtenus possèdent un squelette identique à celui du p(EDOT) qui se forme par clivage des liaisons silicium–carbone (Si—C) au cours de l'électropolymérisation.

Mots clés : polythiophènes, EDOT, silicium, électropolymérisation, clivage de la liaison Si—C, conductivité.

Introduction

Polythiophene and its derivatives are widely used in transistors (1–3), light emitting diodes (4), electroluminescent devices (5, 6), photovoltaic cells (7), and bioelectrochemical sensors (8, 9). Despite the existence of a wide variety of thiophene monomers, the preparation of novel thiophene motifs remains a quest for many scientists as part of the search for new materials with properties such as low band gaps, electrochromism ranges, etc. One derivative of thiophene that has become immensely popular is 3,4-ethylenedioxy)thiophene (EDOT) (**1**) (10). The corresponding polymer, p(EDOT), is exceptionally stable in its doped state and highly conducting. It also exhibits a low oxidation potential with respect to classical polythiophene derivatives (11). Recently, Wudl and co-workers reported that p(EDOT) have promising applications in the field of "plastic electronics" (12, 13).

1

Different strategies have been used to synthesize new polymers incorporating EDOT. For example, the incorporation of alkyl chains in the ethylene moiety increases the solubility and conductivity of the corresponding polymers (14). Another approach involves polymers consisting of alternating EDOT with aryl groups (e.g., benzene, furan, carbazole) to provide a large range of redox and optical properties (15–17). Hybrid conjugated organic EDOT – metal-containing polymers have also been explored (18, 19). Another recent approach has been the incorporation of main group elements. We recently synthesized a monomer bis(3,4-ethylenedioxy-2-thienyl)sulfide in which two EDOT moieties are connected to a divalent sulfur atom; its corresponding polymer exhibits high electrochemical stability in its oxidized and reduced states and good conductivity for a nonconjugated polymer (20).

Other main group elements have been introduced into conducting polymer systems, including silicon. Ferraris and co-workers (21) prepared bridged bithiophenes linked by

dimethylsilyl units for which the corresponding polymers exhibited interesting electrochromic properties, and silicon has also been incorporated into oligo- and poly(siloles) (22–24). We became interested in the possibility of preparing EDOT-based polymers linked by simple (nonheterocyclic) silane groups. To this end, herein we present the synthesis of new monomers based on EDOT and biEDOT motifs linked via silicon.

Result and discussion

Synthesis and characterization of "monomers"

The lithiated salt of EDOT **1** and biEDOT **2** reacts with Me_2SiCl_2 to afford silicon-bridged thiophenes **3** and **4** in high yield (Scheme 1). Product **3** was purified via column chromatography on silica gel, but product **4** decomposed on attempted chromatography and so was purified by precipitation using pentane. Products **3** and **4** are air-stable in the solid state and solution, in air and in the presence of organic solvents.

In CH_2Cl_2, compounds **1**–**4** exhibit single irreversible oxidation waves at potentials of +1.60, 1.04, 1.63, and 1.02 V (vs. Ag/AgCl*),* respectively, as shown in Fig. 1 for monomers **1** and **3**. No significant differences in oxidation potentials were observed between **1** and **3** and similar behavior was observed in the case of **2** and **4**. The presence of the silicon element, therefore, does not strongly affect the oxidation peak potential of thiophenes. The oxidation peak potential of the monomers and the oxidation potential of the corresponding polymers are summarized in Table 1. Also shown in Table 1 are the solution λ_{max} from the electronic spectra of the monomers. In comparing each "parent" EDOT and bi EDOT with their corresponding silicon derivatives (**1** vs. **3** and **2** vs. **4**), it can be seen that the absorption maxima are identical (25).[2] These results are in agreement with the electrochemical data; silanes do not effect the electronic configurations of these monomers.

Electrochemcial polymerization and polymer properties

The electrochemical polymerizations of monomers **1**, **3**, and **4** (0.01 mol/L) were carried out in CH_2Cl_2 (the low solubility of **3** and **4** precluded performing these experiments in more polar solvents) containing 1 mol/L $(n\text{-Bu})_4NBF_4$ via repeated electrochemical cycling at the oxidation potential of the monomers using a scan rate of 0.1 V/s. The relatively

[2]The absorption maxima for **2** differ from the literature values of 313, 319, and 305nm in ref. 29. This may be due to solvent effects; the previous literature spectrum was obtained in chloroform while ours was obtained in dichloromethane. In support of this we note that a *a*,*w*-dihexyl-substituted biEDOT has been reported (25) that has a nearly identical UV–vis solution spectrum (λ_{max} 333, 349 nm) to our data of of **2** in CH_2Cl_2. The hexyl groups are not expected to exert a measurable electronic effect on the electronic spectrum.

Scheme 2.

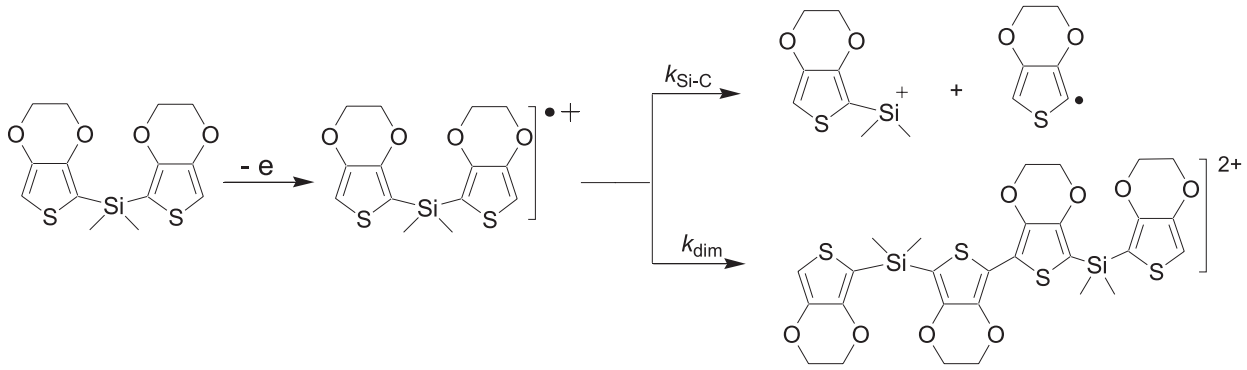

Fig. 2. Electropolymerization of **4** in CH_2Cl_2 at a 100 mV/s scan rate.

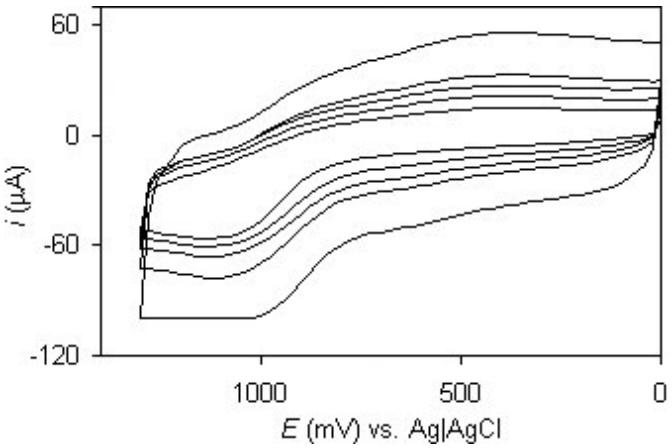

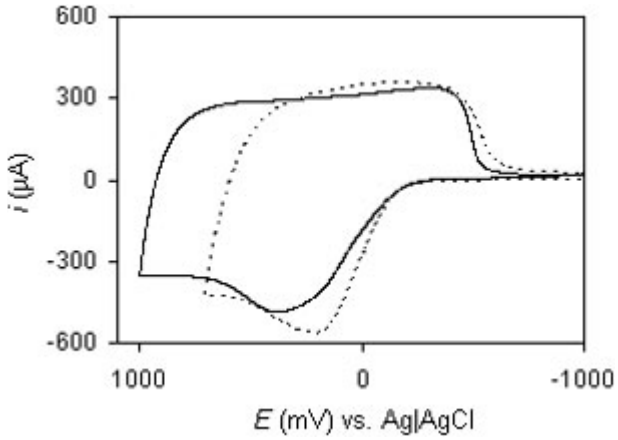

Fig. 3. CV of **Poly1** (solid line) and **Poly4** (dashed line) on a Pt electrode at 100 mV/s in CH_2Cl_2.

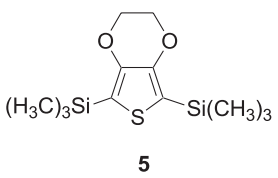
high supporting electrolyte concentration of 1 mol/L was employed for the electropolymerization process because at this concentration, the current of the platinum-modified electrode remained constant after 100 scans, which shows a good adhesion and stability of the polymer on the surface of the electrode. Figure 2 shows a typical cyclic voltammetry (CV) curve for the electropolymerization of **4**. A new reversible wave appears at a more negative potential, which corresponds to the formation and deposition of the polymer onto the surface of the platinum electrode.

The electrochemical properties of the platinum-modified electrodes were studied in monomer-free solutions. Cyclic voltammograms of **Poly1** and **Poly4** are shown in Fig. 3. **Poly1**-, **Poly3**-, and **Poly4**-modified platinum electrodes all exhibit a broad reversible wave and are qualitatively very similar. The oxidation potentials ($E_{1/2}$ is the average of peak oxidation and reduction potentials) of **Poly1**, **Poly3**, and **Poly4** were similar and were found to be in the range –0.100 and +0.150 V (vs. Ag/AgCl). The electropolymerization of **1** follows an *E*(CE)n mechanism in which the first step is the formation of the radical cation (26, 27), which is further engaged in a chain process that leads to **Poly1** after the expulsion of protons. Following the oxidation of **3** (shown in Scheme 2) and **4**, the resulting carbocations $\mathbf{3}^{\cdot+}$ and $\mathbf{4}^{\cdot+}$ will further be engaged either in a Si—C bond cleavage or a dimerization process. The putative dimer $[\mathbf{3}–\mathbf{3}]^{2+}$ (to the extent that it is formed) is also susceptible to Si—C bond cleavage reactions. Ultimately, all of the silicon is extruded during the electropolymerization, leading to **Poly3** whose identity is very likely similar in structure to pEDOT (see the following).

Hapiot et al. (28) have reported the dimerization of the carbocation resulting from bithiophene substituted by a trimethylsilyl group in position 2, 2′ (Me_3Si-2T-$SiMe_3$) to afford a dimer $(Me_3Si\text{-}4T\text{-}SiMe_3)^{2+}$. They also reported that the desilylation depends on the nature of the solvent and on the number of thiophenes end-capped by the silyl group (28). The electrochemical properties of the polymers derived from **3** and **4** do not, in and of themselves, permit an assessment of their chemical composition.



Reynolds and co-workers (29) reported the electropolymerization in acetonitrile for related silane-substituted EDOT compounds **5** and **6**. They found that after the formation of the radical cation, the electropolymerization is initiated by a Si—C cleavage and the leaving group was the trimethylsilyl cation. The loss of a trimethyl silyl group is identical to the loss of a proton in the conventional polymerizations of EDOT and thiophenes. Moreover, they reported that the film resulting from desilylation had a rapid response time in optical switching rates and better adhesion on the surface of the electrode than the resulting polymer from the direct electropolymerization of naked EDOT (29).

Other characterization data point to a common structure for all polymers. The UV–vis spectra for the neutral films of **Poly1**, **Poly3**, and **Poly4** on indium tin oxide (ITO) are tabulated in Table 2 and shown in Fig. 4. All spectra possess absorption peaks in the range 400–500 nm for all undoped polymers, which proves that the backbones of **Poly1**, **Poly3**, and **Poly4** are very similar in nature. No significant differences were observed in the IR spectra of **Poly1**, **Poly3**, and **Poly4**. Most telling is the fact that the elemental analyses of **Poly3** and **Poly4** shows that the amount of silicon present in the polymers is negligible (<0.3%).

The electrical conductivity was measured using a four-point method on a pellet. As shown in Table 2, **Poly1**, **Poly3**, and **Poly4** are highly conducting in comparison to others formed via other chemical polymerizations, i.e., $FeCl_3$ (12, 30), or by solid state polymerization (13). The maximum conductivity was found to be 60 S/cm for **Poly4**. On the other hand, the conductivity of **Poly3**, (25 S/cm) was ranging by half of that and may be due to less ordering in the backbone of the polymer after the Si—C bond cleavage of the $\mathbf{3}^{\cdot+}$.

Conclusions

We have reported the synthesis of organosilanes based on (3,4-ethylenedioxy)thiophene and 2,2′-bis-(3,4-ethylenedioxy)thiophene. The presence of silicon does not perturb the fundamental electrochemical and optical properties of the EDOT chromophores. Electrochemical polymerizations of **3** and **4** proceed via Si—C bond cleavage to afford stable, highly conducting polymers that are in all likelihood p(EDOT). Subtle differences in the properties of the polymers derived from the different monomers are probably due to chain length and (or) morphological effects. This is consistent with previously reported work on EDOT-silanes (29) and reinforces the observation that the silane – aromatic carbon bond in EDOT is highly reactive under the conventional electropolymerization conditiaions. This provides an interesting contrast to silanes containing unsubistuted thiophenes, which appear to be electropolymerizable with retention of the thiophene–silicon skeleton in the resulting polymers (21).

Fig. 4. UV–vis of different polymers reduced by hydrazine hydrate in CH_2Cl_2.

Experimental section

Materials and reagents

All reagents were purchased from Aldrich and used as received. biEDOT (2) was prepared according to a literature method (29). Solvents were dried and distilled under argon prior to use (CH_2Cl_2, CaH_2, THF, Na–benzophenone).

Physical methods

NMR spectra (^1H, ^{13}C, ^{29}Si NMR) were obtained on an AMX 300 MHz Bruker. IR spectra were recorded on a PerkinElmer FT-IR spectrometer. UV–vis data were collected on a Cary 100 SCAN spectrophotometer. The electrochemical experiments were performed using a CV-50 W voltammetric analyzer (BAS) at room temperature (22 ± 2 °C). Voltammetric measurements were performed in CH_2Cl_2 containing 1 mol/L of n-Bu_4NBF_4. The platinum electrode (BAS, diameter 1.6 mm) was used as working electrode. Platinum wire and Ag/AgCl were used as auxiliary and reference electrodes, respectively. The reference electrode was calibrated vs. the ferrocene/ferrocenium redox (E^0 = 0.580 vs. Ag/AgCl) internal reference. The working electrode was polished on alumina before use. *iR* compensations were applied for all experiments. The bulk electrolyses were performed using a controlled potential in a cell with one compartment using a platinum plate (3 cm^2) as the cathode and anode. The electrical conductivity was estimated using a four-point method.

Synthesis of bis-(2,3-dihydro-thieno[3,4-*b*][1,4]dioxin-5-yl)-dimethylsilane (3)

To a solution of EDOT (2.10 g, 14.8 mmol) dissolved in 50 mL of THF under argon was added 7.4 mL (14.8 mmol) of *n*-BuLi (2 mol/L) dropwise. After stirring for 1 h at room temperature, the mixture was cooled to –78 °C. Dichlorodimethylsilane (0.98 g, 7.6 mmol) was added dropwise and the mixture was stirred for a further 3 h at –78 °C followed by 21 h at room temperature. The mixture was then poured

into 100 mL of water and the product was extracted using 2 × 100 mL portions of CH_2Cl_2. The organic layers were combined and dried over $MgSO_4$. After evaporation of the solvent, the product was purified by chromatography on silica gel using CH_2Cl_2 as the eluent. The product was colorless and crystallized slowly after a few weeks affording a yield of 75% (1.9 g, 5.6 mmol). ^{1}H NMR (CD_2Cl_2, 300 MHz) (ppm) δ: 0.60 (s, 6H), 4.20 (m, 8H), 6.60 (s, 2H). ^{13}C NMR (CD_2Cl_2, 75 MHz) (ppm) δ: –1.20, 64.7, 64.8, 106.1, 109.1, 142.8, 148.2. ^{29}Si NMR ($CDCl_3$, 100 MHz) (ppm) δ: –16.83. MS LSI-MS *m*/*z*: 340 (M^+, 100%). HR-MS (EI) calcd. for $C_{14}H_{16}S_2O_4Si$ [M^+]: 340.0259; found: 340.0262.

Synthesis of dimethyl-bis-(2,3,2′,3′-tetrahydro-[5,5′]bi[thieno[3,4-*b*][1,4]dioxinyl]-7-yl)-silane (4)

To a solution of biEDOT (1.52 g, 5.4 mmol) dissolved in 50 mL of THF under argon was added 2.7 mL (5.40 mmol) of *n*-BuLi (2 mol/L) dropwise. After stirring for 1 h at room temperature, the mixture was cooled at –78 °C. Dichlorodimethylsilane (0.38 g, 2.9 mmol) was added dropwise and the mixture was stirred for a further 3 h at –78 °C and then for 21 h at room temperature. Following that, the mixture was poured in 100 mL of water and the product was extracted using 2 × 100 mL portions of diethyl ether. The organic layers were combined and dried over $MgSO_4$. After evaporation of ether, the crude was dissolved in acetone, and precipitated by adding pentane and freezing the mixture overnight. A pale yellow solid was formed (1.2 g, 1.9 mmol) in a 70% yield. ^{1}H NMR ($CDCl_3$, 300 MHz) (ppm) δ: 0.60 (s, 6H), 4.30 (m, 16H), 6.20 (s, 2H). ^{13}C NMR ($CDCl_3$, 75 MHz) (ppm) δ: –0.9, 64.6, 64.8, 64.9, 65.2, 97.9, 106.4, 110.4, 115.8, 137.5, 138.0, 141.4, 147.5. ^{29}Si NMR ($CDCl_3$, 100 MHz) (ppm) δ: –17.12. MS LSI-MS *m*/*z*: = 620 (M^+, 100%). HR-MS (EI) calcd. for $C_{26}H_{24}S_4O_8Si$ [M^+]: 620.0123; found: 620.0116.

Electrosynthesis of the polymers

Poly1, **Poly3**, and **Poly4** were prepared by controlled potential electrolysis in CH_2Cl_2 containing 1 mol/L of *n*-Bu_4NBF_4. The concentration of the monomer was 0.01 mol/L. At the end of the electrolysis, a dark film formed on the surface of the electrode. The film was removed from the electrode and washed with 500 mL of CH_2Cl_2 and dried under vacuum for 30 h. **Poly1**: yield 80%. Anal. calcd. for $C_6H_4O_2S_1B_{0.67}F_{2.8}$ (%): C 36.36, H 2.04, S 16.18; found (%): C 36.90, H: 2.64, S 18.08. **Poly3**: yield 76%. Anal. calcd. for $C_6H_4O_2S_1B_{0.40}F_{1.6}$ (%): C 41.24, H 2.31, S 18.35; found: C 41.13, H 2.71, S 18.14. **Poly4**: yield 85%. Anal. calcd. for $C_6H_4O_2S_1B_{0.45}F_{1.8}$ (%): C 40.24, H 2.25, S 17.91; found: C 40.07, H 2.56, S 18.41.

Group IV phosphinimide amide complexes

Emily Hollink, Pingrong Wei, and Douglas W. Stephan

Abstract: Complexes of formula $TiCp(NPR_3)(NMe_2)_2$ (R = *t*-Bu **1**, Ph **2**) were prepared via salt metathesis of $TiCp(NPR_3)Cl_2$ with a slight excess of $LiNMe_2$. The species $Ti(NP\text{-}t\text{-}Bu_3)(NMe_2)_3$ (**3**) was obtained as a by-product. The related derivative $ZrCp(NP\text{-}t\text{-}Bu_3)(NMe_2)_2$ (**4**) was also prepared. Reaction of $TiCp(NP\text{-}t\text{-}Bu_3)Cl_2$ with $LiNHC_6H_3(2,6\text{-}i\text{-}Pr_2)$ afforded $TiCp(NP\text{-}t\text{-}Bu_3)(NHC_6H_3(2,6\text{-}i\text{-}Pr_2))Cl$ (**5**) and $Ti(NP\text{-}t\text{-}Bu_3)(NHC_6H_3(2,6\text{-}i\text{-}Pr_2))_3$ (**6**). In a similar manner, the Zr analogs $ZrCp(NP\text{-}t\text{-}Bu_3)(NHC_6H_3(2,6\text{-}i\text{-}Pr_2))Me$ (**7**) and $ZrCp(NP\text{-}t\text{-}Bu_3)(NHC_6H_3(2,6\text{-}i\text{-}Pr_2))_2$ (**8**) were also prepared. X-ray structural data for compounds **5**, **6**, and **8** are reported. Reactivity of these phosphinimide–amide derivatives was explored. While these species do not yield imide derivatives upon thermolysis, reaction of **5** with excess $AlMe_3$ afforded $TiCp(NP\text{-}t\text{-}Bu_3)Me_2$ while reaction with 1 equiv. of $AlMe_3$ gave $TiCp(NP\text{-}t\text{-}Bu_3)MeCl$ (**9**) and $Al_2(m\text{-}NHC_6H_3(2,6\text{-}i\text{-}Pr_2))_2Me_4$ (**10**).

Key words: titanium, zirconium, phosphinimide, amide, ligand metathesis.

Résumé : On a préparé des complexes de formule $TiCp(NPR_3)(NMe_2)_2$ (R = *t*-Bu **1**, Ph **2**) par la métathèse du sel de $TiCp(NPR_3)Cl_2$ avec un léger excès de $LiNMe_2$. On a obtenu l'espèce $Ti(NP\text{-}t\text{-}Bu_3)(NMe_2)_3$ (**3**) comme sous-produit. On a aussi préparé le dérivé apparenté $ZrCp(NP\text{-}t\text{-}Bu_3)(NMe_2)_2$ (**4**). La réaction du $TiCp(NP\text{-}t\text{-}Bu_3)Cl_2$ avec du $LiNHC_6H_3(2,6\text{-}i\text{-}Pr_2)$ conduit à la formation de $TiCp(NP\text{-}t\text{-}Bu_3)(NHC_6H_3(2,6\text{-}i\text{-}Pr_2))Cl$ (**5**), et de $Ti(NP\text{-}t\text{-}Bu_3)(NHC_6H_3(2,6\text{-}i\text{-}Pr_2))_3$ (**6**). Opérant de la même façon, on a aussi préparé les analogues $ZrCp(NP\text{-}t\text{-}Bu_3)(NHC_6H_3(2,6\text{-}i\text{-}Pr_2))Me$ (**7**) et $ZrCp(NP\text{-}t\text{-}Bu_3)(NHC_6H_3(2,6\text{-}i\text{-}Pr_2))_2$ (**8**). On a déterminé les structures des composés **5**, **6** et **8** par diffraction des rayons X. On a examiné la réactivité de ces dérivés phosphinimide–amides. Alors que la thermolyse de ces espèces ne conduit pas à des dérivés imides, la réaction de **5** avec un excès de $AlMe_3$ conduit à la formation de $TiCp(Np\text{-}t\text{-}Bu_3)Me_2$ alors que la réaction avec un équivalent de $AlMe_3$ fournit les composés $TiCp(Np\text{-}t\text{-}Bu_3)MeCl$ (**9**) et $Al_2(\mu\text{-}NHC_6H_3(2,6\text{-}i\text{-}Pr_2))_2Me_4$ (**10**).

Mots clés : titane, zirconium, phosphinimide, amide, métathèse de ligand.

[Traduit par la Rédaction]

Introduction

Group IV amide complexes have received enormous attention because of their remarkable diversity, serving as precursors for imido derivatives (1–5), olefin polymerization catalysts (6–11), precursors in chemical vapour deposition processes (12–18), and as hydroamination (pre)catalysts (19–22). In addition, the propensities of Ti- (23–25) or Zr- (2, 3, 26, 27) imide complexes to effect C-H activation and hydroamination (21) are the subject of theoretical (28, 29) and experimental interest. In our own work, we have demonstrated that phosphinimide ligands can replace cyclopentadienyl ligand derivatives to give highly active olefin polymerization catalysts (30–32). Studies of the structure–reactivity relationship have shown that a range of sterically demanding phosphinimide ligands provide effective catalysts (33–38), whereas sterically less-demanding ligands prompt novel reactivity with Lewis acids including C-H activation processes (39–41). In an effort to broaden the range of reactivity of group IV phosphinimide complexes, we undertook the syntheses of phosphinimide–amide complexes. In this manuscript we describe the syntheses, characterization, and our initial studies of the reactivity of the group IV phosphinimide–amide complexes. These systems are compared with the metallocene analogs.

Experimental

All syntheses were performed employing an atmosphere of dry, oxygen-free nitrogen in a Vacuum Atmospheres inert atmosphere glove box or standard Schlenk techniques using oven-dried (140 °C) glassware unless otherwise stated. ^1H NMR data were acquired on a Bruker Avance 500 MHz spectrometer, while ^{13}C and ^{31}P NMR data were obtained from a Bruker Avance 300 MHz spectrometer. ^1H and ^{13}C chemical shifts are listed relative to $SiMe_4$ in ppm and were referenced to the residual proton or carbon peak of the solvent. ^{31}P NMR data were referenced using 85% H_3PO_4 as an external standard. All NMR spectra were recorded in C_6D_6 unless otherwise noted. University of Windsor Analytical Services, using a Perkin Elmer 2400 Series II instrument, performed the combustion analyses. Despite repeated attempts, carbon analyses for Zr complexes consistently gave systematically low values as a result of the formation of ZrC (i.e., incomplete combustion). Reagent grade solvents were purchased from Aldrich Chemical Co. and were predried using Grubbs' column systems, manufactured by Innovative

Technologies, Inc. (42). Deuterated benzene, toluene, and methylene chloride were purchased from Canadian Isotopes Laboratories and degassed by at least four freeze–pump–thaw cycles before storing over 4 Å molecular sieves. The reagents *n*-BuLi (2.0 mol L^{-1} in hexanes), Al_2Me_6, $TiCp_2Cl_2$, $LiNMe_2$, and $NH_2C_6H_3(2,6\text{-}i\text{-}Pr_2)$ were purchased from Aldrich Chemical Co. $NH_2C_6H_3(2,6\text{-}i\text{-}Pr_2)$ was vacuum distilled from KOH, and all other reagents were used without further purification. The compounds $Ti(NP\text{-}t\text{-}Bu_3)Cl_3$ (37) and $TiCp(NP\text{-}t\text{-}Bu_3)Cl_2$ (32) were prepared according to literature methods, and $LiNHC_6H_3(2,6\text{-}i\text{-}Pr_2)$ was prepared via a modification of a literature procedure (43).

Synthesis of $TiCp(NP\text{-}t\text{-}Bu_3)(NMe_2)_2$ (1) and $TiCp(NPPh_3)(NMe_2)_2$ (2)

These compounds were prepared in a similar fashion and thus one preparation is detailed. Solid $LiNMe_2$ (46 mg, 0.90 mmol) was added in several portions to a clear solution of $TiCp(NP\text{-}t\text{-}Bu_3)Cl_2$ (179 mg, 0.45 mmol) in benzene (20 mL). The slurry was stirred for 20 h, after which time the mixture was filtered through Celite. The solvent was removed in vacuo affording a bright orange solid. The residue was washed with pentanes (3 × 5 mL) and dried to afford a fine, orange powder (126 mg, 67%). Small quantities (typical yields ca. 10%–15%) of the by-product $Ti(NP\text{-}t\text{-}Bu_3)(NMe_2)_3$ (**3**) were isolated from the pentane washings (**1**). For **1**: ^{1}H NMR δ: 6.18 (s, 5H, Cp), 3.28 (s, 12H, NMe_2), 1.24 (d, 27H, $^3J_{P\text{-}H}$ = 13 Hz, *t*-Bu). ^{13}C NMR δ: 109.7, 50.5, 40.6 (d, $^1J_{P\text{-}C}$ = 28 Hz), 29.7. ^{31}P NMR δ: 28.9. Anal. calcd. for $C_{21}H_{44}N_3PTi$ (%): C 60.42, H 10.62, N 10.07; found: C 60.34, H 10.52, N 9.67. For **2**: yellow solid (312 mg, 77%). ^{1}H NMR δ: 7.75 (m, 6H, Ph), 7.06 (m, 9H, Ph), 5.99 (s, 5H, Cp), 3.34 (s, 12H, NMe_2). ^{13}C NMR δ: 135.9 (d, $^1J_{P\text{-}C}$ = 58 Hz), 132.4 (d, $^2J_{P\text{-}C}$ = 6 Hz), 128.3, 128.6 (d, $^3J_{P\text{-}C}$ = 7 Hz), 109.8, 50.1. ^{31}P NMR δ: –9.3. Anal. calcd. for $C_{27}H_{32}N_3PTi$ (%): C 67.93, H 6.76, N 8.80; found: C 67.67, H 6.54, N 8.52.

Synthesis of $Ti(NP\text{-}t\text{-}Bu_3)(NMe_2)_3$ (3)

A slurry of $LiNMe_2$ (44 mg, 0.87 mmol) in benzene (1 mL) was added to a suspension of $Ti(NP\text{-}t\text{-}Bu_3)Cl_3$ (105 mg, 0.28 mmol) in the same solvent (10 mL). After stirring for 12 h at 25 °C, the mixture was filtered through Celite. Removal of the solvent in vacuo afforded an orange crystalline solid (83 mg, 75%). ^{1}H NMR δ: 3.40 (s, 18H, NMe_2), 1.27 (s, 27H, $^3J_{P\text{-}H}$ = 13 Hz, *t*-Bu). ^{13}C NMR δ: 46.3, 39.9 (d, $^1J_{P\text{-}C}$ = 48 Hz), 29.5. ^{31}P NMR δ: 29.8. Anal. calcd. for $C_{18}H_{45}N_4PTi$ (%): C 54.54, H 11.44, N 14.13; found: C 54.74, H 11.63, N 13.78. Deep orange-red crystals suitable for X-ray diffraction were grown by slow evaporation from hexanes–pentanes.

Synthesis of $ZrCp(NP\text{-}t\text{-}Bu_3)(NMe_2)_2$ (4)

Solid $LiNMe_2$ (193 mg, 3.6 mmol) was added in several portions at 25 °C to a clear solution of $ZrCp(NP\text{-}t\text{-}Bu_3)Cl_2$ (411 mg, 0.90 mmol) in benzene (50 mL). The slurry was stirred for 18 h and was subsequently filtered through Celite. The solvent was removed in vacuo affording **4** as a fine, white powder (340 mg, 82%). ^{1}H NMR δ: 6.32 (s, 5H, Cp), 3.14 (s, 12H, NMe_2), 1.21 (s, 27H, $^3J_{P\text{-}H}$ = 12 Hz, *t*-Bu). ^{13}C NMR δ: 109.6, 46.3, 39.9 (d, $^1J_{P\text{-}C}$ = 48 Hz), 29.6. ^{31}P NMR δ: 31.4. Anal. calcd. for $C_{21}H_{44}N_3PZr$ (%): C 54.74, H 9.62, N 9.12; found: C 53.73, H 9.64, N 8.49.

Synthesis of $TiCp(NP\text{-}t\text{-}Bu_3)(NHC_6H_3(2,6\text{-}i\text{-}Pr_2))Cl$ (5)

Solid $LiNHC_6H_3(2,6\text{-}i\text{-}Pr_2)$ (1.51 g, 12.2 mmol) was added in small portions at 25 °C over a 1 h period to a clear solution of $TiCp(NP\text{-}t\text{-}Bu_3)Cl_2$ (4.91 g, 12.2 mmol) in benzene (150 mL). The slurry was stirred for 20 h, after which time the mixture was filtered through Celite. The solution was concentrated in vacuo to ca. 20 mL, during which time a bright yellow solid precipitated. The solid was filtered, washed with pentanes (3 × 20 mL), and dried to afford a fine, yellow powder (5.94 g, 89%). ^{1}H NMR δ: 9.65 (br, 1H, NH), 7.23 (br, 2H, C_6H_3 (*m*-H)), 7.05 (t, 1H, $^3J_{H\text{-}H}$ = 7 Hz, C_6H_3 (*p*-H)), 6.21 (s, 5H, Cp), 3.26 (sep, 2H, $^3J_{H\text{-}H}$ = 7 Hz, *i*-Pr), 1.39 (d, 12H, $^3J_{H\text{-}H}$ = 7 Hz, *i*-Pr), 1.19 (d, 27H, $^3J_{P\text{-}H}$ = 13 Hz, *t*-Bu). ^{13}C NMR δ: 153.9, 128.3, 123.3, 123.1, 112.8, 41.5 (d, $^1J_{P\text{-}C}$ = 27 Hz), 29.5, 28.1, 22.6. ^{31}P NMR δ: 39.0. Anal. calcd. for $C_{29}H_{50}ClN_2PTi$ (%): C 64.38, H 9.32, N 5.18; found: C 63.95, H 9.06, N 4.74. Bright yellow crystals suitable for X-ray diffraction were grown by slow evaporation from benzene.

Synthesis of $Ti(NP\text{-}t\text{-}Bu_3)(NHC_6H_3(2,6\text{-}i\text{-}Pr_2))_3$ (6)

A slurry of $LiNHC_6H_3(2,6\text{-}i\text{-}Pr_2)$ (591 mg, 4.8 mmol) in benzene (20 mL) was added over a 0.5 h period at 25 °C to a clear solution of $TiCp(NP\text{-}t\text{-}Bu_3)Cl_2$ (380 mg, 0.96 mmol) in the same solvent (25 mL). The slurry was stirred for an additional 10 h, then filtered through Celite. The solvent was removed in vacuo, and the residue was washed with hexanes (3 × 10 mL) to afford a yellow solid (586 mg, 77%). ^{1}H NMR δ: 7.80 (br, 3H, NH), 7.11 (d, 6H, $^3J_{H\text{-}H}$ = 8 Hz, C_6H_3 (*m*-H)), 6.96 (t, 3H, $^3J_{H\text{-}H}$ = 8 Hz, C_6H_3 (*p*-H)), 3.70 (sep, 6H, $^3J_{H\text{-}H}$ = 7 Hz, *i*-Pr), 1.28 (d, 36H, $^3J_{H\text{-}H}$ = 7 Hz, *i*-Pr), 1.06 (d, 27H, $^3J_{P\text{-}H}$ = 13 Hz, *t*-Bu). ^{13}C NMR δ: 150.9, 137.6, 123.0, 120.8, 40.6 (d, $^1J_{P\text{-}C}$ = 46 Hz), 29.4, 29.2, 24.1. ^{31}P NMR δ: 37.4. Anal. calcd. for $C_{48}H_{81}N_4PTi$ (%): C 72.70, H 10.30, N 7.06; found: C 72.49, H 10.60, N 7.28. Deep red crystals suitable for X-ray diffraction were grown by slow evaporation from benzene.

Synthesis of $ZrCp(NP\text{-}t\text{-}Bu_3)(NHC_6H_3(2,6\text{-}i\text{-}Pr_2))Me$ (7)

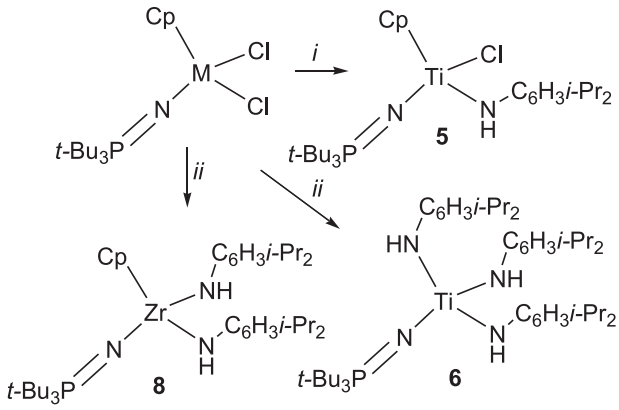
$NH_2C_6H_3(2,6\text{-}i\text{-}Pr_2)$ (58 mL, 0.31 mmol) was added dropwise to a clear solution of $ZrCp(NP\text{-}t\text{-}Bu_3)Me_2$ (125 mg, 0.31 mmol) in benzene (20 mL) at 25 °C. After stirring for 12 h, the volatile products were removed in vacuo to afford a beige solid (162 mg, 92%). ^{1}H NMR δ: 7.21 (d, 2H, $^3J_{H\text{-}H}$ = 8 Hz, C_6H_3 (*m*-H)), 7.04 (t, 1H, $^3J_{H\text{-}H}$ = 8 Hz, C_6H_3 (*p*-H)), 6.51 (br, 1H, NH), 6.20 (s, 5H, Cp), 3.45 (sep, 2H, $^3J_{H\text{-}H}$ = 7 Hz, *i*-Pr), 1.36 (d, 6H, $^3J_{H\text{-}H}$ = 7 Hz, *i*-Pr), 1.35 (d, 6H, $^3J_{H\text{-}H}$ = 7 Hz, CMe_2H), 1.13 (d, 27H, $^3J_{P\text{-}H}$ = 13 Hz, *t*-Bu), 0.47 (s, 3H, ZrMe). ^{13}C NMR δ: 150.9, 137.7, 122.7, 120.1, 110.0, 40.0 (d, $^1J_{P\text{-}C}$ = 47 Hz), 29.0, 27.9, 27.9, 23.8, 22.8. ^{31}P NMR δ: 34.3. Anal. calcd. for $C_{30}H_{53}N_2PZr$ (%): C 63.89, H 9.47, N 4.97; found: C 62.84, H 9.43, N 4.90.

Synthesis of $ZrCp(NP\text{-}t\text{-}Bu_3)(NHC_6H_3(2,6\text{-}i\text{-}Pr_2))_2$ (8)

A slurry of $LiNHC_6H_3(2,6\text{-}i\text{-}Pr_2)$ (527 mg, 2.9 mmol) in benzene (20 mL) was added over a 15 min period at 25 °C to a solution of $ZrCp(NP\text{-}t\text{-}Bu_3)Cl_2$ (320 mg, 0.72 mmol) in

© 2004 NRC Canada

the same solvent (25 mL). The slurry was stirred for an additional 10 h, after which time it was filtered through Celite. The solvent was removed in vacuo, and the residue was washed with hexanes (3 × 5 mL) to afford a beige solid (486 mg, 93%). ^{1}H NMR δ: 7.18 (d, 4H, $^3J_{H-H}$ = 8 Hz, C_6H_3 (*m*-H)), 7.02 (t, 2H, $^3J_{H-H}$ = 8 Hz, C_6H_3 (*p*-H)), 6.34 (s, 5H, Cp), 5.75 (s, 2H, NH), 3.73 (sep, 4H, $^3J_{H-H}$ = 7 Hz, *i*-Pr), 1.34 (d, 24H, $^3J_{H-H}$ = 7 Hz, *i*-Pr), 1.04 (d, 27H, $^3J_{P-H}$ = 13 Hz, *t*-Bu). ^{13}C NMR δ: 151.9, 138.7, 122.9, 120.2, 111.4, 39.9 (d, $^1J_{P-C}$ = 47 Hz), 29.5, 28.7, 24.3. ^{31}P NMR δ: 35.8. Anal. calcd. for $C_{41}H_{68}N_3PZr$ (%): C 67.90, H 9.45, N 5.79; found: C 66.62, H 9.84, N 5.86. Colourless crystals suitable for X-ray diffraction were grown by slow evaporation from benzene (Scheme 1).



Generation of TiCp(NP-*t*-Bu$_3$)MeCl (9) and Al$_2$(*m*-NHC$_6$H$_3$(2,6-*i*-Pr$_2$))$_2$Me$_4$ (10)

Neat Al_2Me_6 (0.14 mL, 0.14 mmol) was added dropwise at 25 °C to a clear orange solution of **5** (153 mg, 0.28 mmol) in benzene (15 mL). The solution became deeper yellow in colour and was stirred for an additional 2 h, after which time the solvent was removed in vacuo. The residue was recrystallized from pentanes to afford yellow and colourless crystals (combined yield: 162 mg, 94%). X-ray analysis of the crystals isolated from the mixture confirmed the presence of **9** and **10**, although because of their similar solubility properties, they could not be adequately separated. Thus, microanalysis was performed on the mixture, confirming a 1:1 ratio of the two products. Anal. calcd. for $C_{32}H_{59}AlClN_2PTi$ (%): C 64.50, H 9.83, N 4.85; found: C 65.19, H 10.25, N 5.01. Both, however, were identified spectroscopically. **9**: ^{1}H NMR δ: 6.27 (s, 5H, Cp), 1.20 (s, 3H, TiMe), 1.04 (d, 27H, $^3J_{P-H}$ = 20 Hz, *t*-Bu). ^{13}C NMR δ: 113.3, 41.4 (d, $^1J_{P-C}$ = 45 Hz), 29.4, 25.2. ^{31}P NMR δ: 42.0. **10**: ^{1}H NMR: 7.06 (d, 2H, $^3J_{H-H}$ = 8 Hz, C_6H_3 (*m*-H)), 6.98 (t, 1H, $^3J_{H-H}$ = 8 Hz, C_6H_3 (*p*-H)), 4.58 (br, 1H, NH), 3.40 (sep, 2H, $^3J_{H-H}$ = 7 Hz, *i*-Pr), 1.26 (d, 12H, $^3J_{H-H}$ = 7 Hz, *i*-Pr), –0.32 (s, 6H, AlMe). ^{13}C NMR δ: 139.2, 137.7, 124.6, 123.8, 29.0, 25.0, –7.2. The spectroscopic and crystallographic data for Al$_2$(*m*-NH(2,6-*i*-Pr$_2$)C$_6$H$_3$)$_2$Me$_4$ were consistent with literature data.

X-ray data collection and reduction

Crystals were manipulated and mounted in capillaries in a glove box, thus maintaining a dry, O_2-free environment for each crystal. Diffraction experiments were performed on a Siemens SMART System CCD diffractometer. The data were collected in a hemisphere of data in 1329 frames with 10 s exposure times. The observed extinctions were consistent with the space groups in each case. The data sets were collected ($4.5° < 2q < 45°$–$50.0°$). A measure of decay was obtained by recollecting the first 50 frames of each data set. The intensities of reflections within these frames showed no statistically significant change over the duration of the data collections. The data were processed using the SAINT and XPREP processing packages. An empirical absorption correction based on redundant data was applied to each data set. Subsequent solution and refinement was performed using the SHELXTL solution package operating on a Pentium-3 computer (Table 1).

Scheme 1. Synthesis of **5**–**8**: (*i*) 1 equiv. of LiNHC$_6$H$_3$(2,6-*i*-Pr$_2$); (*ii*) 2 equiv. of LiNHC$_6$H$_3$(2,6-*i*-Pr$_2$).

Structure solution and refinement

Non-hydrogen atomic scattering factors were taken from the literature tabulations (44). The heavy atom positions were determined using direct methods employing the SHELXTL direct methods routine. The remaining non-hydrogen atoms were located from successive difference Fourier map calculations. The refinements were carried out by using full-matrix least-squares techniques on *F*, minimizing the function $\omega(|F_o| - |F_c|)^2$ where the weight ω is defined as $4F_o^2/2s$ (F_o^2) and F_o and F_c are the observed and calculated structure factor amplitudes. In the final cycles of each refinement, all non-hydrogen atoms were assigned anisotropic temperature factors in the absence of disorder or insufficient data. In the latter cases atoms were treated isotropically. C-H atom positions were calculated and allowed to ride on the carbon to which they are bonded assuming a C—H bond length of 0.95 Å. H-atom temperature factors were fixed at 1.10 times the isotropic temperature factor of the C atom to which they are bonded. The H-atom contributions were calculated, but not refined. The locations of the largest peaks in the final difference Fourier map calculation as well as the magnitude of the residual electron densities in each case were of no chemical significance. Additional details are provided in the supplementary data.[2]

Results and discussion

Complexes of formula TiCp(NPR$_3$)(NMe$_2$)$_2$ (R = *t*-Bu **1**, Ph **2**) were prepared via salt metathesis of TiCp(NPR$_3$)Cl$_2$ with a slight excess of LiNMe$_2$ affording the desired products in 67% and 77% yields, respectively. In the case where R = *t*-Bu, the by-product Ti(NP-*t*-Bu$_3$)(NMe$_2$)$_3$ (**3**) was also

generated in low yields (ca. 10%–15%). While the formation of **3** was unexpected as it requires Cp–M cleavage, such reactions are not unprecedented (45–48). This by-product **3** was prepared in a more conventional manner by a metathesis route in 75% yield from Ti(NP-*t*-Bu_3)Cl_3 and an excess of the lithium amide reagent. The related Zr derivative ZrCp(NP-*t*-Bu_3)$(NMe_2)_2$ (**4**) was also prepared in 82% yield from the dichloride precursor using an excess of the Li amide. Similarly the preparation of the related complexes TiCp′$(NMe_2)_3$ (Cp′ = Cp, C_5Me_5, indenyl) have been previously reported (9, 49). The ^{1}H NMR chemical shift of the amido-methyl groups for **3** and TiCp*$(NMe_2)_3$ were observed at 3.40 and 3.09 ppm, respectively. Preliminary X-ray data[3] for **3** was obtained from rather poor quality crystals. While these data confirmed the connectivity and inferred that **3** exhibits threefold symmetry in the solid state (Fig. 1), the poor quality of the crystals precludes a discussion of the metric parameters.

Similarly, reaction of TiCp(NP-*t*-Bu_3)Cl_2 with Li-NHC_6H_3(2,6-*i*-Pr_2) afforded TiCp(NP-*t*-Bu_3)(NHC_6H_3(2,6-*i*-Pr_2))Cl (**5**) and Ti(NP-*t*-Bu_3)$(NHC_6H_3(2,6\text{-}i\text{-}Pr_2))_3$ (**6**). However, unlike the dialkyl amide reaction, preparation of TiCp(NP-*t*-Bu_3)$(NHC_6H_3(2,6\text{-}i\text{-}Pr_2))_2$ could not be achieved cleanly, presumably a result of excessive steric crowding about the metal centre. The room-temperature ^{1}H NMR spectrum of **5** exhibited broad resonances attributed to the methine protons on the isopropyl groups and a doublet signal originating from the methyl groups. Variable-temperature studies confirmed restricted rotation about the Ti—N amide bond with coalescence of the methine protons of the isopropyl groups at 308 K. The free energy of activation

Fig. 1. PLUTO drawing of **3** (30% thermal ellipsoids are shown). Hydrogen atoms are omitted for clarity.

($\Delta G^{\ddagger}$) for rotation of the N—C_{ipso} bond was determined to be 58.1(5) kJ mol^{-1} at 298 K. This value is greater than those reported for Ti$(NR_2)_3$Cl (R = Me, Et) (<42 kJ mol^{-1}), but compares well with an estimation of 55.6 kJ mol^{-1} obtained for rotation of the N—C_{ipso} bond in the related complex Zr($(NC_6H_3(2,6\text{-}i\text{-}Pr_2)CH_2]_2CH_2)Me_2$ (50). The higher activation energies reflect the greater steric crowding around the metal center (51, 52). Compounds **5** and **6** were also characterized crystallographically (Figs. 2 and 3, Table 2). In both cases, the Ti—N bond for the phosphinimide ligands were significantly shorter than the Ti—N amide bonds, con-

[3]Preliminary X-ray data for **3**: $C_{18}H_{45}N_4PTi$, trigonal, *R*3, *a* = 14.066(6), *c* = 11.023(7), *V* = 1888.9(7). **9**: $C_{18}H_{35}ClNPTi$, orthorhombic, *Pbca*, *a* = 10.294(5), *b* = 14.828(8), *c* = 28.49(1), *V* = 4348(5). **10**: $C_{28}H_{46}N_2Al_2$, orthorhombic, $Pna2_1$, *a* = 18.810(8), *b* = 10.160(4), *c* = 15.902(7), *V* = 3039(2).

sistent with the strength of the Ti—phosphinimide bond. The related compound ZrCp(NP-*t*-Bu_3)(NHC_6H_3(2,6-*i*-Pr_2))Me (**7**) was prepared in 92% yield via a stoichiometric protonolysis reaction of ZrCp(NP-*t*-Bu_3)Me_2 with NH_2(2,6-*i*-Pr_2)C_6H_3. In contrast, the bis-amido analog ZrCp(NP-*t*-Bu_3)(NHC_6H_3(2,6-*i*-Pr_2))$_2$ (**8**) was prepared in 93% yield via metatheses of the chloride ligands of ZrCp(NP-*t*-Bu_3)Cl_2 with $LiNHC_6H_3$(2,6-*i*-Pr_2). The crystallographic data for **8**

Fig. 4. ORTEP drawing of **8** (30% thermal ellipsoids are shown). Hydrogen atoms are omitted for clarity.

revealed that the Zr—N bond distances were slightly longer than those in the Ti complexes as expected (Fig. 4, Table 2).

Reactivity of these phosphinimide–amide derivatives was explored. Attempts to effect the thermolytic formation of group IV phosphinimide imide complexes (1–3, 5, 53–56) were unsuccessful, affording instead the elimination of both free amine and phosphinimine. Similarly, attempts to prepare imido derivatives directly employing Mountford's precursor Ti(N-*t*-Bu)Cl_2(*t*-BuPy)$_2$ (57) were also unsuccessful.

In other chemistry, reaction of **5** with excess $AlMe_3$ resulted in the clean, near-quantitative isolation of TiCp(NP-*t*-Bu_3)Me_2. However, when 1 equiv. of $AlMe_3$ was used, TiCp(NP-*t*-Bu_3)MeCl (**9**) and the dimer Al_2(*m*-$NH(C_6H_3$(2,6-*i*-Pr_2))$_2Me_4$ (**10**) were obtained. The formation of **9** and **10** were confirmed via preliminary crystallographic data.[3] Similar methylations using $AlMe_3$ have been previously reported to replace alkoxide (58) or amide (59) ligands.

We noted the work of Doye and co-workers (60) who reported moderate conversion of 3-hexyne and 4-methylaniline to the secondary amine using TiCp($NPPh_3$)Me_2 as a catalyst. Efforts to effect similar transformations using **6**–**8** as catalyst precursors were unsuccessful resulting again in liberation of amine and phosphinimine ligands. It is interesting to note that while the phosphinimide ligand is an effective replacement for Cp in olefin polymerization catalysts, the present data imply that this is not the case for hydroamination catalysts. Intuitively, this may be related to the Lewis basicity of the phosphinimide N and its affinity for small Lewis acids such as protons. Nonetheless, efforts are continuing to ex-

Total synthesis of (–)-xyloketal D and its enantiomer — Confirmation of absolute stereochemistry

Jeremy D. Pettigrew, Rebecca P. Freeman, and Peter D. Wilson

Abstract: The total synthesis of (–)-xyloketal D and its enantiomer have been achieved by the reaction of an *ortho*-quinone methide with (4*R*)- and (4*S*)-4,5-dihydro-2,4-dimethylfuran via a diastereoselective inverse electron demand Diels–Alder reaction. This total synthesis confirmed the absolute stereochemistry of the natural product. The *ortho*-quinone methide was generated by reaction of an appropriately functionalized Mannich base with methyl iodide. The Mannich base was prepared in one step from 2,4-dihydroxyacetophenone, formaldehyde, and morpholine. The enantiomeric dihydrofurans were prepared from (2*R*)- and (2*S*)-2-methylpent-4-ynoic acid via a three-step reaction sequence. These chiral nonracemic synthetic precursors were prepared from the corresponding (*R*)-phenylglycinol-derived diastereomeric amides of the readily available racemic carboxylic acid. The absolute stereochemistry of these carboxylic acids was firmly established by conversion to a known compound that had been previously prepared from a chiral pool starting material.

Key words: xyloketal D, inverse electron demand Diels–Alder reaction, *ortho*-quinone methide, dihydrofuran.

Résumé : Faisant appel à une réaction de Diels–Alder diastéréosélective, avec une demande d'électron inversée, on a réalisé une synthèse totale de (–)-xylocétal D et de son énantiomère par réaction d'une *ortho*-quinone méthide avec les (4*R*)- et (4*S*)-4,5-dihydro-2,5-diméthyfurane. Cette synthèse totale confirme la stéréochimie absolue du produit naturel. L'*ortho*-quinone méthide a été générée par réaction de l'iodure de méthyle avec une base de Mannich portant une fonctionnalisation appropriée. La base de Mannich a été préparée en une étape à partir de la 2,4-dihydroxyacétophénone, du formaldéhyde et de la morpholine. On a préparé les dihydrofuranes énantiomères en trois étapes par une série de réactions à partir des acides (2*R*)- et (2*S*)-2-méthylpent-4-ynoïque. On a préparé ces précurseurs de synthèse chiraux non racémiques à partir des amides diastéréomères correspondants dérivés du (*R*)-phénylglycinol et de l'acide carboxylique racémique commercialement disponible. La configuration absolue de ces acides carboxyliques a été fermement établie par conversion en un composé connu qui avait précédemment été préparé à partir d'un produit appartenant à un ensemble chiral.

Mots clés : xylocétal D, réaction de Diels–Alder avec demande d'électron inversée, *ortho*-quinone méthide, dihydrofurane.

[Traduit par la Rédaction]

Introduction

The natural products xyloketal A (**1**), B (**2**), C (**3**), D (**4**), and E (**5**) were isolated from a mangrove fungus of the *Xylaria* species (Fig. 1) (1). The molecular structures of these novel secondary metabolites were determined by extensive spectroscopic methods and by X-ray crystallography. In addition, the absolute stereochemistry of xyloketal A (**1**) and D (**4**) were determined by interpretation of their CD spectra. Xyloketal A (**1**) has a unique chiral, C_3-symmetric molecular structure and was shown to be an inhibitor of acetylcholine esterase (1, 2). Xyloketal D (**4**) is the simplest member of this family of natural products. We have previously reported the synthesis of (±)-11-norxyloketal D, the first total synthesis of (±)-xyloketal D (±)-**4** and model studies towards the total synthesis of xyloketal A (**1**) (3).[2] These syntheses featured the cycloaddition reactions of appropriately functionalized *ortho*-quinone methides and dihydrofurans as a key step (4).

The synthesis of (±)-11-norxyloketal D (**10**) (43% yield), via the *ortho*-quinone methide **9**, was achieved by heating the Mannich base **7** and commercially available 4,5-dihydro-2-methylfuran (**8**) (3 equiv.) with methyl iodide (1.05 equiv.) in benzene at reflux for 5 days (Fig. 2) (4–6). The Mannich

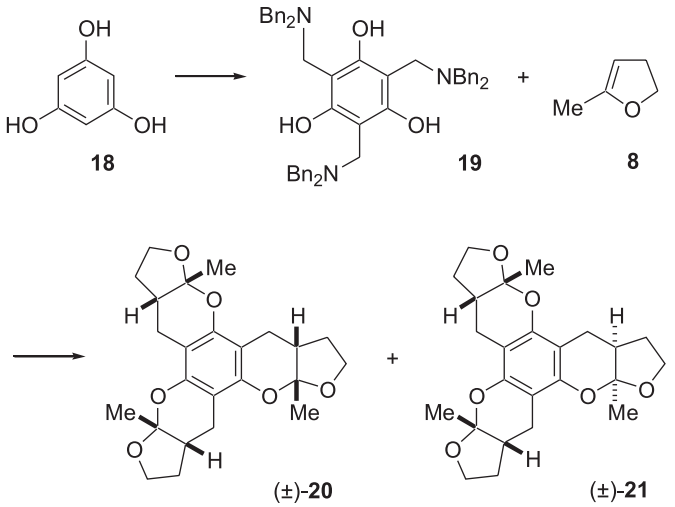
base **7** was prepared as a single regioisomeric product from 2,4-dihydroxyacetophenone (**6**), formaldehyde, and morpholine in 83% yield (7).

The total synthesis of (±)-xyloketal D ((±)-**4**) involved a new synthesis of the known racemic dihydrofuran (±)-**14** (Fig. 3) (8). The racemic carboxylic acid (±)-**11** was prepared by alkylation of propionic acid with propargyl bromide, which in turn was reduced with lithium aluminum hydride to afford the racemic alcohol (±)-**12** (9, 10). Heating this alcohol with a sub-stoichiometric amount of sodium amide afforded the exocyclic dihydrofuran (±)-**13**, which was isomerized thermally to afford the required dihydrofuran (±)-**14** (8). The cycloaddition reaction of the Mannich base **7** with the dihydrofuran (±)-**14** (3 equiv.), under the reaction

Fig. 3. Total synthesis of (±)-xyloketal D ((±)-**4**), (±)-2,6-*epi*-xyloketal D ((±)-**15**), and the diastereomeric spiroacetals (±)-**16** and (±)-**17** (3).



conditions described above, afforded (±)-xyloketal D ((±)-**4**), (±)-2,6-*epi*-xyloketal D ((±)-**15**), and the diastereomeric spiroacetals (±)-**16** and (±)-**17** as a mixture of products (11:1:3:3) in a combined yield of 54%. The spectral data for synthetic (±)-xyloketal D ((±)-**4**) were in agreement with those reported for the natural product (1). This diastereoselective cycloaddition reaction (11:1 dr) was controlled by the C4-methyl substituent of the dihydrofuran (±)-**14**. We attributed the formation of the isomeric spiroacetal reaction products (±)-**16** and (±)-**17** to the isomerization and subsequent cycloaddition reaction of the corresponding exocyclic dihydrofuran (±)-**13**. Of note, related spiroacetal reaction products were not isolated from the cycloaddition reaction of the dihydrofuran **8** that was employed in the synthesis of (±)-11-norxyloketal D (**10**). We concluded that the additional methyl substituent of dihydrofuran (±)-**14** decreased the reactivity of this endocyclic dihydrofuran in the cycloaddition reaction.

The preliminary model studies towards the total synthesis of (±)-xyloketal A ((±)-**1**) involved the reaction of the Mannich base **19**, the dihydrofuran **8** (9 equiv.), and methyl iodide (3 equiv.) (Fig. 4). This afforded a mixture (1:4) of the desired C_3-symmetric xyloketal A analogue (±)-**20** and the diastereoisomer (±)-**21** in 19% combined yield. This unprecedented and direct synthetic process involved nine individual reactions (three alkylation reactions, three elimination reactions, and three subsequent cycloaddition reactions). Of additional note, the Mannich base **19** was prepared in one step by adaptation of a literature procedure from phloro-

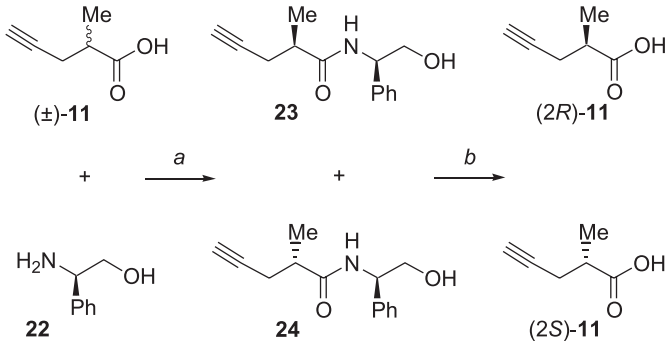
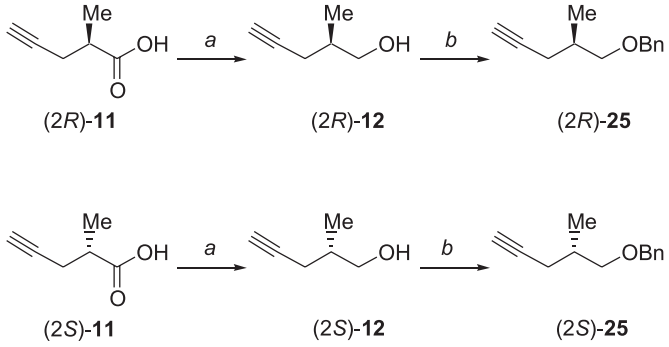
Fig. 4. Synthesis of xyloketal A analogues (±)-**20** and (±)-**21** (3).

glucinol (**18**), *N*,*N*-dibenzylamine, and formaldehyde (11, 12).



We have subsequently attempted to prepare (±)-xyloketal A ((±)-**1**) from the dihydrofuran (±)-**14** and the Mannich base **19**. However, it was not possible to isolate the desired target compound from a complex mixture of reaction products. Presumably, this process was complicated by the formation of diastereomeric as well as spirocyclic reaction by-products.

In this paper, we report an efficient resolution procedure for the racemic carboxylic acid (±)-**11**, a proof of the absolute stereochemistry, and the asymmetric synthesis of (–)-xyloketal D (**4**) as well as its enantiomer. This study was also undertaken to confirm the absolute stereochemistry of the natural product. Recently, Krohn and co-workers (13) have reported an alternative asymmetric synthesis of (–)-xyloketal D (**4**) and the C2,C6-epimer (8.5:1.5 dr) from (3*R*)-3-methylbutyrolactone (93% ee) and 2,4-dihydroxyacetophenone (**6**), as well as model studies towards the total synthesis of xyloketal A (**1**).

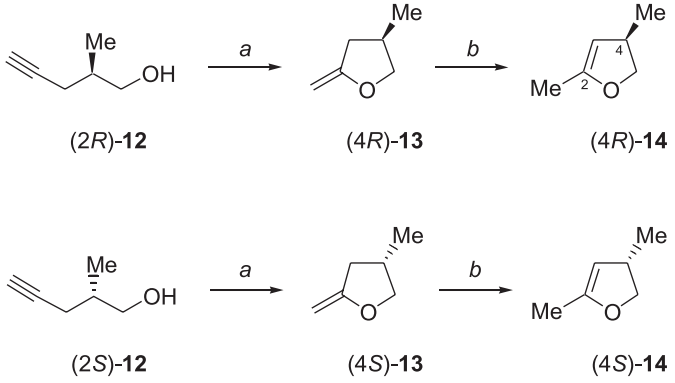


Results and discussion

A variety of methods were investigated to identify an efficient resolution procedure for the racemic carboxylic acid (±)-**11** (3).[3] It was not possible to separate the diastereomeric salts that were formed between the carboxylic acid and (*R*)-methylbenzylamine or (*R*)-(1-naphthyl)-ethylamine by fractional recrystallization. The racemic carboxylic acid (±)-**11** was also converted to the corresponding acid chloride and condensed with a series of commercially available chiral nonracemic alcohols.[4] All of the diastereomeric esters that were prepared could not be separated by fractional recrystallization or by chromatographic methods. The corresponding acid chloride of the carboxylic acid was also condensed with an extensive series of chiral nonracemic amines.[5] It was found that the diastereomeric amides **23** and **24** prepared from (*R*)-phenylglycinol (**22**) could be separated readily by flash chromatography on a multigram scale (Scheme 1) (14, 15).[6,7] The chiral nonracemic carboxylic acids (2*R*)-**11** and (2*S*)-**11** were then prepared by hydrolysis of the diastereomeric amides **23** and **24** under acidic reaction conditions (14, 16).

Scheme 1. Resolution of (±)-2-methylpent-4-ynoic acid ((±)-**11**). Reagents and conditions: (*a*) $(COCl)_2$, CH_2Cl_2, DMF (cat.), 0 °C to room temperature, 2 h; (*R*)-phenylglycinol (**22**), NEt_3, CH_2Cl_2, 0 °C to room temperature, 16 h, 36% (**23**), 34% (**24**); (*b*) 3 mol L^{-1} H_2SO_4, *p*-dioxane, reflux, 7 h, 76% ((2*R*)-**11**), 86% ((2*S*)-**11**).

Scheme 2. Synthesis of (2*R*)-2-methylpent-4-yn-1-ol ((2*R*)-**12**) and (2*S*)-2-methylpent-4-yn-1-ol ((2*S*)-**12**): confirmation of absolute stereochemistry. Reagents and conditions: (*a*) $LiAlH_4$, THF, 0 °C to room temperature, 16 h, 89% ((2*R*)-**12**), 85% ((2*S*)-**12**); (*b*) NaH, BnBr, DMF, THF, 6 h, 90% ((2*R*)-**25**), 90% ((2*S*)-**25**).



The chiral nonracemic carboxylic acid (2*R*)-**11** was reduced with lithium aluminum hydride to afford the corresponding alcohol (2*R*)-**12** (Scheme 2) (17). A sample of this alcohol was then converted to the benzyl ether (2*R*)-**25**. The latter compound has been prepared previously from an expensive chiral pool starting material and the optical rotation

[3] A full experimental procedure for the preparation of the racemic carboxylic acid (±)-**11** is provided in the supplementary material.[10]
[4] For example, the diastereomeric esters prepared from menthol, isomenthol, and (2*R*)-butan-2-ol were copolar by TLC.
[5] The chiral nonracemic amines that were employed in these reactions included: (*R*)-methylbenzylamine and (*R*)-(1-naphthyl)-ethylamine, the methyl esters of (*S*)-alanine, isoleucine, leucine, phenylalanine, proline, tryptophan, and (*R*)-phenylglycine, as well as (*S*)-valinol and (1*S*,2*R*)-norephedrine.
[6] The diastereomeric amides that were prepared from (*S*)-valinol were also chromatographically separable.
[7] Attempts, albeit unsuccessful, were also made to resolve the racemic alcohol (±)-**12** on condensation with a series of commercially available chiral nonracemic carboxylic acids and sulfonyl chlorides.

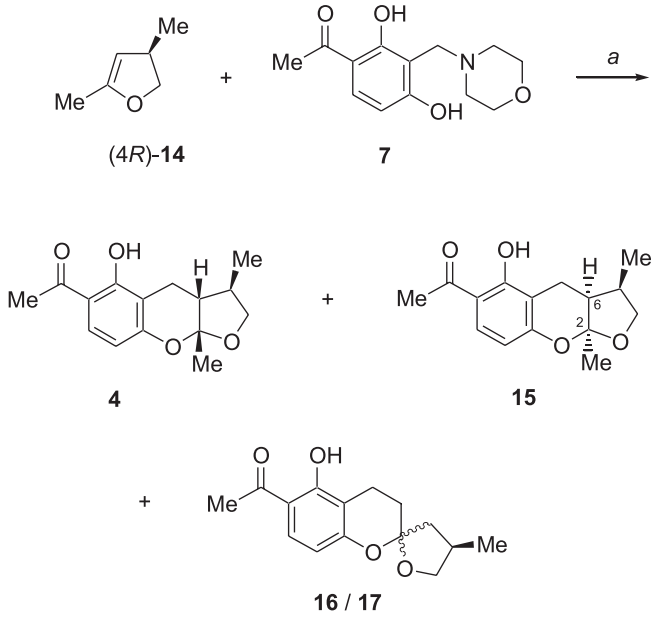
Scheme 3. Synthesis of (4*R*)-4,5-dihydro-2,4-dimethylfuran ((4*R*)-**14**) and (4*S*)-4,5-dihydro-2,4-dimethylfuran ((4*S*)-**14**). Reagents and conditions: (*a*) $NaNH_2$, reflux, 2 h; (*b*) reflux, 2 h, 44% (over two steps) ((4*R*)-**14**), 36% (over two steps) ((4*R*)-**14**).

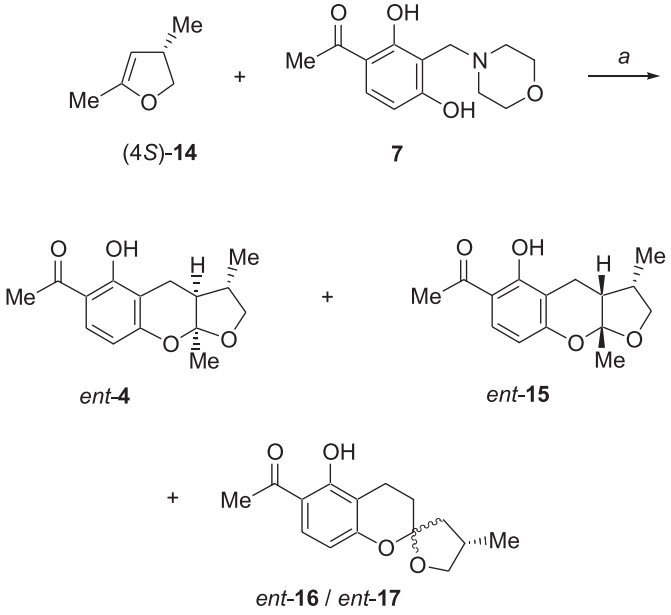


has been reported (18). Thus, the absolute stereochemistry and high optical purity of the resolved carboxylic acid (2*R*)-**11** was firmly established (see Experimental section). To complete the total synthesis of (–)-xyloketal D (**4**) and its nonnatural enantiomer, the carboxylic acid (2*S*)-**11** was reduced with lithium aluminum hydride to afford the alcohol (2*S*)-**12**. A sample of this compound was also converted to the corresponding benzyl ether (2*S*)-**25**, which proved to be the enantiomer of a known compound (18).

The chiral nonracemic alcohol (2*R*)-**12** was then used to prepare the dihydrofuran (4*R*)-**14** as described earlier for the racemic compound (Scheme 3).[8] This compound would serve as the precursor of (–)-xyloketal D (**4**) and would allow for the confirmation of the absolute stereochemistry of the natural product. In an identical fashion, the alcohol (2*S*)-**12** was used to prepare the dihydrofuran (4*S*)-**14**. This compound would serve as the precursor of the nonnatural enantiomer of xyloketal D.

The chiral nonracemic dihydrofuran (4*R*)-**14** (3 equiv.) and the Mannich base **7** were heated in benzene at reflux with methyl iodide (1 equiv.) (Scheme 4).[9] This reaction afforded a mixture (8:1:2:2) of (–)-xyloketal D (**4**), 2,6-*epi*-xyloketal D (**15**), and the diastereomeric spiroacetals **16** and **17** in a combined yield of 40%. The reaction was also repeated using dimethyl sulfate instead of methyl iodide. This reaction proceeded at a faster rate and afforded a mixture of reaction products (16:1:4:4) in a similar combined yield. A diastereomerically and analytically pure sample of the synthetic natural product, (–)-xyloketal D (**4**), was obtained by repeated chromatography and recrystallization. An analytically pure sample of the diastereomeric spiroacetals **16** and **17** was also isolated as a mixture (4:5) by repeated chromatography and recrystallization.

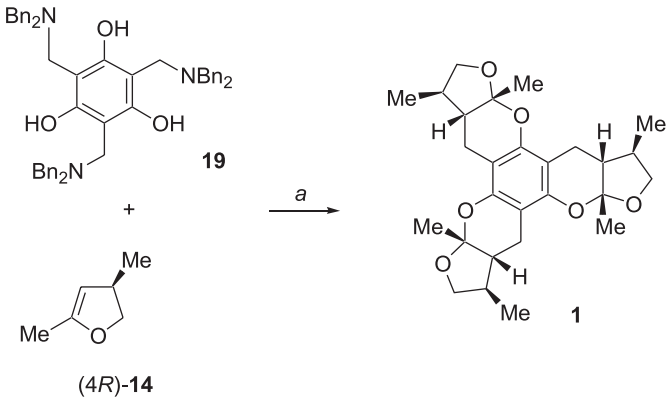
Scheme 4. Synthesis of (–)-xyloketal D (**4**), 2,6-*epi*-xyloketal D (**15**), and the diastereomeric spiroacetals **16** and **17**. Reagents and conditions: (*a*) dihydrofuran (4*R*)-**14** (3 equiv.), MeI (1 equiv), benzene, reflux, 8 days, 40% (**4**, **15**, **16**, and **17** (8:1:2:2)) *or* dihydrofuran (4*R*)-**14** (3 equiv.), Me_2SO_4 (1 equiv.), benzene, reflux, 3 days, 37% (**4**, **15**, **16**, and **17** (16:1:4:4)).



The ^1H NMR spectrum and ^{13}C NMR data of synthetic (–)-xyloketal D (**4**) were identical to those of the natural product[10] (1).[11] The sign of the optical rotation of synthetic (–)-xyloketal D (**4**) was in agreement with that reported for the natural product. This confirmed the absolute stereochemistry of the natural product that had been assigned previously by the interpretation of CD data (1, 13). However, the magnitude of the rotation was slightly lower than reported for the natural product (92% ee based on the optical rotation of the natural product) (1). To determine the enantiomeric purity of synthetic (–)-xyloketal D (**4**), efforts were also made to separate the enantiomers of a sample of racemic xyloketal D ((±)-**4**) (3). This was not possible by analytical chiral HPLC (Daicel Chiracel OD column) or by GC (Cyclosil-B column). Similarly, ^1H NMR spectroscopy using a chiral shift reagent ($Eu(hfc)_3$) was unsuccessful. Derivatization of the phenol moiety of racemic xyloketal D ((±)-**4**) with (*S*)-(+)-α-methoxy-α-trifluoromethyl-phenylacetyl chloride afforded the corresponding Mosher's esters (19). The ^1H NMR (600 MHz) signals of the methoxy substituents were clearly resolved.[12] Subsequent derivatization of synthetic (–)-xyloketal D (**4**) afforded the corresponding Mosher's ester as a single diastereoisomer. This confirmed

[8] The lower yield for the preparation of the chiral nonracemic dihydrofuran (4*R*)-**14** than that reported for the racemic compound is reflective of the smaller scale that this reaction was performed on. See ref. 3.
[9] We have previously reported full experimental procedures for the preparation of Mannich base **7**. See ref. 3.
[10] Detailed experimental procedures and complete product characterization data for all of the additional compounds synthesized, as well as ^1H and ^{13}C NMR spectra for compounds (±)-**11**, **23**, **24**, (2*R*)-**12**, (2*R*)-**25**, (4*R*)-**14**, **4**, **16**, **17**, and the Mosher's ester derivatives of (±)-xyloketal D ((±)-**4**) and synthetic (–)-xyloketal D (**4**) may be purchased from the Directory of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically).
[11] Of note, the ^1H NMR signal of natural (–)-xyloketal D (**4**) centred at 2.15 ppm should have been reported at 2.08 ppm.
[12] The ^{19}F NMR (470 MHz) signals of the Mosher's ester derivatives were separate but poorly resolved.

© 2004 NRC Canada



Scheme 5. Synthesis of (+)-xyloketal D (*ent*-**4**), *ent*-2,6-*epi*-xyloketal D (*ent*-**15**), and the diastereomeric spiroacetals *ent*-**16** and *ent*-**17**. Reagents and conditions: (*a*) dihydrofuran (4*S*)-**14** (3 equiv.), MeI (1 equiv.), benzene, reflux, 6 days, 46% (*ent*-**4**, *ent*-**15**, *ent*-**16** and *ent*-**17** (13:1:3:3)) *or* dihydrofuran (4*S*)-**14** (3 equiv.), Me_2SO_4 (1 equiv.), benzene, reflux, 3 days, 36% (*ent*-**4**, *ent*-**15**, *ent*-**16**, and *ent*-**17** (20:1:3:3)).

that the synthetic material was enantiomerically pure.[10] The melting point of synthetic (–)-xyloketal D (**4**) (71–73 °C) was, however, significantly lower than that reported for the natural product (111–113 °C). We were unable to increase the melting point of our synthetic material by repeated recrystallization from petroleum ether. Krohn et al. (13*b*) have reported that synthetic (–)-xyloketal D (**4**) (93% ee calculated from optical rotation and 93% ee based on the enantiomeric purity of a synthetic precursor) also had a lower melting point (87 °C, ether–pentane). They also reported that subsequent recrystallization from ether–pentane afforded the natural product, which had a melting point of 110 to 111 °C. We have also recrystallized our synthetic material from this solvent system. However, in our hands this procedure did not increase the melting point. We have concluded that our sample is either contaminated with a trace amount of the enantiomer, which has significantly depressed the melting point, or that we have isolated the natural product in a different crystal form.[13]

The Mannich base **7** was also reacted with the chiral nonracemic dihydrofuran (4*S*)-**14** using the two procedures described previously (Scheme 5). These reactions afforded mixtures of (+)-xyloketal D (*ent*-**4**), *ent*-2,6-*epi*-xyloketal D (*ent*-**15**), and the diastereomeric spiroacetals *ent*-**16** and *ent*-**17**. A diastereomerically and analytically pure sample of the enantiomeric natural product, (+)-xyloketal D (*ent*-**4**), was also prepared and fully characterized following repeated chromatography and recrystallization.

Scheme 6. Attempted synthesis of (–)-xyloketal A (**1**). Reagents and conditions: (*a*) dihydrofuran (4*R*)-**14** (9 equiv.), MeI (3 equiv.), benzene, reflux, or dihydrofuran (4*R*)-**14** (9 equiv.), Me_2SO_4 (3 equiv.), benzene, reflux.

The total synthesis of (–)-xyloketal A (**1**) was also attempted (Scheme 6). The Mannich base **19** and a large excess of the chiral nonracemic dihydrofuran (4*R*)-**14** were heated in benzene at reflux with methyl iodide and with dimethyl sulfate.[14] The natural product was not isolated from the complex mixtures of products that were produced in these reactions.

It was anticipated that the stereochemistry of this attempted cycloaddition reaction would have been directed efficiently by the C4-methyl substituent of the chiral nonracemic dihydrofuran (4*R*)-**14**. However, it appears that the competing isomerization reaction of the dihydrofuran (4*R*)-**14** and the subsequent nonstereoselective cycloaddition reaction of the exocyclic dihydrofuran (4*R*)-**13** is a dominant complicating factor.

Conclusions

The racemic carboxylic acid (±)-**11** was resolved by the chromatographic separation of the corresponding diastereomeric amides **23** and **24** that were prepared from (*R*)-phenylglycinol (**22**). The absolute stereochemistry and the enantiomeric purity of the chiral nonracemic carboxylic acid (2*R*)-**11** were determined by conversion to the benzyl ether (2*R*)-**25**, which had been prepared previously from a chiral pool starting material. The total synthesis of (–)-xyloketal D (**4**) and its enantiomer were completed from the chiral nonracemic dihydrofurans (4*R*)-**14** and (4*S*)-**14**. These dihydrofurans, which were prepared in three steps from the carboxylic acids (2*R*)-**11** and (2*S*)-**11**, were reacted with an appropriately functionalized *ortho*-quinone methide **9** that was generated from the Mannich base **7**. These results confirmed the absolute stereochemistry of the natural product that was reported by Lin and co-workers (1, 13). The synthesis of (–)-xyloketal A (**1**) from the chiral nonracemic dihydrofuran (4*R*)-**14** and the Mannich base **19** was unsuccessful. Thus, alternative synthetic routes are actively being

[13]Professor Krohn has informed us that he has recently checked the melting point of a sample of natural (–)-xyloketal D (**4**), which was kindly provided by Professor Lin, and found it to be 107 to 108 °C (Büchi SMP-20 melting point apparatus).
[14]We have previously reported full experimental procedures for the preparation of Mannich base **19**. See ref. 3.

pursued to complete the total synthesis of this unique and biologically relevant natural product.

Experimental section

For general experimental details refer to the supplementary material.[10]

(2*R*)-*N*-[(1*R*)-1-Phenyl-2-hydroxyethyl]-2-methyl-4-pentynamide (23) and (2*S*)-*N*-[(1*R*)-1-phenyl-2-hydroxyethyl]-2-methyl-4-pentynamide (24)

To a solution of the racemic carboxylic acid (±)-**11** (3) (5.40 g, 48.2 mmol) in dichloromethane (100 mL) at 0 °C were added oxalyl chloride (5.5 mL, 58 mmol) and *N*,*N*-dimethylformamide (2 drops). The resultant solution was allowed to warm to room temperature over 2 h and then was concentrated in vacuo to afford the corresponding acid chloride. A solution of this acid chloride in dichloromethane (50 mL) was then added to a stirred solution of (*R*)-phenylglycinol (**22**) (6.60 g, 48.2 mmol) and triethylamine (8.0 mL, 58 mmol) in dichloromethane (150 mL) at 0 °C. The resultant solution was allowed to warm to room temperature over 16 h and then water (50 mL) was added. The reaction mixture was extracted with ethyl acetate (3 × 50 mL) and the combined organic layers were washed with brine (50 mL), dried over anhydrous sodium sulfate, and concentrated in vacuo. Purification by flash chromatography using petroleum ether – ethyl acetate (1:2) as the eluant afforded the title compounds **23** (4.01 g, 36%) and **24** (3.82 g, 34%) as white solids. Amide **23**: R_f = 0.37 (petroleum ether – ethyl acetate, 1:2), mp 78–82 °C, petroleum ether – ethyl acetate. $[\alpha]_D^{24}$ = –63 (*c* 1.31, $CHCl_3$). (2*R*)-2-Methylpent-4-ynoic acid ((2*R*)-11)

To a solution of the amide **23** (5.44 g, 23.5 mmol) in *p*-dioxane (60 mL) at room temperature was added sulfuric acid (3 mol L^{-1}, 60 mL). The resultant solution was heated at reflux for 7 h and then was cooled to 0 °C. The reaction mixture was basified to pH ~10 with an aqueous solution of sodium hydroxide (50 wt. %), then diluted with water (50 mL) and extracted with dichloromethane (3 × 50 mL). The aqueous layer was acidified to pH ~2 with sulfuric acid (3 mol L^{-1}) and then extracted with dichloromethane (3 × 50 mL). The combined organic layers were dried over anhydrous sodium sulfate and concentrated in vacuo. Purification by distillation at reduced pressure afforded the title compound (2*R*)-**11** (2.01 g, 76%) as a colourless oil. R_f = 0.48 (hexanes – ethyl acetate, 1:2), bp 103–106 °C, 5 mmHg (1 mmHg = 133.322 Pa) (lit. value (9) bp 106.5–109.5 °C, 14–15 mmHg (1 mmHg = 133.322 4 Pa)) for the racemic carboxylic acid (±)-**11**)). $[\alpha]_D^{20}$ = +6.5 (*c* 1.50, $CHCl_3$). All other spectroscopic data were identical to those reported for the racemic carboxylic acid (±)-**11**.[10]

(2*S*)-2-Methylpent-4-ynoic acid ((2*S*)-11)

The title compound (2*S*)-**11** (1.91 g, 86%) as a colourless oil was also prepared from the corresponding amide **24** (4.56 g, 19.7 mmol). $[\alpha]_D^{20}$ = –6.1 (*c* 1.52, $CHCl_3$). All other spectroscopic data were identical to those reported for the racemic carboxylic acid (±)-**11**.[10]

(2*R*)-2-Methylpent-4-yn-1-ol ((2*R*)-12)

To a suspension of lithium aluminum hydride (0.79 g, 20.8 mmol) in tetrahydrofuran (35 mL) at 0 °C was added a solution of the carboxylic acid (2*R*)-**11** (1.17 g, 10.4 mmol) in tetrahydrofuran (10 mL) and the resultant suspension was stirred at room temperature for 16 h. Water (0.8 mL), an aqueous solution of sodium hydroxide (2 mol L^{-1}, 0.8 mL), and water (2.4 mL) were then added in succession and the resultant mixture was filtered. The filter cake was rinsed with ether (100 mL) and the combined organic filtrates were concentrated in vacuo. Purification by distillation at reduced pressure afforded the title compound (2*R*)-**12** (0.91 g, 89%) as a colourless oil. R_f = 0.55 (hexanes – ethyl acetate, 1:2), bp 61–66 °C, ~20 mmHg (1 mmHg = 133.322 4 Pa) (lit. value (9) bp 64–64.5 °C, 10 mmHg (1 mmHg = 133.322 4 Pa) (for the racemic alcohol (±)-**12**)). $[\alpha]_D^{20}$ = +10.9 (*c* 1.10, $CHCl_3$). IR (ef, cm^{-1}): 3409, 2961, 2922, 1641, 2117, 1461, 1430, 1037, 651. ^1H NMR (400 MHz, $CDCl_3$) δ: 1.01 (d, *J* = 6.9 Hz, 3H), 1.56 (broad s, 1H), 1.90 (m, 1H), 1.98 (t, *J* = 2.7 Hz, 1H), 2.21 (ddd, *J* = 16.8, 6.4, 2.7 Hz, 1H), 2.29 (ddd, *J* = 16.8, 6.2, 2.7 Hz, 1H), 3.59 (d, *J* = 6.1 Hz, 2H). ^{13}C NMR (126 MHz, $CDCl_3$) δ: 16.0, 22.2, 34.8, 66.8, 69.6, 82.6. MS (CI) *m*/*z* (rel. intensity): 99 (M + H, 100).

(2*R*)-Benzyl-(2-methylpent-4-ynyl) ether ((2*R*)-25)

To a suspension of sodium hydride (60 wt. % in mineral oil, 81.3 mg, 2.03 mmol, prewashed with hexanes) in *N*,*N*-dimethylformamide (4.0 mL) at 0 °C were added a solution of the alcohol (2*R*)-**12** (181 mg, 1.85 mmol) in tetrahydrofuran (1 mL) and benzyl bromide (230 µL, 1.93 mmol). The resultant mixture was stirred at room temperature for 6 h. The reaction mixture was then diluted with ether (10 mL) and washed with water (3 × 10 mL) and brine (10 mL). The organic layer was dried over anhydrous magnesium sulfate and concentrated in vacuo. Purification by flash chromatography using hexanes–ether (50:1) as the eluant afforded the title compound (2*R*)-**25** (313 mg, 90%) as a colourless oil. R_f = 0.77 (hexanes–ether, 4:1). $[\alpha]_D^{20}$ = +16.1 (*c* 1.40, $CHCl_3$) (lit. value (18*a*) $[\alpha]_D^{20}$ = +16 (*c* 1.20,

© 2004 NRC Canada

$CHCl_3$) and lit. value (18*b*) $[\alpha]_D^{20}$ = +16.3 (*c* 0.95, $CHCl_3$)). IR (ef, cm^{-1}): 3289, 3031, 2857, 2117, 1609, 1496, 1454, 1112, 749. ^1H NMR (400 MHz, $CDCl_3$) δ: 1.03 (d, *J* = 6.8 Hz, 3H), 1.95 (t, *J* = 2.6 Hz, 1H), 2.02 (m, 1H), 2.21 (ddd, *J* = 16.7, 6.9, 2.6 Hz, 1H), 2.35 (ddd, *J* = 16.7, 5.5, 2.7 Hz, 1H), 3.39 (d, *J* = 6.5 Hz, 2H), 4.52 (s, 2H), 7.33 (m, 5H). ^{13}C NMR (126 MHz, $CDCl_3$) δ: 16.3, 22.5, 32.8, 69.3, 73.0, 74.1, 82.7, 127.48, 127.51, 128.3, 138.5. MS (CI) *m*/*z* (rel. intensity): 189 (M + H, 78), 171 (17), 111 (M – Ph, 100).

(2*S*)-2-Methylpent-4-yn-1-ol ((2*S*)-12)

The title compound (2*S*)-**12** (1.17 g, 85%) as a colourless oil was also prepared from the corresponding carboxylic acid (2*S*)-**11** (1.57 g, 14.0 mmol). $[\alpha]_D^{20}$ = –11.1 (*c* 1.83, $CHCl_3$). All other spectroscopic data were identical to those reported for the enantiomeric alcohol (2*R*)-**12**.

(2*S*)-Benzyl-(2-methylpent-4-ynyl) ether ((2*S*)-25)

The title compound (2*S*)-**25** (248 mg, 90%) as a colourless oil was also prepared from the corresponding alcohol (2*S*)-**12** (144 mg, 1.47 mmol). $[\alpha]_D^{20}$ = –15.9 (*c* 1.05, $CHCl_3$). All other spectroscopic data were identical to those reported for the enantiomeric ether (2*R*)-**25**.

(4*R*)-4,5-Dihydro-2,4-dimethylfuran ((4*R*)-14)

The alcohol (2*S*)-**12** (0.91 g, 9.28 mmol) and sodium amide (50 mg, 1.28 mmol) were heated, without solvent, at reflux for 2 h. Direct distillation of the reaction mixture at atmospheric pressure afforded the exocyclic dihydrofuran (4*R*)-**13** and a small amount of the endocyclic dihydrofuran (4*R*)-**14** as a colourless oil. ^1H NMR (500 MHz, C_6D_6, ~90% pure) δ: 0.58 (d, *J* = 6.2 Hz, 3H), 1.80 (m, 2H), 2.27 (m, 1H), 3.27 (dd, *J* = 8.1, 6.5 Hz, 1H), 3.77 (dd, *J* = 8.1, 6.0 Hz, 1H), 3.92 (m, 1H), 5.46 (m, 1H). This material was heated at reflux for 2 h and then distilled at atmospheric pressure to afford the title compound (4*R*)-**14** (0.40 g, 44%) as a colourless oil, bp 97–103 °C, ~760 mmHg (1 mmHg = 133.322 4 Pa) (lit. value (3) bp ~100 °C, ~760 mmHg (1 mmHg = 133.322 4 Pa) for the racemic dihydrofuran (±)-**14**)). $[\alpha]_D^{24}$ = +11.8 (*c* 0.82, $CHCl_3$). IR (ef, cm^{-1}): 2961, 2875, 1674, 1453, 1383, 1243, 1043, 1008, 886. ^1H NMR (400 MHz, C_6D_6) δ: 0.86 (d, *J* = 6.6 Hz, 3H), 1.68 (apparent t, *J* = 1.5 Hz, 3H), 2.76 (m, 1H), 3.71 (dd, *J* = 8.7, 6.5 Hz, 1H), 4.21 (dd, *J* = 9.5, 8.6 Hz, 1H), 4.43 (m, 1H). ^{13}C NMR (101 MHz, C_6D_6) δ: 13.6, 20.9, 37.9, 77.2, 101.4, 155.0. MS (CI) *m*/*z* (rel. intensity): 99 (M + H, 100).

(4*S*)-4,5-Dihydro-2,4-dimethylfuran ((4*S*)-14)

The title compound (4*S*)-**14** (0.42 g, 36%) as a colourless oil was also prepared from the corresponding alcohol (2*S*)-**12** (1.17 g, 11.9 mmol). $[\alpha]_D^{20}$ = –12 (*c* 0.44, $CHCl_3$). All other spectroscopic data were identical to those reported for the enantiomeric dihydrofuran (4*R*)-**14**.

(–)-Xyloketal D (4), 2,6-*epi*-xyloketal D (15), and the diastereomeric spiroacetals (16) and (17)

Method A

To a solution of the dihydrofuran (4*R*)-**14** (295 mg, 3.01 mmol) in benzene (10 mL) at room temperature were added the Mannich base **7** (251 mg, 1.00 mmol) and methyl iodide (65.0 μL, 1.05 mmol). The resultant solution was then heated at reflux until the Mannich base **7** had completely reacted (8 days, TLC analysis). The reaction mixture was then cooled to room temperature, filtered, and concentrated in vacuo. Purification by flash chromatography using dichloromethane as the eluant afforded a mixture (8:1:2:2) of (–)-xyloketal D (**4**), 2,6-*epi*-xyloketal D (**15**), and the diastereomeric spiroacetals **16** and **17** (105 mg, 40%) as a yellow solid. Repeated flash chromatography using hexanes–ether (4:1) as the eluant on TLC grade silica gel (5–25 μm) afforded a mixture (20:1) of (–)-xyloketal D (**4**) and 2,6-*epi*-xyloketal D (**15**) as a pale cream solid and a separate mixture (4:5) of the two diastereomeric spiroacetals **16** and **17** as a pale cream solid. An analytically pure sample of synthetic (–)-xyloketal D (**4**), as pale pink prisms, was prepared by recrystallization from petroleum ether. An analytically pure sample of a mixture (4:5) of the diastereomeric spiroacetals **16** and **17**, as white needles, was also prepared by recrystallization from petroleum ether.

Method B

To a solution of the dihydrofuran (4*R*)-**14** (121 mg, 1.23 mmol) in benzene (5 mL) at room temperature were added the Mannich base **7** (103 mg, 0.41 mmol) and dimethyl sulfate (41 μL, 0.43 mmol). The resultant solution was heated at reflux until the Mannich base **7** had completely reacted (3 days, TLC analysis). The reaction mixture was then cooled to room temperature and decanted. The remaining solid residue was extracted with dichloromethane (3 × 5 mL) and the combined organic extracts were concentrated in vacuo. Purification by flash chromatography using dichloromethane–ether (19:1) as the eluant afforded a mixture (16:1:4:4) of (–)-xyloketal D (**4**), 2,6-*epi*-xyloketal D (**15**), and the diastereomeric spiroacetals **16** and **17** (40 mg, 37%) as a yellow solid. (–)-Xyloketal D **4**: R_f = 0.24 (hexanes–ether, 4:1), mp 71–73 °C as pale pink prisms from petroleum ether (lit. value (1) mp 111–113 °C) and mp 68–70 °C as white crystals on recrystallization from ether–pentane (lit. value (13) mp 110 to 111 °C, ether–pentane). $[\alpha]_D^{20}$ = –110.1 (*c* 0.102, $CHCl_3$) (lit. value (1) $[\alpha]_D^{25}$ = –119.5 (*c* 0.113, $CHCl_3$)). IR (ef, cm^{-1}): 3399, 2967, 2927, 2884, 1620, 1491, 1421, 1382, 1370, 1332, 1272, 1117, 1070, 1006. ^1H NMR (500 MHz, $CDCl_3$) δ: 1.07 (d, *J* = 6.5 Hz, 3H), 1.53 (s, 3H), 1.98 (ddd, *J* = 11.3, 6.5, 1.1 Hz, 1H), 2.08 (m, 1H), 2.55 (s, 3H), 2.72 (dd, *J* = 17.9, 6.5 Hz, 1H), 2.97 (d, *J* = 18.0, 1H), 3.57 (apparent t, *J* = 8.4 Hz, 1H), 4.20 (apparent t, *J* = 8.3 Hz, 1H), 6.36 (d, *J* = 8.9 Hz, 1H), 7.52 (d, *J* = 8.9 Hz, 1H), 13.12 (s, 1H). ^{13}C NMR (101 MHz, $CDCl_3$) δ: 15.8, 18.0, 22.7, 26.1, 35.1, 47.0, 74.3, 106.2, 108.3, 108.8, 113.1, 130.0, 159.5, 162.9, 202.6. MS (CI) *m*/*z* (rel. intensity): 263 (M + H, 100). Anal. calcd. for $C_{15}H_{18}O_4$: C 68.68, H 6.92; found: C 68.52, H 6.98. Diastereomeric spiroacetals **16** and **17** (4:5 mixture): R_f = 0.32 (hexanes–ether, 4:1), mp 60 to 61 °C, petroleum ether. $[\alpha]_D^{20}$ = +26.9 (*c* 0.71, $CHCl_3$). IR (ef, cm^{-1}): 3423, 2958, 2878, 1626, 1488, 1419, 1369, 1331, 1270, 1247, 1136, 1060, 1018, 853. ^1H NMR (400 MHz, $CDCl_3$) δ: 1.10 (d, *J* = 6.6 Hz, 3H), 1.18 (d, *J* = 6.6 Hz, 3H), 1.55 (dd, *J* = 12.8, 9.5 Hz, 1H), 2.00 (m, 5H), 2.27 (dd, *J* = 13.4, 9.4, 1H), 2.36 (dd, *J* = 12.9, 7.3, 1H), 2.46 (m, 1H), 2.54 (s, 3H), 2.55 (s, 3H), 2.78 (m, 5H),

3.54 (t, *J* = 7.7 Hz, 1H), 3.64 (t, *J* = 8.4 Hz, 1H), 4.09 (t, *J* = 7.9 Hz, 1H), 4.21 (t, *J* = 7.9 Hz, 1H), 6.34 (d, *J* = 8.9 Hz, 1H), 6.37 (d, *J* = 9.0 Hz, 1H), 7.50 (d, *J* = 8.9 Hz, 1H), 7.51 (d, *J* = 8.9 Hz, 1H), 13.01 (s, 1H), 13.02 (s, 1H). ^{13}C NMR (126 MHz, $CDCl_3$) δ: 16.3, 16.5, 17.6, 18.0, 26.2, 29.3, 29.6, 31.9, 33.0, 45.2, 45.3, 75.0, 75.4, 108.1, 108.9, 109.0, 110.0, 110.1, 113.16, 113.24, 129.58, 129.62, 159.6, 162.2, 202.7, 202.8. MS (CI) *m/z* (rel. intensity): 263 (M + H, 100), 111 (12). Anal. calcd. for $C_{15}H_{18}O_4$: C 68.68, H 6.92; found: C 68.58, H 6.99.

ent-Xyloketal D (*ent*-4), *ent*-2,6-*epi*-xyloketal D (*ent*-15), and the diastereomeric spiroacetals (*ent*-16) and (*ent*-17)

Method A

A solution of the dihydrofuran (4*S*)-**14** (237 mg, 2.42 mmol), the Mannich base **7** (202 mg, 0.804 mmol), and methyl iodide (52 µL, 0.84 mmol) in benzene (8 mL) was heated at reflux for 6 days. Isolation and purification of the reaction products, as described previously, afforded a mixture (13:1:3:3) of *ent*-xyloketal D (*ent*-**4**), *ent*-2,6-*epi*-xyloketal D (*ent*-**15**), and the diastereomeric spiroacetals *ent*-**16** and *ent*-**17** (96 mg, 46%) as a yellow solid. Additional purification and recrystallization of these reaction products, as described previously, afforded an analytically pure sample of *ent*-xyloketal D (*ent*-**4**) as pale pink prisms and an analytically pure mixture (4:5) of the diastereomeric spiroacetals *ent*-**16** and ent-**17** as white needles.

Method B

The procedure described in the previous section was also used to prepare a mixture (20:1:3:3) of *ent*-xyloketal D (*ent*-**4**), *ent*-2,6-*epi*-xyloketal D (*ent*-**15**), and the diastereomeric spiroacetals *ent*-**16** and *ent*-**17** (64 mg, 36%) as a yellow solid. *ent*-Xyloketal D (*ent*-**4**): mp 70 to 71 °C as pale pink crystals from petroleum ether and mp 68–71 °C as white crystals from ether–pentane. $[\alpha]_D^{20}$ = +113.1 (*c* 0.122, $CHCl_3$). All other spectroscopic data were identical to those reported previously for (–)-xyoketal D (**4**). Diastereomeric spiroacetals *ent*-**16** and *ent*-**17** (4:5): mp 59–61 °C, petroleum ether. $[\alpha]_D^{20}$ = –26.7 (*c* 1.05, $CHCl_3$). All other spectroscopic data were consistent with that reported for the diastereomeric spiroacetals **16** and **17**.

Acknowledgments

We are grateful to the Natural Sciences and Engineering Research Council of Canada (NSERC) and Simon Fraser University (SFU) for financial support. We also wish to acknowledge the Canadian Foundation for Innovation (CFI) and AstraZeneca Canada Inc. for support of our research program. J.D.P. thanks SFU for an entrance scholarship and NSERC for a PGSA award. We thank Mr. Jason A. Bexrud for preliminary investigations. We are also grateful to Professor Yongcheng Lin for kindly providing a copy of the ^{1}H NMR spectrum of xyloketal D (**4**) for comparison purposes.

Lithiation of 1-arylimidazol-2(1*H*)-ones and 1-aryl-4,5-dihydroimidazol-2(1*H*)-ones

Carme Cantos Llopart, Conchita Ferrer, and John A. Joule

Abstract: 1-Arylimidazol-2(1*H*)-ones are shown to be readily lithiated, using 2 mol equiv. of *n*-butyllithium, on the benzene ring, ortho to the heterocycle. 1-Aryl-4,5-dihydroimidazol-2(1*H*)-ones also undergo metalation on the aromatic substitutuent ortho to the heterocycle, but less efficiently. 1-Aryl-3-methylimidazol-2(1*H*)-ones are lithiated on the heterocyclic ring and then on the benzene ring ortho to the heterocycle. No ortho-directing effect was found for 1-aryl-4,5-dihydro-3-methylimidazol-2(1*H*)-ones.

Key words: ortho-lithation, ureas for directed ortho metalation, 1-arylimidazol-2-ones, 1-arylimidazolidin-2-ones.

Résumé : On a démontré que les 1-arylimidazol-2(1*H*)-ones, sous l'action de 2 équivalents molaires de *n*-butyllithium, subissent facilement une réaction de lithiation sur le noyau benzénique, en position ortho par rapport à l'hétérocycle. Les 1-aryl-4,5-dihydroimidazol-2(1*H*)-ones subissent aussi une métallation sur le substituant aromatique ortho par rapport à l'hétérocycle, mais la réaction est moins efficace. Les 1-aryl-3-méthylimidazol-2(1*H*)-ones subissent une réaction de lithiation sur le noyau hétérocyclique avant de procéder à une lithiation sur le noyau benzénique en ortho de l'hétérocycle. On n'a pas observé d'effet d'orientation vers la position ortho avec les 1-aryl-4,5-dihydro-3-méthylimidazol-2(1*H*)-ones.

Mots clés : lithiation en ortho, urées pour des métallations orientées en ortho, 1-arylimidazol-2-ones, 1-arylimidazolidin-2-ones.

[Traduit par la Rédaction]

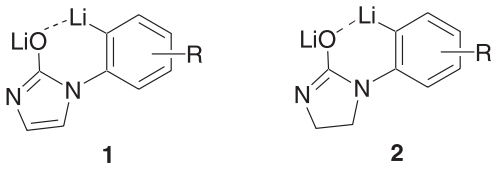
Introduction

We have described (1) our investigations into the use of the heterocyclic substituent in 1-arylpyrimidin-2(1*H*)-ones and in 1-aryl-3,4,5,6-tetrahydropyrimidin-2(1*H*)-ones to assist lithiation at an ortho position (2, 3). In the former case, the use of the pyrimidinone as a directing group was foiled by its strong tendency to undergo addition of the lithiating reagent. In the case of the six-membered cyclic ureas (1-aryl-3,4,5,6-tetrahydropyrimidin-2(1*H*)-ones), we showed that the substituent has a weak ortho directing effect (1). Our study was designed to produce intermediates for a route (4), alternative to those (5–7) previously described, to the biologically active variolin group (8) of alkaloids. The route will allow flexibility and easy introduction of diverse analogues for subsequent biological assessment. We have now examined the analogous five-membered compounds as a further element of eventual diversity in this context.

In the work described here, we have demonstrated the formation and exploitation of intermediates that are summarized as **1** and **2**, formed from **3** and **4**, implying significant ortho-directing effects in these cyclic ureas, which we believe have considerable potential in synthesis. We have also examined the lithiation of *N*-methyl analogues, **5** and **6**, and found no ortho assistance in the case of the latter; the former underwent lithiation in the heterocyclic ring and then ortho to the heterocycle. We are aware of no other attempts to use imidazolones or 4,5-dihydroimidazolones as ortho-directing groups in this way.

Aside from our own work (1), there are only two reports of the use of ureas as ortho-directing substituents, and in both of these, the urea was acyclic. Quéguiner and co-workers (9) lithiated *N*,*N*-dimethyl-*N*′-(quinolin-3-yl)urea with lithium di-isopropylamide leading to the 2-lithio derivative as the thermodynamic product. Smith et al. (10) used 2.5 equiv. of *n*-butyllithium or *tert*-butyllithium at 0 °C to deprotonate *N*-aryl-*N*′,*N*′-dimethylureas ortho to the urea unit; in some cases, the use of *tert*-butyllithium led to lithiation at *N*-methyl as well as, or instead of, ring lithiation.

Carpenter and Chadwick (11) examined the lithiation of five-membered aromatic heterocycles carrying a 1,3-dimethylimidazolidin-2-yl substituent at an α-position and found a weak ortho-directing effect. Earlier, it had been shown that in 1,3-dimethyl-2-phenylimidazolidine, efficient ortho lithiation of the phenyl ring is possible with *n*-butyllithium at room temperature (12). Simig and co-workers (13) demonstrated ortho lithiation in 2-aryl-2-methyl-1,3-dioxolanes; when a meta-chlorine was present on the benzene ring, lithiation took place at the carbon between the chlorine and the ketal-directing groups.



Following the efficient ortho lithiation of 2-phenylimidazoline (14), Chadwick and Ennis (15) examined 2-(2-heteroaryl)imidazolines and confirmed a strong ortho-directing effect. With an appropriate choice of lithiating agent (*sec*-BuLi–TMEDA at –78 °C) ortho lithiation of 2-(2-

methylphenyl)-4,4-dimethyloxazolidine can be made to compete with lithiation of the methyl group (16). The ortho-directing strength of a 1*H*-tetrazol-5-yl-substitutent was shown to be more than that of a methoxyl but less than that of diethylaminocarbonyl and this in turn less than that of a 2-(triphenylmethyl)-2*H*-tetrazol-5-yl substituent (17).

Syntheses of 1-arylimidazol-2(1*H*)-ones (3a–3d and 5a–5d) and 1-aryl-4,5-dihydro-imidazol-2(1*H*)-ones (4a–4d and 6a–6d)

The commercially available phenyl and 2-, 3-, and 4-methoxyphenyl isocyanates were each reacted with amino-acetaldehyde dimethyl acetal (18) and the resulting ureas **7** cyclised (19) by treatment with acid producing the imidazolones **3a**–**3d**. Reaction of each of these with 1 mol equiv. of *n*-butyllithium and then iodomethane cleanly gave their *N*-methyl derivatives, **5a**–**5d** (Scheme 1).

1-Aryl-4,5-dihydroimidazol-2(1*H*)-ones **4a**–**4d** were prepared following the method reported (20) for the synthesis of **4b**, namely cyclising *N*-aryl-1,2-diamines **8**, obtained by reaction of the aromatic amines with 2-bromoethanamine, using carbonyl diimidazole (CDI). The imidazolidinones **4a**–**4d** reacted smoothly with 1 mol equiv. of *n*-butyllithium and then iodomethane giving their *N*-methyl derivatives, **6a**–**6d** (Scheme 2).

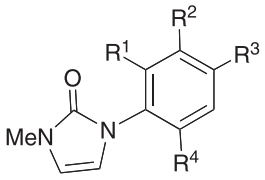
Lithiation of 1-arylimidazol-2(1*H*)-ones 3a–3d and 5a–5d

Treatment of the *N*-hydrogen imidazolones **3a**–**3d** with 2.5 mol equiv. of *n*-butyllithium and then excess iodomethane proceeded smoothly and gave rise to *N*- and benzene-ring-dimethylated products in good yields (Table 1). Noteworthy are: (*i*) the absence of products of nucleophilic addition to the unsaturated five-membered ring (cf. 1-arylpyrimidin-2(1*H*)-ones in ref. 1); (*ii*) the clean nature of the transformations, even in the substrate **3a** with no electron-withdrawing methoxyl on the benzene ring (→ **5e**); (*iii*) the regiochemistry of lithiation of the meta-methoxy substrate **3c** — between the methoxyl group and the imidazolone (→ **5h**) — the combined effect of the two groups producing this result; (*iv*) the formation from the ortho-methoxy substrate **3b** of a mixture of dimethylated products (**5f** and **5g**) from lithiation either ortho to the heterocycle (18%) or ortho to the methoxyl (25%); and (*v*) the regiochemistry of lithiation of the para-methoxy substrate **3d** in which there was no trace of lithiation ortho to the methoxyl group — the influence of the imidazolone being the greater (→ **5i**). Where there was ambiguity regarding the position of the introduced aromatic methyl, nOe experiments were employed. Thus, in **5g** the proximity of the methoxyl methyl and the ring methyl was established, and for **5i** there was no nOe on the methyl (δ 2.23) on irradiation of the methoxyl methyl (δ 3.83) and conversely, irradation at 2.23 had no effect on the methoxyl but did show an nOe to the imidazolone signal at δ 6.27. We interpret the trapping results as involving the double methylation of dilithio species **1**, the formation of which are favoured by the aromatic character of the five-membered ring in these.

Experiments with **3a**–**3d** again using 2.5 mol equiv. of *n*-butyllithium, but with phenyl isocyanate as the trapping electrophile, produced *N*- and *C*-disubstituted, biuret-anilide products **9b**–**9e** and **9h**, with exactly comparable regioselectivity, but only in moderate yields, and in some cases accompanied by minor amounts of the mono-*N*-substituted biuret (**9a**, **9f**, **9g**) (Table 1).



To determine whether an imidazolone that is not capable of *N*-deprotonation could act as an ortho-directing group, in partial analogy to the use of an *N*,*N*-dialkylamide as an ortho-directing group, we treated the *N*-methyl imidazolones **5a**–**5d** with *n*-BuLi and quenched with iodomethane. Here, there was a complete reversal of selectivity and a total preference for lithiation of the five-membered heterocycle when using approximately 1 equiv. of the strong base, though not very efficiently. Both 4- and 5-methylated products were formed — **5j/5k**, **5l/5m**, **5n/5o** — with the 4-methylated isomers predominating (Table 1). The regiochemistry of the methylation was established by nOe experiments — for the 3,4-dimethylimidazolones, e.g., **5k**, irradation of the *N*-methyl signal (δ 3.26) gave an effect with the *C*-methyl (δ 2.11), but not the remaining imidazolone ring proton (δ 6.33).

Even more intriguingly, when 2.5 mol equiv. of *n*-butyllithium were employed for the lithiation of **5a**–**5d**, dimethylated products were obtained in which one methyl had been introduced onto the benzene ring ortho to the imidazolone, presumably with its assistance, and the other at

C-4 of the imidazolone, with no C-5-methylation. Products **5p**, **5q**, and **5s** were formed very efficiently, but **5r** only in poor yield (Table 1). Again, nOe experiments involving irradiation of the *N*-methyl signals in the products **5p**–**5s** caused nOe enhancement of the *C*-methyl signal in each case, but had no effect on the imidazole C-5-proton signals.

The results described above in the lithiations of **5a**–**5d** were unexpected and a full understanding will require further experimentation. We offer the following explanation (Scheme 3) as a speculative rationalization for the observations. We suggest that initial lithiation of **5a**–**5d** takes place at C-4 of the imidazolone ring, giving **A** and that trapping of this species in the experiments using 1 mol equiv. of *n*-BuLi leads to the 3,4-dimethylated products **5k**, **5m**, and **5n**. We further speculate that **A** can undergo ring opening to generate an alkyne, rather as has been reported for lithiated isoxazoles (21) and oxazoles (22), generating **B**, which after conversion to the *C*-lithiated species **C** gives rise to the 3,5-dimethylated products **5j**, **5l**, and **5o** via alkyne *C* methylation then ring closure of **D**. In the experiments where 2.5 mol equiv. of the base were employed, benzene ring C lithiation of **B** using the second equivalent of base with ortho assistance, would give **E** and thence benzene-ring-methylated **F**, final closure of which would lead specifically

to the trimethylated 3,4-dimethylimidazolones **5p**–**5s** as shown.

Lithiation of 1-arylimidazolidin-2(1*H*)-ones (4a–4d) and attempted lithiation of 6a–6d

The use of 2.5 mol equiv. of *n*-butyllithium and then excess iodomethane gave rise to products **6e**–**6j** dimethylated on nitrogen and the benzene ring; when the *N*-hydrogen imidazolidinones **4a**–**4d** were examined (Table 1), however, these transformations were not as efficient as those involving the imidazolones **3a**–**3d**. Noteworthy are: (*i*) benzene ring lithiation ortho to the heterocycle (→ **6e**), even in the substrate **4a** with no electron-withdrawing methoxyl; (*ii*) the regiochemistry of lithiation of the meta-methoxy-substrate **4c** — between the methoxyl group and the imidazolidinone (→ **6h**); and (*iii*) the regiochemistry of lithiation of the ortho-**4b** and para-methoxy **4d** substrates — alternative lithiations ortho to either methoxyl or imidazolidinone groups being observed in both cases, giving **6f/6g** (ortho to the heterocycle 28% and ortho to the methoxyl 37%) and **6i/6j** (ortho to the heterocycle 9% and ortho to the methoxyl 12%), respectively.

The significantly more facile ortho lithiations observed with the *N*-arylimidazolones **3** as opposed to the *N*-arylimidazolidinones **4** seem unlikely to reside in their relative ease of *N*-deprotonation, even though in the former case, an aromatic alkoxide anion is generated. Rather, we suggest that subtle stereochemical factors, that influence the ease with which ortho assistance can be conveyed, are at play. We hope to be able to comment further on this aspect in future publications.

Attempted lithiation ortho to the *N*-methylimidazolidinone unit in substrates **6a**–**6d** failed.

Typical procedure for synthesis of ureas (7)

N-*(2-Methoxyphenyl)*-N′-*(2,2-dimethoxyethyl)*urea *(7b)*

2-Methoxyphenyl isocyanate (4.77 g, 31.98 mmol) was added over a period of 5 min to aminoacetaldehyde dimethyl acetal (3.36 g, 31.98 mmol, 1 equiv.) while cooling in an ice bath. The reaction was allowed to warm up to rt for 1 h during which time a yellow crystalline mass was formed. The solid was washed with petroleum ether, dissolved in CH_2Cl_2, and the solution evaporated. Column SiO_2 chromatography (50% EtOAc in hexane) gave *N*-(2-methoxyphenyl)-*N′*-(2,2-dimethoxyethyl)urea **7b** as white crystals (6.98 g, 85%), mp 92–94 °C. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 3.42 (2H, m, CH_2CH), 3.48 (6H, s, 2 × OCH_3), 3.88 (3H, s, OCH_3), 4.47 (1H, t, J = 5.2, CH_2CH), 5.05 (1H, bt, J = 5.5, NH), 6.86–7.06 (4H, m, Ar-H), 8.05 (1H, m, Ar-NH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 41.8, 54.4, 55.5, 103.4, 110.0, 119.5, 121.0, 122.3, 128.5, 142.1, 155.6. *m*/*z* (CI): 255 (MH^+, 100%), 223 (95), 75 (30). Anal. calcd. for $C_{12}H_{18}N_2O_4$ (M): 254.126 65; found (M^+): 254.126 9.

Scheme 3.

N-*(Phenyl)*-N′-*(2,2-dimethoxyethyl)urea (7a)*

N-(Phenyl)-*N′*-(2,2-dimethoxyethyl)urea (**7a**) was prepared as above from phenyl isocyanate (5 g, 41.9 mmol) and aminoacetaldehyde dimethyl acetal (4.5 mL, 41.9 mmol, 1 equiv.) giving **7a** as a white crystalline solid (9.53 g, 89%), mp 89–91 °C, lit. value (18) mp 86–89 °C. IR ν_{max} (film, cm^{-1}): 755, 1070, 1130, 1238, 1311, 1441, 1499, 1555, 1597, 1654, 3340. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 3.41 (6H, s, OCH_3), 3.41 (2H, m, CH_2CH), 4.43 (1H, t, *J* = 5.1, CH_2CH), 5.82 (1H, t, *J* = 5.8, NH), 7.03 (1H, m, ArH), 7.28 (4H, m, ArH), 7.58 (1H, s, NH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 41.7, 54.5, 103.5, 120.1, 123.1, 128.9, 138.8, 156.3. *m/z* (CI): 225 (MH^+, 74%), 193 (100), 75 (92). Anal. calcd. for $C_{11}H_{16}N_2O_3$ (M): 224.116 1; found (M^+): 224.115 9.

N-*(3-Methoxyphenyl)*-N′-*(2,2-dimethoxyethyl)urea (7c)*

N-(3-Methoxyphenyl)-*N′*-(2,2-dimethoxyethyl)urea (**7c**) was prepared as above from 3-methoxyphenyl isocyanate (1 g, 6.7 mmol) and aminoacetaldehyde dimethyl acetal (0.7 g, 6.7 mmol, 1 equiv.) giving **7c** as a white crystalline solid (1.615 g, 95%) pure enough for its subsequent use. An analytical sample was recrystallized from EtOAc–hexane, mp 102 °C. IR ν_{max} (film, cm^{-1}): 1556, 1606, 1653, 2875, 2958. ^{1}H NMR (300 MHz, d_6-DMSO) δ: 3.44 (2H, m, CH_2CH), 3.44 (6H, s, 2 × OCH_3), 3.72 (3H, s, OCH_3), 4.39 (1H, t, *J* = 5.1, CH_2CH), 6.49 (1H, apparent dd, *J* = 8.2, 2.9, ArH), 6.84 (1H, apparent dd, *J* = 8.2, 2.9, ArH), 7.12 (1H, bs, ArH), 7.14 (1H, bs, NH), 7.15 (1H, t, *J* = 8.2, ArH), 8.6 (1H, s, NH). ^{13}C NMR (75 MHz, d_6-DMSO) (DEPT) δ: 41.0 (d), 53.7 (q), 55.2 (q), 102.9 (d), 103.7 (d), 106.9 (d), 110.3 (d), 129.7 (d), 141.9 (s), 155.4 (s), 160.0 (s). *m/z* (CI): 255 (MH^+, 7%), 208 (25), 191 (100). N-*(4-Methoxyphenyl)*-N′-*(2,2-dimethoxyethyl)urea (7d)

N-(4-Methoxyphenyl)-*N′*-(2,2-dimethoxyethyl)urea (**7d**) was prepared from 4-methoxyphenyl isocyanate (5 g, 33.5 mmol) and aminoacetaldehyde dimethyl acetal (3.61 mL, 33.5 mmol, 1 equiv.) giving **7d** as a white crystalline solid (7.9 g, 92%), mp 112–114 °C. IR ν_{max} (film, cm^{-1}): 1240, 1509, 1551, 1560, 1638, 1654, 3400. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 3.40 (6H, s, OCH_3), 3.40 (2H, d, *J* = 5.0, C*H*$_2$CH), 3.78 (3H, s, $ArOCH_3$), 4.41 (1H, t, *J* = 5.0, CH_2C*H*), 6.82 (1H, d, *J* = 6.9, ArH), 7.19 (2H, d, *J* = 6.9, ArH), 7.21 (1H, s, NH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 41.7, 54.4, 55.4, 103.4, 114.3, 123.2, 131.4, 156.2, 156.7. *m/z* (CI): 255 (MH^+, 100%), 223 (90), 75 (100). Anal. calcd. for $C_{12}H_{18}N_2O_4$ (%): C 56.68, H 7.13, N 11.02; found (%): C 57.07, H 7.00, N 10.99. Anal. calcd. for $C_{12}H_{18}N_2O_4$ (M): 254.126 7; found (M^+): 254.126 4.

Typical procedure for the synthesis of imidazolones (3)

1-(2-Methoxyphenyl)imidazol-2(1H)-one (3b)

N-(2-Methoxyphenyl)-*N′*-(2,2-dimethoxyethyl)urea (**7b**) (1.12 g, 4.4 mmol) was dissolved in aq. 2 mol L^{-1} HCl (10 mL). The solution was stirred at rt for 20 h. The resulting clear solution was made basic with aq. 2 mol L^{-1} NaOH, extracted with CH_2Cl_2, then the extract was dried over $MgSO_4$ and evaporated, yielding 1-(2-methoxyphenyl)imidazol-2(1*H*)-one **3b** as a white crystalline solid (0.92 g, 82%), mp 160–162 °C. IR ν_{max} (film, cm^{-1}): 764, 1024, 1244, 1283, 1431, 1465, 1510, 1684, 2934. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 3.88 (s, 3H, OCH_3), 6.39 (1H, apparent t, *J* = 2.6, ImH), 6.44 (1H, apparent t, *J* = 2.6, ImH), 7.07 (2H, m, ArH), 7.37 (1H, m, ArH), 7.49 (1H, dd, *J* = 7.6, 1.6, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 55.7, 108.5, 112.2, 113.5, 120.8, 125.0, 128.2, 129.0, 154.2, 154.4. *m/z* (CI): 191 (MH^+, 100%). Anal. calcd. for $C_{10}H_{10}N_2O_2$ (%): C 63.15, H 5.30, N 14.73; found (%): C 63.23, H 5.40, N 14.55. Anal. calcd. for $C_{10}H_{10}N_2O_2$ (M): 190.074 2; found (M^+): 190.074 5.

1-Phenylimidazol-2(1H)-one (3a)

1-Phenylimidazol-2(1*H*)-one (**3a**) was prepared as above from *N*-(phenyl)-*N′*-(2,2-dimethoxyethyl)urea **7a** (7 g, 31.2 mmol) in aq. 2.5 mol L^{-1} HCl (60 mL) giving **3a** as a white crystalline solid (3.27 g, 65%), mp 127 °C, lit. value (19) mp 123–126 °C. IR ν_{max} (film, cm^{-1}): 756, 1424, 1503, 1598, 1667, 3061, 3156. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.45 (1H, apparent t, *J* = 2.5, ImH), 6.57 (1H, apparent t, *J* = 2.5, ImH), 7.31 (1H, m, ArH), 7.48 (2H, m, ArH), 7.61 (2H, m, ArH), 11.1 (1H, bs, NH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 109.6, 111.0, 122.3, 126.1, 129.2, 136.9, 153.8. *m/z* (CI): 178 (MNH_4^+, 100%), 161 (MH^+, 99). Anal. calcd. for $C_9H_8N_2O$: (M): 160.063 7; found (M^+): 160.063 8.

1-(3-Methoxyphenyl)imidazol-2(1H)-one (3c)

1-(3-Methoxyphenyl)imidazol-2(1*H*)-one (**3c**) was prepared as above from *N*-(3-methoxyphenyl)-*N′*-(2,2-dimethoxyethyl)urea **7c** (1.2 g, 4.7 mmol) in aq. 2.5 mol L^{-1} HCl (20 mL) giving **3c** as a white crystalline solid (0.87 g, 97%), pure enough for its subsequent use, mp 136 °C. IR ν_{max} (film, cm^{-1}): 1230, 1497, 1687. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 3.88 (s, 3H, OCH_3), 6.50 (1H, d, *J* = 2.5, ImH), 6.62 (1H, d, *J* = 2.5, ImH), 6.86 (1H, dd, *J* = 8.1, 2.5, ArH), 7.17 (1H, apparent d, *J* = 8.1, ArH), 7.23 (1H, bs, ArH), 7.38 (1H, t, *J* = 8.1, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 55.4, 108.3, 109.6, 111.0, 111.8, 114.4, 129.9, 138.0, 153.8, 160.2. *m/z* (CI): 208 (MNH_4^+, 30%), 191 (MH^+, 100). Anal. calcd. for $C_{10}H_{10}N_2O_2$ (M): 190.074 2; found (M^+): 190.073 8.

1-(4-Methoxyphenyl)imidazol-2(1H)-one (3d)

1-(4-Methoxyphenyl)imidazol-2(1*H*)-one (**3d**) was prepared as above from *N*-(4-methoxyphenyl)-*N′*-(2,2-dimethoxyethyl)urea **7d** (7 g, 27.5 mmol) in aq. 2.5 mol L^{-1} HCl (60 mL) giving **3d** as a white crystalline solid (4.69 g, 89%), mp 158 °C. IR ν_{max} (film, cm^{-1}): 1234, 1247, 1512, 1667. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 3.86 (s, 3H, OCH_3), 6.42 (1H, apparent t, *J* = 2.5, ImH), 6.49 (1H, apparent t, *J* = 2.5, ImH), 7.00 (2H, d, *J* = 6.9, ArH), 7.48 (2H, d, *J* = 6.9, ArH), 11.1 (1H, s, NH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 55.5, 109.2, 111.5, 114.4, 124.3, 129.9, 157.9. *m/z* (CI): 208 (MNH_4^+, 2%), 191 (MH^+,100). Anal. calcd. for $C_{10}H_{10}N_2O_2$ (%): C 63.15, H 5.30, N 14.73; found (%): C 63.20, H 5.38, N 14.79. Anal. calcd. for $C_{10}H_{10}N_2O_2$ (M): 190.074 2; found (M^+): 190.073 9.

Typical procedure for synthesis of 1-aryl-3-methylimidazolones (5)

1-(2-Methoxyphenyl)-3-methylimidazol-2(1H)-one (5b)

A solution of 1-(2-methoxyphenyl)imidazol-2(1*H*)-one **3b** (0.26 g, 1.37 mmol) in anhyd. THF at –78 °C was treated with *n*-BuLi (1.6 mol L^{-1}, 0.89 mL, 1.1 equiv.) over 30 min under N_2. The solution was warmed up to 0 °C for 2 h and then cooled to –78 °C for the addition of iodomethane (0.09 mL, 1.43 mmol, 1.1 equiv.). The reaction mixture was allowed to warm up to rt and after 20 h the reaction was quenched with satd. aq. NH_4Cl and evaporated to remove the THF. The organic residue was dissolved in CH_2Cl_2, the solution washed with brine, dried and evaporated to give 1-(2-methoxyphenyl)-3-methylimidazol-2(1*H*)-one **5b** as a clear yellow oil (0.25 g, 94%). IR ν_{max} (film, cm^{-1}): 1045, 1224, 1270, 1405, 1461, 1497, 1605, 1687. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 3.35 (3H, s, NCH_3), 3.87 (3H, s, OCH_3), 6.31 (1H, d, *J* = 2.9, ImH), 6.47 (1H, d, *J* = 2.9, ImH), 7.04 (2H, apparent t, *J* = 8.0, ArH), 7.34 (1H, m, ArH), 7.47 (1H, dd, *J* = 8.0, 1.6, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 30.5, 55.7, 107.2, 110.1, 111.3, 112.1, 112.2, 120.8, 127.9, 128.6, 154.0. *m/z* (CI): 222 (MNH_4^+, 22%), 205 (MH^+, 100). $C_{11}H_{12}N_2O_2$ (M): 204.089 9; found (M^+): 204.090 0.

3-Methyl-1-phenylimidazol-2(1H)-one (5a)

3-Methyl-1-phenylimidazol-2(1*H*)-one (**5a**) was prepared as above from 1-phenylimidazol-2(1*H*)-one **3a** (0.5 g, 3.12 mmol) and *n*-BuLi (1.6 mol L^{-1}, 2.15 mL, 1.1 equiv.) then iodomethane (0.29 mL, 4.7 mmol, 1.5 equiv.) giving **5a** as a white solid (0.52 g, 96%). An analytical sample was prepared by column SiO_2 chromatography (50% EtOAc in hexane), mp 119–121 °C, lit. value (23) mp 119 °C. IR ν_{max} (film, cm^{-1}): 766, 1266, 1344, 1402, 1452, 1459, 1507, 1600, 1672, 3060, 3135. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 3.35 (3H, s, NCH_3), 6.35 (1H, d, *J* = 3.0, ImH), 6.59 (1H, d, *J* = 3.0, ImH), 7.26 (1H, m, ArH), 7.44 (2H, apparent t, *J* = 8.0 ArH), 7.63 (2H, m, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ:

30.4, 109.1, 112.6, 111.06, 121.5, 125.6, 129.1, 137.3, 155.4. *m/z* (CI): 192 (MNH_4^+, 32%), 175 (MH^+, 100).

1-(3-Methoxyphenyl)-3-methylimidazol-2(1H)-one (5c)

1-(3-Methoxyphenyl)-3-methylimidazol-2(1*H*)-one (**5c**) was prepared as above from 1-(3-methoxyphenyl)imidazol-2(1*H*)-one **3c** (0.8 g, 4.2 mmol) and *n*-BuLi (1.6 mol L^{-1}, 2.9 mL, 1.1 equiv.) then iodomethane (0.29 mL, 4.6 mmol, 1.1 equiv.) giving **5c** as a clear yellow oil (0.73 g, 86%). ^1H NMR (300MHz, $CDCl_3$) δ: 3.35 (3H, s, NCH_3), 3.87 (3H, s, OCH_3), 6.35 (1H, d, *J* = 3.0, ImH_a), 6.59 (1H, d, *J* = 3.0, ImH_b), 6.81 (1H, dd, *J* = 8.1, 3.0, ArH), 7.15 (1H, dd, *J* = 8.1, 3.0, ArH), 7.29 (1H, s, ArH), 7.34 (1H, t, *J* = 8.1, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 30.4, 55.3, 107.2, 109.1, 111.6, 111.7, 112.6, 113.3, 129.7, 138.5, 160.2. *m/z* (CI): 222 (MNH_4^+, 22%), 205 (MH^+, 100). Anal. calcd. for $C_{11}H_{12}N_2O_2$ (M): 204.089 9; found (M^+): 204.090 5.

1-(4-Methoxyphenyl)-3-methylimidazol-2(1H)-one (5d)

1-(4-Methoxyphenyl)-3-methylimidazol-2(1*H*)-one (**5d**) was prepared as above from 1-(4-methoxyphenyl)imidazol-2(1*H*)-one **3d** (0.5 g, 2.6 mmol) and *n*-BuLi (1.6 mol L^{-1}, 1.8 mL, 1.1 equiv.) then iodomethane (0.24 mL, 3.9 mmol, 1.5 equiv.) giving **5d** as a white solid (0.516 g, 96%), mp 116–118 °C, lit. value (23) mp 114 °C. IR ν_{max} (film, cm^{-1}): 1248, 1458, 1514, 1678, 2360. ^1H NMR (300 MHz, $CDCl_3$) δ: 3.32 (3H, s, NCH_3), 3.83 (3H, s, OCH_3), 6.31 (1H, d, *J* = 2.9, ImH), 6.50 (1H, d, *J* = 2.9, ImH), 6.95 (2H, d, *J* = 6.9, ArH), 7.48 (2H, d, *J* = 6.9, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 30.4, 55.4, 109.7, 111.8, 112.2, 114.2, 123.4, 130.5, 157.5. *m/z* (CI): 222 (MNH_4^+, 22%), 205 (MH^+, 100). Anal. calcd. for $C_{11}H_{12}N_2O_2$ (M): 204.089 9; found (M^+): 204.089 7.

Typical procedure for the synthesis of aryldiamines (8)

N-*(2-Methoxyphenyl)-1,2-diaminoethane (8b)*

A mixture of freshly distilled *o*-anisidine (19.7 g, 160 mmol) and 2-bromoethylamine hydrobromide (19.7 g, 160 mmol, 1 equiv.) in dry toluene (40 mL) was heated at reflux temperature for 18 h, and then cooled. A solution of 50% aq. NaOH and CH_2Cl_2 were added and the layers separated. The aqueous layer was saturated with NaCl and extracted with CH_2Cl_2. The combined organic layers were dried over $MgSO_4$, filtered and evaporated to dryness. Dry flash column SiO_2 chromatography (40%–100% of CH_2Cl_2 in hexane) yielded *N*-(2-methoxyphenyl)-1,2-diaminoethane **8b** (9.99 g, 75%) as a light brown low oil. ^1H NMR (24) (300 MHz, $CDCl_3$) δ: 1.98 (2H, bs, NH_2), 3.02 (2H, t, *J* = 5.6, CH_2), 3.24 (2H, t, *J* = 5.6, CH_2), 3.5 (1H, bs, NH), 3.9 (3H, s, $ArOCH_3$), 6.70 (2H, m, ArH), 6.80 (1H, m, ArH), 6.90 (1H, m, Ar). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 41.3, 46.5, 55.4, 109.7, 110.2, 116.5, 121.4, 138.0, 146.8. *m/z* (CI): 167 (MH^+, 100%). Anal. calcd. for $C_8H_{11}N_2O$ (M – Me): 151.082 1; found: 151.063 7.

N-*Phenyl-1,2-diaminoethane (8a)*

N-Phenyl-1,2-diaminoethane (**8a**) was prepared as above from aniline (5 g, 53 mmol) and 2-bromoethylamine hydrobromide (5.5 g, 26 mmol, 0.5 equiv.) giving **8a** (1.5 g, 42%) as a clear oil (23). IR ν_{max} (film, cm^{-1}): 749, 1320, 1506, 1602, 2862, 2937, 3024, 3048, 3343. ^1H NMR (300 MHz, d_6-DMSO) δ: 2.85 (2H, t, *J* = 6.3, CH_2), 3.16 (2H, m, CH_2), 5.07 (2H, bs, NH_2), 5.75 (1H, bs, NH), 6.57 (3H, m, ArH), 7.10 (2H, m, ArH). ^{13}C NMR (75 MHz, d_6-DMSO) δ: 39.7, 44.3, 112.8, 116.6, 129.7, 149.4. *m/z* (CI): 137 (MH^+, 100%).

N-*(3-Methoxyphenyl)-1,2-diaminoethane (8c)*

N-(3-Methoxyphenyl)-1,2-diaminoethane (**8c**) was prepared as above from *m*-anisidine (20 g, 0.16 mmol) and 2-bromoethylamine hydrobromide (16.6 g, 0.8 mol, 0.5 equiv.) giving **8c** (9.78 g, 73%) as a brown semi-solid, lit. value (24) mp 45 to 46 °C. ^1H NMR (300 MHz, $CDCl_3$) δ: 1.42 (2H, bs, NH_2), 2.98 (2H, m, CH_2), 3.17 (2H, m, CH_2), 3.80 (3H, s, OCH_3), 6.20–6.35 (3H, m, ArH), 7.12 (1H, t, *J* = 8.1, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 41.1, 46.4, 54.9, 98.8, 102.4, 106.0, 129.8. *m/z* (CI): 167 (MH^+, 100%), 136 (20).

N-*(4-Methoxyphenyl)-1,2-diaminoethane (8d)*

N-(4-Methoxyphenyl)-1,2-diaminoethane (**8d**) was prepared as above from *p*-anisidine (5 g, 40 mmol) and 2-bromoethylamine hydrobromide (4.15 g, 20 mmol, 0.5 equiv.) giving **8d** (1.35 g, 40%) as a brown solid, mp 60–62 °C, lit. value (25) mp 64 °C. IR ν_{max} (film, cm^{-1}): 823, 1034, 1236, 1512, 1668, 2932. ^1H NMR (300 MHz, CD_3OD) δ: 2.78 (2H, t, *J* = 6.1, CH_2), 3.07 (2H, t, *J* = 6.1, CH_2), 3.26 (1H, bs, NH), 4.83 (1H, bs, NH_2), 6.60 (2H, d, *J* = 9.0, ArH), 6.81 (2H, d, *J* = 9.0, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 41.6, 47.8, 56.1, 114.6, 115.2, 126.0, 142.9. *m/z* (CI): 167 (M^+, 100%), 136 (20), 124 (65).

Typical procedure for the synthesis of *N*-arylimidazolidinones (4)

4,5-Dihydro-1-(2-methoxyphenyl)imidazol-2(1H)-one (4b)

To a solution of *N*-(2-methoxyphenyl)-1,2-diaminoethane **8b** (9.97 g, 0.06 mol) in anhyd. THF (50 mL), 1,1-carbonyldiimidazole (18.44 g, 0.145 mol, 2.4 equiv.) was added under N_2. The solution was refluxed for 21 h and then evaporated to dryness to remove the THF. The yellow residue was taken up with EtOAc, the solution washed with brine, dried over $MgSO_4$ and evaporated. Column SiO_2 chromatography (25% of EtOAc in hexane) yielded 4,5-dihydro-1-(2-methoxyphenyl)imidazol-2(1*H*)-one **4b** as a white crystalline solid (2.77 g, 25%), mp 150–152 °C, lit. value (26) mp 151–153 °C. ^1H NMR (300 MHz, $CDCl_3$) δ: 3.60 (2H, t, *J* = 8.2, ImH), 3.85 (2H, t, *J* = 8.2, ImH), 3.90 (3H, s, OCH_3), 5.18 (1H, bs, NH), 6.99 (2H, m, ArH), 7.26 (1H, m, ArH), 7.39 (1H, dd, *J* = 7.7, 1.6, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 38.7, 47.3, 55.5, 111.9, 120.9, 127.7, 127.8, 128.6, 155.2, 162.0. *m/z* (CI): 193 (MH^+, 100%). Anal. calcd. for $C_{10}H_{12}N_2O_2$ (M): 192.089 9; found (M^+): 192.089 4.

*4,5-Dihydro-1-(4-methoxyphenyl)imidazol-2(1*H*)-one (4d)*

4,5-Dihydro-1-(4-methoxyphenyl)imidazol-2(1*H*)-one (**4d**) was prepared as above from *N*-(4-methoxyphenyl)-1,2-diaminoethane **8d** (1 g, 6 mmol) and 1,1′-carbonyldiimidazole (3.9 g, 52 mmol, 3.9 equiv.) giving **4d** as a white crystalline solid (0.45 g, 44%), mp 205–207 °C, lit. value (28) mp 211 °C. IR ν_{max} (film, cm^{-1}): 830, 1034, 1251, 1519, 1679, 3476, 3583. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 3.90 (3H, s, OCH_3), 3.97 (2H, t, J = 7.9, ImH), 4.17 (2H, t, J = 7.9, ImH), 7.01 (2H, d, J = 7.8, ArH), 7.41 (2H, d, J = 7.8, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 37.9, 46.2, 55.8, 114.3, 120.3, 141.6, 142.2, 158.7. *m*/*z* (CI): 210 (MNH_4^+, 10%), 193 (MH^+, 100).

Typical procedure for the synthesis of 1-aryl-3-methylimidazolidinones (6)

*4,5-Dihydro-1-(2-methoxyphenyl)-3-methylimidazol-2(1*H*)-one (6b)*

A solution of 4,5-dihydro-1-(2-methoxyphenyl)imidazol-2(1*H*)-one **4b** (0.250 g, 1.3 mmol) in anhyd. THF was treated with *n*-BuLi (1.6 mol L^{-1}, 0.9 mL, 1.1 equiv.) at –78 °C over 30 min under N_2. The solution was warmed then maintained at 0 °C for 2 h and cooled down to –78 °C again for the addition of iodomethane (0.09 mL, 1.43 mmol, 1.1 equiv.). The reaction mixture was warmed up to rt and after 20 h quenched with satd. aq. NH_4Cl and evaporated to remove the THF. The colourless residue was dissolved with CH_2Cl_2, the solution washed with brine, dried over $MgSO_4$ and evaporated to yield 4,5-dihydro-1-(2-methoxyphenyl)-3-methylimidazol-2(1*H*)-one **6b** (0.26 g, 95%) as a dark yellow oil. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.92 (3H, s, NCH_3), 3.48 (2H, t, J = 7.7, ImH), 3.78 (2H, t, J = 7.7, ImH), 3.88 (3H, s, OCH_3), 6.92 (2H, m, ArH), 7.25 (1H, m, ArH), 7.38 (1H, dd, J = 7.8, 1.6, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 31.5, 44.6, 45.4, 55.5, 111.8, 120.8, 127.4, 128.4, 129.3, 155.1, 160.0. *m*/*z* (CI): 207 (MH^+, 100%). Anal. calcd. for $C_{11}H_{14}N_2O_2$ (M): 206.105 5; found (M^+): 206.105 5.

*4,5-Dihydro-3-methyl-1-phenylimidazol-2(1*H*)-one (6a)*

4,5-Dihydro-3-methyl-1-phenylimidazol-2(1*H*)-one (**6a**) was prepared as above from 4,5-dihydro-1-phenylimidazol-2(1*H*)-one **4a** (0.162 mg, 1 mmol), *n*-BuLi (1.6 mol L^{-1}, 0.68 mL, 1.1 equiv.) then iodomethane (0.06 mL, 1.1 mmol, 1.1 equiv.) giving **6a** as a white crystalline solid (126 mg, 71%). An analytical sample was prepared by column SiO_2 chromatography (50% of EtOAc in hexane), mp 99 °C, lit. value (29) mp 110 to 111 °C. IR ν_{max} (film, cm^{-1}): 742, 899, 1275, 1387, 1404, 1439, 1476, 1504, 1598, 1702, 2826, 2887, 2917, 2952. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.93 (3H, s, NCH_3), 3.48 (2H, t, J = 8.3, ImH), 3.80 (2H, t, J = 8.3, ImH), 7.05 (1H, dt, J = 7.3, 1.0, ArH), 7.32 (1H, m, ArH), 7.60 (1H, m, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 31.4, 42.5, 44.3, 117.4, 122.4, 129.0, 140.9, 158.4. *m*/*z* (CI): 177 (MH^+, 100%), 105 (2).

*4,5-Dihydro-1-(3-methoxyphenyl)-3-methylimidazol-2(1*H*)-one (6c)*

4,5-Dihydro-1-(3-methoxyphenyl)-3-methylimidazol-2(1*H*)-one (**6c**) was prepared as above from 4,5-dihydro-1-(3-methoxyphenyl)imidazol-2(1*H*)-one **4c** (200 mg, 1.04 mmol, 1 equiv.) and *n*-BuLi (1.6 mol L^{-1}, 0.875 mL) then iodomethane (0.60 mL, 1.04 mmol, 1 equiv.) giving **6c** (200 mg, 93%) as white solid, mp 95 °C, lit. value (29) mp 97–99 °C. IR ν_{max} (film, cm^{-1}): 1221, 1452, 1500, 1601, 1703. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.93 (3H, s, NCH_3), 3.50 (2H, apparent t, J = 7.9, ImH), 3.83 (2H, m, ImH), 3.85 (3H, s, OCH_3), 6.63 (1H, dd, J = 8.2, 2.2, ArH), 7.04 (1H, dd, J = 8.2, 2.2, ArH), 7.25 (1H, t, J = 8.2, ArH), 7.41 (1H, m, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 31.1, 42.3, 43.9, 55.2, 103.1, 108.1, 109.1, 109.7, 129.3, 141.9, 159.9. *m*/*z* (CI): 207 (M^+, 100). Anal. calcd. for. $C_{10}H_{12}N_2O_2$ (M): 206.105 5; found (M^+): 206.105 5.

*4,5-Dihydro-1-(4-methoxyphenyl)-3-methylimidazol-2(1*H*)-one (6d)*

4,5-Dihydro-1-(4-methoxyphenyl)-3-methylimidazol-2(1*H*)-one (**6d**) was prepared as above from 4,5-dihydro-1-(4-methoxyphenyl)imidazol-2(1*H*)-one **4d** (0.25 g, 1.3 mmol) and *n*-BuLi (1.6 mol L^{-1}, 0.89 mL, 1.1 equiv.) then iodomethane (0.085 mL, 1.43 mmol, 1.1 equiv.) giving **6d** (180 mg, 68%) as a solid, mp 56 to 57 °C. IR ν_{max} (film, cm^{-1}): 828, 1038, 1252, 1686, 2948. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.83 (3H, s, NCH_3), 3.39 (2H, apparent t, J = 7.6, ImH), 3.71 (2H, apparent t, J = 7.6, ImH), 3.73 (3H, s, OCH_3), 6.82 (2H, d, J = 8.9, ArH), 7.39 (2H, d, J = 8.9, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 31.6, 43.1, 44.6, 55.8, 114.4, 119.5, 134.4, 146.2, 155.6. *m*/*z* (CI): 207 (MH^+, 100). Anal. calcd. for. $C_{10}H_{12}N_2O_2$ (M): 206.105 5; found (M^+): 206.105 8.

Typical procedure for reaction of imidazolones (3a–3d) and imidazolidinones (4a–4d) with 2.5 equiv. of *n*-BuLi then trapping with MeI

*1-(2-Methoxy-3-methylphenyl)-3-methylimidazol-2(1*H*)-one (5g) and 1-(2-methoxy-6-methylphenyl)-3-methylimidazol-2(1*H*)-one (5f)*

A solution of 1-(2-methoxyphenyl)imidazol-2(1*H*)-one **3b** (0.26 g, 1.3 mmol) in anhyd. THF was treated with *n*-BuLi (1.6 mol L^{-1}, 2 mL, 2.5 equiv.) at –78 °C over 30 min under N_2. The solution was warmed up to then maintained at 0 °C for 2 h and cooled down to –78 °C again for the addition of iodomethane (0.2 mL, 3.25 mmol, 2.5 equiv.). The reaction

© 2004 NRC Canada

mixture was allowed to warm up to rt and after 20 h quenched with satd. aq. NH_4Cl, and evaporated to remove the THF. The organic residue was taken up with CH_2Cl_2, the solution washed with brine, dried and evaporated. Column SiO_2 chromatography (50% of EtOAc in petroleum ether) yielded firstly 1-(2-methoxy-3-methylphenyl)-3-methylimidazol-2(1*H*)-one **5g** (70 mg, 25%), secondly 1-(2-methoxy-6-methylphenyl)-3-methylimidazol-2(1*H*)-one **5f** (50 mg, 18%) as yellow oils. Spectroscopic data for **5g**: ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.25 (3H, s, $ArCH_3$), 3.27 (3H, s, NCH_3), 3.57 (3H, s,OCH_3), 6.24 (2H, d, *J* = 3.0, ImH), 6.45 (1H, d, *J* = 3.0, ImH), 7.07 (1H, d, *J* = 8.2, ArH), 7.15 (1H, d, *J* = 8.2, ArH), 7.35 (1H, t, *J* = 8.2, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 15.9, 30.5, 55.7, 111.4, 111.8, 111.9, 124.0, 125.4, 128.7, 129.6, 130.2, 156.0. *m*/*z* (CI): 219 (MH^+, 100%). Anal. calcd. for. $C_{12}H_{14}N_2O_2$ (M): 218.105 5; found (M^+): 218.105 6. Spectroscopic data for **5g**: ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.22 (3H, s, $ArCH_3$), 3.37 (3H, s, NCH_3), 3.82 (3H, s, OCH_3), 6.23 (2H, d, *J* = 2.9, ImH), 6.32 (1H, d, *J* = 2.9, ImH), 6.84 (1H, d, *J* = 7.9, ArH), 6.91 (1H, d, *J* = 7.9, ArH), 7.27 (1H, t, *J* = 7.9, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 18.2. 31.2, 55.8, 109.2, 111.8, 111.9, 113.3, 122.4, 125.9, 129.1, 138.0, 155.9. *m*/*z* (CI): 233 (MNH_4^+, 10%), 219 (MH^+, 100), 205 (20). Typical procedure for lithiation of imidazolones (3a–3d) with 2.5 equiv. *n*-BuLi and then reaction with phenyl isocyanate

These experiments followed exactly the method described previously for trapping with iodomethane, but used phenyl isocyanate as the electrophile.

1-Phenyl-3-(phenylaminocarbonyl)imidazol-2(1H)-one (9a) and 3-(phenylaminocarbonyl)-1-[(2-phenylaminocarbonyl)phenyl]imidazol-2(1H)-one (9b)

1-Phenyl-3-(phenylaminocarbonyl)imidazol-2(1*H*)-one (**9a**) and 3-(phenylaminocarbonyl)-1-[(2-phenylaminocarbonyl)phenyl]imidazol-2(1*H*)-one (**9b**) were made from 1-phenylimidazol-2(1*H*)-one **3a** (0.2 g, 1.25 mmol) with *n*-BuLi (1.6 mol L^{-1}, 1.95 mL, 2.5 equiv.), then phenyl isocyanate (0.34 mL, 3.12 mmol, 2.5 equiv.) was added giving from chromatography firstly **9a** as a yellow solid (12 mg, 3%), mp 122 °C, lit. value (18) mp 123 °C, and secondly, **9b** as a white solid (300 mg, 86%), mp 150 °C. Spectroscopic data for **9a**: IR ν_{max} (film, cm^{-1}): 755, 1077, 1236, 1259, 1412, 1502, 1555, 1598, 1690, 1730. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.81 (1H, d, J = 3.2, ImH), 7.20 (1H, m, ArH), 7.28 (1H, d, J = 3.2, ImH), 7.40 (4H, m, ArH), 7.59 (5H, m, ArH), 10.91 (1H, bs, NH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 108.6, 111.7, 120.0, 122.4, 124.4, 127.1, 129.0, 129.4, 136.9, 147.3, 150.3, 162.7. *m/z* (CI): 297 (MNH_4^+, 20%), 280 (MH^+, 100). Anal. calcd. for. $C_{16}H_{13}N_3O_2$ (M): 279.100 8; found (M^+): 279.100 5. Spectroscopic data for **9b**: IR ν_{max} (film, cm^{-1}): 754, 1234, 1320, 1411, 1443, 1495, 1553, 1601, 1678, 1730. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.59 (1H, d, J = 3.2, ImH,), 7.12 (2H, m, ArH), 7.22 (1H, d, J = 3.2, ImH), 7.35 (5H, m, ArH), 7.58 (6H, m, ArH), 7.79 (1H, d, J = 7.3, ArH), 8.49 (1H, bs, NH), 10.65 (1H, bs, NH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 109.1, 113.9, 119.9, 120.1, 124.5, 124.7, 127.7, 128.3, 129.0, 129.3, 129.4, 131.5, 132.0, 135.0, 136.7, 137.6, 146.7, 151.4, 164.7. *m/z* (CI): 416 (MNH_4^+, 5%), 399 (MH^+, 8), 297 (20), 280 (100). Anal. calcd. for. $C_{23}H_{18}N_4O_3$ (M): 398.137 9; found (M^+): 398.137 5.

3-(Phenylaminocarbonyl)-1-[6-methoxy-2-(phenylaminocarbonyl)phenyl]imidazol-2(1H)-one (9c) and 3-(phenylaminocarbonyl)-1-[2-methoxy-3-(phenylaminocarbonyl)phenyl]-imidazol-2(1H)-one (9d)

3-(Phenylaminocarbonyl)-1-[6-methoxy-2-(phenylaminocarbonyl)phenyl]imidazol-2(1*H*)-one (**9c**) and 3-(phenylaminocarbonyl)-1-[2-methoxy-3-(phenylaminocarbonyl)phenyl]imidazol-2(1*H*)-one (**9d**) were made from a solution of 1-(2-methoxyphenyl)imidazol-2(1*H*)-one **3b** (0.23 g, 1.2 mmol) with *n*-BuLi (1.6 mol L^{-1}, 1.95 mL, 2.5 equiv.), then phenyl isocyanate (0.34 mL, 3.12 mmol, 2.5 equiv.) was added giving firstly from chromatography **9c** (80 mg, 15%, slightly contaminated by a phenyl isocyanate derivative), and secondly, **9d** (97 mg, 18%) as low mp yellow solids. Spectroscopic data for **9c**: IR ν_{max} (film, cm^{-1}): 754, 1055, 1233, 1409, 1440, 1492, 1550, 1599, 1680, 1707, 1728. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 3.85 (3H, s, OCH_3), 6.42 (1H, d, J = 3.2, ImH), 7.01–7.81 (14H, m, ArH + ImH), 8.54 (1H, s, NH), 10.63 (1H, s, NH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 56.4, 102.9, 108.7, 113.9, 115.4, 120.0, 120.4, 120.7, 124.8, 124.9, 126.6, 128.6, 129.0, 129.3, 131.4, 138.0, 156.0, 163.3, 164.8. *m/z* (CI): 446 (MNH_4^+, 25%), 429 (MH^+, 40), 310 (100). Anal. calcd. for. $C_{24}H_{20}N_4O_4$ (M): 428.148 4; found (M^+): 428.149 3. Spectroscopic data for **9d**: IR ν_{max} (film, cm^{-1}): 753, 1441, 1598, 1710, 3329. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 3.75 (3H, s, OCH_3), 6.24 (1H, bs, ImH), 6.30 (1H, bs, ImH), 7.03 (3H, m, ArH), 7.21 (4H, apparent t, J = 8.0, ArH), 7.29 (2H, apparent d, J = 7.7, ArH), 7.43 (2H, t, J = 8.0, ArH), 7.60 (2H, d, J = 7.7, ArH), 9.60 (1H, s, NH), 9.97 (1H, s, NH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 56.3, 109.4, 113.6, 115.0, 115.5, 120.2, 120.6, 121.1, 122.5, 124.5, 128.1, 129.1, 130.9, 131.9, 138.5, 138.7, 142.2, 154.8, 156.0, 165.3. *m/z* (CI): 446 (MNH_4^+, 2%), 429 (MH^+, 4), 327 (8), 310 (100), 217 (5), 102 (5). Anal. calcd. for. $C_{24}H_{20}N_4O_4$ (M): 428.148 4; found (M^+): 428.149 2.

1-[(3-Methoxy-2-phenylaminocarbonyl)phenyl]-3-phenylaminocarbonylimidazol-2(1H)-one (9e) and 1-(3-methoxyphenyl)-3-(phenylaminocarbonyl)imidazol-2(1H)-one (9f)

1-[(3-Methoxy-2-phenylaminocarbonyl)phenyl]-3-phenylaminocarbonylimidazol-2(1*H*)-one (**9e**) and 1-(3-methoxyphenyl)-3-(phenylaminocarbonyl)imidazol-2(1*H*)-one (**9f**) were made from 1-(3-methoxyphenyl)imidazol-2(1*H*)-one **3c** (0.27 g, 1.42 mmol) with *n*-BuLi (1.6 mol L^{-1}, 2.2 mL, 2.5 equiv.) then phenyl isocyanate (0.39 mL, 3.5 mmol, 2.5 equiv.) giving from chromatography firstly **9e** as a white solid (160 mg, 36%), mp 101 °C, and secondly, **9f** as a white solid (95 mg, 21%), mp 180 °C. Spectroscopic data for **9e**:

Typical procedure for the reaction of 1-aryl-3-methylimidazolones (5a–5d) with 1 equiv. of *n*-BuLi and trapping with iodomethane

1-Phenyl-3,5-dimethylimidazol-2(1H)-one (5j) 1-phenyl-3,4-dimethylimidazol-2(1H)-one (5k)

A solution of 3-methyl-1-phenyl-imidazol-2(1*H*)-one **5a** (0.2 g, 1.15 mmol, 1 equiv.) in anhyd. THF was treated with *n*-BuLi (1.6 mol L^{-1}, 0.79 mL, 1.1 equiv.) at –78 °C over 30 min under N_2. The solution was warmed up to then maintained at 0 °C for 2 h and cooled down to –78 °C again for the addition of iodomethane (0.1 mL, 1.72 mmol, 1.5 equiv.). The reaction mixture was allowed to warm up to rt and after 20 h quenched with satd. aq. NH_4Cl, and evaporated to remove the THF. The white organic residue was taken up with CH_2Cl_2, the solution washed with brine, dried over $MgSO_4$ and evaporated. Column SiO_2 chromatography (50%–70%–100% of EtOAc in hexane) yielded firstly 1-(2-methylphenyl)-3,5-dimethylimidazol-2(1*H*)-one **5j** (28 mg, 12%) as a low mp solid, and secondly, 1-(2-methylphenyl)-3,4-methylimidazol-2(1*H*)-one **5k** (96 mg, 46%) as a solid mp 130 °C. Spectroscopic data for **5j**: IR ν_{max} (film, cm^{-1}): 1401, 1500, 1638, 1655, 1676, 1685. ^1H NMR (300 MHz, $CDCl_3$) δ: 1.84 (3H, s, $ImCH_3$), 3.19 (3H, s, NCH_3), 5.94 (1H, bs, ImH), 7.21 (2H, m, ArH), 7.28 (1H, apparent d, *J* = 7.2, ArH), 7.37 (1H, apparent t, *J* = 7.2, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 10.9, 30.1, 108.5, 118.5, 127.3, 127.5, 129.0, 134.7, 152.7. *m/z* (CI): 206 (MNH_4^+, 15%), 189 (MH^+, 100). Anal. calcd. for. $C_{11}H_{12}N_2O$ (M): 188.095 0; found (M^+): 188.094 9. Spectroscopic data for **5k**: IR ν_{max} (film, cm^{-1}): 760, 1400, 1430, 1455, 1503, 1595, 1639, 1680, 1717. ^1H NMR (300 MHz, $CDCl_3$) δ: 2.11 (3H, s, $ImCH_3$), 3.26 (3H, s, NCH_3), 6.33 (1H, bs, ImH), 7.21 (1H, m, ArH), 7.41 (1H, apparent t, *J* = 7.5, ArH), 7.37 (1H, apparent t, *J* = 7.5, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 10.2, 27.1, 104.9, 120.2, 121.1, 125.1, 125.6, 128.9, 137.3, 153.3. *m/z* (CI): 206 (MNH_4^+, 20%), 189 (MH^+, 100), 175 (42). Anal. calcd. for. $C_{11}H_{12}N_2O$ (M): 188.095 0; found (M^+): 188.094 8.

1-(2-Methoxyphenyl)-3,5-dimethylimidazol-2(1H)-one (5l) and 1-(2-methoxyphenyl)-3,4-dimethylimidazol-2(1H)-one (5m)

1-(2-Methoxyphenyl)-3,5-dimethylimidazol-2(1*H*)-one (**5l**) and 1-(2-methoxyphenyl)-3,4-dimethylimidazol-2(1*H*)-one (**5m**) were prepared from 1-(2-methoxyphenyl)-3-methylimidazol-2(1*H*)-one **5b** (0.25 g, 1.2 mmol) with *n*-BuLi (1.6 mol L^{-1}, 1.3 mL, 1.5 equiv.), then iodomethane (0.15 mL, 2.4 mmol, 2 equiv.) was added giving from chromatography a mixture (129 mg) (Anal. calcd. for $C_{12}H_{14}N_2O_2$ (M): 218.105 5; found (M^+): 218.204 9) of **5l** (12%, estimated by ^1H NMR) and its isomer **5m** (36%, estimated by ^1H NMR) as yellow oils. Spectroscopic data for **5l**: ^1H NMR (300 MHz, $CDCl_3$) δ: 2.20 (3H, s, $ImCH_3$), 3.30 (3H, s, NCH_3), 3.81 (3H, s, OCH_3), 5.95 (1H, bs, ImH), 6.86–7.50 (4H, m, ArH). *m/z* (CI): 233 (MNH_4^+, 51%), 219 (MH^+, 100). Spectroscopic data for **5m**: ^1H NMR (300 MHz, $CDCl_3$) δ: 2.12 (3H, bs, $ImCH_3$), 3.28 (3H, s, NCH_3), 3.87 (3H, s, OCH_3), 6.21 (1H, s, ImH), 7.01–7.50 (4H, m, ArH). *m/z* (CI): 233 (MNH_4^+, 51%), 219 (MH^+, 100).

1-(4-Methoxyphenyl)-3,4-dimethylimidazol-2(1H)-one (5n) and 1-(4-methoxyphenyl)-3,5-dimethylimidazol-2(1H)-one (5o)

1-(4-Methoxyphenyl)-3,4-dimethylimidazol-2(1*H*)-one **5n** and 1-(4-methoxyphenyl)-3,5-dimethylimidazol-2(1*H*)-one **5o** were prepared from 1-(4-methoxyphenyl)-3-methylimidazol-2(1*H*)-one **5d** (0.2 g, 0.98 mmol) with *n*-BuLi (1.6 mol L^{-1}, 0.67 mL, 1.1 equiv.), then iodomethane

© 2004 NRC Canada

(0.09 mL, 1.47 mmol, 1.5 equiv.) was added giving from chromatography firstly **5n** as yellow oil (104 mg, 49%), and secondly, **5o** as a yellow solid, mp 118–120 °C (33 mg, 16%). Spectroscopic data for **5n**: IR ν_{max} (film, cm^{-1}): 1251, 1516, 1678. ^1H NMR (300 MHz, $CDCl_3$) δ: 2.12 (3H, s, $ImCH_3$), 3.27 (3H, s, NCH_3), 3.83 (3H, s, OCH_3), 6.26 (1H, bs, ImH), 6.94 (2H, d, J = 9.1, ArH), 7.48 (2H, d, J = 9.1, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 10.1, 30.4, 55.4, 105.5, 109.7, 112.2, 114.2, 123.0, 130.7, 157.1. *m/z* (CI): 236 (MNH_4^+, 10%), 219 (MH^+, 100), 205 (90). Typical procedure for dilithiation of (5a–5d) with 2.5 equiv. *n*-BuLi and trapping with iodomethane

*1-(2-Methylphenyl)-3,4-dimethylimidazol-2(1*H*)-one (5p)*

A solution of 3-methyl-1-phenylimidazol-2(1*H*)-one **5a** (0.1 g, 0.57 mmol) in anhyd. THF was treated with *n*-BuLi (1.6 mol L^{-1}, 0.89 mL, 2.5 equiv.) at –78 °C over 30 min under N_2. The solution was warmed up to then maintained at 0 °C for 2 h and cooled down to –78 °C again for the addition of iodomethane (0.09 mL, 1.43 mmol, 2.5 equiv.). The reaction mixture was allowed to warm up to rt and after 20 h quenched with satd. aq. NH_4Cl, and evaporated to remove the THF. The organic residue was taken up with CH_2Cl_2, the solution washed with brine, dried over $MgSO_4$, and evaporated to give the title compound **5p** as a yellow oil (109 mg, 95%). IR ν_{max} (film, cm^{-1}): 716, 757, 1401, 1432, 1463, 1497, 1689, 1718, 2922. ^1H NMR (300 MHz, $CDCl_3$) δ: 2.15 (3H, s, $ImCH_3$), 2.30 (3H, s, $ArCH_3$), 3.30 (3H, s, NCH_3), 6.07(1H, s, ImH), 7.25 (4H, m, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 10.6, 18.4, 27.7, 107.8, 119.8, 126.8, 127.7, 128.3, 129.3, 131.3, 135.7, 152.6. *m/z* (CI): 220 (MNH_4^+, 37%), 203 (MH^+, 100). Anal. calcd. for $C_{12}H_{14}N_2O$ (M): 202.110 6; found (M^+): 202.110 2.

*1-(2-Methoxy-6-methylphenyl)-3,4-dimethylimidazol-2(1*H*)-one (5q)*

1-(2-Methoxy-6-methylphenyl)-3,4-dimethylimidazol-2(1*H*)-one **5q** was prepared from 1-(2-methoxyphenyl)-3-methylimidazol-2(1*H*)-one **5b** (0.1 g, 0.49 mmol) with *n*-BuLi (1.6 mol L^{-1}, 0.76 mL, 2.5 equiv.), then iodomethane (0.08 mL, 1.22 mmol, 2.5 equiv.) was added giving **5q** as a yellow oil (0.1 g, 88%). IR ν_{max} (film, cm^{-1}): 776, 1080, 1271, 1399, 1433, 1464, 1475, 1495, 1687, 2928. ^1H NMR (300 MHz, $CDCl_3$) δ: 2.11 (3H, s, $ImCH_3$), 2.17 (3H, s, $ArCH_3$), 3.29 (3H, s, NCH_3), 3.78 (3H, s, OCH_3), 5.97 (1H, s, ImH), 6.80 (1H, d, J = 8.0, ArH), 6.87 (1H, d, J = 8.0, ArH), 7.23 (1H, t, J = 8.0, ArH). ^{13}C NMR (75 MHz, $(CD_3)_2CO$) δ: 9.7, 17.5, 30.0, 55.5, 107.8, 109.6, 112.5, 119.2, 120.7, 122.3, 128.9, 134.4, 156.4. *m/z* (CI): 250 (MNH_4^+18, 4%), 232 (MH^+, 100), 219 (30). Anal. calcd. for $C_{13}H_{16}N_2O_2$ (M): 232.121 2; found (M^+): 232.121 5.

*1-(3-Methoxy-2-methylphenyl)-3,4-dimethylimidazol-2(1*H*)-one (5r)*

1-(3-Methoxy-2-methylphenyl)-3,4-dimethylimidazol-2(1*H*)-one **5r** was prepared from 1-(3-methoxyphenyl)-3-methylimidazol-2(1*H*)-one **5c** (0.17 g, 0.83 mmol) with *n*-BuLi (1.6 mol L^{-1}, 1.3 mL, 2.5 equiv.), then iodomethane (0.09 mL, 1.5 mmol, 1.9 equiv.) was added giving **5r** as a clear oil (0.43 mg, 24%). IR ν_{max} (film, cm^{-1}): 1140, 1261, 1402, 1433, 1475, 1589, 1638, 1686. ^1H NMR (300 MHz, $CDCl_3$) δ: 2.11 (3H, s, $ArCH_3$), 2.12 (3H, bs, $ImCH_3$), 3.28 (3H, s, NCH_3), 3.86 (3H, s, OCH_3), 6.04 (1H, bs, ImH), 6.86 (2H, d, J = 8.1, ArH), 7.20 (1H, t, J = 8.1, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 10.3, 11.1, 27.3, 55.6, 107.6, 109.5, 119.35, 119.5, 124.6, 126.4, 136.7, 152.5, 158.4. *m/z* (CI): 250 (MNH_4^+, 7%), 233 (MH^+, 100), 219 (25). Anal. calcd. for $C_{13}H_{16}N_2O_2$ (M): 232.121 2; found (M^+): 232.121 0.

*1-(4-Methoxy-2-methylphenyl)-3,4-dimethylimidazol-2(1*H*)-one (5s)*

1-(4-Methoxy-2-methylphenyl)-3,4-dimethylimidazol-2(1*H*)-one **5s** was prepared from 1-(4-methoxyphenyl)-3-methylimidazol-2(1*H*)-one **5d** (0.1 g, 0.49 mmol, 1 equiv.) with *n*-BuLi (1.6 mol L^{-1}, 0.76 mL, 2.5 equiv.), then iodomethane (0.076 mL, 1.22 mmol, 2.5 equiv.) was added giving **5s** as a yellow oil (0.107 g, 97%). IR ν_{max} (film, cm^{-1}): 1044, 1096, 1161, 1252, 1401, 1432, 1463, 1508, 1686, 2932. ^1H NMR (300 MHz, $CDCl_3$) δ: 2.11 (3H, s, $ArCH_3$), 2.18 (3H, s, $ArCH_3$), 3.28 (3H, s, NCH_3), 3.81 (3H, s, OCH_3), 6.01 (1H, s, ImH), 6.80 (2H, m, ArH), 7.12 (1H, d, J = 8.6, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 10.6, 18.5, 27.7, 55.7, 108.0, 112.0, 116.2, 119.4, 128.7, 129.1, 137.2, 142.2, 159.2. *m/z* (CI): 250 (MNH_4^+, 26%), 233 (MH^+, 100), 146.2, 164.5. *m/z* (CI): 163 (MH^+, 100%). Anal. calcd. for $C_{13}H_{16}N_2O_2$ (M): 232.121 2; found (M^+): 232.121 7.

The complex photochemistry of 2,3-dibenzylidenesuccinates

Tokouré Assoumatine, Brigitte L. Yvon, and James L. Charlton

Abstract: The photochemistry of diethyl *E,E*-2,3-(3,4,5-trimethoxybenzylidene)succinate (**8**) is solvent dependent. In both protic and aprotic solvents, there is a photoequilibrium established between **8** and its *E,Z*-isomer (**9**). In chloroform at high light intensity, very little **9** is formed and the main product is 1,4-dihydronaphthalene (**10**), formed via photoinduced intramolecular [1,3]-sigmatropic hydrogen shift within an intermediate 1,8a-dihydronaphthalene (**11**). In protic solvents, irradiation of either **8** or **9** ultimately gives primarily the *cis*-1,2-dihydronaphthalene product (**13**), along with smaller amounts of the trans isomer (**14**). By using deuterated solvents, it was shown that **13** and **14** are formed by solvent protonation (or deuteration) of the 1,8a-dihydronaphthalene intermediate (**11** or **12**).

Key words: 2,3-dibenzylidenesuccinate, photocyclization, dihydronaphthalene, lignan.

Résumé : La photochimie du *E,E*-2,3-(3,4,5-triméthoxybenzylidène)succinate de diéthyle (**8**) dépend de la nature du solvant. Dans les solvants tant protique qu'aprotique, il s'établit un photoéquilibre entre le composé **8** et son isomère *E,Z* (**9**). Dans le chloroforme, à une intensité lumineuse intense, il se forme très peu de composé **9** et le produit principal est le 1,4-dihydronaphtalène (**10**) qui se forme, à partir de l'intermédiaire 1,8a-dihydronaphtalène (**11**), par un déplacement photoinduit d'hydrogène [1,3]-sigmatropique. Dans les solvants protiques, l'irradiation des composés **8** ou **9** conduit toujours à des quantités importantes du produit *cis*-1,2-dihydronaphtalène (**13**) aux côtés de plus faibles quantités de l'isomère trans (**14**). En utilisant des solvants deutérés, il a été possible de démontrer que les composés **13** et **14** se forment par protonation (ou deutération) d'un intermédiaire 1,8a-dihydronaphtalène (**11** ou **12**) par le solvant.

Mots clés : 2,3-dibenzylidènesuccinate, photocyclisation, dihydronaphtalène, lignane.

[Traduit par la Rédaction]

Introduction

There is a rich literature on the photochemistry of *E,E*-2,3-dibenzylidenesuccinate derivatives (1–23). Although the majority of the work deals with the photochemical cyclization of fulgides (the cyclic anhydrides of *E,E*-dibenzylidenesuccinic acids; **1**, X = O), there are also examples of photoreactions of fulgimides (the cyclic imides of *E,E*-dibenzylidenesuccinic acids; **1**, X = NR), dibenzylidenebutyrolactones, and acyclic derivatives. Heller and co-workers (6) have provided a general mechanistic scheme to explain the photochemistry that has been observed for various fulgides and fulgimides (Scheme 1, where R represents various aromatic substitution patterns).

Although the results of irradiation vary with substituents R and solvents, photoinduced isomerization between the *E,E*- and *E,Z*-isomers **1** and **2** is generally observed. Isomers **1** and **2** also undergo photochemical conrotatory ring closure to form the *cis*- and *trans*-1,8a-dihydronaphthalenes (1,8a-DHNs) **3** and **4,** respectively. The thermal disrotatory opening of **3** and **4** to give **2** and **1,** respectively, is assumed to be the mechanism for the photoinduced isomerization of **1** and **2**. The 1,8a-DHNs **3** and **4** are seldom isolated owing to their thermal and photochemical instability, and the final isolated products (other than **1** and **2**) are more often the 1,4-DHN **5** and (or) the 1,2-DHNs **6** and **7** (or the corresponding naphthalenes if oxygen is present). On the basis of temperature and pH effects, Heller and co-workers (6) tentatively concluded that 1,4-DHN **5** was formed photochemically from **3** and **4** (a [1,3]-intramolecular sigmatropic H-shift) and that 1,2-DHNs **6** and **7** were formed by an acid-catalysed rearrangement of **3** and **4,** respectively, rather than by a thermal intramolecular [1,5]-sigmatropic shift (Scheme 1) (6). In previous papers by Heller's group, it had been assumed that the latter rearrangement involved an intramolecular [1,5]-sigmatropic H-shift (17, 18, 20).

While there have been many published studies of the photochemistry of cyclic derivatives of dibenzylidenesuccinates, such as the fulgides and fulgimides discussed above, there have been fewer published examples of the study of the photochemistry of the corresponding acyclic succinate derivatives. In an earlier paper (23), we reported the first example of the photolysis of a dibenzylidenesuccinate diester. In that preliminary study, we reported that the photolysis of *E,E*-2,3-(3,4,5-trimethoxybenzylidene)succinate (**8**) in ethanol acidified with trifluoroacetic acid (TFA), followed by column chromatography of the photolysis product, gave the dihydronaphthalene esters **13** (34% yield) and **14** (2% yield) (Scheme 2) (23). We have now conducted a more detailed study of the photochemical behaviour of **8** in various solvents and observed that the products depend quite strongly

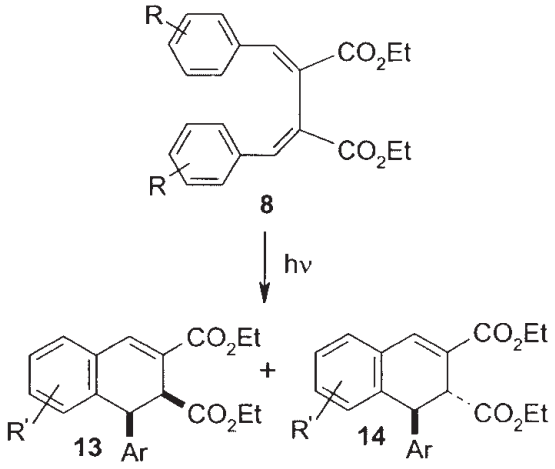
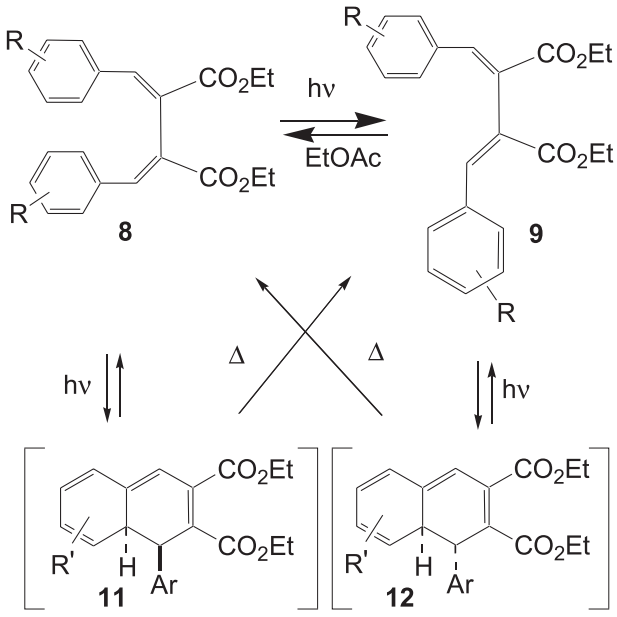
on the solvent and reaction conditions. By using deuterated solvents, we have established the mechanisms of the various prototropic rearrangements.



It is hoped that a better understanding of the photochemistry of 2,3-dibenzylidenesuccinates will make their photochemical reactions more useful for the synthesis of lignans, particularly the aryltetralin and aryldihydronaphthalene types. This goal has been partially achieved with the recent publication of an asymmetric synthesis of (+)-lyoniresinol dimethyl ether from a derivative of compound **8** (24).

Results and discussion

Diethyl *E,E*-2,3-(3,4,5-trimethoxybenzylidene)succinate (**8**) was prepared as previously described (23). Although **8** is shown in Scheme 2 in an *s*-cis conformation, it should be noted that this molecule does not have a planar butadiene system. Molecular mechanics calculations show that it exists as an equilibrating mixture of twisted *s*-cis and *s*-trans conformers. A fuller discussion of its conformation can be found in our previous publication (24). In the synthesis (23), **8** is formed in an *E,E* configuration as the sole product. This product is easily distinguished from the corresponding *E,Z* and *Z,Z* isomers by NMR (17).

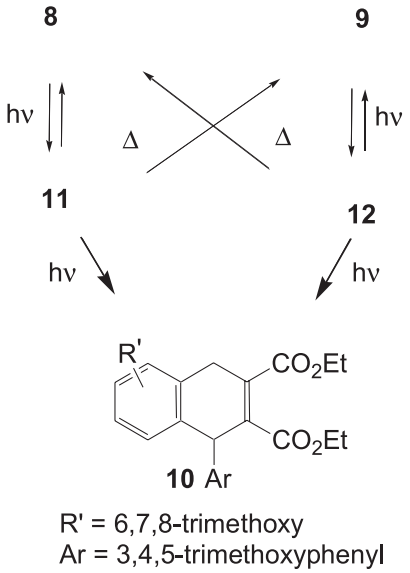


Irradiation of **8** in ethyl acetate with a medium-pressure mercury lamp through Pyrex glass gave only a slow and incomplete conversion of **8** to the corresponding *E,Z*-isomer **9** (Scheme 3). Further irradiation of the mixture resulted in the formation of several products (including **10**; see below). It

Scheme 2. Previous study of photolysis of *E,E*-2,3-(3,4,5-trimethoxybenzylidene)succinate (**8**).

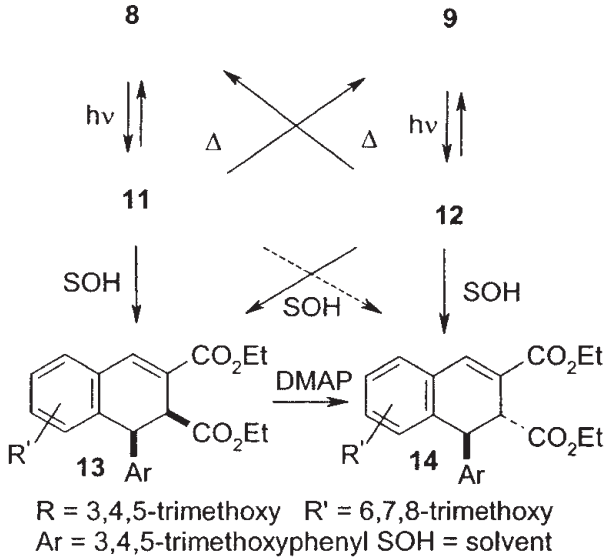
R = 3,4,5-trimethoxy R' = 6,7,8-trimethoxy
Ar = 3,4,5-trimethoxyphenyl

Scheme 3. Irradiation of **8** in ethyl acetate.



R = 3,4,5-trimethoxy R' = 6,7,8-trimethoxy
Ar = 3,4,5-trimethoxyphenyl

was possible to separate **9** from **8** by HPLC and to characterize **9** by ^{1}H and ^{13}C NMR. A possible mechanism for the conversion of **8** to **9** is photochemical cyclization to the 1,8a-DHN **11** followed by thermal disrotatory opening to **9**. It is also possible that there is a direct photoisomerization of the double bond. The irradiation of isolated **9** in ethyl acetate gave the same mixture of **8** and **9**, and the conversion of **9** to **8** may pass through intermediate **12**.



Surprisingly, irradiation of **8** in chloroform gave the 1,4-DHN **10** almost exclusively (Scheme 4). The reaction was most efficient if low concentrations of **8** were irradiated in tubes placed very close to the lamp (higher light intensity).

Scheme 4. Irradiation of **8** in chloroform.

Scheme 5. Irradiation of **8** in alcoholic solvents.

On moving the sample further from the lamp (30 cm), it was possible to detect the concurrent formation of the *E,Z*-isomer **9,** which, although it appeared early in the reaction, also slowly disappeared to form the 1,4-DHN **10**. When **8** was irradiated in deuterochloroform (that had been washed with D_2O to prevent any possibility that traces of water would protonate an intermediate), there was no incorporation of deuterium into the 1,4-DHN **10**. The lack of any deuterium incorporation when the reaction was run in D_2O-washed deuterochloroform confirmed that the proposed conversion of **11** to **10** was an intramolecular 1,3-sigmatropic hydrogen shift, an allowed photochemical pericyclic reaction. It thus appears that **11** (or **12**) is photochemically converted to **10** and that this allowed photochemical sigmatropic reaction competes very well with thermal opening of **11** (or **12**) to **9** (or **8**). The intermediate formation of *E,Z*-isomer **9** during irradiation in chloroform at lower light intensities, and its ultimate conversion to **10**, suggests that this is also a two-step photochemical conversion via the 1,8a-DHN **12**.

Irradiation of **8** in alcoholic solvents (methanol, ethanol, or 2-propanol), until the disappearance of **8**, gave primarily the *cis*-1,2-DHN **13** accompanied by the *trans*-1,2-DHN **14** in a 4:1 ratio (Scheme 5). Similar results were reported in a preliminary publication (23). However, irradiation for shorter periods of time showed that the *E,Z*-isomer **9** was initially formed along with the two DHN derivatives **13** and **14**. When **9** reached about 80% of the concentration of **8,** it ceased to increase and both **8** and **9** subsequently diminished as **13** and **14** formed. It therefore appears that a photoequilibrium between **8** and **9** also takes place in alcoholic solvents. A similar irradiation of **9** in methanol produced **8** and thereafter a slow conversion to a mixture of **13** and **14** in a 4:1 ratio.

Cis-1,2-DHN **13** could be quantitatively converted to *trans*-1,2-DHN **14** by warming with a trace of *N,N*-dimethyl-4-aminopyridine (DMAP) in ethanol, confirming that the trans ester **14** is thermodynamically more stable than **13**. When the irradiation of **8** was conducted in perdeuteromethanol (CD_3OD), a mass spectrum revealed that the 1,2-DHN product **13** was monodeuterated. This shows that rearrangement of **8** to **13** involves protonation by solvent. It seems likely that the 1,8a-DHN **11** (or **12**) is thermally protonated at the 2-position followed by the loss of a proton at carbon 8a. This mechanism is consistent with that proposed by Heller and co-workers for the acid-catalysed reactions of 1,8a-DHN formed from fulgides (6).

It was not possible to conclusively determine whether dihydronaphthalenes **13** and **14** were being formed via solvent protonation of both **11** and **12**, although it seems likely. In any event, an earlier suggestion by Heller and co-workers that the *trans*-DHN **14** is coming exclusively from irradiation of the *E,Z*-isomer seems incorrect for this series of compounds (6).

In summary, we have provided the first detailed study of the photochemistry of an *E,E*-2,3-dibenzylidenesuccinate diester and proposed a mechanism for the products formed in various solvents. In aprotic solvents, there is an equilibrium between **8** and **9**, in competition with the two-step photochemical conversion to the 1,4-DHN **10**. It is proposed that the isomerization between the *E,E*-isomer and the *E,Z*-isomer occurs by disrotatory closure to 1,8a-DNH **11** (or **12**) followed by conrotatory thermal opening to **9** (or **8**). In protic solvents, there is also an equilibrium between **8** and **9,** but solvent protonation of **11** (and (or) **12**) produces primarily (but not exclusively) the *cis*-1,2-DHN **13**. The possibility that **13** is formed via an intramolecular thermal [1,5]-sigmatropic hydrogen shift was ruled out by the fact that deuterium is incorporated from deuterated solvents.

Experimental

General methods

Proton and ^{13}C-NMR spectra were recorded on a Bruker AM-300 FT instrument using residual $CHCl_3$ in the $CDCl_3$ as internal standard, unless otherwise specified. Silica gel (40–63 μm) (Silicycle, Quebec City, Que.) was used for all chromatography. High-resolution mass spectra (HRMS) were obtained on a VG Analytical 7070E-HF instrument. Irradiations were conducted with a 450-W medium-pressure mercury lamp housed in a Pyrex water-cooled jacket or with

© 2004 NRC Canada

a circular set of low-pressure mercury lamps (254 nm, 100 W). In all cases, the temperature of the solutions being irradiated was 25 ± 5 °C. HPLC was conducted on a reverse-phase C_{18} column using methanol (50–80%) in water as eluent. Literature references for known compounds are: **8** (23)**, 13** (23), and **14** (25).

Diethyl *E,Z*-2,3-(3,4,5-trimethoxybenzylidene)succinate (9)

A solution of diethyl *E,E*-2,3-(3,4,5-trimethoxybenzylidene)succinate (**8**) (0.020 g, 0.040 mmol) in EtOAc (4 mL) in a Pyrex test tube was purged with N_2 for 5 min. The test tube was sealed, fixed at 24 cm from the medium-pressure mercury lamp, and irradiated for 6 h. The solvent was evaporated to leave a mixture of the *E,E*- and *E,Z*-isomers, **8** and **9** (approximately 57:43 as determined by ^{1}H NMR). The *E,Z*-isomer **9** was separated from the mixture by HPLC. ^{1}H NMR ($CDCl_3$) δ 1.17 (t, *J* = 7.1 Hz, 3H), 1.33 (t, *J* = 7.1 Hz, 3H), 3.78 (s, 6H), 3.81 (s, 6H), 3.84 (s, 3H), 3.85 (s, 3H), 4.18 (q, *J* = 7.1 Hz, 2H), 4.29 (q, *J* = 7.1 Hz, 2H), 6.63 (s, 2H), 6.73 (s, 1H), 6.91 (s, 2H), 7.75 (s, 1H). ^{13}C NMR ($CDCl_3$) δ 14.0, 14.3, 56.0 (2C), 56.1 (2C), 60.9, 60.9 (2C), 61.3, 106.5 (2C), 107.8 (2C), 127.8, 129.9, 130.3, 130.7, 140.8, 141.9, 152.8 (3C), 153.0 (3C), 166.9, 167.5.

Diethyl 1-(3,4,5-trimethoxyphenyl)-6,7,8-trimethoxy-1,4-dihydronaphthalene-2,3-dicarboxylate (10)

A solution of **8** (0.138 g, 0.260 mmol) in $CHCl_3$ (26 mL) in a Pyrex test tube was purged with N_2 for 5 min. The test tube was sealed, fixed at 7 cm from the medium-pressure Hanovia mercury lamp, and irradiated for 3 h. The solvent was evaporated, and the residue mixture was purified by flash chromatography on silica gel using 50% EtOAc in hexanes to give the product (0.464 g, 33% yield). ^{1}H NMR ($CDCl_3$) δ 1.18 (t, *J* = 7.1 Hz, 3H), 1.30 (t, *J* = 7.1 Hz, 3H), 3.63 (dd, *J* = 2.6 and 21.5 Hz, 1H), 3.87 (dd, *J* = 4.2 and 21.5 Hz, partly obscured by OMe signal at 3.85 Hz, 1H), 3.51 (s, 3H), 3.75 (s, 6H), 3.76 (s, 3H), 3.79 (s, 3H), 3.85 (s, 3H), 4.08–4.25 (m, 2H), 4.25 (q, *J* = 7.1 Hz, 2H), 5.21 (dd, *J* = 2.6 and 4.3 Hz, 1H), 6.37 (s, 2H), 6.52 (s, 1H). ^{13}C NMR ($CDCl_3$) δ 14.16, 14.22, 31.9, 43.5, 56.1, 56.3 (2C), 60.5, 60.9, 61.0, 61.3, 61.5, 105.8 (2C), 106.3, 123.0, 127.7, 131.5, 137.2, 138.4, 138.6, 141.3, 151.0, 153.0, 153.2 (2C), 167.7 (*C*=O), 167.8 (*C*=O). MS *m/z* (relative intensity): 530 (M^+, 64), 484 (60), 456 (35), 411 (56), 380 (27), 362 (26), 317 (100), 289 (66), 245 (12), 181 (28), 168 (21); HRMS calcd. for $C_{28}H_{34}O_{10}$: 530.2152; found: 530.2148.

Diethyl *cis*- and *trans*-1-(3,4,5-trimethoxyphenyl)-6,7,8-trimethoxy-1,2-dihydronaphthalene-2,3-dicarboxylate (13 and 14)

The characterizations of **13** and **14** are reported elsewhere (23, 24) but are included here for completeness.

13. ^{1}H NMR ($CDCl_3$) δ 0.89 (t, *J* = 7.2 Hz, 3H), 1.24 (t, *J* = 7.2 Hz, 3H), 3.46 (s, 3H), 3.71 (s, 3H), 3.72 (s, 6H), 3.82 (s, 3H), 3.86 (s, 3H), 4.08 (dd, *J* = 2.8, 9.1 Hz, 1H), 4.17 (m, 2H), 4.76 (d, *J* = 9.1 Hz, 1H), 6.32 (s, 2H), 6.63 (s, 1H), 7.36 (d, *J* = 2.8 Hz, 1H). ^{13}C NMR ($CDCl_3$) δ 13.8, 14.3, 40.5, 48.1, 56.10, 56.13 (2C), 60.4, 60.5, 60.7, 60.8 (2C), 106.4 (2C), 108.0, 123.7, 126.2, 127.1, 135.4, 136.4, 137.2, 144.2, 151.1, 152.6 (2C), 152.9, 167.3, 171.5; MS *m/z* (relative intensity): 530 (M^+, 100), 484 (44), 456 (62), 411 (65), 384 (33), 358 (69); HRMS calcd. for $C_{28}H_{34}O_{10}$: 530.2151; found: 530.2139.

14. ^{1}H NMR (300 MHz, $CDCl_3$) δ 1.19 (t, *J* = 7.2 Hz, 3H), 1.31 (t, *J* = 7.1 Hz, 3H), 3.67 (s, 3H), 3.72 (s, 6H), 3.77 (s, 3H), 3.88 (s, 3H), 3.89 (s, 3H), 4.06 (d, *J* = 1.2 Hz, 1H), 4.12 (2 overlapping quartets, *J* = 7.2 Hz, 2H), 4.23 (2 overlapping quartets, *J* = 7.1 Hz, 2H), 5.00 (d, *J* = 1.2 Hz, 1H), 6.28 (s, 2H), 6.71 (s, 1H), 7.62 (s, 1H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ 14.1, 14.3, 39.4, 46.2, 56.0 (4C), 60.71, 60.77 (one quaternary carbon not observed). EIMS *m/z* = 530 [M^+], 456 (base), 411, 384, 196; HRMS calcd. for $C_{28}H_{34}O_{10}$: 530.2152; found: 530.2129.

Comparison of the free radical scavenger activities of quercetin and rutin — An experimental and theoretical study

Carolina Aliaga and Eduardo A. Lissi

Abstract: Natural radical scavengers have recently received considerable interest owing to the role of free radicals in causing oxidative stress in living organisms. Flavonoids constitute one of the most important families of molecules with antioxidant activities, a characteristic associated with the presence in their structure of hydroxyl groups bound to aromatic rings. Quercetin is a potent antioxidant whose high reactivity could be associated with the presence of the OH group in the C ring. To address the role of this group in quercetin's free radical scavenging capacity, we have carried out experimental determinations and theoretical calculations regarding the reactivity of quercetin and rutin. The reactivity of both compounds towards free radicals was assessed employing the radical anion 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonate) and peroxyl radicals. These measurements indicate that quercetin is more reactive and has more reactive centers than rutin, suggesting that the extra OH group located in the C ring could directly contribute to reactivity of quercetin. This conclusion is in agreement with the evaluation of local reactivity indexes, such as the Fukui function.

Key words: quercetin, rutin, antioxidant activity, $ABTS^{\bullet-}$, peroxyl radicals, Fukui function, local reactivity index.

Résumé : Les pièges naturels de radicaux ont récemment fait l'objet de beaucoup d'attention en raison du rôle que jouent les radicaux libres dans les réactions oxydantes dans les organismes vivants. Les flavonoïdes forment l'une des plus importantes familles de molécules ayant des activités antioxydantes, une caractéristique associée à la présence dans leur structure de groupes hydroxyles liés à des noyaux aromatiques. La quercétine est un puissant antioxydant dont la grande réactivité peut être liée à la présence d'un groupe hydroxyle dans le cycle C. Afin de pouvoir étudier le rôle de ce groupe dans les capacités de la quercétine à piéger les radicaux libres, nous avons effectué des déterminations expérimentales et des calculs théoriques concernant la réactivité de la quercétine et de la rutine. Pour évaluer la réactivité de ces deux composés vis-à-vis des radicaux libres, on a utilisé l'anion radical 2,2′-azinobis-(3-éthylbenzothiazoline-6-sulfonate) et les radicaux peroxyles. Ces mesures indiquent que la quercétine est plus réactive et possède plus de centres réactifs que la rutine, ce qui suggère que le groupe hydroxyle additionnel sur le cycle C peut contribuer directement à la réactivité de la quercétine. Cette conclusion est en accord avec l'évaluation des indices de réactivité locale, telle que la fonction Fukui.

Mots clés : quercétine, rutine, antioxydant, $ABTS^{\bullet-}$, radicaux peroxyles, fonction de Fukui, indice de réactivité locale.

[Traduit par la Rédaction]

Introduction

Flavonoids are one of the most abundant families of natural compounds with antioxidant activity (1–5). This antioxidant activity is mostly related to their ability to act as free radical scavengers due to the presence of one or several phenolic groups (6). These groups can react according to:

[1] $R\bullet + XOH \rightarrow RH + XO\bullet$

The antioxidant activity of the phenols is then promoted by the lability of the O–H bond in phenols (7) and the low reactivity of the phenoxyl radical, which favors termination reactions, thereby reducing the length of free radical chains.

Most flavonoids bear more than one potentially reactive group (8, 9), and their antioxidant activity mainly functions on the basis of an efficient hydrogen transfer capacity. However, a role for their metal-chelating potential towards iron- and copper-induced free radical reactions has also been associated with the presence of vicinal phenol groups (1, 10). The polyfunctional property of these molecules makes it difficult to establish which is the primary target for free radical attack. Two approaches can be employed to address this issue. Experimentally, the reactivity of the parent compound can be compared with that of derivatives in which some of the reactive centers are blocked (11). The second approach relies on the evaluation of local reactivity indexes, such as

Rutin; R =

the Fukui function, one of the most commonly used descriptors of site reactivity. In the case of flavonoids, the latter approach has been only scarcely employed (12, 13).

Rutin and quercetin (Scheme 1) are two closely related polyphenols that differ only in the substitution at the C3 position of the C ring. To establish which is the more reactive locus in quercetin and, in particular, if the reactivity towards free radicals is dominated by a reaction involving the OH group located at the C3 position, we have compared the reactions of rutin and quercetin with peroxyl radicals and with the radical anion derived from 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonate) (ABTS). To further investigate whether the OH located at the C3 position of the C ring would be the most reactive center in quercetin, local reactivity indexes have been obtained by semiempirical AM1 and ab initio HF/3-21G** level calculations.

Experimental

All experiments were carried out in phosphate buffer solutions, 100 mmol/L, pH 7.0.

Bleaching of pre-formed ABTS-derived radical anion ($ABTS^{\bullet-}$)

The methodology employed was similar to that described previously (14–16). The main difference is the method employed to produce the radical. In the present study, the ABTS-derived radicals were produced by the MnO_2-promoted oxidation of ABTS. The addition of 2 mg of MnO_2 to 25 mL of a 100 mol/L solution of ABTS instantaneously produces a blue color characteristic of the radical anion. After centrifugation and filtering to remove the excess oxide, the absorbance of the solution remains stable for several hours. The incorporation of an aliquot of a polyphenol solution produces a decrease in absorbance (measured at 734 nm) that is directly related to the capacity of the polyphenol to bleach the pre-formed radical. We have evaluated the fast absorbance decay at 734 nm, measured ca. 10 s after polyphenol addition, and the total bleaching, measured 15 min after polyphenol addition. A comparison of these values with that obtained instantaneously after Trolox addition provides an estimation of the total number of groups that react instantaneously and the number of groups that react slowly with the pre-formed radical. Thus, the number of equivalents reacting during the fast step of the reaction (ERF) and the total number of equivalents reacting towards the end of the reaction (ERT) are evaluated according to eqs. [2] and [3], respectively:

$$[2] \qquad \mathrm{ERF} = \frac{\Delta A[\mathrm{Trolox}]}{\Delta A^{0}[\mathrm{additive}]}$$

$$[3] \qquad \mathrm{ERT} = \frac{\Delta A[\mathrm{Trolox}]}{\Delta A^{15}[\mathrm{additive}]}$$

where ΔA represents the change in absorbance measured after addition of the corresponding Trolox concentration, and ΔA^0 and ΔA^{15} represent the decrease in ABTS-derived radical absorbance measured at 734 nm at 10 s and 15 min, respectively, after addition of quercetin or rutin.

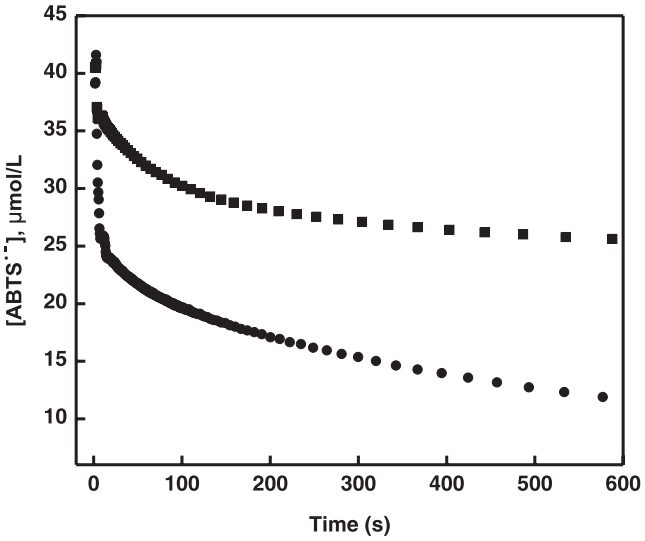
All experiments were carried out at room temperature (21 ± 1 °C).

Protection against c-phycocyanin fluorescence bleaching

The methodology applied follows that described by Cao et al. (17), with c-phycocyanin employed as the target molecule in place of β-phycoerythrin (18). All experiments were carried out at 37 °C employing 2,2′-azobis(2-amidinopropane) dihydrochloride (AAPH, 10 mmol/L) as free radical source. Consumption of c-phycocyanin was monitored by the decrease in fluorescence intensity (excitation 620 nm; emission 640 nm) measured in a Spex Fluorolog spectrofluorimeter.

Theoretical calculations

All calculations were performed with a Gaussian94 program (19) that included a short routine added to the Mulpop link 601 of the main program (20). This added routine permits, through a single-point calculation, an evaluation of the overlap term that takes into account the interaction between orbitals. Optimization of the structures of the investigated polyphenols was carried out at the semiempirical AM1 and ab initio HF/3-21G** levels. The ab initio calculation was carried out after optimization at the AM1 level. This type of calculation has proven to be useful in the theoretical treatment of simple phenols (21).



Results and discussion

The structures of quercetin and rutin are shown in Scheme 1. Both compounds are frequently present in plants, fruits, and beverages (22, 23) and contribute to their antioxidant activity (24, 25). As may be seen in Scheme 1, the only difference between the two compounds is the substitution of the OH group at position C3 in quercetin with a rutinose group in rutin. As such, the comparisons of these two compounds provide information regarding the role of the OH group at position C3 in the antioxidant capacity and free radical scavenging reactions of quercetin.

The reactivity of quercetin and rutin towards free radicals was evaluated in two in vitro systems, comprising the radi-

Fig. 1. Decrease of ABTS radical anion absorbance, measured at 734 nm, after addition of 10 μmol/L of quercetin (●) and rutin (■).

cals derived from ABTS (26) and peroxyl radicals generated in the aerobic decomposition of AAPH (27).

Reactivity of quercetin and rutin towards ABTS radical anions

ABTS-derived radicals in additive-free solutions are stable over a period of ca. 30 min. Addition of quercetin or rutin readily bleaches the absorbance of the radical. Typical profiles of the decay of the absorbance, measured at 734 nm, are shown in Fig. 1. These profiles reveal a biphasic behavior, characteristic of complex samples and (or) compounds bearing several potentially reactive groups (28). The fast decay, which is nearly complete after ca. 10 s, correlates with the number of centers of high reactivity. The extent of the bleaching observed after a relatively long reaction time (15 min) is determined by the total number of potentially reactive groups. The analysis of the curves given in Fig. 1 shows that both the number of groups of high reactivity and the total number of reactive groups are larger in quercetin than in rutin. It has been shown that, in spite of the fact that the ABTS radical consumption can be influenced by stoichiometric factors (14), the extent of bleaching correlates with the total number of phenolic groups in complex mixtures and in polyfunctional compounds (29).

The efficiency of bleaching of ABTS radical anions by each of the flavonoid molecules, "instantaneously" (during the first 10 s) and after 15 min incubation, is shown in Table 1. These data show that an extra Trolox equivalent participates in quercetin and that this extra reaction occurs very quickly. This would indicate that quercetin has one more group of high reactivity than rutin, suggesting that the OH group located in the C ring is able to readily bleach the ABTS-derived radical. Nearly two more Trolox equivalents in quercetin than in rutin have also been found in the classical Trolox equivalent antioxidant capacity (TEAC) assay involving myoglobin as a source of ABTS-derived radicals (2).

Table 1. Efficiency of rutin and quercetin in bleaching ABTS radical anion absorbance.

Additive	Concn. (μmol/L)	ΔA^0	ΔA^{15}	ERF	ERT
Trolox	2.5	0.418±0.01	—	1	1
Rutin	1.9	0.081±0.016	0.247±0.01	1.5	4.3
Quercetin	2.5	0.192±0.05	0.398±0.015	2.4	4.9

Note: Values tabulated are the decrease in ABTS radical anion absorbance (measured at 734 nm) evaluated at 10 s (ΔA^0) and 15 min (ΔA^{15}) reaction times and the number of equivalents reacting during the fast step of the reaction (ERF) and the total number of equivalents reacting towards the end of the reaction (ERT) (given in Trolox equivalents) measured after 10 s and 15 min reaction times, respectively.

The fact that the "fast" reaction takes place in a few seconds prevents an evaluation of its decay kinetics, which would require the use of fast stop-flow techniques (30). To gain some insight into the reactivity of the OH group at the C ring, relative to the phenolic groups present in the A and B rings, we carried out measurements in the c-phycocyanin–AAPH–additive system.

Protection against peroxyl-promoted bleaching of c-phycocyanin by quercetin and rutin

c-Phycocyanin fluorescence is readily bleached when the protein is incubated in the presence of a free radical source, such as AAPH (Fig. 2). The bleaching process follows nearly first-order kinetics (Fig. 3). The addition of micromolar concentrations of quercetin or rutin partially protects against the bleaching process (Fig. 2). The data in Fig. 2, obtained at equal concentrations of the two flavonoids, show that more protection is afforded by quercetin. The origin of this extra protection becomes clear when the data are plotted according to first-order kinetics (Fig. 3). The data given in Fig. 3 show that the extra protection provided by quercetin lasts for ca. 20 min, after which the bleaching rates in the presence of quercetin or rutin are similar. This suggests the presence of an extra group in quercetin that is consumed after ca. 20 min incubation. In fact, a comparison of this induction time with that elicited by the same amount of Trolox indicates that this extra protection can be assigned to a single extra group of very high reactivity towards peroxyl radicals.

The above results clearly show that, as in other free radical models (31), the reactivity of quercetin towards free radicals is greater than that of rutin. Three explanations can be given to account for this difference. First, substitution at the O3 position in the C ring may introduce a steric hindrance that reduces the coplanarity of the whole conjugated system, thereby reducing the reactivity of the phenol groups localized in the B ring. The second possibility could be a faster reaction of the catechol-like group located at the B ring of quercetin, due to its lower redox potential, as suggested in other systems (32, 33). The third explanation could be a high and dominant reactivity of the OH group at position C3 of the C ring in quercetin. Blocking of this group, as in rutin, would then reduce the compound's free radical scavenging capacity. The results given in Table 1 and Fig. 3, which suggest the presence of an "extra" very reactive center in quercetin, would support this last proposal. To test these

possibilities, theoretical calculations of geometry and local reactivity indexes in both compounds were performed.

Theoretical framework

AM1 and HF/3-21G** level calculations were performed to obtain the radical Fukui index ($f_k^{\bullet}$) and the regional local softness ($s_k^{\bullet}$) centered on oxygen atoms of all the OH groups. The theoretical treatment also provided the geometry of the molecule.

Reactivity indexes were calculated using density functional theory (DFT) as the starting point. This theory provides a series of electronic descriptors that correlate with a variety of molecular properties, such as acidity/basicity and reactivity of various organic compounds. The Fukui function is a local quantity that has been formally defined as the derivative of electronic density $\rho(r)$ with respect to the total number of electrons N in the system, under adiabatic conditions (constant external potential $\upsilon(r)$):

$$[4] \qquad f(r) = \left[\frac{\partial \rho(r)}{\partial N}\right]_{\upsilon(r)}$$

Thus, this index represents and provides information regarding changes in the electronic density at the reaction locus at the initial part of the reaction coordinate. This function is normalized to unity by its integration over the entire molecular space. The Fukui function will be used here to analyze locally the radical activity on the oxygen atoms linked to the active hydrogen atom of the polyphenols for hydrogen atom transfer reactions. The value at a given atom can be considered to be a measure of the specific reactivity at that reaction center (i.e., O3). An exact definition for this index is derived from the electronic density of the HOMO and (or) LUMO orbitals of a particular center. In general, the molecular frontier function is given by

$$[5] \qquad f^{\alpha}(r) = \left|\Phi^{\alpha}(r)\right|^2$$

where $|\Phi^{\alpha}(r)|^2$ represents the electronic density on the frontier orbital. A negative value of α (i.e., $\Delta N < 0$) identifies an electrophilic process, and a positive α value (i.e., $\Delta N > 0$) identifies a nucleophilic attack. Expansion of the molecular frontier function according to a linear combination of atomic orbitals (LCAO) allows an evaluation of the orbital component of the Fukui function. Finally, the amount condensed to the site k can be obtained by the summation over all the orbitals of the k center (20).

For radical processes such as those considered in the present work, the radical Fukui function was equated to the average of the functions corresponding to nucleophilic and electrophilic reactions:

$$[6] \qquad f_k^{\bullet} = \frac{f_k^{+} + f_k^{-}}{2}$$

Another quantity that can be employed to estimate the reactivity at a given center is the regional local softness, $s_k^{\bullet}$. This parameter evaluates the electronic or spin polarizability at the site k (34, 35). The value of $s_k^{\bullet}$ is obtained from the product of the Fukui function at the site k and the global softness of the system (S):

$$[7] \qquad s_k^{\bullet} = f_k^{\bullet} S$$

The global softness corresponds to the inverse of the molecular global hardness (η) and hence, at the level of Koopman's aproximation (36), is given by:

$$[8] \qquad \eta = \frac{1}{S} = \frac{\varepsilon_L - \varepsilon_H}{2}$$

where ε_L and ε_H are *eigenvalues* corresponding to LUMO and HOMO orbitals, respectively.

Theoretical calculations

Computational time was reduced by carrying out optimizations for rutin with a methyl group in place of the R group bound to the oxygen in the C3 position. It was found that the most stable structure is obtained when the three

Table 2. Regional Fukui functions and local softness for quercetin and rutin.

		$f_k^\bullet$		$s_k^\bullet$	
Molecule	(k)-Site[a]	AM1	HF/3-21G	AM1	HF/3-21G
Quercetin	O3′	0.016	0.0219	0.1123	0.1244
	O4′	0.0397	0.0309	0.2786	0.1755
	O7	0.0073	0.0069	0.0513	0.0392
	O5	0.0085	0.0118	0.0597	0.067
	O3	0.0407	0.0316	0.2857	0.1795
Rutin	O3′	0.0201	0.0242	0.1387	0.1326
	O4′	0.0479	0.0333	0.3301	0.1825
	O7	0.0003	0.0056	0.0021	0.0115
	O5	0.0069	0.0115	0.0476	0.063
	O3	0.0214	0.0201	0.1476	0.1101

Note: The values for global softness S obtained by AM1 methods (and by ab initio methods, in parentheses) are 7.02 (5.68) and 6.90 (5.48) atomic units for quercetin and rutin, respectively.

[a]Numbering of the atoms corresponds to that in Scheme 1.

rings remain coplanar. Partial optimization employing the whole rutin molecule provided the same answer, with the substituent at the C3 position displaced out of the molecular plane.

The values of the $f_k^\bullet$ and $s_k^\bullet$ indexes for all of the oxygen atoms in OH moieties present in quercetin and rutin are given in Table 2. The data in this table show that:

(*i*) In quercetin, both methods assign the highest index to the oxygen at the C3 position. This applies both to the $f_k^\bullet$ and $s_k^\bullet$ indexes. This may indicate that this OH group is the most reactive. However, it should be noted that this value is only marginally different from that assigned to the oxygen located at the C4′ position, which could explain the contribution of 2.4 groups to the ERF index (see Table 1).

(*ii*) All the reactivity indexes of the remaining OH groups in rutin are similar to those of the corresponding atoms in quercetin. This is the result expected if the molecule remains nearly planar, in spite of the substitution at the O3 position. Furthermore, this indicates that the reduced reactivity of rutin mainly results from the blocking of the O3 position and is not due to a change in reactivity of the remaining OH groups. The observed reduction from 2.4 (in quercetin) to 1.5 Trolox equivalents for rutin during the fast step of the reaction with ABTS-derived radicals could be ascribed to the absence of this key reactive site. Interestingly, the presence of this OH group in the C ring has been considered to increase the antioxidant activity of flavonols (37).

Conclusions

Taken together, the experimental data and the theoretical calculations presented in this paper suggest that the high reactivity of quercetin is primarily due to reaction of the OH group located at the C ring, and not to an increased reactivity of the vicinal OH groups located at the B ring (28, 32, 33, 38). This proposal is in agreement with conclusions reached by Erkoç et al. (13) based on electronic properties of the radical isomers derived from quercetin. This would lead initially to a radical centered in the C ring that could decay, by inter- and (or) intramolecular processes, to the "classical" radical mostly localized in the B ring (32). Blocking of the O3 position in the C ring in rutin accounts then for the reduced reactivity of this compound, both towards ABTS-derived radicals and towards peroxyl radicals. Conflicting results showing that blocking of the C4′ position in the B ring reduces the antioxidant activity of quercetin more than blocking at the O3 position of the C ring (39) can be related to a reduction in the chelating activity of the former compound (40).

The high reactivity of quercetin has usually been explained by considering that the hydroxyl group in the C ring increases the reactivity of the catechol-like structure of the B ring (2, 32, 33, 41, 42). However, we consider that the data obtained in this work, suggesting the presence of an "extra" very reactive center in quercetin, points to a preferential reactivity of the hydroxyl group located in the C ring. This proposal is compatible with the theoretical calculations that show that this OH group is at least as reactive as the catechol-like group located at the B ring. In any case, it must be considered that the main locus of reaction must depend on the attacking radical, the pH, and the solvent, rendering generalizations of the present results unwarranted.

Effect of cyclodextrins on iron-mediated dechlorination of trichloroethylene — A proposed new mechanism[1]

Salma Shirin, Erwin Buncel, and Gary W. vanLoon

Abstract: This paper evaluates the possibility of using cyclodextrins (CDs) as solubility-enhancing agents that could be employed to increase the rate of the mass delivery of trichloroethylene (TCE) to an iron wall where dechlorination will occur. Dechlorination of TCE by zero-valent iron was performed in the absence and in the presence of CDs in batch (*static*) and column (*dynamic*) systems. The presence of CDs slowed the overall degradation of TCE. The effect of various concentrations of different CDs on the rate of TCE degradation was evaluated, and it was found that as the CD concentration increased, reaction rate decreased. However, the overall decrease in reaction rate could not be explained solely on the basis of TCE:CD host-guest complexation. A novel mechanism involving CD binding to the iron surface, in addition to TCE:CD complexation, was proposed, and this enabled satisfactory interpretation of the kinetic data. A central feature of the proposal is that Fe:CD binding impedes electron transfer from the underlying iron metal to the TCE molecule. The overall rate of TCE degradation by zero-valent Fe in the presence of CDs is governed by several factors: the extent of binding of CD with the iron surface, the binding constant between CD and TCE, and the degradation of complexed TCE (TCE:CD), where CD is, in turn, associated with the iron surface. It appeared that CD binding to the iron surface depends largely on the type of substituent groups present in the β-CD derivatives as well as their degree of substitution. Association constants for the Fe:CD interaction were determined. The new hypothesis explained well both batch and column data, and the magnitude of Fe:CD binding constants was found to be similar in the two systems.

Key words: cyclodextrin, trichloroethylene, zero-valent iron, reductive dechlorination.

Résumé : Dans ce travail, on a évalué la possibilité d'utiliser les cyclodextrines (CD) comme agents d'augmentation de la solubilité pour augmenter la vitesse de distribution du trichloroéthylène (TCE) vers un mur de fer où une déchloruration se produira. On a réalisé la déchloruration du TCE par du fer zérovalent, en présence et en l'absence de CD, dans des systèmes par lots (*statiques*) et sur des colonnes (*dynamiques*). La présence de CD a ralenti la dégradation globale du TCE. On a évalué l'effet de diverses concentrations de différentes CD sur la vitesse de dégradation du TCE et on a observé qu'une augmentation de concentration de CD abaisse la vitesse de réaction. Toutefois, la diminution globale de la vitesse de réaction ne peut pas être expliquée uniquement sur la base d'une complexation hôte-invité TCE:CD. On propose un nouveau mécanisme impliquant une fixation de la CD sur la surface du fer, en plus de la complexation TCE:CD. La caractéristique centrale de cette proposition est que la fixation de la CD sur le Fe inhibe le transfert d'électron du fer métallique sous-jacent vers la molécule de TCE. La vitesse de dégradation du TCE sous l'influence du Fe zérovalent est déterminée par plusieurs facteurs: le taux de fixation de la CD sur la surface du Fe, la constante de fixation entre la CD et le TCE et la dégradation du TCE complexé (TCE:CD) où la CD est, à son tour, associée à la surface du fer. Il semble que la combinaison de la CD sur la surface du fer dépend beaucoup sur le type de substituants qu'on retrouve sur les dérivés de la CD ainsi que sur leur degré de substitution. On a déterminé les constantes d'interaction Fe:CD. La nouvelle hypothèse permet d'expliquer les données relatives aux systèmes statique et dynamique et on a trouvé que l'amplitude des constantes de fixation Fe:CD sont semblables dans les deux systèmes.

Mots clés : cyclodextrine, trichloroéthylène, fer zérovalent, déchloruration réductrice.

Introduction

Subsurface contamination by hazardous organic chemicals and the associated risks to humans and to the environment have become issues of global importance. According to the United States Environmental Protection Agency (US EPA), there are approximately 330 000 hazardous waste sites in the United States where the groundwater may be contaminated (1). Chemicals can enter the subsurface environment from accidental spills, leaks in the storage tanks, industrial waste pits, and municipal and industrial landfills. Trichloroethylene (TCE) is listed as being among the most frequently detected groundwater contaminants across North America (1, 2). The major industrial uses of this compound are in the automotive, metal, and dry cleaning industries.

The aqueous solubility of TCE is approximately 1100 ppm, and, when released into the subsurface, it does not dissolve completely in groundwater but remains as a separate dense, nonaqueous phase liquid (DNAPL). A plume of dissolved contaminants forms in groundwater when the water contacts either small residual ganglia or a larger pool of DNAPL. The slow release of dissolved TCE creates a persistent source of groundwater contamination. The safe limit for TCE in drinking water, set by the US EPA, is 0.005 ppm (3) whereas in Canada it is 0.05 ppm (4), both limits being much smaller than the aqueous solubility. Trichloroethylene has been described as being potentially carcinogenic and mutagenic (5).

It is known that TCE is resistant to biotic and abiotic degradation under natural environmental conditions (6). However, in anaerobic environments, TCE can undergo partial biodegradation, with vinyl chloride (VC) being identified as one of the degradation products. The VC, a known carcinogen, does not undergo further biotic degradation and can therefore accumulate in the environment (5). Since TCE and other polychlorinated compounds are not rapidly removed by either dissolution or degradation, their life span in the soil/groundwater system can be of the order of several decades, perhaps even centuries. As a result of the environmental persistence and potential harmful effects on living organisms, removal of these compounds from the subsurface has become a priority, and numerous studies have focused on their environmental remediation.

Among various subsurface remediation technologies, pump-and-treat remediation is currently the most widely used, but its limitations have led to the ongoing development of complementary new treatment remediation techniques, including the "iron wall" methodology (1, 2, 7–26). This technology consists of placing a reactive permeable barrier of finely divided zero-valent iron in the path of the groundwater flow in such a way that it will interact with the organic pollutants in the contaminated groundwater and degrade them while they are passing through the treatment zone. Spontaneous reduction of halo-aliphatic compounds, including TCE, by zero-valent iron metal occurs owing to the differences in the reduction potential of the individual half-cell reactions that favour dechlorination (6).

The mechanism for dechlorination of TCE on the zero-valent iron surface has not yet been definitively described. The most recent mechanism proposed by Arnold and Roberts (24) postulated that reduction of TCE by zero-valent iron proceeds via two different but parallel mechanisms: reductive β-elimination (departure of two Cl atoms from the adjacent carbons leading to the formation of a new π-bond between the adjacent carbons) and hydrogenolysis (replacement of Cl by H). In both cases, the TCE was shown to initially form a surface complex with iron followed by dechlorination via either of the mechanisms mentioned above.

It is widely accepted that the degradation of chlorinated aliphatic compounds by Fe^0 is a surface-mediated reaction; i.e., it is necessary that the compound be in close contact with the reactive site of the iron for electron transfer to occur (11, 12, 15, 24, 27). It is, in fact, assumed by many researchers that an initial TCE–Fe^0 precursor complex is formed which leads to dechlorination. The existence of the precursor complex has been inferred from the observation that the quantity of product formed was always markedly smaller than the amount expected based on the quantity of reactant degraded (9, 13, 14, 22). Consequently, the amount of compound that could not be accounted for in the observed mass balance was assumed to be located on the surface, where it continued to undergo dechlorination. Moreover, it has been shown that the rate of TCE degradation increases upon increasing the amount of iron, which further supports the argument that TCE dechlorination by iron is a surface-mediated reaction (9, 24).

Alongside the dechlorination process on the iron surface, corrosion products develop at the Fe^0–H_2O interface owing to the thermodynamic oxidative instability of Fe^0 in the presence of H_2O and O_2. As a consequence, a passive layer is formed that may affect the rate of reductive dechlorination. Electron diffraction and X-ray absorption near-edge spectroscopy of an electrochemically generated oxide film showed that the passive coating consists of an inner layer of magnetite (Fe_3O_4) and an outer layer of maghemite (γ-Fe_2O_3) (28–30). Other than iron oxide formation, siderite ($FeCO_3$) and pyrite (FeS_2) were also detected during the dechlorination process where the carbonate and sulfide species (9, 13, 21) were present in the system. A mixed-valence iron (hydr)oxide salt (with an interlayer containing anions such as Cl^-, CO_3^{2-}, and SO_4^{2-}), known as green rust, is another commonly found aqueous product of corrosion (30, 31). Thus, the passive layer on the oxide surface is essentially a complex mixture of iron oxides and hydroxides, iron oxyhydroxide salts, and other mineral precipitates. The structure and mineralogy of the passive film can be variable depending on the experimental conditions.

Formation of this mixed layer in the course of Fe^0-mediated dechlorination reactions has been observed in many cases (9, 13, 15, 21). When present, this coating may inhibit the dechlorination process by acting as a physical barrier between the underlying metal and the dissolved chlorinated compound. Scherer et al. (30) have suggested that the reduction process remains operative when an oxide layer is present on the iron surface. Gaspar et al. (32) have recently shown, however, that where a passive layer is present, to a significant extent the reduction takes place at pits where zero-valent iron is exposed, rather than on the oxide layer itself.

The effectiveness of using an iron wall as a reactive barrier in groundwater treatment is limited by the low aqueous solubility of chlorinated compounds. Thus, the complete

© 2004 NRC Canada

treatment of a DNAPL-contaminated zone by an emplaced iron wall barrier could require decades owing to the slow mass delivery to the treatment zone.

Cyclodextrins (CDs), which are six-, seven-, or eight-membered cyclic glucose oligosaccharides, are able to increase the aqueous solubility of a range of nonpolar to low-polarity organic compounds, including TCE (33–35). Solubility enhancement occurs by means of host–guest complexation. To overcome the limitations associated with low aqueous solubility in the iron wall remediation technology, researchers have explored the idea of using CDs to increase mass delivery to the treatment facility (16, 36, 37).

This paper evaluates the dechlorination of TCE by Fe^0 both in the absence and in the presence of various amounts of different substituted β-CDs. Since TCE:CD complexation occurs in parallel with TCE degradation by Fe^0, the effect of complexation on the degradation kinetics requires exploration. A number of substituted β-CDs, having varying degrees of substitution, have been considered since variously substituted CDs have shown different abilities to enhance the aqueous solubility of TCE (35); this feature could also affect the Fe^0-mediated dechlorination process. Additionally, the performance of individual β-CD derivatives (considering the types and number of substituent groups) on the degradation kinetics is evaluated. Kinetic results obtained from both batch (static) and column (dynamic flow-through) experiments are compared.

Experimental

TCE, perchloroethylene (PCE), *cis*-dichloroethylene (*cis*-DCE), *trans*-dichloroethylene (*trans*-DCE), and HPLC-grade acetonitrile were obtained from Aldrich Chemicals. All chemicals were analytical grade at 99.99% purity and were used as received. The iron was 100-mesh (0.145 mm particle size) zero-valent electrolytic iron powder, obtained from Fisher Scientific. Reported purity was 99.99%, and it was used as received without any pretreatment.

The specific surface area ($m^2\ g^{-1}$) of the iron powder was determined by Micromeritics Co. (Norcross, Ga.) to be 0.3158 $m^2\ g^{-1}$, using single-point nitrogen gas adsorption Brunauer–Emmett–Teller (B.E.T.) analysis (38). The fractional porosity of the zero-valent iron powder was determined gravimetrically and was found to be 0.496 ± 0.009.

The substituted β-cyclodextrins (β-CDs) used in this study were a hydroxypropyl-β-CD (HPβ-CD, D.S.[4] 5.5) (Aldrich), two sulfated β-CDs (Sβ-CD1, D.S. 4: Sβ-CD2, D.S. 14), a methyl-β-CD (Mβ-CD, D.S. 12), and a carboxymethyl-β-CD (CMβ-CD1, D.S. 3.0), all supplied by Cerester, and a second carboxymethyl-β-CD (CMβ-CD2), synthesized in the laboratory of Professor G.R. Thatcher at Queen's University. Further characteristics of these CDs are provided in ref. 35. All CDs were used as received; the aqueous solubility of each was determined to be >50% (*w*/*v*).

Batch experiments

For each set of experiments, 9.0-g portions of Fe^0 powder were added to 40-mL Pyrex glass vials. The vials were completely filled with aqueous solution of TCE without or with CDs, taking care that no headspace remained, and then were closed immediately using a Teflon-lined cap equipped with a MININERT™ valve. For the experiments that involved CDs, the required amount of CD had been added to the TCE stock solution and mixed completely before transferring to the vials. Each experiment included two vials, one containing Fe^0 and an aqueous solution of TCE (without or with CD) and the other containing an aqueous solution of TCE without any Fe^0. The vials were placed into the head-over-head mixer (30 rpm) at room temperature (maintained at 23 ± 2 °C) to allow for continuous mixing. At different time intervals, vials were withdrawn from the mixer and centrifuged, and a portion of aqueous sample (ca. 40 μL) was withdrawn using a gas-tight syringe for analysis. For each measurement, a sample from the control vial was analyzed along with one from the reaction vial to confirm that there had been no loss of TCE due to volatility or sorption on the container walls. By measuring changes in concentration of TCE over time, degradation kinetics were followed for at least 3–5 half-lives.

Column experiments

The glass column constructed for use in this study was 30 cm long with an i.d. of 2.85 cm. Twelve sample ports were located along the column: port 1, in the glass-bead portion at the base of the column, and ports at distances of 1.4, 3.4, 6.4, 9.4, 12.5, 15.4, 18.5, 21.3, 24.3, 27, and 30 cm from the bottom of the column. Iron powder was poured into the column in small portions with careful tapping so that no gaps remained in the column packing. After the column had been packed with iron powder, it was purged with argon for 16 h to remove oxygen that could contribute to rusting of the iron. The deaerated influent solution (aqueous TCE or aqueous TCE + CD) was then pumped at the rate of 1.2 mL min^{-1} from an air-free collapsible Teflon bag through the column using a peristaltic pump. All connections in the column system were made with Teflon tubing. The TCE degradation profile was determined by analyzing samples taken from different ports along the column under steady-state conditions (39). For sampling, a Luer-lock stainless steel needle (point style 5) was inserted through the septum of the open cap of the Teflon-lined sampling port to withdraw ~100 μL of sample. The initial concentration of TCE in any given experiment was determined by removing the sample from port 1. This measurement also served as control and was checked periodically throughout each experiment.

Using procedures described previously (35), liquid chromatography (LC) was employed for analysis of the samples from both batch and column systems. Direct analysis of samples was carried out immediately following withdrawal.

Results

In both batch and column systems, the concentrations of TCE were found to decrease as the reaction proceeded while the TCE concentration in the control remained constant (within 3%–6%) throughout the experimental period. Observed pseudo-first-order rate constants (k_{obs}) were obtained graphically using the following equation:

$$[1] \qquad \ln C_t = \ln C_0 - k_{obs}\, t$$

[4] D.S., degree of substitution.

© 2004 NRC Canada

where C_t is the concentration of analyte (TCE) at time t and C_0 is the initial concentration of analyte at time 0. Linear plots of eq. [1] produced good fits with correlation coefficient ranging from 0.965 to 0.997.

To represent the kinetic data for the dechlorination of TCE by Fe^0 in a more general way, the k_{obs} values were normalized to 1.00 m^2 of iron surface per liter of solution, giving a normalized rate constant, k_{SA}, as follows (12):

$$[2] \qquad \ln C_t = \ln C_0 - k_{SA}\rho_a t$$

where ρ_a is the surface area concentration of zero-valent iron.

Batch results

In experiments performed in the absence of CD, linear kinetic plots (eq. [1]) were obtained for each TCE concentration (ranging from 35 to 325 ppm). Correlation coefficients (R^2) ranged between 0.985 and 0.998. The observed rate constants (k_{obs}), the normalized rate constants (k_{SA}), and half-lives are listed in Table 1; the k_{obs} values remained relatively constant over the range of TCE concentrations used in this study.

The effect of CD on the zero-valent iron-mediated dechlorination of TCE was evaluated with each of HPβ-CD, Mβ-CD, CMβ-CD1, and CMβ-CD2 at five different CD concentrations ranging from 0.5% to 5% (*w*/*v*) (corresponding to ca. 0.0033 to 0.033 mol L^{-1}). In the case of Sβ-CD2, TCE degradation was investigated at only three different concentrations because there appeared to be very little change in rate when higher CD concentrations were used. Only one concentration for Sβ-CD1 was used because of the limited amount available. In all experiments where CDs were present, the TCE concentration was kept constant at 0.0019 mol L^{-1} (250 ppm). The degradation of TCE was inhibited by the presence of each of the CDs. Values of k_{obs} are listed in Table 2.

When the degradation of TCE (with or without CD) was followed using LC analysis, peaks corresponding to *cis*-DCE and *trans*-DCE (as reaction products) were observed. These compounds accumulated at a very low rate as the reaction proceeded and reached a final value, with no further decay being observed. Without CDs, the concentrations of the cis and trans isomers observed at completion of the various experiments were 4–5 and 2–3 ppm, respectively, whereas with CDs the corresponding values were 2–3 and ~1 ppm, respectively. The maximum concentration of the products represented ≤8% of the initial concentration of parent compound.

Column results

To obtain a kinetic trace from the column system, the distance of each port along the column was converted to time units employing Darcy's law (39). Linear plots using eq. [1] resulted; the correlation coefficient ranged from 0.978 to 0.994 for all TCE concentrations (38.5–250 ppm). The observed rate constants (k°_{obs}), the normalized rate constants (k_{SA}), and half-lives are listed in Table 3.

Using the column system, the kinetics of TCE degradation was evaluated by varying the concentration of two CDs, HPβ-CD and CMβ-CD2, from 0.5% to 3.0% (*w*/*v*) (corresponding to 0.0030 to 0.020 mol L^{-1}). In these experiments, the TCE concentration was kept constant at 0.00050 mol L^{-1} (66 ppm). In each experiment, the linear plot obtained from eq. [1] produced a satisfactory fit (correlation coefficient of 0.975–0.996). Kinetic data are presented in Table 4.

Table 1. Observed rate constants (k°_{obs}),[a] half-lives ($t_{1/2}$), and normalized rate constants (k_{SA}) for degradation of TCE in presence of zero-valent 100-mesh electrolytic iron powder in batch systems.

Note: Iron surface area concentration (ρ_a) = 71.1 m^2 L^{-1}, T = (23.0 ± 2.0) °C, mixing rate = 30 rpm.

[a]Observed rate constant for TCE degradation with Fe^0 without any CD is termed as k°_{obs}.

[b]Error in k°_{obs} values is the deviation from the mean of two values.

[c]Average k°_{obs} = (4.09 ± 0.55) × 10^{-2} h^{-1}.

[d]Average k_{SA} = (5.75 ± 0.79) × 10^{-4} L m^{-2} h^{-1}.

In the column experiments without CDs, *cis*-DCE and *trans*-DCE were observed as reaction products and reached a final value, as in the batch experiments, with 2–3 ppm *cis*-DCE and 1–2 ppm *trans*-DCE being observed in various experiments. However, in the column system, only the cis isomer (0.2–0.6 ppm) was observed when reactions were performed in the presence of CDs.

In this study, these were the only products observed during both batch and column experiments. The formation and the proportions of the *cis*- and *trans*-DCE products are in agreement with literature values (9, 13, 21). While other products (such as ethylene, acetylene, vinyl chloride, and ethane) have been reported in the literature when GC was used as an analytical technique (9, 13, 20, 21, 24), these could not be detected using the HPLC techniques employed in this study.

Discussion

This paper explores issues surrounding the use of CDs as solubility-enhancing agents to increase the rate of mass delivery of TCE to an iron wall where dechlorination can occur. To date, however, there have been no published works to study the consequences of using solubility-enhancing agents regarding rates and mechanisms of zero-valent iron-mediated TCE dechlorination. As part of a remediation protocol, the effects of CDs both on solubilization and on dechlorination must be considered together.

Based on results obtained in the batch experiments, two mechanistic approaches will be employed in an attempt to account for the dechlorination kinetic behavior. Rate reductions in the presence of CDs were obtained in all cases, and these will first be examined by attributing inhibition as due exclusively to TCE:CD host–guest binding (mechanism I). Secondly, a novel possibility will be considered, namely, the possible interaction between the added CD and the iron surface (mechanism II). This interaction, if it occurs, could par-

tially block access to the surface, limiting the extent to which the TCE molecule would make contact and be reduced by the zero-valent iron. Kinetic equations and schemes that incorporate the dual possibilities of CD binding either with TCE or with iron will then be used to rationalize the experimental data; both thermodynamic and kinetic parameters will be determined from these equations. Finally, a similar approach will be used to explain the results of the continuous-flow column experiments, and the parameters derived from these will be compared with those determined from batch studies.

Kinetic measurements of dechlorination using Fe^0

In this study, relatively high initial concentrations of TCE were used since one practical goal was to deliver a greater quantity of the contaminant to a reactive iron wall. Although the degradation process is generally considered to be pseudo-first-order with respect to the substrate, it is also known to be a surface-mediated process (9–11, 15, 24) as mentioned in the Introduction. Thus, one would anticipate that, at some upper limit in contaminant concentration, the reactive sites would be saturated and the reaction rate would become concentration-independent with respect to substrate. However, since changing the initial TCE concentration over one order of magnitude did not result in any change in observed rate constant (k°_{obs}) values in both batch and column systems (Tables 1 and 3), it appears that all experiments were, in fact, conducted under pseudo-first-order conditions.

2.3	0.65±0.01	1.97±0.02
3.0	0.53±0.01	1.78±0.01

Note: Iron surface area concentration (ρ_a) = 2140 m^2 L^{-1}, T = (23.0 ± 2.0)°C, flow rate = 1.2 mL min^{-1}. Numbers in parentheses are binding constant (K_{11}) values of TCE with CDs, taken from ref. 35. Error in k_{obs} values is the deviation from the mean of two values.

TCE was found to degrade faster in the column system (half-life = 40 min, Table 3) compared to the batch system (half-life = 17 h, Table 1) because the iron surface area concentration (ρ_a) was much higher in the column system (2140 m^2 L^{-1}) than in the batch system (71.1 m^2 L^{-1}). However, when the rate constants were expressed as k_{SA} values (rate constant normalized to 1 m^2 surface area of iron per liter of solution) for each system, they agreed rather well ((5.75 ± 0.79) × 10^{-4} m^{-2} L h^{-1} and (4.86 ± 0.56) × 10^{-4} m^{-2} L h^{-1} (Tables 1 and 3 for batch and column, respectively)).

Batch experiments: Dechlorination of TCE in the presence of CD

Since the rate constant for the TCE degradation was independent of initial concentrations between 35.0 and 325 ppm, TCE degradation in the presence of CDs was carried out using an initial TCE concentration of 0.0019 mol L^{-1} (250 ppm) and varying the CD concentration. In every case, the rate of TCE degradation was inhibited by the presence of CD, and the extent of inhibition was greater with increased concentration of CD (Table 2). The inhibitory effect has been attributed to the fact that the TCE:CD host–guest complexation shields the TCE molecule, making it less available for reaction at the iron surface.

Rate reduction due to host–guest binding (mechanism I)

To test this explanation for rate reduction, the extent of host–guest binding of TCE was determined using known binding constant (K_{11}·L mol^{-1}) values, and the kinetic equations were modified accordingly. Binding constants of TCE

© 2004 NRC Canada

with the CDs used in this work have been reported elsewhere (35). Because stronger binding means reduced availability for dechlorination, one would expect greatest inhibition to be associated with CDs having the largest binding constants.

Following ref. 16, a quantitative treatment can be deduced from Scheme 1, where the rate reduction is attributed solely to TCE:CD complexation. The rate equation corresponding to Scheme 1 is given by:

$$[3] \qquad -\frac{d[TCE]}{dt} = k^{\circ}_{obs}[TCE]_{free} + k_c[TCE:CD]$$

According to Scheme 1, in addition to TCE being directly degraded on the iron surface, TCE molecules are also in rapid equilibrium with CD, forming the TCE:CD complex. The decrease in the observed rate constants for the TCE degradation in the presence of CDs (Table 2) implies that an inhibitory effect arises due to formation of the unreactive host–guest complex between TCE and CD. It has been shown that when the substrate is included inside the CD cavity, reaction does not proceed via attack from an external agent (40). Since the dechlorination of TCE is known to be a surface-mediated process, electron transfer to the TCE:CD complex present in solution is unfavourable. Thus, the k_c[TCE:CD] term in eq. [3] can be ignored and the equation rewritten as

$$[4] \qquad -\frac{d[TCE]}{dt} = k^{\circ}_{obs}[TCE]_{free}$$

The rate of TCE degradation in the presence of CD can then be expressed as

$$[5] \qquad \text{Rate} = k_{obs}[TCE]_{total}$$

$$[6] \qquad = k_{obs}([TCE]_{free} + [TCE:CD])$$

$$= k_{obs}([TCE]_{free} + K_{11}[TCE]_{free}[CD])$$

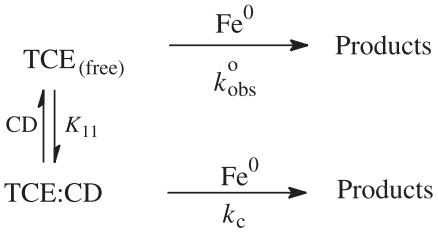
$$[7] \qquad = k_{obs}[TCE]_{free}(1 + K_{11}[CD])$$

Now

$$-\frac{d[TCE]}{dt} = \text{Rate}$$

Hence, from eqs. [4] and [5],

$$[8] \qquad k^{\circ}_{obs}([TCE]_{free} = k_{obs}[TCE]_{free}(1 + K_{11}[CD])$$



$$[9] \qquad k_{obs} = \frac{k^{\circ}_{obs}}{(1 + K_{11}[CD])}$$

where k_{obs} is the observed rate constant for TCE degradation in the presence of CD and k°_{obs} is the rate constant in the absence of CD.

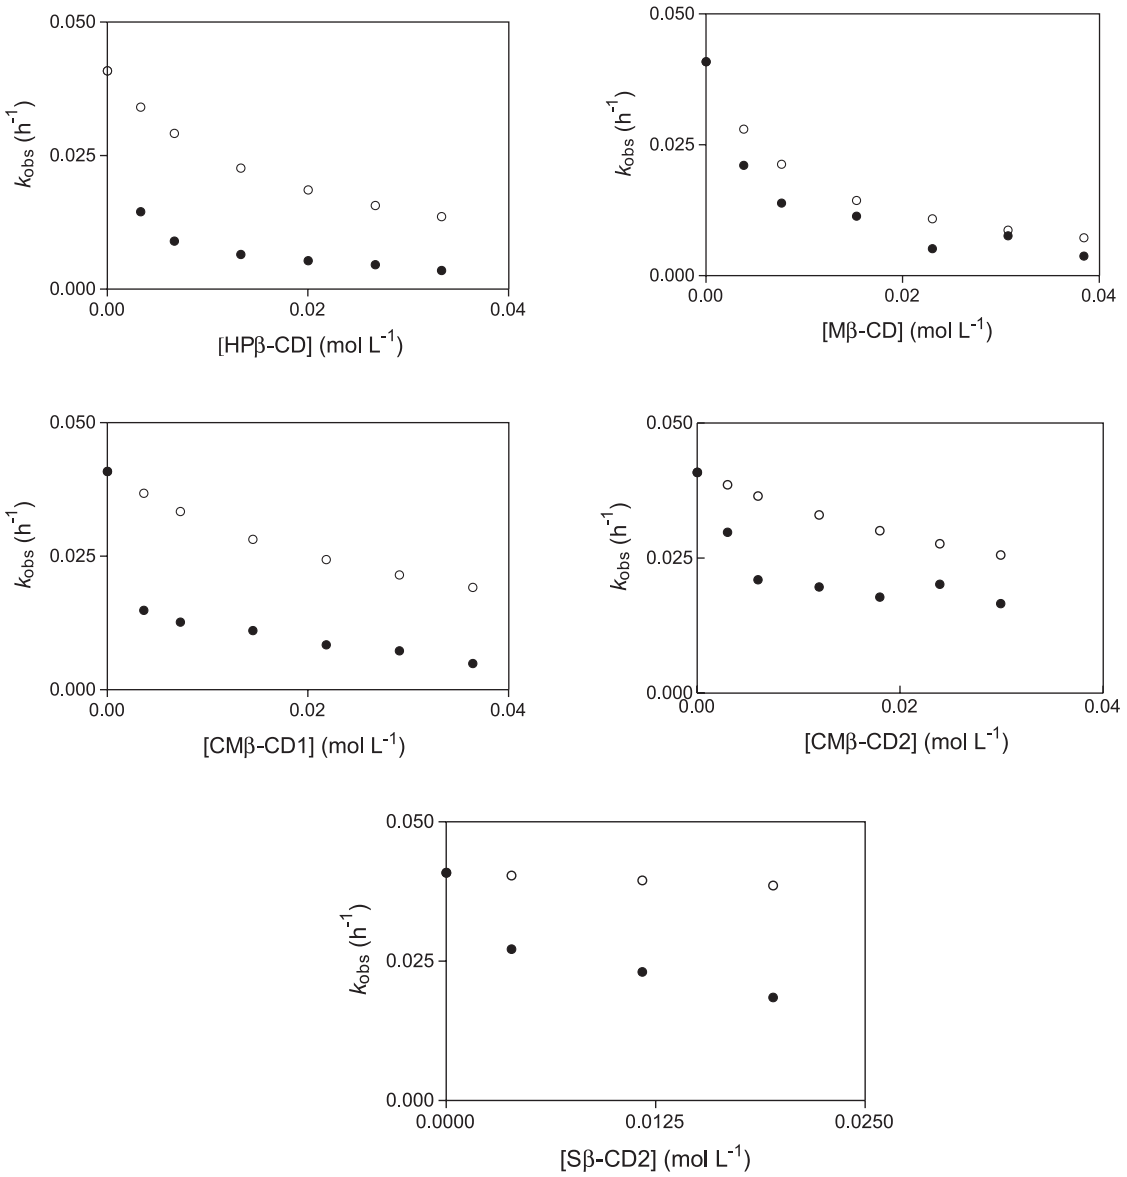
Using eq. [9], the theoretical observed rate constant values for TCE degradation in the presence of CD can be calculated since the binding constant (K_{11}) and the rate constant for the TCE degradation in the absence of CD (k°_{obs}) are known independently (Table 1). For comparison, both theoretical and experimentally obtained k_{obs} values from Table 2 are plotted together for each CD in Fig. 1.

It is seen from Fig. 1 that large differences between the theoretical (open circles) and experimental (solid circles)

Scheme 1. Mechanism I for TCE degradation.

k_{obs} values were found in all cases with the exception of Mβ-CD, where the differences were considerably smaller. In each case, experimental k_{obs} values were lower than theoretically calculated values. This suggests that, apart from inhibition arising from complexing with the CD, other factors operating in the system contribute to additional lowering of the rate of TCE degradation. With most of the CDs, the difference between the theoretical and experimental k_{obs} value is greater at lower CD concentration.

Enhanced rate depression due to Fe–CD surface binding (mechanism II)



To explain the enhanced inhibition of dechlorination in the presence of CD, we propose that the CD (which is present in large excess in the solutions) may itself undergo interaction with the iron surface (which may contain an oxide or hydroxide surface layer). When this occurs, the surface area occupied by CD molecules becomes unavailable as a site for contact between iron and TCE molecules, which reduces the probability of surface-mediated electron transfer that leads to reductive dechlorination.

It has been shown that surface oxide and hydroxide groups on iron (hydr)oxide can take part in forming coordination complexes with a variety of organic ligands containing functional groups such as –OH and –COOH (41, 42). In a study of the dechlorination of CCl_4 by zero-valent iron, it was similarly shown that the presence of ligands, including borate, catechol, ascorbate, and acetate, slowed the observed rate of reaction (43). This was ascribed to specific binding between surface hydroxyls on the iron and the oxygen-containing ligands. The authors suggested that CCl_4 could be sorbed both at reactive and at nonreactive sites by weak hydrophobic or induced-dipole interactions. The strongly bound specific complex involving borate or other ligands blocks the reactive surface, reducing the probability of forming the weak Fe:CCl_4 precursor complex essential for dehalogenation. In another study (44), Tratnyek et al. have shown that the reduction of TCE and CCl_4 by Fe^0 was inhibited in the presence of natural organic matter (NOM). The authors concluded that NOM, which contains a variety of redox-active functional groups, competes with TCE and CCl_4 for the iron oxide surface, causing depression in the rate of reduction of chlorinated compounds.

Native CD molecules possess primary and secondary –OH groups, and, upon derivatization, some of these groups are replaced by the substituents, including $–CH_2CH(OH)CH_3$, $–CH_3$, $–CH_2COO^-$, and $–SO_4^-$. Additionally, through the –OH of the glucose molecules that make up the CDs, similar types of coordination with iron (hydr)oxide can be predicted. Since derivatization to form Mβ-CD replaces –OH groups by neutral substituents, it would be expected that the formation

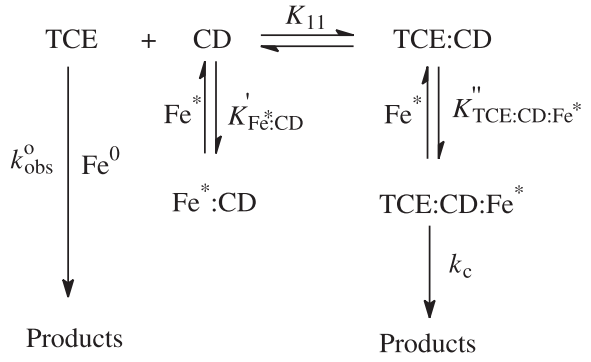
Fig. 1. Effect of various CDs on the observed rate constant for TCE degradation by Fe^0 in batch system (ρ_a = 71.1 m^2 L^{-1}, 30 rpm, 23 ± 2 °C). Open and solid circles represent rate constants calculated using eq. [9] and experimental rate constant values, respectively.

of coordination complexes with (hydr)oxide layers would be less effective in these CDs compared to the free and otherwise substituted CDs.

Partially blocking access to the iron surface as a result of CD–iron (hydr)oxide complexation would limit the extent to which the TCE molecule could make contact with the iron as the first step in the reductive dechlorination process. One would anticipate a preferential interaction of CD with the iron surface, compared with TCE, owing both to its large excess as well as to the ability of its functional groups to form coordinate or covalent bonds with the iron surface.

Proposal of a new model for degradation of TCE in the presence of CDs

To account for the effect arising from formation of complexes between CD and the iron surface (the various Fe^0, Fe–O, and Fe–OH species being represented as Fe^*), and the subsequent effect on the rate of degradation of TCE, a competitive surface complexation model is now proposed. In this model, the processes operating in the TCE–CD–Fe^* system can be depicted as shown in Scheme 2. Considering the processes described in Scheme 2, the rate equation can be expressed as follows (refer to the Supplementary material[5] for full derivation):



$$[10] \qquad k_{obs} = \frac{k^{\circ}_{obs} + k' K_{Fe^*:CD} K_{11}[CD]}{1 + K_{11}[CD] + K_{Fe^*:CD}[CD] + K_{Fe^*:CD} K_{11}[CD]^2}$$

From eq. [10], on plotting k_{obs} for degradation of TCE in the presence of various concentrations of CD against [CD], one

Scheme 2. Proposed new mechanism II for TCE degradation.

can calculate the parameters $K_{Fe^*:CD}$ (association or binding constant of CD (free CD or CD complexed with TCE) on iron surface) and k' (rate constant for the degradation of complexed TCE, i.e., TCE:CD, where CD is in turn, associated with the iron surface) using nonlinear regression analysis and minimizing the sums of the squares of the residuals. Note that dechlorination of complexed TCE:CD was not considered in mechanism I, while in mechanism II the TCE-complexed CD is also taken as a degrading species. In the latter mechanism, TCE is assumed to be in close proximity to the iron surface through CD:Fe binding; this situation might facilitate electron transfer from iron metal to the bound TCE molecule.

Duplicate experimental data sets for TCE degradation in the presence of various concentrations of several CDs (Table 2) were fitted to eq. [10] and analyzed for the two unknowns, $K_{Fe^*:CD}$ and k'. Figure 2 illustrates the fitting of an experimental data set for each CD, and Table 5 lists the $K_{Fe^*:CD}$ and k' values obtained from the curve fitting. It is apparent from Fig. 2 that there is close agreement between the observed and calculated rate constants for degradation as described by mechanism II, which is consistent with the argument of CD binding to the iron surface shown in Scheme 2.

The k' values (rate constant for the degradation of complexed TCE, i.e., TCE:CD, where CD, in turn, is associated with the iron surface) listed in Table 5 range from 1% to ca. 15% of the k°_{obs} (rate constant for TCE in the absence of CD; Table 1). This may be explicable on the basis of the following: (*a*) most of the CD molecules bound to the Fe surface do not contain TCE and (or) (*b*) electron transfer from iron to complexed TCE is less favourable than that involving free TCE. One additional noteworthy observation from Table 5 is the generally inverse relationship between K_{11} (values obtained from ref. 35) and k'; a higher K_{11} value means stronger binding, thus leading to smaller k'.

The model as elaborated in Scheme 2 for the Fe^0-mediated degradation of TCE in the presence of CDs can be further analyzed in terms of the reaction sequence given by eqs. [11]–[15], where eq. [15] represents the overall hydrodehalogenation and eq. [11] represents initiation via the half-cell process $Fe^0 \rightarrow Fe^{2+} + 2e^-$ (E = –0.771 V). In this scheme, eq. [12], representing electron transfer from Fe^0 to the antibonding C–Cl σ* orbital of TCE, is the rate-limiting step, which is followed by fast expulsion of Cl^-, though the latter process could occur concertedly with electron transfer. The radical R• will then accept an electron and a proton from the aqueous medium, completing the hydrodehalogenation.

[11] $Fe^0 \rightarrow Fe^{2+} + 2e^-$

[12] $R–Cl + e^- \rightarrow R–Cl^-$

[13] $R–Cl^- \rightarrow R\bullet + Cl^-$

[14] $R\bullet + H^+ + e^- \rightarrow R–H$

[15] $R–Cl + H^+ + 2e^- \rightarrow R–H + Cl^-$

Reactions [12] and [13] find analogy with the radical $S_{RN}1$ mechanism of nucleophilic substitution of aryl and alkyl halides (45, 46). While similar mechanisms for dechlorination of related halogen compounds have been proposed by other workers (12, 13), the present study differs from previous ones through the role imparted by the presence of CDs. Previously, a di-σ-bonded Fe-surface-bound chlorinated alkene intermediate was postulated in the rate-determining step (24); however, in the present study, the formation of such an intermediate would be precluded by the CD, which effectively covers the iron surface through Fe*:CD binding. This would then account for a substantial reduction in the rate of dechlorination. At the same time, where TCE is encapsulated within the CD, it is envisaged that electron transfer to the analyte from Fe^0 could occur, up to a separation of approximately 10 Å.

Factors affecting extent of surface binding of CDs

There is considerable variation in the extent to which each CD inhibits degradation of TCE, and this is reflected in the differing $K_{Fe^*:CD}$ values. The $K_{Fe^*:CD}$ parameter measures the strength of binding between iron (hydr)oxide and CD. In these CD molecules, both unsubstituted –OH groups and the derivatized ones are available for complexation with the iron surface. Ideally, one could anticipate the relative order of $K_{Fe^*:CD}$ values amongst the different substituted CDs to be related to the type and number of substituent groups present. Accordingly, one would expect that, among the CDs employed here, Mβ-CD would be the least effective in forming complexes with the oxidized iron surface since there would be less tendency for the methyl substituents to complex with the polar surface (hydr)oxide groups. This would leave only the remaining unsubstituted –OH groups on the CD molecule (9 for Mβ-CD) to participate in bonding. This is borne out in that the $K_{Fe^*:CD}$ value for Mβ-CD is smaller than the others except that for Sβ-CD2, and there is correspondingly less inhibition of the reduction process, as shown in Table 2.

An interesting feature in Table 2 merits further consideration. It appears that $K_{Fe^*:CD}$ is directly correlated with the average number of underivatized –OH groups in the CD molecule. In the native β-CD molecule, there are 21 –OH groups where substitution can take place (33). The average D.S. of the substituted β-CDs used in this work are listed in Table 5, and it appears that as the average D.S. decreases (i.e., higher number of unsubstituted –OH groups), the $K_{Fe^*:CD}$ parameter increases. This correlation supports the earlier argument regarding the important role played by the –OH group in binding of CD to iron oxide surface.

If –OH groups play the dominant role in forming complexes between iron oxide and CD, one might then expect that HPβ-CD would have the highest $K_{Fe^*:CD}$ value since

Fig. 3. Effect of two CDs on the observed rate constant for TCE degradation by Fe^0 in column system (ρ_a = 2140 m^2 L^{-1}, flow rate = 1.2 mL min^{-1}, 23 ± 2 °C). Open and solid circles represent rate constants calculated using eq. [9] and experimental rate constant values, respectively.

HPβ-CD contains 21 –OH groups arising from either native –OH or $–CH_2CH(OH)CH_3$ substitution. However, it is clear from Table 5 that this is not the case, since CMβ-CD1 has in fact the highest $K_{Fe^{*}:CD}$ value, and. one can then speculate that the contribution from native CD–OH groups predominates. Given that CD–OH appears to be the key group responsible for the binding of CD to iron, thereby blocking the surface, one might expect that the observed differences between the theoretical and experimental k_{obs} values should be similar in situations involving CDs containing a similar number of unsubstituted –OH groups. Therefore, Sβ-CD2 and Mβ-CD would show similar differences between the theoretical and experimental k_{obs} values, since both contain a similar number of native –OH groups (on average 7 for Sβ-CD2 and 9 for Mβ-CD). However, based on Fig. 1 this is clearly not the case. As seen in the figure, Sβ-CD2 exhibited greater differences between theoretical and experimental k_{obs} values than did Mβ-CD. This discrepancy can be rationalized in that k_{obs} is a composite of the terms $K_{Fe^{*}:CD}$, K_{11}, and k', and, in this instance, the inhibitory effect associated with Mβ-CD on TCE degradation is substantially due to complexation of TCE; this in turn is evidenced by the large K_{11} value observed for Mβ-CD.

The average association constant (K_s) between TCE and Fe has been determined previously and was found to be 191 L mol^{-1} (47). In all cases, it is seen that the $K_{Fe^{*}:CD}$ values are substantially higher than K_s. For this reason and because the concentration of CD present in solution is manyfold greater than that of TCE, the number of Fe sites occupied by surface-bound CD will be much greater than sites occupied by TCE, and binding of TCE itself to the iron surface can be neglected. For this reason, such binding is omitted from Scheme 2, and K_s does not appear in the equation describing k_{obs}.

Column experiments: Dechlorination of TCE in the presence of CD

Following degradation of TCE by Fe^0 in a flowing system allows for further testing of the proposed mechanism to describe inhibition by CDs. For the column kinetic experiments, only two derivatized β-CDs, HPβ-CD (with a neutral substituent group) and CMβ-CD2 (with a charged substituent group), were studied.

As previously found in the batch system, the rate of TCE degradation was inhibited by the presence of both CDs (Table 4). This finding agrees with the literature report that the relative extent of PCE degradation in the column system decreased as the HPβ-CD concentration increased from 0.1% to 7.0% (16). In this work, the TCE degradation rate decreased as the CD concentration increased, attaining a minimum at 1% CD. Above this concentration, the rate of TCE degradation remained nearly constant for CMβ-CD2, and very little change was observed for HPβ-CD. However, the relative overall decrease in the rate of TCE degradation is greater with HPβ-CD than with CMβ-CD2, in agreement with results obtained in batch experiments. As with the batch systems, theoretical rate constants could be calculated to compare with experimental results in the column experiments. When mechanism I was considered to be operative, in both cases the experimental values were again found to be smaller than those determined by calculation (Fig. 3). However, when mechanism II was used as the basis for calculations, agreement between theory and experiment was much better (Fig. 4). In a similar manner as for the batch system, values for $K_{Fe^{*}:CD}$ and k' were obtained from nonlinear regression analysis, and these are listed in Table 6. Good fits were obtained in all cases as shown in Fig. 4.

As in the batch experiments, k' values are smaller than the rate constant for free TCE (k°_{obs} = 1.04 h^{-1}) in the absence of CD. The k' value range from ≤1% to ≤3% of the average k°_{obs} value obtained from the column experiments.

The $K_{Fe^{*}:CD}$ values reported in Table 6 for HPβ-CD and CMβ-CD2 for the column experiments are also similar in magnitude to the corresponding values measured in batch systems. Interestingly, the associated errors (deviations from the mean) in $K_{Fe^{*}:CD}$ values for HPβ-CD and CMβ-CD2 obtained from the column system are smaller than in the case of the batch system (Table 5). Recall that with HPβ-CD and CMβ-CD2 in the batch system, data points in the region of steepest slope (lowest concentration) displayed significant deviations between the two data sets. As a result, the deviation from the mean value of $K_{Fe^{*}:CD}$ was significant in those cases. However, this type of experimental scatter in data

Asymmetric formal synthesis of (–)-cryptosporiopsin, a metabolite of *Phialophora asterris*, and its 3-deschloro congener

David I. MaGee, Tammy Mallais, and George M. Strunz

Abstract: An asymmetric formal synthesis of the fungal metabolites (–)-cryptosporiopsin and (–)-3-deschlorocryptosporiopsin has been accomplished. The asymmetry was introduced via a diastereoselective [2+2]-cycloaddition between an enoxy-ester, bearing a bulky chiral auxiliary, and dichloroketene. Diastereomeric ratios of 10:1 were obtained from the reaction mixture, but this could be increased by simple crystallization. Completion of the synthesis was only accomplished after the serendipitous discovery of a base-catalyzed rearrangement to furnish the requisite 3-chloroenone moiety.

Key words: diastereoselective [2+2]-cycloaddition, rearrangement, chiral auxiliary.

Résumé : On a effectué une synthèse asymétrique formelle des métabolites de champignons, les (–)-cryptosporiopsine et (–)-3-deschlorocryptosporiopsine. L'asymétrie a été introduite par le biais d'une cycloaddition diastéréosélective [2+2] entre le dichlorocétène et un ester énoxy portant un auxiliaire chiral auxiliaire volumineux. On a obtenu des rapports de diastéréomères de 10:1 à partir du mélange réactionnel, mais il a été possible de les augmenter par cristallisation simple. On n'a complété la synthèse qu'après la découverte fortuite d'une transposition catalysée par les bases qui permet d'obtenir la portion 3-chloroénone requise.

Mots clés : cycloaddition diastéréosélective [2+2], transposition, auxiliaire chiral.

[Traduit par la Rédaction]

Introduction

Cryptosporiopsin (**1**, Fig 1) and chlorinated cyclopentenone congeners were isolated in 1969, independently from *Sporormia affinis* (1), *Cryptosporiopsis* sp. (2), and *Periconia macrospinosa* (3). Several biogenetically related dihydroisocoumarins from *P. macrospinosa* (e.g., **2**) had been reported previously (4), and new members of the group, including the enantiomeric (–)-cryptosporiopsin (**3**) from *Phialophora asterris* (5), were subsequently disclosed (6). The antibiotic activity of cryptosporiopsin against an array of plant pathogenic fungi and other microorganisms was described (7) and this, together with its intriguing richly functionalized structure, provided the impetus for development of a synthetic route to the metabolite.

Total synthesis of cryptosporiopsin, in racemic form, was first accomplished in 1973 via a biomimetic pathway (8). The key step in this synthesis, ring contraction of a phenolic precursor through the action of alkaline hypochlorite, though providing access to advanced intermediate in a single operation, was a capricious and low-yield process. A later synthesis involving ring contraction of a pre-formed quinonoid intermediate provided a somewhat more efficient route to cryptosporiopsin (9).

Following elucidation of the interesting chemistry associated with dichloroketene cycloaddition with olefins (10), the important synthetic potential of this reaction allowing ready access, inter alia, to a variety of substituted four- and five-membered ring systems (see, e.g., refs. 10 and 11) was recognized.

In 1999, a highly efficient racemic synthesis of 3-deschlorocryptosporiopsin (**4**), a metabolite of *S. affinis* (1), was reported from our laboratories (12), in which the pivotal step was cycloaddition of dichloroketene with methyl 2-trimethylsilyloxy-2-hexenoate (**5**) (Fig. 2). Whereas the original biomimetic route to cryptosporiopsin via contraction of a six-membered ring was not readily amenable to chiral modification, the dichloroketene cycloaddition process can be conducted diastereoselectively, e.g., when the olefin bears a suitable chiral auxiliary (13).

In the present paper we report application of this strategy in an enantioselective synthesis of (–)-cryptosporiopsin, a product of *Phialophora asterris* (5), as well as that of an enantiomer of the *S. affinis* metabolite, 3-deschlorocryptosporiopsin (1).

Greene et al. (14) have shown that diastereoselectivities of around 16:1 can be realized in the cycloaddition of dichloroketene with a chiral enol ether such as **7** in Fig. 3. We considered that the most effective chiral induction for our purposes might be realized if the cycloaddition of dichloroketene was conducted with a cyclic precursor, such

Fig. 1. Various fungal chlorinated metabolites.

as the dioxolanone **8** or lactone **9** (15). In any event, the failure of both of these olefins to undergo satisfactory cycloaddition with dichloroketene led us to explore instead the diastereoselectivity of dichloroketene cycloaddition with a series of simple chiral 2-silyloxy-2-hexenoic esters (15), of which **10** (which has a (*t*-butyldimethylsilyl (TBS) group) proved to be functional. Useful enantioselectivity has not been observed in conjugate addition of nucleophilic reagents to conjugated chiral esters or during their reaction with diazomethane to give pyrazolines (16). It was reasoned, however, that the presence of a moderately, but not excessively,[2] sterically demanding silyloxy group in the 2-position of a suitable conjugated chiral ester might exert conformational effects resulting in enhanced asymmetric induction during a cycloaddition process.

This hypothesis was substantiated, and optimum diastereoselectity (>10:1) was, in fact, observed in dichloroketene cycloadditions with the 2,2-diphenylcyclopentane esters of 2-silyloxy-2-hexenoic acids (15). Molecular mechanics calculations[3] suggested that the preferred conformation of the (–)-2,2-diphenylcyclopentane ester of 2-*t*-butyldimethylsilyloxy-2-hexenoic acid (**10**), a candidate synthetic precursor, should favour a *Si* approach of the dichloroketene (Fig. 4). This ester thus emerged as the precursor of choice for the enantioselective synthesis of the *P. asterris* metabolite, (–)-cryptosporiopsin.

Cycloaddition of **10** (17) with dichloroketene afforded, after crystallization from hexanes, cyclobutanone **11** (Scheme 1) in 69% yield with 11.5:1 diastereoselectivity. Treatment of **11** with diazomethane (12) effected regiospecific ring expansion to produce diastereometrically enriched cyclopentanone **12** in 90% yield.[4]

This was deemed an appropriate point in the projected synthetic sequence for removal of the chiral auxiliary, preferably concomitant with direct transesterification. Familiar synthetic terrain, traversed previously (though with trimethylsilyloxy rather than *t*-butyldimethylsilyloxy protection) (12), would thus be attained. In any event, attempts at direct transesterification of **12** to the corresponding methyl ester using conventional methodology (see, e.g., ref. 15) were unsuccessful, undoubtedly as a result of the considerable steric encumbrance in the vicinity of the ester group. (In many cases the dimethyl acetal of the ketone resulted.) The chiral auxiliary could, however, be successfully removed by treatment of **12** with neat trifluoroacetic acid (TFA) (18) under reflux which, not surprisingly also removed the *t*-butyldimethylsilyl alcohol protecting group. The product, **13,** without purification, was directly esterified with diazomethane to afford the methyl hydroxy ester **14** in an overall yield of 53%.[5]

Difficulties were encountered in attempts at resilylation of the free hydroxyl group of **14** (including formation of an acyclic product by a retro-aldol process when basic conditions were used), suggesting that the silylation step might be better conducted following desaturation of the ring. Accordingly, **14** was converted to cyclopentenone **16** (54% yield, based on consumed starting material) by treatment with excess selenium dioxide (12). Reaction of **16** with trimethylsilyl trifluoromethanesulfonate (TMSOTf) then afforded **17**, identical in all respects, other than optical rotation, with its racemic counterpart, prepared in the course of the earlier synthesis (12). Preparation of **17** thus constitutes a formal total synthesis of the enantiomer of natural 3-deschlorocryptosporiopsin (cf. refs. 1 and 12).

In the racemic synthesis, the cyclopentenone was next transformed to the corresponding trimethylsilyl (TMS)-dienol ether **20** prior to introduction of the side-chain unsaturation. Under somewhat modified conditions, **17** with chlorotrimethylsilane in refluxing triethylamine afforded, to our pleasant surprise, not the expected TMS-dienol ether but the rearranged product **18** in modest yield. Further investigation revealed that the rearrangement occurred simply on heating **17** at reflux in THF with 2 mole equivalents of triethylamine alone, in the absence of chlorotrimethylsilane!

A rigorous explanation for the rearrangement of **17** to **18** requires additional mechanistic studies, beyond the scope of the present synthetic project. It may be noted, however, that the *gem*-dichloroketone (**17**) can be expected to be a rela-

[2] Cycloaddition failed when attempted with the excessively bulky 2-*t*-butyldiphenylsilyloxy-2-hexenoic diphenylcyclopentyl ester.

[3] Molecular mechanics calculations were performed using the MMFF94 program. No restrictions on bond rotations were imposed. Although there were approximately 20 low-energy conformations within 2.5 kcal/mol, 15 of them adopted the *s*-cis conformation (the lowest-energy *s*-cis conformation had a calculated potential energy of 89.1 kcal/mol). Each of these conformations indicated that the *Si*-face was more accessible for cycloaddition. The remaining low-energy conformations had the *s*-trans arrangement (the lowest-energy *s*-trans conformation had a calculated potential energy of 91.2 kcal/mol), again with the *Si*-face appearing more accessible. Of particular note was that a dihedral angle much less than 180°, and in some instances as low as 139°, between the carbonyl and the carbon–carbon double bond (O=C–C=C) was observed. This helps to corroborate our rationale as to why [2+2]-cycloadditions with these alkenes proceed while those with **8** and **9** do not.

[4] The absolute configurations depicted in **11** and **12** and subsequent structures were, in fact, only rigorously confirmed on completion of the synthesis.

[5] The free acid could, in fact, be obtained without removal of the TBS group by degradation of **12** to **15**, through the agency of ruthenium trichloride in the presence of sodium periodate (19), followed by decarboxylative elimination using 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU). The yield of the desired silyloxy carboxylic acid, however, was not competitive with that from the TFA procedure adopted and described in the text.

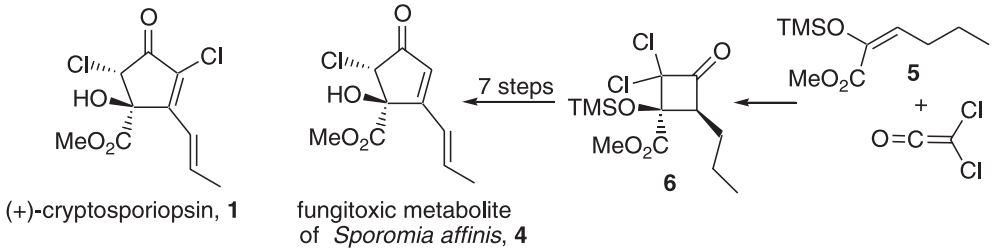

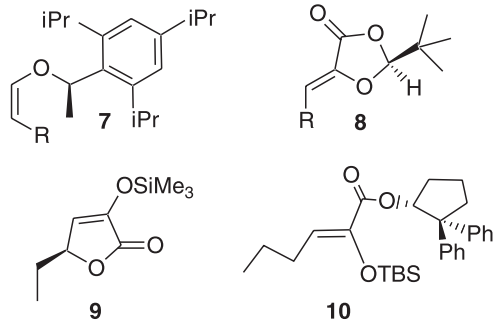

Fig. 3. Greene's enol ether and various other enol ethers investigated.

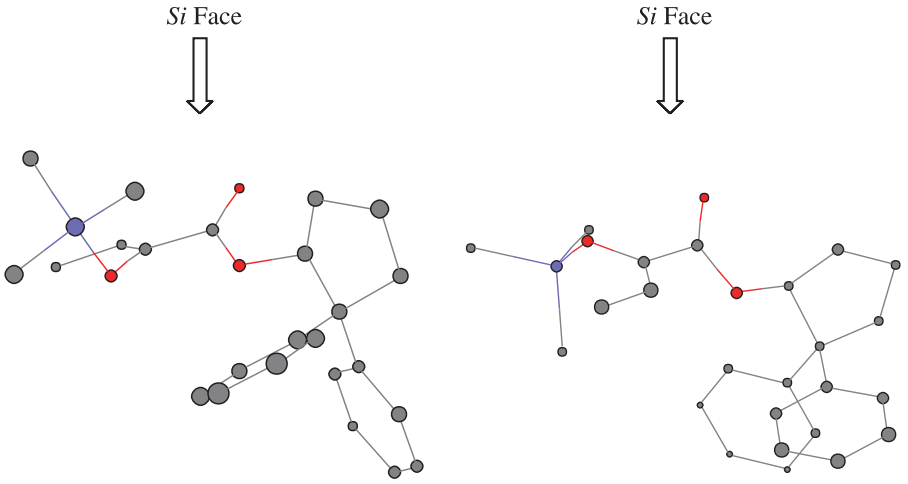
tively efficient source of electrophilic chlorine, perhaps capable of chlorinating triethylamine to a reactive triethylchloroammonium cationic species, as in Scheme 2. The dienolate **ii** formed from **i** via prototropic shifts could then undergo α-chlorination by the latter reactive species, affording the observed product **18**. The fact that the putative intermediate **ii** undergoes α-chlorination, in contrast to the *gem*-dichlorosilyl enol ether **20** (which reacts with electrophiles at the γ-position) (12), may be due to steric differences and the possible existence of **ii** as a tight ion pair. That said, one cannot rule out the possibility that enolate **ii**, in contrast to Kabanyane's TMS-dienol ether **20**, is simply more susceptible to α-chlorination owing to the increased electron density, or higher HOMO, on the α-carbon.

A slight permutation on the above mechanism may also be considered, in which **17**, as its dienolate (or dienol), undergoes direct chlorination by a second molecule of **17**, to furnish trichloro and monochloro intermediates. The monochloro species, as its conjugated dienolate (or dienol, following prototropic shifts), could then undergo halogenation at its free α-position by transfer of one of the geminal chlorine atoms of the trichloro product. In our experience (12), *gem*-dichloroenones such as **17** tend to react with electrophiles at the γ- rather than the α-position, so one might expect the latter mechanism to produce a mixture of α- and γ-chlorinated products. As only the α-chlorination product **18** was observed, we are inclined to favour the former mechanism. That the chlorine at C5 assumes the correct configuration relative to the functionality at C1 under the equilibrating conditions employed has much precedent (6, 12).

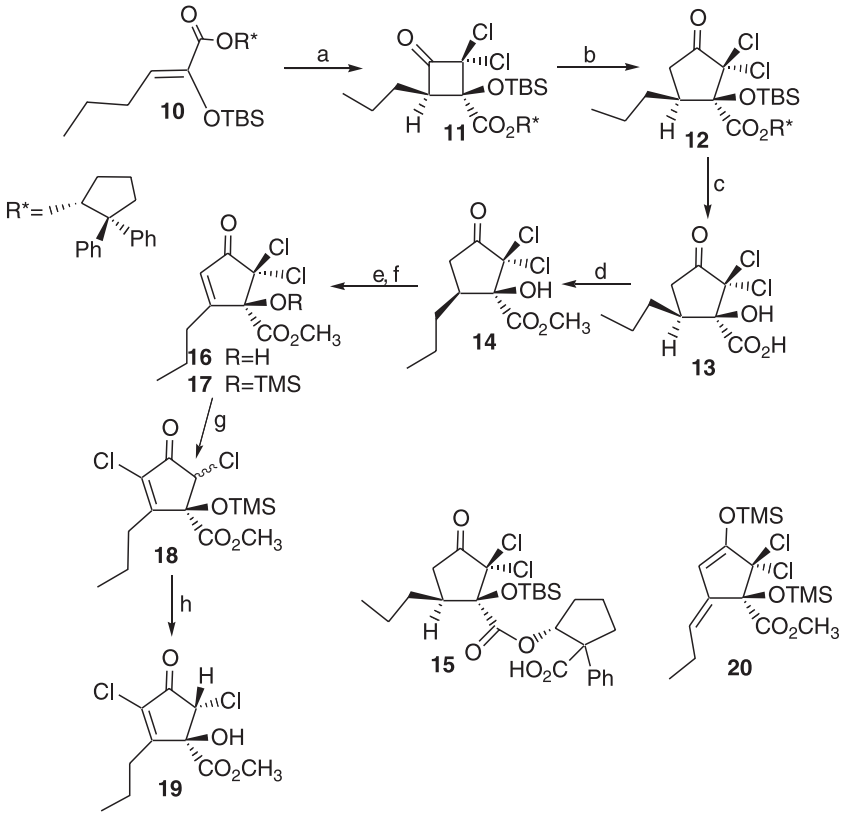
Finally, an alternate pathway to account for the rearrangement of **17** to **18** is shown in Scheme 3.[6] Initially, enone **17** may undergo γ-deprotonation with triethyamine to produce dienolate **i**; if this then suffers an S_N1 type solvolysis of one of the chlorine atoms, oxyallyl cation **ii** is produced. Trapping of **ii** with in situ chloride would generate enolate **iii**, which after protonation and conjugation of the alkene, produces **18**. Unlike the two aforementioned mechanistic proposals, the product formed via this pathway is produced by a nucleophilic chlorine source. This mechanistic rationale is also attractive since base-induced oxyallyl cation formations are well documented (20).

The formal synthesis of (+)-cryptosporiopsin was completed by removal of the TMS protecting group using known methodology (12). The product, **19**, obtained in a modest 41% yield from **18** via base-induced (K_2CO_3) desilylation was identical in all respects, other than its opposite optical rotation, with (–)-dihydrocryptosporiopsin, obtained by catalytic hydrogenation of (+)-cryptosporiopsin (2). The optical rotation of the dihydro derivative obtained from the natural product was +187° and that of synthetic **19**, –160°. This represents an enantiomeric excess of 85%. As desaturation of racemic dihydrocryptosporiopsin to racemic cryptosporiopsin has been accomplished previously (8), the present work constitutes a formal total synthesis of the *P. asterris* metabolite (–)-cryptosporiopsin (5).



Experimental procedures

All reactions, unless stated otherwise, were performed under inert atmospheres of either argon or nitrogen in flame-dried glassware (Pyrex). Solvents, such as ether, tetrahydrofuran, xylenes, benzene, and toluene, were distilled over sodium, using benzophenone as an indicator, prior to use. Other solvents such as dichloromethane, triethylamine, and acetonitrile were freshly distilled over calcium hydride. Standard techniques were used in handling air-sensitive reagents. Silica gel chromatography (TLC) was performed with DC-Fertigplatten SIL G-25 UV_{254} glass plates (purchased from Aldrich Chemicals, Mississauga, Ont.) or by flash chromatography using Silicycle Ultra Pure Silica Gel for chromatography (Silicycle, Quebec City, Que.). All ^1H and ^{13}C NMR spectra were recorded on a Varian UNITY 400-MHz spectrometer using $CDCl_3$ as solvent. Optical rotations were recorded on a Perkin-Elmer 241 polarimeter using the Na lamp. All IR spectra were recorded on a Bruker IFS 25 instrument using NaCl windows. All high-resolution mass spectra (HR-MS) were run on a Kratos MS50 instrument.



[6] The authors wish to thank one of the referees for suggesting and pointing out the possibility of this mechanism.

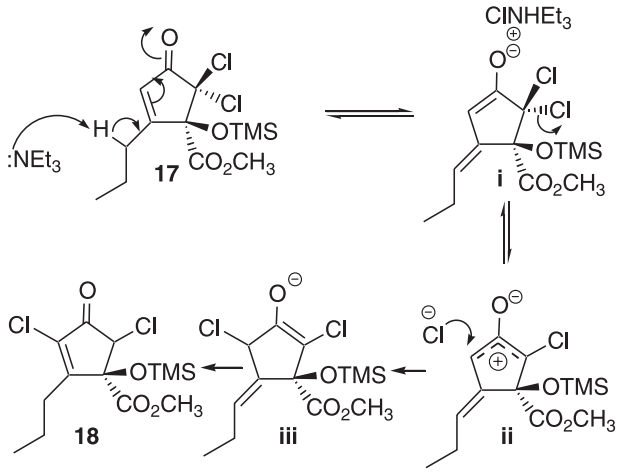
1-*t*-Butyldimethylsilyloxy-2,2-dichloro-3-oxo-4-propylcyclobutanecarboxylic acid (*S*)-(2,2-diphenyl)cyclopentyl ester (11)

Activated Zn dust[7] (1.12 g, 17.1 mmol) was flame-dried in a flask under argon. After cooling to room temperature, ether (10 mL) was added followed by dropwise addition over 4–5 h of a mixture of trichloroacetyl chloride (1.53 mL, 13.7 mmol) and silyl enol ether **10** (3.20 g, 6.9 mmol) (18). The heterogenous solution was stirred for 16 h at RT, diluted with diethyl ether, and filtered through Celite®. The



[7] Zn dust was activated by vigorously stirring with 10% HCl for 1–2 min, filtered, and then washed with H_2O (3×) followed by acetone (3×). Zinc activated in this manner was stored in an oven at 140 °C until it was needed.

Scheme 3. An alternate mechanism for the rearrangement of **17** and **18**.

filtrate was concentrated to 1–5 mL by rotary evaporation, diluted with pentane (15 mL), and then vigorously stirred for 5 min to induce precipitation of Zn salts. After the precipitate had been allowed to settle, the pentane solution was decanted from the Zn salts. This decanting/washing protocol was repeated twice more. The combined pentane extracts were washed with cold saturated $NaHCO_3$ (5%, 2×), H_2O (1×), and brine (1×) and dried over Na_2SO_4. The solvent was evaporated, and the crude residue was purified by filtration through a short column of SiO_2 (20:1 hexane:ethyl acetate) followed by recrystallization from hexanes to furnish cycloadduct **11** (2.68 g, 69% yield) as a colorless solid; mp 76–78 °C. ^{1}H NMR ($CDCl_3$) δ: 0.22 (s, 3H), 0.36 (s, 3H), 0.73 (t, J = 7.3 Hz, 3H), 0.92 (s, 9H), 1.29 (m, 2H), 1.51 (m, 3H), 1.87 (m, 1H), 2.04 (m, 1H), 2.31 (m, 1H), 2.47 (m, 1H), 2.65 (m, 1H), 2.95 (t, J = 7.7 Hz, 1H), 6.24 (d, J = 4.8 Hz, 1H), and 7.23 (m, 10H). ^{13}C NMR δ: –2.8, 14.1, 19.9, 20.7, 21.2, 26.3, 26.7, 28.8, 30.3, 35.2, 59.9, 64.3, 83.9, 126.3, 126.5, 126.7, 126.8, 127.6, 128.4, 128.5, 128.7, 128.8, 144.5, 145.1, 168.2, and 194.8. IR (cm^{-1}): 3030, 2878, 1818, 1735, 1518, 1460, 1225, and 920. $[\alpha]_D^{25}$ = –65.2° (c = 2.5, CH_2Cl_2).

1-*t*-Butyldimethylsilyloxy-2,2-dichloro-3-oxo-5-propylcyclopentanecarboxylic acid (*S*)-(2,2-diphenyl)cyclopentyl ester (12)

Dichlorocyclobutanone **11** (2.65 g, 4.69 mmol) was dissolved in diethyl ether (20 mL) and cooled to 0 °C, and then diazomethane in ether (0.2 mol/L, 28 mL, 5.6 mmol) was carefully added dropwise. Anhydrous methanol (5 mL) was subsequently added and the reaction mixture was stirred at 0 °C for 5–10 min. The excess diazomethane was quenched with glacial acetic acid (2 drops) and then the solvent was removed in vacuo. (*Note*: The reaction mixture can be left overnight at RT before removal of the solvent to ensure that all the diazomethane has been quenched or evaporated.) The residue was purified by SiO_2 chromatography (30:1 hexane:ethyl acetate) to provide dichlorocyclopentanone **12** (2.50 g, 90% yield) as a colorless oil. ^{1}H NMR ($CDCl_3$) δ: 0.14 (s, 3H), 0.39 (s, 3H), 0.74 (m, 3H), 0.82 (s, 9H), 0.96 (m, 4H), 1.65 (m, 1H), 1.97 (m, 3H), 2.17 (m, 1H), 2.46 (m, 3H), 2.75 (m, 1H), 6.35 (d, J = 4.4 Hz, 1H), 7.15 (m, 2H), 7.26 (m, 6H), and 7.37 (d, J = 7.69 Hz, 2H). ^{13}C NMR ($CDCl_3$) δ: –2.8, –2.2, 14.0, 19.4, 20.2, 20.5, 26.1, 26.2, 30.7, 31.6, 34.6, 36.4, 39.9, 59.3, 83.4, 86.8, 126.1, 126.2, 127.3, 128.0, 128.2, 128.4, 128.5, 128.6, 144.3, 144.9, 168.0, and 197.8. IR (cm^{-1}): 3030, 2404, 1776, 1738, 1518, 1424, 1218, and 926. HR-MS: $(C_{32}H_{42}Cl_2O_4Si - C_4H_9)_{obs.}$ = 531.15287; $(C_{32}H_{42}Cl_2O_4Si - C_4H_9)_{calcd.}$ = 531.15252. $[\alpha]_D^{25}$ = –42.4° (c = 2.5, CH_2Cl_2).

Methyl 2,2-dichloro-1-hydroxy-3-oxo-5-*n*-propylcyclopentane carboxylate (14)

Cyclopentanone **12** (2.47 g, 4.2 mmol) and trifluoroacetic acid (150 mL) were heated at reflux for 15 h. Upon cooling, the solvent was removed in vacuo to give **13** as a black oil. The oil was dissolved in ether (100 mL) and cooled to 0 °C, and diazomethane (0.2 mol/L, 33.5 mL, 5.0 mmol) was added dropwise. The reaction mixture was allowed to stir at 0 °C for 5 min, then warmed to RT, and stirred for 30 min. The dark reaction mixture was quenched with glacial acetic acid (10 drops) and the solvent evaporated. The residue was purified by SiO_2 chromatography (10:1 hexane:ethyl acetate) to furnish cyclopentanone **14** (0.602 g, 53% yield) as a colorless oil. ^{1}H NMR ($CDCl_3$) δ: 0.94 (t, J = 7.2 Hz, 3H), 1.31 (m, 2H), 1.52 (m, 2H), 2.21 (dd, J_1 = 9.1, J_2 = 18.9 Hz, 1H), 2.85 (dd, J_1 = 9.2, J_2 = 19.0 Hz, 1H), 3.11 (m, 1H), 3.69 (d, J = 1.88 Hz, 1H), and 3.94 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 14.1, 20.7, 31.5, 36.5, 37.2, 53.4, 83.5, 87.0, 169.0, and 198.0. IR (cm^{-1}): 3480, 2958, 2874, 1778, 1728, 1450, 1156, and 820. HR-MS: $(C_{10}H_{14}Cl_2O_4)_{obs.}$ = 268.02769; $(C_{10}H_{14}Cl_2O_4)_{calcd.}$ = 268.02692. $[\alpha]_D^{25}$ = +40° (c = 2.0, EtOH).

Methyl 5,5-dichloro-1-hydroxy-4-oxo-2-*n*-propyl-2-cyclopentene carboxylate (16)

Selenium dioxide (0.70 g, 6.4 mmol) was added to a solution of cyclopentanone **14** (0.57 g, 2.13 mmol) in toluene (20 mL). The solution was heated at reflux for 24 h, cooled to room temperature, then diluted with hexane and filtered through Celite®, and the solvent was evaporated. After purification by SiO_2 chromatography (5:1 hexane:ethyl acetate), cyclopentenone **16** (0.25 g, 63% yield based on consumed cyclopentanone **14**) was obtained as a colorless oil. ^{1}H NMR

($CDCl_3$) δ: 0.98 (t, J = 7.3 Hz, 3H), 1.58 (m, 2H), 2.23 (m, 1H), 2.47 (m, 1H), 3.82 (s, 3H), 4.47 (s, 1H), and 6.28 (s, 1H). ^{13}C NMR ($CDCl_3$) δ: 13.6, 19.7, 30.9, 54.6, 86.7, 87.0, 127.2, 169.8, 173.3, and 189.4. IR (cm^{-1}): 3480, 2952, 1736, 1640, 1464, 1272, 1176, 952, and 840. HR-MS: $(C_{10}H_{12}Cl_2O_4 - Cl)_{obs.}$ = 231.04094; $(C_{10}H_{12}Cl_2O_4 - Cl)_{calcd.}$ = 231.04248. $[\alpha]_D^{25}$ = –143° (c = 0.65, EtOH).

Methyl 5,5-dichloro-4-oxo-2-*n*-propyl-1-trimethylsilyloxy-2-cyclopentene carboxylate (17)

Trimethylsilyl trifluoromethanesulfonate (0.03 mL, 0.14 mmol) was added dropwise to a solution of alcohol **16** (18.8 mg, 0.07 mmol), triethylamine (0.03 mL, 0.17 mmol), and diethyl ether (1 mL). The reaction mixture was stirred at RT for 30 min, then quenched with saturated NH_4Cl (1 mL). The organic layer was separated, washed with brine (1×), and dried over $MgSO_4$, and the solvent was evaporated. Preparative TLC (5:1 hexane:ethyl acetate) provided **17** (14.5 mg, 61% yield) as a colorless oil. ^{1}H NMR ($CDCl_3$) δ: 0.35 (s, 9H), 0.99 (t, J = 7.3 Hz, 3H), 1.61 (m, 2H), 2.20 (m, 2H), 2.41 (m, 2H), 3.73 (s, 3H), and 6.19 (s, 1H). ^{13}C NMR ($CDCl_3$) δ: 2.1, 13.7, 19.8, 30.8, 53.4, 90.6, 125.3, 168.8, 175.5, and 189.9. IR (cm^{-1}): 3000, 1752, 1640, 1448, 1224, 894, and 856. HR-MS: $(C_{13}H_{20}Cl_2O_4Si - CH_3)_{obs.}$ = 323.02643; $(C_{13}H_{20}Cl_2O_4Si - CH_3)_{calcd.}$ = 323.02731. $[\alpha]_D^{25}$ = –109° (c = 0.97, EtOH).

Methyl 3,5-dichloro-4-oxo-2-*n*-propyl-1-trimethylsilyloxy-2-cyclopentene carboxylate (18)

A mixture of enone **17** (16.9 mg, 0.049 mmol) and triethylamine (0.014 mL, 0.099 mmol) was heated at reflux in THF and monitored by TLC. When the starting material was completely consumed, the solvent was removed in vacuo and the residue was purified by SiO_2 chromatography (10:1 hexane:ethyl acetate) to furnish **18** (10.5 mg, 62% yield) as a colorless oil. ^{1}H NMR ($CDCl_3$) δ: 0.27 (s, 9H), 0.97 (t, J = 7.4 Hz, 3H), 1.51 (m, 2H), 2.40 (m, 1H), 2.50 (m, 1H), 3.71 (s, 3H), and 4.44 (s, 1H). ^{13}C NMR ($CDCl_3$) δ: 2.1, 14.2, 20.4, 29.3, 53.2, 66.4, 86.1, 132.5, 168.2, 168.8, and 188.2. IR (cm^{-1}): 2961, 2877, 1769, 1622, 1436, 1253, 878, and 761. HR-MS: $(C_{13}H_{20}Cl_2O_4Si - CH_3)_{obs.}$ = 323.02695; $(C_{13}H_{20}Cl_2O_4Si - CH_3)_{calcd.}$ = 323.02731. $[\alpha]_D^{25}$ = –75° (c = 0.6, EtOH).

(–)-Dihydrocryptosporiopsin (19)

Chloroenone **18** (11.8 mg, 0.03 mmol) was dissolved in methanol (1 mL) and cooled to 0 °C. Potassium carbonate (6 mg, 0.04 mmol) was added in one portion, and the reaction mixture was stirred at 0 °C. When TLC showed complete consumption of the starting material, the mixture was poured into cold H_2O and extracted with ether (3×). After drying with $MgSO_4$, the solvent was removed in vacuo and the residue was purified by SiO_2 chromatography (5:1 hexane:ethyl acetate) to give (–)-dihydrocryptosporiopsin (**19**) as a colorless solid (4 mg, 41% yield), which had identical spectroscopic properties, except rotation, with a sample derived from the natural compound. ^{1}H NMR ($CDCl_3$) δ: 0.98 (t, J = 7.4 Hz, 3H), 1.52 (m, 2H), 2.42 (ddd, J_1 = 6.6 Hz, J_2 = 9.6 Hz, J_3 = 13.3, 1H), 2.55 (ddd, J_1 = 6.0 Hz, J_2 = 9.3 Hz, J_3 = 13.2 Hz, 1H), 3.82 (s, 3H), 4.40 (bs, 1H), and 4.55 (s, 1H). ^{13}C NMR ($CDCl_3$) δ: 14.4, 20.6, 29.4, 54.6, 65.6, 83.7, 133.9, 166.5, 170.8, and 188.0. IR (cm^{-1}): 3504, 3040, 3008, 1736, 1620, 1524, 1420, 1216, and 932. HR-MS: $(C_{10}H_{12}Cl_2O_4)_{obs.}$ = 266.01014; $(C_{10}H_{12}Cl_2O_4)_{calcd.}$ = 266.01126. $[\alpha]_D^{25}$ = –160° (c = 0.1, $CHCl_3$). Comparison with spectral data of the authentic sample of (+)-dihydrocryptosporiopsin: ^{1}H NMR ($CDCl_3$) δ: 0.98 (t, J = 7.3 Hz, 3H), 1.50 (m, 2H), 2.42 (ddd, J_1 = 6.6 Hz, J_2 = 9.6 Hz, J_3 = 13.3, 1H), 2.55 (ddd, J_1 = 6.0 Hz, J_2 = 9.3 Hz, J_3 = 13.2 Hz, 1H), 3.82 (s, 3H), 4.40 (s, 1H), and 4.57 (s, 1H). ^{13}C NMR ($CDCl_3$) δ: 14.4, 20.6, 29.4, 54.6, 65.7, 83.7, 133.9, 166.5, 170.7, and 188.0. $[\alpha]_D^{25}$ = +187° (c = 0.5, $CHCl_3$).

Platinum pyridinecarboxaldimine complexes containing boronate esters

Hanni A. Darwish, Stephen J. Scales, Jennifer L. Horton, Liliya G. Nikolcheva, Haiwen Zhang, Christopher M. Vogels, Mazen T. Saleh, Robert J. Ireland, Andreas Decken, and Stephen A. Westcott

Abstract: Condensation of 2-pyridinecarboxaldehydes with 2-, 3-, and 4-$H_2NC_6H_4Bpin$ (pin = 1,2-$O_2C_2Me_4$) gave the corresponding boron-containing pyridinecarboxaldimines (N–N_{Bpin}). Addition of these ligands to $[PtCl_2(coe)]_2$ (coe = *cis*-cyclooctene) gave complexes of the type *cis*-$PtCl_2(N–N_{Bpin})$ in moderate yields. The platinum complexes have been examined for their potential cytotoxicities against OV2008 (human ovarian carcinoma) and the analogous cisplatin-resistant cell line C13.

Key words: boronate esters, pyridinecarboxaldimines, cytotoxicity, platinum, boron.

Résumé : La condensation des pyridine-2-carboxaldéhydes avec les 2-, 3- et 4-$H_2NC_6H_4Bpin$ (pin = 1,2-$O_2C_2Me_4$) conduit à la formation des pyridinecarboxaldimines contenant du bore (N–N_{Bpin}). L'addition de ces ligands au $[PtCl_2(coe)]_2$ (coe = *cis*-cyclooctène) conduit à la formation de complexes du type *cis*-$PtCl_2(N–N_{Bpin})$, avec des rendements modérés. On a étudié les cytotoxicités potentielles des complexes du platine vis-à-vis du OV2008 (carcinome ovarien humain) et la série de cellules C13 apparentées, qui est résistante au cisplatine.

Mots clés : esters de l'acide boronique, pyridinecarboxaldimines, cytotoxicité, platine, bore.

[Traduit par la Rédaction]

Introduction

Interest in compounds containing boronic acids $[RB(OH)_2]$ or boronate esters $[RB(OR')_2]$ arises from their remarkable versatility in catalysed carbon–carbon bond formation reactions, solid-phase synthesis, macrocyclic chemistry, organometallic and organic syntheses, and as glucose sensors for diabetes therapy (1). Interest in these compounds also arises from their potent biological activities (2–11). For instance, α-aminoboronic acids are effective and reversible inhibitors of serine proteases, a diverse group of proteolytic enzymes whose numerous physiological functions include digestion, growth, differentiation, and apoptosis. Proteases are also vital in the generation of most disease processes and, as a result, much effort has focused on the synthesis of α-aminoboronic acids for possible applications as enzyme inhibitors. Indeed, the boron compounds boromycin (12) and aplasmomycin (13) are powerful antibiotics and analogous amino acids containing boronic acids, such as L-4-boronophenylalanine, have also been investigated for their use in boron neutron capture therapy (BNCT) for the treatment of cancer (14–16). BNCT is a bimodal form of therapy, which depends on selectively depositing boron-10 atoms into the cancerous tumour prior to irradiation by slow (thermal) neutrons. These known biological activities, along with their ability to transport water insoluble reagents through membranes (17, 18), prompted us to investigate the use of boronate ester compounds as carrier ligands for biologically-active metal complexes.

Cisplatin, *cis*-$[PtCl_2(NH_3)_2]$, and a few related platinum-based complexes are currently used as anticancer agents against testicular and ovarian malignancies (19–25). However, there are several limitations to platinum therapy such as neural and kidney toxicity as well as intrinsic and acquired resistance of tumor cells to the drugs (19). These complications have provided incentive for further research in the development of platinum-based complexes with increased solubility and enhanced specificity towards cancer cells. Recent studies have shown that *cis*-amminedichloro(2-methylpyridine)platinum(II) (AMD473 or ZD0473, **1** in Fig. 1) shows considerable cytotoxicity in cisplatin-resistant cell lines (26, 27). Steric crowding from the methyl group is

1 **2**

believed to decrease the rates of hydrolysis, and substitution reactions of AMD473 thereby permit high selectivity in binding with DNA (28). The primary mechanism of action in these platinum drugs is believed to arise from the interaction of the metal with DNA.

We have begun to develop AMD473 analogues by replacing the NH_3 group with a pendant imine group. Previous studies have shown that the platinum complex derived from aniline, **2** (Fig. 1), has shown considerable activity against the hormone independent human mammary carcinoma cell line MDA-MB 231 (29). Varying the aniline functionality allows us to design compounds with a wide range of physical and chemical properties that may provide steric congestion around the platinum atom (29). As well, the use of bidentate ligands prevents trans labilization and undesired displacement of the ligands by sulfur and nitrogen donors in biomolecules, interactions believed responsible for some of the adverse side effects associated with cisplatin (19). We report herein our results on the synthesis and initial cytotoxic testing of *cis*-dichloro(pyridin-2-ylcarboxaldimine)platinum(II) compounds containing boronate esters.

Experimental

General

Reagents and solvents used were obtained from Aldrich Chemicals. K_2PtCl_4 was purchased from Precious Metals Online Ltd. (Melbourne, Australia) and $[PtCl_2(coe)]_2$ (coe = *cis*-cyclooctene) was made following an established procedure (30). 2-APBpin (pin = 1,2-$O_2C_2Me_4$) was synthesized by modification of a reported synthesis (31). Pyridinecarboxaldimine ligands were prepared as described elsewhere (32) and (6-methyl-pyridin-2-ylmethylene)-[4-(4,4,5,5-tetramethyl-[1,3,2]-dioxaborolan-2-yl)phenyl]amine was synthesized under a nitrogen atmosphere and used in situ. NMR spectra were recorded on a JEOL JNM-GSX270 FT or a Varian Mercury Plus 200 NMR spectrometer. ^{1}H NMR chemical shifts are reported in ppm and are referenced to residual protons in a deuterated solvent at 270 and 200 MHz. ^{11}B NMR chemical shifts are referenced to external $BF_3{\cdot}OEt_2$ at 87 MHz. ^{13}C NMR chemical shifts are referenced to solvent carbon resonances as internal standards at 68 and 50 MHz. Multiplicities are reported as singlet (s), doublet (d), triplet (t), multiplet (m), broad (br), and overlapping (ov). Infrared spectra were obtained using a Mattson Genesis II FT-IR spectrometer and are reported in cm^{-1}. Melting points were measured uncorrected with a Mel-Temp apparatus. Microanalyses for C, H, and N were carried out at Guelph Chemical Laboratories Ltd. (Guelph, Ont.).

Compound 3a

Under a nitrogen atmosphere, a THF (2 mL) solution of pyridin-2-ylmethylene-[2-(4,4,5,5-tetramethyl-[1,3,2]-dioxaborolan-2-yl)phenyl]amine (0.09 g, 0.29 mmol) was added to $[PtCl_2(coe)]_2$ (0.10 g, 0.13 mmol) in THF (3 mL). The reaction mixture was stirred for 18 h at which point a precipitate was collected by suction filtration and washed in turn with cold THF (3 × 1 mL) and Et_2O (3 × 5 mL) to afford **3a** (0.06 g, 39%) as a yellow-orange solid; mp 270–272 °C (decomposition). Spectroscopic NMR data (in DMSO-d_6): ^{1}H δ: 9.50 (d, $J_{H\text{-}H}$ = 7 Hz, $J_{H\text{-}Pt}$ = 62 Hz, 1H, Ar), 9.35 (s, $J_{H\text{-}Pt}$ = 92 Hz, 1H, C(*H*) = N), 8.47 (t, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 8.22 (d, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 8.01 (t, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 7.74 (d, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 7.60 (t, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 7.42 (t, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 7.34 (d, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 1.21 (s, 6H, $O_2C_2(CH_3)_4$), and 1.15 (s, 6H, $O_2C_2(CH_3)_4$). ^{11}B{^{1}H} δ: 29.1 (br). ^{13}C{^{1}H} δ: 173.0, 157.7, 152.7, 149.7, 141.2, 135.4, 131.5, 130.1, 130 (br, *C*-B), 129.7, 128.3, 124.9, 84.5, 25.4, and 25.1. IR (cm^{-1}) (Nujol): 2926, 2856, 1601 (C=N), 1462, 1377, 1300, 1240, 1200, 1144, 1076, 964, 860, 779, and 654. Anal. calcd. (%) for $C_{18}H_{21}N_2BCl_2O_2Pt$, C 37.64, H 3.69, N 4.88; found: C 37.94, H 3.33, N 4.84.

Compound 3b

Pyridin-2-ylmethylene-[3-(4,4,5,5-tetramethyl-[1,3,2]-dioxaborolan-2-yl)phenyl]amine (0.09 g, 0.29 mmol) in CH_2Cl_2 (5 mL) was added to $[PtCl_2(coe)]_2$ (0.10 g, 0.13 mmol) in CH_2Cl_2 (5 mL) and the reaction mixture was stirred for 1 h at which point solvent was removed under vacuum to give an oil. Following trituration with hexane (3 × 10 mL) an orange solid was recovered and recrystallized from THF (5 mL) at room temperature to afford **3b** (0.08 g, 54%) as a red-orange solid; mp 316 °C (decomposition). Spectroscopic NMR data (in $CDCl_3$): ^{1}H δ: 9.76 (d, $J_{H\text{-}H}$ = 7 Hz, $J_{H\text{-}Pt}$ = 60 Hz, 1H, Ar), 8.88 (s, $J_{H\text{-}Pt}$ = 84 Hz, 1H, C(*H*) = N), 8.19 (t, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 7.97 (d, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 7.83 (d, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 7.81–7.72 (ov m, 2H, Ar), 7.66 (d, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 7.43 (t, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), and 1.27 (s, 12H, $O_2C_2(CH_3)_4$). ^{11}B{^{1}H} δ: 32.5 (br). ^{13}C{^{1}H} δ: 168.3, 156.5, 150.0, 146.1, 139.5, 135.6, 129.0, 129 (br, *C*-B), 128.9, 128.4, 127.5, 127.4, 84.0, and 24.7. IR (cm^{-1}) (Nujol): 2895, 2856, 1610 (C=N), 1462, 1377, 1329, 1234, 1151, 933, 854, 816, 777, and 706. Anal. calcd. (%) for $C_{18}H_{21}N_2BCl_2O_2Pt$, C 37.64, H 3.69, N 4.88; found: C 37.25, H 3.62, N 4.73.

Compound 3c

Pyridin-2-ylmethylene-[4-(4,4,5,5-tetramethyl-[1,3,2]-dioxaborolan-2-yl)phenyl]amine (0.18 g, 0.58 mmol) in CH_2Cl_2 (5 mL) was added to $[PtCl_2(coe)]_2$ (0.20 g, 0.26 mmol) in CH_2Cl_2 (5 mL) and the reaction mixture was stirred for 7 h at which point solvent was removed under vacuum to give an oil. Following trituration with hexane (3 × 10 mL) an orange solid was recovered and recrystallized from THF (5 mL) at room temperature to afford **3c** (0.19 g, 64%) as an orange solid; mp 304 °C (decomposition). Spectroscopic NMR data (in DMSO-d_6): ^{1}H δ: 9.48 (d,

$J_{H\text{-}H}$ = 7 Hz, $J_{H\text{-}Pt}$ = 65 Hz, 1H, Ar), 9.33 (s, $J_{H\text{-}Pt}$ = 84 Hz, 1H, C(*H*) = N), 8.45 (t, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 8.24 (d, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 8.00 (t, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 7.77 (d, $J_{H\text{-}H}$ = 7 Hz, 2H, Ar), 7.46 (d, $J_{H\text{-}H}$ = 7 Hz, 2H, Ar), and 1.32 (s, 12H, $O_2C_2(CH_3)_4$). $^{11}B\{^1H\}$ δ: 33.1 (br). $^{13}C\{^1H\}$ δ: 173.1, 157.6, 149.8, 149.6, 141.2, 134.8, 130.4, 130.2, 129.5 (br, *C*-B), 124.4, 84.5, and 25.2. IR (cm^{-1}) (Nujol): 2941, 2914, 2858, 1601 (C=N), 1460, 1377, 1356, 1315, 1263, 1144, 1084, 1018, 968, 858, 764, 723, and 656. Anal. calcd. (%) for $C_{18}H_{21}N_2BCl_2O_2Pt$, C 37.64, H 3.69, N 4.88; found: C 37.31, H 3.50, N 4.69.

Compound 4a

Under an atmosphere of nitrogen, a THF (1 mL) solution of (6-methyl-pyridin-2-ylmethylene)-[2-(4,4,5,5-tetramethyl-[1,3,2]-dioxaborolan-2-yl)phenyl]amine (0.09 g, 0.28 mmol) was added to $[PtCl_2(coe)]_2$ (0.09 g, 0.12 mmol) in THF (3 mL). The reaction mixture was stirred for 8 h at which point a precipitate was collected by suction filtration and washed with Et_2O (3 × 5 mL) to afford **4a** (0.06 g, 42%) as an orange solid; mp 285 °C (decomposition). Spectroscopic NMR data (in $CDCl_3$): ^1H δ: 8.77 (s, $J_{H\text{-}Pt}$ = 84 Hz, 1H, C(*H*) = N), 8.02 (t, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 7.86 (d, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 7.68 (d, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 7.56 (d, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 7.50 (t, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 7.36 (t, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 7.29 (d, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 3.25 (s, 3H, CH_3), and 1.25 (br s, 12H, $O_2C_2(CH_3)_4$). $^{11}B\{^1H\}$ δ: 29.3 (br). $^{13}C\{^1H\}$ δ: 161.9, 159.5, 155.2, 138.4, 136.8, 133.1, 129.1, 128.5, 126 (br, *C*-B), 119.6, 115.6, 114.8, 83.7, 25.2, and 24.3. IR (cm^{-1}) (Nujol): 2924, 2854, 1603 (C=N), 1462, 1377, 1348, 1144, 1072, 1018, 962, 858, 725, 654, and 596. Anal. calcd. (%) for $C_{19}H_{23}N_2BCl_2O_2Pt$, C 38.79, H 3.95, N 4.76; found: C 38.95, H 4.05, N 4.78.

Compound 4b

(6-Methyl-pyridin-2-ylmethylene)-[3-(4,4,5,5-tetramethyl-[1,3,2]-dioxaborolan-2-yl)phenyl]amine (0.08 g, 0.25 mmol) in CH_2Cl_2 (5 mL) was added to $[PtCl_2(coe)]_2$ (0.08 g, 0.11 mmol) in CH_2Cl_2 (5 mL) and the reaction was heated at reflux for 24 h. Removal of solvent under vacuum gave an oil which was triturated with hexane (3 × 10 mL) to afford a red-orange solid which was dissolved in a CH_2Cl_2:Et_2O (5:5 mL) solution and stored at 0 °C for 18 h. The resulting precipitate was collected by suction filtration to afford **4b** (0.08 g, 62%) as an orange solid; mp 264 °C (decomposition). Spectroscopic NMR data (in $CDCl_3$): ^1H δ: 8.91 (s, $J_{H\text{-}Pt}$ = 80 Hz, 1H, C(*H*) = N), 7.97 (t, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 7.81–7.77 (ov m, 2H, Ar), 7.70 (s, 1H, Ar), 7.59–7.51 (ov m, 2H, Ar), 7.40 (t, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 3.21 (s, 3H, CH_3), and 1.33 (s, 12H, $O_2C_2(CH_3)_4$). $^{11}B\{^1H\}$ δ: 29.6 (br). $^{13}C\{^1H\}$ δ: 168.6, 167.9, 157.6, 146.5, 138.8, 136.0, 131.8, 129 (br, *C*-B), 128.7, 127.8, 127.7, 126.3, 84.3, 28.1, and 25.0. IR (cm^{-1}) (Nujol): 2927, 2856, 1599 (C=N), 1568, 1462, 1428, 1377, 1319, 1252, 1228, 1166, 1144, 1101, 970, 924, 854, 798, 731, 704, and 606. Anal. calcd. (%) for $C_{19}H_{23}N_2BCl_2O_2Pt$, C 38.79, H 3.95, N 4.76; found: C 38.97, H 3.90, N 4.73.

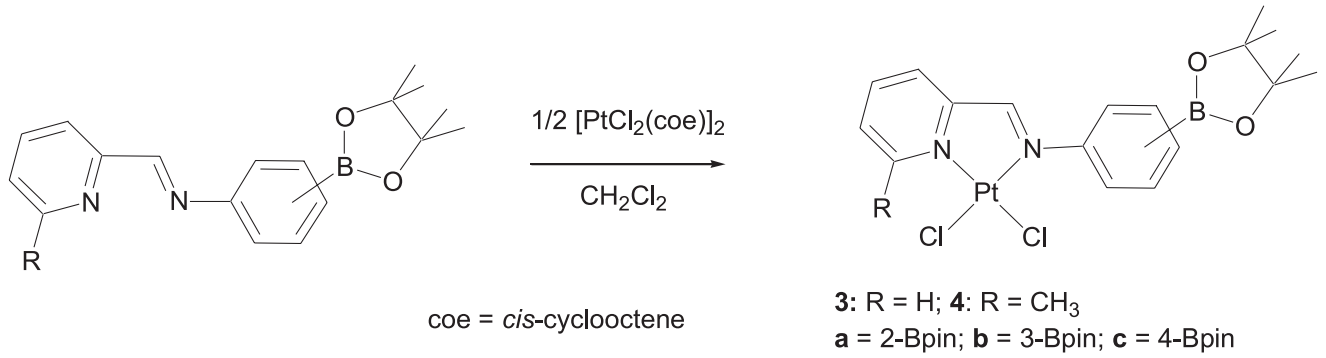
Compound 4c

(6-Methyl-pyridin-2-ylmethylene)-[4-(4,4,5,5-tetramethyl-[1,3,2]-dioxaborolan-2-yl)phenyl]amine (0.08 g, 0.25 mmol) in CH_2Cl_2 (5 mL) was added to $[PtCl_2(coe)]_2$ (0.08 g, 0.11 mmol) in CH_2Cl_2 (5 mL) and the reaction was heated at reflux for 24 h. Removal of solvent under vacuum gave an oil which was triturated with hexane (3 × 10 mL) to afford a red-orange solid which was dissolved in a CH_2Cl_2:Et_2O (5:5 mL) solution and stored at 0 °C for 18 h. The resulting precipitate was collected by suction filtration to afford **4c** (0.10 g, 77%) as an orange solid; mp 277 °C (decomposition). Spectroscopic NMR data (in $CDCl_3$): ^1H δ: 8.94 (s, $J_{H\text{-}Pt}$ = 78 Hz, 1H, C(*H*) = N), 7.94 (t, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 7.86 (d, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 7.79 (d, $J_{H\text{-}H}$ = 7 Hz, 2H, Ar), 7.47 (d, $J_{H\text{-}H}$ = 7 Hz, 1H, Ar), 7.41 (d, $J_{H\text{-}H}$ = 7 Hz, 2H, Ar), 3.15 (s, 3H, CH_3), and 1.33 (s, 12H, $O_2C_2(CH_3)_4$). $^{11}B\{^1H\}$ δ: 31.2 (br). $^{13}C\{^1H\}$ δ: 169.4, 167.4, 157.6, 149.1, 138.9, 135.0, 131.7, 131 (br, *C*-B), 127.4, 123.3, 84.2, 28.0, and 25.0. IR (cm^{-1}) (Nujol): 2925, 2856, 1581 (C=N), 1463, 1377, 1358, 1336, 1270, 1173, 1134, 1092, 1016, 935, 845, 787, 729, and 656. Anal. calcd. (%) for $C_{19}H_{23}N_2BCl_2O_2Pt$, C 38.79, H 3.95, N 4.76; found: C 38.70, H 3.99, N 4.76.

X-ray crystallography

Crystals of **3b** and **4a** were grown from saturated CH_2Cl_2 solutions at 5 °C. Single crystals were coated with Paratone-N oil, mounted using a glass fibre, and frozen in the cold stream of the goniometer. A hemisphere of data was collected on a Bruker AXS P4/SMART 1000 diffractometer using ω and θ scans with a scan width of 0.3° and 30 s exposure times. The detector distances were 4 (**3b**) and 5 cm (**4a**). The data were reduced (33) and corrected for absorption (34). The structures were solved by direct methods and refined by full-matrix least squares on F^2 (35). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located in Fourier difference maps and refined isotropically (**3b**) or included in calculated positions and refined using a riding model (**4a**).

Cell culture



OV2008 (human ovarian carcinoma) and the analogous cisplatin-resistant cell line C13 were a generous gift from Dr. Barbara C. Vanderhyden of the Centre for Cancer Therapeutics, Ottawa Regional Cancer Centre, Ont. Both cell lines were cultured in complete RPMI-1640 medium with L-glutamine, supplemented with 5% fetal bovine serum, penicillin (50 units/mL), and streptomycin (50 mg/mL). Cells were incubated in a humidified atmosphere of 5% CO_2 at 37 °C and were subcultured twice weekly using trypsin-EDTA.

Cell growth inhibition assay

Cells were seeded in 96-well plates at a concentration of 0.1–1.0 × 10^4 cells/well in 200 µL of complete media and incubated for 24 h at 37 °C in a 5% CO_2 atmosphere to allow for cell adhesion. Stock solutions (15 mmol/L) of the compounds made in DMSO were filter sterilized, then diluted to 10 mmol/L in phosphate buffered saline (PBS, 0.02 mol/L phosphate, 0.11 mol/L NaCl, pH 7.0, sterile). The 10 mmol/L solutions were diluted to 50 µmol/L and 1.4 mmol/L in complete media for treatment against OV2008 and C13 cell lines, respectively, where 20 µL of compound solutions were added to 180 µL of fresh medium in wells to give final concentrations of 5 µmol/L against

Fig. 2. Synthesis of platinum complexes **3–4**.

OV2008 and 140 μmol/L for C13. All assays were performed in two independent sets of quadruplicate tests. Control groups containing no drug were run in each assay, along with standards of cisplatin and a previously studied *cis*-dichloro(pyridin-2-ylcarboxaldimine)platinum(II) complex (**2**).

Following 48 h of exposure, each well was carefully rinsed with 200 μL of PBS solution. 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) solution (50 μL, 1 mg/mL doubly distilled (dd)H_2O) along with 200 μL of fresh, complete media were added to each well, and plates were incubated for 45 min. Following incubation, the media was removed and the purple formazan precipitate in each well was solubilized in 200 μL of DMSO. Absorbances were measured using a VersaMax tunable microplate reader (Molecular Devices, Sunnyvale, Calif.) at 570 nm. Reduction of cell proliferation was determined as a fraction of the absorbance values for each drug treatment (T) by the mean absorbance of the no-drug control (C), and calculated using the expression 1 – T/C × 100%. Data from the separate trials were combined using a *t*-test ($P < 0.05$).

Results and discussion

Ligands

Aniline derivatives containing boronate ester groups were used, in place of the related boronic acids, in an attempt to increase the solubility of the ligands and the subsequent platinum complexes in organic solvents, and to prevent unwanted formation of anhydrides often seen in reactions with the acids (36, 37). Addition of these primary amines to 2-pyridinecarboxaldehydes gave the corresponding pyridinecarboxaldimine ligands (N–N_{Bpin}) in high yield (38–41). All new ligands were characterized by multinuclear NMR spectroscopy. For example, a singlet at ca. δ 8.4 ppm is observed in the ^{1}H NMR spectra for the imine methine peak and a broad peak at ca. δ 30 ppm in the ^{11}B NMR spectra for these ligands is indicative of a three coordinate boron atom. This latter result suggests that no appreciable inter- or intramolecular interaction between the Lewis-acidic boron and the basic imine or pyridine functionality is occurring in solution (42).

Platinum complexes

We have found that platinum complexes containing boronate ester appendages ($PtCl_2$(N–N_{Bpin}), Fig. 2) could be readily prepared by addition of pyridin-2-ylcarboxaldimine ligands to CH_2Cl_2 solutions of $[PtCl_2(coe)]_2$ (43).

All new platinum complexes have been characterized by a number of physical methods, including multinuclear NMR spectroscopy. A significant downfield shift in the ^{1}H NMR is observed for the imine proton upon coordination of the ligand to the metal center. For instance, the singlet at δ 8.36 ppm for the free 2-C_5H_4NCH=N[2-$C_6H_4BO_2C_2Me_4$] ligand shifts to 9.35 ppm in complex **3a**. Platinum satellites are also observed for this resonance ($J_{H\text{-}Pt}$ = 92 Hz) upon complexation of the ligand to the metal. Similar trends are observed for the pyridine hydrogen alpha to the nitrogen atom as the chemical shift changes from δ 8.50 to 9.50 ppm ($J_{H\text{-}Pt}$ = 62 Hz). Two distinct Bpin resonances are observed in both the ^{1}H (δ: 1.21 and 1.15 ppm) and ^{13}C{^{1}H} (δ: 25.4 and 25.1 ppm) NMR spectra for complex **3a**, arising from inequivalent methyl groups (Fig. 3). It is therefore possible that two of the Bpin methyl groups are lying over the plane of the platinum atom in a manner similar to that observed for AMD473.

Although we were unable to obtain single crystals of **3a** to verify if an appropriate conformational prerequisite for the shielding effect was occurring, complex **3b** has been characterized by an X-ray diffraction study (Fig. 4). Crystallographic data are given in Table 1.[3] The nitrogen–platinum bonds of 2.023(2) Å (pyridine) and 2.023(3) Å (imine) are similar to those reported in other platinum systems (37–39). Slightly longer Pt—N bond distances are observed in related five coordinate Pt(II) (37, 38) and Pt(IV) complexes (42). The imine C(7)—N(8) distance of 1.298(3) Å is in the range of accepted carbon–nitrogen double bonds (43). Interestingly, the angle between the aromatic ring on the imine nitrogen and the N(1)-Pt-N(8) plane is 108.1°, a trend that is observed in related diimine systems (44). Indeed, this structural feature has been used to create active and selective catalyst precursors for the polymerization of alpha olefins, where ortho substitution of the aniline group with bulky groups is believed to shield and stabilize the metal center.

wR_2[b] (all data)	0.0903	0.0317

[a] $R_1 = \Sigma(|F_o| - |F_c|) / \Sigma|F_o|$.

[b] $wR_2 = (\Sigma[w(F_o^2 - F_c^2)^2] / \Sigma[F_o^4])^{1/2}$, where $w = 1/[\sigma^2(F_o^2) + (0.0637 \cdot P)^2]$ (**3b**) and $w = 1/[\sigma^2(F_o^2)]$ (**4a**), where $P = (\max(F_o^2, 0) + 2 \cdot F_c^2)/3$.

The boronate ester group in **3b** is roughly coplanar with the aromatic group in order to maximize the donation from the ring *p*π electrons to the empty *p* orbital on boron. No significant interaction of the bulky pinacol group is observed, however, with the metal center.

We carried out an X-ray diffraction study on **4a** to see if the boronate ester group in the ortho position could effectively crowd the platinum atom in a fashion similar to the methyl group of AMD473. The molecular structure of **4a** is shown in Fig. 5 and its crystallographic data is summarized in Table 1. While similar trends observed for **3b** are found in **4a**, inequivalent platinum nitrogen distances are observed, Pt—N(9) 1.9936(19) Å (imine) and Pt—N(1) 2.057(2) Å (pyridine). The longer Pt—N(1) bond reflects the large strain due to the presence of the methyl group in the ortho position to the binding atom in the pyridine ring. Bond angles in **4a** are also similar to those found in **3b** and the twist angle to the phenyl ring in **4a** is 64.7°. Unfortunately, however, there appears to be no significant interaction of the Bpin group with the platinum center. For instance, two of the methyl groups of the Bpin moiety lie over the Pt with long Pt—C(20) and Pt—C(21) distances of 5.133 and 6.023 Å, and the Pt—O and Pt—B distances are 4.158 and 4.483 Å, respectively, and are too far away for any significant interaction. These results suggest that the ortho Bpin groups in these complexes may not shield the platinum atom as effectively as the methyl group in AMD473.

Cytotoxic activity

We have tested the cytotoxic activity of all new platinum complexes against both cisplatin-sensitive and cisplatin-resistant human ovarian cells (Table 2), OV2008 and C13, respectively, at concentrations corresponding to cisplatin's IC_{50} value against either cell line (45–49). While no activity was observed against cisplatin-sensitive cells OV2008, compounds **3a** (with the Bpin group in the ortho position, Entry 3), **3b** and **4b** (with the Bpin group in the meta position, Entries 4 and 7, respectively) showed only minimal activity against cisplatin-resistant cell line C13. Interestingly, the analogous picoline complex **4a** showed diminished activity as compared with **3a**. In general, the presence of the Bpin groups in these complexes seems to greatly reduce their activity, compared to the non-borylated analogue **2**. It is possible that the Lewis-acidic boron atom in these complexes is competing with, and concomitantly deactivating the platinum centre, by coordinating to the nitrogen donors in biomolecules. Further in vitro studies are therefore needed to address the structure activity relationships in these complexes in order to design a potent drug candidate.

Conclusion

Pyridinecarboxaldimines derived from the condensation of 2-pyridinecaboxaldehydes and aminoboronate esters $H_2NC_6H_4Bpin$ have been prepared in high yields and used as

8	**4c**	0	0

ligands for platinum. The resulting metal complexes have shown negligible cytotoxicity against both cisplatin-sensitive and cisplatin-resistant human ovarian cells, OV2008 and C13, respectively, where the addition of a Lewis-acidic boron moiety appears to deactivate the metal complexes ability to coordinate to DNA.

Crystal structure, spectroscopic studies, and nonlinear optical (NLO) properties of Schiff base metal complexes containing an N, S donor ligand

Zhao–Ming Xue, Ying-Wen Tang, Jie–Ying Wu, Yu–Peng Tian, Min–Hua Jiang, H.-K. Fun, and A. Usman

Abstract: A new ligand, 4-dipropylaminobenzaldehyde thiosemicarbazone (abbreviated as HL), and its complexes ML_2 (M = Ni, Pd, and Cu) have been synthesized and fully characterized by elemental analyses, EI-MS, IR and UV–vis spectroscopy, and photoluminescence measurements. All of the compounds exhibit a blue–green color with dual fluorescence in DMF solution. The quantum yield ratio ($\Phi'(CT)/\Phi(LE)$) decreases in the order $NiL_2 > HL > PdL_2 > CuL_2$. The ligand HL crystallizes in the monoclinic system, space group $P2_1/n$, with a = 15.1680, b = 8.5573, and c = 25.3920 Å, β = 100.3457°, and V = 3242.2 Å^3. The nickel complex (NiL_2) crystallizes in the triclinic system, space group $P\bar{1}$, with a = 8.3093, b = 9.7540, and c = 10.2802 Å, α = 101.383°, β = 107.693°, γ = 96.703°, and V = 764.12 Å^3. In these complexes, HL has lost a proton from its tautometric thiol form and acts as a single negatively charged bidentate ligand coordinating to the nickel ion via the mercapto sulfur and β-nitrogen atoms. The geometry around Ni(II) is almost square-planar with two equivalent Ni—N and two equivalent Ni—S bonds. The monomeric structure of HL or NiL_2 is extended into an infinite two-dimensional network via hydrogen bonds. The two-photon absorption of HL and ML_2 solutions (in DMF) was measured at 532 nm by the open-aperture Z-scan technique.

Key words: crystal structure, metal complex, dual fluorescence, NLO.

Résumé : On a réalisé la synthèse d'un nouveau ligand, la thiosemicarbazone du 4-dipropylaminobenzaldéhyde (abrév.: HL), et de ses complexes ML_2 (M = Ni, Pd et Cu) qu'on a caractérisés par analyse élémentaire, par spectroscopie « EI-MS », IR et UV–visible ainsi que par des mesures de photoluminescence. En solution dans le DMF, tous les composés présentent une couleur bleu-vert avec double fluorescence. L'ordre des rapports des rendements quantiques ($\Phi'(CT)/\Phi(LE)$) est $NiL_2 > HL > PdL_2 > CuL_2$. Le ligand HL cristallise dans le système monoclinique, groupe d'espace $P2_1/n$ avec a = 15,1680, b = 8,5573 et c = 25,3920 Å, β = 100,3457° et V = 3242,2 Å^3. Le complexe de nickel (NiL_2) cristallise dans le système triclinique, groupe d'espace $P\bar{1}$, avec a = 8,3093, b = 9,7540 et c = 10,2802 Å, α = 101,383°, β = 107,693° et γ = 96,703° et V = 764,12 Å^3. Le ligand HL a perdu un proton à partir de sa forme tautomère thiol et il agit vis-à-vis du nickel comme un ligand bidentate portant une seule charge négative qui conduit à une coordination avec l'ion nickel par le biais des atomes de soufre du mercapto et de l'azote en β. La géométrie autour du Ni(II) est pratiquement plan-carré avec deux liaisons Ni—N et Ni—S équivalentes, respectivement. La structure monomère de HL et de NiL_2 se répercute dans un réseau bidimensionnel infini par le biais de liaisons hydrogènes. L'absorption de deux photons à partir de solutions de HL et de NiL_2 (dans le DMF) a été mesurée à une longueur d'onde d'environ 532 nm par la technique du balayage Z à grande ouverture.

Mots clés : structure cristalline, complexe métallique, double fluorescence, NLO.

Introduction

There have been extensive studies of π-conjugated organic compounds concerning their large two-photon absorption (TPA) (1–4) and dual fluorescence phenomena (5–8). In contrast, TPA of transition metal complexes has received little attention (9, 10) and there has been virtually no report on dual fluorescence. In recent years, π-conjugated metal complexes have found applications in many areas of chemistry and materials science. For example, luminescent metal compounds can function as emitters in light-emitting devices (11). They are known to be very stable to intense irradiation in the near-infrared region and have been investigated as promising optical limiting materials (12, 13). To our knowledge, a metal complex with both efficient dual fluorescence and TPA has not been reported. The organic chromophore 4-

 doi: 10.1139/V04-142 © 2004 NRC Canada

dipropylaminobenzaldehyde thiosemicarbazone, which is a π-electron delocalized system containing mixed sulfur and nitrogen donors, was considered as a potential new efficient compound for obtaining one-photon- and two-photon-excited dual fluorescence (14) and prepared in our laboratory. Following the success of our initial work (15–18), we are particularly interested in further using it as a ligand to coordinate to transition metal ions to form metal complexes that show efficient dual fluorescence and TPA. We have selected Ni^{2+}, Pd^{2+}, and Cu^{2+} as the central metal ions to form metal complexes with it. In this paper, we present the dual fluorescence and two-photon absorption properties of the complexes.

Theory

Dual fluorescence

4-(*N*,*N*-Dimethylamino)benzonitrile (DMABN) is the prototype of a group of organic donor–acceptor compounds that can undergo intramolecular charge transfer (ICT) in the excited singlet state. In polar solvents, it exhibits dual fluorescence. Apart from normal emission from the locally excited (LE) state, which is also present in the gas phase and in nonpolar solvents, the spectrum observed in polar solvents exhibits a second, anomalous strongly red-shifted band, which is attributed to a charge-transfer (CT) state (19). This phenomenon has been mostly explained by the twisted intramolecular charge transfer (TICT) mechanism (20). In the TICT model, a 90° twist of the dimethylamino group with respect to the phenyl ring was considered to have occurred in the CT state of DMABN. The dimethylamino group was thereby assumed to be electronically decoupled from the rest of the molecule — the principle of minimum overlap. The CT/LE fluorescence quantum yield ratio $\Phi(CT)/\Phi(LE)$ increases with the efficiency of the ICT reaction.

Experimental

General procedures

All chemicals and solvents were dried and purified by usual methods. Elemental analyses were performed with a Perkin-Elmer 240 instrument. IR spectra were recorded with a Nicolet FT-IR 170SX instrument (KBr discs) in the 4000–400 cm^{-1} region. UV–vis spectra were recorded with a Shimadzu UV-265 spectrophotometer. The photoluminescence measurements were carried out in DMF solutions, and the spectra were collected with a Perkin-Elmer LS55 spectrofluorimeter. Mass spectra were obtained with a ZAB-HS mass spectrometer (FAB source).

Strategy of syntheses of HL and ML_2

4-Dipropylaminobenzaldehyde and 4-dipropylaminobenzaldehyde thiosemicarbazone (HL) were synthesized as described previously (14).

Syntheses of ML_2

$M(OAc)_2{\cdot}nH_2O$ (M = Ni(II), Cu(II)) or $PdCl_2(CH_3CN)_2$ (1 mmol) and HL (2 mmol) were disso1ved in ethanol (50 mL). After refluxing for 4 h, the mixture was cooled to room temperature. The precipitate was thoroughly washed with ethanol three times and dried in vacuo over P_2O_5. Yield 90%. Anal. calcd. for $C_{28}H_{42}N_8S_2Ni$ (%): C 54.63, H 6.83, N 18.21; found: C 54.64, H 6.82, N 18.24. mp 249~250 °C. Black crystals of NiL_2 were isolated by slow evaporation of a CH_2Cl_2 solution covered with ethanol. Anal. calcd. for $C_{28}H_{42}N_8S_2Pd$ (%): C 50.11, H 6.23, N 17.31; found: C 50.23, H 6.34, N 17.41. Anal. calcd. for $C_{28}H_{42}N_8S_2Cu$ (%): C 53.66, H 6.67, N 18.54; found: C 53.82, H 6.74, N 18.32.

X-ray crystal structure determinations

A crystal of HL with approximate dimensions 0.50 × 0.28 × 0.20 mm^3 and a crystal of complex NiL_2 with approximate dimensions 0.44 × 0.38 × 0.22 mm^3 were used for the X-ray structure determinations. Data were collected on a Siemens SMART-CCD area detector diffractometer using Mo Kα radiation in ω-scan mode at 293 K. The data collection covered a hemisphere of reciprocal space by a combination of three sets of exposures; each set had a different φ angle (0.88° and 180°) for the crystal and each exposure of 10 s. The crystal-to-detector distance was 4 cm, and the detector swing angle was –35°. Coverage of the unique set is over 99% complete. Crystal decay was monitored by repeating 30 initial frames at the end of data collection and analyzing the duplicate reflections and was found to be negligible.

The unit cell parameters were determined using SMART (21). The three sets of data collected were reduced using the program SAINT (22). The structure was solved with direct methods using the program SHELXTL (23). All the non-hydrogen atoms were located from the trial structure and then refined anisotropically with SHELXTL using a full-matrix least-squares procedure. Weighting schemes of $w = 1/[\sigma^2(F_o^2) + (0.0777P)^2]$, with $P = [(F_o)^2 + 2(F_c)^2]/3$, and $w = 1/[\sigma^2(F_o^2) + (0.1207P)^2]$, with $P = [(F_o)^2 + 2(F_c)^2]/3$, were applied for HL and NiL_2, respectively. The hydrogen atoms were geometrically fixed at calculated positions attached to their parent atoms and were treated as riding on them.

Results and discussion

Description of the structures of HL and NiL_2

Selected crystallographic experimental data for HL and NiL_2 are given in Table 1. The ORTEP diagrams of HL and NiL_2 with the atom numbering schemes are shown in Fig.1. Selected bond lengths and angles are listed in Tables 2 and 3. A view of the molecular packing of HL in the crystal is given in Fig. 2. Additional crystallographic data are available as Supplementary material.[4]

The ORTEP drawing of HL shows that there are two different structures of HL, cis and trans (refer to the structures of dipropyl). The corresponding bond lengths and angles of

[4] Supplementary data may be purchased from the Directory of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically). CCDC 200310 and 200311 contain the crystallographic data for this manuscript. These data can be obtained, free of charge, via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, U.K.; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

C(12)-N(1)-C(9)	117.5(3)	115.4(5)
C(7)-N(2)-N(3)	115.1(3)	115.1(3)
C(8)-N(3)-N(2)	122.5(3)	113.5(3)

the two structures are not distinctly different. The bond lengths of N(2)—N(3) (1.372 Å) and C(8)—N(3) (1.334 Å) suggest that these bonds have some double bond character but are nearly single bonds. The lengths of S(1)—C(8) (1.683 Å) and C(7)—N(2) (1.255 Å) suggest that these bonds have some double bond character. All the carbon atoms in the benzene ring are almost coplanar (mean deviation form the plane 0.0071 Å), and C(7), N(2), N(3), C(8), N(4), and S(1) are also nearly coplanar (mean deviation from the plane 0.0091 Å). The dihedral angle of the two planes is 3.31° and shows that they are nearly coplanar. All these crystallographic data suggest that there is a highly π-conjugated and electron-delocalized system in the molecule.

The nickel atom is coordinated in a square-planar configuration with two equivalent Ni—N bonds (l.937 Å) and two equivalent Ni—S bonds (2.l63 Å). The HL has lost a proton from its tautomeric thiol form and acts as a single negatively charged bidentate ligand coordinating to the nickel ion via the mercapto sulfur and β-nitrogen atoms. S(1), N(2), S(1a), N(2a), and Ni(II) are almost coplanar, as are S(1), C(8), N(3), N(2), and Ni(II) (mean deviation from the plane 0.0048 Å), and these two planes form a dihedral angle of 9.6°. The very small dihedral angle indicates the high extent of delocalization of electrons in the π-conjugated system of the two Schiff base ligands and the coordination system.

The monomeric structure of HL is extended into an infinite two-dimensional network via hydrogen-bond contacts between two neighboring molecules (Fig. 3). There are no intramolecular donor hydrogen bonds. A similar case exists for NiL_2. For HL, four hydrogen atoms attached to amino nitrogen atoms N(3A), N(3B), N(4A), and N(4B) have the potential to form donor hydrogen bonds (Fig. 3). Two hydrogen atoms attached to N(4A) and N(3B) formed intermolecular donor hydrogen bonds of the types 4AB (N(4A)-H···S(1B) (1 – x, 1 – y, 1 – z)) and 3BA (N(3B)-H···S(1A) (1 – x, 1 – y, 1 – z)). The N···S separations are 3.478(3) Å for N(4A)···S(1B) and 3.472(6) Å for N(3B)···S(1A). The N-H···S angles are 161.7(4)° for N(4A)-H···S(1B) and 157.6(6)° for N(3B)-H···S(1A). Two hydrogen atoms attached to N(3A) and N(4B) also formed intermolecular donor hydrogen bonds of the types 3AB (N(3A)-H···S(1B) (1 – x, –y, 1 – z)) and 4BA (N(4B)-H···S(1A) (1 – x, –y, 1 – z)). The N···S separations are 3.430(4) Å for N(3A)···S(1B) and 3.614(0) Å for N(4B)···S(1A). The N···S angles are 156.1(0)° for N(3A)-H···S(1B) and 163.6(2)° for N(4B)-H···S(1A).

For NiL_2, one hydrogen atom attached to amino nitrogen atom N(4) has the potential to form a donor hydrogen bond. The hydrogen atom attached to N(4) formed an intermolecular donor hydrogen bond of the type N(4)-H···N(3) (–x, –1 – y, –z). The N(4)···N(3) separation is 3.307(4) Å, and the N(4)-H···N(3) angle is 149.8(1)°.

It is interesting to compare the structure of HL in the free state with that in the nickel complex. The largest difference is found in the bond lengths around C(8). In the free ligand, the bond distances of C(8)—N(3) (1.334 Å) and C(8)—S(1) (1.683 Å) suggest that C(8)—N(3) has nearly single bond character and C(8)—S(1) has nearly double bond character,

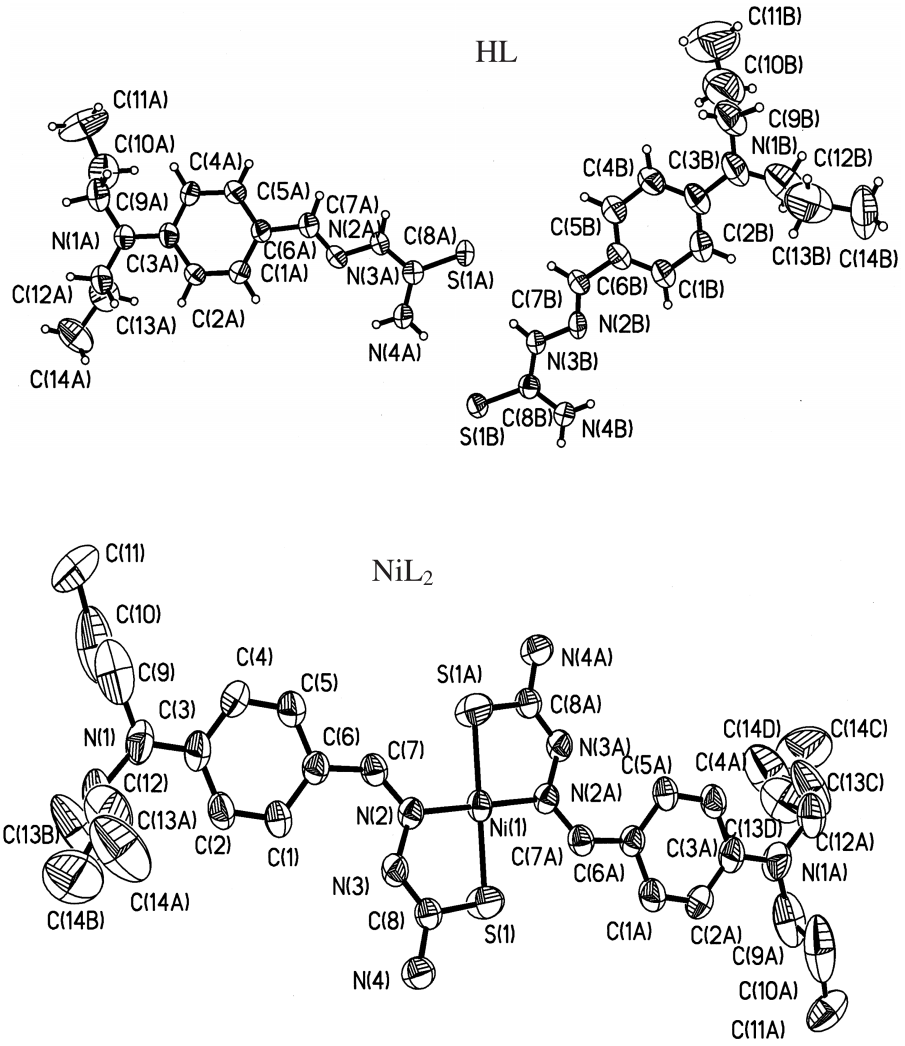

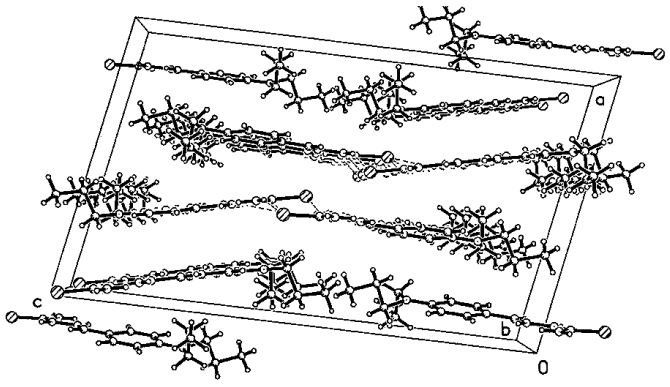

Fig. 2. A view of the molecular packing of HL in the crystal.

while in the complex the bond distances of C(8)—N(3) (1.279 Å) and C(8))—S(1) (1.722 Å) show that C(8)—N(3) is a double bond and C(8)—S(1) is a single bond. Comparing the bond lengths for C(7)—N(2) and C(6)—C(7) in HL with those in NiL_2, C(7)—N(2) is a shorter bond in HL (1.225 Å) than in NiL_2 (1.299 Å) and the C(6)—C(7) bonds are almost the same length (1.452(5) and 1.450(6) Å, respectively). These results, together with the spectral characterization of the nickel complex, indicated the presence of the C–S–M group formed by enolization of the -NH-C=S group in the free ligand to -N=C-SH and coordination to the metal ion through the sulfur after deprotonation (24, 25).

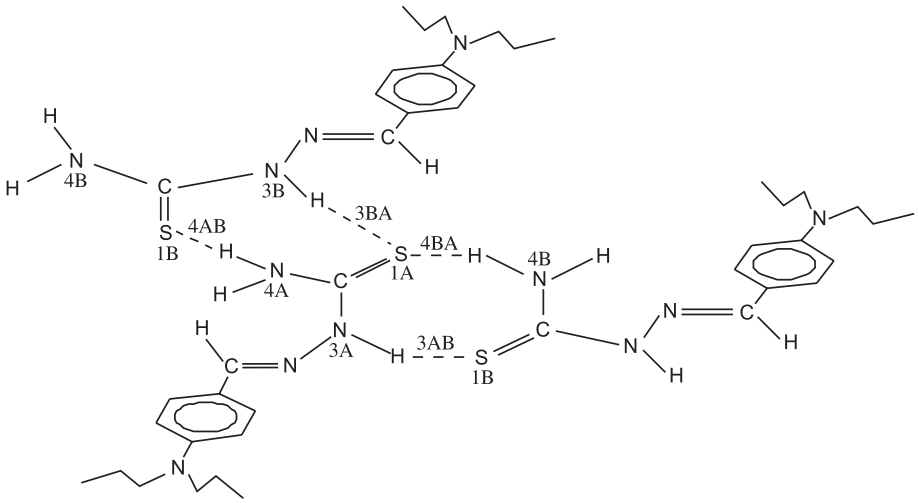
The deprotonation and formation of the metal complexes made the configuration of the ligand quite different. The ligand undergoes some conformational changes during the complex formation. Figure 4 shows the superposition of the ligand in the complex and in the free state. The major conformational changes are in the $NH_2NHC(S)NH_2$ moiety. The trans → cis and cis → trans (referring to the structure of NC(S)N) transitions around certain bonds facilitate the coordination of HL to the metal ion as a bidentate ligand via the β-nitrogen atom and the thio S atom.

FT-IR spectroscopy of HL and ML_2

FT-IR data for HL and ML_2 (M = Ni, Pd, Cu) are listed in Table 4. The spectrum of HL exhibits a strong band at 3152 cm^{-1}, which can be assigned to $\nu_{N\text{-}H}$ of the free ligand. The peak disappears in the IR spectra of the metal complexes, which suggests that the proton on the α-nitrogen

© 2004 NRC Canada

Fig. 3. H-bonds between two neighboring HL molecules.



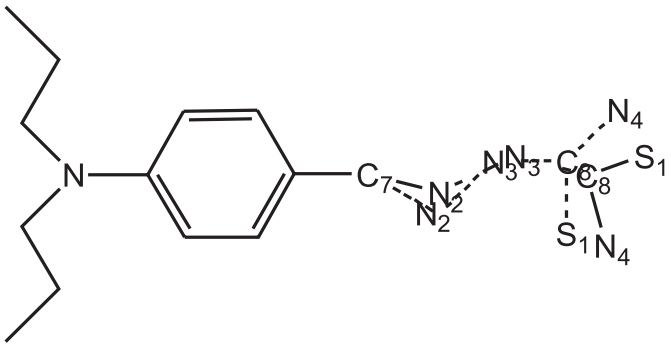


Fig. 4. Superposition of the ligand molecule in the complex (solid lines) and the free state (dashed lines).

atom is lost upon complex formation with the metal ion. A strong band at 1291 cm^{-1} in the IR spectrum of HL is assigned to $\nu_{C\text{-}N}$. This band is shifted to higher frequencies by ca. 11–19 cm^{-1} in the IR spectra of the metal complexes. This increase of $\nu_{C\text{-}N}$ on complexation is attributed to an increase of the C(8)—N(3) bond order as a result of deprotonation of the α-nitrogen atom. This tendency of HL to deprotonate may be attributed to the stabilization of the deprotonated form by conjugation of the -C=N-N=C– group. A strong band at 1046 cm^{-1} in the IR spectrum of HL is tentatively assigned to $\nu_{C=S}$. This band is absent in the spectra of the metal complexes. This observation can be explained by the change in the nature of the C(8)—S(3) bond on coordination of the ligand through the sulfur atom. This is proven by the crystal structure determinations for HL and NiL_2, which yielded C(8)—S(3) bond lengths of 1.683(4) and 1.722(4) Å, respectively. The peak at ca. 1589 cm^{-1} may be safely assigned to the C(7)=N(2) stretching vibration of the azonal group, since the frequency of this band is lowered by ca. 14–18 cm^{-1} in the spectra of the metal complexes. This decrease in $\nu_{C=N}$ on complexation is attributed to a decrease in the C=N bond order as a result of M–N bond formation. The very strong peak at ca. 1518 cm^{-1} in the IR spectra of HL is attributed to the aromatic C=C vibration. The band is very little affected upon complex formation.

Table 4. FT-IR data of HL and ML_2.

	$\nu_{N\text{-}H}$	$\nu_{C=S}$	$\nu_{C=N}$	$\nu_{C\text{-}N}$	$\nu_{N\text{-}N}$	ν_{Ph}
HL	3152	1046	1589	1291	955	1518
NiL_2	—	—	1571	1312	965	1516
PdL_2	—	—	1578	1299	964	1514
CuL_2	—	—	1576	1298	965	1516

These FT-IR data for HL and ML_2 (M = Ni, Pd, Cu) as well as the results of elemental analyses and MS, together with the crystal structures of HL and NiL_2, show that the Schiff base ligand formed stable metal complexes with the three metal ions. The ligand HL was deprotonated on complexation to the divalent M(II), forming the stable neutral complex ML_2 (as shown in Scheme 1).

Absorption spectra

The electronic absorption spectra of HL, NiL_2, PdL_2, and CuL_2, measured in DMF solution (d_0 = 1.0 × 10^{-5} mol/L), are shown in Fig. 5. HL, NiL_2, PdL_2, and CuL_2 all exhibit an intense and low-lying (near-UV region) absorption band and at least two peaks between 250 and 380 nm, with tailing at long wavelengths. The large molar absorption coefficients (log ε = 3.8–4.8) of the near-UV band are indicative of highly π-onjugated systems. The two peaks at shorter wavelengths are at 264 and 366 nm for HL, 267 and 377 nm for NiL_2, 266 and 374 nm for PdL_2, and 266 and 376 nm for CuL_2. The shorter-wavelength peak in each couple is the $\pi \rightarrow \pi^*$ absorption of larger π-conjugated systems, and the second peak is the $n \rightarrow \pi^*$ absorption associated with *p*–π conjugation of nitrogen lone-pair electrons with benzene. An additional peak due to a metal-to-ligand charge transfer (MLCT) absorption is observed at 425, 393, and 394 nm in the spectra of NiL_2, PdL_2, and CuL_2, respectively. There is no linear absorption in the wavelength range from ~500 to 800 nm.

Comparing the two peaks between 250 and 380 nm in the spectra of HL with those in the spectra of ML_2, the shorter-wavelength peak for ML_2 is red-shifted by about 2–3 nm compared to that of HL, and the longer-wavelength peak is red-shifted by about 8~11 nm. Such red shifts are consistent

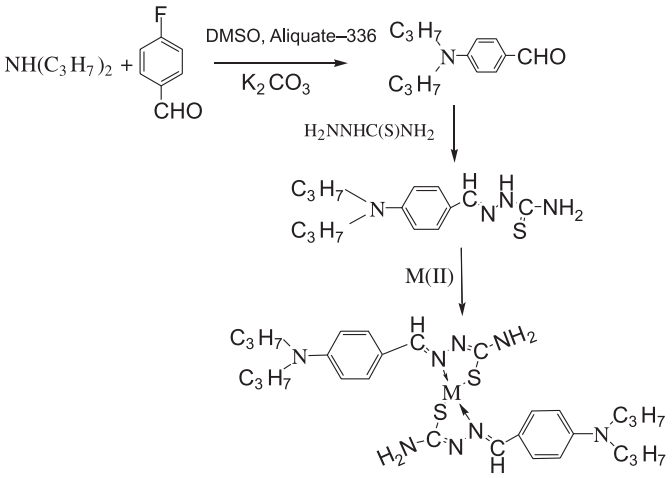

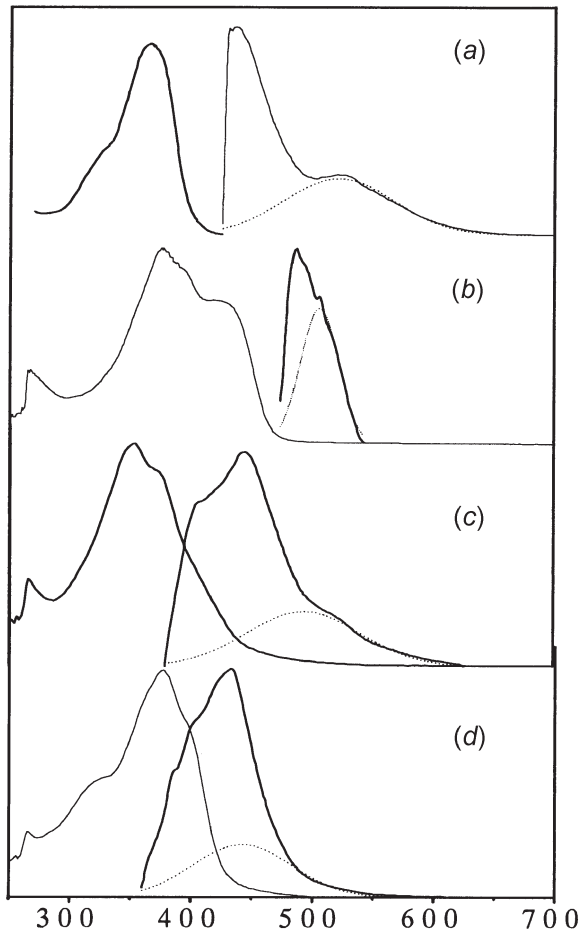

Fig. 5. Room-temperature UV–vis absorption and emission spectra of HL and ML_2 in DMF solution: (*a*) HL, one-photon excitation (OPE) at 400 nm; (*b*) NiL_2, OPE at 400 nm; (*c*) PdL_2, OPE at 434 nm; (*d*) CuL_2, OPE at 337 nm. Dotted curves represent "anomalous" emission from the CT state.

with the fact that when the N and S atoms of HL are coordinated to M(II), the new rings enhance the π-electron delocalization along the unsaturated system and reinforce the electronic density on the larger π-conjugated system and the *p*–π conjugation.

Fig. 6. Open-aperture Z-scan data. Normalized transmittance of ML_2.

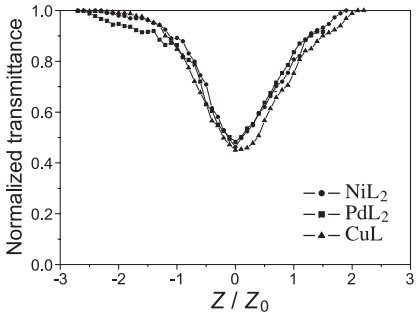

Table 5. TPA coefficients β and cross sections σ (in DMF solution).

	β (cm/GW)	$\sigma \times 10^{46}$ (cm^4 s/photon)
HL	—	—
NiL_2	0.47	0.84
PdL_2	0.48	0.98
CuL_2	0.51	0.99

One-photon-excited dual fluorescence

The one-photon steady-state emission spectra of HL, NiL_2, PdL_2, and CuL_2, measured in DMF solutions (d_0 = 1.0×10^{-7} mol/L), are shown in Fig. 5. HL, NiL_2, PdL_2, and CuL_2 emit a blue–green color with dual peaks and a large Stokes shift (LE peak, ~30–180 nm) when irradiated (one-photon processes) by UV at 400, 320, 320, and 337 nm, respectively. The characteristic benzaldehyde moiety bands had peaks at 523 and 430 nm for HL, 507 and 488 nm for NiL_2, 493 and 444 nm for PdL_2, and 444 and 434 nm for CuL_2. The quantum yield ratio $\Phi'(CT)/\Phi(LE)$ ($d_0 = 1.0 \times 10^{-7}$ mol/L) decreased in the order NiL_2 (2.12) > HL (0.79) > PdL_2 (0.45) > CuL_2 (0.43).

Two-photon absorption

The two-photon absorptions of HL and ML_2 solutions (in DMF) were measured by use of the open-aperture Z-scan technique (26) at a wavelength of 532 nm and are shown in Fig. 6. The normalized transmittance $T(z)$ in Fig. 6 was analyzed theoretically with the following equation:

$$T(z, s = 1) = \sum_{m=0}^{\infty} \frac{[1 - q_0(z)]^m}{(m+1)^{3/2}} \qquad \text{for } |q_0| < 1$$

where $s = 1$ indicates an open aperture, and $q_0(z) = \beta I_0(t) L_{\text{eff}}/(1 + z^2/z_0^2)$,where β is the TPA coefficient, $I_0(t)$ is the intensity of the laser beam at the focus ($z = 0$), $L_{\text{eff}} = [1 - \exp(-\alpha_0 L)]/\alpha_0$ is the effective thickness with α_0 the linear absorption coefficient and L the sample thickness, z_0 is the diffraction length of the beam, and z is the sample position. Nonlinear absorption of ML_2 in an open-aperture Z-scan, which is used to observe third-order phenomena that all molecules exhibit, can be explained mainly by the TPA mecha-

© 2004 NRC Canada

nism. Numerical calculations were performed using the optimal value for the parameter β. The best-fit values for the TPA cross section $\sigma = h\nu\beta/(N_A d_0 10^{-3})$ for HL and ML_2 are listed in Table 5. From the results above, it can be seen that the complexes have obvious two-photon absorption. However, the ligand has no two-photon absorption.

Conclusions

We have synthesized a new class of novel blue luminescent complexes based on a Schiff base. All compounds emit a blue-green color with dual fluorescence in DMF solution and show a large Stokes shift (LE peak, ~30–180 nm). The quantum yield ratio Φ′(CT)/Φ(LE) ($d_0 = 1.0 \times 10^{-7}$mol/L) decreases in the order NiL_2 (2.12) > HL (0.79) > PdL_2 (0.45) > CuL_2 (0.43). All of the compounds exhibit good one-photon fluorescent properties. The complexes have more highly π-conjugated and electron-delocalized systems than the free ligand and also have strong third-order nonlinear optical properties.

Chemical-shift link to the Kamlet–Taft β parameter

Keith C. Brown, Muhsin El-Bermani, and John A. Weil

Abstract: In investigating liquid-phase proton NMR spectra of 2,2-dimethyl-1-(2,4,6-trinitrophenyl)hydrazine in various solvents, we have found an interesting correlation, at sufficiently low temperatures *T*, between the chemical-shift difference (splitting) of the picryl proton peaks, measured as *f*(*T*), and the Kamlet–Taft hydrogen-bonding basicity parameter β. The observed solvolytic effect offers a convenient way of determining and checking the value of the empirical parameter β. The phenomenon discloses that the molecular geometric configuration is affected vividly by hydrogen bonding with the surrounding solvent molecules. It follows that the internal conformation interchange taking place (in a higher *T* range) is not in fact solely a unimolecular property.

Key words: picryl proton NMR, chemical shift, solvent effects, hydrogen bonding, Kamlet–Taft β.

Résumé : Lors d'une étude en phase liquide des spectres RMN du proton de la 2,2-diméthyl-1-(2,4,6-trinitrophényl)hydrazine dans divers solvants, on a observé une corrélation intéressante, à des températures *T* suffisamment basses, entre la différence de déplacement chimique (dédoublement) des pics des protons picryles, mesurée sous la forme de *f*(*T*), et le paramètre β de basicité par formation de liaison hydrogène de Kamlet–Taft. L'effet solvolytique observé offre une méthode de déterminer et de vérifier la valeur du paramètre empirique β. Le phénomène montre que la configuration géométrique moléculaire est grandement affectée par les liaisons hydrogènes avec les molécules de solvant avoisinantes. Il s'en suit que l'échange de conformation interne que se produit à des températures plus élevées n'est pas uniquement une propriété unimoléculaire.

Mots clés : RMN du proton du picryle, déplacement chimique, effets de solvant, liaison hydrogène, paramètre β Kamlet–Taft.

[Traduit par la Rédaction]

Introduction

The 2,2-dialkyl- and 2,2-diaryl-1-(2,4,6-trinitrophenyl)hydrazines have been the subject of various liquid-phase nuclear magnetic resonance (NMR) studies (1–3), especially because their internal "hindered rotations" are clearly evident from such spectroscopy. Furthermore, some of these species are important because they form stable free radicals (hydrazyls) via oxidation, i.e., by loss of a hydrogen atom from the hydrazinic nitrogen attached to the picryl group, as studied by electron paramagnetic resonance (EPR) spectroscopy.

For decades now, both ^{1}H and ^{13}C NMR spectroscopy at various frequencies and temperatures have been utilized to investigate the internal conformation switching within various picrylamines and also within the above-cited picrylhydrazine molecules (1), with special emphasis on 2,2-diphenyl-1-picrylhydrazine. In particular, study of the collapse of the AB quartet observed at low sample temperature *T* to a broad single peak (coalescence) and eventual sharpening of this peak with increasing *T* has been very fruitful (3). A study (2) of the effect of the solvent on the activation parameters revealed correlation of these with the solvent's hydrogen-bonding basicity, as measured by the Kamlet–Taft β parameter (see refs. 4 and 5; see ref. 6 for a recent review of solvent polarity scales).

The solvent parameter β has been proven by many research groups to be meaningful and useful, in that many solute physical properties (namely, infrared line positions, electronic transition frequencies, and ^{19}F NMR chemical shifts) have shown very good linear relationships with β (5, 7, 8). In the present paper, we present recent data obtained with 2,2-dimethyl-1-(2,4,6-trinitrophenyl)hydrazine (DMPH), which reveal that the chemical-shift difference δ for the two picryl-proton peaks, measured in deuterated solvents at temperatures below the onset of the intramolecular reorientation effects, correlates nicely with β. In principle, any picrylamine RNH(Picr) (Picr = 2,4,6-trinitrophenyl) with a sufficiently bulky group R could serve as a suitable solute for the type of NMR work described herein (including replacement of the 4-substituent in Picr).

We do not have knowledge of how deuteration affects the β values of the solvents and trust that this fine point can be addressed in future research. For that matter, we do not know of any review adequately discussing the general accuracy of parameter β as listed multiply in the literature.

As part of the overall project, an X-ray-diffraction structural study of DMPH has recently been published by us (9).

Fig. 1. The N–H and picryl (AB quartet) region of the ^{1}H NMR spectrum of DMPH in acetonitrile-d_3 at 240 K, taken at ν_0 = 500.13 MHz. The N–H peak occurs at 9.2338 ppm, center of doublet A at 9.0390 ppm, and center of doublet B at 8.576 ppm; all chemical shifts from TMS. The ^{13}C satellites (singlets and doublets, respectively) are barely visible, at 50.0 Hz from the N–H peak and at ca. 86 Hz from each picryl doublet.

Thus, appreciable information about its likely conformation(s) in liquid solution is available. One aspect of our interest is that DMPH, unlike its analogues, does not readily oxidize to form a hydrazyl free radical.

Experimental

The NMR spectra were taken on a Bruker DRX spectrometer operating at ν_0 = 500.13 MHz, without sample spinning, using either probe TXI or BBI. The variable-temperature unit on it is a BVT-3000.

The solvents used were commercially available deuterated materials, These perdeutero solvents, obtained from Sigma-Aldrich, were used as received. All the DMPH solutions were yellow–orange in color.

The temperatures used were below those temperatures at which DMPH "conformerization" began to be evident in the NMR spectra but of course were all above the solvent's melting point. The temperatures measured were judged to be accurate to better than ±1 K.

While investigating the conformerization kinetics, we noted the striking temperature dependences of $\nu_0\delta$ in some of the solvents used and deemed this latter effect worthy of separate study, as presented herein. Thus, we focus attention herein onto the chemical-shift difference δ between the proton NMR peaks arising from the two picryl protons of DMPH. Whenever spin–spin splitting into doublets was evident, the average position of these was taken. A typical spectrum is shown in Fig. 1.

We observed, in a series of samples of DMPH, prepared with various concentrations (10^{-3}–10^{-1} mol/L) both in acetone and in toluene-d_8, that δ did not vary appreciably within this range.

Results

The centers of the multiplet peaks A and B were measured, ignoring any ^{1}H–^{1}H spin–spin splittings present (resolved or not). The peak spacings between A and B equal the shift difference $\nu_0\delta$ to good approximation, since spin–spin coupling parameter J_{AB} is relatively small (ca. 2.6 Hz) compared to $\nu_0\delta$ (e.g., see ref. 10, p. 69). The spacings $\nu_0\delta$ were plotted (Fig. 2) against the sample temperature T, excluding the higher-temperature data where the points curve downward dramatically as a result of the onset of doublet collapse caused by the conformation-transfer phenomenon. Such plots were produced for the 8 solvents investigated (Table 1). Since the plots proved to deviate appreciably from being linear, two types of best-fit parameters were obtained, using both a linear and a quadratic polynomial. Thus, δ was fitted to the relations (*i*) $\delta_0 + \sigma T$ as well as (*ii*) $q_0 + q_1 T + q_2 T^2$, with T expressed in kelvins. Both functions gave quite satisfactory fits.

The values of the intercept and of the slope parameters obtained in this way were plotted against β. All these coefficients showed similar and gratifying correlations with β. A convenient way to present the results is to evaluate the fitted shift at T = 300 K (see Table 1) from the above relations. These data are given in Table 1, for relation (*i*), and are depicted in Fig. 3. We note the excellent correlation. The same is true for relation (*ii*).

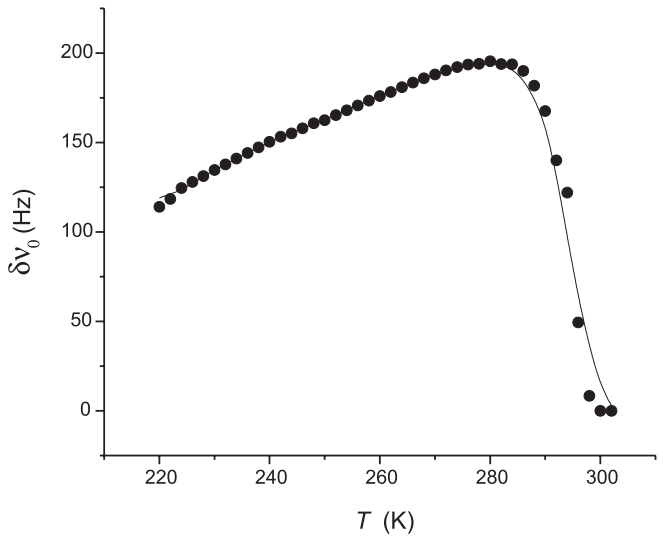
2-Propanone-d_6	179.0	0.48	244–274	16	225.6	1.253±0.011	–150.3±3.0	0.396
Tetrahydrofuran-d_8	172.0	0.55	242–274	17	215.6	1.289±0.037	–171.1±9.1	3.040
Dimethylformamide-d_7	212.0	0.69	230–266	19	127.1	1.77±0.02	–404.0±5	0.960

[a]The melting point temperatures (mp) are for the deuterated solvents.
[b]This temperature was chosen as being a convenient standard reference point. Closely analogous results were obtained at other choices, at lower temperatures, within the thermal region actually measured. Thus at 270 K, for example, $\nu_0\delta$ = 329.8 Hz for toluene-d_8.
[c]We note that intercept parameter $\nu_0\delta_\beta$ = 0 represents an extrapolation over a very large thermal range and thus may have limited physical meaning.

Fig. 2. Typical plot of the chemical-shift difference $\nu_0\delta$ of the picryl protons 3 and 5, as a function of sample temperature, for DMPH in acetone-d_6. Curve best-fit via Program "Origin 7".



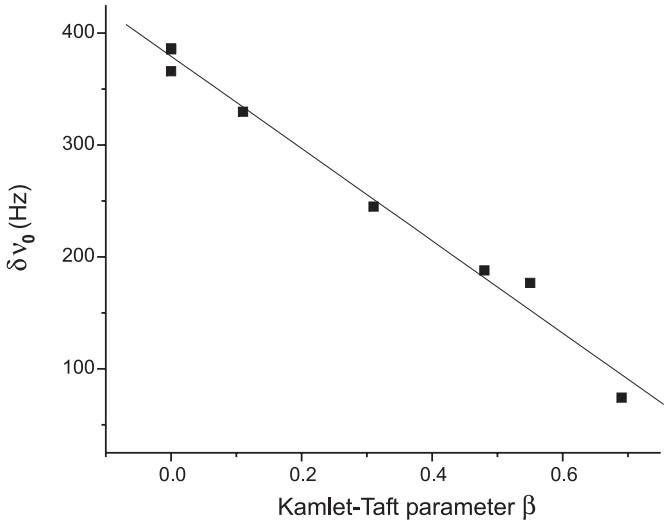


Fig. 3. The chemical-shift differences $\nu_0\delta$, calculated for 300.0 K using the best-fit data in Table 1, plotted against the Kamlet–Taft β values of the solvents used and listed therein. The best-fit straight line yielded slope –328 ± 20 Hz/β and intercept $\nu_0\delta_{\beta=0}$ = 374 ± 7 Hz, with an rms error of 12.74 Hz. For comparison, we cite that at 270.0 K, slope –412 ± 21 Hz/β and intercept $\nu_0\delta_{\beta=0}$ = 379 ± 8 Hz were found, with an rms error of 13.2 Hz.

With dimethylformamide-d_7, the highest-β solvent investigated, the slope of δ plotted against T is sufficiently large (Table 1) and the liquid-phase range available was sufficient that δ was found to cross through 0, at T = ca. 236 K. Ball-and-stick molecular models of DMPH and DMF indicate that there may be a close-fit dimer of these two, featuring two standard O···H hydrogen bonds between them.

Incidentally, we note that the chemical shifts between the methyl peaks and the picryl peaks A and B of DMPH, when plotted against T, show that both the latter peaks vary thermally in a parallel manner (as ascertained in chloroform-d and toluene-d_8).

We also have observed, somewhat to our surprise, that the two methyl groups in DMPH act as completely equivalent at even the lowest temperatures investigated, in the various solvents utilized, as investigated by us via ^{1}H NMR as well as ^{13}C NMR spectroscopy.

Discussion

It is thought that the inequivalence of the "meta" protons (3 and 5) in the picryl ring arises primarily from differences in the orientations of the "ortho" nitro groups (at carbons 2 and 6) (1, 11). This then gives rise to nonzero values of δ. In turn, the two nitro groups differ in orientation because one of these (either one) is H-bonded to the N–H proton (9). We have published some detailed quantum-mechanical modeling of the internal hindered reorientation for the closely related molecule 2-propanone-(2,4,6-trinitrophenyl)hydrazone (11). We also believe that there is competition for the hydrazinic H-bond between the adjacent nitro group and whatever solvent molecule is nearby.

Table 2. Solvent-dependent chemical shifts (ppm, relative to TMS) of the ^{1}H NMR lines of picryl A and B, N–H, and $N(CH_3)_2$ protons (at 500.13 MHz), all measured at 270 K for DMPH in various solvents.

Solvent	Picryl line A	Picryl line B	N–H	$N(CH_3)_2$
Tetrachloromethane	9.196	8.423	9.022	2.667
Trichloromethane-d_1	9.247	8.465	9.065	2.617
Dichloromethane-d_2	9.222	8.487	9.044	2.605
Toluene-d_8[a]	8.285	7.645	8.474	1.933
Ethanenitrile-d_3	9.037	8.568	9.147	2.111
2-Propanone-d_6	9.074	8.749	9.583	2.642
Tetrahydrofuran-d_8	9.076	8.776	9.406	2.567
Dimethylformamide-d_7	9.026	8.883	10.030	2.646

[a]The toluene-d^8 ^{1}H peaks for DMPH (checked at several concentrations) are all shifted upfield (smaller chemical shifts relative to TMS) by ca. 0.8 ppm from those predicted from the above table, likely due to the aromatic ring-current effect. Happily, this phenomenon does not affect the chemical-shift difference δ. We note that the toluene-d_8 peaks do occur as listed in the literature.

The two picryl-proton multiplets shift observably with β (Table 2) relative to the null of chemical shift (TMS), with the higher-field peak (B) moving more dramatically. It has been suggested (2) that peak A arises from the proton next to the nitro group H-bonded to the N–H group, but further study is called for. As β increases, the shift difference δ moves toward zero; i.e., the two nitro groups 2 and 6 act more alike, presumably because the N–H proton has been captured by the solvent molecule.

The methyl-peak positions (relative to null) for the various solvents, at say 300 K, show little correlation with β (Table 2). However, the N–H proton peak does show a steady shift to lower magnetic fields as β is increased, suggesting increased hydrogen bonding to the solvent molecules (see ref. 12, p. 407).

DMPH in the solid state contains no solvent molecules when crystallized out of absolute ethanol (9). However, other picrylhydrazines such as 2,2-diphenyl-1-picrylhydrazines readily incorporate solvent molecules upon crystallization (13). With DMPH, there is crystallographic evidence that considerable nonclassical hydrogen bonding between molecules occurs, and this may well be the cause of much of its crystal stability. Thus, there are no fewer than nine distances of < 2.9 Å between nitro-group oxygens and methyl protons on adjacent molecules, and the N–H proton, besides forming its major H-bond to its nearest nitro-group oxygen (on the same molecule), also is at 2.6 Å from a nitro-group oxygen of a neighbor molecule.

It is interesting to note (Table 1) that the three halogenic solvents exhibit the largest shift differences δ among the set investigated. They have the smallest β values and thus compete least with the nitro group for hydrogen bonding to the N–H protons of DMPH. They alone yield slopes of δ vs. T that are negative, presumably due to a thermal decrease in the difference in the environments at the picryl protons.

Obviously, both the parameter δ as measured herein and the parameter β as tabulated in the literature are subject to uncertainties. We have listed in Appendix A some of the factors coming to mind that are relevant to this topic.

The thermal behavior of δ in various solvents as presented herein will allow us to carry out a more accurate analysis of the conformerization kinetics, planned for the future. Thus, we are now in a better position to derive and present quantitative results describing DMPH's internal conformerization and plan to make these available in a subsequent publication.

Conclusions

The present measurements demonstrate that certain convenient NMR chemical-shift measurements correlate very well with the Kamlet–Taft solvolytic β, allowing checks and new evaluations of this parameter. They strengthen the belief that β is a meaningful empirical descriptor of solvent properties. They reveal, clearly, that the hindered rotations in DMPH and related hydrazines are affected by hydrogen bonding to the solvent. This realization, with use of the temperature dependences found, will make evaluation of the conformerization kinetics more accurate.

Chemical oxidation of fluoroanilines to fluoroazobenzenes and fluorophenazines with potassium ferricyanide and potassium hydroxide

Elisa Leyva, Concepción Medina, Edgar Moctezuma, and Socorro Leyva

Abstract: The oxidation of several fluoroanilines with potassium ferricyanide and potassium hydroxide is described. In this oxidation, the major products are fluoroazobenzenes. In the case of 2-fluoro-substituted anilines, heterocyclic fluorophenazines were obtained in low to moderate yields. The optimal conditions for the reaction and the mechanism are presented.

Key words: oxidation, fluoroanilines, fluoroazobenzenes, fluorophenazines.

Résumé : On décrit l'oxydation de plusieurs fluoroanilines avec du ferricyanure de potassium et de l'hydroxyde de potassium. Dans cette oxydation, les produits principaux sont des fluoroazobenzènes. Dans le cas des 2-fluoroanilines, des fluorophénazines hétérocycliques ont été obtenues avec des rendements allant de faibles à moyens. On présente les conditions optimales et le mécanisme de cette réaction.

Mots clés : oxydation, fluoroanilines, fluoroazobenzènes, fluorophénazines.

[Traduit par la Rédaction]

Introduction

Fluoroazobenzenes are extensively used as dyes and analytical reagents (1). They are also useful as materials with nonlinear optical properties (2–5). These fluorocarbon compounds exhibit the properties of water and oil repellency, high lubricity, and thermal and chemical stability (6). They are useful synthetic intermediates. Decafluoroazobenzene has been used as a precursor of several hydroxyfluoroazobenzenes that have been evaluated as inhibitors of steroid biosynthesis (7).

The oxidation of substituted anilines to azobenzenes with a variety of oxidizing agents, such as barium manganate (8), lead tetraacetate (9), sodium hypochlorite (10) and manganese dioxide (11), has been reported. However, the oxidation of fluoroanilines with inorganic oxidants in aqueous solution is complicated by the poor solubility of anilines under these conditions. The addition of an organic solvent inmiscible with the aqueous phase slows the reaction further, since the solubility of the fluoroanilines is inhibited. The oxidation of pentafluoroaniline under phase-transfer conditions (12) gave decafluoroazobenzene in only 28% yield. Tatlow and coworkers (13) reported the formation of decafluoroazobenzene (18%) and octafluorophenazine (6%) during the electrochemical oxidation of pentafluoroaniline.

The oxidation of aromatic anilines with potassium ferricyanide and KOH was first reported by Goldstein and McNelis (14). Mesidine was oxidized by this reagent in a methanol–water mixture at 45 °C for 10 days to give the corresponding azobenzene. In a short communication, we reported the oxidation of fluoroanilines with this oxidant (15). In the present paper, we report the oxidation of several fluoroanilines **1** to azobenzenes **2** and phenazines **3** by means of potassium ferricyanide and KOH. The optimal conditions for this reaction and the mechanism are presented.

Results and discussion

In general, the oxidation of fluoroanilines with inorganic oxidants in aqueous media gives very low yields due to the poor solubility of anilines under these conditions. The addition of an inmiscible organic solvent does not improve the yields. In our hands, several fluoroanilines **1a**–**1h** (Scheme 1) reacted with potassium ferricyanide to give the corresponding fluoroazobenzenes **2a**–**2h** in good to moderate yields when a mixture of ethanol and water was used as the solvent. All the fluoroanilines had good solubility in the solvent mixture used, although some are not very soluble in other solvents such as dichloromethane.

For each aniline **1a**–**1h**, the main product was the corresponding fluoroazobenzene **2a**–**2h** (Table 1). A particularly high yield (94%) was obtained with 4-fluoroaniline **(1c)**. Even the oxidation of pentafluoroaniline **(1h)** gave decafluoroazobenzene **(2h)** in higher yield than that previously reported (12). With 2-fluoro-substituted anilines **1a**, **1d**, **1e**, **1f**, and **1h**, in addition to the fluoroazobenzenes **2**, the corresponding phenazines **3** were also obtained in variable amounts as yellow crystalline compounds. With 2,4-

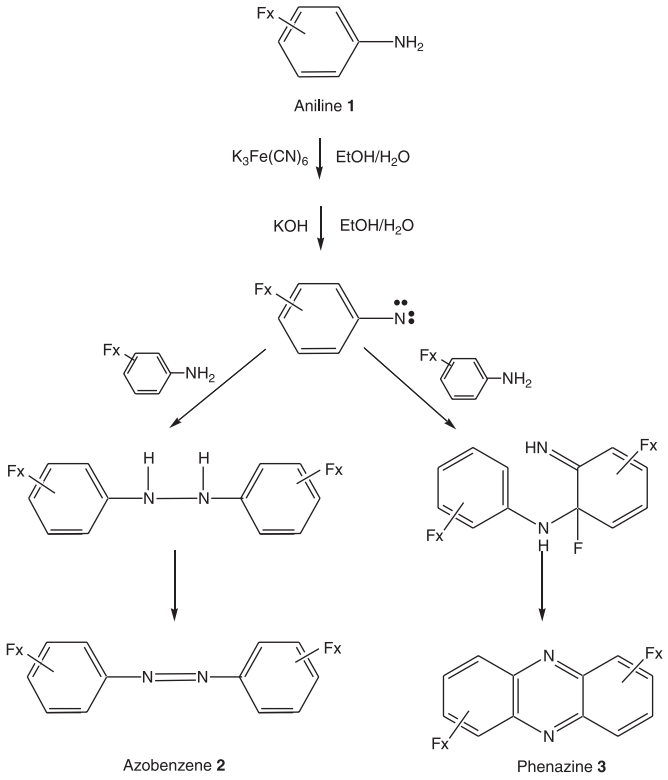
1h: Pentafluoroaniline	60	25



difluoroaniline (**1d**), phenazine **3d** was obtained in moderate yield. In the case of anilines with two *o*-fluoro substituents, the yields of phenazines were slightly higher.

The formation of the products observed in the oxidation of fluoroanilines can be explained by a mechanism involving a singlet fluorophenylnitrene as an intermediate (Scheme 2). Under these conditions, the fluorophenylnitrene would form from the fluoroaniline by reaction with potassium ferricyanide and KOH. Singlet fluorophenylnitrene is anticipated to be an ambident electrophile because the electron deficiency of the nitrogen could be neutralized by attack of a nucleophile not only on nitrogen but also on the ortho position of the aromatic ring. Nucleophilic attack by remaining fluoroaniline on nitrogen would give the fluorohydrazobenzene, which would oxidize to form the fluoroazobenzene. On the other hand, the electron-deficient singlet fluorophenylnitrene could be attacked at the ortho position of the aromatic ring by the nucleophilic aniline. Elimination of HF, heterocyclic ring closure, and further elimination of HF would give the phenazine **3**. In agreement with this mechanism is the observation that several equivalents of oxidant are required for the reaction to occur. A similar mechanism has been proposed for the oxidation of pentafluoroaniline to decafluoroazobenzene with sodium hypochlorite (12). Consistent with the proposed intermediacy of fluorophenylnitrene in this oxidation is the reported formation of both decafluoroazobenzene and octafluorophenazine in the thermal decomposition of azidopentafluorobenzene in the presence of pentafluoroaniline, where singlet nitrene is considered to be an intermediate (16).

Conclusions

The oxidation of fluoroanilines with potassium ferricyanide and KOH in an ethanol–water mixture gives the corresponding fluoroazobenzene in good to moderate yields. With 2-fluoro-substituted anilines, the corresponding fluorophenazines are also obtained in variable amounts. With 2,4-difluoroaniline, the phenazine is obtained in moderate yield. In the case of anilines with two *o*-fluoro substituents, the yields of phenazines are slightly higher.

Scheme 2.

Experimental section

General methods

All melting points were measured with a Fisher-Johns apparatus. IR spectra were recorded on a Nicolet 205 FT-IR spectrometer. UV–vis spectra were determined on a Shimadzu UV-2401PC spectrophotometer. ^{1}H NMR spectra were obtained on a Varian EM-200 using deuterated chloroform as solvent and were recorded in ppm from tetramethylsilane. ^{19}F NMR spectra were obtained on a Bruker AC 250 with a QNP probe and were recorded in ppm from trifluoroacetic acid or hexafluorobenzene. Mass spectra were obtained with a Hewlett Packard Model 5971 gas chromatograph equipped with a Hewlett Packard 5972 quadrupole mass detector. The chromatographic separation was performed on a capillary column (crosslinked 5% phenyl methyl silicone, 0.2 mm i.d. 0.33 μm × 25 m) using helium as carrier gas.

General procedure for oxidation

A given fluoroaniline (0.01 mol) was dissolved in an ethanol–water (1:1) mixture. Then, potassium hydroxide (0.018 mol) in a 1:1 ethanol–water mixture was added. Finally, potassium ferricyanide (0.04 mol) was added slowly. The resulting mixture was kept under reflux for 6 h. After this time, the mixture was filtered to remove the remaining

© 2004 NRC Canada

oxidant and extracted with dichloromethane. The organic phase was washed several times with water and dried with anhydrous sodium sulfate. The solvent was removed in a rotary evaporator, and the resulting mixture was passed through a silica gel column using hexane as the solvent to obtain the corresponding fluoroazobenzene as a crystalline orange solid. In the case of 2-fluoro-substituted anilines, fluorophenazines were obtained in low to moderate yields as yellow crystalline solids.

A novel crown ether generation containing the pyrilium heteroaromatic cation — Synthesis, characterization, and solid-phase ^{13}C NMR[1]

Abolghasem Moghimi, Majid Faal Rastegar, and Mehdi Ghandi

Abstract: The synthesis and structural characterization of two members, **5** and **6**, of a novel generation of crown ethers containing the pyrilium cation are reported. These two compounds contain two and three benzo-9-crown-3 (B9C3) units, respectively, connected to the 2 and 6 or 2, 4, and 6 positions of a central pyrilium cation. The crown ethers **5** and **6** were obtained from the condensation reaction of appropriate aldehydes and methyl ketones in the presence of $POCl_3$. A variety of physicochemical methods including electrospray mass spectroscopy, solution ^1H and ^{13}C NMR, and solid-phase ^{13}C NMR were applied for structural characterization. The ^1H and ^{13}C NMR studies indicate rapid rotation of the B9C3 unit about the C–C bond that connects the two units to each other. The solid-phase ^{13}C NMR spectra of these two crown ethers reveal that there are deviations from planarity for the two phenyl rings attached at the 2 and 6 positions of the central pyrilium cation.

Key words: crown ether, pyrilium, solid-phase NMR, crownpyrilium, heteroaromatic.

Résumé : On a réalisé la synthèse et la caractérisation de deux nouveaux termes, **5** et **6**, d'une nouvelle génération d'éthers couronnes contenant le cation pyrillium. Ces deux composés contiennent deux et trois unités de benzo-9-couronne-3, B9C3, reliées aux positions 2 et 6 ou 2, 4 et 6 d'un cation pyrillium central. Les éthers couronnes **5** et **6** ont été obtenues par une réaction de condensation des aldéhydes ou des méthylcétones appropriés en présence de $POCl_3$. La caractérisation de la structure a été réalisée à l'aide de diverses méthodes physicochimiques, dont la spectroscopie de masse avec ionisation par électronébulisation, la résonance magnétique nucléaire du ^1H et du ^{13}C en solution et la RMN du ^{13}C en phase solide. Les études de RMN du ^1H et du ^{13}C indiquent que l'unité B9C3 donne lieu à une rotation rapide autour de la liaison C–C qui réunit les deux unités l'une à l'autre. La RMN du ^{13}C en phase solide de ces deux éthers couronnes révèle que les deux noyaux phényles attachés aux positions 2 et 6 du cation pyrillium central ne sont pas planaires.

Mots clés : éther couronne, pyrillium, RMN en phase solide, couronnepyrillium, hétéroaromatique.

Introduction

The synthesis and X-ray crystal structures of a novel crown ether generation containing different heteroaromatic cations such as pyrilium, thiopyrilium, and pyridinium was recently reported by our research group (1). We call these new crown ethers *crownpyrilium*, *crownthiopyrilium*, and *crownpyridinium dyes*. Crown ethers (2) and heteroaromatic cations (3) are two important classes of organic compounds and, as such, their synthesis and structural properties have been extensively investigated. Owing to their specific metal ion complexing ability and high extraction efficiency, crown ethers have been widely used as suitable neutral carriers in such important applications as selective metal transport through liquid membranes (4), preparation of ion-selective membrane sensors, (5), and phase transfer catalysis (6). Heteroaromatic cations have been applied as active materials in laser dyes, photosensitizers, and organic conductors (7). In a recent article, a class of pyrilium dyes with high efficiency in lasing and two-photon absorption fluorescence has been reported (7*a*). A search of the literature indicates that there are limited reports on the synthesis of pyrilium, thiopyrilium, and pyridine corands (8*a*, 8*b*) as well as hemispherand-like macrocycles containing the pyrilium subunit (8*c*, 8*d*).

The crown ether unit in the crownpyrilium compounds is expected to have the potential to form a host–guest complex with inorganic and organic cations, while the heteroaromatic cationic unit can behave as an anion receptor or interact with those functional groups that have the capability to form hydrogen bonds. Thus, these compounds are prominent in the design of ditopic artificial receptors for amino acid recognition, which is currently an area of great interest (9). In our

Fig. 1. Chemical structure of 2,6-diphenyl-4-B9C3-pyrilium perchlorate **1**.

1

previous paper (1), three new crown ethers, in which a benzo-9-crown-3 (B9C3) unit was attached to the 2,6-diphenyl heteroaromatic cation units at the 4-position, were investigated. Compound **1** (Fig. 1) is an example of these compounds. Spectrophotometric studies in methanol solution revealed that this class of crownpyrilium dyes can be successfully applied to selective amino acid recognition. Thus, the crown cavity in the corresponding laser dye systems is expected to play a unique role in both the fine adjustment of the absorption and emission spectra as well as the fluorescence enhancement, as was observed in the case of crownpyrilium dye **1**. The excitation and emission spectra of **1** revealed that this crown ether has an absorbance at about λ_{max} = 450 nm and a fluorescence at about λ_{max} = 580 nm, and the fluorescence intensity is sensitive to the concentration of an appropriate amino acid. This rather interesting behaviour attracted our attention, and we became more interested in extending this field of research by preparing and characterizing other similar compounds. Therefore, in this paper, we wish to report the synthesis of crownpyriliums **5** and **6** (Scheme 1), using the same synthesis methodology as applied previously in the preparation of **1**, and to discuss their solid-phase NMR spectra. The excitation properties will also be discussed and compared with those of **1**.

Experimental

Instrumentation

Solution NMR spectra were recorded on a 400-MHz Bruker AMX-400 spectrometer. Samples for both ^{1}H and ^{13}C NMR were prepared in $CDCl_3$ or DMSO-d_6 solution at a concentration of 0.1 mol/L, and their spectra were obtained in 5-mm tubes. All chemical shifts are reported in ppm downfield from Me_4Si (TMS). The mass spectra were recorded on a MS80RFA mass spectrometer by electron ionization (EI) at 70 eV and positive ion electrospray (ES). The IR spectra were obtained with a Shimadzu FTIR spectrometer using KBr discs. The melting points were measured on a digital Electrothermal 9000 apparatus and are uncorrected. Elemental analyses were performed at Ottawa University. The solid-phase ^{13}C NMR spectra were obtained at 50.3 MHz using a Bruker ASX-200 spectrometer under the same conditions as described previously (1). The spinning rate was 5 kHz. Chemical shifts were measured relative to external hexamethylbenzene (HMB) (methyl resonance at 16.9 ppm) and then converted to the TMS scale. The dipolar dephasing experiment was carried out by interruption of the ^{1}H decoupling for 40 μs immediately following the cross-polarization sequence.

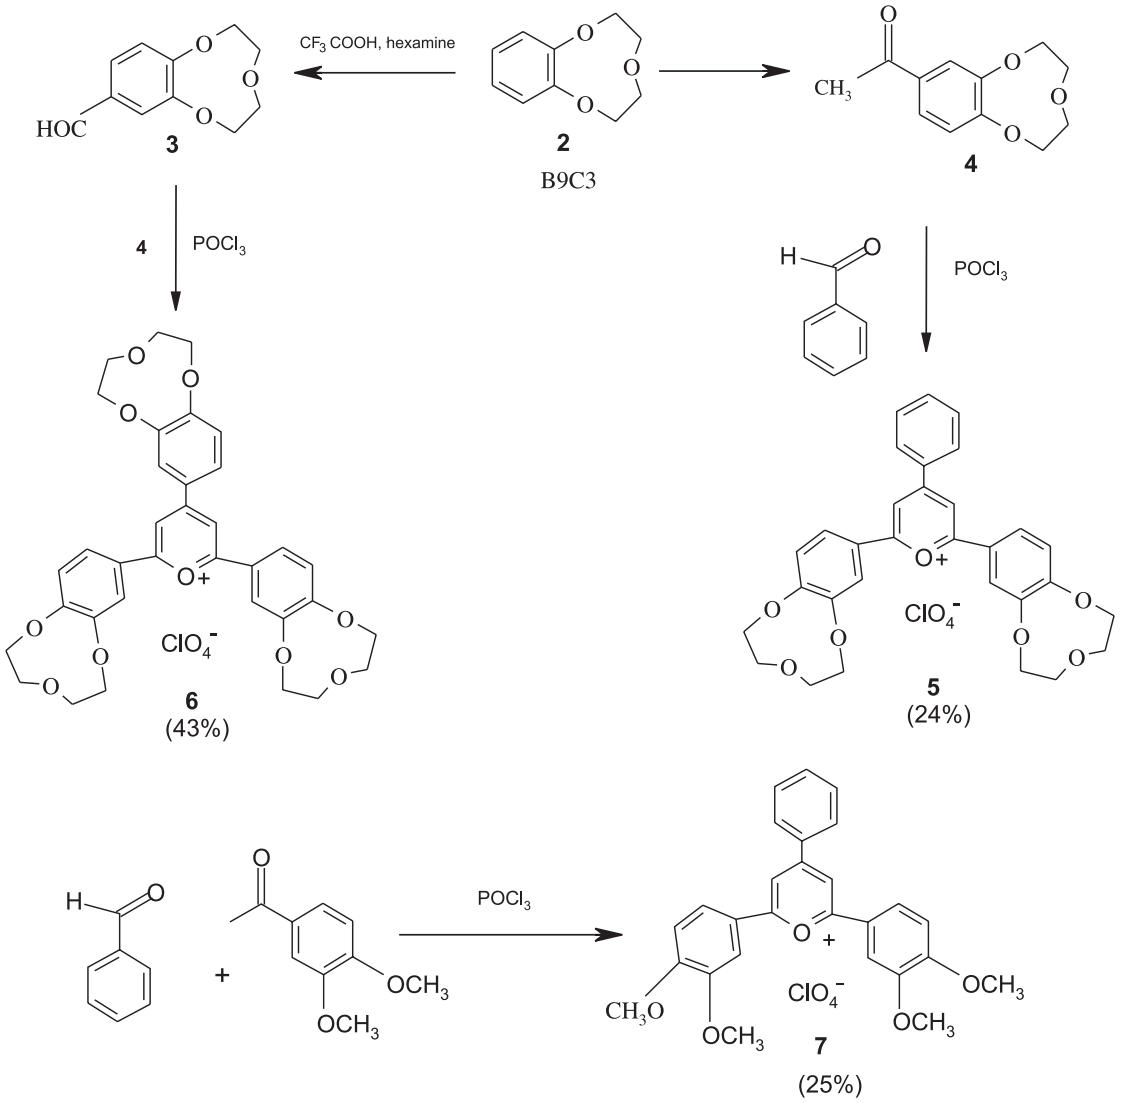
Materials

B9C3 crown ether **2** (10), HCO-B9C3 crown ether **3** (11), and pyrilium crown ether **1** (1) were synthesized following the procedures described previously. Other reagents were purchased from Merck.

Synthesis of 4′-acetyl-B9C3 (4)

A 500-mL flask was charged with B9C3 (9 g, 0.05 mol), 150 mL of nitrobenzene, and 13.4 g (0.1 mol) of $AlCl_3$ under nitrogen. Acetyl chloride (4.2 g, 0.05 mol) was then added dropwise to the mixture, in an ice bath, over 30 min while stirring. The reaction was allowed to proceed at 0 °C for 3 h and subsequently at room temperature overnight. Then 150 mL of water was added to the mixture to quench the reaction followed by steam distillation. The aqueous solution thus obtained was extracted with CH_2Cl_2 (3 × 150 mL), and the combined organic extracts were dried over anhydrous sodium sulphate. After filtration and solvent removal, 10.1 g of light-brown oil was obtained. The oil was extracted with boiling hexane (3 × 150 mL). Upon cooling the hexane solution, 8.4 g (75.7%) of 4′-acetyl-B9C3 was obtained as light-yellow cubic crystals.

^{1}H NMR ($CDCl_3$) (ppm) δ_H: 7.64, 7.60, 7.58, 6.99, 4.59, 4.28, 3.93, and 3.90. ^{13}C NMR ($CDCl_3$) (ppm) δ_C: 196.5, 155.7, 150.6, 132.6, 125.1, 124.1, 121.9, 75.1, 72.7, 72.2, and 71.8. EI-MS *m/z* (%): 224 (M + 2, 0.5), 223 (M + 1, 3.7), 222 (M, 27.9), 207, 193, 178, 163, 149, 135, 107, 94, 79, 69, 63, 51, and 44. Anal. calcd. (%) for $C_{12}H_{14}O_4$: 222.10876; found: 222.08792.



Synthesis of 2,6-bis(B9C3)-4-phenylpyrilium perchlorate (5)

Crown ether **4** (6.66 g, 30 mmol) was added to benzaldehyde (1.8 g, 15 mmol) in a 50-mL flask. The reaction mixture was cooled in an ice/water bath, and 5.37 g (35 mmol) of $POCl_3$ was added dropwise to the mixture. The reaction mixture, while stirring, was then warmed in a water bath (50–60 °C). The stirring was continued for 3 h followed by evaporation of excess $POCl_3$ on a rotary evaporator. The residue was dissolved in 200 mL of hot absolute ethanol and was heated to boiling. Next, 3 mL of 60% perchloric acid was added to the hot ethanol solution, and the solution was then allowed to cool to room temperature. The crystalline product was filtered, washed with diethyl ether, and finally vacuum dried. The orange crystalline product was recrystallized from acetic acid. After suction filtration and washing the orange needle crystals with diethyl ether, 2.2 g (24%) of **5** were obtained (mp 158–159 °C).

^{1}H NMR (DMSO-d_6) (ppm) δ_H: 8.9 (s, 2H, CH pyrilium), 8.5 (d, 2H, $^3J_{HH}$ 7.6 Hz), 8.2 (d, 2H, $^4J_{HH}$ 2.2 Hz), 8.1 (dd, 2H, $^3J_{HH}$, 8.4 Hz, $^4J_{HH}$ 2.2), 7.8 (t, 1H, $^3J_{HH}$ 7.3 Hz), 7.7 (dd, $^3J_{HH}$ 7.6 Hz, $^3J_{HH}$ 7.3 Hz), 7.2 (d, 2H, $^3J_{HH}$ 8.4 Hz), 4.7 (m, 4H), 4.4 (m, 4H), and 3.9 (m, 8H). ^{13}C NMR (DMSO-d_6) (ppm) δ_C: 168.5, 163.4, 156.9, 151.3, 134.7, 132.7, 129.7, 129.6, 125.0, 124.7, 123.2, 122.8, 113.5, 74.9, 72.0, 71.1,

and 70.8. EI-MS *m*/*z* (%): 410 (1.5), 252 (80), 167 (53), 152 (12), 109 (100), 91 (27), and 45 (26). ES-MS *m*/*z* (%): 515.0 (M + 2, 7.1%), 514.0 (M + 1, 33.4%), 513.0 (2,6-di(B9C3)-4-phenylpyrilium cation, 100%), 329.9, and 304.1. FAB-MS *m*/*z* (%): 513.2 (2,6-di(B9C3)-4-phenylpyrilium cation, 25%), 462.2 (2%), 370.2 (4%), 278.1 (7%), 186.1 (25%), 149.1 (10%), and 75.0 (100). Anal. calcd. (%) for $C_{31}H_{29}O_{11}Cl$: C 60.73, H 4.73; found: C 59.50, H 4.67.

Synthesis of 2,4,6-tri(B9C3)-pyrilium perchlorate (6)

Crown ethers **4** (8.88 g, 40 mmol) and **3** (4.16 g, 20 mmol) in a mole ratio of 2:1 were mixed and well ground and were then placed in a 50-mL flask. Then 6.9 g (45 mmol) of $POCl_3$ was added dropwise to the reaction mixture. The mixture, while stirring, was warmed in a water bath (50–60 °C). The stirring was continued for 2 h followed by evaporation of excess $POCl_3$ on a rotary evaporator. The residue was dissolved in 250 mL of hot absolute ethanol and was heated to boiling. Then 5 mL of 60% perchloric acid was added to the hot ethanol solution, which was then allowed to cool to room temperature. The red crystalline product was filtered, washed with diethyl ether, and finally vacuum dried to obtain 6.2 g (43%) of **6** (mp 149–150 °C).

^{1}H NMR (DMSO-d_6) (ppm) δ_H: 8.74 (s, 2H, CH pyrilium), 8.34 (d, 1H, $^4J_{HH}$ = 2.2 Hz), 8.25 (dd, 1H, $^3J_{HH}$ = 8.7 Hz, $^4J_{HH}$ = 2.2 Hz), 8.20 (d, 2H, $^4J_{HH}$ = 2.2 Hz), 8.06 (dd, 2H, $^3J_{HH}$ = 8.7 Hz, ^4J = 2.2 Hz), 7.25 (d, 2H, $^3J_{HH}$ = 8.7 Hz), 7.22 (d, 1H, $^3J_{HH}$ = 8.7 Hz), 4.73 (m, 2H), 4.69 (m, 4H), 4.36 (m, 6H), and 3.87 (m, 12H). ^{13}C NMR (DMSO-d_6) (ppm) δ_C: 167.6, 161.7, 157.2, 156.6, 151.4, 151.3, 126.8, 126.4, 126.0, 124.7, 124.3, 123.4, 122.8, 122.4, 112.0, 75.0, 74.7, 72.0, 71.9, 71.3, 71.0, 70.9, and 70.8. ES-MS *m*/*z* (%): 615.0 (2,4,6-tri(B9C3)-pyrilium, 100), 517.0 (1), 369.0 (13), and 151.8 (2).

Synthesis of 2,6-bis(dimethoxyphenyl)-4-phenylpyrilium perchlorate (7)

This compound was prepared following a similar procedure to that used in preparing compound **5**. Yield 25%, mp 227–228 °C.

^{1}H NMR (DMSO-d_6) (ppm) δ_H: 8.82 (s, 2H, CH pyrilium), 8.43 (d, 2H, $^3J_{HH}$ = 7.5 Hz, ph), 8.15 (dd, 2H, $^3J_{HH}$ = 8.8 Hz,

© 2004 NRC Canada

$^4J_{HH}$ = 2.0 Hz,), 7.85 (d, 1H, $^3J_{HH}$ = 2.0 Hz), 7.72–8.84 (m, 3H, ph), 7.30 (d, 1H, $^3J_{HH}$ = 8.7 Hz), 3.97 (s, OCH_3), and 3.95 (s, OCH_3). ^{13}C NMR (DMSO-d_6) (ppm) δ_C: 168.6, 163.0, 154.8, 149.4, 134.3, 132.7, 129.5, 129.4, 123.7, 121.1, 112.8, 112.3, 110.2, 56.1, and 55.9.

Results and discussion

Synthesis and MS analysis

The synthetic pathway is shown in Scheme 1. The cyclization reaction of catechol and bis(dichloroethyl ether) under high dilution conditions in water as solvent (2*m*) followed by formylation of the resulting B9C3 with hexamine in the presence of CF_3COOH afforded compound **3** (4′-HCO-B9C3) in an overall 22.5% yield (1). Compound **4** was obtained in 75.7% yield from the acylation of B9C3 using acetyl chloride and $AlCl_3$ in nitrobenzene solvent. Among a number of procedures used in the literature for the synthesis of pyrilium cations (8), the condensation of appropriate aldehydes and ketones in the presence of $POCl_3$ was chosen to prepare the perchlorate salts of 2,6-diphenyl-4-B9C3-pyrilium (**1**), 2,6-di-B9C3-4-phenylpyrilium (**5**), 2,4,6-tri-B9C3-pyrilium (**6**), and 2,6-bis(dimethoxyphenyl)-4-phenyl-pyrilium perchlorate (**7**), which were obtained in yields of 29, 24, 43, and 25%, respectively. The melting points of the resulting pyrilium cations **1**, **5**, and **6**, (i.e., 248–250, 158–159, and 149–150 °C, respectively) decrease with increasing number of B9C3 units connected to the central pyrilium cation.

For the structural characterization of the resulting crown-pyrilium cations, MS and NMR spectroscopy were applied. Since it has been noted that EI-MS is not a suitable technique for structural characterization of organic salts such as heteroaromatic cations (1, 12), and considering that fast atom bombardment mass spectrometry (FAB-MS) and ES-MS have been successfully applied for some heteroaromatic cations (13, 14), the latter two methods were applied to both **5** and **6**. The appropriate base peaks at *m/z* = 513 and 615.0 in the ES-MS spectra that correspond to the naked 2,6-di-B9C3-4-phenylpyrilium and 2,4,6-tri-B9C3 pyrilium cations, respectively, were then detected. The elemental analysis data for **5**, $C_{31}H_{29}O_{11}Cl$, was found to be reasonably in agreement with the expected formula.

UV–vis spectroscopy

The UV–vis spectra of crownpyriliums **1**, **5**, and **6** and pyrilium **7** were recorded in MeOH to compare the absorption data and investigate the influence of the B9C3 substitution at the 2, 4, and 6 positions of pyrilium. The absorption data are collected in Table 1. The λ_{max} values are in the order of **5** > **6** > **1**. The influence of the crown cavity on the UV absorption characteristics of the pyrilium moiety is of particular interest. Comparison of the absorption data for each crownpyrilium (**5** and **6**) and their closely related methyl ether pyrilium derivative (**7**) indicates that there are noticeable differences between these compounds. As is clear from Table 1, pyrilium **7** shows a red shift in comparison with crownpyriliums **5** and **6**. This implies that the oxygen atoms directly attached to the phenyl rings in **7** behave as a better electron-donating group than the crownpyriliums **1**, **5**, and **6**. This might be due to the orientation of oxygen lone pairs imposed by the nine-membered ring crown ether in these compounds.

Table 1. UV-vis data for crownpyriliums **1**, **5**, and **6** and pyrilium **7**.

Compound	Solvent	Absorptions (nm)

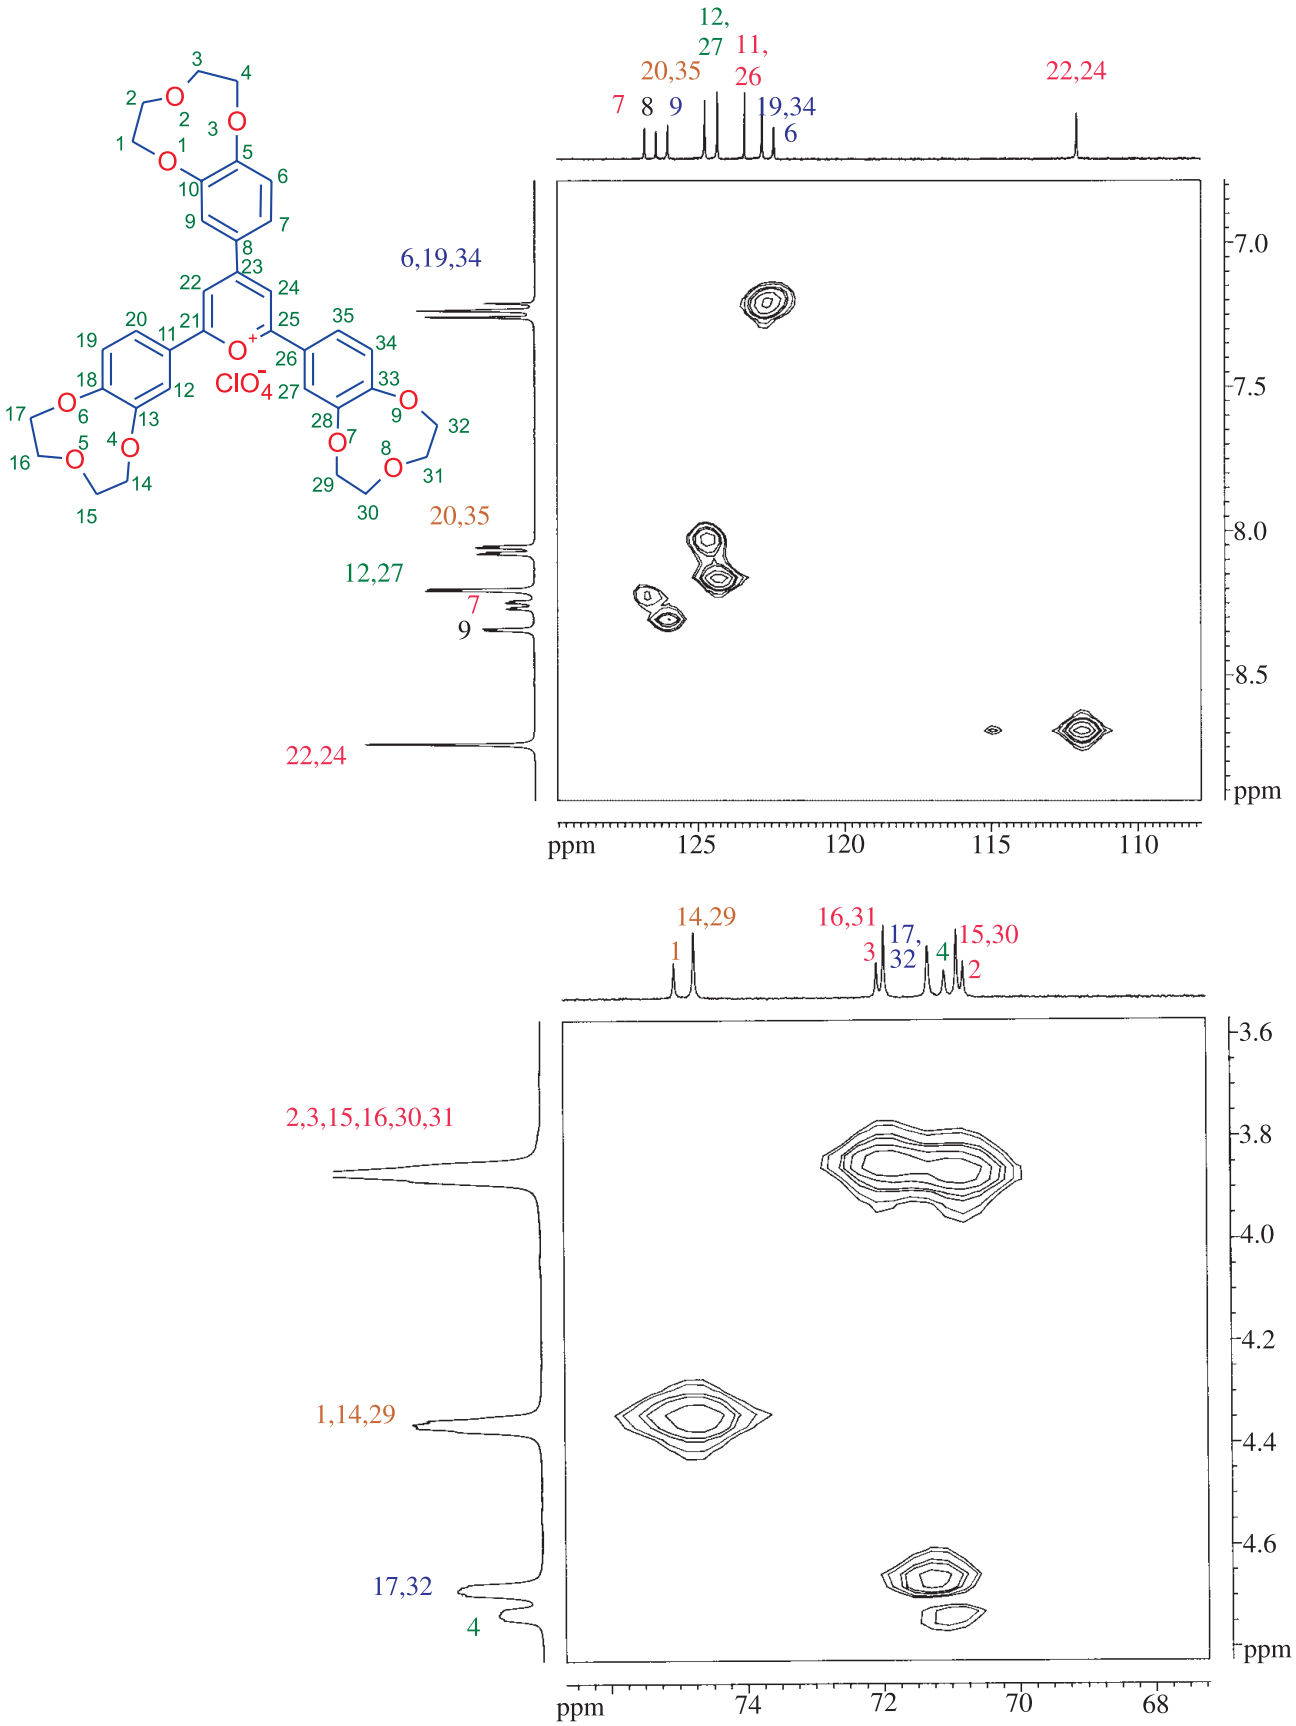
[a]The atom numbering for the pyrilium ring and phenyl groups in compound **7** is considered to be similar to that of compound **5**.
[b]Chemical shift differences (in ppm) between resonances of **7** and those of **5**.



Solution ^1H and ^{13}C NMR

Proton and ^{13}C NMR spectra of **5** and **6** were recorded in DMSO-d_6. The analysis of the resulting data was performed using the known characteristic resonances of compound **1** (1) as well as the NMR data obtained for compound **7** and the two-dimensional NMR spectra. A typical two-dimensional ^1H-^{13}C HETCOR is given in Fig. 2 for compound **6**. Both **5** and **6** show a distinct singlet signal at about 9 ppm in their ^1H NMR spectra for the two pyrilium ring protons, which are equivalent as a result of fast B9C3 rotation on the NMR time scale. Other easily distinguishable ^1H resonances are the three and four multiplets in the 3.6–4.8 ppm region corresponding to the crown ether methylene protons of **5** and **6**, respectively. The more deshielded methylene resonances are due to the directly attached CH_2O groups on the phenyl rings. These well-separated peaks characterize the remote electronic effect of the pyrilium unit as an efficient electron-withdrawing group. The 8 and 12 CH_2O carbons in **5** and **6** clearly show 4 and 8 resolved ^{13}C resonances, respectively. The AMX spin system pattern for the three protons of the 4′-substituted- B9C3 benzene rings can be easily identified in the aromatic region. Based on known ^1H and ^{13}C NMR resonances, the other resonances were assigned using two-dimensional spectra. As shown in Fig. 2, for instance, the ^{13}C methylene and aromatic resonances can be identified from the ^1H-^{13}C HETCOR.

An interesting fact to be noted is that the chemical shifts for pyrilium and the three phenyl rings at the 2, 4, and 6 positions are influenced quite differently from those of the two

nine-membered rings of B9C3 in **5** and **6** and the four methoxy groups in **7**. To obtain an estimate for the contribution of the B9C3 crown ring on the NMR resonances of compound **5**, NMR data for compound **7** were obtained under the same conditions as used for compound **5**, and some of these NMR data are listed in Table 2. As seen, large chemical shift differences ($\Delta\delta C$) are observed for the carbon atoms at the 6 and 26 positions, while there are moderate differences for those at positions 8 and 12. The downfield shifts indicated in Table 2 reveal the lesser electron-donating ability of the nine-membered crown ring as compared to the methoxy groups. This could be the result of the restricted orientation of attached oxygen atoms to the phenyl rings in **5** and **6** that results from the rigid nine-membered ring crown

Fig. 4. Normal (*bottom*) and dipolar dephased (*top*) solid-phase ^{13}C NMR spectra of **6**.

cavity. This supports our explanation for the UV–vis absorption. Considering the fact that particular guests, such as Be^{2+} (5*c*), can strongly interact with the crown cavity, one would expect that fine adjustment of both absorption and emission bands could be achieved by choosing an appropriate combination of guest and concentration.

Solid-phase ^{13}C NMR

Since our efforts to obtain single crystals of **5** and **6** for X-ray analysis failed, solid-phase ^{13}C NMR was chosen to obtain some insight into the solid-state structures of **5** and **6**. The normal and dipolar dephased solid-phase ^{13}C NMR spectra of **5** and **6** are presented in Figs. 3 and 4, respectively. To analyze the solid-phase NMR spectra, the previously reported solid-phase ^{13}C NMR data for B9C3, B9C3-d_4 (10), 4′-HCO-B9C3, and 4′-HCO-B9C3-d_4 (11), as well as the solution ^{13}C NMR data and dipolar dephased ^{13}C CPMAS spectra obtained in the present study, were all considered.

It was noticed that the overall spectral patterns are more or less similar to the one previously reported for crownpyrilium **1** (1). The nonprotonated carbons are readily

© 2004 NRC Canada

distinguishable in the dipolar dephased spectra. Examination of the ^{13}C CPMAS spectra reveals three distinct regions: a 67–79 ppm region for crown cavity CH_2O carbons, a 150–169 ppm region for nonhydrogenated phenyl carbons attached to oxygen atoms and the carbons α and γ to the pyrilium O^+ as a result of the inductive and resonance effects of pyrilium, and finally a 110–137 ppm region for the remaining, mostly CH, carbons.

As expected, the number of CH_2O resonances in **6** is greater than in **5**. The corresponding carbons in **1** have shown only one broadened singlet signal at 76.7 ppm (1). The deshielded resonances in the aliphatic CH_2O region correspond to the CH_2O carbons para to the pyrilium rings.

The multiplicity in the solid-state spectra of crown-pyrilium **5** and the chemical shift difference for the two C11 and C15 pyrilium carbons, i.e., 2.4 ppm, might be due to the lack of symmetry in its solid-phase structure. It is noted that the $\Delta\delta C$ values for the two C5 and C10 methylene carbons in **5** and the two corresponding C13 and C18 carbons in **6** are 5.6 and 5.9 ppm, respectively. Interestingly, these solid-phase $\Delta\delta C$ values are very close to the corresponding values in solution ^{13}C NMR spectra, indicating the similarities between the factors influencing the chemical shifts of these carbon atoms.

Conclusion

Two members, **5** and **6**, of a novel generation of crown ethers containing the pyrilium cation can be synthesized by the same strategy, and different crownpyrilium compounds containing two and three B9C3 units connected at the 2 and 6 or 2, 4, and 6 positions of a central pyrilium cation can be successfully synthesized. These novel crown ethers are obtained from the condensation reaction of appropriate aldehydes and methyl ketones in the presence of $POCl_3$. Other members of this crown ether generation with larger size crown cavity are expected to be synthesized by following the same synthetic method. The crown ether units in these compounds are potentially capable of forming host–guest complexes with inorganic and organic cations while the heteroaromatic cationic unit is suitable for binding with anions. Both ES-MS and FAB-MS methods are suitable for the characterization of this class of crown ethers. The ^1H and ^{13}C NMR studies indicate rapid rotation of the B9C3 unit about the C—C bond that connects the B9C3 units to the central pyrilium ring. The solid-phase ^{13}C NMR spectra of these compounds, as well as the X-ray crystal structure of **1**, reveal that there are deviations from planarity for the two phenyl rings attached at the 2 and 6 positions of the central pyrilium cation. The fluorimetric titration of **5** and **6** with some amino acids has indicated that these molecules can indeed function as host molecules. Further details will be published elsewhere.

Synthesis and characterization of a series of 4-methyl-1-[2-aryl-1-diazenyl]-1,4-diazepanes and 1,4-di-[2-aryl-1-diazenyl]-1,4-diazepanes[1]

Shasta Lee Moser and Keith Vaughan

Abstract: 1-Methylhomopiperazine was coupled with a series of diazonium salts to afford the 4-methyl-1-[2-aryl-1-diazenyl]-1,4-diazepanes (**6**), a new series of triazenes. These compounds are, in the main, stable crystalline solids (some of the series are stable oils), and they have been characterized by ^{1}H and ^{13}C NMR spectroscopy, IR spectroscopy, and mass spectrometry. NMR assignments were determined by 2D NMR and variable-temperature NMR experiments and by comparison with model compounds. A second series of new compounds, namely, 1,4-di-[2-aryl-1-diazenyl]-1,4-diazepanes (**5**), were prepared by coupling unsubstituted homopiperazine (1,4-diazepane) with 2 molar equivalents of the diazonium salt and were similarly characterized. The crystal and molecular structure of the parent member of this bis-triazene series (**5**, X = H) has been determined by single-crystal X-ray diffraction analysis.

Key words: triazene, bis-triazene, diazenyl, bis-diazenyl, diazonium salt, NMR, diazepane.

Résumé : On a couplé la 1-méthylhomopipérazine avec une série de sels de diazonium pour obtenir des 4-méthyl-1-[2-aryldiazén-1-yl]-1,4-diazépanes (**6**), une nouvelle série de triazènes. Ces composés sont généralement des solides cristallins stables (quelques-uns sont des huiles stables) et on les a caractérisés par spectroscopie RMN du proton et du carbone-13, spectroscopie IR et spectrométrie de masse. Les attributions des bandes de RMN ont été assistées par des expériences de RMN 2D et de RMN à températures variables ainsi que par comparaison avec des composés modèles. On a préparé et caractérisé de la même manière une seconde série de nouveaux composés, des 1,4-di-[2-aryldiazén-1-yl]-1,4-diazépanes (**5**), par couplage de l'homopipérazine non substituée (« 1,4-diazépane ») avec deux équivalents molaires du sel de diazonium. Faisant appel à la diffraction des rayons X sur des cristaux uniques, on a déterminé la structure cristalline et moléculaire du composé fondamental de la série des bis-triazènes (**5**, X = H).

Mots clés : triazène, bis-triazène, diazényle, bis-diazényle, sel de diazonium, RMN, diazépane.

[Traduit par la Rédaction]

Introduction

The term *bis-triazene* has been coined to describe any molecule that contains two triazene units in the same molecule, with a link or spacer between the triazene moieties. Recent progress in the synthesis of bis-triazenes has been reviewed (1), and the variety of known bis-triazenes can be described by the general structures **1** and **2**. In bis-triazenes of type **1,** the triazenes are linked at the N3 of each triazene unit through the spacer (2, 3) whereas in bis-triazenes of type **2** the spacer is attached at the N1 of each triazene unit (4). Mixed bis-triazenes of type **3**, where the triazene is linked at N1 via a spacer to the N3 of the second triazene, are at present unknown.

Previously (2), we reported on the synthesis and characterization of the series *N*,*N*′-bis(aryldiazenyl)-*N*,*N*′-(dimethyl)ethan-1,2-diamines (**4**), which are bis-triazenes of type **1**. These bis-*N*-aryldiazenyl compounds showed some novel features in the NMR spectra, which were interpreted as arising from the rotational equilibrium in the triazene moiety. A natural extension of this previous work presented itself to us in the form of *N*,*N*′-bis(aryldiazenyl)homopiperazines (**5**), systematically known as the 1,4-di-[2-aryl-1-diazenyl]-1,4-diazepanes. There is one previous report of the synthesis of a bis-triazene of type **5**, namely, the unsubstituted parent compound **5k** (5). In the course of this undertaking, it seemed appropriate to synthesize the simpler mono-triazenes, the 4-methyl-1-[2-aryl-1-diazenyl]-1,4-diazepanes (**6**), which might serve as model compounds for the bis-triazenes (**5**). Another model system for comparison would be the *N*,*N*′-bis(aryldiazenyl)piperazines (**7**).

Furthermore, the triazenes of types **5** and **6** are members of a larger class of 1-aryldiazenyl-(1,*x*)-diazacycloalkanes that we are studying in a comprehensive manner. Very recently (6), we reported on the synthesis and characterization of a series of 1-methyl-4-[2-aryl-1-diazenyl]piperazines (**8**),

which exhibit important spectroscopic features in relation to the characterization of the triazenes **5** and **6**. Moreover, these new triazenes of types **5** and **6** are derivatives of the perhydro-1,4-diazepine (diazepane), a heterocyclic ring system with significant medicinal importance. Many well-known clinical tranquilizers, e.g., librium and valium, are 1,4-diazepine derivatives (7), and some benzodiazepines have been shown to be antitumour antibiotics (8). Thus, it is just conceivable that the new triazenes **5** and **6** may have useful biological activity.

Experimental

All reagents were reagent-grade materials purchased from Sigma-Aldrich Canada and were used without further purifi-

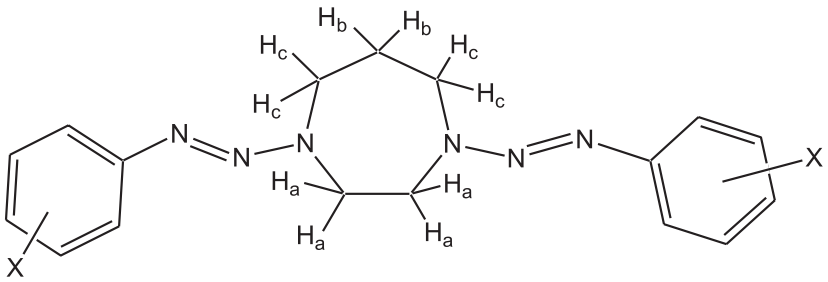
cation. Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. Infrared spectra were obtained using Nujol mulls or KBr discs on a Bruker Vector 22 spectrometer. Proton and ^{13}C NMR spectra were obtained with either (*i*) Bruker AC 250- and 500-MHz spectrometers at the Atlantic Regional Magnetic Resonance Center at Dalhousie University or (*ii*) the Anasazi 60-MHz EFT spectrometer at Saint Mary's University (SMU). Chemical shifts were recorded in $CDCl_3$ solutions at 20 °C (unless specified otherwise) and are relative to Me_4Si as internal standard. Elemental analyses were performed by the Canadian Microanalytical Service Ltd. (Delta, B.C.). Accurate mass measurements were made on a CEC 21–110B mass spectrometer operated at a mass resolution of 8000 (10% valley) by computer-controlled peak matching to appropriate PFK reference ions. Spectra were obtained using electron ionization (EI) at 70 V and a source temperature of 175 °C, with samples being introduced by means of a heatable quartz probe. The standard deviation of mass measurement is ±0.0008 amu, which is an average of 3.6 ppm over the mass range of 100–300 amu.

General procedure

1,4-Di-[2-aryl-1-diazenyl]-1,4-diazepanes (5a–5o)



The aromatic primary amine (0.02 mol) was dissolved in 20 mL of 3 mol/L hydrochloric acid, with the aid of heat if necessary, and the resulting solution was cooled in an ice/salt bath to 0 °C. The solution was diazotized with a solution of sodium nitrite (1.52 g) in water (10 mL) while maintaining the temperature below 5 °C, and then stirred for a further 30 min in the cold. The solution was then neutralized with saturated sodium bicarbonate solution, after which the neat homopiperazine (1.1 g, 0.011 mol) was slowly added to the mixture. After stirring for a further 30 min, the mixture was further neutralized with saturated sodium bicarbonate solution and then left to stir until precipitation was deemed to be complete (1–3 h). The solid product was filtered under suction, dried, and recrystallized from an appropriate solvent. Physical data of the products, i.e., yield, mp, recrystallization solvent, and IR data, are listed in Table 1. Table 2 is a list of ^1H NMR chemical shift data, with appropriate assignments, and ^{13}C NMR data are listed in Table 3. The elemental analysis of selected compounds in this series are reported in Table 4. High-resolution EI mass spectral data of selected compounds of type **5** are given in Table 5.

4-Methyl-1-[2-aryl-1-diazenyl]-1,4-diazepanes (6a–6n)

The aromatic primary amine (0.01 mol) was dissolved in 10 mL of 3 mol/L hydrochloric acid, with the aid of heat if necessary, and the resulting solution was cooled in an ice/salt bath to 0 °C. The solution was diazotized with sodium nitrite (0.76 g) in water (10 mL) while maintaining the temperature below 5 °C, and then stirred for a further 30 min in the cold. The mixture was then neutralized with saturated aqueous sodium bicarbonate, after which the neat

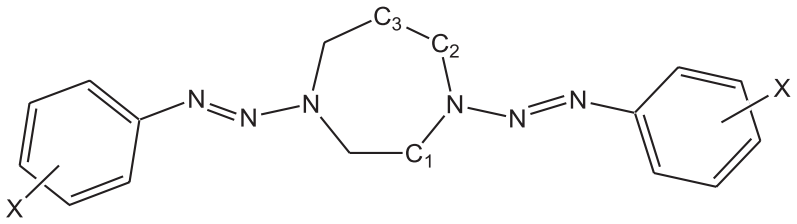
[a]Coupling constants (*J*) in Hz.



1-methylhomopiperazine (1.4 mL, 0.011 mol) was slowly added to the mixture. After stirring for a further 30 min, the mixture was further neutralized with saturated sodium bicarbonate solution and then left to stir until precipitation was deemed to be complete (1–3 h). The solid product was filtered under suction, dried, and recrystallized from an appropriate solvent. In some cases, notably the ones with an ortho substituent in the aryl group, the product was an oil in which case separation was achieved by extraction into dichloromethane. Physical data of the products, i.e., yield, mp recrystallization solvent, and IR data, are listed in Table 6. Tables 7 and 8 contain lists of the ^{1}H and the ^{13}C NMR chemical shift data, respectively, with appropriate assignments, for the triazenes of series **6**. High-resolution EI mass spectral data of selected compounds of type **6** are given in Table 5.

Discussion

Bis-diazonium coupling of an arenediazonium salt with homopiperazine (1,4-diazepane) (**9**) proceeded smoothly in aqueous solution to afford good yields of the 1,4-di-[2-aryl-1-diazenyl]-1,4-diazepanes (**5**). These bis-triazenes are stable, crystalline solids (Table 1) that recrystallize readily

from ethanol or ethyl acetate or a mixture of the two, with the exception of the anthranilate derivative **5o**, which would not recrystallize. (Characterization of **5o** is based on NMR and mass spectral data of the crude compound.) Infrared spectra of the bis-triazenes confirmed the presence of the functional group X in the aryl moiety and also exhibited the appropriate out-of-plane (OOP) bending vibration band.

9 R = H

10 R = Me

Proton NMR spectra of the bis-triazenes (**5**) (Table 2) provide evidence for the characterization of these new compounds. The chemical shift of the four equivalent protons in the two-carbon spacer between nitrogens (H_a) occurs in the range 4.08–4.25 ppm. This observation correlates favourably with the chemical shift reported (2) for the methylene protons in bis-triazenes of type **4** and with the observed chemical shift (ca. 4.0 ppm) of the piperazine ring protons of the bis-triazene of type **7**.[3] The protons in the three-carbon spacer of the homopiperazine ring predictably give two signals at ca. 2.1 (H_b) and 4.0 (H_c), with a 1:2 integral ratio. However, the multiplicity of these signals is not evident in most spectra owing to line broadening; when the multiplicity is evident, e.g., in the spectra of **5j**, **5k**, and **5l**, the expected triplet–quintuplet pattern is evident. In several of these spectra, some chemical shifts are doubled, which suggests the existence of a mixture of conformational isomers.

The origin of the line broadening and frequency doubling in these proton spectra is probably a combination of conformational and rotational phenomena. The seven-membered homopiperazine ring could have numerous conformations, and it seems likely that the universal line broadening in the ^{1}H NMR spectra of series **5** is caused by the dynamic equilibrium between these conformations. However, the doubling of the NMR frequencies is most likely attributable to the restricted rotation around the N(2)–N(3) bond of the triazene moiety (10), resulting in the equilibrium shown in eq. [1]. This equilibrium is affected strongly by the nature and location of the substituent X in the aromatic ring, which would explain why the doubling of signals is more evident in the bis-triazenes with ortho substituents.

Table 3 shows the ^{13}C NMR data obtained for a number of the bis-triazenes of series **5**. Acquisition of the ^{13}C NMR data was severely limited by the low solubility of the bis-triazenes and by extreme broadening of the signals, presumably due to the combination of conformational and rotational phenomena referred to earlier. However, the chemical shift data are consistent within the series and in comparison with other triazenes. The observed chemical shift range of the ring carbon atoms (C1 and C2) adjacent to the triazene moiety is ca. 47 and 54 ppm. In the triazene of type **8**, the piperazine ring carbons adjacent to the triazene resonate at ca. 47 ppm (6), and in the bis(aryldiazenyl)piperazines (**7**), the piperazine ring carbons give a signal in the range 46–48 ppm.[4] The central carbon (C3) of the propane bridge in the ring of **5** resonates in the range 25–30 ppm, which seems appropriate for this chemical environment and is similar to the chemical shift (25 ppm) of the analogous carbon (C5) in the model triazene (**6**) (see Table 8). The ^{13}C NMR spectra of the bis-triazene of series **5** do show doubling of some signals, presumably due to the rotational equilibrium shown in eq. [1].

The speculation that two forms of the bis-triazene exist was confirmed by a variable-temperature NMR study with the *p*-cyano derivative **5a**. At 303 K, the ^{1}H spectrum of **5a** has broad signals at 2.13 (H_b) and 4.02 (H_c) ppm. As the temperature is lowered, these signals resolve at 283 K into two broad signals each; at this temperature the sharp signal at 4.18 ppm, assigned to the H_a protons, also resolves into two signals. At 263 K, the fine structure of the signals is evident; further lowering of the temperature to 243 K does not change the spectrum significantly. At 236 K, the 2.13 ppm signal of H_b resolves into a broad signal at 2.14 ppm and an apparent quintuplet at 2.29 ppm. The 4.02 ppm signal of H_c resolves into a triplet at 3.87 ppm (J = 6.0 Hz) and a quintuplet at 4.08 ppm (J = 5.7 Hz). The signal of the H_a protons resolves into two singlets of unequal intensity at 4.20 and 4.23 ppm. The aromatic signals resolve into a system with eight lines.

As part of the study of the characterization of the bis-triazene series **5**, it seemed appropriate to synthesize and characterize the simple triazene series **6**, to be used as model compounds. 1-Methylhomopiperazine (**10**) was coupled in a 1:1 molar ratio with a series of diazonium salts. The physical properties of the 4-methyl-1-(2-aryldiazenyl)-1,4-

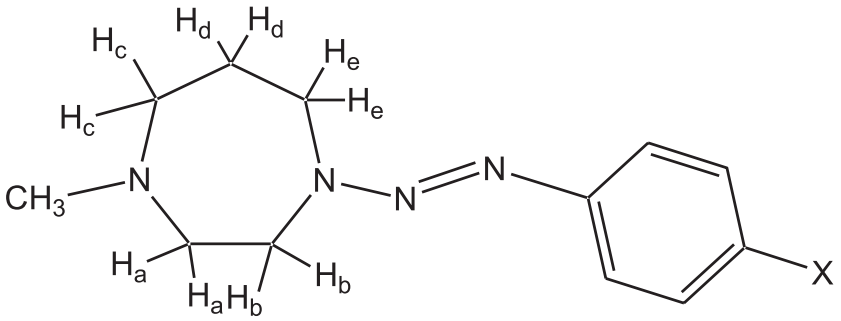
diazepanes (**6**) are listed in Table 6. Many of these products are oils, and the solid compounds are relatively low-melting materials, which recrystallize with difficulty from nonpolar solvents. On the other hand, the high level of solubility of these compounds made it possible to obtain good ^{13}C NMR spectra in concentrated solution in $CDCl_3$ using the SMU in-house low-frequency Anasazi EFT spectrometer.



The assignment of chemical shifts in the ^1H and ^{13}C NMR spectra of the triazene series **6** was made possible by analysis of several 2D NMR spectra of the *p*-cyano derivative (**6a**). Significantly, the signals at 2.72 and 4.17 ppm correlate with each other but not with any other signals. These signals can be assigned to the H_a and H_b protons, respectively, in the major rotamer of the mixture; the assignment of the lower-field 4.17 ppm signal to H_b instead of H_a is based on an intuitive consideration of its proximity to the triazene moiety. Also, the smaller signals at 2.81 and 3.93 ppm correlate only with each other, so these signals can be assigned to H_a and H_b, respectively, in the minor rotamer. It can also be seen that the signals at 2.09, 2.64, and 3.85 ppm correlate with each other and can be assigned to H_d, H_e, and H_c, respectively, in the major rotamer, again based intuitively on the proximity of the protons to the triazene moiety and the N1 nitrogen of the homopiperazine ring. That leaves the signals at 1.96, 2.63, and 4.09 ppm to be assigned to H_d, H_e, and H_c, respectively, in the minor rotamer. It should be noted that the contour plots for the 2.63 and 2.64 ppm signals are barely separated in the 2D spectrum.

The heteronuclear single quantum coherence (HSQC) spectrum of **6a** provides information about proton–carbon linkages and thereby provides a means of assigning the ^{13}C signals to respective carbons as shown in Table 8. In the major rotamer, the 2.09 ppm ^1H signal correlates with the carbon signal at 25.3 ppm, which thus can be assigned to C5. The 2.64 and 2.63 ppm signals of H_e correlate with both the 58.86 and 58.37 ppm carbon signals, so these carbon signals can be assigned to C4 in the major and minor rotamers, respectively. The signal of H_a at 2.72 ppm correlates with the 59.08 ppm carbon signal, which must be assigned to C2. Similar analysis assigns the signal at 54.8 ppm to C3 and at 49.0 to C6 in the major rotamer; the assignment of the ^{13}C signals of the minor rotamer follows a similar pattern. These results are surprising in that the low-field signals, 58.86 and 59.08 ppm, are assigned to the carbons *furthest away* from the triazene moiety. Intuitively, these signals would be assigned to the carbon adjacent to the electron-withdrawing triazene moiety, but these results and conclusions are consistent with a similar analysis of the piperazine series **8** (6), in which the higher-field carbon signal was assigned to the carbon atom adjacent to the triazene moiety.

Table 7 shows the complete chemical shift data from the ^1H NMR spectra of the triazene series **6**. The NMR spectra suggest very clearly that there are two different forms of these molecules, and, surprisingly, a complete set of signals is seen clearly for each form in the ambient temperature spectra. The two forms are present in unequal amounts; the ratio of the major to the minor form was estimated, by measurement of the relative heights of the peaks, to be about 2:1. In Table 7, the chemical shifts of the major form are presented in the top line of the entry for each compound, followed by those of the minor form in parentheses. The multiplicity of the signal is shown in the lower line of each

entry. In most of the compounds in the series, the methylene protons, H_a and H_b, appear as triplets with some line broadening and an unusual feature — the triplets are inside out; the inner peak is smaller than the outer peaks! This phenomenon is seen throughout the series from **6a** to **6o**; many of the triplets (multiplets) are inside out. An example of a spectrum of one of these triazenes (**6n**) is shown in Fig. 1.

The coupling constants of the homopiperazine ring protons in the triazenes (**6**) are in the range 3.8–4.6 Hz for J_{ab}, 4.9–5.2 Hz for J_{de}, and 5.8–6.2 Hz for J_{cd}. Analysis of these coupling constants confirmed the chemical shift assignments that were based on the 2D NMR spectrum and listed in Table 7. For example. in the spectrum of **6b** the 2.79 and 4.24 ppm signals have the same *J* value, i.e., 4.6 Hz; the minor peaks associated with these signals, 2.87 and 3.99 ppm, also have the same *J* value, 5.2 Hz. Careful measurement of these coupling constants corroborates the pairing of the signals from the major and the minor forms. For example, in the spectrum of **6b**, the 4.24 ppm major signal is paired with the 3.99 ppm minor signal, and not with the 4.13 ppm minor signal; the latter is correctly paired with the 3.88 ppm major signal.

The structures of several of the bis-triazene series **5** have been corroborated by elemental analysis (Table 4) and by high-resolution EI mass spectrometry (Table 5). Principal fragments in the mass spectra of **5** arise from cleavage of one of the *N*-aryldiazenyl bonds to give two fragments. All compounds showed molecular-ion peaks except **5b**, **5f,** and **5g**, but the observed fragments in the low-resolution spectra of **5b**, **5f,** and **5g** confirmed the structures. In the spectrum of **5b**, the base peak at *m/e* 150 is assigned to the fragment $O_2NC_6H_4N_2^+$, and the peak at *m/e* 247 is the mass of the *N*-(aryldiazenyl)homopiperazine fragment (less one H atom). Compound **5f** fragments in the same way to give fragments at *m/e* 148 and 245, and the sulfonamide **5g** gives fragments at *m/e* 184 and 283.

The X-ray crystal structure of the unsubstituted bis-triazene (**5k**) has been determined (11). The ORTEP diagram of this molecule is shown in Fig. 2. Full details of this structure will be published elsewhere.

Conclusion

The results reported in this paper, which is Part II of a new series (6), describe a new series of novel bis-triazenes (series **5**) and a new series of novel heterocyclic triazenes (series **6**). In the course of characterizing these two families of compounds, much has been learned about the spectroscopic correlation of the ring carbon atoms of the homopiperazine rings and of the protons attached to them. Together with the results reported in Part I, in which two series of *N*-aryldiazenylpiperazines were described (6), a significant body of knowledge is being established. The synthetic methodology is being laid as a foundation for future work, and a useful correlation of NMR spectroscopic chemical shifts (both ^1H and ^{13}C) is being established. This will provide a basis for future projects involving the synthesis of new analogues of these triazenes and bis-triazenes.

Using ellipsoids to model charge distributions in gas phase protein complex ion dissociation

Susan Csiszar and Mark Thachuk

Abstract: Gas phase protein complex dissociation was modelled using ellipsoids on which discrete charges were placed in randomly chosen charge sites. A number of sizes, shapes, orientations, and types of ellipsoids were considered. For each case, charge transfer parameters and electrostatic energies were calculated as a function of the fractional surface area. It was found that to within 10–15%, the charge on product ions after dissociation is distributed according to their fractional surface area. This can imply, for example, that in experiments measuring the dissociation of homodimers, charge asymmetries of greater than 10–15% in the product ions signal that one of the ions has greatly increased its surface area, such as would occur with unfolding. This assumes that proton transfer occurs on a timescale fast enough that the dissociation products adopt the minimum electrostatic energy configuration. Calculation of this energy shows that it is minimized when one or more of the monomers is in an extended conformation.

Key words: protein complex dissociation, ellipsoid charge model, charge asymmetry.

Résumé : On a développé un modèle de la dissociation d'un complexe de protéine, en phase gazeuse, en faisant appel à des ellipsoïdes sur lesquelles on a placé des charges ponctuelles sur des sites chargés choisis au hasard. On a considéré un certain nombre de tailles, formes, orientations et types d'ellipsoïdes. Dans chaque cas, on a calculé les paramètres de transfert de charge et d'énergies électrostatiques en fonction de la superficie de la surface fractionnaire. On a trouvé que, dans des limites allant de 10 à 15 %, la charge sur les ions produits après dissociation est distribuée suivant la superficie de leur surface fractionnaire. Par exemple, ceci pourrait impliquer que, dans des expériences de mesures de dissociation d'homodimères, la présence d'asymétries de charge supérieures à 10 à 15 % pourrait indiquer que la superficie de la surface d'un des ions a connu une forte augmentation, tel que cela se produit lorsqu'une protéine se déplie. Cette conclusion implique que le transfert de proton se produit à une échelle de temps qui est suffisamment rapide pour que les produits de dissociation adoptent une configuration d'énergie électrostatique minimale. Le calcul de cette énergie montre qu'elle est minimale lorsqu'un ou deux des monomères existe dans une conformation étendue.

Mots clés : dissociation d'un complexe de protéine, modèle avec charge éllipsoïdale, asymétrie de charge.

[Traduit par la Rédaction]

Introduction

The advent of electrospray ionization (1) has led to the development of numerous advances in mass spectrometry, and has allowed for the study of non-covalent complexes, especially those with biological significance (2–12). Recently, a series of experiments (13–21) have examined the dissociation of charged protein complexes in the gas phase, including the charge and mass distributions of the product ions. In several systems, it has been observed that charge distributions can be quite asymmetric. For example, Schwartz et al. (17) studied the streptavidin tetramer and found that the tetramer dissociation into monomer and trimer ions was favoured over the dissociation into two dimer ions, that is,

[1] $$[4M + 14H]^{14+} \rightarrow [M + 7H]^{7+} + [3M + 7H]^{7+}$$

in which 4M, 3M, and M represent the tetramer, trimer, and monomer, respectively, and *n*H represents the number, *n*, of protons bound to each species. This dissociation path is asymmetric in two ways; the masses of the two fragments are unequal and the charge distribution is also asymmetric in the sense that the monomer has a greater charge per mass than the trimer. Heck and co-workers (19) performed similar experiments on dimers and hence ensured the protein complex would dissociate into equal monomer fragments. Four different dimers were studied. They found that dissociation products of dimers of either *E. coli* Glyoxalase I or horse heart cytochrome *c* had quite asymmetric charges, while those of dimers of either human Galectin I or hen egg lysozyme were distributed symmetrically. Similar asymmetries have been observed with tetrameric avidin (16), tetramers of a variety of hemoglobins (16, 18), and pentamers of Shiga-like toxin I (20). Recently, Jurchen and Williams (21) have performed a series of sustained off-resonance irradiation collision activated dissociation (SORI-CAD) experiments in which several variables were systematically investigated. It was found for the dissociation of dimers of cytochrome *c* that the charge asymmetry in the products depends upon the initial charge state of the ion complex, with lower charges giving more asymmetry. As well, it was shown that dissocia-

 doi: 10.1139/V04-154 © 2004 NRC Canada

tions that occurred with higher internal energy (due to greater collision-induced heating) tended to give more symmetric dissociation products. The supposition from these experiments was that the dissociation occurs via a transition state that includes the unfolding of one of the monomers in the dimer. This was tested by examining complexes with varying degrees of conformational rigidity.

While the dissociation of these complexes involves many different time scales, and many types of interactions, one significant influence must be due to the Coulombic interactions of the charges present, since there is no surrounding medium to ameliorate them (as there would be in solution). The goal of the present work is to model these electrostatic interactions using discretely charged ellipsoids of varying shapes, sizes, and orientations.

This analysis was conducted for spheres with the charged droplet model (CDM) of Ryce and Wyman (22). The CDM models the fission of a spherical liquid drop into two droplets by considering the charge distribution among the two droplets. The CDM uses continuous charge distributions and assumes that charge transfer between the droplets can occur at any distance. Since the model considers the drop undergoing fission into two droplets connected by a thin bridge, charge can flow through this bridge between the droplets. The bridge is not explicitly modelled. A CDM has been formulated both with and without the explicit treatment of charge polarization. Essentially, for each droplet size and separation, the total energy, which is considered as the sum of the electrostatic energy and that due to surface tension, is minimized as a function of charge per droplet. The analysis produces analytic expressions for the fraction of charge associated with each child droplet.

When the CDM is applied to proteins, it fails to predict the observed results. Schwartz et al. (17) showed that the model agrees qualitatively with their results but not quantitatively, and Heck and co-workers (19) showed that the CDM does not agree at all with their results if one assumes that the dissociation produces equal mass fragments, for which case the charge distribution is predicted to be symmetric.

To refine somewhat the CDM, a new model is proposed here which approximates the nature of proteins more accurately, by using discrete charges and ellipsoidal shapes. Details of this model, and results of its predictions, are discussed in the following sections.

Results and discussion

Discretely charged ellipsoid model

In the discretely charged ellipsoid model (DCEM), the shapes of protein monomers are approximated as ellipsoids, both of the prolate and oblate varieties. Prolate or oblate ellipsoids are generated by rotating an ellipse about its major or minor axis, respectively. By varying the lengths of the major and minor axes, ellipsoids with many different sizes and shapes can be generated.

On each ellipsoid are placed a particular number of charge sites. These are randomly placed by choosing from a random number generator the spheroidal coordinates of each site. Two ellipsoids are placed in contact with a fixed relative orientation and size. Charges are then placed among the charge sites. Typically there are many more charge sites than charges. A computer program was written that recursively considers every possible charge arrangement and then finds the one with the lowest energy. This brute force approach guarantees that the absolute minimum energy configuration is always found. Unfortunately, no simple analytic expressions exist for charge distributions between ellipsoids. Even for ellipsoids with continuous charge distributions and restricted orientations, analytic expressions lead to complex formulae involving a series of elliptic integrals (23). For discrete charges, no simple expressions exist for the minimum charge distribution, not even for spherical systems. Thus, one is forced to adopt a completely numerical approach.

Note that only one charge is allowed per charge site, and that in the calculation of the electrostatic energy, a dielectric constant of unity is used, and thus the effect of differing dielectric constants within the body of the ellipsoid (protein) is not explicitly treated. This is not to imply that the protein would not affect the electrostatic energy calculation. A uniform dielectric constant would simply lead to an overall scaling of the energies, changing their absolute values but leaving their relative values the same. The difficulty is that the line of separation of some charges lies solely within one ellipsoid or another but there are others that lie between two different ellipsoids. These latter charges really do interact through free space. There should be, in principle, differing electrostatic energy factors depending upon the specific locations of the charges. This is a very complex calculation and it was not performed in the present case. For this reason, the calculated electrostatic energies should be used in a qualitative fashion with their absolute magnitudes being treated as upper limits to the true energies. However, their relative values should be more quantitative.

All charge sites are placed on the surface of the ellipsoid. While it is certainly the case in proteins that all protonation sites do not lie on the surface, the mechanism of the electrospray process tends to produce charges located there. As such, protonation sites that lie on the surface will tend to be protonated in preference to those buried within the core. However, even if a charge did become localized away from the surface, its effect could still be felt at the surface itself. Thus, in the DCEM, the surface charge sites could represent actual protonation sites, or may represent sites on the surface at which the effect of buried charges is most pronounced. For each fixed ellipsoid orientation and size, many instances of the energy minimization are performed each with differing randomly selected charge sites, and the resulting energies and charge distributions are averaged. By averaging over many different random configurations of charge sites, the dependence on this random choice should be minimized in the results. In most cases, 50 such initial configurations are used in the averaging process and, in most cases, the distributions are found to be quite narrow. In other words, the division of charge among the product ions depends only weakly on the particular location of the random charge sites, although the energy associated with this division can vary somewhat, depending upon the particular random distribution of charge sites.

In this particular study, the dissociation of two identical monomers is considered. So, the volume of each monomer is fixed to the same value, as is the number of charge sites on each. This again is a simplification of a true protein system

© 2004 NRC Canada

in which the volume and number of charge sites can vary with conformation. However, the charge asymmetries of the product ions in the DCEM were found to be only weakly dependent upon the volume and number of charge sites of the monomers.

In order to quantify the charge asymmetry, two parameters (charge transfer parameters) will be defined. The first is identical to that used by Ryce and Wyman (22), namely

$$[2] \qquad \varepsilon_V = g - f_V$$

in which the fractional charge g is defined as

$$[3] \qquad g = \frac{q_1}{q_1 + q_2}$$

with q_1 and q_2 being the charges on the product ions. The fractional volume f_V is defined as

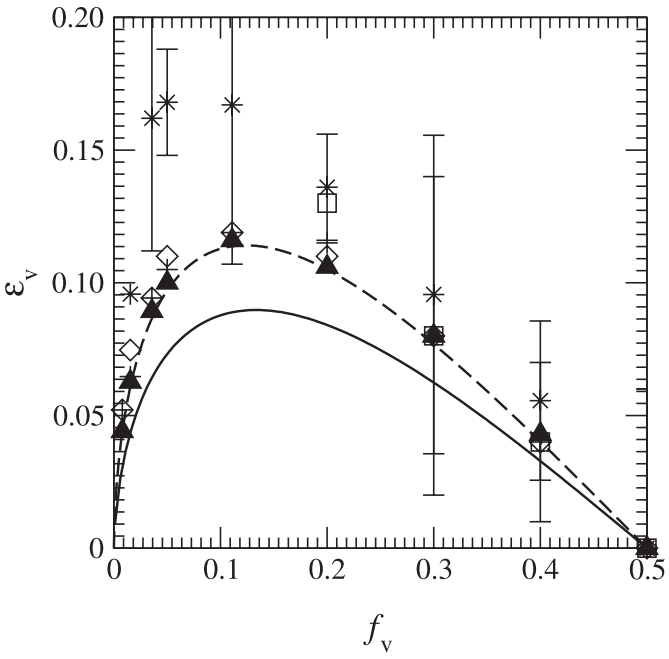
$$[4] \qquad f_V = \frac{r_1^3}{r_1^3 + r_2^3}$$

in which r_1 and r_2 are the radii of the product ions. The charge transfer parameter, ε_V, as defined above, is only valid for spheres since the expression for f_V is only valid in this case. For other shapes, one would have to properly determine the fractional volume of each product ion. The value of the ε_V gives a measure of the deviation of charge symmetry as compared with the fractional volume of the product ions. In other words, if the charges on the product ions are distributed in the same way as their volumes then the $\varepsilon_V = 0$. A non-zero value of the ε_V implies that one product has received more charge than would be expected from its fractional volume. If a uniform density is assumed between the precursor and product ions, then the fractional volume is synonymous with the fractional mass of each product ion.

In the DCEM, as in the CDM, all charges are located on the surface, so it is more relevant from a physical point of view to use surface charge densities when comparing different systems. In fact, for all the ellipsoids used in the present work, the volumes of each product ion are held fixed. All scenarios would then give $f_V = 0.5$ regardless of the shape or orientation of the ellipsoid. Clearly, in this case, the ε_V is not going to be a sensitive enough probe of charge asymmetry. Rather, an analogous parameter using surface area ratios is defined instead, that is

$$[5] \qquad \varepsilon_S = g - f_S$$

in which the fractional surface area f_S is defined as



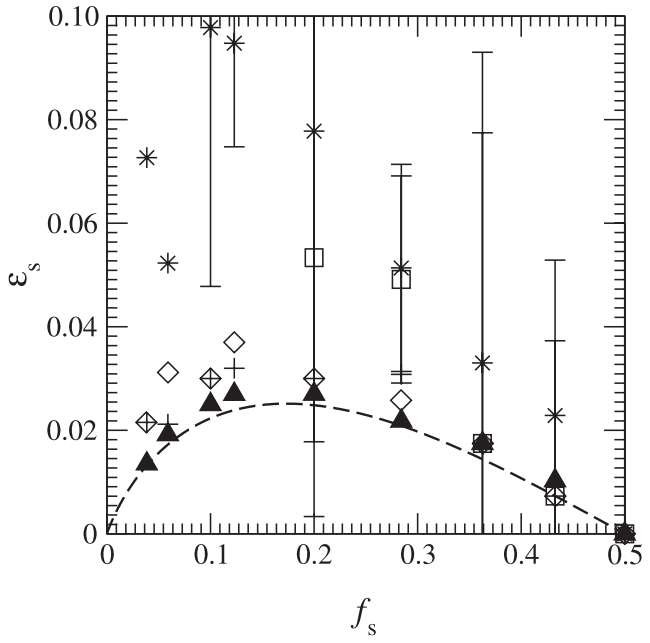
$$[6] \qquad f_S = \frac{S_1}{S_1 + S_2}$$

with S_1 and S_2 being the surface areas of the product ions. Unless otherwise stated, quantities with the subscript 1 will be associated with the product ion having the smallest volume and (or) surface area.

Spheres

Before considering the results for ellipsoidal systems, data was obtained for two spherical systems so that the DCEM and CDM results could be compared. The results of the comparison can be found in Figs. 1 and 2. A plot of the ε_V as a function of the fractional volume between two spheres that are touching is illustrated in Fig. 1, while in Fig. 2 the same results are expressed in terms of the surface area quantities, ε_S and f_S. All results are for touching spheres ($\alpha = 1$ in the notation of ref. 22).

Fig. 1. Plots of the charge transfer parameter, ε_V, as a function of the fractional volume, f_V, for two touching spheres. The solid line shows the prediction of the charged droplet model (CDM) with an approximation of uniform charge density. The dashed line gives the exact CDM prediction, including the effects of charge polarization. The results of the discretely charged ellipsoid model (DCEM) have 9 charges distributed among the two spheres. These DCEM results were determined in two ways; keeping the charge site density constant (stars) and varying the charge site density (open squares). The error bars represent the range of values possible as the location of the charge sites vary. The results of a dynamic model, which allows charge to move continuously on the surface of the sphere, are shown for 100, 200, and 1000 charges by open diamonds, pluses, and filled triangles, respectively.



The DCEM values were calculated with 9 charges distributed among the two spheres with 10 charge sites per sphere for the $f_V = f_S = 0.5$ data points. For the other points, two different sets of data were taken; one with a constant and one with a varying charge site density. In the former case, the number of charge sites per surface area was kept constant as the sizes of the spheres changed. In the latter case, the number of charge sites was increased linearly with the radius of the sphere.

Two curves representing the CDM results are also given. The solid line plots the prediction using the approximation that the surface charge density on each sphere is uniform. The dashed line plots the results for the exact electrostatic solution, thereby allowing for charge polarization effects. The difference between the solid and dashed lines then represents the change in charge transfer after the charges on

© 2004 NRC Canada

Fig. 2. Plots of the charge transfer parameter, ε_S, as a function of the fractional surface area, f_S, for two touching spheres. The symbols and error bars are defined as in Fig. 1.

each sphere are allowed to interact with each other and distort each other's charge distribution.

It is straightforward to show that the CDM with the approximation of uniform charge densities predicts that $\varepsilon_S = 0$ for all f_S in Fig. 2. The predictions for the exact solutions of the CDM are more subtle to obtain, especially in the case of two touching spheres, so this procedure will be briefly outlined below.

Following the notation of ref. 22, given a value of f_V or f_S, one can determine the value of λ which equals r_1/r_2. The value of g can be determined from eq. [20] of ref. 22, and is given by

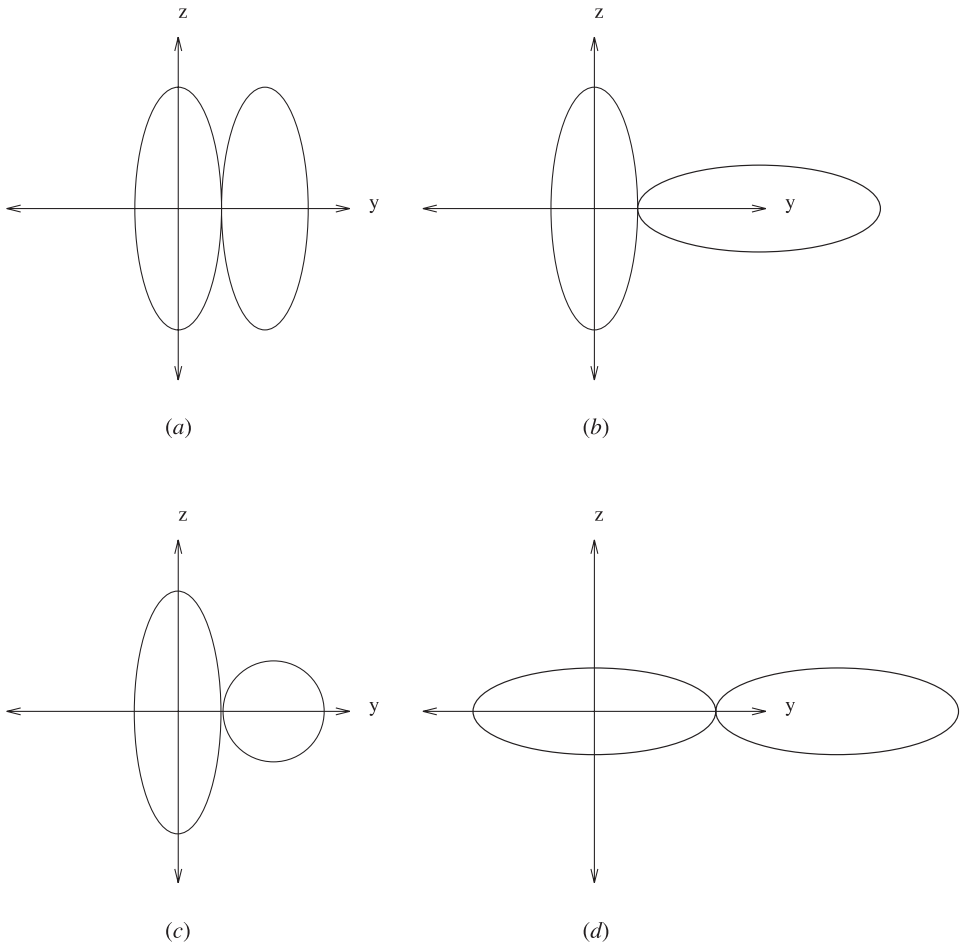
$$[7] \qquad g = \frac{1}{1 + \left(\frac{SU - T}{S - T}\right)}$$

We wish to determine the value of the right-hand side of eq. [7] in the limit of two touching spheres, namely $\alpha = 1$. In this limit, the values of β, μ, and μ' in ref. 22 all tend towards zero, and the expressions for S, U, and T that depend upon these parameters develop a singularity that must be removed by a proper limiting procedure. This is accomplished by expanding trigonometric hyperbolic functions in a Taylor series and retaining those terms involved with the singularity. When this is done consistently, the following results are obtained, namely

$$[8] \qquad \lim_{\beta \to 0} = \frac{1}{1+\lambda} \qquad \lim_{\beta \to 0} \frac{\mu'}{\beta} = \frac{\lambda}{1+\lambda}$$

$$[9] \qquad \lim_{\beta \to 0} (SU - T) = \frac{1}{\lambda} - \frac{\lambda}{(1+\lambda)^2} \quad \sum_{n=1}^{\infty} \frac{1}{n\left(n + \frac{\lambda}{1+\lambda}\right)}$$

$$[10] \qquad \lim_{\beta \to 0} (S - T) = 1 - \frac{1}{(1+\lambda)^2} \quad \sum_{n=1}^{\infty} \frac{1}{n\left(n + \frac{1}{1+\lambda}\right)}$$



The right-hand sides of eqs. [9] and [10] are well-behaved functions of λ that can be evaluated with known numerical routines. Substituting the results from eqs. [9] and [10] (which are only valid in the limit of two touching spheres) into eq. [7], and then employing eqs. [2] and [5] allows one to calculate the values for the dashed curves in Figs. 1 and 2.

The other three curves in Figs. 1 and 2 arise from a dynamic model. In order to investigate the effects of charge discreteness, many more charges were added to the system. Rather than use a brute force minimization method, for which the calculation time grows considerably with the number of charges considered, a new model was devised to determine the minimum energy charge configuration. This model works by restricting charges to the surface of the spheres and giving the charges an initial velocity and a drag force. The charges eventually come to rest when the drag force and electrostatic force balance each other. This gives the configuration with the minimum electrostatic energy. Studies were done with 100, 200, and 1000 charges distributed among the two spheres. With this dynamic model, the charges are allowed to move to any position on the surface of the sphere, so that explicit charge sites are not used. In principle, these results should then approach the exact CDM ones once the number of charges becomes sufficiently large to adequately approximate a continuous distribution. Examination of the results in Figs. 1 and 2 shows that indeed this is the case when 1000 charges are used.

A number of conclusions can be drawn from Figs. 1 and 2. First, in all cases, there is a positive charge transfer towards the smaller sphere, that is this smaller sphere should carry more charge than predicted simply by its fractional volume or surface area. Second, it is important to consider polarization effects when determining minimum charge configurations. These effects account in total for the non-zero values of the ε_S and about 20% or so of the value of the ε_V. Third, the values of the ε_S are uniformly smaller than the ε_V. This implies that generally speaking, the charges distribute themselves more according to the fractional surface area of the spheres rather than their fractional volume. This is to be expected since the charges in all cases are located on the surface. Thus, the ε_S is the preferred charge transfer parameter to use when examining charge configurations. Fourth, while the results for several hundreds of charges are essentially identical to the results for continuous charge distributions, this is not the case when only a few charges are present. Both figures show large fluctuations in the ε_V and ε_S for the DCEM results which use only 9 charges. These fluctuations arise simply from the discreteness of the charge and the configurational restrictions imposed by the location of charge sites. Great care should be taken when using models based on continuous charge distributions for predicting results when a small finite number of charges are involved. In other words, charge asymmetry can arise simply because a system has a small number of discrete charges restricted to a small number of charge sites.

Fig. 3. The four orientations studied for the ellipsoid geometries. Note: In orientation (*c*) the major axis of the ellipsoid to the right is perpendicular to the plane of the page.

Ellipsoids

Different types of systems can be studied by varying the shapes and the relative orientations of ellipsoids. The shapes of the ellipsoids can be varied in two ways. The relative lengths of the major and minor axes can be varied, or the ellipsoid can be changed from one type to another, that is from prolate to oblate or vice versa. All these variations were examined.

Figure 3 shows the four different relative orientations of each ellipsoidal system studied. This figure shows prolate ellipsoids explicitly. The orientations for oblate ellipsoids are analogous, except with the roles of the major and minor axes interchanged. Data was calculated for systems consisting of two prolate ellipsoids, two oblate ellipsoids, and two ellipsoids one of each type. For each of the systems consisting of two of the same ellipsoid type, data was calculated for the four orientations shown in Fig. 3. For the mixed systems, one of the types was never rotated while the other ellipsoid was rotated according to orientations (*a*) through (c). In all calculations, the ellipsoid on the left was always held fixed while the size of the ellipsoid on the right was varied to give differing f_S values. For all cases, the ellipsoids are positioned so that they touch at the points shown in Fig. 3.

The volumes of the ellipsoids were held fixed at 19 720.17 $Å^3$, even when their sizes were changed. This value was chosen to mimic horse heart cytochrome *c*. In general, ellipsoids have three axes. In the present work, the two smaller axes (the minor axes) were set to the same length. To obtain ellipsoids with the same volume but different surface areas, the ratio of the major to minor axis was first increased, and then their absolute values were adjusted to keep the ellipsoid volume constant. In other words, the relative shapes of the ellipsoids change in this process. All the ellipsoids have 15 charge sites and 11 charges are distributed among both of them. These numbers are of the same order of magnitude as those found for protein systems and, at the same time, are computationally viable. In the lower panels of Figs. 4–7 charge transfer parameters, ε_S, are plotted as a function of f_S for the orientations shown in Fig. 3 for four different ellipsoidal systems, corresponding to two prolate ellipsoids, two oblate ellipsoids, a constant oblate – varying prolate ellipsoid pair, and a constant prolate – varying oblate ellipsoid pair, respectively.

The values of the ε_S are negative in Figs. 4 and 6, indicating charge transfer to the ellipsoid whose surface area is increasing. In both these cases, this ellipsoid is of the prolate type. On the other hand, when an oblate ellipsoid is increasing in surface area, as in Figs. 5 and 7, the ε_S is positive, indicating charge transfer to the fixed ellipsoid (which is of the oblate type in one case, and prolate in the other). Thus,

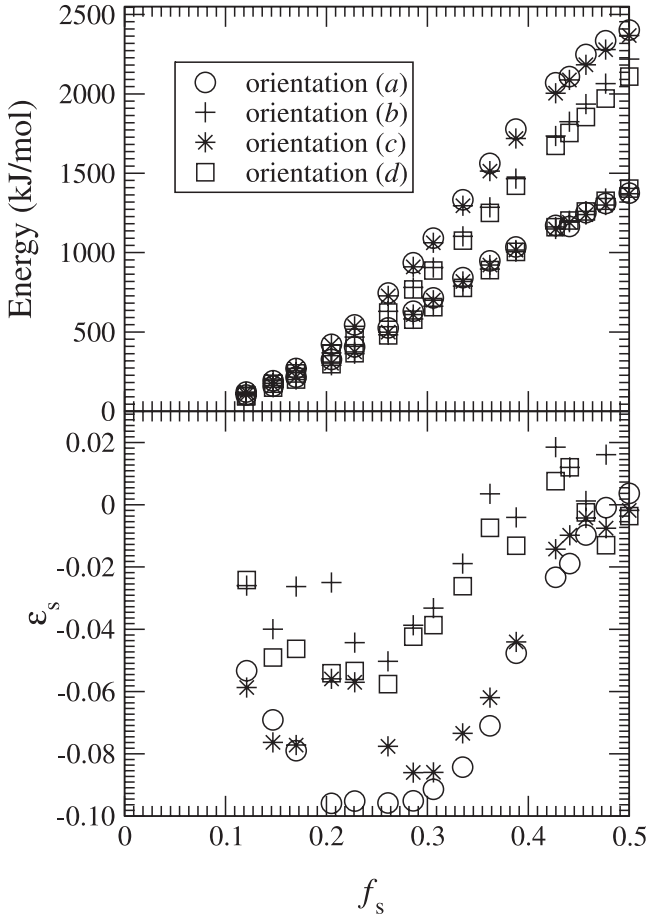
Fig. 4. Plots of electrostatic energy and ε_S as a function of the f_S for two prolate ellipsoids in contact, as predicted by the DCEM configured with 15 charge sites per ellipsoid and 11 charges in total distributed among the two ellipsoids. In the top panel, the upper points give the total electrostatic energy of the minimum energy configuration, while the lower points give the total interaction energy (that is the electrostatic energy due to charge pairs between ellipsoids). Results for orientations (*a*), (*b*), (*c*), and (*d*) (defined in Fig. 3) are given by open circles, pluses, stars, and open squares, respectively.



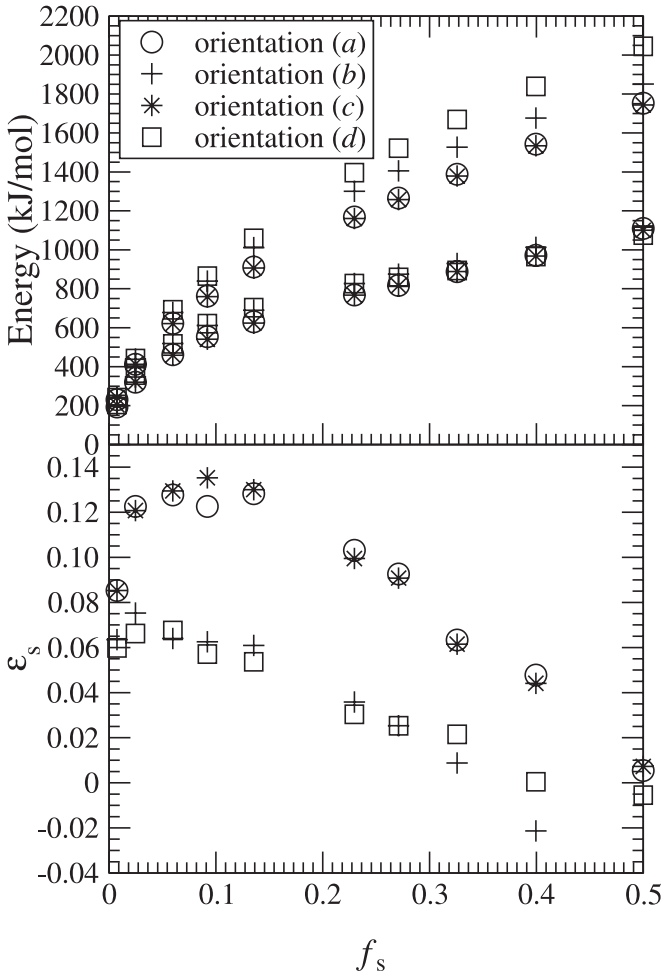


Fig. 5. The symbols are as defined in Fig. 4, except that these values correspond with two touching oblate ellipsoids.

the direction of the charge transfer depends upon the type of the ellipsoid with the larger surface area, not on the one with the smaller surface area. A larger prolate ellipsoid gains charge while an oblate ellipsoid loses charge, relative to its fractional surface area. For a fixed volume, in the way that the shapes of the ellipsoids were changed here, the larger prolate ellipsoids tend to be longer and pencil-like while the larger oblate ellipsoids tend to be flatter and disk-like. The longer shape of the prolate ellipsoid allows for greater separation of charges and hence charge transfer is favoured, as compared with the oblate ellipsoids.

Generally speaking, orientations (*a*) and (*c*) each produce about the same charge transfer and this is larger than orientations (*b*) and (*d*). This is expected because in orientations (*a*) and (*c*), the two ellipsoids are on average closer to each other than in orientations (*b*) and (*d*). This should lead to greater charge polarization in the former case, which as already seen in Figs. 1 and 2, leads to greater charge transfer. When the ε_S is negative, the maximum in charge transfer occurs when $f_S \approx 0.3$, while when the ε_S is positive, the maximum occurs when $f_S \approx 0.1$.

Two energies are plotted in the upper panels of Figs. 4–7. The uppermost points show the total electrostatic energy of the average minimum charge configuration. This energy was calculated by summing all the Coulombic pair interactions using a dielectric constant of unity. The lowermost points show the interaction energy between the ellipsoids, in other words, the sum of the pair interactions between charges on different ellipsoids. This interaction energy is the potential energy that would be available if the ellipsoids were separated to an infinite distance. The difference between these two sets of points is the self-energy of the ellipsoids, that is the Coulombic repulsive potential among the charges in each ellipsoid. This self-energy cannot be changed unless the shape of the ellipsoid changes, or charge transfer occurs.

Examining the upper panels in Figs. 4–7 shows a number of trends. First, although there is some variation in the total energy, there is essentially no variation in interaction energy with respect to the orientation of the ellipsoids. The differences in total energy arise solely from differences in the self-energies of each ellipsoid. However, there is substantial variation in interaction energy depending upon the type of

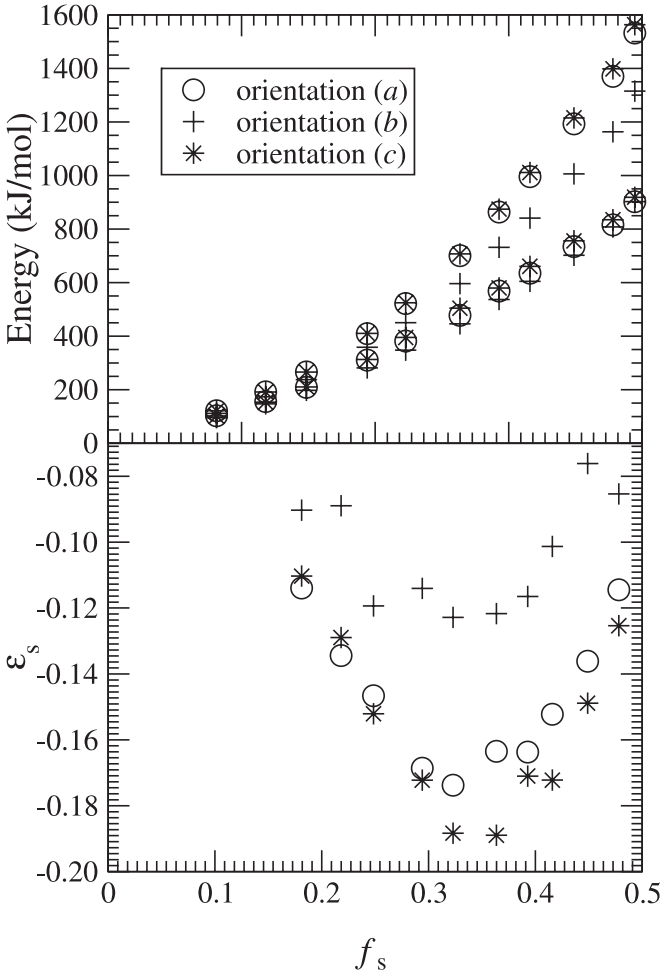
Fig. 6. The symbols are as defined in Fig. 4, except that these values correspond with two touching ellipsoids — the one on the left being oblate (with fixed dimensions) and the one on the right being prolate (with changing dimensions as reflected by the f_S).



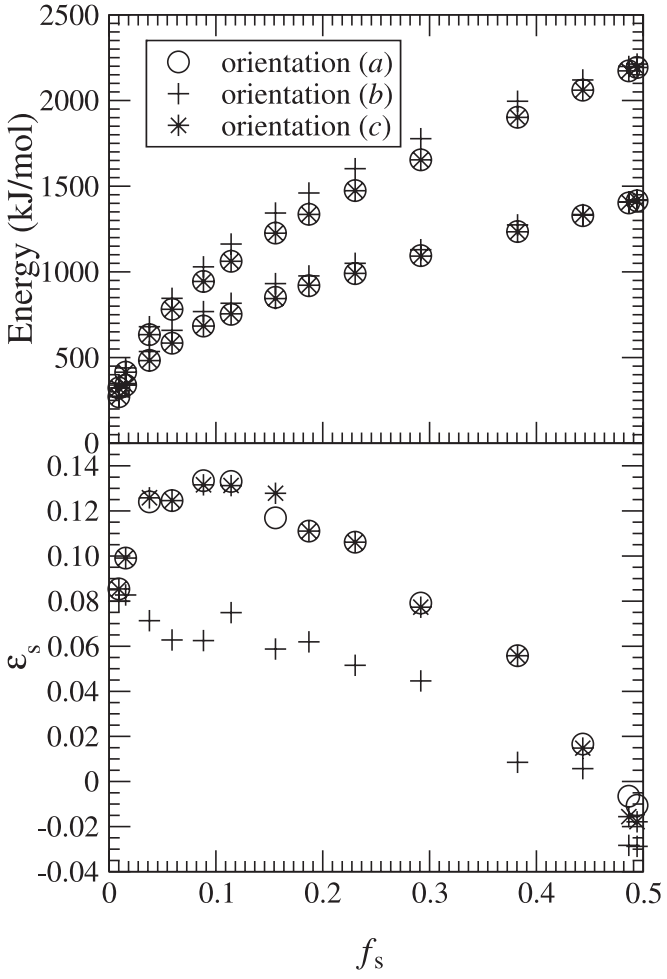


Fig. 7. The symbols are as defined in Fig. 4, except that these values correspond with two touching ellipsoids — the one on the left being prolate (with fixed dimensions) and the one on the right being oblate (with changing dimensions as reflected by the f_S).

ellipsoidal system. The highest interaction energies occur when the ellipsoid with the smaller surface area is prolate (Figs. 4 and 7). Interaction energies about 30% smaller occur when the ellipsoid with the smaller surface area is oblate (Figs. 5 and 6).

In all cases, the highest energies occur with $f_S = 0.5$, that is when both ellipsoids are the same. It is always energetically favourable for one ellipsoid to increase its surface area, thereby allowing lower energy charge configurations to become accessible. In principle, the energy would also be lower if both ellipsoids increased their surface areas, although this particular case was not calculated.

Application of the DCEM to protein complex dissociation

The DCEM describes the behaviour of discrete charges distributed among charge sites residing on the surface of ellipsoids of varying sizes and shapes. This is relevant to the dissociation of gas-phase protein complexes provided several assumptions are made.

The first assumption is that the mechanism for protonation of the complex always results in the lowest electrostatic energy configuration. This assumption is necessary because all the results presented here are for minimum energy charge configurations, that is charges that have been allowed to adopt the lowest energy configuration for a given set of charge sites. If intramolecular proton transfer occurs in the gas phase, and changes in a monomer occur during the dissociation process, then this assumption implies that the charges move to adopt the lowest energy configuration, even when conformation changes occur. On the other hand, if charges remain fixed on charge sites, then this assumption implies that the positions of these charges, (for example, determined during the electrospray process) are in the minimum energy configuration. A variety of intermolecular proton exchange mechanisms have been proposed in the gas phase (24). Some of these may be relevant for intramolecular proton exchange if appropriate conformational changes occur in a monomer or between monomers in a complex. Gas phase hydrogen/deuterium exchange experiments on cytochrome *c* have indicated that protons are mobile on the protein (25–27). Other experiments have shown that proton transfer can depend and be sensitive to experimental conditions (14, 28).

© 2004 NRC Canada

The second assumption is that the Coulomb interactions dominate the energetics in the dissociation process. Clearly, many types of interactions are present in protein complexes, and the electrostatic contributions considered here form one part of these. Some calculations (29, 30) have indicated that this assumption becomes more valid the larger the charge on the complex. However, it is also known that the dissociation process must overcome an activation barrier. Arrhenius parameters have been determined experimentally for several systems (20, 31) and indicate that dissociation is accompanied by large entropy changes, as would be present if part of the complex moved to a more extended configuration.

To the extent that these two assumptions are valid, several conclusions can be drawn. First, because the values of the ε_S were always less than about 0.1–0.15, it follows that to within about 10–15%, regardless of the particular shape or orientation of monomers in a protein complex, the fractional charge of a product ion is the same as its fractional surface area. Recall that the charge transfer parameters measure the deviation from this balance. In other words, if the dissociation of a homodimeric complex occurs with charges on the product ions that differ from each other by more than 15%, then one of the product ions increased its surface area. The greater the charge difference between the products, the greater the change in surface area that must have resulted.

This is consistent with the supposition of Jurchen and Williams (21) who propose that protein unfolding must accompany complex dissociation when the charges produced are asymmetric. Such unfolding greatly increases the surface area of one of the product ions. Note that this charge asymmetry can occur only if one, not both, of the monomers unfolds.

Similarly, if a multimeric complex dissociates into a monomer and a remaining complex, each carrying away equal charges, then the current results imply that the surface area of the monomer and remaining complex must be approximately equal, that is the monomer must undergo conformational changes that greatly increase its surface area. In all these cases, the product with the greater surface area carries the larger charge. In this context, surface area refers to the area of a convex surface that would encase a protein complex or monomer. This conclusion is consistent with the electrostatic Coulombic repulsion energy calculations of Klassen and co-workers (20) for B_5^{n+} ions of Shiga-like toxin I. They showed that while it is energetically unfavourable to charge enrich one monomer in the complex, such an enrichment could be driven by entropy resulting from conformational changes in the monomer, such as unfolding. This enrichment essentially transfers a significant amount of the Coulombic repulsion into intermolecular repulsion between the monomer and remaining complex, thereby favouring loss of the monomer and leaving the remaining complex with a greatly reduced intramolecular electrostatic repulsion.

At a finer level, conclusions are more speculative. Generally speaking, a value of the ε_S determined from experimental measurements would probably have errors comparable to the values seen in Figs. 4–7, so that in practice it will be difficult to extract any information about the relative orientations of the units in the complex. The sign of the ϵ_S appears to be more robust, indicating that greater charge asymmetries are possible if the larger ion is prolate shaped, as opposed to oblate shaped. However, the energetics of a particular scenario may not necessarily favour this degree of charge asymmetry. These results then imply that the energetics and charge asymmetry in complex ion dissociation depend only weakly on the relative orientations or shapes of the component monomers.

These results also indicate that fractional surface areas should be the preferred physical parameter to use when evaluating charge asymmetries, rather than fractional volumes. This follows mainly from the observation that at close distances, charges tend to distribute themselves more according to surface area than volume.

Second, the unfolding of a monomer and the resulting charge redistribution is greatly favoured energetically. Even considering the rather crude energy calculations presented in Figs. 4–7, many hundreds of kJ/mol of potential energy are available to help the system move towards the state where at least one of the products is unfolded to give a greater surface area. For the dissociation of a homodimer, the unfolding of both monomer units would in turn produce an even lower electrostatic energy, although the DCEM would predict a symmetric charge distribution in this case. Thus, if asymmetric charge distributions are observed, the DCEM would predict the unfolding of only one of the monomer units in this case.

While the DCEM can be used to explain some aspects of the dissociation of gas phase protein complexes, it provides only static information. In particular, it contains no dynamic information and is not able to address any questions concerning the manner in which the complex moves from one configuration to another, or how the unfolding of one monomer unit might be coupled with the dissociation of the complex. For example, whether monomer unfolding occurs prior to charge transfer, or concomitant with charge transfer cannot be distinguished. It also does not address any kinetic barriers that might exist between different states.

However, the goal of the DCEM is not to fully explain protein dissociation events but rather to provide a model for understanding the electrostatic interactions in such events at a level of description that is closer to reality than spherical models, such as the CDM. While the DCEM can provide some insight into the dissociation mechanism of protein complexes in the gas phase, more refined protein models are needed. Such models are currently being developed in our group to address dynamic issues.

A novel unexpected two-dimensional layer-like luminescent dysprosium coordination polymer $[Dy_2(phth)_3H_2O]_n$ by hydrothermal synthesis

Yi-Shan Song, Bing Yan, and Zhen-Xia Chen

Abstract: Assembling potassium acid phthalate (KHphth) and dysprosium nitrate, a novel luminescent two-dimensional layer-like dysprosium coordination polymer with the formula $[Dy_2(phth)_3H_2O]_n$ has been synthesized by a hydrothermal process. It is unexpected that the complex exhibits a new coordination mode with phthalate and an asymmetrical structure for the two dysprosium fragments in the molecular unit. The title coordination polymer crystallizes in the monoclinic system, space group $P2_1/c$, with lattice parameters a = 7.913(2) Å, b = 26.360(7) Å, c = 11.563(3) Å, β = 106.864(3)°, V = 2308.3(11) Å^3, D_c = 2.404 Mg/m^3, Z = 4, $F(000)$ = 1576, GOF = 1.079, R_1 = 0.0282. The luminescence spectrum shows that the blue emission intensity of the $^4F_{9/2} \rightarrow {}^6H_{15/2}$ transition is stronger than the yellow emission intensity of the $^4F_{9/2} \rightarrow {}^6H_{13/2}$ transition.

Key words: dysprosium (III), two-dimensional layer-like coordination polymer, molecular structure, luminescence, hydrothermal synthesis.

Résumé : L'assemblage du phtalate acide de potassium (KHphth) et du nitrate de dysprosium par un procédé hydrothermique conduit à la synthèse d'un nouveau polymère luminescent de coordination du dysprosium, à couche bidimensionnelle, de formule $[Dy_2(phth)_3H_2O]_n$. Il n'était pas prévu que ce complexe présenterait un nouveau mode de coordination avec le phtalate et une structure asymétrique comportant deux fragments de dysprosium par unité moléculaire. Le polymère de coordination mentionné dans le titre cristallise dans le système monoclinique, groupe d'espace $P2_1/c$, avec a = 7,913(2) Å, b = 26,360(7) Å et c = 11,563(3) Å, β = 106,864(3)°, V = 2308,3(11) Å^3, D_c = 2,404 Mg/m^3, Z = 4, $F(000)$ = 1576, GOF = 1,079 et R_1 = 0,0282. Le spectre de luminescence montre que l'intensité de l'émission dans le bleu de la transition $^4F_{9/2} \rightarrow {}^6H_{15/2}$ est plus grande que celle de l'émission dans le jaune de la transition $^4F_{9/2} \rightarrow {}^6H_{13/2}$.

Mots clés : dysprosium(III), polymère de coordination à couche bidimensionnelle, structure moléculaire, luminescence, synthèse hydrothermique.

[Traduit par la Rédaction]

Introduction

In the past few decades, lanthanide complexes have received much attention because of their interesting photophysical properties, which have potential application in the active centers for luminescent materials or in luminescent probes for chemical or biological macromolecules (1–6). Consequently, considerable studies have been focused on the design and assembly of lanthanide complexes with organic ligands such as aromatic carboxylic acids, β-diketones, cryptands, calixarenes, and heterocyclic ligands. Especially the lanthanide complexes with aromatic carboxylic acids readily form dimeric or infinite-chain polymeric structures, which show higher thermal or luminescent stabilities for practical application than other lanthanide-complex systems (7–10). Among the various types of carboxylic acids, benzenedicarboxylate dianions are widely used in the construction of coordination polymers owing to their capability of acting as bridging ligands in various coordination modes (11).

Many coordination polymers of lanthanides with benzenedicarboxylate ligands such as phthalates as bridging groups between metal centers have been reported, and there has been much interest in the preparation of lanthanide aromatic carboxylates under hydrothermal conditions (12–22). In the work reported in this paper, we synthesized a novel dysprosium coordination polymer, $[Dy_2(phth)_3H_2O]_n$ (phth = phthalate), by a hydrothermal process and studied its photophysical properties. Unexpectedly, we found a new coordination mode of phth anions in the structure, which leads the title complex to form a novel two-dimensional layer-like structure. In addition, the dysprosium coordination polymer exhibits strong luminescence of Dy^{3+}.

Experimental

Synthesis of $[Dy_2(phth)_3H_2O]_n$

Aqueous solutions of $Dy(NO_3)_3{\cdot}6H_2O$ (139 mg, 0.3 mmol) and KHphth (61 mg, 0.3 mmol) were mixed in 10 mL of deionized water. After stirring for 30 min, the mixture was placed in a 25-mL Teflon-lined reactor and heated at 160 °C in an oven for 3 days. Upon slow cooling to room temperature, pillar-like crystals of the title complex suitable for X-ray diffraction analysis were obtained. Anal calcd. (%) for $C_{24}H_{14}Dy_2O_{13}$: C 34.48, H 1.68; found: C 35.69, H 1.52. IR data: 1414.9 cm^{-1} ($\nu_s COO^-$), 1541.5 cm^{-1} ($\nu_{as} COO^-$).

X-ray crystallography

X-ray diffraction data were obtained for a crystal with dimensions 0.15 mm × 0.05 mm × 0.03 mm on a CCD area detector four-circle diffractometer with graphite-monochromated MoKα radiation. The data were collected by the ω–2θ scan technique. The structure was solved by direct methods. All non-hydrogen atoms were refined anisotropically by full-matrix least-squares methods. The hydrogen atoms were added geometrically and not refined. The final *R* and R_w were 0.0404 and 0.1016, respectively. All calculations were performed using SHELXS-97 and SHELXL-97 (23, 24). Details of data collection and refinement are given in Table 1. Atomic coordinates and selected interatomic distances and angles are presented in Tables 2 and 3, respectively. Full crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited as Supplementary material.[2]

[2] Supplementary data may be purchased from the Directory of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically). CCDC 225117 contains the crystallographic data for this manuscript. These data can be obtained, free of charge, via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, U.K.; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

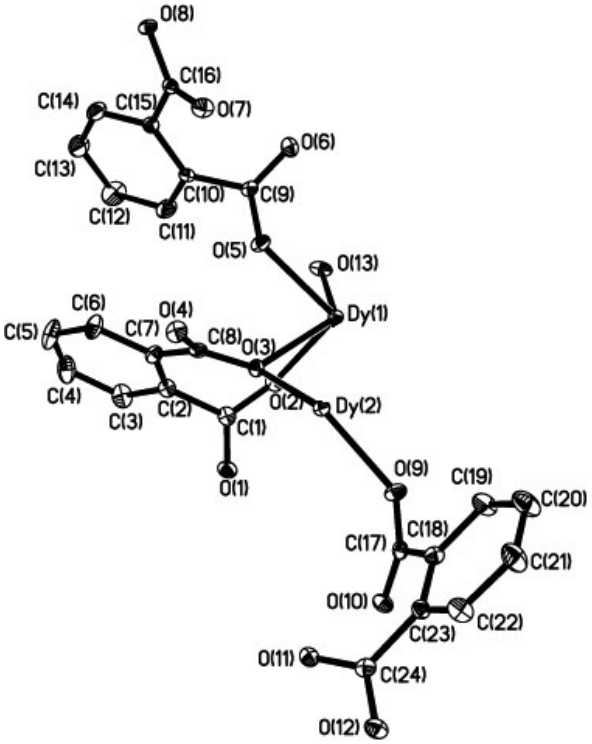
Note: Symmetry transformations used to generate equivalent atoms: for #1, $-x + 2$, y, $-z + 3/2$; for #2, $-x + 2$, $-y$, $-z + 2$; for #3, x, $-y$, $z - 1/2$; for #4, $x + 1$, y, z; for #5, x, $-y + 3/2$, $z - 1/2$; for #6, $x - 1$, $-y + 3/2$, $z - 1/2$.

Physical measurements



Elemental analyses (C, H, N) were determined on an Elementar Cario EL elemental analyzer. Infrared spectroscopy on KBr pellets was performed on a Nexus 912 AO446 FT-IR spectrophotometer in the range of 4000–400 cm^{-1}. Low-temperature luminescence (excitation and emission) spectra (77 K) for a solid sample of the title complex were measured with a Perkin-Elmer model LS-55 spectrophotometer.

Results and discussion

The asymmetric unit of the title complex, shown in Fig. 1, contains two dysprosium ions. X-ray diffraction crystal structure analysis reveals that it leads to a two-dimensional layer-like structure with the formula $[Dy_2(phth)_3H_2O]_n$. There are two types of metal environment in the structure of the title complex. The Dy(1) ion is eight-coordinated by eight oxygen atoms from five phth anions and has one coordinated water molecule, and the coordination geometry can be described as a distorted square monoantiprism geometry (Fig. 2*a*). The Dy(2) ion is nine-coordinated by nine oxygen atoms from six phth anions, and the coordination geometry can be described as a tricap-trigonal prism geometry (Fig. 2*b*). The distance between the Dy(1) ion and the Dy(2) ion is 3.7208(7) Å. It is interesting that a water molecule is coordinated only to the Dy(1) ion. In the coordination envi-

ronment of Dy(1), four oxygen atoms (O2, O3, O10, O11) from two phth anions are bound to the Dy(1) ion, among which the two pairs of chelating oxygen atoms (O2 and O3, O10 and O11) each come from different carboxylate groups of one phth anion. The distance between the Dy(1) ion and these oxygen atoms ranges from 2.256(3) to 2.502(3) Å, and the bond angle consisting of Dy(1) and the oxygen atoms from one phth anion are 70.38(11)° and 69.17(11)°, respectively. In addition,, three oxygen atoms (O4, O5, O8) from three chelating phth anions are bound to the Dy(1) ion, with the distance between Dy(1) and these oxygen atoms ranging from 2.271(3) to 2.365(3) Å, and there is one coordinated oxygen atom from the water molecule (O13), with the Dy(1)—O(13) distance being 2.366(4) Å. The average Dy(1)—O distance bond is 2.360 Å. In the coordination environment of Dy(2), six oxygen atoms (O1, O2, O7, O8, O11, O12) from three phth anions are bound to Dy(2), among which each pair of chelating oxygen atoms (O1 and O2, O7 and O8, O11 and O12) comes from the same carboxylate group. The distance between Dy(2) and these oxygen atoms ranges from 2.388(3) to 2.909(4) Å, and the bond angle consisting of Dy and the oxygen atoms from one phth anion ranges from 47.47(11) to 52.68(11)°. In addition, three oxygen atoms (O3, O6, O9) from three chelating phth anions are bound to the Dy(2) ion, with the bond distance ranging from 2.218(4) to 2.377(3) Å. The average Dy(2)—O bond distance is 2.456 Å, which is longer than the average Dy(1)—O bond distance. The reason is essentially that the chelating oxygen atoms belong to one carboxylate group, which prolongs the distances of the coordination bond.

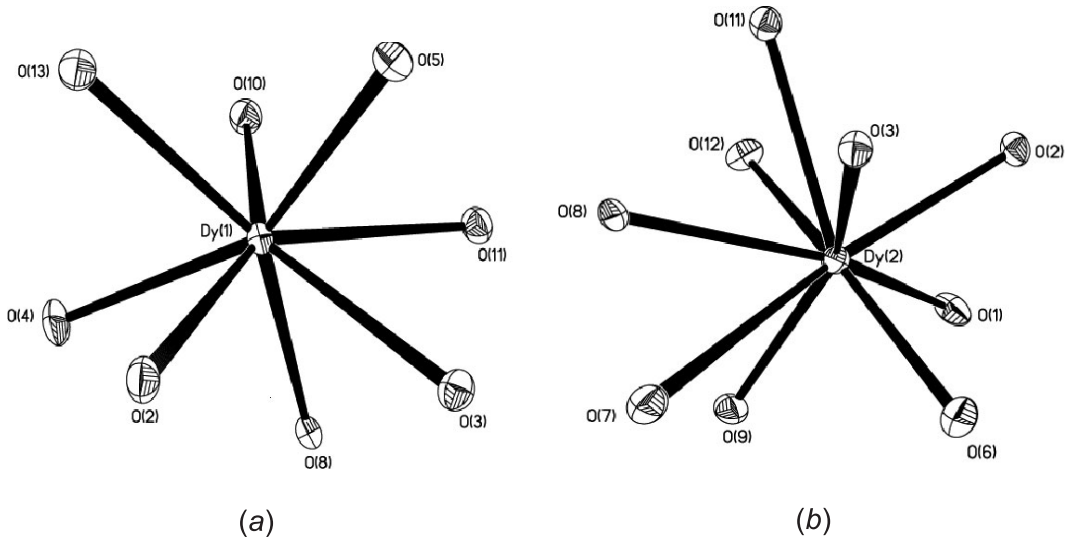
All phth anions are completely deprotonated, and all the oxygen atoms take part in the coordination to the central metal. It can be considered that three phth anions are present in one unit of $[Dy_2(phth)_3H_2O]_n$, and it is noteworthy that they coordinate to the Dy ions in three different modes (Scheme 1):

(*a*) Bridging/chelating pentadentate and chelating monodentate (Scheme 1*a*): Oxygen atom 2 and oxygen atom 3 bridge three central metals (Dy1, Dy2, Dy2#). Dy1 and Dy2 are in one asymmetric unit, and Dy2# is in another unit, which has the same coordination environment as Dy2. In addition, oxygen atom 1 and oxygen atom 2 chelate Dy2#, while oxygen atom 4 is coordinated to Dy1#.

(*b*) Bridging/chelating tridentate and chelating bidentate (Scheme 1*b*): Oxygen atom 7 and oxygen atom 8 chelate/bridge Dy1 and Dy2, while oxygen atom 5 and oxygen atom 6 are connected to Dy1# and Dy2#, respectively.

(*c*) Bridging/chelating tetradentate and chelating monodentate (Scheme 1*c*): Oxygen atom 10, oxygen atom 11, and oxygen atom 12 chelate/bridge Dy1 and Dy2, while oxygen atom 9 is coordinated to Dy2#.

From Scheme 1, we can see that three units are bridged in coordination modes (*a*) and (*b*), while two are bridged in mode (*c*). To our knowledge, coordination modes (*b*) and (*c*) have been seldom reported, and coordination mode (*a*) has never been observed in ref. 9. All coordination modes of phth anions result in a two-dimensional layer structure (Fig. 3). Consequently, the three oxygen atoms O3, O8, and O11 actually link two dysprosium ions of one unit, and only O(2) bridges dysprosium ions of adjacent units; the other oxygen atoms use the chelating monodentate mode.



The carboxylic group forms one type of intermolecular hydrogen bond, which is the O(13)—H(13A)···O(7)#2 or O(13)—H(13B)···O(11)#7 intermolecular hydrogen bonding between the oxygen atoms of the bridged phth ligands and the oxygen atoms of the coordinated water molecules in the adjacent layers. Distances and angles of these hydrogen bond interactions are presented in Table 4. Such intermolecular hydrogen bonding links the adjacent layers, and, accordingly, a three-dimensional network (Fig. 4) is established and stabilizes the whole structure.

The UV–vis absorption spectrum for the title complex in water (10^{-4} mol L^{-1}) exhibits dominant absorption peaks in the narrow UV region between 200 and 330 nm, and the maximum absorption peaks are located at around 297 nm, which can be attributed to the characteristic absorption of the H_2phth ligand. The results indicate that H_2phth is the energy donor and luminescence sensitizer of the Dy^{3+} ion.

The phosphorescence spectrum of the title complex was measured (Fig. 5). From the phosphorescence emission, it is indicated that three apparent phosphorescence bands appear and the maximum phosphorescence wavelengths are at 402 and 415 nm, which correspond to the characteristic 0–0 and 0–1 transitions of the H_2phth ligand. The shortest wavelength of the phosphorescence emission band is assumed to be the 0–0 transition, so the energy of the lowest triplet state of H_2phth can be determined to be 24 875 cm^{-1}. The energy difference between this triplet state and the emitting levels of Dy^{3+} (20 875 cm^{-1}) was calculated to be 4000 cm^{-1}. According to the energy transfer and intramolecular energy mechanism (25–27), it can be predicted that the triplet-state energy of H_2phth is more suitable for the luminescence of the dysprosium ion.

the five different excitation wavelengths, and they showed similar emission position, except for some slight differences in luminescent intensities. This indicates that the five excitation bands are all the effective energy excitation for the luminescence of Dy^{3+} ions. The emission spectrum of the title complex exhibits two apparent emission bands under 241-nm excitation (Fig. 6), and the maximum emission wavelengths are at around 480 and 572 nm, respectively, which are attributed to the characteristic emission for $^4F_{9/2} \rightarrow {}^6H_J$ (J = 15/2, 13/2) transitions of the Dy^{3+} ion. The luminescence spectrum shows that the blue emission intensity of the $^4F_{9/2} \rightarrow {}^6H_{15/2}$ transition is stronger than the yellow emission intensity of the $^4F_{9/2} \rightarrow {}^6H_{13/2}$ transition.

Scavenging of photogenerated singlet molecular oxygen and superoxide radical anion by sulpha drugs — Kinetics and mechanism

Marta Díaz, Marta Luiz, Sonia Bertolotti, Sandra Miskoski, and Norman A. García

Abstract: The ability of the sulfanilic antibiotics (SDs), dapsone (DAP), sulfisoxazole (SFX), sulfadiazine (SFD), and sulfanilic acid (SFNA) to act as scavengers of the visible-light-photogenerated species superoxide radical anion ($O_2^{\bullet-}$) and singlet molecular oxygen ($O_2(^1\Delta_g)$) was studied employing the natural pigment riboflavin (Rf) and the artificial dye Rose Bengal as photosensitisers. A complex mechanism, common to all the SDs studied, was elucidated through stationary photolysis, polarographic detection of oxygen uptake, fluorescence spectroscopy, time-resolved phosphorescence detection of $O_2(^1\Delta_g)$, and laser flash photolysis. Visible-light irradiation of aqueous and aqueous methanolic solutions of Rf (ca. 0.02 mmol/L) plus SD (ca. 0.5 mmol/L) photogenerated excited singlet and triplet Rf (^{1}Rf* and ^{3}Rf*). Under these experimental conditions, only ^{3}Rf* is quenched either by oxygen, giving rise to $O_2(^1\Delta_g)$ by electronic energy transfer to dissolved ground-state oxygen, or by SD, yielding semireduced Rf through an electron-transfer process. Complementary experiments performed in pure water employing superoxide dismutase and sodium azide inhibition of oxygen uptake, in parallel with laser flash photolysis data, showed that $O_2^{\bullet-}$ is also formed, probably due to the reaction of the anion radical from Rf with dissolved oxygen, yielding also neutral, ground-state Rf. Both active oxygen species, namely, $O_2^{\bullet-}$ and $O_2(^1\Delta_g)$, are quenched by the SDs and, as a result, photodegradation of the SDs — each to a different extent — and photodegradation of the sensitiser itself were observed. The SDs that kinetically behave as the better physical quenchers of $O_2(^1\Delta_g)$, which are in principle good candidates as photoprotectors, namely, DAP and SFD, suffer photooxidation, exhibiting high to moderate oxygen consumption rates due to the $O_2^{\bullet-}$ oxidative pathway, whereas for SFNA and SFX, oxidation predominantly occurs through an $O_2(^1\Delta_g)$-mediated mechanism. Microbiological results for SFX, taken as a representative SD, indicate that the photodegradation of the drug, upon visible-light Rf-sensitised irradiation, is accompanied by a net loss in bacteriostatic activity.

Key words: photooxidation, singlet oxygen, superoxide radical anion, sulpha drugs.

Résumé : Utilisant comme sensibilisateur la riboflavine (Rf), un pigment naturel, et le Rose du Bengale, un colorant artificiel, on a étudié les possibilités des antibiotiques sulfaniliques (« SD »), soit dapsone (DAP), sulfisoxazole (SFX), sulfadiazine (SFD) et l'acide sulfanilique (SFNA), à agir comme pièges pour l'anion radical du superoxyde ($O_2^{\bullet-}$) et l'oxygène moléculaire ($O_2(^1\Delta_g)$), des espèces photogénérées par la lumière visible. On a élucidé le mécanisme complexe, commun pour toutes les espèces « SD » étudiées, par le biais de la photolyse stationnaire, de la détection polarographique de l'absorption d'oxygène, de la spectroscopie de fluorescence, de la détection de la phosphorescence résolue en fonction du temps du $O_2(^1\Delta_g)$ et de la photolyse éclair au laser. L'irradiation, à l'aide de lumière visible, de solutions aqueuses et méthanoliques aqueuses contenant environ 0,02 mmol/L de riboflavine et environ 0,5 mmol/L de « SD » conduit à la photogénération des états singulet et triplet excités de la riboflavine (^{1}Rf* et ^{3}Rf*). En travaillant dans ces conditions expérimentales, seul l'état triplet ^{3}Rf* est désactivé soit par l'oxygène, conduisant à $O_2(^1\Delta_g)$ par un transfert d'énergie électronique vers l'oxygène à l'état fondamental dissous, ou par les « SD », conduisant à une riboflavine partiellement réduite par le biais d'un processus de transfert d'électron. Des expériences complémentaires, effectuées dans de l'eau pure en utilisant de la dismutase de superoxyde et de l'azoture de sodium pour inhiber l'absorption de l'oxygène et en parallèle avec des données de photolyse éclair au laser, ont permis de montrer qu'il se forme aussi du $O_2^{\bullet-}$, probablement par la réaction de l'anion radical de la riboflavine avec de l'oxygène dissous, qui conduit aussi à la formation de riboflavine neutre, dans son état fondamental. Les deux espèces actives, soit le $O_2^{\bullet-}$ et le $O_2(^1\Delta_g)$, sont désactivées par les « SD » et il en résulte une photodégradation des « SD », chacun à un degré différent, ainsi qu'une photodégradation du sensibilisateur. En raison de la voie oxydante du $O_2^{\bullet-}$, les dérivés qui d'un point de vue cinétique sont les meilleurs désactivateurs physiques du $O_2(^1\Delta_g)$, soit DAP et SFD, et qui pourraient éventuellement être les meilleurs photoprotecteurs subissent des photooxydations accompagnées de vitesses de consommation de l'oxygène

qui vont d'élevées à modérées; par ailleurs, avec le SFNA et le SFX, l'oxydation prévalente se produit par un mécanisme impliquant le $O_2(^1\Delta_g)$. Les résultats microbiologiques obtenus avec le SFX, utilisé comme modèle représentatif des antibiotiques sulfaniliques, indiquent que la photodégradation du médicament sous l'influence d'une irradiation avec de la lumière visible et sensibilisée par de la riboflavine s'accompagne d'une perte nette de son activité bactériostatique.

[Traduit par la Rédaction]

Introduction

The scavenging action of daylight-photogenerated oxygen active species by pharmacological agents is increasingly being investigated (1). The main motivation for these studies is the evaluation of the potential antioxidative activity of the substrates and the extent and nature of possible photodamage as a result of their interactions with the oxidative species. The substrates can physically quench photogenerated oxidants and (or) simply undergo oxidation, lowering their specific therapeutic effects. In this context, the prevalence of physical quenching is an interesting possibility, since in this way the oxidative species are eliminated without any chemical transformation of the drugs.

The most frequent mechanism of daylight-promoted production of oxidative agents is represented by the photosensitised process by which absorption of daylight by a coloured species generates its electronic excited states and, under aerobic conditions, may initiate a cascade of photoprocesses, some of which frequently involve the production of transient oxidative species. A natural visible-light-absorbing pigment of particular interest is vitamin B_2, or riboflavin (Rf), which generates the oxidative species singlet molecular oxygen ($O_2(^1\Delta_g)$) and superoxide radical anion ($O_2^{\bullet-}$) with quantum yields of 0.48 and 0.009, respectively (2). Rf has been postulated as a possible sensitiser for the photooxidative degradation of numerous biologically relevant natural substrates and drugs (3, 4).

An important family of compounds, transparent to daylight, is made up of the antibiotics and bacteriostatics derived from sulfanilic acid, termed sulpha drugs (SDs), which belong to a known class of biologically active and commercially valuable substrates (5). The understanding of their behaviour in the presence of photogenerated oxidative species, and particularly kinetic and mechanistic information on possible oxidative processes, may be of great interest in pharmaceutical and medical fields, in relation to the potential occurrence of photoreactions in the presence of photosensitisers able to absorb daylight. The aim of the present study was to analyse the behaviour of the SD derivatives sulfanilic acid (SFNA), dapsone (DAP), sulfadiazine (SFD), and sulfisoxazole (SFX) (Scheme 1) under visible-light photoirradiation and in the presence of two different types of photosensitisers: the natural pigment Rf and, for comparative purposes, the synthetic dye Rose Bengal.

Materials and methods

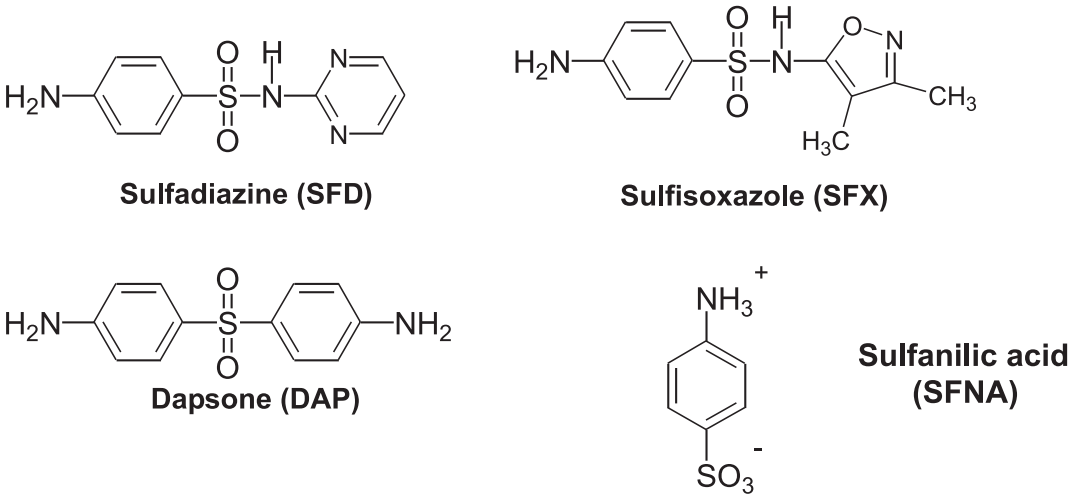
Chemicals

Dapsone, sulfadiazine, sulfisoxazole, sulfanilic acid, riboflavin, D_2O (99.9%D), superoxide dismutase (SOD), and sodium azide (NaN_3) were purchased from Sigma. Rose Bengal was from Aldrich, and furfuryl alcohol (FFA) was from Riedel deHaën. Water was triply distilled, and MeOH (HPLC quality) was from Sintorgan (Buenos Aires, Argentina). In some experiments, water was replaced as a solvent by 1:1 (*v*/*v*) MeOH–water to increase the solubility of the SD. D_2O was employed instead of H_2O in the time-resolved phosphorescence detection (TRPD) experiments to lengthen the $O_2(^1\Delta_g)$ lifetime (6). The pH 7 and pD 7 buffered solutions were prepared according to a literature procedure (7).

Instrumentation and methods

Absorption and fluorescence measurements

Ground-state absorption measurements were carried out with a Hewlett Packard 8452A diode array spectrophotometer. For the static Rf fluorescence experiments, a Shimadzu RF5301-PC spectrofluorimeter was used; measurements were performed at 25 ± 1 °C on air-equilibrated solutions. Excitation and emission wavelengths were 445 and 515 nm, respectively. The Stern–Volmer constants (K_{SV}) for the interaction of the SD with the singlet excited state of Rf (^{1}Rf*) were determined by evaluation of the static fluorescence intensity of Rf in the presence (I) and in the absence (I_0) of SD, through a Stern–Volmer treatment (eq. [1]).



$$[1] \qquad I_0/I = 1 + K_{SV}[SD]$$

Static photolysis and determination of k_r

Static aerobic and anaerobic photolysis of aqueous and methanolic solutions containing SD and the sensitisers Rf and Rose Bengal was carried out in a home-made photolysis unit, previously described (8). Cut-off filters (420 nm) ensured that the light was absorbed only by the sensitiser. Anaerobic and aerobic photodecomposition rates of Rf were determined by evaluation of the initial slopes of Rf consumption (decrease of absorbance at 446 nm) vs. irradiation time. The rate constants of the chemical reaction of SD with $O_2(^1\Delta_g)$, k_r, were determined using Rose Bengal as a sensitiser and actinometric methods (9), which are based on the comparison of the slopes of the time course (first-order plots) of oxygen uptake by the substrate and by a reference compound with a known k_r value (k_{rR}). The ratio of the first-order slopes of oxygen uptake by SD and the reference, both determined at identical substrate concentration (5×10^{-4} mol/L), is equal to k_r/k_{rR}, assuming that the SD:O_2 stoichiometry is 1:1 and that the reaction of $O_2(^1\Delta_g)$ with the quencher is the only pathway for oxygen consumption. FFA, a pH-independent photooxidizable compound (10), was used as a reference with $k_{rR} = 1.2 \times 10^8$ L mol^{-1} s^{-1}. The oxygen

Scheme 1. Structures of the sulpha drugs employed.

consumption was monitored with a specific electrode (Orion 97–08).

Time-resolved phosphorescence detection of $O_2(^1\Delta_g)$ and determination of k_t

The laser-kinetic spectrophotometer for TRPD has been previously described (11). Briefly, it consisted of a Nd:YAG laser (Spectron) as the excitation source. The output at 532 nm was employed to excite Rose Bengal. The emitted radiation (mainly 1270 nm) was detected, after passing through appropriate filters, at right angles using an amplified Judson J16/8Sp germanium detector. The output of the detector was coupled to a digital oscilloscope and to a personal computer for processing the signal. To get a good signal-to-noise ratio, 16 shots were usually averaged, from which the decay times were calculated. The sensitiser, Rose Bengal, had an $A_{532} \cong 0.4$.

The $O_2(^1\Delta_g)$ lifetimes were evaluated in in the presence (τ) and in the absence (τ^0) of the quencher, SD. The data were plotted according to a simple Stern–Volmer treatment (eq. [2]):

$$[2] \qquad 1/\tau = 1/\tau^0 + k_t[SD]$$

where k_t is the overall rate constant for $O_2(^1\Delta_g)$ quenching (processes (8), (9), and (10) in Scheme 2, discussed in the Results section) and is given by $k_t = k_r + k_q$. The rate constants k_r and k_q refer to the chemical (reactive) and physical quenching, respectively, of $O_2(^1\Delta_g)$.

Laser flash photolysis experiments and determination of k_{q3}

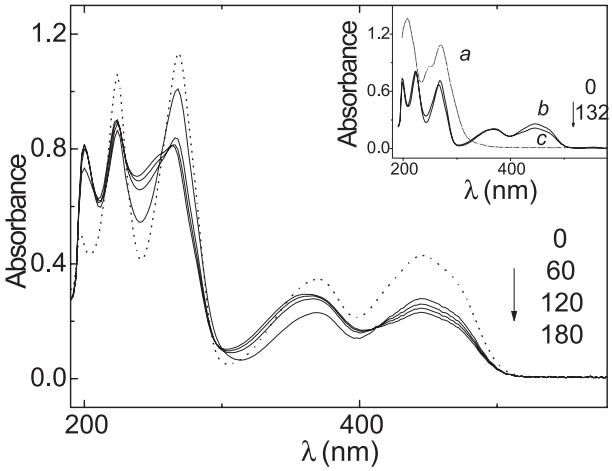
N_2-saturated aqueous solutions of Rf (0.01 mmol/L) were photolysed using a flash photolysis apparatus. A nanosecond Nd:YAG laser system (Spectron) at 355 nm was the excitation source, employing a 150-W xenon lamp as analysing light. The detection system comprised a PTI monochromator and a red-extended photomultiplier (Hamamatsu R666). The signal, acquired and averaged by a digital oscilloscope (Hewlett-Packard 54504A), was transferred to a PC via a HPIB parallel interface, where it was analysed and stored. The disappearance of the Rf excited triplet state (^{3}Rf*), generated by the 355-nm laser pulse, was monitored from the first-order decay of the absorbance at 670 nm, a wavelength at which interference from other possible species is negligible. The decay of ^{3}Rf* was measured at low Rf concentration (typically 0.02 mmol/L) and at low enough laser energy to avoid undesirable effects such as self-quenching and triplet–triplet annihilation. The lifetime of ^{3}Rf* was evaluated in the presence (τ_3) and in the absence (τ_3^0) of the quencher, SD. The data were plotted according to a Stern–Volmer treatment (eq. [3]):

$$[3] \qquad 1/\tau_3 = 1/\tau_3^0 + k_{q3}[SD]$$

To obtain SD concentrations higher than those allowed by the solubility of SD in water, the solvent mixture MeOH–H_2O (1:1, *v*/*v*) was employed in the determinations of the interactions of the antibiotics with singlet and triplet excited states of Rf.

Microbiological determinations

The antibacterial activity of SFX was evaluated at different irradiation times, employing the agar-well diffusion method (12) and using the standard strain *Pseudomonas aeruginosa* (ATCC 27853). The nutritive agar was inoculated with a water suspension of the microorganism from irradiated and nonirradiated pH 7 aqueous solutions, in the presence of Rf ($Abs_{445\ nm} = 0.5$) and SFX 0.5 mmol/L), and incubated at 37 °C for 48 h, after which the diameter of the inhibitory *halo* was measured.



Results

No perturbations indicative of any kind of ground-state association between SDs and Rf within the concentration range used for the photochemical experiments employing either pH 7 H_2O or 1:1 (*v*/*v*) MeOH–H_2O as solvent were observed in difference spectra (SD (0.4–1 mmol/L) + Rf (0.01–0.04 mmol/L) vs. Rf).

Figure 1 shows the time evolution of the spectral changes produced in the Rf-sensitised aerobic irradiation of a MeOH–water solution of SFD (0.3 mmol/L) containing Rf at a concentration of ca. 0.02 mmol/L. It is evident that both the sensitiser and the substrate were transformed as a result of

Fig. 1. Time evolution of the absorption spectrum of SFD (0.3 mmol/L) + Rf (0.02 mmol/L) upon Rf-sensitised photoirradiaton in MeOH–H_2O. The dotted spectrum is that of Rf (ca. 0.03 mmol/L) in 1:1 (*v*/*v*) MeOH–H_2O. Inset: Time evolution of the absorption spectrum of SFD + Rf upon Rf-sensitised photoirradiation in H_2O (*b*, *c*). The upper trace (*a*) in the inset is a spectrum of SFD vs. H_2O (molarity not determined), included for comparative purposes. Numbers on the spectra represent irradiation time in seconds.

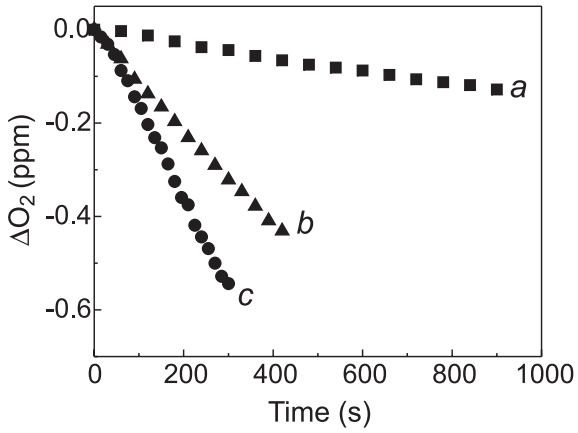
the photoirradiation. The same was true when SFD was replaced by SFX, DAP, or SFNA.

When aerated individual solutions of any of the three SD derivatives (0.4 mmol/L) and Rf (0.02 mmol/L) in pH 7 water were irradiated with visible light, oxygen consumption was observed (see Fig. 2*c* for a typical case). The relative rates of oxygen uptake are shown in Table 1. In the presence of NaN_3 (1 mmol/L), the rate of oxygen uptake was decreased but not suppressed (Fig. 2*b*). The salt NaN_3 is a selective quencher of the species $O_2(^1\Delta_g)$, with reported k_t values of $5 \times 10^8 - 15 \times 10^8$ L mol^{-1} s^{-1} in water (6). Concentrations of NaN_3 of the order of 1 mmol/L have been used previosuly to ascertain whether $O_2(^1\Delta_g)$ participates in a given reaction mechanism (6, 13, 14). A relatively low rate of oxygen uptake was observed in an aqueous solution containing Rf alone (0.02 mmol/L) (Fig. 2*a*).

In the presence of SOD (14 μg/mL), the rate of oxygen consumption in photoirradiated solutions of SFD (0.5 mmol/L) plus Rf (0.02 mmol/L) clearly decreased as compared to that in similar runs in the absence of the enzyme. This effect was practically absent in the corresponding runs with SFNA and SFX, and an intermediate situation (small decrease in the oxygen consumption rate) was observed for DAP (see data in Table 1). SOD, which catalyses the dismutation of $O_2^{\bullet-}$, has been utilised (15–18) as a quencher of $O_2^{\bullet-}$-mediated photooxidations, in similar concentrations to those employed in this work.

It is known that in the absence of oxygen, Rf photodegrades from its excited triplet state (^{3}Rf*), and the rate of this process can be determined from the initial evolution of the visible-absorption bands as a function of irradiation time (19). Figure 3 shows these spectral changes in 1:1 (*v*/*v*) methanol–water solutions through which N_2 was bubbled. In the presence of low concentrations of any SD (in the

Fig. 2. Oxygen consumption vs. irradiation time for (*a*) Rf (0.02 mmol/L), (*b*) SFX (0.4 mmol/L) + Rf (0.02 mmol/L) + NaN_3 (1 mmol/L), and (*c*) SFX (0.4 mmol/L) + Rf (0.02 mmol/L); solvent: H_2O.



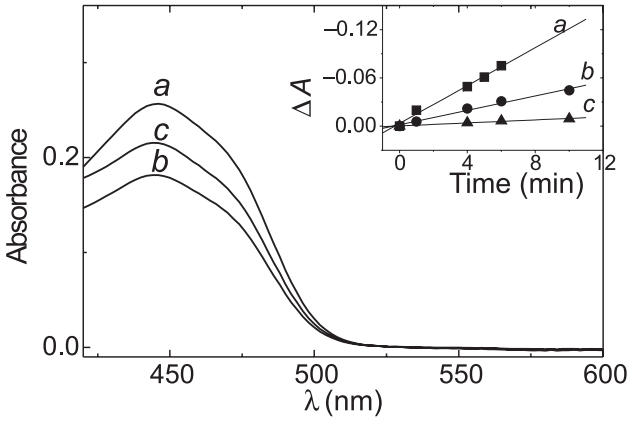


Fig. 3. Evolution of the 445-nm band of Rf in 1:1 (*v*/*v*) MeOH–H_2O upon irradiation with visible light (cutoff 400 nm). (*a*) Rf (0.015 mmol/L) not irradiated; (*b*) Rf (0.015 mmol/L) irradiated for 6 min; (*c*) Rf (0.015 mmol/L) + SFD (0.05 mmol/L), irradiated for 6 min. Inset: Rate of decrease of the 445-nm absorption band of Rf (0.015 mmol/L) upon irradiation with visible light in 1:1 (*v*/*v*) MeOH-H_2O. (*a*) Rf (0.015 mmol/L) alone; (*c*) Rf (0.015 mmol/L) + SFD (0.05 mmol/L); (*b*) Rf (0.015 mmol/L) + SFNA (0.05 mmol/L).

mmol/L range), the photodegradation rate of Rf was clearly decreased, suggesting a probable quenching of ^{3}Rf* by the SD. A typical illustration of this behaviour for SFD and SFNA is shown in the inset of Fig. 3.

Three experimental facts can be established through the combined analysis of the above results: (*a*) SD and Rf photodegrade upon visible-light irradiation in the presence of oxygen; (*b*) oxygenated species participate in the processes; and (*c*) electronically excited states of Rf participate in the generation of oxidative species and (or) in the photodegradation of the SD.

Results were interpreted and discussed on the basis of the kinetic scheme presented as Scheme 2. It shows the possible set of photoprocesses that could take place when a solution containing Rf and SD is irradiated with visible light in the

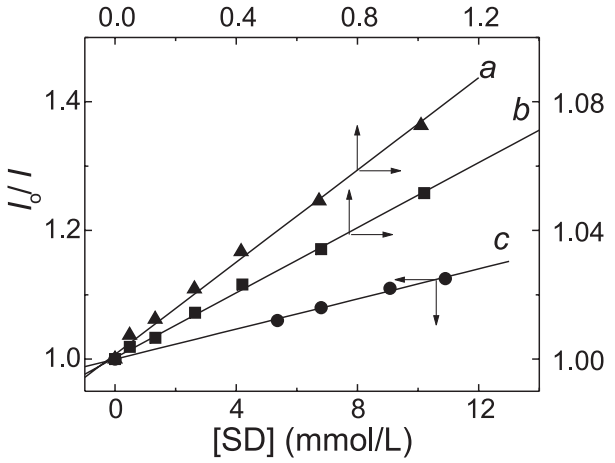
Scheme 2. Possible reaction pathways for the Rose Bengal- and riboflavin-sensitised photooxidation of sulpha drugs.



presence of oxygen. The initially generated excited singlet state ^{1}Rf* (process 1) can decay to the ground state (process 2), can be quenched by SD (process 3), or can undergo intersystem crossing to the excited triplet state ^{3}Rf* (process 4). The latter decays to the ground state or yields products (process 5), can be quenched by ground-state oxygen ($O_2(^3\Sigma_g^-)$) (process 6) dissolved in the medium, generating $O_2(^1\Delta_g)$ by energy transfer, or can be quenched by SD, yielding semireduced Rf ($Rf^{\bullet-}$) (process 7). $Rf^{\bullet-}$ can generate $O_2^{\bullet-}$ by reaction with molecular oxygen (process 12). The species $O_2(^1\Delta_g)$ can react with either SD (process 8) or Rf (process 10) or can be physically quenched by either SD (process 9) or the medium (process 11). In parallel, the generated species $O_2^{\bullet-}$ can react with Rf (process 13) or with SD (process 14).

To elucidate the reaction mechanism involving SD and Rf, under visible-light irradiation, we investigated the behaviour of electronically excited states of Rf and their potential interactions with ground-state SD in the absence and in the presence of dissolved molecular oxygen. Rf has a fluorescence emission band centered at 515 nm, with a fluorescence quantum yield of 0.25 (20, 21). In the presence of SD in concentrations much higher than 1 mmol/L, the stationary Rf-fluorescence emission intensity decreased, but the shape of the emission spectrum did not change. The Stern–Volmer constants for this interaction, K_{SV}, were determined (Fig. 4). Assuming that the fluorescence inhibition is a consequence of the quenching of ^{1}Rf* by SD, the K_{SV} values obtained will be equal to the ratio k_{q1}/k_{d1}, where k_{q1} and k_{d1} are the respective rate constants for the quenching of ^{1}Rf* by SD and for the deactivation of ^{1}Rf* (processes 3 and process 2, respectively, in Scheme 2). The respective k_{q1} values were obtained employing the literature value of 5.75 ns for $1/k_{d1}$ (22) and are shown in Table 1. These results indicate that ^{1}Rf* is practically unaffected by the presence of SD under the experimental conditions employed in static photolysis

© 2004 NRC Canada

Fig. 4. Stern–Volmer plots for the static fluorescence quenching of Rf (0.01 mmol/L) in 1:1 (*v*/*v*) MeOH–H_2O. (*a*) DAP; (*b*) SFD; (*c*) SFX.

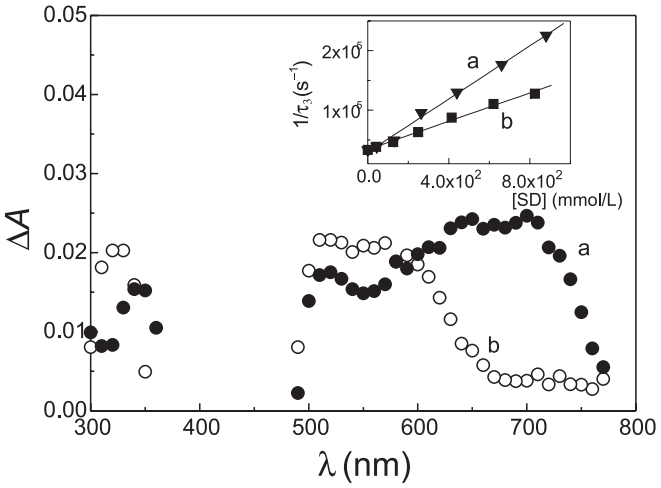
(observation of the spectral changes and oxygen uptake experiments). As an example, less than 2% ^{1}Rf* is quenched in the presence of DAP (the most efficient quencher of ^{1}Rf*) at a concentration of 0.5 mmol/L, whereas for the quenching of 50% ^{1}Rf*, a DAP concentration of 30 mmol/L is necessary.

The interaction between ^{3}Rf* and SD (process 7) was studied through laser flash photolysis experiments in the absence of oxygen. The monoexponential decay curves indicated that the ^{3}Rf* lifetime appreciably decreased in the presence of any SD in the submillimolar concentration range. As before, a Stern–Volmer treatment (Fig. 5, inset) yielded the corresponding values of the bimolecular rate constant k_{q3} for the interaction (Table 1).

The transient absorption spectrum of the Rf solution 5 μs after the laser pulse (Fig. 5, trace *a*) is similar to that reported for ^{3}Rf* (22–24). A different spectrum was observed in the presence of 0.5 mmol/L of either of the two SDs studied (as illustrated in Fig. 5 (trace *b*) for the case of SFX), with a shape similar to that described (25) to account for electron-transfer processes to ^{3}Rf* from electron-donor substrates such as 2,6-dimethylphenol (26) and nucleotides (24), with the simultaneous generation of the well-known radical anion $Rf^{\bullet -}$ (24, 27, 28). The transient spectrum reported for $Rf^{\bullet -}$ (25), which possesses a non-pronounced maximum in the range of 530 nm, a region where the absorption of triplet Rf is comparatively low, and a smooth decrease up to ca. 700 nm, is closely coincident with trace *b* of Fig. 5.

As mentioned in the Introduction, the species $O_2^{\bullet -}$ and $O_2(^1\Delta_g)$ are usually present in aerobic Rf-phosensitised processes (27). Rf itself is also a moderate quencher of $O_2(^1\Delta_g)$ (Scheme 2, process 10), with a k_{rRf} value of 6×10^7 L mol^{-1} s^{-1}. To selectively study the potential contribution of the $O_2(^1\Delta_g)$-mediated process to the overall phototransformation of SD, TRPD and oxygen uptake experiments employing the sensitiser Rose Bengal were performed. This dye is possibly the most widely employed photosensitiser in $O_2(^1\Delta_g)$-mediated reactions, with a quantum yield of 0.76 for the generation of the oxygenated species (29). All SDs quenched the phosphorescence emission of $O_2(^1\Delta_g)$ to various extents (Fig. 6, inset). Table 1 shows the respective k_t values for the four SDs.

Fig. 5. Transient absorption spectra of Rf (0.02 mmol/L) in argon-saturated aqueous solution, in 1:1 (*v*/*v*) MeOH–H_2O: (*a*) 5 μs after the laser pulse, in the absence of SFX; (*b*) 30 μs after the laser pulse, in the presence of SFX (0.1 mmol/L). Inset: Stern–Volmer plot for the quenching of Rf excited triplet state by SFNA (*a*) and SFX (*b*).



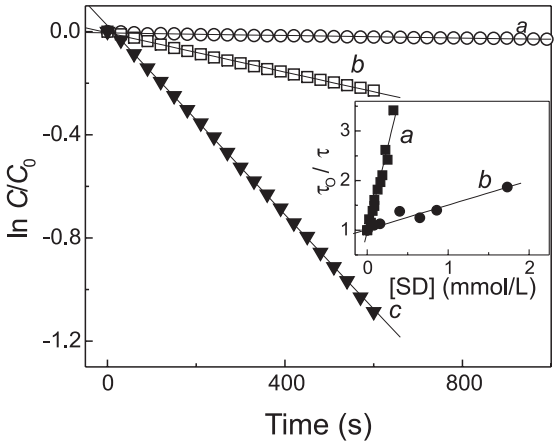


Fig. 6. First-order plots for oxygen uptake by SDs and the reference compound FFA (C_0 and C are the respective dissolved oxygen concentrations before photolysis and after photolysis) upon photoirradiation in 0.4 mmol/L aqueous solution in the presence of Rose Bengal ($Abs_{530\ nm}$ = 0.5) as a sensitiser: (*a*) DAP, (*b*) SFX; (*c*) FFA. Inset: Stern–Volmer plots for the phosphorescence quenching of $O_2(^1\Delta_g)$ in D_2O: (*a*) SFX; (*b*) SFNA.

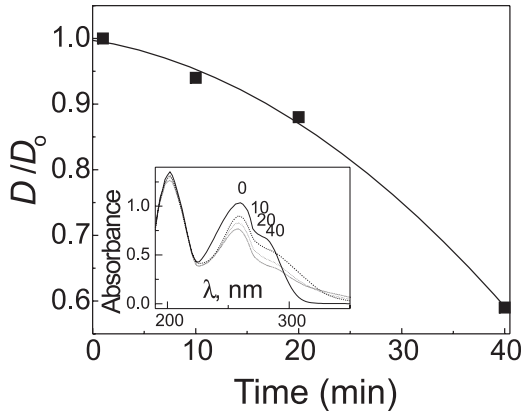

From oxygen uptake experiments (Fig. 6), kinetic data on the reactivity of SD towards $O_2(^1\Delta_g)$ were evaluated. The resulting k_r values are also shown in Table 1. In ancillary experiments performed in the presence of 1 mmol/L NaN_3, oxygen uptake by SD upon Rose Bengal sensitisation was practically eliminated, demonstrating the exclusive occurrence of the $O_2(^1\Delta_g)$-mediated mechanism, as unambiguously confirmed by the TRPD experiments.

Finally, the impact of the Rf-sensitised irradiation of SDs on their bacteriostatic power was tested. Figure 7 shows a plot of the ratio of the normalised diameter of the bacterista-

© 2004 NRC Canada

Fig. 7. Plot of the ratio of the normalised diameter of the bacteristatic inhibitory *halo* before photolysis (D_0) to that after photolysis (D) of a pH 7 aqueous solution of Rf ($Abs_{445\ nm}$ = 0.5) and SFX (0.5 mmol/L), as a function of photoirradiation time. Inset: Evolution of the absorption spectrum of the pH 7 aqueous solution of Rf ($Abs_{445\ nm}$ = 0.5) and SFX 0.5 mmol/L. Numbers on the spectra represent irradiation times in minutes.

tic inhibitory *halo* before photolysis to that after photolysis of a solution of SFX and Rf as a function of photoirradiation time. The results clearly show a decrease of the bacteriostatic activity of SFX due to the phototransformation, which was monitored through the respective absorption spectra of the nonirradiated and irradiated solutions.

Discussion

The data in Table 1 demonstrate that the relative rates of oxygen consumption in experiments employing Rose Bengal as a sensitiser do not parallel the respective data employing Rf sensitisation. One possible explanation for this discrepancy could be the operation of different mechanisms of oxygen uptake in the oxidation of SDs. When Rose Bengal is employed as a sensitiser, the relative reactivity via the $O_2(^1\Delta_g)$-mediated mechanism is important. In the case of Rf sensitisation, the experiments involving inhibition of oxygen uptake by NaN_3 and SOD demonstrate that a second mechanism, besides the $O_2(^1\Delta_g)$-mediated mechanism, could be operating. Although Rf is a fairly good generator of $O_2(^1\Delta_g)$ (2), it has been reported that several substrates are also oxidized by an Rf-sensitised process involving $O_2^{\bullet-}$ (30–32). Nevertheless, the direct generation of $O_2^{\bullet-}$ by Rf (step not included in Scheme 2) can be practically disregarded owing to the low quantum yield reported for such a process (2). Even so, its generation is possible through process 7, followed by process 12. The spectral evidence shown in Fig. 5 demonstrates the presence of the intermediate $Rf^{\bullet-}$. As indicated in Scheme 2, $^3Rf^*$ can be quenched by $O_2(^3\Sigma_g^-)$, producing $O_2(^1\Delta_g)$ (process 6), or by SD (process 7). It is currently accepted that the rate constant k_{ET} of process 6 is ca. 1/9 that of the diffusional value in the solvent used (33). Assuming a value for k_{ET} of 8×10^8 L mol^{-1} s^{-1}, i.e., 1/9 of the average diffusional rate constants in H_2O and MeOH (34), as well as an oxygen concentration in air-saturated MeOH–H_2O solutions of 1.2 mmol/L (35), it can be inferred that at an SD concentration of 0.4 mmol/L — similar to the concentration employed in the oxygen uptake experiments — the rate of process 7 ($k_{q3} \times$ [SD]), with a mean value of 1.5×10^9 L mol^{-1} s^{-1} for k_{q3} (Table 1), is only 20% lower than the rate of generation of $O_2(^1\Delta_g)$ (process 6) ($k_{ET} \times [O_2(^3\Sigma_g^-)]$). In other words, the species $Rf^{\bullet-}$ and $O_2(^1\Delta_g)$ seem to be generated to a similar degree, through process 6 and process 7, respectively.

In previous work (30, 36), we demonstrated the photochemical production of the species $Rf^{\bullet-}$ in several systems. It is known that under aerobic conditions $Rf^{\bullet-}$, in a subsequent step, produces the radical anion $O_2^{\bullet-}$, with a reported rate constant value of 1.4×10^8 L mol^{-1} s^{-1} for process 12. This reaction at the same time regenerates ground-state Rf, a crucial step in living organisms for which $O_2^{\bullet-}$ is a key intermediate in the oxygen redox chemistry (37). Hence, the oxygen consumption upon Rf-sensitised irradiation of SD could be due to two different mechanisms, and the prevalence of a given mechanism could depend on the reactivity of the oxygenated species towards the different substrates. Regarding the structure–reactivity analysis for the $O_2(^1\Delta_g)$ mechanism in the Rose Bengal-sensitised photoirradiation, it can be observed that SFNA, which contains the molecular moiety common to all SDs, interacts with $O_2(^1\Delta_g)$, and no substantial differences in k_t are observed to result from substitution by the groups aniline (DAP) or aminopyrimidine (SFD). On the other hand, both the overall and reactive interaction with $O_2(^1\Delta_g)$ dramatically increased upon incorporation of the isoxazole moiety as a substituent, as in the case of SFX. Nevertheless, according to the k_r/k_t ratio, higher photooxidation efficiency was exhibited by SFNA, whereas relatively low values of this ratio, and close to each other, were obtained for DAP and SFD. This means that DAP and SFD are fairly good photoprotectors against $O_2(^1\Delta_g)$, provided that they scavenge the oxidative species with a minimum of effective photodegradation. From a combined analysis of these results, and taking into account the inhibitory effect of SOD in the oxygen uptake experiments, it arises that only SFD and DAP are good reactants towards $O_2^{\bullet-}$, whereas the main source of oxygen uptake for SFX and SFNA is represented by the reaction with $O_2(^1\Delta_g)$.

Nevertheless, and regarding the potential activity of SDs as antioxidants, it is difficult to select the best photoprotector, simultaneously active against the oxygenated species $O_2(^1\Delta_g)$ and $O_2^{\bullet-}$. Those SDs that behave as the better $O_2(^1\Delta_g)$ physical quenchers concurrently exhibit high oxygen consumption rates due to the $O_2^{\bullet-}$ oxidative pathway.

Finally, the microbiological results for SFX, taken as a representative model for SDs, are self-explanatory: the photodegradation, upon Rf-sensitised visible-light irradiation of the drug is accompanied by a net loss of bacteriostatic activity.

Efficient photodecarboxylation of 3- and 4-acetylphenylacetic acids in aqueous solution

Lawrence A. Huck, Musheng Xu, Kaya Forest, and Peter Wan

Abstract: The photochemistry of 3- and 4-acetylphenylacetic acids (**6** and **7**) has been studied in aqueous solution. This work is a continuation of research efforts aimed at understanding the structural effects on the efficacy for benzyl carbanion photogeneration via photodecarboxylation. The nitro group (at the 3- and 4-positions) is known to be an exceptionally good activating group on the benzene ring — because of its enhanced electron-withdrawing effect in the excited triplet state — for photodecarboxylation and the related photo-retro-aldol type process. It is shown in this work that the acetyl group is an equally good activating group for the photodecarboxylation. Thus, the photochemistry of **6** and **7** parallels much of what was observed for the corresponding nitrophenylacetic acids **1** and **2**. Both **6** and **7** photodecarboxylate efficiently (Φ_d = 0.60 and 0.22, respectively, at pH 7) via the carboxylate form, to give observable (by laser flash photolysis) benzyl carbanion or related intermediates. The meta isomer **6** displays an acid-catalyzed pathway for photodecarboxylation at pH < 3 and along with its enhanced overall reactivity, is consistent with a meta effect of the acetyl group. Triplet state reactivity is inferred from sensitization and laser flash photolysis experiments. Based on the results of this work, the acetyl group may now be viewed as an "enhanced" electron-withdrawing group (in the excited state) when attached to a benzene ring (i.e., in acetophenone derivatives) that is capable of inducing ionic reactions, which is not the traditional photochemistry that is expected from such compounds.

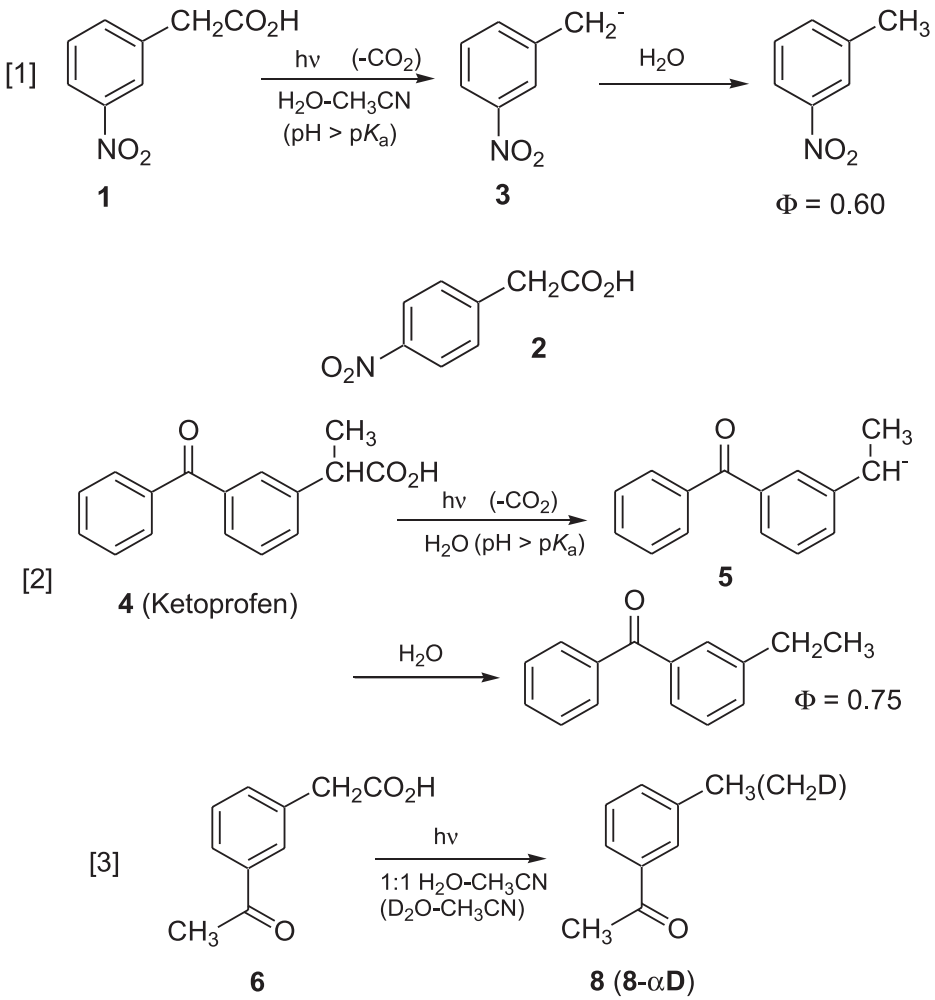
Key words: photodecarboxylation, acid catalysis, acetophenone, photogenerated carbanion, enol, enolate.

Résumé : On a étudié la photochimie des acides 3- et 4-acétylphénylacétiques (**6** et **7**) en solution aqueuse. Ce travail est une continuation des efforts de recherche déployés pour comprendre les effets structuraux sur l'efficacité de la photogénération du carbanion benzyle par le biais d'une photodécarboxylation. Il est connu que, en raison de l'augmentation de leur effet électroaffinitaire dans l'état triplet excité, les groupes nitro (en positions 3 et 4) activent le noyau benzénique d'une façon exceptionnelle lors de réactions de photodécarboxylation et autres processus apparentés du type photo-rétro-aldolique. Dans ce travail, on a démontré que le groupe acétyle est aussi un bon groupe activant pour la réaction de photodécarboxylation. La photochimie des composés **6** et **7** est donc parallèle à ce qui a été observé avec les acides nitrophénylacétiques correspondants, **1** et **2**. Les composés **6** et **7** se décarboxylent d'une façon efficace (Φ_d = 0,60 et 0,22 respectivement, à un pH de 7), par le biais de la forme carboxylate, pour conduire à la formation du carbanion benzyle et d'autres intermédiaires apparentés qui peuvent être observés par photolyse éclair au laser. À des pH < 3, l'isomère méta, **6**, donne lieu à une photodécarboxylation impliquant une catalyse acide et, combiné avec sa plus grande réactivité globale, cette observation est en accord avec un effet méta du groupe acétyle. On déduit la réactivité de l'état triplet d'expériences de sensibilisation et de photolyse éclair au laser. Sur la base des résultats de ce travail, on peut considérer que, dans l'état excité, l'effet électroaffinitaire d'un groupe acétyle attaché à un noyau benzénique (comme dans les dérivés de l'acétophénone) est rehaussé, qu'il est capable d'induire des réactions ioniques ce qui ne correspond pas à la photochimie traditionnelle à laquelle on peut s'attendre avec de tels composés.

Mots clés : photodécarboxylation, catalyse acide, acétophénone, carbanion photogénéré, énol, énolate.

[Traduit par la Rédaction]

Introduction



Decarboxylation is one of the simplest extrusion reactions in organic chemistry with wide-relevance in both organic synthesis (1) and in biological chemistry (1, 2). Photodecarboxylation is also well-known and has been studied extensively for a variety of organic substrates, where a number of mechanistic pathways are known to operate for the loss of CO_2 initiated by light (3). With respect to the photodecarboxylation of aromatic compounds, phenylacetic acids have been the most studied as they provide the obvious basis for Hammett-type studies, by varying substituents on the phenyl ring (3). Although we are not aware of any extended systematic studies in this approach — perhaps thwarted by the fact that the parent and many simple alkyl-substituted phenylacetic acids react with only low quantum efficiency (Φ < 0.02) (3) — it is known that 3- and 4-nitrophenylacetic acids (**1** and **2**, respectively, and related compounds) both react with very high quantum efficiency in the carboxylate form (Φ = 0.6) (4) via nitrobenzyl carbanion intermediates (e.g.,

3-nitrobenzyl carbanion (**3**) in eq. [1]). More recently, we have shown (5) that both the benzoyl (PhCO) and acetyl (CH_3CO) moieties also act as "enhanced" electron-withdrawing groups (when attached to a benzene ring) in the excited state, capable of mediating highly efficient photodecarboxylations of the corresponding substituted phenylacetic acid, providing a rational explanation for the previously reported efficient photodecarboxylation of ketoprofen (**4**) (via benzyl carbanion **5**, eq. [2]), a nonsteroidal anti-inflammatory drug that is known to be phototoxic (6). In this work, we detail our complete results on a study of the photodecarboxylation of 3- and 4-acetylphenylacetic acids (**6** and **7**, respectively) and show that their photochemical behaviour essentially *parallels* that observed for the corresponding nitro-substituted compounds **1** and **2**. Moreover, the results show that the acetyl group may be thought of as an enhanced "electron-withdrawing" group in the excited state, capable of inducing photochemistry that would not have been normally be anticipated when these compounds are viewed as substituted acetophenones.

Results and discussion

Product studies

The substrates for study (**6** and **7**) were readily prepared from the corresponding methylacetophenones (**8** and **9**) by initial NBS bromination of the methyl group, followed by substitution of the bromine by cyanide ion, and subsequent acid hydrolysis. Photolysis of **6** in H_2O–CH_3CN (1:1, pH 7, water portion, 10^{-3} mol L^{-1}, 254 or 300 nm, Rayonet RPR 100 photochemical reactor, 1–10 min, deoxygenated by argon purge) gave exclusively the corresponding photodecarboxylation product **8** in high yield (>80%, eq. [3]). Quantitative conversion was observed at sufficiently long photolysis times. No reaction was observed in the absence of light or when photolyzed in neat CH_3CN, the latter consistent with photoreactivity via the carboxylate ion (vide infra). Photolysis in D_2O–CH_3CN (1:1, pD 1 and 7) gave exclusively the corresponding α-deuterated product **8-αD**, consistent with the formation of a benzyl-carbanion-type intermediate in the photodecarboxylation. The overall reaction yield was only about 10%–20% lower in D_2O, indicative of a secondary solvent isotope effect for reaction, although the exact source of this effect is not known.

Similar photolysis of the para-isomer **7** gave two products at all conversions, the expected photodecarboxylation product **9** and a "dimer" **10** (formally derived from the coupling of two 4-acetylphenylmethyl radicals) (eq. [4]). Independent photolysis of **9** did not produce **10**. Photolysis in D_2O–CH_3CN gave the α-deuterated product **9-αD**, consistent with the formation of a benzyl-carbanion-type intermediate; no deuterium was incorporated into dimer **10**. The ratio of

[b]pH of the aqueous portion (H_2O–CH_3CN, 1:1).

products **9** vs. **10** was found to be pH dependent (Table 1), with increasing yield of the dimer **10** (maximum relative yield ≈ 30%) with increasing pH. This trend is consistent with a mechanism in which the initially formed benzyl carbanion intermediate (**19a**) can react via two pathways, simple protonation to give **9** and a more complex "bimolecular" pathway (disproportionation-type route, vide infra) to give **10**. The protonation pathway would be favoured at lower pH, and this was indeed observed. Since the dimer **10** was observed as a photoproduct under relatively low lamp intensities (Rayonet photochemical reactor), it is unlikely that it arises via secondary photolysis of the anticipated intermediate carbanion (**19a**) of the photodecarboxylation (vide infra).

The above results observed for 4-acetylphenylacetic acid (**7**) is very similar to what is known in the photodecarboxylation of 4-nitrophenylacetic acid (**2**) (4) (Scheme 1). Photodecarboxylation of **2** gave a mixture of the expected 4-nitrotoluene (**11**) via simple protonation of the initially formed 4-nitrobenzyl carbanion (**12**) and a "dimeric" product (4,4′-dinitrobibenzyl, **13**). The relative yield of dimer **13** is enhanced at higher pH, becoming the major (>80%) product at pH > 10. Thermally generated **12** (via the deprotonation of **11** using strong bases and where there is no possibility of photoexcitation of the carbanion **12**) also gave **13** (7). The mechanism for the formation of **13** from **12** appears to be complex. Radical ions are believed to be involved (7) as strong EPR signals are observed. For the photodecarboxylation pathway, Craig and Pace (8) suggested the possibility of dimerization of the initially formed **12** based on kinetic studies for its decay, to give the radical dianion **14** (expected to be EPR active and consistent with the EPR signals observed) (8), which on work-up, is oxidized to give **13**. The very long lifetime of photogenerated **12** ($\tau \approx 60$ s, aqueous solution, pH 7) (7) would indicate slow reaction via simple protonation of the anion (carbon protonation is generally "slow" even in thermodynamically favourable cases), and hence, the possibility of dimerization to give radical dianion **14**. Such a mechanism does not operate for the 3-isomer **1** since the corresponding benzyl carbanion intermediate **3** is expected to be shorter lived. Indeed, the 3-nitrobenzyl carbanion (**3**) has never been detected as a transient, although the reason for this is still not clear.

The high yields and clean photochemistry observed for both **6** and **7** is further evidence for the enhanced activating effect of the acetyl group for photodecarboxylation. Moreover, no products were observed that are derived from the photochemistry of the carbonyl end of the molecule (e.g., via photoreduction or hydrogen abstraction), which is consistent with the notion that this group participates only as an enhanced electron-withdrawing group. Without the acetyl group, phenylacetic acid itself photodecarboxylates with only marginal quantum yields (<0.02) (3). That there is substantial charge transfer character (with negative charge polarized towards the carbonyl oxygen) in the reactive excited state of these compounds is further evidenced by observation of acid catalysis for the photodecarboxylation of **6** (vide infra).

Quantum yields

Quantum yields for photodecarboxylation were measured as a function of pH, using the photodecarboxylation of ketoprofen (**4**, $\Phi_d = 0.75$ (*6a*)) as a secondary standard (Fig. 1). H_2O–CH_3CN (1:1, v/v) was employed as the solvent in these studies because of experimental difficulties in performing semipreparative photolysis in 100% water. All the quoted pH are of the aqueous portion prior to mixing except for pH 4–8, where the pH was measured in the mixed solvent as adjustment to the pH had to be made with NaOH upon dissolution of the substrate. Since the quantum yield plot is for qualitative purposes only, the exact pH values are of less consequence. The quantum yields for photodecarboxylation (Φ_d) for both **6** and **7** are substantial at pH 7 (0.60 and 0.22, respectively), indicative of the highly activating nature of the acetyl group. For both compounds, the highest quantum yields were observed for the carboxylate form of the molecule (in the region where pH > pK_a; estimated pK_a for these compounds ≈ 3 to 4). Indeed, this is suggestive that only the carboxylate form is reactive in photodecarboxylation, as is the case for most arylacetic acids reported to date (3, 4). This is indeed the case for the para isomer **7** since the quantum yield vs. pH plot for this compound approaches zero at

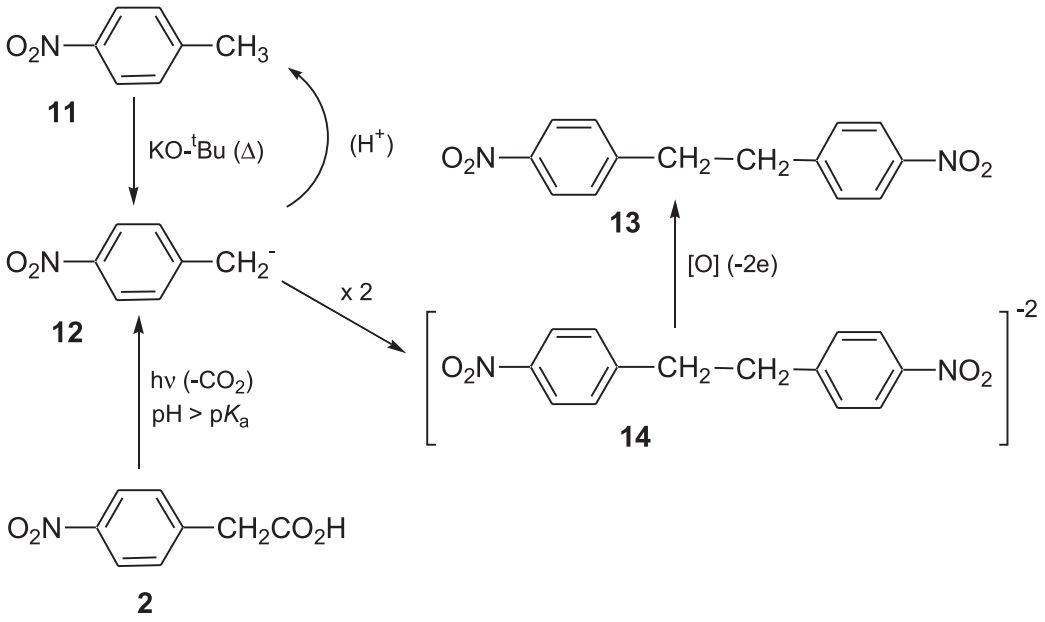
Scheme 1.



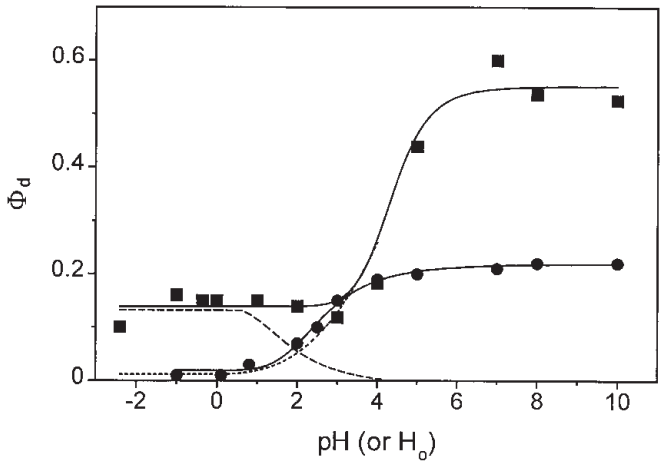


Fig. 1. Plots of quantum yields for photodecarboxylation (Φ_d) vs. pH for acetylphenylacetic acids **6** (squares) and **7** (circles) in H_2O–CH_3CN (1:1). The short-dashed line shows the expected trend for **6** if acid catalysis does not operate; the long-dashed line shows the resolved acid-catalyzed photodecarboxylation pathway.

pH < 1. For 3-acetylphenylacetic acid (**6**), the quantum yield is substantial (≈0.13) in acidic solution, which is indicative of an acid-catalyzed mechanism that operates only for the meta isomer. As shown in Fig. 1, the short-dashed line represents the expected trend in the absence of an acid-catalyzed pathway. The long-dashed line is the "resolved" contributing acid-catalyzed pathway. The "plateau" region observed in the pH 2 to H_o –2 region is therefore the sum of the acid- and "base"-catalyzed mechanisms. It should be emphasized at this point that product studies of **6** in the acid region discussed here also gave only one photoproduct (viz., **8**). Additionally, photolysis of **6** at pD 1 (where the mechanism is believed to be almost exclusively in the acid-catalyzed regime) gave **8**-α**D** exclusively. That is, the quantum yield vs. pH plot observed for **6** in Fig. 1 over the entire pH region is due to photodecarboxylation and not some other contributing photochemical reaction that may have been overlooked in the product studies.

The above "unusual" photoreactivity displayed by the meta acid **6** may be interpreted as another example of the well-known "meta effect" for the photochemistry of substituted benzenes that has been well-documented and studied by Zimmerman (9). That is, the meta-acetyl group in **6** can activate (in the excited state, by electron withdrawal) the corresponding attached acetic acid moiety more than a corresponding para-acetyl group. This results in a more reactive compound (as manifested in the higher quantum yields observed for **6** at all pH) as well as the operation of an observable acid-catalyzed pathway (vide infra).

Nanosecond laser flash photolysis (LFP) and reaction mechanisms

Although the results presented so far, based on product studies and quantum yield measurements vs. pH, show a close analogy in photochemical behaviour between the nitrophenylacetic acids (**1** and **2**) and the acetylphenylacetic acids (**6** and **7**), LFP results show mechanistic details for **6** and **7** that appear to be more complex than those reported for **1** and **2**. LFP studies of **6** and **7** were first performed in dry CH_3CN, where there is no photoreaction. Only one strong and broad ($\Delta OD \approx 0.12$) transient formed immediately after the laser pulse was observed for both compounds, with λ_{max} 330 nm (Fig. 2, shown for **7**), which was efficiently quenched by oxygen. This transient exhibited the same decay kinetics over the 330–430 nm region of the spectrum and hence assignable to one transient. For **6**, the lifetime (all single exponential fits) was 800 ns under N_2 and 50 ns under O_2; for **7**, 1200 ns under N_2 and 170 ns under O_2. This transient is assigned to the triplet state, in agreement with the known triplet state absorption for acetophenone itself (λ_{max} 330 nm (10)), although there is a

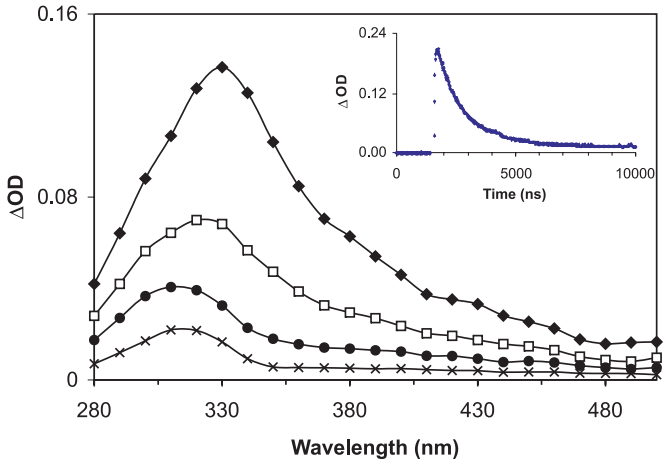
Fig. 2. Transient observed on LFP of **7** in 100% CH_3CN (266 nm excitation, N_2 purged). The signal at 340 nm is assigned to the triplet state. (130 ns (◆), 220 ns (□), 410 ns (●), 3000 ns after the laser pulse (×)). Inset: first-order decay at 340 nm; $\tau \approx 1000$ ns.



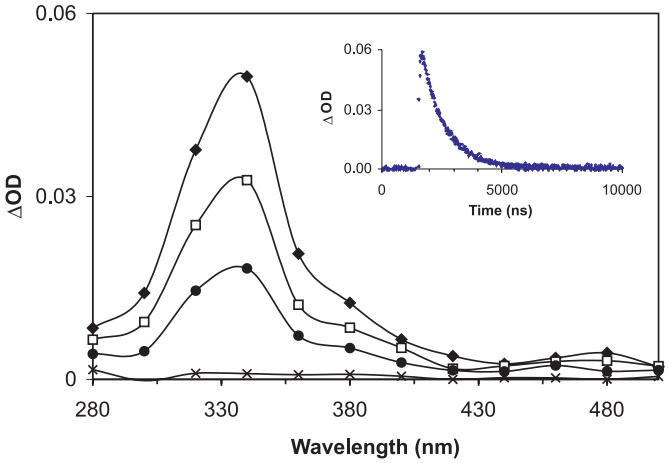


Fig. 3. Transient observed on LFP of **6** in H_2O–CH_3CN (1:1, pH 7) (266 nm excitation, N_2 purged). The transient is assigned to carbanion **15** or **16**. The decay is first order (130 ns (◆), 280 ns (□), 480 ns (●), 3000 ns after the laser pulse (×)). Inset: first-order decay at 340 nm; $\tau \approx 400$ ns.

weak residual longer lived signal at ca. 310 that was not assigned.

LFP studies of **6** and **7** were then carried out in H_2O–CH_3CN (1:1, at several different pH), a solvent where these compounds photodecarboxylate efficiently (except for **7** at pH < 2). The transient observed immediately upon the laser pulse for **6** in pH 7 is shown in Fig. 3. The spectral band is narrower and weaker than that observed in 100% CH_3CN, with λ_{max} at 340 nm. The same decay kinetics (single exponential decay) was observed across the whole spectral range with no significant residual signals. In addition, the transient is significantly longer lived in D_2O (about twofold) and is somewhat sensitive to oxygen but not to the same extent as the transient observed in 100% CH_3CN (Table 2). Therefore, although this transient has absorption in about the same spectral region as the triplet state assigned above, it *cannot* be the triplet state. Indeed, the absence of the triplet state in aq. CH_3CN would suggest that it may be the reactive state in the photodecarboxylation, given that aromatic ketones are known to intersystem cross very efficiently. Triplet sensitization experiments were carried out in which D_2O–CD_3CN (1:1) was replaced with D_2O–acetone-d_6 (1:1, with λ_{ex} = 300 nm), which resulted in 30% higher yield (when acetone-d_6 was used). Since most of the exciting light is absorbed by acetone in these experiments, the inference is that the triplet state of **6** is reactive towards photodecarboxylation, consistent with the LFP data. However, we cannot rule out reaction from the singlet state, although such a pathway is probably insignificant.

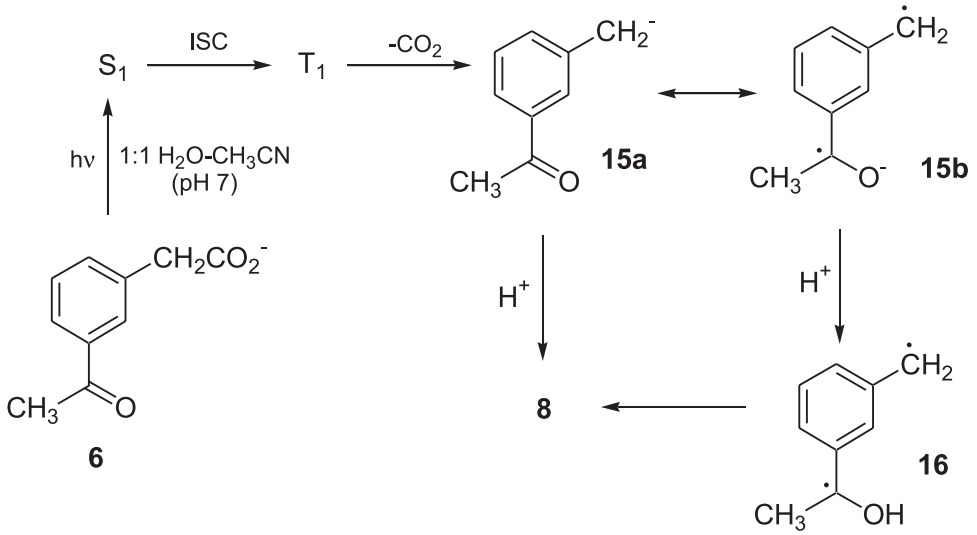
Table 2. Lifetimes of observed transients for **6** and **7** by LFP.

	Observed lifetimes (ns)[a]			
λ[b]	**6** (In H_2O)[c]	**6** (In D_2O)[c]	**7** (In H_2O)[c]	**7** (In D_2O)[c]
310			4600 (600)	4400 (630)
320			3400 (400)	3200 (460)
340	390 (220)	910 (190)	1800 (260)	1700 (300)
400	460 (140)	920 (190)	1700 (420)	3900 (710)

[a]Lifetimes obtained from first-order decays at the respective wavelength under N_2, except for 310, 320, and 340 nm of **7**, which did not obey first-order kinetics and the lifetimes are estimated based on force fitting to a single exponential decay. Values in brackets obtained under O_2. Estimated error: ±10% of quoted value. All transients were observed immediately after the laser pulse.

[b]Wavelength at which decay was monitored. Corresponds to λ_{max} for **6** at 340 nm and for **7** at 310 and 400 nm (shoulder).

[c]At pH(D) = 7. Cosolvent is 50% CH_3CN.



Scaiano and Monti and their respective co-workers (6*b*–6*d*) have carried out extensive LFP studies of the photodecarboxylation of ketoprofen (**4**), a reaction that is closely related to the ones being studied in the present work. They assigned a transient with λ_{max} at 330 and 580 nm as owing to carbanion **5**, although its spectral characteristics suggested that this anion might have substantial contribution from the radical anion (non-Kekulé) resonance form **5a**.

Lifetimes of this species has been reported to be about 200 ns in aqueous solution with much longer lifetimes when photogenerated in some organic solvents (6*b*–6*d*). In addition, a simple benzyl anion is known to absorb at ca. 350 nm (11). In view of these literature precedents and the observed primary solvent isotope effect on decay of the observed 340 nm LFP transient for **6**, it seems reasonable that it be assigned to (singlet ground state) benzyl carbanion **15a/15b** (Scheme 2). It is assumed that if the benzyl carbanion was initially photogenerated in its triplet state that intersystem crossing has occurred during the laser pulse. We cannot rule out formation of the corresponding (ground state) non-Kekulé enol **16** at this pH since the pK_a of some aromatic ketyls are known to be in the 7 to 8 range (6*c*). Indeed,

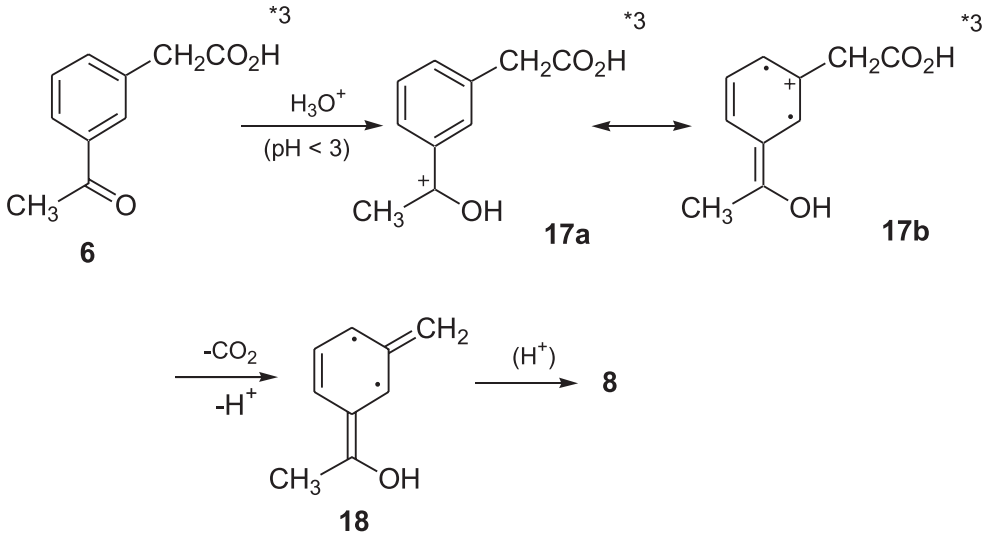

Scheme 2.

protonation at oxygen would be diffusion controlled in this case (at pH 7 or lower), further arguing that the transient may actually be the non-Kekulé biradical **16**. This species would still be quenchable by oxygen and sensitive to D_2O. LFP studies at pH 3 gave essentially the same transient but at pH 0, only very weak signals were observed, consistent with a change in reaction mechanism as required from data presented in Fig. 1. The acid-catalyzed photodecarboxylation pathway is given in eq. [5]. Support for this mechanism comes from the recent work of Wirz and co-workers (12) who showed that aromatic ketones such as benzophenone and acetophenone are readily photoprotonated via the triplet excited state, giving rise to reactive electronically excited carbocations that can undergo overall hydration (which for the parent systems studied are entirely reversible). In the case of acetophenone – phenylacetic acid **6**, such a photoprotonation would give rise to **17a/17b**, since Wirz and co-workers (12) have also shown that most of the positive charge of such cations reside at the meta positions (a form of meta activation (9)). An activated species such as **17b** would be expected to decarboxylate (with concerted loss of the carboxylic acid proton to water), to generate a species such as **18** (which may or may not be identical to **16**). In any event, in an acid medium, we anticipate that **18** will quickly form **8**. This mechanistic scheme also gives an explanation as to why acid catalysis for photodecarboxylation was not observed for the para-acid **7** since the positive charge of the protonated species would not be expected to be localized significantly at the para position. The question of why the quantum yields measured in acid reach a plateau below pH 1 (Fig. 2) can be explained simply by noting that **17a/17b** can deactivate back to ground state **6** without continuing on to **18**. In addition, triplet excited state **6** could also suffer simple nonproductive quenching by protons, which would compete with the acid-catalyzed photodecarboxylation process itself. Thus, one would not expect the quantum yields to continue to rise until quantum yield of unity is reached.

LFP results for the para-isomer **7** are more complex. Although strong signals (ΔOD up to 0.1, Fig. 4) were observed immediately upon the laser pulse, three major transients could be discerned at 310, 355, and 400 nm (Table 2). At least two transients are contained within the broad absorp-

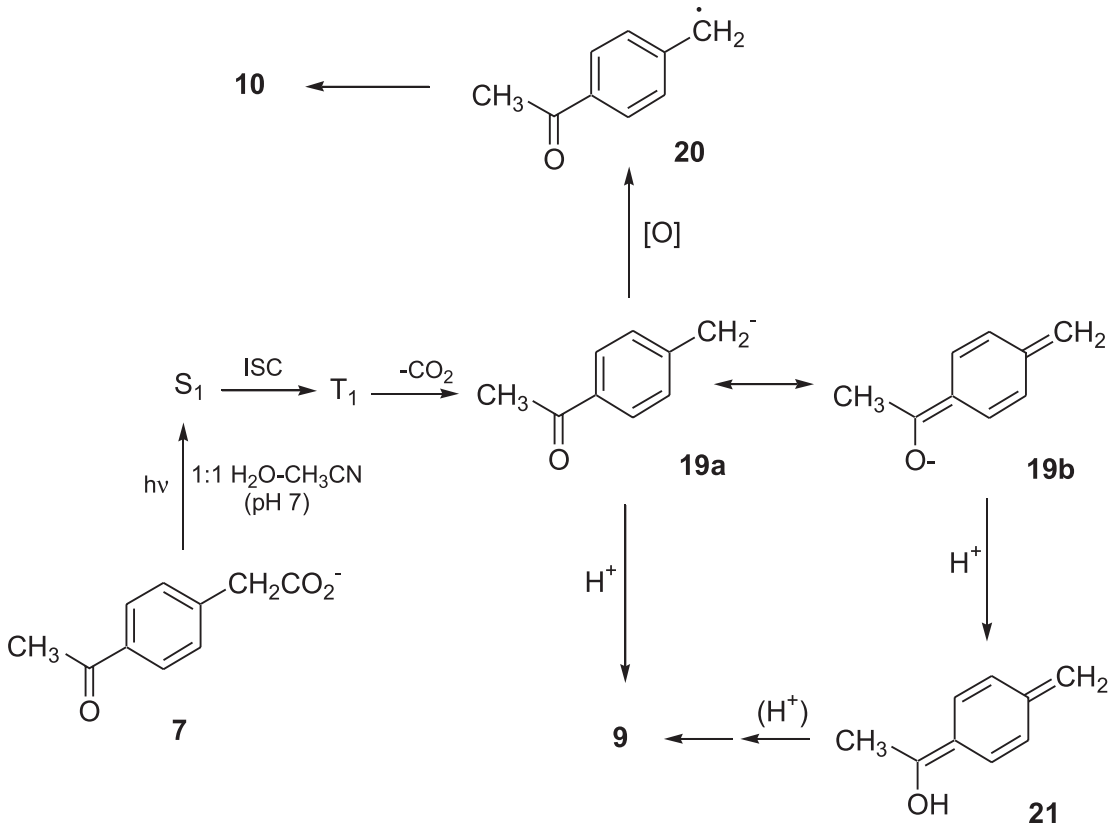
Scheme 3.



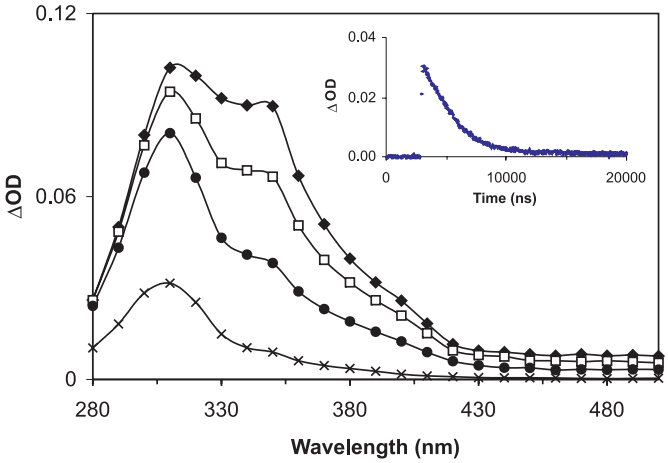


Fig. 4. Transients observed on LFP of **7** in H_2O–CH_3CN (1:1, pH 7, 266 nm excitation, N_2 purged); 500 ns (◆), 800 ns (□), 1600 ns (●), 13 000 ns after the laser pulse (×)). The transient at 400 nm (shoulder) is assigned to **19** or **21** and decays with first-order kinetics (inset) with $\tau \approx 1700$ ns.

tion in the 300–380 nm region, where the decays do not obey simple first-order kinetics, likely caused by the overlapping absorptions; only the 400 nm transient exhibited first-order decay. This increased complexity is not surprising since this compound gave two photoproducts (**9** and **10**) at all pH. Analogous experiments to **6** (vide supra) were performed to identify as many of the observed transients as possible, within the scope of the time resolution of the laser equipment. When H_2O was replaced with D_2O, an increase in lifetime (by about twofold) of the 400 nm transient was observed, while the lifetimes of the other transients were essentially unaffected. The products of the photodecarboxylation of **7** are formally derived from a benzyl carbanion **19** (to give **9**) and a benzyl radical **20** (to give **10**). Therefore, we assign the 400 nm transient to (ground state) carbanion **19a/19b** (Scheme 3), although we cannot rule out that it is in fact the corresponding enol **21**. The mechanism of photodecarboxylation of **7** (Scheme 3) proceeds in a similar fashion as proposed for **6**. After extrusion of CO_2 (via the carboxylate form), a benzyl carbanion (**19**) is generated, which can follow two possible routes to the product. It is either carbon protonated immediately to give **9** or is protonated at the oxygen to give enol **21**. Either pathway eventually leads to product **9**. The LFP transient at 400 nm could be reasonably assigned to either **19** or **21**. Compared to the analogous transient **15/16** for the meta acid **6**, the present transient is longer lived since the structure would have better resonance stablization. Improved resonance stabilization also explains the observed red shift (≈60 nm) of this transient.

The benzyl radical **20** is likely contained within the broad strong 300–380 nm absorption. These transients are all sensitive to oxygen, as would be required for such a radical. The parent benzyl radical itself is known to absorb at ≈315 nm (11). Although our results cannot discern among the various mechanisms possible for formation of **10,** we propose that one possible pathway is formation of **20** via oxidation of **19** (either by residual oxygen or by absorption of a photon). Another possibility is the coupling of two mole-

© 2004 NRC Canada

cules of **19**, giving a diradical dianion, which is then oxidized, similar to that proposed for **2** (Scheme 1). However, the much shorter lived **19** (1700 ns) compared to the para nitro analogue **12** (60 s) makes this less likely. However, it would appear that the longer lifetime of **19** compared to the corresponding meta carbanion **15** does allows for the minor "radical" pathway giving rise to the corresponding dimer **10**.

Summary

We have shown that acetophenone derivatives **6** and **7** undergo efficient photochemistry that is best rationalized as being due to the enhanced electron-withdrawing character of the acetyl group in the triplet excited state. The photochemistry mirrors some of the observed behaviour for the much-studied nitrophenylacetic acids **1** and **2**. The triplet state is reactive, although we cannot rule out residual singlet state reaction. Our results suggest that new types of photochemistry via ionic intermediates may be available for aromatic ketones, which will require a reevaluation of the present theoretical understanding of ketone photochemistry, at least in polar solvents such as water.

Experimental

General

^{1}H NMR spectra were recorderd on a Bruker AC300 (300 MHz) instrument in $CDCl_3$ unless otherwise specified. MS and HR-MS were obtained on a Kratos Concept H (EI) instrument. UV–vis spectra were recorded on a Varian Cary 5 instrument. Acetonitrile (HPLC or spectral grade) used for LFP experiments was dried by distillation from calcium hydride. Organic extracts were dried over anhydrous magnesium sulfate and filtered. pH(D) values were measured using a Fisher Accumet 915 pH meter.

Materials

3-Acetylphenylacetic acid (6)

3-Methylacetophenone (Aldrich, 5.17 g, 38 mmol) was added to a solution consisting of 100 mL CCl_4, 1.2 equiv. *N*-bromosuccinimide (8.23 g, 46 mmol), and a catalytic amount of benzoyl peroxide, and refluxed for 20 h under N_2. The bromination product was isolated by first evaporation of the solvent and subsequent dissolution in CH_2Cl_2 (with back-wash with water). This crude material was then dissolved in 10% H_2O–CH_3CN and refluxed for 4 h with 1.1 equimolar of NaCN. The resulting crude cyano derivative was hydrolyzed directly with concd. HCl (refluxed in 50 mL for 5 h). The crude acid product was isolated by evaporation of the solvent to give a brown solid, which was then dissolved in a minimum of hot water, filtered, and cooled. The crude product was recrystallized again in water to yield a white powder (0.38 g, 12% overall yield); mp (uncorrected) 96–99 °C (lit. value (13) 106 °C). ^{1}H NMR (300 MHz) δ: 2.59 (s, 3H, CH_3), 3.71 (s, 2H, $ArCH_2$), 7.43 (m, 2H, ArH), 7.86 (m, 2H, ArH), 10.8 (in acetone-d_6, br, COOH). ^{13}C NMR (250 MHz) δ: 26.6 (CH_3), 40.7 (CH_2), 127.5 (ArCH), 128.9(ArCH), 129.3 (ArCH), 133.8 (*ipso*), 134.1(ArCH), 137.5 (*ipso*), 176.6 (CO_2H), 197.9 (R_2CO). HR-MS calcd. for $C_{10}H_{10}O_3$: 178.0630; found: 178.0631.

4-Acetylphenylacetic acid (7)

The desired product was synthesized in a similar procedure and with comparable yield to **6** previously. The compound is a white powder, mp (uncorrected) 106–108 °C (lit. value (13) 119 °C). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.58 (s, 3H, CH_3), 3.70 (s, 2H, $ArCH_2$), 7.36 (d, J = 8 Hz, 2H, ArH), 7.92 (d, J = 8 Hz, 2H, ArH), 12.4 (in acetone-d_6, br, COOH). ^{13}C NMR (250 MHz) δ: 26.6 (CH_3), 40.8 (CH_2), 128.7 (CH), 129.7 (CH), 136.2 (*ipso*), 138.6 (*ipso*), 176.1 (CO_2H), 197.8 (R_2CO). HR-MS calcd. for $C_{10}H_{10}O_3$: 178.0630; found: 178.0629.

Product studies

Preparative photolyses for **6** and **7** were carried out with samples (10–100 mg) dissolved in the appropriate solvent (40–100 mL) and transferred to a 100 mL quartz tube. The solution was irradiated in a RPR-100 photochemical reactor fitted with 254 nm or 300 nm lamps with continuous cooling (by a cold finger) and purging by a stream of argon for approximately 10 min before and continuously during irradiation (via a long stainless steel needle). Photolysis times ranged from 1 to 30 min, depending on the conversion desired, the efficiency of the reaction, and the size of the sample. After photolysis, aqueous samples were acidified (if necessary) and extracted with CH_2Cl_2. Direct evaporation of the organic solvent was used when samples were irradiated in wholly organic solvents. As the photoproducts are somewhat volatile, the temperature was kept under 30 °C during evaporation and the flask was returned to atmospheric pressure as soon as the solvent was removed. Typical experiments are described in the following.

Photolysis of 6 (pH 7)

Compound **6** (50 mg) was dissolved in 100 mL of H_2O–CH_3CN (1:1) and the pH was adjusted to 7 using aq. NaOH. The solution was irradiated using 4 × 254 nm lamps for 15 min. After photolysis, the solution was made acidic with concd. HCl (to pH < 2) and extracted with CH_2Cl_2 (3 × 40 mL). The solvent was dried over $MgSO_4$ and concentrated on a rotary evaporator. The ^{1}H NMR (300 MHz) was obtained in $CDCl_3$ and gave a spectrum identical to that of the commercial 3-methylacetophenone δ: 2.40 (s, 3H, $ArCH_3$), 2.58 (s, 3H, $COCH_3$), 7.37 (m, 2H, ArH), 7.74 (m, 2H, ArH). Conversion to **8** was 100%. MS (*m*/*z*): 134 (M^+).

Photolysis of 6 (pH ≈ 0)

Compound **6** (50 mg) was dissolved in 10% H_2SO_4–CH_3CN (1:1). Procedure as for pH 7 previously. The NMR spectrum of the product was the same as pH 7, with unreacted **6**. Conversion to **8** was 15% by ^{1}H NMR.

Photolysis of 6 (pD 7)

Compound **6** (100 mg) was dissolved in 100 mL of D_2O–CH_3CN (1:1) and the pD was adjusted to 7 with a solution of NaOD–D_2O. The ^{1}H NMR (300 MHz) spectrum of the photoproduct (76% yield) was identical to that of commercial 3-methylacetophenone except that the aromatic methyl group was monodeuterated (product **8**-α**D**). It was separated from the product mixture using column chromatography (CH_2Cl_2, R_f = 0.73): δ: 2.38 ("t", 2H, J = 2 Hz, $ArCH_2D$), 2.58 (s, 3H, $COCH_3$), 7.34 (m, 2H, ArH), 7.74 (m, 2H, ArH).

© 2004 NRC Canada

Photolysis of 7

Compound **7** (100 mg) was dissolved in 80 mL of H_2O–CH_3CN (1:1) and the pH was adjusted to 7.5 using aq. NaOH. The solution was irradiated using 254 nm lamps for 30 min. After photolysis, the solution was made acidic with concd. HCl (so the pH < 2) and extracted with CH_2Cl_2 (3 × 40 mL). The solvent was dried with $MgSO_4$ and concentrated. The products were separated by preparative TLC (5% EtOAc–CH_2Cl_2) to give two photoproducts, 4-methylacetophenone (**9**, 78%) and a dimer **10** (22%). The ^{1}H NMR (300 MHz) spectrum of **9** was identical to that of the commercial 4-methylacetophenone δ: 2.25 (s, 3H, $ArCH_3$), 2.42 (s, 3H, $COCH_3$), 7.20 (d, J = 8 Hz, 2H, ArH), 7.80 (d, J = 8 Hz, 2H, ArH). MS (EI, m/z): 134 (M^+). Dimer **10**: ^{1}H NMR (300 MHz) δ: 2.58 (s, 6H, CH_3CO), 3.00 (s, 4H, $ArCH_2$-), 7.20 (d, 4H, J = 8 Hz, ArH), 7.85 (d, 4H, J = 8 Hz, ArH). MS (EI, m/z): 266 (M^+).

Triplet sensitization of 6

Compound **6** (9.1 mg) was dissolved in 3.0 mL of D_2O–CD_3CN (2:1). Two aliquots (0.5 mL) were removed and diluted, one was with 0.5 mL CD_3CN and the other with 0.5 mL acetone-d_6. The solutions (8×10^{-3} mol L^{-1}) were placed into NMR tubes and purged with argon. The solutions were photolyzed for 90 s (8 × 300 nm lamps). Photodecarboxylation yields (by ^{1}H NMR) were 33% and 43% for D_2O–CD_3CN vs. D_2O–acetone-d_6 solutions, respectively.

Quantum yields

Photodecarboxylation quantum yields for **6** and **7** were determined using relative methods that involved comparison of the yields of decarboxylated product between ketoprofen (**4**) with a known quantum yield (secondary actinometric standard) of 0.75 (6) and those of the compounds in question, as determined by ^{1}H NMR integration. A known amount of standard was dissolved in CH_3CN–H_2O (1:1, 2×10^{-3} mol L^{-1} adjusted to pH 7) and photolyzed as above for 1 min (4 lamps, 254 nm). An equimolar amount of the compound of unknown quantum yield was irradiated under the same conditions and decarboxylation determined by ^{1}H NMR integration of the benzyl methyl protons.

Nanosecond laser flash photolysis (LFP)

LFP studies were carried out at the University of Victoria laser flash photolysis facility. A Spectra-Physics Nd:YAG laser (266 nm, ~10 ns, <30 mJ/pulse) was used for excitation and signals were digitized with a Tektronix TDS 520 recorder. Samples of OD ~ 0.4 at 266 nm were prepared and irradiated in 7 mm quartz cells. Flow cells were used to obtain spectra and kinetic data. Runs using static cells in aqueous solution gave irreproducible results because of efficient depletion of substrate because of efficient photochemical decarboxylation. Solutions were purged (with N_2 or O_2) prior to and continuously during LFP studies.

Acknowledgments

The Natural Sciences and Engineering Research Council of Canada (NSERC) and the University of Victoria are acknowledged for continued support of this research. We thank Matt Lukeman for help with some initial LFP experiments.

Synthesis and thermolysis of a spiro-fused oxadiazoline — Evidence for sequential formation of carbene and oxirane intermediates, and for oxirane dimerization

Arkadiusz Klys, Wojciech Czardybon, John Warkentin, and Nick Henry Werstiuk

Abstract: The spiro-fused oxadiazoline, 3,4-diaza-2,2-dimethyl-1,6,10-trioxaspiro[4.5]dec-3-ene, when thermolysed in a sealed tube in benzene-d_6 at 110 °C, afforded acetone and an apparent oxirane intermediate (2,2-dimethyl-1,4,8-trioxaspiro[2.5]octane) that could not be isolated. Attempts to isolate the oxirane gave a dimer (8,8,11,11-tetramethyl-1,5,7,10,12,16-hexaoxadispiro[5.2.5.2]hexadecane) as the major product. The oxirane is thermally stable at 110 °C but it is very sensitive to water, as indicated by its gradual disappearance after the tube was opened. The dimer of the oxirane is believed to form from a cation arising from the ring-opening of the oxirane when it reacts with moisture. This cation then reacts with the oxirane itself to regenerate water, which is effectively a catalyst for conversion of the oxirane to the dimer.

Key words: carbene, dioxacarbene, dialkoxyoxirane, oxadiazoline, 2,5-dihydrooxadiazole.

Résumé : Opérant dans un tube scellé, en solution dans du benzène-d_6 et à une température de 110 °C, on a réalisé la thermolyse de l'oxadiazoline à fusion spiro, 3,4-diaza-2,2-diméthyl-1,6,10-trioxaspiro[4.5]déc-3-ène, qui conduit à la formation d'acétone et d'un intermédiaire qui n'a pas été isolé et qui serait le 2,2-diméthyl-1,4,8-trioxaspiro[2.5]octane. Des essais en vue d'isoler l'oxirane ont conduit à la formation, comme produit majeur, du dimère 8,8,11,11-tétraméthyl-1,5,7,10,12,16-hexaoxadispiro[5.2.5.2]hexadécane. L'oxirane est thermiquement stable à 110 °C, mais il est très sensible à l'eau, comme on peut en déduire de sa disparition graduelle une fois que le tube est ouvert. On croit que le dimère de l'oxirane se forme à partir d'un cation qui se formerait à partir d'une ouverture de cycle de l'oxirane par réaction avec de l'eau. Ce cation pourrait alors réagir avec l'oxirane lui-même pour régénérer l'eau qui ne serait de fait qu'un catalyseur dans la conversion de l'oxirane en dimère.

Mots clés : carbène, dioxacarbène, dialkoxyoxirane, oxadiazoline, 2,5-dihydrooxadiazole.

[Traduit par la Rédaction]

Introduction

Many 2,2-dialkoxy-5,5-dialkyl-Δ^3-1,3,4-oxadiazolines (**1**), also known as 2,5-dihydro-2,2-dialkoxy-5,5-dialkyl-1,3,4-oxadiazoles, have been prepared and thermolyzed in benzene solution at temperatures near 110 °C (1). Their thermolysis is generally formulated as involving a 1,3-dipolar cycloreversion, by loss of N_2, to form a carbonyl ylide intermediate (**2**). Experimental evidence for a possible carbonyl ylide intermediate has been presented in only a few instances (2), suggesting that they are short-lived, if they bear two alkoxy groups, or that they are not real. Recent computational results[2] suggest that whether or not an ylide is a real intermediate in thermolysis of some oxadiazolines depends on the level of theory employed. In any case the ultimate products of oxadiazoline fragmentation are N_2, a ketone, and a dialkoxycarbene (**3**). An ylide intermediate, if real, fragments rapidly to the latter two products, Scheme 1. The carbene, a nucleophile, could then add to the ketone carbonyl group, either in a stepwise process via intermediate **4** or in a concerted reaction leading directly to oxirane **5**.

The existence of a ylide intermediate in oxadiazoline thermolysis has been questioned, on the basis of results of computation at a low level of theory. Smith (3) proposed a concerted reaction to afford a dialkoxycarbene without the intermediacy of a carbonyl ylide. If that were the case, products from apparent ylide intermediates could still arise via **4** or **5**, from attack of the carbene on the ketone, if **5** were to open to **2**.

We now present evidence for the formation of carbene **8** and oxirane **9** intermediates in the thermolysis of the spiro-fused oxadiazoline **6**, Scheme 2. Although a carbonyl ylide

Scheme 1.

Scheme 2.

intermediate **7** is possible from a mechanistic point of view, there is not any experimental evidence for it in this case.

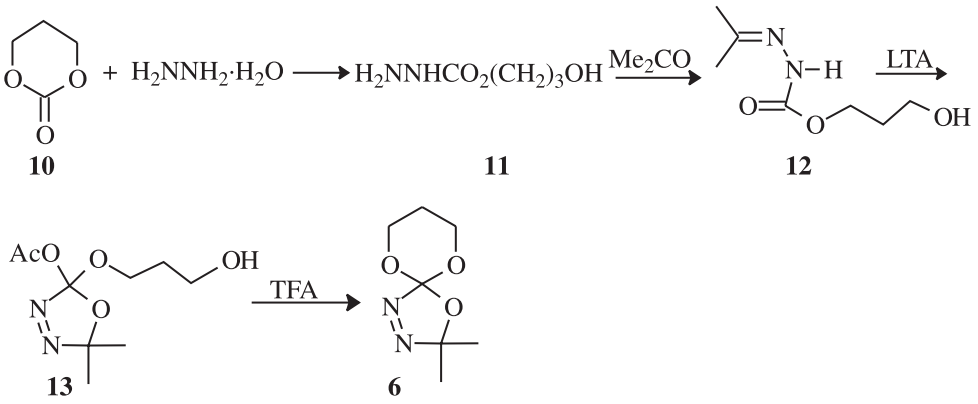
Results and discussion

Oxadiazoline **6** was prepared by hydrazinolysis of carbonate **10**, conversion of the product (**11**) to the isopropylidene hydrazone **12**, oxidative cyclization of **12** to **13** with $Pb(OAc)_4$ in dichloromethane (2*b*), and acid catalysed cyclization of **13** to **6**, Scheme 3. Heating of a benzene solution of **6** (72 h) at 110 °C in a sealed tube gave a major product (ca. 60% by GC) and several minor products, one of which had a longer GC retention time. The initial major product was transformed, at room temperature, into the latter minor product after the tube was opened. Sometimes this process took a few hours and sometimes about one day. It is probably related to the rate at which the solution absorbed water from the atmosphere after the reaction tube was opened. Chromatography of the initial reaction mixture caused the same transformation.

We suggest the following interpretation of these results, Scheme 4. Thermolysis of **6** leads to loss of N_2 to form carbonyl ylide **7**. Fragmentation of **7** to **8** is probably slowed, relative to the rate of fragmentation of analogous ylides that lead to an acyclic dialkoxycarbene, because carbene **8** is U-shaped. The U-conformation of allyloxymethoxycarbene lies about 11 kcal mol^{-1} higher in energy than the W-conformation (4). That energy difference could mean that the transition state for formation of a U-shaped dialkoxycarbene from a carbonyl ylide is higher in energy than an analogous transition state for fragmentation to a W-shaped dialkoxycarbene. Nevertheless, a large fraction of the ylide fragments to the carbene (**8**) and acetone, as discussed below.

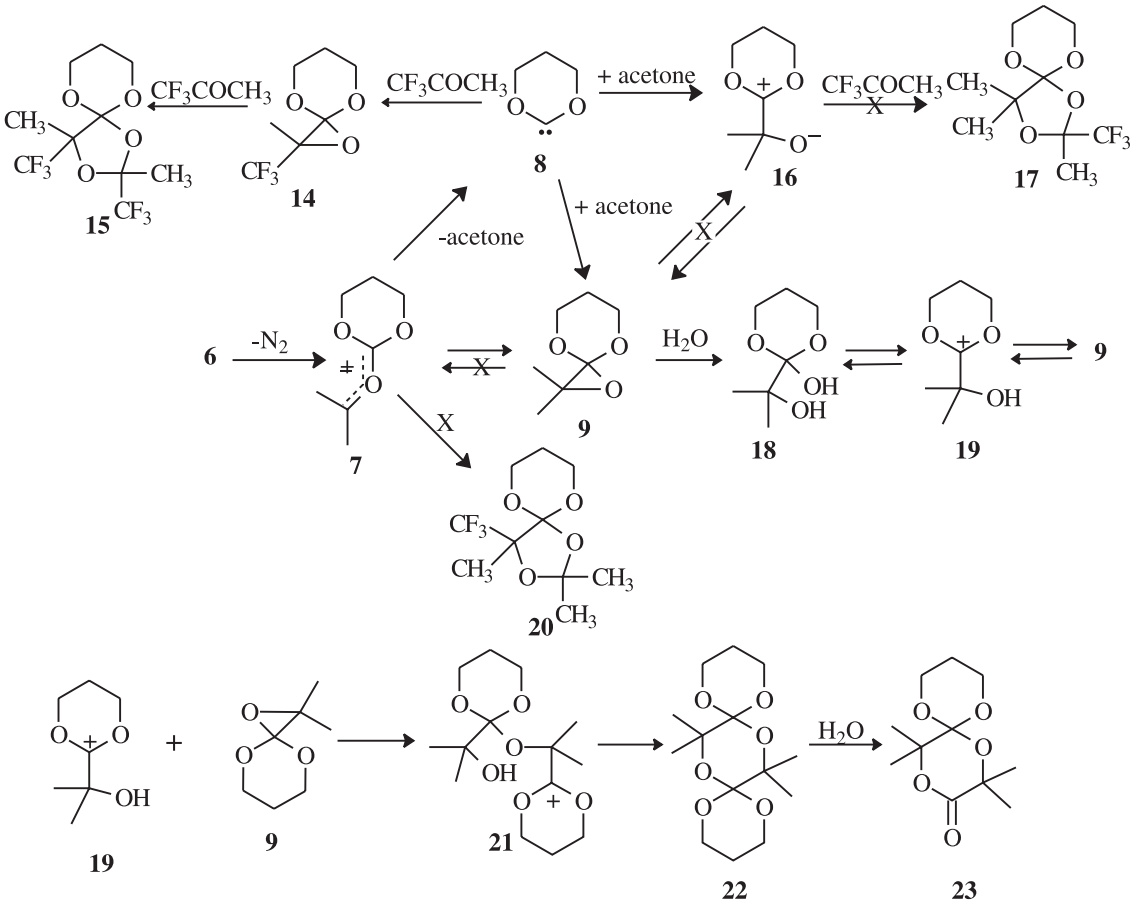
The longer lifetime of **7** could lead to some closure to oxirane **9**, which was a major initial product, but **9** must also come from attack of the carbene on acetone, as indicated by the results of inclusion of 1,1,1-trifluoroacetone, at two different concentrations, during the thermolysis. With a 5-fold excess of trifluoroacetone (0.5 mol/L), oxiranes **9** (3 parts) and **14** (7 parts) as well as diol **18** (4 parts) were the major products obtained before workup. With a 10-fold excess of trifluoroacetone (1.0 mol/L), oxirane **9** was not detected but **14** and **18** were observed in approximately a 4:3 ratio. Workup led to the conversion of **14** to a single diastereomer of **15** and to the loss of **18**. Products from **18** were not identified. The fact that formation of **9** was suppressed at the higher concentration of trifluoroacetone must mean that most of the **9** observed when trifluoroacetone was absent, or present at a low concentration, arose from addition of the free carbene (**8**) to acetone. Thus, fragmentation of presumed ylide **7**, although slowed because of the conformation imposed on carbene **8**, must still be fast relative to electrocyclic ring closure of **7** to **9**. Oxirane **9** must be formed primarily by reaction of carbene **8** with acetone. Trifluoroacetone, when present at a relatively high concentration, is expected to trap essentially all of the free carbene to form **14**. How **14** reacts to afford **15** is not known.

We did not find any **17**, which should have been present if **9** were in equilibrium with **16**, nor was any **20** detected. Compound **20** would be an expected product from the alternative ring opening of **9** to ylide **7**.



The finding of **9** and **14** is supported by precedent. One cyclic dialkoxyoxirane model (**24**) for **9** is known (5), and one 2,2-dimethoxyoxirane **25** has been reported (1*g*). In the absence of water, **9** must be relatively stable, since it can survive heating of **6** at 110 °C in benzene for 72 h. Oxirane **9** cannot undergo reversible ring opening rapidly, either to the carbonyl ylide **7** or to the isomeric zwitterion **16**, because those intermediates would react with trifluoroacetone.

In the presence of moisture, which enters slowly from the atmosphere once the sealed tube has been opened, oxirane **9** undergoes ring opening to the dihydroxy compound **18**, which must itself be in equilibrium with oxirane **9**, via cationic intermediate **19**, Scheme 4. Cation **19** reacts with oxirane **9** to afford 8,8,11,11-tetramethyl-1,5,7,10,12,16-hexaoxadispiro[5.2.5.2]hexadecane (**22**) the structure of which was secured by means of single crystal X-ray diffraction. Presumably the mechanism of formation of **22** involves intermediate **21**. Such a reaction would be unlikely in the presence of excess water, because there would not be any oxirane available, but it is likely when the available water is that absorbed from the atmosphere. Water is probably catalytic at very low concentrations, promoting the conversion of **9** to **22** without being consumed significantly. Lactone **23** is presumably the result of partial hydrolysis of **22** during the workup.



The present results may be surprising in view of the fact that oxadiazoline **26**, upon thermolysis in benzene, was reported (2*b*) to afford the carbene dimer **27** (ca. 20%), Scheme 5. An oxirane dimer, analogous to **22**, was not re-

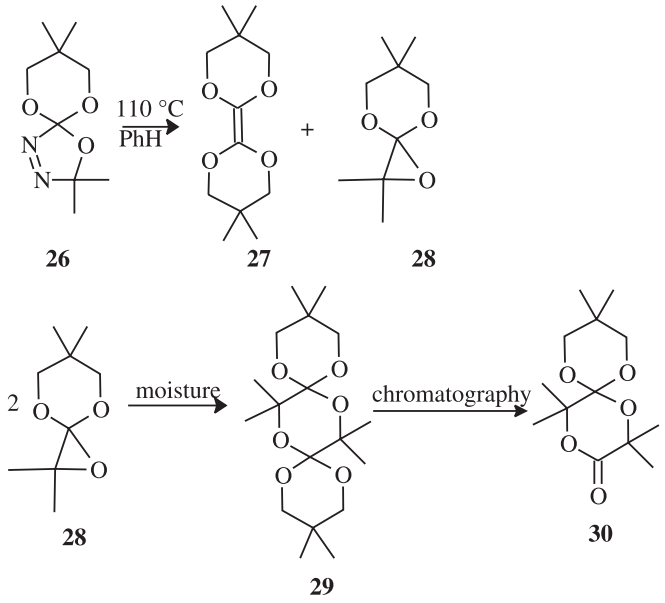
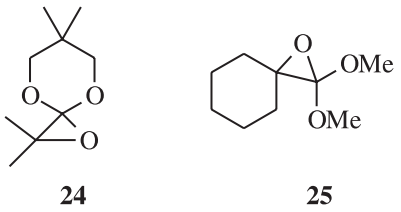
Scheme 4.



ported and in the present case, a carbene dimer was not isolated from thermolysis of **6**. Checking the NMR spectra and mass spectra again confirmed that the compound isolated from **26** was indeed **27**. However, **27** was obtained in only about 20% yield and only one additional, minor product (**30**) was identified. Compound **30**, analogous to **23**, is presumably derived from dimerization of oxirane **28** to **29** and partial hydrolysis of the latter, Scheme 6 (2*b*). The presumed intermediates, **28 and 29**, were not seen. Similarly, the thermolysis of **6** in the absence of trifluoroacetone gave many products that could have included the dimer of **8**.

In conclusion, it is likely that **6** and **26** undergo thermolysis by analogous mechanisms, affording products from the appropriate carbenes and from reaction of those carbenes with acetone. Although not all of the products were isolated and identified by different workers, there is no conflict between the results from thermolysis of **6** and **26**, which are expected to be qualitatively the same. However, it appears that the products are very sensitive to the humidity and to the adsorbent used in chromatographic separations.



Catalysis of organic reactions by water is rare but not new. It is believed to occur, for example, during chlorination of olefins (6) and in the ketonization of enols (7). In the present case, water protonates and opens a highly reactive dialk-

oxyoxirane and the cationic intermediate attacks an oxirane molecule to afford an oxirane dimer.

Experimental

^{1}H NMR spectra run in benzene-d_6 are referenced to the signal for residual H in the solvent, set at 7.15 δ for benzene. ^{13}C NMR spectra were run in $CDCl_3$ and are referenced to the solvent signal at 77.16 δ for the center line.

1,3-Dioxan-2-one

1,3-Propanediol (15.6 g, 0.20 mol) and diethyl carbonate (30 g, 0.25 mol) in a 100 mL round-bottom flask fitted with a distillation column, were treated with freshly prepared NaOMe made from Na (0.18 g) and MeOH (3 mL). The solution was slowly heated to 100 °C and alcohols (methanol and ethanol, 70–85 °C at the top of the column) were collected. The temperature in the flask was slowly increased to 170 °C over a 5 h period. During this time about 80% of the product distilled at 130–150 °C. After cooling, the column was removed, excess diethyl carbonate and a trace amount of ethanol were distilled out (oil pump) and the product was distilled at 130–160 °C. Some fractions crystallized spontaneously; those that did not were dissolved in ether and the solutions were cooled to –55 °C to cause crystallization. The total yield of white crystalline product (8) was 7.65 g (30%), mp 45–46 °C. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.13 (quint, ^3J = 5.6 Hz, 2H) and 4.44 (t, ^3J = 5.6 Hz, 4H).

Synthesis of hydrazinecarboxylic acid, 3-hydroxypropyl ester (11)

To compound **10** (2.0 g, 20 mmol) in 10 mL of ethanol, in a round-bottom flask with an efficient condenser, was added hydrazine hydrate (98%, 20 mmol) during 20 min. After refluxing for 18 h the volatiles were evaporated leaving a colourless oil (2.7 g, 99%) that solidified in the freezer (9). ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.75 (quint, ^3J = 6.3 Hz, 2H), 3.57 (t, ^3J = 6.3 Hz, 2H), and 4.08 (t, ^3J = 6.3 Hz, 2H).

Synthesis of 12

After acetone (15 mL) and **11** (1.0 g, 7.5 mmol) had formed a homogeneous solution (30–45 min), it was treated overnight with anhydrous Na_2SO_4. Decanting and evaporation of the acetone left **12** as a colourless oil (1.29 g, 99%). ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.83 and 1.91 (s and m, 5H), 2.05 (s, 3H), 3.72 (t, ^3J = 5.8 Hz, 2H), and 4.40 (t, ^3J = 5.8 Hz, 2H).

Synthesis of 6

To an ice-cooled heterogeneous mixture of $Pb(OAc)_4$ (LTA) (7.4 g, 16.5 mmol) in dry CH_2Cl_2 (15 mL) was added slowly, during 1h, a solution of **12** (2.5 g, 14.4 mmol) in 10 mL of CH_2Cl_2. Glacial acetic acid (two drops) was added and the yellow mixture was stirred for 4 h at 0 °C and for 16 h at room temperature. Filtration through Celite, washing with a $NaHCO_3$ solution (5%, 2 × 50 mL), drying over Na_2SO_4, and concentration gave a crude material **13** that was dissolved in CH_2Cl_2 (20 mL). Trifluoroacetic acid (3 drops) was added and, after stirring for 90 min, thin layer chromatography (TLC) analyses showed that conversion of **13** to **6** was complete. Concentration and column chromatography on silica gel (hexane/EtOAc = 4:1) gave **6** that could be crystallized from pentane at –55 °C to give 0.55 g (22%) of pure **6,** mp 63–64 °C. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.53 (s, 6H), 1.88 (m, 1H), 2.17 (m, 1H), 4.20 (m, 2H), and 4.60 (m, 2H). The methyl groups of the oxadiazoline ring of a close analog of **6** absorb at δ = 1.52 (1*b*).

Thermolysis of 6 in benzene

A solution of **6** (344 mg, 2.0 mmol) in dry benzene was sealed into a glass tube and the tube was immersed in an oil bath at 110 °C for 72 h. One major product was detected by GC along with two minor products having longer retention times. A GC-MS gave a mass of 144 for the major product, which is consistent with oxirane **9**. The major product was transformed into one of the minor products as the feedstock aged. Isolation of the growing minor product and single crystal X-ray diffraction showed it to be **22**. The other material with a long retention time was identified as **23** on the basis of spectroscopy and analogy. A compound similar to **23**, except for a phenyl substituent, has been reported (2*b*). Chromatography (Chromatotron, SiO_2) afforded primarily the material with the longer GC retention time.

Compound 9

Compound **9** could not be isolated. In the ^{1}H NMR spectrum of the crude (200 MHz, C_6D_6) there was a strong singlet signal at 0.42 δ that disappeared slowly when the tube was opened. GC-MS *m/z*: 144 (M^+), 143 $(M-1)^+$,129 $(M-Me)^+$, 114 $(M-CH_2O)^+$, and 87 ($C_4H_7O_2^+$, 100%).

© 2004 NRC Canada

Compound 22

^{1}H NMR (500 MHz, C_6D_6) δ: 0.72 (d, J = 12 Hz, 2H), 1.68 (s, 12H), 1.73 (m, 2H), 3.44 (m, 4H), and 4.10 (t, J = 12 Hz, 4H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 24.76, 24.86, 30.21, 59.47, 79.13, and 108.43. MS (CI, NH_3) m/z: 289 $(M + H)^+$ (100), 288 (M^+, 14), 145 $(M/2 + H)^+$ (37), and 128 (33). The molecular structure of **22** was secured by means of single crystal X-ray diffraction.

Compound 23

^{1}H NMR (200 MHz, C_6D_6) δ: 1.35 (m (br), 2H), 1.44 (s, 6H), 1.51 (s, 6H), 3.28 (m, 2H), and 3.78 (m, 2H). ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 23.8, 24.3, 28.6, 29.8, 60.3, 84.9, 108.0, and 172.5. MS (EI) m/z: 231 (M + 1), 215, 200, 172, 164, 129, 103, and 70 (100%); MS (CI, NH_3) m/z: 231 $(M + H)^+$ (100), 173 (3), 145 (13), and 128 (34).

Thermolysis of 6 in benzene containing 1,1,1-trifluoroacetone in 5-fold excess

A solution of **6** (172 mg, 1.0 mmol) in benzene (10 mL) containing 1,1,1-trifluoroacetone (560 mg, 5.0 mmol) was heated as described above. Three products, with GC retention times (rt) of 5.2, 6.1, and 6.9 min were obtained. The fraction with rt = 6.9 min was collected and shown to be **15** (one diastereomer) by means of NMR spectroscopy (^{1}H, ^{19}F) and mass spectrometry. The mass spectra of the other fractions did not match the expectation for **17** which, like **15**, should have provided $(M + H)^+$ and $(M + NH_4)^+$ signals in the CI, NH_3 spectra.

Compound 15

^{1}H NMR (200 MHz, C_6D_6) δ: 1.38 (s, 3H), 1.43 (s, 3H), 1.52 (m, 2H), 3.34 (m, 2H), 3.74 (m, 2H). ^{19}F NMR (188.3 MHz, $CDCl_3$, ref. external $CFCl_3$ at –71.3 δ) δ: –78.82 (s), and –78.84 (s). MS (CI, NH_3) m/z: 328 $(M + NH_4)^+$ (12), 311 $(M + H)^+$ (100), 241(37), and 199 (15).

Compound 18

This material was not isolated in pure form. Structure **18** was assigned tentatively on the basis of its GC retention time, its mass spectrum (GC-MS) in which $(M\text{-}H_2O)^+$ was prominent at m/z = 144, and the ^{1}H NMR spectrum (200 MHz, C_6D_6) of a crude sample, that showed absorption at δ = 0.72, 1.74 (s, 5H), 3.41(m, 4H), 4.33 (s, 1H), and 5.95 (s, 1H). As expected for structure **18**, the compound was very unstable.

Thermolysis of 6 in benzene containing 1,1,1-trifluoroacetone in 10-fold excess

A solution of **6** (172 mg, 1.0 mmol) in benzene (10 mL) containing 1,1,1-trifluoroacetone (1.12 g, 10 mmol) was heated as described above. Two products were identified by GC as **15** and, tentatively, as the trifluoromethyl analogue of **18**.

Effects of di-, tri-, and tetraethylene glycols on the thermodynamic and micellar properties of Triton X-100 in water

Gwen MacIsaac, Aiysha Al-Wardian, Karen Glenn, and Rama M. Palepu

Abstract: Micellar and surface thermodynamic properties of aggregation of Triton X-100 (TX-100) in mixed solvent systems containing di-, tri-, and tetraethylene glycol with water have been investigated by employing surface tension, density, and fluorescence methods. The differences in Gibbs energies of micellization between water and binary solvent mixtures were determined to evaluate the influence of the co-solvent on the micellization process. From the surface tension measurements, the effects of the co-solvent on parameters such as surface excess, minimum area per molecule, and surface pressure indicate that the surface activity of the surfactant decreases with increasing concentration of the glycol co-solvent. Partial specific volumes, obtained from density measurements, indicate that the fraction of solvent molecules interacting with the micelles by hydrogen bonding vary with the type of additive. Fluorescence studies reveal that quenching of the pyrene probe by cetyl pyridinum chloride in TX-100 micelles is accompanied by simultaneous static and dynamic processes.

Key words: Triton X-100, glycols, thermodynamics, micelles, fluorescence quenching.

Résumé : Faisant appel à des méthodes de tension superficielle, de densité et de fluorescence, on a étudié les propriétés thermodynamiques micellaires et de surface d'un agrégat de Triton X-100 dans des solvants mixtes contenant des di-, tri- et tétraéthylèneglycols et de l'eau. Afin de pouvoir évaluer l'influence du cosolvant sur le processus de micellisation, on a déterminé les différences dans les énergies de Gibbs de micellisation entre l'eau et des mélanges de solvants binaires. Sur la base de mesures de tension superficielle, les effets du cosolvant sur de paramètres tels que l'excès de surface, la superficie minimale par molécule et la pression de surface semblent indiquer que l'activité de surface de l'agent de surface diminue avec une augmentation de la concentration du glycol agissant comme cosolvant. Les volumes spécifiques partiels, obtenus à partir de mesures de densité, indiquent que la fraction de molécules de solvant interagissant avec les micelles par liaison hydrogène varie avec le type d'additif. Les études de fluorescence révèlent que le piégeage de la sonde pyrène par le chlorure de pyridinium de cétyle des micelles de Triton X-100 s'accompagne de processus simultanés statiques et dynamiques.

Mots clés : Triton X-100, glycols, thermodynamique, micelles, piégeage de fluorescence.

[Traduit par la Rédaction]

Introduction

The self-aggregation of surfactant molecules is known to be highly dependent on the nature of the dispersion medium (1–3). Considerable research has been conducted on the effects of polar organic solvents, such as glycerol, formamide, and ethylene glycol, on the micellization process (4, 5). Studies of the micellar aggregation of surfactants in polar solvents mainly employ ionic surfactants (6–19). However, the effects of polar solvents on the micellar properties of non-ionic surfactants have been less extensively investigated and some of the results are contradictory (20–25). Penfold et al. (24) reported an increase in the micellar size on the addition of ethylene glycol, sorbitol, or glycerol, while Cantú et al. (22) observed that the micellar size of octaoxyethylene *n*-dodecyl ether ($C_{12}E_8$) decreased with the addition of glycerol. Similar decreases in micellar sizes for Pluronic P105 were also observed by Alexandridis and Yang (25). As part of a program dealing with the effects of glycols on the micellar and thermodynamic properties of poly-oxyethylene sorbitan-fatty acid esters (Tweens) and *p-tert*-octylphenoxy polyethylene ether (TX-100) in aqueous media (26–28), we present in this paper a study of the effects of diethylene glycol (DEG), triethylene glycol (TEG) and tetraethylene glycol (TTEG) co-solvents on the micellar properties of TX-100 in water. The non-ionic surfactant TX-100 is widely used to separate proteins from cell membranes (29, 30), extract DNA (31), etc. Mixed micelles of TX-100 with various lipid-like substances are extensively employed in many chemical and industrial applications (32–34). The effective-

ness of mixed micelle systems for these applications depends on the micelle size, shape. and other solution properties. In this study we report on both bulk and surface thermodynamic properties of TX-100 in the presence of glycol oligomer co-solvents employing surface tension, density, and fluorescence methods.

Experimental

Materials

All chemicals employed were of analytical grade quality. The surfactant TX-100 (Sigma) and the glycols (Aldrich) were used as supplied. Pyrene (Sigma) was purified by sublimation and recrystallized from ethanol. Cetyl pyridinum chloride (CPC) from Sigma was recrystallized from acetone.

Methods

Surface tension measurements were carried out on a Fisher 21 Tensiomat (model 21) equipped with a 13-mm diameter Pt-Ir ring. Details of the experimental procedure for the surface tension measurements are given in our earlier study (27).

Density measurements were carried out with an Anton-Paar DMA 5000 densimeter. The instrument was calibrated with air and water at 298.15 K. The temperature was controlled within ±0.001 °C.

Fluorescence measurements were carried out employing a Spex Fluoro Max-3 Spectrofluorometer. The emission spectrum of pyrene was measured in the 360 to 400 nm range by exciting pyrene probe molecules at 340 nm. The concentration of pyrene in the micellar solutions was of the order of 10^{-3} mmol/L. Surfactant concentrations for the determination of micro-polarity were of the order of 25 mmol/L. The quencher CPC concentration was varied in the range 0.1 to 0.9 mmol/L for the quenching studies and for aggregation number determination.

Results

Critical micelle concentration

A representative plot of surface tension (γ) for solutions of TX-100 in mixtures of water and glycols as a function of the surfactant concentration is presented in Fig. 1. The intersection point is taken as the critical micelle concentration (cmc) of TX-100. The small dip in the surface tension plots near the intersection point is attributed either to a trace of surface active impurity or because of the composition distribution arising from varying degrees of ethoxylation in TX-100 (35). The cmc values obtained from the surface tension measurements are presented in Table 1.

The cmc values in the presence of additives at 298 K were also determined by the variation in I_1/I_3 ratio (intensity ratio I_1 at 372 nm and I_3 at 304 nm) of pyrene with the concentration of surfactant. This method is based on the dependence of the I_1/I_3 ratio on the vibrational structure of the microenvironment of the probe. In the absence of micelles, the probe senses a polar environment, leading to higher values of the I_1/I_3 ratio. In the presence of micelles, the probe may reside in the palisade region of the micelles where the polarity is decreased, resulting in a lower I_1/I_3 ratio. The I_1/I_3 ratio as a function of surfactant concentration in various

glycol and water mixtures is presented in Fig. 2. The surfactant concentrations at the break point, as indicated in the plots, were taken as the cmc values. The characteristic vibrational structure of pyrene was not modified by the added glycol, except for a very small change in the I_1/I_3 ratio.

Surface properties

The surface excess concentration Γ_{max} and minimum area per molecule A_{min} at the air/solvent interface were obtained (36) by solving the following the equations

$$[1] \qquad \Gamma_{max} = -\frac{1}{RT}\left[\frac{\partial\gamma}{\partial \ell nc}\right]_{P.T.}$$

$$[2] \qquad A_{min} = \frac{1}{N_A\Gamma_{max}}$$

and the results are presented in Table 2. The symbols in eqs. [1] and [2] have the usual meanings. The values of surface pressure at the cmc (π_{cmc}) were obtained by employing eq. [3]

$$[3] \qquad \pi_{cmc} = \gamma_0 - \gamma_{cmc}$$

where γ_0 and γ_{cmc} are the surface tension of the pure solvent and the value at the cmc, respectively.

Thermodynamics of micellization

The Gibbs free energy of micellization (ΔG°_{mic}) was calculated using an equation based on the phase separation model (36)

$$[4] \qquad \Delta G^\circ_{mic} = RT \ln X_{cmc}$$

where X_{cmc} is the cmc value on the mol fraction scale.

The enthalpy (ΔH°_{mic}) and entropy (ΔS°_{mic}) of micellization were calculated using the following equations.

$$[5] \qquad \Delta H^\circ_{mic} = -RT^2\left(\frac{\partial \ell n X_{cmc}}{\partial T}\right)_P$$

$$[6] \qquad \Delta S^\circ_{mic} = (\Delta H^\circ_{mic} - \Delta G^\circ_{mic})/T$$

Finally, the effect of the co-solvent on the free energy of transfer ($\Delta\Delta G^\circ_{mic}$) process was obtained from the following equation.

$$[7] \qquad \Delta\Delta G^{\circ}_{mic} = \Delta G^{\circ}_{mic}(\text{glycol} + H_2O) - \Delta G^{\circ}_{mic}(H_2O)$$

The Gibbs energy of adsorption (ΔG°_{ad}) was obtained from

$$[8] \qquad \Delta G^{\circ}_{ad} = \Delta G^{\circ}_{mic} - \frac{\pi_{cmc}}{\Gamma_{max}}$$

and the results are listed in Table 3 along with other thermodynamic properties.

In the calculation of the ΔG°_{ad}, the standard state is defined as having the surface covered with a monolayer of amphiphile at a surface pressure equal to zero (37).

Discussion

In the presence of glycol additives, the cmc values increase considerably. The increase is attributed to the structure-breaking ability of the glycol additives (26). The increase in the cmc is larger than for ionic surfactants (17). Glycols may be considered as co-solvents in the present

© 2004 NRC Canada

study as well as structure-breaking solutes, thereby decreasing the hydrophobic effect. The cmc values obtained by the fluorescence method are slightly higher than those obtained by the surface tension method. The differences in the cmc values determined by the different techniques are attributed to the response of each technique to the individual property (36).

The increase in cmc values with temperature at a given concentration of glycol is due to the disruption of the solvent structure with temperature. It is therefore expected that the ΔG°_{mic} values would become less negative at higher temperature in the presence of the additive. However, the slightly more negative values of the ΔG°_{mic} at higher temperature in the presence of additive indicate that the change in the ln X_{cmc} term is more than compensated for by the change in the RT term, thereby resulting in a more negative value of ΔG°_{mic} (38). Also, at a given concentration of glycol additive, the ΔG°_{mic} values become less negative with increasing number of ethylene member groups in the glycol oligomers.

The ΔH°_{mic} is negative and follows the order TTEG > TEG > DEG. The ΔS°_{mic} values are positive and follow the order DEG > TEG > TTEG, indicating a decrease in hydrophobic interactions on the addition of glycol. The considerably lower values of the ΔS°_{mic} for the TTEG additive indicate that the TTEG is more effective in decreasing the hydrophobic effect compared to the other two additives. The values of the $\Delta\Delta G^{\circ}_{mic}$ are positive in all cases, further substantiating the hypothesis that the addition of glycol decreases the hydrophobic interactions due to improved solvation (39).

The values of Γ_{max} and π_{cmc} decrease with increasing diethylene glycol content and are lower for 10% TEG and TTEG aqueous mixtures when compared to the values for TX-100 in water. One can infer the hydrocarbon moiety of the glycols interacts with the backbone of the glycols, thereby shifting surfactant molecules from the interface to the bulk solution. This results in an increase in the minimum area per surfactant molecule and a decrease in the Γ_{max} with the addition of glycol oligomers. The effect of temperature (Table 3) indicates poor packing at the liquid/air interface. The more negative values of ΔG°_{ad} (Table 3) compared to ΔG°_{mic} (Table 2) indicate that more work has to be performed when micelles are formed from the monomeric surfactant molecules at the interface to the micellar state in the mixed solvent system.

The partial specific volume (v) of the micelle may be considered as the volume occupied per gram of dry micelle. The values of v for TX-100 in 10% DEG, TEG, and TTEG aqueous mixtures were calculated by employing the equation

$$[9] \qquad v = \frac{1}{\rho_0}\left(1 - \frac{\partial \rho}{\partial c}\right)$$

where ρ_o and ρ are the densities of solvent and micellar solution, respectively and c is the concentration of TX-100 solution in g/mL. The plot of density as a function of surfactant concentration in different glycol and water mixtures is presented in Fig. 3. The values of the partial specific volumes calculated from the slopes of the plots are presented in Table 4. The partial specific volumes of TX-100 changed slightly on addition of DEG, TEG, and TTEG. The values

follow the order DEG > TEG > TTEG > H_2O. This indicates that part of the micellar solvation of TX-100 micelles (via hydrogen bonding) is mildly affected by the addition of DEG, TEG, and TTEG (40).

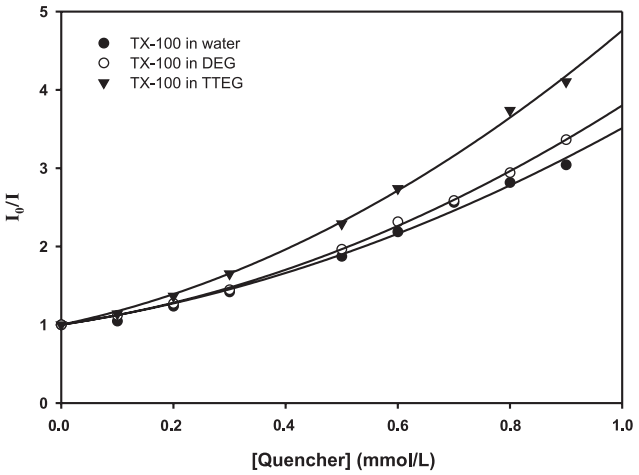
Fluorescence measurements were undertaken to determine the micropolarity of the pyrene resident in the palisade layer and to determine the aggregation numbers of the micelles in the mixed solvent system. The I_1/I_3 values of the probe in 25 mmol/L TX-100 in various glycol and water mixtures are presented in Table 4. The I_1/I_3 ratio indicates that the probe is sensing a more polar environment with increasing glycol content. This may be attributed to the decrease in the aggregation number and the steric hindrance associated with the quenching process (17).

Attempts to determine the aggregation numbers for the TX-100 micelles in the presence of glycols employing the static quenching method (41) were unsuccessful. Pyrene and

© 2004 NRC Canada

Fig. 4. 3D plot of fluorescence quenching of pyrene probe as a function of cetyl pyridinum chloride (CPC) concentration in 10% aqueous DEG solution.

CPC were used as probe and quencher, respectively. Fluorescence quenching of the pyrene probe as a function of CPC concentration in the TX-100 micellar medium is presented in Fig. 4. The aggregation numbers obtained by this method were considerably low for the TX-100 micelles and there is no definite dependence of aggregation numbers on the concentration of the glycol additives. To rationalize the situation, the quenching data were analysed in terms of the Stern–Volmer (SV) equation. The analysis indicates that the quenching in our system was accompanied by simultaneous dynamic and static processes. Taking both processes (42) into account, the modified SV equation



$$[10] \quad I_0/I = (1 + K_{SV}[Q])(1 + K_S[Q])$$

was fitted to the experimental data, where [Q] is the quencher concentration and the K_{SV} and K_S values represent the dynamic and static quenching constants, respectively. The modified SV equation is second order with respect to [Q], which accounts for its upward curvature (Fig. 5). The values of K_{SV} and K_S were determined by employing a nonlinear least squares method and are presented in Table 4. For all of our systems, the K_{SV} and K_S are similar in magnitude, so dynamic and static quenching processes both play important roles.

Conclusions

From the study of the effect of glycols on the micellization of TX-100, we have observed that the micellization process is less favourable in the presence of glycols. This is attributed to the structure-breaking abilities of glycols. In the presence of these additives the surface activity of TX-100 is also reduced. The minimum surface area increases with the glycol content in the mixture. Fluorescence studies indicate that the change in micropolarity sensed by the pyrene probe is due to improved solvation of the micelles. The quenching process of the pyrene probe by

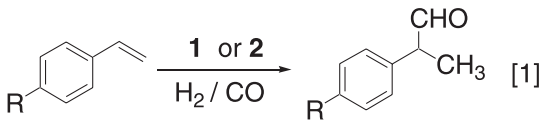
Chiral bidentate *N*-heterocyclic carbene complexes of Rh and Pd

Li Ren, Austin C. Chen, Andreas Decken, and Cathleen M. Crudden

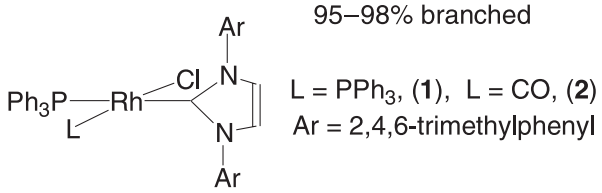
Abstract: The synthesis of a new chiral, bidentate oxazoline/imidazolidene carbene precursor is described. This species is reacted with various metal salts in the presence of a base to generate rhodium and palladium complexes, which are characterized spectroscopically and crystallographically.

Key words: chiral *N*-heterocyclic carbene, rhodium, palladium, oxazolidine, asymmetric catalysis.

Résumé : On décrit la synthèse d'un nouveau précurseur chiral et bidentate du carbène oxazoline/imidazolidène. On a fait réagir cette espèce avec divers sels métalliques, en présence de base, pour générer des complexes du rhodium et du palladium qu'on a caractérisés par des méthodes spectroscopiques et cristallographiques.

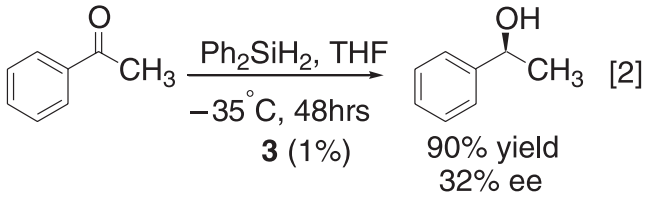


Mots clés : carbène chiral *N*-hétérocyclique, rhodium, palladium, oxazolidine, catalyse.

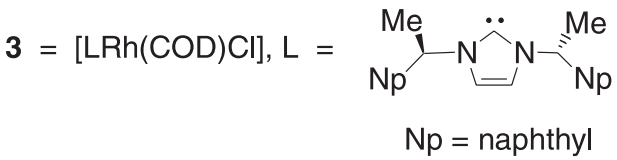


[Traduit par la Rédaction]

Introduction



The use of *N*-heterocyclic carbenes as ligands for transition metals has experienced a renaissance of late (1). These ligands display intriguing properties relative to the more commonly employed phosphine ligands. Most importantly, the binding constants of carbene ligands with catalytically active transition metals such as Ru are approximately double that of the related phosphine ligands (2, 3). Carbene ligands have proven to be extremely useful in important reactions such as Ru–catalyzed metathesis reactions (4) and Pd–catalyzed coupling reactions (5).



We have reported that mixed rhodium complexes **1** and **2**, which contain both phosphine and *N*-heterocyclic carbene ligands, are effective catalysts for the hydroformylation of vinyl arenes, giving the branched isomer with up to 98:2 selectivity (eq. [1]) (6). The activity of the carbene/phosphine complex (**2**) was twice that of the related bis-phosphine ([$RhCl(CO)(PPh_3)_2$]) under identical conditions. Furthermore, the carbene complex was more selective for the branched isomer than the bis-phosphine complex (96:4 vs. 88:12). With the regioselectivity and reactivity of these complexes established for the important hydroformylation reaction, we began the more challenging task of preparing chiral versions of these carbene complexes.

Several examples of chiral *N*-heterocyclic carbenes and their corresponding metal complexes have been reported in the literature (7–13) and an increasing number are being tested in catalytic reactions (14–20). In 1997, Herrmann reported the hydrosilylation of acetophenone with chiral monodentate carbene complex **3**, which proceeded in 32% enantiomeric excess (ee) (eq. [2]) (14*b*). The hydrosilylation of cyclohexylmethyl ketone was also examined with chiral

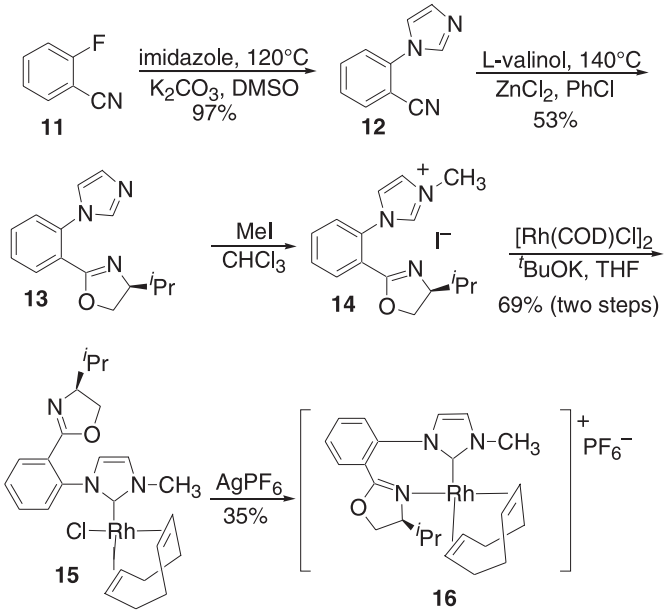
Chart 1. Successful chiral *N*-heterocyclic carbene complexes and carbene precursors.



triazolium complexes and proceeded with up to 44% ee (14*c*, *d*).

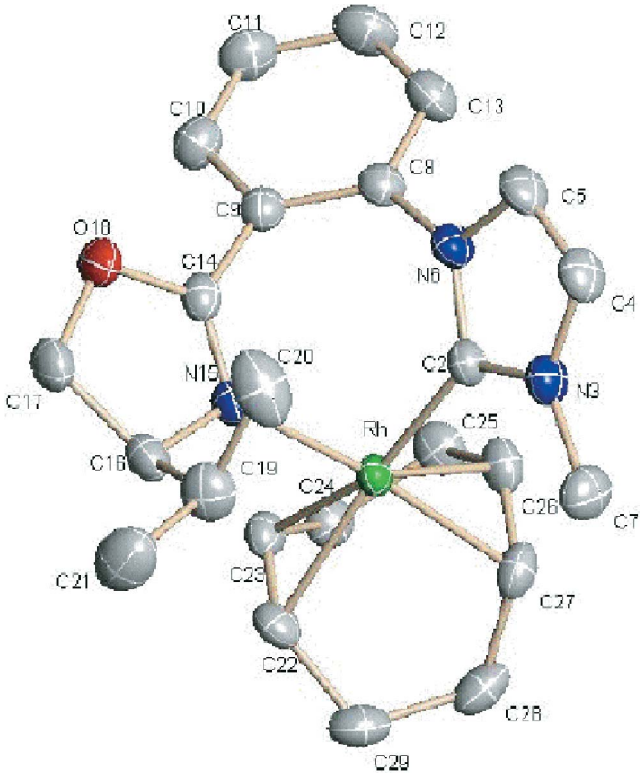
Grubbs (15), Hoveyda (16), Hartwig (17), and Burgess (18) have reported carbene ligands that give high enantioselectivity for metathesis, arylation of ketones, and hydrogenation reactions, respectively (Chart 1). Recent reports from the groups of Shi (19), Douthwaite (14*h*), and Andrus (20) have described more complex carbenes that provide >90% ee in hydrosilylation, allylic alkylation, and enone arylation, respectively. Although high selectivities have been obtained using these catalysts for specific reactions, substrate generality still needs improvement.

Inspired by the successes of Pfaltz (21) and Brunner (22) with chiral phosphine/oxazoline ligands, we have prepared carbene ligands that have a chiral oxazoline as the second point of ligation. Related oxazoline/carbene complexes have been prepared by Herrmann (14), and complex **7** was introduced by Burgess during this study (18). With the aim of increasing the transfer of chiral information by increasing the rigidity between the carbene and the oxazoline, we embarked on the synthesis of carbene precursor, **14**.

Scheme 1. Synthesis of Rh complex **16**.

Results and Discussion

Beginning with commercially available 2-fluorobenzonitrile (**11**), nucleophilic aromatic displacement of the fluoride with imidazole proceeded quantitatively yielding **12** (Scheme 1). Subsequent condensation with optically pure valinol (23) followed by methylation with methyl iodide furnished carbene precursor **14**.



Although attempts to prepare and isolate the free carbene were unsuccessful, rhodium carbene complex **16** could be obtained in two steps from $[Rh(\eta^4\text{-}1,5\text{-}COD)(\mu\text{-}Cl)]_2$ and **14**. Thus, reaction of crude **14** and the rhodium complex in the presence of potassium *t*-butoxide followed by chlorine abstraction with silver hexafluorophosphate generated **16**. The ^{13}C NMR spectrum of this material contained a signal at 181 ppm, corresponding to the ligated carbene carbon, with a distinctive rhodium-carbon coupling constant of 50 Hz.

X-ray quality crystals[4] of **16** were obtained by recrystallizing the air-stable, yellow rhodium complex from dichloromethane/hexane. The crystal structure (see Fig. 1) revealed that the rhodium adopts a distorted square planar geometry with combined angles of 359.2°. The bite angle of the carbene-imidazoline ligand in complex **16** is 84.2°. As expected, the carbene–rhodium bond ((Rh—C(2) = 2.0150(16) Å) is much shorter than the oxazoline nitrogen–rhodium bond ((Rh—N(15) = 2.0954(14) Å). A stronger trans influence of the carbene ligand could be inferred from the longer distances separating the rhodium and the olefinic carbons trans to the carbene ((Rh—C(22) = 2.2085(16) Å, Rh—C(23) = 2.2097(17) Å) relative to those trans to the

[4] Crystal data for **16**: $C_{24}H_{31}F_6N_3OPRh$, crystal size 0.125 mm^3 × 0.150 mm^3 × 0.275 mm^3, orthorhombic, $P2_12_12_1$, a = 11.6588(4) Å, b = 13.3143(5) Å, c = 16.6038(6) Å, $\alpha = \beta = \gamma = 90°$, V = 2577.39(16) Å^3, Z = 4, 2θ (max) = 32.50°, ω and φ scans, 28 697 reflections scanned, 8910 unique reflections (R_{int} = 0.0179), T = 173(2) K, full-matrix least-squares on F^2, wR_2 = 0.0547, R_1 = 0.0231. Full details of the crystallographic analysis of **13** are described in the Supporting information.[6]

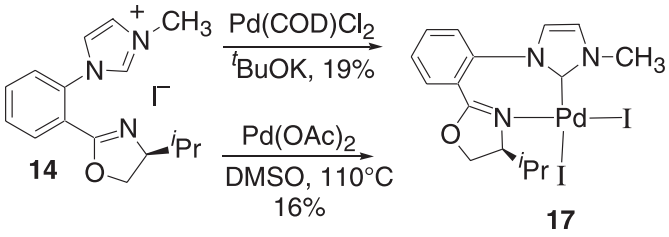
Fig. 1. View of the cation of **16**. Thermal ellipsoids are at the 30% probability level and hydrogen atoms have been removed for clarity.

oxazoline nitrogen ((Rh—C(26) = 2.1206(17) Å, Rh—C(27) = 2.1509(18) Å). However, the carbon–carbon double bond trans to the oxazoline ((C(26)—C(27) = 1.390(3) Å) is slightly longer than the C=C bond trans to the carbene ((C(22)—C(23) = 1.374(3)Å).

The corresponding palladium complex **17** could be prepared from either palladium acetate or [Pd(η^4-1,5-COD)Cl_2] (Scheme 2). Specifically, treatment of imidazolium salt **14** with [Pd(η^4–1,5–COD)Cl_2] in the presence of potassium *tert*-butoxide at room temperature, or simply heating **14** in DMSO with palladium acetate gave the same palladium-carbene iodide complex **17** (24). This structure was unambiguously demonstrated by X-ray crystallography[5] (see Fig. 2). The palladium, with the sum of the angles equal to 359.98°, is in a nearly perfect square-planar environment. Like its rhodium analogue, the palladium–iodide bond trans to the carbene (Pd—I(2) = 2.6571(3) Å) is longer than that trans to the oxazoline nitrogen (Pd—I(1) = 2.5657(3) Å). It is also noteworthy that within each asymmetric unit are two independent molecules with almost identical metric parameters. The main difference between them lies in the disposition of the two methyl residues of the isopropyl group (θ (C(21)—C(19)—C(20) = 112.0(4)° and C(41)—C(39)—C(40) = 115.3(4)°).

The catalytic activity of the new chiral rhodium-carbene

Scheme 2. Synthesis of Pd complex **17**.



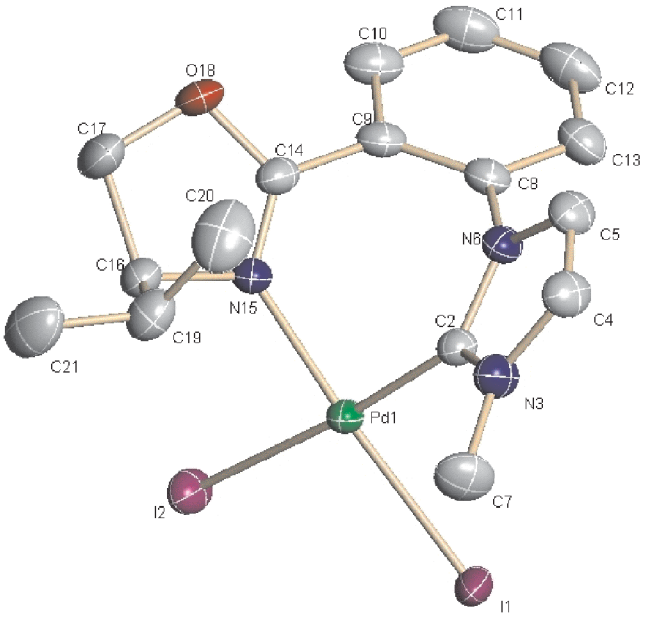


Fig. 2. View of the cation of **17**. Thermal ellipsoids are at the 30% probability level and hydrogen atoms have been removed for clarity.

complex **16** was evaluated in hydroboration and hydrosilylation reactions. Despite the chelating, monomeric form of the catalysts, the enantioselectivity of the described reactions never exceeded 10% ee. It is especially noteworthy that the bidentate ligand proved to be inferior to the monodentate ligand **3** in the hydrosilylation reaction under very similar conditions. One key difference between complex **16** and Herrmann's catalyst **3** is the C_2-symmetry of the latter species. This cannot be the sole reason for the poor performance of this species, as Pfaltz and co-workers (21) and Brunner (22) have shown that C_2-symmetry is not a necessary parameter for asymmetric induction. Regardless, it is clear that Herrmann's catalyst creates a chiral environment more effectively than the carbene derived from **14**.

Our synthetic method requires that the second group introduced onto the imidazole ring be a reactive electrophile. In this case methyl iodide was employed, with the consequence that the coordination site cis to the carbene is relatively unhindered. This may be the reason for the poor asymmetric induction observed in the reactions of complex **16**.

[5] Crystal data for **17**: $C_{32}H_{38}I_4N_3OPd$, crystal size 0.175 mm^3 × 0.250 mm^3 × 0.325 mm^3, monoclinic, *P*2(1), *a* = 8.8335(4) Å, *b* = 14.3771(7) Å, *c* = 15.7653(7) Å, α = γ = 90°, β = 99.630(1)°, *V* = 1973.98(16) Å^3, *Z* = 2, 2θ (max) = 30.00°, ω and φ scans, 19 249 reflections scanned, 10 005 unique reflections (R_{int} = 0.0168), *T* = 296(1) K, full-matrix least-squares on F^2, wR_2 = 0.0450, R_1 = 0.0206. Full details of the crystallographic analysis of **14** are described in the Supporting information.[6]

Conclusions

In conclusion, a chiral, bidentate oxazoline/carbene precursor can be prepared in three simple steps from commercially available starting materials. Herrmann's in situ deprotonation method obviates the need for the synthesis of the free carbene. The Rh catalyst **16** was examined in the hydrosilylation of acetophenone and the hydroboration of styrene. Although the catalyst was active, it gave less than 10% ee under all experimental conditions examined.

Experimental Section

General methods and materials

All solvents were dried according to standard procedures immediately prior to use and, where necessary, were purged using repeated freeze–pump–thaw cycles. Acetophenone was distilled under argon from phosphorous pentoxide. Styrene was fractionally distilled under a partial vacuum and percolated through a column of dry, neutral alumina immediately prior to use. Catecholborane was distilled from a partial pressure of argon to remove $B_2(catechol)_3$ and stored under argon in a Schlenk flask at –25 °C. All other reagents were used as received.

Instrumentation

Proton and ^{13}C NMR spectra were recorded on a Varian 400 MHz instrument using the solvent resonance as the internal standard. Gas chromatography (He carrier, 12.5 psi of head pressure (1 psi = 6.894 757 kPa), 1.14 mL/min flow) was performed with flame ionization (FI) detection using a split/splitless injector (split ratio 50) and hexane solutions. Retention times are given in min. All analyses were carried out using a 2,3-di-*O*-acetyl-6-*O*-*tert*-butyldimethylsilyl-β-cyclodextrin column (30 m, 0.25 mm diameter, 0.25 μm thickness).

Crystallography

Single crystals of **16** were coated with Paratone-N oil, mounted using a glass fibre and frozen in the cold nitrogen stream of the goniometer. Single crystals of **17** were coated with Paratone-N oil and mounted on a glass fibre with epoxy glue. A hemisphere of data was collected on a Bruker AXS P4/SMART 1000 diffractometer using ω and θ scans with a scan width of 0.3° and 30 s (for **16**) or 10 s (for **17**) exposure times. The detector distance was 4 cm. The data were reduced (SAINT) (25) and corrected for absorption (SADABS) (26). The structure was solved by direct methods and refined by full-matrix least squares on F^2(SHELXTL) (27). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in calculated positions and refined using a riding model for **17**. For **16**, hydrogen atoms were found in Fourier difference maps and refined isotropically. Thermal ellipsoid plots are at the 30% probability level. In some plots, hydrogen atoms have been omitted for clarity.

(2-Cyanophenyl)imidazole (12)

A 100 mL flame-dried, round-bottomed flask was charged with 3.634 g of 2-fluorobenzonitrile (**11**, 30 mmol), 3.064 g of imidazole (45 mmol), and 8.293 g of potassium carbonate (60 mmol) in 30 mL of DMSO. The reaction mixture was stirred at 120 °C under argon for 36 h. The reaction mixture, after cooling to room temperature, was poured into 50 mL of water to precipitate **12** as a white powder. The resulting suspension was filtered, washed, and dried in vacuo to give 4.894 g (97% yield) of the desired product. ^1H NMR (400 MHz, $CDCl_3$) δ: 7.88 (s, 1H), 7.85 (dd, 1H, J = 1.6, 7.6 Hz), 7.77 (dt, 1H, J = 1.6, 7.6 Hz), 7.56 (dt, 1H, J = 1.2, 7.6 Hz), 7.49 (dd, 1H, J = 1.2, 8.4 Hz), 7.38 (t, 1H, J = 1.2 Hz), and 7.30 (t, 1H, J = 1.2 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 139.4, 136.7, 134.5, 134.3, 130.8, 128.4, 125.6, 119.6, 115.8, and 108.1

2-[(4S)-4-Isopropyloxazolyl]phenyl imidazole (13)

Zinc chloride (0.331 g, 2.43 mmol) was fused in a 250 mL flame-dried, round-bottomed flask. Then 4.083 g of (2-cyano-phenyl)imidazole (**12**, 24.3 mmol), 3.756 g of L-valinol (36.4 mmol), and 80 mL of chlorobenzene were added sequentially. The reaction mixture was left stirring at 140 °C under argon for 60 h. Following removal of the volatiles in vacuo, the pinkish residue was taken up in 100 mL of dichloromethane and washed with water (30 mL × 3). The aqueous wash was back-extracted with another 100 mL of dichloromethane. The organic layers were combined and dried over magnesium sulfate. Filtration and concentration in vacuo afforded a viscous oil that was identified as a mixture of unreacted starting material and desired product. Due to its very low solubility in ether, the starting material was removed by trituration with diethyl ether. Filtration, followed by concentration of the filtrate in vacuo afforded 3.276 g of the desired product (53% yield). ^1H NMR (400 MHz, $CDCl_3$) δ: 7.87 (dd, 1H, J = 1.2, 7.6 Hz), 7.62 (d, 1H, J = 0.8 Hz), 7.56 (dt, 1H, J = 2.0, 7.6 Hz), 7.48 (dt, 1H, J = 1.2, 7.6 Hz), 7.34 (dd, 1H, J = 1.2, 8.0 Hz), 7.14 (d, 1H, J = 1.2 Hz), 7.10 (t, 1H, J = 1.2 Hz), 4.22 (dd, 1H, J = 7.6, 8.8 Hz), 4.01–3.89 (m, 2H), 1.80–1.70 (m, 1H), 0.94 (d, 3H, J = 6.8 Hz), and 0.88 (d, 3H, J = 6.8 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 161.8, 137.6, 131.5, 131.1, 129.2, 129.1, 128.5, 126.8, 120.6, 120.5, 72.7, 70.7, 32.7, 18.7, and 18.3.

1-(2-[(4S)-4-Isopropyloxazolyl]phenyl)-3-methyl imidazolium iodide (14)

255 mg of 2-[(4*S*)-4-isopropyloxazolyl]phenyl imidazole (**13**, 1.0 mmol) was dissolved in 20 mL of chloroform in a 50 mL round-bottomed flask. Excess methyl iodide (852 mg, 6.0 mmol) was then added dropwise to this mixture. After stirring for 16 h in the dark at room temperature, the volatiles were removed in vacuo to afford 395 mg of the desired product, which could not be purified by column chromatography or recrystallization. The crude material thus obtained was spectroscopically pure and was used in the next step without further purification. ^1H NMR (400 MHz, $CDCl_3$) δ: 9.69 (s, 1H), 8.09–8.06 (m, 1H), 7.86–7.83 (m, 1H), 7.73–7.66 (m, 2H), 7.52–7.48 (brs, 1H), 7.25 (s, 1H), 4.37 (dd, 1H, J = 8.0, 9.2 Hz), 4.27 (s, 3H), 4.02–3.89 (m, 2H), 1.68–1.60 (m, 1H), 0.86 (d, 3H, J = 2.8 Hz), and 0.84 (d, 3H, J = 2.8 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 158.9, 138.3, 133.0, 132.5, 131.4, 131.1, 128.3, 124.2, 123.6, 123.0, 73.4, 70.3, 37.6, 32.9, and 18.7 (2).

(η^4-1,5-Cyclooctadiene)(1-(2-[(4S)-4-isopropyloxazolyl]phenyl)-3-methylimidaz-olin-2-ylidene)rhodium-(I)-hexafluorophosphate (16)

In a 100 mL flame-dried, round-bottomed flask, 0.572 g of $[Rh(COD)Cl]_2$ (1.16 mmol) was dissolved in 15 mL of THF. Under vigorous stirring and an argon purge, 325 mg of potassium *tert*-butoxide (2.90 mmol, 1.25 equiv.) was then added. The resulting suspension was stirred at room temperature for 10 min and then transferred via cannula into another 100 mL flame-dried, round-bottomed flask containing 920 mg of 1-(2-[(4*S*)-4-isopropyloxazolyl]phenyl)-3-methyl imidazolium iodide (**14**, 2.32 mmol) dissolved in 5.0 mL of THF. After stirring under argon at room temperature for 40 h, the solvent was removed and the product was purified by column chromatography, eluting with solvent systems of increasing polarity (pure dichloromethane to 10% methanol in dichloromethane). The neutral rhodium(I) complex **12** was isolated as an orange foam in 69% yield (821.2 mg). This was then redissolved in 20 mL of THF and 402.7 mg of silver hexafluorophosphate (1.59 mmol) was added. A white precipitate formed immediately. After stirring for 1 h, the suspension was filtered through a sintered glass funnel and the filtrate concentrated in vacuo. The resulting residue was then purified by column chromatography, eluting with solvent systems of increasing polarity (pure dichloromethane to 2% methanol in dichloromethane). Crystallization from dichloromethane/hexane furnished the desired product as yellow crystals (500 mg, 35% yield). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.89 (dd, 1H, J = 1.6, 8.0 Hz), 7.79 (dt, 1H, J = 1.6, 7.6 Hz), 7.65 (dt, 1H, J = 1.2, 8.0 Hz), 7.48 (dd, 1H, J = 1.2, 8.0 Hz), 7.28–7.24 (m, 2H), 4.88–4.80 (m, 1H), 4.73 (dd, 1H J = 9.2, 10.4 Hz), 4.49–4.41 (m, 1H), 4.27 (dd, 1H, J = 7.2, 9.2Hz), 4.10–4.03 (m, 4H), 3.84–3.77 (m, 1H), 3.71–3.64 (m, 1H), 2.52–2.34 (m, 2H), 2.13–1.63 (m, 6H), 0.88 (d, 3H, J = 6.8 Hz), and 0.79 (d, 3H, J = 6.8 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 181.1 (d, $J_{Rh\text{-}C}$ = 50.2 Hz), 162.9, 137.7, 133.6, 130.6, 129.1, 126.3, 124.6, 123.73, 123.69, 98.8 (d, $J_{Rh\text{-}C}$ = 7.2 Hz), 95.7 (d, $J_{Rh\text{-}C}$ = 7.2 Hz), 79.3 (d, $J_{Rh\text{-}C}$ = 13.6 Hz), 72.1, 71.4, 71.2 (d, $J_{Rh–C}$ = 5.6 Hz), 37.7, 32.6, 31.9, 30.8, 29.6, 27.9, 17.2, and 17.1.

(1-(2-[(4S)-4-Isopropyloxazolyl]phenyl)-3-methylimidazolin-2-ylidene) palladium-(II)-diiodide (17)

In a 100 mL round-bottomed flask, 348.3 mg of $Pd(COD)Cl_2$ (1.22 mmol) was dissolved in 15 mL of THF. To this was added 161.6 mg of potassium *tert*-butoxide (1.44 mmol). An immediate colour change from yellow to black was observed. After stirring at room temperature for 10 min, the reaction mixture was transferred via cannula into another 100 mL flame-dried, round-bottomed flask containing 474 mg of 1-(2-[(4*S*)-4-isopropyloxazolyl]-phenyl)-3-methyl imidazolium iodide (**14**, 1.2 mmol) in 5.0 mL of THF. The resulting mixture was then stirred for another 24 h. The solvent was then removed and the residue purified by column chromatography, eluting with solvent systems of increasing polarity (6:1 hexane/dichlormethane to pure dichloromethane). The desired product was then crystallized from dichloromethane/hexane yielding dark orange crystals (100 mg, 19% yield).

Alternatively, the same complex can be prepared as follows: In a 100 mL flame-dried, round-bottomed flask, 0.444 g of 1-(2-[(4*S*)-4-isopropyloxazolyl]phenyl)-3-methyl imidazolium iodide (**11**, 1.12 mmol) and 0.251 g of palladium acetate (1.12 mmol) was dissolved in 10 mL of DMSO. The reaction mixture was stirred under argon at 50 °C for 2 h and then at 110 °C for another 48 h. The solvent was then removed and the residue purified by column chromatography, eluting with pure dichloromethane. The desired product was then crystallized from dichloromethane/hexane yielding dark orange crystals (102 mg, 16%). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.88 (dd, 1H, J = 1.6, 7.6 Hz), 7.80 (dt, 1H, J = 1.6, 8.0 Hz), 7.66 (dt, 1H, J = 1.2, 8.0 Hz), 7.55 (dd, 1H, J = 1.2, 8.0 Hz), 7.23 (d, 1H, J = 2.0 Hz), 7.19 (d, 1H, J = 2.0 Hz), 5.24 (ddd, 1H, J = 3.2, 3.6, 3.6 Hz, 1H), 4.64 (dd, 1H, J = 9.2, 10.4 Hz), 4.34 (dd, 1H, J = 6.8, 9.2 Hz), 4.16 (s, 3H), 2.40 (m, 1H), 0.88 (d, 3H, J = 6.8 Hz), and 0.60 (d, 3H, J = 6.8 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 162.4, 136.9, 134.1, 131.0, 129.5, 126.7, 124.3, 123.8, 122.2, 72.6, 70.4, 40.7, 30.4, 17.9, and 14.8.

Hydroboration of styrene

In a 10 mL flame-dried, round-bottomed flask, 12.5 mg of rhodium complex **9** (0.01 mmol) was suspended in 2 mL of dried, deoxygenated THF. Freshly purified styrene (0.11 mL, 0.96 mmol) was then added to the reaction vessel and the mixture was stirred at room temperature for 10 min. Upon cooling to the desired temperature (0 °C or –30 °C) catecholborane (0.16 mL, 1.5 mmol) was added dropwise as a solution in 1 mL of THF over 20 min. Care was taken to minimize the variation in internal reaction temperature during this addition. After 16 h, 2 mL of methanol was added. The temperature was brought to 0 °C and the boronate ester was treated, under an atmosphere of nitrogen, with 1 mL of a 2 mol/L aqueous sodium hydroxide solution and 0.2 mL of hydrogen peroxide (30% (*w*/*v*)). The resulting black reaction mixture was then diluted with ether and the organic layer was separated. The aqueous layer was extracted further with ether (5 mL × 3). The organic extracts were combined, washed with brine (5 mL), and dried over magnesium sulfate. Filtration through a sintered glass funnel, followed by concentration of the resulting mixture in vacuo yielded the crude alcohols. The linear-to-branched ratio was elucidated from ^{1}H NMR of the crude product mixture with a 30 s delay inserted between each acquisition. Spectroscopically pure 1-phenylethanol was obtained by flash chromatography with 4:1 hexane/ether as eluent and its enantiomeric purity was determined by chiral GC (temperature protocol, 80 °C, 3 min, then increase 1 °C per min to 130 °C; retention times (*R*) = 33.5 min, (*S*) = 35.4 min). The following results were obtained at 0 °C: 58% combined yield, branched:linear = 55:45, ee = 7%.

Hydrosilylation of acetophenone

In a 25 mL flame-dried, round-bottomed flask was dissolved 27 mg of rhodium complex **9** (0.04 mmol) in 2 mL of deoxygenated, dried THF. Then 0.5 mL of freshly purified acetophenone (4.3 mmol) was added to the reaction mixture and the resulting pale yellow solution was cooled to –25 °C. Next 0.8 mL of diphenylsilane (4.3 mmol) was added neat, dropwise, over a period of 15 min and the reaction mixture was stirred under argon at –25 °C for 41 h. Hydrolysis of the silyl ether was accomplished through the addition of 1 mL

© 2004 NRC Canada

of methanol and a few crystals of *p*-toluenesulfonic acid. Complete hydrolysis was achieved after 10 h at room temperature. Spectroscopically pure 1-phenylethanol was obtained by flash chromatography with 4:1 hexane/ether as eluent (141 mg, 27% yield, 34% conversion by NMR). Enantiomeric excess (2%) was determined by chiral GC (temperature protocol, 80 °C, 3 min, then increase 1 °C per min to 130 °C; R = 33.5 min, S = 35.4 min).

Supplementary material

Supporting information available lists details of the crystal structure determination for compounds **13** and **14**.[6]

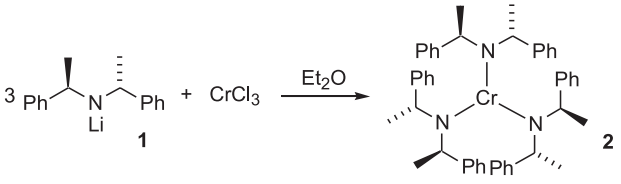
RAPID COMMUNICATION / COMMUNICATION RAPIDE

Synthesis and X-ray crystal structure of $Cr(NR_2)_3$ (R = CH(Me)Ph)

Ryan S. Samuel, Brian O. Patrick, and Kevin M. Smith

Abstract: The reaction of $CrCl_3$ with three equivalents of the lithium salt of [*R*-(*R**,*R**)]-(+)-bis(α-methylbenzyl)amine produces the trigonal planar Cr(III) tris(amido) complex. The X-ray structure of $Cr[N\{CH(Me)Ph\}_2]_3$ is reported.

Key words: chromium, X-ray crystal structure, amido ligands, chiral ligands.



Résumé : La réaction du $CrCl_3$ avec trois équivalents du sel de lithium de la [*R*-(*R**,*R**)]-(+)-bis(α-méthylbenzyl)amine conduit à la formation du complexe tris(amido) Cr(III) à plan trigonal. On a déterminé la structure du $Cr[N\{CH(Me)Ph\}_2]_3$ par diffraction des rayons X.

Mots clés : chrome, structure cristalline, diffraction des rayons X, ligands amido, ligands chiraux.

[Traduit par la Rédaction]

Chiral lithium amide bases have been widely employed by organic chemists in asymmetric synthesis (1). For example, the lithium salt of [*R*-(*R**,*R**)]-(+)-bis(α-methylbenzyl)-amine (**1**) has been used in the synthesis of planar chiral complexes by the enantioselective directed ortho-metallation of prochiral (arene)$Cr(CO)_3$ compounds (2). Although transition metal amido complexes are widely recognized for their exceptional stoichiometric (3, 4) and catalytic (5–7) reactivity, to the best of our knowledge chiral amide **1** has not been used as a ligand for a transition metal. In this report we describe the preparation and X-ray crystal structure of a chiral Cr(III) tris(amido) complex.

The achiral $Cr[N(CHMe_2)_2]_3$ complex was first reported over 35 years ago (8), one of the first three-coordinate complexes stabilized by bulky monodentate anionic ligands (9, 10). The relative stability of this trigonal planar Cr(III) complex with respect to β-H elimination (11) and its utility as a precursor to a range of Cr(VI) (12) and Cr(II) (13) amido complexes prompted us to prepare the corresponding chiral $Cr[N\{CH(Me)Ph\}_2]_3$ complex **2** as shown in eq. [1].

[1] 

In an inert atmosphere glovebox, 10.88 mmol (2.518 g) of solid lithium amide **1**, obtained by deprotonation of commercially available [*R*-(*R**,*R**)]-(+)-bis(α-methylbenzyl)amine with *n*-BuLi, was added portionwise to a suspension of 3.26 mmol (0.516 g) of anhydrous $CrCl_3$ in 30 mL of Et_2O. After stirring for 5 days, the solvent was removed in vacuo, and the residue was extracted with pentane and filtered through Celite supported on a sintered glass frit. The very dark-red–brown filtrate was concentrated under reduced pressure until a precipitate began to form. After addition of 5 mL of toluene, the solution was cooled to –32 °C for 2 days to provide 0.117 g (0.161 mmol, 5% yield based on $CrCl_3$) of dark-brown crystals of $Cr[N\{CH(Me)Ph\}_2]_3$ suitable for single-crystal X-ray diffraction. Anal. calcd (%) for $C_{48}H_{54}CrN_3$: C 79.52, H 7.57, N 5.80; found: C 79.71, H 7.86, N 5.93. IR (KBr) (cm^{-1}): 3056 (m), 3026 (m), 2973 (s), 2837 (m), 2360 (m), 1600 (w), 1492 (m), 1452 (m), 1370 (m), 1315 (m), 1269 (m), 1269 (m), 1205 (w), 1096 (s), 1064 (s), 1040 (m), 1028 (m), 993 (m), 892 (s), 757 (s), 697 (s). UV–vis (pentane): λ_{max} (ε) 345 nm (6126 L mol^{-1} cm^{-1}), 467 nm (5884 L mol^{-1} cm^{-1}). Mp: 187–193 °C.

Compound **2** is highly air- and water-sensitive and is very lipophilic: attempts to recrystallize pentane solutions of **2** at –30 °C led to the deposition of amorphous, semisolid material. However, the addition of toluene to saturated room-temperature pentane solutions of **2** followed by cooling did lead to the isolation in low yield of crystals suitable for X-ray analysis. A similar strategy has previously been reported

Largest diff. peak and hole (e Å^{-3})	0.52 and –0.43

by Köhn et al. (14), who used Me_6Si_2 to aid in the crystallization of $Cr[N(SiMe_3)_2]_3$. Owing to the paramagnetic nature of the system, we are unable to confirm that the low isolated yield of crystals of **2** is due entirely to its evident lipophilicity, or if decomposition processes such as an H-atom abstraction from an amido ligand (11, 15) or oxidation of Cr (16) are occurring during or after the synthesis of **2**.

The X-ray diffraction measurements of **2** were made on a Rigaku/ADSC CCD area detector. The material crystallizes as a two-component twin, related by a 180° rotation about an axis perpendicular to the (0,0,–1) plane. The twin law was determined by and the integration carried out using the Twinsolve function of CrystalClear (17). The structure was solved by direct methods (18) using non-overlapped data from component 1, while a full-matrix least-squares refinement was carried out using all data, both overlapped and non-overlapped, from both components (19). The material crystallizes with two half-molecules in the asymmetric unit, each residing on a twofold rotation axis. Non-hydrogen atoms were refined anisotropically, while hydrogen atoms were added in calculated positions. The crystallographic data for **2** are shown in Table 1, and the ORTEP diagram of **2** with significant bond lengths and angles is shown in Fig. 1.

Fig. 1. ORTEP diagram of **2** (50% ellipsoids). Selected bond lengths (Å) and angles (°): Cr(1)—N(1) 1.91(1), Cr(1)—N(2) 1.858(6), N(1)—C(1) 1.451(9), N(2)—C(9) 1.486(10), N(2)—C(17) 1.48(1), N(1)–Cr(1)–N(2) 122.6(2), N(2)–Cr(1)–N(2_2) 114.8(4), Cr(1)–N(1)–C(1) 125.1(4), C(1)–N(1)–C(1_2) 109.7(8), Cr(1)–N(2)–C(9) 129.5(5), Cr(1)–N(2)–C(17) 118.2(5), C(9)–N(2)–C(17) 112.2(6).

The CIF tables of the crystal structure determination have been deposited as Supplementary material.[2]

Owing to the presence of the chiral amido ligands, complex **2** crystallizes in the chiral space group *C*2. While the trigonal arrangement of three C_2 symmetrical ligands about the Cr center could potentially result in a molecule with D_3 symmetry, complex **2** displays only a single crystallographic C_2 axis, lying along the Cr(1)–N(1) bond. Both the Cr center and the N atoms display trigonal planar geometries, with the sum of the bond angles around these atoms being very close to 360°.

The molecular structure of **2** is similar to that of achiral $Cr(NR_2)_3$ complexes, where NR_2 are the amido ligands derived from deprotonation of bis(trimethylsilyl)amine (14), diisopropylamine (20), *N*-*tert*-butyl-3,5-dimethylaniline (9), *N*-adamantyl-3,5-dimethylaniline (16), 2,2,6,6-tetramethylpiperidine (16), or dicyclohexylamine (21). The relatively short Cr—N bond lengths in **2** are very similar to those found for other $Cr(NR_2)_3$ complexes and are indicative of chromium–amido π-bonding interactions. The dihedral angles between the planes containing the N and Cr atoms fall in the range of 61.0°–64.2°, very close to the optimum angle of 62° calculated by Alvarez and co-workers using density functional theory on the sterically unhindered model compound $Cr(NH_2)_3$ (22).

In the past five years, chromium complexes with chiral ligands have been employed in a wide range of catalytic applications. In particular, chiral Cr(salen) complexes have been characterized as belonging to the class of "privileged

[2] Supplementary data may be purchased from the Directory of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically). CCDC 255457 contains the crystallographic data for this manuscript. These data can be obtained, free of charge, via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, U.K.; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

chiral catalysts" (23), owing to their utility in such mechanistically unrelated processes as asymmetric epoxide ring opening with Me_3SiN_3 (24), copolymerization of epoxides and CO_2 (25), and reductive coupling of organic halides and aldehydes (26, 27). While new chiral chromium complexes continue to be developed (28), to the best of our knowledge, **2** is the first chromium complex with a chiral amido (NR_2^-) ligand (29).

Given the single electron transfer reactivity exhibited by $Ti[N(R)Ar]_3$ complexes with organic substrates (30), $Cr(NR_2)_3$ complexes such as **2** may potentially serve as catalysts for pinacol coupling reactions. The first enantioselective Cr catalyst for this process was very recently reported (31). While the Cr(II) disilylamido complex $Cr[N(SiMe_3)_2]_2(THF)_2$ reacts readily with alcohols (32, 33), including salicylaldimines,[3] the corresponding Cr(III) complex $Cr[N(SiMe_3)_2]_3$ does not react under similar conditions. Preliminary results suggest that both $Cr(N^iPr_2)_3$ and **2** react with salicylaldimines, although unlike $HN(SiMe_3)_2$, the $HN[CH(Me)R]_2$ by-products of the amine elimination reactions are sufficiently strong Brønsted bases to deprotonate acidic salicylaldimines.[3] LoCoco and Jordan have recently demonstrated how chiral amido ligands can be used as directing groups for the enantioselective synthesis of chiral organometallic complexes of zirconium (34). Complex **2** is also of interest in the context of chromium amido complexes as pre-catalysts for ethylene polymerization (35, 36).

Although asymmetric processes mediated by chiral transition-metal complexes are of considerable academic and industrial interest, inorganic chemists have yet to explore the coordination chemistry of chiral amido ligands (29, 34) despite the widespread use of chiral lithium amide bases in organic chemistry. Recently, another reagent used in conjunction with BuLi in enantioselective ortho-metallation reactions, (–)-sparteine, has found use in the preparation of well-defined transition-metal compounds (37, 38). Perhaps amido ligands such as **1** may yet find applications as chiral ancillary ligands in C–C bond forming reactions mediated by chromium (26) or other early transition metal complexes.

AWARD LECTURE / CONFÉRENCE D'HONNEUR

2004 Bader Award Lecture
Metal-ion-catalyzed acyl and phosphoryl transfer reactions to alcohols: La^{3+}-promoted alcoholysis of activated amides, carboxylate esters, and neutral organophosphorus esters[1]

R. Stan Brown, Alexei A. Neverov, Josephine S.W. Tsang, Graham T.T. Gibson, and Pedro J. Montoya-Pelaez

Abstract: Unlike metal-ion-catalyzed hydrolysis processes, metal-ion-catalyzed methanolysis processes have received scant attention in the literature particularly from the standpoint of mechanistic studies. La^{3+}, introduced into methanol solution as its triflate or perchlorate salt, is particularly effective in promoting methanolysis reactions of unactivated and activated esters, phosphate triesters, and activated amides such as acetyl imidazoles and lactams. Studies of the kinetics of methanolysis of these substrates as a function of solution pH and $[La^{3+}]$ indicate that the solution comprises lanthanum dimers with one to five associated methoxides ($La_2^{3+}(^{-}OCH_3)_{1-5}$), the most catalytically active form being $La_2^{3+}(^{-}OCH_3)_2$, which is produced at near neutral pH in methanol (8.4). Mechanisms for all the acyl and phosphoryl transfer reactions are proposed where the metal ion serves a dual role of acting as a Lewis acid to activate the C=O or P=O system to nucleophilic attack by a metal-coordinated methoxide nucleophile. In cases where direct comparisons can be made, the La_2^{3+} catalyst system is more active for the methanolysis of nonactivated substrates than for activated substrates. Another general characteristic of this system is that the catalytic rate constant for the metal complex exceeds the second-order rate constant for free methoxide, in some cases by as much as 4600-fold. Overall the catalytic effects exhibited by the La_2^{3+} system is spectacular for such substrates as paraoxon, where as little as 2 mmol L^{-1} $La(OTf)_3$ in the presence of equimolar $NaOCH_3$ accelerates the methanolysis by 10^9-fold relative to the background reaction at neutral pH and ambient temperature.

Key words: kinetics of methanolysis, metal ion catalysis, lanthanides, methanolysis of carboxylate esters and phosphate esters.

Résumé : Contrairement aux processus d'hydrolyse catalysés par des ions métalliques, les processus de méthanolyse catalysés par les ions métalliques n'ont pratiquement pas été étudiés, en particulier, d'un point de vue mécanistique. Les ions La^{3+}, introduits dans des solutions méthanoliques sous la forme de triflate ou de perchlorate, sont particulièrement efficaces pour promouvoir les réactions de méthanolyses d'esters, activés ou non, de triesters de l'acide phosphorique et d'amides activés, tels les acétyl imidazoles et les lactames. Des études cinétiques des méthanolyses de ces substrats en fonction du pH de la solution et de la concentration en ions La^{3+} indiquent que la solution comprend des dimères du lanthane associés à un à cinq ions méthylates ($La_2^{3+}(^{-}OCH_3)_{1-5}$), la forme catalytiquement la plus active étant $La_2^{3+}(^{-}OCH_3)_2$ qui se forme à un pH pratiquement neutre, qui dans le méthanol est 8,4. Pour toutes les réactions de transfert d'acyle ou de phosphoryle, on propose des mécanismes dans lesquels l'ion métallique joue un double rôle comme acide de Lewis pour activer le système C=O ou P=O à l'attaque nucléophile par un méthanolate nucléophile coordiné à un métal. Dans les cas où on peut faire des comparaisons directes, le système de catalyseur à base de La_2^{3+} est plus actif pour la méthanolyse de substrats non activés par rapport aux substrats activés. Une autre caractéristique générale de ce système est que la constate de vitesse catalytique pour le complexe métallique est supérieure à la

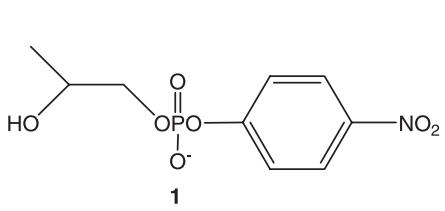
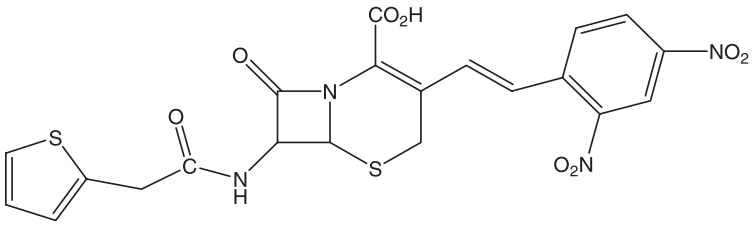
Introduction

Metal-catalyzed hydrolytic reactions of esters, amides (1), and phosphorus esters (2) have been studied for many years and, in general, these are relatively well-understood processes. These reactions involve catalytically active M^{x+}-($^-$OH) species where the metal ion serves several purposes such as: (*i*) decreasing the pK_a of the metal-associated HOH so that a M^{x+}-coordinated hydroxide can be formed at reduced pH; (*ii*) a bifunctional role for $M^{x+}(^-OH)$ acting as a Lewis acid and provider of the coordinated hydroxide to attack the C=O or P=O group; (*iii*) a possible additional role for the metal ion of promoting accelerated breakdown of any intermediates through coordination of the leaving group to the metal ion. By contrast, transition or lanthanide metal-catalyzed alcoholysis reactions, while being important industrial processes for carboxylate esterification or transesterification (3) are less understood with respect to mechanistic aspects and, as far as we are aware, have not been applied to phosphoryl transfer processes except in our labs. Buncel and co-workers (4) have extensively investigated the ethanolysis of phosphinate and phosphate esters promoted by alkali metal ethoxides, but these reactions occur under highly basic conditions through the intermediacy of $M_n^+(^-OEt)_m$ clusters, whereas the M^{2+}- and M^{3+}-catalyzed methanolysis reactions we discuss below occur under essentially neutral pH conditions.



One might expect that M^{x+}-promoted alcoholysis reactions will be subject to the same mechanistic generalities as M^{x+}-promoted hydrolysis reactions. The bulk of our studies show that this is the case although, as will be shown below, there are important mechanistic and practical differences, which in certain ways simplify mechanistic study of the alcoholysis processes and circumvent at least two of the problems associated with metal hydroxides. First, in water at pH values above the pK_a of the M^{x+}(HOH), the active metal hydroxides form oligomeric–polymeric gels or precipitates that complicate the mechanistic analyses. In some cases this can be overcome by complexing the metal ion to ligands that block the oligomerization and prevent the precipitation of the metal hydroxides. However, this approach introduces other problems: for the most part the ligands employed are those that are readily available or easily synthesized and not necessarily the ideal ones for controlling geometry and reactivity of the complexes. Second, metal hydroxides in water are not particularly effective intermolecular catalysts and so the most effective catalytic systems are ones where the metal ion is held, through transient or fixed association with some proximal binding group, close to the scissile C=O or P=O linkage.

Moving to alcohol solvents ameliorates the above problems but requires due consideration of other factors, namely control and measurement of pH in alcohol solutions (5). Bosch and co-workers (6) have recently described simplified methods for determining the ^s_spH [3] in methanol solution, which have greatly enabled our work by allowing control of the $[CH_3OH_2^+]$ through the use of buffers in methanol, and now one can perform detailed mechanistic studies in methanol under buffered conditions as simply as one can in water. There is an additional consideration stemming from the fact that the autoprotolysis constant for methanol is $10^{-16.77}$, which means that neutral ^s_spH in methanol is ~8.4 (6). Using potentiometric titration in methanol we have determined the ^s_spK_a values for formation of the metal bound alkoxides of several transition and lanthanide metal ions (7). Interestingly, in the case of La^{3+}, catalytically active dimers such as $La_2^{3+}(^-OCH_3)_{1,2,3\ldots}$ are formed spontaneously in solution without the need for any binding ligands. Methanol, as a solvent, has additional benefits related to its low dielectric constant relative to that of water (31.5 vs. 78 (8)), which favours enhanced substrate solubility, greater ion-pairing between the catalytic metal ion and any anionic substrates, and greater Lewis acid interaction between neutral substrates and metal ions. Thus, as will be shown later, many acyl and phosphoryl transfer reactions to methanol can be greatly accelerated by $M^{x+}(^-OCH_3)$ species in contrast to the hydrolytic reactions in water where the $M^{x+}(^-OH)$ species have little or no activity.



La^{3+} catalysis of acyl or phosphoryl transfer falls into two general classes. In the first category are substrates that ionize to give carboxylate or phosphate anions that bind very tightly to the metal ion and then are subject to rapid metal-catalyzed methanolysis. For example, La^{3+} can provide up to 10^{10}-fold acceleration of the methanolysis of diphenyl phosphate, di-*p*-nitrophenyl phosphate, and methyl *p*-nitrophenyl phosphate (9), and an impressive 4.6×10^{10}-fold acceleration of the methanolysis of RNA analogue β-hydroxypropyl-*p*-nitrophenyl phosphate (**1**) relative to the methoxide reac-

[3] For the designation of pH in nonaqueous solvents we use the forms described by Bosch and co-workers (6) based on the recommendations of the IUPAC (*In* Compendium of Analytical Nomenclature. Definitive Rules 1997. 3rd ed. Blackwell, Oxford, UK. 1998). If one calibrates the measuring electrode with aqueous buffers and then measures the pH of an aqueous buffer solution, the term ^w_wpH is used; if the electrode is calibrated in water and the "pH" of the neat buffered methanol solution then measured, the term ^s_wpH is used; and if the electrode is calibrated in the same solvent and the pH reading is made, then the term ^s_spH is used.

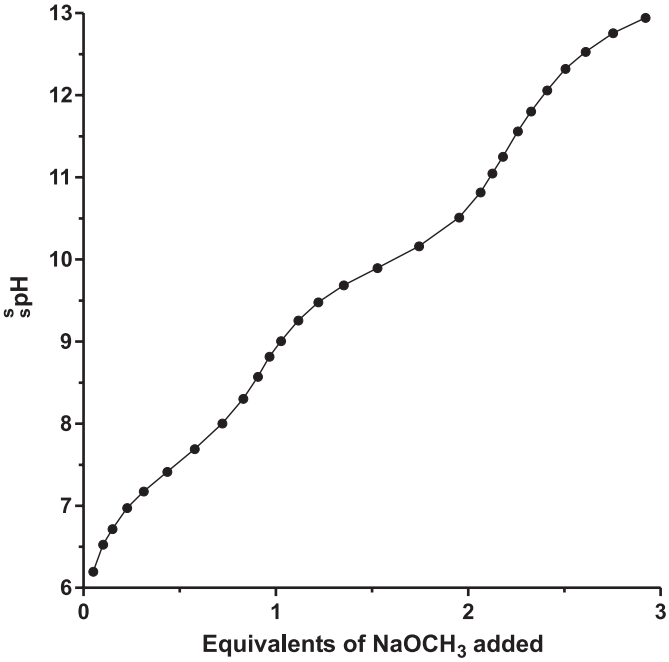
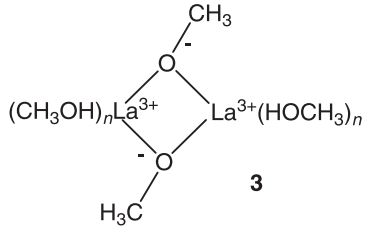
tion (10). More recently, we found that La^{3+} promotes the methanolysis of nitrocefin (**2**) by 10^5-fold relative to the methoxide reaction at a near neutral $^{s}_{s}$pH of 8 (11). Much of this work was reviewed recently (12) and thus will not be repeated here.



In the second category are neutral substrates such as carboxylate esters (13), phosphate triesters (14), activated amides such as acetyl imidazole and its pentamino Co^{III} derivative (15), and neutral β-lactams (11). These substrates have no strong binding with the metal ion and, after acyl or phosphoryl transfer to methanol, form products that are still neutral and thus will not be inhibitory as they bind to the metal ions with affinities similar to the original starting materials. It is these reactions that interest us here and in what follows we will give a chronological account of the major discoveries stemming from our studies of the La^{3+} catalysis of acyl and phosphoryl transfer from neutral substrates.

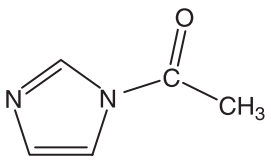
Results and discussion

Potentiometric titration of La^{3+} in methanol

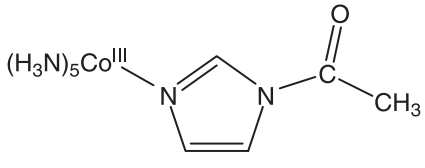


We have applied the methods described by Bosch and coworkers (6) to the potentiometric titration of several transition and lanthanide metal ions in methanol (7) and presented in Fig. 1 is a typical titration curve for La^{3+} introduced as its triflate salt. A cursory visual inspection of the profile indicates that there is an event consuming 1 equiv. of methoxide–La^{3+} with an apparent $^{s}_{s}pK_a$ ~ 7.5 and a second consuming 1.5 equiv. of methoxide–La^{3+} with an apparent $^{s}_{s}pK_a$ of ~10.4. Notable is the rather steep appearance of the titration curve, which suggests that dimeric or oligomeric species are formed. In the simplest analysis we proposed (13, 15) that in the neutral $^{s}_{s}$pH region the species formed is a bis-methoxy bridged La^{3+} dimer (**3**, $(La^{3+})_2(^{-}OCH_3)_2$) while in the high $^{s}_{s}$pH domain the species is $(La^{3+})_2(^{-}OCH_3)_5$. While not specified in those early studies, in the intermediate $^{s}_{s}$pH domain there must be La^{3+} complexes with intermediate numbers of methoxides and later we present a more sophisticated analysis that indicates that dimers containing one to five methoxides are present, the relative amounts of which are $^{s}_{s}$pH dependent.

Fig. 1. Potentiometric titration curve ($^{s}_{s}$pH vs. equiv. of added methoxide) of 1.33×10^{-3} mol L^{-1} $La(OTf)_3$ in methanol.



Acetyl imidazole



While it is an atypical amide, acetyl imidazole (**4a**) serves as a useful starting point for investigating the generalities of La^{3+}-catalyzed methanolysis since it is: (*i*) highly activated toward nucleophilic attack on the C=O and toward departure of the leaving imidazole; (*ii*) its hydrolytic mechanisms are well-studied and thus readily compared with the methanolysis processes; and (*iii*) its hydrolysis is *not* catalyzed by metal ions in water unless there is a proximal binding site, which places the bound metal ion in proximity to the C=O linkage (15). Shown in Fig. 2 is a typical set of plots of the k_{obs} for methanolysis of **4a** and **4b** vs. $[La^{3+}]$ at two $^{s}_{s}$pH values. Similar graphs are seen at different $^{s}_{s}$pH values and all have the common features of upward curvatures at low $[La^{3+}]$, followed by a linear plot at higher $[La^{3+}]$ (shown in Fig. 4 of ref. 15). The upward curvature suggests the involvement of a process that is higher than first order in

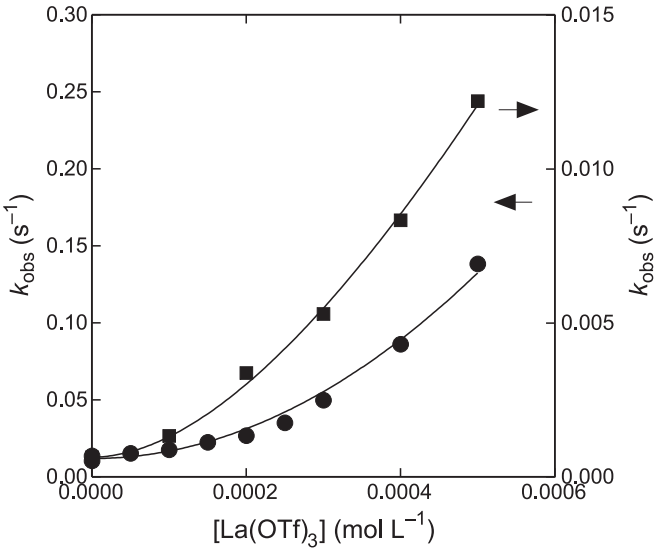

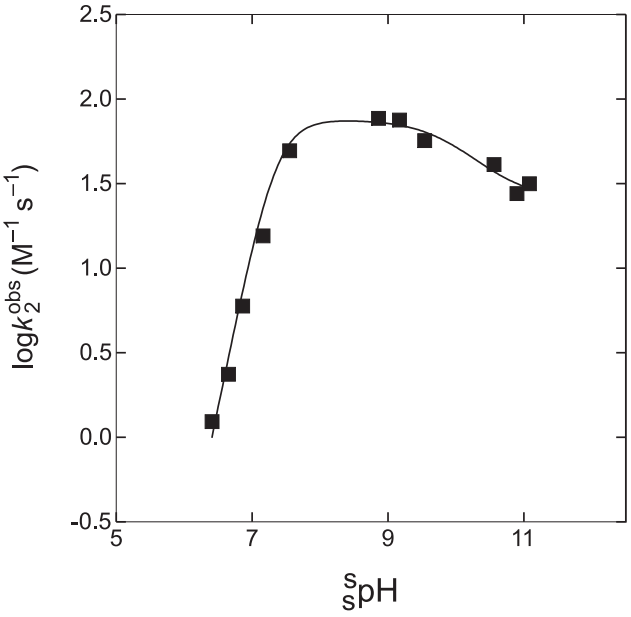

Fig. 3. Plots of the log of the second-order rate constant (k_2^{obs}) vs. ${}^{s}_{s}pH$ for $La(OTf)_3$-catalyzed methanolysis of AcIm (■) and $AcImCo(NH_3)_5^{3+}$ (●). Curves are the result of NLLSQ fitting of the experimental data to eq. [7] in ref. 15.

$[La^{3+}]$, possibly one involving a dimer of La^{3+}, and if its formation constant is large, e.g., $\geq 10^5$ M^{-1}, then above ~1 to 2×10^{-4} mol L^{-1} $[La^{3+}]$, the dimer is fully formed and the plot becomes linear. The slopes of the linear parts of the graphs at each ${}^{s}_{s}pH$ we define as k_2^{obs}, the observed second-order rate constant for $La_2{}^{3+}$-catalyzed methanolysis of **4a** and **4b**, and when $\log k_2$ is plotted as a function of ${}^{s}_{s}pH$ as in Fig. 3, it immediately becomes clear that there is an ascending wing of slope 2, followed by a plateau above ${}^{s}_{s}pH$ of ~7.5–7.8. There are two important points to be made concerning this plot. First, both **4a** and **4b** adhere to the same general plots with a kinetic ${}^{s}_{s}pK_a$ similar to the ${}^{s}_{s}pK_a$ determined via titration, and second, the ascending slope of 2 in each case indicates that the catalytically competent form acting on both substrates must have two methoxides. This also rules out any type of catalysis where the distal imidazole N is involved with La^{3+} as the pentamino Co^{III} blocks access to that site but the catalytic curve for **4b** has the same general ${}^{s}_{s}pH$ dependence as does **4a**. Fits of the kinetic data to equations developed in ref. 15 provide the lines through the data in Fig. 2 with the best-fit ${}^{s}_{s}pK_a$ value of 7.27 ± 0.15 and respective maximum second-order rate constants of 1.5×10^3 and 1.42×10^2 M^{-1} s^{-1} for methanolysis of **4a** and **4b** catalyzed by the $(La^{3+})_2(^{-}OCH_3)_2$ dimer. Based on the above experimental results, we propose that the catalytic mechanism proceeds as in Scheme 1 where the dimer **3** opens one of the methoxy–La^{3+} bridges to reveal a species capable of both Lewis acid activation of the C=O, and delivery of a La^{3+}-coordinated methoxide to the carbon. Notable is the fact that while the unaided $^{-}OCH_3$ nucleophile is 5900-fold more reactive with **4b** than with **4a** (k_{OCH_3} = 4.69×10^7 vs. 7.9×10^3 M^{-1} s^{-1} (15)) the catalysis afforded by **3** is 10-fold more effective for the neutral substrate **4a** than for the positively charged substrate **4b**, in line with the mechanism suggested in Scheme 1 since the Lewis acid interaction with the C=O of **4b** is expected to be poorer than with **4a**.

Methanolysis of carboxylate esters and β-lactams

The suggestion that the mechanism for La^{3+}-catalyzed methanolysis of acetyl imidazole proceeded through a transition state where the catalyst exercises a dual role of Lewis acid and delivery of nucleophile suggested that the same catalyst should be capable of promoting the methanolysis of other neutral C=O containing entities such as carboxylate esters and β-lactams. Our initial investigation probed the ability of the La^{3+} system to promote the methanolysis of various esters such as **5**–**11** to investigate the electronic and structural effects on catalysis (13). The kinetics of

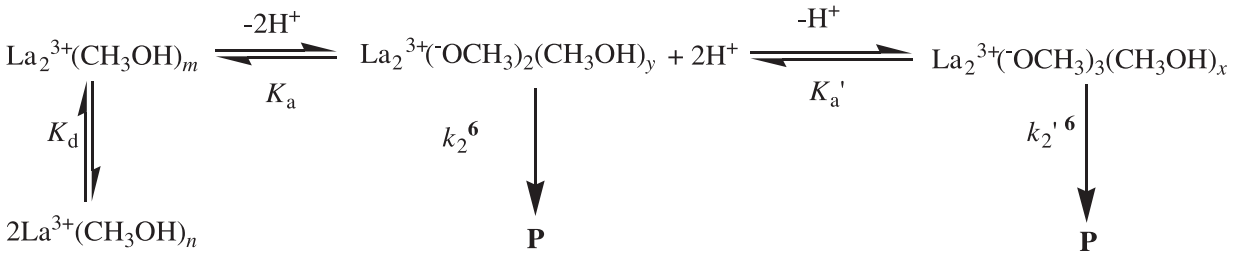

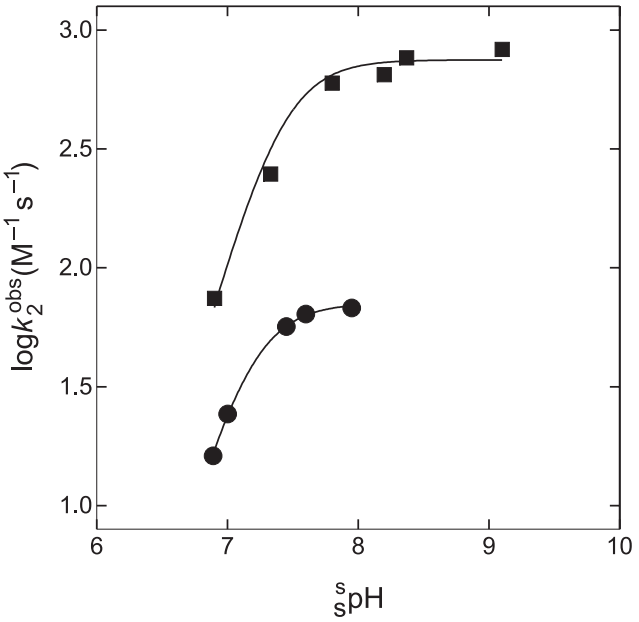

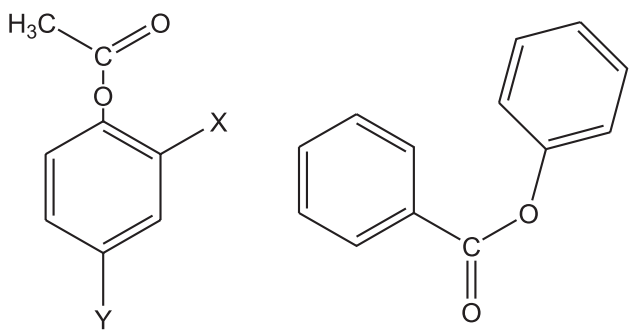

Fig. 4. A plot of the $\log k_2^{obs}$ (referring to the rate constant attributable to La^{3+} dimer) vs. $^{s}_{s}$pH for the La^{3+}-catalyzed methanolysis of *p*-nitrophenyl acetate (**6**); T = 25 °C (from ref. 13). Line through the data computed on the basis of fit to the kinetic equation derived for the process in Scheme 2.

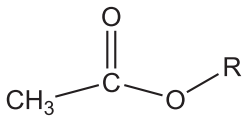

methanolysis of *p*-nitrophenyl acetate (**6**) were investigated for the $^{s}_{s}$pH and [La^{3+}] dependence under buffered conditions. These studies showed that the active catalyst was in general accord with that active for the acetyl imidazole series since in both cases there was an upward curvature in the plots of k_{obs} vs. [La^{3+}] eventually leading to linear dependencies at all $^{s}_{s}$pH values, the gradient of which is taken to be the k_2 value for La_2^{3+} catalysis. Shown in Fig. 4 is a logk_2 vs. $^{s}_{s}$pH plot for the catalyzed methanolysis of **6**, which shows an initial slope of 2, followed by a plateau and then a drop suggestive of a decreased catalytic ability of whatever La^{3+} species is formed at higher $^{s}_{s}$pH. Overall the process is modeled according to the simplified process given in Scheme 2 where the dominant catalytic species is $(La^{3+})_2(^{-}OCH_3)_2$ and the reduced activity form is exclusively $(La^{3+})_2(^{-}OCH_3)_3$. Fitting the data to the appropriate expression derived for the process in Scheme 2 (13) yields the line through the data in Fig. 4 and the computed $^{s}_{s}pK_a$ ($^{s}_{s}pK_a'$) and $k_2^{\mathbf{6}}$ ($k_2'^{\mathbf{6}}$) values of 7.35 ± 0.1 (10.2 ± 0.4) and 72 ± 1 M^{-1} s^{-1} (11.9 ± 4.5 M^{-1} s^{-1}).

Since the maximal kinetic activity appears to be in the plateau region of $^{s}_{s}$pH 8–10 (neutrality is $^{s}_{s}$pH = 8.4), the kinetics for the other esters were investigated in that region with the various rate constants being given in Table 1. Comparing the rate constants for La^{3+}-catalyzed methanolysis with the rate constant for methoxide attack on a given ester ($k_2^{ester}/k_{OMe^-}^{ester}$) makes it apparent that the less-activated aryl esters are more susceptible to catalyzed alcoholysis than the activated esters, a fact first noted in this study (13) and a following one investigating Eu^{3+}-catalyzed methanolysis of **6** and **7** (16) and subsequently described for an example of Cu^{2+}-catalyzed methanolysis of methyl acetate vs. *p*-nitrophenyl acetate (17). In fact, for esters **7**–**10**, the $k_2^{ester}/k_{OMe^-}^{ester}$ values are >1 if La^{3+} is used, as is the case for Eu^{3+}-catalyzed methanolysis of phenyl acetate. At first this seems peculiar since a normal Brønsted relationship would suggest that the methoxide bound to a metal ion would be a worse nucleophile than free methoxide. However, this can be taken as good evidence for the dual role for the catalyst in providing Lewis acid activation of the C=O unit and intramolecularly supplying the nucleophile (18). For the nonactivated esters

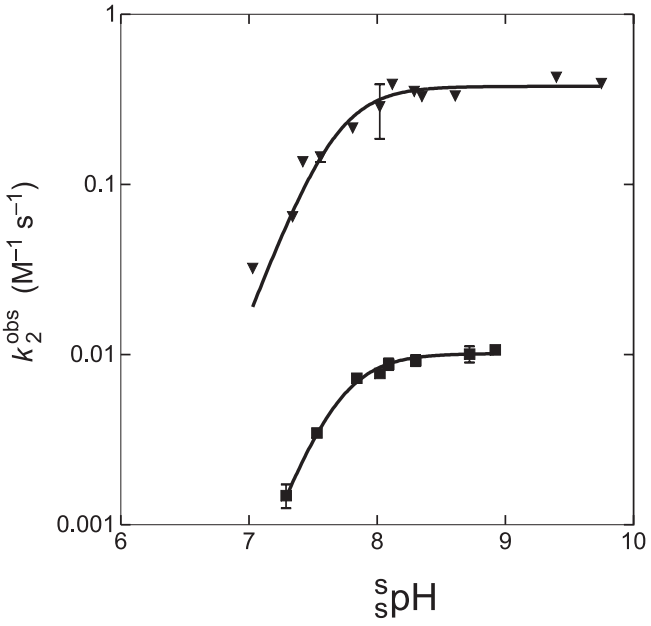
the catalysis afforded in the neutral ${}^{s}_{s}pH$ region relative to the background reaction is quite spectacular, varying from (1–20) × 10^6-fold at room temperature, which, as far as we are aware, represents the greatest acceleration reported for any intermolecular metal-catalyzed acyl transfer reaction.

The likely mechanism for the transesterification involves a preequilibrium binding of the ester to one of the metal ions in the La^{3+} dimer followed by breaking of one of the methoxy–La^{3+} bonds on the way to a transition structure analogous to what we proposed in Scheme 1 for the methanolysis of acetyl imidazole. The reason why the catalysis is so large in methanol and so poor in water likely stems from a composite of effects such as increased preequilibrium association of the La^{3+} complex with the ester C=O and a less well solvated $(La^{3+})_2(^-OCH_3)_2$ in the reduced dielectric medium leading to enhanced electrophilic–nucleophilic properties. Indeed, such an ensemble coordinatively stabilizes both the tetrahedral intermediate and the transition state leading to it. For esters having good leaving groups such as *p*-nitrophenyl acetate, once the tetrahedral intermediate is reached its subsequent breakdown to expel the *p*-nitrophenoxy group probably does not require assistance by the metal ion. However, in the case of nonactivated esters such as ethyl acetate, microscopic reversibility arguments require that if the La^{3+} mediates the delivery of methoxide to form the tetrahedral intermediate (T_o^-), then its decomposition via expulsion of ethoxide must also be La^{3+}-mediated, which requires a translocation of the metal ion between the labile alkoxy groups. Interestingly, we have been unable to observe any reaction with tertiary esters such as *tert*-butyl acetate, probably because of a combination of rate-retarding electronic and steric effects where the translocation of the metal ion to the *tert*-butoxy group in the tetrahedral intermediate is precluded.

The study of the La^{3+}-catalyzed methanolysis of β-lactams **12** and **13** proved very interesting from kinetic and analytical standpoints (11) because it pointed out for the first time that the La^{3+} catalyst may comprise dimeric forms in addition to the originally assumed $La_2{}^{3+}(^-OCH_3)_2$. Although the general traits of curvature in the plots of k_{obs} vs. low $[La^{3+}]$ followed by a linear dependence at high $[La^{3+}]$ were evident, the plots of $\log k_2$ vs. ${}^{s}_{s}pH$ (see Fig. 5) did not show the initial slope of 2 as was so evident in the acetyl imidazole and ester cases. This suggested that the species responsible for the catalysis were somewhat different from that initially assumed in the case of esters and acetyl imidazole.

The answer to this dilemma required a more extensive analysis of the titration curves for La^{3+} in methanol, in particular determining the formation constants for the various $La_2{}^{3+}(^-OCH_3)_{1,2,3...}$ forms and their concentrations as a function of ${}^{s}_{s}pH$ under conditions



$$[1]\qquad La_2{}^{3+}(^-OCH_3)_n \rightleftharpoons 2La^{3+} + nOCH_3{}^-$$

$$[2]\qquad {}^{s}_{s}K_n = [La^{3+}{}_2(^-OCH_3)_n]/[La^{3+}]^2[OCH_3{}^-]^n$$

that mirror those present in the kinetic studies. In a detailed study of the titration of various transition and lanthanide metal ions in methanol (7) we used the computer program Hyperquad (19) to analyze the La^{3+} potentiometric titration data by fitting these to the dimer model presented in eq. [1], where n assumes values of 1–5, to give the stability constants (${}^{s}_{s}K_n$) that are defined in eq. [2]. From the five computed stability constants, $\log {}^{s}_{s}K_{1-5}$ = 11.66 ± 0.04, 20.86 ± 0.07, 27.52 ± 0.09, 34.56 ± 0.20, and 39.32 ± 0. 26, respectively, one can compute the concentrations of the various $La_2{}^{3+}(^-OCH_3)_n$ forms as a function of ${}^{s}_{s}pH$ at $[La(OTf)_3]_{total}$ = 2×10^{-3} mol L^{-1} using HySS, a component of the Hyperquad suite of programs (19). For ease of visualization, the species distribution diagram is shown in Fig. 6 where it is evident that dimeric forms containing one to five methoxides are successively formed at increasing ${}^{s}_{s}pH$. It is possible to analyze the kinetic data as a linear combination of the contributions of the various dimeric forms determined by their individual rate constants and concentrations at a given ${}^{s}_{s}pH$ according to eq. [3] where $k_2{}^{2:1}$, $k_2{}^{2:2}$, and $k_2{}^{2:n}$ are the second-order rate constants for the dimer containing one, two, and n (up to five) methoxides and $[La(OTf)_3]_t$ is the

Fig. 5. Plots of the k_2^{obs} vs. $^{s}_{s}$pH for the La^{3+}-catalyzed methanolysis of β-lactams **12** (■) and **13** (▼) at 25 °C under buffered conditions. Lines through the data are computed on the basis of fits to eq. [5] containing up to three $La_2^{3+}(^{-}OCH_3)_n$ species (vide infra).

$$[3] \qquad k_2^{obs} = (k_2^{2:1}[La_2^{3+}(^{-}OCH_3)_1] + k_2^{2:2}[La^{3+}{}_2(^{-}OCH_3)_2]... \; k_2^{2:n}[La_2^{3+}(^{-}OCH_3)_n])/[La(OTf)_3]_t$$

total amount of La^{3+} in solution. It should be recognized that each $La_2^{3+}(^{-}OCH_3)$ species is operative in a different $^{s}_{s}$pH range, and so one can only perform satisfactory fits to a given species when the kinetic data are acquired in the appropriate $^{s}_{s}$pH domain. In the case of **12**, for which limited kinetic data are available, a satisfactory plot (not shown) is obtained using only $La_2^{3+}(^{-}OCH_3)_2$, but for lactam **13**, where there is a slightly more extended $^{s}_{s}$pH range for the kinetic points, the plot shown in Fig. 7 is nicely analyzed as originating from the collective contributions from the three dimeric forms $La_2^{3+}(^{-}OCH_3)_{1,2,3}$. The computed rate constants for these forms reacting with **13** are given in Table 2.

12 X = H
13 X = NO_2

There are additional points of note stemming from what we observe for the lactams. First, as part of this study we attempted to catalyze the methanolysis of **12** and **13** using Zn^{2+} in methanol solvent containing 0 to 1 equiv. of methoxide, but no catalysis was observed. However, in the presence of La^{3+} strong catalysis was observed, a phenomenon probably associated with the dual catalytic nature of the active dimeric forms that act both as Lewis acids and deliverers of the methoxide nucleophile. For the two lactams, $La_2^{3+}(^{-}OCH_3)_2$ is the dominantly active species with computed second-order rate constants of 0.026 and 0.98 M^{-1} s^{-1} for the methanolysis of **12** and **13**, respectively. For **13** there

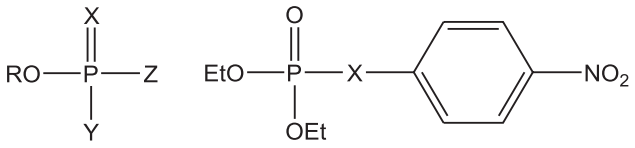
Table 2. Computed rate constants for $La_2^{3+}(^-OCH_3)_n$ species to the methanolysis of **12** and **13** determined through fits of k_2^{obs} at each ^s_spH to eq. [3].[a]

$La_2^{3+}(^-OCH_3)_n$ species		$k_2^{2:n}$ (M^{-1} s^{-1})
12	$^-OCH_3$	$k^{\mathbf{12}}_{OCH_3} = 0.0026$
	$La_2^{3+}(^-OCH_3)_2$	$k_2^{2:2} = 0.026\pm0.003$
13	$^-OCH_3$	$k^{\mathbf{13}}_{OCH_3} = 0.43$
	$La_2^{3+}(^-OCH_3)_1$	$k_2^{2:1} = 0.06\pm0.01$
	$La_2^{3+}(^-OCH_3)_2$	$k_2^{2:2} = 0.98\pm0.11$
	$La_2^{3+}(^-OCH_3)_3$	$k_2^{2:3} = 1.23\pm0.13$



[a]Errors computed from the average % deviation in the fitted numbers calculated by eq. [3] from the actual kinetic data reported in ref. 11.

are some uncertainties in the $k_2^{2:2}$ and $k_2^{2:3}$ terms, which could have been reduced by obtaining the kinetic data over a wider ^s_spH range, but inclusion of the $k_2^{2:3}$ term is justified since its omission leads to a poorer overall fit. Also for **13**, the rate constant for $La_2^{3+}(^-OCH_3)_3$ is larger at 1.23 M^{-1} s^{-1} than the term for $La_2^{3+}(^-OCH_3)_2$, but overall the trimethoxy form does not contribute so much to the kinetics because its concentration is lower than that of $La_2^{3+}(^-OCH_3)_2$. These constants can be compared with the second-order rate constants for the methoxide reactions, 0.0026 and 0.43 M^{-1} s^{-1}, respectively, for **12** and **13** (20)[4] once again showing that the dimeric catalysts with metal-bound methoxides are actually more reactive than free methoxide. The overall catalytic effect of the composite reactions catalyzed by all the species can be judged in comparison to the base-catalyzed reaction at a neutral ^s_spH of 8.4, where the [$^-OCH_3$] is 4.27 × 10^{-9} mol L^{-1} and a 1 mmol L^{-1} solution of catalyst (generated from 2 mmol L^{-1} of La(OTf)$_3$) accelerates the methanolysis of **12** by ~2 × 10^7-fold and **13** by ~5 × 10^5-fold. Interestingly, there is a 40-fold larger catalytic effect for the less reactive lactam, which probably results from a fine balance of electronic effects on the preequilibrium binding of the lactam to metal ion (expected to be less favourable for the nitro derivative) followed by a rate-limiting attack on the coordinated C=O (expected to be faster for the nitro derivative).

It now becomes apparent that for La^{3+}-catalyzed methanolysis of acyl transfer the $(La^{3+})_2(^-OCH_3)_n$ speciation changes as a function of ^s_spH and the possibility exists that each of these can be catalytically active. In a given case, the observed ^s_spH/rate constant profile must be viewed as a sum of contributions determined by the individual rate constants and the concentration of each of the active species. Since La^{3+} dimers with one to three associated methoxides have activity with lactam **13** there is no reason to suspect that the La^{3+}-catalyzed methanolysis of esters such as *p*-nitrophenyl acetate **6** should not be mediated by other dimers such as $(La_2^{3+})(^-OCH_3)_{1,3,4,5}$. Accordingly, we reanalyzed the kinetic data for methanolysis of **6** shown in Fig. 4 by fitting of the k_2 values as a linear combination of rate constants for the various $La_2^{3+}(^-OCH_3)_n$ species as shown in eq. [3] to provide rate constants of (91.8 ± 8.8) M^{-1} s^{-1} for $La_2^{3+}(^-OCH_3)_2$ and (38.0 ± 5.6) M^{-1} s^{-1} for $La_2^{3+}(^-OCH_3)_4$ with no apparent involvement of $La_2^{3+}(^-OCH_3)_3$. Subsequently, we will see that catalysis by several dimers is a prevalent phenomenon for phosphoryl transfer from neutral phosphate triesters, and in fact that at high ^s_spH the situation becomes complicated by the deleterious formation of oligomers of reduced catalytic activity.

Paraoxon (15) and its thiol derivative, *O*,*O*-diethyl *S*-*p*-nitrophenyl phosphorothioate (16)

Activated neutral organophosphate, phosphinate, and phosphonate esters (OP esters) of the general form **14** are potent acetylcholinesterase inhibitors if they contain at least one leaving group whose conjugate acid has a pK_a of 8 or less (21). These have important uses as animal and crop protectants (22) and as chemical warfare (CW) agents (23). The OP family includes the insecticides parathion (RO=Z=OEt; X=S; Y=$OC_6H_4NO_2$) and paraoxon (**15**), as well as the alkylphosphonofluoridate nerve G-agents, for example Soman (RO=$(CH_3)_3CCH(CH_3)O$; Z=CH_3; X=O; Y=F) and Sarin (RO=$(CH_3)_2CHO$; Z=CH_3; X=O; Y=F), and finally the V-agents such as VX (Z=Et; X=O; Y=$SCH_2CH_2N(CH(CH_3)_2)_2$). OP compounds of these types are among the most deadly of man-made materials since all are designed to effect a single biological outcome, namely death of the target organism because of acute respiratory failure after exposure.

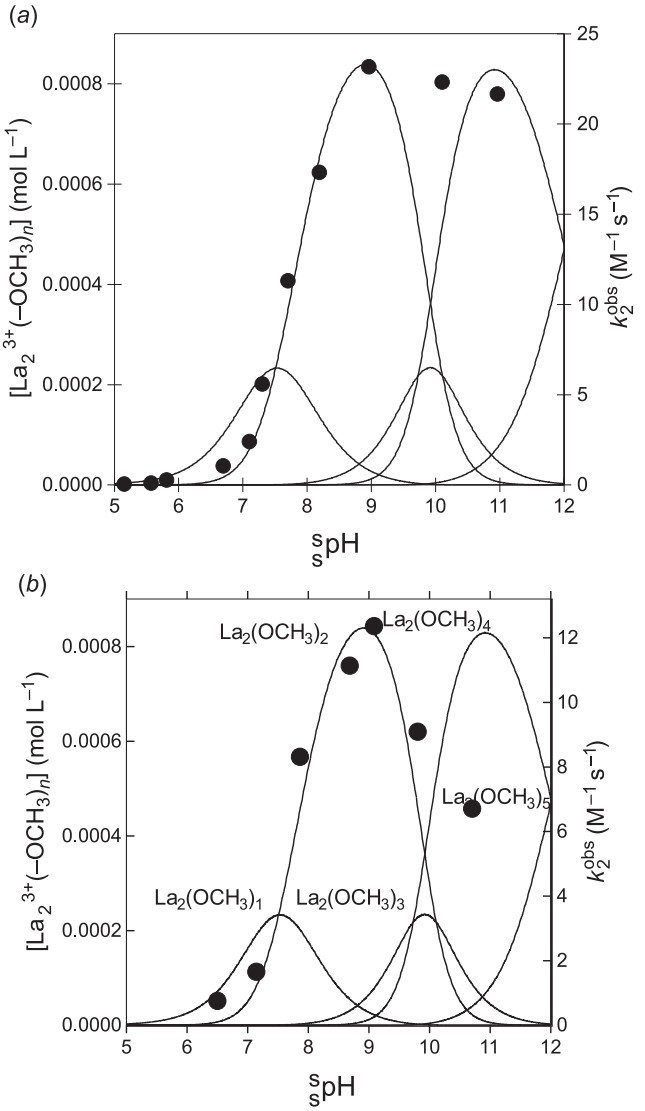
14 **15** X = O **16** X = S

In many cases, the toxic uses as pesticides are considered beneficial, at least to man, as they assure larger crop yields, generally healthier animals, and reduce the incidence of insect infestation and insect-borne diseases. Despite these seemingly beneficial properties, world usage of organophosphate pesticides is declining due to their persistence in foodstuffs and the environment and also because of unselective negative effects on non-target species. Nevertheless, the most recent statistics available indicate that in 1999 some 9 000 000 pounds (1 pound = 0.45 kg) of these were used in the US, comprising 72% of all insecticides used commercially, in home and garden, and the government sector (24). By some estimates world use is roughly 10 times this amount, or 90 000 000 pounds per year (1 pound = 0.45 kg), and there is increasing concern over soil and water contamination that arises from spills and improper use.

Because of their toxicity and the attention drawn to them by the 1992 Chemical Weapons Convention Treaty (25) that requires total destruction of chemical weapons stockpiles by the signatories by 2007, considerable effort has been directed toward methods of facilitating the controlled decomposition of the OP CW materials particularly through hydrolysis and oxidation (23, 26). Although some very effective methods for destruction of organophosphorus materi-

[4]By way of comparison, the HO^- reaction in water on **12** and **13** has reported second-order rate constants of 1.3 × 10^{-3} and 50 × 10^{-3} M^{-1} s^{-1}, respectively (A.P. Laws and M.I. Page. J. Chem. Soc. Perkin Trans. 2, 1577 (1989)).

© 2004 NRC Canada



als are available, none is applicable to all situations or classes of compounds. At the present time the task of destruction of these materials is a problem of gigantic proportions given looming deadlines, the amounts of materials to be handled, and the fact that no ideal methodology exists when one considers all factors including the disposal of the end products of reaction. For example, the US and Russia have declared that their respective stockpiles of OP CW material comprise some 25 000 tons (27) and 32 000 tons (28), and destruction using conventional means of burning and (or) hydrolysis is projected to cost some $24 billion US and $20 billion US, respectively, probably requiring at least to 2012 to complete. Even so, the existing methodologies are not without problems given the technical difficulties of purification of waste stream from hydrolysis, or public outcry from burning.

It appeared to us that La^{3+}-catalyzed alcoholysis reactions might offer an attractive alternative to the present hydrolysis and burning strategies. The ideal benefits would be rapid conversion of the starting materials to nontoxic neutral phosphate or phosphonate alkoxy esters, which can be disposed of using conventional burning, a reaction medium that solvates the starting materials efficiently, and the ability to provide an effective process for the decomposition of V-agents (29).[5] As simulants for the methanolysis of the G-agents and V-agents, respectively, we studied the La^{3+}-catalyzed methanolysis of the insecticide paraoxon **15** (14) and its phosphorothioate derivative **16** (30) as a function of ${}^{s}_{s}$pH and $[La^{3+}]$.

As is the case for the La^{3+}-catalyzed methanolysis of esters and activated amides, plots of k_{obs} vs. $[La^{3+}]$ for methanolysis of both **15** and **16** showed upward curvature at low $[La^{3+}]$ followed by linear domains at higher concentrations. The gradients of the linear portions at each ${}^{s}_{s}$pH were taken as the second-order rate constants (k_2^{obs}) for La^{3+}-dimer catalyzed methanolysis of each species and when these are overlaid on the La^{3+}-speciation diagram as illustrated in Figs. 8*a* and 8*b*, it can be seen that the maximum activity stems from the $(La^{3+})_2(^{-}OCH_3)_2$ and $(La^{3+})_2(^{-}OCH_3)_4$ forms. As is shown in Fig. 9 for **16**, the k_{obs} vs. $[La^{3+}]$ plots at the highest ${}^{s}_{s}$pH values (~11) exhibit an apparent saturation behaviour consistent with the formation of oligomeric forms of $La_x^{3+}(^{-}OCH_3)_n$ similar to what we have seen previously for Eu^{3+}-catalyzed methanolysis of esters (16). To obtain the k_2^{obs} values at high ${}^{s}_{s}$pH for inclusion in Figs. 8*a* and 8*b* one needs either to determine the slope of the k_{obs} vs. $[La^{3+}]$ plots at $[La^{3+}] < 2 \times 10^{-4}$ mol L^{-1}, or perform the kinetic experiments in the presence of a ligand, such as 18-crown-6, which will break up the oligomers, thus minimizing the oligomer formation. An approach similar to this was used by Gómez-Tagle and Yatsimirsky (31) to stabilize a bis-hydroxy-bridged La^{3+} dimer by coordinating each of the metal ions to bis-tris propane as in **17,** which stabilized the dimeric form and made it soluble in the buffered aqueous solution. The Fig. 9 data indicate that the k_{obs} values obtained in the presence of 18-crown-6 lie on the same straight line obtained at low k_{obs} vs. free $[La^{3+}]$ suggesting that its presence does not affect the catalytic viability of the La^{3+} species to any great extent. The slope of this line is taken as the k_2^{obs} for $(La^{3+})_2(^{-}OCH_3)_n$ catalysis of the methanolysis of **16**.

The k_2^{obs} kinetic data in Figs. 8*a* and 8*b* can be fit to the linear combination of La_2^{3+} species given in eq. [3] to provide the rate constants for each of the reactive forms $(La_2^{3+}(^{-}OCH_3)_n)$ responsible for the catalyzed methanolysis

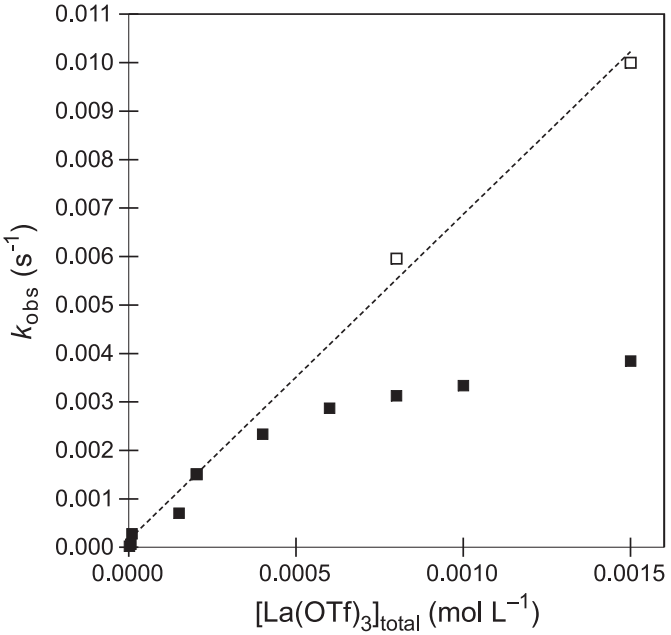


Fig. 8. Speciation diagram for the distribution of $La_2^{3+}(^{-}OCH_3)_n$ forms (n = 1–5) as a function of ${}^{s}_{s}$pH. Speciation calculated (7) for $[La(OTf)_3] = 2 \times 10^{-3}$ mol L^{-1}. Data represented as (●) correspond to second-order rate constants (k_2^{obs}) for La^{3+}-catalyzed methanolysis of (*a*) **15** (data from ref. 14, right vertical axis) and (*b*) **16** (data from ref. 30).

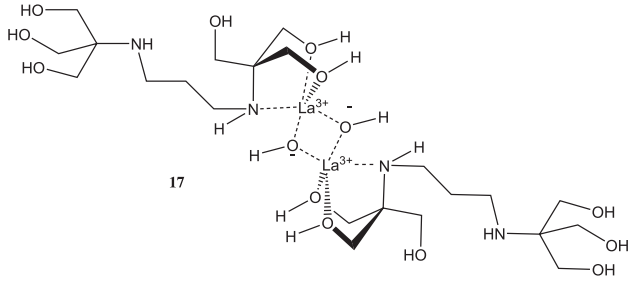

[5] In certain cases, alcoholysis may proceed with different selectivity than hydrolysis as is known to be the case for the uncatalyzed methanolysis of the V-agents where the reaction with alkoxide proceeds largely to displace the SR^{-} group leading to phosphonate oxyesters. For example, when V-agents are hydrolyzed with hydroxide in water about 90% of the product arises from P–SR cleavage, and 10% from P–OR cleavage, but the latter product is toxic and unreactive to further hydrolysis as it is a phosphonic acid derivative. Methanolysis reactions, even if they lead to some P–OR cleavage, cannot produce nonreactive phosphonic acid intermediates and thus should lead to complete destruction of the starting material.

Plot of k_{obs} vs. [La(OTf)$_3$] for the methanolysis of *O*,*O*-diethyl *S*-(*p*-nitrophenyl phosphorothioate (**16**, 8.1 × 10^{-5} mol L^{-1}) in 1:1 Et_3N–$HClO_4$ buffer $^{s}_{s}$pH 10.7, *T* = 25 °C, data obtained without 18-crown-6 (■); data obtained with added 18-crown-6, 1:1 with added [La^{3+}] (□).

17

of **15** and **16**, the various values being given in Table 3. From these computed rate constants and the speciation as a function of $^{s}_{s}$pH are constructed the plots showing the individual kinetic compositions comprising the overall k_2^{obs} vs. $^{s}_{s}$pH profile, which are shown in Figs. 10*a* and 10*b*.

The appearance of the plots indicates there is a rather large plateau region for each ester between $^{s}_{s}$pH 8 and 11. In the case of paraoxon, a 2 mmol L^{-1} solution of La^{3+} (corresponding to 1 mmol L^{-1} dimer) gives a $t_{1/2}$ of ~20 s at $^{s}_{s}$pH 8.3, which amounts to an acceleration of 10^9-fold relative to the background methoxide reaction ($k^{\mathbf{15}}_{OCH_3}$ = 0.011 M^{-1} s^{-1}), which is computed to have a $t_{1/2}$ of ~600 years at that same $^{s}_{s}$pH. The catalysis for the thioate derivative **16** is also impressive: a 2 mmol L^{-1} solution of La^{3+} at $^{s}_{s}$pH 8.3 gives a $t_{1/2}$ of ~31 s, which amounts to an acceleration of 5.4 × 10^7-fold relative to the background reaction ($k^{\mathbf{16}}_{OCH_3}$ = 0.12 M^{-1} s^{-1}), which is computed to have a $t_{1/2}$ of ~54 years at that $^{s}_{s}$pH.

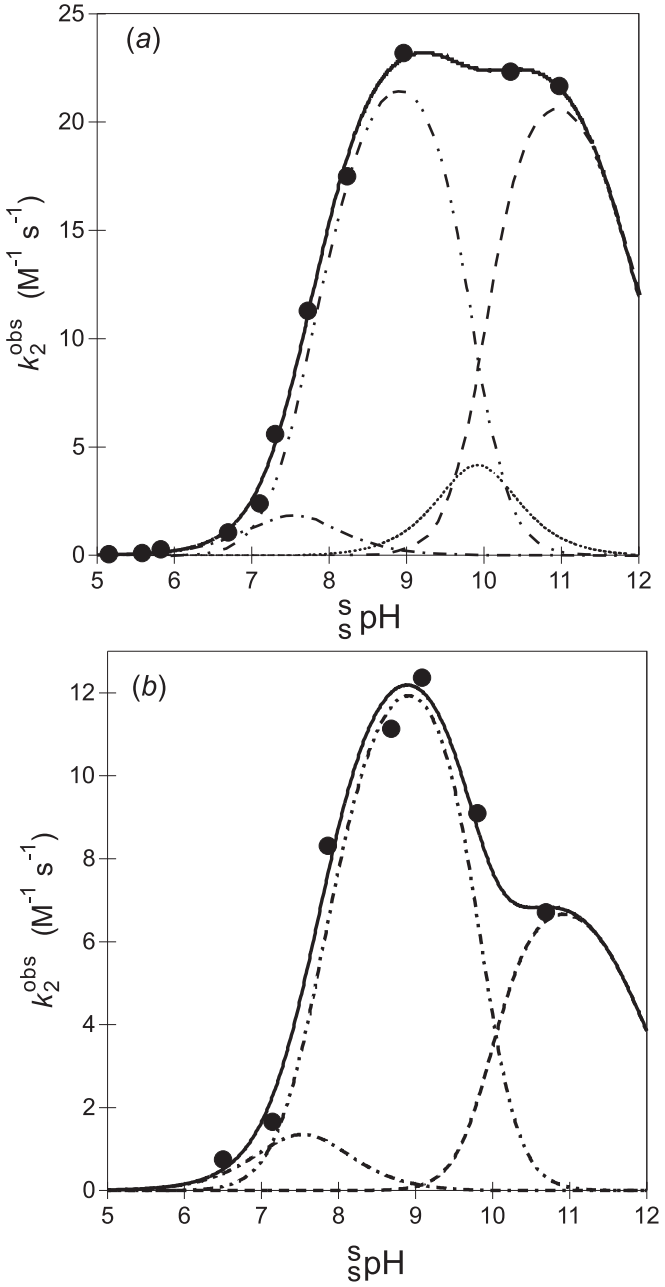
To check for catalytic turnover, we investigated by ^{31}P NMR the methanolysis of a 10-fold excess of **15** or **16** buffered at $^{s}_{s}$pH ~8.8 in the presence of La(OTf)$_3$. In the two cases, the starting materials were gone in less than 10 min and 103 s, respectively (14, 30). In a third experiment with the far less reactive *O*,*O*-diethyl *S*-phenyl phosphorothioate in 100-fold excess over the La^{3+}, we observed that the reaction was essentially complete within 70 min indicating that 100 turnovers had occurred within that time, and importantly that the products do not inhibit the reaction (30).



Do other metal ions exhibit exalted catalysis of alcoholysis of carboxylate and phosphate esters?

As indicated above, we have studied the methanolysis of certain esters (most extensively *p*-nitrophenyl acetate) promoted by Eu(OTf)$_3$ (16). Detailed kinetic studies conducted as a function of [Eu^{3+}] and $^{s}_{s}$pH revealed that the active form of the catalyst is the monomeric form $Eu^{3+}(^{-}OCH_3)$ that, at higher $^{s}_{s}$pH, gives way to an inactive form of stoichiometry $Eu^{3+}(^{-}OCH_3)_2$, which seems to exist in solution as an oligomer ($(Eu^{3+}(^{-}OCH_3)_2)_n$). Highest activity for the Eu^{3+} system is obtained in a $^{s}_{s}$pH 7.1–7.2 solution, midway between the two macroscopic kinetic $^{s}_{s}pK_a$ values of $^{s}_{s}pK_a^{\mathbf{1}}$ = 6.33 ± 0.06 and $^{s}_{s}pK_a^{\mathbf{2}}$ = 8.02 ± 0.10 for formation of the mono and dimethoxy forms. The catalysis of the methanolysis of esters such as *p*-nitrophenyl acetate (**6**), phenyl acetate (**7**), and ethyl acetate (**9**) at the $^{s}_{s}$pH maximum of 7.12 is substantial, being 8 530 000-fold, 95 000 000-fold, and 7 813 000-fold, respectively.[6] The efficiency of this catalyst and the fact that it operates as a monomer suggest that it

[6]The acceleration is computed relative to the reaction of methoxide at $^{s}_{s}$pH 7.12, where the [CH_3O^-] = 2.24 × 10^{-10} mol L^{-1}, using the second-order rate constants for methoxide attack on **6**, **7**, and **9** of 220, 2.66, and 5.7 × 10^{-2} M^{-1} s^{-1}, respectively (see Table 1) and the second-order rate constants (k_2^{max}) determined in the Eu work of 42, 11.7, and 1 × 10^{-2} M^{-1} s^{-1}, respectively.

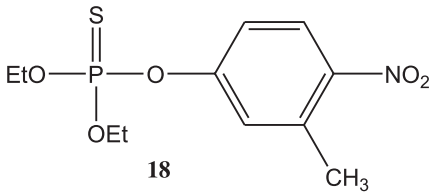
Fig. 10. Kinetic plot of the overall second-order rate constant for $La_2^{3+}(^{-}OCH_3)_n$-catalyzed methanolysis of: (*a*) **15** (k_2^{obs}) as a function of $^{s}_{s}$pH showing the best-fit kinetic contributions of each dimer bearing one to four methoxides and (*b*) **16** (k_2^{obs}) as a function of $^{s}_{s}$pH showing the best-fit kinetic contributions of dimers bearing one, two, and four methoxides.



might have quite different selectivities than does the La^{3+} dimer catalyst.

In a preliminary screening we have looked at the ability of a series of lanthanide and transition metal ions, introduced as their triflate salts, to catalyze the ethanolysis of paraoxon (**15**). Since all the La^{3+}-catalyzed methanolysis reactions discussed above showed maximal catalytic activity at a $[La^{3+}]/[^{-}OCH_3]$ of 1.0, we studied the ethanolysis reactions under three conditions where the $[M^{x+}]/[NaOEt]$ ratio varied from 0.5 to 1.0 to 1.5.[7] For all the lanthanides, the maximum constants were obtained when the ratio was 1.0. Shown in Table 4 are the pseudo-first-order rate constants from which it can be determined that all the lanthanides have some activity, the best being La^{3+}, while some of the transition metal ions catalyze the reaction as well. Interestingly, when we investigated the ethanolysis of the P=S derivative fenitrothion (**18**), none of the lanthanides promoted the reaction, presumably because of the fact these are considered "hard" in the Pearson "hard soft" sense (32), although two of the softer transition metal ions (Zn^{3+} and Cu^{2+}) did, which prompted us to study the alcoholysis reactions promoted by transition metal ions in more detail.

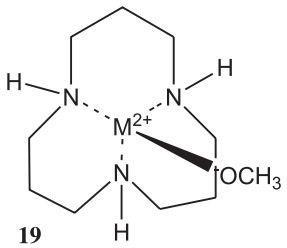


Table 4. Summary of observed rate constants for Ln^{3+}- and M^{2+}-catalyzed ethanolysis of paraoxon (**15**); T = 25 °C, determined at $[M^{x+}]$ = [NaOEt] = 10^{-3} mol L^{-1}.

More recent studies have concentrated on the effect of Zn^{2+} and Cu^{2+} and some of their complexes with phenanthroline, 2,9-dimethylphenanthroline, 2,2′-bipyridyl and 1,5,9-triazacyclododecane, each as their mono-methoxy forms ($L:M^{2+}(^{-}OCH_3)$), to promote the methanolysis of **15** and **18** (33), a variety of carboxylate esters (34), and phosphate triesters[8] where the leaving group is varied. The above Zn^{2+} and Cu^{2+} complexes are reactive as monomers, but in the case of the phenanthroline and bipyridyl complexes, form unreactive dimers as in eq. [4], which limits the catalytic efficiency. However, when bound by the tridentate ligands such as dipicolylamine or triazacyclododecane (eg. **19**) the complexes are monomeric and prove to be efficient catalysts for both phosphate esters. Given in Table 5 are the second-order catalytic rate constants (k_m) for complex **19** along with those for the copper and zinc methoxides, and the rate constants for methoxide attack on the two phosphates (33). Uncatalyzed attack of CH_3O^- on paraoxon (**15**) is faster by roughly 15-fold than on **18**. The $Cu^{2+}(^{-}OCH_3)$ system alone or bound in the form of **19** is more effective for **18** than **15**, while the $Zn^{2+}(^{-}OCH_3)$ systems have similar selectivity for the P=O and P=S esters. This is quantified by the relative selectivity (RS) parameter given in Table 5, which compares the relative reactivity of the $M^{2+}(^{-}OCH_3)$ reactions and free methoxide attack on the P=S and P=O substrates $((k_m(\mathbf{18})/k_{OCH3}(\mathbf{18}))/(k_m(\mathbf{15})/k_{OCH_3}(\mathbf{15})))$. The RS parameters clearly correlate with the hard/soft properties (32) of the metal ion. The hard ion La^{3+} exhibits exclusive selectivity for the P=O substrate (RS ~ 0), while the softer Zn^{2+} ion shows almost equal affinity for P=O and P=S substrates (RS ~ 1). Of the three ions, Cu^{2+} appears to be the softest and exhibits high selectivity for the P=S substrate with RS values from ~55–70. It is also of note that all the metal-catalyzed rate constants listed in Table 5 exceed those for the free methoxide, indicating that the metal ions, even in the case of the monomeric forms, must be involved in a dual role of Lewis acid and delivery of the methoxide nucleophile.

Conclusions

Our recent work on the La^{3+}-catalyzed methanolysis of neutral esters, lactams, activated amides, and phosphate triesters has revealed cases where the activities of the metal ion are much more prominent than in aqueous solution. Indeed in aqueous solution, metal ion catalysis of acyl or phosphoryl transfer is poor or nonexistent unless there is some proximal binding group that positions the metal ion close to the scissile bond. Metal ions in water are also well-known to have limited or little solubility at high pH because of formation of the metal-hydroxo forms, but in our experience metal alkoxides are soluble throughout the $^{s}_{s}$pH region where the important catalysis is observed. Our original kinetic work with acetyl imidazole and esters indicated that the active form was a La^{3+} dimer having two associated methoxides. Subsequently, a more detailed speciation analysis revealed that in the concentration range where the kinetic studies were performed, there were five $^{s}_{s}$pH dependent dimeric forms of general structure $La_2^{3+}(^{-}OCH_3)_n$, n = 1–5. Maximum catalysis is observed in the neutral $^{s}_{s}$pH region of 8–10, with the dominant active form being $La_2^{3+}(^{-}OCH_3)_2$. Depending upon what substrate is being investigated, the

Scheme 3. Methanols of solvation omitted for clarity.

ssspH/rate profiles vary in shape in a nonobvious, but easily analyzed way, which attributes the overall curve to the sum of the contributions of each dimeric form.

1. All evidence points to a common mechanism for the catalysis exhibited by the $La_2^{3+}(^{-}OCH_3)_n$ system acting on all the neutral C=O and P=O substrates we have investigated, which is best illustrated for the phosphorus esters in Scheme 3 using the La^{3+} dimer with two methoxides (**3**). It is difficult to envision any mechanism that does not involve a preequilibrium binding of the substrate to **3** to form the transient complex **20**. While we have never observed saturation kinetics we assume that switching the medium from water to the less polar alcohol increases the equilibrium binding constant thus providing one method of increasing the reaction rate. Because the methoxide in **20** is bound between two electropositive La^{3+} ions, it is unlikely that it is sufficiently nucleophilic to attack an unactivated ester or phosphate (35), so we propose that one of the methoxide–La^{3+} bonds is transiently cleaved as in **21** to reveal a Lewis acid activated P=O adjacent to a metal-bound methoxide nucleophile. Nucleophilic attack creates the five-coordinate intermediate **22**, which in the case of good aryloxy or thioaryloxy leaving groups, probably decomposes without the requirement for La^{3+} assistance. Turnover to reform **3** is accomplished by methanol addition, deprotonation, and release of the transiently bound trialkoxy phosphate ester product.
   In the case of unactivated carboxylic acid esters such as ethyl acetate, the La^{3+}-catalyzed transesterification is very effective and probably proceeds in much the same way involving a tetrahedral intermediate bound to one of the La^{3+} ions in the complex. Any proposed mechanism involving formation of an intermediate that requires delivery of a La^{3+}-bound methoxide must, by microscopic reversibility, require the departure of a La^{3+}-bound ethoxide, but for better leaving groups such as aryloxy, assistance of departure might not be required. Current work in our laboratories is aimed at determining the effects of changing the leaving groups in carboxylic and phosphorus esters in the hopes of shedding light on the mechanistic differences between the two classes of compounds (34).[8]
2. Another feature of the dimeric La^{3+} system is the fact that the k_2/k_{OCH_3} or $k_2^{2:n}/k_{OCH_3}$ ratios for many of the nonactivated esters, the lactams, and the phosphates are greater than unity. In fact, where direct comparison can be made, the k_2/k_{OCH_3} ratio is greater when the substrate is less activated. For example, the k_2/k_{OCH_3} ratios are 21 and 0.07 for phenyl acetate and dinitrophenyl acetate, respectively, and ~10 and 2 for the $k_2^{2:2}/k_{OCH_3}$ ratio with lactams **12** and **13**. Since normal Brønsted considerations suggest that a methoxide bound to an electropositive metal ion is less nucleophilic than free methoxide, a dual role for the catalyst is implied where Lewis acid activation is concurrent with nucleophilic delivery of methoxide. That the catalysis is actually more effective for the less-activated substrates suggests that there is a counterbalance of electronic effects on the binding (activation) step and nucleophilic delivery step.
3. La^{3+} catalysis of the methanolysis of the phosphate triesters is quite spectacular in terms of the rate enhancements relative to the background reactions. In addition, the $k_2^{2:n}/k_{OCH_3}$ values (n = 2–4) are very large, ranging from ~3200–4600 for paraoxon to 135–230 for the phosphorothioate derivative **16**. As far as we know,

© 2004 NRC Canada

these are among the largest ratios reported for any metal-ion-catalyzed phosphoryl transfer,[9] which points to the fact that metal-ion-catalyzed alcoholysis processes are possessed of special catalytic benefits for such systems.

4. As a final point of note, the catalytic system described herein can be made simply in situ for preparative work by formulating a 2–20 mmol L^{-1} solution of $La(OTf)_3$ in methanol and treating with 1 equiv. of $NaOCH_3$. The $^{s}_{s}$pH of this solution is close to neutrality (8.4).

[9] Recent work from our laboratories has shown that transition metal ion complexes, for example the 1,5,9-triazacyclododecane complexes of Cu^{2+}:$^{-}OCH_3$ or Zn^{2+}:$^{-}OCH_3$, provide very efficient catalysis of the methanolysis of paraoxon and fenitrothion (34*a*, 34*b*), with k_2/k_{OCH_3}-ratios as high as 17 000-fold for reaction with fenitrothion (**18**).

NOTE OF APPRECIATION / NOTE DE RECONNAISSANCE

The quality of the papers in this journal depends a great deal on the efforts of those who agree to act as critical readers of manuscripts. The editors gratefully acknowledge the following who helped us between 1 November 2003 and 31 October 2004:

La qualité des articles publiés dans notre revue dépend beaucoup de ceux qui acceptent de faire une lecture critique des manuscrits. Les directeurs scientifiques expriment leur reconnaissance aux personnes suivantes qui nous ont aidés, du 1er novembre 2003 au 31 octobre 2004 :
